[a]Total microcystins determined via MMPB using LDTD-APCI-HRMS. [b]Total microcystins determined via MMPB using LDTD-APCI-MS/MS. [c]Microcystins determined via the summation of all microcystins for which standards allowed detection and quantification (i.e., MC-LA, MC-LR, MC-RR, and MC-YR) using LC-MS/MS. [d]Values in bold represent concentrations above the MQL. [e]nd, not detected.

LDTD-APCI technology. Finally, CEAEQ results using a standard analytical method for MCs in fish tissue are presented for the same samples. Of the 49 samples (Table S1), 24 had a positive response to MCs, including 22 that were above the detection limit (Table 3). Concentrations varied between 2.7 and 13.2 μg kg^{-1} of fresh fish tissues weight. Four samples (1−4) had relatively higher detected concentrations, which could be explained by the type of fish tissue. Indeed, three of these samples from a bottom feeder, the white sucker, included the viscera known to concentrate higher amount of MCs, but that are not generally consumed by fisherman. Interestingly, the second highest concentration was for a headed and gutted rainbow smelt, these small fish are eaten as is. Smelt's preferred habitat is the metalimnion, which is also the habitat of the blue green algae *Planktothrix* responsible for the Lac Vert's contamination by MCs. Smelt consume crustacean, zooplankton and insect larvae that are themselves algae consumers. Only four results were above the estimated MQL values, although yellow perch and lake whitefish were quite close. Of the 24 samples with positive MC detection, only 5 were detected using the LDTD-APCI-MS/MS technique with relative differences in values of −13% on average. This difference was explained by the different response of matrix effects using MS/MS, for which the signal recovery was 82%. The detection and quantification limits of the method were 6.8 and 20.4 μg kg^{-1}, respectively. Whereas these values are comparable with those obtained in previous studies, the use of HRMS offered better sensitivity (i.e., 2.7 and 8.2 μg kg^{-1}, respectively), which supports the choice of our detection method.

Using the CEAEQ's standard analytical method, only one sample showed the positive detection of MCs at 2.0 μg kg^{-1} of MC-YR congener. This value represents 15% of the recovered total MCs from the same sample. The detection limit of each studied MC variant was 1 μg kg^{-1}, and detection method sensitivity therefore cannot explain this discrepancy. Two reasons may explain the substantial underestimation of MCs. First, it is possible that the extraction method may not be able to release the covalently bound MCs from the tissue. Williams et al. provided experimental evidence, using Lemieux oxidation, MMPB-GC/MS, radiolabeled MMPB, and MeOH extraction-PPase, to demonstrate that a substantial amount of MCs was covalently bound in vivo.[38,39] MeOH extraction actually recovered ≈24% of the total MC-LR measured with MMPB in the liver of salmon intraperitoneally injected. This underestimation is similar to what this study obtained for whole fish in the only sample with a detection using the conventional extraction method. Other authors estimated that as much as 60−90% of total MCs could be covalently bound.[38−41] Second, other variants and variant isomers present in the samples could have been missed altogether. Indeed, some tissue samples from the same lake and date had MC detections suspected by CEAEQ to be YR isomer (data not shown). Due to the absence of appropriate standards for LC-MS/MS, the CEAEQ analytical laboratory could not certify the identification and concentration of the suspected isomer, although its characteristics were so close to the available standard that it was deemed with a very high probability to be an isomer of MC-YR. As was recently demonstrated with total MCs in water,[20] this study also illustrates the inherent risk of relying on a limited number of

J. Agric. Food Chem. 2015, 63, 7440−7449

standards when the total MC contamination in tissue is assessed. Our results show the importance of analyzing total MCs in fish tissue using proper sample preparation and extraction methods along with selective and sensitive detection methods.

Risk Assessment. The maximum lifetime TDI for humans (i.e., 0.04 μg/kg/day) set out by the WHO has been used in several exposure scenarios to estimate the potential risk for fish consumers. Scenarios aiming to protect at-risk groups (e.g., children[42] or important consumers of locally caught fish[43]) are expected to be the most stringent. Assuming that no exposure would come from drinking water or recreational exposure, the TDI would transfer to ≈8 μg kg^{-1} of fish for a 60 kg adult who consumes 300 g of fish per day, on average,[43,44] or to ≈24 μg kg^{-1} for those who consume 100 g per day.[45] Some of the results presented in Table 3 would then exceed the TDI if fish consumption is high enough. These results are noteworthy because only 1 of the 49 samples was over the detection limit (i.e., 1 μg kg^{-1}) of the initial LC-MS/MS analysis. However, it was observed that only three samples were detected above the estimated MQL (8.2 μg kg^{-1}). Although further studies are required to improve sensitivity, the findings here were satisfactory for MCs detection around the WHO's TDI.

Likewise, assuming that 15% of the total MCs were detected in studies analyzing only unbound concentrations, several studies including this one would have MC levels above the WHO's TDI using our method.[45−49] Overall these results suggest that certain groups may be at a higher risk than previously estimated and that more research on the toxicity of total MCs is needed.

Moreover, the WHO has classified MCs as a "possible human carcinogenic" (class II-B).[50] It is therefore important to enhance our ability to estimate the total concentration from all sources of exposure to this class of pollutants because cancer may develop after a long latency period and possibly at relatively low exposure levels.

Although the variants, isomers, conjugates, and covalently bound MCs probably all have different toxicological properties that have yet to be understood, a method to analyze quickly total MCs is nevertheless essential to make prudent exposure measurements while research progresses. Furthermore, this new method for total MCs in tissue would be helpful in a tiered approach to screen out samples that do not contain these toxins, enabling resource allocation where other variants could be playing an unnoticed role in toxicity. Although many studies have explored the availability of MCs in aquatic animal consumption after cooking and digestion, the bioavailability and toxicity of bound MCs are still poorly understood.[51−53] However, findings showed that serious risk to animal and human health is most likely possible and that contamination monitoring could prevent eventual poisoning cases. It would therefore be beneficial to understand the fate, transportation, and accumulation of MCs in the food web, with or without other analyses and assays.[54]

In conclusion, a new approach to detect total microcystins in fish tissue has been demonstrated and validated using LDTD-APCI-HRMS. MCs are known to covalently bind with animal tissue, and effective sample preparation is therefore necessary to analyze both free and bound fractions and the possible MC congeners. We explored the possibility of using sodium hydroxide as a digestive agent for fish tissue prior to a well-known oxidation step, Lemieux oxidation, for total MC analysis. A new approach for sample cleanup was also explored using an SDB-L SPE cartridge for recovery enhancement and eliminating the salts present in solution. The use of LDTD-APCI has already been reported for the analysis of MMPB in water, but HRMS detection with the Q-Exactive was chosen for better sensitivity and selectivity. The use of LDTD-APCI-HRMS enabled ultrafast analysis times at 10 s per sample. Digestion and oxidation were optimized, and recoveries ranged from 70 to 75%, respectively. SPE recoveries ranged from 86 to 103%, and signal recoveries from matrix effects ranged from 90 to 93%. An internal calibration was used with 4-PB, and the validated method gave linear correlation coefficients (R^2) of 0.999; MDL and MQL were 2.7 and 8.2 μg kg^{-1}, respectively. Accuracy and interday/intraday variation coefficients for target compounds were below 10%. Interday and intraday precisions were evaluated below 10%. Of a total of 49 fish samples from lakes with HABs, 25 (51%) had a positive response for total microcystins with concentrations ranging from 2.9 to 13.2 μg kg^{-1} fresh weight in tissue. Using standardized extraction and LC-MS/MS methods, only one sample (2%) had a microcystin response with a concentration of 2 μg kg^{-1} of MC-YR. For that sample, the total MCs were 7 times higher than the initial value. These results suggest that MC concentration in fish tissues could be significantly underestimated using standard analytical methods and that a suitable extraction method combined with total MC detection is required for prudent risk management.

previous literature.[22,23] To demonstrate signature peptide quantitation by LC-MS/MS as a suitable multiplex platform to quantify multiple proteins within a single analysis, we report a comprehensive development and validation of a multiplex LC-MS/MS method for the determination of the aryloxyalkanoate dioxygenase (AAD-12), 5-enol-pyruvylshikimate-3-phosphate synthase (2mEPSPS), and phosphinothricin acetyltransferase (PAT) herbicide-tolerant proteins in Enlist E3 soybean tissues.

MATERIALS AND METHODS

Materials. Soybean plants were grown in a Dow AgroSciences greenhouse (Indianapolis, IN), and leaf, root, and seed tissues were lyophilized, ground to a fine powder, then stored at −80 °C. Recombinant protein standards were expressed in and purified from *Pseudomonas fluorescens* (>95% purity), and aliquots were stored at −80 °C for single usage with protein concentrations assessed by amino acid analysis using acid hydrolysis, automated OPA/FMOC derivatization, and C18 reverse-phase separation with fluorescence detection. Synthetic peptides representative of natural abundance peptides from each protein, defined as surrogate peptides, and heavy-labeled peptide internal standards (L-lysine-$^{13}C_6$,$^{15}N_2$ or L-arginine-$^{13}C_6$,$^{15}N_4$, depending on protein sequence) were obtained from New England Peptide (Gardner, MA). Phosphate-buffered saline containing 0.05% Tween 20 (PBST) was obtained from Teknova (Hollister, CA). Casein was purchased from SurModics (Eden Prairie, MN). Albumin chicken egg (OVA), polyvinylpyrrolidone (PVP), and HPLC solvents were obtained from Sigma-Aldrich (St. Louis, MO). Ammonium bicarbonate, dithiothreitol, and formic acid were obtained from Fisher Scientific (USA). Sequencing-grade trypsin was purchased frozen from Promega Corporation (Madison, WI).

LC-MS/MS Method Overview. All surrogate peptide LC-MS/MS method development and validation was carried out at Dow AgroSciences (Indianapolis, IN). Briefly, a total of 1.5 mL of PBST and two metal beads were added per 15 mg of lyophilized soybean leaf, root, or seed tissue weighed into low-binding microcentrifuge tubes. Samples were extracted in a bead grinder (Geno/Grinder, Swedesboro, NJ) at 1500 strokes per minute for 3 min followed by centrifugation at 4 °C and >3000 rpm for 10 min. A total of 100 μL of supernatant was transferred to a clean microcentrifuge tube with the addition of 7.5 mM dithiothreitol (DTT) and incubated at 95 °C for 45 min followed by cooling at 4 °C. After the samples were cooled to room temperature, 60 μL of 50 mM ammonium bicarbonate, 20 μL of heavy-isotope-labeled peptide internal standard, and 5 μg of trypsin enzyme (enzyme/substrate ratio ≈ 1:75 (w/w), on the basis of BCA assay results for total extractable protein content from respective tissues) were added. The synthetic natural abundance peptide reference standards were spiked into control soybean tissue and processed in the same manner as the unknown samples. The samples and peptide reference standards were incubated overnight at 37 °C, followed by quenching with formic acid/H_2O (50:50, v/v). The samples were centrifuged at >3000 rpm for 10 min to pellet any undigested insoluble particulate, followed by LC-MS/MS analysis. Quantitation of detected surrogate peptides was carried out with linear regression and $1/x^2$ weighting, followed by conversion into respective protein concentrations using the following equation and information found in Table 1.

$$\text{Protein Concentration} = \text{Detected Peptide Concentration} \times \left(\frac{\text{Protein Molecular Weight}}{\text{Peptide Molecular Weight}}\right)$$

The LC-MS/MS system included an AB Sciex 4000 QTRAP with turbo ion-spray source and Waters Acquity H-Class UPLC. The autosampler temperature was kept at 4 °C during analysis. A total of 5 μL of sample was injected onto an Acquity UPLC BEH130 C18 1.7 μm (2.1 mm × 50 mm) column set at 50 °C. The reverse phase analysis was carried out using an organic mobile phase (MPB) acetonitrile containing 0.1% formic acid and the aqueous mobile phase (MPA) was water containing 0.1% formic acid. The LC flow rate was 0.5 mL/min with a linear gradient from 0.1% MPB to 28% MPB over 6 min, followed by 100% MPB for 1 min to wash the column, and 0.1% MPB for 1 min to re-equilibrate the column. The needle wash and seal wash contained 50:50 methanol/water with no detected carryover between samples.

The mass spectrometer was operated in positive ion mode with ion-spray voltage of 5500 V and temperature set at 450 °C. MS/MS transitions and collision energy for each peptide can be found in Table 1. Other relevant instrument parameters included curtain gas of 35 psi, ion-source gas 1 and 2 of 55

DOI: 10.1021/acs.jafc.5b03083
J. Agric. Food Chem. 2015, 63, 7450−7461

psi, collision gas set to medium, entrance potential of 10 V, declustering potential of 80 V, and collision cell exit potential of 15 V.

LC-MS/MS Method Validation. *Extraction Efficiency.* Extraction efficiency (EE) was evaluated by repeatedly extracting transgenic soybean tissue samples containing AAD-12, 2mEPSPS, and PAT proteins and determining the amount of protein from each extraction. After extraction, the samples were centrifuged and the supernatant transferred to a new vial, and the extraction of the pellet was repeated. Each extract was analyzed for surrogate peptide concentrations by LC-MS/MS, and the levels of transgenic proteins in the extracts and the pellet were confirmed by Western blotting. The extraction efficiency for each protein in each tissue was calculated as the percentage of peptide detected in the first extraction relative to the peptide found in all soluble extractions by the following equation:

$$\mathrm{EE} = \left(\frac{\text{Amount of peptide recovered in 1st extraction}}{\text{Sum of peptide recovered from all extractions}}\right) \times 100$$

Western Blotting. Briefly, 750 μL of Laemmli buffer was added to each pelleted tissue after the fifth serial extraction and extracted with the Geno Grinder at 1500 strokes/min for 3 min followed by centrifugation at 4 °C and > 3000 rpm for 5 min. The first and fifth extraction supernatants were diluted 1:2 into 2× concentrated Laemmli buffer; all prepared solutions were heated at 95 °C for 10 min, loaded onto a gel along with recombinant protein standards with XT MES running buffer, and separated by electrophoresis for approximately 1 h at 160 V. Each gel was transferred to a nitrocellulose membrane, washed 3 times with PBST, and incubated with each corresponding primary antibody in PBST overnight at 4 °C with gentle shaking. After primary antibody incubation, the membranes were washed 3 times with PBST. The membranes were then incubated with respective HRP-conjugated secondary antibodies prepared in blocking solution for 1 h at room temperature with gentle shaking. After incubation with secondary antibodies, the membranes were washed 3 times with PBST. The membranes were exposed to X-ray film after addition of chemilumenscence substrate to the membrane.

Accuracy. Method accuracy was assessed by determining the recovery of surrogate peptides (described in Table 1) produced from the digestion of AAD-12, 2mEPSPS, and PAT recombinant proteins that had been fortified into non-GE control soybean tissues at the proposed limit of quantitation (LOQ), a midrange concentration, and a high-range concentration for each protein. Briefly, control soybean tissue (leaf, root, or seed depending on which matrix was being evaluated) was extracted with PBST, and the supernatant was pooled together. Each pooled tissue extract was then fortified with all three proteins, denatured, digested, and analyzed by LC-MS/MS. Recovery was determined as a percentage of fortified recombinant proteins via the following equation:

$$\%\ \text{Recovery} = \frac{\text{Detected Peptide Concentration} \times \left(\frac{\text{Protein Molecular Weight}}{\text{Peptide Molecular Weight}}\right)}{\text{Theoretical Protein Fortification Concentration}} \times 100$$

Precision and Ruggedness. Precision and ruggedness were determined by evaluating the recovery of surrogate peptides produced from the digestion of AAD-12, 2mEPSPS, and PAT recombinant proteins that had been fortified into control soybean tissues at the LOQ and midrange and high-range concentrations for each protein across multiple days.

Peptide Stability. Digested peptide stability was examined over the course of 5 days. A sample set of non-GE control tissues fortified with AAD-12, 2mEPSPS, and PAT recombinant proteins at the LOQ and midrange and high-range concentrations was digested, and analyzed along with reference peptide standards prepared in control tissue by LC-MS/MS (day 0). The reference standard peptides and fortified tissue samples were stored at 4 °C for 5 days and reanalyzed using the same instrument parameters as the day 0 analysis. The difference in recovery of peptides from day 0 to 5 was assessed.

Sensitivity. The preliminary quantitative range for the LC-MS/MS multiplex assay was empirically defined on the basis of assay parameters such as analyte signal intensity, background noise intensity, matrix contributions, and analyte stability from an overnight digest. Three times the signal-to-noise ratio and ten times the signal-to-noise ratio of peptide standard response to digested control sample were used to define limit of detection (LOD) and LOQ, respectively (Table 2). The calibration standard range was defined to be at least 20% above and below the quantitative range for all proteins with acceptable correlation coefficients ≥0.995.

Table 2. AAD-12, 2mEPSPS, and PAT Quantitative Range Comparison for Individual ELISA and Multiplex LC-MS/MS Methods

	LC-MS/MS		ELISA	
protein	LOQ (ng/mg)	ULOQ (ng/mg)	LOQ (ng/mg)	ULOQ (ng/mg)
AAD-12	6.60	165.00	1.00	10.00
2mEPSPS	12.20	305.00	8.00	200.00
PAT	6.50	163.00	0.12	0.60

Interlaboratory Method Assessment. An independent assessment of the LC-MS/MS method was carried out at Critical Path Services, LLC (Garnet Valley, PA). Control soybean tissues described in the Materials section were fortified with recombinant AAD-12, 2mEPSPS, and PAT proteins at the LOQ and midrange and high-range concentrations and analyzed following the method described in the LC-MS/MS Method Overview section. The LC-MS/MS analysis was carried out on an Agilent 1290 UHPLC coupled to an Agilent 6410B mass spectrometer.

ELISA and LC-MS/MS Comparison. Leaf tissue containing AAD-12, 2mEPSPS, and PAT proteins from nine individual soybean plants was analyzed using ELISA and LC-MS/MS. The leaf samples were analyzed by LC-MS/MS following the analytical method described in the LC-MS/MS Method Overview section. Individual sandwich-based ELISA methods were developed and validated under good laboratory practice guidelines for each protein. For each ELISA method described below, a total of 1.5 mL of respective extraction buffer and two metal beads were added to 15 mg of soybean leaf tissue and extracted in a Geno/Grinder at 1500 strokes per minute for 3 min and then centrifuged at 4 °C and >3000 rpm for 5 min. The assays were measured using purified recombinant protein as standards with quadratic regression.

The AAD-12 protein was extracted from soybean leaf tissue with PBST buffer with 0.75% ovalbumin. The extract was centrifuged; the aqueous supernatant was collected, diluted, and assayed using a specific AAD-12 ELISA kit (Envirologix,

DOI: 10.1021/acs.jafc.5b03083
J. Agric. Food Chem. 2015, 63, 7450−7461

Portland Maine). An aliquot of the diluted sample was incubated with enzyme-conjugated anti-AAD-12 protein monoclonal antibody in the wells of an anti-AAD-12 polyclonal-antibody-coated plate. At the end of the incubation period, the unbound reagents were removed from the plate by washing with PBST followed by incubation of enzyme conjugate with an enzyme substrate. The reaction was quenched with acid, and the absorbance was read at 450 nm minus absorbance at 650 nm using a plate reader.

The 2mEPSPS protein was extracted from soybean leaf tissue with a PBST and 2× casein (PBST/casein). The extract was centrifuged; the aqueous supernatant was collected, diluted with PBST/casein, and assayed using a specific 2mEPSPS ELISA kit made in-house at Dow AgroSciences. An aliquot of the diluted sample was incubated in the wells of an anti-2mEPSPS polyclonal-antibody-coated plate, and then the unbound samples were removed from the plate by washing with PBST. An excess amount of enzyme-conjugated anti-2mEPSPS monoclonal antibody was subsequently added to the wells. At the end of the incubation period, the unbound reagents were removed from the plate by washing with PBST. Subsequent addition of an enzyme substrate generated a colored product. The reaction was quenched with acid, and the absorbance was read at 450 nm minus absorbance at 650 nm using a plate reader.

The PAT protein was extracted from soybean leaf tissue with a buffer consisting of PBST and 1% polyvinylpyrrolidone (PBST/PVP). The extract was centrifuged; the aqueous supernatant was collected, diluted and assayed using a specific PAT ELISA kit (Envirologix, Portland Maine). An aliquot of the diluted sample was incubated with enzyme-conjugated anti-PAT monoclonal antibody in the wells of an anti-PAT polyclonal-antibody-coated plate in a sandwich ELISA format. At the end of the incubation period, the unbound reagents are removed from the plate by washing with PBST. The presence of PAT was detected by incubating the antibody-bound enzyme conjugate with an enzyme substrate, generating a colored product. The reaction was quenched with acid, and the absorbance was read at 450 nm minus absorbance at 650 nm using a plate reader.

RESULTS AND DISCUSSION

Method Development. *Target Peptide Selection.* Traditional bottom-up proteomics employs a protease of known cleavage specificity and a protein's primary sequence to cleave high-molecular-weight proteins into smaller peptide chains of predicted sequence suitable for analysis by tandem mass spectrometry.[24] These peptides are defined as surrogate peptides and are representative of the target proteins.[25] The enzyme trypsin was chosen for this assay because of its high specificity to cleave at the C terminus of lysine and arginine residues. For method development, all possible tryptic peptides for each target protein from a theoretical digestion were considered and surveyed using specific criteria during the peptide selection process. Initial selection criteria required 6–20 amino acids in length because fewer than 4 residues can lead to nonspecific identification.[26] Peptide residues susceptible to modification such as those produced from N-terminal cleavage or residues prone to oxidation such as methionine and cysteine were excluded from selection. Digested recombinant protein standards were analyzed using a targeted information-dependent acquisition (IDA) in the mass spectrometer to determine relative fragmentation ratios and highest abundance MS/MS fragment ions for each tryptic peptide candidate. Using the most abundant MS/MS fragmentation ions and considering charge state, peptides were further profiled for sensitivity and reproducibility from an overnight digestion and minimal isobaric interference in comparison to control tissue (specificity). Two surrogate peptides were chosen per protein for further optimization representing different locations of the protein sequence to prevent missed identification during analysis caused by truncation. One peptide was defined as the quantitation peptide with the second peptide serving as a confirmation peptide during quantitation (Table 1).

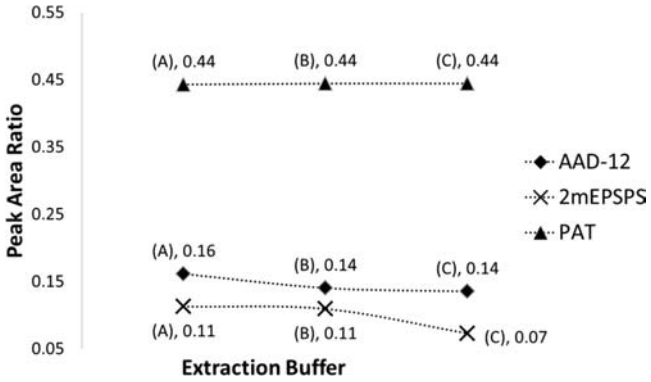

Figure 1. Example extraction buffer evaluation for leaf tissue using (A) PBST, (B) 50 mM Tris(hydroxymethyl)aminomethane hydrochloride, or (C) 50 mM ammonium bicarbonate. A 15 mg sample of soybean leaf tissue containing AAD-12, 2mEPSPS, and PAT proteins was extracted with each respective buffer, digested, and analyzed by LC-MS/MS. Peptide response from the overnight digest was plotted (peak area ratio) versus individual extraction buffers for each protein. The optimized amount of tissue per volume buffer and buffer choice for the multiplex LC-MS/MS method was 15 mg lyophilized tissue per 1.5 mL PBST.

Extraction. The LC-MS/MS extraction mirrored individual ELISA methods for AAD-12, 2mEPSPS, and PAT to incorporate direct comparison of the assays. PBST is the base component of each of the ELISA methods. Tissue containing AAD-12, 2mEPSPS, and PAT proteins was extracted with different extraction buffers offering a large range of biochemical properties (PBST, 50 mM Tris(hydroxymethyl)aminomethane hydrochloride (pH 8.0), or 50 mM ammonium bicarbonate), digested, and analyzed by LC-MS/MS. Results demonstrated little change in peptide response, confirming PBST as suitable for extraction for all three proteins in the multiplex method (Figure 1). Many ELISA extraction buffer components (nonvolatile detergents such as Tween 20, surfactants, etc.) are less favorable for extended LC-MS/MS analysis.[27] Because surrogate peptide analysis decouples from accepted ELISA methodology, further optimization of extraction buffers to reduce surfactants and detergents or removal of these components all together before analysis can improve sensitivity for detection by LC-MS/MS. The optimized amount of tissue per volume buffer and buffer choice for the multiplex LC-MS/MS method was 15 mg lyophilized tissue per 1.5 mL PBST.

Digestion. The underlying foundation for surrogate peptide analysis relies on protease digestion that is 100% efficient in order for the resulting peptide fragments to be present in equal molar amounts compared to the original target protein prior to digestion. Proteins can differ greatly in their susceptibility to proteolysis, and this requires a digestion protocol that is optimal for all proteins in a multiplex analysis for accurate

J. Agric. Food Chem. 2015, 63, 7450–7461

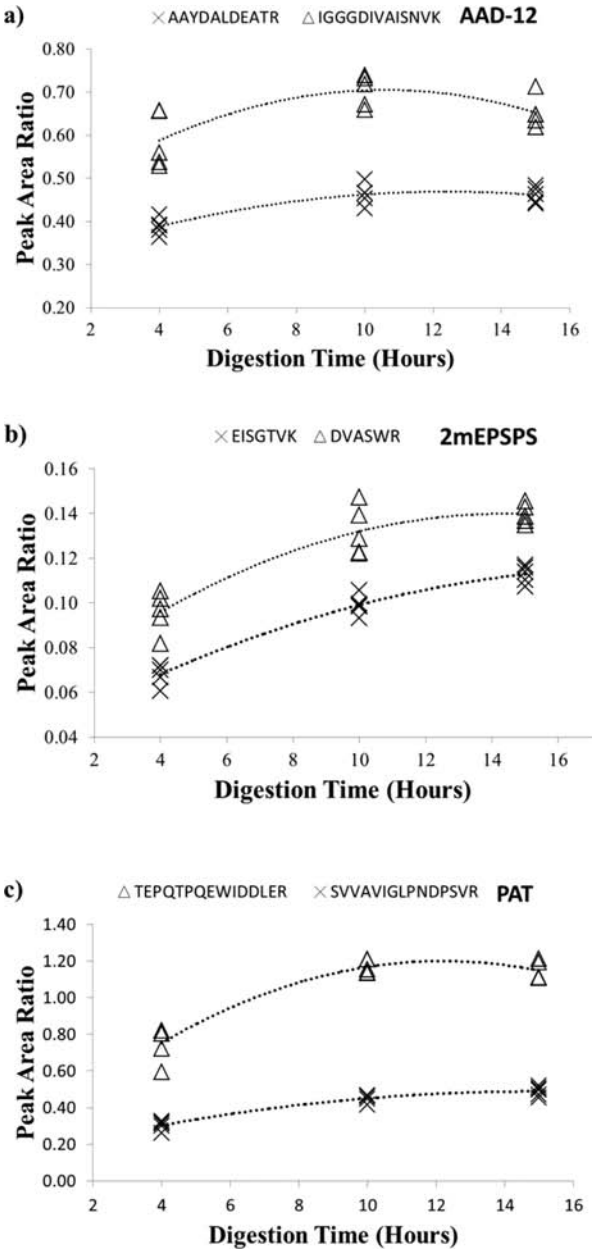

Figure 2. – Time-course digestion efficiency evaluation for (a) AAD-12, (b) 2mEPSPS, and (c) PAT. Digestion was monitored (peak area ratios plotted versus digestion time) for individual replicates and quenched with acid at 4, 10, and 15 h time points to simulate an overnight digestion. An enzyme–substrate ratio of 1:75 used in the method demonstrated digestion completeness at the 12 h digestion time because longer digestion time did not improve detection and the signal was stable at time points representative of an overnight digestion.

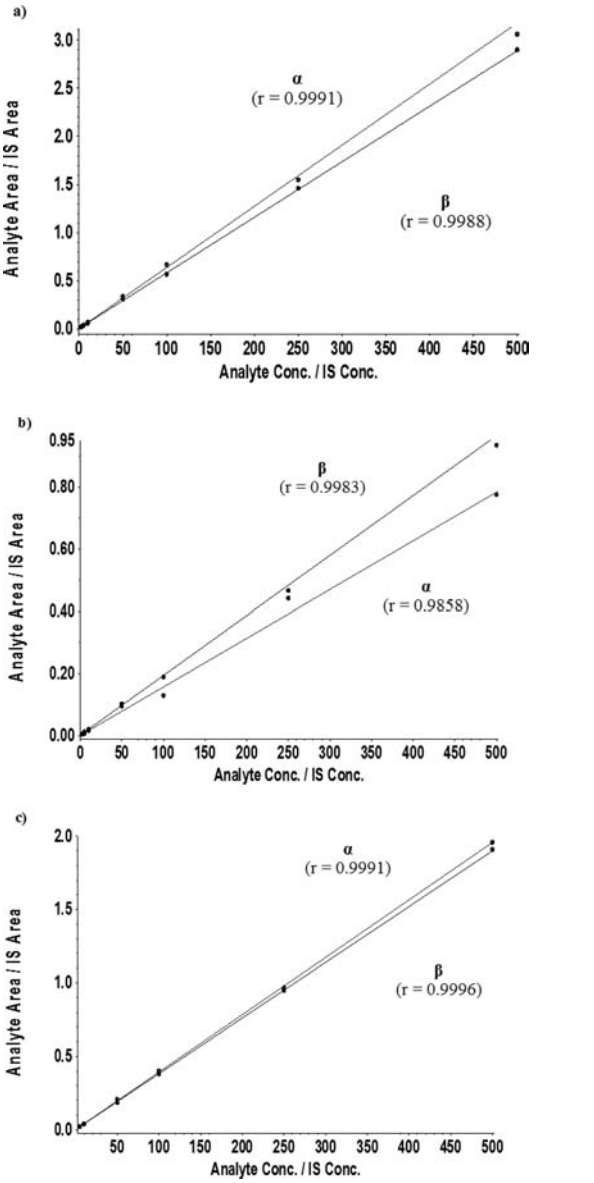

Figure 3. Example calibration curves for (a) AAD-12 (AAYDALDEATR, 598.3/704.4), (b) 2mEPSPS (EISGTVK, 367.2/404.3), and (c) PAT (TEPQTPQEWIDDLER, 928.9/813.9) from two separate multiplex analyses carried out on separate days. The calibration curve labeled "α" was prepared in PBST and the calibration curve labeled "β" was prepared in digested soybean control leaf tissue. Good linearity was observed for AAD-12 and PAT in both analysis formats (panels a and c). 2mEPSPS observed peptide loss caused by surface absorption to lab materials during sample preparation, affecting both signal intensity and linearity (panel b). Linearity of the 2mEPSPS calibration curve was recovered when prepared in digested control tissue.

measurements. Prior to digestion, proteins were denatured to primary structure at high temperatures and reduced in the presence of DTT to allow for efficient proteolytic cleavage. Optimized conditions were found to be 95 °C for 45 min because lower temperature and time incurred lower accuracy from recombinant protein spike recovery. The trypsin concentration, peptide stability over a particular digest time interval, and buffer selection (pH) were key variables in the digestion development. A trypsin enzyme–substrate ratio of 1:75 enabled 100% digestion efficiency because increasing the concentration of trypsin did not increase detected peptide response from the overnight digestion. Detergents, such as Tween 20 used in the extraction buffer, can impact enzymatic digestion efficiency and downstream LC-MS/MS analysis.[28] To minimize these effects and achieve an optimal digestion condition for trypsin (pH 7.5–8.5), the denatured supernatant was diluted into 50 mM ammonium bicarbonate prior to addition of trypsin enzyme for the overnight digestion.

A time-course evaluation for digestion efficiency has been documented in literature to demonstrate digestion completeness;[29] the abundance of target signal and stability of signal

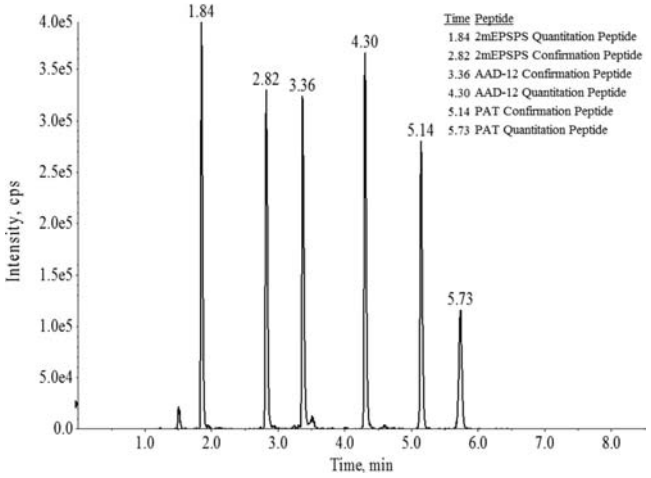

Figure 4. Typical total ion chromatogram (TIC) of a 250 ng/mL peptide standard to demonstrate the detection of AAD-12, 2mEPSPS, and PAT quantitation and confirmation of surrogate peptides in a single analysis.

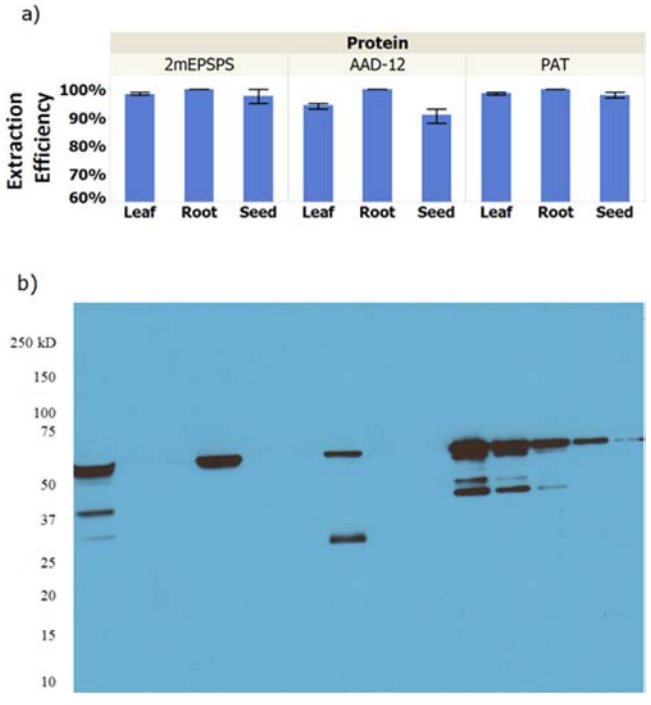

Figure 5. (a) Summary of extraction efficiency for three biological replicates of leaf, root, and seed tissues expressing AAD-12, 2mEPSPS, and PAT serial extracted 5 times each, calculated with the equation EE = ((Amount of peptide recovered in first extraction)/(Sum of peptide recovered from all extractions)) × 100 applied. (b) Example Western blot confirmation for extraction efficiency, 2mEPSPS ∼ 47.5 kDa. (PAT and AAD-12 Western blots can be found in the Supporting Information.) An immunoreactive band of the expected 47.5 kDa size is observed in lanes 10−14, representing the 2mEPSPS recombinant protein standard at concentrations of 2000, 1000, 500, 100, and 50 ng/mL, respectively. Some cross-reactivity with nontarget plant proteins was observed at lower molecular weights; however, the 47.5 kDa immunoreactive band is detected in the first extraction, represented in lanes 1 (leaf), 4 (root), and 7 (seed). No immunoreactivity is observed in lanes 2 (leaf), 5 (root), and 8 (seed), representing the fifth serial extraction or in lanes 3 (leaf), 6 (root), and 9 (seed), representing the pelleted tissue after the fifth serial extraction, which is evidence supporting effective extraction.

over the length of time of the digest were considered. Individual replicates were extracted in PBST, digested, and quenched with acid at three time points (4, 10, and 15 h to simulate an overnight digestion), and peak area ratios were plotted versus digestion time (Figure 2). Confidence in digestion completeness can be inferred because longer digestion time did not improve detection and the signal was stable at time points representative of an overnight digestion. An enzyme−substrate ratio of 1:75 and 12 h digestion time were selected for the method.

Reference Standards. Representative synthetic peptides were chosen as reference standards instead of recombinant proteins that are commonly used in ELISA analysis. Digested recombinant protein standards may provide a linear quantitative range; however, because of reliance on proteolysis, some intrinsic variability will exist from analysis to analysis, adding complexity to interpretation of results. Once completeness of digestion and peptide stability have been validated for a particular trypsin concentration and digestion time interval, the use of synthetic peptide standards may offer a more straightforward approach to quantifying incurred peptide residues from proteolysis. Initially, the reference peptide standards were prepared in extraction buffer; however, peptide loss was observed that was due to surface absorption of more hydrophobic peptides to labware during the sample preparation affecting the accuracy of the standard curve (Figure 3).[30] To overcome these effects, reference standards were prepared in digested control soybean matrix in which native proteins provide a protective medium to minimize peptide surface absorption. Proteins such as bovine serum albumin or ovalbumin are commonly used as buffer additives with the same intent as the digested control matrix. Further characterization of materials used during sample treatment may allow for the standard curve to be prepared in extraction buffer alone, simplifying the analytical procedure.

Multiplexing Assay. The multiplex detection of AAD-12, 2mEPSPS, and PAT surrogate peptides in reference standards and unknown samples was carried out by tandem mass spectrometry. Selected reaction monitoring (SRM) refers to the selectivity of tandem mass spectrometry where a precursor ion (in this case, a peptide) with a specific mass-to-charge ratio (m/z) is identified and fragmented into one or more product ions or MS/MS transitions. SRM LC-MS/MS-based detection is specific by virtue of chromatographic separation (Figure 4) and selective MS/MS detection. A second layer of specificity is produced from monitoring multiple product ions per peptide, defined as a confirmation ratio.[31] The confirmation ratio represents the relative abundance between two product ions derived from the same precursor ion, demonstrating real-time validation of results. Further specificity from the method is obtained from the addition of a structurally identical heavy-labeled peptide internal standard (HIS) to normalize all samples and reference standards and to reduce the impact of common technical pitfalls such as signal suppression or enhancement (matrix effects) and ion drift, among others. The precursor and product ions of the HIS should coelute with those of the natural abundance peptide, producing a peak area ratio.[32] The peak area ratio in the unknown sample is interpolated to the peak area ratios produced from the reference standard curve for a quantitative result. The use of peak area ratios of unknown samples to reference standards normalizes results across different analytical runs and instruments because the quantitation is not strictly limited to the

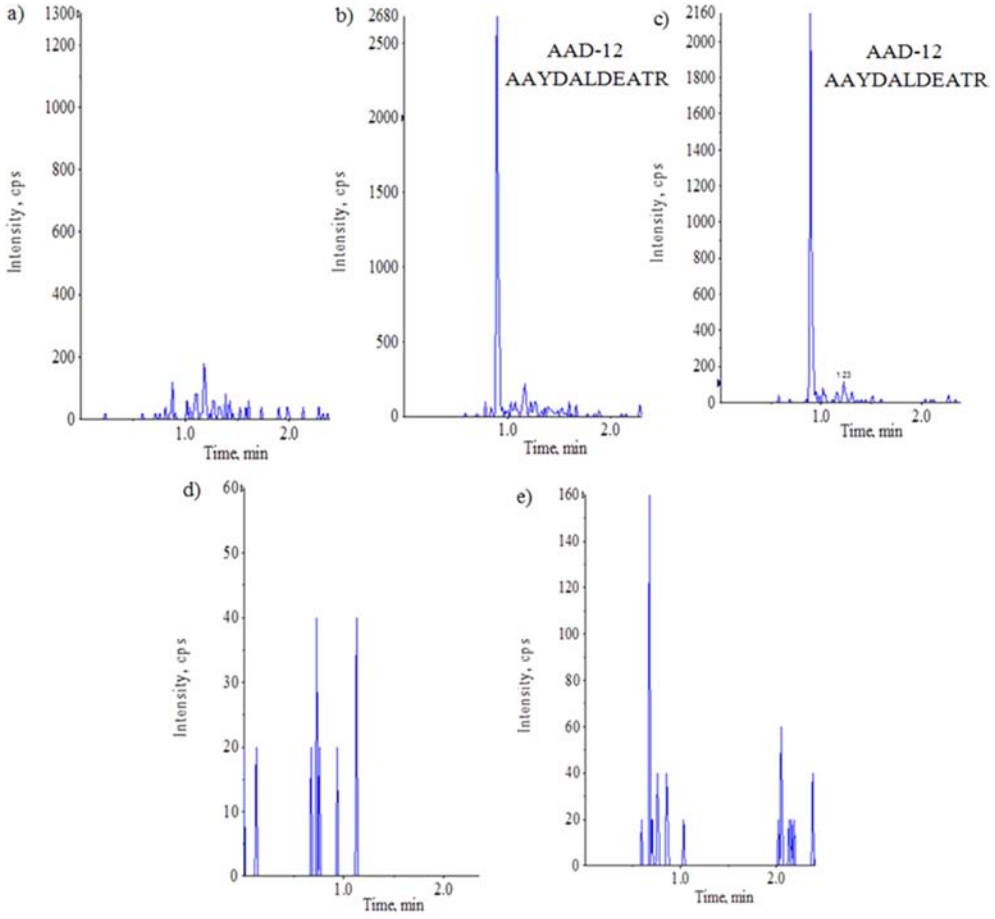

Figure 6. Example specificity assessment for AAYDALDEATR during AAD-12 peptide selection: (a) control tissue, (b) tissue containing AAD-12, (c) digested recombinant AAD-12 protein standard, (d) digested recombinant 2mEPSPS standard, and (e) digested recombinant PAT protein standard. The AAYDALDEATR peptide (0.90 min) is present in tissue expressing AAD-12 and the recombinant protein standard and absent in digested control leaf tissue and 2mEPSPS and PAT recombinant protein standards.

intensity of signal, leading to more reproducible data and a greater degree in confidence for interpretation of results. Although only one peptide is typically reported for quantitation results, two peptides are monitored per protein in the analytical method to confirm complete digestion during sample analysis.

Method Validation Results. *Extraction Efficiency (EE).* The extraction was found to be effective with efficiencies for all proteins ranging between 90 and 100% for all tissues (Figure 5a). Western blotting was used to qualitatively confirm the extraction results and demonstrated that the surrogate peptides were truly representative of intact AAD-12, 2mEPSPS, and PAT proteins in plant extracts (Figure 5b). No immunoreactivity was observed in the last serial extraction supernatant or in the pelleted tissue after the last extraction, which is evidence supporting effective extraction.

Accuracy. Good recovery of surrogate peptides from intact recombinant protein fortifications reinforces complete digestion and supports the use of synthetic peptide reference standards as a calibration source. The assay accuracy was indicated as percentage peptide recovery from recombinant protein fortifications carried out across multiple days. The accuracy of the multiplex method is acceptable for AAD-12, 2mEPSPS, and PAT with observed mean recoveries for all tissues between 70 and 123% (Table 3).

Precision and Ruggedness. Precision of the multiplex method was evaluated across two separate analyses for each tissue. To avoid any potential loss during extraction impacting precision results, control samples were extracted with buffer, pooled together, and fortified with recombinant protein standards. The precision results showed in general CVs $\leq$ 20% for both inter- and intraday analysis for all three proteins (Table 3).

Specificity/Matrix Effects. Specificity is the ability of an analytical method to differentiate a target analyte from other components in a complex matrix. Evaluations for ELISA commonly address assay specificity by spiking nontarget proteins into control tissue at a range of concentrations to determine the level of immunoreactive cross-reactivity and through comparison of standard curves prepared in different dilutions of extracted control tissue to standard curves prepared in buffer to assess matrix effects. Surrogate peptide LC-MS/MS specificity should be addressed during peptide selection in method development with evaluation of recombinant protein standards fortified into control tissue, unfortified control tissues, and tissues containing the protein of interest (Figure 6). Following peptide selection, assay specificity is not as great of an issue with LC-MS/MS because of HIS being used to normalize all samples (not as the quantitation source) and the aforementioned chromatographic separation coupled to MS/MS detection.

Peptide Stability. In addition to peptide stability from an overnight digestion (evaluated from the time-course digestion

[a]AAD-12, 2mEPSPS, and PAT recombinant proteins fortified into leaf, root, and seed control tissues analyzed on Day 0. Fortified tissues and reference peptide standards were stored at 4 °C and reanalyzed on Day 5.

and fortification experiments), digested peptide stability in storage conditions over a length of time was assessed to incorporate sample reinjection and instrument issues, among other factors. The digested AAD-12, 2mEPSPS, and PAT recombinant proteins in control tissue were confirmed to be stable for at least 5 days when stored at 4 °C with acceptable mean recoveries of 70−120% (Table 4).

Sensitivity. The LOD is defined as the analyte concentration that gives a significant difference from the analyte-free sample. The quantitative range is generally defined as the highest and lowest concentrations which can be determined with an acceptable degree of accuracy. The quantitative range was proposed during method development to encompass the general protein levels observed in transgenic plants rather than reflecting the true assay quantitative range. The dynamic range of LC-MS instrumentation has been shown to span 3−5 orders of magnitude,[33] which can be further optimized to increase the defined upper range of quantitation for the assay. The targeted LOD and LOQ (Table 2) for each protein were empirically defined on the basis of assay parameters such as peptide signal intensity and signal-to-noise ratio. In addition to accuracy of recovery, the LOD and LOQ were also verified by statistical approaches[34] using 3 and 10 times the standard deviation, respectively, from the LOQ recovery results for each protein (Table 3). The statistically calculated LOD and LOQ results were less than the target LOD and LOQ results for AAD-12 and PAT in all tissues as well as leaf tissue for 2mEPSPS (Table 3). Statistical calculations of 2mEPSPS were slightly higher for root and seed because of low recovery in one sample from each analysis, potentially caused by the previously mentioned peptide absorption to materials during sample preparation. Overall, the results provide appropriate estimates of the quantitative range of the assay.

Interlaboratory Validation. Independent laboratory assessment of accuracy and precision of the LC-MS/MS method was carried out with AAD-12, 2mEPSPS and PAT recombinant proteins fortified into non-GE control tissues by Critical Path Services, LLC. Recovery results were comparable to data obtained from the full validation carried out by Dow AgroSciences (Tables 3 and 5) and demonstrated LC-MS/MS as a robust workflow incorporating different analysts and instrumentation (vendor, ionization source, and detector) with reproducible results. In addition, minimal optimization was carried out to the original MS/MS instrument parameters during the independent laboratory assessment, yielding similar results between laboratories and demonstrating the ease of transferring the methodology (as has been previously documented in literature).[35]

[a]Interlaboratory method evaluation carried out by Critical Path Services, LLC. Results indicate recovery (%) of recombinant proteins (detected surrogate peptide converted into protein concentrations) fortified into soybean leaf, root, and seed tissues at the LOQ, midrange, and high-range concentrations.

ELISA and LC-MS/MS Comparison. ELISA immunochemistry uses antibodies highly specific to target proteins. Quantitation depends on a single signal produced most commonly from the addition of an enzyme substrate to a specific antibody sandwich containing target protein, producing a colored product. The resulting colored product, measured via optical density, is proportional to the concentration of protein in the sample, which is correlated to the optical densities produced from reference standards. In contrast, SRM LC-MS/MS-based detection is specific by virtue of the chromatographic separation and selective MS/MS detection. SRM LC-MS/MS

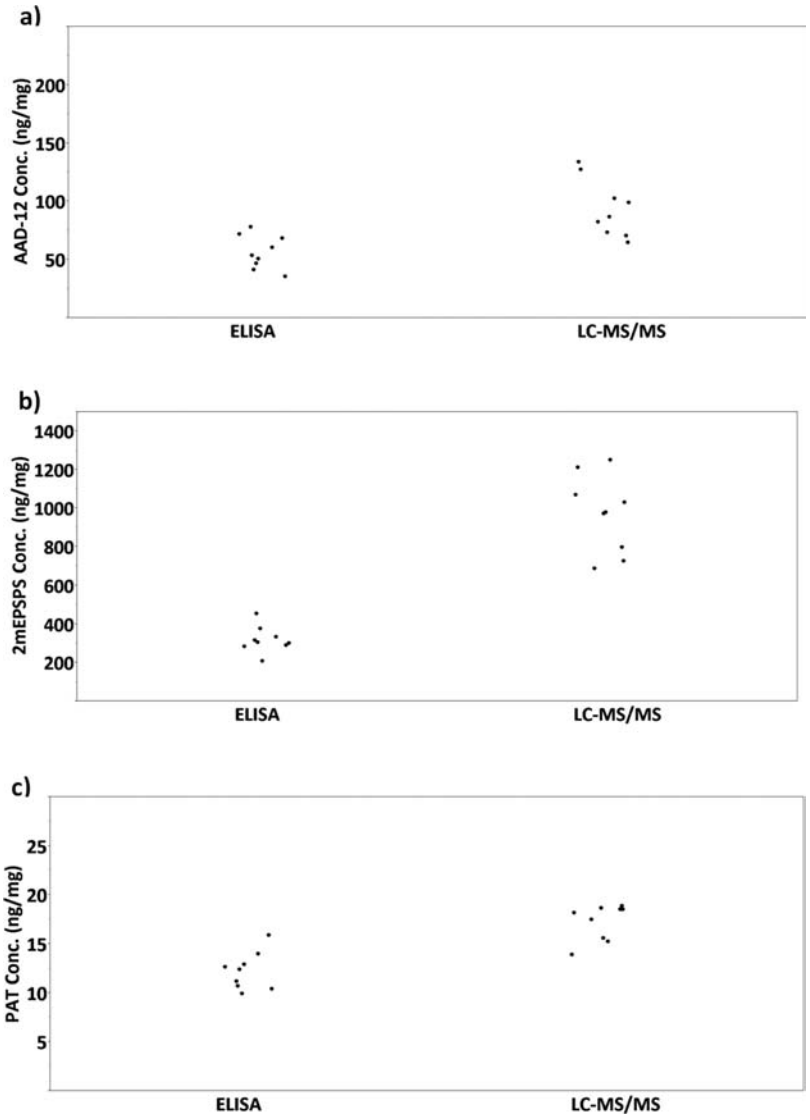

Figure 7. Results (ng/mg) for (a) AAD-12, (b) 2mEPSPS, and (c) PAT proteins in leaf tissue from nine individual soybean plants analyzed by surrogate peptide LC-MS/MS and ELISA.

employs multiple signals to evaluate the concentration of target analyte such as MS/MS confirmation ratios, peak area ratios, and monitoring multiple peptides representing multiple areas of the protein sequence, providing greater confidence in obtained results.[36] The samples and natural abundance peptide reference standards are standardized by virtue of HIS, increasing the precision and accuracy across multiple analysis compared to ELISA. In addition to multiplex capability, the increased dynamic range of LC-MS/MS compared to ELISA (generally 3−5 orders of magnitude compared to 2−3) allows for fewer reanalyses of samples because of the need for sample dilution into the reference standard range. The LOQ for LC-MS/MS was comparable to that of the individual ELISA assays (Table 2).

ELISA measures immunoreactivity of intact proteins by largely depending on protein conformation, whereas surrogate peptide LC-MS/MS measures total abundance of denatured linear peptide chains where unstable protein in tissues will have less impact on quantitation results. Because of the complexity and intrinsic variability of biological analysis that is present in addition to typical analytical challenges, perfect agreement between two vastly different technologies such as ELISA and LC-MS/MS is not expected; however, correlation of the data does support validation of surrogate peptides representative of intact proteins. Nine individual plants were analyzed for AAD-12, 2mEPSPS, and PAT protein levels by ELISA and LC-MS/MS (Figure 7). The LC-MS/MS results were consistently higher likely because of the detection of native and denatured forms of the protein; however, the data demonstrated that both results were comparable for AAD-12 and PAT. Further work is needed for 2mEPSPS to understand the larger than expected difference between ELISA and LC-MS/MS results that in addition to detecting both native and denatured forms of the protein can be explained by the aforementioned surface absorption of reference standard peptides to labware or a larger portion of 2mEPSPS population in a denatured form that would not be detected by ELISA.[37]

This research demonstrates a multiplex format specifically identifying three proteins in a single injection with high confidence. The signature peptides defined in the multiplex LC-MS/MS method were validated to represent intact proteins because the accuracy of target peptide mean recovery values

DOI: 10.1021/acs.jafc.5b03083

from recombinant AAD-12, 2mEPSPS, and PAT proteins fortified into three different types of matrices fell between 70 and 123% across different analysts, laboratories, and instrumentation and because data correlated well with ELISA. The ease of transfer of the method with reproducible results and the ability to quantify multiple proteins from a single injection make LC-MS/MS a suitable technology to quantify transgenic proteins in GE crops.

States, less than 5% of the total crop area is treated with these compounds. In the European Union, the situation of the Netherlands stands out in particular, because the utilization of azole fungicides has almost doubled since the mid-1990s.[13] Several reasons are usually forwarded to justify the use of azoles in agriculture, in particular, the fact that these compounds are not expensive and that they exhibit broad spectrum activity. However, because azoles are very stable molecules, they can persist active in the soil and water for several months[14] as well as in several fruits and vegetables.[15−17] Although the azole residues detected in many samples do not reach health hazard toxic levels, the amount could vary considerably. Data from the literature show that considerable quantities of azole residues could persist in some food products for a long time.[5]

Farmers have been strongly encouraged to follow guidelines aiming to reduce the probability of developing resistance to agricultural antifungals, to minimize its extent, and/or to increase the chance that any developed resistance would still be reversible. Such practices include the rotating use of antifungal products with different modes of action as well as the preferential practice of a limited number of interventions using higher dosages as opposed to more frequent applications with lower dosages. This does not, however, imply that the use of antifungal substances in agriculture should not be closely monitored, considering the risk of accumulation of azoles in the soils (the half-life time of azoles is usually longer than 1 year) and because the newer compounds may also be at the origin of resistance development.

USE OF AGRICULTURAL AZOLE FUNGICIDES IN PORTUGAL

In the particular case of Portugal, there is a real need to promote agriculture and invest in training farmers. According to the results of the Agricultural Census report,[18] the social characterization of the Portuguese family farm population consists of 793 000 individuals representing, 7% of the resident population. The rural population aged considerably between 1999 and 2009; the average age increased from 46 to 52 years. The educational level is rather low; 40% of subjects only attended the first cycle, and 22% have no schooling. However, despite these social indicators, significant improvements were registered during the 10 year period under study; illiteracy rate decreased by 7%, and the frequency of senior secondary cycle and higher education increased by 3%. At the present, the typical profile of the Portuguese farmer nowadays is a 63-year-old male, having just completed the first cycle of basic education, only having practical agricultural training, and working in agricultural activities about 22 h per week.

By December 31, 2012, 907 PPP, based on 248 active substances, were available in Portugal.[19] The largest volume of these substances available at the national market belong to the fungicides group, followed by herbicides and insecticides, representing the remaining products about 15% of the total PPP marketed. According to the Agricultural Statistics report, the ratio between sales of PPP/agricultural area used was in 2008, 2009, and 2010 of 4.6, 3.8, and 3.8, respectively. In the case of the total sales volume being subtracted with the value of sulfur and derivates, this ratio corresponds to values of 1.9, 2.0, and 1.9, respectively.[19]

Sales figures of PPP at the national level constitute an indicator that can provide an estimation about the use of such products in Portugal. The amount of PPP sold in Portugal during 2012 corresponded to a total of 12 462 237 kg, expressed as active substances. The fungicides contributed to about 68.3% of the total of active substances sold, whereas sulfur represented 49.8% of the total sales and 71.4% of all of the fungicides sold. Figure 2 depicts an overview of fungicide

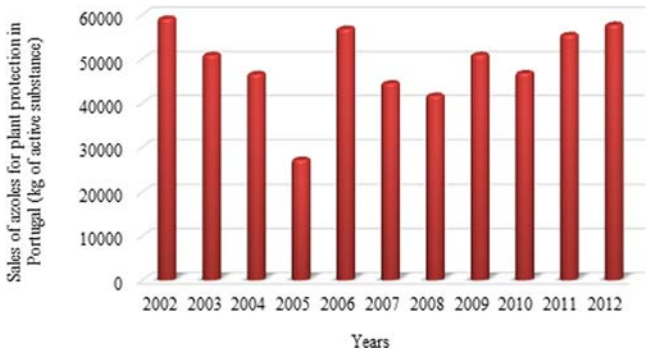

Figure 2. Sales of fungicides in Portugal between 2002 and 2012.[20]

sales by chemical group in Portugal between 2002 and 2012. Overall, a decrease in fungicide sales was registered from 2008 until 2012.[20] With respect to azoles, a consecutive decrease in sales was registered between 2002 and 2005; however, after 2006, the values started to increase again, reaching a peak in 2012 (Figure 3).[20]

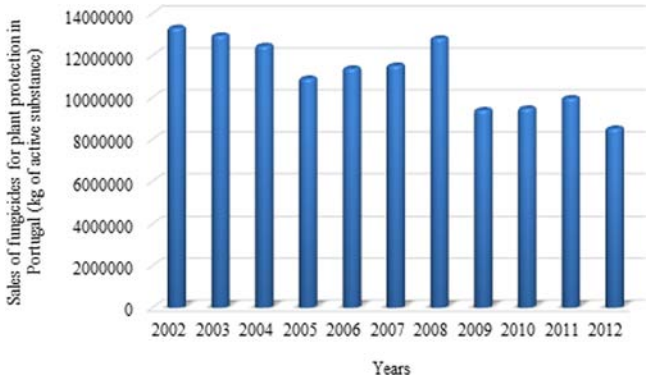

Figure 3. Sales of agricultural azole in Portugal between 2002 and 2012.[20]

MODE OF ACTION OF AZOLE DRUGS

Concerning the mode of action, all of the azole drugs interact and target the same active site in fungal enzyme; thus, agricultural azole fungicides share the mode of action with medical azoles.[21] This results in a fungistatic rather than fungicidal effect; in this sense, the terminology often used in agriculture "fungicides" is ambiguous.

This class of compounds are sterol demethylation inhibitors (SBIs) and impair the synthesis of ergosterol.[5,21] Azole drugs interfere with the activity of fungal lanosterol 14α-demethylase, an enzyme responsible for the transformation of lanosterol in ergosterol. Ergosterol is an important compound of the fungal cytoplasmatic membrane; the impairment of its metabolism induces cell membrane disorganization and decreases fungal growth. Moreover, fungal growth arrest can also result from the accumulation of toxic ergosterol precursors.[22]

The available SBIs—fungicides can be classified into four classes according to their respective target sites, which are membrane-bound enzymes, namely, thiocarbamates or allylamines (squalene epoxidase), inhibithors of C_{14} demethylation or DMIs, amines (Δ^{14} reduction or $\Delta^{8} \rightarrow \Delta^{7}$ isomerization), and hydroxyanilides (C_4 demethylation). However, several resistance mechanisms to SBIs have been described. The two major mechanisms involve either alterations of the target enzyme, which result in a reduced affinity to fungicides, or a decrease of the intracellular drug accumulation, which is linked to an overexpression of membrane transporter proteins, usually, namely, effux pumps.

HYPOTHETICAL LINK BETWEEN AZOLE USE IN AGRICULTURE AND HUMAN HEALTH

Several reports claim that antibiotic resistance can be a natural occurrence in the soil. In fact, microorganisms inhabiting soil have to strive for energy sources; it is known that some bacteria and fungi develop the ability to produce antibiotic compounds to destroy their competitors. Such microorganisms are thus naturally immune to the effects of their own excretions.[23]

The development of resistance to azoles among plant fungal pathogens is complex and generally progressing in small steps. First descriptions date from a long time ago and claim that some plant pathogens acquired azole resistance following agricultural exposure.[24] Data from the literature describe resistance or tolerance to triazole fungicides for pathogens of crops, such as wheat, barley, and strawberry.[25] While, in Portugal, resistance to triazoles in vineyard powdery mildew has been detected in the past,[26] still recent studies describe this situation.[27]

Over the last 2 decades, clinically important fungal infections have become more prevalent because medical progress allows for the survival of an increasing number of immunocompromised patients. However, resistance to antifungal drugs also became a critical medical problem.

It has been proposed that there may be a direct relation between the development of resistance to azole fungicides used in agricultural practice and the development of resistance to azole antifungals observed in clinical settings.[28] Exposure of a microorganism to any antibiotic involves a risk of emergence of resistance through the process of selection. The knowledge about the rate and extent of the emergence of resistant organisms[29] and whether this resistance is reversible or not is a very relevant issue to clinical medicine. Resistance depends upon a variety of factors and conditions, including the mechanisms of action of the compound, the target site(s) in the organism and their number, the risk of resistance transference between individual organisms and species, and the mechanism of such resistance.

Resistance in fungi and the mechanisms involved in its development and transmission differ to some extent from those seen in bacteria. There is no evidence that the genes that confer resistance to fungi can be transferred horizontally, a key difference with bacteria. There are two forms of resistance, primary (or intrinsic) and secondary. In primary resistance, the fungal organism cannot be inhibited even by high concentrations of an antifungal drug. For example, *Aspergillus fumigatus* is intrinsically resistant to fluconazole and does not respond at all to this drug. Similarly, *Candida krusei* and *Candida glabrata* isolates are often intrinsically resistant to fluconazole. Conversely, fluconazole resistance in *Candida albicans* can emerge *de novo* during prolonged treatment, which is an example of secondary resistance.[30]

There are at least three different mechanisms by which antifungal drug resistance might arise. They can involve increased efflux of drug, altered target demethylase sites, and availability of alternative pathways for the synthesis of cell membrane sterols. *C. krusei* shows intrinsic resistance to fluconazole largely as a result of the last mentioned mechanism.

There is also evidence that, in clinical settings, the adoption of some therapeutic strategies to treat patients over long periods or to prevent infection through antifungal prophylaxis can result in selection of resistant organisms, of either the same or different species. Several studies have shown that a strong and persistent antimicrobial pressure upon a microbial population will undoubtedly lead to the selection of resistant clones, particularly whenever the antimicrobial agent induces a static effect instead of a biocidal effect.[23] This situation can happen in fungi submitted to azole pressure. Because azoles represent first line clinical antifungals, the topic of azole resistance is of great medical relevance. Azole resistance can thus hypothetically result from exposure to azole compounds, which can happen *in vivo* (azole-treated patients) or as a result of the presence of these compounds in the environment, namely, agriculture use.[31] The massive use of azoles in agriculture could stress susceptible species of the fungal flora, both in nature but also at human endogenous niches. This disturbance in the fungal flora ecology could result in changes among the population of medically important fungi; human fungi pathogens may thus persist and thrive.[5] In this situation, health risks might increase seriously. In addition, new resistance mutations could also develop in the environment. Studies addressing the epidemiology of invasive fungal infections are of high relevance to determine the hipothetical impact of anthropogenic activities upon the susceptibility profile of yeast and filamentous fungi and also to report any emergent species. In Portugal, two studies conducted at the same institution, within a 10 year interval, revealed several relevant differences not only in susceptibility patterns but, most importantly, with regard to species distribution.[29,32]

Invasive aspergillosis is a very dangerous opportunistic fungal infection. The conidia of *Aspergillus* spp. usually become airborne from soil or decaying organic matter, and patients become infected usually by inhalation from such a reservoir.[13] In 2009, Snelders and co-workers provided for the first time evidence that patients with invasive aspergillosis as a result of azole-resistant *A. fumigatus* might have acquired the organism from the environment.[31] According to this study, resistant

DOI: 10.1021/acs.jafc.5b02728
J. Agric. Food Chem. 2015, 63, 7463−7468

strains of *A. fumigatus* to medical azoles were found in the soil and compost from areas nearby the admission hospital.[31] The dominance of a single resistance mechanism and the genetic homology between the clinical and environmental isolates suggested that the acquisition of azole-resistant isolates from the environment was the most important infection route.

Azole resistance among *A. fumigatus* isolates was not only found in Dutch hospitals;[33] resistant isolates were also detected in several European countries, such as Spain,[34] Belgium,[35] Denmark,[36] Sweden,[37] and France.[38]

Human and animal fungal pathogens, such as *Coccidioides*, *Histoplasma*, *Aspergillus*, and *Cryptococcus*, also thrive in the environment, including plants and food products. It should also be stressed that only a few yeast species are endogenous to the flora of healthy humans; in most occasions, the fungal pathogens are taken up from the environment. Thus, environmental-resistant isolates could have developed antifungal resistance following a prolonged environmental-selective azole pressure. Therefore, the probability that an individual might be exposed to environmental-resistant fungal organisms is real and high. Nevertheless, the stress of residual azoles that might be present in vegetables and other food products upon the endogenous native fungal flora of humans should not be neglected and may also contribute to the emergence of antifungal resistance at endogenous niches.

In the case of *A. fumigatus*, it was concluded that two distinct models of resistance might have developed. One of them occurs following long time exposure to azole treatment, as might occur in clinical settings, supported by several possible genetic mutations, and the other model is facilitated by a single mechanism, TR/L98H mutation, that occurs in environmental isolates under the selective pressure of agricultural azole fungicides. This kind of mutation started spreading worldwide and has nowadays also been described outside Europe.[39] A very recent study conducted in France describes a clinical case of a French farmer who developed invasive aspergillosis caused by an azole-resistant *A. fumigatus* with the TR34/L98H mutation following hematopoietic stem cell transplantation.[40] This farmer had worked in fungicide-sprayed fields from where *A. fumigatus* TR34/L98H isolates were also recovered. This study supports the assumption that humans might indeed be infected with environmental azole-resistant isolates.

Measures to control this problem should be adopted, in particular in the Netherlands, where the TR/L98H mutation became endemic.[5] Interestingly, in Portugal, back in 2007, Araújo et al.[41] compared the antifungal susceptibility profile of different *Aspergillus* species recovered from environmental and clinical sources and found high minimal inhibitory concentration (MIC) levels of clinical antifungals among environmental strains.

Verweij and co-workers reported cross-resistance between azole drugs, which constitutes a very relevant clinical issue, with relatively few therapeutic options available in the case of invasive *Aspergillus* infections.[42] More recently, several studies demonstrated the development of cross-resistance between agricultural and medical azoles.[13,21] Faria-Ramos and co-workers[43] clearly demonstrated that exposure of clinically relevant molds and yeast organisms to azoles used in agriculture does result in the emergence of cross-resistance to clinical azoles, which may not be reversible.

Additional research efforts aiming to reduce the emergence of fungicide resistance are urgently needed, in both agriculture and medical settings. Because the mechanisms providing the basis for fungicide resistance are likely to be conserved between plant and human pathogens, plant pathologists and medical microbiologists should develop effective strategies counteracting the development of antifungal resistance, in a concerted action.

PORTUGUESE NATIONAL STRATEGIE PLAN FOR A SUSTAINABLE USE OF PPP

The Directive no. 2009/128/EC is an innovation in the context of the European Community legislation about PPP; for the first time, legislation was provided about the use of PPP, to protect human health and the environment from possible risks inherent to its use.

To operationalize the implementation of this Directive at the national level, the law no. 26/2013 was published; it regulates the distribution, sales, and application of PPP by professional users as well as adjuvants for PPP and also sets the monitoring procedures for the use of PPP. Together with the law no. 86/2010 (which establishes a mandatory inspection scheme of PPP and its application using equipment authorized for professional use), it constitutes the transposition into national legal order of that European Community law.

The article 51 of this law envisaged the creation of National Action Plans. These plans aimed at reducing the risks and effects of the use of PPP on human health and the environment and to promote the development of integrated protection technical alternatives to reduce dependence of the use of conventional PPP.

The Portuguese National Plan has been prepared with the collaboration of various agents, from either public or private sector, without which would not have been possible to achieve the intended goals. It must also be pointed out that the implementation of this plan will only be effective with the committed collaboration of all of the agents involved in manufacture, storage, sale, and use of PPP as well as those responsible for managing the effects and risks associated with the use of PPP. The correct application of PPP can be encouraged by the training of professionals, appropriate counselling at the point of sale, and monitoring/supervision of compliance by professional users. In the act of sale, adequate information about the use of PPP and the risks and safety instructions regarding human health should be provided to buyers, to enable the adequate management of the risks inherent to the products concerned.

The protection of professionals configures primarily a matter of safety and health regarding the professional handling field use and application of pesticides. Risks may include not only acute intoxication but also chronic and subchronic risks resulting from prolonged exposure. The lines of action chosen for this intervention area are (i) protection of professional users (commercial and storage settings), (ii) reduction of exposure, and (iii) limitation of the use of certain PPP.[44]

The main measure of protection regarding non-professional users is restricting its access to a limited category of PPP. In any case, buyers should be provided awareness of the risks associated with PPP use and about promotion of good general practices regarding its use.

To assess the progress made in reducing the risks and adverse effects of the use of PPP, to both human health and the environment, monitoring plans should be in place so that, on the basis of a sample of professional users and predefined criteria, it will be possible to assess the progresses resulting the

DOI: 10.1021/acs.jafc.5b02728
J. Agric. Food Chem. 2015, 63, 7463−7468

implementation of the general principles of integrated protection.

In addition, it should be emphasized the relevance of the contribution of scientific research and field application of the most recently available scientific and technological information in improving resources and instruments available to the professional users, including complementary or alternative means of use of PPP.

In conclusion, fungicide-based plant protection is at present indispensable for efficient and large-scale crop production. Notably, modern fungicides should exhibit negligible acute toxicity, and the regulations for fungicide application should ensure the availability of safe food. Because long time periods and enormous financial investments are required to develop new fungicides, serious efforts must be taken to prevent emergence of fungicide resistance. This is particularly important because fungicides with novel modes of action are rarely found and resistance to single-target fungicides may occur within the first few years of its field use.

The key to prevent or at least delay the onset of development of fungicide resistance in agriculture is the preparation of efficient fungicide mixtures as well as the rotation between fungicides with different modes of action during a crop campaign. The recommendations are to maintain highly efficient fungicides in the market, precluding the use of monofungicides, to keep its use above a threshold allowing for quantitative resistance to develop. The strategy adopted during the last few decades was to apply single-target fungicides, resulted in a strong selective pressure for mutants with a modified fungicide-binding site. Because fungicides with more than one target are not easy to overcome by mutations, the focus in fungicide screening should also be directed toward identifying multi-site inhibitors. After having such fungicides available, the risk of rapid occurrence of qualitative resistance might be strongly and effectively reduced. Nevertheless, particular attention should be devoted to the assessment of the development of cross-resistance to clinical antifungals, strict monitoring of the emergence of fungal strains with resistance mechanisms, and variations in species distribution regarding both plant and human pathogens, which should be implemented.

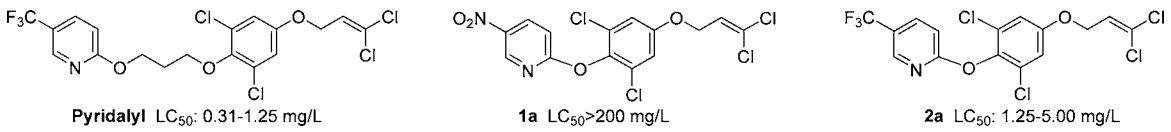

Figure 1. Pyridalyl, NO_2 and CF_3 analogue quantitative structure−activity profiles.

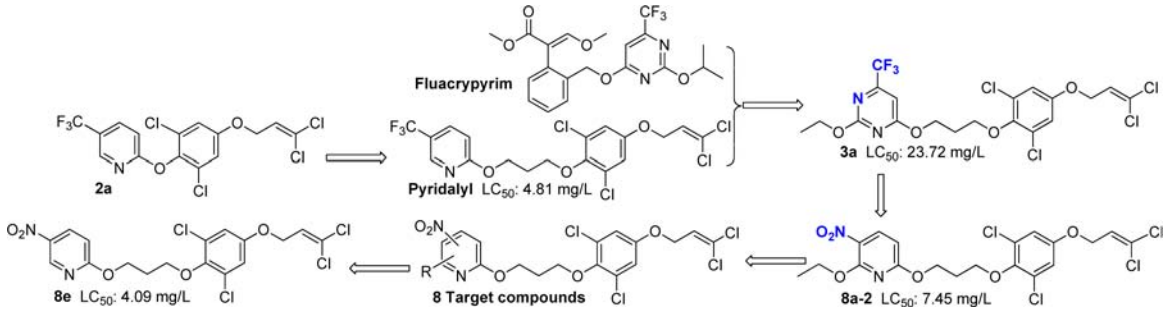

Figure 2. Design strategies of the target compounds containing nitropyridyl.

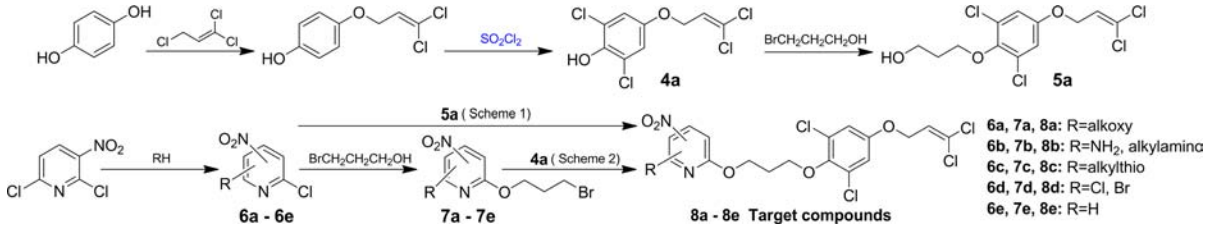

Figure 3. Synthetic pathways for the novel nitropyridyl-based dichloropropene ethers.

suggested that the trifluoromethyl group on the 5-position was required, our other works on nitropyridyl-based compounds indicated that hydrogen exhibited insecticidal activities similar or stronger than that with 6-alkoxy. Therefore, **8a-2** was optimized by replacing the ethoxy with hydrogen to give **8e**. Bioassay results indicated that **8e** exhibited insecticidal activities against major agricultural pests such as *M. separata*, *P. xylostella*, and *P. litura* at levels similar to that of Pyridalyl. The design strategies of all compounds are shown in Figure 2.

MATERIALS AND METHODS

Unless otherwise noted, reagents and solvents were used as received from commercial suppliers. NMR spectra were obtained with a Varian INOVA-300 spectrometer using tetramethylsilane (TMS) as the internal standard and deuteriochloroform ($CDCl_3$) as the solvent. LC-MS were recorded with an Agilent 1260/6120 series and GC-MS with an Agilent 7890-5975C series. Uncorrected melting points were taken in a WRS-1A digital melting points apparatus. Elemental analyses were obtained with a Vario EL III from Elementar.

Synthesis. The general synthetic methods for the target compounds **8** are shown in Figure 3. Representative procedures are given below. Yields were not optimized. All reactions were carried out under a protective atmosphere of dry nitrogen or utilizing a calcium chloride tube.

*2,6-Dichloro-4-(3,3-dichloroallyloxy)phenol (**4a**).* 1,1,3-Trichloropropene (27.6 g, 190 mmol) in *N*,*N*-dimethylformamide (DMF; 30 mL) was added dropwise to a solution of hydroquinone (23.1 g, 210 mmol) and potassium carbonate (30.4 g, 220 mmol) in DMF (100 mL) at room temperature. After 6−8 h of stirring, the reaction was poured into ice−water (500 mL) and extracted with ethyl acetate (2 × 250 mL). The combined ethyl acetate extracts were washed with water and dried with anhydrous sodium sulfate. Then the solvent was removed using a rotary evaporator. The residue was separated by silica gel column chromatography with petroleum ether and ethyl acetate (10:1 by volume) as eluant to give 99.5% (GC) 4-((3,3-dichloroallyl)-oxy)phenol, 26.2 g (63.0%). Sulfuryl dichloride (35.0 g, 260 mmol) was added dropwise to the solution of 4-((3,3-dichloroallyl)oxy)-phenol (26.2 g, 120 mmol) and triethylamine (0.70 g, 7.0 mmol) in toluene (150 mL) at 90−100 °C. The reaction was stirred for 8−10 h. After the extra sulfuryl dichloride was removed, the resulting solution was poured into ice−water (500 mL), washed with saturated sodium hydrogen carbonate solution and then water, and dried with anhydrous sodium sulfate. The solvent was removed to give 95.5% (GC) **4a**: 26.6 g (73.7%).

*2,6-Dichloro-4-(3,3-dichloroallyloxy)phenyl 3-Hydroxypropyl Ether (**5a**).* 3-Bromopropanol (2.02 g, 14.5 mmol) in DMF (20 mL) was added dropwise to a solution of **4a** (2.88 g, 10 mmol) and potassium carbonate (2.00 g, 14.5 mmol) in DMF (60 mL) at room temperature. The reaction mixture was stirred for 26−28 h, after which the reaction was poured into ice−water (150 mL) and extracted with ethyl acetate (2 × 100 mL). The combined ethyl acetate extracts were washed with water and dried with anhydrous sodium sulfate. Then the solvent was removed using a rotary evaporator. The residue was separated by silica gel column chromatography with petroleum ether and ethyl acetate (10:1 by volume) as eluant to give 96.0% (GC) **5a**: 2.14 g (59.4%).

*6-Chloro-2-ethoxy-3-nitropyridine (**6a-2**).* Ethanol (2.40 g, 52.0 mmol) in toluene (10 mL) was added dropwise to a solution of 60% sodium hydride (4.48 g, 112 mmol) in toluene (80 mL) at 0 °C and stirred for 30−45 min. 2,6-Dichloro-3-nitropyridine (10.0 g, 52.0 mmol) in toluene (40 mL) was added dropwise to the reaction mixture. After 2−4 h of stirring at room temperature, the reaction was poured into ice−water (250 mL) and extracted with toluene (2 × 150 mL). The combined toluene extracts were washed with water and dried with anhydrous sodium sulfate. The solvent was removed to give a residue, 9.80 g. Separation by silica gel column chromatography with petroleum ether and ethyl acetate (100:1−50:1 by volume) as eluant gave 95.2% (GC) **6a-2**: 7.92 g (71.7%); GC-MS (EI, 70 eV) (*m*/*z*) 202 (50% M^+), 174 (70% $M^+ - 28$), 158 (100% $M^+ - 44$), 117 (60% $M^+ - 85$); ^{1}H NMR ($CDCl_3$) δ 1.45 (3H, t, J = 7.2 Hz, CH_3), 4.55 (2H, q, J = 7.2 Hz, CH_2), 7.01 (1H, d, J = 8.1 Hz, Py H), 8.24 (1H, d, J = 8.1 Hz, Py H).

DOI: 10.1021/acs.jafc.5b02279
J. Agric. Food Chem. 2015, 63, 7469−7475

*2-Chloro-6-ethoxy-3-nitropyridine (**6a′-2**).* Sodium ethanolate (4.10 g, 60 mmol) in ethanol (20 mL) was added dropwise to a solution of 2,6-dichloro-3-nitropyridine (11.6 g, 60 mmol) in ethanol (40 mL) at 0 °C. After 4−5 h of stirring at room temperature, the reaction was poured into ice−water (350 mL) and extracted with ethyl acetate (2 × 100 mL). The combined ethyl acetate extracts were washed with water and dried with anhydrous sodium sulfate. Then the solvent was removed using a rotary evaporator to give a residue, which was then recrystallized from petroleum ether and ethyl acetate to give 97.0% (GC) **6a′-2**: 5.62 g (44.7%); GC-MS (EI, 70Ev) (*m*/*z*) 202 (30% M^+), 187 (100% $M^+ - 15$), 174 (60% $M^+ - 28$), 158 (60% $M^+ - 44$), 117 (30% $M^+ - 85$); ^{1}H NMR δ($CDCl_3$) 1.40 (3H, t, *J* = 7.2 Hz, CH_3), 4.44 (2H, q, *J* = 7.2 Hz, CH_2), 6.74 (1H, d, *J* = 8.7 Hz, Py H), 8.24 (1H, d, *J* = 8.7 Hz, Py H).

*2-(3-Bromopropoxy)-6-ethoxy-3-nitropyridine (**7a′-2**).* **6a′-2** (2.02 g, 10 mmol) in tetrahydrofuran (THF; 20 mL) was added dropwise to a solution of 60% sodium hydride (0.52 g, 13 mmol) in THF (30 mL) at 0 °C and stirred for 15−30 min. 3-Bromopropanol (1.39 g, 10.0 mmol) in THF (15 mL) was then added dropwise. The reaction mixture was stirred at room temperature for 2−3 h, after which the reaction was treated as described for the synthesis of **5a**. The residue was separated by silica gel column chromatography with petroleum ether and ethyl acetate (50:1 by volume) as eluant to give 98.9% (GC) **7a′-2**: 2.00 g (64.9%); GC-MS (EI, 70 eV) (*m*/*z*) 304 (60% M^+), 289 (15% $M^+ - 15$), 169 (100% $M^+ - 135$), 156 (75% $M^+ - 148$), 140 (65% $M^+ - 164$); ^{1}H NMR ($CDCl_3$) δ 1.40 (3H, t, *J* = 7.05 Hz, CH_3), 2.36−2.42 (2H, m, CH_2), 3.67 (2H, t, *J* = 6.15 Hz, CH_2), 4.43 (2H, q, *J* = 7.1 Hz, CH_2), 4.62 (2H, t, *J* = 6.0 Hz, CH_2), 6.35 (1H, d, *J* = 8.7 Hz, Py H), 8.32 (1H, d, *J* = 8.7 Hz, Py H).

*2,6-Dichloro-4-(3,3-dichloroallyloxy)phenyl 3-[6-Ethoxy-5-nitro-2-pyridyloxy] propyl Ether (**8a-2**).* **5a** (0.88 g, 2.54 mmol) in THF (10 mL) was added dropwise to a solution of **6a-2** (0.52 g, 2.54 mmol) and 60% sodium hydride (0.12 g, 3.00 mmol) in THF (20 mL) at 0 °C and then stirred for 8−10 h at 20−30 °C. The reaction mixture was poured into ice−water (120 mL) and extracted with ethyl acetate (2 × 50 mL). The combined ethyl acetate extracts were washed with water and dried with anhydrous sodium sulfate. After the solvent was removed, the crude product was separated by silica gel column chromatography using petroleum ether and ethyl acetate (200:1 to 100:1 by volume) as eluant to give 95.7% (HPLC) **8a-2** as an oil: 0.38 g, yield 28.0%; LC-MS (APCI, Pos) (*m*/*z*) 511 ($M^+ + 1$); calcd for $C_{19}H_{18}Cl_4N_2O_6$ C 44.56, H 3.54, N 5.47; found C 44.65, H 3.59, N 5.42; ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.45 (3H, t, *J* = 7.1 Hz), 2.26−2.34 (2H, m), 4.10 (2H, t, *J* = 5.9 Hz), 4.54 (2H, q, *J* = 7.1 Hz), 4.56 (2H, t, *J* = 6.3 Hz), 4.57 (2H, d, *J* = 6.6 Hz), 6.09 (1H, t, *J* = 6.2 Hz), 6.34 (1H, d, *J* = 8.7 Hz), 6.84 (2H, s), 8.31 (1H, d, *J* = 9.0 Hz); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 14.39, 29.34, 63.76, 64.15, 65.41, 69.66, 115.19, 120.55, 124.43, 124.93, 126.53, 129.58, 138.61, 145.53, 154.00, 157.03, 164.93.

*2,6-Dichloro-4-(3,3-dichloroallyloxy)phenyl 3-[6-Ethoxy-3-nitro-2-pyridyloxy]propyl Ether (**8a′-2**).* **7a′-2** (1.62 g, 5.30 mmol) in THF (10 mL) was added dropwise to a solution of 60% sodium hydride (0.26 g, 6.50 mmol) and **4a** (1.53 g, 5.30 mmol) in THF (20 mL) at 0 °C. The reaction mixture was stirred for 25−30 min at 0 °C and then for 10−12 h at 20−30 °C. The reaction was then treated as described for the synthesis of **8a-2** to give 96.6% (HPLC) **8a′-2** as an oil: 1.05 g, yield 37.6%; LC-MS (APCI, Pos)(m/z0) 511 (M^++1); calc for $C_{19}H_{18}Cl_4N_2O_6$ C 44.56, H 3.54, N 5.47; found C 44.59, H 3.50, N 5.52; ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.39 (3H, t, *J* = 7.1 Hz), 2.31−2.39 (2H, m), 4.17 (2H, t, *J* = 5.9 Hz), 4.41 (2H, q, *J* = 7.1 Hz), 4.56 (2H, d, *J* = 6.3 Hz), 4.75 (2H, t, *J* = 6.3 Hz), 6.09 (1H, t, *J* = 6.2 Hz), 6.32 (1H, d, *J* = 8.7 Hz), 6.82 (2H, s), 8.31 (1H, d, *J* = 8.7 Hz); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 14.36, 29.37, 63.45, 64.27, 65.44, 69.73, 102.56, 115.18, 124.50, 124.90, 126.26, 129.58, 138.54, 145.54, 154.00, 157.03, 165.05.

The syntheses of **8a′-1**, **8a-3**−**8a-10**, **8b-1**−**8b-10**, **8c′-1**, **8c-2**−**8c-4**, **8d-1**−**8d-4**, **8e′**, and **8e** with ≥95.0% purity (HPLC) were similar to that of **8a-2** or **8a′-2**, and their structures are supported by spectroscopic data in Tables 1 and 2.

Biological Assay.[11−14] *Test Insects.* Stock colonies of test insects were reared in a conditioned room maintained at 25 (±1)°C, 60 (±5)% relative humidity, and 14:10 h light/dark.

Test Compounds. Stock solution of every test compound was prepared in DMF or acetone at a concentration of 1.0 g L^{-1} and then diluted to the required test concentrations (1−500 mg L^{-1}) with water containing 0.2% Tween 80.

Activity against M. separats. Ten third-instar of *M. separata* and five pieces of corn fragments were placed in a Petri dish and sprayed with test solutions using a potter sprayer. After air-drying, the dishes were kept in a room for normal cultivation. Mortality was determined 72 h after treatment. A control group was tested with the solvent only. The test was run three times, and results were averaged. Data were subjected to probit analysis, and the median lethal concentrations (LC_{50}) value of tested compounds were calculated (95% FL).[15]

Activity against Plutella xylostella or Prodenia litura. Cabbage leaves were dipped into test solutions for 10 s. After air-drying, five leaves were put into a Petri dish with 10 third-instar of test insects, kept in a room for normal cultivation. Mortality was assessed 72 h after treatment. A control group was tested with the solvent only. The test was run four times. Data were treated as described for *M. separata*.

RESULTS AND DISCUSSION

Chemistry. The synthesis scheme shown in Figure 3 provides moderate yields of the test compounds. The structures of all synthesized compounds were analyzed and confirmed by ^{1}H NMR and MS. Due to the structural similarity of compounds **8**, only some representative compounds, such as **8a′-1**, **8a-2**, **8a′-2**, **8b-2**, **8e**, and **8e′**, were analyzed and confirmed by ^{13}C NMR and **8a-2**, **8a′-2** and **8e** by elemental analysis. Table 1 summarizes the chemical structures, MS data, and physical characteristics of compounds **8**. NMR and elemental analysis data are listed in Table 2.

Due to the presence of the nitro group on the pyridyl ring, we expected to observe positional isomers on compounds **8**. Selective synthesis of positional isomers of **6** can be achieved by selecting different solvents. In aprotic solvent, the reaction of 2,6-dichloro-3-nitropyridine and nucleophilic alcohol yields mostly 3-NO_2 product **6a′**; in protic solvent, however, the same reaction gives mainly 5-NO_2 product **6a**. Also in protic solvent, the reaction of 2,6-dichloro-3-nitropyridine and nucleophilie amine or thiol gives 3-NO_2 product **6b′** or **6c′**.

Positional isomers may be differentiated with ^{1}H NMR data. Because NO_2 is a strongly electron-withdrawing group, when NO_2 is on the ortho position of $-OCH_2CH_2CH_2O-$ (defined as 3-NO_2), the maximum value of δ_H in $-OCH_2CH_2CH_2O-$ is usually ≥4.75 ppm; however, when NO_2 is on the para position of $-OCH_2CH_2CH_2O-$ (defined as 5-NO_2), the maximum value of δ_H in $-OCH_2CH_2CH_2O-$ is often <4.75 ppm. For example, δ_H = 4.56 for **8a-2** and δ_H = 4.75 for **8a′-2**.

Another way to identify positional isomers of compounds **8** is to study the ^{1}H NMR or GC-MS of their corresponding intermediate **6** and **7**. In ^{1}H NMR, the hydrogen on the ortho position of chlorine on the pyridyl ring has a lower chemical shift value than the hydrogen on the ortho position of alkoxy, alkylthio, or alkylamino on the pyridyl ring. For example, δ_H = 7.01 for **6a-2** and δ_H = 6.74 for **6a′-2**. In GC-MS, when the alkoxy locates between the nitro group and the nitrogen atom in the pyridyl ring, the base peak is usually $M^+ -$ alkoxy + 1 or $M^+ -$ alkyl + 1 because alkoxy or alkyl can be removed easily. For example, the base peak of **6a-2** is 158 ($202 - OCH_2CH_3 + 1$), but the base peak of **6a′-2** is 187 ($202 - CH_3$).

Insecticidal Activity. All compounds prepared were evaluated for initial activity against *M. separata* at 100 mg/L by typical assay above, and LC_{50} was calculated through further

[a]40 mg/L. [b]12.5 mg/L. [c]No test.

assay in which five to six different concentrations were used and are listed in Table 1. A few representative compounds were evaluated against *P. xylostella* and *P. litura*, and LC_{50} values of **8a-2** and **8e** are listed in Table 3. The activities of Pyridalyl are also shown in Tables 1 and 3.

As shown in Table 1, all compounds **8** except **8a-9**, **8a-10**, **8d-2**, **8d-4**, and **8′** exhibit 100% insecticidal activity against *M. separata* at 100 mg/L, and some compounds have shown potent insecticidal activities when compared with commercial insecticides. For example, **8a-2**, **8a-4**, **8a-5**, **8b-2**, **8d-1**, and **8e** have LC_{50} (mg L^{-1}) values of 7.45, 5.58, 8.58, 7.13, 8.37, and 4.09, respectively. Particularly, the LC_{50} value of **8e** is at the same level as that of Pyridalyl.

Apparent Structure–Activity Relationship. The general structure of compounds **8** (Figure 3) was optimized through the R moiety and the position of the nitro group. Different choices of R and position of NO_2 can greatly affect insecticidal activity (Table 1).

When the nitro group was kept on the 5-position, the insecticidal activity against *M. separata* was influenced by the nature of the R group. Changing the R group from 6-alkoxy to 6-alkylamino or 6-alkylthio maintained or slightly reduced the insecticidal activity. For example, the insecticidal activities were correlated as follows: **8c-2** < **8b-2** ≈ **8a-2**, **8b-3** < **8c-3** < **8a-3**, **8c-4** < **8b-4** < **8a-4**. For 6-substituted analogues, the results in Table 1 show that a C_2–C_3 saturated alkyl chain was required for the development of optimal insecticidal activity, and there was no obvious relationship between activity and the number of carbon atoms in alkyl; for 3-substituted analogues, the insecticidal activities of the corresponding compounds increased. For example, the insecticidal activities of **8d-1** and **8d-3** were stronger than those of **8d-2** and **8d-4**, respectively; for R = H, the resulting compound **8e** showed the highest activity among compounds **8** and possessed levels of insecticidal activity comparable to that of Pyridalyl. When the position of the nitro group was changed from 5-NO_2 to 3-NO_2 and R was kept constant, the insecticidal activity of the corresponding compound decreased as illustrated by the orders **8a′-2** ≪ **8a-2** and **8e′** ≪ **8e**.

In general, for compounds **8** the activity order of NO_2 is 5-NO_2 ≫ 3-NO_2. The activity order of R is H > 6-$OCH(CH_3)_2$ > 6-OCH_2CH_3, 6-$NHCH_2CH_3$ > 6-$O(CH_2)_3CH_3$, 3-Cl > 6-$O(CH_2)_2CH_3$, 6-$NHCH(CH_3)_2$, 6-SCH_2CH_3 > 6-$NHCH_3$,

Table 3. LC_{50} against *P. xylostella* and *P. litura* of 8a-2, 8e, and Pyridalyl (3 Days)

no.	$Y = a + bx$	r	LC_{50}(mg/L)
	P. xylostella		
8a-2	$Y = 2.6262 + 2.77x$	0.993	7.07
8e	$Y = 4.0618 + 1.4006x$	0.9964	4.68
pyridyl	$Y = 3.9255 + 1.6996x$	0.9880	4.29
	P. litura		
8a-2	$Y = -3.1505 + 4.6849x$	0.9659	54.92
8e	$Y = 2.8096 + 2.0033x$	0.9734	11.66
pyridyl	$Y = 2.8738 + 2.1177x$	0.9942	10.07

6-$S(CH_2)_2CH_3$ > 3-NH_2, 6-$NHCH_2CH{\equiv}CH$, 6-$NH(CH_2)_2CH_3$, 6-$NHCH_2CH{=}CH_2$, 6-$NHCH_2C_6H_5$.

The above results demonstrate that besides the trifluoromethyl group in Pyridalyl,[6] a nitro group on the 5-position of the pyridyl ring is also viable for the development of optimal insecticidal activity when the chain between the phenyl ring and the pyridyl ring is $-OCH_2CH_2CH_2O-$. Further studies on the biological activity and structure−activity relationships of this series of compounds are in progress.

and development of the insects.[15] Thus, the composition of single polyphenols in plant tissues may be influenced by nutrition, cultivars, rootstock, growing technology, and pathogen attack.[16,17] However, Mikulič Petkovšek et al.[18] found that leaf development had no effect on polyphenolic content. In pear fruit, the predominant phenolic constituents are chlorogenic, caffeic, *p*-coumaroylquinic and *p*-coumaric acids, arbutin, and a number of procyanidins and flavonol glycosides.[19]

Plant resistance to phytophagous insects[20] can be achieved through antixenosis (insect deterrence) or inhibition of insect growth, development, reproduction, and survival (antibiosis), or alternatively, the plant may acquire an increased ability for herbivore tolerance.[21] Although both antixenosis and antibiosis are generally associated with resistant pear genotypes, some of these expressed only one of the two traits, suggesting genetic independence.[4]

Resistance of deciduous trees to phloem feeding insects is hypothesized to result from a combination of constitutive and induced physical and chemical defenses.[22] Despite the fact that a comprehensive knowledge concerning pear foliar phenolics is recognized as mandatory for understanding their involvement in defense mechanisms, little is known about their composition. Therefore, our aim was to study the preformed or constitutive content of polyphenols in leaves of pear cultivars of diverse origin and with different resistance to psylla. Furthermore, we sought to clarify whether one or several of the phenolic compounds in pear leaves are putatively involved in pear resistance to psylla. To this end, the most important foliar pear polyphenols were defined using principal component analysis (PCA). Conclusions from this study can provide us guidance in future pear breeding programs.

MATERIALS AND METHODS

Plant Material. The plant material for comparison was obtained from a five-year-old pear orchard in Grocka (44° 66′ N and 20° 72′ E) near Belgrade, Serbia. In this experimental orchard, 22 pear cultivars (Table 1) were chosen according to their different resistance to psylla and origin. Using data in the literature[23,24] and after empirical observation, the cultivars were divided into two groups, where the first included 16 cultivars of *P. communis*, and the second consisted of five cultivars of *P. pyrifolia* and one interspecific hybrid (*P. pyrifolia* x *P. communis*). Planting distance was 4 × 1.2 m, and Quince BA29 was used as the rootstock. The soil is classified as Eutric Cambisol. The trees were trained in spindle bush shape and were grown under nonirrigated standard cultural conditions.

Each cultivar was represented by three plants, with each replicate being composed of 20 leaves, sampled from a single tree randomly from all around the canopy. Leaves were gathered on the same day, from the median section of one-year branches at the end of June, when fully formed. None of the leaves had any disease or pest symptoms, so there were no induced plant responses. After collection, leaves were air-dried for 10 days and kept in a dark ventilated place. The leaves were then bagged and stored at room temperature until the analysis. All data presented in the tables are means of three replicates.

Reagents and Standards. Acetonitrile and formic acid (both of MS grade), methanol (HPLC grade), hydrochloric acid, sodium carbonate, sodium acetate, sodium hydroxide, and Folin-Ciocalteu reagent were purchased from Merck (Darmstadt, Germany). Ultrapure water (Thermofisher Scientific, Bremen, Germany) was used to prepare standard solutions and blanks. Syringe filters (13 mm, PTFE membrane 0.45 μm) were purchased from Supelco (Bellefonte, PA, USA).

2,2-Diphenyl-1-picrylhydrazyl (DPPH) and phenolic standards (gallic, protocatechuic, chlorogenic, *p*-hydroxybenzoic, gentisic, caffeic, ellagic, *p*-coumaric and ferulic acids; aesculin, epicatechin, catechin, rutin, naringin, umbelliferone, quercetin, and *trans*-resveratrol) were purchased from Fluka AG (Buch, Switzerland).

Preparation of Standard Solutions. A 1000 mg/L stock solution of a mixture of each phenolic standard was prepared in methanol. Dilution of the stock solution with methanol yielded working solutions at concentrations of 0.025, 0.050, 0.100, 0.250, 0.500, 0.750, and 1.000

DOI: 10.1021/acs.jafc.5b03394
J. Agric. Food Chem. 2015, 63, 7476−7486

mg/L. Calibration curves were obtained by plotting the peak areas of the standards against their concentration. Calibration curves revealed good linearity, with R^2 values exceeding 0.99 (peak areas vs concentration).

Preparation of Sample Extracts. To prepare leaf samples for measurement of total phenolic content (TPC), radical scavenging activity (RSA) and UHPLC-MS/MS Orbitrap analysis, 2 g of dry leaves (lamina with midrib and lateral veins) were ground into powder and extracted three times with 100 mL of a mixture of methanol/water (70/30) containing 0.1% HCl in an ultrasonic bath for 1 h at room temperature. The residue after evaporation was dissolved in a mixture of methanol/water as described by Pavlović et al.[25]

UHPLC–MS/MS Orbitrap Analysis of Polyphenolic Compounds. The compounds of interest were separated using a liquid chromatography system. This consisted of a quaternary Accela 600 pump and Accela Autosampler connected to a linear ion trap-orbitrap hybrid mass spectrometer (LTQ OrbiTrap XL) with a heated-electrospray ionization probe, HESI-II (ThermoFisher Scientific, Bremen, Germany).

Separation was achieved on a 100 × 2.1 mm i.d., 1.7 μm, Syncronis C18 analytical column (ThermoFisher Scientific, Bremen, Germany). The mobile phase consisted of (A) water + 0.1% formic acid and (B) acetonitrile + 0.1% formic acid. A linear gradient program at a flow rate of 0.300 mL/min was used as follows: 0.0–1.0 min 5% B, 1.0–12.0 min from 5% to 95% B, 12.0–12.2 min from 95% to 5% B, then 5% B for 3 min. The injection volume was 5 μL.

The mass spectrometer was operated in negative mode. HESI–source parameters were described previously.[26] Phenolics were identified and quantitated according to the corresponding spectrometric characteristics of reference standards: mass spectra, accurate mass, characteristic fragmentation, and characteristic retention time. Xcalibur software (version 2.1) was used for instrument control, data acquisition, and data analysis. The generated MS/MS spectra were processed by ToxID software (version 2.1.1). Quantitative analysis was done according to the exact mass search method (±5 ppm) by comparing the retention times and exact mass of available standards.

Full scan analysis was employed for detection of the monoisotopic masses of deprotonated unknown compounds, while the MS/MS experiment provided fragmentation pathways. Unknown compounds were identified on the basis of their monoisotopic mass and MS/MS fragmentation, and confirmed using previously reported MS fragmentation data. This exact mass search of unknown compounds was based on high resolution MS analysis (OrbiTrap), online database searching and prediction of MS/MS fragmentation and fragmentation pathway using Mass Frontier 6.0 software (ThermoFisher Scientific, Bremen, Germany).

Determination of TPC and DPPḢ Radical Scavenging Activity. The total phenolic content in leaf extracts was determined as described by Singleton and Rossi[27] using the Folin-Ciocalteu reagent. The TPC values were expressed as grams of gallic acid equivalent (GAE) per kilogram dry weight (DW), based on a standard curve for 20–100 mg of gallic acid/L. The radical scavenging activity of the leaf extracts was measured employing the DPPḢ method of Pavlović et al.[25] The Trolox calibration curve was plotted as a function of the percentage inhibition of the DPPH radical. The results are expressed as millimoles of Trolox equivalents per kilogram of sample (mM TE/kg).

Statistical Analysis. Data for all measurements made in triplicate are expressed as the mean ± standard error (SE). One-way analysis of variance (ANOVA) was used to evaluate the experimental data, followed by Tukey's test to detect significant differences ($p \leq 0.05$) between the mean values. Pearson's coefficient of correlation between values for TPC, RSA and the content of phenolic compounds was also determined. These analyses were performed with the statistical program MS Excel (Microsoft Office 2007 Professional). PCA was carried out employing the PLS_Tool Box software package for MATLAB (Version 7.12.0). All data were group-scaled prior to PCA. The singular value decomposition algorithm (SVD) and a 0.95 confidence level for Q and T2 Hotelling limits for outliers were chosen.

RESULTS AND DISCUSSION

Determination of Total Phenolic Content and DPPḢ Scavenging Activity. Samples were characterized by determination of total phenolic content (TPC) and radical scavenging activity (RSA) as shown in Table 2. TPC values ranged from 27.03 ('Kumoi') to 56.93 g of GAE per kg of DW in 'Coscia' cultivar. Generally, European pear cultivars (*P. communis*), which are susceptible to psylla, had somewhat higher TPC values (43.04 g of GAE per kg DW) than *P. pyrifolia* cultivars (38.06 g of GAE per kg DW). Although it is generally known that pest resistance is influenced by polyphenols, total phenolic levels may not be as important as high levels of one or a few specific compound(s) that exhibit activity toward *C. pyri*. The results for RSA ranged from 0.15 ('Precoce de Trevoux') to 0.35 mmol TE/g DW ('Coscia'). ANOVA showed a statistically significant difference between RSA values obtained for *P. communis* and *P. pyrifolia* cultivars ($P < 0.001$; $F = 92.15$; $F_{crit} = 1.80$). Similarly, a statistically significant difference was found between *P. communis* and *P. pyrifolia* cultivars for total phenolics ($P < 0.001$; $F = 540.87$; $F_{crit} = 1.80$). Therefore, Tukey's test was used to determine the significance of differences ($P \leq 0.05$) between individual samples (Table 2).

[a]Different letters in the same column denote a significant difference according to Tukey's test, $p < 0.05$.

Analysis of Phenolic Compounds. A UHPLC system coupled to an OrbiTrap MS was utilized in order to obtain a comprehensive profile of individual phenolic compounds (Figure 1, Table 3). A total of 17 compounds were quantitated by comparing retention times and MS spectra with available standards (Table 4). The results showed that the analyzed leaf samples contained roughly the same types of phenolics,

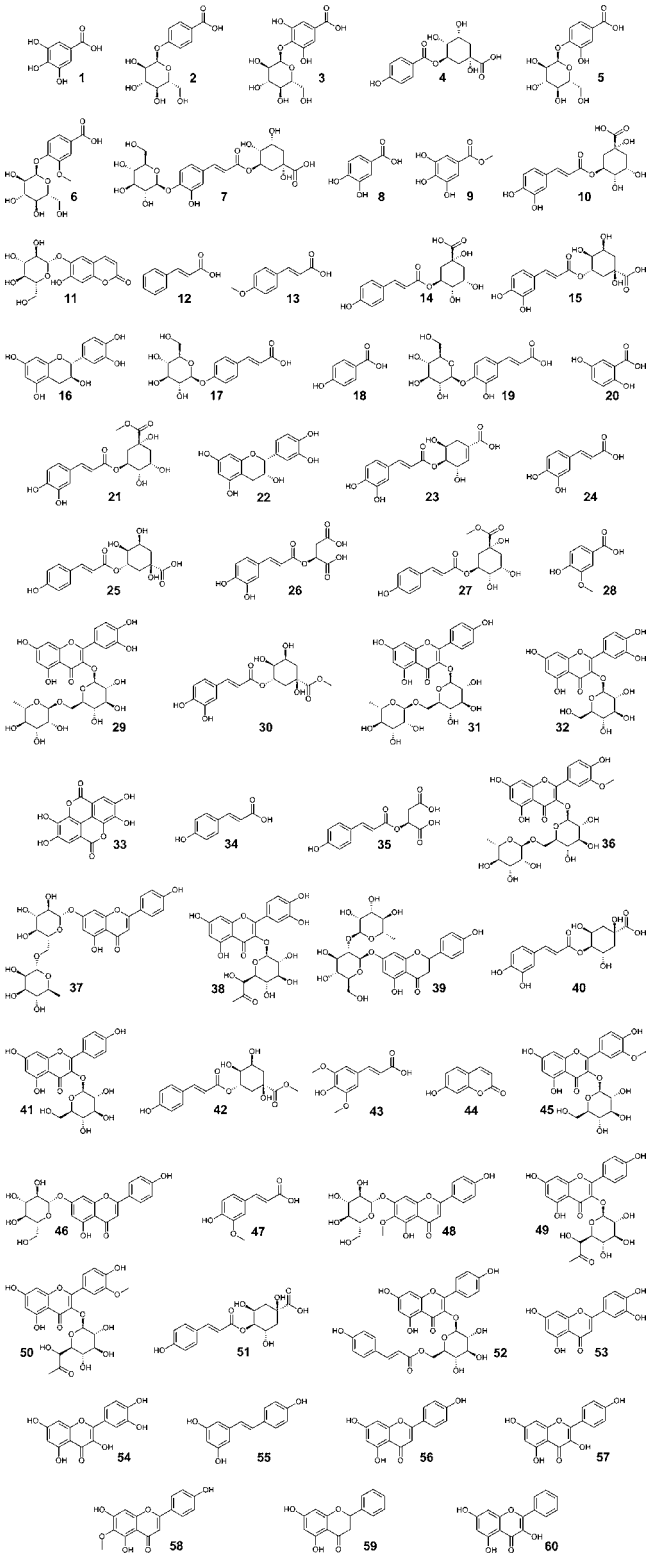

Figure 1. Structures of phenolic compounds found in pear leaf samples. Glycosylation position is uncertain.

although differences in concentration of individual compounds were detected between cultivars.

Chlorogenic (5-*O*-caffeoylquinic) acid was the most abundant phenolic compound, accounting for an average of 44% of the total polyphenolics quantitated in leaves of all pear cultivars, which is consistent with the findings of Colarič et al.[28] In addition, pear leaves stored significant amounts of *p*-coumaric acid (20%), ferulic acid (15%), and rutin (10%).

Among the hydroxybenzoic acids, we measured gentisic acid, protocatechuic acid, gallic acid, and *p*-hydroxybenzoic acid. Together they accounted for 5% of the total quantitated phenolics. In resistant (Oriental) pear cultivars, the mean value for *p*-hydroxybenzoic acid ranged from 5.37 ('Nijisseiki') to 133.22 mg/kg DW ('Niitaka'). In *P. pyrifolia* cultivars, its level was 45% higher than in European cultivars. Conversely, mean values for protocatechuic acid and gallic acid in European cultivars were 41% and 40%, respectively, higher than in Oriental ones. It was interesting to note that 'Santa Maria', a highly susceptible cultivar, accumulated large quantities of gentisic acid (36.88 mg/kg DW), i.e. ∼11-fold higher than the average for all other cultivars examined. This can be explained by the fact that gentisic acid has a role as an intermediary signal in compatible plant−pathogen interactions, where it can act as a defensive component of the antipathogenic response, with progressive accumulation showing correlation with disease development.[29] 'Santa Maria' had probably been attacked previously by some pathogen (viroids, viruses, fungi, or bacteria), which had induced such a reaction.

Hydroxycinnamic acids (chlorogenic acid, caffeic acid, ferulic acid, and *p*-coumaric acid) were other major phenolic compounds detected in the pear leaves. The total content showed a wide range; from 722.63 mg/kg DW ('Ilinjača') to 2227.91 mg/kg DW ('Williams') and varied from 61% in 'Ilinjača' up to 95% of the total quantitated phenols in 'Nijisseiki'. As previously documented, the main hydroxycinnamic acid found here was chlorogenic acid. This compound was most abundant in almost all cultivars, except for 'Santa Maria', 'Williams', 'Kieffer', and 'Precoce de Trevoux', where *p*-coumaric acid showed predominance. The level of chlorogenic acid in European cultivars was between 477.63 mg/kg DW ('Santa Maria') and 1185.99 mg/kg DW ('Coscia'), while in Oriental cultivars it varied from 358.22 mg/kg DW ('Kumoi') to 765.56 mg/kg DW ('Nijisseiki').

Thus, Oriental pears stored 42% lower levels of chlorogenic acid than European pears, which confirm the results of Cui et al.[30] and Gunen et al.,[31] who reported that European pears are a much better source of this compound. Leiss et al.[32] claimed that chlorogenic acid acts as a feeding deterrent and a growth inhibitor for various leafhoppers, aphids, and thrips. European cultivars that stored higher amounts of chlorogenic acid showed moderate resistance to psylla ('Alexander Lucas', 'Bella di Giugno', 'Carmen', 'Moldova's early', 'Abbé Fétel', 'Coscia', etc.), while some with low values ('Santa Maria', 'Butirra Precoce Morettini', and 'Precoce de Trevoux') were highly susceptible. The only exception was 'Jeribasma', sharing both a moderate level of chlorogenic acid and high resistance to psylla, a combination of traits which resembles that of Oriental pears. This favors the supposition that one of the progenitors of this cultivar must have been *P. pyrifolia*, which agrees with the conclusion of Bell and Stuart.[23]

P. pyrifolia and *P. communis* cultivars stored different amounts of caffeic and *p*-coumaric acid. The mean values for caffeic and *p*-coumaric acid in European cultivars were 32% and 29%, respectively, which were higher than those in Oriental cultivars (Table 4). The concentration of ferulic acid, another compound belonging to this group, was very cultivar dependent, with 'Bella di Giugno' showing the lowest value (18.05 mg/kg DW) and 'Nijisseiki' having the highest concentration (412.92 mg/kg DW). In Oriental pears the

[a]Confirmed using available standards; all the other compounds were identified based on MS/MS data.

mean ferulic acid concentration was 54% higher than in the European cultivars. This was expected since ferulic acid was reported to be a factor in resistance of peanut species to thrips.[33]

Catechin was detected only in four pear cultivars ('Carmen', 'Beurre Bosc', 'Williams', and 'Kieffer'), where amounts varied from 1.04 mg/kg DW in 'Kieffer' to 15.80 mg/kg DW in 'Williams'. Among highly resistant cultivars (Oriental), only 'Kieffer', which is a hybrid of *P. pyrifolia*, and 'Williams', contained small quantities of catechin, while in others this compound could not be detected. In contrast, the susceptible cultivar 'Williams' stored relatively large quantities of catechin. Epicatechin was found in half of the cultivars (Table 4). The content was rather variable, ranging from 1.15 mg/kg DW in 'Niitaka' up to 91.21 mg/kg DW in 'Williams'.

From the flavonol group only rutin and quercetin were quantitated in pear leaves. Rutin showed quite a wide range, from 6.31 mg/kg DW in 'Shinsui' to 541.98 mg/kg DW in 'Precoce de Trevoux'. The mean value for this compound in European cultivars was 317.64 mg/kg DW compared to 33.02 mg/kg DW for Oriental cultivars. Namely, *P. communis* stored ~90% more rutin than *P. pyrifolia*. Such results were predicted, since rutin has been shown to be a phago- and oviposition stimulant.[15] Determination of quercetin content disclosed that some cultivars did not store this compound. The leaves of the cultivar 'Santa Maria', which is highly susceptible to psylla, accumulated the highest level of quercetin (239.40 mg/kg DW). Clearly, the role that flavonols play in defending plants against insect attack is complex and probably species (cultivar)-specific.

Aesculin showed a relatively wide concentration range among cultivars, from 2.76 in 'Alexander Lucas' to 10.63 mg/kg DW in 'Shinsui'. In general, cultivars of *P. pyrifolia* had ~32% more of this coumarin glucoside than cultivars originating from *P. communis*. The situation regarding naringin, a flavanone glycoside, was almost the same. Oriental pears had a 56% higher level of this compound than European pears. According to Atteyat et al.[34] naringin can be used as a botanical insecticide leading to significant mortality of nymphs and adults of the woolly apple aphid, *Eriosoma lanigerum* (Hausmann).

Umbelliferone, a natural coumarin, was present in ten cultivars. Within Oriental pears, umbelliferone was not detected, except for trace quantities in 'Nijiieseiki' (0.07 mg/kg DW). Moreover, some European cultivars also did not store any ('Poire de Cure', 'Ilinjača', 'Carmen', 'Beurre Bosc', 'Moldova's early', 'Abbé Fétel', 'Bella di Giungo', and 'Coscia'), while 'Williams' accumulated the largest amount (10.92 mg/kg DW). 'Kieffer' probably inherited this trait intermediately, as the level of umbelliferone was between those for Oriental pears and 'Williams'.

The stilbene phytoalexin, *trans*-resveratrol, was undetectable only in 'Coscia'. In European cultivars, levels ranged from 7.64 mg/kg DW ('Beurre Bosc') to 62.16 mg/kg DW ('Williams'), and in Oriental ones, from 22.92 mg/kg DW ('Nijiieseiki') to 54.47 mg/kg DW ('Kieffer'). In Oriental pears the mean value for *trans*-resveratrol was 22% higher than in European pears. According to Wang et al.,[35] levels of *trans*-resveratrol were found to be affected by genotype, cultural practices, and environmental conditions.

In the absence of standards, a total of 43 phenolic compounds were identified based on the search for $[M-H]^-$ deprotonated molecules and their fragmentation. The retention times (t_R, min), molecular formula, calculated and exact masses

[a]Number of compounds corresponding to Figure 1 and Table 3.

DOI: 10.1021/acs.jafc.5b03394
J. Agric. Food Chem. 2015, 63, 7476−7486

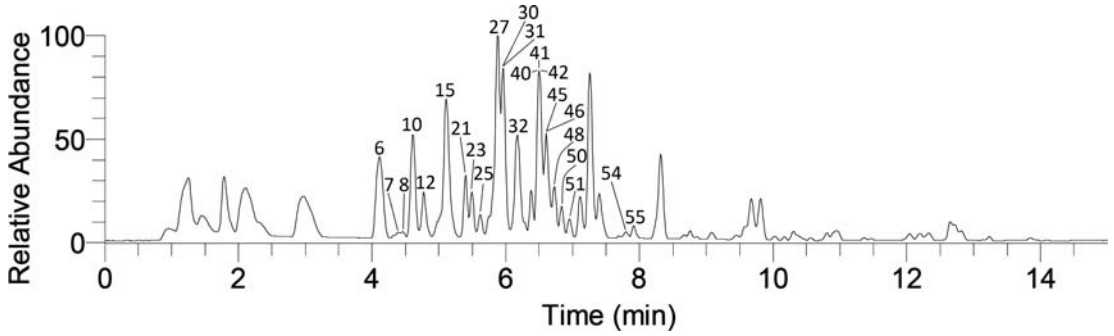

Figure 2. Base peak chromatogram of "Shinsui" pear leaf extract. Number of compounds corresponding to Figure 1 and Table 3.

([M−H]$^-$, m/z), mass accuracy errors, as well as major MS/MS fragment ions are summarized in Table 3. As the exact nature of the sugar moiety could not be ascertained, tentative structures of identified phenolics are given in Figure 1. A selected base peak chromatogram of a representative leaf extract ('Shinsui') is shown in Figure 2. Peak identification was based on published chromatographic and MS/MS data. In this section an explanation is given on fragmentation utilized for the identification of individual phenolic compounds. The total intensities of individual phenolics obtained from the full scan spectra were used for semiquantitative comparison of their contents in the pear leaf samples.

Examination of mass spectra for our pear leaf extracts revealed numerous phenolic acids and their derivatives. Hydroxycinnamic acids were identified as free acids (cinnamic and sinapic acid), while derivatives were esters with organic acids (malic, quinic, and shikimic acid) and glycosides. All derivatives were characterized on the basis of their exact mass fragmentation pattern recorded in the available literature.[36] *p*-Hydroxybenzoic acid 4-*O*-hexoside and *p*-hydroxybenzoyl-quinic acid were identified in all investigated samples, showing an MS/MS base peak fragment at m/z = 137.

Identification of flavonol and flavone glycosides was largely based on the MS/MS data (Table 3).[37] In the analyzed leaf extracts it was possible to identify hexosides (loss of 162 Da), acetyl-hexosides (loss of 204 Da), rutinosides (loss of 308 Da), and one derivative of *p*-coumaroyl-hexoside. Regarding flavonol glycosides, derivatives of kaempferol, quercetin, and isorhamnetin were found, giving MS/MS base peaks belonging to the deprotonated aglycones at m/z 285, 301, and 315, respectively. Kaempferol 3-*O*-(6″-*O*-*p*-coumaroyl)-hexoside at 7.61 min with the molecular ion at m/z 593 produced an MS/MS base peak at m/z 285 ([kaempferol−H]$^-$) and a secondary MS/MS peak at m/z 307 ([M−kaempferol]$^-$).[38] The compound at 8.60 min, with the molecular ion at m/z 299, and the MS/MS base peak at m/z 284 (obtained by elimination of a methyl group) were tentatively identified as the flavone hispidulin. Furthermore, we identified hispidulin 7-*O*-hexoside (t_R = 6.70 min, m/z 461) with an MS/MS base peak at m/z 299 and a secondary MS/MS peak at m/z 446.[39] Another two apigenin glycosides were also found (apigenin 7-*O*-rutinoside and apigenin 7-*O*-hexoside), both of them showing an MS/MS base peak at m/z 269, which is the mass of deprotonated apigenin.[37] Confirmation for traces of flavonoid aglycones (luteolin, apigenin, kaempferol, pinocembrin, and galangin) was based on data for standards and fragmentation published in the literature.[26]

Although kaempferol was present in the leaves of all tested pear cultivars, its derivate, kaempferol 3-*O*-(6″-*O*-*p*-coumaroyl)-hexoside, and hispidulin were found in almost all *P. pyrifolia* cultivars together with 'Jeribasma'. The former was not detected in 'Nitaka', and the latter in 'Kumoi' and 'Chojuro' cultivars. A similar situation was observed for apigenin 7-*O*-rutinoside, which was present in the same cultivars (Oriental pear cultivars and 'Jeribasma'), as previously. The flavone pinocembrin was detected in cultivars with different psylla susceptibility, from the susceptible cultivar 'Precoce de Trevoux' to the fully resistant 'Chojuro' and 'Shinsui', which leads to the conclusion that this polyphenol could be cultivar dependent.

The most intriguing results are related to the presence of apigenin, a polyphenol connected with insect resistance.[40] This compound was found in the most susceptible cultivar 'Santa Maria', in resistant 'Jeribasma', and in Oriental pears (except 'Kumoi'). There is a possibility that its production is genetically coded, but we believe that this compound is synthesized in response to some kind of stress, not necessarily due to psylla but probably in reaction to some other pest or environmental stress, since it has already been shown to display strong effects against pathogenic fungi.[41] Thus, Potters et al.[42] recorded that synthesis of apigenin can occur in response to some environmental stresses, such as high UV-B and/or UV-A + UV-B radiation in genotypes with large, thin leaf blades, as in 'Santa Maria'.

Civolani et al.[43] examined pear cultivars resistant to *C. pyri* and excluded the existence of surface (trichomes, repellent volatiles, color or toughness of leaf surface), epidermis/mesophyll, and mesophyll/phloem resistance but strongly supported the hypothesis that factors located in phloem sap are responsible for pear resistance. Resistant selections mainly exhibit pronounced nymphal antibiosis, expressed by lower honeydew emission, increased development time, and marked nymphal mortality.[44] Since we examined whole leaf compounds, not just those from the midrib and lateral veins, we are not sure which leaf tissue in *P. pyrifolia* cultivars stored elevated levels of *p*-hydroxybenzoic acid, ferulic acid, naringin, aesculin, kaempferol 3-*O*-rutinoside, apigenin, apigenin 7-*O*-rutinoside, and hispidulin. Considering the findings of Butt et al.,[44] it seems likely that the psylla would sense these compounds during probing, but phloem specific compounds would be more important for inhibition of feeding and antibiosis than whole leaf compounds. Also, according to Hilker and Meiners[45] ovipositional antixenosis is the most important plant defense against herbivorous insects. Horton and Krysan[46] showed that psylla ovipositional activity is more selective than settling and probing activity. Psylla can colonize and feed on nonoptimal hosts, such as *Malus* spp., but they do not lay eggs.

Principal Component Analysis. This part of our study aimed to determine which polyphenolics could be responsible for differentiation of European and Oriental pear leaf samples.

DOI: 10.1021/acs.jafc.5b03394
J. Agric. Food Chem. 2015, 63, 7476−7486

Chemical markers, such as polyphenolics, have been proposed to be useful for classifying pear leaves according to their variety.[47] Several studies have considered relations between different pear species and polyphenolic profiles and have indicated the usefulness of polyphenols as biomarkers.[30,48]

The total intensities of all characterized phenolic compounds, obtained from the full scan spectra processed through ToxID software, were used as variables together with total phenolic content and the radical scavenging activity for PCA. The initial matrix 22 (the number of pear leaf samples) × 62 (total intensities of phenolics, TPC, and RSA) was processed using the covariance matrix with autoscaling. PCA resulted in seven PCs explaining 75.0% of the variation of the data set. The first principal component accounted for 25.2%, the second 11.7%, and the third component 10.6% of the total variance. In Figure 3A (PCA scatter plot) it is evident that the cultivars were clustered in two main groups along the PC1 axis. The first group included six cultivars originating from *P. pyrifolia* and one interspecies hybrid (*P. pyrifolia* x *P. communis*). The loading plot (Figure 3B) revealed the most influential variables

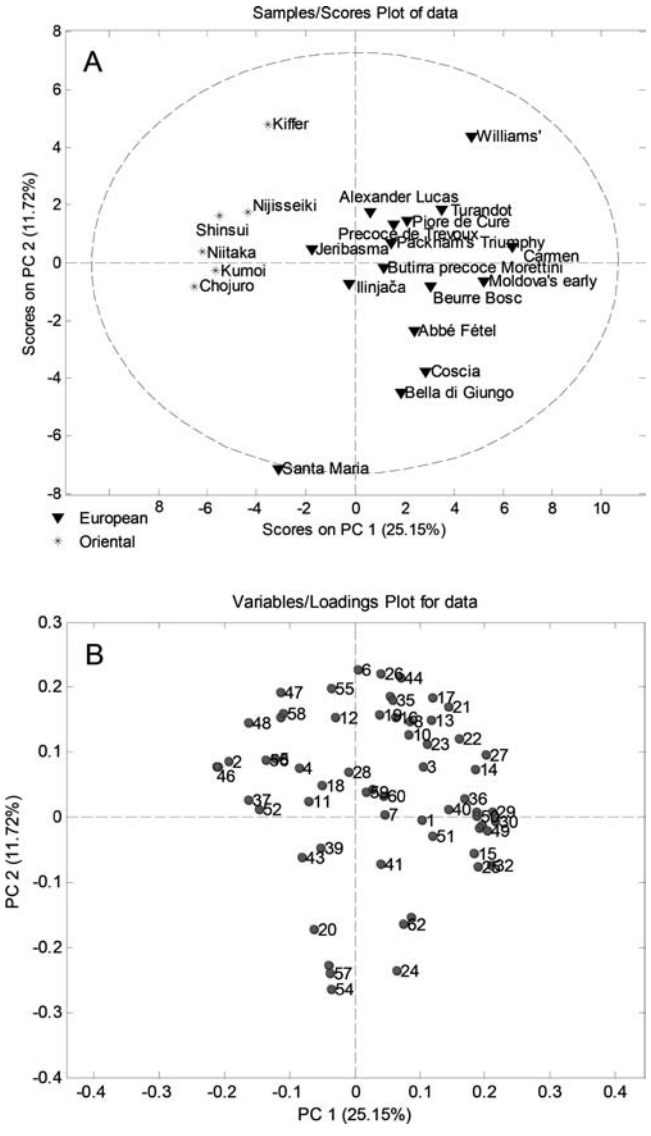

Figure 3. (A) PC scores plot of pear leaf samples; (B) Loadings plot of pear leaf samples.

responsible for classifying the pear leaf samples into two groups. Phenolic compounds that discriminate five cultivars originating from *P. pyrifolia* and the interspecies hybrid (*P. pyrifolia* x *P. communis*) from European cultivars are *p*-hydroxybenzoic acid 4-*O*-hexoside, kaempferol 3-*O*-rutinoside, apigenin 7-*O*-rutinoside, apigenin 7-*O*-hexoside, ferulic acid, hispidulin 7-*O*-hexoside, and kaempferol 3-*O*-(6″-*O*-*p*-coumaroyl)-hexoside. Higher contents of total phenolics, RSA values, and caffeic acid were the most influential in distinguishing 'Coscia' and 'Bella di Giungo' from the other varieties, and the separation was achieved along PC2.

The specific polyphenolic profile of cultivar 'Jeribasma' (named 'Eribasma' in some previous studies) in some respects resembled Oriental cultivars and most probably has *P. pyrifolia* as one of its ancestors.[23] Extremely high levels of quercetin and gentisic acid and the presence of kaempferol and methyl gallate, among other coumpounds, made cultivar 'Santa Maria' an outlier.

Correlations. Relationships between TPC, RSA, and the quantitated phenolic compounds were examined using Pearson correlation analysis. The close correlation between TPC and RSA ($r = 0.855$, $P < 0.001$) suggests that the antioxidant activity of leaves is derived mainly from their phenolic compounds. Significant correlations between some phenolic acids (chlorogenic acid, gentisic acid, and caffeic acid) and quercetin, on the one hand, and between some phenolic acids and TPC ($r = 0.455–0.703$, $P = 0.000–0.033$), on the other, suggest that those polyphenols represent the most important components of TPC. Regarding quercetin, the results were predictable, since it is well-known that it is a powerful antioxidant.[49] Also, some phenolic compounds, such as chlorogenic acid, caffeic acid, and quercetin, were found to be positively correlated with RSA ($r = 0.456$, $r = 0.721$, and $r = 0.446$, respectively, $P = 0.000–0.038$), which is similar to the findings of Sánchez et al.[50] for pear phenolics and antioxidant activity. However, *trans*-resveratrol, a phenolic compound that indicates stress, was negatively related with RSA ($r = -0.427$, $P = 0.047$). Among all phenolics investigated, caffeic acid, *p*-hydroxybezoic acid, and naringin did not correlate with any other polyphenolic components, indicating that those traits are genetically and/or physiologically independent.

This study attempted to discriminate a wide variety of preformed polyphenolics in pear leaves that can be sensed by an adult female, which will process the information and decide whether to initiate egg-laying and/or feeding. Although chlorogenic acid was found to be the predominant polyphenolic compound, followed by ferulic acid and *p*-coumaric acid, in leaves of all tested pear cultivars, *P. pyrifolia* and *P. communis* cultivars in most cases contained roughly the same types of phenolics. However, Oriental pears stored much more *p*-hydroxybenzoic acid, ferulic acid, aesculin, and naringin than European cultivars. We hypothesized that the levels of those four polyphenolics, together with the presence of kaempferol 3-*O*-rutinoside, apigenin, apigenin 7-*O*-rutinoside, and hispidulin, which were exclusively found in resistant pear cultivars, are most probably responsible for pear resistance to psylla. We assume that these results will be investigated further in bioassays of psylla against specific compounds.

Correlation analysis showed the genetic independence of caffeic acid, *p*-hydroxybenzoic acid, and naringin, when compared with the other compounds detected. If so, genes that code the synthesis of those substances could be easily inherited in some future planned hybridization. This analysis of

pear leaves represents a contribution to numerous studies aimed at discovering possible relations between chemical content and plant responses against insects. Thus, our findings could be used as a basis for further investigations of resistance mechanisms at the metabolic and chemical levels. Finally, our results may provide guidance in future pear breeding programs and early seedling selection, because it is possible to recognize ideal combinations of foliar phenolics as a natural defense mechanism against insects. Since phloem specific compounds important for inhibiting psylla feeding and ovipositional antixenosis still remain unidentified, subsequent studies should incorporate other specific phenolics as well as the ratios between them. Besides resistance assays (psylla against specific compounds), new experiments should include analysis of other compounds, such as types and amounts of nitrogenous compounds, especially amino-acids, which directly influence the growth and fecundity of psylla.

their adsorptivity on the surface of a tongue.[16−20] This retention of fat on the tongue can cause residual taste perception (i.e., aftertaste) of flavor compounds that they are interacting but to varying extents.[21]

In this study a systematic approach was used to mechanistically understand the relationship between salt release behavior and perception as affected by biopolymer−salt interactions. The objectives of this study were to specifically evaluate the extent of protein−salt interactions at different solution concentrations and to characterize interfacial effects when biopolymers are structured around nanoscale lipid droplets on salt transport and perception. We modified a chromatography column with a porcine tongue to simulate salt transport in the mouth. Analytical results for salt transport and adsorptivity were then correlated with sensory evaluation to elucidate the mechanisms controlling the perception of saltiness in such colloidal systems. In the subsequent paper we investigated the effects of lipid−protein−salt interactions on the hydration rate, and subsequent salt release, from low-moisture (i.e., freeze-dried) samples.

MATERIALS AND METHODS

Materials. Sodium caseinate (Na-cas) and sodium chloride (NaCl) (USP grade) were both purchased from Sigma-Aldrich (St. Louis, MO, USA). Corn oil was purchased from a local supermarket. The porcine tongues were obtained from the meat laboratory at the University of Minnesota (St. Paul, MN, USA). In all sample preparations and experiments, sodium-free nanopure water was used. In house deionized water was further purified by using a Barnstead Nanopure Diamond water purification system (Thermo Scientific, Dubuque, IA, USA) to obtain nanopure water. Protein solutions (0−10 wt %) were prepared by overnight stirring in nanopure water at room temperature. Emulsions at different protein/lipid ratios were prepared using a hot homogenization technique.[22] Briefly, hot protein solutions (1−5 wt %) were mixed with corn oil (0−20 wt %) using a high-speed blender to form a coarse emulsion. The emulsion premix was then passed through a microfluidizer (M-110Y Microfluidizer, Microfluidics, Newton, MA, USA) at ca. 60−65 °C (3 passes at 1200 bar). After the samples cooled to room temperature, salt was added and stirred for 4−5 h.

Analytical Measurements. Salt adsorptivity and retention on a model tongue surface were evaluated by using a modified gel permeation chromatography column accompanied by a porcine tongue (Figure 1). The front section of the fresh porcine tongue was cut as a disk (2.1 cm in diameter and 0.2−0.3 cm in thickness) and kept frozen at −20 °C until used. The thawed tongue pieces were then placed on the bottom plunger surface covering the base. Then, aliquots of samples (ca. 0.15 mL) were added to the tongue surface, and the top plunger was adjusted to about 0.1−0.2 cm above the tongue, leaving a negligible amount of empty space above the tongue surface. Salted protein solutions and oil-in-water emulsions were then washed from the tongue surface using an HPLC system (Shimadzu 10A series, Columbia, MD, USA) with nanopure water at a rate of 5 mL/min. The effluent was collected at 1 min intervals by a fraction collector. Each fraction was analyzed for sodium concentrations using an atomic absorption spectrometer (AAS) (PerkinElmer Inc., Waltham, MA, USA) coupled with a K−Na lumina hallow cathode lamp (PerkinElmer Inc.) and for dissolved solids using an evaporative light scattering detector (ELSD) (PL-ELSD 2100 Ice, Agilent, Santa Clara, CA, USA). The fractions from the column effluent were diluted in water to be within the dynamic range of the instrument. The ELSD was calibrated using reference dispersions with various protein and lipid concentrations similar to that measured for the sample fractions.

Particle Size Measurements. The average hydrodynamic diameter of the emulsions was determined by dynamic light scattering. The samples were diluted to ca. 1:100 with nanopure water, and then the particle size was analyzed using a Delsa Nano C Particle Analyzer (Beckman, Brea, CA, USA). The measurement was performed at 25 °C and at a 165° scattering angle. Mean hydrodynamic diameter was calculated on the basis of size distribution by weight, assuming a log-normal distribution. Ten individual size measurement runs were performed, with each run recording 100 size events. The droplet size (i.e., Sauter mean diameter) of the emulsions was found to be 0.2 μm.

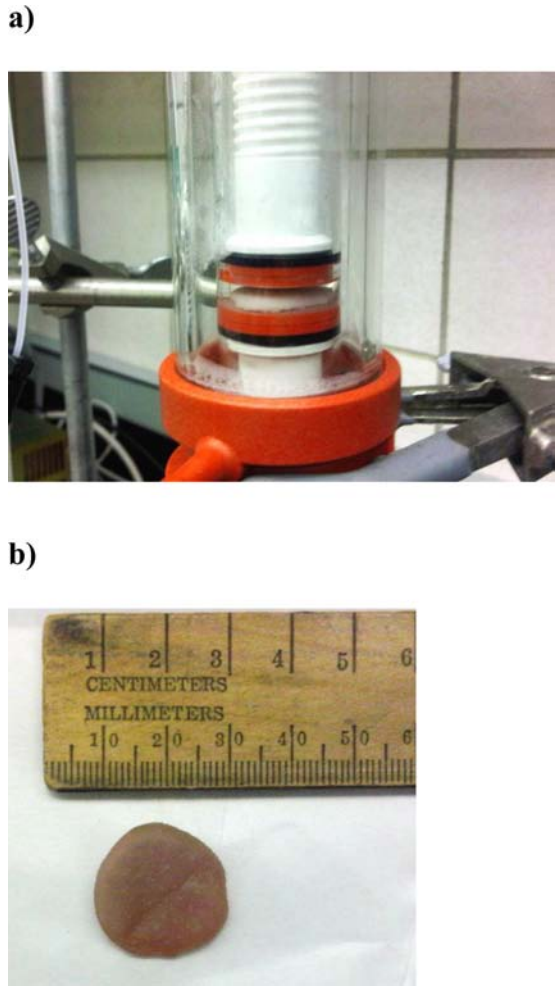

Figure 1. Picture of the chromatography column modified to work with circular porcine tongue (2.1 cm) and coupled to an HPLC system.

Sensory Analysis. A trained descriptive analysis panel of 11 panelists evaluated the salty intensity of the samples. Panelists were trained on a 15-point intensity scale, with NaCl reference solutions at 0.2, 0.35, 0.5, 0.64, and 0.75% corresponding to intensity scores of 2.5, 5, 8.5, 12, and 15, respectively. The panelists were trained during 12 1-h sessions over a period of 3 weeks. The performance of the panelists was assessed using blind references during training.

Samples were evaluated in triplicate using a randomized block design. Four samples were evaluated each session. The samples were served in 20 mL plastic cups, coded in random three-digit codes. During the sample evaluation the panelists were instructed to pour 10 mL of sample onto their tongue, hold for 5 s, and then expectorate the sample back into a container (time zero for aftertaste analysis) for further analysis of the residual sodium. Panelists rated the saltiness aftertaste intensity at 0, 15, 30, 60, 120, 180, 240, and 300 s after expectorating the sample. Panelists waited 10 min between samples. Water and unsalted crackers were used as palate cleansers.

Panelists were classified into two groups on the basis of their rating of saltiness intensity after rinsing their mouth with a 1% salt solution and waiting 1 min prior to evaluation. High and low saliva flow rates were classified for those who rated saltiness at <2 and >2 at 1 min after sample introduction, respectively.

Statistical Analysis. Results were evaluated for statistical significance using a t test for a pairwise comparison of two samples at $\alpha = 0.05$. All samples were prepared and analyzed in triplicate.

RESULTS AND DISCUSSION

It is known that the salty taste of food is produced by the transduction of the sodium ions via epithelial sodium channels, albeit all of the cellular mechanisms related to the perception of saltiness are still under investigation.[23] To taste sodium ions they need to be released from the food to be adsorbed on the surface of the tongue to start electrochemical signaling producing the sensation of saltiness. However, during consumption food products typically have very short retention time in the oral cavity, limiting the available sodium contributing to the salty taste. In a food matrix such ions can interact with other larger molecules, especially biopolymers (e.g., proteins), via electrostatic interactions, and as a result affect their transport kinetics and retention on the surface of the tongue. In the current study our goal was to focus on the nature of interactions between protein and salt molecules affecting the transport kinetics of salt ions in aqueous solutions and, in turn, mechanisms that influence salt perception. The delivery profile of sodium in protein−salt solutions was initially investigated using a tongue surface in a modified chromatography column coupled to an HPLC system (Figure 1). As the first step, we validated the performance of the designed tongue−column system to study the transport kinetics of sodium. Simple aqueous solutions of sodium chloride (0.5−10 wt %) were injected onto the column−tongue system, and the adsorptivity of sodium on the tongue surface was monitored from the effluent (Figure 2). The first data point in the sodium concentration versus time graph corresponds to the sodium concentration in the first fraction of the effluent (0−1 min). The linear relationship reported between the initial concentrations of the salt solutions and the sodium concentrations in the first fraction collected from the tongue−column system indicated that this design was working as expected, and therefore it was deemed suitable to study the transport kinetics of sodium. The rate of sodium removal from the tongue's surface was very fast, being quantitatively depleted within 2 min. In the next step, we investigated the effects of dissolved protein on sodium retention on the tongue's surface.

Three protein−salt solutions consisting of 1, 5, and 10% protein at a constant 1% NaCl level were made using sodium caseinate, the sodium salt of the major protein in milk. The intrinsic levels of sodium in sodium caseinate were negligible with regard to the amount of NaCl added to the samples. It is highly soluble in water and often used in low-fat product formulations. Addition of the protein was predicted to bind the sodium ions via electrostatic interactions and change the availability of sodium to the aqueous phase during consumption and subsequently alter salt perception. The sodium concentration in the aqueous effluent as monitored from the model tongue system (Figure 1) for the three protein solutions is shown in Figure 3. As seen in Figure 3a, the sodium concentrations in the first minute of the effluent decreased with increasing protein concentrations, specifically for the 5 and 10% protein solutions. The release of sodium in the effluent for the 1% protein solution was similar to that for the pure salt solution (no protein), indicating there were not sufficient protein interactions at this dosage level to alter the initial salt amount washed off the tongue system. Protein−salt interactions largely depend on the anionic charged segments of the

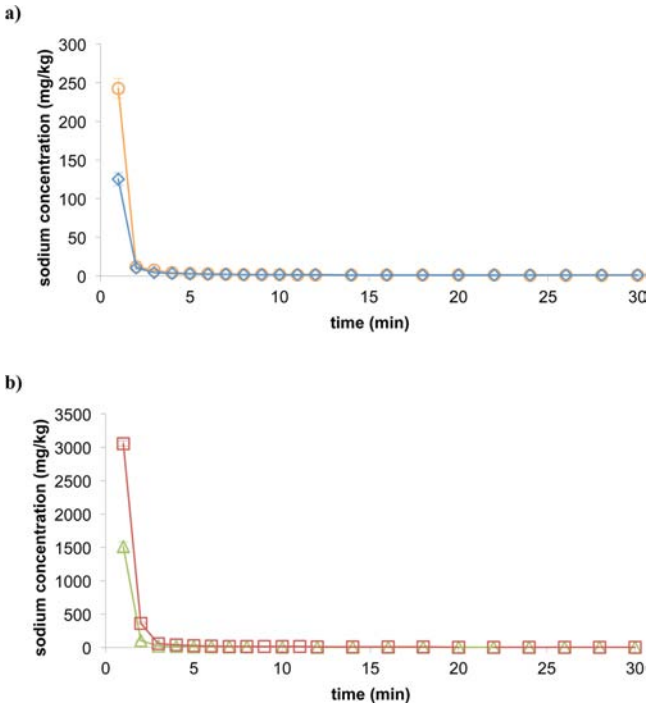

Figure 2. Sodium concentrations in the effluent after (a) 0.5% (diamonds) and 1% (circles) salt solutions and (b) 5% (triangles) and 10% (squares) salt solutions were washed from the model tongue surface (5 mL/min) as collected in fractions at 1 and 2 min intervals (13−30 min). The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

available protein and would increase with higher concentration of protein in these solutions (i.e., higher protein/salt ratio) as well as with the charge potential of the proteins. After this initial minute, the higher protein samples reported higher sodium concentrations in the effluent over time (Figure 3b). For example, from 1 to 4 min the amount of sodium in the effluent was approximately 2 times higher for the 5 and 10% protein solutions in comparison to the 1 or 0% protein solutions. The increased release of sodium over time from the higher protein solution could be explained by protein adhesion to the tongue's surface that would serve as a salt reservoir and release sodium over time into the aqueous phase.

Other researchers have also reported salt perception was influenced by polymer−salt interactions based on various mechanisms. Rosett et al. showed that the charge on the biopolymer was more important to determine the perception of salty taste, rather than the viscosity.[5] Oral processing has also been reported to modify food−tastant interactions. For example, it has been shown that saliva amylase can break down large starch molecules, decreasing the apparent viscosity of the solutions but also the mixing efficiency, which limits the molecular diffusion of salt and reduces the salt perception.[24] De Jongh and Janssen reported the retention time of liquid foods in the oral cavity increased when the viscosity was increased (by protein and carbohydrate addition) and likewise altered taste perception.[20]

The noted influence of the protein/salt ratio on the sodium transport behavior in Figure 3 could potentially be confounded by the change in the sample solids content on molecular diffusion.

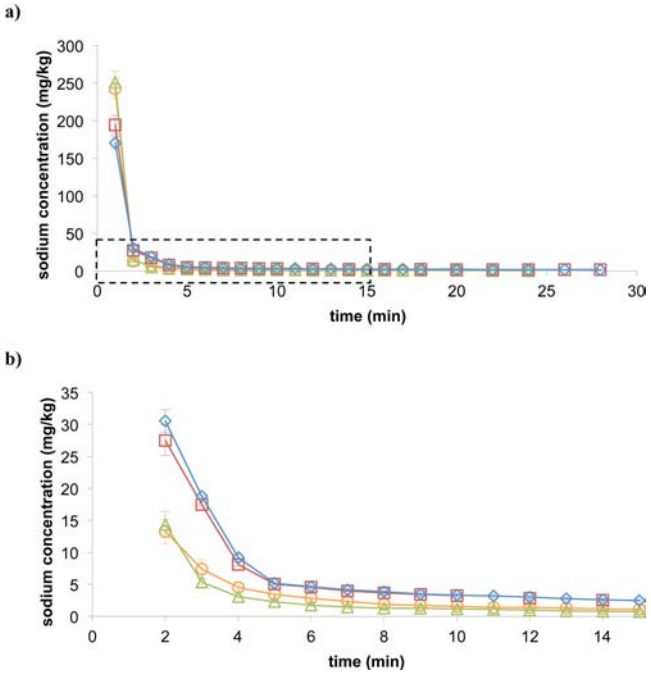

Figure 3. (a) Sodium concentrations in the effluent of 1% salt solutions containing 0% (circles), 1% (triangles), 5% (squares), and 10% (diamonds) casein after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min intervals. (b) The dashed area from the top graph was zoomed for better resolution from 1 to 15 min. The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

To further ascertain if changes in the solids content affected the sodium release profiles in Figure 3, sodium release was monitored from two protein solutions at 5 and 10% that were formulated at the same protein/salt ratio of 10:1 (Figure 4).

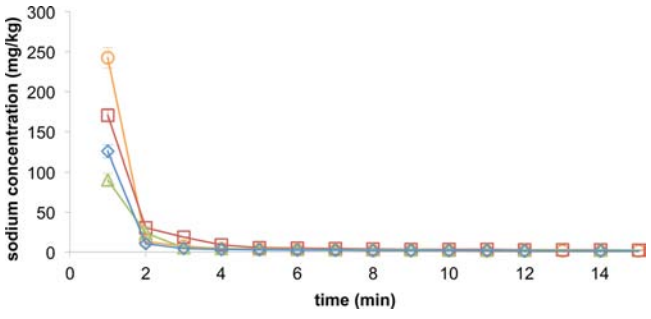

Figure 4. Sodium concentrations in the effluent of 0.5% salt solutions containing 0% (diamonds) and 5% (triangles) casein and 1.0% salt solutions containing 0% (circles) and 10% (squares) casein after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min intervals. The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

For both the 5 and 10% protein solutions the decreases in sodium concentration in the first fraction (0−1 min) relative to the corresponding salt solution were effectively the same ($p > 0.05$). The sodium concentrations reported in the first fractions for the 5 and 10% were significantly smaller ($p > 0.05$) and 1.39 ± 0.03 and 1.42 ± 0.02 times less than the corresponding pure salt solutions. An effective diffusivity (k_{eff}) constant was also calculated assuming pseudo-first-order kinetics for the fractions between 1 and 6 min (i.e., k_{eff} was calculated from the slope). Similarly, k_{eff} was not statistically different for 10% (0.81 s^{-1}) and 5% (0.82 s^{-1}) protein solutions at the same protein/salt ratio (10:1), although the solution thicknesses were different. However, when the salt concentration in the 5% protein solution was increased to a protein/salt ratio of 5:1 (1% salt, Figure 3), both the sodium concentration change in the first fraction (1.31 ± 0.02%) and the k_{eff} (0.86 s^{-1}) were significantly larger than for the 10:1 ratio. These findings indicate viscosity effects from the protein added to the solutions were not an important factor that influenced the difference in salt delivery reported between the 5 and 10% protein solutions in Figure 3 and supported protein ionic binding as an important mechanism of salt delivery.

The extent of ionic protein−salt interactions would be governed by the accessibility of the ionic groups to the aqueous phase. To investigate this concept, protein−salt interactions in emulsion systems were characterized using casein and oil colloid systems. When oil is emulsified with caseinate, the hydrophilic protein segments (volume fraction is about 0.9) surround the outside of the oil droplets as a dense outer layer that is approximately 1 nm in thickness, whereas a diffuse hydrophobic segment (volume fraction is about 0.1) forms an inner layer in the oil droplet that can extend up to 10 nm in thickness.[25] Moreover, proteins on these lipid droplets are known to have a net negative charge around neutral pH (i.e., pH above their isoelectric point).[26] It has been shown that such interfacial structures of caseinate can affect the distribution profiles of small molecules and cause localization around the droplets' interface.[22] This electrostatic charge around the droplets could further affect the rate of ion exchange between the aqueous phase and the droplet surface. For example, the oxidation of protein-stabilized omega-3-enriched oil-in-water emulsions can be inhibited at pH below the p*I* of proteins (i.e., due to cationic properties of the emulsion droplets).[27,28] In a similar manner, the net negative charge around the droplet can attract cationic sodium ions and serve to enhance the localization of sodium ions around the charged outer layer segments of the caseinate molecules on the lipid droplets.

The release of sodium from the aqueous emulsion systems is illustrated in Figure 5. Two different emulsion formulations of 1% protein−4% lipid and 2.5% protein−2.5% lipid were compared to a 5% protein aqueous solution and a aqueous salt solution, all at 1% salt. The sodium concentration in the first fraction of the effluent (0−1 min) was significantly reduced for the emulsion systems compared to the 5% protein solution, even though the percent protein levels in the emulsions were comparatively lower in amount. Additionally, the emulsion with 4% lipid and 1% protein reported a lower salt concentration (at 0−1 min) compared to the 2.5% lipid and 2.5% protein emulsion. Although the emulsion systems had a lower percent protein, when the lipid amount increased relative to the percent protein, a higher interfacial area is expected that ultimately enhanced the exposure of the anionic groups in the aqueous phase and thus the ionic interactions with sodium. The release of sodium from the emulsion systems from 1 to 14 min is further shown in a magnified view in Figure 5b and showed similar trends as Figure 3b. Samples that lowered the salt concentration the most in the first minute had the highest release of sodium after this first minute, in this case the 1% protein−4% lipid sample.

J. Agric. Food Chem. 2015, 63, 7487−7493

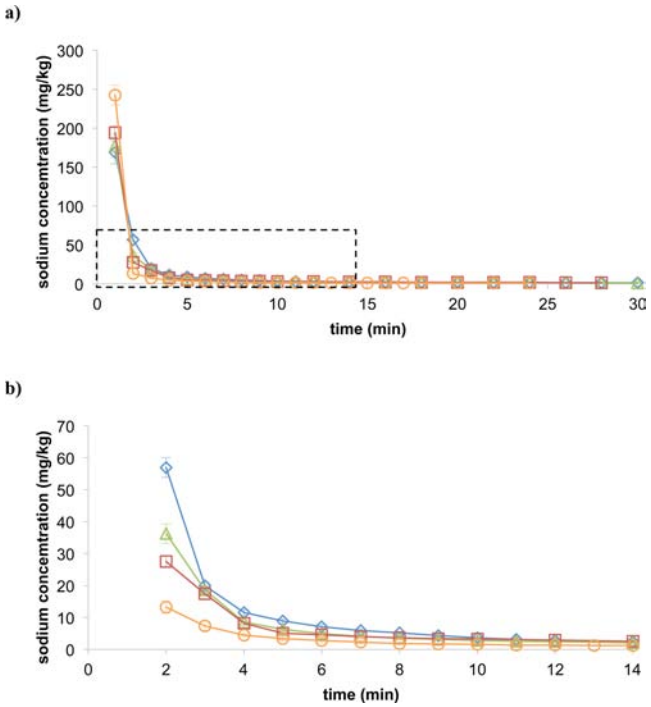

Figure 5. (a) Sodium concentrations in the effluent of emulsions (5% organic phase) compared to that of the 1% salt solution (circles) after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min intervals. The emulsified phase was formulated as 1% protein−4% lipid (diamonds), 2.5% protein−2.5% lipid (triangles), or 5% protein−0% lipid (squares). (b) The dashed area from the top graph was zoomed for better resolution for fractions between 1 and 14 min. The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

To further single out the interfacial effects of emulsions on sodium interactions (i.e., as a function of surface area and number of droplets), sodium release rates from emulsions with the same protein content (5%) and different lipid concentrations (5 and 20 wt %) at 1% salt were compared (Figure 6). Similar results were obtained; the droplet surface area increased (by increasing the lipid content) and the initial release rate decreased. Therefore, the electrostatic interactions between protein and salt molecules were enhanced by conferring the anionic properties of the proteins to the aqueous phase of the emulsified droplets. The higher retained sodium was then washed off the tongue surface at a higher rate over time.

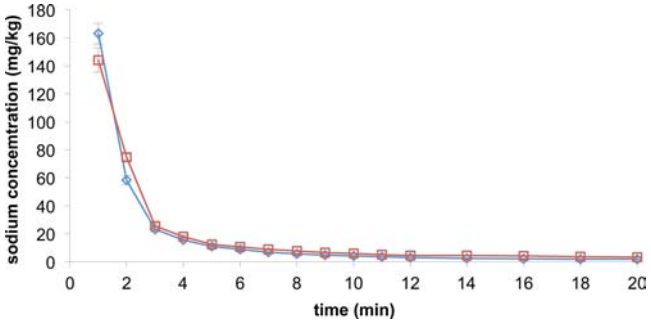

Figure 6. Sodium concentrations in the effluent of emulsions stabilized with 5% casein and containing 5% (diamonds) or 20% (squares) lipid, after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min intervals. The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

On the basis of the observed influence of protein on the retention of salt and corresponding higher amounts of salt released over time (compared to aqueous salt) in the model tongue column (Figures 3 and 5), the protein material was suggested to adhere to the tongue's surface and function as a salt reservoir and release salt with continued washing. To further examine the interaction of the protein in the tongue column, the total solute concentration in the effluent was also measured from 0 to 14 min by using an ELSD, and the data are shown in Figure 7. Review of the solute concentration in the effluent over time confirmed our previous statement that the organic phase (i.e., protein) adhered to the tongue's surface. In parallel, the highest absorptivity (i.e., slowest diffusivity) was observed for the emulsions with the highest lipid concentrations. Consequently, this supported our statement that the protein material functioned as a reservoir of sodium that released sodium over time into the aqueous phase.

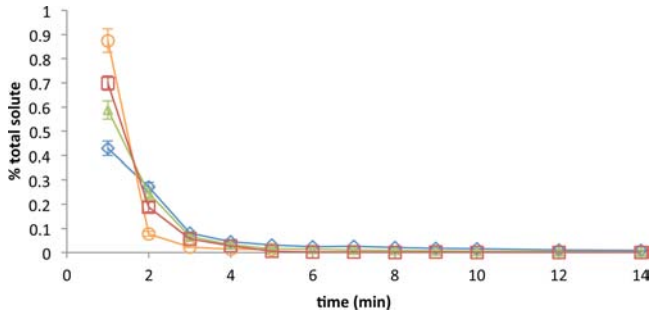

Figure 7. Total solute concentration in the effluent of emulsions after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min intervals and analyzed by evaporative light scattering detector. Samples consisted of 1% salt solution (circles), 1% protein−4% lipid (diamonds), 2.5% protein−2.5% lipid (triangles), and 5% protein−0% lipid (squares). The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

Sensory descriptive analysis of the salt intensity was further conducted on the protein−salt solutions (Figure 8) as well as the emulsion systems (Figure 9) to extrapolate the analytical data to human perception. For the sensory evaluations, the panelists were classified into two groups, low and high saliva flow rates. For the protein solution (Figure 8), the sensory data were in agreement with analytical results (Figure 3). With increasing protein content of the salt solutions, a lower salt intensity rating was reported for the initial time period with a corresponding higher salt intensity afterward (aftertaste). For example, in the low saliva flow regimen, the salty taste of the salt solution (no protein) disappeared within 120 s, whereas there was still a residual salty taste lingering after 180 s for the 10% casein solution. Although the salty ratings in both groups with high and low saliva flow rates followed the same trend, the time−salt intensity curves more clearly separated at the low saliva flow regimen. Therefore, we further discussed the sensory ratings of this group for the emulsion samples.

The presence of colloidal lipid considerably changed the perception of saltiness (Figure 9). Interestingly the initial intensities of the emulsions at a constant 5% organic content were not significantly different ($p < 0.05$) from that of the 1% salt solution itself (Figure 9a) in contrast to the analytical data

J. Agric. Food Chem. 2015, 63, 7487−7493

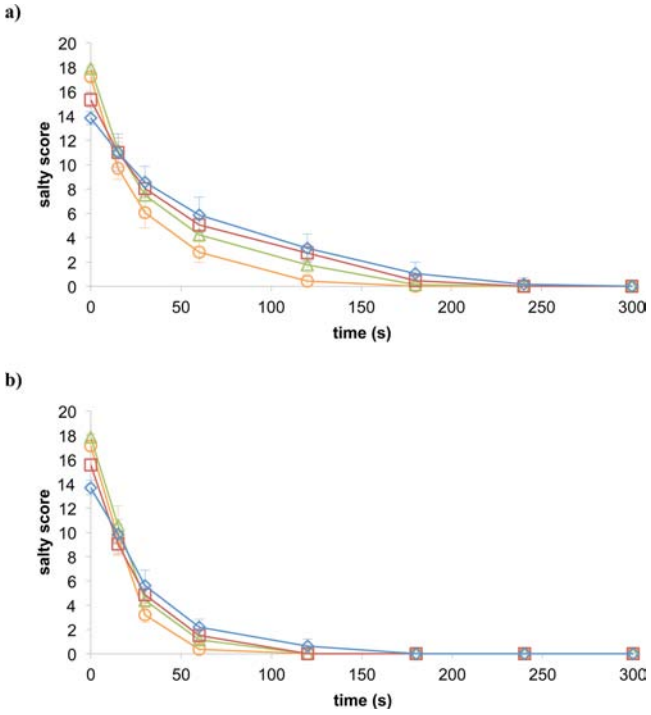

Figure 8. Time–intensity plot for salty intensity rating of 1% salt solutions containing 0% (circles), 1% (triangles), 5% (squares), and 10% (diamonds) casein for (a) low saliva flow rates and (b) high saliva flow rates. The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

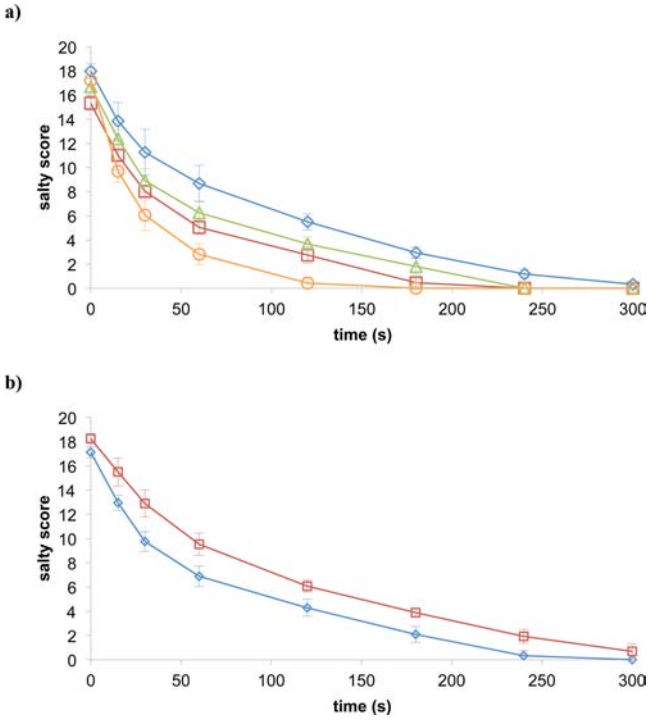

Figure 9. Time–intensity plot for salty intensity rating of 1% salt emulsions for samples formulated as (a) 5% total organic phase containing 1% protein–4% lipid (diamonds), 2.5% protein–2.5% lipid (triangles), 5% protein–0% lipid (squares), 1% salt solution (circles) and (b) 5% protein with 5% lipid (diamonds) or 20% lipid (squares). The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

(Figure 5a). The nanoscale dimensions of lipid droplets may have facilitated sodium availability on the tongue's surface. However, increasing the lipid concentrations caused higher salt intensity aftertaste, which was in line with the analytical data (Figure 5b). Emulsion samples with the same amount of protein (5%) at two lipid concentrations (5 and 20%) were compared for their time course salt intensity behaviors (Figure 9b). The sensory results followed the same trend as the analytical data (Figure 4): increasing the number of lipid droplets provides more interface for proteins, further enhancing the salt–protein interactions and resulting in longer salty aftertaste.

In this study, we showed that protein–salt interactions could play an important role in determining the transport properties of sodium in solutions. We designed an analytical system to study sodium retention on a tongue surface and compared the results to sensory analysis. Overall, our data supported the importance of intermolecular interactions (i.e., electrostatic interactions) in determining the perception of salty taste. These results can serve as a guideline to control sodium availability, and subsequently its perception, when food products are formulated for lower sodium content while enhancing salt perception. In the following paper, we studied the effect of protein–salt interactions on the salt perception and the hydration rates of low-moisture samples as a function of lipid levels.

maximum intensity profiles and enhancing the overall salt perception.[4,13] This effect may also depend on the initial salt content.

Previously we showed that ionic interactions between cationic sodium ions and anionic sodium caseinate molecules can affect sodium transport to the tongue and its absorptivity on the surface of the tongue to enhance the perception of saltiness and create a longer aftertaste.[6] Such interactions can be further modified via interfacial effects in emulsions. The overall objective of this study is to expand this knowledge and to further understand the influence of protein in low-moisture systems on sodium release during hydration and perceived saltiness intensity. The effect of the emulsion-associated interfacial properties of a protein on sodium delivery was similarly investigated, and analytical results were compared to sensory analyses.

MATERIALS AND METHODS

Materials. Sodium caseinate (Na-cas) and sodium chloride (NaCl) (USP grade) were both purchased from Sigma-Aldrich (St. Louis, MO, USA). Corn oil was purchased from a local supermarket. The porcine tongues were obtained from the meat laboratory at the University of Minnesota (St. Paul, MN, USA). All sample preparations and experiments used in house deionized water that was further purified by the Barnstead Nanopure Diamond water purification system (Thermo Scientific, Dubuque, IA, USA) to obtain nanopure water.

Protein solutions (0−5 wt %) and oil-in-water emulsions (0−20 wt % corn oil) were prepared as described in the previous paper.[6] Briefly, protein solutions were prepared by overnight stirring in nanopure water at room temperature. Emulsions at different protein/lipid ratios were prepared using a hot homogenization technique, where a coarse emulsion premix was passed three times at 1200 bar through a microfluidizer (M-110Y Microfluidizer, Microfluidics, Newton, MA, USA) at ca. 60−65 °C. After the samples cooled to room temperature, salt was added and stirred for 4−5 h. Then, samples were frozen at −20 °C and dried by lyophilization (at 100 mT) using a Virtis Freezemobile 35EL (SP Scientific, Warminster, PA, USA).

Analytical Measurements. Salt adsorptivity and retention on a porcine tongue surface were evaluated by using the modified GPC column−tongue setup coupled to an HPLC system as previously described.[6] Briefly, total mass equivalents (same amount of total mass for each sample, 7.5 mg) or salt equivalents (i.e., same amount of salt but various total mass, i.e., 1.5 mg of salt) of freeze-dried powders of protein solutions and oil-in-water emulsions were placed directly and homogeneously on the surface of the tongue, and the column was sealed by fixing the top plunger at 0.1−0.2 cm above the tongue surface. Powder samples were then washed from the tongue's surface using an HPLC system (Shimadzu, Columbia, MD, USA) with nanopure water at a rate of 5 mL/min. The effluent was collected at 1 min intervals using a fraction collector. Each fraction was analyzed for sodium concentrations using an atomic absorption spectrometer (AAS) (PerkinElmer Inc., Waltham, MA, USA) coupled with a K−Na lumina hallow cathode lamp (PerkinElmer Inc.) and for dissolved solids using an evaporative light scattering detector (ELSD) (PL-ELSD 2100 Ice, formerly Polymer Laboratories, presently Agilent, Santa Clara, CA, USA). Fractions were diluted in water to be within the dynamic range of the instrument, and the ELSD was calibrated using reference dispersions with various protein and lipid concentrations similar to those measured for the sample fractions.

Sensory Analysis. A trained descriptive analysis panel of 11 panelists evaluated the salty intensity of the samples. Panelists were trained on a 15-point intensity scale with NaCl reference solutions at 0.2, 0.35, 0.5, 0.64, and 0.75% corresponding to intensity scores of 2.5, 5, 8.5, 12, and 15, respectively. The panelists were trained during 12 1-h sessions over a period of 3 weeks. The performance of the panelists was assessed using blind references during training.

The samples were evaluated in triplicate using a randomized block design. Three samples were evaluated each session. For the sample evaluation panelists were instructed to put 0.1 g of sample on the center of their tongue, and the timer was started as time zero. Panelists rated the saltiness intensity at 0, 10, 20, 30, 60, 120, 180, 240, and 300 s. The dissolution time of the powder (i.e., time needed to completely hydrate the powder in the mouth) and the final time for complete removal of the salty taste were also recorded. Panelists waited 10 min between samples. Water and unsalted crackers were used as palate cleansers.

Statistical Analysis. Results were evaluated for statistical significance using a t test for a pairwise comparison of two samples at $\alpha = 0.05$. All samples were prepared and analyzed in triplicate.

RESULTS AND DISCUSSION

In a preceding study, we demonstrated that the presence of protein can affect the transport kinetics of sodium from aqueous salt solutions and, likewise, salt perception.[6] The extent of these interactions could further be enhanced by promoting the availability of charged segments of the protein via interfacial effects as seen in nanoemulsions. In the current study, we investigated the effects of such intermolecular interactions in low-moisture systems during hydration on salt release and consequently on the perception of saltiness. A modified chromatography column coupled to an HPLC system as described in the preceding paper was utilized to model sodium release and hydration and in parallel samples were evaluated by sensory analysis.[6]

Sodium release from freeze-dried powders derived from protein solutions (5% Na-cas) of various salt concentrations (0.5, 1, and 10% NaCl) at 10:1, 5:1, and 1:2 protein/salt ratios during hydration wsd analyzed. The sodium release profiles for samples at equivalent mass are shown in Figure 1a. The samples with excess salt (i.e., 1:2 protein/salt ratio) showed a monotonous decrease of salt concentration in the effluent, whereas when the ratio of protein to salt increased, a different behavior was observed. The sodium concentration in the effluent of samples with 10:1 and 5:1 protein/salt ratios first increased followed by a subsequent decrease over time. This noted difference in sodium release between the samples with excess sodium to protein versus the samples with excess protein to salt was likely due to amount of free sodium (i.e., fraction not associated with the protein). The sodium less associated with protein more readily hydrated and dissolved.

Additionally, we considered that the presence of salt likely influenced the hydration rates of proteins. The configurations of proteins are modified in aqueous solutions by salt ions, which can be approximated by the Hofmesiter series.[14,15] Recent research indicated direct ion−macromolecule interactions determine the solubility and hydration capacity of the macromolecules, in contrast to earlier models that assumed the water structure is modified by the salt ions.[16] Consequently, it is likely that protein−salt interactions altered the hydration rates of the powders in the current study and contributed to the release profile noted for the samples with excess protein to salt composition in Figure 1a.

A similar trend was also observed when the total mass of sample placed on the tongue's surface was adjusted to provide equivalent sodium contents for each sample at different protein/salt ratios (Figure 1b). These findings indicated sample size or changing the amount of protein between samples (5:1 or 10:1) was not affecting the sodium release profile. Consequently, the sodium ions more associated with the proteins limited the release of sodium and became available only after the protein was hydrated. These findings are in agreement with Lauverjat et al.,[9] who showed that casein

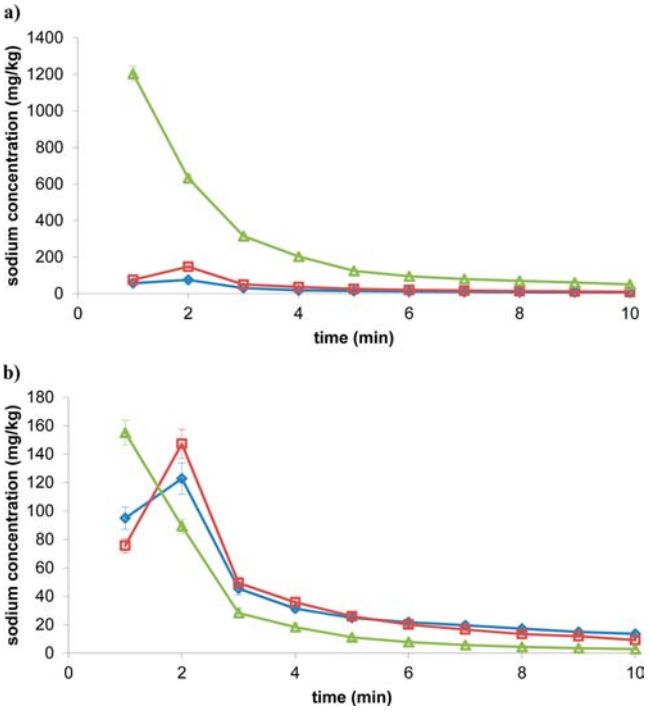

Figure 1. Sodium concentrations in the effluent of protein powders with 10:1 (90.9% protein, 9.1% salt) (diamonds), 5:1 (83.3% protein, 16.7% salt) (squares), and 1:2 (33.3% protein, 66.7% salt) (triangles) casein/salt (w/w) ratios for (a) total mass equivalents (7.5 mg sample) and (b) equivalent sodium amounts (1.5 mg), after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min and at 2 min intervals (after 12 min). The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

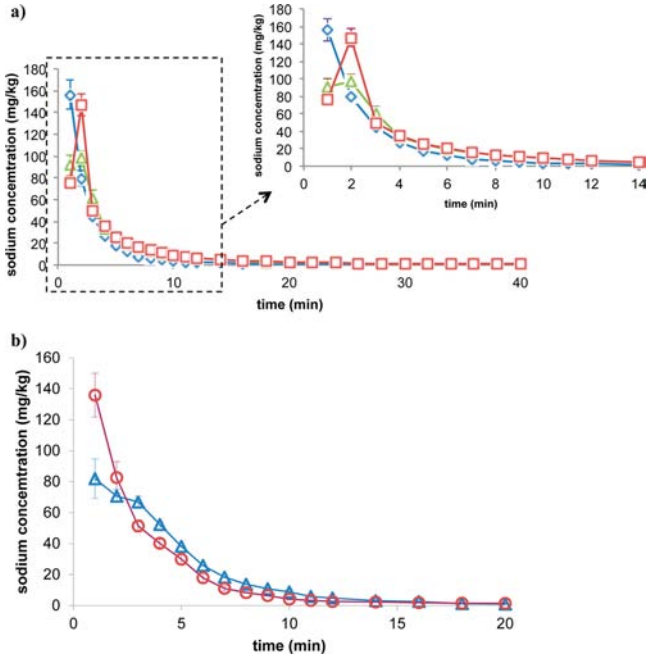

Figure 2. Sodium concentrations in the effluent of emulsion powders for total mass equivalents (7.5 mg sample) of (a) constant organic phase/salt ratio (5:1) where organic phase formulated at 5:0 (83% protein, 0% lipid, 17% salt) (squares), 1:1 (41.5% protein, 41.5% lipid, 17% salt) (triangles), and 1:4 (17% protein, 67% lipid, 17% salt) (diamonds) protein/lipid ratios (the dashed area was zoomed for higher resolution from 1 to 15 min as shown in the inset) and (b) the same protein/salt ratio (5:1) but with various protein/lipid contents as 1:1 (45.5% protein, 45.5% lipid, 9% salt) (triangles) from 5% protein−5% lipid emulsions and 1:4 (19.2% protein, 77% lipid, 3.8% salt) (circles) from 5% protein−20% lipid emulsions, after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min and at 2 min intervals (after 12 min). The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

molecules in cheese could bind sodium ions, slowing the mobility and release during hydration. In the following part of the current study, we further investigated the influence of modifying the protein structure through interfacial effects in the presence of colloidal lipids on subsequent sodium delivery during hydration.

The release of sodium during hydration of the freeze-dried emulsions with a constant protein/salt (5:1) ratio and changing lipid levels is shown in Figure 2b. Increasing the lipid concentration would increase the protein interfacial area and expose more of the hydrophilic segments of the protein to the aqueous phase of the emulsion.[17] Indeed, the casein structure around lipid droplets was described earlier on the basis of neutron scattering measurements as a diffuse hydrophilic protein layer, which can extend up to 10 nm from the droplet surface as compared to a dense inner hydrophobic layer with a 1 nm thickness.[18] Therefore, the diffuse protein structure formed around the lipid droplets is anticipated to enhance the availability of protein material to water to hydrate more quickly and the associated sodium ions and ultimately increase sodium release during hydration of the sample. The results in Figure 2 were in agreement with this hypothesis; the dried emulsion sample at the higher lipid level resulted in a faster release of sodium during the initial hydration step when compared to the lower lipid content sample. A delayed release rate was also observed for the lower lipid content sample, indicating that when the protein was less structured at the interface, the salt−protein interactions reduced the immediate availability of sodium but also prolonged its retention on the tongue surface.

In a similar way, Lawrence et al. showed that sodium ions associate with anionic liposome matrixes, which can enhance the salt release and subsequent salty taste perception in cheese products.[19] Similar results were observed when the sample size was held constant but the protein and fat levels were altered (see Figure 2a). At a lower protein to fat ratio, more protein would be structured at the interface. As expected, the 1:4 protein/lipid emulsion samples had a higher initial sodium release than the 1:1 protein/lipid emulsion samples or the protein salt mixtures.

In addition to sodium concentration measurements, total dissolution kinetics were also evaluated by analyzing the solute concentration in the effluent of freeze-dried emulsions with constant organic phase/salt (5:1) ratio by using ELSD (Figure 3). In parallel with sodium measurements, the fastest dissolution rate was observed for powder with 4:1 versus the 1:1 lipid/protein ratio, and the pure protein powder had the lowest initial release of solutes. The powder with 1:1 protein/lipid ratio showed S-shape two-stage dissolution kinetics. Initially, the lipid particle portion of the powder dissolved quickly, and the dissolution rate slowed as the protein fraction not structured around the lipid droplet dominated.

The localization of sodium in a food product is of critical importance in determining the molecular mobility of sodium and therefore the availability for perception. We further

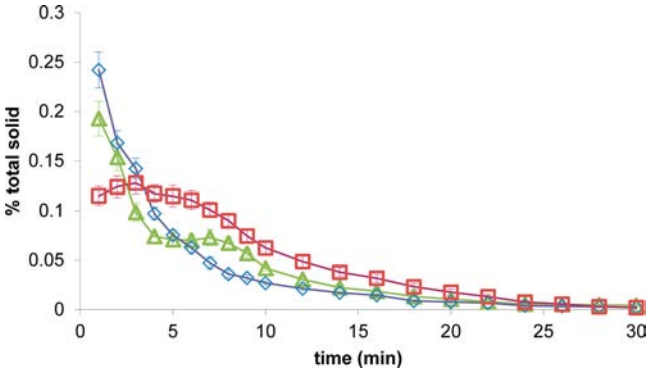

Figure 3. Total solute concentration change as percentage of initial solute concentration in the effluent of dried emulsion powders containing 1% salt after washing from the model tongue surface (5 mL/min) as collected in fractions at 1 min and at 2 min intervals (after 10 min) and as analyzed by ELSD. The powders are formulated as 5:0 (83% protein, 0% lipid, 17% salt) (squares), 1:1 (41.5% protein, 41.5% lipid, 17% salt) (triangles), and 1:4 (17% protein, 67% lipid, 17% salt) (diamonds) protein/lipid ratios. The bars on the data show standard deviation. The straight lines between data points are merely used to aid in visual analysis.

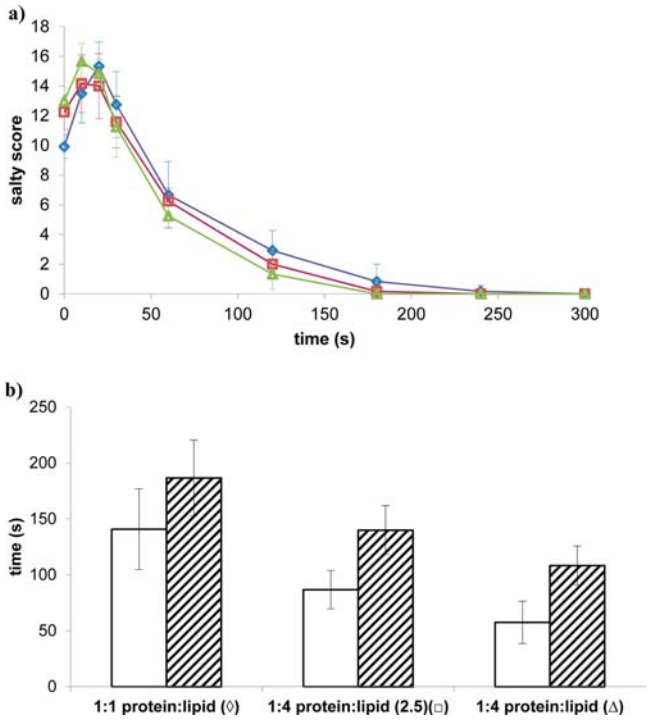

Figure 4. (a) Time–intensity plot for salty intensity rating of emulsion powders at low saliva flow rates, formulated as (at constant protein/salt ratio) 1:1 protein/lipid ratio (45.5% protein, 45.5% lipid, 9% salt) (diamonds) and 4:1 protein/lipid ratio (19.2% protein, 77% lipid, 3.8% salt) (triangles) with total mass equivalents (0.1 g) and 4:1 protein/lipid ratio (19.2% protein, 77% lipid, 3.8% salt) (squares) with equivalent sodium amounts to 1:1 protein/lipid (the amount tested is 2.5 times more than constant organic phase/salt ratio samples). The straight lines between data points are merely used to aid in visual analysis. (b) Dissolution time for the powder in the mouth (white bars) and final time for the salty taste to disappear (shaded bars). The bars on the data show standard deviation.

evaluated the effects of the hydration rates of the emulsion powders on saltiness perception using a trained sensory panel. Panelists rated the saltiness intensity of the emulsion powders over a period of 5 min (Figure 4a). In general, the time–salt intensity curves followed the same pattern of release as the analytical results (Figure 2). The initial intensity of the powder with 1:4 protein/lipid ratio (19.2% protein, 77% lipid, and 3.8% salt) was higher than that for 1:1 protein/lipid ratio (45.5% protein, 45% lipid, and 9% salt). This higher initial intensity was due to faster dissolution rates, which also served to decrease the retention of the powder on the tongue over time and, hence, the faster removal of the salty taste (i.e., shorter time for the residual taste). The sample weight of the 1:4 protein/lipid ratio was also increased 2.5 times for evaluation to have the equivalent amount of salt as in the 1:1 protein/lipid sample. Although the amount of powder consumed slightly affected the dissolution behavior, the profile of the salt time–intensity curve was similar to the lower sample size: the higher the lipid content, the faster the dissolution with higher initial intensity (Figure 4a).

To confirm the relationship between the dissolution rates of the powders and residual salty taste, we asked the panelists to record the time required for complete dissolution of the powders and final time for the salty taste to disappear (Figure 4b). These results are in agreement with previous observations that samples with longer dissolution times resulted in longer salty aftertaste. Increasing the lipid levels (i.e., number of lipid nanoparticles) resulted in shorter powder dissolution times. Moreover, a greater degree of difference was observed between the dissolution time and final time for saltiness perception between the samples with 1:4 and 1:1 protein/lipid ratios, likely because after the lipid particles hydrated, the resulting emulsified droplets have higher adsorption on the tongue than the protein material that is not emulsified, as previously discussed.[6]

The localization of sodium in our samples was shown to affect molecular mobility and therefore availability for perception. In the preceding study we showed that the extent of ionic interactions between sodium and caseinate were enhanced when the protein was structured around the lipid droplets, when the protein was at a net negative charge.[6] In the present study, we showed that such protein structure around the lipid droplets can be a powerful tool to enhance the hydration rates of powders to control sodium release from low-moisture food products and control the perception of salty taste. Therefore, when integrated to formulations of low-moisture foods, such systems can allow more sodium ions to reach sodium channels before swallowing to contribute to the salty taste.

butanal, 2-methylfuran, 2-methylpropanal, 2-nonanone, 2-pentylfuran, 2,3,5-trimethylpyrazine, 3-mercaptohexanol, 3-methylbutanal, 3-methylbutyl acetate, 3-methylbutanoate, 5-methyl-2-furfural, 6-methyl-5-hepten-2-one, acetaldehyde, acetic acid, benzaldehyde, benzothiazole, benzyl alcohol, butanal, butyl acetate, camphor, *cis*-jasmone, *cis*-linaloloxide, dihydroactinidiolide, dimethyl disulfide, dimethyl sulfide, dimethyl sulfoxide, dimethyl trisulfide, (*E*)-2-heptenal, (*E*)-2-hexenal, (*E*)-2-pentenal, (*E*,*E*)-2,4-heptadienal, (*E*,*E*)-2,4-hexadienal, ethyl acetate, (*E*)-2-octenal, ethanethiol, furan, furfural, geraniol, heptanal, heptanoic acid, heptanol, hotrienol, hexanal, hexanoic acid, hexanol, indole, methanethiol, methyl benzoate, methyl hexanoate, methyl jasmonate, methyl salicylate, nerolidol, nonanal, octanal, octanoic acid, pentanal, propanal, propanethiol, phenyl acetaldehyde, phenylethyl alcohol, (*R*)-(−)-linalool, *S*-methyl thioacetate, *trans*-linalooloxide, (*Z*)-3-hexen-1-ol, and (*Z*)-4-heptenal were purchased from Alfa Aesar Corporation (Tianjin, China). Furfurylthiol, methional, methionol, and C_6−C_{30} *n*-alkane standard were purchased from Sigma-Aldrich Corporation (Shanghai, China). All of the chemical standards used above were of GC quality.

Sample Preparation. Twenty grams of oolong tea was weighed and placed in a prewarmed tea pot, and 1000 mL of 80 °C distilled water was added. The tea was brewed for 5 min and swirled 10 times clockwise while brewing. Then, the tea was poured through a porcelain strainer into a prewarmed porcelain bowl. These samples were stored in a refrigerator (4 °C) after the tea infusions had cooled down to room temperature.

Solid Phase Microextraction (SPME) Absorption of Aroma Compounds. The manual SPME holder, together with 20 mL vials, Teflon covers, and one 75 μm divinylbenzene-carboxyl-polydimethylsiloxane (DVB-CAR-PDMS) fiber, were purchased from Supelco, Inc. (Bellefonte, PA, USA). Before chemical absorption, the fiber was preconditioned for 30 min on an Agilent 6890 gas chromatograph (Agilent Technologies, USA) with the injector temperature of 250 °C.

The main parameters that were known to influence the methodology were investigated, such as fiber, extraction time, extraction temperature, and sample volume. According to the results obtained (data not shown), optimized SPME experimental conditions were established, i.e., 30 min of extraction time, and a sample volume of 5 g. It is worth pointing out that the volatile compounds in tea infusions were very likely artifacts formed during the heat impact. Therefore, the extraction temperature was set at 25 °C. Then 5 g portions of the treated samples were transferred to the vials and sealed with a Teflon cover. The vials were kept at 25 °C on a water bath for 30 min with shaking at regular intervals. After the SPME fiber had been exposed in the upper space of the bottle for 30 min, it was then withdrawn and directly introduced to the GC injector for desorption and analysis.

Calibration of Standard Curves. To obtain a matrix similar to that of tea infusion, model solution was prepared containing 25 mg/g caffeine, 5 mg/g (+)-catechin (C), 5 mg/g (−)-epicatechin (EC), 10 mg/g (−)-epicatechin gallate (ECG), 20 mg/g (−)-epigallocatechin (EGC), 10 mg/g (−)-gallocatechin gallate, 40 mg/g (−)-epigallocatechin gallate (EGCG), 4 mg/g theanine, 0.8 mg/g Glu, 0.5 mg/g Pro, 0.5 mg/g Val, and 0.5 mg/g Ser in Milli-Q deionized water.[6,13,14]

A standard stock solution was prepared containing 50 mg/kg methanethiol, 5 mg/kg ethanethiol, 2 mg/kg propanethiol, 1500 mg/kg dimethyl sulfide, 10 mg/kg dimethyl trisulfide, 150 mg/kg dimethyl sulfoxide, 10 mg/kg dimethyl disulfide, 0.1 mg/kg 3-mercaptohexanol, 1 mg/kg *S*-methyl thioacetate, 2 mg/kg benzothiazole, 1 mg/kg methionol, 2 mg/kg methional, and 0.1 mg/kg furfurylthiol in Milli-Q deionized water. The standard stock solution was then diluted with water to 1:2, 1:10, 1:20, 1:50, and 1:200 strengths. In order to construct the calibration curves, 0.01 g of each of those diluted solutions of sulfur compounds and 0.01 g of the internal standard solution containing 2 mg/kg of dipropyl disulfide were introduced to the 5 g of model solution in a 20 mL vial, which was extracted by SPME, as was performed for the tea infusions.

The standard curves were shown in the research, where *y* represented the peak area ratio (peak area of sulfur volatile standard/peak area of internal standard) and *x* represented the concentration ratio (concentration of sulfur volatile standard/concentration of internal standard). The calibration curves were obtained from Chemstation software (Agilent Technologies Inc.) and used for calculation of volatiles in tea infusions. Quantitation of other volatile compounds was carried out by standard curves obtained by each compound from six different concentrations in water with the internal standard of 2-octanol (0.01 g of 5 mg/kg).

GC−MS Identification of Aroma Compounds. The analyses were performed using a Hewlett-Packard 7890 GC with a 5975 mass selective detector (MSD) (Agilent Technologies) instrument operating under electron ionization (EI) mode (70 eV, ion source temperature 230 °C) with the quadrupole in a scanning mode (scan range was *m*/*z* 30−450 at a scan rate of 1 scan/s). Separation of compounds was achieved on Innowax-Wax (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies) and DB-5 (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies). Helium (purity = 99.999%) was used as a carrier with a constant flow velocity of 1 mL/min. The quadrupole mass filter was at 150 °C. The oven temperature was held at 40 °C for 6 min, then ramped to 100 °C at the rate of 2 °C/min, and ramped at the rate of 5 °C/min to 230 °C for the last 10 min.

The volatile compounds were identified by comparing retention indices and authentic standards, or with mass spectra in the Wiley and NIST11 libraryies. The RIs were determined via sample injection with a homologous series of alkanes (C5−C30) (Sigma-Aldrich).

Gas Chromatography−FPD. Gas chromatography equipped with a 5380 FPD detector from Agilent (Santa Clara, CA) was used in the sulfur mode. Separation of compounds was achieved on Innowax-Wax (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies, USA) and DB-5 (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies, USA). The oven temperature was held at 40 °C for 6 min, then ramped to 100 °C at the rate of 2 °C/min, and ramped at the rate of 5 °C/min to 230 °C for the last 10 min. GC was operated in a constant flow mode (1 mL/min) with helium as the carrier gas. The FPD detector was set at 250 °C, and the photomultiplier tube (PMT) voltage was set at 500 V. The sulfur-containing compounds were confirmed by comparison with authentic standards on both columns, RI value matching, and aroma descriptor. The quantification method was identical to the GC analysis as described in the above section. The samples were run in triplicate.

GC−Olfactometry Analysis. GC−olfactometry analysis was carried out on an Agilent 6890N GC equipped with flame ionization detection (FID) system and an olfactometer (Gerstel, Inc., Baltimore, MD). The Innowax (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies, USA) and DB-5 (60 m × 0.25 mm i.d. × 0.25 μm film thickness, Agilent Technologies, USA) were used. The oven temperature was held at 40 °C for 6 min, then ramped to 100 °C at the rate of 2 °C/min, and ramped at the rate of 5 °C/min to 230 °C for the last 10 min. The column effluent was split 1:1 into the FID and the heated sniffing port (250 °C) using two deactivated and uncoated fused silica capillaries. The column carrier gas was nitrogen at a constant flow rate of 2 mL/min. A panel of ten trained panelists (5 males and 5 females) evaluated the effluents enriched with purified, humidified air (120 mL/min). Each of the panelists was trained before sensory analysis in order to get familiar with an odor description by using solutions of artificial odorants. The aroma-active compounds perceived by ten panelists were recorded as the time for onset and end while sniffing the effluent from the sniffing mask. The panelists were also required to note the perceived odor characteristic and intensity. With the same time, the computer automatically recorded the retention time and sniffing time of aroma-active compound individually. The odor intensities were evaluated using a 6-point intensity scale from 0 to 5; "0" was none, "3" was moderate, and "5" was extreme. The experiment was replicated in triplicate by each panelist. Finally, the aroma intensity was the average from ten panelists.

Odor Activity Values (OAV). The contribution of each odor to the overall fruit wine aroma was evaluated by the odor activity value, which was measured as the ratio of the concentration of each compound to its detection threshold. The threshold values were taken from information available in the references.

[a]Code for the volatile compounds detected in the tea infusions. [b]Retention index of compounds on DB-5 and Innowax Column. [c]The lowercase letters (a−c) following the values in the DHP, TGY, and DDWL entries in the same row are significantly different according to the Duncan test ($p < 0.05$). [d]Method of identification: RI, retention index; Std, confirmed by authentic standards; AD, aroma descriptor; PFD, flame photometric detector. [e]The aroma intensities were evaluated by GC−O. [f]Not perceived.

Sensory Analysis. Quantitative descriptive analyses (QDA) were performed for evaluating three types of samples by ten assessors (5 females and 5 males). All the assessors were previously trained in the ability to recognize, describe, and discriminate different aroma qualities. Each of them completed 150 h of specific training with tea infusions. Five sensory attributes were commonly selected to describe the overall aroma by the panelists: "roast", "sweet", "green and grassy", "sulfur", and "floral". These five aroma terms were defined as the following aromas: 2,3,5-trimethylpyrazine for "roast" attribute, β-damascenone for "sweet" note, hexanal for "green and grassy" attribute, dimethyl sulfide for "sulfur" attribute, and geraniol for "floral" attribute. After the training period, the respective samples (10 g) were placed in capped glasses with different three-digit numbers for the sensory assessors. Each assessor rated the intensity of the five attributes on a ten-point scale (0, none; 5, moderate; 10, very strong), and the results were averaged for each sensory note and plotted in a radar diagram. The sensory evaluations of each sample were performed in triplicate at room temperature (20 ± 1 °C).

Statistical Analysis. The data were processed with analysis of variance (ANOVA). ANOVA and Duncan's multiple range tests were applied to the data to determine significant differences ($P < 0.05$). The correlation analysis was employed to show the correlations between attribute variables and the aroma-active volatile profile. All statistical analyses were operated using XLSTAT ver.7.5 (Addinsoft, New York, NY, USA).

RESULTS AND DISCUSSION

GC−O Results for Tea Infusions. The results of aroma intensity (AI) testing of the compounds are summarized in Table 1. The aroma compounds were confirmed by comparison with authentic standards on columns, RI, and aroma descriptor. Application of the GC−O to the tea infusions revealed forty-three, forty-five, and forty-eight aroma-active compounds (AI ≥ 2) in the TGY, DHP, and DDWL infusions, respectively. There were five unidentified volatile compounds that were found in samples. The differences in the number of aroma-active compounds in the tea infusions were mainly caused by concentration differences thereof. As seen in Table 1, the DHP infusions contained more aroma-active compounds than other samples. The compounds having the highest AI (4.4) were nerolidol for DHP infusions, (*R*)-(−)-linalool and (*E*)-2-heptenal (4.3) for TGY infusions, and indole and nerolidol (4.5) for DDWL infusions.

Aldehydes and alcohols were important classes of aroma-active compounds in the three types of tea infusions. Odor threshold values are generally lower than concentrations of those compounds; thus, they have an important potential effect on the overall aroma of a sample.[15] Aldehydes and alcohols are generally characterized by intense sensory description by panelists and are associated with greenery, freshly mown grass, green plants, citrusy, fatty, and sweet notes. The total numbers of aroma-active aldehydes and alcohols were nineteen, twenty, and eighteen, and four, six, and six in DHP, TGY, and DDWL infusions, respectively. Of those aroma-active compounds, hexanal, heptanal, (*E*)-2-hexenal, (*E*)-2-heptenal, (*Z*)-3-hexen-1-ol, and 1-penten-3-ol were the most powerful aroma-active compounds contributing to the aroma profile of tea infusions. The result was consistent with previous investigations, which presented aldehydes with six to ten carbons as being perceived as having green, fatty, or tallow aromas. This green aroma is sometimes referred to as a fresh note, and the chemicals responsible are predominantly C6 alcohols and aldehydes, preferably unsaturated.[6] From Table 1, DDWL infusions exhibited the highest AI of those aldehydes among the three types of samples. As the degree of fermentation increased, the concentrations of those compounds with grassy and green aromas gradually declined. This might have been associated with the withering process of the teas. During this process, a series of biochemical and chemical reactions occurred. As a result, many low-boiling point compounds with green aromas are transformed and volatilized.[6]Besides those aroma compounds, (*E,E*)-2,4-heptadienal and (*E,E*)-2,4-hexadienal, which exhibited relatively high AIs among all the samples, also exerted a significant influence on the aroma of the tea infusions. The result was consistent with that arising from a recent study on green teas.[16] (*E,E*)-2,4-Heptadienal and (*E,E*)-2,4-hexadienal are mostly derived from lipid degradation during manufacture.

Terpenes were another significant class of aroma-active compounds found in the three types of tea infusions. In total, six aroma-active terpenes were found in these three types of samples. Of the aroma-active compounds, nerolidol, (*R*)-(−)-linalool, geraniol, *cis*-linaloloxide, hotrienol, β-ionone, and *trans*-linalool oxide were the most powerful aroma-active compounds contributing to the aroma profile of tea infusions. Nerolidol was responsible for rose and apple aromas, which presented the highest AIs in the DHP infusions (4.4). Therefore, nerolidol might be a major contributor to the characteristic floral aroma note common to the DPH cultivar investigated. β-Damascenone, which might be responsible for the sweet-like and fruity odor, exhibited a high AI (4.1) in the DHP infusions. The result was consistent with a recent study which shows that β-damascenone, with its extremely low human odor perception threshold (0.05 μg/kg),[17] exerted a significant influence on black tea aroma.[16] Given this conclusion, β-damascenone was also likely to enhance the fruity aroma of tea. In addition, the AIs of (*R*)-(−)-linalool found in samples were high enough to be considered representative of an active compound, suggesting that floral characteristics may encapsulate the dominant tea infusion aroma. The AIs of nerolidol, β-damascenone, and (*R*)-(−)-linalool were dominant in DHP infusion teas. This might have resulted from different tea varieties, various manufacturing processes, or cultivation practices. The formation of those

compounds was the result of material transformation and enzymolysis of aroma precursors. The formation of intercellular channels promoted contact between substrate and enzymes and the release of the enzymes, which were largely related to aroma compounds.[18]

Ketones were also an important class of aroma-active compound in the three types of tea infusions. The total numbers of aroma-active ketone compounds were eight, four, and seven in the three types of samples, respectively. Within these aroma-active compounds, *cis*-jasmone, 6-methyl-5-hept-en-2-one, β-ionone, 2,3-butanedione, and 2,3-pentanedione were the most powerful aroma-active compounds contributing to the aroma profile of the tea infusions. Unsaturated fatty acid is oxidatively degraded to small molecules of ketone compounds with fatty oxidase.[19] Macromolecular ketone is produced by β-carotene oxidation and degradation. During fermentation, low boiling point ketone compounds were transformed and high boiling point compounds gradually accumulated. 2,3-Butanedione and 2,3-pentanedione accounted for the typical butter note present in the tea infusions. The DHP infusions exhibited higher AIs (2.3 and 2.7) for these compounds than the DDWL infusions. Interestingly, those compounds were not perceived from GC–O in TGY infusions. However, it does not mean that those were absent from the TGY infusions.

It should be noted that methyl jasmonate and indole might be important aroma-active compounds in tea infusions. The AIs of methyl jasmonate were similar in the three types of samples. Methyl jasmonate contributed to the tea having floral odors.[20] Indole, which might be considered an animal-like aroma, exhibited the highest AI (4.5) in the DDWL infusions and the lowest AI (4.0) in the DHP infusions. This compound might positively strengthen the overall nature of the tea aroma.[21]

Stabilization of VSCs in Tea Infusions. It has been reported that sulfur compounds are extremely reactive and artifacts can be formed during analysis.[22,23] In this work, all standards were tested individually for stability during sample extraction and analysis. Most of the compounds were stable and only gave a single chromatographic peak. The chromatogram data of VSCs are shown in the Supporting Information. It was noteworthy that methanethiol could be easily oxidized to form dimethyl disulfide and dimethyl trisulfide, probably due to the presence of oxygen and transition metals.[23,24] As a result, it was unreliable to quantify VSCs in food. Thus, some measurements should be taken to prevent the formation of artifacts. The pretreatment of the instrument was indispensable to the

analysis of sulfur compounds. In this experiment, the GC injection port was deactivated with bis(trimethylsilyl)-trifluoroacetamide. Finally, sulfur standards were checked individually and only single peaks were detected: this indicated that artifact formation was prevented under this experimental condition. The observation was consistent with previous studies.[25−27] Furthermore, a recovery study was performed to investigate the influence of model solution and tea infusions on the recovery of 13 VSCs, which were detected in tea infusions. For the model solution, and real tea infusions, recoveries ranged from 88.3% to 104% for all compounds with relative standard deviations (RSD) below 10% for all compounds (Table 2). The result demonstrated that this method was reliable when quantifying those VSCs.

As shown in Table 3, thirteen sulfur volatiles were detected in this investigation: these were identified on the basis of their retention index in two dissimilar columns compared with standard chemicals and aroma descriptor. A sulfur-specific FPD response indicated that the peaks detected did contain sulfur. On the basis of their chemical structure, these compounds included thioesters, sulfides, polysulfides, heterocyclic forms, and thio forms.

Qualitatively, eight, eleven, and twelve sulfur compounds were identified in DDWL, TGY, and DHP infusions, respectively. Among these compounds, seven compounds were present in all samples. The observed differences in the sulfur compounds present in tea infusions obtained from the different cultivars and manufacturing processes were both quantitative and qualitative. Quantitatively, dimethyl sulfide, dimethyl disulfide, and dimethyl sulfoxide were the predominant volatile compounds, followed by methanethiol and dimethyl trisulfide. The result demonstrated that sulfide, sulfides, and polysulfides presented relatively higher contents in samples than other sulfur compounds. It was noteworthy that the 3-mercaptohexanol and furfurylthiol presented trace contents in the samples. Dimethyl sulfide, dimethyl disulfide, and dimethyl trisulfide have been reported in tea, wine, tomato, and onions.[11,16,28−30] Dimethyl sulfide described as an "asparagus", "corn", and "molasses" aroma was considered a beneficial compound in low concentrations.

The formation of dimethyl sulfide happens during leaf maturation and fermentation and is caused by a yeast mechanism involving cleavage of *S*-methyl-L-methionine to homoserine and dimethyl sulfide.[31,32] Among samples, dimethyl sulfide was identified at a concentration of between 7.81 μg/kg for DHP infusions and 1.45 × 10^3 μg/kg for DDWL infusions. The different concentrations of dimethyl sulfide between these samples might be ascribable to the variety, manufacture, fermentation process, and even small differences in withering conditions, such as withering temperature and withering time. The result agreed with data from a previous investigation,[6] which showed that the aroma composition and their quantities in different types of teas varied widely. It is well-known that the degree of fermentation of DDWL (10 to 20%) was generally lower than in DHP (60 to 80%). Thus, the aroma of DDWL was close to green tea, which contained a significant amount of dimethyl sulfide. The same corroborating results were also obtained by previous research,[33] which indicated that dimethyl sulfide contributed significantly to the aroma properties of green tea. Furfurylthiol, named "coffee aldehyde", has been found in roasted coffee, meat, wheat bread, and popcorn.[34] Concentrations of furfurythiol were almost two times as high in sample DHP infusions (0.05 μg/kg) compared to sample TGY infusions (0.03 μg/kg). It was worth noting that the low concentrations of aroma compounds might influence the perceived aroma intensity in samples due to their low detection thresholds (0.01 μg/kg).[26] On the other hand, methanethiol, ethanethiol, and propanethiol were responsible for sulfur, gasoline, and garlic aromas being detected. The relatively high contents of those compounds in sample DHP infusions (49.9, 5.05, and 1.85 μg/kg) suggested that these compounds were related to the tea manufacturing process. Along with the degree of fermentation being increased, those compounds might be gradually released from the tea leaves by enzymatic reactions. The other important VSC was methional, with its distinctive potato odors.[11] The absence of methional in DDWL infusions, and its presence in DHP and TGY infusions, was a clear indication that fermentation had liberated this compound due to degradation of the nonvolatile sulfur-containing amino acid, such as methionine.[35] 3-Mercaptohexanol has been previously reported in grapefruit and red wine, with passionfruit and grapefruit odors.[36] It is worth noting that 3-mercaptohexanol was of particular importance to tea aroma due to its extremely low threshold (60 ng/kg) of detection.[36]

Quantitative Analysis of Volatile Compounds. The concentrations and odor-activity values (OAVs) of volatile compounds obtained by GC−MS are presented in Table 4. The major volatile constituents of the tea infusions were heptanal (6.70 × 10^3 to 9.60 × 10^3 μg/kg), (*R*)-(−)-linalool (628−868 μg/kg), benzaldehyde (2.18 × 10^3− to 3.66 × 10^3 μg/kg), 1-penten-3-ol (1.56 × 10^3 to 2.39 × 10^3 μg/kg), and 5-methyl-2-furfural (1.63 × 10^3−3.60 × 10^3 μg/kg). The AIs and OAVs of these compounds were greater than 1, which were considered as odor-active compounds in tea infusions.

On the other hand, β-damascenone (3.74 × 10^{-2} to 7.66 × 10^{-2} μg/kg), indole (3.84−5.52 μg/kg), 3-methylbutanal (2.40 × 10^{-2} to 70.7 μg/kg), and octanal (19.2−91.4 μg/kg) were present at low concentrations (<100 μ g/kg). Despite their low levels, these compounds might have a significant impact on tea infusion aroma because of their low odor detection threshold values.

In this study, OAVs were calculated using odor detection thresholds determined in water, which was appropriate because tea infusions were mainly an aqueous product. From Table 4, volatile compounds like 2-methylpropanal (230−455), 3-methylbutanal (1−353), 2-methylbutanal (34−68), nerolidol (108−184), (*E*)-2-heptenal (148−294), hexanal (134−230), octanal (28−131), β-damascenone (29−59), indole (96−138), 6-methyl-5-hepten-2-one (34−67), (*R*)-(−)-linalool (63−87), and dimethyl sulfide (7−1320) presented relatively higher OAVs than those of other compounds, indicating the importance of these compounds in the overall aroma of tea infusions.

Generally, many compounds like nerolidol, (*R*)-(−)-linalool, β-damascenone, indole, hexanal, and (*E*)-2-hexenal presented both high AIs and high OAVs, which confirmed the positive relationship between GC−O and OAV. However, volatile compounds like 2-methylpropanal, pentanal, heptanal, (*Z*)-3-hexen-1-ol and nonanal that had high AI but a relatively low OAV, which could be related to the difference of thresholds in air and water.

Although GC−O is a useful technique for screening odor-active compounds, it does not provide information about the contribution of individual compounds to the overall aroma. The reason might be that these odorants were detected based

[a]Aroma compounds detected in the tea infusion. [b]Retention indices of compounds on DB-5 and Innowax Column. [c]The lowercase letters (a−c) following the values in the DHP, TGY, and DDWL entries in the same row are significantly different according to the Duncan test ($p < 0.05$). [d]Method of identification: MS, mass spectrum comparison using Wiley library; RI, retention index in agreement with literature value; Std, confirmed by authentic standards. [e]Reference number. [f]The detection threshold was not found in reference. [g]Authentic standards were obtained from Alfa Aesar Corporation (Tianjin, China). All of the chemical standards used above were of GC quality.

J. Agric. Food Chem. 2015, 63, 7499−7510
DOI: 10.1021/acs.jafc.5b02358

on odor activity in air without considering interactions with the food matrix. For this reason, the use of OAVs may provide a better assessment of the odor activities of compounds as long as the quantitative data and the odor detection thresholds are accurate. However, the accuracy of identification of aroma-active compounds in tea infusions with GC−O or OAV methods should be further verified by other methods, such as aroma recombination.

Sensory Analysis. Sensory analysis was performed by an evaluation of the organoleptic qualities of tea infusions, using five descriptors including "roast", "sweet", "green and grassy", "sulfur", and "floral" aromas. ANOVA was used to distinguish different tea samples by their sensory evaluation scores. Statistical analysis showed that the "roast", "sweet", "green and grassy", "sulfur", and "floral" attributes were significantly different ($p < 0.05$) (Figure 1).

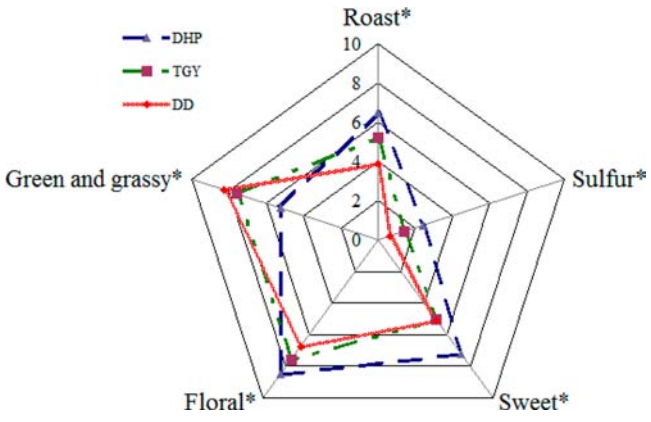

Figure 1. Aroma profiles of tea infusions obtained from DHP, TGY, and DDWL infusion samples. In sensorial parameters indicated with an (*) a difference among some trials is verified for $p < 0.05$.

The total roast attribute intensity for DHP infusions was 6.5 compared to 3.9 for DDWL infusions. The major compounds involved in this aroma category included 2,5-dimethylpyrazine, 2,3,5-trimethylpyrazine, and furfurylthiol. 2,5-Dimethylpyrazine and 2,3,5-trimethylpyrazine were typically associated with roast aromas, as described from GC−O. Those compounds might have been produced by the Maillard reaction occurring during fermentation. A previous study finds that these compounds are derived from amino acids and sugars.[37]

"Sweet" was an important flavor attribute for tea infusions: the DHP infusions returned the highest score (7.2) in this category compared to 5.0 in the TGY infusions. The major aroma-active compounds in the sweet category included 6-methyl-5-hepten-2-one and β-damascenone; the β-damascenone was considered to have been the characteristic sweet aroma. Although 6-methyl-5-hepten-2-one greatly contributed to the fruity aroma, it could enhance the perception of sweetness in tea infusions.[16]

"Green/grassy" was also a typical aroma attribute in tea infusions. It exhibited the highest aroma intensity in DDWL infusions (8.3) and lowest intensity in DHP infusions (5.2). It was mainly composed of aldehydes and alcohols such as hexanal, heptanal, octanal, nonanal, (*E*)-2-hexenal, (*E*)-2-heptenal, (*E*)-2-octenal, 1-pentanol, 1-penten-3-ol, and (*Z*)-3-hexen-1-ol. Previous research found that the fermentation method could cause a change of volatile flavor component in terms of quality and quantity, and it the fermentation process can probably cause the loss of grassy/green aromas.[6,38]

The DHP infusions were rated as having the highest value (2.4) in the "sulfur" attribute category, whereas TGY infusions returned a low sensory evaluation score (0.6). The major aroma-active compounds included dimethyl sulfide, dimethyl disulfide, methionol, methional, and 3-mercaptohexanol. Traditionally, these sulfur compounds were typically associated with a negative sensory contribution to tea samples; however, those compounds might improve the aroma quality of teas when present in appropriate amounts. Although sulfur compounds presented common sulfur aroma, those compounds exhibited characteristic aroma themselves, e.g., dimethyl sulfide with cabbage, corn, and molasses aroma; methional with its distinctive cooked potato aroma; 3-mercaptohexanol with passionfruit and grapefruit aroma.[36]

"Floral" was also a typical aroma attribute in tea infusions. It had its highest aroma intensity in DHP infusions (8.5) and lowest in DDWL infusions (6.7). It was mainly composed of terpenes and ketones such as β-ionone, nerolidol, *cis*-jasmone, methyl jasmonate, and (*R*)-(−)-linalool. "Floral" was a characteristic aroma of oolong tea, which was one of the important indications for distinguishing it from other types of tea.

Correlation Analysis. Correlation analysis could be manipulated to further illustrate the relationships between the volatile compounds and sensory attributes. From Table 5, positive correlations were found between "roast" attribute and 2,5-dimethylpyrazine ($r = 0.996$), furfurylthiol ($r = 0.994$), furfural ($r = 0.983$), and 5-methyl-2-furfural ($r = 0.986$); "sulfur" attribute and methanethiol ($r = 0.908$), dimethyl disulfide ($r = 0.908$), furfurylthiol ($r = 0.984$), and methional ($r = 0.992$); "sweet" attribute and 6-methyl-5-hepten-2-one ($r = 0.955$), β-damascenone ($r = 0.990$), geraniol ($r = 0.920$), and nerolidol ($r = 0.918$); "floral" attribute and hotrienol ($r = 0.973$), geraniol ($r = 0.999$), phenylethyl alcohol ($r = 0.937$), β-ionone ($r = 0.958$), methyl jasmonate ($r = 0.956$), and nerolidol ($r = 0.918$); and "green and grassy" attribute and butanal ($r = 0.990$), hexanal ($r = 0.932$), (*E*)-2-pentenal ($r = 0.965$), heptanal ($r = 0.981$), (*E*)-2-hexenal ($r = 0.990$), (*E*)-2-heptenal ($r = 0.951$), and (*Z*)-3-hexen-1-ol ($r = 0.999$). The result was partly according to the analysis of GC−O and sensory analysis. On the other hand, negative correlations were found between "roast" attribute and (*Z*)-3-hexen-1-ol ($r = -0.981$) and hotrienol ($r = -0.972$); "sulfur" attribute and butanal ($r = -0.921$), 3-methylbutanal ($r = -0.916$), (*E*,*E*)-2,4-heptadienal ($r = -0.933$), and hotrienol ($r = -0.986$); "sweet" attribute and butanal ($r = -0.921$), 3-methylbutanal ($r = -0.912$), hexanol ($r = -0.946$), hotrienol ($r = -0.945$), and phenyl acetaldehyde ($r = -0.952$); "floral" attribute and hexanal ($r = -0.998$), (*E*)-2-hexenal ($r = -0.988$), and (*E*,*E*)-2,4-heptadienal($r = -0.954$); and "green and grassy" attribute and methanethiol ($r = -0.982$), dimethyl disulfide ($r = -0.946$), *cis*-linaloloxide ($r = -0.926$), furfural ($r = -0.992$), *trans*-linalooloxide ($r = -0.939$), and geraniol ($r = -0.917$). Positive as well as negative correlations suggest that the perception of an aromatic note was influenced not only by the presence of a few compounds whose aroma forms the attribute but also by the presence of other odorants that affect negatively in the perception of such aromatic attribute.[39]

using the VIDEO-Sniff method (vocabulary−intensity−duration of elementary odors by sniffing),[13] a hybrid olfactometry method combining detection frequency, intensity, and descriptive vocabulary of the judges, and their quantitation by HS-SPME-GC-MS/PFPD.

To date, and to the authors' knowledge, there is no publication reporting the comparative study of differently manufactured Swiss Tilsit cheeses using olfactometry and with a focus on VSC odor impact and quantitation.

MATERIALS AND METHODS

Chemicals. Chemical compounds were purchased from Sigma-Aldrich Chemie GmbH (Buchs, Switzerland) and Alfa Aesar GmbH & Co KG (Karlsruhe, Germany): acetic acid (Aldrich 320099), 2-acetyl-2-thiazoline (Aldrich W381718), allyl sulfide (Aldrich A35801), benzaldehyde (Aldrich W212709), benzyl alcohol (Aldrich 305197), bis(methylthio)methane (Aldrich W387800), butane-2,3-dione (Aldrich B85307), butan-2-one (Aldrich 360473), butanoic acid (Aldrich W222119), carbon disulfide (Aldrich 335266), decan-2-one (Aldrich W510637), (2*E*,4*E*)-deca-2,4-dienal (Aldrich W313505), dimethyl disulfide (Aldrich W353604), 2,5-dimethylpyrazine (Aldrich W327204), dimethyl sulfide (Aldrich W274623), dimethyl sulfone (Aldrich M81705), dimethyl sulfoxide (Aldrich D8418), dimethyl trisulfide (Aldrich W327506), ethanol (Aldrich 02860), ethyl butanoate (Aldrich W242705), ethyl hexanoate (Aldrich W243906), 4-ethylguaiacol (Aldrich W243604), ethyl isobutyrate (Aldrich W242802), ethyl methyl sulfide (Aldrich 238317), ethyl octanoate (Aldrich W244902), hexanal (Aldrich 115606), hexanoic acid (Aldrich W255904), 3-methylbutyl acetate (Aldrich W205532), methanethiol (Aldrich 742805), 3-methylbutanal (Aldrich W269204), 3-methylbutanoic acid (Aldrich W310204), 3-methylbutan-2-ol (Aldrich 110949), 3-methylindole (Aldrich W301912), methyl isothiocyanate (Aldrich 112771), 2-methylpropanoic acid (Aldrich W222216), 5-methylnonan-5-ol (Aldrich S505021), 4-methylpentanoic acid (Aldrich 277827), *S*-methyl thioacetate (Aldrich CDS001513), 2-methyltetrahydrothiophen-3-one (Aldrich W351202), methyl thiocyanate (Aldrich 722197), 3-(methylthio)propanal (Aldrich W274704), nonanal (Aldrich W278203), δ-octalactone (Aldrich w321405), octanal (Aldrich W279706), octanoic acid (Aldrich W279900), oct-1-en-3-ol (Aldrich W280518), oct-1-en-3-one (Aldrich W351504), oct-3-en-2-one (Aldrich W341606), pentanoic acid (Aldrich W310107), phenol (Aldrich P1037), potassium thiocyanate (Aldrich 207799), polyethylene glycol 200 (P3015), 2-phenylethanol (Aldrich 77861), pentane-2,3-dione (Aldrich W284106), α-pinene (Aldrich 147524), sodium sulfide nonahydrate (Aldrich 208043), sulfuric acid 98% (Aldrich 320501), tridecan-2-one (Aldrich W338818), undecan-2-one (Aldrich W309311), and *m*-xylene (Aldrich 95670).

Carbonyl sulfide was prepared according to the method of Svoronos and Bruno.[16] The solution was stored at −80 °C during a maximum of 1 week.

Hydrogen sulfide was prepared according to the method of Vazquez-Landaverde et al.[17] The solution was stored at 4 °C during a maximum of 1 week.

A stock solution of 1% methanethiol was prepared by bubbling gas in cold (4 °C) polyethylene glycol 200. The solution was stored at −20 °C during a maximum of 1 week.

Cheese Samples. Ten pieces of Swiss Tilsit cheese of each type and of similar commercial size and weight (approximately 200 g) were obtained from a supermarket located in Bern, Switzerland (Table 1). The cheeses were kept at 4 °C in vacuum-sealed plastic bags for a maximum of 1 month until analysis.

Sample Preparation. The samples for all analyses were obtained on the basis of a procedure described by Burbank and Qian.[7] In the present study, 2 cm of rind and cheese were removed from all sides of the cheese to provide a sample as homogeneous as possible. The sample was then finely cut with a ceramic knife to avoid contact with metal, thus limiting the oxidation of sulfur compounds. Cut cheese (2.00 ± 0.10 g) was placed in 20 mL HS vials (Interchim, Montluçon, France). For calibration curves, cut cheese was homogenized together with 10 μL of an internal standard solution containing ethyl methyl sulfide (2 mg kg^{-1}) dissolved in polyethylene glycol 200. The mixture was homogenized using a glass pestle. The vials were placed in an ice bath at 0 °C to cool the exothermic reaction when 4.00 ± 0.10 g of $CaCl_2$ was added to each mixture. Three replicates per sample were prepared. To prevent oxidation, the vials were flushed with argon for 5 s with two needles to create an "argon stream" in the vial after it had been hermetically sealed with a blue silicone/Teflon septum (Interchim).

Table 1. Description of Cheeses (www.Tilsiter.ch, 2014)

	green Tilsit	red Tilsit	yellow Tilsit
thermal treatment	pasteurized milk	partially thermized milk	pasteurized milk with higher fat content
fat in dry matter (FDM)	at least 45% FDM	at least 45% FDM	at least 55% FDM
approx fat content in 100 g	28 g	29.5 g	33 g
ripening time	30−60 days	70−110 days	30−75 days
taste perception	mild aroma, slightly sour	rich, spicy, pungent	creamy, slightly sour, mild aroma

Solid-Phase Microextraction (SPME) and Chromatography. *Identification and Quantitation of VSCs by GC-MS/PFPD.* Samples were extracted using a 1 cm carboxen/polydimethylsiloxane (CAR/PDMS) 85 μm StableFlex fiber (Supelco, Bellefonte, PA, USA) per the manufacturer's recommendation, and the literature[9,18−22] revealed that this coating is the best solution for the extraction of highly volatile sulfur compounds, such as carbonyl sulfide, hydrogen sulfide, or methanethiol from foodstuffs.

The fiber was conditioned according to the supplier's recommendations (300 °C for 60 min). The analyses were realized using an MPS2 autosampler equipped with Maestro1 software, V.1.4.8.14/3.5 (Gerstel, Sursee, Switzerland), a Trace GC Ultra GC coupled with a DSQ II mass selective detector (MSD) (Thermo Finnigan, Milan, Italy), and a PFPD (OI Analytical, College Station, TX, USA).

The headspace was extracted for 120 min at 60 °C with an agitation rate of 250 rpm without preheating. Bound volatiles were desorbed for 1 min at 250 °C in the injector, which was in the splitless mode for 30 s, and then the split valve was opened (split flow = 80 mL min^{-1}). Volatile compounds were separated on a TRB-FFAP fused silica capillary column (100% polyethylene glycol PEG with nitroterephthalic acid, bonded and cross-linked, 30 m × 0.32 mm, 1.0 μm film; Teknokroma, Barcelona, Spain) with helium as the carrier gas at a constant flow of 2.1 mL min^{-1} (37 cm s^{-1}).

The oven temperature was programmed as follows: 5 min at 35 °C, then heated to 150 °C at a rate of 10 °C min^{-1}, held for 1 min, and then heated to 220 °C at a rate of 20 °C min^{-1}, with a final hold time of 5 min. The settings of the PFPD were as follows: 250 °C, voltage at 540 V, ignitor current at 2.6 A, trigger level at 300, range at 10, and attenuation at 32 with flow rates of air1 at 17 mL min^{-1}, H_2 at 14 mL min^{-1}, and air2 at 10 mL min^{-1}. The MS settings were as follows: transfer line at 230 °C, source temperature at 230 °C, and analytes monitored in SCAN mode between 30 and 150 amu without solvent delay.

Calibration curves were established by the method of standard additions in the cheese matrix. One hundred microliters of calibration solution prepared in polyethylene glycol 200 was added to the matrix as given in Table 3, together with 10 μL of the internal standard solution containing ethyl methyl sulfide (2 mg kg^{-1}) to correct variations during the extraction.

The detector response signals were integrated using the Xcalibur 2.0.7 software (Thermo Fisher Scientific AG, Reinach, Switzerland). The NIST/EPA/NIH mass spectral library (NIST11) version 2.0 g (NIST, Gaithersburg, MD, USA) was used for peak identification. The PFPD signal was used to trace the VSCs in the chromatogram.

Gas Chromatography−Olfactometry. Odor-active compounds were analyzed using a two-way odor detection port (ODP2; Gerstel) connected to a 6890N Agilent gas chromatograph (2W-GC-O) coupled with a 5973N MSD (Agilent Technology, Santa Clara, CA, USA) and a

Table 2. Distribution of Vocabulary Items by 8 GC-O Sniffers in 11 Classes

odor class	odor descriptors
buttery-cheesy	acid, animalic, buttery, caramel, creamy, butyric acid, cheese, cheesy, rancid, raclette cheese, sweaty, vomit, propionic acid, cooked milk, Tilsit, ripe, pungent, cheesy surface, diacetyl, old socks, cellar
earthy-undergrowth	earthy, mushrooms, forest, musty, old wardrobe, pine green, champignons
empyreumatic	bread, burned, roasted, cooked, smoked
floral-fruity	floral, fresh gum, fruity, strawberry, sweet, mint, pineapple, rose, vanilla, artificial fruit, rubbery, citrus, honey, terpene, cooked apple, cherry, fresh fruit, wine
green-fatty	fatty, green, fresh vegetable, grass, plant, oil, persil, old fat, wax, colored pencil, basilica, fresh-cut grass, cut grass, bee wax, vitamin supplier
malty-chemical	chemical, malty, cleaning product, plastic, gum, solvent, urine, acetic acid, medical like a hospital, glass cleaner, alcoholic, cork
meaty	bouillon, cooked meat, ham
nutty	cooked nut, chestnut, nutty
spicy	sesame-spicy, spicy
sulfur	garlic, gas, potatoes, putrid, methanethiol, onion, sulfury, pungent, rotten, decomposed, compost, moldy
undefined	?, nd, warm, unpleasant, unknown

PFPD (OI Analytical) and equipped with an MPS2 autosampler and the Maestro1 software, V.1.4.8.14/3.5 (Gerstel, Sursee, Switzerland).

For GC-O analyses, volatile organic compounds were extracted using a 2 cm 50/30 μm divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) StableFlex fiber (Supelco). To obtain a representative evaluation of the odor of the samples in olfactometry, a DVB/CAR/PDMS fiber is suitable for the extraction of volatile and semivolatile compounds and was reported to give good odor representativeness for dairy products.[23] The fiber was conditioned according to the supplier's recommendations (270 °C for 60 min).

The cheese headspace was extracted for 16 h at 45 °C with an agitation rate of 250 rpm without preheating. The SPME extraction time was optimized for an optimal olfactory analysis to obtain clearly perceivable odorant signals.[9] The absence of artifact formation was checked using 16 h as the incubation time and only 45 min for the extraction, and the results were compared with short incubation and extraction conditions (5 min incubation, 45 min extraction). Bound volatiles were desorbed for 1 min at 250 °C in the injector, which was in the splitless mode for 30 s; then the split valve was opened (split flow = 80 mL min^{-1}). Volatile compounds were separated on a TRB-FFAP fused silica capillary column (60 m × 0.32 mm, 0.5 μm film; Teknokroma) with helium as the carrier gas at a constant flow of 2.3 mL min^{-1} (39 cm s^{-1}).

The oven temperature was programmed as follows: 5 min at 35 °C, then heated to 150 °C at a rate of 10 °C min^{-1}, held for 1 min, and then heated to 220 °C at a rate of 20 °C min^{-1} with a final hold time of 5 min.

The olfactometric ports were provided by Gerstel and are designed for two panelists to detect volatile compounds simultaneously. The dimensions and capillaries after the GC separation were adapted to obtain an optimal and timely synchronized signal between the physical detectors and the two sniffers.[24] The sample is split through deactivated silica capillaries into the proportions MSD/PFPD/ODP/ODP 1:1:1.5:1.5, corresponding to flow rates of 0.46 mL min^{-1}/0.46 mL min^{-1}/0.69 mL min^{-1}/0.69 mL min^{-1}. The transfer line for each ODP is heated at 220 °C to prevent the condensation of volatiles in the capillaries.

Olfactory analyses were performed by a trained panel of eight sniffers. A single individual response is by definition not reproducible, and a minimum of eight sniffers is required to obtain a reliable aromagram.[25,26] Panelists are equipped with a microphone and must simultaneously press a button and comment on the odor they perceive while indicating its intensity on a scale from 1 to 5, 1 being barely perceptible and 5 being a very strong odor. Comments are registered and processed at the end of each session with AcquiSniff version 6.5.9 (INRA, Clermont-Ferrand, France).

The aromagrams were computed using the VIDEO-Sniff method and the AcquiSniff software. All vocabulary employed by the judges was sorted into the 11 olfactory classes (Table 2).[27]

The settings of the PFPD were as follows: 250 °C, voltage at 540 V, ignitor current at 2.6 A, trigger level at 300, range at 10, and attenuation at 32 with the flow rates air1 at 17 mL min^{-1}, H_2 at 14 mL min^{-1}, and air2 at 10 mL min^{-1}. The MSD settings were as follows: transfer line at 230 °C, source temperature at 230 °C, and the analytes were monitored in SCAN mode between 30 and 150 amu without solvent delay.

The detectors' response signals were integrated using Chemstation Data Analysis software version E.02.00.493 (Agilent Technologies). Aromagrams were recorded and processed using the VIDEO-Sniff method and AcquiSniff Software, as described in the literature.[13] The NIST/EPA/NIH mass spectral library (NIST11) version 2.0g (NIST) was used for peak identification.

GC−Olfactometry Panel Training. GC-O is used to identify odor-active compounds with the aid of the human nose.[13] It is not necessary to be specially trained to participate as an olfactometry panelist. However, it is very convenient for data processing to work with panelists who are familiar with odors and use the same language. For this, all panelists were trained statically for 4 months to memorize 17 odorant molecules (ethyl isobutyrate, 3-methylbutyl acetate, oct-1-en-3-ol, oct-1-en-3-one, pentane-2,3-dione, 2-phenylethanol, 3-methylindole, α-pinene, allyl sulfide, dimethyl trisulfide, butanoic acid, 4-ethylguaiacol, 3-(methylthio)propanal, 2-acetyl-2-thiazoline, nonanal, (2*E*,4*E*)-deca-2,4-dienal, and 3-methylbutanal) of 10 different odor families commonly present in cheese and dairy products (buttery-cheesy, empyreumatic, floral-fruity, green-fatty, malty-chemical, meaty, spicy, nutty, sulfur, and earthy-undergrowth). After successful completion, they were familiarized with the GC-O setup and trained three times using a standard solution containing the 17 molecules. Panel performance was monitored through regular training, and information was recorded in a database.

Determination of "Average Odor Activity Values by Sniffing ($aOAV_{sniff}$)" Using Gas Chromatography−Olfactometric Detection Limits of the Compounds (GCO_t) and "Average Absolute Quantified Amounts (aAQA)". GC-O detection limits of target VSCs (GCO_t)[28] were determined by the injection of several standard solutions of pure compounds at known concentrations, using a dilution factor of 2, until the molecule was no longer identifiable by the panelists with the same GC-O method as described above and used in all applications. The procedure was repeated with two trained panelists, and the average values for each compound were used. The method was successfully verified using two different GC-O units to confirm the feasibility of the technique.

During sniffing analyses of the cheeses, aAQA were determined by MS quantitation as described to ensure that these data correspond to the run during which olfactometric perception was recorded. Finally and according to the classical concept of OAV,[29] $aOAV_{sniff}$ values are calculated by dividing the aAQA by the GCO_t (Table 3).

Statistical Analysis. Olfactory charts and statistics were realized using AcquiSniff version 6.5.9 (INRA, Clermont-Ferrand, France).

RESULTS AND DISCUSSION

Olfactometry Evaluation. A total of 36 odorant zones were perceived during the sniffing of the three kinds of Tilsit cheese by the eight panelists. Red Tilsit showed the most odorant zones in the aromagram with 31 odorant zones, followed by yellow Tilsit with 29 odorant zones and green Tilsit with 25 odorant zones.

Altogether, 41 odorant compounds were found to be responsible for the 36 odorant zones and could be identified by combining odor, linear retention indices (LRI), PFPD, and quadrupole mass spectrometer (qMS) information. The results are presented in Table 4. A minimum of 50% of the panelists detected 17 odorant zones in the red Tilsit, 15 odorant zones in the yellow Tilsit, and 13 odorant zones in the green Tilsit. Detection frequency of <50% is generally considered as noise,[30] but molecules detected by <50% of the panel might also contribute to the overall odor of a sample. The aromagrams of the three cheeses are given in Figure 1.

A common core of odorant compounds of the three Tilsit cheeses with a detection frequency of at least 50% consists of hexanal (peak 6 in Figure 1; odor descriptors: green, grass, floral; GC-O-VIDEO-Sniff characteristics in all three cheeses such as the mean intensity × detection frequency value and detection frequency in percentage are given in Table 4), octanal (peak 12; fruity), butane-2,3-dione (peak 4; buttery, creamy, cheesy), non-8-en-2-one$^{t(std)}$ (peak 10; cooked potatoes, earthy, roasted, meaty, salty meat; ^{t} = tentatively identified, e.g. reference compound not injected ($^{t(std)}$) or odor descriptor ($^{t(Odor)}$) or reference compound not exactly matching and/or no detection by MS ($^{t(MS)}$)), 3-methylbutan-2-ol$^{t(Odor)}$ (peak 8; plastic, fatty, chemical, solvent, gum), butanoic acid (peak 31; cheesy, rancid), 3-methylbutanoic acid (peak 32; cheesy, rancid raclette cheese), MeSH (peak 1; cheesy, old socks, cabbage, cellar, rancid, putrid), DMDS (peak 7; pungent, sulfur), bis(methylthio)methane (peak 13; animalic, cheesy, sulfury, garlic, onion, rancid), DMTS (peak 17; garlic, sulfury, gas, metallic), and 3-(methylthio)propanal (peak 23; boiled potatoes, sulfury).

Two odor-active compounds, oct-1-en-3-one (peak 14; earthy, mushrooms, green) and 2-methylpropanoic acid (peak 26; green, fatty, fruity, rancid), were perceived in both red and yellow Tilsit with a detection frequency of at least 50%. Acetic acid (peak 21; chemical, green, fresh, acid, pungent, spicy) was perceived in both yellow and green Tilsit.

Some compounds were found exclusively in one of the cheeses with a detection frequency of at least 50% and lower than 50% in the other ones. Red Tilsit contains a wider variety of such compounds, with five specific odor-active compounds that were found only in red Tilsit: 3-methylbutanal (peak 3; burned, cooked, roasted, spicy), octa-3,5-dien-2-one$^{t(std)}$ (peak 28; floral, earthy), ethyl butanoate (peak 5; fruity, floral), 2-methyltetrahydrothiophen-3-one$^{t(odor\ threshold)}$ (peak 27; cheesy, sulfur, pungent), and *m*-xylene$^{t(odor)}$ (peak 9; roasted, fatty, old oil, bread). Two specific odor-active compounds were detected exclusively in yellow Tilsit, undecan-2-one (peak 30; floral, fresh, fruity, mint) and 2,3-dimethyl-5-(1-propenyl)pyrazine$^{t(std)}$ (peak 29; green, cut grass, plant), and one specific odor-active compound was detected exclusively in green Tilsit, 2,5-dimethylpyrazine (peak 15; mushroom, green).

In addition, 18 compounds were perceived with a detection frequency of panelists <50% but could be easily identified by LRI, qMS, or odor. Again, red Tilsit shows a greater number of these odorant compounds with 14 such molecules, of which 3 were exclusively perceived in red Tilsit. Yellow Tilsit contains 12 molecules, including 2 specific compounds, and green Tilsit contains the least, with only 9 molecules without specific compounds. The following compounds were identified with a detection frequency of <50%: nonanal$^{t(odor)}$ (peak 16; fruity, cooked, roasted, vanilla, honey), benzaldehyde (peak 25; sesame-spicy, fatty, green, oily, animalic), butan-2-one (peak 2; burned plastic, plastic), decan-2-one (peak 24; cooked, roasted, boiled potatoes), oct-3-en-2-one (peak 18; mushrooms), tridecan-2-one$^{t(odor)}$ (peak 34; wax, fatty), δ-octalactone (peak 38; fatty, green, floral, fruity, creamy, buttery), 5-methylnonan-5-ol (peak 20, green, chemical, earthy), benzyl alcohol (peak 37; urine, wax, fruity, ball pen), phenol (peak 39; plastic), ethyl hexanoate (peak 11; fruity, sweet), ethyl octanoate$^{t(odor)}$ (peak 19; wine, cork, chemical), hexanoic acid (peak 36; cheesy, sweaty), pentanoic acid (peak 33; cheesy, rancid), octanoic acid (peak 40; cheesy, rancid, fatty, ham), 4-methylpentanoic acid (peak 35; cheesy, rancid), and 2,6-diethylpyrazine$^{t(LRI,\ std)}$ (peak 22; chemical, green, sulfury, plastic).

The coelution of odor-active compounds complicates the identification of an odorant zone. A coelution example with hexanal (green, grass) and DMDS (pungent, sulfur), described using both green and pungent descriptors, illustrates the difficulty of identifying the compound using only the odor perception descriptors given by the panelists.

Distribution according to the number of citations of the odor families shows that the dominant odor family contributing to the odor of the different cheeses is "cheesy-buttery", as expected (citation percentages: green Tilsit, 42%; red Tilsit, 41%; and yellow Tilsit, 33%). It is followed by the "sulfur" family (green Tilsit, 24%; yellow Tilsit, 20%; and red Tilsit, 14%), the "malty-chemical" family (red Tilsit, 13%; yellow Tilsit, 12%; and green Tilsit, 5%), and the "fatty-green" family, especially in red and yellow Tilsit (yellow Tilsit, 12%; red Tilsit, 10%; and green Tilsit, 8%). Other odor families also contribute to the overall flavor but to a lesser extent, especially in green Tilsit. The "cheesy-buttery" and "sulfur" families together account for >50% of all odor citations in all three cheeses (green Tilsit, 66%; red Tilsit, 55%; and yellow Tilsit, 53%).

The citation percentages of the dominant class "buttery-cheesy" depicted in yellow in the aromagram (Figure 1) are very similar for the green and red Tilsit (41−42%) and are a little less predominant in the yellow Tilsit (33%). The "buttery-cheesy" odor zones are mainly evoked by three compounds: butanoic acid (cheesy, rancid), 3-methylbutanoic acid (cheesy, rancid, raclette cheese), and butane-2,3-dione (buttery, creamy, cheesy). These odorant compounds were detected by at least 50% of the panelists (Table 4).

The odor class "sulfur" depicted in blue represents 24% of total detected odor zones in green Tilsit, despite a lower overall sulfur compound concentration (Table 3). This might be explained by the nature of the matrix as well as the distribution and release of the compounds.

The "fatty-green" class depicted in green represents 10−12% in red and yellow Tilsit and is less frequently evoked in green Tilsit (8%). However, a single strong "fatty-green" odor zone evoked due to hexanal (green, grass, and floral) was more intense in the green Tilsit (Table 4, peak 6).

The class "malty-chemical" shown in brown is less represented in green Tilsit and is mainly due to three compounds (3-methylbutanal, benzaldehyde, and 5-methylnonan-5-ol), which seem to be mainly present in red and yellow Tilsit.

The "fruity-floral" class shown in pink is slightly more frequent in red Tilsit and comes from the presence of esters, such as ethyl butanoate (fruity, floral) or ethyl hexanoate (fruity, sweet).

"Spicy" notes depicted in violet are present in the form of acetic acid (chemical, green, fresh, acid, pungent, spicy) in all cheeses, and benzaldehyde (spicy, fatty, green, oily, animalic) is present only in red and yellow Tilsit.

The "earthy-undergrowth" notes shown in dark green come from the perception of mushroom notes. The compounds

[a]LRI on nonpolar (DB-5MS) and polar (TRB-FFAP) stationary phases, determined with a series of *n*-alkanes (C5−C25). [b]Mean intensity given by eight judges (on a scale from 1 to 5). [c]Detection frequency over eight judges. [d]Peak number according to Figure 1. [e]Compounds are listed in elution order on a TRB-FFAP column. [f]Description of odors given by the judges. [g]Identification methods: LRI = linear retention index, odor = comparison of the odor descriptors of the reference compound to the judges' descriptions, $odor^{lit}$ = comparison of the judges' descriptions to the literature, qMS = mass spectrum obtained by quadrupole mass spectrometry, std = reference compounds injection. [t]Tentatively identified (reference compounds not injected $^{(std)}$ or odor descriptor of reference compound not exactly matching $^{(odor)}$ and/or no detection by MS $^{(MS)}$; superscript precisions are given for, e.g., coelutions where the identification column does not provide all information, and in the text. [h]ND = not determined.

responsible were partially identified (Table 4: non-8-en-2-one$^{t(std)}$, oct-1-en-3-one, oct-3-en-2-one, and octa-3,5-dien-2-one$^{t(std)}$). Two additional specific aroma-active zones with a strong "earthy-undergrowth" note are present only in green Tilsit between peaks 21 and 23 and between peaks 37 and 38 (Figure 1). Due to the very low amount in the sample, these molecules could not be identified.

The class "nutty" shown in orange contributes to 1% of all detected items in cheeses. This odor class was described by the panelists as cooked nut, chestnut, and nutty. The very low concentrations in the cheeses did not allow for identification by conventional detectors in the present study.

Calculation of Average Odor Activity Values by Sniffing ($aOAV_{sniff}$). The olfactory impact of a compound depends on both its concentration in a sample and its odor threshold. In general, to account for these two parameters, the literature refers to the odor activity value (OAV), which is the ratio of the concentration of a compound to its odor threshold, to describe how strongly an odorant compound is perceived by the human nose.[29] The odor threshold values are usually taken from the literature and are determined in a simple matrix, such as water, oil, or air, using a static method. It is therefore difficult to apply such OAVs, especially to a complex matrix such as cheese.

However, the odor perception threshold is the lowest concentration of a compound that can be perceived in a matrix. It is different from the odor recognition threshold at which an odorant is both perceived and its odor recognized/identified/described. In general, perception thresholds are 2−5 times lower than identification thresholds.[31] Sniffing analysis is a dynamic method, and the panelists are trained to detect and describe odorant zones. However, for both perception and identification, the compound concentration has to be higher than the respective thresholds, and the time during which the thresholds are high enough might be too short for the panelists to react, or the panelists might be exhaling and thus miss the stimulus. This is why it is preferable to work with identification thresholds, which ensure that the determined OAV is truly the one of the target compounds, and not with perception thresholds.

Therefore, we decided not to employ the classic concept used in the literature, but to determine such gas chromatography−olfactometric detection limits as GCO_t for target odorant VSCs[28] and use them for $aOAV_{sniff}$ calculations: $aOAV_{sniff}$ values of target odorant VSCs were calculated by dividing the average absolute quantified amount (aAQA) of a VSC found during sniffing analyses in the sample by the GCO_t and are given in Table 3.

The $aOAV_{sniff}$ can help to estimate the potential odor impact a compound might have on the overall odor profile. As it is based on the theory of the classical OAV, an $aOAV_{sniff}$ with a high value is a strong indication that the compound contributes greatly to the cheese aroma.[29]

Sulfur Profiles of the Three Swiss Tilsit Cheeses. A total of 21 VSCs were detected by GC-PFPD in the studied cheeses: 21 in yellow Tilsit, 18 in red, and 18 in green. Of these 21 compounds only 6 were found to be odorant by 2W-GC-O: 6 in green Tilsit, 6 in red Tilsit, and 5 in yellow Tilsit. Fifteen selected sulfur compounds were quantified at parts per billion (ppb) levels (Table 3).

MeSH, DMDS, bis(methylthio)methane, DMTS, and 3-(methylthio)propanal, all known for their low odor thresholds, were found at ppb levels in all three cheeses and were also detected by 2W-GC-O.

2-Methyltetrahydrothiophen-3-one$^{t(odor\ threshold)}$ was also detected in all cheeses and was confirmed by LRI, qMS, PFPD, and

DOI: 10.1021/acs.jafc.5b02536

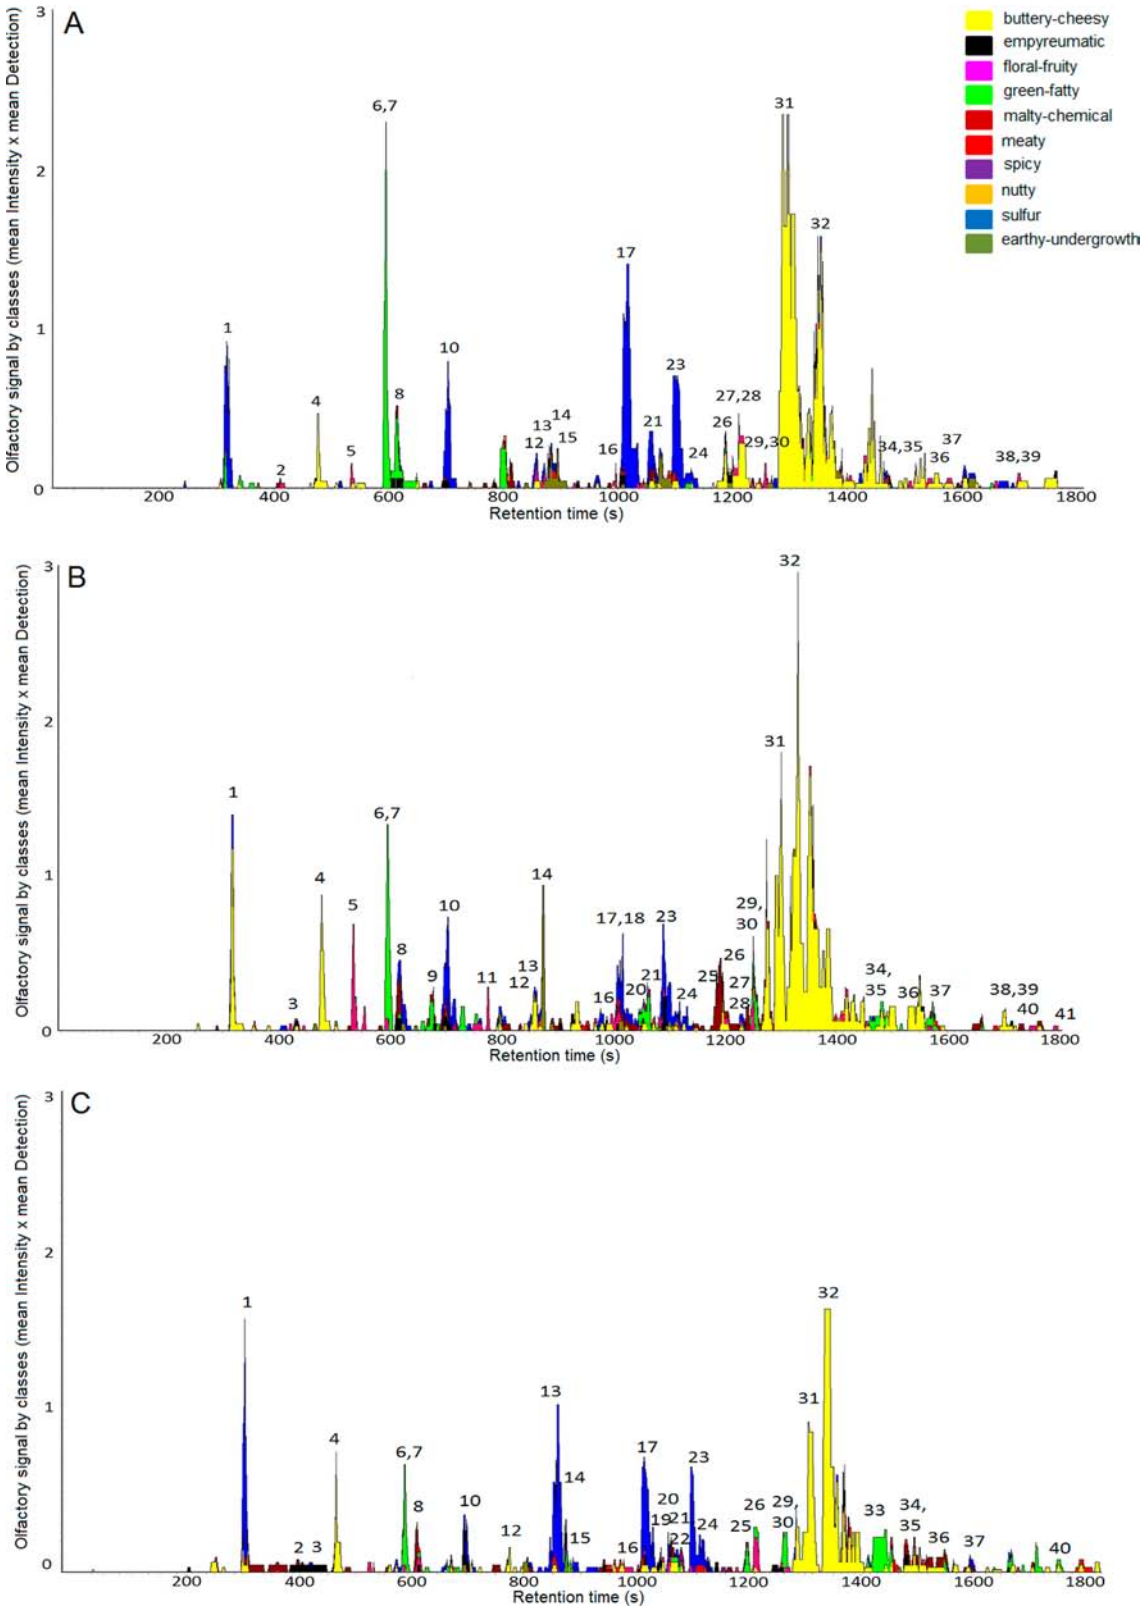

Figure 1. Mean olfactory signal by classes ($\overline{OSC}_{Int \times Det}$) of green (A), red (B), and yellow (C) Tilsit over eight judges. The signals are classified in 10 distinct odor families of the 11 families represented in Table 2. The family "undefined" is not represented in the aromagram. Labels corresponding to the peak numbers are given in Table 4. The compounds were separated on a TRB-FFAP capillary column.

odor specifications. Using its absolute quantified amount found during sniffing analyses in the samples and its GCO_t (100 ng) determined with the pure reference compound, an $aOAV_{sniff} < 1$ was calculated for 2-methyltetrahydrothiophen-3-one$^{t(\text{odor threshold})}$. Hence, it should in theory not be detectable by the panelists. Numerous reasons could explain why the compound was nevertheless smelled and confirmed by odor descriptor comparison; the following two hypotheses may be

DOI: 10.1021/acs.jafc.5b02536
J. Agric. Food Chem. 2015, 63, 7511−7521

proposed: (1) The molecule has an asymmetric carbon and hence two enantiomers exist. There are no stereochemistry specifications for the commercially available mixture used to determine the molecule properties (LRI, qMS, and odor specifications), and it might differ from the compound or enantiomer ratio found in the cheeses. (2) A synergistic effect or coelution, as octa-3,5-dien-2-one$^{t(std)}$ elutes at the same time. Further investigations will be needed to elucidate this question.

When the amounts (in $\mu g\ kg^{-1}$) of all the quantified VSCs are added, the total amount of quantified VSCs is 4377 $\mu g\ kg^{-1}$ in yellow Tilsit, 2800 $\mu g\ kg^{-1}$ in green Tilsit, and 2761 $\mu g\ kg^{-1}$ in red Tilsit. When only odorant VSCs detected during 2W-GC-O were considered, the overall amounts add up to 664.5 $\mu g\ kg^{-1}$, corresponding to 15.2% of the total quantified VSCs in yellow Tilsit; 327.0 $\mu g\ kg^{-1}$, corresponding to 11.8% in red Tilsit; and 54.4 $\mu g\ kg^{-1}$, corresponding to 1.9% in green Tilsit. COS, H_2S, CS_2, DMS, MeSAc, MTC, MITC, DMSO, and Me_2SO_2 were also quantified, but due to their high odor thresholds or odorless aspect, they were not considered.

Calibration curves on five points show correlation coefficients R^2 >0.97 for all quantified compounds. Of 15 compounds, 10 were above the quantitation limits (LOQ). DMS in green Tilsit was below the LOQ. MITC was below the LOQ in all Tilsits, and 3-(methylthio)propanal was below the LOQ in the green and yellow Tilsit.

The contribution of MeSH (odor description, Table 4: cheesy, old socks, cabbage, cellar, rancid, putrid) as the sulfur compound with an $aOAV_{sniff}$ of 400 is the most important in the studied cheeses. It was perceived with almost the same intensity in each of the cheeses. However, the quantified concentration of MeSH is higher in yellow Tilsit (15 times higher than in green Tilsit and 3 times higher than in red Tilsit). Its olfactory impact is so important that the signal covers DMS, which has a close retention time. The next most important VSC is DMTS (garlic, sulfury, gas, metallic), with an $aOAV_{sniff}$ of 150. Although its concentration is 11 times lower in green Tilsit than in yellow Tilsit, it was found to be more intense in the latter than in the other cheeses. The nature of the matrix can explain this phenomenon, as can the variability of the panelists. The samples were not measured on the same day, and the environment and the physical state of the panelists may influence the results. 3-(Methylthio)propanal (boiled potatoes, sulfury) with an $aOAV_{sniff}$ of 25 also contributes equally to the overall odor of all cheeses. It is difficult to evaluate the impact of DMDS (pungent, sulfur) in this experiment as it coeluted with hexanal (green, grass, floral) and its $aOAV_{sniff}$ is only 3.5. Bis-(methylthio)methane (animalic, cheesy, sulfury, garlic, onion, rancid) with an $aOAV_{sniff}$ of 3 has a strong impact in yellow Tilsit despite being present at the same concentration in the red Tilsit. The variability of the panelists can explain this difference.

The other quantified VSCs are odorless, such as COS, DMSO, and Me_2SO_2, or the $aOAV_{sniff}$ is <1 (H_2S, CS_2, MTC, MITC, and 2-methyltetrahydrothiophen-3-one$^{t(odor\ threshold)}$). Therefore, they do not directly affect the overall odor because their concentrations are below the odor threshold. However, they might still contribute due to synergistic effects, which were not evaluated in the present study.

Origin of Sulfur Compounds in a Cheese Matrix. Several VSCs were found to have an impact on the odor of the studied Swiss Tilsit cheeses. Their origin in a cheese matrix is of great interest, especially as variations in their concentrations may strongly influence the cheese's odor profile. VSCs in cheese originate from the enzymatic or nonenzymatic degradation of the amino acids cysteine and methionine by the action of microorganisms. Methionine, present in larger amounts in the cheese than cysteine, is the most important source of VSCs.[32,33] The vast majority of complex sulfur compounds derive from two major and highly reactive compounds, MeSH and H_2S. H_2S is formed by Strecker degradation of cysteine with diketones such as butane-2,3-dione and pentane-2,3-dione, or it can also be formed by thermal degradation of thiamin, during which the rearrangement of a thiazole group liberates H_2S.[34] Another metabolic pathway through the degradation of cysteine by the activity of cystathionine lyases of *Lactobacillus casei* can also explain the formation of H_2S in cheese.[35] MeSH is formed by Strecker degradation of methionine,[36] and a study carried out by Bogicevic et al.[35] shows the major role of deamination and dethiolation by lyases in cheese. Strains of *L. casei* with genes *ctl1* and *ctl2* present exhibited cystathionine lyase activity and broke down methionine. The presence and the formation of CS_2 is not well-defined. A high concentration is correlated with the heat treatment of milk, and the concentration of CS_2 decreases with storage time.[37] CS_2 may also be an extraction artifact due to the reaction of COS with the matrix.[16] This hypothesis was confirmed by internal laboratory tests. A large part of DMS can come from animal feed due to the nonenzymatic degradation at a pH of 7.5 of the *S*-methylmethionine sulfonium salt present in cattle feed.[34] MeSAc can be formed by *Brevibacterium linens*, but in general, the biosynthetic pathway involved in thioester production is not yet elucidated.[38] However, the combination of *Micrococcus* strains with *B. linens* shows a vastly higher concentration in MeSAc compared to when the strains are present separately in the cheese matrix. These microorganisms appear on the surface of the cheese after ripening periods of 2 and 3 weeks,[39,40] and their metabolites have been found to contribute to cheese flavor.[41] MeSH can react with free fatty acids to form *S*-methyl thioesters, such as MeSAc, and contribute to a cooked cauliflower aroma.[7] DMDS is the result of the Strecker degradation of methionine and the reaction of methionine with riboflavin. It also originates from the oxidation of MeSH during heat treatment of milk.[34] DMTS is mainly due to the oxidation of DMDS, the latter being a product of the oxidation of MeSH.[42] Oxidative reactions are accelerated by the presence of transition metals such as Cu(II) or Fe(III).[4] These metals are commonly present in low concentrations in cheese produced traditionally or industrially in production facilities, for example, in cheese kettles. The formation of 3-(methylthio)propanal requires the decarboxylation of 4-methylthio-2-ketobutyrate, and this reaction can be carried out by *Lactococcus lactis* strains.[36] DMSO is an intermediate oxidation step of DMS, the final oxidation product being Me_2SO_2.[34] MTC and MITC can be produced by a few *Pseudomonas* strains, which are naturally present in milk before heat treatment.[43] Bis(methylthio)methane can be formed through condensation or the aldol reaction of the MeSH with the formaldehyde. This compound has already been found in Gouda and Camembert cheeses.[44,45] 2-Methyltetrahydrothiophen-3-one$^{t(odor\ threshold)}$ has been found in many foodstuffs, such as coffee, whiskey, yogurt, and cheese. This molecule is formed by chemical reactions or is produced by microorganisms. The microbial mechanism is still unknown.[46−48]

To conclude, quantitation of VSCs shows a clear difference in concentration between the cheeses. Red Tilsit made from partially thermized milk and yellow Tilsit made with pasteurized milk and a higher fat content contain the highest amounts of most of the target VSCs. This can, however, not be explained by a unique reason, but can be caused by several factors such as

DOI: 10.1021/acs.jafc.5b02536
J. Agric. Food Chem. 2015, 63, 7511−7521

treatment of the raw milk, a longer ripening time, and fat content and also by a wide variety of indigenous microflora in raw milk.

According to the literature, a higher fat content can affect the growth of microflora, enzymatic activity, partitioning, and matrix effects, thus influencing the concentration of VSCs.[49] The literature showed that flavor compound retention by lipids can be significant for sulfur compounds. A lipid concentration >10% in the matrix can decrease the release of sulfur compounds into the headspace by up to 20%.[50] In the present case, all cheeses contain >10% fat (between 28 and 33 g fat per 100 g of cheese), and despite this, no negative influence of fat content on VSC release was observed with the employed analytical protocol. The protein content, on the other hand, has not been found to influence flavor release in a cheese matrix[50] and was not evaluated in the present study.

GC-O analyses in the employed analytical conditions suggest that the overall odor of the studied Tilsit cheeses is mainly determined by cheesy-buttery odor notes, followed by sulfur, malty-chemical, and fatty-green odor zones. When all perceived odor zones in the cheeses were summed (mean intensity × detection frequency values, Table 4), green Tilsit had an overall value of 40.2, red Tilsit had an overall value of 48.0, and yellow Tilsit had an overall value of 45.8. These values illustrate that red Tilsit is the most flavorful cheese of the three samples, followed by yellow Tilsit. Green Tilsit, as expected, shows the least intense overall odor. Numerous odorant compounds were identified in all three cheeses, but the number of compounds that were found in only one of the cheeses and not in the others was higher for red Tilsit, which alone of the three cheeses had *m*-xylene$^{t(odor)}$, ethyl hexanoate, oct-3-en-2-one, and unknown peak 41.

With regard to VSCs, 2W-GC-O showed that MeSH, DMDS (coelution with hexanal), bis(methylthio)methane, DMTS, 3-(methylthio)propanal, and 2-methyltetrahydrothiophen-3-one$^{t(odor\ threshold)}$ (coelution with octa-3,5-dien-2-one$^{t(std)}$) were the only identified VSCs to have a strong impact on the odorant profile of the tested cheese samples. In total, the "sulfury" odor family represents up to 14% of the total odor profile. The aromagrams of the cheeses show differences, but the differences in VSCs were not as pronounced as one might expect on the basis of the quantitation results. This might be due to either the use of optimal analytical conditions for each technique or a limitation of the methodology: when the concentration of a given compound greatly exceeds the odor threshold, the panelist cannot rate the intensity of the perceived odor stronger than the maximum of the employed scale (1−5), and detection frequency cannot exceed 100%. This is particularly the case for the most intense peaks and might explain why, despite clear differences in quantified VSC amounts, these are not directly translated in the aromagrams. However, when the number of times a certain odor family is perceived are counted, differences become more evident but are not congruent with the quantitation results.

Our work allowed for the clear differentiation of the three commercial Tilsit cheeses in terms of VSCs, odorant VSCs, and GC-O profiles. GC-O results confirm the general opinion that Tilsit cheese made from raw milk has a more intense and more diverse overall flavor than cheese manufactured with pasteurized milk. VSC quantitation could not be directly linked to this statement, as optimal analytical conditions were employed for each technique and other factors, such as limitation of GC-O methodology, but also fabrication process, fat content, and ripening time are likely to have an impact. Further research, including practice trials, is necessary to determine the precise causes of the differences found in this study, and future results should be combined with sensory profiling information.

RBS-HtrA: *htrA* ribosome binding site. Ter-HtrA: *htrA* terminator region. *emR*: erythromycin resistance gene. *specR*: spectinomycin resistance gene. The inset reveals the PCR amplification of *prtS* gene. M: DNA molecular weight marker. Lanes 1, 2, 3, and 4 indicate PCR product obtained from the genomic DNA of *S. thermophilus* CNRZ1066, LMD-9-Δ*prtS*, LMD-9-Δ*prtS*-Δ*htrA*, and LMD-9, respectively.

the growth of $PrtS^-$ strains, since these strains acidified their growth medium at a rate similar to $PrtS^+$ strains when this medium contained a mixture of peptides, i.e., bactotryptone.[7] Contrariwise, such cell-associated extracellular peptidase activities might be undesirable for the stability of milk-derived peptides carrying a given biological activity, eventually added to the fermented milk products or produced from milk proteins by the PrtS activity during the fermentation process. This hypothesis is reinforced by a current study in which Hafeez and colleagues[11] revealed hydrolysis of several milk-derived bioactive peptides by cell-associated extracellular peptidases of *S. thermophilus* strains.

Isracidin corresponds to the 1−23 fragment of bovine α_{s1}-casein (CN) and is released by chymosin digestion of this casein. It exhibits an antimicrobial activity against different bacteria such as *Escherichia coli* and staphylococci.[12,13] It could be applied as a biopreservative in the dairy products due to its inherent antimicrobial properties.[14] Besides this, isracidin has been widely employed as a substrate to determine cleavage specificities of the surface proteases of different LAB.[15,16] Indeed, relatively large peptide size and presence of three proline residues make isracidin an ideal substrate for this purpose, as certain enzymes are unable to hydrolyze peptide bonds involving proline residue. Thereby, Fernandez-Espla and colleagues[6] determined the cleavage preference of the purified PrtS of *S. thermophilus* CNRZ 385 on isracidin, showing that PrtS displayed a specificity that was intermediate between the specificities of $PrtP_I$-type and $PrtP_{III}$-type cell-envelope proteases of *Lactococcus lactis*. Knowing that *S. thermophilus* strains also possess cell-associated extracellular peptidases and hydrolyze different bioactive peptides of smaller size,[11] we have chosen to use isracidin as substrate to study the proteolytic effect of PrtS and cell-associated extracellular peptidases (strain $PrtS^+$ phenotype) as well as that of cell-associated extracellular peptidases alone (strain $PrtS^-$ phenotype), on this peptide.

Therefore, first, we determined the contribution of PrtS activity of LMD-9 strain, among all of the other proteolytic activities present at the cell surface, in the hydrolysis of isracidin, and we investigated the subsequent evolution of the peptides formed by a kinetics approach. Second, in order to investigate the level of hydrolysis of isracidin by known cell-associated extracellular peptidase activities (aminopeptidase and X-prolyl dipeptidyl peptidase), two mutant strains, i.e., Δ*prtS* and Δ*prtS*-Δ*htrA*, constructed from strain LMD-9, were incubated with the peptide. In addition, the level of hydrolysis of isracidin by the strain CNRZ1066 that does not naturally display any PrtS activity has been studied.

MATERIALS AND METHODS

Bacterial Strains, Growth Conditions, and Construction of Mutants. *S. thermophilus* CNRZ1066 came from the CNRZ (Centre National de Recherches Zootechniques, INRA, Jouy-en-Josas, France) while *S. thermophilus* LMD-9 (ATCC BAA-491) came from ATCC (American Type Culture Collection, Manassas, VA, USA) collections. Their genomes have been entirely sequenced.[17,18]

S. thermophilus LMD-9-Δ*prtS* mutant used in this study was obtained in a previous study.[19] Briefly, it was planned to replace the ORF of *prtS* gene by a fragment consisting of the ORF of *prtH* gene fused with the ORF of an erythromycin resistance (*emR*) gene. During this mutant construction, a clone presenting the LMD-9-Δ*prtS* sequence was obtained (Figure 1A).

To construct *S. thermophilus* LMD-9-Δ*prtS*-Δ*htrA* mutant strain, *htrA* gene (locus_tag: *STER_RS09790*; NCBI Accession Number:

DOI: 10.1021/acs.jafc.5b01647
J. Agric. Food Chem. 2015, 63, 7522−7531

NC_008532.1) located between positions 1854162 and 1855397 on the *S. thermophilus* LMD-9 chromosome was replaced by *specR* gene that encodes spectinomycin adenyltransferase. For this purpose, *htrA* (upper and down) and *specR* fragments were amplified form genomic DNA of *S. thermophilus* LMD-9-Δ*prtS* mutant strain and pSET4s plasmid, respectively, as described by Hafeez et al.[11] The overlap extension polymerase chain reaction was carried out using the above three amplicons, and then *S. thermophilus* LMD-9-Δ*prtS* mutant strain was transformed with final amplicon (Figure 1B).[11]

The strains were conserved at −80 °C in sterile reconstituted skim milk (10%). They were grown overnight at 42 °C by inoculation (1%) in fresh sterile reconstituted skim milk (10%), and the precultures were then inoculated at 1% in LM17 medium (M17[20] broth supplemented with 20 g/L lactose) and incubated at 42 °C. When required, erythromycin was added to the culture media at final concentration of 5 μg/mL as selection pressure for LMD-9-Δ*prtS* and both erythromycin and spectinomycin at concentrations of 2.5 and 150 μg/mL, respectively, to select LMD-9-Δ*prtS*-Δ*htrA* mutant strain.

Polymerase Chain Reaction Analysis for Detection of *prtS* Gene. The presence or the absence of PrtS was determined using forward and reverse primer pairs of *prtS* gene and genomic DNA of *S. thermophilus* LMD-9, as well as mutant strains, i.e., LMD-9-Δ*prtS* and LMD-9-Δ*prtS*-Δ*htrA*, and of *S. thermophilus* CNRZ1066 as template.

Chromosomal DNA of *S. thermophilus* strains were purified from 50 mL LM17 cultures after growth to an optical density at 650 nm (OD_{650nm}) of about 1.0 as described by Fischer et al.[21] The standard polymerase chain reaction (PCR) was conducted in a Mastercycler Pro thermocycler (Eppendorf, Hamburg, Germany) to detect the *prtS* gene. The forward (5′-CAATTCCATCTGTCTTCATTC-3′) and reverse (5′-CCGTTGTTAATTGTGTTGAGT-3′) primers used to amplify an internal fragment of the *prtS* gene were synthesized by Eurogentec (Serain, Belgium). The PCR reaction was performed in a final reaction volume of 20 μL consisting of 0.5 units of *Taq* DNA polymerase (Thermo Fisher Scientific, Villebon-sur-Yvette, France), 1× *Taq* buffer, 0.2 mM of each deoxyribonucleotide triphosphate (dNTP), 1.5 mM of $MgCl_2$, 0.5 μM of each primer, and about 100 ng of purified DNA as template. PCR amplification was carried out under the following conditions: initial denaturation step at 95 °C for 3 min, 30 cycles consisting of denaturation at 95 °C for 30 s, annealing at 58 °C for 30 s, and an extension at 72 °C for 60 s followed by a single 10 min final elongation at 72 °C. As expected, after agarose gel electrophoresis, the single nucleotide band with the anticipated molecular mass of the *prtS* gene was detected only in *S. thermophilus* LMD-9 (Figure 1 inset). This thus confirmed that the *prtS* gene is absent from the genome of LMD-9-Δ*prtS*, LMD-9-Δ*prtS*-Δ*htrA*, and CNRZ1066 strains.

Evaluation of Cell Lysis. In order to verify cell integrity in the pH 6.5, 12.5 mM potassium phosphate/acetate buffer (PAB), the activity of intracellular peptidases, potentially liberated by a cell lysis during cell incubation in the medium, was measured using the lysine-*para*-nitroanilide (Lys-*p*-NA) chromogenic substrate (Sigma-Aldrich France, Saint-Quentin Fallavier, France). The substrate was prepared at 2 mM as described elsewhere,[8] whereas the samples were prepared as follows: the log phase (OD_{650nm} = 1.00 ± 0.05) cells of each *S. thermophilus* strain grown in LM17 medium were centrifuged at 3100*g* for 10 min at 20 °C and resuspended in PAB to the initial OD_{650nm} of about 1 preceded by two washings with PAB. A part of the resuspended cells was frozen at −20 °C while the other part was incubated at 42 °C with shaking at 200 rpm (revolutions per min). After 0, 2, and 6 h incubation, cells were removed by centrifugation at 12000*g* for 5 min at 20 °C and the supernatant obtained was filtered through a sterile 0.22-μm filter (Merck Millipore, Darmstadt, Germany) to obtain cell free filtrate. Frozen cell suspensions of *S. thermophilus* were thawed on ice and disrupted by sonication 3 × 1 min, power 5, and active cycle 50% with a Vibra-cell (Fisher Scientific SAS, Illkirch, France). The cell lysate was recovered by centrifugation at 13400*g* for 10 min at 4 °C and used as such as positive control of intracellular peptidase activity, as intracellular peptidases have the ability to hydrolyze Lys-*p*-NA substrate. 100 μL volume samples of both cell free filtrate and cell lysate (intracellular proteins) were added to 1 mL of the substrate and incubated 1 h at 37 °C. The hydrolysis of Lys-*p*-NA was determined by measuring absorbance at 410 nm using BioSpectrometer Basic (Eppendorf France S.A.S., Le Pecq, France).

Isracidin Preparation. α_{s1}-CN from sodium caseinate was first purified by batch fractionation according to the method of Miclo et al.[22] and then hydrolyzed with rennet from *Mucor meihei*, type II (Sigma-Aldrich), as described by Lahov and Regelson[12] with some modifications to get pure isracidin. Crude isracidin was separated from the residual α_{s1}-CN by solid phase extraction (SPE) using Plus C_{18} Sep-Pak cartridges (Waters, Milford, MA, USA) as follows: the cartridges were equilibrated with 5 mL of solvent A (5% acetonitrile and 0.1% trifluoroacetic acid in water) at a flow rate of approximately 1 mL/min. The α_{s1}-CN hydrolysate (2 mL) prepared at 5 mg/mL in solvent A was loaded onto the cartridges. The salts were removed by washing the cartridges with 5 mL of solvent A while the crude isracidin was eluted with 5 mL of solvent B (30% acetonitrile and 0.1% trifluoroacetic acid in water). The liquid chromatography−mass spectrometry analysis (LC/ESI-MS/MS; see below) showed that the crude isracidin was a mixture of 1−23 and 3−23 peptides in a molar ratio 10:1 (data not shown). This crude isracidin was then injected into Uptisphere C_{18} column (length and internal diameter 250 × 10 mm, particle size 5 μm, porosity 10 nm; Interchim, Montluçon, France) connected to an Alliance high-performance liquid chromatography (HPLC) unit (Waters) to get pure 1−23 peptide. A linear gradient of 25−38% acetonitrile in water in the presence of 0.1% trifluoroacetic acid was applied at a flow rate of 3.0 mL/min and at 30 °C. Finally, isracidin was detected with a photodiode array detector 996 (Waters) at 215 nm, collected, and lyophilized.

Hydrolysis of Isracidin. *S. thermophilus* strains were grown to the exponential phase (OD_{650nm} of 1.00 ± 0.05) in LM17 medium with or without antibiotic(s). The cells were harvested by centrifugation at 3100*g* for 10 min at 20 °C and the resulting cell pellet was washed twice with PAB, followed by resuspension of the cells to obtain the initial OD_{650nm} of 1.00 ± 0.05 in the same buffer. Crude and pure isracidin solutions prepared in the PAB were then added to the cell suspensions to a final concentration of 20 nmol/mL and incubated at 42 °C with shaking at 200 rpm. A sample (500 μL) was aliquoted immediately, and other samples of the same volume were collected after 10, 20, 45, 60, 120, 180, 240, and 360 min of incubation. The hydrolysis reaction was stopped by adding 15 μL of trifluoroacetic acid to each sample. The cells were removed by filtration through a 0.45-μm filter (Phenomenex, Le Pecq, France), and the hydrolysis products were stored at −20 °C until the LC/ESI-MS/MS analysis. The experiments were done in duplicate. Stability of the isracidin in PAB was checked in the same conditions without bacteria.

Identification of Peptides by LC/ESI-MS/MS. The peptide fragments resulting from isracidin hydrolysis were analyzed by reversed-phase HPLC on an Ultimate 3000 system (Thermo Fisher Scientific/Dionex) coupled to electrospray ionization tandem mass spectrometry (RP-HPLC/ESI-MS/MS) using a spectrometer equipped with a linear trap quadripole ion trap mass analyzer LQT-XL (Thermo Fisher Scientific). Peptides were separated using a C_{18} Alltima reversed-phase column (length and inner diameter 150 × 2.1 mm, 5-μm porosity; Grace/Alltech, Darmstadt, Germany) equipped with a C_{18} Alltima precolumn (7.5 × 2.1 mm, 5-μm porosity; Grace/Alltech) at 25 °C. The peptides were eluted using a linear gradient of 5−60% acetonitrile in water in the presence of 0.1% (v/v) trifluoroacetic acid for 60 min at a flow rate of 0.2 mL/min and quantified with a double photodiode array detector (Thermo Fischer Scientific/Dionex). Peptides were detected by photodiode array detector and by mass spectrometric detector allowing UV semiquantification at 214 nm and also accurate MS semiquantification due to specific screening of peptide ions, seen on single ion parent chromatograms (SIC). To perform the quantification by UV detection at 214 nm, the molar extinction coefficient of each identified peptide was calculated according to Kuipers and Gruppen.[23]

The mass spectrometry was conducted under the following conditions: ESI positive ionization mode was used; spray voltage was set at 4.5 kV; source gases were set (in arbitrary units per min) for sheath gas, auxiliary gas, and sweep gas at 20, 5, and 5, respectively;

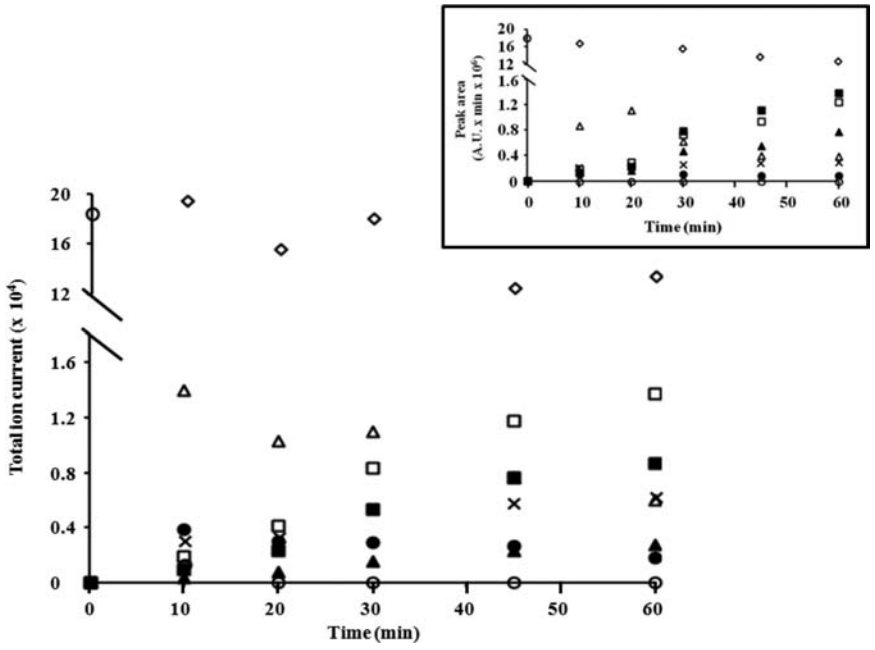

Figure 2. Hydrolysis kinetics of isracidin (empty circle) by *S. thermophilus* LMD-9 with generation of fragments ([1]RPKHPIK[7], filled triangle; [1]RPKHPIKH[8], filled square; [1]RPKHPIKHQ[9], empty square; [1]RPKHPIKHQGLPQ[13], cross; [1]RPKHPIKHQGLPQEVL[16], empty triangle; [1]RPKHPIKHQGLPQEVLN[17], empty diamond; and [1]RPKHPIKHQGLPQEVLNENLL[21], filled circle) analyzed by using single parent ion chromatograms. Isracidin (20 nmol/mL) was incubated at 42 °C under shaking at 200 rpm with log phase cells of this bacterial strain in phosphate/acetate buffer 12.5 mM, pH 6.5. The inset indicates similar hydrolysis kinetics of isracidin after peak area integration at 214 nm corrected by the molar extinction coefficients according to Kuipers and Gruppen.[23] A.U.: absorption unit.

capillary temperature was set at 250 °C; capillary voltage at 26 V; tube lens, split lens, and front lens voltages at 90 V, −42 V, and −5.75 V, respectively. The ion optics parameters were optimized by automatic tuning using a standard solution of the dipeptide Val-Trp at 0.1 g/L infused in mobile phase (50% acetonitrile in water and in the presence of 0.1% trifluoroacetic acid) at a flow rate of 5 μL/min. Full scan MS spectra were repeatedly performed from 100 to 2000 *m/z* during the time of the run and, second, automatized MS/MS scans were realized in order to identify the peptides with certainty. The peptide masses were given with a precision of 0.01%.

RESULTS

Hydrolysis of Isracidin by Surface Proteolytic System of *S. thermophilus* LMD-9. The ability of the surface proteolytic system of *S. thermophilus* LMD-9 to hydrolyze isracidin was evaluated. For this, the pure isracidin was incubated with nongrowing log phase cells of LMD-9 strain in PAB at pH 6.5 and 42 °C. It was determined by MS screening of isracidin corresponding to $[M + 2H]^{2+}$ double charged parent ion that about 99% of the isracidin was already lost after 10 min incubation and that no intact peptide was detected after 20 min (Figure 2). This hydrolysis was attributed to the proteolytic activity of the LMD-9 strain and not to an eventual instability of the peptide since isracidin was not hydrolyzed when incubated without cells in the PAB under the same conditions.

The degradation products were then analyzed by RP-HPLC/ESI-MS/MS, and the peptides identified are listed in Table 1. It was observed that the cell-associated proteolytic system of *S. thermophilus* LMD-9 cleaved the isracidin at K^7–H^8, H^8–Q^9, Q^9–G^{10}, Q^{13}–E^{14}, L^{16}–N^{17}, N^{17}–E^{18}, and L^{21}–R^{22} peptide bonds. Hydrolysis kinetics revealed that a large quantity (determined by peak area integration using single parent ion chromatogram) of peptide 1−17 was present just after a 10-min exposure of isracidin to the nonproliferating cells of LMD-9 strain (Figure 2) followed by smaller quantity of the peptide 1−16. The quantity of both peptides decreased throughout 1 h of incubation, unlike the peptides 1−8, 1−9, and 1−13, the quantity of which increased slowly and consistently. On the other hand, the increase in the quantity of peptides 1−7 and 1−21 was noted at much lower intensity during 1 h incubation (Figure 2). According to the results of Fernandez-Espla et al.,[6] who reported the preferential cleavage sites of purified PrtS on the pure isracidin, and to those of Miclo et al.,[1] who analyzed hydrolysis of the 1−23 region of the α_{s1}-CN by cells of various strains of *S. thermophilus*, the cleavage sites observed in this study could be attributed to the protease PrtS. Indeed, these authors reported that the PrtS cleaved the bonds N^{17}–E^{18} and L^{16}–N^{17} most preferably followed by the bonds H^8–Q^9 and Q^9–G^{10}. The bonds Q^{13}–E^{14} and L^{21}–R^{22} are cleaved to a

medium and lesser extent, respectively. Hydrolysis of the bond K^7-H^8 was reported only by Miclo et al.,[1] who used bacterial cells and not purified PrtS. Only slight differences in the evolution of the quantity of the peptides (appeared or disappeared) were observed as a function of time when quantified using either single parent ion chromatograms or absorbance at 214 nm by taking into account the different molar extinction coefficients (Figure 2 inset).

Hydrolysis of Isracidin by Cell-Associated Extracellular Peptidases. To assess the contribution of cell-associated extracellular peptidases in hydrolysis of isracidin, strains without cell surface PrtS activity (CNRZ1066, LMD-9-Δ*prtS*, and LMD-9-Δ*prtS*-Δ*htrA*) were used. The purpose of deleting *htrA* gene was to remove all the surface protease activities of LMD-9 strain whether they make part of the proteolytic system or not. The isracidin was incubated individually for 6 h with the resting intact cells of these three strains. The hydrolysis of the peptide was less important than with the LMD-9 strain since 50% of isracidin was intact after 1 h of hydrolysis by CNRZ1066 and 78% by LMD-9 mutants. The released peptides were identified by RP-HPLC/ESI-MS/MS (Table 2) and seemed to be the result of different cell-associated extracellular peptidase activities and were grouped into five different categories. The Figure 3 presents an overview of the different categories of peptides generated according to the different exopeptidase activities highlighted for the three $PrtS^-$ strains. The category A included all those peptides, which resulted from isracidin cleavage at $L^{21}-R^{22}$, $N^{19}-L^{20}$, $N^{17}-E^{18}$, $V^{15}-L^{16}$, $Q^{13}-E^{14}$, Q^9-G^{10}, and K^7-H^8 peptide bonds (Figure 3). This thus indicated the consecutive removal of dipeptides from the C-terminal of the isracidin, indicating a peptidyl dipeptidase activity (for informations on this kind of activity see http://www.brenda-enzymes.org). The presence of the C-terminal dipeptide $^{22}RF^{23}$ was highlighted, but no other dipeptides were found by mass spectrometry analysis. On the other hand, peptidyl dipeptidase activity was not observed when a Pro residue was encountered at a potential cleavage site, as in the case of $L^{11}-P^{12}$, P^5-I^6, and R^1-P^2 peptide bonds. The peptides, whose release involved the cleavage of these bonds, as peptide 1−9 by example, were formed by previous action of other enzymes (see below). The type of cleavage leading to the release of peptides belonging to category A referred to a peptidyl dipeptidase activity and was observed for each of the three *S. thermophilus* strains exhibiting a $PrtS^-$ phenotype, i.e., CNRZ1066 as well as both LMD-9-Δ*prtS* and LMD-9-Δ*prtS*-Δ*htrA*. Furthermore, the release of the C-terminal Phe residue as well as of peptides whose number of residues was an even number (category B; Table 2) revealed a carboxypeptidase activity that might act in a recurrent manner. The existence of the peptides 1−14, 1−16, and 1−20 might also reveal a combined action of peptidyl dipeptidase and carboxypeptidase activities. As an example, the peptide 1−20 might be formed by the successive action of the peptidyl dipeptidase activity at peptide bond $L^{21}-R^{22}$ of isracidin (formation of peptide 1−21) followed by the action of carboxypeptidase activity at peptide bond $L^{20}-L^{21}$ (Figure 3). The peptides 1−14 and 1−16 seemed to be generated in a similar manner, whereas the release of carboxyl-terminal Phe residue might be produced likewise or by the action of the aminopeptidase activity mentioned below (see peptides belonging to category C) on the dipeptide $^{22}RF^{23}$. Both peptidyl dipeptidase and carboxypeptidase activities were associated with the cell wall because no such activities were observed in cell free filtrate obtained even after 6 h incubation of the bacterial cells in PAB (data not shown). This thus confirmed the absence of cell lysis which could have led to the release of intracellular peptidases in the incubation buffer. To our knowledge, peptidyl dipeptidase and carboxypeptidase activities associated with the cell wall have never been reported before in this bacterium.

[a]Identified in the case of CNRZ1066 with crude isracidin (mixture of peptides 1−23 and 3−23 in a ratio 10:1) as substrate; the crude isracidin was not tested with the LMD-9 mutant strains.

The second main group is the category C, which is composed of peptides generated by an aminopeptidase activity. Table 2 shows all the peptides identified by mass spectrometry that were the result of consecutive removal of N-terminal amino acids. Peptides ending with the Phe^{23} residue and the first residue of which corresponded to the 3rd to the 18th residue of isracidin were recovered except for peptides 2−23, 5−23, and 12−23. In the case of the latter three peptides, the

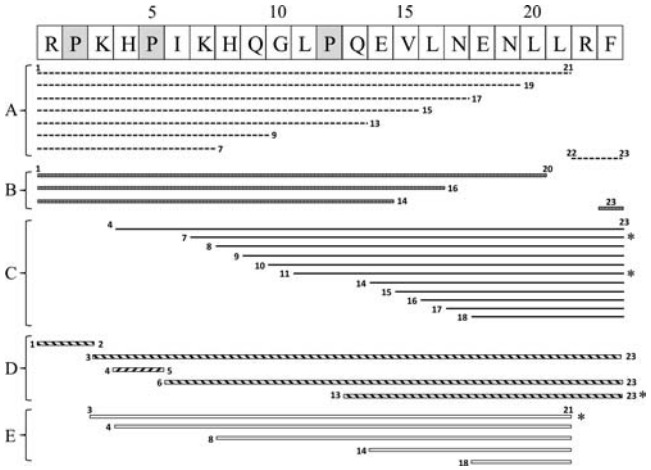

Figure 3. Peptides identified by RP-HPLC/ESI-MS/MS released from 0- to 6-h contact of isracidin with PrtS$^-$ strains, i.e., *S. thermophilus* CNRZ1066, LMD-9-Δ*prtS*, and LMD-9-Δ*prtS*-Δ*htrA* in phosphate/acetate buffer 12.5 mM, pH 6.5. The peptides were obtained as a result of peptidyl dipeptidase activity (class A), carboxypeptidase activity (class B), aminopeptidase activity (class C), X-prolyl-dipeptidyl peptidase activity (class D), and a combination of previous activities (class E). Peptides with an asterisk symbol were identified with CNRZ1066 with crude isracidin (mixture of peptides 1−23 and 3−23 in a ratio 10:1) as substrate; the crude isracidin was not tested with LMD-9-Δ*prtS* and LMD-9-Δ*prtS*-Δ*htrA*.

aminopeptidase activity was blocked due to the presence of a proline residue at the carboxyl side or P1′ position (according to the nomenclature of Schechter and Berger)[24] of the bonds R^1−P^2, H^4−P^5, and L^{11}−P^{12}. Initially the aminopeptidase activity was detected upon incubation of *S. thermophilus* CNRZ1066 with the crude isracidin, which contains, in addition to 1−23, a low amount of fragment 3−23 (in a molar ratio 10:1 between the two peptides). Under these conditions, all the peptides belonging to category C (Figure 3) were found as hydrolysis of peptide 3−23 did not need the cleavage of the first bond of isracidin involving a Pro residue. Meanwhile, the existence of the dipeptides 1−2 and 4−5 (category D) showed that the isracidin was also cleaved by an X-prolyl dipeptidyl peptidase activity, which removed dipeptides containing proline residue and allowed aminopeptidase activity to continue downstream of these proline residues. However, the dipeptide 11−12 was not identified in our experimental conditions. The release of this peptide needed the cleavage of numerous bonds by the conjugated actions of (i) the aminopeptidase and X-prolyl dipeptidyl peptidase activities and (ii) peptidyl dipeptidase and/or carboxypeptidase activities on the polypeptide chain. The unknown relative rates and residue preferences of these activities do not allow to predict if the generation of this peptide is possible.

The presence of certain peptides indicated that they were produced due to action of two or more peptidase activities. All the PrtS$^-$ strains of *S. thermophilus*, i.e., CNRZ1066, LMD-9-Δ*prtS*, and LMD-9-Δ*prtS*-Δ*htrA*, produced these peptides, and they are listed in category E (Figure 3).

Kinetic Approach To Distinguish PrtS Activity from Exopeptidase Activities. Through three examples of selected peptides (1−13, 1−17, and 22−23), kinetics of isracidin degradation showed that all four *S. thermophilus* strains, i.e., CNRZ1066, LMD-9, LMD-9-Δ*prtS*, and LMD-9-Δ*prtS*-Δ*htrA*, were able to cleave isracidin at N^{17}−E^{18}, Q^{13}−E^{14}, and L^{21}−R^{22} peptide bonds, but differently (Figure 4). As shown in Figure 4A, the peptide 1−17 was produced in substantially high amount by LMD-9 strain and seemed likely to be the result of PrtS activity, whereas in the case of the PrtS$^-$ phenotype strains

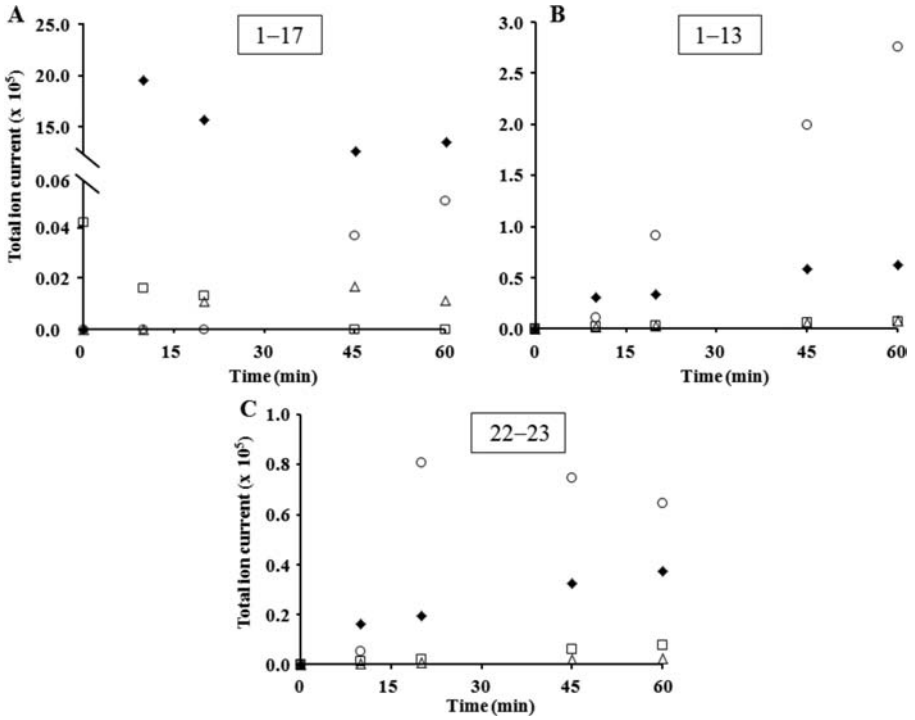

Figure 4. Distinct release pattern of peptide fragments (A) 1−17, (B) 1−13, and (C) 22−23 by cell-associated extracellular proteolytic activities of *S. thermophilus* strains LMD-9 (filled diamond), LMD-9-Δ*prtS* (empty square), LMD-9-Δ*prtS*-Δ*htrA* (empty triangle), and CNRZ1066 (empty circle) upon 6-h incubation with isracidin in phosphate/acetate buffer 12.5 mM, pH 6.5.

J. Agric. Food Chem. 2015, 63, 7522−7531

such as CNRZ1066 and LMD-9 mutant strains, a minor quantity was produced as a result of action of peptidyl dipeptidase and/or carboxypeptidase activities. In contrast, the peptides 1−13 and 22−23 were generated in greater quantities by peptidase activities of CNRZ1066 strain than by PrtS and/or peptidase activities of the strain LMD-9 (Figures 4B and 4C). However, among the PrtS$^-$ phenotype, peptidase activities leading to generation of peptides 1−13 and 22−23 in strain CNRZ1066 appeared to be much higher than in both mutant strains of LMD-9.

DISCUSSION

Isracidin is a substrate widely used to determine cleavage specificities of the surface proteases of different LAB.[15,16] In the present study, the impact of surface protease PrtS as well as exopeptidase activities of *S. thermophilus* on the degradation of isracidin was explored, as it has been shown that the 1−23 N-terminal region of α_{s1}-CN is sensitive toward proteolytic attack of *S. thermophilus* (such as the LMD-9 strain) and other LAB strains that possess the main cell wall-associated protease.[1,6,15,16]

Isracidin was completely hydrolyzed after exposure to the intact cells of *S. thermophilus* LMD-9. It has been reported by Fernandez-Espla et al.[6] that the purified PrtS of *S. thermophilus* CNRZ385 preferentially and primarily cleaved isracidin at N^{17}−E^{18} and L^{16}−N^{17} peptide bonds, and we have found similar results upon exposure of isracidin to the cells of *S. thermophilus* LMD-9. In another study the same results were obtained with the highly acidifying *S. thermophilus* strains PB302, PB385, 4F44, and ATE19PB8.[1] Hence, it appeared that the proteolytic activity toward isracidin highlighted for *S. thermophilus* LMD-9 was overwhelmingly due to the activity of PrtS. Nevertheless some differences were noted, as the hydrolysis of peptide bond L^{21}−R^{22} to a medium extent in this study whereas this bond appeared to be poorly hydrolyzed by PrtS of the strain CNRZ385.[6] Moreover K^7−H^8, H^8−Q^9, and Q^9−G^{10} peptide bonds were poorly hydrolyzed, in the present study, while they appeared to be preferred cleavage sites of PrtS in other studies,[1,6] although the peptide bond K^7−H^8 was not hydrolyzed by PrtS of strain CNRZ385.[6] The perceptible difference in the preference of some peptide bond hydrolysis might be explained by the difference in pH of incubation buffer. This observation is consistent with the previous findings that pH of the medium is one of the factors that alter the preference for bonds in the 1−23 fragment of α_{s1}-CN, which can even result in a completely changed specificity.[15,25] As shown in Figure 5, the cleavage preference of the PrtS protease for the peptide bonds N^{17}−E^{18} and L^{16}−N^{17} remains unchanged regardless of the pH tested. However, PrtS has pronounced cleavage preference toward K^7−H^8, H^8−Q^9, and Q^9−G^{10} peptide bonds at pH 7.5 compared to pH 6.5, since no hydrolysis of K^7−H^8 peptide bond is observed at pH 8.0. Contrariwise, the weak hydrolysis of the peptide bond between the residues L^{21} and R^{22} is reported at pH 8.0 and 5.2. The peptide bond Q^{13}−E^{14} is cleaved by PrtS in a similar way at all tested pH except 5.2 (Figure 5). In conclusion, the hydrolysis of a maximum of peptide bonds in the isracidin was observed at a pH (6.5−7.5) close to the initial pH of the milk fermentation process. This emphasizes that the sensitivity of the peptide toward PrtS can be modulated in the fermented products by changing the pH.

Having a relatively large chain length, isracidin appeared to be a suitable substrate for further unveiling the potential

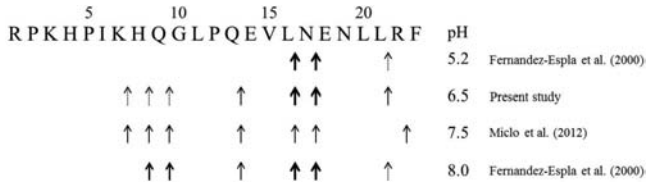

Figure 5. Cleavage site preferences of *S. thermophilus* LMD-9 nonproliferating cells (Miclo et al.[1] and this study) and of purified PrtS of *S. thermophilus* CNRZ 385 (Fernandez-Espla et al.[6]) on isracidin at different pH. In the case of work of Miclo et al.,[1] the peptide bond 22−23 is cut preferably instead of bond 21−22 as α_{s1}-casein and not isracidin is the substrate. The relative cleavage rates are indicated by large (major site), medium (medium site), and dotted (minor site) arrows except for Miclo et al.,[1] where the cleavage rates are not given.

exopeptidase activities acting both at the N-terminal and C-terminal extremities. Moreover, the presence of three proline residues in the 1−12 N-terminal region of isracidin permitted us to highlight the X-prolyl dipeptidyl peptidase and aminopeptidase activities simultaneously as the latter is inhibited by proline residues. Two mutant strains of LMD-9 devoid of PrtS or both PrtS and HtrA, i.e., LMD-9-Δ*prtS* and LMD-9-Δ*prtS*-Δ*htrA*, were used in this study. The LMD-9-Δ*prtS* strain permitted highlighting of peptidase activities associated with cell that were masked in the presence of PrtS in LMD-9 wild type strain, whereas the LMD-9-Δ*prtS*-Δ*htrA* strain helped to conclude that observed hydrolysis was not due to the protease HtrA, another surface protease, which is involved in the hydrolysis of extracellular misfolded proteins. The strain CNRZ1066 represented naturally PrtS$^-$ phenotype and provided the means to evaluate the variability of the surface exopeptidase system by comparison with the LMD-9 mutant strains.

When one or the other LMD-9 mutant strains was incubated with isracidin, hydrolysis of isracidin occurred in a similar way. The LMD-9 mutant strains displayed exopeptidase activities such as carboxypeptidase, peptidyl dipeptidase, aminopeptidase, and X-prolyl dipeptidyl peptidase that could act simultaneously or successively in an undefined order. Moreover, almost similar peptidase activities were shown by *S. thermophilus* CNRZ1066 after exposure to the isracidin. All these activities were cell-associated extracellular activities as no peptidase activity was observed in cell free filtrate.

In this study, the identified carboxypeptidase activity was observed only on some of the peptides released after peptidyl dipeptidase activity as evidenced by the absence of the peptide 1−22. The poor carboxypeptidase and higher peptidyl dipeptidase activity could be the result of nonoptimal reaction conditions for carboxypeptidase, or of specificity of carboxypeptidase toward peptide bonds, or of relative velocity of the enzymatic activities or a combination of these hypotheses. It has been stated that the internal carboxypeptidase and dipeptidase of *Lactobacillus casei* NCDO 151 require different pH and temperature for their optimal activity.[26] Macedo and workers[27] also detected lower carboxypeptidase activity than the corresponding dipeptidase activity in the intracellular enzymatic extracts of *Lactobacillus paracasei* subsp. *paracasei* ESB230 and *Lactococcus lactis* subsp. *lactis* ESB117. However, to our knowledge, only one study highlighted the presence of intracellular carboxypeptidase activity in *S. thermophilus*.[28] Moreover, Kang and colleagues[29] reported the predicted presence of a membrane carboxypeptidase, and the gene of

DOI: 10.1021/acs.jafc.5b01647
J. Agric. Food Chem. 2015, 63, 7522−7531

this peptidase is present in the genome of many strains of *S. thermophilus* available in databases. This carboxypeptidase corresponds to low molecular mass penicillin binding protein that cross-links disaccharide chains of peptidoglycan by peptide bridges. The presence of an arginine carboxypeptidase[30] and of a dipeptidyl carboxypeptidase (peptidyl dipeptidase)[31] associated with the cell wall has also been reported in *Streptococcus mitis* ATCC 15909 and *Streptococcus gordonii* FSS2, respectively.

To our knowledge, no cell-associated extracellular peptidyl dipeptidase activity was ever reported in *S. thermophilus*. The peptide bonds $L^{11}-P^{12}$, P^5-I^6, or R^1-P^2 were not hydrolyzed by peptidyl dipeptidase activity, as no fragment corresponding to such a hydrolysis was generated (Figure 3). This might be correlated to the presence of proline residue. Indeed, Dasarathy et al.[32] have reported that peptides containing a proline residue at ultimate or penultimate position are not hydrolyzed by the extracellular peptidyl dipeptidase-4 of *Pseudomonas maltophilia*. Contrarily, hydrolysis at P^2-K^3 and P^5-I^6 peptide bonds leading to the generation of the dipeptides 1−2 and 4−5 seemed more likely to be the result of X-prolyl dipeptidyl peptidase activity rather than that of peptidyl dipeptidase. With regard to aminopeptidase and X-prolyl dipeptidyl peptidase activities, recently, the presence of cell-associated extracellular aminopeptidase and X-prolyl dipeptidyl peptidase activities has been described in two *S. thermophilus* strains, i.e., LMD-9 and CNRZ1066.[11] Similarly, aminopeptidase activity in the growth medium of *S. thermophilus*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, and *Bifidobacteria* has also been detected.[33] Moreover, different cell wall-associated aminopeptidases such as those from *Lactobacillus helveticus* ITGL1,[34] *Lactobacillus lactis*,[35] and *Lactococcus lactis* subsp. *cremoris*[36] have been purified and characterized. Besides, *Streptococcus suis* and *S. gordonii* FSS2 also possess extracellular and cell wall-associated arginine aminopeptidase activity.[37,38]

However, in the present study, the aminopeptidase activity on the isracidin was exhibited only after the action of the X-prolyl dipeptidyl peptidase, showing that the presence of proline residue as the second residue of the peptide precluded the aminopeptidase activity. Recently, the absence of hydrolysis of the β-casomorphin-7 (YPFPGPI) by cell-associated extracellular aminopeptidase of *S. thermophilus* has been reported due to the presence of proline residue at position P1′.[11] Moreover, a cell-associated peptidase activity has been described after exposure of the antihypertensive dodecapeptide (FFVAPFPEVFGK) of bovine α_{s1}-casein to *Lactobacillus delbrueckii* subsp. *bulgaricus*. Similarly, the cell-associated peptidase activity was not observed once a proline residue was encountered at position P1′.[39] The presence of extracellular and cell-wall X-prolyl-dipeptidyl peptidase activity has already been described in *Lactococcus lactis* subsp. *cremoris*,[40] *Lactococcus lactis* subsp. *lactis* IFPL359,[41] and *Streptococcus gordonii* FSS2.[42]

This study provides new insights into the surface proteolytic system of *S. thermophilus*. Indeed, *S. thermophilus* possesses the well-known PrtS activity that is essentially pH-dependent, indispensable for milk fermentation and may also be involved in increasing the functional properties of fermented products by releasing bioactive peptides from milk proteins. Besides this activity, this bacterium also displays a broad range of exopeptidase activities associated with the cell. In the absence of PrtS, four distinct exopeptidase activities, i.e., carboxypeptidase, peptidyl dipeptidase, aminopeptidase, and X-prolyl dipeptidyl peptidase, were identified. The existence of cell-associated extracellular carboxypeptidase and peptidyl dipeptidase activities in both $PrtS^+$ and $PrtS^-$ phenotypes of *S. thermophilus* has been highlighted for the first time. This indicated that the surface proteolytic system of *S. thermophilus* is more complex than reported in previous studies. Now, it is clear that these cell-associated extracellular peptidase activities may play a role for the $PrtS^-$ phenotypes of *S. thermophilus* in the use of milk caseins to generate free amino acids, vital for bacterial growth. Nevertheless, this growth is slower because the proteolytic activity of these peptidases is weaker than that of PrtS as it was shown in this study where the presence of PrtS concealed peptidase activities. Second, the desirability of the *S. thermophilus* strains in certain cheeses could be associated with its cell-associated extracellular peptidase activities, as they may be involved in the degradation of bitter peptides comprising proline or hydrophobic residues (Leu, Phe), where the released amino acids ultimately act as flavor precursors. The detection of the *S. thermophilus* cell-associated extracellular peptidases should motivate further biochemical and genetic studies to understand completely their role in milk fermentation, which is still not clear.

anthocyanin profiles of cranberry have also been applied as authenticity markers.[21]

Whereas methods for the separation and detection of anthocyanins are established and usually well-reported, sample preparations, including the different extraction techniques, vary considerably, and frequently, their description lacks detail. Besides classic approaches, such as Soxhlet, liquid–liquid, and solid–liquid extractions, some new extraction techniques have emerged in the last few decades. These include ultrasound-assisted extraction (UAE), microwave-assisted extraction, and accelerated solvent extraction (ASE).[22,23] The great variety of extraction methods inevitably raises the question of comparability of the corresponding results. This problem is addressed in the present study by comparing the influence of ASE and UAE on the profile of anthocyanins in bilberry, lowbush blueberry, and American cranberry extracts of lyophilized berries. In addition, fresh samples of the named fruits were investigated applying UAE. Finally, the established method influences on the anthocyanin profiles were interrelated with the natural profile diversity by comparison to a data set of 26 bilberry and blueberry samples using a linear discriminant analysis. It should be emphasized that the scope of the study was the assessment of the anthocyanin profiles and not the optimization of anthocyanin yields.

MATERIALS AND METHODS

Chemicals. Ultrapure water was obtained from a Synergy purification system (Millipore, Molsheim, France). High-performance liquid chromatography (HPLC)-grade acetonitrile and acetic acid were from VWR (Mannheim, Germany). Formic acid (≥98%) was purchased from Sigma-Aldrich (St. Louis, MO). Methanol was from Th. Geyer (Renningen, Germany). Diatomaceous earth (Chromabond XTR) and regenerated cellulose filters (Chromafil RC-20/15 MS) were supplied by Macherey-Nagel (Düren, Germany). Malvidin 3-*O*-glucoside (≥87%) was obtained from Phytoplan (Heidelberg, Germany).

Samples. Wild bilberries (*Vaccinium myrtillus* L.; n = 21) and lowbush blueberries (*Vaccinium angustifolium* Ait.; n = 5) were mainly collected manually in Germany and Poland between 2013 and 2014 or harvested in Ukraine and Canada between 2009 and 2014 and provided by Rudolf Wild GmbH & Co. KG (Eppelheim, Germany), Faethe Labor GmbH (Paderborn, Germany), and Haus Rabenhorst O. Lauffs GmbH & Co. KG (Unkel, Germany). American cranberries (*V. macrocarpon* Ait.; n = 1) harvested in the U.S.A. in 2012 were obtained from Haus Rabenhorst O. Lauffs GmbH & Co. KG (Unkel, Germany). All samples were stored at −20 °C until freeze-drying or extraction.

Freeze-Drying Protocol. Freeze-drying was conducted using an Alpha 2-4 LSC freeze-dryer (Christ, Osterode, Germany) at 0.070 mbar for 3 days with a condenser temperature of −90 °C.

Extraction Methods. *Sonication.* Fresh berry material (6 g) or lyophilized berry powder (1.2 g) were filled in centrifuge tubes in three replicate samples and treated with 20 mL of extraction solvent consisting of methanol/water/acetic acid (A, 20:75:5; B, 80:15:5, v/v/v). The suspension was homogenized with an Ultra-Turrax and, afterward, placed upright into a sonication bath (1100 W) for 10 min. Subsequently, the samples were centrifuged at 10947*g* for 10 min, and the supernatant was decanted. The residue was extracted again under the same conditions, excluding the homogenization step, with 10 mL of extraction solvent. Finally, the supernatants were pooled and made up to 50 mL with water. This solution was used for ultrahigh-pressure liquid chromatography (UHPLC) analysis after membrane filtration (0.2 μm) with regenerated cellulose.

Accelerated Solvent Extraction. Lyophilized berry powder was extracted using an accelerated solvent extractor model ASE 350 (Thermo Scientific, Inc., Braunschweig, Germany). For this purpose, 0.2 g of lyophilized berry powder was mixed with diatomaceous earth and packed into a 10 mL stainless-steel extraction cell. The cells were prepared with two cellulose filters on the bottom and top of the cells. The same extraction solvents as mentioned before were used, and each sample was extracted in triplicate. Extraction parameters were 5 min static time, 3 cycles, 40 °C, and 100% flush volume. Finally, all extracts were adjusted to 25 mL with water and used for UHPLC analysis after membrane filtration with regenerated cellulose.

UHPLC–Mass Spectrometry (MS) Identification of Anthocyanins. The identification of anthocyanins was conducted on a Waters Aquity I-Class system (Milford, MA) coupled with a Thermo Scientific, Inc. LTQ-XL ion trap mass spectrometer (Braunschweig, Germany). The column was a Kinetex C-18, 1.7 μm particle size (150 × 2.1 mm) (Phenomenex, Inc., Aschaffenburg, Germany) equipped with a security guard cartridge of the same material (2.1 × 5 mm, 1.7 μm). At a flow rate of 0.4 mL/min, the following gradient was used: 0 min, 4% B; 4 min, 4% B; 8 min, 4.5% B; 14 min, 7% B; 20 min, 15% B; 25 min, 30% B; 25.1 min, 100% B; 27.9 min, 100% B; 28 min, 4% B; and 32 min, 4% B, where eluent A was water/formic acid (95:5, v/v) and eluent B was acetonitrile/formic acid (95:5, v/v). The experimental conditions of MS were as follows: The capillary was set to a temperature of 300 °C during positive electrospray ionization (ESI) and a voltage of 180 V. The source voltage was maintained at 4 kV at a current of 100 μA. The tube lens was adjusted to 110 V. Nitrogen was used as sheath, auxiliary, and sweep gas at a flow of 45, 10, and 3 arbitrary units, respectively. Collision-induced dissociation spectra were obtained at 35 eV using helium as the collision gas.

UHPLC–Diode Array Detector (DAD) Quantification of Anthocyanins. Anthocyanin quantification was performed on a Nexera UFLC system (Shimadzu, Kyoto, Japan) equipped with two high-pressure gradient pumps LC-30AD, a degasser DGU-20A5R, an autosampling unit SIL-30AD (cooled to 10 °C, injecting 2 μL), a column oven CTO-20AC (at 40 °C), and a DAD SPD-M20A. The column, gradient, and solvent were the same as for the identification. Anthocyanins were detected at 520 nm and quantified as malvidin 3-*O*-glucoside equivalents by external calibration. The mean standard deviations of all triplicate determinations ranged from 1 to 10% and were, therefore, considered acceptable for repeatable and precise quantification (see Table 1 of the Supporting Information). The total anthocyanin content was calculated as the sum of individual anthocyanins.

Statistics. For statistical and discriminant analyses, the software XLSTAT was used. An analysis of variation (ANOVA) with a Dunn–Sidak post-hoc test as a result of heterogeneity of variances was performed to determine significant differences. The level of significance was defined as $p \leq 0.05$.

RESULTS AND DISCUSSION

Because ASE and UAE have overcome most problems of conventional extraction methods, such as Soxhlet and maceration, they are of increasing importance for the extraction of bioactive compounds, such as polyphenols, for further analysis.[24] UAE is based on the principle of cavitation, which means the production, growth, and collapse of bubbles in the extraction solvent and sample material.[25] In contrast, ASE uses high pressure to keep solvents liquid above their boiling point,[26] which facilitates the extractability of the analytes. Among the broad range of extraction techniques, UAE and also ASE were extensively reviewed by Azmir et al. According to these authors, both methods are applied for the extraction of a broad range of different polyphenols. In particular, the extraction of anthocyanins from berry fruits was shown by Monrad et al. and Santos et al.[27,28] The extraction conditions chosen in the present study are based on applications of ASE and UAE reported for polyphenol extraction. Briefly, both polar[29,30] and unpolar[31,32] solvents had been applied for the extraction of anthocyanins. Furthermore, acidified solvents were used because of the higher anthocyanin stability and

DOI: 10.1021/acs.jafc.5b02255
J. Agric. Food Chem. 2015, 63, 7532–7538

extractability at low pH values.[33] Accordingly, two acidified extraction solvents with different polarities were applied in this study. Preliminary work had revealed no significant influence of the extraction time on the target analytes during ASE, and thus, the extraction time for UAE was adjusted to the total time of the ASE methods (approximately 25 min). Besides the extraction of lyophilized berry material, also the application of fresh berries had previously been reported and was therefore investigated as well using UAE as the manufacturer suggested, applying only dry sample materials in ASE. As reference extraction conditions, the application of UAE with 80% methanol on fresh berries was chosen, with the purpose to retain the anthocyanin profile as natural as possible using unprocessed berries. Moreover, sonication baths are more common than accelerated solvent extractors, and the majority of publications showed that less polar solvents are most efficient for the anthocyanin extraction.

For fast and reliable quantification of anthocyanins, a UHPLC−DAD method was developed that is capable of separating 15 individual anthocyanins from bilberry fruits within 20 min and requires only 8 mL of solvent per chromatographic run. Conventional HPLC methods are either not suitable for the separation of all anthocyanins present in bilberries or require more time and solvent.[31,34,35] In addition, thus far, only few UHPLC−DAD methods have been reported that show similar separation capabilities.[36,37]

Anthocyanin Content of Bilberry and Lowbush Blueberry in UAE and ASE Extracts. The 15 anthocyanins were individually quantified after application of two different extraction techniques and extraction solvents to determine the influence of the extraction technique (UAE versus ASE) and solvent composition (20 versus 80% acidified methanol) on the yields. The anthocyanins were identified according to their absorption spectra,[38] order of elution[31] (Figure 1), and

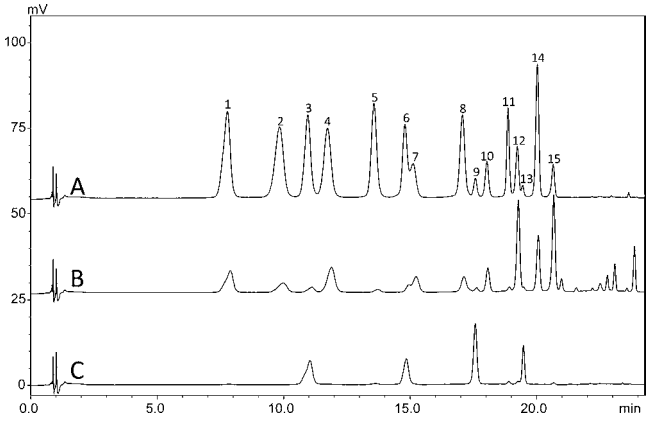

Figure 1. UHPLC−DAD chromatogram (520 nm) of the fruit extracts under reference conditions (80% methanol, fresh berries, UAE): (A) bilberry, (B) lowbush blueberry, and (C) American cranberry, for (1) dp-3-gal, (2) dp-3-glu, (3) cy-3-gal, (4) dp-3-ara, (5) cy-3-glu, (6) pt-3-gal, (7) cy-3-ara, (8) pt-3-glu, (9) pn-3-gal, (10) pt-3-ara, (11) pn-3-glu, (12) mv-3-gal, (13) pn-3-ara, (14) mv-3-glu, and (15) mv-3-ara.

UHPLC−MS experiments. For this purpose, masses and fragmentations of anthocyanins previously reported were used.[39] For bilberries, the contents of total anthocyanins ranged from 15.9 to 200.1 mg/g of dry weight (DW) and from 4.5 to 26.2 mg/g of DW for lowbush blueberries, respectively (see Table 1 of the Supporting Information). These results are in accordance with previously published concentrations.[30,32,40]

The wide range of concentrations are related to differing extraction conditions. For bilberry, the total amount of anthocyanins using 80% methanol as the extraction solvent is significantly higher than the corresponding amounts after application of 20% methanol. For lyophilized berries, ASE yields a significantly higher anthocyanin amount than the corresponding UAE method. As expected, the anthocyanin contents of lowbush blueberries are considerably lower than those of bilberries. The total anthocyanin contents after extraction of lyophilized berries with 20 and 80% methanol are about 2-fold higher using ASE compared to UAE, respectively. With regard to the extraction solvent, the extraction with 80% methanol leads to higher total anthocyanin amounts than the respective extraction with 20% methanol.

Differences in Anthocyanin Profiles of Bilberries. Anthocyanin profiles indicated by the percentage of each compound contributing to the sum of all anthocyanins were used to compare the different extraction methods (see Table 2 of the Supporting Information). To interrelate those methods, correlation coefficients considering the whole anthocyanin profile of all 15 anthocyanins were calculated, leading to high correlations between 0.995 and 0.976. To visualize how the different extraction conditions influence the individual anthocyanins, spider web plots were used. They efficiently reveal the effects of different extraction solvents, techniques, and materials. Figure 2 illustrates these effects for all individual

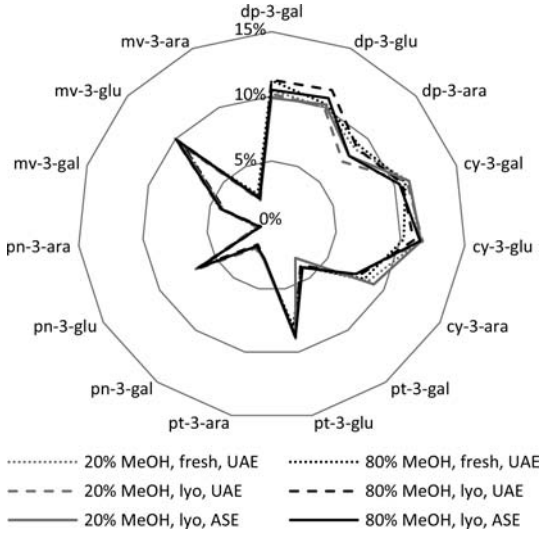

Figure 2. Anthocyanin proportions of bilberry after different extraction methods. UAE, ultrasound-assisted extraction; ASE, accelerated solvent extraction; fresh, fresh berries; and lyo, lyophilized berries.

anthocyanins in bilberry, whereby the aglycones are arranged according to their polarity (dp > cy > pt > pn > mv). It is obvious that the anthocyanins are not affected equally. Although the overall profiles are similar as reflected in good correlation coefficients and the variation of the extraction methods show only little effect especially on less polar anthocyanins, more polar anthocyanins show significant variances. Apparently, the delphinidin glycosides as well as cyanidin glucoside and arabinoside are affected most. In particular, the application of 80% methanol leads to higher delphinidin glycoside proportions, whereas cyanidin glycoside

DOI: 10.1021/acs.jafc.5b02255
J. Agric. Food Chem. 2015, 63, 7532−7538

proportions are lower compared to proportions after the usage of 20% methanol as the extraction solvent. Besides these compounds, which are altered considerably in proportions, other anthocyanins are not subjected to method-induced profile variations. Especially cyanidin and malvidin galactosides as well as petunidin and peonidin arabinosides are not affected significantly by any extraction conditions. It is interesting to note that comparing the results of different extraction conditions to the reference method (80% methanol, fresh berries, UAE), a glycoside-type-derived pattern can be found. Almost all extraction conditions lead to higher proportions of anthocyanin glucosides compared to the reference methods, whereas arabinosides and galactosides tend to show lower relative amounts (see Table 2 of the Supporting Information).

Obviously, the changes in the anthocyanin profile as affected by the extraction method are inconsistent and show different variabilities. Moreover, a trend toward greater variabilities in terms of more polar anthocyanins of bilberries can be observed. Consequently, the differing patterns exhibit that profile changes are caused by different extraction techniques (ASE versus UAE) as well as by different solvent composition (20 versus 80% methanol).

Differences in Anthocyanin Profiles of Lowbush Blueberries. The anthocyanin profiles of lowbush blueberries were used to interrelate the effects of all six extraction methods. They showed good correlations between 0.906 and 0.998, which means that the anthocyanin profiles are very similar. However, the variabilities of all individual anthocyanins are not homogeneous, meaning that all anthocyanins are individually affected (Figure 3). While dp glycosides reveal significantly

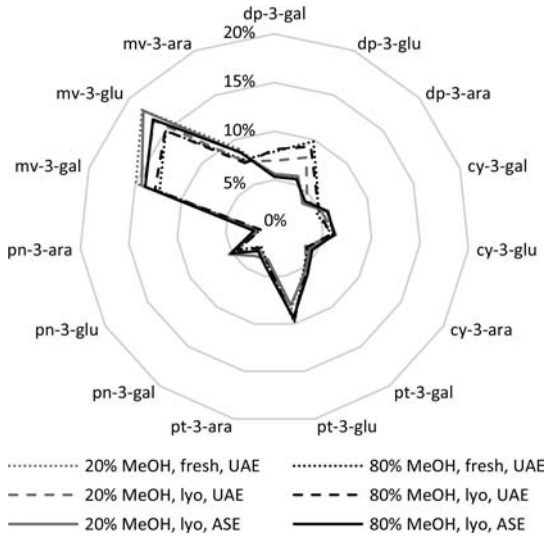

Figure 3. Anthocyanin proportions of lowbush blueberry after different extraction methods. UAE, ultrasound-assisted extraction; ASE, accelerated solvent extraction; fresh, fresh berries; and lyo, lyophilized berries.

higher proportions after UAE compared to ASE, all other anthocyanins are either not affected or show lower proportions. With regard to equal extraction techniques with different solvents, it can be stated that, in terms of ASE, the pt glucoside proportion is significantly higher and mv glucoside is significantly lower when 80% methanol is used instead of 20% methanol. In contrast, the application of 80% methanol in UAE leads to higher dp glycoside and lower mv glycoside proportions than the usage of 20% methanol. The extraction of fresh berry material shows the same trend to a greater extent considering the extraction solvent effects. These results reveal that individual anthocyanins are differently affected by different extraction methods. Apparently, dp as the most polar and mv as the most abundant aglycones are affected most in lowbush blueberries as the variability between all extraction methods reveals. In contrast, proportions of all other aglycones seem to be much more robust against method variations (see Table 2 of the Supporting Information).

Interestingly, the individual differences of lowbush blueberry anthocyanins are not in line with those of the individual differences determined for bilberry anthocyanins. Obviously, profile variations as a result of differing extraction methods are plant-dependent and not generally consistent and, thus, not predictable.

Anthocyanin Contents of American Cranberry in UAE and ASE Extracts. Six major anthocyanins in American cranberry were identified by their absorption spectra, order of elution, and characteristic fragmentation patterns.[39] They were individually quantified after application of the two extraction methods and solvents. The contents of total anthocyanin range from 1.51 to 2.20 mg/g of DW, which is in accordance with the results described by Pappas and Schaich (see Table 1 of the Supporting Information).[18]

Differences in Anthocyanin Profiles of American Cranberry after ASE and UAE. The application of ASE and UAE with different extraction solvents results in very similar anthocyanin yields, whereas slightly higher contents were obtained via ASE and 80% methanol.

Even the anthocyanin profiles are very similar, indicated by very high correlation coefficients between 0.994 and 0.997 (Figure 4). Nevertheless, the post-hoc analysis shows significant differences as a result of very low standard deviations of each method. When 80% methanol is used instead of 20% methanol, a significant decrease in the cy galactoside proportion during ASE and an increased cy arabinoside proportion via UAE can be observed. These differences can only be noticed for fresh fruits. The anthocyanin profile of lyophilized berry material is

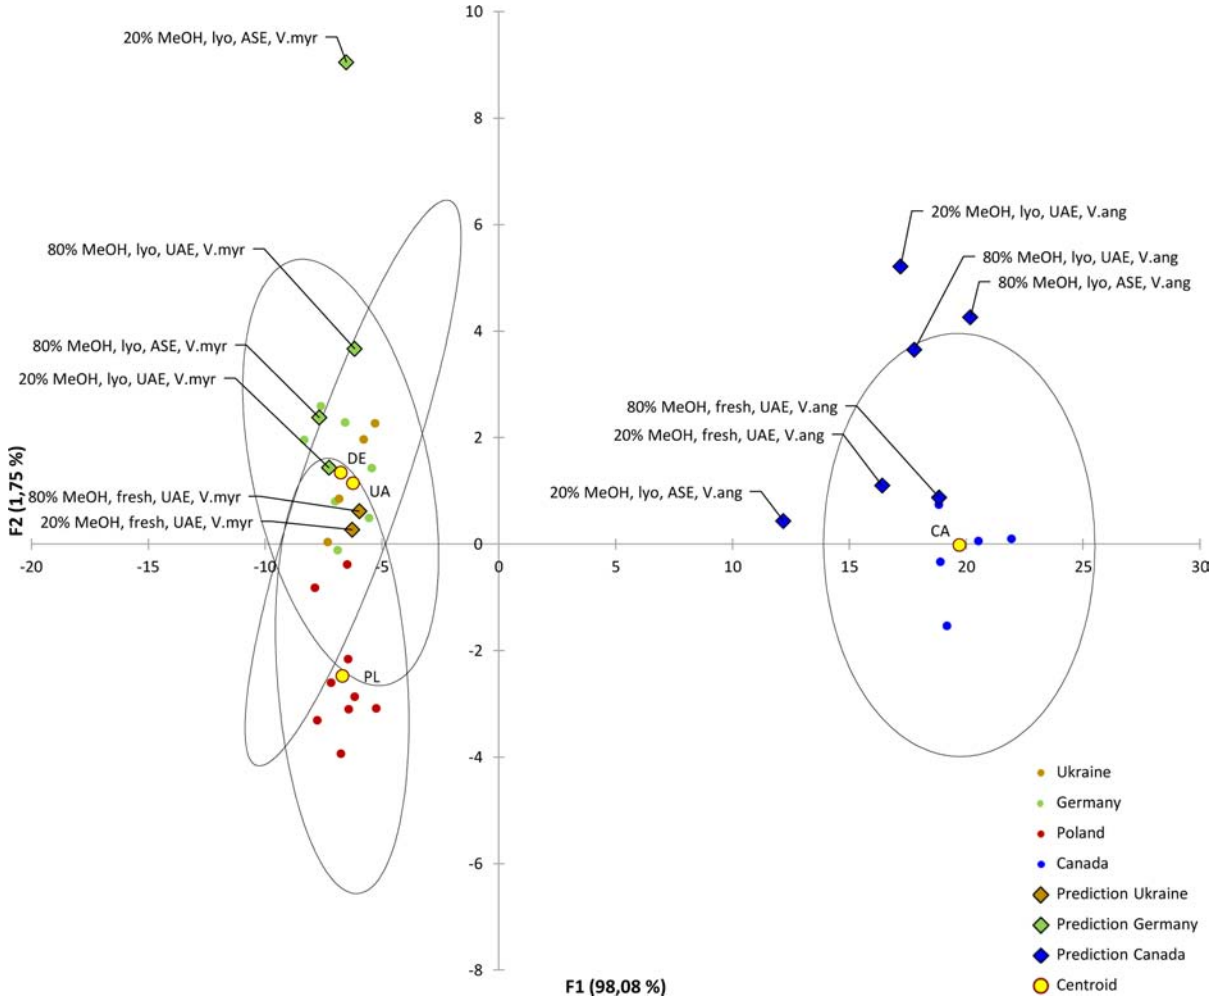

Figure 5. LDA of bilberry and lowbush blueberry samples from different origins extracted under reference conditions (80% methanol, fresh berries, UAE) and prediction of samples extracted under various extraction conditions. UAE, ultrasound-assisted extraction; ASE, accelerated solvent extraction; fresh, fresh berries; and lyo, lyophilized berries.

not affected by the extraction solvent using UAE. Therefore, the effects of the investigated extraction methods on the anthocyanin profile of American cranberry seem to be negligible.

Differences in Anthocyanin Profiles of Bilberries and Lowbush Blueberries from Various Origins. Because authenticity data are often based on specific profiles of individual compounds, the acquisition of the corresponding data has to be reproducible and should ensure good comparability. Several studies investigated whether there are typical fingerprints according to varieties,[31] geographical origins,[19,41,42] and climatic conditions.[43] Some of these authors showed that botanical differences and external factors could be correlated to ratios of certain individual compounds. It could be of great interest to interrelate such findings, performing a meta-analysis. However, the comparison might be critical, because different extraction methods were applied.

To classify the profile variations induced by different extraction methods, 21 bilberry (*V. myrtillus*) cultivars from Germany, Poland, and Ukraine as well as 5 lowbush blueberry (*V. angustifolium*) cultivars from Canada were analyzed. The average total anthocyanin content in bilberries from Germany, Poland, and Ukraine was 6.0 ± 0.3, 6.4 ± 0.8, and 5.2 ± 0.6 mg/g of fresh weight (FW), respectively. Canadian lowbush blueberries had a total anthocyanin content of 1.5 ± 0.2 mg/g of FW. To obtain comparable anthocyanin profiles, this set of authentic samples was extracted with the reference method applying UAE with 80% methanol on fresh berries (see Table 3 of the Supporting Information). For evaluation of the results, linear discriminant analysis (LDA) was performed. The LDA subdivides the multivariate space in as many subspaces as previous classes (CA, DE, PL, and UA) were defined. The resulting orthogonal discriminant functions are linear combinations with a maximized between class variance and a minimized within class variance. Figure 5 shows the result of a two-dimensional LDA of the authentic data set. It is obvious that samples from Canada related to the species *V. angustifolium* can be easily discriminated along F1 (explaining 98.08% of the total variances) from the group of European samples related to the species *V. myrtillus*. However, the samples from Germany, Poland, and Ukraine cannot be separated well. A slight differentiation along F2 can be observed, but the interclass variances are too high, leading to overlapping confidence ellipses. As seen in Table 3 of the Supporting Information, dp and cy glycosides show the greatest variations, while pt glycosides reveal the most consistent proportions. This may be of interest if authenticity markers shall be chosen from the anthocyanin profile. Compounds that are incorporated in

DOI: 10.1021/acs.jafc.5b02255
J. Agric. Food Chem. 2015, 63, 7532−7538

constant amounts should be preferred to those that are constrained to natural fluctuations to obtain robust authenticity information. In addition, high variances between samples of the same species but different growing conditions prove that geological factors as well as climate conditions apparently influence the biosynthesis of anthocyanins and, thus, the profiles. However, the results obtained from the data set analyzed also show that anthropogenic borders do not need to go along with these differences. Therefore, a differentiation of European samples solely based on the anthocyanin profile is barely reasonable.

Extraction Method Induced Profile Variations versus Natural Variations. As mentioned above, anthocyanin profiles are subjected to considerable variations as a result of different extraction conditions. To assess the relevance of these variations, the results of the application of different extraction methods have to be evaluated in the context of naturally occurring between species differences and interspecies variances. As the different extraction methods were applied to a Ukrainian *V. myrtillus* and a Canadian *V. angustifolium* sample, the anthocyanin profiles obtained were assigned to one of the classes of the discriminant analysis derived from the authentic data set using the prediction of the discriminant function. It becomes apparent that samples extracted under reference conditions are assigned correctly and are located close to the centroid of the respective class, which validates the discriminant function. Anthocyanin profiles of samples extracted under non-reference conditions, however, vary widely, indicating considerable method effects. In terms of the predicted Ukrainian samples, only those samples extracted from fresh berries are assigned to the correct origin. Here, it has to be stressed that the calculated discriminant function is not capable of differentiating the different European origins but allocate only samples to the species *V. myrtillus* or *V. angustifolium*. The method-dependent variations are so predominant that some predictions even fall out of the respective area of confidence, meaning that they cannot be assigned to one of the classes with a probability greater than 95%. Especially samples extracted under conditions, which differ a lot from the reference conditions, show greater distances from the centroids to which they are supposed to be assigned. Nevertheless, all predictions regarding the species assignment are correct. This is because a discriminant analysis only enables a "hard" classification, meaning that a predicted sample must be assigned to the most likely class, independent from how low the probability.

In conclusion, the current study addresses one of the crucial problems regarding the comparability of authenticity data sets. Different techniques and solvents applied for the extraction of bilberry, lowbush blueberry, and American cranberry anthocyanins resulted in considerably altered yields and peak ratios. In particular, peak proportions of more polar compounds, such as dp and cy, were affected by the applied extraction conditions, whereas other compounds, such as pt glycosides, are only marginally influenced.

Comparing the differences caused by the extraction method to the natural differences within a set of 26 bilberry and lowbush blueberry samples of different origins revealed that profile variations induced by the extraction method are in a similar scale to profile variations as a result of geographic and climatic differences. LDA could not differentiate between bilberry samples of different European origins, but prediction models allocated differently extracted samples outside of the area of confidence. Application of different methods for the extraction could lead to a false allocation of samples. On the one hand, samples with a very similar genuine profile could be considered as different. On the other hand, actually different samples could erroneously be allocated as similar.

Possible correlations between anthocyanin profiles and individual origins may not be accounted for by assumed intrinsic profile differences but rather reasoned on disparate sample preparations. Furthermore, the results for the different fruits are not completely consistent regarding the resulting profile differences after ASE and UAE and, hence, do not inevitably demonstrate systematic differences between the investigated extraction methods but rather illustrate plant-specific differences. In view of these results, a cautious review not only of the analytical methods but also of the sample preparation applied, in particular extraction methods, is a prerequisite for the reliable comparison of analytical data in general and authenticity data in particular.

evidenced between whole cells and cell walls. Seed and skin tannins exhibited a high affinity for whole yeast cells, associated with high adsorption levels (between 300 and 700 mg g^{-1} for average degree of polymerization (aDP) 21 skin tannins) and low reversibility (about 20%). By contrast, adsorption remained very low and mostly reversible with cell walls (on the order of 50 mg g^{-1} for aDP 21 skin tannins, with 60% reversibility). Experiments were repeated with red wine polyphenols. Adsorption primarily concerned oligomeric and polymeric tannins and pigments. That of monomers was very small. Once again, wine tannin and pigment sorption strongly differed between whole cells and cell walls, with maximum adsorbed amounts around 350 and 20−30 mg g^{-1}, respectively. This last point was quite unexpected and led us to wonder about the exact part played by cell walls in the adsorption of wine polyphenols. We suggested that grape and wine tannins, even those with high molecular weight, were able to diffuse quite easily through the wall network of dead cells and that the differences observed were related to their accumulation in the periplasmic space and/or their interactions with cell membrane.

The aim of the present work was to identify the location of polyphenol compounds in yeast cells. This was achieved through scanning electron microscopy, light epifluorescence, and confocal microscopy.

MATERIALS AND METHODS

Purification of Grape Skin Tannins and Red Wine Polyphenols. The grape skin tannin fraction was extracted from the skin of Muscat berries according to the procedure proposed by Mane.[20] It was further purified by extractions with hexane, followed by adsorption on a styrene/divinylbenzene Diaion resin and chromatography on a Toyopearl TSK HW-50 (F) gel (Tosoh Corp., Tokyo, Japan), as described in detail previously.[19] This procedure allowed the recovery of a high molecular weight tannin fraction, which was freeze-dried and stored at −80 °C before use. The composition of the fraction was determined by UPLC after acid-catalyzed cleavage in the presence of thioglycolic acid.[21] Its mean degree of polymerization was 20.1 ± 0.7, and its percentage of epigallocatechin units was 16.8 ± 1.2%. The yield of the depolymerization reaction was 73.9%. This fraction was named skin21.

The red wine polyphenol fraction (WP) was purified from a Merlot wine by chromatography on a styrene/divinylbenzene Diaion resin and analyzed as detailed in our previous work.[19] This fraction contained residual polysaccharides and nitrogenous compounds, which represented about 15% of the dry weight. Its polyphenol composition was as follows: 29.3 mg g^{-1} anthocyanins, 7.7 mg g^{-1} flavan-3-ol monomers, 32.7 mg g^{-1} phenolic acids, 24.2 mg g^{-1} stilbenes, 5.9 mg g^{-1} flavonols, and 95.0 mg g^{-1} tannins. The average degree of polymerization and composition of the tannins, determined by phloroglucinolysis, were aDP, 7.3 ± 1.1; epigallocatechin units (EgC), 24.2 ± 2.3%; and epicatechin-gallate (Ec-G), 3.3 ± 0.3%. The yield of the depolymerization reaction was very low (around 13%). This was attributed to the presence in this fraction of a large amount of derived pigments and tannins. The latter are formed by chemical reactions during winemaking and aging and are resistant to usual depolymerization methods.[1,21,22]

Yeast Cells and Preparation of Yeast Cell Walls. The yeast strain used was a commercial *S. cerevisiae* strain (Lallemand, Montreal, Canada), commonly used in enology. The yeast biomass (Y), the inactivated yeast (IY), and the yeast inactivated after autolysis (A-IY) were produced by the manufacturer according to the protocols described previously.[19] The yeast biomass was produced in aerobic conditions. Part of this biomass was frozen at −20 °C and conserved as such until further use. The viability of the cells was determined before interaction experiments. Results obtained by flow cytometry (1%) and growth on Petri plates (2.4%) indicated that most cells in Y were dead. Another part of the biomass (IY) was inactivated by thermal treatment (70 °C, 15 min). The last part (A-IY) was first submitted to autolysis (pH 5.5 at 55 °C for 20 h), and cells were recovered by centrifugation and inactivated in the same conditions as IY. Both IY and A-IY were spray-dried and stored at 4 °C. Cell walls (CW) were purified at the laboratory from the biomass Y by mechanical disruption,[19] according to the protocol described by Dallies et al.[23] The cell wall suspension obtained was heated (72 °C, 15 min) to remove residual enzymatic activities. The suspension was then stored at 4 °C in the presence of sodium azide (0.02% w/v) until use. Cell walls represented around 20% of the whole cell dry weight, which was in accordance with literature data.[24,25] Neutral sugars represented 80% of their dry weight, and Kjeldahl analyses indicated a nitrogen content of about 2% (w/w).

Sorption Experiments. Suspensions were prepared as described in Mekoue Nguela et al.[19] Briefly, yeast cells (Y, IY, or A-IY) (2×10^8 cells mL^{-1}) or yeast cell walls (CW) (0.88 mg mL^{-1}) were suspended in a model wine (12% ethanol, 2 g L^{-1} tartaric acid, 50 mM NaCl, pH adjusted to 3.5 with KOH, 25 mg L^{-1} SO_2). An equal volume of grape skin tannins or wine polyphenol pool solution (8 mg mL^{-1} in model wine) was added to yeast cells or yeast cell wall suspensions, and the mixtures were gently stirred for 24 h. Suspensions were then centrifuged and the pellets recovered. Centrifugation conditions were 1500*g* for 5 min at 5 °C and 10000*g* for 5 min at 5 °C for yeast whole cells and cell walls, respectively. Pellets were washed four times with 1 mL of PBS buffer to remove the nonsorbed polyphenols and resuspended in 1 mL of the same buffer. Yeast cells and yeast cell walls suspended in the same conditions in a model wine without polyphenol served as controls.

Light and Epifluorescence Microscopy. Samples and controls were observed under normal light and epifluorescence. Imaging was performed with a Zeiss Axiophot microscope using a DAPI filter (DAPI = 4′6-diamidino-2-phenylindole; λ_{exc} = 340−380 nm, λ_{em} = 425−800 nm).

Confocal Microscopy. Confocal imaging was performed with a Zeiss Axiovert microscope 200 M 510 META fitted with a Plan-Apochromat ×40/1.2 W Zeiss objective. Excitations were obtained for tannins with a 405 nm blue diode, and emissions were collected for tannins with a (505−550 nm bandpass) filter.[26] For images acquired in lambda scanning mode, the emission spectra were obtained on sample regions of interest (ROIs) by spectral acquisition (lambda stack, excitation at 405 nm). The detection bandwidth was set to collect emissions from 400 to 750 nm, using an array of 32 photomultiplier tube (PMT) detectors, each with a 10.7 nm bandwidth. The method of linear unmixing was applied with advanced iterative and one residual channel.

Transmission Electron Microscopy (TEM). PBS was removed from the samples and controls, and the pellets were resuspended in a solution of 2% acrolein and 2% glutaraldehyde in cacodylate buffer (0.05 M, pH 7) for 12 h at 4 °C.[27] They were then rinsed several times in cacodylate buffer and postfixed in a 1% osmic acid for 2 h in the dark and at room temperature. After two rinses in cacodylate buffer, the samples were dehydrated in a graded series of acetone solutions (30−100%) at room temperature. They were then embedded in EmBed 812 using automated microwave tissue processor for electronic microscopy (Leica EM AMW). Thin sections (70 nm; Leica-Reichert Ultracut E) were collected at different levels of each block. These sections were stained sequentially with uranyl acetate and lead citrate. They were then observed using a Hitachi 7100 transmission electron microscope with 75 kV accelerating voltage in the Centre de Ressources en Imagerie Cellulaire de Montpellier (France).

RESULTS AND DISCUSSION

Epifluorescence and Confocal Microscopy. Untreated yeast cells (Y) were observed in light microscopy (Figure 1A) as regular spheres (average diameter = 3 μm). Yeast cells after contact with grape skin tannins (treated cells) showed the same morphology as untreated cells and formed stacks (Figure 1B). Untreated yeast cells exhibited no fluorescence (Figure 1C), whereas treated ones fluoresced strongly in blue (Figure 1D).

DOI: 10.1021/acs.jafc.5b02241
J. Agric. Food Chem. 2015, 63, 7539−7545

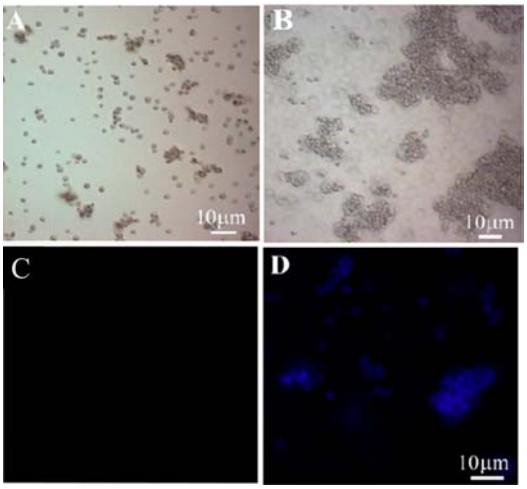

Figure 1. Views of untreated (A, C) and treated (B, D) yeast cells with grape skin tannins under light and epifluorescence microscopy (λ_{exc} = 340−380 nm, λ_{em} = 425−800 nm).

This fluorescence was within the range of that of tannins in the applied experimental conditions.

Confocal microscopy was performed on yeast cells (Y), inactivated yeasts (IY, A-IY), and yeast cell walls (CW) (Figure 2). Untreated yeast cells and inactivated yeasts showed an extremely faint and almost invisible blue fluorescence; the same was observed for purified cell walls (Figure 2). After contact with skin21 (grape skin tannins), yeast cells and inactivated yeasts showed an intense blue fluorescence in their inner core (Figure 2); some plasmolyzed cells were observed with Y, and they showed, in addition to their fluorescent core, a corona fluorescing in blue. Cell walls exhibited a blue fluorescence and were devoid of internal content. With Y and CW, some scarce residual fluorescent cytoplasmic elements were observed (Figure 2). An examination of treated cells (Y) by confocal spectral analysis revealed particles (diameter = 3 μm) (Figure 3A) exhibiting an autofluorescence emission spectrum (Figure 3B) with several maxima in the 500−600 nm range. Spectral analysis of this fluorescence in comparison with purified grape tannins[26] indicated this was due to tannins.

Thus, after contact with skin21, the yeast biomass (Y) and the inactivated yeasts (IY and A-IY) showed a strong blue fluorescence in their cytoplasm. This indicated the presence of tannins inside the cells. Another site of fluorescence, the cell wall, was identified on plasmolyzed cells and purified cell walls.

Transmission Electron Microscopy. TEM was performed on yeast cell biomass (Y) and yeast cell wall (CW) without and after contact with grape skin tannins (Figure 4) or with wine polyphenol pool (Figure 5). Untreated yeast cells (Y) appeared typical, in comparison with published TEM images[28−30] being spherical and with the electron-dense fibrillary network of the cell wall (thickness = 200 nm) evident (Figures 4A−C and 5A−C). At higher magnification (Figures 4B,C and 5B,C), the distinction of regions within the cell wall became evident. Yeast cell wall is described as a two-layered structure made of β-(1→3) and β-(1→6)-glucans, mannoproteins, and chitin, which can be covalently linked to form higher order complexes.[25,31] TEM views showed the more electron-dense outer brush-like layer enriched in mannoprotein, over the more electron transparent microfibrillar glucan-rich layer.[30,32] In particular, one must note the regular design of mannoproteins bound to the outer face of the cell wall; it appears as fibers extending from the wall. Within

yeast cells, plasma membrane and ultrastructure granular elements were visible.

Following exposure to grape tannins (Figure 4) or wine polyphenols (Figure 5), cells and cell walls, compared with untreated cells, showed obvious differences at their cell wall and cytoplasm levels. The outer brush-like layer of cell walls appeared as electron-dense aggregated elements (Figures 4D−F and 5D−F). Another major difference was observed in the cytoplasm of polyphenol-treated cells: indeed, and contrary to untreated cells, the entire cytoplasm appeared as highly electron-dense. Finally, at the junction between the cytoplasm and the cell wall, an electron-dense thin layer was visible (Figure 5D−F). The enhanced electron-dense character observed in the outer mannoprotein layer and within the cytoplasm can be attributed to the presence of tannins. Indeed, postfixation of samples for TEM observations was performed with osmic acid, and the tendency of osmium to strongly stain tannins has been evidenced.[26] Whereas the grape skin tannin fraction consists only of flavan-3-ol polymers with an aDP of 21, red wine polyphenols consist of a complex mixture of native

polyphenols monomers (mainly phenolic acids, flavanol monomers, and anthocyanins) and tannins, along with so-called derived pigments and tannins formed during wine-making.[1,3,21,22] We evidenced previously that interactions between red wine polyphenols and yeast cells or cell walls mainly concerned oligomeric and polymeric forms.[19] Thus, TEM observations confirmed that interactions between yeast cells and native or derived condensed tannins/pigments occur not only in the cell wall but also with their cytoplasmic components.

Plasmolysis of some yeast cells was helpful for description of interactions between tannins and mannoproteins. On intact cells, mannoproteins bound to the outer face of the plasma membrane were hardly visible, the plasma membrane being stuck to the wall (Figure 5A,B); after contact with tannins, only a fine osmophilic layer appressed between the wall and plasmalemma was visible (Figure 5D−F). After plasmolysis, fine structures were unveiled in the space generated: on treated cells, mannoproteins were seen attached by GP1 anchor (glycosyl-phosphatidylinositol)[25] to the outer face of the plasmalemma (Figure 6A−C). The inner mannoproteins formed large aggregated electron-dense structures still attached through their GPI anchor to the plasmalemma (Figure 6B,D). In this area, we noted that, under the influence of plasmolysis tearing force, the mannoproteins were cleaved, a large proportion remaining attached to the inner face of the wall. Interactions of the plasmalemma proteins with tannins were also well visible on plasmolyzed yeast cells (Figure 6C). The weakly electron-opaque cell wall [mainly β-(1→3)-glucan and chitin] did not show any typical structure.

Tannin and Red Wine Polyphenol Interactions with Dead/Inactivated Yeast Cells and Cell Walls. These results evidenced that interactions between yeast cells and grape or wine tannins are not necessarily limited to cell walls when dealing with dead and/or inactivated cells. Grape tannins and wine tannins/pigments are liable to enter the periplasmic space through the cell wall and to interact with the cell membrane and its cytoplasmic content. According to their average degree of polymerization, a 3 nm average hydrodynamic volume could be estimated for aDP 21:[33] thus, the polysaccharide wall in our study was permeable to molecules of this size. These observations explained the very large differences observed in our previous work[19] between whole cells and cell walls regarding their ability to bind grape and red wine tannins. Indeed, adsorption isotherms evidenced that the amount of polyphenols adsorbed at concentrations corresponding to those found in red wines was about 10-fold higher with whole cells (nonviable yeast biomass and inactivated cells) than with cell walls. In addition, the reversibility of the interactions was also much more important with cell walls.

The property of tannins to form complexes with proteins is well-known.[34,35] Proteins relevant to the yeast wall include

not all, of the proteins in these two groups are glycosylated. The third group consists of single-pass plasma membrane proteins, mechanosensors that detect cell wall stress.[25] TEM observations evidenced that among cell wall constituents (mannoproteins, proteins, β-glucans, and chitin), mannoproteins are likely primarily involved in the interaction with tannins. This observation is in accordance with previous works evidencing interactions in solution between mannoproteins and tannins or tannin aggregates.[36−38] Considering whole cells and cytoplasmic constituents, it can be supposed that interactions occur with the proteins of the plasmalemma or of other cell membranes or with cytoplasmic proteins. Indeed, proteins represent between 40 and 50% of the yeast cell dry weight.[39] The much higher reversibility of the interactions between cell walls and tannins compared to that observed with whole yeast cells and tannins can be related to the high glycosylation level of mannoproteins: it has been demonstrated that mannosylated yeast invertase presents a 10-fold lower ability to bind red wine tannins than bovine serum albumin.[36]

Potential Implications in Winemaking. The present results have several potential implications in winemaking and aging. The latter concerns first the role of yeast-derived products, especially inactivated yeasts and yeast cell walls, and their use in red winemaking for their potential impact on wine mouthfeel and color stability. Although the exact mechanisms are not solved yet, this impact has mainly been attributed to interactions between mannoproteins and wine tannins. Interactions may occur in solution, due to the release of mannoproteins from cell walls,[15,40,41] or at the interface, due to tannin interactions with mannoproteins located in the outer layer of walls.[10,15] Interactions between condensed grape skin tannins or red wine tannins/derived pigments and mannoproteins in the cell walls have been evidenced here by TEM for the first time. They induce aggregate formation in the initially brush-like structure of the outer mannoprotein layer. However,

DOI: 10.1021/acs.jafc.5b02241
J. Agric. Food Chem. 2015, 63, 7539−7545

when dealing with whole dead or inactivated cells, most of the interactions (about 90%) occur with the yeast cellular constituents. It can then be expected that a quite different impact on red wine polyphenol composition will be obtained depending on the exact structure and composition of the yeast-derived product used:[17] inactivated yeast, yeast inactivated after autolysis treatment and autolysis conditions, yeast walls or hulls. Indeed, autolysis may strongly affect the yeast cell wall composition and cytoplasmic content[42−45] and thus their interactions with wine polyphenols. The autolyzed and inactivated yeast (A-IY) used in our study did not present changes in their ultrastructure detectable by TEM, and only small differences were observed between IY and A-IY in their interactions with red wine polyphenols.[19] Besides the degree of autolysis, also the yeast strain and culture conditions have a potential impact on the composition of the yeast-derived products that deserves to be further explored.[12,17]

Inactivated cells and cell walls are proposed as wine quality enhancers to replace aging on lees. Cell growth conditions used to produce yeast biomass and yeast-derived products strongly differ from those found in winemaking. This may induce different behavior of dead cells toward their interactions with wine polyphenols by comparison to the yeast biomass Y used in our work. However, for a close initial tannin concentration, the amount of polyphenols adsorbed by the yeast biomass Y in our study was similar to that adsorbed by yeast lees in the previous work of Mazauric et al.[10,15] In that case, lees were obtained after alcoholic fermentation in a model must and the strain was not the one used in the present study. This tends to indicate that results obtained in the present work are not related only to the strain and its growth conditions (aerobiosis versus anaerobiosis). This will need to be further explored. Likewise, we focused in the present work on condensed tannins and red wine polyphenols. Although their phenolic compositions are very different, white and rosé wines also contain flavan-3-ol oligomers and derived pigments that can develop physicochemical interactions with yeast cells. For instance, it has been hypothesized that direct interactions between small flavan-3-ols and yeast cytoplasmic membrane lipids could explain the protective effect of yeast lees toward polyphenol oxidation in white wines. Thus, it will be of importance to identify the exact sites of interaction between white and rosé polyphenols and yeast cells to better understand the mechanisms involved in the impact of yeasts and yeast-derived products on wine quality.

(octadecatrienoic acid) found in tung oil using UV spectrophotometry at 273 nm. The CAT assay has several advantages over the ORAC assay.

First, the CAT assay was performed under a heterogeneous system (oil-in-water emulsions). Thus, the effect of the locations of antioxidants in O/W emulsions (antioxidant partitioning) on their antioxidative performance has been incorporated into the model. Second, the amount of antioxidants used in the CAT assay was approximately 100 times less than that of the substrate. Under this condition, the reaction kinetic had a realistic trend in terms of natural antioxidant phenomena.[9]

Recently, the CAT assay has been used in many research experiments to explore an optimum degree of lipophilization of phenolic compounds[16] using AAPH (a water-soluble peroxyl radical initiator) to accelerate lipid oxidation in oil-in-water emulsions. However, due to the complexity of lipid oxidation in emulsion systems, locations of free radicals in the system could be differently partitioned not only into the water phase, but also into the oil/lipid interfacial region and/or the lipid core at which lipid oxidation was hypothesized to occur in emulsions. Thus, it is worthy of investigating the influence of using a lipid-soluble free radical initiator on antioxidant behaviors in the CAT-based assay as an additional complementary method to the original CAT assay using different ways to initiate lipid oxidation.

In this research, the apolar radical-initiated conjugated autoxidizable triene (ApoCAT) assay, a modified CAT assay, was proposed by using a lipid soluble free radical azo initiator (dimethyl 2,2′-azobis(2-methylpropionate) so-called V601or AIBME) instead of AAPH. According to chemical information, AIBME is a non-nitrile azo initiator which is very insoluble in water. It was hypothesized that the ApoCAT assay may be more relevant to autoxidation of oil-in-water emulsions, since it was believed that lipid oxidation in O/W emulsions occurs at the interface of oil droplets[17,18] instead of acceleration from the aqueous phase.

In addition, these two assays may be suitable for studying combinations of antioxidants. It was reported that the locations of antioxidants in O/W emulsions also impacted the overall antioxidative performances of combined antioxidants, resulting in different interaction behaviors, such as synergistic, additive, and antagonistic effects.[19]

This research aimed to investigate the effects of hydrophilic and lipophilic peroxyl radical initiators on the antioxidative performances of some synthetic antioxidants and natural extracts, to study the relationship between the CAT and ApoCAT assays, and to explore antioxidant interactions using these assays.

MATERIALS AND METHODS

Chemicals and Materials. Ethylenediaminetetraacetic acid (EDTA), 2,4,6-tris(2-pyridyl)-s-triazine (TPTZ), silicic acid, Folin-Ciocalteau's reagent, sodium carbonate, ferric chloride, tung oil, Brij 35, ascorbic acid, ascorbyl palmitate, gallic acid, lauryl gallate, and mixed tocopherols were purchased from Sigma-Aldrich (St. Louis, USA). Hydrochloric acid was purchased from Fisher Scientific (Loughborough, UK). Absolute ethanol was purchased from RCI Labscan (Thailand). 2,2′-Azobis-2-methylpropanimidamide, dihydrochloride (AAPH),dimethyl 2,2′-azobis(2-methylpropionate) (AIBME) or V601 and activated charcoal were purchased from Wako Chemical (Japan). Miglyol812N, a medium chain triglyceride (MCT) mixture, was purchased from Sasol Germany Gmbh (Witten,Germany). Commercial grape seed (95% oligomeric proanthocyanidins; OPC) and rosemary (60% carnosic acid) extracts were purchased from Changsha Nutramax Inc. (Changsha, China). Commercial green tea extract was purchased from Specialty Natural Products Co., Ltd. (Chonburi, Thailand). All commercial extracts were processed without any additive and carriers. Double-distilled and deionized water was used for the preparation of all solutions. All organic solvents used were analytical grade.

Total Phenolic Content (TPC) Assay. Total phenolic contents of antioxidants and plant extracts were determined by the method of Deetae et al. (2012)[8] with some modifications. The reaction was performed in a 96-well microplate. Briefly, 30 microliter of sample was mixed with 150 μL of Folin-Ciocalteau's reagent (10-times dilution). Then, 7.5% w/v of sodium carbonate (120 μL) was added. The mixtures were kept in the dark for 30 min. The absorbance of mixture was recorded at 765 nm using a microplate reader (SpectraMax 190, Molecular Devices, USA). Gallic acid was used as a standard phenolic compound. In the case of synthetic antioxidants, result is expressed as millimole of gallic acid per one mole of antioxidant (mmole GAE/mol antioxidant). In the case of natural extracts, result is expressed as mg of gallic acid per one gram of antioxidants (mg GAE/g extract).

ABTS Radical Scavenging Activity Assay. Free radical scavenging activity of antioxidants and plant extracts was performed according to the ABTS assay described by Deetae et al. with some modification.[8] ABTS cation radical ($ABTS^{\bullet+}$) was generated by reacting 10 mL of 7 mM ABTS stock solution with 179 μL of 140 mM potassium persulfate. Then, the mixture was incubated at room temperature for 16 h. $ABTS^{\bullet+}$ solution was diluted to obtain an absorbance of 0.7 at a wavelength of 734 nm before use. Twenty microliters of samples were added into 280 μL of $ABTS^{\bullet+}$ solution in a microplate. The mixtures were mixed using the microplate mixer, and then incubated in the dark at room temperature for 6 min. The absorbance of mixture was then read at 734 nm by a microplate reader (Spectra Max 190, Molecular Devices, USA). Ascorbic acid was used as a standard phenolic compound. In the case of synthetic antioxidants, result is expressed as millimole of ascorbic acid per one mole of antioxidant (mmole ascorbic acid/mol antioxidant). In the case of natural extracts, result is expressed as mg of ascorbic acid per one gram of antioxidants (mg ascorbic acid/g extract).

Ferrous Reducing Antioxidant Power (FRAP) Assay. Ferric reducing antioxidant power (FRAP) assay was performed using a method described by Deetae et al. with some modification.[8] Shortly, FRAP reagent was freshly prepared by mixing 300 mM acetate buffer (pH 3.6), 10 mM TPTZ in 40 mM HCl, and 20 mM $FeCl_3.6H_2O$ at the ratio of 10:1:1. Sample (30 μL) was added into 270 μL of FRAP reagent in a 96-well microplate. The microplate was kept in the dark at 37 °C for 8 min. The absorbance of the mixture was measured at 595 nm using a microplate reader (SpectraMax 190, Molecular Devices, USA). Ascorbic acid was used as a standard phenolic compound. In the case of synthetic antioxidants, result is expressed as millimole of ascorbic acid per one mole of antioxidant (mmole ascorbic acid/mol antioxidant). In the case of natural extracts, result is expressed as mg of ascorbic acid per one gram of antioxidants (mg GAE/g extract).

Oxygen Radical Absorbance Capacity (ORAC) Assay. Oxygen radical absorbance capacity (ORAC) assay was performed according to Nkhili et al.[10] Briefly, a series of varying concentrations of antioxidant was prepared. Twenty microliters of samples were added into a 96-well black microplate (Eppendorf). Then, 160 μL of 78 nM fluorescein in PBS solution (pH 7.2) was added. The mixture was incubated at 37 °C for 5 min in the dark. The reaction started when 12 mM AAPH (20 μL) was added. Fluorescent intensity of the mixture was recorded using a fluorescent microplate reader (SpectraMax M5, Molecular Devices, USA) with an excitation wavelength of 485 nm and an emission wavelength of 520 nm at 2 min intervals for 3 h in kinetic mode.

Conjugated Autoxidizable Triene (CAT) Assay. Conjugated autoxidizable triene (CAT) assay was assessed as described by Laguerre and co-workers[20] with some modification. Conjugated triene triacylglycerols in tung oil was used as a substrate and UV probe for monitoring the progress of the oxidation reaction. Polar compounds of tung oil were stripped by using a method explained by Boon et al.[21] Briefly, silicic acid (100 g) was washed three times with a total of 3 L of distilled water followed by drying at 110 °C for 20 h.

A chromatographic column (3.0 cm internal diameter and 35 cm height) was then packed sequentially with 22.5 g of silicic acid followed

DOI: 10.1021/acs.jafc.5b02493
J. Agric. Food Chem. 2015, 63, 7546−7555

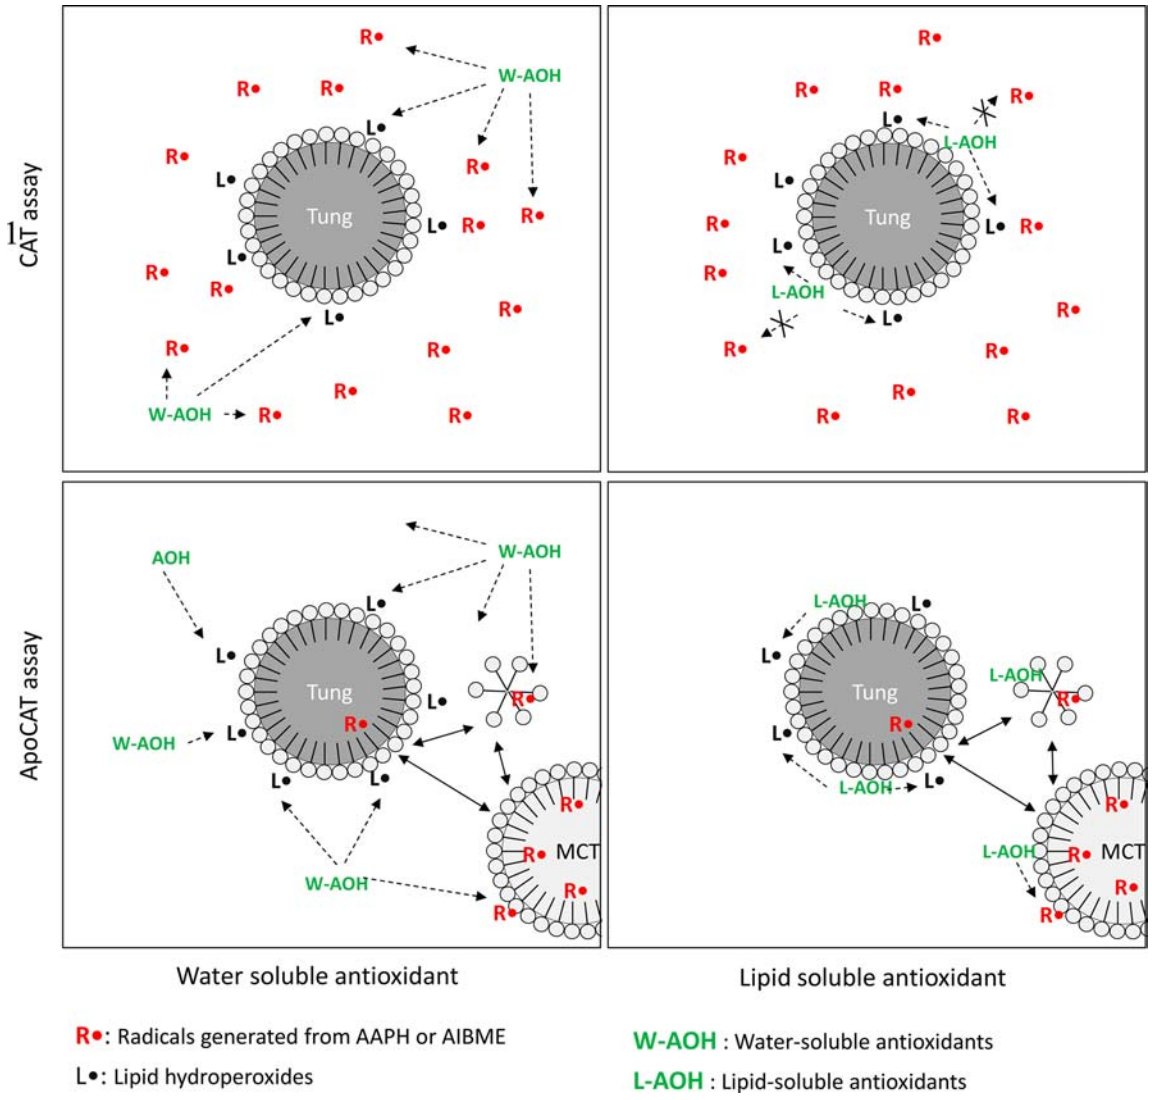

Figure 1. Proposed mechanisms of oxidants and antioxidants in the CAT and ApoCAT assays.

by 5.625 g of activated charcoal and then another layer of silicic acid (22.5 g). Tung oil (30 g) was dissolved in 30 mL of *n*-hexane and passed through the column. Tung oil was eluted with addition of *n*-hexane (270 mL). The collected triacylglycerols were held in an ice bath, and covered with aluminum foil to inhibit lipid oxidation. The solvent in stripped tung oil was removed using a vacuum rotary evaporator (BÜCHI Rotavapor R-114, Switzerland) at 37 °C, and traces of the remaining solvent were removed by flushing with nitrogen. The stripped tung oil was transferred into small vials, and stored at −80 °C until performing an experiment.

The CAT assay was performed with two main steps as the following details. First, for emulsion preparation, 25 mL of PBS solution (pH 7.2) containing 34 μM Brij 35 was added into a beaker containing 6(±0.5) mg of stripped tung oil. Oil-in-water emulsions were made by homogenizing the mixture at 6,500 rpm for 90 s (Ultra-Turrax T25 basic, IKA Werke, Germany). The emulsion was then centrifuged using a centrifuge (Model 5810 R, Eppendorf, Germany) at 10,000 g, 10 °C for 5 min in order to remove the unstable part (large oil droplets), providing more homogeneous size distribution of O/W emulsions.

Second, a series of different concentrations of samples in PBS solution (50 μL) was transferred to a UV-Star 96-well microplate (Costar, Corning, USA), followed by addition of the prepared emulsion (125 μL). The samples were mixed at 1,200 rpm, 37 °C for 5 min using a microplate mixer (Thermomixer R, Eppendorf, Germany). After mixing, the samples were immediately mixed with 25 μL of 8 mM AAPH solution in PBS solution and recorded at 273 nm at 1 min intervals for 3 h using a microplate reader (SpectraMax 190, Molecular Devices, USA). Trolox was used as a standard antioxidant to compare against other treatments.

The CAT value, expressed as mg of trolox per one gram (or mole) of an antioxidant, was calculated from a relationship between net protection areas under the curve (AUC) and concentrations of antioxidants compared to trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid).

Apolar Radical-Initiated Conjugated Autoxidizable Triene (ApoCAT) Assay. The ApoCAT assay was adapted from the original CAT assay described by Laguerre et al.[20] Instead of using AAPH, the lipid-soluble free radical initiator, dimethyl 2,2′-azobis (2-methylpropionate), was used. All procedures were performed as described in the CAT assay except for the preparation of free radical initiator.

In brief, MCT oil-in-water emulsion was prepared exactly the same way as described in tung oil-in-water emulsion. MCT emulsion solutions was mixed directly with the lipid-soluble free radical initiator to obtain a final concentration of 8 mM dimethyl 2,2′-azobis (2-methylpropionate) in MCT oil-in-water emulsion. Twenty-five milliliters of V601 loaded MCT oil-in-water emulsion were mixed with 125 μL of tung oil-in-water emulsions and 50 μL of samples in PBS solution to start the oxidation reaction.

Calculation of Antioxidant Interaction Indexes in the CAT and ApoCAT Assays. Interaction indexes of combined effects between α-tocopherol (lipid soluble) and water-soluble antioxidants were

J. Agric. Food Chem. 2015, 63, 7546−7555

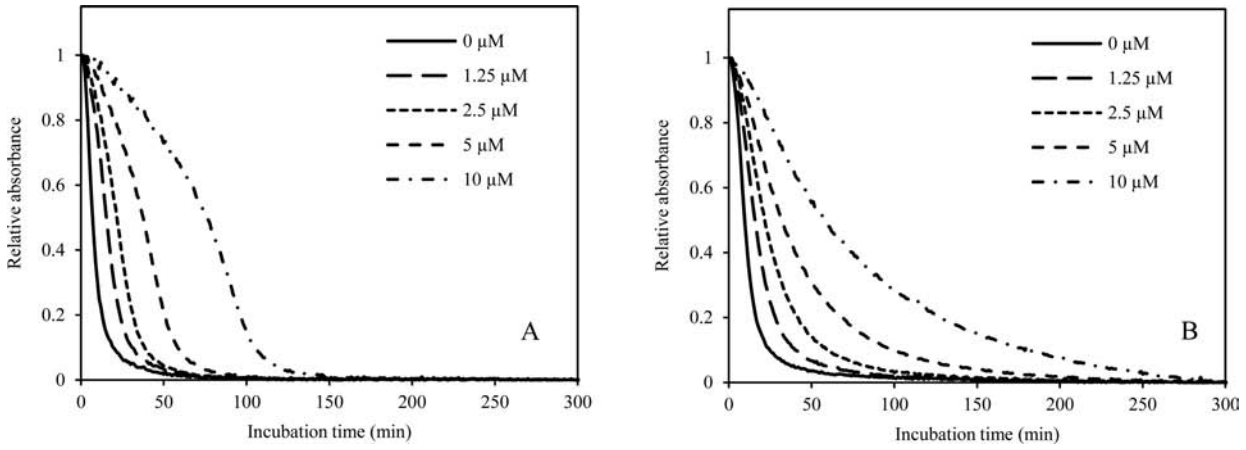

Figure 2. Kinetic decay of conjugated triene in the CAT (left) and the ApoCAT (right) assays treated with trolox (A and B).

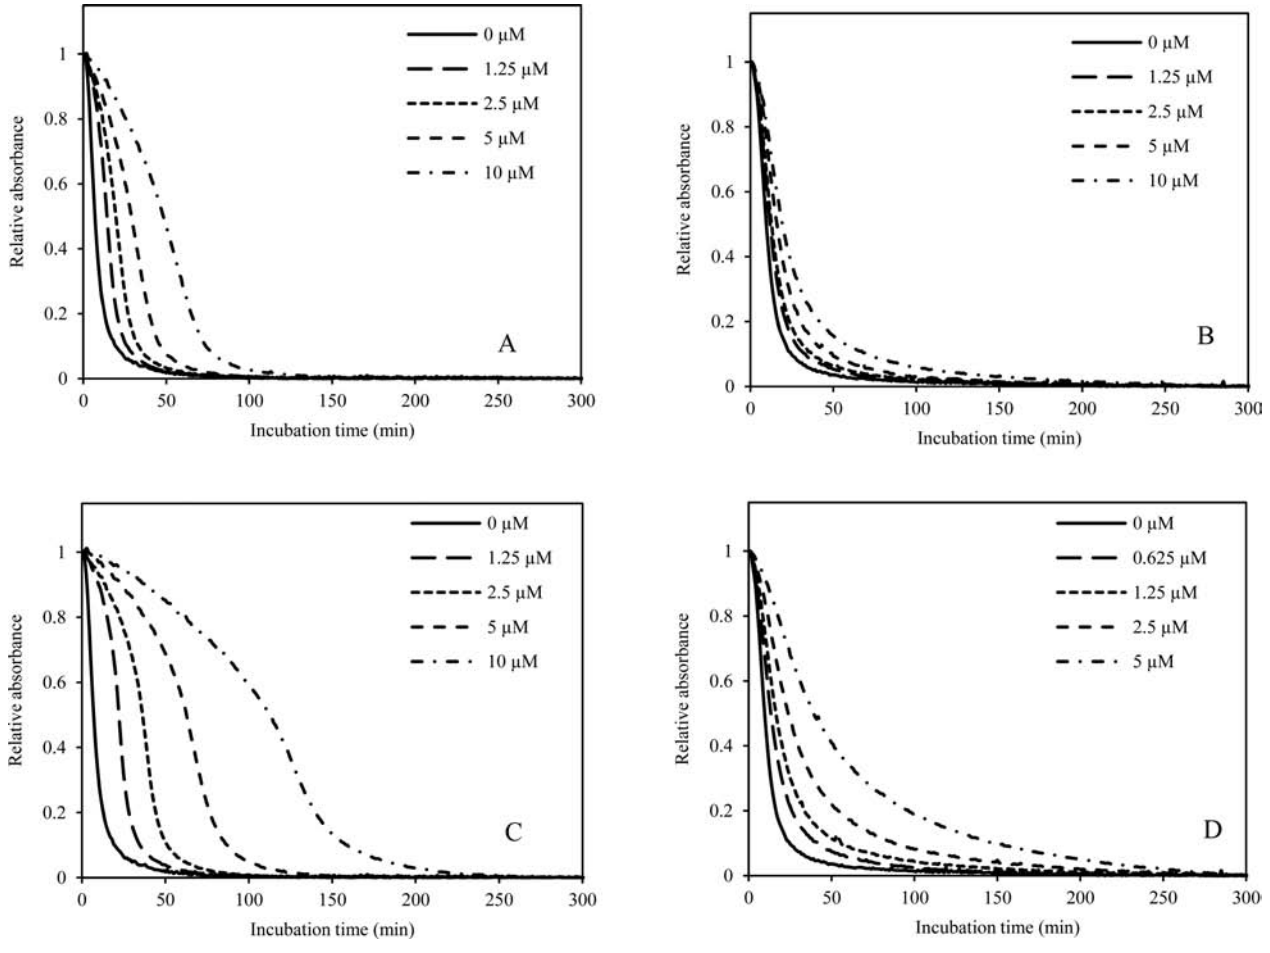

Figure 3. Kinetic decay of conjugated triene in the CAT (left) and the ApoCAT (right) assays treated with gallic acid (A and B) and lauryl gallate (C and D).

investigated using the CAT and the ApoCAT assays. Different ratios of water to lipid soluble antioxidants (1:3, 1:1, 3:1, 5:1, and 7:1) were prepared in ethanolic solution based on molar mass basis of antioxidants. To estimate the interaction indexes, individual and combined antioxidants were performed in the same 96-well microplate. Antioxidant capacities of individual antioxidant could be observed directly. For the expected antioxidant capacities of the combination, it could be estimated as described in the following equation.

$$\text{Interaction Index} = \frac{\text{Observed CAT value of the combination}}{\text{Expected CAT value of the combination}} = \frac{\textit{the CAT value of combined } (A + B)}{\textit{the CAT value of } A \times F1 + \textit{the CAT value of } B \times F2}$$

Where, A and B represent α-tocopherol and another antioxidant, respectively. Individual CAT or ApoCAT values of A and B were used to calculate the expected CAT or ApoCAT of the combined A and B. F1and F2 represent fractions of the combination. For example, a ratio between antioxidants was 3 to 1. The F1 and F2 are 3/4 and 1/4,

J. Agric. Food Chem. 2015, 63, 7546−7555

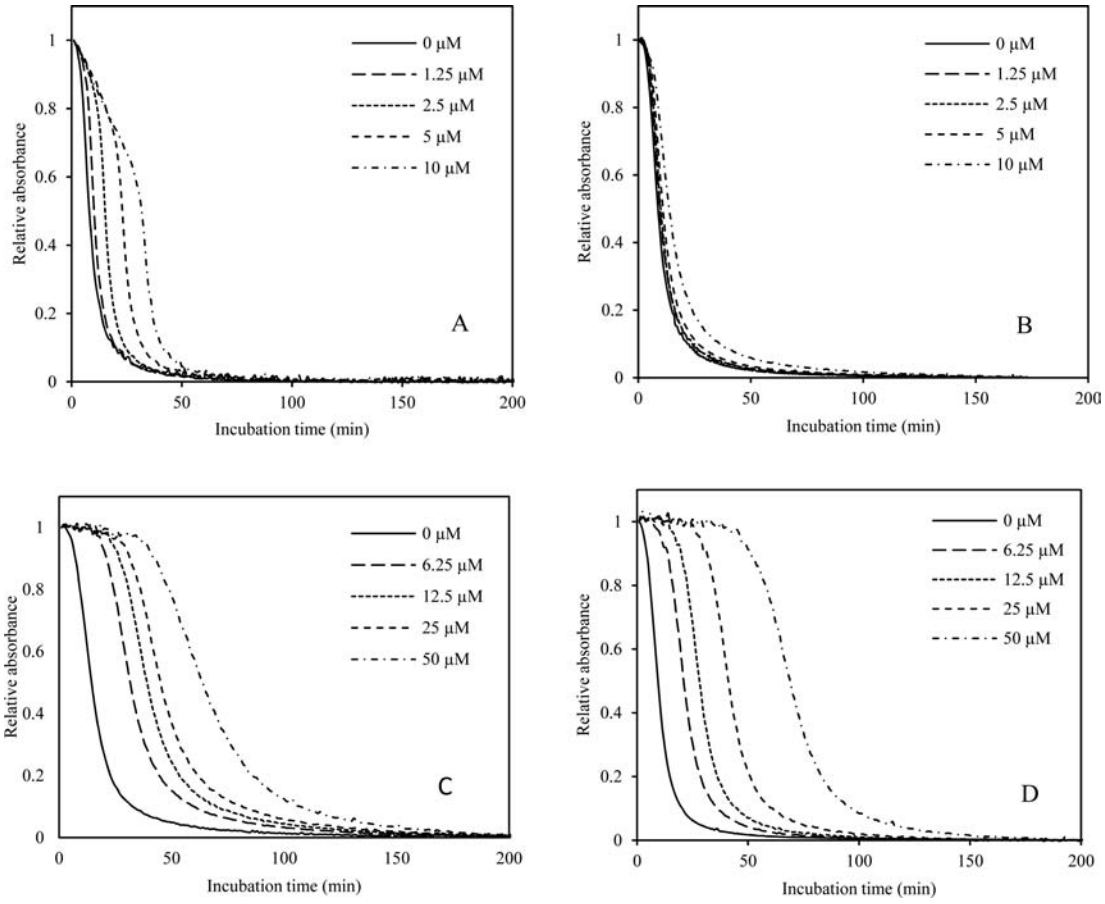

Figure 4. Kinetic decay of conjugated triene in the CAT (left) and the ApoCAT (right) assays treated with ascorbic acid (A and B) and ascorbyl palmitate (C and D).

respectively. Interaction indexes were expressed as synergistic (>1), additive (≈1) and antagonistic (<1) antioxidant effects.

Statistical Analysis. All analyses were performed on triplicate samples. In all cases, comparisons of the means were performed using Duncan's multiple-range tests. A significance level of $p < 0.05$ was defined as being statistically different. All calculations were performed using SPSS18.0 (http://www.spss.com; SPSS Inc., Chicago, IL).

RESULTS AND DISCUSSION

Effect of Hydrophilic and Lipophilic Azo Radical Initiators on Antioxidant Capacities in the CAT Assay. Water-soluble (AAPH) and lipid soluble (AIBME) azo radical initiators were used to investigate the influences of different oxidant locations in the CAT assay on the antioxidant capacities of a variety of antioxidants. Instead of using water-soluble AAPH, the ApoCAT assay has been developed by using lipid-soluble AIBME in the original CAT assay. One of the problems in the development of the ApoCAT assay was finding a suitable delivery system for the incorporation of AIBME into the tung oil emulsions. To avoid large impacts on antioxidant distributions in the emulsion system from using solvents and surfactants, AIBME incorporated MCT oil-in-water emulsions were prepared using the same protocol as that for the tung oil emulsions. It was observed that using ethanol as a solvent to dissolve AIBME impacted on the emulsion stability of tung oil emulsions (data not shown). Hence, using excess surfactant concentrations could change the distribution of antioxidants in the systems, as previously reported by Panya et al. that the antioxidant activity of medium-chain alkyl ester (4−12 carbons) antioxidants (rosmarinic acid) decreased, while the activity of the ong-chain alkyl ester (20 carbons) antioxidant rosmarinic acid was improved by the addition of Tween 20.[15]

Figure 1 demonstrates proposed mechanisms of oxidants and antioxidants in the CAT and ApoCAT assays. In the CAT assay, water-soluble antioxidants are supposed to be mainly distributed in the water phase, so they have high possibility to react with radicals generated in the water phase. Because of the limitation of lipid soluble antioxidants to dissolve in water, lipid soluble antioxidants could only react with radicals generated near the oil/water interfacial regions.

However, in the case of the ApoCAT assay, lipid-soluble radicals and nonpolar antioxidants could be partitioned into several hydrophobic regions, such as lipid cores of tung and MCT oil droplets, micelles, and the oil/water interfaces. As a result, lipid-soluble antioxidants could mainly inactivate free radicals generated in the lipid phase, while water-soluble antioxidants could only interact with lipid-soluble radicals at the interfacial regions. It should be noted that dynamic exchanges of lipid soluble radicals and antioxidants between the tung oil and MCT oil emulsion droplets could be also facilitated by surfactants due to the formation of micelles.

As illustrated in Figure 2, without addition of Trolox, oxidation rates of tung oil-in-water emulsions in the ApoCAT assay were slightly slower than that of the CAT assay. At the same concentration of Trolox, the oxidation rates of tung oil emulsions of the ApoCAT assay were also slower than what was observed in the CAT assay. As a result, the net protection areas against various concentrations of Trolox observed in the ApoCAT assay

DOI: 10.1021/acs.jafc.5b02493
J. Agric. Food Chem. 2015, 63, 7546−7555

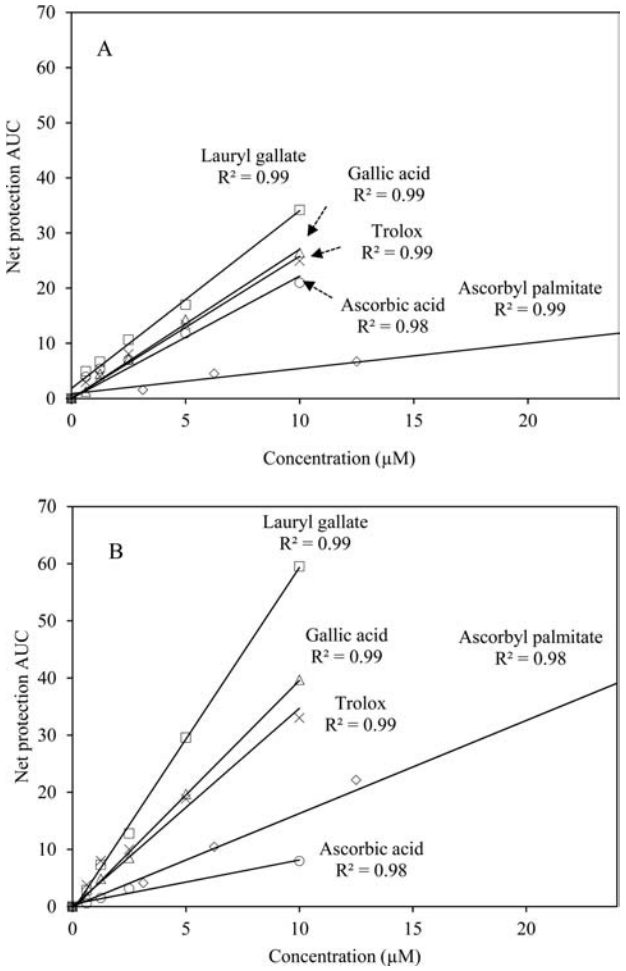

Figure 5. Area under the curve (AUC) vs concentrations of antioxidants in the CAT (A) and ApoCAT (B) assays.

was higher than that observed in the CAT assay. This could be due to the 10 h half-life decomposition temperature of AIBME is 66 °C, while that of AAPH is 44 °C. Thus, in general, the radical generation rate of AIBME is slower than that of AAPH under the same experiment condition.

From a kinetic point of view, Trolox exhibited different behaviors in both assays. Trolox could suppress oxidation more effective in the CAT assay than in the ApoCAT assay, as indicated by larger oxidation lag phase and/or slower initial oxidation rates. Laguerre and co-workers[9] have also reported that Trolox exhibited retarder behavior in the CAT assay. However, it was noted that, in this research, Trolox showed a pure retarder behavior (with an insignificant oxidation lag phase) in the ApoCAT assay. Results implied that a water-soluble antioxidant could exhibit higher antioxidant activity in the CAT assay than that observed in the ApoCAT assay.

The relationships between the CAT and ApoCAT assays were investigated using several water-and lipid-soluble antioxidants. The kinetics of absorbance bleaching in the presence of water-soluble (gallic acid and ascorbic acid) and lipid soluble (lauryl gallate and ascorbyl palmitate) antioxidants performed in the CAT and ApoCAT assays are shown in Figures 3 and 4, respectively. The results suggested that there was a strong influence of oxidant locations on the oxidation behaviors of water-and lipid-soluble antioxidants, as indicated by changes in the decay kinetics of tung oil emulsions with several antioxidants.

In the ApoCAT assay, gallic acid exhibited as a strong retarder as a result of the faster decay rate of the oxidation in comparison with what was observed in the CAT assay. The same was true in the case of lauryl gallate. In the CAT assay, lauryl gallate showed a significant lag phase, while, in the ApoCAT assay, lauryl gallate did not exhibit any lag phase. As illustrated in Figure 4, similar results were observed for ascorbic acid and ascorbyl palmitate. Ascorbic acid exhibited higher antioxidant activity in the CAT assay (Figure 4A) than in the ApoCAT assay (Figure 4B). However, ascorbyl palmitate showed higher antioxidant activity in the ApoCAT assay (Figure 4D) than in the CAT assay (Figure 4C). It should be noted that ascorbyl palmitate exhibited as a strong chain-breaker due to a significant lag phase.

From these results, it should be noted that the kinetic behaviors of antioxidants, as indicated by lag times and net protective areas under the curve (AUC), were changed according to how the systems were accelerated. This could be due to the fact that antioxidant partitioning was different in the CAT and ApoCAT systems. It was postulated that water-soluble antioxidants, mostly distributed in aqueous phase, could be able to mainly react with radicals generated in the aqueous phase and near the oil/water interface of tung oil emulsions, in the case of the CAT assay, and of both tung oil and MCT oil emulsions, in the case of ApoCAT. In comparison with the CAT assay, aqueous antioxidants in the ApoCAT model may have less chance to react with aqueous phase radicals, so decreases in the antioxidant performance of water-soluble antioxidants were observed, resulting in shorter or insignificant oxidation lag phases.

In the case of lipid soluble lauryl gallate (12 carbons), its oxidation lag time was clearly observed in the CAT assay, while it was not found in the ApoCAT assay. These results were different in comparison with ascorbyl palmitate (16 carbons), with an oxidation lag time being longer in the ApoCAT assay than in the CAT assay. It was hypothesized that this could be due to the fact that the polarity of ascorbyl palmitate was lower than that of lauryl gallate, so the distribution of ascorbyl palmitate should be mainly associated with the emulsion droplets. However, the antioxidant performance of lauryl gallate had dramatically

Table 1. Comparisons of Antioxidant Capacities of Synthesized Antioxidants[a]

[a-]Means within a column with different letters are significantly different ($p < 0.05$).

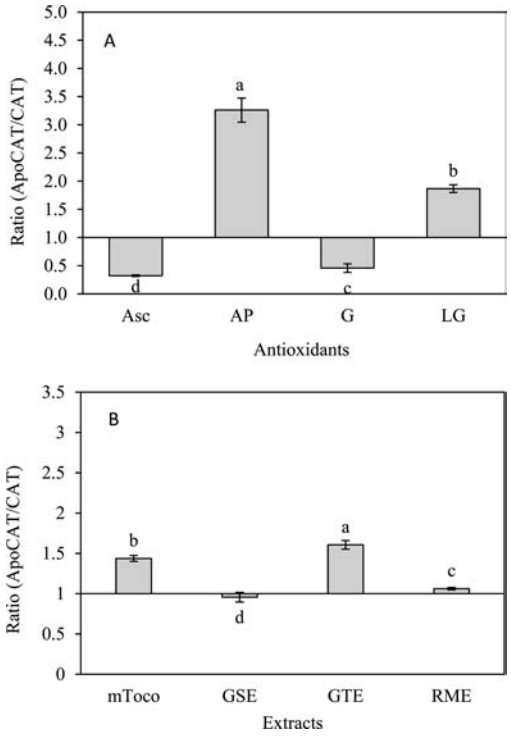

Figure 6. Ratio of antioxidant capacity of pure chemical antioxidants between the CAT and the ApoCAT assays. Synthetic antioxidants are ascorbic acid (Asc), ascorbyl palmitate (AP), gallic acid (G) and lauryl gallate (LG). Natural crude antioxidants are mixed tocopherol (mToco), grape seed extract (GSE), green tea extract (GTE), and rosemary extract (RME). Values are the means of three replicates. The different letters (a, b, c, and d) of interaction index obtained from different ratios of the same assay indicate significant differences ($p < 0.05$).

changed in both assays. The results suggested that the majority of lauryl gallate molecules may be distributed in the water phase instead of in oil droplets

The relationships between the net AUC of selected antioxidants in the CAT and the ApoCAT assays are shown in Figure 5A and B, respectively. The results suggested that the AUC of the ApoCAT assay was higher than that of the CAT assay. This could be due to the slower oxidation rate of the AIBME in comparison to the AAPH because the 10 h half-life decomposition temperature of AIBME (66 °C) was higher than that of AAPH (44 °C). In addition, the same concentrations of AAPH and AIBME were used in both assays.

The results suggested that the ApoCAT assay showed a strong impact on the antioxidant activities of nonpolar antioxidants (ascorbyl palmitate and lauryl gallate) in the same manner. For instance, it was noticed that the antioxidant activities of ascorbic acid and ascorbyl palmitate were strongly impacted. Ascorbic acid exhibited a strong antioxidant activity in the CAT assay, while it showed a poor antioxidant activity in the ApoCAT assay. On the contrary, ascorbyl palmitate exhibited higher antioxidant activity in the ApoCAT assay than in the CAT assay. Overall, it could be concluded that nonpolar antioxidants performed better in the ApoCAT assay than in the CAT assay, and vice versa.

Comparisons of the Performance of the CAT and ApoCAT Assays to Those of Conventional Antioxidant Activity Assays. As illustrated in Table 1, antioxidant capacities of ascorbic acid, gallic acid and their esters were investigated in TPC, ABTS, FRAP, ORAC assays in comparisons with the CAT and the ApoCAT assays. It should be noted that TPC, ABTS, FRAP and ORAC assays were considered as homogeneous systems, while the CAT and the ApoCAT assays were concerned as heterogeneous systems. Results showed that ascorbic acid and gallic acid exhibited higher antioxidant capacities than their ester forms in TPC, ABTS, FRAP, and ORAC assays. Hence, the solubility of antioxidants in the aqueous systems should be one of the important factors affecting on the overall antioxidant activities.

However, in the CAT assay, ascorbyl palmitate exhibited lower antioxidant capacity than ascorbic acid, while lauryl gallate showed higher antioxidant capacity than gallic acid, based on trolox equivalents. Results indicated that the cutoff effect could be observed in ascorbyl palmitate. Laguerre and co-workers[9,22] explained the cutoff effect in several heterogeneous systems that too low polarity of an antioxidant may impact on the locations of the antioxidant, distributing into the lipid core inside and/or self-aggregation outside emulsion droplets. However, in the case of the ApoCAT assay, it was noted that a different antioxidant behavior was observed. Ascorbyl palmitate exhibited higher antioxidant capacity than ascorbic acid, based on trolox equivalents.

In addition, these models were performed on various commercial antioxidant extracts as shown in Table 2. Based on homogeneous models, TPC, ABTS and FRAP assays showed a similar antioxidant behavior that green tea extract had the lowest antioxidant capacity followed by rosemary extract, mixed tocopherol and/or grape seed extract. On the contrary, the obtained results from the ORAC assay differed from other assays. In this model, mixed tocopherol had the lowest antioxidant capacity followed by green tea, grape seed, and rosemary extracts, respectively.

The CAT and the ApoCAT assays showed a similar antioxidant pattern that green tea had the lowest antioxidant capacities, while rosemary extract had the highest antioxidant capacity. To understand the effect of oxidant locations, the ApoCAT/CAT ratios of tested antioxidants were calculated as illustrated in Figure 6. It should be noted that the higher the

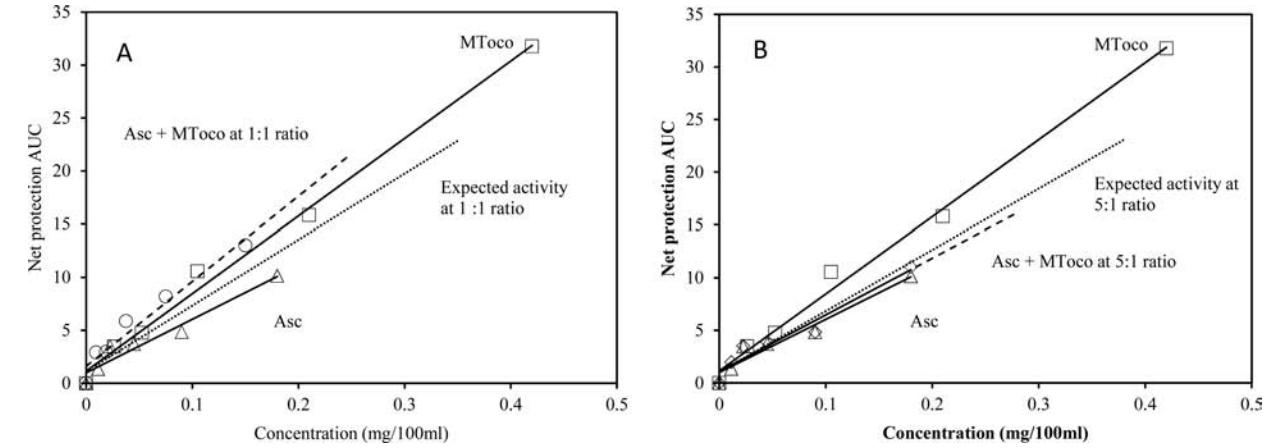

Figure 7. Demonstration of estimating interaction index of ascorbic acid and α-tocopherol at the ratio of 1 to 1 and 5 to 1 in the CAT assay.

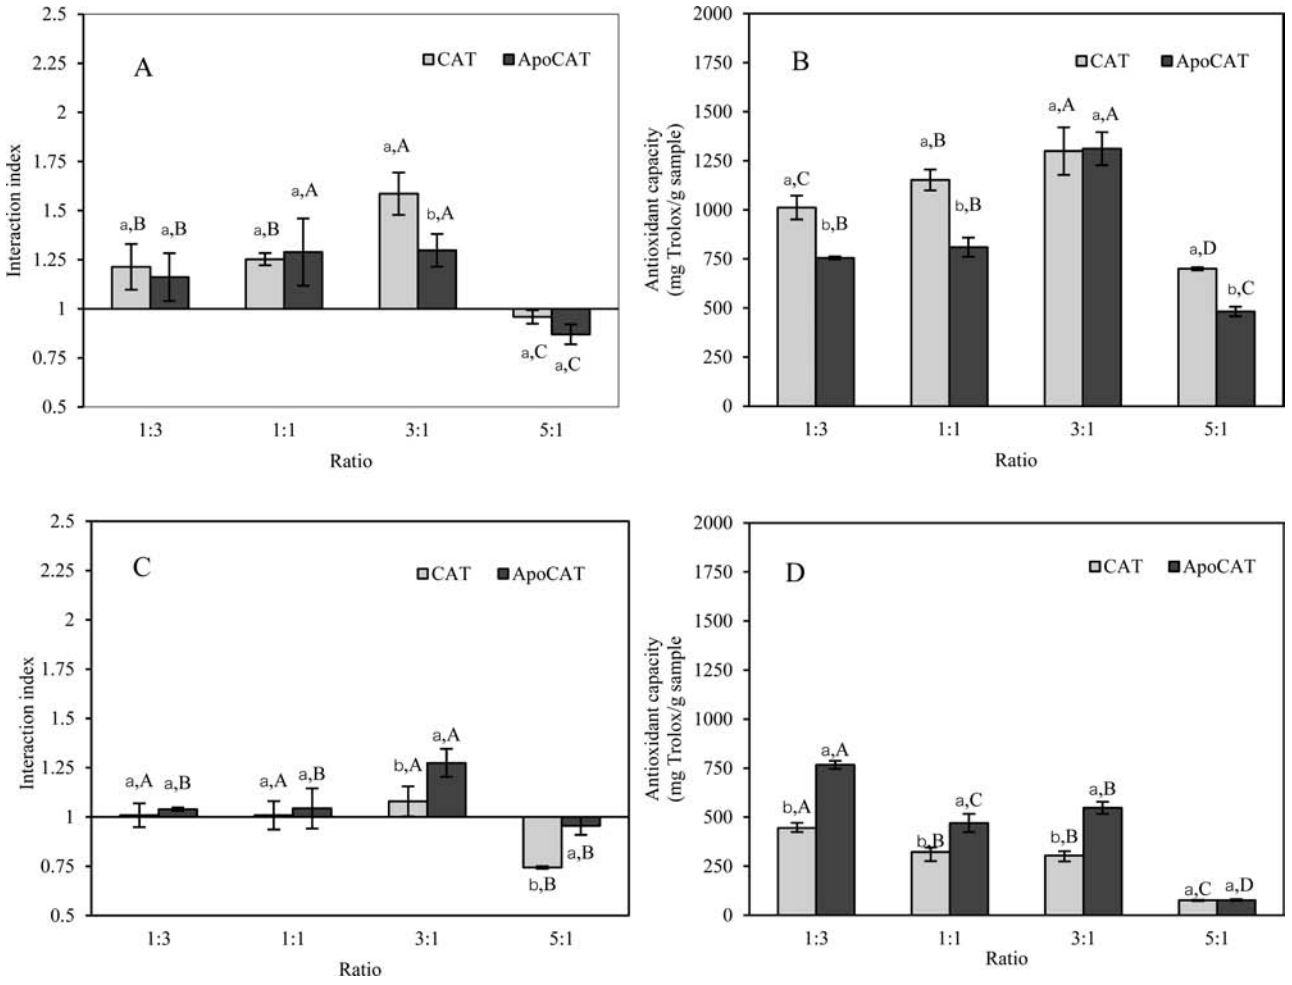

Figure 8. Antioxidant interactions (left) and capacities (right) between selected antioxidants and mixed tocopherols in both CAT and ApoCAT assays. Combination of ascorbic acid and mixed tocopherols (A and B), and combination of green tea extract and mixed tocopherols (C and D). Values are the means of three replicates. The different letters (a and b) of interaction index from the CAT and the ApoCAT assays at the same ratio indicate significant differences ($p < 0.05$). The different letters (A, B, C, and D) of interaction index obtained from different ratios of the same assay indicate significant differences ($p < 0.05$).

ApoCAT/CAT ratio, the better antioxidative performance of an antioxidant was observed in a lipid phase radical-initiating system. As shown in Figure 6A, all ester forms had higher ApoCAT/CAT ratios than their acid forms. For example, ascorbyl palmitate showed an improved performance in the ApoCAT assay, while ascorbic acid showed the opposite trend. In addition, the same was true for gallic acid and its ester.

Overall, the ApoCAT/CAT ratio could provide more information on the characteristics of antioxidants preferring free radicals in water and/or lipid phases. This concept was also applied for characterizing some commercial antioxidants and

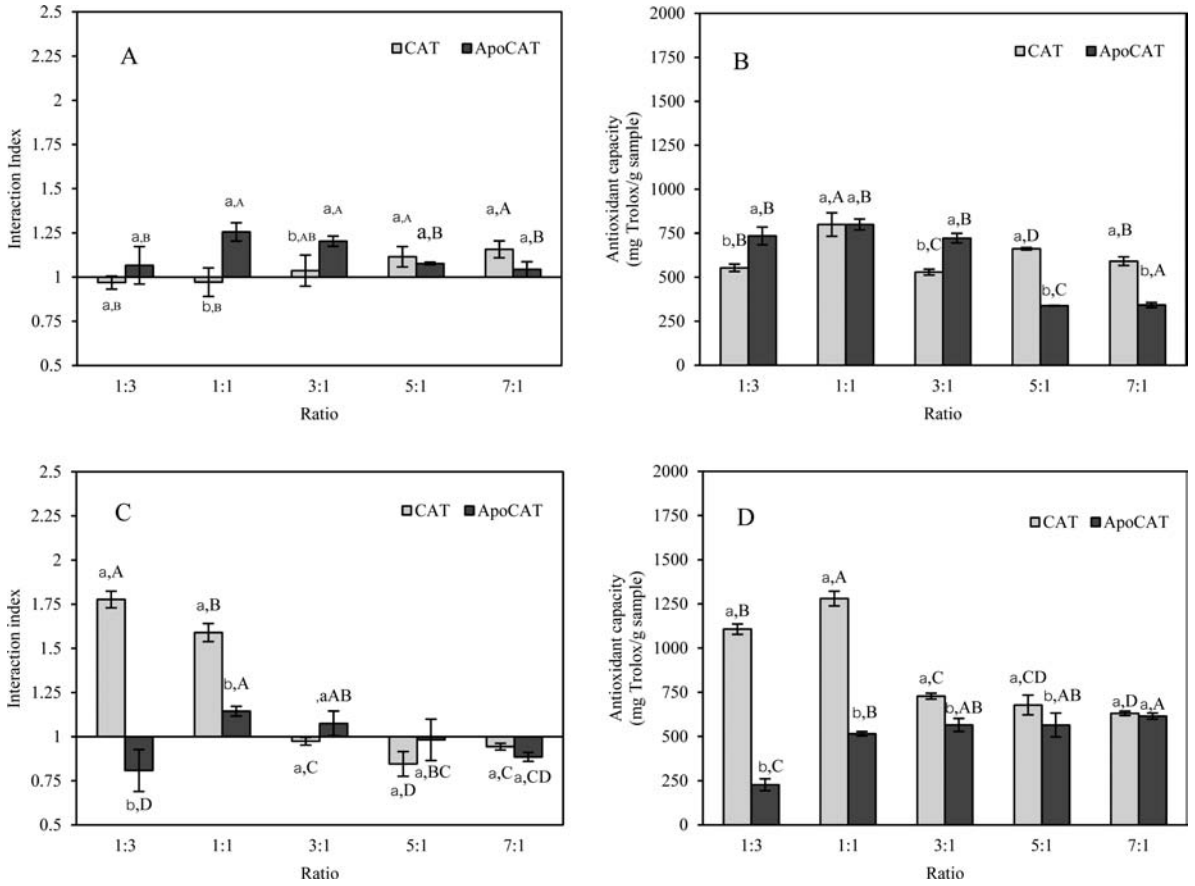

Figure 9. Antioxidant interactions (left) and capacities (right) between selected antioxidants and mixed tocopherol in both CAT and ApoCAT assays. Combination of grape seed extract and mixed tocopherol (A and B), and combination of rosemary extract and mixed tocopherol (C and D). Values are the means of three replicates. The different letters (a and b) of interaction index from the CAT and the ApoCAT assays at the same ratio indicated significant differences ($p < 0.05$). The different letters (A, B, C, and D) of interaction index obtained from different ratios of the same assay indicate significant differences ($p < 0.05$).

natural plant extracts as shown in Figure 6B. As expected, mixed tocopherols performed better in the ApoCAT assay, since they are lipid soluble antioxidants. Interestingly, the performances of green tea and rosemary extracts have also been increased, while grape seed extract showed no significant difference in both assays. The results suggested that mixed tocopherols, green tea extract, and rosemary extract could be good antioxidant candidates for preventing oxidation in oil-in-water emulsion systems.

Investigation of Antioxidant Interactions Using the CAT and the ApoCAT Assays. The combined effects of selected antioxidants were investigated using the CAT and ApoCAT assays at various ratios. Figure 7 shows linear relationships between observed individual and combined antioxidants, and expected combined antioxidants of various ratios of ascorbic acid/α-tocopherol mixtures based on mass basis. Results indicated that increasing the ratio of ascorbic acid to α-tocopherol from 1:1 to 5:1 changed antioxidant interactions from synergism to antagonism. In the case of a synergistic effect, the observed slope of the antioxidant activity was higher than the expected slope of the antioxidant activity, and vice versa for the antagonistic effect. Using this calculation, the relationships between ratios of polar and nonpolar antioxidants, and antioxidant interactions in O/W emulsions could be investigated.

As shown in Figures 8 and 9, increasing the ratios of various polar antioxidants to mixed tocopherol (nonpolar antioxidant) resulted in altered antioxidant interactions and overall antioxidant capacities. Depending on antioxidants and evaluation methods, the optimal combination ratios to obtain the highest antioxidant synergy and capacities could be different. As illustrated in Figure 8, combining ascorbic acid or green tea with α-tocopherol exhibited the highest interaction index at a 3:1 ratio. It should be noted that increasing the ratio further than this level resulted in an antagonistic effect (at 5:1 ratio).

Similar behaviors of the combinations were observed in the combined effects of grape seed and rosemary extracts. For the combinations with grape seed extract, the optimal ratios for synergy were observed around 1:1 to 3:1 ratios; however, for rosemary extract, the highest synergy was observed at 1:3 ratios. It was noted that the combination with ascorbic acid (Figure 8A) and rosemary (Figure 9A) extracts exhibited similar combination behaviors in such a way that the CAT assay provided a significantly higher interaction index in comparison with the ApoCAT assay. However, green tea (Figure 8C) and grape seed (Figure 9C) extracts exhibited a weak synergy in the ApoCAT assay higher than in the CAT assay.

Overall, results demonstrated that the performance of antioxidants could be improved by a combined strategy between water-and lipid-soluble antioxidants. It was hypothesized that water-soluble antioxidants could provide active prevention against radicals generated from AAPH in the water phase in addition to passive prevention of the radicals generated at the oil-in-water interface of the emulsion droplets. This could explain

DOI: 10.1021/acs.jafc.5b02493
J. Agric. Food Chem. 2015, 63, 7546−7555

why the strong synergy was strongly observed in the CAT assay rather than the ApoCAT assay.

However, due to the complexity of antioxidant mechanisms, it is impossible to explain antioxidant interactions using a simple explanation. Several reports showed that antioxidant regeneration was one of the important mechanisms to obtain a strong antioxidant synergy. By principle, the primary antioxidant is regenerated by the secondary antioxidant based on differences in their reduction potentials. For instance, ascorbic acid is able to regenerate α-tocopherol, which is more active in the system.[23] In addition, several compounds were reported to exhibit some antioxidant interactions with α-tocopherol, such as β-carotene, amino acids, peptides, and phospholipids.[24−30]

J. Agric. Food Chem. 2015, 63, 7546−7555

importance because it reacts with electrophilic or oxidizing species before they interact with critical cellular constituents such as nucleic acids or proteins.[8] Gardiner et al.[9] reported that RNA profiling of DON-treated barley spikes showed strong up-regulation of gene transcripts encoding glutathione-*S*-transferases and cysteine synthases. Suggested structures for DON−GSH conjugates include addition of GSH on the double bond at C-9[3,9] and nucleophilic attack on the hydroxylated C-7 atom or at the carbonyl carbon at C-8.[9] Frühmann et al.[10] proposed that DON−GSH is broken down in planta, resulting in methylthiodeoxynivalenol as the final product. They synthesized methylthiodeoxynivalenol and showed that their product was a mixture of the C-8 hemiketal and ketone, produced via addition of thiourea to the double bond of DON.

Here we report studies using mercaptoethanol as a model thiol for reaction with DON and other trichothecenes to identify the reaction pathways for DON with thiols. We also show that the same pathways are important for reaction of DON with a wide variety of thiols including cysteine and glutathione. In contrast to earlier reports, we identified the epoxide group as an important target for thiol addition to DON.

MATERIALS AND METHODS

Chemicals and Reagents. HPLC grade water and acetonitrile were obtained from Thermo Fisher Scientific (Waltham, MA, USA). Ammonium formate (Fluka, puriss. p.a. for HPLC), deoxynivalenol (DON) (≥98%), lipopolysaccharide (LPS) from *Escherichia coli*, CD_3CN (99.95 atom % D), 5.0 mm Wilmad NMR tubes, sodium carbonate (pro analysis), 2-mercaptoethanol (≥99.0%), 2-aminoethanethiol (≥98%), sodium methanethiolate (technical grade (>90%)), sodium 2-mercaptoethanesulfonate (≥98%), L-cysteine (≥98%), and reduced L-glutathione (≥98%) were from Sigma-Aldrich (Steinheim, Germany). Phosphate-buffered saline (pH 7.3, 0.172 M) was prepared from ready-to-use tablets (Oxoid, Hampshire, UK). Sodium bicarbonate (pro analysis, Merck, Darmstadt, Germany) and sodium carbonate were used to prepare 0.2 M buffers at pH 9.2 and 10.7. Buffer pH was measured at ambient temperature with a Mettler Delta 320 pH meter. Solutions of T-2 tetraol (50.3 μg/mL) and de-epoxy-DON 50.5 μg/mL) in acetonitrile were from Biopure (Romer Laboratories, Tulln, Austria). Standards of norDON B and norDON C were provided by Institute of Food Chemistry, Münster, Germany. Alamar Blue and human TNF-α Cytoset were from Invitrogen (Life Technologies, Carlsbad, CA, USA), and human IL-1β/IL-1F2 Duoset was from R&D Systems (Minneapolis, MN, USA). RPMI 1640, culture medium, penicillin/streptomycin, fetal bovine serum (EU standard, FBS), and PBS were from Lonza (Verviers, Belgium). Phorbol-12-myristate-13-acetate (PMA) was from Calbiochem (La Jolla, CA, USA). Hydrogen peroxide (30%) was from Merck.

Reaction of Trichothecenes with Thiols. All reactions were conducted in 2 mL HPLC vials and monitored by LC-MS or LC-HRMS.

Procedure 1. Aliquots (0.33 μmol) of the stock solutions of DON, de-epoxy-DON, and T-2 tetraol in acetonitrile were evaporated under a stream of N_2 at 60 °C and dissolved in carbonate buffer (pH 10.7; 1.0 mL), and mercaptoethanol 0.5 μL (7.13 μmol) was then added. The vials were flushed with argon, sealed, and placed in the autosampler set to 25 °C. Reactions (together with thiol-free controls) were followed by LC-MS (method A1), half-hourly for the first 8 h and then at 1−2 day intervals thereafter for 1 month. The reaction of DON with mercaptoethanol was also carried out in buffer at pH 9.2 and 7.3.

Procedure 2a. Mercaptoethanol (10 μL, 142 μmol) was added to DON (1.0 mg, 3.3 μmol) in buffer (1 mL; pH 10.7), and the reaction was followed by LC-MS for ca. 3 weeks (method A1), by which time DON was absent and the peak intensity of **1a**/**1b** was equal to that of **2b** (Figure S1).

Procedure 2b. Mercaptoethanol (15 μL, 210 μmol) was added to DON (1.5 mg, 5.1 μmol) in buffer (1.5 mL; pH 10.7), and the reaction was followed by LC-MS for 14 days, by which time the peak intensities of **2a** and **2b** were about equal and dominated the chromatogram (Figure S2a).

Procedure 3. Solutions of other thiols (71.3 mM, 1 mL) (i.e., other than mercaptoethanol) in buffer (pH 10.7) were added to solid DON (100 μg, 0.33 μmol), and reactions were monitored by one or more LC-MS methods (methods A1, A2, B1, or B2) for 3 weeks.

Oxidation of 1a/1b. Hydrogen peroxide (30%, 50 μL) was added to an aliquot (150 μL) of the reaction mixture obtained from the procedure 1 containing **1a**/**1b**. Reaction was followed for 1 h, when **1a**/**1b** were no longer detectable.

LC-MS. HPLC was performed using an Atlantis T3 column (150 × 2.1 mm, 3 μm; Waters). The flow rate was 0.3 mL/min, and the injection volume was 1.5 μL. Mobile phase A was 5 mM ammonium formate in MeCN/water (19:1), and mobile phase B was aqueous ammonium formate (5 mM). Gradient 1: Separation was performed by elution with a linear gradient of 5−15% A over 15 min and then to 100% A at 20 min, with a 3 min hold followed by a return to 5% A with a 3 min hold to equilibrate the column. Gradient 2: This was identical to gradient 1 except that the gradient started and ended with 0.5% A (instead of 5% A). Gradient 3 was identical to gradient 1, apart from the mobile phase containing 2.5 mM ammonium formate and 2.5 mM formic acid.

Method A1. A Finnigan Surveyor HPLC system was used with gradient 1 and interfaced to an LTQ linear ion trap mass spectrometer (Thermo Fisher Scientific) operated in negative ionization full scan mode (m/z 180−600) and fitted with an electrospray ionization (ESI) interface. This method was used to monitor the reactions of DON, T-2 tetraol, and de-epoxy-DON with mercaptoethanol, as well as reactions of DON with sodium methanethiolate and sodium 2-mercaptoethanesulfonate. Capillary voltage and tube lens offset were tuned with continuous infusion of DON (10 μg/mL) in acetonitrile into a mobile phase composed of 10% A. The spray voltage was set to 3 kV, the sheath gas and auxiliary gas flow rates were 58 and 11 units, respectively, and the capillary temperature was 250 °C

The MS^n (n = 2−5) fragmentation of DON was studied using collision-induced dissociation in the ion trap by directly infusing 10 μg/mL DON in acetonitrile into a mobile phase composed of 10% A, via the instrument syringe pump (5 μL/min). The ESI settings were as described above. Individual precursor ions were selected with an isolation width of 2 m/z, the activation Q was set to 0.25, and the activation time was set to 30 ms. The collision energy was chosen such that the intensity of the precursor ion was <10% relative peak intensity. Product spectra were recorded for 30 s.

Method A2. Method A2 was performed as for method A1, except that gradient 2 was used for elution and the MS was run in positive mode for m/z 100−1000 in order to monitor the reaction of DON with 2-aminoethanethiol, glutathione, or cysteine.

Method B1. A Waters Acquity UPLC (Milford, MA, USA) used with gradient 1 was interfaced to a Q Exactive Fourier-transform high-resolution mass spectrometer (Thermo Fisher Scientific) and used for analysis of the products from the reactions of DON, T-2 tetraol, and de-epoxy-DON with mercaptoethanol and of DON with sodium methanethiolate and sodium 2-mercaptoethanesulfonate. A heated electrospray interface was used for ionization with a spray voltage of 3.8 kV and a temperature of 300 °C. The mass spectrometer was run in the negative full-scan mode in the mass range m/z 150−600. The mass resolution was set to 70000 at m/z 200. Other important interface parameters included a capillary temperature of 250 °C, a sheath gas flow rate of 55 units, and an auxiliary gas flow rate of 25 units.

For targeted MS/MS, $[M + HCOO]^-$ ions of mercaptoethanol derivatives were selected and subjected to higher energy collisional dissociation at a normalized collision energy of 35 eV. The resolution was set to 17500 at m/z 200, and the product ions were scanned in the mass range m/z 50−365, 50−445, or 50−525 (as appropriate).

Method B2. Method B2 was as described for method B1 except that gradient 2 was used for elution and the MS was run in positive mode

DOI: 10.1021/acs.jafc.5b02864
J. Agric. Food Chem. 2015, 63, 7556−7566

for m/z 100−1000 in order to monitor the reaction of DON with 2-aminoethanethiol, glutathione, or cysteine.

Method C. Preparative LC-MS was performed by injecting portions (150 μL) onto an Atlantis T3 column (250 × 10 mm, 5 μm; Waters). The column was eluted with a Shimadzu LC-20AD pump (Shimadzu Corp., Kyoto, Japan) at 3 mL/min. A portion of the column effluent (0.1%) was continuously split into an LCQ Fleet ion trap mass spectrometer (Thermo Fisher), whereas individual fractions containing target compounds were collected manually.

Purification of DON−Mercaptoethanol Derivatives. Reaction mixtures from pocedures 2A and 2B were fractionated on Strata-X SPE columns (500 mg; Phenomenex, Torrance, CA, USA). The SPE column was conditioned with methanol (10 mL) and then water (10 mL), and the reaction mixture was applied. The columns were eluted with 5 mL each of 0, 5, 10, 15, 20, 25, 40, and 50% MeOH in water and then finally with MeOH. The 40 and 50% MeOH fractions from procedure 2A contained **1a**/**1b** and **2a**/**2b** and were combined and evaporated to ca. 1 mL under a stream of N_2. The components were purified by preparative LC-MS (method C) using a linear gradient of water (A) and acetonitrile (B) (from 5 to 21% B over 17 min, then 100% B for 3 min, and finally to 5% B for 5 min to equilibrate the column), with **1a**/**1b** eluting at 14.5 min and **2a**/**2b** (ca. 1:5 by NMR) at 16.8 min.

When the mixture obtained from procedure 2B was chromatographed by SPE (as above), the 40% MeOH fraction contained **2a**/**2b**. This material was concentrated to 1 mL as above and purified by preparative LC-MS (method C) using isocratic elution with 21% MeCN in water, with **2a**/**2b** (ca. 1:1 by NMR) coeluting at 6.6 min (Figure S2b).

NMR Spectroscopy. 1-D (^{1}H, SELTOCSY, SELROESY, ^{13}C, JMOD, DEPT135) and 2-D (COSY, TOCSY, HSQC, HMBC, NOESY, ROESY) NMR experiments were conducted with Bruker Avance AV 600 MHz and AVII 600 MHz NMR spectrometers equipped with 5 mm CP-TCI (^{1}H/^{13}C, ^{15}N−^{2}H) triple-resonance inverse cryoprobes with *Z*-gradient coils. Compounds were dissolved in CD_3CN in 5.0 mm Wilmad NMR tubes. Data were recorded and processed using Bruker TOPSPIN (version 2.1 and 3.0) software, and chemical shifts, determined at 25 °C, are reported relative to internal CHD_2CN (1.96 ppm) and CD_3CN (118.26 ppm).[11]

Cell Culture and Treatments. The human acute monocyte leukemia cell line (THP-1) was obtained from the European collection of cell cultures (ECACC) and grown in RPMI 1640 supplemented with 10% heat-inactivated FBS, penicillin (100 U/mL), and streptomycin (100 μg/mL). The cells were cultured at 37 °C under 5% CO_2 in a humidified incubator and kept in a logarithmic growth phase at (5−15) × 10^5 cells/mL through routine subculturing, according to standard ECACC protocol. The passage number was kept below 20. DON and its derivatives were dissolved in PBS and applied to the cells at a final concentration of 4 μM.

Proliferation. THP-1 cells (monocytes) were seeded at 150,000 cells/cm^2 and, following exposure to DON and the conjugates, the metabolic activity of the cells was measured using the Alamar Blue assay according to the manufacturer's protocol. The dark blue oxidized form of Alamar Blue is reduced to a highly fluorescent form in functional mitochondria,[12] and the measured fluorescence intensity is thus proportional to the number of viable cells. The fluorescence (585 nm) was quantified using a VICTOR^2 Multilabel Counter (PerkinElmer, Boston, MA, USA).

Cytokine Measurement, ELISA. Secreted cytokines were measured with an enzyme-linked immunosorbent assay (ELISA). THP-1 cells were seeded at 260,000/cm^2 and differentiated into macrophages by treatment with PMA (50 ng/mL) for 24 h. The medium was then replaced, and the cells were rested for 24 h before exposure. The cells were then treated with LPS (0.05 ng/mL) for 3 h, followed by toxin exposure for an additional 24 h. The medium was harvested and centrifuged (500*g*, 4 °C, 10 min) to remove cell debris. Levels of TNF-α and IL-1β in supernatants were measured by ELISA, using human TNF-α Cytoset or human IL-1β/IL-1F2 Duoset, respectively, according to the manufacturers' guidelines. The absorbances were measured using a plate reader (TECAN Sunrise, Phoenix Research Products, Hayward, CA, USA) equipped with analyzing software (Magellan VI).

Statistical Analysis. Data analyses were performed using Sigma Plot version 13.0. Statistical significance ($p < 0.05$) was assessed using one-way-ANOVA, followed by Dunnett's post-test.

RESULTS AND DISCUSSION

Reaction of DON, De-epoxy-DON, and T-2 tetraol with Mercaptoethanol. Initial experiments followed the reaction of DON using LC-MS (method A1, gradient 3) for up to 1 month, with mercaptoethanol as a model thiol under neutral and weakly basic conditions (procedure 1). Mercaptoethanol was used because it was expected to produce DON derivatives with retention times and ionization properties similar to those of DON itself, thereby facilitating monitoring of the reaction and its products by LC-MS. At pH 10.7 there was rapid formation of **1d** and **1e** (Figure 2) with a mass difference of 78 Da relative to the formate adduct of DON, corresponding to a single addition of mercaptoethanol. The broad peak observed for **1e** was suspected to be caused by the presence of formic acid in gradient 3; however, use of a neutral eluent (gradient 1) did not appreciably sharpen this peak. After 30 min, peaks corresponding to **1a**/**1b** (not resolved) and **1c** were also detected with the same m/z (Figure 2), along with **2a** and **2b** (Figure 2) exhibiting a mass difference of 156 Da

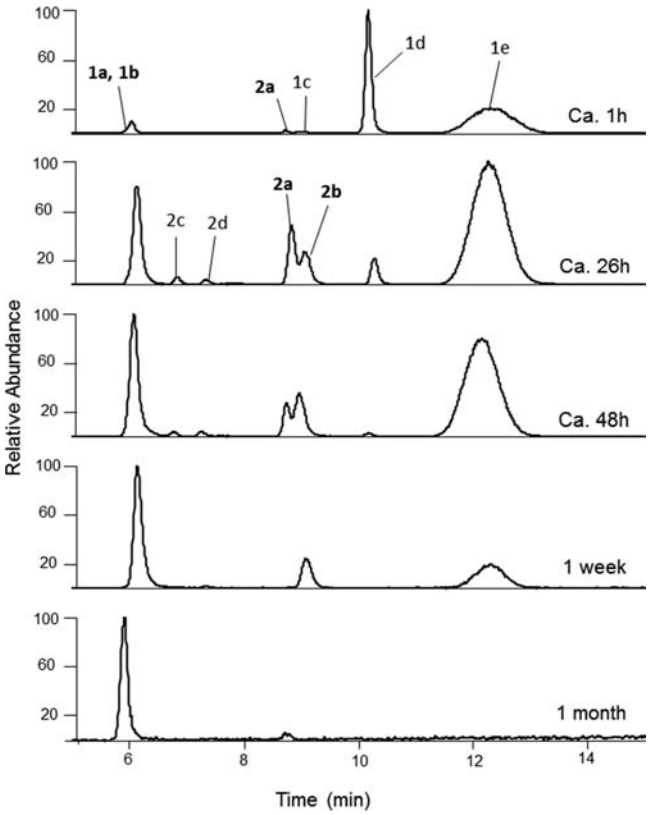

Figure 2. LC-MS extracted ion chromatograms (m/z 419 + m/z 497) from the reaction of DON with mercaptoethanol (method A1, pH 10.7, 25 °C). Adduct peaks are annotated 1 (m/z 419) or 2 (m/z 497) to indicate the number of mercaptoethanol units adducted to DON and with lower case letters then used to indicate separate peaks. Peaks labeled with bold text refer to adducts with structures determined by NMR spectroscopy (Figure 4). Note, a small drift in retention time occurred toward the end of the study.

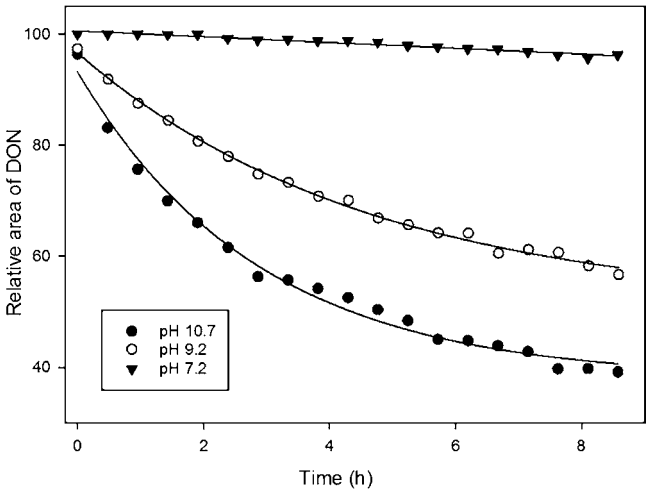

Figure 3. Change in the concentration of DON (measured by LC-MS, as a percentage of the total concentration of DON derivatives) with time upon treatment with mercaptoethanol at 30 °C at selected pH values. Lines show data fitted to exponential decay curves (pseudo-first-order kinetics).

relative to DON (corresponding to the addition of two molecules of mercaptoethanol). The ratios of these peaks continued to change over time, with **1a**/**1b** becoming more prevalent until they were the only compounds remaining in the mixture. Initially, four peaks corresponding to addition of two molecules of mercaptoethanol were detected, but **2c** and **2d** were minor and were no longer detectable after 1 week. Products **2a** and **2b** were the prominent double-addition conjugates, but **2a** disappeared in less than a week, leaving **2b** as the most prominent double-addition conjugate. However, **2b** also slowly disappeared with time, so that after 1 month the major peak was from **1a**/**1b**. The intensity of the LC-MS peak from DON gradually decreased as the reaction progressed (Figure 3) and was no longer detectable after 3 weeks.

We anticipated that thiol addition was most likely to occur reversibly at the C-10 carbon of the α,β-unsaturated ketone in DON and irreversibly at the epoxy group in DON. To test this hypothesis, we compared the reactions of DON, T-2 tetraol, and de-epoxy-DON with mercaptoethanol (Figure S17). In T-2 tetraol the C-8 carbon is hydroxylated, resulting in a 9,10-double bond that is not conjugated, whereas in de-epoxy-DON the epoxide ring has been reduced to an olefinic methylene (Figure 1). The reaction of T-2 tetraol was followed for 10 days by LC-MS (method A1), during which time just one new, later-eluting peak appeared, corresponding to addition of one mercaptoethanol molecule. LC-HRMS analysis (method B1) of this peak revealed it had m/z 421.1541, corresponding to $C_{18}H_{29}O_9S^-$ ([T-2 tetraol + HSEtOH + HCOO]$^-$, Δ 0.9 ppm) (Figures S3). Similarly, the reaction mixture containing de-epoxy-DON gave in total four peaks with m/z 403.1437−403.1443 corresponding to $C_{18}H_{27}O_8S^-$ ([de-epoxy-DON + HSEtOH + HCOO]$^-$, Δ 1.2−2.9 ppm). After 10 h of reaction, an earlier-eluting peak had almost the same intensity as de-epoxy-DON, whereas a later-eluting peak was higher in intensity (Figure S4a), and two other peaks had very low intensities. After 10 days, analysis revealed de-epoxy-DON was the most intense peak, with the later-eluting mercaptoethanol adduct now having an intensity 4 times lower than that of de-epoxy-DON (Figure S4b), indicating reversibility of the reaction. In contrast, reanalysis of the T-2 tetraol reaction after 10 days revealed the same two peaks as detected early in the reaction, but with the mercaptoethanol adduct having increased in intensity relative to T-2 tetraol. No double adducts of mercaptoethanol with de-epoxy-DON or T-2 tetraol were detectable at any stage of the reactions. These observations are consistent with reversible Michael addition of thiols to the conjugated double bond in type B trichothecenes and a slower irreversible addition of thiols to C-13 on the 12,13-epoxy group of trichothecenes (Figures 11 and S17).

These results suggested that **1c**, **1d**, and **1e** were products from Michael addition of mercaptoethanol to the 9,10-double bond of DON, whereas the relatively early eluting **1a**/**1b** was attributable to addition of mercaptoethanol to the epoxy group in DON.

During the reaction of DON with mercaptoethanol under basic conditions, several minor products with masses similar to that of DON were detected by LC-HRMS. The same products were also observed in thiol-free control samples, and these appeared to be identical to those reported earlier by Bretz et al.,[13] thought to be products from degradation of DON under basic conditions. Two of the degradation products, norDON B and norDON C,[13] were confirmed in the DON−mercaptoethanol reaction mixtures using authentic standards. Because these DON degradation reactions compete with the thiol addition, higher concentrations of thiols were used in the semipreparative reactions to reduce the reaction time and thereby minimize the effect of the degradation reactions.

Minor peaks affording ions with a 16 Da higher mass (m/z 435), relative to the DON−mercaptoethanol adducts, were also detected during the reaction, suggesting the presence of sulfoxide derivatives. Addition of H_2O_2 to an aliquot of a reaction mixture containing **1a**/**1b** resulted in rapid oxidation, affording products with the same masses and retention times as the putative sulfoxide derivatives (Figure S5). This indicates that m/z 435 peaks are due to the sulfoxides of thiol adducts **1a**/**1b**. Similar autoxidation was also seen with DON derivatives of the other thiols including cysteine or glutathione. Purified DON conjugates were therefore stored under argon to minimize the autoxidation.

Preparative Synthesis and Purification. DON and mercaptoethanol were reacted on a semipreparative scale to identify the major products. Two reactions were followed by LC-MS: one was stopped by SPE when almost equal ratios of **1a**/**1b** and **2b** were present (procedure 2a) and the other when the ratios of **2a** and **2b** were identical (procedure 2b). Fractionation of the reaction mixtures by SPE followed by semipreparative LC-MS afforded pure mixtures of **1a** together with **1b** and of **2a** together with **2b**.

Structural Elucidation. NMR structural elucidation of major products was done on mixtures of **1a** and **1b**, and of **2a** and **2b**, in CD_3CN, with DON used for spectral comparison. LC-HRMS showed a single peak for **1a**/**1b**, with m/z 419.1383 consistent with $C_{18}H_{27}O_9^-$ (DON + HSEtOH + HCOO]$^-$), indicating the addition of one molecule of mercaptoethanol to DON. However, NMR spectroscopy revealed the presence of two isomeric compounds (Table 1) in a ratio of 5:1. Three of the most diagnostic pairs of signals were methyl singlets at 1.27 and 1.24 ppm (H-14), methyl triplets at 1.74 and 1.81 ppm (H-16), and signals due to olefinic protons (both doublets of quartets) at 5.35 and 6.44 ppm (H-10). The presence of an olefinic proton in **1a** and **1b** indicated the presence of a double bond and thus showed that mercaptoethanol had not been added to C-10.

[a]In the format: chemical shift in ppm (multiplicity, coupling constants in Hz). [b]Orientation of the protons was distinguishable (except for H-15 of DON and **1b**), and they are presented in the order α-H and β-H. [c]Resonance hidden under solvent signal. [d]Coupling constant measured from the HSQC spectra. [e]Shifts to two decimal places due to very close, but distinguishable resonances. [f]Coupling constants measured from TOCSY spectra. [g]ND, not detected.

Examination of the COSY and TOCSY spectra of the major isomer (**1a**) revealed a number of relatively short spin systems corresponding to H-16/H-10/H-11, H-2/H-3/3-OH/H-4α/H-4β/H-14, H-13a/H-13b, H-7/7-OH, H-15α/H-15β, and H-1′/H-2′/2-OH. The corresponding protonated carbon resonances were assigned from HSQC correlations, and connections between spin systems were established via correlations observed in HMBC spectra. Of particular note were HMBC correlations from the methyl triplet at 1.74 ppm (H-16) to 104.7 (C-8), 142.4 (C-9), and 122.9 (C-10) ppm and from H-15α/H-15β (3.31 and 4.09 ppm) to 104.7 (C-8), 77.7 (C-7), 50.8 (C-5), and 51.8 ppm (C-6). The latter established **1a** as a C-8 hemiketal derivative generated by intramolecular addition of the oxygen atom on C-15 to the C-8 carbonyl. Furthermore, correlations observed in the HMBC spectra from H-13a/H-13b (2.99/3.55 ppm) and C-1′ (37.0 ppm) and between H-1′ (2.71 ppm) and C-13 (36.3 ppm), showed attachment of the mercaptoethanol moiety at C-13 as a result of nucleophilic attack on the epoxy group of DON.

Examination of the corresponding spectra of the minor component (**1b**) revealed similar spin systems and correlations. Notable differences from **1a** included the presence in **1b** of HMBC correlations of the methyl protons at 1.81 ppm (H-16) to carbon signals at 200.7 (C-8), 134.9 (C-9), and 139.7 (C-10) ppm (Figure S6). Also, the COSY/TOCSY spectra of **1b** included a spin system corresponding to H-15α/H-15β/15-OH. The multiplicity of the signals from the H-15 resonances in **1b** (doublet of doublets) was consistent with ^{3}J coupling to the 15-OH proton, in contrast to **1a**, where H-15 resonances were observed as a pair of doublets due to the absence of a 15-OH. These results revealed the minor component (**1b**) to be the ketone analogue of **1a** (Figure 4). These observations are in accord with the known keto−hemiketal equilibration of type-B

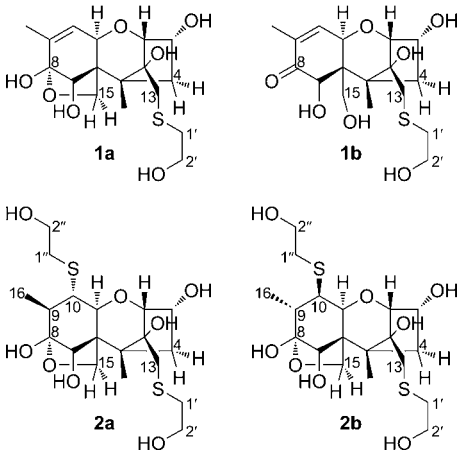

Figure 4. Structures of the major products purified from the reaction of DON with mercaptoethanol. **1a** and **1b** are the ketone and hemiketal pair resulting from addition of mercaptoethanol to the epoxide ring of DON, whereas **2a** and **2b** are a pair of diastereoisomers of the hemiketal form of adducts of mercaptoethanol to both the double bond and the epoxide ring of DON.

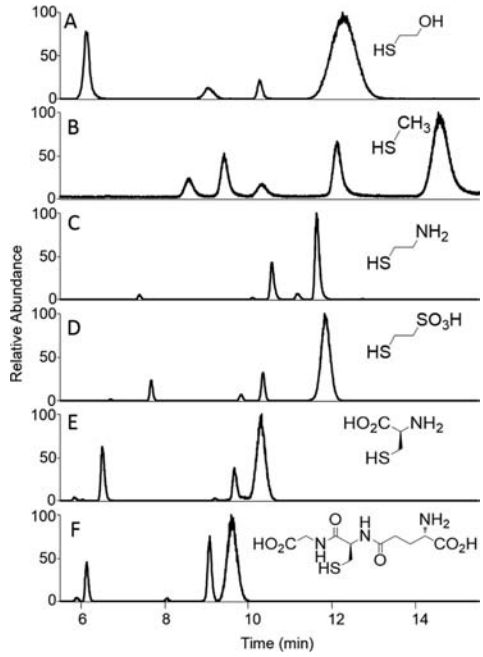

Figure 6. Extracted ion LC-MS chromatograms at the specified value of m/z for monoadducts of DON after reaction with various thiols at pH 10.7: (A) mercaptoethanol at 24 h, m/z 419.1381 ($[DON + HSCH_2CH_2OH + HCOO]^-$), negative ion mode; (B) sodium methanethiolate at 7 h, m/z 389 ($[DON + HSCH_3 + HCOO]^-$), negative ion mode; (C) 2-aminoethanethiol at 6 h, m/z 374.1632 ($[DON + HSCH_2CH_2NH_3]^+$), positive ion mode; (D) sodium 2-mercaptoethanesulfonate at 18 h, m/z 437.0945 ($[DON + HSCH_2CH_2SO_3]^-$), negative ion mode; (E) cysteine at 46 h, m/z 418.1530 ($[DON + CYS + H]^+$), positive ion mode; (F) glutathione at 48 h, m/z 604.2171 ($[DON + GSH + H]^+$), positive ion mode.

trichothecenes,[14] with the hemiketal form appearing to be favored by derivatization of the 9,10-olefinic group.[5,10,15]

Compounds **2a** and **2b** were isolated twice as a mixture, once in an approximate 1:1 ratio and once in a 1:5 ratio, which facilitated identification of NMR signals associated with the two components (Figure S7). LC-HRMS showed that **2a** and **2b** afforded ions with m/z 497.1524 and 497.1523, respectively, corresponding to $C_{20}H_{33}O_{10}S_2^-$ (Δ 0.7 and 0.6 ppm, respectively), consistent with the addition of two mercaptoethanol molecules to DON (i.e., $[DON + (HSEtOH)_2 + HCOO]^-$). The COSY, TOCSY, and SELTOCSY NMR spectra were used to identify spin systems corresponding to H-16/H-9/H-10/H-11, H-2/H-3/3-OH/H4α/H-4β/H-14, H-15α/H-15β, H-7/7-OH, H-13a/H-13b, H-1′/H-2′/2′-OH, and H-1a″/H-1b″/H-2″/2″-OH for both **2a** and **2b**. Protonated carbon resonances were assigned from correlations in HSQC spectra, whereas HMBC correlations were used to assign nonprotonated carbon resonances and to connect the spin systems. Correlations observed in the ROESY and SELROESY spectra established the relative stereochemistries in **2a** and **2b**. In contrast to **1a**/**1b** and DON, the NMR spectra of **2a** and **2b** lacked resonances attributable to olefinic protons or carbons, indicating thiol addition to C-10 in **2a** and **2b**. Consistent with this, the H-16 methyl resonances of **2a** and **2b** were shifted upfield relative to DON and **1a**/**1b** and appeared as doublets (J = 7 Hz), indicating the presence of a proton at C-9. The H-9 signal in **2a** and **2b** was further coupled (COSY) to H-10 as well as to the H-16 methyl, establishing that addition of a mercaptoethanol molecule had occurred at C-10 (Michael

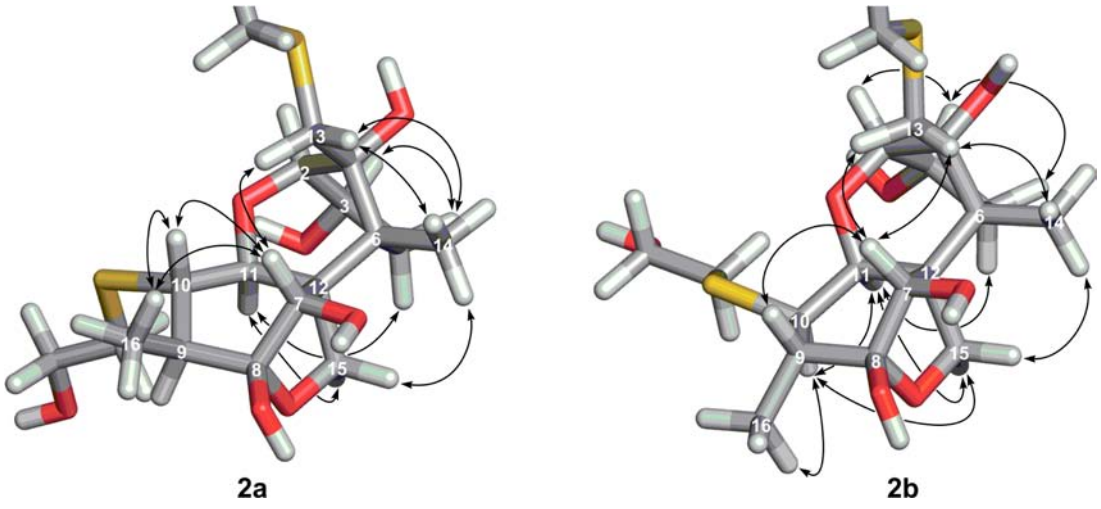

Figure 5. 3D models of **2a** and **2b**, showing selected structurally significant correlations (arrows) observed in ROESY and SELROESY NMR spectra.

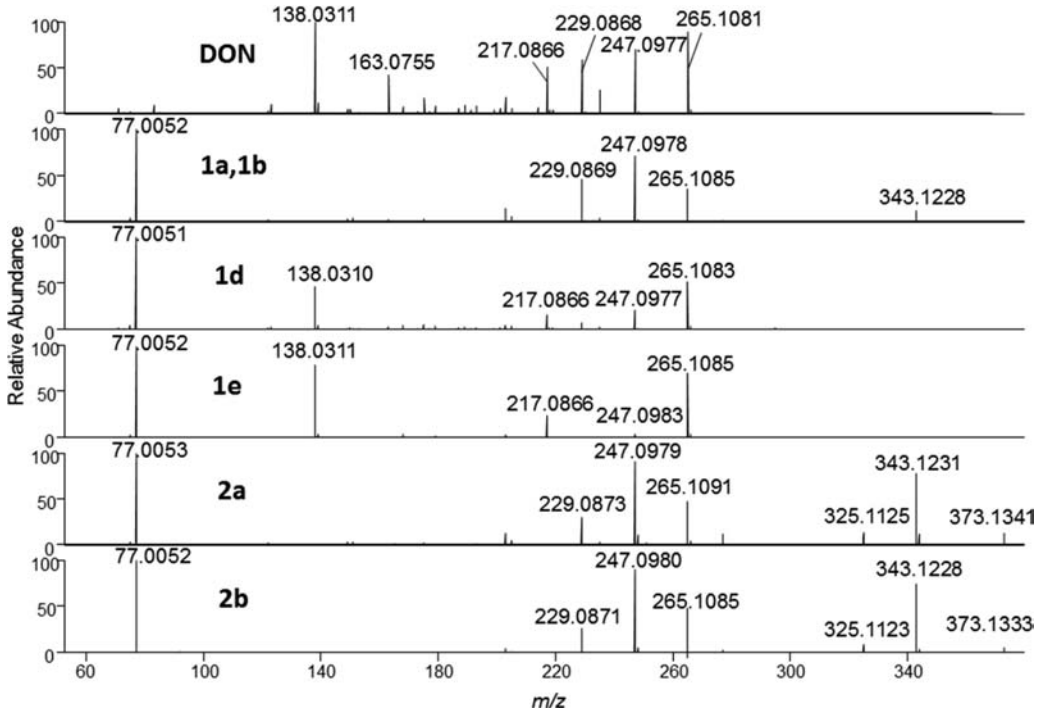

Figure 7. Product ion mass spectra from LC-HRMS^2 of the formate adduct ions of DON and its mercaptoethanol derivatives **1a**/**1b** (derivatized at the epoxide), **1d** and **1e** (Michael addition at C-10) and **2a** and **2b** (both epoxide and Michael addition). The prominent ion at *m*/*z* 77.0052 appears to correspond to $HOCH_2CH_2S^-$ (Δ 19 ppm) and is present in the spectra of all mercaptoethanol adducts regardless of the position of attachment of the thiol.

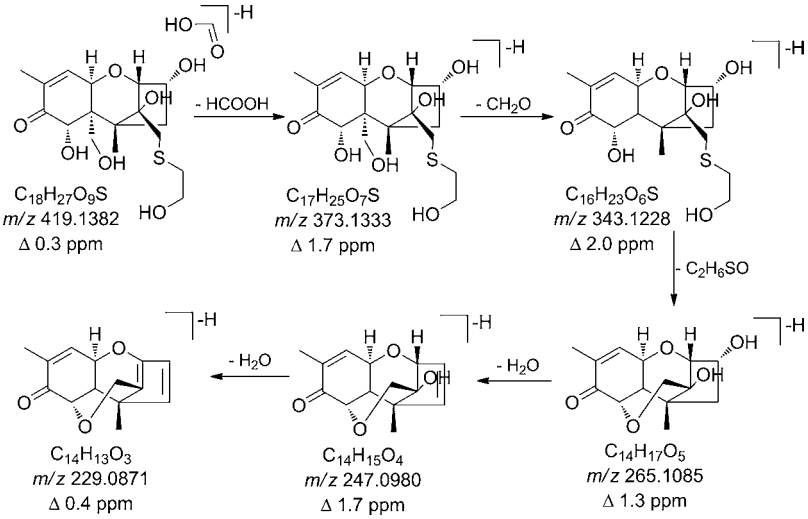

Figure 8. Possible negative ion mass spectral fragmentation pathway for mercaptoethanol adducts of the epoxide group of DON. The *m*/*z* values were measured by LC-HRMS.

addition) of DON. This conclusion was supported by HMBC correlations observed between H-10 (2.41/2.77 ppm) and both C-16 (17.4/13.3 ppm) and C-1″ (35.6/35.1 ppm) (Figure S8). No carbonyl resonances were observed in the ^{13}C, JMOD, or HMBC spectra of **2a** and **2b**. However, the HMBC spectra showed that both H-16 (1.13/1.12 ppm) and H-15 (3.51/4.11 and 3.49/4.16) correlated with a hemiketal carbon (C-8, 107.7/106.6 ppm) for both **2a** and **2b**. Furthermore, the H-15 doublets showed no TOCSY correlations to a 15-OH, indicating that **2a** and **2b** were both hemiketals (Figure 4). Correlations from H-13a (2.94/3.09 ppm) to C-2 (80.9/83.1 ppm), C-12 (81.6/81.3 ppm), C-5 (50.4/51.0 ppm), and C-1′ 36.8/37.1 ppm) confirmed the presence of a mercaptoethanol moiety at C-13 of **2a** and **2b**. Thus, **2a** and **2b** have the same skeleton and differ only in their stereochemistries at C-9 and C-10, which is reflected in the differing ^3J coupling constants for this spin system (Table 1). The stereochemistries at C-9 and C-10 were established from ROESY (Figure S9) and SELROESY NMR experiments (Figure 5). For **2a**, the ROESY spectra showed correlations between H-7 and both H-16 (not observed for **2b**) and H-10, locating H-10 and the 16-methyl together with H-7 on the β-face of the molecule. In the case of **2b**, however, H-7 showed a ROESY correlation to H-9, whereas H-10 showed ROESY correlations to H-11, H-15α (3.49 ppm),

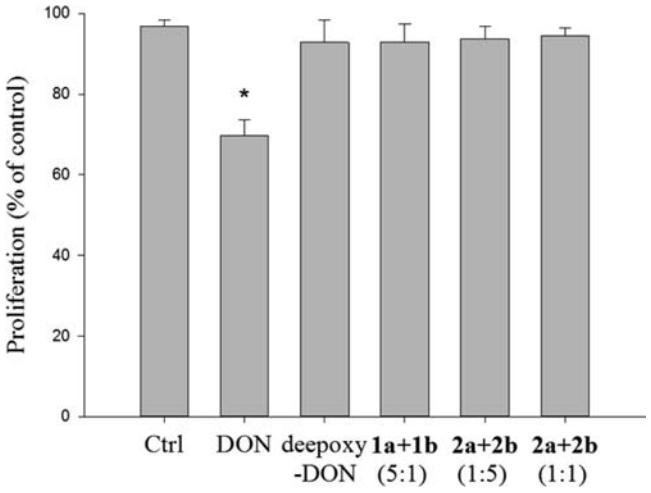

Figure 9. Proliferation of THP-1 cells after treatment with 4 μM DON or its derivatives for 24 h, measured with Alamar Blue. Data represent mean ± SD of three independent experiments. (*) Significantly different from control (one-way-ANOVA with Dunnett's post-test, $p < 0.05$). Two samples with different ratios of **2a** and **2b** were tested.

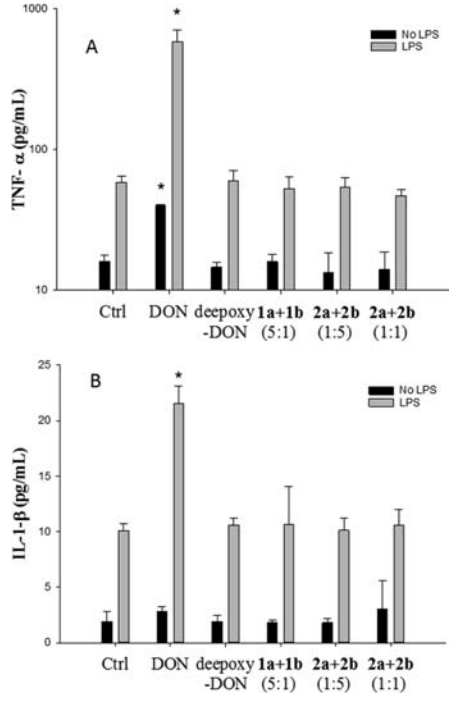

Figure 10. Cytokine secretion measured by ELISA in THP-1 cells treated for 3 h with LPS (0.05 ng/mL) followed by treatment with DON and its derivatives (4 μM) for 24 h. Data represent the mean ± SD of three independent incubations. (*) Significantly different from control (one-way-ANOVA with Dunnett's post-test, $p < 0.05$). Two samples with different ratios of **2a** and **2b** were tested.

and H-16. This locates H-10 and the 16-methyl group on the α-face and H-9 on the β-face of **2b**. This situation places the 16-methyl and mercaptoethanol substituents attached at C-9 and C-10, respectively, equatorially on the ring in both **2a** and **2b** (Figures 5 and Figure S10) and would be expected to result in the least steric crowding in this region of these molecules. Thus, **2a** and **2b** have the structures shown in Figure 4.

Reaction of DON with Other Thiols. A set of experiments was carried out to see if DON reacted similarly with other thiols, including the biologically relevant amino acid cysteine and the tripeptide glutathione. Reactions were monitored for 1 week by LC-MS (Figure 6) and the chromatograms all showed peaks corresponding to the addition of a single thiol molecule to DON. The chromatograms displayed patterns of broad and sharp, later- and earlier-eluting peaks similar to those observed from the mercaptoethanol reaction (Figure 2). A wider array of thiol addition products formed in a shorter time for the reactions with smaller thiols, presumably as a consequence of reduced steric hindrance. Double conjugates were also present in all of the reaction mixtures (Figure S11). When mixtures were analyzed after aproximately 45 days at room temperature, there was only one early-eluting peak present having a mass that corresponded to addition of a single thiol (data not shown) believed to be analogous to the identified **1a**/**1b** epoxide adducts in the DON−mercaptoethanol reaction.

LC-HRMS and LC-MS^n. We studied the MS characteristics and fragmentation patterns of DON and its mercaptoethanol derivatives using LC-HRMS and LC-HRMS^2 as well as multiple-stage ion trap LC-MS^n. Upon electrospray ionization in the negative ion mode, **1a**−**1e** afforded formate adducts with m/z 419.1382−419.1384, corresponding to an elemental composition of $C_{18}H_{27}O_9S^-$ (Δ 0.3−0.5 ppm), whereas **2a**−**2d** afforded formate adducts with m/z 497.1523−497.1524 corresponding to an elemental composition of $C_{20}H_{33}O_{10}S_2^-$ (Δ 0.5−0.7 ppm). The formate adducts of **1a**/**b**, **1d**/**1e**, and **2a** and **2b** showed different fragmentation patterns during LC-HRMS^2 (Figure 7), attributable to different fragmentation pathways for the epoxide conjugates and Michael addition products, potentially allowing the two types of addition products to be distinguished by MS alone. To understand these differences, the fragmentation spectra of the mercaptoethanol adducts were compared to those of DON (Figure 7). The fragmentation pathways of DON were studied in more detail by multiple-stage ion trap MS^n (Figure S12). Fragmentation of the deprotonated molecular ions of DON (m/z 295), obtained from collision-induced MS^2 fragmentation of the corresponding formate adduct (m/z 341), primarily yielded m/z 265 (loss of CH_2O). Further fragmentation of m/z 265 (MS^4) yielded m/z 247 (loss of H_2O), m/z 217 (loss of H_2O and CH_2O), and m/z 138 as the most abundant product ions. The two losses of CH_2O during MS fragmentation of DON are attributable to cleavage of the CH_2OH side chain at C-6 and cleavage of the epoxide, as proposed previously.[16] The m/z 138 fragment appears to be a rare radical anion and has earlier been suggested to be the result of cleavage through the B-ring of the molecule.[16] An m/z 138.0311 product ion was present in the LC-HRMS^2 spectra of the DON, **1d** and **1e**, but not in compounds where mercaptoethanol was known to be added to the epoxy group (**1a**/**1b**, **2a**, and **2b**) (Figure 7). Additionally, HRMS^2 analysis of de-epoxy-DON did not reveal the presence of a m/z 138.0311 fragment (Figure S13). The foregoing information suggests that the formation of the m/z 138 fragment ion is associated with the presence of an intact 12,13-epoxy group, and **1d** and **1e** are thus suspected to be Michael adducts of mercaptoethanol at C-10 of DON. Another diagnostic feature that may assist in distinguishing between a Michael addition product and a reaction product from monoaddition of mercaptoethanol to the epoxy group is the presence of an m/z 343.1228 product ion ($C_{16}H_{23}O_6S^-$, Δ 2.9 ppm) in the LC-HRMS^2 spectra of the epoxide conjugates (Figure 7). These ions are formed by loss of formate and of CH_2O, presumably from the C-6 position of the molecular ion.

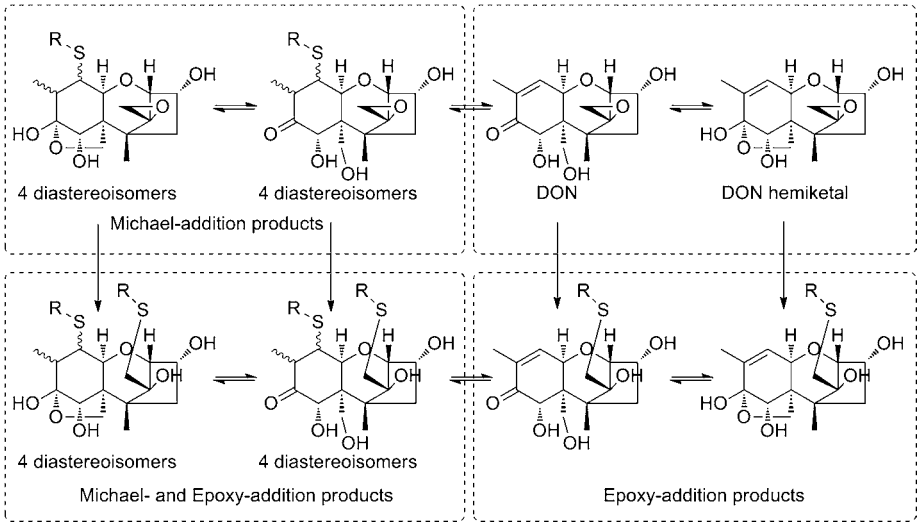

Figure 11. Generalized scheme showing proposed reaction of DON with a thiol (RSH) under basic conditions, as well as hemiketal−ketone equilibration at C-8.

In the LC-MS^n spectra, fragmentation of m/z 343 (MS^4) afforded m/z 265 (loss of 78 Da, corresponding to the mass of mercaptoethanol), m/z 247 (additional loss of H_2O), and m/z 229 (further loss of H_2O). Formation of the m/z 265 ion could occur via linkage of the 7-OH group and C-13 during the mercaptoethanol elimination to form a six-membered ring (Figure 8).

Cellular Effects. DON is able to cause cellular effects, such as inflammation and toxicity, through its ability to target ribosomes and to cause ribotoxic stress.[17] Because de-epoxy-DON does not affect ribosomes, it has been proposed that the 12,13-epoxy group is critical for DON's action on ribosomes.[17] To compare the effects of DON, de-epoxy-DON, and mercaptoethanol derivatives **1a**/**1b** and **2a**/**2b** on proliferation of THP-1 monocytes, we used the Alamar Blue assay, as previous studies[18] showed toxicity of DON with Alamar Blue in different cell lines. THP-1 cells were treated with DON, de-epoxy-DON, and purified mixtures of **1a**/**1b** and **2a**/**2b** for 24 h. DON decreased the proliferation of THP-1 monocytes, but de-epoxy-DON and DON−mercaptoethanol adducts **1a**/**1b** and **2a**/**2b** did not (Figure 9). These results support the epoxide moiety as an important structural feature for the toxicity of DON.

DON induces the expression of several pro-inflammatory cytokines, such as TNFα, IL-1b, IL-6, and IL-8,[19] and pretreatment (i.e., priming) with LPS potentiates this effect.[20,21] To examine pro-inflamatory responses induced by DON, de-epoxy-DON, and mercaptoethanol derivatives **1a**/**1b** and **2a**/**2b**, we analyzed the levels of TNF-α and IL-1β secretion by PMA-differentiated macrophages, with and without LPS priming. Regardless of the absence or presence of LPS, there was an increase in TNF-α in response to DON, but not to any of the derivatives (Figure 10A), although the sensitivity was higher with LPS present. Similarly, DON increased the release of IL-1β in LPS-primed cells, whereas de-epoxy-DON, **1a**/**1b**, and **2a**/**2b** did not (Figure 10B), although cells that were not treated with LPS did not show an IL-1β response to any of the compounds, including DON.

Thus, DON, but not de-epoxy-DON or mercaptoethanol derivatives **1a**/**1b** and **2a**/**2b**, reduced proliferation of THP-1 monocytes and induced pro-inflammatory responses in PMA-differentiated LPS-primed THP-1 macrophages. The lack of toxic responses to **1a**/**1b** and **2a**/**2b** (both of which involve derivatization of the 12,13-epoxy group of DON) supports the involvement of the epoxy group in the toxicity of trichothecenes—a hypothesis hitherto based solely on observations with de-epoxy-DON. Whereas all of the mecaptoethanol adducts isolated in the present study were derivatized at C-13 of the epoxy group of DON and were nontoxic, previous studies[22,23,10] have also demonstrated reduced toxicity for Michael addition products of DON.

Effect of pH on Reaction Rate. DON and mercaptoethanol were reacted at pH 7.3, 9.2, and 10.7, and the reaction was monitored by LC-MS. Neither DON nor mercaptoethanol contain acidic or basic groups, so DON and its mercaptoethanol derivatives can be expected to have similar responses in LC-MS. This makes it possible to estimate the proportions of DON and its reaction products by integrating areas under the peaks in the LC-MS chromatograms. We used a large excess of the thiol and observed pseudo-first-order reaction kinetics and followed the depletion of DON by plotting the relative peak area over time (Figure 3). However, the reaction kinetics are expected to be more complex, with several reversible reaction equilibria including Michael addition of the thiol to the double bond and hemiketal−ketone exchange (Figure 11). Furthermore, autoxidation of the thiol to form the disulfide can be expected to reduce the thiol concentration over time. Therefore, the reaction of DON with mercaptoethanol displayed pseudo-first-order kinetics only for the first few hours. Nevertheless, a dramatic increase in reaction rate was observed when the pH was increased from 7.2 to 9.2, with a further increase when the pH was increased to 10.7. These observations support nucleophilic attack by the thiolate ion as the dominant reaction mechanism, as the pK_a of mercaptoethanol has been reported to be approximately 9.7.[24] Regardless of the pH, there was always the same progression in the formation of the reaction products, as shown in Figure 2, and even at physiological pH adducts **1d** and **1e** appeared first. Attack of thiolate on the 12,13-epoxy group is expected to be essentially irreversible, whereas thiolate attack on C-10 of DON (Michael addition) should be reversible. In contrast, attack of thiolate on the isolated double bond in DON hemiketal is not expected, and

J. Agric. Food Chem. 2015, 63, 7556−7566

isomerization of the thia-Michael addition products of DON to their hemiketal forms should hinder the elimination of thiol from C-10. The reaction scheme shown in Figure 11 thus accounts for the products identified in the reaction and, together with the well-known autoxidation of thiols to disulfides,[25] for the presence of only epoxy adducts **1a** and **1b** at extended reaction times. The late-eluting broad peak in the LC-MS analyses (Figures 2 and 6) may be due to on-column ketone−hemiketal isomerization, as this peak partially resolved when the mercaptoethanol addition products of DON were analyzed without the presence of formic acid in the mobile phase (data not shown).

Thus, DON and other trichothecenes have been shown to react with several natural and synthetic thiolates via Michael addition to C-10 of the α,β-unsaturated ketone and addition to C-13 of the 12,13-epoxy group. These reactions occurred rapidly in weakly basic conditions, but proceeded even at physiological pH, and could potentially result in the formation of adducts with cysteine-containing proteins or peptides even in the absence of enzymatic catalysis. None of the products from the reaction of DON with mercaptoethanol in which the thiol had been conjugated with the epoxy group showed any signs of toxicity in vitro.

MS) without derivatization has also been reported on a variety of stationary phases, such as reversed phase,[34−36] hydrophilic interaction chromatography (HILIC),[37−39] mixed-mode,[40] and ion exchange.[41] Only a handful of these published methods have employed a stable isotope-labeled analogue of leucine for quantitative analysis, and of those which did, none has achieved satisfactory chromatographic separation between the isobaric amino acids leucine and isoleucine.[40−42]

The work described herein reports the development and validation of a new, direct, quantitative, and confirmatory analytical method based on LC−MS without derivatization for the analysis of HMB, KIC, HICA, and free leucine in human breast milk. The applicability of the developed method was demonstrated by carrying out (for the first time) a mini-survey of the presence and abundance of these four analytes in human breast milk, collected at various stages of lactation.

MATERIALS AND METHODS

Safety. Methanol and formic acid should be dispensed in a hood, and appropriate laboratory safety glasses, coat, and gloves should be worn.

Chemicals and Reagents. L-Leucine (≥99.5%), L-leucine-5,5,5-d_3 (99 atom % D), L-isoleucine (pure), *trans*-4-hydroxy-L-proline (≥99%), α-ketoisocaproic acid (also known as 4-methyl-2-oxovaleric acid or 2-keto-4-methylpentanoic acid) (≥98% by titration), α-hydroxyisocaproic acid (also known as 2-hydroxyisocaproic acid) (99%), and formic acid (≥96%) were purchased from Sigma-Aldrich Corp. (St. Louis, MO). Calcium β-hydroxy-β-methylbutyrate monohydrate (≥99.5%) was supplied by Lonza Group (Basel, Switzerland). 3,4-Methyl-$^{13}C_3$-3-hydroxyisovaleric acid (99% purity, 99 atom % ^{13}C) was purchased from Cambridge Isotope Laboratories, Inc. (Andover, MA). Sodium 2-keto-4-methyl-d_3-pentanoate (99 atom % D) was purchased from CDN Isotopes (Pointe-Claire, Quebec, Canada). Methanol (LC−MS grade) was purchased from Fisher Scientific (Fair Lawn, NJ). Laboratory deionized water was purified through a Milli-Q (EMD Milipore, Millerica, MA) water purification system.

Stock Solutions and Calibration Standards. Individual stock solutions of HMB and 2-keto-4-methyl-d_3-pentanoic acid (KIC-d_3) were prepared at concentrations of ca. 1000 mg/L by dissolving the corresponding calcium and sodium salts, respectively, in 0.1% formic acid. Individual stock solutions of L-leucine (leucine), L-leucine-5,5,5-d_3 (leucine-d_3), 3,4-methyl-$^{13}C_3$-3-hydroxyisovaleric acid ($^{13}C_3$-HMB), KIC, and HICA were prepared at concentrations of ca. 1000 mg/L in Milli-Q water. Stock solutions were prepared fresh every 30 days and were determined to be stable when stored at +5 °C during this time period.

An intermediate stock solution containing 2 mg/L HMB, 2 mg/L KIC, 1 mg/L HICA, and 10 mg/L leucine was prepared in Milli-Q water. An intermediate internal standard stock solution containing 4 mg/L $^{13}C_3$-HMB, 10 mg/L KIC-d_3, and 200 mg/L leucine-d_3 was prepared in Milli-Q water.

Calibration standards containing 2, 4, 10, 20, 100, and 200 μg/L of HMB, 2, 4, 10, 20, 100, and 200 μg/L of KIC, 1, 2, 5, 10, 50, and 100 μg/L of HICA, 10, 20, 50, 100, 500, and 1,000 μg/L of leucine, and 20 μg/L each of $^{13}C_3$-HMB, 50 μg/L each of KIC-d_3, and 100 μg/L each of leucine-d_3 were prepared in Milli-Q water.

Samples. Pooled, mature (lactation stage III) human breast milk and six samples of human breast milk from individual donors (lactation stages I, II, and III) was purchased from BioreclamationIVT (Westbury, NY). Samples were received in frozen state and were kept at −20 °C until analysis.

Sample Preparation. After thawing at ambient temperature and vortexing, 0.5 mL of human breast milk or water (for method blanks) was pipetted into a 2 mL Eppendorf centrifuge tube. Appropriate aliquots of spiking solution were added [for quality control (QC) accuracy determination], followed by 25 μL of the intermediate internal standard stock solution. After brief vortexing, 0.75 mL of methanol was added. The tube was capped, shaken for 30 s, and centrifuged at 3000 rpm for 5 min at ambient temperature.

For analysis of HMB, KIC, and HICA, a 250 μL portion of the supernatant was transferred to a clean 2 mL Eppendorf centrifuge tube, followed by the addition of 750 μL of 0.1% formic acid in water. The tube was vortexed briefly, and its content was filtered through a 0.2 μm pore size polytetrafluoroethylene (PTFE) syringe filter into a 2 mL autosampler vial.

For analysis of leucine, a 25 μL portion of the supernatant was transferred to a clean 2 mL Eppendorf centrifuge tube, followed by the addition of 975 μL of 0.1% formic acid in water. The tube was vortexed briefly, and its content was filtered through a 0.2 μm pore size PTFE syringe filter into a 2 mL autosampler vial.

Samples were also prepared for confirmatory analysis on a HILIC column. For this purpose, 100 μL of human breast milk was added to 900 μL of acetonitrile. After brief vortexing, the extract was filtered through a 0.2 μm pore size PTFE syringe filter into a 2 mL autosampler vial.

Instrumentation. Analysis was performed on a Waters ACQUITY ultra-performance liquid chromatograph coupled to a Xevo TQ-S triple quadrupole mass spectrometer. Chromatographic separation was carried out on an ACQUITY UPLC HSS C18, 1.8 μm, 2.1 × 100 mm column (Waters Corp., Milford, MA), operated at 40 °C at a flow rate of 0.3 mL/min with a mobile phase system consisting of 0.1% formic acid in water/0.1% formic acid in methanol. The injection volume was 10 μL. For analysis of HMB, KIC, and HICA, the following gradient program was used: 0−2 min, 15% B; 2−3 min, 15−30% B; 3−6 min, 30% B; 6−9 min, 100% B; and 9−12 min, 15% B. For analysis of leucine, the following gradient program was used: 0−2 min, 0% B; 2−7 min, 0−100% B; 7−9 min, 100% B; and 9−12 min, 0% B.

The mass spectrometer was operated in both positive (leucine) and negative (HMB, KIC, and HICA) electrospray ionization (ESI) mode with both quadrupoles tuned for unit resolution. Selected operating parameters were as follows: capillary voltage, 3.5 kV; cone voltage, 20 V; desolvation temperature, 350 °C; desolvation gas (N_2), 800 L/h; cone gas (N_2), 250 L/h; and collision gas (Ar), 0.15 mL/min. One multiple reaction monitoring (MRM) transition was recorded for each compound (Table 1).

Table 1. MRM Transitions Used for Considered Analytes and Internal Standards

compound	polarity	MRM	CE[a] (eV)	dwell (s)
HMB	ESI^-	117 > 59	10	0.1
$^{13}C_3$-HMB	ESI^-	120 > 59	10	0.1
KIC	ESI^-	129 > 129	5	0.1
KIC-d_3	ESI^-	132 > 132	5	0.1
HICA	ESI^-	131 > 85	10	0.1
leucine	ESI^+	132 > 86	7	0.4
leucine-d_3	ESI^+	135 > 89	10	0.4

[a]CE = collision energy.

Confirmatory analysis was carried out on an ACQUITY UPLC HILIC, 1.7 μm, 2.1 × 150 mm column (Waters Corp., Milford, MA). The mobile phase consisted of 10 mM ammonium acetate in 10:90 water/acetonitrile (isocratic) at 0.3 mL/min and 40 °C. The injection volume was 10 μL.

RESULTS AND DISCUSSION

Method Development. Sample preparation consisted of a two-step extraction−dilution approach, i.e., protein precipitation with methanol, followed by further dilution with 0.1% formic acid to achieve compatibility with the starting mobile phase composition. The dilution factor incurred along the extraction procedure from human breast milk to final extract was 10 for the analysis of HMB, KIC, and HICA and 100 for the analysis of leucine. The separate analysis of leucine after

[a]Estimated concentration (below the LOQ).

100-fold dilution of human breast milk was necessary as a result of two factors: (i) the naturally occurring concentrations of leucine in human breast milk are ca. 3 orders of magnitude higher than its metabolites HMB, KIC, and HICA, and (ii) after 100-fold dilution, the concentration of methanol in the final extract is reduced to 1.5%, achieving compatibility with the starting mobile phase for the analysis of leucine, which is 100% aqueous. The use of 100% aqueous mobile phase during the first 2 min of the analysis is necessary to achieve adequate separation between isobaric leucine and isoleucine. Isobaric hydroxyproline eluted in the column void volume (ca. 0.7 min), and hence, it did not interfere with the determination of

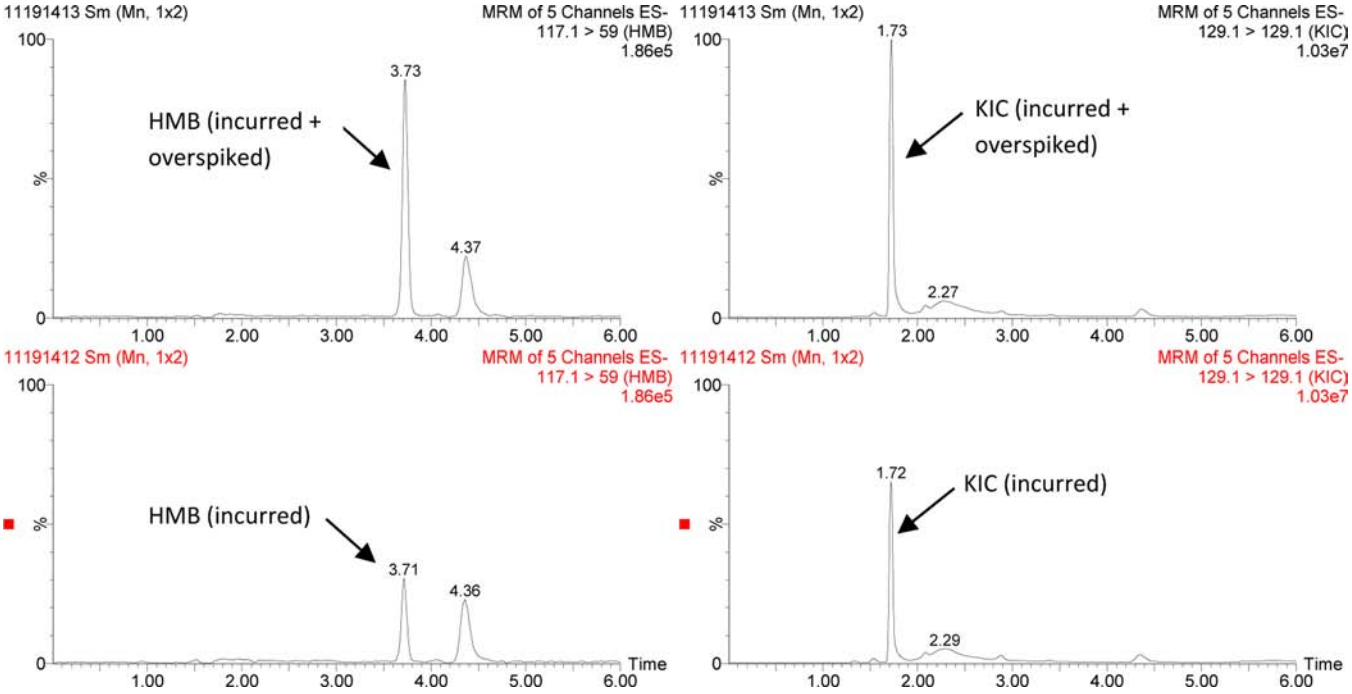

Figure 2. Orthogonal confirmation of HMB and KIC in human breast milk extract by HILIC.

leucine. Both isoleucine and hydroxyproline are naturally occurring amino acids in human breast milk. One single aliquot of 0.5 mL of human breast milk is used for both analyses, which are carried out using the same chromatographic column and the same mobile phase system employing different gradients. Representative chromatograms of all analytes in neat standard solution and in human breast milk extract are shown in Figure 1.

Because of the low molecular weight of considered analytes, one single MRM transition was available for each analyte. KIC and its isotopically labeled analogue KIC-d_3 did not undergo any significant fragmentation in the collision cell. Hence, their pseudo-molecular ions $[M - H]^-$ at m/z 129 and 132, respectively, were used for quantitation (Table 1). Stable isotope-labeled internal standards were used for the quantitation of HMB, KIC, and leucine. HICA, which lacks a commercially available stable isotope-labeled analogue was quantified using $^{13}C_3$-HMB as an internal standard. Confirmatory analysis of selected analytes was attempted on alternative stationary phases with orthogonal selectivity (e.g., HILIC).

Method Validation. Calibration standards were analyzed at the beginning and end of each run. A linear regression model ($1/x$ weighted) was used. Coefficients of determination (R^2) were ≥0.99. Residuals were ≤20% at the lowest calibration level and ≤15% at all other levels.

An analyte-free blank human breast milk matrix was not available. Hence, analytes were spiked into human breast milk at appropriate concentrations on top of incurred concentrations. Three core validation runs consisting of a minimum of five replicates each at low, medium, and high QC spiking levels (QCL, QCM, and QCH) were conducted on 3 different days. A minimum of five replicate analyses were also performed with no spiking to assess the background (incurred) concentrations of analytes. Overall, 68 data points each were collected for HMB, KIC, and HICA. For leucine, overall, 72 data points were collected, of which 2 were rejected as outliers (accuracy outside of the 80−120% range).

Accuracy (relative to the sum of incurred and spiked concentrations), within-day precision, between-day precision, and overall (intermediate) precision were calculated as described in ref 43 and are summarized in Table 2. Accuracy and overall (intermediate) precision were 89−117% and <10% relative standard deviation (RSD), respectively, for all analytes at all three QC levels. The use of a stable isotope-labeled internal standard in the present method significantly improved precision of results for HMB compared to the method reported previously,[21] in which an analogue internal standard was used. Acceptable accuracy and precision were obtained even for HICA, which lacked a stable isotope-labeled internal standard. The consistent performance of the method in terms of accuracy and precision over 3 core validation runs have demonstrated its ruggedness.

LOQs for HMB, KIC, and HICA in human breast milk were 20, 20, and 10 μg/L, respectively. These concentrations corresponded to the lowest calibration levels used for each compound, after the 10-fold dilution incurred during sample extraction. LOQ for leucine in human breast milk was 1 mg/L, corresponding to the lowest calibration level after the 100-fold dilution incurred during sample extraction.

The matrix effect was evaluated by comparing the average peak areas of the internal standards $^{13}C_3$-HMB, KIC-d_3, and leucine-d_3 in sample extracts and neat calibration standards, respectively. The matrix effect was not significant (<15%) for $^{13}C_3$-HMB and leucine-d_3. For KIC-d_3, a positive matrix effect of ca. 30% was noticed; however, this did not adversely affect quantitation.

Extract stability was determined by reanalyzing an entire core validation run after maintaining the samples on the autosampler tray for 48 h at ambient temperature. The run met accuracy and precision criteria described above. The stability of individual stock solutions was also established over 30 days at +5 °C.

Confirmatory Analysis of HMB and KIC in Human Breast Milk by Orthogonal Chromatography. Confirmatory analysis of HMB and KIC was carried out by HILIC, which is orthogonal to reversed-phase chromatography. This is justified because both HMB and KIC have low molecular masses, and hence, only one MRM transition was available for monitoring each analyte. Both HMB and KIC were confirmed in human breast milk on the HILIC column by the retention time agreement between the peaks of incurred and overspiked analytes (Figure 2). Because HICA was present only in trace amounts in human breast milk and because of its less than ideal peak shape on the HILIC column, no further confirmation was possible. Leucine is a major natural component of human breast milk, and further confirmation was not deemed necessary.

Survey of HMB, KIC, HICA, and Leucine in Human Breast Milk. To demonstrate the applicability of the method, six samples of human breast milk collected from individual donors at various stages of lactation (I, II, and III, corresponding to 0−7, 8−21, and >21 days, respectively) were analyzed for HMB, KIC, HICA, and free leucine. Results of this survey (averages of duplicate analyses) are summarized in Table 3.

Table 3. Results of the Survey of Concentrations of HMB, KIC, HICA, and Leucine in Six Samples of Human Breast Milk from Various Stages of Lactation

sample number	stage of lactation	HMB (μg/L)	KIC (μg/L)	HICA (μg/L)	leucine (mg/L)
1	I	62.4	93.5	<10.0	10.7
2	I	164	1057	<10.0	88.5
3	II	42.1	<20.0	<10.0	2.07
4	II	55.9	23.5	<10.0	4.03
5	III	46.0	<20.0	<10.0	2.63
6	III	44.6	33.9	<10.0	2.88

Concentrations of HMB in human breast milk were between 42 and 164 μg/L. All samples contained higher concentrations of HMB than reported previously in bovine whole milk (20−29 μg/L).[21] One sample of stage I (colostral) human breast milk contained a particularly high concentration of HMB (164 μg/L) compared to all other samples. Concentrations of KIC varied from below the LOQ (<20 μg/L) to 1057 μg/L. The same particular sample of stage I (colostral) human breast milk mentioned previously contained the highest concentration of KIC as well. A small trace of HICA below the LOQ (<10 μg/L) was present in all six samples surveyed. However, HICA was present at a quantifiable level (17 μg/L) in the pooled human breast milk sample used for method validation (Table 2). The concentration of free leucine ranged between 2.1 and 88.5 mg/L, with the highest concentration being determined in the same particular sample of stage I (colostral) human breast milk referred to above.

To our knowledge, this is the first report on the presence and abundance of leucine metabolites HMB, KIC, and HICA in human breast milk. Concentrations of free leucine in human breast milk (determined by a derivatization approach) have been reported previously by several authors and were in the range of 1.7−253 mg/L.[30−33] Our findings reported herein for free leucine are in agreement with those published in previous reports.

Along with our previous report,[21] this is the first description of the development and comprehensive validation of a direct, quantitative, and confirmatory method based on LC−MS without derivatization for the analysis of leucine metabolites HMB, KIC, and HICA in a biological matrix. It is also the first report on the direct and quantitative analysis of leucine in a biological matrix by stable isotope dilution mass spectrometry, where the need for the chromatographic resolution of leucine from isobaric isoleucine has been adequately addressed. The presence and abundance of HMB, KIC, and HICA in human breast milk is being reported here for the first time. The concentrations of HMB, KIC, and leucine present in human breast milk could potentially affect rates of protein synthesis, protein breakdown, and consequently, infant growth.

nowadays mandatory for accredited WADA laboratories,[9,10] it is applied in the food safety arena to a minor extent.[11]

The first aim of the presented research was to develop a common analytical backbone able to provide carbon isotopic measurements for main metabolites of 17β-testosterone (βT), namely, etiocholanolone (Etio) and 17α-testosterone (αT), and of 17β-estradiol (βE2), namely, 17α-estradiol (αE2), thus allowing the simultaneous detection of the abuse of synthetic homologues of androgenic and estrogenic steroid hormones. The second aim was to apply the validated method for an experimental study involving treatment of a bull and a heifer, determining the detection window capability of the analytical approach and allowing a direct comparison with other strategies including the monitoring of steroid esters in blood.

MATERIALS AND METHODS

Chemicals. All reagents and solvents were of analytical grade and were provided by Sigma-Aldrich (Bornem, Belgium). The solvents for liquid chromatography were of LC- and HPLC-grade from Biosolve (Valkenswaard, The Netherlands). 17β-Testosterone acetate was supplied by Sigma-Aldrich (Bornem, Belgium). Other steroids were obtained from Steraloids (Wilton, NY, USA). SPE C_{18} cartridges were provided by Achrom (Zulte, Belgium). *Escherichia coli* β-glucuronidase was from Roche Diagnostics GmbH (Mannheim, Germany). Dry pyridine and acetic anhydride were from Sigma-Aldrich (Bornem, Belgium).

Sample Description. *Animal Experiment.* One male bovine and one female bovine (Belgian white-and-red breed), aged 22 and 19 months and weighing 310 and 269 kg, respectively, were used for an administration study. After arrival at the farm until the end of the experiment, they were fed with a typical feed concentrate (2.0 kg daily), which contained mainly C3-plant material with added vitamins and minerals, and had access to dried grass, chopped corn and water ad libitum. It needs to be noted that the amount of chopped corn, consumed by the animals, was significantly larger than that of the feed concentrate and the dried grass. After 21 days, they were treated with a single intramuscular injection into the dorsal neck muscles, containing 1 mg kg^{-1} bw testosterone (administered as 1.194 mg kg^{-1} 17β-testosterone propionate (βTP)) and 0.2 mg kg^{-1} bw estradiol (administered as 0.276 mg kg^{-1} 17β-estradiol-3-benzoate (βE2B)) as an oil based preparation. Urine samples were collected before and during the first 28 days after administration and stored frozen at −21 °C. When all the samples were collected, they were stored at −85 °C in a monitored temperature environment until assay.

The animal experiment was performed at the Department of Veterinary Medicine of Ghent University (B), in line with the guidelines of the ethical committee, with approval code EC2011/163.

Compliant Samples. Eleven urine samples of nontreated pregnant cows were collected at different farms. Additionally, 12 urine samples from animals, a priori nontreated according to routine analyses, were added to obtain a sufficiently large reference population. The samples were stored at −85 °C in a monitored temperature environment until assay.

Spiked Samples. A urine sample which contained low concentrations of AEdiol (12.4 μg L^{-1}), Etio (3.5 μg L^{-1}), αE2 (not present), and αT (0.45 μg L^{-1}) was spiked with these substances at 100 μg L^{-1} and divided into eight subsamples to be used during the method validation.

GC-MS/C/IRMS Sample Preparation and Analysis. To provide adequate GC-MS/C/IRMS data, an extensive sample preparation is necessary to definitely avoid signal interferences that may generate inaccuracy in the $^{13}C/^{12}C$ measurement. After hydrolysis for 15 h with β-glucuronidase at 37 °C and pH 6.8, the urine samples, with a volume of 10 mL, were brought onto a C_{18} solid phase extraction (SPE) column, washed with 6 mL of H_2O and 5 mL of H_2O/acetonitrile (ACN) (80/20; v/v), and finally eluted with 8 mL of H_2O/ACN (10/90; v/v). Then, two subsequent liquid−liquid extractions (LLEs) with 4 mL of *n*-pentane/diethyl ether (92.5:7.5; v/v) at different pH values (pH 14 and pH 5.2) were performed to separate estrogenic and androgenic steroids. The extracts are further purified using reversed phase HPLC-fractionation followed by a normal phase for particular fractions containing target compounds. The four obtained fractions containing the isolated targeted analytes (αE2, AEdiol, Etio, and αT) are eventually acetylated overnight at room temperature with pyridine and acetic anhydride before separate injection into the GC-MS/C/IRMS, with noretiocholanolone being added as internal standard. Details of the sample preparation procedure and instrumental setup are described in a previous published work.[12] However, a limited number of adjustments, described below, have been introduced in the original analytical backbone to include a wider range of steroid metabolites, including those of 17β-testosterone.

Sample Preparation. The volume of the glycerol solution, used as a keeper after the LLE steps, was reduced from 100 to 30 μL. Medroxyprogesterone replaced fluoxymesterone as the internal standard in the estrogen fraction during reversed phase HPLC. Finally, progesterone was used as internal standard during the normal phase HPLC step instead of medroxyprogesterone. Because of the weak UV-detector response for Etio, a progesterone standard was used instead to determine the adequate fractionation windows during the HPLC steps.

HPLC/UV. For the reversed phase HPLC, the C_{18} functionalized precolumn and analytical column were replaced by Kinetex (Security Guard Ultra C18 for 2.1 mm ID) and Kinetex C_{18} columns (XB-C18; 250 mm × 4.6 mm; 5 μm), respectively. The chromatographic conditions were slightly altered: column temperature was changed from 40 to 50 °C, flow rate from 0.6 mL min^{-1} to 0.8 mL min^{-1}, and mobile phase composition from 37:63 to 35:65 (A:B; v/v), with H_2O/MeOH (95:5; v/v) as solvent A and MeOH as solvent B.

The normal phase HPLC-setup, using two diol functionalized columns in series (LiChrospher Diol; 250 mm × 4 mm; 5 μm) and a constant mobile phase of isooctane/isopropanol (85:15; v/v), was left unchanged.

GC-MS/C/IRMS. The T-pieces, used to split the sample after the GC-column to the mass spectrometer and isotope ratio mass spectrometer for simultaneous detection, were replaced by SilFlows (SGE Analytical Science). The RXI 5 SIL MS column (Restek −30 m; 0.25 mm i.d.; 0.25 μm df) GC-column was replaced by an Optima 17MS column (Machery Nagel −30 m; 0.25 mm i.d.; 0.25 μm df). The injection and GC program were adapted accordingly. The initial injector temperature was set at 100 °C, which was held for 0.10 min with a vent flow of 20 mL min^{-1}. The temperature was raised at 8 °C min^{-1} and held at 320 °C for 2 min during sample transfer on column. The initial GC oven temperature was 110 °C, which was held for 1.5 min. The temperature was then subsequently raised to 220 °C at 30 °C min^{-1}, to 270 °C at 6 °C min^{-1}, and to 300 °C at 2 °C min^{-1}. Finally, the temperature was raised to 330 °C at 50 °C min^{-1} and held for 3 min. The carrier gas was helium at a constant flow rate of 1.2 mL min^{-1}. The injection volume of 8 μL was left unchanged.

LC-MS/MS Sample Preparation and Analysis. *LC-MS/MS Analysis.* The quantitative analyses performed in this study were carried out on a Thermo Accela HPLC system coupled to a Thermo TSQ Quantum Ultra triple quadrupole mass spectrometer.

The LC was equipped with a C_{18} column (Kinetex C18; 2.1 mm × 150 mm; 1.7 μm) at a temperature of 70 °C. Solvent A was prepared by adding 400 μL of acetic acid to 1600 g of MeOH. For the preparation of solvent B, 1600 g of H_2O was mixed with 320 g of MeOH and 400 μL of acetic acid. Initially, the mobile phase composition was set at 35:65 (A:B; v/v). Between 1 and 4 min, the composition was linearly increased to 50:50 (A:B; v/v). During the following minute, the composition changed to 75:25 (A:B; v/v). After a final rapid increase in 10 s, the mobile phase was held at 95:5 (A:B; v/v).

The triple quadrupole was operated in the electrospray ionization mode, and the signals were recorded in the selected reaction monitoring mode (SRM). Prior to sample analysis, a solvent blank and two standard solutions containing 20 ng mL^{-1} of the analytes (αE2, αT, AEdiol, and Etio) in H_2O/MeOH (56:44; v/v) were injected, all with added internal standard (1 ng mL^{-1} of 17β-

DOI: 10.1021/acs.jafc.5b02746
J. Agric. Food Chem. 2015, 63, 7574−7581

testosterone-d_2 and 40 ng mL^{-1} of 17β-estradiol-d_3). This was done to calculate the one-point calibration curve covering 0 to 40 ng mL^{-1}.

Sample Preparation. The sample preparation protocol used for this analysis, was very similar to the protocol used prior to the GC-MS/C/IRMS described above but adapted to a sample volume of 5 mL and omitting a number of steps. Since there was no need to isolate the different analytes for quantification, the alkaline LLE and the two HPLC-purifications were unnecessary. Also, there was no need to derivatize the compounds. Thus, the sample preparation consists of a hydrolysis with β-glucuronidase, followed by one SPE and one LLE purification step. Finally, the extract was reconstituted in 125 μL of MeOH/H_2O (80:20; v/v) of which 10 μL was injected into the LC-MS/MS. Samples were spiked at 2 ng mL^{-1} with 17β-testosterone-d_2 and at 80 ng mL^{-1} with 17β-estradiol-d_3 to serve as internal standards for the quantification of the androgens and estrogens, respectively.

Analysis of the Preparation. The administered βE2B and βTP were dissolved separately in methanol to prepare standard solutions of 10 ng μL^{-1}. Next, 100 μL of each solution was hydrolyzed using 2 mL of 1 M NaOH in MeOH. After 15 min at 65 °C, 8 mL of 2 M formic acid in H_2O was added to stop the hydrolysis. Then, the samples were brought onto a SPE C_{18} column, washed with 6 mL of H_2O, and eluted two times with 4 mL of MeOH. The eluate was evaporated to dryness under a nitrogen stream at 37 °C and reconstituted into 40 μL of MeOH and 70 μL of H_2O. Afterward, a reversed phase HPLC fractionation and an acetylation step were performed identical to those used during the preparation of the urine samples. Finally, the samples were reconstituted into 80 μL of isooctane and analyzed with GC-MS/C/IRMS.

RESULTS AND DISCUSSION

Used Analytical Strategies. *GC-MS/C/IRMS Method.* The primary objective of the current research was to develop a method allowing the detection of βT abuse. On the basis of the literature,[7,13,14] Etio and αT were retained as diagnostic markers of βT administration.

During the two HPLC steps, separate fractions for both metabolites were successfully collected, resulting in very pure extracts suitable for IRMS analysis, as illustrated in Figure 1.

Finally, in combination with the already included fractions from a previous study,[12] the method allows for the simultaneous detection of estrogen and androgen abuse, with αE2 as a metabolite of βE2 and AEdiol as endogenous reference compound (ERC) for both βE2 and βT. The extraction yield for αT and Etio was between 36 and 69%, and between 31 and 71%, respectively, which is very similar to the yield of AEdiol and αE2 that was previously published.[12]

HPLC-MS/MS Method. While performing the analysis for the routine detection of estrogen abuse in 2013, it became clear that the majority of the received urine samples did not contain a sufficient quantity of αE2 to provide an IRMS measurement within the linear range. This is in line with findings from the literature, placing an average concentration of αE2 at around 6000 pg mL^{-1} for heifers and less than 500 pg mL^{-1} for bulls.[15,16] Therefore, a quantitative screening method with a similar but severely simplified sample preparation was initially developed to assess which samples contained more than 20 ng mL^{-1} necessary to provide IRMS-analysis within the linear range, filtering out large numbers of samples and avoiding unnecessary work.

Afterward, when including the testosterone metabolites into the method, the quantitative screening gained a second functionality. Because of the low UV-absorption of Etio, it was not possible to determine the adequate dilution of this fraction for IRMS analysis based on UV-detection during the straight phase HPLC fractionation, as is done for the other analytes. However, it was possible to determine the dilution and provide measurements within the linear range based on the LC-MS/MS output.

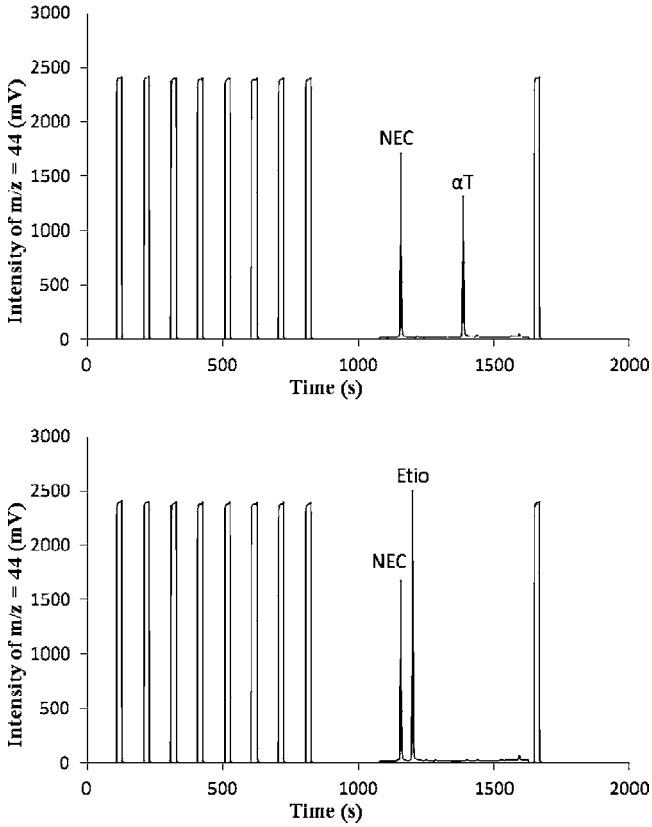

Figure 1. IRMS chromatograms (m/z = 44) of a compliant bovine urine sample, showing the internal standard noretiocholanolone acetate (NEC), 17α-testosterone (αT) (above), and etiocholanolone (Etio) (below).

Finally, it must be pointed out that, although this method provides accurate and reproducible results in the lower concentration range, a linear calibration curve only provided a perfect match (R^2 > 0.99) up to 50 ng mL^{-1}. Concentrations between 50 and 100 ng mL^{-1}, mentioned with regard to the animal experiment, should be considered as an approximation, whereas even higher concentrations must be interpreted as "elevated". Still, these data were found valuable to include.

Hydrolysis of the Steroid Preparations. The existence of steroid preparations having $\delta^{13}C_{VPDB}$ values similar to endogenous steroids has recently been reported for sports doping products.[17−20] To ensure that the $\delta^{13}C_{VPDB}$ values of the preparations used during the animal experiment were not within the endogenous range, the preparations were analyzed prior to treatment. An alkaline hydrolysis protocol for preparations, based on present experience at the laboratory and similar to published methods,[18,20] was used. To confirm complete hydrolysis of the preparations and avoid any potential influence on the $\delta^{13}C_{VPDB}$ values, the absence of intact steroid esters was verified by UV-detection during the HPLC-separation. The measured $\delta^{13}C_{VPDB}$ values, corrected for the acetate moieties, after hydrolysis were −32.13‰ and −31.70‰ for βE2 and βT, respectively, which is significantly different from endogenous values and should allow for the detection of the administration.

Method Validation. The method validation was performed similar to the previous study,[12] and the most important results are summarized in Table 1 and Figure 2.

Table 1. Summary of the Method Validation Results of 5-Androstene-3β,17α-diol (AEdiol), 17α-Estradiol (αE2), 17α-Testosterone (αT), and Etiocholanolone (Etio)

validation parameter	AEdiol (ERC)	αE2	αT	Etio
intermediate precision (‰) (sample standard deviation (n = 8))	0.21	0.35	0.35	1.05
mean difference between spiked water samples and standards (‰) (n = 8)	0.18	0.66	0.33	0.61
linear range (ng of analyte on column) (min−max)	7.5−50	15−80	10−80	10−80
AMDIS "net match" factor (specificity)	94	90	94	99
AMDIS "purity" factor	91	88	81	87

The validation results for AEdiol and αE2 were comparable to those obtained during the previous study, and for αT, similar results were obtained. For Etio, however, two results stand out. First, the intermediate precision was noticeably higher than that for the other compounds. Still, similar and even higher values have been considered acceptable both in published methods for sports doping control[21,22] and lifestock control,[23,24] although reported for other steroids or matrices. For the determination of the intermediate precision during the initial validation, the 8 spiked urine subsamples were analyzed two by two in four separate measurement series, performed by three different analysts over a time span of three months. To reevaluate the result for Etio afterward, the measurements of the compliant control sample for routine analyses, analyzed in 14 different measurement series over a time span of eight months, were assessed. The calculated intermediate precision based on these data (n = 14) was 0.76‰, which is significantly better.

Second, the noncompliance $\Delta^{13}C_{VPDB}$ threshold value, based on 21 measurements from untreated cows, executed in five series of measurements over a time span of four months, was 3.47‰, which is above the 3‰ threshold value usually applied, as is displayed in Figure 2. Remarkably, similar observations have been made with regard to sports doping control, where a number of reference population studies indicated that a 3‰ threshold is too low in certain cases.[21,22] Because of these observations, the new guidelines of the World Anti Doping Agency (WADA) include that each laboratory for sports doping control must perform a reference population study to determine a laboratory specific threshold value, which must be used in case it is higher than the WADA fixed threshold.[10] Additionally, the fixed threshold for the metabolite Etio in human urine was elevated to 4‰. The presented findings suggest that a similar precaution must be used for the analysis of bovine urine. Therefore, the applied threshold for routine analysis was fixed at 3‰ for the couples αE2-AEdiol and αT-AEdiol, and at 4‰ for Etio-AEdiol.

Specificity of the method was verified according to legal criteria,[3] and the absence of impurities and coelutions was verified by inspection of the MS data. Additionally, AMDIS, specialized software to evaluate peak purity and identification of the analyte peaks, was used for this purpose.

Finally, the trueness was evaluated by the injection of standards of dehydroepiandrosterone acetate and 17β-testosterone acetate with known and certified $\delta^{13}C_{VPDB}$ values. These standards were included into the five series of measurement, performed for the method validation, and allowed to verify the absence of a system bias. The mean difference between the certified and the measured $\delta^{13}C_{VPDB}$ values was 0.88‰ and 0.25‰ for dehydroepiandrosterone acetate and 17β-testosterone acetate, respectively.

Results of the Animal Experiment. An administration study was required to assess the capability of the developed method to detect steroid abuse in cattle and to adequately evaluate the pharmacokinetics and the detection window after administration. To be able to observe gender differences, male and female animals were treated. Prior to treatment, the diet of both animals was kept constant for 3 weeks, to ensure stable $\delta^{13}C_{VPDB}$ values for the ERCs during the experiment. Finally, the animals were treated with 400 mg of βT and 80 mg of βE2, injected as a propionate and benzoate ester, respectively. While a typical approved dosage in the USA, administered by implant, is 20−45 mg per animal for βE2 and 140−200 mg for βT,[25] laboratory experience with the analysis of injection sites indicated dosages sometimes up to several hundred milligrams more. The selected treatment holds the middle ground between both scenarios.

Effect of the Treatment on Measured $\delta^{13}C_{VPDB}$ Values. The $\delta^{13}C_{VPDB}$ values of the four measured analytes in the urine samples after treatment are displayed in Figure 3.

The measured $\delta^{13}C_{VPDB}$ values of AEdiol remain stable after treatment at −15.49 ± 0.49‰ and −14.80 ± 0.57‰ in the male and female, respectively, confirming the functionality as a reference compound for both androgens and estrogens, as already described elsewhere.[6,13] This enriched level for endogenous values fits well with the reported measurements from cattle fed with a diet containing a high percentage of maize.[6,13] As expected, gender does not influence the endogenous $^{13}C/^{12}C$ ratio of the ERC significantly.

Already the first day after treatment, the $\delta^{13}C_{VPDB}$ of the metabolites of both βE2 and βT approached their lowest values,

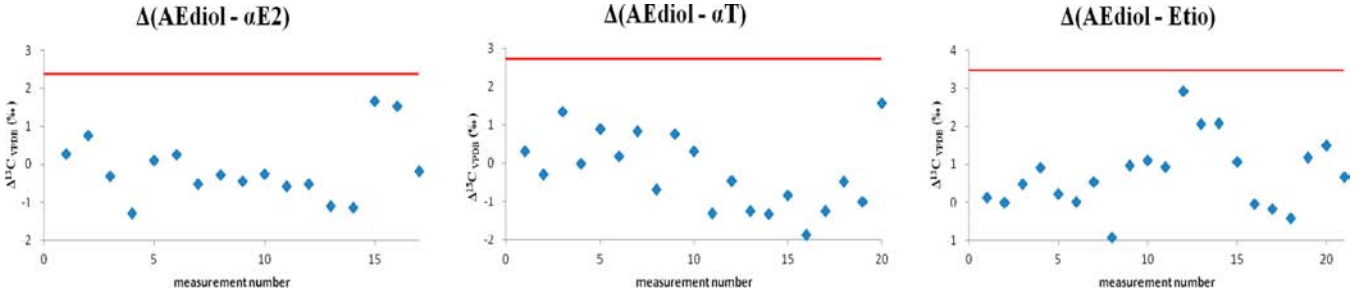

Figure 2. $\Delta^{13}C_{VPDB}$ values (expressed in ‰) of 17α-estradiol (αE2) (left), 17α-testosterone (αT) (middle), and etiocholanolone (Etio) (right), with 5-androstene-3β,17α-diol (AEdiol) as the endogenous reference compound, from a compliant control population.

DOI: 10.1021/acs.jafc.5b02746
J. Agric. Food Chem. 2015, 63, 7574−7581

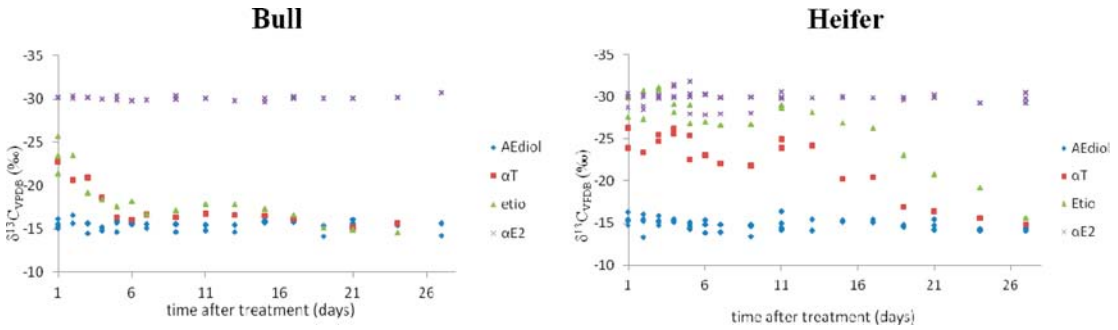

Figure 3. $\delta^{13}C_{VPDB}$ values (expressed in ‰) of 5-androstene-3β,17α-diol (AEdiol), 17α-estradiol (αE2), 17α-testosterone (αT), and etiocholanolone (Etio) in the urine samples from a bull (left) and a heifer (right) after treatment with 17β-testosterone propionate and 17β-estradiol benzoate.

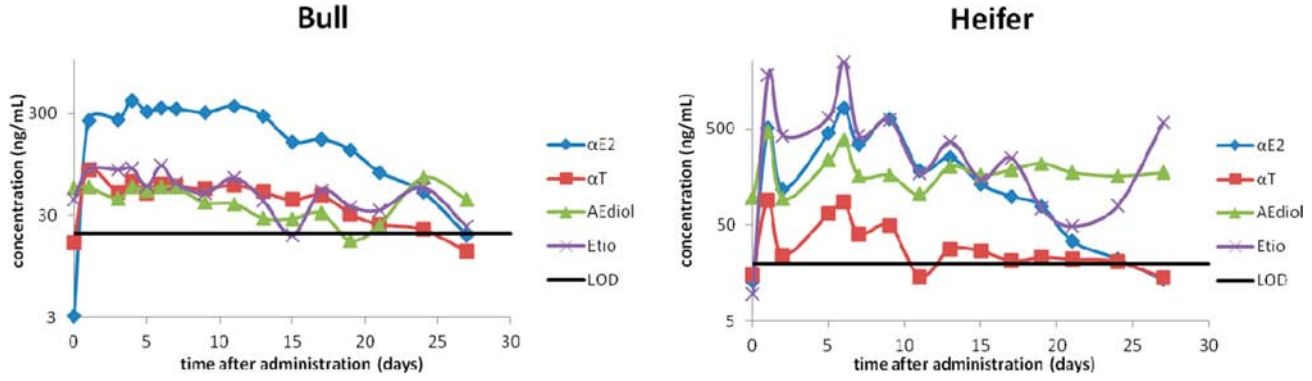

Figure 4. Concentrations (expressed in ng mL^{-1}), measured with LC-MS/MS, of 5-androstene-3β,17α-diol (AEdiol), 17α-estradiol (αE2), 17α-testosterone (αT), and etiocholanolone (Etio) in the urine samples from a bull (left) and a heifer (right) after treatment with 17β-testosterone propionate and 17β-estradiol benzoate.

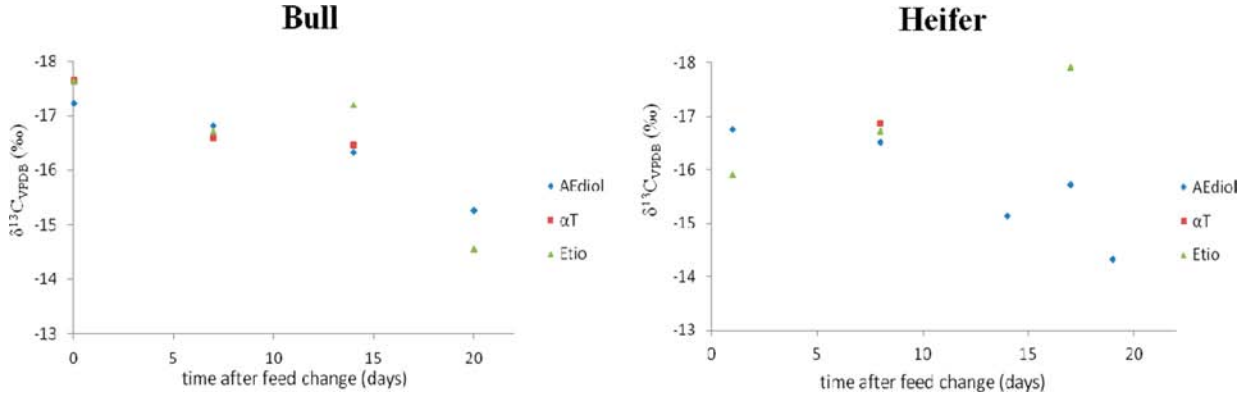

Figure 5. $\delta^{13}C_{VPDB}$ values (expressed in ‰) of 5-androstene-3β,17α-diol (AEdiol), 17α-testosterone (αT), and etiocholanolone (Etio) in the urine samples from a bull (left) and a heifer (right) after changing the feed composition.

contrary to previous testosterone administration studies, in which a more gradual decline over a time span of several days was described.[7,26,27] This difference can be contributed to the currently used preparation, 17β-testosterone propionate, which is known to have a more rapid and shorter lasting effect because of the short carbon chain length of the ester, as opposed to 17β-testosterone enanthate, although influence of other factors such as age, weight, or type of feed of the animals cannot be excluded.

The $\delta^{13}C_{VPDB}$ values of αE2 remain stable after injection, at −30.13 ± 0.24‰ and −29.90 ± 0.70‰ for the male and female, respectively. The small difference in value between the used preparation and the urine samples indicate a very low endogenous production of estrogens, and therefore, the treatment remained visible until the end of the experiment, 27 days after administration.

However, regarding the androgen metabolites, differences between both animals are more pronounced. The difference between the injected testosterone $\delta^{13}C_{VPDB}$ value and the more depleted $\delta^{13}C_{VPDB}$ value in the various female urine samples is close to zero for both Etio and αT. It would indicate that the contribution of the endogenous steroids in the female is insignificant versus the concentration of exogenous residues. For the male, the relative concentration contribution of the endogenous steroids is rather high as attested by the difference observed between $\delta^{13}C_{VPDB}$ values of the injected testosterone

and the most depleted level of Etio found in the urine samples after treatment (6‰).

As a consequence, while βTP treatment could be proven up to 24 days after injection in the female, this was limited to 3 days for the male. However, since βE2 was proven to be a more powerful growth promoter in male animals than βT, both substances can be expected to be administered together to enhance the effects.[28] Still, the detection of βE2 administration has its boundaries as well. While endogenous dilution determines the detection window for the androgens, it is limited for the estrogens by their abundance in the urine samples (Figure 4). While the results 27 days after administration still indicate the administration in both animals, the measurements are just below the linear range of the IRMS and would have been discarded during routine analysis.

When evaluating the results for both testosterone metabolites, the carbon enrichment was prolonged in Etio, compared to αT for which the $^{13}C/^{12}C$ ratio returned to the endogenous value within 2 days after treatment in the bull, making it a less suitable metabolite in male animals.[13] In the heifer, however, the $\Delta^{13}C_{VPDB}$ value for αT remained above the threshold for up to 17 days, thus proving its usefulness.

Effect of the Feeding on Measured $\delta^{13}C_{VPDB}$ Values. After the animals were obtained, their feeding regime was kept constant during the entire experiment. The treatment was only performed after 21 days to ensure that the measurements of the ERC after treatment were stable and reflected the current diet. Urine samples were collected during this adaptation period as well, whose the results are displayed in Figure 5. In the samples from the bull, an upward trend in measured $\delta^{13}C_{VPDB}$ values is visible, which corresponds with the described effect of an enlarged portion of maize in the feed.[24,26] The values of both the ERC and the metabolites shift simultaneously, with the $\Delta^{13}C_{VPDB}$ values never exceeding 0.89‰. However, this trend is not very pronounced since apparently, the previous diet already contained a significant portion of C4 plant material, and for the heifer, this trend was only visible for AEdiol. Unfortunately, the four target analytes could not be measured simultaneously in any of the samples before treatment, and for αE2, none of the samples contained a sufficient amount to provide an adequate result.

Comparison to Other Detection Methods. As an alternative to the analysis of urine samples with IRMS, abuse of synthetic homologues of naturally occurring steroid hormones in cattle can also be proven by the detection of the intact steroid esters, used for the treatment, in hair or blood samples, using other mass spectrometric techniques.[29] During the administration study, serum samples were collected at different times from both animals for the detection and quantification of βTP and βE2B using ultrahigh performance liquid chromatography/tandem mass spectrometry. The used method, as well as the obtained results from these and other treated animals, were discussed by Kaabia et al.[30] The amount of βE2B in the serum samples increases rapidly already 1 day after injection and only starts decreasing between 9 and 13 days after injection in both animals. A good correspondence can be observed between the kinetic curve of βE2B in serum and the concentration of αE2 in the urine samples of both animals (Figure 6). βE2B remained detectable up to 17 days after administration. Unfortunately, no βTP was detected in the samples from the bull. However, in samples from three other heifers which received a similar treatment, βTP remained detectable up to 2 days, indicating a high esterase activity.

Thus, the detection window for the administration of both substances was wider when using the GC-MS/C/IRMS approach, while the difference between both analyses was most pronounced when looking at testosterone abuse in the heifer, which could be detected up to 17 days longer compared to the analysis of the serum samples. However, it is expected that the IRMS detection windows will become narrower as the relative portion of C3 plant material in the feed increases, whereas it is unlikely that a dietary change would affect the presence of the administered steroid esters in serum. Also, the analytical method for the analysis of the plasma samples is significantly less complex and time-consuming than the sample preparation prior to IRMS analysis.

As mentioned above, a third way to undisputedly demonstrate the abuse of synthetic homologues of naturally occurring steroid hormones is by detection of the intact steroid esters in hair. Unfortunately, no hair samples were analyzed during the current study. However, detection methods using GC-MS/MS and LC-MS/MS and results from administration studies with esters of βT and βE2 are available.[29,31−33]

Regarding a single intramuscular βE2B administration, detection windows from 2 weeks up to 70 days have been reported.[29,31] Regarding βTP, no data could be produced on the successful detection of its incorporation into bovine hair after treatment, although this could have been due to the low dosage used in the study.[33] Nevertheless, in studies using other esters of testosterone, detection windows similar to those reported above for βE2B were observed, up to 70 days after treatment.[29,33] Even though this method offers great

DOI: 10.1021/acs.jafc.5b02746
J. Agric. Food Chem. 2015, 63, 7574−7581

perspectives due to its large detection windows, the result is highly variable and influenced by additional factors such as pigmentation of the hair and sampling distance from the injection site. It is clear that GC-MS/C/IRMS is an excellent technique for the detection of abuse of homologues of naturally occurring steroids and that the presented method is functioning well. However, the inclusion of additional ERCs would provide an even more powerful result, and since different steroids are often abused together, the addition of metabolites of other substances to the analysis would broaden the scope and detection possibilities. Still, as illustrated by this study, the technique is limited by both the abundance of steroids in urine samples and the required complex sample preparation. Therefore, this technique is complementary to the detection of steroid esters in blood, for which a far less laborious and time-consuming sample preparation can be used, and in hair, which could offer a larger time frame for detection.

combination of NMR and chemometrics can help to identify metabolic patterns in plants under stress conditions such as those caused by diseases.

In this context, the present work aimed to apply NMR and chemometrics to the metabolomic evaluation of HLB-affected leaves and roots in the asymptomatic and symptomatic stages of the disease.

MATERIALS AND METHODS

Plant Material. Leaf and secondary root samples of symptomatic (SYM) and asymptomatic (ASY) HLB-affected trees were collected in August 2012 from a 6-year-old grove with Valencia sweet orange (*Citrus sinensis* L. Osbeck) on Rangpur Lime rootstock (*Citrus limonia* Osbeck) in a commercial citrus orchard near Taquaritinga in the central part of São Paulo state. All trees received normal grove management, pest control, and fertilization.

The SYM plants showed the typical yellowish asymmetrical chlorosis of the leaves, as well as small and lopsided fruits, whereas the ASY plants showed normal shoots, leaves, and fruits. Samples from roots were collected on the same side of the canopy from which leaf samples were taken. All samples (the SYM and ASY groups) were subjected to a titer estimation of *Ca.* Liberibacter asiaticus using quantitative real-time PCR (qPCR).

A total of 10 neighboring orange trees in the same planting row were collected: 5 SYM and 5 ASY biological samples. About 40 leaves and a piece of secondary root per tree were sampled. Among five ASY biological samples, one plant did not show a detectable level of bacterium in the leaves by qPCR analysis, but it showed a detectable level of bacterium in roots (in this study) and fruits (data not shown). The same case occurred for one root. As reported by Chin and co-workers,[13] the bacteria are not evenly distributed throughout the tree; thus, false negatives can occur in qPCR. Therefore, the negative samples for *Ca.* Liberibacter asiaticus are highlighted in the principal component analysis (PCA) figures (Figures 2A and 3A) as ASY-ND (nondetected HLB in the ASY samples), but they belong to the ASY group.

Sample Preparation and qPCR Analysis. The sample preparation and analysis by qPCR were performed according to the procedure outlined by Coletta-Filho et al.[7] The qPCR data showed averaged cycle threshold (Ct) values of 23.6 ± 1.3 for the SYM leaves and 36.3 ± 2.3 for the ASY leaves, whereas the Ct values for roots were 31.6 ± 3.9 for the SYM samples and 38.8 ± 0.7 for the ASY samples. Samples with Ct value ≥40 were negative for *Ca.* Liberibacter asiaticus.

Sample Preparation and NMR Analysis. Each biological sample was independently analyzed, with three technical replicates. For each replicate, 80 mg of leaves or roots was manually macerated for 2 min. Extractions were performed with 1 mL of TMSP-d_4/D_2O 0.05% solution in phosphate buffer (KH_2PO_4/Na_2HPO_4) at pH 5.4 and sonicated for 20 min. The extracts were centrifuged, filtered, and maintained at approximately 1 °C until the NMR analyses were performed. The extracts were directly inserted into 5 mm NMR tubes.

The ^{1}H NMR measurements were obtained using a Bruker DPX 300 (7.05 T) spectrometer, which operated at 300.13 MHz for ^{1}H. The ^{1}H NMR spectra were acquired at 20 °C using a composite pulse presaturation sequence to suppress the solvent signal (D_2O), with 128 scans, 65,536 points, an acquisition time of 3.64 s, a relaxation delay of 2 s, and a spectral window of 30 ppm. The spectra were processed with 65,536 points in the Fourier transformation and subjected to exponential multiplication of 0.30 Hz with manual phase and baseline corrections. Two-dimensional experiments (gHSQC, gHMBC, and gTOCSY) were conducted at the default parameters to further support compound identification.

Principal Component Analysis and Statistical Analysis. The ^{1}H NMR spectra were introduced into the AMIX program (3.8 Bruker) and subjected to exploratory analyses using PCA. The 0.75−8.26 ppm proton region of the leaf extracts and the 0.70−8.10 ppm proton region of root extracts were evaluated; the region between 4.60 and 5.20 ppm, which corresponds to the deuterated water signal, was excluded. Buckets were constructed through a simple rectangular format with 0.04 ppm of width and integrated, normalizing by the sum of the absolute intensities. The samples were mean-centered, and Pareto scaling preprocessing was applied for leaves and roots.

Statistical analyses were performed using the integration values from the signals with high loadings in PCA relative to the TMSP-d_4 signal in the ^{1}H NMR spectra. Student's t test was applied to assess the differences between the means of the ASY and SYM groups. PCA and

statistical analyses were performed with a 95% confidence level. A P value below 0.05 was used to indicate statistical significance.

RESULTS AND DISCUSSION

Identification of Metabolites in the Leaves and Roots.

The ASY and SYM leaves and roots had similar spectral profiles but different signal intensities (Figure 1). The ^{1}H NMR spectra associated with the two-dimensional experiments and the literature[16−19] supported the identification of carbohydrates, amino acids, organic acids, and other compounds. The identified metabolites and their chemical shifts are reported in Table 1.

Multivariate Analysis by PCA in the Leaves and Roots.

The changes caused by HLB in the leaves and roots of the citrus plants were evaluated using PCA, which enabled the observation of the natural clustering of the samples and unsupervised pattern recognition. The ASY and SYM leaves were distinguished on the

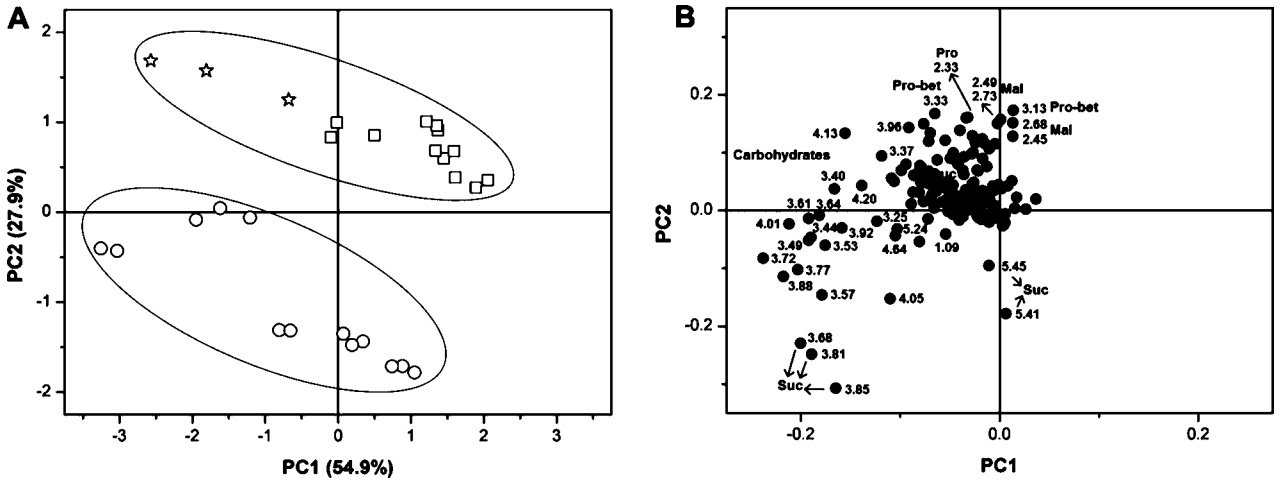

Figure 2. PCA score (A) and loading (B) plots from ^{1}H NMR spectra of the extracts from nondetected HLB (☆) and asymptomatic (□) and symptomatic (○) leaves. Mal, malate; Pro, proline; Pro-bet, proline betaine; Suc, sucrose.

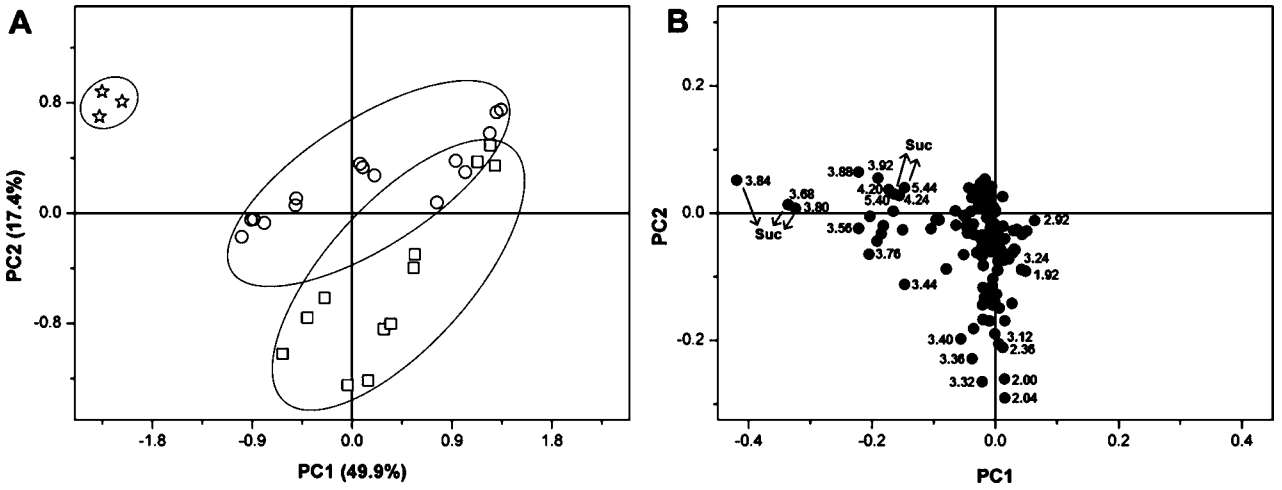

Figure 3. PCA score (A) and loading (B) plots from ^{1}H NMR spectra of the extracts from nondetected HLB (☆) and asymptomatic (□) and symptomatic (○) roots. Suc, sucrose.

score plot (Figure 2A). The characteristic spectral region of carbohydrates was responsible for the disposition of the SYM samples in the negative PC1 values, which included the signals related to sucrose (Figure 2B). The loadings that corresponded to malate and proline betaine were important for allocating the ASY samples to the more positive values of PC2. The ASY-ND scores are close to those of the ASY leaves, although they were allocated to the positive PC2 axis because of the greater contribution of proline, proline betaine, and malate and the smaller contribution of sucrose.

In Figure 3A, the roots of the asymptomatic plants were indistinguishable from those of symptomatic ones. However, there was a tendency of separation between these groups of samples. The ASY-ND roots were detached from the HLB-affected ones on the PC1 axis. The sucrose signals were the variables responsible for allocating the ASY-ND roots to the more negative values of PC1 (Figure 3B).

Figure 4 illustrates the relative proportion of highlighted metabolites in the loading plots (sucrose, proline betaine, malate, and proline), which are responsible for the separation of the ASY and SYM samples. The SYM leaves had a higher sucrose content than the ASY ones (Figure 4A1; $P = 4.77 \times 10^{-5}$), although the ASY and SYM roots were not significantly different in terms of sucrose content (Figure 4A2; $P = 0.086$). The SYM leaves showed a significant decrease in the proline betaine and malate contents (Figure 4A3,A4; $P = 3.71 \times 10^{-9}$ and $P = 2.18 \times 10^{-6}$, respectively), whereas the proline contents were not significantly different between the ASY and SYM leaves (Figure 4A5; $P = 0.65$).

Role of Sucrose, Proline Betaine, Proline, and Malate in HLB-Affected Citrus. Our results indicate that sucrose is an important metabolite for evaluating HLB-affected leaves. Sucrose is the principal source of energy that is transported by the phloem in plants, whereas starch is a stable source of energy that can be stored in the plants. Several studies have indicated the accumulation of starch in HLB-affected trees.[8,10,20,21] However, starch accumulation is detrimental to the plants because of the large volume that it occupies, which disintegrates the thylakoid membrane and causes chlorosis of the leaves.[9]

The starch and sucrose formations occur simultaneously, so an increase in sucrose concentration may cause a source−sink metabolic imbalance. The transcriptome data from young HLB-infected leaves also show that the genes involved in both sucrose metabolism and starch biosynthesis were up-regulated.[22]

Fan et al. found no significant difference in sucrose content between asymptomatic and symptomatic leaves; however, both

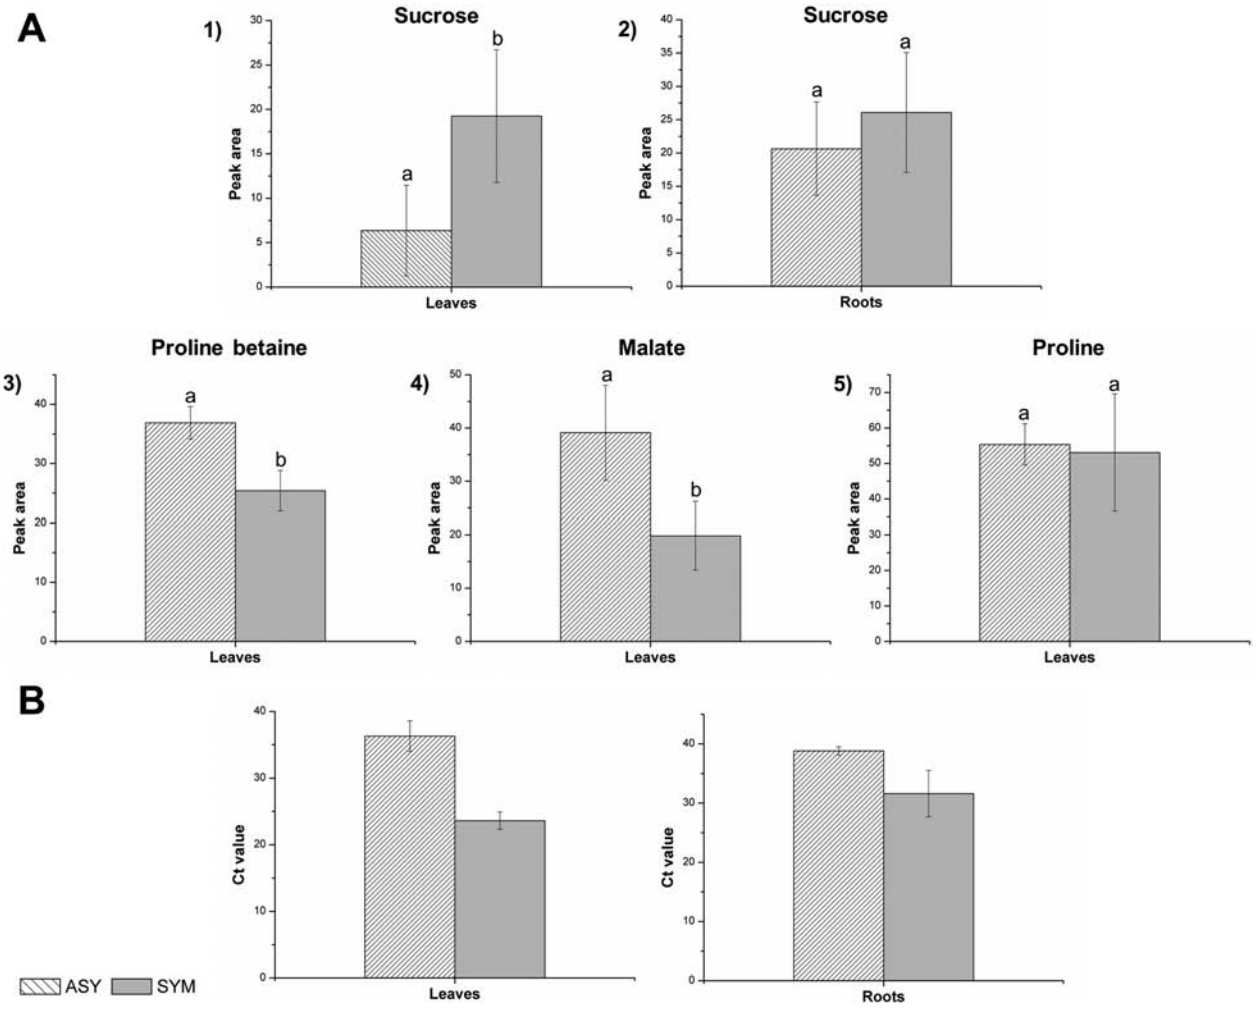

Figure 4. (A) Relative ratio (obtained by integration from signal of the compound in the ^{1}H NMR spectra normalized by TMSP-d_4 signal) of sucrose in the extracts from leaves (1) and roots (2); proline betaine (3), malate (4), and proline (5) in the extracts from leaves. Data are displayed as a mean of relative ratio ± standard deviation. Different letters on bars indicate significant differences ($P < 0.05$). (B) Averaged cycle threshold (Ct) values from qPCR for ASY and SYM leaves and roots.

types of leaves were sampled from infected plants with HLB symptoms.[11] In our case, the asymptomatic leaves were collected from asymptomatic plants; thus, we observed a sucrose accumulation in the SYM leaves (Figure 4A1). The high concentration of sucrose in the SYM leaves suggests that this metabolite cannot be normally transported to other parts of the plant. For the roots, this accumulation was not observed (Figure 4A2) because the phloem vessel was blocked by the *Ca.* Liberibacter spp. bacteria, which alters the transport of sucrose to all parts of the plant.

Proline betaine is commonly found in the Rutaceae species and can be formed by consecutive methylations of proline.[23] Proline and proline betaine are traditionally considered nontoxic compatible osmolytes[24] and are generally associated with the osmotic adjustment and protection of subcellular structures during abiotic[23,25−28] and biotic stresses.[29]

We detected a decrease in proline betaine content in the SYM leaves (Figure 4A3), whereas no significant variation was observed for proline (Figure 4A5). Proline betaine has not been reported in HLB-affected citrus leaves,[30] but it has been observed in juices of HLB-affected oranges with negligible variation.[12,13] As noted by Seifi et al.,[31] the redox-regulating potential of proline may be important in its defense against pathogens, but the pathogens can also exploit these mechanisms to induce susceptibility. Lower proline levels were found in the juices from asymptomatic and symptomatic fruits.[13] These results are different from the findings of Cevallos-Cevallos et al.,[30] who reported significantly higher concentrations of this amino acid in HLB-affected leaves.

Despite the observed accumulation of proline in response to the abiotic and biotic stresses in many plant species, the metabolic alterations in proline and proline betaine content in the HLB-symptomatic leaves remain unclear and may indicate a specific plant−pathogen relationship that specifically modifies this metabolic pathway. Therefore, further studies on the precursors, cofactors, expression, and activities of the key enzymes in the metabolism and catabolism of proline and proline betaine are necessary to understand and characterize the role of these amino acids in the citrus response to HLB infection in different tissues and stages of disease development.

Malate is reported to be a substrate that performs various functions in the cells,[32] which include supplying carbon skeletons for the biosynthesis of amino acids.[33] It is an important intermediary component in the citric acid cycle,[34] and variations in malate content have been associated with the plant response to stress conditions.[35] Malate can be formed from phosphoenolpyr-

DOI: 10.1021/acs.jafc.5b03598
J. Agric. Food Chem. 2015, 63, 7582−7588

uvate, which is a product of glycolysis. Phosphoenolpyruvate is carboxylated by the action of the PEP carboxylase enzyme to produce oxaloacetate, which is reduced to malate by the action of malate dehydrogenase.[36] An important functionality in plants is the action of the NAD-malic enzyme, which converts malate to pyruvate. Consequently, malate plays an important role in maintaining the activities of the citric acid cycle and in the production of some amino acids.[37]

In our study, a decrease in malate content was observed in the SYM leaves (Figure 4A4). This result suggests that HLB significantly changes the essential metabolic processes and affects normal plant development. The change in malate content may indicate the greater consumption of this metabolite to maintain the normal functions of the citric acid cycle, which suggests that other substrates may be consumed for the plant defense.

Relationship between NMR Metabolic Profiles and qPCR. It is possible to relate the observed changes in metabolic profiles with the quantity of bacteria in the samples (Figure 4). The performed NMR analyses in this work show that greater sucrose content in the leaves (Figure 4A1) is observed when the symptoms are observable, that is, when there is a high bacterial concentration (Ct value of 23.6 ± 1.3 for the SYM leaves, Figure 4B). Thus, the HLB-affected leaves with a low quantity of bacteria that do not show any symptoms (Ct value of 36.3 ± 2.3 for the ASY leaves, Figure 4B) do not display sucrose accumulation, although they are already infected with the disease.

Meanwhile, equivalent sucrose content was detected in both the ASY and SYM HLB-affected roots (Figure 4A2). Therefore, even in the ASY roots (Ct value of 38.8 ± 0.7, Figure 4B), HLB sufficiently alters the phloem to inhibit the transport of sucrose from the leaves to the roots, as expected for the SYM roots (Ct value of 31.6 ± 3.9, Figure 4B).

The proline betaine and malate contents (Figures 4A3,A4) show an inversely proportional decrease with the level of bacteria in the leaves (Figure 4B). The plant response can be observed in the SYM leaves because of a reduction in content of these compounds, which may be associated with their catabolism for plant defense.

In summary, our data show modifications in the metabolic profiles of the leaves and less pronounced changes in the roots, which proves that NMR and chemometrics approaches are effective techniques for the metabolomic study of HLB-affected plants. An increase in sucrose content in the leaves and the negligible changes of this metabolite in the roots demonstrate the collapse of the phloem transportation, which is caused by *Ca.* Liberibacter asiaticus. The decrease in proline betaine and malate contents suggests that these compounds are associated with response mechanisms. This study provides important results to further the understanding of the progression of HLB in citrus trees, which can be helpful in developing strategies to control HLB in the future.

and its recent developments using columns with smaller particle size and enabling increased resolution. Structural information can be obtained online on the basis of UV−visible, mass, and nuclear magnetic resonance spectra. However, extraction, sample cleaning, fractionation, and compound isolation are often essential steps in the development of analytical procedures. Solid phase extraction (SPE) and liquid chromatography on various solid phases and centrifugal partition chromatography have proven very helpful for the isolation of polyphenol fractions and purification. Purification of anthocyanins has been achieved by combining SPE with supramolecular complex formation.[7]

Tentative identifications can be reasonably proposed on the basis of relative retention times, UV−visible spectra, and mass spectra, including fragmentation patterns obtained through multiple stages of ionization/fragmentation in MS/MS or MS^n experiments and accurate mass determination provided by high-resolution mass spectrometers such as Fourier transform ion cyclotron resonance (FT-ICR) MS. Chemotaxonomic information and common structural patterns within families of molecules can provide important clues for data interpretation. However, formal identification requires the use of nuclear magnetic resonance (NMR), involving a combination of ^1H, ^{13}C, and two-dimensional homo- and heteronuclear techniques. LC-NMR can be performed online in the stopped-flow mode, but it suffers from a lack of sensitivity. To overcome this problem, a solid phase extraction (SPE) or lyophilization step can be introduced after the HPLC to concentrate the analytes and replace the elution solvent with a deuterated solvent for NMR analysis.

Moreover, for compounds containing asymmetric carbons, the absolute configuration needs to be determined. Indeed, enantiomeric purity is crucial, especially for medical applications, as the activity or toxicity of a compound may be specific of a given chirality. Electron circular dichroism (ECD) spectroscopy and vibrational circular dichroism (VCD) spectroscopy are the most universal techniques for the determination of absolute configuration, especially when X-ray techniques cannot be applied.[8] Progress in computational technologies allows ECD and VCD spectra to be predicted by using quantum mechanics calculations based on density functional theory (DFT) and the absolute configuration established by comparing calculated and experimental spectra. Another strategy using chiral ionic liquids (CILs) as chiral solvating agents in NMR has been proposed.

High-Throughput Profiling and Metabolomics. Paralleling the development of other omics approaches, metabolomics profiling of polyphenol composition in plants, foods, and biological fluids, including targeted and nontargeted approaches, has become very important in studies related to plant, animal, and human metabolism, plant varietal selection, product authentication, etc. Applications of targeted and untargeted methods to study tea composition have been recently reviewed.[9]

Mass spectrometry is commonly used for high-throughput polyphenol profiling in metabolomics or authentication studies. MS analysis after direct flow injection[10] or after UPLC separation with a 2 min gradient elution[11] provided fingerprints of wine polyphenols. New approaches involving interpretation of high-resolution MS data using petroleomics-inspired strategies are starting to emerge.[12] Structures arising from cascade oxidation reactions were thus proposed for theaflavins, a major but poorly characterized polyphenol fraction of black tea. However, these approaches are restricted to rather low molecular weight compounds and provide only putative identification. NMR, especially ^1H NMR, is also widely used for untargeted metabolomics, but detection of secondary metabolites such as polyphenols can be hindered by the presence of more abundant components. The use of two-dimensional NMR increases signal discrimination and facilitates assignment. High-resolution diffusion-ordered spectroscopy (HR-DOSY) NMR, giving access to diffusion data as an additional dimension, appears very promising for the analysis of phenolic compounds in complex mixtures without prior separation.[13]

Quantitative Analysis. Quantitative analysis is classically performed on the basis of HPLC peak areas after spectrophotometric or fluorometric detection, using external calibration. Although some papers report quantitation based on mass signal intensities, multiple reaction monitoring (MRM) based on MS/MS fragmentation of a selected parent mass followed by monitoring of a specific fragment allows increased sensitivity and selectivity and thus appears as the method of choice for mass spectrometric quantitation. A common limitation to these quantitative approaches is the lack of suitable standards. Indeed, molar absorption coefficients as well as ionization and fragmentation efficiency in mass spectrometry may vary widely within a molecular family so that expression as standard equivalent is usually not accurate. Moreover, a matrix effect can result in signal enhancement or suppression and should be carefully checked in method validation. Quantitative NMR (qNMR) enables universal quantitation of analytes from the integration of ^1H signals, reflecting the molar proportions of nuclei and/or molecules present in the solution. Absolute measurements of seven catechins and of other constituents present in green tea samples could thus be obtained by using an internal calibrant.[14]

Poorly Resolved Polymers. The focus on well-known (e.g., commercially available as standards, spectra available in databases) or easily detected compounds often leads the immersed part of the polyphenol iceberg, that is, unresolved polymers and unextractable polyphenols, being overlooked. Indeed, resolution in liquid chromatography becomes limiting as the sample complexity increases, especially for the analysis of polymers. Gel permeation chromatography (GPC), also called size exclusion chromatography (SEC), has been applied for the molecular weight separation of tannins[15] and of pigments derived from anthocyanins and tannins,[16] but interpretation is limited by the lack of suitable calibration standards. The use of a multiangle laser light scattering detector (MALLS) associated with a concentration detector (e.g., UV) enables determination of the average size and absolute mass of the molecules. MALLS can be hyphenated to SEC and to asymmetric flow field-flow fractionation (AF4) that separates macromolecules according to their size for molecular weight determination.[17]

Complex polyphenol fractions can be characterized by mass spectrometry (Oliveira et al., in this issue). Molecular distribution of proanthocyanidins has been studied by matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) MS. Higher molecular weight polymers are underestimated by both methods, especially in the presence of lower molecular weight compounds. However, ESI-MS, after optimization, has proven suitable for analyzing tannins with average degrees of polymerization below 26,[18] whereas MALDI-MS analysis of tannin complexes with bovine serum albumin combined with fractionation provided information on the molecular weight distribution of very large and polydisperse

J. Agric. Food Chem. 2015, 63, 7589−7594

tannins.[19] Both qualitative and quantitative information can also be obtained by NMR analysis. Other approaches are based on the analysis of the products released after acid-catalyzed depolymerization or hydrolysis. HPLC analysis after acid-catalyzed cleavage in the presence of a nucleophile (e.g., thiolysis, phloroglucinolysis) provides qualitative and quantitative information on proanthocyanidin composition. However, high reaction yield is essential to ensure the reliability of qualitative data such as average degree of polymerization. Further information can be obtained by acidic and alkaline hydrolysis, releasing sugar and acyl groups, respectively, from complex phenolic structures. Hydrolysis of wine polyphenols provided evidence of acylation with various acids and confirmed that acetaldehyde and anthocyanins are involved in polymer formation.[20] However, half of the composition remained uncharacterized. The development of methods to determine the composition of polymers including reaction products formed during processing thus remains a major challenge.

Unextractable Compounds. The identification of unextractable polyphenols is even more challenging. This includes lignins and hydroxycinnamates involved in cell wall polymer cross-linking, especially in cereals[21] but also other types of polyphenols that are found in both extractable and unextractable fractions. Nonextractable polyphenols exceed extractable ones in many plant-derived foods and, therefore, may represent a major proportion of the polyphenol dietary intake, as recently concluded in a study on the Spanish diet.[22] This material can be released by performing thiolysis, butanolysis, or hydrolysis on the extraction residue or analyzed by ^{13}C solid state NMR.[23] Considerable variations were reported in proanthocyanidin extractability from plant foods, from totally extractable (in plum) to totally unextractable (in banana).[24] Large differences are also observed between studies. This may result from differences in the preparation of the plant material (e.g., frozen versus freeze-dried), in the analysis method (thiolysis versus butanolysis), and in the calibration standards used.[25] Acidic hydrolysis also released hydroxycinnamic and benzoic acids from fruit unextractable fraction.[22] Finally, these methods proved inefficient for archeological samples. A more drastic pyrolysis method involving a thermally assisted hydrolysis−methylation followed by gas chromatography—mass spectrometry analysis released phenolic markers that can serve as signature compounds for the detection of wine traces in ceramics.[26]

■ CHEMICAL REACTIVITY AND TRANSFORMATIONS

Chemical reactivity and transformations of polyphenols are basic and very important topics of the conference.

During biosynthesis and storage in plant tissues and in food-processing systems, reactions of phenolic compounds, sometimes also involving other compounds (e.g., acetaldehyde), occur to give varieties of new compounds, including pigments.

Tea leaves give various products, including green tea, black tea, oolong tea, and others, because of differences in production processes. Studies on the transformation of tea polyphenols, promoted by the progress of instrumental analytical methodologies, were one of the most important and attractive topics. Theaflavin and theasinensin are known to be major polyphenol components in black tea. The structure of theasinensins seemed to be a simple dimer of epigallocatechin gallate (EGCG); however, this compound was not obtained by a radical coupling of EGCG, but produced from an unstable precursor. Tanaka reported in his plenary lecture that in vitro oxidation of EGCG using a pear polyphenol oxidase yielded the theasinensin precursor, dehydrotheasinensin A. He revealed that theasinensins were formed by oxido-reductive disproportionation reaction.[27] The formation mechanism of oolongtheanins was reported to occur by oxidation of EGCG by $CuCl_2$.[28,29] Pigment compositions of red grape pomace (Oliveira et al., in this issue) and of apple juice (Le Deun et al., in this issue) have also been presented.

Curcumin, an ingredient of turmeric, also attracted attention because of its wide variety of activities; many preclinical studies are going on. This compound exists as a mixture of tautomers and is very unstable. To evaluate the metabolism of curcumin by identification of its degradation products, isotopically labeled curcumin was synthesized. Schneider's group synthesized hexadeuterated curcumin and $^{14}C_2$-labeled curcumin and, using these compounds, they found new metabolites, bicyclopentadione derivatives by LC-MS and NMR analysis (Schneider et al., in this issue). Synthetic studies of curcumin analogues are also useful for clinical studies. Synthesis of C_5-curcuminoids and structure−activity relationships on antitumor activities are reported. A designed probe connected to biotin allowed the identification of the target protein as a KH-type splicing regulatory protein.

The synthesis of chemical probes of bioactive polyphenols that can be used for searching the target protein is very important for pharmaceutical studies to clarify the mode of action. The number of studies in this area is increasing, as illustrated in the conference. Quideau and his group presented a molecular design of affinity-based probes of flavonoids and studies of polyphenol−protein interactions. They synthesized biotinylated catechins to capture leucoanthocyanidin dioxygenase, a key enzyme of anthocyanidin biosynthesis.[30] Kan et al. also reported the synthesis of hapten probe and fluorescent catechin and theaflavin probes.[31] They synthesized a positron emitting tomography (PET) probe containing ^{11}C, the half-life period of which is 20 min. The PET imaging study of nobiletin and EGCG using rat clarified the distribution of the compounds in living organisms.[31]

Other synthetic studies of polyphenols are now promoted by developing new reagents and reactions. Pohjoispää and Wähälä reported deuteration of polyphenol (in this issue), Ohmori and Suzuki presented biosynthesis-inspired isoflavone synthesis and procyanidin oligomer synthesis,[32] and Yamada et al. established synthesis of ellagitannins containing a highly oxygenated diaryl ether residue, C−O digallates.[33]

On the subject of wood polyphenols, the number of studies has increased and much new progress has been reported. Miyakoshi presented in his plenary lecture the oxidative polymerization mechanism of Japanese urushi lacquer, involving a first-stage enzyme (laccase) catalyzed oxidation and a second-stage autoxidation. He also presented the potential of the hybrid lacquer, which is obtained by silication of natural lacquer, as more stable and robust.[34] Many researchers in wood chemistry attended the conference, and reports on the biosynthesis of lignin using imaging mass analysis,[35] synthetic studies, and model reactions were presented. A new research area on materials science of polyphenols should be developed with a tight discussion in ICP.

In the biosynthesis of glucosylated and acylated flavonoids, Ozeki et al. reported a new glucose and acyl donor, acylglucose, as a "Zwitter donor". Up to now, the glucosyl donor of

DOI: 10.1021/acs.jafc.5b01173
J. Agric. Food Chem. 2015, 63, 7589−7594

flavonoids has been considered to be UDP-glucose; however, sinapoyl-glucose and *p*-hydroxybenzoyl-glucose are now proposed as new donors.[36,37]

PHYSICOCHEMICAL PROPERTIES AND ACTIVITIES

In the conference, recent advances in the chemical aspects of polyphenols as plant and food pigments were discussed. In addition to reactions leading to new pigments as discussed above, multiple copigmentation interactions and complexation of metal ions with pigments change the hue of colors. Recent studies with advanced analytical methods show that the color finally observed is a consequence of the co-occurrence of different phenolic compounds that interact with anthocyanins and other organic molecules and inorganic ions that modulate these physicochemical interactions.[38] The transformation and stabilization of anthocyanins, depending on pH change and the presence of copigments, have been interesting subjects in flower coloration. Stabilization of anthocyanins with clathrate compounds, cucurbit[7]uril, and β-cyclodextrin, was reported by Pina (Basílio et al., in this issue). Kondo presented the suppression of hydration reaction of anthocyanins by molecular stacking and metal complexation to give a stable blue flower petal coloration. Oyama et al. reported the structure of elusive blue pigment of hydrangea and, using a synthetic quinic acid ester, the interaction between anthocyanin chromophores and copigments was clarified (in this issue). Multiple copigmentation in anthocyanin−flavanol−flavonol mixtures and its implication in the color of red wines was also studied (Gordillo et al., in this issue).

Although the chemical process of interaction of tannins with proteins is well-known and has been used for industrial processes for a long time, it is still a matter of active scientific research as these interactions are very relevant for food organoleptic properties (astringency, mouthfeel, bitterness, etc.), food and feed antinutritional properties, crop protection against herbivores, and health effects through interaction with human proteins and receptors.

With regard to sensory-related aspects, astringency has long been studied and has been directly associated with interactions of tannins with saliva proteins. There are advances in the knowledge of the relationship between chemical features of polymeric and oligomeric polyphenols and the astringency (mouthfeel) sensation. This field will continue advancing as the analytical methods available, and the genetic characterization of the individuals with different polymorphisms affecting taste, allow a better study of this food-quality related phenomenon.[39]

It was also shown that some polyphenols that can be absorbed after dietary intake interact with serum proteins, and this can be a mode of transportation of polyphenols through the bloodstream to different systemic tissues. The analysis of these associations with the true circulating metabolites and the release of the polyphenols under specific physiological conditions (i.e., inflammation) is also a matter of active research.[40]

The interaction of specific polyphenols with receptors, enzymes, and transporters is also providing evidence of the mechanisms explaining the physiological effects of polyphenols in humans and other animals.[41]

In addition to proteins, evidence was provided about polyphenols interacting with other biological molecules such as lipids and carbohydrates. A study was presented on the effect of polyphenols protecting lipids and proteins from oxidation and degradation during transit through the gastrointestinal tract and the adsorption of polyphenols on cellulose and interaction with nondigestible saccharides such as fructo-oligosaccharides that modulate the effects of polyphenols on rat intestinal cells.

Polyphenols can also be degraded through different mechanisms, including oxidation, during technological processing, storage, and digestion, and the degradation metabolites can also show significant biological effects, positive or negative, that need to be considered. This was clearly illustrated for the turmeric phenolic pigment, curcumin. Little is known of the activity of these degradation products, and the study of this topic in the future is warranted.

Polyphenols can also interact with other relevant food chemical processes, as is the case of the Maillard reaction that has sensory and safety implications. These indirect effects of polyphenols have to be considered to understand relevant chemical processes occurring in complex foods.

Another important field of research regarding polyphenol properties is the study of the role of polyphenols in human health. In this field advances in bioavailability and metabolism, in the mechanisms of action, and in the evidence of health effects in animal models and humans have been reported.[42]

In the bioavailability and metabolism of polyphenols, factors affecting absorption, metabolism, and excretion and intra-individual and interindividual variability were reviewed.[43] For some phenolic compounds, pharmacokinetic studies are still needed, as there is evidence that genetic polymorphisms involved in polyphenol transport and metabolism have a relevant impact on the types and amounts of metabolites present in circulation and in urine.[43]

The interindividual variability of polyphenol metabolites present in plasma and urine after the intake of different polyphenols (isoflavones, lignanes) that has been described previously[44] is now been correlated with human gut microbiota composition and/or genetic polymorphisms, and it will be potentially associated with specific health effects, although the evidence about this is still scarce.

In vivo studies with animal models (mice and rats) or clinical studies show physiological effects of some dietary polyphenols but also show the large interindividual variation mentioned above that divides the participants in the studies into responders and nonresponders.[45] The presented in vivo studies on the effect of polyphenols on cardiovascular health and cognitive function were particularly relevant.

As was highlighted in previous polyphenols meetings,[38,46] for mechanistic studies, the need to use the polyphenol metabolites that reach the target tissues and at the concentrations found in vivo was agreed upon. This approach is not always followed but should be encouraged to reach conclusions that are biologically significant and not simply a nice laboratory exercise. Different types of cells were used for these mechanistic studies going from intestinal cells to neuronal cells.

The interaction of polyphenols with microbes is becoming a hot topic, not only for the role of polyphenols as antimicrobial agents but also for their activity as modulators of the human gut microbiota, which has been correlated with a dozen relevant human diseases.[47,48] In addition, gut-colonizing microbes metabolize dietary polyphenols, leading to metabolites that are often better absorbed than the precursors and, in addition, show interesting health effects including anti-inflammatory and phytoestrogen-like effects.[48]

THE 27TH INTERNATIONAL CONFERENCE ON POLYPHENOLS AND 8TH TANNIN CONFERENCE

These conferences have been held jointly, for the first time in their history, in Nagoya, Japan, during September 2014 and hosted 500 participants from 35 countries. ICP 2014 was divided into six topics: (1) Chemistry, Physicochemistry, and Materials Science; (2) Biosynthesis, Genetics, and Metabolic Engineering; (3) Plant and Ecosystem, Lignocellulose Biomass; (4) Food, Nutrition, and Health; (5) Natural Medicine and Kampo; (6) Tannins and Their Functions. An additional feature of ICP 2014 was that papers on lignin chemistry were also presented. As previously mentioned, lignin was one of the major targets of polyphenol research in the early days. Now in relation to biomass and ecosystems, and the development of new materials, the significance of this topic deserves special attention. Chemical studies of polyphenols must be the platform and basis of all the scientific research of polyphenols. In this special issue, a selection of high-quality original research presented at ICP 2014 is published. Now the countdown to ICP 2016, which will be organized by Prof. Karl Stich, in Vienna, Austria, from July 11−15, 2016, is on.

chromatography (GC) with various detection systems. By far the predominant and most popular applications for analyzing lignans and other phytoestrogens are the (HP)LC-MS methods. In contrast to GC-MS, LC-MS has the advantage that it is not necessary to prepare volatile derivatives and that conjugated forms, such as the glycosides, can be analyzed as well.[26−28] However, the phytoestrogen contents are usually very low in biological matrices, and these techniques remain largely qualitative unless authentic standards are available. Thus, isotopically and isomerically pure polydeuterated lignans and other phytoestrogens are needed as references for the quantitation of these compounds in biological samples. The use of structural analogues as internal standards, rather than authentic isotope labeled isotopologues (i.e., substances that differ only in isotopic composition, e.g., CH_3OH, CD_3OH, CH_2DOH), is undesirable because the former will have different behaviors in sample preparation as well as different retention times and ionization properties compared with the analytes. An authentic stable isotope labeled analogue of a compound is essentially identical to the compound of interest except for mass.

One of the most reliable and sensitive methods of quantification is based on the addition of a stable isotope analogue of the analyte of interest into a sample at a known concentration. The technique is called stable isotope dilution (SID).[29] Because the analyte and its isotopologue possess almost identical chemical and physical properties, the isotopic ratios remain stable, as they are affected equally by variations in extraction, sample preparation, injection, and instrument parameters.[30] In the ion chromatogram, the analyte and its labeled analogue usually have the same retention time. Thus, all of the losses during sample preparation can be corrected for and the analytes reliably identified and quantified.

REQUIREMENTS FOR THE INTERNAL STANDARDS

In quantitation methods, internal standards are used to take into account all of the losses during the process and the behavior of the compounds during the measurement. A stable, chemically, isomerically, and isotopically pure isotopologue of the analyte is the optimal standard. As the physicochemical properties of an isotope labeled analogue are very similar to those of the analyte, no separation takes place during the process: the analyte and its labeled analogue have the same retention times in chromatography but different m/z values in mass spectrometry.

Labeled compounds that are used as internal standards in quantitative analytical techniques such as GC-MS and LC-MS must fulfill certain important criteria. First, the compounds and the labels must remain stable during the entire sample preparation procedure and analysis. Second, there cannot be any unlabeled species present in the standard. Third, the labeled analogue and the analyte should have a difference of at least 3 units, or more if the analyte contains elements other than C, H, O, and N, in the M^+ m/z value to avoid overlap with the internal standard.[31] On the other hand, it has been suggested that for internal standards an optimal number of deuteriums would be from three to five, as more deuteriums in the molecule may cause chromatographic separation between the standard and the analyte.[32,33] However, no chromatographic separation of a deuterated compound from the corresponding unlabeled compound has been reported for lignans.

LABELS FOR LIGNANS

Apart from radioactive labels, the possible labels for lignans are ^{18}O, ^{13}C, and D, the heavier stable isotopes of oxygen, carbon, and hydrogen, respectively. ^{18}O-labeled compounds are used to study reaction mechanisms,[34,35] but they could also be used as stable isotope labeled analogues for quantitative determinations. $^{16}O/^{18}O$ exchange is limited to compounds such as carboxylic acids that contain functional groups prone to facile oxygen exchange reactions.[36] Oxygen labeling has been used also when reactive phenols, for example, resorcinol moieties, are present, but the labeling conditions required were quite harsh (180 °C for 16 h), the yields were low, and protecting groups were needed.[37] To the best of our knowledge, no ^{18}O-labeled lignans have been synthesized apart from those in our mechanistic studies.[35]

In the literature there are some examples of carbon-labeled lignan precursors[38] that have been used to examine the biosynthesis and mechanisms of formation of lignans and neolignans.[18,24,39] The nonradioactive isotope of carbon, ^{13}C, might be considered as an optimal, general-purpose label because the isotope effects with ^{13}C are small (compared with $^{18}O/^{16}O$ and D/H), it can be used to label the fairly stable carbon backbone of lignans, and it cannot be exchanged for ^{12}C under ordinary conditions. However, the stability advantage is offset by the necessity of total or partial synthesis using expensive ^{13}C-labeled reagents or starting materials. Only one total synthesis of stable ^{13}C-labeled lignan derivatives has been reported in the literature.[40,41] After the first ^{13}C label was introduced, this synthesis took 11 or 12 steps to obtain the final triply labeled target, and although the yields for most of the steps are very good, the overall yields were 0.3−2%.[40,41]

On the other hand, deuterium labeling provides by far the most important route to stable isotope labeled standards in organic analysis. This is a result from the wide distribution of hydrogen in the target material, the ease of H/D exchange in most cases, and the cheap and ready availability of deuterated solvents and reagents. Furthermore, depending on the functional groups of the target molecules, it is often possible to acquire the desired label without any synthesis by performing simple exchange reactions on the native molecules in deuterated solvents.[36] The various deuteration reagents and solvents, such as D_2O, CH_3OD, DCl, D_2SO_4, and NaOD for deuterium exchange, and the reducing agents $LiAlD_4$ and $NaBD_4$, used in total synthesis approaches, are readily available and less costly than ^{18}O- and ^{13}C-labeled reagents.

As a result of the isotope effects, deuterated analogues may have certain defects as internal standards. There may be a small separation of the deuterated internal standard and its endogenous protium form during chromatography.[42] Ion fragmentation is sensitive to the kinetic isotope effect, but differences in ionization efficiency between labeled and unlabeled compounds are very small and become unmeasurable when the labeling site is remote from the charge center, even in the case of deuterium.[43] Yet, structural analogues are even less representative of the endogenous compounds because, in addition to differences in retention time, the structural analogue can show different absorption loss.[42] Thus, exchange−deuteration has remained the most important labeling method for obtaining stable isotope labeled compounds.

CHARACTERIZATION OF THE DEUTERATED COMPOUNDS

Isotopic purity is an important feature of an isotope-labeled compound. However, in the literature and in the catalogs of commercial suppliers there are no established practices on how to define or measure the isotopic purity, isotope distribution, or isotope content. In this paper, the isotope distribution is determined by NMR and the isotopic purity is indicated as the percentage of the most abundant D species, determined from the molecular ion region in EI mass spectra by comparison with those of the undeuterated compounds.

The number of deuterium atoms in a product as well as the isotopic purity is determinable by MS. The isotopic purities of deuterated compounds may be determined from the ion clusters in the molecular ion region in the EI or ESI mass spectra by comparison with those of undeuterated compounds. For the native butyrolactone and tetrahydrofuran type lignans the M − 1 and M − 2 peaks usually are very small (2−5% of the intensity of the molecular ion peak) or totally absent (Figure 2).[44] For flavonoids, which may have intense M − 1 and M − 2 fragments, an equation to determine the isotopic purity is reported.[45]

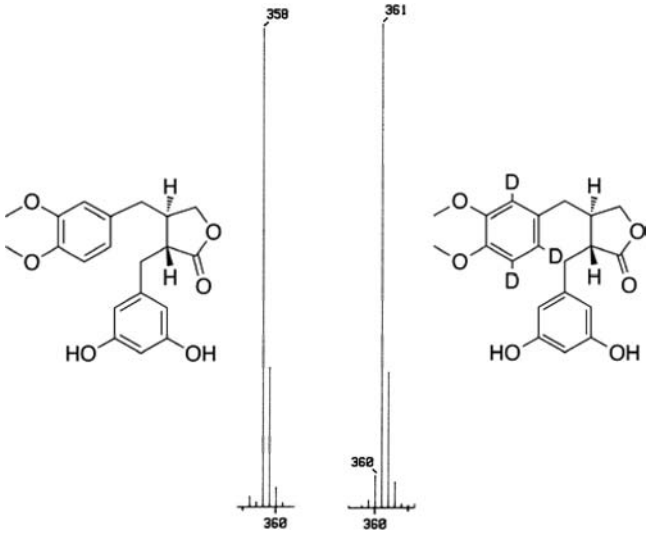

Figure 2. Molecular ion regions of an unlabeled butyrolactone type lignan (M = 358) and its stable deuterium-labeled D_3 analogue (M = 361).[44]

The locations of the deuterium atoms can be established from ^1H and ^{13}C NMR studies. In the ^{13}C NMR spectrum, the carbon atom bearing a deuterium atom produces a low-intensity triplet (instead of the relatively intensive aromatic C−H singlet) because the spin of deuterium is 1 (Figure 3). The ^1H NMR spectra of deuterium-labeled compounds are the same as for unlabeled compounds, with the exception that the aromatic deuterons cannot be seen and the coupling patterns of the protons attached to the adjacent carbons are simplified (Figure 4).

DEUTERATED LIGNANS

Introducing Deuteriums via Reduction. In the literature there are some reports of the introduction of deuterium into the lignan skeleton via reduction. The first reported synthesis for deuterium-labeled lignans was a multistep total synthesis for D_2-enterolactone and D_2- and D_4-enterodiol,[48,49] utilizing the method based on Pelter et al.'s synthesis of *trans*-dibenzylbutyrolactones via tandem conjugate addition.[50] The Michael addition−alkylation method was modified by using D_2-butenolide D_2-**3** as starting material to produce D_2-enterolactone D_2-**4** (Figure 5). Deuterium-labeled enterodiol was available in two forms: D_2-**5**, either by reducing unlabeled enterolactone **4** with $LiAlD_4$ or by reducing labeled enterolactone D_2-**4** with $LiAlH_4$, and D_4-**5** by reducing the labeled lactone D_2-**4** with $LiAlD_4$.

Neidigh et al. synthesized monodeutero-labeled podophyllotoxin precursors from podorhizone by using $NaBD_4$ as a reducing agent.[51]

A two-step synthesis[52] of symmetrically substituted butyrolactone lignans was applied to prepare hexadeuterated benzyl protected derivatives of matairesinol **6** (Figure 6).[53] The first step is the formation of a fulgenic acid **7** by the Stobbe condensation of 4-benzyloxy-3-methoxybenzaldehyde **8** and dimethyl succinate **9**. The second, deuteration step is a ruthenium-catalyzed ring closure with simultaneous deuteration, giving the benzyl protected D_6-matairesinol derivatives *trans*-D_6-**6** and *cis*-D_6-**6** in a 10:1 ratio (the yield of the reaction was not mentioned).

Labeling via H/D Exchange of Aromatic Protons. All of the other syntheses for deuterium-labeled lignans are based on H/D exchange within the complete molecular framework. In the case of lignans, the exchangeable protons are in the aromatic rings, and the benzylic or α-carbonyl sites remain unaffected.

The first efforts to deuterate aromatic compounds were in 1934, three years after the discovery of the heavy hydrogen isotope.[54] Horiuti and Polanyi heated benzene in 3% heavy water in the presence of a nickel catalyst.[55] Later in the same year Ingold et al. introduced deuterium into the aromatic nucleus by means of ordinary electrophilic reagents, namely, concentrated aqueous sulfuric acid (without heterogeneous catalysis).[56] They also proposed that the mechanism of the exchange is an electrophilic aromatic substitution[57] and proved the theory with comparison of the efficiencies of some acidic and basic deuterating agents and the influence of some aromatic substituents.[58,59] In lignans the aromatic substituents usually are hydroxy and/or methoxy groups.[60] When an electrophilic substitution reaction, such as deuteration, is performed, the existing substituents determine which position the new group will take and whether the reaction will be slower or faster than that with benzene. Both hydroxy and methoxy are *ortho*−*para* directing and activating groups.[61]

The first deuterium exchange within a lignan skeleton was performed with DBr (PBr_3 in D_2O, Figure 7).[62] The protons of phenolic groups were replaced with deuterons by D_2O treatment before the deuteration procedure, and the predeuterated enterolactone **10** was labeled with deuterium by exchange in DBr−D_2O to give the hexadeuterated enterolactone D_6-**4**. Aromatic protons that are *ortho* or *para* to the directing and activating phenolic OH groups were exchanged, whereas the protons that are *meta* to OH remained unaffected. The H/D treatment was repeated to ascertain complete deuteration and >90% isotopic purity. After final exchange, the reaction products were treated with a large excess of H_2O or ethanol to restore the protic hydroxy groups.

Deuterated phosphoric acid D_3PO_4 was used to synthesize a D_6 derivative of matairesinol **11** (Figure 8).[21] Matairesinol **11** was first predeuterated with CH_3COOD, made from freshly

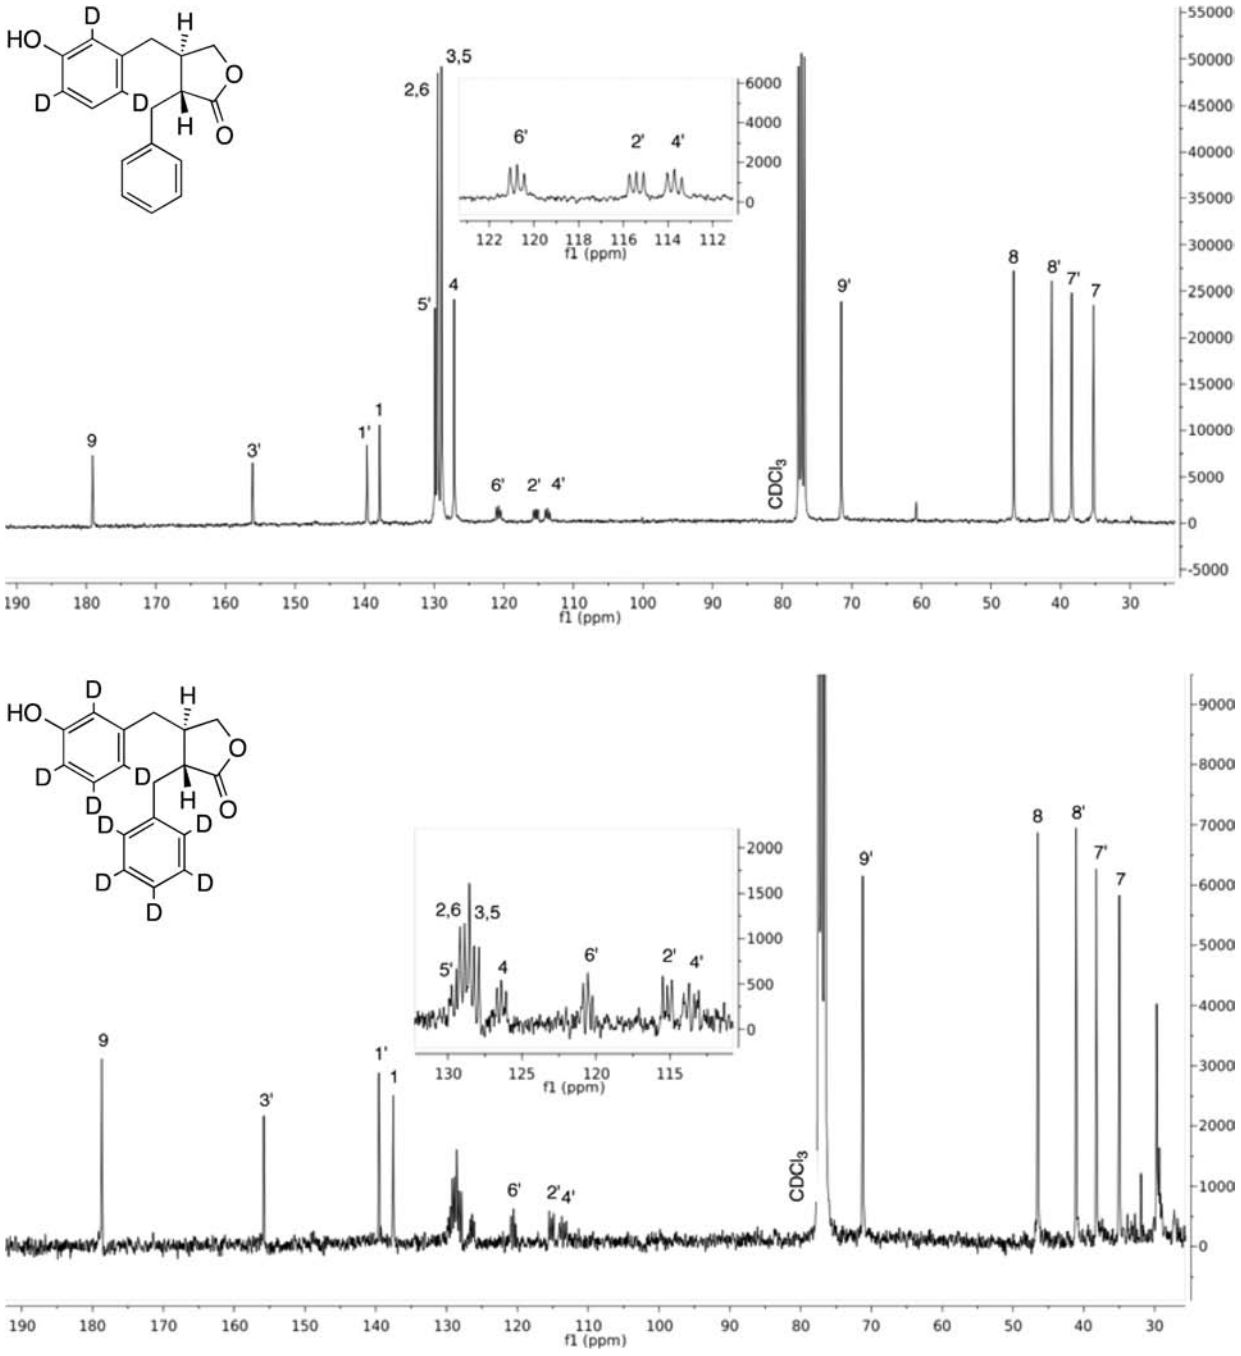

Figure 3. ^{13}C NMR spectra of D_3- and D_9-labeled 3′-hydroxylignano-9,9′-lactones (in $CDCl_3$).[44,46,47] The C−H singlets for deuterated sites are replaced by low-intensity C−D triplets (expanded).

distilled acetic anhydride by slow addition to heavy water and stirring the solution under argon for 2 h. The phenolic protons were exchanged with deuteriums by dissolving matairesinol in labeled acetic acid, leaving it to stand for several hours and finally evaporating the solvent. The labeled phosphoric acid D_3PO_4 was prepared by adding D_2O to P_2O_5. Predeuterated matairesinol was added to deuterated phosphoric acid under argon, and the reaction mixture was stirred at 80 °C for 3 days. Deuteration and workup were repeated three times. The isotopic purity was estimated from the mass spectrum to be 95% for D_6-**11** and 5% for the D_5 derivative.

Neidigh et al. prepared a <20 mg portion of hexadeutero-labeled matairesinol D_6-**17** by stirring the unlabeled lignan with $DClO_4$ (68% in D_2O) in THF/$CDCl_3$ at room temperature in only 4 h.[51]

An effective method using the deuterated phosphoric acid−boron trifluoride complex $D_3PO_4{\cdot}BF_3/D_2O$ was developed in our group initially to synthesize a stable deuterium-labeled isoflavone genistein[63] and, later, also other related compounds.[64−66] Originally tetradeuterogenistein was synthesized by refluxing predeuterated genistein **12** in CF_3COOD for 2 days to obtain D_4-genistein [6,8,3′,5′-D_4]-**12** in 75% yield and >90% isotopic purity ("a" in Figure 9).[21] However, it was found later that the most highly activated 6- and 8-site labels were unstable during the ID-GC-MS-SIM analytical procedure and were lost to some extent, making the [6,8,3′,5′-D_4]-**12**

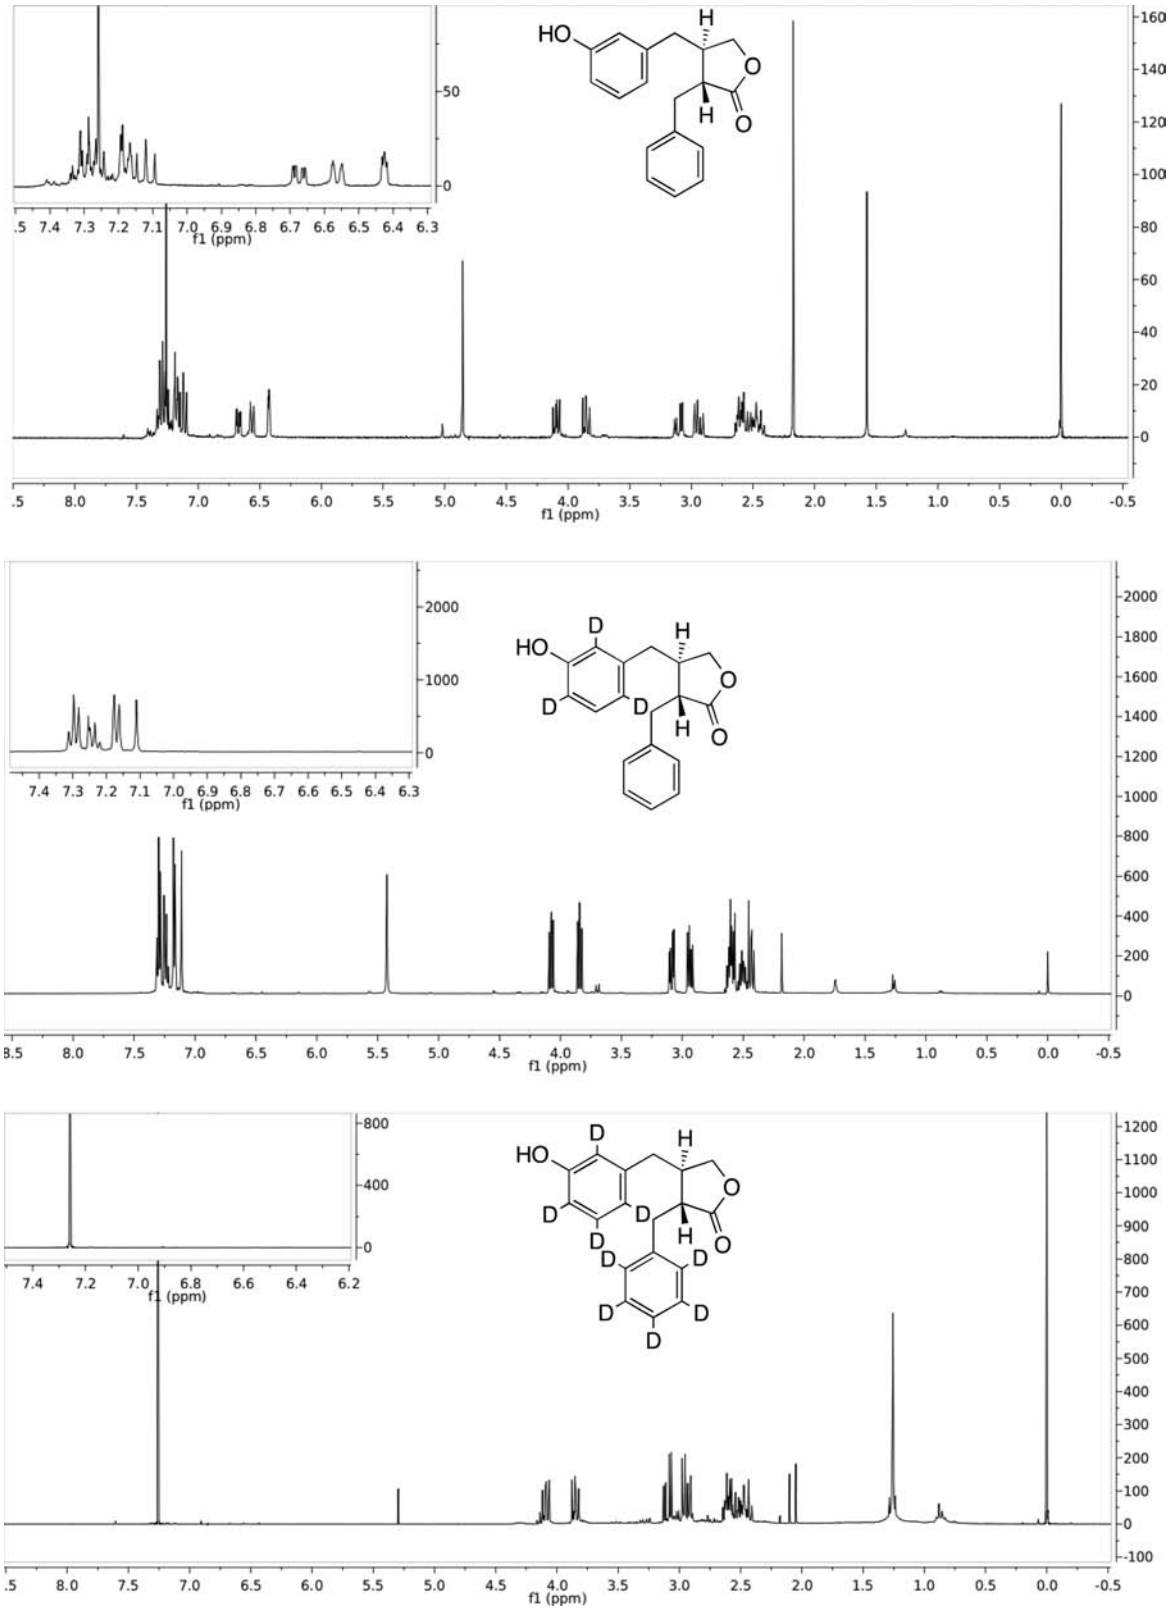

Figure 4. ^{1}H NMR spectra of unlabeled, D_3-labeled, and D_9-labeled 3′-hydroxylignano-9,9′-lactone (in $CDCl_3$).[44,46,47] In the expanded aromatic region it is clearly seen that proton signals are lacking when the aromatic positions are deuterated.

unsuitable as an internal standard. In fact, the labile deuterium labels at sites 6 and 8 were readily exchanged back to hydrogens, and the two remaining deuteriums at sites 3′ and 5′, although stable, were not enough to avoid the interference of fairly intense M + 1, M + 2, and M + 3 ions of the natural isotopes of the unlabeled compounds in mass spectra (as discussed above). Thus, several reagents were tested to overcome the problem. For example, D_3PO_4, which was used

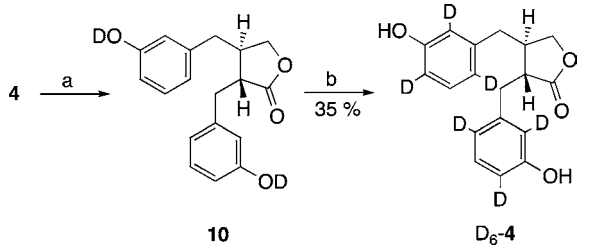

Figure 7. Reagents and conditions: (a) D_2O; (b) (i) PBr_3, D_2O, reflux, 5 h; (ii) H_2O.[62]

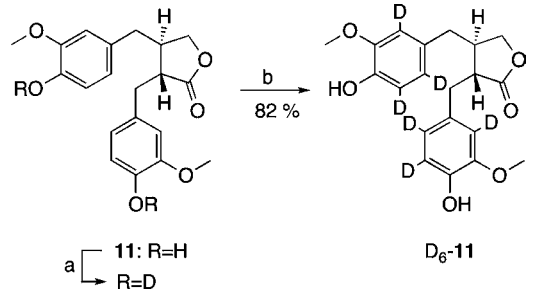

Figure 8. Reagents and conditions: (a) CH_3COOD; (b) (i) D_3PO_4, 80 °C, 9 days in total, (ii) H_2O.[21]

for deuteration of the lignan matairesinol **17** to good effect,[21] could exchange only a third of the ring A protons and none from the B ring. However, the deuterated phosphoric acid−boron trifluoride complex $D_3PO_4{\cdot}BF_3/D_2O$ was active enough to exchange all of the aromatic ring protons ("b" in Figure 9).[63] After the removal of the labile 6- and 8-labels ("c" in Figure 9) an isotopically pure and stable [2′,3′,5′,6′-D_4]-isotopologue of tetradeuterogenistein d_4-**12** was obtained.[45]

The deuteration reagent $D_3PO_4{\cdot}BF_3/D_2O$ is used also to deuterate various lignans. The reagent is freshly prepared by dissolving dry P_2O_5 in D_2O at 0 °C, and the resulting deuterated phosphoric acid is saturated with BF_3 gas bubbling through the acid at room temperature. Treatment of matairesinol **11** worked as expected to give the hexadeuterated matairesinol D_6-**11** much more quickly than with D_3PO_4 alone (Figure 10), that is, in 20 h instead of 9 days.[67] Additionally, the reaction with enterolactone **4** was remarkably found to give the fully aryl deuterated D_8-**4** (Figure 10).[68] All eight aromatic protons, even from the nonactivated C-5 and C-5′ sites, were exchanged at room temperature, giving D_8-labeled product in >99% isotopic purity. No exchange was observed at the *α*-carbonyl or benzylic sites.[47]

The use of dielectric microwave heating has been increasingly utilized in organic synthesis since the pioneering works of Gedye[69] and Giguere[70] in 1986. Despite being commonly employed in laboratory work, microwave techniques had not been reported in the synthesis or labeling of lignans until very recently.[71−73] It was found that the use of 35% DCl in D_2O and the ionic liquid 1-butyl-3-methylimidazolium chloride, [bmim]-Cl, as a cosolvent under microwave irradiation is a fast and high-yielding deuteration method for polyphenolic compounds including lignans.[71,74] The reaction times were shortened significantly (from several days to 40 min). The selectivities were not different from those observed under conventional heating.

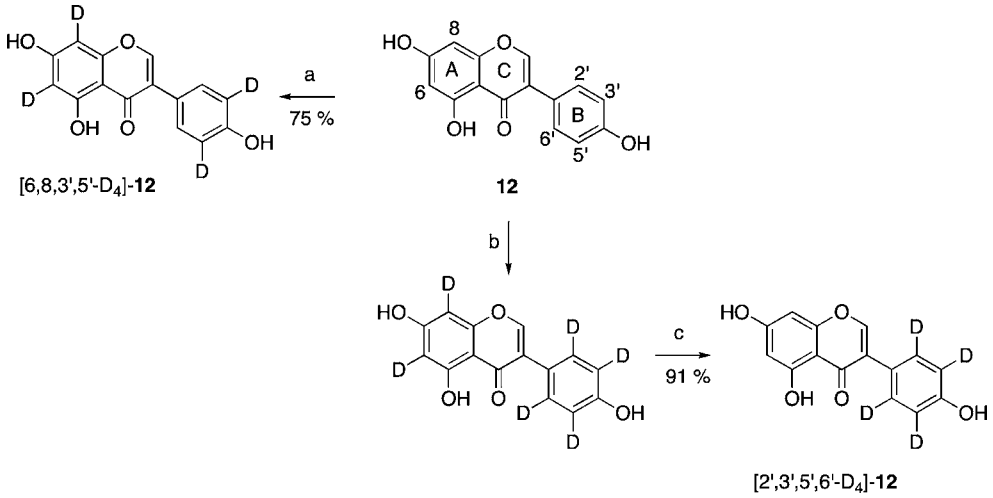

Figure 9. Reagents and conditions: (a) CF_3COOD;[21] (b) (i) D_2O/acetone, (ii) $D_3PO_4{\cdot}BF_3/D_2O$, 55 °C, 3 days, (iii) H_2O/EtOH; (c) 1% CH_3COCl in MeOH, reflux, 30 min.[63]

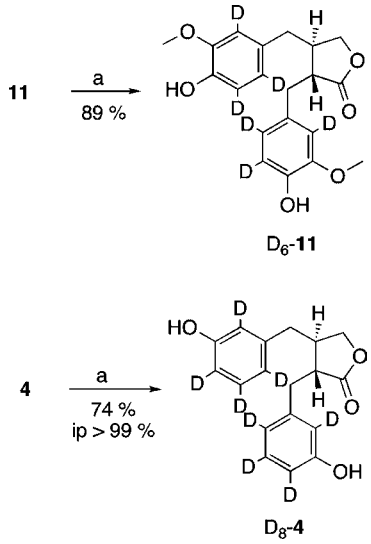

Figure 10. Reagents and conditions: (a) (i) D_2O/acetone, (ii) $D_3PO_4{\cdot}BF_3/D_2O$, room temperature, 20 h; (iii) H_2O.[67,68]

Lignans have been shown to be susceptible to heating.[44] The method using DCl/D_2O together with microwave heating works well for lignans even at lower temperatures (40 °C) and in some cases also without an ionic liquid solvent. Several tetrahydrofuran and butyrolactone type lignans were deuterated.[46]

SELECTIVITIES IN ELECTROPHILIC AROMATIC DEUTERATION

Relative Ease of H/D Exchange at Various Aromatic Positions. When $D_3PO_4{\cdot}BF_3/D_2O$ was used for the isoflavones daidzein and dihydrodaidzein, the degree of deuteration could be modulated by the reaction temperature.[64,66] In the case of isoflavonoids[64] and flavones,[65] raising the temperature to 55 °C does not seem to diminish the yields, but the lignan framework is found to be more fragile.[44] Hence, the deuteration reactions were carried out at room temperature. It is also interesting that within the lignan skeleton, all of the aromatic sites undergo exchange at room temperature (Figure 10),[47,68] whereas in the case of the isoflavone daidzein, only three positions were deuterated at room temperature in 3 days. Repeating the reaction deuterated the fourth position, and raising the temperature to 55 °C deuterated the fifth position.[64]

Deuteration using the highly acidic $D_3PO_4{\cdot}BF_3/D_2O$ also exchanges protons to deuteriums at the less reactive aromatic sites, giving, for example, a fully aryl deuterated derivative of 3′-hydroxylignano-9,9′-lactone **13** (D_9-**13**, Figure 11).[47] The other reported acidic methods, however, work in a more conventional way. For example, DCl in D_2O exchanges protons of **13** at the substituted B-ring only and at the activated sites *ortho* and *para* to the hydroxy group (Figure 11).[46]

As the deuteration reagent $D_3PO_4{\cdot}BF_3/D_2O$ was found to be very efficient in labeling isoflavones and especially lignans, exchanging protons for deuterium even at the unactivated aromatic positions of the lignan skeleton (see D_8-**4** in Figure 10 and D_9-**13** in Figure 11), several new deuterium-labeled

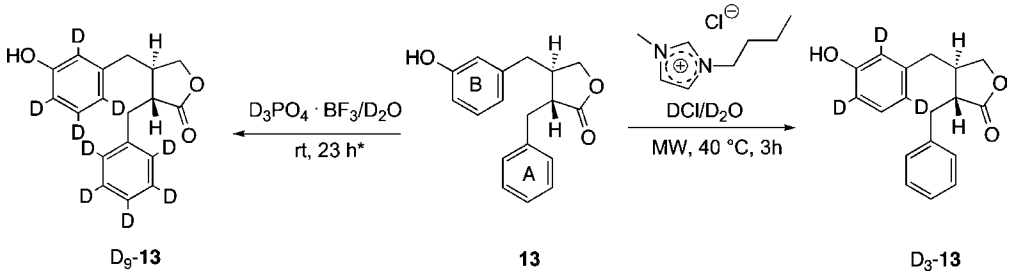

Figure 11. Deuteration of 3-hydroxylignano-9,9′-lactone **13**.[46,47] * The deuteration reaction was repeated with fresh reagent until the isotopic purity was >85%.

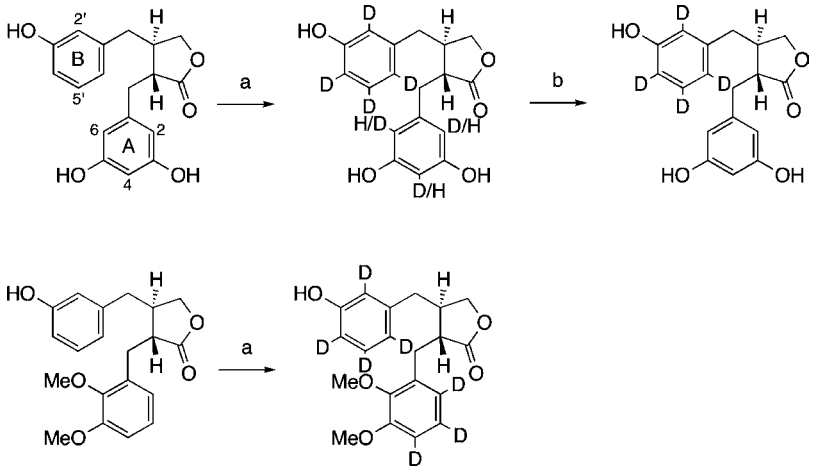

Figure 12. Synthesis of stable deuterated lignano-9,9′-lactones. Reagents and conditions: (a) (i) $D_3PO_4{\cdot}BF_3/D_2O$ (freshly prepared), room temperature; (ii) H_2O; (b) CH_3COCl, MeOH, reflux.[47]

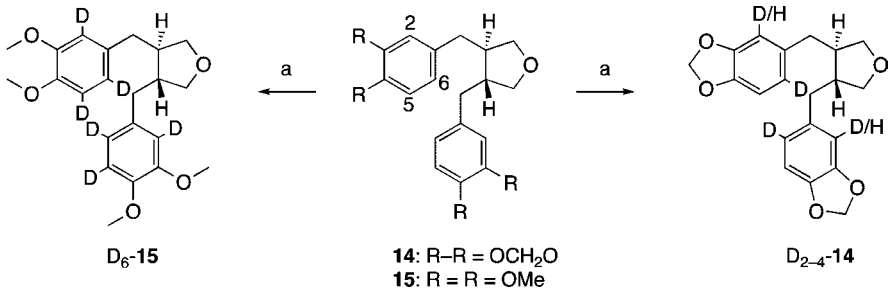

Figure 13. Deuteration of dehydroxycubebin **14** and brassilignan **15**. Reagents and conditions: (a) (i) 35% DCl in D_2O, [bmim]Cl, MW, 40 °C; (ii) H_2O.[46]

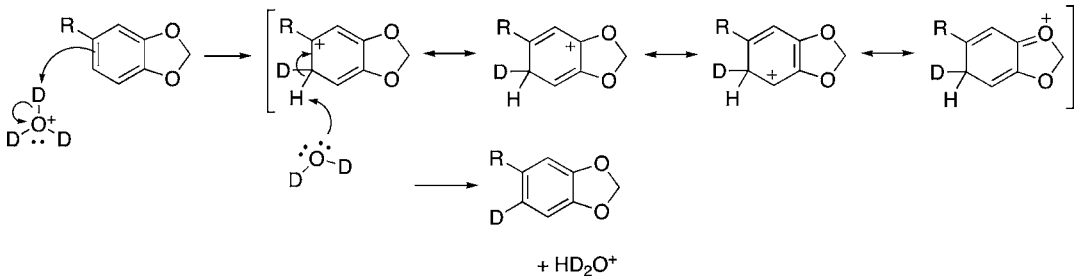

Figure 14. Mechanism of H/D exchange. R is for the rest of the lignan molecule.

lignanolactones were synthesized to examine the influence of the substitution pattern on the deuteration order.[47,75]

The exchange order of hydrogens, that is, the relative ease of H/D exchange at the various aromatic positions, was determined by following the progress of the deuteration reaction by ^1H NMR. In addition, electrostatic potential (ESP) charges were calculated to study the relative reactivities of the aromatic protons. The observed reactivities were compared with the calculated reactivities and found to be in good agreement.[47] The very inactive 5-position in the 3-hydroxyphenyl moiety (see 5′ in Figure 12) was tardy in reacting and in some cases needed several repetitions with fresh deuteration reagent. On the other hand, the presence of the two *meta*-substituted hydroxy or methoxy groups in ring A highly activated the aromatic sites 2, 4, and 6 (Figure 12). Because of the strong activation at these sites (2, 4, and 6), back exchange from deuterium to hydrogen occurred to some extent during quenching of the deuteration reaction into a large volume of ice-cold water (0.5 L water/100 mg lignan).[44] Thus, when the deuteration had reached a satisfactory level, that is, the isotopic purity was >85%, the remaining labile deuterium labels were selectively back exchanged to hydrogens in refluxing 0.5−1% CH_3COCl in methanol ("b" in Figure 12). This approach of deuteration with $D_3PO_4{\cdot}BF_3/D_2O$ and subsequently removal of the labile deuteriums in CH_3COCl/MeOH was very efficient in synthesizing labeled lignans possessing three to nine deuteriums in the aromatic rings. The deuterated lignans were isomerically and isotopically pure (>85% isotopic purity), and the yields were good (81−97%).[47] These deuterated standards have been successfully used in quantitating lignan contents in food samples.[76]

Aberrant Selectivity in Deuteration of Methylenedioxy Substituted Compounds. The deuteration of several butyrolactone and tetrahydrofuran type lignans with DCl in D_2O gave the expected behavior, exchanging protons to deuteriums at all of the activated positions (see D_3-**13** in

DOI: 10.1021/acs.jafc.5b00214
J. Agric. Food Chem. 2015, 63, 7595−7605

Figure 11). However, dehydroxycubebin **14** gave unexpected results (Figure 13).[46] The deuteration was only partial, giving a mixture of di-, tri-, and tetradeuterated products D_{2-4}-**14**. In contrast, brassilignan **15**, a close analogue of dehydroxycubebin, was successfully hexadeuterated with >97% isotopic purity.

As mentioned above, the mechanism of the H/D exchange is an ordinary electrophilic aromatic substitution,[57] where hydroxy and alkoxy groups are *ortho*−*para* directing and activating. The methylenedioxy substituent, however, causes aberrant selectivity. In the model compound 1,3-benzodioxole (1,2-methylenedioxybenzene, Figure 14: R = H) the positions *meta*/*para* to the methylenedioxy substituent were fully deuterated, whereas the *ortho* positions were only partially deuterated.[46] The higher *para*-selectivity of 1,3-benzodioxole in electrophilic aromatic substitution, in comparison to its cyclohomologues or veratrole, has been observed and rationalized by a distortion of the aromatic ring when annelated to a small ring and by quasiaromatic nature of the heterocyclic ring.[77]

The deuteration mechanism takes place in two steps: first, the electrophile attacks, giving rise to positively charged resonance stabilized intermediate, and the leaving group departs in the second step (Figure 14). Simultaneous attack and departure mechanisms are not known.[61] With regard to the mechanism, computational studies suggested another, conformation-dependent factor responsible for the deviant behavior preventing the complete deuteration of **14**.[46] The calculations imply that under the reaction conditions, the tetrahydrofuran type lignans prefer π-stacked, so-called sandwich, conformations, suggesting that the first reaction step, that is, addition of the deuterium, occurs from the solvent-exposed face of the molecule where the steric pressure is weaker, and the second step, that is, departure of the protium, occurs from the internal face. The first step is possible for both structures **14** and **15**; however, the second step of the electrophilic aromatic substitution is sterically prevented for one of the dehydroxycubebin **14** conformers. Presumably, due to interactions with the rigid methylenedioxy substituent, there is increased coplanarity between the aromatic rings of **14**, compared to **15**, which has two freely rotating methoxy groups.[46]

The butyrolactone and tetrahydrofuran type lignan structures undergo electrophilic aromatic substitution in deuteration reactions under acidic conditions. The degree of reactivity and selectivity of the deuteration is generally straightforward and predictable, enabling isotopically pure and stable polylabeled analogues to be prepared. However, some aberrant behavior is detected. The deuteration reagent $D_3PO_4{\cdot}BF_3/D_2O$ has the remarkable ability to exchange protons even at the unactivated aromatic positions, completely inaccessible with the other reported methods. Additionally, methylenedioxy substituents may cause unexpected deficiencies in the degree and orientation of atomatic deuteration, particularly in polycyclic aromatics.

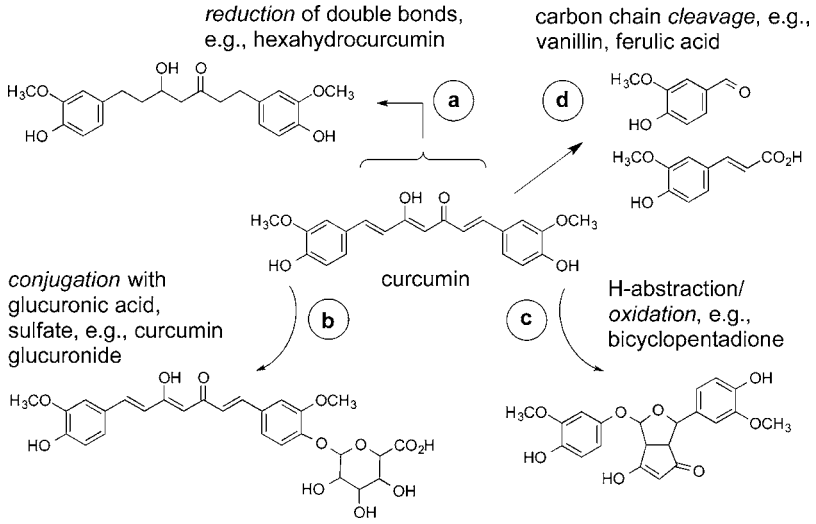

Figure 2. Metabolic and degradation pathways of curcumin: (a) reduction; (b) conjugation; (c) oxidation; (d) cleavage.

the in vivo and in vitro biological activities of curcumin will be discussed in the following.

DEGRADATION OF CURCUMIN IN CELL CULTURE

Although the chemical instability of curcumin is widely recognized, this fact is less considered in the interpretation of studies with cultured cells in vitro. Curcumin degrades quickly at physiological pH but more slowly when incubated in the presence of serum or with cultured cells.[24] Protein increases the half-life of curcumin from a few minutes to 1−2 h.[24] Nevertheless, there is sufficient time for curcumin to degrade during a typical 4−8 h incubation before cultured cells are harvested and analyzed. When cells have been treated with curcumin for several hours, it is impossible to decide whether the observed effects are due to curcumin or its degradation products. Unless interpreted with a consideration of what active or inactive metabolites of curcumin may be formed (or not) during an assay, results can be misleading and give only limited insight into the in vivo biological activity of curcumin.

Similar considerations are relevant for studies claiming that the mechanism of action of curcumin is due to the induction of oxidative stress ("reactive oxygen species", ROS) in cells. In many instances, the role of curcumin-induced ROS has been shown indirectly, that is, by addition of a reducing antioxidant, for example, *N*-acetylcysteine, that abolished the effects of curcumin.[25−29] The action of the antioxidant, however, is not only to reduce ROS formation but also to delay or prevent degradation of curcumin. Thus, unless specific probes against ROS are used rather than a general antioxidant, it is not possible to decide whether effects caused by curcumin are mediated by the induction of oxidative stress or its degradation products.

Another facet of curcumin that is not sufficiently considered is its heterogeneity as a natural product. "Curcumin" is used to describe the chemically pure compound or an extract from the turmeric rhizome that is enriched in curcuminoids, that is, a mixture of curcumin, demethoxycurcumin (DMC), and bisdemethoxycurcumin (BDMC). Their relative abundance in commercial extracts is about 80:15:5. Whether pure curcumin or a mixture of curcuminoids is used in an assay is relevant not only because curcumin, DMC, and BDMC may have distinct activities but also because the stability of the mixture is different from that of the pure compounds.[30]

THE DEGRADATION IS AN AUTOXIDATION

For many years cleavage of the heptadienedione chain reported by Wang and co-workers in the late 1990s was considered the prevailing degradation reaction, resulting in vanillin, ferulic acid, and feruloylmethane as products.[24] Meanwhile, there is evidence from revisiting the degradation reaction that chain cleavage is only a very minor pathway[31] and thus irrelevant for understanding the biological effects of curcumin in vitro. Interestingly, vanillin, ferulic acid, and feruloylmethane were described to be minor products already in the original paper by Wang and co-workers, and the major product detected was tentatively identified as *trans*-6-(4′-hydroxy-3′-methoxyphenyl)-2,4-dioxo-5-hexenal, the assignment being uncertain because NMR data were not available.[24] In hindsight, the identification of the major product was probably incorrect, and the major product detected by Wang and co-workers was likely the bicyclopentadione product of autoxidative transformation of curcumin.[16]

The degradation of curcumin in buffer is a spontaneous, free radical-driven incorporation of O_2 that meets the criteria of an autoxidative process (Figure 3).[16] The major product of the autoxidation of curcumin is a bicyclopentadione, formed by oxygenation and double cyclization of the heptadienedione

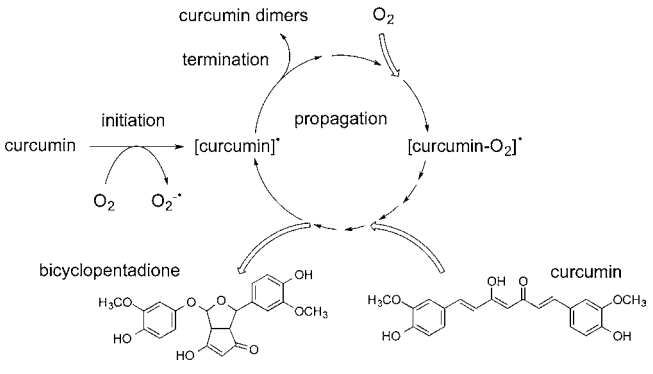

Figure 3. Degradation of curcumin is an autoxidation to a bicyclopentadione.

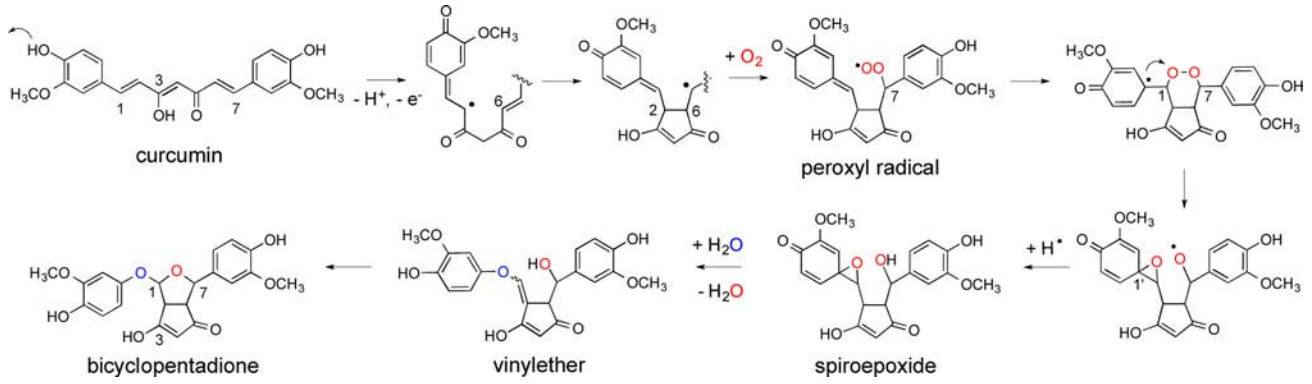

Figure 5. Proposed mechanism for the formation of the bicyclopentadione during autoxidation of curcumin.

chain connecting the two methoxyphenol rings of curcumin.[16] This complex transformation is the result of incorporation of O_2 and further rearrangement through several key intermediates.[32] Autoxidation is initiated by O_2 serving as the initial electron acceptor. The propagation results in a 1:1 molar reaction of curcumin with molecular oxygen: for every molecule of curcumin converted, one molecule of oxygen is consumed.[16] Thus, the terms "degradation" and "autoxidation" are equivalent in describing the spontaneous transformation of curcumin in vitro.

■ PRODUCTS OF OXIDATIVE TRANSFORMATION

We analyzed the degradation products of curcumin using [$^{14}C_2$]curcumin as tracer for RP-HPLC analyses.[32] We isolated seven novel compounds and determined their structures using LC-MS, HR-MS, and NMR analyses (Figure 4). Six products had oxygen substitutions at C-1 and C-7 of the former heptadienedione chain. The oxygen atoms were present in hydroxy, keto, epoxy, ether, and hemiketal moieties. Two products that did not incorporate oxygen were a cyclobutylcyclopentadione and diguaiacol, an obvious cleavage product. Two of the isolated products, the spiroepoxide and the vinylether cyclopentadiones, were intermediates in the reaction to the bicyclopentadione. The others were end products formed in addition to the bicyclopentadione. Neither vanillin nor ferulic acid was formed in sufficient amount to be detected by the radiodetector.[32] Vanillin, however, can be detected as a minor product when a more sensitive UV diode array detector is used.[31]

An explanation of why these novel products have not been described before is probably their minor abundance (e.g., the cyclobutylcyclopentadiones and diguaiacol) combined with unexpectedly high polarity on RP-HPLC, especially in the case of the dihydroxy, ketohydroxy, and hemiketal cyclopentadiones, and sensitivity to acid. Even brief exposure of the spiroepoxide and vinylether to acidic pH will result in transformation to the bicyclopentadione. Unless precautions are undertaken, the newly identified products undergo further reaction, are not extracted, or elute in the void volume if standard extraction procedures and RP-HPLC conditions are employed.[32]

Depending on reaction time and sample workup different product profiles of curcumin autoxidation reactions were obtained. Reactions conducted for longer than 4 h followed by acidification and extraction (solid-phase or liquid/liquid) gave the bicyclopentadione diastereomers as the almost exclusive products with little to no curcumin remaining.[31] Shorter reaction times, between 30 min and 4 h, followed by acidification and extraction also gave the bicyclopentadiones as major products and, in addition, several smaller unidentified peaks were detected.[16] If reactions are shortened to 20−45 min and injected directly on RP-HPLC (without acidification and extraction), the chromatograms show prominent products that are more polar than the bicyclopentadiones.[32] These peaks comprise the spiroepoxide and vinylether as major products and the dihydroxy, ketohydroxy, and hemiketal cyclopentadiones as minor products.

Time course experiments established that at physiological pH the spiroepoxide has a longer half-life than curcumin. Whether this holds true under more physiological conditions is not clear. The spiroepoxide is electrophilic and subject to reaction with thiols.[32]

J. Agric. Food Chem. 2015, 63, 7606−7614

MECHANISM OF OXIDATIVE TRANSFORMATION

Curcumin and the bicyclopentadione are structurally very different. It is obvious that the degradation must involve a series of discrete reactions resulting in double cyclization and oxygenation of the heptadienedione chain (Figure 5).[32] The two methoxyphenol rings are required for the reaction but participate only indirectly by facilitating certain reaction steps (see below).[30]

Because the molecular weight of the bicyclopentadione is increased by 32 mass units compared to that of curcumin, it seemed plausible that O_2 would be inserted during the autoxidation and end up in the bicyclopentadione. It was quite surprising then that one ^{18}O from $H_2{}^{18}O$ was incorporated into the bicyclopentadione when degradation reactions of curcumin were conducted in labeled buffer.[32] Thus, although it is true that O_2 is inserted into curcumin during autoxidation, only one of the two oxygen atoms remains in the final product.

The initiating event of the autoxidation is hydrogen abstraction from one of the phenolic hydroxyls to form a phenoxyl radical.[16] The hydrogen abstraction likely occurs as a two-step process of proton loss in the slightly alkaline medium (pH 7.4−8) followed by electron transfer[33,34] from the phenolate anion to molecular oxygen, which is reduced to superoxide.[16] H abstraction can also be catalyzed by peroxidases with curcumin acting as a cosubstrate, providing an electron to reduce a peroxide. As expected, the addition of H_2O_2 to the peroxidase-catalyzed transformation of curcumin resulted in a large increase of the enzymatic turnover rate.[16]

The 1,2-*E* double-bond conjugated to the methoxyphenol ring enables delocalization of the radical to C-2 of the chain, leaving the aromatic ring oxidized to a quinone methide. The C-2 radical performs a 5-*exo* cyclization with the 6-*E* double bond to form the cyclopentadione ring that is present in all products except for diguaiacol.[32] The carbon-centered radical is now localized at C-7 where it reacts with O_2 to a peroxyl radical. The peroxyl radical is poised to quench the unstable quinone methide by forming a C-1/C-7 endoperoxide. This brings the radical back to the semiquinone ring. The tertiary radical reacts with the endoperoxide in an intramolecular homolytic substitution reaction (S_Hi).[35,36] S_Hi results in cleavage of the endoperoxide O−O bond to give an epoxide (C-1/C-1′-spiroepoxide) and an alkoxyl radical at C-7. Reduction of the alkoxyl radical results in a spiroepoxide cyclopentadione. The reduction may occur as a hydrogen abstraction from curcumin and propagate the free radical chain reaction. The spiroepoxide is the earliest product in the degradation pathway that has been isolated, compatible with being the first nonradical product in the proposed mechanism (Figure 5).[32]

Although hydrolysis of the epoxide by nucleophilic attack of the C-7 hydroxyl could directly lead to the bicyclopentadione,[16] this does not occur.[32] Instead, the spiroepoxide is transformed to a vinylether as the immediate precursor to the bicyclopentadione. Unexpectedly, the opening of the spiroepoxide also involves the exchange of the epoxide oxygen (that is derived from O_2) for an oxygen from H_2O. These results can be explained by a mechanism in which the electron-donating effect of the *m*-methoxy group of the spiroepoxide triggers S_N1 opening of the epoxide that is facilitated by hydrogen bonding with the cyclopentadione hydroxyl (Figure 6).[32] Addition of water to the *o*-quinone intermediate results in a vicinal diol that

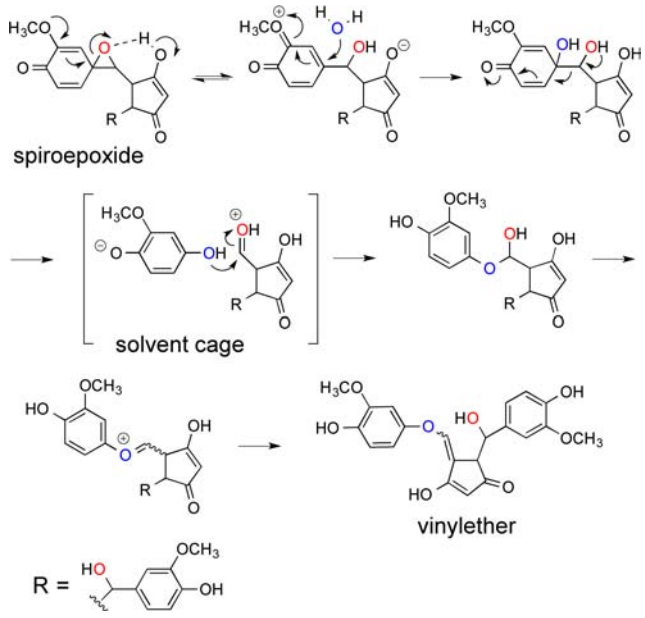

Figure 6. Proposed mechanism of the exchange of water during transformation of the spiroepoxide to the vinylether.

undergoes C−C bond cleavage, driven by rearomatization of the ring, to an aldehyde and methoxyhydroquinone. The two molecules are in a solvent cage and instantly recombine to a hemiacetal that loses water (containing the original epoxide oxygen) on the way to the vinylether.

The byproducts of the autoxidation are formed by alternative reactions of intermediates in the proposed mechanism:[32]

(i) Cyclobutyl cyclopentadione: The peroxyl radical can undergo *β*-fragmentation (i.e., the loss of O_2 to regain the C-7 carbon radical) at a rate that is fast enough to enable 4-*exo* cyclization with C-1 to form the cyclobutyl ring. Although the rates for these steps have not been determined, the formation of the cyclobutyl product indicates that the quinone methide intermediates have a considerable lifetime to undergo alternative reactions, especially with nucleophilic protein or small molecule thiols.

(ii) Dihydroxy, ketohydroxy, and hemiketal cyclopentadiones: The endoperoxide radical intermediate is a branching point from which not only the spiroepoxide emerges. Reduction of the tertiary radical gives a covalently complete endoperoxide, which is predicted but has not been confirmed by isolation (Figure 7). The curcumin endoperoxide is unstable and opens to the ketohydroxy cyclopentadione in a Kornblum−DeLaMare rearrangement.[37] The ketohydroxy cyclopentadione is in equilibrium with its hemiketal form. Reduction of the endoperoxide gives the dihydroxy cyclopentadione. These reactions are reminiscent of the reactions of the cyclooxygenase-derived prostaglandin endoperoxide PGH_2 and its transformations to prostaglandins PGD_2, PGE_2, and $PGF_{2\alpha}$.[38]

(iii) Diguaiacol: The mechanism of formation of diguaiacol is uncertain. Most likely, it involves cleavage of the carbon bond connecting the methoxyphenol ring to the heptadienedione chain. Such a cleavage could be facilitated by, for example, further oxygenation of the endoperoxide radical as has been described to occur during chain cleavage of lipid hydroperoxides.[39,40]

DOI: 10.1021/acs.jafc.5b00244
J. Agric. Food Chem. 2015, 63, 7606−7614

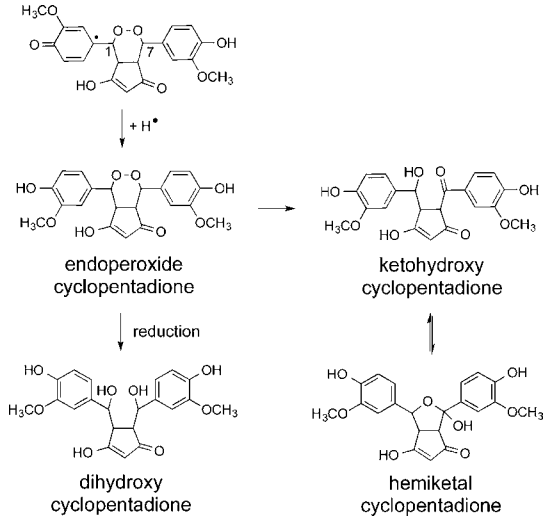

Figure 7. Formation of dihydroxy, ketohydroxy, and hemiketal cyclopentadiones from a proposed endoperoxide intermediate.

(iv) Vanillin: Trace amounts of vanillin detected in RP-HPLC/UV diode array analyses might be formed by C−C bond cleavage of the alkoxyl radical intermediate. Cleavage is competing with reduction of the alkoxyl radical to the spiroepoxide by H abstraction from curcumin. This origin of vanillin is compatible with data by Wang and co-workers, who noted that vanillin was increased when curcumin was incubated in buffer for an extended time.[24] Upon prolonged incubation, the reaction will run out of curcumin as a hydrogen donor, and the alkoxyl radical may be prone to undergo cleavage into vanillin.

OXIDATIVE TRANSFORMATION OF DMC AND BDMC: ROLE OF THE *m*-METHOXY GROUP

The less abundant curcuminoids DMC and BDMC also can be oxidatively transformed.[30] There were, however, two important differences in the oxidation of DMC and BDMC compared to curcumin. First, the rate of autoxidation of DMC was markedly reduced such that its half-life is in the range of hours rather than minutes (Table 1). This trend was enhanced in BDMC that did not autoxidize at all. Second, whereas DMC formed the expected demethoxy bicyclopentadione, BDMC formed a bisdemethoxy spiroepoxide when forced to oxidize. The bisdemethoxy spiroepoxide was stable and did not further transform to a bisdemethoxy bicyclopentadione analogue.[30]

The mixture of curcuminoids as it is present in turmeric extract was more stable to autoxidation than predicted on the basis of the relative abundance of curcumin, DMC, and BDMC in the mixture. Thus, not only are DMC and BDMC more stable toward autoxidation, they also appear to protect curcumin from autoxidation.[30]

These findings point toward a crucial role of the methoxy groups in determining the stability of the curcuminoids toward

Table 1. Structures, Autoxidation, and Products of Curcumin and Analogues

Compound/structure	Autoxidation (approx. $t_{1/2}$)	Main product
 curcumin	fast (minutes)	 bicyclopentadione
 demethoxycurcumin (DMC)	slow (hours-days)	 demethoxybicyclopentadione
 bisdemethoxycurcumin (BDMC)	stable; requires enzymatic or chemical oxidation	 bisdemethoxyspiroepoxide
 4'-O-methylcurcumin	slow (hours-days)	 methylbicyclopentadione
 4',4"-O-dimethylcurcumin	stable	N/A

DOI: 10.1021/acs.jafc.5b00244
J. Agric. Food Chem. 2015, 63, 7606−7614

autoxidation as well as the product profile (Table 1). The electron-donating effect of the methoxy group facilitates transfer of an electron from the phenolate anion to molecular oxygen. The lack of one methoxy group in DMC significantly slows the rate of electron transfer (hydrogen abstraction), although loss of the methoxy group and hydrogen abstraction occur on opposite ends of the molecule. BDMC, lacking both methoxy groups, is stable toward autoxidation. BDMC can be forced to oxidize using horseradish peroxidase/H_2O_2 or the oxidizing agent potassium ferricyanide.[30]

The methoxy group also affects the hydrolysis of the spiroepoxide. The contribution of the methoxy group to S_N1 hydrolysis of the epoxide moiety was discussed above.[32] It can be deduced that in a DMC spiroepoxide (which is predicted to be formed but has not been isolated) the methoxy group is in the ring that forms the epoxide and thus is positioned to induce hydrolysis of the epoxide. Lack of both methoxy groups in the BDMC spiroepoxide (which has been isolated) considerably increases stability, and the compound was stable to acid treatment to pH 3. It is less stable, however, in organic solvent, where it quickly decomposes to a mixture of products that have not been identified.[30]

As the site of the initial H abstraction, the phenolic hydroxyl also plays a key role in the disposition of curcumin and analogues toward autoxidation. Chemical modification to eliminate the abstractable hydrogen compromises autoxidation (Table 1). Substitution of one phenolic hydroxyl by a methoxy group (4′-*O*-methylcurcumin) greatly enhances stability, although oxidation can still be achieved enzymatically (HRP or cyclooxygenase-2/H_2O_2) or chemically (potassium ferricyanide). The product is a bicyclopentadione with the additional methyl group in the aromatic ring connected to C-7.[32] As expected, methylation of both phenolic hydroxyls (4′,4″-*O*-dimethylcurcumin) abolished oxidative transformation entirely.[16]

DOES AUTOXIDATION OCCUR IN VIVO?

Autoxidation is a prominent reaction when curcumin is incubated with cultured cells in vitro. Whether autoxidation also occurs in vivo is a crucial question for its biological relevance. Because so far there is no evidence that oxidative transformation of curcumin does indeed occur in vivo, it is worthwhile to consider factors relevant to this question:

(i) Curcumin is usually consumed as turmeric extract, containing also the minor curcuminoids DMC and BDMC. DMC and BDMC contribute to the stability of curcumin in vitro.[30] Whether the presence of DMC and BDMC in turmeric extract results in stabilization of curcumin in vivo remains an open question.

(ii) Albumin and protein in general increase the stability of curcumin toward autoxidation.[24] There is little doubt that the abundance of cellular protein in vivo enhances the stability of curcumin toward autoxidation.

(iii) Glucuronidation of curcumin at the phenolic hydroxyl is a major phase II metabolic pathway in vivo. Glucuronidation contributes to enhancing the stability of curcumin by blocking the free hydroxyl required for autoxidative transformation (O.N.G., P.B.L., and C.S., unpublished results).

(iv) Peroxidases can utilize curcumin as reducing cosubstrate, which may result in enzyme-catalyzed oxidative transformation in vivo.[16]

(v) Oxidative stress at inflammatory sites may contribute to oxidative transformation of curcumin.

(vi) Oxidative transformation to the bicyclopentadione proceeds through several reactive electrophilic intermediates. In vivo, these will be subject to interception by cellular antioxidant defense mechanisms such as adduction with glutathione and *N*-acetylcysteine.[32] As long as the cellular antioxidant defense is functional, only a small fraction of reaction intermediates is predicted to "make it" past the antioxidant barrier and form the bicyclopentadione. Thus, any bicyclopentadione detected in vivo might only be the tip of an iceberg and indicate that oxidative transformation may be an abundant metabolic pathway.

(vii) The glutathione or *N*-acetylcysteine adducts of the quinone methide and spiroepoxide reaction intermediates could be more appropriate markers of oxidative transformation of curcumin than the bicyclopentadione.

(viii) The reaction intermediates will adduct not only to small soluble thiols but also to reactive cysteine residues in proteins. Covalent adduction to protein may be a major mechanism by which oxidative metabolites of curcumin exert biological effects.

Thus, there are a number of factors that imply that oxidative transformation might or might not occur in vivo. We consider this an open question that we plan to address by careful analysis of in vivo samples.

PUTTING METABOLISM, AUTOXIDATION, AND BIOLOGICAL ACTIVITY TOGETHER

How does oxidative transformation relate to the structure–function of curcumin? Curcumin can act as a metal chelator, antioxidant, and Michael acceptor (Figure 8).[41−47] The metal

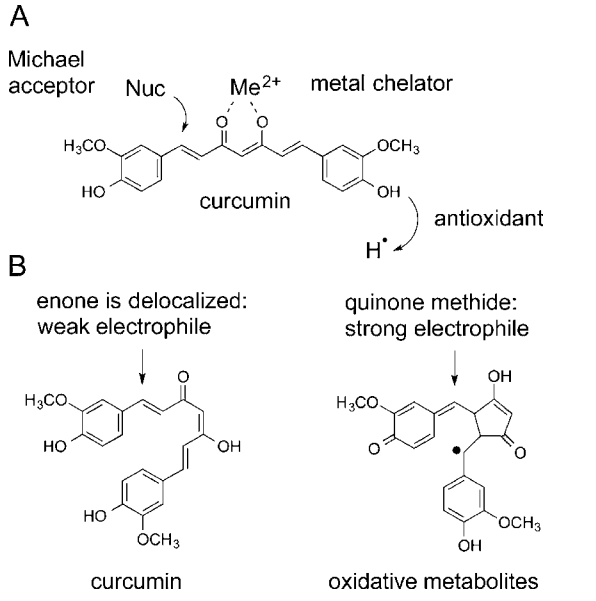

Figure 8. Structure–activity features of curcumin and its quinone methide.

chelating activity of the β-diketo moiety may be disturbed by the formation of the more rigid cyclopentadione ring, which is also more nucleophilic (acidic) than the β-diketo moiety of curcumin.

The antioxidant activity of curcumin is dependent on how readily a hydrogen can be abstracted from the phenolic hydroxyl by a lipid peroxyl radical *and* whether the resulting curcumin radical is less prone to initiate a new lipid

DOI: 10.1021/acs.jafc.5b00244
J. Agric. Food Chem. 2015, 63, 7606−7614

peroxidation chain in turn.[48] The hydrogen abstraction is the initiation of curcumin autoxidation with the resulting radical reactions as described in Figure 5. Dimerization of two curcumin quinone methide radicals has been described as a mechanism of termination.[49] The same group also identified linoleate peroxyl radical coupling products with curcumin.[50] These studies were performed in organic solvent (where curcumin does not autoxidize), and it would be interesting to analyze equivalent reactions in aqueous medium.

The Michael acceptor activity is undoubtedly influenced by autoxidation of curcumin. We hypothesize that it is even dependent on autoxidation.[51] The 1,3-enone (α,β-unsaturated carbonyl) in curcumin is only a weak electrophile because it is part of a delocalized system that spans the entire molecule. Oxidative transformation, specifically the initial hydrogen abstraction and delocalization of the radical into the heptadienedione chain, forms a quinone methide as a strong electrophile (Figure 8). As discussed above, the quinone methide has a considerable lifetime, and because it is present in three distinct intermediates (before and after 5-*exo* cyclization and in the peroxyl radical; cf. Figure 5), it possesses a range of reactivities that can be anticipated to react with different strength cellular nucleophiles. Interestingly, in either case (i.e., in curcumin or its quinone methide) the electrophilic carbon is the same, namely C-1.

A second electrophilic species formed in the autoxidation is the spiroepoxide. HPLC-isolated spiroepoxide readily formed a covalent adduct with *N*-acetylcysteine that was detected in LC-MS analyses.[32] A similar adduct was formed in peroxidase-catalyzed oxidation reactions of curcumin conducted in the presence of *N*-acetylcysteine. Interestingly, ions representing adducts of curcumin or the quinone methide with *N*-acetylcysteine were not detected.[32] These findings support our interpretation of the effect of *N*-acetylcysteine as inhibiting curcumin autoxidation and scavenging reactive electrophiles rather than counteracting ROS formation as a cellular response.

Because oxidative transformation is abundant under cell culture conditions, its products and intermediates need to be considered as mediators of biological effects. We hypothesize that the quinone methide and/or the spiroepoxide are the functional electrophiles in reactions where curcumin is proposed to form a covalent adduct with nucleophilic protein cysteine residues.[52−57] The hypothesis is also indirectly supported by the crucial role of quinone methides as the acting principle in many anticancer drugs as well as toxic DNA methylating agents.[58−60] The requirement for oxidative transformation has clearly been shown for the topoisomerase IIα poisoning activity of curcumin.[61] Neither 4′,4″-*O*-dimethylcurcumin (which does not autoxidize; Table 1) nor reaction conditions that prevented autoxidation of curcumin resulted in poisoning of topoisomerase IIα. The quinone methide intermediates were suggested as the electrophiles binding to active site cysteines, although the spiroepoxide could not be ruled out.[61]

Another pertinent example for Michael adduction is the anti-inflammatory activity of curcumin, especially when effects on the NF-κB pathway are invoked.[62−64] Both NF-κB and its upstream kinase, IKKβ, are targets of curcumin, and both are inhibited by small molecule electrophiles adducting covalently to regulatory cysteines in critical regions of the protein. A Michael type adduction by curcumin via its enone has been invoked as mechanism, whereas we suggest that the quinone methide is the adducting electrophile. This mechanism of adduct formation requires oxidative transformation of curcumin to form the reactive electrophile. This is a crucial difference because conditions for oxidative transformation may not be met in vivo, which could result in a discrepancy between in vitro and in vivo effects. There is an expanding number of proteins that are redox-regulated through strategically placed cysteines that undergo reversible redox cycling to sulfenic acids and can be adducted by small molecule electrophiles.[65] Identification of which of these might be cellular targets of curcumin will require proteomics approaches.

A second reason why oxidative transformation is relevant for understanding the biological activity of curcumin is the surprising number of products formed (Figure 4). When added to cultured cells, curcumin rapidly changes from a single molecule to a family of diverse chemotypes. It is not unreasonable to suggest that the free radical, quinone methide, endoperoxide, alkoxyl radical, dihydroxy, hemiacetal, ketohydroxy, spiroepoxy, vinylether, and other cyclopentadiones each have a distinct set of cellular targets. Together, these products and their biological activities may add up to the "polypharmacology" of curcumin. We are at the beginning of understanding the remarkable transformations of curcumin in vitro and in vivo. Future studies will show which of the many biological effects of curcumin are due to the parent and which are due to its degradation products.

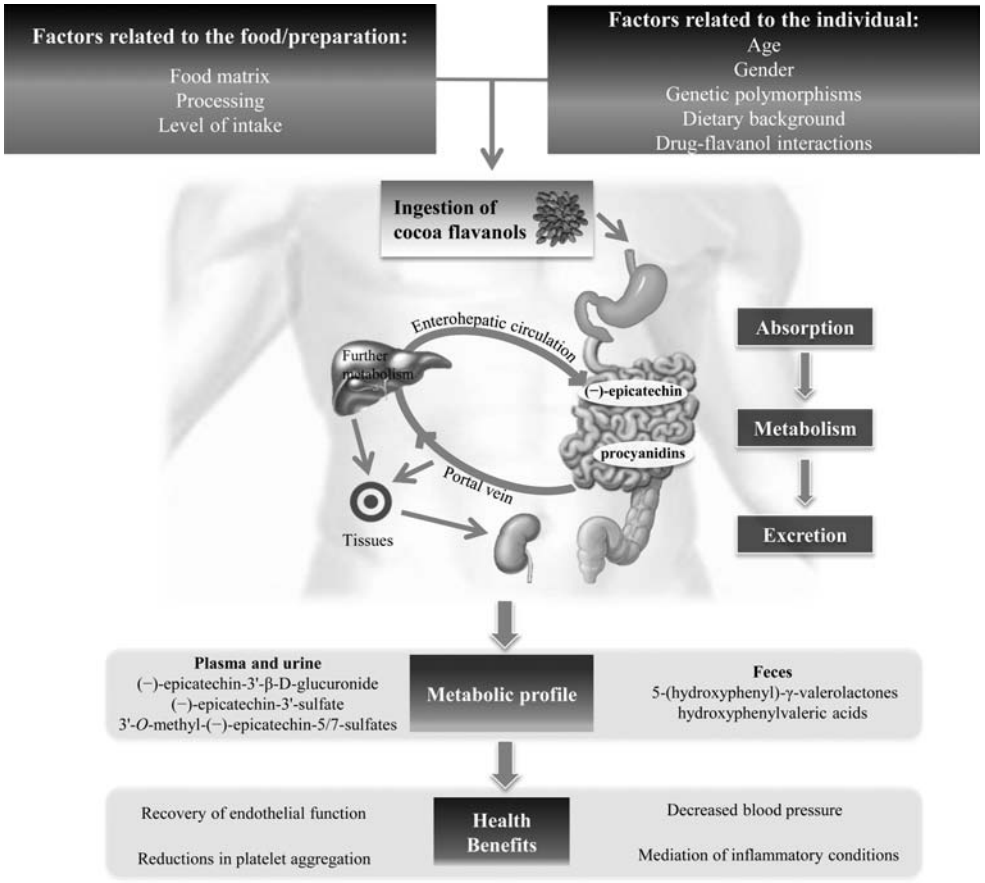

Figure 1. Schematic describing the main factors affecting the absorption, metabolism, and excretion of cocoa flavanols, together with the health benefits mediated by the circulating (−)-epicatechin metabolites.

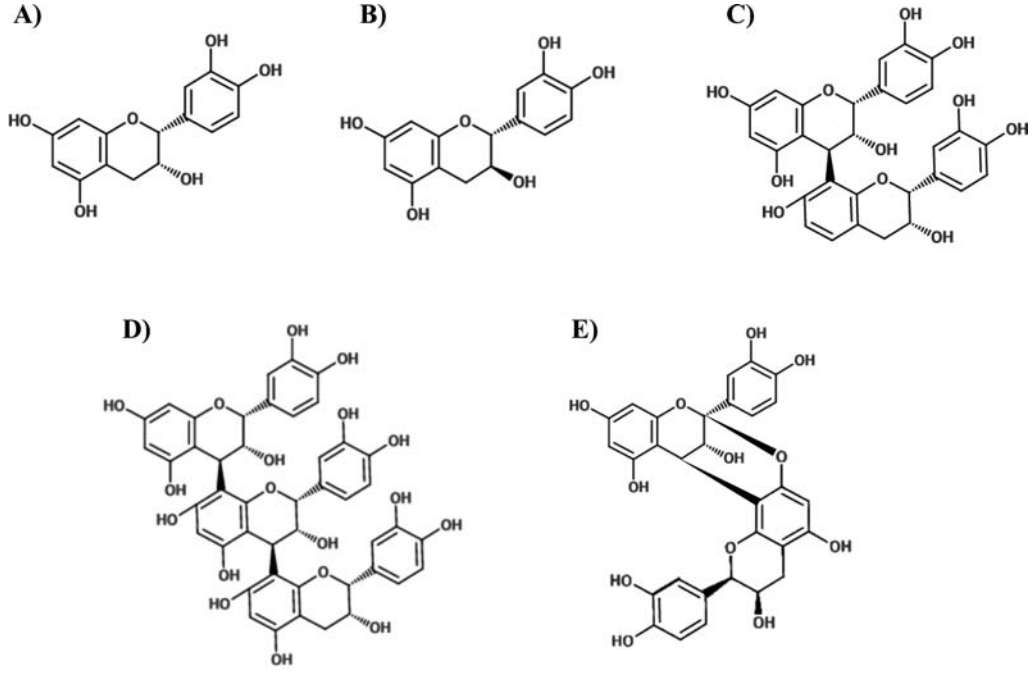

Figure 2. Chemical structures of (A) (−)-epicatechin, (B) (+)-catechin, (C) procyanidin dimer B2, (D) procyanidin trimer C1, and (E) procyanidin tetramer A2.

The polyphenol content of cocoa consists predominately of flavanols (monomeric forms: (−)-epicatechin, (+)-epicatechin, (−)-catechin, and (+)-catechin), procyanidins (oligomeric and polymeric derivatives of flavanols characterized by their degree of polymerization (DP), also named proanthocyanidins), and, to a lesser extent, anthocyanins.[10] The term "cocoa flavanols"

[a] C_{max}, maximum plasma concentration; t_{max}, time to reach maximum concentration; AUC, area under the curve of the concentration over time; EC, epicatechin; C, catechin; BW, body weight. [b] Urine collected over a 24 h period. [c] Data interpreted visually from a graph. [d] Values represent total epicatechin metabolites summed by the author. [e] Values derived by subtracting baseline values. [f] –, unavailable data in the manuscript.

includes both the monomeric forms (mainly (−)-epicatechin and to a lesser extent (+)-catechin) and the oligomeric procyanidins ranging from dimers to decamers (DP 2–10) (Figure 2). The average intake of cocoa flavanols has been recently estimated in Europe at 105 mg/day,[11] below the 200 mg/day considered by EFSA to be sufficient to help maintain normal endothelium-dependent vasodilation.[12] The primary flavanol in cocoa beans is (−)-epicatechin, ranging from 0.1 to 13.5 mg/g, with lower levels of (+)-catechin,[13−15] whereas oligomeric and polymeric procyanidin content ranges from 18 to 27 mg/g and from 9 to 16 mg/g, respectively.[16] In milk and dark chocolates, the epicatechin content (both enantiomers, (−) and (+) forms) has been reported between 0.18 and 1.25 mg/g, with catechin between 0.05 and 0.40 mg/g and oligomeric and polymeric procyanidin content around 1.1–11.2 and 0.8–7.0 mg/g, respectively.[16−18] The flavanol monomer content of chocolate is predominantly in the (−) form, accounting for approximately 95 and 89% of EC and catechin present, respectively.[18] Considering that cocoa beans do not contain (−)-catechin, it has been reported that the presence of this stereoisomer in chocolate might be due to the epimerization of (−)-epicatechin to (−)-catechin during processing.[14,19]

ADME

After oral intake, (−)-EC is exposed to enterocytes[20,21] in the small intestine, where they enter via passive diffusion[22] and are rapidly metabolized. The aglycone undergoes phase II enzymatic metabolism forming sulfate, glucuronide, and methylated sulfate/glucuronide metabolites through the respective actions of sulfotransferases (SULTs), uridine-5′-diphosphate glucuronosyltransferases (UGTs), and catechol-*O*-methyltransferases (COMTs).[23,24] Once absorbed, any unmetabolized (−)-EC undergoes rapid glucuronidation, sulfation, and O-methylation in the liver. Although a degree of enterohepatic recirculation was initially proposed,[25] recent intestinal perfusion studies have reported only a relatively modest elimination of (−)-EC via the bile.[26] Procyanidins were suggested to undergo depolymerization in the gastrointestinal (GI) tract, resulting in monomers,[27] although subsequent studies have indicated that this is unlikely and that they are very poorly absorbed, if at all, in humans.[8,28] Indeed, to date, only flavanol dimers have been detected in human plasma and in very low amounts compared with monomers.[29] However, once in the large intestine, procyanidins together with flavanol monomers undergo rapid C-ring fission induced by the gut microbiome, yielding a host of smaller phenolic acids and 5-(hydroxyphenyl)-γ-valerolactones.[8,9,30] These are absorbed and further metabolized in the liver prior to their renal excretion.

J. Agric. Food Chem. 2015, 63, 7615−7623

The pharmacokinetics of (−)-EC in blood and urine following cocoa flavanol consumption has been extensively studied in numerous human intervention trials (Table 1), although it should be noted that the accurate identification and quantification of flavanols have been limited for several reasons. First, the analytical methodology used often fails to capture the full metabolic profile, for example, by failing to profile flavanol metabolite stereoisomers. Added to this, a lack of reference standards has made it difficult to accurately standardize flavanol metabolite characterization in different studies. Instead, it has been necessary to report total flavanol absorption based on the hydrolysis of sulfates of (methyl)epicatechins using enzymes to convert the conjugated forms to aglycones. It is now known that such an approach is flawed due to the ineffective cleavage of flavanol conjugates under experimental conditions and has led to an underestimation of total EC bioavailability.[31] The stereochemical configuration of flavanols has also been reported to play a crucial role with regard to the absorption and metabolism of cocoa flavanols. The oral bioavailability of the stereoisomers has been studied and indicated that flavanol monomeric enantiomers significantly differed from each other with regard to their levels of nonmethylated metabolites present in plasma and urine ((−)-epicatechin > (+)-epicatechin = (+)-catechin > (−)-catechin).[32]

Generally, in the majority of human trials the amounts of monomers epicatechin and catechin consumed by the volunteers ranged between 20 and 300 mg, a level that leads to maximum plasma concentrations of epicatechin and catechin of around 30 and 5000 nM, between 0.9 and 3.2 h after consumption (Table 1). Only one study has reported maximum concentrations of around 21 μM after consumption of 1 g of EC, an amount unlikely to be relevant to dietary intake even following the consumption of a high-flavanol diet.[33]

With respect to the precise metabolic profile, access to chemically synthesized EC metabolites has allowed the identity of the major flavanol metabolites to be elucidated.[6,7] After consumption of a cocoa flavanol drink containing 1.8 mg of (−)-epicatechin/kg of body weight, the conjugates (−)-epicatechin-3′-β-D-glucuronide, (−)-epicatechin-3′-sulfate, and 3′-*O*-methyl-(−)-epicatechin-5/7-sulfate were the major in vivo metabolites found in the circulation 2 h after intake, accounting for 46, 28, and 17% of all plasma flavanol metabolites, respectively, whereas (−)-epicatechin-5-sulfate and (−)-epicatechin-7-sulfate (representing 3.1 and 1.1%, respectively) were present at lower levels.[7] These data are in agreement with another human trial in which volunteers consumed dark chocolate containing 79 mg of (−)-epicatechin. In this case, 3′-*O*-methyl-(−)-epicatechin-4-sulfate and (−)-epicatechin-4′-β-D-glucuronide were also identified, accounting for 7 and 4% of all metabolites detected in the bloodstream.[6] The urinary excretion of structurally related EC metabolites has been reported between 21 and 30% of the ingested dose over a period of 24 h, of which >80% was excreted in the first 8−10 h,[6,34,35] with the exception of two studies that reported <6% of total intake.[7,8] The elimination of epicatechin metabolites is quite rapid ($t_{1/2} \approx 2-4$ h), and their accumulation in the blood or tissues is thought unlikely to occur.[6,36]

It has been reported that 45% of parent (−)-EC ingested is neither absorbed nor metabolized in the upper GI tract,[26] but passes to the large intestine where the actions of the resident bacteria lead to the generation of microbial metabolites that appear in circulation and urine at later time points (6−48 h). After regular cocoa flavanol intake, analysis of 24 h urine revealed a significant level of glucuronide and sulfate conjugates of 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone and 5-(3′-methoxy-4′-hydroxyphenyl)-γ-valerolactone.[9] Such metabolites may be generated from both monomeric and oligomeric flavanols, and data indicate that intake of monomeric flavanols or procyanidins (degree of polymerization ranging from 2 to 10) results in urinary levels of γ-valerolactone metabolites representing 43 and 54% of intake, respectively.[8] The excretion of phenolic acids, mainly vanillic, ferulic, 3,4-dihydroxyphenylacetic, and 3-hydroxyphenylacetic acids, is also known to be increased 6−48 h after flavanol intake,[9,37] with vanillic acid showing a different peak excretion between 0 and 3 h.[30] In plasma, glucuronide conjugates of dihydroxyphenylvalerolactones were increased after regular cocoa intake,[9] whereas a recent study also reported an enhancement of circulating total phenolic acids between 0 and 6 h after consumption of a cocoa−nut cream containing 176 μmol (51.1 mg) of EC and catechin.[37]

In summary, although there are a number of studies relating to the absorption, metabolism, and excretion of cocoa flavanols, only very recently has the precise and detailed profile of flavanol ADME been elucidated due to developments in analytical techniques and the availability of authentic flavanol metabolites. Much is known about structure microbiota-derived catabolites, but data relating to the extent to which specific bacterial profiles may alter the generation of smaller phenolic metabolites are presently lacking.

FACTORS AFFECTING FLAVANOL ADME

The extent to which (−)-EC is absorbed/metabolized from cocoa and other flavanol-rich foods in the small intestine, yielding structurally related epicatechin metabolites, depends on numerous variables including (1) the structure of the food matrix, including its physical state and macronutrient composition; (2) the processing steps that the flavanol-containing foodstuff has been subjected to, notably heating, fermenting, etc.; (3) the interactions of flavanols with other nutrient and non-nutrient components (nutrient−nutrient interactions); (4) the level of intake; and (5) individual genetic polymorphisms in relevant metabolic enzymes, most notably, SULTs, GST, and COMT. The current data available regarding the influence of these factors on the ADME of cocoa flavanols are limited, and there are some discrepancies that exist among individual studies, again mainly due to the differences in analytical methodology and study design.

Food Matrix Effects. The main food matrix factors influencing flavanol absorption in vivo include its physical state and its macronutrient composition. Flavanols are not typically consumed as purified supplements but rather in complex matrices both natural (plant material, typically fruits and vegetables) or as formulated/manufactured products. Thus, flavanol interactions with, or binding to, other nutrients/non-nutrients may significantly influence the accessibility of flavanols to the intestinal lumen and thus their potential to undergo transfer across it. As such, the kinetics of flavanol absorption/metabolism is thought to be heavily influenced by the food delivery system.

Physical State. Most of the studies investigating the absorption and metabolism of EC after consumption of chocolate (solid confection)[6,34,38−44] or cocoa (liquid beverage)[7,34,35,44−49] have reported similar plasma flavanol concentrations and times to reach the maximum concentration (t_{max}) between 1 and 2 h, although in some cases the number of time

DOI: 10.1021/acs.jafc.5b00443
J. Agric. Food Chem. 2015, 63, 7615−7623

points evaluated was limited. To our knowledge, only two studies have assessed the effect of physical structure on EC bioavailability comparing solid versus liquid matrix delivery of flavanols. Comparison of solid (solid chocolate) and liquid (cocoa drink) in five volunteers has indicated no significant effect of food matrix with respect to t_{max} for the appearance of EC metabolites in the circulation (2 h for both). Despite this, at 1 h after consumption, the plasma concentrations of total nonmethylated epicatechin metabolites were significantly higher in the cocoa drink group, suggesting a subtle effect of matrix on flavanol O-methylation.[34] In contrast, total flavanol (AUC) and maximum concentration (C_{max}) were observed to be significantly higher following intake of a cocoa drink compared to that of solid chocolate.[38] Additionally, the time to reach the maximum concentration was 0.9 ± 0.1 h for beverages and 2.3 ± 0.8 h for chocolate confection, although these differences were not significant. Two recent studies in healthy volunteers have reported a t_{max} of 2 h after intake of a cocoa drink[7] and a t_{max} around 3.2−3.8 h after solid chocolate consumption.[6] Taken all together, these data suggest faster absorption rates and earlier peak plasma concentrations of EC from liquid food matrices relative to solid chocolate, probably due to a rapid digestive release and rapid stomach-emptying from liquids compared to solids.

Macronutrient Composition. Carbohydrate-, lipid-, or protein-rich meals have been reported to have a pronounced effect on the metabolism of many xenobiotics.[50,51] As such, it is hypothesized that such macronutrients may also influence the efficacy and profile of flavanols from different foods/beverages. Although information regarding lipid−flavanol interactions remains scarce, carbohydrates and, in particular milk proteins, have been relatively well studied for their potential to affect flavanol absorption and metabolism.

(a) Lipid Effects. To our knowledge, only one study has investigated the effect of coconsumption of lipids (delivered as butter; 28.6 g of fat), which suggested that lipid−flavanol interactions do not influence total flavanol absorption of total plasma flavanols.[36] However, future larger scale pharmacokinetic studies are warranted and required well-characterized lipid and food matrix controls.

(b) Carbohydrate Effects. Carbohydrate interactions are important because in many flavanol-containing foods/beverages there are commonly high levels of sugars present. Data have suggested that codelivery of flavanols in a matrix containing carbohydrate may increase flavanol absorption in rats[52] and humans.[36,38,41] For example, the co-administration of sugar with a flavanol-rich cocoa resulted in significant increases in plasma C_{max} (18%) and AUC (22%) of epicatechin plus catechin and accelerated their renal elimination.[36] Similarly, the consumption of a sucrose-containing hard chocolate resulted in a 20% higher C_{max} and 21% greater AUC for total plasma flavanols compared to a maltitol-containing equivalent, although the O-methylation pattern of conjugated metabolites was unaffected by sugar type.[41] Additionally, human endothelial function has been shown to be increased to a higher degree (although not significantly) following the consumption of a sugar-sweetened cocoa beverage compared to that observed with a sugar-free cocoa drink.[53] In contrast, no significant differences in the plasma flavanol pharmacokinetics were observed after ingestion of a high-sucrose-containing hard chocolate compared with a low-sucrose control dark chocolate containing the same amount of flavanols,[38] although the methodology used here was capable of resolving only pure EC and catechin and not their conjugated metabolites, which may explain the lack of significance. On the basis of the available evidence, it seems plausible that carbohydrate-rich meals may act to enhance flavanol absorption without influencing metabolism, although further research is required to confirm such initial observations.

(c) Protein and Milk Effects. Flavanols, and in particular flavanol oligomers, have been suggested to interact with proteins in a manner that might, in turn, result in altered bioavailability/bioefficacy of dietary flavanols.[54] In vitro data have demonstrated that β-lactoglobulin, a major milk protein, can stably bind to epicatechin and catechin via covalent bonding.[55] Co-intervention with meat (beef steak; 47.7 g of protein) with cocoa flavanols was observed not to affect either the AUC or the C_{max} for total plasma flavanols when compared to the intake of cocoa alone, although the rate of elimination was significantly faster.[56]

Unlike the levels of carbohydrate and protein, the fat composition in milk varies widely, and thus it is a major confounding factor in determining the specific effects of milk protein on flavanol absorption. Indeed, there has been controversy regarding the effects of milk on the bioavailability of flavanols. On the one hand, the consumption of 100 g of dark chocolate with 200 mL of milk significantly reduced the (−)-EC levels in plasma (calculated as AUC) compared with the consumption of dark chocolate lacking milk.[57] In contrast, two studies report no impact of milk protein on plasma flavanol concentrations following intake of either a cocoa flavanol beverage[58] or hard chocolate.[38] As the former study was not performed under isocaloric and isolipidemic conditions, it is conceivable that other components in the matrix might be responsible for the differences on flavanol absorption. More recent data tend to support the latter observations that whole milk[35,47,56] and skimmed milk[59] do not influence flavanol absorption.

With regard to the urinary excretion, only a couple of studies have evaluated the effect of milk on the flavanol metabolite excretion profile in urine with contradictory results. Milk co-administration with flavanol-containing cocoa did not significantly affect the total amount of (−)-epicatechin metabolites excreted in the urine, although the metabolite profile indicated high levels of sulfation relative to glucuronidation over the first 6 h of urinary excretion.[60] In contrast, milk was observed to significantly decrease the urinary excretion of epicatechin plus catechin metabolites following administration of a cocoa−milk-containing beverage.[35] However, it should be noted that the lipid content was different between products, and protein content was not described. Thus, it remains unclear as to which particular compounds were causing the reduced flavanol absorption. The influence of milk on flavanol absorption in the colon has also been investigated, showing that, of 15 phenolic acids assessed, the urinary excretion of 3,4-dihydroxyphenylacetic, protocatechuic, 4-hydroxybenzoic, 4-hydroxyhippuric, hippuric, caffeic, and ferulic acids decreased when milk was co-administered, whereas urinary concentrations of vanillic and phenylacetic acids were increased.[61]

In conclusion, it appears that milk does not have an overall effect on the absorption of cocoa flavanols, but it might have a small impact on the profile of metabolites produced and their excretion. Further research is necessary, in particular, studies with well-characterized milk−cocoa interventions.

Processing Effects. Although the evidence regarding the influence of cocoa processing on the pharmacokinetics of

DOI: 10.1021/acs.jafc.5b00443
J. Agric. Food Chem. 2015, 63, 7615−7623

flavanols is scarce, there is evidence to suggest that a significant decrease of monomeric flavanols and procyanidins occurs during fermentation, drying, roasting, and alkalization.[13−15,62,63] Fermentation (from 4−5 days to 10 days) results in reductions in EC levels of around 80% compared with that of unfermented beans,[14,63] whereas drying of cocoa beans has been shown to lead to lesser losses of around 14%.[15] When cocoa beans are roasted for 30 min at 45 °C and the temperature is steadily increased, data report that EC degradation occurs at roast temperatures above 70 °C, with only around 18% of epicatechin remaining following roasting at 120 °C.[63] However, roasting data are variable with another study reporting less significant losses at 140−150 °C (73, 43, and 70% for total EC, procyanidin B1, and procyanidin B2, respectively).[15] With regard to the impact of alkalization, the analysis of commercially available cocoa powders with various degrees of alkali processing resulted in a 40% reduction in total flavanols for those lightly alkalized (pH 6.5−7.2), a 22% reduction for medium alkalized (pH 7.2−7.6), and an 11% decrease for heavily alkalized cocoa powders (pH ≥7.61).[62] In agreement with these data, alkalization of natural cocoa powder at pH 7.2 resulted in losses of 67% for (−)-epicatechin, 36% for (+)-catechin, and 69 and 67% for dimer B2 and trimer C1, respectively.[13]

To our knowledge, only one study has investigated the impact of cocoa processing on flavanol absorption in vivo. In that study, 10 healthy volunteers consumed a nonalkalized, medium-alkalized, or heavily alkalized cocoa, and, as expected, reductions in flavanol content in the cocoa resulted in reduced levels of total plasma flavanols.[64] In addition to flavanol losses, significant interconversion of flavanol stereoisomers also occurs during cocoa processing. Notably, a large increase in (−)-catechin, a stereoisomer not naturally present in cocoa, has been reported following fermentation, roasting, and alkalization of cocoa beans, presumably due to the epimerization of (−)-epicatechin to (−)-catechin.[14,65] In support of this, (−)-catechin has been measured in 23 commercially available chocolate samples, with an average ratio of 1:0.1 (−)-catechin/(+)-catechin.[18] Because the preferred order of absorption has been recently ranked as (−)-epicatechin > (+)-catechin > (−)-catechin,[66] such epimerization together with other processing techniques is likely to greatly affect the bioavailability and bioactivity of cocoa flavanols.

Drug−Flavanol Interactions. As described previously, flavanols are substrates of phase II conjugation enzymes and thus share a metabolic pathway similar to that of many drugs.[23,24,67] However, the extent to which flavanols may alter drug metabolism in vivo is currently unknown, although a few studies have shown that flavanols may modulate the activity of phase II enzymes in vitro.[68−70] Notably, EC has been shown to inhibit the enzyme UGT2B17, albeit at concentrations above those that are physiologically possible.[69] EC and catechin have also been observed to inhibit human SULT1A1 and SULT1A3 with IC_{50} values in the micromolar range.[70] Catechin and EC, however, appear unable to influence P-glycoprotein drug transporter activity in intestinal cells.[68] Although these in vitro studies suggest that EC might be able to alter drug metabolism, results without in vivo confirmation should be interpreted with caution. A recent in vitro study investigating the cellular uptake and metabolism of EC and its major in vivo metabolites showed that the conjugates formed in the cells only account for one of the four major metabolites in human plasma, suggesting that the in vitro models do not accurately reflect the in vivo situation.[21] In vitro studies with both parental flavanols and their metabolites at physiologically relevant concentrations and human in vivo studies investigating potential drug−flavanol interactions are warranted.

Intake. The influence of the intake level of overall absorption and metabolism has also been investigated. Consumption of 27, 53, and 80 g of chocolate resulted in measured plasma EC levels (C_{max} and AUC) that increased in an intake-dependent fashion.[44] The same trend was observed in another study providing 40 and 80 g of chocolate, although in this case t_{max} was slightly delayed from 2 to 2.6 h, respectively.[40] Together the data suggest that there is a good correlation between intake and C_{max} (R^2 = 0.954), considering the diversity of the study conditions (Figure 3). When 1 g of pure (−)-EC

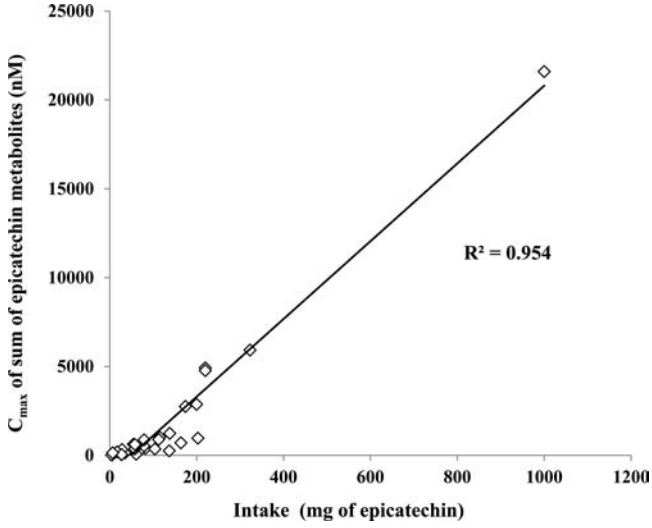

Figure 3. Linear correlation between plasma concentrations of epicatechin metabolites (expressed as C_{max}) and intake of epicatechin for 22 studies shown in Table 1.

was consumed, plasma concentrations of total EC metabolites were 6269 ng/mL (≈21.56 μM) at 1 h after consumption,[33] whereas consumption of only 6.7 mg of (−)-EC from a cocoa drink resulted in C_{max} values of 143 nM.[35] The average C_{max}, normalized to the ingestion of 1 mg of EC, indicates that 9.4 ± 1.3 nM of total EC metabolites is present in the circulation per milligram of EC consumed (Table 1). As such, it appears that the saturation of (−)-EC absorption does not occur in this dosage range. However, it remains unclear as to how increasing amounts of (−)-EC intake might influence the overall pattern of flavanol metabolism. For example, in rats it has been reported that increased (−)-EC methylation occurs at higher intake levels.[71] To what extent this may occur in humans remains to be established.

Genetic Polymorphisms. Interindividual variability in the absorption and metabolism of cocoa flavanols is thought to be at least partially caused by genetic polymorphisms, in particular, in phase II enzymes involved in flavanol metabolism. A single nucleotide polymorphism (SNP) in the gene encoding for COMTs, which is responsible for flavanol O-methylation, involves a single G to A transition that result in a change from valine to methionine.[72] In this polymorphism (COMT Val^{158}Met) the variant allele COMT-Met (also called COMT-A) has shown a 40% reduction of enzymatic activity compared with the wild type allele COMT-Val (also named

DOI: 10.1021/acs.jafc.5b00443
J. Agric. Food Chem. 2015, 63, 7615−7623

COMT-G) in in vitro studies.[73] Thus, polymorphisms such as the COMT Val[158]Met might result in modified flavanol O-methylation relative to other forms of the enzyme. Although there are no studies addressing this issue specifically for cocoa flavanols, studies have investigated the effect of COMT Val[158]Met polymorphism on flavanol absorption and metabolism following green tea consumption. In a cross-sectional analysis with 660 subjects, men possessing the low-activity genotype (COMT-AA) had lower urinary levels of five tea polyphenol metabolites, including epigallocatechin, *O*-methyl-epigallocatechin, EC, and valerolactones, relative to the other genotypes (COMT-GG and COMT-AG).[74] In contrast, in an intervention study investigating the same polymorphism with 10 volunteers harboring allele COMT-A and 10 volunteers with the wild type allele COMT-G, no significant differences in the plasma catechin concentrations were observed between COMT groups following intake of a decaffeinated green tea extract,[75] although significantly lower urinary levels of 4′-*O*-methylepigallocatechin during the first 5.5 h were reported in the COMT-AA group (lowest activity genotype).[76]

Further large-scale pharmacokinetics studies are warranted to expand these investigations along with studies designed to assess the impact of other polymorphic variants of phase II drug-metabolizing enzymes such as UGTs and SULTs.

SUMMARY AND FUTURE RESEARCH

Current literature strongly supports the notion that the consumption of cocoa flavanols is causally related to benefits in the cardiovascular function. Importantly, the large majority of circulating flavanols are present in the form of their phase II metabolites, which are likely to mediate these effects. Despite their being a number of dietary intervention studies reporting the absorption, metabolism, and excretion of flavanols, only very few report the precise structures, profile, and quantification of flavanol metabolites in the systemic circulation in humans. Further research is required to conclude on the pharmacokinetic profiles of microbiota-derived catabolites, such as valerolactones and phenolic acids, and ultimately whether these may underpin biological activity in humans.

The extent to which (−)-EC is absorbed/metabolized from cocoa depends on numerous factors. The food matrix influences flavanol bioavailability in different ways, with EC absorption from liquid food matrices occurring more rapidly than that observed for solid chocolate. The codelivery of flavanols in a carbohydrate matrix may also increase flavanol absorption. In contrast, lipids, proteins, and milk appear not to influence overall flavanol absorption, although milk may affect the metabolic profile of flavanol metabolites generated. Further investigation is also required to establish how intake level, common food-processing techniques, drugs, and genetic polymorphisms influence the absorption, metabolism, and excretion of cocoa flavanols in humans. Finally, the influence of age, sex, reproductive status, and/or dietary background on flavanol intake/health markers should be a focus of immediate future research. Such data will help to define a minimum amount of flavanols necessary to achieve population-based health benefits and thus contribute to the creation of flavanol-specific dietary guidelines and recommendations.

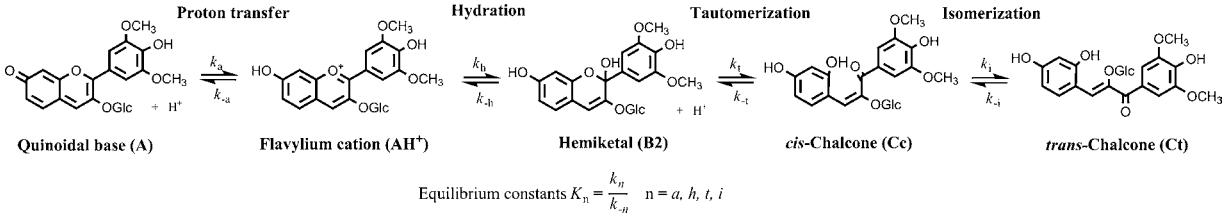
Scheme 1. Representation of the Network of Chemical Reactions for Malvidin 3-Glucoside (Oenin)



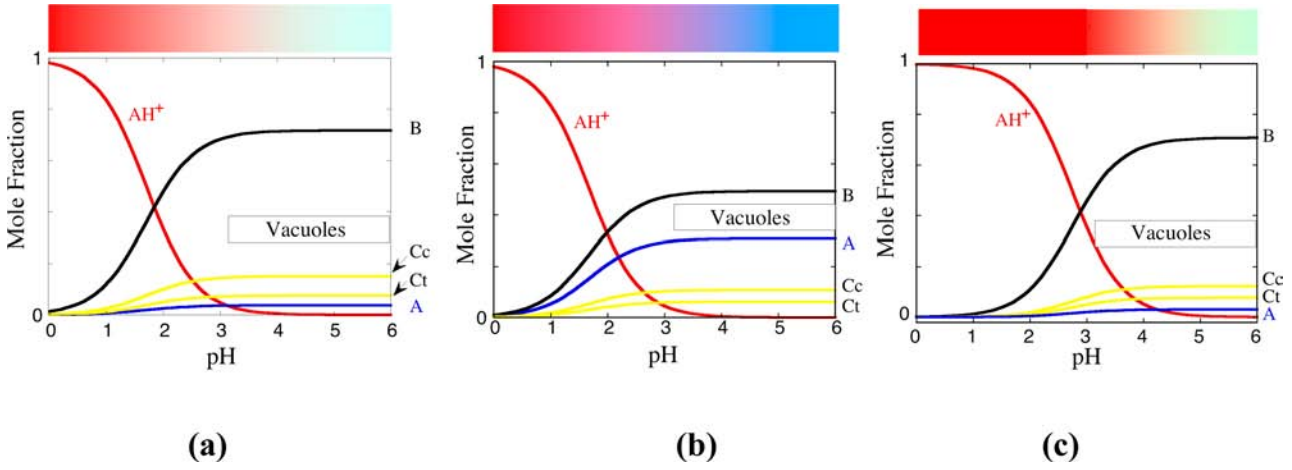


Figure 1. Mole fraction distribution of the several multistate species of malvidin 3,5-diglucoside: (a) free (pK_{ap} = 1.7); (b) simulation in the case of copigmentation (1:1) with **A** for a copigment concentration of 0.1 M and an association constant, K_{cp} = 100 M^{-1}; (c) same as (b) but when exclusive copigmentation with $\mathbf{AH}^+$ occurs. The upper bands simulate the color as a function of pH. Reprinted with permission from ref 7. Copyright 2000 Elsevier.

of the blue color. In the case of the blue color, beautiful work from Goto, Kondo, and Yoshida has been reported in recent decades.[8−10] The blue color is achieved by means of supramolecular structures involving anthocyanins, flavone, and metals, the first bearing a cathecol unit to allow the metal binding. Additionally, the fraction of colored species at moderately acidic or neutral pH values can be augmented through the formation of adducts with colorless organic aromatic compounds (copigments) driven by $\pi-\pi$ stacking, hydrophobic, and charge-transfer interactions.[11−16]

A simple model considering the possibility of an adduct formation (1:1) with species **A** and another compound (copigment 0.1 M) with association constant K_{cp} = 100 M^{-1} is reported in Figure 1b. The mole fraction distribution of species **A** increases dramatically. On the other hand, the adduct with the same constant involving the flavylium cation gives rise to a shift of the pH domain of the red color toward higher pH values. Summarizing, anthocyanins are not able to give color in plants unless they participate in more or less complex structures.

The red and blue colors of anthocyanins can also be accomplished by self-aggregation.[17,18] Increasing the total concentration of the anthocyanin, the domain of the red flavylium is shifted toward higher pH values and the mole fraction distribution of the blue quinoidal base increases.[17]

Cucurbit[*n*]urils and cyclodextrins are macrocyclic molecules with tridimensional hydrophobic cavities capable of forming inclusion complexes with molecules and ions of suitable size, shape, and charge/polarity. Whereas cyclodextrins are formed by α-(1,4)-linked maltooligosaccharides with α-, β-, and γ-cyclodextrin consisting of six, seven, and eight glucose units, respectively, cucurbit[*n*]urils are composed of *n* glycouril units linked by methylene bridges. Due to their structural characteristics, cyclodextrins display higher selectivity for hydrophobic and neutral molecules, whereas cucurbiturils preferentially bind organic cations.[19] However, it should be stressed that cucurbiturils also show high affinity for neutral organic molecules with stability constants that can be orders of magnitude higher than those found for cyclodextrins.[20] With respect to their applications as food additives, cyclodextrins were demonstrated to be fit for human consumption and are applied to improve the stability of flavors, colorants, vitamins, etc.[21] To the best of our knowledge, the safety of cucurbiturils as food additives has not been explored, but these compounds were shown to display low toxicity, and their use as drug delivery vehicles has been suggested.[22] If their use as compatible food additives is demonstrated, they present some advantages with respect to cyclodextrins related to the usually higher stability of their inclusion complexes, which translates into better performance and lower quantity of material required to achieve full complexation.

In this work positive and negative copigmentation effects in anthocyanins analogues are mimicked by host−guest interaction with cucurbit[7]uril (CB7) and (2-hydroxypropyl)-β-cyclodextrin (2-HP-β-CD). The effect of these hosts on the degradation rate of anthocyanidins was also investigated.

MATERIALS AND METHODS

Materials and Stock Solutions. Cucurbit[7]uril (CB7) and 7-hydroxyflavylium were available from previous studies.[23,24] (2-Hydroxypropyl)-β-cyclodextrin (2-HP-β-CD, Sigma-Aldrich) and pelargonidin and cyanidin chlorides (Extrasynthese, France) were obtained from commercial suppliers. Stock solution of 7-hydroxyflavylium was prepared in 0.1 M of HCl, whereas stock solutions of

J. Agric. Food Chem. 2015, 63, 7624−7629

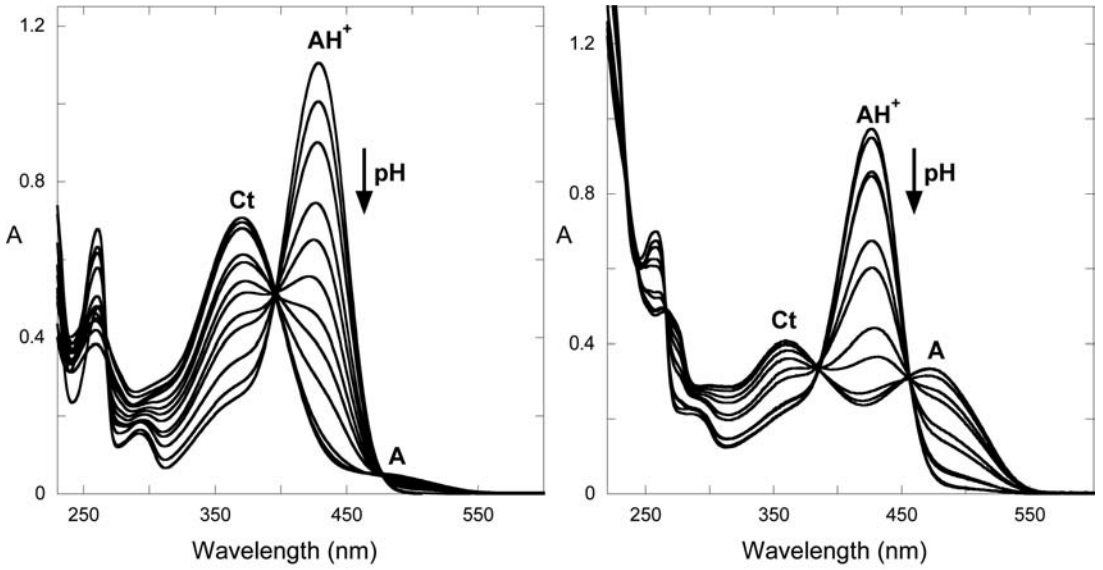

Figure 2. Spectral variations of the model compound 7-hydroxyflavylium (1.7×10^{-2} mM) as a function of pH: (a) in the absence of CB7; (b) in the presence of [CB7] = 1 mM.

pelargonidin and cyanidin were prepared in ethanol/concentrated HCl 99:1 (v/v) to avoid degradation and stored at 4 °C. Under these conditions the cationic flavylium form is the main species and the colorants remain stable for several weeks as monitored by UV−vis spectroscopy. Stock solutions of CB7 and 2-HP-β-CD were prepared in high-purity Milli-Q water.

Methodology. Equilibrated solutions of 7-hydroxyflavylium were prepared by adding 0.5 mL of the stock solution at pH 1 to a cuvette containing 0.5 mL of 0.1 M NaOH and 2 mL of universal buffer of Theorell and Stenhagen at the desired pH and concentration.[25] A similar procedure was used for experiments performed in the presence of host molecules. The final concentration of Na^+ was 0.045 M in all cases. Solutions were allowed to equilibrate overnight, and the UV−vis absorbance spectra were recorded in a Cary 100 spectrophotometer (Varian). Superposition of the UV−vis spectra registered after some hours (ca. 6−8) confirmed that the system was equilibrated.

The degradation kinetics of anthocyanidins was studied by UV−vis spectroscopy. An aliquot of the anthocyanidin stock solution was added to a cuvette containing the required amounts of NaOH to neutralize the acid contained in the aliquot and universal buffer at the desired pH. The spectral acquisition was immediately started. The final contents of ethanol in the cuvettes were 2 and 10% for pelargonidin and cyanidin, respectively. Observed rate constants were obtained from the variation of the absorbance versus time data.

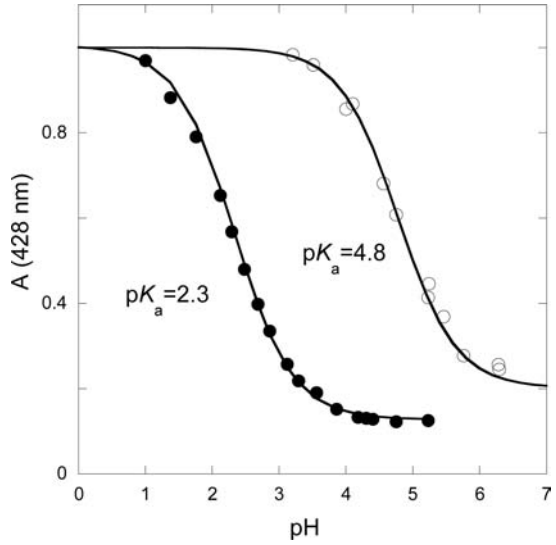

Figure 3. pH dependence of the normalized absorption of the model compound 7-hydroxyflavylium as a function of pH: (●) in the absence of CB7; (○) in the presence of [CB7] = 1 mM.

RESULTS AND DISCUSSION

Effect of the Host in the Final Equilibrium of 7-Hydroxyflavylium. Figure 2 reports the spectral variations of the model compound 7-hydroxyflavylium as a function of pH in the absence (a) and presence (b) of cucurbit[7]uril (CB7) = 1 mM. Inspection of these curves clearly indicates that the absorption band appearing around 477 nm, characteristic of the quinoidal base, increases dramatically in the presence of CB7 and the pK'_a is shifted from 2.3 to 4.8 (Figure 3). Both data show that in the presence of CB7, $\mathbf{AH^+}$ is stabilized in comparison with **CB** (eq 5), and identical stabilization occurs for **A** in its partition with **B**, **Cc**, and **Ct**. In conclusion, CB7 stabilizes preferentially the species that give color, similarly to the copigmentation effect described for anthocyanins and related compounds.[11−16] This result suggests that the heterogeneities in cell vacuoles could in some way modulate the color, which depends on the composition of the cells' environment where the anthocyanins are located and the organization of anthocyanins within vacuole.[26] The copigmentation models in homogeneous solution are thus one simple approximation of a more complex phenomenon.

Identical behavior was reported for the compound 3′,4′,7-trihydroxyflavylium in the presence of CB7, but both effects were smaller.[27]

The mimicking of the copigmentation effect can be visualized in Figure 4. Increasing quantities of CB7 were added (up to 2.5 mM) to the model compound 7-hydroxyflavylium at pH 4 (a)

DOI: 10.1021/acs.jafc.5b00765
J. Agric. Food Chem. 2015, 63, 7624−7629

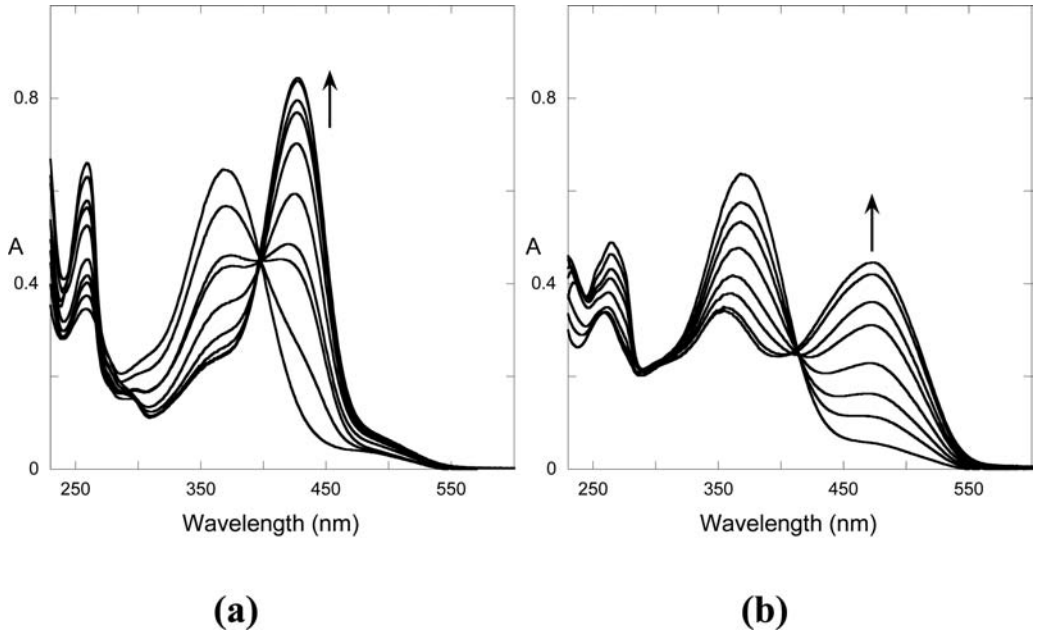

Figure 4. Mimicking copigmentation effect with the model compound 7-hydroxyflavylium in the presence of added CB7 up to 2.5 mM at pH 4 (a) and pH 6 (b).

and 6 (b), and the solutions were allowed to equilibrate in the dark.

In Figure 4a the addition of the host has a dramatic effect shifting the multistate system toward the flavylium cation. The same experiment carried out at pH 6 (Figure 4b) leads to the appearance of the quinoidal base.

The interaction of flavylium derivatives with another host, β-CD, leads to a completely different behavior.[28] Previous results have shown that the pK'_a of the model compound 3′,4′,7-trihydroxyflavylium decreases from 3.1 to 2.2 in the presence of this host at 4.8 mM, indicating that **CB** is stabilized in comparison with $\mathbf{AH}^+$. Moreover, whereas in the absence of β-cyclodextrin (β-CD) the composition of **CB** is approximately 90% **Ct** and 10% **A**, in the presence of β-CD 4.8 mM becomes 97% **Ct** and 3% **A**. With regard to the kinetic processes of the network, β-CD increases the rate constant of the flavylium cation hydration to give the hemiketal and decreases the reverse rate constant (dehydration). Identical results were reported for the compound 4,7-dihydroxyflavylium,[29] as well as 4′-(2-hydroxyethoxy)-7-hydroxyflavylium.[30] In this last example the encapsulation of this guest into the host was observed by induced circular dichroism.

The interaction of the natural compound dracoflavylium (7,4-dihydroxy-5-methylflavylium, a dye from the resin of dragon's blood (*Dracaena draco*), with 2-HP-β-CD was also reported.[31] The pK'_a changes from 3.8 to 2.4 (host 16 mM) and the composition of **CB** = 63% **A** + 37% **Ct** to **CB** = 13% **A** + 87% **Ct**.

The observation that cyclodextrins promote discoloration in anthocyanins, the so-called anti-copigmentation effect,[32−34] was previously reported. Our findings confirm that the same is observed for the model compounds.

Effect of the Host in Anthocyanidin Degradation. Anthocyanidins are known to suffer a relatively fast degradation in aqueous solution. Profiting the preferential stabilization of the flavylium cation by CB7, the kinetics of the degradation process of pelargonidin was studied as a function of pH. UV−vis titration of pelargonidin with CB7 at pH 1.0 is compatible with a 1:1 association with constant $(4.5 \pm 0.3) \times 10^3\ M^{-1}$. The pH-dependent bell-shaped curve for the disappearance of pelargonidin (Figure 5) is similar to the one found for cyanidin.[4]

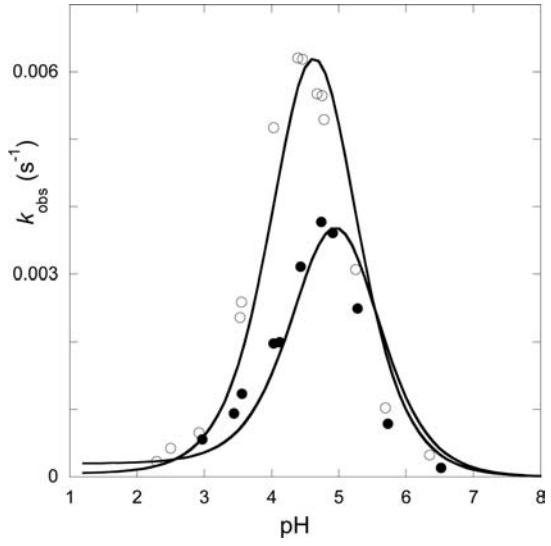

Figure 5. Rate constant for pelargonidin disappearance as a function of pH: (○) in the absence of cucurbit[7]uril; (●) in the presence of CB7 = 1.9 mM.

One minute after preparation at moderately acidic pH values, for example, pH 4.6, 35% of the anthocyanidin is already decomposed. This behavior is compatible with a sequence of chemical reactions as reported in eq 6[4,5] and is accounted for by eq 7, where k_{dis} is the rate of the anthocyanidin decomposition, the other rate and equilibrium constants being defined in Scheme 1.[4,5]

DOI: 10.1021/acs.jafc.5b00765
J. Agric. Food Chem. 2015, 63, 7624−7629

$$\mathbf{A} \underset{H^+}{\overset{\text{equilibrium}\ K_a}{\rightleftharpoons}} \mathbf{AH}^+ \underset{k_{-h}H^+}{\overset{k_h}{\rightleftharpoons}} \mathbf{B} \underset{k_{-t}}{\overset{\text{equilibrium}\ k_t}{\rightleftharpoons}} \mathbf{Cc(Ct)} \xrightarrow{k_{dis}} \text{products} \quad (6)$$

$$k_{obs} = \frac{\frac{[H^+]}{[H^+]+K_a} K_h K_t k_{dis}}{[H^+] + \frac{K_t k_{dis}}{k_{-h}}} \quad (7)$$

The experimental data (Figure 5) can be fitted with eq 7 (Table 1). The bell-shaped curve was also observed for the reversible transformation of some flavylium derivatives to the respective *trans*-chalcones.[35] In that case the low-pH branch of the curve is controlled by the isomerization, whereas the descending part is controlled by the hydration. Evidence that the degradation of anthocyanidins takes place via chalcones and that the same equation used to account for the reversible processes can be used if the isomerization constant is substituted by the degradation rate constant ,k_{dis}, was reported previously.[4,5] The fitting parameters are reported in Table 1 for pelargonidin.

Table 1. Fitting Parameters of Equation 7 for Pelargonidin in the Absence and Presence of CB7

[CB7]	pK_a	$K_h K_t k_{dis}$/M (s^{1-})	$K_t k_{dis}/k_{-h}$/M	k_h (s^{-1})
	3.8	1.4×10^{-6}	8×10^{-6}	0.18
1.9 mM	4.8	3.5×10^{-7}	3.0×10^{-5}	0.012

The effect of CB7 in the protection of the pelargonidin degradation is relatively modest. This is due to the existence of two contradictory effects, both accounted for by eq 7: (i) by one side the hydration (k_h) is reduced ca. 15 times, contributing to slow the process; (ii) by the other the decreasing of the acidity constant (K_a) accelerates the observed rate constant.

The effect of 2-HP-β-CD in the degradation of anthocyanidins was checked with cyanidin (Figure 6). In this case two opposing effects are expected: (i) the hydration rate constant is expected to increase, leading to an increase of the observed rate in eq 7; (ii) increasing of the acidity constant (K_a) will have an opposite effect (Table 2).

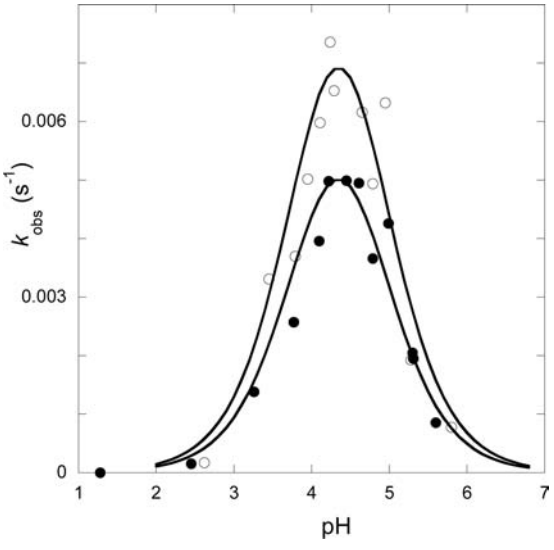

Figure 6. Rate constant for the cyanidin disappearance as a function of pH (10% ethanol): (○) in the absence of 2-HP-β-CD; (●) in the presence of 10 mM 2-HP-β-CD.

Table 2. Fitting Parameters of Equation 7 for Cyanidin in the Absence and Presence of 2-HP-β-CD

[2-HP-β-CD]	pK_a	$K_h K_t k_{dis}$/M (s^{-1})	$K_t k_{dis}/k_{-h}$/M	k_h (s^{-1})
	4.8	1.6×10^{-6}	1.4×10^{-4}	0.011
10 mM	4.4	8×10^{-7}	4×10^{-5}	0.02

Previous studies based on NMR data have shown that the two hosts here reported are able to form inclusion complexes with flavylium derivatives.[23,27−33] The different behavior of flavylium derivatives upon interaction with CB7 and β-CD can be attributed to the nature of the cavities: curcubit[7]uril exhibits a negative charge density, whereas β-CD is essentially neutral.[19]

The interaction of anthocyanins models with curcubit[7]uril and β-CD mimics the copigmentation or the so-called anti-copigmentation effect, respectively. At the pH of the vacuoles the dominant species is the colorless hemiketal, and thus the appearance of color implies a shift of the flavylium multistate system toward flavylium cation or quinoidal base, respectively, for the red and blue. Our results suggest the possibility of using cucurbiturils possessing the adequate cavity dimension to form inclusion complexes with anthocyanins. Preliminary data suggest that cucurbiturils have low toxicity and can be used as drug delivery vehicles to profit from the anthocyanins' antioxidant properties.[22]

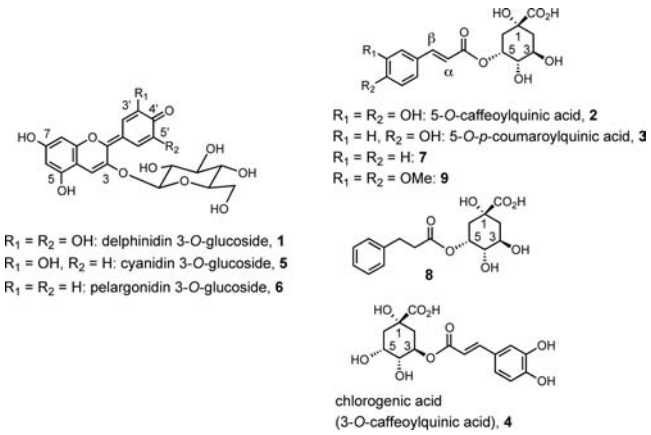

Figure 2. Structures of anthocyanins (**1**, **5**, **6**) and copigments (**2**−**4**, **7**−**9**).

with significant diferences.[16,17] We also quantified the contents of **1**−**4** and the Al^{3+} in blue and red cells. The equivalents of 5-*O*-acylquinic acids (**2** and **3**) and Al^{3+} compared to **1** in the blue cells were 12.8 and 1 equiv, respectively, significantly higher than those in the red cells (3.6 and 0.03 equiv).[18] To obtain structural information on the blue complex, we synthesized various natural and unnatural copigments.[17,19−21] Using the unnatural copigment for reproduction experiments, the essential structural components of the copigment for blue coloration were determined to be the 1-COOH, 1-OH, and 5-*O*-aromatic acyl groups in the quinate.[17,19,20] However, the molecular structure of the blue metal complex pigment in hydrangea remains obscure.

Many blue flower colorations are due to metal coordination to the anthocyanins,[22−25] and these metal complex pigments are categorized into two types; one is a stoichiometric supramolecule named metalloanthocyanin found in blue dayflower,[24,26−29] blue cornflower,[30−33] and blue salvias;[34−36] and the other comprises nonstoichiometoric pigments found in hydrangea,[15,19,20,24] tulip,[37] and blue poppy.[38,39] Detailed chemical structures of the former were determined by X-ray crystallographic analysis as commelinin[28,29] from dayflower and protocyanin from cornflower.[33] In metalloanthocyanins, the metal ions coordinate only to di-OH groups at the B-ring of the anthocyanidin chromophore, not to the copigments.[24,25,28,29,32,33] However, in the blue complex of the hydrangea sepals, the ratio of each component in not stoichiometric, but fluctuates within a certain range. In addition, Al^{3+} may have some interactions with both the anthocyanin and the copigment.[17,19,20] The Al^{3+} complex with **1** appears blue; however, this complex is not water-soluble, but MeOH- and EtOH-soluble,[19,40,41] and copigments **2** and **3** have a solubilizing effect on the **1**−Al^{3+} complex in water with some coordination to Al^{3+}.[19,20]

To clarify the basis of such a curious character of the hydrangea-blue complex and to obtain its structural information and the chemical mechanism of the blue color development, we attempted to reconstruct the same blue color as the sepals according to the physiological data of the colored vacuoles.[16,18,42] The previous experiments reported that the color of the blue solution changed with the difference in pH, composition of copigments, and equivalents of Al^{3+} to anthocyanin (**1**).[6,18,42] Furthermore, it was indicated that the hydrangea-blue pigment exists only in aqueous solutions; any crystallization trials of the blue complex pigment composed of **1**, **2**, or **3**, and Al^{3+} as in the same procedure for commelinin[26−29] and protocyanin[33] failed.[17,19] These results strongly suggest that in the aqueous solution each component of the hydrangea-blue complex might be under equilibrium and the molar ratio changes under the condition. In the living vacuoles the concentration of **1** and copigments is very high, approximately 5−20 mM,[18,42] suggesting that general solution chemistry may not hold true. In this study we examined the mixing conditions for their reconstruction, and the obtained solutions were evaluated by visible absorption spectrum, circular dichroism (CD), and nuclear magnetic resonance (NMR) spectrometry. We will discuss the special arrangement of **1** and **2** in the complex.

MATERIALS AND METHODS

General. The visible absorption spectrum was recorded on a V-560 spectrometer (JASCO, Japan), and CD was measured with a J-720 spectrometer (JASCO, Japan). ^{1}H NMR spectra were recorded in a tube (5.0 mm i.d.) on a ECA-500 (^{1}H, 500 MHz; ^{13}C, 125 MHz; JEOL, Japan). Chemical shifts for ^{1}H NMR were reported on a scale relative to the shignal of *t*-BuOH (δ 1.29). Measurement of pH was carried out with a D-21 pH meter (HORIBA, Japan) with a LAQUA 9618 electrode. The adjustment of the electrode was carried out using the standard buffer of pH 7 and 4, and the value of pD in deuterated buffer solution was noted as addition of 0.4 to the recorded value.

Plant Materials. The blue cultivar of *H. macrophylla* cv. Narumi Blue was donated by Okumura Farm (Toyoake, Aichi) and cultivated in a greenhouse (daytime, approximately 25 °C; nighttime, >10 °C) of the Botanical Garden, Nagoya University Museum, before use.

Materials. Delphinidin 3-*O*-glucoside, **1**, cyanidin 3-*O*-glucoside, **5**, and pelargonidin 3-*O*-glucoside, **6**, were isolated from the seed coat of *Phaseolus coccineus*, *Glycine max*, and *Phaseolus vulgaris*, respectively.[43] 5-*O*-Caffeoylquinic acid, **2**, 5-*O*-*p*-coumaroylquinic acid, **3**, 5-*O*-cinnamoylquinic acid, **7**, 5-*O*-(3-phenylpropionyl)quinic acid, **8**, and 5-*O*-(3′,4′-dimethoxycinnamoyl)quinic acid, **9**, were synthesized according to our procedures.[21] Chlorogenic acid (3-*O*-caffeoylquinic acid), **4**, was purchased (Tokyo Chemical Industry Co., Ltd. (TCI), Japan). $AlNH_4(SO_4)_2{\cdot}12H_2O$ was purchased (Nacalai Tesque, Inc., Japan). All commercially available reagents and solvents were used directly without further purification.

^{1}H NMR Measurement of Al^{3+} Complex of 5-*O*-Caffeoylquinic acid, 2. **2** was dissolved in D_2O and dried up in vacuo. To the residue were added D_2O and deuterated $AlNH_4(SO_4)_2$ (0.5 and 1.0 equiv to **2**) at the concentration of **2** as 5 mM. The pH of the mixture was adjusted to be 3.6 (pD 4.0) by addition of CD_3COOD and/or NaOD−D_2O. After the addition of *t*-BuOH as an internal standard, the mixture was filtered by using a cartridge (pore size, 0.45 μm), and ^{1}H NMR was recorded.

Procedure of Blue Pigment Reconstruction. Trifluoroacetic acid (TFA) salt of **1** (1.77 mg, 3 μmol, TFA salt), **2** (1−3 equiv to **1**), and a trivalent metal salt (1−4 equiv to **1**) were dissolved in a deuterated buffer solution (206 μL of CD_3COOD, 175 μL of 2 M NaOD, and 214 μL of D_2O), and then the solution was adjusted to pH 4.0 (pD 4.4) by the addition of 2 M NaOD. The visible absorption spectrum and CD were measured in a quartz cell (0.1 mm path length). For the ^{1}H NMR measurements, *t*-BuOH was added as an internal standard.

RESULTS AND DISCUSSION

Complexation of Copigment with Al^{3+}. In the hydrangea-blue complex, it was suggested that copigment 5-*O*-caffeoylquinic acid, **2**, also might coordinate to Al^{3+} in aqueous solution. Therefore, we first measured ^{1}H NMR of **2** coexisting with Al^{3+} in D_2O at pD 4.0 (Figure 3). By addition of 0.5 equiv of Al^{3+} (2.5 mM) to **2** (5 mM) the signals became complicated (Figure 3B), and when the amount of Al^{3+} was increased to 1.0 equiv (5 mM) to **2** (5 mM), the signals converged to a simpler one (Figure 3C). Compared with the spectra of Figure 3A,C, the spectrum of Figure 3B (0.5 equiv of Al^{3+} to **2**) seemed to be just a 1:1 mixture of the spectra of Figure 3A and 3C. Therefore, it was concluded that addition of 1 equiv of Al^{3+} might give **2**−Al^{3+} complex completely and addition of 0.5 equiv of Al^{3+} might give a half amount of **2**−Al^{3+} with remaining noncomplexed **2**. In the spectrum of **2**−Al^{3+} (Figure 3C) signals attributable to caffeoyl residue shifted upfield. The signals of quinic acid (H-2a,b and H-6a,b) also shifted slightly compared with those of H-3,4,5. These results indicated that the chelating position might be at the catechol part of the caffeoyl residue and 1-OH and 1-COOH of quinic acid. In contrast, 5-*O*-*p*-coumaroylquinic acid, **3**, and 3-*O*-caffeoylquinic acid, **4**, did not show such a phenomenon under coexisting with Al^{3+}. Thus, the formation of Al^{3+} complex of copigment in D_2O at pH 4.0 (pD 4.4) was a special phenomenon

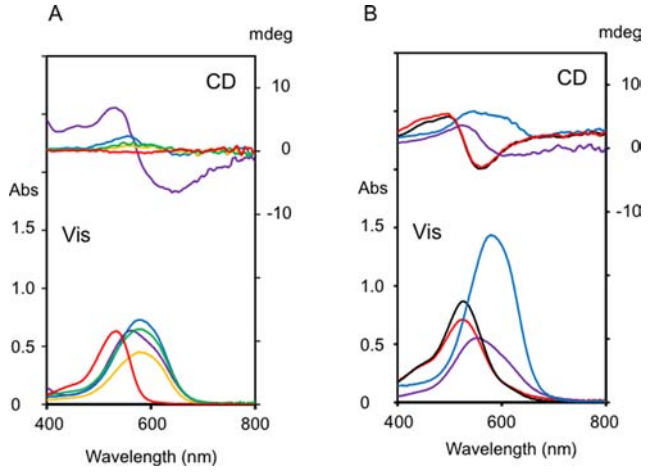

Figure 4. Visible absorption spectra and CD of the mixtures of **1** coexisting with copigment **2** and Al^{3+} for reconstruction of hydrangea-blue complex. observed only with **2**, which has a catechol moiety on the axial acyl substituent.

Reconstruction Conditions for the Same Blue Color as Hydrangea Sepals. We surveyed the combination of components and mixing conditions.[15,18−20,42] To analyze the structure and spatial arrangement of components in the hydrangea-blue complex, measurements of visible absorption spectrum, CD, and ^{1}H NMR should give useful information. To evaluate whether the same complex as the hydrangea-blue complex is reproduced or not, those spectra were compared. At

J. Agric. Food Chem. 2015, 63, 7630−7635

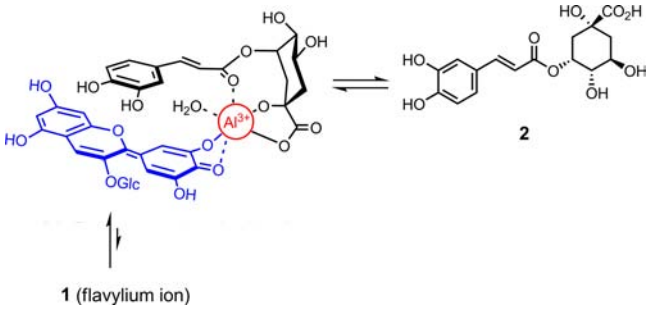

Figure 6. Schematic model of hydrangea-blue complex composed of **1**, **2**, and Al^{3+} in aqueous solution.

first the chelating position in the anthocyanin component was studied by using **1**, cyanidin 3-*O*-glucoside, **5**, and pelargonidin 3-*O*-glucoside, **6**, which have different numbers of OH groups on the B-ring (Figure 1). In 200 mM acetate buffer (pH 4) **1**, **5**, and **6** (3 mM) were mixed with **2** (3 mM) and Al^{3+} (6 mM). Delphinidin 3-*O*-glucoside, **1**, and cyanidin 3-*O*-glucoside, **5**, gave bathochromic shift in visible absorption spectrum; however, the mixture of pelargonidin 3-*O*-glucoside, **6**, did not show such a blue shift, but the color was red, supporting the previous report that Al^{3+} is chelating to the *o*-dihydroxy group at the B-ring of anthocyanin.[15,19] In ^{1}H NMR spectra of the lower field, the signals of **1** and **5** seemed very broad, but those of **6** were sharp and assigned it in the flavylium cation form. In the **1**−**2**−Al^{3+} and **5**−**2**−Al^{3+} complexes the signals of **2** seemed to be two sets, similar to Figure 3B, indicating that the Al^{3+} complex of **2** also existed in the solution. These complex ^{1}H NMR spectra made it very difficult to analyze the structure; therefore, we reexamined the mixing condition.

To clarify the effect of copigment in hydrangea-blue complex composed of **1**, **2**, and Al^{3+}, comparison of ^{1}H NMR spectra of the hydrangea-blue complex with the simple **1**−Al^{3+} complex is essential. However, previously the **1**−Al^{3+} complex was reported to be insoluble in aqueous buffer;[19,40,41] then, the ^{1}H NMR spectrum was recorded only in CD_3OD. We found that a concentrated acetate buffer (>6 M) could solubilize both the hydrangea-blue complex and simple **1**−Al^{3+} complex. In addition, in 6 M buffer, the **2**−Al^{3+} complex did not form and the signals of **2** became simple. Therefore, we optimized the concentration of the buffer and the ratio of each component, **1**, **2**, and Al^{3+}, by reproduction experiments (Figure 4). The concentration of anthocyanin **1** was fixed at 5 mM, which was nearly the same as that in the sepal cells,[18,42] and other conditions were evaluated with the obtained spectra by the similarity between the visible absorption spectrum and the CD to those of the colored cells, which specifically included the value of λ_{max}, the absorbance, and the curve shape (Figure 1).[16−18] As shown in Figure 4A, all of the spectra of **1** (5.0 mM) with 1 equiv of **2** and 4 equiv of Al^{3+} with differing concentrations of buffer (1−11.6 M) exhibited a blue color with a λ_{max} of approximately 580 nm, but in acetic acid, the mixture was red (λ_{max} 533 nm). However, the CD in a 1 M buffer solution showed a negative exiton-type Cotton effect, indicating the different arrangement of anthocyanins: existence of self-association of anthocyanins, **1**, with an anticlockwise stacking manner. After optimization experiments, the ratio of **1**, **2**, and Al^{3+} to **1** was determined to be 1:2:2 (Figure 4B, blue line).

Using the optimized condition, visible absorption spectrum and CD were compared to analyze the structure of hydrangea-blue complex (Figure 4B). **1** in the buffer solution was red (λ_{max} at 527 nm) and in CD, a negative exciton-type Cotton effect was observed, indicating anticlockwise stacking of the chromophores (Figure 4B, red line). When 1 equiv of Al^{3+} was added to **1**, the visible absorption spectrum exhibited a bathochromic shift (λ_{max} at 558 nm) with a negative exciton-type Cotton effect (Figure 4B, purple line), indicating that the anthocyanidin chromophores still self-associate in an anticlockwise stacking manner in the Al^{3+} complexed state. The mixture of **1** and **2** exhibited no bathochromic shift but a small effect on increase in absorbance with the same exciton-type Cotton effect (Figure 4B, black line). The visible spectrum of blue complex pigment composed of **1**, **2**, and Al^{3+} showed very high intensity at its λ_{max} compared with the other mixture mentioned above (Figure 4B, blue line). In the CD, the exciton-type negative Cotton effect disappeared. This indicates that no self-association exists in the solution of hydrangea-blue complex and that copigmentation between **1** and **2** became stronger than the mixture of **1** and **2**. The arrangement of each component resulted in the increase of population of the blue anhydrobase anion form.

To optimize the reconstruction condition suitable for ^{1}H NMR measurements, the replacement of the metal ions with other ions of the same valency and copigments with unnatural synthetic ones was carried out. We reconstructed the blue complex by mixing various trivalent metal ions (Sc^{3+}, Ga^{3+}, In^{3+}, La^{3+}, Yb^{3+}, and Bi^{3+}); however, only Ga^{3+} gave a blue solution with a low absorbance (λ_{max} 580 nm), and other ions did not give stable blue solutions. This result indicated that Al^{3+} is essential for the formation of hydrangea-blue complex. We previously reported that the aromatic plane of the 5-acyl group of **2** is also essential for reconstruction of the hydrangea-blue complex.[17,19,20] To re-examine these phenomena in the 6 M buffer conditions, reconstruction experiments using other copigments, **4**, **7**, **8**, and **9**, were carried out (Figure 1). It was confirmed that the conjugated system of the 5-*O*-acyl group in the copigment was crucial for the reconstruction of the natural-type hydrangea-blue complex. Furthermore, the oxygen atoms at the aromatic ring of the cinnamate residue may not be directly involved in coordination to Al^{3+} but instead assist in the stabilization of the blue complex pigment.

^{1}H NMR Analysis of Blue Complex Pigment. Using the optimized reconstruction conditions, the hydrangea-blue complex was analyzed by ^{1}H NMR. In the NMR spectrum the signals of sugar residues were very complicated and thus not assignable; therefore, only the signals at lower field attributable to aromatic protons were analyzed. To obtain structural information on hydrangea-blue complex, solutions of **1**, **2**, **1**−Al^{3+} complex, a mixture of **1** and **2**, and **2** and Al^{3+} at pD 4.4 were measured and the signals were compared (Figure 5). In addition, various 2D NMR experiments were carried out.

The ^{1}H NMR spectrum of **1** showed typical signals of the flavylium cation form of delphinidin nucleus (Figure 5A); in the aromatic region very broad H-4 (8.67 ppm) and H-2′ and H-6′ (7.60 ppm) peaks as well as two sets of H-6 and H-8 peaks were observed. However, the intensity of the visible absorption spectrum is low (Figure 4B, red line), and several broad signals (Figure 5A, black arrows) suggested that **1** may exist under an equilibrium mixture of the pseudobase−flavylium cation−quinonoidal base form.[44,45] Very broad signals at 7.0, 6.6, and 6.1 ppm could be assigned as signals of the pseudobase.[44,45] In a dilute solution (<0.05 mM) at pH 4, the anthocyanidin monoglycoside typically adopts the pseudobase form, but in the highly concentrated, 5 mM, solution, the flavylium cation form is stabilized by self-association of the chromophores. This

J. Agric. Food Chem. 2015, 63, 7630−7635

indicates that the equilibrium constant between the pseudobase−flavylium cation−quinonoidal base form may change depending on concentration.

In previous studies, a simple Al^{3+} complex of **1** was not water-soluble and the ^1H NMR spectrum was recorded in organic solvent such as CD_3OD.[19,40,41] In our study we found 6 M acetate buffer as a new solvation system and could measure the **1**−Al^{3+} complex in aqueous solution for the first time. In the ^1H NMR spectrum of **1** with 1 equiv of Al^{3+}, the additional signals to Figure 5A appeared, and those signals were assigned as protons of the **1**−Al^{3+} complex (Figure 5B). The signal of H-4 (Figure 5B, blue numbers) was determined by NOESY correlation between the anomeric proton of the sugar. The NOESY correlation between H-4 (red) and H-4 (blue) and between H-2′,6′ (red) and H-2′,6′ (blue) suggested that **1** may attain equilibrium of the flavylium cation−quinonoidal base−quinonoidal base anion by adding 1 equiv of Al^{3+} to **1**.

Figure 5C,D shows the ^1H NMR of copigment **2**. The signals of **2** were very sharp and easily assignable (Figure 5C). The addition of Al^{3+} did not induce remarkable spectral changes in **2** (Figure 5D), indicating that 2 equiv of Al^{3+} in 6 M acetate buffer had no effect. It was concluded that Al^{3+} may not coordinate with **2**, although in a diluted buffer **2** forms a complex with Al^{3+} and gave a complex signal. The results of mixing **1** (5 mM) and **2** (10 mM) are shown in Figure 5E. In the ^1H NMR spectrum the signals for H-4, H-2′, H-6′, H-6, and H-8 of **1** shifted slightly upfield, but no such shift was observed with the signals of **2**. This upfield shift could be the copigmentation effect by hydrophobic interaction between the chromophore of **1** and the caffeic acid ring of **2**. This indicated that **1** and **2** may interact with one another, but this interaction is not strong.

The ^1H NMR spectrum of the hydrangea-blue complex composed with **1** (5 mM), **2** (10 mM), and Al^{3+} (10 mM) showed a completely different spectrum attributable to the signals of delphinidin chromophore (Figure 5F). There were no similar signals found in Figure 5A (flavylium cation form) and Figure 5B (Al^{3+} complex of **1**). However, the signals of **2** were almost the same as found in Figure 5C−E. Concerning the signals of delphinidin chromophore, new, broad signals appeared at approximately 8.0, 7.1, 6.8, 6.6, and 5.9 ppm (Figure 5F, black arrows). Among these signals, a broad peak at 6.6 ppm disappeared after 1 day. It was hard to find the signals attributable to H-6 and H-8; however, the protons of 5-OH free anthocyanin rapidly changed with D in D_2O.[45] Using this phenomenon, we assigned the signals. Thus, this signal was assigned to H-6 and/or H-8 of **1**. As mentioned above, the major signals of **2** were sharp and remained unchanged, but the newly appeared signals at 5.9 and 7.1 ppm were assigned as H-α and H-β, respectively, by COSY and the *J* values (16.0 Hz). These signals were also shifted upfield, indicating that the anisotropic effect caused by stacking with **1** may occur.

For the study of blue coloration of hydrangea we investigated reconstruction conditions and obtained the same blue complex, the hydrangea-blue complex, which was composed of **1**, **2**, and Al^{3+} in a ratio of 5:10:10 mM. In a 6 M deuterated acetate buffer, ^1H NMR spectra of the blue complex were measured and several aromatic protons were assigned. In the blue solution, multiple anthocyanin and copigment signals were observed, indicating that the complex structure is not fixed but instead under equilibrium. It was clarified that the blue anhydrobase anion form of delphinidin 3-glucoside, **1**, is formed by complexation with Al^{3+} and the complex is stabilized by nonflavonoid copigment, **2**, which also chelates to Al^{3+} (Figure 6). However, the whole supramolecular structure may not be a static structure but instead a fluctuating structure in equilibrium state. The combination of **1**, **2**, and Al^{3+} may construct a very unique and special coordination structure, and this imparts a very elusive character to hydrangea blue.

centrifugation. The aqueous fractions (extracts 1 and 2) without proteins were lyophilized and then analyzed by LC-DAD/MS and MALDI-TOF.

Fractionation of the Grape Pomace Extracts. One gram of GP extract 1 was applied on top of a C18 (20 g) column, and different fractions were obtained by elution with water acidified with formic acid (1%), ethyl ether, ethyl acetate, and aqueous solution with increasing percentages of methanol (10, 30, 60, and 100%, v/v) acidified with formic acid. Additionally, 100 mg of the same extract was fractionated by TSK Toyopearl 40-HW(S) column chromatography using different aqueous solvents with increasing percentages of methanol (0, 10, 20, 30, and 100%, v/v). The obtained fractions were analyzed by LC-DAD/MS and MALDI-TOF.

One gram of extract 2 dissolved in 200 mL of water was submitted to a liquid−liquid extraction procedure with ethyl acetate (3 × 200 mL) and isoamyl alcohol (2 × 200 mM). All of the fractions were analyzed by LC-DAD/MS.

LC-DAD/MS. The anthocyanin and anthocyanin-derived compound composition of each fraction was evaluated by LC-DAD/MS. An Accela series liquid chromatograph, equipped with a 150 × 4.6 mm i.d., 5 μm, LicroCART reversed-phase C18 column was used, and detection was carried out between 200 and 600 nm using an Accela PDA detector. The mass detection was performed using an LTQ Orbitrap XL mass spectrometer (Thermo Fischer Scientific, Bremen, Germany) controlled by LTQ Tune Plus 2.5.5 and Xcalibur 2.1.0. Solvents were (A) H_2O/HCOOH (99:1) and (B) HCOOH/H_2O/CH_3CN (1:69:30). The gradient was performed using an Accela 600 Pump and consisted of 20−85% B for 70 min at a flow rate of 0.3 mL/min. The column was washed with 100% B for 10 min and then stabilized with the initial conditions for another 10 min. The capillary voltage of the electrospray ionization (ESI) was set to 3100 V, and the capillary temperature was 275 °C. The sheath gas flow rate (nitrogen) was set to 5 (arbitrary units as provided by the software settings). The capillary voltage was 49 V and the tube lens voltage 250 V. Spectra were recorded in positive-ion mode between m/z 50 and 2000. The mass spectrometer was programmed to do a series of three scans: a full scan mass, a zoom scan of the most intense ion in the first scan (selected ion monitoring, SIM), and a MS-MS of the most intense ion using relative collision energies of 30 and 60 V.

MALDI-TOF (Matrix-Assisted Laser Desorption Ionization−Time of Flight) Analysis. The different GP fractions were analyzed by MALDI-TOF using an UltrafleXtreme mass spectrometer (Bruker, Bremen, Germany) operating in positive reflectron ion detection mode with laser SmartBeamIII and under FlexCompass 1.4 software control (Bruker Daltonics, Germany). For each sample the laser power was adjusted to 55%, the detector gain 4.0× (2410 V), and the mass range between 200 and 3500.

For the sample preparation, a tIAA (*trans*-3-indolacrylic acid) matrix (≥98.5%, Sigma-Aldrich, USA), 50 mg/mL, was prepared in an aqueous solution of 70% (v/v) acetone. Moreover, each grape pomace fraction was prepared in the same solvent in a concentration of 5 mg/mL. The polyphenolic fractions eluted from the Toyopearl column were mixed with the matrix solution at volumetric ratios of (1:2). The analyte/matrix mixture was first deionized with Dowex 50X8-400 cation exchange resin (Supelco), equilibrated in 70% aqueous acetone (v/v). Positive ion mode was used for the detection of anthocyanins. Two microliters from each sample (after mixing with the matrix and the resin) was applied onto a stainless steel target plate (MTP 394 target plate ground steel BC, Bruker Daltonics) and fully air-dried. For each assay, three sample spot replicates were analyzed, and samples were spotted in triplicate.

RESULTS AND DISCUSSION

GP Anthocyanic Profile by LC-DAD/MS. According to the LC-DAD analysis of the red GP extract 1, without using any

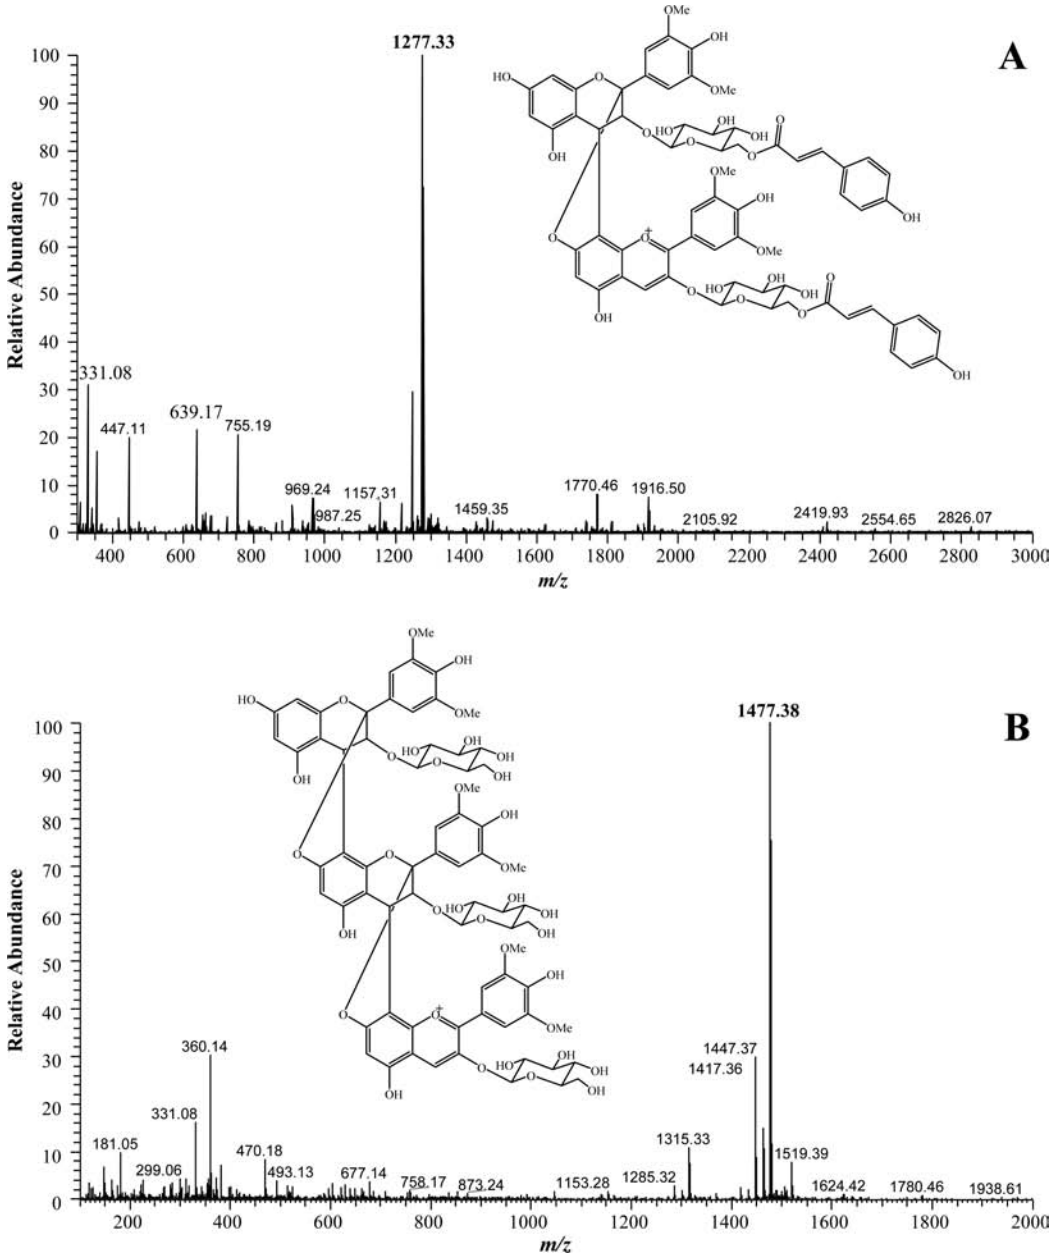

Figure 2. ESI-MS analysis performed in the positive-ion mode of a GP fraction (60% (v/v) methanol) showing the presence of anthocyanin dimers and trimers: (A) full mass spectrum (*m*/*z* 1277) of the malvidin-3-*O*-coumaroylglucoside dimer (**49**); (B) full mass spectrum (*m*/*z* 1477) of the malvidin-3-*O*-glucoside trimer (**4**).

previous fractionation methodology it was possible to observe in the chromatogram recorded at 520 nm the presence of 12 peaks (Figure 1A). The main compound was identified by its UV−visible spectra, retention time, ion mass (*m*/*z* 639) in the positive ion mode, and fragmentation pattern (MS^2 331) and was attributed to malvidin-3-*O*-coumaroylglucoside (peak 43) (Figure 1 and Table 1). The area of malvidin-3-*O*-coumaroylglucoside represents around 65% of the total area. The chromatographic profile (Figure 1) of the GP extract is quite different from one that is usually observed in grapes and young red wines, where, generally, malvidin-3-*O*-glucoside is the main anthocyanin present with the coumaroyl-derivative being the second most intense, especially in the Douro region.[13] The appearance of this chromatographic profile can be due to the specificities of the winemaking process, or it can be explained by the lower solubility of the coumaroyl derivative in aqueous solution, slowing or limiting its diffusion to the hydroalcoholic solution during the fermentation/winemaking process. In addition to the malvidin-3-*O*-coumaroylglucoside pigment, other peaks were detected in the same GP extract corresponding to the four nonacylated anthocyanin-3-*O*-glucosides mainly present in grapes and red wines (delphinidin, petunidin, peonidin, and malvidin) and to some of their acetylated, coumaroylated, and caffeoylated derivatives (Figure 1 and Table 1). The presence of the A- and B-type vitisin compounds was also observed (peaks 10 and 13, respectively) (Figure 1 and Table 1). Moreover, the detection of a compound (peak 40) (Figure 1) with the same ion mass as the malvidin-3-*O*-coumaroylglucoside (*m*/*z* 639) (peak 43) in the positive ion mode was observed. Similarly to what was reported in the literature by Monagas et al.[14] and Núñez et al.,[15] in grapes and wines from *Vitis vinifera* this can be attributed to the occurrence of the *cis* isomer of the

DOI: 10.1021/acs.jafc.5b00256
J. Agric. Food Chem. 2015, 63, 7636−7644

malvidin-3-*O*-(6-*p*-coumaroyl)-glucoside (**40**) in GP that is present in smaller amounts when compared with the *trans* isomer.

To obtain fractions with different chemical compositions and therefore better characterize the GP extract polyphenolic composition, a fractionation methodology was developed. First, the anthocyanin and anthocyanin-derived compounds from extract 1 were separated in a reverse phase C-18 resin and eluted with solvents that present different polarities, namely, ethyl ether, ethyl acetate, water, and aqueous solutions with increasing percentages of methanol. With the less polar solvent (ethyl ether) it was possible to remove the chlorophylls and the hydrophobic fractions, but due to its lack of solubility in water or methanolic solvents, this fraction was not analyzed by LC-DAD/MS. No additional peaks were detected in those fractions obtained from the fractionation of the GP with C-18 resin or with Toyopearl HW-40(S) gel when compared to direct analysis of the GP extract (extract 1). The main exception was the fraction eluted with 60% (v/v) methanol, where it was possible to detect by LC-MS in positive-ion mode the presence of the malvidin-3-*O*-coumaroylglucoside dimer (**49**) (*m*/*z* 1277) and the malvidin-3-*O*-glucoside trimer (**4**) (*m*/*z* 1477) (Figure 2), both already reported in the literature to be present in red grapes and wines.[16−18] The possibility of detecting anthocyanins self-assembling by LC-MS made us think that these signals detected in fraction 60% (v/v) methanol could be due to the auto-association of malvidin-3-*O*-coumaroylglucoside and malvidin-3-*O*-glucoside, respectively, leading to the formation of the dimer and trimer. To confirm that dimer and trimer are isolated compounds and not products formed during the anthocyanins' autoassociation, MALDI-TOF analysis was used, and the results are discussed below.

However, the high complexity of the red GP was recognized after the LC-DAD/MS analysis of GP extract 2, where the solid/solvent contact time was increased to 18 h. In this extract >50 different anthocyanin and anthocyanin-derived compounds were detected and most of them identified (Table 1). In this extract the five anthocyanin-monoglucosides (delphinidin, cyanidin, petunidin, peonidin, and malvidin), two acetylglucoside derivatives (petunidin and malvidin), five coumaroyl derivatives, and three caffeoyl-derivatives (delphinidin, peonidin, and malvidin) were identified on the basis of their ion mass, fragmentation patterns (Table 1), and UV−visible spectra (data not shown). The presence of these anthocyanins in GP is not surprising because they are present in red grapes and therefore are also expected to be present in the resulting red GP.[19,20] Additionally, in the mass spectrum in the positive-ion mode was detected an ion mass at *m*/*z* 655 (peak 5) and two fragments *m*/*z* 493 (− 162 amu) and *m*/*z* 331 (− 2 × 162 amu). The fragmentation pattern is in agreement with the presence of the malvidin aglycone (*m*/*z* 331) and two glucose moieties (− 2 × 162 amu) as is observed in malvidin-3,5-diglucoside (malvin). This is also corroborated by the retention time that is smaller (RT 39.13 min) than the one observed for malvidin-3-glucoside (RT 42.92 min) as is expected for a diglucoside (more polar) in a reverse phase C-18 column. The presence of malvin is not expected to occur in *Vitis vinifera* grapes but only in other *Vitis* sp. Even though its occurrence in *V. vinifera*-based GP has never been reported in the literature, Baldi et al. and Heier et al. have detected small amounts of anthocyanin-3,5-diglucosides in *V. vinifera* L. grapes and wines.[20,21] Moreover, the same ion mass (*m*/*z* 655) was observed later in the mass chromatogram (RT 65.43 min), but in this case the fragmentation pattern

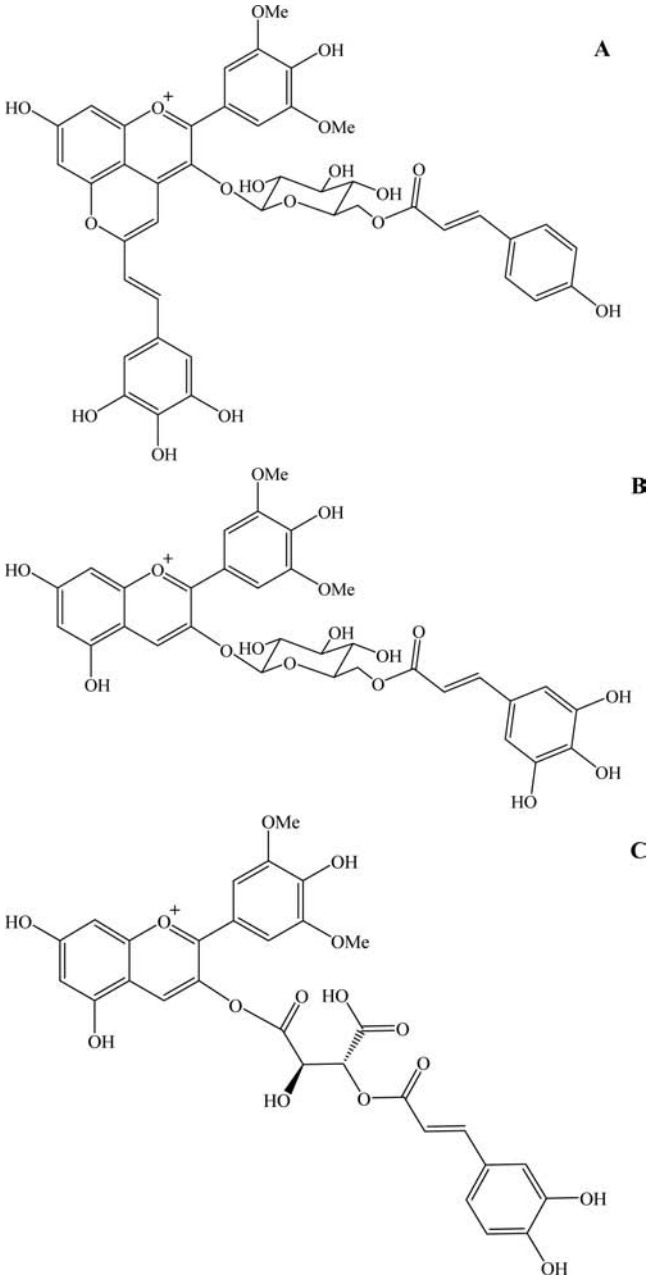

Figure 3. Hypothetic structures of the compounds (A) **48** (vinyl-pyranomalvidin-3-*O*-coumaroylglucoside-pyrogallol), (B) **41** (malvidin-3-*O*-galloylglucoside), and (C) **11** (malvidin-3-*O*-caftaric acid) detected by LC-MS in the positive-ion mode in GP extract 2.

was *m*/*z* 331 (corresponding to the loss of a caffeoylglucoside moiety, − 324 amu) and by this was attributed to the malvidin-3-*O*-caffeoylglucoside (**32**). Furthermore, seven A-type vitisins (petunidin-, peonidin-, and malvidin-based, nonacylated, acetylated, coumaroylated, and caffeoylated) were also detected in red GP and identified by comparison with their known fragmentation patterns (Table 1) reported in the literature.[22−24] Similarly, five B-type vitisins and three methyl-pyranoanthocyanins were also identified on the basis of their fragmentation patterns (Table 1).[25,26] The typical fragmentation pattern of A- and B-type vitisins is the loss of their sugar moiety that can be in their nonacylated (glucose − 162 amu) or acylated (acetylglucose − 204 amu, coumaroylglucose − 308 amu, or caffeoylglucose − 324 amu) forms giving origin to the

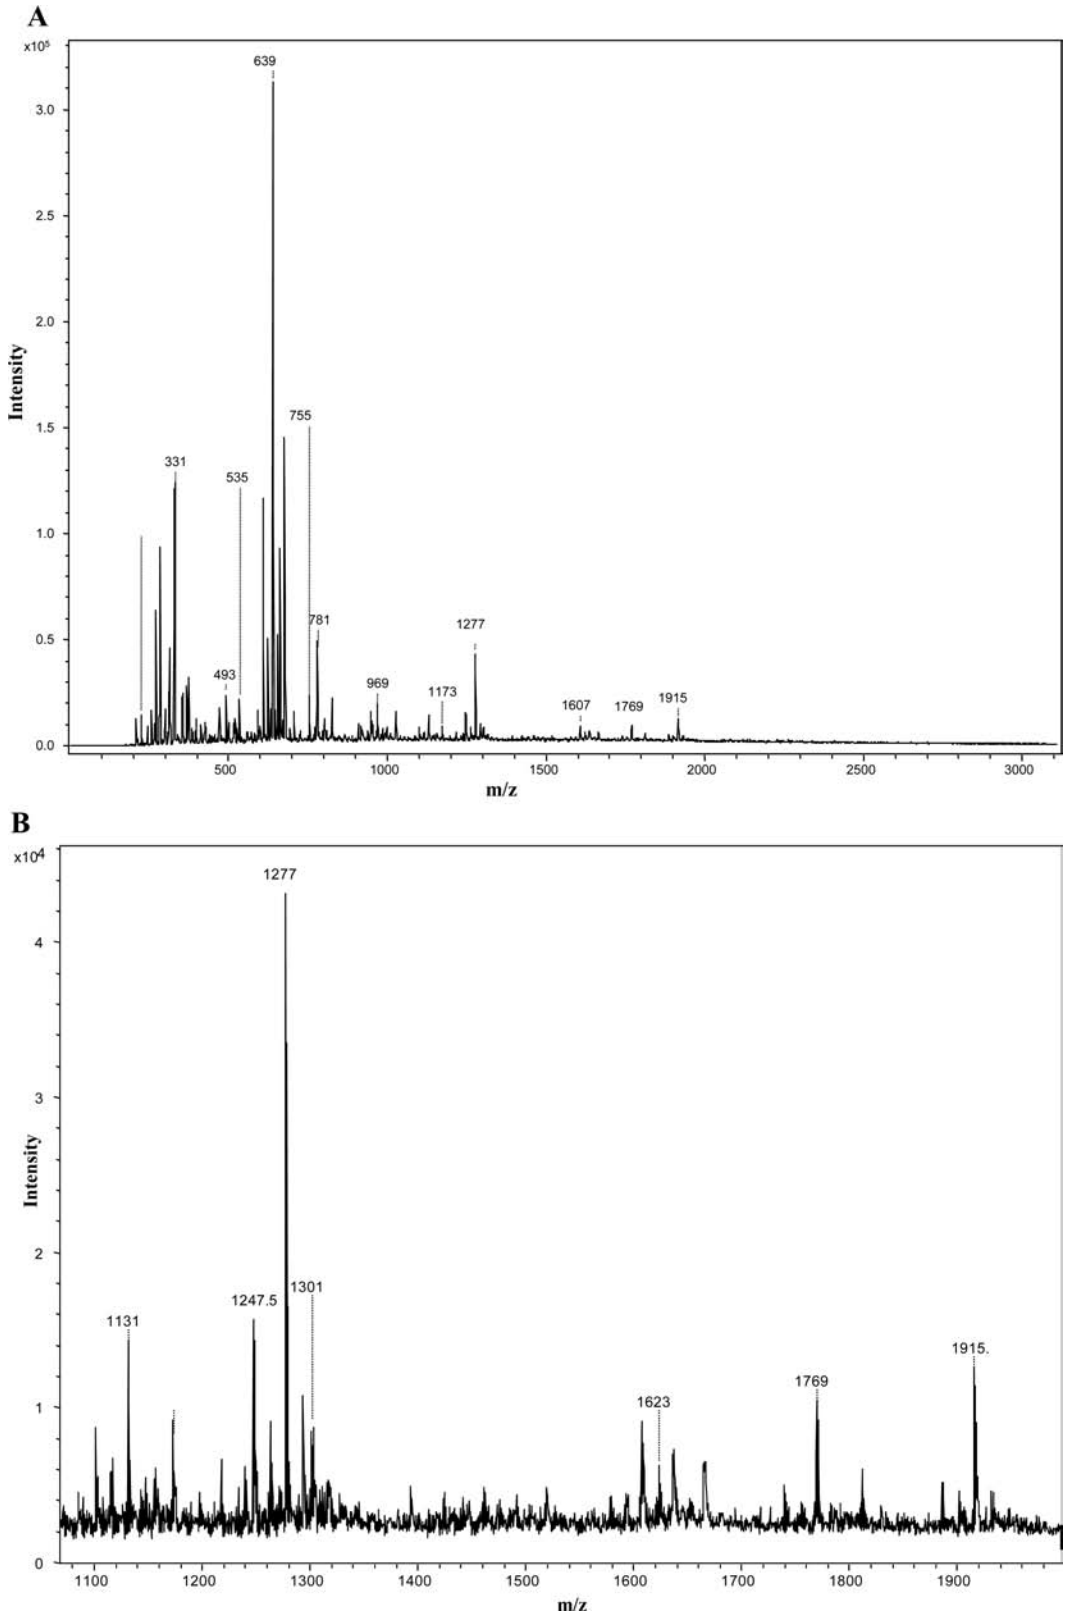

Figure 4. (A) MALDI-TOF analysis in the positive ion mode of the red GP extract (extract 1); (B) same analysis from m/z 1000 to 2000.

respective A and vitisin aglycones (m/z 399 and 355, respectively for the malvidin-derived compounds). The presence of these anthocyanin-derived pigments, although expected, has never been reported in the literature for grape pomace.

Besides, anthocyanin-derived compounds containing a catechin moiety were also detected in GP. These compounds belong to the family of the malvidin-methylmethine-catechin pigments and were identified by their ion mass (m/z 809) and characteristic fragmentation patterns (m/z 519 and 357)

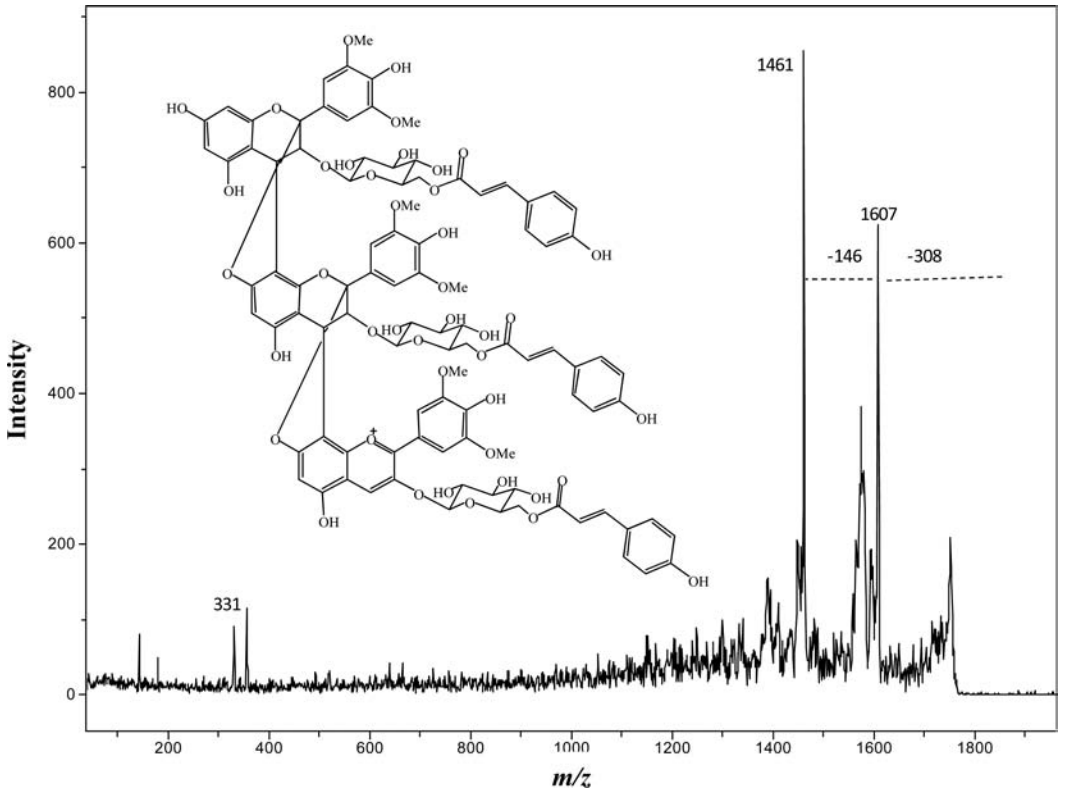

Figure 5. MALDI-TOF-TOF fragmentation of the ion at m/z 1915.

according to the data reported in the literature.[27] These ion mass and fragmentation patterns were observed for two compounds (**15** and **21**) (Table 1), and two explanations can be given for this. First, the malvidin-methylmethine-catechin pigment has an asymmetric carbon in the methylmethine group, and this way two enantiomers are possibly present. Another explanation is the possibility of formation of a similar compound but in this case with (−)-epicatechin instead of (+)-catechin. As (+)-catechin and (−)-epicatechin are isomers, the same ion mass and fragmentation patterns are expected to occur in (−)-epicatechin-based pigments. The unequivocal identification of these compounds is not possible to achieve through LC-MS spectrometry, and only by using NMR spectroscopy could the structure be confirmed. The coumaroyl derivative of this compound was also found to occur in GP (**42**) (Table 1). Moreover, the presence of two pyranomalvidin compounds with a phenol moiety was also detected and identified by LC-DAD/MS in the GP extract, namely, the pyranomalvidin-3-*O*-glucoside-phenol (**46**) and the respective coumaroyl derivative (**50**). The ion mass detected at 82.85 min with m/z 813 and fragment m/z 505 could be identified as a vinylpyranomalvidin-3-*O*-coumaroylglucoside-pyrogallol (**48**) (Figure 3A; Table 1) with a structure similar to that of B-type portisins but that has never been described in the literature. However, this is only a hypothetical structure because no full characterization by NMR has been performed on the compound due to its small concentration in GP. On the other hand, the ion mass m/z 671 detected in GP extract with a fragment at m/z 331 was attributed to the malvidin-3-*O*-galloylglucoside (**41**) (Figure 3B; Table 1). The galloylated derivative of anthocyanins has never been described in the literature. However, this identification is based on only the fragmentation pattern of the molecule as the full characterization of the compound by NMR was not possible. Additionally, small amounts of the malvidin-3-*O*-caftaric acid (**11**) (Figure 3C; Table 1) were also detected in the GP extract. Moreover, some compounds with known fragmentation patterns, namely, loss of glucose or retro-Diels–Alder (RDA) fragmentation, indicate the presence of a flavanol moiety was also observed; nevertheless, the identity of these compounds was not achieved. Their ion masses are not reported in the literature, and using only mass spectrometry it is not possible to fully identify these anthocyanin-derived compounds. Additionally, the small amounts of the compounds present in the GP extract make its full characterization by NMR nearly impossible to accomplish. These compounds are indicated in Table 1 as "unknown".

MALDI-TOF. The use of the mass spectrometry MALDI-TOF technique to characterize the oligomeric nature of the GP extract was of crucial importance because the presence of the oligomeric anthocyanin ion masses (m/z 1277, 1477, 1623, and 1915) in the ESI-MS could be due to a self-assembling mechanism that sometimes is possible to observe when the concentration of the sample is high in this mass spectrometry technique. In MALDI-TOF stacking has not been reported to occur.

Figure 4 shows the MALDI-TOF analysis of the GP extract (extract 1). It can be observed that the ion at m/z 639 is the most intense, which is in agreement with Figure 1, malvidin-3-*O*-coumaroylglucoside (compound **43**).

Figure 4B shows a series of masses that could correspond to oligomeric coumaroylated anthocyanins: the ion at m/z 1131 might be a monocoumaroylated malvidin-3-*O*-glucoside dimer, the ion at m/z 1277 could correspond to the malvidin-3-*O*-coumaroylglucoside dimer (compound **49**, Table 1), the ion at m/z 1623 could be a monocoumaroylated malvidin-3-*O*-glucoside trimer (compound **23**, Table 1), the ion at m/z 1769 might be dicoumaroylated malvidin-3-*O*-glucoside trimer, and finally the ion at m/z 1915 could correspond to a trimer of

DOI: 10.1021/acs.jafc.5b00256
J. Agric. Food Chem. 2015, 63, 7636−7644

malvidin 3-*O*-coumaroylglucoside. The latter in its nonacylated glucoside form has already been detected in a young Port wine.[18]

MALDI-TOF-TOF fragmentation of the ion at *m*/*z* 1915 gave fragments at *m*/*z* 1607 (−308), *m*/*z* 1461, and *m*/*z* 331 (Figure 5). The loss of 308 mass units corresponds to a glucose acylated with a coumaric acid, and the loss of 146 mass units corresponds to a coumaric acid moiety; therefore, it can be concluded that these fragmentations confirm the suspected nature of the trimer.

MALDI-TOF has already been used in the analysis of oligomeric food polyphenols,[28] mainly procyanidins; however, it is not commonly used in anthocyanin analysis because monomeric anthocyanins have a molecular weight of around 500 mass units, which is a difficult mass range for MALDI-TOF analysis. However, oligomeric pigments containing both anthocyanins and flavanols have already been detected by MALDI-TOF to occur in cranberry fruit.[28,29] Nevertheless, to our knowledge, this is the first study in which MALDI-TOF was used for the analysis of oligomeric anthocyanins.

One of the late-eluting fractions (obtained with 100% organic solvent in low-pressure chromatography with Toyopearl HW-40(S) gel) was particularly enriched in less hydrophilic pigments. This fraction was mainly composed of coumaroyl derivatives of anthocyanins (monomers and oligomers).

Grape pomace is an interesting source of anthocyanin-based pigments (both native and derived), as >50 different anthocyanin-based compounds were detected in this study. Oligomeric anthocyanins with coumaroylated derivatives of malvidin were detected by means of mass spectrometry for the first time in this work, and the influence of oligomeric anthocyanins on wine color remains unknown; these oligomeric anthocyanins (malvidin-3-*O*-glucoside trimer) have already been detected in young Port wine; however, the less hydrophilic nature of oligomeric coumaroylated anthocyanins raises the question of their extractability in wine. Moreover, recently the equilibrium forms of malvidin-3-*O*-glucoside trimer present in grape skins were studied in aqueous solution at different pH values through UV−visible spectroscopy. It was observed that the reactivity of this compound is strongly dominated by acid−base chemistry, with the hydration reaction accounting for <10% of the overall reactivity.[30] This indicates that polymerization may be a natural stabilization mechanism for the red color of anthocyanins.

colorless flavonoids and anthocyanins when these compounds coexist together in a complex food matrix such as red wines.

In red wine, copigmentation occurs in a "multiple" way, and more than one copigment can interact simultaneously with anthocyanins. Under these conditions, it is expected that there will be competition between the copigments and pigments in the same solution.[4] The preference or order for these associations could result in positive or negative synergies on the color and color stability, as has been previously reported for other important properties of phenolic compounds such as antioxidant activity.[18−20]

Studies focused on the mechanism of these multiple interactions in model solutions and its effects on copigmentation are scarce,[21,22] and some aspects are still not well understood such as the possible additive, synergistic, or antagonistic effects among the components present in multiple mixtures and the way to quantify the extent of the process.

From a sensory point of view, the objective assessment of copigmentation seems to be critical for understanding the relationship between grape composition and color in young red wines.[21] It is assumed that positive effects of copigmentation include greater color stability and also quantitative and qualitative color changes. Therefore, an adequate description of the color variations caused by copigmentation requires considering the changes produced in the entire visible spectral curve (380−770 nm), and not only in its visible λ_{max} portion. The color characterization of the multiple copigmentation process in the CIELAB color space by differential colorimetry provides the opportunity of assessing this phenomenon in a global way by considering the modifications in the whole visible spectrum, and conclusions related to the later color stability could be extracted. Research into the industrial evaluation of color variations based on differential colorimetry has shown significant progress in recent years.[23−25] The CIELAB color attributes lightness, chroma, and hue, and their related color-difference formulas are widely used for industrial applications that require accurate measurement of color changes related to perception and acceptability. Nonetheless, there is very little previous information about the application of differential colorimetry into the study of copigmentation.[14,26] Recently, differential colorimetry has led to a new point of view in the knowledge of the chemistry of the anthocyanin color and to the interpretation of the copigmentation effects on its visual assessment, both in model solutions and in wines.[9,15,22,27]

Thus, with the aim to further the knowledge of the copigmentation interactions and their implication in the chemical and colorimetric stability of the color of red wine anthocyanins, we have studied the combined effect of anthocyanin−flavanol−flavonol ternary mixtures by differential colorimetry. The levels of flavanols and flavonols in the multiple mixtures were modified to simulate the effect of applying such enological procedures as adding white skins (flavonols) or seeds (flavanols) during the vinification of red wines. The pigment considered in this study represents the main anthocyanin of red grapes and wines (malvidin-3-glucoside). The copigment (+)-catechin was selected as it is one of the main monomeric flavanols present in grape seed, and quercetin-3-β-D-glucoside was representative of flavonols present in grape skin.

MATERIALS AND METHODS

Chemicals and Standards. Malvidin-3-glucoside (≥97%) was purchased from Extrasynthese (Genay, France). The copigments (+)-catechin (≥96%) and quercetin-3-β-D-glucoside (≥90%) were purchased from Sigma-Aldrich (Madrid, Spain). All chromatographic solvents (acetonitrile and formic acid) were of HPLC grade (Merck, Darmstadt, Germany). Purified water was obtained from a NANOpure Diamond system (Barnsted Inc., Dubuque, IA, USA). All other chemicals (methanol, tartaric acid, and sodium chloride) were of analytical grade and supplied by Panreac Química (Barcelona, Spain).

Preparation of Ternary Copigmented Solutions. All copigmented solutions used were prepared in a wine-like medium containing 5 g/L tartaric acid in 12% ethanol with ionic strength adjusted to 0.2 M by the addition of sodium chloride and pH adjusted to 3.6 with NaOH.

Two copigmented solutions based on binary combinations of malvidin-3-glucoside with (+)-catechin (MC) and malvidin-3-glucoside with quercetin-3-β-D-glucoside (MQ) were prepared at the same pigment/copigment concentration (200:200 mg/L). MC and MQ solutions were filtered (0.45 μm Millipore-AP20 filters) and stored closed in darkness at 25 °C for 2 h to reach equilibrium. Then, quercetin-3-β-D-glucoside was added in concentrations 50, 100, and 200 mg/L to three aliquots of the MC solution to obtain the following ternary mixtures: MC+Q50, MC+Q100, and MC+Q200. In the same way (+)-catechin was added in concentrations of 50, 100, and 200 mg/L to three aliquots of the MQ solution to obtain the following ternary mixtures: MQ+C50, MQ+C100, and MQ+C200.

All of the copigmented solutions, in both binary and ternary combinations, were prepared in triplicate and stored closed in darkness at 25 °C. The final anthocyanin concentration was the same in all cases (200 mg/L). Samples (n = 24) were taken periodically for the colorimetric and chemical analysis at 2, 24, and 72 h and at 1, 2, and 3 weeks.

HPLC-DAD Analysis. The content of malvidin-3-glucoside in the model solutions and its evolution over the storage period were evaluated by HPLC-DAD using a Hewlett-Packard 1200 series liquid chromatograph (Palo Alto, CA, USA), equipped with a quaternary pump, column heater, UV−vis diode array detector, automatic injector, and ChemStation software. A Zorbax SB C18 column (4.6 mm × 250 mm, 4.6 μm particle size) thermostated at 38 °C was used. The solvents used were (A) acetonitrile/formic acid/water (3:10:87) and (B) acetonitrile/formic acid/water (50:10:40). The elution profile was as follows: 0−5 min, 94% A; 5−7.5 min, 70% A; 7.5−12.5 min, 60% A; 12.5−16 min, 55% A; 16−19 min, 50% A; 19−20 min, 94% A. The flow rate was 1 mL/min, and the injection volume was 50 μL. UV−vis spectra were recorded from 200 to 800 nm with a bandwidth of 2.0 nm. The quantification was performed at 525 nm by HPLC-DAD using calibration curves of malvidin-3-glucoside standard. All analyses were carried out in duplicate, and results were expressed as milligrams per liter.

Analysis of Copigmentation by Colorimetric Measurements. The absorption spectra (380−770 nm) of all solutions were recorded at constant intervals ($\Delta\lambda$ = 2 nm) with a Hewlett-Packard UV−vis HP8453 spectrophotometer, using 5 mm path length glass cells and distilled water as a reference. The CIELAB parameters were calculated from the absorption spectra by using the original software CromaLab,[28] following the recommendations of the Commission International de L'Eclariage: CIE 1964 10° Standard Observer and the Standard Illuminant D65, corresponding to natural daylight.[29] CIELAB parameters were calculated: L^* (the correlate of lightness; ranging from 0, black, to 100, white) and two color coordinates, a^* (which takes positive values for reddish colors and negative values for greenish ones) and b^* (positive for yellowish colors and negative for bluish ones). From these coordinates, other color parameters are defined: the hue angle (h_{ab}, the correlate of chromaticity or tone, and the chroma C^*_{ab}, the correlate of saturation or intensity of color). Moreover, L^*, C^*_{ab}, and h_{ab} can be distinguished as quantitative or qualitative parameters as they indicate quantitative (L^* and C^*_{ab}) or qualitative (h_{ab}) attributes of color.

The color changes of solutions induced by copigmentation and their color stability over the storage period were evaluated by differential colorimetry according to the methodology described in Gordillo et al.,[15] which is based on the application of various different

color-difference formulas. The color difference between pairs of samples was computed as the Euclidean distance between two points in the three-dimensional CIELAB space by means of the CIE76 color difference formulas: $\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$. Also, on the basis of ΔE^*_{ab} the parameter total color was calculated as the color difference between the color of each sample (L^*, a^*, and b^*) and distilled water, which correspond with an achromatic reference (L^* = 100, a^* = 0, b^* = 0), as follows:

$$\text{Total color: } [(L^* - 100)^2 + (a^* - 0)^2 + (b^* - 0)^2]^{1/2} \quad (1)$$

The trend of the changes in each individual color attribute between pairs of samples was evaluated by means of the absolute lightness, chroma, and hue differences (ΔL^*, ΔC^*_{ab}, Δh_{ab}). Also, the relative contribution of each color attribute that makes a given color difference value (ΔE^*_{ab}) was calculated as the quadratic differences of lightness, chroma, and hue ($\%\Delta^2 L$, $\%\Delta^2 C$, and $\%\Delta^2 H$), expressed as percentages:

$$\text{rel contribution (\%) of lightness: } \%\Delta^2 L = [(\Delta L^*)^2/(\Delta E^*_{ab})^2] \times 100$$

$$\text{rel contribution (\%) of chroma: } \%\Delta^2 C = [(\Delta C^*_{ab})^2/(\Delta E^*_{ab})^2] \times 100$$

$$\text{rel contribution (\%) of hue: } \%\Delta^2 H = [(\Delta h)^2/(\Delta E^*_{ab})^2] \times 100$$

ΔH is mathematically deduced from $\Delta H = [(\Delta E^*_{ab})^2 - ((\Delta L)^2 + (\Delta C)^2)]^{1/2}$.

Statistical Analysis. All statistical analyses were performed using Statistica v.8.0 software.[30] Univariate analysis of variance (Tukey test, p < 0.05.) was applied to establish statistical differences for the anthocyanin concentration and the colorimetric characteristic between binary and multiple copigmented solutions.

RESULTS AND DISCUSSION

Effect of Multiple Copigmentation on Color Characteristics by Differential Colorimetry. Table 1 shows the influence of increasing concentrations of quercetin-3-β-O-glucoside and (+)-catechin on the colorimetric parameters (L^*, a^*, b^*, C^*_{ab}, and h_{ab}) and total color of MC and MQ solutions, respectively, at 2 h after their preparation. Results showed that the two copigments studied have quite different abilities to interact with malvidin-3-glucoside in multiple copigmentation conditions. In particular, the addition of quercetin-3-β-D-glucoside caused an immediate increase in the total color of the MC solutions, which reflects the preferential binding between quercetin-3-β-D-glucoside and the flavylium ions and the shift of the equilibrium toward the colored forms. The magnitude of this effect, expressed as the relative increases of the Total color, was significantly (p < 0.05) correlated with the quercetin-3-β-D-glucoside concentration. Specifically, the Total color was increased by 5, 12, and 20% at 50, 100, and 200 mg/L of quercetin-3-β-D-glucoside. Thus, quercetin-3-β-D-glucoside was demonstrated to have a strong affinity for malvidin-3-glucoside in the presence of (+)-catechin. Also, the addition of quercetin-3-β-D-glucoside to MC solutions produced a progressive decrease in lightness and hue values (L^* and h_{ab}), followed by an increase of chroma (C^*_{ab}), which means a gradual and significant intensification of the color.

In contrast, the addition of (+)-catechin did not greatly influence the colorimetric characteristics of MQ solutions at any tested level, with the exception of the b^* and hue values, which were significantly (p < 0.05) decreased at 200 mg/L. These slight variations observed in the qualitative attributes of color (b^* and hue values) denote a bluish effect. In any case, no statistically significant differences were found in the total color, chroma, and lightness (quantitative attributes) between MC and MQ+C solutions, indicating similar color intensity in both binary and ternary mixtures. Thus, in comparison to quercetin-3-β-D-glucoside, (+)-catechin was demonstrated to have a much lower affinity for malvidin-3-glucoside in multiple conditions.

The different abilities of quercetin-3-β-D-glucoside and (+)-catechin to modify the copigmentation equilibrium in multiple conditions can be explained in terms of their specific binding strengths and concentrations resulting in variable effects in color.[4] With respect to the MQ solutions, our results suggest that the strong interaction initially established between quercetin-3-β-D-glucoside and malvidin-3-glucoside prevents the subsequent binding with (+)-catechin. As expected, quercetin-3-β-D-glucoside offers larger extended π conjugation that makes the molecule more planar and facilitates the $\pi-\pi$ interactions to form stable copigmentation complexes,[16,31] so the availability of the flavylium ion to interact with (+)-catechin could be strongly

limited. Similar results were obtained by Rustioni et al.,[17] who concluded that some flavonols are capable of displacing flavanols when they coexist in competitive equilibrium.

However, the opposite effect occurred when increasing concentrations of quercetin-3-β-D-glucoside were added to MC solutions. In this case, the initial copigmentation effect observed between malvidin-3-glucoside and (+)-catechin was comparatively weaker (note that the total color of MC was much lower than that of MQ). This fact probably favored the later interaction of the quercetin-3-β-D-glucoside with the anthocyanin chromophore, which gradually forced the global copigmentation equilibrium to a greater extent.

To establish whether the observed changes in the CIELAB parameters were visually relevant, color variations between binary and ternary copigmented solutions were calculated and expressed as colorimetric differences ΔE^*_{ab} (see Table 2, data referred to 2 h). Also, in an attempt of understand the significance of the color changes, the absolute lightness, chroma, and hue differences (ΔL^*, ΔC^*_{ab}, and Δh_{ab}) were calculated. According to Martinez et al.,[24] ΔE^*_{ab} around 3 units indicates, approximately, color differences appreciable to the human eye (as an average observer). On the basis of this premise, the most perceptible color changes were produced when quercetin-3-β-D-glucoside was added to the MC solutions. This color variation became more perceptible with higher concentrations of quercetin-3-β-D-glucoside, which was consistent with the effects observed in the total color and the magnitude of copigmentation. Specifically, the tendency was always toward higher decreases of ΔL^* and Δh_{ab} (negative values), which correspond to visually increasing darkening and bluish effects. Simultaneously, chroma differences ΔC^*_{ab} tended toward higher increases (positive values), resulting in more saturated solutions. Thus, it could be verified that in multiple copigmentation conditions quercetin-3-β-D-glucoside makes an important contribution to color intensity and tonality. In contrast, the color variations induced by (+)-catechin can be considered negligible at all of the concentrations tested as ΔE^*_{ab} values in all color pairs were <2 units. Similarly, ΔL^*, ΔC^*_{ab}, and Δh_{ab} showed relatively minor changes. This fact confirms again the greater difficulty of (+)-catechin binding malvidin-3-glucoside in the presence of quercetin-3-β-D-glucoside.

Moreover, by comparing the relative contributions of lightness ($\%\Delta^2 L$), chroma ($\%\Delta^2 C$), and hue ($\%\Delta^2 H$) to each color difference (ΔE^*_{ab}) it was possible to evaluate which color attribute was the most influenced (Figure 1). Taking into account only solutions with the largest perceptible color changes (MC+Q100 and MC+Q200), it can be observed that quercetin-3-β-D-glucoside induced similar color effects independently of the concentration tested. Results showed that the lightness was the most overall influential parameter ($\%\Delta^2 L \sim 50\%$), whereas the weights of the chroma and hue modifications were in general comparatively lower, but similar among them ($\%\Delta^2 C$ and $\%\Delta^2 H$ ~25%).

Effect of Multiple Copigmentation on Color Stability by Differential Colorimetry. The evolution of the total color of solutions during the 3 weeks of storage in darkness at 25 °C is shown in Figure 2, where the mean value and standard deviation of samples are included. It can be observed that the addition of quercetin-3-β-D-glucoside is more effective in maintaining the total color of the MC solutions than the addition of (+)-catechin to the MQ solutions. As shown in Figure 2A, the Total color hardly decreased in MC binary solutions after 2 weeks of storage (around 28%), whereas in the ternary solutions containing 50, 100, and 200 mg/L of quercetin-3-β-D-glucoside the total color losses were 13.6, 10.4, and 4%, respectively. Contrary to that, higher decreases of total color were observed in MQ+C ternary solutions as the (+)-catechin ratio increased in the mixtures (Figure 2B).

The assessment of changes in the CIELAB parameters during storage was also decisive to establish the copigment having the greatest impact on the stability of the quantitative (L^* and C^*_{ab}) or qualitative (h_{ab}) color attributes (Figures 3 and 4). As can be observed, the chroma values decreased in all solutions over time while the hue values increased toward positive values. This means that the color variation that took place during stabilization in both binary and ternary mixtures was due to a decrease of the quantity of color and bluish hue (h_{ab} nearer to 0°, redness color).[10]

In particular, quercetin-3-β-D-glucoside was shown to better preserve the lightness than chroma and hue of MC+Q ternary solutions (Figure 3). Independently of the concentration tested, the global variations of lightness values were always below 3.5% after 3 weeks of storage (Figure 3A). On the other hand, the evolution of chroma and hue (Figure 3B,C) suggests a greater stabilization effect at the highest concentration of quercetin-3-β-D-glucoside because the global losses of the quantity of color and bluish hues were less intense at 200 mg/L.

J. Agric. Food Chem. 2015, 63, 7645−7653

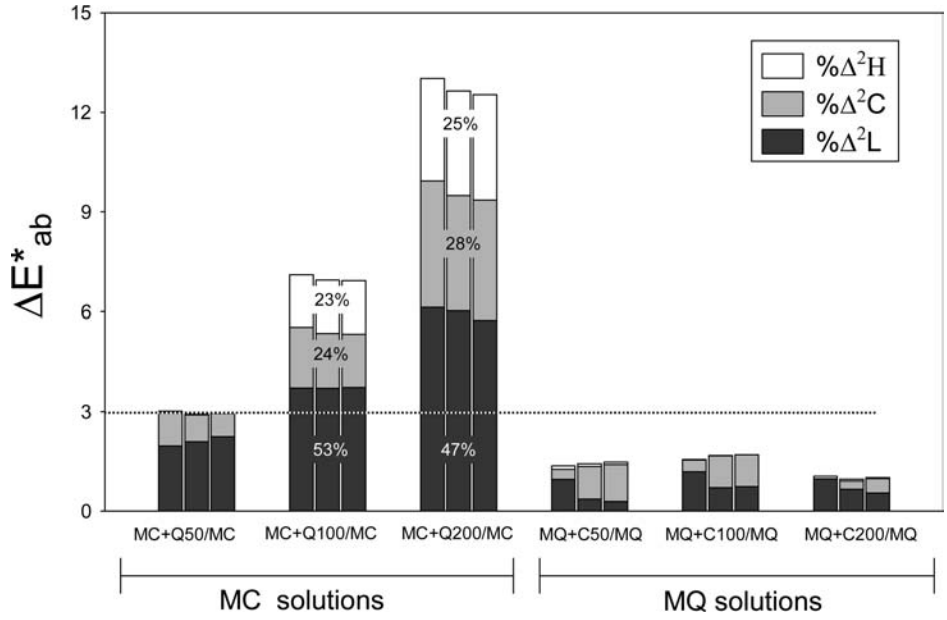

Figure 1. Color differences (ΔE^*_{ab}), with the relative contribution of lightness, chroma, and hue ($\%\Delta^2L$, $\%\Delta^2C$, $\%\Delta^2H$), between binary and ternary copigmented solutions after the addition of increasing concentrations of quercetin-3-β-*O*-glucoside to MC solution and (+)-catechin to MQ solutions, calculated at 2 h (25 °C).

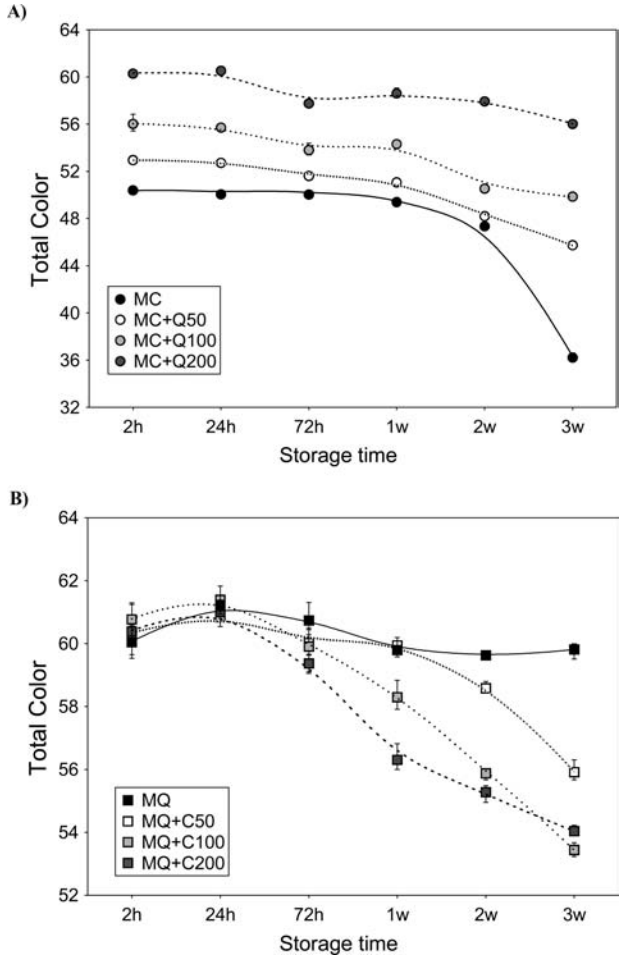

Figure 2. Influence of increasing concentrations of quercetin-3-β-*O*-glucoside and (+)-catechin on the evolution of the total color of MC and MQ binary and ternary solutions, respectively, over the storage period at 25 °C: (A) MC solutions; (B) MQ solutions.

(+)-Catechin showed a lower protective effect on the quantitative attributes of color, especially for chroma variations (Figure 4A,B). During storage, the chroma values notably decreased about 13% with concentrations of (+)-catechin up to 100 mg/L. Thus, surprisingly, the binary solution MQ showed greater color stability over time than in the presence of increasing concentrations of (+)-catechin. These results highlight that adding copigments does not always lead to a stabilizing effect, but depends on the type of copigments as well as on its concentration.

Furthermore, the assessment of the color differences (ΔE^*_{ab}) occurring at 24 and 72 h and at 1, 2, and 3 weeks, in relation to samples taken at 2 h, provides an objective evaluation of the chromatic stability for each solution over time (Figure 5). The lower values of ΔE^*_{ab} during storage in MC+Q ternary solutions than in MC binary solutions indicate lower color variation and, thus, higher color stability (Figure 5A). Considering the whole period of storage, the lowest color differences corresponded to MC+Q200 and MC+Q100 solutions compared to MC+Q50 and MC (ΔE^*_{ab} = 9.8, 10.5, 12.1, and 16.4, respectively). In contrast, growing ΔE^*_{ab} values in MQ+C ternary solutions relative to those in MQ binary solution indicate higher color variation and, thus, lower color stability (Figure 5B). Nevertheless, this negative effect seemed to greatly depend on the (+)-catechin concentration in the mixtures. It can be observed that the color modification experienced by MQ+C50 solution was not easily detectable ($\Delta E^*_{ab} < 3$)[24] until the end of the storage period. This means that (+)-catechin does not cause important color destabilization in multiple conditions at low concentrations (50 mg/L in our conditions). However, at (+)-catechin concentrations up to 100 mg/L, ΔE^*_{ab} values were detectable from the first weeks of storage.

As a consequence of the different color stabilities over time, MC+Q and MQ+C ternary solutions could be differentiated at the end of storage period in terms of luminosity, intensity, and chromaticity from their respective MC and MQ binary solutions (Table 1). Specifically, MC+Q solutions showed

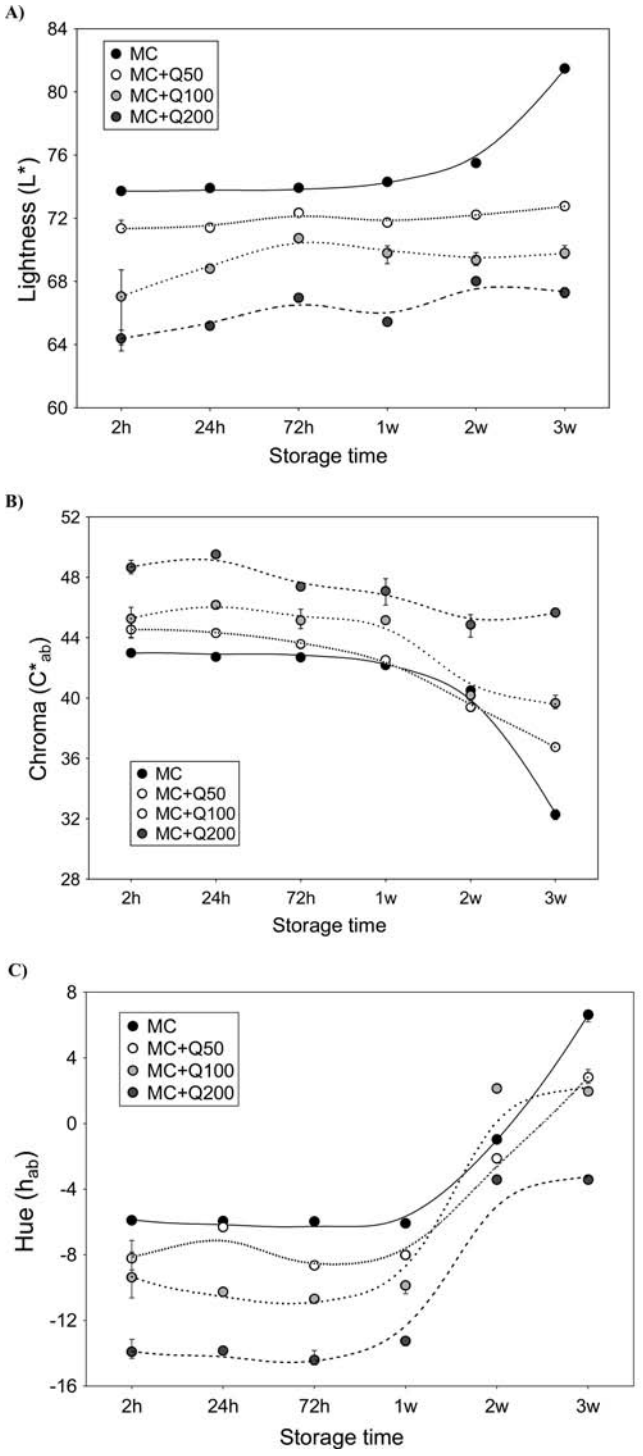

Figure 3. Influence of increasing concentrations of quercetin-3-β-*O*-glucoside on the evolution of the CIELAB colorimetric parameters of MC binary and ternary solution over the storage period at 25 °C in darkness: (A) lightness, L^*; (B) chroma, C^*_{ab}; (C) hue, h_{ab}.

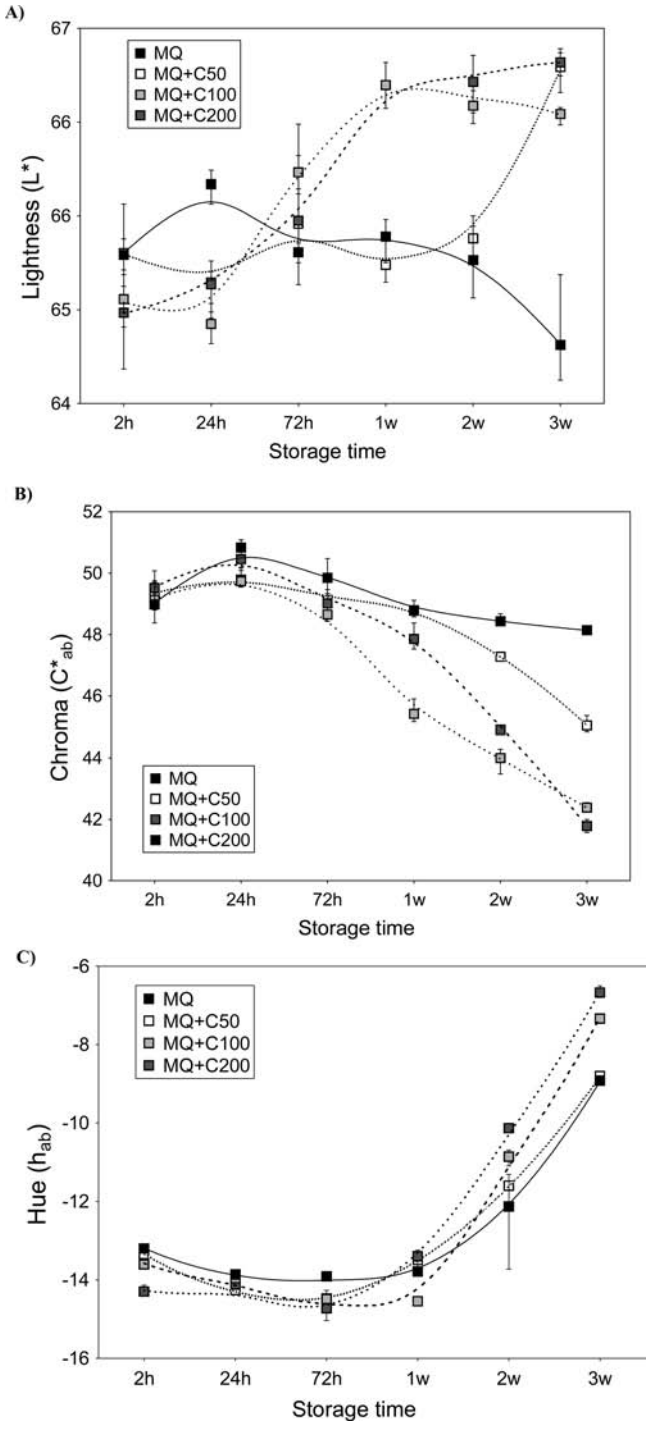

Figure 4. Influence of increasing concentrations of (+)-catechin on the evolution of the CIELAB colorimetric parameters of MQ binary and ternary solution over the storage period at 25 °C in darkness: (A) lightness, L^*; (B) chroma, C^*_{ab}; (C) hue, h_{ab}.

significantly lower values of L^* and hue but higher values of total color and C^*_{ab} than MC solution. In terms of detectable color variations[24] (Table 2), the highest color difference value was obtained between MC and MC+Q200 solutions (ΔE^*_{ab} = 20.6). The negative values of lightness and hue differences found among them (ΔL^* = −14.2, Δh_{ab} = −10.0°), but positive chroma difference (ΔC^*_{ab} = +13.3), means that MC +Q200 solutions had darker and more intense color with more bluish hue than MC solutions.

On the other hand, MQ+C solutions showed significantly higher values of L^* but lower total color and C^*_{ab} than MQ solutions (Table 1). In this case, the trend of the lightness and chroma differences among pairs of solutions was the opposite. Positive values for ΔL^* and negative values for ΔC^*_{ab} indicate that the final color of MQ+C solutions was lighter and less saturated than that of MQ solution. Again, the color differences were most appreciable with the highest concentration of (+)-catechin (MC+Q100 and MC+Q200 solutions).

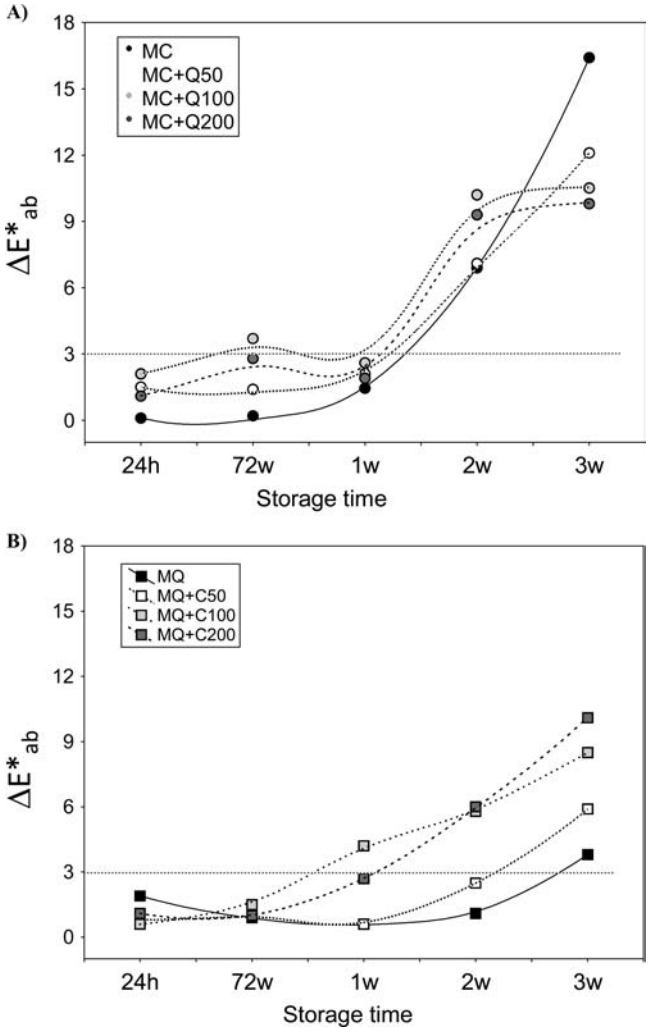

Figure 5. Influence of increasing concentrations of quercetin-3-β-*O*-glucoside and (+)-catechin on the color variation (ΔE^*_{ab}) of MC and MQ binary and ternary solutions, respectively, over the storage period at 25 °C: (A) MC solutions; (B) MQ solutions.

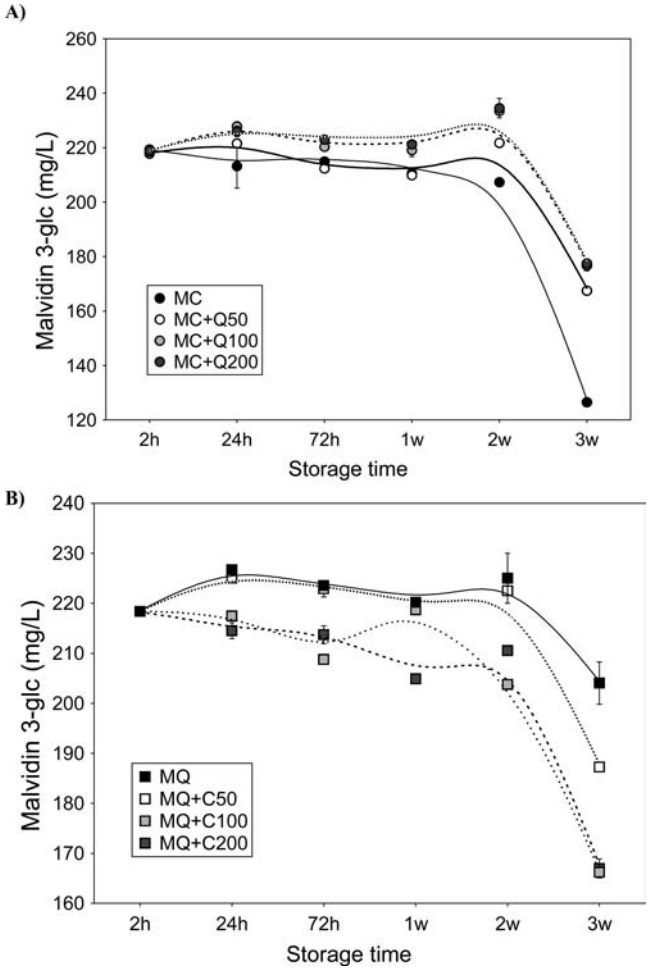

Figure 6. Influence of increasing concentrations of quercetin-3-β-*O*-glucoside and (+)-catechin on the evolution of the malvidin-3-glucoside content of MC and MQ binary and ternary solutions, respectively, over the storage period at 25 °C: (A) MC solutions; (B) MQ solutions.

Thus, with the whole set of data taken into account, it was confirmed that the addition of increasing amounts of quercetin-3-β-D-glucoside to MC binary mixtures led to MC+Q ternary solutions with more stable color that kept their intensity and vivid bluish tonalities for a longer time, which represent color characteristics highly appreciated in young red wines. In contrast, the addition of increasing amounts of (+)-catechin to MQ binary mixtures led to MQ+C ternary solutions with less stable color that maintain their vivid red intensity for only a short time, so their value as potential additives in the wine industry could be rather questionable because the minimization of color fluctuation is essential to maintain the global quality of wines.

Effect of Multiple Copigmentation Interactions on Chemical Stability. Figure 6 shows the changes in the concentration of malvidin-3-glucoside (mg/L ± SD) in solutions over time. Although the presence of the copigments does not impede the loss of the anthocyanin content, the protective effects of quercetin-3-β-D-glucoside and (+)-catechin in multiple conditions were quite different. As observed in Figure 6A, the content of malvidin-3-glucoside in MC and MC+Q solutions is maintained more or less constant during the first 2 weeks of storage. After this, the amount of malvidin-3-glucoside declines dramatically, the rate of degradation being less intense in the presence of quercetin-3-β-D-glucoside. The global content of malvidin-3-glucoside decreased over the whole storage period by 42% in MC binary solutions. In comparison, the anthocyanin degradation was notably reduced to 24, 19.5, and 19% with the addition of 50, 100, and 200 mg/L of quercetin-3-β-D-glucoside, respectively. These observations confirm that quercetin-3-β-D-glucoside behaved as a protective copigment in multiple conditions by preventing excessive pigment loss. In general terms, the higher the concentration of quercetin-3-β-D-glucoside in MC solution, the greater protective effects against anthocyanin degradation, which was in accordance with the amplitude of the effects observed in color stability. Nevertheless, the positive effect of quercetin-3-β-D-glucoside cannot be raised to an unlimited extent because no further improvement in the anthocyanin stability was produced when its concentration exceeded a certain level (in our conditions, up to 100 mg/L). This observation was in agreement with previous studies.[2,32] The analysis of variance (ANOVA, Tukey test) revealed significant differences ($p < 0.05$) for the final levels of malvidin-3-glucoside between MC and MC+Q solutions. MC solution showed the lowest content in malvidin-3-glucoside (126.5 ± 0.2 mg/L). As expected, no statistically significant differences were found for the anthocyanin content between MC+Q100 and MC+Q200 solutions (176.7 ± 2.8 and

J. Agric. Food Chem. 2015, 63, 7645−7653

177.5 ± 0.3 mg/L, respectively) because the losses of malvidin-3-glucoside were very similar in both ternary solutions. Thus, the application of quercetin-3-β-D-glucoside as wine copigments appears to be promising because it tends to significantly improve the stability of the anthocyanins in multiple conditions over time.

On the other hand, the anthocyanin stability of MQ and MQ+C solutions during storage is presented in Figure 6B. It can be observed that the malvidin-3-glucoside degradation occurred more rapidly in the presence of (+)-catechin (MQ+C solutions), which is in accordance with the color evolution. In particular, more remarkable losses occurred from the earliest moment of storage at concentrations of (+)-catechin up to 100 mg/L (approximately by 24%). After 3 weeks of storage, significantly ($p < 0.05$) higher contents of malvidin-3-glucoside were found in MQ and MQ+C50 solutions (204.8 ± 5.9 and 187.3 ± 0.3 mg/L, respectively), whereas this value fell to 166.1 ± 1.2 and 166.9 ± 2.7 mg/L in MQ+C100 and MQ+C200 solutions. This fact seems to indicate that, at high concentrations, (+)-catechin can interfere with the existing malvidin-3-glucoside/quercetin-3-β-D-glucoside equilibrium, diminishing their chemical stability. This antagonistic effect, clearly potentiated with time in our conditions, was also observed by Rustioni et al.,[17] who demonstrated that certain combinations of copigments (especially those from seeds, as could be (+)-catechin) can negatively affect the global copigmentation equilibrium by breaking tannin−anthocyanin interactions.

In summary, this work has shown that quercetin-3-β-D-glucoside and (+)-catechin exhibit quite different abilities to interact with malvidin-3-glucoside in ternary mixtures depending on their specific binding strength and concentration, which have important consequences on the color and chemical stability during storage. Differential colorimetry has demonstrated the fundamental role of quercetin-3-β-D-glucoside as a potential wine additive due to its immediate copigmentation effect in multiple systems and higher potential for stabilization over time. Our findings also showed the greater difficulty of (+)-catechin binding to malvidin-3-glucoside in the presence of quercetin-3-β-D-glucoside and its lower potential to lead to chemical and colorimetric stabilization. It should be borne in mind, therefore, that certain flavonoid combinations do not always result in positive effects on color by multiple copigmentation but also could cause negative effects. In this sense, further studies need to be done to better understand the mechanisms involved in the anthocyanin−flavanol−flavonol multiple interactions under different conditions (pH, temperature, sulfites, etc.) as well as to strategically select appropriate flavonoid combinations that promote synergistic interactions and avoid antagonisms.

mechanical properties of grape skins and proanthocyanidin extractability were found by Rolle and co-workers,[10] who determined that denser grapes provided higher phenolic extraction and who also stated that thinner skins assisted proanthocyanidin extraction. Recently, Bindon and co-workers[11] found that ripening affects cell wall porosity and its ability to adsorb proanthocyanidins, thus limiting their extraction to maceration media. Ripening also has an influence on the molecular weight of the extracted compounds, which was higher in riper grapes.

Some studies have related ripeness degree to grape skin flavonol composition,[3,4,12,13] but little is known about the influence of ripening on the extraction behavior of these compounds.[5]

The aim of this study was to evaluate the influence of cell wall composition on the extraction of flavan-3-ols and flavonols from red grape skins during ripening. To achieve this goal, red grapes of *Vitis vinifera* L. cv. Tempranillo were harvested at three different ripeness stages (preharvest, harvest, and over-ripened) and three soluble solid contents (22, 24, and 26 °Brix) within each ripeness degree.

MATERIALS AND METHODS

Grape Samples. *V. vinifera* L. cv. Tempranillo red grape samples were collected from a vineyard located in Lleida (Spain), which is under the influence of the Mediterranean climate. The samples were collected at three different ripeness degrees: preharvest (22 days before harvest date), harvest, and over-ripened (20 days after harvest date). In the studied samples notations P, H, and O were used to indicate preharvest, harvest, and over-ripened, respectively. Thirty clusters were collected at each stage, and their grapes were sorted according to their density. The density of grapes was estimated by flotation of berries in different NaCl solutions (130−150, 150−170, and 170−190 g L^{-1}) corresponding to different solid content (22, 24, and 26 °Brix, respectively). As a result, nine samples were obtained, with three different solid content (22, 24, or 26 °Brix) within each sampling date (P, H, or O). Grape skins were manually separated from the whole grapes, and three subsamples were taken from each sample, one for the exhaustive methanolic extraction, another for the hydroalcoholic extraction, and the third for cell wall isolation and characterization.

Cell Wall Analysis. Cell wall material was isolated from grape skins as the 70% ethanol insoluble residue as previously described.[14] Noncellulosic polysaccharides, pectins' esterification degree, lignin, cellulose, protein, and total phenolic compounds in cell wall material were determined as described in our previous work.[15]

Briefly, noncellulosic polysaccharides (i.e., arabinogalactans, mannans, homogalacturonans, xyloglucans, arabinans, rhamnogalacturonans-I, and rhamnogalacturonans-II) were obtained using an iterative calculation methodology[16] from monosaccharide profiles. Monosaccharides were determined by gas chromatography−mass spectrometry (GC-MS) of their trimethylsilyl ester *O*-methyl glycolsyl derivates (TMS) obtained after acidic methanolysis and derivatization following a modification of the Guadalupe et al. procedure[17]

Pectin esterification degree was determined as described by Femenia et al.[18] using the spectrophotometric measurement as proposed by Blumenkrantz and Asboe-Hansen,[19] but using *o*-hydroxydiphenyl solution[20] and recording the absorbance at 520 nm after 5 min of reaction.

Cellulose was determined as glucose in accordance with Lurie et al.[21] using the phenol method proposed by DuBois et al. for its spectrophotometric determination.[22] Lignin was gravimetrically determined as Klason lignin,[18] following the Saeman procedure.[23]

Flavanol and Flavonol Extractions. *Exhaustive Methanolic Extraction.* Extraction was performed as previously described.[15,24] Briefly, 10 g of grape skins was macerated at 4 °C in methanol containing 0.1% of 12 M HCl until colorless. Methanolic phases were successively pooled, a few milliliters of water was added, and the extract was concentrated under vacuum at 30 °C until methanol was removed and finally made up to 100 mL with ultrapure water.

Hydroalcoholic Extraction. Extraction was performed as previously described.[15,24] Briefly, 10 g of grape skins was macerated in 100 mL of model wine solution (4 g L^{-1} tartaric acid, 12.5% ethanol, adjusted at pH 3.6 with 0.5 M NaOH). The vials were kept at 25 °C and in darkness throughout the experiment. At regular intervals (1, 3, 5, 7, and 9 days) 1500 μL of extraction medium was taken and subjected to chromatographic analyses.

Sample Preparation for Chromatographic Analyses. Samples were prepared as previously described.[25]

For flavonol analysis, the extract was diluted 1:1 with 0.1 M HCl, filtered through 0.45 μm pore size filters, and directly injected into the chromatographic system to determine flavonols as described in the following section.

For the flavan-3-ol analysis, samples were fractionated prior to chromatographic analysis following the procedure described by Gonzalez-Manzano et al.:[26] 1 mL of each extract diluted (1:1) with 0.1 M HCl was eluted through Oasis MCX (Waters Corp., Milford, MA, USA) cartridges previously conditioned with 2 mL of methanol and 2 mL of water. After a washing with 4 mL of ultrapure water, flavan-3-ols and phenolic acids were eluted with 8 mL of methanol, whereas anthocyanins and flavonols were retained in the cartridges. A small volume of water was added to the eluate and concentrated under vacuum at <30 °C until complete elimination of methanol. The aqueous residue was adjusted to a volume of 0.5 mL with ultrapure water, filtered (0.45 μm), and analyzed by HPLC-DAD-MS as described in the following section.

HPLC-DAD-MS Analyses. An Agilent 1200 series HPLC system (Agilent Technologies, Palo Alto, CA, USA) consisting of an autosampler, a quaternary pump, a vacuum degasser, a thermostated column compartment, and a diode array detector (DAD) and controlled by ChemStation software (version B.04.01; Agilent Technologies) was used for chromatographic analyses. The HPLC system was coupled to a hybrid triple-quadrupole/linear ion trap (QqLIT) mass spectrometer API 3200 QTrap (Applied Biosystems, Foster City, CA, USA) equipped with a Turbo V ionization source and controlled by Analyst software (version 1.5; Applied Biosystems) via the DAD cell outlet.

Flavonol analysis was performed as described elsewhere.[27] Briefly, an Aqua C18 column (4.6 mm × 150 mm, 5 μm particle size) thermostated at 35 °C was used. Solvents were (A) 0.1% trifluoroacetic acid and (B) 100% HPLC grade acetonitrile. The elution profile was as follows: isocratic 10% B for 3 min, from 10 to 15% B for 12 min, isocratic 15% B for 5 min, from 15 to 18% B for 5 min, from 18 to 30% B for 20 min, and from 30 to 35% B for 5 min. The flow rate was 0.5 mL min^{-1} and the injection volume, 100 μL. UV−vis spectra were recorded from 250 to 770 nm with a bandwidth of 2 nm. Flavonols were detected at 360 nm as the preferred wavelength. MS analysis was carried out in positive mode (ESI^+) as described elsewhere:[28] declustering potential (DP), 41 V; entrance potential (EP), 7.5 V; ion spray voltage (IS), 5000 V; ion source gas 1 (GS1), 40 psi; ion source gas 2 (GS2), 50 psi (600 °C); curtain gas (CUR), 20 psi; and collision gas (CAD), set as "high". Both quadrupoles were set at unit resolution. Mass method consisted of three mass experiments: full mass analysis (EMS mode, collision energy (CE) 10 V), MS^2 analysis (EPI mode, CE 25 V), and MS^3 analysis (CE 30 V, excitation energy (AF2) 50 V). Spectra were recorded between m/z 150 and 1100.

Flavan-3-ol chromatographic separation was performed on a reversed-phase column Spherisorb ODS-2 (150 × 4.6 mm, 3 μm) from Waters maintained at 25 °C. Mobile phases A and B were, respectively, 0.25% acetic acid in water and acetonitrile The following linear gradient was used to achieve the chromatographic separation: from 0 to 10% B in 5 min, from 10 to 14.5% B in 35 min, from 14.5 to 19% B in 5 min, from 19 to 55% B in 5 min, hold at 55% B for 5 min, from 55 to 80% B in 5 min, hold at 80% B for 3 min, from 80 to 0% B in 2 min, and hold at 0% B for 5 min. The flow rate and the injection volume were set at 0.5 mL min^{-1} and 100 μL, respectively. UV−vis

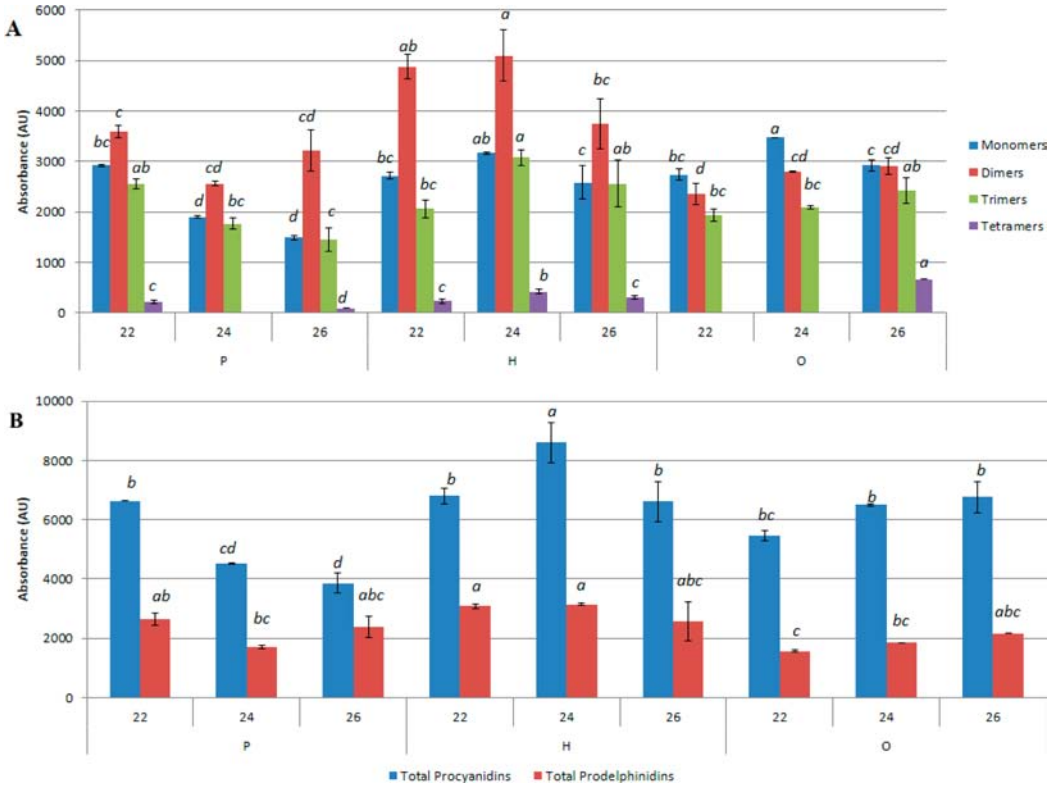

Figure 1. Total proanthocyanidin contents in exhaustive methanolic extracts grouped according to the number of subunits present in the molecule (A) and the structural characteristics (B). Within each group of compounds, different letters indicate statistical differences ($p < 0.05$) between samples by the Tukey HSD test.

spectra were recorded from 200 to 600 nm during acquisition at a selected wavelength of 280 nm.

The mass spectrometer was operated in the negative electrospray ionization (ESI) mode under the following specific conditions: IS, −4500 V; source temperature (TEM), 400 °C; CUR, 20 arbitrary units; GS1, 40 arbitrary units; GS2, 30 arbitrary units; DP, −40 V; EP, −7 V; and CE, −20 eV. Nitrogen (>99.98%) was employed as curtain, ion source, and collision gas. The detection was accomplished in the enhanced MS (EMS) full-scan mode, from m/z 100 to 1700, and in the enhanced product ion (EPI) mode to obtain the corresponding full-scan MS/MS spectra.

Extractabilities. Flavan-3-ol and flavonol extractabilities were calculated as percentages using the ratio between the DAD-HPLC peak areas obtained from hydroalcoholic and exhaustive methanolic extractions, as previously reported for anthocyanin extractability.[24]

Statistical Treatment. Principal components analysis (PCA), an unsupervised pattern recognition method, was used for data analysis. The IBM SPSS 21 for Windows software package (SPSS, Inc., Chicago, IL, USA) was used for data processing.

RESULTS AND DISCUSSION

Cell Wall Composition. Cell wall composition of grape skins harvested at different ripeness stages and with different soluble solid content within each stage has been detailed in our previous work.[15] Results obtained are in agreement with those reported in Ortega-Regules et al.[29] Cell wall composition is summarized in Table 1.

Flavan-3-ol and Flavonol Composition. Extracts obtained after exhaustive extraction of 10 g of grape skins were

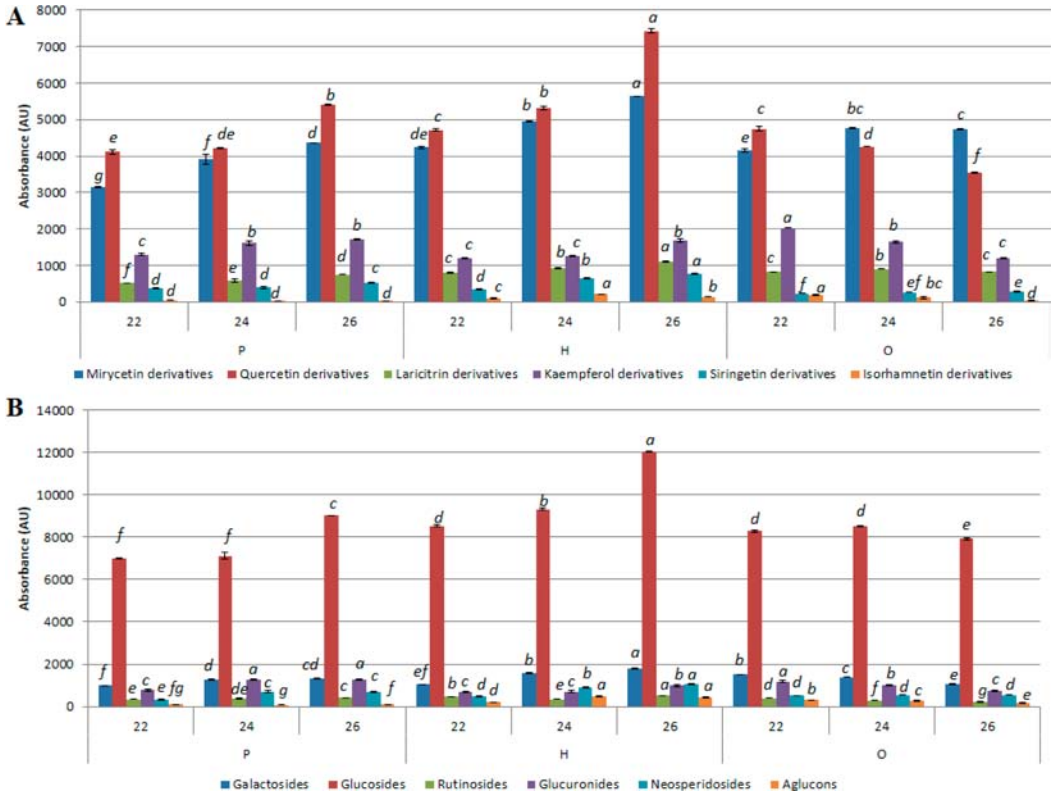

Figure 2. Flavonol total contents in exhaustive methanolic extracts grouped according to flavonol moiety (A) or the sugar moiety (B) present in the molecule. Within each group of compounds, different letters indicate statistical differences ($p < 0.05$) between samples by the Tukey HSD test.

analyzed to ascertain their flavanolic and flavonolic composition.

With regard to polymerization degree, as can be seen in Figure 1A, dimers were the most abundant compounds in preharvest and harvest samples, whereas monomers were, in general, the most abundant ones in over-ripened (O) samples. Trimers represented 20.9−28.4% of the proanthocyanidins quantified in the studied samples, being in all samples the third group in abundance, reaching levels similar to monomers in P 26, H 24, and H 26 samples. Tetramers were the least abundant oligomers in all of the studied samples, showing levels under quantification limits in three of the analyzed samples.

Flavan-3-ol compounds were classified according to their structure in two groups, procyanidins, which only catechin or epicatechin subunits present in their structure, or prodelphinidins, which present one or more gallocatechin or epigallocatechin subunits in their structure. Procyanidin and prodelphinidin contents in grape skins followed the same pattern (Figure 1B), increasing their level from preharvest to harvest and showing a slight decrease in over-ripened (O) samples, although these differences were not significant (Tukey HSD test, $\alpha = 0.05$) for several of the different samples. Despite higher prodelphinidin contents in harvest (H) samples, their percentages were bigger in preharvest (P) samples, varying from 27.5 to 38.3%, than in harvest samples, where they represented 26.8−31.2% of the quantified compounds. O samples presented the lowest percentages of this kind of compound. The abundance of prodelphinidins in red wines has been previously related to good maturity level of the grapes[30] and to the ability to produce high-quality wines.[31]

Up to 17 flavonol compounds were identified and quantified in the studied samples. They included quercetin, myricetin, kaempferol, laricitrin, syringetin, and isorhamnetin derivatives, esterified with different sugar moieties or in their nonglycosylated form. Figure 2A shows flavonol contents grouped as a function of the flavonol moiety present in the molecule for the nine analyzed samples. Flavonol content tended to increase as soluble solid content grew in preharvest and harvest samples, whereas over-ripened samples showed the opposite trend. The highest levels were reached in harvest samples, whereas preharvest and over-ripened samples showed quite lower levels. With regard to the kind of derivative, quercetin and myricetin derivatives were the most abundant compounds in all of the studied samples, as previously reported for Tempranillo grapes.[3,32] Quercetin derivatives were the most abundant found in seven of the nine analyzed samples, which is in agreement with the flavonol profile of the Tempranillo variety.[33] Myricetin derivatives were predominant in the two remaining samples, namely, O 24 and O 26. Kaempferol, laricitrin, syringetin, and isorhamnetin derivatives were also detected and quantified.

With regard to the sugar moiety linked to the flavonol moiety (Figure 2B), the most abundant derivatives were glucosylated compounds, displaying levels from 66.1 to 74.7%. Galactosides and glucuronides were also quite abundant, and small percentages of rutinosides, neosperidosides, and aglucons were also found.

Flavan-3-ol Extractabilities. In previous studies dealing with the average degree of polymerization of wine proanthocyanidins, we have determined in Tempranillo wines values varying from 2.9 to 4.3. That made us focus this extractability study on monomers and oligomers up to four.[26,34]

Up to 22 different flavanols were detected in our samples. Extractability statistical analyses were performed using the

compounds grouped as a function of their polymerization degree or their structural characteristics, i.e., procyanidins (polymers of catechin and/or epicatechin) and prodelphinidins (polymers of gallocatechin and/or epigallocatechin).

The maximum values obtained in our study for total proanthocyanidin extractability (Figure 3A) were reached the last day of the study in all samples. Llaudy et al. had observed that the amount of proanthocyanidin extracted to the maceration media from grape skins reached its maximum level after 4−5 days of maceration and then remained stable.[35] In our study, the extraction is extended (10 days), and it could be inferred that it would probably have increased if the maceration had been lengthened. This fact is especially noticeable in over-ripened samples, showing a steeper slope than preharvest and harvest samples, which presented very similar patterns (Figures 3A−C). As can be seen in Figure 3B,C, clear differences between procyanidin and prodelphinidin extractabilities can be observed. Prodelphinidin extractability increases with ripening, whereas this is not so evident for procyanidins. In fact, extractability of procyanidins in O samples is similar to that in H samples and even lower than that in P samples during the first days of the study.

DOI: 10.1021/acs.jafc.5b00261
J. Agric. Food Chem. 2015, 63, 7654−7662

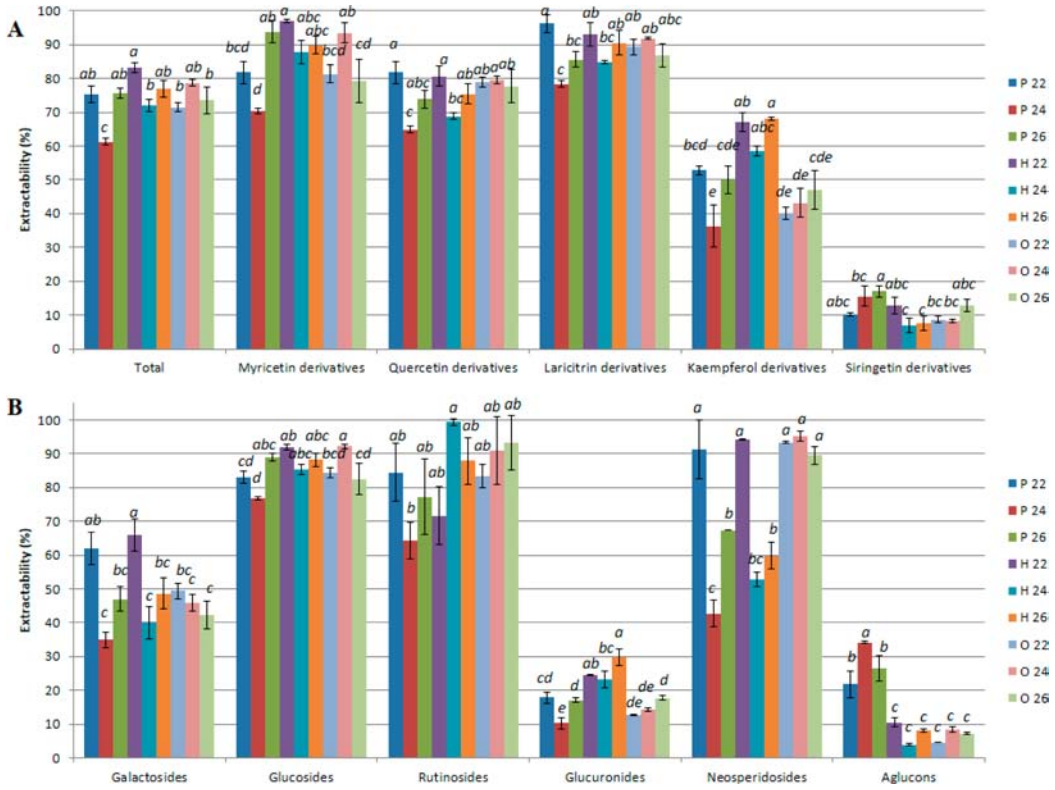

Figure 5. Percentages of extractability of flavonols, on the fifth day of study for the different samples, grouped according to the flavonol moiety (A) and the sugar moiety (B) present in the molecule. Within each group of compounds, different letters indicate statistical differences ($p < 0.05$) between samples by the Tukey HSD test.

Nevertheless, as extraction time increases, the extraction yield of procyanidins in O samples tends to be higher than in H and P samples, indicating that, during ripening, the cell walls become more porous and flavanols would be retained in these pores, reducing the extraction.[11] However, it should be assumed that once the pores are blocked, extractability could be favored due to structural degradation that may occur in over-ripened grapes. This would explain the behavior that we have observed, although further experiments need to be performed to confirm this hypothesis. Furthermore, it seems that the adsorbed flavanol compounds into the pores would consist mainly of procyanidins rather than prodelphinidins. In fact, the extraction of prodelphinidins seems to be faster the first days of the study, although afterward it tends to slow. This could be related to changes in the selectivity pattern of the pore of the cell walls that have been observed as the concentration of flavanols in the medium increases.[11] To our knowledge, no previous studies had evaluated the differences between procyanidin and prodelphinidin extractabilities.

No clear pattern is observed for soluble solid content (data not shown). The absence of a relationship between sugar content and proanthocyanidin extraction in hydroalcoholic media is in good agreement with previously reported studies.[8]

In relation to polymerization degree, as can be seen in Figure 3D, in general monomers were easily extracted in all samples, whereas dimers, trimers, and tetramers had variable behaviors. It is worth noting that tetramers are extracted only in three of the nine samples; this could indicate that the extraction of flavanols becomes more difficult as the polymerization degree increases.

PCA was conducted as unsupervised pattern recognition to observe relationships between proanthocyanidin extractabilities at the last day of the study, when maximum extraction levels were reached, stage of ripening, °Brix, and cell wall composition. The first principal component (PC 1) describes 37.66% of the variability in the data, and the second principal component (PC 2) describes 26.74% of the variability.

As can be seen in Figure 4, stage of ripening showed a clear positive relationship with total proanthocyanidin extractability and also with procyanidin and prodelphinidin extractabilities, whereas soluble solid content did not present any influence on the compound extraction. With regard to cell wall composition, total insoluble material displayed the biggest opposition to proanthocyanidin extractabilities. Some of the components of the cell wall showed a relationship with the proanthocyanidin extractabilities. This indicates that progression of ripening might cause changes in skin cell wall composition that could facilitate the release of proanthocyanidins. Those oppositions are quite stronger for total proanthocyanidins and total procyanidins, whereas they were weaker for prodelphinidin extractability. This behavior reflects a higher tendency of procyanidins to interact with components of cell walls than that of prodelphinidins.

Among cell wall constituents, some polysaccharide families exert an influence on proanthocyanidin total extractability and procyanidin extractability, namely, arabinogalactans (AG), mannans, RG-I, homogalacturonans (HG), xyloglucans (XG), and total polysaccharides content. All of these cell wall components displayed a negative relationship with proanthocyanidin extractabilities; thus, the higher the content of these compounds in the cell wall, the lower the proanthocyanidin extraction. The opposition to prodelphinidin extractability of those cell wall components is weaker than for procyanidins.

J. Agric. Food Chem. 2015, 63, 7654−7662

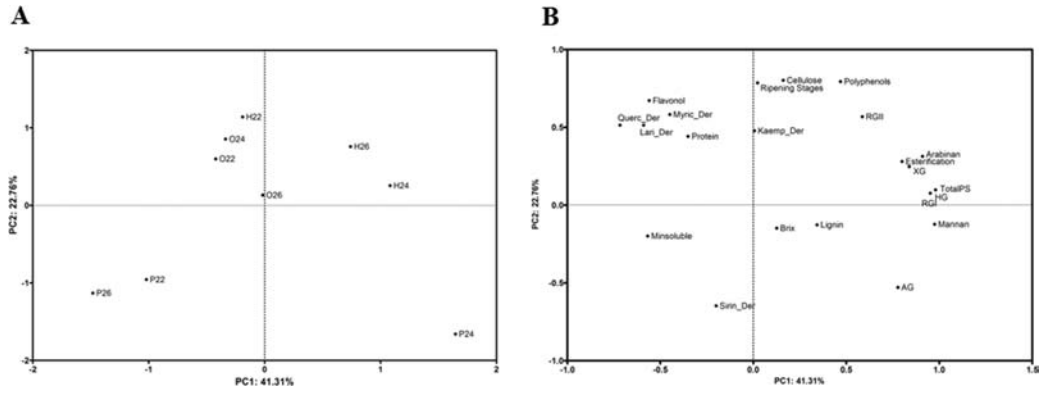

Figure 6. Projection of the samples on the plane defined by the first and second principal components (A) and the corresponding loading plot (B) for flavonol extractability. Minsoluble, insoluble material; Protein; Polyphenols; Lignin; Cellulose; AG, arabinogalactans; Mannans; HG, homogalacturonans; XG, xyloglucans; arabinans; RGI, rhamnogalacturonans-I; RGII, rhamnogalacturonans-II; total PS, total polysaccharide contents; Esterification, degree of esterification of pectins; Brix, soluble solid content; Ripening Stages; TotalFlavonol, maximum flavonol extractability; Querc-der, maximum extractability of quercetin derivatives; Myric-der, maximum extractability of myricitrin derivatives; Lari-der, maximum extractability of laricitrin derivatives; Kaempf-der, maximum extractability of kaempferol derivatives; Sirin-der, maximum extractability of siringitrin derivatives.

Orfila and Knox[36] reported that pit fields contain homogalacturonan. Therefore, a lower content in homogalacturonan is in accordance with the lesser presence of pores and, hence, with an increase in the proanthocyanidin extractability and mainly in procyanidin extractability. This would be in agreement with the negative correlation we have observed. Cellulose showed a strong positive relationship with prodelphinidin extraction and also with procyanidin and total proanthocyanidin extractabilities. Recently, it has been stated that cellulose presents a low affinity for proanthocyanidin binding,[37] whereas the galacturonan rich-fraction of cell wall material, obtained from grape skins, has a high propensity to associate with proanthocyanidins. The above-mentioned results for proanthocyanidin extraction confirm those observations; the higher amount of AG, RG-I, HG, and XG is related to a lesser proanthocyanidin extractability, whereas the higher the cellulose presence, the higher the proanthocyanidin extractability, probably due to the different ability of these polysaccharides to bind proanthocyanidins. With regard to the influence of cell wall composition on the extractability of compounds grouped on the basis of the number of subunits that make up the molecule, the extractability of dimers and trimers of proanthocyanidins displayed an opposition to total insoluble material and it was positively related to the presence of cellulose. The extractability of monomers and tetramers presented high opposition to total polysaccharide content and also to XG, HG, RG-I, and mannans. The above-mentioned results revealed that proanthocyanidin extractability is mainly influenced by harvest date and total insoluble material and to a lesser extent by some cell wall components. The pattern exhibited for proanthocyanidin extractability is quite similar to that previously reported for anthocyaninin extractability.[15]

Flavonol Extractabilities. Flavonol extractabilities reached their maximum at the fifth day of extraction (Figure 5), except for sample P 26, which reached the maximum at the third day of hydroalcoholic extraction, and samples P 24 and O 22, showing their maximum levels at the seventh day of extraction. H 24 extraction shows two maxima, the first one at the fifth day of extraction and the second one at the ninth day, although the percentages of extractability across the two maxima were very similar.

The pattern shown for flavonol extractability points out that flavonol are extracted from grape skins more slowly than anthocyanin compounds.[24] Quercetin, myricetin, and laringetin derivatives were more efficiently extracted than kaempferol or syringetin derivatives (Figure 5A), whereas isorhamnetin derivatives were not extracted in hydroalcoholic media. With regard to the sugar moiety in the molecule (Figure 5B), glucosides, rutinosides, and neosperidosides were more efficiently extracted than galactosides. Glucuronides and aglucons were the less extracted compounds to the hydroalcoholic maceration media.

PCA was conducted to establish relationships between flavonol extractabilities and cell wall composition. PC 1 described 41.31% of the variability observed in the data, and PC 2 described 22.76%. The projection of the samples in the plane defined by PC 1 and PC2 and the obtained loading plot are shown in Figure 6. This analysis revealed that ripening stage or soluble solid content was not related to total flavonol extractability. It showed also the lack of influence of the insoluble material contents on flavonol extractability. Some cell wall components presented a relationship with flavonol extractability; the presence of AG and mannans would decrease total flavonol extractability, whereas protein presence is positively related to total and major flavonol compounds (i.e., quercetin and myricetin derivatives) and to laricitrin derivative extractabilities. A possible explanation for the different behaviors shown for flavonol and other polyphenolic compounds extractabilities (anthocyanins and proanthocyanidins) is the different locations of the diverse polyphenolic compounds in the tissues; flavonol glucosides are located in epidermal cell layers in broad bean leaves,[38] and it is likely that they could be also located in epidermal layers in grape skins, bearing in mind that flavonols are related to UV protection, whereas anthocyanins and proanthocyanidins are located in hypodermal cell layers in grape skins.[39] Moreover, anthocyanins are accumulated inside cell vacuoles,[40] and proanthocyanidins have been found inside vacuoles, linked to proteins in the internal face of tonoplasts and also linked to cell wall polysaccharides.[39] It is possible that the extended release of proanthocyanidins from grape skins to the extraction media observed in this study is related to their different locations; thus, some of them are present as free forms, which would be

DOI: 10.1021/acs.jafc.5b00261
J. Agric. Food Chem. 2015, 63, 7654−7662

easily released during the first days of maceration, whereas there is also a linked fraction that would need a long maceration period to be loosened. Flavonol cellular location is not clear; some authors have determined the flavonol concentrations inside vacuoles, but other histochemical studies have suggested that they could be in cytoplasm as free forms in flower petals,[41] whereas other authors have pointed out the possibility of association between nucleus structures and flavonol compounds,[38,42] primarily due to the ability of these compounds to avoid cell damage caused by sunlight exposure.

Epidermal cells are covered by an external cuticule layer,[43] composed mainly of waxes, which could act as a barrier for flavonol extraction during winemaking. It is possible that the lack of a relationship between flavonol extraction and insoluble material might be due to the existence of this barrier on the outer surface of the epidermal cell layers, where flavonols are mainly located, whereas this barrier existence would not be related to proanthocyanidin or anthocyanin extraction because those compounds are located in hypodermal cells.

In conclusion, proanthocyanidin and flavonol extractabilities were influenced to some extent by cell wall composition, whereas ripening stage affected only proanthocyanidin extractability. Harvest samples presented the highest contents of both flavonols and flavan-3-ols. The extractions from grape skins were slower than those reported for anthocyanins, reaching their maxima in general on the fifth day for flavonol extraction and on the ninth day for proanthocyanidin extraction. To our knowledge, this is the first time that flavonol extractability throughout ripening has been studied. Flavan-3-ol extractability is increased with ripeness stage, whereas soluble solid contents had a negligible influence. Those differences between flavan-3-ol and flavonol extractabilities could be due to their different tissue and cellular locations in grape skins.

This study points out the importance of the maceration time for phenolic compound extraction during winemaking. This can help in the choice of the optimum maceration time to extract the desired amounts of phenolic compounds, reducing this time to avoid the complete extraction of proanthocyanidins and thus wine astringency or extending this maceration in the case of low phenolic content grapes.

istics of the soil.[20−22] As a result, important differences in the levels of acids, anthocyanins, and phenolics could be found within the same vineyard that can lead to variations in the composition and quality of wines.[23,24]

The numerous physiological and chemical changes that grape berries undergo during grape ripening induce modifications not only in their chemical composition but also in their texture features.[25] These textural modifications have been studied through the evaluation of the grape mechanical properties, which, in turn, have been correlated to grape quality.[26,27] A strong relationship between texture parameters and phenolic ripeness degree and grape variety has been reported.[28−30] In addition, these textural parameters have been demonstrated to be a useful tool to study phenolic extractability from grape skins.[31] However, studies in the literature about the relationship between grapevine-related characteristics, berry mechanical properties, and phenolic composition of grapes are scarce.

Due to the importance of phenolic compounds for wine organoleptic properties, phenolic composition has to be taken into account for the selection of harvest date. However, the harvest date is traditionally and chiefly selected on the basis of the technological maturity of grapes, which is related to the sugar concentration of grapes and therefore determines the alcohol content of wine. Nevertheless, the environmental and climatic conditions may cause technological maturity to be reached before phenolic maturity, and it seems that global climate change is going to increase this delay,[32] making it even more difficult to choose the appropriate harvest date to obtain high-quality wines. For this reason, knowledge about the detailed phenolic composition of grapes can be helpful in establishing strategies for harvest planning.

The purpose of this study was to evaluate the usefulness of parameters related to grapevine vigor and grape texture as indicative tools of the grape skin phenolic composition. Specifically, the main objective of this work was to study the relationship between the phenolic composition of *Vitis vinifera* L. cv. Tempranillo grape skins and the vigor-related grapevine characteristics. In addition, the relationship between texture properties of the berries and their phenolic composition has also been assessed.

MATERIALS AND METHODS

Samples. Thirteen different locations of a vineyard (100 ha) located in Zamora, Spain (coordinates 41°18′26″ N 5°21′45″ W), were selected on the basis of different orographic terrain features, such as orientation, altitude, and slope. For each location, all of the grapes (*V. vinifera* L. cv. Tempranillo) from two different grapevines were collected. All grape samples were collected on the same day at harvest time. Grape samples consisted of 300 berries randomly selected from all collected grapes.

Analysis of Phenolic Composition. Skins were manually separated from berries and extracted following Ferrer-Gallego and co-workers.[33] The detailed phenolic composition of grape skins (mg/g of skin) was analyzed by means of HPLC-DAD-MS. Grape skin extracts were directly analyzed for determining anthocyanin composition, whereas they were fractionated as explained below before analysis of flavanols. In both cases, HPLC analyses were performed in a Hewlett-Packard 1200 series HPLC (Agilent Technologies, Waldbronn, Germany). Mass spectrometry was carried out using an API 3200 Qtrap equipped with an ESI source and a triple-quadrupole linear ion trap mass analyzer that was controlled by Analyst 5.1 software (Applied Biosystems, Darmstadt, Germany). All of the analyses were performed in triplicate.

Anthocyanin composition was determined by using the methodology described by Alcalde-Eon and co-workers.[3] Twenty-three different anthocyanins were identified and quantified and grouped into 11 variables depending on the type of anthocyanidin and the type of anthocyanin derivative (see Table 1). Quantification was performed by HPLC-DAD using external calibration curves of standards of 3-*O*-

glucosides of delphinidin, cyanidin, petunidin, peonidin, and malvidin, purchased from Extrasynthèse (Lyon, France). Each determined anthocyanin was quantified using the calibration curve of the corresponding anthocyanin monoglucoside.

To analyze flavanols and phenolic acids, grape skin extracts were fractionated prior to HPLC-DAD-MS analysis with the objective of eliminating the anthocyanins. Fractionation was carried out according to the procedure described by González-Manzano and co-workers for wine samples.[34] Chromatographic analysis was performed following the methodology reported by Ferrer-Gallego and co-workers.[10] Detection was carried out at 280 nm (proanthocyanidins) and 330 nm (phenolic acids) as the preferred wavelengths. Quantification was performed by HPLC-DAD using external calibration curves of purchased standards except for standards of dimeric and trimeric procyanidins, which were isolated in our laboratory as described by González-Manzano and co-workers.[34] Nineteen different flavanols were determined and grouped into 12 variables depending on the type of flavanol and the polymerization degree (see Table 1). The calibration curves of catechin, dimeric procyanidin, and trimeric procyanidin were employed for quantifying catechin and epicatechin, dimeric procyanidins, and trimers and tetramers of procyanidins, respectively. Galloylated procyanidins were quantified using the epicatechin 3-*O*-gallate calibration curve, whereas gallocatechins and prodelphinidins were quantified using the gallocatechin calibration curve. Two hydroxybenzoic acids and 11 hydroxycinnamic acids and their tartaric esters or glucosidic derivatives were determined and grouped into seven variables (see Table 1). Hydroxybenzoic acids and hydroxycinnamic acids were quantified using the gallic acid and *p*-coumaric acid calibration curves, respectively.

Biophysical and Technological Variables. Eight different biophysical variables were studied (see Table 1), which were also determined at harvest time for each grapevine selected. Data are the average of the values determined for two grapevines of the same location. Leaf area (m^2) was the total leaf area of grapevine. To calculate this value, the number of long, medium-length, and short vine shoots of each grapevine was determined. Considering that long vine shoots have on average 20 knots with each having 4 big-size leaves, whereas medium-long ones have 12 knots with 3 medium-size leaves each and short vine shoots have 8 knots with 2 small-size leaves each, the total number of leaves of each size could be calculated. The average area of each kind of leaf was determined from the area of 10 leaves of each size, which was used to calculate the total leaf area. The grape production (kg) was the total weight of bunches of each grapevine. The average weight of bunches was calculated as the average of the weight of all bunches collected from the same grapevine. The average weight of berries was calculated from the weight of 50 different berries collected from the same grapevine. Moreover, the percentage (w/w) that skin and seeds represented in berry weight was also measured after manual separation of skin and seeds from berries. Grapevines were also pruned after leaf fall, allowing us to calculate the weight of fresh wood. The pruned wood was then dried for 72 h at 60 °C, and the weight of dried wood was determined.

°Brix and pH were directly measured in the grape must by using an optical refractometer and a pH-meter, respectively. Titratable acidity was calculated after acid−base titration of must employing 0.1 M NaOH and expressed as tartaric acid equivalents (g/L).[35]

Instrumental Mechanical Properties. The mechanical properties of the berries were assessed following the method of Letaief and co-workers.[36] A whole-berry texture profile analysis (TPA) double-compression test was carried out at a test speed of 1 mm/s until 25% of sample deformation (2 s waiting time between compressions), with the hardness (N), gumminess (N), and chewiness (mJ) parameters calculated from the force−distance curve.[36] Berry skin break force (F_{sk}, N) was evaluated with a puncture test on the intact berry performed at a test speed of 1 mm/s until 3 mm of sample deformation,[36] whereas the berry skin thickness (Sp_{sk}, μm) was assessed with a 0.2 mm/s compression of a piece of skin using a 2 mm flat cylindrical probe.[36] These parameters were determined by analyzing 30 randomly selected berries collected from the two grapevines of each location.

Statistical Analysis. Principal component analysis (PCA) was used for data analysis as an unsupervised pattern recognition method. The data matrix was constituted by the values determined for all 46 variables described in Table 1 for each selected location. Correlation analyses were carried out, and Pearson's coefficient and two-tailed *p* values were obtained. Backward stepwise multiple linear regression (MLR) was performed to assess the relationship between phenolic composition and the rest of variables. The coefficient of determination (R^2) and the significance (*p* value, bilateral) of the built models were

studied. The software package IBM SPSS Statistics v. 21.0 (IBM, Armonk, NY, USA) was used for data processing.

RESULTS AND DISCUSSION

Study of Correlations. PCA was conducted as unsupervised pattern recognition technique to observe relationships between biophysical, technological, and texture variables and those related to phenolic composition. Figure 1 shows the projection of the samples on the plane defined by the first and second principal components and also the corresponding loadings plot. The first principal component (PC1) describes 44.15% of the variability, and the second principal component (PC2) describes 16.93% of the variability. As can be seen in Figure 1a, the distribution of samples into the score plot did not show any important grouping, thus pointing out the important differences among the selected grapevines (see also Table 1 in the Supporting Information), which will allow us to study possible correlations between the variables employed. Figure 1b shows the variables on the loadings plot. It can be observed that there is a strong opposition along PC1 between flavanol composition of grape skins and some of the biophysical variables studied, such as leaf area (Leaf_area), the average weight of bunch (Bunch_weight), the weight of fresh (Fresh_wood) and dry wood (Dry_wood), and the percentage (w/w) of seeds in total grape weight (Perc_seed). The latter variable also showed a clear negative relationship with the total anthocyanin content (Anthoc). Hence, it seems that it might be a negative relationship between the biophysical features of grapevine determined in this work and the phenolic composition of grapes. In the same way, the acyl derivatives of anthocyanins [mainly the coumaroyl derivatives (Coumar)] showed high negative values in PC2, in contrast to texture variables and leaf area, which showed high positive values in this PC. Thus, there also may be a negative relationship not only between the composition on anthocyanin acyl derivatives of grapes and their texture properties but also between the levels of these compounds and the biophysical features of grapevine. Moreover, from the low loading values obtained for °Brix in PC1 and in PC2 (<0.45 and > −0.08, respectively), it seems that this variable barely contributes to explain sample variability. This could be related to similarities on the sugar content (°Brix) of analyzed grapes (see Table 1 in the Supporting Information), which would indicate that all samples were collected at a similar status of technological maturity. However, phenolic composition is crucial for sample differentiation, which may point out important differences in the phenolic maturity of collected samples. These results indicate that grapes collected from the same vineyard at a similar status of technological maturity can show important differences in phenolic ripeness. These differences, as will be explained below, can be related to differences in grapevine vigor.

To assess the significance of these relationships, the correlation between all variables employed in the study was investigated by means of Pearson's coefficient and its significance. Table 2 shows the most important significant correlations between the phenolic composition of grape skins and the rest of the variables considered in this study. The phenolic composition did not show any significant correlations with the percentage (w/w) of skins (data not shown). However, they corroborate the negative relationship between the percentage (w/w) of seeds in relation to the whole grape (Perc_seed) and the flavanic composition of grape skins indicated in the PCA plotting (Figure 1b). This is in accordance with studies in the literature which have reported that skin weight was not a determining factor for anthocyanin potential of the berries but that seed weight seemed to significantly affect the grape composition.[37] All variables related to flavanic composition showed high negative coefficients of Pearson with Perc_seed variable. Among them, the total content of flavanols (PAC), as well as the total content of procyanidins (PC) and prodelphinidins (PD), showed Pearson's coefficients < −0.76. Moreover, these correlations are highly significant ($p < 0.01$). Thus, it seems that the heavier the seed, the lower amounts of flavanols in the skins. It might be possible that synthesis of flavanols in seeds and in skin could be competitive and that the highest weight of the seed reflects higher synthesis rate of flavanols in this part of the berry, at the expense of the synthesis in the grape skin. This negative correlation is also observed between total hydroxybenzoic acids content in grape skin and the percentage (w/w) of seeds. Because one of the two hydroxybenzoic acids (the major one) found in the skin is gallic acid, and this acid is also found in grape seeds, this negative correlation might be also due to the same reasons as those proposed for flavanols.

Total leaf area of grapevine also correlates negatively with phenolic composition of grape skin. Anthocyanin compounds

DOI: 10.1021/acs.jafc.5b00275
J. Agric. Food Chem. 2015, 63, 7663−7669

presented the highest negative Pearson's coefficients. Malvidin derivatives (Mv) and the acyl-derived anthocyanin (Acyl) levels were the most strongly correlated to leaf area. The acyl-derived, and, in particular, the coumaroyl-anthocyanin derivatives (Coumar), also showed a strong negative relationship with the weight of wood pruned from the grapevine (Fresh_wood and Dry_wood). These two variables, together with leaf area, could be related to vine vigor. Our results are consistent with those recently reported by Song and co-workers[17] which have found that as vine vigor decreased, total soluble solids in grapes and total phenolics and anthocyanins in wines increased, thus pointing out a negative relationship between vine vigor and grape phenolic composition. Moreover, vine vigor could be related to the grapevine water availability that in turn seems to affect the composition of grapes because an excess in water conditions has demonstrated to be more negative for anthocyanin contents than strong deficit conditions.[37]

A significant negative relationship could also be observed (Table 2) between the average weight of bunches (Bunch_weight) and the monoglucoside (Monoglc) and total anthocyanin (Antoc_total) contents. Moreover, the level of anthocyanin caffeoyl derivatives is also strongly correlated ($r = -0.666$, $p < 0.05$) to the average weight of berries (Berry_weight). Therefore, it seems that the heavier the bunches and berries were, the lower were the levels of anthocyanins (both total and monoglucoside and caffeoyl derivatives) the skins and, consequently, the berries showed. These results are in accordance with those reported in the literature showing that the total anthocyanin content (mg/berry) and anthocyanin concentration (mg/kg of berries and in mg/g of skin) were dependent on berry mass variation.[38] Likewise, it seems that the berries in which seeds accounted for a higher weight percentage (Perc_seed) show lower levels of monoglucosides, because a significant negative correlation ($r = -0.600$, $p < 0.05$) between these two variables was observed. It has been reported that berry weight is more related to seed weight than to skin and flesh weight,[37,38] so this might explain why both Berry_weight and Perc_seed variables showed a relationship with anthocyanin composition, whereas no relationship was found with Perc_skin variable. These correlations between physical features of berries and their phenolic composition might be explained because grape development occurs in two main stages. The first stage, comprising the flowering and green berry stages, and maybe even prior to that, during differentiation of the primordia,[39] seems critical in determining berry weight.[38] However, anthocyanin and sugar accumulation takes place in a second stage, from veraison to harvest. Thus, if the first stages were the most important, bunches, berries, and seeds could be heavier but grapes may show lower levels of anthocyanins.

Finally, a strong negative correlation was also observed between the texture features of grape and its phenolic composition. In particular, the berry skin break force (F_{sk}) and the levels of anthocyanidin−coumaroylglucosides ($r = -0.635$, $p < 0.05$) and of total acyl-derived anthocyanin ($r = -0.589$, $p < 0.05$) are negatively correlated (Table 2). These results are in accordance with those reported by Giacosa and co-workers,[40] who have observed in Shiraz grapes significantly lower values of F_{sk} in berries showing higher levels of coumaroyl-anthocyanin derivatives in its composition. These results are also consistent with other studies available in the literature pointing out the potential of the mechanical properties of berry skin (such as F_{sk} and Sp_{sk}) to predict the anthocyanin extractability.[29,31] Moreover, it has also been reported that cell-wall composition affects the anthocyanin extraction; in particular, the presence of higher amounts of glucose, rhamnose, 2-*O*-methylxylose, and lignin in the cell-wall composition would prevent anthocyanin extraction from grape skin.[41] Considering this, there might be a relationship between the cell-wall composition and the levels of coumaroyl-anthocyanin derivatives that may be explained by a possible interaction between the acyl-derived anthocyanins and some components of the grape cell wall, which in turn may determine the texture features of grapes. Further studies about the cell-wall and phenolic composition and texture features of berry skin must be carried out to assess this possibility.

Moreover, a significant positive correlation has been observed between berry hardness and its flavanic composition. It is worth noting the strong correlation between this texture parameter and the level of gallocatechin and epigallocatechin ($r = 0.699$, $p < 0.01$, Table 2). Thus, it seems that berry hardness might be indicative of the levels of flavanols in berry skin. Río Segade and co-workers[30] have reported that break force and thickness of berry skin can be considered mechanical properties adequate for the estimation of the degradability of the skin cell wall. Degradation is related to changes in the structure of the cell wall by depolymerization and formation of new cross-linking bridges[42] and to changes in its composition by loss of galactose and other pectic sugars such as arabinose and rhamnose.[30,43,44] Considering that these texture parameters could be related to cell-wall composition, the correlation found between flavanic composition and berry hardness might be explained, as in the case of acyl-derived anthocyanin, by a specific interaction of flavanols with some cell-wall components. In fact, Ruiz-García and co-workers[45] have pointed out that pectic polysaccharides have an important binding affinity for flavanols, whereas cellulose, due to a low porosity, showed less affinity for these compounds. Thus, both higher levels of flavanols and higher values of hardness of berries might be related to higher levels of cellulose in the cell wall. However, further specific studies about the relationship between cell-wall composition and texture features of berries must be carried out to assess this possibility.

Regression Studies. Considering the aforementioned correlations, different multiple linear regressions (MLR) were carried out to assess the influence of biophysical, technological, and texture variables employed in this work on the phenolic composition of grape skin. A backward-stepwise strategy was employed for MLR, in which all of the considered variables were used at the start of the process and then the least significant one is removed at each step. The model is refitted after each step including only the most significant variables. First, due to the correlation found between the amount of coumaroyl-anthocyanin derivatives and the texture parameters that pointed out a possible relationship between these compounds and cell-wall composition, the variable Coumar was selected as dependent variable, whereas the biophysical, technological, and texture variables described in Table 1 were used as independent variables. Among all of the variables considered, only the dry weight of pruned wood (Dry_wood), the berry skin break force (F_{sk}), and the berry skin thickness (Sp_{sk}) were considered statistically significant ($p < 0.05$) in the fitted final model. The values of the coefficient of determination (R^2), the nonstandardized coefficients (B), and the standardized coefficients (β) were obtained. The coefficient of determination ($R^2 = 0.856$) indicates that the proposed model

DOI: 10.1021/acs.jafc.5b00275
J. Agric. Food Chem. 2015, 63, 7663−7669

explains 85.6% of the variability of the levels of coumaroyl-anthocyanin derivatives, which supposed a good fit to the data. Table 3 shows the values of the regression constant and of the

Table 3. Results of the MLR Carried Out Using the Level of Coumaroyl-Glucoside Anthocyanins (Up) and of Total Flavanols (Down) as Dependent Variables

Dependent Variable: Coumaroyl-Glucoside Anthocyanins (Coumar, mg/g of Skin), R^2 = 0.856			
variable	nonstandardized coefficients (B)	standardized coefficients (β)	p value
Constant	1.934		<0.001
Dry_wood (kg)	−0.333	−0.741	<0.001
F_{sk} (N)	−0.715	−0.300	0.008
Sp_{sk} (mm)	−0.002	−0.352	0.006
Dependent Variable: Total Flavanols (PAC, mg/g of Skin), R^2 = 0.829			
variable	nonstandardized coefficients (B)	standardized coefficients (β)	p value
Constant	2.664		0.020
Leaf_area (m^2)	−8.331	−0.406	0.019
Perc_seed	−0.335	−0.507	0.001
Hardness (N)	0.181	0.310	0.009

β parameter for each variable, which could be considered the best estimation about its contribution to the model. As can be observed in the study of correlations, these three variables (Dry_wood, F_{sk} and Sp_{sk}) showed a negative relationship with the levels of coumaroyl-anthocyanin derivatives. The most important variable in the study was Dry_wood (β = −0.741), thus indicating the importance of grapevine vigor in the levels of these anthocyanin-derived compounds in grapes.

Considering the important role of flavanols in some organoleptic properties of wines such as astringency or color, MLR was also performed using the levels of total flavanols (PAC) as dependent variable and the biophysical, technological, and texture variables described in Table 1 as independent variables. Table 3 shows the result of fitting. The proposed model explained 82.9% of the variability of total flavanol levels (R^2 = 0.829), which indicates the goodness of data fitting. As can be observed in Table 3, the percentage (w/w) of seeds and leaf area showed a negative relationship, whereas berry hardness showed a positive relationship with flavanol content. The most important variable in this model is the percentage (w/w) of seeds, thus pointing out the importance of seed size on the flavanic composition of grape skins.

The proposed models indicated that there is a strong relationship between the biophysical parameters of grapevine (mostly vine vigor represented by leaf area, dry weight of pruned wood, and seed weight), the texture features (evaluated as instrumental mechanical properties) of berries, and the phenolic composition of grape skins. Although this study has been carried out in only one vintage, we have chosen a vineyard large enough to have important differences in orographic terrain features. This could be observed in the PCA and also in the high variability of variables that have been used in this work (see Table 1 in the Supporting Information). Thus, the results here presented set an important precedent because they establish the importance of agronomic parameters and texture properties for estimating the phenolic composition of grape skins. However, further studies involving different vineyards, grape cultivars, and vintages must be done to corroborate the quantitative relationship between these variables.

In conclusion, the results obtained pointed out an important relationship between the phenolic composition of grape skin, biophysical features of grapevines, and berry texture properties. Anthocyanin composition showed significant negative correlation with grapevine vigor-related parameters (such as leaf area and bunch weight), whereas the amount of flavanols of grape skins was negatively correlated with the percentage (w/w) of seeds. Moreover, the phenolic composition is also correlated to some mechanical properties of grapes. Berry skin break force showed a negative correlation with the coumaroyl-anthocyanin derivatives, whereas berry hardness was positively correlated to flavanic composition. Thus, a relationship between both acyl-derived anthocyanins and flavanols and grape cell-wall composition could be proposed. A significant regression was found between coumaroyl-anthocyanin derivatives and some biophysical (weight of pruned wood) and texture (berry skin break force and berry skin thickness) variables. Likewise, a significant regression was also found between flavanol levels and the percentage (w/w) of seeds, leaf area, and berry hardness. These results pointed out that grapevine vigor-related and texture parameters might be useful for estimating the phenolic composition of grape skins.

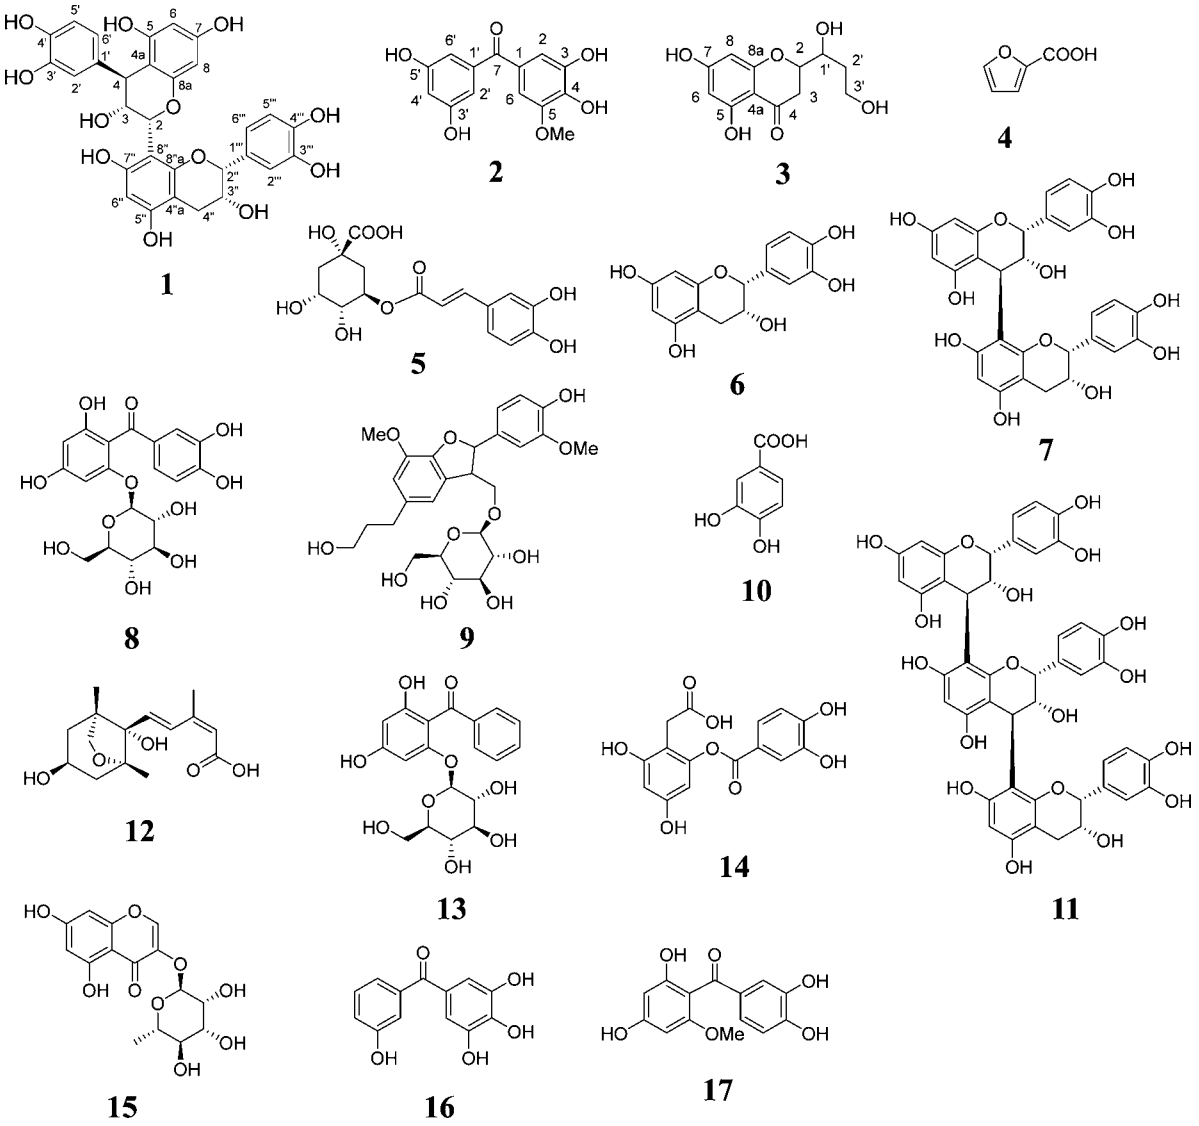

Figure 1. Structures of compounds (**1**–**17**) isolated from mangosteen (*Garcinia mangostana* L.) pericarp.

Healthcare Japan, Tokyo, Japan). Each authentic sample [procyanidin B2 (Extrasynthese, Lyon, France), procyanidin C1 (ChromaDex, Inc., Irvin, CA, USA), chlorogenic acid (Tokyo Chemical Industry, Tokyo, Japan), protocatechuic acid (Wako Pure Chemical Industries, Osaka, Japan)] was purchased from the manufacturer.

Isolation Procedure of Mangosteen Pericarp. The fruits of mangosteen were harvested in Chanthaburi province (eastern Thailand) and Nakhon Si Thammarat province (southern Thailand). The powdered dried mangosteen pericarps (600 kg) were extracted with hot water (90 °C, 5600 L) for 3 h, and the filtered concentrate was powdered with a spray-dryer after the addition of dextrin (to 25%) as diluent to yield hot water extract (92.1 kg). The hot water extract (100 g) was resuspended in water and subjected to liquid–liquid partition to yield *n*-hexane (65.5 mg), ethyl acetate (EtOAc) (2.6 g), *n*-butanol (*n*-BuOH) (12.5 g), and water extract. A part of the *n*-BuOH extract (9.0 g/12.5 g) was chromatographed over MCI-gel CHP20 (40 cm × 1.1 cm i.d.) eluted with water to methanol. The water eluate was further purified using YMC-gel ODS-AQ (40 cm × 1.1 cm i.d.) column chromatography to give six known compounds identified as 2-furancarboxylic acid, **4** (11.2 mg); chlorogenic acid, **5** (6.5 mg); epicatechin, **6** (12.4 mg); procyanidin B2, **7** (10.5 mg); rhodanthenone B, **8** (14.0 mg); and dihydrodehydrodiconiferyl alcohol 9-*O*-glucoside, **9** (2.0 mg) (Figure 1). The EtOAc extract (2.6 g) was chromatographed over a YMC-gel ODS-AQ (40 cm × 1.1 cm i.d.) column and eluted in a stepwise gradient mode with water–methanol. The water and 10% methanol eluate (960.5 mg) was separately chromatographed over Sephadex LH-20 (20 cm × 1.1 cm i.d.) yielding epicatechin, **6** (145.2 mg); procyanidin B2, **7** (28.7 mg); protocatechuic acid, **10** (11.9 mg); and procyanidin C1, **11** (7.4 mg). The 20% methanol eluate (297.4 mg) was further separated by column chromatography over Chromatorex ODS (20 cm × 1.1 cm i.d.) and Sephadex LH-20 (20 cm × 1.1 cm i.d.) to yield GM-3, **3** (1.0 mg); epicatechin, **6** (77.5 mg); dihydrophaseic acid, **12** (5.3 mg); garcimangosone D, **13** (2.7 mg); and 2-*O*-(3,4-dihydroxybenzoyl)-2,4,6-trihydroxyphenylacetic acid, **14** (2.4 mg). The 30% methanol eluate (215.4 mg) was further purified using Sephadex LH-20 (20 cm × 1.1 cm i.d.), Chromatorex ODS (20 cm × 1.1 cm i.d.), and MCI-gel CHP20 (20 cm × 1.1 cm i.d.) column chromatography to give GM-1, **1** (2.2 mg); GM-2, **2** (1.2 mg); garcimangosone D, **13** (2.2 mg); 2-*O*-(3,4-dihydroxybenzoyl)-2,4,6-trihydroxyphenylacetic acid, **14** (2.6 mg); eucryphin, **15** (2.6 mg); 3,4,5,3′-tetrahydroxybenzophenone, **16** (1.2 mg); and 4,6,3′,4′-tetrahydroxy-2-methoxybenzophenone, **17** (1.6 mg). Each structure of known compounds was inferred from the NMR and MS data or from a direct HPLC comparison with an authentic sample.

RESULTS AND DISCUSSION

A hot water extract of mangosteen (*G. mangostana* L.) pericarp was successively partitioned with *n*-hexane, EtOAc, and *n*-BuOH to give respective extracts. The *n*-BuOH extract was subjected to successive column chromatography over MCI-gel CHP20 and YMC-gel ODS-AQ, yielding six known compounds identified as 2-furancarboxylic acid, **4**; chlorogenic acid, **5**; epicatechin, **6**; procyanidin B2, **7**; rhodanthenone B, **8**;[12] and dihydrodehydrodiconiferyl alcohol 9-*O*-glucoside, **9**.[9] The EtOAc extract was similarly separated by successive column chromatography over YMC-gel ODS-AQ, Sephadex LH-20, and Chromatorex ODS, yielding three new compounds (GM-1, -2, and -3), **1**−**3** along with 10 known compounds, which were characterized by NMR data or direct HPLC comparison with authentic samples as epicatechin, **6**; procyanidin B2, **7**; protocatechuic acid, **10**; procyanidin C1, **11**; dihydrophaseic acid, **12**; garcimangosone D, **13**;[9] 2-*O*-(3,4-dihydroxybenzoyl)-2,4,6-trihydroxyphenylacetic acid, **14**;[13] eucryphin, **15**;[14] 3,4,5,3′-tetrahydroxybenzophenone, **16**;[15] and 4,6,3′,4′-tetrahydroxy-2-methoxybenzophenone, **17**[16] (Figure 1). Among the known compounds, **4**, **8**, **9**, **11**, **14**, and **15** were for the first time isolated from mangosteen. Besides the reported xanthones and other low-polarity compounds, we demonstrated that the pericarp of mangosteen contains various types of benzophenones and procyanidins.

GM-1, **1**, was obtained as a pale brown amorphous powder with an assigned molecular formula of $C_{30}H_{26}O_{12}$ inferred from the high-resolution (HR)-ESI-MS data. The ^{1}H−^{1}H correlation spectroscopy (COSY) spectrum showed two pairs of ABX signals, two meta-coupled doublets, a singlet in the aromatic region, and three- and four-spin signals in the aliphatic region, thus suggesting **1** to be a dimeric flavonoid. The heteronuclear multiple-bond connectivity (HMBC) correlations (Figure 2) of H-2 to C-7″, -8″, and -8a″ and of H-4 to C-1′ and -4a indicated that **1** has a 4-aryl-2-flavanylbenzopyran skeleton. Furthermore,

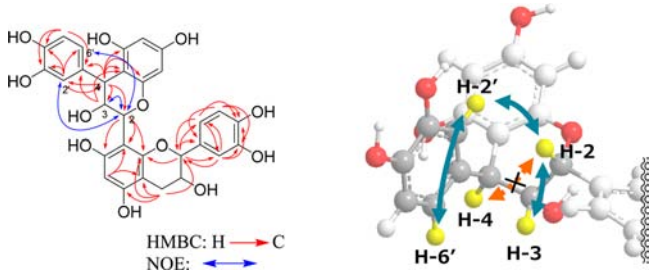

Figure 2. Heteronuclear multiple-bond connectivity (HMBC) correlations and the nuclear Overhauser effect (NOE) correlations of GM-1, **1**.

correlations of H-2 and H-2″ to C-8a″ proved that the intermolecular connection was in the 2→8″ position. The relative configuration of **1** was considered to have 2,3-*cis*-3,4-*trans* configurations on the basis of the nuclear Overhauser effect correlations of H-2 to H-2′, H-6′, and H-3, but no correlation between H-2 and H-4 (Figure 2). Additionally, small coupling constants (J = ca. 2 Hz) of H-2 and H-3 in the ^{1}H NMR spectrum indicated that the heterocyclic ring in **1** adopted the boat form similar to that of 4-aryl-2-flavanylbenzopyrans produced as the artifact from procyanidins under basic conditions.[17] With the co-occurrence of **1** with procyanidins B2 or C-1 taken into consideration, the 2-flavanyl moiety was tentatively assigned as (−)-epicatechin. On the basis of these spectroscopic data, the structure of GM-1 was established as **1** (Figure 1). Although artificial diastereoisomeric analogues of **1** were previously reported,[17] this is, to our knowledge, the first report of this type of compound to be isolated from a natural source.

GM-2, **2**, has the molecular formula $C_{14}H_{12}O_6$, as determined from the HR-ESI-MS data. The ^{1}H NMR spectrum showed three meta-coupled signals [a 2H-doublet (δ 6.53, J = 2.0 Hz), two 1H-doublets (δ 6.01 and 6.02, J = 2.5 Hz), and a 1H-triplet (δ 6.45, J = 2.0 Hz)] in the aromatic region. In the ^{13}C NMR spectrum, equivalent carbon signals assignable to C-2′,6′ (δ 107.2) and C-3′,5′ (δ 158.8) and a carbonyl carbon signal (δ 198.4) indicate that the structure of **2** is a benzophenone derivative. Additionally, the spectra indicated the presence of a methoxy group (δ_H 3.50, δ_C 55.7), which was located on a benzene ring (C-5) with nonequivalent protons. HMBC correlations (Figure 3) also supported the proposed structure. From the above spectroscopic data, the structure of **2** was elucidated as 3,4,3′,5′-tetrahydroxy-5-methoxybenzophenone.

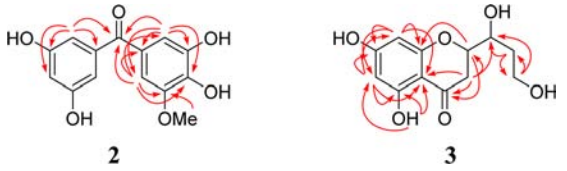

Figure 3. HMBC correlations of GM-2, **2**, and GM-3, **3** (HMBC: H → C).

GM-3, **3**, a pale brown amorphous powder, showed an $[M - H]^-$ ion peak at m/z 253.0711 in the HR-ESI-MS and was assigned the molecular formula $C_{12}H_{14}O_6$ (calculated for 253.0718, $C_{12}H_{14}O_6$ − H). The ^{1}H NMR spectrum of **3** showed a 1H-singlet at δ 12.2 (chelated −OH) and two meta-coupled 1H-doublets (δ 5.90 and 5.94, J = 2.0 Hz) in the aromatic region. In the aliphatic region, two pairs of methylene

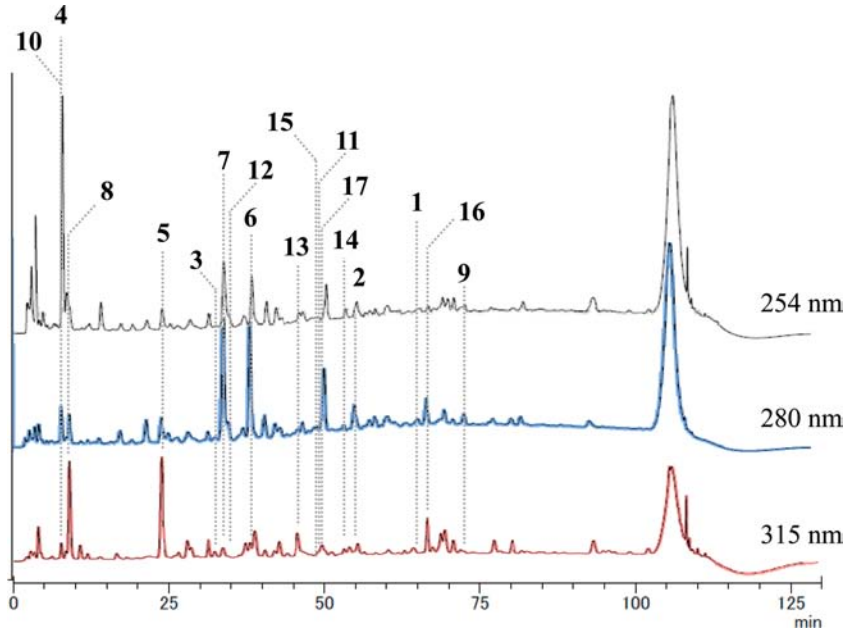

Figure 4. High-performance liquid chromatography (HPLC) profiles of hot water extract of mangosteen pericarp. The numbered peaks on the chromatogram correspond to the structure number in Figure 1: **1**, GM-1; **2**, GM-2; **3**, GM-3; **4**, 2-furancarboxylic acid; **5**, chlorogenic acid; **6**, epicatechin; **7**, procyanidin B2; **8**, rhodanthenone B; **9**, dihydrodehydrodiconiferyl alcohol 9-*O*-glucoside; **10**, protocatechuic acid; **11**, procyanidin C1; **12**, dihydrophaseic acid; **13**, garcimangosone D; **14**, 2-*O*-(3,4-dihydroxybenzoyl)-2,4,6-trihydroxyphenylacetic acid; **15**, eucryphin; **16**, 3,4,5,3′-tetrahydroxybenzophenone; **17**, 4,6,3′,4′-tetrahydroxy-2-methoxybenzophenone.

protons [δ 1.86 (2H, m, H-2′), 2.55 (1H, dd, J = 3.5, 17.5 Hz, H-3), and 3.00 (1H, dd, J = 13.0, 17.5 Hz, H-3)], an oxygen-bearing methylene [δ 3.79 (2H, m, H-3′)], and two oxygenated methines [δ 3.96 (1H, br dt, J = 4.0, 4.0. 9.0 Hz, H-1′), 4.42 (1H, dt, J = 3.5, 3.5, 13.0 Hz, H-2)] were confirmed from COSY and heteronuclear single-quantum coherence correlations. Furthermore, all of the aliphatic proton signals have relay correlations in ^{1}H−^{1}H COSY, and the location of the side chain was established from HMBC correlations of H-2 to C-8a and H-3 to C-4a (Figure 3). Additionally, ^{13}C NMR data also support this structure. From these results, the planar structure of GM-3 was identified as depicted in Figure 1.

Each peak on HPLC of the hot water extract of mangosteen pericarp was assigned by direct comparison with those of individual isolates as shown in Figure 4. Among polyphenolics detected at 280 nm, epicatechin, **6** and procyanidin B2, **7**, were major ingredients in the extract. On the other hand, benzophenones (**8**, **13**, and **16**) and chlorogenic acid (**5**) were readily distinguished from other phenolics by monitoring at 315 nm.

In the present study, along with 14 known compounds, we isolated 3 new compounds and elucidated their chemical structures. α-Mangostin and other xanthones that were known as representative bioactive components of mangosteen were not observed in the hot water extract of the pericarp because of their low polarity. These prenylated xanthones were effectively extracted with ethanol from the mangosteen pericarp. In traditional medicine, mangosteen pericarp is mainly decocted or macerated in water, thus preserving the bioactive properties of catechin and other polyphenols, which were revealed to be the major polar ingredients of the hot water extract. The componential analysis of water-soluble polar compounds would thus provide valuable information to discuss any function (e.g., antioxidant) of the pericarp arising from bioactive components other than xanthones and benzophenones.

when cellular integrity is disrupted. Indeed, plastidial polyphenol oxidases (PPOs) catalyze oxidation of vacuolar phenolic compounds in the presence of oxygen, generating colored *o*-quinones. These species are very unstable and are rapidly involved in nonenzymatic reactions,[18,19] thus forming secondary compounds, most of which are colorless, but some new pigments are produced. Differences in hue and intensity of browning appear to be related to apple phenolic content, speed of enzymatic reaction, and environmental factors such as pH, temperature, and the presence of reducing substances and metallic ions. Many studies have attempted to assess the correlation between browning intensity and phenolic content or PPO activity,[4,7] but there are some contradictory results in the literature.[14] The first difficulty was to find an adequate way of measuring the degree of browning. Amiot et al.[20,21] estimated the susceptibility of apples to browning by measuring the absorbance at 400 nm and the lightness (L^* parameter in the CIE Lab color system) of soluble and insoluble pigments, respectively. It can be noted that most studies were carried out in model solutions. Overall, research has highlighted the crucial role of the relative balance between hydroxycinnamic derivatives and flavanol monomers in oxidative browning.[21−24]

Multiple linear regression analysis has shown that both contribute to darkness (decrease in L^*) and yellowness (increase in b^*).[22] Chlorogenic acid is the best natural PPO substrate in apples.[25] Its oxidation leads to slightly yellow quinones, but secondary products are lighter, suggesting that they are not the most significant compounds involved in color development. Through coupled oxidation reduction reactions, chlorogenic acid quinones accelerate the degradation of flavanol monomers, of which the neo-formed products can be intensely colored[21−24,26] with absorbance maxima at 380 and 420 nm.[23] Some colored dimers are believed to be similar to dehydrodicatechin A.[27] In addition, procyanidins do not appear to be good PPO substrates; they have proved to result in PPO inhibition.[28] Nevertheless, Oleszek et al.[29] showed that enzymatic oxidation of procyanidins B2 and C1 could generate the same color intensity as catechins, but with a slower browning rate. Consequently, their contribution to the final coloration of juice should be considered. Moreover, dihydrochalcones play a role in this coloration despite their low concentration. First, as PPO substrates, they can directly lead to the formation of yellow compounds.[29,30] For example, Le Guernevé et al.[31] characterized, in a model solution, yellow phloridzin oxidation product (POPj), a pigment displaying a bright yellow color up to pH 5 and turning orange at higher pH.[32] This compound may contribute to the yellow color of apple juice. Second, phloretin glycosides may also have synergistic effects on color development when in the presence of chlorogenic acid or catechins[29,30] and could play a significant role in the complex color of real apple juice.

To our knowledge, no previous study has focused on identifying colored compounds present in real apple juices. Our aim was to investigate HPLC-DAD-MS profiles of yellow-orange pigments found in juices resulting from processing of four French cider apple varieties. The phenolic content in these varieties clearly differed, and juices covered a wide range of colors. We assessed varietal diversity of the chromophores and discussed the first structural elements regarding these natural pigments.

MATERIALS AND METHODS

Chemicals. Methanol and acetonitrile were of HPLC grade (Carlo Erba reagents, Val de Reuil, France). Acetic acid was of analytical grade (Carlo Erba reagents). Formic acid and sodium fluoride were purchased from NORMAPUR (VWR Prolabo, Fontenay sous Bois, France). Hydrochloric acid and sodium acetate were purchased from Emprove exp, Merck (Darmstadt, Germany). Ultrapure water was purified with a water purification system (PURELAB Classic model, Elga Véolia, Antony, France). Gelatin was obtained from Rousselot (Courbevoie, France). Phloroglucinol, (+)-catechin, (−)-epicatechin, 5-*O*-caffeoylquinic acid, *p*-coumaric acid, phloridzin, and avicularin (quercetin-3-*O*-arabinoside) phenolic standards were provided by Sigma-Aldrich (Lyon, France). Hyperoside (quercetin-3-*O*-galactoside), ideain chloride (cyanidin-3-*O*-galactoside chloride), procyanidin B1, and procyanidin B2 standards were obtained from Extrasynthèse (Genay, France).

Plant Material. French cider apples have various "taste types" that are described according to the acidity and total polyphenol content of the variety considered.[33] Here, four of the most grown French cider apple varieties were used to produce apple juices: 'Dous Moen' (bittersweet), 'Marie Ménard' (bitter), 'Petit Jaune' (sour), and 'Guillevic' (sharp). Fruits were picked in a local orchard (Iffendic, Brittany, France) in autumn 2012, except for 'Guillevic' fruits, which were picked in the Surzur orchard (Brittany, France). When technological ripeness was reached (50% of fruit had fallen to the ground), fruits were picked off the tree by hand to avoid bruising that causes flesh oxidation and deterioration. Fruits were kept at 10 °C until 100% starch regression (i.e., complete physiological ripeness) was confirmed using the visual iodine test.[34]

Oxidized and O_2-Deprived Juice Preparation. Juices were prepared according to two distinct procedures. In the first case, oxidation was promoted by the presence of air to generate colored juices, just like when cider-makers process their apples. In the second case, the presence of oxygen was avoided throughout all processing steps to prevent oxidation and thus limit juice browning. With regard to the oxidation processing mode, two 20 kg batches of ripe apples were pressed separately for each variety. After crushing, the grated apple flesh was vatted for 20 min in air and pressed at 2.5 bar with a hydraulic press (Hydropresse IT80, Fourage CTI, La Haye Fouassière, France) modified by Demoisy (Baune, France). Pectic substances were degraded enzymatically at 10 °C by adding 2.5 mL of pectinolytic enzyme preparation per hectoliter of crude juice (Endozym Pectofruit, Spindal, Gretz-Armainvilliers, France). The treated juice was stored overnight at 2 °C to let most of the crude juice particles settle. Must was then racked, microfiltered using 0.14 μm tangential filtration (Inside Céram membrane, 39 channels, hydraulic diameter of 2.5, Siva Diam, Nyons, France), and kept at −25 °C until use. For the O_2-deprived processing mode, ripe fruits were first placed under vacuum for 15 min to remove any air inside the fruits. The vacuum was then broken by incorporating pure CO_2. This operation was repeated once. All of the other processing steps were similar to the previous mode, but were achieved in an inert atmosphere with CO_2 or N_2 instead of O_2.

Solid Phase Polyphenol Extraction. Polyphenols were extracted from the juices using C18-solid phase extraction (5 g Sep-Pak Vac 20 cm^3 C18 cartridge, Waters, Milford, MA, USA). Silica sorbent was first preconditioned with 30 mL of methanol and 40 mL of acetic acid 1%, v/v. Potential residual polyphenol oxidase activity was inhibited in microfiltered juices by the addition of sodium fluoride (0.2 M). Juices were diluted twice with acidified water (acetic acid 1%) and then transferred to the solid phase. The sample volumes were adapted so as not to exceed the retention capacity of the solid phase. Forty milliliters of acetic acid 1%, v/v, was used to wash the cartridge and eliminate sugars. Polyphenols retained on the solid phase were then eluted with 40 mL of methanol/acetic acid 1%, 50/50, v/v. Purified phenolic extracts were concentrated under vacuum, frozen at −25 °C, and freeze-dried. Extracts were kept in a desiccator under argon atmosphere until analysis.

HPLC-DAD-MS Analysis of Yellow-Orange Colored Phenolic Compounds. Phenolic extracts were analyzed on a system composed of an SCM1000 degasser (Thermo Scientific, San Jose, CA, USA), an 1100 series binary high-pressure pump (Agilent Technologies, Palo Alto, CA, USA), and a Surveyor autosampler thermostated at 4 °C (Thermo Finnigan, San Jose, CA, USA). Two detectors were connected in series: a UV−visible diode array detector (model UV6000 LP, Thermo Finniga) and an ion trap mass spectrometer equipped with an electrospray ionization source (model LCQ Deca, Thermo Finnigan). The reversed-phase chromatography column used in this part of the work was a ZORBAX Eclipse XDB-C18 column (2.1 × 150 mm; 3.5 μm, Agilent Technologies) equipped with a ZORBAX Eclipse XDB-C8 precolumn (2.1 × 12.5 mm, 5 μm, Agilent Technologies). The analysis procedure was adapted from Guyot et al.[13] The oven was thermostated at 30 °C. Two microliters of sample was injected for analysis. The solvent system was a gradient of A (0.1% formic acid in ultrapure water) and B (0.1% formic acid in acetonitrile), which were filtered on 0.45 μm cellulose acetate and PTFE filters (VWR, Fontenay sous Bois, France), respectively, before use. An elution gradient was applied as follows with a flow rate of 0.2 mL/min: initial, 3% B; 0−5 min, 9% B, linear; 5−15 min, 16% B, linear; 15−45 min, 50% B, linear, followed by washing and reconditioning of the column. UV−visible detection covered the 240−600 nm wavelength range. Particular attention was paid to signals recorded at 420 nm as it corresponds to the response of yellow-orange compounds. The whole effluent was injected in an ESI source. Source parameters were negative ion mode, spray voltage (3.7 kV), capillary voltage (−70 V), sheath gas (67 arbitrary units), auxiliary gas (5 arbitrary units), and capillary temperature (240 °C). The nebulizing gas was nitrogen, and the damping gas was helium. MS spectra were acquired in full scan, negative ionization mode in the m/z 50−2000 range. The signals obtained correspond to the deprotonated molecule $[M - H]^-$. An MS/MS dependent-scan mode was also performed to obtain the daughter ion spectrum of the main molecular ions detected in full scan mode. For the MS/MS experiment, collision energy was selected arbitrarily as 35%. Data obtained were processed with 1.2 Xcalibur software (Finnigan Corp., San Jose, CA, USA).

Determination of CIE Lab Color Parameters. For apple juices, color was characterized using the Commission Internationale de l'Eclairage (CIE, International Commission on Illumination) color parameters. Absorbance spectra were measured at 5 nm intervals in the visible wavelength range, from 400 to 700 nm, with a spectrophotometer (SPECTROstar Nano, BMG Labtech, Ortenberg, Germany). The absorbance data were then converted into CIE L^*, a^*, and b^* parameters using mathematical processing, considering the illuminant D65 and 10° standard observer. They were also expressed and discussed in terms of lightness (L^*), chroma (C^*), and hue angle (h).

Gelatin Fining. Gelatin is a well-known fining agent, often used to remove part of the condensed tannins during beverage production.[33] Here, a gelatin solution and purified polyphenol extract from 'Dous Moen' oxidized juice were combined in 20 mM, pH 4.2, malate buffer. The final concentrations of gelatin and phenolic extract were 1 g/L. The incubation medium was placed at room temperature under mild stirring for the first 30 min and then without agitation for 15 min. After centrifugation for 30 min (4000 rpm, rotor model JA-10, Beckman Coulter, Villepinte, France), the supernatant was recovered and analyzed using HPLC-DAD-MS in the same conditions as described previously.

HPLC-DAD-MS Analysis of Native Polyphenols. Native polyphenols, including catechins, low molecular weight procyanidins, hydroxycinnamic acids, dihydrochalcones, and flavonols, were extracted using 1.2 mL of methanol acidified with 1% acetic acid, v/v. For each apple variety, extractions were performed in triplicate from 500 μL of freeze-dried juice. After homogenization, the extraction medium was placed in ice and ultrasonicated for 15 min. Samples were filtered on 0.45 μm PTFE filters (VWR) and analyzed using HPLC-DAD-MS. Dilutions with methanol/formic acid 0.5%, 50/50, v/v, were used if necessary to avoid saturation of the UV−visible detector. The HPLC system was the same as described above, but the chromatography column was a Hibar HR Purospher STAR RP-18 end-capped column (150 mm × 2.1 mm, 3 μm, Merck). The elution gradient used was initial, 3% B; 0−3 min, 7% B, linear; 3−21 min, 13% B, linear; 21−27 min, 13% B, linear, 27−41 min, 20% B, linear; 41−51 min, 45% B, linear, followed by washing and reconditioning of the column. Native compounds were identified by comparing the retention times, UV−visible spectra, and full MS spectra with those of available standards. Quantitation was performed by integrating peaks on UV−visible chromatograms at 280 nm for flavan-3-ols, procyanidins, and dihydrochalcones, at 320 nm for hydroxycinnamic acids, and at 350 nm for flavonols. (+)-Catechin, (−)-epicatechin, procyanidin B2, caffeoylquinic acid, phloridzin, and hyperoside were quantitated according to their own calibration curves. Quantitation of other compounds was carried out using a reference compound in the same phenolic class displaying a very similar UV−visible spectrum.

Determination of Total Procyanidin Concentration and Average Degree of Procyanidin Polymerization Using HPLC after Phloroglucinolysis. The phloroglucinolysis method was adapted from Kennedy and Jones.[35] The reactions were performed in triplicate on 500 μL of freeze-dried juice using 400 μL of methanol acidified with 0.3 N hydrochloric acid. After the addition of phloroglucinol (50 g/L) and ascorbic acid (10 g/L), the extraction medium was incubated at 50 °C for 30 min. The reaction was stopped by placing the vials in an ice bath and adding 1200 μL of sodium acetate (0.2 mM). Samples were filtered on 0.45 μm PTFE filters (VWR) and analyzed using HPLC-DAD-MS. Dilutions with methanol/formic acid 0.5%, 50/50, v/v, were used if necessary to avoid saturation of the UV−visible detector. The analysis system was the same as described for the native polyphenol analysis. The elution gradient used was initial, 3% B; 0−3 min, 7% B, linear; 3−21 min, 13% B, linear; 21−27 min, 13% B, linear; 27−30 min, 14.5% B, linear,

J. Agric. Food Chem. 2015, 63, 7675−7684

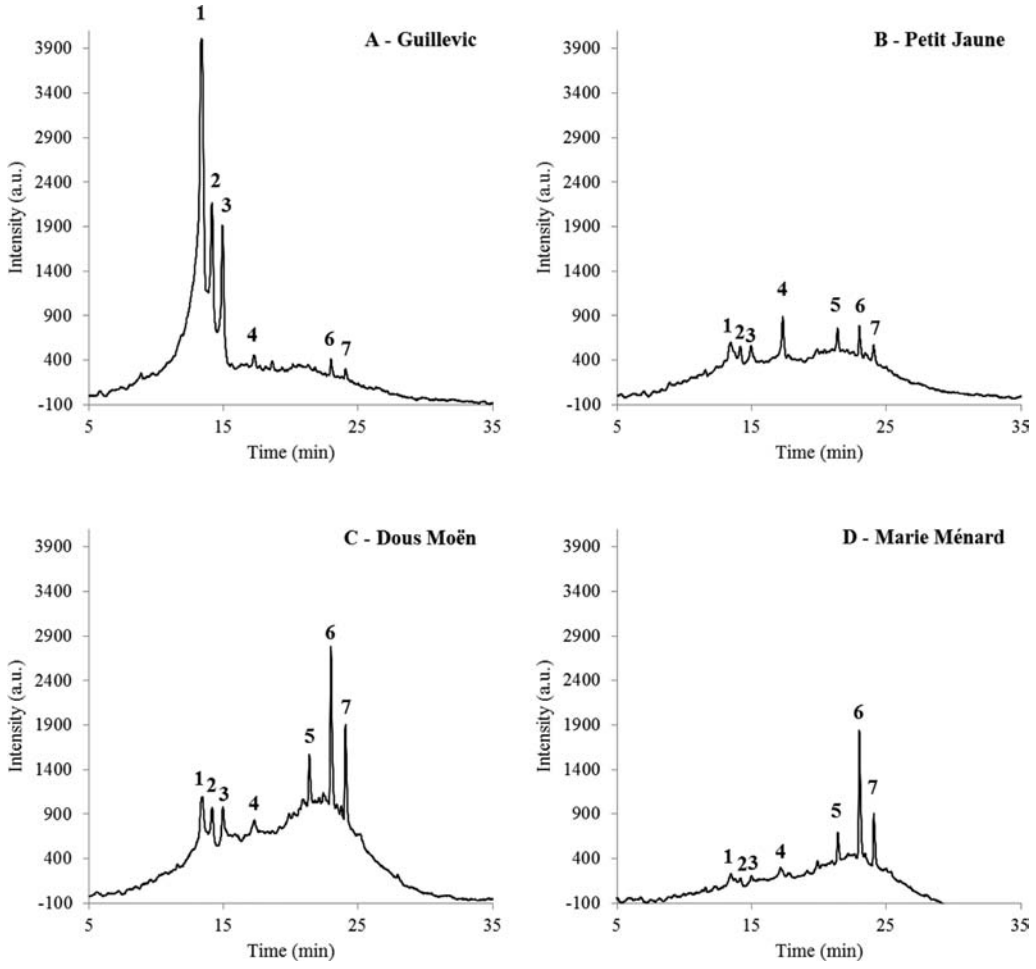

Figure 1. Reversed-phase UV−visible chromatograms at 420 nm of the four apple juice polyphenolic extracts. Fruit varieties used to produce oxidized juices are specified in bold. Numbers 1−7 designate colored compounds producing well-resolved peaks in HPLC.

followed by washing and reconditioning of the column. Peaks corresponding to apple procyanidin reaction products (i.e., (+)-catechin, (−)-epicatechin, and (−)-epicatechin phloroglucinol adduct) were integrated on the 280 nm chromatogram, and quantitation was performed using the corresponding calibration curves.

RESULTS AND DISCUSSION

Varietal Diversity of Cider Apple Juice Color. The four oxidized juices displayed contrasting colors, which is consistent with the range of coloration found in classical French cider products.[36] In contrast, the four juices deprived of oxidation were very bright, as shown by their very high lightness L^* values ranging between 99.3 and 100.1. These juices were almost colorless or very slightly colored, as revealed by their very low chroma C^* values (Table 1). Their "redness", expressed by positive a^* values, was close to 0. The "yellowness", expressed by positive b^* values, was noticeably different for 'Guillevic' juice, suggesting that the others were slightly yellower (b^* values of 2.0 for 'Guillevic' and ranging from 4.1 to 4.5 for 'Petit Jaune', 'Dous Moen', and 'Marie Ménard'). As expected, the considerable differences in the color parameters for the oxidized juices indicate the crucial role of enzymatic oxidation in the generation of apple juice coloration. In a previous study, Falguera et al.[37] described CIE Lab parameters of apple juices made from six different apple varieties. A comparison with our data highlights considerable disparity in the values obtained, particularly for L^* and a^*. This is probably related to the differences in apple processing and the use of dessert apple varieties that have different phenolic content and profiles from cider apple varieties. After oxidation, lightness values remained particularly high in our four juices, varying from 84.9 to 97.3, whereas L^* values of the six juices produced by Falguera et al.[37] ranged from 30.3 to 62.7. These low values could be explained by the fact that only centrifugation was performed before color measurement. Here, juices were microfiltered, leading to very bright, limpid products. In the present work, juices were produced in conditions very similar to the technological processing steps used in the French cider-making industry. Despite all of these variations, two conclusions were similar in both studies. First, the color of the juice differed substantially according to the apple variety. Second, all of the juices had higher yellowness than redness. Indeed, greater variations were observed for b^* values than for a^* values for all four oxidized apple juices. CIE L^*, a^*, b^*, C^*, and h values presented in Table 1 indicate that the four oxidized juices had an overall yellow hue, according to hue angle values, but highlight significant nuances. The shades are described more easily using the hue angle because this polar coordinate directly reflects the hue information on the juice, whereas a^* and b^* orthogonal parameters need to be described together to provide a complete picture of the color. Consequently, in the present study, the colors of the juices are described mainly according to the hue angle. The h value of

J. Agric. Food Chem. 2015, 63, 7675−7684

'Guillevic' juice was 101.4° (which corresponds to the a^* negative value of −4.9), higher than 90° (yellow hue), meaning that 'Guillevic' juice became greenish-yellow after oxidation. 'Dous Moen' (h value of 86.0°) and 'Marie Ménard' (h of 83.1°) juices had a more orangey-yellow hue. The latter is more orange as the hue angle is smaller. 'Petit Jaune' juice clearly had a dominant yellow hue, as the h value was very close to 90° (91.5°). In this case, with an a^* value close to 0 (−1.1), the yellow color of this juice was described directly by the positive value of b^* (40.7). With regard to C^* values, the colors of 'Marie Ménard' and 'Dous Moen' juices were 3 times more intense than the color of 'Guillevic' juice, for which the lightness remained close to 100 even after oxidation. Overall, the higher the C^* values, the lower the lightness values. The varietal differences in terms of hue and color intensity (indicated by chroma C^*) were related to the pigment content formed by polyphenol oxidation during fruit processing. The structures and relative concentrations of these chromophores are crucial in the final color of the juice.

HPLC-UV−Visible Profiles of Yellow-Orange Phenolic Compounds in Juices. Yellow-orange compounds absorb in the range of 400−450 nm. HPLC-UV−visible profiles of purified phenolic fractions of oxidized juices at 420 nm are presented in Figure 1. The four apple juices provided contrasting colored compound profiles. Although most polyphenol oxidation products formed during apple processing were colorless,[38] these chromatographic profiles clearly highlight two kinds of response at 420 nm: several well-defined peaks corresponding to yellow-orange compounds (peaks 1−7 on chromatograms A−D, Figure 1) and a globally unresolved absorbance hump. With regard to the well-resolved compounds, two groups of molecules were distinguished by their chromatographic behavior that reflected their polarity. Indeed, compounds **1**−**3** eluted early, contrary to compounds 5−**7**. Consequently, the polarity of the former was probably greater than the latter and produced wider chromatographic peaks. Compound **4** showed intermediate polarity. Its presence was particularly preponderant in 'Petit Jaune' juice, although it was also detected to a lesser extent in the other juices. The particular greenish-yellow coloration of 'Guillevic' juice discussed previously was clearly related to a specific profile of phenolic pigments (Figure 1A). It appeared less complex compared to the HPLC profiles of the other varieties, with the main pigments being polar compounds **1**−**3**, and the absorbance of the unresolved hump was lower (Figure 1A). 'Dous Moen' and 'Marie Ménard' extracts had very similar 420 nm HPLC profiles, in accordance with their rather similar color parameters (Table 1). In contrast with the 'Guillevic' colored compound profile, there was less of polar compounds **1**−**3** in 'Dous Moen' and 'Marie Ménard' than of the more apolar compounds **5**−**7** indicated by intense peaks at 420 nm. Moreover, the unresolved absorbance hump was well represented in these juices, which displayed a more orange hue than 'Guillevic' and 'Petit Jaune' juices. Consequently, it is suggested that more well-resolved apolar compounds and compounds responsible for the unresolved absorbance hump could be involved in the differences in hue observed. The absorbance maxima in the visible region of compounds **4**, **6**, and **7** (Table 2) shifted slightly (ca. 20 nm) to higher wavelengths in comparison with more polar compounds **1**−**3**. However, UV−visible spectra were acquired in acidified analytical conditions, meaning that pigments were in a different chemical environment from that of the juices. Consequently, this could alter slightly their optical properties measured by the diode array detector. Unfortunately, except for compound **1**, we did not succeed in obtaining clear MS data from the colored compounds displaying well-resolved peaks on 420 nm chromatograms. The structural characterization of compound **1** will be discussed later in a specific paragraph. It must be emphasized that colorless compounds were largely more concentrated than colored compounds in the purified phenolic fractions. Although it was not revealed on the 420 nm chromatograms, numerous coelutions occurred with colorless and UV-absorbing compounds. Thus, MS signals detected at retention times of colored compounds corresponded mainly to native colorless compounds and oxidation products coeluting at those retention times. Lea[27] proposed that some new colored compounds formed after oxidation of apple juices are similar to dehydrodicatechin A and are yellow dimers resulting from oxidative coupling of two catechin molecules.[39] However, the extracted ion chromatogram of the deprotonated molecule $[M - H]^-$ at m/z 575, which corresponds to the molecular ion of dehydrodicatechin A, did not indicate clear traces of this compound in the four oxidized juices studied here (data not shown). Indeed, ions at m/z 575 may also correspond to colorless oxidation products of procyanidin dimers or to product ions of procyanidin polymers that can be produced in the source of the mass spectrometer.[40] Further purification steps and optimized separation will be needed to obtain more information on the structure of these pigments formed in apple juices.

Table 2. Maximal Absorbance in the Visible Region (400−700 nm) of the Yellow Compounds Producing Well-Resolved Peaks on 420 nm Chromatograms

compound	RT (min)	λ_{max} (nm) in the visible region
1	13.17	417
2	13.95	418
3	14.73	419
4	17.10	437
5	21.20	424
6	22.80	437
7	23.88	433

Gelatin fining of the polyphenolic extract of 'Dous Moen' juice resulted in condensed tannin precipitation, and most of these procyanidins were colorless. However, as illustrated in Figure 2, the phenolic profile at 420 nm showed a clear decrease in absorbance of the previously described unresolved hump, suggesting that oxidized tannins were also partly responsible for the coloration of apple juices. In contrast, well-resolved peaks at 420 nm were not affected by gelatin fining, suggesting that those colored products do not have tanning properties. In the literature, "brown polymers" were often mentioned as being responsible for browning in crushed apple tissues.[41] However, to our knowledge, this formation of highly polymerized colored pigments has not been clearly demonstrated. Polymerization mechanisms are not likely to generate more conjugation in molecules and so should not lead directly to the formation of chromophores. Oleszek et al.[29] considered the role of procyanidin oxidation products in enzymatic browning phenomena. In a model solution, the authors showed that enzymatic oxidation of procyanidins B2 and C1 could lead to intense coloration even if the reaction rate was very slow. Nevertheless, these experiments were conducted in a model solution at pH 5.5, close to the optimal pH for PPO

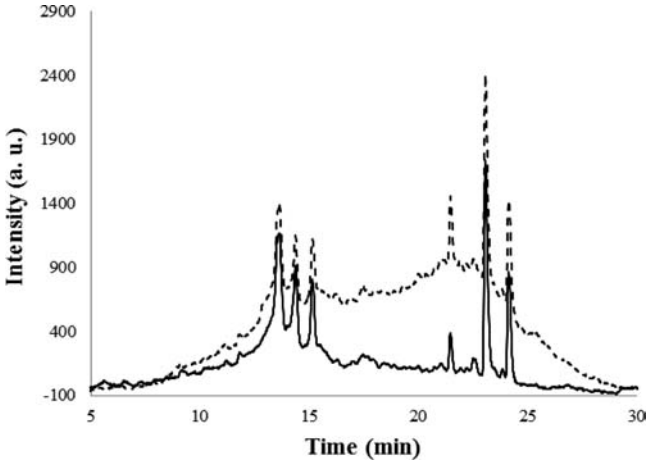

Figure 2. Reversed-phase UV−visible chromatograms at 420 nm of 'Dous Moen' phenolic extract before (dotted line) and after (solid line) gelatin fining.

activity. These pH conditions may favor autoxidation of polyphenols because they are much higher than pH values usually encountered in apple juice. In the present study, the colored oxidized tannins highlighted could result from the addition or coupling of some chromophores such as dehydrodicatechin A or dehydrotricatechin A to procyanidin oligomers and polymers. It could also explain why the deprotonated molecules corresponding to these chromophores were not directly detected in juices.

Flavanol Monomers, Hydroxycinnamic Acids, and Dihydrochalcones: The Main Phenolic Classes Containing Color Precursors. The diversity of apple juice colors is based on the diversity of colored oxidation products that can coexist in juices. These pigments are derived from native colorless polyphenols. Using multiple linear regression analysis, Goupy et al.[22] established that CIE L^*, a^*, and b^* values of an apple phenolic solution were correlated to both initial and oxidized amounts of phenolic classes. Here, native phenolic content of oxygen-deprived and oxidized juices were compared

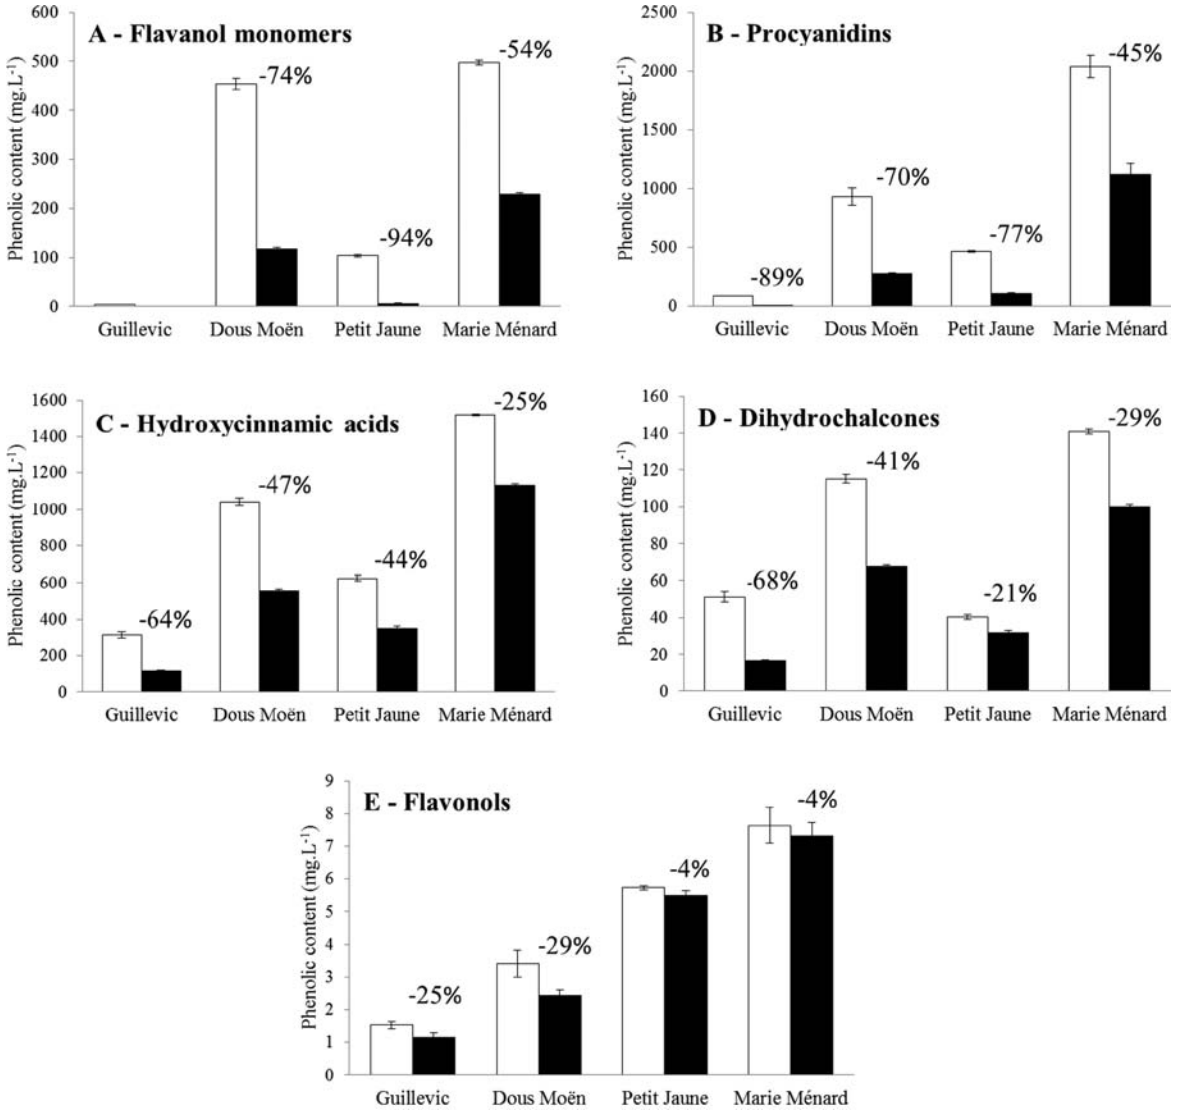

Figure 3. Comparison of content of different phenolic classes according to the oxidation conditions used to produce the French cider apple juices: (A) flavanol monomers; (B) procyanidins; (C) hydroxycinnamic acids; (D) dihydrochalcones; (E) flavonols. White bars correspond to O_2-deprived juices and black bars to oxidized juices. For each phenolic class, the difference in polyphenol content (expressed in %) between O_2-deprived and oxidized conditions is indicated above the black bars.

by discussing the impact of oxidation within different phenolic classes (Figure 3 and Table 3). Details concerning specific compounds in these classes can be found in the Supporting Information. First of all, some varietal discrepancies were clearly noted in accordance with results of previous studies.[42] For example, the original colored profile of 'Guillevic' juice can be related to a distinctive native polyphenol composition. The amount of total polyphenols in this juice was low in comparison with the other varieties (Table 3), as it contained nearly 20 times less polyphenols than 'Marie Ménard' oxidized juice. Moreover, as shown in Figure 3B, the 'Guillevic' juices did not contain any flavanol monomers (i.e., (−)-epicatechin and (+)-catechin), which are known to act as precursors of oxidation products developing intense coloration.[23,24] In addition, 'Guillevic' juices contained very low concentrations of procyanidins (Figure 3B), which were shown to be involved in color formation, as revealed by the gelatin fining of 'Dous Moen' oxidized juices (Figure 2). Therefore, the absence of flavanols in 'Guillevic' juice could explain the considerable difference observed between its weakly saturated greenish-yellow hue and the orange-yellow hue of 'Dous Moen' and 'Marie Ménard' juices. This oxidized juice was also the only one with a CQA/pCoQA ratio below 1 (Table 3). This particular fraction of the hydroxycinnamic acid class could also be a factor of "color limitation". Indeed, *p*-coumaroylquinic acids could act as potential inhibitors of PPO as they are derived from *p*-coumaric acid, a molecule known to be an *o*-diphenolase inhibitor.[43]

For the other juices, the oxidation phenomenon strongly influenced flavanol content, particularly monomers. There was up to 94% less monomers in oxidized 'Petit Jaune' juice than in O_2-deprived juice (Figure 2A). The procyanidin content was also significantly lower, which may first be due to part of the oxidized tannins being adsorbed on parietal material during processing. Second, after oxidation, some procyanidins can become partly resistant to phloroglucinolysis, which could suggest an underestimation of the procyanidin content. Most of the oxidized polyphenols were colorless, but major classes affected by oxidation were probably involved in the generation of oxidized colored compounds. Hydroxycinnamic acids were also well represented in cider apple juices. This class is clearly affected by oxidation, but not to the same extent as flavanol monomers, as illustrated by the differences between O_2-deprived and oxidized juices (Figure 3C). These compounds seem to be more "protected" against oxidation, which can be explained by coupled oxidation−reduction reactions. Indeed, several authors[22−24,26,44] have mentioned the crucial role of the balance between hydroxycinnamic derivatives and flavanols in browning susceptibility. As the best PPO substrate, 5-*O*-caffeoylquinic acid, the major compound in this phenolic class in most apple varieties, generates *o*-quinones that can co-oxidize flavanol monomers. Through these reactions, caffeoylquinic acid *o*-quinones are regenerated as *o*-diphenolic forms with simultaneous oxidation of monomers leading to new compounds, some of which are highly colored products. Consequently, the data shown here seem to be consistent with results in the literature.

Interestingly, the significance of the dihydrochalcone class in the oxidation phenomenon is also highlighted in Figure 2. Indeed, even if the concentrations of these compounds are lower than those of flavanols and hydroxycinnamic derivatives, the dihydrochalcone content decreased by the same order of magnitude as hydroxycinnamic acids in oxidized juices, except for 'Petit Jaune', in which the content decreased less. Previous studies in model solutions have already shown that these molecules can result in yellowish products. Some synergistic effects on the browning rate have even been reported[29,30] when dihydrochalcones are in the presence of chlorogenic acids or flavanol monomers. In previous studies,[31,32] we characterized a yellow colorant consisting of a phloridzin oxidation product (POPj). The variations in dihydrochalcone content in the four juices indicated that the role of compounds in this class in the formation of color in apple juices must be particularly considered in the present study.

Finally, we noted that flavonols (i.e., a series of quercetin glycosides), localized mainly in the apple epidermis and known to be the only phenolic class displaying native yellow compounds, were found in very low quantities in juices (about 1−7 mg/L, Figure 3E). They did not appear to be the main compounds responsible for the color of apple juices.

Identification of a Yellow Compound Formed in Real Apple Juices: Yellow Pigment Phloretin Xyloglucoside Oxidation Product (PXGOPj) as Xyloglucose Analogue of POPj Colorant Previously Identified by Le Guernevé et al.[31] As previously specified, the juice obtained from the 'Guillevic' variety exhibited a singular native phenolic composition. Logically, it led to a particular profile of colored compounds and, consequently, to an oxidized juice with a very specific hue and saturation level. The greenish-yellow coloration of this juice appeared to be related mainly to the presence of three compounds (peaks 1, 2, and 3, Figure 1), also present in lower concentrations in the other juices studied. The MS signal corresponding to peak 1 revealed the existence of a product with a molecular weight of 598 Da ($[M - H]^-$ at m/z

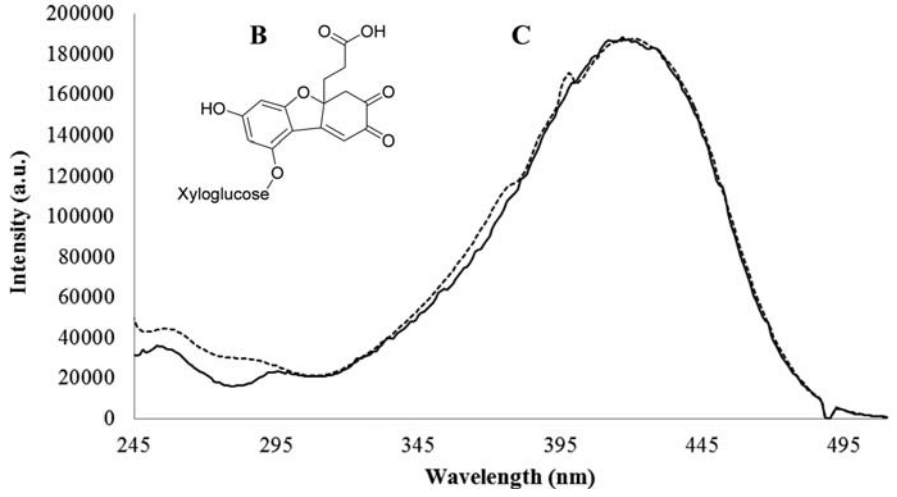

Figure 4. Identification of PXGOPj, a new yellow compound derived from phloretin xyloglucoside in cider apple juice: (A) LC-MS^n features; (B) hypothetical structure; (C) comparison of UV−visible spectra of POPj (dotted line) and PXGOPj (solid line).

597, see Figure 4A). The three main MS/MS product ions of the deprotonated molecule were detected at m/z 553, 259, and 303. Interestingly, this molecular weight and this fragmentation pattern were strictly in accordance with the xyloglucose analogue of the POPj molecule.[32] Indeed, the first product ion (m/z 553) corresponded to the loss of the free carboxylic group (− 44 amu). The MS/MS ion at m/z 259 (losses of 294 and 44 amu) could be obtained after the loss of the sugar moiety and the carboxylic group. Finally, the product ion at m/z 303 corresponded to the remaining phenolic part of the molecule after the loss of the sugar moiety. This new compound was named PXGOPj, and its proposed structure is illustrated in Figure 4B. Fromm et al.[45] previously suggested the formation of a POPj analogue pigment derived from phloretin xyloglucoside during the enzymatic oxidation of apple seed extracts. However, this compound was not clearly detected, and the authors concluded that it was coeluted with POPj in their analytical conditions. PXGOPj could be generated following the same reaction pathway as already described for POPj.[32] Thus, phloretin xyloglucoside could be oxidized by apple PPO involving both cresolase and catecholase activities coupled with intramolecular rearrangement, ring rearomatization, and addition of water.[32] As expected, the UV−visible spectrum of this xyloglucose analogue of POPj was very similar to the POPj spectrum (Figure 4C). Only the sugar moiety differs between both structures, which should not modify the electronic delocalization and, consequently, the chromophore is not modified. Theoretical calculations could be used to confirm this assertion. Interestingly, although phloridzin was significantly present in the oxygen-deprived juice, the extracted ion chromatogram at m/z 465, which corresponds to the POPj deprotonated molecule, revealed only the presence of traces of POPj in the oxidized 'Guillevic' juice (data not shown). This preferential formation of PXGOPj could be related to a higher affinity of polyphenol oxidase for phloretin xyloglucoside than for phloridzin. This would be in accordance with the observations of Oleszek et al.[29] Indeed, these authors showed that in a model solution phloretin xyloglucoside was more readily oxidized by PPO than phloridzin, even if both were PPO substrates. They also noted that enzymatic oxidation of these native dihydrochalcones resulted in yellowish products.

To conclude, the present paper proposed an initial exploration of yellow-orange compounds in apple juices produced in conditions very similar to those in the cider-making industry. The oxidized juices showed contrasting color parameters related to very contrasting phenolic profiles of colored compounds. The relative proportions of the different classes of native polyphenols appear to be important in relation to the final color. Flavanol monomers seem to play an essential role in oxidation, probably via direct enzymatic oxidation, but also with coupled oxidation−reduction reactions involving hydroxycinnamic acids. The significance of the dihydrochalcone class as a precursor of yellow oxidation products was clearly highlighted, and a pigment derived from phloretin xyloglucoside was identified.

The study of colored phenolic compounds encountered in apple juices is far from being accomplished. Further purification steps and attempts to optimize MS detection are still necessary to gain further insight into pigment structures. Moreover, this study focused on the initial phenolic composition of the juices to discuss color generation, but the physicochemical parameters of a beverage may also strongly influence the expression and stability of juice color. Indeed, factors such as pH, the presence of metallic ions, or copigmentation phenomena must not be neglected to understand the final coloration of a beverage.

the influence of different parameters such as ethanol, pH, and glucose on their uptake. After ingestion, anthocyanin bioactivity in vivo will be dependent on the cumulative biological effect of native and resulting metabolites; thus, the research in this field is of crucial importance.

The purpose of this work was to explore the gastric absorption of red wine anthocyanins using an in vitro human stomach cell model, MKN-28, previously developed.[16] The influence of ethanol, glucose, pH, and pre-exposure to red wine on their transport was also performed.

Theoretical studies were conducted to study the interaction between anthocyanins and GLUT receptors. Two different conformations of GLUT receptors and different anthocyanin equilibrium forms were considered.

MATERIALS AND METHODS

Red Wine Extract. The red wine was a table red wine from 2012 made from the traditional Douro varieties (Touriga Nacional, Touriga Franca, Tinta Barroca, Tinto Cão, and Tinta Roriz) and was provided by Sogevinus Fine Wines, S.A. Ethanol was removed through rotative evaporation at 30 °C under vacuum. The dealcoholized wine was purified by reverse phase C-18 silica gel to eliminate all sugars and recover the wine phenolics. The eluents were acidic water (HCl 2% (v/v)) for conditioning of stationary phase and acidic methanol (HCl 2% (v/v)) for eluting. A new evaporation was made to remove methanol from the wine. The resulting wine extract was freeze-dried and stored at −20 °C until use.

Cell and Culture Conditions. Human cancer cell line from stomach, MKN-28, was grown as monolayers and maintained at 37 °C in an atmosphere of 5% CO_2 and 90% relative humidity. For routine maintenance, cells were cultured in 22.1 cm^2 tissue culture dishes as monolayers and maintained in RPMI 1640 AQmedia (Sigma, Germany), supplemented with 10% fetal calf serum (FCS) (Biowhittaker, Lonza, Belgium) and 1% of antibiotic/antimycotic solution (100 units/mL of penicillin, 100 mg/mL of streptomycin, and 0.25 mg/mL of amphotericin B) (Sigma). Cells were harvested by trypsinization (0.25%, w/v, trypsin−$EDTA_4$−Na) once a week.

Transport Studies. Transport experiments were performed according to previously published methods.[4,16] Briefly, MKN-28 cells were plated on 12-well transwell inserts (0.4 μm pore size tissue culture inserts (Corning Costar, Corning, NY, USA)). Cells were cultured at 37 °C in an atmosphere of 5% CO_2, and the medium was changed every 2 days. At 7 days MKN-28 cells were fully confluent and differentiated, so experiments were initiated at that time. Experiments were conducted only in MKN-28 cell monolayers that showed a TEER > 150 Ω·cm^2 (determined at 37 °C).

In transport experiments HBSS, pH 7.4, was the main component of the basolateral medium. In the gastric cell model the apical medium was acidified to 5.0 by adding solid 2-(*N*-morpholino)ethanesulfonic acid (MES) to give a concentration of 25 mM and then adjusting the pH with 5 M HCl.

Medium was removed and cells were washed with Hanks' medium, pH 7.4. Compound solution in Hanks, with a final concentration of 50 μg/mL, was added to the apical side of the cells and Hanks containing 2% FBS was added to the basolateral compartment.

Transepithelial transport was followed as a function of time. A total of 150 μL was taken from the basolateral side and replaced by fresh medium (Hanks containing 2% FBS) at 30, 60, and 120 min of incubation and also at 180 min for the MKN-28 cell line. Each time sample (150 μL) was acidified with HCl to a final concentration of 0.06 M. All samples, from both apical and basolateral sides, were acidified and frozen (−18 °C) to ensure that the cumulative amounts of each compound that were later quantified were not altered during sample delay until uHPLC analysis. Red wine anthocyanins were quantified using the malvidin-3-glucoside calibration curve Abs (520 nm) = 8.725 × concn (μM), R^2 = 0.9789.

Transport efficiency percentages were calculated as ((compound concentrations at the basolateral side overtime)/(compound concentrations at the apical side at 0 h)) × 100.

uHPLC Analysis. uHPLC analysis of the anthocyanins was performed on a Dionex Ultimate 3000 (Thermo Scientific) equipped with a Hypersil GOLD 50 × 2.1 mm i.d. (particle size = 1.9 μm) reversed phase C18 column (Thermo Scientific); detection was carried out at 520 nm using a diode array detector. The solvents were (A) H_2O/HCOOH (9.5:0.5) and (B) CH_3CN. The gradient consisted of 94.5−64% A for 7 min, 64−20% A for 3 min, 20−0% A for 0.1 min, 100% B for 3 min, and 94.5% A for 3 min at a flow rate of 0.5 mL/min.

RNA Isolation and qRT-PCR. Total RNA from cells was isolated using RNA-STAT 60 reagent (AMS Biotechnology, Oxon, UK) according to the manufacturer's instructions. Purity of RNA samples was confirmed with absorbance ratios 260/280 nm superior to 1.8. RNA samples were treated with DNaseI (RQ1 RNase-free DNase, Promega, Portugal). cDNA was synthesized from 5 μg of treated mRNA with an NZY First-Strand cDNA Synthesis Kit (NZYTech, Lisboa, Portugal).

Quantitative real-time polymerase chain reaction (qRT-PCR) was run on Lightcycler96 (Roche Diagnostics, USA). Ten microliter reactions were set on 96-well plates using 0.2 μM of each primer (Table 1) and 5 μL of FastStart Essential DNA Green Master (Roche Diagnostics, USA). Cycling conditions were as follows: denaturation (95 °C for 10 min), amplification and quantification (95 °C for 10 s, annealing temperature (AT) for 10 s, and 72 °C for 10 s, with a single fluorescence measurement at the end of the 72 °C for 10 s segment) repeated for 45 cycles, and a final melting at 95 °C 10 s, 65 °C 60 s, and 97 °C for 1 s. The following human-specific primers were used: HPRT-1 (AT = 59 °C) sense 5′ TGCTGACCTGCTGGATTACA 3′ and antisense 5′ TTTATGTCCCCTGTTGACTGG 3′. Data were analyzed using LightCycler 96 SW analysis software v1.1. The C_q values obtained were transformed into relative quantification data using $2^{(-\Delta C_q)}$.[20]

Anthocyanin/GLUT1 Computational Methods. Two crystallographic structures, extracted from the Protein DataBank (PDB), were

DOI: 10.1021/acs.jafc.5b00412
J. Agric. Food Chem. 2015, 63, 7685−7692

used: (i) an outward-facing conformation of *Escherichia coli*'s D-xylose:, H1 symporter (XylE) complexed with D-glucose (PDB code 4GBZ, resolution = 2.89 Å); and (ii) an inward-facing conformation of the human GLUT1 (hGLUT1) receptor (PDB code 4PYP, resolution = 3.17 Å).[21] The former structure is a homologue to the well-known human glucose transporters GLUT1−4. All of these receptors contain a typical major facilitator superfamily fold of 12 transmembrane segments (TMs), with amino and carboxy termini both located on the intracellular side. The 12 TMs are organized into three distinct domains—the N, C, and ICH domains. TM7 and TM10 belonging to the C domain are both discontinuous helices, which may facilitate conformational changes during substrate transport.[22]

Molecular docking studies were conducted with three different anthocyanins (Cy3glc, Dp3glc, and Mv3glc) in hemiketal, flavilium cation, and anionic quinoidal base forms. The structures were modeled with the GaussView software (Carnegie Office Park Gaussian Inc., Pittsburgh, PA, USA). The receptor PDB structures were protonated with the X-Leap tool of the AMBER 12.0 software,[23] considering their physiological protonation state. The docking procedure was performed with VsLab[24] that uses the Autodock software.[25] A total of 50 poses were generated, employing a genetic algorithm. The docking pocket was defined by the AutoGrid tool. The box dimensions were 23.2 × 20.6 × 21.7 Å. The docking structures were ranked energetically, and the best scores were taken as starting structures for the subsequent molecular dynamics (MD) simulations.

In the MD simulations, the receptors were parametrized with the ff99SB force field from the AMBER software. The parameters for the anthocyanins were derived following a standard protocol[26] using the Antechamber module.[27] The parameters were derived from the GAFF force field,[28] and atomic single-point charges were calculated using the Gaussian 09 software[29] and employing the RESP algorithm.[30]

The MD simulations were performed with the AMBER 12.0 software. Counter ions were added to neutralize the overall charge of the system. The X-Leap program was used for this purpose. An explicit solvation model with TIP3P water molecules was used, filling a truncated rectangular box with a minimum of 12 Å distance between the box edges and the model. Each structure was minimized in two stages. Subsequently, a 100 ps equilibration followed by a 25 ns production MD simulation was carried out. The Langevin temperature equilibration scheme was used to maintain the temperature at 310.15 K,[31] and periodic boundary conditions were imposed. Bond lengths involving hydrogen atoms were constrained using the SHAKE algorithm,[32] and the equations of motion were integrated with a 2 fs time step using the Verlet leapfrog algorithm. The particle-mesh Ewald (PME) method was used to treat long-range interactions,[33] and the nonbonded interactions were truncated with a 10 Å cutoff. All of the MD results were analyzed with the Ptraj module of Amber 12.0.

Statistical Analysis. All values are expressed as the arithmetic means ± SEM. Statistical significance of the difference between various treatments was evaluated by two-way analysis of variance (ANOVA) and by one-way analysis of variance between each group for the different incubation times, followed by the Bonferroni's correction for multiple comparisons. Differences were considered to be statistically significant (*) when $p < 0.05$.

RESULTS AND DISCUSSION

Gastric Transport of Red Wine Anthocyanins. A human adenocarcinoma gastric cell line, MKN-28, was previously developed as a model of human gastric barrier, useful for examining mechanisms of nutraceuticals transport. The transport of anthocyanins was studied in this cell model, and it could be concluded that their transport efficiency increases with incubation time, although no differences were observed among the three anthocyanins studied (Dp3glc, Cy3glc, and Mv3glc).[16]

Besides the importance that this barrier has for anthocyanins due to their rapid appearance in plasma, the possible interference of food components in anthocyanin gastric absorption also deserves investigation because these compounds are consumed as part of a normal diet. In particular, red wine is composed by a complex mixture of polyphenols (anthocyanins, tannins, catechins, etc.), alcohol, and monosaccharides (glucose and frutose), so it is not surprising that the total anthocyanin absorption may be affected by some of these parameters.

All transport experiments were performed in a transwell plate system introducing the Hanks buffer, pH 5, in which the wine extract (50 μg/mL) was previously dissolved, in the donor chamber. The Hanks buffer, 2% SFB and pH 7.4, was placed in the receptor chamber. At predetermined intervals, aliquots of 150 μL were removed from the basolateral chamber and analyzed by HPLC-DAD.

The anthocyanin profile of the red wine extract used is composed by six main anthocyanins (Figure 1).

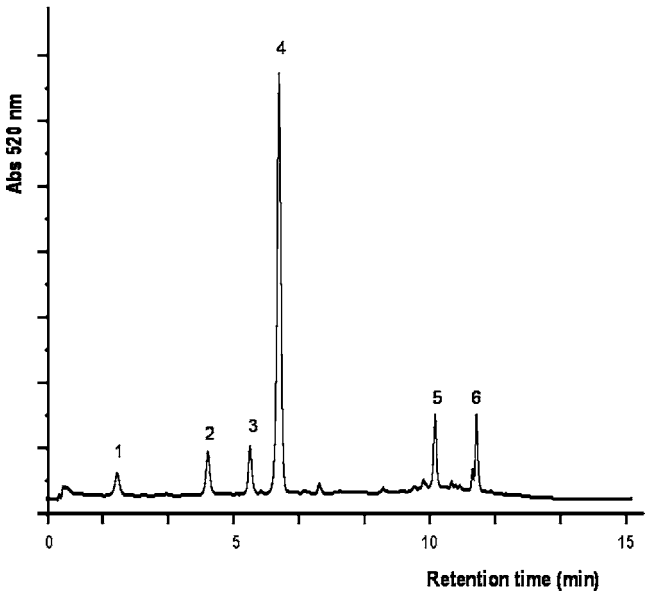

Figure 1. HPLC chromatogram of the red wine extract recorded at 520 nm. Peaks: 1, delphinidin-3-*O*-glucoside (Dp3glc); 2, petunidin-3-*O*-glucoside (Pt3glc); 3, peonidin-3-*O*-glucoside (Pn3glc); 4, malvidin-3-*O*-glucoside (Mv3glc); 5, malvidin-3-*O*-acetylglucoside (Mv3actglc); 6, malvidin-3-*O*-coumaroylglucoside (Mv3cumglc).

All anthocyanins present in the apical side of the transwell insert were detected in the basolateral side of this gastric barrier (data not shown).

Considering the ingestion of a glass of red wine containing 12% alcohol (v/v), this ethanol percentage will suffer a dilution within the gastric fluids, so the influence of 4% may be considered likely reliable in vivo. The effect of DMSO (wine stock solution solvent) and 4% ethanol (individually or co-administered) on the monolayer TEER was assayed. No effect was observed on cell viability or on monolayer integrity (data not shown).

In the presence of 4% ethanol no significant differences were observed in the transport efficiency of the total wine anthocyanins (Figure 2). There are some studies referring to anthocyanins that claim no influence of ethanol on their intestinal absorption[34,35]

The increase in the apical pH for values around 7.4 (similar to intestinal conditions) was associated with a reduction in the transport efficiency with statistical difference after 180 min

DOI: 10.1021/acs.jafc.5b00412
J. Agric. Food Chem. 2015, 63, 7685−7692

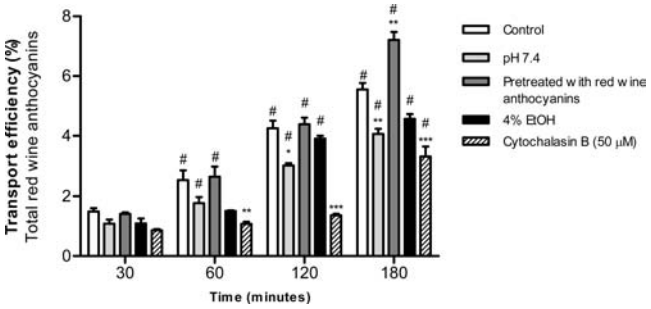

Figure 2. Transport efficiency of total red wine anthocyanins through MKN-28 barrier (apical → basolateral). The experiments were conducted with apical pH 5.0 and basolateral pH 7.4, unless otherwise indicated. The influence of 4% ethanol, pretreatment with red wine anthocyanins (3 h at third and fifth growing days), and apical pH (pH 5 vs 7.4) on total red wine transport efficiency was determined. Results are presented as transport efficiency (%) (mean ± SEM). Transport efficiency percentages were calculated as (compound concentrations at the basolateral side over time)/(compound concentrations at the apical side at 0 h) × 100. Significantly different from control for the same incubation time: ∗, $p < 0.05$; ∗∗, $p < 0.01$; ∗∗∗, $p < 0.001$. Significantly different between the different incubation times: #, $p < 0.001$.

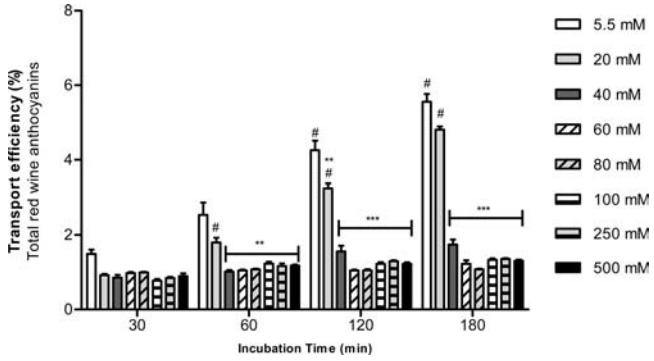

Figure 3. Transport efficiency of total red wine anthocyanins through MKN-28 barrier (apical → basolateral) in the presence of 20−500 mM D-glucose. Results are presented as transport efficiency (%) (mean ± SEM). Transport efficiency percentages were calculated as (compound concentrations at the basolateral side over time)/(compound concentrations at the apical side at 0 h) × 100. Significantly different from control for the same incubation time: ∗, $p < 0.05$; ∗∗, $p < 0.01$; ∗∗∗, $p < 0.001$. Significantly different between the different incubation times: #, $p < 0.001$.

(Figure 2). This result highlights the importance of pH on the anthocyanin transport efficiency that may be related not only to the main anthocyanin forms present but also to the influence on the possible transporters involved in their transport.

For the pretreatment study, transwell cells were incubated during 3 h with red wine anthocyanins (with the same concentration applied on the seventh day) at the third and fifth days postplating. After that incubation, the apical and basolateral medis were renewed. The pretreatment of the transwell system with anthocyanins during cell growth resulted in an increase in anthocyanin uptake for values above 30 min of incubation (Figure 2).

This result may be associated with a cellular adaptation to the presence of anthocyanins that could induce, for instance, an increase in the expression of some type of transporters.

Effect of D-(+)-Glucose. To evaluate the possible implication of glucose transporters in anthocyanin absorption, a range of glucose concentrations (5.5−500 mM) were co-administered to the apical side of the transwell system. According to the results obtained, for concentrations >40 mM glucose, the transport efficiency of anthocyanins is significantly decreased, remaining constant and around 1% during the 3 h of incubation time (Figure 3). This decrease in anthocyanin uptake may result from a competition for the same transporter. In fact, the presence of glucose in the anthocyanin moiety may account for the selective interaction between GLUTs and anthocyanins.

To test the possible implication of glucose transporters in anthocyanin absorption, besides adding their natural substrate, the effects of a glucose transporter inhibitor, cytocalasin B (50 μM), were also evaluated. For incubation time >60 min, the anthocyanins transport was significantly reduced (Figure 2). A similar behavior was observed in a previously work with the Caco-2 cell line.[4]

However, this is not the only molecular determining factor because all anthocyanin forms have glucose in their constitution, and it was seen that anthocyanin uptake was reduced by pH, which alters the anthocyanidin moiety and makes anthocyanin's access to the transporter core difficult. This will be studied by using a theoretical approach, as further discussed.

Characterization of Transporters Expression in MKN-28 Cell Line. Monocarboxylated transporter and organic anion transporter are expressed in intestine and liver but also in stomach.[36] To explore the possible involvement of transporters in the absorption across MKN-28, the expression of some transporters was evaluated by RT-PCR. It was concluded that not only MKN-28 expresses glucose transporters 1 (GLUT1) and 3 (GLUT3) but also monocarboxylated transporter 1 (MCT1) (Figure 4). The expression of glucose transporter 2 (GLUT2), sodium-coupled monocarboxylated transporter 1 (SMCT1), and sodium−glucose transporter 1 (SGLT1) was not observed.

Molecular Docking on XylE and hGLUT1 Receptors. A molecular docking of Cy3glc, Dp3glc, and Mv3glc on hemiketal, flavilium cation, and anionic quinoidal base forms against GLUT transporters was performed. Because the X-ray structure of XylE was complexed with a glucose (glc) molecule, a docking procedure using this unit was first performed to validate the protocol. Figure S1 in the Supporting Information (SI) shows the superimposition between the best docking result and the crystallographic geometry, in which a high similarity in the glc pose is observed with a root-mean-square deviation (RMSd) of 2.03 Å. This small RMSd value and the negative ΔG binding obtained for glucose (−6.6 kcal/mol) validates this docking procedure.

A similar process was applied to dock all anthocyanins into the XylE receptor. The values of ΔG binding obtained for all molecules are presented in Table 2. We observe that all negative free binding energy values were compatible with a favorable association between the polyphenols and XylE. Although all free energy values are similar, it was observed that the Cy3glc and Dp3glc molecules interact more strongly with the receptor than Mv3glc. This may be justified by the high number of hydroxyl groups present in the first two anthocyanins, which can establish strong hydrogen-bond interactions with the amino acids of the periplasmic side of the receptor.

It is also possible to see that all docking solutions of hemiketal forms bind to the periplasmic side of XylE by glucose

DOI: 10.1021/acs.jafc.5b00412
J. Agric. Food Chem. 2015, 63, 7685−7692

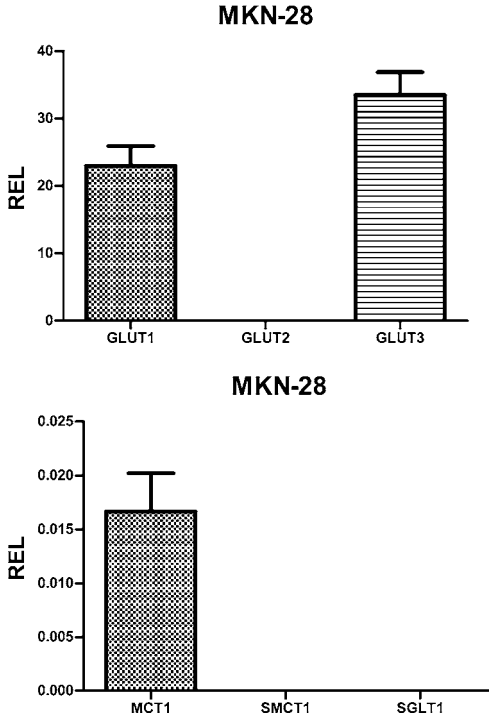

Figure 4. Transporter expression in MKN-28 cell line evaluated by qRT-PCR: glucose transporters 1 (GLUT1), 2 (GLUT2), and 3 (GLUT3), monocarboxylated transporter 1 (MCT1), sodium-coupled monocarboxylated transporter 1 (SMCT1); and sodium−glucose transporter 1 (SGLT1).

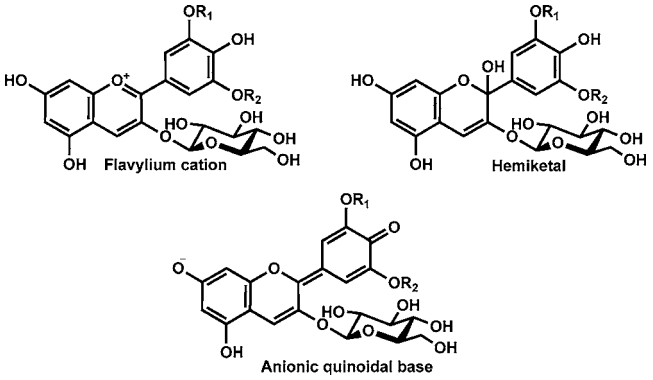

Figure 5. General structures of anthocyanins in flavylium cation, hemiketal, and anionic quinoidal base forms. R_1 and R_2 = H, OH, or OCH_3.

or the B ring, which suggests that both units have a key role in the entrance of anthocyanins. However, the flavilium cation form of anthocyanins appears to enter on XylE mainly by the AC moiety (Figure 5). This could be explained by the positive charge present in the C ring that is not found in the other forms.

Table 3 shows the values of ΔG binding obtained from the docking of the same anthocyanin molecules to the hGLUT1. In all protonation states, the AC moiety of anthocyanins is the one that interacts more deeply with the inward-facing conformation of hGLUT1. This fact reinforces the entrance by the opposite side (B and Glc groups) previously observed for the outward-facing conformation. These results suggest that there are two main conformations of anthocyanins during their entrance from the extracellular side to the outward-facing receptor, which implies that these compounds access the intracellular side mainly by the AC group. To summarize this, Figure 6 shows a proposal for the molecular mechanism by which the anthocyanins cross the cellular membrane through hGLUT receptors.

Figure 7 shows the main residues involved in the binding of anthocyanins to hGLUT1 receptor in both conformations (considering the corresponding residues of the outward-open form of XylE). In the literature, it was proposed that only the C domain is implied in the association of glucose to both XylE and hGLUT1, whereas the N domain works as a secondary place.[21,22] However, these docking results show that the residues involved in the binding of anthocyanins to hGLUT1 belong to both C and N domains. This could be explained due to the larger size of anthocyanins compared to glucose.

Molecular Dynamics (MD) Simulations. The two best docking solutions (S1 and S2) for each anthocyanin, in the three different protonation states, bound to the inward-open hGLUT1 were used as starting structures for the subsequent MD simulations. These two solutions were chosen because the anthocyanins can interact with the binding pocket by different groups (AC, B, or glc units). The unique exception was the Mv3glc hemiketal, in which the binding modes observed in S1 and S2 were very similar. Hence, MD simulations of 25 ns were carried out for the 17 different hGLUT1−anthocyanin complexes. The analysis of the results revealed that all anthocyanins remained in the binding pocket throughout the simulations. Figure S2 in the SI shows the superimposition of the initial pose and the average pose along the MD simulation for Cy3glc flavilium cation, in which we can see that both poses are similar. The same was observed for the other complexes. The RMSd values for the protein backbone complexed with the

[a]The most internal group of the polyphenols reaching the receptor is also depicted. S1 and S2 are the two best solutions obtained from the docking protocol.

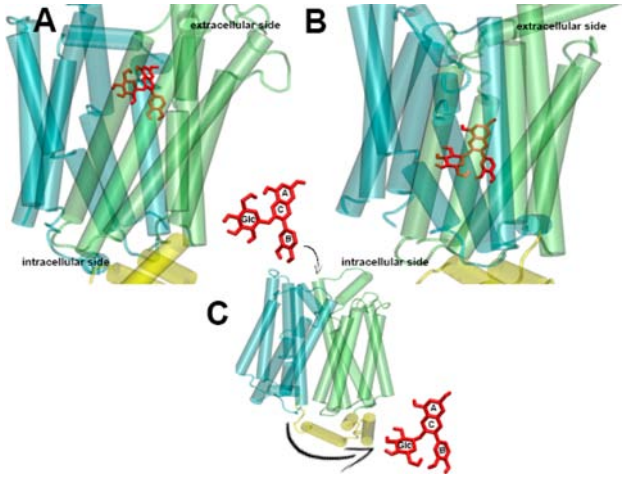

Figure 6. Proposal for the molecular mechanism by which the anthocyanins cross the cellular membrane through GLUT receptors.

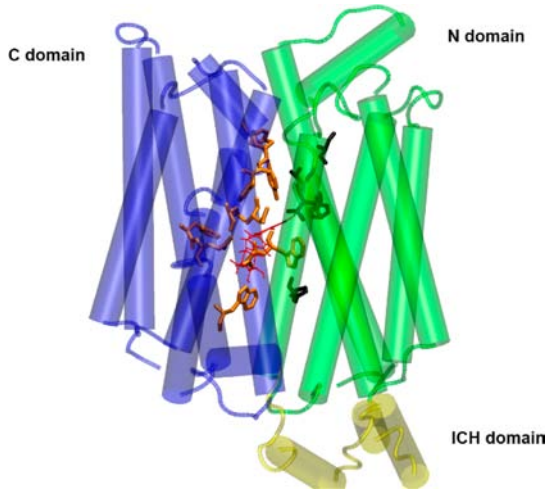

Figure 7. Representation of the main residues involved in the binding of anthocyanins to the hGLUT1 receptor. Cy3glc is represented with lines and colored in red; N, C, and ICH are represented in cartoons and colored in green, blue, and yellow, respectively; residues from N and C are represented in sticks and colored in black and orange, respectively.

anthocyanins during the MD simulations are represented in Figure S3 in the SI. It can be observed that these RMSd values are quite small (oscillating between 1.5 and 2.5 Å), which reveals the higher stability of the complexes. To obtain a measure of the movement of a subset of the system relative to the average structure over the whole simulation, the root-mean-square fluctuation (RMSf) values were also calculated for the protein, by residue, and are shown in Figure S4 in the SI. It was possible to observe an RMSf pattern conserved in all complexes. All of the residues within the binding pocket showed a minimal flexibility, which suggests that they maintain a rigid position during the simulation to reinforce the strong interaction with the several anthocyanins tested.

Structural information on the hGLUT1 binding pocket, in particular the hydrogen bonds established between the anthocyanins and the neighboring residues, were analyzed and are shown in Table S1. The van der Waals contacts established between the polyphenolic rings and the aliphatic side chains are also presented. It was seen that the main hydrogen bonds occur between the hydroxyl groups of anthocyanins and the side chains of Glu380, Asn317, Asn411, Asn415, Tyr292, and Thr30 residues. The major moiety of all anthocyanins involved in hydrogen-bond interactions seems to be glucose, which emphasizes its key role in anthocyanins transport. We have verified the presence of many hydrophobic interactions (stacking effect of $\pi-\pi$ interactions) between the rings of anthocyanins and the high number of aromatic residues present in the periplasmic side of hGLUT1 (Phe379, Trp412, Trp388, Phe72, Phe291, His160). Figure S5 in the SI exemplifies the main hydrophilic and hydrophobic interactions established between the hemiketal Cy3glc and the residues of hGLUT1. All of these interactions strongly contribute to the high stability of the complex formed between the anthocyanins and hGLUT1. Interestingly, Glu380 is the one that interacts with all anthocyanins by one of the shortest hydrogen bonds and has a high time occupancy during the MD simulations, which suggests that this residue has a key role in anthocyanin transport. This result agrees with the proposal by Deng et al.[21]

The number of water molecules within the periplasmic side of hGLUT1 during each MD simulation was also determined. The average numbers of water molecules within a radius of 3 and 5 Å around each anthocyanin were 6 and 9, which confirms that the binding pocket is highly accessible to the solvent. This solvation effect facilitates the binding of anthocyanins because they are highly water-soluble pigments.

These results obtained through computational studies do not superimpose with those obtained experimentally. Indeed, they show that all three forms of anthocyanins have similar affinities to hGLUT1, whereas a decrease of anthocyanin uptake was observed experimentally at pH 7.4. The information yielded from the theoretical studies constitutes very useful data to mechanistically understand the affinity between anthocyanins and glucose transporters. Nevertheless, other variables such as

cellular environment and biomembrane structural issues have to be taken into consideration in further studies.

because different intestinal enzymes exist in animals and humans, animal studies alone may not always be sufficient for predicting compound absorption in humans. There is no report on the absorption of *C. morifolium* in differentiated Caco-2 cells derived from human colorectal carcinoma, a vitro model of absorptive enterocytes. Therefore, we used the differentiated Caco-2 models, with animal in vivo studies, and they might be useful for the aim of predicting the absorption and metabolism in humans. As described above, flavonoids are generally metabolized to their conjugates in the gastrointestinal tract. Because most of these metabolites are not available from commercial sources, their direct analysis is precluded. Thus, in this study on luteolin conjugates in rat plasma and culture media, samples were treated with enzymes having glucuronidase/sulfatase activities to release the parent aglycone for HPLC, and for detailed qualitative analysis, untreated samples were applied to LC-MS.

MATERIALS AND METHODS

Chemicals. Luteolin, luteolin-7-*O*-β-glucoside, and myricetin were purchased from Extrasynthese (Genay, France). MEM nonessential amino acids (NEAA) and penicillin/streptomycin were obtained from Life Technologies (Carlsbad, CA, USA). Fetal bovine serum (FBS) and β-glucuronidase (type H-5 from *Helix pomatia* and type L-II from limpets) were purchased from Sigma-Aldrich (St. Louis, MO, USA). All other chemicals were obtained from Wako Pure Chemical Industries (Osaka, Japan), unless otherwise specified. HPLC solvents were all of analytical grade. The extraction of the dried *C. morifolium* flowers was performed as briefly described below. *C. morifolium* flowers (200 g) were homogenized in 2.0 L of methanol, incubated at 40 °C for 3 h twice, and evaporated.

Animals. Male Sprague−Dawley rats (7 weeks old; SLC, Hamamatsu, Japan) were housed in an air-conditioned room and given free access to MF commercial food pellets (Oriental Yeast Co., Tokyo, Japan) and tap water for 4 weeks before the experiments. After an overnight fast, the rats (11 weeks old) were intragastically administered the *C. morifolium* flower extract (1.7 g/kg body weight (bw)), equivalent to luteolin (22.8 μmol/kg bw) and luteolin-7-*O*-glucoside (58.3 μmol/kg bw), or propylene glycol as a vehicle control via intragastric intubation. At 0, 0.5, 1, 2, 3, and 6 h after administration, blood was collected from the vein into heparinized glass capillaries and centrifuged to obtain plasma. The rats were maintained and handled according to the Guidelines for the Regulation of Animal Experimentation Committee of the University of Shizuoka.

Cell Culture. Caco-2 human intestinal epithelial cells were purchased from the European Collection of Cell Cultures (Wiltshire, UK). Caco-2 cells were grown in EMEM supplemented with 10% heat-inactivated FBS, penicillin (100 U/mL), streptomycin (100 ng/mL), and NEAA at 37 °C under a humidified atmosphere of 95% air and 5% CO_2. To examine the bioavailability of luteolin and luteolin-7-*O*-glucoside, Caco-2 cells were seeded on cell culture inserts for a 12-well plate (Corning, Tewksbury, MA, USA) at a density of 3.4×10^4 cells/filter and used for experiments on days 15−20. The transepithelial electrical resistance (TEER) value of the monolayers was measured using a Millicell-ERS instrument (Millipore Corp., Bedford, MA, USA) according to the methods of Hidalgo et al.[23,24] and Murota et al.[23,24] After confirmation of differentiation by the TEER value (>600 Ω cm^2), the cells were pre-incubated with transport medium (Hank's balanced salt solution with Ca^{2+}, Mg^{2+}, and glucose; 500 μL in the apical compartment and 1500 μL in the basal compartment of the transwell system) for 30 min at 37 °C. The *C. morifolium* flower extract, luteolin, and luteolin-7-*O*-glucoside dissolved in transport medium were then added to the apical side of the cells at specified total concentrations. After incubation of the cells at 37 °C for the required times, the cell culture media from both compartments (apical and basal) were collected for investigation of the bioavailability.

Sample Preparation for HPLC and LC-MS Analysis. The collected plasma samples and medium samples with or without enzymatic deconjugation were treated as described below for determination of luteolin, luteolin glucoside, and conjugated metabolites using HPLC and LC-MS. Individual samples were divided into two aliquots. To hydrolyze conjugated luteolin metabolites, one aliquot of plasma sample was treated with *H. pomatia* β-glucuronidase type H-5 (200 U), which possesses β-glucuronidase, sulfatase, and glucosidase activities, and then incubated at pH 5.0 for 45 min at 37 °C in 0.5 M acetate buffer. Similarly, one aliquot of medium sample was treated with limpet β-glucuronidase type L-II (400−1400 U), which possesses β-glucuronidase and glucosidase activities in 0.1 M phosphate buffer (pH 5.0), and then incubated at pH 5.0 for 45 min at 37 °C in 0.1 M phosphate buffer. The resulting mixtures were acidified with an equivalent amount of 0.01 M oxalic acid. These conditions and the enzyme mixtures yielded the highest amounts of free luteolin from the plasma of *C. morifolium* flower extract-treated rats and from the medium treated with the *C. morifolium* flower extract, luteolin, and luteolin-7-*O*-glucoside in preliminary analyses. The other portions of the plasma and medium samples were retained without hydrolysis by β-glucuronidase and used for direct quantification of nonconjugated metabolites. These samples were also acidified with 0.01 M oxalic acid. After acidification, the hydrolyzed and unhydrolyzed samples were each mixed with myricetin as an internal standard and applied to a Sep-Pak C18 cartridge (Waters, Milford, MA, USA), which had been pretreated by passage with methanol. The cartridge was washed with 0.01 M oxalic acid, distilled water/methanol/0.5 M oxalic acid (88:10:2), and distilled water, and the methanol eluate was obtained. The eluate was evaporated to dryness, and the residue was dissolved in 20% acetonitrile/0.5% phosphoric acid for HPLC analysis and in methanol for LC-MS, respectively. After filtration (0.45 μm filter unit), the filtrate was applied to HPLC and LC-MS analysis.

HPLC Analysis. The sample was injected into an HPLC-electrochemical detection (ECD) system (model 5600A CA767 CoulArray Detector; ESA, Cambridge, MA, USA) equipped with a CAP CELL PAK C18 UG120 column (S-5 μm, 4.6 mm i.d. × 150 mm; Shiseido, Tokyo, Japan). The separation of the compounds was carried out by gradient elution. For detection of luteolin and luteolin-7-*O*-glucoside using the HPLC-ECD system, two gradient systems were employed. For system 1, solvent A was 20% acetonitrile/0.5% phosphoric acid and solvent B was 40% acetonitrile/0.5% phosphoric acid. The gradient program was as follows: 0−5 min, 0% B; 5−15 min, linear gradient to 100% B; 15−19 min, 100% B hold; 19−22 min, linear gradient to 0% B; flow rate, 0.8 mL/min. For system 2, solvents A and B were the same as in system 1, respectively, and the gradient program was as follows: 0−10 min, 0% B; 10−16 min, linear gradient to 10% B; 16−21 min, 10% B hold; 21−30 min, linear gradient to 25% B; 30−35 min, 25% B hold; 35−40 min, linear gradient to 50% B; 40−43 min, 50% B hold; 43−48 min, linear gradient to 100% B; 48−50 min, 100% B hold; 50−55 min, linear gradient to 0% B; flow rate, 0.8 mL/min. Electrochemical detection was performed with a coulometric electrode at 150 mV (for channel 1) and 200 mV (for channel 2).

LC-MS Analysis. For LC-MS analysis, the samples were injected onto Q Exactive (Thermo Fisher Scientific, Waltham, MA, USA). The mass spectrometer was operated in the negative-ion ESI mode with targeted selected ion monitering (SIM) mode for all LC-MS analytes. The samples were separated by UPLC (Accela; Thermo Fisher Scientific) equipped with an ACQUITY UPLC BEH C18 column (1.7 μm, 2.1 mm i.d. × 100 mm; Waters). Gradient elution was performed using a two-solvent system (solvent A, 0.1% formic acid; solvent B, acetonitrile containing 0.1% formic acid). The gradient program was as follows: 0−1 min, 2% B hold; 1−15 min, linear gradient to 98% B; flow rate, 0.3 mL/min.

RESULTS

Time-Dependent Changes in the Plasma Concentrations of Luteolin after Oral Administration of the *Chrysanthemum* Flower Extract. We quantified luteolin and luteolin-7-*O*-glucoside using HPLC-ECD, and representative

DOI: 10.1021/acs.jafc.5b00232
J. Agric. Food Chem. 2015, 63, 7693−7699

chromatograms for luteolin, luteolin-7-*O*-glucoside, and myricetin (internal standard) are shown in the Supporting Information (Supplemental Figure 1A). The peaks of luteolin, luteolin-7-*O*-glucoside, and myricetin were observed at 17.767, 11.167, and 14.733 min, respectively, using the system 1 program. On the basis of the analysis using this system, 1 g of *Chrysanthemum* flower extract contained luteolin and luteolin-7-*O*-glucoside at 13.4 and 34.3 μmol, respectively, giving 47.7 μmol of total luteolin in 1 g of the *Chrysanthemum* flower extract. To measure the total content of luteolin derivatives in plasma, we treated plasma samples with *H. pomatia* β-glucuronidase type H-5, which has hydrolysis activity against glucuronides and sulfates, and confirmed that this enzyme altered luteolin-7-*O*-glucoside to luteolin in preliminary analyses (data not shown).

We examined the time-dependent changes (0.5, 1, 2, 3, and 6 h) in the plasma luteolin concentration in rats administered the *Chrysanthemum* flower extract at 1.64 g/kg bw, equivalent to 81 μmol of total luteolin (Figure 1). In this experiment, the levels

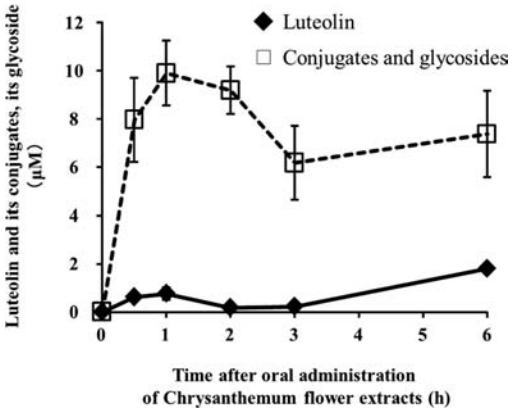

Figure 1. Time-dependent changes in luteolin derivatives in plasma from rats after oral administration of the *Chrysanthemum* flower extract. The concentrations of luteolin and its conjugates were measured in rat plasma after oral administration of the *C. morifolium* flower extract (1.7 g/kg body weight), equivalent to luteolin (22.8 μmol/kg body weight) and luteolin-7-*O*-glucoside (58.3 μmol/kg body weight). Plasma samples were treated with *H. pomatia* β-glucuronidase type H-5, which has hydrolysis activity against glucuronides, sulfates, and glucoside under the present experimental conditions. Thus, the glycosides and conjugates of luteolin were altered to luteolin aglycone. Data represent means ± SE (n = 4).

of free luteolin in plasma increased rapidly at 0.5 h after administration and reached the peak level at 1 h (0.76 ± 0.27 μM). Thereafter, the level of luteolin decreased at 2 h after administration, but increased again at 6 h (1.79 ± 0.17 μM). Meanwhile, the level of conjugated luteolin and luteolin-7-*O*-glucoside in plasma increased rapidly at 0.5 h after administration and reached the peak level at 1 h (9.88 ± 1.35 μM). Thereafter, the level of conjugated luteolin and luteolin-7-*O*-glucoside decreased but also increased again at 6 h after administration (7.35 ± 1.79 μM).

We presumed that the metabolites of luteolin and luteolin-7-*O*-glucoside included luteolin monoglucuronide, luteolin glucoside glucuronide, luteolin diglucuronide, luteolin glucoside sulfate, and luteolin glucuronide sulfate. The presence of these metabolites was confirmed by LC-MS in a qualitative manner. Figure 2A shows the mass chromatogram and mass spectrum of a rat plasma sample obtained 2 h after oral administration of the *Chrysanthemum* flower extract. Compared with the corresponding standard, luteolin-7-*O*-glucoside was identified in the plasma sample at 6.63 min (m/z 449.1033−449.1123). Meanwhile, as shown in Figure 2B, a prominent peak was observed at 6.73 min (m/z 463.0825−463.0917). This peak was possibly one of the presumed conjugates, luteolin monoglucuronide (MW 462.36). The other presumed conjugated metabolites were below the measurable limits.

Changes in Luteolin, Luteolin-7-*O*-glucoside, and Their Conjugated Metabolites in Caco-2 Cells Treated with the *Chrysanthemum* Flower Extract. To investigate the bioavailability in vitro, the *Chrysanthemum* flower extract was applied to the apical side (0.5 mL) of Caco-2 monolayers at a concentration equivalent to 5.0 nmol of total luteolin. As shown in Figure 3A, luteolin-7-*O*-glucoside decreased in the apical solution with incubation time (luteolin, from 0.50 ± 0.24 to 0.09 ± 0.02 nmol/well; luteolin-7-*O*-glucoside, from 4.22 ± 0.65 to 2.62 ± 0.45 nmol/well). Conjugated forms of luteolin in the apical solution appeared at 0.5 h, and their contents tended to increase in a time-dependent manner (from 1.00 ± 0.82 to 1.67 ± 0.65 nmol/well). As shown in Figure 3B, luteolin and luteolin-7-*O*-glucoside increased in the basolateral solution with incubation time (luteolin-7-*O*-glucoside, from 0.006 ± 0.001 to 0.016 ± 0.003 nmol/well; luteolin conjugates, from 0.013 ± 0.010 to 0.052 ± 0.009 nmol/well). Luteolin aglycone in the basolateral solution appeared at 0.5 h (0.016 ± 0.002 nmol/well) and was increased at 2 h (0.056 ± 0.005 nmol/well).

We presumed that the metabolite profile was the same as that observed in the animal experiments. Thereafter, the basolateral solution after 4.0 h of incubation was applied to LC-MS for qualitative analysis. Luteolin-7-*O*-glucoside was identified in the basolateral solution at 6.27 min (m/z 449.1033−449.1123) as shown in Supplemental Figure 2. Meanwhile, as shown in Supplemental Figure 3, prominent peaks were observed at 6.30, 6.78, and 6.97 min (m/z 463.0825−463.0917) and were possibly those of luteolin monoglucuronide (MW 462.36). Luteolin possesses four hydroxyl groups at the 3′-, 4′-, 5-, and 7-positions, and they are available for glucuronidation. Therefore, four types of luteolin monoglucuronides could possibly exist, and these prominent peaks were thought to be three of these monoglucuronides. Because each authentic sample was not commercially available, it was unclear which position of luteolin is a glucuronidation site at the present time. The other presumed conjugated metabolites were below the measurable limits.

Changes in Luteolin, Luteolin-7-*O*-glucoside, and Their Conjugated Metabolites in Caco-2 Cells Treated with Luteolin and Luteolin-7-*O*-glucoside. After luteolin was applied to the apical side of Caco-2 monolayers at the concentration of 10 μM, equivalent to 5.0 nmol of luteolin, both the apical and basolateral solutions were collected. In the apical solution, luteolin aglycone decreased in a time-dependent manner from 3.38 ± 0.22 to 1.40 ± 0.14 nmol/well, and luteolin conjugates tended to increase fom 1.18 ± 0.60 to 1.36 ± 0.34 nmol/well (Figure 4A). In the basolateral solution, luteolin aglycone appeared at 0.5 h (0.95 ± 0.27 nmol/well) and decreased to 0.62 ± 0.10 nmol/well with incubation time (Figure 4B). After application of luteolin-7-*O*-glucoside to the apical side, the detected luteolin-7-*O*-glucoside in the apical solution decreased to 3.66 ± 0.31 nmol/well at 4 h (Figure 5A). Luteolin aglycone tend to increase from 0.08 ± 0.01 to

J. Agric. Food Chem. 2015, 63, 7693−7699

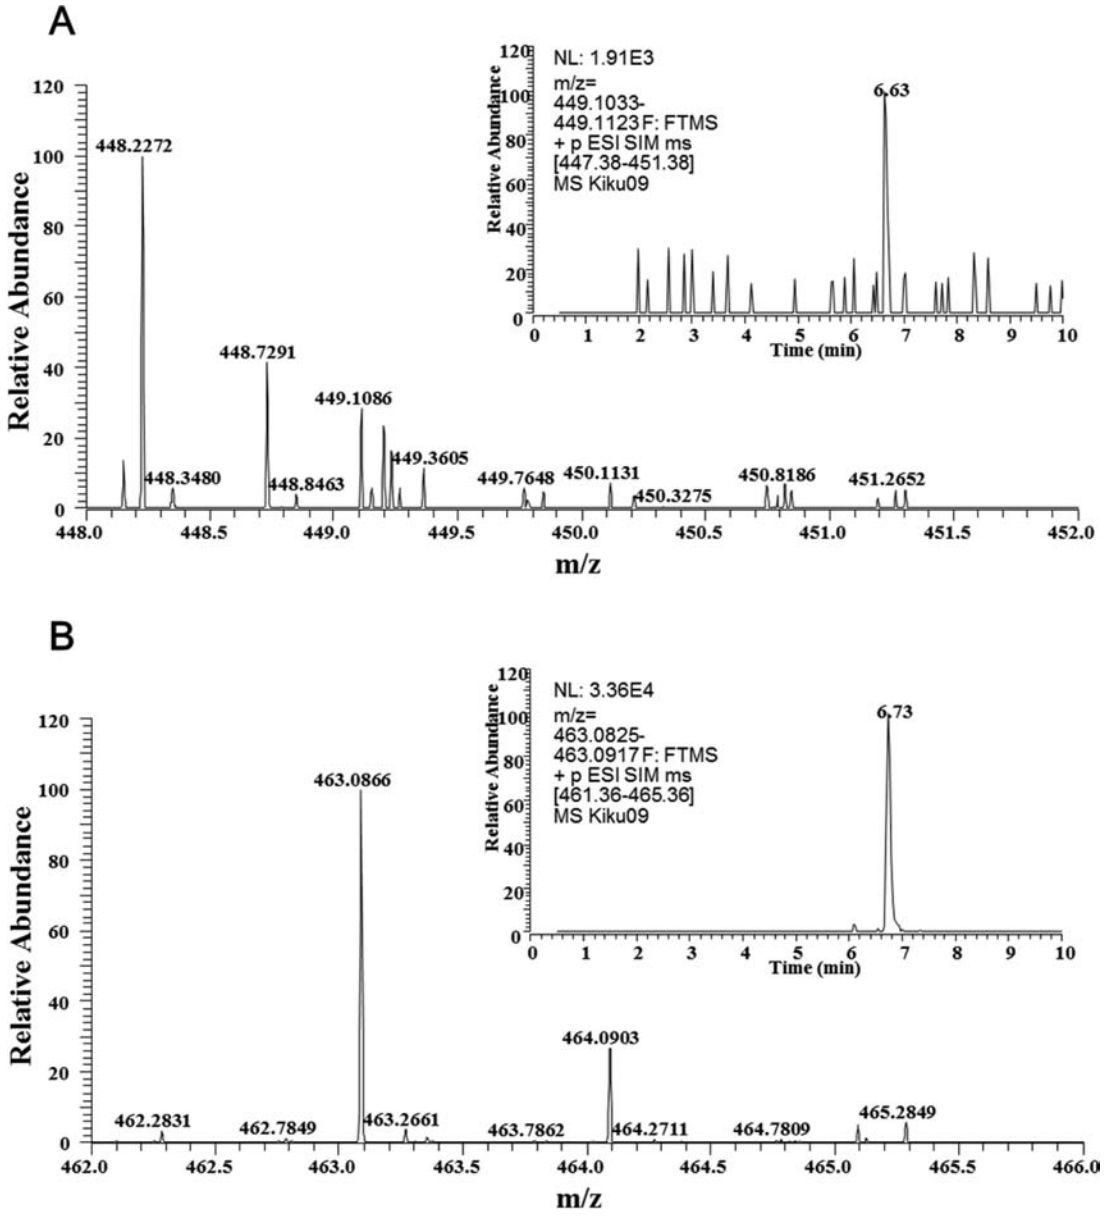

Figure 2. Mass chromatogram and mass spectrum of luteolin-7-*O*-glucoside (A) and luteolin monoglucuronide (B) in plasma from rats 2 h after administration of the *Chrysanthemum* flower extract: (A) mass chromatogram (*m*/*z* 449.1033−449.1123) and mass spectrum (time = 6.63 min); (B) mass chromatogram (*m*/*z* 463.0825−463.0917) and mass spectrum (time = 6.73−6.76 min).

0.12 ± 0.01 nmol/well in a time-dependent manner, and luteolin conjugates were not detected. As shown in Figure 5B, luteolin-7-*O*-glucoside, luteolin, and luteolin conjugates in the basolateral solution tend to increase in a time-dependent manner (luteolin-7-*O*-glucoside, from 0.052 ± 0.014 to 0.125 ± 0.030 nmol/well; luteolin, from 0.006 ± 0.001 to 0.018 ± 0.023 nmol/well; luteolin conjugates, from 0.006 ± 0.014 to 0.018 ± 0.023 nmol/well).

The basolateral solution after 1.0 h of incubation was obtained and applied to LC-MS for qualitative analysis. As shown in Supplemental Figure 4A, luteolin-7-*O*-glucoside was identified in the basolateral solution at 6.09 min (*m*/*z* 449.1033−449.1123). The peak of luteolin monoglucuronide was observed at 6.30 min (*m*/*z* 463.0825−463.0917; Supplemental Figure 4B). The other presumed conjugated metabolites were below the measurable limits.

DISCUSSION

The *Chrysanthemum* flower extract used in the present study contained luteolin and luteolin-7-*O*-*β*-glucoside. The data obtained with rats administered the *Chrysanthemum* flower extract showed that luteolin, luteolin glucuronide, and luteolin-7-*O*-*β*-glucoside were detected in plasma (Figures 1 and 2). Chen et al.[20] reported that luteolin was detected in the deconjugated plasma and urine samples when rats were administered a *Chrysanthemum* flower extract. Li et al.[25] showed that luteolin was detected in human plasma treatment with deconjugating enzyme after administration of a *Chrysanthemum* flower extract. In this study, we find results partly consistent with the knowledge reported previously because luteolin and luteolin glucuronide were detected, and we also newly found that luteolin glucoside can circulate without conjugation.

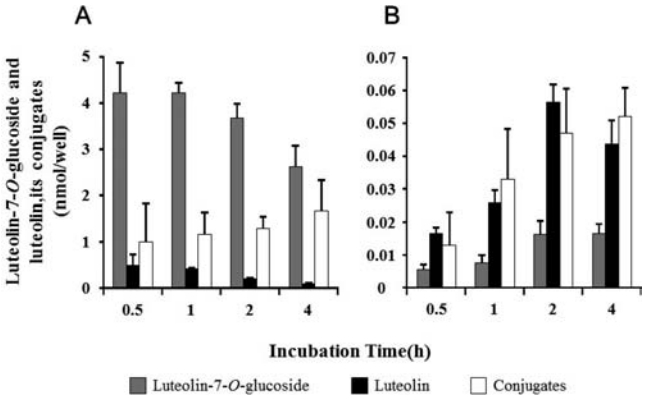

Figure 3. Amounts of luteolin derivatives in culture media from Caco-2 cells treated with the *Chrysanthemum* flower extract. Luteolin-7-*O*-glucoside, luteolin, and its conjugates in the apical solution (A) and basolateral solution (B) of Caco-2 cells treated with the *Chrysanthemum* flower extract, equivalent to luteolin (2.81 μM) and luteolin-7-*O*-glucoside (7.19 μM), are shown. The culture media were treated with limpet β-glucuronidase type L-II, which possesses β-glucuronidase and glucosidase activities in 0.1 M phosphate buffer (pH 5.0), and the conjugates of luteolin were altered to luteolin aglycone. Data represent means ± SD (n = 4−5).

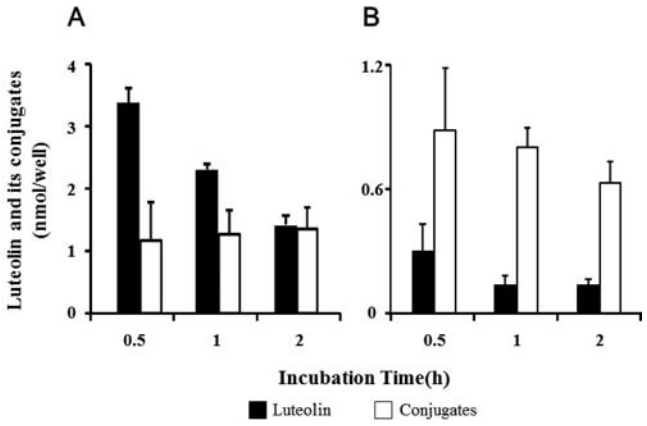

Figure 4. Amounts of luteolin derivatives in culture media from Caco-2 cells treated with luteolin. Luteolin and its conjugates in the apical solution (A) and basolateral solution (B) of Caco-2 cells treated with luteolin (10 μM) are shown. The culture media were treated with β-glucuronidase/sulfatase, and conjugates of luteolin were altered to luteolin aglycone. Data represent means ± SD (n = 5−6).

Glycosylated flavonoids are generally deglycosylated by luminal LPH and/or cleavage within the enterocytes by cytosolic β-glucosidase or bacterial flora in the intestine, followed by diffusion passively across the small intestine brush border.[12−15] According to Shimoi et al.,[26] aglycones of luteolin including the metabolite from the luteolin glycosides were absorbed without any conjugation or converted to glucuronides in the enterocytes of the digestive tract, leading to the appearance of luteolin and glucuronide conjugates in the circulatory system of rats and human. Thus, we showed that luteolin, luteolin glucoside, and luteolin monoglucuronide were detected, and these suggested the possibility that luteolin aglycone and glucoside might be absorbed and circulated with or without conjugation after administration of a *Chrysanthemum* flower extract, partly in agreement with the reported mechanism. Meanwhile, luteolin-7-*O*-glucoside was possibly absorbed also in other mechanisms through SGLT. Yin et al.[27]

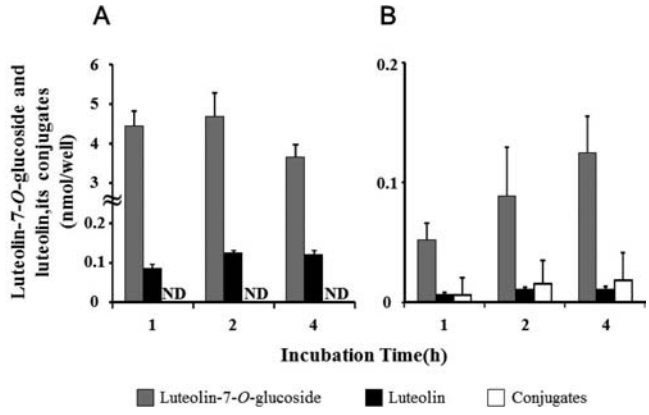

Figure 5. Amounts of luteolin derivatives in culture media from Caco-2 cells treated with luteolin-7-*O*-β-glucoside. Luteolin-7-*O*-glucoside, luteolin, and its conjugates in the apical solution (A) and basolateral solution (B) of Caco-2 cells treated with luteolin-7-*O*-β-glucoside (10 μM) are shown. The culture media were treated with β-glucuronidase/sulfatase, and conjugates of luteolin were altered to luteolin aglycone. Data represent means ± SD (n = 4−5).

investigated the metabolites in rats after administration of an *Ixeris sonchifoliain* (Bge.) extract, containing luteolin glucuronide and luteolin glucoside. They described that the glucuronide and glucoside of luteolin were detected in rat plasma, and a part of the luteolin-7-*O*-β-glucoside, which was not hydrolyzed by LPH and enterobacteria, was possibly absorbed through SGLT1 on the surface of intestinal cells, followed by its appearance in the plasma without conjugation.

As shown in Figure 1, the concentration of luteolin in rat plasma increased to the first and second peak levels at 1 and 6 h (0.76 ± 0.27 and 1.79 ± 0.17 μM), respectively, after dosing with the *Chrysanthemum* flower extract. Conjugated flavonoids are the substrates of efflux transporters (such as MPR2) and can be excreted to the bile and lumen, a phenomenon known as enterohepatic recycling.[20,25,28] This system may entail the reconversion of conjugates that are excreted by efflux transporters with subsequent hydrolysis by intestinal microflora and re-uptake. Otherwise, as described above, flavonoid glycoside is hydrolyzed to its aglycone by LPH in intestinal brush border cells and enterobacteria, and its aglycone is metabolized into conjugates.[12−15] Thus, we further proposed that the conjugates from the glycoside may appear later than those from the aglycone. These results were supported by the case of quercetin glycoside, and they showed that the concentrations of quercetin in rat plasma increased to the first and second peak levels at 30 min and 8 h, respectively, after dosing with αG-rutin, which consists of 4G-α-D-glucopyranosyl rutin and isoquercitrin.[29] However, because the mechanism remains unclear, and to elucidate this phenomena and underlying mechanisms in detail and confirm this speculation, further investigations focusing on kinetic bioavailability are required.

When differentiated Caco-2 cells were treated with the *Chrysanthemum* flower extract, luteolin aglycone, glucoside, and conjugates were detected in basolateral solution (Figure 3) as well as in the plasma from rat after administration of this extract, and luteolin conjugate and glucoside tend to increase in a time-dependent manner in the basolateral solution. Meanwhile, luteolin increased from 0.5 to 2 h there and decreased at 4 h, possibly because luteolin passed from the apical side to the basolateral side through the inside or tight junction of cells, and

DOI: 10.1021/acs.jafc.5b00232
J. Agric. Food Chem. 2015, 63, 7693−7699

luteolin was absorbed in cells again. After the differentiated Caco-2 cells were treated with luteolin-7-*O*-glucoside, luteolin glucoside in the apical solution decreased at 4 h, whereas luteolin aglycone tended to increase in a time-dependent manner and conjugates were not detected (Figure 5A). Previously, Chantret et al.[30] and Faria et al.,[31] reported that LPH was expressed in Caco-2 cells. Thus, we suggested the possibility that a part of the luteolin glucoside was hydrolyzed by LPH and that one part of the aglycone was not absorbed and accumulated in the apical solution, whereas the other part was absorbed into cells and secreted into the basolateral solution. Otherwise, Mukinda et al.[32] showed the possibility that luteolin-7-*O*-glucoside could be detected in the basolateral solution because the glucoside was absorbed through SGLT1 or passed through the intracellular tight junctions; this is in agreememt with the case in rat as described above. Therefore, the aglycone appeared in the basolateral solution (Figure 5B) and also because the glycoside from the absorbent through SGLT1 was hydrolyzed by intracellular glucosidase. This aglycone might be converted to conjugates detected in the basolateral solution. After treatment with luteolin in Caco-2 cells, luteolin was simply absorbed and conjugated as reported as the general mechanisms of flavonoid metabolism.[19] These results suggest that luteolin and luteolin glycoside from the *Chrysanthemum* flower extract might be absorbed and metabolized in the intestine.

Taken together, administration of the *Chrysanthemum* flower extract to rats and treatment-differentiated Caco-2 cells led to the detection of luteolin, luteolin glucoside, and luteolin glucuronide in the plasma and basolateral solution, respectively. Thus, when a *Chrysanthemum* flower extract is administered to humans, it is possible that luteolin glucoside is absorbed in the intestine without conjugation and circulated. Luteolin glucoside as well as luteolin have various beneficial effects.[5,6,30] In addition, as our group[31] showed, glucuronidase is released from stimulated neutrophils or certain injured cells, and subsequently deglucuronidates conjugated luteolin derivatives during inflammation. Thus, administration of the *C. morifolium* flower extract might possibly improve human health, and elucidation of the absorption and metabolism in humans should be clarified to assess the efficacy of this extract.

In conclusion, we showed that luteolin and luteolin monoglucoside were quickly absorbed into the plasma or basolateral solution and existed as the aglycone, monoglucoside, and monoglucuronide after administration of the *C. morifolium* flower extract to rats and differentiated Caco-2 cells. As described above, luteolin, luteolin glucoside, and glucuronide can exert biological functions in the human body.[5,6,33,34] The concentrations of these compounds in plasma also showed a secondary increase, meaning that intake of the *C. morifolium* flower extract led to retention of these compounds in the circulatory system for a long time.

into bile can be hydrolyzed to aglycones by intestinal bacteria, which have β-glucuronidase and arylsulfatase. The phase II conjugation of luteolin has been proven by the treatment of deconjugation with hydrochloric acid or β-glucuronidase/sulfatase. The concentrations of luteolin of samples hydrolyzed by hydrochloric acid and a mixture of β-glucuronidase and sulfatase were much higher than those in untreated samples.[13] The results suggested that sulfuric acid/glucuronic acid conjugates of luteolin are the major metabolites.[14] In addition, *O*-methylation is one of the metabolic pathways for the production of luteolin via catechol-*O*-methyltransferase (COMT) to produce chrysoeriol (3-*O*-methylation of luteolin) and diosmetin (4-*O*-methylation of luteolin).[15,16]

A previous report indicated that apigenin-7-*O*-glucoside can be enzymatically hydrolyzed to produce apigenin through β-glucosidase.[17,18] However, the metabolic mechanism of luteolin and luteolin-7-*O*-glucoside production is not entirely understood. In the present study, we first uncover that the flower of *D. morifolium* is a rich source of luteolin and luteolin-7-*O*-glucoside. To identify these two compounds from ethanolic and water extracts, the techniques of nuclear magnetic resonance (NMR), ^{1}H NMR and ^{13}C NMR, and mass spectrometry were used. Our hypothesis is that the luteolin-7-*O*-glucoside can be enzymatically hydrolyzed to produce luteolin by intestinal β-glucosidase, and then this is absorbed into the blood for circulation. To examine the pharmacokinetic mechanisms of luteolin and luteolin-7-*O*-glucoside, a parallel set of experiments was designed to study the effects of oral and intravenous administration of luteolin (10 mg/kg, iv; 100 mg/kg, po) and luteolin-7-*O*-glucoside (10 mg/kg, iv; 1 g/kg, po).

MATERIALS AND METHODS

Chemicals and Reagents. Luteolin and luteolin-7-*O*-glucoside were purified and isolated from the ethanolic extract of *D. morifolium* in our laboratory. HPLC grade methanol, acetonitrile, orthophosphoric acid (85%), and dimethyl sulfoxide were purchased from E. Merck (Darmstadt, Germany). Apigenin, apigenin-7-*O*-glucoside, and heparin were provided by Sigma-Aldrich Chemicals (St. Louis, MO, USA) and stored at room temperature. Triple-deionized water from Millipore (Bedford, MA, USA) was prepared for all aqueous solutions.

Isolation of Luteolin and Luteolin-7-*O*-glucoside. The flowers of *D. morifolium* were purchased from a drug store in Taipei, Taiwan, and identified by Dr. Lie-Chwen Lin, National Research Institute of Chinese Medicine, Taiwan. A voucher specimen (NHP-00861) has been deposited in the herbarium of the National Research Institute of Chinese Medicine. The dried flowers of *D. morifolium* (5.8 kg) were extracted with ethanol (40 L × 3), and the combined extract was evaporated under a vacuum for the EtOH extract. The ethanolic extract was partitioned successively between H_2O and EtOAc, followed by *n*-BuOH (each 1.5 L × 3). The resulting EtOAc fraction was separated on a Sephadex LH-20 column using MeOH for elution to produce 11 fractions, EA1−EA11. Fraction EA9 (2.4 g) was further purified on a Sephadex LH-20 column using acetone to give luteolin. The *n*-BuOH extract was suspended in $CHCl_3$. Throughout the filtration steps, the precipitates from the suspension were collected. The collected precipitates were dissolved in MeOH and subjected to Sephadex LH-20 with eluent of MeOH to obtain luteolin-7-*O*-glucoside. These isolated compounds were identified by spectral analysis and compared with the published literature.[19]

Spectroscopic Analysis. ^{1}H and ^{13}C NMR spectra were measured with a Varian Unity Inova-500 spectrometer with deuterated solvents (methanol-d_4, DMSO-d_6; Cambridge Isotope Laboratories, Tewksbury, MA, USA) as internal standards. The electrospray ionization technique used in mass spectrometry (ESIMS) was recorded on a Shimadzu LCMS-8030 mass spectrometer (Shimadzu, Kyoto, Japan).

Luteolin: light yellow powder; ^{1}H NMR (CD_3OD, 500 MHz) δ 6.19 (1H, d, *J* = 2.0 Hz, H-6), 6.42 (1H, d, *J* = 2.0 Hz, H-8), 6.52 (1H, s, H-3), 6.88 (1H, d, *J* = 8.5 Hz, H-5′), 7.36 (2H, m, H-2′, H-6′); ^{13}C NMR (CD_3OD, 125 MHz) δ 95.0 (C-8), 100.1 (C-6), 103.9 (C-3), 105.3 (C-10), 114.1 (C-2′), 116.8 (C-5′), 120.3 (C-6′), 123.7 (C-1′), 147.0 (C-3′), 151.0 (C-4′), 159.4 (C-9), 163.2 (C-5), 166.0 (C-2), 166.4 (C-7), 183.9 (C-4); ESIMS *m*/*z* 287 $[M + H]^+$.

Luteolin-7-O-glucoside: yellow powder; ^{1}H NMR (DMSO-d_6, 500 MHz) δ 5.05 (1H, d, *J* = 7.5 Hz, H-1″), 6.43 (1H, d, *J* = 2.0 Hz, H-6), 6.73 (1H, s, H-3), 6.78 (1H, d, *J* = 2.0 Hz, H-8), 6.89 (1H, d, *J* = 8.5 Hz, H-5′), 7.40 (1H, d, *J* = 2.0 Hz, H-2′), 7.43 (1H, dd, *J* = 8.5, 2.0 Hz, H-6′); ^{13}C NMR (DMSO-d_6, 125 MHz) δ 60.8 (C-6″), 69.7 (C-4″), 73.2 (C-2″), 76.5 (C-3″), 77.3 (C-5″), 94.9 (C-8), 99.7 (C-6), 100.1 (C-1″), 103.3 (C-3), 105.5 (C-10), 113.6 (C-2′), 116.1 (C-5′), 119.4 (C-6′), 121.5 (C-1′), 145.9 (C-3′), 150.1 (C-4′), 157.1 (C-9), 161.2 (C-5), 163.1 (C-7), 164.6 (C-2), 182.1 (C-4); ESIMS *m*/*z* 449 $[M + H]^+$.

HPLC-MS/MS Parameters. The HPLC-MS/MS system consisted of an LCMS-8030 triple-quadrupole mass spectrometer (Shimadzu) equipped with an electrospray ionization interface and coupled to a Shimadzu LC-20AD HPLC system. The HPLC system was equipped with two pumps, a system controller, an autosampler, a column oven, and an online degasser. Chromatographic separation of analytes was carried out using an Acquity BEH C_{18} column (100 × 2.1 mm, particle size = 1.7 mm; Waters, Ireland). The column temperature was maintained at 35 °C.

The mobile phase (A, 0.01% formic acid in deionized water; B, 0.01% formic acid in 100% methanol) was eluted at a flow rate of 0.2 mL/min. The gradient started at 50% of mobile phase B and was linearly run to 90% B over 3 min. Subsequently, the eluent composition was maintained for 3 min before it was decreased to 50% of mobile phase B. Then, the gradient was returned to the initial condition (50% B) in 1 min and equilibrated for 1 min. The total run time was 8 min, and the injection volume was 5 μL. The electrospray ion source was operated in positive ionization mode for the two compounds. The other parameters were as follows: DL temperature, 250 °C; heat block temperature, 400 °C; nebulizing gas flow, 3.0 L/min; drying gas flow, 15 L/min; CID gas, 230 kPa.

Animal Experiments. Adult male Sprague−Dawley rats were purchased from the laboratory Animal Center of National Yang-Ming University (Taipei, Taiwan). All animal experiments followed National Yang-Ming University guidelines and procedures. The protocol for this animal study has been approved by the Institutional Animal Care and Use Committee (IACUC, approval no. 990511) by the Institutional Animal Experimentation Committee of National Yang-Ming University.

Before surgery, the rats were allowed free access to food and water at all times. A conscious, freely moving rat model was used to minimize the stress caused by restraint or anesthesia and to simulate the pharmacokinetics in conscious states. During surgery, the rats were anesthetized with pentobarbital (50 mg/kg, ip); for the rats in the intravenous group, a polyethylene tube was implanted in the right jugular vein for blood sampling and in the left femoral vein for drug administration. The tubes crossed the subcutaneous tissue and were fixed at the dorsal neck region. The polyethylene tubes were filled with heparinized saline (20 units/mL) to prevent coagulation. After surgery, the rats were placed in experimental cages for 1 day until recovery from anesthesia. Food was not given for 12 h, and water was available at any time.

HPLC−Photodiode Array System and Sample Preparation. The HPLC system consisted of chromatographic pumps (LC-20AT; Shimadzu), an autosampler (SIL-20AC; Shimadzu), and a photodiode array detector (SPD-M20A; Shimadzu). All analytical samples were separated using a phenyl-hexyl column (150 mm × 4.6 mm i.d.; particle size = 5 μm, Phenomenex Luna, Torrance, CA, USA). The mobile phase of HPLC analysis consisted of two solvent compositions: 0.05 M NaH_2PO_4 and acetonitrile of 80:20, v/v, and 70:30, v/v, for luteolin and luteolin-7-*O*-glucoside, respectively. The pH of 0.05 M NaH_2PO_4 was adjusted to 2.6 by using orthophosphoric acid (85%). The flow rate for the mobile phase was set at 1.0 mL/min. The

DOI: 10.1021/jf505848z
J. Agric. Food Chem. 2015, 63, 7700−7706

temperature in the autosampler was set at 8 °C, the analytical volume was 20 μL of each sample, and the photodiode array detector was monitored at 350 nm.

The resulting plasma sample (100 μL) was mixed with 200 μL of internal standard solution (0.2 μg/mL dissolved in acetonitrile) for protein precipitation. The mixture was centrifuged at 13000*g* for 15 min at 4 °C. The supernatant was evaporated to dryness at 40 °C using a centrifugal evaporator. The dried residue was reconstituted in 100 μL of 20% acetonitrile and filtered by a 0.22 μm filter. An aliquot (20 μL) of the filtrate was applied to the HPLC system for analysis.

Method Validation of Linearity, Accuracy, and Precision. The process of method validation serves to demonstrate that the specific method used for quantification of an analyte in a particular biological sample is reliable and reproducible. Calibration standards were prepared from stock solutions of luteolin or luteolin-7-*O*-glucoside and then added into blank plasma to construct the spiked samples with concentrations of 1, 5, 10, 25, 50, 75, and 100 μg/mL. The standard stock solution of luteolin or luteolin-7-*O*-glucoside (1 mg/mL) was prepared in methanol, and working standard solutions were diluted using 50% (v/v) methanol. These spiked samples were processed as described under Materials and Methods, HPLC–Photodiode Array System and Sample Preparation.

The calibration curve was constructed from the peak area ratio of luteolin and luteolin-7-*O*-glucoside and their corrected internal standards of apigenin and apigenin-7-*O*-glucoside. The coefficient correlation values (r^2) of all calibration curves were required to be at least 0.995.

Six replications of the calibration curve were measured on the same day (intraday) for six continuous days (interday) to evaluate the precision and accuracy of this analytical method. The measure of accuracy describes the proximity of mean results (observed concentration, C_{obs}) from this analytical method to the true concentrations (nominal concentration, C_{nom}). The accuracy could be presented as bias, calculated as follows: bias (%) = $[(C_{obs} - C_{nom})/C_{nom}] \times 100$. The measure of precision represents the closeness of each individual analytical result. The precision, which could be quantified as relative standard deviation (RSD), was calculated as follows: RSD (%) = [standard deviation (SD)/C_{obs}] × 100.

The mean values for the accuracy and the precision must be within 15% of the actual value, except at the LLOQ, where it must not exceed the value by >20%. The method validation for this study was performed according to the guidance given by the U.S. Food and Drug Administration.[20]

Drug Administration. *Oral Administration of Luteolin or Luteolin-7-O-glucoside.* Pentobarbital sodium solution (50 mg/kg) was used to anesthetize rats via intraperitoneal administration. Surgical sites were shaved and cleaned with 70% ethanol solution. Then, the right jugular vein was catheterized with polyethylene tubing for blood sampling. The catheter was guided under the skin to the dorsal neck region and fixed.[21] After surgery, the rats were allowed to recover in a clean cage for at least 24 h before drug administration.

After the stabilization period, luteolin and luteolin-7-*O*-glucoside dissolved in dimethyl sulfoxide/water (1:1) were orally administered to the rats (n = 6) at doses of 100 mg/kg and 1 g/kg, respectively. A 250 μL blood sample was collected from the jugular vein at 0, 5, 15, 30, 60, 90, 120, 180, 240, and 360 min after drug administration. Blood samples were centrifuged at 8000*g* for 10 min at 4 °C to obtain plasma, and the resulting plasma was stored at −20 °C prior to analysis.

Pharmacokinetic Analysis and Statistics. Pharmacokinetic parameters, including maximum plasma concentration (C_{max}), time to reach the maximum concentrations (t_{max}), half-life ($t_{1/2}$), area under concentration–time curve (AUC), and oral clearance (CL), were estimated by a noncompartmental analysis using the pharmacokinetic program WinNonlin Standard Edition version 1.1 (Scientific Consulting, Apex, NC, USA). The bioavailability was calculated according to the following equation: bioavailability (%F) = $(AUC_{po}/dose_{po})/(AUC_{iv}/dose_{iv}) \times 100\%$. All results were expressed as the average mean ± standard deviation (SD). The statistical analyses were calculated using SPSS version 10.0 (SPSS, Chicago, IL, USA). Student's t test was used to compare the differences between groups, and a value of $P < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Isolation and Identification of Luteolin and Luteolin-7-*O*-glucoside. The luteolin-7-*O*-glucoside content was 4.19 and 6.56% in ethanolic and water extracts, respectively. However, the luteolin content was 0.19% in the ethanolic extract, and luteolin was not detected in the water extract. Luteolin was obtained as a light yellow powder. The ^{1}H spectrum of luteolin revealed the presence of a pair of meta-coupled aromatic protons (δ_H 6.19/6.42), an aromatic singlet (δ_H 6.52), and ABC-coupled aromatic protons (δ_H 6.88/7.35/7.36). In combination with the ^{13}C NMR data, which showed signals for a carbonyl group at δ_C 183.9 (C-4), six oxygenated quaternary carbons (δ_C 147.0, 151.0, 159.4, 163.2, 166.0, and 166.4), two sp^2 quaternary carbons (δ_C 105.3 and 123.7), and six sp^2 tertiary carbons (δ_C 95.0, 100.1, 103.9, 114.1, 116.8, and 120.3), and the ESIMS data, we were able to identify the molecules of luteolin[19] (Supporting Information, Figures S1 and S2).

When the ^{1}H spectrum of luteolin-7-*O*-glucoside was compared with that of luteolin, a difference was observed in the aliphatic region where there was an additional glucosyl moiety (δ 5.05/3.17–3.70) in luteolin-7-*O*-glucoside. This region was also associated with the ^{13}C NMR signals of luteolin-7-*O*-glucoside at δ_C 60.8, 69.7, 73.2, 76.5, 77.3, and 100.1 (Supporting Information, Figures S3 and S4). The ESIMS revealed the molecular ion at m/z 447 $[M - H]^-$, which is consistent with the molecular formula $C_{21}H_{20}O_{11}$. Upon further comparison with our previous study,[19] we were able to confirm the chemical structures of luteolin-7-*O*-glucoside and luteolin (Figure 1 and Figure S5).

Optimization of HPLC–Photodiode Array Conditions. An internal standard is a compound that can be used to correct for aliquot taking, instrumental performance, and, in the present study, should be similar in chemical structure to luteolin and luteolin-7-*O*-glucoside. On the basis of U.S. FDA guidelines,[20] an internal standard was used to facilitate quantification of the target analyte(s) during the development of the analysis method. To select a suitable internal standard, we surveyed PubMed and searched the available chemicals in our laboratory, which included apigenin and apigenin-7-*O*-glucoside, baicalein and baicalin, naringenin and naringin, quercetin and rutin, genistein and genistein, daidzein and daidzein, and the flavonoids and their correlated glycosides. Among the compounds tested, apigenin and apigenin-7-*O*-glucoside were found to be the most appropriate internal standards for correlated luteolin and luteolin-7-*O*-glucoside. Apigenin and apigenin-7-*O*-glucoside exhibited an appropriate retention time of within 15 min, a maximum absorbance at the UV wavelength of 350 nm, and a well-resolved peak shape, and they were previously reported to be highly stable.[22]

To optimize efficiency and resolution for liquid chromatography of the compound tested, the stationary phase of reversed C8, C18, and phenyl-hexyl column was examined. Successful separation and quantification of luteolin and luteolin-7-*O*-glucoside from blood, without other endogenous interfering peaks, was achieved using a phenyl-hexyl column in an optimal mobile phase containing 0.05 M NaH_2PO_4 and acetonitrile of 80:20, v/v, and 70:30, v/v, for luteolin and luteolin-7-*O*-glucoside, respectively. The pH value of the mobile phase plays an important role. After replication of the tests, it was found

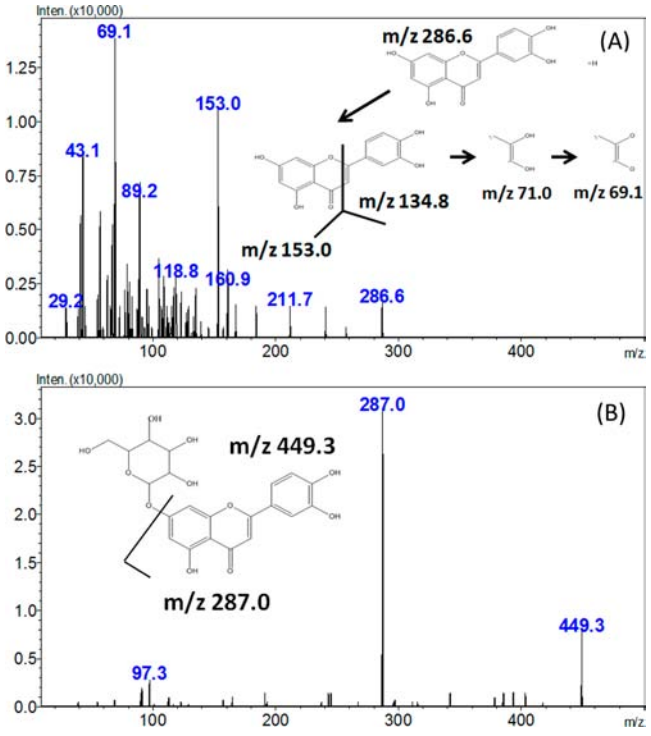

Figure 1. Chemical structures of (A) luteolin and (B) luteolin-7-*O*-glucoside and mass spectra of the analytes and their product ions in UPLC-MS/MS with electrospray in positive ion mode. The mass transitions of luteolin and luteolin-7-*O*-glucoside were m/z 286.6 → 69.1 and 449.3 → 287.0, respectively.

that the optimal pH value of the phosphate buffers (pH 2.6) could reduce the peak tailing of luteolin, luteolin-7-*O*-glucoside, and the internal standards without significant endogenous interference peaks. These results show that the analytical method used here is valid and reproducible. Our results are consistent with a previous study that the peak tailing of jaceosidin was severe in nonpolar columns.[23]

The analytical method established in this study was validated according to U.S. Food and Drug Administration guidelines for validation of bioanalytical methods.[20] Typical chromatograms of luteolin-7-*O*-glucoside and apigenin-7-*O*-glucoside (internal standard) in rat plasma after luteolin-7-*O*-glucoside administration (1 g/kg, po) are shown in Figure 2.

Validation of HPLC Assay. *Linearity, Accuracy, and Precision.* To evaluate linearity, the concentration of the calibration curve was derived from the peak area ratio of luteolin and luteolin-7-*O*-glucoside and their correlated internal standards, apigenin and apigenin-7-*O*-glucoside. The experimental results showed that the linearity range of luteolin and luteolin-7-*O*-glucoside in rat plasma was 0.125−2 μg/mL, and all of the coefficient correlation values (r^2) were >0.995.

The intraday and interday assays were carried out to evaluate the accuracy (as percent bias) and precision (as percent RSD) of luteolin and luteolin-7-*O*-glucoside (Supporting Information, Tables S1 and S2, n = 6). All of the bias and RSD values were <20%, which is the maximum acceptable value. These results revealed that this analytical method is reproducible.[20]

Pharmacokinetics of Luteolin. To describe the preclinical pharmacokinetics of luteolin, a single intravenous bolus of luteolin was administered via the femoral vein at a dose of 10 mg/kg, followed by a series of blood samplings at the designated time points of 5, 15, 30, 60, 90, 120, 180, 240, and 360 min after drug administration. The pharmacokinetic curves representing the changes in luteolin concentrations in the plasma across time are shown in Figure 3. The results suggested that the plasma concentration of luteolin was rapidly distributed and slowly decayed after luteolin administration in rats. The maximum concentration (C_{max}) of luteolin was 7.47 ± 3.78 μg/mL, and this concentration was observed at the first

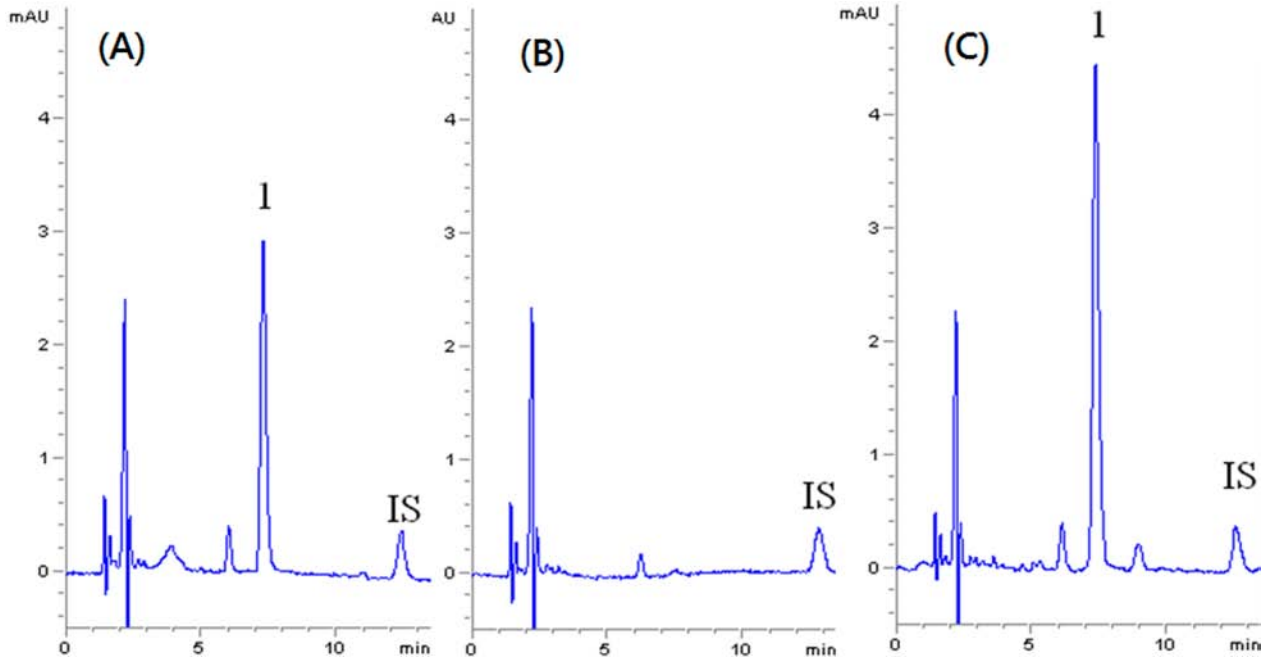

Figure 2. HPLC chromatograms of luteolin-7-*O*-glucoside in rat plasma for po administration of luteolin-7-*O*-glucoside: (A) standard luteolin-7-*O*-glucoside (2.5 μg/mL) and apigenin-*O*-glucoside (0.2 μg/mL); (B) blank plasma; (C) luteolin-7-*O*-glucoside (4.67 μg/mL) after po administration at 60 min. Peaks: 1, luteolin-7-*O*-glucoside; IS, internal standard (apigenin-7-*O*-glucoside).

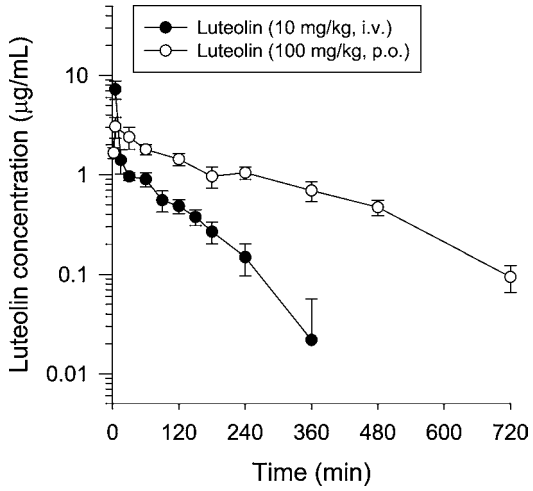

Figure 3. Concentration versus time profiles of luteolin in rat plasma after luteolin administration (10 mg/kg, iv; 100 mg/kg, po). Data are presented as the mean ± standard error, n = 6, for each group.

collected time point of 5 min after luteolin administration (10 mg/kg, iv). After this time point, the concentration of luteolin continually decreased up until the time point of 360 min after luteolin administration, at which time the concentration was undetectable.

When luteolin was given orally, the C_{max} of luteolin was 3.07 ± 0.72 μg/mL, and this concentration was observed at 5 min after luteolin administration (100 mg/kg, po). However, the luteolin concentration slowly decreased after oral administration, and the concentration of luteolin could still be detected up to 12 h after oral administration. The elimination half-lives of luteolin were 78 ± 14 and 132 ± 12 min for intravenous and oral administrations, respectively. The oral bioavailability of luteolin was 26 ± 6% on the basis of the doses used and the experimental animal model described above.

The pharmacokinetic profiles of the concentrations of luteolin in rat plasma versus time after oral administration of luteolin (10 mg/kg, iv; 100 mg/kg, po) are shown in Figure 3. There are multiple peaks at a t_{max} of 0.5 and at 4 h after oral administration of luteolin (100 mg/kg, po). This observance of multiple peaks suggested that enterohepatic circulation is a general phenomenon for the flavonoids,[24] such as luteolin and apigenin,[13] naringenin,[24] baicalein,[25] quercetin,[26] genistein,[27] and daidzein.[28] The concentration plateau appears at 1 and 4 h after luteolin intravenous and oral administration, respectively (Figure 3). This phenomenon reflects that the elimination half-time of luteolin by oral administration, 132 ± 12 h (Table 1), is relatively longer than it is by the route of intravenous

Table 1. Pharmacokinetic Parameters of Luteolin (10 mg/kg, iv; and 100 mg/kg, po)[a]

parameter	luteolin (10 mg/kg, iv)	luteolin (100 mg/kg, po)

CL (mL/min/kg)	41.3 ± 4.87	181 ± 25.5
oral bioavailability (%)		26 ± 6

[a]Data are presented as the mean ± SE (n = 6).

administration, 78 ± 14 h. Crespy et al. reported that the liver is the active site for the methylation of luteolin for additional biliary excretion and that a transporter system may be involved.[29] Then, the phase II methylated luteolins, chrysoeriol and diosmetin, have been identified, which was proved by the treatment of catechol-*O*-methyltransferase inhibitor, entacapone, in rat.[30,31] In the present study, we did not measure the precise nature of the metabolites from the hepatic conjugation. Consistently, we found that the multiple peaks may support the fate of enterohepatic circulation of luteolin.

With regard to the phase II metabolic mechanism of luteolin, we did not find the chromatographic peaks of metabolites in our analytical system. Luteolin can be found after luteolin-7-*O*-glucoside administration, but luteolin-7-*O*-glucoside was undetectable after luteolin administration (Figures 3 and 4).

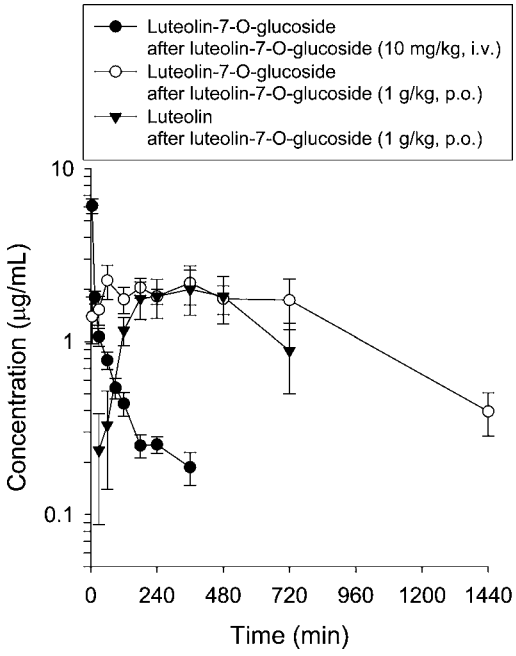

Figure 4. Concentration versus time profiles of luteolin-7-*O*-glucoside and luteolin in rat plasma after luteolin-7-*O*-glucoside administration (10 mg/kg, iv; 1 g/kg, po). Data are presented as the mean ± standard error, n = 6.

However, it has been shown that luteolin mainly undergoes conjugation by uridine diphosphoglucuronosyltransferases (UGTs), sulfotransferases (SULTs),[32] and COMT in vivo.[15,16] Because intestinal and hepatic first-pass effects are widely acknowledged to be responsible for low oral bioavailabilities of flavonoids, the oral bioavailabilities of luteolin and luteolin-7-*O*-glucoside were measured and found to be 26 ± 6 and 10 ± 2%, respectively (Tables 1 and 2).

Pharmacokinetics of Luteolin-7-O-glucoside. Luteolin-7-*O*-glucoside was hydrolyzed to luteolin in the gastrointestinal tract and absorbed into the systemic circulation (Figure 4). The AUCs of luteolin-7-*O*-glucoside were 229 ± 15 and 2109 ± 350 (min μg/mL) after administration of 10 mg/kg luteolin-7-*O*-glucoside, iv, and 1 g/kg, luteolin-7-*O*-glucoside, po, respectively (Figure 4). The oral bioavailability of luteolin-7-*O*-glucoside was approximately 10 ± 2%. In the group administered luteolin-7-*O*-glucoside orally, a biotransformed luteolin product was detected, but it was not detected in the

[a]Data are presented as the mean ± SE (n = 6).

group administered luteolin-7-*O*-glucoside intravenously. These results demonstrate that luteolin 7-*O*-β-glucoside was not readily absorbed alone and that luteolin glucuronides were detected after intestinal absorption.

To clarify the luteolin is the hydrolysis product of luteolin-7-*O*-glucoside, luteolin-7-*O*-glucoside was administered (1 g/kg, po). The concentration versus time curve showed that luteolin was detected in rat plasma after administration of luteolin-7-*O*-glucoside (1 g/kg, po) (Figure 4). It has been reported that intestinal bacteria can hydrolyze glucosides of flavonoids and produce aglycones.[33] Our data demonstrated that both luteolin and luteolin-7-*O*-glucoside can be detected after luteolin-7-*O*-glucoside administration (1 g/kg, po). The oral bioavailability of luteolin-7-*O*-glucoside was 10 ± 2% (Table 2), which suggested that luteolin-7-*O*-glucoside may first be hydrolyzed to luteolin by the bacteria that are present on the surface of the intestinal mucosa. β-Glycosidase is an enzyme that rapidly hydrolyzes glucosides, such as quercetin 3-*O*-glucoside, which had the highest percent of hydrolysis.[34] This phenomenon is consistent with our data that luteolin can be detected at the first collected time point of 5 min after luteolin-7-*O*-glucoside administration (1 g/kg, po). The maximum concentrations (C_{max}) of luteolin and luteolin-7-*O*-glucoside were found at 3.04 ± 0.76 and 2.45 ± 0.55 min after luteolin-7-*O*-glucoside administration (1 g/kg, po).

In conclusion, we first identified that the flower of *D. morifolium* Ramat Tzvel is a highly rich source of luteolin and luteolin-7-*O*-glucoside. We determined that the luteolin-7-*O*-glucoside contents in ethanolic and water extracts were 4.19 and 6.56%, respectively. However, the luteolin content was 0.19% in the ethanolic extract, and luteolin was not detected in the water extract. The oral bioavailability of luteolin was approximately 26 ± 6% after luteolin administration (10 mg/kg, i.v. and 100 mg/kg, p.o.). The oral bioavailability of luteolin-7-*O*-glucoside was approximately 10 ± 2% after luteolin-7-*O*-glucoside administration (10 mg/kg, iv; and 1 g/kg, po). Luteolin is one of the major metabolites present after oral administration of luteolin-7-*O*-glucoside, and we detected a biotransformed luteolin product, although this biotransformed product was not detected in the intravenous administration group. The transformation ratio (the AUC ratio of metabolite/parent compound) of luteolin to luteolin-7-*O*-glucoside was approximately 48.78 ± 0.12%. These results demonstrate that luteolin-7-*O*-glucoside is primarily hydrolyzed to luteolin in the gastrointestinal tract and absorbed into the systemic circulation. These results also imply that people who drink chamomile tea can also retain the benefits from luteolin, due to high transformation ratio of luteolin to luteolin-7-*O*-glucoside.

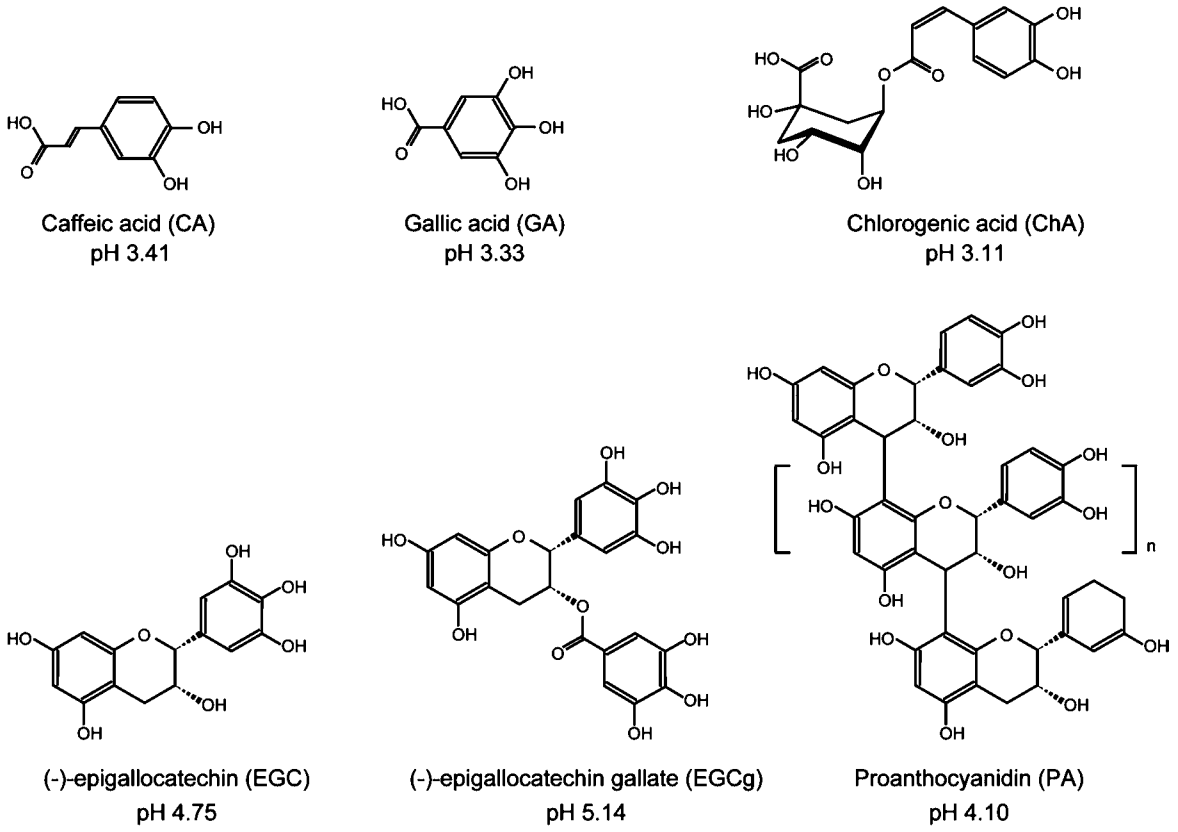

Figure 1. Structures of polyphenols used in the present study.

(Osaka, Japan); proanthocyanidin (PA; Leucoselect) from Indena (Milano, Italy); 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) from Labotec (Tokyo, Japan); chlorogenic acid (ChA) and 4-hydroxy-2,2,6,6-tetramethylpiperidine *N*-oxyl (TEMPOL) from Sigma-Aldrich (St. Louis, MO, USA). All other reagents used were of analytical grade.

Light Source. An experimental device equipped with a light-emitting diode (LED) with a wavelength of 400 nm (NHH105UV, Lustrous Technology, Shiji, Taiwan) was used according to our previous study.[14] The output power of the LED measured using a power meter (FieldMate, Coherent, Santa Clara, CA, USA) was set to be 400 mW/LED corresponding to an irradiance of 130 mW/cm^2 at a distance of 15 mm from the LED. A four-clear-sided methacrylate plastic cuvette containing the sample was placed in the experimental device. LED light irradiation was performed toward both sides of the plastic cuvette (total irradiance = 260 mW/cm^2).

Preparation of Polyphenol Solution. The structures of polyphenols used in the present study are shown in Figure 1. Each polyphenol was dissolved in pure water to be 1.1 mg/mL. On the preparation of CA, ChA, and EGC solutions, the tubes containing samples were put in hot water (90 °C) to heat them up and were agitated so that each polyphenol could be completely dissolved. CA, ChA, and EGC solutions were subjected to high-performance liquid chromatography (HPLC) using a Prominence HPLC system (Shimadzu, Kyoto, Japan) with a Shimpak-HRC ODS colum (5 μm, ø4.6 × 150 mm), and a Flex FX-15 HPLC system (PerkinElmer, Waltham, MA, USA) with a PerkinElmer Brownlee Supra column C18 (2.1 μm, ø2.1 × 100 mm). It was confirmed that the polyphenols were not decomposed by heating. The pH of each polyphenol solution measured using a pH meter (Seven Go SG2, Mettler Toledo, Greifensee, Switzerland) is also shown in Figure 1. The polyphenol solutions were used in the experiments without further pH adjustment.

Comparison of Bactericidal Activity of Photoirradiated Polyphenols. All bacterial species used in the present study were purchased from the Japan Collection of Microorganisms, RIKEN BioResource Center (Wako, Japan). Three different species of Gram-positive bacteria, *Enterococcus faecalis* JCM7783, *S. aureus* JCM 2413, and *Streptococcus mutans* JCM5705, and three different species of Gram-negative bacteria, *Aggregatibacter actinomycetemcomitans* JCM2434, *Escherichia coli* JCM5491, and *Pseudomonas aeruginosa* JCM6119, were used. A bacterial suspension was prepared in sterile physiological saline from a culture grown on brain−heart infusion (BHI) agar (Becton Dickinson Labware, Franklin Lakes, NJ, USA). *E. faecalis*, *S. aureus*, *E. coli*, and *P. aeruginosa* were cultured aerobically at 37 °C for 20 h, whereas *S. mutans* and *A. actinomycetemcomitans* were cultured anaerobically using Anaero Pack (Mitsubishi Gas Chemical Co., Tokyo, Japan) at 37 °C for 48 h before the preparation of bacterial suspension. In a plastic cuvette, 450 μL of polyphenol solution (CA, GA, ChA, EGC, EGCg, or PA) or pure water (PW) was mixed with 50 μL of the bacterial suspension to reach final concentrations of 1 mg/mL for polyphenol and approximately 10^7 colony-forming units (CFU)/mL for the bacteria. Then, the samples were exposed to LED light for 5 or 10 min. After irradiation, 50 μL of the sample was mixed with an equal volume of sterile catalase solution (5000 U/mL) to terminate the bactericidal effect of H_2O_2 generated by photo-oxidation of the polyphenol. A 10-fold serial dilution of the mixture was prepared using sterile physiological saline, and 10 μL of the diluted solution was seeded onto an agar plate. *P. aeruginosa* was seeded onto deoxycholate hydrogen sulfide lactose agar (Becton Dickinson Labware) to obtain colonies with an entire edge for counting, whereas the others were seeded onto BHI agar. The agar plates with each bacterial species were cultured in the same way as described above, and the CFU/mL was determined. In addition, a bacterial suspension that was kept for 10 min in a light-shielding box instead of being exposed to LED light was subjected to the same procedure. The bacterial initial count (inoculum size) in each assay was also evaluated by the viable counting method. All tests were performed in triplicate.

Bactericidal Effect of LED Light on Bacteria Pretreated with Polyphenols. An additional bactericidal assay was conducted to examine if polyphenols taken up by bacteria would exert bactericidal activity. *S. aureus* and *E. coli* were used as representative Gram-positive and -negative bacteria, respectively. In a microtube, 1800 μL of each

[a]Significant differences from the initial bacterial count are shown, $p < 0.05$ (*) and $p < 0.01$ (**). G(+), Gram-positive; G(−), Gram-negative; CA, caffeic acid; GA, gallic acid; ChA, chlorogenic acid; EGC, epigallocatechin; EGCg, epigallocatechin gallate; PA, proanthocyanidin; PW, pure water. Each value represents the mean of triplicate assays.

polyphenol solution was mixed with 200 μL of the bacterial suspension to reach final concentrations of 1 mg/mL for polyphenol and approximately 10^9 CFU/mL for the bacteria. The mixture was incubated for 1 min at room temperature. Then, the bacteria were collected by centrifugation at 5000*g* at 4 °C for 10 min. Following the decantation of the supernatant, the pellet was resuspended in 1000 μL of sterile saline. The suspension was further diluted about 100 times with sterile saline to reach a final concentration of approximately 10^7 CFU/mL. An aliquot (500 μL) of the diluted suspension was put in a plastic cuvette and exposed to LED light for 10 min. After irradiation, determination of CFU/mL was performed in the same way as described above.

Oxidative DNA Damage. To examine if the photoirradiated polyphenol causes oxidative DNA damage in bacteria, biochemical analysis was performed. CA was used as a representative polyphenol, and *S. aureus* and *E. coli* were used as representative Gram-positive and -negative bacteria, respectively. In a plastic cuvette, 1800 μL of CA solution was mixed with 200 μL of the bacterial suspension to reach final concentrations of 1 mg/mL for CA and approximately 10^9 CFU/mL for the bacteria. The sample was exposed to LED light for 5 min. After irradiation, 200 μL of sterile catalase solution (5000 U/mL) was added to the sample. Then, the bacteria were collected by centrifugation, and DNA was extracted using a commercial kit (Isoplant, Nippon Gene, Tokyo, Japan). Concentration of DNA was adjusted to 200 μg/mL by reading an absorbance at 260 nm using a spectrophotometer (Gene Quant 1300, GE Healthcare, Bukinghamshire, UK). The formation of 8-hydroxydeoxyguanosine (8-OHdG), which is a marker of oxidative DNA damage,[19] was analyzed using a commercial kit (OxiSelect Oxidative DNA Damage ELISA Kit, Cell Biolabs, San Diego, CA, USA). The 8-OHdG formation caused by photoirradiated CA [CA(+)L(+)] was compared to the treatment with CA alone [CA(+)L(−)], LED irradiation alone [CA(−)L(+)], and no treatment [CA(−)L(−)]. Under the CA(−) condition, pure water was added to the reaction system. Under the L(−) condition, the samples were kept in a light-shielding box.

H_2O_2 Determination. The H_2O_2 content of each polyphenol solution and pure water with or without the 10 min exposure to LED light was determined by the colorimetric method based on the peroxide-mediated oxidation of Fe^{2+} followed by the reaction of Fe^{3+} with xylenol orange.[20] In brief, 500 μL of reaction mixture consisting of 500 μM ammonium ferrous sulfate, 50 mM sulfuric acid, 200 μM xylenol orange, and 200 mM sorbitol was added to 500 μL of polyphenol solution with or without LED irradiation. The polyphenol solution was diluted with pure water beforehand as appropriate. After the 45 min incubation at room temperature, absorbance at 560 nm was read using a spectrophotometer (Gene Quant 1300). The assay was calibrated using a standard curve, which was obtained in the range between 0.25 and 5 μM H_2O_2. Because the sample was mixed with an equal volume of the reaction agent, the detection limit was 0.5 μM.

Electron Spin Resonance (ESR) Analysis of Hydroxyl Radicals. Qualitative and quantitative analyses of $^{\bullet}$OH generated by photoirradiation of polyphenol solution were performed using an ESR spin trapping technique according to our previous studies.[14,21] In brief, polyphenol solution was mixed with DMPO, a spin trap agent, in a plastic cuvette to reach final concentrations of 1 mg/mL for polyphenol and 300 mM for DMPO. Then, the sample was exposed to LED light for 1 min. After irradiation, the sample was transferred to a quartz cell for ESR spectrometry. The ESR spectrum was recorded on an X-band ESR spectrometer (JES-FA-100; JEOL, Tokyo, Japan). The measurement conditions for ESR were as follows: field sweep, 331.41−341.41 mT; field modulation frequency, 100 kHz; field modulation width, 0.1 mT; amplitude, 200; sweep time, 2 min; time constant, 0.03 s; microwave frequency, 9.420 GHz; and microwave power, 4 mW. TEMPOL (10 μM) was used as a standard to calculate the concentration of spin-trapped radicals, and the ESR spectrum of manganese (Mn^{2+}) held in the ESR cavity was used as an internal standard. The concentration of $^{\bullet}$OH was determined using digital data processing (JEOL).

Statistical Analyses. The statistical significance ($p < 0.05$) in the CFU/mL obtained in the bactericidal test was assessed by Dunnett's multiple-comparison test using the initial bacterial count as a control group. The analyses for the bactericidal test were performed following logarithmic conversion. When a colony was not detected, the value of the detection limit (10^2 CFU/mL) was used for the statistical analysis. Statistical significance ($p < 0.05$) in the 8-OHdG formation was assessed by using the Tukey−Kramer honest significant difference

Significant differences from the CFU/mL of PW-L(−) are shown, $p < 0.05$ (*) and $p < 0.01$ (**). CA, caffeic acid; GA, gallic acid; ChA, chlorogenic acid; EGC, epigallocatechin; EGCg, epigallocatechin gallate; PA, proanthocyanidin; PW, pure water; L(+,−), with or without LED irradiation; ND, not detected.

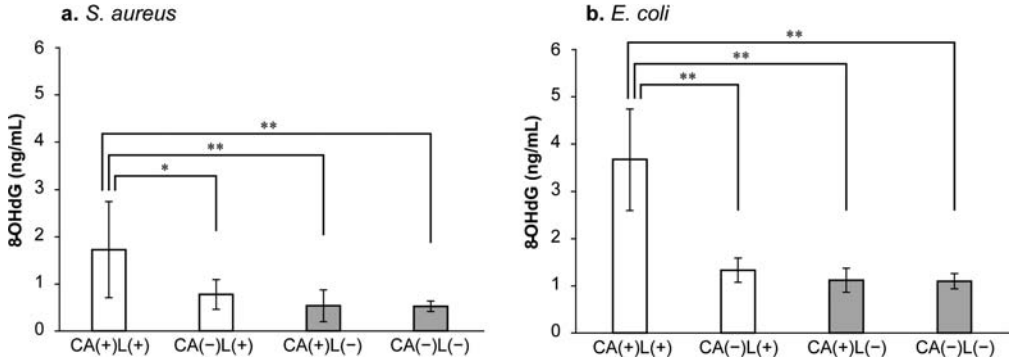

Figure 3. Formation of 8-OHdG in *S. aureus* (a) and *E. coli* (b) suspended in caffeic acid (CA) aqueous solution with or without LED irradiation. Each value represents the mean of sextuplicate assays with standard deviation. Significant differences are shown, $p < 0.05$ (*) and $p < 0.01$ (**). CA(+,−), with or without CA; L(+,−), with or without LED irradiation.

multiple-comparison test, and the yield of H_2O_2 and $^{\bullet}OH$ in each polyphenol solution with or without LED irradiation was assessed by Student's *t* test. When H_2O_2 was not detected, the value of the detection limit (0.5 μM) was used for the statistical analysis.

RESULTS

Bactericidal Assay. The logarithmic reduction of CFU/mL from the initial bacterial counts after each treatment is summarized in Tables 1−3. Under the light-shielding condition, certain bacterial species showed susceptibility to the polyphenols (Table 1). *E. faecalis* was killed by PA with a 2.2 log reduction of CFU/mL in 10 min, whereas the other polyphenols hardly killed the bacteria (Table 1). *A. actinomycetemcomitans* showed high susceptibility to EGCg and was killed with a 3.5 log reduction of CFU/mL (Table 1). Of the bacterial species used in the present study, *P. aeruginosa* was most susceptible to the polyphenols and was killed with a ≥1 log reduction of CFU/mL by CA, GA, ChA, EGCg, and PA (Table 1).

When exposed to LED light, the bactericidal activity of each polyphenol was enhanced in an irradiation time-dependent manner (Tables 2 and 3). Phenolic acids, such as CA, GA, and ChA, showed higher bactericidal activity than flavonoid, such as EGC and EGCg. In particular, photoirradiated CA and ChA killed all bacterial species with a ≥4 log reduction of CFU/mL within 10 min. Following CA and ChA, photoirradiated GA and PA showed relatively high bactericidal effect, although *E. faecalis* and *E. coli* were not effectively killed by GA and PA, respectively. LED irradiation alone (PW) also showed bactericidal activity, especially against *A. actinomycetemcomitans* and *P. aeruginosa*. Compared to PW, photoirradiated EGC showed no or only a little additional bactericidal effect.

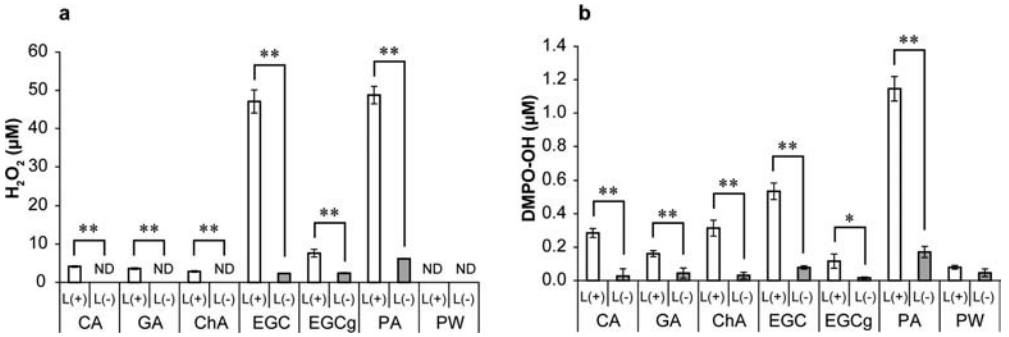

Figure 4. Quantification of H_2O_2 (a) and DMPO-OH, a spin adduct of hydroxyl radical (b), generated in each polyphenol solution with or without LED irradiation. Each value represents the mean of triplicate assays with standard deviation. Significant differences are shown, $p < 0.05$ (*) and $p < 0.01$ (**). CA, caffeic acid; GA, gallic acid; ChA, chlorogenic acid; EGC, epigallocatechin; EGCg, epigallocatechin gallate; PA, proanthocyanidin; PW, pure water; L(+,−), with or without LED irradiation; ND, not detected.

Although photoirradiated EGCg was effective against Gram-negative bacteria, it showed no additional bactericidal effect against Gram-positive bacteria. As a whole, Gram-negative bacteria tended to show higher susceptibility to the disinfection treatment than Gram-positive bacteria.

Bactericidal Effect of LED Light on Bacteria Pretreated with Polyphenols. When *S. aureus* was pretreated with polyphenols for 1 min followed by being exposed to LED light for 10 min, pretreatment with CA, GA, ChA, and PA significantly reduced the CFU/mL from the initial bacterial count (Figure 2a). However, the logarithmic reduction of CFU/mL in all cases was <2 log, which was lower than that obtained in the bactericidal assay where the bacteria suspended in each polyphenol solution were exposed to LED light. In the case of *E. coli* pretreated with each polyphenol, the bactericidal activity of each pretreatment was comparable to that observed in the bactericidal assay where the bacteria suspended in each polyphenol solution were irradiated. (Figure 2b). Pretreatment with CA, GA, and ChA killed the bacteria with a >5 log reduction of CFU/mL when exposed to LED light for 10 min. Pretreatment with EGC, EGCg, and PA followed by LED irradiation for 10 min also significantly reduced the CFU/mL, although the reduction was 1−2 log of CFU/mL. Pretreatment with CA, GA, and ChA without LED irradiation also significantly reduced the CFU/mL from the initial bacterial count, although the reduction was <1 log.

Oxidative DNA Damage. When *S. aureus* suspended in CA aqueous solution was exposed to LED light for 5 min [CA(+)L(+)], the 8-OHdG level significantly increased from the level observed in the no-treatment group [CA(−)L(−)] (Figure 3a). By contrast, treatment with CA alone [CA(+)-L(−)] and LED irradiation alone [CA(−)L(+)] did not elevate the 8-OHdG level. Similar to the case of *S. aureus*, photoirradiated CA significantly increased the 8-OHdG level in *E. coli*, although other conditions did not affect it(Figure 3b).

H_2O_2 Determination. H_2O_2 generation was observed in all polyphenol aqueous solutions used in the present study when irradiated, and the highest yield (approximately 50 μM) was recorded in the EGC and PA solutions, whereas H_2O_2 was not detected in PW regardless of LED irradiation (Figure 4a). In the EGC, EGCg, or PA solution, although H_2O_2 was also generated under the light-shielding condition, the yield of H_2O_2 was significantly lower than that generated in the same polyphenols with LED irradiation.

ESR Analysis of Hydroxyl Radicals. When the polyphenol aqueous solutions containing DMPO were exposed to LED light for 1 min, the ESR signal of DMPO-OH, a spin adduct of $^{\bullet}OH$, was detected. The presence of the spin adduct was confirmed by hyperfine coupling constants of $a_N = a_H = 1.49$ mT.[22] The yields of DMPO-OH generated in each polyphenol solution significantly increased by LED irradiation, whereas LED irradiation of PW did not increase the yield (Figure 4b). The highest yield of DMPO-OH (about 1 μM) was observed in photoirradiated PA, followed by EGC, ChA, CA, GA, and EGCg.

DISCUSSION

The newly developed disinfection technique applying edible polyphenols and blue light was evaluated in the present study. The antimicrobial activity of the polyphenols without LED irradiation against some bacterial species was observed as reported in the previous studies.[9−12] However, the bactericidal effect exerted within 10 min was rather weak (<1 log reduction of CFU/mL) with some exceptions. When bacteria suspended in PW were exposed to LED light, significant reductions of CFU/mL were also observed after 10 min of treatment except for *E. faecalis* and *S. aureus*. This finding agrees with earlier studies, which showed that ultraviolet or blue light could exert bactericidal action depending on the intensity and time of irradiation.[23,24] By comparing the bactericidal effect with different conditions, it was confirmed that photoirradiation enhanced the bactericidal activity of polyphenols. In particular, phenolic acids, such as CA and ChA, killed all bacterial species used in the present study with a ≥4 log reduction of CFU/mL when irradiated for 10 min. The photoirradiated GA and PA also exerted relatively high bactericidal activity, although they were not effective against *E. faecalis* and *E. coli*, respectively. By contrast, the bactericidal activity of photoirradiated flavonoids, such as EGC and EGCg, was limited. Especially, the bactericidal effect of EGC was almost equal to that of PW, which means EGC did not exert bactericidal effect additionally to that of LED irradiation alone.

In general, *E. faecalis* showed higher resistance to the disinfection treatment than other bacteria tested in the present study. It is known that *E. faecalis* is able to survive in hostile conditions and in many harsh environments, such as heat, acid, H_2O_2, hyperosmolarity, sodium hypochloride, and even ultraviolet irradiation.[25−28] Indeed, in our previous studies,[16,29] it has been demonstrated that *E. faecalis* is more resistant to the disinfection treatment based on photolysis of hydrogen peroxide than *S. aureus*, *S. mutans*, and *A. actinomycetemcomitans*. Therefore, it seems to be natural that *E. faecalis* is more

DOI: 10.1021/jf5058588
J. Agric. Food Chem. 2015, 63, 7707−7713

resistant to the disinfection treatment by photoirradiation of the polyphenols. The mechanism by which *E. faecalis* shows higher resistance to photoirradiated polyphenols should be further studied.

The results of quantitative analyses of H_2O_2 and $^{\bullet}OH$ showed that their yields in the polyphenol solutions significantly increased by LED irradiation. These findings are identical to the results of our previous studies, suggesting that the bactericidal activity of photoirradiated polyphenols would be attributable to oxidation by ROS.[14,15] However, when the yields of H_2O_2 were compared in each polyphenol solution, the photoirradiated EGC and PA showed the highest yield, followed by EGCg. Similarly, the photoirradiated PA showed the highest yield of $^{\bullet}OH$, followed by EGC. Because phenolic acids, such as CA, GA, and ChA, showed higher bactericidal activity than flavonoids, such as EGC and EGCg, a correlation was not observed between the yield of ROS and the bactericidal effect. This discrepancy suggests that there is another factor affecting the bactericidal activity other than the yield of the ROS.

One of the possible factors that affect the bactericidal activity of photoirradiated polyphenols is the affinity of polyphenols to bacterial cells as discussed in our previous studies.[14,15] When $^{\bullet}OH$ causes oxidative damage, it should be generated inside or in the vicinity of bacterial cells because it cannot diffuse long distances.[30,31] Thus, the affinity will be important in the mode of action. To verify the importance of affinity, an additional bactericidal assay was conducted. The bacteria were pretreated with the polyphenols for 1 min and were resuspended in saline so that only polyphenols incorporated into cytoplasm and/or bound to cytoplasmic membrane would exist. The result showed that both *S. aureus* and *E. coli* pretreated with the polyphenols could be killed when exposed to the LED light. This suggests that the polyphenols will be incorporated into cytoplasm and/or bound to cytoplasmic membrane as is the case with mammalian cells.[18] It was also demonstrated that the photoirradiation of Gram-negative *E. coli* pretreated with the polyphenols exerted comparable bactericidal effect to the photoirradiation of the bacteria suspended in the polyphenol solutions, whereas the former treatment was less effective against Gram-positive *S. aureus* than the latter. This finding indicates that the affinity of polyphenols to Gram-negative bacteria would be higher than to Gram-positive bacteria. This may explain why Gram-negative bacteria were more susceptible to the disinfection treatment than Gram-positive bacteria. In addition to the bactericidal assay, the biochemical assay for oxidative DNA damage demonstrated that photoirradiated CA increased the 8-OHdG level of *S. aureus* and *E. coli* but LED irradiation alone did not. This finding suggests that CA at least in part would penetrate into the cell. Furthermore, a higher 8-OHdG level was observed in *E. coli* than in *S. aureus*, suggesting that Gram-negative bacteria will take up CA more effectively than Gram-positive bacteria. The underlying mechanism by which polyphenols are incorporated into bacterial cells should be further studied.

Besides the bactericidal activity, we demonstrated that CA, ChA, and PA showed an accelerative effect on fibroblast proliferation.[18] Because fibroblast proliferation is one of the pivotal events for wound healing,[32−34] it can be expected that these polyphenols would contribute to acceleration of wound healing after the disinfection treatment. Furthermore, polyphenols can generally function as an antioxidant to terminate excessive oxidative damage and can exert a cytoprotective effect by improving intracellular oxidative stress response.[2,3,35] Because the polyphenols contained in plant foods are edible, the residual toxicity is likely to be negligible. Thus, treatment utilizing blue light and a polyphenol could be a novel disinfection treatment with a wide variety of applications.

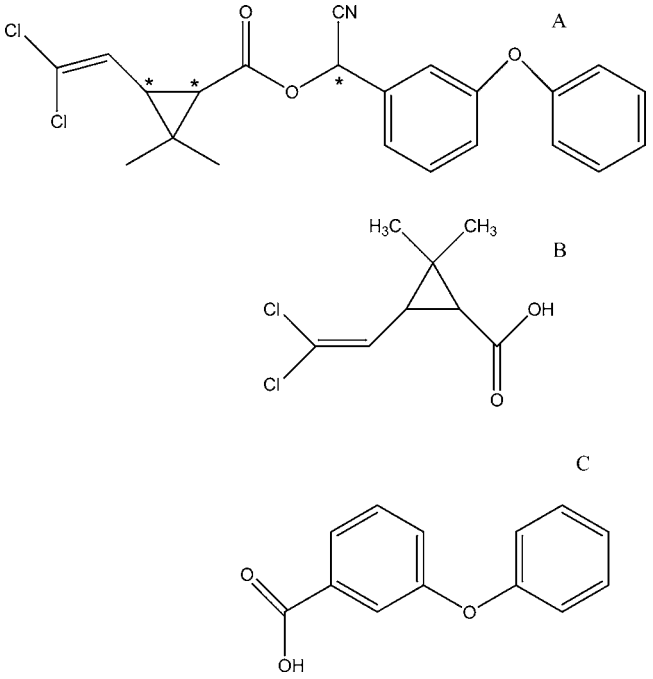

Figure 1. Chemical structures of α-cypermethrin and its metabolites: (A) α-cypermethrin, (B) *cis*-DCCA, and (C) 3-PBA.

ecotoxicity assays according to the Organisation for Economic Co-operation and Development (OECD) guidelines (OECD 1984) and is also used to survey the quality of the terrestrial environment. Traditional ecotoxicity assays and risk assessments have routinely focused on individual chemicals.[20] However, earthworms in soil are usually exposed to a variety of pollutants simultaneously. Therefore, toxicity assays using mixtures of contaminants may better reflect the real-world exposures. Studies about the toxicity of α-cypermethrin have been studied by Diao et al.[21] Little information regarding the toxicity of the metabolites and the combined acute toxicity of α-cypermethrin and its metabolites to earthworms has been reported.

The individual enantiomers of chiral pesticides may show differences in bioactivity, toxicity, metabolism, bioaccumulation, and degradation behaviors.[22,23] α-Cypermethrin is manufactured and applied to agro-ecosystems as racemic forms. The enantioselective environmental behavior of α-cypermethrin in the environment has not been considered for human health and ecological risk assessment. The formation of the metabolites *cis*-DCCA and 3-PBA influences non-target organisms and is also an important issue and should also be considered.

In this study, the enantiomers of α-cypermethrin were separated and the enantioselective transformation of α-cypermethrin in five soils was investigated. The toxicity of *cis*-DCCA and 3-PBA and the combined acute toxicity of *cis*-DCCA, 3-PBA, and α-cypermethrin to earthworms were also determined. This result may be applied to understand the risks of α-cypermethrin application.

2. MATERIALS AND METHODS

2.1. Chemicals and Reagents. The insecticide of α-cypermethrin [≥98.5% purity, enriched in (+)-1*R*-*cis*-*S* and (−)-1*S*-*cis*-*R*] was provided by the Institute for the Control of Agrochemicals, Ministry of Agriculture (ICAMA, Beijing, China). 1,1,1,3,3,3-Hexafluoroisopropanol (HFIP), *N*,*N*-diisopropylcarbodiimide (DIC), 3-phenoxybenzoic acid (3-PBA, 98%), and internal standard (chlorpyrifos, 98%) were purchased from Sigma−Aldrich Corp. (St. Louis, MO). *cis*-DCCA (98%) was purchased from Chem Service (West Chester, PA). Water was purified by a Milli-Q system. Isopropanol, *n*-hexane, and ethyl acetate (analytical grade) were purchased from commercial sources, distilled, and filtered through a 0.45 μm filter membrane before use. All other chemicals and solvents were of analytical grade and purchased from commercial sources.

2.2. Chiral Separation. The high-performance liquid chromatography (HPLC) analysis was performed on an Agilent 1200 Series HPLC system (Agilent Technology) equipped with a G1322A degasser, G1311A pump, G1314B variable wavelength detector (VWD), and G1329A ALS. An AT-930 heater and cooler column attemperator (Tianjin Automatic Science Instrument Co., Ltd., China) was used to control the column temperature. The signal was processed by Agilent ChemStation software. The enantiomers of α-cypermethrin were separated on a Chiralcel OD column (250 × 4.6 mm, Daicel Chemical Industries, Tokyo, Japan) using *n*-hexane and isopropanol in a 98:2 (v/v) ratio at a 0.5 mL/min flow rate (Figure 2A). The injection volume was 20 μL, and the ultraviolet (UV) detection wavelength was 230 nm. The chromatographic separation was conducted at 20 °C. No enantiomerization was observed for α-cypermethrin under this analytical condition.

2.3. Gas Chromatography (GC) Analysis. Agilent 6890N GC with an electron capture detector (ECD, Agilent Technologies, Palo Alto, CA) was used for quantitative analysis of α-cypermethrin and its metabolites. The detection was performed using a HP-5 capillary column (30 m × 0.25 mm inner diameter and 0.25 um film thickness). Nitrogen (>99.999%) was used as a carrier gas at a constant flow rate of 1.0 mL/min. The operating conditions were as follows: the column was held initially at a temperature of 100 °C for 10 min, then ramped at 5 °C/min to 155 °C, held at 155 °C for 5 min, ramped at 15 °C/

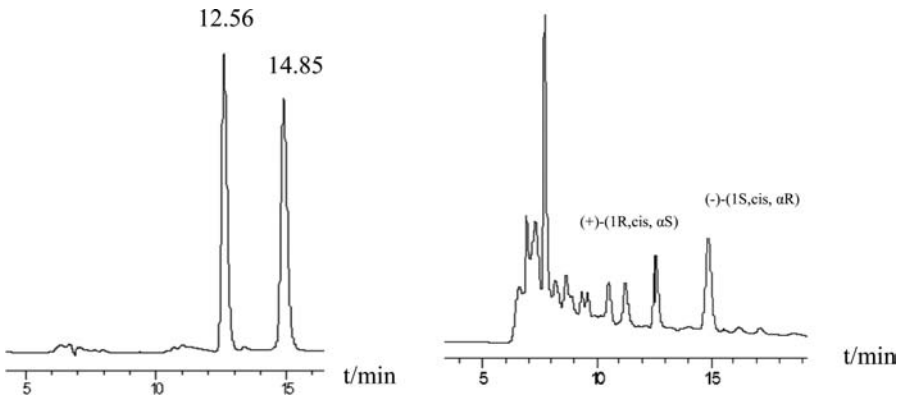

Figure 2. (A) Typical chromatograms of the chiral separation of α-cypermethrin and (B) enantioselective degradation of α-cypermethrin in soil 1 after 42 days.

J. Agric. Food Chem. 2015, 63, 7714−7720

Table 1. Physicochemical Properties of the Soils

number	site	particle size			texture	pH (water)	C_{org} (%)
		sand (%)	silt (%)	clay (%)			
1	Hunan	24.0	44.0	36.0	clay loam	5.18	1.15
2	Heilongjiang	48.0	28.0	24.0	loam	5.79	15.04
3	Beijing	61.2	8.0	30.8	sandy loam	8.14	2.51
4	Hainan	73.2	16.0	10.8	sandy loam	8.17	5.43
5	Neimeng	69.2	12.0	18.8	sandy loam	7.85	6.55

min to 290 °C, and held at 290 °C for 5 min. The total analysis time was 45 min. The temperature of the detector was set at 300 °C.

2.4. Sample Extraction. All of the samples were thawed for about 15 min at room temperature. Soil samples were mixed with 5 g of anhydrous sodium sulfate in a 50 mL polypropylene centrifuge tube, and 25 mL of ethyl acetate was added for extraction. The tube was vortexed for 3 min, exposed to ultrasonic vibration for 10 min, and then centrifuged at 3500 rpm for 5 min. The extraction was repeated following the same step, and the liquid phase was combined. The combined extracts were filtered through 5 g of anhydrous sodium sulfate for dehydration, evaporated to dryness *in vacuo* rotary at 35 °C, and reconstituted to 1 mL with acetonitrile. The solution was divided into two parts: (1) A total of 750 μL was evaporated to dryness under a stream of nitrogen and diluted to 250 μL with *n*-hexane, and a 20 μL aliquot was injected into HPLC for enantioselectivity determination. (2) A total of 250 μL was used for derivatization for GC analysis. The derivatization was conducted in a 5 mL centrifuge tube, with 30 μL of HFIP solution and 10 μL of DIC solution. After thorough mixing, the tube was placed in the oscillator. Derivatization was exposed to ultrasonic vibration for 10 min. After reaction, 500 μL of ultrapure water and 500 μL of *n*-hexane were added to the tube, vortexed for 5 min, and then centrifuged at 3500 rpm for 5 min. A total of 1 μL of *n*-hexane solution was subjected for GC/ECD analysis.

2.5. Method Validation. The GC method described above was validated for the quantitative analysis of α-cypermethrin and its metabolites in soils. Good linearities were observed in the range of 0.015−6 mg/kg for α-cypermethrin and in the range of 0.025−0.3 mg/kg for its two metabolites, with mean coefficients of determination (R^2) higher than 0.993. The average recoveries for α-cypermethrin at levels between 0.015 and 6 mg/kg ranged between 77.8 and 94.8% in the five soils, with relative standard deviation (RSD) below 10%, and the average recoveries of its metabolites at levels between 0.020 and 0.3 mg/kg ranged between 78.4 and 95.0% based on an acceptable RSD below 10%. The limits of detection (LODs) for α-cypermethrin, *cis*-DCCA, and 3-PBA in the tested soils were 0.003, 0.008, and 0.008 mg/kg, respectively, and the corresponding limits of quantitation (LOQs) were 0.015, 0.025, and 0.025 mg/kg, respectively.

2.6. Degradation of α-Cypermethrin in Soils. Five test soils from different agriculture regions (0−10 cm) of China that had not been treated with cypermethrin in the last 5 years were used in this study. Their major properties were shown in Table 1. Test soils were adjusted to a water content of 25% and maintained in the darkness at room temperature for 7 days to activate the microorganisms. To add the pesticide to the soil evenly, 10 g of soil was first placed into a 1000 mL Erlenmeyer flask and 0.5 mL of racemic α-cypermethrin solution (3000 μg/mL, acetone) was added. After the solvent was evaporated, another 290 g of soil was added gradually and stirred thoroughly to a spiked concentration of 5 μg/g (each enantiomer). The flasks were sealed with sterile cotton plugs and stored at 25 °C in the dark for 42 days. The moisture content in each flask was checked gravimetrically at each sampling point. The loss of water by evaporation was compensated by adding distilled water. Triplicate samples were removed from each treatment at different time intervals (0, 7, 14, 21, 28, 35, and 42 days) and immediately transferred to a freezer (−20 °C).

2.7. Acute Toxicity of *cis*-DCCA, 3-PBA, and α-Cypermethrin. According to the OECD guideline 207, the acute toxicity of *cis*-DCCA and 3-PBA to earthworms was tested by a paper contact toxicity assay (OECD 1984). Before the assay, the earthworms were rinsed with tap water and dried by absorbent paper, following a depuration period of 24 h on wet filter paper under dark, to evacuate the gut content of the earthworms. A series of concentrations, 10.0, 30.0, 50.0, 70.0, and 100.0 ng/cm^2 *cis*-DCCA and 3-PBA and 80.0, 159.0, 475.0, 632.0, and 790.0 ng/cm^2 α-cypermethrin, were spiked on filter papers (5.5 × 11.5 cm) by adding *cis*-DCCA, 3-PBA, and α-cypermethrin acetone solutions. Controls were set with the solvent acetone. The filter papers spiked with the test substance were placed in a flat-bottomed glass vial (3.6 cm in diameter and 8 cm in length), and 1 mL of deionized water was added to each vial. A total of 10 replicates were performed for each treatment. The earthworms were placed on the filter papers and kept at 20 ± 2 °C. Mortality was checked after an incubation period of 48 h, and on the basis of that, LC_{50} values were calculated by SPSS, version 18.0 (SPSS, Inc., Chicago, IL).

2.8. Combined Toxicity of *cis*-DCCA, 3-PBA, and α-Cypermethrin. After the LC_{50} values of *cis*-DCCA, 3-PBA, and α-cypermethrin were measured, two kinds of combined toxicity were determined: the binary combination of cis-DCCA + 3-PBA and the ternary combination of *cis*-DCCA + 3-PBA + α-cypermethrin. We chose the modified toxic unit (TU) approach to model the combined toxicity according to the literature.[24] In the TU model, a value of 1 TU is defined as the 50% lethal concentration (LC_{50}) value of the chemical. A series of the sum of the TU (∑TU) was used to set the concentrations of each component at proportions of their respective LC_{50} in the mixture. Therefore, the summations of the concentrations were set equivalent to five levels: ∑0.2 TU, ∑0.5 TU, ∑1.0 TU, ∑2.0 TU, and ∑4.0 TU for *cis*-DCCA + 3-PBA and ∑0.3 TU, ∑0.75 TU, ∑1.5 TU, ∑3.0 TU, and ∑6.0 TU for *cis*-DCCA + 3-PBA + α-cypermethrin. For example of a binary mixture of *cis*-DCCA + 3-PBA, 3.7 ng/cm^2 *cis*-DCCA (0.1 TU) and 5.0 ng/cm^2 3-PBA (0.1 TU) made the mixture of ∑0.2 TU. Therefore, to determine the combined toxicity of *cis*-DCCA + 3-PBA, the series concentrations were 3.7 + 5.0, 9.2 + 12.5, 18.4 + 24.9, 36.7 + 49.8, and 73.4 + 99.6 ng/cm^2, and for the determination of the combined toxicity of *cis*-DCCA + 3-PBA + α-cypermethrin, the concentrations were 3.7 + 5.0 + 19.5, 9.2 + 12.5 + 48.8, 18.4 + 24.9 + 97.6, 36.7 + 49.8 + 195.2, and 73.4 + 99.6 + 390.4 ng/cm^2. The calculation of $LC_{50\ mix}$ (50% lethal concentration of the mixture) was conducted by SPSS, version 18.0. The mixture exhibits synergism, additive, or antagonism effects if the determined $LC_{50\ mix}$ values were lower than 1 TU, equal to 1 TU, or greater than 1 TU, respectively.

2.9. Data Analysis. Degradation curves (concentration in soils versus incubation time) were regressed by Excel 2010 (Microsoft). The first-order polynomial regression analysis model was used to describe the dissipation process for α-cypermethrin enantiomers in the soils. It was assumed that the degradation of α-cypermethrin in five soils followed pseudo-first-order kinetics. The corresponding rate constants (k) were calculated according to the equation $C = C_0e^{-kt}$. The starting point of regressive functions was the maximum value of the enantiomer concentrations in the soils and then decreased in the following days. The half-life ($T_{1/2}$, day) was estimated from equation $T_{1/2} = \ln 2/k = 0.693/k$.

The enantiomeric fraction [EF = (+)/(+) + (−)][25] was used to express the enantioselectivity of a pair of enantiomers. Here, (+) and (−) were peak areas of the (+) and (−) enantiomers of α-cypermethrin. The EF values ranged from 0 to 1, with EF = 0.5 representing the racemic mixture.

3. RESULTS AND DISCUSSION

3.1. Enantioselective Degradation in Soils. Table 2 showed the first-order rate constant, half-life ($t_{1/2}$), and coefficient (R^2), and the results showed that there was great difference in the persistence and enantioselectivity of α-cypermethrin in the soils. The half-lives of the enantiomers ranged from 12.7 to 47.1 days in the soils, with R^2 of 0.8951−0.9837, and the persistence of α-cypermethrin in soil 2 was about 2−3 times longer than that in the others. The observed differences in the persistence of α-cypermethrin in the five soils may be due to the organic carbon content. Soil 2 had the highest organic carbon content among the five soils, which might decrease the dissipation of α-cypermethrin. Soils 1 and 5 had similar pH values; however, the degradation rate of α-cypermethrin in the two soils was totally different, suggesting no significant association between pH values and the degradation rate.

Table 2. First-Order Rate Constants, k, Half-Life ($t_{1/2}$), Coefficient (R^2), and the Enantioselectivity (ES) Values of the Degradation of α-Cypermethrin in Soils

soil	α-cypermethrin enantionmer	k (day^{-1})	$t_{1/2}$ (day)	R^2	ES
soil 1	(−)-(1*S*,*cis*,α*R*)	−0.052	14.40	0.9593	0.046
	(+)-(1*R*,*cis*,α*S*)	−0.057	13.30	0.9580	
soil 2	(−)-(1*S*,*cis*,α*R*)	−0.017	47.08	0.9091	0.227
	(+)-(1*R*,*cis*,α*S*)	−0.027	28.39	0.9837	
soil 3	(−)-(1*S*,*cis*,α*R*)	−0.039	16.56	0.9545	0.103
	(+)-(1*R*,*cis*,α*S*)	−0.048	12.70	0.9668	
soil 4	(−)-(1*S*,*cis*,α*R*)	−0.029	22.21	0.9664	0.134
	(+)-(1*R*,*cis*,α*S*)	−0.038	17.53	0.9717	
soil 5	(−)-(1*S*,*cis*,α*R*)	−0.053	17.12	0.8971	0.070
	(+)-(1*R*,*cis*,α*S*)	−0.051	14.42	0.9248	

The data showed that the two enantiomers dissipated at different rates in the five kinds of soils. The changes of EFs with time have been shown in Figure 3, which increased from the initial value of 0.50 with time in all of the soils, illustrating obvious enantioselectivity with (+)-(1*R*,*cis*,α*S*) being degraded faster than that with (−)-(1*S*,*cis*,α*R*). Figure 2B shows a typical chromatogram of the enantioselective degradation of α-cypermethrin in soil 1 after 42 days of incubation.

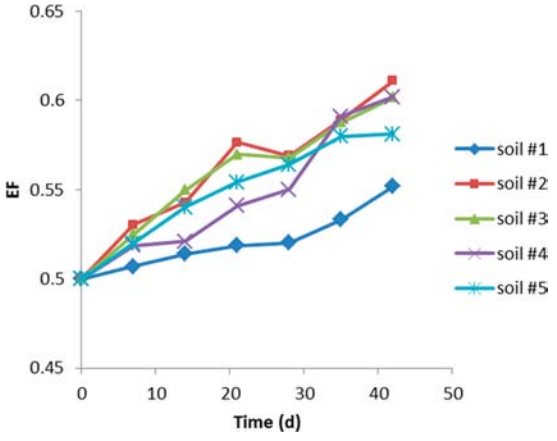

Figure 3. EF curves for the degradation of α-cypermethrin in the five soils.

Li et al. have reportd the enantioselctive degradation of β-cypermethrin in a Tianjin alkaline soil, and the results showed that significant enantioselectivity occurred during the 30 day incubation period, with the enantiomeric ratio (ER) values of one pair of enantiomers of (1*R*,*cis*,α*S*) and (1*S*,*cis*,α*R*) changing from the initial of 1.00 to the final of 0.79.[26] The dissipation of cypermethrin has also been reported in a soil at ambient temperature under aerobic conditions, and the enantiomers of (1*R*,*cis*,α*S*) and (1*S*,*cis*,α*R*) were measured separately, which had half-lives of 63 and 71 days, respectively.[27] The results indicated an enrichment of (1*S*,*cis*,α*R*) in the soils during the degradation process, which were similar to the results in this work.

Enantiomeric selectivity is also a measurement of enantioselectivity, defined as ES = $(k_R - k_S)/(k_S + k_R)$ [where k_R and k_S are rate constants of (+)-(1*R*,*cis*,α*S*) and (−)-(1*S*,*cis*,α*R*) α-cypermethrin in degradation regression equations]. Positive values (0 < ES < 1) indicate a more rapid degradation of (−)-(1*S*,*cis*,α*R*), whereas negative values (−1 < ES < 0) indicate a more rapid dissipation of (+)-(1*R*,*cis*,α*S*), and ES value of 0 shows that the dissipation is not enantioselective. The ES values of α-cypermethrin ranged from 0.0702 to 0.227, showing obvious enantioselectivity in all of the soils, with (+)-(1*R*,*cis*,α*S*) being degraded faster (Table 2). It was found that ES values were positively related to soil organic carbon content after correlation analysis (R^2 = 0.781). Consequently, it can be concluded that the enantioselectivity dissipation of α-cypermethrin was dependent upon the organic carbon content, which may affect chiral signatures by influencing the activity of the microbial community or the level of enzymes in soils.[28] It has been reported that high organic matters in soil increased cypermethrin persistence, which was similar to the result in this experiment.[29]

Some studies reported the enantiomer selectivity of toxicity of cypermethrin. The acute toxicity was measured for the individual enantiomer of α-cypermethrin, and the enantiomer of (+)-(1*R*,*cis*,α*S*) was more toxic than (−)-(1*S*,*cis*,α*R*).[21] The incubation in this paper revealed that (+)-(1*R*,*cis*,α*S*) degraded faster than (−)-(1*S*,*cis*,α*R*), which indicates that enrichment of (−)-(1*S*,*cis*,α*R*) may relieve the toxicity from α-cypermethrin to the earthworm. In addition, in aquatic toxicity, (+)-(1*R*,*cis*,α*S*) was also more toxic than (−)-(1*S*,*cis*,α*R*).[23] Therefore, it is essential to assess the toxicity of pesticide on an enantiomeric level.

3.2. Formation of *cis*-DCCA and 3-PBA. The two metabolites of α-cypermethrin were both detected during its dissipation in the five soils (Figure 4). *cis*-DCCA maintained a higher concentration than 3-PBA through the experimental periods maybe because of the faster degradation of 3-PBA in the soils. *cis*-DCCA could be detected at the 7th day in all of the soils, and the concentration increased with time or was kept at a steady level until the last sample point of 42 day. The final concentrations of *cis*-DCCA in soils 3, 4, and 5 with pH > 7 were 0.59, 0.50, and 0.34 μg/kg, respectively, at the 42nd day, which were higher than the concentrations of 0.11 and 0.17 μg/kg in soils 1 and 5 with pH < 7, respectively. It indicated that *cis*-DCCA was easily generated in alkaline soils.

3-PBA could also be detected at the 7th day in all of the soils. The concentrations increased with time in 1 and 2 soils, reaching a level around 0.11 mg/kg, but only a small amount was found in soil 3 and was undetectable after 21 days. In soils 4 and 5, the highest level appeared at about 14 day at concentrations of 0.13 and 0.31 mg/kg, respectively, and then it

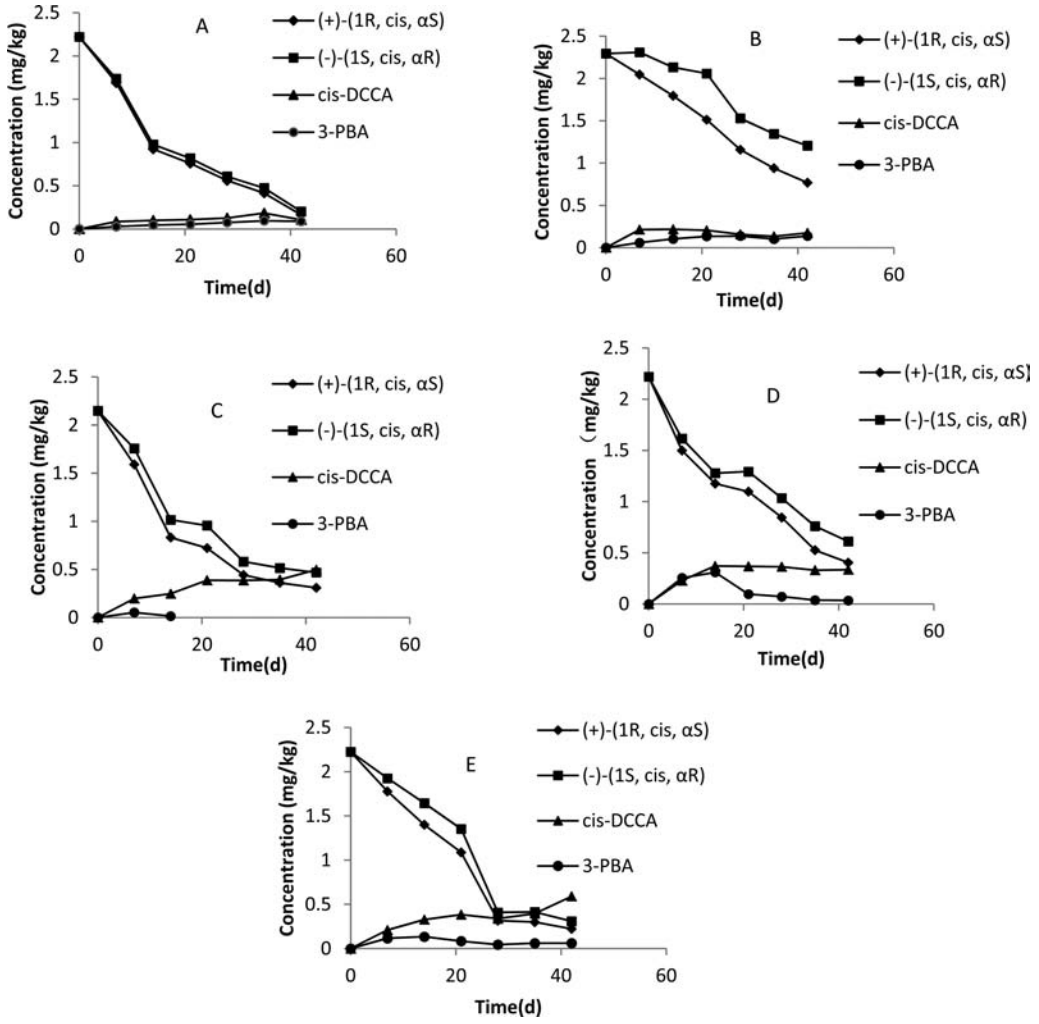

Figure 4. Degradation curves of α-cypermethrin enantiomers and the formation of its metabolites in the five soils.

underwent further degradation. It was found that 3-PBA was more slowly generated and degraded in soils 1 and 2 with pH < 7 than in soils 4 and 5 with pH > 7. It has been reported that the degradation half-life of 3-PBA in Guangzhou soil was 123.7 days,[30] which was much slower than the degradation in soils 3, 4 and 5. This might be caused by the different soil properties. The metabolites were relatively persistent in the soils, which might be a potential problem to the environment for cypermethrin application.

Some epidemiological studies have revealed that 3-PBA has adverse impact on health, such as sperm DNA damage[31] and effect on male reproductive hormone levels,[15] and a number of studies have reported the detection of 3-PBA and *cis*-DCCA in humans. Berkowitz et al. detected 3-PBA in urine samples from pregnant women from ethnic groups (Caucasian, African American, and Hispanic) in New York City, and generally, high levels of 3-PBA (median = 19.3 μg/g of creatinine) were found.[32] Another study in China indicated that the levels of urinary pyrethroid metabolites (3-PBA, *cis*-DCCA, and *trans*-DCCA) were higher than those from the general population of developed countries.[33] Humans may contact those metabolites by a variety of approaches, of which transfer of those from soils by the food chain may be a part.

3.3. Acute Toxicity Assay. By the filter paper contact test, the acute toxicity to earthworm was measured for *cis*-DCCA and 3-PBA. The LC_{50} values for *cis*-DCCA, 3-PBA, and α-cypermethrin were 36.72, 49.81, and 195.22 ng/cm^2, respectively (Table 3). Similar toxicity of α-cypermethrin to earthworm has been reported with the calculated LC_{50} value of 165.61 ng/cm^2.[21] Therefore, the results indicated that the two metabolites were more toxic to the earthworm than the parent compound α-cypermethrin.

Table 3. Calculated LC_{50} Values of *cis*-DCCA, 3-PBA, and α-Cypermethrin for Earthworm

chemicals	48 h LC_{50} (ng/cm^2)	95% confidence intervals	R^2
α-cypermethrin	195.22	138.12−275.94	0.9639
cis-DCCA	36.72	28.76−46.87	0.9794
3-PBA	49.81	37.07−66.89	0.9951

The rate and amount of the metabolites produced varied among the soils. Application of α-cypermethrin to alkaline soils (3, 4, and 5) might be more dangerous to the terrestrial community because more metabolites are produced. In the acidic soils, the metabolites degraded slowly and would last longer, also posing a potential threat to soil animals.

Fast degradation of most pesticides in the environment makes its terrestrial risks acceptable under practical uses. However, evaluations of the ecological risk of corresponding

DOI: 10.1021/acs.jafc.5b03148
J. Agric. Food Chem. 2015, 63, 7714−7720

metabolites are limited at present. Some metabolites may be more persistent and toxic than their parent compounds, which may pose a more detrimental effect on the environment.

The combined toxicities of *cis*-DCCA + 3-PBA and *cis*-DCCA + 3-PBA + α-cypermethrin on earthworms were determined. The combined effect was defined as either concentration additive ($LC_{50\ mix}$ = 1 TU), antagonistic (greater than additive, $LC_{50\ mix}$ > 1 TU), or synergetic (less than additive, $LC_{50\ mix}$ < 1 TU) effects. The $LC_{50\ mix}$ values for *cis*-DCCA + 3-PBA and *cis*-DCCA + 3-PBA + α-cypermethrin were 1.82 TU (1.14−2.90, 95% limits) and 1.72 TU (1.19−2.50, 95% limits), respectively. This result indicated that the combined effect of α-cypermethrin and the two metabolites was antagonistic.

Therefore, it is necessary to evaluate the toxicity of the metabolites and the combined toxicity when assessing the environmental risks from pesticides.

insulin resistance and the lipid profile in rats with diet-induced obesity.[15] Many previous studies have reported that triterpenoid saponins from *P. grandiflorum* exhibit a variety of pharmacological activities, such as anti-inflammatory, anticancer, immune-enhancing, and hepatoprotective effects.[16] Platycodin D (Figure 1), a bioactive compound of *P. grandiflorum*, has been reported to possess anti-inflammatory, neuroprotective, apoptosis-inducing, and antiadipogenic properties.[17,18] However, there has been no study of the influence of *P. grandiflorum* on brown adipocyte differentiation and mitochondria biogenesis.

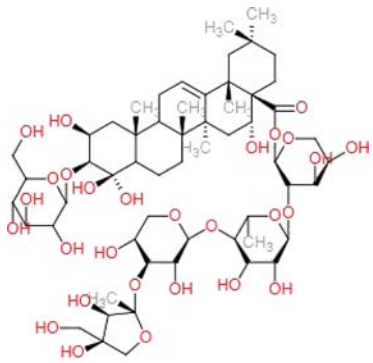

Figure 1. Structure of platycodin D.

In the present study, we investigated the effect of *P. grandiflorum* ethanolic extract (PG) on the differentiation of primary brown adipocytes and compared the antiadipogenic effects of PG and platycodin D in 3T3-L1 cells.

MATERIALS AND METHODS

Preparation of PG. PG was prepared as described previously.[19] Briefly, 1 kg of *P. grandiflorum* was extracted with 80% ethanol for 2 h 20 min using a heating mantle. The solvents were filtered and evaporated under reduced pressure (rotary evaporator model NE-1, Japan), and the remnant was then freeze-dried (freeze-dryer FD-1, Japan) at −56 °C and 9 mm Torr to acquire extracts of the herbal sample.

Reagents. Dulbecco's modified Eagle's medium (DMEM), penicillin−streptomycin, and fetal bovine serum (FBS) were purchased from Gibco RL (Grand Island, NY, USA). Insulin, 3-isobutylmethyxanthine, dexamethasone, indomethacin, 3,3′,5-triiodo-L-thyronine and Oil Red O powder were from Sigma Chemical Co. (St Louis, MO, USA).

HPLC Analysis. The HPLC was equipped with a vacuum degasser, a quaternary pump, and an automatic sample injection system. Chromatographic separation was performed on a Nucleosil C18 (150 mm × 4.6 mm, 5 μm, Teknokroma, Barcelona, Spain). Samples were separated using acetonitrile and phosphate buffer (50:50 v/v), pH 5.5, as the mobile phase at a flow rate of 1.0 mL/min at ambient temperature. Initial elution was performed by acetonitrile−aqueous ammonium acetate 20:80 (v/v). After 10 min, the linear gradient reached 60% acetonitrile.

Cell Culture and Differentiation. Murine 3T3-L1 mouse embryo fibroblasts were obtained from the American Type Culture Collection (Rockwill, MD, USA). Cells were cultured and differentiated as described in our previous study.[20] On day 2, PG was prepared in a differentiation medium at concentrations of 10, 50, and 100 μg/mL. Brown preadipocytes were isolated from the interscapular BAT of mice (age late fetal to postnatal 2−3 days), cultured, and differentiated as described previously.[21] On day 2, PG was prepared in a differentiation medium at concentrations of 10, 50, and 100 μg/mL.

Cytotoxicity Assay. Cell viability was measured using a Cell Proliferation MTS kit (Promega Co., Maddison, WI, USA) as described previously.[20]

Oil Red O staining. Intracellular lipid accumulation was measured using Oil Red O, based on the study of Ramirez-Zacarias et al.[22] as previously described.[20]

RNA Extraction and Real-Time Reverse Transcription Polymerase Chain Reaction (RT-PCR). Total RNA extraction, cDNA synthesis, and the real-time RT-PCR analyses were performed as described previously.[20] The primers used in the experiments are shown in Table 1.

Protein Extraction and Western Blot Analysis. The Western blot analyses were performed as described previously.[20] The antibodies against PPARγ, AMPKα, and pAMPKα were from Cell signaling Technology (Beverly, MA, USA), and the antibodies against C/EBPα, UCP1, PGC1α, and glyceraldehyde-3-phosphate dehydrogenase

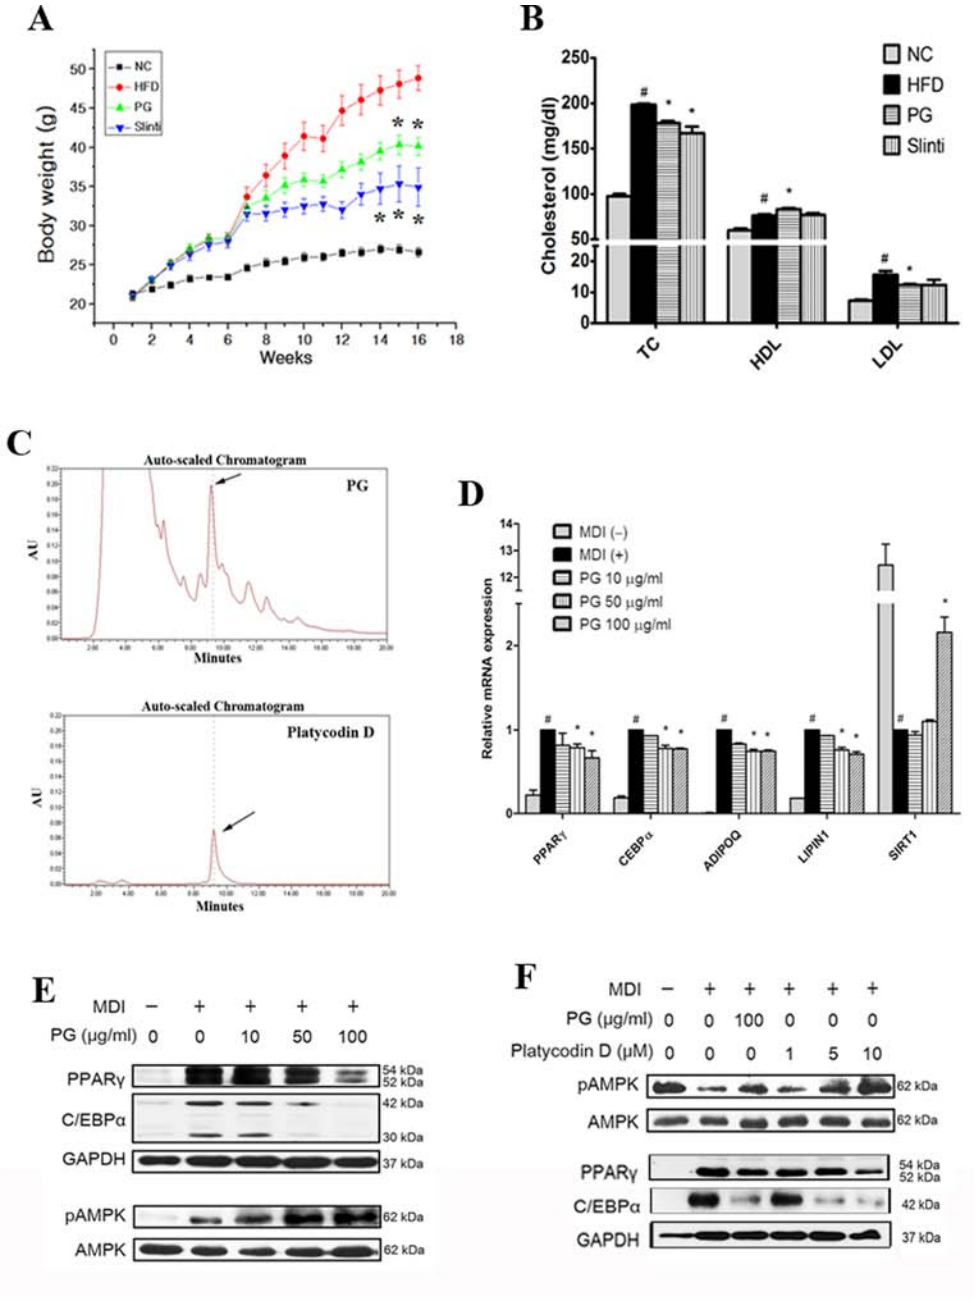

Figure 2. PG attenuates weight gain in HFD-induced obese mice and modulates key transcriptional regulators in 3T3-L1 cells. Mice (n = 5 per group) were administrated PG extract (100 mg/(kg·day)) with a high-fat-diet (HFD) for 12 weeks. Normal control group (NC) was fed normal chow diet. Slinti (5 mg/(kg·day)) was administrated as a positive control. Changes in (A) body weight and (B) serum levels of total, HDL, and LDL cholesterol were measured. (C) HPLC chromatogram of PG. Each peak displays PG (above) and platycodin D (below). PG was extracted with 80% ethanol. (D) The mRNA of PPARγ, C/EBPα, adiponectin, lipin-1, and SIRT1 were analyzed by real-time RT-PCR. (E) PPARγ, C/EBPα, and pAMPK protein levels were analyzed by a Western blot analysis. (F) Effect of PG on PPARγ, C/EBPα, and pAMPK was compared with effect of platycodin D by a Western blot analysis. Results were expressed relative to GAPDH. Values are mean ± SEM of data from three separate experiments. (A, B) $^{\#}p < 0.05$, significantly different from NC; $^{*}p < 0.05$, significantly different from HFD. (D) $^{\#}p < 0.05$ vs MDI-undifferentiated control cells; $^{*}p < 0.05$ vs MDI-differentiated control cells.

(GAPDH) were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA).

Mitochondrial Microscopic Analysis. The mitochondrial analysis was performed as described previously.[21]

Ethics Statement. All procedures used in animal experiments were performed according to a protocol approved by the Animal Care and Use Committee of the Institutional Review Board of the Kyung Hee University (confirmation number, KHUASP (SE)-13-012).

High-Fat-Diet (HFD)-Induced Obese Mice Study. Male 4-week-old C57BL/6J mice were purchased from Daehan Biolink Co. (Eumsung, Korea) and maintained for 1 week prior to experiments. All animals were maintained under a 12 h light−dark cycle in a pathogen-free animal facility. Mice were provided with a laboratory diet and water *ad libitum*. To induce obesity, the mice were fed a HFD (Rodent Diet D12492, Research Diet, New Brunswick, NJ, USA) consisting of 60% fat in accordance with previously published reports.[23] Normal mice were fed a commercial standard chow diet (CJ Feed Co., Ltd., Seoul, Korea). The mice were fed a HFD for 4 weeks before administration with PG or Slinti, a green tea extract used as a positive control (Myoungmoon Pharm. Co., Ltd., Seoul, Korea). The mice

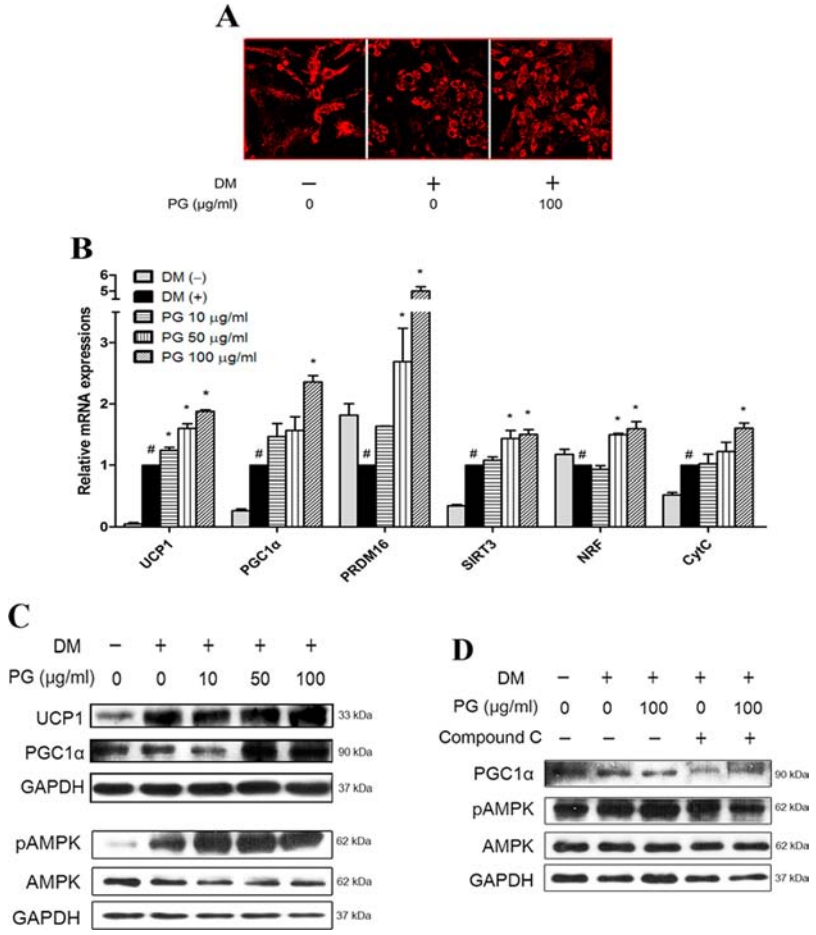

Figure 3. PG increases expressions of mitochondria-related factors in primary brown adipocytes. (A) Mitochondrial abundance in primary brown adipocytes was analyzed by MitoTracker Red staining. (B) The mRNA of UCP-1, PGC1α, PRDM16, SIRT3, NRF, and CytC were analyzed by real-time RT-PCR. (C) UCP1, PGC1α, and pAMPK protein levels were analyzed by a Western blot analysis. (D) Effects of PG with or without cotreatment of compound C on PGC1α and pAMPK were analyzed by a Western blot analysis. Results were expressed relative to GAPDH. Values are mean ± SEM of data from three separate experiments. (B) $^{\#}p < 0.05$ vs DM-undifferentiated control cells; $^{*}p < 0.05$ vs DM-differentiated control cells.

were randomly divided into four groups (n = 5 per group) that were fed a normal diet, a HFD, a HFD plus PG, or a HFD plus Slinti, for 16 weeks. Body weight and food intake were measured three times per week.

***db/db* Mice Study.** Male 5-week-old *Lepr*$^{-/-}$ (*db/db*) mice and age matched nondiabetic (ND) heterozygous mice (both derived from a C57BL/6J background) were purchased from Daehan Biolink Co. (Eumsung, Korea) and maintained for 1 week prior to experiments. All animals were maintained under a 12 h light−dark cycle in a pathogen-free animal facility. All mice were provided with a laboratory diet and water *ad libitum*. Healthy mice were randomly allocated into three groups as follows (n = 5 per group): an ND group, a *db/db* group, and a *db/db* group administered platycodin D. The control groups (ND and *db/db* group) were orally administered distilled water, while the experiment group was orally administered platycodin D prepared in distilled water (5 mg/kg of body weight) five times per week for 5 weeks. Body weight and food intake were measured three times per week.

Hematoxylin and Eosin Staining. After the *db/db* mice were sacrificed, the liver tissues were collected, washed in saline, fixed in 10% formalin, and then dehydrated using grades 70%, 80%, 90%, 95%, and 100% ethanol. After clearing in two changes of xylene, the samples were impregnated with molten paraffin wax, then embedded and blocked out. The tissues were then cut into 4−5 μm sections and stained with hematoxylin and eosin. Microscopic examinations were performed and photographs were taken under a regular light microscope (Olympus Co., Tokyo, Japan).

Serum Analysis. At the end of the treatment, the animals were anesthetized, and serum was separated immediately after blood sampling by centrifugation at 4000g for 30 min. The serum was stored at −70 °C until being used for assays. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), total cholesterol (TC), high-density lipoprotein (HDL) cholesterol, and low-density lipoprotein (LDL) cholesterol were assayed at the Seoul Medical Science Institute (Seoul Clinical Laboratories, Seoul, Korea).

Statistical Analysis. All data, expressed as mean ± SEM, were processed statistically using the software SPSS 12 for Windows (SPSS Inc., Chicago, IL, USA). A value with $p < 0.05$ was considered to indicate statistical significance.

RESULTS

PG Attenuates Weight Gain in HFD-Induced Obese Mice and Modulates Key Transcriptional Regulators Level and the Phosphorylation of AMPK in 3T3-L1 Cells. In the present study, we investigated the effect of PG on primary cultured brown adipocytes, 3T3-L1 cells, and the HFD-induced obesity animal model. First, in order to investigate the antiobesity effects of PG *in vivo*, mice were fed HFD for 4 weeks before administration with PG. The HFD significantly increased the mouse body weights at 4 weeks compared with weights in the standard diet group. After induction of obesity, the mice were subdivided into four groups

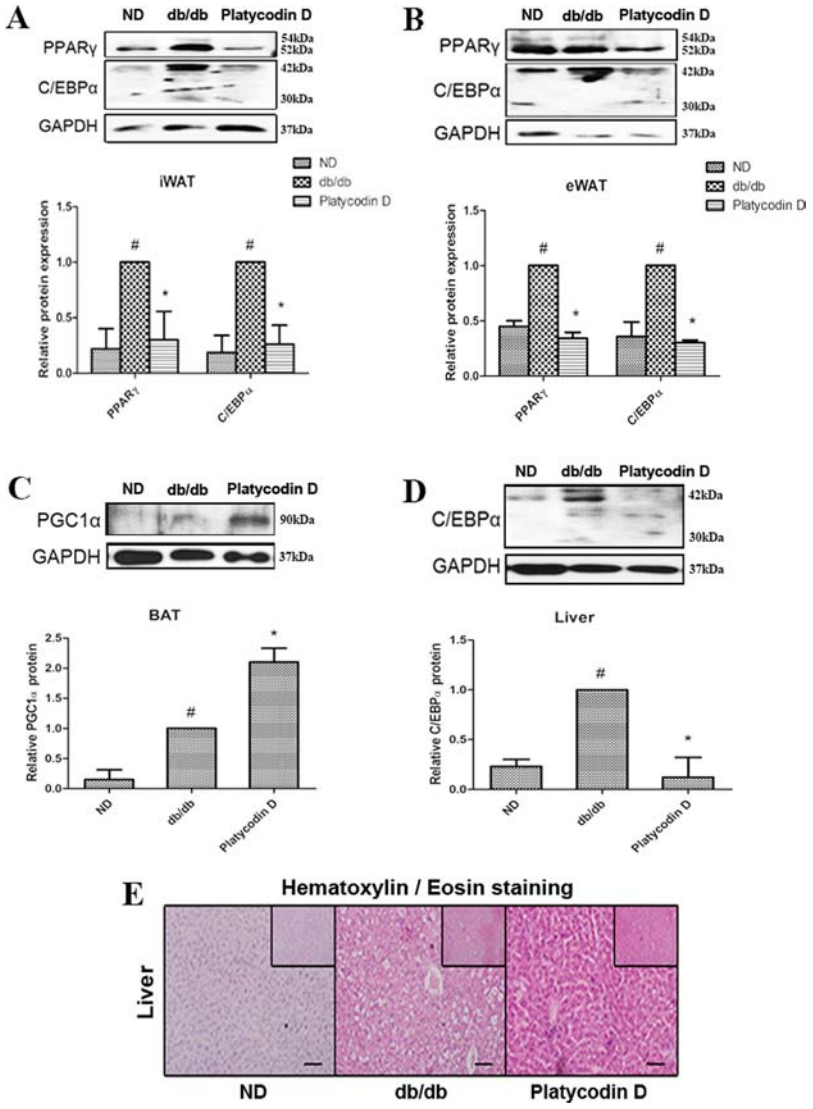

Figure 4. Platycodin D improves adipogenic-related factors and mitochondrial biogenesis factors in *db/db* mice. (A,B) After the study termination, protein expression levels of PPARγ and C/EBPα were measured in iWAT and eWAT. (C) The protein expression level of PGC1α, a thermogenic and mitochondrial biogenesis gene, was measured in BAT. (D) The protein expression level of C/EBPα was measured in liver. Results were expressed relative to GAPDH. (E) Paraffin sections of liver from nondiabetic (ND) mice, *db/db* mice, and *db/db* mice treated with platycodin D at 5 mg/kg were stained with hematoxylin and eosin (H&E), and the histological changes were observed at 200× (scale bar = 100 μm). Values are mean ± SEM of data from three separate experiments. (A−D) $^{\#}p < 0.05$ significantly different from ND; $^{*}p < 0.05$ significantly different from *db/db*.

(n = 5 per group): a normal diet group with vehicle treatment, a 60% HFD group with vehicle treatment, a 60% HFD group with Slinti (5 mg/(kg·day)) treatment as a positive control, and a 60% HFD group with PG (100 mg/(kg·day)). PG significantly suppressed body weight gain compared with the HFD group ($p < 0.05$). The HFD group gained 48.84 ± 1.61 g of weight, while the PG and Slinti groups gained 40.14 ± 0.75 g and 34.89 ± 2.42 g, respectively (Figure 2A). Administration of PG had no effect on food intake compared with the HFD (not shown). The changes in the blood plasma parameters after the 16 week experiment were measured. PG significantly attenuated the levels of TC and LDL cholesterol ($p < 0.05$) (Figure 2B).

A HPLC chromatogram revealed that platycodin D was a major constituent of PG (Figure 2C). To determine the cytotoxicity of PG, 3T3-L1 cells were treated with various concentrations of PG, and the cell viability was measured by an MTS assay. Treatment with 10−100 μg/mL of PG did not cause significant cytotoxic effects ($p < 0.05$; Figure S1A). Due to this result, further treatments were conducted at concentrations of 10, 50, and 100 μg/mL. Next, to investigate the effects of PG on preadipocyte differentiation, the lipid accumulation was measured by an Oil Red O staining assay. As shown in Figure S1C, 100 μg/mL of PG suppressed lipid accumulation in 3T3-L1 adipocytes at levels that were statistically significant ($p < 0.05$), suggesting that PG inhibits adipogenesis in 3T3-L1 cells.

Adipocyte differentiation accompanies the changes in expression of various adipogenic and lipogenic genes. PPARγ and C/EBPα are well recognized adipogenic genes known to have roles in the early stage of adipogenesis.[24,25] Lipin-1 is also required at the early step in adipocyte differentiation for induction of the adipogenic gene transcription.[26] To investigate the antiadipogenic mechanism of PG, its effects on mRNA expression levels of PPARγ, C/EBPα, lipin-1, adiponectin, and SIRT1 were examined. Fully differentiated 3T3-L1 cells were exposed for 48 h to various concentrations of PG. Expressions

DOI: 10.1021/acs.jafc.5b01908
J. Agric. Food Chem. 2015, 63, 7721−7730

of both adipogenic genes, PPARγ and C/EBPα, were significantly decreased by PG treatment ($p < 0.05$). PG also suppressed the expression of adiponectin and lipin-1 in a dose-dependent manner. In addition, SIRT1, an important regulator of preadipocyte differentiation and adipogenesis, was significantly increased by PG ($p < 0.05$; Figure 2D).

We demonstrated that PG treatment resulted in a dose-dependent suppression of PPARγ and C/EBPα. AMPK, a key player in energy homeostasis,[27] was activated by PG during differentiation, because the level of phosphorylated AMPKα was increased while the level of total AMPKα was unchanged (Figure 2E). To compare the effects of PG and platycodin D, AMPK phosphorylation was investigated by Western blotting. Platycodin D at 5 μM showed similar effects to 100 μg/mL of PG on AMPK activation. In addition, platycodin D at 5 μM exhibited decreased expression of PPARγ and C/EBPα, similarly to effects of 100 μg/mL of PG (Figure 2F).

PG Increases the Expression of Mitochondria-Related Genes in Primary Brown Adipocytes and Induces the Differentiation of Primary Brown Adipocytes via the AMPK Signal Pathway. We also investigated the effects of PG on differentiation of primary brown adipocytes. The amount of brown adipose tissue in adult humans has been reported to be highly correlated with their degree of obesity, indicating that brown adipocytes may play an important role in the prevention and treatment of obesity.[28,29] Before any further experiments, we first performed an MTS assay in order to evaluate the cell toxicity of PG on brown adipocytes. A cell viability assay demonstrated that PG (10−100 μg/mL) did not show any cytotoxicity ($p < 0.05$; Figure S1B). Since the activity and number of mitochodria is a typical difference between white and brown adipocytes, the mitochondrial abundance was analyzed. Brown preadipocytes isolated from mice interscapular brown fat were induced to differentiate into mature brown adipocytes. Mitochondria in mature brown adipocytes and adipocyte morphology were then quantified using Mito-Tracker fluorescence images. As a result, PG-treated cells showed stronger staining than control cells (Figure 3A). In addition, to investigate the effects of PG on differentiation of primary brown adipocytes, the level of mitochondia-related genes was measured by real-time RT- PCR. The mRNA of UCP1, PGC1α, PRDM16, SIRT3, NRF, and CytC was significantly increased in a dose-dependent manner by PG ($p < 0.05$) (Figure 3B). Similarly, the proteins of UCP1, PGC1α, and pAMPK were increased by PG (Figure 3C). Brown adipocytes exhibited significant decreases in PGC1α and pAMPK protein expressions by the AMPK inhibitor compound C, which was successfully restored by PG treatment (Figure 3D). These results clearly suggest that PG induces the differentiation of primary brown adipocytes via the AMPK signal pathway.

Platycodin D Modulates Adipose Tissue Metabolism and Alters Histologic Changes of the Livers in *db/db* Mice. To confirm the effects of platycodin D on adipose tissue metabolism *in vivo*, mice were administrated platycodin D for 5 weeks. Platycodin D reduced the protein expression levels of PPARγ and C/EBPα, the adipogenic-related markers in inguinal WAT (iWAT) and epididymal WAT (eWAT) (Figure 4A,B). Also, the protein expression level of C/EBPα in liver was decreased by platycodin D (Figure 4D). Treatment with platycodin D increased the protein expression levels of PGC1α, a specific marker involved in mitochondrial biogenesis in interscapular BAT of *db/db* mice (Figure 4C). Histology of the liver tissues showed that the triglyceride content of the liver in the platycodin D group was lower than the *db/db* group (Figure 4E). These results suggest that platycodin D is an important regulator of adipose tissue metabolism and decreases steatosis in the liver tissue.

DISCUSSION

Obesity has become an epidemic in developed countries and is also rapidly spreading in many developing countries.[30] The rates of obesity and overweight have been continuing to grow in adults, and unfortunately the situation has been worsening by penetrating into the child and adolescent populations.[7] Adipose tissue plays a critical role in energy homeostasis as both an energy reserve and an endocrine organ in animals.[7,31] Obesity is defined as an excessive growth of adipose tissue mass.[32] There are two types of adipose tissues, WAT and BAT, which are primarily composed of white and brown adipocytes, respectively. White adipocytes primarily function as a depot of triglycerides as energy reservoirs, while brown adipocytes generate heat energy at the expense of ATP generation due to their high expression of UCP1.[33−35] Most obesity related studies have focused on the differentiation of white adipocytes; thus the molecular differentiation mechanism of brown adipocytes has not been investigated thoroughly yet.[29,36,37] In the present study, we investigated the effects of PG on obesity in brown/white preadipocytes.

P. grandiflorum has been used as a traditional medicine for treating bronchitis, asthma, pulmonary tuberculosis, hyperlipidemia, and hypercholesterolemia in Asia. It contains numerous triterpenoid saponins, carbohydrates, and fibers.[38,39]

Many studies have focused on the identification of the biological activities of *P. grandiflorum* including anti-inflammation, antihyperlipidemia, antiobesity, and apoptosis.[40−42] Reportedly, *P. grandiflorum* water extract (PWE) significantly reduced plasma TC and TG concentrations, as well as body weight and adipose tissue weight. PWE also decreased the size of subcutaneous adipocytes. Furthermore, the up-regulation of FABP mRNA expression induced by a high-fat feeding was significantly repressed by PWE treatment.[15] Also, *P. grandiflorum* ameliorates obesity and insulin resistance in obese mice via reductions of adipocyte differentiation, followed by the activation of AMPK/ACC pathways.[43] Considering the reports, PG may be useful in the prevention and improvement of obesity.

PPARγ and C/EBPα are known to be regulated in early stages during adipocyte differentiation.[44] PPARγ is viewed as a master regulator of adipogenesis, since expression of PPARγ is sufficient to induce adipogenesis in the absence of extracellular hormones and, on the other hand, deficiency of PPARγ prevents preadipocytes from differentiating into mature adipocytes.[45] C/EBPα, a member of the basic region leucine zipper family of transcription factors, is involved in adipogenesis and hepatic glucose and lipid metabolism.[5,46] In the present study, PG treatment resulted in reduced expression of PPARγ and C/EBPα at both the mRNA and protein levels in 3T3-L1 cells. These results clearly indicated that PG is a potent inhibitor for adipocyte differentiation via the PPARγ and C/EBPα signaling cascade.

Lipin-1 exists in three isoforms, lipin-1α, -1β, and -1γ, and in most cell types, lipin-1 is distributed throughout the cell, because the 1β isoform predominantly exists in the cytoplasm and the 1α isoform mostly in the nucleus, while lipin-1γ is mainly localized in lipid droplets.[47] Adiponectin, an adipocytokine secreted by the adipose tissue, has been confirmed to

DOI: 10.1021/acs.jafc.5b01908
J. Agric. Food Chem. 2015, 63, 7721−7730

regulate glucose metabolism both *in vivo* and *in vitro*.[5] A decrease in the blood level of adiponectin with excessive body fat deposition was reported, while circulating adiponectin is raised with body fat loss, revealing that there is a close connection between adiponectin and body fat deposition.[5,48,49] We found that PG can inhibit adipocyte differentiation through suppression of lipin-1 and adiponectin. SIRT1 has numerous beneficial metabolic effects against those associated with a HFD, and this has been highlighted in SIRT1 deficient and gain of function mouse models. Also, SIRT1 exerts effects similar to those of AMPK on cellular energy metabolism and mitochondrial biogenesis.[50,51] AMPK regulation of fatty acid metabolism and mitochondrial content in response to pharmacological activation as well as exercise has grown AMPK into a potential therapeutic target for treatment of obesity and type 2 diabetes.[52,53] Our results demonstrated that PG significantly down-regulated lipin-1 and adiponectin mRNA expression in 3T3-L1 adipocyte differentiation. PG also significantly up-regulated the expressions of SIRT1 and AMPK during 3T3-L1 adipocyte differentiation. Interestingly, activation of AMPK and SIRT1 by PG seemed to inhibit adipocyte differentiation. Thus, we suggest that PG has a beneficial role in obesity by activating the AMPK/SIRT1 signaling pathway.

Platycodin D, a naturally occurring saponin in the roots of *P. grandiflorum*, has various pharmacological activities, including anti-inflammatory, antihyperlipidemic, and antiobesity.[18,54−56] In this study, we compared the effects of PG and platycodin D in the differentiation of adipocytes. When compared, inhibition rate of PG and platycodin D on lipid accumulation was similar in 100 μL/mL PG and 5 μM platycodin D (36.59% and 41.01%, respectively). In AMPK phosphorylation, 100 μL/mL PG also showed similar effect to that of 5 μM platycodin D on the AMPK activation. These results indicate that similar to PG, platycodin D inhibits adipogenesis in obesity.

Mitochondrial homeostasis is crucial for maintaining proper energy supply and function of tissues. The abundance of mitochondria in a cell is determined by biogenesis, fission/fusion, and mitophagy.[57,58] PGC1α is an important factor in mitochondrial biogenesis and function and is regulated by an acetylation/deacetylation reaction.[59] Also, PGC1α is a transcriptional coactivator that plays a major role in the acquisition of the specific brown adipocyte phenotype. Because of the important role of PGC1α in the differentiation process of brown fat, the stimulatory effects of PG on PGC1α gene transcription suggested that PG might also be able to enhance brown adipocyte differentiation. PGC1α coactivates with nuclear receptors and transcription factors and thereby activates genes involved in thermogenesis, lipid oxidation, and mitochondrial oxidation, which are associated with the specific thermogenic function of BAT.[14,60] In mice, its presence at very high levels in the inner membrane of brown fat cell mitochondria is determined by brown adipocyte precursor cell differentiation along a pathway involving the critical dual presence of PGC1α and PRDM16.[61] PRDM16 is a critical regulator of brown adipocyte development. Downregulation of PRDM16 in brown adipocytes promotes their fate switch to myoblasts.[62,63] PRDM16 drives expression of the browning and thermogenic gene program. Overexpression of PRDM16 in adipose lineage resulted in more energy expenditure, which improved glucose metabolism and enhanced insulin sensitivity.[63] The sirtuins (SIRT1−-SIRT7) are a family of nicotinamide adenine dinucleotide (NAD^+)-dependent protein deacetylases[64,65] and regulate multiple cellular processes, including metabolic homeostasis.[66] SIRT3 is a mitochondrial sirtuin that regulates fatty acid oxidation during fasting and ATP production.[8] We showed that PG significantly up-regulated the major factor expressions of brown adipocytes including PGC1α, PRDM16, SIRT3, and NRF. These genes are largely known to be involved in the regulation of thermogenesis and mitochondrial oxidation. The present findings, that PG up-regulated these genes and it was also associated with a large number of mitochondria, suggest the beneficial effect of PG on mitochondrial biogenesis, thermogenesis, and differentiation in primary cultured brown adipocytes.

We also performed an animal study to confirm the effect of PG *in vivo* using the concentration 100 mg/(kg·day). We showed that the body weight of PG fed mice was decreased in 100 mg/(kg·day). The serum TC and LDL cholesterol were decreased in PG treated mouse. In addition, HDL cholesterol was increased in PG treated mice. The serum levels of AST and ALT indicated that PG did not induce any toxicity (Figure S2). In the present study, we demonstrated the effect of PG on diet-induced obesity improvement and treatment.

Lepr$^{-/-}$ (*db/db*) mice are leptin receptor deficient and develop obesity, hyperglycemia, insulin resistance, and dyslipidemia by 4−8 weeks of age.[67] Two different types of adipose tissue have been described: BAT, composed mainly of brown adipocytes, and WAT, defined by a majority of white adipocytes, both tissues being able to accumulate lipids in intracellular droplets.[68] We performed a *db/db* mouse study to confirm the histologic change in the liver and adipose tissue metabolism induced by platycodin D *in vivo*. As shown in Figure 4, these results clearly suggest that platycodin D regulates the protein expression levels of several adipogenic- and thermogenic-factors in tissues related to metabolism. Therefore, this study provides the evidence that platycodin D is also able to exhibit an antiobesity activity in *db/db* mice.

Taken together, our results indicate that PG suppressed the adipogenesis of white adipocytes and stimulated the differentiation of brown adipocytes through modulation of mitochondria-related genes both *in vitro* and *in vivo*. Thus, our results suggest the potential of their usage for obesity treatment. However, further studies targeting the therapeutic pathways of PG and platycodin D on white/brown adipogenesis and thermogenesis are required, not only to clarify the effects of both materials but also to clarify the understanding of the mechanism link between WAT and BAT function, which is possibly due to AMPK signaling based on our study.

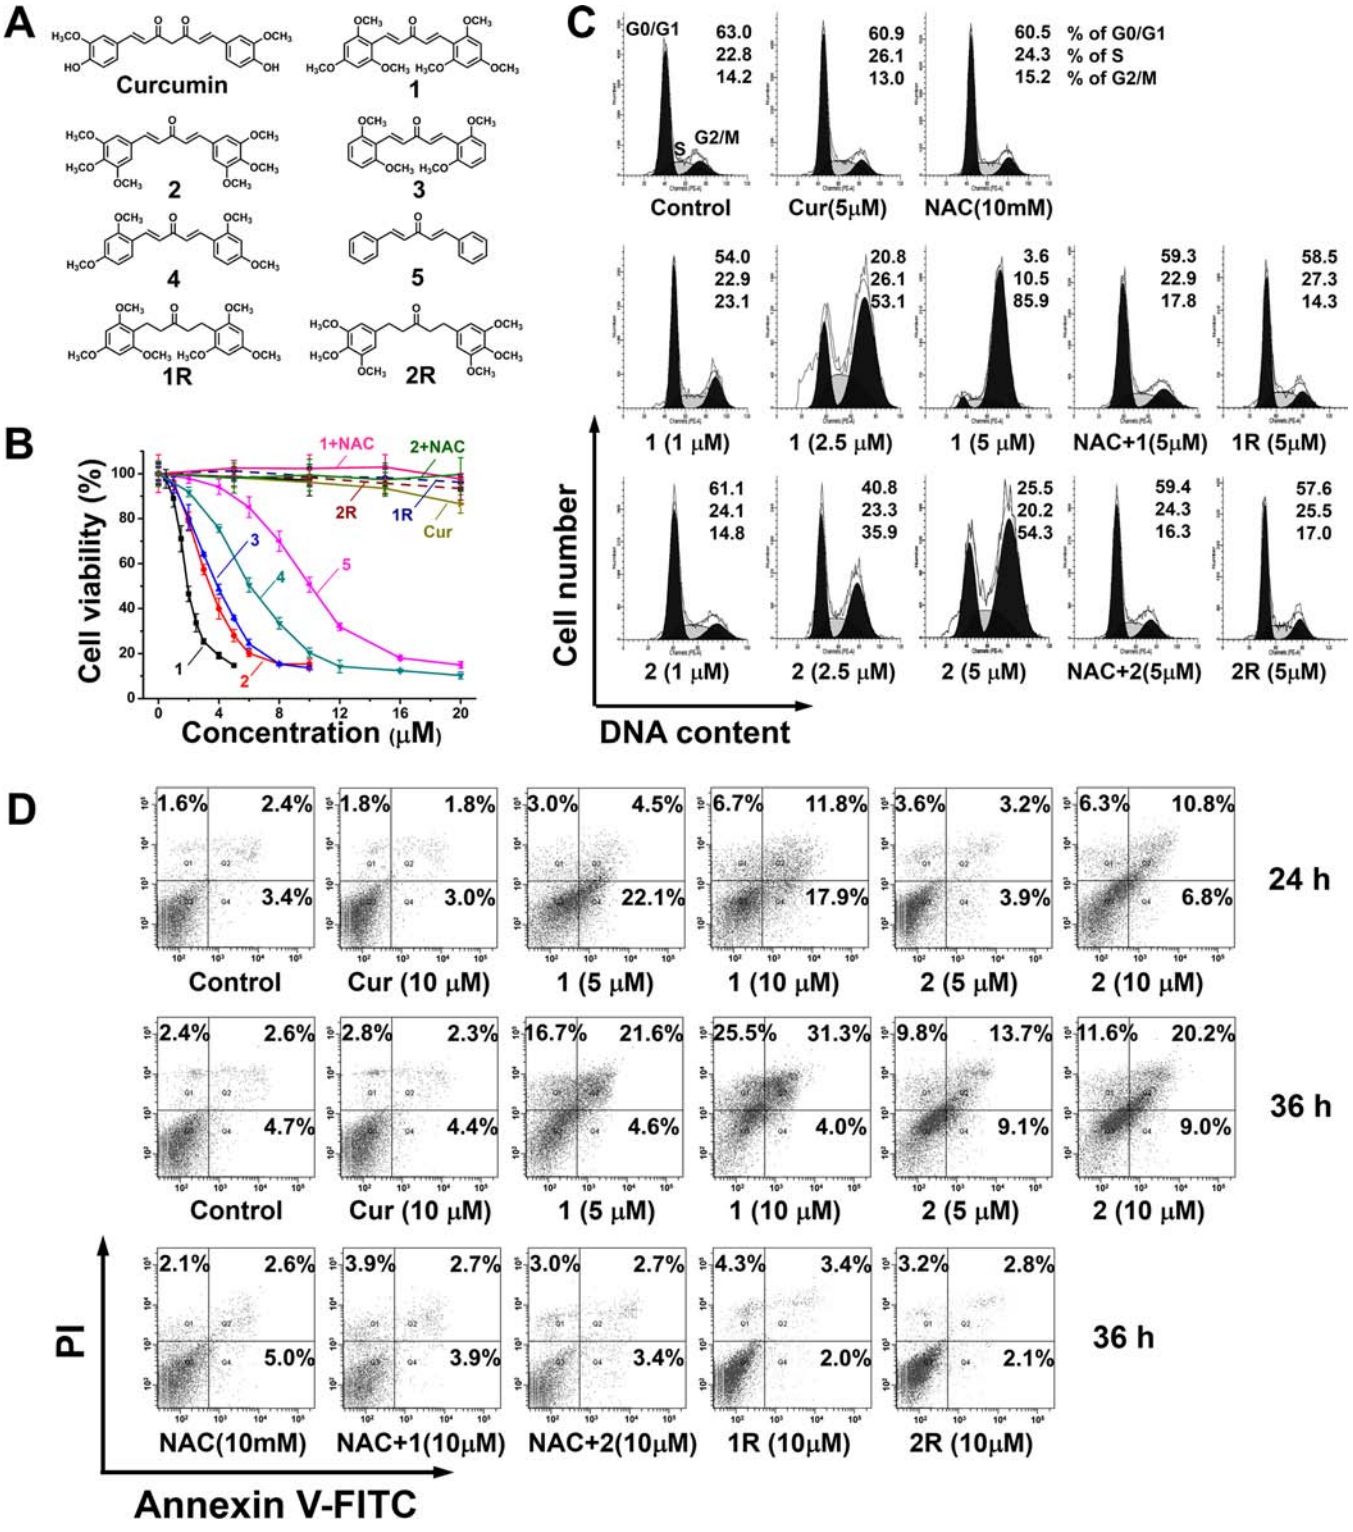

Figure 1. Cytotoxicity of compounds **1** and **2** toward NCI-H460 cells is mediated by the G2/M cell cycle arrest. (A) Chemical structures of curcumin (Cur) and its analogues. (B) Cytotoxicity of Cur and its active analogues. Cells (3×10^3/well) were treated with the test compounds at serial concentrations for 48 h in the absence or presence of 1 h of pretreatment with NAC, and cell viability was measured by the SRB assay as described under Materials and Methods. Data represent the mean ± SD of three experiments. (C) Michael acceptor- and ROS-dependent G2/M arrest induced by compounds **1** and **2** in NCI-H460 cells. Cells (4×10^5/well) were treated with the test compounds at the indicated concentrations for 24 h in the absence or presence of 1 h of pretreatment with NAC and subjected to cell cycle analyses. Representative histograms from three repeat experiments are shown to depict cell cycle distribution. (D) Apoptosis induced by compounds **1** and **2**. Cells (3×10^5/well) were treated with the test compounds with indicated concentrations for 24 or 36 h in the absence or presence of 1 h of pretreatment with NAC and subjected to annexin V-FITC/PI double-staining assay. Cells show four different cell populations marked as follows: necrotic cells (upper left, Q1), late apoptotic cells (upper right, Q2), live cells (lower left, Q3), and early apoptotic cells (lower right, Q4). Data are representative of three independent experiments.

substituted diarylpentadienone displays significantly increased cytotoxicity and apoptosis-inducing activity in A549 cells via ROS-mediated mechanisms; this compound could effectively and irreversibly modify the TrxR on the basis of its electrophilicity, geometry, and good cellular uptake and convert this antioxidant enzyme into a ROS promoter, resulting in a burst of intracellular ROS and collapse of the redox buffering system.[24] Additionally, we have also noted from published data that two symmetrical hexamethoxy-diarylpentadienones, **1**[20,21] and **2**[19,21,23] (Figure 1A), are more potent in inducing cancer cell death than curcumin. However, the action mechanisms are unclear. As part of our research project in pro-oxidant-mediated cancer chemoprevention,[6−8,24] we thus selected the two compounds to investigate their cytotoxic mechanisms. To probe the structure−activity relationships (SAR) and possibility of Michael acceptor-dependent redox intervention, we also synthesized their analogues **3**−**5** and reduced compounds **1R** and **2R** that lack the Michael acceptor units (Figure 1A). On the basis of preliminary screening experiments, we found that all of the test cell lines, including human hepatoma (HepG2 and SMMC-7721) and lung carcinoma (A549 and NCI-H460) cells, showed more significant response to compounds **1** and **2** than curcumin, with the NCI-H460 being the most sensitive cancer cell line for all of the test compounds. Additionally, we noted with interest that the cytotoxicity of compounds **1** and **2** toward NCI-H460 cells was mainly mediated by inducing cell cycle arrest. This is different from our previous results[24] showing that pro-apoptosis ability of another series of diarylpentadienones was responsible for their cytotoxicity in A549 cells. More interestingly, in comparison with compound **2**, compound **1** displayed a relatively weak ability to generate ROS but an increased cell cycle arrest activity and cytotoxicity in NCI-H460 cells. Therefore, we report herein the detailed mechanistic study on the cytotoxicity of compounds **1** and **2** toward NCI-H460 cells, with emphasis placed on elucidating Michael acceptor-dependent redox intervention, clarifying why compound **1** is a stronger G2/M cell cycle arrest agent than compound **2** and emphasizing the possibility of multiple targets involved in the processes.

MATERIALS AND METHODS

Materials. Roswell Park Memorial Institute (RPMI)-1640, sulforhodamine B (SRB), 2′,7′-dichlorofluorescin diacetate (DCFH-DA), L-glutathione reduced (GSH), L-glutathione oxidized (GSSG), glutathione reductase (GR), 2-vinylpyridine, 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), TrxR (from rat liver), Triton X-100, BSA, anti-α-tubulin-FITC antibody, and 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI) were purchased from Sigma-Aldrich (St. Louis, MO, USA). NADPH was from Roche Diagnostics GmbH (Mannheim, Germany). BCA protein assay kit, anti-fade mounting medium, radioimmunoprecipitation assay buffer, and PMSF were from Beyotime Institute of Biotechnology (Jiangsu, China). Antibodies against p53, p21, cyclin B1, cyclin-dependent kinase 1 (Cdk1), glyceraldehyde 3-phosphate dehydrogenase (GAPDH), and TrxR1 were from Cell Signaling Technology (Beverly, MA, USA). The antibody against Cdc25C was purchased from Millipore (Billerica, MA, USA). TRFS-green was a generous gift from Prof. Jianguo Fang (State Key Laboratory of Applied Organic Chemistry, Lanzhou University). DNs-CV, a highly fluorogenic probe for glutathione *S*-transferases (GSTs), was synthesized as previously reported by Zhang.[25] Curcumin and compound **5** were prepared in our previous study.[24,26] All other chemicals were of the highest quality available.

Synthesis. Compounds **1**−**4** were synthesized from appropriate benzaldehydes and acetone under alkaline conditions, and compounds **1R** and **2R** were synthesized by catalytic hydrogenation of **1** and **2** over Pd/C according to our previous works.[24,26] Their structures were characterized by mp; IR, ^{1}H NMR, and ^{13}C NMR spectra; and HRMS (ESI) /MS (EI) analysis.

(1E,4E)-1,5-Bis(2,4,6-trimethoxyphenyl)penta-1,4-dien-3-one ***(1):*** yellow solid; yield 71%; mp 222−224 °C; IR (KBr) 2943, 2834, 1626, 1550, 1458, 1336, 1206, 1149, 1118, 1028 cm^{-1}; ^{1}H NMR (400 MHz, CD_3Cl, 25 °C, TMS) δ 3.86 (s, 6H), 3.91 (s, 12H), 6.14 (s, 4H), 7.48 (d, J = 16 Hz, 2 H), 8.14 (d, J = 16 Hz, 2 H); ^{13}C NMR (100 MHz, CD_3Cl, 25 °C, TMS) δ 55.6 (2C), 56.0 (4C), 90.8 (4C), 107.0 (2C), 126.7 (2C), 133.7 (2C), 161.7 (4C), 162.9 (2C), 192.7 (1C); HRMS (ESI) m/z calcd for $C_{23}H_{26}O_7$ $[M + H]^+$ 415.1751, found 415.1746, error = 1.2 ppm.

Cell Culture. NCI-H460 (human non-small cell lung cancer) cells, obtained from the Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences, were cultured in RPMI-1640 medium supplemented with fetal bovine serum (10%, v/v), $NaHCO_3$ (2 g/L), glutamine (2 mM), penicillin (100 kU/L), and streptomycin (100 kU/L) and maintained in a humidified 5% CO_2 atmosphere at 37 °C.

Cytotoxicity Assay. The SRB assay was used to determine cytotoxicity of the test compounds against NCI-H460 cells. The cells (3×10^3/well) treated with graded concentrations of the test compounds for 48 h were fixed with trichloroacetic acid and stained with SRB (0.4%) for 30 min. When necessary, the cells were pretreated with NAC (10 mM) for 1 h before the test compounds were added. Cells were washed with acetic acid (1%) and added to

J. Agric. Food Chem. 2015, 63, 7731−7742

Tris base solution (10 mM) for absorbance measurements at 570 nm using a microplate reader (Bio-Rad model 550). The cell viability was expressed as the percentage of the control.

Cell Cycle and Apoptosis Analysis. The cell cycle distribution and induction of apoptosis in NCI-H460 cells treated with the test compounds for the indicated durations were analyzed using a FACSCanto flow cytometer (Becton-Dickinson, San Jose, CA, USA), as described in detail in our previous work.[27] A total of 10000 cells were acquired per sample, and data were analyzed using FACSDiva software in both cell cycle and cell apoptosis assays. When necessary, the cells were pretreated with NAC (10 mM) for 1 h before the test compounds were added.

Intracellular ROS Assay. NCI-H460 cells (4×10^5/well), incubated with the test compounds (5 or 10 μM) for 3 or 9 h, were harvested, stained with DCFH-DA (3 μM) for 30 min at 37 °C in the dark, then washed with PBS, and subjected to immediate analysis by flow cytometry. When necessary, the cells were pretreated with NAC (10 mM) for 1 h before the test compounds were added. The ROS levels were calculated relative to the intensity of FITC fluorescence and expressed as fold increase relative to control.

Intracellular Glutathione Assay. A modified GR-DTNB recycling assay method was used to measure intracellular glutathione levels.[28] Briefly, NCI-H460 cells (4×10^5/well) treated with the test compounds were harvested, resuspended in ice-cold HCl (10 mM, 500 μL), and lysed by three freeze−thaw cycles. When necessary, the cells were pretreated with NAC (10 mM) for 1 h before the test compounds were added. The protein concentrations were determined by the BCA protein assay reagent kit. Precooled 5-sulfosalicylic acid (6.5%, 120 μL) was added to the 460 μL residual lysates, vortexed, and kept at 4 °C for 10 min. After centrifugation (8000*g*, 4 °C, 15 min), the supernatant was divided into two groups: one as the total GSH sample (no treatment) and the other as the GSSG sample (100 μL of supernatant added with 5 μL of 2-vinylpyridine, shaken for 1 h to dislodge the GSH). For the total GSH assay, the test solutions containing 5 μL of sample, 35 μL of PBS, and 200 μL of assay buffer (1 mM DTNB, 340 μM NADPH, in PBS) were pre-incubated in a 96-well plate for 5 min and then added to 40 μL of GR (8.5 IU/mL, in PBS). The absorbance change at 412 nm was monitored for 5 min using an Infinite M200 microplate reader (Tecan Group Ltd., Männedorf, Switzerland), whereas for the GSSG assay, the test solutions contained 40 μL of sample and 200 μL of assay buffer. Intracellular total GSH and GSSG concentrations were estimated using a GSH or GSSG standard curve, respectively, and normalized to the determined protein concentrations. Intracellular GSH concentration was calculated from the following formula: [GSH] = [total GSH] − 2[GSSG]. Results were expressed as the percentage of the control.

In Vitro and Intracellular TrxR-Inhibitory Activity Assays. The NADPH-reduced TrxR (120 nM) was incubated with the test compounds (50 μM) in TE buffer (50 mM Tris-HCl, pH 7.4, 1 mM EDTA, 100 μL) for 1 h and added to a mixture of DTNB (2.25 mM) and NADPH (200 μM) in TE buffer (800 μL). TrxR activity was calculated by measuring the slope for the linear increase in absorbance at 412 nm in the initial 90 s using a TU-1901 UV−vis spectrophotometer (Beijing Purkinje General Instrument Co. Ltd., Beijing, China).[29] The inhibitory activity was expressed as a percentage of the control.

Intracellular TrxR-inhibitory activity was imaged in living cells using a fluorescent probe for mammalian TrxR, TRFS-green, kindly provided by Prof. Fang from Lanzhou University, China.[30] NCI-H460 cells seeded on glass coverslips at 2×10^5 cells/coverslip were treated with the test compounds (30 μM) for 4 h and incubated with TRFS green (5 μM) in fresh medium for another 3 h. When necessary, the cells were pretreated with NAC (10 mM) for 1 h before the test compounds were added. The coverslips were rinsed with PBS and inverted onto glass slides with anti-fade mounting medium. The fluorescence images were acquired by a fluorescent microscope Leica DM 4000B (Leica Microsystems CMS GmbH, Wetzlar, Germany) with a ×40 objective lens.

NADPH Oxidase Activity Assay. NADPH-reduced TrxR (120 nM), NADPH (200 μM) in TE buffer (200 μL), was incubated with the test compounds (50 μM) for 30 min at room temperature. After incubation, the rate of oxidation of NADPH was determined by measuring the absorbance decay at 340 nm using an Infinite M200 microplate reader.[13] The activity was expressed as fold increase relative to control.

Western Blot Analysis. NCI-H460 cells (2×10^6 cells/dish) treated with the test compounds (2.5, 5 μM) for 24 h were lysed with the immunoblotting assay buffer containing 1% PMSF at 4 °C. Protein, 40 μg/lane, was used for SDS-PAGE and electroblotted onto PVDF membrane (Bio-Rad Laboratories, Hercules, CA, USA) at 4 °C. The membranes were blocked with 5% skim milk followed by incubation with appropriate primary antibody at 4 °C overnight, then washed, and probed with the corresponding horseradish peroxidase-conjugated secondary antibodies for 1 h at room temperature. The signals were finally detected using an enhanced ImageQuant chemiluminescence system (GE Healthcare, Pittsburgh, PA, USA).

Whole Cell Analysis of Tubulin Polymerization. Whole cell analysis of tubulin polymerization was conducted according to the established procedures.[31] Specifically, NCI-H460 cells (4×10^5/well) incubated with the test compounds for 24 h were harvested, fixed in 4% paraformaldehyde for 10 min, and then pelleted (500*g*, 8 min), followed by 10 min of permeabilization in ice-cold 90% methanol at −20 °C. When necessary, the cells were pretreated with NAC (10 mM) for 1 h before the test compounds were added. The permeablized cells were washed with microtubule stabilizing buffer consisting of 80 mM Pipes (pH 6.8), 1 mM $MgCl_2$, 5 mM EDTA, and 0.5% Triton X-100 and blocked in antibody diluting solution containing PBS (pH 7.4), 0.2% Triton X-100, 2% BSA, and 0.1% NaN_3 for 1 h. The cells were then incubated with anti-α-tubulin-FITC antibody (1:50 diluted) in the dark for 3 h and subjected to analysis by flow cytometry.

Intracellular GST-Inhibitory Activity Assays. The GST activity was evaluated in NCI-H460 cells by imaging experiments using DNs-CV, a previously reported fluorescent probe for GSTs.[25] NCI-H460 cells seeded on glass coverslips at 2×10^5 cells/coverslip were treated with or without the test compounds (30 μM) for 4 h followed by their removal and incubation with DNs-CV (2 μM) in serum-free medium without phenol red at 37 °C for 30 min. The cells were then fixed with 2% formaldehyde for 15 min and stained with 0.5 μg/mL DAPI for 10 min at room temperature. The coverslips were rinsed with PBS and inverted onto glass slides with anti-fade mounting medium. The fluorescence images were captured using a fluorescent microscope Leica DM 4000B (Leica Microsystems CMS GmbH) with a ×40 objective lens.

Cellular Uptake Assay. NCI-H460 cells seeded in 100 mm dishes at 2×10^6 cells/dish were treated with the test compounds (30 μM) for 0.5, 1, 2, 4, 6, or 8 h. After incubation, the medium was aspirated, and the cells were rapidly washed three times with excess ice-cold PBS, collected by trypsin, and further washed with medium and PBS in turns by centrifuging. Ice-cold methanol (500 μL) was then added and incubated for 10 h at 4 °C to lyse the cells. The cell lysates were centrifuged for 10 min at 10000 rpm at 4 °C, and the compound concentrations in the supernatants were then measured using an M850 fluorescence spectrophotometer (Hitachi, Japan; curcumin, Ex = 422 nm, Em = 536 nm; compounds **1** and **2**, Ex = 366 nm, Em = 512 nm).[32] The uptake was expressed as nanomoles per million cells.

Statistical Analysis. Data are expressed as the mean ± SD. Statistical comparisons among the results were performed using analysis of variance. Significant differences ($P < 0.05$) between the means of two groups were analyzed by Student's *t* test.

RESULTS

Cytotoxicity of Compounds 1 and 2 Was Mediated by G2/M Cell Cycle Arrest. We initially assessed the cytotoxicity of curcumin and its analogues (**1**−**5**) toward NCI-H460 cells by the SRB assay. The IC_{50} values (concentration of the test agent that is required for 50% inhibition of the cell viability)

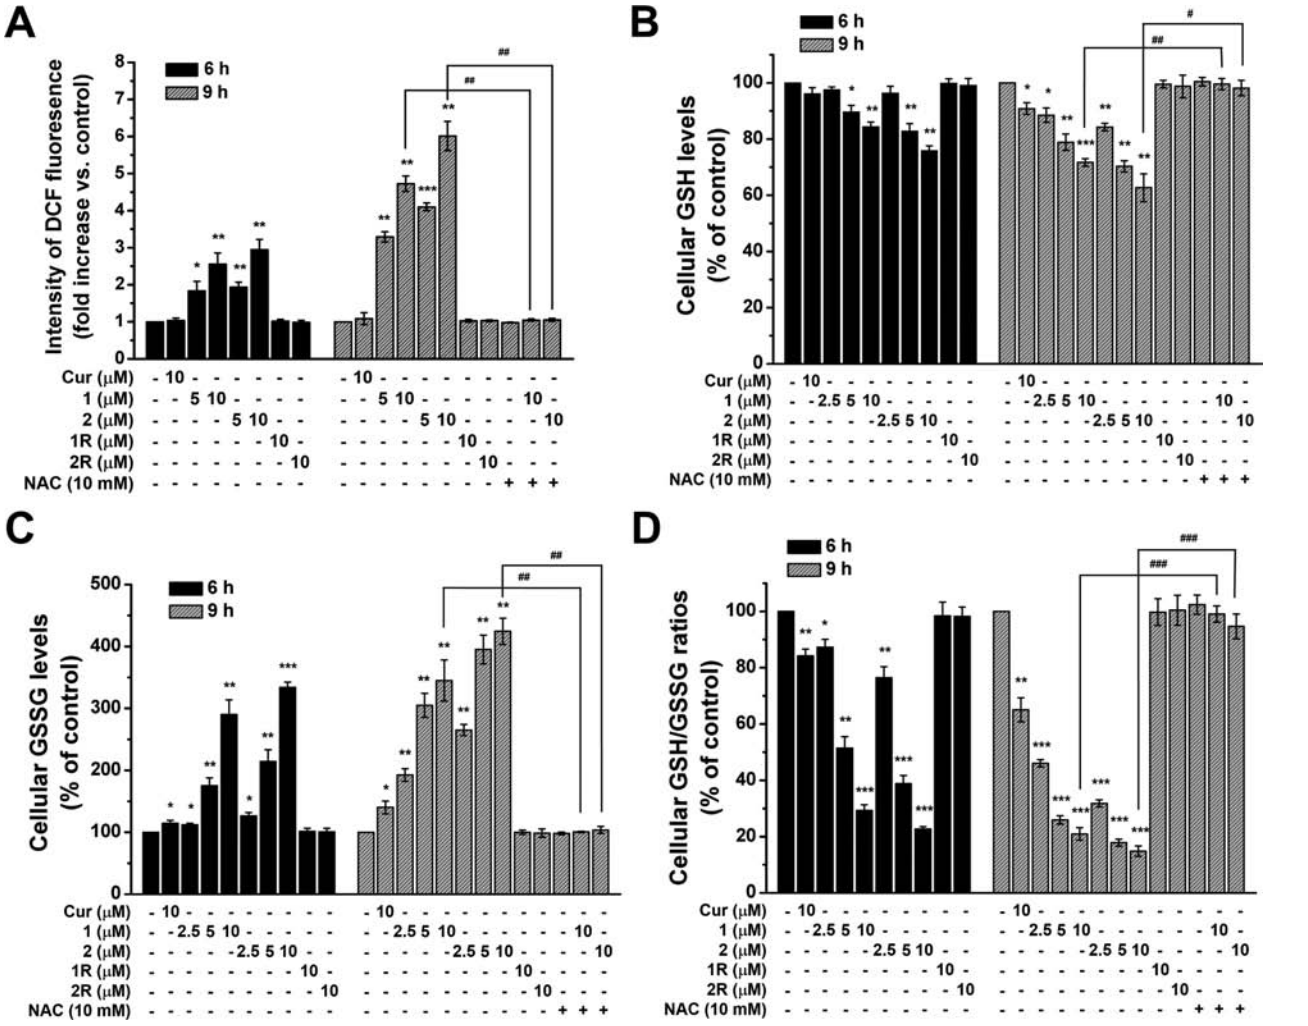

Figure 2. Compounds **1** and **2** cause ROS accumulation associated with imbalance of cellular redox homeostasis (A) ROS accumulation induced by curcumin (Cur) and its active analogues in NCI-H460 cells. Cells (4×10^5/well) were treated with the test compounds at the indicated concentrations for 6 or 9 h in the absence or presence of 1 h of pretreatment with NAC and subjected to DCFH-DA staining assay. (B–D) Alterations of intracellular GSH levels (B), GSSG levels (C), and GSH/GSSG ratios (D) induced by Cur and its active analogues. Cells (4×10^5/well) were treated with the test compounds with indicated concentrations for 6 or 9 h in the absence or presence of 1 h of pretreatment with NAC and subjected to intracellular glutathione assay as described under Materials and Methods. Data are expressed as the mean ± SD, $n = 3$: (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$ versus control; (#) $P < 0.05$, (##) $P < 0.01$, amd (###) $P < 0.001$.

were obtained from a series of dose–response curve (Figure 1B). All of the tested monocarbonyl compounds (**1**–**5**) were more cytotoxic than the leading curcumin (IC_{50} = 38.5 ± 1.1 μM), with the IC_{50} values being 1.9 ± 0.1, 3.4 ± 0.1, 3.8 ± 0.2, 6.1 ± 0.3, and 9.8 ± 0.3 μM, respectively. Among the test compounds, the symmetrical hexamethoxy-diarylpentadienones (**1** and **2**) were the most active ones and displayed 20- and 11-fold more potent activity than curcumin, respectively. In contrast, their reduced analogues **1R** and **2R**, where the Michael acceptor units are completely abolished, showed no obvious effect on the cell viability (IC_{50} > 100 μM; Figure 1B), Additionally, pretreatment of *N*-acetylcysteine (NAC), acting as both a ROS scavenger and a sulfhydryl-containing nucleophile to react preferentially with the Michael acceptor units, almost completely abrogated the cytotoxicity induced by compounds **1** and **2** (Figure 1B). The above results indicate an indispensable role of the Michael acceptor units and the importance of ROS generation in determining the cytotoxicity of compounds **1** and **2**.

To investigate the possible mechanisms by which curcumin and its active analogues **1** and **2** exhibit cytotoxicity, we further analyzed their effects on cell cycle distribution by flow cytometry. As shown in Figure 1C, 24 h of treatment with compounds **1** and **2** induced a remarkable accumulation of cells in G2/M phase in a dose-dependent fashion. Specifically, compound **1** with increasing concentrations from 1 to 5 μM led to a successively increased accumulation of cells in G2/M phase, from ~23 to ~86% of the total cell count. However, under the same conditions, 5 μM curcumin exhibited no appreciable effect on the cell cycle distribution. The cell cycle arrest activity follows the sequence **1** > **2** > curcumin, in line with the results obtained by the cytotoxicity assay.

To further elucidate the cytotoxic mechanisms, we next conducted an apoptosis analysis by flow cytometry with annexin-V-FITC/propidium iodide (PI) double staining (Figure 1D). High-dose (10 μM) and long-duration (36 h) treatment with compounds **1** and **2** indeed caused obvious cell apoptosis and necrosis. However, under the conditions of low-dose (5 μM) and short-duration (24 h), they induced only a

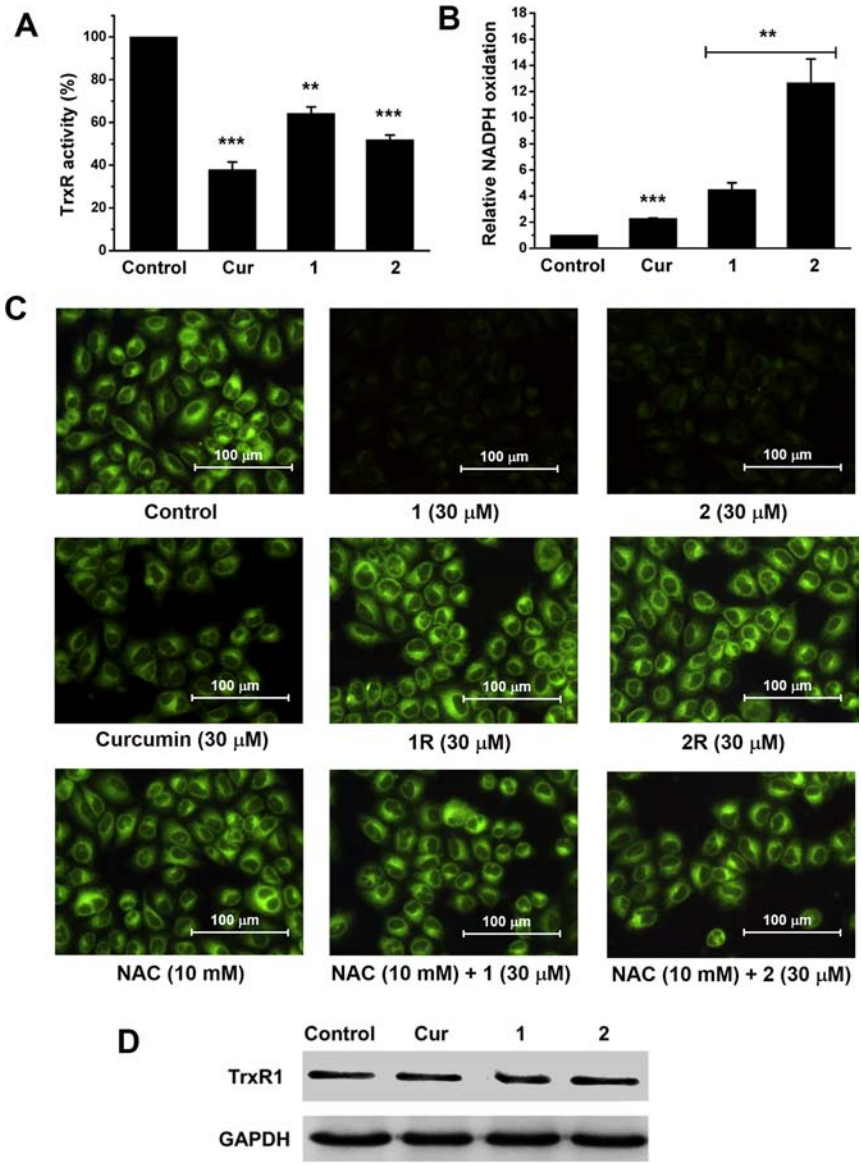

Figure 3. Inhibition of TrxR by curcumin (Cur) and its active analogues and NADPH oxidation induced by the resulting modified TrxR. (A) In vitro inhibition of TrxR by Cur and its analogues. NADPH-reduced TrxR was incubated with 50 μM compounds for 1 h, and the enzyme activity was determined by DTNB reduction assay as described under Materials and Methods. Data are expressed as the mean ± SD, n = 3: (**) $P < 0.01$ and (***) $P < 0.001$ versus control. (B) NADPH oxidase-like activity of the resulting modified TrxR. NADPH oxidation was monitored by a decrease of absorbance at 340 nm as described under Materials and Methods. Data are expressed as the mean ± SD, n = 3: (**) $P < 0.01$ and (***) $P < 0.001$ versus control. (C) Inhibition of TrxR by Cur and its analogues in NCI-H460 cells. Cells (2×10^5/well) were treated with the test compounds (30 μM) for 4 h in the absence or presence of 1 h of pretreatment with NAC, stained with TRFS-green (5 μM), a fluorescent probe for TrxR, and observed as described under Materials and Methods. Representative images are shown from three independent experiments. (D) No alteration in the TrxR1 protein levels in NCI-H460 cells induced by Cur and its analogues. Proteins were prepared from cells treated with the test compounds (30 μM) for 4 h and analyzed by Western blotting with an antibody against TrxR1.

small amount of apoptosis (Figure 1D), but induced significant G2/M phase arrest. The above results support the conclusion that the cytotoxicity of compounds **1** and **2** toward NCI-H460 cells is predominately mediated by G2/M cell cycle arrest, even though the arrest further triggers obvious cell apoptosis and necrosis in the case of high dose or long duration.

In line with the results obtained from the cytotoxicity assay, pretreatment of NAC reversed practically the cell cycle arrest and apoptosis induced by compounds **1** and **2**. Moreover, **1R** and **2R** were inactive in inducing cell cycle arrest and apoptosis (Figure 1C,D). The above results support an indispensable role of the Michael acceptor units and the importance of ROS generation in inducing cell cycle arrest and apoptosis.

Compounds 1 and 2 Caused ROS Accumulation and Imbalance of Cellular Redox Homeostasis. To further clarify the involvement of ROS in cell cycle arrest, we also measured the intracellular ROS levels by flow cytometry (Figure 2A). Treatment with either compound **1** or **2** caused dose- and time-dependently a substantial increase in DCFH-DA-reactive ROS, which reached a 6-fold increase in the case of 10 μM compound **2** after 9 h of treatment. In contrast, curcumin was almost inactive in increasing the ROS levels under the same conditions. Moreover, compound **1** and **2**-

DOI: 10.1021/acs.jafc.5b02011
J. Agric. Food Chem. 2015, 63, 7731−7742

enhanced DCF fluorescence intensity was entirely decreased to control group levels by pretreating the cells with NAC for 1 h (Figure 2A). This result coupled with the inactivity of **1R** and **2R** in inducing intracellular ROS accumulation (Figure 2A) emphasizes a dependence of ROS generation on the Michael acceptor units. Noticeably, compound **2** is a stronger ROS generator but a relatively weaker cell cycle arrest and cytotoxic agent than compound **1** (Figures 2A and 1C), implying that in addition to ROS generation, there must be other factors contributing to their cell cycle arrest activity and cytotoxicity. We will clarify this point in the following sections.

To investigate whether ROS generation was associated with the collapse of the cellular redox buffering system, we also determined the levels of reduced and oxidized glutathione (GSH and GSSG). Panels B and C of Figure 2 show a dose- and time-dependent decrease and increase for the GSH and GSSG levels, respectively, in the cells treated with compound **1** or **2**. A comparison of Figure 2B with Figure 2C clearly indicates that the alternation is much more pronounced in the GSSG levels than in the GSH levels. According to the measured GSH and GSSG levels, the GSH/GSSG ratios, an important index reflecting the cell redox status, were quantified. As shown in Figure 2D, the test compounds sharply decreased the ratios with the activity order **2** > **1** > curcumin. Obviously, the activity order accords with their ROS-generating ability, supporting a close connection between ROS generation and collapse of the intracellular redox buffering system. Likewise, pretreatment of NAC also abolished completely the change of the GSH and GSSH levels induced by compounds **1** and **2**; **1R** and **2R** were inactive in changing the GSH and GSSH levels (Figure 2B–D).

Compounds 1 and 2 Could Target TrxR To Generate ROS. The thioredoxin (Trx) system, consisting of NADPH, TrxR, and Trx, is pivotal for maintaining cellular redox balance.[33] In this system, TrxR catalyzes the NADPH-dependent reduction of Trx, which participates in many redox events.[33] It has been reported that curcumin could irreversibly modify TrxR by its Michael acceptor units, and the modified enzyme thereby exhibits the NADPH oxidase-like activity to generate ROS.[13] On the basis of the structure similarity among curcumin and its active analogues, we postulated that compounds **1** and **2** could trigger ROS accumulation likewise by inhibiting TrxR. To test this possibility, we assessed their TrxR-inhibitory activity in vitro by the DTNB reduction assay.[29] After incubation with compounds **1** and **2** for 1 h, the TrxR activity was reduced to ~60 and ~50% of control (Figure 3A), respectively. The lost activity was irrecoverable even after the test compounds were removed (data not shown), indicating an irreversible inhibition. Interestingly, compounds **1** and **2** were weaker in the TrxR-inhibitory activity in vitro than curcumin (Figure 3A), but the enzyme modified by them rather than by curcumin showed much higher NADPH oxidase-like activity (Figure 3B). Among the test compounds, compound **2** is the most active with a 12.7-fold increased oxidation of NADPH relative to the control, followed by compound **1**, whereas curcumin is the worst. The activity is fully in agreement with their ROS-generating ability in NCI-H460 cells. To further elucidate whether they can target intracellular TrxR, we employed a newly reported fluorescent probe (TRFS-green)[30] to image the TrxR activity in living NCI-H460 cells. On the basis of the bright green fluorescence intensity reflecting the intracellular TrxR activity (Figure 3C), we can conclude that after only 4 h of treatment, compounds **1** and **2** (30 μM) abrogate almost completely the intracellular TrxR activity and are approximately equipotent in the ability, whereas curcumin is obviously inferior to them. The intracellular TrxR-inhibitory activity order is completely different from that obtained from the in vitro DTNB reduction assay. Although the intracellular TrxR activity was significantly inhibited by the above compounds, the cytosolic TrxR1 protein levels remained unchanged (Figure 3D). Additionally, consistent with the results obtained from the ROS level assay, complete reversion of the intracellular TrxR-inhibitory activity of compounds **1** and **2** by NAC pretreatment as well as the inactivity of **1R** and **2R** (Figure 3C) was also observed, emphasizing that the Michael acceptor units are necessary for the activity.

Molecular Mechanisms for Compound 1- and 2-Mediated G2/M Cell Cycle Arrest. The progression through the cell cycle phase is orchestrated by promotion of cyclins, cyclin-dependent kinases (Cdks), and Cdc25 phosphatases as well as by inhibition of Cdk inhibitors such as p21.[34,35] To clarify the mechanisms for compound **1** and **2**-mediated G2/M cell cycle arrest in NCI-H460 cells, we examined their effects on expression of proteins that are critical for G2/M transition, including Cdk1, cyclin B1, Cdc25C, p21, and p53, by Western blotting (Figure 4). When the cells were treated with either

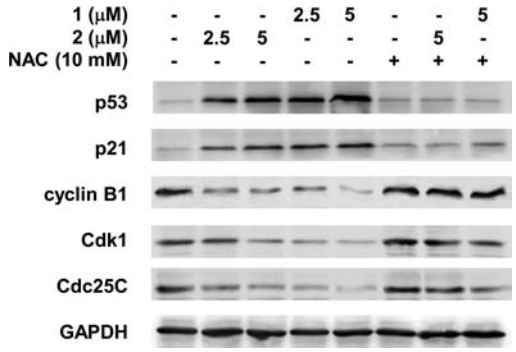

Figure 4. Alteration of G2/M cell cycle checkpoints induced by compounds **1** and **2** via a ROS- and Michael acceptor-dependent pathway. Proteins were prepared from cells (2×10^6 cells/dish) treated with the indicated concentrations of compounds for 24 h in the absence or presence of 1 h of pretreatment with NAC and subjected to Western blotting using corresponding antibodies. Data are representative of three independent experiments.

compound **1** or **2** for 24 h, a marked dose-dependent decrease of Cdk1, cyclin B1, and Cdc25C expression was observed. Conversely, the p53 and p21 expression increased in a dose-dependent manner. At the same concentration, both the inhibition and stimulation effects on protein express were much more pronounced by compound **1** than by compound **2**. This outcome is in accordance with their G2/M cell cycle arrest ability. In addition, pretreatment of NAC completely reversed the above changes in protein expression, highlighting a central role of the Michael acceptor units and ROS generation in regulating the expression of the redox active cell cycle regulatory proteins.

Inhibition of Tubulin Polymerization by Compound 1. As mentioned above, compound **2** is a stronger ROS generator but a relatively weaker G2/M cell cycle arrest agent than compound **1**. Therefore, we believe that as small molecular compounds, they can target not only TrxR to generate ROS but also other proteins related to cell cycle arrest by virtue of their Michael acceptor units. Microtubules, as key components of the

DOI: 10.1021/acs.jafc.5b02011
J. Agric. Food Chem. 2015, 63, 7731−7742

cytoskeleton, are composed of tubulin and are responsible for mitosis and cell division, and interfering with microtubule dynamics could induce cell cycle arrest during the M phase.[36,37] Some electrophiles such as 6-shagol[38] and dially trisulfide[39] can target sulfhydryl groups of cysteine residues (Cys-12β and Cys-354β) in tubulin, thereby perturbing tubulin polymerization, causing mitotic arrest and triggering cell death. To check whether compounds **1** and **2** affect tubulin polymerization, a flow cytometry method was employed to achieve a rapid and quantitative analysis of the whole cell tubulin polymerization levels. Paclitaxel and colchicine were used as reference compounds with known functions to stabilize and destabilize microtubules, respectively. As shown in Figure 5, compound **1**,

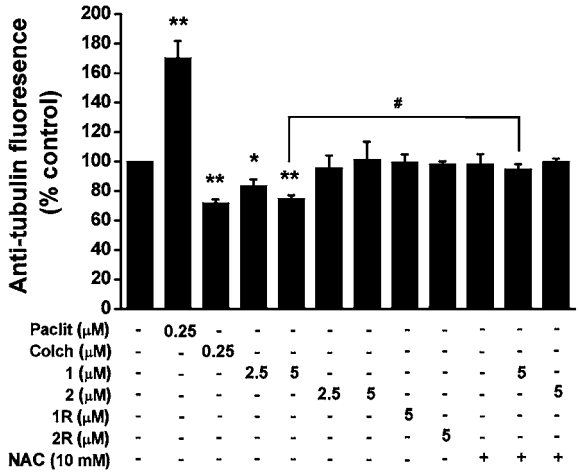

Figure 5. Effect of compounds **1** and **2** on tubulin polymerization in NCI-H460 cells. Cells (4×10^5/well) were treated with the test compounds at the indicated concentrations for 24 h in the absence or presence of 1 h of pretreatment with NAC and subjected to the whole cell tubulin quantitation analysis. Colchicine (Colch) and paclitaxel (Paclit) were used as references. Data are expressed as the mean ± SD, $n = 3$: (*) $P < 0.05$ and (**) $P < 0.01$ versus control; (#) $P < 0.05$.

acting like the microtubule destabilizer colchicine, obviously reduced the anti-tubulin fluorescence signal in a dose-dependent manner, indicating an inhibition of microtubule polymerization. In contrast, compounds **2** and **1R** failed to exhibit the effect. Furthermore, adding NAC almost blocked the inhibition of microtubule polymerization by compound **1**. These results reflect that the inhibitory activity of compound **1** against microtubule polymerization relies on not only the Michael acceptor units but also the installation mode of methoxy groups on the aromatic rings and is independent of ROS generation.

Higher GST-Inhibitory Activity by Compound 1 than by Compound 2. GSTs are a family of phase II detoxification enzymes that catalyze the conjugation of GSH to a broad spectrum of endogeneous and exogeneous electrophilic compounds, resulting in their removal from the cells.[40,41] GSTs have emerged as a promising therapeutic target because they are overexpressed in a wide variety of tumors and contribute to resistance to chemotherapeutics.[40,41] It has been reported that camptothecin-induced S or G2/M arrest of HeLa cells is intensified by silencing glutathione *S*-transferase P1 (GSTP1) gene.[42] Additionally, curcumin has also been identified as an inhibitor of human GSTs,[43] and its pro-apoptosis activity against K562 cells is mediated by inhibiting the GSTP1 expression at the level of transcription.[44] Therefore, to further elucidate the reason for the increased G2/M cell cycle arrest activity by compound **1** compared with compound **2**, we compared their GST-inhibitory activity together with that of curcumin in NCI-H460 cells by using GST (DNs-CV),[25] a red fluorescent probe applied to the imaging of GST activity in living cells. As illustrated in Figure 6, after only 4 h of treatment, compound **2** decreased obviously the fluorescence signal localized to an area adjacent to the nucleus, which reflects the intracellular GST activity, but to a lesser extent than compound **1** did. The order of intracellular GST-inhibitory activity further corresponds to the increased activity of compound **1** in the cell cycle arrest. Besides, the Michael acceptor-dependent effect of compounds **1** and **2** in relation to the GST-inhibitory activity was observed as evidenced by both complete blockage of their activity by NAC pretreatment and failure of **1R** and **2R** in exhibiting the activity.

Increased Cellular Uptake of Compound 1 Compared with Compound 2 and Curcumin. Considering that cellular uptake is also a probable factor in determining the cell cycle arrest activity apart from the ROS-generating ability, microtubule-destabilizing effect, and GST-inhibitory activity, we finally assayed intracellular concentrations of curcumin and its active analogues at different time points by fluorescence analysis of methanol extracted cell lysates. As shown in Figure 7, uptake of curcumin reached a maximum value after 2 h of incubation followed by its rapid decay during 8 h. Compound **2** was analogous to curcumin in the time course of uptake and decay, but appeared to exhibit a relatively rapid and high peak uptake. Notably, compound **1** exhibited the most efficient uptake, which was almost 6 times greater than that of compound **2**, and its decay occurred only after 4 h of incubation.

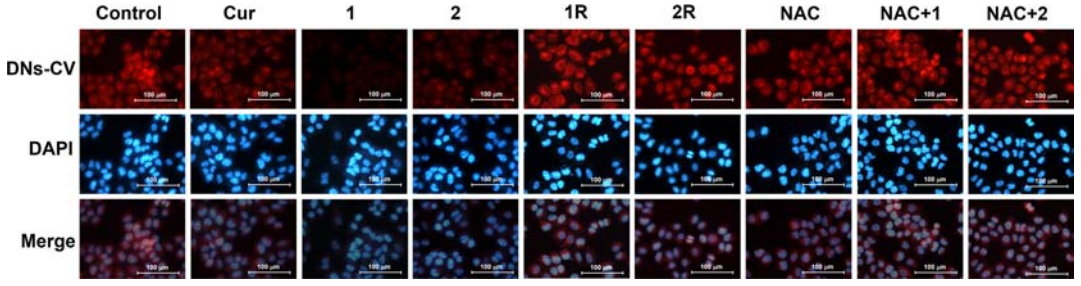

Figure 6. GST-inhibitory activity of curcumin (Cur) and its active analogues evaluated by fluorescence imaging of NCI-H460 cells. Cells (2×10^5/well) treated with the test compounds (30 μM) for 4 h were stained with a fluorescent probe for GSTs, DNs-CV (2 μM), for 30 min at 37 °C, and DAPI (0.5 μg/mL) was used to visualize the nuclei.

DISCUSSION

The past two decades have witnessed much interest in investigating cancer chemoprevention and chemotherapy mechanisms of curcumin due to its multitargeted activity, selectivity, and safety for human use as a dietary molecule.[9−11] Like most polyphenols, although curcumin is a well-known natural antioxidant, it is also a pro-oxidant able to promote ROS generation under special conditions such as high concentrations[12,45−47] and in the presence of cupric ions.[48,49] Another efficient means of curcumin as a pro-oxidant is to covalently modify cysteine (selenocysteine) residues in redox-sensitive target proteins such as TrxR[13,14] by virtue of its Michael acceptor units. More importantly, the pro-oxidant property of curcumin is responsible for its apoptosis-inducing activity in various cancer cells and thus therapeutic effect.[12] In this study, we selected symmetrical hexamethoxy-diarylpentadienones, **1** and **2** (as the active and metabolically stable curcumin analogues) to investigate the cytotoxic mechanisms toward NCI-H460 cells from a chemical and biological point of view and tried to provide useful information for understanding the Michael acceptor-dependent redox intervention and designing curcumin-inspired anticancer agents by a pro-oxidant strategy.

The IC_{50} values of curcumin and compounds **1**−**5**, **1R**, and **2R** against NCI-H460 cells enable us to deduce the activity order **1** > **2** ∼ **3** > **4** > **5** > curcumin > **1R**, **2R** and allowed us to identify the following SAR: the Michael acceptor unit is necessary for the cytotoxicity, whereas the position and number of the methoxy groups on the aromatic rings further contribute to the activity. Abrogating the cytotoxicity of compounds **1** and **2** by NAC (Figure 1B), acting as both an antioxidant and a nucleophile, further supports the Michael acceptor-dependent cytotoxicity and contribution of ROS to the activity. Subsequently, in NCI-H460 cells, compounds **1** and **2** were identified as the G2/M cell cycle arrest agents to mediate the cytotoxicity via Michael acceptor- and ROS-dependent mechanisms (Figure 1C and 2A). Similarly, compound **2** has been previously found to induce G2/M cell cycle arrest in HCT116 cells.[19] Additionally, the dependency of ROS generation on the Michael acceptor units is supported by the fact that NAC blocks completely the stimulatory effect of compounds **1** and **2** on ROS generation; as well, **1R** and **2R** are inactive in inducing ROS accumulation (Figure 2A).

With regard to the ROS-generating mechanism, our data (Figure 3) show that compounds **1** and **2**, similar to curcumin,[13,14] could irreversibly inhibit TrxR depending on their Michael acceptor units, and the resulting covalently modified TrxR serves as an important source of ROS. The in vitro assay shows the weaker TrxR-inhibitory potency of compounds **1** and **2** relative to that of curcumin (curcumin > **1** > **2**; Figure 3A), but the higher NADPH oxidase-like activity of the TrxR modified by them than by curcumin (**2** > **1** > curcumin; Figure 3B). In contrast, the in vivo experiments suggest that compounds **1** and **2** are much more effective inhibitors of TrxR in NCI-H460 cells than curcumin (**1** ∼ **2** > curcumin; Figure 3C). The inconsistent results between the in vitro and in vivo TrxR-inhibitory activity are due, at least in part, to the increased cell uptake of compounds **1** and **2** compared with that of curcumin (Figure 7D). Notably, the SAR in the NADPH oxidase-like activity of the TrxR modified by curcumin and compounds **1** and **2**, as well as their in vivo TrxR-inhibitory activity, correlate well with their ROS-generating activity order (**2** > **1** > curcumin). The correlation also raises the possibility that TrxR is one of the targets by which compounds **1** and **2** promote ROS generation. Additionally, the cytosolic TrxR1 protein levels remained unchanged after cells were exposed to curcumin and its active analogues (Figure 3D), suggesting that the decrease of TrxR activity is mediated by directly inhibiting enzyme activity, instead of down-regulating protein expression. The above results also emphasize a broad substrate specificity of TrxR based on the following reasons: its penultimate selenocysteine residue locates at the flexible C-terminal tails and is thus easily accessible for inhibitors; its low pK_a value of 5.2 renders it easy to ionize at physiological pH, resulting in the formation of a highly active and nucleophilic selenolate.[33,50] Therefore, despite the different installation mode of methoxy groups on the aromatic rings, both compounds **1** and **2** could effectively target intracellular TrxR.

ROS generation and collapse of the intracellular redox buffering system (decrease in the GSH/GSSG ratios) induced by compounds **1** and **2** occurred almost simultaneously according to the time points of 6 and 9 h (Figure 2). This invites inevitably the following questions: Do ROS induce reduction of GSH, or does low GSH cause an increase in ROS generation? Currently, our cumulative data are not yet sufficient to clarify this point. However, the preferential reactivity of compounds **1** and **2** with TrxR at micromolar concentrations,[51] despite the presence of millimolar concentrations of GSH,[52] might result in the priority of ROS generation. The preferential reactivity is based on the fact that, as discussed above, selenocysteine is more easily ionized than GSH at physiological pH and nucleophilicity of the resulting selenolate is far stronger than that of thiolate. Furthermore, it could be also supported by our previous results showing that a double *o*-trifluoromethyl-substituted diarylpentadienone, structurally similar to compounds **1** and **2**, induced a dramatic increase in the GSSG levels, whereas it barely changed the GSH levels in A549 cells.[24] Besides, the almost simultaneous occurrence of ROS generation and collapse of the redox buffering system just reflects that the redox intervention style would be a vicious cycle, especially when the intervention occurs in such a double-effect pathway including both irreversibly inhibiting TrxR and converting it into a pro-oxidant.

Cell cycle progression is precisely regulated by cyclins, Cdks and Cdk inhibitors, and is also subject to a redox control fashion because ROS can influence the presence and activity of these proteins.[34,35] The G2/M phase transition and completion of the M phase require binding of cyclin B to Cdk1 and

DOI: 10.1021/acs.jafc.5b02011
J. Agric. Food Chem. 2015, 63, 7731−7742

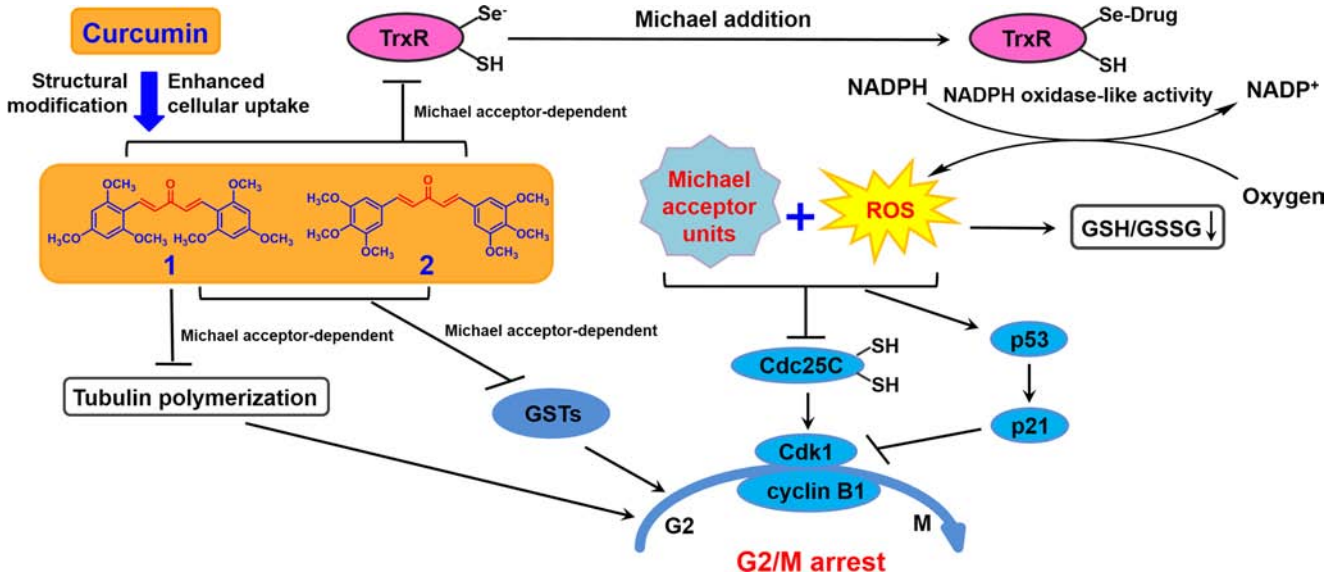

Figure 8. Mechanisms for the G2/M cell cycle arrest induced by compounds **1** and **2** in NCI-H460 cells.

subsequent Cdk1 activation.[34,35] Western blotting results reveal that both compounds **1** and **2** decrease dose-dependently the expression levels of cyclin B1 and Cdk1 (Figure 4). Additionally, p53 and p21 levels are up-regulated in the G2/M cell cycle arrest (Figure 4). It is generally agreed that p53, a multifunctional tumor suppressor, plays an important role in cell cycle arrest through its downstream mediator p21, especially under a stressed situation.[53] When the cellular redox state is shifted toward a more oxidative condition, the activity of the cyclin B1/Cdk1 complex can be inhibited through up-regulation of a p53-inducible cell cycle inhibitor p21,[54,55] thus causing the G2/M cell cycle arrest. Cdc25C phosphatase is another redox sensitive cell-cycle-regulatory protein that activates the cyclin B1/Cdk1 complex activity by dephosphorylating pThr14 and pTyr15 on Cdk1.[56] ROS can target the highly reactive cysteine 330 and 377 at the active site in Cdc25C, leading to the enzyme inactivation, and the ROS-inactivated Cdc25C is expected to prevent cell-cycle progression at the G2/M phase via inhibiting the cyclin B1/Cdk1.[56] A decrease of Cdc25C expression was also observed in the case of compounds **1** and **2** (Figure 4). In addition, all of the alterations of the regulatory proteins can be rescued by NAC (Figure 4). This further supports that compounds **1** and **2**, by virtue of their Michael acceptor units, can collapse the cell-cycle-regulatory system in NCI-H460 cells by both inducing a burst of ROS and directly modifying cysteine residues of the above redox-sensitive target proteins. The contribution of the latter can be deduced from the fact that compound **1**, compared with compound **2**, is more effective in inducing alteration in the cyclin B1, Cdk1, p53, p21, and Cdc25C expression, the G2/M cell cycle arrest activity, and, thus, the cytotoxicity but is relatively less effective in promoting ROS generation.

To clarify why compound **1**, compared with compound **2**, displays a relatively weak ability to generate ROS but increased cell cycle arrest activity and cytotoxicity, we turn to another target, tubulin/microtubule. Most microtubule-interfering agents cause cell cycle arrest during the M phase by either stabilizing or destabilizing tubulin.[36,37] Notably, compound **1** was an effective microtubule destabilizer, whereas compounds **2** and **1R** were ineffective (Figure 5). We can conclude from the SAR that both the Michael acceptor units and the installation mode of methoxy groups on the aromatic rings are indispensable for the inhibitory activity of compound **1** against microtubule polymerization. More importantly, compound **2** failed to display the effect despite its strong ROS-generating ability, clearly indicating that the microtubule-destabilizing effect of compound **1** is independent of ROS generation and contributes to its increased G2/M cell cycle arrest activity. Notably, the abrogative effect of NAC on the microtubule-destabilizing activity of compound **1** should be only due to its function as a nucleophile (not as an antioxidant) to react preferentially with the Michael acceptor acceptors of compound **1**, thereby inhibiting binding of compound **1** to active cysteine residues in tubulin.

Considering that camptothecin-induced S or G2/M arrest of HeLa cells is intensified by silencing the GSTP1 gene,[42] and curcumin-induced apoptosis of K562 cells is mediated by inhibiting the GSTP1 expression,[44] we also investigated the GST-inhibitory activity cucumin and its active analogues **1** and **2**. Our results show that the activity is Michael acceptor-dependent, and compound **1** is the most active, followed by compound **2**; curcumin is the worst (Figure 6). This provides another possible explanation for the increased G2/M cell cycle arrest activity of compound **1** despite its relatively weaker ROS-generating ability than that of compound **2**.

To sum up, in this work, the active curcumin analogues **1** and **2** were identified as the G2/M cell cycle arrest agents to mediate cytotoxicity toward NCI-H460 cells via Michael acceptor-dependent redox intervention. As summarized in Figure 8, they could act as dual-effective TrxR inhibitors, not only inactivating TrxR by their Michael acceptor units but also converting this antioxidant enzyme into a ROS promoter with a NADPH oxidase-like activity, leading to a burst in ROS associated with collapse of the redox buffering system. Depending on the Michael acceptor unit and ROS generation, they cause a final G2/M cell cycle arrest in NCI-H460 cells by decreasing the expression levels of cyclin B1 and Cdk1 via up-regulation of p53 and p21 and down-regulation of Cdc25C. Additionally, the increased cell cycle arrest activity of compound **1** compared with compound **2** is derived, at least in part, from its Michael acceptor-dependent microtubule-

destabilizing effect and greater GST-inhibitory activity, as well as its enhanced cellular uptake.

of stored maize, *S. zeamais*,[14] have yet been performed. The aim of this investigation was to determine the antifungal effect of 10 recognized VOCs from cereal kernels on *F. verticillioides*, its mycotoxin production, and the insecticidal effects against its insect vector *S. zeamais*.

MATERIALS AND METHODS

Chemicals. The chemicals (2*E*)-2-hexenal (w256005, purity > 95%), (2*E*)-2-nonenal (255653, 97%), (2*E*,6*Z*)-2,6-nonadienal (w337706, > 96%), 1-pentanol (76929, > 99%), 1-hexanol (471402, > 99%), 1-butanol (281549, > 99%), 3-methyl-1-butanol (309435, > 99%), pentanal (w309818, > 97%), 2-decanone (w510637, > 98%), 3-decanone (268194, 98%), and propionic acid (101362192, 99.5%) were purchased from Sigma−Aldrich (Buenos Aires, Argentina). DDVP (dicholrvos, positive control, technical grade, > 98% purity) was purchased from Chemotécnica S.A (Buenos Aires, Argentina).

Fungal Strain. An isolate of *F. verticillioides* (Sacc) Niremberg (= *F. moniliforme* Sheldon teleomorph *Gibberella fujikuroi* (Sawada) Ito in Ito and Kimura[31] strain M3125 (provided by Dr. Robert Proctor, United States Department of Agriculture, Agricultural Research Service, National Center for Agricultural Utilization Research, Peoria, IL, United States)) was used for all experiments. This fumonisin-producing strain was isolated from maize in California.[32]

Inoculum Preparation. *F. verticillioides* M3125 was grown on Czapek-dox agar Petri plates for 7 days at 28 °C in the dark, to allow profuse sporulation. Then, sterile distilled water was added to each plate, and a conidia suspension was obtained by scraping the colony surface with a sterile Drigalsky spatula, which was then filtered through a cheesecloth. The conidial concentration (1×10^6 conidia/mL) was standardized using a hemocytometer.

Insects. *S. zeamais* (Motschulsky) were reared on sterilized whole maize grain in sealed containers. Insects were reared under controlled temperature and humidity (28 °C and 60−70%) and a light/dark regime of 12:12.[33] Adults of a strain of *S. zeamais* were obtained from Metán, Salta province, Argentina. The colony was maintained in our laboratory for one year without exposure to insecticides. The male and female weevils used in all the experiments were approximately 2 weeks old. All experiments were conducted in complete darkness in a climatic chamber (28 °C and 60−70% relative humidity).

Effect of Volatile Organic Compounds on Fungal Growth and Fumonisin Production. The antifungal activity of the VOCs was tested determining the radial growth of the fungal colony following a methodology proposed by Neri et al.[34] Briefly, a paper filter was placed on the inside cover of the maize meal extract agar (3%) Petri dish. The VOCs were added separately to 90 mm paper filter as pure liquid compounds, and the concentrations (0.03, 0.06, 0.13, 0.27, 0.53, 1.06, 2.12, and 4.24 mM) were expressed as 10^{-3} mol on filter paper per dish volume. A paper filter without VOCs was used as the control. Then, 10 μL of a conidial suspension (1×10^6 conidia/mL) of *F. verticillioides* M3125 was added aseptically to the center of the Petri dishes. The maize meal extract agar (3%) Petri dishes were then covered, wrapped in parafilm, and incubated in the dark at 28 °C. The colony diameter of *F. verticillioides* was measured after 7 days of incubation, and the colony area was calculated using the formula for the area of a circle ($\pi \times r^2$). The minimum inhibitory concentration (MIC) was defined as the lowest concentration of the VOCs at which no fungal growth was observed. To study the effects of the VOCs on FB_1 production, the inoculated plates were incubated in the dark at 28 °C for 28 days. After this incubation, the parafilm and filter papers were removed, and the agar in the experimental plates was dried for 96 h at 60 °C in a forced-air oven before being ground to a fine dry powder. Finally, 5 mL of water was added to the dried agar from each disk, and FB_1 was extracted by shaking the dried dishes with water for 120 min on an orbital shaker, with the mixture then being centrifuged at 5000 rpm for 15 min. The experiments were repeated twice in triplicate.[35]

Fumonisin B_1 Quantitation. The quantitation of the samples was performed following a methodology proposed by Shephard et al.[36] Briefly, samples (1000 μL) from the FB_1 extracts were diluted with acetonitrile/water (1:1), and then, an aliquot (50 μL) was derivatized prior to injection: during 3.5 min with 200 μL of a solution, which was prepared by adding 5 mL of 0.1 M sodium tetraborate and 50 μL of 2-mercaptoethanol to 1 mL of methanol containing 40 mg of *o*-phthaldialdehyde. Derivatized samples were analyzed using a PerkinElmer HPLC equipped with a fluorescence detector, with the wavelengths used for excitation and emission being 335 and 440 nm, respectively, and with an analytical reverse phase C_{18} column (150 mm × 4.6 mm internal diameter and 5 μm particle size) connected to a precolumn C_{18} (20 mm × 4.6 mm and 5 μm particle size). For the mobile phase, methanol and 0.1 M NaH_2PO_4 (75:25) were used, with the pH being set at 3.35 ± 0.2 with orthophosphoric acid and a flow rate of 1.5 mL/min. The quantitation of FB_1 was carried out by comparing the peak areas obtained from samples with those corresponding to the analytical standards of FB_1 (PROMEC, Program on mycotoxins and experimental carcinogenesis, Tygerberg, Republic of South Africa).

Insecticidal Assay. The insecticidal effect on *S. zeamais* was tested using a fumigant toxicity assay described by Huang et al.,[37] with some modifications. Briefly, different amounts of pure VOCs at concentrations corresponding to 20−600 μL/L air were placed onto Whatman filter paper disks of 2 cm diameter. Only the lowest concentrations were diluted in *n*-hexane, and in these cases, each filter paper disk was air-dried for 30 s and placed on the underside of the screw cap of a glass vial (30 mL). Ten adult *S. zeamais* were placed into each vial, and a nylon gauze piece was fitted 1 cm under the screw cap of each glass vial, to avoid direct contact of the weevils with the VOCs. The experiment was performed in five replicates twice per concentration, and control treatments were kept under the same conditions without pure compounds. DDVP was used as a positive control due to its high vapor pressure and known insecticide activity. Insect mortality was checked after 24 h, with the mortality percentages and lethal concentration (LC_{50}) values being calculated according to Finney.[38]

Repellent/Attraction Activity Bioassay. The behavioral response of *S. zeamais* adults to individual VOCs was tested in a two-choice olfactometer bioassay described by Herrera et al.[35] Briefly, two flasks (250 mL) were connected with a glass tube of 30 cm × 1 cm of diameter. In the middle (15 cm from the two flasks), a small hole was made of 1 cm × 1 cm. The connections between the two flasks and the tube were sealed with rubber plugs, which were covered with parafilm to prevent gas leakage. A filter paper of 2 cm diameter was placed within each flask where the compounds were added. Twenty insects, deprived of food for at least 4 h, were placed in the hole of the glass tube. These were then released and tested for 2 h in a climatic chamber, with the experiments being carried out between 10:00 and 16:00 h. The position of the flasks was changed at every replication, and the insects that did not show any response in the experiment were not used to calculate the response index (RI). Insects were given a choice between a specific dose of the test compound and the solvent (*n*-hexane) used as a control. The experiments were performed five times for each assay, with insects only being used once. For each experiment, an independent control (without any compound) showed that the movement of the beetles toward either flask was random (RI = −2.1 ± 7.5). Propionic acid was used as the positive control for repellent.[39]

In each trial, a RI was calculated by using the equation RI = $[(T - C)/\mathrm{Tot}] \times 100$, where T is number of insects responding to the treatment, C is number of insects responding to the control, and Tot is the total number of insects released.[40] Positive values of RI indicate attraction to the treatment, while negative values indicate repellence.

Statistical Analysis. Data were analyzed using InfoStat/Professional 2010p[41] at $p = 0.05$. Randomized complete block design was used for the experimental designs, and a one-way analysis of variance was used to study the experimental data. The Shapiro−Wilk test was utilized to test the normality of the experimental data, and comparisons between treatments were carried out using the Duncan test. Experimental data without a normal distribution were statistically analyzed by the Kruskal−Wallis nonparametric test (at $p < 0.05$). A pairwise comparison was used to compare means among treatment

DOI: 10.1021/acs.jafc.5b02315
J. Agric. Food Chem. 2015, 63, 7743−7749

ranges. The lethal concentrations (LC_{50} and LC_{95}) were calculated from dose−mortality values, using probit regression analysis by POLO−PLUS Software.[42] The significance of the mean RI in each treatment of the two-choice olfactometer bioassay was evaluated by the Student's *t* test for paired comparisons.[40] The chemical properties lipophilicity (log P: logarithm of the octanol/water partition coefficient) and the vapor pressure of the VOCs compounds were obtained from the ChemSpider database.[43]

RESULTS

Antifungal and Antimicotoxicogenic Activities. The inhibitory effects mediated by the VOCs on *F. verticillioides* growth was dose-dependent, with the most active compounds being the aldehydes: (2*E*)-2-nonenal, (2*E*)-2-hexenal, (2*E*, 6*Z*)-2,6-nonadienal, and pentanal, which exhibited MIC values of <0.03, 0.06, 0.06, and 0.53 mM, respectively (Table 1). Of the alcohols tested, 1-hexanol revealed the highest activity, while of the alkyl ketones, 3-decanone had a greater inhibitory effect on fungal growth than 2-decanone, at several concentrations. Treatments such as (2*E*)-2-hexenal (0.06 mM), 1-pentanol (4.24 mM), 1-hexanol (2.12 and 4.24 mM), pentanal (0.53 and 1.06 mM), 2-decanone (4.24 mM), and 3-decanone (2.12 and 4.24 mM) all caused a delay in the fungal growth, with no growth being observed on the seventh day. However, on the 28th day postinoculation, fungal growth was apparent, and the FB_1 concentration was determined. On the other hand, 1-pentanol showed a slight stimulatory effect on fungal growth at lower concentrations. The VOC effects on FB_1 production are presented in Table 2, where it can be observed that (2*E*)-2-hexenal, (2*E*)-2-nonenal, and (2*E*, 6*Z*)-2,6-nonadienal caused a total inhibition of mycelium growth, implying an absence of FB_1 production. 1-Hexanol (4.24 mM) and 1-butanol (0.53 mM and 4.24 mM) effectively inhibited fumonisin production by *F. verticillioides*.

Insecticidal and Repellent/Attraction Effects. The results of fumigant insecticidal activity of VOCs tested on *S. zeamais* are shown in Table 3. After 24 h exposure, the most active compounds were 2- and 3-decanone, with LC_{50} values of 50.4 and 54.6 μL/L, respectively. 1-Hexanol, 1-pentanol, 1-butanol, and (2*E*)-2-hexenal showed insecticide LC_{50} values between 224.1 and 306.6 μL/L, while (2*E*)-2-nonenal and pentanal did not show any insecticidal activity in the range of the evaluated concentrations (20−600 μL/L). The LC_{50} values of (2*E*,6*Z*)-2,6-nonadienal and 3-methyl-1-butanol could not be determined because they did not show a dose-dependent relationship. However, at a dose of 150 μL/L, the mortality was 98.0% (±4.5) for 3-methyl-1-butanol and 28.7% (±19.4) for (2*E*,6*Z*)-2,6-nonadienal (data not shown).

The behavioral responses of *S. zeamais* adults to VOCs are shown in Figure 1. All the compounds showed a repellent effect at 4 μL/L. Moreover, only (2*E*,6*Z*)-2,6-nonadienal showed repellent effects at 0.05 μL/L (0.31 μM), with a RI of −37.3 ± 14.0. On the other hand, 3-methyl-1-butanol and 1-butanol showed attractant effects at 0.4 μL/L.

DISCUSSION

The results obtained in the present work show the capacity of 10 natural VOCs present in the headspace volatiles of several cereal kernels[26,27,29,39,44] to affect the fungal growth of *F. verticillioides* and FB_1 production. In addition, these VOCs showed insecticidal and repellent effects against its insect vector *S. zeamais*. Our findings revealed that aldehydes had higher levels of antifungal activity than alcohols or alkyl ketones. In

[a]Values are expressed as medians ± standard error. Values having different letters are significantly different from each treatment. The experiments were performed twice in triplicate. ND: Not determined. FB_1 inhibition was not determined because there was no fungal growth. (−): Indicates FB_1 stimulation. [b]Indicates significant difference with the control according to the Kruskal–Wallis nonparametric test ($H = 249.27$. $P < 0.0001$). An all pairwise comparison was used to compare the means among treatments ranges.

agreement, a previous report by Mita et al.[24] showed antifungal activity of C_6 and C_9 aldehydes against *A. carbonarius* and *F. proliferatum*, with (2*E*)-2-nonenal being the most effective compound. In addition, other studies reported high antifungal activity of (2*E*)-2-hexenal, (2*E*)-2-nonenal, and (2*E*,6*Z*)-2,6-nonadienal.[26−28,45] Moreover, the results presented here suggest that a relationship between the antifungal activity and the molecular properties, such as lipophilicity (log P) and vapor pressure, may exist in compounds with the same functional group. In the present work, the most active compound against *F. verticillioides* was (2*E*)-2-nonenal, which is the aldehyde with the highest lipophilic property. The relationship between log P and antifungal activity of plant phenolic compounds against *F. verticillioides* has been previously reported by Dambolena et al.[46] In the present study, (2*E*)-2-hexenal, (2*E*)-2-nonenal, and (2*E*, 6*Z*)-2,6-nonadienal also prevented FB_1 production because these compounds completely inhibited fungal growth at the tested concentrations. Previous investigations have reported aflatoxin B_1 being inhibited by (2*E*)-2-hexenal.[26,27] However, this compound did not have any effect on FB_1 production.[28]

Kernels fed on by insects provide a favorable environment for *F. verticillioides* growth and FB_1 production[43] and contribute to the dispersal of fungal spores. Hence, insect control could be considered a key strategy for controlling fungal growth in stored maize kernels. So, the repellent and insecticidal effects of VOCs against *S. zeamais*, an insect vector of *F. verticillioides* in stored maize, were also determined. The VOCs emitted by cereal grains are detected by the antennal sensila of the granary weevil and induce behavioral responses at different doses.[39,47] All the evaluated VOCs show repellent effects against *S. zeamais* at 4 μL/L; however, at very low concentrations (0.4 and 0.05 μL/L), the repellent effect was only shown by (2*E*,6*Z*)-2,6-nonadienal (one of the most antifungal compounds). In agreement with our results, Germinara et al.[39] demonstrated a repellent effect of diolefinic aldehydes, alkyl ketones, and the aliphatic alcohol 1-hexanol and the attractive effects of butyl alcohols on *S. granarius*. 2-Decanone and 3-decanone revealed strong fumigant activities against *S. zeamais*. On the other hand, the most antifungal and repellent compounds, (2*E*,6*Z*)-2,6-nonadienal and (2*E*)-2-nonenal, did not show strong fumigant toxicity against *S. zeamais* at the tested concentrations. However, Hubert et al.[30] reported insecticidal activity of (2*E*,6*Z*)-2,6-nonadienal and (2*E*)-2-nonenal (LD_{50} ranging 0.44−2.76 mg/g) against *S. granarius* and *S. oryzae* in fumigant assays.

Summing up, our results demonstrate that the different biological activities are mainly related with the functional group of the compounds tested, with the most active antifungal and insect repellent compounds being the aldehydes, while the most insecticidal compounds were the ketones. (2*E*,6*Z*)-2,6-Nonadienal demonstrated a complete inhibition of *F. verticillioides* growth and a repellent activity against its insect vector *S. zeamais*, thus preventing FB_1 occurrence, dispersion of fungal spores, and broken grains. These results reveal the strong potential for this compound to be used as a natural alternative to synthetic fungicides. In addition, LD_{50} values of aldehyde VOCs show slight toxicity (≤5 g/kg) in rats.[48] On the other hand, other evaluated VOCs showed a potential capacity to be used as a natural insecticidal (ketones) or as a lure for *S. zeamais* (alcohol). Therefore, the future use of VOCs opens up possibilities for a safer and economically viable option for the conservation of stored kernels and pest management.

Santa Cruz Biotechnology (Santa Cruz, CA, USA). Anti-GAPDH and glutathione peroxidase (GPx-1) antibodies were purchased from Cell Signaling Technology (Beverly, MA, USA). Alexa 488-conjugated anti-sheep, Alexa 594-conjugated anti-mouse, and Alexa 633-conjugated anti-sheep antibodies were purchased from Invitrogen (Carlsbad, CA, USA). A blocking solution was purchased from Dako (Santa Clara, CA, USA), and mounting medium was purchased from Vector Laboratories (Burlingame, CA, USA). Zoletil and Rumpun were purchased from Virbac Laboratories (Fort Worth, TX, USA) and Bayer (Newbury, UK), respectively, and used as anesthesia. All other chemicals and reagents were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Plant Materials and Sample Preparation. *D. kaki* was collected in Gangneung, Gangwon province, Korea, in August 2013. A voucher specimen (D-521) was deposited at the KIST Gangneung Institute. Eight hundred grams of the dried *D. kaki* leaves was extracted three times with 7 L of ethanol at room temperature for 3 h in an ultrasonic cleaning bath (model RK 158s, Bandelin, Berlin, Germany) and filtered through Whatman no. 1 filter paper. The combined filtrate was concentrated to dryness by rotary evaporation at 40 °C to obtain 33 g (yield = 4.13%) of the ethanol extract of *D. kaki* leaves (EEDK). HPLC-PDA-MS analysis was applied using a Thermo Accela HPLC system and LCQ FLEET ion trap mass spectrometer (Thermo Fisher Scientific Inc., San Jose, CA, USA) for compound determinations in EEDK. The mobile phase consisted of 0.1% formic acid in water (solvent A) and 0.1% formic acid in acetonitrile (solvent B), which was used with a YMC-Triart C18 column (3 μm particle size, 150 mm × 4.6 mm i.d., YMC Co., Kyoto, Japan). A linear gradient (from 10 to 60% solvent B for 30 min) at a flow rate of 1 mL/min was used at 254 nm. The mass spectrometer conditions were as follows: negative ion mode; mass range, m/z 200−800; capillary voltage, 10.0 V; capillary temperature, 350 °C. The NMR spectra were recorded on a Varian 500 MHz NMR system (Varian, Palo Alto, CA, USA) at 500 MHz for ^{1}H NMR and 125 MHz for ^{13}C NMR in DMSO-d_6. Compounds **1**−**9** were purified by semipreparative HPLC.

Animals. Six-week-old male C57BL/6J mice weighing 20−25 g (Central Laboratory Animal Inc., Seoul, Korea) were housed at 23 ± 0.5 °C and 10% humidity, with a 12 h light−dark cycle. All animals were acclimated for at least 1 week, caged in groups of five or fewer, and fed a diet of animal chow and water ad libitum.

All animal studies were performed in a pathogen-free barrier zone at the KIST Gangneung Institute in accordance with the procedure outlined in the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research. Procedures used in this study were approved by the Animal Care and Use Committee of the KIST Gangneung Institute (No. 2014-011).

MNU was used as a negative insult for retinal degeneration and was induced by a single intraperitoneal (ip) injection of 50 mg/kg MNU (50 mg/kg body weight) in C57BL/6J mice.[20] After the injection of MNU, EEDK was orally administered in doses of 10, 50, or 100 mg/(kg·day) for 4 weeks. Animals were examined at 1 and 4 weeks after the injection of MNU. Eyes were dissected and examined either for histological or Western blot analysis. Fixed eyes were cut into 4 μm slices and were then studied by staining with hematoxylin and eosin (H&E) or by immunofluorescence.

Spectral Domain Optical Coherence Tomography (SD-OCT). SD-OCT imaging was performed at 1 and 4 weeks after 50 mg/kg MNU treatment. The animals were anesthetized using a mixture of Zoletil (1.6 μg/g, Virbac Laboratories, Fort Worth, TX, USA) and Rumpun (0.05 μL/g, Bayer, Newbury, UK). Anesthetized animals were placed in front of the Spectral OCT system (Heidelberg Engineering, Germany) and analyzed as described previously.[21]

H&E Staining. H&E staining of the retina slides was performed using a standard procedure. Briefly, the retina slides were treated with hematoxylin buffer (0.1% hematoxylin and 10% ammonium) at room temperature. The slides were then washed three times with distilled water and dipped in 1% eosin Y solution. Next, the slides were washed twice with 95% alcohol and mounted. Histological analysis was evaluated under a CKX41 inverted phase contrast microscope (Olympus, Tokyo, Japan).

Western Blot Analysis. Proteins were separated on 10 or 12% SDS-PAGE gels and then transferred onto polyvinylidene difluoride (PVDF) membranes. The membranes were blocked at room temperature in 5% skim milk before overnight incubation at 4 °C with antibodies (diluted as indicated in PBS) against nestin (1:1000), GFAP (1:1000), GAPDH (1:2000), rhodopsin (1:1000), SOD-1 (1:1000), SOD-2 (1:1000), SOD-3 1 (1:1000), or GPx-1 (1:1000). Binding of the primary antibodies was detected following incubation with appropriate horseradish peroxidase-conjugated IgG secondary antibodies (diluted 1:5000) for 2 h at room temperature. The membranes

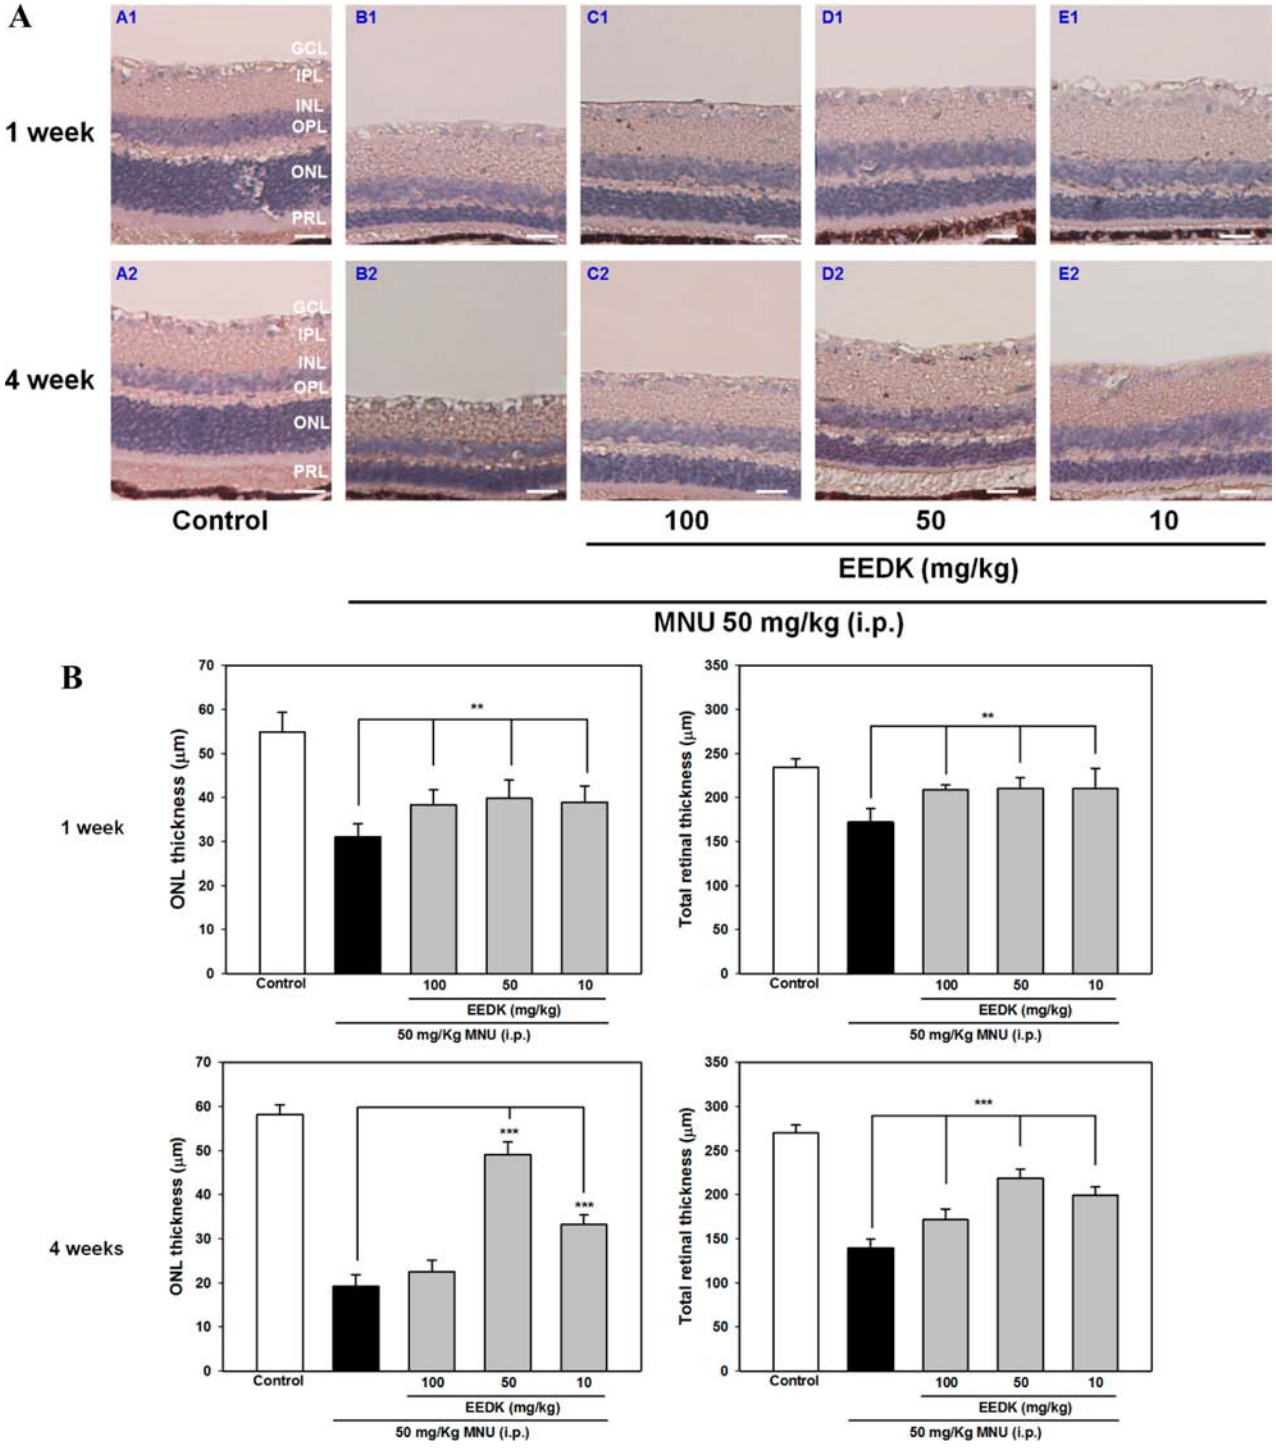

Figure 2. Histological evaluation in hematoxylin and eosin (H&E) staining. Panel A shows retinal cross sections of control (A1, A2), MNU-treated (B1, B2), MNU plus EEDK (100 mg/kg)-treated (C1, C2), MNU plus EEDK (50 mg/kg)-treated (D1, D2), and MNU plus EEDK (10 mg/kg)-treated (E1, E2) mice at 1 and 4 weeks, with or without MNU and/or EEDK treatment. Panel B shows total retinal thicknesses and outer layer thicknesses at the indicated time points. Scale bar = 50 μm. Experimental values are expressed as mean ± SEM. (**) $p < 0.01$ and (***) $p < 0.001$ from three independent experiments (n = 9 mice per group).

were developed using an enhanced chemiluminescence detection kit (Thermo Scientific, Waltham, MA, USA) and measured by densitometry using an LAS-4000 image reader and Multi Gauge 3.1 software (Fujifilm, Tokyo, Japan). GAPDH expression was detected as a loading control.

Immunofluorescence Staining. Paraffin-embedded retinal sections were deparaffinized and blocked in normal goat serum overnight at 4 °C. Subsequently, the sections were incubated with specific primary antibodies against nestin (diluted 1:200), GFAP (diluted 1:200), and rhodopsin (diluted 1:200) overnight at 4 °C. The sections were washed three times with PBST buffer (8 g/L NaCl, 0.2 g/L KCl, 1.44 g/L Na_2HPO_4, 0.24 g/L NaH_2HPO_4, and 0.1% Triton X-100) and incubated with matching secondary antibodies (Alexa 488-conjugated anti-sheep, Alexa 594-conjugated anti-mouse, and Alexa 633-conjugated anti-chicken antibodies; diluted 1:500) for 2 h at room temperature in the dark. The sections were washed with PBST, mounted, and

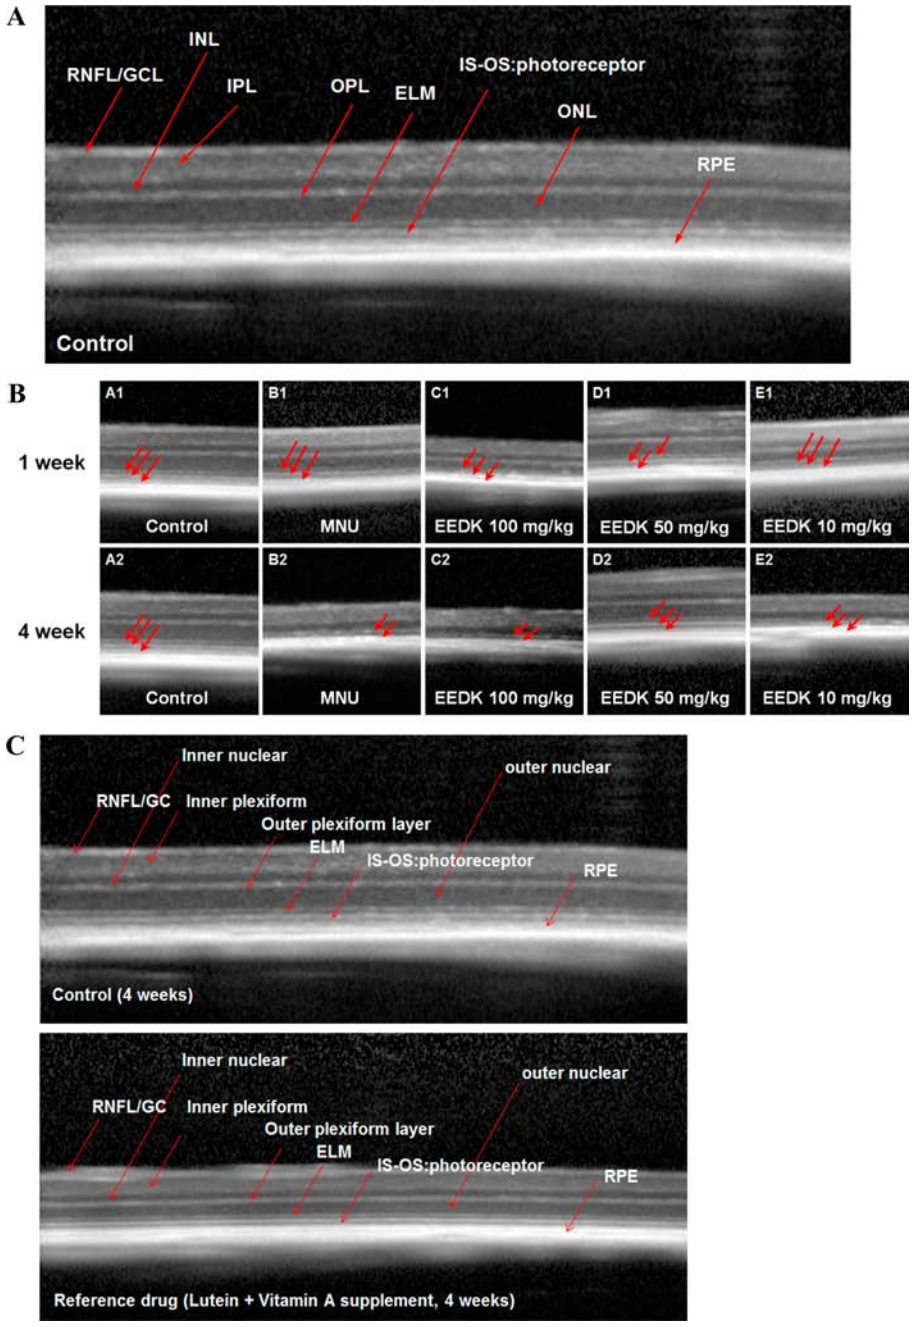

Figure 3. Evaluation of retinal thicknesses by optical coherence tomography. (A) SD-OCT cross-sectional image of a control retina. The following retinal layers were labeled: RNFL/GC, retinal nerve fiber layer/ganglion cell layer; IPL, inner plexiform layer; INL, inner nuclear layer; OPL, outer plexiform layer; ONL, outer nuclear layer; ELM, external limiting membrane; RPE, retinal pigment epithelium. (B) Representative images obtained from the experimental animal retina at 1 and 4 weeks after, with or without MNU and/or EEDK treatment: control (A1, A2), MNU-treated (B1, B2), MNU plus EEDK (100 mg/kg)-treated (C1, C2), MNU plus EEDK (50 mg/kg)-treated (D1, D2), and MNU plus EEDK (10 mg/kg)-treated (E1, E2). (C) Lutein plus vitamin A supplement used as reference drug (Bright lutein, Ildong Pharmaceutical, Korea). Reference drug group received lutein plus vitamin A supplement (0.2%/kg/day). Scale bar = 50 μm.

covered with a glass coverslip. Staining images were examined using a Leica TCS SP5 confocal microscope system (Leica, Wetzlar, Germany).

Cell Culture. Immortalized rat retinal precursor cells (R28 cells) were purchased from Kerafast (Kerafast, Inc., Boston, MA, USA). R28 cells were grown in 75 cm^2 culture flasks in low-glucose Dulbecco's modified Eagle's medium (DMEM; HyClone, Logan, UT, USA) supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS; HyClone) and 100 U/mL penicillin/streptomycin (HyClone). Cultures were maintained at 37 °C in a humidified atmosphere containing 5% CO_2. The cells were passaged twice a week. R28 cells were pretreated with the indicated compounds for 1 h after 300 μM hydrogen peroxide (H_2O_2) was added to cultures for 24 h.

Cell Viability. R28 cell viabilities were determined by performing 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assays. Briefly, MTT assays were performed by treating cells with MTT solution (0.5 mg/mL final concentration) for 1 h at 37 °C. After a 1 h incubation, the blue formazan crystals that formed in intact cells were solubilized with DMSO, and absorbance values at 570 and 590 nm were measured with a microplate reader (BioTek Instruments, Winooski, VT, USA). Results are expressed as the percent of MTT reduction.

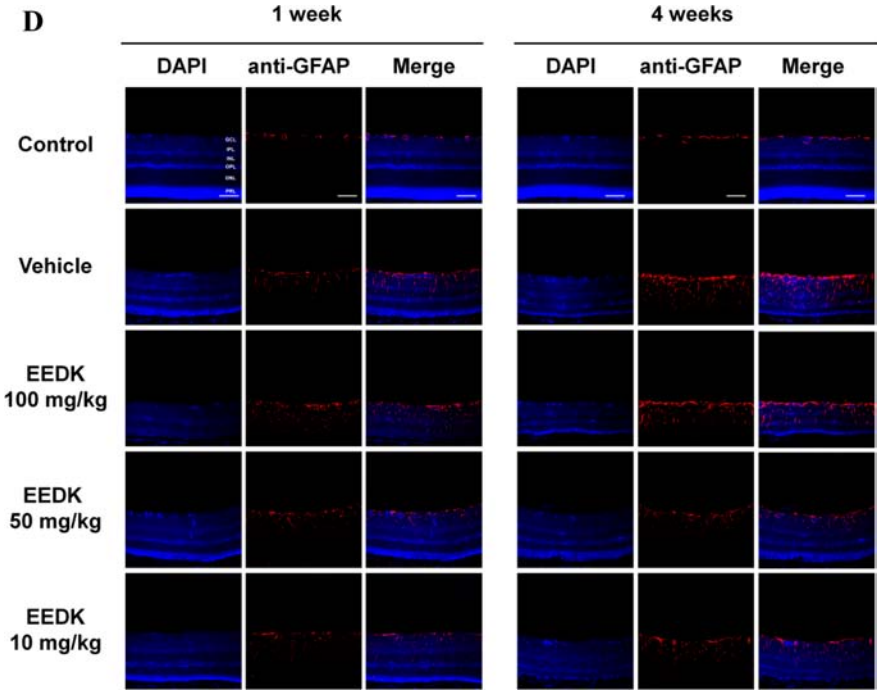

Figure 4. (A) Western blot analysis showing the effects of EEDK treatment on protein expression levels of nestin (Müller cell marker; ~220−240 kDa), glial fibrillary-acidic protein (GFAP; Müller cell and astrocyte marker; 51 kDa), rhodopsin (photoreceptor marker; 40 kDa), and GAPDH (loading control; 37 kDa) in C57BL/6J mice treated with 50 mg/kg MNU, at 1 and 4 weeks. (B) Quantification of relative protein levels. (C, D) Representative immunostaining images were stained with anti-netin (purple), anti-rhodopsin (green), and anti-GFAP (red) in the retina (nuclei were stained with DAPI) and obtained by confocal microscopy (original magnification, 630×). Retinal cross sections were from control, MNU-treated, MNU plus EEDK (100 mg/kg)-treated, MNU plus EEDK (50 mg/kg)-treated, and MNU plus EEDK (10 mg/kg)-treated mice at 1 and 4 weeks, with or without MNU and/or EEDK treatment. Scale bar = 50 μm. Experimental values are expressed as mean ± SEM. (*) $p < 0.05$ and (**) $p < 0.01$ from four independent experiments (n = 9 mice per group).

Assessment of ROS Production. To quantify intracellular ROS production, we used DCFH-DA as a probe for free radicals.[22] The R28 cells were seeded at a density of 5.0×10^3 cells per well into 96-well plates and incubated in a humidified atmosphere of 95% air and 5% CO_2 at 37 °C. Twenty-four hours later, the cell culture medium was replaced with DMEM containing 1% FBS. Superoxide radicals effectively oxidize nonfluorescent dichlorofluorescein (DCFH) to fluorescent dichlorofluorescein (DCF). The cells were loaded with the radical probe DCFH-DA (10 μM) through incubation for 20 min at 37 °C. Then, the cell culture medium was replaced to remove the excess probe. To generate radical species, we added KO_2 at 1 mM ($O_2^{\bullet-}$) to the radical probe-loading medium. Fluorescence was then measured after various durations, using excitation and emission wavelengths of 485 and 535 nm, respectively (Luminescence Spectrometer LS50B, PerkinElmer Ltd., Seer Green, UK).

Statistical Analysis. Experimental values were analyzed by Kruskal−Wallis and Mann−Whitney tests using the Bonferroni correction and are presented as the mean ± standard deviation. A result of $p < 0.05$ was considered to be statistically significant. Quantification of Western blotting results was performed using Fujifilm Multi Gauge software, version 3.0. All statistical analyses were performed using SPSS, version 16.0 (IBM Corp., Armonk, NY, USA).

RESULTS AND DISCUSSION

The chromatogram of EEDK showed nine major peaks (Figure 1). Peak 1 was identified as *p*-salicylic acid by mass (Figure 1) and NMR spectra. The major NMR peaks detected by ^{1}H NMR were 12.33 (1H, s, OH-7), 10.22 (1H, s, OH-4), 7.77 (2H, d, J = 8.7 Hz, H-2, 6), and 6.80 (2H, d, J = 8.7 Hz, H-3, 5), whereas the major peaks detected with ^{13}C NMR were 167.6 (C-7), 162.0 (C-4), 132.0 (C-2, 6), 121.9 (C-1), and 115.6 (C-3, 5). Peaks 2−9 were identified by MS as quercetin, kaempferol, or their glycoside, galactoside, or galloylated derivatives (Figure 1). The chromatograms and spectral data of peaks 2−9 were consistent with results with a previous study.[23]

The concentrations of compounds **1**−**9** in EEDK were measured as 0.8 ± 0.02 mg/g (**1**), 4.8 ± 0.08 mg/g (**2**), 10.6 ± 0.18 mg/g (**3**), 12.7 ± 1.24 mg/g (**4**), 9.4 ± 0.15 mg/g (**5**), 17.3 ± 0.27 mg/g (**6**), 17.2 ± 0.23 mg/g (**7**), 2.1 ± 0.03 mg/g (**8**), and 5.0 ± 0.08 mg/g (**9**).

To observe retinal degeneration caused by MNU treatment, we performed H&E staining of retinal tissues, as shown in Figure 2. The total thickness of the retinal layer and outer nuclear layer significantly decreased in the mouse group treated with MNU alone (Figure 2). However, the retinas of C57BL/6J mice administered EEDK were protected against MNU-induced retinal degeneration (Figure 2). During the observation period, the inner nuclear layer and ganglion cell layer appeared to be unaffected except in the MNU-treated group at 4 weeks post-MNU treatment. Our results also revealed that EEDK administration protected the outer retina against MNU-induced retinal degeneration. These results are consistent with those from a previous study demonstrating that MNU affects the outer layer by causing a reduction in the number of photoreceptors in the retina[24] and demonstrate protective effects of EEDK against retinal degeneration.

We observed further morphological changes in the retinas of live mice via SD-OCT scanning, as shown in Figure 3.[25]

SD-OCT is a noninvasive scanning technique that has been widely adopted clinically to assess retinal disorders involving changes in retinal thickness, structural changes, and edema, among others. SD-OCT enables accurate analysis because it can

DOI: 10.1021/acs.jafc.5b02578
J. Agric. Food Chem. 2015, 63, 7750−7759

provide cross-sectional images of retinas with high resolution. Recently, OCT has been used in many studies to evaluate changes occurring during retinal degeneration in small-animal model studies.[21]

Figure 3A shows an OCT image of a normal retina. The thickness of the outer retinal layer was slightly reduced in the MNU-treated group at 1 week, compared to the control group (Figure 3B). After 4 weeks, significant differences were found in retinal thickness between the control and MNU-treated groups (Figure 3B). However, MNU-induced retinal thinning was significantly attenuated by pretreatment with EEDK (Figure 3B). The reference drug lutein also showed a protective effect against MNU-induced retinal thinning (Figure 3C).

Western blot analysis was conducted to investigate the effects of EEDK treatment on nestin, GFAP, and rhodopsin expression in mouse retinal tissues after MNU-induced retinal degeneration. Nestin, a type VI intermediate filament protein, is expressed in stem cells and progenitor cells, as well as the related Müller cells that differentiate in the central nervous system.[26] The observed configuration of Müller cells and astrocytes has demonstrated that these glial cells help maintain the structural integrity of the retina.[27] Up-regulated nestin expression is often observed during late-stage pathology of neurodegenerative diseases.[28,29] As shown in Figure 4, nestin protein expression was considerably increased in the MNU-treated group at 1 week compared to the control group, but nestin expression was not increased at 4 weeks post-MNU treatment. This result may have been due to the low number of cells preserved in the whole retina.

Importantly, the elevation in nectin protein expression was significantly attenuated by EEDK administration (Figure 4A,B).

The results of recent studies have indicated that GFAP, a type III intermediate filament protein, is present in astrocytes and Müller cells in the retina. Increased GFAP expression is a reliable biomarker of retinal degeneration.[30] GFAP protein expression was up-regulated in a time-dependent manner after mice were treated with MNU alone, compared to the control group; this up-regulation was inhibited by EEDK administration (Figure 4A,B). The dose of 50 mg/kg EEDK showed a significant inhibition, compared with the MNU-treated group.

Rhodopsin is a photosensitive pigment in the rod-containing outer retinal layer and plays a key role in the visual system.[24] In the MNU-treated group, expression of the rhodopsin protein was down-regulated in a time-dependent manner compared to the control group. However, rhodopsin protein expression was maintained by EEDK administration (Figure 4A,B), and the photoreceptor tissue layer was well preserved by EEDK treatment. These results demonstrated that the protective effects of EEDK treatment on retinal degeneration might be related to the expression of retinal factors including nestin, GFAP, and rhodopsin during MNU-induced retinal degeneration.

To further evaluate the protective effects of EEDK on retinal degeneration, we analyzed nestin, GFAP, and rhodopsin expression by immunofluorescence staining, as shown in Figure 4C,D. Immunofluorescence staining revealed that the expression levels of nestin and GFAP, which are related to early signs of gliosis, were significantly increased in the MNU-treated group compared with the control group (Figure 4C,D). However, the 50 and 10 mg/kg EEDK-treated groups showed decreased nestin and GFAP protein expression compared with the MNU-treated group.

The loss of photoreceptor cells was evaluated by immunofluorescence staining for rhodopsin. The expression of rhodopsin was considerably decreased in the MNU-treated group relative to that observed in the control group (Figure 4C,D). In contrast, rhodopsin protein expression was preserved in the 50 and 10 mg/kg EEDK-treated groups (Figure 4C,D). As shown in Figures 2–4, the 100 mg/kg EEDK-treated groups showed no significant differences compared with the MNU-treated group. Thus, administration of EEDK can potentially confer a protective benefit, but a high dose may elicit retinotoxicity.

As observed by Western blot analysis, immunofluorescence staining demonstrated the capacity of EEDK to inhibit retinal degeneration by down-regulating nestin and GFAP expression and by up-regulating rhodopsin expression.

Cell viability assays were performed to confirm the protective effects of compounds **1**–**9** (Figure 5). As shown in Figure 5A,

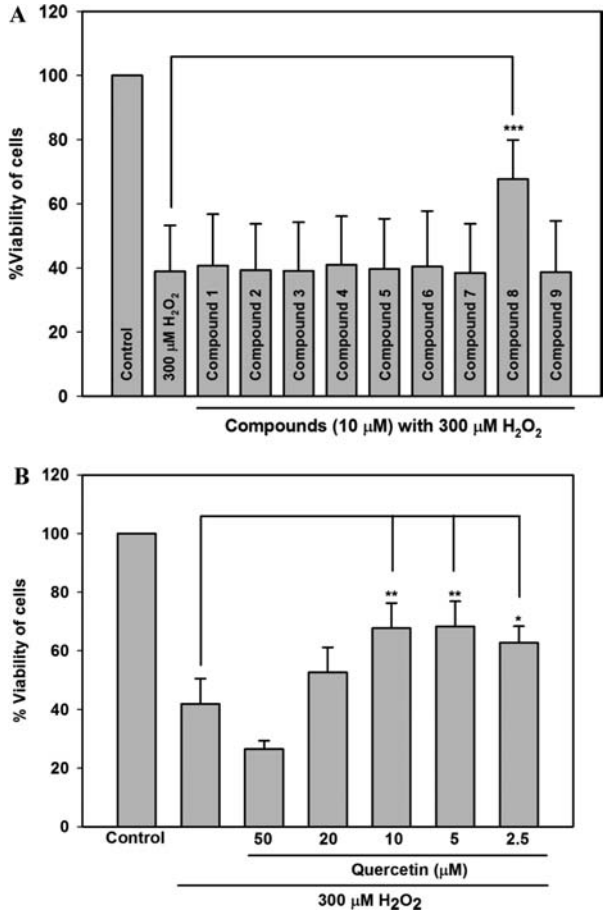

Figure 5. (A) Effects of nine compounds (10 μM concentration) isolated from an ethanol extract of *D. kaki* on R28 cell viability after treatment with 300 μM H_2O_2 for 24 h, as measured by the MTT assay. (B) Effects of compound **8** (quercetin) on H_2O_2-induced R28 cell death. Experimental values are expressed as a percentage of the viable cells with error bars indicating ± SEM from three independent experiments. (*) $p < 0.05$ and (**) $p < 0.01$ indicate statistically significant differences from the cells exposed to H_2O_2 alone.

only quercetin (10 μM; compound **8**) significantly inhibited H_2O_2-induced cell death (~65%) among compounds **1**–**9**. The inhibition of H_2O_2-induced cell death by quercetin occurred in a dose-dependent manner (Figure 5B).

Recently, Keiichi et al. reported that the administration of exogenous antioxidants such as α-tocopherol, ascorbic acid, Mn(III) tetrakis(4-benzoic acid) porphyrin, and α-lipoic acid protected against oxidative damages in an *rd1* mouse model.[31] Quercetin is known to possess antioxidant and free radical-scavenging activities.[32]

DOI: 10.1021/acs.jafc.5b02578
J. Agric. Food Chem. 2015, 63, 7750–7759

DCFH-DA was used as a radical probe to quantify intracellular ROS production. The intracellular ROS levels caused by $O_2^{\bullet-}$ were increased relative to the control by up to 360%. However, pretreating cells with EEDK and quercetin decreased the ROS levels in a dose-dependent manner (Figure 6A,B).

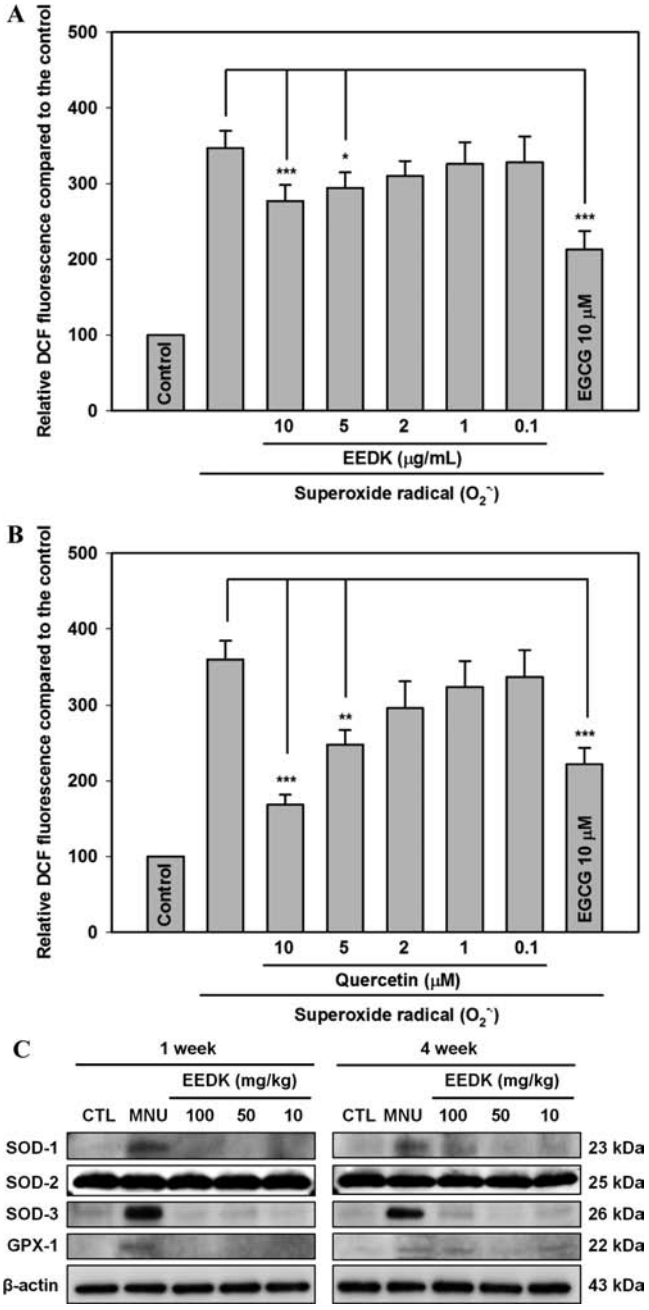

Figure 6. Capacity of EEDK or compound **8** (quercetin) to scavenge superoxide radical ($O_2^{\bullet-}$) in R28 cells. (A, B) The intracellular ROS level was determined on the basis of peroxide-sensitive DCF fluorescence. The results show that EEDK, compound **8** (quercetin), and EGCG as positive controls attenuated ROS production caused by superoxide radical, respectively. Experimental values are expressed as the mean ± SEM. (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ from four independent experiments. (C) Western blot analysis showing the effects of EEDK treatment on antioxidant associated protein expression levels of SOD-1 (Cu/Zn-SOD; 23 kDa), SOD-2 (mitochondrial SOD; 25 kDa), SOD-3 (extracellular SOD; 26 kDa), GPx-1 (glutathione peroxidase-1; 22 kDa), and β-actin (loading control; 43 kDa) in C57BL/6J mice treated with 50 mg/kg MNU, at 1 and 4 weeks.

The expression levels of antioxidant proteins such as SOD 1−3 and Gpx-1 induced by MNU in mouse retina were evaluated by Western blot analysis. Our results showed that SOD-1, SOD-3, and Gpx-1 expression levels were significantly inhibited by EEDK treatment (Figure 6C).

Endogenous antioxidant enzymes, including SODs, GPx, and catalase, served to reduce the oxidative stress of photoreceptors in retinas. Previous findings have shown that endogenous antioxidant enzymes up-regulated under oxidative stress conditions decreased ROS production and prevented cone cell death in several retinitis pigmentosa models.[33,34]

Therefore, the protective effects of EEDK in MNU-induced retinal degeneration may be due to its direct or indirect antioxidative properties.

In summary, our results showed that EEDK has protective effects against oxidative stress-induced cell death in vitro and considerably alleviated MNU-induced retinal degeneration in vivo. In particular, compound **8** (quercetin) could possibly be the acting compound due to antioxidative capacity. Quercetin glycosides, compounds **2**−**4**, did not show significant activity. However, it was known that flavonoid monoglucosides such as quercetin-3-*O*-*β*-glucoside are hydrolyzed by lactase phlorizin hydrolase[35] and cytosolic *β*-glucosidase[36,37] to be absorbed in the small intestine as aglycone forms. This demonstrates that compounds **2**−**4** (quercetin-3-*O*-*β*-galactoside, quercetin-3-*O*-*β*-glucoside, and quercetin-3-*O*-*β*-2″galloylglucoside) may be absorbed from the small intestine of humans as aglycone forms to exhibit antioxidative activity. Collectively, our findings indicate that EEDK may be useful as a potential agent for the prevention and treatment of retinal degeneration, such as with retinitis pigmentosa and AMD.

Table 1. Total Food Intake, Total Caloric Intake, and Final Body Weight of Diabetic Model Mice Fed with Normal (n = 13), HFS (n = 13), HFS + PFE (n = 13), and HFS + AG (n = 13) Diets[a]

parameter	normal	HFS	HFS+PFE	HFS+AG
total calorie intake (kcal)	1262 ± 18 a	1240 ± 25 a	1220 ± 27 a	1266 ± 40 a
total food intake (g)	318 ± 4.5 a	241 ± 4.9 b	240 ± 5.2 b	247 ± 7.7 b
body weight (g)	44.9 ± 0.76 a	48.6 ± 0.92 b	49.6 ± 1.1 b	49.3 ± 1.4 b

[a]Data are shown as the means ± SE. Values with different letters differed significantly at $p < 0.05$ (Tukey's test).

Pharma Co., Tokyo, Japan) once every 2 weeks. At the end of the feeding period, whole blood was collected from the postcaval vein to measure HbA1c using the enzymatic assay[17] (Norudia-HbA1c kit, Sekisui Medical Co., Ltd., Tokyo, Japan), serum AGEs using the ELISA assay (rat/mouse glyceraldehyde-derived AGE ELISA Kit, Up Well Co. Ltd., Fukuoka, Japan), and lipid peroxide using the thiobarbituric acid reactive substances assay[18] (Oxiselect TBARS Assay Kit, Cell Biolabs, Inc., San Diego, USA) according to the manufacturer's instructions. The present study was conducted in accordance with the Animal Experiment Guidelines of Josai University.

In Vitro Experiments. BSA (50 mg/mL) and sugar (100 mM glucose, 100 mM fructose, and 10 mM glyceraldehyde) were dissolved in 0.2 M phosphate buffer (pH 7.4). Each PFE-related sample was added to this solution to final concentrations of 10, 100, and 1000 μg/mL for PFE, and 10, 100, and 1000 μM for GA, EA, PC, and PG. The nonsupplemented BSA + sugar solution was used as a control. The mixture was incubated at 37 °C in total darkness: 15 days for the glucose-containing mixture, 5 days for the fructose-containing mixture, and 1 day for the glyceraldehyde-containing mixture. After incubation, the mixture was transferred to a 96-well black plate (Greiner Bio-One, Tokyo, Japan) to measure the fluorescence intensity (excitation = 370 nm, emission = 440 nm) using Spectra Max M2 (Molecular Devices, Sunnyvale, CA, USA). The rate of AGE formation was calculated as follows:

$$\text{AGE formation rate (\%)} = [\text{fluorescence intensity of sample (after incubation} - \text{before incubation)}]/[\text{fluorescence intensity of control (after incubation} - \text{before incubation)}] \times 100$$

Statistical Analysis. Statistical analysis was performed with StatMate III software (ATMS Co., Ltd., Tokyo, Japan). The data were analyzed by Dunnett's test and Tukey's test. Differences were considered significant at $p < 0.05$. The data are expressed as means ± SE.

RESULTS

Food Intake and Body Weight. To evaluate the antiglycation effect of PFE in vivo, glycation markers such as glycoalbumin, HbA1c, and serum AGEs of KK-A^y mice fed the sample (PFE with HFS) diet for 8 weeks after induction of hyperglycemia were analyzed. Table 1 shows total caloric intake and total food intake during the experimental diet, and body weight at the end of the experiment. Although the amount of food intake during the sample feeding was significantly lower in HFS-based groups (HFS, PFE, and AG) than the normal group, the total calorie consumption of all groups was virtually identical. The net intake of PFE was calculated as 1.5 mg/g/day. Final body weight was significantly higher in the HFS-based groups than in the normal group. There were no differences in caloric intake and weight gain between the HFS groups.

Blood Glucose, Glycation Products, and Lipid Peroxide Levels. The fasting blood glucose concentration was consistently higher in the HFS-based groups than in the normal group (Figure 2). Although the glycoalbumin levels of the HFS group tended to be higher than those of normal group, feeding of PFE and AG with HFS significantly decreased those levels

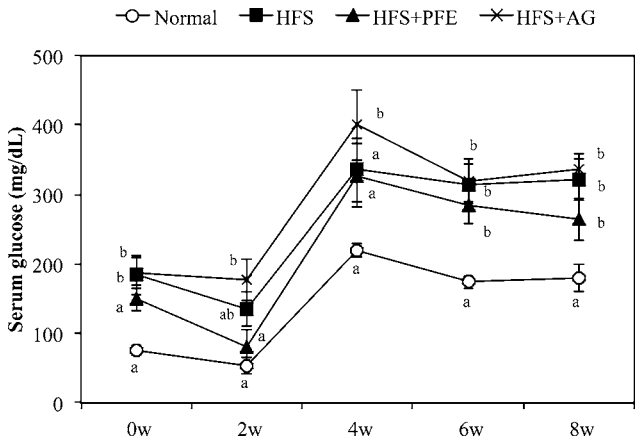

Figure 2. Fasting serum glucose levels in diabetic model mice fed with normal (n = 11−12), HFS (n = 12−13), HFS + PFE (n = 12−13), and HFS + AG (n = 11−13) diets. Data are shown as the means ± SE (n = 10−13), Tukey's test $p < 0.05$.

DOI: 10.1021/acs.jafc.5b02766
J. Agric. Food Chem. 2015, 63, 7760−7764

after 4 and 6 weeks, respectively (Figure 3A). PFE also significantly reduced HbA1c levels at 8 weeks as well as AG

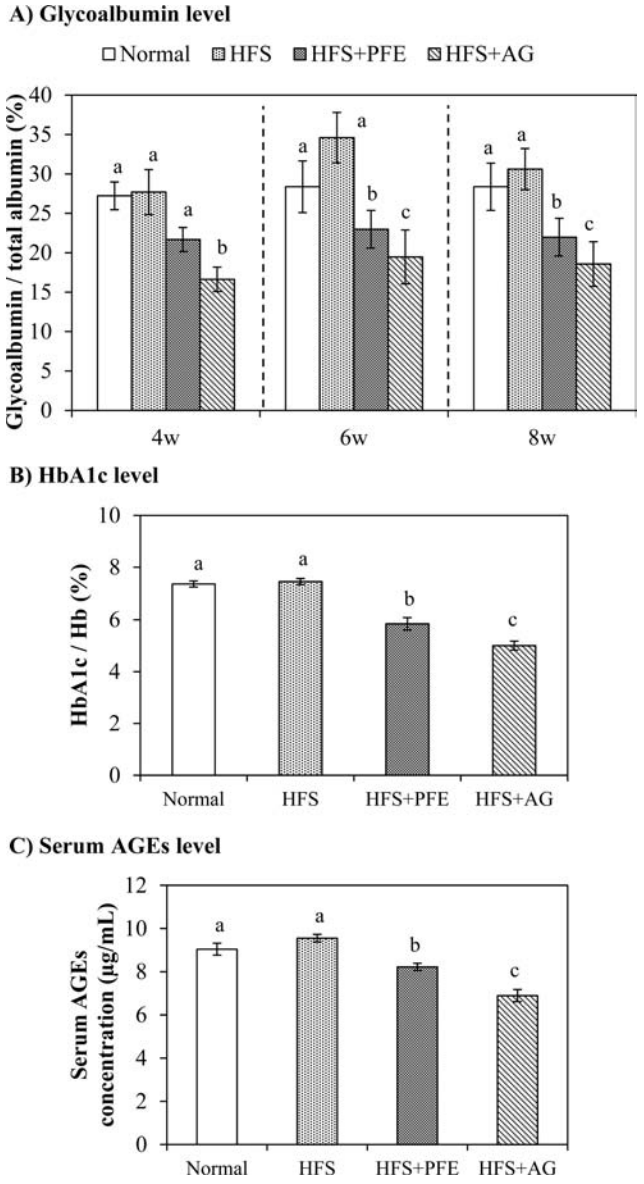

Figure 3. Serum glycation markers of (A) glycoalbumin levels (n = 11−13) at 4, 6, and 8 weeks, (B) hbA1c levels (n = 11−13) at 8 weeks, and (C) serum AGEs (n = 4) at 8 weeks in diabetic model mice fed normal, HFS, HFS + PFE, and HFS + AG diets. Data are shown as the means ± SE, Tukey's test $p < 0.05$.

(Figure 3B). Serum AGE concentration showed a trend similar to that of glycoalbumin and HbA1c (Figure 3C). Among significant increases in serum lipid peroxide in all HFS-based groups, PFE slightly suppressed the level as compared to HFS (p = 0.059) (Figure 4).

In Vitro Experiments. The AGE formation derived from BSA with glucose, fructose, and glyceraldehyde in vitro was concentration-dependently suppressed by addition of PFE and its components (Figure 5A−C). An even lower concentration of PFE (10 μg/mL) significantly suppressed the AGE formation from fructose and glyceraldehyde (Figure 5A). The anti-AGE-formation potency of the PFE components was similar in the assays using different sugars. The potency of EA

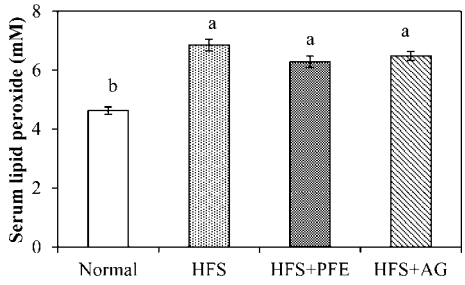

Figure 4. Serum lipid peroxide in diabetic model mice fed normal, HFS, HFS + PFE, and HFS + AG diets. Data are shown as the means ± SE (n = 10), Tukey's test $p < 0.05$.

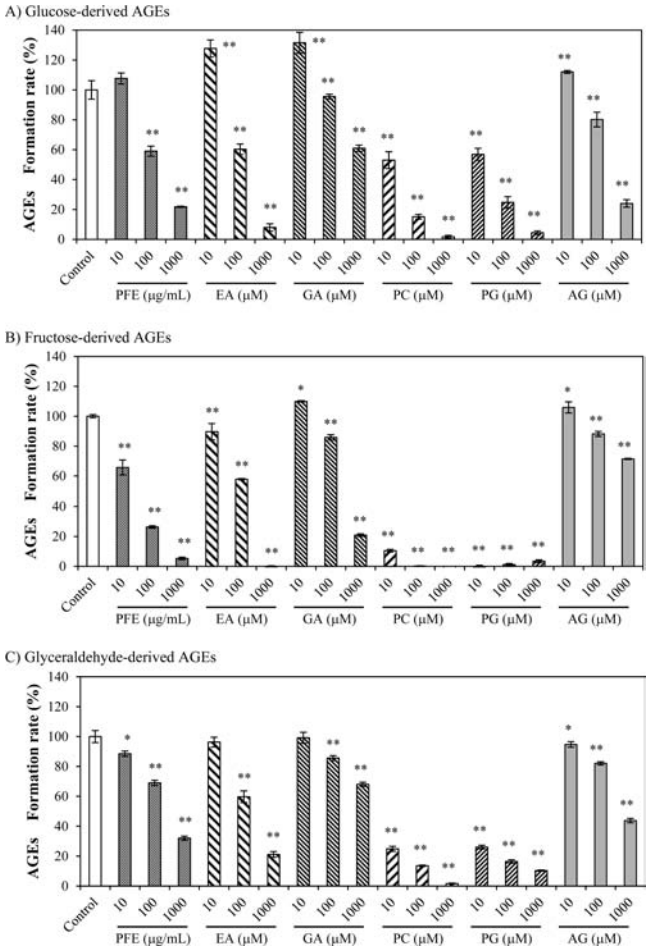

Figure 5. Antiglycation effects of PFE and its polyphenols on (A) glucose-derived, (B) fructose-derived, and (C) glyceraldehyde-derived AGE formation. Data are shown as the means ± SE (n = 3), Dunnett's test, *$p < 0.05$, **$p < 0.01$.

and GA was comparable to that of AG. PC and PG showed higher potency than EA and GA. The lowest concentration of PC and PG (10 μM) remarkably inhibited the AGE formation, especially with fructose (Figure 5B).

DISCUSSION

Most reports concerning the antiglycation effect of PFE have been performed in vitro, in which the suppression of AGE formation was via inhibition of the binding of proteins with sugars.[11−13] However, it has been unclear precisely what components of pomegranate contribute to this suppression.

DOI: 10.1021/acs.jafc.5b02766
J. Agric. Food Chem. 2015, 63, 7760−7764

Only one in vivo study reported that PFE inhibited collagen-derived AGEs in humans.[19] However, there has been no investigation about the antiglycation effects of pomegranate in vivo. Therefore, we have evaluated the antiglycation effects of pomegranate in type 2 diabetes model mice, in which it is relatively easy to induce conditions that promote glycation. Additionally, the effect of the individual components of PFE was investigated by an antiglycation in vitro assay. The results indicate that pomegranate contains several components that have the ability to suppress AGE formation in type 2 diabetic mice. Oral administration of PFE might not affect glucose absorption from meals in the intestine because there were no significant differences in caloric intake and body weight gain between HFS and HFS plus PFE. Higher levels of the fasting blood glucose concentration in the HFS plus PFE group indicate that PFE could not completely reverse the hyperglycemia. Therefore, the PFE-mediated reduction in HbA1c and glycoalbumin might be caused by inhibition of the reaction between the protein and glucose, that is, glycation. The accumulation of glycated albumin already started to decrease at 4 weeks after oral administration of PFE, also suggesting that PFE inhibited the early stages of glycation. The suppression of HbA1c by PFE also supports our hypothesis. The decreased accumulation of these glycation products probably resulted in the lower concentration of AGEs in PFE-fed mice. The additional benefit of PFE could be antioxidant effects that were observed as a slight decline in blood lipid peroxide levels. PFE and its constituent polyphenols have shown in vitro antiglycation effects as evaluated by the formation of glucose- and fructose-derived AGEs.[20,21] In this study, we revealed that PFE and its component polyphenols suppressed the generation of glyceraldehyde-derived AGEs in vitro, especially the ellagitannins PC and PG comparable to the antiglycation therapeutic aminoguanidine. Glyceraldehyde more easily reacts with protein than fructose and glucose,[2,22] and the glyceraldehyde-derived AGEs are thought to be highly toxic.[4] The anti-AGE-formation potency seemed to depend on the number of phenolic groups, suggesting that these polyphenols acted as an antioxidant in the latter stages of glycation in vitro. However, orally administered ellagitannins hardly transfer to the blood because of their relatively high molecular weight.[23−25] Ellagitannins like PC and PG are digested by gastric acid to EA, some of which will appear in the blood. The rest of EA is metabolized by intestinal bacteria into urolithin, which also will appear in the blood.[23,24,26,27]

Liu et al. reported that urolithin possessed antiglycation effect similar to aminoguanidine.[13] Therefore, the antiglycation effect of PFE shown in this in vivo study might be induced by these metabolites that had been degraded from ellagitannins in the digestive tract. Additionally, ellagitannins might contribute to the inhibition of exogenous AGE formation in the gastrointestinal tract. Further study is needed to clarify the mechanism of how the metabolites incorporated into the blood inhibit early stages of glycation.

laboratory by a papain enzymatic method. Captopril was bought from YTHX Biotechnology Co., Ltd. (Beijing, China). RNAstore reagent, RNAprep pure Tissue Kit, FastQuant RT Kit, and SuperReal PreMix Plus (SYBR Green) Kit were purchased from Tiangen Bio Co., Ltd. (Beijing, China). The Rat Angiotensin Converting Enzyme Immuno Assay Kit, Angiotensin Type 1 Receptor ImmunoAssay Kit, Angiotensin Type 2 Receptor ImmunoAssay Kit, Angiotensin Converting Enzyme 2 ImmunoAssay Kit, Angiotensin II Immuno-Assay Kit, and Angiotensin-(1−7) ImmunoAssay Kit were from R&D Systems Inc. (Minneapolis, MN, USA).

Preparation of *S. platensis* Hydrolysates. *S. platensis* powder (10 g) was suspended by 30 mL of distilled water and stored at −80 °C, and then the suspension was thawed (frozen−thawed five times in total). After sonication for 3 min, the suspension was centrifuged at 6000*g* for 20 min at 4 °C and lyophilized. The protein content of the supernatant was determined by using a Total Protein Quantification Kit (Nanjing Jiancheng Bioengineering Institute, Nanjing, China). Before the hydrolysis reaction, 5.0 U of papain (Sigma Chemical Co., St. Louis, MO, USA) was added to 30 mL of redissolved protein solution (2% of substrate contained). The pH of the hydrolysis reaction system was adjusted to 7.0, and the reaction was performed at 70 °C for 9 h. Soon after the reaction was completed, the reaction system was transferred to 100 °C for 10 min to inactivate the enzyme. After centrifugation at 6000*g* for 10 min at 4 °C, the supernatant was ultrafiltered by 10000 and 5000 Da ultrafiltration membranes (Sartorius Co., Goettingen, Germany) successively. Finally, the products were lyophilized and stored at −20 °C. The percentages of IQP and VEP in SH were determined by RP-HPLC as 1.81 and 2.14%, respectively.

Animal Experiments and Blood Pressure Measurements. Eighty 5-week-old male SHRs were provided by Vital River Laboratories (Beijing, China). After 3 weeks of adaption to the environment and tail-cuff blood pressure measurement, SHRs were divided into five groups based on blood pressure (n = 16). Animals were kept in groups of five and maintained on a 12 h light/dark cycle under standard conditions at a temperature of 23 ± 2 °C, and a humidity of 60 ± 10%. The standard basal diet (HFK Bio., Beijing, China) according to the China National Standard (GB 14924.3-2001) and tap water were freely available. Systolic blood pressure (SBP), diastolic blood pressure (DBP), and heart rate (HR) were measured twice a week at 10:00 a.m. in the middle and at the end of the week from 9 to 16 weeks of age by a Kent Scientific CODA noninvasive blood pressure motoring system (Torrington, CT, USA) with a tail-cuff method. Before measurement, rats were kept on a warming pad for 10−15 min until pulsations in the tail artery were detectable. Given that the rats would be nervous during the measurements, the results of blood pressure were calculated and presented as weighted systolic blood pressure (WSBP) and diastolic blood pressure (WDBP), WSBP = SBP/HR × AveHR; WDBP = DBP/HR × AveHR, where AveHR is the mean heart rate of all SHRs measured in that time.[8] The body weights and diet and tap water intakes were measured twice a week. Between the 9th and 14th weeks of age at 9:00 a.m. every day, the five groups of SHRs were orally administered distilled water (negative control) 10 mL/kg/day, IQP 10 mg/kg/day, VEP 10 mg/kg/day, SH 10 mg/kg/day, or captopril (positive control) 10 mg/kg/day by a "passive swallow" gavage (filling the gavage needle in front of the esophagus to make a passive swallow instead of filling the needle directly into the stomach) to protect the rats' esophagus during the long-term experiment. From the 15th week of age, the treatments were withdrawn. At the end 11th, 14th, and 16th weeks of age, five or six rats per group were anesthetized and euthanized by 50 mg/kg pentobarbital (Sigma Chemical Co.). The left and right ventricles of the rats were separated and weighed. The left ventricular mass index (LVMI) and right ventricular mass index (RVMI) were calculated using the formulas LVMI (mg/g) = left ventricular mass (mg)/body weight (g) and RVMI (mg/g) = right ventricular mass (mg)/body weight (g).[11] Myocardial tissues were removed and stored in RNAstore reagent or in saline for 24 h at 4 °C, and then they were removed from the solutions and stored at −80 °C.

All rat experiments were performed in accordance with the Guidelines for the Care and Use of Laboratory Animals, Committee of Beijing Experimental Animal Care and Use, and were authorized by the Ethics Committee of the Beijing Experimental Animal Association.

Isolation of RNA, Reverse Transcription, and Quantitative Real-Time Polymerase Chain Reaction (qRT-PCR). Total RNA of myocardial tissues was extracted by using a Tiangen RNAprep pure Tissue Kit according to the manufacturer's guidelines, and the RNA concentrations and purities were determined by the ratios of A_{260}/A_{280} and A_{260}/A_{230} with a NanoDrop 2000 UV−vis spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). Reverse transcription for cDNA synthesis was done using a two-step method according to the instructions of the Tiangen FastQuant RT Kit with a 20 μL system to transcript 500 ng of cDNA in each sample, in which 2 μL of 10× Fast RT Buffer,1 μL of RT Enzyme Mix, and 2 μL of FQ-RT Primer Mix were mixed. Then the cDNA was stored at −20 °C. For qRT-PCR, a 20 μL qRT-PCR system with SYBR Green dye was set up following the instructions of the Tiangen SuperReal PreMix Plus (SYBR Green) Kit. A three-step procedure was followed for the qRT-PCR reaction using a CFX96 Touch Real-Time PCR Detection System (Bio-Rad Laboratories, Hercules, CA, USA) with 1 cycle of pre-denaturation at 95 °C for 15 min and 45 cycles of reaction, including denaturation at 95 °C for 10 s, annealing (different annealing temperatures were used for different genes, Table 1) for 20 s, and extension for 20 s at 72 °C. The primers for GAPDH, ACE, ACE2, AT1, AT2, and Mas were synthesized by Sangon Biotech Ltd. (Shanghai, China). GAPDH was used as a housekeeping gene. The sequences of real-time PCR primers are shown in Table 1.

Enzyme-Linked Immunosorbent Assay (ELISA). Myocardial tissues were homogenized in a glass homogenizer at 0 °C and then

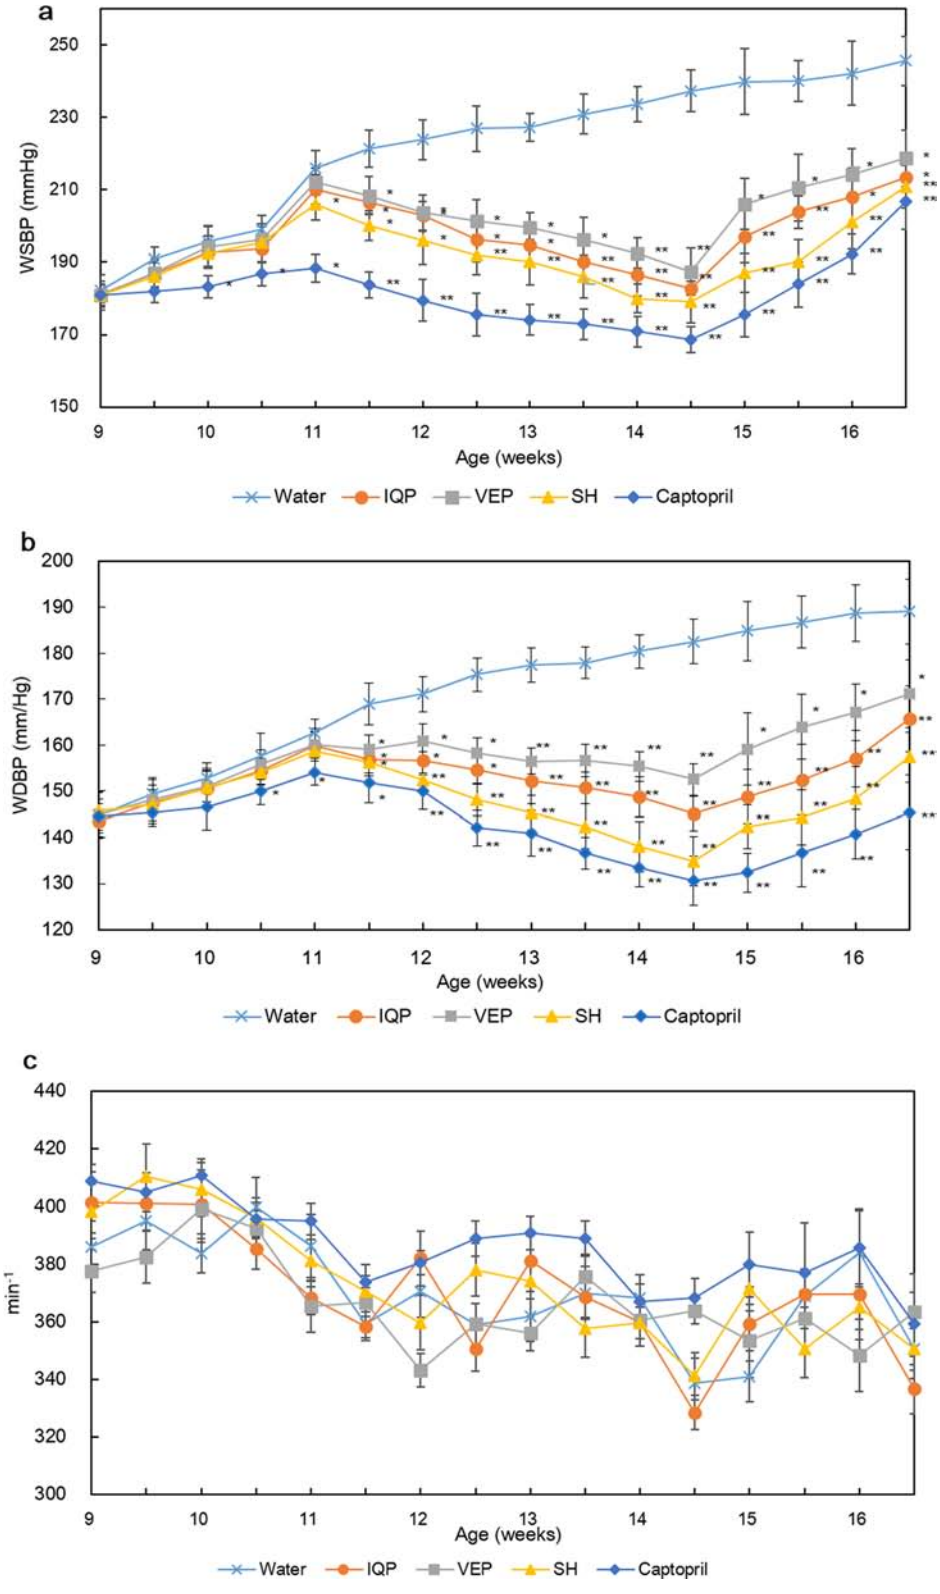

Figure 1. Blood pressure and heart rate changes of SHRs during the 8 week experimental period: (a) change of weighted SBP; (b) change of weighted DBP; (c) change of heart rate. The results are shown as means ± SE (9−11 weeks of age, n = 15; 12−14 weeks of age, n = 10; 15−16 weeks of age, n = 5): (∗) $p < 0.05$ and (∗∗) $p < 0.01$ versus the group fed distilled water. The "↓" represents the euthanasia time.

centrifuged at 3000g for 10 min at 4 °C. The total protein content of supernatants was measured by a Coomassie Brilliant Blue Total Protein Quantification Kit (Nanjing Jiancheng Bioengineering Institute). The protein/peptide contents of ACE, ACE2, AT1, AT2, Ang II, and Ang-(1−7) were assayed using R&D rat ELISA kits according to the manufacturer's instructions. Samples in 96-well microplates were read by a Multiskan MS ELISA reader (Helsinki, Finland) within 15 min after the reaction was stopped.

Western Blotting. Mas receptor protein concentrations were determined by Western blotting, and GAPDH was used as a reference.

DOI: 10.1021/acs.jafc.5b02801
J. Agric. Food Chem. 2015, 63, 7765−7774

The total protein of myocardial tissues was extracted by a Total Protein Extraction Kit (ProMab Biotechnologies, Albany, CA, USA), and the tissue lysates were heated at 100 °C for 10 min in a loading buffer. Equivalent amounts of total protein were separated on a 10% polyacrylamide gel in a 0.1% SDS buffer with SDS-PAGE. Then the proteins were transferred onto a nitrocellulose membrane (Pierce Chemical Co., Rockford, IL, USA). The membrane was blocked with nonfat dry milk (5%) in TBST buffer (20 mM Tris-HCl, pH 7.6, 137 mM NaCl, 0.5% Tween 20) for 2 h at 37 °C before the protein was incubated with MAS1L primary antibody (Abcam Inc., Cambridge, MA, USA) for the Mas receptor at a dilution of 1:500 for 2 h or GAPDH primary antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) at a dilution of 1:800 for GAPDH. After four 5-min washes with TBST buffer, the membrane was probed by goat anti-rabbit IgG/HRP secondary antibody (Abcam Inc.) at a dilution of 1:4000 for Mas receptor or by goat anti-mouse IgG/HRP secondary antibody (Santa Cruz Biotechnology) at a dilution 1:8000 for GAPDH, followed by four 5-min washes with TBST buffer. Visualization was carried out by electrochemiluminescence (ECL) detection system (Bio-Rad Laboratories, Hercules, CA, USA). The content of Mas receptor protein was determined relative to GAPDH. Gel pro4.0 software (Media Cybernetics, Rockville, MD, USA) was used to analyze the integrated optical density (IOD) of the protein bands.

Statistical Analysis. The results are shown as means ± standard error (SE). One-way variance analysis (ANOVA) was estimated by SPSS 20.0 software (SPSS Inc., Chicago, IL, USA) followed by Scheffe test as a post hoc test. $P < 0.05$ between means was considered a significant difference, and $P < 0.01$ was considered a very significant difference.

RESULTS

Effects on SHR Blood Pressure. Changes in WSBP, WDBP, and heart rates of SHRs during the 8 week experimental period are shown in Figure 1. Before treatment, the mean WSBP was 181 ± 1 mmHg and the mean WDBP was 145 ± 1 mmHg. During 9−11 weeks of age, the blood pressure of all five groups increased, and there was no significant difference among the groups treated with distilled water (negative control), IQP, VEP, or SH. However, the group treated with captopril (positive control) showed a moderate increase in blood pressure and the lowest blood pressure by WSBP or WDBP. At the end of 11 weeks of age, the blood pressures of the treatment groups began to decrease compared with the negative control group. The captopril group had the lowest WSBP and WDBP, followed by the SH, IQP, and VEP groups. In addition, from the middle of 11 weeks of age, the other four groups showed significant differences in blood pressure compared with the negative control group. At 14 weeks of age, the IQP, VEP, SH, and captopril groups had 27, 25, 27, and 19 mmHg mean decreases in WSBP, respectively, and 15, 9, 24, and 21 mmHg decreases in WDBP, respectively, compared to blood pressure at 11 weeks of age, whereas the negative control group experienced a 16 mmHg increase in WSBP and a 14 mmHg increase in WDBP. When treatment was stopped at the start of the 15th week of age, the blood pressures of the IQP, VEP, SH, and captopril groups increased. However, they were still significantly lower than that of the negative control group. The WSBPs of the IQP, VEP, SH, and captopril groups had a mean lower value of 54, 50, 58, and 68 mmHg compared with the distilled water group at 14 weeks of age, whereas WDBPs were 38, 28, 48, and 52 mmHg, respectively. Throughout the experimental period, heart rates among the groups did not show significant differences (Figure 1c).

Growth Parameters of SHRs. In Figure 2, the body weights of SHRs at 9−16 weeks are shown. The body weights

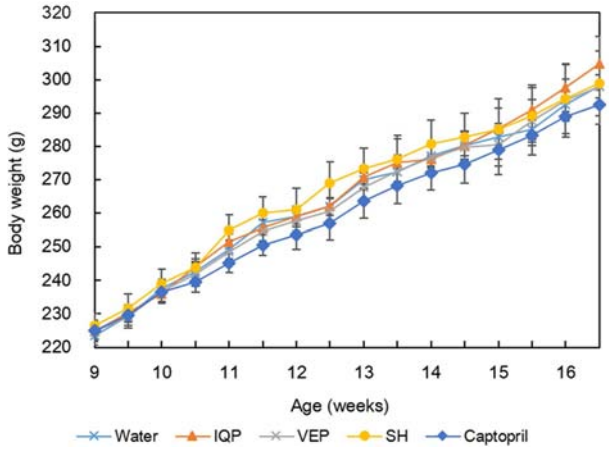

Figure 2. (a) Body weight changes of SHRs during the 8 week experimental period. The results are shown as means ± SE (9−11 weeks of age, $n = 15$; 12−14 weeks of age, $n = 10$; 15−16 weeks of age, $n = 5$).

of all SHR groups increased steadily, although the captopril group gained weight at a slower rate than other groups and the SH group gained weight at a faster rate. Tables 2 and 3 show the diet intake and water intake of SHRs during the experimental period. The diet intake was reduced at 10 weeks of age and then increased with slight fluctuations in the IQP group at 13 weeks, and at 14 weeks of age it was relatively higher but not significantly so. The results of water intake indicated that the captopril group drank the most water during 9−14 weeks of age, whereas the distilled water group drank the least. The other three groups had values between the positive and negative control groups, but were not significantly different. The trend of water intake also declined at 10 weeks of age, but then increased until 12 weeks of age and then showed a fluctuating pattern.

Left Ventricular Mass Index (LVMI) and Right Ventricular Mass Index (RVMI). LVMI and RVMI of SHRs euthanized at the end of 11, 14, and 16 weeks of age are shown in Figure 3. Both LVMI and RVMI of the negative control group were higher than the other groups and then were in the order VEP > IQP > SH > captopril. However, after the first 3 weeks, IQP, VEP, and SH groups showed no significant difference with the negative control group in RVMI but showed significant difference in LVMI. After 6 weeks of treatment, the differences in ventricular mass indices between the negative control group and other groups increased. However, when treatment was stopped for 2 weeks, the ventricular mass indices of the IQP, VEP, SH, and captopril groups were higher than during the treatment period. The LVMI of IQP, SH, and captopril groups still exhibited significant difference compared with the water group. However, only the captopril group and the SH group had significant differences compared with the water group in RVMI.

mRNA Expression Levels of ACE, ACE2, AT1, AT2, and Mas in the Myocardium of SHRs. The mRNA expression levels of ACE, ACE2, AT1, AT2, and Mas genes in the five groups were detected by qRT-PCR, and GAPDH was used as a housekeeping gene. The results are shown in Figure 4. The administration of IQP, VEP, SH, and captopril significantly lowered the mRNA expression levels of ACE and AT1 genes at 3 and 6 weeks of treatment, whereas significantly increased levels were observed for the ACE2, AT2, and Mas genes. The

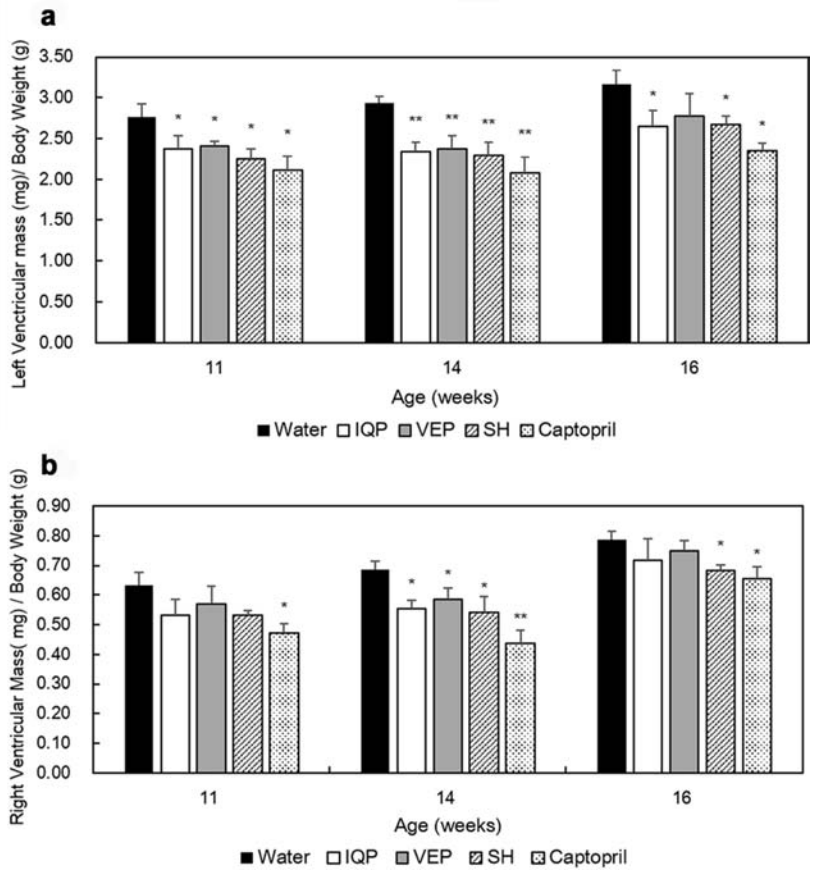

Figure 3. (a) Left ventricular mass index and (b) right ventricular mass index of SHRs euthanized at the end of 11, 14, and 16 weeks of age. The results are shown as means ± SE (n = 5): (*) $p < 0.05$ and (**) $p < 0.01$ versus the group fed distilled water.

trend of all gene expression after 6 weeks of treatment was slightly more significant than that after 3 weeks of treatment, and the differences in ACE, AT1, and AT2 gene expression were greater among the groups. After 6 weeks of treatment, the relative mRNA expression levels of the ACE gene and AT1 gene in the IQP, VEP, and SH groups were approximately 0.5-fold less than those of the negative control group. On the contrary, ACE2 gene and Mas gene expression levels were about 0.5-fold greater than those of the negative control group, whereas their AT2 gene expression levels were 1-fold greater

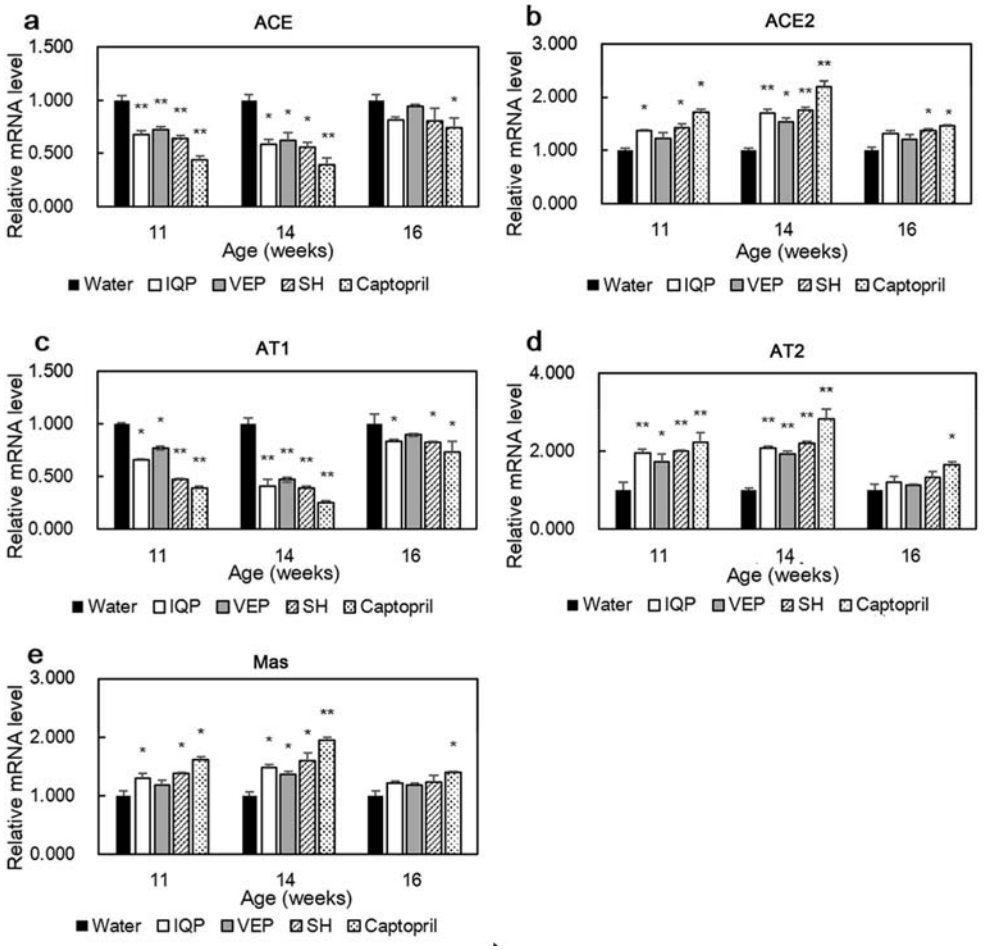

Figure 4. mRNA expression levels of (a) ACE, (b) ACE2, (c) AT1, (d) AT2, and (e) Mas genes at the end of different experimental periods. The gene expression of the group fed distilled water was used as a reference, and GAPDH was the housekeeping gene. The results are shown as relative level to the reference genes, as means ± SE (n = 5): (∗) $p < 0.05$ and (∗∗) $p < 0.01$ versus the group fed distilled water.

than that of the negative control group. The degree of treatment impact on mRNA expression levels was captopril > SH > IQP > VEP. When the treatments were stopped for 2 weeks, the differences among the groups became smaller.

Protein/Peptide Concentrations of ACE, ACE2, Ang II, Ang-(1−7), AT1, AT2, and Mas Receptor in the Myocardium of SHRs. The protein content of ACE, ACE2, AT1, and AT2 and the peptide content of Ang II and Ang-(1−7) were detected by ELISA (Figure 5), and the protein levels of Mas receptor were determined by Western blotting relative to that of GAPDH (Figure 6). The administration of IQP, VEP, SH, and captopril decreased the protein/peptide content of ACE, Ang II, and AT1, whereas increased content of ACE2, Ang-(1−7), AT2, and Mas receptor was observed after 3 and 6 weeks of treatment. This was similar to the trend for their mRNA expression levels. After 3 weeks of treatment, there were significant differences between the negative control group and the treatment groups in nearly all studied RAS substrates. As the treatment continued for another 3 weeks, the differences among the groups became more significant, and the withdrawal of the treatment reduced the difference in magnitude, although the trend remained the same. The degree of treatment impact on protein/peptide content was captopril > SH > IQP > VEP.

DISCUSSION

Anti-hypertensive peptides derived from foods have been a hot research topic in recent decades, and numerous studies have been performed to isolate the anti-hypertensive peptides from natural products to explore their in vitro and in vivo blood pressure regulatory characteristics and their anti-hypertensive mechanisms.

This study was based on previous studies of two *S. platensis*-isolated tripeptides, IQP and VEP.[6−9] IQP and VEP were isolated and purified by gel filtration chromatography and reverse-phase high-performance liquid chromatography and showed ACE inhibitory activity in vitro (IC_{50} = 5.77 ± 0.09 μM for IQP and IC_{50} = 27.36 ± 0.14 μM for VEP).[6,7] It was revealed that in 24 h and 1 week experiments, IQP and VEP demonstrated in vivo anti-hypertensive effects in SHRs, and some components of the RAS including renin, Ang, ACE, Ang II, AT1, and AT2 were influenced by treatment.[8,9] However, these studies were short-term experiments and mainly focused on the ACE−Ang II−AT1 axis. Long-term observation of blood pressure and regulation of the ACE−Ang II−AT1 and ACE2−Ang-(1−7)-Mas axes are required to complete the integrated evaluation of the anti-hypertensive effects of IQP and VEP. To compare the anti-hypertensive effects of these two tripeptides isolated from *S. platensis*, we used hydrolysates derived from *S. platensis* containing these two tripeptides, other peptides, or substrates as reference molecules.

SHRs are often used for studies of the anti-hypertensive effects of foods and food protein-derived bioactive peptides because their hypertension patterns are similar to those in humans.[12,13] Male SHRs usually have a higher blood pressure than females of the same age, so they are easier to use for observation studies.[14] At the initial stages of SHR life, the blood pressure increases significantly and then stabilizes.[15,16] We also observed this pattern in the 3 weeks of adaption (data not shown) and first 3 weeks of treatment. However, the positive control group (captopril group) experienced a lower growth rate in both WSBP and WDBP compared with the other groups, and the negative control group showed a greater growth rate. After the end of 11 weeks of age, both the WSBP and WDBP of all groups excluding the negative control group began to decrease gradually and showed significant differences with the negative group ($P < 0.05$). This significance remained

DOI: 10.1021/acs.jafc.5b02801
J. Agric. Food Chem. 2015, 63, 7765−7774

until the end of the experiment, although the data of the IQP, VEP, SH, and captopril groups increased after the withdrawal of the treatment. We noticed that significant anti-hypertensive effects among the treatment groups appeared from the middle of 11 weeks of age in this study, which showed a delay of about 1 week compared to our short-term study.[8,9] The reason might be that the "passive swallow" method caused some deviation in daily actual intakes compared with direct gavaging into the stomach. Nonetheless, we suggest that such deviation would be more controllable than dissolving the treated compounds in daily drink water. Captopril is a well-known ACE-inhibitory drug for anti-hypertensive treatment in the clinic and showed the most prominent blood pressure lowering effect, followed by SH, IQP, and VEP. Saito et al.[17] found that in sake lee-derived ACE-inhibitory peptides, IYPRY had a higher in vivo SBP lowering effect than its hydrolyzed fragments IY, YP, and RY. Marczak et al.[18] also found similar results for anti-hypertensive peptides isolated from rapeseed. The subtilisin hydrolysates of rapeseed had a stronger anti-hypertensive effect than its fragmented peptides. Sipola et al.[19] compared the fermentative milk derived tripeptides, Iln-Pro-Pro (IPP) and Val-Pro-Pro (VPP), and sour milk containing these two peptides and found that sour milk had a more extensive SBP lowering effect than either IPP or VPP and proposed that there might be other anti-hypertensive factors such as electrolytes of calcium, magnesium, potassium, or sodium in the sour milk, which could regulate the blood pressure. Because *S. platensis* possesses abundant high-quality proteins, mineral substances, and other nutritional components, electrolytes and/or other unknown anti-hypertensive peptides in *S. platensis* hydrolysates alone or in combination might have contributed to the extensive attenuation of blood pressure in the SHRs. Furthermore, there were not very huge differences between the captopril group and other treated groups, although there is a huge difference between their IC_{50} values (2−15 nM for captopril).[20] It was reported that food-derived ACE inhibitory peptides might exert higher anti-hypertensive activities in vivo than their expected IC_{50} values in vitro compared to captopril.[8,21] This phenomenon might due to the higher affinity of ACE inhibitory peptides to target tissues and their slower elimination.[5,8,21,22]

Miguel et al.[15] reported that SHRs treated with captopril gained weight at a lower rate than the other groups, similar to the trend in the current study between 10 and 16 weeks of age, although this was not statistically significant. In contrast, the SH group gained weight at a slightly higher rate. The fluctuation of diet and water intake in the first 2 weeks of treatment might be caused by the SHRs' inadaptability to the administration. Diet intakes of the IQP, VEP, and SH groups were slightly higher than those of the other groups at 11−14 weeks of age. ACE-inhibitors have been proven to induce thirst and increase water intake in rats, and indeed the captopril group consumed the most water during the treatment period.[15] These factors might explain the increase of water intake of SHRs in the groups that had lower blood pressures.

During the pathogenesis of hypertension, long-term increased peripheral resistance and blood pressure can lead to changes in the compensatory structures of myocardial tissue, resulting in myocardial hypertrophy, myocardial fibrosis, and ventricular cavity expansion. Elevation of blood pressure can induce an increase in cardiac load, stretching of the myocardial fibers, hypoxia of myocardial tissue, accumulation of metabolites, and increased rate of protein synthesis, which can result in myocardial hypertrophy.[23] The high blood volume return to the right atrium and preload of the left atrium increased the left ventricular filling pressure, left ventricular volume, and cardiac output.[24] Increased left ventricular volume can cause left ventricular wall tension, causing the left ventricular mass to be elevated and produce a thicker myocardial wall to adapt to these changes.[25,26] Left ventricular hypertrophy predisposes the heart to congestive heart failure.[24] In SHRs, left ventricular hypertrophy is formed after approximately the 10th week of life.[27] Our study found that both the LVMI and RVMI of the IQP, VEP, SH, and captopril groups were lower than the negative control group after 6 weeks of treatment, indicating these peptides might inhibit myocardial hypertrophy. This result might be related to the anti-hypertensive effects of IQP, VEP, SH, and captopril. The study of Natsume et al.[28] showed that both the LVMI and RVMI of SHRs were lowered by treatment with captopril for 4 weeks. Besides, Horinaka and Frohlich[29] found celiprolol, a cardioselective β1 adrenergic receptor antagonist, could significantly reduce both the left and right ventricular mass in SHRs and discussed the effect of celiprolol as being similar to that of angiotensin enzyme inhibitors in SHRs. We also found that the anti-hypertensive and anticardiac hypertrophy effects of IQP and VEP in this study matched their IC_{50} values in vitro, suggesting that the IC_{50} of ACE inhibitory activities may also affect the cardiac function. However, the mechanisms of these functions require further study to explore the cardioprotective effects of these peptides.

The trends of change in protein/peptide content of RAS components were in accordance with their corresponding mRNA expression in the myocardium. Groups with lower blood pressure showed a down-regulation of the expression of ACE, Ang II, and AT1 but an up-regulation of ACE2, Ang-(1−7), Mas, and AT2. The trends in the regulation of ACE, Ang II, AT1, and AT2 in the IQP, VEP, and captopril groups were similar to that for the short-term regulation of IQP and VEP.[8,9] The regulatory trends of peptides on the ACE2-Ang-(1−7)-Mas axis were consistent with the regulation of adriamycin-induced heart failure rats treated by telmisartan and losartan, two Ang receptor blockers (ARBs) that prevent cardiotoxicity.[30] RAS plays a critical role in the cardiovascular system by influencing blood pressure regulation, electrolyte balance, water−electrolyte metabolism, vascular tone, and heart and kidney signaling.[31] Recent studies suggest RAS is regulated by two axes: the ACE−Ang II−AT1 axis and the ACE2−Ang-(1−7)−Mas axis.[10] The components of these two axes exist in many tissues, including the kidneys and heart.[10,32] At the beginning of RAS, renin hydrolyzes Ang into Ang I.[33] In the ACE−Ang II−AT1 axis, Ang II is synthesized from Ang I by ACE, and then Ang II binds to two major subtypes of receptors, AT1 and AT2.[10,33,34] The binding of Ang II to AT1 receptors mediates regional blood flow and leads to vasoconstriction and oxidative stress, and the combination of AT2 with Ang II conversely leads to lower blood pressure and inhibition of malignant cell proliferation.[35−37] Therefore, hyperactivity of the ACE−Ang II−AT1 axis can lead to CVDs, such as hypertension, stroke, and coronary heart disease.[36] In the ACE2−Ang-(1−7)−Mas axis, Ang-(1−7) is produced from ACE2 by cleaving Ang II, which then binds with the G protein-coupled receptor Mas, inducing the release of nitric oxide from endothelial cells and exerting vasodilative, antiproliferative, and anti-hypertensive functions.[10,38] The ACE2−Ang-(1−7)−Mas axis has an opposite effect from the ACE−Ang II−AT1 axis and plays a key role in blood pressure regulation and blood

DOI: 10.1021/acs.jafc.5b02801
J. Agric. Food Chem. 2015, 63, 7765−7774

vessel protection.[10,36,39] Furthermore, as elevated Ang II levels lead to infarcted hearts and other heart dysfunctions, ACE2, Ang-(1−7), and Mas receptor were contrarily reported to be associated with cardioprotective functions, and the elevated expression of Ang-(1−7) in failing heart tissue and the expression of its forming enzyme ACE2 are present in parallel to reduce heart dysfunction. Ang-(1−7) protects cardiac remodeling by decreasing hypertrophy and fibrosis, and Mas receptor prevents impaired heart functions in SHRs caused by high blood pressure.[38,40−43]

We studied the two axes in the myocardium and observed the countereffects of the ACE−Ang II−AT1 and ACE2−Ang-(1−7)−Mas axes (including the countereffects of AT1 and AT2), which were influenced by different treatment, and were related to the regulation of blood pressure in SHRs. After 3 weeks of treatment, there were differences in blood pressure regulation, mRNA expression levels, and protein/peptide content of the studied components in RAS among all of the groups. As the treatment time increased for another 3 weeks, the differences among the groups became more significant, and the withdrawal of the treatment for 2 weeks reduced the significance of the differences, although the general trends in blood pressure difference, mRNA expression levels, and protein/peptide concentrations of the substrates studied were maintained. However, we observed slightly more significant differences in mRNA expression levels and in protein/peptide content of the components of the ACE−Ang II−AT1 axis (including AT2) compared with the components of the ACE2−Ang-(1−7)−Mas axis. This suggested that the ACE−Ang II−AT1 axis might have a major role in myocardial RAS regulation compared with the ACE2−Ang-(1−7)−Mas axis.

In conclusion, this study suggests that the long-term oral intake of 10 mg/kg IQP, VEP, or SH can attenuate hypertension and myocardial hypertrophy in SHRs and regulate the RAS components that subsequently up-regulate the components in ACE2−Ang-(1−7)−Mas axis and AT2, while down-regulating the components in the ACE−Ang II−AT1 axis. Because most studies on the anti-hypertensive mechanisms of food-derived peptides have focused on the ACE−Ang II−AT1 axis, such as ACE-inhibitors, ARB, and renin inhibitors, the exploration of food-derived sources with ACE2 activation activity and with the ACE2−Ang-(1−7)−Mas axis has been limited. Our results revealed that bioactive tripeptides and hydrolysates derived from *S. platensis* can inhibit the ACE−Ang II−AT1 axis while activating the ACE2−Ang-(1−7)−Mas axis, and may serve as cardioprotective substrates. In addition to IQP and VEP, other peptides or substrates in SH might also show cardioprotective effects, and thus further studies should be dedicated to exploring the unknown components in *S. platensis* hydrolysates and their detailed regulatory mechanisms in the cardiovascular system.

compounds. Ethanol, as the major gastric acid stimulating constituent in wine, can be neglected because (i) the ethanol contents in red and white wines are similar and (ii) previous studies by Singer et al.[4] and Teyssen et al.[5] demonstrated that only fermented beverages such as beer and wine stimulate gastric acid output, whereas distilled alcoholic beverages with higher ethanol concentrations show very little or no effect.[4,5] Moreover, ethanol itself induced gastric acid secretion only in concentrations lower than those present in wine.[21] On the basis of these results, Teyssen and colleagues[22] fractionated fermented glucose and identified the organic acids maleic acid and succinic acid as strong stimulants of gastric acid secretion when administered to healthy subjects. Because the major organic acids in wine are tartaric, citric, malic, succinic, and lactic acid, one of our previous studies aimed to identify whether these constituents contribute to the stimulating effect of wine on gastric acid secretion.[3] All tested organic acids stimulated proton secretion, with malic acid in wine representative concentrations showing the most pronounced effect. Hydroxyl and carboxyl groups were proposed to be the functionally active groups of the organic acids.[3,22] Because these structural characteristics are shared by phenolic compounds as well, we hypothesized that phenolic constituents, which are present at higher concentrations in red wine as compared to white wine, contribute to the more pronounced effect of red wine on gastric acid secretion.

To our knowledge, no studies have investigated the effect of the phenolic compounds of wine on gastric acid secretion. However, we found one study in which the effect of phenolic compounds on proton secretion was tested; Ono and colleagues[23] measured [^{14}C]aminopyrine accumulation as an index of acid production in isolated parietal cells of guinea pigs. The isolated cells were stimulated with histamine or dibutyryl-cAMP and compared to cells treated with histamine or dibutyryl-cAMP combined with pentagalloylglucose (PGG) extracted from paeoniae radix or with gallic acid. The amount of [^{14}C]aminopyrine accumulation in the cells reflects the acid secretory state of the cells. PGG inhibited the histamine- or dibutyryl-cAMP-provoked effect in isolated parietal cells, whereas gallic acid, a compound also present in wine, had no effect.

The aim of this study was to identify whether the different effects of red wine versus white wine on mechanisms of gastric acid secretion can be explained by the different concentrations of malic and lactic acid and/or phenolic compounds. The secretory activity of four red wines and six white wines was tested using the well-established HGT-1 cell model.[3,7,16,18] The results on cellular proton secretion were correlated with the quantitated content of organic acids and phenolic compounds. The most promising compounds were tested individually and in a recombinate of all, which was added to a white wine sample that showed the least pronounced effect on proton secretion.

MATERIALS AND METHODS

Chemicals. DL-Lactic acid, L-malic acid, (+)-catechin, syringic acid, procyanidin B2, histamine, MTT reagent, and chemicals for the cell culture experiments, trypsin, glutamine, penicillin/streptomycin, and Dulbecco's modified Eagle's medium (DMEM) were purchased from Sigma-Aldrich. 1,5-Carboxy-seminaphtorhodafluor acetoxymethyl ester (SNARF-1-AM), nigericin, and fetal bovine serum were obtained from Invitrogen (Vienna, Austria). All other chemicals were obtained from Roth (Karlsruhe, Germany).

Samples. Wine samples were provided by the Federal College and Research Institute for Viticulture and Pomology, Klosterneuburg, Austria. A total of four red wine samples of the varieties "Blauer Burgunder" 2010 (R1), "Rösler" 2009 (R2), and "Cabernet Sauvignon-Merlot" 2009 (R3) produced by the Federal College and Research Institute for Viticulture and Pomology, Klosterneuburg, Austria, and "Zweigelt Reserve" 2009 (R4) produced by Rosner, Lower Austria, and a total of six white wine samples of the varieties "Grüner Veltliner" 2010 (W1) produced by Rosner, Lower Austria, "Gelber Muskateller" 2010 (W2), "Grüner Veltliner" 2010 (W3), "Chardonnay ice wine" 2009 (W4), "Chardonnay" 2010 (W5), and "Riesling" 2010 (W6) produced by the Federal College and Research Institute for Viticulture and Pomology, Klosterneuburg, Austria, were tested. For cell culture experiments, samples were diluted 1:100 in DMEM.

Cell Culture. For cell culture experiments, the human gastric tumor cell line HGT-1, obtained from Dr. C. Laboisse (Laboratory of Pathological Anatomy, Nantes, Frances), was used. They were cultured in DMEM with 4 g/L glucose, supplemented with 10% fetal bovine serum, 2% L-glutamine, and 1% penicillin/streptomycin under standard conditions at 37 °C, 95% humidity, and 5% CO_2.

Cell Vitality. Cytotoxic effects of wine samples were excluded by staining the cells with the yellow tetrazole MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) reagent. A total of 100,000 cells per well were seeded in a 96-well plate and allowed to settle for 24 h. Afterward, the medium was discarded, and cells were treated with wine samples in a 1:100 dilution, individual compounds in wine-representative concentrations, and white wine (W6) in combination with a recombinate of catechin, procyanidin B2, and syringic acid added to DMEM for 30 min under standard conditions. Test samples were removed, and 100 μL of MTT-working solution, consisting of 1 part 5 mg/mL MTT solution and 5 parts DMEM, was added. In this assay, viable cells reduce the yellow tetrazole MTT to a purple formazan. After 15 min, the MTT solution was removed and the formazan was diluted in dimethyl sulfoxide. Absorbance was measured at 550 nm and at a reference wavelength of 690 nm using an Infinite 200 Pro Plate Reader (Tecan, Männderdorf, Switzerland). Cell viability was determined relative to medium-only treated control cells (untreated controls = 100%).

Intracellular pH Measurement in HGT-1 Cells. The intracellular pH was measured as a marker of proton secretion in HGT-1 cells by means of the pH-sensitive fluorescent dye SNARF-1-AM.[3,7,16,18] HGT-1 cells were seeded in a 96-well plate at a density of 100,000 viable cells per well under standard conditions at 37 °C, 95% humidity, and 5% CO_2 and allowed to settle for 24 h. Afterward, cells were washed once with Krebs−HEPES buffer (KRHB; 10 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), 11.7 mM D-glucose, 4.7 mM KCl, 130 mM NaCl, 1.3 mM $CaCl_2$, 1.2 mM $MgSO_4$, and 1.2 mM KH_2PO_4, brought to a pH of 7.4 with 5 M KOH), and loaded with 3 μM SNARF-1-AM in KRHB for 30 min at standard conditions. The cells were washed twice and treated with either the wine samples or the wine constituents in wine representative concentrations or white wine (W6) in combination with a recombinate of catechin, procyanidin B2, and syringic acid in DMEM, all diluted 1:100, for 10 min at standard growth conditions. As positive control, 1 mM histamine was used. Afterward, the test substances were removed and the cells washed twice with KRHB, and 100 μL of KRHB per well was added prior to the measurement of fluorescence using an Infinite 200 Pro Plate Reader (Tecan, Männderdorf, Switzerland). Fluorescence was detected at 580 and 640 nm emission after excitation at 488 nm. The ratio between the two measured emission wavelengths was used to calculate the pH using a standard calibration curve. The calibration curve was generated by treating the cells with potassium buffer solutions of various pH values, ranging from 7.2 to 8.2 in the presence of 2 μM nigericin, to equilibrate intracellular and extracellular pH in the cells. The potassium buffer calibration solutions consisted of 20 mM NaCl, 110 mM KCl, 1 mM $CaCl_2$, 1 mM $MgSO_4$, 18 mM D-glucose, and 20 mM HEPES. The analyzed intracellular pH of the calibration solutions was fit to a linear regression. Using the intracellular pH, the intracellular H^+ concentration was calculated. The ratio between treated and medium-only/nontreated cells was calculated and $\log_2$ transformed to determine the intracellular proton index (IPX).[3,7,16,18] The lower the IPX, the stronger the proton secretion by the cell.

Quantitation of Wine Constituents and Parameters. *Analysis of General Wine Parameters.* Reducing substances, titratable acidity, volatile acidity, pH value, and free and total sulfurous acid were analyzed by means of standard methods as described by Eder and Brandes.[24] For reducing substances, the traditional iodometrical titration with Fehling reagent was applied. Titratable acids were determined potentiometrically with 0.1 N NaOH up to an end point of pH 7.0. The pH measurement was performed in the undiluted sample using a pH-sensitive electrode. For the determination of volatile acids, the acid content of water steam distillate was measured by titration with 0.01 N NaOH and phenolphthalein as indicator (pH 8.1). The effect of disturbing sulfurous acid was subtracted by extra iodometric titration. Free and total sulfurous acid were determined acidimetrically following the procedure described by Paul.[25]

Organic Acids. Quantitation of the major organic acids (tartaric, malic, lactic, citric, oxalic acid) was achieved by ionic chromatography as described by Prasnikar et al.[26] Succinic acid was quantified using an enzymatic kit from Megazyme International (Wicklow, Ireland) according to the protocol of the manufacturer.

Sugars, Glycerol, and Acetic Acid. Fructose, glucose, glycerol, acetic acid were analyzed enzymatically[27] using the Konelab 20 automatic system as described by Stojanović et al.[28]

Aromatic Phenols. The concentrations of aromatic phenols (vanillin, syringaldehyde, coniferylaldehyde, sinapaldehyde, and scopoletin) were determined after solid phase enrichment on a LiChrolut EN 200 mg, 3 mL, column (Merck) as described by Matejicek et al.[29] The SPE column was conditioned by subsequent washing with 3 mL of dichlormethane, 3 mL of methanol, and 3 mL of ethanol (13% (v/v) in water). Then 5 mL of the sample with internal standard (4-methoxybenzaldehyde) was slowly applied onto the column. After the column was washed with 2−3 volumes of ethanol (13% (v/v) in water), the column was dried by drawing nitrogen for 30 min. Finally, the phenols were eluted by twice adding 1 mL of dichloromethane. The eluate was dried on a rotavapor (240 mbar, 40 °C) and redissolved in 1 mL of HPLC solvent (0.5% formic acid, 10% methanol). Before injection into HPLC system, the eluate was purified by membrane filtration (Multoclear, 13 PVDF, 0.45 μm). HPLC was performed on a Rapid Resolution system (RR 1200 Agilent) equipped with a binary pump (SL, Agilent) and a diode array detector (DAD, Agilent) as well as a fluorescence detector (1260 Infinity FLD, Agilent). Separation was achieved on a reversed-phase column Zorbax SB-C-18 (150 × 2.1 mm, 1.8 μm) with gradient elution of (a) 0.5% formic acid and (b) methanol within 87 min. Flow rate was set at 0.25 mL/min and column oven temperature at 40 °C. Detection wavelengths were 260, 280, 290, 313, and 350 nm. Scopoletin was also detected using the FLD (excitation, 345 nm; emission, 460 nm). A volume of 5 μL of the filtered SPE eluate was injected for analysis of the phenolic acids (vanillic acid, syringic acid, ellagic acid, and gallic acid).

Phenolic Substances. The other phenolic substances (caftaric acid, *cis*- and *trans*-coutaric acid, fertaric acid, *p*-coumaric acid, ferulic acid, caffeic acid, catechin, epicatechin, tyrosol, and procyanidins B1 and B2) were analyzed with a modified HPLC method published by Vrhovsek et al.[30] The HPLC system consisted of a Rapid Resolution 1200 system with binary pump, DAD detector (Agilent) and a Poroshell 120 SB-C18 column (150 × 2.1, 2.7 μm; Agilent). A gradient elution with solvent (a) formic acid (0.5%) and (b) methanol and a flow rate of 0.2 mL/min was performed. Injection volume was 5 μL, and detection was at 280 and 320 nm.

Anthocyanins. Total monomeric anthocyanins were separated and detected by HPLC-UV, and the content was calculated as malvidol-3-glucoside as a reference compound, as described by Eder et al.[31] For the determination of the total phenol content, a photometric method using the Folin−Ciocalteu reagent was used as described by Linskens and Jackson.[32]

Gene Expression. A total of 100,000 HGT-1 cells per well were seeded in six-well plates and grown until confluence. Then the cells were treated with 10 mg/L DL-lactic acid and 10 mg/L L-malic acid for 5, 10, 15, 20, 25, and 30 min and harvested for RNA isolation using the RNeasy Mini Kit and SV Total RNA Isolation System (Promega, Madison, WI, USA). RNA quantity and quality were checked spectrophotometrically at 260 and 280 nm by calculation of the ratio of those wavelengths using the nanoquant plate for the Infinite 200 Pro Plate Reader (Tecan, Männderdorf, Switzerland). All cell samples had a ratio between 1.8 and 2.2. cDNA synthesis was carried out with the high-capacity RNA to cDNA Master Mix (Applied Biosystems, Munich, Germany) according to the manufacturer's protocol. Peptidylprolyl isomerase A (PPIA) was used as internal control. Primers for the H^+,K^+-ATPase α-subunit (*ATP4A*), the histamine H2 receptor (*HRH2*), the somatostatin receptor (*SSTR2*), and the acetylcholine receptor M3 (*CHRM3*) and *PPIA* were designed and validated previously[3,7,14,17] and were carried out as previously described.[3]

Statistical Analysis. The concentration of organic acids and phenolic compounds in wine was correlated to the IPX of the 10 wine samples using the correlation analysis after Spearman with SPSS 19.0.0 (IBM Statistics). Data below the limit of detection were replaced by the LOD/$\sqrt{2}$. Statistical analysis was performed using Excel 2007 (Microsoft), SigmaPlot software 11.0 (Systat Software). Outliers were excluded by Nalimov outlier analysis. Cytotoxic effects of the samples on HGT-1 cells compared to nontreated cells were determined with the two-tailed Student's *t* test and considered to be significant at $p < 0.05$. Significant differences in the data set of the intracellular pH measurements were determined by a one-way ANOVA with Holm−Sidak post hoc analysis or the two-tailed Student's *t* test as indicated in the figure captions. The two-way ANOVA with Holm−Sidak post hoc analysis was applied for analyzing time-dependent effects on gene expression. At least three biological replicates and two technical replicates were analyzed for each cell culture experiment. Data under Results as well as in diagrams are given as the mean ± SEM, unless indicated otherwise.

RESULTS

Cell Vitality of HGT-1 Cells after Treatment with Wine Samples and Wine Additions. We previously showed that red wine in concentrations higher than a 1:100 dilution caused cytotoxic effects in HGT-1 cells.[3] To exclude cytotoxic effects of the wine samples used in this study, we conducted an MTT assay using the same dilution (Table 1). The MTT assay is an indicator for the metabolic status of the cell. Data are represented as percent relative to nontreated cells. Lower values for sample-treated cells indicate a reduction of the metabolic status, which is an early indicator of cytotoxic effects. Neither the wine samples nor any of the individual wine constituents tested nor the combination of the white wine Riesling (W6) with the recombinate showed cytotoxic effects on HGT-1 cells.

Effect of Wine Samples on Proton Secretion in HGT-1 Cells. For studying the influence of the four red wines and six white wines on proton secretion in HGT-1 cells, cells were treated with 1:100 dilutions of each wine sample, and effects were compared to nontreated cells (control). Each wine sample itself stimulated proton secretion ($p < 0.001$, one-way ANOVA with Holm−Sidak post hoc test vs control) (Table 2). The red wine varieties "Blauer Burgunder" and "Roesler" showed the highest secretory activity ($p < 0.001$), with IPX values of −0.39 ± 0.02 and −0.37 ± 0.02, respectively. The white wine variety "Riesling" showed the least pronounced stimulation of the tested wines with an IPX of −0.10 ± 0.02. The average of the IPX values of the red wine samples was lower ($p < 0.016$) than that of the red wine samples (Figure 1), clearly demonstrating the more pronounced stimulating effect on proton secretion for red wines.

Characterization of Wines. All wines were produced in Lower Austria from the 2009 and 2010 vintages. The characteristics of the four red wines and six white wines are reported in Tables 2 and 3. Alcoholic strength was in the range of 13.0−14.1% for red and 11.8−13.1% for white wines. Titratable acidity was higher in white wines, ranging from 5.9 to 10.5 g/L, compared to red wines, ranging from 4.9 to 5.8 g/L. Organic acid

wines to nearly similar amounts as in red wine samples. Coniferylaldehyde and sinapaldehyde were not detected, either in white or in red wine. The phenolic compound with the highest amounts in wine samples was catechin, with concentrations ranging from 29.5 to 85.5 mg/L in red wines and from 1.8 to 4.8 mg/L in white wines.

Correlation between IPX and Wine Parameters. To determine which of the wine constituents quantified correlate with the stimulatory effect of wine samples on proton secretion in HGT-1 cells, the IPX data of the 10 wine samples were correlated with the amount of organic acids and phenolic compounds. Table 4 shows the results of the correlation analysis. Negative correlations indicating a pro-secretory effect were determined for lactic acid, procyanidins B1 and B2, ellagic acid, syringic acid, syringaldehyde, vanillic acid, and vanillin. According to the hypothesis that a higher amount of hydroxyl and carboxyl groups induces gastric acid secretion, we further investigated procyanidin B2 (10 hydroxyl groups) and syringic acid (1 hydroxyl and 1 carboxyl group). Because catechin (5 hydroxyl groups) showed the highest amount in the red wine samples of the measured phenolic compounds and is the parent structure of procyanidin B2 and several other phenolic compounds in wine, it has been included for further analysis. In addition, lactic and malic acid were investigated because both are present only either in white or in red wine.

Effect of DL-Lactic Acid and L-Malic Acid on Intracellular Proton Concentration. L-Malic and DL-lactic acid were tested in a concentration range quantified in the 10 wine samples, namely, 20−40 and 30−60 mg/L, respectively (Figure 2). Both organic acids stimulated proton secretion ($p < 0.001$) in HGT-1 cells in a concentration-dependent manner compared to nontreated cells (lactic acid, −0.30 ± 0.01 to −0.52 ± 0.02; malic acid, IPX ranging from −0.26 ± 0.03 to −0.44 ± 0.03).

Gene Expression of HGT-1 Cells after Treatment with Lactic Acid and Malic Acid. To gain a mechanistic insight into whether DL-lactic acid or L-malic acid affects the regulation of secretory-relevant genes, HGT-1 cells were treated with 10 mg/mL DL-lactic or L-malic acid over a time period of 30 min, and gene expression of *ATP4A*, *HRH2*, *SSTR2*, and *CHRM3* was determined by qPCR.

Gene expression of the target genes is presented as ratios normalized to the endogenous control *PPIA* (control = 1) (Figure 3). Treatment of HGT-1 cells with lactic acid or malic acid down-regulated expression of *ATP4A* and *HRH2* at 10 min (*ATP4A*, 0.57 ± 0.06 and 0.55 ± 0.06; *HRH2*, 0.66 ± 0.09 and 0.54 ± 0.08, respectively). None of the tested organic acids affected the expression levels of *CHRM3*. The main difference in effects between DL-lactic acid and L-malic acid were detected on expression levels of *SSTR2*. L-Malic acid reduced expression of *SSTR2* at 10 min (0.64 ± 0.08, $p < 0.01$). In contrast, DL-lactic acid increased mRNA expression of *SSTR2* at 25 min (1.29 ± 0.08, $p < 0.05$), an effect that was significantly different from that of L-malic acid at 25 min (0.95 ± 0.08, $p < 0.01$).

Effect of Catechin, Procyanidin B2, and Syringic Acid on Intracellular Proton Concentration. Catechin, syringic acid, and procyanidin B2 were tested in a wine representative concentration range. Catechin in the range of 0.1−1 mg/L stimulated proton secretion (IPX, −0.27 ± 0.03) as well as procyanidin B2 in the concentration range of 0.01−0.25 mg/L and syringic acid in the concentration range of 0.1−2.5 mg/L to

the highest extent, with IPX values of −0.17 ± 0.03 and −0.25 ± 0.05, respectively (Figure 4).

Enhancing the Stimulating Effect of White Wine on Proton Secretion via Addition of a Phenolic Recombinate. To verify that catechin, syringic acid, and procyanidin B2 can stimulate proton secretion in a complex wine matrix, a recombination of these substances in two concentrations was added to the white wine of the variety Riesling (W6). This wine showed the lowest pro-secretory activity (Table 2). Treatment of the cells with the W6 sample in combination with three phenolic compounds in concentrations representative for red wine led to IPX values of −0.14 ± 0.02 ($p < 0.05$), whereas treatment with a 2-fold addition of the recombinate (IPX, −0.16 ± 0.02) increased the proton secretion by 65 ± 21% ($p < 0.05$) compared to the cells treated with the white wine solely (IPX, −0.10 ± 0.02) (Figure 5).

DISCUSSION

In two previous studies, red wine was demonstrated to stimulate gastric acid secretion to a greater extent than white wine. However, because one of these studies was carried out in dogs with vagally denervated Haidenhain pouches[20] and in the other study only one red wine was tested versus one white wine in six

wine contribute to this effect. Forty wine parameters were analyzed in four red wine samples and in six white wine samples. The major quantitative differences were analyzed for two classes of compounds: the organic acids malic acid and lactic acid, which were quantified in only white and red wine samples, respectively, and phenolic compounds. Correlation analysis between the quantitative data of the given constituents and the proton secretory activity of the 10 wine samples in parietal HGT-1 cells, a well-established cell culture model representing mechanisms of gastric acid secretion in humans,[3,7,16,18] revealed significant associations for the two organic acids as well as the phenolic compounds procyanidins B1 and B2, ellagic acid, syringic acid, syringaldehyde, vanillic acid, vanillin, and scopoletin. Because the red wine samples were, again, demonstrated to stimulate more pronounced proton secretion compared to the white wines, the contribution of malic acid, lactic acid, and selected phenolic compounds was studied.

In one of our previous studies, malic acid and lactic acid were identified to increase proton secretion in HGT-1 cells, independent of the ethanol content of the wine sample.[3] However, this finding was left on a descriptive level because no mechanistic data were provided. In this study, we were able to demonstrate that both organic acids regulate the mRNA expression of gene involved in proton secretion to a similar extent when tested in wine-representative concentrations, which is in line with their effect on proton secretion. However, the proton secretory activity of malic and lactic acid cannot chiefly account for the different effect of red versus white wine, because malic acid was only quantified in white wine, whereas lactic acid, in a similar concentration range, was quantified in red wine solely. This can be explained by the fact that the majority of red wines undergo malolactic fermentation, whereas this technology is less commonly used for the production of white wines.[33] In malolactic fermentation, a secondary fermentation after completion of the alcoholic fermentation, L-malic acid is transformed to the less sour L-lactic acid.[34] This reaction is used to reduce the acidic taste, to modify the organoleptic character, and to improve the microbial stability of wine.[33] Although the malolactic fermentation makes the red wine taste smoother, our findings suggest that this technology does not reduce its secretory potential.

Phenolic compounds were also hypothesized to contribute to the gastric acid secretory potential of red wine. This hypothesis was not only based on the quantitative differences of phenolic compounds in red versus white wine and their correlation with the effect on proton secretion. Previous results from Teyssen et al.[22] and our own group[3] suggest that the length of the carbon chain and the presence of carboxylic and hydroxyl groups are structural determinants for compounds to stimulate gastric acid secretion. Therefore, procyanidin B2 (10 hydroxyl groups, complex carbon molecule structure, bitter and astringent taste) and syringic acid (1 hydroxyl and 1 carboxyl group, astringent taste) as well as catechin as parent structure (10 hydroxyl groups, bitter taste, and astringent compound) were selected. For all three phenolic compounds, a contribution to bitter and/or astringent taste of wine has been reported.[35] To our knowledge, this is the first study that tested and demonstrated a stimulating effect of phenolic compounds on gastric acid secretion in wine-representative concentrations. Furthermore, when these compounds were added to the least active white wine (Riesling W6)

DOI: 10.1021/acs.jafc.5b02879
J. Agric. Food Chem. 2015, 63, 7775−7783

in concentrations 2-fold higher than those quantified in red wine, a significant increase in proton secretion was determined. This result clearly demonstrates that catechin and syringic acid as well as procyanidin B2 elicit a pro-secretory activity even when added to a complex solution such as white wine. Moreover, we suggest that the higher amount of phenolic compounds in red wine contributes to its higher stimulatory effect on gastric acid secretion compared to white wine. The majority of phenolic compounds in red wine are condensation products of flavan-3-ol units, which join to form oligomer structures (procyanidins) and polymers (condensed tannins). The monomers, epicatechin and catechin, are the most abundant units of procyanidins and condensed tannins.[36] Condensed tannins or higher oligomers of procyanidins are difficult to isolate or synthesize and, for most of them, not commercially available. However, in this study we showed that catechin, the monomer of procyanidins, and procyanidin B2, a dimer of epicatechin, stimulated proton secretion, indicating that the degree of polymerization might play a role in the proton secretory potential of procyanidins.

In conclusion, we have demonstrated that red wines stimulated mechanisms of gastric acid secretion more effectively than white wines. Furthermore, we showed for the first time that the organic acids DL-lactic acid and L-malic acid regulate gene expression relevant for gastric acid secretion. In addition, the phenolic constituents catechin, procyanidin B2, and syringic acid were demonstrated to stimulate proton secretion in gastric parietal cells and are suggested to contribute to the more pronounced effect of red wine on gastric acid secretion compared to white wine.

flavonoids on the basis of their structure[22] and concluded that the hydroxyl groups on the C-5 and C-7 of flavnoids were favorable for XO inhibition.[21,22] However, few investigations have examined the interactions of flavonoid−XO and the inhibitory activities of flavonoids against XO.

In this study, the inhibitory activities against XO of 20 flavonoids with C5−OH and C7−OH, which mimic the structural frame of xanthine (Figure 1), were determined

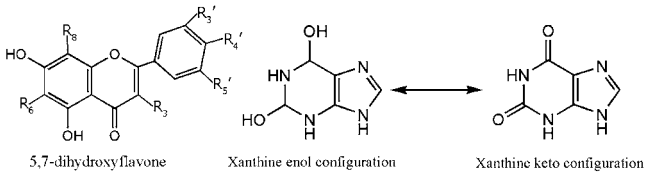

Figure 1. Comparison of structure similarities of xanthine enol form with 5,7-dihydroxylflavone. Structural similarity between xanthine enol form and 5,7-dihydroxylflavone suggests a similar binding location in XO allosteric center.

through UV spectrometry, and their binding affinities for XO were obtained by fluorescence titration method. With the application of molecular simulation, both the structure−activity relationship for inhibitory effects of flavonoids on XO and the relationship between the binding affinities and inhibitory activities were discussed. This study affords the opportunity to further explore the potential of these flavonoid-rich products for a successful application as gout-treating functional nutrients, especially by increasing their anti-XO effects and maintaining low side effects. It also provides new insights into clinical research of flavonoids as effective XO inhibitors.

MATERIALS AND METHODS

Materials. XO (35.7 units mL^{-1}, from bovine milk) and xanthine were both purchased from Sigma-Aldrich Co. (St. Louis, MO, USA) and then prepared as stock solutions with 50 M Tris-HCl buffer (pH 7.4). The stock solutions of XO and xanthine were freshly prepared just before the experiments. Luteolin, rutin, quercetin, morin, myricetin, myricetrin, and epicatechin were from Aladdin Reagent Int. (Shanghai, China). Chrysin, apigenin, galangin, kaempferol, diosmetin, hyperin, and curcumin were purchased from National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China), and phloretin was from Shanghai Yuanye Bio-Technology Co., Ltd. They were all dissolved in absolute ethyl alcohol to prepare stock solutions (5.0×10^{-3} mol L^{-1}), and the final alcoholic concentrations in the experiments were <1%, thus avoiding effects on the structure and activity of XO. All other reagents were of analytical reagent grade, and fresh ultrapure water (18.2 MΩ cm) used throughout the study was produced by a Millipore Simplicity Water Purification System (Millipore, Molsheim, France).

Cell-free Enzyme Activity. A Shimadzu UV-2450 spectrophotometer (Shimadzu, Japan) with a 1.0 cm quartz cell was used in the enzyme activity assay. The inhibition of XO was measured by using the method described previously.[10] Briefly, an array of 2 mL mixtures of XO solution (75 nM), Tris-HCl buffer, and various concentrations of tested flavonoid solutions was incubated for 3 h at 37 °C. The reaction was started by adding substrate xanthine (the final concentration was 50 μM), and the absorbance of the mixture was measured spectrophotometrically by continuously recording uric acid formation at 290 nm every 5 s. The enzymatic activity assay without inhibitor was defined as 100%. Thus, the relative enzymatic activity (%) = (S_{sample})/

DOI: 10.1021/acs.jafc.5b03386
J. Agric. Food Chem. 2015, 63, 7784−7794

(S_{blank}) × 100%, where S_{sample} is the slope of the reaction kinetics equation obtained from the reaction with inhibitor and S_{blank} is the slope of the reaction kinetics equation obtained from the reaction without inhibitor. Allopurinol was used as the positive control. All assays were run in triplicate at minimum. The concentration of inhibitor required for 50% inhibition of XO activity (IC_{50}) was assessed by plotting the relative enzymatic activity against the corresponding inhibitor concentration.

Kinetic Analysis for Inhibitory Type. The same method as XO activity assay was used to determine the inhibitory type of flavonoids against XO.[23] The inhibition type of the tested flavonoids was analyzed by using the nonlinear regression Michaelis−Menten enzyme kinetics and the corresponding Lineweaver−Burk plots. Each concentration of the inhibitor (three different concentrations in each case) was mixed with four different concentrations of substrate. Each experiment was performed in triplicate.

Fluorescence Quenching Study of XO. The fluorescence spectra were recorded on a Hitachi spectrofluorometer (model F-7000, Hitachi, Japan) equipped with a 150 W xenon lamp and a thermostat bath. The excitation wavelength was 280 nm, and the excitation and emission bandwidths were both set at 2.5 nm. The fluorescence spectra of XO in the absence and presence of flavonoids were measured as reported earlier.[23]

Fluorescence Data Processing. To determine the quenching mechanism of flavonoid binding to XO, the fluorescence quenching data were described by the Stern−Volmer equation[24]

$$\frac{F_0}{F} = 1 + K_{SV}[Q] = 1 + K_q\tau_0[Q] \quad (1)$$

where F_0 and F represent the fluorescence intensities in the absence and presence, respectively, of flavonoids, [Q] is the concentration of flavonoids, K_q is the quenching rate constant, τ_0 is the average lifetime of the fluorophore in the absence of the quencher (its value for XO was 2.80×10^{-9} s),[10] and K_{SV} is the Stern−Volmer quenching constant. The binding constants (K_a) and the number of binding sites (n) were calculated according to the following formula:[25]

$$\log\frac{F_0 - F}{F} = n\log K_a - n\log\frac{1}{[Q_t] - n\frac{(F_0 - F)[P_t]}{F_0}} \quad (2)$$

All of the fluorescence data in this study were corrected for absorption of excitation light and reabsorption of emitted light according to the literature.[10]

Molecular Modeling. The molecular docking studies were carried out by the MGL tools 1.5.6 with AutoGrid4.0 and AutoDock4.0. It docked flexible ligand into the rigid protein conformationally and exhibited the detail of binding. The bovine milk XO (PDB code 3ETR) complexed with lumazine (substrate) was downloaded from the Protein Data Bank (http://www.rcsb.org/pdb). The 3D structures of ligands (flavonoids and allopurinol) were depicted in Chem3D Ultra 8.0. Before Gasteiger charges were assigned to the macromolecule file, all of the water molecules were removed and the hydrogen atoms were added. A dimension grid box (110 Å × 100 Å × 110 Å) was set up to enclose the active site with grid spacing of 0.37 Å. Docking calculations were performed with the default parameters except that the number of GA runs was set at 100 times. From the outcomes, the best-scoring docked model (the lowest docking energy) of the ligand was proposed as the feasible binding mode of the inhibitor in the active site of XO predicted by this program. The outputs were further rendered with Pymol to obtain visible combination models.

Statistical Analysis. All data for enzyme kinetic assays and plotting were obtained using Origin 8.0. Data were analyzed by one-way ANOVA for statistical significance using the SAS statistical package (SAS Institute, Cary, NC, USA). A p value of ≤0.05 was considered statistically significant.

RESULTS AND DISCUSSION

XO Inhibition. The inhibition of 20 flavonoids on XO was explored in vitro, and the results in the form of α (= $IC_{50(flavonoid)}/IC_{50(allopurinol)}$) are shown in Table 1. The inhibitory activities of flavonoids depended on their structures. The IC_{50} value of allopurinol was 2.93 μM. As a conclusion, it was possible to establish three distinct categories among all of the flavonoids studied. The first group was composed of the most active flavonoids with low α values (≤10). These compounds showed an inhibitory potency against XO in the micromolar range. The most active ones were chrysin and genistein (α values of 0.49 and 0.59, respectively) with α values below 1, indicating that less of these compounds was needed to inhibit XO compared with allopurinol. Additionally, quercetin (α = 9.76) and kaempferol (α = 5.76) were less active than apigenin (α = 1.20), which was consistent with previous results.[7,19,26] The second group referred to the flavonoids that expressed intermediate activity ($10 < \alpha \leq 50$). Most of them were flavonols, such as morin, myricetin, diosmetin, isorhamnetin, and hyperin. In the last group ($\alpha > 50$), compared with rutin (α = 57.29) and baicalin (α = 50.13), naringenin and silybin exhibited much weaker inhibition (α = 140.4 and 189.6, respectively). It could be found that these compounds all possessed a bulky substituent group. Phloretin, curcumin, and epicatechin did not even show XO inhibition activity.

Several studies have suggested the inhibitory ability of flavonoids on XO activity.[21,26,27] To further characterize the binding region in XO, the kinetic assay of some potent inhibitors ($\alpha \leq 50$) was conducted and Lineweaver−Burk double-reciprocal plots were applied. The results from the experiments and previous studies are summarized in Table 1. Allopurinol is a known competitive inhibitor. As shown in Figure 2a, inhibition of XO by chrysin was competitive, which was characterized by similar V_{max} and distinctly different K_m values, which was also seen for other flavones (apigenin and luteolin), suggesting binding of flavones to the XO active center, thereby replacing xanthine. Apigenin, kaempferol, and luteolin exhibited competitive inhibition (plot not shown), which conformed to the previous results that they could bind to XO at a single binding site and the binding was driven mainly by hydrophobic interactions.[10,23,28] Genistein and quercetin also exhibited competitive inhibition as reported previously.[19] Myricetin[19] showed mixed type inhibition (Figure 2b) as well as morin,[22] which can be concluded from different V_{max} and K_m values. These results indicated that some flavonoids are competitive or mixed competitive inhibitors of XO.

Quenching Effect of Flavonoids on XO Fluorescence. The fluorescence spectra of XO quenched by flavonoids were investigated. All flavonoids tested could quench the fluorescence of XO sharply with increasing concentrations. As representative cases, the fluorescence spectra of XO in the presence of chrysin (Figure 3a), phloretin (Figure 3b), myricetin (Figure 3c), and genistein (Figure 3d) are displayed. There were no obvious shifts in the peak at 340 nm of XO fluorescence for chrysin and genistein, whereas the maximum peak (λ_{em} = 340 nm) of XO fluorescence was obviously blue-shifted in the presence of phloretin and myricetin, suggesting that they were placed in a more hydrophobic environment;[29] that is, the molecular conformation of XO was affected. Individually, phloretin exhibited a slight affinity for XO, but it was a very weak inhibitor toward XO, and this feature could also be seen in the curumin−XO and epicatechin−XO systems.

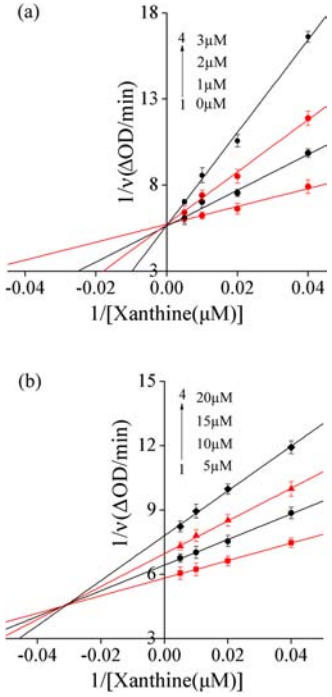

Figure 2. (a) Lineweaver–Burk plot for chrysin. The inhibition of XO by chrysin is competitive, as can be seen from similar V_{max} and distinctly different K_m values. (b) Lineweaver–Burk plot for myricetin. Inhibition of XO by myricetin shows mixed type inhibition, as can be concluded from different V_{max} and K_m values.

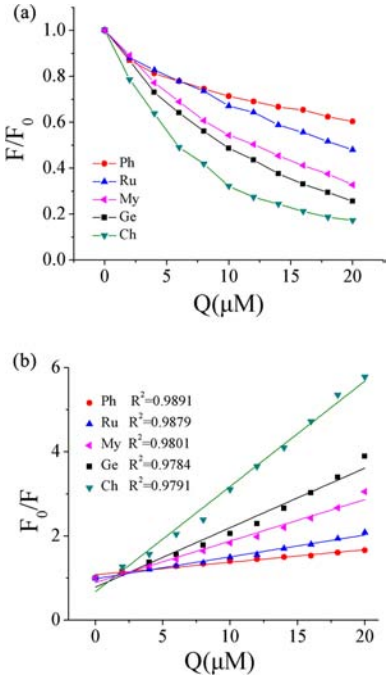

Figure 4. (a) Quenching ratio (F/F_0) of XO fluorescence spectra with addition of chrysin (Ch), myricetin (My), genistein (Ge), phloretin (Ph), and rutin (Ru). (b) Stern–Volmer plots for XO fluorescence quenching by these flavonoids at 298 K.

Moreover, different quenching ratios (F/F_0) of XO fluorescence with increasing flavonoid concentration were observed (Figure 4a). The fluorescence intensities of XO decreased sharply with increasing concentrations of chrysin, genistein, and myricetin, respectively, whereas the intensities of XO showed much slower decreasing rates with the addition of phloretin and rutin. Chrysin at 10.0 μM quenched the XO fluorescence by 69.4%; genistein, myricetin, and rutin quenched XO fluorescence by 51.9, 48.4, and 31.2%, respectively, but the corresponding concentration of phloretin quenched the XO

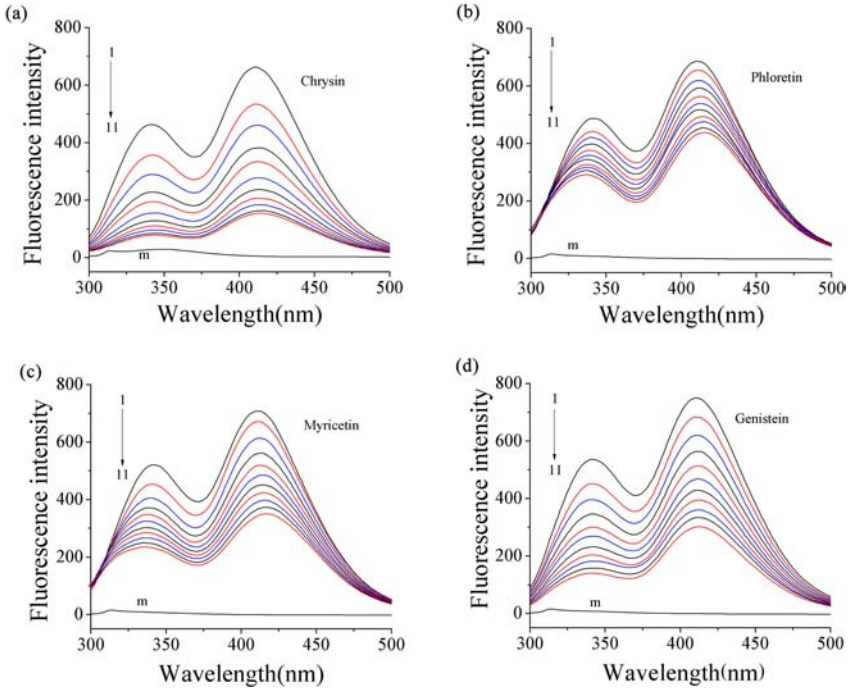

Figure 3. Quenching effects of chrysin (a), phloretin (b), myricetin (c), and genistein (d) on XO fluorescence spectra at 298 K. λ_{ex} = 280 nm. c(XO) = 0.5 μM. c(flavonoids) = 0, 2.0, 4.0, 6.0, 8.0, 10.0, 12.0, 14.0, 16.0, 18.0, and 20.0 μM for curves 1–11, respectively; curve m in every panel represents the individual spectrum of the corresponding flavonoid.

J. Agric. Food Chem. 2015, 63, 7784–7794

fluorescence by only 29.1%. These phenomena implied that the quenching of XO fluorescence might rely on the structures of flavonoids.

Figure 4b shows the Stern−Volmer plots for XO fluorescence quenching by chrysin, genistein, myricetin, rutin, and phloretin. The linear plots indicated that the K_{SV} and K_q values of XO fluorescence quenching by flavonoids could be assessed from eq 1. The calculated K_q values ($0.98-2.50 \times 10^{13}$ L mol^{-1} s^{-1}) were much higher than the maximum scatter collision quenching constant of various quenchers with a biopolymer (2.0×10^{10} L mol^{-1} s^{-1}), indicating that the fluorescence quenching of XO by flavonoid was probably initiated by static quenching resulting from the formation of the flavonoid−XO complex.[25,30] These results are in accordance with previous studies,[10,23] suggesting that the static fluorescence quenching of XO by morin, kaempferol, luteolin, and quercetin originated from the formation of the complexes.

Nature of Flavonoid−XO Noncovalent Interaction. Generally, the noncovalent interactions between flavonoids and proteins are caused by four major forms, namely, hydrogen bonding, van der Waals interaction, hydrophobic interaction, and electrostatic interaction.[29,30] The nature of the flavonoid−XO interaction was studied by investigating the molecular property−affinity relationship. Herein, the hydrogen bond acceptor/donor numbers and the lipophilicity of flavonoids were investigated. The relationships between the hydrogen bond acceptor/donor numbers (obtained from PubChem Public Chemical Database) of flavonoids and the affinities for XO (lg K_a) are shown in Figure 5a. The affinities for XO obviously decreased with increasing hydrogen bond acceptor numbers of flavonoids, which implied that the hydrogen-bonding force was not the main force in the binding of flavonoids to XO.[31]

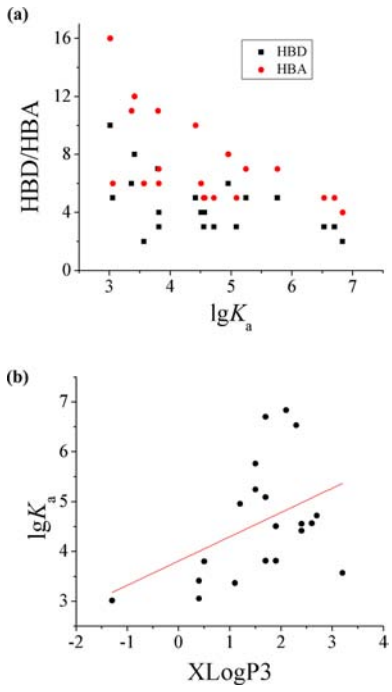

Figure 5. (a) Relationships of the hydrogen bond acceptor/donor number of flavonoids with the affinities (lg K_a) for XO. The hydrogen bond acceptor/donor numbers were taken from the PubChem Public Chemical Database. (b) Relationship of apparent binding constants (lg K_a) with partition coefficient (XLogP3) of flavonoids. The partition coefficient (XLogP3) was taken from the PubChem Public Chemical Database.

For an in-depth investigation of whether or not the lipophilicity played a main role in the binding of flavonoids to XO, the lipophilicity of the compounds under study was assessed by their partition coefficient values (XlgP3) according to the PubChem Public Chemical Database. As shown in Figure 5b, there was a relationship between XlgP3 values and lg K_a values for flavonoids. Generally, the binding affinities increased with an increase in the XLogP3 values. These results indicated that the hydrophobic force instead of lipophilicity may be the main acting force for driving the binding of flavonoids to XO, which was supported by the previous studies in some flavonoids.[32−34] In terms of these results, the noncovalent interaction between flavonoids and XO seemed to be different from the previously reported interaction of flavonoid−β-globulin[35] but similar to the interactions of flavonoid binding to serum albumin, hemoglobin,[29] common plasma proteins,[33] and milk proteins.[36]

Relationship between Affinities and XO Inhibitory Activities. XO is a dimer; each monomer contains an active site, which is believed to be surrounded by many amino acid residues.[37] Glu802, Glu1261, and Arg880 residues in the molybdenum center of the gorge play key roles in catalyzing xanthine oxidation,[38] whereas some residues at the entrance of the cavity, such as Leu648, Phe649, Phe914, Phe1009, Val1011, Phe1013, and Leu1014, modulate the entry of small molecules including substrates or inhibitors into the center.[10,23,37] For the inhibition on the catalytic activity of XO, flavonoids might directly enter the gorge to cover the active site or might just bind to the vicinity and hinder the entrance for xanthine. Thus, the relationship between the affinities for XO and their XO inhibition was discussed. Figure 6a shows that there was no obvious relationship between the affinities and inhibition for flavonoids,[39] but the inhibitory activities increased generally with the increasing affinities within the class of flavones and flavonols. These results might be due to the fact that the higher binding affinity increases the opportunity to enter and affect the catalytic site, whereas the inhibition finally rested with the direct interaction between the flavonoids and the active site. Interestingly, it was recently found that several clinically significant drug−enzyme complexes were similarly high-affinity active site-directed inhibitors that compete with substrates.[40]

Relationship between Topological Polar Surface Area (TPSA) and XO Inhibitory Activities. The TPSA is defined as the surface sum over all polar atoms. TPSA has been shown to be a descriptor characterizing passive molecular transport through membranes, which has been successfully used to predict the human intestinal absorption, bioavailability, Caco-2 monolayer permeability, and blood−brain barrier penetration.[41] It has been reported that molecules with a TPSA value of >140 Å^2 showed low human intestinal absorption and tended to be poor in permeating cell membranes.[42,43] The TPSA values were obtained from the PubChem Public Chemical Database. Figure 6b shows the relationship between TPSA and XO inhibitory activities of flavonoids. The relationship was not evident, but it might be roughly divided into four types considering their inhibitory activities. Type I was the most favorable group with high inhibitory activities (low α value) and penetration abilities (low TPSA), and type II was the less preferred group with good penetration abilities but low inhibitory activities (high α value). Although the flavonoids in type III group had great inhibitory activities on XO in vitro, little absorption may make them

ineffective in treating gout. Type IV was supposed to be the most unfavorable inhibitor. Moreover, the binding affinity of flavonoids with XO was investigated (Figure 6c). TPSA values were found to generally decrease with increasing lg K_a flavonoids for XO, which was similar to the relationship as reported earlier between flavonoids and HSA.[35,43]

Structure–Activity of Flavonoids on XO Inhibition and Affinity for XO. *Hydroxylation.* Previous investigations have indicated that the patterns of the hydroxyl and methoxyl groups on the rings of flavonoids are involved in the bioactivities and binding affinities for proteins.[44−47] The effects of hydroxylation of flavonoids on their affinities for XO and XO inhibition are shown in Table 2. Baicalein with an extra C6−OH exhibited 9.84 times lower XO inhibition than chrysin, but their affinities did not change too much, indicating that the hydroxylation on the C6 (ring A) of flavones weakened the inhibitory activity obviously and the binding affinities slightly. Moreover, luteolin and quercetin with additional hydroxyl groups on position C3′ (ring B) showed 1.50 and 0.70 times lower inhibition than apigenin and kaempferol, respectively, whereas their affinity decreased by 0.25 and 0.28 times, respectively. Both the hydroxylation on C4′ (ring B) of chrysin (→apigenin) and galangin (→kaempferol) weakened their XO inhibition abilities by nearly 1.4 times. The hydroxylation on C5′ (ring B) of quercetin (→myricetin) decreased its inhibition and affinity by, respectively, 2.66 and 0.14 times.[48] These results indicated that the hydroxyl groups in the B ring may be particularly important for flavonoids in inhibiting XO and binding to XO. Consequently, the α values of galangin, kaempferol, quercetin, and myricetin increased gradually, indicating that the extra hydroxyl substituents in the B ring may be unfavorable for the inhibitory activity of flavonols. These results could be also concluded within flavones (Table 1). This may be explained by the fact that ring B was reported to stabilize in the hydrophobic region of XO;[26,28] therefore, the enhancive hydroxy groups were unfavorable for the stability of flavonols. Moreover, galangin (kaempferol) exhibited lower affinity and inhibition than chrysin (apigenin), implying that the presence of a hydroxyl group at position C3 of the flavone significantly reduced the ability to bind to XO as well as its inhibition on XO. This effect was also obtained in the inhibition of flavonoids toward lipoxygenase[39] and human aromatase (estrogen synthetase).[49]

Methylation. As shown in Table 2, the affinity of isorhamnetin for XO was weaker than that of its unmethoxylated form (kaempferol) by 0.37 times, indicating that an additional methoxy group at C5′ (ring B) decreased their binding affinities for XO. C4′-methylation of luteolin (→diosmetin) hardly affected the affinity for XO, with similar values of lg K_a, but in both conditions, their inhibition on XO obviously decreased. However, a previous study found that the methylation of hydroxyl groups in flavonoids enhanced their binding affinities for HSA by 2−16 times.[33] Here, the methylation of flavonoids exhibited great effect on the

inhibition toward XO, whereas the effect on the affinity for XO was uncertain.

Glycosylation. The dietary flavonoids in nature occur mostly as β-glycosides. The flavonols are found mainly as 3- and 7-*O*-glycoside, although the 4′-position may also be glycosylated in some plants.[29,32] As shown in Figure 7, compared with

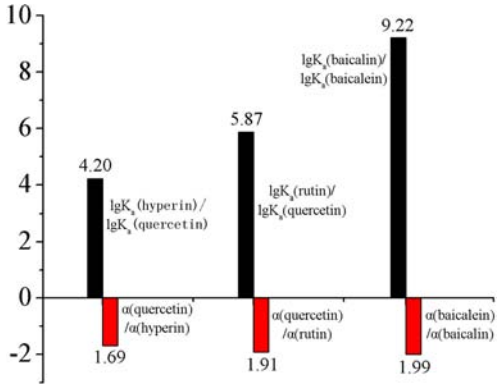

Figure 7. Effect of glycosylation of flavonoids on their affinities for XO and XO inhibitory activities.

quercetin, its galactoside (hyperin) showed a lower binding affinity and inhibition by 1.69 and 4.20 times, respectively. The inhibitions on XO of rutin and baicalin were about 5.87 and 9.22 times lower than that of quercetin and baicalein, respectively. Then by comparing their corresponding lg K_a, it was found that glycosylation of flavonoids lowered the affinity for XO depending on the conjugation site and the class of sugar moiety. The decreasing affinity for XO after glycosylation may be caused by the nonplanar structure; steric hindrance and hydrophilicity were other possible causes for the decreased affinity.[28,39] The behavior of depressed inhibition against XO could be explained by the fact that the increase in the size of the flavonoid compound may also increase the possibility of repulsive interactions in the active site, thus inhibiting the formation of the flavonoid−XO complex. Moreover, the presence of several hydroxyls in the galactoside group may act as an unstable element inside the highly nonpolar region, which finally resulted in a lower inhibitory activity and affinity, which was consistent with previous results. In addition, the previous studies reported that the glycosylation of dietary flavonoids decreased the affinities for plasma protein in vitro.[50] The present result that glycosylation decreased the inhibitory activities against XO was similar to the conclusion in a recent review that glycosylation of flavonoids decreased the inhibitory activities on both α-amylases and α-glucosidases.[51]

Hydrogenation of the C2═C3 Double Bond. The flavonoids with chromone (flavones, flavonols, and isoflavones) exhibited stronger inhibition with smaller values of α than those without (flavanone, others). The hydrogenation of the C2═C3 double bond decreased the inhibiting ability as well as the binding affinity of flavonoids. For example, naringenin showed a much higher α value and slightly lower lg K_a value than apigenin (Table 1), indicating that the hydrogenation of the C2═C3 of flavonoids decreased the inhibitory activities on XO more fiercely than the affinities for it. Phloretin and curumin without dual rings even showed no inhibition on XO, but still exhibited affinity. This may be because the C2═C3 double bond in conjugation with a 4-oxo group played an important role in the flavonoids in maintaining a plane molecular structure,[19] which was beneficial for inhibiting XO.[21,26] The fact that the benzopyran ring resembles the moieties of allopurinol (Figure 1) also might be a reason.[22] Generally, some of the structural elements that influence the inhibition of flavonoids against XO could be concluded. When the affinities and inhibitory activities were considered simultaneously, it was notable that the affinities of flavonoids changed consistently with the inhibitory activities, but not proportionally.

The typical structure properties of flavonoids affecting the inhibitory effect against XO are illustrated in Figure 8. The

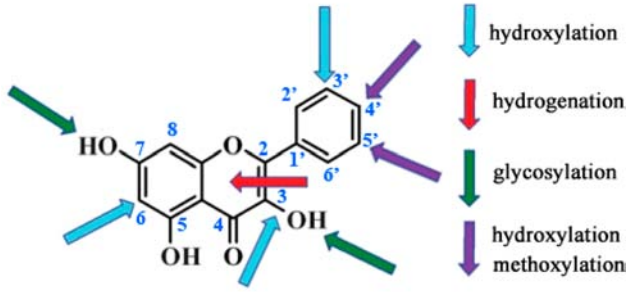

Figure 8. Structural elements that influence the inhibitions of 5,7-dihydroxyflavone to XO. The up arrows represent an increase in the inhibition; the down arrows represent a decrease in inhibition.

hydrogenation of the C2═C3 double bond on flavonoids decreased the inhibition on XO; hydroxylation of 3C (ring C) and the glycosylation of 3C—OH were unfavorable for the inhibition. The hydroxylation and methoxylation on ring B also decreased the inhibitory activity; moreover, the hydroxylation of 6C (ring A) and glycosylation of 7C—OH significantly decreased the inhibitory ability.

Computational Docking Analysis. From kinetic assay results, the active site of XO is specific for effective flavonoids, and the main focus will be the dockings of flavonoid into the Mo-pterin domain of XO. Herein, typical flavonoids (chrysin, apigenin, galangin, quercetin, rutin, genistein) were compared in their binding conformations to obtain conclusions on structural elements required for effective inhibition toward XO by performing a computational docking study. Allopurinol, as a well-known inhibitor, was used as a reference compound. Figure 9a shows allopurinol and flavonoids occupied the active cavity of XO (yellow), which was a long and narrow channel leading to the black catalytic site (Mo-pterin center). This once again supported that the mimic planar structure as xanthine was essential for potent inhibitory activity on XO.[19,22] The close-up views of computer-generated model (Figure 9b−e) reveal that all of the flavonoids plugged the channel (represented as Leu648, Phe649, Leu873, Phe914, Phe1009, Thr1010, Val1011, Phe1013, and Leu1014) and covered the access of designated substrate LUZ by interacting with the surrounding residues with different orientations. It was obvious that once the channel was mostly occupied by inhibitor, it might block the landing of substrate and ultimately prevent its oxidation. Figure 9b shows a close-up view of the active cavity of XO along with allopurinol. It docked in the Mo-pterin domain, showed a close position to LUZ, and formed hydrogen bonds with Lys 771 and Glu802.[52]

In Figure 9c, we superimposed two flavones of apigenin and chrysin, showing that their benzopyranone rings overlapped and both bound in the channel leading to the buried cofactor

J. Agric. Food Chem. 2015, 63, 7784−7794

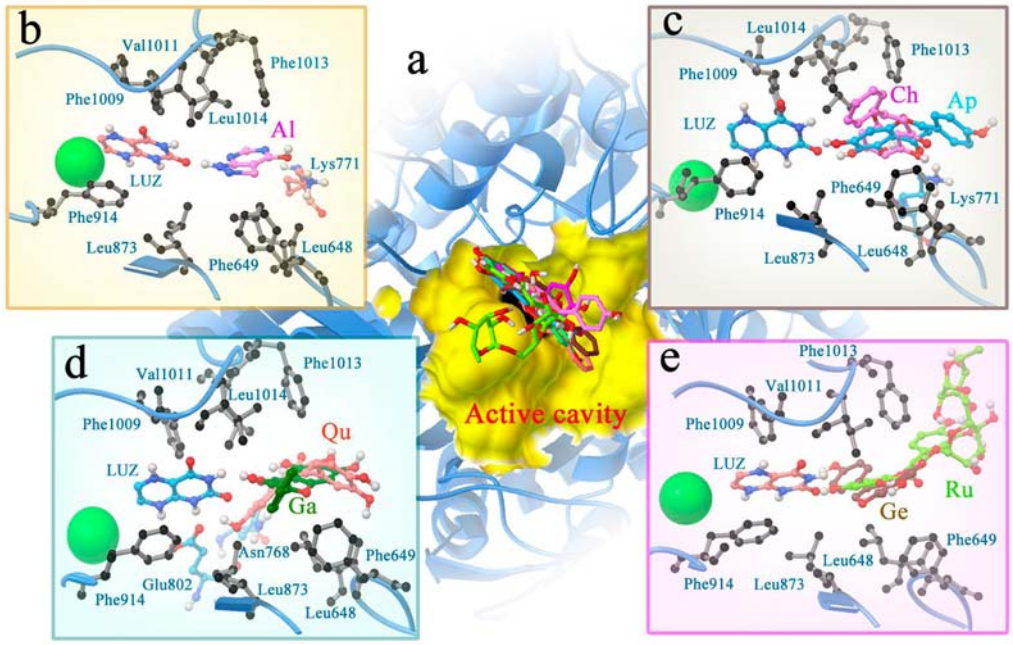

Figure 9. (a) Section view of flavonoids (stick) occupying the catalytic site cavity (surface view: yellow) of XO. The black domain is the surface of coenzyme factor (Mo-pterin cofactor). The close-up view of interaction of flavonoids with hydrophobic residues (shown in black ball and gray stick representation and labeled with their numbers) lining the access channel to Mo (green ball) center are shown as (b) allopurinol (Al), (c) chrysin (Ch) and apigenin (Ap), (d) galangin (Ga) and quercetin (Qu), and (e) geninstein (Ge) and rutin. Backbone segments are shown in cyan, and the residues of forming hydrogen bond with the corresponding flavonoids are in full color (Asn768, Glu802, Lys771).

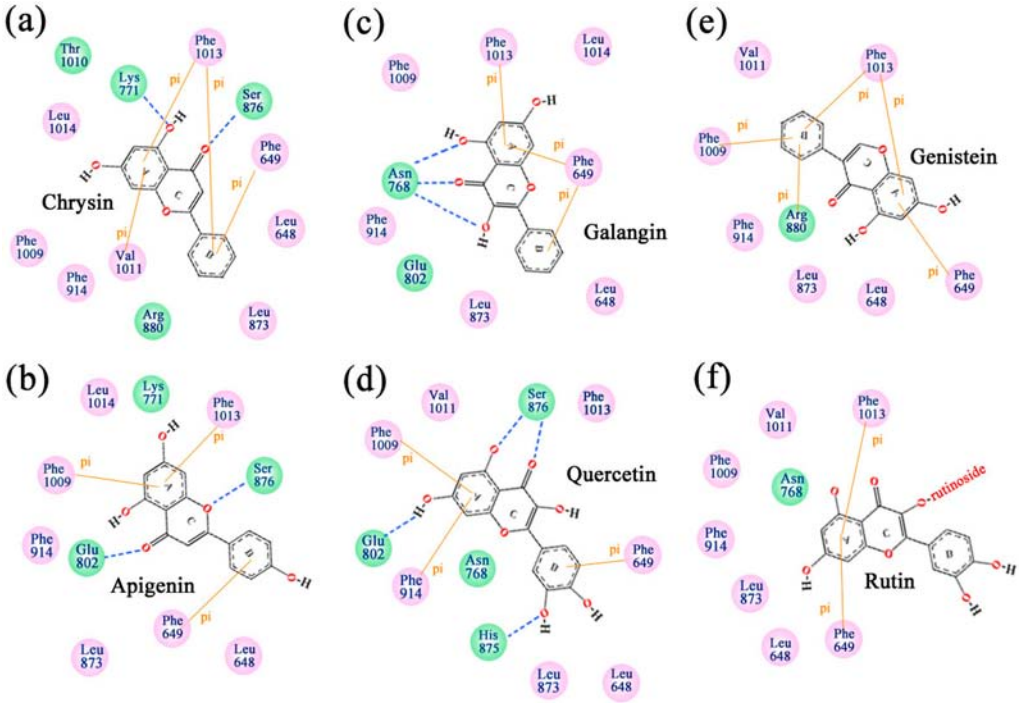

Figure 10. Key interactions of chrysin (a), apigenin (b), galangin (c), quercetin (d), genistein (e), and rutin (f) with the key residues in the active cavity of XO. Pink circles indicate hydrophobic amino acids, and green circles indicate hydrophilic amino acids. The blue short-dash lines indicate hydrogen bonds to side-chain residues. The orange lines represent π-interactions.

with slight difference. Chrysin showed hydrogen bonding of 5C—OH and 4C═O groups with side chain of Lys771 and Ser876 residues (Figure 10a), whereas hydrogen bonds were observed between 4C═O and the ether group of apigenin with the side chains of Glu802 and Lys771 residues, respectively (Figure 10b).

The overlay of binding poses of flavonol in the XO active site is displayed in Figure 9d; galangin and quercetin had almost identical binding modes at the active sites with each having ring A and C docked into the channel. Their polar 3C−OH stretched to the space surrounded by nonpolar Phe649, Leu648, and Leu1014. Thus, the weaker inhibition and

DOI: 10.1021/acs.jafc.5b03386
J. Agric. Food Chem. 2015, 63, 7784−7794

interaction of flavonol relative to flavone could be explained by the unsteadiness of polar hydroxyl in the hydrophobic region.[26] The destabilization of polar hydroxyl stretching into the hydrophobic region may cause the lower binding affinity; thus, the more hydroxyl groups in ring B within one subclass, the weaker inhibitory ability it exhibited (Table 1). The hydrogen bonds between 3C−OH of galangin and Asn768 residue (Figure 10c) and between 3′C−OH of quercetin and His875 residue (Figure 10d) might be the reason for their different orientations of ring B.

Three common features of binding with XO existing in both flavone and flavonol (Figure 10a−d) could be concluded. First, several hydrogen bonds and $\pi-\pi$ interactions existed in their docking into the active pockets.[37] For example, there were $\pi-\pi$ interactions between ring A and the aromatic residue of Phe1013 and Val1011; interactions between ring B and Phe1013 and Phe649 are shown in the chrysin−XO system (Figure 10a). Several hydrogen bonds were observed, including C5 hydroxyl bound to Lys771 (Figure 10a), Asn768 (Figure 10c), or Ser876 (Figure 10d) and C7 hydroxyl bound to Glu 802 (Figure 10d). This might support the previous result that C5 and C7 hydroxyl groups of flavonoid assist in the inhibitory activity against XO.[19,22] Second, the 4C═O group (ring C) of both flavonoids formed hydrogen bonds with the side chains of the residue within the cavity. A third significant feature of both flavonoids was shown by inserting ring A and ring C into the hydrophobic cavity instead of ring B. Additionally, each flavonoid docked into the active site of XO uniquely.

Genistein is a constitutional isomer of apigenin with a difference in the phenolic group substitution on ring C. The simulation revealed that the binding of genistein was in the opposite orientation to apigenin, with ring B inserting into the active site and approaching the Mo-center (Figure 9e). Herein, rutin had a comparable binding position to genistein with its benzopyranone bicyclic ring stretching beyond the hydrophobic pocket and ring C inserting into the Mo-pterin domain, but it exhibited fairly low affinity to the enzyme. These phenomena could be explained by the fact that the bulky rutinoside moiety located outside the active cavity, which was supposed to badly destabilize its binding; that is, the bulky rutinoside created a steric clash with the surrounding residues, thereby preventing productive binding to XO.[20] Moreover, the $\pi-$cation interactions of ring B (genistein) and the NH_2 of Arg880 (Figure 10e) and $\pi-\pi$ interactions between these flavonoids and Phe1013, Phe1009, and Phe649 (Figure 10e,f) also contributed to the tethering of the two flavonoids to the active sites. All together, our structural and experimental data indicated that these potent flavonoids occupy the active substrate-binding sites in the enzymatic pocket, although with different orientations, physically excluding the landing of substrate, further intervening in the xanthine oxidation activity of XO and hindering the redundant mechanism for uric acid.

In summary, this work reinforced flavonoids as effective inhibitors of XO in vitro. It was also possible to establish a structure−activity relationship for the inhibitory activity of flavonoids against XO. Data analysis indicated that the hydrophobic force was the main force of flavonoids to bind with XO. The inhibitory activities increased generally with increasing affinities within the class, especially for flavones and flavonols, which might be because the higher affinity increases the chance to enter the catalytic gorge, but the inhibition finally depends on the direct interaction between the flavonoid and the active site. The typical structure properties of flavonoids affecting the inhibitory effect against XO are illustrated in Figure 8. The hydrogenation of the C2═C3 double bond on flavonoids decreased the inhibition on XO, hydroxylation of C3 (ring C) and glycosylation of 3C−OH were unfavorable for the inhibition, and the hydroxylation and methoxylation on ring B also decreased the inhibitory activity; moreover, the hydroxylation of C6 (ring A) and glycosylation of 7C−OH siginificantly affected the inhibitiory ability.

The structure−activity relationship coupled with the results of computer modeling revealed several key factors of flavonoid binding in the active site of XO and inhibition against XO. Specifically, due to their mimic rings (A and C rings) of the xanthine (Figure 1), these compounds bound to the active site effectively. The C2═C3 that maintains a planar structure of flavonoids was essential for potent inhibitory activity on XO.[19,22] The hydroxyl moiety at C7 and C5 contributed favorable hydrogen bonds and interactions between inhibitors and the active site. However, C3−OH exhibited weaker inhibition, which could be due to the destabilization of polar hydroxyl stretching into the hydrophobic region of the active site and causing lower binding affinity. The methylation of flavonoids exhibited a great effect on the inhibition toward XO, whereas their effect on the affinity for XO was uncertain. The bully substitution of glycosyl on aromatic rings of flavonoids created a steric clash with the surrounding residues, hindering a lower binding affinity for XO. Generally, the occupancy of the active site by the potent flavonoids reduced the landing of substrate to the active sites and further intervened in the xanthine oxidation activity of XO and hindered the redundant mechanism for uric acid.

These results provide a molecular basis regarding the binding nature and structural requirements of phytochemical flavonoids to inhibit XO, which may be useful for developing new potential drugs for XO blockade. Thus, flavonoid-containing fruits and vegetables should be included in the diet of patients suffering gout. These examples also illustrate how knowledge of the inhibition mechanism can promote the development of novel therapies. However, the results from this in vitro study may be different from the results obtained from in vivo studies due to metabolic conversion processes; therefore, cell culture and animal studies including these chemicals should be further initiated. In fact, there was a study showing that flavonoids (genistein, apigenin, quercetin, rutin, and astilbin) had a significant effect on XO activities in vivo (serum XO).[20] However, it is still necessary to conduct more experiments in vitro and vivo to illuminate if the flavonoids are suitable candidates for replacing allopurinol for the treatment of gout.

Molecular mechanisms of tumor cell proliferation inhibited by rBTI may be involved in the disorder of mitochondrial membrane potential and mitochondrial dysfunction. Thus, in this article, we will focus on the molecular mechanisms by which cells coordinate the mitochondria and mitophagy,[16] as induced by rBTI, and also examine the relationship between autophagy and reactive oxygen species (ROS).[17] Our results indicated that the rBTI directly targeted mitochondria, which caused a dose-dependent overproduction of ROS, leading to breakdown of mitochondrial membrane potential and ultimately mitophagy.

MATERIALS AND METHODS

Materials and Reagents. The rBTI was generated previously via cloning, protein expression, and one-step affinity purification in our laboratory.[18] The Hep G2 cells were obtained from the Biology Institute (Shanxi, China). Fetal bovine serum, penicillin, streptomycin, trypsin, and dimethyl sulfoxide (DMSO) were purchased from Sijiqing Company (Hangzhou, China). A superoxide dismutase (SOD) assay kit with WST-1, a catalase (CAT) assay kit, and a reduced glutathione assay kit were available from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). A reactive oxygen species assay kit, an ATP assay kit, a mitochondrial membrane potential assay kit, a cell mitochondria isolation kit, cell lysis solution, and protein A+G agarose and Rabit IgG were obtained from Beyotime Institute of Biotechnology (Shanghai, China). TurboFect transfection reagent was purchased from Thermo Fisher Scientific (Massachusetts, US). Tom20 antibody (F-10) (sc-17764), Cox IV antibody (F-8) (sc-376731), ATG5 antibody (C-1) (sc-133158), p62 antibody (D-3) (sc-28359), and Tim23 antibody (sc-13298) were purchased from Santa Cruz Biotechnology, Inc. (California, US). Beclin 1 antibody (B6186) and LC3B antibody (L7543), monodansylcadeverine (MDC) (30432), and bafilomycin A1(B1793) were purchased from Sigma-Aldrich (St. Louis, MO). Cyto-ID Green Detection Kit was acquared from Enzo Life Sciences (Farmingdale, NY).

Cell Culture and Transfection. The human hepatoma cells (Hep G2) were cultured in Dulbecco's modified Eagle's medium (DMEM); supplemented with 10% fetal bovine serum (Hyclone, Logan, UT), 100 U/mL penicillin, and 100 g/mL streptomycin at 37 °C; and stored in a humidified 5% CO_2 atmosphere. The cells were cultured on tissue culture plates and harvested 24 h after plating when a confluent monolayer culture was achieved. Transfected Hep G2 cells were obtained by treatment with Turbo Fect transfection reagent according to the manufacturer's protocol.

Transmission Electron Microscopy (TEM). Hep G2 cells, treated or untreated with rBTI, were pelleted at 45 *g* and fixed in 1.5% PFA, 1.5% glutaraldehyde in 0.1 M cacodylate buffer, pH 7.4 overnight at 4 °C. For block contrasting, the samples were washed three times for 10 min each in cacodylate buffer and incubated for 2 h in the dark in 1% osmium tetroxide/cacodylate buffer. Samples were washed three times for 10 min each in cacodylate buffer and twice for 10 min each in distilled water, and then incubated overnight in the dark in half saturated uranylacetate solution. Uranylacetate was removed by washing two times for 10 min each with distilled water. Samples were prepared for embedding by dehydrating in acetone (two times for 10 min, 70%; two times for 10 min, 90%; and three times for 10 min, 100%) and by preincubating in 1:1 epoxy resin/acetone (1 h), 4:1 epoxy resin/acetone (1 h), and pure epoxy resin, overnight. Finally, the samples were embedded in epoxy resin and hardened at 40 °C for 20 h and 60 °C for 40 h. Ultrathin sections (50−70 nm) were then generated and placed on hexagonal copper grids. For sample contrasting, the sections were incubated with 5% uranylacetate in distilled water (10 min, 60 °C) and lead citrate (3 min, room temperature (RT)) then dried and analyzed by TEM.

Laser Scanning Confocal Fluorescence Microscopy. The detection of mitochondrial membrane potential was undertaken using a laser scanning confocal fluorescence microscope (Fluoview FV1000; Olympus, Japan) at λ_{ex} 488 and 600 nm. To investigate the mitochondrial membrane potential after rBTI treatment, Hep G2 cells were seeded onto glass coverslips in six-well plates (5×10^4 cells/well). The cells were treated with rBTI. After incubation with rBTI, cells were stained with the $\Delta\Psi_m$-specific probe JC-1 and autophagy marker MDC according to the manufacturer's protocol.

Fluorescence channels for different dyes were separated into different wells using sequential scanning to ensure there was no bleach from one channel. Samples were undertaken on a laser scanning confocal microscope with fluorescein isothiocyanate (FITC, green), tetramethyl rhodamine isothiocyanate (TRITC, red), and 4′,6-diamidino-2-phenylindole (DAPI, blue) channels. Confocal microscopy was conducted with an Olympus spectral confocal microscope using the XYZ mode and a 0.25/0.40 μm section height. For quantitative analysis, the fluorescence intensities were quantified by the ImageJ software (NIH, US) and the results were expressed as mean ± SEM.

Flow Cytometry. The Hep G2 cells were seeded on a 12-well plate at a density of $3-4 \times 10^4$ cells/well and incubated for 24 h at 37 °C. The cells were then treated with 50 μg/mL rBTI for 2 and 4 h. Hep G2 cells were trypsinized and collected by centrifugation. The analysis of ROS, mitochondrial membrane potential, and the autophagosomes were performed using the reactive oxygen species assay kit, mitochondrial membrane potential assay kit, and Cyto-ID green detection kit, according to the manufacturer's protocols. The cells were analyzed by flow cytometry using an excitation/emission of 488/520 nm.

Antioxidant Enzyme Activity Assay. The Hep G2 cells were seeded on a 6-well plate at 2×10^5 cells/well and incubated for 24 h at 37 °C. The cells were then treated with 50 μg/mL rBTI for different lengths of time. After incubation with rBTI, the growth medium was removed and the cells were washed twice with PBS. Then 100 μL of cell lysis solution was added to each well and MicroPette Plus was used to blow the liquid for 2−3 s. The cell debris and lysis solution were put into 1.5 mL eppendorf tubes, incubated on ice for 20 min, and centrifuged for 10 min at 13 500*g* at 4 °C before the supernatants were collected. The supernatant containing total cell protein was used for protein determination. Protein concentration in all samples was monitored by spectrophotometry using the BCA protein assay reagent. The supernatant was used only for SOD, CAT, and glutathione peroxidase (GSH) content assays.

SOD was evaluated using the superoxide dismutase assay kit. In this assay, WST-1 produces a water-soluble formazan dye upon reduction with a superoxide anion, which is a byproduct from the catalytic reaction of xanthine oxidase. The assay was performed in 96-well microplates according to the manufacturer's instruction. The absorbance was read at 450 nm using a plate reader.

CAT needed to be measured using the catalase assay kit. CAT activity can decompose H_2O_2 to produce water and oxygen. The unconverted H_2O_2 reacts with ammonium molybdate to produce a yellow product, the absorbance of which can be evaluated using a spectrophotometer. The assay was performed in 96-well microtiter plates according to the manufacturer's instructions, and the absorbance was read at 405 nm.

GSH content was evaluated using the glutathione reductase assay kit. Briefly, 40 μL of metaphosphoric acid was added into 10 μL of Hep G2 cell lysates. The mixtures was then centrifuged at 10 000 g for 10 min at 4 °C. The supernatant was used for both the GSH and oxidized glutathione (GSSG) assay. The total GSH level was monitored using a DTNB-GSSG recycling assay. The GSSG level was quantified using the total GSH assay, after supernatants were pretreated with 1% 1 mol/L 2-vinylpyridine solution to remove the reduced GSH.

MTT Assays. Hep G2 cells were seeded into 96-well microtiter plates at a density of 5×10^3 cells/mL in 100 μL of complete DMEM medium. The cells were allowed to adhere at different time points in fresh medium and then treated with 50 μg/mL rBTI and/or 3-MA for 12 or 24 h. Then, 20 μL of MTT (5 mg/mL) was added to the culture medium and the cells were incubated at 37 °C for an additional 4 h. The medium and MTT were removed, and 150 μL of dimethyl sulfoxide (DMSO) was added to each well. The plates were then

DOI: 10.1021/acs.jafc.5b02644
J. Agric. Food Chem. 2015, 63, 7795−7804

placed on a shaker for 5 min at room temperature. For each well, absorbance at 490 nm was measured using a microtiter plate ELISA reader (model 550; Bio-Rad, Hercules, CA).

Measurement of Cellular ATP. The ATP assay kit, based on the production of light from ATP and luciferin in the presence of luciferase, was used to measure ATP concentrations. Hep G2 cells were plated at a density of 2×10^5 cells/well in 6-well plates. After overnight incubation, the cells were treated with 50 μg/mL rBTI for different lengths of time. Following treatment, the medium was removed and the cells were washed twice with cold PBS, then 200 μL of cell lysis buffer was added to each well. The cells were then placed on ice for 20 min, then the lysate was cleared by centrifugation at 13 500*g* for 10 min at 4 °C and the supernatant (total cell lysate) was used immediately. ATP measurements were carried out using a luminometric assay, according to the manufacturer's instructions. The ATP concentration in the wells was determined using a standard curve and normalized to protein content.

Mitochondrial Morphology. Hep G2 cells transfected with the pDsRed2-Mito plasmid were seeded onto glass coverslips at a density of 2×10^5 cells/well in 6-well plates, each sample in triplicate. Following an overnight incubation, cells were treated with or without 50 μg/mL rBTI for different lengths of time. Following incubation, cells were fixed for 10 min at RT in 4% paraformaldehyde in 0.1 M PBS at pH 7.4. The cells were subsequently washed 3 times with 0.01 M PBS containing 0.85% NaCl at pH 7.4 and fixed in 4% paraformaldehyde.

Colocalization of FITC-BTI or LC3 with Mitochondria. The stable cell line (Hep G2/mito-RED) was transfected with pEGFP-LC3. Cells transfected with pEGFP-LC3 were incubated with 50 μg/mL rBTI, while the cells (Hep G2/mito-RED) were treated with FITC-rBTI for different lengths of time. Labeling of rBTI with FITC was carried out in accordance with the method published by Cui et al.[19] Following incubation with or without rBTI, we investigated the colocalization of mitochondria with rBTI or GFP-LC3. The transfected cells were maintained on coverslips in six-well plates overnight then left untreated or treated with 50 μg/mL rBTI for 4 h. The cells were then washed twice with PBS, and the cellular localization pattern of mitochondria was then photographed using confocal fluorescence microscopy.

Subcellular Fractionation. Subcellular fractionation of cells to separate mitochondrial and cytosolic fractions was carried out according to the instructions provided with the cell mitochondria isolation kit. Hep G2 cells collected from three 10 cm culture dishes with trypsination were washed once with PBS and then resuspended in 1 mL of mitochondria isolation buffer. After incubation on ice for 15 min to promote hypotonic swelling, cells were homogenized by 30 strokes with a glass homogenizer. The homogenate was centrifuged at 600*g* for 10 min at 4 °C, and the collected supernatant was transferred to a clean chilled tube for further centrifugation at 11 000 *g* for 15 min at 4 °C. The supernatant representing the cytosolic fraction was collected without any treatment and stored at −20 °C for later analysis. The resulting pellet representing the mitochondrial fraction was resuspended in 40 μL of mitochondria dissociation buffer.

Western Blot. Cells were collected and washed with PBS. Whole cellular proteins were extracted and cytosolic fractions were prepared according to the manufacturer's guidelines (Beyotime, China). The protein concentration in all samples was measured using the classic BCA assay. Equal amounts of sample lysates were subjected to 12% SDS-PAGE and then transferred onto PVDF membranes. The PVDF membranes were blocked with 5% nonfat milk in TBST buffer (20 mM Tris pH 7.5, 500 mM NaCl, 0.1% Tween-20) overnight at room temperature. The membranes were subsequently incubated with the relevant primary antibodies (1:1000 dilution) at 4 °C overnight and then with enzyme-linked secondary antibodies (1:10 000 dilution) for 1 h at room temperature. Immunoreactive bands were visualized with Enlight regents (Engreen, Beijing, China).

Immunoprecipitation. Hep G2 cells grown to a confluence of 90% were treated with 50 μg/mL of rBTI for 2 h and then washed once with PBS and lysed for 30 min on ice using NP-40 lysis buffer (Beyotime, Jiangsu, China). Cell lysates were then centrifuged at 12 000 *g* for 20 min. The soluble fraction was collected and the protein concentration was determined using the BCA protein assay kit (Beyotime, Jiangsu, China). Next, 1 mg of the extracted protein in lysis buffer was immunoprecipitated overnight with anti-Tom20 or anti-BTI antibody at 4 °C and then with protein A+G agarose beads for another 4 h. After that, the protein A+G agarose beads were washed three times with lysis buffer. The beads were then boiled in 1% SDS loading buffer for Western blotting with the indicated antibodies.

Statistical Analysis. Data were obtained from at least three independent experiments and presented as the mean ± SEM. Statistical evaluation of the results was performed by one-way ANOVA. Data represent ±standard error of the mean (SEM) from more than three independent experiments.

RESULTS AND DISCUSSION

rBTI Induces Mitophagy. To determine whether rBTI promotes autophagy and the type of autophagy, Hep G2 cells were incubated in medium containing either vehicle (control) or 50 μg/mL and 100 μg/mL rBTI for 12 h. Subsequently, cells were prepared for EM studies. Unequivocal evidence for autophagy was obtained from electron microscopy. Representative electron microphotographs of control and rBTI-treated cells are shown in Figure 1A. We found mitochondria inside an autophagosome structure in rBTI-treated Hep G2 cells, but not in untreated cells. Numerous membrane packaged structures were apparent inside the cells, and these structures could contain damaged mitochondria. When cells were treated with 100 ug/mL rBTI for 12 h, multiple autophagolysosome structures appeared in the cells. To confirm the effect of rBTI on autophagy, Hep G2 cells were transfected with pEGFP-LC3 and then incubated in medium containing either buffer or 50 μg/mL rBTI for different lengths of time. Following incubation, cells were examined by confocal microscopy. Representative microphotographs of autophagic activity stimulated by rBTI are presented in Figure 1B. rBTI strongly increased the LC3 protein conversion, as well as formation of GFP-LC3 punctate structures, indicating that rBTI induces autophagy (Figure 1B). At the same time, Hep G2 cells transfected with pDsRed2-Mito were used to monitor the changes of mitochondria induced by rBTI. When Hep G2/pDsRed2-Mito cells were treated with rBTI, mitochondria mainly existed in a form of Red-Mito punctate structures that could be clearly distinguished from the dispersed mitochondria seen in cells that were left untreated with rBTI (Figure 1B). Under rBTI treatment, mitochondria underwent fragmentation within a few hours; the mitochondrial pattern was disrupted, and the mitochondria partially disappeared.

Induction of autophagy was supported by MDC staining. Figure 1C shows clearly that control cells display very rare green fluorescent punctate structures, indicating a lack of acidic vesicular organelles. However, rBTI-treated cells showed an increase in the number of green fluorescent punctate structures at different time points post-treatment, when compared with the control. This indicates significant autophagic vesicle formation in Hep G2 cells exposed to rBTI. These autophagic vacuoles are then fused with lysosomes, and eventually the delivered contents are degraded by lysosome enzymes such as acid phosphatase and the mature form of cathepsin D.

We also investigated the alteration of mitochondrial proteins Cox IV and Tom20. Both of these proteins were decreased in rBTI-treated cells, whereas an ER protein GRP94 was not changed (Figure 1D). In particular, Hep G2 cells that had been treated with 100 μg/mL rBTI for 12 or 24 h showed significant reduction of Cox IV and Tom20, compared with cells treated

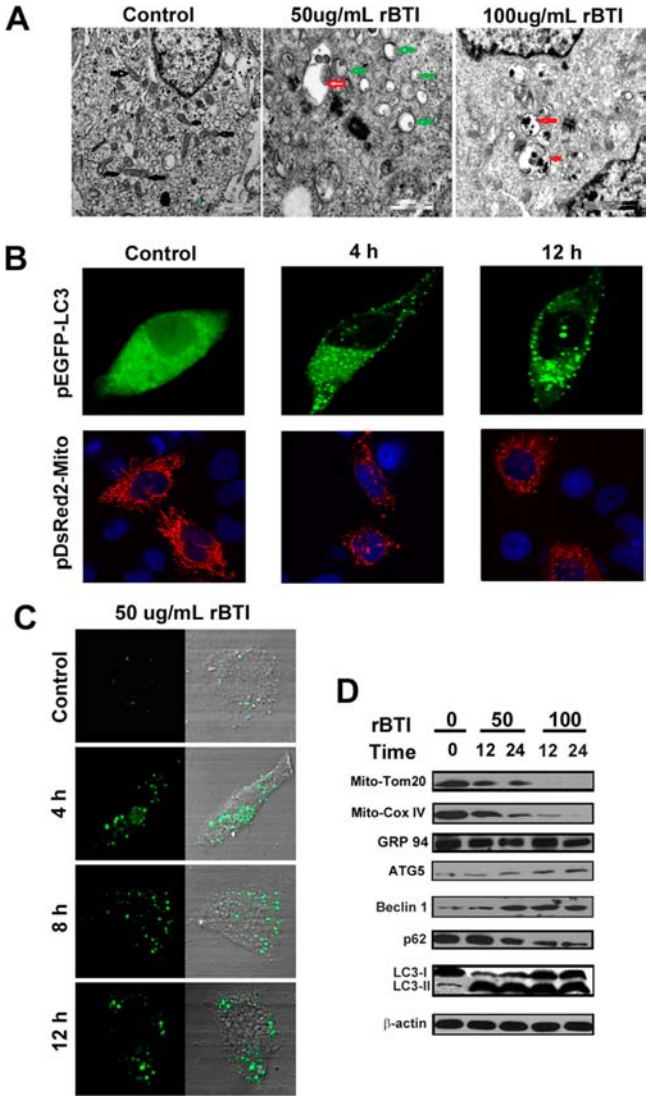

Figure 1. rBTI induces mitophagy. (A) Transmission electron microscopy pictures show rBTI-induced autophagic encapsulation of mitochondria. Hep G2 cells were treated with 50 μg/mL and 100 μg/mL rBTI for 12 h. Black arrow, mitochondria; green arrow, mitochondrial fragmentation; red arrow, autophagosome structures. (B) rBTI increases the number of GFP-LC3 punctate structures and induced mitochondrial fragmentation in Hep G2 cells. (C) MDC staining shows autophagy was activated in Hep G2 cells after treatment with rBTI. (D) Western blot was used to examine the mitochondrial protein and marker proteins involved in autophagy.

only with 50 μg/mL rBTI and the control group. Marker proteins involved in autophagy were also tested. As shown in Figure 1D, rBTI significantly increased the level of phosphatidylethanolamine-conjugated LC3-II, whereas unconjugated LC3-I levels were significantly decreased. Beclin-1, also known as the autophagy-related gene Atg 6, was also shown to be required for the initiation of autophagosome formation. Similar to LC3-II expression, beclin-1 levels were enhanced by rBTI treatment, and the autophagy substrate p62 was also reduced. Taking these data into account, we concluded that rBTI could induce the autophagic selective removal of mitochondria.

rBTI Depolarized Mitochondria and Increased ROS. We had an interest in understanding why autophagy induced by rBTI contributed to the degradation of mitochondria in Hep G2 cells. Therefore, first we tested the mitochondrial membrane potential (MMP) of Hep G2 cells under rBTI treatment. The cells were marked with JC-1; then, the mitochondrial membrane potential was analyzed by both flow cytometry and laser scanning confocal microscopy. The relative proportion of red and green fluorescent intensity indicates the mitochondrial depolarization ratio. Dramatic decline of mitochondrial potential was observed at the initial 4 h after rBTI treatment. Afterward, membrane depolarization was gradually recovered to the normal state, similar to that of the control at 24 h post-treatment (Figure 2A). The mitochondrial membrane potential was observed by laser scanning confocal microscopy following labeling of cells with JC-1 (Figure 2B). After 50 μg/mL of rBTI treatment for 2 and 4 h, mitochondria with normal MMP displayed red fluorescence, whereas those with abnormal MMP demonstrated green fluorescence. In this experiment, we observed an increase in green fluorescence but a decrease in red fluorescence in rBTI-treated cells.

It is well-known that ROS generation is correlated with depolarized mitochondrial membrane potential. Given that rBTI could quickly enter cells and negatively influence the mitochondrial membrane potential, we decided to examine the levels of cellular ROS after treatment with rBTI, utilizing H_2DCFH-DA staining and flow cytometry. Indeed, we observed a clear time-dependent increase in cellular ROS after treatment with 50 μg/mL rBTI. We found there was an increase in ROS production after treatment with rBTI for only 0.5 h, and ROS levels continuously increased for 2 h after exposure. ROS increased sharply between 2 and 4 h and reached a maximal level at 18 h. ROS levels then declined at 24 h, but were still higher than control levels (Figure 2C). Thus, rBTI is indeed a potent inducer of ROS. The relationship of mitochondrial membrane potential and ROS is shown in Figure 2D. Reduction of MMP and the consequent changes in ROS levels indicate a direct effect of rBTI rather than an indirect downstream effect.

rBTI Changed the Antioxidant System. Reactive oxygen species, including superoxide anions, hydroxyl radicals, and their byproducts, are toxic to diverse cell types as they can induce lipid peroxidation, DNA fragmentation, and protein oxidation. These reactive oxygen species can be scavenged by endogenous antioxidants including SOD, CAT, and glutathione peroxidase. In this study, the activities of SOD, CAT, and GSH in the cells were determined at various time points. As shown in Figure 3A, the activity of SOD in Hep G2 cells slowly increased after rBTI treatment for 0.5−6 h, with a peak value occurring at 8 h, although the activity at 18 and 24 h was still higher than that of the control group. CAT activity in Hep G2 cells showed no statistically significant difference after treatment with rBTI for 0−8 h, but the activity at 18 and 24 h slowly increased (Figure 3B). Total GSH level was significantly enhanced after rBTI treatment for 4−24 h, and at the same time the GSH/GSSG ratio also increased (Figure 3C,D). The significant increase in total GSH level and GSH/GSSG ratio also indicates that Hep G2 cells exposed to rBTI exhibited elevated antioxidant capacity.

Mild and Transient Oxidative Stress Induces Mitophagy. We were concerned with the role of ROS in regulating autophagy in Hep G2 cells under rBTI stress conditions. The amount of mitochondria undergoing autophagy was quantified by two assays using flow cytometry and confocal fluorescence microscopy. A Cyto-ID green detection kit−combined flow cytometric analysis was utilized to quantitatively determine the

(D) Graph showing the relationship between mitochondrial membrane potential and the level of ROS.

presence of autophagosome or autolysosome induced by rBTI in Hep G2 cells. After cells were incubated with rBTI and/or 3-MA and NAC, the average fluorescent intensity was measured by flow cytometry. The results showed that autophagy was significantly stimulated in Hep G2 cells when treated for 8 and 24 h. When Hep G2 cells were treated with rBTI combined with the autophagy inhibitor 3-MA and the ROS inhibitors NAC, respectively, the level of autophagy was dramatically decreased (Figure 4A). These results indicate that mild and transient ROS induced by rBTI were important signaling molecules required for the formation of autophagosomes.

LC3 has been considered an autophagosomal marker because of its localization and aggregation on autophagosomes. In this study, pEGFP-LC3 plasmid was transiently transfected into Hep G2 cells to determine if LC3 was involved in autophagy induced by rBTI. As shown in Figure 4B, rBTI-treated cells (at 8 and 24 h post-treatment) exhibited a significantly increased number of green LC3 punctate structures in the cytoplasm as compared to the nontreated control. In contrast, cells treated with rBTI and NAC or rBTI and 3-MA demonstrated apparently reduced numbers of GFP-LC3 puncta as compared to cells treated with rBTI alone. These data indicate decreasing ROS by NAC could reduce rBTI-mediated autophagy activation, which was comparable to the effect of 3-MA. In addition, ATP levels were reduced by rBTI treatment, indicating that the number of mitochondria was also reduced (Figure 4C). According to the results of MTT cytotoxicity assay, the inhibition rates of Hep G2 cells treated with either rBTI (50 μg/mL) or 3-MA alone were approximately 10% and 30% at 12 and 24 h post-treatments, respectively. However, the combined treatment could significantly reduce the inhibition rate. We also investigated the alteration of mitochondrial proteins Cox IV and Tom20 as well as the marker proteins involved in autophagy LC3 and P62 after Hep G2 cells were treated with rBTI (50 μg/mL), 3-MA/NAC alone, or combined with 3-MA/NAC for 24 h. The results showed

J. Agric. Food Chem. 2015, 63, 7795−7804

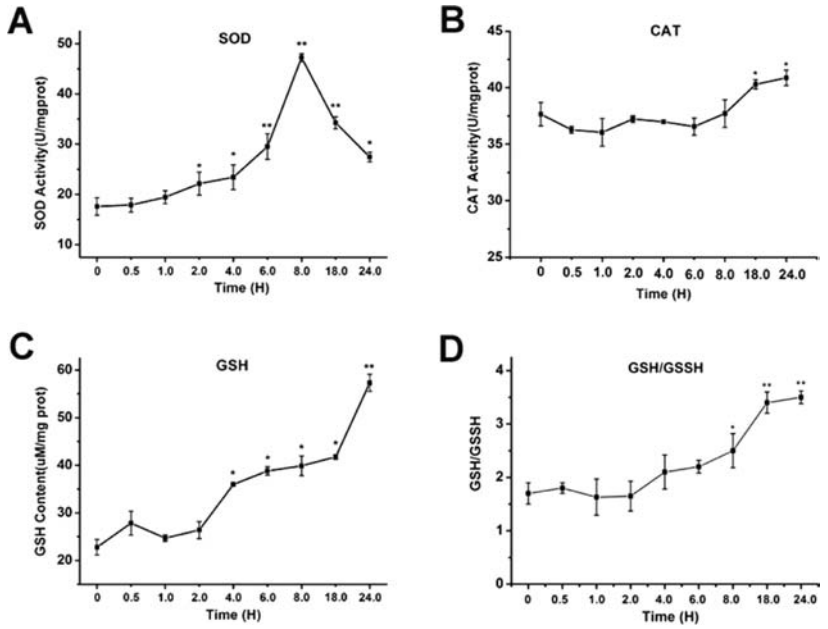

Figure 3. Analysis of antioxidant enzymes in Hep G2 cells. (A) Activity change of SOD. (B) Activity change of CAT. (C) Content change of GSH. (D) GSH/GSSG ratio in the Hep G2 cells. Cells were treated with 50 μg/mL rBTI for the indicated times (0, 0.5, 1, 2, 4, 6, 8, 12, and 24 h). After treatment, total cell lysates were prepared according to the protocol for each assay, and the activity/content of SOD, CAT, and GSH was measured. *, $P < 0.05$; **, $P < 0.01$ vs control group.

that 3-MA/NAC partly counteracted rBTI-mediated increment of autophagy activation as well as loss of mitochondrial outer membrane proteins Tom 20 and Cox IV (Figure 4E). Another antophagy inhibitor, bafilymocin A1, was used to check the autophagy flux. The result showed that autophagosome accumulation is due to autophagy induction rather than blockade of autophagic flux in the downstream steps (Figure 4F). Taken together, both assays show that mitophagy is induced by mild oxidative stress in rBTI-treated Hep G2 cells.

Subcellular Localization of rBTI. For immunofluorescence staining, transfected Hep G2 cells expressing pDsRed2-Mito were treated with FITC-BTI for 4 h and then fixed with 4% (w/v) paraformaldehyde for 10 min. In Figure 5A, the yellow color in the merged image indicates colocalization of FITC-BTI with mitochondria and that FITC-BTI and mitochondria mainly form punctate structures in the cytoplasm. This indicates that rBTI could target the mitochondria and induce mitochondrial fragmentation.

To further understand rBTI-mediated mitophagy, we investigated mitochondrial localization with LC3. Hep G2 cells transfected with pDsRed2-Mito and pEGFP-LC3 were incubated with or without rBTI; then, the colocalization of mitochondria with GFP-LC3 was examined. Consistently, treatment with rBTI increased colocalization of mitochondria with GFP-LC3, when compared to nontreated control. The yellow color in the merged image indicates colocalization of mitochondria and GFP-LC3 puntates (Figure 5B).

To support the immunofluorescence data, biochemical fractionation of crude extracts from Hep G2 cells was performed at 4 °C. Cytoplasmic and mitochondrial proteins were further analyzed by Western blot. As controls for proper cytosolic and mitochondrial separation, β-actin, p62, Tom 20, and Tim 23 were used as markers for the cytosol and mitochondria. In accordance with the immunofluorescent results, rBTI was found to be localized at both mitochondrial and cytoplasmic fractions (Figure 5C). An interesting phenomenon is that Tom 20 was found not only in the mitochondrial fraction but also in the cytoplasm when cells were treated with rBTI. Furthermore, by performing immunoprecipitation and Western blot assays, we found that rBTI specifically associates with Tom 20 (Figure 5D). Thus, Tom 20 may be the direct target of rBTI.

Mitochondria are essential regulators of cell death and respond to many different stress signals, including loss of growth factors, hypoxia, oxidative stress, and DNA damage. Mitochondria are a major source of ROS, which are byproducts of mitochondrial electron transport activity. Under normal conditions, cells develop a highly efficient antioxidant system that can neutralize ROS. However, destroyed mitochondria can produce excessive ROS at levels that exceed the capacity of the antioxidant system, which can result in cell death or autophagy. In recent years there has been much research showing that mitochondrial ROS signals affect signaling pathways and cellular processes. It is now recognized that mitochondrial ROS are required for the cellular response to hypoxia,[20] to regulate cell cycle progression,[21] to trigger E2F1-dependent apoptosis,[22] to regulate telomere stability,[23] and for organismal lifespan.[24] Additionally, signaling pathways such as Notch[25] and Akt[25] are now known to be modulated by mitochondrial ROS. In addition, ROS plays an important role in inducing autophagy in cells, but exactly how ROS regulates autophagy is unknown. ROS as signaling molecules can activate the protease Atg4B, which could cleave the C-terminus of LC3-I, an essential precursor to conversion of LC3-I to LC3-II.[26] Mitochondrial ROS could activate autophagy by activating AMPK, but independent of an increase in AMP/ATP ratio.[27]

In previous studies, we showed that rBTI has a strong cytotoxic effect on a wide variety of cancer cell lines, such as EC9706, Hep G2, HeLa, and other solid tumor cells, although the exact molecular mechanism is not certain. In this study, we utilized Hep G2 cells as an experimental model to evaluate the toxicity of rBTI and to investigate the effect of rBTI on

DOI: 10.1021/acs.jafc.5b02644

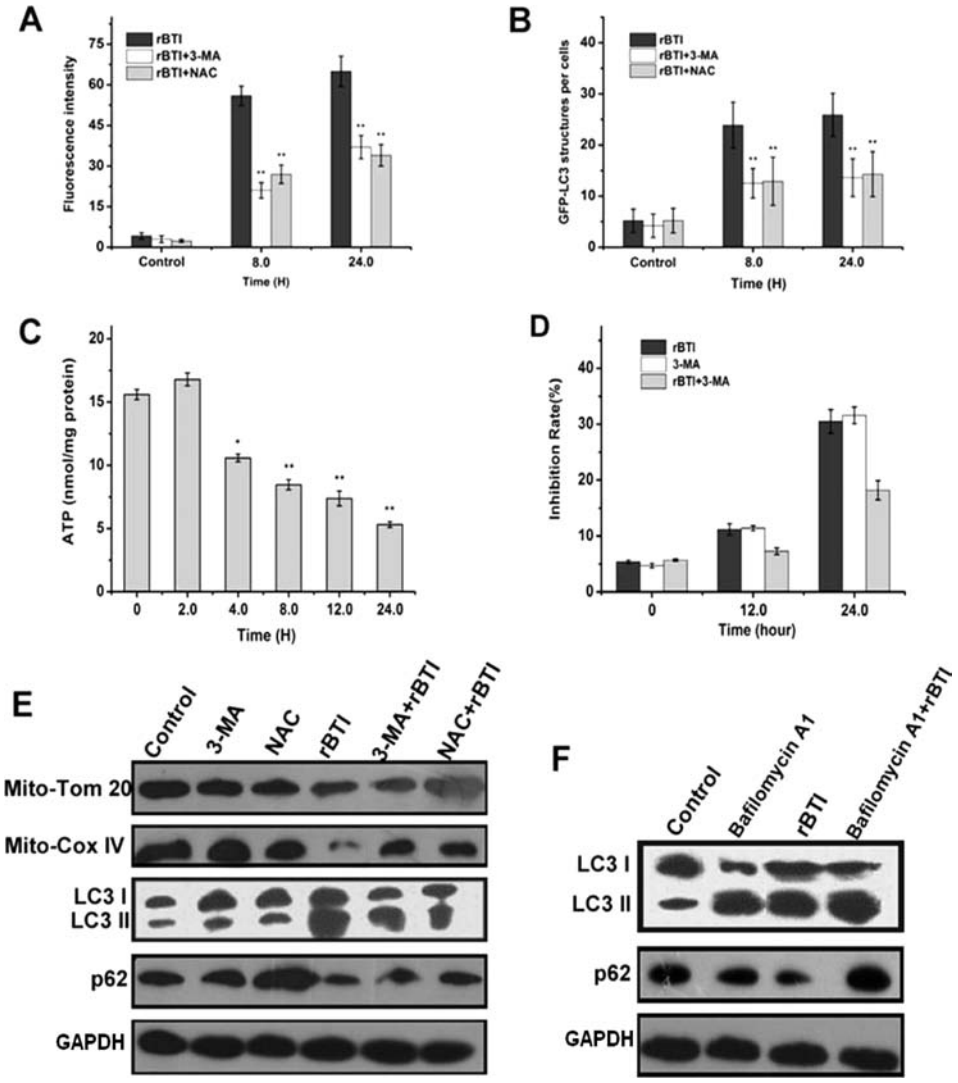

Figure 4. Mild and transient oxidative stress induced by rBTI-driven mitophagy. (A) Quantitative analysis of autophagy induced by rBTI was assessed by flow cytometry. Cells were incubated with rBTI and/or 3-MA and NAC; then, the average intensity of fluorescence was detected via flow cytometry. (B) Number of GFP-LC3 punctate structures in the cytoplasm. Hep G2/GFP-LC3 cells were exposed to rBTI and/or 3-MA, and NAC and autophagic GFP-LC3 punctate were counted in the pictures obtained from confocal microscopy at various time points. (C) Effect of rBTI on intracellular ATP levels in Hep G2 cells. Cells were treated with 50 μg/mL rBTI for different time points (2, 4, 8, 12, and 24 h) before measurement of ATP by a luminometric assay. (D) Cytotoxicity of rBTI. Hep G2 cells were treated with or without rBTI (50 μg/mL) and 3-MA for 12 or 24 h; then the cell viability was determined by standard MTT assay. (E) Effect of rBTI/3-MA/NAC on the level of autophagy and mitochondrial mass after rBTI treated. Hep G2 cells were treated with rBTI (50 μg/mL), 3-MA(2 mM)/NAC(1 mM) alone or combined with 3-MA/NAC for 24h, and then the level of Tom20, Cox IV, LC3 and p62 were analyzed by immunoblotting. (F) The level of autophagy in Hep G2 cells with or without rBTI (50 μg/mL) and Bafilomycin A1(10 nM). * $P < 0.05$, ** $P < 0.01$ vs control group.

mitochondrial function. Depending on the immunofluorescent staining, the autophagy level in Hep G2 was enhanced in those cells treated with rBTI. Taking into account the changes in mitochondrial morphology and the data from the Western blots, we concluded that rBTI could induce autophagic selective removal of dysfunctional mitochondria (Figure 1). We then studied the role of ROS in autophagy as well as the colocalization of rBTI and mitochondria in Hep G2 cells. We found that rBTI can directly target mitochondria to cause mitochondrial dysfunction and at the same time drive release of ROS from damaged mitochondria as signaling molecules to activate autophagy and quickly remove damaged mitochondria. Taken together, these results suggest that mitochondrial dysfunction plays an important role in mitophagy induced by rBTI.

ROS-scavenging enzymes include catalase, superoxide dismutase, monodehydroascorbate reductase, dehydroascorbate reductase, glutathione peroxidase, peroxiredoxin, ascorbate peroxidase, and glutathione reductase. Among these enzymes, SOD converts superoxide $O_2^{\bullet-}$ into H_2O_2, which is further detoxified into H_2O and O_2 by catalase or peroxidases.[28] In this study, we found an increasing trend of SOD activity after treatment with rBTI. Therefore, rBTI promotes Hep G2 cells to produce $O_2^{\bullet-}$. However, the detoxification of endogenous $O_2^{\bullet-}$ by SOD in different cellular compartments is always accompanied by the production of H_2O_2, which is toxic and often regulated by enzymes such as CAT and GSH-Px. As a consequence, we measured the increased content of GSH and an elevated ratio of GSH/GSSG in the treatment group, suggesting that cells can keep more glutathione in the reduced

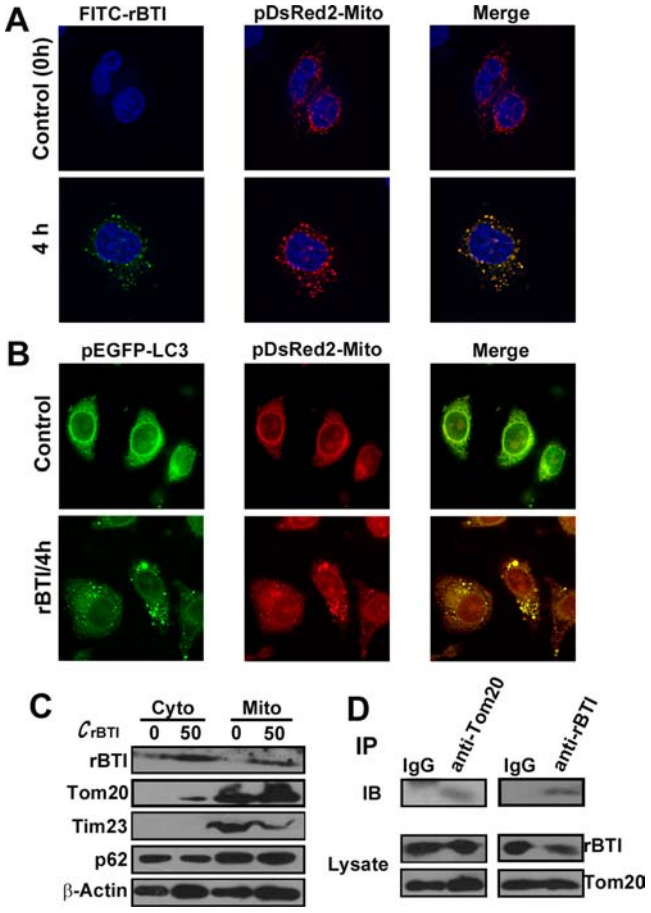

Figure 5. Mitochondrial targeting of rBTI in Hep G2 cells. (A) Colocalization of FITC-BTI with mitochondria. Cells transfected with pDsRed2-Mito are treated with FITC-BTI for 4 h and analyzed by confocal microscopy. (B) Colocalization of GFP-LC3 with mitochondria. Hep G2 cells were cotransfected with pDsRed2-Mito and pEGFP-LC3; after 24 h, thee cells were treated with 50 μg/mL rBTI for 4 h. (C) Western blot analysis of mitochondrial and cytosolic cell fractions. Mitochondrial and cytosolic fractions were obtained using a cell mitochondria isolation kit (Beyotime Institute of Biotechnology) after being treated with 50 μg/mL rBTI for 2 h in Hep G2 cells. These fractions were then analyzed by Western blot for the endogenous proteins Tom23, Tom20, and p62. β-Actin was used as a loading control, and rBTI in each fraction was also blotted. (D) Co-immunoprecipitation of rBTI with endogenous Tom 20 in Hep G2 cells after being treated with 50 μg/mL rBTI for 2 h in Hep G2 cells.

state by increasing enzymatic activity. When Hep G2 cells were treated with rBTI and NAC, the level of autophagy was drastically decreased. These results show that ROS induced by rBTI was mild and transient and that these kinds of ROS are important signaling molecules needed to induce the formation of autophagosomes.

Mitophagy promotes turnover of dysfunctional mitochondria that would otherwise damage the cell. Loss of mitochondrial membrane potential and mitochondrial fragmentation precede mitophagy,[4,29] suggesting that this plays a role in their selective uptake by autophagosomes. Indeed, mitochondrial depolarization plays a direct role in activating Parkin-dependent mitophagy by inducing PINK1 kinase stabilization at the OMM.[30,31] Mitochondrial membrane depolarization also induces proteolytic cleavage and degradation of the fusion protein Opa-1. This in turn decreases the size of mitochondria and is likely to favor uptake of mitochondria by phagophore membranes, while also linking mitochondrial turnover to loss of function.[32,33]

The duality of autophagy function in cancer (both pro- and antitumorigenic) makes it clinically questionable to generically target the entire autophagy process. Basal levels of mitophagy are important for maintaining cellular homeostasis and protecting cells against accumulation of dysfunctional mitochondria. However, enhanced levels of mitophagy can lead to excessive removal of mitochondria, loss of cardiac myocytes, and development of heart failure. Because tumor cells already produce increased ROS compared to normal cells,[34] the combined effect of increased ROS and reduced mitochondrial metabolism arising from inhibition of mitophagy may be synergistic and promote efficient tumor cell killing. Cancer cells decreased mitochondrial activity and instead shift to aerobic glycolysis for ATP production, a phenomenon known as the Warburg effect. An alternative approach may be to combine mitophagy inhibition with drugs that induce other forms of mitochondrial stress signaling, such as metformin that inhibits respiratory chain complex I or with antibiotics, such as tetracycline and doxcycline that inhibit mitochondrial protein translation, thereby inducing a "mitonuclear" protein imbalance and a mitochondrial unfolded protein response that might be predicted to depend on mitophagy to clear damaged and dysfunctional mitochondria.[35,36] With overwhelming mitochondrial damage, apoptosis becomes dominant, and inactivation of critical proteins of the autophagy pathway allow for cell death. Sodium valproate inhibits mitochondrial respiration and leads to mitochondrial dysfunction, oxidative stress, and increased cell death.[37] Shikonin could accumulate in the mitochondria of cancer cells, disrupt mitochondrial function, and lead to apoptosis.[38] Hence, drugs that induce mitochondrial dysfunction could have some potential for cancer treatment.

In summary, our results indicate that rBTI directly targets the mitochondria of cancer cells, disrupts mitochondrial function, and stimulates ROS production, resulting in mitophagy to remove dysfunctional mitochondria. In addition, rBTI could induce mitochondrial fragmentation and may therefore have potential as a mitochondria-penetrating peptide for use in the treatment of cancer.

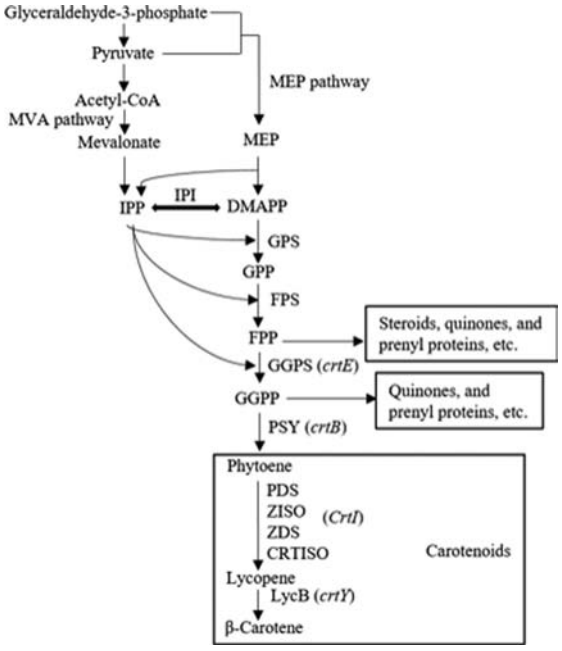

Figure 1. Isoprenoid biosynthetic pathway in the chloroplasts of plants and algae. IPP and DMAPP are synthesized using MVA and MEP pathways. MEP, 2-C-methyl-D-erythritol-4-phosphate; IPP, isopentenyl pyrophosphate; DMAPP, dimethylallyl pyrophosphate; GPP, geranyl diphosphate; FPP, farnesyl pyrophosphate; GGPP, geranylgeranyl diphosphate; IPI, isopentenyl pyrophosphate isomerase; GGPS, geranylgeranyl diphosphate synthase; PSY, phytoene synthase; PDS, phytoene desaturases; ZDS, ζ-carotene desaturases; ZISO, 15-cis-ζ-carotene isomerase; CRTISO, carotenoid isomerase; and LycB, lycopene β-cyclase. *CrtB*, *crtE*, *crtI*, and *crtY* encode the corresponding genes in bacteria.

The unique ability of *D. bardawil* to accumulate very large amounts of β-carotene under defined experimental conditions makes it an excellent choice for studying the intermediates of carotenoids. *PSY*[16] and *ZDS*[17] from *D. bardawil* and *PDS*[18] from *Dunaliella salina* have been isolated and characterized. In this study, *GGPS* from *D. bardawil* (*DbGGPS*) was first cloned and characterized. Then, heterologous expression using pET32a plasmid and functional complementation of *DbGGPS* using plasmids pACCRT-EIB and pACCAR16Δ*crtX* in *E. coli* were carried out to identify the cDNA encoding functional GGPS. This provides new gene sources for carotene genetic engineering and is helpful for understanding carotene biosynthesis.

MATERIALS AND METHODS

Algal Strains and Cultivation Conditions. The green algae *D. bardawil* was obtained from the Institute of Hydrobiology, Chinese Academy of Science. *D. bardawil* cells were grown in defined medium[19] containing 2 mol/L NaCl at 26 °C in a controlled chamber for 10−14 days and 8000 lx provided by cool-white fluorescent lamps, under a 16/8 h light/dark cycle with shaking at 96 rpm.

Bacterial Strains and Plasmids. *Escherichia coli* DH5α was used as the host for the multiplication of plasmids. The plasmids pACCRT-EIB and pACCAR16Δ*crtX*[8] were kindly provided by Norihiko Misawa, professor at Ishikawa Prefectural University, Japan.

Cloning of GGPS from *D. bardawil*. The total RNA was prepared from 8 mL of *D. bardawil* cells grown at the late log phase with Trizol reagent (Life Technology) according to the manufacture's instructions. The reverse transcription (RT) reaction was performed with the parameters set as 42 °C for 60 min followed by 70 °C for 5 min, according to the RevertAid First Strand cDNA Synthesis Kit (Thermo Scientific). To clone the *DbGGPS* cDNA, two degenerate primers (5′-ATGMGHTAYTCNBTDYTNGC-3′ and 5′-DSCRAT-RWAVTYNGCHARVSC-3′) were designed on the basis of the two conserved amino acid regions (upstream MRYSLLA and downstream AKYIGYR, Figure S1) from the GGPS protein sequences of several species (*Dunaliella viridis*, ADL16411.1; *Chlamydomonas reinhardtii*, XP_001703169.1; *Volvox carteri* f. *nagariensis*, XP_002953468.1; *Arabidopsis thaliana*, NP_195399.1; *Chrysanthemum boreale*, AGU91431.1; *Nicotiana tabacum*, ADD49734.1; *Croton sublyratus*, BAA86284.1; *Adonis palaestina*, AAV74395.1; *Taxus Canadensis*, AAD16018.1; *Cistus incanus* subsp. *Creticus*, AAM21638.1), then the expressed sequence tag (EST) of *DbGGPS* was acquired.

Then, on the basis of the switching mechanism at the 5′ end of the RNA transcript (SMART) technique, 5′-RACE PCR was performed using a modified oligo (dT) primer, 5′ SMARTer II A Oligonucleotide primer, and the SMARTScribe Reverse Transcriptase (a variant of MMLV RT) (BD Clontech). On the basis of the obtained EST of *DbGGPS*, two gene specific primers (5′-TCCTCTCCGTAC-ACCTTGTGGTTGGTGG-3′ and 5′-TGTCCCCTCCGACTAATT-CACAGGCAGC-3′) were designed to carry out the 5′ RACE-PCR. The following gradient PCR program was used: initial denaturalization at 95 °C for 3 min, followed by 5 cycles of 94 °C for 30 s and 72 °C for 3 min; another 5 cycles of 94 °C for 30 s, 70 °C for 30 s, and 72 °C for 3 min; a final 20 cycles of 94 °C for 30 s, 68 °C for 30 s, and 72 °C for 3 min; and last, 72 °C for 5 min. For nested PCR of 5′-RACE, the following PCR program was used: initial denaturalization at 95 °C for 3 min, followed by 25 cycles of 94 °C for 30 s, 68 °C for 30s, and 72 °C for 3 min; and last, 72 °C for 5 min.

3′-RACE was performed using the RNA PCR Kit (AMV) Ver. 3.0 (TaKaRa) according to the following protocol: RT reaction was implemented to synthesize the first strand of cDNA using Oligo dT-Adaptor Primer supplied. The first PCR of 3′-RACE was primed by a specific upstream primer (5′-TGCGGACGACGTGACAGTGGA-3′) and Oligo dT-Adaptor Primer supplied by the manufacturer. For nested PCR of 3′-RACE, the primers used were as follows: another specific upstream primer (5′-CCTCGCGTTCCAGGTGGTTGA-3′) and Adaptor Primer (5′-GTTTTCCCAGTCACGAC-3′). The PCR procedure was as follows: 1 cycle of 94 °C for 5 min; 30 cycles of 94 °C for 30 s, annealing temperature for 30 s, and 72 °C for 1 min/kb.

All of the amplified fragments were cloned to pCR2.1 vector (Life Technology) and transformed into *E. coli* DH5α for multiplication, then sequenced before further experiments.

Genomic DNA Isolation from *D. bardawil* and Manipulation. Genomic DNA extraction from *D. bardawil* cells in the log or late log phase was performed according to the E.Z.N.A.HP Plant DNA Kit. Genome walking was implemented with gene-specific primers to identify the genomic DNA of *DbGGPS* (as for the primers, data not shown). The initial PCR was fulfilled using gene-specific primers complemented with 3′-UTR of *DbGGPS* and genomic DNA as template. Subsequently, additional gene-specific primers were synthesized for genome walking on the basis of the initial PCR product. Genome walking was carried out by genome walking kit (TaKaRa). All the manipulations were on the basis of the user manual.

Bioinformatics Analysis. Sequence analysis was performed using BLAST software (http://blast.ncbi.nlm.nih.gov/). Component analysis of ACL was calculated using DNAStar software 7.1.0. Multiple alignments among similar enzymes were conducted using ClustalX 1.83. The open reading frame (ORF) of DbGGPS was predicted by ORF Finder on NCBI (http://www.ncbi.nlm.nih.gov/gorf/gorf.html). Physical and chemical features of DbGGPS were analyzed by the ProtParam tool (http://expasy.org/tools/protparam.html). Subcellular localization was predicted by TargetP 1.1 Server (http://www.cbs.dtu.dk/services/TargetP/). Conserved domains in DbGGPS were detected using the Conserved Domains Search tool (http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi). Protein domains, families, and functional sites were predicted by Prosite (http://prosite.expasy.org/). The protein secondary structures were predicted by Phyre2 (http://www.sbg.bio.ic.ac.uk/phyre2/html/page.cgi?id=index). The 3D structure of DbGGPS was automatically predicted by 3D-JIGSAW Protein Comparative Modeling Server (http://bmm.can-

cerresearchuk.org/~3djigsaw/), and the results were visualized by RasMol software 2.7.2.1.1.

Construction of Plasmid for DbGGPS Expression in *E. coli*. The coding region of a cDNA of DbGGPS was amplified by PCR using specific primers *Eco*RI-GGPS (5′-TCCGAATTCATG-GCCGCCCATCAAATGCA-3′) with an *Eco*RI site and *Xho*I-GGPS Rev (5′-GTGCTCGAGGTTTTGGCGGTAGCCAATGT-3′) with an *Xho*I site, respectively. The PCR product was purified, digested with *Eco*RI and *Xho*I, and then ligated to expression vector pET32a, which was predigested with the same restriction enzymes. The resulting recombinant plasmid pET32a-DbGGPS was then sequenced to confirm for the insertion of the ORF. Subsequently, the expression plasmid pET32a-DbGGPS was transformed into the host strain *E. coli* BL21 (DE3) for protein expression.

A single colony of *E. coli* BL21 cells harboring the expression plasmid pET32a-DbGGPS was inoculated at 37 °C in Luria−Bertani (LB) medium containing ampicillin (100 mg/L) and inoculated with shaking (200 rpm) at 37 °C until the optical density OD_{600} reached about 0.6. Then, the protein expression was induced by addition of IPTG (isopropyl-*β*-D-thiogalactoside) to a final concentration of 0.6 mM. The cultivation was continued for 4 h. The expression levels of the protein were assessed by analyzing total protein on SDS-PAGE followed by Coomassie Brilliant Blue R250 staining. A single colony of *E. coli* strain BL21 cells harboring the expression plasmid pET32a was used as control.

Functional Complementation Expression of DbGGPS in *E. coli*. The plasmid pACCRT-EIB contains the gene cluster *crtE*, *crtI* and *crtB*, and the *E. coli* DH5*α* harboring the plasmid pACCRT-EIB can produce lycopene. The plasmid pACCAR16Δ*crtX* contains the gene cluster *crtE*, *crtI*, *crtB* and *crtY*, and the *E. coli* DH5*α* harboring the plasmid pACCAR16Δ*crtX* can produce *β*-carotene.

The plasmids pAC-IBΔ*crtE* and pAC-IBYΔ*crtE*, where the *crtE* encoding GGPS had been deleted, were constructed in this study and used as the control. The linearized pAC-IBΔ*crtE* (or pAC-IBYΔ*crtE*) was amplified from pACCRT-EIB or pACCAR16Δ*crtX* by using the primers 5′-TCGGGCTGTCCTTATAAACGGA-3′ and 5′-TAAG-GATGCTGCATGAGCCATTTC-3′. The plasmids pAC-IBΔ*crtE* and pAC-IBYΔ*crtE* were constructed by incubation the linearized sequences with T4 DNA ligase (Takara) at 16 °C for 30 min, respectively, and then transformed in *E. coli* DH5*α*, respectively.

To test if *DbGGPS* encoded the anticipated functional protein, the plasmids pACCRT-*DbGGPS*-IB and pACCRT-*DbGGPS*-IBY were constructed from the corresponding plasmids pACCRT-EIB and pACCAR16Δ*crtX*, where *crtE* was replaced by *DbGGPS* using In-Fusion Enzyme (Clontech). The primers (5′-ATAAGGACAGCC-CGA**ATG**GCCGCCCATCAAATGCAGC-3′ and 5′-CATGCA-GCATCCTTA**CTA**GTTTTGGCGGTAGCCAATG-3′) for amplifying the *GGPS* sequence were designed with 15 bp (5′) extensions that are complementary to the ends of the linearized vector. The carotenoids were extracted from the transformants mentioned above.

Extraction of Carotenoids from *E. coli*. For *E. coli* cells biomass analysis, first *E. coli* cells (200 mL) were cultivated in LB medium with shaking (200 rpm) at 37 °C overnight. The absorbance values of the *E. coli* cultures (using blank medium diluted into different proportion; 1:1, 1:2, 1:5, 1:10, and 1:15) were read at 600 nm in a spectrophotometer, and a corresponding concentration of blank medium without *E. coli* was used as the control sample. For *E. coli* biomass dry weight measurement, an *E. coli* sample (100 mL) was harvested by centrifugation at 10 000 g for 2 min, washed twice with distilled water, and dried at 80 °C to a constant weight (24 h). Then, the relationship curve between *E. coli* OD_{600} and cell dry weight was obtained.

For extraction of carotenoids from *E. coli*, first *E. coli* samples (10 mL) were taken from each culture media after mixing thoroughly. Cells were harvested by centrifugation at 12 000 g for 2 min. Then, the cell pellets were washed twice with distilled water and mixed with 2 mL of acetone. The mixtures were shocked for 1 min and incubated for 15 min at 55 °C in the dark, then centrifuged for 20 min at 14 000 g to recover the supernatant with the pigment until colorless. Acetone extracts were collected and subsequently filtered through a 0.2 *μ*m hydrophobic fluorophore membrane (Sigma-Aldrich).

Analysis of Carotenoids. Carotenoid content was analyzed using the high-performance liquid chromatography (HPLC) method. Lycopene (or *β*-carotene) was separated using an Agilent HPLC system equipped with a Welch Ultimate XB-C18 column (250 mm × 4.6 mm, 120 Å) with an isocratic solvent system consisting of acetonitrile/methanol/isopropanol (45:10:45) at a flow rate of 1.2 mL/min at a wavelength of 473 (or 453) nm. The standards used were lycopene (95%) and *β*-carotene (95%), which were obtained from Sigma.

RESULTS

Isolation and Characterization of the *DbGGPS* cDNA. For the EST isolation of *DbGGPS*, according to the multiple sequences alignment result (Figure S1), a 768 bp fragment (Figure 2A) was isolated by RT-PCR reaction, and BLAST results showed high homology to *Dunaliella viridis GGPS* mRNA (HM114366.1) with 82% identity (632 identified nucleotides), indicating that the EST was from GGPS of *D. bardawil*. Furthermore, RACE manipulations were carried out to obtain the 5′ and 3′ ends of *DbGGPS* cDNA. Two fragments were recovered corresponding to the 5′ and 3′ ends, respectively, with lengths of 556 bp (Figure 2B) and 804 bp (Figure 2C). Sequence assembly revealed a 1814 bp cDNA of *DbGGPS*. ORF search found a 1074 bp (Figure 2D) coding

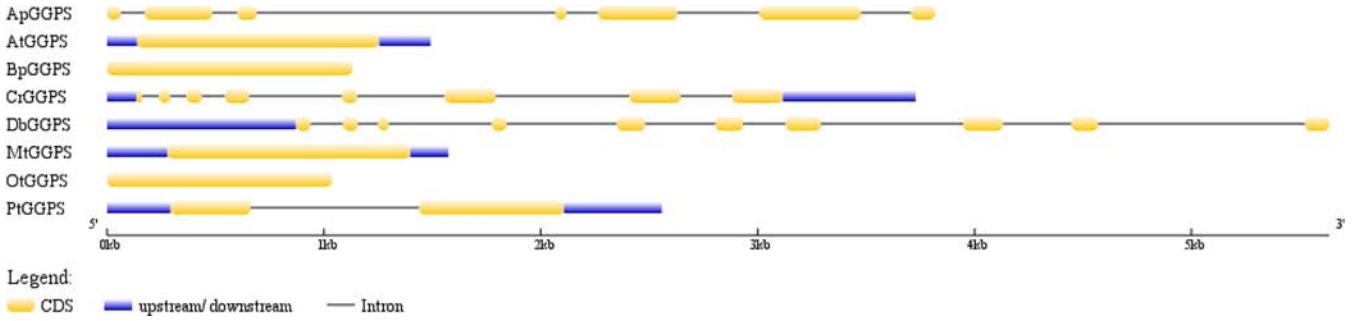

Figure 3. Distribution of exons and introns in the genomic DNA of GGPS. The sequences used for analysis are as follows: GGPS from microalgae, *DbGGPS* (in this study); ApGGPS, *Auxenochlorella protothecoides* (NW_011934251.1); BpGGPS, *Bathycoccus prasinos* (NC_024002.1) ; CrGGPS, *Chlamydomonas reinhardtii* (NW_001843980.1); OtGGPS, *Ostreococcus tauri* (NC_014437.1); GGPS from plants, AtGGPS, *Arabidopsis thaliana* (CP002687.1); MtGGPS, *Medicago truncatula*, (AC137839.19); and PtGGPS, *Populus trichocarpa* (NC_008475.2).

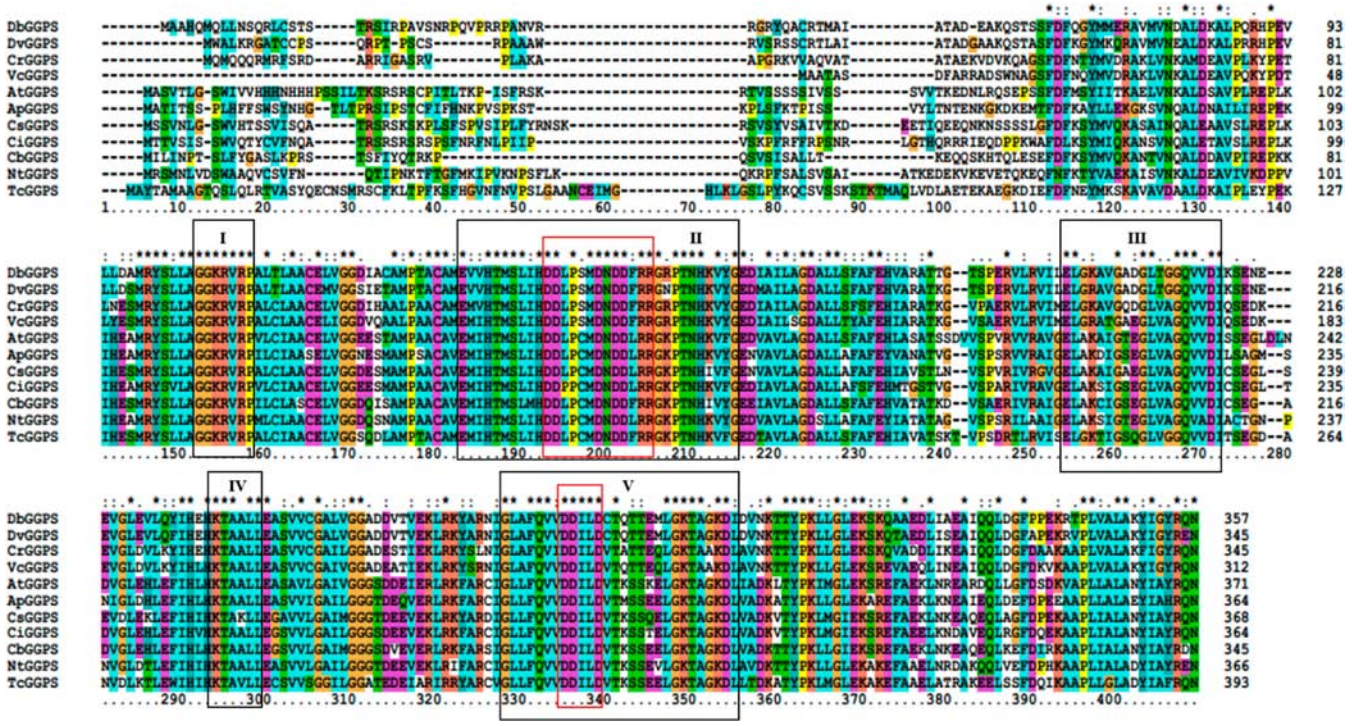

Figure 4. Alignment of amino acid sequences of DbGGPS and other algal and plant GGPSs. The following sequences were used for comparison: DbGGPS, GGPS from *D. bardawil* in this study; DvGGPS, *D. viridis* (HM114366.1); CrGGPS, *Chlamydomonas reinhardtii* (XP_001703169.1); VcGGPS, *Volvox carteri f. nagariensis* (XM_002953422.1); AtGGPS, *Arabidopsis thaliana* (NM_119845.3); ApGGPS, Adonis palaestina (AY661706.1); CsGGPS, *Croton sublyratus* (AB034249.1); CiGGPS, *Cistus incanus* (AF492022.1); CbGGPS, *Chrysanthemum boreale* (KC202428.1); NtGGPS, *Nicotiana tabacum* (GQ911583.1); and TcGGPS, *Taxus canadensis* (AF081514.1). The conserved domains were boxed in black and numbered (I, II, III, IV and V). The highly conserved aspartate-rich motif in the II and V domains of the GGPSs were boxed in red.

sequence (CDS) encoding 357 amino acids, which displayed 294 and 237 identical amino acids (88 and 77% homology, separately) with those of *D. viridis* and *C. reinhardtii*, respectively.

Analysis of the Genomic Structure of *DbGGPS*. The required genomic sequence of *DbGGPS* was 5636 bp. It contained a 4765 bp coding region (from ATG to TAA) and 871 bp upstream of the coding region. Analysis of the nucleotide sequence of the cloned genomic DNA fragment indicated that *DbGGPS* contained 10 exons interrupted by 9 introns, which is much more complicated than other algal and plant *GGPS* genes (Figure 3). As shown in Figure 3, some algal GGPS genomic DNA sequences were intron-rich (such as GGPS from *Auxenochlorella protothecoides*, *Chlamydomonas reinhardtii*, and *D. bardawil*), whereas some had no introns (such as GGPS from *Bathycoccus prasinos* and *Ostreococcus tauri*). Plant GGPS genomic DNA also seemed to be intronless, i.e., having no introns. The total length of the introns was 3691 bp, about 3.44-fold of the total length of exons (1074 bp). The average *DbGGPS* intron was about 410 bp in length. Each intron started with GT and ended with AG, belonging to the most common style of exon.

Sequence Analysis. On the basis of the analysis of the nucleotide sequence, we demonstrated that the *DbGGPS* full-length cDNA contained 1814 bp nucleotides with a 1074 bp long putative ORF, flanked by a 183 bp long 5′ untranslated region upstream of the start codon and a 557 bp long 3′ untranslated region after the stop codon. The 1074 bp putative ORF encoded a 357 amino acid peptide. Analysis by ProtParam

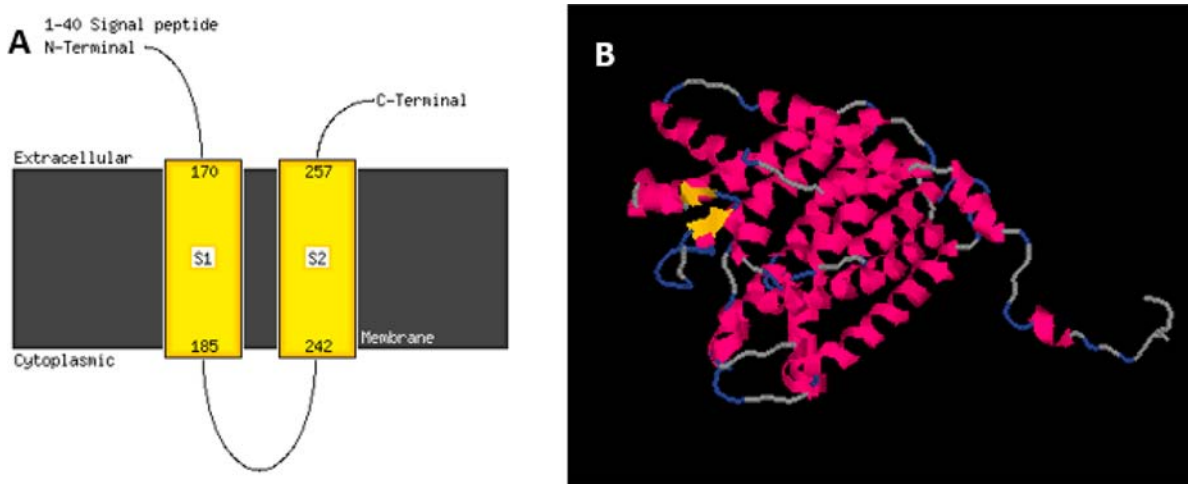

Figure 5. Schematic representations of transmembrane protein structure prediction and 3D model of the DbGGPS. (A) Transmembrane protein structure prediction of DbGGPS. (B) 3D model of the DbGGPS. Comparative modeling was performed using 3D-JIGSAW based on homologues of known structures automatically. The structures were visualized using RasMol version 2.7.2.1.1. The α-helix region of the putative protein is indicated with pink ribbons. Two TM-helix regions were indicated with yellow arrows. The loop regions are also indicated in the schematics.

tool revealed that the molecular weight of DbGGPS was 38.88 kDa and that the isoelectric point was 6.27.

The predicted amino acid sequence of DbGGPS has high similarity to other algal and plant GGPS (56−88%). Amino acid sequences of GGPSs from other algal and plant species were aligned according to the algorithm of the ClustalW, and the result was shown in Figure 4. Five domains (from I to V) found in the same relative locations as those described for prenyltransferases[20] were also identified in all the aligned sequences. Domains II and V contained aspartate-rich motifs (ARMs), referred to as the first ARM (FARM, $DD(X)_4D$) and the second ARM (SARM, $DD(X)_2D$)), respectively, that were proposed to be diphosphate-binding sites.[20] Domain II represented a longer region that contained highly conserved DD (Asp) and RR (Arg) dipeptides, $DD(X)_9RR$ (Figure 4). The DDXXD motif in domain V was the most conserved region and was proposed to be an allyl isoprenoid binding site.[21] Both $DD(X)_9RR$ and DDXXD motifs were important for the catalytic activity of GGPS.[21] In addition, two polyprenyl synthases signatures (at positions 143−159 and 275−287 in DbGGPS amino acid sequence) have been predicted by the Prosite tool, and they corresponded to ARMs. GGPS can be classified into three types on the basis of their amino acid sequences.[11] Type-I GGPS found in archaea have only two amino acids inserted in the FARM (DDXXD) and one aromatic amino acid residue at the fifth position upstream from the FARM. Plant and eubacterial (type-II) GGPS possess four amino acids inserted in the FARM. However, this type of GGPS lacks an aromatic amino acid residue at the fifth position upstream from the FARM. Type-III GGPS, found in eukaryotes (except plants), contain two inserted amino acids in the FARM and also lack an aromatic amino acid residue at the fifth position upstream from the FARM. Plant and algal GGPS are type-II GGPSs because the FARM is $DD(X)_4D$, as shown in Figure 4.

Conserved domains analysis using the NCBI Conserved Domain Database (Figure S2) showed that the deduced protein DbGGPS was conserved in substrate binding sites, active sites, catalytic center, and two aspartate-rich regions. However, there was little homology among the N termini of other GGPSs because these regions encoded plastidial transit peptides in which amino acid sequences varied much.[22] The predicted DbGGPS transit peptide was identified by TargetP, showing that DbGGPS had a 48 amino acid transit peptide at its N terminus to target to the plastids.

Protein Structure Prediction. The protein secondary structure was predicted by Phyre2. As shown (Figure S3), there were 70% α-helix regions, no β-sheet regions, 19% disordered regions, and 9% transmembrane (TM)-helix regions in DbGGPS. The schematic view of the transmembrane protein structure prediction was shown in Figure 5A. An ~40 amino acid signal peptide at the N terminus of DbGGPS was predicted, which was very close to the prediction of TargetP tool. Two TM-helix regions were at the positions 170−185 and 242−257 in DbGGPS amino acid sequence, which corresponded to the two yellow arrows in the 3D structure of DbGGPS predicted by 3D-JIGSAW (Figure 5B).

Heterologous Expression of DbGGPS in *E. coli* BL21 (DE3). To express DbGGPS, the gene was cloned into the plasmid pET32a to construct pET32a-DbGGPS. Upon induction by IPTG, DbGGPS was expressed as a major protein product in the total cellular protein (Figure 6). SDS-PAGE patterns of total cellular protein, visualized by Coomassie

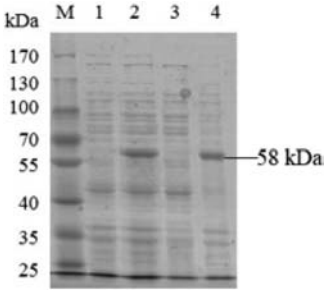

Figure 6. Expression of DbGGPS in pET32a vector analyzed by SDS-PAGE. M, molecular mass standards; lane 1, control (*E. coli* transformed with pET32a); lane 2, total protein extract of *E. coli* transformed with pET32a-GGPS after 4 h of IPTG induction; lane 3, soluble cytoplasmic fraction of *E. coli* transformed with pET32a-GGPS treated with IPTG; and lane 4, insoluble fraction of *E. coli* transformed with pET32a-GGPS treated with IPTG.

The absorbance maximum of lycopene is at a wavelength of 473 nm. (F) Absorption spectrum of β-carotene. The absorbance maximum of β-carotene is at a wavelength of 453 nm.

Brilliant Blue R250 staining, showed that recombinant protein (pET32a-DbGGPPS) expression was achieved at 4 h after IPTG induction. The molecular weight of the expressed recombinant protein was estimated to be about 58 kDa fused with ~20 kDa of tags (two His·Tags, one Trx·Tag, and one S·Tag). Therefore, the size of expressed DbGGPS protein was predicted to be 38−39 kDa, which was in good agreement with that predicted by bioinformatics method (38.88 kDa). It was also found that the recombinant protein was expressed in insoluble fraction of the total bacterial cultures as an inclusion body. The expression and purification of the DbGGPPS protein would be a preparation for investigating its detailed function and facilitate the future research in *D. bardawil*.

Functional Complementation of DbGGPS in the *E. coli* Transformants. Functional activity of expressed GGPS was investigated by genetic complementation with the carotenogenic *crt* gene cluster. Carotenoids are produced in *E. coli* harboring a *crt* cluster gene from *E. uredovora*. Replacements of a *crt* gene with an unknown gene with the same activity can be used to determine the function of the gene. Herein, the

DOI: 10.1021/acs.jafc.5b02732
J. Agric. Food Chem. 2015, 63, 7805−7812

DbGGPS gene was used to replace *crtE* to construct the plasmids pACCRT-*DbGGPS*-IB and pACCRT-*DbGGPS*-IBY, and the plasmids pAC-IBΔ*crtE* and pAC-IBYΔ*crtE* were used as the control, respectively. All the plasmids were transformed into *E. coli* DH5α. The characteristics of the plasmids and the transformants has been listed in Table 1. The pink color of carotenoid was observed in the transformants *E. coli* DH5α/pACCRT-EIB and *E. coli* DH5α/pACCRT-*DbGGPS*-IB, and the carotenoids of the transformants were lycopene (Figure 7A). The yellow color of carotenoid was observed in the transformants *E. coli* DH5α/ pACCAR16Δ*crtX* and *E. coli* DH5α/pACCRT-*DbGGPS*-IBY, and the carotenoid produced by the transformants was β-carotene (Figure 7B). *E. coli* cells do not produce lycopene or β-carotene but can produce IPP and DMAPP, which are the essential precursors of carotenoids,[23] so a tiny bit of pink color was seen in *E. coli* DH5α/pAC-IBΔ*crtE*. However, no carotenoids could be detected in the transformants *E. coli* DH5α/pAC-IBΔ*crtE* and *E. coli* DH5α/pAC-IBYΔ*crtE* by HPLC (Table 1 and Figure 7C,D). All these results suggested that *DbGGPS* can substitute the *crtE* gene, and the coding region of a cDNA of *DbGGPS* encodes a functional GGPS. However, the lycopene production in *E. coli* DH5α/pACCRT-*DbGGPS*-IB was decreased by 77.86% relative to that in *E. coli* DH5α/pACCRT-EIB (Table 1 and Figure 7C). The β-carotene production in *E. coli* DH5α/pACCRT-*DbGGPS*-IBY was decreased by 89.80% relative to that in *E. coli* DH5α/pACCAR16Δ*crtX* (Table 1 and Figure 7D). These results indicated that that the function of DbGGPS expressed in *E. coli* was not as effective as that of *crtE* from *E. uredovora*.

DISCUSSION

Traditionally, GGPS enzymatic activity can be detected in *E. coli* cell extracts or by color complementation assay.[2] The gene encoding GGPS was constructed into a prokaryotic expression vector, such as pBluescript II SK(−)[13,24] and pQE30.[11] Then, the resulting plasmid and the plasmid carrying the *Erwinia uredovora crt* gene cluster from which the *crtE* gene (encoding GGPS) was deleted were used to cotransform into *E. coli*. The resultant *E. coli* transformant could produce carotenoid. One example was that carotenoid production was observed in *E. coli* harboring pACCAR25Δ*crtE* from *E. uredovora* and plasmid carrying *C. forskohlii* GGPS.[24] In this study, just one plasmid carrying the *E. uredovora crt* gene cluster in which the *crtE* gene (encoding GGPS) was replaced with *DbGGPS* was used to transform into *E. coli*, and the transformant still can produce corresponding carotenoids. Although we found that *E. coli* harboring the plasmid with *crtI*, *crtB*, *crtY* (or no *crtY*), and DbGGPS can produce fewer corresponding carotenoids than that harboring pACCRT-EIB and pACCAR16Δ*crtX*, *DbGGPS* has been verified to encode a functional protein and played an important role in carotenoid pathway flux.

As for the reason why fewer carotenoids were produced in *E. coli* harboring the plasmid with *crtI*, *crtB*, *crtY* (or no *crtY*), and *DbGGPS*, it may be that the SD sequence and promoter of the gene *crtE* cannot identify the expression of DbGGPS effectively. Codon optimization of *DbGGPS* or the eukaryotic expression system may solve this problem. (Over)expression of genes involved in carotenoid biosynthesis has been studied in detail in *E. coli*.[25−27] Recently, (over)expression of genes involved in carotenoid biosynthesis in yeast and algae have been paid attention. It was reported that expression of PSY from *Dunaliella salina* in *Chlamydomonas reinhardtii* under the control of the RBCS2 and HSP70A promoters caused the stable production of the corresponding PSY transcript and a significant increase in the content of carotenoids.[28] As for the overexpression of GGPS, it seemed to have a limitations of the carotenoid pathway.[29] It was reported that maximum astaxanthin biosynthesis could be achieved by engineered *Xanthophyllomyces dendrorhous* that overexpressed the enzyme GGPS in combination with advantageous cultivation conditions like dim light illumination of and enhanced air supply.[29]

In contrast, as a very first step toward the genetic manipulation of the terpenoid pathway, overexpression of GGPS is rarely manipulated alone. Among the genes involved in the carotenoid biosynthetic pathway, GGPS is a key gene that produces the general key precursor for carotenoid and a potential target for metabolic engineering. Besides carotenoids, FPP and GGPP are essential precursors for a variety of products including steroids, diterpenes, and quinones (Figure 1).[30] It was reported that the expressions of three key enzymes of the general isoprenoid pathway, IPI, FPS, and GGPS, resulted in an increase in the final carotenoid accumulation in *Mucor circinelloides*.[31] GGPS catalyzes the ultimate non-carotenoid-specific step in the pathway, participating not only in the synthesis of the carotenoids but also in that of the quinones and the prenyl groups of several proteins. It seems more important for enhancement of the IPP and DMAP supply, so genetic manipulation of GGPS is usually coupled with that of the enzyme IPI. The introduction of GGPS and IPI from *Blakeslea trispora* increased the β-carotene content in *E. coli* from 0.5 to 0.95 mg/g dry weight.[32] Another report has shown that genetic engineering of the complete carotenoid pathway (expression of the genes of 3-hydroxymethyl-3-glutaryl coenzyme A reductase, GGPS, phytoene synthase/lycopene cyclase, and astaxanthin synthase) resulted in extremely high astaxanthin accumulation in *Xanthophyllomyces dendrorhous*. This could also be achieved in algae like *Chlamydomonas* and *Dunaliella*.

We have successfully cloned the GGPS gene from the unicellular alga *Dunaliella bardawil*. GGPS catalyzed the production of GGPP, a key precursor for carotenoid biosynthesis. The successful isolation and verified activity of the DbGGPS gene will enable us to regulate an important step involved in carotenoids biosynthesis by genetic engineering in the future. Also, a new way to determine the function of the unknown gene involved in carotenoids biosynthesis was provided by replacing the *crt* gene from *E. uredovora* in the plasmid (pACCRT-EIB, pACCAR16Δ*crtX*, or pACCAR25Δ*crtX*) with an unknown gene.

[a]The contents of the mineral elelments are presented as milligrams per kilogram in the milled rice. P, phosphorus; K, potassium; Mg, magnesium; Ca, calcium; Zn, zinc; Mn, manganese; and Cu, copper.

were selected for three generations based on genotyping of polymorphic markers located in the target QTL region. Three new RHs with sequential heterozygous segments, which jointly covered the entire QTL region, were identified. The three plants were each selfed to produce a NIL-F_2 population, from which 20 non-recombinant homozygous plants, including 10 maternal and 10 paternal homozygotes, were selected. Selfing seeds of these plants resulted in the development of three NIL sets, which were segregated in the intervals RM4923−RM19410, RM19410−Si2950, and Si2944−RM204 and named TF6-2, TF6-15, and TF6-17, respectively (Figure 1).

Field Experiments. The rice lines were planted in the paddy field at the China National Rice Research Institute, Hangzhou, Zhejiang, China. For each line, 12 plants were grown in one row with spacing of 16.7 cm between plants and 26.7 cm between rows. While 243 RILs were tested without replication, the NILs were planted in two replications with a randomized complete block design. Field management followed the normal agricultural practice. At maturity, seeds from five middle plants of each row were harvested.

Phenotype Determination. The grains were dried to a moisture content of about 13% and stored at room temperature for 3 months. They were then dehulled on a Satake Rice Machine (Satake Co., Tokyo, Japan). After polishing on a desktop rice miller (NSART, Sangyong Machinery Industry Co., Jungu, South Korea), the milled rice was ground into flour using a Cyclotec 1093 Sample Mill (Foss Tecator, Sweden) and passed through a 100-mesh sieve. The rice flour was stored at 4 °C.

Extraction of macro- and microelements was conducted by a digestion method. In briefly, about 0.50 g of rice flour and 5 mL of ultrapure nitric acid were added to a Teflon digestion vessel and then put on the microwave digestion instrument (CEM Mars, Matthews, NC). The digestion procedure was set as the followings: raising from room temperature to 120 °C, 0−5 min; holding at 120 °C, 6−7 min; raising from 120 to 180 °C, 8−17 min; and holding 180 °C, 18−32 min. After cooling to room temperature, the solution was transferred to a 50 mL volumetric flask and diluted to 50 mL with deionized water. The contents of P, K, Ca, Mg, Mn, Zn, and Cu were determined by inductively coupled plasma−atomic emission spectrometry (ICP−AES, Thermo Elemental, Franklin, MA) at the wavelengths of 213.6, 766.5, 183.8, 280.3, 257.6, 213.9, and 324.8 nm, respectively. The contents of elements were calibrated using the certified standards in rice flour samples (GBW10010, CRM Rice) obtained from the National Institute Center of Standards. Results were presented as milligrams per kilogram of rice flour. All of the determinations were conducted in duplication.

Marker Genotyping. A total of 16 DNA markers as shown in Figure 1 were used in the NIL development. Total DNA was extracted following the method of Zheng et al.[15] Polymerase chain reaction (PCR) amplification was performed according to Chen et al.,[16] and the products were visualized on 6% non-denaturing polyacrylamide gels using silver staining. All of the SSR markers were selected from the Gramene database (www.gramene.org). InDel markers Si2944 and Si2950 were designed according to the difference between ZS97 and MY46 detected by whole-genome re-sequencing. Primers used were 5′-AAACCACAAGATTAGGCTCTAAGT-3′ for Si2944-F and 5′-AAGTGAGGGAAACCACATTCTAC-3′ for Si2944-R and 5′-AGGCACTCACAACCATAAC-3′ for Si2950-F and 5′-TAGTACATGACAATGGAGCTATC-3′ for Si2950-R.

QTL Mapping. A linkage map has been constructed for the ZS97/MY46 RIL population, consisting of 256 DNA markers and spanning 1814.7 cM.[17,18] QTL analysis was performed with the Composite Interval Mapping (CIM) and Multiple Interval Mapping (MIM) of the Windows QTL Cartographer 2.5.[19] Candidate loci were selected with CIM using a threshold of log of odds (LOD) > 2.5 and tested with MIM using the Bayesian Information Criterion (BIC) default value $c(n) = \ln(n)$. Those showing significant effects were claimed as putative QTLs and designated as proposed by McCouch and the Committee on Gene Symbolization, Nomenclature and Linkage (CGSNL).[20]

For each of the three NIL sets, two-way analysis of variance (ANOVA) was conducted to test phenotypic differences between the two genotypic groups using SAS procedure general linear model (GLM) as described by Dai et al.[21] Given the detection of significant difference ($p < 0.05$), the same model was applied to estimate the

DOI: 10.1021/acs.jafc.5b02882

additive effect of the QTL and the proportion of phenotypic variance explained by the QTL.

RESULTS AND DISCUSSION

Phenotypic Performance of the RIL Population. Descriptive statistics of the mineral contents in milled rice of the ZS97/MY46 RIL population are presented in Table 1. Large variations with strong transgressive segregation were observed for all of the traits. While the contents in the female parent ZS97 were higher for macroelements (P, K, Mg, and Ca) and lower for microelements (Zn, Mn, and Cu) than in the male parent MY46, the parental differences were small compared to the variations among the RILs. Although the contents of macroelements were higher than that of microelements, the coefficients of variation were similar among the seven elements. In comparison to the mineral contents in brown rice determined for 304 *indica* landraces and 28 *indica* improved cultivars,[22] the contents in milled rice measured in our study were much smaller for P, K, Mg, Ca, and Cu but comparable for Zn. Consistent content of Zn in brown and milled rice was also found when more reports were compared,[6,9,11,23,24] along with the higher contents of P, K, Mg, Ca, and Cu in brown rice.[6,11,23] These results are in accordance with the understanding that most of the mineral elements are concentrated in the outer part of the rice grain but Zn has an relatively even distribution.[12,13,25,26] For the remaining element tested in our study, Mn, no consensus could be achieved because the content in brown rice had a large variation ranging from 7.3 to 35.0 mg/kg.[6,8,11,22,23]

Correlation coefficients between the contents of P, K, Ca, Mg, Mn, Zn, and Cu of the 243 RILs were all highly significant ($p < 0.01$), indicating the feasibility of improving these elements simultaneously in rice grain. The coefficients between the three elements having the largest contents, P, K, and Mg, were larger than those between the microelements. While the largest coefficient of 0.851 was observed between K and Mg, the lowest value of 0.213 was found between K and Cu (Table 2). In a previous QTL mapping for mineral contents using an interspecific cross,[6] all seven elements analyzed in our study were included and tested for 2 years. Of the 42 correlations between the seven elements, 24 were positively significant and the others were not significant. While correlations between the macroelements were all significant, Zn was not significantly correlated with other elements in 1 or 2 years and Cu was only significantly correlated with one element in 1 year. In another study using an inter-subspecific cross, positively significant correlations were found between P, Mn, Zn, and Cu, except that Mn was not significantly correlated with Zn and Cu.[10] It seems that positively significant correlations between the contents of different elements in rice grain are more achievable in populations that are less diverse.

Table 2. Coeffcients of Correlation between the Seven Traits in the RIL Population

trait[a]	K	Mg	Ca	Zn	Mn	Cu
P	0.621[b]	0.750[b]	0.515[b]	0.608[b]	0.495[b]	0.354[b]
K		0.851[b]	0.320[b]	0.268[b]	0.415[b]	0.213[b]

Ca				0.596[b]	0.689[b]	0.432[b]
Zn					0.448[b]	0.580[b]
Mn						0.415[b]

[a]The contents of the mineral elelments are presented as milligrams per kilogram in the milled rice. P, phosphorus; K, potassium; Mg, magnesium; Ca, calcium; Zn, zinc; Mn, manganese; and Cu, copper. [b]$p < 0.01$.

QTLs Detected in the RIL Population. A total of 20 QTLs distributed on six chromosomes were detected for the seven traits (Table 3 and Figure 2). The proportion of phenotypic variance explained by a single QTL (R^2) ranged from 4.2 to 11.8%.

For the contents of macroelements P, K, Mg, and Ca, the numbers of QTLs detected were 2, 3, 1, and 3, respectively. All of these QTLs, except *qCa5*, had the enhancing allele derived from the male parent MY46. Of the two QTLs for phosphorus content, *qP3* explained 11.8% of the phenotypic variance with an additive effect of 114.78 mg/kg, which were much larger than the values of 4.3% and 67.11 mg/kg estimated for *qP1*, respectively. It is also noted that the only QTL detected for magnesium content, *qMg3*, had the same location and allelic direction as *qP3*. The three QTLs for potassium content showed little difference in the magnitude, along with the three QTLs for calcium content. While the R^2 of *qK1*, *qK6.1*, and *qK6.2* ranged from 4.5 to 6.7% with the additive effects ranging from 45.19 to 55.06 mg/kg, the R^2 of *qCa5*, *qCa6* and *qCa10* ranged from 4.3 to 6.6% with the additive effects ranging from 3.33 to 4.27 mg/kg.

For the microelements Mn, Zn, and Cu, the numbers of QTLs detected were 4, 5, and 2, respectively. The QTL having the largest effect for manganese content, *qMn6*, was located at a region close to marker RM190 for the *Wx* gene on the short arm of chromosome 6, explaining 10.3% of the phenotypic variance, with the MY46 allele increasing the Mn content by 1.20 mg/kg. Two other QTLs, *qMn1.1* and *qMn1.2*, were linked in repulsion on the short arm of chromosome 1, having slightly lower effects compared to *qMn6*. The remaining QTL for this trait, *qMn11*, had a R^2 of 4.2%, with the MY46 allele decreasing the Mn content by 0.77 mg/kg.

All five QTLs for zinc content, except *qZn11*, had the enhancing allele derived from MY46. The QTL having the largest effect, *qZn3*, explained 11.7% of the phenotypic variance, with an additive effect of 1.59 mg/kg. The four other QTLs had R^2 ranging from 4.4 to 6.5% and additive effects ranging from 0.98 to 1.18 mg/kg. The two QTLs for copper content both had the enhancing allele derived from MY46. While *qCu6* located near RM190 had a R^2 of 11.2% and an additive effect of 0.31 mg/kg, the values estimated for *qCu10* were 7.4% and 0.25 mg/kg, respectively.

Two of the QTL regions described above were shown to be especially important. One was the RZ142−RZ613 interval on the long arm of chromosome 3, in which three QTLs were located, including *qMg3*, the only QTL detected for magnesium, and *qP3* and *qZn3*, the two QTLs having the largest effects for the contents of phosphorus and zinc in the ZS97/MY46 RIL population, respectively. The other was a region near the marker RM190 on the short arm of chromosome 6, in which five QTLs were located, including *qMn6* and *qCu6* having the largest effects for the contents of manganese and copper and *qK6.1*, *qCa6*, and *qZn6* that were associated with the contents of potassium, calcium, and zinc, respectively.

On the basis of the physical position of DNA markers linked to QTLs for mineral contents in rice grain, 12 of the QTLs detected in this study were coincident with those reported previously (Table 3). It is noteworthy that three members of

[a]Additive effect of replacing a maternal allele by a paternal allele. [b]Proportion of phenotypic variance explained by the given QTL. [c]Previous reports in which a QTL for the content of the same elelment in brown or milled rice was detected in a simliar location.

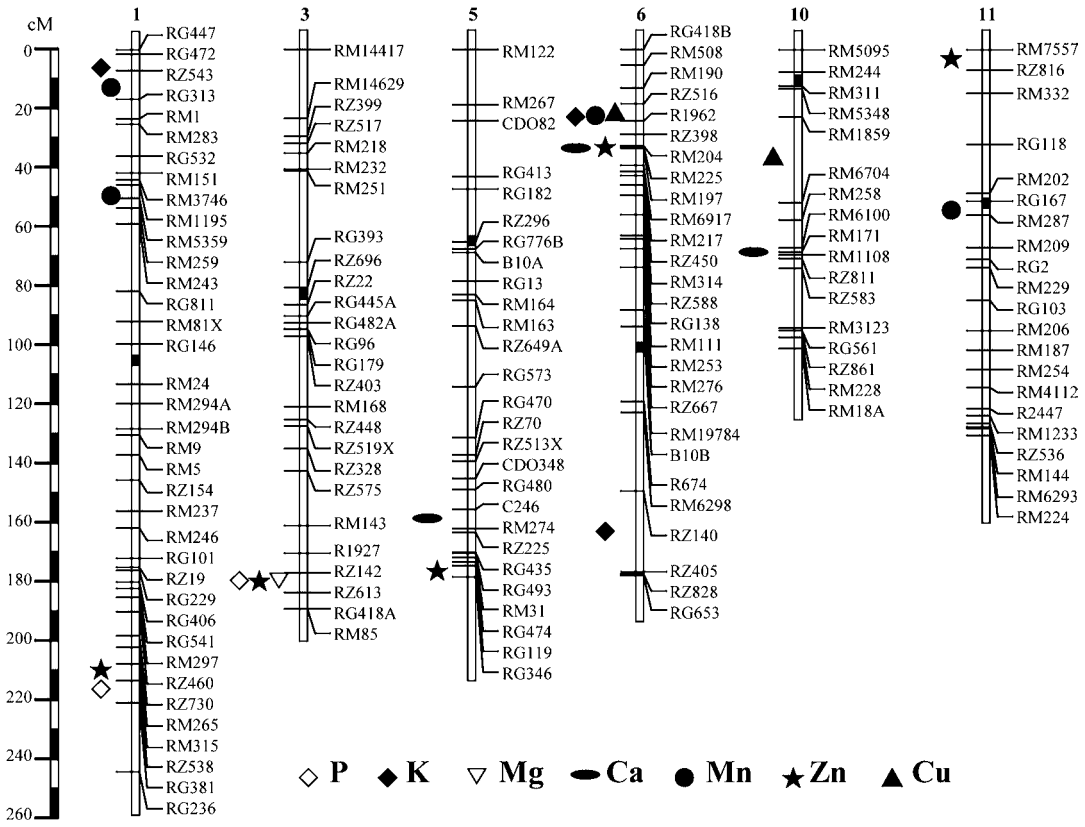

Figure 2. Genomic distribution of QTLs for mineral element contents in milled rice detected in the RIL population of ZS97/MY46.

the QTL cluster *qK6.1/qCa6/qMn6/qZn6/qCu6* have been previously detected, of which *qZn6* was detected for the Zn content in milled or brown rice in three studies[4,7,8] and *qK6.1* and *qCu6* were detected for the contents of K and Cu in brown rice as reported by Du et al.[11] and Garcia-Oliveira et al.,[6] respectively. Because this region was found to be associated with multiple mineral elements in a few independent studies, it was selected for validation and fine mapping.

QTL Fine Mapping Using NILs. Three sets of NILs with sequential segregating regions jointly covering the entire region flanked by RM4923 and RM204 (Figure 1) were used for QTL fine mapping. For NIL sets TF6-2, TF6-15, and TF6-17, which consisted of two homozygous genotypic groups differing in the

[a]Zhenshan 97 homozygote. [b]Milyang 46 homozygote. [c]Additive effect of replacing a maternal allele by a paternal alelle. [d]Proportion of phenotypic variance explained by the given QTL.

regions of RM4923−RM19410, RM19410−Si2950, and Si2944−RM204, respectively, significant phenotypic differences between the two genotypes in the same NIL set would be an indication for allelic difference of a QTL within the segregating region.

Results of the two-way ANOVA are shown in Table 4. In NIL set TF6-15, highly significant effects ($p < 0.0001$) were detected for all seven traits, with the R^2 ranging from 63.13 to 86.63%. In agreement with the five QTLs detected in the RIL population, *qK6.1*, *qCa6*, *qMn6*, *qZn6*, and *qCa6*, the MY46 allele always acted for increasing the mineral contents in TF6-15. In NIL set TF6-2, a small effect with low significance ($p = 0.0123$) was detected for the zinc content and no significant effect was detected for the other six traits. Obviously, the major QTL detected in TF6-15 was not segregated in TF6-2. More work is needed to test whether a minor QTL for mineral contents is located in the segregating region of TF6-2. In NIL TF6-17, small effects with low significance ($p = 0.0419$−0.0109) were detected for the contents of four elements, P, K, Mg, and Mn, with the MY alleles always decreasing the contents. This indicates that a QTL having small effects for mineral content may locate in the segregating region of TF6-17.

On the basis of QTLs detected in the three NIL sets, it could be concluded that a major QTL having pleitropic effects for the contents of multiple elements was located in a region that was segregated in TF6-15 and homozygous in TF6-2 and TF6-17. As shown in Figure 1, this is a region flanked by RM19410 and Si2944, corresponding to a physical distance of 29.9 kb extending from 2 915 081 to 2 945 012 bp on chromosome 6 in the Michigan State University (MSU) Rice Genome Annotation Release 7 (http://rice.plantbiology.msu.edu/). Because the highest R^2 was detected for Zn, *qZn6* was chosen as the name for this QTL.

It is found that three annotated genes were located in the *qZn6* region, including *LOC_Os06g06300* and *LOC_Os06g06320* encoding phosphatidylethanolamine-binding proteins and *LOC_Os06g06310* encoding hypothetical proteins (http://rice.plantbiology.msu.edu/). This region was also located within a QTL region for hull silicon content, flag leaf length, and yield traits.[27,28] This suggested that the same QTL might be responsible for many traits, including mineral contents in milled rice, hull silicon content in the hull, and yield-related traits. Gene cloning is underway to determine the gene responsible for *qZn6*.

ammonia-lyase, chalcone synthase (CHS), chalcone isomerase (CHI), flavanone 3-hydroxylase (F3H), flavonoid 3′-hydroxylase, flavonol synthase (FLS), dihydroflavonol reductase (DFR), and leucoanthocyanidin dioxygenase.[16] Flavonols, anthocyanins, and proanthocyanidins share the same pathway before separating at the point of dihydroflavonol. Then, dihydroflavonols are biosynthesized to anthocyanins or flavonols by DFR or FLS, respectively. In *Arabidopsis*, AtMYB11, AtMYB12, and AtMYB111 activate the expressions of *CHS*, *CHI*, *F3H*, and *FLS1* without having a bHLH partner.[17] In grapevine, VvMYBF1 can regulate *VvFLS1* expression independent of the bHLH transcription factor.[18] However, in maize, *ZmFLS1* expression is controlled by a complex of MYB-bHLH transcription factors.[19] Altogether, these studies indicated that, in some plants, flavonol biosynthesis is regulated by MYB transcription factors with or without the collaboration of the bHLH transcription factor.

In *B. napus*, some flavonoid structural genes have been identified, such as *BnDFR* (GenBank DQ767950), *BnF3H-1* (GenBank DQ288239), *BnCHS* (GenBank DQ767948), and *BnC4H-1* (GenBank DQ485130). However, to the best of our knowledge, no studies on *FLS* genes in *B. napus* have been conducted. Therefore, we attempted to identify the *B. napus FLS* (*BnFLS*) gene, whose cDNA sequences were retrieved from expressed sequence tag (EST) data.[20] Transgenic *B. napus* plants that overexpress *BnFLS* (*BnFLS-ox*) show significantly higher flavonol accumulation than wild-type plants. In this study, we examined whether the cloned putative *BnFLS* is a real *FLS* gene of *B. napus*. To address this question, we overexpressed the *BnFLS* gene in *Arabidopsis atfls1-ko* mutant and found that this gene can complement the lack of the *AtFLS1* gene in terms of flavonol accumulation. By overexpression of the *BnFLS* gene, flavonol (kaempferol and quercetin) levels were recovered in the *atfls1-ko* mutant, while anthocyanin content was lower in this line (*BnFLS-ox/atfls1-ko*) than in *Arabidopsis* wild-type plants. In addition, we found that the higher endogenous flavonol levels of *BnFLS-ox* in vitro shoots correlated with slightly higher ROS scavenging activities. Thus, our results indicate that the *BnFLS* gene encodes for a BnFLS enzyme that can be manipulated to specifically increase flavonol accumulation in oilseed plants and other species such as *Arabidopsis*.

MATERIALS AND METHODS

Plant Materials and Growth Conditions. In this study, *B. napus* L. Hanla was used for all the experiments. Seeds were sterilized and germinated on Murashige and Skoog (MS) medium supplemented with 2% (w/v) sucrose and 0.4% (w/v) Phytagel (pH 5.8), and the following growth conditions were used: 23 °C and 16-h light/8-h dark cycle. For inducible abiotic-stress treatments, 5-day-old seedlings were submerged in MS medium supplemented with the indicated concentrations of sucrose, abscisic acid (ABA), gibberellic acid (GA_3), NaCl, and mannitol for 24 h before use.

RNA Extraction and RT-PCR. Total RNA was extracted from 3-week-old leaves of *B. napus* growing in amplification media, as described by Sánchez and Carbajosa.[21] First-strand cDNA was synthesized using M-MLV Reverse Transcriptase, according to the manufacturer's instructions (iNtRON Biotechnology, Inc., Republic of Korea). PCR was performed using the cDNA and specific primers (Supporting Table 1).

***BnFLS* Cloning and Transformation.** Full-length *BnFLS* cDNA was isolated from *B. napus* Hanla by using RT-PCR and cloned using the pCR8/GW/TOPO TA Cloning Kit (Invitrogen). *BnFLS* was then subcloned into *pEarleyGate202* vector[22] to generate the construct *35Spro:FLAG:BnFLS*.

Agrobacterium-mediated transformation of *B. napus* was conducted according to a previously reported protocol[23] with some modifications. A single colony of *Agrobacterium* was inoculated into 25 mL of LB containing 25 μg/mL of rifampicin and 50 μg/mL of kanamycin and cultured at 30 °C with shaking (200 rpm) for 48 h. *Agrobacterium* cells were spun down and resuspended in MS liquid medium supplemented with 2% sucrose to achieve OD_{650} = 0.5 for generating the infection medium. Cotyledons were cut from 4-day-old seedlings grown in the dark and submerged in the infection medium for 10 min. The infected explants were then regenerated in various types of media, namely, cocultivation medium (2 days), callus induction medium (2 days), shoot initiation medium (2 weeks), shoot outgrowth medium (3 weeks), selection medium (3 weeks), and root initiation medium (3 weeks). Subsequently, the T1 transgenic plants were transferred to soil and grown in green house to collect seeds. These in vitro transgenic plants were also cultured in amplification medium for 3 weeks before further use. Detailed information on all the above-mentioned media is listed in Supporting Table 2.

Measurement of Anthocyanin Levels. Anthocyanin levels were measured according to a previously described method with some modifications.[24] The samples were ground to a fine powder in liquid nitrogen and extracted with 250 μL of methanol and 1% (v/v) HCl at 4 °C overnight. Then, 250 μL of distilled water and 250 μL of chloroform were added to the extracted samples, and the mixtures were vortexed and centrifuged for 5 min at 9 000*g* to separate the anthocyanin-containing phase. The aqueous phase was collected, and OD was measured at 535 and 650 nm. Anthocyanin levels were calculated as $OD_{535} - OD_{650}$/fresh weight (grams).

High-Performance Liquid Chromatography. Three-week old shoots on amplification medium were analyzed by high-performance liquid chromatography (HPLC) using Ultimate 3000 HPLC system (Dionex, Sunnyvale, CA). The flavonol was analyzed on an YMC-Triart C18+ column (4.6 mm × 250 mm, 5 μm) (YMC, Kyoto, Japan) using a mobile phase consisting of 100% methanol and 0.1% formic acid for elution. The flow rate was 0.6 mL/min and injection volume was 10 μL. The temperature was set at 4.5 °C for autosampler and 30 °C for column oven. The UV detector was set at 360 nm. Quercetin and kaempferol were selected as the standard samples.

Antioxidant Activity Measured Using 2,2-Diphenyl-1-picrylhydrazyl (DPPH) Assay. Radical scavenging activity was measured using DPPH assay, as reported previously with some modifications.[25] About 250 mg of the samples were ground in liquid nitrogen and extracted with 1 mL of 70% (v/v) acetone by sonication for 10 min. The samples were then separated to collect the supernatant by a centrifuge and extracted twice more. The supernatants were combined, dried by evaporation, and 1 mL of ethanol was added for resuspension and centrifuged. Then, 100 μL of the supernatant was mixed with 100 μL of DPPH solution (200 μM in ethanol) and maintained for 20 min at room temperature. Radical scavenging activity was shown as the decrease in absorbance at 517 nm because of DPPH radicals from the blank test by using 100% ethanol.

3,3′-Diaminobenzidine (DAB) Staining. In situ detection of hydrogen peroxide was performed by staining with DAB (Sigma-Aldrich), according to an adaptation of a previously reported method.[26] Briefly, the samples were immersed in 1 mg/mL of DAB solution containing Tween 20 (0.05% v/v) and 10 mM sodium phosphate buffer (pH 7) and gently shaken for 4−6 h. The staining reaction was terminated and fixed in 3:1:1 ethanol/glycerol/acetic acid (bleaching solution) placed in a water bath at 95 °C for 15 min. The leaves were reimmersed in the bleaching solution until the chlorophyll was completely depleted and then visualized under white light and photographed.

DBPA Staining. Flavonol accumulation in root tips was observed using DPBA staining, as described previously[27] with some modifications. Briefly, seedlings were stained for 5−15 min by using saturated (0.25%, w/v) DPBA with 0.02% (v/v) Triton X-100 and were then washed three times in distilled water for 5 min. The samples were visualized using a confocal laser scanning microscope (LSM 700, Carl-Zeiss).

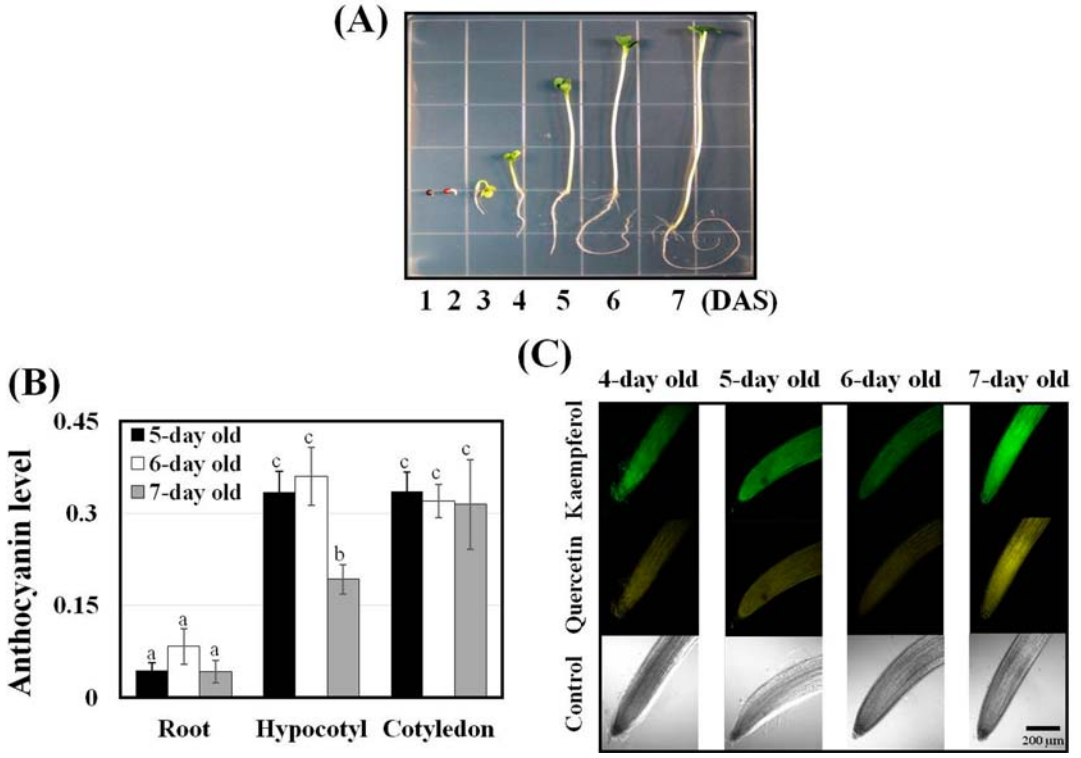

Figure 1. Wild-type *Brassica napus* seedlings and flavonoid accumulation. (A) 1- to 7-day-old *B. napus* L. Hanla seedlings (from left to right). (DAS: day after seeding). (B) Anthocyanin accumulation in various tissues (root, hypocotyls, and cotyledons) of 5-, 6-, and 7-day-old seedlings. Wild-type seedlings were grown under normal conditions for 5, 6, and 7 days and used for anthocyanin measurement. (C) Flavonol accumulation in *B. napus* seedlings. Wild-type seedlings were grown under normal conditions for 5, 6, and 7 days and used for flavonol detection. The experiment was repeated three times and Duncan's tests ($p < 0.05$) were performed. The letters above the columns indicate significant differences. Bars reflect standard errors.

Statistical Analyses. Statistical analyses were performed using Duncan's tests at 95% confidence level.

RESULTS

Flavonoid Accumulation in Wild-Type *B. napus* Seedlings. *B. napus* Hanla seeds were sown on MS medium for germination and grown for 7 days (Figure 1A). To investigate flavonoid accumulation in the oilseed plants, we first detected anthocyanin and flavonol levels in 5-, 6- and 7-day-old wild-type seedlings (Figure 1). As demonstrated in Figure 1B, the anthocyanin levels were not different between 5- and 6-day-old seedlings. Besides, while roots and cotyledons of the 5-, 6- and 7-day-old seedlings showed similar anthocyanin levels, hypocotyls of the 7-day-old seedlings accumulated a lesser amount of anthocyanin than younger seedlings (Figure 1B). Flavonol accumulation in the root tips of the seedlings was observed using DPBA staining. Root-tip tissues displayed green and yellow fluorescence because of kaempferol and quercetin accumulation, respectively. Flavonol levels in the root tips of 4- and 5-day-old seedlings showed no differences, while this accumulation decreased in 6-day-old seedlings and increased in 7-day-old seedlings (Figure 1C). Because anthocyanin accumulation was higher in hypocotyls of 5- and 6-day-old seedlings than in those of 7-day-old seedlings and flavonol accumulation was higher in root tips of 5-day-old seedlings than in those of 6-day-old seedlings, we chose 5-day-old seedlings for stress treatments. Five-day old seedlings were exposed to several stress conditions for 24 h and then used for measuring anthocyanin and flavonol accumulation. Anthocyanin levels increased in response to sucrose, ABA, NaCl, and mannitol treatments, but no difference was observed between GA_3 treatment results and control conditions (Figure 2A,B). In addition, flavonol levels in the root tips increased in response to sucrose, GA_3, NaCl, and mannitol treatments, but no difference was observed between ABA treatment results and control conditions (Figure 2C). These results suggest that flavonoid levels increased in response to salt and drought stress conditions in young *B. napus* seedlings.

Since flavonoids serve as antioxidants, we wanted to check whether stress treatment resulted in increased radical scavenging activity due to enhanced accumulation of flavonoids in *B. napus* seedlings. To measure radical scavenging activity, the DPPH assay was performed using 5-day-old wild-type seedlings grown under stress conditions. As shown in Figure 3, radical scavenging activity was slightly increased in response to NaCl and mannitol treatments, while sucrose, ABA, and GA_3 treatments showed no effects (Figure 3). On the basis of these results, we can conclude that the increase in flavonoid levels is positively correlated with higher radical scavenging activity in response to salt and drought stress conditions.

Isolation of *BnFLS* Gene from Wild-Type *B. napus* Seedlings. Overexpression of *AtPAP1* transcription factor has been reported to result in the enhancement of anthocyanin levels in transgenic *B. napus* plants.[2] Thus, in this study, we aimed to clone a *B. napus FLS* gene to test whether we can specifically increase flavonol levels in *B. napus* by manipulation of *BnFLS*, because flavonols can be used as antioxidants for food and medical purposes. For example, flavonols, including quercetin and kaempferol, are known to have antiproliferative effects on human cancer cells.[14] cDNA fragments of *BnFLS*

mannitol. (C) Flavonol accumulation in the root tips of 5-day-old seedlings. The 5-day-old seedlings were grown under normal conditions and used for indicated treatments; control [MS liquid medium supplemented with 20 g/L of sucrose (2%)], ABA, sucrose, GA_3, NaCl, or mannitol with indicated concentrations in the figure. After 24 h, these seedlings were used for anthocyanin measurement and flavonol detection. The experiment was repeated three times and Duncan's tests ($p < 0.05$) were performed. The letters above the columns indicate significant differences. The letters ("ab" or "bc") above the columns indicate no significant difference with a, b, or c, respectively. Bars reflect standard errors.

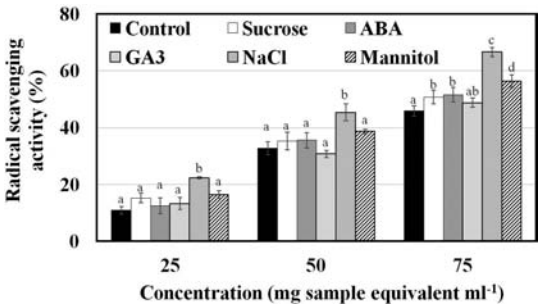

Figure 3. Radical scavenging activity of wild-type *Brassica napus* seedlings in response to various signals. The 5-day-old seedlings were grown under normal conditions and exposed to various signals; control [MS liquid medium supplemented with 20 g/L of sucrose (2%)], 10 μM ABA, 60 g/L sucrose, 20 μM GA_3, 200 mM NaCl, and 200 mM mannitol. After 24 h, these seedlings were subjected for DPPH assay to determine the radical scavenging activity. The experiment was repeated 3 times and Duncan's tests ($p < 0.05$) were performed. The letters above the columns indicate significant differences. The letters ("ab") above the column indicates no significant difference with a or b, respectively. Bars reflect standard errors.

from Expressed Sequence Tag (EST) data[20] were used to design a full-length specific primer pair for this gene. Total RNA was extracted from 5-day-old wild-type seedlings and used for synthesizing a first-strand cDNA library. PCR was performed using this primer set and the cDNA library. The PCR product was then cloned into TOPO vector (Invitrogen) and used to confirm the *BnFLS* sequence (Supporting Figure 1). The putative *BnFLS* sequence was translated to the amino acid sequence, and alignment results showed that BnFLS is highly homologous to BrFLS1 and AtFLS1 (Figure 4). Because the flavonol accumulation in root tips was altered in response to different treatments as shown in Figure 2C, we then examined whether *BnFLS* can be induced by these conditions (Figure 5). As shown in Figure 5, *BnFLS* was highly expressed in response to mannitol treatment. However, expression of *BnFLS* was slightly decreased by sucrose, GA_3, and NaCl treatments.

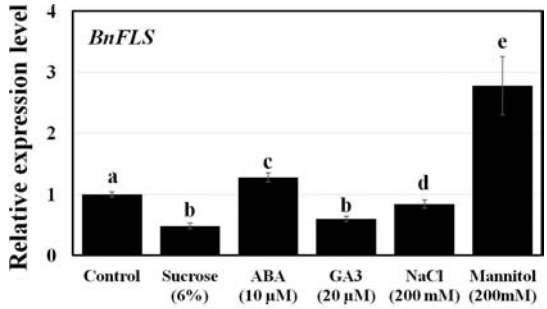

Figure 5. *BnFLS* expression in wild-type *Brassica napus* seedlings in response to various plant growth regulators and stress conditions. The 5-day-old seedlings were exposed to 6% sucrose, 10 μM ABA, 20 μM GA_3, 200 mM NaCl, and 200 mM mannitol for 24 h; mRNA was then extracted to produce cDNA for *qRT-PCR*. The control medium was 2% sucrose. The *BnACTIN* was used for internal control. The primer information was shown in Supporting Table 1.

Complementation Assay to Confirm That *BnFLS* Encodes a Functional FLS Enzyme by Using *Arabidopsis atfls1-ko* Mutant. Although we found that the BnFLS sequence was highly homologous to BrFLS1 and AtFLS1, we needed to examine whether this gene encodes a functional FLS protein. To address this, we introduced *BnFLS* into *Arabidopsis* wild-type (Col-0) and *atfls1-ko* mutant plants. Using the floral-dipping transformation method,[28] we obtained several transgenic plants on Col-0 (*BnFLS/Col-0* #1; #2) and *atfls1-ko* (*BnFLS/atfls1-ko* #1; #2) backgrounds. RT-PCR results confirmed *BnFLS* overexpression in these transgenic plants (Figure 6A). As shown in Figure 6B, flavonol accumulation was

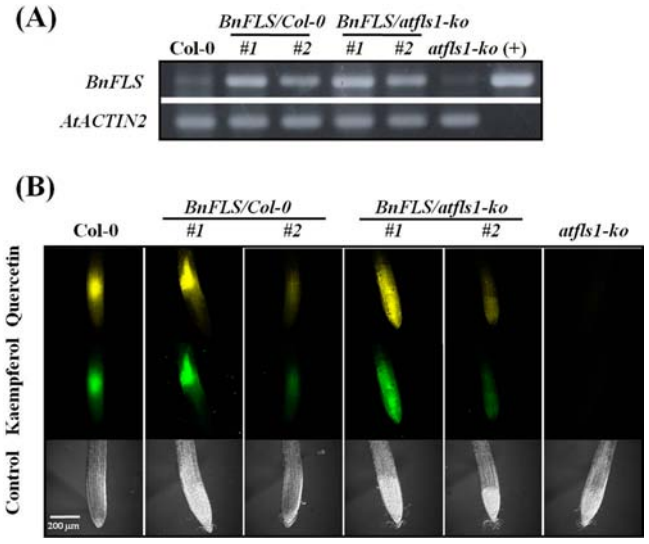

Figure 6. Functional complementation analysis of the *BnFLS*. (A) The *BnFLS* gene was introduced into *Arabidopsis* Col-0 (*BnFLS/Col-0*) as well as the *atfls1-ko* mutant seedlings (*BnFLS/atfls1-ko*) to examine whether this gene can recover the genetic defects of the *atfls1-ko* mutant. Seedlings of the wild-type (Col-0), *BnFLS/Col-0*, *BnFLS/atfls1-ko*, and *atfls1-ko* grown on 1/2× MS medium were used for RNA extraction and *RT-PCR* using specific primers (Supporting Table S1). *ACTIN2* was used as an internal control. (+) indicates the PCR product from bacterial plasmid containing the *BnFLS* gene. (B) Root tips of the wild-type (Col-0), *BnFLS/Col-0*, *BnFLS/atfls1-ko*, and *atfls1-ko* grown on 1/2× MS medium were used for the detection of flavonol by using DPBA staining. *BnFLC: BnFLS* transforms into Col-0; *BnFLf: BnFLS* transforms into *fls1-ko*. The 6-day-old seedlings grown under normal conditions were used for flavonol detection.

observed in root tips of 6-day-old seedlings by using DBPA staining; *BnFLS/Col-0* #1 showed higher flavonol accumulation than Col-0, but *BnFLS/Col-0* #2 showed decreased flavonol levels. In contrast, fluorescence of *atfls1-ko* was less intense, showing lower flavonol accumulation. However, the higher flavonol accumulation of *BnFLS/atfls1-ko* #1 and #2 than *atfls1-ko* confirmed that BnFLS serves as an FLS enzyme.

Generation of Transgenic Seedlings That Ectopically Express *BnFLS*. After confirming the flavonol synthase function of BnFLS, we decided to generate *B. napus* transgenic plants that overexpress the gene. To do this, the cDNA of *BnFLS* was cloned into *pEarleyGate202*,[22] in which the expression of this gene was driven by the cauliflower mosaic virus 35S promoter (*CaMV 35Spro*; Figure 7A). Next, the *35Spro:FLAG:BnFLS* construct was transformed into wild-type *B. napus* Hanla cotyledon samples, according to a method described by Bhalla and Singh.[23] The putative transgenic plants were confirmed using several methods (Figure 7). First, the putative transgenic plants were tested using instant strips that can detect the *BAR* gene product (Figure 7B). Real transgenic lines exhibited two bands instead of only one band, which is indicative of the wild-type as well as nontransgenic plants (Figure 7B). The putative transgenic plants were also examined using PCR with genomic DNA and PCR primers (Figure 7C and Supporting Table 1). In addition, RT-PCR was performed to show that these transgenic plants exhibited increased expression of *BnFLS* (Figure 7D). The expression levels of other genes involved in the flavonoid biosynthesis were similar in the wild type and transgenic *BnFLS-ox* plants (Supporting Figure 2).

Accumulation of Anthocyanins and Flavonols in *B. napus BnFLS-ox* Plants. Transgenic *BnFLS-ox* plants (T_1) were transferred onto amplification medium for further propagation (Supporting Table 2). After 3 weeks of growth on the amplification medium, around 5 new shoots were produced from the original shoot (Figure 8A). These shoots were separated and transferred to MS medium for further experiments. *In vitro* shoots of *Brassica* wild-type and *BnFLS-ox* (#1, #2, #3, and #4 lines) were transferred to MS medium supplemented with sucrose (2% or 6%) for growth and measurement of anthocyanin levels (Figure 8B). As shown in Figure 8B, anthocyanin levels of the wild-type and *BnFLS-ox* (#1, #2, #3, and #4) shoots were not significantly different in response to a low concentration of sucrose (2%). However, a higher concentration of sucrose (6%) increased anthocyanin accumulation in the wild-type samples, while there was no change in the *BnFLS-ox* shoots (Figure 8B). Next, we determined flavonol levels in the *in vitro* shoots by using HPLC (Figure 8C). The results showed that quercetin and kaempferol accumulation was higher in the *BnFLS-ox* line than in the wild-type, but sucrose treatment (6%) slightly decreased flavonol levels in comparison with control conditions (2%; Figure 8C). The transgenic shoots were transferred to MS medium and allowed to produce roots without adding any hormones in order to observe flavonol accumulation by using DPBA staining. As shown in Figure 8D, flavonol content in the *BnFLS-ox* (#1 #2, #3, and #4 lines) increased in comparison to the wild-type.

Next, we checked whether the *BnFLS-ox* plants have increased antioxidative ability because of enhanced flavonol levels. Leaves of the *BnFLS-ox* and wild-type plants growing in the amplification medium were used for DAB staining to check reactive oxygen species (ROS) levels. An intense brown stain indicated that the samples had high levels of ROS (Figure 9). ROS levels were higher in wild-type leaves than in the *BnFLS-ox* leaves, which indicated that the *BnFLS-ox* plants may have higher scavenging activity than the wild-type.

DISCUSSION

Anthocyanins and flavonols are biosynthesized using the flavonoid biosynthesis pathway. In this pathway, dihydroflavonols can be catalyzed to produce anthocyanins or flavonols by DFR or FLS, respectively. In a DFR-defective mutant, accumulation of flavonols is higher than that in wild-type plants,[29] whereas anthocyanin content is higher in the *atfls1-ko* mutant than in wild-type plants.[30,31] Therefore, it is important for plants to decide which enzymes need to be activated on the basis of the conditions. In this study, we cloned a newly isolated *B. napus FLS* and characterized transgenic plants that overexpressed this gene aiming for a high production of

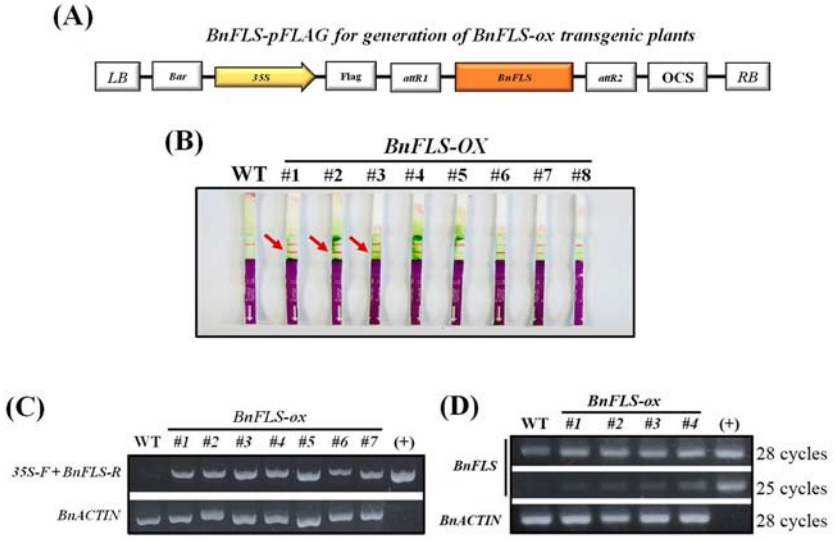

Figure 7. Generation of the *BnFLS* overxepressing transgenic *Brassica napus* plants (*BnFLS-ox*). (A) Construction map of the *35Spro:FLAG:BnFLS* plasmid for the generation of *BnFLS-ox* transgenic plants. *Bar*: Basta resistant gene; *35S*: cauliflower mosaic virus 35S promoter; FLAG: FLAG epitope tag for target proteins; *BnFLS*: *Brassica napus Flavonol Synthase* gene. (B) Selection method of real *BnFLS-ox* transgenic plants; the wild-type or nontransgenic plants showed only one band when instant basta detection strips were used, while real transgenic lines exhibited one additional band indicated with red arrows. (C) Genotyping of the *BnFLS-ox* transgenic plants by using PCR with genomic DNA and specific primers (Supporting Table 1). (D) Three-week-old *BnFLS-ox* transgenic plants were grown under normal conditions and used for RT-PCR to check for *BnFLS* expression level in two different PCR cycles. *BnACTIN* was used for internal control (primer information is listed in Supporting Table 1). (+) indicates the PCR product from bacterial plasmid containing the *BnFLS* gene. WT: wild type.

flavonols. In particular, we intended to redirect the flavonoid biosynthesis pathway by using genetic manipulation to increase the production of specific flavonoids, such as quercetin or kaempferol, in the oilseed plants.

Several genes that encode FLS enzymes have been isolated and characterized from various plant species, including *A. thaliana*,[32] *Ginkgo biloba*,[33] and *Glycine max*.[34] *Arabidopsis* is known to contain 6 *FLS* genes, while several other flavonoid biosynthesis enzymes are encoded by only 1 gene.[32,35] Flavonols such as kaempferol and quercetin exhibit variations in their accumulation levels and tissue specificities under different environmental circumstances, implying the involvement of various *FLS* genes.[17,36,37]

In the current study, anthocyanins accumulated more in the hypocotyls and cotyledons of the wild-type *B. napus* seedlings than in the roots (Figure 1B). This result was expected because it is well-established that anthocyanins have light-protection and light-filtration functions in plants. We observed that anthocyanin levels significantly decreased in 7-day-old seedlings, indicating the younger seedlings may be more active in producing anthocyanins. Young seedlings may be vulnerable to various types of biotic or abiotic agents, resulting in a high production of flavonoids to combat against these attacks like in other plant systems.[38] We observed that the levels of both anthocyanins and flavonols were significantly enhanced in the wild-type in response to several stresses (Figure 2). Interestingly, ABA increased anthocyanin levels but did not affect flavonol accumulation (Figure 2). In contrast, GA_3 did not alter anthocyanin levels but enhanced flavonol accumulation (Figure 2). These plant growth regulators are reported to control flavonoid biosynthesis by regulating the expression levels of certain transcription factor genes.[39,40] For instance, GA_3 inhibits the induction of *DFR* expression by sucrose but barely affects *FLS* expression, while ABA can increase *DFR* expression.[41] Several studies have reported that anthocyanin biosynthesis is promoted by UV-B light in *Arabidopsis thaliana*[42] and *B. rapa*.[43] In many cases, flavonoids serve antioxidants in stress tolerance. Flavonoids have been shown to function as excellent free radical scavengers because they are strongly reactive as hydrogen or electron donors.[44] Previous studies proposed that the radical scavenging activity of flavonoids can be determined by the number and location of the phenolic OH groups in their structure.[44] Overaccumulation of flavonols and anthocyanins was proposed to increase drought stress tolerance and antioxidant activity in *A. thaliana*.[44] This led us to examine radical scavenging activity in *B. napus* plants after stress treatment. Radical scavenging activity was higher in response to salt and drought stress conditions, which appears to be correlated with the increase in flavonoid accumulation in response to various stresses (Figures 2 and 3).

In *B. napus*, several structural genes for flavonoid biosynthesis, such as *BnF3′H*,[45] *BnIS*,[46] and transcription factor genes *BnTT2*,[47] *BnTT16*,[48] have been identified and studied, while no studies have been conducted on *BnFLS*. This prompted us to characterize *BnFLS* and generate *BnFLS-ox* transgenic plants to expand our understanding on the functions of FLS in *B. napus*. On the basis of gene expression data for *B. napus*,[20] we found 2 cDNA fragments of *BnFLS*, which is a homologue of *AtFLS1*. Alignment results of *BnFLS* and *AtFLS1* sequences helped us to deduce the full-length cDNA sequence of *BnFLS* (Supporting Figure 1). On the basis of this sequence, we designed a specific primer pair to amplify and clone *BnFLS* from *B. napus* cDNAs. The sequence of the cloned putative *BnFLS* was checked, and the open reading frame was confirmed to be 1011 bp (Supporting Figure 1). Then, *BnFLS* cDNA sequences were converted into amino acid sequences and aligned again with AtFLS1 and BrFLS1 amino acid sequences. This alignment indicated that BnFLS is highly homologous to BrFLS (98%) and AtFLS1 (91%) (Figure 4). The high homology between

Figure 8. continued

used for anthocyanin and flavonol detection. The experiment was repeated three times and Duncan's tests ($p < 0.05$) were performed. The letters above the columns indicate significant differences. The letters ("ab" or "bc") above the columns indicate no significant difference with a, b, or c, respectively. Bars reflect standard errors. (D) Flavonol accumulation in the root tips of in the wild type and *BnFLS-ox* lines. After growing for 3 weeks in the amplification medium, the roots were used for DPBA staining.

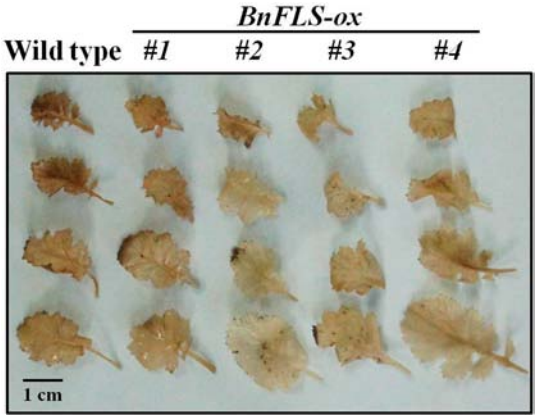

Figure 9. DAB staining of *BnFLS-ox* transgenic plants. Leaves of 3-week old wild type and *BnFLS-ox* (#1, #2, #3, #4 lines) shoots grown in the amplification medium were incubated in liquid medium supplemented with DAB reagent to visualize the ROS levels. Four separate leaves were examined.

BrFLS and BnFLS may be explained by the theory of origin of *B. napus*.[49,50] In addition, *BnFLS* cDNA was transformed into the *Arabidopsis fls1-ko* mutant and was shown to complement the flavonol-lacking phenotype of this mutant (Figure 6B). *Arabidopsis atfls1-ko* showed a strong reduction in flavonol content (Figure 6B) and accumulated higher levels of anthocyanins and glycosylated dihydroflavonols than the wild-type.[30,31,35] However, differences in substrate preference between the enzymes of different plant species or the expression of other flavonol synthase genes may be the reasons why flavonol accumulation in *BnFLS/Col-0* #2 and *BnFLS/atfls1-ko* #2 root tips were lower than that in Col-0.

To characterize the functions of *BnFLS*, we generated *BnFLS-ox* plants and confirmed the expression level of *BnFLS* in these transgenic plants by using RT-PCR (Figure 7C). In addition, we measured anthocyanin and flavonol levels in *BnFLS-ox* transgenic and wild-type seedlings (Figure 8). Higher expression of *BnFLS* in *BnFLS-ox* shoots was related to higher flavonol content (Figure 8C). Anthocyanin levels in 3-week-old seedlings of the wild-type were significantly increased in response to a high sucrose concentration (6%; Figure 8B). However, this high sucrose concentration could not succeed in promoting anthocyanin biosynthesis in the *BnFLS-ox* plants. Because DFR and FLS catalyze the same substrate, overexpression of *BnFLS* led to a higher accumulation of flavonols and resulted in lower anthocyanin levels in these transgenic plants (Figure 8). According to our observations, *BnFLS* overexpression confers increased antioxidative capability to transgenic oilseed plants, because ROS levels were decreased in the *BnFLS-ox* plants (Figure 9). Since high levels of flavonols as well as anthocyanins were suggested to be correlated with increased drought stress tolerance in *A. thaliana*,[44] it would be of great interest to examine *BnFLS-ox* plants in the future.

compositional parameters and the evaluation of their organoleptic significance. Hence, the aim of this work was to characterize the formation of (i) key odorants, (ii) polyphenols, and (iii) lipid from the pistachio cultivar Uzun (*Pistacia vera*) under two different roasting conditions. Moreover, a purge-and-trap method for obtaining an aroma extract was optimized.

MATERIALS AND METHODS

Samples. The Uzun cultivar samples of *P. vera* pistachio nuts from Gaziantep, Turkey, were supplied by a local company. In the same factory, the pistachios were subjected to standard roasting processes to obtain single-roasted (160 °C for 20 min) and double-roasted (160 °C for 22 min) samples and then cooled for 10 min at room temperature. The three types of samples, raw, single-roasted, and double-roasted, were then stored in vacuum-sealed plastic bags prior to analysis. Raw nuts were used as the control to compare against the effect of two different roasting conditions.

Chemicals. Hexane, methanol, acetonitrile, formic acid, dichloromethane, and chloroform were purchased from LabScan (Dublin, Ireland) and Merck (Darmstad, Germany); potassium hydroxide and sodium sulfate-1-hydrate from Panreac (Barcelona, Spain); and 1,2,3-tritridecanoylglycerol (99%) and dilinolein (98%) from Sigma (St. Louis, USA). Reference milk fat butter CRM-519 (EU Commissions; Brussels, Belgium) was purchased from Fedelco Inc. (Madrid, Spain). FAME standards mix GLC-Nestlé36 and tritridecanoin (99%) were from Nu-Chek Prep, Inc. (Elysian, Minnesota, USA). Protocatechuic acid, catechin, chlorogenic acid, eriodictyol-7-*O*-glucoside, rutin, eriodictyol, and luteolin were purchased from Sigma-Aldrich (St. Louis, USA). *n*-Pentanal, α-pinene, 2,3-pentanedione, β-pinene, *N*-methylpyrrole, hexanal, (*E*)-2-pentenal, limonene, methyl pyrazine, styrene, ocimene, furfural, terpinolene, 2,5-dimethyl pyrazine, acetic acid, 2,6-dimethyl pyrazine, 2-ethylpyrazine, 2-ethyl-6-methylpyrazine, 2-ethyl-3-methylpyrazine, acetylfuran, trimethylpyrazine, 2-ethyl-3,5-dimethylpyrazine, 2-ethyl-3,6-dimethylpyrazine, 1-octen-3-ol, γ-butyrolactone, benzaldehyde, furfuryl alcohol, (−)-menthol, 1-methyl-2-pyrrolidinone, p-cymene-8-ol, hexanoic acid, benzyl alcohol, 2-phenylethanol, pyrrole-2-carboxaldehyde, 5-methyl-1*H*-pyrrole-2-carbaldehyde, octanoic acid, *p*-cresol, and 4-ethylphenol were purchased from Sigma-Aldrich (St. Louis, USA). Deionized water was obtained via the Milli-Q water purification system by Millipore Corp. (Saint-Quentin, France). For retention index calculation, mixtures C_8−C_{20} and C_{21}−C_{40} were purchased from Fluka. All other reagents used were of analytical grade.

Phenolic Compounds Analysis and Antioxidant Activity. Extraction of Phenolic Compounds. The extraction of phenolic compounds was carried out according to Tsantili et al.[11] after some modifications. The pistachio samples were ground (with seed coat) with a laboratory blender, and 5 g samples were prepared in duplicate. Each sample was extracted with 15 mL of 85% methanol by mixing with a magnetic stir bar for 2 h. The extract was separated and the solid was washed with 5 mL of 85% methanol. The two extracts were combined, filtered, and evaporated in a vacuum under 20 °C until the volume was reduced to 3 mL. Then, the extract was filtered through a 0.45-μm pore size membrane filter before injection.

HPLC Analysis of Phenolic Compounds. An Agilent 1100 HPLC system (Agilent Technologies, Palo Alto CA, USA) with a diode array detector operated by Windows NT based ChemStation software was used for the phenolic compounds analysis. Separation was performed on a Beckman Ultrasphere ODS column (Roissy, France; 4.6 mm × 250 mm, 5 μm). The mobile phase consisted of water with 5% formic acid (solvent A; v/v) and acetonitrile with 40% solvent A (solvent B; v/v). Phenolic compounds were eluted under the following conditions: 1 mL/min flow rate with the temperature set at 25 °C; isocratic conditions from 0 to 15 min with 0% solvent B; gradient conditions from 0% to 20% solvent B in 30 min; from 20% to 50% solvent B in 40 min; and from 50% to 100% solvent B until 5 min. The wavelengths of the diode array detector (DAD) were set at 280, 320, and 360 nm for monitoring phenolic compounds. The identification of the phenolic compounds was obtained by using authentic standards and by comparing the retention times and spectra.[11] Quantification was performed by external calibration with standards. Concentration was expressed as mg per 100 mg of pistachio sample.

Antioxidant Capacity (DPPH Assay). The electron donation ability of the extract was measured by bleaching of the purple-colored solution of 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical according to the method of Tsantili et al.[11] An aliquot of 0.1 mL of the methanol/water phenolic extract of the pistachio samples (diluted 1/25) was added to 3.9 mL of DPPH solution in methanol (6×10^{-5} M). The mixture was shaken vigorously and left standing at room temperature for 30 min. The absorbance of the resulting solution was then measured at 515 nm after 30 min by a Shimadzu UV-1700 spectrophotometer (Kyoto-Japan). Results were expressed as Trolox equivalent antioxidant capacity. Trolox standard solutions were prepared at a concentration ranging from 1 to 50 μM.

Obtaining of Aroma Extract (Purge and Trap System) and Olfactometric Analysis. The purge and trap system used to carry out the extraction process consisted of a nitrogen source controlled by a flow-meter and connected to a splitter system to divide the flow in several channels in order to purge three samples at the same time. A standard 20 mL vial capped with a crimp cap with a septum was used to contain the solid sample. The needle of the source of N_2 and the cartridge were installed through the septum to purge and trap the aroma compounds. As adsorbent, 200 mg of Lichrolut EN resins from Merck was chosen as the most suitable material for aroma compounds retention according to the literature.[18,19] The temperature of the vial sample was controlled by a thermostated bath. The sample of pistachio, previously shelled and milled with a laboratory blender, was placed into a 20 mL vial (3 g in order to avoid the caking of the solid) removing oxygen from the headspace with nitrogen. The optimized conditions of the purge and trap method were the following: sample was preincubated at the optimized purging temperature (60 °C) for 10 min. The purge and trap process was carried out for 90 min with a nitrogen flow of 500 mL/min. After this was completed, the compounds retained in the cartridge were eluted with 6 mL of dichloromethane at very a slow flow. The eluate was dried with sodium sulfate and concentrated with a Dufton column until 200 μL remained (at 45 °C). β-Ionone and 2-octanol were used as internal standards. The samples were stored at −20 °C until GC analysis. The aroma compounds evaluated for the optimization of purge and trap method belong to different chemical families with a wide range of volatility, and they are presented in Table 1. The repeatability of the purge and trap method for the optimized conditions is also presented in Table 1. For the optimization all experiments were carried out in duplicate with the double roasted sample.

Table 1. Compounds Selected for Optimization of Purge-and-Trap Method

compound	LRI[a]	molecular weight	boiling point (°C)	log *P*[b]	RSD (%)[c]
limonene	1156	136	178	4.57	7.2

GC-FID, GC-MS, and GC-MS-O Analyses of Aroma Compounds. The gas chromatography system consisted of an Agilent 6890 chromatograph equipped with a flame ionization detector (FID) (Wilmington, DE, USA), an Agilent 5973 mass selective detector (MSD) (Wilmington, DE, USA), and a Gerstel ODP-2 (Baltimore, MD, USA) sniffing port. This system allowed us to simultaneously obtain a FID signal, MS signal (for the identification), and the odor

DOI: 10.1021/acs.jafc.5b02576
J. Agric. Food Chem. 2015, 63, 7830−7839

characteristics of each compound detected in the sniffing port. The oven temperature of the DB-Wax column was first held at 40 °C (for 10 min) and then increased from 40 to 160 °C at a rate of 3 °C/min and then to 240 °C at 6 °C/min, with a final hold at 240 °C for 25 min. The pressure of the column was constant at 20.0 psi and 3 μL was injected in pulsed splitless mode. The MS (electronic impact ionization) conditions were ionization energy of 70 eV, mass range m/z of 33−350 amu in combined SCAN/SIM mode. Contents of volatile compounds were expressed as relative peak area to internal standard (β-ionone). Retention index were calculated by injection of commercial mixtures of alkanes.

Aroma Extract Dilution Analysis (AEDA). Olfactometric analysis was carried using two experienced sniffers. For AEDA, the concentrated aromatic extract (200 μL) of the pistachio samples was stepwise diluted 1:1 using dichloromethane as the solvent to obtain dilutions of 1:2, 1:4, 1:8, 1:16, with dilutions continuing through 1:512. Odor evaluation of the dilutions was continued until no odorant could be detected by GC-O. Each odorant was thus assigned a flavor dilution factor (FD factor) representing the last dilution in which the odorants was still detectable. The identification of aroma compounds was carried out by comparison with the mass spectra of commercial compounds (when available) and with the mass spectra of NIST library.

Lipid Profile Analysis. *Isolation of Lipids.* Shelled pistachios (40 g) were carefully cut into small pieces. Samples were then crushed into fine particles at 8000 rpm using an ultraturrax T25 (Ika-Werke, Staufen, Germany). A portion equaling 3 g was transferred into a 50 mL glass falcon tube (Vidrafoc, Barcelona, Spain), and lipids were isolated according to the Folch method modified by Iverson et al.[20] Finally, extracts were centrifuged (5 min, 8000g) to avoid impurities and chloroform removed by using rotatory evaporation. Then, lipids were accurately weighed. Extraction was carried out in triplicate.

Analysis of Triacylglycerols and Diacylglycerols. Triacylglycerols (TG) and diacylglycerols (DG) were analyzed on a CLARUS 400 gas chromatograph (PerkinElmer, Massachusetts, USA) equipped with FID detector and a Rtx-65TG column (30 m × 0.25 mm × 0.10 μm; Restek Corporation, Bellefonte, Pennsylvania, USA) using injector, detector, oven temperature and chromatographic conditions as prescribed by Fontecha et al.[21] Response factors were calculated by the injection of CRM-519 and dilinolein. Under these conditions, the limits of quantification (LOQ) were 1.14 mg TG/mL (R^2 = 0.9996) and 1.22 mg DG/mL (R^2 = 0.9993). Injections were performed in triplicate.

Analysis of Fatty Acid Methyl Esters. For the determination of the fatty acid composition, samples measuring 25 mg were added with tritridecanoin (200 μL, 1.24 mg/mL) and derivatized to fatty acid methyl esters (FAME) with 2 N methanolic KOH solution according to the International Dairy Federation procedure (ISO-IDF, 2002).[22] FAME were analyzed (1 μL; 1:10 split ratio) in a 6890 Agilent GLC (Palo Alto, California, USA) equipped with a MS detector (Agilent 5973N), fitted with a CPSil-88 capillary column (100 m × 0.25 mm id × 0.2 μm film thickness, Chrompack, Middelburg, Netherlands). The MS conditions were 250 °C transfer line temperature; 230 °C source temperature; 150 °C quad temperature; electron impact ionization of 70 eV; and scan operational mode, 50−550 Da. Oven temperature program and conditions were set according to Rodríguez-Alcalá et al.[23] Response factors were calculated by injection of GLC-Nestlé36. Under these conditions, the limit of quantification (LOQ) was 0.05 μg/mL (R^2: 0,9991). All analyses were carried out in triplicate.

Statistical Analysis. In a first instance all data were first subjected to an exploratory analysis to test normal distribution and homogeneity of variance. Thus, results regarding composition of volatiles and phenolics as well as antioxidant capacity were submitted to the one-way analysis of variance (ANOVA). Version 7.1 of STATISTICA for Windows was used for data processing (StatSoft, Inc., 2005, www.statsoft.com).

For the lipid profile, data were analyzed according to ANOVA with the Bonferroni test as a follow-up in order to evaluate statistical differences among groups using version 22 of IBM SPSS Statistics for Mac (IBM, Armonk, NY). For all the analysis the level of significance was set to $p < 0.05$, while $0.05 < p < 0.1$ was established as the trend.

RESULTS AND DISCUSSION

Phenolic Composition and Antioxidant Capacity of Pistachios. The phenolic acids and flavonoids identified in hydroalcoholic extracts of raw, single-roasted, and double-roasted pistachios are presented in Table 2. A total of seven phenolic compounds (protocatechuic acid, catechin, chlorogenic acid, eriodictyol-7-*O*-glucoside, rutin, eriodictyol, luteolin) were detected and quantified. The total phenolic content increased alongside the heat treatment in the samples, with the double-roasted nuts having the highest total phenolic compound content (42.4 mg/100 g fw). These results are in line with similar studies conducted using other types of nuts such as peanuts and almonds.[24,25] Thermal processing may release more bound phenolic acids from the breakdown of cellular constituents, although disruption of cell walls also releases the oxidative and hydrolytic enzymes that can destroy the antioxidants in fruits and vegetables.[26]

Table 2. Phenolic Compounds and Antioxidant Capacity of Pistachios (mg/100 g fw)[a]

compound	raw	single-roasted	double-roasted
protocatechuic acid	3.14 ± 0.26 a	3.96 ± 0.05 b	8.59 ± 0.33 c
catechin	4.81 ± 0.52 a	8.64 ± 1.48 b	8.72 ± 0.82 b
chlorogenic acid	4.96 ± 0.13	3.99 ± 0.78	5.79 ± 0.09
eriodictyol-7-*O*-glucoside	4.10 ± 0.42	3.64 ± 1.15	3.91 ± 0.35
rutin	3.01 ± 0.12 a	3.51 ± 0.10 b	5.43 ± 0.10 c
eriodictyol	2.17 ± 0.04	2.19 ± 0.01	2.67 ± 0.28
luteolin	0.78 ± 0.01 a	0.72 ± 0.02 a	1.22 ± 0.06 b
total	26.2 ± 1.2 a	32.4 ± 1.0 b	42.4 ± 1.9 c
antioxidant capacity (μmol of TE g of fw)	8.05 ± 0.21	9.76 ± 0.22	11.5 ± 2.0

[a]Different letters in a row for significant effect of processing ($p < 0.05$).

The phenolic acids in the pistachios were protocatechic acid and chlorogenic acid, positively identified by comparing their retention and UV−vis characteristics to commercial standards. Protocatechuic acid varied between 3.14−8.59 mg per 100 g of pistachios. Double-roasted nuts had almost three times as much protocatechuic acid as their raw and single-roasted counterparts, suggesting a liberation of protocatechuic acid during heat processing. Thus, double-roasted kernels contained significantly ($p < 0.05$) more protocatechuic acid than the other samples. Conversely, thermal processing did not affect the content of chlorogenic acid present in pistachio extracts, and there was no significance in the results obtained. In a previous study, Liu et al.[27] quantified the bioactives in the whole nut, nutmeat, and skin of California pistachios and found protocatechuic acid to be between 0.2 and 4.6 mg/100 g fw. Mandalari et al.[28] not only observed that protocatechuic acid concentration increased with heat treatment in pistachios, but also identified a small amount of chlorogenic acid solely in the salted and roasted nuts. The phenolic compounds may differ with respect to their binding status, dependent on specific aspects of their chemical structures. Thus, the most effective processes to release phenolic acids from plant tissues may not be the same.

Major flavonoids identified in the present study were catechin, eriodictyol-7-*O*-glucoside, and rutin, comprising

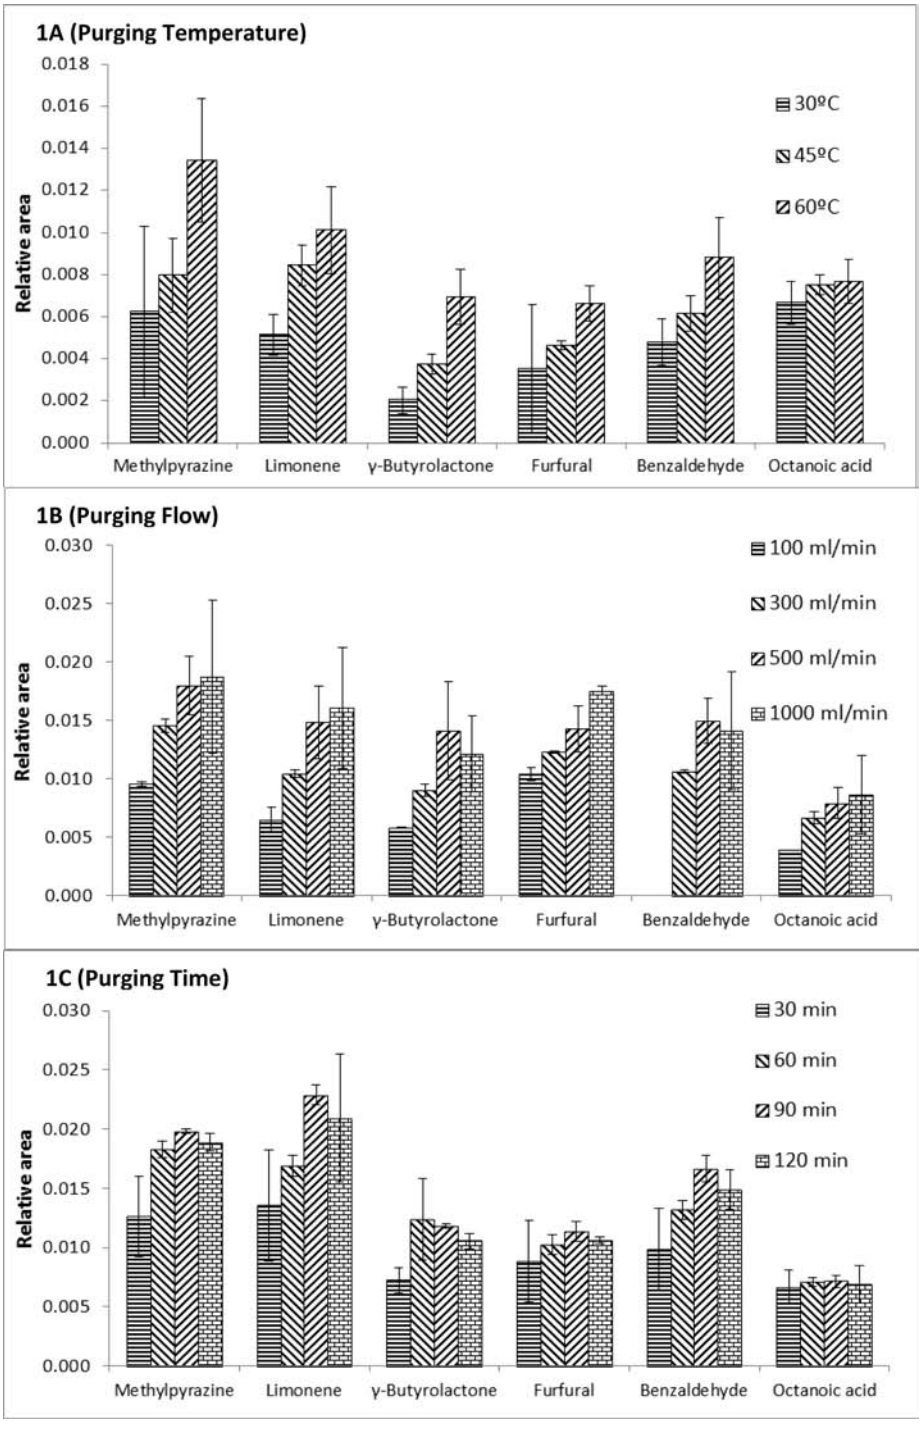

Figure 1. Optimization of the purge and trap method: effect of temperature (1A), nitrogen purging flow (1B), and purging time (1C) on recovery of volatiles from pistachio.

4.81−8.72 mg, 3.1−3.91 mg, and 3.01−5.43 mg per 100 g of pistachios, respectively. Our results shows that double-roasted samples had a 2-fold higher flavonoid content compared to raw and single-roasted nuts. It is well-established that flavonoids are effective natural antioxidants. The results obtained in the HPLC analysis suggest release and isomerization of such compounds during heat treatment of pistachios. Chandrasekara et al.[25] measured the effect of roasting on phenolic content and antioxidant properties of testa-containing and testa-free kernels of cashew nuts. These authors found the highest levels of flavonoids at high-temperature treatments, followed by low-temperature treatments, and last raw samples, which concurs with the present study. Furthermore, Tomanio et al.[8] and Martorana et al.[29] investigated the phenolic composition of pistachio seed and skin obtained from nuts grown in Bronte, Sicily. They quantified rutin as the major phenolic compound of the Bronte variety of *P. vera*.

The antioxidant potential of the pistachio samples was assessed by using the DPPH assay method (Table 2), revealing a slight trend of increasing DPPH values with the roasting process. Similarly, Chandrasekara et al.[25] mentioned that the antioxidant levels of cashew nuts increased as the roasting time

LRI (linear retention index); MS tent. (tentatively identified by MS); std (chemical standard). When only MS or LRI is available for the identification of compounds, it must be considered as an attempt of identification.

and temperature increased. The differences in antioxidants among the three pistachio samples could be explained by their phenolic content and composition differences. Phenolic compounds with antioxidant properties are lost during the roasting of the nuts; nonetheless, the antioxidant levels of the nuts is partially restored by the development of compounds possessing more antioxidants.[30] These compounds were reported as the intermediate Maillard reaction products (MRPs), as well as the resultant melanoidins, characterized by high antioxidant levels and related to the presence of reduction-type structures. Together with oxidation, condensation, and complexation of polyphenol compounds, and following suit to protein and starch hydrolysis, the Maillard reaction involves not only the reduction of sugars and amino acids but also the production of carbonyl compounds from lipid oxidation.[31,32]

Optimization of Purge-and-Trap Method to Obtain Pistachio Aroma Extract. The initial conditions were chosen based on the literature[7,18] (60 °C for sample incubation, 300 mL/min of N_2 purge flow and 60 min purging time). The results of the optimization of each parameter, purge temperature, purge time, and nitrogen flow are presented in Figure 1 (*Y*-axis units are expressed as relative peak area to 2-octanol). As expected, an increase in peak areas from 30 to 60 °C was observed (Figure 1A) because most of the compounds presented have high boiling points (>115 °C). Although higher temperatures would produce more sensitive extractions, 60 °C was fixed as the maximum temperature to avoid any sample changes during testing time.[7] As observed in Figure 1B, the nitrogen purge flow generally increased the extraction efficiency between 100 mL/min and 500 mL/min. After 500 mL/min the extraction efficiency fluctuated slightly up and down until 1000 mL/min. In order to avoid loss of compounds or no retention on the cartridge, 500 mL/min was chosen. Finally, after the temperature and flow were fixed (60 °C and 500 mL/min N_2), the effect of purging time was evaluated (Figure 1C). As can be observed, the peak areas show a steady increase until 90 min and then either remain constant or experience a slight drop-off. On the basis of these results, optimal conditions were set with temperature at 60 °C and flow at 500 mL/min for 90 min.

In order to increase the sensitivity of the method in the olfactometric analysis, the dichloromethane extracts of two samples were combined, and the volume was reduced to 200 μL. Under these conditions, the error (Table 1) of the method is less than 10% for most of the compounds except for the less volatile octanoic acid (17.9%). These results showed that the method allowed aroma extraction of the volatile and semi-volatile compounds of pistachio with an acceptable repeatability. In the case of compounds with a high molecular weight, high boiling point, and high/low hydrophobic constant, the method showed some variations. However, the compounds with lower volatility and higher molecular weight would most likely have negligible significance at the sensory level.

Volatile Composition of Pistachios. The analysis of the aroma extracts by GC-MS and a deep study of the chromatograms has allowed tentative identification via mass spectrometry of numerous volatile compounds in the three sample types: raw, single-roasted, and double-roasted. The results are shown in Table 3 as relative peak areas to β-ionone. As can be seen, 39 compounds were identified in the raw sample (not roasted), while in single-roasted and double-roasted samples, 56 and 60 compounds were identified, respectively, indicating the importance of the roasting process on the number of compounds detected. The compounds were classified according their chemical characteristics: carbonyl compounds, terpenes, alcohols, phenols, furanic compounds, pyrazines, pyrroles, lactones, acids, phenolic, and benzene derivatives. Among them, only the volatile phenolics did not show any statistical differences created by the roasting process. Clearly, the increase in carbonyl compounds, pyrazines, pyrroles, and furanic compounds was related to the roasting process since these compounds are formed by Maillard reactions.[33]

With regard to the pyrazines, among the 16 detected in the double-roasted samples, only five were observed in the raw samples: methylpyrazine, trimethylpyrazine, 2-ethyl-5-methylpyrazine, 2-ethyl-6-methylpyrazine, and 2-ethyl-3-methylpyrazine. The production of pyrazines during the roasting process was also very significant in the nuts roasted a second time; indeed, most pyrazines increased between 8 and 15 times the amount identified in single-roasted samples. Our results are in accordance with Vazquez-Araujo et al.[34] and Agila et al.[35] who observed the strong effect of roasting time on pyrazine production in almonds. The number and type of pyrazines for single-roasted samples detected in our study are similar to the results in the GC-O study by Aceña et al.[7,36] in which pistachios were roasted at 160 °C for 20 min. However, Hojjati et al.[1] observed fewer differences in pyrazine levels for Iranian pistachios, both raw and roasted at 135 °C for 20 min, detecting only two pyrazines in the roasted samples that could be attributed to the less-intense roasting process. The sensory importance of pyrazines depends on the substituents of the molecule, as they are less potent with methyl groups than with ethyl ones.[33]

Like the pyrazines, most of the pyrroles and furans existed in virtually undetectable amounts in raw samples, subsequently increasing in amount over the course of the roasting process.[37] Thus, in raw samples, only the less volatile ones were detected, i.e., furfural and *N*-methylpyrrole; however, the levels of all these compounds increased with the roasting time but less dramatically than with pyrazines.[34] Furfural and derivatives generally possess caramel-like, sweet, and fruity notes, while pyrroles, depending on their substituents, could possess favorable (caramel-like, sweet, corn-like) or unfavorable notes.

In addition, another reaction related to the Maillard was the Strecker degradation of α-amino acids initiated by carbonyl compounds, producing an aldehyde and α-aminoketone. Although some aldehydes are highly volatile compounds and could be lost in the heating process through evaporation, our results showed an increase of the amount of aldehydes, including hexanal, pentanal, benzaldehyde, and (*E*)-2-pentenal, which may be due to their formation via Strecker degradation. Other compounds, such as short chain acids and lactones, were affected by roasting time since they also can be formed by Maillard reactions.[38]

Table 4. Aroma-Active Regions of Raw, Single-Roasted, and Double-Roasted Pistachio Samples

odor region	LRI[b]	odor description	FD Factor[a]			compound[c]
			raw	single-roasted	double-roasted	
1	960	solvent, rancid			2	*n*-pentanal
2	1185	burnt, toasted			4	styrene
3	1235	burnt, plastic			128	unknown
4	1242	chemical, solvent			2	an alcohol
5	1262−1269	popcorn, toasted	4	8	128	2,6-dimethyl pyrazine; 2-ethylpyrazine
6	1292	fatty, roasted			2	an alcohol
7	1346	popcorn, oily, toasted		4	4	unknown
8	1379	fatty, negative		8		unknown
9	1390	burnt			16	2-ethyl-3,5-dimethylpyrazine
10	1426	toasted		8	32	2-methyl-3,5-diethylpyrazine
11	1447	burnt, toasted		2		unknown
12	1475	popcorn, roasted		2	2	unknown
13	1516	popcorn		8	4	5-methyl-1*H*-pyrrole-2-carbaldehyde
14	1534	roasted			8	a pyrazine
15	1586	toasted, pharmacy			2	1-methyl-2-pyrrolidinone
16	1719	toasted, burnt			2	1-(2-furanylmethyl)-1*H*-pyrrole
17	1891	fatty		2		unknown
18	1914	phenolic		2		unknown
19	2059	plastic, chemical			8	4-ethylphenol

[a]FD factor is the highest dilution of the extract at which an odorant is determined by aroma extract dilution analysis. [b]Linear retention index calculated on DB-WAX capillary column. [c]Odor description as perceived by panelists during olfactometry.

The variation in the amount of other compounds in the raw samples, such as terpenes, benzene derivatives, and alcohols, is probably more related to a concentration effect in the sample through the loss of water and the subsequent evaporation of these compounds during roasting. Among them, it is remarkable that terpenes showed, in general, the highest values in single roasted samples. This group of compounds is the most interesting since numerous terpenes have been detected in oils of *P. vera* leaves[39] as well as in fruit pistachio oils and other edible nuts.[40] Among the nine terpene compounds detected in the present study were terpinolene, α-pinene, β-pinene, limonene, 3-carene, and camphene, which were detected in the Uzun variety of the raw Turkish pistachio,[2] in the raw and roasted Iranian pistachio,[1] and in the "Kerman" pistachio from California.[40]

Evaluation of the Aroma-Active Compounds of Pistachios. The results of the olfactometric analysis and the application of AEDA on the extracts of the three pistachio sample types (raw, single-roasted, and double-roasted) are presented in Table 4. As can be expected, the number of odor-active regions in the raw samples was much lower than in the roasted samples. Indeed, in raw samples, an odor-active region was detected only between LRI 1262 and 1269 with popcorn and toasted notes most likely associated with 2 pyrazines: 2,6-dimethyl-pyrazine and 2-ethylpyrazine having FD factors of 4. Although these two compounds were not identified in the chromatograms of the raw samples (Table 3), due to the sensitivity of the method, both compounds were detected in the other two sample types. It is remarkable that these two pyrazines were not detected in olfactometric analysis by other authors in raw samples of the pistachio (*P. vera*),[2] suggesting the probable existence of some thermic effects on the sample during harvesting and processing. Moreover, other studies undertaking chemical analyses have not detected pyrazines in raw pistachio samples (*P. vera* and *P. terebinthus*).[1,17]

The roasting process had a significant effect on the number of odor-active regions, with 9 regions observed for single-roasted samples and 15 for double-roasted samples. Single-roasted samples did not show a very high flavor dilution factor (FD), with a maximum value at 8 for four odor-active regions: 5 (popcorn/toasted), 8 (fatty/negative), 10 (toasted), and 13 (popcorn). The compounds responsible for these aroma regions could only be identified in some cases: region 5 was the same as that detected in the raw samples; region 10 was identified as 2-methyl-3,5-diethylpyrazine and camphor; and region 13 was identified as a pyrrole (5-methyl-1*H*-pyrrole-2-carbaldehyde). In addition, other regions at LRI 1346 (region 7) with a FD of 4, and several with FD of 2 (regions 11 and 12) which had aroma characteristics described as popcorn/toasted, are probably due to pyrazines or pyrrolic compounds, although the compounds were not identified.

Two regions at LRI 1891 and 1914 (regions 17 and 18) with fatty and phenolic notes, respectively, contained unknowns. Noteworthy those aroma notes detected in single-roasted samples that were not detected in double-roasted samples (regions 8, 11, 17, and 18). This could be due to compounds present in the original samples or generated during the roasting process in the first roasting and later degraded or evaporated away in the second roasting. Another possibility is the formation of these compounds in the first roasting and their subsequent transformation into others as roasting time is longer. Vazquez-Araujo et al.[34] studied the formation of toasty aroma notes in almonds and their volatile profile, observing that different roasting times are necessary to form different pyrazines and slight aroma loss at some points in the roasting process. In addition, the big differences in the odor thresholds of pyrazines is a function of their substituents (methyl or ethyl), which could significantly affect the quality and intensity of the aroma notes.[33]

As expected the double-roasted sample exhibited the highest flavor dilution factors. Thus, two regions presented a FD of 128: region 3 (burnt/plastic) and region 5 (popcorn/toasted). The compounds responsible for the notes in region 5 were 2,6-dimethylpyrazine and 2-ethylpyrazine, which were reported as

DOI: 10.1021/acs.jafc.5b02576
J. Agric. Food Chem. 2015, 63, 7830−7839

important contributors to roasted pistachio aroma.[36] In fact, 2,6-dimethylpyrazine has a very low odor threshold of 74 ng/L in air.[41] However, the significance of the 2-ethylpyrazine is expected to be lower because this compound has a higher odor threshold. On the other hand, the compounds of region 3 could not be identified. Odor region 10 (toasted) should be highlighted, with a FD of 32 and which was identified as camphor and 2-methyl-3,5-diethylpyrazine. Further, region 9 was characterized by a burnt note and a FD of 16. The last odor zone was identified as 2-ethyl-3,5-dimethylpyrazine. The pyrazine of region 9 showed a low odor threshold (0.011 ng/l of air)[41] and was detected by other authors[17,36] in roasted samples of *P. vera* and *P. terebinthus*. Two regions had a FD of 8. Specifically, region 14 was comprised of roasted notes probably due to a pyrazine, and, region 19, with both a plastic note and a chemical note were attributed to 3,4-dimethylphenol and 4-ethylphenol, the latter of which has also been detected through GC-O analysis of roasted pistachios.[7] Three more regions were identified with a FD of 4: region 2 had burnt and toasted notes identified as styrene; region 7 had a popcorn/oily/toasted notes; and region 13 had a popcorn note identified as a pyrrole. The remaining five regions had a FD of 2: region 1 had solvent and rancid notes identified as *n*-pentanal; region 4 had chemical and solvent notes probably due to alcohol; region 13, which was also detected in roasted samples; and regions 15 and 16 with toasted notes attributable to pyrrolic compounds.

Fatty Acid and Di- and Triacylglyceride Composition. Lipid content in the raw, single-roasted and double-roasted samples was 41.47 ± 0.85, 41.49 ± 0.75, and 41.96 g oil/100 g pistachio ($p > 0.05$), respectively.

DG and TG composition of the raw, single-roasted, and double-roasted pistachios is presented in Table 5. Contents of TG were 96.39 g/100 oil for raw samples, 96.49 g/100 oil for single-roasted samples, and 96.58 g/100 oil for double-roasted samples. In all of the samples assayed, TG CN54 was the main compound (74.87 g/100 oil for raw, 74.71 g/100 oil for single-roasted, and 74.69 g/100 oil for double-roasted), while TG CN52 and CN50 were lower. Two compounds were detected by DG composition, CN36 (0.50 g/100 oil for raw; 0.46 g/100 oil for single-roasted, and 0.48 g/100 oil for double-roasted) and DG CN38 (3.11 g/100 oil for raw, 3.05 g/100 oil for single-roasted, 2.94 g/100 oil for double-roasted). Holčapek et al.[42] reported the TG and DG composition of pistachio oil as equivalent carbon number ranging from 40 to 50 and 20 to 34, respectively. However, if TG and DG are calculated as CN, results are similar to those found in the current research study. The data revealed that TG in the assayed samples was not affected by processing. However, the results for DG CN38 ($0.05 < p < 0.1$) suggest that quantities were slightly reduced as a result of processing.

Table 5. Total Contents and Molecular Species Composition (%) of Di- and Triacylglycerides in the Assayed Pistachio Samples[a]

	raw	single-roasted	double-roasted	*p*
CN36	0.50 ± 0.01	0.46 ± 0.05	0.48 ± 0.02	0.43
CN38	3.11 ± 0.15	3.05 ± 0.15	2.94 ± 0.10	0.09
total DG	3.61 ± 0.16	3.51 ± 0.20	3.42 ± 0.12	0.39
CN50	2.07 ± 0.04	1.97 ± 0.39	2.10 ± 0.04	0.56
CN52	19.45 ± 0.19	19.82 ± 0.83	19.88 ± 0.24	0.25
CN54	74.87 ± 0.02	74.71 ± 1.32	74.60 ± 0.31	0.67
total TG	96.39 ± 0.16	96.49 ± 0.20	96.58 ± 0.12	0.39

[a]DG: diacylglycerides; TG: triacylglycerides; *p*: significance level ($p < 0.05$).

The analysis of fatty acid methyl esters (FAME) showed three main compounds (Table 6) which were palmitic (C16—72.50 mg/g oil for raw, 69.16 mg/g oil for single-roasted, and 73.85 mg/g oil for double-roasted), oleic (C18:1 c9—684.21 mg/g oil for raw, 691.60 mg/g oil for single-roasted, and 670.61 mg/g oil for double-roasted), and linoleic acid (C18:2 c9, c12—186.40 mg/g oil for raw, 186.68 mg/g oil for single-roasted, and 197.93 mg/g oil for double-roasted). Stearic (C18), palmitoleic (C16:1 c9), C18:1 c11 and α-linolenic acid (C18:3 c9, c12, c15) were also present by FAME analysis, demonstrating that the overall composition is similar to that reported elsewhere for pistachios in Turkey.[6]

In general terms, the fatty acid composition was stable after single roasting and double roasting. However, it was observed that double-roasted samples had significantly higher concentrations of elaidic acid (C18:1 t9, 0.12 mg/g oil) compared to raw (0.06 mg/g oil) and single-roasted (0.08 mg/g oil) samples. It was also observed that levels of oleic acid were lower ($p < 0.05$) in double-roasted samples than in the others.

The lipid composition of pistachios has a high concentration of unsaturated fatty acids. It is well-established that such compounds are prone to alteration by oxidative reactions. Thus, after drying Iranian pistachios at 70 °C, Kashani et al.[43] reported concentration levels of total free fatty acids associated with hydrolysis of TG, 1,3-DG, and phospholipids. The present study's results about DG CN38 are in line with those prior findings. In further investigations studying the effects of roasting (190 °C for 10 min), salting, and packing samples from Lebanon, it was concluded that thermal processing was the main factor leading to the production of hydroperoxides and total trans fatty acids.[44] On the other hand, studies focused on the possible effects of heating of butter (20—350 °C), found isomerization of oleic in elaidic acid explained through oxidation reactions.[45] Trans double bonds are more stable than cis bond when compared under the same conditions, with trans formation favored by temperature and time.[46] Other authors have[47,48] described that unsaturated fatty acids can be isomerized into cis/trans compounds at the intramolecular level,[49] catalyzed by thiyl radicals formed from thiols groups in proteins. The present results about variations in the amounts of oleic and elaidic are in line with the aforementioned studies. However, this is the first study describing exactly which trans compounds are involved in such changes.

In conclusion, the results obtained in this study showed the strong effect of roasting on the chemical composition of pistachios. The total amount of polyphenols increase with the roasting treatment; however, not all phenolic compounds demonstrated this behavior. In regard to the volatile composition and the aroma-active compounds, the effect of the roasting process on the number and intensity of the odor-active regions was clearly observed. Nevertheless, although the highest intensities were generally observed in double-roasted samples, in some cases odor regions in single-roasted samples had lower intensity than double-roasted samples. This observation can be used to optimize the roasting time in order to improve the organoleptic quality of the pistachios. Finally, the lipid analysis indicates that the roasting treatment of pistachio nuts reduced the concentration of DG CN38 and increased the amount of elaidic acid due to the isomerization of oleic acid by oxidative reactions.

azine (IBMP) with a vegetative, green odor occur in many vegetables as aroma-relevant compounds[17] and also in *Vitis vinifera* varieties.[18] However, they can also contribute to earthy off-flavors in water,[19] fish,[20] and other foodstuffs.[6] IPMP is also known as major component contributing to the so-called 'ladybug taint' in wine, associated with beetles that are harvested together with the grapes.[21]

Further known substances capable of producing corky off-flavors in wine are other haloanisoles like 2,4,6-tribromoanisole (TBA), 2,3,4,6-tetrachloroanisole (TeCA), and pentachloroanisole (PCA).[8,22,23] Although their sensory characteristics are rather similar to TCA, they originate from the microbial degradation of halophenols (in pesticides or flame retardants) that then produce the potent haloanisoles. These compounds represent a contamination of the wine cellar and not the cork itself. However, migration may occur depending on storage and wine production conditions. Halogenation of phenolic compounds with further microbial transformation into potent haloanisoles is a well-known problem in general and can particularly be found in the wood processing industry.[24,25]

In plant anatomy, cork is part of the periderm in the bark system of the cork oak tree (*Quercus suber* L.) and consists primarily of suberin, lignin, and polysaccharides.[26] As a consequence of the halogenation of lignin, Kugler and Rapp[3] detected various chloroguaiacols and other chlorophenolic compounds in cork.

On the basis of the substantiated state of knowledge on the typical cork off-flavor as well as other musty substances, we wanted to identify compounds particularly responsible for atypical cork taint, an off-flavor that had not been fully characterized so far. Cork samples that had been considered off-odorous should be submitted to a purge and trap extraction followed by gas chromatography–olfactometry analysis (GC-O). Detected off-flavor regions in the chromatograms deviant from the control samples should be further processed by a set of multidimensional gas chromatographic methods to characterize the structural identity of the underlying chemical substances.

MATERIALS AND METHODS

Chemicals. Reference compounds used were 2,4,6-trichloroanisole, pentachloroanisole, 2,4,6-tribromoanisole, geosmin (100 μg/mL in methanol), 2-methylisoborneol (10 mg/mL in methanol), 3-isopropyl-2-methoxypyrazine, and 3-isobutyl-2-methoxypyrazine (Sigma–Aldrich, Steinheim, Germany); 2,3,4,6-tetrachloroanisole and 3,5-dichlorocatechol (LGC Promochem, Wesel, Germany); guaiacol (Fluka, Buchs, Switzerland); 3,5-dimethyl-2-methoxypyrazine (Bellen Chemistry Co. Ltd., Beijing, China); 1-octen-3-one (Alfa Aesar, Karlsruhe Germany); 1-octen-3-ol (BASF, Ludwigshafen, Germany); 2,6-dichloroanisole (Riedel-de Haën, Seelze, Germany); and 3,4,6-trichloroveratrole (kindly supplied by Professor Juha Knuutinen, University of Jyväskylä, Finland). Chlorophenolics standard mixtures regulated by U.S. Environmental Protection Agency (EPA) method 1653A were from Cambridge Isotope Laboratories (Andover, MA), comprising pentachlorophenol, tetrachlorocatechol, tetrachloroguaiacol, 2,3,4,6-tetrachlorophenol, 3,4,5-trichlorocatechol, 3,4,6-trichlorocatechol, 3,4,5-trichloroguaiacol, 3,4,6-trichloroguaiacol, 4,5,6-trichloroguaiacol, 2,4,5-trichlorophenol, and 2,4,6-trichlorophenol in methanol (EM-4181); 3,4,5-trichlorosyringol in acetone (EM-4182); 4-chlorocatechol, 4-chloroguaiacol, 4-chlorophenol, 3,4-dichlorocatechol, 3,6-dichlorocatechol, 4,5-dichlorocatechol, 3,4-dichloroguaiacol, 4,5-dichloroguaiacol, 4,6-dichloroguaiacol, 2,4-dichlorophenol, and 2,6-dichlorophenol in methanol (EM-4183); and 2-chlorosyringaldehyde, 5-chlorovanillin, 6-chlorovanillin, 2,6-dichlorosyringaldehyde, and 5,6-dichlorovanillin in acetone (EM-4184).

Reagents used for synthesizing further references were trimethylsilyldiazomethane (2 M in diethyl ether; Sigma–Aldrich) and 1,3-propylene glycol and *p*-toluenesulfonic acid (Fluka). Commercial chemicals were usually of analytical grade and used as such.

Synthesis of Reference Compounds. On the basis of multicomponent standard mixes containing chlorophenolic substances (EM-4181, EM-4182, EM-4183, and EM-4184), the corresponding *O*-methylated derivatives were synthesized by use of trimethylsilyldiazomethane (TMSD) according to Ranz et al.[27] An aliquot (40 μL) of the standard mixture (EM-4181, EM-4182, or EM-4183) with 250–1000 μg/mL of the chlorophenolic substances was mixed with TMSD (40 μL of 2 M in diethyl ether) and methanol (160 μL). After 2 h at 40 °C the reaction was complete as monitored by gas chromatography–mass spectrometry (GC-MS). 3,5-Dichlorocatechol was methylated accordingly. Chlorophenolic substances containing a carbonyl group (standard mixture EM-4184) yielded mixtures of reaction products. In this case the carbonyl group was protected as a cyclic acetal by use of 1,3-propylene glycol. Briefly, 1,3-propylene glycol (100 μL), a catalytic amount of *p*-toluenesulfonic acid, and molecular sieve were added to 50 μL of the standard mixture EM-4184 and kept at 45 °C overnight. The reaction mixture was then washed with a $NaHCO_3$ solution (4.8 g/L) and extracted with dichloromethane. The organic phase was used for *O*-methylation as described above. Thereafter, the carbonyl group was deprotected by adding 3 M hydrochloric acid (250 μL) to the organic solution, with agitation and heating at 50 °C until completion of the reaction (monitored by GC-MS). The dichloromethane phase was separated and used for characterization by GC. Linear retention indices (LRI), mass spectral data, and odor descriptions of the *O*-methylated derivatives are listed in Table S1 in Supporting Information.

Preselection of Conspicuous Cork Stoppers. In the industrial quality control process of raw natural cork stoppers (before processing, for example, coating and imprinting), sensory evaluation of cork stoppers was performed by three panelists experienced for years in assessing the odor of cork stoppers. A consistent vocabulary for odor descriptions of the cork stoppers had early been determined by repeatedly sniffing about 100 exemplary cork stoppers and comparing their individual odor descriptions. Technically, cork stoppers were moisturized by dipping in purified water, put in screw-top jars, and left overnight at room temperature. After the supernatant air was sniffed, cork stoppers were classified in a first step by their odor into four classes: no deviant odor (class 1), slightly deviant odor (class 2), strongly deviant odor (class 3A), and typical TCA taint (class 3B). Whereas cork stoppers of class 2 could be clearly distinguished from inconspicuous cork stoppers, the off-odor description was not further defined, also due to a high variability of subtle off-flavor notes. For our study of atypical cork taint, strongly deviant cork stoppers of class 3A were further sorted into the subgroups musty (dusty-musty), moldy (mildewed, 2-methylisoborneol-like, earthy, mushroom), cellarlike (wet cloth, musty wet cellar), earthy (woody, mossy, earthy), and green (vegetative, bell pepper, pea). The definition of these subgroups was done prior to analysis and was based on common and dominating subtle sensory notes (nuances). Cork stoppers of class 1 were used as inconspicuous control sample.

Extraction of Volatiles from Natural Cork Stoppers. The extraction of cork stoppers followed a standard quality control procedure applied in the cork industry to monitor TCA. In our case, six cork stoppers of each group were soaked in an aqueous solution of 10% (vol) ethanol (absolute) for 24 h at 40 °C, repeated three times. The combined cork soaks were transferred into a wide-neck glass bottle with a GLS 80 thread and a poly(tetrafluoroethylene) (PTFE) screw cap with connection ports (Bohlender GmbH, Grünsfeld, Germany). Volatiles were purged by bubbling nitrogen (purified by an activated charcoal inline filter) with a metal-frit sparger through the solution, similar to a setup previously described.[28] The purged gas passed a solid phase extraction (SPE) tube containing Lichrolut EN (0.4 g; Merck, Darmstadt, Germany) as sorbent via a self-made glass adapter. Each cork soak was purged for 7 h at 37 °C with a nitrogen flow of about 100 mL/min. The necessary purge time was evaluated in

DOI: 10.1021/acs.jafc.5b02793
J. Agric. Food Chem. 2015, 63, 7840–7848

a preliminary experiment, in which the SPE cartridge was changed every 100 min. Breakthrough of compounds was evaluated with a second cartridge connected in series. Trapped volatiles were then eluted with dichloromethane and the organic phase was kept at −25 °C overnight to remove moisture. Extracts obtained were finally concentrated to a volume of about 0.1 mL by use of a microdistillation apparatus according to Bemelmans.[29] These extracts containing the purgeable volatiles from the cork soaks were used for further analysis by various GC approaches.

Detection of Off-Flavor Compounds by Heart-Cut Multidimensional Gas Chromatography−Olfactometry. GC-O experiments (sniffings) were carried out by two panelists in separate runs using heart-cut multidimensional gas chromatography (H/C MDGC) utilizing a moving capillary stream switching (MCSS) device described previously.[30] Two GC instruments (model 8560, Mega II series) from C.E. Instruments (today ThermoFisher Scientific, Dreieich, Germany) were connected via a heated transfer line. The GC in the first dimension (^{1}D) was equipped with the MCSS device, allowing heart-cutting of GC fractions. For a first evaluation of odorous elution zones (odor or aroma events), sniffing occurred after separation in ^{1}D. Later, individual odor events were transferred onto the second dimension (^{2}D) separation column with a transfer window of the ^{1}D LRI ±25 units. The basic components of the MDGC system are outlined in the following sections.

First-Dimension System. The ^{1}D column configuration consisted of a 1 m × 0.32 mm i.d. phenylmethylsilylated precolumn (BGB Analytik, Rheinfelden, Germany) that was connected via a press-fit to a fused silica capillary column (20 m × 0.25 mm i.d.) coated with 0.5 μm of a poly(ethylene glycol) phase (ZB-Wax, Phenomenex, Aschaffenburg, Germany). The carrier gas used was helium with an inlet pressure of 70 kPa (*P*1) and a midpoint pressure of 47 kPa (*P*2). The actual inlet pressure for the ^{2}D column was given by the readout on the pressure gauge, *P*2*, and was at 30 kPa. A flame ionization detector (FID) was set to 250 °C and used as ^{1}D monitor detector when sniffing occurred after ^{2}D separation. For sniffing after ^{1}D separation, a sniffing adapter was installed instead of the FID, keeping the detector base temperature at 250 °C. Cork extracts (3 μL) were injected via a cold on-column injector. The oven temperature was programmed from 40 °C (5 min isothermal) at 8°/min to 250 °C (15 min isothermal). Control of the MCSS system as well as data processing was achieved by the Chromcard data acquisition software, version 2.2 (ThermoFisher).

Second-Dimension System. A deactivated fused silica capillary (1.5 m × 0.25 mm i.d., Phenomenex) was guided through a heated transfer line (200 °C), connecting the two GC ovens. The transfer capillary from the first oven was connected via a press-fit to the ^{2}D analytical column (11 m × 0.32 mm i.d. fused silica capillary) with 1 μm of 5% phenylmethylpolysiloxane (DB-5, Agilent, Waldbronn, Germany). At the end of the analytical column, the eluent flow was split via a Y-splitter connecting a deactivated fused silica capillary of 0.4 m × 0.25 mm i.d. (BGB Analytik) with the sniffing port and a 0.6 m × 0.22 mm i.d. (SGE, Victoria, Australia) leading to the FID, respectively. The sniffing port (detector base) was set to 250 °C and the FID was set to 280 °C. The oven temperature program was initiated via external event activation 1 s after the start signal of the ^{1}D oven. The oven temperature was raised from 35 °C (32 min isothermal) at 10°/min to 280 °C (5 min isothermal). LRIs were calculated by use of a series of *n*-alkanes (C10−C25). For determination of LRIs after ^{2}D separation, alkanes injected into ^{1}D were fully transferred into ^{2}D. Keeping the oven temperature in ^{2}D at 35 °C allowed cold trapping from C10 on, and following this transfer, oven temperature programming was done as in the analytical run.

Identification of Odorous Compounds. Retention indices after ^{1}D and ^{2}D separation of odor events, as well as their odor descriptions, were compared with those of reference compounds. Thus, tentatively identified substances were verified by injection of reference material, applying MDGC conditions as described in the previous section. The identification was further supported by additional analyses via MDGC-MS-MS and GC × GC-MS (described below). Odor events that could not be identified in this way demanded further specific sample enrichment and mass spectrometric detection. For this purpose, compounds eluting in the dedicated odor event zone (after H/C and ^{2}D separation) were trapped by use of thermodesorption tubes packed with polydimethylsiloxane (PDMS) foam (Gerstel, Mülheim an der Ruhr, Germany). PDMS foam was chosen due to its high capacity and known moderate bleed characteristics in thermodesorption applications compared to, for example, Tenax or other polymer-based sorbents. Good sorption properties for various aroma compounds have been demonstrated with solid phase microextraction (SPME) and stir bar sorptive extraction (SBSE) applications.[31] For higher sensitivity the Y-splitter was removed and a deactivated fused silica capillary of 0.6 m × 0.32 mm i.d. (BGB Analytik) was directly connected to the ^{2}D analytical column, guided through the heated detector base, and connected with the trap on top of the detector base with a homemade press-fit-type adapter made of a 6 mm i.d. polyethylene tube. In a separate GC (HP6890, Agilent) equipped with a MPS2 autosampler, a thermodesorption unit (TDU), and a cold injection system (CIS 4; all Gerstel), the trapped components were thermodesorbed at 250 °C for 10 min (in splitless mode) with a purge flow of 60 mL/min. The transferline between TDU and CIS was set to 300 °C. During thermodesorption, the CIS was set to −100 °C and operated in solvent vent mode. After thermodesorption, the CIS temperature was raised at 12°/s to 280 °C (1.5 min isothermal), with closed split valve for 2 min. The analytical column was a 30 m × 0.25 mm i.d. fused silica capillary column coated with 0.25 μm of 5% phenylmethylpolysiloxane (ZB-5, Phenomenex). Carrier gas used was helium at a constant flow rate of 1.2 mL/min. The oven temperature was raised from 50 °C (2 min isothermal) at 10°/min to 280 °C (5 min isothermal). MS acquisition was done with an Agilent MSD 5975 at 70 eV (EI+) in full-scan mode from *m*/*z* 29 to 400. Ion source and quadrupole were heated at 230 and 150 °C, respectively. The MS transfer line was set to 280 °C. Instrument control and MS data acquisition were performed via MSD ChemStation (version E.02.02.1431, Agilent) and Gerstel Maestro (version 1.4.23.11). Identification of unknowns was then based on mass spectra matching National Institute of Standards and Technology (NIST) library (version 2011), LRIs, and reference substances and also application of deconvolution algorithms (AMDIS software).

Methods for Specific Compound Identification. *Determination of 2,4,6-Trichloroanisole, 2,4,6-Tribromoanisole, and 2,3,4,6-Tetrachloroanisole.* Confirmation of haloanisoles in cork stoppers was done by analyzing the cork soaks, before purging, with the headspace (HS)-SPME-MDGC-electron capture detection (ECD) system described in an earlier work.[32]

Determination of Alkylmethoxypyrazines. Detection of alkylmethoxypyrazines (MDMP, IPMP, and IBMP) was achieved with the H/C enantio-MDGC-MS-MS system described previously.[33] Injection of the cork extracts (3 μL) was done in programmed temperature vaporizer (PTV) on-column mode (simile on-column liner, ThermoFisher Scientific) after attaching a 1 m × 0.53 mm i.d. phenylmethylsilylated precolumn (BGB Analytik) via a press-fit connector. PTV on-column injection was done at 50 °C (PTV temperature; 1 min hold) and then raised at 14.5°/s to 190 °C (0.5 min hold) and at 10°/s to 270 °C (hold during remaining runtime). The splitless time was 2 min. Temperature program, cut windows, and cryo time were adjusted accordingly.

Determination of Geosmin and 2-Methylisoborneol. Confirmation of GSM and MIB was done with the previously mentioned H/C MDGC-MS-MS system, modified as follows. The original 15 m ^{1}D column was replaced by a 30 m × 0.25 mm i.d. fused silica capillary column, coated with 0.25 μm of Stabilwax-MS (Restek, Bad Homburg, Germany). Inlet pressure was 197 kPa and midpoint pressure was 121 kPa (Deans' Switch). A ^{1}D column backflush (releasing the effluent through the PTV in split mode) was initiated after heart-cutting (24 min) by lowering the PTV inlet pressure to 15 kPa. Oven temperature was programmed from 50 °C (5 min isothermal) at 10°/min to 130 °C (0 min hold) and at 5°/min to 179 °C (155 °C for MIB). Then the temperature was lowered to 100 °C (80 °C for MIB) at 30°/min (2 min isothermal) before the ^{2}D GC separation started by raising the temperature to 150 °C at 5°/min and then to 190 °C at 30°/min (5

DOI: 10.1021/acs.jafc.5b02793
J. Agric. Food Chem. 2015, 63, 7840−7848

min hold). Cut windows and cryo time were adjusted accordingly. The optimized MS-MS transfers and collision energies were 182 → 112 (12 V), 182 → 97 (12 V) and 112 → 97 (12 V) for GSM and 107 → 65 (20 V), 107 → 91 (12 V), 135 → 91 (15 V), 135 → 107 (8 V), and 150 → 107 (12 V) for MIB.

Additional Compound Identification Supported by Comprehensive Multidimensional Gas Chromatography. A comprehensive multidimensional GC system (GC × GC) equipped with a PTV injector and a dual-jet carbon dioxide modulator (Trace GC × GC Ultra, ThermoFisher Scientific) was coupled to a quadrupole MS (DSQ, ThermoFisher Scientific). The analytical column system consisted of a 1 m × 0.53 mm i.d. phenylmethylsilylated fused silica capillary (BGB Analytik) used as a precolumn, a 30 m × 0.25 mm i.d. fused silica capillary column coated with a poly(ethylene glycol) phase of 0.5 μm (ZB-Wax, Phenomenex) as ^{1}D column, and a 2 m × 0.15 mm i.d. fused silica capillary coated with 0.25 μm of a 5% phenylmethylpolysiloxane phase (BPX-5, SGE) as ^{2}D column. Helium was used as carrier gas at a constant flow of 1.2 mL/min. Injection (3 μL) was done in PTV on-column mode at 50 °C (PTV temperature; 1 min hold), then raised at 14.5°/s to 260 °C (1 min hold) and at 10°/s to 270 °C (hold during remaining runtime). The splitless time was 2 min. The oven temperature was programmed from 50 °C (5 min isothermal) to 250 °C at 4.5°/min (5 min hold). Cryomodulation occurred on the last section of the ^{1}D column and was started after a delay time of 6 min. The modulation period was 6 s. The MS transfer line was set to 250 °C and the ion source was set to 240 °C. MS data acquisition was done in electron ionization (EI+) mode at 70 eV. The mass scan range was segmented into m/z 40−250 from 5 to 30 min and m/z 60−350 after 30 min. The scan rates were 16 and 13 Hz, respectively. Data acquisition was done with Xcalibur software (version 1.4, ThermoFisher Scientific), and processing of two-dimensional data was done with HyperChrom software version 2.5 (ThermoFisher Scientific). Compound identification was based on mass spectra matching NIST library (version 2011), LRI, and reference substances and application of deconvolution algorithms (AMDIS software) when required.

RESULTS AND DISCUSSION

Sample Selection and Preparation. About 150 000 individual natural cork stoppers were sensorially evaluated by trained panelists. As described in the Materials and Methods section, rejected cork stoppers were described either with a slightly deviant odor (class 2, 1.15%), a strong deviant odor (class 3A, 0.35%), or a typical TCA taint (class 3B, 0.04%). The cork stoppers classified as class 3B (typical TCA taint) represent only a minor part of those classified with adverse sensory properties. Within the strongly deviant cork group (class 3), class 3B is about a tenth of its sum. Already indicated by these numbers, the atypical off-odor seems to be a problem even more crucial to the industry than the typical TCA taint. Only cork stoppers from class 3A were further investigated (additionally subdivided into five groups) to determine the substantial base underlying these off-odors. The basic workflow of the various analytical approaches applied in this investigation is illustrated in Figure 1. Based on established analytical procedures, known haloanisoles responsible for musty cork taint (TCA, TBA, and TeCA) were analyzed by HS-SPME-MDGC-ECD from cork soaks. In order to target hitherto unknown compounds, volatiles were purged from pooled cork soaks and trapped on a sorbent material. Purge time for an individual extraction step was determined by detecting off-odors from trap extracts (each taken after 100 min) with sensory evaluation. After 400 min (four consecutive traps), off-odors could still be detected in the GC-O experiment. For practical reasons (working day), the overall purge time was set to 7 h for all samples.

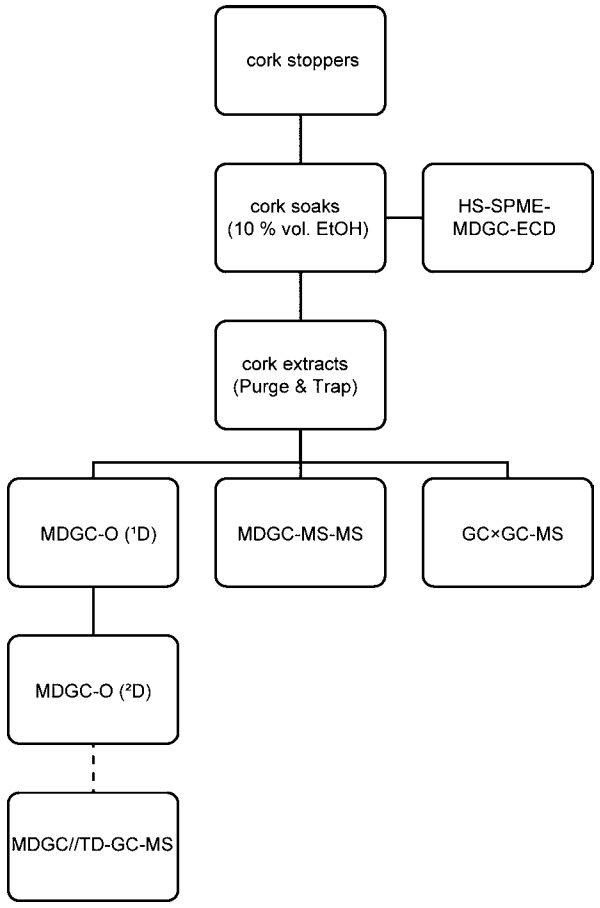

Figure 1. Workflow for identification of compounds responsible for atypical cork taint.

Olfactometric Analysis and Identification of Compounds Responsible for Off-Odors. Considering the complexity of a concentrated extract of a natural material such as cork, we expected coelution problems in standard one-dimensional GC-O. Therefore, we based our GC-O system on H/C MDGC-O with at first a ^{1}D GC-O experiment for detecting odorous elution zones in general. Such odor events were then individually transferred onto a second analytical column with different separation properties. The thus-reduced matrix allowed, in the following ^{2}D GC-O experiment, a more reliable detection of odorous events, as visualized with the example of Figure 2. The odor event with a ^{1}D LRI of 1442 that had been described with the sensory attributes 'nutty, musty, dusty' actually resulted in five odor events after ^{2}D separation and a number of additional non-odorous compounds producing a FID signal. This result reveals that GC-O odor events (particularly after a ^{1}D separation only) may be generated from a number of individual flavor compounds. Synergistic, antagonistic, or even suppressive effects can then influence the resulting odor sensation. Our approach with H/C MDGC-O thus provides a much higher resolution of odor events, eventually resulting in the sniffing of single components.

In general, sniffing of the cork extracts under investigation resulted in about 35−40 odor events per sample after ^{1}D separation. Compared to the extract from the control sample (class 1 cork stoppers), 4−8 odor events (depending on subgroup) were different with regard to musty or vegetative off-odors. The MDGC-O results after ^{1}D and ^{2}D sniffing are summarized in Table 1. Compounds responsible for the

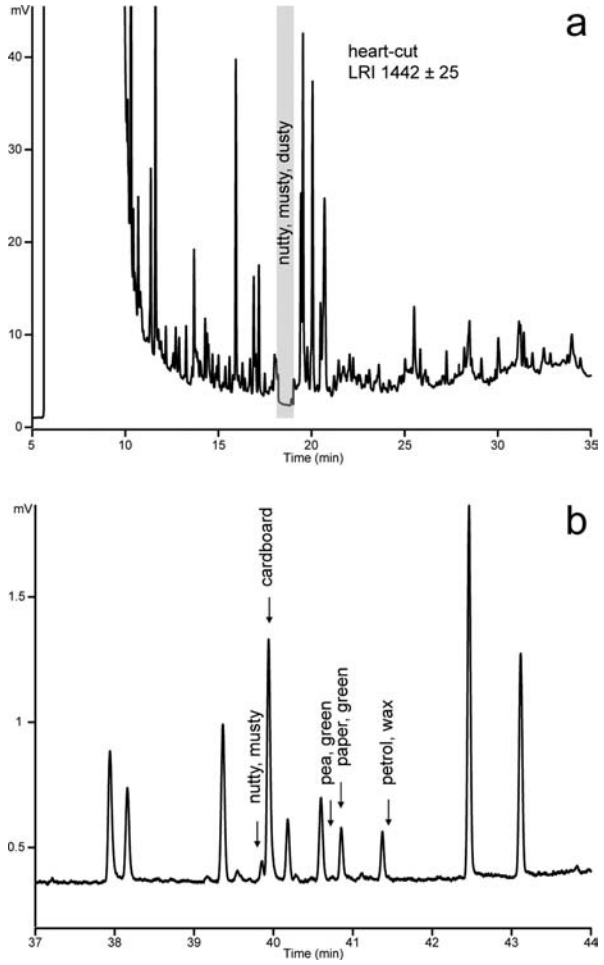

Figure 2. Enhanced resolution for determination of odorous zones responsible for cork taint after MDGC-O. (a) ^{1}D FID chromatogram with transfer of odor event. (b) Resulting ^{2}D FID chromatogram with indication of multiple odor events. Conditions were as described in the text.

individual odor events were tentatively identified by comparing the odor descriptions and LRIs on two stationary phases (ZB-Wax, DB-5) with those of authentic reference substances. Further confirmation was achieved by target analysis with established analytical methods such as MDGC-MS-MS or MDGC-ECD. The latter allows direct quantitation of TCA (and also TBA and TeCA) from the original cork soaks. Based on a previous work[2] suggesting guaiacol and 1-octen-3-one as compounds negatively affecting cork aroma, these two compounds could be confirmed in our study by use of GC × GC-MS as a supplementary method (see also Figure 1).

Although the investigated cork stoppers had been described with a musty odor deviant from TCA, this typical cork taint compound was perceived in all subgroups, including even the unaffected control cork stoppers. The intensity of the perceived TCA was highest in the moldy, musty, and cellarlike subgroups. This corresponds well with the analytical data obtained from the original cork soaks with TCA concentrations at 20 ng/L (moldy), 54 ng/L (musty), or 46 ng/L (cellarlike). The control sample was determined with <0.4 ng/L (limit of quantitation), whereas 0.7 and 11 ng/L were found in the green and earthy subgroups, respectively.

Another substance that was perceived in each extract was MDMP. This substance was first described as a compound associated with 'fungal must' in wine and found in cork stoppers by Simpson et al.[4] and was later confirmed by Prat et al.[5] and Chatonnet et al.[16] Besides, MDMP has not yet been described in other studies with respect to corky off-flavor. However, it was found among other alkylmethoxypyrazines as a potent and contributing off-flavor compound in wine related with the so-called 'ladybug taint'. Originally, this off-flavor was associated with a structural isomer of MDMP, 2,5-dimethyl-3-methoxypyrazine (DMMP).[34] Since retention properties on common stationary phases used for GC are almost identical for both isomers with furthermore non-distinguishable mass spectra, an unequivocal identification is critical. Such identification presupposes a chromatographic separation of MDMP and DMMP and also the availability of fully

characterized standards, as was outlined recently.[33] The origin of MDMP in cork is not yet fully understood. There is some evidence that microorganisms may produce MDMP.[5,15,16] Prat et al.[5] isolated microorganisms from cork and inoculated sterilized cork granules with bacterial or fungal suspensions. Resulting cork samples that were sensorially evaluated and described with vegetative and musty-earthy attributes contained MDMP, as was confirmed by GC-MS analysis. Chatonnet et al.[16] identified a bacterium capable of synthesizing high amounts of MDMP that is widespread in soil. A hypothetical contamination may occur during storage of cork barks or during cork stopper production in a process that has yet to be determined.

Besides MDMP and TCA, also 1-octen-3-one and guaiacol were present in all cork extracts and showed no distinct difference to the control. Both 1-octen-3-one and its reduced version 1-octen-3-ol are common metabolites of molds,[35] known to derive from enzymatic oxidation of unsaturated fatty acids. The ketone has a very low odor threshold in wine (20 ng/L in dry white wine)[2] that is 1000 times lower than the corresponding alcohol. Therefore, it is an important contributor to the off-flavor of affected wines or corks. It is well-known that widespread fungi like *Penicillium* species or *Botrytis cinerea* produce 1-octen-3-one and, among others, GSM and MIB.[36] During the production of cork stoppers, contamination with molds occurs, and thus contamination with such compounds can be explained. Guaiacol has already been described as a flavor-relevant compound affecting cork stoppers.[2] However, its odor threshold in wine is comparable to that of 1-octen-3-ol and its flavor contributes to smoky or medicinal attributes. Its production by degradation of vanillic acid with microorganisms isolated from cork has been described earlier.[37]

Within the moldy and cellarlike cork subgroups, GSM and MIB were the major contributing compounds, together with increased presence of TCA and also MDMP. Two other potent alkylmethoxypyrazines, IPMP and IBMP, were primarily found in cork stoppers with a green odor description. IPMP and IBMP are known for musty, earthy off-flavors in water and some foodstuffs.[6,19,20] Allen et al.[38] have already hypothesized the contamination of cork with IPMP in a situation where individual IPMP concentrations were found in different bottles of the same wine. Again, a synthesis by microorganisms was described earlier.[39] Migration of IPMP or IBMP from cork to wine and its potential for a negative effect on wine sensory properties has not been studied yet. One may assume similar defects as seen with the ladybug taint. However, if there is a negative influence, this cork stopper class can clearly be differentiated from musty- or moldy-type notes experienced with the other subgroups.

Further known compounds contributing to typical cork taint, like the haloanisoles TBA, TeCA, and PCA, were not detected by MDGC-O or further GC analyses, besides traces of PCA found in some extracts with GC × GC-MS. In principle, this could be expected as they are related to an anthropogenic entry into the environment (cellar and winery). Detection of traces of PCA in some cork stoppers may indicate that there might still be residues of pentachlorophenol, a biocide extensively used a few years ago also in cork forests.[3,40−42]

Identification of Unknown Compounds. In addition to the previously discussed odor events, there were five that remained unknown (unknowns A−E) after MDGC-O and comparison of LRIs of suspicious compounds known from literature. As a first identification step, visual comparison of GC × GC-MS chromatograms (control versus affected cork stoppers) in the conspicuous retention time ranges of the unknown compounds was performed. In some samples, recurring differences in the peak patterns corresponding to the retention of unknowns A−C could be detected and are shown as examples in Figure 3. A first comparison (NIST

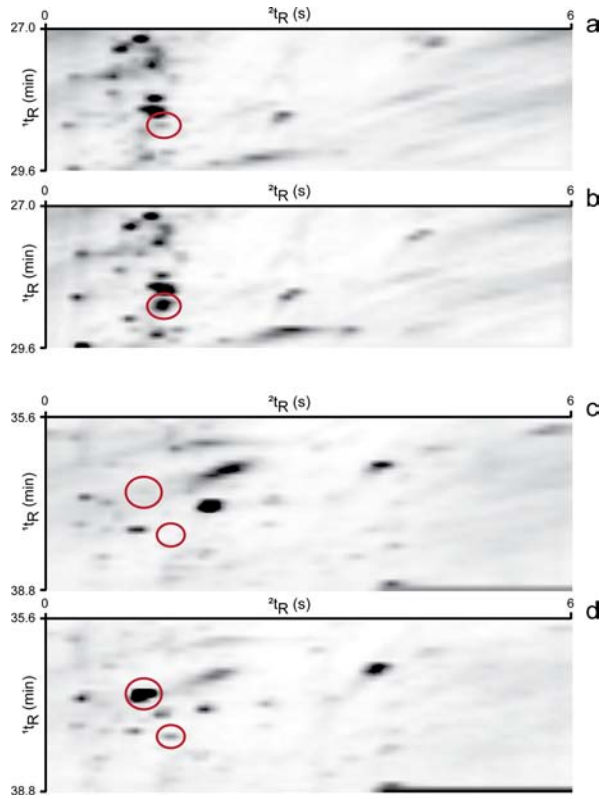

Figure 3. Comparison of GC × GC chromatograms (sections) of cork extracts. (a, c) Inconspicuous control samples; (b, d) tainted cork samples. Differences within peak patterns correspond to unknown odor events.

database) and interpretation of mass spectra obtained for the three highlighted peaks indicated the presence of chlorinated phenolic compounds. For further identification, the corresponding elution zones after MDGC were trapped and analyzed by thermal desorption (TD) GC-MS as described in the Materials and Methods section (MDGC//TD-GC-MS). Trace-level mass spectra interpretation was hindered by bleed produced from the sorbent used (PDMS). Subtraction of data obtained from a blank and application of deconvolution algorithms (AMDIS) finally yielded the corresponding mass spectra presented in Figure 4 that could also be observed with GC × GC-MS. Conclusive information for the remaining unknowns D and E could not be achieved. On the basis of the hypothesized presence of chlorophenolic compounds, we investigated structurally related compounds present in commercially available environmental contaminant standard mixtures. On the background that chlorophenols are *O*-methylated by microorganisms (as is known from the generation of TCA), we synthesized their *O*-methylated derivatives. In the case of aldehydes (5-chloro-, 6-chloro-, and 5,6-dichlorovanillin and 2-chloro- and 2,6-dichlorosyringaldehyde), intermediate protection of the carbonyl function was necessary before *O*-methylation. The corresponding chromato-

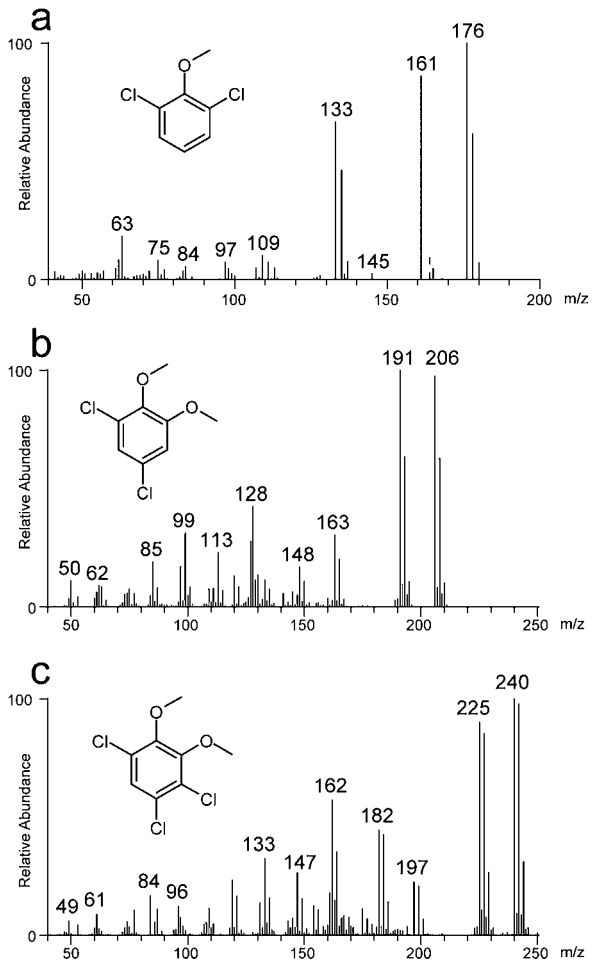

Figure 4. Mass spectra of chlorinated compounds identified after MDGC//TD-GC-MS analysis: (a) unknown A (2,6-dichloroanisole), (b) unknown B (3,5-dichloroveratrole), and (c) unknown C (3,4,6-trichloroveratrole). For detailed information, see text.

graphic (LRI on two different stationary phases), mass spectrometric, and sensory (GC-O) data were determined and are summarized in Table S1 (LRIs and MS data of chlorophenols are presented in Table S2). Since the synthesis of the *O*-methylated derivatives was based on a mixture of phenols, the correct assignment, particularly of isomeric compounds of the *O*-methylated products, was achieved by comparison of their LRIs with data published in the literature[43−46] (see also Supporting Information). Based on comparison of the two LRIs from MDGC-O, mass spectrometric, and sensory information, 2,6-dichloroanisole (unknown A), 3,5-dichloroveratrole (unknown B), and 3,4,6-trichloroveratrole (unknown C) could be identified and were verified with individual reference substances. Their chemical structures are similar to that of TCA, which may explain their comparable sensory properties.

Among the chlorinated compounds detected in cork stoppers were dichloroanisoles[1,47] and chloroveratroles.[1] A mono- and a dichloroveratrole (unassigned isomers) were also detected in the volatile fraction of microorganism cultures isolated from cork.[48] However, an exact identification of chloroveratrole isomers as well as sensory descriptions were not given earlier, so to the best of our knowledge, 3,4,6-trichloroveratrole and 3,5-dichloroveratrole are described here for the first time as a constituent of cork stoppers with off-flavor and were characterized by GC-O. Since Kugler and Rapp[3] found relatively high amounts of chloroguaiacols and 6-chlorovanillin in cork stoppers, we also considered these compounds but were not able to identify these in our samples.

The overall contribution of chlorinated compounds to today's cork taint situation was relativized in a review by Sefton and Simpson[9] due to the discontinuation of chlorine bleaching in the cork industry. However, in our results such chlorinated compounds were found, probably originating from the chlorination of lignin, then putting up the question of their origin. This is in accordance with the results of Sponholz and Muno.[40] They found trace amounts of pentachlorophenol and trichlorophenol even in non-chlorinated cork stoppers and suggested an environmental influence.

In addition to the previously mentioned compounds, we were able to detect isomers of dichlorophenol and dichloroanisole by targeted screening of the GC × GC chromatograms based on data published in Tables S1 and S2. However, they were not perceived by MDGC-O.

In general, such chlorinated substances are well-known to the wood processing industry as they are produced during the pulp bleaching process.[24,25,49] Chlorinated lignin is degraded to chlorocatechols and chloroguaiacols. Various microorganisms are then able to metabolize them to the corresponding *O*-methylated compounds, producing chloroveratroles.[49,50]

In conclusion, across the individual subgroups with atypical cork taints, the well-known TCA was present besides the hitherto not often described MDMP. Obviously, TCA is a good marker for cork taint in general, but analytical monitoring has to be extended by MDMP, particularly for the detection of atypical cork taint. Specific sensory subgroups showed high intensities of GSM and MIB (moldy and cellarlike) or of IPMP and IBMP (green), probably contributing with their potent individual flavor notes. Other compounds like 1-octen-3-one, guaiacol, and chlorinated compounds discussed above seem to play a minor role, possibly contributing to subtle sensory deviations. Future studies should investigate potential synergisms, as mostly mixtures of different compounds classes were found. Our results are in good agreement with compounds identified by Prat et al.[5] who also concluded that the diversity of microorganisms possibly found on the surface of corks generate their individual mix of substances. Based on some preliminary sensory trials performed in our laboratory, the reduced fruitiness perceived in wines seems to be associated with MDMP migrating from affected cork stoppers into the wine. In a future work this should be investigated in more detail. In this respect, further sensory studies based on recombination experiments are necessary to fully elucidate the role of the compounds described here.

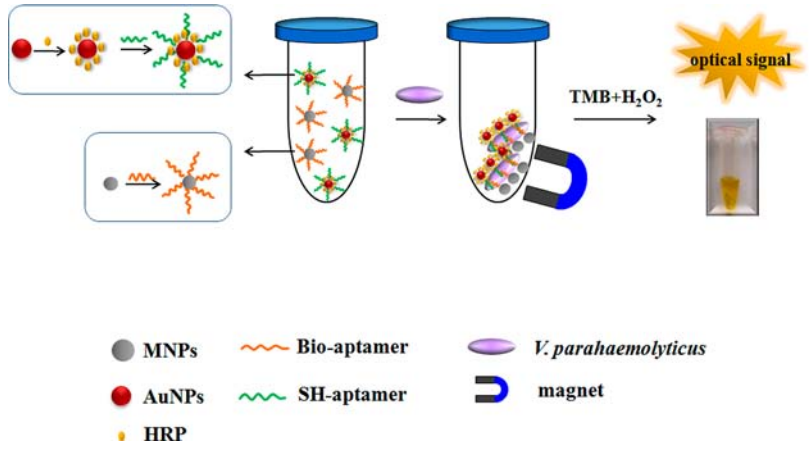
Scheme 1. Schematic Presentation of *V. parahaemolyticus* Detection Using a Colorimetric Aptasensor Based on HRP



Gold nanoparticles (AuNPs) containing a large amout of horseradish peroxidase (HRP) and aptamer were used as signal amplifiers. MNPs−aptamer−target−aptamer−HRP−AuNPs sandwich complexes would be formed based on the recognition of aptamers and target. In the addition of TMB−H_2O_2, HRP on the sandwich complexes was catalyzed and generated an optical signal.

MATERIALS AND METHODS

Materials. Chloroauric acid ($HAuCl_4$), streptavidin, and 3,3′,5,5′-tetramethylbenzidine (TMB)−H_2O_2 were obtained from Sigma-Aldrich (St. Louis, MO, USA). HRP was purchased from Sangon Biotechnology (Shanghai, China). Trisodium citrate, 1,6-hexanediamine, anhydrous sodium acetate, $FeCl_3{\cdot}6H_2O$, glycol, 25% glutaraldehyde ($OHC(CH_2)_3CHO$), and polyethylene glycol (PEG) were of analytical grade and were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). The *V. parahemolyticus* aptamer was prepared in our laboratory[17] and synthesized and purified by high-performance liquid chromatography (Sangon Biotechnology, Inc.). The sequences of *V. parahemolyticus* aptamers were 5′-SH-TCTAAA-AATGGGCAAAGAAACAGTGACTCGTTGAGATACT-3′ (apt 1) and 5′-bio-TCTAAAAATGGGCAAAGAAACAGTGACTCGTTG-AGATACT-3′ (apt 2).

Instrumentation. Transmission electron microscopy (TEM) images were acquired with JEM-2100HR (TEM, JEOL Ltd., Tokyo, Japan). FT-IR spectra of nanoparticles were measured on a Nicolet Nexus 470 Fourier transform infrared spectrophotometer (Thermo Electron Co., Boston, MA, USA). UV−vis spectra and absorbance were obtained using a UV-1800 spectrophotometer (Shimadzu Co., Kyoto, Japan).

Bacteria Strains. The *V. parahemolyticus* ATCC 17802 was kindly donated by the Animal, Plant and Food Inspection Centre, Jiangsu Entry-Exit Inspection and Quarantine Bureau (Nanjing, China). *V. parahemolyticus* was cultured in alkaline peptone with 3% NaCl (w/v) overnight past the logarithmic phase. One hundred microliters of the bacterial culture was diluted with medium and coated on the agar plates and cultured at 37 °C for 18 h to count colony-forming units (cfu). The rest of the bacteria were collected carefully by centrifugation at 3000 rpm and 4 °C and washed twice in a 1× binding buffer (50 mM Tris-HCl at pH 7.4, 5 mM KCl, 100 mM NaCl, and 1 mM $MgCl_2$) at room temperature.

Synthesis of HRP-Labeled AuNPs. Briefly, all glassware used in the experiment was cleaned with aqua regia (HNO_3/HCl, 3:1, v/v), rinsed thoroughly in ultrapure water, and dried prior to use. Half a milliliter of 1% $HAuCl_4$ solution and 49.5 mL of ultrapure water were heated to the boiling point for 10 min with continuous stirring. Then, 1.5 mL of 1% trisodium citrate was rapidly added, stirred, and boiled for 15 min. The solution color changed from gray to blue, then purple, and finally to wine red during this period. The heating source was removed, and the colloid was cooled to room temperature. HRP-labeled AuNPs were prepared according to the previous study, with slight modifications.[18] The prepared AuNPs (1 mL) were adjusted to pH 8.5 and mixed with 17.5 μL of HRP molecules (1 mg/mL) to incubate for 10 min at 25 °C under gentle shaking. Then, the mixed solution was allowed to stand overnight at 4 °C. After incubation with PEG (0.5%, w/v) for 30 min at 25 °C, the mixture was centrifuged (12000 rpm, 20 min) to remove the unbound HRP molecules and PEG and washed with PBS three times. The final deposition was suspended in 200 μL of PBS and stored at 4 °C for further use.

Synthesis of Aptamer-Functionalized HRP-Labeled AuNPs. HRP-labeled AuNPs modified by aptamer were prepared according to the literature with some modification.[19] This protocol was based on the Au−S interaction between the gold lattice and thiolated aptamer. Briefly, 10 μL of 10 μM apt 1 was added to 190 μL of the already prepared HRP-labeled AuNPs solution and reacted for 16 h. Then the HRP-labeled AuNPs−apt 1 complex was aged with salts (0.1 M NaCl, 10 mM phosphate, pH 7.0) for 40 h. The prepared complex was centrifuged at 12500 rpm for 15 min twice to remove the free aptamer. Then, the HRP-labeled AuNPs−apt 1 was dispersed in 200 μL of binding buffer for subsequent experiments.

Synthesis of MNPs and Aptamer-Functionalized MNPs. The amine-functionalized MNPs were prepared by a one-step solvothermal method according to ref 20. Typically, 6.5 g of 1,6-hexanediamine, 2.0 g of anhydrous sodium acetate, and 1.0 g of $FeCl_3{\cdot}6H_2O$ were dissolved in 30 mL of glycol to form a transparent solution with vigorous stirring at 50 °C. The mixture was subsequently transferred into a Teflon-lined autoclave and heated to 198 °C for 6 h. The product was cooled to room temperature and then washed with water and ethanol (two or three times) followed by drying at 50 °C.

The primary amine groups on the surface of MNPs were activated by glutaraldehyde, allowing amine groups on aptamer oligonucleotides to be covalently attached. Briefly, 1 mg of the MNPs was dispersed in 1 mL of 10 mM phosphate buffer solution (PBS, pH 7.4), and 0.25 mL of 25% glutaraldehyde was added into the solution. The reaction was continued for 2 h at room temperature with gentle shaking, followed by three washings with PBS. The resultant MNPs were dispersed in 1 mL of 10 mM PBS, and 50 μL of apt 2 (10 μM) was added and incubated for 2 h at 37 °C with gentle shaking. Next, the MNPs−apt 2 complexes were magnetically collected and rinsed twice with PBS.

Procedure for Analysis of *V. parahemolyticus*. In a typical experiment, 200 μL of AuNP−HRP−apt 1 and 150 μL of MNPs−apt 2 (1 mg/mL) were first mixed. Then, 50 μL of binding buffer containing various concentrations of *V. parahemolyticus* was added and incubated for 30 min at 37 °C with gentle shaking. After incubation, the magnetic beads were magnetically collected and rinsed with PBS twice. Then, 100 μL of TMB−H_2O_2 solution was added to each tube, and these tubes were incubated at 37 °C for 15 min with gentle shaking. Color development was stopped by adding 100 μL of

0.5 M sulfuric acid. After the magnetic separation, the absorbance at 450 nm of the supernatant was read with a UV spectrophotometer.

Real Sample Treatment. The water samples were collected from Tai Lake, the Yellow Sea, laboratory tap water, and groundwater in China, respectively. Then the water samples were filtered through a 0.45 μm filter. Different *V. parahemolyticus* concentrations were then added to the prepared samples for the experiments.

RESULTS AND DISCUSSION

Principle of the Aptasensor. Scheme 1 shows the principle of this developed aptasensor. MNPs were modified with aptamer to act as the capture probe. AuNPs were coated with a large amout of HRP and linked to aptamer to act as signal amplifiers. In the presence of target, aptamers on the surface of both MNPs and AuNPs bound with the target with high affinity and specificity, leading to the formation of MNPs−aptamer−target−aptamer−HRP−AuNPs sandwich complexes. With an extra magnetic field, unbound AuNPs−HRP−aptamer was removed. With the addition of TMB−H_2O_2, HRP on the sandwich complexes was catalyzed and generated an optical signal. With the carrier of AuNPs, a large amount of HRP could be loaded, resulting in an amplified signal, and the sensitivity would be improved.

Characteristics of AuNPs and MNPs. The morphology characteristics of AuNPs are shown in Figure 1A. The AuNPs are monodisperse and spherical with an average size of 15 nm. As shown in Figure 1B, the UV−vis spectrum of AuNPs solution (black line) exhibited a characteristic plasmon absorption peak at 520 nm. After modification of HRP on the surface, the UV−vis spectrum of the AuNP complex showed a small surface plasmon shift from 520 to 524 nm (red line). The shift after modification of AuNPs with HRP was

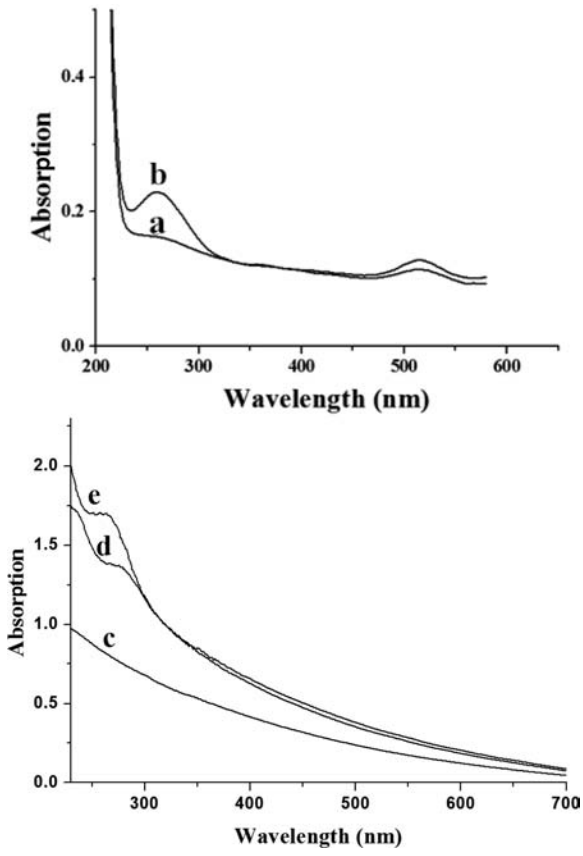

Figure 2. Absorption spectra of bare AuNPs-HRP (a), apt 1-functionalized AuNPs−HRP (b), bare MNPs (c), avidin conjugation to MNPs (d), and apt 2-functionalized MNPs (e).

J. Agric. Food Chem. 2015, 63, 7849−7854

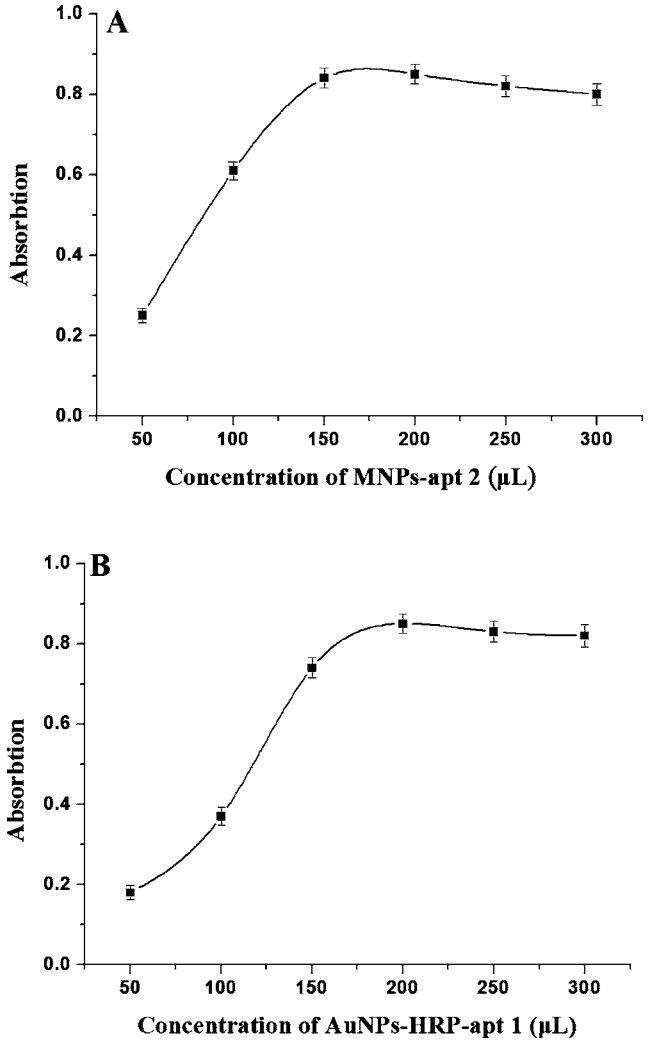

Figure 3. Optimization of MNPs−apt 2 concentration (A) and AuNPs−HRP−apt 1 complex concentration (B). (Concentration of *V. parahemolyticus* was 10^4 cfu/mL.)

attributed to changes in the particle size and the dielectric nature surrounding the AuNPs due to the presence of protein. Both results suggested successful immobilization of HRP onto the AuNPs.

The TEM and FT-IR techniques were used to obtain information about the as-synthesized MNPs. Figure 1C shows a TEM image of the MNPs, indicating a good dispersibility and morphology. Figure 1D shows the FT-IR spectra of MNPs. Formation of MNPs was confirmed by a strong IR band at 586 cm^{-1} that comes from the Fe−O vibrations. The bands around 1590, 1410, and 1060 cm^{-1} were NH bending mode and C−N stretching vibration, respectively. The results from FT-IR revealed that the MNPs have been functionalized with amino groups in the synthetic process.

Characteristics of the Nanoparticles Conjugated to Aptamer. We applied UV−vis spectrophotometer to validate the successful coupling of thiolated labeled aptamer (apt 1) to AuNPs−HRP through Au−S bonding and biotin-labeled aptamer (apt 2) to avidin-modified MNPs through biotin−avidin specific bonding. As shown in Figure 2A, AuNPs−HRP shows an absorbance peak at 524 nm (curve a); with the addition of apt 1, another peak at 260 nm, which is the characteristic absorption of DNA, has been observed (curve b).

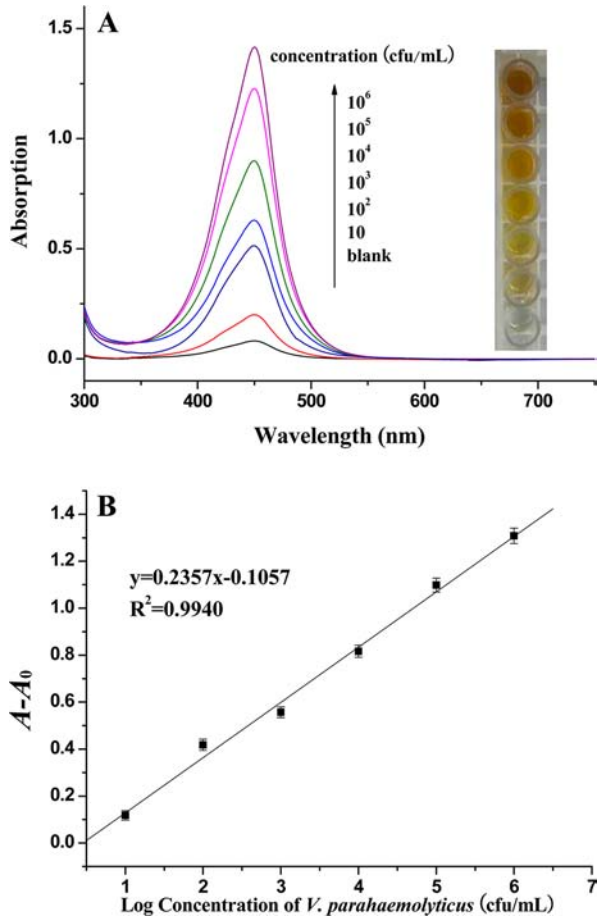

Figure 4. (A) Typical recorded output for the detection of different concentrations of bacteria by the developed method. (Inset) Color change by the naked eye. (B) Standard curve of the related absorbance ($A - A_0$) versus the concentrations of bacteria.

Similarly, no strong absorbance peak was detected for MNPs (curve c). After conjugation to avidin, a new absorption peak at approximately 280 nm, which is a characteristic absorption peak of avidin, was observed (curve d). With the subsequent addition of apt 2, the peak at 260 nm was also observed (curve e). These results demonstrate that aptamers were successfully coated on the nanoparticles.

Optimization for the Assay. According to the principle of the assay, experimental parameters such as the amount of aptamer functionalized MNPs and aptamer functionalized AuNPs−HRP complex would affect the signal response. The effect of the MNPs−apt 2 was first studied. As shown in Figure 3A, response signals increased with increasing MNPs−apt 2, and a maximum was attained at 150 μL (1 mg/mL). Further increase in MNPs−apt 2 concentration had very little additional beneficial effect. Therefore, an optimal volume of 150 μL of MNPs−apt 2 was chosen in subsequent experiments. Figure 3B shows optimization of the AuNPs−HRP−apt 1 complex concentration. The value of A_{450} was found to increase as the AuNPs−HRP−apt 1 complex concentration was increased until 200 μL, after which the A_{450} plateaued and remained constant. Therefore, 200 μL of the AuNPs−HRP−apt 1 complex was used for subsequent experiments.

Analytical Performance. Utilizing the optimal conditions in this system, the catalytic ability of the HRP-labeled AuNPs on TMB oxidation in the presence of different concentrations

DOI: 10.1021/acs.jafc.5b03224
J. Agric. Food Chem. 2015, 63, 7849−7854

of *V. parahemolyticus* was investigated. Results were evaluated in terms of $(A - A_0)$, where A_0 and A are the absorbance of the colorimetric aptasenosr method in the absence and presence of *V. parahemolyticus*, respectively. As displayed in Figure 4A, the absorbance was increased along with the *V. parahemolyticus* concentration. A clear change from light yellow to dark yellow could be obviously differentiated by the naked eye (inset A). As shown in Figure 4B, $A - A_0$ exhibits a good linear relationship with *V. parahemolyticus* in the concentration range from 10 to 10^6 cfu/mL. The linear regression equation of *V. parahemolyticus* is described as $Y = 0.2357x - 0.1057$ ($R^2 = 0.9940$), and the detection limit was found to be 10 cfu/mL.

Specificity, Interference, and Practical Performance of the Assay. To investigate the selectivity of the developed method, the AuNPs and MNPs complexes were employed to detect other pathogenic bacteria, including *Vibrio alginolyticus*, *Vibrio vulnificus*, *Vibrio mimicus*, *Escherichia coli*, *Salmonella typhimurium*, and *Staphylococcus aureus* at a concentration of 10^5 cfu/mL, which might affect the detection of *V. parahemolyticus* in real sample analysis. As shown in Figure 5, it is clearly seen

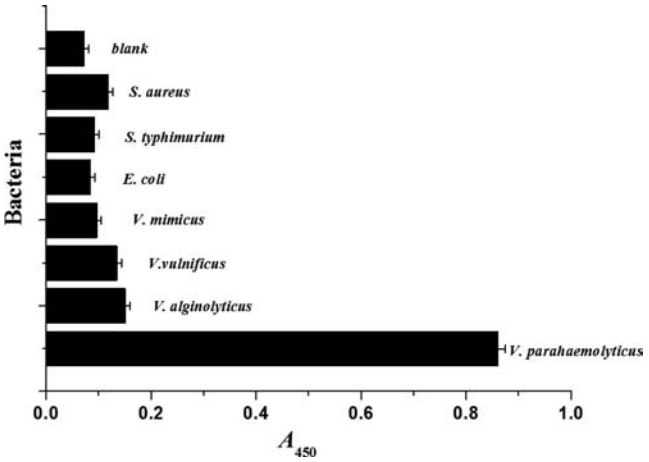

Figure 5. Specificity studies against other bacteria. Concentration of *V. parahemolyticus* was 10^4 cfu/mL, whereas the other concentrations were 10^5 cfu/mL.

that only *V. parahemolyticus* induces a dramatic increase of absorbance, whereas other species produced signals as low as the blank control. These results clearly demonstrated that the developed method is appropriate for the selective detection of *V. parahemolyticus*.

In addition, we examined the effect of a variety of possible interfering substances in this system. We used a range of proteins, small molecules, and ions to determine the selectivity for *V. parahemolyticus*. Under the optimized conditions (the concentration of *V. parahemolyticus* was set as 10^4 cfu/mL), none of the other interferents affected detection signals, even at concentrations as high as 2% bovine serum albumin, 10 μg/mL of immunoglobulin G, 100 mM resorcinol or microcystic toxins, and 500 mM Na^+, K^+, Pb^{2+}, or Cd^{2+}. Thus, the results clearly demonstrate that the developed method specifically identified *V. parahemolyticus* in a real environment.

The practical performance of the developed method was validated with four real water samples. The accuracy of this method was evaluated by determining the recoveries of *V. parahemolyticus* in the water samples by standard addition method. The water samples were spiked with *V. parahemolyticus* at the desired concentrations (2×10^2 and 2×10^3 cfu/mL) and were analyzed by standard culture and colony-counting method. Then, the spiked samples were analyzed by the colorimetric aptasensor method. As can be seen from Table 1, the recoveries of *V. parahemolyticus* in the four real water samples are between 92.0 and 102.0%. These results show that recoveries of *V. parahemolyticus* and the reproducibility are satisfactory.

In summary, we developed a colorimetric aptasensor to detect *V. parahemolyticus* in which AuNPs were used as carriers of HRP and aptamer, and MNPs−aptamer were used as supporting substrates for capture targets. The AuNPs−HRP−aptamer complex loaded a high amount of HRP amplification enzyme; thus, the developed assay based on the AuNPs complex exhibited improved sensitivity. This feature, as well as its convenient magnetic separation, made it a promising alternative to conventional pathogenic bacteria methods. This assay system displayed excellent specificity, sensitivity, and linearity for the quantitative detection of the target molecules, along with the production of a color signal that can be detected by the naked eye. In addition, this method has the potential to detect other bacteria by changing aptamers.

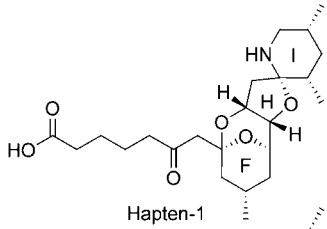
Here we report the use of the polyclonal antibody against AZAs,[27] after further immunizations of the same sheep, to develop the first ELISA method for quantitation of these compounds in mussels at concentrations below the current regulatory limit.

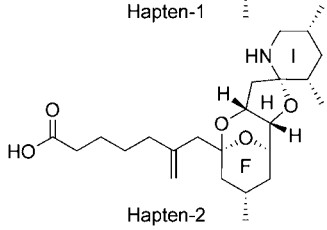
MATERIALS AND METHODS

Materials. AZA-1 was from the Marine Institute, Ireland.[30] Bovine serum albumin (BSA), ovalbumin (OVA), L-cysteine, bromine (Br_2), and Freund's incomplete adjuvants were from Sigma-Aldrich (St. Louis, MO, USA). Cationized BSA (cBSA) was prepared according to standard methods.[31] Maxisorp immunoplates (96 flat-bottom wells) were from Nunc (Roskilde, Denmark), poly(vinylpyrrolidone) 25 (PVP) was from Serva Electrophoresis (Heidelberg, Germany), rabbit–anti-sheep horseradish peroxidase conjugate (anti-sheep–HRP) was from Zymed (now Invitrogen, Paisley, UK), and the HRP-substrate K-blue Aq. was from Neogen (Lexington, KY, USA). Certified reference materials (CRMs) of AZA-1, AZA-2, AZA-3, microcystin-LR, and okadaic acid were from the National Research Council of Canada (Halifax, NS, Canada). Quantitative laboratory reference materials (LRMs) of AZA-4–10, AZA-33, AZA-34, and 37-*epi*-AZA-1 were prepared as described by Kilcoyne et al.[32−34] Pinnatoxin G was from Cawthron Institute (Nelson, New Zealand). All other inorganic chemicals and organic solvents were of reagent grade or better. Plate-coating buffer was carbonate buffer (50 mM, pH 9.6). Phosphate-buffered saline (PBS) contained NaCl (137 mM), KCl (2.7 mM), Na_2HPO_4 (8 mM), and KH_2PO_4 (1.5 mM), pH 7.4. ELISA washing buffer (PBST) was 0.05% Tween 20 in PBS. Sample buffer was 10% MeOH (v/v) in PBST, and the antibody buffer consisted of 1% PVP (w/v) in PBST.

Immunogen. The synthetic AZA-hapten-1 was prepared and conjugated to cBSA as described by Forsyth et al.[27] Hapten-2 was prepared by using a novel synthetic route[35] and conjugated to cBSA in the same manner as for hapten-1 to form cBSA–hapten-2 (Figure 2).



Hapten-1



Hapten-2

Figure 2. Structures of hapten-1 and hapten-2 used for preparing immunogens and the initial plate-coating antigen. Both haptens consist of the constant region of AZAs (C-26–C-40).

The immunogen was washed through multiple centrifugations with PBS in a Vivaspin 5.0 mL concentrator with a 10000 MW cutoff (Sartorius Stedim Biotech GmbH, Goettingen, Germany) to remove unreacted hapten and excess reagents. The cBSA–hapten-2 was dispensed as aliquots (1 mg in 100 μL), lyophilized, and stored at −20 °C.

Plate Coating Antigen (OVA–BrAZA-1). Purified AZA-1 (40 μg) was dissolved in MeOH (100 μL), to which was added 50 μL of bromine solution (5 μL of Br_2 in 10 mL of MeOH). After 1 h, the solution was evaporated to dryness under a stream of nitrogen to remove solvent and residual bromine. The residue was dissolved in MeOH (100 μL) and added to a solution of ovalbumin (5 mg) in coating buffer (1 mL). After reaction for 18 h, 1 mL of 5 mg/mL L-cysteine in PBS was added to quench unreacted bromides for 2 h at 4 °C. The OVA–BrAZA-1 was washed, dispensed as aliquots (1 mg in 405 μL), lyophilized, and stored as for the immunogen.

Polyclonal Antibodies. Six sheep were immunized, three in New Zealand (Romney breed) and three in Norway (Nor X breed). The first six immunizations were with cBSA–hapten-1 (Figure 2),[27] followed by five immunizations with cBSA–hapten-2. During these 11 immunizations, the sheep were given three long resting periods to mature the immune response. Immunizations in New Zealand were, in general, performed as described by Briggs et al.[36] (300 μg of immunogen in 1.0 mL of water-in-oil emulsion) and those in Norway as described by Samdal et al.[37]

ELISA. Maxisorp immunoplates were coated overnight at ambient temperature with plate-coating antigen OVA–BrAZA-1 in coating buffer (100 μL/well) at 10 μg/mL. After incubation, the plates were washed four times with PBST. The plates were blocked for 1 h with 1% PVP in PBS (300 μL/well) and then washed twice with PBST.

J. Agric. Food Chem. 2015, 63, 7855−7861

Noncompetitive assays were used to estimate titers of the sera giving a maximum absorbance of 1.0. This was done by combining equal volumes (50 μL) of sample buffer (10% MeOH in PBST) and dilution series of antisera in antibody buffer (1% PVP in PBST) in wells and incubating for 1 h. After four washings with PBST, bound antibody was detected by adding anti-sheep−HRP conjugate diluted 1:3000 in antibody buffer (100 μL/well) for 2 h and then washing four times before the addition of the HRP substrate (100 μL/well). After 15 min, the reaction was stopped by adding 50 μL of 10% H_2SO_4, and absorbances were measured at 450 nm using a model 1420 Victor^2 plate reader (Wallac, Turku, Finland). All incubations were performed at ∼20 °C.

Competitive ELISAs were performed as described above, by adding appropriate amounts of standard or sample, and antiserum was added to the wells after blocking. Concentrated standards in MeOH, usually AZA-1 (1.31 μg/mL), were diluted in PBST to give a MeOH concentration of 10% and then in a 3-fold dilution series in sample buffer, giving standard concentrations of 0.0066−131 ng/mL. Shellfish extracts in MeOH were similarly diluted 10 times with PBST to adjust for the MeOH concentration, followed by a dilution series in sample buffer. All sample and standard dilutions were analyzed in duplicate wells. The remaining ELISA steps were as described for the noncompetitive ELISA.

Optimization. Optimal concentrations of plate-coating antigen (10 μg/mL), antiserum AgR367-11b (1:8700), and anti-sheep−HRP (1:3000) were determined by checkerboard titrations followed by optimization of the standard curve. Assay standard curves were calculated using logistic treatment of the data. The assay working range was defined as the linear region at 20−80% of maximal absorbance (A_{max}).

Cross-Reactivity. The relative specificity of the immunoassay toward the available AZAs, microcystin-LR, okadaic acid, and pinnatoxin G was determined by assaying a dilution series of each compound in sample buffer. The I_{50} values (molar concentration giving 50% inhibition) are expressed as a percent I_{50} relative to the AZA-1 CRM.

LC-MS/MS Analysis. Quantitation of AZA-1−3 and -6 was performed on a 2695 LC coupled to a Micromass triple-stage quadrupole (TSQ) Ultima (both from Waters, Manchester, UK) operated in multiple reaction monitoring (MRM) mode, with the following transitions: AZA-1, m/z 842.5 → 654.4 and 842.5 → 672.4; AZA-2 m/z 856.5 → 654.4 and 856.5 → 672.4; AZA-3 m/z 828.5 → 640.4 and 828.5 → 658.4; AZA-6 m/z 842.5 → 640.5 and 842.5 → 658.4. The cone voltage was 60 V, and the collision voltage was 40 V; the cone and desolvation gas flows were set at 100 and 800 L/h, respectively, and the source temperature was 150 °C.

Binary gradient elution was used, with phase A consisting of water and phase B of 95% acetonitrile in water (both containing 2 mM ammonium formate and 50 mM formic acid). Chromatography was performed with a 50 mm × 2.1 mm i.d., 3 μm, Hypersil BDS C8 column, with a 10 mm × 2.1 mm i.d. guard column of the same material (Thermo Scientific, Waltham, MA, USA). The gradient was from 30 to 90% B over 8 min at 0.25 mL/min, held for 5 min, then held at 100% B at 0.4 mL/min for 5 min, returned to the initial conditions, and held for 4 min to equilibrate the system. The injection volume was 5 μL, and the column and sample temperatures were 25 and 6 °C, respectively.

Mussel Extracts. AZA-contaminated raw mussel (*M. edulis*) samples, tested as part of the routine monitoring program in Ireland, were selected for analysis. The shellfish were shucked and homogenized using a Waring blender before extraction. Tissue samples were weighed (2 g) and duplicate samples sealed in 50 mL centrifuge tubes. One sample was placed in a water bath and heated to 90 °C for 10 min and then allowed to cool. Both samples were extracted by vortex mixing for 1 min with 9 mL of MeOH and centrifuged at 3950 *g* (5 min), and the supernatants were decanted into 25 mL volumetric flasks. The remaining pellet was further homogenized and extracted using an Ultra Turrax (IKA, Staufen, Germany) for 1 min with an additional 9 mL of MeOH and centrifuged at 3950 *g* for 5 min, and the supernatant was decanted into the same 25 mL volumetric flask, which was then brought to volume with MeOH. Extracts were analyzed by LC-MS/MS and ELISA.

Spiked Tissue Extracts. A mussel extract that had trace levels of AZAs (<0.1 ng/mL by LC-MS/MS) was spiked with an AZA-1 CRM at six concentrations ranging from 5 to 200 ng/mL.

RESULTS AND DISCUSSION

Hapten Synthesis, Conjugation, and Immunogen Preparation. A critical step in designing hapten chemistry to generate an immunoassay with appropriate specificity is deciding which substructures within the analyte should be recognized by the antibodies and which should not be recognized. Just as important, when one is dealing with numerous variants of AZA with modifications at several sites on the parent molecule, is to balance the preference of the antibodies for particular toxin variants to achieve uniform cross-reactivity.

Most AZAs have very similar structures, with all of the published analogues differing in the C3−C16 area and at C-22, C-23 and C-37 in the molecule (Figure 1). Therefore, with the aim of developing an ELISA with broad specificity to AZA-3, and the structurally conserved region C-26−C-40 appeared to be a favorable area to raise antibodies against. Furthermore, the scarcity of AZA-1 at the time, and the development of several partial syntheses of AZAs, made the constant C26−C40 area of the AZAs even more attractive as an immunogen. Subsequent attempts at raising antibodies against AZA-1 itself have encountered problems with toxicity.[28]

Two similar haptens were synthesized (Figure 2), representing the major structural elements of the AZA C26−C40 region (Figure 1). Hapten-1, an AZA fragment with a ketone at the position corresponding to C-26 in AZA-1, was synthesized and initially used for immunization.[27] Later, hapten-2, with an olefinic methylene instead of the ketone in hapten-1, was synthesized to resemble AZAs more closely[35] and used to continue the immunization program. Both haptens were conjugated to cBSA to make them immunogenic. Both immunogens present the structurally conserved region of AZAs (C-26−C-40) to the sheep's immune system, and it was hoped that this would result in antibodies specific to the C-26−C-40 moiety and therefore with good recognition for the wide range of known AZA variants.

Plate-Coating Antigen. For small molecules such as AZAs, ELISA format options are limited to competitive assays, where the antibody can bind either to the AZA on the plate-coating antigen (or on a reporter molecule) or to free AZAs in the sample. Because the assay is based on competition between the plate-coating antigen and the analyte for the antibody's binding sites, the plate-coating chemistry is important in the development of a competitive immunoassay, especially with polyclonal antisera. During assay development, several plate-coating antigens were prepared and tested. These initially used hapten-1, later hapten-2, and finally BrAZA-1 bound to OVA.

Precharacterization of AZA Antibodies. Between immunizations, antisera were screened by indirect ELISA for AZA-specific antibodies initially using OVA−hapten-1 and later OVA−hapten-2. Hapten-specific antibodies were detectable in each antiserum after the first booster injection. Antisera titers were determined by noncompetitive ELISA. Antiserum from sheep AgR367 gave the highest antibody titer (1:200,000) after four immunizations, whereas antisera from other sheep had much lower (5−200-fold) titers. Initial screening for competition, by addition of AZA-1, showed that acceptable standard

DOI: 10.1021/acs.jafc.5b02513
J. Agric. Food Chem. 2015, 63, 7855−7861

curves could be obtained using only antiserum AgR367 (I_{50} at 160 ng/mL). Therefore, this antiserum was used for assay development and optimization.

ELISA Optimization. The ELISA was optimized with 10% MeOH in all samples and standards to be compatible with standard methods for extraction and analysis of mussels for lipophilic algal toxins. To obtain maximum ELISA sensitivity, the assay conditions, such as the concentration of reagents, the blocking agent, and temperature, need to be optimized. Optimal concentrations of assay reagents were determined by checkerboard titrations and standard curves. Criteria used to evaluate optimization were A_{max}, working range (I_{20}–I_{80}), I_{50}, slope of the curve, and limit of quantitation (LOQ; I_{20} based on the mean of several assays and multiplied by the dilution factor (i.e., 10 for MeOH-extracts)). Note that AZAs in mussel tissue were diluted 12.5-fold during extraction with 100% MeOH, and the LOQ for AZAs in mussel tissue is therefore the assay I_{20} multiplied by 12.5 and then 10.

Assay optimization was carried out using bulk collections of antisera taken from sheep AgR367 after 4, 6, 10, and 11 immunizations (AgR367-4b, -6b, -10b, and -11b). Assay sensitivity was increased by using 1% PVP as the blocker, rather than 1% BSA, 1% OVA, 1% Superblock, or 1% casein. Furthermore, use of PVP as the blocker resulted in up to a 5-fold reduction in the amount of antiserum required for the assay.

Assay sensitivity and competition were improved by changing the plate-coating antigen from OVA–hapten-1 to OVA–hapten-2. The working range improved from 17–1054 to 4–62 ng/mL and the sensitivity (I_{50}) from 135 to 16 ng/mL, increasing assay sensitivity approximately 8-fold (using AgR367-4b). With OVA–BrAZA-1 as plate-coating antigen, the optimized assay (average of 13 assays) had a working range (I_{20}–I_{80}) of 0.45–8.6 ng/mL and the I_{50} was 1.9 ng/mL. This change to OVA–BrAZA-1 (and AgR367-11b) made the assay 8-fold more sensitive than with OVA–hapten-2 and 71-fold more sensitive than with OVA–hapten-1. This improved sensitivity may be due the antibodies' affinity for OVA–BrAZA-1 being closer to that for free AZAs (the analyte) than was the case for OVA–hapten-1 and OVA–hapten-2. This would be expected to lead to more effective competition by the analytes and, thus, higher assay sensitivity for AZAs. Standard curves obtained with the CRMs of AZA-1, AZA-2, and AZA-3 are shown in Figure 3.

Specificity. Reduction in the competitive ELISA signal upon addition of AZA-1 indicates competition, but does not show which other target analyte can bind to the antibodies. Often, ELISAs are aimed at recognizing one compound specifically. In this case, we aimed to develop an assay recognizing all AZAs containing the right-hand part of the AZA structure (C-26–C-40). Therefore, the response of the optimized assay to AZA-1–10, AZA-33, AZA-34, and 37-*epi*-AZA-1 (Figure 1), all of which are reported to be toxic,[34] was tested over a range of concentrations to determine cross-reactivity (Table 1). All AZA standards caused concentration-dependent inhibition of antibody binding. On the basis of I_{50} values, the molar cross-reactivities relative to AZA-1 were 75–140% for the CRMs of AZA-1, AZA-2, and AZA-, and 57–145% for LRMs of the remaining AZAs (Table 1). The antibodies in the assay therefore have a similar affinity for these other AZAs as they do for the reference standard, AZA-1. Similar tests with microcystin-LR (50 ng/mL), okadaic acid (1.4 μg/mL), and pinnatoxin G (1.0 μg/mL) resulted in no inhibition. Cross-reactivity to these toxins is <1% with the antibody, indicating that the antibody binds specifically to AZAs.

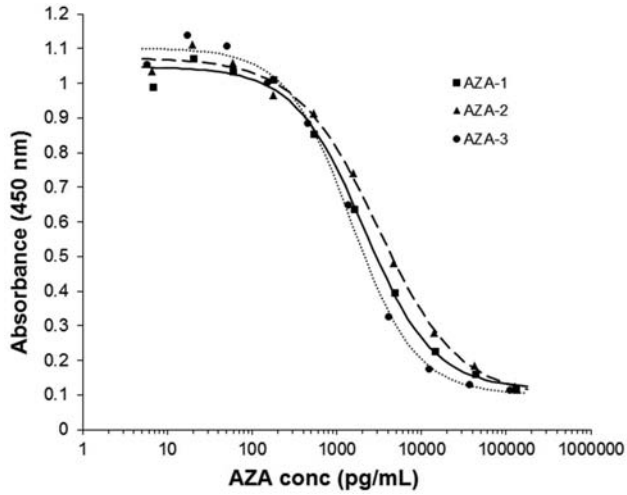

Figure 3. Standard curves obtained with CRMs of AZA-1, AZA-2, and AZA-3 in the AZA-ELISA using antibody AgR367-11b on plate coater OVA–BrAZA-1.

Table 1. Molar Cross-Reactivities of a Series of AZA Analogues in the AZA-ELISA

			assay range[a] (pg/mL)			
compound	origin	*n*	I_{20}	I_{80}	I_{50}	% CR[b]
AZA-1[c]	NRC	13	428	8047	1828	100
AZA-2[c]	NRC	6	504	14462	2666	75
AZA-3[c]	NRC	6	335	5228	1312	140

AZA-34[d]	MI	3	302	9364	1630	110
37-*epi*-AZA-1[d]	MI	3	440	15315	2586	77

[a] I_{20}, I_{50}, and I_{80} are the concentrations of analogue giving 20, 50, and 80% inhibition, respectively, of binding of antibody to the coating antigen (OVA–BrAZA-1). All values are corrected for AZA impurities in the standards. [b] Molar cross-reactivity; CR = 100 × (I_{50} AZA-1 CRM)/(I_{50} analogue). Intra-assay variation (CV) was 6–24% for I_{50} values based on 3–13 competition curves. [c] CRM. [d] LRM

Cross-reactivity studies indicated that recognition of analogues by antibodies in the ELISA was slightly reduced for AZA-2, AZA-7, AZA-33, and 37-*epi*-AZA-1 (Table 1), whereas it was slightly increased for AZA-3, AZA-4, AZA-6, and AZA-10. This may indicate that substitution of the methyl group at C-22 (R^3) for hydrogen slightly favors binding to the antibody, although AZA-5 does not show the same increase. The substituents at C-3, C-8, and C-23 (R^1, R^2, and R^4) seem to have less influence on antibody binding, which is as expected given that these substituents are not part of the C-26–C-40 present in the immunogens. A lack of standards of the other AZAs prevented characterization of the cross-reactivity of AZA-11 to AZA-32, but it is anticipated that the antibodies will recognize most of the known analogues, because they all

DOI: 10.1021/acs.jafc.5b02513
J. Agric. Food Chem. 2015, 63, 7855–7861

contain the C-26−C-40 region of the AZA (Figure 1). Furthermore, that the ELISA gave essentially identical results from cooked and uncooked mussels suggests that the 22-carboxy congeners AZA-17, -19, -21, and -23 also have similar cross-reactivities to their corresponding thermal degradation products (AZA-3, -6, -4 and -9, respectively).[38] Cross-reactivity with AZA-33 (57%) confirms that rings A−D are not included in the antibody binding site.

37-*epi*-AZA-1 is identical to AZA-1 except for a stereochemical change at C-37, where the methyl group is orientated axially (37*R*) instead of equatorially (37*S*) as in all the other AZA analogues. The ELISA cross-reactivity was 77% for 37-*epi*-AZA-1. This structural change is in the "constant region" and may explain the slightly lower response, but nevertheless suggests that antibody binding is not especially sensitive to stereochemistry at C-37.

The ELISA therefore appears to detect all of the reported AZA congeners. It should be noted, however, that although the assay estimates the total content of AZAs, this does not necessarily reflect the toxicity of the sample because different congener structures vary in toxicity.

Standards. The availability of reliable standards is critical for the development and validation of analytical methods. One obstacle in this study was the relatively limited array of AZA analogues that were available for cross-reactivity studies. The criteria for what constitutes a good standard may vary between analytical methods. For example, standards adequate for LC-MS may contain contaminating analogues that do not interfere with quantitation due to differences in mass and retention time. However, for antibody-based detection, contaminating AZA analogues can affect the response. Even for highly pure standards, all analytical methods require that standards are quantitatively accurate to produce reliable results. Consequently, cross-reactivity data should be regarded only as indicative, except where high-purity quantitatively verified standards have been used. When calculating cross-reactivities for the various AZA standards, the known impurities in the CRMs and LRMs were corrected for. However, because the AZA standards were relatively pure, these corrections resulted in only minor changes to the calculated cross-reactivities in Table 1.

Preliminary Validation. Preliminary investigations with methanolic extracts from mussels, scallops, oysters, and algal extracts showed minimal matrix effects (data not shown). The LOQ for total AZAs in whole shellfish was calculated to be 57 μg/kg (2 g extracted with 25 mL of MeOH).

AZA-1 was spiked into extracts of a natural sample of Irish mussel previously shown by LC-MS to contain only trace levels of AZAs. The sample was spiked with six concentrations of AZA-1 (Figure 4A). Analyses determined by the optimized ELISA and LC-MS/MS were compared with the calculated AZA-1 concentrations. The results for AZAs by ELISA and for AZA-1 by LC-MS/MS were very similar (Figure 4A), and the ELISA correlates well with LC-MS/MS (within ±20%) between 10 and 150 ng/mL (corresponding to 125−1875 μg/kg in whole shellfish). Both methods, however, appeared to underestimate the levels for very high concentrations (12−16 times the regulatory level of AZA-1). The average recovery by ELISA was 102%, well within the acceptable limits for assay recovery (100 ± 20%).

To confirm its applicability to real samples, the ELISA was used to analyze AZAs in 13 shellfish samples (*M. edulis*). Of these 13 samples, all were extracted as raw tissues and analyzed,

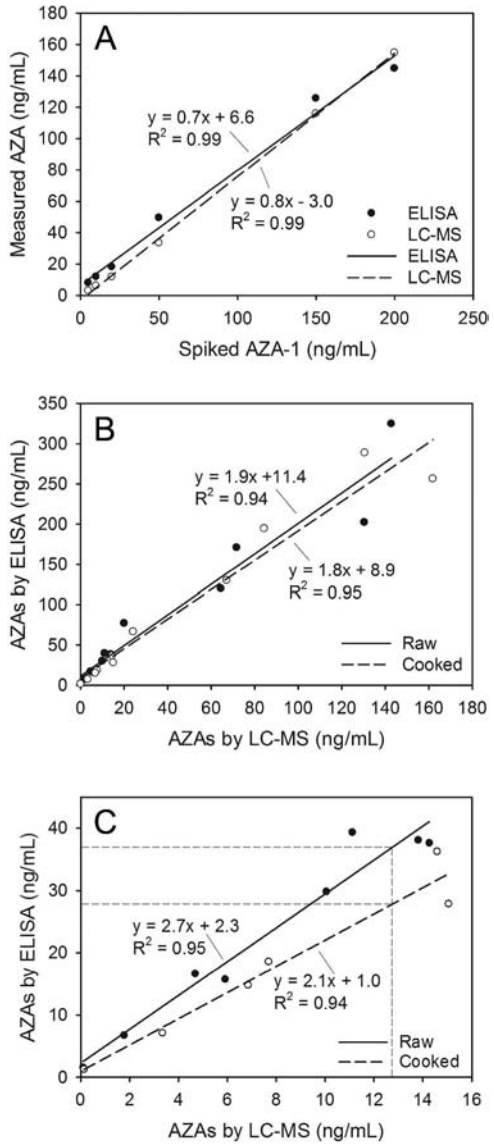

Figure 4. Comparison of total AZAs determined by ELISA and LC-MS/MS for samples of mussels (*M. edulis*): (A) spiking of a mussel sample with 5, 10, 20, 50, 150, and 200 ng/mL of AZA-1; (B) analysis of 13 raw (●) and 11 cooked (○) naturally contaminated samples for AZA-1, -2, -3, and -6 by LC-MS and for total AZAs by ELISA; (C) expansion of graph B showing the data from 0 to 16 ng/mL by LC-MS/MS, that is, close to and under the regulatory limit. The vertical dotted line at 12.8 ng/mL corresponds to the regulatory limit for AZA-1−3 in European shellfish.
