whereas 11 were also extracted as cooked shellfish tissues, without changing the water content, and analyzed (Figure 4B,C). For comparison, all samples were also analyzed by ELISA for AZAs and by LC-MS for AZA-1, AZA-2, AZA-3, and AZA-6. Figure 4B shows results for all samples (13 raw and 11 cooked), whereas Figure 4C shows only results up to around the regulatory level of 160 μg/kg,[25] which corresponds to 12.8 ng/mL in the extracts (8 raw and 6 cooked samples). ELISA results were ∼2-fold those obtained by analysis with LC-MS/MS for AZA1−3 and AZA-6. Presumably this is due to the presence of minor AZAs that were not targeted in the LC-MS/MS analysis, because LC-MS/MS and the ELISA showed an excellent 1:1 correlation for AZA-1-spiked shellfish. Results by ELISA were essentially identical regardless of whether the

J. Agric. Food Chem. 2015, 63, 7855−7861

shellfish had been cooked or not, whereas LC-MS/MS results were ~20% lower for uncooked shellfish. This difference is attributable to the heat-promoted conversion of the mussel metabolites AZA-17 and AZA-19 (not analyzed for by LC-MS/MS), present in the uncooked tissue, into AZA-3 and AZA-6 (which were analyzed for) by cooking and suggests that the antibodies recognize AZA-17 and AZA-19 with approximately the same cross-reactivity as for AZA-3 and AZA-6.

The method used for extracting azaspiracids from mussels was unfortunately not well suited to the AZA-ELISA. Extraction with a lower volume of solvent, and containing a higher percentage of water (so that a smaller dilution of the extract was required), would be expected to considerably improve the LOQ of the ELISA for total AZAs in mussels.

In summary, we report the development of the first ELISA for the detection of AZAs. The antibodies were developed using two synthetic fragments of AZA, respectively hapten-1, as reported previously,[27] and with further immunizations with conjugates of the improved hapten-2.[35] In this paper we have applied the resulting antibodies to the development of an AZA-ELISA. This ELISA is specific for AZAs, with similar cross-reactivity to a broad range of AZA analogues, so that the total content of analogues and metabolites can be measured. The antiserum together with the plate-coating antigen (OVA−BrAZA-1) provides an ELISA with good sensitivity and broad specificity.

This ELISA for AZAs is a sensitive and rapid analytical method that uses inexpensive instrumentation and is suitable for use as a tool for shellfish toxin analysis. The broad specificity of the antibodies means that the ELISA provides an estimate of the total content of AZA analogues present in the sample. The AZA-ELISA detects all the analogues that the European Commission[26] currently require testing for, that is, AZA-1, AZA-2, and AZA-3 (with cross-reactivities of 100, 75, and 140%, respectively). In addition, the ELISA can also detect a wide range of other AZAs, including AZA-17 and AZA-19, which are converted to AZA-3 and AZA-6, respectively, during cooking. Thus, the assay detects all of the regulated AZAs, as well as some of their precursors, and in addition it detects other AZA metabolites such as AZA-4, AZA-5, and AZA-7−10, which are also known to be toxic.[33] Comparison of the ELISA and LC-MS should facilitate detection of new metabolites of AZAs in a similar manner as reported for yessotoxins.[39]

■ ACKNOWLEDGMENTS

Sheep for antibody development were provided and cared for by farm staff at AgResearch, Hamilton, New Zealand, and The Animal Production Experimental Centre at The Norwegian University of Life Sciences, Ås, Norway. Immunizations and blood sampling were done with assistance from Arne Flåøyen and Jens Børsum at the Norwegian Veterinary Institute and Colleen Podmore (including initial antiserum screening) at AgResearch. All animal experiments were in accordance with the three R's, laws, and regulations and approved by the AgResearch Ruakura Animal Ethics Committee (Application 11832) or the Norwegian Animal Research Authority. We thank Dr. Y. Ding for synthetic assistance. Standards of AZA-1−3 were kindly provided by M. A. Quilliam at National Research Council of Canada.

hydrolysis (e.g., neosolaniol, T2-triol, and T2-tetraol), oxidation (e.g., 3′-hydroxy-HT2 and 3′-hydroxy-T2), de-epoxidation (e.g., de-epoxy-3′-hydroxy-HT2, de-epoxy-T2-triol, and de-epoxy-HT2), and glucuronide conjugation of biotransformation products such as HT2 and neosolaniol.[9] De-epoxidation is an important detoxification mechanism and together with metabolic changes (e.g., conjugation) of the hydroxyl group at C-3 has the greatest impact on reducing the toxicity of trichothecenes.[10]

In plants, conjugation of xenobiotics with glucose, sulfate, glutathione, or amino acids constitute well-known and effective detoxification strategies.[3] The resulting metabolites are chemically distinct compounds produced by enzyme-catalyzed reactions, belonging to the so-called "masked mycotoxins".[11] Formation of glucosylated trichothecenes in artificially and naturally contaminated cereals was first shown for the type-B trichothecenes deoxynivalenol (DON)[12] and nivalenol,[13] followed by HT2 and T2.[14] Nonetheless, metabolic products similar to those reported in animals have been detected in T2-treated *Baccharis* spp., namely, HT2, 3′-hydroxy-HT2, and T2-tetraol.[15] To date, very limited information exists with regard to the metabolic fate of HT2 and T2 in cereal grains and natural occurrence of their plant-derived metabolites. In a recent survey study, HT-2 toxin-3-*O*-*β*-glucoside (HT2-3-Glc) was quantified in naturally contaminated barley, wheat, and oats, reaching concentrations of up to 300 μg/kg.[16]

To study the metabolism of xenobiotics *in planta* comprehensively, unbiased methods offer the chance to probe the entire metabolic space of the biological system under investigation. While liquid chromatography−high resolution mass spectrometry (LC-HRMS) methods are principally suited to measure hundreds of metabolites simultaneously, they come with the drawback of primarily detecting unspecific signals of nonbiological origin.[17] Stable isotope labeling (SIL)-assisted untargeted metabolomics may resolve several of these limitations. SIL workflows have been recently applied in conjunction with HRMS to investigate the metabolism of DON in wheat and identification of novel plant-derived DON-metabolites.[18] This approach has also been useful for the characterization of the fungal secondary metabolomes of *Aspergillus fumigatus*[19] and *F. graminearum*.[20]

The aim of this study was to investigate the *in planta* metabolic fate of T2 and HT2 in wheat. Putative identification of novel metabolites was performed with untargeted SIL-assisted metabolic profiling using LC-HRMS. Data were processed with MetExtract,[21] and annotation was based on accurate mass measurements as well as LC-HRMS/MS spectra.[22] Time course kinetics of the identified metabolites were also studied in two wheat lines ranging from the flowering stage until full ripening.

MATERIALS AND METHODS

Chemicals and Reagents. HPLC grade acetonitrile and methanol were obtained from VWR (Vienna, Austria), and formic acid (LC-MS grade) and TWEEN 20 were purchased from Sigma-Aldrich (Vienna, Austria). Ammonium formate solution (5 M) was provided by Agilent Technologies (Waldbronn, Germany). Water was purified successively by reverse osmosis using an ELGA Purelab Ultra-AN-MK2 system (Veolia Water, Vienna, Austria). Crystalline nonlabeled T2 (purity 85%) and HT2 (purity 92%), as well as uniformly labeled U-[$^{13}C_{24}$] T2 (purity 98%; degree of enrichment 99.6 atom % ^{13}C) and uniformly labeled U-[$^{13}C_{22}$] HT2 (purity 86%; degree of enrichment 99.3 atom % ^{13}C) standards were purchased from Romer Labs GmbH (Tulln, Austria). Solutions from lyophilized labeled and nonlabeled T2 (10.0 g/L) and HT2 (10.0 g/L) were prepared separately by dissolving the compounds in acetonitrile. Certified standard solutions of T2 and HT2 (100.4 mg/L and 100.6 mg/L, respectively, in acetonitrile) were also obtained from Romer Labs GmbH. The analytical standard of HT2-3-Glc was enzymatically produced from HT2 (Michlmayr et al., manuscript in preparation). 3-Acetyl-T2 was synthesized from T2 using acetic anhydride in dichloromethane/pyridine with 4-dimethylaminopyridine as catalyst. Stock solutions in acetonitrile were prepared and were stored in sealed vials at −20 °C until use.

Plant Materials. The plant experiments are described according to the Metabolomics Standard Initiative (MSI) for the Proposed Minimum Information Set for reporting plant biological experimental designs. For the metabolomics profiling experiment, the spring wheat (*Triticum aestivum* L.) variety "Remus" ("Sappo"/"Mex"/"Famos") was selected. The awn-free variety was developed at the Bavarian State Institute for Agronomy in Freising, Germany. It possesses well-adapted agronomic characteristics for cultivation in Central Europe but is highly susceptible to Fusarium head blight (FHB) and DON.[23,24] The time-course experiment was conducted on the wheat variety Remus and the FHB-resistant variety "CM-82036-1TP-10Y-OST-10Y-OM-OFC" (abbreviated to "CM-82036") which originated from the cross of the varieties "Sumai-3" and "Thornbird" and possess awns.[24] Seeds of Remus and CM-82036 were first germinated. No vernalization was required, but the wheat seedlings were routinely submitted to a cold treatment at 5 °C for 1 week to improve tillering. Pots (diameter 23 cm) were filled with 7 L of a substrate (consisting of 500 L heat-sterilized compost, 250 L peat, 10 kg sand, and 250 g rock flour). Five seedlings of the same wheat line were planted in each pot.

Experiments were conducted in a greenhouse with computer-controlled settings for light, temperature, and relative air humidity. Light intensity (outside dark) was 360 μmol/sm^2 at 1 m above the soil throughout the complete experiment. Relative air humidity was set between 60 and 70% during plant growth. Temperature (day/night) and duration of illumination (hours) varied according to the development stage of the plants: from planting until the end of tillering (stage 3 on the Feekes scale[25]), 12 °C/10 °C/12 h; end tillering to midstem extension when the ear starts to swell (stage 8), 14 °C/10 °C/14 h; mid stem extension to start heading (stage 10.1), 16 °C/14 °C/14 h; from the start of heading to the start of flowering (stage 10.51), 18 °C/14 °C/14 h; from the start of flowering (stage 10.51) until the end of the experiment, 20 °C/18 °C/16 h. In total, the seedlings needed 9−10 weeks to reach the flowering stage.

During the experiment, the pots were watered if required (typically three times/week). Water was applied until the substrate was completely wet and the water started to seep out through the holes in the bottom of the pot. The soil substrate contained sufficient minerals to support seedling growth. At the end of tillering (stage 5 on the Feekes scale), 2 g of a mineral fertilizer (COMPO Blaukorn ENTEC, Münster, Germany; N/P/K/Mg: 14/7/17/2) was applied per pot. To prevent mildew, the cabinet was treated twice during plant cultivation with sulfur overnight (sulfur evaporator, Nivola, Lisse, The Netherlands).

Treatment of Wheat Plants and Sampling. The experimental design was a completely randomized block with three biological replicates. Upon reaching the correct developmental stage (stage 10.51 on the Feekes scale), flowering ears were selected and individually labeled. Only one ear per plant was used in the experiment to prevent possible systemic effects of an earlier treated ear on other later flowering ears of the same plant. A woolen thread was used to label the lowest treated spikelet in the lower part of the ear (approx. 2/3 from the ear tip). In general, spikelets were treated by injecting 10 μL of the respective test solution into each of the outer floret (hence, 20 μL per spikelet) after placing the pipet tip in the spikelet using an electronic pipet Multipette Xstream (Eppendorf, Hamburg, Germany). After each treatment, the ear was covered for 24 h with a small transparent plastic bag internally wetted by spraying ca. 2 mL of bidistilled water with a handhold sprayer. This assured a high relative humidity promoting diffusion of the mycotoxins into the plant cells.

J. Agric. Food Chem. 2015, 63, 7862−7872

In the metabolic profiling experiment a 50:50 (v/v) mixture of ^{13}C-labeled and nonlabeled solutions of HT2 or T2 (in acetonitrile:water (50:50, v/v) and 1% TWEEN) was used. As controls, ears were treated with a mock solution containing only acetonitrile:water (50:50, v/v) and 1% TWEEN. At time point zero, two neighboring spikelets were treated, and 48 h later the second treatment on the same ears was performed using the next pair of adjacent spikelets located above those treated previously. At 96, 120, and 144 h after the first application, treatments on the same ear continued as described, always selecting the next pair of spikelets in acropetal direction. In total, 200 μg of the $^{12}C/^{13}C$ toxin mixture was applied per ear. Sampling was performed 24 h after the last round of toxin application by removing the ear with a surgical scissor and dividing the wheat ear into three parts, but only the middle part was later used for LC-MS analysis: lower part (upper part of the stem and nontreated spikelets in basipetal direction of the treated ones), middle part (spikelets treated with toxins), and upper part (spikelets above the treated spikelets). All samples were weighed, shock-frozen in liquid nitrogen, and stored at −80 °C until further processing.

For the time course study, wheat ears were treated with nonlabeled T2 or HT2 or with the mock solution (methanol:water (50:50, v/v) and 1% TWEEN) similar to the process described above. The only difference was that 10 pairs of neighboring spikelets were treated with 10 μL each in one treatment resulting in a single dose of 200 μg per ear. Samples were collected at eight time points (0 h, 6 h, 12 h, 1 day, 2 days, 3 days, 1 week, and at full ripening) in triplicate. Wheat ears were removed from the plants with a surgical scissor, weighed as a whole, and immediately frozen with liquid nitrogen to prevent any metabolic activity until analysis. All collected samples were stored at −80 °C until further processing.

Sample Preparation. The frozen wheat ears were ground into a fine powder using a ball mill (MM 301 Retsch, Haan, Germany). The samples were placed inside 10 mL stainless steel vessels, precooled with liquid nitrogen, and were milled for 30 s at 30 Hz. After homogenization, (100 ± 2) mg of wheat material were weighed into 1.5 mL Eppendorf tubes and extracted with 500 μL of acetonitrile:water:formic acid (79:20.9:0.1, v/v/v) for 90 min with 200 rpm at room temperature on a GFL3017 rotary shaker (Burgwedel, Germany). Afterward, the extracts were centrifuged for 10 min at 22 570*g* using an Awel centrifuge MF 48-R (Blein, France). The supernatants (ca. 200 μL) were transferred to HPLC vials containing microinserts. The time course samples were partly further diluted 1:10 or 1:50 (v/v) in acetonitrile:water (50:50, v/v) to allow quantification of target analytes.

UHPLC-QTOF-MS Analysis. Measurements were performed with a 1290 series ultra high performance liquid chromatography (UHPLC) system coupled to a 6550 iFunnel quadrupole time-of-flight (QTOF)-MS system (both Agilent Technologies, Waldbronn, Germany) equipped with an electrospray ionization (ESI) interface. Chromatographic separation was achieved on a reversed-phase Zorbax SB-C18 column (2.1 × 150 mm, 1.8 μm particle size; Agilent Technologies) kept at 30 °C. In the isotope-assisted, untargeted metabolic profiling experiment, gradient elution was carried out with water (solvent A) and methanol (solvent B), both containing 0.1% formic acid, and applying the following gradient 1: 0−0.5 min 10% B, 0.5−20 min linear gradient from 10 to 100% B, 20−22 min flushing at 100% B and column re-equilibration with the initial chromatographic conditions (10% B) from 22 to 25 min. During the first 2 min and after the 22 min point mark, the eluent flow was directed to the waste. The flow rate of the mobile phase was 0.25 mL/min, and the injection volume was set to 3 μL. To avoid carry over, the needle was flushed with acetonitrile:water (50:50, v/v) for 5 s immediately prior to injection. For the time course experiment, 5 mM ammonium formate was added to both solvents to promote the formation of ammonium adducts. Furthermore, gradient 2 was shortened to 10 min (0−0.5 min, 20% B; 0.5−6.0 min, 20−100% B; 6.0−8.0 min, 100% B; 8.0−8.1 min, 100−20% B; 8.1−10.0 min, 20% B) for faster analysis.

Full scan spectra were acquired in the range of m/z 50−1500 in positive and negative ESI modes at an acquisition rate of 3 spectra per second. The source conditions were set as follows: gas temperature, 130 °C; drying gas flow, 14 L/min; nebulizer, 30 psig; sheath gas temperature, 300 °C and flow, 10 L/min; capillary voltage, 4000 V; and nozzle voltage, 500 V. Targeted LC-HRMS/MS experiments for identification and characterization of the formed metabolites were performed with gradient 1, but 5 mM ammonium formate was added in the solvents to obtain ammonium adducts for improved fragmentation. An isolation width of m/z 1.3 was applied for precursor selection; the acquisition speed in MS/MS was set to 3 spectra per second, and the applied collision energies (5, 10, and 20 eV) depended on the analytes. The QTOF was tuned and calibrated prior to use on the same day, and during the run two reference masses (positive mode, m/z 121.0508 and 922.0098; negative mode, m/z 112.9855 and 966.0007) were constantly infused via a second nebulizer to ensure mass accuracy.

Data were acquired with Mass Hunter Data Acquisition version B.05.01, and evaluation of data was performed using Mass Hunter Qualitative and Quantitative Analysis version B.06.00 (all Agilent Technologies), as well as Excel 2010 (Microsoft Co., Redmond, WA).

Data Processing for Detection of HT2 and T2 Wheat Metabolites. Acquired raw, full-scan LC-HRMS data were centroided and converted to the mzXML format with MSConvert from the ProteoWizard package (version 3.0.3959; http://proteowizard.sourceforge.net/). The ^{13}C-enrichment (∼99.5%) and the applied nonlabeled to ^{13}C-labeled tracer ratio (∼1) were determined for the highly abundant $[M + Na]^+$ adducts of the T2 and HT2 tracers using TOPPView (version 1.10).[26] All biotransformation products of the T2 and HT2 tracer were expected to show a very similar ^{13}C-enrichment and nonlabeled-to-^{13}C-labeled ratio in the recorded LC-HRMS data. Successively, MetExtract[21] was utilized to screen for T2 and HT2 derived biotransformation products present as nonlabeled and partially ^{13}C-labeled ions. The principal processing steps of the software are as follows: Mass peak pairings of nonlabeled (M) and ^{13}C-labeled (M′) biotransformation product ions were searched for in each recorded mass spectrum (min intensity abundance, 500 counts; M:M′ ratio, 0.5−1.5). Each mass peak pairing had to have an m/z difference that corresponded to the number of labeled carbon atoms (max allowed relative m/z tolerance window, ± 4 ppm). The isotope patterns of both the nonlabeled and the partially ^{13}C-labeled ions were then tested against the determined number of labeled carbon atoms (one isotopolog tested; max allowed abundance deviation, ± 15%). Detected mass peak pairings were clustered (max m/z deviation of ions of a single cluster, ± 9 ppm; min number of detected mass peaks, 3), and for each cluster, both the extracted ion chromatogram (EIC) of the native and the EIC of the labeled biotransformation product ions were extracted (EIC window, ± 10 ppm). Chromatographic peaks were detected in both EICs using the wavelet algorithm of Du et al.[27] Only chromatographic peak pairs present in both EICs that eluted at the same retention time (max allowed deviation, ± 10 scans) and had a highly similar peak shape (min Pearson correlation coefficient, 0.85) were considered to be biotransformation product ions of both nonlabeled and ^{13}C-labeled T2 and HT2 tracers. Other also detected chromatographic peaks in either one of the EICs were discarded as these did not represent nonlabeled and ^{13}C-labeled biotransformation product ions of T2 and HT2 but other metabolites of wheat or contaminants. Finally, detected biotransformation product ions were convoluted into feature groups (max allowed retention time deviation, ± 10 scans; min Pearson correlation coefficient, 0.85), each representing one biotransformation product of T2 and HT2 in wheat. Ions assigned to a single group were investigated with respect to the presence of known mass increments between the detected ion species with the aim to annotate ion species. Commonly observed species during ESI positive mode were $[M + H]^+$, $[M + NH_4]^+$, $[M + Na]^+$, and $[M+K]^+$ ions, while in negative mode $[M-H]^-$, $[M + Cl]^-$, $[M + HCOO]^-$ ions were regularly detected.

Validation of the Method for Quantification Purposes. For those analytes for which analytical standards were available (T2, HT2, HT2-3-Glc, and 3-acetyl-T2), an in-house validation was performed. Mock samples of the variety Remus were weighed (100 ± 2 mg) using the biological triplicates and were spiked with a solution containing all target analytes in acetonitrile before extraction on one level

(1500 μg/kg, corresponding to 300 μg/L in the "undiluted" sample extract). The samples were stored overnight at room temperature to ensure solvent evaporation and to achieve equilibrium between the analytes and the matrix. The next day, the samples were extracted according to the procedure described above. Calculating ratios of the EIC (target $m/z \pm 30$ ppm) peak area achieved in these samples with those in a neat solvent standard (300 μg/L, mean value from triplicate analysis) multiplied with 100 resulted in the apparent recovery (R_A). For the evaluation of matrix effects (expressed as signal suppression or enhancement, SSE), mock samples of the same type (again in biological replicates) were extracted, and the raw extracts of the undiluted samples and 1:10 and 1:50 (v/v) diluted samples were spiked at a concentration of 300 μg/L. A comparison of EIC abundance values with the neat solvent standard (300 μg/L) provided the SSE values of the respective dilution. The extraction recovery was calculated by dividing R_A with the SSE of the undiluted sample and multiplying with 100. For the calculation of the corresponding relative standard deviation, the propagation of uncertainty was taken into account.

For the quantification of HT2, HT2-3-Glc, T2, and 3-acetyl-T2, neat solvent standards ranging from 3 to 300 μg/L for 3-acetyl-T2 and from 10 to 1000 μg/L for the other three compounds were prepared in acetonitrile−water (50:50, v/v). They were measured along with the different dilutions of the sample extracts, and calibration was performed using $1/x$ weighted calibration curves.

RESULTS AND DISCUSSION

HT2 and T2 Metabolite Annotation and Characterization. Raw UHPLC-QTOF-MS data derived from HT2- and T2-treated samples were processed by MetExtract, and the automatically generated features and feature groups were further manually inspected for false positives. Erroneously picked features, which by chance fulfilled MetExtract screening criteria, were easily recognized by certain characteristics such as imperfect coelution of assumed ^{12}C and ^{13}C EIC traces, a $^{12}C/^{13}C$ mass shift higher than the number of C atoms contained in the intact tracer, or implausible isotopolog intensity ratios. Finally, a total of 15 (HT2) and 16 (T2) feature groups (i.e., metabolites) including the native, non-modified toxins were obtained. Of those, 12 (HT2) and 13 (T2) feature groups were of sufficient intensity, enabling their further structural elucidation by MS/MS, verifying their tentative chemical structure (shown in Tables 1 and 2). Each of these feature groups consisted of up to 25 $^{12}C/^{13}C$ ion pairs

DOI: 10.1021/acs.jafc.5b02697
J. Agric. Food Chem. 2015, 63, 7862−7872

originating from adducts and/or in-source fragments that shared the same retention time and chromatographic peak shape. It is worth mentioning that in mock samples, no feature pairs corresponding to T2 or HT2 metabolic products were detected by automated data processing, demonstrating the high selectivity of the used isotope-assisted untargeted workflow. Annotation of biotransformation products was based on accurate m/z values, assumed ion species, number of toxin-derived ^{13}C atoms per metabolite ion, and LC-HRMS/MS spectral interpretations. The detailed structural characterization procedure is described in Meng-Reiterer, Varga, and co-workers[28] who performed a similar study on the metabolism of T2 and HT2 in barley. Briefly, characteristic fragments obtained from standard measurements (T2, HT2, HT2-3-Glc, and 3-acetyl-T2) or described in the literature were compared with those experimentally obtained here for the MetExtract derived metabolites. LC-HRMS/MS measurements of pairs of corresponding nonlabeled and labeled precursor provided further information. The LC-HRMS/MS spectra of the observed metabolites of HT2 and T2 in barley[28] were compared with those obtained in wheat and were shown to be identical. Figure 1 shows an overlay of EICs of all detected

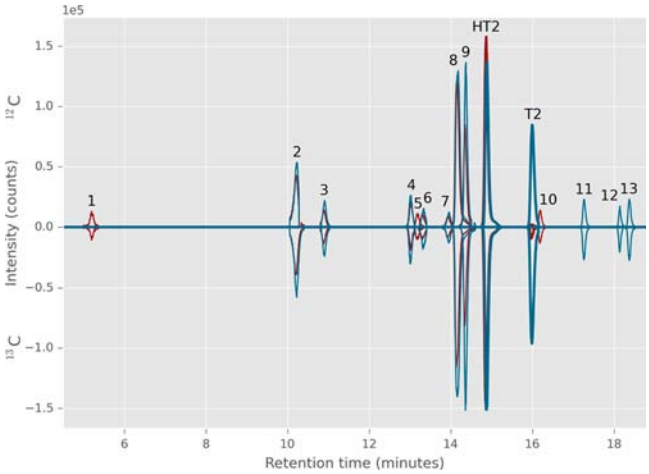

Figure 1. Overlaid extracted ion chromatograms (EICs) based on MetExtract data processing output showing the biotransformation products of a sample treated with a mixture of $^{12}C/^{13}C$-HT-2 toxin (red trace) and one treated with a mixture of $^{12}C/^{13}C$ T-2 toxin (blue trace). EICs of nonlabeled metabolites are displayed with positive intensity values; those of the corresponding labeled metabolites are displayed as negative intensities. Perfect coelution, similar peak shape, and $^{12}C/^{13}C$-intensities of EIC peaks verify the detected ions are truly tracer-derived metabolites.

biotransformation products, and Tables 1 and 2 provide a summary of the annotated metabolites in HT2- and T2-treated wheat ears of the variety Remus.

In the samples which had been treated with HT2 (m/z 447.1989, $[M + Na]^+$), a mass difference between the ^{12}C and ^{13}C ion pairs of 22.0738 Da (corresponding to the mass difference between 22 ^{12}C and ^{13}C atoms) signified that the conjugated metabolites contained the intact molecule of HT2. Formation of HT2-3-Glc (Table 1, peak 8), an already known monoglucosylated HT2 metabolite, was verified by measurements of an authentic standard and was also detected in T2-treated samples (Table 2, peak 8). Only one peak for the m/z ratio corresponding to HT2-3-Glc was found in the treated wheat samples. This peak was perfectly matching in retention time and HR MS/MS fragmentation with the authentic standard of HT-2 toxin-3-O-β-glucoside. Additionally, two tentative diglucosylated HT2 isomers (Table 1, peaks 6 and 7) with slightly different retention times were detected in the wheat samples. We postulate that because monoglucosylation of HT2 was found to occur only at C-3, the additional sugar moiety is most likely transferred by a different enzyme, presumably leading to β-1,4 or β-1,6 diglucosides. Likewise, HT2-malonyl-glucoside is formed by conjugation of malonic acid to the glucose moiety of HT2-3-Glc. In addition to the metabolites identified in barley,[28] also dehydro-HT2-glucoside was tentatively identified. Its HRMS/MS spectrum is provided as Figure S1 in Supporting Information. The absence of m/z 101.0608 and the occurrence of a fragment ion with m/z 99.0456 indicate the loss of two hydrogen atoms from the isovaleryl moiety, most likely after cleavage of water from hydroxy-HT2-glucoside. It should be noted that full structural elucidation of all detected metabolites would require purification and subsequent nuclear magnetic resonance (NMR) measurements, which was beyond the scope of this study.

The majority of the other metabolites were derived from HT2-3-Glc by additional conjugations and/or changes in the HT2 skeleton. Evaluation of mass shifts between corresponding $^{12}C/^{13}C$ feature pairs revealed that two metabolites contained less than 22 ^{13}C carbon atoms in their HT2 backbone (Table 1, peaks 1 and 4). These ions correspond to the putative metabolites 15-acetyl-T2-tetraol-glucoside (loss of the isovaleryl moiety at C-8) and T2-triol-glucoside (loss of the acetyl group at C-15). The fact that no 15-acetyl-T2-tetraol, T2-triol, or hydroxy-HT2 were detected even at the earlier time points indicates that the respective phase I type reactions hydrolysis, deacetylation, and oxidation, generally assumed to occur prior to conjugation of xenobiotics, took place after the conjugation of glucose to the HT2 backbone. Hence, direct conjugation of unaltered mycotoxins with plant constituents can result in metabolites susceptible to phase I reactions, under appropriate conditions, as has already been reported in the literature for pesticides.[29]

As previously described for HT2, metabolites containing the intact T2 carbon backbone (m/z 489.2095, $[M + Na]^+$) should reveal a mass difference of 24.0805 between the ^{12}C and ^{13}C ion pairs. Nevertheless, only three such biotransformation products were found. Putative metabolites including an intact T2 skeleton were 3-acetyl-T2 and two tentatively isomeric peaks of feruloyl-T2 (Table 2, peaks 11−13). As ferulic acid (4-hydroxy-3-methoxycinnamic acid) naturally exists majorly as *trans*-ferulic acid,[30] the second isomer is more likely isoferuloyl-T2 rather than a diastereomer of feruloyl-T2. It is worth mentioning that T2-glucoside could not be detected in this study as a biotransformation product of T2, although it has previously been documented in T2-contaminated wheat.[14,31] The majority of metabolites in T2-treated wheat were formed after deacetylation of the toxin to HT2 and further metabolism according to the same metabolic pathways.

***In Planta* Acetylation of HT2.** Many organisms, including plants, are capable of deacetylating T2 to HT2. However, with the $^{12}C/^{13}C$ experimental setup, we were able to show that wheat is also capable of acetylating HT2. The feature pair m/z 489.2083 (^{12}C)/511.2823 (^{13}C) recognized by MetExtract indicates the presence of 22 tracer-derived carbon atoms (as for the originally applied HT2), and the m/z value fits to the sum formula of the ^{13}C-HT2 backbone to which a nonlabeled acetyl

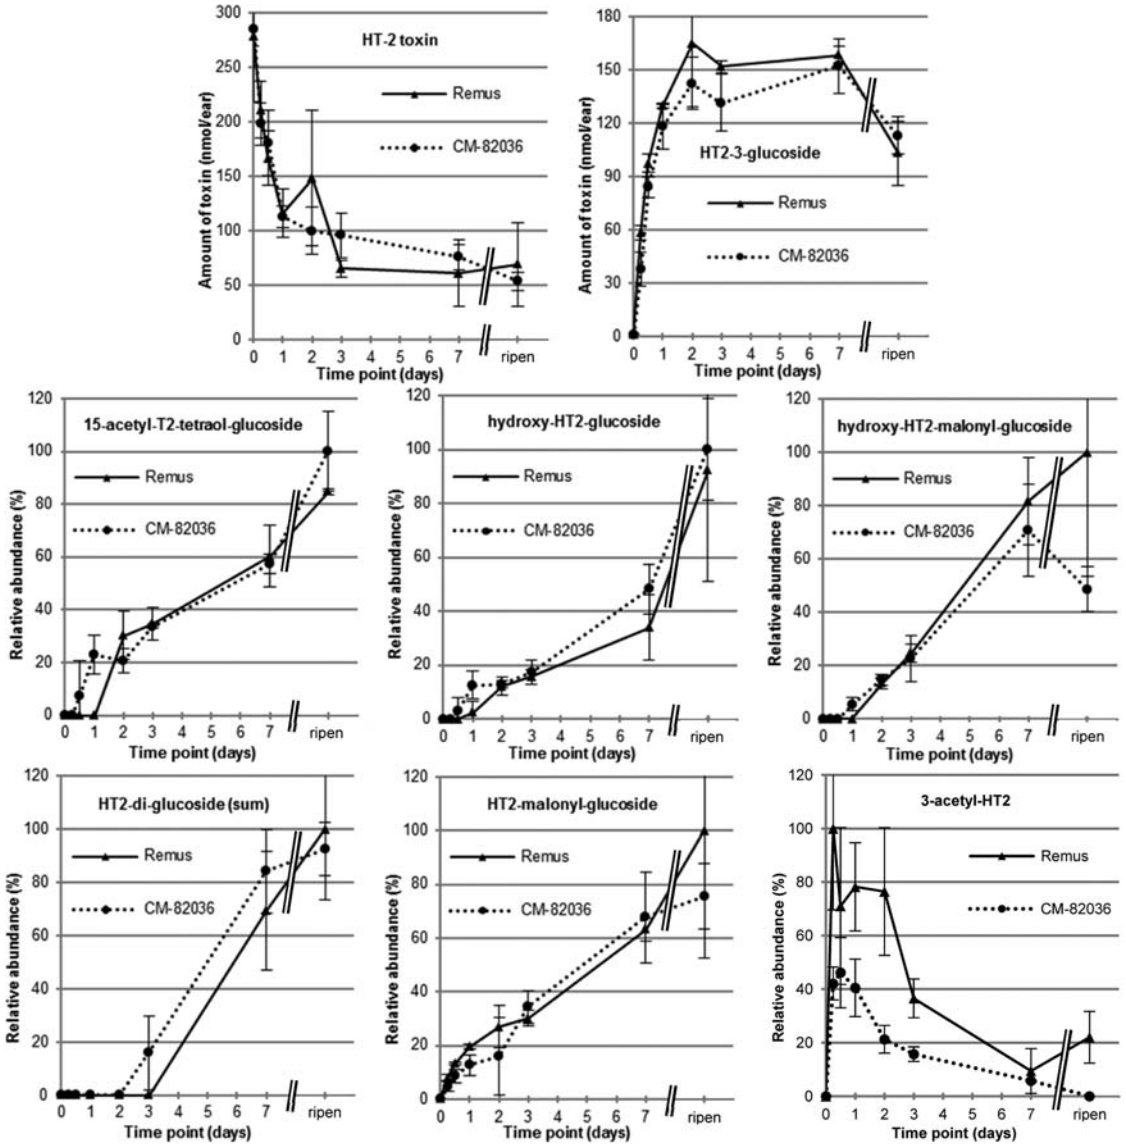

Figure 2. Results from the time course kinetics experiment. After exposure to a single dose of 200 μg/ear HT-2 toxin (HT2), the whole ears (n = 3) were harvested immediately after treatment (0 h), after 6 h, 12 h, 1 day, 2 days, 3 days, and 1 week, as well as at full ripening (ca. 8 weeks after treatment). For the parent toxin (HT2) and the major metabolite HT-2 toxin-3-glucoside, the absolute amounts (in nanomoles per ear) are provided together with the standard deviation of the biological triplicate. These values are based on quantitative measurements using the respective analytical standards and are corrected for matrix effects occurring during liquid chromatography−mass spectrometric analysis; the individual ear weights were taken into consideration. For all other metabolites no analytical standard was available; therefore, the relative abundances (in percent) are provided together with the standard deviation of the biological triplicate. Those values are based on the peak areas of the ammonium adduct (for 3-acetyl-HT-2 toxin the sodium adduct was used) multiplied with the individual ear weight. All values were set into correlation with the highest observed normalized area (usually the full ripening samples of Remus or CM-82036).

group has been conjugated ($^{13}C_{22}C_2H_{34}O_9$; calculated m/z for Na-adduct 511.2833). HT2 has two hydroxyl groups at positions C-3 and C-4, which might be acetylated, and T2 differs from HT2 only by the acetyl-group at position C-4. Because the obtained retention time of 16.2 min (Figure 1, peak 10) was close to, but did not match with those of a T2 standard (16.0 min), it was postulated that the acetyl moiety of this HT2 metabolite results from acetylation at the position C-3 instead of C-4. With MS/MS measurements (see Figure S2 in Supporting Information) it was not possible to determine differences in fragmentation between native T2 and the putative 3-acetyl-HT2. Quantification of the presumed 3-acetyl-HT2 using T2 as standard resulted in about 40 μg/kg that accounts for less than 0.4% of the applied HT2. In a similar study with barley,[28] no acetylated forms of HT2 could be confirmed. This acetylation reaction at C-3 can be regarded as a detoxification process because it has also been described to be a strategy employed by the trichothecene-producing fungus during toxin biosynthesis for self-protection.[32] Finally, it should be mentioned that the small EIC-peak (m/z 511.2832) at 16.0 min could be T2. However, the second isotopolog of ^{13}C-T2 (present as impurity of the ^{13}C-HT2 used for spiking) will also lead to this signal, rendering this assumption inconclusive. To sum up, the presence of an acetylated form of HT2 other than T2, (presumably) 3-acetyl-HT2, was confirmed in wheat samples. Whether also T2 might be formed from HT2 remains unclear on the basis of our data. In any case, the deacetylation of T2 in wheat is seemingly far faster, compared to the potential

J. Agric. Food Chem. 2015, 63, 7862−7872

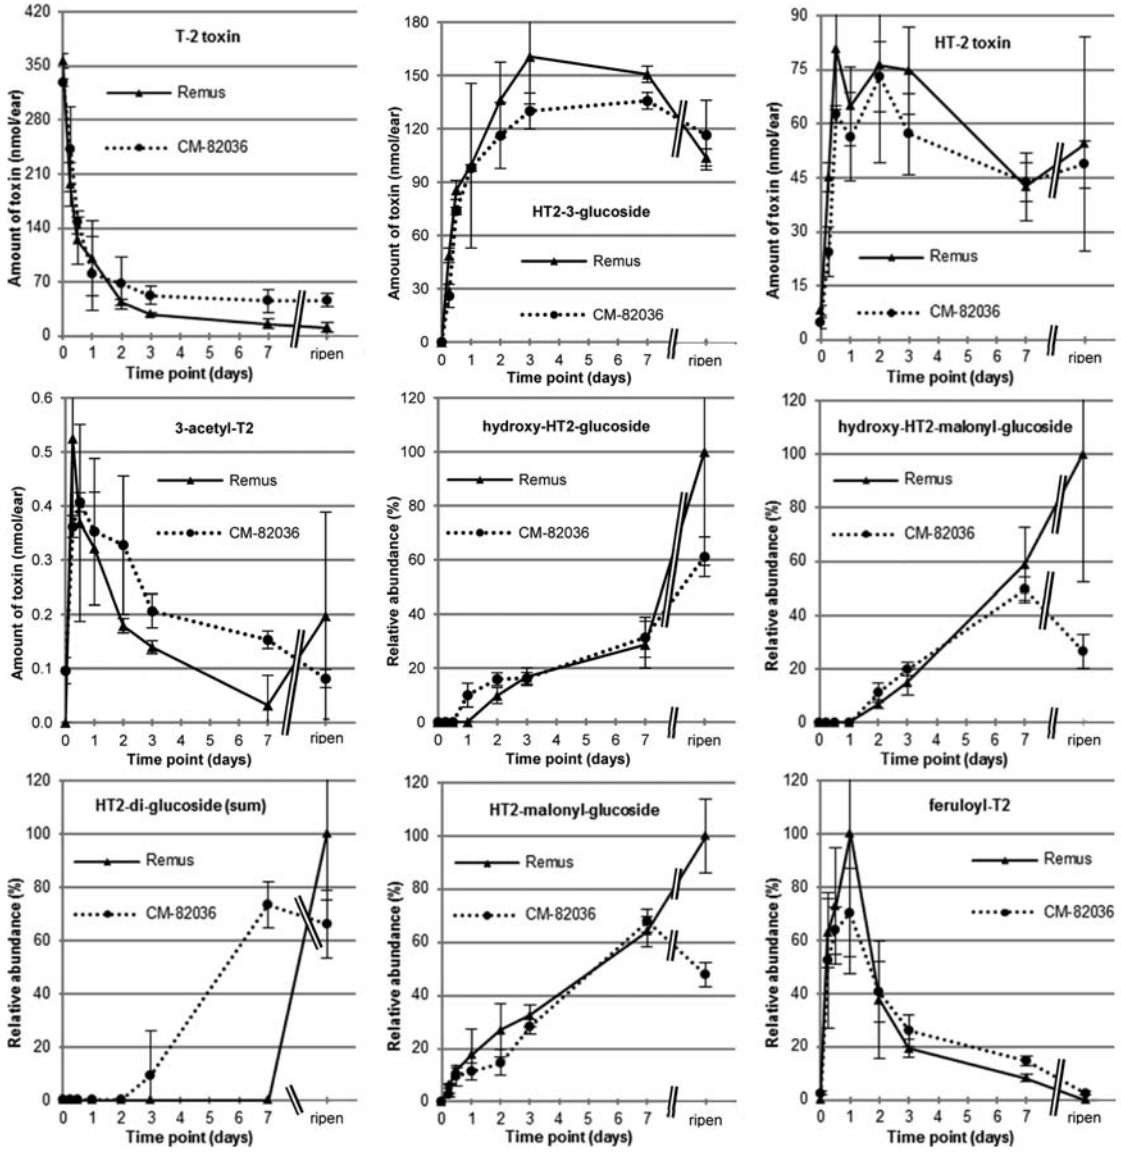

Figure 3. Results from the time course kinetics experiment. After exposure to a single dose of 200 μg/ear T-2 toxin (T2), the whole ears (n = 3) were harvested immediately after treatment (0 h), after 6 h, 12 h, 1 day, 2 days, 3 days, and 1 week, as well as at full ripening (ca. 8 weeks after treatment). For the parent toxin (T2), the two major metabolites HT-2 toxin and HT-2 toxin-3-glucoside, as well as 3-acetyl-T-2 toxin, the absolute amounts (in nanomoles per ear) are provided together with the standard deviation of the biological triplicate. These values are based on quantitative measurements using the respective analytical standards and are corrected for matrix effects occurring during liquid chromatography−mass spectrometric analysis; the individual ear weights were taken into consideration. For all other metabolites, no analytical standard was available; therefore, the relative abundances (in percent) are provided together with the standard deviation of the biological triplicate. Those values are based on the peak areas of the ammonium adduct multiplied with the individual ear weight. All values were set into correlation with the highest observed normalized area (usually the full ripening samples of Remus or CM-82036).

reverse acetylation of HT2, so that the potential occurrence of 3-acetyl HT2 or T2 after metabolization from HT2 in wheat is only marginal.

Method Validation. A small validation study was performed with wheat samples of the variety Remus to ensure absolute quantification for HT2, HT2-3-Glc, T2, and 3-acetyl-T2. Biological triplicates (1 day and full ripening) from mock samples were spiked on one level before extraction to obtain R_A. In the fully ripened samples, lower recoveries (56−124%) and higher relative standard deviations (up to 31%) were observed than in the samples harvested 1 day after treatment (74−132% and up to 3.5%, respectively; see Table S1 in Supporting Information). Additionally, different dilutions (undiluted, 1:10, and 1:50 (v/v)) of blank extracts of these biological triplicates were spiked on one level to assess matrix effects. For HT2 and HT2-3-Glc, some matrix enhancement was observed. The determined extraction recoveries (R_E) were approximately 100%; therefore, obtained quantitative values in the kinetic experiment were only corrected for SSE in the respective dilution. The SSE values obtained for the samples harvested after full ripening were used for the correction of both varieties. For all other time points the SSE values determined for the day 1 samples were used.

Time Course Kinetics and Metabolic Pathways. The kinetic profiles of T2 and HT2 metabolites were studied with a time course experiment conducted in wheat lines susceptible (Remus) and resistant (CM-82036) to FHB. Treated wheat ears did not show premature bleaching after a single exposure

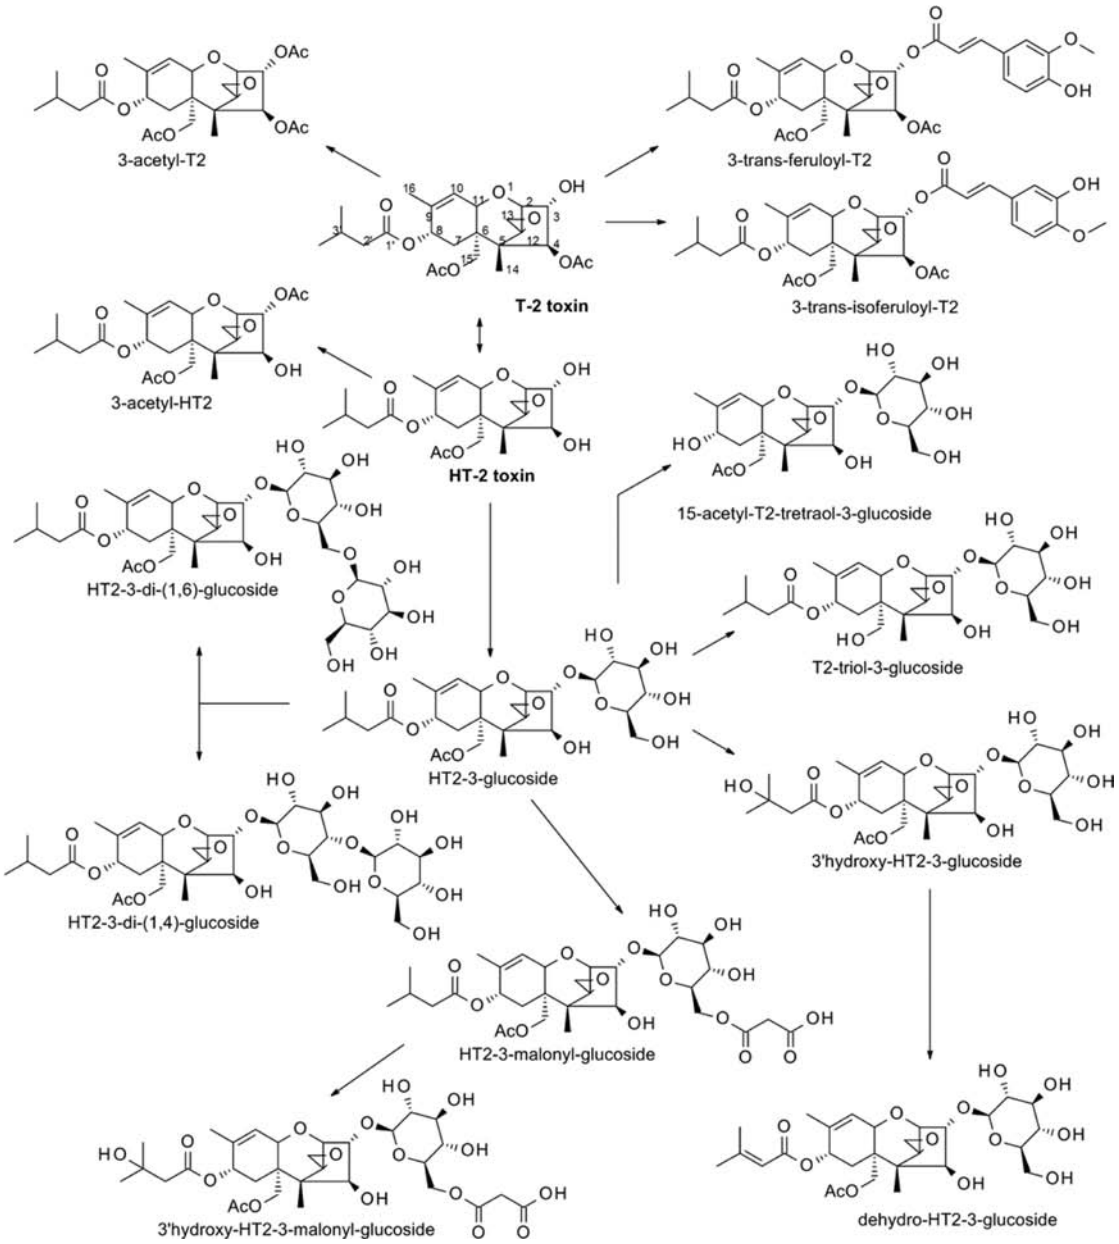

Figure 4. Proposed metabolic pathways of HT-2 toxin (HT2) and T-2 toxin (T2) in wheat.

to 200 μg of HT2 or T2, and in both wheat lines the same metabolites were determined. The kinetics of the major metabolites T2, HT2, and HT2-3-Glc in Remus and CM-82036 are illustrated in Figure 2 (HT2-treated sample) and Figure 3 (T2-treated sample). The absolute values were quantified with analytical standards, corrected for the observed SSE at the respective dilution, corrected for the individual ear weight, and calculated in nanomoles per ear. In T2-treated samples deacetylation of T2 to HT2 progresses rapidly, and already after 12 h only ca. 30% of the initially added toxin could be determined. This is in line with the study of Lattanzio et al.,[33] reporting the enzymatic hydrolysis of T2 to HT2 after 120 min of incubation in wheat (conversion rate 89%), as well as other cereals. At the same time, rapid glucosylation of HT2 to form HT2-3-Glc occurred. Biotransformation of HT2 was also activated at a very early stage, regardless of whether it originated from direct application or deacetylation of T2. HT2-3-Glc was the major metabolite 6 h after exposure and accounted for approximately 33% of the added toxin after a treatment time of 1 week. Another interesting observation is that HT2-3-Glc reached a maximum concentration between 3 days and 1 week, after which its concentration decreased until harvest because of further metabolization.

For all other metabolites, analytical standards were not available; thus, the data obtained from EIC integrated peak areas were corrected only for the individual ear weight. The values were set into correlation with the highest observed area (usually the full ripening samples of Remus or CM-82036) (HT2-treated samples in Figure 2, T2-treated samples in Figure 3). According to these findings, C3-acetylation of both toxins and (iso)ferulic acid conjugation of T2 are the immediate responses of plant detoxification mechanisms, apart from glucosylation. However, these compounds were further metabolized or covalently bound to plant matrix, as their concentration decreased over time. To accurately assess their abundance under field conditions at harvest, natural occurrence

DOI: 10.1021/acs.jafc.5b02697
J. Agric. Food Chem. 2015, 63, 7862−7872

studies in cereals for these compounds are necessary. Conjugations with an additional glucose moiety or malonic acid to existing HT2 monoglucosides occurred later. Hydrolysis of the acetyl group of HT2-3-Glc in C-15, leading to the formation of T2-triol glucoside, is presumably a consecutive later reaction as the compound was detectable only in ripened samples. The proposed metabolic pathway of HT2 and T2 metabolization is summarized in Figure 4.

The average weight of wheat ears of these two lines were significantly different. While CM-82036 ears on average weighed (0.92 ± 0.20) g, Remus ears weights were (1.61 ± 0.33) g on average. In addition, the ear weight (and the relative moisture content) changed over the investigated time frame. Therefore, data can be shown either as metabolite amounts per ear or as concentration (nanomoles of metabolite per gram of ear). Figures 2 and 3 represent data normalized to the weight of whole wheat ears. No significant differences in the amounts of HT2 and T2 metabolites in the two different wheat lines were determined. Another way of representing the same data would show that CM-82036 wheat plants more efficiently metabolize the toxins, as less biomass (of the treated ear) was able to produce approximately the same amount of metabolites. To compare the two wheat varieties in a truly quantitative manner it would be necessary to normalize the amount of added toxin relative to the different (dry) ears weights, which was beyond the scope of this study. Also, it should be mentioned that the applied toxins might not have had sufficient time to diffuse into the entire ear in the early time points.

Biological Role of Formed Metabolites and Toxicological Implications. According to these findings, the C12−C13 epoxy group of HT2 and T2 that is crucial for toxicity was not affected by wheat biotransformation. The conversion of T2 to HT2 is considered a detoxification step in mammals[8] and also shown for plants in an *Arabidopsis thaliana* detached leaf assay.[34] Formation of HT2-3-Glc was found to be the dominating biotransformation reaction of both HT2 and T2. Glucosylation of trichothecenes at the position C-3, with the anomeric carbon of glucose linked via a β-D-glucosidic bond, has been reported to greatly reduce phytotoxicity.[35]

Inhibition of the growth and spreading of *Fusarium* species due to antimicrobial properties of principal phenolic acids in grains and their role in cell wall thickening have been reported in the literature.[36,37] Our results concerning conjugation of T2 with ferulic acid might be another beneficial property of ferulic acid, assuming a largely decreased toxicity of the conjugate.

In contrast to DON metabolism in wheat,[18] no glutathione or other sulfur-containing conjugates of HT2 and T2 were detected in this study. This does obviously reflect the lack of an α,β-unsaturated carbonyl functionality at C-8 as T2 and HT2, a functionality that is presumed to be the primary conjugation target of glutathione,[38] in type B trichothecenes such as DON.

Although glucosylation of trichothecenes is considered a detoxification process, the resulting conjugates may be reactivated within the mammalian gastrointestinal tract, a fact that is currently regarded as the main health risk associated with masked mycotoxins.[39−41] In this context, limited and contradicting information is available concerning the toxic potential of type A trichothecene hydroxylation products, which could possibly emerge by microbial reactivation in the gut. Existing toxicological studies agree that 3′-hydroxy-HT2 is less toxic compared to its parent form,[42] whereas 3′-hydroxy-T2 has been reported as being more acutely toxic *in vivo* than T2.[43] These novel "activated" metabolites may constitute toxicologically relevant mycotoxin derivatives; thus, further investigations are required. Intestinal hydrolysis and uptake can vary for different conjugated forms. For instance, it has been shown that malonyl isoflavone glucosides are more effectively absorbed than nonmalonylated isoflavone glucosides in rats.[44] Therefore, thorough toxicokinetic and overall toxicological assessment of novel and known masked mycotoxins should be conducted.

In summary, the metabolism of HT2 and T2 mycotoxins in wheat was presented according to data obtained by untargeted metabolomics profiling and time course kinetic studies. Exposure of wheat to either HT2 or T2 primarily activates metabolic reactions involving hydroxylation, (de)acetylation, and various conjugations. HT2 is the major metabolite resulting from exposure to T2 which follows the same pathway to that of directly inoculated HT2. Metabolites such as HT2-malonyl-glucoside, hydroxy-HT2-glucoside, dehydro-HT2-glucoside, T2-triol-glucoside, as well as (iso)feruloyl-T2 were documented for the first time. The interested reader is referred to Meng-Reiterer and Varga et al.[28] for a detailed structural elucidation. Kinetic data revealed that detoxification progresses rapidly, resulting in the almost complete degradation of the toxins, within 1 week, after a single exposure in flowering wheat ears. No different metabolites were observed between the FHB-resistant wheat line CM-82036 and the FHB-susceptible wheat line Remus. Further investigations to compare the role of detoxification efficiency of wheat varieties in FHB resistance are required. Additional studies to assess the toxicological relevance and potential food safety concerns of the *in planta* metabolites emerging from T2 and HT2 mycotoxins are warranted.

glucose, lactate, glutamate/glutamine, and taurine, were proposed for diagnosing NAFLD at various stages.[3] Metabolomic analysis was also used to assess the effects of dietary cholesterol through NMR-based quantitative profiling of liver extracts from $LDLr^{-/-}$ mice. It was found that the levels of hepatic cholesterol, triglyceride (TG), oleic acid, polyunsaturated fatty acid (PUFA)/monounsaturated fatty acid (MUFA) ratio, long-chain polyunsaturated fatty acids, taurine, glutathione, methionine, and carnitine, which are related to fatty acid metabolism and mitochondrial function, were affected in the diet- and time-dependent progression from steatosis to NASH.[4]

Despite the different rodent models established and the few identified metabolites, there is still a need to further verify and identify more key metabolites involved in the pathogenesis and progression of NAFLD in an appropriate animal model that mimics the pathophysiological metabolism of human disease. The high-fat-diet (HFD)-fed C57BL/6J mouse model has been widely applied to investigate metabolic diseases, because it is susceptible to NAFLD development. This model provides an efficient metabolic system for the gradual development of obesity, insulin resistance, hepatic steatosis, and steatohepatitis, which better mimic the etiology and pathogenesis of NAFLD in humans, owing to integration among different environmental factors and multiple genes, as compared to focusing on a single-gene mutant phenotype.[7,8] However, to the best of our knowledge, there have been no previous metabolomic reports on the time-related NAFLD progression in HFD-fed C57BL/6J mice.

In the present study, ultrahigh-performance liquid chromatography coupled with quadrupole time-of-flight mass spectrometry (UHPLC−QTOF−MS) and gas chromatography−mass spectrometry (GC−MS) platform-based metabolomics was employed to analyze the serum metabolic profiles at various stages of NAFLD induced by 4, 8, 12, and 16 weeks of HFD feeding in C57BL/6J mice. On the basis of the results of pathophysiological parameters, potential metabolites, and metabolic pathway responses at the different time points of HFD feeding, we provide a well-established animal model and comprehensive profile of the metabolic changes that occur during the onset and progression of NAFLD. Our findings could help elucidate the metabolic mechanisms underlying the development of NAFLD induced by a HFD.

MATERIALS AND METHODS

Animal Model. Experiments were performed with 6-week-old male C57BL/6J mice (Laboratory Animal Center, National Taiwan University College of Medicine, Taipei, Taiwan) under controlled environmental conditions (temperature of 23 ± 2 °C, relative humidity of 50−70%, and 12 h light/dark cycle) with *ad libitum* access to food and water. Animal care and handling procedures were in accordance with an experimental protocol approved by the Institutional Animal Care and Use Committee (IACUC) of National Taiwan University (IACUC approval number NTU-101-EL-124) and complied with the guidelines described in the Animal Protection Law, amended on June 29, 2011, Hua-Zong-(1)-Yi-Tzi-10000136211, Council of Agriculture, Taiwan. After a 2 week adaptation period, all mice were randomly divided into two groups based on their diet. Control group mice were fed a normal diet containing 13.5% kcal fat (Laboratory Rodent Diet 5001, Lab Diet/PMI Nutrition International, Purina Mills LLC, Gray Summit, MO), while mice in the negative control group were fed a HFD with 60% kcal fat (D12492, Research Diets, Inc., New Brunswick, NJ). Food intake and body weight were recorded once a week. A total of 10−12 mice per group were fasted overnight and sacrificed by CO_2 asphyxiation at weeks 4, 8, 12, and 16 after commencing the diet administration.

Serological Analyses. Whole blood was immediately collected by cardiac puncture and then allowed to clot. After centrifugation at 1000*g* for 10 min at 4 °C, the resultant serum samples were separated and stored individually at −80 °C for subsequent analyses. Serum chemistry for aspartate aminotransferase (AST), alanine aminotransferase (ALT), total cholesterol (TC), and TG levels were subjected to biochemical testing with an automatic chemistry analyzer (SPOTCHEM EZ SP-4430, ARKRAY, Inc., Kyoto, Japan). The serum FFA concentration was measured using the enzyme-based FFA Quantification Kit (BioVision, San Francisco, CA), and the insulin level was determined using an enzyme-linked immunosorbent assay kit (Mercodia AB, Uppsala, Sweden).

Histopathological Examination. Liver and fat pads (subcutaneous, epididymal, and perirenal fat) were harvested, weighed, and photographed. Liver pathological analysis and semi-quantitative evaluation was carried out as previously described.[9] Briefly, paraffin-embedded and frozen sections of liver tissue were routinely processed for hematoxylin and eosin (H&E) and Oil Red O staining, respectively. Each H&E section was then scored for steatosis with morphometric analysis by an experienced pathologist. The degree of steatosis was graded from 1 to 5 according to severity: 1, minimal (<1%); 2, slight (1−25%); 3, moderate (26−50%); 4, moderate/severe (51−75%); and 5, severe/high (76−100%). Lastly, the remaining liver tissues were immediately frozen at −80 °C for further analysis.

Liver Enzymes and Inflammatory Cytokines. Samples of 300 mg liver tissues were homogenized in 3 mL of cold extraction buffer (8 mM KH_2PO_4, 12 mM K_2HPO_4, and 1.5% KCl at pH 7.4) for 10 min on ice and then centrifuged at 10000*g* for 30 min at 4 °C. The protein content in the liver homogenate was determined with a Bio-Rad protein assay (Hercules, CA). Hepatic TG, glutathione (GSH), glutathione peroxidase (GPx), glutathione reductase (GRd), catalase (CAT), and superoxide dismutase (SOD) were assayed by enzymatic colorimetric methods (Cayman Chemical Co., Ann Arbor, MI). Hepatic TC and lipid peroxidation were evaluated fluorometrically using the cholesterol and thiobarbituric acid-reactive substances (TBARS) assay kits (Cayman Chemical Co., Ann Arbor, MI), respectively. In addition, enzyme-linked immunosorbent assays were used for the quantitative detection of hepatic tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6) (eBioscience, Inc., San Diego, CA). All procedures complied with the manufacturer instructions.

Serum Sample Preparation. A 100 μL aliquot of each mouse serum sample was extracted for 2 min in 400 μL of ice-cold methanol using a Geno/Grinder 2010 Spex SamplePrep (Metuchen, NJ). Following centrifugation at 4 °C and 15000*g* and for 5 min, the remaining pellet was extracted twice with the same process. The serum extracts were pooled and evaporated using the Thermo SpeedVac SPD111V (Waltham, MA) for 4 h. For UHPLC−QTOF−MS analysis, the dried extracts were subsequently reconstituted in 200 μL of 50% methanol. After centrifugation at 15000*g* for 5 min, the resulting supernatant was filtered through a 0.22 μm Ministart RC 4 filter (Sartorius, Goettingen, Germany) and subjected to UHPLC−QTOF−MS analysis. For GC−MS, the dried residues were derivatized with trimethylsilylation through the subsequent addition of 10 μL of *O*-methylhydroxylamine hydrochloride (40 mg/mL in pyridine) and 90 μL of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane at 40 °C for 90 and 30 min, respectively. Finally, the derivatized samples were subjected to GC−MS analysis. For quality control, equal amounts of each sample aliquots were pooled and applied to monitor the stability of the analytical performance in the two platforms.

UHPLC−QTOF−MS Analysis. Chromatographic separations of the serum extracts were performed using an Agilent 1290 UHPLC system (Agilent Technologies, Santa Clara, CA) with an Acquity HSS T3 column (2.1 × 100 mm, 1.8 μm, Waters, Milford, MA) maintained at 40 °C. The mobile phases A and B were 0.1% formic acid in water and 0.1% formic acid in acetonitrile, respectively. The gradient elution program was initiated with 2% B for 1.5 min, linear gradient to 50% B in 7.5 min, linear gradient to 95% B in 5 min, and then held at 95% B

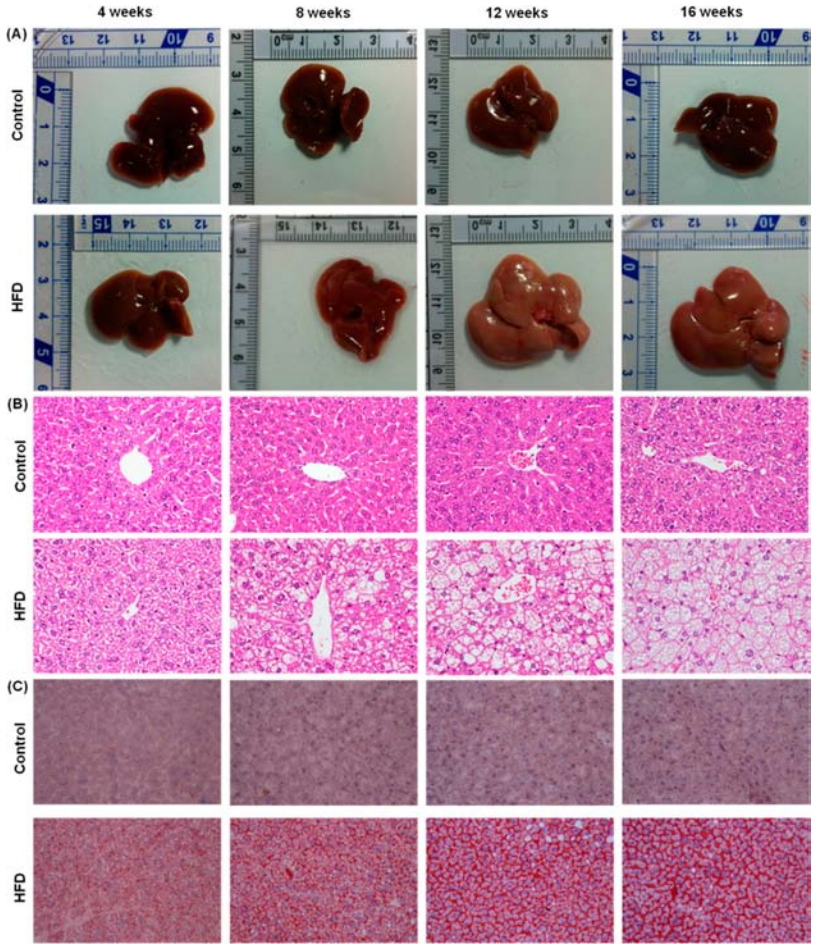

Figure 1. Effect of a HFD on liver histopathological alterations at different time points after induction: (A) liver morphology, (B) H&E stain, and (C) Oil Red O stain in C57BL/6J mice fed a normal diet or HFD for 4, 8, 12, and 16 weeks. Liver sections were stained with H&E and Oil Red O to visualize lipid droplets (in red). Representative images (400× magnification) of each group are shown. HFD, high-fat diet.

for 3 min. The flow rate was 0.3 mL/min, and the injected sample volume was 2 μL. The eluent was subsequently introduced into the Burker maXis QTOF mass spectrometer (Bruker Daltonics, Bremen, Germany) coupled to an electrospray ionization source, with capillary voltage set at 4500 V in positive- and negative-ion modes and end plate offset at 500 V. The parameters were used as follows: nebulizer pressure, 2.0 bar; dry gas temperature, 200 °C; and flow rate, 8 L/min. The full-scan mass range was from m/z 50 to 1500. To ensure accuracy and reproducibility, the mass instrument was calibrated with sodium formate before daily use with lock mass of hexakis between runs.

GC−MS Analysis. An Agilent 7890 GC system equipped with a 5975 quadrupole mass selective detector (MSD, Agilent, Santa Clara, CA) and a DB-5MS column (30 m × 0.25 mm inner diameter × 0.25 μm film thickness, Agilent, Santa Clara, CA) was employed to acquire metabolic profiles of the derivatized products. A total of 1 μL of the sample was injected in split mode (split ratio of 1:5) with an inlet temperature of 250 °C. Helium was used as the carrier gas in constant flow mode. The initial oven temperature was set to hold at 60 °C for 1 min, followed by a ramp to 325 °C at 10 °C/min, and finally held for 10 min. The mass spectrum was acquired in full-scan mode from m/z 50 to 550. Electron impact ionization at 70 V was operated with an ion source temperature of 250 °C.

Data Processing and Analysis. The UHPLC−QTOF−MS data were exported to True Ion Pick (TIPick) software for peak detection, alignment, and normalization as previously described.[10] For GC−MS data, all of the spectral processing was performed using the Automated Mass Spectral Deconvolution and Identification System (AMDIS) software. The acquired data from UHPLC−QTOF−MS and GC−MS were used to identify the compounds corresponding to those in the NTU MetaCore metabolomics chemical standards database and Fiehn library, respectively. Finally, the variables existing in at least 80% of either group were retained for further analysis.

Statistical Analysis. Principal component analysis (PCA) was carried out to discriminate visually the general structure of each data set based on their UHPLC−QTOF−MS or GC−MS metabolic profiles. The changes in peak intensity between two groups were compared by fold-change analysis. All pathophysiological data are presented as the mean ± standard deviation (SD). Statistical differences between the compared groups were assessed by the Student's t test, with p values less than 0.05 regarded as significant.

RESULTS

Animal Characteristics. The characteristics of C57BL/6J mice fed a normal diet or HFD (60% kcal from fat) for 4, 8, 12, and 16 weeks are shown in Table 1. Despite a higher food intake in control groups, the average daily caloric intake of mice in the HFD groups (16.0−17.9 kcal) were significantly higher ($p < 0.01$) than those of mice in the control groups (12.9−14.0 kcal) at all time points (4, 8, 12, and 16 weeks). The average body and fat pad weights of mice in each group showed increasing trends throughout the experimental period. After 4 weeks, HFD-fed mice immediately appeared obese, as reflected by marked enlargement of subcutaneous, epididymal, and perirenal fat pads in comparison to controls ($p < 0.001$). Noticeably, the epididymal and perirenal fat pads were slightly

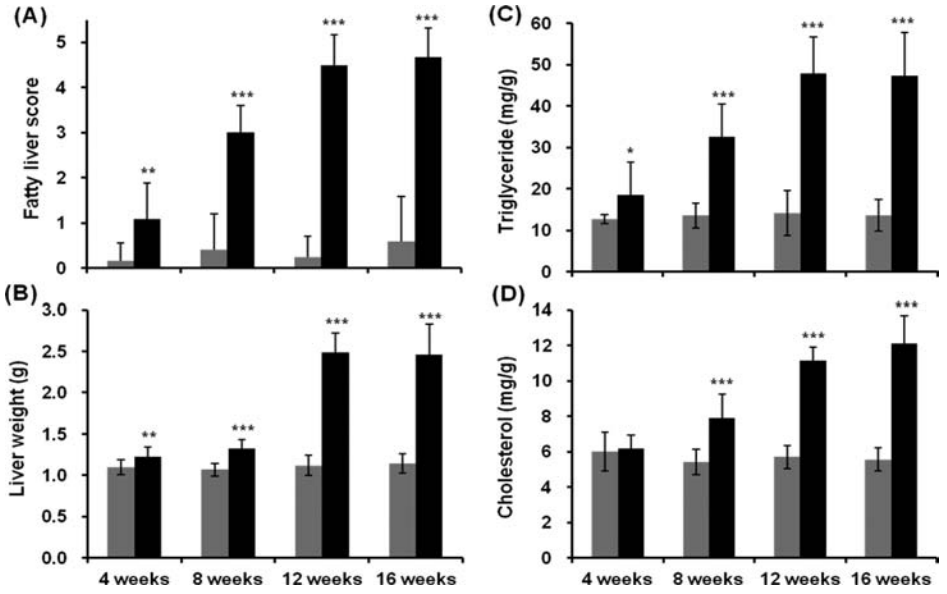

Figure 2. Effect of a HFD on hepatic lipid content at different time points after induction: (A) fatty liver score, (B) liver weight, (C) hepatic TG, and (D) cholesterol in C57BL/6J mice fed a normal diet or HFD for 4, 8, 12, and 16 weeks. Data are presented as the mean ± SD (n = 10−12 mice per group). Comparison was made between HFD and their age-matched controls by Student's t test: (∗) $p < 0.05$, (∗∗) $p < 0.01$, and (∗∗∗) $p < 0.001$. (Gray bars) Control and (black bars) HFD.

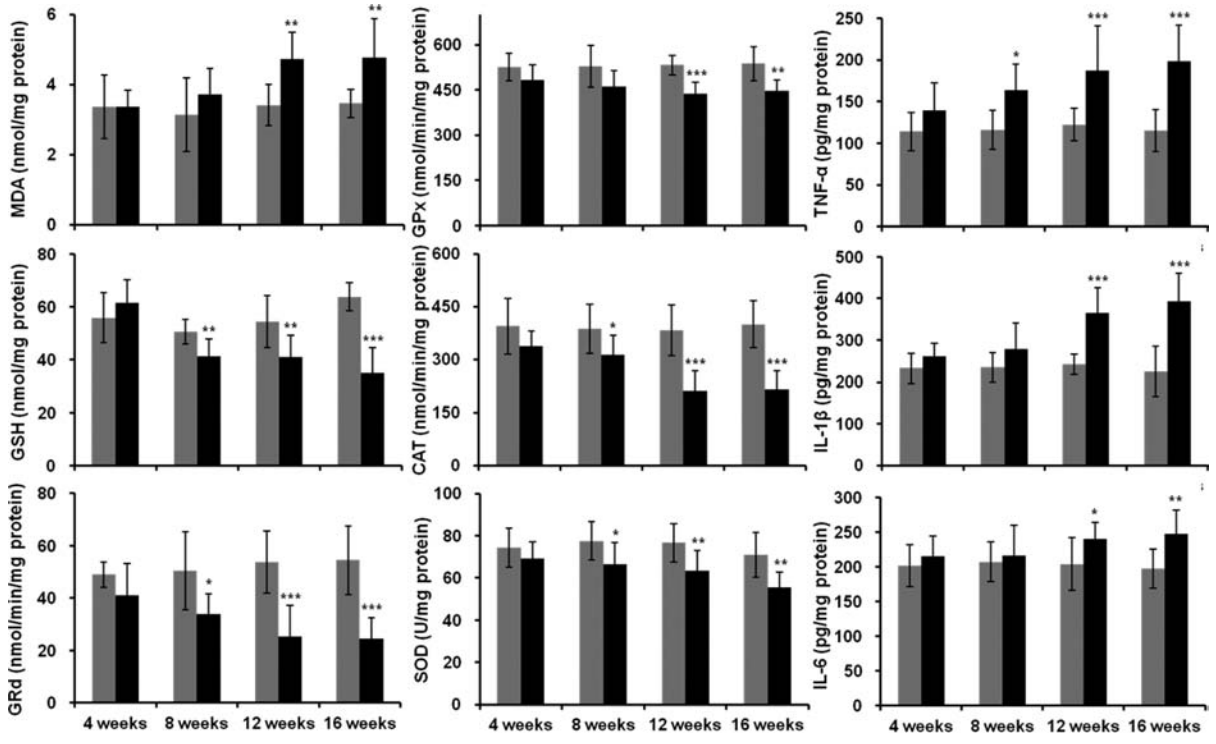

Figure 3. Effect of HFD on hepatic antioxidant capacity and pro-inflammatory cytokines at different time points after induction. C57BL/6J mice were fed a normal diet or HFD for 4, 8, 12, and 16 weeks. Data are presented as the mean ± SD (n = 10−12 mice per group). Comparison was made between HFD and their age-matched controls by Student's t test: (∗) $p < 0.05$, (∗∗) $p < 0.01$, and (∗∗∗) $p < 0.001$. (Gray bars) Control and (black bars) HFD. MDA, malondialdehyde; GSH, glutathione; SOD, superoxide dismutase; CAT, catalase; GPx, glutathione peroxidase; GRd, glutathione reductase; TNF-α, tumor necrosis factor-α; IL-1β, interleukin-1β; and IL-6, interleukin-6.

decreased in HFC mice after 12 weeks (−15.6%) and 16 weeks (−3.4%) of feeding, respectively, compared to previous weeks. However, the subcutaneous fat pads of HFD-fed mice increased continuously over time. We speculated that excess adipose tissue might accumulate in the subcutaneous tissues, liver, or other organs after 12 weeks on the HFD.

After 4 weeks, the HFD mice exhibited significantly higher serum concentrations of glucose ($p < 0.001$) and TC ($p < 0.001$) than those in the controls (Table 1). After 4 more weeks, the HFD-fed mice also developed hyperinsulinemia and hypertriglyceridemia, demonstrated by the markedly increase serum levels of insulin and TG, 1.6-fold ($p < 0.05$) and 1.2-fold

J. Agric. Food Chem. 2015, 63, 7873−7884

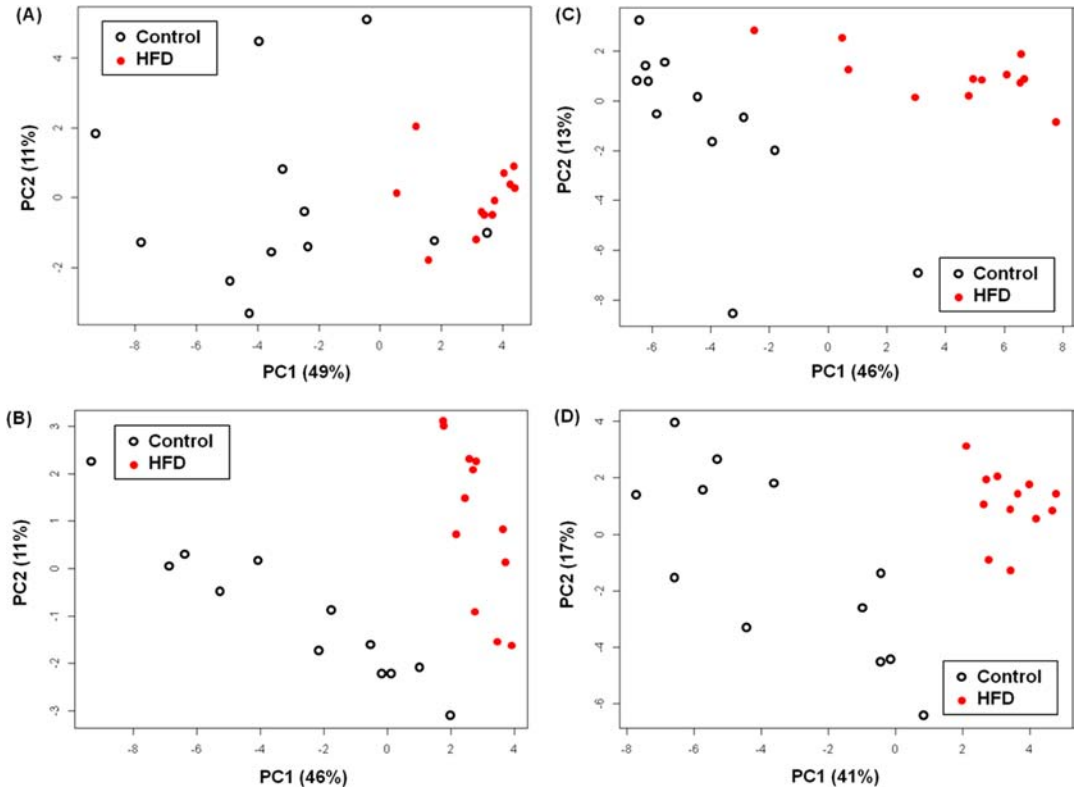

Figure 4. PCA score plots derived from the UHPLC−QTOF−MS spectrum of serum samples from control and HFD mice after (A) 4 weeks, (B) 8 weeks, (C) 12 weeks, and (D) 16 weeks of feeding. HFD, high-fat diet.

($p < 0.05$) the levels in controls, respectively. At the end of 12 and 16 weeks, the HFD group showed significantly higher serum levels of FFA ($p < 0.001$), AST ($p < 0.01$, or $p < 0.001$), and ALT ($p < 0.001$) than those in the controls, suggesting successful induction of the physiological indicators for NAFLD development.

Hepatic Steatosis and Histopathological Examination. Figure 1 shows that, in comparison to the control group, the macroscopic liver appearance of the HFD group indicated remarkable hepatomegaly with significant histopathological changes over time. Liver sections were evaluated by H&E staining and further staining with Oil Red O to visualize the lipid droplets of these vacuoles. Histopathological examinations revealed no abnormalities in control mice, whereas lipid vacuoles and lipid droplets accumulation progressively increased in the HFD-fed mice over the induction period. Correspondingly, the steatosis score indicated that macrovesicular fatty infiltration of hepatocytes was minimal (1.1), moderate (3.0), severe/high (4.5), and severe/high (4.7) after 4, 8, 12, and 16 weeks of HFD feeding, respectively (Figure 2). These morphological changes paralleled the significant increases in liver weight by 1.1-fold ($p < 0.01$), 1.2-fold, 2.2-fold, and 2.1-fold ($p < 0.001$), hepatic TG level by 1.5-fold ($p < 0.05$), 2.4-fold, 3.4-fold, and 3.5-fold ($p < 0.001$), and hepatic TC level by 1.0-fold (no significant difference), 1.5-fold, 2.0-fold, and 2.2-fold ($p < 0.001$) in the HFD-fed mice compared to those in controls at 4, 8, 12, and 16 weeks, respectively (Figure 2). Taken together, the maximal differences ($p < 0.001$) in both histopathological examination and hepatic biochemical parameters were observed after 8 weeks of HFD feeding.

Hepatic Oxidative Stress and Inflammation. As shown in Figure 3, none of the parameters of hepatic antioxidant capacity and pro-inflammatory cytokines were significantly different between the HFD and control groups after 4 weeks of feeding. At 8 weeks, HFD-fed mice showed noticeably reduced hepatic GSH levels ($p < 0.01$) and CAT, SOD, and GRd ($p < 0.05$) activities were reduced by 12.9−33.0%. In contrast, TNF-α content significantly increased by 29.0% ($p < 0.05$). At the end of 12 and 16 weeks, HFD induced oxidative stress and inflammation in the liver, as indicated by 16.7−49.5% inhibition of hepatic GSH, GPx ($p < 0.01$, or $p < 0.001$), SOD ($p < 0.01$), CAT, and GRd ($p < 0.001$) and 14.9−42.8% elevation of hepatic MDA ($p < 0.01$), TNF-α, IL-1β ($p < 0.001$), and IL-6 ($p < 0.05$, or $p < 0.01$).

Metabolomic Profile of Serum Extracts. Serum metabolomics based on UHPLC−QTOF−MS and GC−MS data was used to investigate the pathophysiological mechanism of HFD-induced hepatic steatosis in C57BL/6J mice at different time points (4, 8, 12, and 16 weeks). Among the normalized intensities of low-molecular-weight metabolites extracted from serum samples, a total of 244 and 101 distinct metabolites were identified by UHPLC−QTOF−MS and GC−MS, respectively. To discriminate the different metabolic profiles affecting the NAFLD mice at each time point, a PCA score plot was employed to visualize the sample distribution of the multivariate patterns. The two-dimensional scatter plot of the UHPLC−QTOF−MS spectrum was defined by the first and second principal components PC1 and PC2. As shown in Figure 4, PC1 discriminated the control and HFD groups after 4, 8, 12, and 16 weeks and explained 60, 57, 59, and 58% of the total variation, respectively. The serum PCA score plot from the GC−MS spectrum (Figure 5) was similar to that derived from the UHPLC−QTOF−MS data. The HFD group was clearly separated from their age-matched controls along PC1,

DOI: 10.1021/acs.jafc.5b02830
J. Agric. Food Chem. 2015, 63, 7873−7884

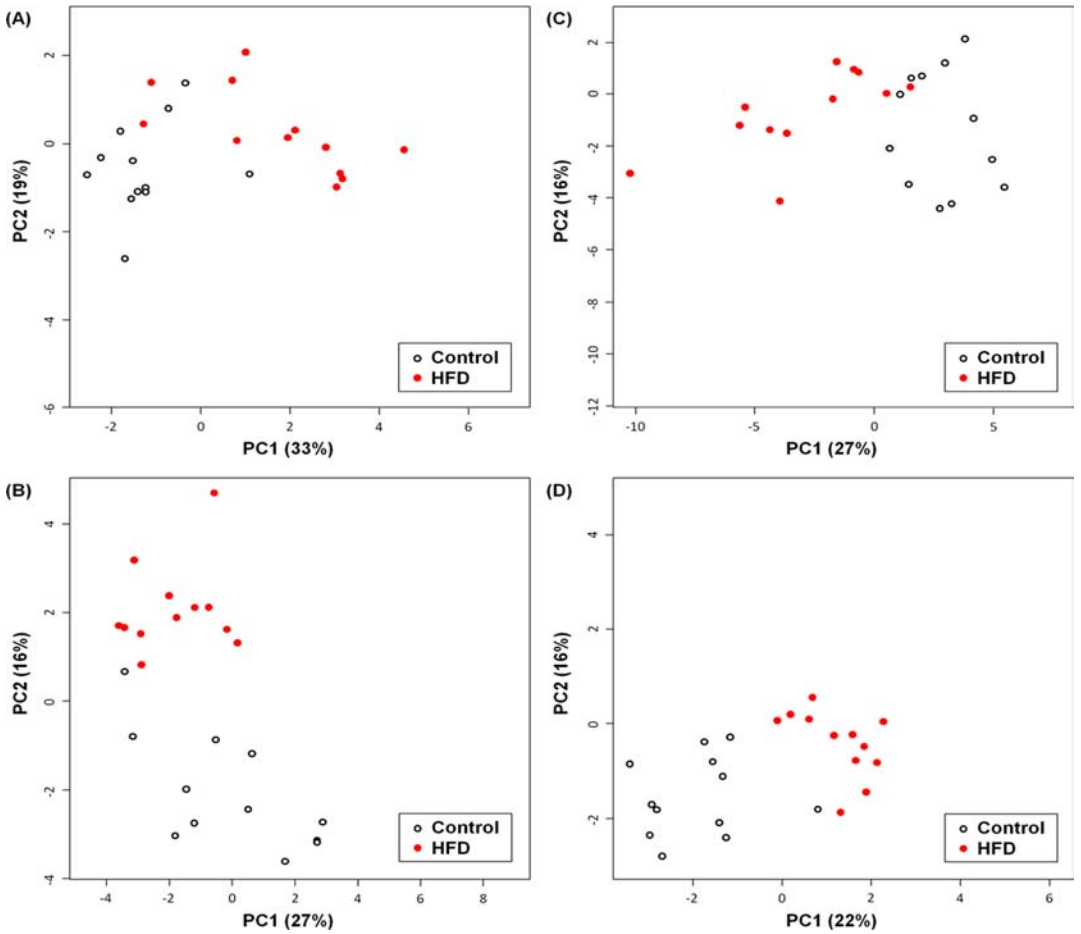

Figure 5. PCA score plots of serum GC−MS spectrum obtained from control and HFD mice after (A) 4 weeks, (B) 8 weeks, (C) 12 weeks, and (D) 16 weeks of feeding. HFD, high-fat diet.

while the mice fed the HFD for 8 weeks were discriminated from the control and other HFD groups by PC2. At 4, 8, 12, and 16 weeks of feeding, PC1 and PC2 together explained 52, 43, 43, and 38% of the total variance, respectively. These results indicated that the control and HFD groups were individually clustered and well-separated at all four time points. Therefore, metabolic variability exists in the mouse serum during long-term HFD intervention, confirming the validity of this animal model of NAFLD.

Potential Biomarkers and Metabolic Pathways. To further investigate the major alteration trends of all variables between the control and HFD-fed mice at each time point (4, 8, 12, and 16 weeks), the potential metabolites that were significant ($p < 0.05$) in the Student's t test were determined. Of various serum metabolites, 21 and 9 molecular species were assigned as the continually significant metabolites by UHPLC−QTOF−MS and GC−MS (Tables 2 and 3, respectively). To gain insight into the metabolic mechanism involved in the significantly different metabolites affected by the HFD during NAFLD onset and progression, the major metabolic pathways and possible physiological reactions of potential biomarkers were identified on the basis of the KEGG database, Human Metabolome Database (HMDB), and related references (Tables 2 and 3 and Figure 6).

A total of 11 metabolites were found to have changed significantly in the HFD mice relative to controls after 4 weeks of induction. These potential metabolites were D-xylose/D-ribose/D,L-arabinose, glucuronate, catechol, 4-coumarate, hippurate, L-kynurenine, kynurenate, 4-hydroxyproline, L-proline, L-lysine, and allantoin. This finding suggested that the early processes in NAFLD development are mainly associated with carbohydrate metabolism, hepatic biotransformation, collagen synthesis, and gut microbial metabolism. An additional 5 metabolites significantly changed after 8 weeks of induction, including *trans*-aconitic acid, α-ketoglutarate, L-glutamic acid, stearic acid, and sebacic acid, which are mainly correlated with impaired insulin secretion and lipid metabolism in the mid-term of NAFLD progression. In addition, 14 additional metabolites, including D-mannose, glycerol 3-phosphate, methylhippuric acid, palmitic acid, ketoleucine, 2-ketohexanoic acid, taurocholate, glycocholate, glycochenodeoxycholate, hydroxyphenyllactic acid, succinate, histamine, methionine, and L-tryptophan, were observed at the end of 12 and 16 weeks in the development of NAFLD. These metabolites are predominantly related to bile acid synthesis disorders, oxidative stress, inflammation, and mitochondrial dysfunction. These findings demonstrate the potential biomarkers that are closely associated with key metabolic pathways and that changed over time in the evolution of NAFLD.

DISCUSSION

We reported here the metabolomic assessment of serum from mice induced NAFLD by 4, 8, 12, and 16 weeks of HFD feeding through UHPLC−QTOF−MS and GC−MS analyses. Despite extensive research, there has been no systemic study of

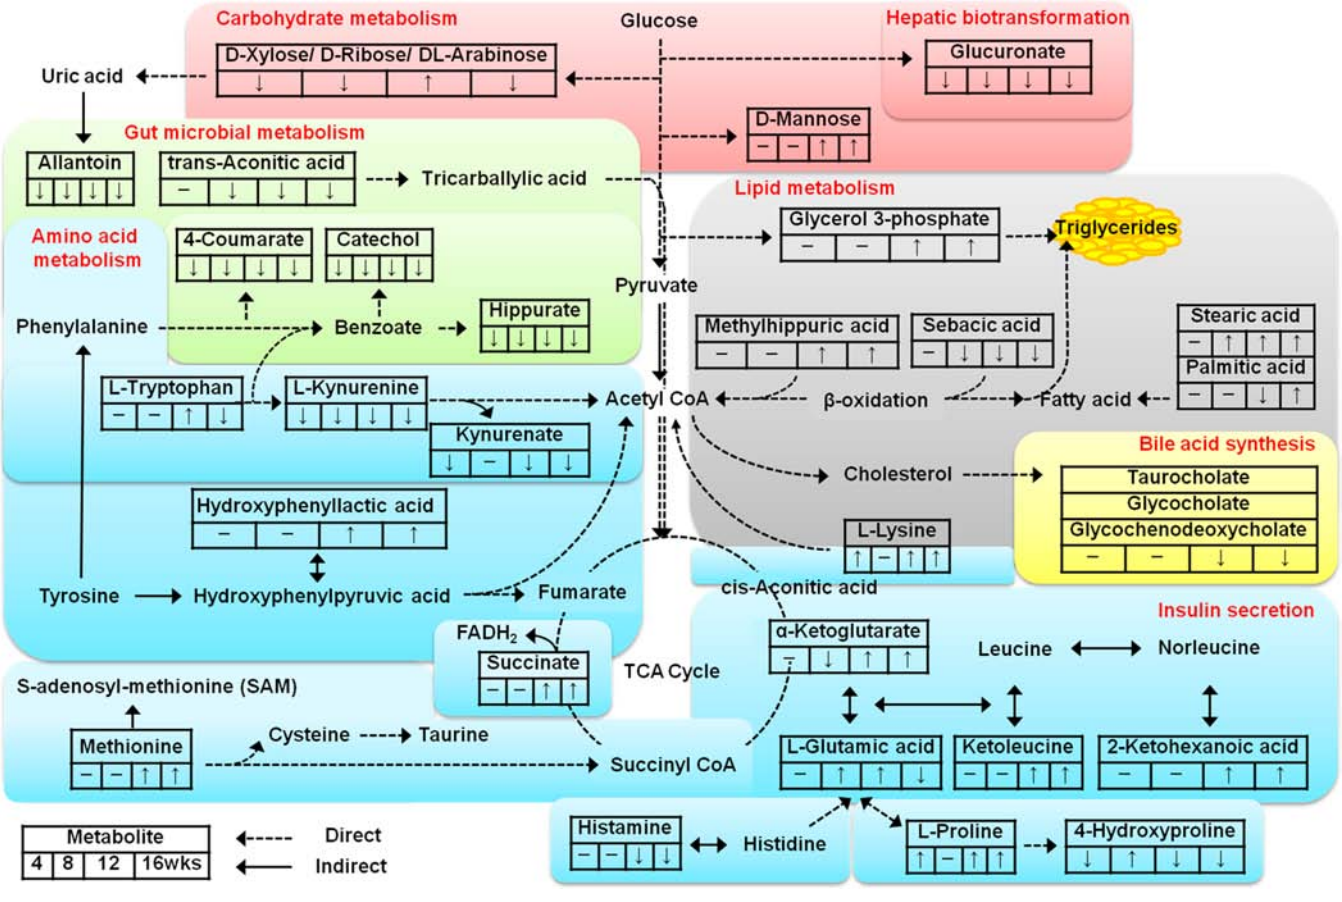

Figure 6. Major metabolic pathways in progressive NAFLD induced by HFD based on serum metabolite analysis. Solid and dashed arrows indicate the single and multiple steps involved between two metabolites, respectively. The up arrow (↑) indicates relative increase in signal. The down arrow (↓) indicates relative decrease in signal. The dash (−) represents no statistically significant difference. TCA, tricarboxylic acid.

pathophysiological characteristics and metabolic profiling in C57BL/6J mice fed a HFD to induce NAFLD development. Our results revealed that NAFLD onset and progression from early metabolic disturbances arise from minimal/moderate fatty infiltration (4 and 8 weeks) to alterations in various metabolic pathways following severe/high hepatic lipid accumulation (12 and 16 weeks). We identified a total of 30 potential biomarkers that were strongly associated with the development of NAFLD. Among these, 11 metabolites were identified to be mainly related to carbohydrate metabolism, hepatic biotransformation, gut microbial metabolism, and collagen synthesis, which are characteristics of a state of obesity, as well as high levels of serum glucose, TC, and hepatic TG during the onset of NAFLD (4 weeks). An additional 5 metabolites identified in the mid-term of NAFLD progression (8 weeks), which are chiefly involved in perturbation of lipid metabolism and insulin secretion, could be reflective of the pathophysiology associated with hyperinsulinemia, hyperlipidemia, and hepatic steatosis. In combination of the foregoing metabolic abnormalities, 14 additional metabolites that were predominantly correlated to abnormal bile acid synthesis, oxidative stress, and inflammation, representing hepatic inflammatory infiltration, were observed at

the end of 12 and 16 weeks of feeding in the development of NAFLD. Below, we discuss the reliable and abundant evidence for the potential biomarkers associated with the related metabolic disorder and their potential pathological roles.

In this study, we observed that D-ribose, D-xylose, D,L-arabinose, and D-mannose are associated with carbohydrate metabolism in HFD-induced NAFLD. These metabolites play various physiological roles, including control of pentolysis, biosynthesis of ribose-5-phosphate, glucuronate, and ascorbate, and functions of the ATP-binding cassette (ABC) transporters. Abnormal metabolism of carbohydrates and changes in metabolites, such as D-xylose, D,L-arabinose, and D-mannose, have been detected in patients with NAFLD or NASH.[11,12] Moreover, this study showed that glucuronate is involved in the hepatic biotransformation of HFD-induced NAFLD mice. Glucuronate normally participates in xenobiotic metabolism through glucuronidation.[13] Previous studies have suggested that HFD or NAFLD could interfere with hepatic glucuronidation.[14] In addition, glucuronate participates in ascorbic acid biosynthesis, which protects tissues from oxidation and promotes cholesterol metabolism. Furthermore, we noticed that 4-hydroxyproline, L-proline, and L-lysine are associated with collagen synthesis in HFD-induced NAFLD mice. 4-Hydroxyproline is the product of L-proline hydroxylation by the cofactor ascorbic acid. Excessive levels of L-proline and 4-hydroxyproline in the blood are potential indicators of increased collagen production in the liver.[15] Studies have confirmed that NAFLD can increase collagen synthesis in the liver, especially in patients with chronic hepatitis.[16] L-Lysine is not only important for collagen synthesis in the body but is also considered a precursor for carnitine biosynthesis in the liver. Normal L-lysine metabolism depends upon ascorbic acid, which is the electron donor for collagen hydroxylation and carnitine synthetase.[17] Excessive amounts of L-lysine have been linked with increased levels of TG and cholesterol.[18] Significant increases in lysine levels are found in mice with HFD-induced NAFLD.[4] Clinical metabolic studies have revealed significantly higher serum lysine levels in patients with NASH than in healthy subjects.[11]

This study revealed that hippurate, catechol, 4-coumarate, *trans*-aconitic acid, and allantoin are associated with the gut microbial metabolism in HFD-induced NAFLD. Food-derived amino acids, such as tryptophan, tyrosine, and phenylalanine, are metabolized by the gut microbiota to form benzoate. Benzoate is conjugated with glycine in the hepatic mitochondria via the phenylalanine metabolic pathway to form hippurate.[19] Catechol and 4-coumarate affect the degradation of aromatic compounds and the benzoate and phenylalanine metabolic pathways.[20,21] Studies have shown that HFD significantly reduced the gut microbial metabolites of hippurate, which is regarded as an indicator for assessing the risks of obesity and hepatic functional impairment.[11,22] In the intestinal tract, *trans*-aconitic acid is converted to tricarballylic acid by the gut microbiota. A rat model of HFD-induced obesity showed a significant change in *trans*-aconitic acid content,[23] which was assumed to be related to the influence of gut microbial metabolism. Allantoin is the product of uric acid catabolism in various organisms. Approximately one-third of the uric acid pool is excreted into the intestinal tract, where it is degraded by the gut microbiota to allantoin.[24] In comparison to the healthy control group, significantly lower levels of allantoin are found in the disease group, which is considered a biomarker of diet-induced obesity, NAFLD, and NASH.[25,26]

In the current study, we noticed that sebacic acid, methylhippuric acid, glycerol 3-phosphate, stearic acid, and palmitic acid are involved in lipid metabolism in HFD-induced NAFLD. A metabolite of fatty acid catabolism in the liver, sebacic acid is a straight-chain dicarboxylic acid with 10 carbon atoms. In the hepatic mitochondria and peroxisomes, medium-chain dicarboxylic acids mainly undergo β-oxidation, which is consistent with the oxidation of fatty acids.[27,28] Methylhippuric acid is a secondary metabolite of fatty acids, and an increased level of this metabolite is a diagnostic indicator of diseases associated with anomalous mitochondrial functions related to fatty acid β-oxidation. Significant changes in methylhippuric acid were detected in patients with chronic hepatitis.[29] In addition, a significantly increased level of methylhippuric acid was detected in a rat model of HFD-induced NAFLD, suggesting that methylhippuric acid affects the pathways of lipid metabolism.[25] Glycerol 3-phosphate is an intermediate of glycolysis. A HFD can promote esterification of a FFA, increase the glycerol 3-phosphate level in the liver tissues, and promote lipogenesis, eventually resulting in NAFLD.[30] Stearic and palmitic acids are the most common saturated fatty acids in the body, and high levels of these metabolites have been detected in the serum lipid profile of patients with NAFLD or NASH, indicating that metabolic disturbances affecting FFA may be an important factor in the pathogenesis and progression of diseases.[31,32]

This study showed that 2-ketohexanoic acid, ketoleucine, α-ketoglutarate, and L-glutamic acid participate in the regulation of insulin secretion in mice with HFD-induced NAFLD. 2-Ketohexanoic acid can directly inhibit the ATP-sensitive potassium channel in pancreatic β cells, thereby stimulating insulin secretion.[33] Ketoleucine is also believed to stimulate the release of insulin, which is the major factor responsible for the pathogenesis of obesity-induced insulin resistance.[34] Stimulation of insulin secretion by 2-ketohexanoic acid and ketoleucine can simultaneously increase the production of α-ketoglutarate in pancreatic β-cell mitochondria,[35] which enters the cytoplasm to indirectly stimulate insulin secretion. Therefore, α-ketoglutarate has also been viewed as an effective biomarker in the pathogenesis of diabetes and insulin resistance associated with NAFLD and NASH.[11,36,37] In addition, L-glutamic acid stimulates insulin secretion by promoting Ca^{2+}-dependent exocytosis.[38] Metabolic profiling studies have shown that the level of L-glutamic acid is strongly correlated with insulin resistance.[39] Studies on patients with NAFLD or NASH with significantly high insulin levels have revealed significantly higher serum glutamate levels than those in healthy subjects;[11] this finding suggests that serum L-glutamic acid is a possible biomarker of the progression of NAFLD and NASH.[3]

This study revealed that glycocholate, glycochenodeoxycholate, and taurocholate are associated with bile acid synthesis in HFD-induced NAFLD. In the hepatocytic microsomes and cytosol, cholesterol participates in primary bile acid biosynthesis to form primary conjugated bile acids, such as glycocholate, glycochenodeoxycholate, taurocholate, and taurochenodeoxycholate.[40] Studies have indicated that NAFLD and NASH may cause hepatic injury and inflammation, resulting in bile acid dysmetabolism and significant changes in blood metabolites of glycocholate, glycochenodeoxycholate, and taurocholate.[11,41]

We also observed dysregulation of several amino acids, including succinate, methionine, histamine, hydroxyphenyllactic acid, L-tryptophan, L-kynurenine, and kynurenate, which are

DOI: 10.1021/acs.jafc.5b02830
J. Agric. Food Chem. 2015, 63, 7873−7884

predominantly related to the oxidative stress and inflammation in HFD-induced NAFLD. Succinate is a key participant of the tricarboxylic acid (TCA) cycle. In HFD-induced NAFLD, a relatively high succinate level may cause disturbances in the mitochondrial TCA cycle,[25] thereby promoting increased oxidative stress, impairment of hepatic mitochondrial function, and the release of cytokines, eventually leading to hepatitis.[42] In hepatocytes, methionine is metabolized to *S*-adenosyl methionine, cysteine, and taurine, which regulate lipid metabolism, oxidative stress, and bile metabolism, respectively.[43] Patients with NAFLD or NASH tend to have aberrant methionine metabolism, which is considered a key mechanism of hepatic oxidative damage.[44] Histamine, produced by decarboxylation of histidine, is mainly present in mast cells and basophils as a chemical transmitter that regulates oxidative stress and inflammatory and immune responses.[45] An abnormal level of histamine disrupts energy metabolism and forms the basis of the pathogenesis of NASH.[46] As a metabolic product of tyrosine, hydroxyphenyllactic acid can promote the production of ROS in the mitochondria and neutrophils, resulting in increased oxidative stress.[47] Indeed, relatively high levels of hydroxyphenyllactic acid are found in patients with liver diseases.[48] L-Tryptophan is known to effectively alleviate hepatitis by reducing the levels of proinflammatory cytokines in patients with NASH.[49] Studies have shown that long-term chronic inflammation induced by a HFD can cause degradation of L-tryptophan in hepatic cells to L-kynurenine and kynurenate, which can regulate inflammatory damage;[50] these findings demonstrate that tryptophan metabolism is a key metabolic pathway in the inflammatory infiltration of the liver associated with NAFLD.[11,25]

The present study identified several key metabolites in major metabolic pathways involved in the development of NAFLD, similar to those observed in clinical cases of NAFLD. These metabolites could be considered as potential biomarkers for early risk assessment of NAFLD as well as improved monitoring and management of NAFLD-related disease. Moreover, these results provide comprehensive insights into the metabolic processes underlying the onset and progression of NAFLD induced by HFD.

revealed that depression leads to an altered intestinal microbiota profile in OBx mice.

It is noted that anxiety and depression are generally considered to be correlated with stress. Increasing data show that stress has also been associated with changes in the GI microbiota via the sympathetic nervous system and adrenergic response. By deprivation of food, water, and bedding in mice inoculated with *Salmonella*, it was shown that environmental and dietary stresses significantly alter the gut microbiota in mice: stressed mice had lower levels of lactobacilli compared with control mice.[19] Maternal separation in rodents is a well-studied model of early-life stress. O'Mahony et al.[20] demonstrated that maternal separation stress causes marked population-based alterations in the fecal microbiota of separated animals, and such a disrupted microbiota can persist into adulthood. Bailey et al.[21] demonstrated that a prolonged restraint stressor significantly reduced microbial richness and diversity, such as a reduction in the family Porphyromonadaceae. Another study from this laboratory also showed that social disruption significantly changed the community structure of the microbiota, specifically, increasing the relative abundance of the genus *Clostridium* and decreasing the relative abundance of the genus *Bacteroides*.[22] In addition, it has been found that grid floor-induced stress significantly increased the relative abundance of *Odoribacter*, *Alistipes*, and an unclassified genus from the Coriobacteriaceae family.[23] These findings suggest that stress leads to anxiety/depression by altering the gut microbiota (Table 1) and that anxiety/depression influences the gut microbiota, which also affects anxiety and depression.

Table 1. Link between Microbiota and Brain Function

brain function	altered microbes	refs
stress	Porphyromonadaceae ↓	21
stress	*Clostridium* ↑, *Bacteroides* ↓	22
stress and anxiety	*Odoribacter* ↑, *Alistipes* ↑, Coriobacteriaceae ↑	23
autism	*Clostridium* ↑	27−29
	Akkermansia muciniphila ↓	30
	Sutterella ↑, *Ruminococcus torques* ↑	7, 31, 32
	Desulfovibrio ↑, *Bifidobacterium* ↓	
	Prevotella ↓, *Coprococcus* ↓, Veillonellaceae ↓	33

Gut Microbiota and Autism. Autism spectrum disorders (ASD) comprise a complex neurobiological disorder; its characteristics include impairment in social interaction and communication and restricted, repetitive, and stereotyped patterns of behavior, interests, and activities.[24] Genetic and environmental factors are involved in the pathogenesis of ASD. In particular, one potentially important environmental factor is abnormal intestinal microbiota, as GI disturbances are frequently reported in infants with ASD,[25] and there is a strong positive correlation between GI problems and ASD severity.[26] Indeed, altered compositions of the intestinal microbiota have been reported in several studies. Specifically, the *Clostridium* species were higher in the ASD patients compared to control.[27−29] Moreover, lower levels of the mucolytic bacterium *Akkermansia muciniphila*[30] and *Bifidobacterium* species,[31] higher levels of *Sutterella*, *Ruminococcus torques*, and *Desulfovibrio* species,[7,32] and significantly lower abundances of the genera *Prevotella*, *Coprococcus*, and unclassified Veillonellaceae[33] were found in ASD patients (Table 1).

Modulation of Gut Microbiota−Brain Axis for the Healthy Brain. The reported link of gut microbiota to brain health and disorders raises the question of how to modulate the microbiota for re-equilibration of the gut microbiota compositions altered by brain disorders. There is a growing body of evidence documenting the ability of probiotics, prebiotics, synbiotics, and other diets to normalize the dysbiotic microbiota associated with psychological disorders.[34]

Probiotics-Based Modulation. Although a complex relationship between gut microbiota and anxiety/depression exists, it is possible to improve anxiety and depression by probiotics modulation (Table 2). For example, Bercik et al.[35] indicated that *Bifidobacterium longum* normalized anxiety-like behavior induced by the noninvasive parasite *Trichuris muris* infection; Bravo et al.[36] showed that chronic treatment with *Lactobacillus rhamnosus* (JB-1) reduced the anxiety- and depression-related behavior in the *Trichuris muris*-infected mice.

Recently, using the maternal immune activation (MIA) mouse model of ASD in mouse offspring, Hsiao et al.[37] showed that oral administration of the human commensal *Bacteroides fragilis* reversed the abnormalities in gut permeability and ASD-related behaviors. Interestingly, these behavioral effects are not specific to *Bacteroides fragilis*, as *Bacteroides thetaiotaomicron* also significantly improves anxiety-like behavior, although *Enterococcus faecalis* does not exhibit anxiolytic action in MIA offspring.

Especially, ingestion of selected probiotics also exhibits effects on brain activity in humans. After 2 months of administration of *Lactobacillus casei* strain Shirota in chronic fatigue syndrome patients, there were significant rises in both *Lactobacillus* and *Bifidobacterium* and also a significant decrease in anxiety symptoms among those taking the probiotic versus controls.[38] The oral administration of *L. helveticus* R0052 and *B. longum* R0175 for 2 weeks was shown to alleviate anxiety and depressive symptoms in healthy volunteers, as measured by the Hopkins Symptom Checklist (HSCL-90), the Hospital Anxiety and Depression Scale (HADS), the Perceived Stress Scale, the Coping Checklist (CCL), and 24 h urinary free cortisol (UFC).[39] Similarly, after 4 weeks of consumption of a fermented milk product with probiotics (FMPP) (containing *Bifidobacterium animalis* subsp. *lactis*, *Streptococcus thermophiles*, *Lactobacillus bulgaricus*, and *Lactococcus lactis* subsp. *lactis*) by healthy women, Tillisch et al.[40] found that FMPP intake affected the activity of brain regions that control central processing of emotion and sensation, including affective, viscerosensory, and somatosensory cortices.

Several studies have spurred better understanding of the acting mechanisms of probiotics involved in gut−brain axis signaling. After exposure to *Bifidobacterium infantis*, the levels of brain-derived neurotrophic factor (BDNF) and *N*-methyl-D-aspartate (NMDA) receptor subunit 2a (NR2a) in the cortex and hippocampus were reduced in GF animals compared to SPF controls.[41] Likewise, the induced anxiety-like behavior in *Trichuris muris*-infected mice was still present after vagotomy, which was also associated with decreased hippocampal BDNF mRNA and increased circulating tumor necrosis factor-α and interferon-γ. When *Bifidobacterium longum* reversed the anxiety-like behavior in infected mice, the hippocampal BDNF expression was also restored, although the cytokines were not affected.[35] This means that visceral signals derived from bacterial colonization can be transmitted to the brain, and the anxiolytic actions of *Bifidobacterium infantis* and *Bifido-*

Table 2. Modulation of Brain Behaviors by Probiotics and Prebiotics

model	behavior tests	intervention	duration	effects	refs
Trichuris muris-infected mice	light/dark preference and step-down tests	*Bifidobacterium longum*	14 days	normalized anxiety behavior	35
Trichuris muris-infected BALB/c mice	open field, elevated plus maze, fear conditioning, stress-induced hyperthermia	*Lactobacillus rhamnosus* (JB-1)	28 days	reduced anxiety- and depression-related behavior	36
maternal immune activation C57BL/6N mice	open field, marble burying, social interaction, and adult ultrasonic vocalizations	*Bacteroides fragilis*, *Bacteroides thetaiotaomicron*	6−9 weeks	reversed autism spectrum disorder, improved anxiety-like behavior	37
chronic fatigue syndrome patients	Beck Depression and Beck Anxiety Inventories	*Lactobacillus casei*	8 weeks	decreased anxiety symptoms	38
Wistar rats and humans	conditioned defensive burying test, Hopkins Symptom Checklist, Hospital Anxiety and Depression Scale, Perceived Stress Scale, Coping Checklist	*Lactobacillus helveticus* R0052, *Bifidobacterium longum* R0175	14 days/30 days	reduced anxiety-like behavior in rats, alleviated psychological distress in humans	39
humans	brain response to an emotional faces attention task and resting brain activity	fermented milk product with probiotics (FMPP) (containing *Bifidobacterium animalis* subsp. *lactis*, *Streptococcus thermophiles*, *Lactobacillus bulgaricus*, and *Lactococcus lactis* subsp. *lactis*)	4 weeks	reduced task-related response of a distributed functional network containing affective, viscerosensory, and somatosensory cortices	40
humans	stress hormone, cortisol, and emotional processing	galactooligosaccharides	3 weeks	lowered cortisol awakening reactivity and increased attentional vigilance to positive versus negative stimuli	59

bacterium longum were mediated by a BDNF-dependent and cytokine-independent pathway.

However, in Sprague−Dawley rats treated for 14 days with *Bifidobacterium infantis*, Desbonnet et al.[42] showed that there are significant decreases of cytokines (IFN-γ, TNF-α, and IL-6), 5-HIAA concentration in the frontal cortex, and DOPAC in the amygdaloid cortex, but remarkable increases in plasma concentrations of tryptophan and kynurenic acid, in the *Bifidobacteria*-treated rats relative to controls. Moreover, the same team assessed the potential benefits of *Bifidobacterium infantis* in the rat maternal separation (MS) model of depression.[43] The results showed that Bifidobacteria treatment reversed behavioral deficits, restored basal noradrenaline (NA) concentrations, and normalized immune response; especially peripheral interleukin (IL)-6 release and amygdala corticotrophin-releasing factor mRNA levels were enhanced. These findings point to immune response-dependent antidepressant properties of *Bifidobacterium infantis*.

Wall et al.[44] reported that the administration of a *Bifidobacterium* strain to mice had a significant impact on the fatty acid composition of the brain. Significantly higher concentrations of arachidonic acid (ARA) and docosahexaenoic acid (DHA) were observed in mice receiving the bacteria for 8 weeks, compared to control mice. These fatty acids play a critical role in neurotransmission and protection against oxidative stress[45,46] and are also involved in the improvement of cognitive functions such as memory and learning.[47,48] These data indicate that probiotics are able to enhance brain function by modulating the metabolism of the host.

Bravo et al.[36] indicated that the reduced anxiety/depression effects in *Lactobacillus rhamnosus*-treated mice were accompanied by the reduction of corticosterone, the region-dependent alterations of γ-aminobutyric acid (GABA) and its receptors in the brain. Specifically, GABAB1b was up-regulated in cortical regions and down-regulated in the hippocampus, amygdala, and locus coeruleus; GABA(Aα2) was increased in the hippocampus but reduced in the prefrontal cortex and amygdala, compared to the control mice. However, these neurochemical and behavioral changes caused by *Lactobacillus rhamnosus* were not observed in vagotomized mice. This highlights that the vagus nerve is involved in the direct communication between the bacteria and the brain, supporting the important role of GABA-mediated signaling pathway in the bidirectional communication of the gut microbiota−brain axis.

Except for GABA secreted by certain strains of *Lactobacillus* and *Bifidobacterium*,[49] other important bacterial metabolites include norepinephrine produced by *Saccharomyces*, *Bacillus*, and *Escherichia*; serotonin produced by *Enterococcus*, *Streptococcus*, *Escherichia*, and *Candida* and dopamine from *Bacillus* and *Serratia*.[50] All of these neurotransmitters play a major role in the action of antidepression.

The administration of *L. helveticus* for 21 days can prevent high fat diet-induced anxiety-like behavior in wild type micel; however, in immunocompromised (IL-10 deficient) mice, high fat diet-induced anxiety-like behavior was not prevented by *L. helveticus* administration, demonstrating the importance of IL-10 signaling in the microbiota−brain communication pathway.[51]

In *Citrobacter rodentium*-infected mice, Gareau et al.[5] demonstrated that treatment with a combination of probiotics of *Lactobacillus rhamnosus* R0011 and *Lactobacillus helveticus* R0052 improved learning and memory behaviors; normalized the population of *Firmicutes* and *Eubacterium rectale* but elevated the levels of *Bacteroides*; restored hippocampal c-Fos and BDNF expression; and ameliorated serum corticosterone and colonic IFN-γ, but not TNF-α, levels. This reflects a BDNF- and IFN-dependent mechanism of action for probiotics to normalize the memory dysfunction occurring in *Citrobacter rodentium*-infected mice exposed to acute stress.

Hsiao et al.[37] reported that oral administration of *Bacteroides fragilis* and *Bacteroides thetaiotaomicron* significantly restored the relative abundance of the Lachnospiraceae family as well as unclassified Bacteriodales and normalized ASD-like behavior in MIA offspring. Importantly, on the basis of an altered serum metabolomic profile in MIA offspring, they found that *Bacteroides fragilis* changed back the abundance of 34% of the plasma metabolites, including 4-ethylphenylsulfate (4EPS), indolepyruvate, serotonin, glycolate, imidazole propionate, and *N*-acetylserine. Interestingly, the systemic administration of the single metabolite 4EPS (with a 46-fold increase) to

DOI: 10.1021/acs.jafc.5b02404
J. Agric. Food Chem. 2015, 63, 7885−7895

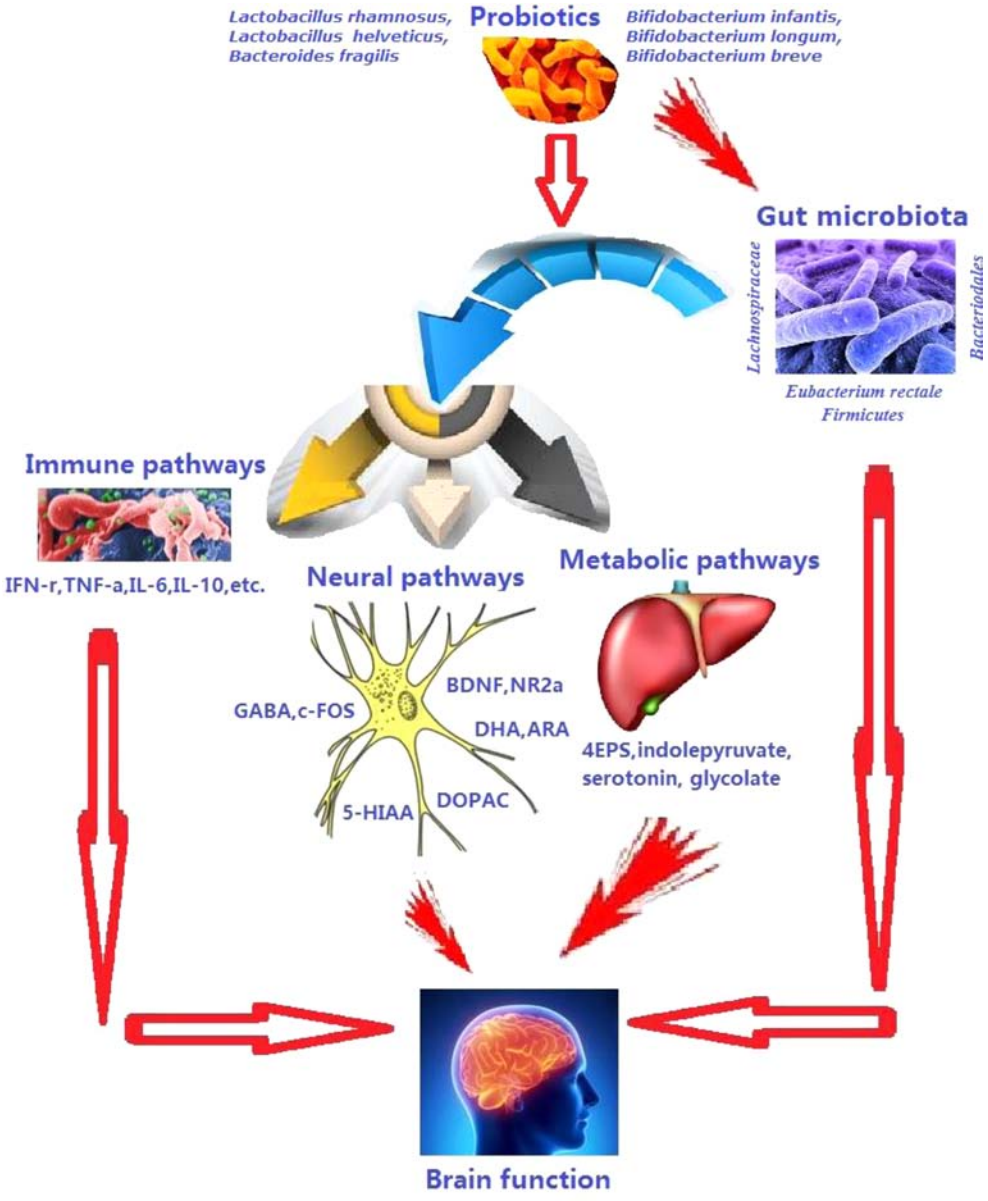

Figure 1. Proposed mechanism for probiotics-based modulation in the gut microbiota−brain axis. Probiotics modulate brain function by altering the composition of gut microbiota or regulating multiple signaling pathways including neural pathways, immune pathways, and metabolic pathways. INF-γ, interferon-gamma; TNF-α, (umor necrosis factor-alpha; IL-6, interleukin-6; IL-10, interleukin-10; BDNF, brain-derived neurotrophic factor; NMDA, *N*-methyl-D-aspartate; NR2a, receptor subunit 2a; GABA, gamma-aminobutyric acid; 5-HIAA, 5-hydroxyindoleacetic acid; DOPAC, dihydroxyphenylacetic acid; DHA, docosahexaenoic acid; ARA, arachidonic acid; 4EPS, 4-ethylphenylsulfate.

healthy mice is sufficient to induce anxiety-like behavior. It has been shown that commensal microbes are required for the production of serum 4EPS in mice; the precursor 4-ethylphenol is believed to be produced by several species of *Clostridium*;[52] the putative ASD biomarker *p*-cresol with a structure similar to that of 4EPS also derives from *Clostridium* species.[53] In addition, the elevated indolepyruvate in MIA offspring, which is also corrected by *Bacteroides fragilis* treatment, is reported to be produced by bacterial metabolism.[54] These findings suggest the critical role of the microbially modulated metabolism signaling pathway in modulating neurodevelopmental disorders.

Overall, as discussed above, the mechanisms of action are largely speculative and are not well-defined. On the basis of current knowledge, probiotics treatment alters the composition of gut microbiota, and multiple pathways may be involved in the conversation between gut microbiota and brain (Figure 1): vagus nerve-mediated pathways,[5,35,36,41] immune response-mediated pathways,[5,20−23] and metabolite-mediated pathways.[37]

Prebiotics-Based Modulation. It has been shown that varieties of polysaccharides can improve brain function in controlled human, animal, and in vitro studies after oral, systemic, and localized administration.[55] For example, ingestion of isolichenan, an α-glucan from the lichen *Cetrariella islandica*, reversed ethanol-induced memory impairment in mice.[56] Supplementation with a mixed polysaccharide product (Ambrotose complex) significantly improved cognitive function and mood in healthy middle-aged adults.[57] The oral administration of arabinoxylan from the yeast *Triticum aestivum* and β-glucan from barley were able to preserve memory in a mouse model of vascular dementia.[58]

A recent study explored the neuroendocrine and affective effects of two prebiotics (fructooligosaccharides, FOS, or

DOI: 10.1021/acs.jafc.5b02404
J. Agric. Food Chem. 2015, 63, 7885−7895

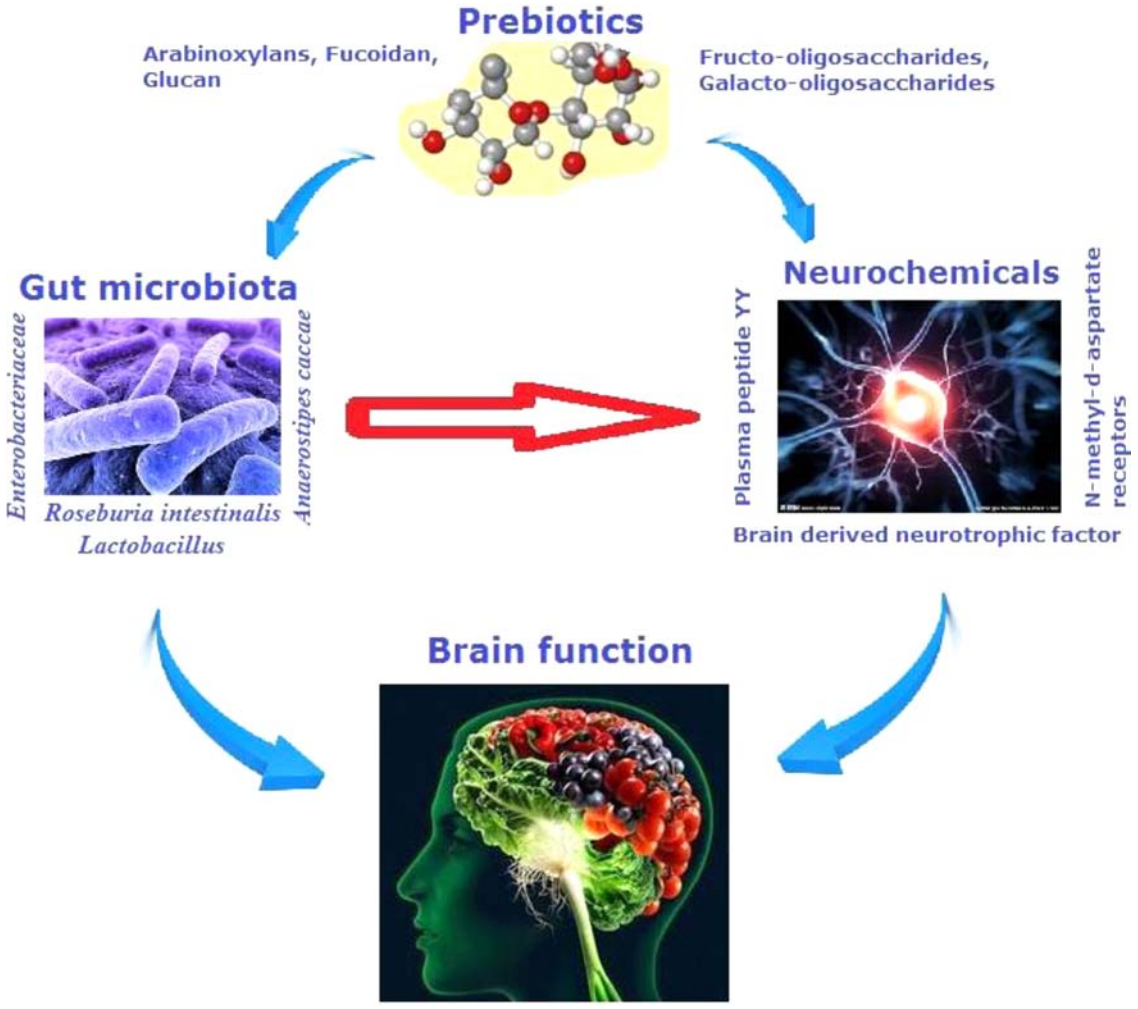

Figure 2. Proposed mechanism for prebiotics-based modulation in the gut microbiota–brain axis. Prebiotics modulate brain function by altering the composition of gut microbiota or influencing the production of neurochemicals.

Bimuno-galactooligosaccharides, B-GOS) in healthy human volunteers (Table 2).[59] Results revealed that no effects were found after the administration of FOS. In contrast, B-GOS lowered cortisol awakening reactivity and increased attentional vigilance to positive versus negative stimuli on the dot-probe task compared to the placebo group. The cortisol-awakening response is a reliable marker of HPA axis activity, which was increased in individuals at high risk of depression.[60] This indicates that B-GOS administration may have an antidepression effect by modulating the HPA axis.

Then, how do prebiotics act on the gut microbiota–brain axis? On the one hand, plant polysaccharides have major influences on gut microbiota. For example, the above-mentioned arabinoxylan was found to stimulate the growth of known butyrate producers (*Roseburia intestinalis*, *Eubacterium rectale*, *Anaerostipes caccae*);[61] fucoidan was reported to reduce the Enterobacteriaceae population in the newly weaned pig;[62] glucan, which is highly fermentable by the intestinal microbiota in the cecum and colon, can enhance the growth of *Lactobacillus* strains in the human intestine.[63] On the other hand, prebiotics directly influence signaling molecules in brain. In a recent study, Savignac et al.[64] revealed that prebiotics (FOS and galacto-oligosaccharides (GOS)) increased hippocampal BDNF and NR1 subunit expression, but did not alter amino acids associated with glutamate neurotransmission compared to controls. The intake of GOS also increased hippocampal NR2A subunits, frontal cortex NR1, and plasma peptide YY (PYY). This suggests that the prebiotics-mediated effect of the gut microbiota on brain chemistry is similar to that of probiotics, increasing brain BDNF expression probably through the involvement of gut hormones (Figure 2). However, the detailed mechanisms of prebiotic action, including how alterations in gut bacteria can affect these brain functions and behaviors, are not yet explored in these studies. Additional research is needed to determine whether these prebiotics-induced changes in brain physiology convincingly lead to cognitive and mood outcomes.

Moreover, compared with probiotics-based modulation, prebiotics could be advantageous to some extent, due to the presence of a survival problem in the GI tract for probiotics. In particular, genetic factors could have major impacts. For example, a single host gene, FUT2, is strongly associated with the diversity and composition of the human bifidobacterial population.[65] Specifically, several genotypes, including *Bifidobacterium bifidum*, *Bifidobacterium adolescentis*, and *Bifidobacterium catenulatum/pseudocatenulatum*, were absent or rarely colonized in the individuals without the FUT2 gene. On the other hand, probiotics are usually supplemented by one or several species at one time, whereas prebiotics supplementation

DOI: 10.1021/acs.jafc.5b02404
J. Agric. Food Chem. 2015, 63, 7885–7895

could stimulate a number of beneficial species simultaneously, which is good for their synergestic actions.

Diet-Based Modulation. Except for probiotics and prebiotics, diet can affect neural activity in the central nervous system. Hanstock et al.[66] reported that a fermentable carbohydrates-based diet increased anxiety and aggression behaviors in rats, and these effects were not related to the concentrations of dopamine and 5-HT in the brain, suggesting the mechanism of action could be neurotransmitter-independent. Haghpanah et al.[67] showed that oral administration of kefir (a fermented product of milk) can significantly improve spatial learning and consolidation of memory in rat. However, these studies did not examine the alterations in the bacterial populations. In fact, diet not only affects behavior but also alters the composition of the GI microbiota. For example, using male CF1 mice fed standard rodent chow (PP diet) or chow containing 50% lean ground beef (BD diet) for 3 months, Li et al.[68] showed that significantly higher bacterial diversity was observed in the BD group compared with the PP group. Three genera (*Atopobium*, *Bacteroidales*, and *Erysipelothrix*) were exclusively present in the PP group, whereas 12 genera (*Alistipes*, *Allobaculum*, *Chthoniobacter*, *Dorea*, *Eggerthella*, *Gemella*, *Leuconostoc*, *Proteus*, *Sarcina*, *Serratia*, *Staphylococcus*, and *Turicibacter*) were unique to the BP group. Furthermore, BD diet mice also displayed increased learning and memory behaviors as well as decreased levels of anxiety-like behavior compared to PP-fed animals. Notably, the nutritional components for both the PP and BD diets were approximately equal with the exception of taurine and fat, which were present at 18 and 1.5 times the concentrations in BD compared to PP diet, respectively. Although taurine improved learning behavior in aged mice[69] and high fat fed C57Bl/6ByJ mice increased learning and memory behaviors compared to regular chow fed mates,[70] it is not clear how BD diet-induced alterations in bacterial diversity lead to altered learning and memory behaviors.

FUTURE CHALLENGES

Selection of a Suitable Model or Strain for a Specific Behavior or Mood Is Essential. Except for the intrinsic complex in the gut microbiota−brain communication, one major impact factor is the use of different research methods, such as the selection of a suitable animal model or strain. For example, when using the bacterial infection method to induce anxiety-like behavior in animals, different infections will certainly lead to different anxiety models due to the different central sensing of GI infections. Indeed, acute infection with *Campylobacter jejuni* results in anxiety-like behavior by nonimmune responsive activation of vagal pathways,[71] whereas a recent study[36] reported that chronic *Trichuris muris*-infected mice exhibit anxiety-like behavior (present even after vagotomy), which is associated with decreased hippocampal BDNF and increased circulating tumor necrosis factor-α and interferon-γ, as well as the kynurenine, suggesting an inflammation-dependent and vagus nerve-independent pathway. Moreover, it is also possible to generate different anxiety models, even using the same bacterial species. For example, *Citrobacter rodentium* infection, an animal model of inflammatory bowel disease (IBD), induces anxiety-like behavior in mice during the early phase of infection (7−8 h post-infection), which is accompanied by unchanged plasma levels of the cytokines IFN-γ, TNF-α, and IL-12 and elevated c-Fos protein in vagal sensory ganglia.[72] These findings suggest that the behavioral effect is likely mediated by vagal sensory neurons, not by inflammation-related stress.[72] In another study,[5] *Citrobacter rodentium*-infected mice exhibit stress-induced memory dysfunction but no anxiety-like behavior during the late phase of infection (10 and 30 days post-infection), with decreased serum corticosterone, hippocampus BDNF, and c-Fos expressions; increased colonic IFN-γ and TNF-α levels; and altered gut microbiota (significantly elevated *Firmicutes*, Enterobacteriaceae, *Eubacteria rectale*, and *Bacteroides*), suggesting a neural and cytokine-mediated sensing pathway and highlighting the pronounced impacts of measuring behaviors at different time points.

On the other hand, the difference in the commonly used strains of mice (CD-1, MF1, NIH Swiss, C57BL6/J, and BALB/C) should be considered when using them to establish behavioral models. That is, BALB/c mice express more anxiety-like behavior and timidity and higher levels of serotonin and dopamine (may be genetically determined) in the colon than NIH Swiss mice, which are generally more gregarious and less timid.[13−15] It is imaginable that the results should be variable when investigating the effect of environmental factors on their behaviors, even under the same experimental conditions. Therefore, it is very important to identify the most suitable model or strain for a specific brain disorder model.

Strain−Strain Differences Are Important Factors for Modulating the Gut Microbiota−Brain Axis. Studies have supported a role of probiotics in modulating gut microbiota and improving brain behaviors, but the beneficial effects are divergent and are dependent on the strain. For example, Wall et al.[44] showed that reduced proportions of Eubacteriaceae (3 vs 12%) and increased proportions of Clostridiaceae (25 vs 12%) were observed in mice supplemented with *Bifidobacterium breve* DPC 6330 compared to mice supplemented with *Bifidobacterium breve* NCIMB 702258. Interestingly, administration of *Bifidobacterium breve* NCIMB 702258 was found to have a greater effect on the fatty acid composition of the brain; for instance, there were significantly higher concentrations of arachidonic acid (ARA) and docosahexaenoic acid (DHA) in the brain of mice supplemented with *B. breve* NCIMB 702258 than in the brain of mice supplemented with *B. breve* DPC 6330. Studies have indicated that ARA and DHA play important roles in neurogenesis and neurotransmission,[45,46] and their concentrations in the brain influence cognitive processes such as learning and memory.[47,48] Therefore, it is important to perform extensive studies on whether or not the strain-dependent differences in the compositions of gut microbiota and brain fatty acids or other neurochemicals result in remarkably functional consequences for the host.

Communication among the Gut, Gut Microbiota, and Brain. Although the existence of multiple signaling pathways including immune, neural, and metabolic pathways in the modulation of the gut microbiota−brain axis is discussed above, it is still challenging to fully understand how the gut, gut microbiota, and brain cooperate to maintain the functioning of the host.

The gut possesses its own nervous system, named the enteric nervous system (ENS). It is well-known that the ENS maintains constant and direct communication with the central nervous system (CNS) via nerves.[1] Therefore, the remaining issue is the communication between ENS or CNS and gut microbiota. Notably, the ENS is separated from gut microbiota by mucosal cell layers, which makes the intestinal commensal microbes inaccessible to ENS. Thus, there are two possibilities to realize

DOI: 10.1021/acs.jafc.5b02404
J. Agric. Food Chem. 2015, 63, 7885−7895

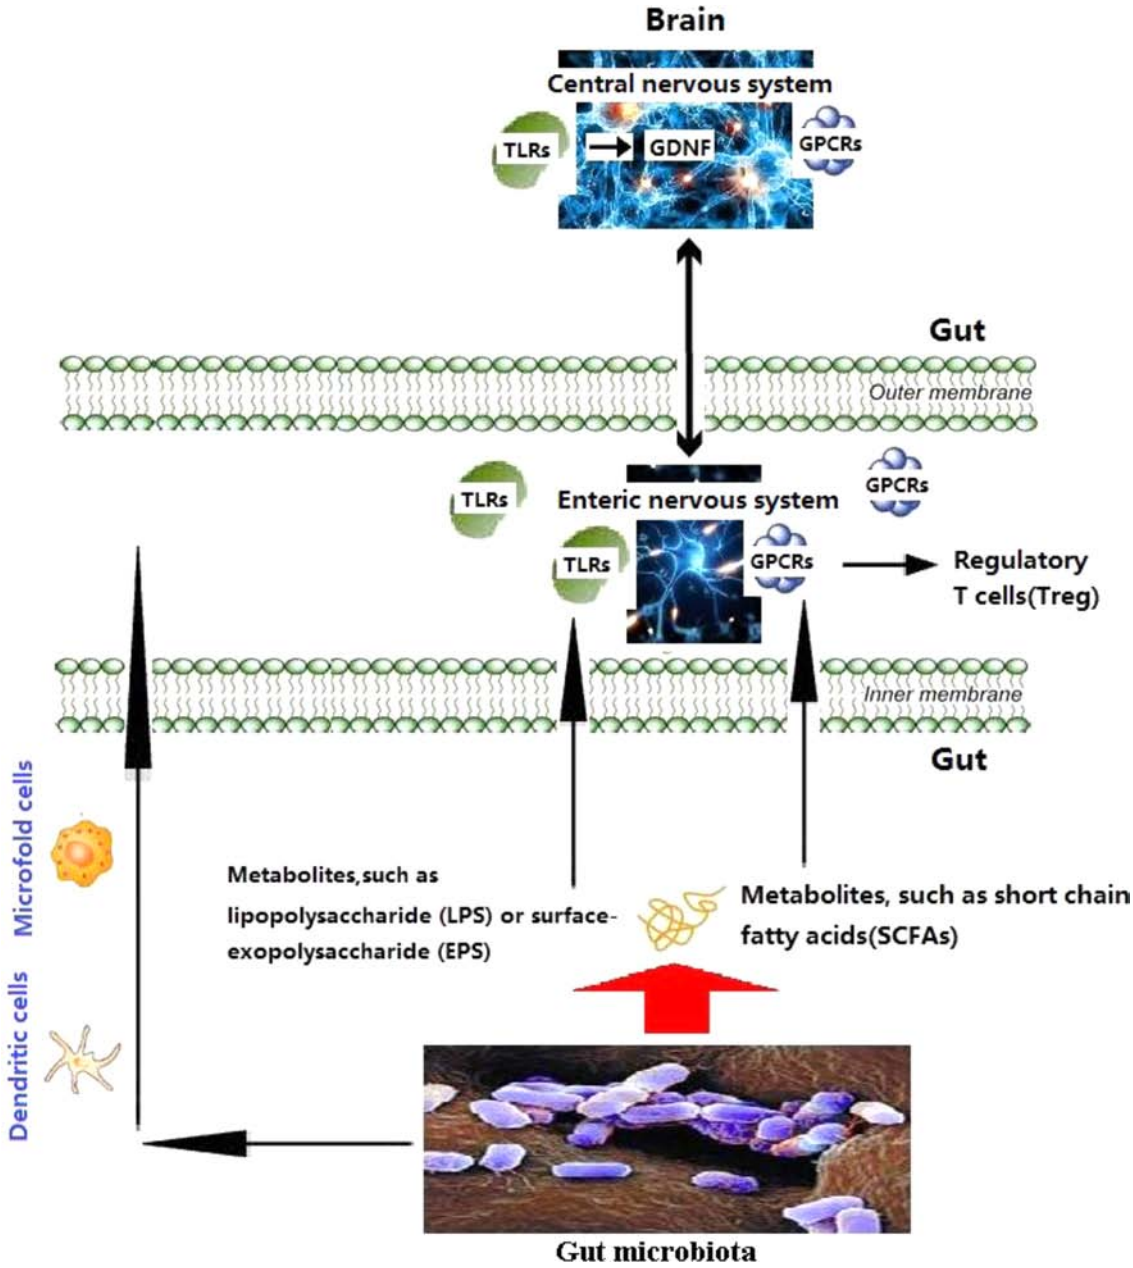

Figure 3. Communication among the gut, gut microbiota, and brain. The enteric nervous system (ENS) directly communicates with the central nervous system (CNS). The resident microbes translocate to the lamina propria from the intestinal lumen by the microfold cells and/or by dendritic cells. The microbiota-generated components, such as bacterial lipopolysaccharide (LPS), surface exopolysaccharide (EPS), and short-chain fatty acids (SCFAs), cross or bypass the epithelium to act directly on the ENS. The resident microbes or their metabolites are able to interact with some specific receptors such as Toll-like receptors (TLRs) and G-protein coupled receptors (GPCRs). The gut microbiota regulates the ENS by TLR signaling, stimulates the expression of a glial cell line-derived neurotrophic factor (GDNF), and increases the number of enteric neurons and glial cells. SCFAs regulate colonic regulatory T cell (cTreg) homeostasis by acting on GPCRs.

communication between gut microbiota and ENS: (1) the resident microbes translocate to the lamina propria from the intestinal lumen by microfold cells and/or dendritic cells, probably by direct entrance in disease state due to "leaky" intestinal wall; (2) the microbiota-generated components access the lamina propria. Indeed, bacterial lipopolysaccharide (LPS) or polysaccharide A (PSA) or surface-exopolysaccharide (EPS), short-chain fatty acids, glutamate, and so on, are able to cross or bypass the epithelium to act directly on the ENS.[73] After the resident microbes (probably secreted products or metabolites) or their products/metabolites translocate to the lamina propria, they are able to interact with some specific receptors, such as pattern recognition receptors including Toll-like receptors (TLRs) and G-protein coupled receptors (GPCRs).

TLRs are universally distributed in macrophages, endothelial cells, glia, and neurons.[74] In the immune system, TLRs recognize the invading microorganisms, and in the nervous system, TLRs recognize endogenous ligands released by undifferentiated or necrotic/injured cells; their activities are associated with brain disorders.[75] After interaction, the ENS and immune system are activated to release cytokines and neurohumoral mediators.[76] In fact, Brun et al.[77] revealed that gut microbiota regulate ENS integrity by TLR-2 signaling,

DOI: 10.1021/acs.jafc.5b02404
J. Agric. Food Chem. 2015, 63, 7885−7895

stimulate the expression of a glial cell line-derived neurotrophic factor (GDNF), and increase the number of enteric neurons and glial cells, hence facilitating the development and survival of many types of neurons. Depletion of gut microbiota significantly reduced the expression of GDNF in mice; TLR-2-deficient mice increased susceptibility to inflammation, whereas the severity of inflammation was reduced by administration of GDNF. This highlights the importance of the gut microbiota−TLR-2−GDNF axis in modulating the ENS and inflammation.

GPCRs are also universally expressed in many sites, including in the CNS, especially in the striatum,[78] and these receptors play a critical role in the regulation of metabolism, inflammation, neurological/psychiatric disorders, and other diseases.[79,80] Short-chain fatty acids (SCFAs) are produced by the gut microbiota during the fermentation of partially digestible or nondigestible polysaccharides. Except for inhibition of histone deacetylases (HDACs), another major SCFA signaling mechanism is activation of GPCRs. Especially, GPR43, GPR41, and GPR109A have been identified as receptors of SCFAs.[81] Smith et al.[82] reported that acetic acid, propionic acid, and butyric acid, the three most abundant microbial-derived SCFA, display an exciting role in regulating colonic regulatory T cell (cTreg) homeostasis and protecting against colitis by acting on GPR43. This is supported by Atarashi et al.,[83] who found that a rationally selected mixture of *Clostridia* strains from the human microbiota enhances Treg induction. In particular, De Vadder et al.[84] showed that SCFAs such as propionate from fermentation of gut microbiota on prebiotic GOS promote metabolic benefits on body weight and glucose control via a gut−brain neural circuit involving the fatty acid receptor GPR41. This highlights the importance of the gut microbiota−GPCRs−brain axis in regulating host functions.

Thus, although the exact mechanism describing the communication among gut, gut microbiota, and brain still warrants further study, it can be speculated that various axes of gut microbiota−receptors−brain could be responsible for the realization of many functions between the gut and brain (Figure 3), such as the gut microbiota−TLRs−brain axis for probiotics modulation and the gut microbiota−GPCRs−brain axis for prebiotics modulation.

Novel Technologies in the Gut Microbiota−Brain Axis. To extensively explore the detailed mechanism underlying the gut microbiota−brain axis, novel techniques are highly needed. One technology is functional magnetic resonance imaging (fMRI), which has shown the potential for studies of gut−brain signaling in humans over the past few years. For example, using fMRI, Van Oudenhove et al.[85] found that there was a significant fat−emotion interaction effect on the blood oxygen level-dependent signal (BOLD signal) in multiple regions of interest, including medulla/pons, midbrain, hypothalamus, thalamus, caudate head, putamen, cerebellum, AND right hippocampus, suggesting that fatty acid infusion attenuated the behavioral and neural responses to sad emotion induction in humans. By physiological/pharmacological MRI (phMRI), Jones et al.[86] revealed that intragastric dodecanoate caused strong bilateral activation of a matrix of CNS areas, including the brain stem, hypothalamus, and limbic areas, and ghrelin bolus decreased the BOLD signal in feeding-activated areas of the CNS. Very recently, Tillisch et al.[40] demonstrated that the reactivity of a widely distributed network of brain regions to an emotional attention task was reduced in women who had ingested FMPP, including primary interoceptive and somatosensory regions, prefrontal cortex, precuneus, basal ganglia, and the parahippocampal gyrus. This provides important clues for further exploring the mechanism of action.

Another technology is omics analysis (i.e., transcriptomics, proteomics, metabolomics, and systems biology). For example, transcriptomics, which is the study of the complete set of RNA transcripts produced in cells or tissues, was applied to explore in vivo mucosal responses of healthy adults to probiotics.[87,88] The results revealed that gene-regulatory networks and pathways were differentially induced in the human mucosa and were dependent on the preparations of living and heat-killed *Lactobacillus plantarum* bacteria and the specific species (*L. acidophilus*, *L. casei*, and *L. rhamnosus*). Transcriptomic comparisons of two breast milk-derived *Lactobacillus* (*L. reuteri* ATCC 55730 and ATCC PTA 6475) identified candidate genes involved in the survival and persistence in the gut, and genes responsible for immunomodulation and health-promoting factors such as antimicrobial agents and vitamins especially predicted a complete pathway for thiamin biosynthesis in strain 55730 for the first time.[89]

Proteomics is the large-scale study of the entire set of proteins produced or modified by an organism or system, which is largely an underexploited approach at the interface of gut microbiota and brain physiology.[90] In a *Trichuris muris*-infected mice model, Bercik et al.[36] showed that anxiety-like behavior was induced and CNS biochemistry was changed, and several proteins related to inflammation and neural function were identified by proteomic analysis. Using comparative proteomics, Kim et al.[91] investigated the response of *Bifidobacterium longum* subsp. *infantis* to different prebiotics. ATP-dependent sugar transport systems related to the consumption of different prebiotics was determined, providing molecular foundations for different prebiotics consumption in *B. infantis* and evidence for differential impacts on brain health.

Metabolomics is simultaneously analyzes hundreds to thousands of small-molecule metabolites in biological samples by an array of analytical techniques including mass spectrometry and high-resolution nuclear magnetic resonance spectroscopy. Real-time analysis of the small-molecule metabolites derived from the gut, microbes, and brain is increasingly useful for deciphering inherent and intimate gut microbiota−brain relationships.[92] Using capillary electrophoresis with time-of-flight mass spectrometry (CE-TOFMS), Matsumoto et al.[93] identified 196 metabolites from the cerebral metabolome in both GF and Ex-GF mice (inoculated with suspension of feces obtained from specific pathogen-free mice); among them, 38 metabolites differed significantly, and 10 of these metabolites are known to be involved in brain function. A novel relationship between gut microbiota and cerebral glycolytic metabolism was found. These findings suggest that the intestinal microbiota is closely connected with brain health and disease through the gut microbiota−brain axis. Indeed, an excellent study conducted by Hsiao et al.[37] supported this observation. In this study, MIA-associated changes in serum metabolites were profiled using gas chromatography−liquid chromatography with mass spectrometry (GC-LC/MS)-based metabolomics technology, demonstrating that 8% of all serum metabolites were significantly altered by MIA induction and 34% of all metabolites were significantly affected by *B. fragilis* treatment. Among them, 4-ethylphenylsulfate (4EPS) displayed a 46-fold increase in serum levels of MIA offspring and is completely restored by *B. fragilis* treatment. Strikingly, systemic administration of the single metabolite, 4EPS, to healthy mice is sufficient to induce

DOI: 10.1021/acs.jafc.5b02404
J. Agric. Food Chem. 2015, 63, 7885−7895

anxiety-like behavior. This highlights an important role of a single metabolite regulated by gut microbes in the molecular connections between the gut and the brain. It is believable that more metabolic signatures in the gut microbiota−brain axis can be identified when this method is applied to other neurodevelopmental disorders.

In summary, abnormalities of brain function are associated with the altered composition of the gut microbiota. The use of probiotics, prebiotics, and functional foods can partly or completely reverse the dysbiosis in the microbiota caused by some brain disorders. Multiple pathways are involved in the modulation of the gut microbiota−brain axis: vagus nerve-mediated pathways, immune response-mediated pathways, and metabolite-mediated pathways. The availability of novel techniques such as functional magnetic resonance imaging, metatranscriptomes, metaproteomics, and metabolomics will rapidly expand our knowledge on the complex mechanisms of action underlying the interactions between microbiota components and the host. A comprehensive understanding of the gut microbiota−brain axis may provide novel approaches for the prevention and treatment of brain dysfunctions.

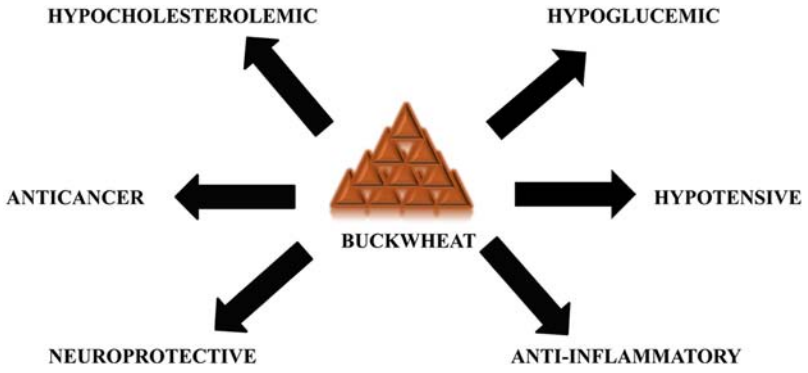

Figure 1. Simplified scheme summarizing the health benefits associated with buckwheat consumption.

Table 1. General Composition of Common and Tartary Buckwheat (BW) (A) Groats and (B) Sprouts

parameter	level (%) common BW	level (%) tartary BW
(A) Groats (Dry Matter)		
starch	54.50	57.40
soluble carbohydrates[a]	1.60	1.78
dietary fiber	7.0	10.60
protein	12.30	13.15
lipids	3.80	3.84
ash	2.0	2.70
other compounds[b]	18.40	10.53
(B) Sprouts (Fresh Weight)		
water	92.80	92.34
dietary fiber	0.70	0.73
protein	0.17	0.14
lipids	0.38	0.14
ash	0.68	0.49

[a]Including sucrose and fagopyritols. [b]Organic acids, phenolic compounds, tannins, phosphorylated sugars, nucleotides and nucleic acids, and unknown compounds.

broad spectrum of biological activities exerted by emodin, it may be an important bioactive factor in BW.[26]

Buckwheat proteins (BWPs) have a high biological value due to a well-balanced amino acid composition. They are rich in lysine, which is generally the first limiting amino acid in other plant proteins, and arginine. However, the content in glutamine and proline is much lower than in wheat,[27] and threonine and methionine are the first and second limiting amino acids, respectively. Thiamin-binding proteins isolated from BW may be used in the care of people who suffer from the lack of thiamin.[7] Furthermore, many researchers have reported that the low digestibility of BWPs and lysine/arginine and methionine/glycine rates are critical factors in determining the cholesterol-lowering effects of the plant proteins.[7,28]

The contents and composition of flavonoids are dissimilar in different BW species. Generally, the flavonoid content in *F. tataricum* (40 mg g^{-1}) is higher than in *F. esculentum* (10 mg g^{-1}), reaching concentrations of 100 mg g^{-1} in tartary BW flowers, leaves, and stems.[2] BW seeds (groats and hull) and sprouts are important sources of rutin (quercetin-3-rutinoside), and its content depends on the variety and growth conditions.[29,30] Tartary BW groats (BWG) contain more rutin (80.94 mg g^{-1} dm) than common BW (0.20 mg g^{-1} dm),[31,32] whereas tartary BW sprouts (BWS) possess 2.2-fold more rutin than common BWS.[33] Rutin has attracted increasing attention mainly due to its numerous beneficial effects observed in vitro and in vivo: anti-inflammatory, antidiabetic, hypocholesterolemic, antiatherosclerotic, and anticarcinogenic.[34] Its activity has been associated with its antioxidant capacity, although the precise mechanism of protection is not known. Quercitrin (quercetin-3-rhamnoside) is another glycoside present in BW at concentrations ranging from 0.01 to 0.05% dm in tartary BW and from 0.54 to 1.80% dm in common BW.[31,35] Isoquercetin (quercetin-3-glucoside) is present in BW hypocotyls (1.4 μM g^{-1} dm),[36] and it has been shown to exert antidiabetic and anticancer activities.[37−39] The aglycone quercetin is present in BWG (0.001 mg g^{-1} dm) and BW hull (0.009−0.029 mg g^{-1} dm) at lower concentration than rutin.[12,32] The flavone *C*-glycosides present in BW seedlings (vitexin, isovitexin, orientin, and homoorientin), the content of anthocyanins and proanthocyanins,[36] and the presence of squalene, epicatechin, and vitamin E (tocopherols)[40] make BW a good antioxidant source in the human diet.

Phenolic acids of BW also contribute to its antioxidant capacity. 4-Hydroxybenzoic (*p*-hydroxybenzoic), 3-(4-hydroxy-3-methoxyphenyl)-2-propenoic acid (ferulic), and 3,4-dihydroxybenzoic (protocatechuic) acids are prominent in the seeds of different cultivars of tartary BW, and other phenolics, including 4-hydroxycinnamic (*p*-coumaric), 3,4,5-trihydroxybenzoic (gallic), 3,4-dihydroxycinnamic (caffeic), 4-hydroxy-3-methoxybenzoic (vanillic), and 3,5-dimethoxy-4-hydroxybenzoic (syringic) acids, have been detected.[41] Several phenolic acids were described in the inflorescences of different varieties of BW: 3-(3,4-dihydroxycinnamoyl)quinic (chlorogenic), 4-methoxybenzoic (*p*-anisic), 2-hydroxybenzoic (salicylic), and methoxycinnamic acid.[42] The most abundant phytosterol in BW flour (BWF) is β-sitosterol (0.86 mg g^{-1} dm) followed by campesterol (0.11 mg g^{-1} dm) and stigmasterol (0.02 mg g^{-1} dm).[43]

BW is also an important source of vitamins. Total vitamin B content, including B_1 (thiamin, 2.2−3.3 μg g^{-1} dm), B_2 (riboflavin, 10.6 μg g^{-1} dm), B_3 (niacin, 18 μg g^{-1}), B_5 (pantothenic acid, 11 μg g^{-1}), and B_6 (piridoxine, 1.5 μg g^{-1}), is higher in tartary BW than in common BW, and the levels of vitamin C have been reported as 50 μg g^{-1} dm, reaching 250 μg g^{-1} dm in sprouts.[5,44,45] Along with vitamins, other compounds such as glutathione (1.10 mmol g^{-1} dm in BWG), phytic acid (35−38 mg g^{-1} dm in BW bran), carotenoids (2.10 mg g^{-1} dm in BW seeds), and melatonin (470 pg g^{-1} dm in BWG) have been detected and may contribute to the antioxidant activity of BW.[4,32]

Recently, γ-aminobutyric acid (GABA) and 2″-hydroxynicotianamine (2HN) have been found to serve as functional compounds in BW. Seeds and sprouts contain GABA, whereas

2HN has been recently identified in BWF. These compounds have been reported to reduce blood pressure in humans and to inhibit the angiotensin I converting enzyme (ACE) activity.[46−48]

HEALTH BENEFITS AND BUCKWHEAT

Antioxidant Activity. Increasing appreciation of the nutritional and functional properties of BW has also encouraged some investigations about its antioxidant properties. The antioxidant features of BW pseudocereals appear reflected in human intervention studies. There have been reported increases in the total antioxidant capacity of plasma samples from healthy donors after consuming 1.5 g of BW honey kg^{-1} (single dose, $n = 37$),[49] or when BW honey was added to water or black tea (160 g honey L^{-1}, $n = 25$)[50] as well as after BW-enriched wheat bread consumption.[51]

The biological antioxidant capacity of BW is further supported by in vivo experimental models fed a BWH-containing diet (0.75% in diet, 14 days),[52] a BW byproduct-enriched diet (15% for 4 weeks),[53] and 100 and 200 mg of BW kg^{-1} day^{-1} for 20 days.[54] The results showed increased activity of antioxidant enzymes, including superoxide dismutase (SOD), catalase (CAT), and gluthatione peroxidase (GSH-Px), and reduced lipid peroxidation parameters such as thiobarbituric acid reactive substances (TBARS), malondialdehyde (MDA), and fluorescent substance (FLS) in plasma samples, red blood cells, and several different organs (heart, kidney, liver, and brain). In contrast, total plasma antioxidant status and the activities of SOD and GSH-Px were unaltered in healthy rats fed a normal diet containing 30% expanded BW seeds or 5% of BWS for 4 weeks.[55]

In vitro antioxidant activity of BW has been assessed in relation to its phenolic content and composition[41,42,56−59] and compared to that of other cereals and pseudocereals.[60−63] In this sense, Zieliński and Kozłowska established the following hierarchy of antioxidant activity: BW > barley > oat > wheat ∼ rye.[64] The high antioxidant capacity of BW is connected with its high polyphenol content, especially rutin.[65,66] Liu et al. described the antioxidant effects of BWS in human hepatoma HepG2 cells, revealing that tartary and common BW had a positive effect on the production of intracellular peroxide and superoxide anions. Tartary BW was more effective than common BW, and this effect was associated with the higher concentration of rutin.[16] Studies by Zhou et al. also reported that BW honey showed protective effects on hydroxyl radical-induced DNA damage through is antioxidant activity.[67] These studies seem to indicate that BW may exert its beneficial effects through its antioxidant activity.

Hypocholesterolemic Activity. Increased cholesterol intake can induce oxidative stress and cause an increase in blood cholesterol level, leading to the up-regulation of low-density lipoproteins (LDL) and oxidized LDL (oxLDL), contributing to the development of chronic diseases such as atherosclerosis.[68] In vitro and in vivo studies have proposed that BW's protective effect against cardiovascular diseases may come from its ability to modulate the cholesterol (Ch) level.

The number of studies investigating the cholesterol-lowering activity of BW in humans is small (Table 2). The investigation carried out by Zhang et al. in 2007 is one of the biggest studies in relation to the consumption of BW and health: 3542 Mongolians in two adjacent counties of Inner Mongolia (China) were randomly sampled in a cross-sectional study to assess the association of hypertension, dyslipidemia, and hyperglycemia with lifetime consumption of BW seed as a staple food. The authors described a reduction of total cholesterol (TCh) (4%; $p < 0.05$), triglycerides (TG) (4.85%; $p > 0.05$), and LDL (9.05%; $p < 0.01$) and an increase of high-density lipoproteins (HDL) (6.9%; $p < 0.01$) in the participants who consumed BW ($n = 1628$) compared with the population who consumed corn ($n = 1914$). In addition to this, a decrease in blood glucose concentration (14.5%; $p < 0.01$) was also described in the group that consumed BW compared to the other group.[69] In 2011, Wieslander et al. performed a double-blind randomized crossover study with 62 healthy volunteers who were divided in two groups consuming four cookies elaborated either with tartary or with common BW for 4 weeks. A decrease in serum TCh (13.56%; $p < 0.001$) and HDL (15.44%; $p < 0.001$) and myeloperoxidase (MPO) (enzyme involved in oxidative stress and inflammation) was documented.[70]

The hypocholesterolemic effect of BW has also been observed in an important number of in vivo and in vitro studies to a similar extent. Early work investigating the hypocholesterolemic effect of BW consumption on animals dates back to the 1990s. In 1995, Kayashita et al. reported that BWP consumption by Sprague−Dawley rats reduced body fat content, decreased TCh, and increased the level of HDL in plasma compared to those groups that consumed soy protein or casein.[71] In a second study, lower Ch (14.4%; $p < 0.05$) and TG (38.1%; $p < 0.01$) levels in plasma and liver, respectively, were observed in rats fed a BWP-enriched diet compared with those fed a casein diet.[72] This hypocholesterolemic effect exerted by BWP was more effective in rats consuming Ch-containing diets than in those consuming Ch-free diets.[73]

It has been suggested that the Ch-lowering activity of BWP is mediated by its influence on fecal excretion of bile acids and neutral sterols. In 2001, Tomotake et al. found that Sprague−Dawley rats consuming BWP-enhanced Ch-free diets showed lower plasma TCh levels (11−22%) and higher fecal excretion of bile acids and neutral and acidic steroids relative to animals consuming a casein- or soy protein-enriched diet.[74] Studies investigating the effect of BWP in rats fed a high-Ch diet reported a Ch-lowering effect accompanied by higher fecal excretion of neutral sterols. Tomotake et al. also reported that a BWP-containing diet markedly suppressed gallstone formation compared with casein- and soy protein-enriched diets, and this effect was related to the lower level of Ch in gallbladder, plasma, and liver and the higher fecal excretion of bile acids and steroids.[75] This effect of BWP suppressing gallstone formation and enhancing excretion of bile acids and steroids was also observed in ddY mice and Sprague−Dawley rats fed a Ch-enhanced diet.[76] It has been suggested that the Ch-lowering effect and enhanced level of sterol secretion may be associated with the low digestibility of BWP.[77]

BW extracts (BWext) have also been reported to exhibit a hypocholesterolemic effect, reducing intestinal absorption of dietary Ch. In vitro studies have reported a decrease in the uptake of Ch micelles in Caco-2 cells in the presence of common BWPext.[78] This effect may be mediated by reducing the gut transit time after BW consumption.[79] Another possible mechanism was recently proposed by Yang et al., which investigated the Ch-lowering effect of the diet supplemented with tartary BWF, wheat, or rice in hamsters. BW (but not wheat and rice) reduced plasma as well as hepatic Ch levels and led to a greater neutral sterol excretion along with a down-regulation of intestinal acyl-CoA:Ch acyltransferatse 2 (ACAT2) and Niemann−Pick C1-like 1 (NPC1L1),[80] two intestinal transporters that have been suggested to play a critical role in cholesterol absorption.[81]

[b]Not significant.

BW consumption also seems to have an effect on the activity and mRNA expression of enzymes involved in lipid metabolism. The intake of BWP exerted a lipid-lowering effect accompanied by a decrease in hepatic activities of glucose-6-phosphate dehydrogenase (G6PDH) and fatty acid (FA) synthase.[72,76] Other BWext, such as an ethanol extract of germinated BW rich in rutin, and BW bran extracts down-regulated mRNA expression of the adipogenic transcription factors peroxisome proliferator-activated receptor-γ (PPAR-γ), CCAAT/enhancer-binding protein-α (C/EBPα), sterol regulatory element-binding protein 1c (SREBP1c), and carbohydrate responsive element-binding protein (ChREBP) and of lipogenic genes acetyl-coenzyme a carboxylase 1 or 2 (ACC1 and 2), stearyl-coenzyme A oxidase (SCD1), and FA synthase.[82,83] Meanwhile, BWS has been shown to up-regulate the expression of Ch-7-α-hydroxylase and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA).[84]

Antidiabetic Activity. Diabetes is a chronic disease caused by deficient insulin secretion or ineffective insulin activity, which lead to an increase in plasma glucose levels.[85,86] In the past few years there has been a considerable interest in the possibility of improving diabetic control by altering the glycemic impact of the carbohydrates ingested. A low glycemic index (GI) diet has been related to advantages in the prevention and treatment of diabetes.[87]

BW for dietary use is one way to prevent diabetes in China.[88] In the study of Skrabanja et al., 10 healthy volunteers consumed (single dose) boiled BW groats, bread enriched with 50% of BW groats, or white wheat bread. The postpandrial plasma glucose and insulin production were lower in volunteers who consumed BW products, especially BW groats, than those who consumed white wheat bread.[89] Su-Que et al. randomly recruited 10 type 2 diabetic subjects. All patients showed a decrease of 51% ($p < 0.05$) in the postpandrial 2 h plasma glucose after consumption of BW compared with those who consumed white wheat bread.[90] Reduction of energy consumption is an important consideration for those attempting to control glycemia. In the aforementioned study[89] the volunteers consuming BW products, especially groats, showed high postprandial satiety. Berti et al.

DOI: 10.1021/acs.jafc.5b02498
J. Agric. Food Chem. 2015, 63, 7896−7913

also described a positive effect of BW lasagna consumption on energy intake and time satiety in healthy volunteers.[91] In a single-blind, controlled, crossover study conducted by Stringer et al., the efficacy of BW crackers compared with rice crackers to modify glucose metabolism in both healthy and type 2 diabetic subjects was investigated. No changes were observed in glucose or insulin concentrations. However, a modulation of the gastrointestinal satiety hormones such as glucagon-like peptide-1 (potentiator of insulin secretion) and glucagon-dependent insulinotropic peptide (GIP) was documented after consumption (single dose) of BW cracker in healthy and type 2 diabetic volunteers.[92] Therefore, BW consumption may modulate satiety by altering the postprandial levels of satiety hormones.

Attempts to identify the bioactive compounds responsible for the observed effects and the mechanisms associated have led to several publications looking at the antidiabetic effects of different BWext or their individual compounds in vitro and in vivo. Previous studies by Larner et al. have highlighted the role of DCI mediating mechanisms associated with diabetes.[93−97] Kawa et al. investigated the effects of a BW concentrate (common BW), containing 10 and 20 mg DCI kg^{-1} of body weight, on serum glucose concentrations of streptozotonic (STZ) rats in comparison with normal rats, demonstrating that a single oral dose of BW concentrate reduced the serum glucose level by 12−19% in STZ rats after 90−120 min of treatment.[98] Using hyperinsulinemic KK-A^y mice, Yao et al. studied the effect of DCI-enriched tartary BW bran extract (equivalent to 40 mg kg^{-1} DCI) supplementation for 5 weeks on blood glucose, lipid profile, and other markers related to diabetes. The results showed that oral administration of 45−182 mg kg^{-1} of DCI-enriched tartary BW bran extract lowered plasma glucose, C-peptide level, glucagon, TG, and plasma urea and improved glucose tolerance and insulin immunoreactivity.[99] Diabetic rats administered 100−400 mg kg^{-1} day^{-1} of the overall flavonoids from BW flowers and leaves showed lower blood glucose (20.8−27.7%) and improvement in renal damage.[100] BW bran extract decreased the blood glucose level in nondiabetic Balb/c mice following sucrose administration, which was associated with the capacity of this extract to inhibit α-glucosidase activity, an enzyme that hydrolyzes carbohydrates in the gastrointestinal tract.[101] Lee et al. investigated the antihyperglycemic and anti-insulin resistance of an ethanol BWext (tartary BW), rutin, and quercetin in vitro and in vivo. These authors demonstrated that ethanol BWext (50 mg kg^{-1} body weight (bw)), rutin (11.5 mg kg^{-1} bw), and quercetin (3 mg kg^{-1} bw) improved hyperglucemia and hyperinsulinemia in C57BL6 mice fed a high-fructose diet for 8 weeks, suggesting that rutin was the major active compound of the extract. The in vitro assay revealed that the hypoglycemic effect may be due to an increase in the glucose uptake mediated by increasing levels of glucose transporter 2 (GLUT2) in FL83B cells, the major glucose transporter in hepatocytes. These hypoglycemic effects were accompanied by a reduction of oxidative stress, induction of antioxidant enzymes, and improvement of plasma and hepatic lipids.[102] Further evidence of the antidiabetic properties of BW has been reported recently by Lee et al., describing that ethanol BWext (200 mg mL^{-1}) and rutin (40 mg mL^{-1}) reduced oxidative stress, attenuated AGE formation, and inhibited α-amylase and α-glucosidase activity.[103]

Although the animal and in vitro studies support the antidiabetic effect of BW in humans after its consumption, some investigators have reported contradictory results. Schrader et al. described that BW (0.1 and 1 g kg^{-1} diet) had no blood glucose-lowering effect in db/db mice, but a dose-dependent PPAR-γ activity, a molecule involved in regulating insulin sensitivity and glucose homeostasis,[104] was shown in COS-1 cells.[105] Another study carried out by Curran et al. described that BW inhibited glucose uptake in rat H4IIE hepatoma cells. Furthermore, these authors reported that other compounds, such as DCI, rutin, or quercetin, were not the active components responsible for the observed effects.[106] These contradictory results point out the need for future studies to clarify the cellular and molecular mechanisms underlying the beneficial effects attributed to BW and its individual compounds and the compound(s) responsible for the observed effects.

Anticancer Activity. Cancer is the leading cause of death in economically developed countries and the second leading cause of death in developing countries.[107] Functional food for the prevention of chronic diseases such as cancer is one of the century's key global challenges. In the study carried out by Shen et al. (2008) in Xuanmei (China), the frequent consumption of different foods, including BW, was associated with a reduced risk of lung cancer.[108]

Because oxidative DNA damage is implied in cancer initiation and promotion,[109] the anticancer activity of BW has been associated with its antioxidant properties. It has been reported that ethanol BWext from tartary and common BW protected DNA from being damage by hydroxyl radical.[110] Methanolic extracts of common and tartary BWF, rutin, and quercetin showed high antioxidant capacity (DPPH scavenging activity) and reduced *tert*-butylhydroperoxide-induced DNA damage in the HepG2 cell line.[111] In addition to the antioxidant capacity, mechanisms of action such as alteration of gene expression, inhibition of proliferation, cell cycle arrest, and/or the induction of apoptosis have been documented in vivo and in vitro. Sprague−Dawley rats fed a BWPext showed a decreased development in mammary tumor by lowering serum estradiol[112] and a lower incidence of colon adenocarcinoma (Table 3).[113] In the latter study a decrease in the colonic cell proliferation and a down-regulation in the expression of *c-myc* and *c-fos*, genes involved in colon cancer development, were also described.[114] Different fractions of an ethanolic BWext decreased tumor formation in mice treated with sarcoma cells and inhibited the cell growth of different cancer cell lines.[115] BWHext rich in polyphenols exhibited antioxidant activity and growth inhibitory activity in HeLa cancer cells (up to 50% at 100 μg mL^{-1}, 72 h).[116]

Flavonoids,[39,117,118] polysaccharides,[119] lectins,[120] and phenylpropanoids[121,122] from BW have been shown to induce apoptotis, differentiation, and cytotoxicity against a wide range of cancer cell lines in vitro. In a recent study, Yuan et al. observed that a ribonuclease isolated from BW seeds inhibited the proliferative activity of HepG2 (IC_{50} = 79.2 μM) and MCF-7 (IC_{50} = 63.8 μM) cancer cells.[123] BW proteins have also been revealed to exert anticancer activity. As reviewed by de Mejia and Dia, isolated BWPs such as BW protease inhibitors (BWI-1 and BWI-2a) and the recombinant form of BWI-1 (rBWI-1) have anticancer activity, evidenced mainly by induction of apoptosis and growth inhibition against a wide range of cancer cell models.[124] Recent studies have reported new BWPs that show anticancer activity. Leung and Ng isolated a peptide from BW seeds that exhibited antiproliferative activity against HepG2 cells (IC_{50} = 33 μM), leukemia L1210 (IC_{50} = 4 μM), breast cancer MCF-7 (IC_{50} = 25 μM), and liver embryonic WRL68 (IC_{50} = 37 μM) cell lines.[125] TBWSP31 protein, isolated from tartary BW, has been identified as novel antitumor protein showing antiproliferative activity, causing cell cycle arrest in G_0/G_1

phase, and inducing apoptosis in human mammary cancer cell Bcap37 at concentrations ranging from 5 to 200 μg mL^{-1}.[126,127]

Although these studies open a door to new therapies for the prevention and treatment of malignancies such as cancer, more in vitro and in vivo studies must be performed to substantiate the potential health-promoting functions of BW and its individual compounds.

Anti-inflammatory Activity. Inflammation is a normal biological process in response to tissue injury, microbial pathogens, and chemical irritation.[85] Because chronic inflammation is a well-documented risk for promoting cancer,[128] elimination or prevention of chronic inflammation has been proposed as a major way to prevent cancer.

Nuclear factor kappa B (NF-κB) plays a pivotal role in the regulation of the genes related to inflammation including tumor necrosis factor alpha (TNF-α), interleukin (IL)-1β, IL-8, and IL-6[129] and important mediators of the inflammatory response, such as inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2).[130] Hole et al. demonstrated that different phenolic BWext (30−50 mg mL^{-1}) and the phenolic acids present in BW 8,5-difeluric (10 mg mL^{-1}), feluric (70 mg mL^{-1}), and *p*-coumaric (70 mg mL^{-1}) reduced the lipopolisaccharide (LPS)-induced NF-κB activity in the U937 cell line.[131] Karki et al. reported that both tartary BWSext (100 and 500 μg mL^{-1}) and rutin (100 μg mL^{-1}) inhibited the NF-κB activation in LPS-stimulated macrophages (RAW264.7). This effect was accompanied by a decrease in the expression of COX-2 and iNOS, and a reduction of TNF-α and IL-6 levels.[132] Ishii et al. evaluated the anti-inflammatory activity of an BWSext in vitro and in vivo. BWSext was able to diminish the LPS-induced gene expression and serum concentration of several pro-inflammatory cytokines including IL-6, IL-8, or TNF-α in mice (100 μg mL^{-1}) and in different cancer cell models (1 mg mL^{-1}). However, the six flavonoids present in the BWext (orientin, isoorientin, vitexin, isovitexin, chlorogenic acid, and rutin) exerted no anti-inflammatory effect on LPS-stimulated CoLoTC cells, indicating that other compounds are responsible for the effects observed.[133] Similarly, Lee et al. found that the levels of IL-6, IL-1β, and TNF-α were significantly reduced by ethanol BWext (50 mg kg^{-1} bw) in the liver of mice and rats treated with ethanol and CCl_4. Rutin (11.5 mg kg^{-1} bw) and quercetin (3 mg kg^{-1} bw) could also reduce ethanol- and CCl_4-induced expression of the cytokines.[134]

These studies indicate that BW, through its phenolic acids and flavonoids, has potential anti-inflamatory properties. Nevertheless, it is difficult to draw conclusions due to the low number of studies performed so far. Therefore, further studies investigating the anti-inflammatory effects of BW are required.

Effects on the Vascular System. It was reported that >25% of the population worldwide (approximately 1 billion) were affected by hypertension in 2000, and this figure is predicted to increase to 1.56 billion by 2025.[135] The renin−angiotensin system regulates blood pressure. Plasma renin is responsible for the conversion of angiotensinogen into angiotensin I, which in the presence of angiotensin I-converting enzyme (ACE) is transformed into angiotensin II, a vasoconstrictor that increases blood pressure.[136] Therefore, the use of ACE inhibitors is believed to lower hypertension.

Although there is increasing interest in the identification of antihypertensive foods, the number of studies investigating the hypotensive effect of BW consumption is scarce. Li et al. cited a study performed by Kawasaki et al. in which a clinical examination made in the Mustang District of Nepal, where the inhabitants rely on BW as their principal food, demonstrated that the pathogenesis of hypertension was quite low (<25% in the Thakali Tribe) regardless of their salt tea intake.[137,138]

This hypotensive effect observed in humans consuming BW appears reflected in in vitro and in vivo studies. BW has been found to have high levels of ACE inhibitory activity.[139] A decrease in systolic blood pressure and a reduction of the oxidative damage in aortic endothelial cells was observed in spontaneously hypertensive rats (SHRs) and normotensive Wistar Kyoto rats after they had consumed raw and germinated BWext (300−600 mg kg^{-1}) for 5 weeks.[140] The administration of 0.01−10 mg kg^{-1} of lactic-fermented BWS to SHRs decreased systolic and diastolic blood pressure, and this effect was

associated with a decrease of the ACE activity and vasoralaxation effect on the blood vessel rings.[141,142] Recently, Merendino et al. evaluated the hypotensive and antioxidant responses of pasta containing tartary BWS by measuring the levels of some molecules involved in the regulation of blood pressure and the antioxidant status in normotensive Wistar Kyoto rats and SHRs. In this study, an increase in the expression of bradykinin (BK) and NO (vasodilators), a decrease in endothelin-1 (ET-1) (vasoconstrictor), and an improvement in the antioxidant status were reported.[143]

J. Agric. Food Chem. 2015, 63, 7896−7913

Several studies have tried to determine which compounds present in BW may be involved in the hypotensive effect observed. 2HN is a recently discovered compound that is present in BW flour, which has been reported to exhibit high inhibitory activity (IC_{50} = 0.08 μM) toward ACE.[47,144] Koyama et al. indicated that lactic fermentation in BWS increases the amount of blood pressure lowering compounds such as γ-aminobutyric acid (GABA) and tyrosine, which could contribute to the blood pressure lowering effect exerted by lactic-fermented BWS on SHRs rats.[141] BW flavonoids might be also implied in the hypotensive effects associated with BW consumption. Tsai et al. described that extracts of different portions of BW, as well as rutin and quercetin, presented a remarkable inhibitory ACE activity.[145] Ushida et al. exposed isolated rat thoracic aorta to rutin-free tartary BWext, observing vasorelaxant effects. In this study, it was suggested that these vasorelaxants effects may be mediated through NO.[146]

A series of reports by several researchers attest to the existence of several proteins capable of generating peptides that can contribute to the blood pressure lowering effect. Kawakami et al. reported that a hydrolysate of BW protein exerted a strong ACE interference.[147] Li et al. documented that tartary BW peptides generated after in vitro digestion exhibited ACE inhibitory activity both in vitro and in vivo.[137] A tripeptide isolated from common BW has also been reported to exert ACE inhibitory activity (IC_{50} = 6.25 μg protein mL^{-1}).[148] Recently, Koyama et al. found that different peptides isolated from lactic-fermented BWS inhibited ACE activity in thoracic aorta tissue and suppressed angiotensin II-mediated vasoconstriction.[149]

Neurodegenerative Diseases. Alzheimer's disease is associated with mental dysfunction and impairment in cognitive function.[150] Aggregation of amyloid β peptides, induction of reactive oxygen species (ROS), and induction of pro-inflammatory mediators such as NO, PGE_2, ILs, and TNF-α represent important neuropathological hallmarks of Alzheimer's disease.[151]

BW consumption has been reported to exhibit neuroprotective effects in animal models. The administration of 600 mg kg^{-1} for 21 days of common BW to rats subjected to repeated cerebral isquemia ameliorated spatial memory impairment by inhibiting glutamate release, reducing the generation of NO_x^- (NO_2^- + NO_3^-), and preventing hippocampal cell necrosis and apoptosis.[152] These effects were confirmed later by Pu et al., showing that common BW comsumption (600 mg kg^{-1}) by rats significantly improved the spatial memory impairment induced by scopolamine in an eight-arm radial maze. To determine the mechanism of BW protective action, the authors exposed primary cultures of rat hippocampal neurons to common BWext. This extract showed DPPH radical-scavenging activity and reduced cell damage induced by glutamate, kainite, and β-amyloid.[153] In an in vitro study, ethyl acetate and ethanol extracts of the seeds, stem, and aerial parts of common BW showed neuroprotective effects through acetylcholisterase, butylcolinesterase, and tyrosinase inhibitory and antioxidant activities.[154] These studies suggest that common BW exerts neuroprotective effects. However, it should be considered that cells of the nervous system do not contact the whole extract in vivo. Therefore, these in vitro studies do not represent a physiological situation.

The number of studies investigating the possible beneficial effects of tartary BW is small. Choi et al. compared the neuroprotective effect of common and tartary BW in an in vivo mouse model of Alzheimer's disease. Oral administration (100 mg kg^{-1} day^{-1}, 14 days) of methanol extracts of tartary and common BW improved cognition and memory function and reduced the NO levels and lipid peroxidation (MDA), tartary BW exerting a stronger protective activity than common BW.[155] Recent studies have suggested that rutin seems to be involved in the neuroprotective effects attributed to BW,[156] although the identity of the compound(s) responsible for the observed effects remains unknown.

Other Effects. Different BW-derived products have been investigated and have been shown to exert health benefits other than those reported above, including prebiotic, antifatigue, wound healing, immunomodulation, and leg edema protection effects and improvement of stomach activity (Table 4).

CONCLUSION

Overall, the animal studies and in vitro work carried out so far begin to define the mechanisms by which BW may help to prevent chronic diseases. The strong antioxidant activity exhibited by BW may help to prevent lipid and DNA oxidation, delaying the development of chronic diseases such as cancer, inflammation, hypercholesterolemia, and neurological diseases. Furthermore, newly discovered mechanisms of action, such as the ones described in this review, can help to explain the beneficial effects exerted by BW. BW protein and polyphenols, especially rutin and quercetin, have been considered partially responsible for the effects observed. Nevertheless, most animal studies described above were carried out with BW-derived extracts, which contain not only polyphenols but also fiber, sugars, and other compounds that may be responsible in whole or in part for the observed effects. Although most of the in vitro cell studies included in this review indicate that BW may prevent cancer, hypertension, or neurological disorders, some of them do not represent dietary/physiological conditions: (i) the concentrations of BW products used in some cases are higher than those described in vivo;[157] (ii) in vivo, lung cells, hepatocytes, cells of the vascular wall, or cells of the nervous system are not exposed to whole extracts or original compounds, but mainly to derived metabolites formed and absorbed after gastrointestinal digestion and metabolic conjugation, including glucuronides, methyls, and sulfates.[158,159] Therefore, future in vitro studies need to be carefully designed so that the results obtained can contribute to clarifying which compounds are responsible for the observed effects and the cellular and molecular mechanisms underlying the beneficial effects attributed to BW. In addition, future research should be directed to epidemiologic studies and toward consolidating the mechanisms of action, especially in humans. These studies will give a valuable approach for using this pseudocereal in the design of novel and healthy foods and enhance its consumption.

the cytotoxicities of the enantiomers for the first time using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium (MTT) method and flow cytometry. Interactions between the propisochlor enantiomers in the cytotoxicity tests were also studied using an isobologram and a combination index (CI). The interaction studies improved our understanding of the cytotoxicities of each of the enantiomers and allowed for the toxic effects caused by interactions between the enantiomers to be identified.

MATERIALS AND METHODS

Reagents. Racemic propisochlor [98%, 2-chloro-*N*-(isopropylmethyl)-*N*-(2-ethylmethyl-6-methyl)phenylacetamide], MTT, dimethyl sulfoxide, culture medium RPMI-1640, penicillin, and streptomycin were purchased from Sigma (St. Louis, MO). Fetal bovine serum was purchased from Hangzhou Sijiqing Biological Engineering Materials Co. (Hangzhou, China). An Annexin V-fluorescein isothiocyanate (FITC)/propidium iodide (PI) apoptosis detection kit and a 4′,6-diamidino-2-phenylindole (DAPI) staining kit were purchased from the Nanjing Jiancheng Bioengineering Institute (Nanjing, China). A Chiralpak AD-H column [150 mm long, 4.6 mm inner diameter, with an amylose tris(3,5-dimethylphenylcarbamate) stationary phase] was obtained from Daicel (Tokyo, Japan). Other solvents and chemicals were of chromatographic or analytical grade.

Separating Propisochlor Enantiomers by HPLC. The propisochlor enantiomers were separated using a Shimadzu LC-20A series HPLC system equipped with a LC-20AT intelligent gradient pump, a SPD-20A ultraviolet−visible (UV−vis) light absorbance detector, a CTO-10AS vp temperature-controlled column compartment, a SIL-20A automatic sampler, and a CMB-20A data collector (Shimadzu, Kyoto, Japan). A Chiralpak AD-H column, kept at 35 °C, was used in the HPLC system. The mobile phase was a 99:1 (by volume) mixture of *n*-hexane and isopropanol. The fractions containing the separated propisochlor enantiomers were collected automatically at the outlet and then evaporated to dryness under vacuum. The separate enantiomers obtained in this way were used in the subsequent experiments.

Cell Culture. SP2/0 cells were cultured in RPMI-1640 medium containing 10% (v/v) fetal bovine serum. Cells were incubated with different concentrations of *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer for 12, 24, or 48 h. Interactions between *R*-(+) and *S*-(−) isomers were identified by exposing cells to mixtures of the enantiomers at different ratios for 24 h. The cells were analyzed at the end of each test using the MTT assay.

Assessing Cell Viability. The enantioselective effects of propisochlor on SP2/0 cell viability were examined by assessing the growth of cells exposed to propisochlor using the MTT assay. Aliquots of the cells were taken, and the medium in each was replaced with medium containing 0, 10, 50, 100, 200, 400, 600, or 800 μM *rac*-propisochlor, *R*-(+) isomer, or *S*-(−) isomer. The cultures were then incubated for 12, 24, or 48 h, and then 20 μL of MTT (1 mg/mL) was added to each well. The plate was incubated at 37 °C for another 4 h. The cultured cells were then collected and centrifuged. The supernatant was discarded, and then 150 μL of dimethyl sulfoxide were added to each well. The cells were then shaken for 10 min, and the absorbance at 490 nm was measured using a 1420 multilabel counter (PerkinElmer, Waltham, MA). The experiments were carried out using 96-well plates, and four replicates of each test were performed. Cell viability was calculated using the equation

$$\text{cell viability (\% of control)} = \frac{\text{OD}_{490\text{ nm}} \text{ of the test wells}}{\text{OD}_{490\text{ nm}} \text{ of the control wells}} \times 100$$

where $\text{OD}_{490\text{ nm}}$ is the optical density at 490 nm.

The half maximal effective concentration (EC_{50}) values were calculated using nonlinear statistical regressions, performed using GraphPad Prism 5.0.1 software.[20] The result for each test is later expressed as the mean ± standard deviation of the four independent replicates of the test.

Annexin V-FITC/PI Double Staining. The Annexin V-FITC/PI double staining assay was used to determine the effect of propisochlor on apoptosis in the SP2/0 cells. Aliquots of the SP2/0 cells were taken, and each was treated with a 0, 10, 50, 100, or 200 μM solution of *rac*-propisochlor, *R*-(+) isomer, or *S*-(−) isomer for 24 h. The cells were then centrifuged at 1000 rpm for 10 min, and the supernatant solutions were discarded. The precipitated cells were then washed twice with phosphate-buffered saline, resuspended in 500 μL of binding buffer, and then stained with 5 μL of Annexin V-FITC and 5 μL of PI. The cells were then stored in the dark for 5−15 min at room temperature. The stained cells were then analyzed by flow cytometry using a Cytomics TMFC500 instrument (Beckman Coulter, Brea, CA). Four replicates of each test were performed. The result for each test is later expressed as the mean ± standard deviation of the four independent replicates of the test. Statistical analyses of the apoptosis ratios of the SP2/0 cells exposed to propisochlor were performed using SPSS 19.0 software (IBM, Armonk, NY).

Observing Changes in Cellular Morphology Induced by Propisochlor. Growing SP2/0 cells were allowed to adhere to glass plates. The SP2/0 cells on the glass plates were exposed to different concentrations of *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer for 24 h, and then the cells were harvested and fixed with 4% polyformaldehyde for 10 min and then washed 3 times with phosphate-buffered saline (PBS). One drop of DAPI staining solution was placed on each glass plate, and the plates were stored in the dark. The morphologies of the cells on the plates were observed, and photographs were taken using a fluorescence microscope (Nikon, Tokyo, Japan).

Interactions between Propisochlor Enantiomers. A 100 μL aliquot of the RPMI-1640 medium containing SP2/0 cells (giving 3×10^5 cells/well) was added to each well of a 96-well culture plate. To each well was added a 5:1, 3:1, 1:1, 1:3, or 1:5 mixture of *R*-(+) and *S*-(−) isomers of propisochlor to give a final total propisochlor concentration of 0, 10, 50, 100, 200, 400, 600, or 800 μM. The cells were then incubated for 24 h, and then cell viability was assessed as described in the "Assessing Cell Viability" subsection above.

Interactions between *R*-(+) and *S*-(−) isomers were identified using an isobologram and using CI values.[21−23] A normalized isobologram for *R*-(+) and *S*-(−) isomers at their EC_{50} values was constructed using OriginPro 8.5.1 software (OriginLab, Northampton, MA). Interactions between the isomers were identified from the positions of the EC_{50} values for the five isomer mixture compositions that were used in the normalized isobologram. The normalized isobologram was divided into three areas, representing synergism (area A), additive effects (area B), and antagonism (area C), as shown in Figure 6. The CI values were calculated using the formula

$$\text{CI} = \frac{a}{A} + \frac{b}{B}$$

where *A* and *B* are the concentrations of the separate enantiomers required to produce the same effect as the combination tested and *a* and *b* are the proportions of the two enantiomers in the combination tested.

A CI value less than 0.9 was taken to indicate synergism; a CI value higher than 1.1 was taken to indicate antagonism; and a CI value between 0.9 and 1.1 was taken to indicate additivity.

RESULTS

Chiral Resolution of the Enantiomers. Baseline separation between the two enantiomers in the *rac*-propisochlor was achieved using the Chiralpak AD-H column at 35 °C with a 99:1 (by volume) mixture of *n*-hexane and isopropanol mobile phase at a flow rate of 1 mL/min. A resolution of 2.41 was achieved, and the results are shown in Figure 2. The retention mechanism and the enantiomer selection at the temperature used were the same as we have found previously. We concluded that the propisochlor enantiomers were separated and isolated successfully. We have previously demonstrated that *R*-(+)

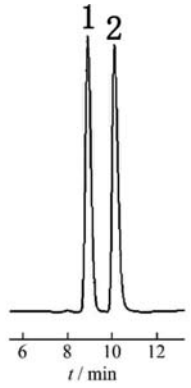

Figure 2. Chromatogram of propisochlor on the Chiralpak AD-H column with a mobile phase *n*-hexane/isopropanol (99:1, v/v), flow velocity of 1 mL/min, and column temperature at 35 °C. Peak 1 was *R*-(+) isomer enantiomer, and peak 2 was *S*-(−) isomer enantiomer.

isomer eluted first (peak 1) and *S*-(−) isomer eluted second (peak 2).

Enantioselective Cytotoxicity to SP2/0 Cells. SP2/0 cells were incubated with different concentrations of *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer for 12, 24, and 48 h. As shown in Figure 3 and Table 1, the cell viability decreased as the *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer concentrations increased. The EC_{50} values for *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer after 24 h of incubation were 111 ± 0.15, 68 ± 0.09, and 99 ± 0.21 μM, respectively. According to the EC_{50} values, the cytotoxicity to SP2/0 cells decreased in the order *R*-(+) isomer > *S*-(−) isomer > *rac*-propisochlor. The cells exposed to 200 μM propisochlor (as *rac*-propisochlor, *R*-(+) isomer, or *S*-(−) isomer) were 20% less viable than the control group cells after 24 h.

Apoptosis occurred in more than 70% of the cells treated with a propisochlor [as *rac*-propisochlor, *R*-(+) isomer, or *S*-(−) isomer] concentration higher than 50 μM, and apoptosis occurred in more cells treated with *R*-(+) isomer than with *rac*-propisochlor or *S*-(−) isomer, as shown in Figure 4. We concluded from the cell viability and apoptosis analyses that *R*-(+) isomer is more toxic than *rac*-propisochlor and *S*-(−) isomer to SP2/0 cells. The apoptosis ratios for the SP2/0 cells exposed to propisochlor were statistically analyzed using SPSS 19.0, and the results are shown in Figure 4, in which asterisks indicate significant differences ($p < 0.05$).

Changes in Cellular Morphology. Nuclear pyknosis is a reliable indicator of cell damage.[24] The nuclei of untreated SP2/0 cells were integrated and homogeneous, as seen in Figure 5D. The nuclei of cells exposed to 50 μM *rac*-propisochlor were similar to the nuclei of untreated cells, as seen in Figure 5A1. Pyknosis occurred in cells exposed to *rac*-propisochlor at concentrations higher than 50 μM (Figure 5A2). Pyknosis occurred in the nuclei of cells treated with *R*-(+) isomer at a concentration of 50 μM and cells treated with *S*-(−) isomer at a concentration of 200 μM, as seen in panels B and C of Figure 5. These results suggest that *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer may all affect the vitalities of and apoptosis in SP2/0 cells by affecting the cell nuclei.

Interactions between the Propisochlor Enantiomers. Interactions between the propisochlor enantiomers were investigated by analyzing the effects on the SP2/0 cells of combinations of *R*-(+) and *S*-(−) isomers at five different

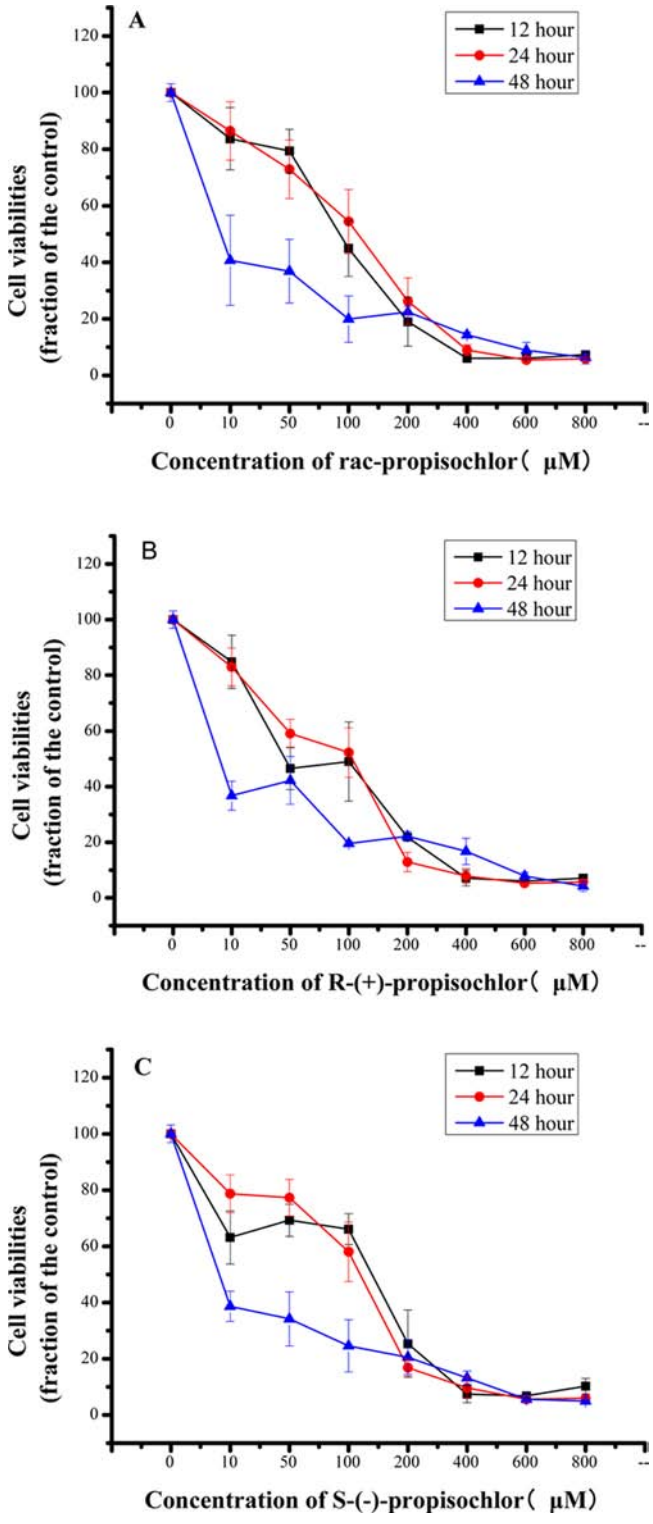

Figure 3. Effects of (A) *rac*-propisochlor, (B) *R*-(+) isomer, and (C) *S*-(−) isomer on the cell viabilities of SP2/0 were analyzed by the MTT assay after exposure to varying concentrations of propisochlor for 12, 24, or 48 h.

ratios. A dose−response curve and an EC_{50} value were produced for each combination. The results of the interaction analyses are shown in Figures 6 and 7, and the EC_{50} values are shown in Table 2. The CI values were less than 0.9 when the *R*-(+) to *S*-(−) isomer ratio was 5:1, 3:1, or 1:5, indicating that the enantiomers interacted synergistically. However, antago-

Table 1. EC_{50} Values of *rac*-Propisochlor, *R*-(+) Isomer, and *S*-(−) Isomer after Exposure to Varying Concentrations of Propisochlor for 24 h

propisochlor	EC_{50} (μM)	95% confidence intervals	coefficient of determination (R^2)
rac-propisochlor	111 ± 0.15	96.13−127.3	0.97
R-(+) isomer	68 ± 0.09	50.73−90.49	0.93
S-(−) isomer	99 ± 0.21	86.79−112.1	0.97

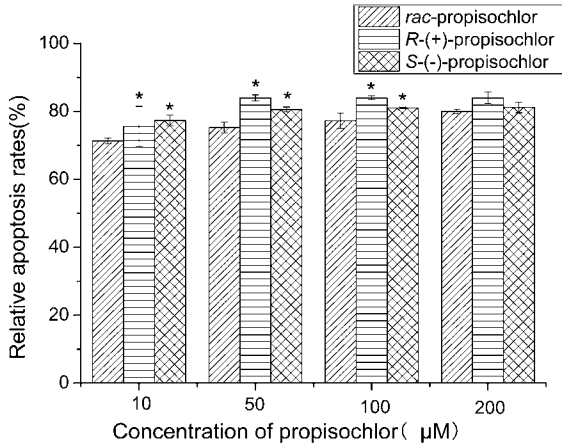

Figure 4. Apoptosis rates of SP2/0 after treated with propisochlor for 24 h. The apoptosis rates of SP2/0 cells were detected by flow cytometry after staining with Annexin V-FITC/PI. The apoptosis rates of SP2/0 after treating with *R*-(+) isomer were higher those of *rac*-propisochlor and *S*-(−) isomer. The asterisks represented significant difference ($p < 0.05$).

nistic interactions (CI > 1.1) were found when the *R*-(+) to *S*-(−) isomer ratio was 1:1 or 3:1. These results show that *R*-(+) and *S*-(−) isomers in *rac*-propisochlor could interact, resulting in less cytotoxicity occurring than if either was present alone.

DISCUSSION

We assessed the cytotoxicities of *rac*-propisochlor and both enantiomers. The EC_{50} values for *R*-(+) and *S*-(−) isomers, determined from the MTT analysis results, were 68 ± 0.09 and 99 ± 0.21 μM, respectively, as shown in Table 1. *R*-(+) isomer was found to be 1.46 times more cytotoxic than *S*-(−) isomer to the SP2/0 cells. As shown in Figure 3, the cytotoxicity increased more rapidly as the concentration of *R*-(+) isomer was increased from 0 to 400 μM than when the concentration of *S*-(−) isomer was increased from 0 to 400 μM. Less than 40% of the cells exposed to either enantiomer for 48 h remained viable, and as little as 20% of the cells remained viable at concentrations of 200 μM. Several studies focused on the enantioselective cytotoxicities of pesticides with asymmetric chiral centers have been performed, and these studies have shown that the enantiomers of chiral pesticides may have different biological activities both *in vitro* and *in vivo*.[25] Interestingly, our results showed that the cytotoxicity of the axial chiral herbicide propisochlor is also enantioselective, with *R*-(+) isomer being more toxic than *S*-(−) isomer to SP2/0 cells.

The differences between the cytotoxicities of the propisochlor enantiomers were investigated further by identifying differences between the abilities of the enantiomers to induce apoptosis in SP2/0 cells and changes in the cell nuclei. The relative amounts of apoptosis induced in SP2/0 cells by *rac*-

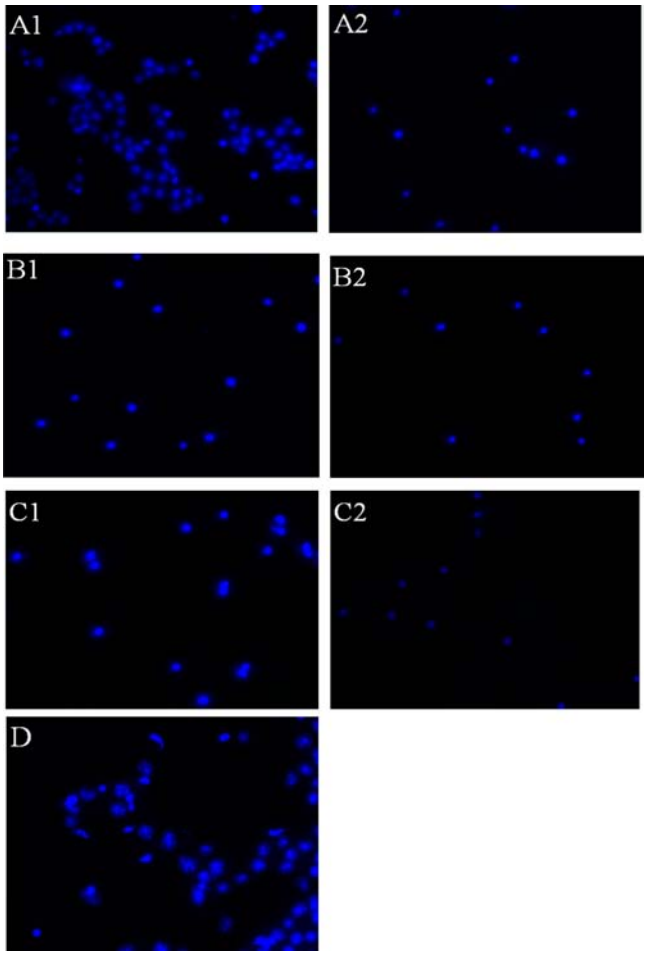

Figure 5. Cellular morphology change induced by different concentrations of propisochlor (400×): (A1 and A2) 50 and 200 μM *rac*-propisochlor, (B1 and B2) 50 and 200 μM *R*-(+) isomer, (C1 and C2) 50 and 200 μM *S*-(−) isomer, and (D) control group.

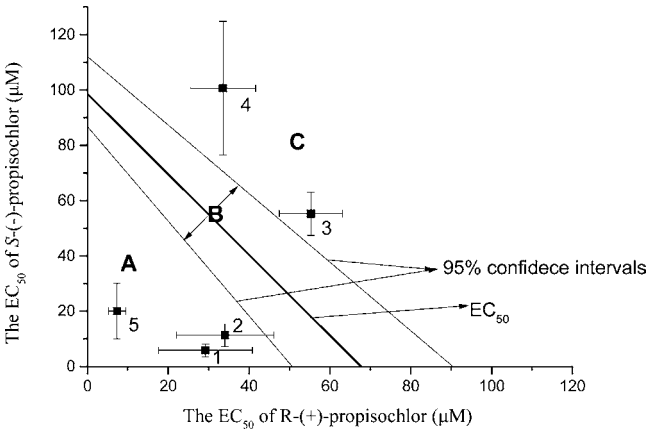

Figure 6. Normalized isobologram analyzes the interaction of the two propisochlor enantiomers. The numbers 1, 2, 3, 4, and 5 mean that the rates of *R*-(+) isomer and *S*-(−) isomer were 5:1, 3:1, 1:1, 1:3, and 1:5, respectively. The three areas of the normalized isobologram were, namely, A, B, and C, which represent synergism, additive, and antagonism, respectively. According to the positions of the five combinations, the positions of 1, 2, and 5 exhibit synergism, while the positions of 3 and 4 exhibit antagonism.

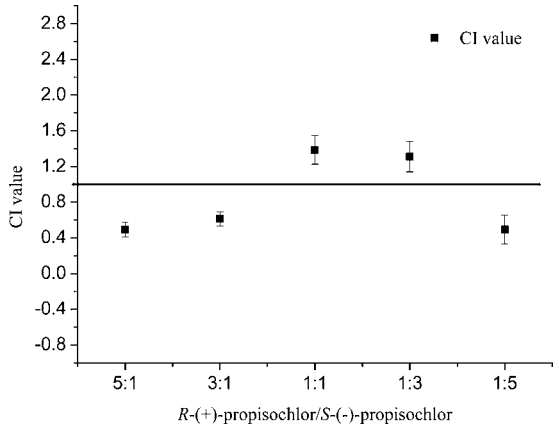

Figure 7. CI values of different rates of *R*-(+) isomer and *S*-(−) isomer. After exposure with different combinations of *R*-(+) isomer and *S*-(−) isomer (5:1, 3:1, 1:1, 1:3, and 1:5, respectively), the CI values were calculated by the formula showed as 2.7. CI values were less than 0.9, between 0.9 and 1.1, more than 1.1, which indicated synergy, additivity, and antagonism, respectively. When the ratio of *R*-(+) isomer and *S*-(−) isomer was 5:1, 3:1, and 1:5, the CI values indicated synergy. However, the CI values indicated antagonism when the ratio of *R*-(+) isomer and *S*-(−) isomer was 1:1 and 1:3.

Table 2. Interaction of Two Propisochlor Enantiomers

rates of *R*-(+) isomer and *S*-(−) isomer	EC_{50} (μM)	95% confidence intervals	coefficient of determination (R^2)	CI
1:0	67.75	50.73−90.49	0.93	
5:1	35.03	23.81−51.55	0.91	0.493 ± 0.08
3:1	45.40	32.04−64.31	0.91	0.614 ± 0.079
1:1	110.6	96.13−127.3	0.97	1.385 ± 0.16
1:3	134.2	105.7−170.3	0.92	1.31 ± 0.17
1:5	44.17	29.8−66.20	0.94	0.495 ± 0.16
0:1	98.64	86.79−112.1	0.97	

propisochlor and the separate enantiomers after 24 h of exposure are shown in Figure 4. The apoptosis rates were higher in the SP2/0 cells treated with *R*-(+) isomer than in the cells treated with *S*-(−) isomer. Changes in the cell nuclei were seen when the cells were exposed to *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer for 24 h. As seen in Figure 5A1, the amount of pyknosis that occurred in the cell nuclei increased as the concentration of *rac*-propisochlor or either isomer increased but similar amounts of pyknosis occurred in cells exposed to 50 μM *rac*-propisochlor and untreated cells. Various factors can influence cell vitality and apoptosis. In this study, *rac*-propisochlor and *R*-(+) and *S*-(−) isomers may have affected SP2/0 cell vitality and apoptosis by causing changes to occur in the cell nuclei.

The cytotoxic mechanisms of chiral pesticides have been described in previous publications.[26−32] Bifenthrin (BF) is a synthetic pyrethroid (SP). SPs are commonly used to control agricultural and indoor insect pests. It has been found that *cis*-BF can induce apoptosis through the enantioselective activation of the JNK/MAPK signaling pathway, causing changes in the control of intracellular reactive oxygen species (ROS) and allowing DNA damage to occur. SPs have also been found to be estrogenic endocrine-disrupting chemicals (EDCs). It has been shown that *S*-(+)-acetofenate (AF) is clearly more toxic than *R*-(−)-AF and *rac*-AF to macrophages and that *S*-(+)-AF induces the generation of intracellular ROS, causes DNA damage, and upregulates p53 gene expression.[6] Some chiral herbicides have been found to induce the generation of ROS, increase the malondialdehyde (MDA) concentration, increase superoxide dismutase (SOD) activity, and trigger toxin production.[28] Chiral pesticides and herbicides have been found to cause enantioselective ecotoxicological effects.[33−36] The effects of the chiral herbicide diclofop-methyl (DM) and its major metabolite diclofop acid (DA) on *Microcystis aeruginosa* have been studied, and *rac*-DA was found to be more toxic than DM, *R*-DA, and *S*-DA.[37] The results described above significantly improved our understanding of the cytotoxicities of pesticides with asymmetric chiral centers and the risks that they pose to ecological and human health. The enantioselective cytotoxicities of pesticides with asymmetric chiral axes have seldom been studied. We have shown here that the cytotoxicity of the axial chiral herbicide propisochlor is enantioselective, although we have not identified the specific toxic mechanisms involved.

The EC_{50} values showed that *rac*-propisochlor, *R*-(+) isomer, and *S*-(−) isomer had different cytotoxicities to SP2/0 cells; therefore, we supposed that a combination effect could have occurred when SP2/0 cells were exposed to both isomers simultaneously. We therefore used an isobologram and CI values to identify interactions between *R*-(+) and *S*-(−) isomers.[21,22] At least three types of interactions (synergism, additive, and antagonism) can occur between two different chemicals interacting with a cell line.[38] Analysis of our isobologram and our CI values showed that antagonism occurred when the *R*-(+) to *S*-(−) isomer ratio was 1:1 (Figures 6 and 7). To the best of our knowledge, this is the first time an interaction between *R*-(+) and *S*-(−) isomers of propisochlor has been found.

Propisochlor is an axial chiral herbicide with two enantiomers, *R*-(+) and *S*-(−) isomers. Propisochlor belongs to the chloroacetamide group of herbicides, which is the most widely used group of herbicides around the world. It has been shown in several studies that applying mixtures of different chloroacetamide herbicides markedly increases the effectiveness with which weeds are killed. Metolachlor is another chloroacetamide herbicide. Applying high doses of dimethenamid-p and *S*-metolachlor together has been found to cause transient injuries to but not to interfere with the maturities and yields of pinto and small red Mexican beans.[39] However, the effects of the co-exposure of non-target organisms to different herbicides and specific interactions between different herbicides have not previously been reported. In this study, we co-exposed SP2/0 cells to both propisochlor isomers and found that some *R*-(+) to *S*-(−) isomer ratios gave synergistic cytotoxic effects and other ratios gave antagonistic cytotoxic effects. A relatively environmentally benign herbicide must be a broad-spectrum herbicide, interfere little with the crops that it is applied to, and must have few toxic effects on non-target organisms. Mixtures of different herbicides, including with different isomer ratios, may prove to be useful treatments.

We investigated the cytotoxicities of *rac*-propisochlor and *R*-(+) and *S*-(−) isomers of propisochlor and the interactions between the two enantiomers for the first time. We found that *R*-(+) isomer is more toxic than *S*-(−) isomer and *rac*-propisochlor. The apoptosis rates that we found showed that *R*-(+) and *S*-(−) isomers may have different biological activities. More importantly, we found that *R*-(+) and *S*-(−) isomers can interact antagonistically, meaning that *rac*-propisochlor is less cytotoxic than either enantiomer. Our results suggest that interactions between enantiomers should be considered when

J. Agric. Food Chem. 2015, 63, 7914−7920

developing and using chiral pesticides and that this may result in a decrease in pesticide application rates and reduced harm to the environment.

practical to use cancer chemopreventive agents such as D3T as feed additives. In addition to these limitations, bans by European countries on the use of synthetic antioxidants due to their side effects in livestock feed have made natural plant-derived antioxidant compounds increasingly attractive as feed additives. The use of abundant plant-derived antioxidants such as tea catechins (TCs) is feasible due to lower costs and strong antioxidant properties, provided their effectiveness can be demonstrated in these animals. TCs are known to positively regulate the expression of antioxidant enzymes and to scavenge reactive oxygen species.[8] Similar to D3T, TCs have been reported to exert antioxidant activity through the Nrf2−Keap1 signaling pathway in humans.[9] Several studies have reported that TCs have potent antioxidant properties against oxidative stress in vivo and in vitro[10] and that TCs improved meat quality by decreasing lipid oxidation, enhancing meat color stability, and changing fatty acid composition in goat meat.[11,12] The partial gene sequence of goat Keap1 has been cloned in our laboratory (GenBank KF038327.1), demonstrating the presence of this antioxidant system. However, functional studies are needed to reveal whether TCs can afford protection to goat muscle tissue against oxidative stress through modulation of Keap1 and induce phase 2 antioxidant enzyme expression, subsequently improving meat quality.

The objectives of this study were (1) to study the effectiveness of TCs against oxidative stress in goat skeletal muscle cells (SMCs) through modulation of Keap1-mediated phase 2 antioxidant enzyme expression compared with a known enzyme inducer in vitro and (2) to determine whether the above mechanisms function to improve oxidative health and meat quality in live goats when TCs are administered as a dietary supplement in vivo.

MATERIALS AND METHODS

Chemicals. All chemicals, cell culture reagents, and D3T were obtained from Sigma Chemical Co. (St. Louis, MO, USA) unless otherwise stated. Primary antibodies were purchased from Abcam Co. (San Francisco, CA, USA). Secondary antibodies and all Western blot reagents were ordered from KenGen Co. (Nanjing, China).

TC Preparement. The TCs (purity of 80.11%) were extracted from green tea leaves (*Camellia sinensis* L.) by high-pressure liquid chromatography (Waster 600, Waters Corp., Milford, MA, USA) and contained 57.67% (−)-epigallocatechin gallate, 1.61% (+)-catechin and (−)-catechin, 5.77% (−)-epicatechin, 0.47% (−)-epigallocatechin, 13.03% (−)-epicatechin gallate, and 1.56% (−)-gallocatechin gallate. In addition, the extracted mixture contained caffeine.

In Vitro Experimental Procedures. The use of the animals and the experimental procedures were approved by the Animal Care Committee, College of Animal Science and Technology, Jilin Agricultural University, Changchun, Jilin, China.

Isolation, Cell Culture, and Treatment. One male early weaned Boer goat at the age of 4 weeks was electrically stunned and slaughtered by exsanguination using commercial procedures conducted according to the recommendations of the animal ethics committee at the Jilin Agricultural University. The *longissimus dorsi* (LD) muscle was collected for cell culture. The procedures of LD muscle collection and the primary SMC isolation and culture were the same as described in Zhong et al.[8] Briefly, the isolated SMCs were seeded in 60 flasks (25 cm^2) at a density of 3×10^6 cells/mL and in two 96-well plates at a density of 2.5×10^5 cells/mL in Dulbecco's modified Eagle's medium (DMEM; Gibco BRL, Gaithersburg, MD, USA) supplemented with 10% heat-inactivated fetal calf serum, 100 U of penicillin−streptomycin/mL, and 5 μg/mL gentamicin. The cells were cultured at 37 °C in a humidified atmosphere of 5% CO_2.

After 24 h of culture, cells in flasks and plates were assigned to one of five treatments, and each treatment was replicated six times. The five treatments were defined as H_2O_2-induced as control (H_2O_2), H_2O_2-induced + D3T incubation (H_2O_2D3T), H_2O_2-induced + TC incubation (H_2O_2TC), D3T incubation (D3T), and TCs incubation (TC) groups, respectively. Briefly, cells in all H_2O_2-induced groups were preincubated with 1 mM H_2O_2 for 3 h. Then, cells in H_2O_2D3T, H_2O_2TC, D3T, and TC groups were subsequently treated with 50 μmol/L D3T, 2.5 μg/mL TC, 50 μmol/L D3T, and 2.5 μg/mL TCs, respectively, according to the concentrations recommended by Zhong et al. and Cao et al.[8,13] Cells were harvested at 45 h postincubation with D3T or TCs. Media from each treatment in two 96-well plates were collected to analyze cell membrane integrity. Cells in 30 flasks (6 flasks per treatment) were disrupted in media and centrifuged, and then the supernatant was used to analyze enzyme activities.[15] Cells in the other 30 flasks (6 flasks per treatment) were collected by centrifugation to analyze enzyme mRNA and protein expression levels.

Cell membrane integrity was determined by the presence of lactate dehydrogenase (LDH) in the growth media and was measured using an in vitro LDH activity assay kit (Jiancheng Biology Co., Nanjing, China). Catalase (CAT) activity in the SMC homogenates was assayed using the spectrophotometric method of Aebi,[14] in which the disappearance of H_2O_2 in a phosphate buffer is detected at 240 nm. The activity of CuZn-SOD in the SMC homogenates was assayed by monitoring the inhibition of the rate of xanthine oxidase-mediated reduction of cytochrome *c* as described by Spitz and Oberley.[15] The GPx activity in the SMC homogenates was measured spectrophotometrically according to the method of Levander et al.[16] The activity of NQO1 in cells was measured according to method of Prochaska and Santamaria[17] and expressed as nanomoles of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl tetrazolium bromide (MTT) reduced per minute per milligram of protein. The activity of total GST was measured using 1-chloro-2,4-dinitrobenzene as the substrate and expressed as milliunits of conjugate formed per milligram of protein (1 mU = 1 nmol of conjugate formed/min).[18]

RNA Isolation, cDNA Synthesis, and Real-Time Quantitative RT-PCR. Oligonucleotide primers of CAT, CuZn-SOD, GPx, GST, NQO1, Keap1, and β-actin genes were designed using Premier 5 software (Premier Co., Canada). The details of the oligonucleotide primer sequences, primer lengths, and predicted amplified product lengths are listed in Table 1. The procedures of total RNA isolation, cDNA synthesis, and real-time qRT-PCR for CAT, CuZn-SOD, GPx, NQO1, GST, and Keap1 expressions are performed according to methods of Zhong et al.[8] Changes in mRNA expression levels determined by real-time qRT-PCR were calculated according to the $2^{-\Delta\Delta CT}$ method.[19]

Western Blot Analysis. Total proteins in SMCs were extracted using a commercial kit (KEP210, KeyGEN Biotech, Nanjing, China), and total protein content was measured according to the method of Lowry et al.[20] The extracted proteins were denatured, separated by reducing 10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis gel (Bio-Rad, Hercules, CA, USA), transferred onto polyvinylidene fluoride membranes (Millipore, Bedford, MA, USA), and incubated with CAT, CuZn-SOD, GPX, NQO1, GST, Keap1, and β-actin primary antibodies (Abcam Co., ab50434, ab62800, ab50434, ab166778, ab150000, ab166958, and ab15263) at concentrations of 3.0, 0.02, 2.0, 0.5, 1.0, 1.0, and 2 μg/mL. Subsequently, the protein affinity with primary antibodies was tested by horseradish peroxidase conjugated secondary antibodies for 2.5 h at 4 °C. The intensity of each protein was determined by enhanced chemiluminescence reagent (GE Healthcare, Waukesha, WI, USA) and visualized by exposure to Hyperfilm ECL (GE Healthcare). β-Actin served as an internal control. The relative expressions of proteins were expressed as the ratio of band intensities of proteins to β-actin.

In Vivo Experimental Procedures. *Animals and Treatment.* Thirty male early weaned Boer goats, aged 4 weeks and with initial body weights (BW) averaging 15.8 ± 0.7 kg, were randomly assigned to one of five groups (n = 6 goats/group) according to their BWs for a feeding period of 21 days. The five treatments consisted of (1) H_2O_2-infused group (H_2O_2), (2) H_2O_2-infused and fed 0.5 mmol/kg of BW D3T (H_2O_2D3T), (3) H_2O_2-infused and fed 0.5% of TCs (dry matter (DM) basis of feed) (H_2O_2TC), (4) fed 0.5 mmol/kg of BW D3T

(D3T) without H_2O_2 infusion, and (5) fed 0.5% of TCs (TC) without H_2O_2 infusion. Goats in the stressed control were fed the basal diet (30% *Aneurolepidium chinense*, 47.5% ground corn grain, 15.0% solid soybean meal, 5.0% molasses, 1.0% dicalcium phosphate, 0.5% limestone, and 1.0% trace mineral salt and vitamins for ruminants) formulated according to the NRC.[21] Goats in the other experimental groups were fed the same basal diet and supplemented with D3T or TCs.

Each goat was assigned to a single metabolism cage in the same environmentally controlled bard barn at 25 °C, with free access to fresh water. The experimental diets were prepared every day by mixing D3T or TC powder with the basal diet before morning and afternoon feeding. Goats were fed twice daily at 6:00 a.m.and 6:00 p.m. The feed supply and orts for each goat were recorded daily. From days 0 to 21, goats in stressed groups were continuously infused a total amount of 50 μmol/g BW H_2O_2 into the jugular vein for 1 h at 5:00 a.m. to induce oxidative stress according to the procedure of Lee et al.[22] Goats in unstressed groups were subjected to the same infusion with saline as the goats in stressed groups. After 21 days of feeding period, all goats were humanely slaughtered and samples collected.

Sampling and Analytical Procedures. At days 0, 7, 14, and 21, blood samples (7 mL) were taken from the jugular vein of each goat before the morning feeding and H_2O_2 infusion and centrifuged at 2500*g* for 15 min at 4 °C to harvest plasma for biochemical indices and enzyme activity determination. The total protein, albumin, globulin, total cholesterol, high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), triglyceride, and urea nitrogen (PUN) concentrations in plasma were measured using an automated biochemical analyzer (Hitachi, 7020, Beijing, China) and commercial kits (Jiancheng Biology Co., Nanjing, China). The activity of lipoprotein lipase (LPL) was determined according to method of Karpe et al.[23] The activities of CAT, CuZn-SOD, GPx, and GST in plasma were determined using the methods described above for cell lysates.

After 21 days, all goats were electrically stunned and slaughtered by exsanguination using procedures accepted by the animal ethics committee at the Jilin Agricultural University. After slaughter, the carcasses were allowed to bleed until they were drained, after which the left side of the carcass was kept under aseptic conditions at 4 °C for sampling. The left LD muscle (10 g) from the same region of each animal was removed and snap-frozen at −70 °C for determination of Keap1 protein expression according to the method of Kavitha et al.[24] Another 200 g of the left LD muscle from the same region of each animal was sampled at 24 h post-mortem for determination of meat quality parameters. Briefly, the pH value of the LD samples was

measured using a portable pH-meter (Testo 205, Testo AG, Lenzkirch, Germany) with a plastic body, a spear-tipped probe coupled with a temperature probe. Shear force analysis was conducted using a Warner-Bratzler shear device (C-LM3B, Beijing, China). The lipid oxidation levels of the LD samples were measured using the 2-thiobarbituric acid reactive substance (TBARS) method modified as described by Olsvik et al.[25] The intramuscular fat content of the LD samples was determined using the methods of ether extraction on a Sohxtex.[26] The total heme pigment content was determined according to the methods of Zhong et al.[11] In addition, a Minolta color-meter (model CR410, Minolta Camera Co. Ltd., Osaka, Japan) was used to measure the meat color parameters of lightness (L^*), redness (a^*), and yellowness (b^*).

Statistical Analyses. Data from the analysis of gene and protein expression levels and enzyme activities in cells and meat quality parameters were analyzed using a General Linear Model followed by Duncan's multiple-range tests.[27] The data from the blood metabolite measurements were analyzed with SAS[27] using the MIXED model procedure described by Littell et al.,[28] with a model consisting of dietary treatment, sampling time, and treatment × time interaction as fixed effects and with the animal as the random effect. The measurements obtained from each goat at different sampling times were treated as repeated measures for each blood metabolite measurement. The means were separated using the least-squares mean and are presented with the standard error of the mean (SEM). The results were considered statistically significant at $P \leq 0.05$.

RESULTS

Treatment of goat SMCs with D3T or TCs affected phase 2 antioxidant enzyme activities (Table 2). However, effects were different between H_2O_2-induced and noninduced cells, and changes in enzyme activity were different among enzymes. Treatment with D3T or TCs increased CuZn-SOD and NQO1 activities regardless of oxidative stress induction ($P < 0.001$). In contrast, activities of CAT and GST in H_2O_2-induced cells increased but decreased in noninduced cells following D3T and TCs treatment ($P < 0.001$). Treatment with D3T or TCs decreased LDH activity in cells regardless of oxidative stress induction compared to treatment with H_2O_2 alone ($P < 0.001$).

Real-time qRT-PCR was performed to detect mRNA expression of the phase 2 antioxidant enzymes in treated SMCs (Table 2). The expression levels of all enzyme genes in the H_2O_2D3T group were up-regulated ($P < 0.001$) relative to the H_2O_2 group. Treatment of unstressed cells with D3T caused an increase in the expression of CuZn-SOD, GPx, and GSTA2, but not CAT and NQO1, relative to the H_2O_2 group. The expression levels of CAT, GSTA2, and NQO1 genes in both the H_2O_2TC and TC groups were up-regulated ($P < 0.001$) compared with the H_2O_2 group. However, the mRNA expression levels of CuZn-SOD in the TC group and GPx in the H_2O_2TC group did not change compared with the H_2O_2 group. The mRNA expression levels of Keap1 in the D3T and TC groups were up-regulated ($P = 0.002$) but did not change in the H_2O_2D3T and H_2O_2TC groups compared with the H_2O_2 group.

The protein expression levels of enzymes and Keap1 in SMCs are shown in Figure 1. The protein expression levels of all enzymes in the H_2O_2D3T and D3T groups, except for CuZn-SOD in the H_2O_2D3T and NQO1 in the D3T group, increased ($P < 0.001$) compared with the H_2O_2 group. The capacity of TCs to regulate protein expression of enzymes was different in stressed cells compared to unstressed cells. The protein expression levels of CAT and CuZn-SOD in the TC group were elevated approximately 3- and 2-fold, respectively ($P < 0.001$) but did not change in the H_2O_2TC group when

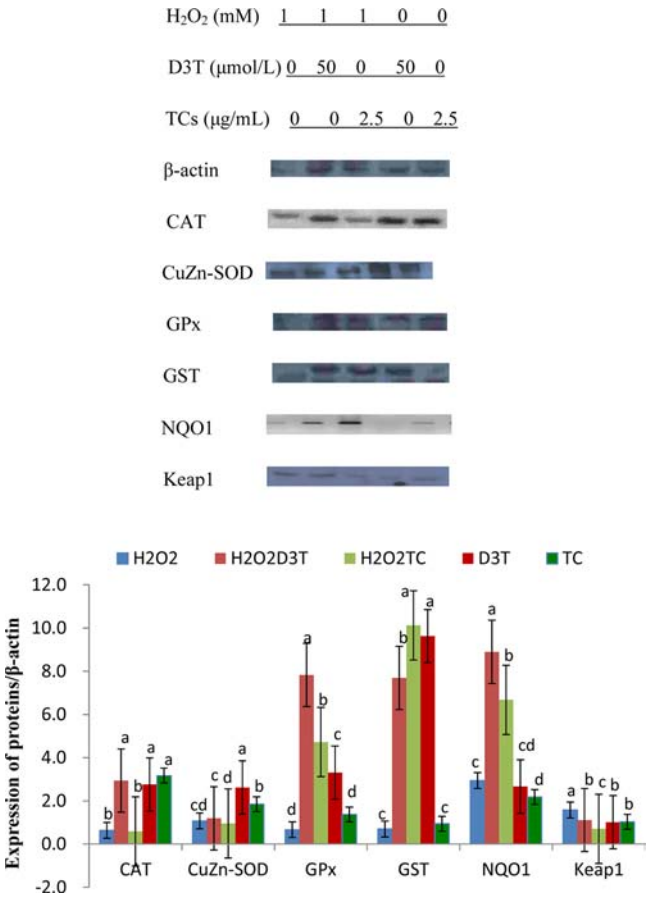

Figure 1. Effects of tea catechins (TCs) and D3T incubation on expression level of proteins in H_2O_2-induced skeletal muscle cells (SMCs).

compared with the H_2O_2 group. Treatment with D3T and TC decreased ($P < 0.001$) the protein expression level of Keap1 in stressed and unstressed SMCs compared with the H_2O_2 group.

In the vivo experiment, the dry matter intakes of goats from each group were 0.81, 0.94, 0.97, 0.85, and 0.88 kg/day, respectively (not shown in the tables). The average daily gain of goats from each group was 205, 232, 226, 265, and 234 g/day, respectively. The average amounts of TCs consumed in the H_2O_2TC and TC groups were 21.6 and 19.5 g/kg BW of animals. The blood biochemical parameters of goats are listed in Table 3. Results showed that an interaction effect on the contents of total protein ($P < 0.001$), albumin ($P = 0.001$), globulin ($P < 0.001$), triglyceride ($P < 0.001$), total cholesterol ($P < 0.001$), HDL-C ($P < 0.001$), and plasma urea nitrogen ($P < 0.001$) and the activities of CAT, CuZn-SOD, GPx, GST, and LPL in plasma ($P < 0.001$) was identified between treatment and sampling time. Overall, the values of triglyceride, cholesterol, and HDL-C and the activity of LPL in the H_2O_2D3T, H_2O_2TC, D3T, and TC groups were lower than those in the H_2O_2 group. However, these values increased as the duration of the feeding period increased. The activities of plasma CAT, CuZn-SOD, GPx, and GST increased as the duration of the feeding period increased ($P < 0.001$).

The values of L^* ($P = 0.001$) and a^* ($P < 0.001$) and the contents of total heme pigment and IMF ($P < 0.001$) in goats fed D3T or TCs increased regardless of whether goats were H_2O_2 infused or not (Table 4). The TBARS value in LD of D3T goats was significantly lower than those in other groups (P

[a]Mean values with different letters in the same row differ significantly ($P < 0.05$). [b]*L**, lightness; *a**, redness; *b**, yellowness; TBARS, thiobarbituric acid reactive substances; MDA, malondialdehyde; NQO1, NADPH:quinine oxidoreductase; Keap1, Kelch-like ECH-associated protein 1.

= 0.012). Shear force of LD in the H_2O_2D3T, H_2O_2TC, and TC groups, but not in the D3T group, decreased ($P < 0.001$) compared with that in the H_2O_2 group. There were no differences in pH values among all groups ($P = 0.610$). The protein expression levels of Keap1 decreased in D3T- and TC-fed goat meat no matter whether goats were H_2O_2 infused or not ($P < 0.001$).

DISCUSSION

Oxidative stress has been implicated in numerous disease processes in small ruminants. The use of in vitro cell culture models to study responses to oxidative stressors such as H_2O_2 is a recognized way to study the mechanisms of action of antioxidants. Multiple papers have described high (usually ≥50 μM) levels of H_2O_2 as being cytotoxic to a wide range of animal, plant, and bacterial cells in culture.[29,30] The administration of plant-derived polyphenolic antioxidants is effective in preventing skeletal muscle damage induced by oxidative stress in rats.[31] Here, we showed that direct exposure of goat SMCs to 1 mM H_2O_2 led to serious injury of cell membrane and that incubation with TCs or with D3T provided protection to cell membrane integrity based on reduced LDH activity in SMCs. Thus, our results suggest that the SMC model of oxidative/antioxidative status is effective in assessing the antioxidant properties of antioxidant compounds such as TCs and D3T.

Antioxidant enzymes function as the first line of defense against oxidative stress by detoxifying free radicals. Tea catechins affect the gene expression of phase 2 antioxidant enzymes through activating the Nrf2−Keap1 signaling pathway in numerous organs, including skin, liver, lung, muscle, and small intestines, and in cultured human and mouse cells.[32,9] D3T exerts its chemopreventive capacity by inducing cellular GST and NQO1 expression.[33] Our previous studies reported that TCs increase CAT and CuZn-SOD mRNA and protein expression levels and associated enzyme activities in goat SMCs induced by H_2O_2 in a dose-dependent manner.[8] Here, we further demonstrate that TCs promote the protein expression of all the enzymes we examined but that the effects on enzyme activities were slightly different, and sometimes even opposite, in stressed versus unstressed cells. The effect of D3T and TCs on CuZn-SOD and GPx was minimal. As expected, the overall changed tendencies of enzymes in D3T-treated cells are similar to those in TCs-treated cells, especially for stressed SMCs. Similar findings were reported in a recent study by Yang et al.[34]

Previous studies have confirmed that the protective effects of D3T on cancer have been associated with the induction of detoxifying phase 2 enzymes via Nrf2−Keap1 signaling.[35] Our results show that D3T increases the activities of phase 2 antioxidant enzymes and suppresses Keap1 protein expression, but does not change Keap1 mRNA expression levels in SMCs. This is consistent with previous studies showing that D3T directly covalently modifies the sensitive cysteine residues of Keap1 and thereby disrupts the Keap1−Nrf2 complex, releasing Nrf2 so that it can migrate to the nucleus.[13] Plant polyphenolic compounds such as TCs contain α,β-unsaturated ketone elements, which are believed to modify the cysteine and thiol groups in Keap1 and thereby activate the Nrf2−Keap1 pathway.[36] Kavitha et al.[24] also reported that TC inclusion inhibits Keap1 expression to activate the Nrf2−Keap1 pathway and downstream phase 2 and antioxidant enzyme expression. The results presented here imply that the pathway through which TCs regulate phase 2 antioxidant enzymes is mediated by Keap1 protein in goat SMCs and is highly similar to pathways employed by D3T.

To further verify the protective effects of TCs and D3T against oxidative stress in goat muscles, an in vivo experiment was conducted to compare the antioxidant activities of D3T and TCs in goats. Findings in our previous study have demonstrated that dietary TC (0.2−0.4% of feed) supplementation did not affect blood metabolites.[37] However, the differences between both experiments are that the amount of TCs in diets was increased to 0.5% of feed, the animals in the present study were subjected to early weaning stress, and different results were observed in the present study in which plasma total protein, globumin, and LDL-C contents increased and plasma triglyceride, total cholesterol, and HDL-C decreased after TCs or D3T treatment. Moreover, the changes were amplified by extending the length of the experiment in the current study. In addition, the animals in the previous studies were not maintained under stressful conditions, whereas the goats in this study were maintained under greater oxidative stress induced by a combination of daily H_2O_2 infusion and stress induced by early weaning. Results of increased plasma total protein content and decreased plasma triglyceride and cholesterol contents in both H_2O_2TC and TC treatments

DOI: 10.1021/acs.jafc.5b00816
J. Agric. Food Chem. 2015, 63, 7921−7928

compared with H_2O_2 treatment and our previous results[37] indicate that TCs exert potent positive effects on improving the health of goats exposed to oxidative stress, and a feeding 0.5% TCs for 21 days was sufficient for testing effects of TCs on blood metabolisms according to the review by Crespy and Williamson.[38] However, these protective effects are less pronounced when the animals are raised under normal physiological conditions. Similar trends were also observed in the activities of antioxidant enzymes in in vitro experiments. In addition, both D3T and TCs had a positive effect on plasma lipid metabolites; changes were observed in levels of triglyceride, TP, and HDL-C contents. This provides direct evidence for profound impacts of D3T on lipid metabolism reported by Kwak et al. and Huang et al.[7,39] The effects may be associated with the antioxidant properties of TCs on lipid peroxidation and activity of LPL, a key enzyme that transforms triglycerides of chylomicrons and LDL-C into free fatty acids, thus permitting their uptake by adipocytes.[40]

In in vivo experiments, the activities of CuZn-SOD and GST in the plasma of goats fed D3T and TCs increased, regardless of whether the goats were infused with H_2O_2. In contrast to the present in vitro results, in which the effect on the enzymes was dependent upon the presence of H_2O_2 stress, the changes in antioxidant enzymes induced by TCs or D3T in blood from stressed goats are consistent with those from unstressed goats (with the exception of CAT). This difference has a simple explanation: in vitro enzyme activities in cell cultures do not always correlate with in vivo activities and responses of in vitro experiments in a flask cannot accurately replicate the complex metabolic and regulatory interplay present in vivo due to transcript production and modification, translation, post-translational modification, and metabolic feedback.[41]

Higher meat quality is the ultimate aim of improving the antioxidant pathway activity of industrially raised goats. In the present study, D3T and TCs enhanced meat color stability, tenderness, and IMF contents of goats under H_2O_2 induction or noninduction conditions. The improvement might be associated with changes in plasma antioxidant enzymes.[10,11] The suppression protein levels of Keap1 in meat of D3T and TCs treatments are consistent with results in vitro, implying that TCs target Keap1 and therefore induce phase 2 and antioxidant enzyme expression to protect goats against oxidative stress.

In summary, results from the in vitro and in vivo experiments presented here provide the first evidence that TCs exert their antioxidant activity in goats through targeting the Keap1 protein and downstream pathways. We showed that TCs modulate the Keap1 protein and induce phase 2 antioxidant enzyme expression, protecting muscle tissue against oxidative stress in goats. Thus, we demonstrate that supplementation of goat feed with moderate levels of an affordable, accessible, natural supplement may significantly improve the quality of meat produced by goats raised under conditions that are typical in the small-ruminant industry.

plasma and liver, the hepatic expression of genes related to lipid metabolism, and the plasma metabolic profiles of the hamsters.

MATERIALS AND METHODS

Chemicals. GSN was purchased from Chengdu Must Biotechnology Co., Ltd. (Chengdu, China). Oil-Red O and 2-propanol were from Sigma-Aldrich (Shanghai, China). TRIzol Reagent was obtained from Invitrogen (Carlsbad, CA, USA). Moloney murine leukemia virus reverse transcriptase and dNTPs were purchased from TaKaRa Bio, Inc. (Dalian, China). EvaGreen reagents were provided by Biotium Inc. (Hayward, CA, USA). D_2O was obtained from Cambridge Isotope Laboratories, Inc. (Tewksbury, MA, USA), and sodium trimethylsilyl propionate was obtained from Merck KGaA (Darmstadt, Germany).

Animal Treatment and Management. A total of 45 male golden Syrian hamsters (9 weeks old) were purchased from Charles River Company (Vital River, Beijing, China). After acclimation for 1 week, the hamsters were randomly assigned to one of the following dietary groups (n = 15 each): normal-fat diet (NFD) group, HFD group, or HFD + 2 g/kg GSN group (equivalent to 76 mg/kg body weight). GSN (98%) was mixed in with the feed. The dose of GSN used in this study was based on that used in a former study in which the serum and hepatic lipids of mice fed a HFD were not affected until the level of dietary GSN supplementation reached 2 g/kg.[10] No adverse effects occurred at the dose used, on the basis of a 90-day feeding study that showed no toxicity in animals fed GSN at doses up to 63 mg/kg bodyweight/day or a GSN/daidzein isoflavone mixture (2:1) at 100 mg/kg bodyweight/day.[18] The present study was conducted over 6 weeks, and the hamsters were given access to feed and water ad libitum. Dietary consumption and bodyweight were measured every week and after 6 weeks. The NFD (protein 22 g %, fat 5 g %, carbohydrate 54 g %) was formulated on the basis of the hamsters' nutritional requirements and was produced by Beijing Keao Xieli Feed Co., Ltd. (Beijing, China). The HFD (protein 20 g %, fat 21 g %, carbohydrate 50 g %) was purchased from Research Diets, Inc. (New Brunswick, NJ, USA). The animals were housed in steel cages (five hamsters per cage) in an environmentally controlled room (20−24 °C, 12 h alternating light/dark cycle). The study protocol was approved by the Animal Care and Use Committee of the Chinese Academy of Agricultural Sciences.

Sample Collection. To meet the statistical requirements of metabonomics data ($n \geq 6$) and to reduce errors resulting from sampling time, six hamsters from each treatment group were sampled. (Were all the hamsters sampled, sampling would have taken a whole day.) After fasting for 12 h, six hamsters from each treatment group were killed under anesthesia induced with pentobarbital. Blood was obtained from the orbital vein with heparin-treated glass capillary tubes. Plasma was obtained after the blood was centrifuged (3000 rpm at 4 °C for 10 min) and stored at −80 °C until analysis. The liver, heart, kidney, and abdominal and epididymal fat were separated, weighed, and flash frozen in liquid nitrogen.

Plasma Parameters, Hepatic Lipid Determination, and Oil-Red O Staining. The plasma total cholesterol (TC), triglycerides (TG), high-density lipoprotein cholesterol (HDL-C), and LDL cholesterol (LDL-C) were determined with an autoanalyzer (Hitachi 7060, Hitachi, Chiyoda, Tokyo, Japan) with commercial kits (BioSino Biotechnology and Science Inc., Beijing, China). The superoxide dismutase (SOD), malondialdehyde (MDA), and free fatty acids (FFA) in the plasma and hepatic TC and TG were measured with commercial kits (Jiancheng Biotechnology, Nanjing, China). The same liver lobes were sampled from the hamsters in each group, immersed in liquid nitrogen, and stored at −80 °C until frozen sectioning. The sections were rinsed with distilled water, stained with 0.2% Oil-Red O and 60% 2-propanol for 10 min at 37 °C, and then rinsed again with distilled water. Lipid accumulation in the liver was then observed under a microscope (Leica DM4000B, Bensheim, Germany) and photographed.

Real-Time PCR. The expression of 13 genes involved in lipid metabolism in the liver was determined with real-time PCR. Total RNA was extracted from the liver with TRIzol Reagent, and quantified spectrophotometrically. Complementary DNA was synthesized with Moloney murine leukemia virus reverse transcriptase, random hexamers, deoxyribonucleosides, RNase inhibitor, and 4 μg of total RNA. The mRNA expression of the target genes was determined with real-time PCR using EvaGreen reagents in an MJ-Chromo 4 thermocycler (Bio-Rad, Hercules, CA, USA). Changes in fluorescence during the PCR were calculated according to the manufacturer's instructions. The amplification of glyceraldehyde phosphate dehydrogenase (GAPDH) mRNA was used as the internal control. The real-time PCR results were normalized as previously described.[19] The gene-specific primers are listed in Table 1.

[a]GAPDH, glyceraldehyde phosphate dehydrogenase; LDL-R, low-density lipoprotein receptor; ER, estrogen receptor; SREBP-2, sterol regulatory element binding protein 2; CYP7A1, cholesterol 7 α-hydroxylase; CYP27A1, sterol 27-hydroxylase; ERK, extracellular regulated protein kinase; JNK, c-Jun N-terminal kinase; AR, androgen receptor; PPARα, peroxisome proliferator-activated receptor alpha.

Plasma ^{1}H NMR Metabonomics. Before the measurements were made, the plasma samples (200 μL) were mixed with 300 μL of D_2O and 100 μL of sodium trimethylsilyl propionate D_2O solution (1 mg/mL) and then centrifuged (13 000 rpm at 4 °C for 10 min). The supernatant of each sample was transferred individually to a 5 mm NMR tube.

All NMR measurements were made on a Varian Inova 600 MHz spectrometer (Varian Inc., Palo Alto, CA, USA) equipped with a triple-resonance inverse probe. A total of 64 transients were collected into 32 K data points for each spectrum, with a spectral width of 8000 Hz and a recycle delay of 2 s. The plasma was analyzed using the Carr−Purcell−Meiboom−Gill (CPMG) pulse sequence to detect low-molecular-weight metabolites and with the bipolar-pair longitudinal-eddy-current (BPP-LED) pulse sequence to detect high-molecular-weight metabolites. Two ^{1}H NMR spectra were acquired for each sample. The CPMG spectra were acquired using the CPMG pulse

[a]NFD, normal-fat diet; HFD, high-fat diet; HFD + 2 g/kg GSN, high-fat diet +2 g/kg genistein; ADFI, average daily feed intake; BW, bodyweight. [b]Mean values were significantly different from those of the HFD group: *, $P < 0.05$, **, $P < 0.01$, and ***, $P < 0.001$. [c]Fifteen replicates were used for BW, three for ADFI, and six for organ weight and visceral fat weight per group.

sequence $(-RD-90°-(\tau-180°-\tau)n-ACQ)$ with a total spin−spin relaxation delay $(2n\tau)$ of 320 ms and a delay T_e of 400 μs. Irradiation of the water resonance was used during recycle delay. The BPP-LED spectra were acquired using the BPP-LED pulse sequence (−RD−90°−G1−180°−G1−90°−T−90°−G1−180°−G1−90°−τ−90°−ACQ) with a diffusion delay of 100 ms and a delay T_e of 5 ms, with water peak irradiation during recycle delay. The free induction decay signal was zero-filled. Line-broadening factors of 0.5 Hz (CPMG) and 3 Hz (BPP-LED) were added and then Fourier transformed to the ^{1}H NMR spectra. The ^{1}H NMR spectra were manually corrected for phase and baseline, with reference to the lactate doublet signal at 1.33 ppm. The CPMG and BPP-LED spectra were binned into 0.01 and 0.04 ppm integral regions, respectively. To exclude the water signal, the region from 4.6−5.0 ppm was not included in the statistical analysis. The spectra were normalized to remove any concentration effects.

Statistical Analysis. Bodyweight, feed intake, organ weight, plasma parameters, hepatic lipid content, and the relative expression of mRNAs are shown as mean values and their standard errors (SE). Student's *t* test was used to compare differences (NFD vs HFD, HFD vs HFD + 2 g/kg GSN). Differences were considered significant at $P < 0.05$. The ^{1}H NMR metabonomic data were examined with multivariate analysis using the SIMCA-P+ software package (version 11; Umetrics, Umeå, Sweden), with the binned integral regions used as input. The plasma metabonomic data were analyzed after centering was applied. Principal components analysis (PCA), an unsupervised pattern-recognition technique, was used to analyze the data sets. The data sets were then explored further with a supervised multivariate data analytical tool, orthogonal signal correction partial least-squares (OSC-PLS). The quality of each model was judged by its R^2 and Q^2 values. Permutation testing was carried out on each OSC-PLS model to assess its validity (with 20 permutations).

RESULTS

Feed Intake, Bodyweight, and Organ Weight. The different dietary groups did not differ in their bodyweights at the end of the study (Table 2). The hamsters in the HFD group had lower average daily feed intake and heart weights ($P < 0.05$) and higher liver, abdominal, and epididymal fat weights ($P < 0.05$) than did the NFD group. Although the average daily feed intake and the liver and epididymal fat weights of the HFD and HFD + 2 g/kg GSN groups did not differ significantly ($P > 0.05$), the hamsters fed the GSN diet had a significantly lower abdominal fat weight than those fed the HFD ($P < 0.05$).

Plasma Parameters and Hepatic Lipids. Table 3 shows that the TC, TG, LDL-C, MDA, and FFA concentrations were all significantly higher in the plasma of the HFD group than in that of the NFD group ($P < 0.05$). The TC, TG, LDL-C, and MDA contents of the GSN-treated group were all significantly lower than those of the HFD group ($P < 0.05$). The plasma FFA levels of the GSN-treated group were 29% lower than those of the HFD group, although the difference was not significant.

Table 3. Effects of 2 g/kg Dietary Genistein on Plasma Biochemical Parameters in Hamsters Fed a High-Fat Diet[a]

	NFD		HFD		HFD + 2 g/kg GSN	
indices[c]	mean[b]	SE	mean	SE	mean[b]	SE

FFA (μmol/L)	2767***	678	9337	843	6598	1255

[a]NFD, normal-fat diet; HFD, high-fat diet; HFD + 2 g/kg GSN, high-fat diet +2 g/kg genistein; TC, total cholesterol; TG, triglycerides; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; SOD, superoxide dismutase; MDA, malondialdehyde; FFA, free fatty acid. [b]Mean values were significantly different from those of the HFD group: *, $P < 0.05$, **, $P < 0.01$, ***, $P < 0.001$. [c]Six replicates were used per group.

The hepatic lipid contents in the HFD group were higher than those in the NFD group (29.9 vs 12.2 μmol/g for TC, respectively, and 37.1 vs 24.8 μmol/g for TG, respectively; $P < 0.05$). The HFD + 2 g/kg GSN group had significantly lower hepatic TC (20.9 μmol/g; $P < 0.05$) and 16.6% lower TG (31.0 μmol/g; $P = 0.223$) than did the HFD group (Figure 1a). Oil-Red O staining showed that the hepatic lipid droplets in the HFD + 2 g/kg GSN group were smaller than those in the HFD group (Figure 1b).

Hepatic mRNA Expression. The mRNA expression of the lipid metabolism genes in the liver is shown in Figure 2. Some genes related to LDL-C clearance, including those encoding the LDL-R and sterol regulatory element binding protein 2 (SREBP-2), were downregulated in the HFD group compared with their expression in the NFD group ($P < 0.05$). LDL-R

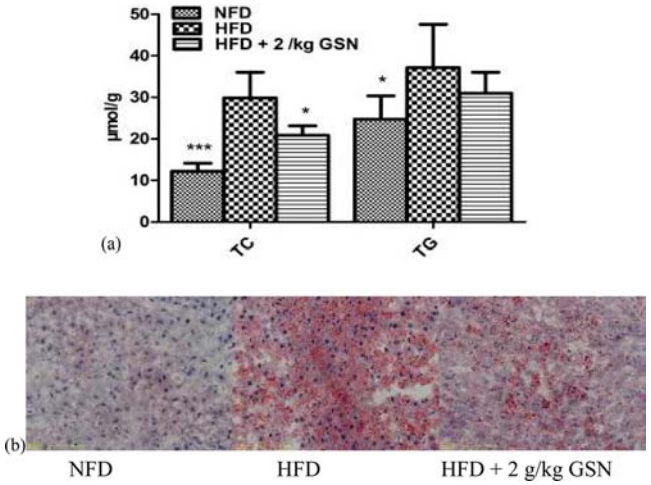

Figure 1. (a) Concentrations of total cholesterol (TC) and triglycerides (TG) in the liver. Values are presented as means (n = 6) and standard errors. Mean values were significantly different from those of the HFD group at *, $P < 0.05$ and ***, $P < 0.001$. (b) Histology (Oil-Red O staining, 400×) of a representative liver section from each group. NFD, normal-fat diet; HFD, high-fat diet; HFD + 2 g/kg GSN, high-fat diet +2 g/kg genistein.

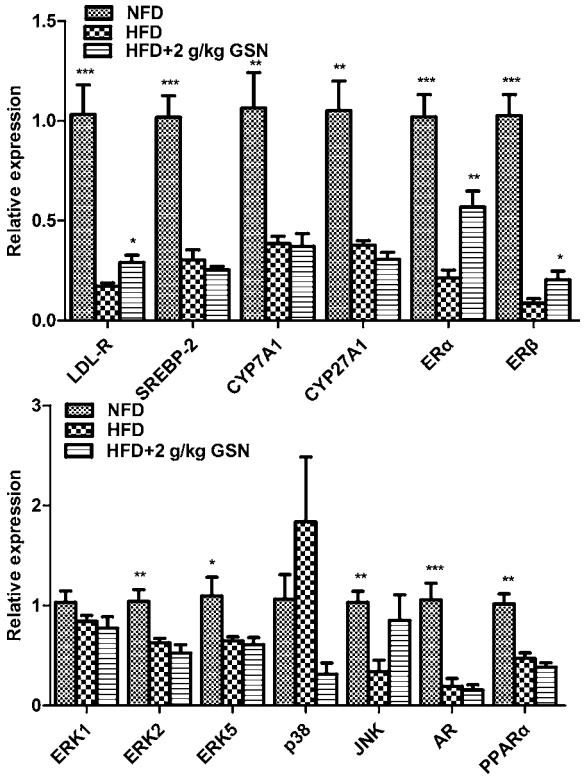

Figure 2. Relative mRNA expression of genes related to lipid metabolism in the livers of the normal-fat diet (NFD), high-fat diet (HFD), and high-fat diet +2 g/kg genistein (HFD + 2 g/kg GSN) groups. The genes analyzed encoded the low-density lipoprotein receptor (LDL-R), sterol regulatory element binding protein 2 (SREBP-2), cholesterol 7 α-hydroxylase (CYP7A1), sterol 27-hydroxylase (CYP27A1), estrogen receptor (ER), extracellular regulated protein kinase (ERK), c-Jun N-terminal kinase (JNK), androgen receptor (AR), and peroxisome proliferator-activated receptor α (PPARα). GAPDH mRNA was amplified as the internal control. Mean values were significantly different from those of the HFD group at *, $P < 0.05$, **, $P < 0.01$, and ***, $P < 0.001$.

expression was significantly higher in the HFD + 2 g/kg GSN group than in the HFD group ($P < 0.05$). The expression of cholesterol 7 α-hydroxylase (CYP7A1) and sterol 27-hydroxylase (CYP27A1) was lower in the HFD group than in the NFD group ($P < 0.05$) and were unaffected by GSN treatment. The different diets significantly affected the expression of the estrogen receptor (ER). The expression of both ERα and ERβ was downregulated in the HFD group compared with the NFD group ($P < 0.05$) but was upregulated in the HFD + 2 g/kg GSN group compared with the HFD group ($P < 0.05$).

The hepatic expression of ERK2, ERK5, and c-Jun N-terminal kinase (JNK), which are involved in the MAPK pathway, was downregulated in the HFD group as compared with their expression in the NFD group ($P < 0.05$). However, there were no significant differences between the HFD and HFD + 2 g/kg GSN groups in ERK1, ERK2, or ERK5 mRNA expression. The transcription of both p38 and JNK almost returned to normal in the HFD + 2 g/kg GSN group relative to that in the HFD group, but the change was not significant. The expression of the androgen receptor (AR) and PPARα was downregulated in the HFD group ($P < 0.05$), but it was unaffected by the GSN treatment.

Plasma ^{1}H NMR Metabonomics. As indicated by the CPMG score plots shown in Figures 3a,c, the plasma metabolic profiles of the NFD and HFD groups were clearly separated in both the PCA and OSC-PLS analyses. However, the HFD and HFD + 2 g/kg GSN groups could not be differentiated with PCA (Figure 3a) but were separated with OSC-PLS (Figure 3c). In the OSC-PLS analysis, the NFD group was on the right half of the ellipse, and the HFD group was on the left half of the ellipse. The samples in the HFD + 2 g/kg GSN group were differentiated from those in the HFD group and were shifted closer to those in the NFD group. Validation of the OSC-PLS model with permutation testing resulted in a Q_2 intercept of (0.0, − 0.27).

Figure 4 presents the results of BPP-LED analyzed with both PCA and OSC-PLS. In PCA, the HFD group was distributed between the lower ($^5/_6$) and upper ($^1/_6$) ellipse, the NFD group was in the left ellipse, and the HFD + 2 g/kg GSN group was distributed between the right ($^5/_6$) and left ($^1/_6$) ellipse (Figure 4a). The plasma BPP-LED results were also subjected to OSC-PLS, and three clusters were apparent: the NFD, HFD, and HFD + 2 g/kg GSN groups. This result indicates that metabolic changes occurred in the hamster plasma in response to the different dietary treatments (Figure 4c). The metabolic profiles of the HFD + 2 g/kg GSN group differed from those of the HFD group and were closer to those of the NFD group. The OSC-PLS model was validated with permutation testing, which had a Q_2 intercept of (0.0, − 0.27).

Table 4 shows the changes in the plasma metabolite concentrations according to CPMG and BPP-LED. The concentrations of lactate and lipoprotein in the HFD group were lower and higher, respectively, than those in the NFD group. Very low-density lipoprotein (VLDL; lipid, CH_3), LDL and VLDL (lipid, CH_2), VLDL (lipid, CH_2), lipid (CH_2CH_2CO), lipid ($CH_2C{=}C$), lipid (CH_2CO), and unsaturated fatty acids (UFA, $=CH$) levels were higher in the HFD group than they were in the NFD group. Most of the abnormal lipid metabolites, including VLDL (lipid, CH_3), VLDL (lipid, CH_2), lipid (CH_2CH_2CO), lipid ($CH_2C{=}C$), lipid (CH_2CO), phosphatidylcholine, and UFA ($=CH$), were reversed by GSN supplementation.

DISCUSSION

Feed Intake, Bodyweight, Organ Weight, and Plasma and Hepatic Lipid Levels. There has been little agreement on the effects of GSN on the feed intake and bodyweights of animal models. Some researchers have reported that GSN reduces feed intake or bodyweight,[20,21] whereas others have shown no effect of dietary GSN on feed intake and bodyweight.[22] These discrepancies may be attributable to differences in the animal models used, HFD compositions, GSN doses, or the durations of the experiments. It is unclear whether the changes in feed intake caused by GSN influence the experimental results because this factor is not accounted for in many experiments. Feed intake was not affected by GSN in this study, so all the results were attributable to the biological effects of GSN rather than to different patterns of food intake. Although 2 g/kg of dietary GSN significantly reduced the liver weights of mice fed a HFD (18% fat),[10] liver weight was not significantly affected by the same concentration of GSN in the present study, which could be explained by the differences in the HFD composition (21% fat in this study) and the animal species used. GSN has previously been shown to affect adipose deposition,[21] and we also observed significantly less abdominal fat in the hamsters fed 2 g/kg GSN than in the HFD hamsters.

Plasma and hepatic lipid levels reflect the lipid metabolism in animals. At the end of 6 weeks, the plasma and liver lipids in the HFD group were all significantly higher than those in the NFD group, suggesting the induction of hyperlipidemia. This hyperlipidemia was alleviated in the 2 g/kg GSN group, which had lower lipid levels in both the plasma and liver than did the HFD group. Previous studies have shown that GSN reduces the plasma and hepatic lipids in animal models, although the lowest observable levels have varied in different studies.[10,11,23] One study found that 2 g/kg of dietary GSN reduced plasma TC and liver TG in mice fed a HFD.[21] Another study found that the serum and liver lipids of mice fed a HFD were not affected until GSN was increased to 2 g/kg.[10] In this study, the lipids in both the plasma and livers of the 2 g/kg GSN group were lower than those in the HFD group, which is consistent with previous studies.[10,21] We also found that GSN exerted an antioxidant effect by reducing plasma MDA production, which is consistent with a previous study in which lipid peroxidation was inhibited by GSN treatment.[24] The biochemical parameters of the plasma and liver demonstrated that 2 g/kg dietary GSN improved the lipid metabolism of hamsters with diet-induced hyperlipidemia by reducing lipid circulation and inhibiting lipid peroxidation.

Hepatic mRNA Expression. Several mechanisms have been proposed to explain the antihyperlipidemic effects of GSN. One study reported that of the 97 transcripts altered in the HFD-fed group, the expression of 84 were normalized with GSN supplementation.[21] Genes that are involved in cholesterol metabolism are regulated by GSN,[7] which was confirmed here by the observed increase in hepatic LDL receptor mRNA expression, indicating an improvement in LDL-C clearance. Isoflavones have previously been reported to increase the mature nuclear form of SREBP-2 in vitro.[25] However, hepatic SREBP-2 mRNA expression was not affected by GSN in the present study, consistent with another study.[11] CYP7A1 and

CYP27A1 were upregulated in mice fed a soy protein diet plus 2% cholesterol.[26] We observed no effect of GSN on CYP7A1 or CYP27A1 expression in this study, which warrants further investigation. Because GSN has a structure similar to that of estradiol, it is reported to bind both ERα and ERβ,[27] the two nuclear ERs upon which estradiol acts. The binding of estradiol to the ERs inhibits lipogenesis primarily by reducing the activity of lipoprotein lipase, an enzyme that regulates lipid uptake by adipocytes.[6] Hepatic expression of ERα and ERβ mRNA was upregulated in the GSN group, indicating that the ERs were activated by GSN ingestion. This may explain the primary mechanism underlying the hypolipidemic effects of GSN in this study, although more evidence is required to demonstrate the molecular mechanism of GSN activity on hyperlipidemia.

Increasing evidence has established that GSN acts not only through the ERs but also via other pathways. PPARα is important in the β oxidation of fatty acids and is mainly expressed in tissues such as the liver, where lipoprotein metabolism is crucial. GSN binds directly to and activates PPARα in vitro, which may result in lipid catabolism and reduce blood lipids.[6,9] However, hepatic PPARα mRNA expression was not affected by GSN supplementation in vivo.[10,11] We also found no difference in hepatic PPARα mRNA expression in this study. Although GSN reportedly upregulates the expression of ERK1/2 in vitro,[12] we saw no significant effect of GSN treatment on any gene involved in the liver MAPK pathway. Therefore, the actions of GSN in vivo and in vitro may not be consistent, so further studies of this discrepancy are required.

Plasma ^{1}H NMR Metabonomics. The aim of the ^{1}H NMR metabonomic analysis was not to quantify absolutely the differences between the groups but rather to compare their relative differences. The distinct plasma metabolic profiles of the HFD and NFD groups indicate that ^{1}H NMR metabonomic data directly reflect the abnormal metabolic profiles induced by HFD in hamsters, which recapitulates the results of previous studies.[28,29] Although numerous studies have reported the beneficial effects of GSN on lipid metabolism, this is the first study to use an ^{1}H NMR metabonomic analysis of plasma metabolites profiles to identify the biological effects of GSN in hamsters fed an HFD. The restoration of the plasma metabolic profiles in the 2 g/kg GSN group indicates that GSN improved hamster hyperlipidemia. These results are consistent with the plasma and hepatic results that we obtained with traditional approaches.

A multivariate statistical analysis of the NMR spectra of the plasma samples revealed differences in the intensities of the different spectral regions, which could be ascribed to differences in lipoproteins, lactate, VLDL, LDL, phosphatidylcholine, UFA, or other lipids among the three groups, as listed in Table 4. Lactate, an important intermediate of glycometabolism, was lower in the HFD group than in the NFD group, consistent with a previous study,[29] and the change was reversed in the GSN group. A reduction in blood lactate implies that glycolysis is inhibited and that the energy consumption pattern may shifted to lipid oxidation in response to hyperlipidemia.[29] Therefore, the reversion of lactate levels by GSN might contribute to the restoration of normal energy consumption patterns. However, other NMR metabonomic studies have

Table 4. Metabolic Differences in Plasma among the Normal-Fat Diet, High-Fat Diet, and High-Fat Diet +2 g/kg Genistein Groups[a]

NMR spectral region (ppm)	assignment	HFD[b]	HFD + 2 g/kg GSN[b]
	CPMG Spectra		
0.84−0.90	lipoprotein	↑	↓
1.26−1.30	lipoprotein	↑	↓
1.32−1.34 4.09−4.10	lactate	↓	↑
	BPP-LED Spectra		
0.82, 0.86	VLDL/LDL (lipid, CH_3)	↓	↑
0.90	VLDL (lipid, CH_3)	↑	↓
1.22	LDL (lipid, CH_2)	↓	↑
1.26	LDL/VLDL (lipid, CH_2)	↑	↑
1.30, 1.34	VLDL (lipid, CH_2)	↑	↓
1.58	lipid (CH_2CH_2CO)	↑	↓
2.02, 2.06	lipid ($CH_2C{=}C$)	↑	↓
2.22, 2.26	lipid (CH_2CO)	↑	↓
3.22	PCho	↓	↑
5.3, 5.34	UFA (=CH)	↑	↓
		NFD	HFD

[a]NFD, normal-fat diet; HFD, high-fat diet; HFD + 2 g/kg GSN, high-fat diet +2 g/kg genistein; VLDL, very low-density lipoprotein; LDL, low-density lipoprotein; Pcho, phosphatidylcholine; UFA, unsaturated fatty acids; CPMG, Carr−Purcell−Meiboom−Gill pulse sequence; BPP-LED, bipolar-pair longitudinal-eddy current. [b]The symbols ↑ and ↓ indicate higher and lower concentrations in groups listed in the top compared with groups at the bottom of the table.

reported that blood lactate is higher in hamsters fed a HFD.[30,31] Therefore, further research is required. The BPP-LED spectra were dominated by the signals from lipids, and GSN treatment restored the signal intensities of VLDL, phosphorylcholine, UFA, and other lipids to those of the NFD group. VLDL and LDL, which are considered to be the major cholesterol-containing lipoproteins implicated in the development of atherosclerosis, were restored to normal levels in the GSN group. LDL-C is mainly cleared by the hepatic LDL-R pathway, in which ERs are critically involved.[32] Therefore, in this study, the reversion of VLDL and LDL in the GSN group observed with ^{1}H NMR metabonomics may be explained by the upregulated expression of hepatic ERα, ERβ, and the LDL receptor. Polyunsaturated fatty acids, which have a high degree of unsaturation in the *n*-6 and *n*-3 series, accelerate cell-mediated LDL peroxidation and therefore aggravate the atherosclerotic process.[33] The restoration of the plasma lipid profiles after GSN supplementation suggests that hyperlipidemia was globally ameliorated in these hamsters.

We have demonstrated that dietary 2 g/kg GSN ameliorated hyperlipidemia in hamsters by reducing the weight of abdominal fat and decreasing plasma and hepatic lipid contents. The improvement in lipid metabolism was associated with the upregulated expression of hepatic LDL receptor, ERα, and ERβ mRNAs. ^{1}H NMR and multivariate data analyses showed that both the abnormal small and macromolecular metabolic plasma profiles in the HFD group of hamsters were shifted toward normal profiles by GSN supplementation. Further research to quantify absolutely the plasma lipid profiles in relation to GSN ingestion would be of great value.

J. Agric. Food Chem. 2015, 63, 7929−7936

was subsequently evaporated, and the residue was extracted with ethyl acetate three times. The combined organic layers were washed with brine, dried over anhydrous $MgSO_4$, filtered, and concentrated under reduced pressure to give h-MHES (37 g) as a yellow solid. The product was dissolved in dimethyl sulfoxide (DMSO) prior to use in cell experiments.

Analysis of h-MHES by Means of High-Performance Liquid Chromatography (HPLC). HPLC analysis was performed by using an Agilent 1220 Infinity LC (Agilent Technologies, Santa Clara, CA, USA) with UV detection (254 nm) and an InertSustain C18 column (⌀ 3.0 × 50 mm, GL Science, Tokyo, Japan). The temperature of the column oven was set at 40 °C. The mobile phase consisted of 0.1% formic acid in water (solution A) and acetonitrile (solution B); the run conditions were as follows: isocratic elution, 70% A/30% B, 0−1.5 min; linear gradient from 70% A/30% B to 30% A/70% B, 1.5−5.5 min; linear gradient from 30% A/70% B to 0% A/100% B, 5.5−6.0 min. The flow rate was 1.0 mL/min.

Isolation of Flavanones (AG1, AG2) and Chalcones (AG3, AG4). Thin-layer chromatography (TLC) was performed by using TLC silica gel 60 F_{254} (Merck, Darmstadt, Germany); spots were visualized by using UV light and treatment with phosphomolybdic acid stain followed by heating. Flash column chromatography was performed by using Hi-Flash column silica gel (Yamazen, Osaka, Japan). Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance 600 spectrometer with Cryoprobe (Bruker, Newark, DE, USA). Chemical shifts (δ) are reported in parts per million based on the resonance of tetramethylsilane (0 ppm for ^{1}H NMR in $CDCl_3$) or the respective solvent (^{1}H NMR, 2.49 ppm in DMSO-d_6; ^{13}C NMR, 77.0 ppm in $CDCl_3$ or 39.7 ppm in DMSO-d_6) as the internal standard.

The h-MHES (3.32 g) was fractionated by using flash column chromatography and eluted with hexane/ethyl acetate/methanol. Ten fractions (F1−F10) were collected.

5,7-Dihydroxy-3′,4′-dimethoxyflavanone (AG1) (865 mg) was obtained as a white solid by recrystallizing the F2 fraction from hexane/ethyl acetate: ^{1}H NMR (DMSO-d_6) δ 12.13 (1H, s), 10.80 (1H, s), 7.11 (1H, d, J = 1.9 Hz), 7.01 (1H, dd, J = 8.3, 1.9 Hz), 6.95 (1H, d, J = 8.3 Hz), 5.88 (1H, d, J = 2.2 Hz), 5.87 (1H, d, J = 2.2 Hz), 5.46 (1H, dd, J = 12.9, 3.0 Hz), 3.75 (3H, s), 3.74 (3H, s), 3.32 (1H, d, J = 17.1, 12.9 Hz), 2.68 (1H, dd, J = 17.1, 3.0 Hz); ^{13}C NMR (DMSO-d_6) δ 196.3, 166.6, 163.5, 162.8, 149.0, 148.7, 130.9, 119.3, 111.4, 110.5, 101.7, 95.8, 95.0, 78.5, 55.5, 42.1.

7-Hydroxy-5,3′,4′-trimethoxyflavanone (AG2) (609 mg) was obtained as a pale yellow solid from the F7 and F8 fractions: ^{1}H NMR (DMSO-d_6) δ 10.53 (1H, s), 7.07 (1H, d, J = 1.9 Hz), 6.98 (1H, dd, J = 8.4, 1.9 Hz), 6.94 (1H, d, J = 8.4 Hz), 6.04 (1H, d, J = 2.1 Hz), 5.95 (1H, d, J = 2.1 Hz), 5.35 (1H, dd, J = 12.7, 2.8 Hz), 3.75 (3H, s), 3.73 (3H, s), 3.71 (3H, s), 3.03 (1H, d, J = 16.5, 12.7 Hz), 2.52 (1H, dd, J = 16.5, 2.8 Hz); ^{13}C NMR (DMSO-d_6) δ 188.1, 164.7, 164.6, 162.6, 149.3, 149.1, 131.8, 119.4, 111.9, 110.8, 104.8, 96.0, 93.6, 78.6, 56.0, 55.9, 45.3.

4′-Hydroxy-3,4,2′,6′-tetramethoxychalcone (AG3) (156 mg) was obtained as a pale yellow solid from the F5 fraction: ^{1}H NMR (DMSO-d_6) δ 9.82 (1H, s), 7.25 (1H, d, J = 2.0 Hz), 7.15 (1H, dd, J = 8.4, 2.0 Hz), 7.10 (1H, d, J = 16.0 Hz), 6.93 (1H, d, J = 8.4 Hz), 6.84 (1H, d, J = 16.0 Hz), 6.10 (2H, s), 3.77 (3H, s), 3.76 (3H, s), 3.62 (6H, s); ^{13}C NMR (DMSO-d_6) δ 194.1, 160.4, 158.4, 151.3, 149.4, 144.4, 127.7, 127.6, 123.3, 111.9, 110.9, 110.2, 92.4, 55.99, 55.95, 55.89.

4′,6′-Dihydroxy-3,4,2′-trimethoxychalcone (AG4) (112 mg) was obtained as an orange solid from the F3 fraction: ^{1}H NMR (DMSO-d_6) δ 13.72 (1H, s), 10.58 (1H, s), 7.69 (1H, d, J = 15.6 Hz), 7.60 (1H, d, J = 15.6 Hz), 7.26 (2H, m), 7.00 (1H, d, J = 8.8 Hz), 5.99 (1H, d, J = 2.1 Hz), 5.89 (1H, s), 3.85 (3H, s), 3.81 (3H, s), 3.79 (3H, s); ^{13}C NMR (DMSO-d_6) δ 192.2, 166.4, 165.1, 162.9, 151.4, 149.3, 142.9, 128.1, 125.6, 123.1, 112.1, 111.1, 105.6, 96.2, 56.4, 56.0, 55.9.

Synthesis of 2′,4′,6′-Trihydroxy-3,4-dimethoxychalcone (AG5). To a stirred solution of 2′,4′,6′-trihydroxyacetophenone monohydrate (2.01 g) in tetrahydrofuran (50 mL), diisopropylethylamine (18.8 mL) and chloromethyl methyl ether (3.28 mL) were added at 0 °C; the mixture was then stirred at room temperature for 9.5 h. After the solution was cooled to 0 °C, water (10 mL) was added. Then the mixture was extracted with ethyl acetate. The organic layer was washed with 0.5 M HCl and brine, dried over anhydrous $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was purified by using flash chromatography (hexane/ethyl acetate) to give 2′-hydroxy-4′,6′-bis-methoxymethoxyacetophenone (1.71 g, 62%) as a white solid: ^{1}H NMR ($CDCl_3$) δ 13.71 (1H, s), 6.24 (1H, d, J = 2.5 Hz), 6.22 (1H, d, J = 2.5 Hz), 5.23 (2H, s), 5.15 (2H, s), 3.50 (3H, s), 3.45 (3H, s), 2.64 (3H, s); ^{13}C NMR ($CDCl_3$) δ 203.2, 166.8, 163.4, 160.3, 106.9, 97.1, 94.4, 94.0, 56.7, 56.5, 33.1.

To a stirred solution of 2′-hydroxy-4′,6′-bis-methoxymethoxyacetophenone (1.12 g) in methanol (20 mL), veratraldehyde (728 mg) and potassium hydroxide (2.85 g) in water (2 mL) were added at 0°C, and the mixture was stirred at room temperature for 55 h. Then, the mixture was neutralized with 2 M sodium hydroxide (30 mL) and extracted twice with ethyl acetate. The combined organic layers were washed with brine, dried over anhydrous $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was purified by using flash column chromatography (hexane/ethyl acetate) to give 6′-hydroxy-3,4-dimethoxy-2′,4′-bis-methoxymethoxychalcone (1.13 g, 64%) as a yellow solid: ^{1}H NMR (DMSO-d_6) δ 12.15 (1H, s), 7.49 (1H, d, J = 15.7 Hz), 7.45 (1H, d, J = 15.7 Hz), 7.28 (1H, d, J = 1.9 Hz), 7.24 (1H, dd, J = 8.4, 1.9 Hz), 6.99 (1H, d, J = 8.4 Hz), 6.26 (1H, d, J = 2.3 Hz), 6.23 (1H, d, J = 2.3 Hz), 5.24 (2H, s), 5.20 (2H, s), 3.785 (3H, s), 3.783 (3H, s), 3.375 (3H, s), 3.368 (3H, s); ^{13}C NMR (DMSO-d_6) δ 192.8, 162.0, 161.2, 157.8, 151.1, 148.9, 143.6, 127.4, 125.6, 123.1, 111.6, 110.3, 109.1, 96.6, 94.53, 94.45, 93.8, 56.2, 55.9, 55.6, 55.4.

To a stirred solution of 6′-hydroxy-3,4-dimethoxy-2′,4′-bis-methoxymethoxycalcone (1.13 g) in methanol (60 mL), 1M HCl (30 ml) was added at room temperature, and refluxed for 50 min. After the solution was cooled to room temperature, the mixture was diluted with water (60 mL), and extracted twice with ethyl acetate. The combined organic layers were washed with brine, dried over anhydrous $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was purified by using flash chromatography (hexane/EtOAc) to give 2′,4′,6′-trihydroxy-3,4-dimethoxychalcone (AG5) (585 mg, 66%) as an orange solid: ^{1}H NMR (DMSO-d_6) δ 12.53 (2H, s), 10.40 (1H, s), 8.01 (1H, d, J = 15.6 Hz), 7.65 (1H, d, J = 15.6 Hz), 7.25−7.23 (2H, m), 7.01 (1H, d, J = 8.9 Hz), 5.82 (2H, s), 3.792 (3H, s), 3.788 (3H, s); ^{13}C NMR (DMSO-d_6) δ 191.6, 164.8, 164.4, 150.9, 148.9, 142.1, 127.8, 125.0, 122.6, 111.7, 110.6, 104.2, 94.8, 55.6, 55.4.

Cell Culture. Human epidermal keratinocytes (Cascade Biologics, Portland, OR, USA) were grown in EpiLife medium containing 0.06 mM Ca^{2+}, human keratinocyte growth supplement (0.4% bovine pituitary extract, 10 μg/mL insulin, 0.67 μg/mL hydrocortisone, and 0.1 ng/mL human epidermal growth factor), and an antibiotic mixture (50 μg/mL gentamicin and 50 ng/mL amphotericin B) (Cascade Biologics). HEK293 cells (American Type Culture Collection, Manassas, VA, USA) were grown in Dulbecco's modified Eagle medium (Gibco, Grand Island, NY, USA) with 10% fetal bovine serum (Gibco) and 1% penicillin/streptomycin (Invitrogen, Carlsbad, CA, USA). Both cell types were grown at 37 °C in a humidified atmosphere of 5% CO_2 and 95% air until 80% confluence and then used for experiments.

Microarray Analysis. Total RNA was extracted by using the RNeasy Mini Kit (Qiagen, Venlo, The Netherlands). cRNA synthesis and labeling reactions were performed using a Low Input Quick Amp Labeling Kit (Agilent Technology) according to the manufacturer's protocol. Array hybridization was performed using a Whole Human Genome microarray 4 × 44K ver.2 (Agilent Technology). The hybridized array slide was scanned with a SureScan Microarray Scanner (Agilent Technology).

The microarray data were normalized by using GeneSpring GX 11.5 software (Agilent Technology). The cutoff value was set at 0.5−2.0 for the ratio (>2.0, up-regulation; <0.5, down-regulation). Ingenuity Pathway Analysis (IPA) software (Ingenuity, Redwood City, CA, USA) was then used to identify the specific pathways involved in the response to treatment with h-MHES.

J. Agric. Food Chem. 2015, 63, 7937−7944

Real-Time PCR Analysis. Total RNA was extracted by using an RNeasy Mini Kit (Qiagen) according to the manufacturer's instructions. cDNA was generated by using a High Capacity RNA-to-cDNA Kit (Applied Biosystems, Foster City, CA, USA). mRNA expression levels were determined by use of the TaqMan gene expression assay with the 7500 Real Time PCR System (Applied Biosystems). The primer and probe sets for the target genes were as follows: G6PD, Hs00166169_m1; GCLC, Hs00155249_m1; GCLM, Hs00157694_m1; GPX2, Hs01591589_m1; GSR, Hs00167317_m1; HMOX1, Hs01110250_m1; NFE2L2, Hs00232352_m1; NQO1, Hs00168547_m1; PRDX1, Hs03044567_g1; SRXN1, Hs00607800_m1; TXN, Hs01555212_g1 and TXNRD1, Hs00917067_m1. Target gene expression was normalized to RPLP0 (Hs99999902_m1) gene expression.

Extraction of Nuclear Protein. Nuclear extracts were obtained from the keratinocytes by using a Nuclear Extract Kit (Active Motif, Carlsbad, CA, USA) according to the manufacturer's instructions.

SDS-PAGE and Western Blotting. Cells were washed with cold PBS and lysed in RIPA buffer (25 mM Tris-HCl, pH 7.6, 150 mM NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS) (Pierce, Rockford, IL, USA) containing protease inhibitor cocktail (Sigma-Aldrich, St. Louis, MO, USA) and phosphatase I and II inhibitor cocktail (Sigma-Aldrich) by passing them through a 25G needle. After incubating on ice for 15 min, the lysates were centrifuged at 15000*g* for 15 min at 4 °C, and then supernatants were collected. Protein concentration was determined by using a BCA protein assay kit (Pierce). The supernatants normalized by protein concentration were mixed with SDS sample buffer (Novagen, Madison, WI, USA) and denatured by boiling at 95 °C for 5 min.

Ten micrograms of protein per sample was loaded onto 4−15% gradient polyacrylamide gels (Bio-Rad, Hercules, CA, USA), and the samples were separated electrophoretically in Tris−glycine−SDS buffer (25 mM Tris, 192 mM glycine, 0.1% SDS; pH 8.3) (Bio-Rad). The separated proteins were transferred to polyvinylidene fluoride membranes (Bio-Rad) in Tris−glycine buffer (25 mM Tris, 192 mM glycine; pH 8.2) (Bio-Rad) containing 20% methanol. After being blocked at room temperature for 1 h in Tris-buffered saline−Tween (TBS-T) buffer (200 mM Tris, 5 M NaCl, 0.1% Tween-20; pH 7.4) (Bio-Rad) with 5% skim milk (Wako Pure Chemical Industries, Osaka, Japan), the membranes were incubated at 4 °C overnight in immunoreaction enhancer solution (Can Get Signal Solution 1; Toyobo, Osaka, Japan) containing a 1:1000 dilution of antibodies against HO-1 (Santa Cruz Biotechnology, Santa Cruz, CA, USA; sc-10789), GCLC (Abcam, Cambridge, UK; ab40929), β-actin (Cell Signaling Technology, Beverly, MA; 4970), Nrf2 (Santa Cruz Biotechnology; sc-722), histone H1 (Santa Cruz Biotechnology; sc-10806), phosphorylated p38 (Thr180/Tyr182) MAPK (Cell Signaling Technology; 4511), p38 MAPK (Cell Signaling Technology; 8690), phosphorylated Akt (Ser473) (Cell Signaling Technology; 4058), Akt (Cell Signaling Technology; 4691), phosphorylated ERK1/2 (Thr202/Tyr204) (Cell Signaling Technology; 4370), ERK1/2 (Cell Signaling Technology; 4695), phosphorylated SAPK/JNK (Thr183/Tyr185) (Cell Signaling Technology; 4671), and SAPK/JNK (Cell Signaling Technology; 9252). The membranes were then washed three times in TBS-T and incubated for 1 h at room temperature in immunoreaction enhancer solution (Can Get Signal Solution 2; Toyobo) containing a 1:5000 dilution of anti-rabbit IgG, HRP-linked secondary antibody (GE Healthcare, Piscataway, NJ, USA). Protein-blot analysis was carried out using the ECL plus Western blotting detection reagent (GE Healthcare) with the luminescent image analyzer LAS-4000 (Fujifilm, Tokyo, Japan).

Determination of Intracellular Glutathione Levels. Cells were frozen at −80 °C and subsequently thawed at 37 °C in 5% metaphosphoric acid solution. Lysates were centrifuged at 1000*g* for 5 min, and supernatants were used for the glutathione (GSH) assay. Intracellular GSH was determined by using a commercial assay kit (Northwest Life Science Specialties, Vancouver, WA, USA) according to the manufacturer's protocol.

Luciferase Reporter Assay. ARE-luciferase reporter plasmids were generated by using the pGL3-promoter vector (Promega, Madison, WI, USA). The sense and antisense oligonucleotides containing three copies of the human GCLC ARE[16] (GCLC 3×ARE_F, CTAGCTCCCCGTGACTCAGCGCTTTGCCCTCCC-CGTGACTCAGCGCTTTGCCCTCCCCGTGACTCAGCGCTT-TGC; GCLC 3×ARE_R, TCGAGCAAAGCGCTGAGTCACGGG-GAGGGCAAAGCGCTGAGTCACGGGGAGGGCAAAGCGCTG-AGTCACGGGGAG) were annealed. The double-strand oligonucleotide was ligated to the *Nhe*I and *Xho*I sites of the pGL3-promoter vector.

HEK293 cells were grown at 37 °C in a humidified atmosphere of 5% CO_2 and 95% air until 80% confluence and then cultured in growth factor-free medium for 16 h. The cells were then cotransfected with the pARE-luc and pRL-TK (Promega) reporter plasmids by using the SuperFect transfection reagent (Qiagen). Cells were treated with h-MHES for 16 h, and then the luciferase assay was performed using the dual-luciferase reporter assay system (Promega). Firefly luciferase activities stemming from the pARE-luc plasmid were standardized to the corresponding Renilla luciferase activities from the pRL-TK control plasmid.

Transfection of Small Interfering RNA. Nrf2 siRNA and control siRNA were purchased from Santa Cruz Biotechnology. Keratinocytes were transfected with 5 nM Nrf2 or control siRNA by using the HiPerFect transfection reagent (Qiagen) according to the manufacturer's protocol. At 16 or 24 h after transfection, the cells were used for each experiment.

Treatment with Kinase Inhibitors. For kinase inhibitor experiments, keratinocytes were pretreated with growth factor-free medium containing 20 μM SB203580 (Sigma-Aldrich), LY294002 (Sigma-Aldrich), PD98059 (Sigma-Aldrich), or SP600125 (Sigma-Aldrich) for 1 h, and then h-MHES (final concentration = 16.5 μg/mL) was added. The cells were then incubated for a further 24 h. Treated cells were then washed twice with cold PBS and used for mRNA or protein analysis.

Determination of Intracellular Reactive Oxygen Species (ROS) Levels. The production of cellular ROS was detected by using 2′,7′-dichlorodihydrofluorescein diacetate (H_2DCFDA) (Invitrogen). Cells were pretreated with h-MHES (16.5 μg/mL) for 16 h. Then, the cells were incubated with Hank's balanced salt solution (HBSS) containing 10 μM H_2DCFDA at 37 °C for 20 min. After that, the cells were washed and incubated in HBSS buffer with 0, 100, or 200 μM H_2O_2 or irradiated with 0, 20, or 60 mJ/cm^2 UVB (1 mW/cm^2) by using GL20SE UVB lamps (emission peak, 306 nm; Sankyo denki, Tokyo, Japan). After 30 min of H_2O_2 treatment or 15 min of UVB irradiation, ROS generation was measured by the fluorescence intensity at 535 nm after excitation at 485 nm on an EnVision 2104 multilabel reader (PerkinElmer, Waltham, MA, USA) and imaged by means of confocal laser scanning microscopy (TCP-SP5; Leica, Mannheim, Germany).

Statistical Analysis. Data are expressed as the mean ± standard error (SEM). Analysis of variance and a two-tailed unpaired Student's *t* test were used for statistical analysis. Differences between groups were considered to be significant at $P < 0.05$.

RESULTS

Preparation of h-MHES. h-MHES was prepared by acid hydrolysis of MHES, as described under Materials and Methods. HPLC analysis of h-MHES showed that it consisted mainly of four compounds (Figure 1A). This hydrolyzed MHES was used in experiments in this study. In addition, we fractionated h-MHES, by means of flash column chromatography, and isolated two flavanones and two chalcones. Structure determination from NMR data revealed that peak a was 7-hydroxy-5,3′,4′-trimethoxyflavanone (AG2), peak b was 4′-hydroxy-3,4,2′,6′-tetramethoxychalcone (AG3), peak c was 5,7-dihydroxy-3′,4′-dimethoxyflavanone (AG1), and peak d was 4′,6′-dihydroxy-3,4,2′-trimethoxychalcone (AG4) (Figure 1). Sakieki et al. reported that MHES is a mixture of six methylated derivatives of hesperidin,[9,10] and we expected that five aglycons

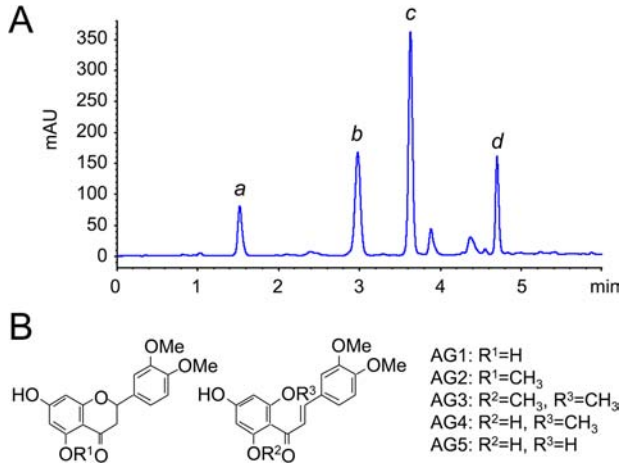

Figure 1. Chemical structures of h-MHES: (A) chromatogram for acid-hydrolyzed MHES; (B) chemical structures of flavanone and chalcone derivatives. AG1, 5,7-dihydroxy-3′,4′-dimethoxyflavanone (peak c); AG2, 7-hydroxy-5,3′,4′-trimethoxyflavanone (peak a); AG3, 4′-hydroxy-3,4,2′,6′-tetramethoxychalcone (peak b); AG4, 4′,6′-dihydroxy-3,4,2′-trimethoxychalcone (peak d); AG5, 2′,4′,6′-trihydroxy-3,4-dimethoxychalcone.

Table 1. h-MHES Up-regulates the mRNA of Antioxidant-Related Genes[a]

gene symbol	description	h-MHES (fold change) 2 h	8 h	24 h
G6PD	glucose-6-phosphate dehydrogenase	1.1	1.4	2.0
GCLC	glutamate-cysteine ligase, catalytic subunit	1.4	4.9	6.6
GCLM	glutamate-cysteine ligase, modifier subunit	1.2	3.2	2.4
GPX2	glutathione peroxidase 2	1.1	1.7	3.8
GSR	glutathione reductase	1.0	1.7	2.3
HMOX1	heme oxygenase 1	2.6	15.3	2.9
NQO1	NAD(P)H:quinone oxidoreductase 1	1.1	2.6	2.9
SRXN1	sulfiredoxin 1	1.4	4.6	5.1
TXN	thioredoxin	1.0	1.2	2.1
TXNRD1	thioredoxin reductase 1	1.7	6.7	4.1

[a]Keratinocytes were treated with h-MHES (16.5 μg/mL) for 2, 8, or 24 h. G6PD, GCLC, GCLM, GPX2, GSR, HMOX1 (HO-1), NQO1, SRXN1, TXN, and TXNRD1 expression levels were analyzed by using qRT-PCR. Fold changes in transcript levels relative to the control transcript level (untreated cells) are shown.

would be produced from the MHES by hydrolysis. As expected, AG1, AG2, AG3, and AG4 were produced, but there was no 2′,4′,6′-trihydroxy-3,4-dimethoxychalcone (AG5) in h-MHES. It may be that AG5 was completely converted to the corresponding flavanone (AG1) during acid hydrolysis. We, therefore, prepared AG5 by chemical synthesis (Figure 1B).

h-MHES Induces Antioxidant-Related Gene Expression. In a preliminary study to investigate the pharmacological effects of h-MHES, we treated keratinocytes and fibroblasts with h-MHES under conditions of UVB irradiation or cytokine stimulation. By using the Agilent Whole Human Genome Array, we found that h-MHES changed the gene expression as follows: In UVB-irradiated keratinocytes, 947 transcripts were either up-regulated or down-regulated (fold-change >2.0 or <0.5, respectively) by h-MHES. Similarly, 3346 transcripts were either up-regulated or down-regulated by h-MHES in IL-1β-stimulated fibroblasts. A total of 181 transcripts were common to both experiments. Of these 181 transcripts, 134 transcripts showed the same direction of change in both experiments. Transcriptomic analysis of these 134 transcripts suggested a highly significant association with the Nrf2-mediated oxidative stress response (data not shown). To validate the microarray data, we measured the mRNA levels of detoxication and antioxidant genes, including the rate-limiting enzyme for bilirubin biosynthesis (HO-1) and the enzymes associated with glutathione (GSH) synthesis and recycling (GCLC, GCLM, GSR) by using quantitative RT-PCR. Treatment of keratinocytes with h-MHES for 24 h increased mRNA expression levels of G6PD (2.0-fold), GCLC (6.6-fold), GCLM (2.4-fold), GPX2 (3.8-fold), GSR (2.3-fold), HO-1 (2.9-fold), NQO1 (2.9-fold), SRXN1 (5.1-fold), TXN (2.1-fold), and TXNRD1 (4.1-fold) (Table 1). The effect of h-MHES on HO-1 and GCLC induction was concentration dependent (Figure 2A,C), peaking at 8 h for HO-1 and at 24 h for GCLC (Figure 2B,D).

h-MHES Induces Glutathione Synthesis. h-MHES induced the expression of GCLC and GCLM, which are the rate-limiting enzymes in glutathione (GSH) biosynthesis. We therefore examined whether h-MHES could increase the level of GSH in keratinocytes. Total GSH levels of h-MHES-treated keratinocytes increased in a time-dependent manner, reaching a 2.8-fold high after 24 h of treatment (Figure 3A). To assess whether h-MHES affects GSH depletion, h-MHES-pretreated keratinocytes were irradiated with UVB, and total GSH levels were measured. At 3 and 6 h after UVB irradiation, the GSH levels in the h-MHES-pretreated keratinocytes were 1.7- and 1.9-fold higher, respectively, than in the control keratinocytes. h-MHES thus attenuated the depletion of the cellular GSH (Figure 3B).

h-MHES Promotes Nrf2 Nuclear Translocation and ARE Luciferase Activity. To determine whether the induction of antioxidant gene expression by h-MHES was mediated through the activation of Nrf2, we examined ARE luciferase activity and the nuclear translocation of Nrf2 in h-MHES-treated cells. Cells were transfected with pARE-luc vector, and the reporter luciferase activity was measured. h-MHES enhanced the ARE luciferase activity in a concentration-dependent manner (Figure 4A). Keratinocytes were treated with h-MHES for 16 h and assessed for nuclear accumulation of Nrf2 protein. We found that nuclear translocation of Nrf2 was enhanced 1.8-fold by h-MHES treatment (Figure 4B). To determine whether antioxidant gene induction by h-MHES is mediated via Nrf2 activation, we transfected cells with Nrf2 siRNA and assessed the expression of HO-1, GCLC, and NQO1 by using qRT-PCR. The h-MHES-induced up-regulation of HO-1, GCLC, and NQO1 was totally abolished by Nrf2 knockdown (Figure 4C). These findings indicate that h-MHES up-regulates antioxidant genes such as HO-1, GCLC, and NQO1 via the Nrf2−ARE pathway.

p38 MAPK Contributes to h-MHES-Induced Antioxidant-Related Gene Expression. To further elucidate the upstream pathway of antioxidant gene expression induced by h-MHES, we examined the phosphorylation level of several kinases in cells treated with h-MHES. After treatment with h-MHES, the level of phosphorylated p38 mitogen-activated protein kinase (MAPK) increased in a time-dependent manner (Figure 5A). In contrast, the levels of phosphorylated Akt, phosphorylated extracellular signal-regulated kinase (ERK), and

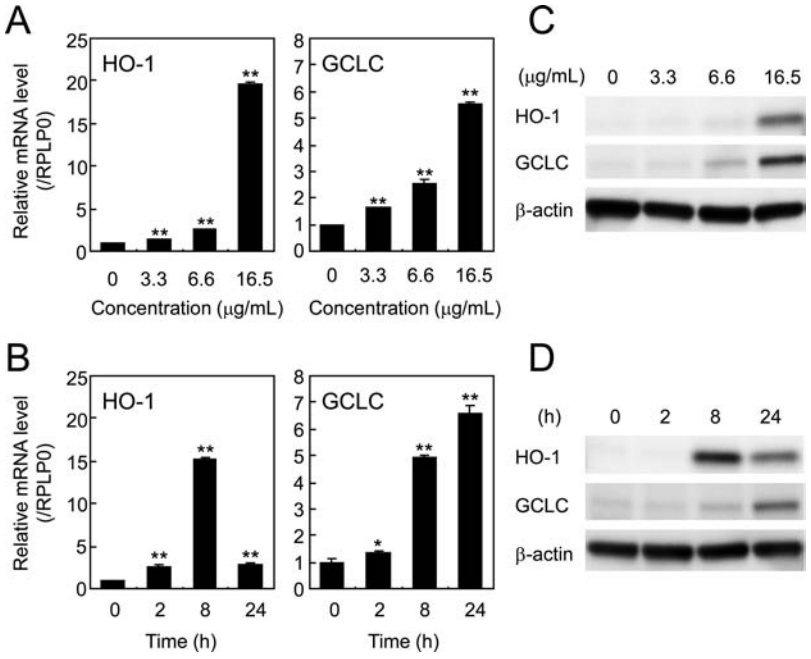

Figure 2. h-MHES induces HO-1 and GCLC. (A, B) Effect of h-MHES on mRNA levels. Keratinocytes were incubated with growth factor-free medium containing h-MHES (0, 3.3, 6.6, or 16.5 μg/mL) for 24 h (A) and with h-MHES (16.5 μg/mL) for the indicated period (B). HO-1 and GCLC expression levels were analyzed by use of qRT-PCR. Data are presented as the mean ± SEM (n = 3). (*) $P < 0.05$ and (**) $P < 0.01$ versus negative control (0 μg/mL or 0 h). (C, D) Effect of h-MHES on protein levels. Keratinocytes were incubated with growth factor-free medium containing h-MHES (0, 3.3, 6.6, or 16.5 μg/mL) for 24 h (C) and with h-MHES (16.5 μg/mL) for the indicated period (D). HO-1 and GCLC protein levels were determined by use of Western blotting with appropriate antibodies. β-Actin was used as an internal control.

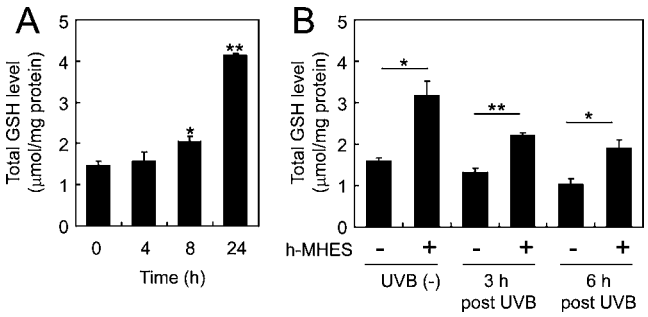

Figure 3. h-MHES enhances GSH production. (A) Effect of h-MHES on GSH content. Keratinocytes were incubated with growth factor-free medium containing h-MHES (16.5 μg/mL) for 0, 4, 8, or 24 h. Data are presented as the mean ± SEM (n = 3). (*) $P < 0.05$ and (**) $P < 0.01$ versus 0 h. (B) Effect of h-MHES on GSH depletion induced by UVB. Keratinocytes were pre-incubated with growth factor-free medium containing h-MHES (16.5 μg/mL) for 16 h and irradiated with UVB (20 mJ/cm^2) in PBS. Then, the cells were incubated with growth factor-free medium containing h-MHES (16.5 μg/mL) for 0, 3, or 6 h. Data are presented as the mean ± SEM (n = 3). (*) $P < 0.05$ and (**) $P < 0.01$.

phosphorylated c-jun N-terminal kinase (JNK) did not increase in h-MHES-treated keratinocytes. We also examined the effects of SB203580, LY294002, PD98059, and SP600125, which are specific inhibitors of p38 MAPK, phosphoinositide-3 kinase (PI3K), ERK, and JNK, respectively. h-MHES-induced HO-1 and GCLC expressions were suppressed by SB203580 and LY294002; however, inhibition of ERK and JNK had no effect (Figure 5B). These results suggest that p38 MAPK and PI3K participate in the regulation of h-MHES-induced HO-1 and GCLC expression.

h-MHES Decreases Intracellular ROS Levels. Intracellular ROS levels were determined by measuring the oxidative conversion of 2′,7′-dichlorodihydrofluorescein diacetate (H_2DCFDA) to the fluorescent compound 2′,7′-dichlorofluorescein (DCF). The intracellular ROS levels in UVB-irradiated keratinocytes were 2.4- and 4.5-fold higher at 20 and 60 mJ/cm^2, respectively, than those in non-irradiated keratinocytes (Figure 6A). h-MHES attenuated the increase in ROS production caused by UVB irradiation (Figure 6B). h-MHES also suppressed H_2O_2-induced ROS accumulation in keratinocytes, but it failed to suppress ROS production in Nrf2 siRNA-treated keratinocytes (Figure 6C,D). These findings indicate that h-MHES prevents UVB- and H_2O_2-induced ROS production via the Nrf2 pathway.

Isolation and Comparison of h-MHES Derivatives. A comparison of h-MHES derivatives showed that the methoxychalcones (AG3, AG4) induced highly enhanced ARE activity and significantly up-regulated the gene expression of HO-1 and GCLC (Figure 7A,B). Furthermore, these methoxychalcones had an inhibitory effect on ROS generation (Figure 7C). In contrast, the flavanones (AG1, AG2), including hesperetin, which is the aglycon form of hesperidin, barely activated the Nrf2−ARE pathway (Figure 7A).

DISCUSSION

In the present study, we investigated the pharmacological activity of h-MHES, the aglycon form of methylated derivatives of the citrus flavonoid hesperidin, and found that h-MHES attenuated oxidative stress through the Nrf2−ARE pathway. In addition, we identified the methoxychalcones AG3 and AG4 as active components of h-MHES.

Nrf2 functions as a master regulator of antioxidant systems that are involved in cytoprotection in response to oxidative and

electrophilic stresses.[17] We predicted that h-MHES may activate the Nrf2−Keap1 pathway, because h-MHES induced several antioxidant genes (Table 1). Nrf2 siRNA inhibited h-MHES-induced HO-1, GCLC, and NQO1 mRNA expression (Figure 4), indicating that h-MHES induced these antioxidant genes via Nrf2. Moreover, the nuclear translocation of Nrf2 was observed after h-MHES treatment, although h-MHES did not affect Nrf2 mRNA levels (Figure 4). This result suggests that h-MHES-induced antioxidant gene expression is mediated not by the induction of the Nrf2 transcript but by the activation of Nrf2 nuclear translocation. Previous studies have demonstrated that several kinase pathways are involved in Nrf2 activation.[18] We observed that h-MHES enhanced the phosphorylation of p38 MAPK and that an inhibitor of p38 MAPK (SB203580) abolished h-MHES-induced expression of HO-1 and GCLC. These results indicate that h-MHES induced antioxidant gene expression through the activation of p38 MAPK. An inhibitor of PI3K (LY294002) also attenuated HO-1 and GCLC expression induced by h-MHES, yet phosphorylated Akt was not increased by h-MHES. Therefore, h-MHES does not seem to induce phosphorylation of Akt directly, even though PI3K participates in the regulation of h-MHES-induced HO-1 and GCLC expression. Our study suggests that h-MHES stimulates the Nrf2−ARE pathway mainly via p38 MAPK activation, but further work is needed to elucidate the precise mechanism involved.

HPLC and NMR analysis revealed that h-MHES was a mixture of methoxyflavanones and methoxychalcones. We showed that two methoxychalcones, AG3 and AG4, activated the Nrf2−ARE pathway to a greater extent than did the methoxyflavanones. Chalcones bear an α,β-unsaturated ketone moiety and could therefore act as Michael acceptors that have the potential to change the cellular redox environment and direct cysteine modification in Keap1.[19] However, AG5, one of the methoxychalcones, did not activate the Nrf2−ARE pathway in the present study, and previous studies have shown that not all chalcones have the ability to activate Nrf2.[19,20] Therefore, further studies are needed to clearly determine whether h-MHES derivatives activate Nrf2 by direct thiol modification of Keap1, ROS production, or some other mechanism.

HO-1, GCLC, GSR, and GPX, which are h-MHES-induced genes, participate in antioxidant and cytoprotective systems.[21] HO-1 catalyzes the conversion of heme into biliverdin, free iron, and carbon monoxide (CO)[22] and provides cytoprotection against oxidative stress and inflammation.[23,24] GCLC is a component of glutamate cysteine ligase (GCL), which is the rate-limiting enzyme in glutathione (GSH) synthesis.[25] GSH is a ubiquitous intracellular peptide with diverse functions that include detoxification, antioxidant defense, and maintenance of thiol status.[25] The activity of GSH is dependent on not only a

steady supply of GSH but also the support of glutathione-cycle related enzymes such as GPX and GSR. GPX catalyzes the oxidation of GSH to oxidized GSH (GSSG), and the resulting GSSG is recycled back to reduced GSH by GSR using NADPH. h-MHES increased the expression of these antioxidant-related genes and the intracellular GSH content, suggesting that h-MHES could protect cells from oxidative stress. Accordingly, we assessed whether h-MHES could enhance cellular antioxidant capacity through the activation of biological antioxidant systems. h-MHES pretreatment of keratinocytes prevented UVB- and H_2O_2-induced intracellular ROS production (Figure 6), indicating that h-MHES provided the cells with resistance to oxidative stress.

MHES likely has unique pharmacological effects that are absent in hesperidin, because h-MHES activated the Nrf2 pathway to a much greater extent than did hesperetin (hesperidin aglycon). UVB-irradiated Nrf2−/− mice show a stronger sunburn reaction and accelerated photoaging, such as coarse wrinkle formation, loss of skin flexibility, and epidermal thickening.[26,27] However, Nrf2 activation strongly reduces UVB-induced apoptosis.[28] These reports suggest that the Nrf2−ARE pathway plays an important role in protection against UVB damage. Therefore, MHES, as an Nrf2 activator, may protect the skin from oxidative stress caused by UVB in vivo.

In conclusion, we found that h-MHES activates the Nrf2−ARE pathway, resulting in the induction of cytoprotective gene expression and attenuation of oxidative stress in keratinocytes. Our findings reveal MHES as a new agent for protecting cells against oxidative stress through its ability to enhance biological antioxidant capacity.

again by molecular modeling, we investigated for comparison the interaction of peptide **1** with the catalytic site of HMGCoAR.

MATERIALS AND METHODS

Chemicals. Dulbecco's modified Eagle's medium (DMEM), L-glutamine, fetal bovine serum (FBS), phosphate-buffered saline (PBS), penicillin/streptomycin, chemiluminescent reagent, and 96-well plates were purchased from Euroclone (Milan, Italy). Bovine serum albumin (BSA), RIPA buffer, HMGCoAR assay kit, lovastatin, and the antibody against β-actin were bought from Sigma-Aldrich (St. Louis, MO, USA). The antibody against HMGCoAR was bought from Abcam (Cambridge, UK). The antibodies against SREBP-2, rabbit Ig-HRP, mouse Ig-HRP, phenylmethanesulfonylfluoride (PMSF), Na-orthovanadate inhibitors, and goat anti-rabbit Ig-HRP were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). The antibodies against LDLR were bought from Pierce (Rockford, IL, USA); the inhibitor cocktail Complete Midi was purchased from Roche (Basel, Swiss). Mini protean TGX precast gel 7.5% and Mini nitrocellulose Transfer Packs were purchased from BioRad (Hercules, CA, USA). YVVNPDNDEN and YVVNPDNNEN were bought from PRIMM (Milan, Italy), which certified >95% purity by HPLC.

Computational Methods. The structures of peptides **1**−**3** were built by using two different strategies. The shortest derivatives (peptides **2** and **3**) were manually modeled in a canonical α-helix by using the Peptide Builder function of the VEGA suite of programs; then, their conformational profiles were explored by a MonteCarlo procedure, which produced 20 000 conformers by randomly rotating the backbone torsions only. The final geometries were then clustered according to their similarity to discard redundant ones; here, two conformations were considered as nonredundant when they differed by more than 60° in at least one backbone torsion angle. For each cluster, the lowest energy structure was collected and memorized. By contrast, the structure of the longest peptide (**1**) was generated by homology modeling, using the Fugue online program, on the basis of the resolved structure of phaseolin as the template (Protein Database (PDB) ID: 2PHL). This model was completed by adding side chains and hydrogen atoms and then minimized by keeping the backbone atoms fixed to preserve the predicted folding.

Among the resolved human HMG-CoA reductase structures, the study involved the complex between the enzyme and a statin (i.e., (3*R*,5*R*)-7-[2-(4-fluorophenyl)-4-{[(1S)-2-hydroxy-1-phenylethyl]-carbamoyl}-5-(1-methylethyl)-1H-imidazol-1-yl]-3,5-dihydroxyheptanoic acid, PDB ID: 3CCZ) because this showed the best resolution (1.70 Å).[21] Even though the resolved structure is a homotetramer, the simulations were focused on a functionally active homodimer, which completely encompasses the catalytic binding site. After deleting water molecules, ions, and crystallization additives, the selected dimer bound to the statin was completed by adding the hydrogen atoms and then optimized by keeping the backbone atoms fixed to preserve the resolved folding. The inhibitor was finally deleted, and the obtained protein structure underwent the following docking simulations.

Although requiring different strategies, all docking simulations were carried out by using the program Protein−Ligand ANT System (PLANTS, release 1.1),[23] which generates reliable ligand poses by using ant colony optimization algorithms (ACO).

For the shortest peptides (peptides **2** and **3**), docking simulations involved the 20 lowest energy conformations as derived by the previous MonteCarlo analysis in order to minimize the biasing effects of the starting conformation on the obtained results. In detail, the search was focused on a 15.0 Å radius sphere around the bound statin, thus including the entire binding cavity. PLANTS was used with default settings and without geometric constraints: Speed 1 was used, and 5 poses were generated and scored for each conformer by using the ChemPLP function. The obtained poses were evaluated by considering both the docking scores and the conformational energies of the docked conformers. The best poses were then minimized, keeping fixed all atoms inside a 15.0 Å radius sphere around the bound peptide. Although adopting the same computational procedures already described, the docking study for the longest peptide **1** was focused on the single conformation as derived by homology modeling.

The computed complexes for peptide **1** and **2** underwent 10 ns molecular dynamic (MD) study. It should be noted here that the MD simulations had the primary objective of assessing the stability of the generated complexes as well as of their key stabilizing contacts and were not aimed at investigating the conformational changes induced by the bound ligand on the protein structure because this would have clearly required longer simulations. First, the complexes were embedded in a cubic box of water (85 Å × 85 Å × 85 Å) containing 16 250 solvent molecules. The systems were then minimized to optimize the relative position of the solvent molecules and then were subjected to MD runs with the following characteristics: (a) Periodic boundary conditions (95 Å × 95 Å × 95 Å) were applied to stabilize the simulation space. (b) Newton's equation was integrated using the r-RESPA method (every 4 fs for long-range electrostatic forces, 2 fs for short-range non bonded forces, and 1 fs for bonded forces). (c) The long-range electrostatic potential was computed by the Particle Mesh Ewald summation method (80 × 80 × 80 grid points). (d) The temperature was maintained at 300 ± 10 K by Langevin's algorithm. (e) Lennard-Jones (L-J) interactions were calculated with a cutoff of 10 Å, and the pair list was updated every 20 iterations. (f) A frame was memorized every 10 ps, thus generating 1000 frames. (g) No constraints were imposed on the systems. The simulations were carried out in two phases: an initial period of heating from 0 to 300 K over 300 000 iterations (300 ps, i.e., 1 K/ps) and the monitored phase of 10 ns. The mentioned minimizations were carried out using the conjugate gradient algorithm until the rms gradient was smaller than 0.01 kcal mol^{-1} $Å^{-1}$. All calculations were carried out by Namd2.10,[24] with the force-field CHARMm v22 and Gasteiger's atomic charges.

HMGCoAR Activity Assay. HMGCoAR (catalytic domain), NADPH, assay buffer, and substrate solution were provided in the HMGCoAR assay kit (Sigma-Aldrich, St. Louis, MO, USA). The experiments were carried out at 37 °C following the manufacturer's instructions. In particular, each reaction (200 μL) was prepared by adding the reagents in the following order: 1X assay buffer; peptide **2** (at 100, 125, 150, and 250 μM), and peptide **3** (at 150, 175, 200, and 250 μM), or vehicle (C); NADPH (4 μL); substrate solution (12 μL); and finally HMGCoAR (2 μL). Subsequently, the samples were mixed, and the absorbance at 340 nm was read by a microplate reader (Synergy H1 from Biotek, Bad Friedrichshall, Germany) at 0 and 10 min. The HMGCoA-dependent oxidation of NADPH and the inhibition properties of soy peptides were measured by the absorbance reduction, which is directly proportional to enzyme activity.

Cell Line Culture. The HepG2 cell line was bought from ATCC (HB-8065, ATCC from LGC Standards, Milan, Italy). It was cultured in high-glucose DMEM with stable L-glutamine supplemented with 10% FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin (complete growth medium) and incubated at 37 °C under 5% CO_2 atmosphere. HepG2 cells were used for no more than 20 passages after thawing because the increase of passage number may change cell characteristics and impair assay results.

Western Blot Analysis. HepG2 (1.5×10^5 cells/well of a 24-well plate) were treated with peptides **2** and **3** (each 350 and 500 μM) for 24 h. After each treatment, cells were scraped in 40 μL of ice-cold lysis buffer (RIPA buffer + inhibitor cocktail + 1:100 PMSF + 1:100 Na-orthovanadate) and transferred in an ice-cold microcentrifuge tube. After centrifugation at 16 060 g for 15 min at 4 °C, the supernatant was recovered and transferred to a new ice-cold tube. Total proteins were quantified by the Bradford method, and 50 μg of total proteins were loaded on a precast 7.5% sodium dodecyl sulfate−polyacrylamide (SDS-PAGE) gel at 130 V for 45 min. Subsequently, the gel was pre-equilibrated with 0.04% SDS in H_2O for 15 min at room temperature (RT) and transferred to a nitrocellulose membrane (Mini nitrocellulose Transfer Packs), using a Trans-blot Turbo at 1.3 A and 25 V for 7 min. Target proteins on the milk-blocked membrane were detected by primary antibodies as follows: rabbit anti-SREBP2, anti-LDLR, anti-HMGCoAR, and anti-β-actin. Secondary antibodies conjugated with HRP and a chemiluminescent reagent were used to visualize target proteins, and their signal was quantified using the

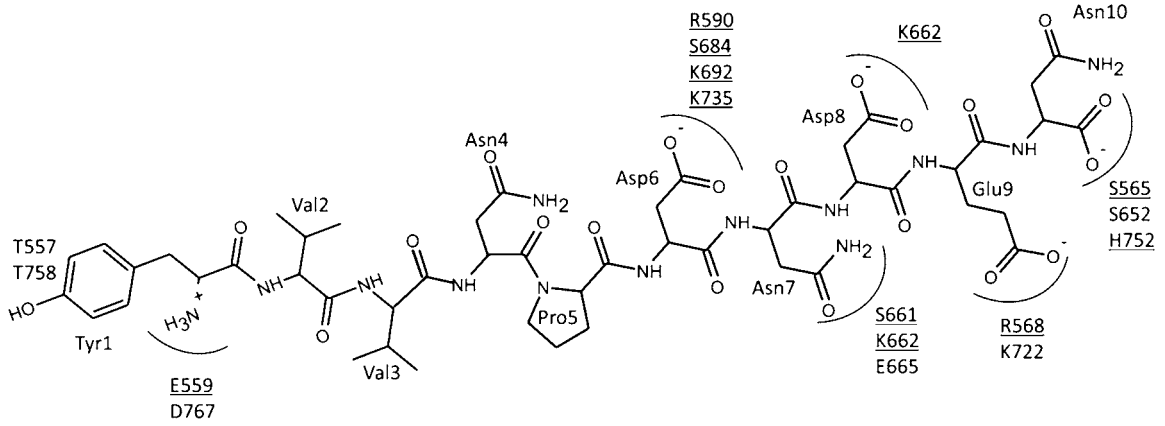

Figure 1. Bidimensional scheme reporting the key interactions stabilizing the putative complex for peptide **2**. The residues involved in the binding of the statin as found in the resolved crystal structure utilized here (PDB ID: 3CCZ) are underlined.

ImageJ Software. The internal control β-actin was used to normalize loading variations.

Fluorescent LDL Uptake Cell-Based Assay. A total of 3×10^4 HepG2 cells were seeded per well of 96-well plates and kept in complete growth medium for 2 days before treatment. On the third day, cells were treated with peptide **2** and **3** at the concentrations of 50 and 100 μM, respectively, or mock treatment (H_2O) for 24 h. At the end of the treatment period, the culture medium was replaced with 50 μL/well LDL-DyLight 550 working solution (Cayman Chemical Company, Ann Arbor, Michigan, USA). The cells were additionally incubated for 2 h at 37 °C; then, the culture medium was aspirated, washed, and replaced with PBS (100 μL/well). The degree of LDL uptake was measured using the Synergy H1 fluorescent plate reader from Biotek (excitation and emission wavelengths 540 and 570 nm, respectively).

Statistical Analysis. Statistical analyses were carried out by one-way ANOVA (Graphpad Prism 6) followed by Dunnett's test and/or *t* test. Values were expressed as means ± SEM; *P* values < 0.05 were considered to be significant.

RESULTS

Molecular Modeling Investigation. An in silico modeling study was undertaken to investigate the potential interaction of peptides **1**−**3** with the catalytic domain of HMGCoAR. Figure 1 shows a bidimensional scheme summarizing the key interactions stabilizing the putative complex between peptide **2** and the enzymatic cavity of HMGCoAR, whereas Figure S1A gives an overall view of the pose of peptide **2** within the HMGCoAR displayed by cartoon. Notably, most key polar interactions are elicited by the last five residues of the C terminus, whereas the first N-terminal residues are mostly involved in hydrophobic contact, with the exception of the N-terminal ammonium head, which is engaged in ionic interactions with Glu559 and Asp767, and the phenolic function of Tyr1, which stabilizes H bonds with Thr557 and Thr758. In detail, Asp6, Asp8, and Glu9 are engaged in an extended network of ion pairs involving the rich set of positively charged residues, which characterize the catalytic pocket of HMGCoAR and surround the C-terminal portion of the bound peptide, whereas the carboxyl terminus and Asn6 elicit only H bonds.

Figure 1 highlights (underlined) the residues stabilizing the key contacts with the peptide **2** that were also found to be involved in the stabilization of the experimentally resolved complex between HMGCoAR and a statin. Notably, the underlined residues mostly interact with the negatively charged C-terminal portion of peptide **2**, thus confirming that this segment is primarily involved in the inhibition of HMGCoAR by mimicking most of the polar interactions already seen for the binding of the statin polar moieties. In contrast, the hydrophobic N-terminal portion is inserted in a deeper and rather apolar subpocket that does not match that accommodating the statin hydrophobic moieties but rather roughly corresponds to that harboring the NADPH cofactor. Indeed, the statin polar groups interact with the residues contacting the HMG groups, whereas the statin apolar moieties are accommodated in the apolar subpocket interacting with the pantothenic acid moiety of CoA, and no region of the NADP(H) binding site is engaged by statins. Here, a different arrangement is observed because the hydrophobic portion of peptide **2** is partly accommodated in the elongated binding cavity of the cofactor, thus suggesting that it may also affect the NADPH binding. Similar docking simulations of peptide **3** revealed that the mutation Asp8 into Asn8 does not markedly affect the interaction pattern because Asn8 elicits H bonds with Lys662 (already seen for peptide **2**) and Glu665 (complex not shown).

Figure S1B shows the pose of peptide **1** and suggests the β-hairpin motif stabilized by several intramolecular polar contacts, among which the salt bridge between the two ionized termini has a key role in determining such a folded structure. Figure S1B also reveals that this longer peptide is accommodated within a more superficial region of the binding cavity compared to peptide **2**, and its inhibition can be due to a sort of lid mechanism involving additional regions adjacent to the rim of the catalytic pocket.

Figure S2 is a schematic representation of the key contacts stabilizing the putative complex as computed for the longer peptide **1**. Similar to what was seen for the shorter derivative, Figure S2 reveals that the conserved portion between Asp15 and Asn19 is involved in the key polar interactions with the ionizable residues lining the HMGCoAR binding cavity. Apart from Arg21, which stabilizes two ion pairs with Glu559 and Asp767, the remaining residues are generally engaged in an extended network of intramolecular and intermolecular hydrophobic contacts that contribute to the overall stabilization of the obtained complex. Remarkably, there are some residues (highlighted in green), especially in the N-terminal region, that are exclusively involved in intramolecular contacts. One may imagine that such intramolecular interactions can play a dual role because they stabilize the folded conformation and shield some unfit side chains, thus minimizing potential repulsing

DOI: 10.1021/acs.jafc.5b03497
J. Agric. Food Chem. 2015, 63, 7945−7951

contacts with surrounding enzyme residues (as in the case of Arg2).

A primary objective of the MD simulations thus carried out was to assess the stability of the computed complexes. Hence, Figure 2 compares the rmsd values of the two bound peptides

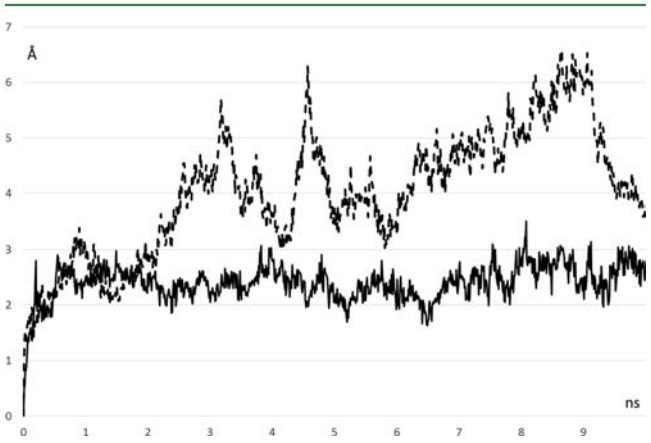

Figure 2. Rmsd profiles for the simulated peptides bound to the enzyme as derived by MD runs considering the backbone atoms only (solid black line = peptide **1**, dashed black line = peptide **2**).

as computed during the MD runs considering only the backbone atoms. It reveals two markedly different profiles because peptide **2** shows a low and rather constant profile, which is suggestive of a very stable complex in which most residues are tightly involved in key contacts. Figure S3A reports the rmsd values as dissected per residue and computed considering all atoms and confirms the key role of the ionized residues, which indeed remains nearly fixed during all the MD run.

In contrast, peptide **1** shows a higher and more variable profile, which may suggest that not all residues are equally involved in the key contacts and that some portions of peptide **1** conserve a notable mobility even within the HMGCoAR binding cavity. To better investigate this finding, Figure S3B shows the rmsd values as dissected per residue and reveals a significant variability between the thus-computed rmsd values in line with the number of polar contacts elicited by each residue. In detail, Figure S3 confirms that the region between Asn13 and Arg21 plays a key role in complex stabilization and indeed remains stably bound to the enzyme, whereas the segment between Ala5 and Val12 is engaged at most in apolar contacts and is arranged in a more superficial region of the HMGCoAR binding cavity, thus conserving a marked mobility during the MD simulation. The two terminal segments show an intermediate flexibility probably due to the ionic contact between the two terminal ionized groups. Overall, these results suggest that the computed pose of peptide **1** is stable even though a such an extended peptide cannot be completely stabilized within the enzyme catalytic site, thus explaining the observed residual flexibility.

The satisfactory stability of the two simulated complexes is further confirmed by the dynamic profile of some representative contacts as derived from MD runs and compiled in Table 1. Indeed, the reported distance values emphasize that most key ionic contacts are completely stable because the corresponding distances are comprised in very narrow ranges.

Peptides 2 and 3 Inhibit the HMGCoAR in Vitro. The experimental characterization of the molecular mechanism

through which peptides **2** and **3** may potentially mediate a hypocholesterolemic effect was carried out in two steps: first, evaluating their capacity to inhibit the catalytic activity of HMGCoAR; second, investigating in HepG2 cells how they modulate cholesterol metabolism and modify the LDL uptake. To confirm that indeed peptides **2** and **3** inhibit the catalytic activity of HMGCoAR as their main molecular target, an in vitro assay was carried out using the purified catalytic domain of this enzyme. A concentration range from 100 and 250 μM was tested. Each peptide inhibited HMGCoAR activity in a dose-dependent manner, with an IC_{50} of about 150 and 200 μM for peptides **2** and **3**, respectively (Figure 3). On the basis of these results, we decided to treat HepG2 cells in the following experiments at slightly higher concentrations, i.e., 350 and 500 μM.

Peptides 2 and 3 Induce the LDLR-SREBP2 Pathway. To verify the consequences of the HMGCoAR inhibition activity exerted by peptides **2** and **3** on the modulation of the LDLR-SREBP2 pathway, HepG2 cells were treated with both peptides at the concentrations of 350 and 500 μM, and each sample was investigated with immunoblotting experiments. Figure 4A–D shows that the treatment with each peptide induced an up-regulation of the N-terminal fragment of the SREBP2 protein level (mature form with a molecular weight of 68 kDa). In particular, peptide **2** up-regulated the mature SREBP2 protein level by 134.0 ± 10.5 and 141.1 ± 18.0% at 350 and 500 μM, respectively, whereas peptide **3** up-regulated the mature SREBP2 protein level by 158.0 ± 9.2 and by 155.2 ± 14.6% at 350 and 500 μM, respectively, versus the untreated sample.

In the same experiments, the LDLR and HMGCoAR protein level variations were also measured by immunoblotting (Figure 4B,C). All peptides increased the LDLR and HMGCoAR protein levels, in agreement with their capacity to up-regulate the transcriptional active SREBP2 fragment (mature-SREBP2) protein level. In particular, peptide **2** increased the LDLR protein level by 152.0 ± 20.0 and 167.0 ± 31.7% and peptide **3** by 164.0 ± 17.9 and 182.2 ± 41.8% versus the untreated sample at 350 and 500 μM, respectively (Figure 4E). Peptide **2** enhanced the production of the HMGCoAR protein by 171 ± 29.9 and by 187 ± 34.6% versus the untreated sample at 350 and 500 μM, respectively, whereas peptide **3** induced an

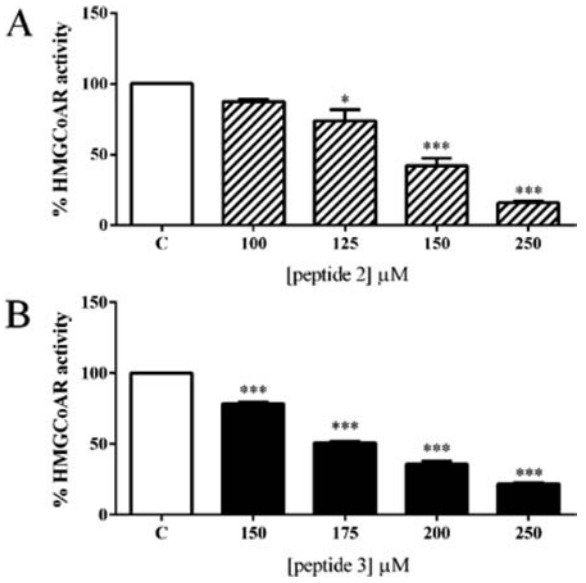

Figure 3. Effects of peptides **2** and **3** on the catalytic domain of HMGCoAR. Bars indicate the effects on the HMGCoAR activity of (A) peptide **2** (100, 125, 150, and 250 μM) and (B) peptide **3** (150, 175, 200, and 250 μM). The HMGCoAR physiologically catalyzes the four-electron reduction of HMGCoA to coenzyme A (CoA) and mevalonate (HMGCoA + 2NADPH + $2H^+$ → mevalonate +$2NADP^+$ + CoA-SH). In this assay, the absorbance decrease at 340 nm, which represents the oxidation of NADPH by the catalytic subunit of HMGCoAR in the presence of the substrate HMGCoA, was measured spectrophotometrically. The data points represent the averages ± SEM of three independent experiments in triplicate. *, $P < 0.05$, and ***, $P < 0.0001$ vs C. C = untreated samples.

increase of the HMGCoAR protein by 170 ± 50.0 and by 177.0 ± 40.5% versus the untreated sample at 350 and 500 μM, respectively (Figure 4F).

Peptides 2 and 3 Increase HepG2 Ability to Uptake Extracellular LDL. Fluorescent LDL uptake experiments permitted us to evaluate the change of the functional capability of HepG2 cells to uptake extracellular LDL after treatment with these peptides. As shown in Figure 5, each peptide is able to

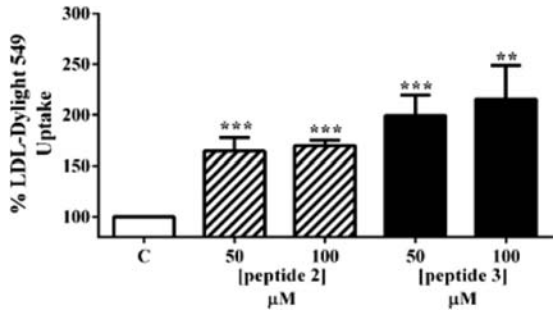

Figure 5. LDL uptake after peptide **2** and **3** treatments. HepG2 cells (3×10^4) were treated with 50 and 100 μM of each peptide for 24 h. LDL-Dylight 549 (10.0 μg/mL) was then incubated for additional 2 h. Excess of LDL-Dylight 549 was removed, cells washed twice with PBS, and specific fluorescent LDL-uptake analyzed by Synergy H1 (Biotek). The data points represent the averages ± SEM of three independent experiments in triplicate. **, $P < 0.001$, and ***, $P < 0.0001$, vs C. C = untreated sample.

increase the LDL uptake versus the untreated sample in a statistically significant way. In fact, the treatments with peptide **2** and **3**, at concentrations of 50 and 100 μM, led to an increase of the LDL uptake by 64 ± 29.9 and 70 ± 14.4% and 100 ± 53.1 and 215 ± 88.1%, respectively, versus the untreated sample.

DISCUSSION

Recently, our research group is dedicating much effort to investigate the potential bioactivity of plant food peptides[13,17,25] because this is a very promising area in functional foods.[26−28] In the framework of research aimed at investigating and characterizing the hypocholesterolemic effects of soy peptides, we have recently studied the mechanism of action through which three peptides from soy glycinin exert their hypocholesterolemic effects in HepG2 cells.[19] Unfortunately, the relevant

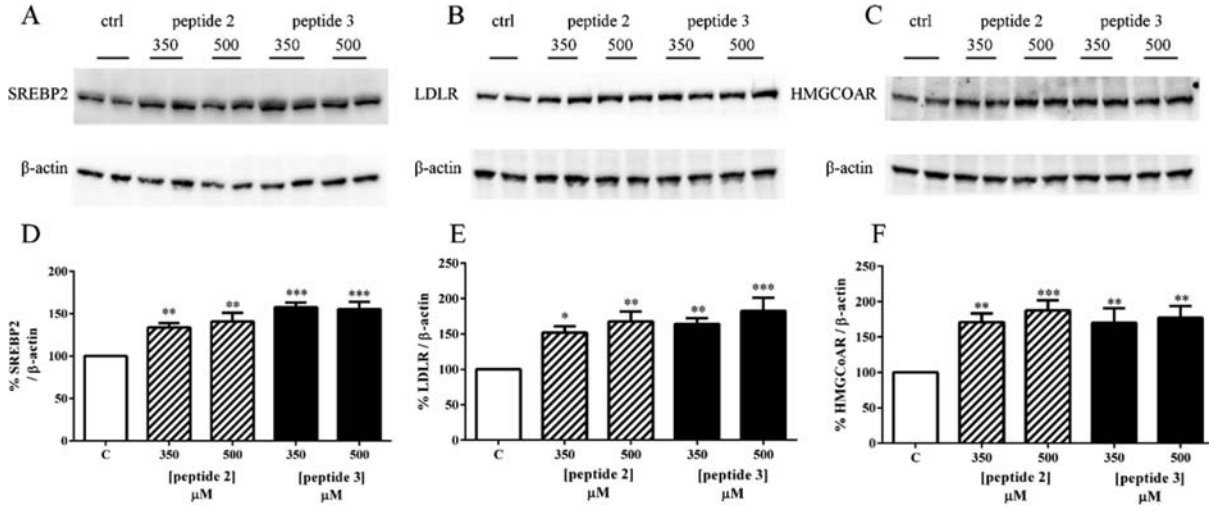

Figure 4. Effects of peptides **2** and **3** on the SREBP2, LDLR, and HMGCoAR protein levels. HepG2 cells (1.5×10^5) were treated with 350 and 500 μM of each peptide for 24 h, respectively. (A−C) SREBP2, LDLR, HMGCoAR, and β-actin immunoblotting signals were detected using specific anti-SREBP2, anti-LDLR, anti-HMGCoAR, and anti-β-actin primary antibodies, respectively. (D) SREBP2, (E) LDLR, and (F) HMGCoAR signals were quantified by ChemiDoc Image Lab (Biorad) and normalized with β-actin signals. Bars represent the averages of duplicate samples ± SEM of three independent experiments. *, $P < 0.05$, **, $P < 0.001$, and ***, $P < 0.0001$ vs C. C = mock treatments.

J. Agric. Food Chem. 2015, 63, 7945−7951

issue of the actual absorbability and bioavailability of those peptides in the gut remained unsolved.[16] The present research represents a main progress in respect to that paper because peptides **2** and **3** are very likely to be bioavailable.[22]

Another important aspect of this work is that it provides new information on peptide **1**, which has been shown to modulate LDL uptake and degradation in HepG2 cells about 15 years ago,[7] without any further verification of a direct interaction with HMGCoAR either in vitro or in silico. Our modeling study shows that the interaction of this peptide with HMGCoAR is partially impaired by its excessive length, whereas the interaction with the shorter peptide **2** encrypted in peptide **1** is much more favorable. Thus, it seems possible to hypothesize that peptide **2** may be the active part of peptide **1**.

The computational study emphasizes that a suitable HMGCoAR inhibitor should combine a negatively charged portion (residues DNDEN in peptide **2**) that mimics the HMGCoAR substrate with a more hydrophobic portion (residues YVVNP in peptide **2**). It is useful to underline that a similar situation is also observed in statins but with some differences because the statin apolar moieties mimic the pantothenic acid of coenzyme A, whereas the hydrophobic regions of these soy peptides appear to be inserted in the cofactor binding cavity.[20,21]

The in vitro experiments aimed at assessing whether peptides **2** and **3** are direct inhibitors of HMGCoAR have demonstrated for the first time that indeed these peptides, deriving either from the α or α' subunits of β-conglycinin, are able to act as competitive inhibitors of HMGCoAR with a statin-like behavior, in agreement with the in silico investigation.

The studies carried out on human hepatic cells have shown that either peptide **2** or **3** is able to modulate cholesterol metabolism. In particular, the functional results suggest that the improved capability of HepG2 cells to uptake the LDL is strictly correlated with the molecular increase of the intracellular LDLR protein levels induced by these peptides upon inhibition of the HMGCoAR activity. The outcomes of these experimentations, i.e., increase of LDLR protein levels through activation of SREBP2 and enhanced cell capacity to uptake LDL cholesterol, appear to be perfectly in line with the behavior of three soy glycinin peptides, i.e., IAVPGEVA, IAVPTGVA, and LPYP, recently investigated by us.[19] In practice, we have demonstrated that the hypocholesterolemic effects can be exerted by peptides deriving from hydrolysis of either β-conglycinin and glycinin, in contrast to what has been indicated in the past.[11]

To our knowledge, this is the first work showing the molecular mechanism through which two conglycinin peptides modulate the cholesterol pathway in HepG2 cells. It may indicate how these bioavailable peptides function in cholesterol homeostasis in the liver.

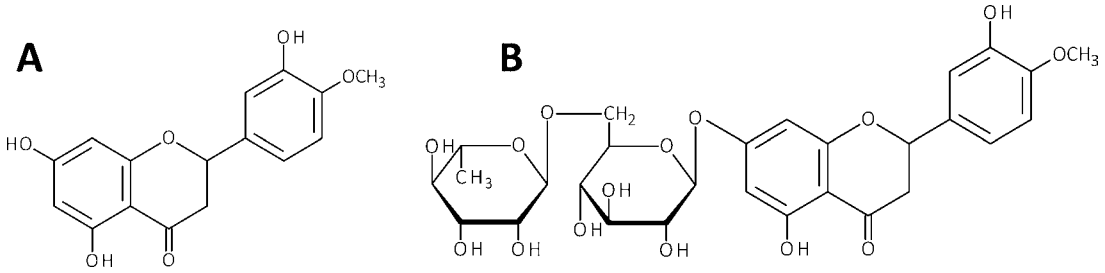

Figure 1. Chemical structures of (A) hesperetin and (B) hesperidin (hesperetin-7-*O*-rutinoside).

Table 1. Percentage Composition of Experimental Diets[a]

	control	0.5% hesperetin	1.0% hesperidin
casein	20	20	20
DL-methionine	0.3	0.3	0.3
corn starch	55	55	55
sucrose	10	10	10
corn oil	5.0	5.0	5.0
cellulose powder	5.0	4.5	4.0
mineral mix	3.5	3.5	3.5
vitamin mix	1.0	1.0	1.0
choline bitartrate	0.2	0.2	0.2
hesperetin	–	0.5	–
hesperidin	–	–	1.0

[a]Source of ingredients: casein, corn starch, sucrose, cellulose powder, mineral AIN-76 mix, and vitamin AIN-76 mix (Oriental Yeast Co., Ltd., Tokyo, Japan); DL-methionine and choline bitartrate (Wako Pure Chemical Industries, Ltd., Osaka, Japan).

(16.4 mmol/kg diet). The rats had free access to tap water and the experimental diets for 3 weeks. Food intake and body weight were determined three times weekly. All feces were collected during the third week of the feeding period and stored at −40 °C until further processing. At the end of the experiment, rats were sacrificed by drawing blood from the heart under diethyl ether anesthesia. Cecum and abdominal adipose tissues were immediately excised and weighed. The cecum content was stored at −40 °C until use. This study was approved by the Animal Research Committee of Tokyo Kasei Gakuin University, and all experimental procedures followed the guidelines for the care and use of experimental animals.

Determination of Fecal Bacterial 16S rRNA Gene Copy Number. Before analysis, all fecal samples collected for a week were freeze-dried and ground by a grinder mill (type TML161, Tescom Co., Ltd., Tokyo, Japan). DNA was extracted according to the method of Tanigawa et al.[14] The bacterial 16S copy number was calculated from the standard curve of known bacterial 16S copy number by quantitative real-time PCR of 16S rRNA gene using 341f (5′-CCTACGGGAGGCAGCAG-3′) and 534r (5′-ATTACCGCGGCT-GCTGG-3′) primers.[15] Amplification reactions were performed by a Rotor-Gene Q apparatus (Qiagen, Germany) using the SYBR Premix Ex *Taq*II (Tli RNaseH Plus, Takara Bio, Shiga, Japan).

Fecal Microbial Composition Analysis. Fecal samples of rats were analyzed by targeting the bacterial 16S rRNA genes using a terminal restriction fragment length polymorphism (T-RFLP) technique according to the procedure described by Nagashima et al.[16] The fluorescently labeled primers 516f (5′-TGCCAGCAGCCG-CGGTA-3′) and 1510r (5′-GGTTACCTTGTTACGACTT-3′) were used to amplify the 16S rRNA genes. The purified PCR products were digested with the restriction enzyme *Bsl*I (New England BioLabs Japan, Inc., Tokyo, Japan). The length of the terminal restriction fragments was determined using an automated sequence analyzer (ABI PRISM 3130xl DNA Sequencer, Applied Biosystems, Carlsbad, CA, USA). The abundance of each terminal restriction fragment was determined on the basis of fluorescence intensity using the software GeneMapper ver. 4 (Applied Biosystems). Fragment sizes were assigned to categories of operational taxonomic units (OTU). The OTU data were used to identify the phylotypes by matching to those predicted from various phylotypes in the literature.[16]

Analyses of SCFA in Cecum Content. The SCFA (acetic, propionic, and butyric acids) in the homogenate of cecum content were derivatized with 2-nitrophenylhydrazine hydrochloride in the presence of 1-ethyl-3-(3-(dimethylamino)propyl)carbodiimide hydrochloride and were measured by a high-performance liquid chromatography (HPLC) system.[17] The derivatives were separated using a reversed-phase column (type FA, 6.0 mm × 250 mm, YMC Co., Ltd., Kyoto, Japan) with an acetonitrile/methanol/water (30:16:54, v/v/v) mobile phase at the flow rate of 1.2 mL/min and were detected with a variable-wavelength monitor with the absorbance set at 400 nm.

Analyses of Starch and Proteins in Feces. The concentrations of undigested starch in the feces were determined after hydrolysis with thermostable α-amylase and amyloglucosidase, followed by a determination of the released glucose using an enzymatic colorimetric assay kit (Glucose CII-test, Wako Pure Chemical Industries, Ltd.).[18] Results were corrected to a starch basis by multiplying them by 0.9. Total fecal nitrogen was determined by Kjeldahl's method,[19] and results were multiplied by 6.25 to calculate the amount of protein in the feces.

Analyses of HP and HD in Feces. The flavonoids were extracted with the mixture of dimethyl sulfoxide and methanol (1:1, v/v).[3] One hundred milligrams of the ground fecal samples was sonicated three times with 3 mL of the extraction solvent for 1 min (Branson Ultrasonics, Ltd., Danbury, CT, USA). After centrifugation at 1000*g* for 10 min, the supernatants were combined, and the volume of combined extracts was adjusted to 10 mL. After a 10-fold dilution, the resulting extract was filtered with a 0.45 μm membrane filter and was injected into the HPLC system. The flavonoids were separated using a reversed-phase column (type Unison UK C_{18}, 4.6 mm × 150 mm, Imtakt Co., Kyoto, Japan) by a two-solvent linear gradient program from initially acetonitrile/water/phosphoric acid (10:90:0.05, v/v/v) to finally acetonitrile/water (80:20, v/v) in 20 min at the flow rate of 0.8 mL/min. The flavonoids were detected at UV 285 nm.

In Vitro Pancreatic α-Amylase Inhibition. Porcine pancreatic extract was suspended in 20 mM phosphate buffer (pH 6.9) containing 6 mM sodium chloride. The reaction mixture was composed of 0.1 mL of the various concentrations of test samples, 0.7 mL of 10 mg/mL soluble starch, and 0.1 mL of 0.1 mg/mL porcine pancreatic extract and was incubated at 37 °C for 30 min. The reaction was terminated by adding 1.0 mL of acetonitrile. After centrifugation at 2000*g* for 10 min, the supernatant was filtered with a 0.45 μm membrane filter. The liberated maltose levels in the filtrate were measured by the HPLC system with a refractive index detector. Separation was carried out by using an amino-bonded silica column (type Unison UK-amino, 4.6 mm × 150 mm, Imtakt Co.) with an acetonitrile/water (80:20, v/v) mobile phase.

Statistical Analysis. All data are shown as the mean ± standard deviation (SD). The bacterial 16S rRNA gene copy numbers were converted into logarithm values before the statistical analysis. Significant differences among the groups were determined by one-way ANOVA, followed by Tukey's test, using a commercial software package (GraphPad Prism 5 for Windows, GraphPad Software, Inc., San Diego, CA, USA). Differences were considered significant at $P < 0.05$.

RESULTS

Body Weight Gain and Organ Weights. There were no differences among the groups in food intake or body weight gain during the 3 week experiment (Table 2). Averaged daily intakes of HT and HD were 0.40 g (1.34 mmol) and 0.83 g (1.36 mmol) per kilogram of body weight. The rats fed the HT diet had a lower weight of abdominal adipose tissues (the mass of mesenteric, perirenal, and epididymal adipose tissues) compared with those fed the control diet. The HT diet led to a significant increase in the weight of cecum content, whereas the HD group showed no differences with the control group.

Table 2. Food Intake, Body Weight Gain, and Organ Weights in Rats Fed the Experimental Diet for 3 Weeks[a]

	control	0.5% hesperetin	1.0% hesperidin
food intake (g)	471 ± 3	459 ± 14	464 ± 11
initial body wt (g)	136 ± 8	136 ± 8	137 ± 8
final body wt (g)	291 ± 11	291 ± 7	289 ± 11
body wt gain (g)	155 ± 7	155 ± 3	152 ± 11
liver wt (g)	13.6 ± 3.5	12.5 ± 1.4	11.4 ± 0.7
abdominal adipose tissue[b] (g)	12.8 ± 2.1 b	10.4 ± 1.6 a	12.1 ± 1.5 ab
mesenteric	3.5 ± 0.7	3.1 ± 0.2	3.6 ± 0.4
perirenal	4.2 ± 0.9	3.5 ± 1.0	4.2 ± 0.7
epididymal	5.1 ± 1.1 b	3.8 ± 0.5 a	4.4 ± 0.7 ab
cecum content wt (g)	2.2 ± 0.6 a	3.4 ± 0.9 b	2.7 ± 0.5 ab

[a]Values are the mean ± SD (n = 7). Treatments with different letters are significantly different (P < 0.05). [b]Sum of the mass of mesenteric, perirenal, and epididymal adipose tissues.

Fecal Microbiota. The dry weight of feces collected during the third week of the feeding period did not show statistical significances among the groups (Table 3). Changes in the bacterial 16S rRNA gene copy number and composition in the feces of five randomly selected rats of each group are shown in Table 4. There was no significant difference in the copy numbers of 16S rRNA gene of all bacteria among the groups. After 3 weeks of feeding, the taxonomic composition of the fecal microbiota significantly differed among the groups. In the control rats, the T-RFLP analysis revealed that the order of *Clostridium* was the most predominant group, followed by *Lactobacillales*. The fecal microbiota of rats that received HT in their diet presented a remarkable alteration in the proportion of *Clostridium*. In particular, feeding the HT diet resulted in a significant decrease in the ratio of *Clostridium* subcluster XIVa in the fecal microbiota compared to other diets. In contrast, the feces of rats fed the control diet displayed very low proportions of *Clostridium* clusters IV and XVIII, but the HT diet significantly increased their ratios. Treatment with HT in the diet slightly affected the abundance of *Bifidobacterium* and *Lactobacillales*, although these results did not reach significance.

Table 3. Fecal Excretions of Starch, Protein, Hesperetin, and Hesperidin in Rats Fed the Experimental Diets[a]

	control	0.5% hesperetin	1.0% hesperidin
dry wt[b] (g/7 days)	14.4 ± 0.5	14.3 ± 1.1	13.5 ± 1.5
fecal nutrient			
starch (mg/7 days)	65 ± 2 a	91 ± 36 b	61 ± 5 a
protein (g/7 days)	1.4 ± 0.2	1.6 ± 0.2	1.5 ± 0.1
fecal flavonoid			
hesperetin (mmol/7 days)	–	0.9 ± 0.3	1.1 ± 0.6
hesperidin (mmol/7 days)	–	–	0.4 ± 0.1

[a]Values are the mean ± SD (n = 7). Treatments with different letters are significantly different (P < 0.05). [b]Collected during the third week of experimental diet feeding period.

Table 4. Effect of Dietary Hesperetin and Hesperidin on the Profile of Microbiota in Feces of Rats[a]

	control	0.5% hesperetin	1.0% hesperidin
16S rRNA Gene Copy Number (log_{10} Copies)			
all bacteria (per g dry feces)	12.0 ± 0.1	12.2 ± 0.1	12.1 ± 0.1
all bacteria (per 7-day dry feces)	13.2 ± 0.1	13.4 ± 0.1	13.3 ± 0.1
Ratio of Peak Area of Each OTU[b]

[a]Values are the mean ± SD (n = 5). Treatments with different letters are significantly different (P < 0.05). [b]Values are expressed as percentages of the peak area of a particular OTU to the total peak area of all OTUs.

Amount of Starch and Proteins in Feces. Little starch was excreted in the feces of rats fed the control diet, whereas the feces of rats fed the HT diet contained a significant amount of starch (Table 3). However, the HD diet had little impact on the fecal starch level. Both treatments with HT and HD did not lead to significant differences in protein excretions in the feces as compared with the control.

Cecal SCFA Pools. Figure 2 summarizes the cecal SCFA pools in rats fed the different experimental diets. Feeding the HT diet resulted in significant increases in the cecal pools of acetic and butyric acids as compared to the control, but treatment with the HD diet did not yield significantly different results compared with the control. The additions of these flavonoids to the diet had little influence on the cecal pool of propionic acid.

Fecal Excretions of HT and HD. Parts of dietary HT and HD were excreted in the feces in unchanged forms. Feces collected during the third week of feeding contained 0.9 mmol of HT in the 0.5% HT diet group and 0.4 mmol of HD in the 1.0% HD diet group (Table 3). Because the rats consumed 2.7 mmol of HT or HD from their respective diet, 33 and 15% were estimated to be excreted in the feces in the unchanged form, respectively. In addition, the feces collected from the rat fed the 1.0% HD diet also contained 1.1 mmol of HT.

Inhibition of Pancreatic α-Amylase in Vitro. HT inhibited the enzyme activity of porcine pancreatic α-amylase in a concentration-dependent manner (Figure 3), but HD lacked the inhibitory activity for α-amylase.

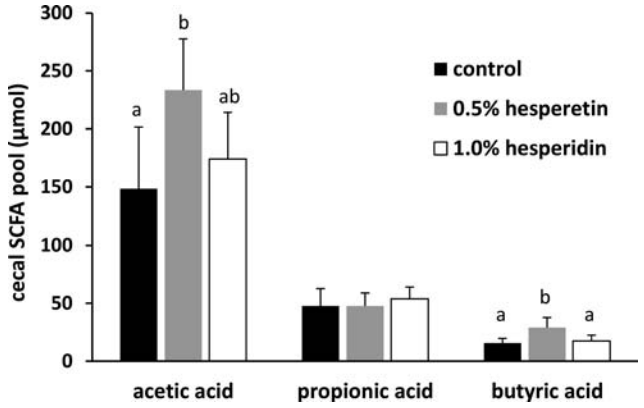

Figure 2. Effects of dietary supplementations of hesperetin and hesperidin on the cecal SCFA pool. The cecal SCFA pool (μmol) = SCFA concentration (μmol/g) × cecum content (g). Values are the mean ± SD (n = 7). Statistical comparisons were performed using one-way ANOVA with Tukey's post hoc test. Treatments with different letters are significantly different (P < 0.05).

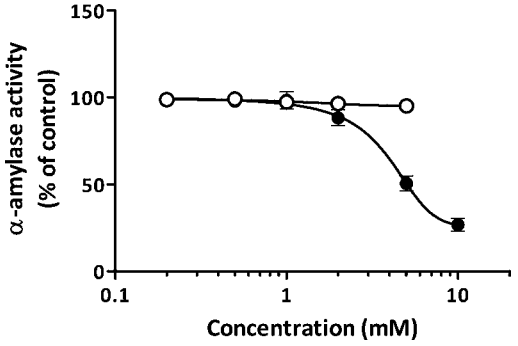

Figure 3. Dose-dependent inhibition of hesperetin against pancreatic α-amylase activity. Data are the mean ± SD from triplicate measurements. Open circles and solid circles indicate hesperidin and hesperetin, respectively.

DISCUSSION

It is well recognized that the structure and activity of microorganisms inhabiting our gut are influenced by dietary intake. Such diet-induced changes in gut microbial communities could be responsible for the development of metabolic disorders. It is of current interest that dietary polyphenols raise a possibility for modulating the composition of intestinal microorganisms and the formation of fermentation end products, which may be involved in their underlying mechanisms for beneficial health effects. Citrus flavonoids exhibit a range of biological activities and beneficial health effects.[20] In a type 2 diabetes animal model, dietary supplementation of 1% (w/w) HD resulted in decreases in blood glucose and serum triacylglycerols.[21] This study aimed to evaluate the impact of dietary supplementation with two types of citrus flavonoids on the structure and activity of gut microbiota in rats, in relative relation to the presence of sugar moiety to the flavonoid skeleton.

The rats consumed the respective experimental diets that were supplemented with equimolar concentrations of HT and HD. Compared to the control diet, feeding the 0.5% HT diet resulted in a significant increase in starch excretion in the feces. This finding let us understand that dietary HT could interfere with starch digestion in the small intestine, leading to the influx of undigested starch into the large intestine. Indeed, the result of in vitro experiments offers supporting evidence that HT had an inhibitory effect against pancreatic α-amylase in a concentration-dependent fashion. Parts of the starch undigested in the small intestine can then be microbially hydrolyzed to monosaccharides in the cecum (rodents) and colon (humans), where they are further degraded into biologically active metabolites represented by SCFA.[22] It is commonly understood that the growth of pathogenic microorganisms could be inhibited by reducing luminal pH with more SCFA productions, eventually increasing the growth and/or activity of beneficial bacteria.[23] Feeding the HT diet raised the proportion of *Bifidobacterium* and the *Lactobacillales* to a lesser extent, but there were no significant changes. In addition, it is worth noting that HT served to modulate the abundance of *Clostridium* spp. Particularly, the present study demonstrated that the proportion of *Clostridium* subcluster XIVa in the feces was significantly decreased by the HT diet as compared to the control diet. Similar results were observed in several previous studies in relation to polyphenols from red wine,[24] grape seed extracts,[25] and green tea.[26] Likewise, feeding a diet abundant in resistant starch can reduce the proportion of *Clostridium* cluster XIVa in the luminal contents of pig colon.[27] Resistant starch is a type of dietary fiber that is highly fermentable by colonic bacteria, resulting in the production of SCFA; an acidified condition for the lumen of the large intestine may be involved in reducing the proportion of *Clostridium* subcluster XIVa. In the light of increased levels of SCFA in rat cecum content by feeding the HT diet, it seems reasonable to suppose that dietary HT had some degree of influence in modulating the proportion of *Clostridium* subcluster XIVa through the stimulation of SCFA production.

The close associations among the energy harvest from foods, the development of obesity, and the microbial population inhabiting the intestinal tract are becoming clearer. Obese mice had an increased abundance of bacteria from the *Firmicutes* phylum,[28] the main constituents of which were *Clostridium* cluster IV (mainly *Clostridium* leptum group) and *Clostridium* cluster XIVa (mainly *Clostridium* coccoides group).[29] It is known that *Clostridium* cluster XIVa was substantially increased by high-fat diet feeding, but was reduced by antibiotic treatment.[30] There is evidence that an obesity treatment program comprising a calorie-restricted diet and physical activity over 3 months had an impact on the decreased abundance of the *Clostridium* cluster XIVa on the structure of the fecal microbiota of overweight and obese subjects.[31] Furthermore, vegetarians had a decreased relative abundance of *Clostridium* cluster XIVa bacteria compared with omnivores.[32] In this light, alteration of microbial ecology by HT may be of relevance to a significant reduction of abdominal adipose tissue weights of rats. In addition, it is interesting to note that SCFA themselves regulate the balance among fatty acid synthesis, fatty acid oxidation, and lipolysis in the body.[10] SCFA formed by colonic bacterial fermentation enter the blood circulation from the intestine and are taken up by tissues, where they function as signal molecules. GPR41 and GPR43 have been identified as SCFA receptors. SCFA activate the sympathetic nervous system by stimulating GPR41 in sympathetic ganglia, leading to an increase in energy expenditure.[33] SCFA-mediated activation of GPR43 suppresses insulin signaling in adipocytes and thereby inhibits fat accumulation in adipose tissues.[34] Regulation of the energy metabolism by SCFA may also contribute in a practical way to the loss of body fat in rats fed the HT diet. The present study

DOI: 10.1021/acs.jafc.5b02649
J. Agric. Food Chem. 2015, 63, 7952−7957

also demonstrated that a significant increase in the excretion of starch in the feces was promoted by the dietary addition of HT. Needless to say, an increased energy loss originating from starch in the feces may at least partially influence the body fat reduction by HT.

The present study exhibited considerably different results between HT and HD. The HT diet affected the excretion of starch in the feces and the pools of SCFA in the cecum content, but the HD diet did not. The inhibitory effect of HT on starch digestion was stronger than that of HD. That is to say, the attachment of the rutinose moiety to the flavanone structure can diminish the effectiveness. Limiting the pancreatic α-amylase activity in the small intestine must be the key to producing SCFA in the large intestine. Although certain types of bacterial strains produced amylolytic enzymes in the intestine,[35] it remains to be seen that HT may have an effect on the production and activity of microbial α-amylase. Furthermore, HT also affected the proportion of *Clostridium* subcluster XIVa in rat feces, but HD did not. Because the feces collected from the rat fed the HD diet contained a significant amount of HT, dietary HD reached the large intestine, where the glycosidic linkage of HD was hydrolyzed to generate HT. Given that both treatments yielded the same compound in the large intestine, it is likely that the modulation of gut microbiota only by the HT diet may be a consequential result of the stimulation of SCFA productions in the large intestine, as is the case with resistant starch. Besides, we must keep constantly in mind the fact that the large intestine is a very active site for the microbial catabolism of HT, leading to further degradation of the flavanone skeleton. Such transformations could be mainly due to the genera of *Clostridium* spp. in the colon.[36]

In conclusion, the present study provides detailed insights into the effects of dietary HT on the composition of gut microbiota and the cecal pools of SCFA in rats and may lead to design strategies for functional foods that aim to reduce the risk of obesity in humans. More research also is needed to further elucidate in more depth the underlying molecular mechanisms of dietary polyphenols as well as their microbial metabolites to modulate the composition and activity of gut microbiota and the link to the antiobesity effect.

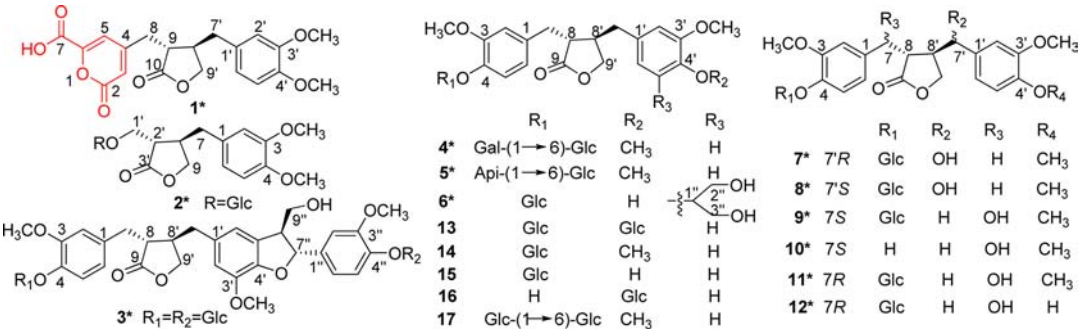

Figure 1. Structures of compounds **1**−**17**.

Extraction and Isolation. Air-dried mature fruits (100 kg) of *A. lappa* L. were extracted with 80% EtOH (3 × 600 L) under reflux three times. The solvent was evaporated under reduced pressure. Then, the residue (4.2 kg) was suspended in H_2O (10 L) and extracted with EtOAc (3 × 10 L). The aqueous layer (400 g) was subjected to an HP-20 macroporous adsorbent resin (4000 g) column and eluted with H_2O (20 L), 15% EtOH (20 L), 30% EtOH (20 L), 50% EtOH (20 L), and 95% EtOH (10 L), which yielded five corresponding fractions (fractions A−E).

Fraction C (86.4 g) was submitted to flash chromatography with a C_{18} column (55 × 8 cm, 20 μm), eluting with a 10-step gradient of MeOH/H_2O (2 L for one step, from 0:100 to 100:0) to provide 13 fractions (fractions C1−C13). Fraction C11 (301 mg) was separated on a Sephadex LH-20 (100 g) column, eluting with H_2O (1.2 L) to yield four fractions (fractions C11-1−C11-4). Then fraction C11-1 (25 mg) was further purified by reverse-phase preparative HPLC, eluting with MeOH/H_2O (25:75) at a flow rate of 5 mL/min to afford **1** (5 mg, 48 min). Fraction C12 (812 mg) was separated on a Sephadex LH-20 column (H_2O, 1.5 L) and then further purified by reverse-phase preparative HPLC, eluting with MeOH/H_2O (40:60) at a flow rate of 5 mL/min to afford **2** (27 mg, 45 min), **12** (5 mg, 51 min), and **13** (33 mg, 32 min). Fraction C13 (1.695 g) was subjected to a Sephadex LH-20 column and eluted with H_2O (2 L) to give eight fractions (fractions C13-1−C13-8). Purification of fraction C13-3 (97 mg) with MeOH/H_2O (30:70) on reverse-phase preparative HPLC at a flow rate of 5 mL/min afforded **6** (10 mg, 37 min) and **7** (13 mg, 49 min). Fraction C13-5 (255 mg) was applied successively to chromatography on Sephadex LH-20 (H_2O, 1.2 L) to yield six fractions (fractions C13-5-1−C13-5-6). Compound **14** (100 mg, 57 min) was obtained from fraction C13-5-3 (188 mg) on reverse-phase preparative HPLC using MeOH/H_2O (27:78) at a flow rate of 5 mL/min. Fraction C13-8 (127 mg) was applied successively to chromatography on Sephadex LH-20 (H_2O, 1 L) to yield five fractions (fractions C13-8-1−C13-8-5). Fraction C13-8-3 (157 mg) was performed on reverse-phase preparative HPLC with MeOH/H_2O (30:70) at a flow rate of 5 mL/min to afford **9** (80 mg, 47 min) and **11** (10 mg, 57 min).

Fraction D (210 g) was submitted to flash chromatography with a C_{18} column (55 × 8 cm, 20 μm), eluting with a 10-step gradient of MeOH/H_2O (4 L for one-step, from 0:100 to 100:0) to yield 40 fractions (fractions D1−D40). Fraction D27 (1.4 g) was separated on a Sephadex LH-20 column and eluted with H_2O (1.5 L) to give six fractions (fractions D27-1−D27-6). Fraction D27-3 (316 mg) was subjected to reverse-phase preparative HPLC, eluting with MeOH/H_2O (35:65) as the mobile phase at a flow rate of 5 mL/min, to afford **4** (7 mg, 23 min), **5** (6 mg, 31 min), **10** (5 mg, 44 min), and **17** (24 mg, 59 min). Fraction D13 (2.3 g) was separated into four fractions (fractions D13-1−D13-4) on Sephadex LH-20 eluted with H_2O (2 L). Fraction D13-1 (42 mg) gave **3** (10 mg, 35 min) after purification over a reverse-phase preparative HPLC column with MeOH/H_2O (40:60) at a flow rate of 5 mL/min. Fraction D13-2 (116 mg), with Sephadex LH-20 (H_2O, 1 L) and reverse-phase preparative HPLC with MeOH/H_2O (45:55) at a flow rate of 5 mL/min, yielded **15** (5 mg, 25 min) and **16** (82 mg, 42 min). Fraction D13-4 (29 mg) was purified via reverse-phase preparative HPLC with MeOH/H_2O (35:65) as the mobile phase at a flow rate of 5 mL/min to afford **8** (4 mg, 27 min). The structures of compounds **1**−**17** are shown in Figure 1.

*Enzymatic Hydrolysis of **2**−**9**, **11**, and **12**.* Compound **2** (3.0 mg) was dissolved in 0.1 M sodium citrate buffer (5.0 mL), and then cellulase (3.0 mg, Sigma-Aldrich, St. Louis, MO, USA) was added. The reaction mixture was maintained at 40 °C for 5 h. The solution was then transferred to a liquid−liquid extractor and extracted with EtOAc

(5.0 mL). The organic layer was evaporated under reduced pressure and purified using reversed-phase preparative HPLC with MeOH/H_2O (45:55) as the mobile phase to afford **2a** (1.1 mg, 43 min). The aqueous layer was evaporated and dried under reduced pressure to yield a monosaccharide residue. This residue was purified by preparative silica gel thin-layer chromatography (PTLC) [$CHCl_3$/MeOH/H_2O (7:3:1)] to afford glucose (R_f = 0.2) with positive optical rotation ($[\alpha]_{25}^{D}$ +36.5). Hydrolysis of **3**−**9**, **11**, and **12** and sugar identification were performed according to the procedure described for **2**. The D-galactose (R_f = 0.16, $[\alpha]_{25}^{D}$ + 62.8) and D-apiose (R_f = 0.5, $[\alpha]_{25}^{D}$ +8.7) were confirmed by TLC analysis [$CHCl_3$/MeOH/H_2O (7:3:1)] in comparison with standard samples.

*$Rh_2(OCOCF_3)_4$-Induced CD Experiments of Compounds **7a** and **8a**.* Compound **7a** (0.2 mg) was dissolved in dried chloroform (1 mL). The CD spectrum of **7a** in the 450−300 nm region was measured. Then, $Rh_2(OCOCF_3)_4$ (2 mg) was added in the solution, and the mixture was stirred at room temperature for 10 min. The CD spectrum of the reaction mixture in the 450−300 nm region was also measured. On the basis of the bulkiness rule for secondary alcohols,[11] a negative Cotton effect at 340 nm (the E band) in the $Rh_2(OCOCF_3)_4$-induced CD spectrum (Figure S49, Supporting Information) indicated the 7′*R* configuration of **7a**. Similarly, the 7′*S* configuration of **8a** was confirmed.

Anti-inflammatory Effects of Compounds. Compounds **1**−**17** were tested for anti-inflammatory activity on BV2 cells.[12,13] After the BV2 cells were pre-incubated for 24 h at 37 °C under a 5% CO_2 atmosphere in a 96-well plate, the cells were treated with various concentrations of the test compounds (1×10^{-5}, 1×10^{-6}, and 1×10^{-7} M), followed by stimulation with LPS for 24 h. The production of NO was determined by measuring the concentration of nitrite in the culture supernatant. $NaNO_2$ was used to generate a standard curve. The absorbances at 540 nm were measured. Curcumin was utilized as a positive control.

RESULTS AND DISCUSSION

Structure Elucidation of the New Compounds. Compound **1**, a white amorphous powder, had the molecular formula $C_{20}H_{20}O_8$ (*m*/*z* 389.1235 $[M + H]^+$ in HRESIMS), which indicated 11 degrees of unsaturation. The IR spectrum exhibited absorption bands attributable to hydroxyl groups (3364 cm^{-1}), carbonyl groups (1765, 1712, and 1640 cm^{-1}), and aromatic rings (1515 and 1465 cm^{-1}). In the ^{1}H NMR spectrum (Table 1), ABX-system aromatic proton signals [δ_H 6.73 (1H, d, *J* = 1.5 Hz, H-2), 6.82 (1H, d, *J* = 8.0 Hz, H-5), and 6.68 (1H, dd, *J* = 8.0, 1.5 Hz, H-6)] and two proton signals that displayed as a broad singlet [δ_H 6.41 (1H, s, H-3) and 7.01

DOI: 10.1021/acs.jafc.5b02838
J. Agric. Food Chem. 2015, 63, 7958−7966

(1H, s, H-5)] were observed in the downfield region. In addition, two oxygenated methylene protons at δ_H 4.46 (1H, dd, J = 8.0, 9.0 Hz, H-9′a) and 4.08 (1H, dd, J = 8.0, 9.5 Hz, H-9′b), four methylene protons at δ_H 2.83 (1H, m, H-8a), 2.69 (1H, m, H-8b), 2.80 (1H, m, H-7′a), and 2.71 (1H, m, H-7′b), two methine protons at δ_H 2.89 (1H, brdd, J = 8.0, 5.0 Hz, H-9) and 2.63 (1H, m, H-8′), and two methoxy groups at δ_H 3.81 (3H, s) and 3.81 (3H, s) were also observed. The ^{13}C NMR spectrum (Table 2) of **1** displayed 20 carbon signals, including two C6−C3 units and two methoxy groups. On the basis of the aforementioned data, compound **1** was determined as a butyrolactone lignan similar to arctigenin, except that NMR resonances for the 6-carboxyl-2-pyrone moiety in **1** were observed in place of the resonances for the 4-hydroxy-3-methoxyphenyl unit in arctigenin. This interpretation was verified by the HMBC and ^{13}C NMR spectra. The correlations from H-8′ to C-8, C-9, C-10, C-1′, C-7′, and C-9′ and from H-9 to C-4, C-8, C-10, C-7′, C-8′, and C-9′ indicated the presence of a benzylbutyrolactone moiety in **1**. Detailed analysis of the ^{13}C NMR spectrum, together with the remaining five degrees of unsaturation, implied the existence of a 6-carboxyl-2-pyrone moiety; this moiety was verified by the HMBC correlations (Figure 2) from H-3 to C-2 and C-5 and from H-5 to C-6 and C-7. The connection between C-8 and C-4 was also determined by the key correlations from H-8 to C-3, C-4, and C-5. The previous study indicated that the relative configuration of H-9 and H-8′ could be determined by the $\Delta\delta_{H9'a-H9'b}$ values ($\Delta\delta_{H9'a-H9'b} \geq 0.2$ for *trans*, $\Delta\delta_{H9'a-H9'b} \approx 0$ for *cis*).[14,15] Therefore, the *trans* configuration of H-9 and H-8′ was established by the H-9′a (δ_H 4.46) and H-9′b (δ_H 4.08) signals in the ^{1}H NMR spectrum. This result, combined with the negative Cotton effect at 230 nm in the CD spectrum, suggested that the absolute configurations of C-9 and C-8′ in **1** were 9*R* and 8′*R*, respectively.[16] Consequently, **1** was identified as in Figure 1 and named arctiidilactone.

Compound **2** was obtained as a white amorphous powder; its molecular formula was confirmed to be $C_{20}H_{28}O_{10}$ on the basis of the positive HRESIMS ion observed at m/z 451.1584 [M + Na]$^+$. The ^{1}H NMR spectrum (Table 1) of **2** showed three aromatic proton signals at δ_H 6.81 (1H, brs, H-2), 6.84 (1H, d, J = 8.0 Hz, H-5), and 6.73 (1H, d, J = 8.0 Hz, H-6), revealing the presence of an ABX-system aromatic ring. Additionally, two methoxy groups at δ_H 3.74 (3H, s) and 3.70 (3H, s) and a glucopyranosyl anomeric proton at δ_H 3.95 (1H, d, J = 7.5 Hz, H-1″) were also observed in the upfield region. In the ^{13}C NMR spectrum (Table 2), signals associated with a C3−C6−C3 unit, two methoxy groups, and a glucopyranosyl group were observed. All of the aforementioned spectroscopic data indicated that **2** was a butyrolactone-type lignan, but without an aromatic ring. The HMBC correlations (Figure 2) from H-7 to C-1, C-2, C-6, C-8, C-9, and C-2′ and from H-1′ to C-8, C-2′, and C-3′ confirmed the benzylbutyrolactone skeleton of **2**. The linkage point of the glucose was identified by the correlation between the anomeric proton H-1″ of glucose and C-1′ in the HMBC experiment. The 8*R*,2′*S* configurations of **2** were deduced from the chemical shifts of H-9 (δ_H 4.22, 3.89) in the ^{1}H NMR spectrum (Table 1) and from the negative Cotton effect at 227 nm in the CD spectrum. Thus, **2** was determined to be arctiiapolignan A.

The IR spectrum of compound **3** showed absorptions for a hydroxyl group (3413 cm^{-1}), methylene (2921 cm^{-1}), benzene ring (1598, 1514, and 1454 cm^{-1}), and carbonyl group (1760 cm^{-1}). The molecular formula of **3** was determined to be $C_{42}H_{52}O_{19}$ on the basis of the positive HRESIMS ion (m/z 883.2981 [M + Na]$^+$). The ^{1}H NMR spectroscopy data (Table 1) of **3** revealed two sets of ABX-system aromatic rings [δ_H 6.78 (1H, d, J = 1.5 Hz, H-2), 6.98 (1H, d, J = 8.5 Hz, H-5), 6.68 (1H, dd, J = 8.5, 1.5 Hz, H-6), 6.94 (1H, d, J = 2.0 Hz, H-2″), 7.04 (1H, d, J = 8.5 Hz, H-5″), 6.83 (1H, dd, J = 8.5, 2.0 Hz, H-6″)] and a 1,3,4,5-tetrasubstituted aromatic ring [δ_H 6.56 (1H, brs, H-2′), 6.60 (1H, brs, H-6′)]. Additionally, two oxymethylene protons [δ_H 4.11 (1H, dd, J = 8.5, 8.5 Hz, H-9′a), 3.87 (1H, dd, J = 8.5, 8.5 Hz, H-9′b), 3.68 (1H, m, H-9″a), 3.59 (1H, m, H-9″b)], an oxymethine proton [δ_H 5.46 (1H, d, J = 4.5 Hz, H-7″)], two methylene protons [δ_H 2.82 (2H, m, H-7), 2.56 (1H, m, H-7′a), 2.46 (1H, m, H-7′b)], three methine protons [δ_H 2.74 (1H, m, H-8), 2.44 (1H, overlap, H-8′), 3.42 (1H, m, H-8″)], three methoxyl protons [δ_H 3.70 (3H, s, 3-OCH$_3$), 3.73 (3H, s, 3′-OCH$_3$), 3.72 (3H, s, 3″-OCH$_3$)], and two glucopyranosyl anomeric protons [δ_H 4.87 (1H, d, J = 7.5 Hz, H-1‴), 4.82 (1H, d, J = 7.5 Hz, H-1⁗)] were observed in the upfield region. The ^{13}C NMR spectrum (Table 2) of **3** displayed 42 carbon signals, 12 of which were assigned to two glucose units; the remaining 30 carbons were assigned to three C6−C3 units and three methoxy groups. These data revealed that **3** was a sesquineolignan.[17] In the HMBC spectrum (Figure 2), the characteristic correlations from H-7 (δ_H 2.82) to C-1, C-2, C-9, and C-8′, from H-7′ (δ_H 2.56, 2.46) to C-1′, C-2′, C-9′, and C-8, and from H-7″ (δ_H 5.46) to C-4′, C-5′, C-1″, and C-9″ suggested the presence of a dihydrobenzofuran unit and a benzylbutyrolactone unit in compound **3**. The HMBC correlation peaks of three methoxy groups at δ_H 3.70, 3.73, and 3.72 with C-3, C-3′, and C-3″ confirmed the linkage positions of these methoxy groups. Two glucose units were determined to be located at C-4 and C-4″ on the basis of the correlations of H-1‴ with C-4 and H-1⁗ with C-4″ in the HMBC spectrum. The chemical shifts of H-9′ (δ_H 4.11 and 3.87) indicated the *trans* configuration of H-8/H-8′. Moreover, the correlation peaks of H-7″ with H-9″ and of H-8″ with H-2″ and H-6″ in the ROESY spectrum (Figure 3) indicated the

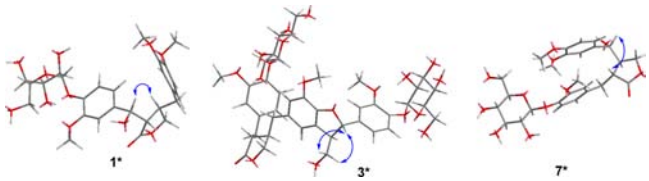

Figure 3. Key ROESY correlations in compounds **1**, **3**, and **7**.

trans configuration of H-7″/H-8″. In the CD spectrum, the negative Cotton effect at 230 revealed the 8*R*,8′*R* configurations of the benzylbutyrolactone unit,[16] and the negative Cotton effect at 290 nm revealed the 7″*R*,8″*S* configurations of the dihydrobenzofuran unit.[18] Therefore, compound **3** was confirmed to be arctiisesquineolignan A.

The spectroscopic data for compound **4** were similar to those of arctiin, except for an additional galactose unit.[19] The downfield shift of C-6″ (δ_C 66.8) of glucose in **4** suggested that the linkage point of the galactose was at C-6″ of glucose, which was further confirmed by the correlations between the anomeric proton H-1‴ of galactose and C-6″ of glucose in the HMBC experiment. The *trans* configuration of H-8 and H-8′ was established on the basis of the H-9′a (δ_H 4.10) and H-9′b (δ_H 3.88) signals in the ^{1}H NMR spectrum (Table 1). The

DOI: 10.1021/acs.jafc.5b02838
J. Agric. Food Chem. 2015, 63, 7958−7966

absolute configurations of C-8 and C-8′ in **4** were defined as 8*R*,8′*R* on the basis of the negative Cotton effect at 230 nm observed in the CD spectrum. Thus, **4** was identified as Figure 1 and named arctigenin-4-*O*-*α*-D-galactopyranosyl-(1→6)-*O*-*β*-D-glucopyranoside.

Compound **5** was demonstrated to have the molecular formula $C_{32}H_{42}O_{15}$ on the basis of HRESIMS with *m*/*z* 689.2430 $[M + Na]^+$. The IR spectrum exhibited signals for a hydroxyl group (3418 cm^{-1}), a methylene (2929 cm^{-1}), aromatic rings (1592, 1515, and 1454 cm^{-1}), and a carbonyl group (1760 cm^{-1}). Detailed analysis of the 1D NMR spectra (Table 1) suggested that the structure of **5** was similar to that of **4**. The difference between these two compounds was the presence of an apiofuranose group[20] at C″-6 in **5** instead of a galactose group at C″-6 in **4**, which was supported by the HMBC correlation between the apiofuranose anomeric proton H-1‴ (δ_H 4.80) and C-6″ (δ_C 68.1) in **5**. The absolute configurations of C-8 and C-8′ in **5** were also confirmed by the same method used to confirm those in **4**. The chemical shifts of H-9′a (δ_H 4.09) and H-9′b (δ_H 3.88) verified the *trans* configuration of H-8/8′. This result, combined with the negative Cotton effect at 230 nm in the CD spectrum, indicated the 8*R*,8′*R* configurations for **5**. Thus, compound **5** was determined to be arctigenin-4-*O*-*β*-D-apiofuranosyl-(1→6)-*O*-*β*-D-glucopyranoside.

Compound **6** had the molecular formula $C_{29}H_{38}O_{13}$, and its IR spectrum exhibited absorption bands that were attributed to a hydroxyl (3426 cm^{-1}), a methylene (2928 cm^{-1}), a carbonyl group (1758 cm^{-1}), and an aromatic ring (1597, 1513, and 1461 cm^{-1}). Comprehensive analysis of the NMR spectra indicated that compound **6** was a dibenzylbutyrolactone lignan glucoside with an additional C3 unit. In the HMBC spectrum, the correlation peaks from H-2″ (δ_H 3.57, 3.64) and H-3″ (δ_H 3.57, 3.64) to C-1″ (δ_C 44.3) and from H-1″ (δ_H 3.14) to C-2″ (δ_C 62.2) and C-3″ (δ_C 62.2), together with their chemical shifts, demonstrated the propanediol structure of the C3 unit. In addition, the HMBC correlations from H-1″ (δ_H 3.14) to C-4′ (δ_C 143.1), C-5′ (δ_C 128.5), and C-6′ (δ_C 121.1) indicated that C-1″ of the propanediol moiety was connected to C-5′ of the dibenzylbutyrolactone lignan by a C−C bond. The absolute configurations of C-8 and C-8′ were determined by the procedure described for **4** and **5**. A negative Cotton effect at 229 nm observed in the CD spectrum, in combination with the chemical shifts of H-9′ at δ_H 4.07 and 3.84, verified the 8*R*,8′*R* configurations for **6**. On the basis of the aforementioned information, compound **6** was confirmed to be 5′-propanediolmatairesinoside.

Compound **7** was obtained as a white amorphous powder with a molecular formula of $C_{27}H_{34}O_{12}$ on the basis of an ion peak at *m*/*z* 573.1954 $[M + Na]^+$ in the HRESIMS spectrum. The spectroscopic data (Tables 2 and 3) for **7** were almost identical to the data for rafanotrachelogenin-4-*O*-*β*-D-glucopyranoside,[21] which was isolated from *Trachelospermum lucidum*. However, the absolute configurations of rafanotrachelogenin-4-*O*-*β*-D-glucopyranoside had not yet been identified. To determine the absolute configuration of C-8, C-7′, and C-8′ in compound **7**, the ROESY spectrum, CD exciton chirality, and $Rh_2(OCOCF_3)_4$-induced CD spectrum were assayed. The relative configuration of H-8 and H-8′ in **7** was defined as *trans* on the basis of the characteristic correlation peaks of H-7′ with H-8 in the ROESY spectrum (Figure 3). In combination with the negative Cotton effect at 230 nm in the CD spectrum, the absolute configuration of C-8 and C-8′ was confirmed as 8*R*,8′*R*. Cellulase hydrolysis of **7** resulted in **7a** (the aglycone) and D-glucose. The 7′*R* configuration was supported by a negative Cotton effect at 340 nm in the $Rh_2(OCOCF_3)_4$-induced CD spectrum of **7a** (Figure S49, Supporting Information).[11] Consequently, **7** was identified as Figure 1 and named (7′*R*,8*R*,8′*R*)-rafanotrachelogenin-4-*O*-*β*-D-glucopyranoside.

Compound **8** was obtained as a white amorphous powder. Its molecular formula was determined to be $C_{27}H_{34}O_{12}$ on the basis of the positive HRESIMS ion observed at *m*/*z* 573.1956 $[M + Na]^+$. A comparison of the IR, UV, and NMR data (Table 2) of **8** with those of **7** revealed that these two compounds possessed the same planar structure. As previously described, the ROESY correlation of H-7′/H-8 indicated the *trans* configuration of H-8/H-8′ in **8**. In the CD spectrum, a negative Cotton effect at 227 nm helped confirm the 8*R*,8′*R* configurations for **8**. The 7′*S* configuration was determined by a positive Cotton effect at 340 nm in the $Rh_2(OCOCF_3)_4$-induced CD spectrum of **8a** (the aglycone) (Figure S57, Supporting Information), which was obtained by cellulase hydrolysis of **8**. Thus, compound **8** was deduced to be (7′*S*,8*R*,8′*R*)-rafanotrachelogenin-4-*O*-*β*-D-glucopyranoside.

Compound **9** had the same molecular formula as **8**: $C_{27}H_{34}O_{12}$. A comparison of the NMR spectra of **9** and **8** revealed that the differences between these two compounds were the linkage point of the alcoholic hydroxyl group. In the HMBC spectrum, the correlation peaks from H-7 (δ_H 5.10) to C-1, C-2, C-6, C-8, C-9, and C-8′ and from H-7′ (δ_H 2.32, 2.05) to C-1′, C-2′, C-6′, C-8′, C-9′, and C-8, together with the chemical shifts of H-7/7′ and C-7/7′, indicated that the hydroxyl was located at C-7. Thus, the planar structure of **9** was elucidated as 4,7-dihydroxy-3,3′,4′-trimethoxyl-9-oxo dibenzylbutyrolactone lignan-4-*O*-*β*-D-glucopyranoside. The relative configuration of H-8 and H-8′ in **9** was defined as *trans* on the basis of the characteristic correlation peak of H-8′ with H-7 in the ROESY spectrum. The 8*S*,8′*R* configuration for **9** was confirmed by the negative Cotton effects at 243 and 282 nm in the CD spectrum. Cellulase hydrolysis of **9** resulted in **9a** (the aglycone), which was purified by preparative HPLC. The 7,8-*erythro* configuration of **9a** was deduced on the basis of the coupling constant $J_{7,8}$ (4.0 Hz) in the ^1H NMR experiment (Figure S66, Supporting Information).[22] Thus, **9** was elucidated to be (7*S*,8*S*,8′*R*)-4,7-dihydroxy-3,3′,4′-trimethoxyl-9-oxo dibenzylbutyrolactone lignan-4-*O*-*β*-D-glucopyranoside.

A comparison of the molecular formula ($C_{21}H_{24}O_7$) and NMR data of **10** with those of **9** (Tables 2 and 3) indicated the absence of glucose unit resonances in **10**. Using the same methods as described for **9** (Figures S74−S76, Supporting Information), we elucidated the 7*S*,8*S*,8′*R* configurations of **10**. Thus, compound **10** was determined to be (7*S*,8*S*,8′*R*)-4,7-dihydroxy-3,3′,4′-trimethoxyl-9-oxo dibenzylbutyrolactone lignan.

Compound **11** had the same planar structure as **9**, as indicated by a comparison of their NMR spectra and molecular formulas. The absolute configurations of C-8 and C-8′ were established as 8*S*,8′*R* by the correlation of H-7/8′ in the ROESY spectrum and the negative Cotton effects at 243 and 282 nm in the CD spectrum. However, in the ^1H NMR spectrum of **11a** (the aglycone) (Figure S84, Supporting Information), which was obtained by hydrolysis of **11**, the coupling constant of H-7 ($J_{7,8}$ = 8.5 Hz) suggested that the relative configuration between C-7 and C-8 was *threo* instead of the *erythro* configuration in **9**.[21] Thus, the 7*R* configuration was

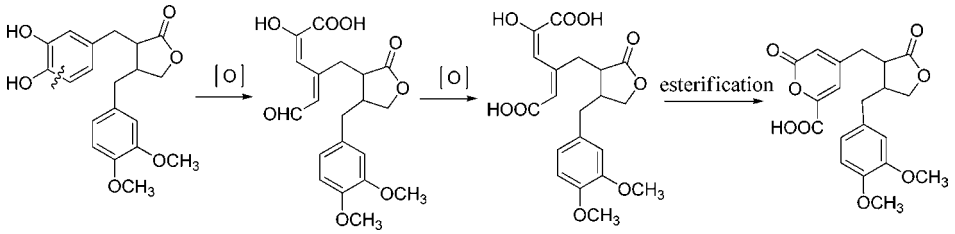
J. Agric. Food Chem. 2015, 63, 7958−7966

Scheme 1. Plausible Biogenetic Pathway of 1



determined and the structure of **11** was characterized as Figure 1 and named (7*R*,8*S*,8′*R*)-4,7-dihydroxy-3,3′,4′-trimethoxyl-9-oxo dibenzylbutyrolactone lignan-4-*O*-*β*-D-glucopyranoside.

The molecular formula of compound **12** was determined to be $C_{26}H_{32}O_{12}$ on the basis of the positive HRESIMS ion observed at *m*/*z* 559.1795 $[M + Na]^+$. The UV, IR, and NMR spectra of **12** were almost identical to the corresponding spectra of **11**; the difference between the compounds was that **12** contained a 4′-OH group in place of the 4′-OCH_3 in **11**. The 7*R*,8*S*,8′*R* configuration of **12** was also confirmed by the ROESY correlation and CD spectrum and by the coupling constant of H-7 ($J_{7,8}$ = 8.0 Hz) in **12a** (the aglycone) (Figure S93, Supporting Information). On the basis of these results, **12** was determined to be (7*R*,8*S*,8′*R*)-4,7,4′-trihydroxy-3,3′-dimethoxyl-9-oxo dibenzylbutyrolactone lignan-4-*O*-*β*-D-glucopyranoside.

The known compounds matairesinol-4,4′-di-*O*-*β*-D-glucopyranoside (**13**),[23] arctiin (**14**),[24] styraxlignolide E (**15**),[25] styraxlignolide D (**16**),[25] and arctigenin-4-*O*-*β*-D-gentiobioside (**17**)[26] were identified by comparison of these physical and spectral data with literature values. In addition, their absolute configurations were established from NMR and CD data.

Cytotoxic Activity. All of the isolated compounds were tested for cytotoxic activity using an MTT assay in HCT-8, Bel-7402, BGC-823, A549, and A2780 cells.[27] Compounds **1**−**17** exhibited no significant cytotoxicity in the cell model systems at a concentration of 10 *μ*M.

Hepatoprotective Activity. Given our previous bioactivity screening results for the lignan glucosides, the hepatoprotective activities[10] of **1**−**17** were tested through in vitro assays. Unfortunately, all of the tested compounds exhibited weak hepatoprotective activities at a concentration of 10 *μ*M.

Anti-inflammatory Activity. Compounds **1**−**17** were tested for anti-inflammatory activity by suppressing the production of NO in lipopolysaccharide-induced BV2 cells. From the data obtained, compounds **1**, **6**, **8**, and **10** exhibited stronger anti-inflammatory effects than the positive control curcumin at a concentration of 10 *μ*M. Among them, compound **1** demonstrated 75.51, 70.72, and 61.17% inhibition at 10, 1, and 0.1 *μ*M, respectively, whereas the positive control curcumin showed 53.02, 36.74, and 0% inhibition at 10, 1, and 0.1 *μ*M. Furthermore, compound **6** exhibited 71.59, 38.64, and 2.27% inhibition at 10, 1, and 0.1 *μ*M, respectively. Compound **8** exhibited 87.77, 53.24, and 11.51% inhibition at 10, 1, and 0.1 *μ*M, respectively. Compound **10** exhibited 63.31, 40.29, and 37.41% inhibition at 10, 1, and 0.1 *μ*M, respectively.

In the continued search for bioactive natural products from Arctii Fructus, 17 butyrolactone type lignans (**1**−**17**) were isolated, including a novel rare butyrolactone lignan with a 6-carboxyl-2-pyrone moiety, named arctiidilactone (**1**); a new apolignan glucoside without an aromatic ring (**2**); a new sesquineolignan with a dihydrobenzofuran unit and a butyrolactone unit (**3**); three new dibenzylbutyrolactone lignans (**4**−**6**); six new dibenzylbutyrolactone lignans with an additional hydroxyl at C-7/7′ (**7**−**12**); and five known compounds (**13**−**17**). A literature search revealed that no butyrolactone lignan with a 6-carboxyl-2-pyrone moiety has been previously reported. A plausible biogenetic pathway of **1** is proposed in Scheme 1. The 6-carboxyl-2-pyrone might be formed from a 3,4-dihydroxy phenyl moiety through oxidative cleavage, oxidation, and esterification.

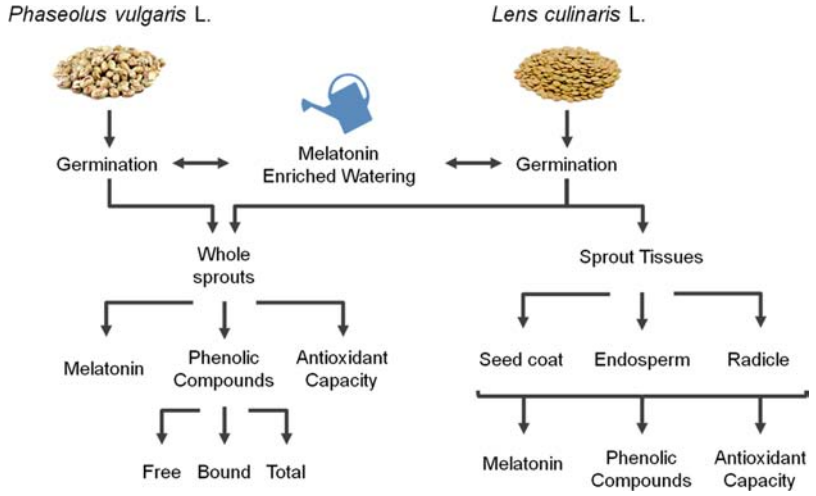

Figure 1. Illustrative diagram of the experimental design.

the effect on the antioxidant capacity in both sprouts. In addition, a sensory analysis was carried out on hummus of lentil sprouts to evaluate the influence of adding exogenous melatonin during their germination, in order to assess the potential legume sprout-based food for improving consumer's health.

MATERIALS AND METHODS

Plant Materials. Two varieties of common legumes, lentil (*Lens culinaris* L., var. *Salmantina*) and kidney bean (*Phaseolus vulgaris* L., var. *Pinta*), were provided by Institute of Food Science, Technology and Nutrition (CSIC, Spain) and stored under refrigeration conditions.

Processing Conditions. Three batches of seeds (20 g of lentils and 50 g of kidney beans) were sterilized in 1% NaClO solution for 30 min to reduce bacterial and fungal growth. Seeds were washed three times with distilled water until neutral pH and then soaked in a 20 μM melatonin solution for 5 h for seed hydration (ratio 1:20, m/v). Seeds were germinated for 3, 6, 8, and 10 days in an incubator (Construcciones Frigoríficas, Confri, S. L.) at 20 °C, 80% RH, and darkness. Seeds were maintained wet by capillarity using a 20 μM melatonin solution. Lentil and kidney bean samples were withdrawn, frozen in N_2, freeze-dried, and milled. Flours were passed through a 50 μm sieve and stored at 4−6 °C for further analysis. In addition, lentil sprouts were separated into different tissues as seed coat, endosperm, and radicle. These samples were also frozen in N_2, freeze-dried, and milled. Flours were passed through a 50 μm sieve and stored at 4−6 °C for further analysis. The experimental design is illustrated in Figure 1.

Melatonin Extraction and Quantification by HPLC-MS/MS. The extraction procedure was carried out according to Aguilera et al.[32] Briefly, lentil and kidney bean flours (2 g) were extracted with 10 mL of methanol (MeOH) for 16 h at 4 °C in darkness. After a brief centrifugation at 2000*g* for 15 min at room temperature, the supernatants were filtered under vacuum by a filter (11 μm, Whatman) and evaporated to dryness under N_2 (g). The residues were resuspended in 2 mL of water, after a mild ultrasonic treatment for 2 min at room temperature. The reconstituted extracts were filtered using solid phase extraction (SPE, cartridge C-18, Waters) as follows: first, a conditioning step was carried out with 1 mL of MeOH and 1 mL of water to activate the column, followed by sample application (1 mL of extract) and washing step with 2 mL of MeOH 10%; finally, 1 mL of MeOH was used for the elution step. The extracts obtained were evaporated to dryness by use of an evaporator centrifuge (Speed Vac SC 200, Savant, USA). The residues were dissolved in MeOH/H_2O (80:20, v/v) + 0.1% formic acid. Melatonin was determined by HPLC-ESI-MS/MS triple quadrupole (Varian 1200L with API-ES between 10 and 1500 Da range mass). The system consisted of two pumps, Varian Prostar 210 and an Intensity Trio C18 (150 mm × 2.0 mm ID, S-3 μm, 12 nm BRYTC18032150; Bruker) column, at a flow rate of 0.2 mL/min. Acetonitrile containing 0.1% formic acid (solvent A) and 0.1% formic acid in H_2O (solvent B) as mobile phase were pumped with the following gradient: 5% solvent A (0−4 min), 5−100% solvent A (4−15 min), 100% solvent A (15−18 min), and 100−5% solvent A (18−25 min) to recover initial conditions. The injection volume was 50 μL. Quantification was performed using the external standard method, using pure melatonin (Sigma-Aldrich Química, Spain) dissolved in MeOH/H_2O (80:20, v/v) containing 0.1% formic acid. Melatonin content was expressed as ng/g dry weight (DW).

Phenolic Compound Extraction and Determination. Extraction of phenolic compounds was carried out following the method of Gou et al.[20] with some modifications. Raw and germinated flours (2 g) were blended using 30 mL of 80% chilled acetone (1:2, w/v) for 5 min and vortex for 10 min. The homogenates were then centrifuged at 2000*g* for 5 min. Supernatants were collected, and the extraction was repeated three times. All the supernatants were pooled and evaporated until 10% of the supernatants remained. The soluble free phytochemical extracts were brought to 10 mL in water and were kept at −40 °C until analysis. For the extractions of bound phytochemicals, the residues from the above soluble free extraction were flushed with N_2 and hydrolyzed directly with 20 mL of 4 M NaOH at room temperature for 1 h with shaking. The mixture was acidified to pH 2 with concentrated HCl, centrifuged at 3000*g* for 5 min, and extracted three times with ethyl acetate. The ethyl acetate fractions were evaporated to dryness and were reconstituted into 1.5 mL of methanol and stored at −40 °C until analysis.

Phenolic compounds were determined by Folin−Ciocalteu colorimetric method according to Singleton et al.[36] using gallic acid as standard. Phenolic compounds were expressed as mg GAE/100 g DW.

Oxygen Radical Absorbing Capacity (ORAC) Assay. The above methanol extracts were used for determining the radical scavenging activity by the ORAC method using fluorescein as a fluorescence probe.[37] Briefly, the reaction was carried out at 37 °C in 75 mM phosphate buffer (pH 7.4), and the final assay mixture (200 μL) contained fluorescein (70 nM), 2,2-azobis(2-methyl-propionamidine)-dihydrochloride (12 mM), and antioxidant standard (Trolox [10−80 μM] or sample extracts). A Polarstar Galaxy plate reader (BMG Labtechnologies GmbH, Offenburg, Germany) was used to read fluorescence at wavelengths of 485 nm excitation and 520 nm emission. The equipment was controlled by the Fluostar Galaxy software version (4.31-0) for fluorescence measurement. Black 96-well untreated microplates (PS Balck, Porvair, Leatherhead, UK) were used. The plate was automatically shaken before preincubation, and the fluorescence was recorded every minute for 80 min. All reaction

DOI: 10.1021/acs.jafc.5b03128
J. Agric. Food Chem. 2015, 63, 7967−7974

mixtures were prepared in duplicate, and at least three independent runs were performed for each sample. Fluorescence measurements were normalized to the oxidation control (phosphate buffer) and stability control (no antioxidant). From the normalized curves, the area under the fluorescence decay curve (AUC) was calculated as

$$\mathrm{AUC} = 1 + \sum_{i=1}^{i=80} f_i/f_0$$

where f_0 is the initial fluorescence reading at 0 min and f_i is the fluorescence reading at time i. The net AUC corresponding to a sample was calculated as follows:

$$\text{net AUC} = \text{AUC antioxidant} - \text{AUC blank}$$

The net AUC was plotted against the antioxidant concentration, and the regression equation of the curve was calculated. The ORAC value was obtained by dividing the slope of the latter curve by the slopes of the Trolox curve obtained in the same assay. Final ORAC values were expressed as μmol of Trolox equivalents/g of dry seed (μmol TE/g DW).

Sensory Analysis. Two different hummuses were prepared using lentil sprouts germinated for 10 days with and without (control) melatonin in the watering. Sensory evaluation was carried out in two sessions involving in total 40 trained and 60 untrained panelists. Sensory analysis was performed using three different tests; a descriptive test and two affective tests. To assess the sensory profile, each evaluated character was scored in a 10-point intensity scale (1 (lowest) to 10 (highest)). Color, odor, fluidity, consistency, texture, astringency, aftertaste, and flavor of the selected hummus, A (hummus prepared with enriched melatonin lentil sprouts) and B (hummus prepared without enriched melatonin lentil sprouts), were tested by 40 trained judges. For each attribute, the average of the panelists' scores was calculated. Satisfaction tests consisted of a 9-point verbal scale showing the acceptance of the product (like extremely = +4; like very much = +3; like moderately = +2; like slightly = +1; neither like nor dislike = 0; dislike slightly = −1; dislike moderately = −2; dislike very much = −3; dislike extremely = −4). Hummus was considered acceptable if their mean value for overall quality scores was equal to or above 0 (neither like nor dislike). Sensory evaluation was completed by a paired preference test. Untrained judges should choose between both samples tested, in order to assessing the distribution of panelists' preferences.

Statistical Analysis. Each sample was analyzed in triplicate. Data were expressed as mean ± standard deviation (SD). The data were analyzed by one-way analysis of variance (ANOVA) and post hoc Duncan's test. Student's t test (independent samples, 2 groups) was used to analyze differences in satisfaction between both hummus samples. Differences in the preference between these hummuses were studied by a binomial test and were considered to be significant at $p < 0.05$. The statistical analysis was performed using SPSS 21.0.

RESULTS AND DISCUSSION

Melatonin. *Melatonin Content in Whole Lentil and Bean Sprouts.* Raw kidney beans exhibited higher melatonin content (1.0 ng/g DW) than lentils (0.5 ng/g DW). These contents can be considered as natural sources of melatonin if they are compared with other plant foods; in general, seeds, such as almond, sunflower, and mustard, exhibited higher melatonin content.[9,38−40] Earlier studies indicated that traditional germination increased melatonin levels of different seeds.[31−33] However, these contents might not be sufficient to be incorporated as dietary supplements to increase melatonin in blood plasma in humans and, consequently, their scavenging and antioxidant actions. Thus, adding exogenous melatonin during watering might be a strategy to increase their melatonin levels during germination processing.

Germination with exogenous melatonin watering (20 μM) showed significant increases of melatonin in both legumes (Figure 2). In lentil sprouts, melatonin concentration increased from 0.5 ng/g DW in raw seeds to 1089.8 ng/g DW at the seventh day. However, a sharp melatonin decrease (42% with respect to the seventh germination day) was observed, reaching to 630.4 ng/g DW on the tenth day. Kidney bean sprouts presented lower melatonin contents than lentil sprouts throughout the whole germination process, although initially raw kidney beans exhibited higher melatonin levels than lentils. At the sixth day of germination, melatonin reached the highest levels in kidney bean sprout (529.1 ng/g DW). Thereafter, its content decreased gradually to 124.9 ng/g DW (76% decrease with respect to sixth germination day).

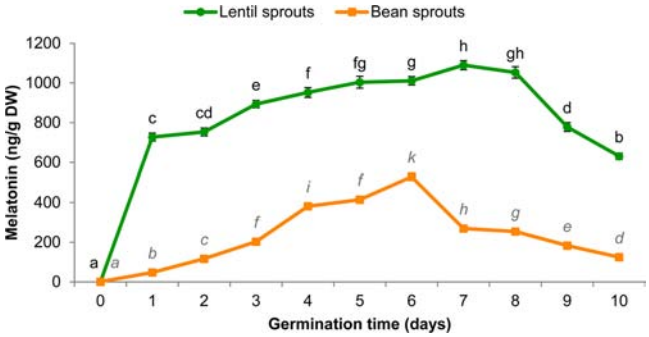

Figure 2. Melatonin contents in lentil (a) and kidney bean (b) sprouts grown with 20 μM melatonin in watering. Points with different letters significantly differ when subjected to Duncan's multiple range test ($p < 0.05$).

From these results, both lentil and kidney bean sprouts experienced a significant decrease of melatonin from the sixth or seventh germination day depending on the type of legumes; these reductions may be interpreted through melatonin metabolism.[33] The process of adding exogenous melatonin to the water increased the melatonin levels in these legumes, in contrast to those germinated by the traditional method (2.5 and 9.4 ng/g DW in lentil and kidney bean, respectively).[32]

It is worth emphasizing that sprouts germinated with exogenous melatonin watering absorbed up to 24% of added melatonin in the case of lentils and up to 11% in kidney beans. These differences were likely due to seed physiological factors such as thickness and surface area of the seed coats. Lentils exhibit seed coat thickness between 25 and 35 μm, depending on cultivar, being 8% of whole seed. However, kidney beans are associated with relatively thicker seed coats (40−60 μm), representing 12% of seeds.[41] Therefore, kidney bean seed coats might not allow melatonin diffusion as well as lentil ones.

Melatonin Content in Lentil Sprout Tissues. There is scarce information about melatonin content in sprouts after using an enriched watering. Because lentil exhibited higher melatonin levels than kidney bean sprouts, a detailed study was designed to measure this bioactive compound in the different tissues of lentil sprouts (seed coat, endosperm, and radicle). From the third day of germination, melatonin levels were higher in the seed coats than in the other tissues (endosperm and radicle) (Figure 3), increasing in all sprout tissues up to the eighth germination day. Afterward, melatonin decreased sharply (34%) in the seed coat from 897.2 ng/g DW to 589.6 ng/g DW, reaching lower levels than those found on the third day. In case of endosperm and radicle, they exhibited lower melatonin levels (92.1 ng/g DW and 26.4 ng/g DW, respectively), but significant increases were observed at the end of germination

period (tenth germination day), showing 150.3 ng/g DW and 58.9 ng/g DW in endosperm and radicle, respectively.

Melatonin Effects on Radicle Development. Melatonin exhibits auxin-like activity, promoting vegetative plant growth in a similar way to indole-3-acetic acid (IAA).[12] Indeed, significant enhancement ($p < 0.05$) of development of roots was observed as in lentil and in kidney bean sprouts (Figure 4).

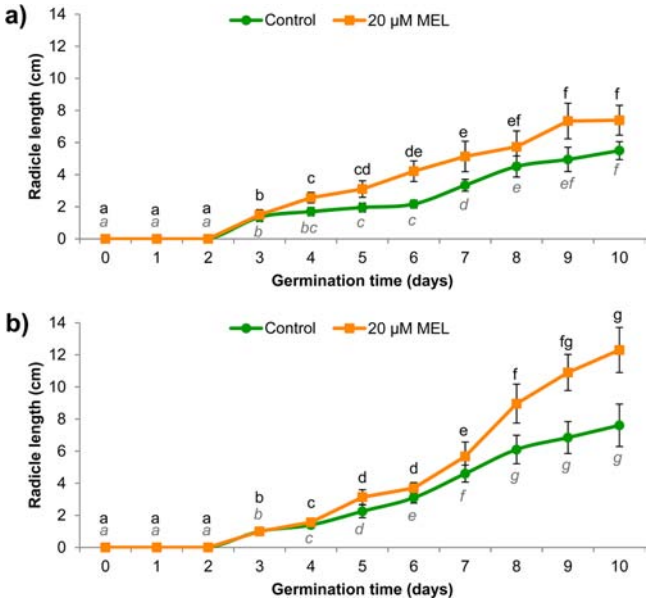

Figure 4. Radicle development in lentil (a) and kidney bean (b) sprouts grown with 20 μM melatonin in watering. Points with different letters significantly differ when subjected to Duncan's multiple range test ($p < 0.05$).

The radicles of lentils watered with 20 μM melatonin grew 1.4-fold more than those watered with H_2O (control); in the case of kidney beans, the increase was 1.6-fold. As described in the literature, the benefits of melatonin in plants vary with concentration. Germination rate and root development can be enhanced or inhibited.[12,15,17,42,43] From our results, 20 μM melatonin solution may suggest use as a correct concentration as biostimulator, as reported Janas and Posmyk.[16] Melatonin is likely to increase the final germination percentage besides the seed growth; therefore, sprout production becomes more economical and may increase sales and mark-up.

Furthermore, melatonin content in endosperms and radicles show positive correlations with the length of the sprouts (r = 0.877−0.879, $p < 0.01$) (Table 1). The increase of melatonin content could be explained not only by the growth stimulation of added melatonin but also by the influence of the germination.

Phenolic Compounds. The free (FPC), bound (cell wall-associated; BPC), and total phenolic compounds (TPC) of lentil and kidney bean sprouts are shown in Figure 5. Raw lentils and kidney beans exhibited lower TPC (487.5 mg GAE/100 g DW and 379.1 mg GAE/100 g DW, respectively) in comparison to TPC found in broad and red beans or in black beans by Amarowicz et al.[44] and Guajardo-Flores et al.[45] Nevertheless, TPC were higher compared with those found in mung bean by Guo et al.[20] and by Huang et al.[46] FPC and BPC in raw legumes were similar to those reported by Aguilera et al.,[32] FPC being the main fraction (95−98%).

Germination with exogenous melatonin watering induced changes in phenolic compound concentrations. Lentils showed slight decreases in a time-dependent manner in FPC from the first day (92% of TPC) to the tenth day (89% of TPC), and inversely, BPC increased 17%, reaching 44.3 mg GAE/100 g DW, attributable to the glycosylation of FPC. The highest decrease in TPC was found on the sixth day (21% of reduction from raw seed), and no more significant decreases were shown. On the tenth day of germination, lentil sprouts displayed 393.7 mg GAE/100 g DW (81% of the initial TPC content). Kidney beans exhibited no significant decrease in TPC nor in FPC. Nonetheless, a slight increase in BPC was shown from the eighth day. Kidney bean sprouts exhibited 36.5 mg GAE/100 g DW, 57% higher BPC compared with raw kidney beans.

Several authors have previously reported decreases in the phenolic content of legumes following germination.[47−49] A similar trend was found by Aguilera et al.,[32] where decreases in TPC in lentils were more accentuated after a traditional germination procedure. The activation of endogenous enzymes during germination could bring about changes in the phenolic composition of beans and lentils.[50] Thus, decreases in TPC could be attributed to the increases in activity of polyphenol oxidase and other catabolic enzymes, as observed by Khandelwal et al.[48] Furthermore, it has been reported that during germination procyanidins and catechins could condense to give more highly polymerized forms.[51] Oxidation could also be the cause of TPC decrease.[47] Melatonin, as antioxidant, could protect the sprout against oxidation, avoiding phenolic compound degradation. The results obtained compared with those obtained by Aguilera et al.[32] could corroborate the above hypothesis.

Antioxidant Activity. Both legumes revealed significant increases in the antioxidant capacity along the germination process (Figure 6), although lentils exhibited higher antioxidant capacity than beans. The antioxidant capacity of lentils increased 1.3 times (85.3 μmol TE/g tissue DW) during the germination process and the capacity of beans increased 1.7 times (55.8 μmol TE/g tissue DW). It is noticed that when melatonin content decreased during germination, the antioxidant capacity levels of these sprouts increased. This fact could be attributed to higher accumulation of compounds as melatonin metabolites from its catabolism. These compounds (AFMK, AMK, and cyclic 3-hydroxymelatonin) are more highly

effective scavengers than melatonin.[5,16,39,52] Melatonin showed a positive correlation with antioxidant capacity in lentil sprouts ($r = 0.855$, $p < 0.01$), but with bean sprouts the correlation was not significant (Table 1).

Because melatonin and phenolic compounds present relevant antioxidant properties, the study of antioxidant capacity was carried out in different tissues of the lentil sprouts; some of them had shown significant levels of these bioactive components (Table 2). Thus, seed coats were the tissues with the highest antioxidant capacity, 6-fold higher compared with endosperms, and they exhibited a significant decrease along germination. As was expected, endosperms showed the lowest antioxidant capacity during germination, although their levels increased to 24% on the tenth day of this process. Finally, radicles exhibited 3-fold higher antioxidant capacity than endosperms but did not show a significant enhancement during germination. Endosperm and radicle exhibited different behaviors compared with that reported by Guajardo-Flores et

Table 2. Antioxidant Activity (μmol TE/g DW) in Different Tissues (Seed Coat, Endosperm, and Radicle) Of Lentil Sprouts Germinated with 20 μM Melatonin in Watering

germination time (days)	lentil sprouts		
	seed coat	endosperm	radicle
3	278.3 ± 25.4 b	44.6 ± 5.6 a	135.4 ± 9.7 a
6	234.8 ± 14.6 a	50.4 ± 4.3 ab	154.5 ± 20.4 a
8	228.5 ± 14.2 a	51.2 ± 3.3 ab	155.9 ± 20.6 a
10	225.9 ± 18.5 a	55.2 ± 3.7 b	161.3 ± 21.3 a

Results are reported as mean ± SD (n = 3). Mean values of each tissue of the lentil sprout followed by different letters significantly differ when subjected to Duncan's multiple range test (p < 0.05).

al.;[45] these differences could be attributed to aspects related to the germination process and watering with melatonin.

Thus, melatonin concentration reveals strong correlations with antioxidant capacity in lentil endosperms and whole sprouts (r = 0.902 and r = 0.855, respectively, p < 0.01). Analogous correlation is established between melatonin and their antioxidant capacity in the radicles. The length of the radicles exhibits positive correlation with the antioxidant capacity in lentils (r= 0.827, p < 0.01) and in beans (r = 0.942, p < 0.01), showing the positive effect of the germination process with enriched melatonin watering on the final antioxidant status of the sprouts.

Sensory Analysis of the Hummus. Figure 7 shows a spider-web diagram comparing descriptive profile results. Most

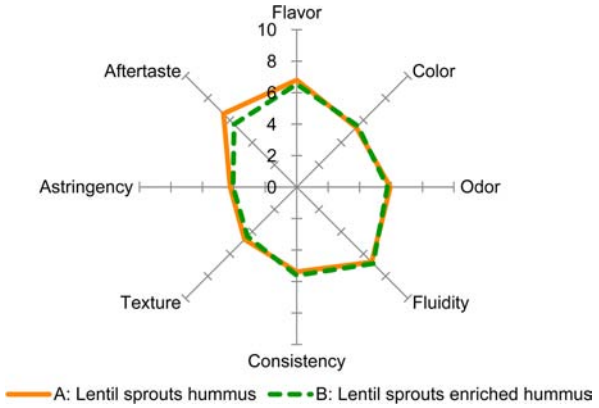

Figure 7. Spider-web diagram of sensorial attributes in lentil hummus. Mean scores (n = 40).

attributes such as flavor, color, aroma, fluidity, and consistency present similar scores, equal to or higher than five. Texture and astringency exhibit a score lower than five, but similar between A (nonenriched hummus) and B (enriched hummus). Only aftertaste brought about different points (7 in case of hummus A and 6 in hummus B). Therefore, melatonin enriched watering seems not to have any impact on the final product sensory quality, although radicle development is different in lentil sprouts germinated with enriched or nonenriched watering, which could increase green taste and grassy odor. Germination could have enhanced bitter taste and aftertaste, reducing sweet flavor and also showing more fibrousness.[40,42,49]

Satisfaction test results (n = 60) revealed a great acceptance of these hummuses; mean scores for the two samples exceeded the acceptance level (A = 1.1 and B = 1.3); t-test showed no significant differences between samples (p = 0.46). Regarding the preference test (n = 60), conclusions were reaffirmed; results do not show statistical significant difference (p = 0.37) (26 individuals preferred hummus A against 34 who preferred B). The panel found the lentil sprout hummus as flavorful products and indicate their probable product purchase if they could be found in the market. Thus, the melatonin-enriched hummus might be a good alternative to increase blood melatonin levels and, thereby, equilibrate the oxidative balance of the organism, as well as promote health, by increasing the dietary intake of plant-based foods.

This alternative method of germination with 20 μM melatonin in watering might be valid in sprout production, either lentils or beans. Adding exogenous melatonin into legume germination seems to increase its production and sprout healthiness, providing higher food quality. Lentil sprouts contained more melatonin than bean sprouts; but their concentration was considerably higher than other plant foods. Both sprouts showed good characteristics in order to be added to healthy diet. Therefore, these sprouts could be employed as functional ingredients by food industry, when developing melatonin-enriched novel foods. They might have an important nutritional impact because of melatonin's beneficial effects for human health.

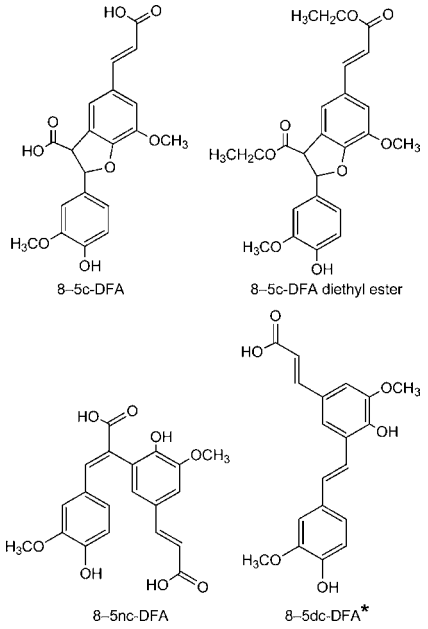

Figure 1. 8−5-Coupled dehydrodiferulate (DFA) compounds. 8−5c-DFA, 8−5c-DFA diethyl ester, and 8−5nc-DFA were synthesized as individual standard compounds for incubation with human fecal suspensions. *8−5dc-DFA was not synthesized as a standard compound, but was observed as a breakdown product of 8−5c-DFA during control (medium without feces) incubations. Abbreviations used: c, cyclic; dc, decarboxylated; nc, noncyclic.

LDL oxidation,[24] a relevant discussion of the physiological effects of DFAs must include their susceptibility to microbial metabolism and the physiological effects of these metabolites.

In vitro metabolism of the 8−*O*−4- and 5−5-DFA regioisomers by human intestinal microbiota, including structural characterization of the metabolites, has been described.[25,26] The 8−5-coupled regioisomer, the most abundant DFA in cereal grains,[27] is also susceptible to attack by human intestinal microbiota,[28] but its microbial metabolites have not been reported. In this study, we examine the structural transformations of free 8−5-DFAs (both the cyclic and the non-native open forms) and an esterified analogue, 8−5-DFA diethyl ester (cyclic), by human intestinal microbiota *in vitro* and structurally elucidate all major metabolites.

MATERIALS AND METHODS

Chemicals. Ferulic acid was from Aldrich (Seelze, Germany). Chromatography and NMR solvents were purchased from VWR (Bruchsal, Germany). Lyophilized peroxidase enzyme from horseradish (type II, 150−250 units/mg) was from Sigma-Aldrich (Munich, Germany). *N*,*O*-Bis(trimethylsilyl)trifluoracetamide (BSTFA) was obtained from Fluka (Buchs, Switzerland).

Synthesis of 8−5-Coupled Dehydrodiferulates. 8−5c-DFA diethyl ester was prepared by biomimetic peroxidase-H_2O_2-catalyzed radical coupling of ethyl ferulate followed by flash chromatography cleanup (Biotage Horizon flash chromatograph, Charlottesville, VA, USA) as described by Ralph et al.[29] Saponification of the diethyl ester (2 M NaOH, 12 h, stirring while protected from light) and subsequent extraction of released acids with diethyl ether following acidification to pH 2 with HCl led to 8−5c- and 8−5nc-DFA, in addition to other DFAs. 8−5c- and 8−5nc-DFAs were semipreparatively separated by HPLC with diode array detection (DAD) (monitored at 280 nm) using a Hitachi (Tokyo, Japan) L-7100 pump and L-7450A DAD detector, a Luna Phenyl-Hexyl column (Phenomenex, Aschaffenburg, Germany, 250 × 10 mm, 100 Å, 5 μm particle size), 3 mL/min flow rate, and the tertiary gradient described by Dobberstein et al.[30] Purity of the three synthesized standard compounds was verified by ^{1}H NMR using a Bruker (Rheinstetten, Germany) AV 250 MHz spectrometer (solvent: acetone-d_6).

Fermentation with Human Fecal Suspensions. A *preliminary* incubation trial was performed to determine appropriate sampling times and incubation length. A fecal sample was provided by a healthy human volunteer who had not taken antibiotics in the three months prior to the study and was consuming a mixed Western diet. The fresh sample was stored under anaerobic conditions using Anaerocult sachets (Merck, Darmstadt, Germany) and kept at room temperature for not longer than 2 h before usage. In an anaerobic workstation (A45, Don Whitley Scientific Limited, Shipley, West Yorkshire, UK; $N_2/CO_2/H_2$ (80/10/10, v/v/v)) feces (2.5 g) were put into a 16 mL Hungate tube containing 10 mL of anaerobic brain-heart medium (pH 7.6, Merck) and homogenized. After incubating for 10 min at 37 °C and centrifuging for 10 min at 300*g* to remove larger particles, equal volumes of the mixtures' supernatants were combined and homogenized. Aliquots (0.5 mL) of the resulting suspension were used to inoculate the samples (substituted with 0.5 mL of medium in the fecal-free controls). The Hungate tubes were supplemented with 8−5c-DFA, 8−5nc-DFA, or 8−5-DFA diethyl ester at a final concentration of 370 μM using 50 μL of the respective stock solution in DMSO. A parallel incubation of 8−5-DFA diethyl ester was also performed at 1/10 the concentration, or 37 μM. The fecal suspension was also incubated in the absence of any standard compounds using 50 μL of DMSO instead of stock solution (fecal control). The tubes were incubated at 37 °C in the dark with slow shaking (6 rpm). Sample aliquots were anaerobically withdrawn at defined incubation times (0, 6, 24, 48, and 120 h) with a syringe and stored at −20 °C until GC-MS analysis.

For the *scaled-up* incubation trial, fecal samples were provided by five healthy human volunteers who had not taken antibiotics in the three months prior to the study and were consuming mixed Western diets. Fresh fecal samples and fecal suspensions were prepared as described above, except that 10 g of feces was mixed with 30 g of medium. Schott flasks containing 200 mL of N_2-gassed medium were supplemented with 8−5c-DFA, 8−5nc-DFA, or 8−5c-DFA diethyl ester at a final concentration of 455, 370, and 340 μM using 1 mL of the respective stock solution in DMSO. A parallel incubation of 8−5nc-DFA was also performed at 1/10 the concentration, or 37 μM. Incubation started with the addition of 7.5 mL of pooled fecal suspension, whereas the fecal-free controls were supplemented with the same amount of medium. Additionally, a fecal control was prepared using 1 mL of DMSO instead of a standard compound stock solution. The flasks were incubated while stirring at 37 °C in the anaerobic workstation in the dark, and 1 mL aliquots were withdrawn at 0, 3, 5, 20, 28, 45, 69, and 117 h for LC-MS screening. On the basis of the results of the *preliminary* trial, additional 30−60 mL samples were taken at appropriate time points for metabolite isolation. All samples were stored at −20 °C until further preparation. The observed microbial metabolites were exclusively detected in the fecal suspensions incubated with 8−5-dimers. None of the metabolites were found in either the fecal-free or fecal controls.

pH Stability Test of 8−5c-DFA. Hungate tubes (16 mL) filled with 10 mL of brain-heart medium were adjusted to pH values of 6.0, 6.4, 6.8, 7.2, and 7.6 (two replicates per pH value). The tubes were gassed with N_2 and autoclaved, monitoring the pH values after each step. Each tube was supplemented with 8−5c-DFA at a final concentration of 370 μM using 50 μL of the respective stock solution in DMSO. The tubes were incubated at 37 °C in the dark on a shaker at 6 rpm without the addition of any fecal components. Sample aliquots were anaerobically withdrawn at defined incubation times (0, 6, 24, 48, and 72 h) with a syringe and stored at −20 °C until LC-MS analysis.

Sample Preparation for GC- and LC-MS Analyses. Aliquots (400 μL) from both the *preliminary* and *scaled-up* trials as well as the 8−5c-DFA pH stability test were acidified to pH ∼2 with 20 μL of 2 M HCl and extracted with ethyl acetate (2 × 800 μL). The organic layers were combined and dried under a nitrogen stream. Dried extracts from the *preliminary* fecal incubation trial were analyzed via GC-MS, and dried extracts from the *scaled-up* incubation trial and 8−5c-DFA pH stability test were analyzed with LC-MS.

DOI: 10.1021/acs.jafc.5b03234
J. Agric. Food Chem. 2015, 63, 7975−7985

GC-MS Analysis. The dried extracts were derivatized by trimethylsilylation with BSTFA (40 μL) and pyridine (10 μL) for 30 min at 60 °C in sealed glass vials. The trimethylsilylated samples were 1:10 diluted with acetonitrile and analyzed on a Shimadzu GC-MS system (Kyoto, Japan; GC-2010-Plus oven, QP 2010 Ultra mass spectrometer, and AOC-20i autosampler). Samples were injected (1 μL, injection port temperature: 275 °C) using a 10:1 split ratio and separated on an Rtx-5MS column (30 m, 0.25 mm diameter, 0.25 μm film thickness) using the following temperature gradient: initial temperature, 220 °C; hold for 1 min; heat to 270 °C at 3 °C/min; hold for 5 min; heat to 280 °C at 4 °C/min; hold for 20 min; heat to 300 °C at 10 °C/min; and hold for 10 min. Helium (40 cm/s) was used as the carrier gas. The transfer line and ion source temperatures were held at 290 and 180 °C, respectively. The ionization energy was 70 eV. Total ion chromatograms were recorded (m/z 50−800 scan range, 0.30 s scan time).

LC-MS Analysis. Dried sample extracts were dissolved in 80 μL of MeOH/H_2O (50/50, v/v). The solution was diluted 1:30 with MeOH/H_2O (50/50, v/v) and analyzed on a Waters LC-MS (Eschborn, Germany) system equipped with a 2690 Separations Module pump and autosampler, a Micromass Quattro Micro mass spectrometer, and a 996 PDA-DAD. Samples (20 μL injection volume) were separated at room temperature on a Phenomenex Kinetex Phenyl-Hexyl column (150 × 4.6 mm, 2.6 μm particle size) with a flow rate of 0.5 mL/min. The following gradient was applied: A = H_2O with 0.01% formic acid, B = acetonitrile with 0.01% formic acid; initially, 90% A, 10% B; B from 10% to 27% in 10 min; B from 27% to 45% in 20 min; B from 45% to 60% in 2 min; B from 60% to 100% in 5 min; hold for 1 min; B from 100% to 10% in 1 min; and re-equilibration for 6 min. The ion source temperature was 100 °C, and the desolvation temperature was 350 °C. Ionization was performed in the ESI negative ion mode with a capillary voltage of 4.00 kV. Ionized molecules were detected in the full scan mode, using a scan range from m/z 180 to 500 and a scan time of 1 s.

Isolation of Metabolites for NMR Spectroscopy. Frozen sample aliquots were thawed and mixed thoroughly before acidifying with 2 M HCl to pH ∼2. The acidified solutions were extracted with ethyl acetate: first with a solvent volume double the total acidified solution volume and then twice with solvent volumes equal to the acidified solution volume. The organic layers were combined and evaporated under reduced pressure using a rotary evaporator (30 °C). The residue was dissolved in 2 mL of MeOH/H_2O (50/50, v/v) and 1 mL of acetonitrile at 35 °C with sonication (15 min), followed by centrifugation (5 min, 4000g). An aliquot of the supernatant (1 mL) was mixed with 500 μL of MeOH/H_2O (50/50, v/v), and the mixture was centrifuged again (5 min, 18500g). The final supernatant was separated on a Knauer (Berlin, Germany) Azura semipreparative HPLC system equipped with a P2.1L pump and a UVD 2.1L UV detector. Samples were manually injected (injection loop volume, 2 mL) and separated at room temperature on a Luna Phenyl-Hexyl column (250 × 10 mm, 100 Å, 5 μm particle size) using a flow rate of 3.5 mL/min. For metabolites of 8−5c-DFA and 8−5nc-DFA the following gradient was used: A = 1 mM trifluoroacetic acid (TFA) in water, B = acetonitrile/1 mM TFA in water (90/10, v/v); initially, 90% A, 10% B; B from 10% to 27% in 10 min; B from 27% to 45% in 20 min; B from 45% to 60% in 2 min; B from 60% to 100% in 5 min; hold for 1 min; B from 100% to 10% in 1 min; re-equilibrate for 6 min. For separation of the 8−5c-DFA diethyl ester metabolites, the same eluents were used with different gradient steps: initial conditions, 85% A, 15% B; B from 15% to 32% in 10 min; B from 32% to 45% in 20 min; B from 45% to 80% in 20 min; B from 80% to 100% in 2 min; hold for 2 min; B from 100% to 15% in 1 min; followed by re-equilibration. Detection wavelength was 260 nm for 8−5nc-DFA metabolites, 238 nm for 8−5c-DFA diethyl ester metabolites, and either 238, 260, or 280 nm for 8−5c-DFA metabolites. Fractions were collected by hand and rotary-evaporated under reduced pressure (30 °C). The residues were frozen and lyophilized overnight to ensure complete dryness.

NMR Spectroscopy. The metabolites were dissolved in 500 μL of acetone-d_6 and analyzed at 298 K on a Bruker Ascend 500 MHz NMR spectrometer equipped with a Prodigy cryoprobe. ^{1}H, ^{1}H−^{1}H-COSY, phase-sensitive ^{1}H−^{13}C-HSQC, and ^{1}H−^{13}C-HMBC experiments (standard Bruker implementations) were performed. Data were analyzed using MestReNova software, and spectra were calibrated against the central acetone residual peak (methyl proton, 2.05 ppm; methyl carbon, 29.84 ppm).[31]

High-Resolution MS. Exact masses of the metabolites were determined by high-resolution MS experiments performed on an LC-ToF-MS/MS system consisting of a 1290 Infinity HPLC system (1290 Bin Pump G4220A with degasser, 1290 Sampler G4226A autosampler, and 1290 DAD G4212A DAD detector from Agilent Technologies, Santa Clara, CA, USA) coupled to a TripleTOF 5600 mass spectrometer (AB Sciex Instruments, Framingham, MA, USA). The same chromatographic conditions described in the LC-MS Analysis section above were used. The Duo Spray ion source was used in ESI negative mode at 650 °C with curtain gas, 45 psi; ion source gas-1, 70 psi; ion source gas-2, 60 psi; and declustering potential, −100 V. ToF-MS experiments were completed over a scan range of m/z 100−1000 using an accumulation time of 200 ms and a collision energy voltage of −10 V. ToF-MS/MS experiments (product ion scans of m/z 50−500 for m/z 317, 327, 331, 387, 389, 401, 427, and 429) were performed with the following parameters, using nitrogen as collision gas: collision energy voltage, −45 V; collision energy spread, 25 V; and accumulation time, 80 ms.

RESULTS

Incubation of 8−5nc-DFA, 8−5c-DFA, and 8−5c-DFA diethyl ester with pooled fecal samples from five donors produced a gradual disappearance of the parental diferulates, with the exception of the diethyl ester, whose concentration decreased for the first 5 h of incubation, increased sharply between 5 and 20 h, and then sank again (see Figure 2A). This pattern likely arose from the poor solubility of 8−5c-DFA diethyl ester in the medium, with only partial initial dissolution of this compound. Metabolism of this initially dissolved portion produced an early concentration decrease, but gradual dissolution of the remaining

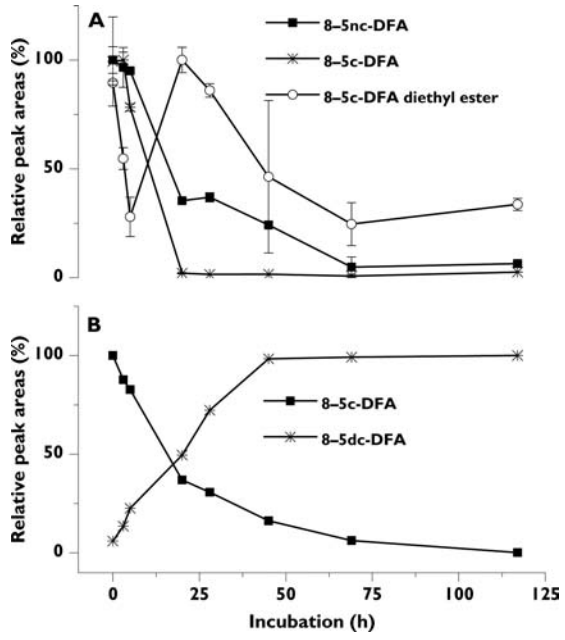

Figure 2. Time course of disappearance of substrate compounds during the *scaled-up* trial. Relative peak areas were calculated as (LC-PDA peak area at time point/maximum peak area of compound during incubation) × 100. When provided, error bars represent the range from two incubation replicates. Compound structures are provided in Figure 1. Abbreviations used: c, cyclic; dc, decarboxylated; DFA, dehydrodiferulate; nc, noncyclic. (A) Disappearance of substrate compounds during incubation with human fecal microbiota. (B) Disappearance of 8−5c-DFA and appearance of 8−5dc-DFA during control incubation (medium without human fecal microbiota).

DOI: 10.1021/acs.jafc.5b03234
J. Agric. Food Chem. 2015, 63, 7975−7985

standard compound resulted in an apparent rise in its concentration between 5 and 20 h. To confirm that the metabolism of 8−5c-DFA diethyl ester was not influenced by this behavior, we performed parallel incubations at two 8−5c-DFA diethyl ester concentrations, 370 and 37 μM, and observed no differences in the resulting metabolite profiles (data not shown).

No metabolites or artifacts were observed in the control incubations of 8−5nc-DFA and 8−5c-DFA diethyl ester. In contrast, a gradual, yet complete, disappearance of 8−5c-DFA and a corresponding appearance of 8−5dc-DFA were observed in the control incubation without fecal inoculum (see Figure 2B). Decarboxylation of 8−5c-dimers is a well-known reaction and has been described before under alkaline conditions.[32] However, Ralph and co-workers described ring-opening of the 8−5c-DFA diethyl ester, ester cleavage, and decarboxylation of the resulting 8−5nc-DFA as a competing reaction to the cleavage of the ester linkages of the 8−5c-DFA diethyl ester. They did not observe ring-opening or decarboxylation during alkaline treatment of the free (nonesterified) 8−5c-DFA. Nevertheless, to test whether the breakdown of 8−5c-DFA independent of bacterial metabolism was caused by the slightly alkaline pH (7.6) of our incubation trial, we incubated 8−5c-DFA again at pH values of 6.0, 6.4, 6.8, 7.2, and 7.6 without the addition of fecal samples. With longer incubation times the peak areas (UV detection) of 8−5c-DFA decreased to the same extent for all tested pH values and the amount of 8−5dc-DFA increased concurrently (see Figure 3). Interestingly, 8−5nc-DFA was not detected. The

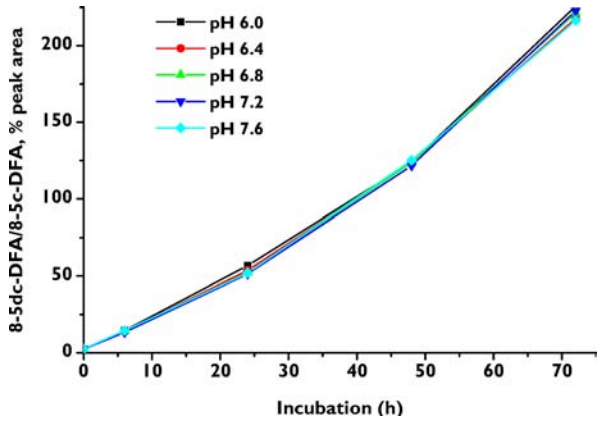

Figure 3. Disappearance of 8−5c-DFA and appearance of 8−5dc-DFA at different medium pH values during the pH stability test. Abbreviations used: c, cyclic; dc, decarboxylated.

extent of decarboxylation was influenced only by incubation length and not by the incubation pH. Reported pH values in the cecum of healthy individuals range from 5.7 to 6.8, with a gradual rise along the colon, leading to rectal pH values between 6.1 and 7.2.[33] Because decarboxylation of 8−5c-DFA was observed at all pH values between 6.0 and 7.6, we hypothesize that the reaction, although independent of microbial influence, is physiologically relevant, provided that none of the medium ingredients were responsible for this behavior.

Conversion of 8−5-Noncyclic Dehydrodiferulic Acid by Human Intestinal Microbiota. 8−5nc-DFA does not exist *in planta*, but is instead formed from 8−5c-DFA esters during exposure to alkaline conditions.[3] Alkaline pretreatment of cereal brans or flours to potentially enhance bioavailability of (di)ferulates[5] partially converts the native cyclic form to the open/noncyclic form. The *preliminary* incubation of 8−5nc-DFA with human fecal microbiota at a substrate concentration of 370 μM produced only a single metabolite structure. To test for a possible antimicrobial effect of 8−5nc-DFA at this concentration, two concentrations (370 and 37 μM) were incubated during the *scaled-up* trial. However, both substrate concentrations again produced the same single metabolite, **NCyc$_1$**. This compound was not detected in either control. LC-DAD/ESI-MS (LC retention time at 14.8 min) showed a UV absorption maximum at 325 nm and a molecular ion of m/z 387 $[M - H]^-$, indicating a gain of two mass units compared to the parent structure. The EI mass spectrum (Figure 4, molecular ion of the trimethylsilylated compound at m/z 676) also suggests a molecular mass of 388, indicating a simple reduction of the propenyl side chain on the B-unit (see structure in Figure 5). This hypothesis was confirmed by NMR data (see Tables 1 and 2) and by high-resolution MS, where the measured molecular ion (m/z 387.1083 $[M - H]^-$) matched the theoretical value for the sum formula $C_{20}H_{19}O_8$ ($[M - H]^-$) almost perfectly. In MS mode, the error was −1.4 ppm, while the intensity-weighted error calculated from 35 MS/MS fragments was 3.2 ppm. Major MS/MS fragments are presented in Table 3. Only a fraction of the parent 8−5nc-DFA compound remained at the end of incubation (see Figure 2A).

Conversion of 8−5-Cyclic Dehydrodiferulic Acid by Human Intestinal Microbiota. In comparison to 8−5nc-DFA, which produced only one microbial metabolite, the native 8−5c-DFA produced six metabolites in the *preliminary* trial, of which five compounds were isolated in semipreparative amounts from the *scaled-up* trial and fully characterized. The first metabolite, **Cyc$_1$**, was formed rapidly, with its peak concentration being found in the 6 h incubation aliquot, but then disappearing after 48 h of incubation (see Figure 6B). Eluting after 16.5 min in the LC system, its UV spectrum showed a maximum at 325 nm, and its ESI-MS (negative ionization) spectrum showed a quasimolecular ion of m/z 387 $[M - H]^-$, or a gain of two mass units compared to the original substrate. Following trimethylsilylation, **Cyc$_1$** produced the EI mass spectrum shown in Figure 4. Besides the molecular ion at m/z 676, a diagnostic fragment at m/z 209 was observed, which represents a resonance-stabilized A-ring carbocation formed via cleavage of the β-bond between C7 and C8 of the A-ring moiety. NMR data (see Tables 1 and 2) showed that the structure was formed by reductive opening of the substrate benzofuran ring (Figure 5). The two H7 protons on the A-ring were chemically distinct, resulting in two H7 signals at 3.32 and 3.04 ppm, respectively. Although the signal at 3.32 ppm lay under the residual water signal in the ^{1}H spectrum and could not be integrated, ^{1}H−^{1}H-COSY showed clear couplings from the proton at 3.32 ppm to both H8 (4.40 ppm) and the H7 proton, represented by the signal at 3.04 ppm, both of which produced integrals corresponding to one proton. Additionally, HSQC data showed that both signals assigned to H7 coupled to the same carbon nucleus. High-resolution MS data (see Table 3) further confirmed this structural characterization. The mass error of the measured molecular ion, m/z 387.1087 $[M - H]^-$, was 0.4 ppm relative to the theoretical value, while the intensity-weighted error determined from 10 MS/MS fragments was 2.8 ppm.

The second isolated metabolite, **Cyc$_2$**, was first detected in trace quantities in the 5 h sample aliquot, rising to its peak concentration at 20 h and then tapering off (see Figure 6B). The compound had an LC retention time of 16.30 min and a UV absorption maximum at 280 nm with no absorption above 300 nm, which indicated reduction of both propenyl side chains. The structure's molecular ion (LC-ESI-MS) was m/z 389 $[M - H]^-$,

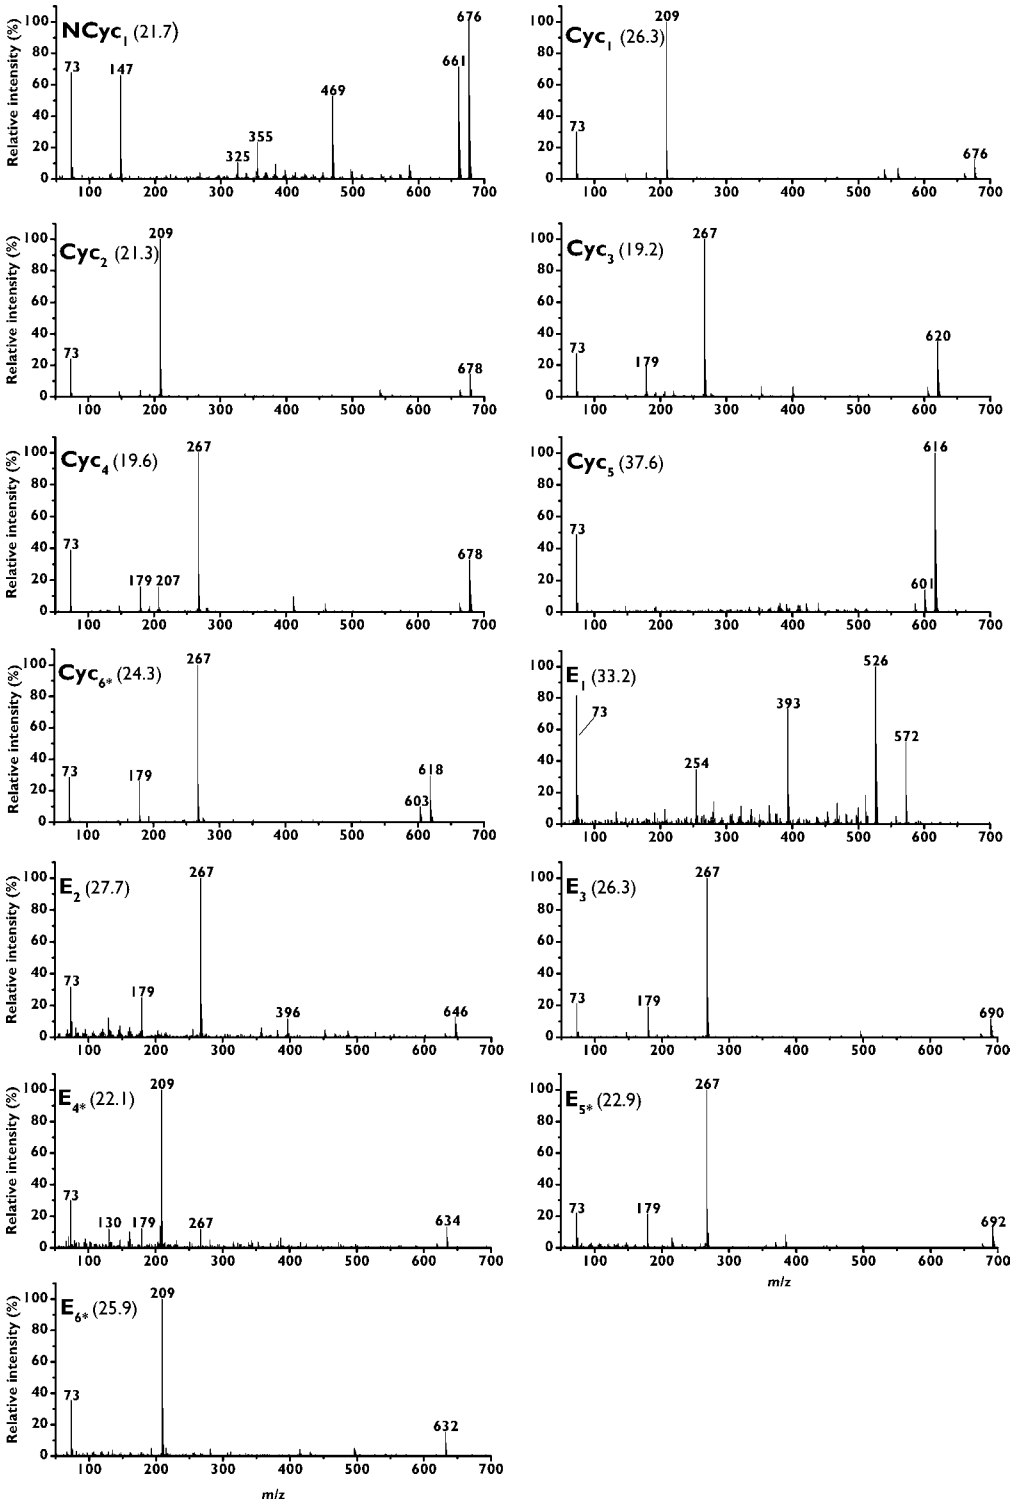

Figure 4. Electron impact mass spectra from trimethylsilylated metabolites of 8−5-coupled dehydrodiferulate (DFA) compounds following incubation with human fecal microbiota. Metabolite structures are provided in Figures 5 and 7. Title of each spectrum includes the abbreviated metabolite name and GC retention time (min) of the trimethylsilylated compound.

a gain of four mass units compared to 8−5c-DFA. The molecular ion of the trimethylsilylated compound, *m*/*z* 678, the same characteristic fragment as **Cyc$_1$**, *m*/*z* 209, and NMR data (see Tables 1 and 2) showed that the **Cyc$_2$** structure was similar to **Cyc$_1$**, except for reduction of the propenyl side chain on the B-unit (Figure 5). The H7 protons on the A-unit were again chemically distinct in the NMR spectrum, producing two ^{1}H signals both integrating to one proton. These data were in agreement with the high-resolution MS and MS/MS results (see Table 3), which produced an accurate mass of *m*/*z* 389.1238 [M − H]$^-$. Deviation from the theoretical exact mass for $C_{20}H_{21}O_8$ ([M − H]$^-$) was only −1.0 ppm in the MS mode and 5.7 ppm in the MS/MS mode (intensity-weighted error was calculated from 19 fragments).

[a]For compound structures, see Figure 5. [b]Values in parentheses indicate relative intensities.

(negative ionization mode) produced a quasimolecular ion with m/z 331 $[M - H]^-$ or a loss of 54 mass units compared to the parent structure. The molecular mass was once again confirmed by GC-MS of the trimethylsilylated compound (see Figure 4). In addition to the molecular ion, m/z 620, the fragment ion at m/z 267 stemming from the formation of a resonance-stabilized A-ring carbocation via cleavage of the β-bond between C7 and C8 of the A-ring moiety was diagnostic, as well as a following fragment reduced by 88 mass units (here m/z 179) often observed in trimethylsilylated phenolic compounds with two vicinal hydroxyl substituents.[34] NMR data (see Tables 1 and 2) confirmed that **Cyc$_3$** had been formed by O-demethylation and decarboxylation of the ferulate A-unit, in addition to reduction of the propenyl side chain on the B-unit. This structure (see Figure 5) was confirmed by high-resolution MS and MS/MS results (see Table 3), which produced an exact mass of m/z 331.1187 $[M - H]^-$, with no observable deviation from the theoretical result for $C_{18}H_{19}O_6$ ($[M - H]^-$) in MS mode and only 2.9 ppm intensity-weighted error (calculated from 16 fragments) in MS/MS mode. The time-course appearance of **Cyc$_3$** showed that, following its initial appearance between 6 and 20 h, its concentration continued to gradually rise throughout the incubation (see Figure 6B).

A similar kinetic pattern was observed for the metabolite **Cyc$_4$**. The LC retention time of **Cyc$_4$** was 15.4 min, and the compound produced a UV absorption maximum at 280 nm with no absorption above 300 nm. The LC-ESI-MS quasimolecular ion (m/z 317 $[M - H]^-$) and GC-MS analysis of the trimethylsilylated compound (molecular ion at m/z 678, see Figure 4) indicated a loss of 68 mass units compared to 8−5c-DFA. The same characteristic GC-MS fragment ions of the trimethylsilylated compound, m/z 267 and 179, were observed, pointing to an A-ring structure similar to **Cyc$_3$**. NMR analysis (see Tables 1 and 2) confirmed these results, showing that **Cyc$_4$** was formed by O-demethylation of both the A- and B-rings, decarboxylation of the A-unit, and reduction of the B-unit propenyl side chain (Figure 5). High-resolution MS results were also satisfactory (see Table 3), with the measured exact mass of m/z 317.1028 $[M - H]^-$ varying from the theoretical calculated

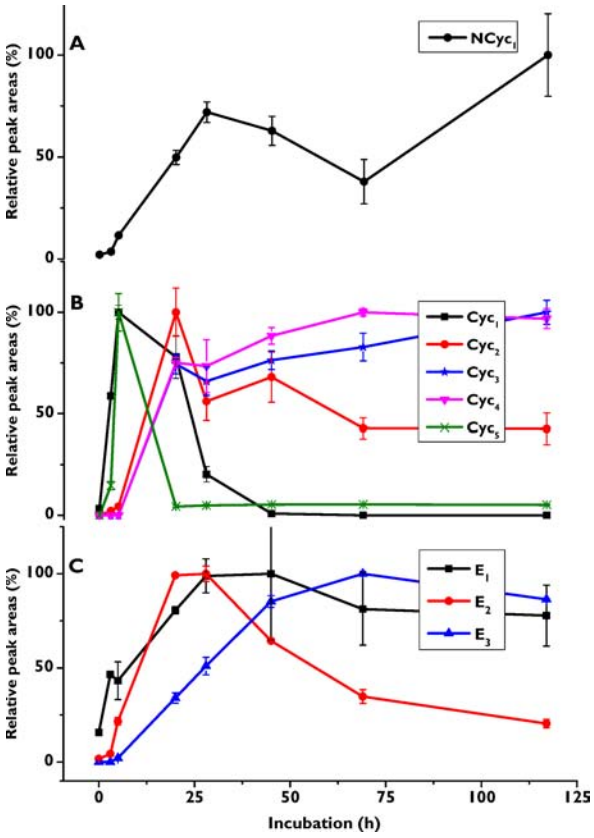

Figure 6. Time course of appearance of 8−5-coupled dehydrodiferulate (DFA) metabolites during the *scaled-up* trial. Relative peak areas were calculated as (LC-PDA peak area at time point/maximum peak area of compound during incubation) × 100. Error bars represent the range from two incubation replicates. Metabolite structures are provided in Figure 5. Abbreviations used: c, cyclic; nc, noncyclic. (A) Appearance of 8−5nc-DFA's metabolite, **NCyc$_1$**, during incubation with human fecal suspension. (B) Appearance of metabolites of 8−5c-DFA during incubation with human fecal suspension. (C) Appearance of metabolites of 8−5c-DFA diethyl ester during incubation with human fecal suspension.

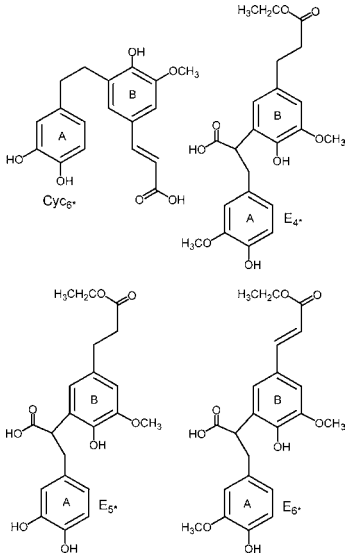

Figure 7. Tentative structures of four additional metabolites of 8−5-coupled dehydrodiferulate (DFA) compounds following incubation with human fecal microbiota. *Proposed structures are based only on GC-EI-MS fragmentation, and structures different from those shown are possible. **E** compounds: metabolites of 8−5-cyclic DFA diethyl ester; **Cyc** compounds: metabolites of 8−5-cyclic DFA.

mass for $C_{17}H_{17}O_6$ ($[M - H]^-$) by only −0.8 ppm in MS mode and 2.8 ppm in MS/MS mode (21 fragment ions).

The final fully characterized 8−5c-DFA metabolite, **Cyc$_5$** (LC retention time: 21.0 min), had a UV absorption maximum at 322 nm, an LC-ESI-MS (negative ionization mode) quasimolecular ion of *m/z* 327 $[M - H]^-$, and a GC-MS molecular ion of the trimethylsilylated compound of *m/z* 616. NMR analysis provided the exact structure, a singly demethylated metabolite of 8−5dc-DFA (see Figure 5 for metabolite structure). The exact mass of the isolated substance as determined by high-resolution MS was *m/z* 327.0875 $[M - H]^-$, which differed from the theoretical calculated mass for $C_{18}H_{15}O_6$ ($[M - H]^-$) by only 0.3 ppm. The intensity-weighted average error in MS/MS mode was 3.0 ppm (19 fragment ions).

A sixth metabolite of 8−5c-DFA, **Cyc$_{6*}$**, was observed in GC-MS analysis, but we were unable to preparatively isolate sufficient amounts of this compound for unambiguous NMR-based structure characterization. However, a *tentative* structure (see Figure 7, please note that the asterisk in the structure's name indicates that the structure must be treated as indefinite and that other structures are possible) can be proposed based on the EI mass spectrum of the trimethylsilylated compound (Figure 4). Because the compound showed the same base fragment as **Cyc$_3$** and **Cyc$_4$** (*m/z* 267, arising from cleavage of the *β*-alkyl bond linking the A- and B-rings to form a strongly resonance-stabilized carbocation on the A-ring moiety), a following fragment reduced by 88 mass units, here *m/z* 179, indicating two phenolic trimethylsilylated vicinal hydroxyl substituents,[34] and a molecular ion of *m/z* 618, two mass units less than **Cyc$_3$**, the compound is likely **Cyc$_3$**'s precursor with an unreduced propenyl side chain on the ferulate B-unit. The maximum GC-MS peak area for this compound was observed at the 6 h incubation point and then dropped off gradually (data not shown), further supporting the idea that this compound is a precursor to **Cyc$_3$**, which first appeared later, in the 20 h incubation samples.

Conversion of the Diethyl Ester of 8−5-Cyclic Dehydrodiferulic Acid by Human Intestinal Microbiota. Incubation of 8−5c-DFA diethyl ester with human fecal microbiota produced several metabolites, three of which were isolated and fully characterized: **E$_1$**, **E$_2$**, and **E$_3$** (see Figure 5 for structures and Figure 6C for the metabolites' time course of appearance). **E$_1$** was detected almost immediately following addition of fecal suspension to the sample (however, the formation required the presence of fecal suspension: no **E$_1$** was detected in the fecal-free control incubation), reaching maximum concentration at 28 h and remaining constant throughout the rest of the incubation. The structure had a UV absorption maximum at 328 nm, an LC-ESI-MS quasimolecular ion at *m/z* 427 $[M - H]^-$ (retention time: 35.6 min), and a GC-MS molecular ion of the trimethylsilylated compound at *m/z* 572 (Figure 4), indicating a loss of 14 mass units from the parent substrate. NMR experiments (see Tables 1 and 2) showed that, compared to the parent structure, **E$_1$** was demethylated on the A-ring. The structure (see Figure 5) was confirmed by high-resolution MS (see Table 3), displaying an exact mass of *m/z* 427.1393 $[M - H]^-$, with only −1.3 ppm difference in MS mode from the theoretical value for $C_{23}H_{23}O_8$ ($[M - H]^-$) and 2.4 ppm intensity-weighted error in MS/MS mode (calculated from 27 fragments).

DOI: 10.1021/acs.jafc.5b03234
J. Agric. Food Chem. 2015, 63, 7975−7985

$\mathbf{E}_2$ was also produced rapidly (although not to the extent of $\mathbf{E}_1$, compare Figure 6C), first appearing in substantial amounts at the 6 h time point, reaching maximum concentration at 24 h and steadily decreasing after 28 h. The compound eluted at 32.6 min on the LC system and had a UV absorption maximum at 329 nm and a quasimolecular ion of m/z 429 $[M - H]^-$, representing a difference of 12 mass units compared to the substrate. The molecular mass of 430 was consistent with the GC-MS results, which produced a molecular ion of the trimethylsilylated compound at m/z 646. As observed for other metabolites, the fragment ion at m/z 267 represents the formation of a resonance-stabilized A-ring carbocation via cleavage of the β-bond between C7 and C8 of the ferulate A-unit. NMR experiments (see Tables 1 and 2) showed that $\mathbf{E}_2$ had been formed from the parent compound by A-ring O-demethylation and reductive opening of the benzofuran ring (see Figure 5). High-resolution MS analysis was in accord with these results, producing an exact mass of m/z 429.1549 $[M - H]^-$, diverging from the theoretically calculated value for $C_{23}H_{25}O_8$ ($[M - H]^-$) by only −1.4 ppm in MS mode. MS/MS fragmentation (see Table 3) also produced only 3.5 ppm error (intensity-weighted, calculated from nine fragments).

$\mathbf{E}_3$ eluted at 23.2 min on the LC and produced a quasimolecular ion of m/z 401 $[M - H]^-$. GC-MS analysis of the trimethylsilylated compound resulted in a molecular ion of m/z 690 (see Figure 4), respectively. The compound absorbed UV energy at 326 nm, suggesting an intact propenyl side chain. On the other hand, the m/z 267 fragment ion in the GC-MS spectrum suggested a reduced ferulate A-ring unit, as observed for $\mathbf{E}_2$. Interpretation of the NMR data (see Tables 1 and 2) showed that, in comparison to $\mathbf{E}_2$, $\mathbf{E}_3$ had been de-esterified on the A-ring moiety (see Figure 5). Kinetic data (see Figure 6C) confirmed the hypothesis that $\mathbf{E}_3$ is formed from $\mathbf{E}_2$, with substantial detection of the compound first occurring after 24 h of incubation and maximum concentration levels at 72 h. The structure was confirmed by high-resolution MS experiments (see Table 3). The measured exact mass, m/z 401.1242 $[M - H]^-$, showed no measurable difference from the theoretical value for $C_{21}H_{21}O_8$ ($[M - H]^-$) in the MS mode and only 2.4 ppm intensity-weighted error in MS/MS mode (calculated from 12 fragments).

Three additional unique metabolites, $\mathbf{E}_{4*}$, $\mathbf{E}_{5*}$, and $\mathbf{E}_{6*}$, were detected in GC-MS analysis of the 8−5c-DFA diethyl ester incubation extracts, but were not isolated in sufficient quantities for NMR analysis. GC-MS fragmentation of the trimethylsilylated compounds (see Figure 4) enabled *tentative* structural proposals (see Figure 7). The first, $\mathbf{E}_{4*}$, which, like $\mathbf{E}_3$, was observed in the 24, 48, and 120 h incubation time points (data not shown), was, in contrast to $\mathbf{E}_3$, likely not demethylated on the A-ring, as indicated by the presence of the m/z 209 fragment, although a small amount of m/z 267 is also present in the spectrum. However, because the m/z 267 fragment was observed to be the dominant fragment in all confirmed structures displaying the necessary A-ring reduction and demethylation, it is more likely that the fragment represents a minor coelution. The molecular ion, m/z 634, would then represent single de-esterification, reductive ring-opening of the benzofuran moiety and reduction of the B-ring propenyl side chain. It was not possible to assign the position of single de-esterification, and it is possible that de-esterification occurred on the B-ring unit instead of the A-ring ferulate unit as depicted in Figure 7.

The EI spectrum of the trimethylsilylated $\mathbf{E}_{5*}$ indicates that the compound is likely identical to $\mathbf{E}_3$, except for reduction of the B-ring propenyl side chain (molecular ion m/z 692). Furthermore, the main fragment, m/z 267, and the following m/z 179 fragment are indicative of a reduced A-ring side chain and A-ring O-demethylation. The hypothesis that $\mathbf{E}_{5*}$ represents a further metabolism of $\mathbf{E}_3$ also corresponds to the observation that the structure was first observed at the 24 h incubation time point and then persisted throughout the rest of the incubation (data not shown). It is possible that de-esterification occurred on the B-ring unit instead of the A-ring ferulate unit as depicted in Figure 7.

$\mathbf{E}_{6*}$ was observed in small amounts at both the 48 and 117 h time points (data not shown). The EI spectrum of the trimethylsilylated compound (Figure 4) presented m/z 209 as the main fragment ion, pointing toward reductive opening of the benzofuran moiety and an intact methoxy substituent on the A-ring. The molecular ion, m/z 632, could correspond to the tentative structure depicted in Figure 7, with single de-esterification (de-esterification could also have occurred on the B-ring unit instead of the A-ring ferulate unit as depicted in Figure 7) and reductive opening of the benzofuran structural component. The emergence of this singly de-esterified, but otherwise relatively unmetabolized structure so late in the incubation time frame stands in contrast to the other 8−5c-DFA diethyl ester metabolites, where de-esterification was observed primarily after or concurrently with other metabolic transformations such as O-demethylation and reduction. Finally, in addition to the six metabolites of 8−5c-DFA diethyl ester described above, we were able to confirm the formation of trace amounts of $\mathbf{Cyc}_2$, $\mathbf{Cyc}_3$, and $\mathbf{Cyc}_4$ after 48 h of incubation of the esterified substrate. The presence of these fully de-esterified compounds establishes the ability of human gut microbiota to release 8−5-coupled diferulates from their ester linkages.

DISCUSSION

Numerous potential health benefits have been suggested for the hydroxycinnamate components of cereal grains,[19] of which DFAs form a substantial portion. Insoluble dietary fiber from maize grain, for example, contains over 12.5 mg DFAs/g fiber.[35] At 35% to 59% of the total DFAs, the 8−5-coupled DFA regioisomer is the most abundant DFA regioisomer in all major cereals.[27] Because the majority of 8−5-coupled DFAs are consumed esterified to cereal arabinoxylans, their bioavailability depends upon their release from the fiber matrix by the cooperative action of microbial xylanases and esterases in the large intestine. As previously demonstrated,[21,28] human intestinal microbiota can cleave ester linkages to DFAs, which we confirmed in this study by the isolation and complete structural characterization of a singly de-esterified metabolite, $\mathbf{E}_3$, the tentative identification of three additional singly esterified metabolites, $\mathbf{E}_{4*}$, $\mathbf{E}_{5*}$, and $\mathbf{E}_{6*}$, and the detection of several fully de-esterified compounds ($\mathbf{Cyc}_2$, $\mathbf{Cyc}_3$, and $\mathbf{Cyc}_4$) following incubation of a model DFA ester, 8−5c-DFA diethyl ester, with a human fecal inoculum. However, although these findings confirm that gut bacterial esterases can cleave ester bonds attached to 8−5coupled-DFAs, the physiochemical properties (especially solubility and steric considerations) of the model diethyl ester used in this study cannot be expected to induce metabolite formation as accurately as an authentic 8−5c-DFA diarabinose ester. O-Demethylation tended to occur faster than hydrogenation of the B-ring propenyl side chain in the esterified compound, as evidenced by $\mathbf{E}_1$, $\mathbf{E}_2$, $\mathbf{E}_3$, and $\mathbf{E}_{5*}$, which all display A-ring O-demethylation without hydrogenation of the B-ring. However, the tentative structure $\mathbf{E}_{4*}$ appeared to be an exception to this pattern, similar to nonesterified, monomeric ferulic acid and 5−5-DFA, where

DOI: 10.1021/acs.jafc.5b03234
J. Agric. Food Chem. 2015, 63, 7975−7985

side chain hydrogenation occurs faster than O-demethylation.[25,28] We also observed reductive opening of the benzofuran ring in several metabolites, although the unambiguous characterization of E_1, which displayed an intact benzofuran ring, showed that benzofuran ring-opening, although rapid, is not spontaneous.

The results from the free acid 8−5c-DFA, which was variously transformed by human gut microbiota via side chain hydrogenation, reductive opening of the benzofuran ring, and O-demethylation, showed no clear preference for the rate of O-demethylation compared to side chain hydrogenation. Several decarboxylated metabolites were characterized that likely arose from microbial metabolism of 8−5dc-DFA, whose decarboxylation occurred independently from microbial metabolism. However, because the 8−5dc-DFA originated under physiologically relevant temperature and pH conditions, these metabolites may be regarded as authentic end points of 8−5c-DFA's exposure to the colonic environment and microbiota, provided decarboxylation was not accelerated by ingredients in the brain-heart medium.

Incubation of 8−5nc-DFA, a non-native byproduct of 8−5c-DFA, produced only one metabolite, substantially fewer than the six metabolites from 8−5c-DFA. In particular, O-demethylation of 8−5nc-DFA was not observed. The reason for the lack of metabolite diversity for 8−5nc-DFA compared to 8−5c-DFA is unknown. These results underline the fine-tuned structure dependence of microbial metabolism and the danger of assuming that comparable structures will be similarly metabolized without laboratory confirmation.

Dehydroxylation was not observed in any metabolites from any of the three substrate compounds. In contrast, bacterial metabolism of ferulic acid monomers results in dehydroxylation of the phenyl ring, producing 3-phenylpropionic acid as an end product.[26] Dehydroxylation was also observed in the bacterial metabolism of 8−*O*−4-DFA, although this occurred only following cleavage of the dimeric DFAs to monomers. Similar to our results with 8−5-coupled DFAs, the 5−5-DFA regioisomer was not susceptible to dehydroxylation.[25] No cleavage to monomers was observed for any of the three 8−5-coupled standard compounds, in contrast to 8−*O*−4-DFA, which is completely converted to monomeric metabolites by human gut microbiota.[25]

Substantial metabolite formation was observed within 28 h from each of the 8−5-coupled DFA standard compounds investigated in this study. Importantly, de-esterification was not necessary for metabolism of the 8−5c-DFA diethyl ester compound (although de-esterification was observed to occur to a measurable extent within this time frame), indicating that the release of already-metabolized 8−5-coupled DFAs instead of only the free acids is theoretically possible. While colonic transit time is influenced by many factors, including age, physical activity level, and diet, with reported literature values ranging from approximately 23 to 30 h in healthy individuals consuming their routine diets,[36,37] these results indicate that 8−5-coupled DFAs are susceptible to microbial degradation within the colonic transit time span. Detection of the described microbial metabolites in urine or plasma (as conjugates) will be necessary to confirm the physiological relevance of these *in vitro* results.

tumor necrosis factor (TNF)-α, mouse interferon (IFN)-γ, and mouse interleukin (IL)-1β were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). All other reagents used in this study were of analytical grade.

Preparation of SCP-1. *Extraction of SCP.* Briefly, fresh *S. constricta* was collected and washed carefully with water. After removal of the shells and impurities, the flesh was crushed by a high-speed disintegrator, and the homogenate was kept in 85% of ethanol (v/v) for 1 week to defat and remove pigments and small molecule substances. The collected flesh was then air-dried at 50 °C and used for the extraction. The dried powder of *S. constricta* was dissolved in deionized water (20 mL/g (v/w) for ratio of water/material) containing 2.0% papain. After incubation at 50 °C for 6 h, the mixture was boiled for 10 min and centrifuged at 3040*g* for 20 min. The supernatant was precipitated with 3 volumes of dehydrated ethanol (ethanol final concentration, 75%) at 4 °C for 12 h, and the resulting precipitates were obtained by centrifugation at 3040*g* for 15 min. The precipitates were dissolved in deionized water, the pH was adjusted with 1.0 M HCl to 2.5, and the mixtures were kept at 4 °C for 4 h and then centrifuged at 3040*g* for 15 min to remove acidic albumen.[24] The supernatant was adjusted to neutral and precipitated again with dehydrated ethanol. Finally, the precipitates were collected by centrifugation at 3040*g* for 15 min and vacuum freeze-dried, affording the crude SCP.

Purification of Crude SCP. The crude SCP was applied to a DEAE-52 cellulose column (2.6 × 50 cm) and eluted stepwise with NaCl solutions from low to high concentration (0, 0.1, and 0.3 M) at a flow rate of 1.0 mL/min. The fractions were collected (10 mL/tube) and checked by tracking the absorbance at 490 nm using the phenol−sulfuric acid method.[25] The major polysaccharide fraction (F-1) was collected, dialyzed, freeze-dried, and loaded onto a column (1.6 × 60 cm) of Sephadex G-100. The column was eluted with deionized water at a flow rate of 15 mL/h, and the elution was checked as described above. As a result, one purified fraction was collected and vacuum freeze-dried, affording SCP-1.

Determination of Contents of Carbohydrate, Protein, Uronic Acid, and Sulfuric Radical. The contents of carbohydrate, protein, uronic acid, and sulfuric radical in SCP-1 were determined according to the reported methods.[26]

Determination of Homogeneity and Molecular Weight. The homogeneity and molecular weight of SCP-1 were determined by high-performance gel permeation chromatography (HPGPC) with an Agilent 1200 series apparatus (Agilent Technologies, Santa Clara, CA, USA) equipped with a Shodex OHpak SB-804 HQ column (8 × 300 mm). The column was eluted with 0.1 M NaCl at a flow rate of 0.5 mL/min, and the column temperature was kept constant at 35 °C. The molecular weight and polydispersity index (M_w/M_n) were estimated by HPGPC, and the column was calibrated by standard D-series dextrans (D-2, D-3, D-4, D-5, D-6, D-7, and D-8) with known molecular weight.

Analysis of Monosaccharide Composition. The monosaccharide composition of SCP-1 was analyzed by HPLC as described previously.[27] The polysaccharide solution (100 μL, 5.0 mg/mL) was mixed with 100 μL of 4.0 M trifluoroacetic acid (TFA) and hydrolyzed at 120 °C for 2 h. The resulting solution was cooled to room temperature, and the excess TFA was removed by repeated codistillations with methanol. The residue was dissolved with deionized water (100 μL) and mixed with 100 μL of 0.6 M NaOH, and half of the mixture was derivatized with 0.5 M methanol solution of PMP (100 μL) for 100 min at 70 °C. After neutralization with 0.3 M HCl, the resultant solution was concentrated to dryness under reduced pressure. Deionized water and chloroform were added to the residue, followed by vortexing. The water phase was filtered through a 0.45 μm membrane and then analyzed by an Agilent HPLC using Eclipse Plus C18 column (4.6 × 250 mm, 5 μm, Agilent) and ultraviolet (UV) detector at a flow rate of 1.0 mL/min at 30 °C. The mobile phase contained 83% phosphate-buffered saline (PBS, 0.1 M, pH 6.7) and 17% acetonitrile (v/v). In a similar manner, the monosaccharide standards were PMP-labeled and analyzed by HPLC.

FT-IR Spectral Analysis. The polysaccharide sample was incorporated into potassium bromide (KBr, spectroscopic grade) and pressed into a 1 mm pellet. The IR spectrum of SCP-1 in a range of 400−4000 cm^{-1} was recorded with a Nicolet 6700 FT-IR spectrometer (Thermo Fisher Scientific Inc., Waltham, MA, USA).

Methylation and GC-MS Analysis. SCP-1 was methylated according to the reported method.[28,29] Briefly, SCP-1 (dried) was dissolved in dimethyl sulfoxide (DMSO), and NaOH was then added. The mixture was treated for 20 min under ultrasonic condition. Then, SCP-1 was methylated under darkness by the addition of methyl iodide with ultrasonic for 2 h, and the remaining methyl iodide was decomposed by the addition of deionized water. The methylated sample was extracted with trichloromethane and evaporated to dryness by a stream of nitrogen. Then, the dried methylated sample was hydrolyzed by 2 M TFA at 120 °C for 2 h, reduced with sodium borodeuteride at 50 °C for 2 h, and acetylated with pyridine and acetic anhydride at 100 °C for 1 h. Deionized water and dichloromethane were added to the acetylated derivatives, and the organic phase was dried under nitrogen, dissolved in dichloromethane, and analyzed by GC-MS. The GC-MS analysis was performed on a HP6890GC/5973MS system equipped with an ion trap MS detector and fitted with a HP-5MS quartz capillary column (30 mm × 0.25 mm, 0.25 μm film thickness, 150−200 °C at 2 °C/min and then 200−280 °C at 5 °C/min).

NMR Analysis. NMR analysis was performed at 298 K on a Bruker DRX Avance III 500 MHz spectrometer (Bruker Corp., Karlsruhe, Germany) equipped with a $^{13}C/^{1}H$ dual probe in FT mode. The freeze-dried SCP-1 was dissolved in deuterium (D_2O, 99.9% D) and lyophilized three times to replace exchangeable protons with D_2O. The lyophilized sample was then dissolved in D_2O at a concentration of 100 mg/mL and analyzed by NMR spectrometer. All chemical shifts are relative to internal sodium 2,2-dimethyl-isotope 2-silapentane-5-sulfonate (DSS).

Assay of Immunomodulatory Activity in Vitro of SCP-1. *Cell Culture.* The murine macrophage RAW264.7 cells were cultured in DMEM supplemented with 10% (v/v) new bovine calf serum and 1% (v/v) penicillin−streptomycin at 37 °C in a humidified atmosphere containing 5% CO_2. The cells were cultivated in sterile tissue culture flasks and subcultured for experimentation.

Assay of Cell Viability. The viability of RAW264.7 cells was assessed by using MTT-based colorimetric assay.[30] Briefly, 100 μL/well of RAW264.7 cell suspension was plated in a 96-well culture plate and incubated (37 °C, 5% CO_2) for 12 h. The adherent RAW264.7 cells were washed twice by PBS and then incubated with medium containing various concentrations of sample (12.5, 25.0, 50.0, 100.0, and 200.0 μg/mL) as well as complete medium alone (blank control) or LPS (10.0 μg/mL, positive control) for 48 h. The stimulated cells were washed twice by PBS, and 200 μL of MTT solution (0.5 mg/mL) was added to each well. After further incubation for 4 h, 150 μL of DMSO was added to each well to dissolve the formazen crystals. The absorbance (Abs) at 570 nm was determined by using a microplate reader. The cell viability was calculated by using the following equation:

$$\text{cell viability} = \text{Abs}_{\text{sample}}/\text{Abs}_{\text{blank control}}$$

Assay of Phagocytosis. The influence of SCP-1 on phagocytic activity was investigated by using the neutral red phagocytosis assay.[31] As described above, confluent cultures of RAW264.7 cells in 96-well plates were exposed to complete medium alone or different concentrations of sample or LPS solution and incubated for 48 h at 37 °C. After removal of supernatant, the nonadherent cells were removed by washing twice with PBS, and 100 μL of neutral red solution was added to each well. The plates were incubated for 1 h, followed by the removal of the supernatant. To remove the excess neutral red solution, the cells were washed with PBS twice. After that, 100 μL of cell lysate (1.0 M acetic acid/ethanol = 1:1, v/v) was then added to each well. After incubation overnight at room temperature, the Abs at 540 nm of each well was measured by a microplate reader. The phagocytosis index of macrophages was calculated by using the following equation:

$$\text{phagocytosis index} = \text{Abs}_{\text{sample}}/\text{Abs}_{\text{blank control}}$$

Assay of Acid Phosphatase. The effect of SCP-1 on acid phosphatase activity of RAW264.7 cells was investigated according to the reported method.[32] The cultured RAW264.7 cells were treated with complete

DOI: 10.1021/acs.jafc.5b03306
J. Agric. Food Chem. 2015, 63, 7986−7994

medium alone or SCP-1 solution (12.5, 25.0, 50.0, 100.0, and 200.0 μg/mL) or LPS (10.0 μg/mL). After incubation for 48 h at 37 °C, the supernatant was aspirated from the wells, 25 μL of 1% Triton X-100 and 150 μL of 1.0 mg/mL *p*-nitrophenyl phosphate (substrate of acid phosphatase) were added to each well, and the plate was incubated at 37 °C for 1 h. The reaction was terminated by the addition of 50 μL of 3.0 M NaOH solution, and the Abs of the culture well was measured at 405 nm by spectrophotometer. The index of acid phosphatase activity was calculated by using the following equation:

$$\text{index of acid phosphatase activity} = \text{Abs}_{\text{sample}}/\text{Abs}_{\text{blank control}}$$

Assay of Cytokine and NO. The levels of NO, TNF-α, IFN-γ, and IL-1β in the supernatants of the RAW264.7 cells from each group were determined by using ELISA kits according to the manufacturers' protocols.

Statistical Analysis. Data were expressed as means ± standard deviations (SD), and a one-way ANOVA was performed, followed by Duncan's multiple-range tests. *P* values of <0.05 were considered to be statistically significant. All statistical analyses were performed using SPSS software version 19.0 (Chicago, IL, USA).

RESULTS AND DISCUSSION

Preparation of SCP-1. The crude SCP was obtained in a yield of 18.4% from dried *S. constricta* through steps of extraction, deproteination, and ethanol precipitation. The crude SCP was first separated through anion-exchange chromatography of DEAE-52, affording two independent elution peaks as detected by the phenol−sulfuric acid assay (Figure 1A). Notably, F-1 (eluted by deionized water) was the main polysaccharide fraction of crude SCP. In the present study, the leading polysaccharide fraction (F-1) was further purified by Sephadex G-100 size exclusion chromatography. As shown in Figure 1B, it yielded a single elution peak, named SCP-1.

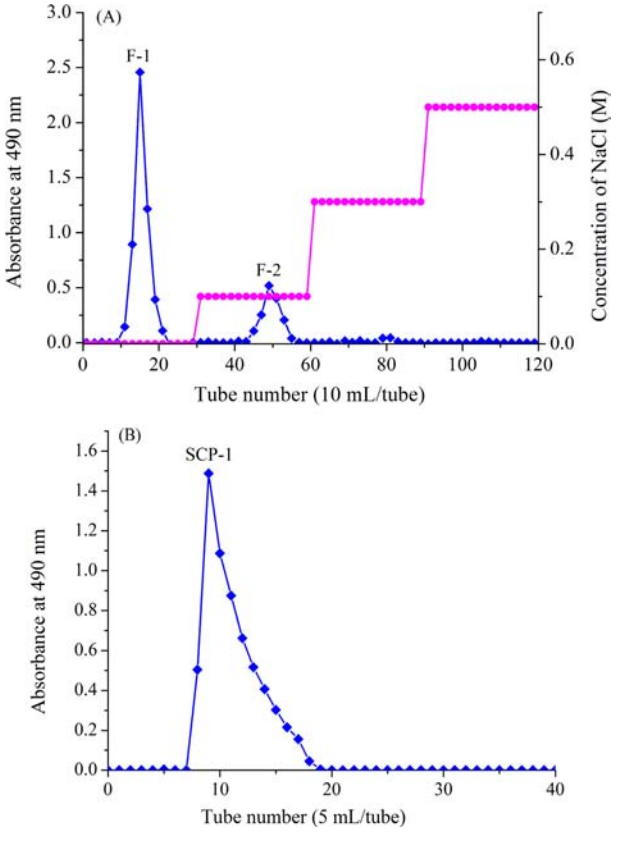

Figure 1. Stepwise elution curve of crude SCP on a DEAE-52 column (A) and elution profile of F-1 on a Sephadex G-100 column (B).

Characterization of SCP-1. *Contents of Carbohydrate, Protein, Uronic Acid, and Sulfuric Radical in SCP-1.* The contents of carbohydrate, uronic acid, and sulfuric radical in SCP-1 were 99.96, 0.13, and 0.20%, respectively. However, SCP-1 had a negative response to the Bradford test and showed no absorption at 280 or 260 nm in the UV spectrum, indicating the absence of protein or nucleic acid in SCP-1.

Molecular Weight and Monosaccharide Composition of SCP-1. As shown in Figure 2, SCP-1 was eluted as a single and symmetrical peak from HPGPC on a Shodex OHpak SB-804 HQ column, indicating that SCP-1 was a homogeneous polysaccharide. The average molecular weight of SCP-1 was estimated to be 15.63 kDa on the basis of calibration with standard D-series dextrans. M_w/M_n was used to determine the width of the molecular weight distribution, which represents the dispersibility and homogeneity of a polymer.[33] As a result, the M_w/M_n for SCP-1 was 1.695 estimated by GPC software version B01.01 (Agilent, USA). Furthermore, the monosaccharide composition of SCP-1 was analyzed by HPLC. Obviously, SCP-1 was composed of only glucose (Figure 3), indicating that it is a homopolysaccharide.

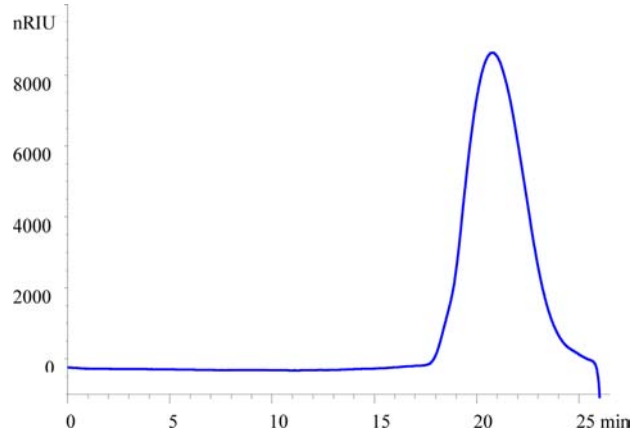

Figure 2. HPGPC profile of SCP-1.

FT-IR Spectrum of SCP-1. The FT-IR spectrum of SCP-1 is shown in Figure 4. The bands at 3359.26 and 2928.54 cm^{-1} were ascribed to the stretching vibrations of O−H and C−H, respectively.[34] The band in the region of 1641.02 cm^{-1} was due to the associated water. Absorption at 849.72 cm^{-1} indicated the presence of an α-type glycosidic linkage, which is consistent

DOI: 10.1021/acs.jafc.5b03306
J. Agric. Food Chem. 2015, 63, 7986−7994

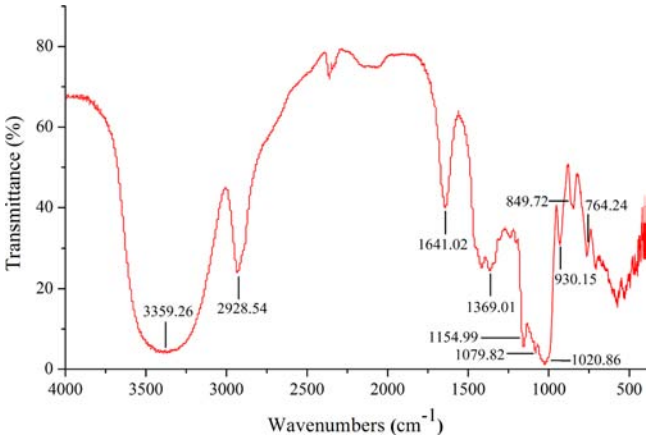

Figure 4. FT-IR spectrum of SCP-1.

with its high positive value of optical rotation ($[\alpha]_D^{25}$ = +172.27° (*c* 0.1, water)).[35] The absorptions at 1020.86, 1079.82, and 1154.99 cm^{-1} also indicated the presence of a pyranose form of sugars.[36,37] The absorption bands at 930.15, 849.72, and 764.24 cm^{-1} suggested that SCP-1 was a D-glucopyranose derivative.[38] Therefore, it can be concluded that SCP-1 belongs to the α-type glucans with a pyran group.

Methylation Analysis of SCP-1. The methylation of SCP-1 yielded *O*-methyl-D-glucans, and the hydrolysis of the methylated polysaccharide and the acetylation of the methyl-D-glucosides yielded residues of 2,3,4,6-tetra-, 2,3,6-tri-, and 2,3-di-*O*-methylglucose, based on GC-MS analysis. The molar ratio of main chain to branch was estimated as (3.87 + 0.74):1.00 from the peak areas (Table 1). These results indicated that SCP-1 had (1→4)-glucose linkage in the main chain and (1→6) glucose linkage in the branch.

NMR Analysis of SCP-1. The structural features of SCP-1 were further elucidated by NMR spectral analysis. The ^{1}H NMR spectrum of SCP-1 is shown in Figure 5A. The three anomeric protons at 5.36, 5.39, and 4.96 ppm were assigned to →4)-α-D-Glc*p*→1 (residue A), →4,6)-α-D-Glc*p*(1→ (residue B), and α-D-Glc*p*(1→ (residue C), respectively.[39] Consistent with the presence of the FT-IR band at 849.72 cm^{-1} and relatively high positive value of optical rotation ($[\alpha]_D^{25}$ = +172.27°(*c* 0.1, water)), the results demonstrated that the sugar residues were α-glycosidically linked.[38,40] Furthermore, the molar proportion of the residues ((A + B)/C) was appropriately 5:1 based on the ratio of peak area of the integration of the H-1 signal for A, B, and C residues. The result is in agreement with the overall substitution pattern observed by methylation analysis (appropriately 4.61:1). The chemical shifts of 3.3−4.0 ppm (in overlapping peaks) were assigned to the protons of carbons C-2−C-6 of the glycosidic rings.[41]

In the ^{13}C NMR spectrum of SCP-1 (Figure 5B), the anomeric carbon signals for the residues of →4)-α-D-Glc*p*→1, →4,6)-α-D-Glc*p*(1→, and α-D-Glc*p*(1→ were assigned at 102.43, 102.43, and 101.19 ppm, respectively.[42] The typical signal of O-substituted C-4 (79.52 ppm) supported the high proportion of α-D-(1→4) linkages in linear arrangement that was previously demonstrated by GC-MS analysis.[43] The branching of C-6 was shown by the signals of O-substituted C-6 and unsubstituted C-6 at 73.84 and 63.14 ppm, respectively.[44,45] All of the chemical shifts of SCP-1 in the ^{1}H and ^{13}C NMR spectra are summarized in Table 2, which are assigned on the data of COSY, ROESY, TOCSY, HMBC (data not shown), and HSQC (Figure 5C) spectra and with reference to previous studies.[45−49] As a result of all of the structural information described above, a possible structural scheme for SCP-1 is proposed as Figure 6.

Immunomodulatory Activity in Vitro of SCP-1. *Effect of SCP-1 on Macrophage Viability.* In contrast to β-glucan, research on the biological activity of α-glucan is scant. To date, it has been reported that α-glucan obtained from different sources has potent biological activities such as anticancer and immunostimulatory activities.[50,51] A growing body of research confirm that the immunostimulatory activity of polysaccharide may be one of the mechanisms in its antitumor, anticomplementary, and anti-inflammatory functions.[32,52] Accordingly, the immunostimulatory activity is considered to be one of the most important biological activities of polysaccharides. Therefore, in the present study, the action of SCP-1 on some parameters of immune activation was evaluated.

The immunological action of polysaccharides may begin with the activation of effector cells such as macrophages.[53] Macrophages play an important role in host defense as part of the nonspecific defense (innate immunity) as well as specific defense (adaptive immunity). Macrophages not only maintain homeostasis but also provide a defense against pathogens and invading cells, such as cancer cells.[54] The viability of macrophages in vitro can be served as an indicator of immunoactivation. In this study, activation of RAW264.7 cells by SCP-1 was investigated by MTT assay. As shown in Figure 7A, it was found that SCP-1 significantly increased the viability of RAW264.7 cells in a dose-dependent manner from 12.5 to 100.0 μg/mL. SCP-1 (≥25.0 μg/mL) significantly promoted the viability of RAW264.7 cells compared with the blank control ($P < 0.01$).

Effect of SCP-1 on Macrophages Phagocytosis. The phagocytosis of macrophages represents the first and imperative step in immune response,[55] and one of the most remarkable characteristics of activated macrophages is an increase in phagocytosis.[56] Thus, the phagocytic ability of RAW264.7 cells was measured via neutral red uptake. As shown in Figure 7B, SCP-1 showed a promoting effect on macrophage phagocytosis in the dose range of 12.5−200.0 μg/mL. The results indicated that SCP-1 might play an important role in the phagocytosis of macrophages in the immune response as other polysaccharides from mollusk (for example, *Glossaulax didyma*) do.[57,58]

Effect of SCP-1 on Acid Phosphatase Activity. As a marker enzyme of lysosome, acid phosphatase is a signal enzyme for macrophage activation.[59] Significant change in an acid

phosphatase activity is associated with the activation or inhibition of macrophages.[60] The immunocompetence of macrophages can therefore be represented by the activity of acid phosphatase. In this study, the effect of SCP-1 on acid phosphatase activity of

[a]The 500 MHz NMR spectra were recorded at 298 K. All chemical shifts are relative to internal sodium 2,2-dimethyl-isotope 2-silapentane-5-sulfonate (DSS) at 0 ppm. Values in boldface indicate positions bearing substitution by sugar residue.

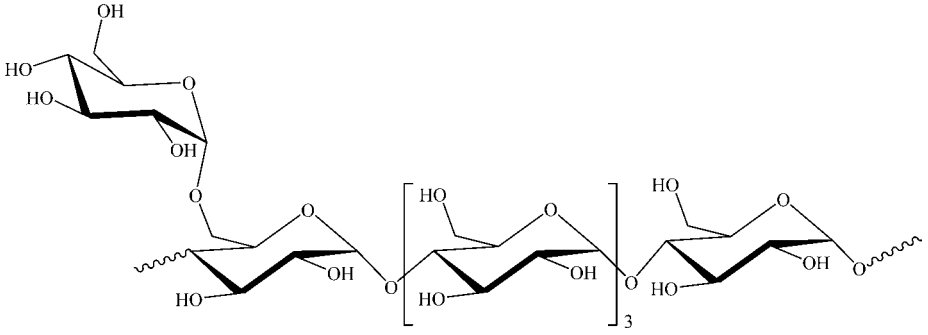

Figure 6. Predicted structure of SCP-1.

RAW264.7 cells is depicted in Figure 7C. The acid phosphatase activity of macrophages increased with the increase of concentration of SCP-1 from 12.5 to 100.0 μg/mL, whereas it tended to decline at a concentration of 200.0 μg/mL.

Effects of SCP-1 on Production of NO and Cytokines. Activated macrophages secrete NO and cytokines including TNF-α, IFN-γ, and IL-1β that are directly involved in removing pathogens and inhibiting cancer cells.[61−63] NO is a highly reactive free radical and plays a pivotal role in host defense.[64] It is also one important cytotoxic mediator contributing to the antimicrobial and tumoricidal activities of the macrophages.[65] It has been reported that various natural polysaccharides derived from animals, fungi, bacteria, and plants can stimulate NO production by macrophages.[66] TNF-α, produced chiefly by activated macrophages, is able to induce the expression of a number of other immunoregulatory and inflammatory mediators and to inhibit tumorigenesis.[67−69] The most important cytokine responsible for cell-mediated immunity is IFN-γ.[62] IL-1β is a pro-inflammatory cytokine responding to infection, injury, and immunological challenges.[70] Therefore, we further investigated the immunocompetence of SCP-1 in activating RAW264.7 cells by monitoring its effects on the production of NO and cytokines including TNF-α, IFN-γ, and IL-1β.

The stimulatory effect of SCP-1 on macrophage NO production is shown in Figure 7D. SCP-1 increased NO production in RAW264.7 cells in a dose-dependent manner. Compared with the untreated group, NO concentration was significantly increased due to the treatment of SCP-1 (12.5−200.0 μg/mL, $P < 0.05$). The concentration of NO reached 12.78 μmol/L after treatment by 100.0 μg/mL of SCP-1, and it is even higher than that for the positive control (LPS, 10.0 μg/mL). Therefore, SCP-1 can increase the NO production, which may play an important role in the host defense system.

The effects of SCP-1 on the production of TNF-α, IFN-γ, and IL-1β are shown in Table 3. Untreated RAW264.7 cells (control) secreted minimum levels of TNF-α, IFN-γ, and IL-1β, whereas the production of cytokines (TNF-α, IFN-γ, and IL-1β) in RAW264.7 cells was enhanced in a dose-dependent manner due to the treatment of SCP-1. Compared with the control, SCP-1 significantly increased the production of TNF-α from 50.0 to 200.0 μg/mL ($P < 0.01$) and the production of IFN-γ and IL-1β from 12.5 to 200.0 μg/mL ($P < 0.01$). These results indicate that SCP-1 can promote the secretion of cytokines in RAW264.7 cells. A report in the literature also provides evidence that α-D-glucan from *Strongylocentrotus nudus* eggs enhances the secretion of pro-inflammatory cytokines such as TNF-α and IL-1β.[71]

It is well-known that bioactivities of polysaccharides are related to their molecular weights, chemical components, branch degrees, type of monosaccharide, and glycosidic linkages.[26] In the present study, the α-glucan from *S. constricta*, SCP-1, had a linear backbone of (1→4)-linked α-D-Glc*p* residue with one branch, α-D-Glc*p*, attached to the main chain by a (1→6) glycosidic bond at every five α-D-Glc*p* units, which was characterized by methylation analysis and NMR spectroscopy. As mentioned above, the contents of carbohydrate, uronic acid, and sulfuric radical in SCP-1 were 99.96, 0.13, and 0.20%, respectively. Thus, the potent immunomodulatory activity of SCP-1 might not be related to the presence of uronic acid and sulfate in SCP-1 due to their low contents. In contrast, the potent immunomodulatory activity of SCP-1 should be caused and influenced by its fine structures such as (1→4)- and (1→6)-glycosidic linkages, molecular size, and the length of side chains, because increasing evidence has demonstrated that α-glucans with various structural features obtained from different organisms such as *Tricholoma matsutake*, *Ipomoea batatas*, and *Arca subcrenata* Lischke show different immunostimulatory potentials.[51,72,73] The structural and conformational features related to the immunostimulatory activity of SCP-1 need to be further studied.

In summary, for the first time, a purified neutral polysaccharide of SCP-1 was successfully obtained from *S. constricta* and characterized. SCP-1 is an α-glucan with a molecular weight of

15.63 kDa that is composed of a α-(1→4)-linked backbone with a side chain of α-(1→6)-linked residue. Moreover, SCP-1 was demonstrated to have a potent immunostimulating activity by enhancing the viability of macrophages, strengthening macrophages to devour neutral red, increasing the activity of acid phosphatase, and promoting the production of NO and cytokines in macrophages. All of these results suggested that SCP-1 had a beneficial effect on immunostimulating activity. The next studies will be focused on the immunomodulatory activity in vivo and the possible mechanisms of immunomodulatory action of SCP-1.

J. Agric. Food Chem. 2015, 63, 7986−7994

Sletr1-1 exhibits impaired petal abscission.[8] In the ripening process, heterozygous *Nr* mutants have a more pronounced impairment than *Sletr1-1* and *Sletr1-2*, so those mutants are more suitable than *Nr* for use in breeding programs for the development of a long-shelf life tomato. Additionally, *Sletr1-2* showed prolonged fruit shelf life without a reduction in carotenoid content.[8]

Crossing commercial tomato cultivars with ripening mutants that have prolonged fruit shelf life, *rin*, *Sletr1-1*, and *Sletr1-2*, may facilitate the development of an F1 hybrid line that has the desired characteristic. Several studies have shown that F1 hybrid lines of *rin* exhibited prolonged shelf life.[13] Hybrids of the *nor* mutant locus have an extended shelf life and intermediate fruit color but no differences in pH, soluble solids content, or fruit size.[12] However, not all ethylene-insensitive mutants can be used for improving the postharvest characteristics of tomato in breeding programs; for instance, *Nr* has an incomplete ripening phenotype, even in the heterozygous form (*Nr/nr*), and also has insufficient red coloration.[7]

High-quality tomato fruit, such as fruit with a long shelf life and high nutrient content, is attractive for consumers. Generating new F1 hybrid lines from *Sletr1-1* and *Sletr1-2* by crossing these mutants with large commercial tomato cultivars will improve tomato fruit quality by combining the prolonged shelf life of these mutants with other desired characteristics from commercial tomato cultivars. The objective of this study was to evaluate the effect of the *Sletr1-1* and *Sletr1-2* mutation on the plant development and fruit quality characteristics of F1 hybrid lines of *Sletr1-1* and *Sletr1-2* crossed with four commercial pure-line tomato cultivars, 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82'.

MATERIALS AND METHODS

Plant Materials and Cultivation. Two ethylene receptor (*SlETR1*) mutant alleles, *Sletr1-1* and *Sletr1-2*, and the wild-type Micro-Tom (WT-MT) were crossed with four pure-line cultivars ('Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82'). Tested plants were cultivated with four biological replications using the nutrient film technique (NFT) cultivation system in the greenhouse of the Agricultural and Forestry Research Center, University of Tsukuba, Japan, during the winter season from October 2013 to February 2014. At the beginning of the plants' cultivation, seeds were sown in paper pots 10 cm in diameter filled with commercial coir coco peat as a growing medium and were fertilized with a commercial nutrient solution (OAT house A, OAT Agrio Co., Ltd., Tokyo, Japan) that had an electrical conductivity (EC) level of 1−1.2 dS/m. After plants produced 5−6 true leaves, they were transplanted into the NFT cultivation system and irrigated with a commercial nutrient solution (OAT house A) with an EC level of 2−2.5 dS/m. Four trusses per plant were maintained for obtaining a test-fruit sample. When the fruits were showing a change of <10% in the surface fruit color from green to yellow, pink, or red, they were tagged as being at the breaker stage (Br). Some parameters were investigated during plant growth and development, for example, number of leaves under the first truss, time to Br, number of flowers per truss, and number of fruits per truss.

Ethylene Triple Response. To investigate the ethylene sensitivity of the seedlings, we investigated all of the F1 hybrid lines via the addition of exogenous ethylene at different concentrations (0, 0.1, 1, 2.5, and 5 ppm). Seeds were sterilized for 20 min by being soaked in 10% commercial bleach including a detergent (Kitchen Haiter, Kao, Tokyo, Japan) and then rinsed with sterilized water three times for 5 min. Three sterilized seeds were grown in a 50 mL glass bottle containing 10 mL of 1/2 Murashige and Skoog (MS) and sealed with rubber septum caps.[8,14] Using a syringe, exogenous ethylene at desired concentrations was injected into the sealed glass bottles containing seeds. The seeds were grown and kept in the dark at 25 °C for 7 days. The seedling triple response was investigated by measuring the hypocotyl and root lengths.

Fruit Characteristic Analysis. The harvested fruits were evaluated to elucidate fruit characterization. All of the tomato fruits were harvested at 6 days after the breaker stage (Br+6), which was characterized by >60% and <90% of the fruit surface having changed to a red color or when the fruit was at the light red stage. The harvesting time was initiated as 0 days post-storage (DPS) and was used as the initial time of fruit storage for the shelf life analysis. The evaluated characteristics were fruit diameter, length, weight, locule number, and pericarp thickness.

Evaluation of Fruit Shelf Life. The Br date was tagged to determine a fruit-harvesting time and the stage of fruit maturation. Investigated fruits were stored on the laboratory bench under the following conditions: temperature, 20 ± 2 °C; humidity, 80%. To evaluate shelf life, fruits were harvested at the same maturation stage (Br+6), which was initiated at 0 DPS when the harvested fruit was at the light red stage and its fruits would be acceptable to consumers in the market. The shelf life was determined by counting the days from the beginning of storage until the fruit quality was lost, which was indicated by the appearance of black spots or wrinkling of >10% of the fruit surface.

Determination of Ethylene Production and Respiration Rate. To elucidate the ethylene production and respiration rate in F1 hybrid lines of *Sletr1-2*, fruits at the same stage of maturation (Br +6) were analyzed. The analysis was repeated every 4 DPS for a total of 12 days. The harvested fruits were kept for 2−3 h before measurement to minimize the contamination of ethylene production from the wound caused by harvesting the fruit from the stalk. Two fruits were stored in a 440 mL sealed plastic chamber at 25 ± 2 °C for 60 min. A 1 mL gas sample was taken from the headspace of the chamber using a syringe to determine ethylene production and respiration rate. For ethylene production, the gas sample was analyzed using a gas chromatograph (GC-18A; Shimadzu, Kyoto, Japan) equipped with a Porapak Q (mesh 60/80) column and flame ionization detector, with helium (He) as the carrier gas and injector, cooling, and detector temperatures of 100, 130, and 100 °C, respectively. The respiration rate was analyzed using a gas chromatograph (GC-8A; Shimadzu, Kyoto, Japan) equipped with a photoionization detector, with He as the carrier gas and 180 and 70 °C detector/injector temperature and column temperature, respectively. Ethylene production and respiration rate were represented as micrograms per gram of fresh weight per hour (μg/g FW/h).

Fruit Color Analysis. Fruit color was evaluated to assess the effects of the mutations in the *SlETR1* gene of the *Sletr1-2* allele on color during the ripening process. Fruit color was evaluated during storage and every 10 days until fruit quality was lost, to a maximum of 30 DPS. The measurement of fruit color was performed according to the CIELAB color space analysis. Color measurements were taken from three points on the surface of individual fruits (the middle, base, and ends of the fruit) using a Minolta Color Reader CR-10 (Konica Minolta Sensing, Inc., Osaka, Japan). Three color parameters were represented as the lightness of the color/brightness (L^*), the red to green scale (a^*), and the yellow to blue scale (b^*). a^* and b^* were used to measure the hue ($h°$), which indicates the pure spectrum colors or the gradation of color, using the following equation:

$$h = \arctan\left(\frac{b}{a}\right)$$

An increased L^* value indicated that the fruit had more brightness, and a decreased $h°$ indicated that the fruit color had changed to red.

Carotenoid Analysis. Because tomato contains high levels of carotenoids, especially lycopene and β-carotene, it has become popular for human consumption. The lycopene and β-carotene contents were analyzed every 10 days from the beginning of storage until fruit quality was lost, to a maximum of 30 DPS. Frozen fruit was ground into a fine powder in liquid nitrogen, and 300 mg of tomato powder was extracted with 3 mL of acetone/hexane (4:6 v/v), resulting in a clear supernatant as described by Nagata and Yamashita.[15] Absorption was measured using a spectrophotometer (Beckman Coulter DU 640

DOI: 10.1021/acs.jafc.5b02742
J. Agric. Food Chem. 2015, 63, 7995−8007

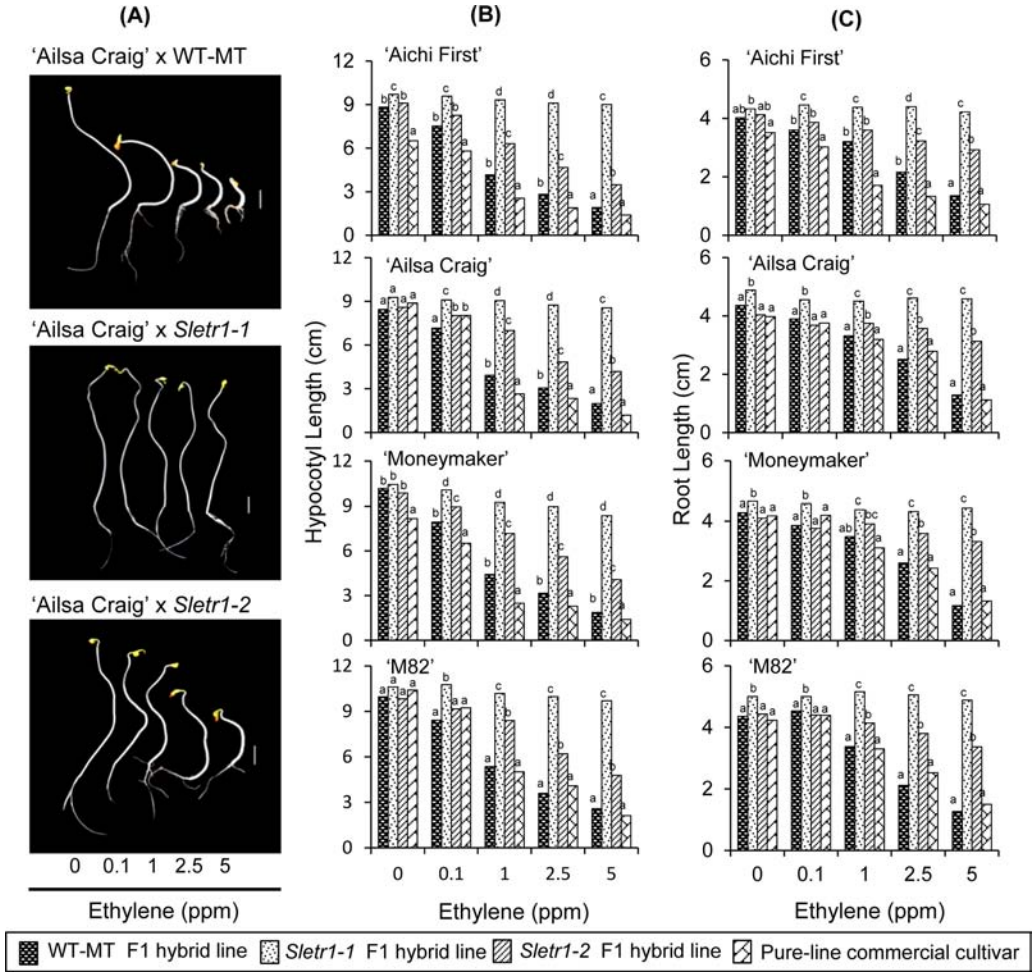

Figure 1. Seedling responses of WT-MT F1, *Sletr1-1* F1, and *Sletr1-2* F1 hybrid lines and pure-line commercial cultivars to exogenous ethylene exposure. (A) Seedling phenotypes of WT-MT, *Sletr1-1*, and *Sletr1-2* crossed with 'Ailsa Craig' as an ethylene response at different concentrations (0−5 ppm). Bar = 1 cm. The seedling quantifications are represented by (B) hypocotyl length and (C) root length of pure-line cultivar parents, WT-MT F1, *Sletr1-1* F1, and *Sletr1-2* F1, on each pure-line cultivar background, 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82'. Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey−Kramer test at $p < 0.05$.

spectrophotometer, Fullerton, CA, USA) at absorbances of 663 (A_{663}), 645 (A_{645}), 505 (A_{505}), and 453 nm (A_{453}). Lycopene (C_{LYC}) and β-carotene (C_{CAR}) were measured using the following equations:

$$C_{LYC} = -0.04584(A_{663}) + 0.204(A_{645}) + 0.372(A_{505}) - 0.0806(A_{453})$$

$$C_{CAR} = 0.216(A_{663}) - 1.22(A_{645}) - 0.304(A_{505}) + 0.452(A_{453})$$

The lycopene and β-carotene contents were represented by micrograms per grams of fresh weight (μg/g FW).

Fruit Firmness Analysis. Firmness is an important characteristic for the marketability of tomato fruit. To analyze the effect of the *Sletr1-2* mutation, we tested the firmness of the fruits. Br+6 fruits were tested using an Ultrasonic Hardness Tester model FHR-5 (Nippon Optical Works Co., Ltd., Tokyo, Japan). The measurement was repeated every 10 days until 30 DPS.

Analysis of the Total Soluble Solids (TSS), pH, and Titratable Acidity (TA). To evaluate the effect of the *Sletr1-2* mutation on four *Sletr1-2* F1 hybrid lines, we measured the TSS, pH and TA. The TSS was used to estimate the sugar level, and TA was used to estimate the organic acid level. The TSS was measured using a refractometer PAL-J (Atago, Tokyo, Japan). The pH and TA was measured using a pH meter SevenCompact pH/Ion S220 (Mettler-Toledo AG, Schwerzenbach, Switzerland). The TA was measured using pH meter methods by titration of 0.1 N sodium hydroxide up to a pH of 8.1 as described by Dalal et al.[16]

Data Analysis. This experiment was conducted in a completely randomized design with four replicates. For statistical data analysis, to test the normality of the data we used the Kolmogorov−Smirnov test. On the basis of this test, we found the data to have normal distribution. Therefore, one factor analysis of variance (ANOVA) was conducted to analyze the data followed by the Tukey−Kramer test at $p < 0.05$ to compare differences among investigated lines.

RESULTS

Under Heterozygous Conditions, *Sletr1-1* and *Sletr1-2* Expressed Ethylene-Insensitive Phenotypes. All of the *Sletr1-1* F1 and *Sletr1-2* F1 hybrid lines showed a similar tendency with ethylene exogenous exposure, that is, reduced hypocotyl and root lengths. These measurements were significantly longer than in the WT-MT F1 hybrid lines and the commercial pure-line cultivars (Figure 1A). All of the *Sletr1-1* F1 hybrid lines resulted in a strong ethylene-insensitive phenotype. Exogenous ethylene exposure of 5 ppm was able to reduce the hypocotyl and root lengths of all of the investigated plants. However, the reductions in the *Sletr1-1* F1 hybrid lines were no more than 19.4% (*Sletr1-1* × 'Moneymaker') and 5.4% (*Sletr1-1* × 'Ailsa Craig'), respectively (Figure 1B,C).

J. Agric. Food Chem. 2015, 63, 7995−8007

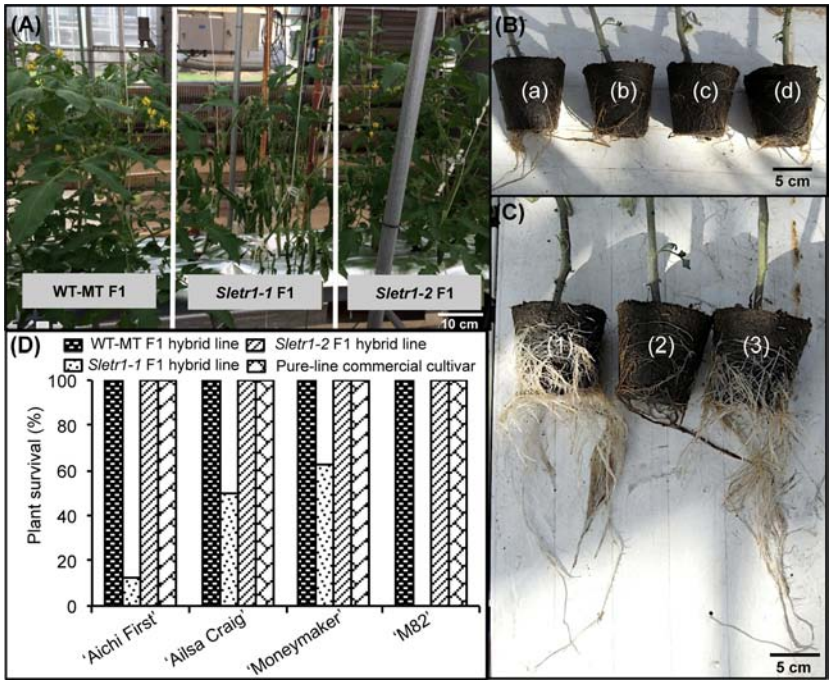

Figure 2. Vegetative growth of WT-MT F1, *Sletr1-1* F1, and *Sletr1-2* F1 hybrid lines and pure-line commercial cultivars. (A) The F1 hybrid line of *Sletr1-1* (crossed with 'Ailsa Craig') showed wilting as a response to the transplanting process to the NFT system; the photograph was taken 3 weeks after transplanting. (B) Injured roots of all of the *Sletr1-1* F1 hybrid lines from crosses with four different pure-line background cultivars: 'Aichi First' (a), "Ailsa Craig" (b), 'Moneymaker' (c), and 'M82' (d). (C) Representative photographs of the root systems of the hybrid lines of MT-WT F1 (1), *Sletr1-1* F1 (2), and *Sletr1-2* F1 (3) (crossed with 'Ailsa Craig'); the photographs were taken 2 weeks after transplanting to the NFT system. (D) Plant survival of two F1 hybrid mutant lines, *Sletr1-1* and *Sletr1*-2, compared with WT-MT F1. Data were taken 4 weeks after transplanting to the NFT system (n = 8).

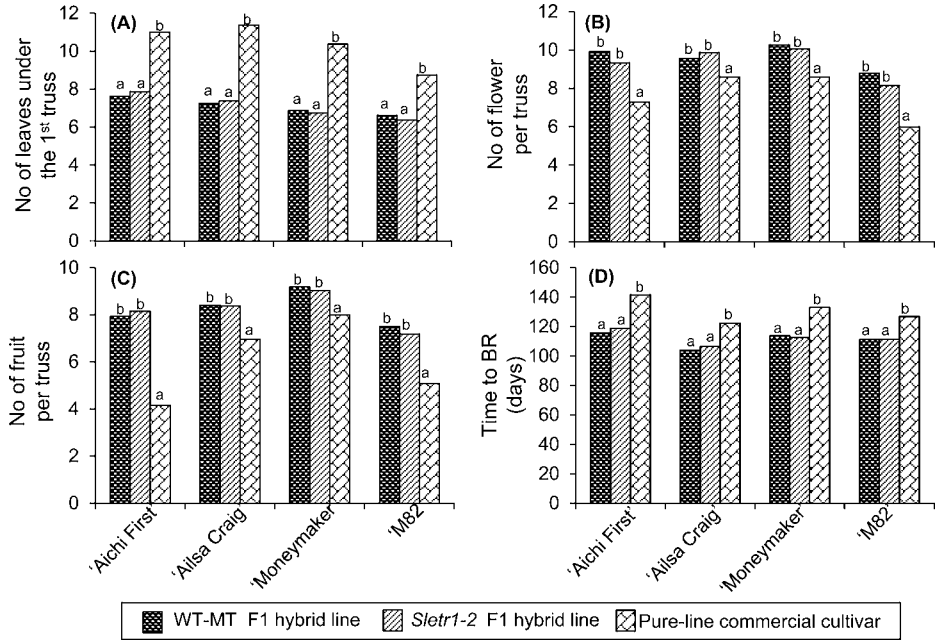

Figure 3. Vegetative characteristics of *Sletr1-2* F1 and WT-MT F1 hybrid lines and pure-line commercial cultivars. (A) The number of leaves under the first truss is the average number of leaves from eight plants. (B) The number of flowers per truss and (C) the number of fruits per truss are the average numbers of flowers and fruits from four trusses per plant. (D) The time to breaker stage for the investigated fruits was observed as the number of days from seed sowing until the first fruit of one plant reached the BR stage or the fruit color changed to pink or yellow. Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey–Kramer test at $p < 0.05$.

Exogenous ethylene exposure in the *Sletr1-2* F1 hybrid lines resulted in an intermediate ethylene-insensitive phenotype. Those hybrid lines expressed weaker ethylene sensitivity phenotypes compared with the *Sletr1-1* F1 hybrid lines; however, these lines were more ethylene-sensitive than the WT-MT F1 hybrid lines and the pure-line commercial cultivar

DOI: 10.1021/acs.jafc.5b02742
J. Agric. Food Chem. 2015, 63, 7995–8007

parent (Figure 1A). Treatment with 5 ppm of exogenous ethylene reduced hypocotyl length by 61.7% (*Sletr1-2* × 'Aichi First') and root length by 29.5% (*Sletr1-2* × 'Aichi First') (Figure 1B,C).

***Sletr1-1* F1 Hybrid Line Shows Weak Phenotype Characteristics during Stress Conditions.** Two weeks after being transplanted to the NFT system, all of the *Sletr1-1* F1 hybrid lines showed stress response, which was characterized by leaf wilting and disease sensitivity. However, the *Sletr1-2* F1 hybrid lines did not show any stress responses (Figure 2A). Plant wilting in *Sletr1-1* F1 hybrid lines was caused by damage to the root system. All of the roots were browning, the root tips were injured, and some of the roots were rotting (Figure 2B). However, in all of the *Sletr1-2* F1 hybrid lines, the roots appeared healthy and were white in color, and no roots were rotting (Figure 2C), which was similar to the characteristics of the WT-MT F1 hybrid line and the pure-line commercial cultivars background. Furthermore, only a few new *Sletr1-1* F1 hybrid lines roots were formed for the 2 weeks after transplanting. At 4 weeks after transplantation, no *Sletr1-1* × 'M82' specimens survived; however, *Sletr1-1* × 'Aichi First', 'Ailsa Craig', and 'Moneymaker' survived at percentages of less than 13, 50, and 63%, respectively (Figure 2D). Because all of the *Sletr1-1* F1 hybrid lines had the lowest rates of plant survival, even *Sletr1-1* × 'M82' did not survive (Figure 2D). Thus, the *Sletr1-1* F1 hybrid lines were not used for further investigation in this study.

Mutation of the *SlETR1* Gene of the *Sletr1-2* Mutant Does Not Affect the Vegetative and Generative Characteristics of Its F1 Hybrid Lines. Crossing all of the pure-line cultivars with WT-MT and *Sletr1-2* resulted in similar tendencies in reducing the number of leaves under the first truss in the F1 hybrid lines, which were significantly different from those of the pure-line cultivar parent but did not show any differences between the *Sletr1-2* F1 and WT-MT F1 hybrid lines. The greatest number of leaves under the first truss was observed on *Sletr1-2* × 'Aichi First', whereas the fewest were observed on *Sletr1-2* × 'M82' (Figure 3A). Crossing *Sletr1-2* with 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82' reduced the average of the number of leaves under the first truss by approximately 3.13, 4.00, 3.63, and 2.38, respectively, compared with the pure-line cultivar parent (Figure 3A). The plant growth type in the hybrid lines was similar to that of the commercial pure-line cultivar parent, which included the indeterminate growth type for 'Aichi First', 'Ailsa Craig', and 'Moneymaker' and the determinate growth type for 'M82'. The data showed that all of the *Sletr1-2* F1 hybrid lines resulted in numbers of flowers and fruits per truss similar to those of the WT-MT F1 hybrid line; however, the numbers were significantly higher than those for the pure-line cultivar parents, for which the average numbers of flowers per truss were 9.34, 9.88, 10.06, and 8.16 and the numbers of fruits per truss were 8.16, 8.38, 9.03, and 7.19 for *Sletr1-2* crossed with 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82', respectively (Figure 3B,C).

The time to the breaker stage for all of the *Sletr1-2* F1 hybrid lines was similar to that for the WT-MT F1 hybrid lines; however, they were significantly faster than the pure-line cultivar parents. The first fruit to reach the breaker stage was *Sletr1-2* × 'Ailsa Craig', with an average time of 104 days after sowing, and the last to reach it was *Sletr1-2* × 'Aichi First', with an average time of 119 days after sowing, or 15 days later than *Sletr1-2* × 'Ailsa Craig' (Figure 3D). The early breaker stage of this F1 hybrid line is most likely correlated with its pure-line cultivar parent, 'Ailsa Craig', which reached the breaker stage earlier than the other three commercial pure-line cultivars at approximately 122 days after sowing (Figure 3D).

***Sletr1-2* F1 Hybrid Resulted in Fruit Characteristics Similar to Its WT-MT F1 Hybrids.** The appearance of the fruits from all of the *Sletr1-2* F1 hybrid lines was similar to that of fruit from the WT-MT F1 hybrid lines, which showed an intermediate fruit size (smaller than the pure-line cultivar parents and bigger than the *Sletr1-2* and WT-MT parents). Moreover, the fruit shapes were slightly similar to those of the Micro-Tom parents (Figure 4). Quantification analysis revealed

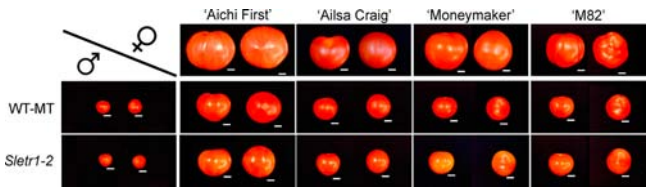

Figure 4. Fruit appearance of *Sletr1-2* F1 and WT-MT F1 hybrid lines and pure-line commercial cultivars. The photograph was taken at Br+6 of the fruit maturation stage. All of the F1 hybrid lines resulted in an intermediate fruit size. The *Sletr1-2* F1 and WT-MT F1 hybrid lines appear to have similar fruit sizes and an almost identical red fruit color. Bar = 1 cm.

that the fruit diameter, fruit length, fruit weight, and pericarp thickness of all of *Sletr1-2* F1 hybrid lines were significantly smaller than those of the pure-line cultivar parents. However, they did not show any significant differences compared with WT-MT F1 hybrid line (Figure 5). The *Sletr1-2* F1 hybrid line from 'Aichi First' resulted in a large fruit that had a greater diameter, length, and weight compared with the other three F1 hybrid lines with average values of 39.73 mm, 34.87 mm, and 32.81 g, respectively (Figure 5A–C). On the other hand, the diameter, length, and weight of the *Sletr1-2* F1 hybrid line from 'Ailsa Craig', 'Moneymaker', and 'M82' were similar to each other, with the length ranging from 29.87 mm (*Sletr1-2* × 'M82') to 30.85 mm (*Sletr1-2* × 'Ailsa Craig'), the diameter ranging from 32.53 mm (*Sletr1-2* × 'M82') to 34.01 mm (*Sletr1-2* × 'Ailsa Craig'), and the weight per fruit ranging from 20.67 g (*Sletr1-2* × 'M82') to 22.00 g (*Sletr1-2* × 'Moneymaker') (Figure 5A–C). The *Sletr1-2* mutant crossed with 'Moneymaker' resulted in the highest reduction in average pericarp thickness compared with the pure-line cultivar parents, with a reduction of approximately 36% (Figure 5E). The locule numbers of all of the *Sletr1-2* F1 hybrid lines from all of the different pure-line cultivar parents were not significantly different from those of the WT-MT F1 hybrid lines. However, the significance varied compared with the pure-line cultivar parent. Among all of the *Sletr1-2* F1 hybrid lines, *Sletr1-2* × 'Aichi First' resulted in the highest number of fruit locules (3.71); the lowest locule number was observed on *Sletr1-2* × 'Moneymaker' (2.46) (Figure 5D).

***Sletr1-2* Mutant Has the Potential To Be an F1 Hybrid Parent for Improving Fruit Shelf Life.** In all of the WT-MT F1 hybrid lines, wrinkles appeared on the fruit surface earlier than on the *Sletr1-2* F1 hybrid lines. At 30 DPS, >50% of the total fruit surface of the WT-MT F1 hybrid line was wrinkled, whereas in *Sletr1-2* F1 hybrid lines, only some of the fruit surface was wrinkled (Figure 6). Although the fruit shelf life of the three *Sletr1-2* F1 hybrid lines from 'Aichi First', 'Ailsa Craig',

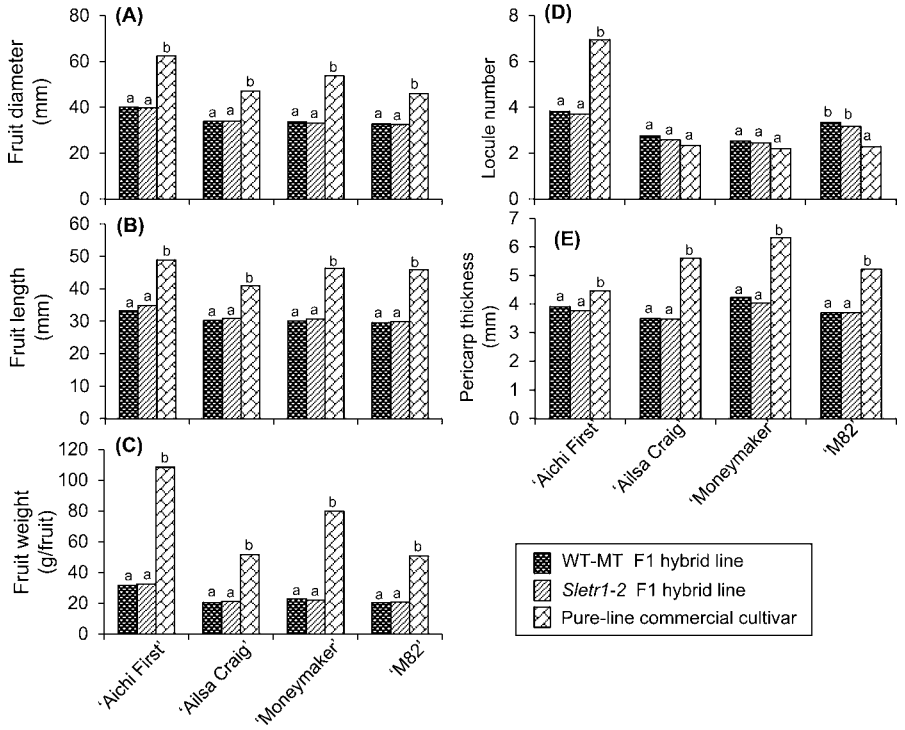

Figure 5. Fruit characterizations of the *Sletr1-2* F1 and WT-MT F1 hybrid lines and pure-line commercial cultivars. Fruit characteristics are represented by (A) diameter, (B) length, (C) weight, (D) locule number, and (E) pericarp thickness. These characteristics were measured from six fruits per replicate at the (Br+6) fruit maturation stage. Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey–Kramer test at $p < 0.05$.

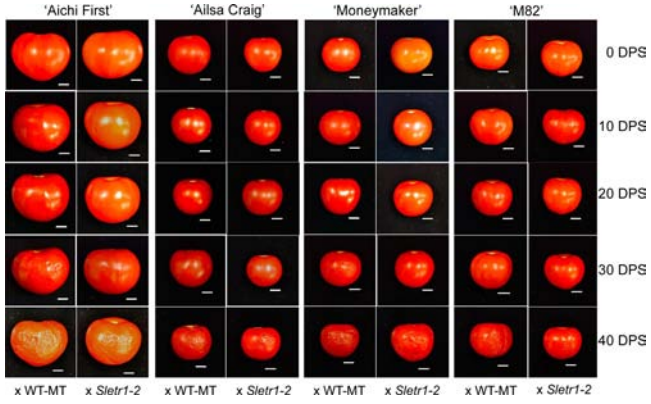

Figure 6. Representative photographs indicating tomato fruit shelf life during storage of *Sletr1-2* F1 and WT-MT F1 hybrid lines and pure-line commercial cultivars. The fruits were stored for 40 days under room conditions (20 + 2 °C) until wrinkling or black spots appeared on the fruit surface. Bar = 1 cm.

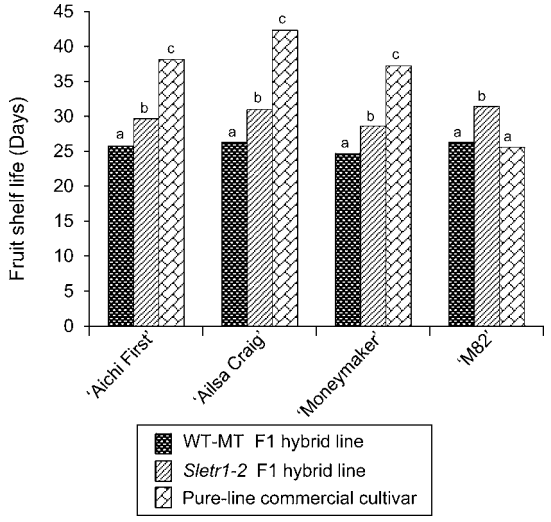

Figure 7. Fruit shelf life of *Sletr1-2* F1 and WT-MT F1 hybrid lines and pure-line commercial cultivars. Shelf life was evaluated under room conditions until wrinkling appeared on the fruit surface. Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey–Kramer test at $p < 0.05$.

and 'Moneymaker' was significantly reduced compared with the pure-line cultivar parent (8.46, 11.33, and 8.63 days shorter than the shelf life for 'Aichi First', 'Ailsa Craig', and 'Moneymaker' fruits, respectively), all of the *Sletr1-2* F1 hybrid lines showed significant improvement in fruit shelf life compared with the WT-MT F1 hybrid lines (Figure 7). In the four genetic backgrounds of pure-line cultivars, the *Sletr1-2* mutation effectively extended the fruits' shelf life up to 3.96, 4.71, 3.92, and 5.13 days longer than the fruit shelf life of WT-MT F1 hybrid line for the *Sletr1-2* F1 hybrid lines from 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82' background, respectively (Figure 7).

Ethylene Production and Respiration Rate of the *Sletr1-2* F1 Hybrid Line Were Similar to Those of the WT-MT F1 Hybrid Line in All of the Pure-Line Cultivar Parents. Our data indicate that ethylene production and the respiration rate of the investigated fruits decreased during storage until 12 DPS. The mutation in the *SlETR1* gene of the *Sletr1-2* F1 hybrid lines did not affect either ethylene production (Figure 8A) or respiration rate (Figure 8B) until

DOI: 10.1021/acs.jafc.5b02742
J. Agric. Food Chem. 2015, 63, 7995–8007

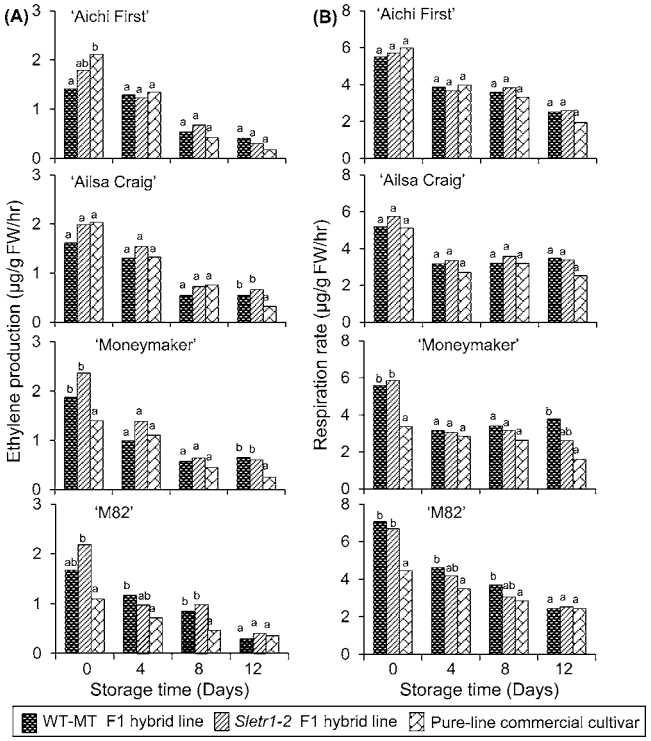

Figure 8. Ethylene production and respiration rate of *Sletr1-2* F1 and WT-MT F1 hybrid lines and pure-line commercial cultivars. Ethylene production (A) and respiration rate (B) were measured every 4 days for 12 DPS. Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey–Kramer test at $p < 0.05$.

12 DPS, which was similar to the findings for WT-MT F1 hybrid lines. Although ethylene production in *Sletr1-2* crossed with all four pure-line cultivar parents was not significantly different from that of the WT-MT F1 hybrid lines, there was a tendency for the ethylene production and respiration rate of all the *Sletr1-2* F1 hybrid lines, except for the respiration rate of *Sletr1-2* crossed with 'M82', to be higher than those of the WT-MT F1 hybrid line (Figure 8A,B). At the beginning of storage, *Sletr1-2* × 'Moneymaker' had the highest ethylene production (2.36 μg/g FW/h) (Figure 8A), whereas the highest respiration rates were reached by both *Sletr1-2* and WT-MT crossed with 'M82,' with values of 6.69 and 7.07 μg/g FW/h, respectively. However, the other F1 hybrid lines showed almost the same values for ethylene production and respiration rate until 12 DPS, at which point the ethylene production of *Sletr1-2* F1 hybrid lines ranged between 0.31 μg/g FW/h (*Sletr1-2* × 'Aichi First') and 0.67 μg/g FW/h (*Sletr1-2* × 'Ailsa Craig') (Figure 8A) and the respiration rate ranged between 2.53 μg/g FW/h (*Sletr1-2* × 'M82') and 3.36 μg/g FW/h (*Sletr1-2* × 'Ailsa Craig') (Figure 8B). Compared with the pure-line commercial cultivars, the ethylene production and respiration rate of *Sletr1-2* F1 hybrid lines varied during 30 days of storage. At 0 DPS, *Sletr1-2* crossed with 'Moneymaker' and 'M82' had significant increases in both ethylene production of 0.96 and 1.09 μg/g FW/h and respiration rate of 2.47 and 2.23 μg/g FW/h, respectively, whereas, at 12 DPS, all of the *Sletr1-2* F1 hybrid lines except for *Sletr1-2* × 'M82' resulted in higher ethylene production than that for the pure-line cultivar; however, it had a similar respiration rate (Figure 8A,B).

Fruit Color Varied among All of the *Sletr1-2* F1 Hybrid Lines from Different Commercial Pure-Line Cultivar Parents. Generally, the L^* and h° values of all of the *Sletr1-2* F1 hybrid lines varied from those of the WT-MT F1 hybrid lines and the pure-line commercial cultivar parents. In all of the *Sletr1-2* F1 and WT-MT F1 hybrid lines, L^* and h° dramatically decreased at 10 DPS, and then their values were stable. However, in the pure-line cultivar, the values were similar during postharvest storage up to 30 DPS. Our statistical analysis of the data showed different significance during postharvest storage under different pure-line cultivar backgrounds. Compared with the WT-MT F1 hybrid lines, the *Sletr1-2* mutation significantly increased the L^* value only in *Sletr1-2* crossed with 'Aichi First' up to 20 DPS (42.13 at 0 DPS, 37.02 at 10 DPS, and 35.70 at 20 DPS) and in *Sletr1-2* crossed with 'Moneymaker' at 0 DPS with the value of 42.29 (Figure 9A). Of all the F1 hybrid lines, *Sletr1-2* crossed with

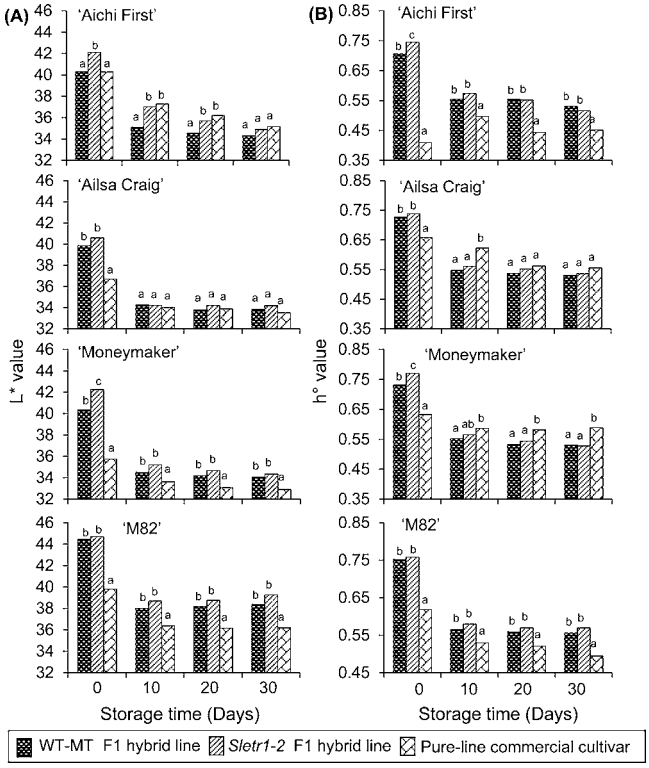

Figure 9. Fruit color of *Sletr1-2* F1 and WT-MT F1 hybrid lines and pure-line commercial cultivars. Color was represented by (A) the L^* value as the lightness of the color, where ($L^* = 0$ indicates black and $L^* = 100$ indicates white), and (B) the h° value, the pure spectrum or the gradation of color (e.g., red, purple, blue). Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey–Kramer test at $p < 0.05$.

'M82' had the highest values of L^* (44.71 at 0 DPS and 39.7 at 30 DPS) (Figure 9A). Compared with the pure-line cultivar, the clear significance in increasing the L^* value of *Sletr1-2* F1 hybrid lines up to 30 DPS was observed from the *Sletr1-2* crossed with 'Moneymaker' and 'M82'. However, in crosses with 'Aichi First' and 'Ailsa Craig', it was observed only at 0 DPS, after which they were similar (Figure 9A).

The h° value was measured to refer to the pure color. The significant effect of the *Sletr1-2* mutation on the h° value was observed at 0 DPS only in *Sletr1-2* crossed with 'Aichi First' and 'Moneymaker', with values of 0.75 and 0.77, respectively, and

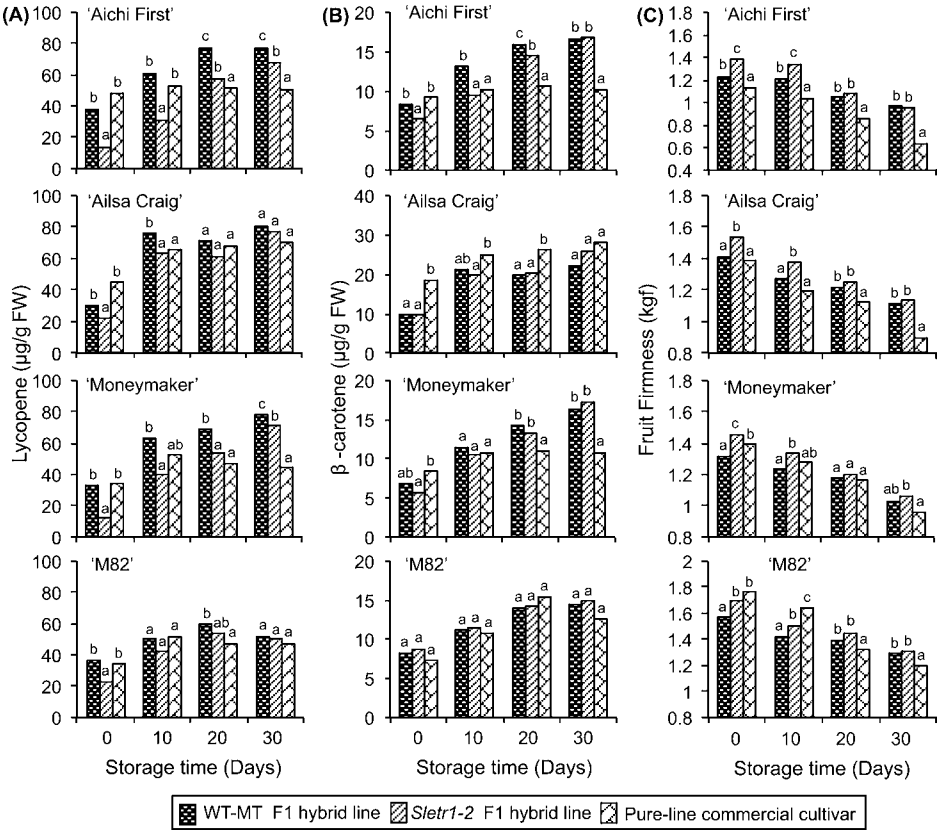

Figure 10. Carotenoid content and fruit firmness of *Sletr1-2* F1, WT-MT F1 hybrid lines, and pure-line commercial cultivars. (A) Lycopene content and (B) β-carotene content represent the carotenoid content of the fruits during postharvest storage. (C) Fruit firmness represents the fruit hardness during the 30 days of storage. Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey–Kramer test at $p < 0.05$.

after 10 DPS, there were no significant differences from the WT-MT F1 hybrid lines. (Figure 9B). Although the $h°$ value of the *Sletr1-2* F1 hybrid lines generally was not significantly different from that of WT-MT F1 hybrid lines during storage time up to 30 DPS, it varied from its pure-line cultivar parent. In *Sletr1-2* crossed with 'Aichi First' and 'M82', the $h°$ value significantly increased up to 30 DPS. In *Sletr1-2* × 'Moneymaker', the $h°$ value was significantly lower during the storage time except at 0 DPS, whereas in *Sletr1-2* × 'Ailsa Craig', the $h°$ value was similar except at 0 and 10 DPS (Figure 9B).

Carotenoid Content of the *Sletr1-2* F1 Hybrid Line Is Slightly Affected by Mutation in the *SlETR1* Gene. All of the *Sletr1-2* F1 hybrid lines synthesized slightly less lycopene than the WT-MT F1 hybrid lines but varied from the pure-line cultivar parent. On the basis of the statistical analyses of the data, at 0 DPS, there was significantly lower lycopene content in all of the *Sletr1-2* F1 hybrid lines than in the WT-MT F1 hybrid lines and the pure-line cultivar parent, with the average value varying between 11.75 μg/g FW (*Sletr1-2* × 'Moneymaker') and 23.25 μg/g FW (*Sletr1-2* × 'M82') (Figure 10A). The lycopene content increased gradually during storage in all of the F1 hybrid lines up to 30 DPS; however, its amount in the pure-line cultivar remained stable after 10 DPS. At 30 DPS, >60 μg/g FW of lycopene was detected in the three *Sletr1-2* F1 hybrid lines (crossed with 'Aichi First', 'Ailsa Craig', and 'Moneymaker') but in *Sletr1-2* × 'M82', at only 50.05 μg/g FW (Figure 10A). Compared with the WT-MT F1 hybrid lines, both *Sletr1-2* × 'Aichi First' and *Sletr1-2* × 'Moneymaker' had significantly lower lycopene content up to 30 DPS, whereas in *Sletr1-2* × 'Ailsa Craig' and *Sletr1-2* × 'M82', no significant differences in lycopene content were detected after 20 and 10 DPS, respectively (Figure 10A). Compared to the pure-line cultivar parent, *Sletr1-2* F1 hybrid lines showed variations in the lycopene content depending on the pure-line cultivar background. At 0 DPS, both *Sletr1-2* × 'Aichi First' and *Sletr1-2* × 'Moneymaker' had significantly lower lycopene content; however, after 20 DPS, the value was significantly higher, whereas in *Sletr1-2* × 'Ailsa Craig' and *Sletr1-2* × 'M82', no significant differences in lycopene content were detected after 10 DPS (Figure 10A).

In addition to the lycopene content, the β-carotene content increased during 30 days of storage. In *Sletr1-2* × 'M82', the β-carotene content did not increase as much as in the three other *Sletr1-2* F1 hybrid lines; the value was only increased 6.05 μg/g FW, whereas in the other *Sletr1-2* F1 hybrid lines, it was increased >10 μg/g FW (Figure 10B). The significant effect of the *SlETR1* gene mutation of the *Sletr1-2* F1 hybrid lines on the β-carotene content was detected only in *Sletr1-2* × 'Aichi First' and *Sletr1-2* × 'Moneymaker' and occurred at 10 and 0 DPS, respectively, whereas at the end of storage, it was similar to that of the WT-MT F1 hybrid lines (Figure 10B). At the beginning of storage, *Sletr1-2* × 'Aichi First' and *Sletr1-2* × 'Moneymaker' had reductions of 21 and 16%, respectively, compared with the WT-MT F1 hybrid lines. The changes in β-carotene in all *Sletr1-2* F1 hybrid lines differed from those of the pure-line cultivar parent. Both *Sletr1-2* × 'Aichi First' and *Sletr1-2* × 'Moneymaker' had significantly lower β-carotene content at the beginning of storage; however, after 20 DPS, it was significantly

J. Agric. Food Chem. 2015, 63, 7995–8007

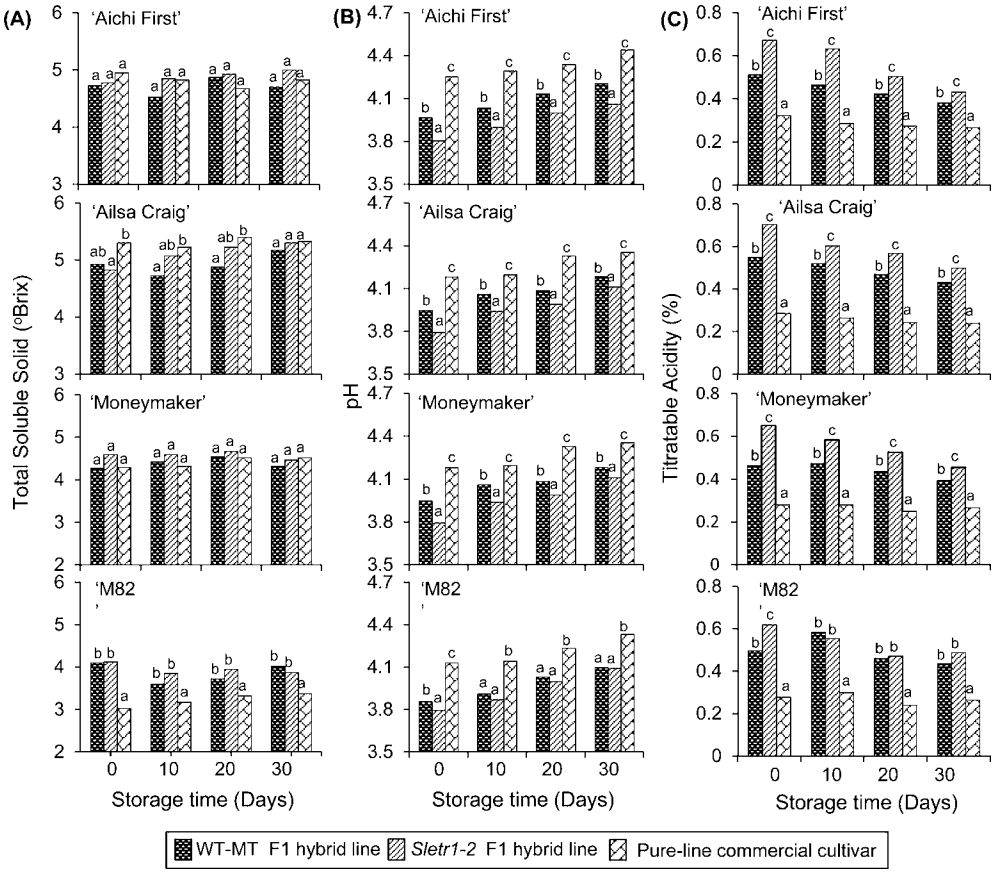

Figure 11. Effect of *Sletr1-2* mutation on fruit taste quality of its F1 hybrid line as represented by (A) total soluble solids, (B) pH, and (C) titratable acidity. Mean values with the same storage time tags followed by the same letters are not significantly different according to the Tukey–Kramer test at $p < 0.05$.

higher. In *Sletr1-2* × 'Ailsa Craig', it was significantly higher than that of the pure-line cultivar parent up to 20 DPS, whereas in *Sletr1-2* × 'M82', no significant differences in β-carotene content were detected (Figure 10B).

Fruit of the *Sletr1-2* F1 Hybrid Lines Is Harder than That of the F1 Hybrid Lines. The hardness of the fruit is indicated by a firmness value, which is an important characteristic for fresh tomato fruit. The firmness of all the investigated fruits decreased during storage up to 30 DPS. The statistical data analysis revealed that, from 0 until 10 DPS for *Sletr1-2* crossed with 'Aichi First', 'Ailsa Craig', and 'Moneymaker' and until 20 DPS for *Sletr1-2* × 'M82', the fruits were significantly harder compared with the WT-MT F1 hybrid lines, with firmness values 0.15, 0.12, 0.14, and 0.12 kgf higher than those for the WT-MT F1 hybrid lines, respectively, at 0 DPS. However, no significant differences were detected at the end of storage, with values of 0.95, 1.13, 1.06, and 1.31 kgf for *Sletr1-2* crossed with 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82', respectively (Figure 10C). Compared with the pure-line cultivar parent, significant improvements in the fruit hardness of the *Sletr1-2* F1 hybrid lines occurred up to 30 DPS, except for *Sletr1-2* × 'M82', which showed a lower fruit firmness at the beginning of storage and a similar one at 30 DPS (Figure 10C). A greater improvement in firmness compared with the pure-line cultivar parents was observed in *Sletr1-2* × 'Aichi First', with an improved firmness of 0.26 kgf (Figure 10C).

Mutation in the *Sletr1-2* Allele Affects the Fruit pH and Titratable Acidity (TA) but Does Not Affect the Total Soluble Solids (TSS). During 30 days of storage, all of the *Sletr1-2* F1 hybrid lines had TSS levels similar to those for the WT-MT F1 hybrid lines; however, these levels differed from those for the pure-line cultivar. At 0 DPS, the TSS from the four *Sletr1-2* F1 hybrid lines (*Sletr1-2* crossed with 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82') were 4.78, 4.83, 4.60, and 4.13 °Brix, respectively, whereas at 30 DPS, they were 5.00, 5.30, 4.48, and 3.88 °Brix (Figure 11A). Crossing both WT-MT and *Sletr1-2*, with 'M82' significantly increased the TSS values of their F1 hybrid lines and resulted in values of 1.10, 0.68, 0.63, and 0.50 °Brix higher than the 'M82' parent at 0, 10, 20, and 30 DPS, respectively (Figure 11A).

The analyzed data indicate that *Sletr1-2* affected the pH and TA of the fruit; however, the effect was dependent on the genetic background of the pure-line cultivar parent. All of the *Sletr1-2* F1 hybrid lines showed the lowest fruit pH and the highest fruit TA during the 30 days of storage compared with the WT-MT F1 hybrid line, except for the pH and TA of *Sletr1-2* crossed with 'M82' that showed similar level after 10 DPS (Figure 11). At 0 DPS, the pH from *Sletr1-2* crossed with 'Aichi First', 'Ailsa Craig', 'Moneymaker', and 'M82' was 3.81, 3.77, 3.79 and 3.80, respectively, whereas at 30 DPS it was 4.06, 4.08, 4.11, and 4.09 (Figure 11B). In all of the investigated fruits, the pH increased during the 30 days of storage; however, the TA decreased. This study showed that the fruits of the *Sletr1-2* F1 hybrid lines with the lowest pH contained the highest TA levels that were significantly different from the levels of the WT-MT F1 hybrid line and the pure-line cultivar parents during the 30 days of storage (Figure 11C). At 0 DPS, the TA from *Sletr1-2* crossed with 'Aichi First', 'Ailsa Craig', 'Moneymaker', and

DOI: 10.1021/acs.jafc.5b02742
J. Agric. Food Chem. 2015, 63, 7995–8007

'M82' was 0.67, 0.70, 0.65, and 0.62%, respectively, whereas at 30 DPS, it was 0.43, 0.50, 0.46, and 0.49% (Figure 11C).

DISCUSSION

Fruit shelf life is an important trait in fresh tomato. Generating new cultivars with longer fruit shelf life may be an interesting approach to improving the postharvest quality of tomato. Mutations in the *Sletr1* mutant alleles, *Sletr1-1* and *Sletr1-2*, resulted in ethylene-insensitive phenotypes in the F1 hybrid lines. However, these F1 hybrid lines showed different ethylene sensitivities at the seedling stage, with the *Sletr1-1* F1 hybrid lines exhibiting less ethylene sensitivity than the *Sletr1-2* F1 hybrid lines (Figure 1). The ethylene-insensitive phenotype of the *Sletr1-1* F1 hybrid line was inherited from the *Sletr1* mutant alleles, which exhibited dominant inheritance.[8] The effect of ethylene on seedling development is characterized by hypocotyl elongation inhibition, hypocotyl base expansion, and primary root elongation inhibition.[17,18] All of the *Sletr1-1* F1 hybrid lines responded slightly to the application of 5 ppm of exogenous ethylene, whereas the *Sletr1-2* F1 hybrid lines responded even at low concentrations (1 ppm) (Figure 1). On the basis of these data, the ethylene sensitivities of *Sletr1-1* and *Sletr1-2* were reduced in the heterozygous condition compared with the homozygous condition, whereas under homozygous condition, the *Sletr1-1* mutant did not show any response to ethylene exposure up to 10 ppm.[8] Reduction of ethylene sensitivity in *Sletr1-1* and *Sletr1-2* mutants and these F1 hybrid lines was due to the mutations in the first and second domains of transmembrane region of the ethylene receptor gene (*SlETR1*), which is an important region for ethylene binding. Amino acid substitution of P51L in the *Sletr1-1* mutant as a result of mutation in the first domain of the transmembrane region is similar to the amino acid substitution of P36L in *Nr* and *Arabidopsis etr2-1*, whereas in *Sletr1-2*, the amino acid substitution of V69D is located in the second domain of the transmembrane region (V69D).[8] In *Arabidopsis* and tomato, mutations in these regions of ethylene receptor genes affect ethylene binding activity and ethylene sensitivity.[9,10,19]

Improving agronomic characteristics in F1 hybrid lines is an important issue in a breeding program. Because favorable allelic interactions at heterozygous loci in F1 hybrid lines improve performance, crossing two homozygous lines that have the characteristics desired for making an F1 hybrid line is a tool used in breeding programs to obtain new and improved agronomic characteristics. *Sletr1* mutant alleles could make interesting contributions to a breeding program because these mutants exhibit dominant inheritance in improving tomato fruit shelf life.[8] However, undesirable characteristics most likely have been expressed in F1 hybrid lines. We detected several undesirable effects of *Sletr1-1* mutation in the *Sletr1-1* F1 hybrid lines; however, these effects were not detected in the *Sletr1-2* F1 hybrid lines (Figure 2). The low survival rate of the *Sletr1-1* F1 hybrid line is most likely due to the fact that this line does not have the capacity to develop and recover new roots when the old roots are injured. Prolonged root damage without recovery caused an inhibition of water uptake that was detrimental to all of the processes involved in plant growth and development. The inability of all of the *Sletr1-1* F1 hybrid lines to recover from root injuries and develop new roots quickly resulted in secondary diseases, such as fungi that attack the root system and the stem neck. The disease symptoms of the *Sletr1-1* F1 hybrid lines were similar to those of the *Sletr1-1* mutant parent, which showed an increased susceptibility to infestation by *Fusarium oxysporum*. An undesirable effect of *ETR1* mutation was also detected in *Arabidopsis Atetr1-1*, which exhibited an increase in disease infection by pathogens such as *Botrytis cinerea*, *Fusarium solani*, *Fusarium oxysporum* f. sp. *matthiolae*, *Xanthomonas campestris* pv. Campestris, and *Pythium* spp.[20−22] Our results are consistent with the *Nr* mutant, which does not have the capacity to produce adventitious roots under waterlogging stress conditions. Ethylene has an important role during flooding stress because it initiates and is involved in adventitious root development.[23,24] Therefore, it plays an important role in mediating plant responses, which may enable the plant to survive. Our data suggest that the *Sletr1-1* F1 hybrid lines exhibited a strong ethylene-insensitive phenotype and a strong sensitivity to biotic and abiotic stresses. Therefore, *Sletr1-1* is not appropriate for breeding. However, *Sletr1-2* may have potential for breeding because its F1 hybrid lines did not show any undesirable effects under those stresses. Other studies have reported that only the *rin* mutant is suitable for use in breeding programs, whereas *Nr* is not suitable because it increases susceptibility to some pathogens.[25−27] Moreover, it has insufficient red coloration.[3,14]

Through breeding programs, the desired characteristics can be obtained. Hence, to improve the growth and yield quality of tomato plants, hybrid breeding can be used efficiently.[28] The vegetative and generative characters of *Sletr1-2* F1 hybrid lines were comparable to those of WT-MT F1 hybrid lines even though these lines were the result of crosses with the four genetic backgrounds of pure-line cultivars (Figures 3−5). Vegetative and generative performance in the *Sletr1-2* F1 and WT-MT F1 hybrid lines was indicated mostly by the intermediate characteristics resulting from the *Sletr1-2* or WT-MT parent (initially from the Micro-Tom cultivar background having both a small plant size (15−20 cm) and a small fruit size)[29] and the commercial pure-line cultivar parents. A similar study on the intermediate characteristics of F1 hybrid line yielded the same findings for *rin* and *nor* F1 hybrid lines, although *rin* had a smaller effect than *nor*.[4] Another study found intermediate average mean values for fruit set, shape, weight, TSS content, and flowers per cluster in the F1 hybrid line.[30,31] On the basis of this study, we conclude that mutation in the *SlETR1* gene of the *Sletr1-2* mutant allele did not affect vegetative and generative performance, although mutation did improve fruit shelf life of its F1 hybrid lines (Figure 7). Similar results have been shown for fruits of the heterozygous *rin* and *nor* F1 hybrid lines that had improved shelf life.[30,32] These results suggest that the effect of the *Sletr1-2* allele on fruit shelf life is a dominant genetic action and is not dependent on genetic background, although the *nor* gene is dependent on genetic background.[33] In the present study, the shelf life of the *Sletr1-2* F1 hybrid line was 4−5 days longer than that of the WT-MT F1 hybrid lines (Figure 7), which was enough to maintain the freshness of the tomato fruit. Prolonged fruit shelf life is important for transportation to distant markets, fruit storage, and handling, especially at markets and for the consumer.

During the ripening process, increases in ethylene production and respiration rate occur, and the peaks are reached in the breaker stage when the first red coloration is visible. Ethylene production and respiration then decline when fruit senescence is reached.[34] In our study, no peaks of ethylene and CO_2 were detected for the investigated fruit during storage because red fruits were used. There were similar declines in ethylene production and respiration rate during storage time until the

DOI: 10.1021/acs.jafc.5b02742
J. Agric. Food Chem. 2015, 63, 7995−8007

fruits reached senescence at 30 DPS for all of the *Sletr1-2* F1, WT-MT F1 hybrid lines, and pure-line cultivar parent (Figure 8). Mutation in the *Sletr1-2* mutant allele did not have significant effects on ethylene production and respiration rate of its F1 hybrid line, even when this mutant was crossed with the different genetic background of the pure-line cultivar parents. The respiration rates of the *Sletr1-2* F1 hybrid lines were similar to those found in the F1 hybrid line of *rin* mutant which showed that the *rin* F1 mutant had no effect on respiration rate.[11] For ethylene biosynthesis, their result for the *rin* F1 mutant conflicted with ours. The *rin* F1 hybrid lines had significantly lower ethylene production, with the peak reduced by approximately 50% in single *rin* mutant hybrids and by 25% in double-mutant hybrids.[4,11,13] The reduction in ethylene production in the *rin* F1 hybrid lines is due to reductions in the *ACO* gene expression levels.[5,35] 1-Aminocyclopropane 1-carboxylate synthase (ACS) and 1-aminocyclopropane 1-carboxylate oxidase (ACO) are involved in and important for the ethylene biosynthesis pathway. Therefore, during the ripening process, the amount of ethylene produced increases. For ethylene biosynthesis, ACS activity is a key step, whereas ACO activity is constitutive.[36] The same level of ethylene production was measured for the *Sletr1-2* F1 and WT-MT F1 hybrid lines, indicating that no changes were caused by the *SlETR1* gene mutation in the ethylene biosynthesis pathway.

The fruit ripening process is associated with several processes, such as increases in respiration rate and ethylene biosynthesis and changes in metabolic properties, including changes in fruit color, softening, texture, aroma, volatiles, sugar content, and pathogen susceptibility.[37] Color performance is an important external characteristic in tomatoes as an indicator of fruit ripeness and postharvest life.[38] Color change is easily detected when the onset of the ripening process occurs due to chlorophyll degradation and the accumulation of carotenoids, which cause the fruit to change to a red color.[5] In our study, fruit color is represented by L^* and h°, which indicate fruit brightness and color purity, respectively. Both the L^* and h° values of the *Sletr1-2* F1 hybrid lines varied according to the different genetic backgrounds of the pure-line cultivar parent, and these values were mostly higher than those for the WT-MT F1 hybrid lines and the pure-line cultivar parents at the beginning of storage (Figure 9). We suggest that the high L^* and h° values indicate that the ripening process was delayed or inhibited. Moreover, we believe that the effect of the *Sletr1-2* mutation on the fruit color was dominant or negative over dominance, depending on the genetic background. Our results are consistent with other studies that have shown that the effect of the *nor* gene on the chroma and L^* indices of color was dependent on the analyzed cross or genetic background.[33] Although the L^* and h° values were significantly different between the *Sletr1-2* F1 hybrid lines and the WT-MT F1 hybrid lines, according to visual inspection, they had almost identical red fruit colors, indicating that the fruit was red-ripened (Figure 6). Similar results for *rin* F1 hybrid lines have also shown the development of red color.[39] Contrasting results have been reported for the *nor* F1 hybrid line, which is incapable of developing a red fruit during ripening.[12]

The color change of the fruit from green to red is due to the transformation of chlorophyll to chromoplasts as a result of the deposition of lycopene and β-carotene in the fruit during the ripening process.[40] Because *Sletr1-2* has a dominant inheritance pattern,[8] *Sletr1-2* F1 hybrid lines exhibited reductions in ethylene sensitivity phenotypes, such as a delay in the ripening process, that affect other physiological changes, such as lycopene biosynthesis. The synthesis of lycopene was seemingly intimately dependent on ethylene for initiation and continuance of the response.[41] In the present study, there was a relationship between fruit color and lycopene content. Fruit with higher L^* and h° values resulted in a lower lycopene content (Figures 9 and 10). Another study showed that the increase in color was related to increases in both β-carotene and lycopene.[42] Lycopene and β-carotene in the F1 hybrid line of the *Sletr1-2* mutant were lower than in the WT-MT F1 hybrid line; however, this effect was dependent on the genetic background of the parent (Figure 10A,B). Although the *Sletr1-2* F1 hybrid line had a lower lycopene content compared with the WT-MT F1 hybrid line, its fruit had the capacity to develop red-ripened fruit (Figures 4 and 6). We believe that *Sletr1-2* has potential for use in breeding for improved tomato fruit shelf life because the lycopene and β-carotene contents and the fruit color of the *Sletr1-2* F1 hybrid lines were nearly the same as those of the wild-type F1 hybrid lines.

Firmness is an important characteristic for both indicating and helping to enhance postharvest fruit quality and shelf life, in addition to water status and cuticle structure.[43,44] Our results showed that the *Sletr1-2* F1 hybrid lines had the highest firmness values (Figure 10C), which means that softening of those fruits was delayed compared with the WT-MT F1 hybrid line and the pure-line cultivar parent. The delayed softening observed in the *Sletr1-2* F1 fruits was characterized by increased firmness during the early fruit maturation stages when the fruits were harvested. Our results are consistent with findings for the *nor* × Ca F1 hybrid line and *alc* × 'Mospomorist', which both showed improved fruit firmness compared with their parents.[33,45] Other studies have reported that the F1 hybrid line of *rin* has a lower softening value and that the F1 *nor* line has delayed fruit ripening.[32,46] From these results, we conclude that the mutation effect of the *Sletr1-2* allele on fruit firmness is a dominant genetic action in different genetic backgrounds. Because the *Sletr1-2* F1 hybrid line exhibits delayed fruit softening, *Sletr1-2* may be an interesting contributor to plant breeding programs for improving the postharvest quality of tomatoes.

For consumers, both shelf life and flavor quality influence the acceptability of fruits. TSS and TA are used in tomato fruits primarily to estimate sugar and organic acids, respectively, which are commonly associated with fruit sweetness and sourness, respectively.[47] During 30 days of postharvest storage, mutation in *Sletr1-2* did not affect the TSS in the *Sletr1-2* F1 hybrid lines, and the TSS of the *Sletr1-2* F1 hybrid lines was comparable to those of the WT-MT F1 hybrid lines. Generally, the effect of the *Sletr1-2* mutation was similar to the effect of 1-MCP in inhibiting ethylene action at the receptor level. It can be seen from other authors who studied 1-MCP that it does not affect the TSS of treated tomato fruits.[48,49] Although the TSS in *Sletr1-2* F1 hybrid line was not affected by the *Sletr1-2* mutation, the TSS was significantly different from that of the commercial pure-line cultivar parent (Figure 11A). This result is consistent with the study on the F1 hybrid line of the *nor* mutant that had a different TSS value from that of the 'Caimanta' parent.[33]

There was detected a relationship between pH and TA in all investigated fruit during storage, when fruit with a lower pH contained higher TA (Figure 11B,C). Another study also found a close relationship between total acidity and pH in tomato.[50] The *Sletr1-2* mutation had a significant effect on the pH and TA

DOI: 10.1021/acs.jafc.5b02742
J. Agric. Food Chem. 2015, 63, 7995−8007

of all of the F1 hybrid lines. Inhibition of the ethylene action as a result of mutation in the *SLETR1* gene was effective at inhibiting the loss of fruit acidity in *Sletr1-2* F1 hybrid lines; however, the effect was dependent on the genetic background of the pure-line cultivar parent. Thus, all *Sletr1-2* F1 hybrid fruits had a higher TA content. Our results are consistent with other studies that showed that the inhibition of ethylene action by 1-MCP significantly increased the TA in tomato fruits.[49] On the basis of these results, pH and TA are ethylene-dependent effects. Many studies have stated that the reduction of organic acid degradation caused by the suppression of the ethylene biosynthesis and action correlated with the reduction of respiration rate because organic acids are substrates for respiration.[47] This result is in contrast to our study, which showed that even though the respiration rates of the *Sletr1-2* F1 hybrid lines were similar to those in the WT-MT F1 hybrid lines and the pure-line cultivar parent (Figure 8B), the TA and pH were different (Figure 11B,C).

In conclusion, all of the results show that *Sletr1-2* exhibited strong inheritance patterns that improved the fruit shelf life of hybrid lines when crossed with different genetic backgrounds. Moreover, the hybrids did not show many undesirable characteristics, such as negative responses to stress conditions and highly reduced lycopene content and red fruit color. The plants provided similar levels of β-carotene and TSS and higher levels of TA and fruit firmness. All of these characteristics are important for the tomato fruit quality traits that appeal to the consumer. We conclude that the *Sletr1-2* mutant has potential as a contributor to breeding programs for the development of new tomato cultivars with improved fruit shelf life.

MATERIALS AND METHODS

Plant Material. The USDA Rice Mini-Core Collection was introduced from the Genetic Stock *Orzya* collection (managed by the Dale Bumpers National Rice Research Center of the USDA ARS, Stuttgart, AR, USA), which consists of 211 *O. sativa*, 5 *O. glaberrima*, 2 *O. rufipogon*, and 1 *O. nivara* accession. In this study, 219 accessions were cultivated in two field locations: the Experimental Farm of Zhejiang University, Zijingang Campus in Hangzhou (environment 1, E1) and the Experimental Farm of Zhejiang Zhijiang Seed Co. in Yuhang (environment 2, E2) during the growing season of 2012. The samples were grown in triplicate in randomized complete block design in both locations. The two locations are not too distant from one another, but the soils in the two locations were quite different; the field in E1 was recently reclaimed and had low fertility made up of fluvo-aquic soils, whereas the field in E2 was a traditional rice-growing area with purplish clayey soils. Routine agronomic practice was adopted during the growth of rice plants. The wild relatives, *O. glaberrima*, *O. rufipogon*, and *O. nivara*, were excluded from association mapping analysis as they contain many rare alleles that may increase the risk of type I errors or spurious associations.[22] Of 219 accessions grown, only 175 flowered early enough to produce seeds. Those with late flowering could not set seeds and hence were excluded from our analysis (Table S1 in the Supporting Information).

Preparation, Extraction, and Measurement of Grain Mineral Elements. The harvested rice grains were dried, cleared, and dehusked in an electrical dehusker (model B-76, Huangyan, Zhejiang, China) and subsequently used for the detection of four microelements (Zn, Fe, Cu, and Mn) and four macroelements (P, Ca, K, and Mg), respectively.

The dehusked rice samples were ground to pass a 100-mesh screen with a cyclone grinder (model 3010-019, Fort Collins, CO, USA). About 0.15 g of powdered material was digested with 6 mL of nitric acid (HNO_3) and 0.2 mLof hydrogen peroxide (H_2O_2) using a microwave digestion system (Microwave 3000, Anton PAAR, Graz, Austria). The microwave digester was programmed to ramp in high temperature and pressure set at a final power of 1200 W for 20 min. The digested samples were adjusted to a volume of 25 mL with double-deionized water. Finally, multielement analysis on grain digests was carried out by inductively coupled plasma optical emission spectrometer or ICP-OES (Optima 8000DV, PerkinElmer, USA). To control the variation within samples, each sample was measured three times, and the mean of triplicate observations was used to represent the content of mineral elements in each sample. For error control among samples, all samples were measured in a set of 20 samples containing two blanks and two standard reference samples with known concentrations of mineral elements. Standard reference samples of rice grains were used to compensate for possible matrix interference variations during microwave digestion, whereas external standards were used to construct the standard curve for calibration of ICP.

Data Analysis. Correlation analysis was performed to characterize the relationships between the examined elements. The Pearson correlation coefficients between traits were calculated on the basis of the mean values over three replications using two significance levels (p < 0.001), via the Correlate Procedure in SPSS version 16.0 for Windows (SPSS Inc., Chicago, IL, USA).

The analysis of variance for eight essential elements was conducted by the MIXED Procedure in SAS version 9.2, where genotype was defined as a fixed factor and replication and interaction between replication and genotype were random factors. Broad-sense heritability was calculated as $H^2 = \sigma g^2/ (\sigma g^2 + \sigma e^2/n)$, where σg^2 is the genotypic variance, σe^2 is the environmental variance, and n is the number of replications.

Genotyping. A total of 155 molecular markers covering the entire rice genome, approximately one marker per 10 cM on average, were used for the genotyping of the 175 accessions in the USDA Mini-Core Collection. Among the markers, 149 SSRs were obtained from the Gramene database (http://www.gramene.org/) and 5 other SSRs, AP5652-1, AP5652-2, AL606682-1, con673, and LJSSR1, with the remaining marker an indel at the *Rc* locus, named Rid 12.[21] The genetic and physical positions of SSR markers were determined using the map of Gramene Annotated Nipponbare Sequence 2009 (http://www.gramene.org/) and Rice TOGO Browser (http://agri-trait.dna.affrc.go.jp/). The obtained information on these markers was thus used to align the SSR marker maps and is reported here on the basis of the markers' cM genetic locations.

Association Mapping. The association between molecular markers and grain elemental content was carried out by the General Linear Model (GLM) and Mixed Linear Model (MLM), implemented in Tassel version 3.0.167 software (http://www2.maizegenetics.net/). Aimed at GLM, the Q method was performed where population membership estimates served as covariates. In MLM analysis markers tested and subpopulation data (Q matrix) were considered as fixed-effect factors, whereas the kinship matrix was considered as a random-effect factor,[23] taking the gross level population structure (Q) and kinship (K) into account.[24,25] The P value (marker) determining

whether the SSR marker is associated with the trait and the R^2 (marker) indicating the fraction of the total variation explained by the marker were recorded. Markers with the adjusted *P* value >0.001 were regarded as significant. Genetic maps were constructed using MapDraw V2.1.[26]

RESULTS

Genotypic and Environmental Effects on Grain Elemental Concentration. The mean values, ranges, heritability and related data of seed mineral concentrations are presented in Table 1. Analysis of variance (ANOVA) demonstrated significant ($p < 0.05$) genotypic and environmental variations for all the elements. Nearly all fell into similar range of concentrations in both environments.

The effects of environment, genotype, and interaction of genotype × environment on concentrations of micro- and macroelements were all highly significant ($p < 0.00001$). The maximum genotypic and genotype × environment effect was observed for Zn and Mg. The greatest effect of environment was detected for Cu (2114.30) and the lowest for Mg (0.96) (Table 1).

The average concentrations of both micro- and macro-elements in grains of E1 were significantly higher than in grains of E2, except Ca and Mn, which were similar in both environments. P was found to be the most abundant grain element, with concentrations of 3474 and 3296 mg/kg in E1 and E2, respectively, followed by K, Mg, and Ca (Table 1). Among the micronutrients, Mn was the most abundant, with concentrations of 31 mg/kg in both E1 and E2, followed by Zn, Fe, and Cu (Table 1).

Frequency distributions of accessions' phenotype from both locations showed clear differences due to the strong environmental effect on the concentrations of micro- and macroele-

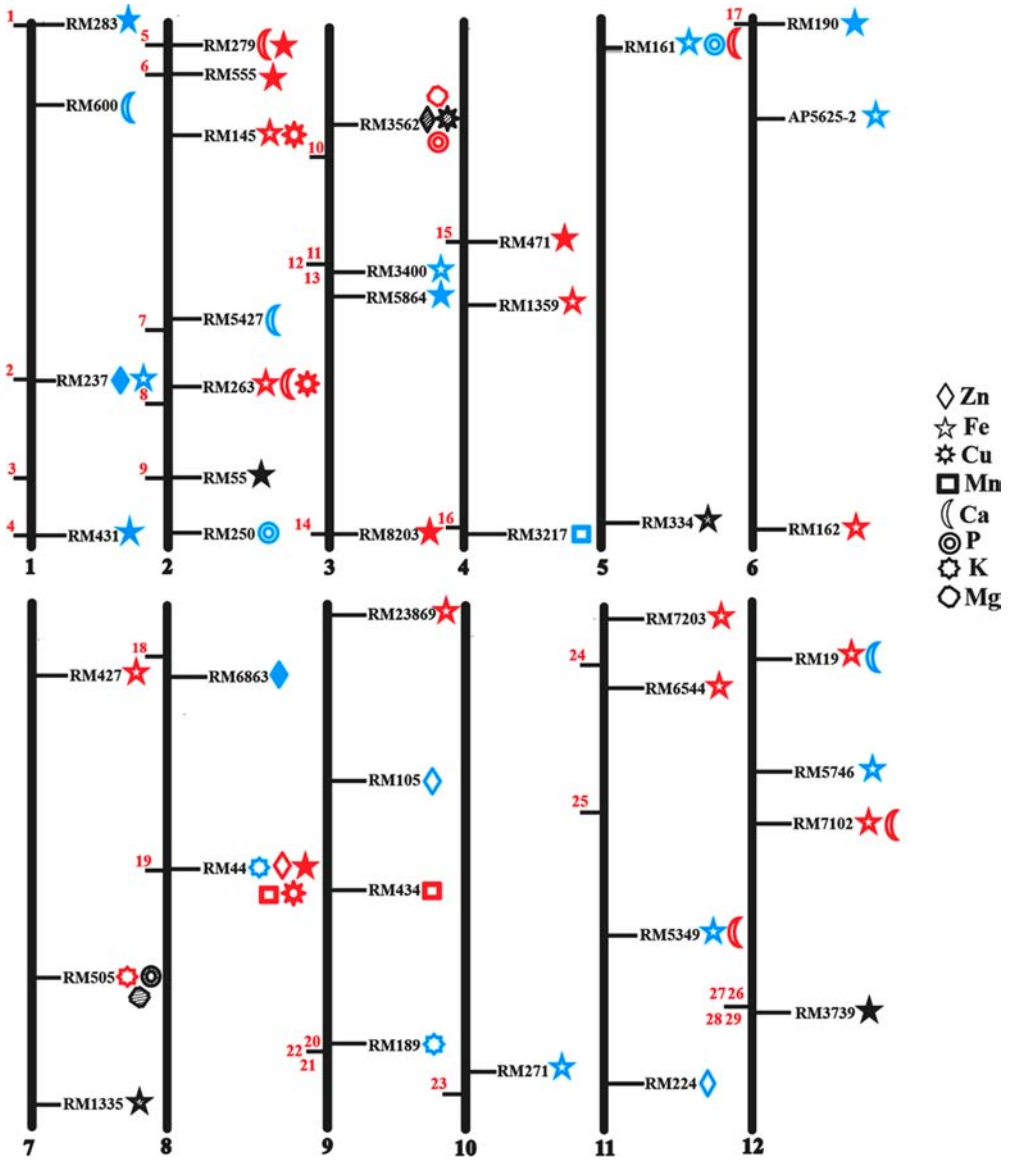

Figure 2. Sketch genetic maps of SSR markers associated with grain (brown rice) Zn, Fe, Cu, Mn, Ca, P, K, and Mg concentrations in different chromosomes. Chromosome numbers are indicated below; horizontal bars represent loci with associated marker name labeled to the right. The location information on these markers was downloaded from Gramene (http://gramene.org/) and Rice Togo Browser (http://agri-trait.dna.affrc.go.jp/). The genetic maps were drawn by Map Draw v 2.1xls. Every element is represented by a specific symbol; solid fill represents association similar to a reference at the same location; striated for consistency of marker across two locations; blue color indicates marker association with data from E1 (Zijingang), red for E2 (Yuhang), and black for both locations. The numbers on the left of each chromosome show the co-located reference from the literature: 1, 3, 14 = Norton et al.;[38] 2 = Stangoulis et al.;[32] 4, 8, 15, 16, 28 = Ishikawa et al.;[30] 5, 6, 10, 11, 12, 18, 18, 20, 21, 22, 23, 25, 26, 27 = Gracia-Oliveira et al.;[37] 7, 13, 24 = Lu et al.;[45] 9, 17, 19, 29 = Zhang et al.[8]].

ments (Figure 1). This variation existed among individual elements in the same environment as well as the same element in different environments. Among the micro and macroelements, highest variation was observed in Cu and K, respectively, in E1. The lowest variation was shown by Fe in both environments, whereas Mg showed greater variation in E2.

Correlations of Grain Elemental Concentrations and Heritability. Correlation analyses revealed a strong positive correlation between the concentrations of macro- and microelements. Overall greater correlations were found among macroelements than among microelements, where stronger correlations were present among the macroelements than among microelements. Element P strongly correlated with other macro- and microelements. The strongest correlation was exhibited among P and Mg, followed by P−K and P−Ca, across E1 and E2. Similarly, Mg and K were strongly correlated from E1 and E2, respectively. Among microelements, P strongly correlated with Fe and Zn (Table 2).

Microelements showed strong to medium correlations that were more or less consistent in the two locations. It was observed that microelements were more strongly correlated with macroelements, as compared to the microelements. The correlation among Zn and Fe was strongly positive in E1 and E2, respectively, followed by Mn and Cu. Among macroelements, Zn showed higher correlations following the descending order K < Mg < Ca.

The proportion of phenotypic variance explained by genotype is also known as broad sense heritability (H^2). The

DOI: 10.1021/acs.jafc.5b01191
J. Agric. Food Chem. 2015, 63, 8008−8016

heritability of each of the eight elements in the two environments was >60%, indicating that these traits were suitable for association mapping (Table 1). Generally high heritability was observed for Fe followed by Cu, Zn, and Ca, which had H^2 > 90% from E2. Microelements exhibited high levels of heritability as well, whereas medium to high levels of heritability were observed for macroelements. Among the macroelements, high heritability was observed for K, followed by P, Ca, and Mg from E1. Although the heritability of Mg was <60% from E1, it was considered for association mapping as it exhibited 69.39% heritability from E2. Similar variation was observed in values of H^2 among microelements across two environments (Table 1).

QTLs/Markers Associated with Grain Elemental Concentrations. A total of 60 QTLs, that is, 30 each in E1 and E2, were identified to have significant association with grain elemental concentrations. Among the eight elements, Fe concentration was associated with the highest number of markers (16/E1 in 13/E2), followed by Zn (5/E1, 2/E2) and Ca (3/E1, 4/E2). Mg was associated only with one marker in each environment. In E1, 16 of the 30 markers were associated with grain Fe, 5 with Zn, 3 with Ca, 2 each with K and P, and 1 each with Cu, Mg, and Mn. Likewise, 13 of the 30 markers in E2 were associated with grain Fe, 5 with Cu, 4 with Ca, 2 each with Zn, Mn, and P, and 1 each with K and Mg (Figure 2).

The 60 element marker associations were often found linked or grouped into multielement clusters, where this clustering was especially common in E2. Three such synchronous associations were detected in E1, for example, RM 237 co-associated with Fe and Zn and RM3562 with Zn and Cu, whereas RM161 co-associated with Fe and P. Similarly, 5 co-associations were identified in E2, for example, RM3562 with Zn, Cu, P, and Mg; RM44 with Zn, Cu, and Mn; RM263 with Fe, Cu, and Ca; RM279 with Fe and Ca, Cu; RM7102 with Fe and Ca; and RM145 with Fe and Cu, respectively (Figure 1 and Figure S2 in the Supporting Information). Markers RM3562, RM3739, RM55, RM1335, RM334, and RM505 were consistently true among both locations. For example, RM3562 associated with Zn and Cu, RM505 with Mg, and the rest with Fe. In addition, the same marker also associated with different traits across two locations. RM44 proved to be a unique marker associating with K (E1), Zn, Fe, Cu, and Mn (E2) (Tables S2 and S3 in the Supporting Information).

DISCUSSION

In this study, we identified 60 QTLs/marker loci associated with rice grain elemental concentrations by using GWA mapping approaches. We also identified co-located markers for different elemental concentrations. Moreover, adequate genetic variations in concentrations of zinc, iron, and other essential elements were also observed among USDA Mini-Core accessions. The USDA Mini-Core Rice Collection has a unique genetic diversity and has been characterized for identification of genes and QTLs for a number of traits. These traits include grain yield, harvest index, sheath blight resistance, hull silica concentration, and protein concentration.[10,27,28] About 20 new marker-grain elemental concentration associations are observed in the present study. These new associations are concerned with important grain elements such as Zn, Fe, and P along with Mn, Cu, Ca, and K. Zn, Fe, and P are considered important as their deficiency is causing hazards for the human race.

A wide range of variation was observed in contents of micro and macroelements of rice grains. These results are in accordance with the values reported by other researchers in different rice populations.[8,29−32] We found that a few accessions performed consistently across the two environments, indicating that these rice varieties can be grown and developed for biofortification programs from a grain elemental concentration perspective, especially zinc and iron. The genotypes with high grain Zn content can be a genetic source for breeding high-Zn varieties (data not shown).

Correlation analysis of different characteristics is considered very useful in exploring interrelationships.[33] In our case, numerous significant correlations were found between the different grain nutrient concentrations. Particularly, close associations existed among all four macronutrients and micronutrients or with each other. These correlations may be due to the impact of a single gene on multiple grain elemental concentrations or co-association of physically close located genes. Our observations are in agreement with previous studies.[8,31−33] The pattern of the frequency distribution in the USDA Mini-Core Collection revealed a continuous variation in all elements analyzed, suggesting that elemental uptake and subsequent accumulation in rice may be controlled by multiple genes.

It is reported that rice accessions derived from different geographic regions react to environmental signals differently.[34] Our data showed that grain concentration traits for all elements were significantly affected by environment and environment × genotype interaction, suggesting genotypic sensitivities to differences in environmental conditions in the two locations. The USDA Mini-Core represents a wide geographical and ecological diversity of rice. Therefore, the prevailing genotype × environment interaction for the accumulation of elements may be the reason for having different association results across the two locations.[35] Further elucidation of genotype × environment interaction for grain elements and related traits is required.

To comprehend the underlying genetics for the accumulation of grain elemental concentration, many researchers used different populations of rice as experimental material such as double haploids, introgression lines, recombinant inbred lines (RILs), and backcross introgression lines (BILs). RILs and BILs maintain more or less different environmental conditions.[8,19,30,32,34,36,37] The lines derived from a biparent cross shared a relatively simple genetic background. The present study is the first report of its kind about GWA mapping of grain elemental concentration in rice. Table S4 in the Supporting Information shows a comparison of a few previous works. Some of the regions associating with markers identified in this study are confirmatory, as they have been previously identified as regions controlling elemental concentration in other rice mapping populations (Table S5 in the Supporting Information).[34,38] For example, in our study zinc was associated with RM237, RM224, RM105, RM6863, RM3562, and RM44 across the two locations. Previously, a number of QTLs/SSR markers linked with zinc were reported around the same regions.[32,37]

Micro- and macroelements were positively correlated, which is reflected in the co-location of associated makers in the current study. The co-locations of markers associated with grain elemental concentration suggest the importance of these regions for mineral accumulation in rice grain and may be due to physiological coupling of the accumulation of certain minerals or tight linkage of different genes.[37] Co-locations of QTLs/markers linked with grain concentration of Zn and Fe have been described by earlier workers.[8,32,37−39] RM505 co-

associated with K, P, and Mg at chromosome 7, making a cluster of all macroelements except Ca, whereas all microelements shared the same loci at chromosome 8 with the exception of K. Zhang et al.[29] reported two loci associated with elements, P, Mg, and K, one each on chromosomes 5 and 7. This co-location of markers is also in congruence with correlation existing among respective elements. The co-locations of multiple traits for element concentration at different loci may be due to underlying genes involved in maintaining elemental/metal homeostasis. We can infer that the co-locations observed in the current study may have resulted from close linkage of genes.

The results of various earlier and recent studies point toward the existence and connection of a complex coordinated system involving many genes associated with the regulation, uptake, sequestration, distribution, mobilization, and localization of minerals in rice.[8,34] We found 16 genetic regions where genes responsible for metal ion binding and transport lie at the same locus or close to the molecular markers associated with element grain concentration (Table 3 and Figure S2 in the Supporting Information). This can be a very important finding for unraveling the mechanism of acquisition and transport of metal/element in rice seeds. Of these, RM3562, which co-associated with Cu, Mg, P, and Zn, has seven genes around this region, including *OsNAS1*, *OsNAS2*, *OsDMAS1*, 14 kDa zinc-binding protein, and cytidine and deoxycytidylate deaminase zinc-binding region family protein. Members of the NAS family have been shown to be involved in enhancing Fe and Zn in rice endosperm.[40,41] Likewise, the role of *OsDMAS1* in iron acquisition was demonstrated by Bashir et al.[42] Five ZIP transporters were also located in the regions associated with Fe and Zn. This information can be useful for future analysis of these genetic regions, linked genes, and traits. We analyzed the *OsZIP4* (Os08g0207500) gene lying in the region of RM6863 and RM44 and found many polymorphic regions (data under process). Future elucidation may result in some novel findings relating to these transporters. The current study presents a novel method of exploiting data and information provided by bioinformatics for exploring genes/factors associated with certain phenotypes.

Another important feature of the current study is the consistency of 6/60 markers across the two environmental locations. This reflects a large environmental effect on the traits under study. Zhao et al.[20] and Norton et al.[35] have previously reported a similar environmental influence on flowering time and grain elemental contents. It has also been demonstrated that the environment greatly affects the accumulation of elements in rice grains.[8,13,29,35,38,43,44]

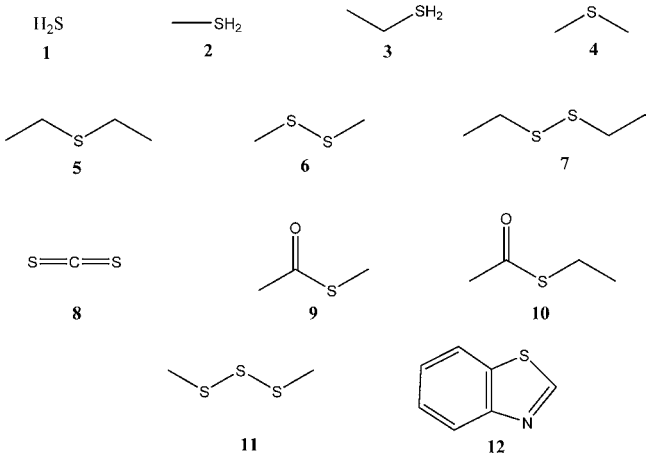

Figure 1. Chemical structures of the VSCs analyzed in this work: hydrogen sulfide (**1**), methanethiol (**2**), ethanethiol (**3**), dimethyl sulfide (**4**), diethyl sulfide (**5**), dimethyl disulfide (**6**), diethyl disulfide (**7**), carbon disulfide (**8**), methyl thioacetate (**9**), *S*-ethyl thioacetate (**10**), dimethyl trisulfide (**11**), and benzothiazole (**12**).

Table 1. SGM Composition As Adapted from Henschke and Jiranek (*Wine Microbiology and Biotechnology* 1993, 77−164 (Table 4.4, p 92))[a]

carbon source, salts, minerals, lipids, and vitamins	amount	nitrogen source	amount (mg/L)
glucose	105 g/L	L-alanine	100
fructose	105 g/L	L-arginine-HCl	484
potassium tartrate	5 g/L	L-aspartic acid	50
malic acid	3 g/L	L-cysteine	5
citric acid	0.2 g/L	L-glutamic acid	100
K_2HPO_4	1.14 g/L	L-glutamine	125
$MgSO_4{\cdot}7H_2O$	1.23 g/L	L-glycine	5
$CaCl_2{\cdot}2\ H_2O$	0.44 g/L	L-histidine	20
$MnCl_2{\cdot}4\ H_2O$	198.2 mg/L	L-isoleucine	25
$ZnSO_4{\cdot}7\ H_2O$	287.5 mg/L	L-leucine	25
$FeSO_4{\cdot}7\ H_2O$	70.1 mg/L	L-lysine-HCl	6
$CuSO_4$	25.3 mg/L	L-methionine	10
H_3BO_3	5.7 mg/L	L-phenylalanine	40
$CoCl_2{\cdot}6H_2O$	23.8 mg/L	L-proline	300
$NaMoO_4{\cdot}2H_2O$	24.2 mg/L	L-serine	60
KIO_3	10.8 mg/L	L-threonine	75
myo-inositol	100 mg/L	L-tryptophan	10
pyridoxine hydrochloride	2 mg/L	L-tyrosine	10
nicotinic acid	2 mg/L	L-valine	30
sodium panthothenate	1 mg/L	$(NH_4)_2HPO_4$	363
thiamin hydrochloride	0.5 mg/L	glutathione	50 mg/L
p-aminobenzoic acid	0.2 mg/L		
riboflavin	0.2 mg/L		
biotin	0.125 mg/L		
folic acid	0.2 mg/L		
ergosterol	15 mg/L		
Tween 80	0.5 mL/L		

[a]The amino acids and diammonium phosphate ($(NH_4)_2HPO_4$), i.e., the nitrogen sources, were modified to reflect Marlborough Sauvignon Blanc (2004, 2005, and 2006) juice and winemaking practice. Amt, amount.

synthetic grape medium (SGM) (pH 3.2, total YAN = 300 mg N/L) (Table 1) or Sauvignon Blanc grape juice (SB juice) from the Rapaura region of Marlborough in New Zealand [21. °Brix (measured at 22 °C), pH 3.14, total YAN = 206 mg N/L] (kindly supplied by Andy Frost of Pernod Ricard NZ Ltd.).

Fermentation and H_2S Quantitation. Fermentations were carried out in triplicate in 250 mL conical flasks containing 100 mL of SGM or SB juice. Flasks were sealed with rubber stoppers fitted with H_2S-detecting, silver nitrate tubes (25−2000 ppm; Komyo Kitagawa, Tokyo, Japan). Fermentation was performed at 28 °C, with rotary shaking at 100 rpm, and was monitored by daily weighing. The concentrations of **1** were recorded by visual reading from the tubes daily. Ferments were considered finished when weight loss was ≤ 0.1 g per 24 h. Wine was separated from yeast cells and solids by centrifugation at 6000 *g* for 10 min and was stored frozen at −20 °C. Dimethyldicarbonate (DMDC), 0.2 μL/L, was used to sterilize the SB juice prior to inoculation and both media after the wine was collected.

Cultures were harvested at time zero and at five different stages of fermentation completion, as estimated by percentage of weight loss: 2, 25, 50, 70, and 100%.

Control ferments of both media with no cells were also analyzed, as well as media harvested immediately after inoculation with yeast.

Samples were kept in 50 mL containers with limited head space and frozen before analysis, remaining frozen for no longer than 14 days as this has been observed to minimize VSC loss.[18]

Quantitation of VSCs. All of the HS-SPME/GC-MS analyses were performed in triplicate. The sample preparation procedure and the analytical method used for quantitation of the sulfur compounds have been described elsewhere.[19,20]

Either the wine samples or serial dilutions in model wine (12% ethanol, 5 g/L tartaric acid, pH 3.2) containing the pure analytes that would make up the calibration curves were separately prepared to a final volume of 10 mL and placed in amber screw-top 20 mL vials. Fifty microliters of the IS mix (30 μg/L d_6-DMS, 2 μg/L DPDS, and 547 μg/L MTH), magnesium sulfate salt, and magnetic stir bars were introduced as described before.[19] To prevent degradation/oxidation reactions from taking place, each sample was purged with argon gas before analysis.

In the cases of **1** and **2**, which are gaseous at room temperature, standards were prepared fresh using sodium sulfide nonahydrate (Sigma) or sodium thiomethoxide (Sigma) in a solution with model wine.

Analysis was carried out on an Agilent Technologies 7890 GC system coupled with a 5975C inert XL MSD (Agilent, USA). The fiber composition was divinylbenzene/carboxen-polydimethylsiloxane (DVB/CAR-PDMS; 50/30 μm × 2 cm) (product 57298U, Supelco, Bellefonte, PA, USA). The separating column was composed of a 30 m × 0.320 mm × 0.25 μm HP-1MS coupled with a 30 m × 0.320 mm × 0.25 μm HP-Innowax fused silica capillary column (Agilent, J&W Scientific, New Zealand). Agitation time and intensity was automated using magnetic stirrer bars in a Gerstel agitator/stirrer controlled by MAESTRO software (version 1.2.0) (Gerstel, Mülheim an der Ruhr, Germany).

Analysis of the samples was performed using the MassHunter workstation software (Agilent Technologies, USA). The ions used for the identification and quantitation of each compound were chosen according to the literature and NIST library. The statistical software used was SPSS (version 22, IBM) using one-way ANOVA ($p < 0.05$) and post hoc Tukey's HSD test ($p < 0.05$).

d_6-DMS was used to quantify **1**−**5**, **9**, and **10**. Isopropyl disulfide was used for **6**−**8** and **11**. **12** was quantified using 3-(methylthio)-1-hexanol as the internal standard.

In the cases for **1** and **12**, the R^2 values of the calibration curves are not ideal. **1** and **12** are the two extremes of the volatility/chromatographic space studied; the chromatography for **1** is not ideal due to its high volatility, which we have overcome by using a second method of detection (Kitagawa columns). In the case of **12**, its absorption on the fiber does not show high reproducibility for reasons that are unclear. Given the broad and novel scope of this paper and the attempt to measure such a wide range of sulfur species, these measurements were nevertheless included to complement the overall screening for VSCs.

RESULTS AND DISCUSSION

The experiments used two yeast strains: BY4743, a diploid auxotrophic version of the widely used laboratory strain S288c; and

DOI: 10.1021/acs.jafc.5b02984
J. Agric. Food Chem. 2015, 63, 8017−8024

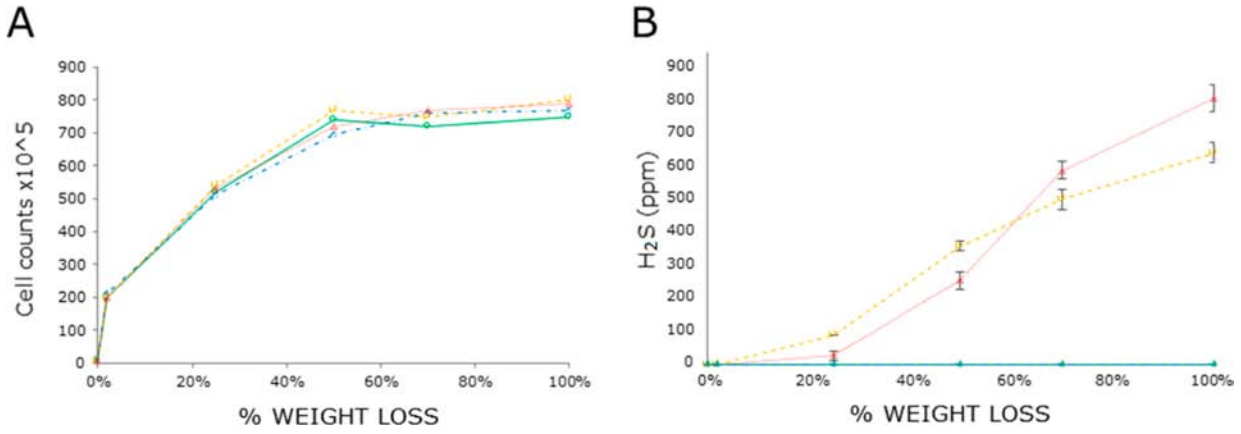

Figure 2. Fermentation progress assessed by (A) growth curves as estimated by colony counts plated and (B) production of **1** measured using detection columns. The data are shown for BY4743 in SGM (solid line green), BY4743 in SB juice (dash-dotted line blue), F15 in SGM (dashed line, orange), and F15 in SB Juice (dotted line, red). Error bars show standard deviation between replicates (n = 3).

F15, a homozygous diploid, prototrophic, commercial wine yeast strain with a known sequence.[21] The strains were grown both in synthetic medium resembling grape juice (SGM) and in Sauvignon Blanc (SB) grape juice. Ferments were sampled in triplicate for HS-SPME/GC-MS analysis of VSCs.

Both strains grew normally in the media provided (Figure 2A). To assess metabolite production, five stages of fermentation were compared with the time zero stage (as well as uninoculated media, see Materials and Methods). The five stages correlate with times during fermentation during which groups of known fermentation genes are activated.[22,23] The stages of 2 and 25% weight loss correlate to early and late stages of exponential growth. By 50% weight loss, most cell growth was completed, with the number of total cells reaching a plateau at around 7.5×10^7 cells for both strains (Figure 2A). From 50 to 100% weight loss, the cells fermented the remaining sugars, producing increased levels of alcohol, but the total number of cells in the culture did not change (Figure 2A).

In this work, of the 12 compounds detected by HS-SPME/GC-MS, only 7 (those for which results are shown in Figure 3) were found at concentrations above the background level, which is defined as the concentration found at time zero, which for all compounds was indistinguishable from the concentration found in media without cells. Of the five compounds that were not detected, the "background level" for three of them was low (**7**, 0.52 ± 0.01 ng/mL; **11**, 2.4 ± 0.2 ng/mL; **6**, 16 ± 1 ng/mL). There was, however, significant background detected for both **8** (0.164 ± 0.001 μg/mL) and **4** (1.341 ± 0.002 μg/mL). These high backgrounds possibly originated as contaminants of these compounds in the internal standard mix injected into the sample.

Arguably the most studied and the most common VSC to arise during winemaking is **1**. It is also the best understood VSC in terms of yeast genetics, with a number of known mutations in the sulfate assimilation pathway that can influence its production during wine making.[21,24,26] Its rotten egg aroma also makes it most undesirable. Low production of **1** is therefore one of the most sought after traits in a winemaking yeast strain.[24,25] In this study, production of **1** was measured daily using detection tubes[16] (Figure 2B), as well as by HS-SPME/GC-MS (Figure 3A). By both measurements, the laboratory strain BY4743 did not produce detectable **1** during fermentation in either media. Both methods, however, did detect **1** from both F15 ferments, and both indicated that the majority of production of **1** by F15 occurred close to the time cell growth was completed (around 50% weight loss, see Figure 2A), although some production was initially detected at 25% weight loss in some samples. By HS-SPME/GC-MS, the final concentrations of **1** by F15 in both media stabilized well above the 1 ng/L sensory threshold,[27] with production in SB juice being higher than in SGM for this strain (Table 2).

The actual concentrations of **1** measured by the two approaches used here differed by 2 orders of magnitude. This difference is perhaps not surprising because the methods measured very different parameters: the tubes measured total accumulated production of **1** from a 100 mL sample over the course of the fermentation, whereas the HS-SPME/GC-MS detection approach measured the steady state concentration of **1** that can be removed from the solution into the head space at each time point. In addition to differences in the sensitivity of both detection methods, the volatility of **1** could have played a role in the different concentrations seen; there may also be effects associated with sample handling when the anaerobic confinement of the culture is broken and the wine is harvested. Recently, it has been revealed that the partition coefficients of VSCs, specifically those of **1** in grape juice media, are dependent on the temperature of the fermentation and the composition of the media, especially its sugar content.[28] The same was observed for the partitioning of higher alcohols and esters[29] and may well be the case for heavier VSCs.**1** is known to be highly reactive and can combine with other compounds to form more complex VSCs.[30] For example, **3** can be formed in vitro by the reaction of **1** with ethanol or acetaldehyde[31] and can combine to form **5**.[32] Interestingly, in this study **3** presented steady state patterns that were generally similar to those of **1**. It was not detected in either ferment of strain BY4743, and yet appeared high in F15, generally rising throughout the course of fermentation (Figure 3B). However, the kinetics were different because the concentration rose early with clear production even at 2% weight loss and achieved its peak of accumulation at 70% weight loss. In the case of SB juice this was followed by a drop at the end of fermentation, indicating that the compound may either be consumed by yeast or act as the substrate for a chemical reaction near the end of fermentation (Table 2).

Following a similar trend, **9** was also not produced by BY4743 in either media, but was produced by F15. In SGM, production had started by 25% weight loss and increased steadily until the end of fermentation; in SB juice, however, it was found only at the final stages of fermentation (Figure 3C).

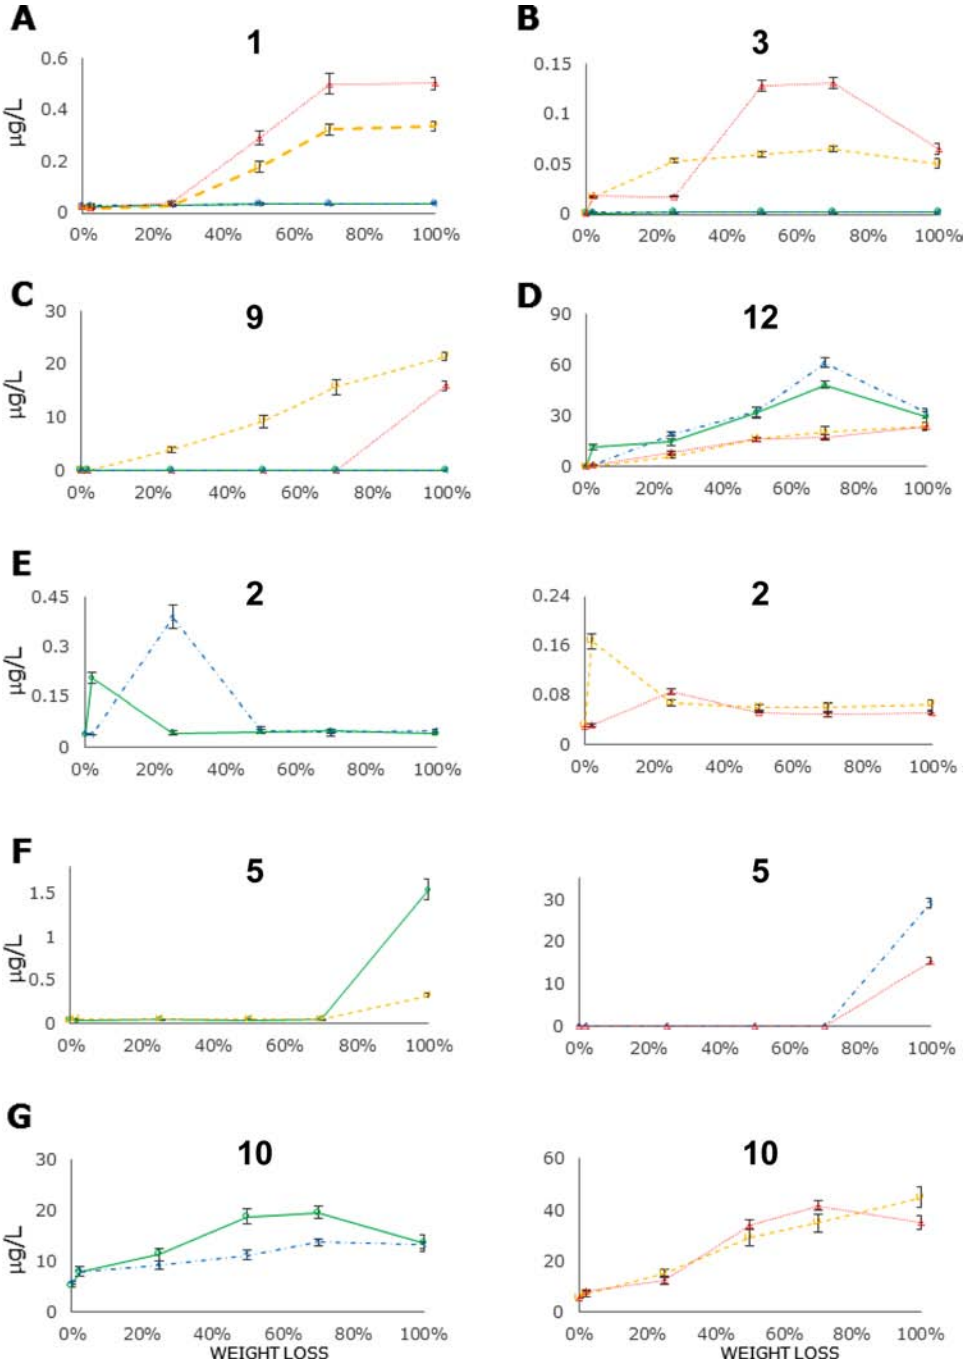

Figure 3. Cumulative concentrations of VSCs produced at 0, 2, 25, 50, 70, and 100% of fermentation for BY4743 in SGM (solid line, green), BY4743 in SB juice (dash-dotted line, blue), F15 in SGM (dashed line, orange), and F15 in SB juice (dotted line, red). Error bars show standard deviation between replicates (n = 3).

Previously, the biosynthesis of **9** has been linked to the availability of a **2** donor in yeast;[33] however, this correlation in the timing of production could not be observed in this study. Previous findings, however, are consistent with genetic strain differences playing a key role in affecting the composition of volatiles in wine.[34,35] Given that the formation of **2** has been linked to **1**,[31] it may be that the biosyntheses of **1**, **3**, and **9** are associated with each other and the latter two derive from high production of **1** by F15. To date, genetic differences in four genes have been related to differential production of **1** by yeast strains: *SKP2, MET5, MET10* and *MET2*.[21,26,36a,b] Of these, the $R_{310}G$ amino acid difference in *MET2* stands out in a comparison of F15 and BY4743, because the same genetic difference has already been shown to be responsible for productivity of **1** in a cross between F15 and another wine yeast, M2.[21] The F15 *MET2* R_{310} allele is less efficient at producing *O*-acetylhomoserine, the nitrogen−carbon skeleton into which **1** is incorporated to form homocysteine. Further experiments are needed to confirm this role for *MET2* in the production of **1** by F15 and to determine whether or how this difference in the production of **1** also affects **3** and **9** concentrations.

The production of **2** had the most distinct kinetics, as shown in Figure 3E. This compound was found as a discrete pulse early during fermentation, with the pulse occurring earlier in

[a]Statistically similar data points are grouped with similar characters. Lower case letters (sig 1): comparison of VSC concentrations at six different time points (0, 2, 25, 50, 70, and 100% weight loss) for each strain and media combination. Capital letters (sig 2): comparison of VSC concentrations within the four treatments of strain and media for each given time point. Av, average concentration of VSC (n = 3 for each data point; SD, standard deviation; sig, significance group. All values are shown in μg/L of wine.

SGM than in grape juice. In SGM, **2** increased dramatically at 2% weight loss, an early exponential stage of growth at which transcription is particularly active.[23] It then dropped just as dramatically by 25% during fermentation in SGM and remained at background levels throughout the remainder of the fermentation. This early peak in the biosynthesis of **2** was conserved for both strains and in both media. Interestingly, there was a delay for this peak in SB juice as opposed to synthetic media for both yeast strains. There was also a strain-specific medium response, with F15 more productive in SGM than in SB juice for this metabolite, whereas the opposite was true for BY4743 (Table 2).

2 was found recently to be formed by a methionine gamma lyase in *Brevibacterium linens*,[37] hinting that a possible enzymatic origin could be found also in yeast. Together with our finding, this could be interpreted if **2** is the product of early, rapid catalysis/assimilation of sulfur-containing nutrients during the first stages of cellular growth. Such sources may be more readily available in SGM (containing methionine, cysteine, glutathione, sulfate, biotin, and thiamine) than those found in SB juice, the sulfur sources of which include peptides and sulfurylated organic molecules as well as those in SGM. Alternative explanations for the difference might include an unknown competitive inhibitor suppressing production of **2** that is present in SB juice but missing in SGM. The subsequent disappearance of **2** during the latter stages of yeast growth could be explained by its being utilized as a substrate for the biosynthesis of more complex sulfur-containing compounds, either via chemical reactions or by a yeast biosynthetic pathway. A detailed experimental procedure will be needed to further test these hypotheses.

Heavier VSCs such as **5**, **10**, and **12** have also been detected in wine,[10] yet to date their origin remains unknown. First, the evolution of **12** production followed a steady increase throughout most of the fermentation (Figure 3D). In the case of BY4743, production in both media was very similar, peaking at 70% weight loss. In both media this strain produced **12** at slightly above the perception threshold (50 μg/L), but concentrations decreased by the end of fermentation. In F15 both media presented similar production curves, but at generally lower concentrations than BY4743. At the end of fermentation, F15 in both media and BY4743 in SB juice attained similar final concentrations, with BY4743 in SGM showing slight, but significant, differences ($p < 0.05$).

Second, **5** was not detected until the end of fermentation, when a marked rise in production was observed. For both strains, this late burst was more pronounced in SB juice than in SGM, achieving values for this metabolite an order of magnitude greater than the sensory threshold of 0.93 μg/L.[27] Significant strain differences were seen, with BY4743 showing higher concentrations than F15 (Figure 3F) (Table 2), which would translate to a large difference in taste for these wines.

Interestingly, together with **1**, both **12** and **5** were produced at concentrations above their perception thresholds. This result does not necessarily associate this set of compounds to the overall off-flavors detected in these wines, because the interaction with other compounds produced during fermentation is known to produce a synergistic effect that lowers the perception limits for some VSCs.[38] Conversely, some compounds that are present well below threshold values are known to influence overall aroma perception (e.g., β-damascenone).[38]

Finally, **10** followed a steadily increasing concentration pattern that was generally similar for both strains and media. This metabolite's biosynthesis was detected early in the fermentation, rising steadily and plateauing at 70% weight loss. Strain differences were evident, with F15 producing twice as much as BY4743 (Figure 3G). For BY4743, production in SGM was higher than in juice (Table 2).

In fact, overall we observed most compounds increased slowly during fermentation, with some plateauing and some peaking at 70% weight loss. None of the compounds clearly followed the cell growth curve (Figure 2A); this is perhaps surprising, because during fermentation of wine yeast in synthetic media, transcription of genes in the sulfur assimilation pathway was induced during the cell growth period and down-regulated subsequently.[22] However, it has been observed that there is sustained induction of the Met4p transcription factor late in the fermentation of Riesling grape juice,[39] and this, in turn, has been confirmed by our own previous data in SB juice,[40,41] which show induced transcription of many genes in the sulfur assimilation pathway late in fermentation (at 70% weight loss).

In summary, we have observed strain differences in either final concentration or production during growth in the biosynthesis of **1**−**3**, **5**, **9**, **10**, and **12**. Progeny studies using these strains or a detailed screening of candidate gene deletions with possible involvement in sulfur−carbon chemical reactions seem to be the best approach to shed light on the origin of these compounds.

Different media also affected the production of some VSCs. In particular, the production of **5** was up to 17 times higher in SB juice fermentation compared to that in SGM, whereas for **2**, SB juice produced a delay in this gas's biosynthetic peak. Although there may be unidentified compounds in juice that are important for these differences, it may also be possible to identify constituents of defined media that affect these parameters.[42]

Within this context, yeast assimilable nitrogen (YAN) supply in grape juice has been well documented to influence yeast growth and metabolism during winemaking.[43] Often observed, a low YAN can lead to stuck or sluggish fermentations. This deficiency, however, can be overcome by supplementation with diammonium phosphate (DAP), an ammonium source. In addition, high nitrogen (e.g., 480 mg N/L) can result in undesirable aromas being produced,[44] including, but not limited to, the accumulation of **1**. In our study, however, F15 produced significantly more of **1** fermenting SB juice (YAN, 206 mg N/L) than SGM (300 mg N/L) (Table 2). The complexity and diversity of nitrogen-containing metabolites within SB juice as compared to that of SGM make it difficult to predict if this difference in YAN is solely responsible for the difference in VSC production in our study. A more thorough and comprehensive study is needed.

Because we measured steady state levels, we cannot distinguish between several alternative explanations for the temporal changes: they may result from differences in production of the compounds or differences in their degradation or their use in subsequent pathways or chemical reactions, or they may even occur as the result of changes in the rate of their transport outside the cell. However, the knowledge of the approximate timing of their peak concentration detailed here will allow these options to be evaluated more fully. The use of precursors with labeling on different atoms and positions will be critical in such work, along with careful selection of optimal sampling times.[45]

Wine quality can be affected dramatically by the production of VSCs, and understanding the parameters and conditions in which they are produced could have profound applications in the wine industry. The differences in the timing of production

by yeast, for the seven VSCs presented here, will facilitate detailed analysis of the biochemical pathways involved, about which very little is currently known. The strain and medium differences noted here should also provide an initial basis for determining some of the genetic and physiological influences on this class of wine aroma molecules.

Table 1. Description of Training Sessions[a]

training session	method	instructions	concentrations of stimuli (% w/w)	replicates
training 1	150 mm VAS (not sweet at all−extremely sweet)	taste the sample (as many sips as needed)	3, 4, 5	duplicate
	duo-trio	choose the sample that is most similar to the reference sample	reference, 4; other samples, 3.5, 4.5	duplicate
training 2	150 mm VAS (not sweet at all−extremely sweet)	taste the sample (as many sips as needed) in comparison to the 3, 4 and 5%	2.5, 3.5, 4, 4.5, 5.5	duplicate
	paired comparison	choose the sample that is sweetest	3.6, 4 and 4, 4.4	duplicate
training 3	150 mm VAS (little sweet−very sweet)	taste the sample (only once) in comparison to the reference sample (4%)	3.6, 4, 4.4	duplicate
			3.7, 4, 4.3	duplicate
	paired comparison	choose the sample that is sweetest	3.8, 4 and 4, 4.2	duplicate
training 4	150 mm VAS (little sweet−very sweet)	taste the sample (only once) in comparison to the reference (4%)	3.7, 4, 4.3	triplicate
			3.8, 4, 4.2	duplicate
training 5	150 mm VAS (little sweet−very sweet)	taste the reference (4%) before, take a sip of water, taste the sample (only once)	3.7, 4, 4.3	triplicate
		taste the reference (4%) before, take a sip of water, process the o/w emulsion (t = 30 s),, expectorate, taste blind 4% sucrose, and score sweetness relative to the reference	4	
			o/w emulsions: 1, 10, and 20	
training 6	150 mm VAS (little sweet−very sweet)	taste the reference (4%) before, take a sip of water, process the o/w emulsion (t = 3, 6, 9, 15 s), expectorate, taste blind 4% sucrose, and score sweetness relative to the reference	4	
			o/w emulsions: 1, 10, and 20	
extra session 1	150 mm VAS (little sweet−very sweet)	taste the reference (4%) before, take a sip of water, taste the sample (only once)	3.8, 4, 4.2	triplicate
extra session 2	150 mm VAS (little sweet−very sweet)	taste the reference (4%) before, take a sip of water, taste the sample (only once)	3.9, 4, 4.1	triplicate

[a]Concentrations are sucrose concentrations, unless specified.

buds to trigger a taste response and consequently leading to a decline in taste intensity. The hypothesis might hold true when oil coatings form a sufficiently thick film covering the tongue surface, which might be the case after orally processing bulk fats and oils. Perceptual effects such as taste−taste, flavor−taste, or texture−taste interactions between the food used to coat the tongue and the subsequently provided tastant stimulus might have an impact when complex, multicomponent commercial products are consumed. To better understand the mechanisms underlying taste suppression due to oil deposition on the tongue surface, it is important to study oral coatings formed by foods with low taste and flavor intensity at realistic oil contents as they occur in foods. Besides the effect of oral coatings on subsequent taste perception, several studies focused on the factors affecting the dynamics of physical clearance of oral coatings after stimulus expectoration.[4−8] Little is known about the dynamics of the formation of oil deposits on the tongue while drinking.

The first aim of this study was to quantitate the dynamic formation of oil deposits on the tongue surface formed by o/w emulsion differing in oil content from 1 to 20% (w/w). For this purpose one sip (20 mL) of o/w emulsion containing 1, 10, and 20% (w/w) oil and 3.2% (w/w) sodium caseinate was processed in the mouth for different times ranging from natural consumption time (3 s) to times that were hypothesized to create maximum oil deposition on the tongue (15 s). In vivo fluorescence measurements were used to quantitate the oil fraction deposited on the tongue at each time point. The second aim of this study was to investigate the effect of oil deposits on the tongue surface formed by o/w emulsions on subsequent sweetness perception of sucrose solutions. A trained panel was used to evaluate the sweetness intensity of 4% (w/w) sucrose solutions after oral processing of the o/w emulsions for different times.

We hypothesize that the oil fraction deposited on the tongue increases with increasing oral processing time until, at longer oral processing times, the amount of oil deposited on the tongue reaches a plateau. We hypothesize that oral processing of o/w emulsions with relatively low oil content does not lead to the formation of a hydrophobic barrier that is sufficient to reduce the accessibility of hydrophilic tastants to the taste buds and, consequently, does not influence subsequent taste perception.

MATERIALS AND METHODS

Materials. Sunflower oil (Albert Heijn, purchased from local retailer), sodium caseinate (Excellion sodium caseinate S, DMV International, The Netherlands, protein content = 91%), and tap water were used for the preparation of the emulsions. Curcumin (7% w/w curcumin dissolved in propylene glycol and polysorbate; L-WS; Sensient, Elburg, The Netherlands) was added to the o/w emulsions as a hydrophobic fluorescent dye. Sucrose (Van Gilse Kristalsuiker, purchased from a local retailer) and bottled mineral water (C1000, purchased from a local retailer) were used for the preparation of the aqueous sucrose solutions. All ingredients were of food grade.

Preparation and Characterization of o/w Emulsions and Sucrose Solutions. All o/w emulsions were prepared in a food grade environment. The aqueous phase of the o/w emulsions consisted of 3.2% (w/w) sodium caseinate solution. The aqueous phase was prepared by dissolving sodium caseinate in tap water at room temperature. The aqueous phase was then prehomogenized with the

DOI: 10.1021/acs.jafc.5b02562
J. Agric. Food Chem. 2015, 63, 8025−8030

sunflower oil (1, 10, and 20% w/w) using an Ultra Turrax (IKA RW 20 Digital) at 4000 min^{-1} for 2 min and homogenized with a two-stage homogenizer (Niro-Soavi S.p.A. NS1001L2K) at pressures between 200 and 350 bar. All o/w emulsions had a neutral pH. The emulsion droplet size distribution was measured by light scattering (Mastersizer 2000, Malvern Instruments) in duplicate using the refractive index of sunflower oil (1.469). The average Sauter diameter of the emulsion droplets, $d_{3,2}$, was determined for each o/w emulsion (average $d_{3,2}$ = 0.70 μm) accounting for differences in batches (one batch of each o/w emulsion was made per week). Emulsions were stored after preparation in a refrigerator at 4 °C and used for further studies no later than 3 days after preparation. Curcumin solutions were added to the o/w emulsions under magnetic stirring before consumption.[5]

Sucrose solutions varying in concentration were prepared by dissolving sucrose in water under stirring at room temperature. For the screening sessions (to find suitable subjects for the experiments), a range of 2−8% (w/w) sucrose solutions was prepared. For the training sessions of selected subjects, 2.5, 3.0, 3.5, 3.6, 3.7, 3.8, 3.9, 4.0, 4.1, 4.2, 4.3, 4.4, 4.5, 5.0, and 5.5% (w/w) sucrose solutions were prepared. For the experiment addressing the second objective of this study, a 4% (w/w) sucrose solution was prepared.

Panel Selection. Twenty-eight subjects (21 females, 7 males; age 25.5 ± 5.2 years) were invited for a screening session of 1 h. The screening session started with a ranking test in which subjects were asked to taste four sucrose solutions (2, 4, 6, and 8% (w/w) sucrose) and rank them in order of increasing sweetness. This was followed by a second ranking test in which subjects were asked to taste five sucrose solutions (2, 3, 4, 5, and 6% (w/w) sucrose) and rank them in order of increasing sweetness. The presentation order of stimuli in the screening session was randomized in both ranking tests. All subjects performed both ranking tests in duplicate. The third test of the screening session was a duo-trio test in which the subjects were asked to first taste the reference stimulus (4% (w/w) sucrose solution) and then choose of two stimuli the one that was most similar to the reference stimulus. The sucrose concentrations of the two stimuli were either 3 and 4% (w/w) or 4 and 5% (w/w). The test was performed in duplicate by all subjects. Presentation order and position were randomized over subjects in the duo-trio test. The performance of each subject on the screening session was determined. The correct answers given were weighted for the difficulty of the task, that is, one-fold for the first ranking test, two-fold for the second ranking test and the duo-trio test. This resulted in an individual performance score for each subject. On the basis of the performance score 15 subjects (12 females and 3 males; age 23.6 ± 3.5 years) with the highest performance scores were selected to participate in the study from the 28 subjects participating in the screening session.

The screening session ended with a consumption time measurement. All 28 subjects were asked to measure the drinking time between ingesting and swallowing a sip (20 mL) of full-fat milk (FrieslandCampina, The Netherlands). A stopwatch was used by each subject. This test was performed in triplicate. The average oral processing time of 20 mL of full-fat milk was found to be 3.3 ± 0.2 s.

All subjects signed a consent form and received financial compensation for their efforts.

Panel Training. The panel (n = 15) was trained on sweetness intensity evaluation of sucrose solutions to ensure that the panel was able to discriminate sweetness intensity of stimuli varying in sucrose concentration by <0.4% (w/w) sucrose relative to a reference stimulus (4.0% (w/w) sucrose). The panel was trained in six sessions of 1 h twice a week for 3 weeks. Each training session started with individual feedback on the performance during the previous training session to improve panel performance. The panel used a 150 mm visual analogue scale (VAS) during all training sessions. The training sessions involved group discussions during which the panel was first introduced to the 150 mm VAS, tasting instructions, reference stimuli, and stimuli with different sweetness intensities. The use of the scale and its suitability were discussed for different sucrose solutions. These group discussions were followed by individual tasting tests.

An overview of the training sessions is given in Table 1. During the first training session, samples representing concentration differences of 1% (w/w) sucrose were presented to the subjects. Because the effects of a coating on sweetness intensity were expected to be small, the sucrose concentration differences between stimuli were lowered during the following training sessions ending with a concentration difference of 0.1% (w/w) (Table 1). During the second training session, samples were assessed in comparison to 3, 4, and 5% (w/w) sucrose. In the first two sessions subjects were allowed to take as many sips as they wanted of the reference and the test stimulus in order to score the sweetness. From the third training session onward, the reference stimuli were presented to the panel. The end points of the 150 mm VAS were defined as the sweetness of 2.5 and 5.5% (w/w) sucrose solutions to demonstrate the limits of the scale and to prevent end-use avoidance. Furthermore, the 4% (w/w) sucrose solution was termed as "reference". The panel was instructed to score this reference in the middle of the scale. The panel was trained to evaluate the samples with respect to how different the sweetness intensity of each sample was compared to the reference. From the third session onward, the panel was instructed to first taste the reference, clean the palate with water, then taste the test sample only once and rate the sweetness perception on the scale. During the fifth and sixth training sessions, the subjects were introduced to and familiarized with the procedure of the final experiments (oral-processing protocol, different o/w emulsions, and different oral-processing times). The panel was instructed to taste the reference (4% (w/w) sucrose), take a sip of water, ingest the o/w emulsion, spit it out after a specified time period, taste the sweet sample (only once), and rate the sweetness of this stimulus. The panel was trained and instructed to focus on the sweetness perception of the sample.

In Vivo Fluorescence Measurements To Determine Oil Fraction Deposited on the Tongue. The method used in the present study has been previously described in detail.[5] Fluorescence measurements were made with a single-point measurement (Flouorolog Instruments SA Inc., HORIBA Jobin Yvon, Longjumeau, France) at an excitation wavelength of 440 nm, an emission wavelength of 495 nm with a slit width of 0.95 mm, and a measurement time of 0.1 s. A fluorescence remote read fiber optic probe was used to measure on tongue surfaces (in vivo for determination of oil fraction and ex vivo for calibration curves). The probe was put perpendicularly to the anterior back part of the tongue surface and with slight pressure to avoid deformation of the papillae and the coating. To convert the fluorescence intensity measured on the subject's tongue surface to the oil fraction deposited on the tongue surface, that is, the mass of oil per area of tongue (mg/cm^2), calibration lines (data not shown) were made following the procedure described previously.[5]

Oral-Processing Protocol. To study the formation of the oil oral coating, 20 mL o/w emulsions (1, 10, and 20% (w/w) o/w emulsion) were processed in the mouth for different time periods (t = 3, 4.5, 6, 9, and 15 s) and then expectorated. The different oral-processing times were chosen to range from the natural drinking time of one sip of 20 mL of full-fat milk (3.3 ± 0.2 s) to a consumption time that hypothetically creates maximum oil deposition on the tongue. To verify whether the oral-processing protocol would influence the perception of the 4.0% (w/w) sucrose solution (reference), that is, to verify whether the panel is able to score the 4.0% (w/w) sucrose solution in the middle of the VAS as in the training sessions, a blank coating stimulus was added to the design. The blank coating stimulus consisted of water with curcumin (to have a similar color as the o/w emulsions) and was processed in the mouth for 9 s. The oral-processing time of 9 s was chosen as it was approximately in the middle of the range of the oral-processing times of the measured o/w emulsions.

To assess the effect of oil deposition on the tongue on subsequent sweetness perception, the trained panel processed in-mouth the three o/w emulsions for different times or the blank stimulus at room temperature. The emulsions or the blank coating were then expectorated and the in vivo fluorescence measurement was performed. Immediately after the fluorescence measurement, which typically took around 1−2 s, the 4.0% (w/w) sucrose solution was tasted and sweetness intensity assessed on a continuous 150 mm VAS (anchored with little sweet on the left end and very sweet on the right

DOI: 10.1021/acs.jafc.5b02562
J. Agric. Food Chem. 2015, 63, 8025−8030

end of the scale). Only one sip of the sucrose solution was tasted with a maximum sip size of 20 mL. The middle point of the scale (75 mm) was marked with an anchor. Sensory data were collected using EyeQuestion (version 3.11.1).

Sixteen conditions ((3 o/w emulsions × 5 oral-processing times) + 1 blank) were tested by the $n = 15$ subjects in triplicate, resulting in 48 measurements per subject. Subjects participated in eight evaluation sessions of 1 h. During each session eight stimuli were assessed by each subject. A completely randomized design was used randomizing the 48 measurements over subjects and sessions.

The panel was not allowed to drink or eat 1 h before the start of a session. Prior to the first measurement, the subjects cleaned their tongue with cold water. Before the consumption of each o/w emulsion or blank coating, the subjects were asked to taste the reference (4.0% w/w sucrose) to refamiliarize themselves with the reference, after which they cleaned the tongue with water. This was followed by a background fluorescence measurement of the tongue. Between the fluorescent measurements the tongue was cleaned extensively to remove the oil deposited at the tongue for which crackers, a tongue scraper, and both room temperature (20 °C) and warm (40 °C) water were used.

Statistical Data Analysis. SPSS Statistics version 21 (IBM Software, Armonk, NY, USA) was used for the statistical analysis. Descriptive statistics were used to obtain the mean and standard error (SE). Outliers ($z > 2$) were removed from the data. The data obtained during the training sessions were used to verify panel performance. The discriminative ability of the panel and the influence of the protocol on perception were tested by an one-way analysis of variance (ANOVA). Subject and replicate effects were verified for both the fluorescence and the sensory data by a one-way ANOVA. Fluorescence intensity data were normalized with a square root transformation. The effects of oil content (within-subject factor: 1, 10, and 20% w/w), oral-processing time (within subject factor: 3, 4.5, 6, 9, and 15 s), and the interaction on the formation of the coating were tested with a repeated-measures ANOVA. The assumption of sphericity was verified by Mauchly's test, being violated for oil content and the interaction effect. Therefore, the Greenhouse−Geisser correction was applied. The effects of oil content (within subject factor: 1, 10, and 20% w/w), oral-processing time (within subject factor: 3, 4.5, 6, 9, and 15 s), and the interaction on sweetness were tested with a repeated-measures ANOVA. The assumption of sphericity was violated, and the Greenhouse−Geisser correction was applied. When significant main effects were found, Bonferroni pairwise tests were performed. A significance level of $p < 0.05$ was chosen.

RESULTS AND DISCUSSION

The aims of this study were to investigate (a) the dynamic formation of oral oil coatings formed by o/w emulsions on the tongue surface and (b) the effect of oil coatings formed by o/w emulsions on subsequent sweetness perception of sucrose solutions.

Panel Training. The results from the training sessions are shown in Figure 1. The panel scored the sweetness intensity of a blind 4.0% (w/w) sucrose solution close to the middle of the 150 mm line scale (75.4 ± 2.1 mm). The discriminative ability of the panel, that is, the minimum difference of sucrose concentration relative to the reference (4% (w/w) sucrose solution) leading to a significant difference of sweetness, was determined (Figure 1). The panel assessed the sweetness of the 3.7% sucrose solution as significantly less sweet ($p < 0.001$) than the 4.0% (w/w) sucrose solution. The sweetness intensity of the 4.3% (w/w) sucrose solution ($p < 0.01$) was significantly higher than the sweetness of the 4.0% (w/w) sucrose solution. The panel did not perceive the sweetness of the 3.8% ($p = 0.118$) and the 4.2% (w/w) solution ($p = 0.168$) as significantly different from the 4.0% (w/w) sucrose solution (Figure 1). The minimum difference in sucrose concentration between stimulus

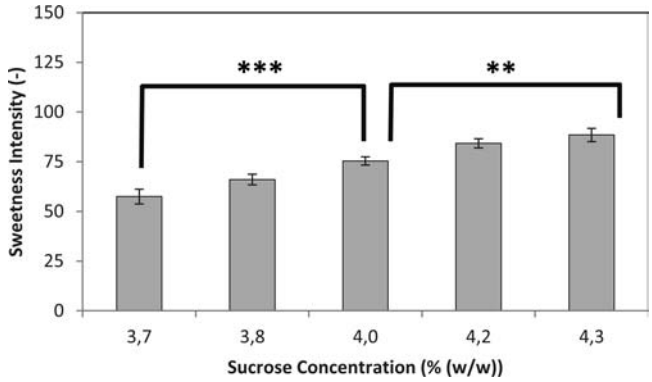

Figure 1. Sweetness intensity of sucrose stimuli varying in concentration rated on a 150 mm VAS scale. Each bar represents the average intensity of $n = 15$ subjects assessing the stimuli in triplicate. Significance level is represented by ** for $p < 0.01$ and *** for $p < 0.001$. Error bars represent the standard error.

and 4.0% (w/w) sucrose solution that led to a significant difference in sweetness intensity was 0.3% (w/w).

Dynamic Formation of Oral Oil Coatings of o/w Emulsions. Figure 2 depicts the oil fraction deposited on the anterior back part of the tongue for 1, 10, and 20% (w/w) o/w emulsions after oral processing of the emulsion for different times. A significant main effect of oil content on the oil fraction deposited on the tongue ($F[1.4, 63.4] = 323.7$ $p < 0.001$) was found with a higher oil content of the o/w emulsions resulting in a higher oil fraction deposited on the tongue surface. All of the o/w emulsions differed significantly from each other at every oral-processing time point ($p < 0.001$).

It was hypothesized that the oil fraction deposited on the tongue increases with increasing oral processing time until, at longer oral-processing times, the amount of oil deposited on the tongue reaches a plateau. The oil fraction deposited on the tongue tended (not significant) to be influenced by oral processing time ($p = 0.057$) (Figure 2). No significant differences in oil fraction deposited on the tongue were observed between o/w emulsions orally processed for $t = 3$ s and longer oral-processing times ($t = 4.5$, 6, 9, and 15 s). This demonstrates that a saturation with oil deposited on the tongue was reached already after an oral-processing time of $t = 3$ s for all emulsions tested. The dynamics of the oil coating formation is similar for the three emulsions studied. This fast saturation of oil deposited on the tongue surface suggests that the o/w emulsions contain oil droplets that can easily adhere to the tongue surface. This suggests that within the natural drinking time of one sip of 20 mL of a liquid stimulus (3.3 ± 0.2 s for full-fat milk), the tongue surface is already coated with the drink's oil, which can adhere to the tongue. We speculate that the observations of previous studies of, for instance, Pivk et al. (study used samples of 0.5−16 mL of bulk MCT oil) and Camacho et al. (study used samples of 20 mL, as is the case of this study), which used an oral-processing time of 30 s to investigate oil deposition on the tongue, are likely to be similar to results that would have been obtained with shorter oral-processing times of <5 s.

Influence of Oil Coatings on Subsequent Sweetness Perception. The influence of the oral-processing protocol during the fluorescence measurements on the evaluation of sweetness intensity of the sucrose samples was verified by adding a blank coating sample (water with curcumin) to the experiment. The sweetness intensity of the 4.0% sucrose sample

J. Agric. Food Chem. 2015, 63, 8025−8030

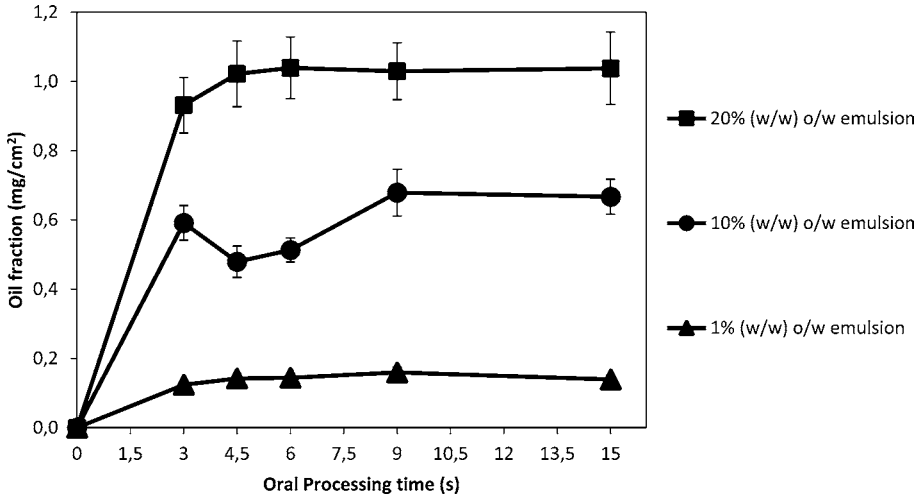

Figure 2. Oil fraction deposited on the back part of the anterior tongue of 1, 10, and 20% (w/w) o/w emulsions processed orally for different time periods. Each point represents the average of n = 15 subjects assessing the stimuli in triplicate. The error bars represent the standard error.

after consumption of the blank (76.7 ± 2.5 mm) did not differ significantly from the sweetness intensity of the 4% sucrose solution without consumption of the blank (75.4 ± 2.1 mm) (p = 0.696). This indicates that the oral-processing protocol did not affect the panel performance and, furthermore, the addition of curcumin did not affect sweetness.

Different oil fractions deposited on the tongue (Figure 2) after different oral-processing times did not significantly affect subsequent sweetness intensity (p = 0.294) (Figure 3).

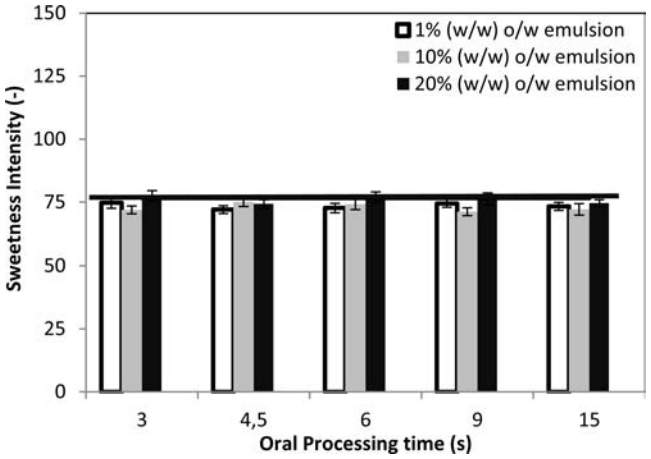

Figure 3. Sweetness intensity after consumption of 1, 10, and 20% (w/w) o/w emulsions for different oral processing times (t = 3, 4.5, 6, 9, and 15 s). Each bar represents the average value of n = 15 subjects assessing the stimuli in triplicate. The error bars represent the standard error. The line represents the average sweetness intensity of the blank sample (i.e., water).

Sweetness intensities of the 4.0% (w/w) sucrose stimulus, after oral processing of the different o/w emulsions for different times, ranged from 71.1 ± 2.1 to 77.4 ± 2.2 mm. Sweetness intensity was not correlated with the oil fraction deposited on the back part of the anterior tongue (Figure 4). We suggest that by orally processing o/w emulsions ranging in oil content from 1 to 20% (w/w), the oil fraction adhering to the tongue surface is not sufficient to form a homogeneous film of oil covering the tongue. We suggest that the oil droplets deposited on the tongue do not form a hydrophobic barrier that is sufficient to

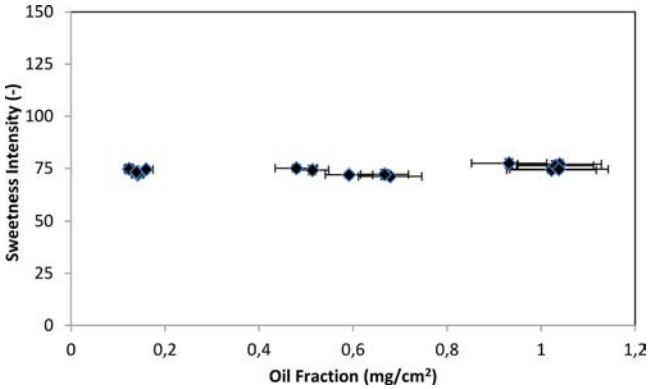

Figure 4. Oil fraction deposited on the back part of the anterior tongue as a function of sweetness intensity for 1, 10, and 20% (w/w) o/w emulsions orally processed for different times (t = 3, 4.5, 6, 9, and 15 s). Each point represents the average of n = 15 subjects assessing the stimuli in triplicate. The error bars represent the standard error.

reduce the accessibility of sucrose to the taste buds. This proposes that the migration of sucrose molecules to the taste buds is not sufficiently reduced and, consequently, sweetness perception is not altered. An additional explanation might be due to the morphology of the tongue. Fungiform papillae, which contain taste buds with taste receptor cells (TRCs), are mainly found in the front part of the anterior tongue. The front part of the anterior tongue has consequently been demonstrated to be more sensitive for taste perception.[9] In previous studies, it was found that less oil deposits at the front part of the anterior tongue compared to the back part.[4−6] Taking the uneven distribution of oil deposition on the tongue into account, tastants could likely migrate to the taste buds and bind to the TRCs present at the tip of the tongue because the amount of oil deposited there is even smaller than on the back part of the tongue. Consequently, no effect of oral oil deposition on sweetness intensity is observed.

The results of this study did not confirm previous findings in the literature,[1-3] which reported that sweetness intensity was suppressed by preceding consumption of bulk oil or dispersed oil. Lynch et al. found that the consumption of either coconut oil or sunflower oil reduced subsequent sweetness intensity of sweet gelatin gels compared to preceding consumption of

DOI: 10.1021/acs.jafc.5b02562
J. Agric. Food Chem. 2015, 63, 8025−8030

water. Valentová and Pokorný found that the consumption of bulk sunflower oil reduced subsequent sweetness intensity of sucrose solutions. Both studies used oils to coat the tongue, whereas this study used o/w emulsions with a maximum oil content of 20% (w/w). The difference in oil content between stimuli used in the literature and our study led to differences in the amount of oil fraction deposited on the tongue. It is likely that the oil coatings formed with bulk oil form a hydrophobic layer and might have created a thicker physical barrier and thus suppress the migration of hydrophilic tastants to the taste buds, leading to a suppression of sweetness perception. Furthermore, coconut oil seemed to have a higher effect in the suppression of sweetness intensity compared to sunflower oil.[1] Coconut oil has a higher viscosity compared to sunflower oil.[10] Viscosity was found to affect taste intensity, indicating a taste−texture interaction.[11] Taste−taste interactions could have also contributed to the sweetness suppression, as coconut oil has an inherent coconut taste, which could have caused sensory adaptation. Therefore, texture−taste or taste−taste interactions might have contributed to the suppression of sweetness intensity due to preceding coconut oil consumption found by Lynch et al. Next to this, the sunflower oil used by Valentová and Pokorný was refined with oily and buttery flavors, which might also have partly suppressed the subsequent perceived sweetness by flavor−taste interactions. Furthermore, although these studies used panels experienced with time−intensity and sensory profiling, it is not explicit whether and how the panels were trained specifically on sweetness perception. The training of subjects to assess taste intensity and the resulting discrimination sensitivity of the subjects used is likely to differ between the different studies. Highly trained subjects should be used because the effects of oil coatings on subsequent taste perception are expected to be small.

Ahn et al. and Valentová and Pokorný both observed sweetness intensity suppression after consumption of bulk oils or foods with high oil content. Those studies used sucrose solutions with concentrationa of 0.12 and 15.5% (w/w), respectively. In our study we did not observe sweetness intensity suppression. We used a sucrose concentration of 4.0% (w/w) and o/w emulsions with up to 20% (w/w) oil. This suggests that the fraction of oil deposited on the tongue is the main factor that determines whether suppression of taste intensity due to oral oil coatings occurs.

Valentová and Pokorný found that consumption of commercial emulsions, that is, yogurt dressing, flavored emulsion, and mayonnaise, resulted in a decrease in subsequent sweetness intensity. However, these products have a complex food matrix and contain not only fat but also tastants and aromas. The ingredients and flavor might have contributed to the suppression of the sweetness by various mechanisms, for example, texture−taste, taste−taste, or flavor−taste interactions.

Milk is known to form a mouth coating.[12] This coating effect was thought to alter perception, because the consumption of milk was found to reduce subsequent perception of sweetness.[3] The suppression of sweetness intensity by milk might be better explained by taste interactions. The sweetness of milk[12] might have resulted in adaptation leading to a suppression in sweetness intensity of the tastant solution. Another reason might be that tastants or aroma molecules present in the oral cavity after the consumption of milk might have masked the succeeding sweetness of the tastant solution.

In conclusion, the dynamics of oral oil deposition is fast with the maximum oil fraction adhering to the tongue surface occurring within the natural drinking time of one sip of a beverage. Longer oral processing does not increase the oil fraction deposited on the tongue. The oil fraction deposited on the tongue after oral processing of o/w emulsion with up to 20% (w/w) oil did not affect subsequent sweetness perception of sucrose solutions. We suggest that this is caused by a limited fraction of oil being deposited on the tip of the tongue where humans have a high density of taste papillae and consequently are most sensitive to taste perception. We suggest that the oil droplets deposited on the tongue did not form a hydrophobic barrier that is sufficient to reduce the accessibility of sucrose to the taste buds and consequently does not suppress taste perception.

proposing the effect of glucosamine degradation on 4-MeI formation.

MATERIALS AND METHODS

Chemicals and Reagents. 4-MeI, sodium hydroxide (50%), and methanesulfonic acid (MSA, 99%) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Methanol, NH_4Cl, and hydrochloric acid (HCl, 35−37%) were of analytic grade and purchased from Merck (Damstadt, Germany). Phosphate buffer solutions (PBS, 0.2 mol/L) of pH 7.4 and Na_2HPO_4−citric acid buffer solutions (0.2 mol/L Na_2HPO_4 stock solution, 0.1 mol/L citric acid stock solution) of pH 5.0, 7.0, and 8.0 were also used. The mixed standard stock solution of 4-MeI (10 mg/L) was prepared by dissolving the analytes into deionized water.

Sample Preparation. In glucose−NH_4^+ Maillard reaction, glucose (40 mmol/L) was mixed with NH_4Cl (free ammonium, 40 mmol/L) in 10 mL of Na_2HPO_4−citric acid buffer solutions (0.2 mol/L) with or without sulfite sodium (40 mmol/L) at various pH values (5, 7, and 8, respectively). In bound amino compound Maillard reaction, glucosamine (40 mmol/L) and *N*-acetylglucosamine (40 mmol/L) were each dissolved in 10 mL of Na_2HPO_4−citric acid buffer solutions (0.2 mol/L) with or without sulfite sodium (40 mmol/L) at various pH values (5, 7, and 8, respectively). Four milliliter mixtures were incubated at 120 °C for up to 120 min in a swing-top bottle. After a defined reaction time, the reaction mixtures were cooled to room temperature by iced water immediately to stop the reaction. One milliliter of reaction mixture was incubated with *o*-phenylenediamine (1 mL, 0.5 mg/mL in 0.2 mol/L PBS of pH 7.4) for 12 h at room temperature, and the rest of the reaction mixture was stored at 4 °C for further analyses.

Absorbance Measurements of Reaction Mixtures. The UV absorbance and browning intensity of the Maillard reaction products were measured according to the literature with a slight modification.[3] A 150-fold dilution of the treated solution was detected at 420 nm using a UV-1901 spectrophotometer (Puxi, Beijing, China).

Analyses of Dicarbonyls by HPLC-UV. Interception of α-dicarbonyls as quinoxalines was carried out according to the method of Gobert et al.[11] with slight modifications. The analyses were performed in an HPLC-DAD system, which consisted of a 5 μm Waters Atlantis T3 150 × 4.6 mm column (Waters Co., Milford, MA, USA), a Waters 600 pump, and a Waters 2998 diode array detector. One milliliter of reaction solution was mixed with 1 mL of OPD solution (0.5 mg/mL) and reacted at 25 °C for 12 h in the dark. The injection volume was 20 μL (sterilized through 0.45 μm filters), and the mobile phases were methanol and water and set as 5% v/v methanol, 0−5 min, then a linear gradient from 5% v/v methanol to 30% v/v methanol, 5−10 min, subsequently changed to 40% v/v methanol, 10−45 min, and, finally, 100% v/v methanol was used for elution from 45 to 65 min at a flow rate of l mL/min. Column temperature was set at 25 °C. Spectral data from all peaks were accumulated in the range of 200−600 nm, and chromatograms were recorded at 315 nm.

The regression equation for 2-methylquinoxaline standard was $a^* = 10^7 \times C_1$ (R^2 = 0.9999), where C_1 = 2-methylquinoxaline concentration (mmol/L) and a^* = peak area of 2-methylquinoxaline. The retention time of 2-methylquinoxaline was about 27.6 min, and the experimental range of MGO was 0.500−50.000 mg/L in this test.

Analyses of 4-MeI by HPCEC-APCI-MS. According to the literature[12] with slight modification, an Ansys SPEC SCX Disc 15 mg/3 mL cartridge (Varian, Walnut Creek, CA, USA) was conditioned with 1 mL of methanol and 1 mL of water. Then 3 mL of Maillard reaction mixtures acidified with 20 μL of HCl (0.1 mol/L) was loaded and passed through the cartridge. The retained 4-MeI was eluted with 6 mL of methanol/ammonia (5%, v/v). The collected extract was evaporated by vacuum concentration at 39 °C, and the residues were dissolved by 3 mL of deionized water for HPCEC-APCI-MS analyses.

HPCEC-APCI-MS was used for the determination and quantitation of 4-MeI. The samples were filtered through a Millex-HN nylon clarification kit of 0.45 μm pore size (Millipore, Bedford, MA, USA) and analyzed on a DX 5000 Dionex system (Dionex Corp., Sunnyvale, CA, USA) with a gradient pump (model EG40) with online degassing. Separation was accomplished on a CS12A cation exchange column (250 × 4 mm, Dionex) and a CS12A guard column (50 × 4 mm, Dionex) using the isocratic elution (10 mmol/L MSA) for 50 min. All tests used a constant flow rate of 0.7 mL/min. The injection volume was 25 μL.

Atmospheric pressure chemical ionization (APCI) (positive ionization mode) (ThermoFisher Co., San Jose, CA, USA) was coupled with the HPCEC system. The desalter was a 4 mm CSRS-300 (PN: 064556) with a constant current of 30 mA on the autosuppression external water mode (regenerant flow rate of approximately 3 mL/min). The spray current was set at 5 μA, capillary voltage was 0.50 kV, and capillary temperature and source temperature were both 300 °C. Nitrogen source was used as sheath and auxiliary gas. Argon was used as the collision gas, and the multiplier was set to 570 V. The m/z 83 parent ion was used to obtain the daughter ions m/z 56 and 42 at a collision energy of 23 eV. Selected ion monitoring (SIM) mode was used to monitor the m/z 83 ion.

The regression equation for 4-MeI standard was $y = 859.9x - 198$ (R^2 = 0.9999), where x is 4-MeI concentration (mg/L) and y is the peak area of 4-MeI. The retention time of 4-MeI was about 15 min, and the detection range was 0.003−0.2 mg/L in this test. The recovery of 4-MeI in reaction mixtures was about 96% (w/w).

Analyses of Pyrazines by Gas Chromatography−Mass Spectrometry (GC-MS). According to the literature,[13] a gas chromatograph HP 5890 series with a mass spectrometric detector 5972 from Hewlett-Packard (Palo Alto, CA, USA) was used to analyze the chemical composition of the brown solution dichloromethane extract. The column employed was an Agilent HP-5MS, 30 m × 0.25 mm (i.d.), film thickness = 0.25 μm. The injector temperature of the GC was 300 °C. The GC oven temperature was programmed as follows: (1) The initial temperature was 60 °C and kept for 2 min. (2) The temperature was then increased from 60 to 140 °C at a rate of 3 °C/min and kept for 1 min. Thereafter, the temperature was increased from 140 to 320 °C at a rate of 8 °C/min and kept for 1 min. (3) The injection volume was 1 μL. (4) The carrier gas was He at a flow rate of 1 mL/min. The MS conditions were as follows: electron impact mode, total ion current recorded. The mass spectra of the compounds were compared to the spectra from the NIST02 spectral library. The mass scan ranged from 50 to 650 Da.

Statistical Analysis. Means and standard deviations of the data were calculated for each treatment. Analysis of variance (ANOVA) was carried out to determine any significant differences ($p < 0.05$) among the applied treatments by the SPSS software package (SPSS 10.0 for windows).

RESULTS

Formation of 4-MeI in Class III Caramel Color. During class III caramel color manufacture, the formation of 4-MeI was influenced by the amino source. The chromatograms from HPCEC-APCI-MS of 4-MeI in model systems are shown in Figure 1. 4-MeI was detected in the glucose−NH_4^+ and glucosamine model systems, but nearly no 4-MeI was detected in the acetylglucosamine model system. Moreover, the level of 4-MeI in the glucose−NH_4^+ model system was higher than that in the glucosamine model system under different pH conditions (pH 5, 7, and 8, respectively.). In addition, the formation of 4-MeI was promoted in the alkaline solution. The detailed data are listed in Table 1.

Formation of 4-MeI in Class IV Caramel Color. Sulfite was an important adduct during the manufacture of class IV caramel color. The effect of sulfite (40 mmol/L) on 4-MeI formation was studied in glucose−NH_4^+, glucosamine or acetylglucosamine model systems, respectively. As shown in Figure 2, sulfite significantly promoted the formation of 4-MeI in the glucose−NH_4^+ model system (pH 7). However, sulfite

slightly promoted 4-MeI formation in the glucosamine or acetylglucosamine model system (Table 1).

Change of Brown Intensity. Browning intensity (A_{420}) is the easiest measurable consequence of the advanced stage of the Maillard reaction. A_{420} intensity is often used as an indication of the extent to which the Maillard reaction takes place in foods.[15] In this study, the amino source in model caramel systems showed a great influence on the change of A_{420} (Figure 3). The value of A_{420} in the acetylglucosamine model system was higher than that in the glucose−NH_4^+ and glucosamine model systems under pH 7 condition. In addition, the value of A_{420} decreased in all three model systems containing sulfite (40 mmol/L).

Formation of MGO in Caramel Model System. MGO was confirmed as the precursor of 4-MeI.[1] In the class III model caramel system, pH was a great factor of MGO formation. As shown in Figure 4, the content of MGO in the alkaline model reaction system (pH 8) was higher than that in the acid model reaction system (pH 5). In addition, the amino source also influenced MGO formation. For example, the level of MGO formed in the glucose−NH_4^+ model reaction system was significantly higher than that in glucosamine or acetylglucosamine model reaction system (Table 1). In the class IV model caramel system, sulfite was the important factor of MGO formation. However, the increased level of MGO was dependent on the amino source. As shown in Figure 5, the

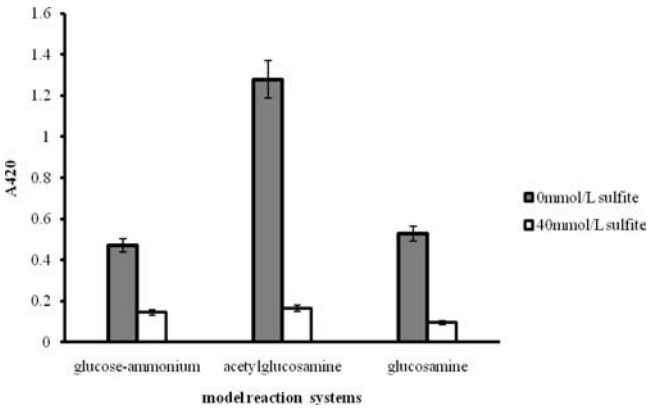

Figure 3. Changes of brown intensity (420 nm) obtained from caramel color model systems with or without sodium sulfite (40 mmol/L).

MGO content in the glucosamine or glucose−NH_4^+ model reaction system was significantly promoted by sulfite (40 mmol/L) under pH 7 condition. However, the MGO content was slightly increased by sulfite (40 mmol/L) in acetylglucosamine model reaction system.

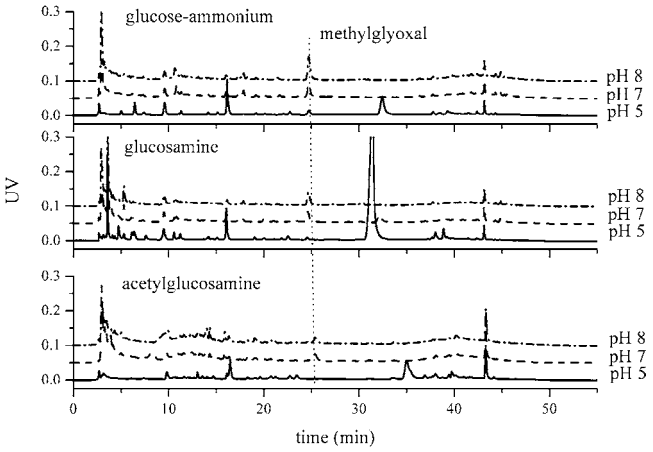

Figure 4. HPLC chromatograms of methylglyoxal obtained from caramel color model systems under various pH conditions (5, 7, 8).

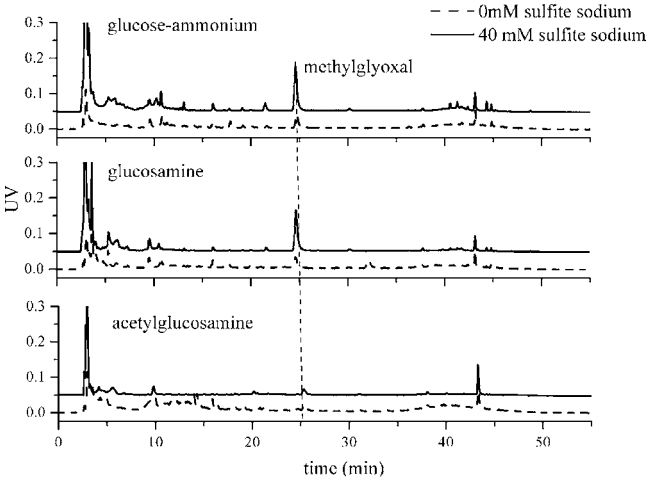

Figure 5. HPLC chromatograms of methylglyoxal obtained from caramel color model systems with (dash line) or without 40 mmol/L sodium sulfite (solid line).

Formation of Pyrazines. Table 2 lists the four types of pyrazines mainly detected in the study of the caramel model system solutions. When sulfite was not spiked into the caramel color model system, the majority of the pyrazines detected were 2-methylpyrazine (**3**), followed by 2,6-dimethylpyrazine (**2**), pyrazine (**4**), and 2-methyl-6-ethylpyrazine (**1**). Moreover, the contents of the four pyrazines in the glucose−NH_4^+ model reaction system were higher than that in the glucosamine or acetylglucosamine model reaction system. In addition, 2-methyl-6-ethylpyrazine (**1**) and 2,6-dimethylpyrazine (**2**) were not observed in the acetylglucosamine model reaction system.

By comparison, sulfite had a great influence on the formation of four pyrazines in the class IV caramel color model system. The formation of 2-methylpyrazine (**3**) and 2,6-dimethylpyrazine (**2**) was promoted by sulfite in glucosamine and glucose−NH_4^+ except for the acetylglucosamine model reaction system. Besides, the formation of pyrazine and 2-methyl-6-ethylpyrazine was significantly inhibited by sulfite in the caramel color model system. Similarly, the content of the four pyrazines in the glucose−NH_4^+ model reaction system was higher than that in the glucosamine or acetylglucosamine model reaction system when sulfite was added.

Table 2. Effect of Sulfite on the Formation of Pyrazines in Maillard Reaction

DISCUSSION

Using model reaction systems to investigate the formation of 4-MeI had been reported in some studies.[1,3,7,14] In this study, the effect of amino source including free ammonium, glucosamine, and acetylglucosamine on the formation of 4-MeI was detailed using a model reaction system. Obviously, the formation of 4-MeI was significantly promoted by free ammonium with respect to glucosamine and acetylglucosamine. Interesting, nearly no 4-MeI was formed in the acetylglucosamine model system. On the basis of the previous studies, the formation of 4-MeI was correlated to the amino aldehyde intermediates formed from methylglyoxal with ammonia, which could produce either 4-MeI by interacting with formaldehyde[15] or pyrazines via condensation reaction with dicarbonyls.[16] In this study, the result of 4-MeI formation was consistent with the result from MGO formation in the model reaction (Figure 4). Thus, the low level of 4-MeI formation in glucosamine analogue model systems was related to the low level of MGO formed from glucosamine analogue model systems with respect to the free ammonium−glucose model reaction system.

On the basis of the early research, MGO formation via the Maillard reaction or caramelization reaction was briefly defined as follows:

Maillard reaction route: glucose + ammonium → ARPs or HRPs →3-DG → MGO.[17]

Caramelization reaction route: glucose → 3-DG → MGO.[11,18]

First, the Maillard reaction route rather than the caramelization reaction route in glucosamine or acetylglucosamine (HRPs analogs) model system was mainly carried out to form a low level of MGO.[19,20] The explanation of this phenomenon was that ARPs or HRPs could mainly form dimerization products via intermolecular reaction[10] or further polymerize into melanoidins (confirmed by brown intensity from Figure 3); these formed products were hardly degraded into MGO. However, in the glucose−ammonium model system, the

DOI: 10.1021/acs.jafc.5b02616
J. Agric. Food Chem. 2015, 63, 8031−8036

caramelization reaction and Maillard reaction were simultaneously carried out, which induced a high level of MGO. Therefore, promotion of the polymerization reaction of HRPs or ARPs was important to induce a low level of MGO and subsequently inhibit 4-MeI formation. The main reason was that the low level of MGO formation inhibited the condensation reaction between dicarbonyls and ammonium, which induced the low level of 4-MeI formed in glucosamine analogue model systems with respect to the glucose−NH_4^+ model system. In addition, the effects of condensation reaction between dicarbonyls and ammonium on 4-MeI formation could be confirmed by the results of pyrazines.

Meanwhile, it was worthwhile to note that the formation of MGO and 4-MeI was affected by the pH value. Obviously, the formation of MGO and 4-MeI under alkaline condition was promoted with respect to the reaction under acid condition. However, the increased ratio of MGO and 4-MeI in the glucosamine analogue model reaction system was lower than that in the glucose−NH_4^+ model system. Therefore, the manufacture of caramel color with a low level of 4-MeI using glucosamine analogues as amino source was slightly affected by the value of pH. Especially, using acetyl to protect the amino group of glucosamine, the formation of MGO and 4-MeI was significantly inhibited. Some studies had indicated that the formation of MGO was degraded from 1- or 3- deoxyglucosone (DG) via enolization and retroaldolization reaction.[21,22] In theory, the acetyl-protected amino group of glucosamine would block the enamine product formation and subsequently inhibit the formation of 1- or 3-DG. Consequently, MGO formation was inhibited in the acetylglucosamine model system, which induced a low level of 4-MeI.

In the class IV caramel color model system, sulfite was usually added as ammonium sulfite, inducing the formation of negative melanoidins, which are mainly applied for coloring beverages.[23] In this study, sodium sulfite as sulfite additive significantly promoted the formation of MGO and 4-MeI in the class IV caramel reaction system but inhibited the melanoidin formation. In our previous study, the addition of sulfite significantly reduced the levels of osones (such as glucosone and pentosone) except for deoxyosones (3-deoxyglucosone and MGO). The effect of sulfite on dicarbonyl formation was comfirmed by H/D exchange experiments, which indicated that the promotion of aldo-eneol transition by sulfite accelerated the 3-C-elimination reaction of 1,2-enediol to form 3-DG, subsequently degraded into the increased MGO. Besides, the inhibition of oxidative dicarbonyl (glucosone, glyoxal, and so on) formation was attributed to the reductive sulfite inhibiting the oxidation of enediol products. Because sulfite inhibited a majority of oxidative dicarbonyl formation except for deoxyosones (3-deoxyglucosone and MGO), the total levels of dicarbonyls in the reaction systems were reduced, which induced the inhibition of brown products formation.

In this study, under pH 7 condition, the promotion effect of sulfite on 4-MeI formation was slight in the glucosamine analogue model system with respect to the glucose−NH_4^+ model system (Figure 2). Meanwhile, the formation of MGO (the precursor of 4-MeI) was slightly affected by sulfite in the acetylglucosamine model reaction system. In contrast, the content of MGO in the glucosamine model system was significantly increased by sulfite. Therefore, the protected amino group on glucosamine inhibited the promotion effect of sulfite on MGO formation.

In the caramel color model reaction system, pyrazines were recognized as the main flavor compounds from the Maillard reaction. Some literature has reported that pyrazines were formed from the condensation reaction between dicarbonyls and ammonium.[14] To some extent, the content of pyrazines in the model reaction marked the development of condensation reaction between dicarbonyls and free ammonium to form 2-aminopropanal analogues, which were the potential precursors of pyrazines or 4-MeI formation.[15] For example, MGO reacted with free ammonia to form 2-aminopropanal, which interacted with formaldehyde to form 4-MeI or reacted with ethylglyoxal to form 2-ethyl-6-methylpyrazine (**1**).[14] In this study, the levels of pyrazines in the glucose−NH_4^+ model system were significantly higher than that in the glucosamine analogue model reaction system. Because the levels of MGO and free ammonium in the glucose−NH_4^+ model system were higher than that in the glucosamine analogue model reaction system, the formation of 2-aminopropanal was promoted in the glucose−NH_4^+ model system with respect to the glucosamine analogue model reaction system. As a result, the formations of pyrazines and 4-MeI derived from 2-aminopropanal were promoted in the glucose−NH_4^+ model system. In contrast, the glucosamine analogues could mainly produce melanoidins via intra-intermolecular polymerization rather than degrade into dicarbonyls and free ammonium. The guessed result could be confirmed by the fact that the brown intensity in the glucosamine analogue model reaction systems was higher than that in the glucose−NH_4^+ model system.

In the class IV caramel color model reaction system, sulfite promoted 2-methylpyrazine (**3**) and 2,6-dimethylpyrazine (**2**) formation but inhibited pyrazine (**4**) and 2-methyl-6-ethylpyrazine (**1**) formation. In our previous studies, sulfite inhibited oxysone (including glyoxal and acetylglyoxal) formation but promoted MGO formation. Therefore, the formation of 2-methylpyrazine (**3**) and 2,6-dimethylpyrazine (**2**) was dependent on the formation of MGO, whereas the formation of pyrazine (**4**) and 2-methyl-6-ethylpyrazine (**1**) was dependent on the formation of oxysones. Similar results could be observed from the data reported by Seo et al.[14]

In summary, high levels of MGO and free ammonium in the caramel glucose−NH_4^+ model resulted in a high level of 4-MeI formation. In addition, the protected amino group on glucosamine analogues as caramel color amino source could reduce the levels of MGO and free ammonium; thus, the manufacture of caramel color with a low level of 4-MeI could be implemented on glucosamine analogues.

conditions. Furthermore, the produced changes in the Strecker aldehyde/amine ratio can be mostly understood on the basis of their formation pathway.

MATERIALS AND METHODS

Chemicals. Different hydroperoxides and lipid-derived reactive carbonyls from ω-3 and ω-6 fatty acids were employed in these studies. 13-Hydroperoxyoctadeca-9,11-dienoic acid (LOOH), methyl 13-hydroperoxyoctadeca-9,11-dienoate (LOOMe), and methyl 13-hydroperoxyoctadeca-9,11,15-trienoate (LnOOMe) were prepared by oxidation of the corresponding fatty acids with lipoxygenase and later esterification with diazomethane following a previously described procedure.[16,17] 2-Octenal (OC) and 2,4-alkadienals [2,4-heptadienal (HD) and 2,4-decadienal (DD)] were purchased from Aldrich (Milwaukee, WI). 4,5-Epoxy-2-alkenals [4,5-epoxy-2-heptenal (EH) and 4,5-epoxy-2-decenal (ED)] were prepared by epoxidation of 2,4-alkadienals (2,4-heptadienal and 2,4-decadienal, respectively) with 3-chloroperoxybenzoic acid.[18,19] 4-Oxo-2-alkenals [4-oxo-2-hexenal (OH) and 4-oxo-2-nonenal (ON)] were synthesized from 2-alkylfurans (2-ethylfuran and 2-pentylfuran, respectively) with *N*-bromosuccinimide.[20,21] 4-Hydroxy-2-nonenal was prepared according to the procedure of Gardner et al.[22] All other chemicals were purchased from Sigma-Aldrich (St. Louis, MO), Fluka (Buchs, Switzerland), or Merck (Darmstadt, Germany) and were analytical-grade.

Phenylalanine/Oxidized Lipid Reaction Mixtures. Model reactions were carried out according to the procedure of Zamora and Hidalgo,[23] which was modified. Briefly, mixtures of phenylalanine and the lipid derivative (10 μmol of each) were singly homogenized with 50−70-mesh sand (600 mg) (Aldrich), 30 μL of 0.3 M buffer, and 80 μL of water. Samples were heated under a controlled atmosphere in closed test tubes at the indicated times and temperatures, usually 1 h at 140 °C. After cooling (5 min at room temperature and 15 min at −30 °C), 20 μL of internal standard (24.09 mg of ethylpyridine in 50 mL of methanol) and 1 mL of methanol/water (80:20) were added. The mixture was stirred for 1 min and centrifuged for 10 min at 2000*g*. A total of 700 μL of the obtained supernatant were transferred to a new test tube and reduced with 1 mg of sodium borohydride for 30 min. After this time, 500 μL of acetone was added and the test tube was stirred and centrifuged for 10 min at 2000*g*. The produced compounds were determined by gas chromatography−mass spectrometry (GC−MS). The ions monitored for the quantitation of the different analytes were $[C_7H_8N]^+$ = 106 for the internal standard, $[C_7H_7]^+$ = 91 for 2-phenylethylamine, $[C_8H_{10}O]^+$ = 122 for phenylacetaldehyde (determined as 2-phenylethanol), and $[C_7H_8O]^+$ = 108 for benzaldehyde (determined as benzyl alcohol).

GC−MS Analyses. GC−MS analyses were conducted with a Hewlett-Packard 6890 GC Plus coupled with an Agilent 5973 mass selective detector (MSD, quadrupole type). A fused-silica CAM capillary column (30 m × 0.25 mm inner diameter, with a coating thickness of 0.25 μm) was used, and 1 μL of sample was injected in the pulsed splitless mode. Working conditions were as follows: carrier gas, helium (1 mL/min at constant flow); injector, 250 °C; oven temperature program, from 80 °C (4 min) to 120 °C at 2 °C/min and then to 220 °C at 15 °C/min; transfer line to MSD, 280 °C; electron ionization (EI), 70 eV; ion source temperature, 230 °C; and mass range, 28−550 amu.

Determination of 2-Phenylethylamine, Phenylacetaldehyde, and Benzaldehyde Contents. Quantitation of 2-phenylethylamine, phenylacetaldehyde (as 2-phenylethanol), and benzaldehyde (as benzyl alcohol) was carried out by preparing standard curves of these compounds in the 600 mg of sand containing 80 μL of water and 30 μL of sodium phosphate buffer at pH 6 and following the whole procedure described above (without heating). A total of 10 different concentration levels of the determined compounds were used (0, 0.25, 0.5, 1, 2, 3, 4, 5, 7.5, and 10 μmol). 2-Phenylethylamine, phenylacetaldehyde, and benzaldehyde contents were directly proportional to the analyte/internal standard area ratio (r = 0.998; p < 0.0001). The coefficients of variation were less than 8%.

Statistical Analysis. All data given are mean ± standard deviation (SD) values of, at least, three independent experiments. Statistical comparisons among different groups were made using analysis of variance. When significant F values were obtained, group differences were evaluated by the Tukey test.[24] Statistical comparisons were carried out using Origin, version 7.0 (OriginLab Corporation, Northampton, MA). The significance level is p < 0.05, unless otherwise indicated.

RESULTS AND DISCUSSION

Formation of 2-Phenylethylamine, Phenylacetaldehyde, and Benzaldehyde in Phenylalanine/Lipid Oxidation Product Reaction Mixtures. When mixtures of phenylalanine and lipid oxidation products were heated together, the formation of 2-phenylethylamine, phenylacetaldehyde, and benzaldehyde was observed. The amount of the formed compounds depended upon the reaction conditions and the lipid oxidation product involved. Table 1 shows the formation of these three compounds in the presence of different lipid oxidation products at two pH values (3 and 6) and in the presence of either nitrogen or air.

[a]Values are mean ± SD values (in nmol/μmol of phenylalanine) of, at least, three independent experiments. Means with the same letters (a−g) in the same column are not significantly different ($p < 0.05$). Abbreviations: DD, 2,4-decadienal; ED, 4,5-epoxy-2-decenal; EH, 4,5-epoxy-2-heptenal; HD, 2,4-heptadienal; HN, 4-hydroxy-2-nonenal; LnOOMe, methyl 13-hydroperoxyoctadeca-9,11,15-trienoate; LOOH, 13-hydroperoxyoctadeca-9,11-dienoic acid; LOOMe, methyl 13-hydroperoxyoctadeca-9,11-dienoate; OC, 2-octenal; OH, 4-oxo-2-hexenal; ON, 4-oxo-2-nonenal; and Phe, phenylalanine.

As observed, phenylalanine was converted into 2-phenylethylamine with a reaction yield of 0−3%, which depended upon the lipid involved, the pH of the reaction, and the presence or not of oxygen. The highest yields were observed when the reaction was carried out in the presence of alkadienals. These compounds produced about 3% of amine when the reaction was carried out under nitrogen, and this yield was reduced to 1% or less when the reaction was carried out under air. Other good producers of 2-phenylethylamine were the assayed hydroperoxides. These compounds produced amine with a yield of 1.4−2.6% at pH 3, and this yield was independent of the presence or not of oxygen. The yield decreased to about 1% at pH 6 in the presence of nitrogen and to about 0.2−0.8% in the presence of air at this pH. Other assayed lipids were worse producers of amine, and the obtained yields were usually lower than 1%, with the exception of 2-octenal (1.5% at pH 3 under air and 2.4% at pH 6 under nitrogen) and 4,5-epoxy-2-decenal (1.2% at pH 3 under air and 1.3% at pH 6 under nitrogen).

Different from 2-phenylethylamine, phenylacetaldehyde was produced to a higher extent under air than under nitrogen. At pH 3, under air, many lipids produced more than 10% phenylacetaldehyde, including hydroperoxides (11−16%), alkadienals (8−13%), and epoxyalkenals (10−12%) but not oxoalkenals (4−7%) or 4-hydroxynonenal (1%). These yields decreased to less than 4% when the reaction was carried out under nitrogen. Phenylacetaldehyde was produced with a reaction yield of 2−5% at pH 6 under air, and this yield decreased to <2.5% when the reaction was carried out under nitrogen at this pH.

A behavior similar to that of phenylacetaldehyde was also observed for benzaldehyde, which is in agreement with the production of benzaldehyde from phenylacetaldehyde as its main formation pathway.[15] Nevertheless, benzaldehyde was produced to a lower extent than phenylacetaldehyde, and there were not too many differences among the different lipid oxidation products. Thus, benzaldehyde was produced with a yield of 1−7% at pH 3 under air, and this yield decreased to 0.5−0.8% when the reaction was carried out under nitrogen at this pH. Analogously, benzaldehyde was produced with a yield of 1−4% at pH 6 under air, and this yield decreased to 0−0.3% when the reaction was carried out under nitrogen at this pH.

All these changes and mainly the changes in the produced 2-phenylethylamine/phenylacetaldehyde ratios can be understood on the basis of the reaction pathway schematized in Figure 1. The obtained results showed that alkenals, alkadienals, hydroxyalkenals, and linoleic acid hydroperoxide but not hydroperoxide methyl esters were the compounds that produced the highest 2-phenylethylamine/phenylacetaldehyde ratios at both pH 3 and 6 under nitrogen. However, there was not a clear difference among the different lipid oxidation products when the reaction was carried out under air. This behavior is likely related to the role of the chain in the charge distribution of azomethine ylide shown in Figure 1. Thus, under nitrogen, the presence of electron-withdrawing groups in the chain, such as oxoalkenals or epoxyalkenals, favored a charge distribution closer to mesomer *b* and, therefore, the formation of aldehyde. On the contrary, the presence of electron-donating groups in the chain, such as alkoxyl or carbon−carbon double bonds, favored a charge distribution closer to mesomer *a* and, therefore, the formation of amine. In the presence of oxygen, double bonds are expected to be oxidized and converted into electron-withdrawing groups. Therefore, under air, there was not so

DOI: 10.1021/acs.jafc.5b02619
J. Agric. Food Chem. 2015, 63, 8037−8043

clear of a difference among the different assayed carbonyl compounds.

To carry out a detailed study of the effect of reaction conditions on the formation of these amino acid degradation products, 2,4-decadienal was selected as the lipid oxidation product because it is a good producer of both 2-phenylethylamine and phenylacetaldehyde and the mechanism by which these two compounds are produced has been previously studied.[9,25]

Effect of the Percentage of Oxygen in the Atmosphere on the Formation of 2-Phenylethylamine, Phenylacetaldehyde, and Benzaldehyde in Phenylalanine/2,4-Decadienal Reaction Mixtures. As expected according to the data shown in Table 1, 2-phenylethylamine on one hand and phenylacetaldehyde and benzaldehyde on the other exhibited oppositing effects in relation to the presence of oxygen at both pH 3 and 6 (Figures S1A and S1B, respectively, of the Supporting Information). 2-Phenylethylamine formation was very sensitive to the presence of oxygen, and, at pH 6, >20% of oxygen completely inhibited its formation. At pH 3, although oxygen inhibited its formation, small amounts of 2-phenylethylamine were also produced in a 100% atmosphere of oxygen. On the contrary, the amount of both phenylacetaldehyde and benzaldehyde usually increased as a function of the oxygen content in the atmosphere. Thus, at pH 3, the amount of both phenylacetaldehyde and benzaldehyde increased rapidly from 0 to 20% oxygen, then the amount of phenylacetaldehyde remained more or less stable, but the amount of benzaldehyde continued to increase but to a lower extent. Something similar occurred at pH 6. The concentration of both phenylacetaldehyde and benzaldehyde increased rapidly from 0 to 20% oxygen and then increased to a lower extent at a higher oxygen content. Therefore, the presence of oxygen rapidly shifted the 2-phenylethylamine/phenylacetaldehyde ratio toward the formation of aldehyde (Figure 2A).

As discussed above, in the presence of oxygen, double bonds should be oxidized and converted into electron-withdrawing groups, consequently favoring a charge distribution closer to mesomer *b* and, then, the formation of aldehyde. This effect was so important that the amount of phenylacetaldehyde increased by 4−5 times in relation to the amount of this compound produced in the absence of air (Table 1). This effect was also observed in the formation of benzaldehyde, although this compound was more dependent upon oxygen and increased about 5−6 times in relation to the amount of this compound produced in the absence of air at pH 3 and about 9−10 times in relation to the amount of this compound produced in the absence of air at pH 6. This higher dependence of benzaldehyde in the presence of air suggests an oxidative formation pathway for this last compound.

Effect of Reaction pH on the Formation of 2-Phenylethylamine, Phenylacetaldehyde, and Benzaldehyde in Phenylalanine/2,4-Decadienal Reaction Mixtures. 2-Phenylethylamine formation did not exhibit big changes as a function of reaction pH (Figure S2A of the Supporting Information), although it seemed to increase linearly (r = 0.85; p = 0.0017) as a function of pH from 2.3% at pH 2.15 to 2.8% at pH 9. On the contrary, the phenylacetaldehyde concentration decreased linearly (r −0.998; p < 0.0001) between pH 2.15 and 6.5 (from 1.6 to 0.4%) and remained unchanged afterward. The benzaldehyde concentration also decreased linearly (r = −0.79; p = 0.0066) as a function of pH from 0.28% at pH 2.15 to 0.06% at pH 9. When the 2-phenylethylamine/phenylacetaldehyde ratio

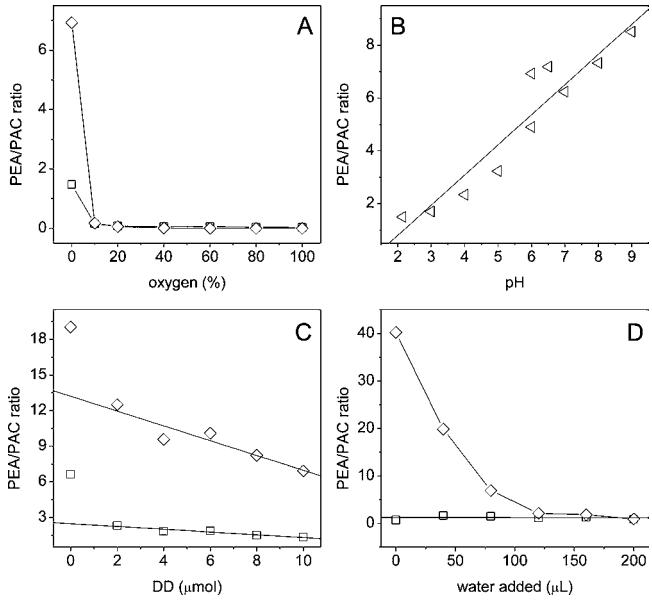

Figure 2. Effect of the (A) oxygen content in the reaction atmosphere, (B) pH, (C) aldehyde concentration, and (D) water on the 2-phenylethylamine/phenylacetaldehyde (PEA/PAC) ratio produced by phenylalanine degradation in the presence of 2,4-decadienal in sodium citrate buffer at pH 3 (□) and sodium phosphate buffer at pH 6 (◇). Samples were heated for 1 h at 140 °C.

was considered (Figure 2B), this ratio increased linearly (r = 0.94; p < 0.0001) as a function of reaction pH along the whole pH range studied (from pH 2.15 to 9). This behavior might be a consequence of either a preference of the electronic distribution of mesomer *a* in Figure 1 at higher pH values or an inhibition of the conversion of amine into aldehyde, which is known to occur a pH ≥ 6.[14]

Effect of the Lipid Concentration on the Formation of 2-Phenylethylamine, Phenylacetaldehyde, and Benzaldehyde in Phenylalanine/2,4-Decadienal Reaction Mixtures. The formation of 2-phenylethylamine, phenylacetaldehyde, and benzaldehyde depended upon the concentration of 2,4-decadienal. At pH 3 (Figure S3A of the Supporting Information), a small concentration of alkadienal (2 μmol) produced a big increase in the concentration of 2-phenylethylamine, which also continued to increase but to a lower extent when higher concentrations of alkadienal were present. On the contrary, phenylacetaldehyde and benzaldehyde produced increased linearly (r > 0.98; p < 0.0004) as a function of the amount of 2,4-decadienal added between 0 and 10 μmol. Something similar occurred at pH 6 (Figure S3B of the Supporting Information). The 2-phenylethylamine concentration increased rapidly from 0 to 4 μmol of 2,4-decadienal and later remained unchanged. On the contrary, phenylacetaldehyde and benzaldehyde concentrations increased linearly (r > 0.94; p < 0.006) as a function of the amount of 2,4-decadienal added between 0 and 10 μmol. An explanation for this different behavior of amine and aldehydes as a function of the concentration of the carbonyl compound can be explained on the basis of the pathway shown in Figure 1. The formation of the amine is accompanied by the recovery of initial reactive carbonyl. Therefore, small amounts of reactive carbonyl will produce amine, and reactive carbonyl will be recovered for producing more amine (the process is catalytic in nature). On the other hand, the formation of Strecker aldehyde and benzaldehyde is

DOI: 10.1021/acs.jafc.5b02619
J. Agric. Food Chem. 2015, 63, 8037−8043

accompanied by the destruction of reactive carbonyl. Therefore, higher amounts of reactive carbonyls will increase the formation of Strecker aldehyde.

Considering the 2-phenylethylamine/phenylacetaldehyde ratio (Figure 2C), an increase in the amount of the carbonyl compound reduced this ratio linearly ($r < -0.94$; $p < 0.015$) at the two pH values studied. This is likely a consequence of both the catalytic nature of the formation of amine from reactive carbonyls described above and the conversion of amine into aldehyde shown in Figure 1, a conversion favored at higher concentrations of lipid-derived carbonyl.[14]

Effect of the Amount of Water Added on the Formation of 2-Phenylethylamine, Phenylacetaldehyde, and Benzaldehyde in Phenylalanine/2,4-Decadienal Reaction Mixtures. The effect of water added was different at pH 3 and 6. At pH 3 (Figure S4A of the Supporting Information), both 2-phenylethylamine and phenylacetaldehyde were produced to a higher extent when 70−80 μL of water was added. An increase in the amount of water decreased the amount of both compounds, and 2-phenylethylamine formation seemed to be more sensitive to the presence of large amounts of water than phenylacetaldehyde. Benzaldehyde formation also decreased when the amount of water increased, and there was not a maximum like the maximum observed for 2-phenylethylamine or phenylacetaldehyde. At pH 6 (Figure S4B of the Supporting Information), 2-phenylethylamine was produced to a higher extent with 0−50 μL of water and decreased afterward. On the contrary, the amount of phenylacetaldehyde produced increased with the addition of water from 0 to 120 μL and remained stable afterward. Finally, the amount of benzaldehyde seemed to increase slightly when the amount of water increased.

Therefore and different from the other analyzed factors, the amount of water added did not always have the same consequences on the 2-phenylethylamine/phenylacetaldehyde ratio (Figure 2D). Thus, this ratio remained more or less unchanged at pH 3 but decreased exponentially at pH 6, a behavior that cannot seem to be easily understood only on the basis of the reaction pathway shown in Figure 1.

Effect of the Reaction Time and Temperature on the Formation of 2-Phenylethylamine and Phenylacetaldehyde in Phenylalanine/2,4-Decadienal Reaction Mixtures. The amount of 2-phenylethylamine formed increased linearly ($r > 0.98$; $p < 0.01$) as a function of time at the different assayed temperatures when phenylalanine was heated in the presence of 2,4-decadienal at both pH 3 (Figure S5A of the Supporting Information) and pH 6 (Figure S6A of the Supporting Information). Reaction rates at the different assayed temperatures were calculated using the following equation:

$$[\text{2-phenylethylamine}] = [\text{2-phenylethylamine}]_0 + kt$$

where $[\text{2-phenylethylamine}]_0$ represents the intercept, k is the rate constant, and t is the time. These rate constants were used in an Arrhenius plot for calculation of the activation energy (E_a) of 2-phenylethylamine formation from phenylalanine in the presence of 2,4-decadienal at pH 3 (Figure 3A) and pH 6 (Figure 3B). The values obtained for E_a were 51 kJ/mol at pH 3 and 65 kJ/mol at pH 6.

Analogously, the amount of phenylacetaldehyde formed also increased linearly ($r > 0.98$; $p < 0.01$) as a function of the time at the different assayed temperatures when phenylalanine was heated in the presence of 2,4-decadienal at both pH 3 (Figure S5B of the Supporting Information) and pH 6 (Figure S6B of the Supporting Information). Reaction rates at the different assayed temperatures were also calculated using

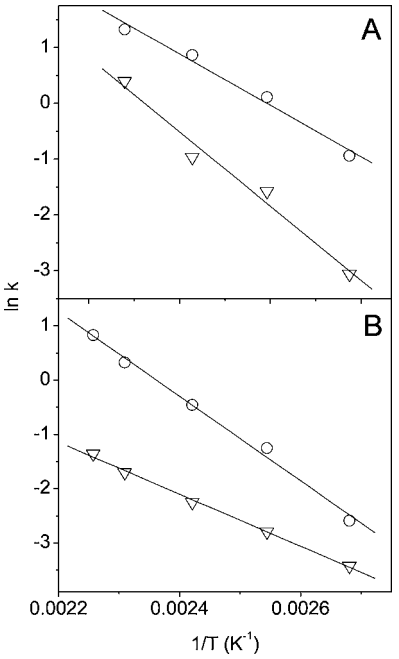

Figure 3. Arrhenius plot for 2-phenylethylamine (○) and phenylacetaldehyde (▽) formation by phenylalanine (Phe) degradation in the presence of 2,4-decadienal. Equimolecular mixtures of both compounds (10 μmol of each) were heated under nitrogen for 1 h in (A) sodium citrate buffer at pH 3 and (B) sodium phosphate buffer at pH 6.

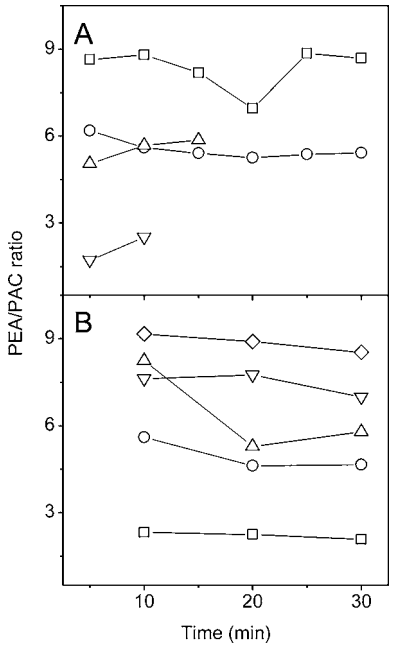

Figure 4. Effect of the time and temperature on the 2-phenylethylamine/phenylacetaldehyde (PEA/PAC) ratio produced by phenylalanine degradation in the presence of 2,4-decadienal in (A) sodium citrate buffer at pH 3 and (B) sodium phosphate buffer at pH 6. Equimolecular mixtures of both compounds (10 μmol of each) were heated under nitrogen at the indicated times and temperatures. The temperatures assayed were 100 °C (□), 120 °C (○), 140 °C (△), 160 °C (▽), and 170 °C (◇).

DOI: 10.1021/acs.jafc.5b02619
J. Agric. Food Chem. 2015, 63, 8037−8043

an equation similar to that described above for 2-phenylethylamine. The obtained rate constants were used in an Arrhenius plot for calculation of E_a of phenylacetaldehyde formation from phenylalanine in the presence of 2,4-decadienal at pH 3 (Figure 3A) and pH 6 (Figure 3B). The values obtained for E_a were 74 kJ/mol at pH 3 and 40 kJ/mol at pH 6.

Different from 2-phenylethylamine and phenylacetaldehyde, benzaldehyde was produced to a very low extent under the assayed conditions and it was not possible to determine its formation E_a.

2-Phenylethylamine/phenylacetaldehyde ratios were more or less constant at each temperature but decreased with the temperature at pH 3 (Figure 4A) and increased with the temperature at pH 6 (Figure 4B), which might be related to the easiness of conversion of amine into aldehyde at the different pH values and temperatures.

All of these data as well as all other data obtained in this study suggest that the 2-phenylethylamine/phenylacetaldehyde ratio can be modified as a function of reaction conditions. Thus, it can be increased using electron-donating groups in the chain of the carbonyl compound, small amounts of carbonyl compound, low oxygen content, increasing the pH, or increasing temperature at pH 6. Contrary conditions (use of electron-withdrawing groups in the chain of the carbonyl compound, large amounts of carbonyl compound, high oxygen contents, low pH values, and increasing temperatures at low pH values) would decrease the 2-phenylethylamine/phenylacetaldehyde ratio and the formation of aldehydes over amines in amino acid degradations would be favored.

important for understanding the gastrointestinal fate of inorganic nanoparticles that may be ingested.

MATERIALS AND METHODS

Materials. The following products were purchased from Sigma-Aldrich Chemicals (St. Louis, MO, USA): 4% osmium tetroxide (OsO_4), phosphotungstic acid (PTA), nitric acid, and hydrochloric acid. AuNPs with different diameters (15, 50, and 100 nm) were purchased from Nanopartz (Loveland, CO, USA). A mitochondrial membrane potential probe (JC-1 dye) was purchased from Life Technologies (Thermo Fisher Scientific, Agawam, MA, USA). Hank's balanced salt solution (HBSS), glutaraldehyde, cacodylate, Formvar/carbon Cu grids 200 mesh, and epoxy resin were purchased from EM Sciences (Hatfield, PA, USA).

Cell Culture. Caco-2 cells (passage 55−65) were cultured in complete Dulbecco's modified essential medium (DMEM) containing high glucose, 10% fetal bovine serum (FBS), 1% antibiotic, and 1% amino acids as we described previously.[19] Cells were seeded at 3×10^5 cells/mL on transwells (Corning Inc., Tewksbury, MA, USA) containing polyester filters (3 mm pore size and 4.7 cm^2 surface area) and grown for 21 days. The transepithelial electrical resistance (TEER) was monitored using a Millicell ERS-2 epithelial voltammeter (World Precision Instruments, Sarasota, FL, USA). The TEER data are presented as resistance per unit surface area, $\Omega \times cm^2$.

Transmission Electron Microscopy (TEM) Analysis. To visualize the AuNPs, a drop of liquid sample was allowed to air-dry onto a carbon-coated 200 mesh copper grid, and then the sample was stained with 2% PTA. Samples were visualized with a transmission electron microscope (Tecani 12 TEM, FEI Co., Hillsboro, OR, USA). To visualize the uptake of AuNPs in intestinal epithelial cells, suspensions of AuNPs (5 μg/mL; 15, 50, or 100 nm) were applied on Caco-2 cell monolayers. After treatment for 0.5, 1, 2, 4, 8, and 24 h, the media in both the apical and basolateral sides were removed and the monolayers were rinsed with HBSS that had been warmed to 37 °C. The monolayers were immediately fixed in 2.5% glutaraldehyde and 2% paraformaldehyde (0.1 M sodium cacodylate buffer, pH 7.4) for 2 h at 37 °C. They were then postfixed in 1% aqueous osmium tetroxide solution and then embedded in epoxy resin. Thin sections were obtained using an ultramicrotome with a diamond knife (DDK, Wilmington, DE, USA). The sections were stained with uranyl acetate followed by lead citrate. The image samples were then viewed with the transmission electron microscope (Tecani 12, FEI Co.).

ICP-MS Analysis. After treatment with AuNPs, the cell monolayers and medium samples were collected at the specific time period from the apical and basolateral sides of the transwell as described above. A bicinchoninic acid (BCA) kit was used to quantify the protein concentration of the monolayers in each well. Each sample was mixed with 0.5 mL of aqua regia and then the sample was diluted to 10 mL with deionized water. A series of standard solutions of Au were prepared under the same conditions. Inductively coupled plasma (ICP) mass spectrometry (MS) measurements were performed on a mass spectrometer (NexION 300X ICP, PerkinElmer, Cambridge, MA, USA).

Calculation of the Number of Gold Nanoparticles. The number of gold nanoparticles in a given sample was calculated from the Au concentration measured by ICP-MS. The number of gold atoms per gold nanoparticle (n) can be estimated from the expression[20]

$$n = \frac{D^3}{d^3}$$

where D is the diameter of a gold nanoparticle and d is the diameter of a single gold atom, which is approximately 0.28 nm.[21] Hence, the number of AuNPs can be calculated from the measured Au concentration as

$$C_n = \frac{C_m}{N_A \times n}$$

where C_n is the number of AuNPs per unit volume, C_m is the measured mass of Au per unit volume, and N_A is Avogadro's constant.

Determination of Mitochondrial Membrane Potential. Aqueous suspensions of AuNPs (5 μg/mL; 15, 50, or 100 nm) were applied onto a well-differentiated Caco-2 monolayer (TEER > 200 Ω). Four hours after the treatment, the apical and basolateral media were removed and the monolayers were rinsed three times with warmed HBSS. A medium containing 10 μg/mL of JC-1 (mitochondrial membrane potential probe) in warmed DMEM solution was added to the Caco-2 cell monolayers. After the incubation for 15 min (37 °C, 5% carbon dioxide, and 100% humidity), the monolayers were washed twice with HBSS and placed onto a microscope slide. After adding a fluorescent dye (DAPI) to the samples, the slides were rapidly sealed and stored overnight at 4 °C. The microstructure of the samples was observed using a confocal fluorescent microscope (Olympus FV-1000, Waltham, MA, USA). The JC-1 treated coverslips were excited at 488 nm, and the emission was recorded simultaneously at 527 and 590 nm by independent detectors.[22] Two-photon excitation of JC-1-labeled Caco-2 cell monolayers allowed for the real-time analysis of mitochondria membrane potential. The data were analyzed using the following expression as described previously:[23]

$$\text{ratio} = 5 \times I_{red}/I_{green}$$

Here I_{red} and I_{green} are the intensities of the signals in the red and green regions of the spectra. The factor "5" is used to transform the ratiometric results into an 8-bit scale of 256 levels.

Statistical Analysis. All values are expressed as means ± standard deviations (SD) unless stated otherwise. The differences among samples were analyzed by ANOVA with a significance level of $p < 0.05$.

RESULTS AND DISCUSSION

Properties of Gold Nanoparticles. The AuNPs used in this study have been reported to be monodispersed spheres in an aqueous sodium citrate buffer that acted as a stabilizer to prevent particle aggregation.[24] The manufacturer reported that the droplet diameters of the three AuNPs samples used were 15, 50, and 100 nm, respectively, and that all of the particles had a negative charge (around −40 mV). The initial gold concentration was given as 50 ppm for all of the AuNPs suspensions when they were adjusted to an optical density of 1 cm^{-1}. The morphology of the AuNPs was confirmed using TEM (Figure 1). All of the samples contained fairly uniform spheres with dimensions that conformed to those stated by the manufacturer. Nevertheless, the TEM images suggested that some of the particles clustered together and formed aggregates. These aggregates may have been present within the initial samples, or they may have been introduced as a result of the method used to prepare the samples for TEM analysis. Previous studies have shown that inorganic nanoparticles (1−100 nm) might affect normal cellular functions, including inducing cell death, in a manner that depended on their particle size.[25,26] We therefore hypothesized that the initial size of the AuNPs used in this study can influence their absorption, accumulation, and cytotoxicity in the intestinal epithelial cells.

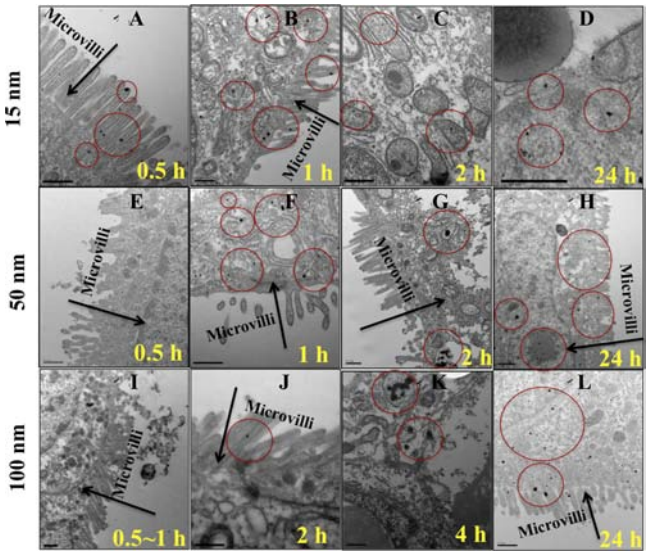

Figure 2. Absorption of AuNPs by intestinal epithelial cells. Caco-2 cell monolayers were incubated with AuNPs (15, 50, or 100 nm) for various time periods (up to 24 h). After a thorough wash, Caco-2 cell monolayers were processed for TEM analysis to visualize AuNPs absorbed by the cells. AuNPs are highlighted by circles. Arrows indicate the direction from apical to basolateral side across microvilli. Different magnifications were used in different images. The scale bar represents 500 nm. Representative images were selected from replicates of at least three.

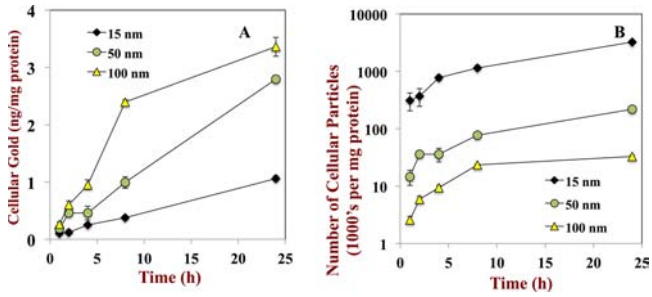

Figure 4. Accumulation of AuNPs within the intestinal epithelium: change in the amount of gold measured in the Caco-2 monolayers after incubation of Caco-2 cell monolayers with 5 μg/mL of AuNPs in the apical compartment of the transwells. The amount of gold was expressed as either particle mass (A) or particle number (B) in the Caco-2 cell monolayer.

Migration of Gold Nanoparticles within Intestinal Epithelium. It is well-known that particle characteristics (such as size, shape, and surface chemistry) play an important role in determining the interactions of inorganic nanoparticles with biological membranes.[27] In this study we focused on the role of particle size on cellular uptake by using AuNPs with the same shape (spherical) and surface chemistry (bare gold), but different diameters (15, 50, and 100 nm).

Caco-2 cells were cultured in the transwells to form well-differentiated and polarized monolayers. The monolayers were used to mimic absorptive functions of intestinal epithelium. Aqueous suspensions of AuNPs (15, 50, or 100 nm) were then placed on the apical side of the polarized monolayers for different incubation periods. The migration of AuNPs across the model intestinal cells was visualized by TEM. The results are shown in Figure 2 (the most apparent AuNPs are highlighted by circles, and arrows indicate the direction from apical to basolateral side across microvilli). It is clear that the migration of AuNPs across the intestinal epithelial cells showed a distinct size-dependent pattern: the smaller the particle size, the faster the migration (Figure 2). At 0.5 h, 15 nm AuNPs

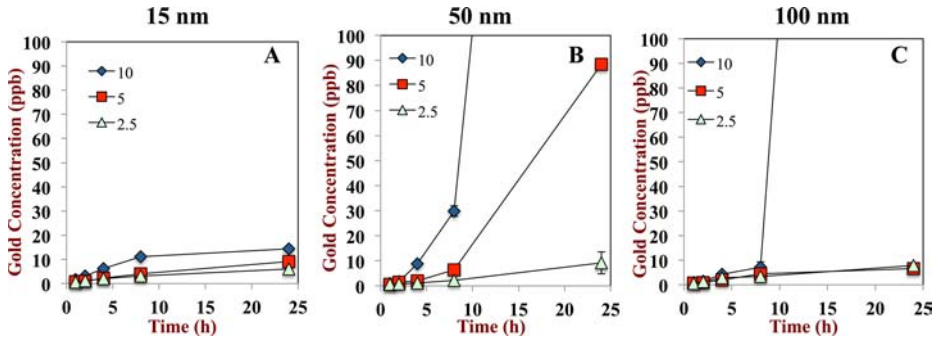

Figure 3. Transport of AuNPs across the intestinal epithelium: change in the concentration of gold measured in the basolateral compartment after incubation of Caco-2 cell monolayers with AuNPs in the apical compartment of the transwells. Suspensions containing different concentrations of gold nanoparticles were used (shown in the figure): 2.5, 5, and 10 μg/mL in the apical medium.

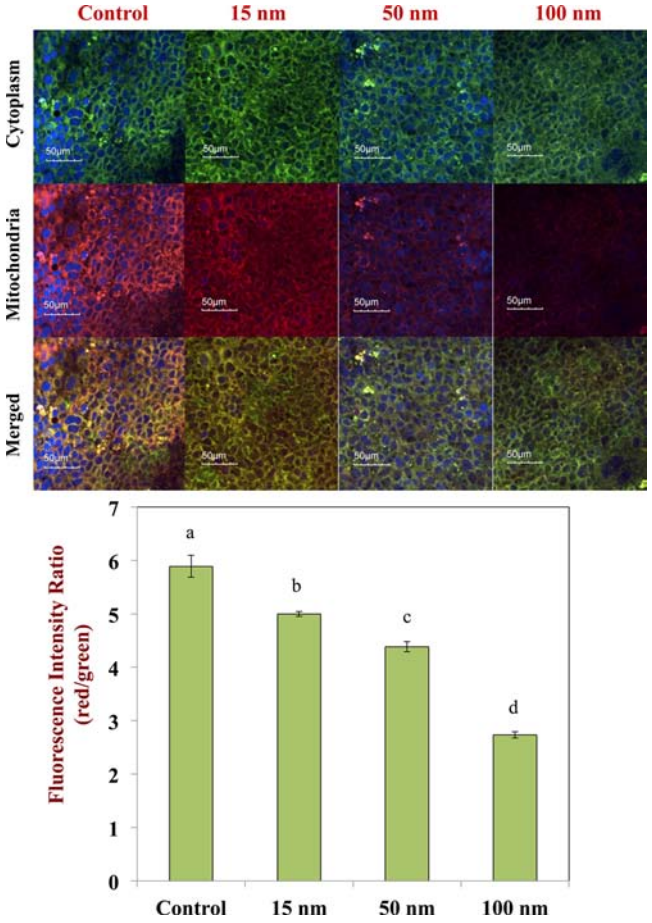

Figure 5. Effects of AuNPs on the mitochondrial membrane potentials of intestinal epithelial cells. Caco-2 cell monolayers were incubated with AuNPs (15, 50, or 100 nm) for 4 h separately. Mitochondria toxicity of AuNPs was visualized by confocal microscope using the red fluorescent dye JC-1 (A). JC-1 exhibits potential-dependent accumulation in mitochondria, indicated by a fluorescence emission shift from green to red. Cells with high mitochondria membrane potential (healthy) promote the formation of dye aggregates that fluoresce red, whereas cells with low mitochondria membrane potential (damaged) remain monomeric JC-1 that fluoresce green. The red/green ratio was quantified using image J (B). Representative images were selected from replicates of three. Different letters indicate statistical difference among the three groups at the given time point ($P < 0.05$).

have already been observed within the microvilli (Figure 2A), whereas no 50 or 100 nm AuNPs were found anywhere in the cells (Figure 2E,II). After 1 h of incubation, an appreciable number of 15 and 50 nm AuNPs could be observed in the cytoplasm (Figure 2B,F). In contrast, only a few 100 nm AuNPs had entered the microvilli after 2 h of incubation (Figure 2J). At 1−2 h, the 15 and 50 nm AuNPs have migrated into various cellular organelles, such as the mitochondria and lysosome (Figure 2B,C,G). In contrast, not until 4 h of incubation were 100 nm AuNPs found in the mitochondria and lysosome (Figure 2K). Some of AuNPs appeared as aggregates in lysosomes (Figure 2G,K), After 24 h of incubation, all AuNPs (15, 50, and 100 nm) were found throughout the entire cell monolayer (Figure 2D,H,L). It is noteworthy that some of the nanoparticles were observed in the cell nuclei (Figure 2H,L), which suggested that AuNPs may have the potential to induce genotoxicity. In general, the smallest gold nanoparticles (15 nm) were internalized at a faster rate than the large ones (50 or 100 nm).

Transport of Gold Nanoparticles across the Intestinal Epithelium. Microscopic analysis is useful for obtaining direct visualization of the migration and location of AuNPs in epithelial cells, but it is less useful for providing quantitative information about the amount of AuNPs that has been transported across the intestinal epithelial monolayer and that has been accumulated inside the epithelial cells. For this reason, quantitative analysis of the gold concentration was carried out using a highly sensitive ICP-MS method.[13] This method utilized acid digestion to dissolve the gold nanoparticles, and then the gold concentration was determined by mass spectrometry.

We established the influence of initial particle size of AuNPs on the transport of the AuNPs across the epithelial monolayers into the basolateral compartment of the transwells. After incubation of the Caco-2 monolayers with AuNPs in the apical compartment of the transwells, a fixed volume of medium was collected from the basolateral compartment of the transwells at different times and then the amount of gold was quantified by ICP-MS (Figure 3). The concentrations of gold in the basolateral compartment increased with increasing incubation time for all three types of AuNPs studied. For 15 and 50 nm nanoparticles (Figure 3A,B), the higher the initial level of AuNPs in the apical compartment, the higher the basolateral concentration of gold that was detected at the same time point, particularly at 8 and 24 h of incubation. This effect can be attributed to the fact that there were more gold nanoparticles per unit surface area in contact with the apical cell membrane (microvilli) at the higher concentration of AuNPs, and so endocytosis occurred more frequently. Interestingly, a much higher concentration of intermediate-sized nanoparticles (50 nm) was transported across the epithelial cell monolayer into the basolateral compartment than small (15 nm) or large (100 nm) ones (Figure 3B). A possible explanation of this phenomenon is the size-dependent nature of the receptor-mediated endocytosis according to previous research.[28,29] The endocytosis of nanoparticles depends on two competitive processes that require two different energies: (i) the binding energy between ligands and receptors and (ii) the free energy for particle envelopment. When nanoparticles have diameters below about 40 nm, they do not produce a sufficiently large free energy change to become completely enveloped by the surface of the membrane. Conversely, when the nanoparticles have diameters greater than about 80 nm, the lack of free receptors limits the ligand−receptor binding energy. This much higher transport rate of 50 nm AuNPs across the intestinal epithelium may lead to higher levels of AuNPs in the systemic circulation, which may have a profound impact on the tissue/organ distribution and potential toxicity of these AuNPs in human body.

In contrast to 15 and 50 nm AuNPs, the transport of 100 nm AuNPs across the epithelial monolayer into the basolateral compartment of the transwells was found to be concentration independent (Figure 3C). At 2.5 and 5 μg/mL, the basolateral concentration of AuNPs remained relatively low after 24 h of incubation, but at 10 μg/mL there was a steep increase (Figure 3C). Correspondingly, the TEER of the monolayers decreased drastically to values below 100 $\Omega \cdot cm^2$, which suggests the monolayers had become leaky, hence the drastic increase in transport of AuNPs across the epithelium. Standard TEER values of healthy cells are around 260 ± 65 Ω.[18] The 10 μg/mL

DOI: 10.1021/acs.jafc.5b03242
J. Agric. Food Chem. 2015, 63, 8044−8049

of AuNPs suspension caused the same problem after 24 h of incubation (Figure 3B). These results suggested that AuNPs (50 and 100 nm) at the concentration of 10 μg/mL damaged the integrity of the epithelial monolayers.

Accumulation of Gold Nanoparticles within the Intestinal Epithelium. On the basis of the above results, we used the nanoparticle suspensions with intermediate gold concentration (5 μg/mL that is not detrimental to the integrity of the epithelial monolayer) to further quantify the cellular accumulation of AuNPs within the Caco-2 cell monolayers. The data on the gold concentration were analyzed in two different but complementary ways (Figure 3B). First, the mass of gold was normalized by the amount of cellular protein in each sample, so the results are presented as mass of gold per unit mass of protein (Figure 4A). Because the diameter of the AuNPs was known, it was also possible to calculate the number of nanoparticles per unit mass of protein (Figure 4B). The incubation of Caco-2 monolayers with AuNPs was stopped after different incubation times, and the amount of gold that had accumulated in the monolayer was quantified by ICP-MS as described under Materials and Methods. The cellular accumulation of AuNPs clearly showed a size-dependent pattern, which depend on the way that the particle concentration was represented. In terms of total particle mass, the smaller the particle size, the lower the total amount of gold accumulated in the epithelial cells: 15 nm < 50 nm < 100 nm. Conversely, in terms of total particle number, the smaller the particle size, the greater the total accumulation of gold within the epithelial cells: 100 nm < 50 nm < 15 nm. This latter trend is similar to that reported previously for in vivo permeation of AuNPs through rat intestine.[30] A similar trend was also reported when Caco-2 cells were exposed to AuNPs of 5 and 30 nm sizes.[31]

The results suggest that smaller gold nanoparticles can more easily penetrate into cells, which leads to a greater number of small particles inside the cells. However, the total mass of gold that accumulates in the cells is greater for the larger AuNPs (even though they penetrate into the cells more slowly) because the number of gold atoms per particle is proportional to the cube of the particle size. These results also indicated that larger AuNPs had a slower excretion rate from inside epithelial cells to the basolateral compartment. This highly size-dependent pattern of cellular accumulation of AuNPs may have a profound impact on the potential toxicity of these AuNPs in epithelial cells.

Effects of Gold Nanoparticles on Mitochondria Potential. The ICP-MS results provided valuable quantitative information about endocytosis, accumulation, and excretion of the AuNPs by the Caco-2 intestinal epithelial cell monolayers. The TEM images indicated that the gold nanoparticles progressively spread throughout the model epithelium cells after absorption and were eventually accumulated within different cellular organelles such as endosomes, lysosomes, Golgi apparatus, mitochondria, and nucleus (Figure 2). The accumulation of AuNPs within these cellular substructures may promote cytotoxicity, because previous studies have shown that AuNPs can depolarize the membranes of the mitochondria in mammalian cells.[17] A decrease in mitochondrial membrane potential is an early indicator of cell death.[12] In addition, impaired mitochondrial function has been shown to result in elevated levels of DNA damage.[32] Hence, we determined the mitochondria potential using a mitochondrion-specific dye (JC-1) after the Caco-2 cell monolayers had been incubated with AuNPs (5 μg/mL in apical medium) for 4 h. At this incubation time, the TEM images showed that the nanoparticles had accumulated within the mitochondria (Figure 2). Cells with high mitochondria membrane potential (healthy) promote the formation of dye aggregates that fluoresce red, whereas cells with low mitochondria membrane potential (damaged) remain monomeric JC-1 that fluoresce green.[33] As a result, the decrease of the red/green intensity ratio provides an indication of the damage of the mitochondria membrane function.

Our results showed a distinct size-dependent trend in the mitochondria toxicity caused by the gold nanoparticles: the larger the nanoparticles, the higher the toxicity, as evidenced by a decrease in the intensity of red florescence when the particle diameter increased (Figure 5A). Quantification of the ratio of red/green florescence further confirmed that the larger the AuNPs, the lower the relative red florescence (Figure 5B) This finding is consistent with our results by ICP-MS that showed the cellular accumulation of total mass of gold follows the trend 100 nm > 50 nm > 15 nm (Figure 4A).

In summary, the absorption, accumulation, and transfer of AuNPs in the intestinal epithelial cells were highly dependent on their particle diameter (15, 50, or 100 nm). AuNPs with intermediate sizes (50 nm) were the most efficiently transported across the intestinal epithelium: taken up from the apical side and excreted into the basolateral side. The smaller AuNPs (15 nm) were more rapidly absorbed by the intestinal epithelial cells and more quickly spread throughout the interior of the cells. Conversely, the larger AuNPs (100 nm) tended to accumulate within the intestinal epithelial cells because their rate of excretion into the basolateral side was slow. The increasing accumulation of the total mass of gold caused by AuNPs resulted in increasing mitochondria toxicity to the intestinal epithelial cells. Overall, this study provided detailed information on the impact of particle size on the absorption, accumulation, and cytotoxicity of AuNPs in the intestinal epithelium.

cereus was applied.[35] The trapping was realized in milk simulating buffer and in sterilized milk (containing 0.3, 1.5, and 3.5% fat) for verification of the suitability of the technique under real conditions. The aptamer-based trapping technique was developed to replace the necessary time-consuming microbiological enrichment of *B. cereus* spores in routine analysis.

The novelty of the presented work is given by the application of aptamers for spore enrichment in different milk samples. The combination of an aptamer-based enrichment by magnetic separation and a specific real-time PCR represents a new and rapid spore detection system. Additionally, due to the fact that spore forming germs are important for many industrial food processes this enrichment technique is easily adaptable to further investigations. In particular the presented system could be adapted for aptamer-based enrichment of, e.g., *Bacillus* spp. from soups, spices, and fruits or *Clostridium* spp. in chilled foods, cheese, and meat products.[36,37]

MATERIALS AND METHODS

Aptamers with an Affinity to *B. cereus* Spores. The aptamers used in this study have been generated via the SELEX process (systematic evolution of ligands by exponential enrichment) (unpublished data). Aptamer sequences (Table 1) were purchased from Invitrogen Life Technologies GmbH (Darmstadt, Germany) for further characterization.

Determination of Dissociation Constants (K_D) of Aptamers Using SPR. *Spore Lysis.* To generate a spore lysate of 10^6 CFU/mL, different *B. cereus* strains (Table 2) were diluted in 400 μL of 10 mM sodium acetate (pH 5.0), and 250 mg of glass beads (⌀ = 0.5 mm) were added. The spore solution was lysed by mechanical treatment (5 min at 30 Hz, twice) using a TissueLyser (Qiagen GmbH, Hilden, Germany). The supernatant with fragmented spores was subsequently used for immobilization on an SPR sensor chip.

[a]This strain was used for aptamer selection.

SPR Chip Preparation. An SPR-2 biosensor system (Sierra Sensors GmbH, Hamburg, Germany) was used for SPR spectroscopy. One channel of this two-channel system was used as active spot and contained the immobilized spore lysate, and the other channel with immobilized bovine serum albumin (BSA) was used as a reference to detect unspecific binders. The temperature control together with an integrated autosampler allowed automated measurements at a temperature of 25 °C. All SPR experiments were carried out with a flow rate of 25 μL/min using degassed PBS buffer containing 0.05% Tween 20 as running buffer.

SPR-AS-AM sensor chips (Sierra Sensors GmbH, Hamburg, Germany) with carboxylated surface were used for immobilization of fragmented spores. Each sensor chip was initially activated for 7 min by injecting a mixture (1/1, v/v) of 100 mM *N*-hydroxysuccinimide (NHS) and 400 mM 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC). Subsequently, fragmented spores diluted in 10 mM sodium acetate (pH 5.0) were injected for 7 min, followed by an injection of 3 min using 50 μg/mL bovine serum albumine (BSA) diluted in 10 mM sodium acetate (pH 5.0). The remaining surface areas were blocked by injecting 1 M ethanolamine (pH 8.5) for 7 min.

SPR Assay Design. The aptamers were diluted (2.5 mM, 5.0 mM, 7.5 mM, and 10.0 mM) in milk simulating buffer (55 mM NaCl, 20 mM $MgCl_2$, 67 mM $CaCl_2$, 80 mM KCl, 40 mM Tris-HCl, pH 6.6). For each assay, aptamers were injected onto the chip surface for 6 min in increasing concentrations. A dissociation time of 3 min was set to observe the binding behavior after completed injection. Bound aptamers were removed by injecting a mixture (1/1, v/v) of 10 mM sodium hydroxide and 1 M sodium chloride for 30 s. Four different concentrations of each aptamer were measured. Response units (RU) of the spot containing spore fragments were subtracted by RU of the reference spot containing BSA and RU of milk simulating buffer injections for 6 min to obtain double-referenced SPR data. The evaluation was performed using AnalyserR2 (Sierra Sensors GmbH, Hamburg, Germany) and Scrubber (BioLogic Software Pty Ltd., Campbell, Australia) software. The mean values of resulting dissociation constants were calculated and presented in nM (Table 1).

Determination of Aptamer Selectivity via SPR. *SPR Chip Preparation.* SPR chips were prepared essentially as previously described with the following modifications: An SPR-4 four-channel biosensor system (Sierra Sensors GmbH, Hamburg, Germany) was used for SPR spectroscopy. Three spots were used as active spots and contained immobilized streptavidin and the three biotinylated aptamers that were used for subsequent aptamer-based trapping of *B. cereus* spores. The fourth spot was used as a reference with immobilized streptavidin without aptamer. The sensor chips SPR-AS-AM were used for immobilization of streptavidin to bind biotinylated aptamers on the sensor chip surface. Initially, the sensor chip was activated as mentioned and streptavidin, diluted in 10 mM sodium acetate (pH 5.0) to a concentration of 0.9 μM, was injected for 7 min, followed by blocking of the remaining surface areas as mentioned. Afterward, biotinylated aptamers were diluted in milk simulating buffer

DOI: 10.1021/acs.jafc.5b03738
J. Agric. Food Chem. 2015, 63, 8050−8057

(10 μM) and injected for 6 min, each on one channel to determine the selectivity of each aptamer individually.

SPR Assay Design. For determination of aptamer selectivity, various *Bacillus* spp. spores (Table 2) were diluted in milk simulating buffer (final concentration 10^7 CFU/mL) and lysed as mentioned above. *B. cereus* strain MHI M1, which was used among other *B. cereus* strains as a selection target, was measured as a reference. For the assay, the spore lysates were injected for 1 min onto the prepared sensor chip surface. A dissociation time of 5 min was set, and afterward the bound spores were removed by injecting a mixture (1/1, v/v) of 10 mM sodium hydroxide and 1 mM sodium chloride for 30 s. The resulting RU signals were put into relation to the obtained RU signal for the reference strain MHI M1 in order to classify the aptamer selectivity of each strain. Data analysis was performed using the AnalyserR2 (Sierra Sensors GmbH, Hamburg, Germany) software.

Fluorescence Microscopy. Fluorescence microscopy was carried out using a fluorescence correlation spectroscope ConfoCor2 (Carl Zeiss GmbH, Jena, Germany) to visualize the aptamer target interactions. Therefore, aptamers were labeled at the 5′-terminus by PCR with fluorescein modified primers as described as follows: After an initial denaturation at 95 °C for 5 min, 25 cycles (95 °C for 30 s, 56 °C for 30 s, and 72 °C for 30 s each) were carried out. For a final elongation, reaction mixtures were incubated for 7 min at 72 °C. The PCR mix consisted of the following: 1× DreamTaq buffer (10×, Fisher Scientific-Germany GmbH, Schwerte, Germany), 0.8 mM dNTPs (10 mM, Bioline GmbH, Luckenwalde, Germany), 0.05 unit of DreamTaq polymerase (5.0 U/μL, Fisher Scientific-Germany GmbH, Schwerte, Germany), 1.0 μM of each primer (Invitrogen Life Technologies GmbH, Darmstadt, Germany), 25 μL of the DNA solution, and ddH2O filled up to 50 μL. For subsequent strand separation 5′-biotinylated aptamer was used. Strand separation was based on binding of biotin to streptavidin-coated magnetic beads (DynaBeads M-280 Streptavidin, Invitrogen Life Technologies GmbH, Darmstadt, Germany) to separate ssDNA for fluorescence microscopy. 5 nM fluorescent labeled aptamers were incubated with *B. cereus* spores (10^6 CFU/mL) in 350 μL of milk simulating buffer for 1 h at 25 °C. After incubation, spore suspensions were washed by centrifugation (5 min at 10500*g*) and spore pellets were resuspended in 350 μL of milk simulating buffer for fluorescence microscopy. The analyses were carried out under the following conditions: argon laser (5 mW), 25% output, transmission 15%, wavelength 488 nm, 40× and 100× lens.

Aptamer-Based Trapping of *B. cereus* Spores in Milk Simulating Buffer and Milk. *Preparation of Aptamer-Linked Magnetic Beads.* Before the aptamers could be used for trapping, they had to be linked to magnetic SiMAG-Carboxyl Beads (chemicell GmbH, Berlin, Germany). Therefore, 200 μL of SiMAG beads were washed twice with 1 mL of MES-buffer (0.1 M 2-(*N*-morpholino)-ethanesulfonic acid, pH 5.0), suspended in 250 μL of MES-buffer containing 10 mg of EDC (1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride) and incubated under agitation for 10 min. Afterward, 50 μL of aminated aptamers was added and the mix was incubated for 2 h. After incubation, magnetic beads were washed three times with 1 mL of PBS buffer and finally redissolved in 1 mL of blocking/storage-buffer (PBS buffer containing 0.1% BSA, 0.05% sodium azide). Before each trapping experiment the required volume of magnetic beads was transferred to a new reaction tube, washed, and taken up in the initial volume of ddH_2O. For the subsequent aptamer-based trapping a mixture of aptamer-linked magnetic beads (BacApt3, BacApt4, and BacApt5) was used to cover a wide range of potential binding sites.

Aptamer-Based Trapping Using Magnetic Separation. Before each experiment, the mixture of aptamer-linked magnetic beads was washed once with the same volume of milk simulating buffer and refolded for 5 min at 95 °C with subsequent cooling to 4 °C to ensure correct aptamer folding. Then 10 μL of aptamer-linked magnetic bead mixture was diluted with 940 μL of (i) milk simulating buffer, (ii) milk with 0.3% fat, (iii) milk with 1.5% fat, and (iv) milk with 3.5% fat. These solutions were spiked each with 50 μL of *B. cereus* spores (10^7 CFU/mL, used strains MHI M1 and two wild types) and incubated for 30 min under agitation. Thereafter, the solution was centrifuged (2 min, 10000*g*) and the supernatant was removed. The resulting bead pellets were washed three times with 1 mL of ddH_2O and finally taken up into 100 μL of ddH_2O. Aptamer-bound spores were then heat eluted for 5 min at 96 °C, and the hot supernatant containing enriched spores was transferred to a new reaction tube. The samples were stored at −20 °C until further use.

Real Time PCR Detection of B. cereus Spores. Real time PCR was performed to demonstrate the success of aptamer-based trapping. Therefore, the solutions containing enriched spores were diluted 1:10 with ddH_2O and lysed as mentioned above, and real time PCR assay was performed using a iCycler iQ5 (BioRad Laboratories, Inc.; Hercules, CA). The used real time assay and conditions have been described in detail elsewhere.[35] The primers used in this assay target the hbID gene of *B. cereus*. Each reaction mix consisted of following components: 1× DreamTaq buffer (10×, Fisher Scientific-Germany GmbH, Schwerte, Germany), 0.8 mM dNTPs (10 mM, Bioline GmbH, Luckenwalde, Germany) 0.25 unit of DreamTaq polymerase (5.0 U/μL, Fisher Scientific-Germany GmbH, Schwerte, Germany), 0.25 μM of each primer (mp3L1R1for and mp3L1R1rev, Invitrogen Life Technologies GmbH, Darmstadt, Germany), 0.3125× SYBR Green I nucleic acid gel stain (10000×, Invitrogen GmbH, Karlsruhe, Germany), 3 μL of enriched and lysed spore solution, and ddH_2O filled up to 20 μL. After an initial denaturation at 95 °C for 10 min, 35 cycles (95 °C for 15 s, 60 °C for 10 s, and 72 °C for 10 s each) were carried out. For final elongation, the reaction mixtures were incubated for 10 min at 72 °C. For quantitation and comparison, an external calibration with *B. cereus* (wild type, 10^3 to 10^7 CFU/mL) was applied. A milk simulating buffer/milk sample spiked at a concentration equal to pre-enrichment was used as control. The assay was additionally performed using *B. subtilis* and *B. thuringiensis* spores as template to demonstrate the specificity of the protocol.

RESULTS AND DISCUSSION

The presented work includes the characterization of aptamers with an affinity to *B. cereus* spores by SPR and fluorescence microscopy and subsequent development of an aptamer-based trapping technique in milk. The trapping was performed in both milk simulating buffer and milk containing different fat contents. Moreover its effectiveness was demonstrated by real time PCR.[35]

Determination of Dissociation Constants (K_D) of Aptamers Using SPR. Suitable SPR sensor chips were prepared to determine the dissociation constants (K_D) of the aptamers to *B. cereus* spores. Immobilization of spores fragmented using glass beads and a TissueLyser enabled the preparation of suitable sensor chips for the determination of dissociation constants.

Spore Lysis. The degree of spore fragmentation proved to be a crucial parameter for successful sensor chip preparation. Thus, several treatments (e.g., ultrasonic disruption), pH values, and spore fragmentation methods were investigated and assessed (data not shown). The developed mechanical treatment with glass beads is applicable for fragmentation of spores and supplies the ideal degree of spore fragmentation for subsequent immobilization on carboxylated SPR sensor chips.

SPR Chip Preparation. During immobilization of fragmented spores on activated SPR sensor chip surfaces approximately 400−800 RU could be observed. According to Karlsson one RU corresponds to approximately 1 pg of immobilized fragmented compounds per mm^2.[38] Thus, on a sensor chip surface of approximately 1.2 mm^2, 440−960 pg of fragmented spores can be immobilized. The high amount of immobilized fragments allows the conclusion that a sufficient amount of spore coat fragments were immobilized and therefore the developed SPR immobilization method is suitable

DOI: 10.1021/acs.jafc.5b03738
J. Agric. Food Chem. 2015, 63, 8050−8057

for investigations concerning interaction of the aptamers and spore surfaces.

SPR Assay. Regeneration conditions were obtained using sodium hydroxide (10 mM) and sodium chloride (1 M) (1/1, v/v) and a contact time of 30 s. The stability and the activity of the chip surface were further monitored by multiple injections of an aptamer solution (10 mM) and subsequent regeneration. Due to the obtained response signals of 214 RU (first aptamer injection) and 191 RU (50th aptamer injection) a decrease of approximately 10.75% in surface activity was determined, which is less than the recommended cutoff value of 20%.[39,40] Therefore, the developed SPR chip surface regeneration procedure fulfilled the compulsory requirements.

SPR analyses were carried out using milk simulating buffer, because the selected aptamers will be used for applications in milk. Milk itself was not suitable for SPR measurements because of its fat content and the included milk sugar. Therefore, the selection conditions were chosen as far as possible similar to the conditions of milk by using a simulating buffer. Dissociation constants of aptamer were measured by immobilization of fragmented spores on chip surface and injection of several aptamer concentrations (2.5 mM, 5.0 mM, 7.5 mM, and 10.0 mM). Exemplary overlays of aptamer injections are shown in Figure 1 and Figure S1. RU of spore

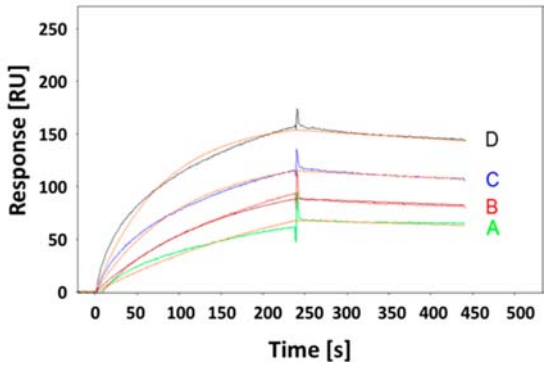

Figure 1. Exemplary overlay of fitted raw data (BacApt2) for evaluation of dissociation constants (K_D). The raw data were fitted using the Langmuir 1:1 model including mass transport limitation. The data was analyzed using AnalyserR2 (Sierra Sensors GmbH, Hamburg, Germany) and Scrubber (BioLogic Software Pty Ltd., Campbell, Australia) software.

fragment containing spots were subtracted by RU of reference spots containing BSA and injections of milk simulating buffer for 6 min to obtain double referenced SPR data. The obtained curves were fitted in accordance with the Langmuir 1:1 model including a mass transport limitation factor to determine the dissociation constants (Figure 1). Although an appropriate multivalent binding kinetic could be more precise for performed experiments, it is not yet available, so that the Langmuir binding model was chosen. SPR data were normally distributed according to David (confidence intervals of 90%) regarding the calculation of dissociation constants.[41] Furthermore, no outlier according to Dixon (confidence intervals of 95%) was identified.[42] A summary of calculated K_D values is shown in Table 1.

In summary, the dissociation constants of aptamers with an affinity to *B. cereus* spores could be detected in a low-nanomolar range. Hence, the selected aptamers were considered suitable for the subsequent development of an aptamer-based trapping technique.

Determination of Aptamer Selectivity via SPR. Aptamer selectivity was determined to investigate the specificity of our trapping protocol and the aptamers used in this study. For that, the three aptamers applied for capturing were immobilized onto an SPR chip surface and binding interaction differences were observed between aptamers and *B. cereus* spores as well as various other *Bacillus* spp. spores (Figure S2). The spores were chosen for their degree of relationship to *B. cereus* and included both closely related (*B. thuringiensis* and *B. subtilis*) and more distant spores (e.g., *B. weihenstephanensis* and *B. coagulans*). The selectivity results were calculated in relation to the strain *B. cereus* MHI M1, which had been one of the targets for aptamer selection. MHI M1 was chosen as a reference because it was expected that aptamers have the highest affinity to their selection target.

Principally, all aptamers exhibited a higher affinity to *B. cereus* spores in comparison to other *Bacillus* spores (Figure S2). However, the selectivity was not equal for all *B. cereus* strains used in this assay. This could be due to small differences in surface composition and spore lysates preparation. For instance, the affinity of BacApt3 to *B. cereus* AH 187 is much higher than to the reference strain MHI M1.

Figure 2 graphically describes the affinity of the three used aptamers to all *Bacillus* spores in comparison. It can be clearly seen that, unsurprisingly, the selectivity toward *B. cereus* spores is highest, followed by closely related spores, i.e., *B. subtilis* and *B. thuringiensis* spores. Considerably lower interactions between the selected aptamers and more distantly related spores could be observed. In conclusion, the use of the selected aptamers for highly selective trapping of targets is limited due to structural similarities of *Bacillus* spp. spores. However, high selectivity can be achieved by performing a highly selective real time PCR following trapping which excludes closely related spores.[43] Real time PCR results will be discussed later.

Fluorescence Microscopy. Fluorescence microscopy was carried out to visualize the interactions of aptamers with *B. cereus* spores and therefore to verify the aptamer affinities. Spores without prior incubation were used as a blank sample to define the optimal settings for fluorescence microscopy. Adjustment of the blank sample settings was necessary to obtain low intrinsic fluorescence of spores (shown in Figure 3, 1A to 1C). The aptamer spore complexes were investigated by microscopy after incubation of fluorescent-labeled aptamers with spores and corresponding washing steps. Furthermore, to generate representative fluorescence images, a mixture of all nine aptamers was used for fluorescence microscopy (shown in Figure 3, 2A to 2C, 3A to 3C).

The visualization of aptamer spore interactions by fluorescence microscopy confirmed the affinity of selected aptamers to *B. cereus* spores and underlined the obtained SPR results, respectively.

Aptamer-Based Trapping of *B. cereus* Spores in Milk. *Aptamer-Based Trapping of B. cereus Spores Using Real Time PCR Detection.* To verify the suitability and specificity of the used real time PCR assay, the PCR was performed using *B. cereus*, *B. subtilis*, and *B. thuringiensis* spores (each 10^3 CFU/mL). An external calibration was used (Figure 4A,B), for which a regression coefficient of 0.99 was obtained. The results demonstrate that *B. cereus* spores were amplified while *B. subtilis* and *B. thuringiensis* spores show no amplification in obtained threshold cycle number (data not shown). The real time PCR

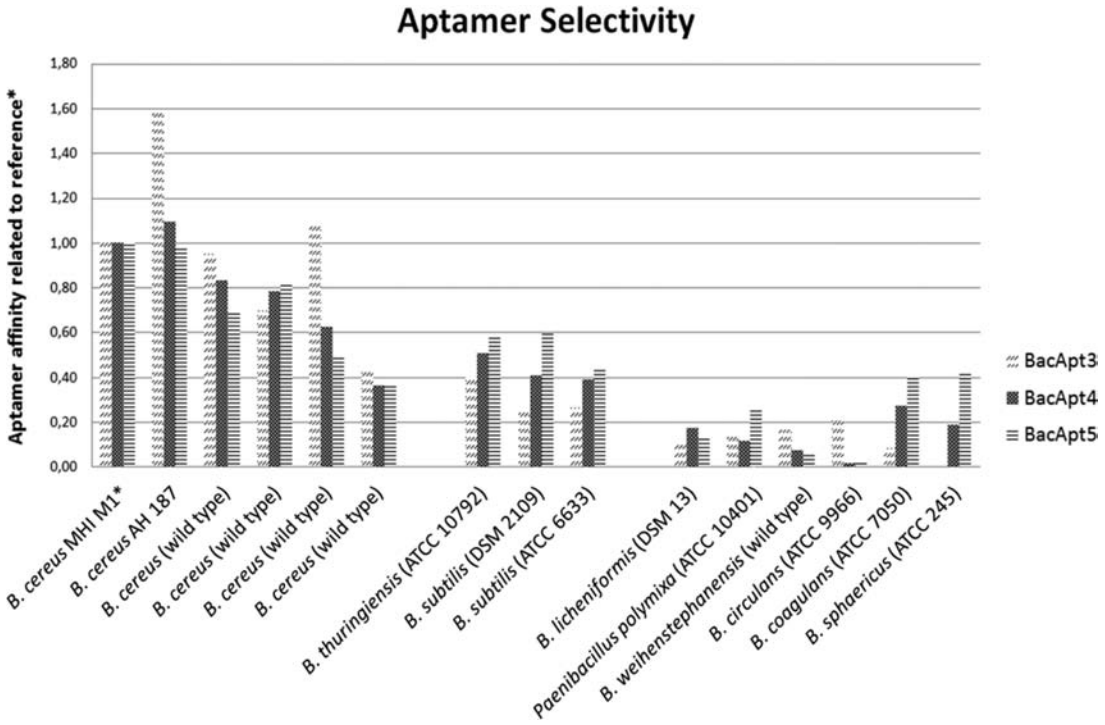

Figure 2. Aptamer selectivity of BacApt3, BacApt4 and BacApt5 determined by SPR measurements with spores of different *Bacillus* strains. As a reference, the affinity of *B. cereus* MHI M1 was set to 1. The selectivity of other spores is assigned as relative affinity compared to the reference.

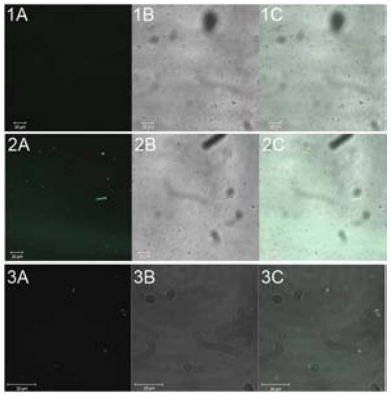

Figure 3. Fluorescence microscopy recordings of *B. cereus* spores in milk simulating buffer as blank sample (1A to 1C with 40× lens). Exemplary images of spores after incubation with a fluorescently labeled mix of obtained aptamers (2A to 2C with 40× lens and 3A to 3C with 100× lens). (A) Fluorescence images; (B) visual images; (C) overlays of the fluorescence and visual images.

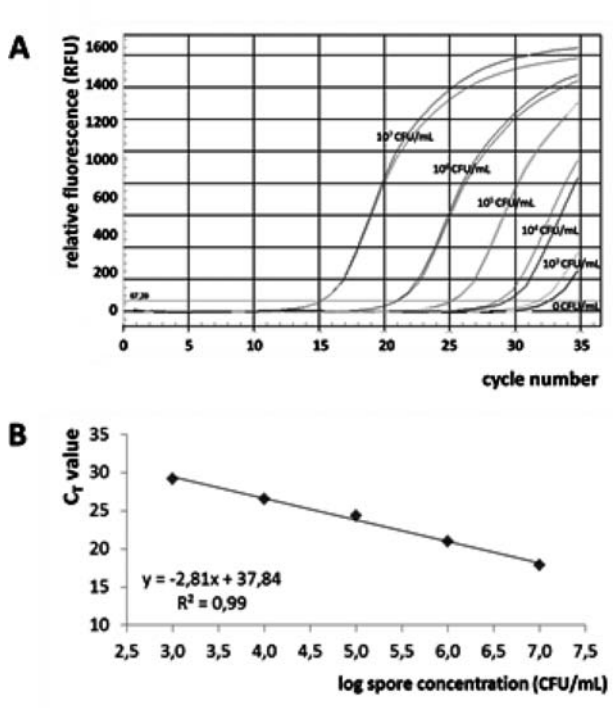

Figure 4. (A) Example of amplification curves during real time PCR with different *B. cereus* MHI M1 spore concentrations (from left to right): 10^7 CFU/mL, 10^6 CFU/mL, 10^5 CFU/mL, 10^4 CFU/mL, 10^3 CFU/mL, and 0 CFU/mL. (B) Resulting calibration line during real time PCR with $R^2 = 0.99$. Spore concentration (from left to right): 10^3 CFU/mL, 10^4 CFU/mL, 10^5 CFU/mL, 10^6 CFU/mL, 10^7 CFU/mL.

assay thus proved to be a highly specific tool for detection and quantitation of *B. cereus* spores after trapping.

Trapping was performed in three different matrices and milk simulating buffer. Milk simulating buffer was included as a trapping matrix since aptamers are expected to achieve highest target affinities in their selection buffer. This is due to conformational changes caused by, e.g., ion concentration and pH value of the medium. Milk simulating buffer was chosen for aptamer selection as it on one hand simulates milk in ion concentration and pH value and on the other hand does not contain substances like sugars and fat which could disturb the SELEX process. Milk with three different fat contents was selected to demonstrate the applicability of the trapping technique under real conditions. This was done to evaluate a possible interference of fat and sugar with aptamer confirmation.

J. Agric. Food Chem. 2015, 63, 8050−8057

Overall enrichment factors between 3.1 and 7.5 (Table 3) could be achieved. As expected, the highest enrichment factor was observed in milk simulating buffer (6.0 ± 1.0 on average). Trapping was also successful in milk, however at a lower efficiency in comparison to milk simulating buffer (on average 3.5 ± 1.0 to 5.4 ± 1.9). No significant differences were observed between different fat contents. Thus, it can be assumed that fat content is not a relevant parameter for trapping. The successful enrichment in milk also allows the assumption that milk sugar does not influence the aptamer–target interaction because aptamers show high affinity despite milk samples containing milk sugar.

Table 3. Obtained Enrichment Factors for Aptamer-Based Trapping in Milk Simulating Buffer and Milk with Different Fat Contents[a]

strain	milk simulating buffer	milk 0.3% fat	milk 1.5% fat	milk 3.5% fat
B. cereus wild type	5.2	3.5	4.3	4.0
B. cereus wild type	5.7	3.1	6.7	4.8
B. cereus MHI M1	7.1	3.9	3.2	7.5
mean value	6.0 ± 1.0	3.5 ± 0.4	4.7 ± 1.8	5.4 ± 1.9
mean value 2	4.91 ± 1.07			

[a]The maximal trapping factor was determined mathematically to 10.

The ion strength of milk (or milk simulating buffer) has been shown to be a disruptive factor for subsequent detection and quantitation via real time PCR. Therefore, it was necessary to include several washing steps of aptamer-linked magnetic beads with ddH_2O following trapping in order to achieve successful real time PCR quantitation. Furthermore, PCR results were improved by diluting the samples prior to measurement to minimize the effect of residual ions (data not shown).

In this study, we demonstrate the successful aptamer-based entrapment of *B. cereus* spores in milk simulating buffer as well as in milk with different fat contents. The presented work includes an extensive characterization of DNA aptamers with an affinity to *B. cereus* spores. The detection of vegetative cells was not considered relevant for the presented study because pasteurization, which is typically performed during the production of milk, inactivates vegetative *B. cereus* cells and only spores survive heat treatment. The aptamers were characterized by SPR and fluorescence microscopy to gain dissociation constants and to determine the selectivity of the aptamers used for trapping. Aptamer affinities in a low-nanomolar range could be obtained. However, more detailed binding properties in terms of kinetics and binding sites are to be determined by further research. Thus, selecting only one aptamer for developed detection methods seems not advisible. Due to the presumption of multivalent binding kinetics, utilization of an aptamer mix for aptamer-based trapping was chosen. It was shown that trapping was successful in buffer and different milk samples, whereby as expected the best enrichment factor was achieved by using milk simulating buffer. Moreover, it was shown that the usage of aptamers to perform a high selective trapping is limited. We recommend to perform a *B. cereus* specific real time PCR following trapping to ensure a reliable detection.[44]

In general, it was shown that aptamers are suitable for applications in trapping and detection tools. Further research could amplify the range of aptamer-based application, e.g., in Apta-PCR, which allows an indirect detection of targets at low concentrations.[45,46] Moreover the development of aptamer-based lateral flow dipsticks/devices (LFDs) could fulfill many expectations for manufacturing industry, because they enable a specific, rapid, and simple optical target detection with less expenditure of instrumentation due to interactions with specific aptamers.[47,48]

PGRs with multiple operations. In addition, to both the experimenter and the environment, tedious operation with high reagent consumption was always unsatisfactory. Consequently, although a few works have been done, there are still challenges in the sensitive, accurate, efficient, and convenient determination of endogenous PGRs in complex samples.

A precolumn derivatization technique is usually applied to overcome the above difficulties by improving sensitivity and selectivity as well as accuracy.[36,37] Practically, derivatization might also contribute to the stabilization of labile PGRs via molecular modification. To the best of our knowledge, no derivatization was found for the simultaneous determination of PGRs involved in a signal transduction system to date. A recently synthesized fluorescent probe, 2-(12,13-dihydro-7*H*-dibenzo[*a*,*g*]carbazol-7-yl)ethyl4-methylbenzenesulfonate (DDCETS), was selected for this study,[42] which, however, provided unsatisfactory derivatization yield and low efficiency in tentative experiments. Microwave proved to be an efficient technique for complex samples.[43] Thus, the combination of microwave-assisted extraction with derivatization will be beneficial to establishing the desired method.

In this study, a method with microwave-assisted extraction−derivatization (MAED) followed by high-performance liquid chromatography (HPLC)−fluorescence detection (FLD) coupled with mass spectra (MS/MS) (MAED-HPLC-FLD-MS/MS) has been developed for the quantification of six acidic PGRs (IAA, IPA, IBA, 1-NAA, 2-NAA, and GA_3) in transgenic and nontransgenic edible oils including soybean oil, sunflower oil, and rapeseed oil. The MAED technique allows for an efficient pretreatment for oil samples, with DDCETS used as fluorescent reagent to improve sensitivity as well as stability. Experimental conditions are optimized by single- and multivariable methods to maximize response of analytes.[44] Instead of gas chromatography (GC), HPLC is selected to avoid the potential decomposition or isomerization caused by high temperature. The combination of FLD with tandem MS/MS enables both the sensitive quantification and the real-time monitoring of labile analyte and interference. This is the first time that the MAED technique has been applied to acidic PGR analysis. Sensitivity, accuracy, precision, recovery, and repeatability are significantly improved, especially for labile PGRs. Correlations between PGRs and components/genes are explored, providing a promising approach to establish an objective evaluation for transgenic foods.

MATERIALS AND METHODS

Materials and Chemicals. Standards of IAA, IPA, IBA, 1-NAA, 2-NAA, and GA_3 were purchased from Shanghai Chemical Reagent Co. (≥98%). HPLC grade methanol, formic acid, and acetonitrile (ACN) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Water was purified on a Milli-Q system (Millipore, Bedford, MA, USA). DDCETS was prepared following a literature method.[42] Transgenic soybean oil, nontransgenic soybean oil, transgenic sunflower oil, nontransgenic sunflower oil, transgenic rapeseed oil, and nontransgenic rapeseed oil were all purchased from a supermarket in Qufu (Shandong province, China).

Preparation of Solutions. Solutions for PGRs (GA_3, 5.46×10^{-3} mol L^{-1}; IAA, 5.65×10^{-3} mol L^{-1}; IPA, 5.18×10^{-3} mol L^{-1}; IBA, 5.62×10^{-3} mol L^{-1}; 1-NAA, 8.22×10^{-3} mol L^{-1}; 2-NAA, 8.27×10^{-3} mol L^{-1}) were prepared by dissolving an appropriate amount of corresponding standard in ACN, respectively. The stock solution (5×10^{-4} mol L^{-1}) was prepared by diluting the mixed solution with ACN. Then, in a similar way, the working solutions for calibration curves and validation (30, 50, 100, 200, 1000, 1500, and 3500 ng mL^{-1}) were prepared. Derivatizing reagent solution (1.04×10^{-2} mol L^{-1}) was prepared by dissolving 120.5 mg of DDCETS in 25 mL of anhydrous ACN. When not in use, all solutions were stored at 4 °C in a refrigerator.

Microwave-Assisted Extraction−Derivatization (MAED). A sample of 3 g was weighed and transferred to a Teflon vessel, to which 6 mL of methanol, 5 mL of *N*,*N*-dimethylformamide (DMF), 1 mL of DDCETS (1.04×10^{-2} mol L^{-1}), and 40 mg of K_2CO_3 were added successively. The screwed vessel was placed into a microwave oven, which was then set at 130 °C (power set as 1000 W) for 35 min with magnetic stirring. The resulting mixture was transferred into a tube for centrifugation (2500*g* for 5 min). The supernatant was concentrated by nitrogen stream (55 kPa) until a final volume of 4 mL, which was then filtered through a 0.22 μm nylon film and injected to HPLC-FLD-MS/MS system. Chemical structures of PGRs and derivatization scheme are shown in Figure 1.

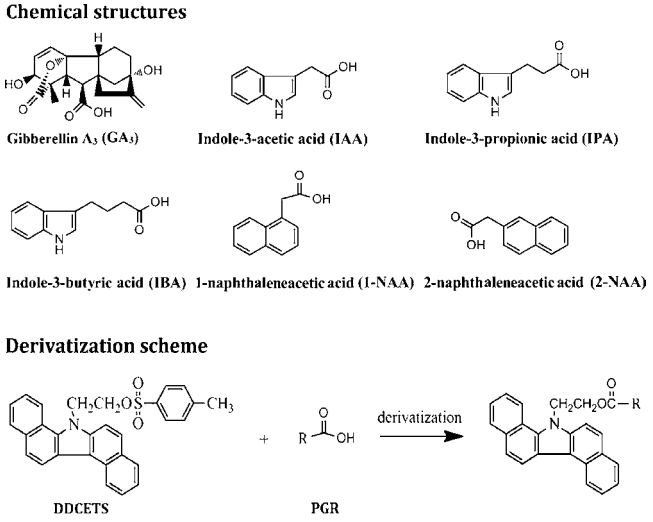

Figure 1. Chemical structures of PGRs (gibberellin A_3 (GA_3), indole-3-acetic acid (IAA), indole-3-propionic acid (IPA), indole-3-butyric acid (IBA), 1-naphthaleneacetic acid (1-NAA), and 2-naphthaleneacetic acid (2-NAA)) and derivatization scheme of DDCETS with PGRs.

Optimization of MAED. First, single-variable experiments were carried out to evaluate factors including extraction solvents (methanol; ACN; chloroform; ethanol; DMF), cosolvents (DMF; ethyl acetate; acetone; dimethyl sulfoxide (DMSO); chloroform), 40 mg of basic catalysts (pyridine; 2-methylpyridine; K_2CO_3; Na_2CO_3; $K_2C_2O_4$), derivatization reagent (concentration = 1.04×10^{-2} mol L^{-1}; volume = 0.6, 0.8, 1.0, 1.2, or 1.4 mL), temperature (80, 100, 130, 135, or 140 °C), and microwave time (15, 25, 35, 45, or 55 min). All experiments were performed at three sample levels (weight = 1.0, 3.0, and 5.0 g). Considering the interaction of factors with each other, Box−Behnken designs[45] with five variables, microwave exposition time (X_1, min), temperature (X_2, °C), DMF volume (X_3, mL), DDCETS volume (X_4, mL), and methanol volume (X_5, mL) were applied to optimize conditions for MAED, which were statistically analyzed by software Design-Expert 7.1.3 Trial.

Instrumental Analysis. An XH-100A microwave synthesis apparatus (Beijing Xiang Hu Science and Technology Development Co. Ltd.) was used to perform MAED operation. HPLC analysis was performed using an Agilent 1100 system equipped with online vacuum degasser (G1322A), quaternary pump (G1311A), autosampler (G1329A), and thermostated column compartment (G1316A). Chromatographic separation was achieved on an Aglient ZORBAX SB-C18 column (150 mm × 4.6 mm, 5 μm i.d., USA). Elution conditions were as follows: 0 min, 35% A and 65% B; 20 min, 20% A and 80% B; 25 min, 0% A and 100% B (stop time, 5 min), where A and B were 5% ACN solution (ACN/H_2O: 5/95, v/v) and 100% ACN, respectively. Flow rate was constant at 1 mL/min, and column

[a]Independent variables were X_1, derivatization time (min); X_2, derivatization temperature (°C); X_3, DMF volume; X_4, DDCETS volume; X_5, methanol volume. [b]Average experimental and predicted total peak areas of derivatives (n = 6). [c]The 46 runs from the BBD were given by the software Design-Expert 7.1.3 trial. [d]Validation: multicriteria (AME, absolute maximum error; CE, coefficient of efficiency; MAE, mean absolute error; RMSE, root mean squared error; MRE, mean relative error; R^2, correlation of determination and nonparametric tests (p value with Wilcoxon rank sum method)).

temperature was kept at 30 °C. The HPLC system was followed in sequence by a fluorescence detector (FLD, G1321A, λ_{ex}= 292 nm and λ_{em}= 402 nm) and an online mass spectrometer 1100 series LC-MSD Trap-SL (ion trap) with an atmospheric pressure chemical ionization (APCI) source (Bruker Daltonik, Bremen, Germany). The auto-MS operation parameters were as follows: APCI in positive ion detection mode; nebulizer pressure, 60 psi; dry gas temperature, 350 °C; dry gas flow, 5.0 L/min; APCI Vap temperature, 350 °C; corona current, 4000 nA; capillary voltage, 3500 V. The injection volume was 10 μL.

Validation of the Proposed Method. Linearity was measured from 30 to 3500 ng mL^{-1} for each PGR. Limit of detection (LOD) and limit of quantification (LOQ) were defined as the minimum detectable amount of analyte with a signal-to-noise ratio (S/N) of 3 and 10, respectively. FLD repeatability was investigated by measuring the relative standard deviations (RSD) for peak area and retention

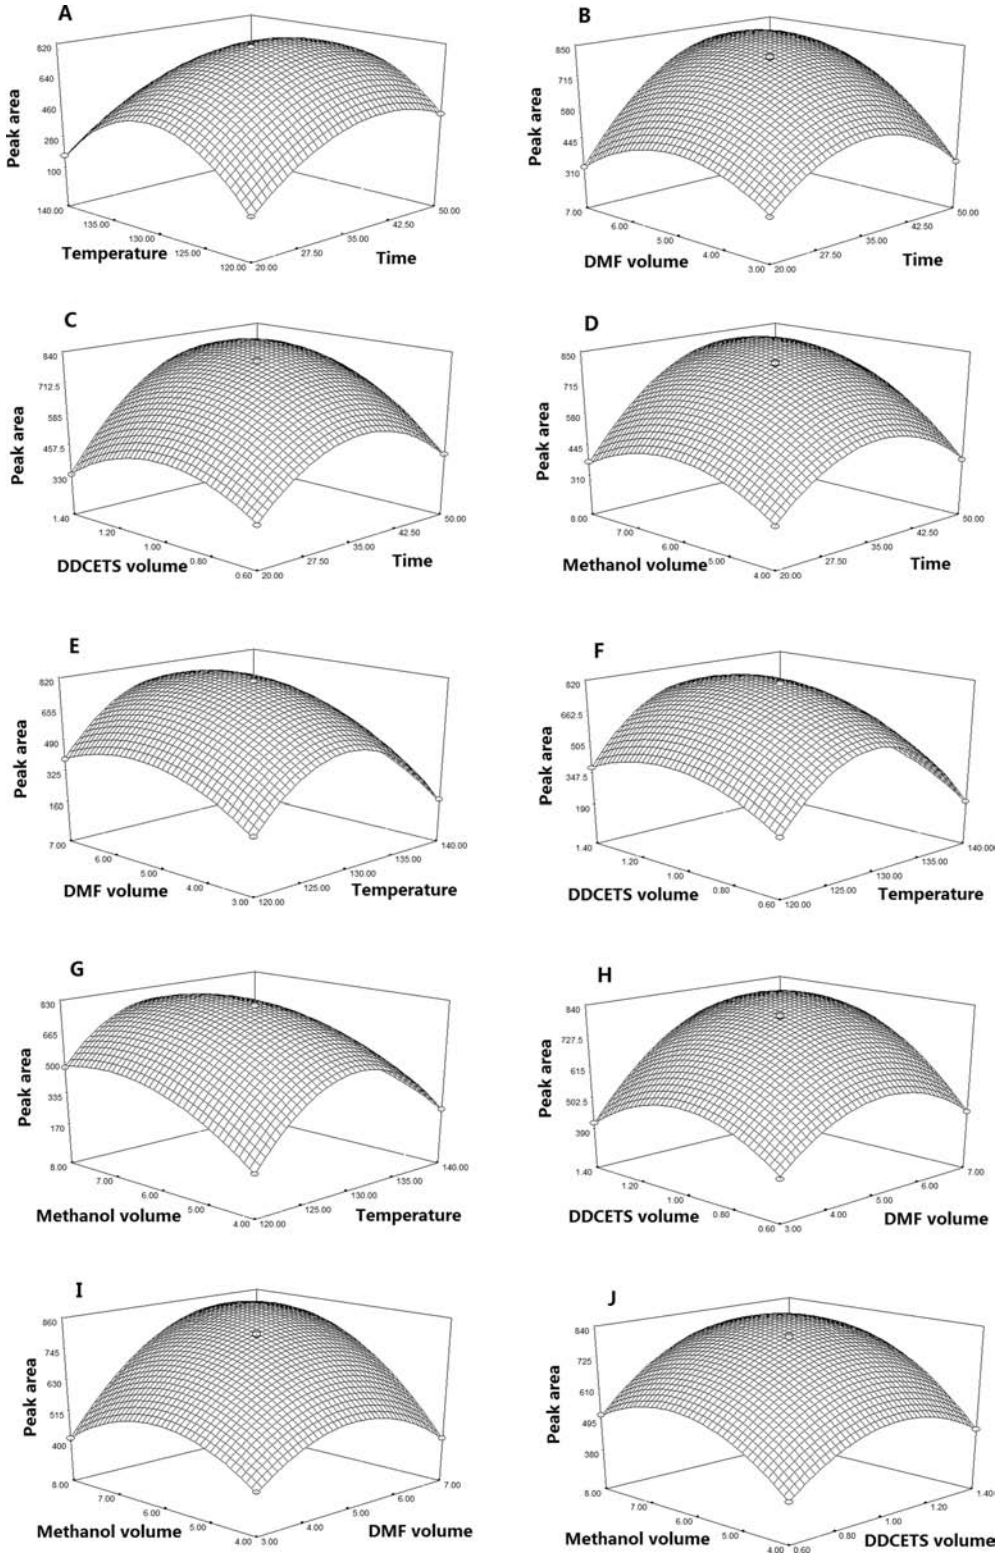

Figure 2. Response surface of the extraction−derivatization yield (expressed as peak area) affected by time and temperature (A), time and DMF volume (B), time and DDCETS volume (C), time and methanol volume (D), temperature and DMF volume (E), temperature and DDCETS volume (F), temperature and methanol volume (G), DMF volume and DDCETS volume (H), DMF volume and methanol volume (I), and DDCETS volume and methanol volume (J).

time with 10 μL of standard sample (0.5 ng of PGR injected; six replicates ($n = 6$)). Recovery was investigated with the equation $(S_2 - S_1)/S_0 \times 100\%$, where S_0, S_1, and S_2 are the peak areas of quality control (QC) solution (20, 50, 100 ng mL^{-1} of standard solutions), samples, and samples spiked with QC solution, respectively. The matrix effect was evaluated as follows: matrix effect (%) = $S_p/S_s \times 100\%$, where S_s and S_p are the peak areas of QC solution and postextraction sample spiked with QC solution, respectively. Intraday and interday precisions were determined by running samples spiked with QC solutions at three levels (50, 200, and 1000 ng mL^{-1}) ($n = 6$).

In view of the potential instability of GA_3, NAA, and IAA,[24,38,39] all PGRs and their DDCETS-labeled derivatives were investigated for short-term (12 h) and long-term stability (7 days). Storage stability was evaluated at 4 °C for 7 days. Freeze−thaw stability was evaluated after two cycles of freeze (−20 °C for 7 days)−thaw (room temperature, spontaneously) performance. Six duplicates spiked at each of three concentration levels (100, 500, and 1000 ng mL^{-1}) were analyzed, and the mean ± standard deviation (SD) with percent relative error (RE%) was calculated.

RESULTS AND DISCUSSION

Optimization of MAED. *Single-Variable Optimization.* On the basis of solvent investigation, absolute methanol was found to be the best medium for high response (Figure S1, 1a−1e). Due to the large structure of derivatized analyte, cosolvent is necessary to improve the solubility. As shown in Figure S1, 2a−2e, DMF proved to be the most suitable cosolvent. Moreover, addition of DMF effectively avoided the precipitation of hydrophobic derivative found in ethyl acetate. Catalyst investigation showed the enhanced response when 40 mg of K_2CO_3 was added, owing to its specifically strong basicity in DMF (Figure S1, 3a−3e). Temperature investigation (Figure S1, 5a−5e) from 80 to 140 °C revealed that, for the efficient extraction−derivatization of PGRs, the system should be heated to a temperature lower than 135 °C, otherwise decomposition might occur. In addition, 35 min of MAED was sufficient for the complete extraction−derivatization of PGRs, which can be seen from Figure S1, 6a−6e, for time investigation.

Multivariate Optimization. For efficient pretreatment, a thorough optimization with 46 runs of experiments for interactive variables is listed in Table 1, and response surfaces are plotted in Figure 2. Results for correlation (R^2 = 0.9875) and coefficient of efficiency (CE = 0.9996 (approximate to 1)) indicated the multivariate model was satisfactorily established. A nonparametric test gave a p value of 0.1177 (>0.05), showing that the differences between experimental and predicted values were statistically insignificant (at the 95% confidence level).[46] Together, these results demonstrated that values correlating well with experimental data can be predicted by regression of the multivariate model. Accordingly, the optimal variables combination (X_1, 34.87; X_2, 130.05; X_3, 4.69; X_4, 1.07; and X_5, 6.24) was achieved, which was confirmed by being applied to three independent replicates of MAED operations, giving a peak area of 809.51, an experimental value quite approximate to the predicted 803.45.

Thus, the optimal conditions for MAED are established: to a 50 mL vessel were added successively 3 g of edible oil, 6 mL of methanol, 5 mL of DMF, 40 mg of K_2CO_3, and 1 mL of DDCETS (1.04×10^{-2} mol L^{-1}); then the vessel was placed in the microwave apparatus at 130 °C with shaking for 35 min.

Method Validation. It can be seen from Table 2 that linear equations with excellent correlation coefficients of ≥0.9996 were developed over the wide ranges. As expected, quite low LODs (0.37−1.36 ng mL^{-1}) and LOQs (1.11−4.22 ng mL^{-1}) were obtained with higher analytical sensitivity than most of those reported,[17,19−22,26−28,35,36] which should be attributed to the strong fluorescence responses and low interferences of this method. The satisfactory repeatability for retention times (0.07−0.26%) and peak areas (1.11−1.51%) demonstrated that FLD quantification was reliable, whereas no obvious analyte loss was observed. Benefiting from the high efficiency, the sensitivity and accuracy (RE%, intraday, −2.96 to 2.60%; interday −4.30 to 3.68%) and precision (RSD%, intraday, 0.49−4.48%; interday, 0.76−6.60%) for these PGRs (Table 2) were improved.[18,31,32] Especially, GA_3 was usually determined with rather unsatisfactory results: accuracy (RE%, intraday, −22 to −2%; interday, −21 to −9%) and precision (RSD%, intraday, 3.5−6.8%, 2.66−10.9%; interday, 4.4−10.8%, 1.73−11.95%),[18,31] whereas with this method, obvious improvements of accuracy (RE%, intraday −2.72 to −0.65%; interday −3.84 to −1.14%) and precision (RSD%, intraday, 0.52−0.66%; interday, 0.76−1.85%) for GA_3 were achieved.

To assess the effect of matrix in blank and real samples, corresponding investigations were performed (Table S1). Results for matrix effects (95.5−103.9%) showed that no obvious interference was caused by blank matrices. Meanwhile, satisfactory recovery (96.1−104.4%) indicated an insignificant effect of real sample matrix on analytes. Therefore, this method was almost not affected by coexistent components, revealing its high selectivity for PGRs.

In addition, stability was studied. From Table S2 it can be found that the loss of PGRs (particularly for GA_3) caused by light or temperature seems to be unavoidable. Meanwhile, a short-term experiment showed the obviously low RE% relative to long term. In view of these facts, it was reasonable to have extraction and quantification finished as soon as possible with analyte being protected. In practice, the rapid experimental process of MAED saved much time, thereby reducing the susceptibility of analytes. Moreover, when PGRs were derivatized, the RE% values were improved, particularly for GA_3, with a significant improvement from −9.91 to −2.70%, indicating the protective effect of MAED pretreatment on labile analyte. Besides, comparing RE% values in 4 °C with those in −20 °C, the storage temperature of 4 °C should be beneficial for all stock solutions and samples.

Method Development and Comparison. Comparisons between previous and present methods are listed in Table S3. GC-MS was usually applied for PGR detection,[21,22] but the elevated temperature was disadvantageous to labile GA_3.[38,39] SPE, LLME, ultrasonic-assisted extraction (UAE), and MAE integrated with LC-MS[17,18,23,27,30−35] were widely used, providing low detection limits but meanwhile needing multiple operations with rather long time (2.5 h−1.5 days). Complicated operations tended to cause high system errors, as poor recoveries for labile GA_3 were usually observed.[18,27,31,33] Among the reported methods, HPLC-FLD with derivatization technique provided more accurate determination with excellent recoveries,[24,36,37] probably because of the stabilizing effect of derivatization (see Table S2). In the present work, instead of using conventional SPE or LLME, this method is improved by integrating the extraction and derivatization in a closed Teflon vessel, thus allowing the pretreatment to be finished with a facile operation in 1.5 h. Moreover, the microwave oven can contain 10 Teflon vessels at least, which makes this method more suitable for batch analysis than conventional 10 sets of instruments equipped with an oil bath or a sand bath, demonstrating the remarkable capacity, efficiency, and convenience relative to conventional methods.[17−37] With the derivatization technique, the detection limits are improved and, more importantly, labile analytes can be stabilized via the molecular modification. Nevertheless, in view of the susceptibility of GA_3, further identification by online MS/MS was followed. As shown in Figure S2, a molecular ion peak (m/z 641.0) and specific fragment ion peaks (m/z 295.7, 346.3, and 374.1) identified the DDCETS-derivatized GA_3. No impurity but excessive probe was observed, showing the good selectivity

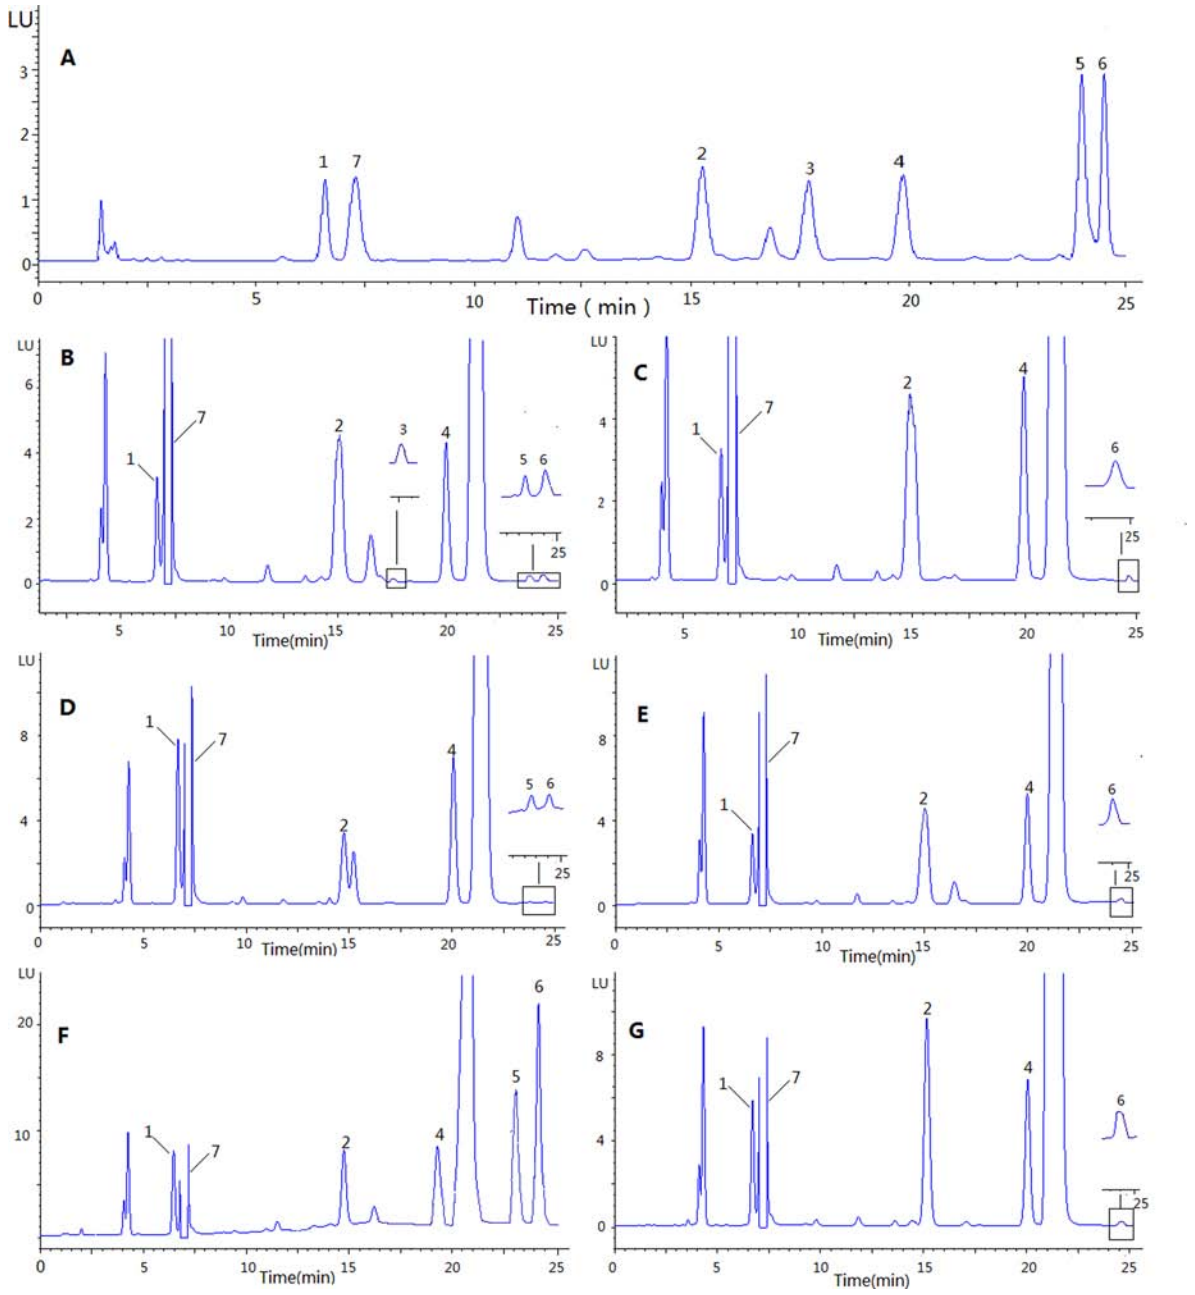

Figure 3. Typical chromatograms for PGR standards (A), nontransgenic soybean oil (B), transgenic soybean oil (C), nontransgenic sunflower oil (D), transgenic sunflower oil (E), nontransgenic rapeseed oil (F), and transgenic rapeseed oil (G). Peaks: 1, gibberellin A_3 (GA_3); 2, indole-3-acetic acid (IAA); 3, indole-3-propionic acid (IPA); 4, indole-3-butyric acid (IBA); 5, 1-naphthaleneacetic acid (1-NAA); 6, 2-naphthaleneacetic acid (2-NAA); 7, excessive DDCETS.

of this method. Thus, the proposed MAED-HPLC-FLD-MS method proved to be more powerful for the accurate, rapid, and convenient determination of PGRs.

Sample Analysis. The developed method was applied to the simultaneous determination of six PGRs in edible oil samples including transgenic and nontransgenic soybean oil, sunflower oil, and rapeseed oil. Chromatography is shown in Figure 3, and PGRs contents are summarized in Table 3. Overall, remarkable differences were observed between transgenic and nontransgenic samples: 1-NAA was detected only in nontransgenic samples; IPA was detected only in transgenic rapeseed oil and nontransgenic soybean oil samples; GA_3, IAA, IBA, and 2-NAA were found in all of the samples at different contents. In the signal transduction system, release of component depends on the PGRs in biosynthesis. GA_3 promoted production of α-amylase, thereby regulating the content of sugar; thus, its higher level in nontransgenic samples (rapeseed oil, 8.86 μg g^{-1}; sunflower oil, 7.66 μg g^{-1}) should be consistent with the fact that nontransgenic foods contained higher levels of sugar than transgenic foods.[47,48] Serine was adjusted by IAA; thus, its contents in transgenic rapeseed oil, nontransgenic soybean oil, and transgenic sunflower oil would be higher.[11] NAA was much higher in nontransgenic rapeseed oil than in the other samples, probably indicating the higher content of fatty acid in the nontransgenic rapeseed.[49] Transgenic food has been criticized and unrecognized, but

this study reflects the advantages of nontransgenic food as well as transgenic foods in terms of some nutrients. Consequently, PGR-induced nutrient variation is promising to be an important index for the objective evaluation of transgenic foods.

On the other hand, for transgenic foods, what should be explored is which and how many genes are directly or indirectly modified. As the ending point of the signal transduction system, variations of genetic trait and composition are reflected by PGRs.[3−5] GA_3 was biosynthesized with the aid of two essential genes (copalyl pyrophosphate synthase and ent-kaurene synthase); thus, its higher levels in nontransgenic samples (rapeseed oil, 8.86 $\mu g\ g^{-1}$; sunflower oil, 7.66 $\mu g\ g^{-1}$) indicated these two genes would decrease after the plant was gene-modified.[10] Similarly, tryptophan monooxygenase and indoleacetamide hydrolase were higher in transgenic rapeseed oil.[12,50] IPA was found in transgenic rapeseed oil (0.03 $\mu g\ g^{-1}$) and nontransgenic soybean oil (0.018 $\mu g\ g^{-1}$), implying that the tryptophan aminotransferase genes in transgenic rapeseed and nontransgenic soybean were relatively higher.[14] The higher IBA level in nontransgenic rapeseed oil (3.79 $\mu g\ g^{-1}$), transgenic soybean oils (2.16 $\mu g\ g^{-1}$), and nontransgenic sunflower oils (2.88 $\mu g\ g^{-1}$) might indicate the higher content of glutamate-γ-semialdehyde participating in the biosynthesis of IBA via the tryptophan pathway.[13] Therefore, the results might reflect the PGR-induced genetic variation in addition to artificial gene modification, which is an added benefit of PGRs determination.

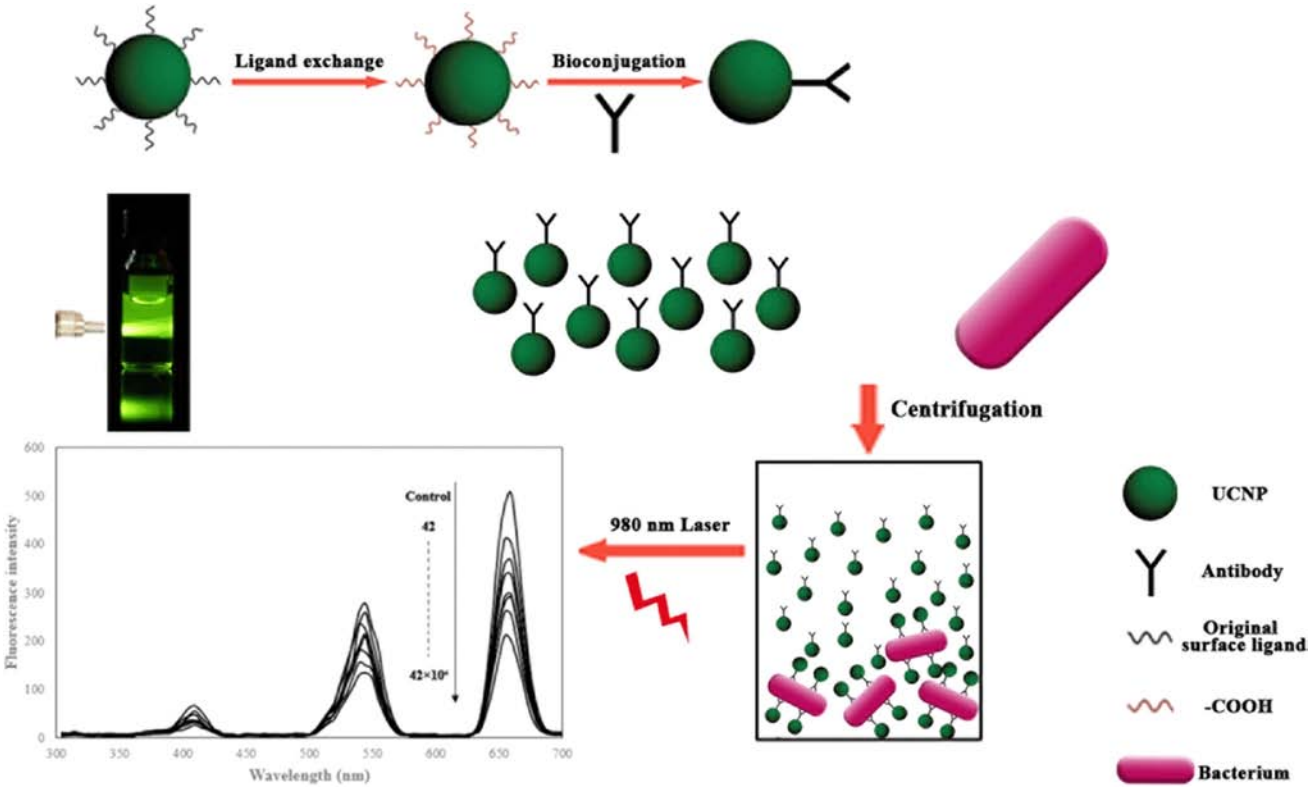

Figure 1. Scheme of this proposed fluorescence bioassay platform.

UCNPs have low toxicities in vitro and in vivo, which are therefore suitable for biological applications.[30,31]

The main objective of this study was to develop a photostable and selective fluorescent probe for rapidly sensing pathogens in food. Figure 1 presents the scheme of this proposed fluorescence bioassay platform. Specific procedures are outlined as follows. (1) Upconversion nanoparticles (UCNPs) were synthesized and functionalized. (2) The resultant water-soluble UCNPs were conjugated with anti-*E. coli* antibodies to produce biological fluorescent probes. (3) A fluorescence standard curve was prepared with different concentrations of *E. coli*. (4) Independent food samples were tested. As an efficient, specific, and technically simple biological probe, these selective sensors can be used for rapidly detecting pathogens in food.

MATERIALS AND METHODS

Reagents. The rare earth salts used in this work, including YCl_3, $YbCl_3$, and $ErCl_3$, were of 99.99% purity and were purchased from Aladdin Industrial, Inc. (Shanghai, China). Methanol, ethanol, oleic acid, 1-octadecene, cyclohexane, toluene, sodium citrate, diethylene glycol, 1-ethyl 3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC), tryptone, beef extract, NaCl, agar, NH_4F, and NaOH were of analytical grade and were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). *N*-Hydroxysuccinimide (NHS) was obtained from Adamas Reagent Co., Ltd. (Shanghai, China). *E. coli* strain O157:H7 (NCTC 12900-2) was purchased from American Type Culture Collection (Manassas, VA), and the corresponding anti-*E. coli* antibody (ab75244) was purchased from Abcam Co., Ltd.

Instruments. X-ray diffraction (XRD) measurements were performed using a D8-advance instrument (Bruker AXS, Ltd.). The size and morphology of UCNPs, UCNP antibodies, and UCNP antibody−*E. coli* complexes were determined using a JEM-2100HR transmission electron microscope (TEM, JEOL, Ltd.) operated at 200 kV. Upconversion fluorescence spectra were measured using a Cary Eclipse fluorescence spectrophotometer (Varian Inc.) modified with an external 0−1300 mW adjustable continuous wave 980 nm laser (Beijing Hi-Tech Optoelectronic Co., Beijing, China). Fourier transform infrared (FT-IR) spectra were obtained using a Nicolet Nexus 470 Fourier transform infrared spectrophotometer (Thermo Electron Co.) with the KBr method.

Synthesis of Water-Soluble Upconversion Nanoparticles (UCNPs). Oleic acid-capped $NaYF_4$:Yb,Er UCNPs were synthesized according to the method reported in refs 32−34 with a few modifications. In a typical experiment, 2 mL of $RECl_3$ [0.2 M; RE = Y (78%), Yb (20%), or Er (2%)] in methanol was added to a 50 mL flask containing 3 mL of oleic acid and 7 mL of 1-octadecene. The prepared solution was heated to 160 °C for 30 min and cooled to room temperature. Thereafter, 5 mL of a methanol solution of NH_4F (1.6 mmol) and NaOH (1 mmol) was added, and the solution was stirred for 30 min. After the methanol evaporated, the solution was heated to 300 °C under argon for 1.5 h and cooled to room temperature. The resulting nanoparticles were precipitated by the addition of ethanol, collected by centrifugation, washed with methanol and ethanol several times, and finally dried in an oven at 60 °C.

The obtained oleic acid-capped UCNPs dispersed well in nonpolar solvents. However, for biological applications, hydrophilic UCNPs are required for compatibility with biomolecules,[35] such as antibodies. Hydrophobic UCNPs were surface-modified via a ligand exchange process as described in ref 20. Briefly, a mixture of 2 mmol of sodium citrate in 15 mL of diethylene glycol was first heated to 110 °C under argon for 30 min. Oleic acid-capped UCNPs (10 mg) were dispersed in cyclohexane. Toluene was added to the mixture, and the reaction mixture was heated to 160 °C to evaporate the cyclohexane and toluene. After the evaporation, the reaction mixture was further maintained at 160 °C for 3 h. Subsequently, water-soluble UCNPs were collected by centrifugation, washed with ethanol and ultrapure water several times, and finally dispersed in ultrapure water.

Bioconjugation of UCNPs with Anti-*E. coli* Antibodies. The bioconjugation of UCNPs with anti-*E. coli* antibodies was performed by EDC/NHS linking chemistry. Here, UCNPs (5 mg/mL in water) were activated with EDC (25 μL, 2 mg/mL) and NHS (12.5 μL, 2

DOI: 10.1021/acs.jafc.5b02331
J. Agric. Food Chem. 2015, 63, 8068−8074

mg/mL) for approximately 3 h at room temperature. The activated UCNPs were purified by centrifugation at 9350*g* for 15 min and redispersed in ultrapure water. Subsequently, 50 μg of anti-*E. coli* antibody was incubated with 1 mg of activated UCNPs. After being shaken overnight at 4 °C, unbound UCNPs were removed by centrifugation at 6000*g* for 5 min at 4 °C. The bioconjugated particles were washed once with ultrapure water and then redispersed in ultrapure water. The centrifugation parameters, i.e., 6000*g* for 5 min, were optimized in preliminary tests with purely water-soluble UCNPs. The obtained UCNP antibody precipitates were validated by FTIR spectra measurements.

Immunoassay Procedure. *Bacterial Culture and Preparation.* Stock cultures of *E. coli* (NCTC 12900-2) were inoculated and grown in Luria-Bertani (LB) medium for 24 h at 37 °C. The cultures were pelleted by centrifugation at 5000*g* for 5 min, washed twice with ultrapure water, and redispersed in ultrapure water. Thereafter, serial 10-fold dilutions were prepared in ultrapure water to produce various concentrations [$1-10^8$ colony-forming units (cfu)/mL] of bacteria. Bacterial counts were determined using the colony counting method.

Capturing Bacteria with UCNP Antibody Probes. The UCNP–antibody (100 μL, 1 mg/mL) probes were mixed with various concentrations ($1-10^8$ cfu/mL) of bacteria and incubated for 2 h at 37 °C with agitation. As a control, 500 μL of ultrapure water was also treated. Thereafter, the reaction suspensions were pelleted by centrifugation at 5000*g* for 5 min to separate redundant UCNP–antibody probes. The resulting supernatants were used to monitor changes in emission fluorescence intensity.

Fluorescence Spectral Measurement. The fluorescence spectra of the obtained supernatants (from 400 to 700 nm) were measured with a fluorescence spectrophotometer equipped with a 980 nm excitation laser at 1.3 W. The intensity differences ($\Delta I = I_0 - I$) between the supernatants and the control (I_0) were used to generate a standard curve against the bacterial concentration (log cfu/mL). Here, the 657 nm peak intensity emission wavelength was used.

RESULTS AND DISCUSSION

Characterization. In this work, bacterium-specific antibodies with high selectivity and sensitivity were conjugated onto the surface of UCNPs to yield UCNP–antibody probes, as illustrated in Figure 1. Prior to the conjugation, the precursor UCNPs were first characterized by X-ray diffraction (XRD), as shown in Figure 2. Here, the diffraction peaks of the XRD pattern were identified as pure hexagonal β-phase $NaYF_4$ crystals (JCPDS Standard Card No. 16-0334); no diffraction peaks corresponding to cubic phase crystals or other impurities were observed. Furthermore, successful bioconjugation, selectivities, sizes, and luminance and spectral properties of UCNPs before and after surface modification were validated by transmission electron microscopy (TEM) and by fluorescence spectral measurements, as presented in Figure 3. The TEM images confirmed the hexagonal UCNP structures and revealed that the particles were uniform with an average diameter of approximately 50 nm before and after surface modification and bioconjugation. The fluorescence spectra of the UCNPs showed the expected characteristic emission peaks at approximately 407, 542, and 657 nm upon NIR (980 nm) excitation, corresponding to blue, green, and red light, respectively (the naked-eye images in the inset show the visible intensity of the UCNPs). The peaks are ascribed to the transitions from the $^2H_{9/2}$, $^4S_{3/2}$, and $^4F_{9/2}$ levels to the $^4I_{15/2}$ ground state of the Er^{3+} ion.[36−38] Additionally, the fluorescence properties were also retained, as both the UCNP antibodies and the UCNPs showed the same characteristic emission peaks upon NIR excitation. When mixed with bacteria, the fluorescence intensity of the supernatant decreased, as shown in Figure 3D. The inset TEM image shows electron-dense dark spheres with diameters of approximately 50 nm, which correspond to the sizes of the UCNPs; these spheres decorated the outer surface of the bacterial cells. Negligible intensity signals were observed within the cytoplasm of the UCNP-labeled bacteria, indicating that the UCNPs were not internalized.

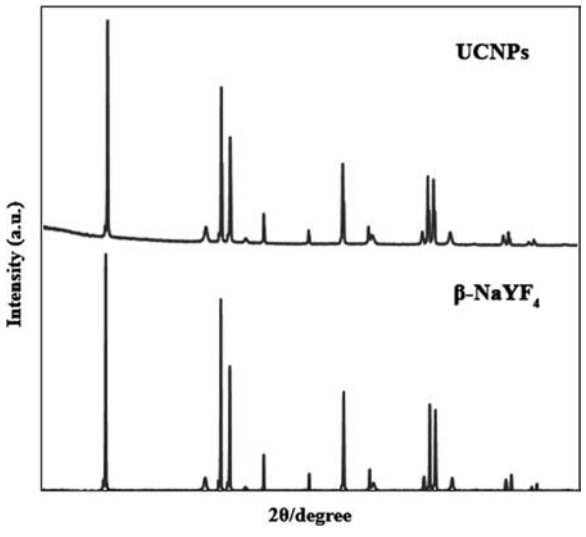

Figure 2. X-ray diffraction (XRD) pattern of oleic acid-capped UCNPs.

Figure 4 displays the Fourier transform infrared (FT-IR) spectra of UCNPs (A), UCNP–antibody probes (B), and UCNP–antibody–bacterium complexes (C), confirming the presence of antibodies on the UCNPs and the presence of UCNP–antibody probes on the bacteria. The water-soluble UCNPs presented with a single broad peak at 3427 cm^{-1}, corresponding to the stretching vibration of hydroxide radicals (-OH). The characteristic peak at 1629 cm^{-1} is related to the asymmetric stretching vibration of carboxyl groups (-COOH) of the citrate ligands on the surface of the UCNPs. These two peaks indicated that the carboxyl groups from the ligand exchange were successfully modified on the surface of UCNPs to produce water-soluble UCNPs. When the EDC/NHS-prepared antibodies were introduced, three characteristic peaks at 2360, 2335, and 1396 cm^{-1} appeared. The peaks at 2360 and 2335 cm^{-1} corresponded to methylene stretching vibrations ($-CH_2-$). The peak at 1396 cm^{-1} corresponded to carboxyl stretching vibrations (COO-) due to the linking reaction between the water-soluble UCNPs and the antibodies. Furthermore, a new peak was observed at 1540 cm^{-1} upon comparison of the spectra of the UCNP–antibody–bacterium complex and the UCNP–antibody probe; this peak is attributed to the distinct amide I and amide II vibration modes characteristic of bacterial proteins and peptides.

On the basis of these characterizations, the proposed UCNP-based method is suitable for sensing bacteria.

Evaluation of Specificity. To evaluate the specificity of the fluorescent probe for *E. coli*, two commonly encountered foodborne pathogens, *Staphylococcus aureus* (ATCC 25923) and *Salmonella typhimurium* (ATCC 14028), were tested. The results are shown in Figure 5 (the concentrations of these bacteria were 10^2 cfu/mL, and the figure was plotted with a peak intensity at 657 nm). Both *S. aureus* and *Sa. typhimurium* induced negligible changes in the fluorescence intensity,

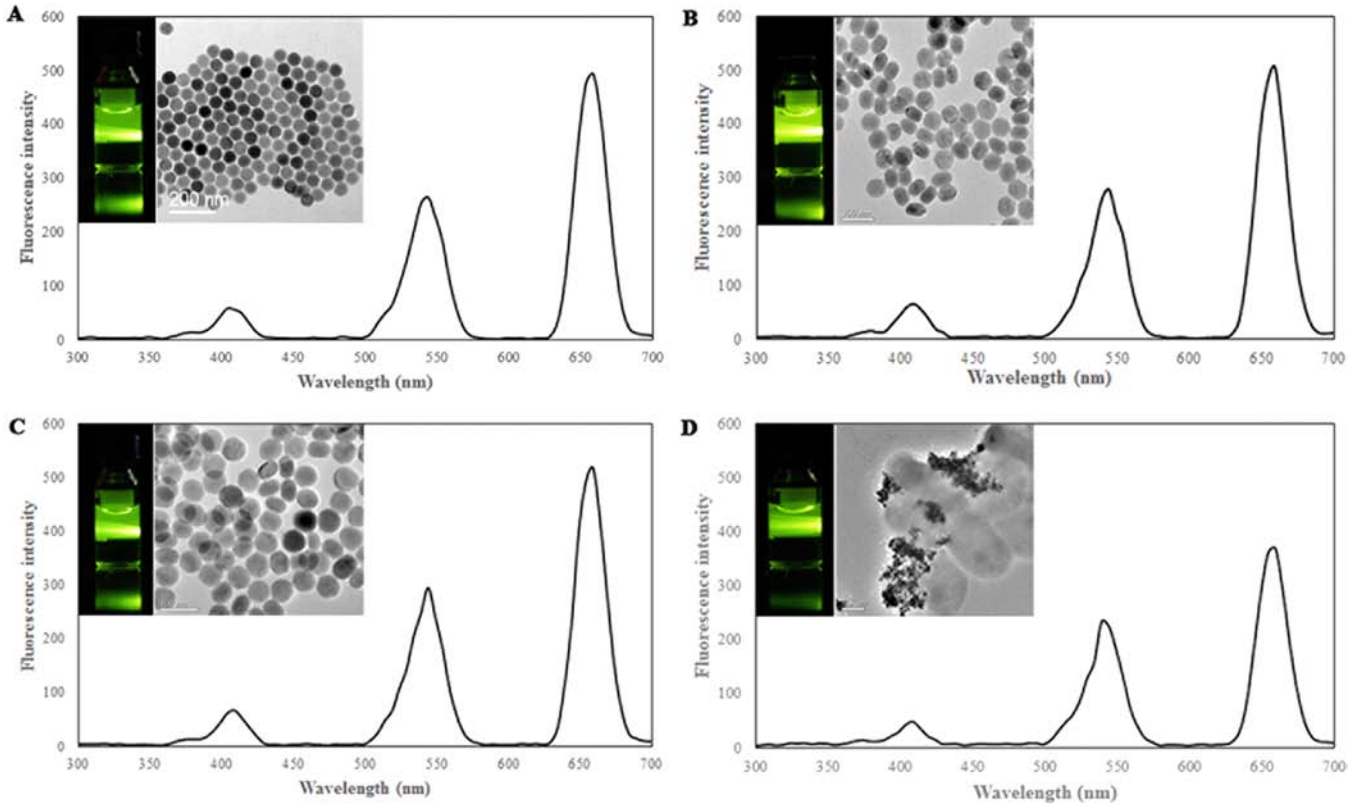

Figure 3. Fluorescence properties of oleic acid-capped UCNPs (A), water-soluble UCNPs (B), bioconjugated UCNPs (C), and UCNP−antibody−bacterium complexes (D). Insets show naked-eye photographs and TEM images of particles.

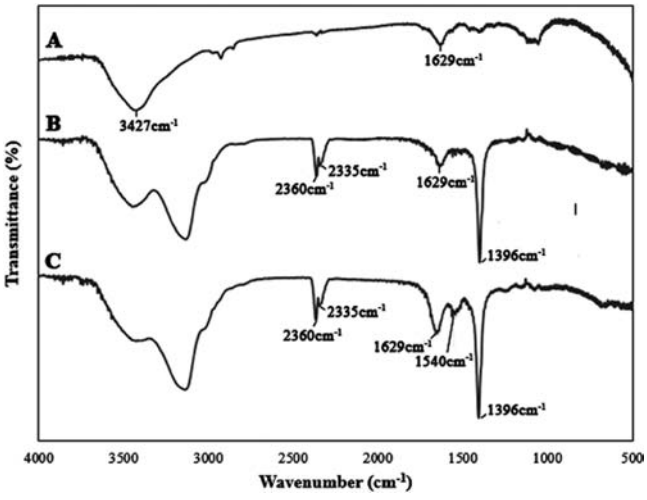

Figure 4. Fourier transform infrared (FT-IR) spectra of UCNPs (A), UCNP−antibody probes (B), and UCNP−antibody−bacterium complexes (C).

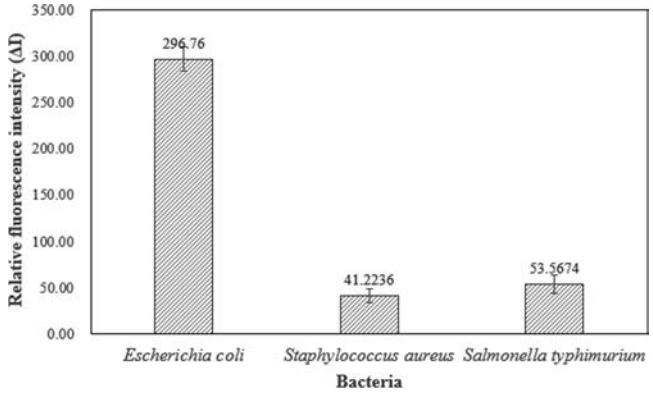

Figure 5. Specific selectivity evaluation of the proposed method for *E. coli* (10^2 cfu/mL) against other bacteria (10^2 cfu/mL).

whereas a significant change was observed for *E. coli*. These results show the specificity of the designed fluorescent probe for *E. coli*.

Bacterial Detection. In a typical experiment, different concentrations of *E. coli* were incubated under agitation with the UCNP−antibody probes for 2 h at 37 °C. On the basis of the specificity of the antibody for the bacteria, UCNP−antibody−bacterium complexes were formed. The samples were subsequently concentrated and separated by centrifugation at 5000*g* for 5 min to separate the unbound UCNP−antibody probes. The centrifugation parameters were previously optimized to maximize the separation of the complex without disrupting the UCNP−antibody probes.

Thereafter, serial dilutions of the supernatants were prepared to examine the fluorescence spectra of the complexes. The 657 nm emission peak was used to monitor the *E. coli* concentration. In the absence of bacteria (i.e., the control), the fluorescence intensity of the supernatant was at a maximum. In the presence of bacteria, the decrease in the fluorescence intensities (ΔI) of the supernatants varied proportionally with the concentration of bacteria. Selections of fluorescence spectra of bacterium-containing supernatants (log cfu/mL) are shown in Figure 6; the fluorescence intensity rapidly decreased as the *E. coli* concentration increased from 42 to 42 × 10^6 cfu/mL. A strong linear correlation (R^2 = 0.9802) was obtained between

UCNPs	42–42×10^6	10	this work

the relative intensity of the upconversion fluorescence and the concentration of *E. coli*: $\Delta I = 31.044c + 52.39$ (c = log cfu/mL). The sensitivity of the developed immunoassay was also investigated. The limit of detection (LOD) is defined as LOD = $3S_0/K$, where S_0 is the standard deviation of n control measurements (n = 10) and K is the slope of the calibration graph. In this work, the LOD of the proposed *E. coli*-sensing method was 10 cfu/mL. The total detection time from the addition of the fluorescent probes to the detection solution to obtaining the final result was <3 h (the water-soluble UCNPs can be produced on a large scale because of their high photostability and stored under appropriate conditions).

Analytical Performance. For comparative purposes, the linear ranges and LODs of several fluorescence-based capturing methods for detecting pathogens are summarized in Table 1. The proposed UCNP-based method has a relatively low LOD compared with those of conventional fluorescence-based capturing methods. Conventional fluorescent dyes are subject to photobleaching, photodamage, and autofluorescence issues; QDs also generate background autofluorescence because a shorter excitation wavelength is used to excite the nanoparticles. The proposed method has overcome these problems and provides a wider detection range and higher sensitivity. Additionally, fluorescent dyes based on antibody–antigen interactions typically achieve better selectivity but cannot be prepared on large scales because of photobleaching and photodamage.[44] The prepared UCNPs had reduced photodamage and prolonged photostability, i.e., properties suitable for industrial processing.

Analytical Applications. To further evaluate the feasibility and reliability of the proposed UCNP-based method for practical applications, the designed fluorescent probes were used to detect *E. coli* in solid (pork) and liquid (milk) samples adulterated with specific amounts of *E. coli*. Prior to probing, a series of pretreatment procedures were performed. For the milk samples, 5 mL of each sample was centrifuged at 7000*g* for 10 min at 10 °C. The upper layer of cream was removed, and the milk was diluted with distilled water at a 1:20 ratio. Finally, the

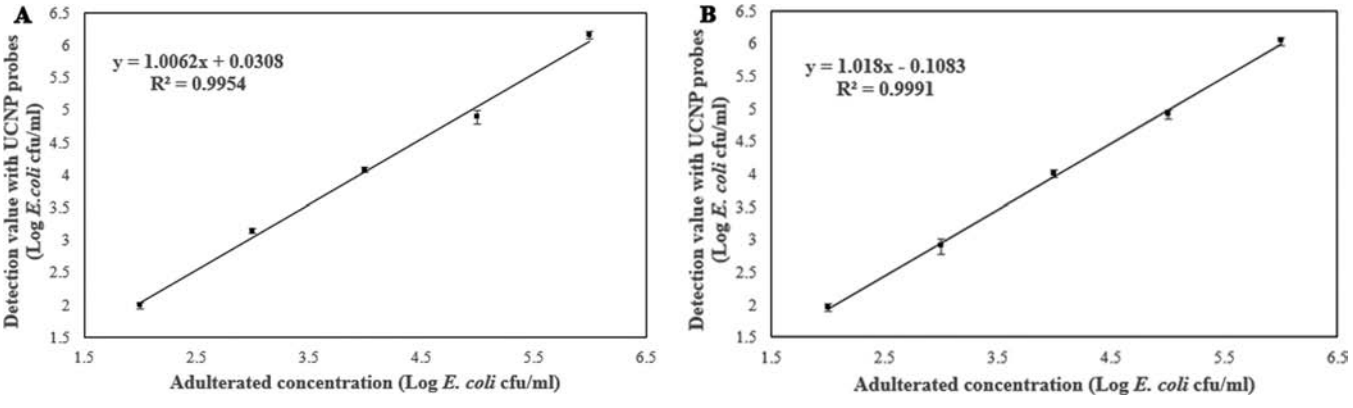

Figure 7. Standard graphs for detecting *E. coli* in milk (A) and pork (B) samples using the proposed UCNP-based method.

DOI: 10.1021/acs.jafc.5b02331
J. Agric. Food Chem. 2015, 63, 8068–8074

supernatant was filtered with a disposable syringe filter holder. For the pork samples, 25 g of pork was aseptically dipped in 225 mL of alkaline peptone with 3% (w/v) NaCl, homogenized for 5 min, and allowed to stand for 30 min to precipitate macroaggregates and seston. Finally, the supernatant was filtered through a 0.45 μm filtration membrane. After these pretreatment steps, both the pretreated and raw adulterated samples were probed using the UCNP-based probes. As shown in Figure 7, the results were similar and highly correlated. This confirmed that the proposed detection method using fluorescent probes can be applied to the detection of bacteria in real samples.

In this study, sensitive fluorescent probes consisting of upconversion nanoparticles conjugated with antibodies were prepared for the rapid detection of bacterial contaminants in food. The fluorescence intensity decreased as the concentration of *E. coli* increased. A linear relationship was established with a correlation coefficient (R^2) of 0.9802 and a LOD of 10 cfu/mL, which significantly expanded the detection range compared with those of other biological labeling methods. The proposed biosensing method can be easily adopted for the detection of other bacterial pathogens by substituting specific antibodies for those pathogens. This novel fluorescent probe, as an efficient, specific, and technically simple biological probe, provides a convenient, sensitive, and stable platform for biological applications.

1−40 mg/kg in horticultural crops in Japan. Thus, a new strategy was examined to develop an adequate sensitive immunoassay for the analysis of boscalid residues in horticultural crops.

In this study, the synthesis of a new hapten, preparation of monoclonal antibodies (MoAb's) to boscalid, methodologies of the direct competitive enzyme-linked immunosorbent assay (dc-ELISA) and SPR-sensor, and comparison of the dc-ELISA and SPR-sensor (using the same MoAb) for determination of boscalid in horticultural crops are described.

MATERIALS AND METHODS

Materials. Boscalid, benalaxyl, fenhexamid, pencycuron, and tecloftalam, which were of analytical grade for pesticide residue analysis, *N*-hydroxysuccinimide, and keyhole limpet hemocyanin (KLH) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Bovine serum albumin (BSA; product no. A7888), hypoxanthine−aminopterin−thymidine (HAT) medium supplement, and polyethylene glycol (molecular weight 1450) solution were purchased from Sigma-Aldrich Co. (St. Louis, MO). 1-Ethyl-3-(3-(dimethylamino)propyl)carbodiimide hydrochloride (EDC) was purchased from Dojindo Molecular Technologies, Inc. (Kumamoto, Japan). Dichloromethane (CH_2Cl_2) was purchased from Kanto Chemical Co., Inc. (Tokyo, Japan). Sodium dodecyl sulfate (SDS), guanidine hydrochloride (GdnHCl), and RPMI 1640 medium were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Fetal bovine serum (FBS) was purchased from PAA Laboratories, GmbH (Pasching, Austria). Ninety-six-well microplates for cell culture (Nunc), 96-well microtiter plates for ELISA (Nunc MaxiSorp), and horseradish peroxidase (HRP)-labeled antimouse IgG (H+L) antibody from rabbit (Invitrogen) and antimouse IgG (H+L) antibody from goat (Pierce) were purchased from Thermo Fisher Scientific K.K. (New York). HRP was purchased from Toyobo Co. Ltd. (Osaka, Japan). Freund's complete adjuvant and incomplete adjuvant (Difco) were purchased from Becton, Dickinson and Co. (Franklin Lakes, NJ). All other chemicals and reagents used were of analytical grade and were purchased from Wako Pure Chemical Industries, Ltd. or Nacalai Tesque, Inc.

Hapten Synthesis. *General Procedure.* Unless otherwise noted, all reactions were performed under an atmosphere of argon. All reactions were monitored by thin-layer chromatography (TLC) on glass plates precoated with silica gel in a layer thickness of 0.2 mm (60 F_{254}) from Merck KGaA (Darmstadt, Deutschland). The products were visualized by irradiation with UV light, by treatment with a solution of phosphomolybdic acid, or by treatment with a solution of *p*-anisaldehyde. Flash column chromatography was performed using silica gel (art. no. 7734) from Merck KGaA. ^{1}H NMR (500 and 400 MHz) and ^{13}C NMR (125 and 100 MHz) spectra were recorded on JEOL JNM-ECX500 and JEOL JNM-ECS400 spectrometers. Chemical shifts are reported as δ values (ppm) relative to $CDCl_3$ (7.26 ppm). Elemental analyses were performed on a Yanaco CHN CORDER MT-6 analyzer. Optical rotations were performed with a JASCO P-1030 polarimeter at the sodium D line (1.0 mL sample cell). DART (direct analysis in real time) mass (positive mode) analyses were performed on an LC-TOF JMS-T100LP spectrometer.

*Synthesis of 2-Chloro-N-(2-iodophenyl)pyridine-3-carboxyamide (**3**).* A solution of chloronicotinoyl chloride (**1**) (704.0 mg, 4.0 mmol) in CH_2Cl_2 (20 mL) was stirred into a mixture of 2-iodoaniline (**2**) (876.1 mg, 4.0 mmol) and Et_3N (836 μL, 6.0 mmol, d = 0.73) in CH_2Cl_2 (4 mL) for over 15 min at 0 °C. The resulting mixture was stirred at room temperature for an additional 2 h. Then the solvent was removed under reduced pressure. The residue was purified by column chromatography on a silica gel that was eluted with a hexane and ethyl acetate mixture (2:1, v/v) to give the desired product **3** (603.4 mg) in 42% yield: ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.56 (dd, 1H, J = 4.88, 1.83 Hz, H-6 Py), 8.43 (br s, 1H, NH), 8.38 (d, 1H, J = 8.24 Hz, H-4 Py), 8.23 (dd, 1H, J = 7.63, 1.83 Hz, H-6 Ph), 7.86 (dd, 1H, J = 8.10, 1.34 Hz, H-3 Ph), 7.41−7.45 (m, 2H, H-5 Py, H-5 Ph), and 6.94 (dt, 1H, J = 7.63, 7.63, 1.53 Hz, H-4 Ph) ppm.

*Synthesis of the Boscalid Hapten Precursor Methyl 2′-(2-Chloronicotinamido)biphenyl-4-carboxylate (**5**).* A mixture of product **3** (179.3 mg, 0.5 mmol), 4-(methoxycarbonyl)phenylboronic acid (**4**) (90.0 mg, 0.5 mmol), $(Ph_3P)_4Pd$ (28.9 mg, 0.0025 mmol), and K_2CO_3 (207.3 mg, 1.5 mmol) in anhydrous *i*-PrOH (6.3 mL) was degassed and exchanged with Ar.[42] The resulting mixture was heated to 50 °C for 2 h and 100 °C for 21 h with stirring. The suspension was then cooled to room temperature and filtered. The solvent was removed under reduced pressure, and the residue was purified by column chromatography on silica gel that was eluted with a hexane and ethyl acetate mixture (2:1 to 1:1, v:v). At this stage, the isopropyl ester produced as a side reaction product was a contaminant, and therefore, the mixture of methyl ester and isopropyl ester was repurified and eluted with a chloroform and acetone solution (30:1, v/v) to give the desired precursor **5** (27.5 mg) in 15% yield: ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.41 (dd, 1H, J = 4.59, 1.91 Hz, H-6 Py), 8.38 (d, 1H, J = 8.03, H-3′ Ph), 8.19 (br s, 1H, NH), 8.09−8.11 (m, 3H, H-4 Py, H-3 and H-5 Ph), 7.47−7.51, 7.29−7.34 (m, 6H, H-5 Py, H-2 and H-6 Ph, H-4′ and H-5′ and H-6′ Ph), and 3.93 (s, 3H) ppm. ^{13}C NMR (125 MHz, $CDCl_3$) δ 166.5, 162.5, 151.2, 146.6, 142.6, 140.0, 134.1, 132.5, 131.0, 130.2, 130.0, 129.8, 129.5, 129.1, 125.4, 122.8, 122.3, and 52.3 ppm; IR (neat) ν 3279, 3045, 1714, and 1676 cm^{-1}; HRMS (DART) m/z calcd for $C_{20}H_{16}ClN_2O_3$ (M + 1$^+$) 367.0849, found 367.0850.

*Boscalid Hapten, 2′-(2-Chloronicotinamido)biphenyl-4-carboxylic acid (**6**).* To a solution of boscalid hapten precursor **5** (36.8 mg, 0.1 mmol) in CH_3OH (1.3 mL) was added a solution of NaOH (40.0 mg, 1.0 mmol) in H_2O (0.5 mL) at 0 °C. The mixture was stirred for 3 h at room temperature and then acidified with a 1 N HCl solution to pH 2.0. The solvent was removed, and the residue was washed with tetrahydrofuran. The tetrahydrofuran mixture was concentrated to give the desired hapten **6** (23.7 mg) in 67% yield: ^{1}H NMR (500 MHz, CD_3OD) δ 8.41 (dd, 1H, J = 4.97, 1.91 Hz, H-6 Py), 8.07−8.10 (m, 2H, H-3 and H-5 Ph), 7.77 (dd, 1H, J = 7.64, 1.91 Hz, H-4 Py), 7.64 (d, 1H, J = 7.64 Hz, H-6′ Ph), 7.55−7.57 (m, 2H, H-2 and H-6 Ph), 7.47−7.51 (m, 1H, H-5′ Ph), and 7.42−7.44 (m, 3H, H-5 Py, H-3′ and H-4′ Ph) ppm; ^{13}C NMR (125 MHz, $CDCl_3$) δ 174.0, 167.1, 151.5, 148.4, 143.0, 139.5, 139.2, 136.5, 134.6, 133.9, 131.5, 130.5, 129.8, 129.5, 128.6, 128.4, and 124.1 ppm; HRMS (DART) m/z calcd for $C_{19}H_{14}ClN_2O_3$ (M + 1$^+$) 353.0693, found 353.0657; IR (neat) ν 3417 and 1644−1660 cm^{-1}.

Preparation of the Hapten−Protein Conjugate. The synthesized hapten was conjugated with proteins (KLH, BSA, or HRP) by the activated ester method as described previously.[23] In brief, 100 μL of the hapten (5 μmol) in anhydrous dimethyl sulfoxide was mixed with 5 μL of *N*-hydroxysuccinimide (6 μmol) and 10 μL of EDC (6 μmol) in anhydrous dimethyl sulfoxide, and the mixture was allowed to stand at room temperature for 1.5 h. Then 1 mL of each of the proteins (10 mg) dissolved in 10 mmol/L PBS (10 mmol/L phosphate buffer and 150 mmol/L NaCl, pH 7.0) was added to the mixture, which was then gently stirred for 1.5 h. The hapten−KLH conjugate and the hapten−BSA conjugate were respectively dialyzed in 10 mmol/L PBS, whereas the hapten−HRP conjugate was purified through gel filtration chromatography. The hapten−KLH conjugate was emulsified with an equal volume of Freund's complete adjuvant or incomplete adjuvant for use in mouse immunization and booster immunization, respectively. The hapten−BSA conjugate was used for the indirect ELISA (i-ELISA), indirect competitive ELISA (ic-ELISA), and SPR-sensor experiments. The hapten−HRP conjugate was used for the dc-ELISA.

Preparation of Monoclonal Antibodies. MoAb's were prepared as described previously.[23] In brief, Balb/c mice (7 week old females) purchased from Japan SLC, Inc. (Shizuoka, Japan) were immunized with 100 μL of the hapten−KLH conjugate (100 μg/mouse) in Freund's complete adjuvant. After 1 month, the booster immunization was performed twice at 2 week intervals using 100 μL of the hapten−KLH conjugate (25 μg/mouse) in Freund's incomplete adjuvant. After 3 days from the last immunization, spleen cells of the mice were

DOI: 10.1021/acs.jafc.5b03637
J. Agric. Food Chem. 2015, 63, 8075−8082

collected and prepared for cell fusion with P3-X63-AG8.653 myeloma cells (5.5×10^7 cells) using polyethylene glycol solution. The fused cells were suspended at 8×10^5 cells/mL in HAT medium (RPMI 1640 medium, 10% FBS, and HAT medium supplement) and transferred to 96-well microplates. After incubation at 37 °C for 7−10 days, colonies secreting antiboscalid MoAb's were identified by i-ELISA and ic-ELISA and picked up. The selected hybridoma cells were cloned by the limiting dilution method. Two MoAb's, BSC7 and BSC72, were purified from the ascite fluid by ammonium sulfate fractionation and anion-exchange chromatography. BSC7 showed the highest reactivity upon the ELISA screenings, whereas BSC72 was the representative MoAb among various MoAb's showing similar reactivity.

The mouse experiments were performed under the guidelines of the Animal Experiment Committee of Kyoto Women's University following bulletin no. 71 (2006) of the Ministry of Education, Culture, Sports, Science and Technology of Japan.

i-ELISA and ic-ELISA. The i-ELISA and ic-ELISA methods were conducted as described previously.[23] The specific conditions were that the hapten−BSA concentration was 1.0 μg/mL and the boscalid standard solution was prepared at concentrations from 0.6 to 2500 ng/mL in 10% methanol.

dc-ELISA. The dc-ELISA method was conducted as described previously.[23] Each well of a 96-well microtiter plate was coated overnight with 100 μL of antimouse IgG goat antibody (5 μg/mL) in 10 mmol/L PBS at 4 °C and then blocked for 1 h with 300 μL of 10 mmol/L PBS containing 0.4% BSA at 25 °C. One hundred microliters of purified MoAb BSC7 (500 ng/mL) or culture fluid containing MoAb BSC72 in 10 mmol/L PBS containing 0.2% BSA was added to the appropriate wells, and incubation was carried out at 25 °C for 1 h. The plate was washed once with washing buffer (10 mmol/L PBS containing 0.02% Tween 20). Each solution (150 μL) of boscalid (0.038−156 ng/mL), boscalid-related pesticides (10 μg/mL) used in a cross-reactivity test, and vegetable samples prepared in 10% methanol was mixed with an equal volume of the hapten−HRP conjugate (250 ng/mL) in 10 mmol/L PBS containing 0.2% BSA. The mixture (100 μL) was added to the wells of the plate for competitive reaction and incubated at 25 °C for 1 h. After the plate was washed three times with the washing buffer, 100 μL of the color development solution (100 μg/mL 3,3′,5,5′-tetramethylbenzidine, 0.006% H_2O_2, and 0.1 mol/L acetate buffer, pH 5.5) was added. After 10 min at 25 °C, 100 μL of 0.5 mol/L sulfuric acid was added to stop the color development reaction. The absorbance was measured at 450 nm with an xMark microplate reader (Bio-Rad Laboratories, Hercules, CA), so that the maximum absorbance reading was around 1.3.

SPR-Sensor. The SPR-sensors consisted of commercially available instruments of microflow type (Biacore T200; GE Healthcare Europe, Munich, Germany), and the sensor chips were coated with carboxymethyl dextran (CM5; GE Healthcare Europe). The sensor chips were functionalized via the following steps, based on the instruction manual.

Step 1: Preparation of the Sensor Chip for Boscalid. The sensor chip was placed in the instrument, and the surface was initially rinsed with 10 mmol/L PBS containing 0.005% Tween 20 at a rate of 5 μL/min for 600 s. It was activated by flushing with a mixture of 80 μL of EDC (400 mmol/L) and 80 μL of *N*-hydroxysuccinimide (100 mmol/L) in distilled water for 350 s. The hapten−BSA (40 μg/mL) solution dissolved in acetic acid buffer (10 mmol/L, pH 5.0) was then flowed through the system for 120 s to bind the chip's activated carboxyl groups to the amino group residues of hapten−BSA. This was followed by flowing ethanolamine (1 mol/L, pH 8.5) through the system for 350 s to block residual carboxy groups. After being rinsed with the running buffer (50 mmol/L phosphate buffer and 75 mmol/L NaCl, pH 7.0, containing 5% methanol and 0.1% BSA), the sensor chip was ready to be used.

Step 2: Preparation of the Samples. The boscalid solutions were serially diluted at final concentrations in the range of 2.4−3100 ng/mL in 10% methanol with distilled water. The other structurally related pesticides were prepared at 10 μg/mL. MoAb BSC7 was diluted to 15 μg/mL with 100 mmol/L PBS (100 mmol/L phosphate buffer and 150 mmol/L NaCl, pH 7.0) containing 0.2% BSA. The boscalid or other pesticide solution (75 μL) was mixed with an equal volume of MoAb BSC7 solution (75 μL) to form the pesticide−MoAb BSC7 complex. This mixture (final 5% methanol solution) was used for pesticide determination by the SPR-sensor.

Step 3: Determination of the Pesticides. The mixed solutions were flushed through the sensor system at 20 μL/min for 180 s to allow free MoAb BSC7 to bind with the hapten−BSA immobilized on the sensor surface. The solution was then changed to the running buffer, which was allowed to flow continuously at 20 μL/min for 180 s.

Step 4: Regeneration of the Sensor Surface. After the pesticide determination had been completed, the MoAb BSC7 was removed from the immobilized hapten−BSA in the following way. The sensor surface was initially washed with GdnHCl (3.0 mol/L) in acetic acid (1.0 mol/L, pH 1.9) at 20 μL/min for 60 s. After being rinsed with distilled water at 20 μL/min for 60 s, the sensor surface was washed with 0.2% SDS at 20 μL/min for 120 s, as described previously.[39] After the regeneration had been completed, the sensor chip was used again, repeating steps 2−4 described above.

Step5: Data Processing. Raw data were output as a resonance unit (RU), where 1000 RU was defined as a 0.1° refractive index shift by the SPR phenomenon. The actual response curve was drawn, where the *x*-axis represented the boscalid concentration and the *y*-axis represented the Δ(RU) between the starting point of the reaction and a time point of 180 s.

Treatment of Vegetable Samples. Cucumber, tomato, green sweet pepper, cabbage, spinach, and orange, purchased from a market in Kyoto city, were used at 100 g each for the recovery examinations. Boscalid-treated tomato (200 g) was harvested from an experimental farm at the Aichi Agricultural Research Center. Real tomato samples were used to examine for correlations between the dc-ELISA or the SPR-sensor and high-performance liquid chromatography (HPLC). The vegetable samples were homogenized in a blender. For the recovery examinations, boscalid was added to the homogenized samples at final concentrations in the range from 1 to 15 mg/kg.

For the dc-ELISA and the SPR-sensor, 25 mL of methanol was added to the homogenized samples (5.0 g) in a 50 mL screw-cap tube. The mixture was first vigorously shaken (Shaker SA320; Yamato Scientific Co., Ltd., Tokyo, Japan) for 30 min to extract the boscalid and then was centrifuged at 3000 rpm at room temperature for 10 min. The supernatant was diluted 8.5-fold with distilled water to prepare a 10% methanol equivalent solution. The diluted sample was applied to the dc-ELISA and the SPR-sensor. Further dilution using 10% methanol with distilled water was carried out to adjust the concentrations of boscalid for most of the samples in the dc-ELISA and a part of the samples in the SPR-sensor.

For HPLC, 100 mL of acetone was added to the homogenized sample (20 g), and the boscalid was extracted for 30 min using a shaker (Recipro Shaker SR-II; Taiyo Chemical Industry, Gunma, Japan). The mixture was filtered through a filter-paper-lined funnel by suction. The residue was then retreated with 60 mL of acetone. Both filtered extracts were mixed, and the acetone was distilled away by evaporation at <40 °C in a flask. The concentrated solution was applied to 20 mL of a porous kieselguhr column (Inert Sep k-solute; GL Science, Tokyo, Japan) and held at room temperature for 10 min. The fraction containing boscalid was eluted with 100 mL of hexane. The eluted sample was evaporated to dryness by evaporation and N_2 purge. The dried sample was dissolved in 5 mL of acetonitrile and then applied to 6 mL of a bilayer column with activated charcoal and aminopropyl silica gel (GL-Pak GC/NH2; GL Sciences). The column was washed three times with 5 mL of acetonitrile, and the boscalid was then eluted with a mixture of acetonitrile and toluene (3:1, v/v; 15 mL). The eluted sample was dried by evaporation and N_2 purge and redissolved with a mixture of acetonitrile and distilled water (50:50, v/v; 2 mL). A portion of the solution (4 μL) was applied to HPLC.

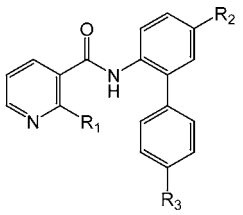
HPLC Analysis. The HPLC system consisted of the Waters Acquity UPLC-PDA detector, equipped with a Waters BEH C18 reversed-phase column (1.7 μm, 2.1 i.d. × 50 mm; Waters, Milford, MA). The mobile phase was a methanol and water mixture (45:55, v/v) running at a flow rate of 0.5 mL/min. The column oven

DOI: 10.1021/acs.jafc.5b03637
J. Agric. Food Chem. 2015, 63, 8075−8082

temperature was 40 °C, and the injection volume of the sample was 4 μL. Boscalid was detected at a wavelength of 230 nm.

RESULTS AND DISCUSSION

Hapten Design. Boscalid is one of the carboxamide fungicides that have two chlorine atoms, as shown in Figure 1. In designing the hapten, the chlorine residues are potent



compound	R_1	R_2	R_3	reference
boscalid	Cl	H	Cl	1
hapten 1	$S(CH_2)_4COOH$	H	Cl	40
hapten 2	Cl	$(CH_2)_5COOH$	Cl	41
hapten 3	Cl	H	$S(CH_2)_4COOH$	41
new hapten	Cl	H	COOH	

Figure 1. Structure of boscalid and the haptens.

candidates for introducing the hapten linker. Abad-Fuentes et al. actually used the chlorine (R_1) for the linker site, and prepared a highly reactive PoAb to boscalid from hapten 1.[40] Esteve-Turrillas et al. (of the same research group) subsequently synthesized the other haptens by introducing an alkanecarboxylic acid to the position of R_2 (hapten 2), as well as introducing a carboxy group to the position of R_3 (hapten 3) using a thiol group.[41] In the dc-ELISAs, the IC_{50} values of the prepared PoAb's were 0.4−1.6 ng/mL for hapten 1, 0.6−1.2 ng/mL for hapten 2, and 0.8−1.6 ng/mL for hapten 3. The reactivity values, however, seemed too sensitive to determine boscalid at the MRLs for horticultural crops (1−40 mg/kg), because the concentration was more than 1000-fold. It seemed that the PoAb with hapten 3 had the lowest reactivity. In our study, therefore, the R_3 position was chosen as the linker site of the newly synthesized hapten. Furthermore, the linker was directly introduced without a thiol group, because the structure is more stable in the mouse abdominal cavity. The key step of the synthesis of the boscalid hapten was achieved by using the Suzuki−Miyaura coupling reaction in the presence of a Pd catalyst, as shown in Figure 2.[42]

Preparation of MoAb's Reacting with Boscalid. The MoAb preparation was carried out by using the conjugate of the new hapten and KLH as the immunogen. MoAb's reacting with the boscalid hapten conjugate were screened, via i-ELISA and ic-ELISA, from 2000 wells in which the colony had formed, and the reactivity of each MoAb was compared with that of the PoAb prepared from the same mouse. Of the two MoAb's finally prepared, MoAb BSC7 had the highest reactivity of all the MoAb's upon screening, whereas MoAb BSC72 was the representative one among various MoAb's showing similar reactivity. As shown in Figure 3, with the ic-ELISA, the IC_{50} values of the PoAb, MoAb BSC7, and MoAb BSC72 were 90, 3.3, and 43 ng/mL, respectively, indicating that the reactivity of MoAb BSC72 was much closer to that of the PoAb. The reactivity of the ic-ELISA seemed adequate when compared with the boscalid MRLs. On the other hand, MoAb BSC7 had a 30 times higher reactivity than PoAb, which was too high for determining the boscalid residue by ic-ELISA. Hence, the test samples would have to be diluted to adequate boscalid concentrations to adjust to the working MRL range.

Reactivity of MoAb's with Boscalid in the dc-ELISA. The dc-ELISA is the most widely used method for pesticide residue analysis among the various immunoassays, and many of the test kits based on the dc-ELISA are commercially available for pesticide determination. The kits have been validated for agricultural products.[24−26] The effectiveness of the dc-ELISA for determining boscalid using MoAb BSC7 and MoAb BSC72 was therefore examined, and the results are shown in Figure 4.

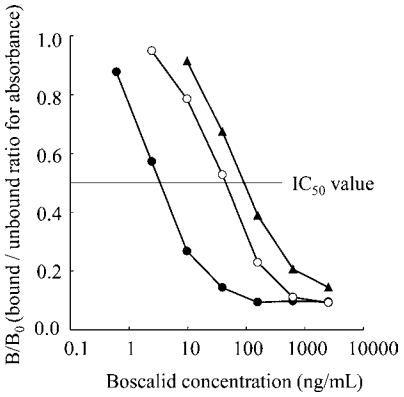

Figure 3. Reactivity of the prepared antibodies with boscalid in ic-ELISA: (●) MoAb BSC7; (○) MoAb BSC72; (▲) PoAb. Each data point is the mean of duplicates in independent examinations.

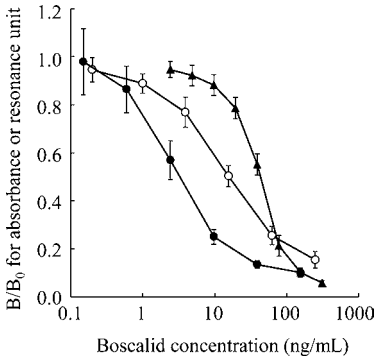

Figure 4. Reactivity of MoAb's with boscalid in the dc-ELISA and in the SPR-sensor: (●) MoAb BSC7 in the dc-ELISA; (○) MoAb BSC72 in the dc-ELISA; (▲) MoAb BSC7 in the SPR-sensor. Each data point is the mean of four replicates in independent examinations; error bars indicate ±SD.

The working range was defined as concentrations between the IC_{20} and IC_{80} values. The IC_{20}, IC_{50}, and IC_{80} values with MoAb BSC7 were 0.8, 3.3, and 16 ng/mL, respectively, similar to the results obtained with the ic-ELISA. These results suggest that it would be possible to use the dc-ELISA with MoAb BSC7 for boscalid residue analysis in horticultural crops, although most of the test samples would have to be diluted to adequate concentrations prior to analysis. On the other hand, the IC_{20}, IC_{50}, and IC_{80} values with MoAb BSC72 were 2.5, 15, and 120 ng/mL, respectively, in the dc-ELISA. The degree of slope on the standard curve for the dc-ELISA was more gradual than that for the ic-ELISA, indicating dc-ELISA's higher sensitivity and hence adequacy for residue analysis around the MRLs of horticultural crops.

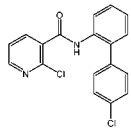
Reactivity of MoAb BSC7 in the SPR-Sensor. SPR-sensors are rarely used for pesticide residue analysis in horticultural crops, although various electrochemical sensors have been applied.[28,39] There may be several reasons for this. First, the organic solvent containing high concentrations of the sample matrixes may gum the microflow channel in the sensor chip by precipitation. To resolve the precipitation problem, the test samples were solubilized in 5% methanol as well as the condition of competitive reaction for the above-described dc-ELISA, and the running buffer was also mixed with 5% methanol to maintain the solubility of the sample. Second, the antibody bound to the immobilized antigen may be unable to dissociate from the sensor chip. A combination of GdnHCl (3.0 mol/L) in acetic acid (1.0 mol/L, pH 1.9) and 0.2% SDS was therefore recently applied to dissociate the bound antibody, as described previously.[39]

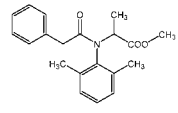
The reactivity of MoAb BSC7 with boscalid was examined in the SPR-sensor, as shown in Figure 4. The working range was defined as concentrations between the IC_{20} and IC_{80} values as well as the dc-ELISA. The IC_{20}, IC_{50}, and IC_{80} values were 17, 42, and 80 ng/mL, respectively. MoAb BSC7 showed a 15-fold lower reactivity in the SPR-sensor than in the dc-ELISA. The reactivity of MoAb BSC72 in the SPR-sensor was too low to determine boscalid residues in horticultural crops (data not shown). The lower reactivity may be because much more MoAb and hapten−BSA were necessary for the SPR-sensor compared with the dc-ELISA.

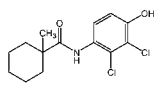
The SPR-sensor with MoAb BSC7 seemed to show adequate sensitivity for determination of boscalid residues in horticultural crops, with higher reproducibility for the standard curve than the dc-ELISA, as shown in Figure 4. The advantages of the SPR-sensor with MoAb BSC7 are its ability to make both quantitative and rapid determinations of boscalid residues in horticultural crops. Further comparisons of the SPR-sensor and the dc-ELISA, using MoAb BSC7 only, were therefore carried out.

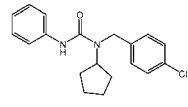
Cross-Reactivity of MoAb BSC7. Cross-reactivity of MoAb BSC7 in the dc-ELISA and the SPR-sensor was examined using other structurally related pesticides: benalaxyl, fenhexamid, pencycuron, and tecloftalam. MoAb BSC7 was highly specific to boscalid, as shown in Table 1. MoAb's generally recognize slight differences in the immunogen, such as the position and molecular size of the functional group, and even the optical isomerism of the molecules. Since the boscalid structure has many differences from the other carboxamide fungicides of the same group, the high assay specificity would be due to its structural uniqueness.

Table 1. Cross-Reactivity of MoAb BSC7 with Boscalid and the Other Structurally Related Pesticides in the dc-ELISA and SPR-Sensor[b]

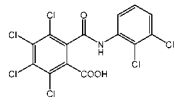
Pesticide	CR (%)[a]		Pesticide	CR (%)	
	ELISA	SPR		ELISA	SPR
boscalid	100	100	benalaxyl	<0.03	<0.4
					




fenhexamid	<0.03	<0.4	pencycuron	<0.03	<0.4
					




tecloftalam	<0.03	<0.4			
					



[a]CR = cross-reactivity (%) compared to the IC_{50} value of boscalid. [b]Each data point is the mean of three replicates in independent examinations.

Boscalid Recovery in Pesticide-Spiked Horticultural Crops. The applicability of the dc-ELISA and the SPR-sensor, using MoAb BSC7, to boscalid residue analysis in horticultural crops was examined by recovery examinations. The limit of quantity values of boscalid for horticultural crops were 0.04 mg/kg in the dc-ELISA and 0.87 mg/kg in the SPR-sensor. The fruit vegetables cucumber (*Cucumis sativus* L.), tomato (*Solanum lycopersicum* L.), and green sweet pepper (*Capsicum annuum* L. var. *grossum*), the leaf vegetables cabbage (*Brassica oleracea* L. var. *capitata*) and spinach (*Spinacia oleracea* L.), and the fruit orange (*Citrus unshiu*) were chosen as the representative horticultural crops. As shown in Table 2, the recovery values were 100−124% in the dc-ELISA and 85.0−109% in the SPR-sensor, indicating that both immunoassays could be applied to boscalid residue analysis in horticultural crops. The SPR-sensor especially showed a higher quantitative performance than the dc-ELISA, since each of the recovery results was closer to the trueness value (100%), except for the results of spinach. The RSD values for the SPR-sensor were also lower than those for the dc-ELISA, although some exceptions were found for green sweet pepper, cabbage, and orange.

The dc-ELISA performance for determination of boscalid residues was as good as that of previously reported dc-ELISAs for other pesticides.[24−26] The SPR-sensor also showed performance equal to or greater than that of the dc-ELISA except for the sensitivity. The reasons would be that for the SPR-sensor (1) sample dilution was not necessary for most of the samples, (2) bound/free separation of the MoAb was not necessary, and (3) labeling of the MoAb, such as with HRP in the dc-ELISA, was not necessary.

Correlation between HPLC and the dc-ELISA or SPR-Sensor. The applicability of the dc-ELISA and the SPR-sensor was also examined by comparing them with HPLC, using real tomato samples to which a boscalid formulation had been applied before harvesting. As shown in Figure 5, the correlation values for HPLC with both immunoassays were high (R^2 = 0.97 with the dc-ELISA; R^2 = 0.95 with the SPR-sensor), suggesting that both of the newly developed immunoassays had high applicability to boscalid residue analysis in horticultural crops. The SPR-sensor had a lower bias (slope 1.14) than the dc-ELISA (slope 1.26), and did not show a visible *y*-intercept difference, whereas the *y*-intercept difference from the dc-ELISA was considerable (0.53 mg/kg). The result suggested that the SPR-sensor has high accuracy even near the lowest determination limit. Therefore, this SPR-sensor would be useful as a rapid, simple, and accurate method for the determination of boscalid residues in horticultural crops. On the other hand, the dc-ELISA has sufficient applicability for on-site analysis. In conclusion, each of the two immunoassays developed for boscalid determination should be used according to the required purpose.

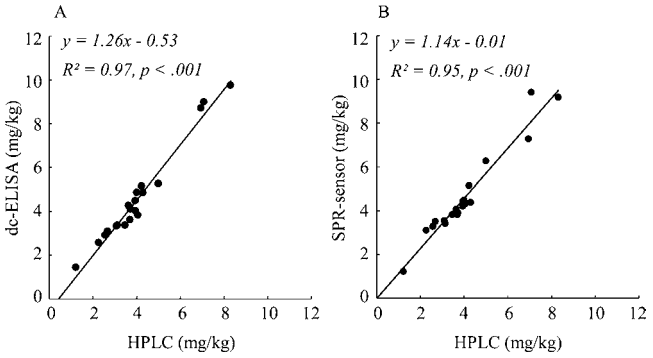

Figure 5. Correlation of the determined boscalid residue in real tomato samples between (A) the dc-ELISA and HPLC or (B) the SPR-sensor and HPLC. Each data point is the mean of duplicates in independent examinations.

[a] ^{1}H chemical shifts (ppm) and their corresponding ^{13}C chemical shifts (ppm) are listed. Bold chemical shifts indicate an identified peak in the spectra. Bold metabolite names indicate metabolites that were found to be statistically significant (in concentration change) in the comparison between resistant and susceptible watermelon tissues.

J. Agric. Food Chem. 2015, 63, 8083−8091

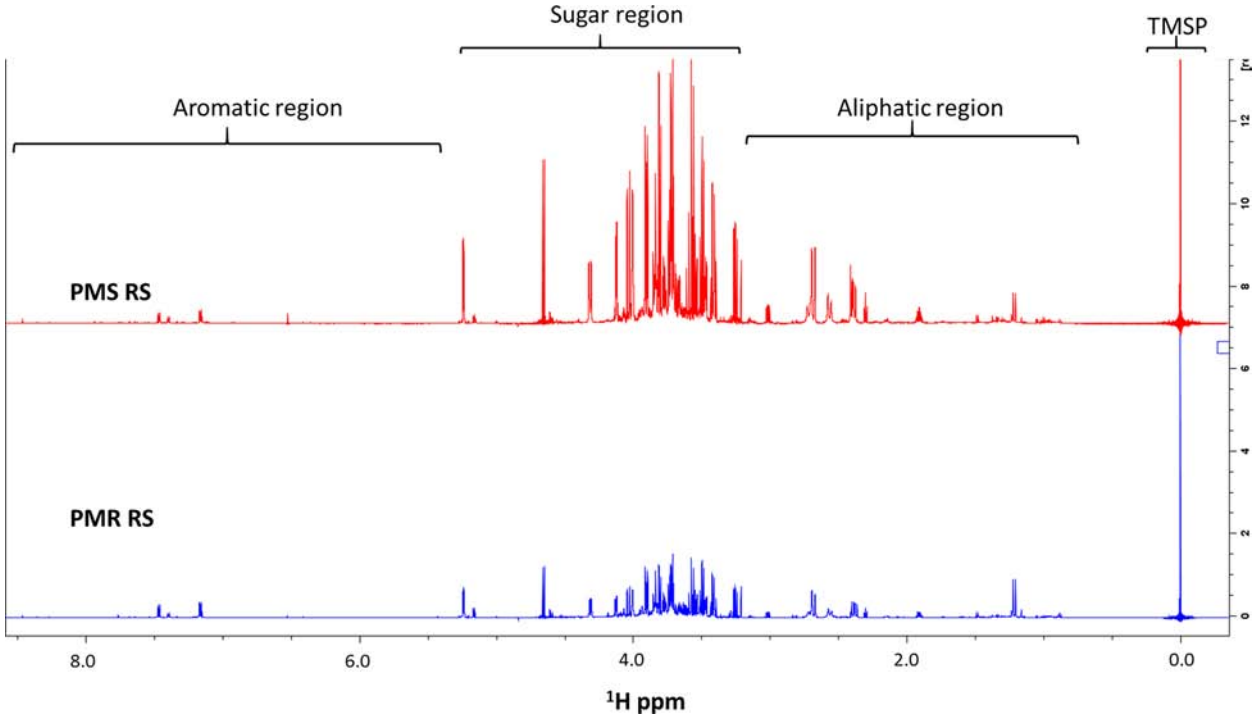

Figure 1. Proton spectral comparisons. Higher intensity of ^{1}H signals were observed for sugar compounds in powdery mildew susceptible rootstocks (PMS RS) compared to powdery mildew resistant rootstocks (PMR RS). The spectra were scaled with the internal reference and standard TMSP (1 mM).

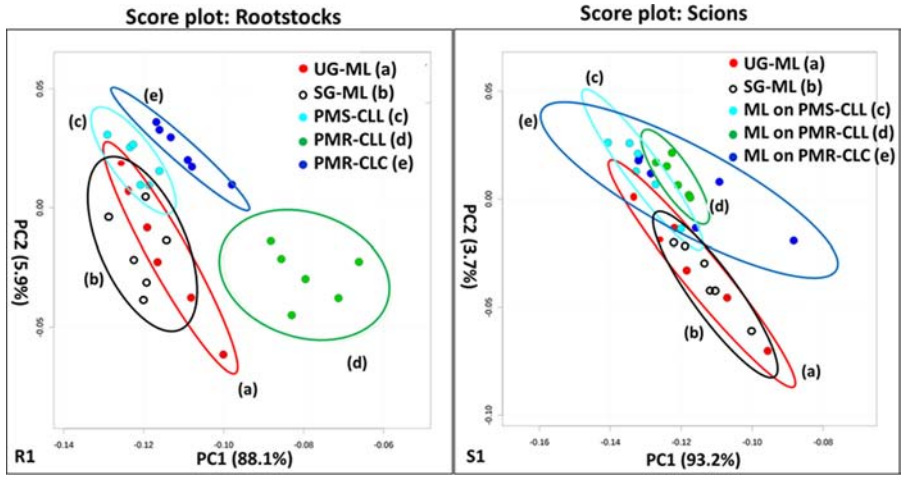

Figure 2. PCA score plots. PC1 versus PC2 score plots are shown for each. The total explained variance is >90%. The ovals represent 95% confidence intervals. Each oval represents a sample group, and each point in the oval represents a single sample/spectrum. R1 represents all of the rootstock samples: UG-ML, ungrafted Mickey Lee (a); SG-ML, self-grafted Mickey Lee (b); powdery mildew susceptible (PMS) rootstock PMS-CLL; (c) powdery mildew resistant (PMR) rootstocks PMR-CLL (d); PMR rootstocks PMR-CLC (e). S1 represents all of the corresponding grafted scions (PMS Mickey Lee) on all rootstocks.

Europe for managing soilborne diseases.[8,9] Watermelon scions are grafted on various rootstocks including bottle gourds, intraspecific squash hybrids, and watermelons.[10,11] Grafting is generally done using various methods such as approach graft, hole insertion graft, or single-cotyledon graft.[10] The U.S. Vegetable Laboratory (USVL), USDA-ARS, in Charleston, SC, USA, has developed a watermelon with resistance to PM as a part of their prebreeding program using grafting techniques. In preliminary experiments, moderate but significant levels of resistance to PM and fruit rot were reported in grafted watermelon (commercial PM susceptible scion grafted on wild PM resistant rootstock). To understand what specific resistance components translocate from resistant rootstocks to the susceptible scion Mickey Lee through grafting, we utilized NMR-based metabolomics, a novel analytical chemical approach for biomarker discovery. This is rapidly being applied to the development of diagnostic tools for a variety of environmental conditions as well as diseases in animals and humans.[12]

In food science, various analytical techniques including NMR, UPLC-MS, and GC-MS are widely used in targeted as well as untargeted metabolomics studies.[13] Among these, NMR-based metabolomics is a burgeoning analytical tool to investigate metabolism due to its nondestructive and unbiased nature, robustness, reproducibility, and simultaneous wide-ranging detection patterns.[12,14] Recently in the plant biotechnology field, the NMR-based metabolomics approach has been extensively applied to develop protocols for plant metabolomics research,[14−20] plant

J. Agric. Food Chem. 2015, 63, 8083−8091

disease research,[21,22] and plant metabolic profiling[23,24] and also in plant tissue culture research.[25−27]

In this study, we compared metabolic profiles of powdery mildew susceptible (PMS) and resistant (PMR) watermelon rootstocks to identify differences in their metabolic profiles using NMR spectroscopy. We also verified translocation of metabolites from resistant rootstocks to susceptible scions in grafted watermelon plants.

MATERIALS AND METHODS

Experimental Design. Mickey Lee (PM susceptible watermelon cultivar) scions individually were grafted using the one cotyledon grafting method[10] to two varieties of watermelon rootstocks, *C. lanatus* var. *lanatus* (CLL) and *C. lanatus* var. *citroides* (CLC), and two lines for each variety (Table 1) for a total of four PMR lines. Each combination of grafting was performed six times (six replications) and planted in trays in a greenhouse. Two independent experiments were conducted for each variety (CLL or CLC) of grafted plant. Additionally, six replicates of ungrafted Mickey Lee (ML-UG) were used as negative controls for both the PMS comparisons and self-grafted Mickey Lee (ML-SG) comparisons. All plants were of the same age and were grown in the same experimental conditions.

Sample Harvesting and Metabolism Quenching. To harvest each sample from 8-week-old grafted plants, 1 cm of rootstock (stem) directly below the grafting site and 1 cm of scion (stem) directly above the grafting site were collected. At the same time, 1 cm leaf tissues as well as cotyledon tissue were collected separately from rootstocks and their corresponding scion. The samples were immediately submerged into liquid nitrogen to quench all metabolic processes and to prevent any stress responses from the cutting process. Frozen samples were then lyophilized for 48 h, at −40 °C and 0.05 mPa, to remove all water and permanently quench metabolism. Once the samples were dried, they were manually homogenized prior to extraction.

Metabolite Extraction. Methanol−chloroform−water extractions of the dried rootstocks were performed as described in ref 15. Briefly, 20 mg of dried and homogenized plant material was used for each sample/replicate, and the solvent volumes were calculated using the dry mass to achieve a constant ratio of 2:2:1.8 of chloroform/methanol/water according to the Bligh and Dyer method.[28,29] The dried plant material was rehydrated with the appropriate ice-cold methanol/water solution. After vortex-mixing, the mixture was transferred into the ice-cold chloroform/water solution in glass tubes. The sample was incubated on ice for 10 min and centrifuged for 10 min at 2000*g* at 4 °C. The top layer, that is, the hydrophilic extract, was transferred into new microcentrifuge tubes. The hydrophilic extracts were dried using a Centrivap centrifuge for ∼15 h and stored at −20 °C until further preparation for NMR analysis.

NMR Sample Preparation and Spectroscopy. The dried hydrophilic extracts from each sample were resuspended in 620 μL of NMR buffer (100 mM sodium phosphate buffer (pH 7.3), 1 mM 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid (internal standard, TMSP; CAS Registry No. 24493-21-8), and 0.1% sodium azide, in 99.9 atom % D_2O) and then vortex-mixed and centrifuged to remove any remaining undissolved material. The experiments were conducted at 298 K using 600 μL of sample in 5 mm NMR tubes (Norell). All NMR spectra were recorded on a Bruker Avance III spectrometer operating at 700 MHz. The first increment of a presat-noesy experiment was acquired using the standard Bruker noesypr1d pulse sequence. This resulted in a one-dimensional ^{1}H spectrum (metabolic profile) for each sample. All data were collected using a spectral width of 16.0 ppm and 64K points resulting in an acquisition time of 2.9 s. The spectra were collected with 120 scans, 4 dummy scans, 3 s relaxation delay, and presaturation at the residual water frequency. The 90° pulse widths were measured for each sample using the automatic pulse calculation experiment (pulsecal) in TopSpin 2.1.1 (BrukerBioSpin, Billerica, MA, USA). Two-dimensional ^{1}H−^{13}C HSQC data were collected for a representative rootstock and scion sample using the Bruker hsqcedetgpsisp2.2 pulse sequence. The ^{1}H was observed in the F2 channel with a spectral width of 11 ppm,

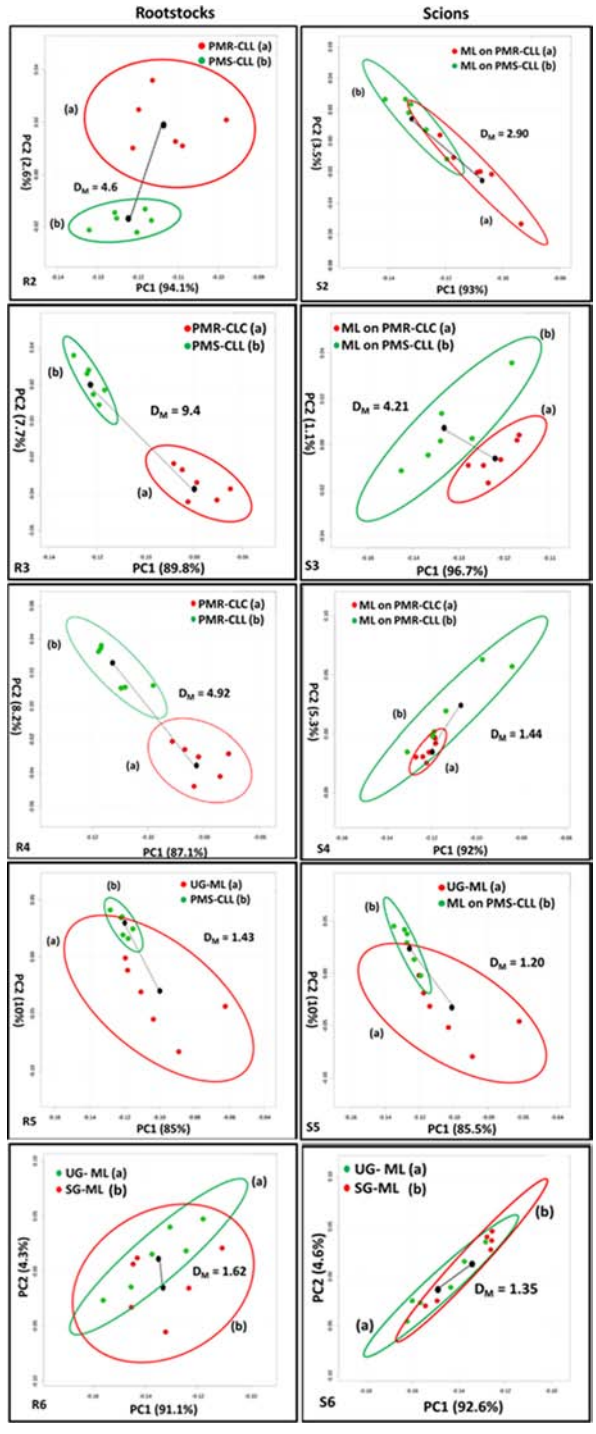

Figure 3. Pairwise PCA score plots. PC1 versus PC2 score plots are shown for each pairwise comparison. In each, the total explained variance is >90%. The ovals represent 95% confidence intervals. R2, R3, R4, R5, and R6 are pairwise comparisons of rootstocks: R2, PMR-CLL (a) versus PMS-CLL (b); R3, PMR-CLC (a) versus PMS-CLL (b); R4, PMR-CLC (a) versus PMR-CLL (b); R5, UG-ML (a) versus PMS-CLL (b); R6, UG-ML(a) versus SG-ML (b). S2, S3, S4, S5, and S6 are pairwise comparisons of the corresponding scions: S2, ML grafted on PMR-CLL (a) versus ML grafted on PMS-CLL (b); S3, ML grafted on PMR-CLC (a) versus ML grafted on PMS-CLL (b); S4, ML grafted on PMR-CLC (a) versus ML grafted on PMR-CLL (b); S5, UG-ML (a) versus ML grafted on PMS-CLL (b); S6, UG-ML (a) versus SG-ML (b). The Mahalanobis distances (D_M) are listed for each.

[a]Mahalanobis distance (D_M), two-sample Hotellings' T^2 test, and F test values shown, where F-true > F-critical indicates a statistically significant separation between the groups. R2, R3, R4, S2, and S3 have statistically significant separations, whereas R5, R6, S4, S5, and S6 do not.

whereas the ^{13}C was observed in the F1 channel with a spectral width of 180 ppm.

NMR Data Analysis. *Multivariate Statistical Analysis.* Prior to principal component analyses (PCA), bucket tables were generated by using AMIX software (version 3.9.7, BrukerBioSpin). Once data were normalized to total intensities, spectra were binned into 0.01 ppm wide buckets over the region of 0.5−10.0 ppm using advanced bucketing in AMIX. Other bucket widths (either larger or smaller) resulted in similar results. The water region (4.75−4.90 ppm) of the spectra was eliminated for all analyses. No scaling method was found necessary. PCA was performed on the bucket tables generated from AMIX using MetaboAnalyst 2.0 (MetaboAnalyst 2.0, a comprehensive server for metabolomic data analysis).[30] For each score plot generated during the analysis, the Mahalanobis distance (D_M), two-sample Hotelling's T^2 statistic (T^2), F values (F_t) and critical F values (F_c) were calculated using MatLabR2010b.[31]

Spectral Analysis and Metabolite Identification. To identify the metabolites that are different in concentration when resistant and susceptible rootstocks and scions were compared, fold changes and related p values were determined for each bucket. The calculations of fold changes and t tests were performed with MetaboAnalyst 2.0 to determine whether or not the changes in bucket intensities were statistically significant. Buckets with corresponding p values <0.05 were considered statistically significant. The metabolites corresponding to these peaks in the buckets were identified using the Biological Magnetic Resonance Data Bank (BMRB) (http://www.bmrb.wisc.edu/metabolomics/), Madison Metabolomics Consortium Database (MMCD) (http://mmcd.nmrfam.wisc.edu/), ChenomX NMR Suite (ChenomX Inc., Edmonton, AB, Canada), and published studies.[32,33] Metabolic data interpretation was facilitated with the Metabolic Pathway Analysis (MetPA) component of MetaboAnalyst 2.0.[30]

RESULTS AND DISCUSSION

NMR-based metabolomics was used to idenitfy and study PMR-related metabolites in resistant wild rootstocks of watermelon as well as metabolite translocation to the corresponding susceptible watermelon commercial cultivar scion, Mickey Lee (ML).

Metabolic Profile Comparisons. Metabolic profile comparisons were made between PMR rootstocks and PMS rootstocks as well as their corresponding susceptible ML scions. Two independent experiments were conducted for each variety of rootstock shown in Table 1. Similar results were observed for repetitive experiments as well as for both varieties of PMR-CLL (USVL531 and USVL516) and PMR-CLC (USVL225 and USVL331); therefore, only the results from one of each experiment are described here.

By 1D ^1H NMR spectroscopy, we identified 27 metabolites from rootstocks as well as their corresponding scions as shown in Table 2 and Supplemental Figure 1. The 1D proton spectral comparison between powdery mildew resistant rootstock and its corresponding PMS ML scion showed distinct differences in signal intensities, specifically in the sugar zone, which is higher in intensity in the case of susceptible cultivar than wild resistant variety due to the presence of high sugar compounds (Figure 1). Similar metabolic profile comparison trends were also investigated for both leaf and cotyledon tissues from resistant and susceptible groups (data not shown). We verified the assignments of the metabolites identified from rootstocks as well as their corresponding scions using 2D $^1H-^{13}C$ NMR spectral data (Supplemental Figure 2).

Multivariate Statistical Analysis. *Rootstock Comparisons.* PCA score plots showed clear separations between the metabolic profiles of susceptible and resistant rootstocks (Figures 2R1 and 3R2,R3), indicating distinct differences in the metabolism of the two types (PMR and PMS) of rootstocks. Pairwise metabolic profile comparisons were made between PMR CLL rootstocks and PMS CLL rootstocks (R2), between PMR CLC rootstocks and PMS-CLL rootstocks (R3), between PMR-CLL rootstocks and PMR-CLC rootstocks (R4), between PMS-CLL rootstocks and ungrafted ML (UG-ML) rootstocks (R5), and between PMS-CLL rootstocks and self-grafted ML (SG-ML) rootstocks (R6). Significant separations between the susceptible and resistant metabolic profiles were observed in R2 and R3 rootstock comparisons (Figure 3 and Table 3). These significant separations indicate distinct differences in the metabolism between the susceptible and resistant rootstocks. In the R4 comparison between two resistant rootstocks (PMR-CLL and PMR-CLC), a significant separation was also observed. This result may be attributed to the fact that these two watermelon varieties have distinct genetic differences.[34,35] Moreover, the R5 comparison did not show significant separations, most likely because both of these varieties are susceptible to powdery mildew. A nonsignificant separation in R6 comparison where SG-ML rootstock was compared with UG-ML rootstock indicates that the stress of the grafting process did not contribute to the metabolic difference between the resistant and susceptible rootstocks.

Scion (Grafted on PMR and PMS Rootstock) Comparisons. PCA score plots also showed separations between the metabolic profiles of ML scions grafted on susceptible and resistant rootstock sources (Figures 2S1 and 3S2,S3), indicating possible translocation of metabolites related to PM resistance from PMR rootstocks to the susceptible scion after grafting. Similar to rootstock comparisons, pairwise metabolic profile comparisons were made between susceptible ML scions grafted on rootstocks of PMR CLL and PMS CLL (S2), between susceptible ML scion grafted on rootstocks of PMR CLC and PMS-CLL (S3), between susceptible ML scion grafted on rootstocks of PMR-CLL and PMR-CLC (S4), between susceptible ML scion grafted on rootstocks of PMS-CLL and UG-ML (S5), and between self-grafted ML scion grafted on rootstocks of ML and UG-ML (S6). Significant separations were observed in S2 and S3 comparisons (Figure 3 and Table 3). S4 comparisons did not show a significant metabolic profile separation, which is most likely because translocation of metabolites from both resistant rootstocks (PMR-CLL and PMR-CLC) could be quantitatively similar, excluding glucose and fructose. Similarly, in the S5 comparison, no significant metabolic profile separations were observed,

DOI: 10.1021/acs.jafc.5b02108
J. Agric. Food Chem. 2015, 63, 8083−8091

probably because both the rootstock and scion sources were susceptible (PMS-CLL and UG-ML). Moreover, in the S6 self-grafted comparison, no significant metabolic profile separations were observed, which indicates minor stress contributions from grafting.

Mahalanobis Distance (D_M). For each pairwise comparison described above and shown in Figure 3, a calculated D_M indicates the magnitude of the metabolic profile separation. This distance was considered significant on the basis of the other calculated values given in Table 3 and described in ref 31. If the F_t value is higher than the F_c value, then D_M represents a statistically significant separation in the comparison, which is the case for R2, R3, R4, S2, and S3.

Identification of Metabolites and Determination of Fold Changes. Each data point in a score plot represents all metabolites present in one sample; therefore, the separations between the grouped metabolic profiles can be based on individual metabolites. Metabolite differences (qualitative or quantitative) that contribute to score plot separations were identified using loading plots (Supplemental Figure 3), and their fold changes were determined using volcano plots (Supplemental Figure 4). On the basis of the fold changes of aligned and normalized bucket intensities, choline, 5-hydroxyindole-3-acetate (IAA), melatonin, fumarate, glucose, and fructose were identified from PMR rootstocks as well as their corresponding PMS scions as significantly different in concentration (Table 4) in the spectra of R2, R3, R4, S2, and S3 comparisons, whereas in spectra used for R5, R6, S4, S5, and S6 comparisons, only glucose and fructose showed significant concentration differences. Choline, IAA, and melatonin have higher concentrations, whereas fumarate, glucose, and fructose have lower concentrations, in PMR rootstocks as well as their corresponding PMS scions (Figure 4 and Supplemental Figure 5). Sugars (glucose and fructose) have decreased concentrations in both the PMR-CLL and PMR-CLC rootstocks. To find out the potential role of these metabolites in disease resistance, we conducted metabolic pathway analysis.

Metabolic Pathway Analysis. Metabolic pathway analysis was performed using MetPA[30] for grafted watermelon metabolites that were affected by powdery mildew disease. Pathway analysis suggested the involvement of 11 statistically significant metabolic pathways based on p values <0.05 and an impact factor threshold >0. Metabolic profile analysis of ML scion 2 months after grafting on PMR and PMS rootstocks revealed that the PM disease regulates an array of metabolites involved in pathways. Levels of choline, IAA, melatonin, fumarate, glucose, and fructose changed significantly in response to grafting on PMR rootstocks and are labeled in the various pathways shown in Figure 5.

This study identified and verified the metabolites choline, IAA, melatonin, fumarate, glucose, and fructose in PMR rootstocks and their corresponding ML scions as significantly different in concentration. Investigation showed significantly increased levels of choline, melatonin, and IAA (1.5, 3.21, and 2.51 FC, respectively) in PMR rootstocks and their corresponding scions and significantly decreased levels (0.62, 0.35, and 0.45 FC, respectively) in PMS watermelon rootstocks and their corresponding scions (Figure 4) and also significantly decreased levels of fumarate, glucose, and fructose (0.62, 0.28, and 0.15 FC, respectively) in PMR rootstocks and their corresponding scions and significantly increased levels (1.45, 2.35, and 3.12 FC, respectively) in PMS watermelon rootstocks and their corresponding scions (Figure 4). Biochemical pathway analysis suggested that significantly higher levels of choline, melatonin, and IAA and lower levels of fumarate, glucose, and fructose are

Table 4. Commonly Identified PMR-Related Significant Metabolites[a]

	fold change = ratio of average bucket intensities ((a) and (b) labels correspond to those in Figure 3)

[a]Choline, melatonin, 5-hydroxyindole-3-acetate, fumarate, glucose, and fructose have significant concentration differences in the spectra of R2, R3, R4, S2, and S3 comparisons. In spectra used for R5, R6, S4, S5, and S6 comparisons, all metabolites are present, but only glucose and fructose showed significant concentration differences. Each numerical value indicates the average fold change of the metabolite and was calculated by taking a ratio of the average bucket intensities: the specific ratio for each comparison is indicated. A fold change >1 indicates metabolites are up-regulated for the sample in the numerator. A fold change <1 indicates metabolites are down-regulated for the sample in the numerator. A dash indicates that the metabolite is present but not significantly different.

J. Agric. Food Chem. 2015, 63, 8083−8091

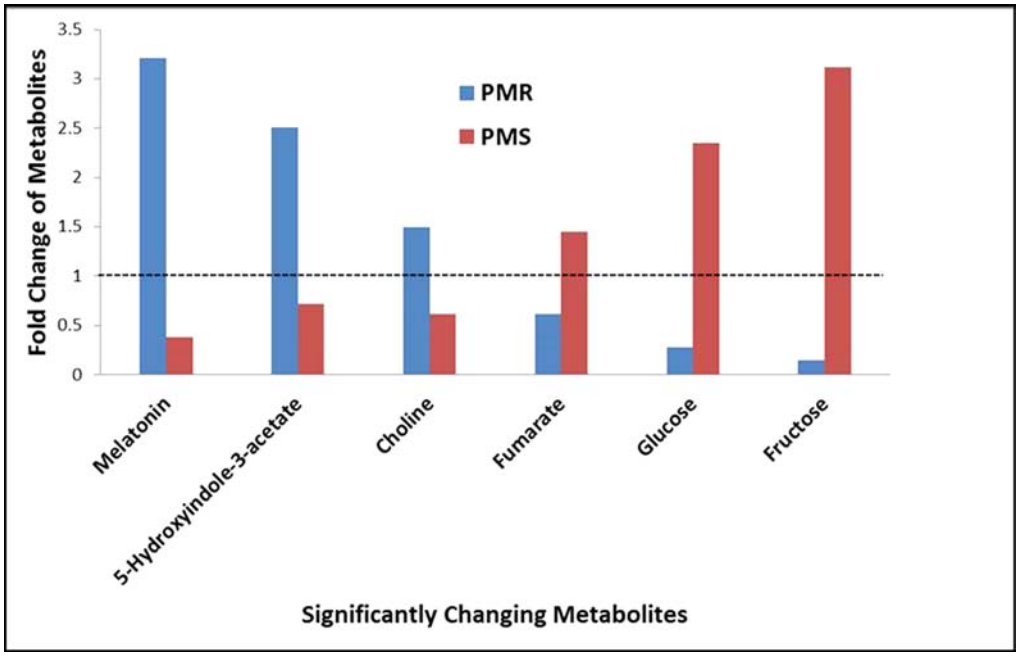

Figure 4. Fold-change analysis. Metabolites were determined to be significant on the basis of volcano plots in PMR of watermelon. Fold changes >1.00 indicate a net increase and fold changes <1.00 indicate a net decrease in the levels of metabolites. Choline, IAA, and melatonin have increased concentrations and glucose, fructose, and fumarate have decreased concentrations in PMR rootstocks as well as their corresponding scions when compared with PMS watermelon.

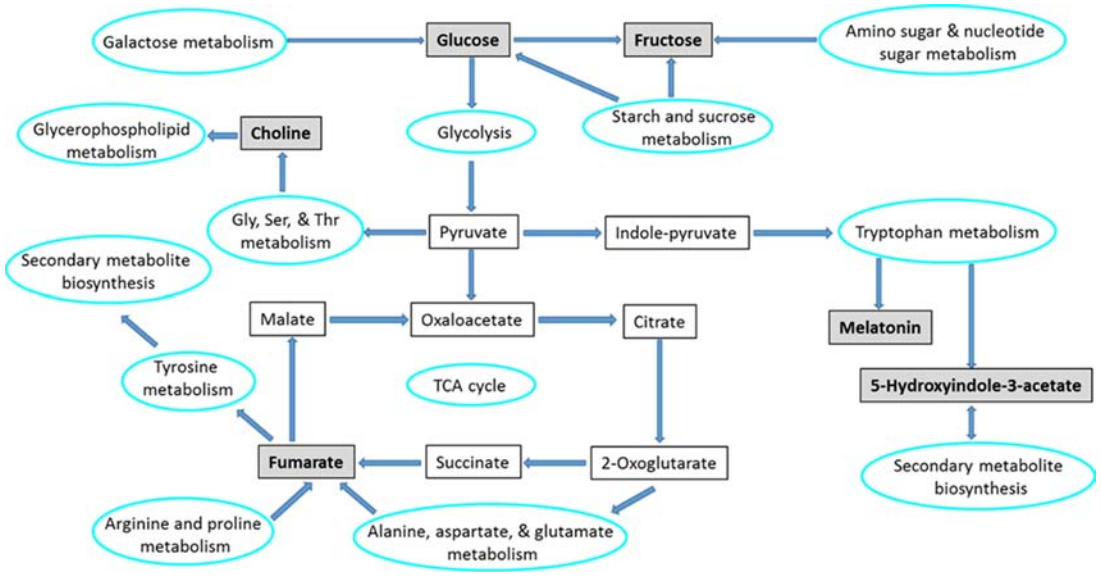

Figure 5. Biochemical pathway analysis. These metabolic pathways contain the metabolites that were determined to be significantly different in concentration when the resistant and susceptible watermelon tissues were compared and could lead to the synthesis of metabolites by response of powdery mildew disease in watermelon. The KEGG database and MetaboAnalyst were used to elucidate metabolic networks. The metabolites that accumulated and were identified as significantly different in concentration by NMR are shown in bold.

related to various amino acid metabolism pathways and may have a link with different secondary metabolite biosynthesis pathways.

Melatonin, an important tryptophan metabolism pathway derivative, has been shown to play a significant role in maintaining cellular stability, which may provide an important mechanism for the survival of many plant species.[36] Also, exogenously applied melatonin improved the resistance capacity to Marssonina apple blotch (*Diplocarpon mali*) and enhanced the activities of plant defense-related enzymes, possibly improving disease resistance.[37] Interestingly, the powdery mildew pathogen (*P. xanthii*) also belongs to the same division as apple blotch (*D. mali*): Ascomycotaas. Melatonin also acts as an effective free radical scavenger and natural antioxidant and even has protective mechanisms in mitochondria and chloroplasts.[38] Additionally, it acts as a plant protector against environmental insults, and high levels of melatonin have been identified in a pollutant-resistant plant: the water hyacinth *Eichhornia crassipes*.[39] Another important metabolite in tryptophan metabolism, IAA, has also been shown to play a significant role in plant defense. For example, in tomato, IAA reduced the tomato wilt pathogen

DOI: 10.1021/acs.jafc.5b02108
J. Agric. Food Chem. 2015, 63, 8083−8091

Fusarium oxysporum lycopersici spore germination, mycelial dry weight, and protein content.[40] IAA and abscisic acid (ABA) are involved in the *Pseudomonas fluorescens*-mediated control of *Fusarium* head blight disease of barley.[41] Resistance to necrotrophic fungi is reduced in IAA signaling mutants.[42] Moreover, plant−pathogen interactions identify IAA as a key character in pathogenesis and plant defense.[43] Some of the phenylpropanoids (caffeoyl and 5-hydroxyferuloyl malate) together with IAA decreased significantly after fungal infection in *Brassica rapa*.[44]

Additionally, choline was found to be involved with glycine, serine, and threonine metabolism and also interacted with fatty acid and secondary metabolite biosynthesis pathways (Figure 5). It is reported that *P. syringae* pv tomato strain DC3000 derived greater osmoprotection from exogenous choline, which is distinct from most bacterial species.[45] Choline and phosphorylcholine are ubiquitous in plants, whereas glycine betaine is produced in detectable amounts by some plant species but not others, and betaine and choline levels have a relationship with NaCl stress.[46] The control plants of *Brassica rapa* were characterized by high levels of choline but their fungal infected counterpart has a lower level of choline.[44] *Brassica rapa* plants infected with *Fusarium oxysporum* fungi produced higher concentrations of glucose and fumaric acids.[44]

We also speculate that the increased concentrations of choline, IAA, and melatonin indicate involvement of these naturally occurring metabolites in powdery mildew or other types of disease resistance in watermelon. From the corresponding PMS Mickey Lee scion metabolic profiles, we also identified the same PMR-related metabolites as significantly increased in concentration, therefore validating our hypothesis that melatonin, IAA, and choline were translocated from PMR rootstocks to the PMS commercial Mickey Lee (watermelon) scion through grafting. Further studies to confirm this hypothesis by applying these chemicals or their analogues on a PMS line are warranted.

In summary, we identified choline, IAA, melatonin, fumarate, glucose, and fructose to be significantly different in concentration in PMR lines compared to the PMS lines. PCA showed significant metabolic profile separations between the susceptible and resistant groups, indicating distinct differences in the metabolisms of the two types of rootstocks as well as their corresponding PMS scion. Pairwise comparisons of each variety of PMR rootstock with the PMS rootstock as well as their corresponding scions showed significant separations, and calculated Mahalanobis distances (D_M) indicated that both PMR-CLL and PMR-CLC varieties have a statistically significant difference in metabolic profiles when compared to the susceptible varieties. Choline, IAA, and melatonin have higher concentrations, whereas fumarate, glucose, and fructose have lower concentrations, in PMR rootstocks and their corresponding scions.

The present study revealed that NMR-based metabolomics is a useful technique to identify potential metabolites that may play a role in powdery mildew resistance in watermelon. Our results stem from the observance of PM resistance on susceptible grafted scions in greenhouse studies.

STRATEGIES FOR THE UTILIZATION OF LIGNOCELLULOSIC MATERIALS: BIOREFINERIES

In general terms, the benefit of LCM can be accomplished according to two different philosophies:

- direct utilization as a whole (for example, by combustion, pyrolysis, liquefaction, or gasification) or
- LCM "fractionation" (in which the major components of the feedstock are separated into "fractions" made up of compounds with related properties) followed by separate processing of each fraction for specific purposes.

LCM fractionation is the conceptual basis of the "lignocellulose biorefinery", which has been defined by the National Renewable Energy Laboratory (NREL) as "a facility that integrates conversion processes and equipment to produce fuels, power and chemicals from biomass". According to this definition, biorefineries are expected to work under a general idea analogous to today's petroleum refineries.[13] The IEA Bioenergy Task 42 broadened the biorefinery concept, proposing that biorefinery stands for "the sustainable processing of biomass into a spectrum of bio-based products (food, feed, chemicals and/or materials) and bioenergy (biofuels, power and/or heat)", so that a biorefinery can be a concept, a facility, a process, a plant, or even a cluster of facilities.[14] Integrated biorefineries, characterized by a reduced carbon footprint of the final products, can provide a sustainable approach to valuable products that can also improve biomass processing economics as well as environmental issues[14] and have been considered crucial for extracting the maximum value from biomass.[15] In the medium term, relatively small-scale biorefineries making use of local or regional resources have been considered as the most favored method to introduce more advanced (green, whole-crop, and lignocellulosic) biorefinery processes into the market.[14]

The main issue in LCM processing lies within its complex structure and chemical composition, an important issue when envisioning new processes.[16]

Usually, LCM fractionation intends the selective separation of the structural components (lignin, cellulose, and hemicelluloses), which have to be recovered and further processed to yield an array of tailored commercial products. A recent analysis of the potential demand, biomass availability, and energy efficiency led to the conclusion that the production of chemicals from biomass is more beneficial than the production of transportation fuels or electricity.[17]

It is desirable that operation in biorefineries should follow the basic principles of green chemistry, for example, regarding an efficient utilization of raw materials and avoiding the utilization of wastes instead of performing end-of-pipe waste remediation,[3] enabling the production of end-products fulfilling societal needs, and shortening the dependence on fossil resources.[18] In this way, a sustainable industrial and societal development can be achieved by meeting the needs of the present generation without compromising the needs of future generations to meet their own needs.[19]

On the other hand, the implementation of biorefineries has been identified as the most promising route to the creation of a new domestic biobased industry (NREL, 2014), paving the way for a future low-carbon bioeconomy,[20,21] which would be driven by clean, sustainable environmental development, economic growth, and green politics,[22] and result in a highly efficient and cost-effective processing of biological feedstocks to a range of biobased products.[23] On this basis, the implementation of biorefineries could also contribute to the revitalization of rural areas.[24] There is a long way to go: only about 5% of the European economy was biobased in 2010, whereas in the United States, about 12% of all products (excluding energy use) in 2010 was originated from biomass.[25]

IONIC LIQUIDS IN LIGNOCELLULOSE BIOREFINERIES

Increasing attention is being paid to the utilization of ionic liquids (ILs) in a variety of fields. ILs are salts composed of large organic cations and inorganic or organic anions, with melting points below 100 °C, which can be designed to be liquid at room temperature.[26] Their low volatility (many ILs can be distilled at 200−300 °C just under significantly reduced pressure and at very low distillation rate)[27] limits the losses in vapor phase. This is an important advantage over the conventional solvents employed in industries, which can be responsible for emissions of volatile organic compounds

DOI: 10.1021/acs.jafc.5b03461
J. Agric. Food Chem. 2015, 63, 8093−8102

(VOC), identified as a major source of waste,[28,29] and show hazards related to inhalation and explosion.[30] Additionally, some ILs present catalytic activity. In this case, they show many of the advantages of both homogeneous and heterogeneous catalysts, such as high acid density, uniform catalytic active centers, easy separation, and recyclability.[31]

The most common ILs can be classified in four groups according to their cations: quaternary ammonium ILs, *N*-alkylpyridinium ILs, *N*-alkyl-isoquinolinium ILs, and imidazolium-based ILs.[32] Among them, the latter group has received special attention and is the focus of this study. Figure 1 presents the general formula of 3-methylimidazolium-based ILs ([mim]) employed for biomass processing, as well as the nomenclature employed in this work for the various ILs.

ILs are considered green chemicals[33,34] and offer a unique environment for chemistry, biocatalysts, separation, material synthesis, and electrochemistry.[35] However, ILs can be used as more than just alternative green solvents, because they differ from molecular solvents by their unique ionic character and their structure and organization, which can lead to specific effects.[27] Nonflammability, lack of toxicity, and thermal and chemical stability are usual ILs properties of special importance for application in biorefineries. An ideal ionic liquid should be inexpensive, nontoxic, biodegradable, and recyclable.[3]

Thermally stable ILs can be employed as reaction media or catalysts to carry out reactions at high temperatures using conventional equipment, in a way that their negligible vapor pressure would facilitate the recovery of volatile reaction products. Due to the unique solvent properties of ILs, these solvents promise advantages with regard to conversion and selectivity, leading to energy savings when compared to conventional solvents.[26] Additionally, their properties can be tuned for specific chemical tasks[36] by selecting the type of constituent cation and anion:[37] for example, a number of ILs show unique solvating properties.[38] Increasing knowledge on the chemical, physical, and technical properties of ILs is expected to allow a wider and more efficient utilization.

POTENTIAL APPLICATIONS OF ILS IN BIOREFINERIES

On the basis of the above information on the nature of LCM and properties of ILs, a number of potential applications of ILs in lignocellulose biorefineries have been identified, including their utilization as agents for separation, cellulose dissolution, and derivatization, LCM fractionation, or LCM pretreatment (see the following sections). The utilization of ILs as reaction media and/or catalyst for the hydrolysis−dehydration of polysaccharides into furans is also an interesting research subject, but it falls outside the scope of this paper.

ILs as Separation Agents for Compounds Present in Biorefinery Streams. ILs find a number of applications in biorefineries, for example, in processes dealing with the production of second-generation biofuels (such as bioethanol or biobutanol) or short-chain organic acids. In these kinds of technologies, LCM are processed to hydrolyze polysaccharides (cellulose and/or hemicelluloses) into sugars, which are fermented to yield the target products.

One of the major techno-economic challenges in biorefineries manufacturing second-generation ethanol from LCM is the comparatively low ethanol content of the fermentation broth. The ethanol concentration can be increased by ordinary distillation up to concentrations near the azeotrope (95.5 wt % ethanol), but the separation becomes increasingly difficult as this threshold is approached. On the other hand, fuel applications require almost anhydrous ethanol, making the utilization of alternative separation technologies (typically, azeotropic or extractive distillation) necessary. Both azeotropic and extractive distillations involve the addition of a third component (entrainer) able to break the azeotrope. Imidazolium-based ionic liquids have been successfully employed as separation agents for the dehydration of ethanol−water mixtures,[26,39,40] as they can greatly enhance the relative volatility of ethanol over water, showing advantages derived from low viscosity, thermal stability, good solubility, and lower corrosiveness with respect to the high melting salts suitable for the same purpose.[40] In a comparative evaluation of [bmim]BF_4, [emim]BF_4, and [bmim]Cl (see Figure 1 for nomenclature), the ability to improve the separation was found to follow the order [bmim]Cl > [emim][BF_4] > [bmim][BF_4], in a way that the two best ILs performed better than the reference compound.[39,41] Figueroa et al.[41] simulated the ethanol recovery using a number of ILs ([bmim]Cl, [emim]Cl, [emim]BF_4, [bmim]Ac, [bmim]BF_4, [bmim]$N(CN)_2$, [hmim]Cl, and [bmim]mSO_4) and concluded that, in the best cases, high-purity ethanol could be obtained at 96 wt % recovery. In a related study, Meinsderma et al.[42] proposed an energy-efficient process for ethanol dehydration based on extractive distillation with [emim]$N(CN)_2$ enabling the production of 99.91% ethanol in facilities at pilot scale. Other reported advantages of ILs as separation agents include:[40]

- ILs do not pollute the distillate due to their nonvolatile character;
- reduced heat duties are required because of their nonvolatility, high selectivities, and heat capacities;
- ILs properties such as solubility, capacity, selectivity, viscosity, and thermal stability can be tailored;
- only one distillation column is required.

Alternatively, ILs can be used for ethanol extraction from aqueous solutions. Arlt et al.[43] proposed a number of ILs (including imidazolium- and phosphonium-based ones) as potential solvents for the extractive separation of close-boiling or azeotropic mixtures, including water−ethanol. This approach was claimed to be superior to conventional extractive rectification in terms of cost-effectiveness and exergetic aspects, as a result of the selectivity and the unusual characteristic profile of the ionic liquids. Solubility data for ternary mixtures of ethanol, water, and a hydrophobic IL ([bmim]PF_6, [hmim]PF_6, or [omim]PF_6) were reported by Swatloski et al.,[44] whereas [hmim]Tf_2N was found to be suitable for separating ethanol from water, but acceptable recovery rates could be achieved only by using unreasonably high solvent/feed ratios.[45] On the basis of ternary liquid−liquid equilibrium studies, a number of tetradecyltrihexylphosphonium-based ILs obtained by combination with seven different anions have been recently proposed as candidates for ethanol recovery from aqueous solutions by liquid−liquid extraction.[46] On the basis of equilibrium calculations, the authors suggested the use of a single liquid−liquid extraction stage coupled to extractive fermentation as a favorable solution to recover ethanol from dilute aqueous solutions, a possibility favored by the comparatively low toxicity of some of the ILs assayed.

Biobutanol (*n*-butanol of biological origin) is an attractive biofuel[47,48] with higher energy density and lower volatility as compared to ethanol. Biobutanol production from LCM presents a number of challenging technological problems,

DOI: 10.1021/acs.jafc.5b03461
J. Agric. Food Chem. 2015, 63, 8093−8102

some of them related to the complex composition of culture media, which contain large amounts of water, microbial cells (usually, bacteria belonging to the *Clostridium* genus), non-polysaccharide byproducts resulting from LCM hydrolysis, residual sugars, and volatile fermentation coproducts (such as acetone and ethanol). Additionally, the fermentation products are toxic to cells, a fact limiting the maximum achievable butanol concentration (which is typically within the 1−2 wt % range). In a screening study, Knoshaug and Zhang[49] found just two *Lactobacillus* strains able to tolerate and grow in up to 3 wt % butanol, the same level achieved by a mutant *Clostridium biejerinckii* strain.[30] Distillation, the technology traditionally employed to separate the volatile components present in this type of fermentation broth,[50] involves high steam consumption.[51] Alternative, energy-efficient separation methods have been proposed, including adsorption−desorption, extraction, and membrane-based technologies. ILs may find application in these two latter technologies.

Very high boiling extractants have been recommended as extraction solvents for butanol fermentation products, a purpose for which ILs are suitable,[30] either by direct contact with the broth inside the fermenter[52] or by downstream processing. ILs containing anions such as PF_6^- or Tf_2N^- are water immiscible and enable the formation of biphasic systems suitable for extraction applications.[53] In particular, ILs such as [hmim]PF_6 or [bmim]Tf_2N, together with others bearing a tetracyanoborate anion (such as [dmim]TCB), have been considered for *n*-butanol extraction,[30,51,54] whereas the same purpose has been achieved using imidazolium-based ILs with alkyl chains of various lengths in combination with tetrafluoroborate or trifluoromethanesulfonate anions.[30] The hydrophobicity was correlated to the butanol distribution coefficient between ILs and water, whereas the extraction efficiency and selectivity were directly related to the polarity.[30] Ha et al.[55] studied 11 imidazolium-based ionic liquids as extraction agents to recover butanol from aqueous media and also found an interrelationship between extraction efficiency, selectivity, and polarity. The best results were achieved with [omim]Tf_2N, which showed high extraction efficiency and allowed >74% butanol recovery in a single extraction stage. Fadeev and Meagher[56] employed [bmim]PF_6 and [omim]PF_6 to extract butanol from aqueous solutions and subjected the ionic liquid-rich phase (simulating the composition in equilibrium with 1 wt % butanol−water solution) to pervaporation through a commercial polydimethylsiloxane membrane, obtaining an IL-free permeate. Pervaporation with IL-supported membranes[51,57] has been employed to reduce the IL demand and to avoid its direct contact with the production organisms, avoiding possible toxic effects.[58]

Imidazolium-based ILs have also been proposed as separation agents for short-chain organic acids, including lactic acid.[59−62] The biotechnological production of lactic acid in biorefineries by hydrolysis−fermentation of LCM is an interesting possibility, because this compound is an important commodity chemical for the production of specialty chemicals such as 2,3-pentanedione, acrylic acid, propionic acid, pyruvic acid, and polylactic acid. Lactic acid can be obtained at high yield by fermentation of LCM-derived pentoses or hexoses.[63] Depending on the operational conditions, the lactic fermentation can be stereospecific, or it may lead mixtures of the two isomers. Interestingly, polylactic acid stereocomplexes with improved properties can be produced from pure optical isomers. Several 1-alkyl-3-methylimidazolium hexafluorophosphates (including [bmim]PF_6, [hmim]PF_6, and [omim]PF_6) have been employed for the extractive fermentation of lactic acid, acting as a water-immiscible phase (instead of conventional organic solvents) to which lactic acid can be transferred in situ from the fermentation broth, avoiding cell inhibition.[59,60] Although the extractability of the organic acid in the pure ILs was poor, the addition of tri-*n*-butylphosphate increased the extraction ability to a level similar to those of conventional organic solvents. The relatively low toxicity of the considered ILs allowed the growth of the fermenting cells (*Lactobacillus*), which were able to consume glucose and to produce lactate. A comparative evaluation of the various ILs showed that the length of the alkyl substituent in the imidazolium cation had little influence on cell survival.[60]

In biorefineries, ILs can play a number of general roles common to other industries, for example, in the removal of VOC and hazardous pollutants from effluents.[64−66] ILs such as [bmim]PF_6, [bmim]Tf_2N, or [bmim]BF_4 can be directly employed in bioreactors, either for performing enzyme-mediated biocatalytic reactions[67] or in the presence of whole cells, for example, in VOC absorption−biodegradation systems,[67,68] enabling the biotransformation of toxic substrates in the presence of an immiscible liquid phase acting as a substrate reservoir.

The ability of ILs to selectively dissolve gases, together with their nonvolatility, makes them potentially useful for gas separations[69] (for example, CO_2), acting as conventional liquid phases in absorbers or as components of supported liquid membranes.[53,70,71] CO_2 has relatively high solubility in a number of imidazolium ILs, particularly in those containing the bis(trifluoromethylsulfonyl)imide anion, whereas there is little difference in CO_2 solubility between ionic liquids possessing the tetrafluoroborate or hexafluorophosphate anion.[69] Amine-functionalized imidazolium ionic liquids have been specifically designed for CO_2 capture.[72]

ILs as Agents for Cellulose Dissolution−Regeneration and Homogeneous Derivatization. Cellulose is hardly soluble in many conventional solvents because of its strong intermolecular hydrogen bonding. Traditional cellulose solvents, such as carbon disulfide, *N*-methylmorpholine-*N*-oxide (NMMO), and mixtures of *N*,*N*-dimethylacetamide and lithium chloride (DMAC/LiCl), show a number of practical drawbacks, including limited dissolving capability, toxicity, high cost, difficult solvent recovery, uncontrollable side reaction, instability during cellulose processing,[73] and/or the need for multistep pretreatments followed by prolonged stirring.[74]

The ability of some molten ILs (*N*-alkylpyridinium or *N*-arylpyridinium chloride salts) to dissolve cellulose (in the presence of a nitrogen-containing base) has been known since the mid-1930s,[75] but interest in this topic was renewed when Swatloski et al.[76] claimed the ability of ILs made of a number cations (including alkyl-imidazolium-based ones) and anions (including Cl^-, I^-, PF_6^-, BF_4^-, acetate, and trifluoroacetate) to achieve cellulose dissolution. Cellulose dissolution in ILs involves the interaction of hydroxyl groups in cellulose with both the cation and anion in IL.[77] The oxygen atoms of OH groups and IL anions act as electron donors during the dissolution process, in a way that anions acting as strong electron donors (for example, halogen and pseudohalogen ions) gave good cellulose dissolution results, whereas hydrogen atoms of hydroxyl groups and IL cations act as electron acceptors. The review by Wang et al.[78] summarizes extensive literature information on ILs able to dissolve cellulose, the

DOI: 10.1021/acs.jafc.5b03461
J. Agric. Food Chem. 2015, 63, 8093−8102

respective cellulose solubilities, and the suitable operational conditions.

After dissolution, cellulose can be regenerated by adding a miscible antisolvent such as water, alcohols, ethers, or ketones. When an antisolvent such as water is added to the homogeneous IL−cellulose system, the IL ions form hydrogen bonds with water molecules and are displaced into the aqueous phase, whereas cellulose (which previously interacted with IL) is expelled and rebuilds its intra- and intermolecular hydrogen bonds and is then precipitated.[79]

Cellulose dissolution/regeneration in ILs is affected by many factors, including the type of anion and cation, the basicity and H-bonding capability of the anion, and the position and length of the side chain in the cation.[80] As representative examples, [bmim]Cl,[76] [amim]Cl,[73,81] and [emim]Ac[82] can dissolve cellulose at comparatively high concentrations. On the basis of their physicochemical properties, ILs with strongly basic anions (such as formate, acetate, or phosphate) have been cited as favorable candidates for cellulose dissolution under mild operational conditions.[73,74,83] The dissolved cellulose could be readily regenerated by antisolvent addition: for example, water, ethanol, or acetone have been employed to regenerate cellulose from [bmim]Cl,[84] whereas Zhang et al.[81] employed water to regenerate cellulose from [amim]Cl.

The regenerated cellulose can be different from the native cellulose in terms of macro- and microstructure, crystallinity, and even degree of polymerization, depending on the processing conditions.[79,85] In fact, cellulose regenerated from ILs was found to be essentially amorphous and porous.[38] Additionally, it can be noted that complete cellulose dissolution in ILs provides the opportunity of working with new functional groups, opening new ways for product design or enabling a better control of the reaction (for example, regarding the degree of substitution).[86] The manufacture of cellulose derivatives in homogeneous systems by esterification, etherification,[73,86] acylation, carbanilation,[87] carboxymethylation, succination, phthalation,[88] alkylation, silylation, and halogenation[86] has been reported. Other interesting examples of cellulose derivatization in ILs have been reported in related studies.[89−94] On the other hand, cellulose dissolution−regeneration enables the recovery of cellulose nanofibers or its utilization as film, powder, gel, or capsule.[95]

ILs as Agents for LCM Fractionation. The complicated chemical composition and morphology of native LCM, characterized by the presence of both nonstructural components and a cross-linked, tridimensional matrix of polysaccharides and lignin, together with the crystalline nature of cellulose, are major hindrances for processing. Considered as feedstocks for chemical and/or biotechnological processess, LCM are recalcitrant substrates that must be deconstructed (or fractionated) to achieve separation of their major components. This is a key step in the conversion of lignocellulosic biomass into fuels and valuable chemicals and materials.[96] LCM dissolution may imply the hydrolysis of carbohydrate polymers or the chemical disruption of the lignocellulose composite.[97] ILs or IL mixtures (eventually in the presence of catalysts, water, and/or other components) have demonstrated great promise as efficient solvents for biomass fractionation, via total or partial dissolution.[98] The interaction of ILs with lignocellulose may involve ionic, $\pi-\pi$, and hydrogen-bonding interactions. LCM dissolution in ILs depends on a number of factors, including the type of constituent cation and anion, the nature and previous processing of biomass (for example, milling or drying), the characteristics of the substrate (including composition, particle size distribution, moisture), the relative amount of LCM, other operational conditions (including temperature heating profile, maximum temperature, and processing time), and the possible presence of additional components in the medium (for example, water, catalysts, or cosolvents). For example, DMSO has been used in combination with [bmim]Cl or [amim]Cl to achieve the partial dissolution of lignified raw materials,[96,99] whereas the utilization of two ILs ([emim]Ac in combination with [amim]Cl or [bmim]Cl) has been proposed for the same purpose.[100]

Complete dissolution has been reported for LCM of low lignin content (such as bagasse, straws, grasses, or husks) but also for recalcitrant substrates such as hardwoods or softwoods. With regard to wood dissolution, [bmim]Cl and [emim]Ac have been identified as the two most promising ionic liquids.[101] Representative studies and reviews on LCM dissolution using a number of imidazolium-based ionic liquids have been reported in the past few years.[37,38,88,96,97,99,102−112] Once biomass is dissolved, the various structural components can be recovered using a number of operational strategies, many of them based on the precipitation of cellulose (or cellulose-enriched solids) upon antisolvent addition.[97]

An alternative to completely dissolving biomass is to selectively dissolve just a single biomass component.[12] This approach may involve hemicellulose hydrolysis or lignin extraction. Delignification-based processes usually enable the recovery of polysaccharides (at least, cellulose) as insoluble solids.[26,113,114] Representative information on the delignification of multiple LCM in media containing imidazolium-based ionic liquids (including [emim]Ac, [emim]Ace, [emim]ABS, [emim][Cl], [bmim]Ac, [bmim]Ace, [bmim]mSO_4, [bmim]Br, [bmim]BF_4, [bmim]PF_6, [amim]Cl, and [hmim]Cl) has been summarized in recent studies.[37,97,100,113,115−118]

The ideal technology for LCM biorefineries would be one in which the three major components of the biomass were obtained at high yields and purities.[119] However, the recovery of hemicelluloses (the most easily hydrolyzable of the three main lignocellulosic polymers) is challenging,[37] as this fraction can be considerably depolymerized and dissolved in ILs and, eventually, decomposed (as has been found in the processing of pine wood with [hmim]Cl),[113] resulting in losses that increase the cost of downstream separation.[110] Although delignification increases with high temperatures, such conditions promote hemicellulose losses.[120] On the other hand, treatments allowing delignification and hemicellulose solubilization simultaneously may entail losses of cellulose as soluble hydrolysis products.[114] In some dissolution−regeneration approaches, hemicellulose and cellulose can be obtained as separated fractions from the regenerated material, using specific solvents to maximize the fractionation process.[37,121] The selective dissolution of hemicelluloses (up to 39% of the total) from extracted or native spruce wood has been addressed in the literature using switchable ionic liquids.[101] Starting from bleached paper grade pulps, separate fractions of hemicelluloses and cellulose (both of high purity) were recovered upon processing with [emim]Ac containing 15−20% water.[122] Under severe conditions (for example, in high-temperature treatments with strongly acidic ILs), the formation of carbohydrate degradation products able to react with lignin (leading to the formation of pseudolignin) has been reported.[114] Oppositely, in treatments with ILs possessing strongly basic anions, hemicelluloses are converted into oligosaccharides, generating only trace amounts

DOI: 10.1021/acs.jafc.5b03461
J. Agric. Food Chem. 2015, 63, 8093−8102

of monomeric sugars (xylose and glucose).[123] In some operational schemes, cellulose and lignin are precipitated sequentially, and the hemicellulose-derived saccharides left in the IL phase are subjected to further chemical modification.[124]

The integral benefit of the various LCM components can be achieved by coupling conventional separation treatments with IL processing. Following this idea, dissolution in [bmim]Cl followed by NaOH extraction has been reported for bagasse utilization,[121] whereas the implementation of a first stage of hemicellulose removal (for example, hydrothermolysis or prehydrolysis) before treatment with ILs (aiming at the separation of cellulose and lignin) has also been proposed.[97] This latter approach follows the philosophy underlying the commercial prehydrolysis−kraft process and is being studied as an alternative to increase the added value from hemicelluloses in conventional kraft pulping technology.

ILs as Pretreatment Agents for the Enzymatic Hydrolysis of Cellulose. The enzymatic hydrolysis of cellulose leads to glucose solutions suitable as fermentation media for manufacturing a wide range of biofuels, solvents, polymers, and other marketable compounds. However, native LCM is recalcitrant to the action of cellulases, a fact attributed to a number of factors, such as substrate accessibility, cellulose degree of polymerization, crystallinity, particle size, and porosity, as well as to the presence of hemicellulose and lignin.[111] In particular, cellulose is embedded in a matrix of lignin and hemicelluloses, which are cross-linked by ester and ether linkages in the plant cell wall, hindering the access of enzymes to the cellulose glycosidic bonds. To disrupt the cell wall structure, some type of processing (by mechanical, biological, physical, and/or chemical methods, individually or in combination) is necessary. This type of processing is referred to in the literature as "pretreatment" and has been extensively reviewed owing to its economic and technological importance. Chemical pretreatments modify the composition of substrates, and some of them can be considered as true fractionation treatments. This dual behavior (as pretreatment and/or fractionation agents) defines well the potential of ILs in the field: in fact, a number of references included in this work (particularly, some of the ones employed to discuss the LCM fractionation by ILs) are directly oriented to the production of substrates suitable for enzymatic hydrolysis, because ILs show ability for removing lignin, disrupting the crystalline structure of cellulose, and increasing the accessibility of enzymes to cellulose.[32] The ILs most frequently utilized for LCM pretreatment are the ones suitable for cellulose dissolution, including [emim]Ac, [amim]Cl, [bmim]Cl, and dialkylimidazolium dialkylphosphates, which have been applied to a number of substrates.[104,112,125−129] Depending on the IL employed, the effects caused by processing may resemble those of aqueous stages performed under alkaline or acidic conditions, as happens for acetate- and chloride-based ILs, respectively.[130] Data on the comparative saccharification efficiency achievable with selected ILs have been reported recently.[129]

In typical processing schemes, LCM are treated with ILs to cause dissolution−regeneration or delignification, yielding cellulose-enriched substrates of decreased crystallinity and improved enzyme accessibility, which are extensively washed to remove the residual IL and further hydrolyzed with enzymes at high yield with fast kinetics. It can be noted that ILs are comparatively expensive and that efficient and cost-effective recovery methods have to be implemented for economic feasibility. The best IL depends on the substrate considered;[112] for a given IL, the optimal processing conditions must be optimized for different substrates.[109] In terms of saccharification yields, material recovery, and delignification, [emim]Ac ranks as the most suitable IL for biomass pretreatment,[130] but [bmim]Cl performed very well for simple cellulosic substrates, and [bmim]HSO_4 has been recommended for processing hybrid aspen.[112] Acetate-based ILs present advantages over chloride-based ILs derived from their lower melting point, lower viscosity, lower corrosive character, and ability to work with higher loadings.[131] Strongly acidic ionic liquids may cause partial polysaccharide depolymerization, hydrolysis, and dehydration, leading to the formation of furans as reaction byproducts.

It must be considered that, in integrated processes, ILs may be present in the aqueous hydrolysis media as a result of recycling streams from IL recovery stages. This is important because the presence of ILs in the hydrolysis media (even in trace amounts) can inhibit or denature enzymes, depending on the type and concentration of the considered IL. According to Turner et al.,[132] *Trichoderma reesei* cellulases are subjected to ionic strength-induced inactivation and unfolding in media containing as little as 22 mM [bmim]Cl. Refolding of denatured cellulase was possible only when the enzyme was contacted with solutions containing 0−5% [bmim]Cl. The Cl^- ion was, in part, responsible for the inactivation of the cellulase, because the IL produces a dehydrating and denaturing environment.

In most cases, the enzyme activity drops quickly when the ionic liquid concentration is increased, but no general conclusions on this subject can be drawn owing to the diversity of conditions assayed. In integrated biorefinery processes, keeping a very low IL concentration in the hydrolysis media would require extensive processing and cleanup of the cellulosic substrates. Because of this, the cellulases should be preferably able to perform optimally in solutions containing up to 15 wt % IL, which corresponds to the amount retained by the hydrolysis substrates upon processing.[133] To deal with this problem, two possible approaches can be followed (individually or simultaneously): utilization of ILs causing minimal inhibition and/or using cellulases with increased tolerance to the IL.

The IL [emim]Ac shows minimal inhibitory effects on enzymes compared to ionic liquids containing Cl^- or Br^- anions,[96,133,134] whereas favorable compatibility has been also reported for [emim]DEP,[135] [mmim]DEP, and [mmim]-DMP.[136] With regard to the role of enzymes, Wahlström and Suurnäkki[125] summarized literature on the action of cellulases and other glycosyl hydrolases in IL solutions. Interesting possibilities lay in the utilization of enzymes from extremophilic strains able to perform at high temperature and salt concentration, as the utilization of enzymes capable of withstanding higher concentrations of salt and ionic liquids and higher pH would make the washing steps less cumbersome, facilitating the industrial biomass conversion process.[133,137] Datta et al.[133] investigated the stability of recombinant, extremophilic enzymes, as a function of IL concentration, and reported that (unlike the reference *Trichoderma viride* cellulase), the tested enzymes retained between 44 and 79% of their activity in the presence of 15% [emim]Ac. In this field, a GH5 family cellulase able to keep activity in the presence of 30% (v/v) IL has been identified,[138] whereas a hyperthermostable archaeal endoglucanase was reported to retain considerable activity (30−50%) in the presence of 25% (v/v) [mmim]DMP.[139]

In conclusion, ILs are potentially suitable for a number of duties in LCM biorefineries. Considered as agents for physicochemical processing of liquid process streams, ILs are suitable as entrainers for the dehydration of ethanol−water mixtures, as well as agents for the in situ separation of microbial metabolites (including selected alcohols and acids) from the fermentation media. ILs are also suitable for preventing pollution from gaseous waste streams, for example, by removing VOC or carbon dioxide from them. With regard to the chemical modification of native LCM, operational schemes based on dissolution−regeneration or delignification provide interesting alternatives for developing alternative processing technologies. One of the most suited schemes for LCM biorefineries (pretreatment/fractionation followed by enzymatic hydrolysis and fermentation) could be conveniently perfomed by using selected ILs (causing limited losses of enzymatic activity and/or showing enhanced compatibility with microorganisms), as well as by using tolerant enzymes produced by extremophilic microorganisms.

activity relationships of the constituent in the target organism. Proteomic and metabolomic tools may be used to gain deeper insight into complex biological processes but also require a structure-targeted approach.[4−6]

Manuscripts can encompass cell-based or other in vitro assays, animal models, human intervention studies, clinical trials, or a combination thereof as the fundamental component; however, target compounds need to be tested at relevant dose levels and test systems applied must be validated, should allow the quantitation of time and dose response effects, and need to be appropriate for in vivo conditions. Antioxidants need to be considered as a prominent example of the sometimes misleading prediction of a bioactive constituent's relationship to human health. Neither have less appropriate in vitro "antioxidant" test assays (ORAC, FRAP, TEAC, etc.) shown that they are able to predict protection against DNA damage or lipid and protein oxidation in vivo, nor has it been established that plasma antioxidant status predicts a physiological benefit. Rather, molecules that stimulate endogenous antioxidant and anti-inflammatory cell signaling cascades in ways that promote health seem to be more relevant to establishing bioactivity.[7]

To demonstrate bioefficacy as an overall aim of the "bioactives research" theme, the bioavailability of the target food constituent has to be substantial and may, in some cases, not be sufficient to exert the desired effect after dietary intake. Therefore, the discussion on nutritional relevance and conclusions on human health aspects need to be carefully formulated considering the experimental design used (appropriate cell-based or other in vitro assays, animal models, clinical human trials, significance of test/trial, relevant dose levels, etc.) and the robustness of the data set obtained and addressing the underlying mechanism of action. If, for example the bioactivity of a given compound is tested in a postabsorptive cell system, the compound's bioavailability characteristics, particularly the chemical structures of the metabolites formed, the metabolite and the parent compound concentrations after dietary intake, and the relevance of the cell line have to be considered. This can be illustrated by the general class of polyphenols, such as the flavonoids, most of which are metabolized by phase II enzymes in the intestinal tissues during the absorption process to render methylated, sulfated, or glucuronidated derivatives[8] or, if present in the food as glycosides, hydrolyzed or directly absorbed, or in the case of rhamnosides or rutinosides cannot be hydrolyzed without the help of gut microbiota to release the aglycones that would be then absorbed.

Overall, the manuscripts submitted to the "Bioactives" section of the *Journal of Agricultural and Food Chemistry* should consider the following five focus areas in increasing our integrated understanding of bioactive compound functions:

- identification of bioactive molecules in agricultural and food products by applying an activity-guided fractionation approach using relevant in vitro assays or any other appropriate target compound directed discovery technologies, followed by an unequivocal structure determination using state-of-the-art spectrometric and spectroscopic techniques;[9]
- accurate quantitation of bioactive target compound(s) using validated biochemical, molecular−biological, and/or chemical analytical tools;[10]
- demonstration of the bioavailability of bioactive constituents in a relevant in vitro model or in/ex vivo;
- unequivocal identification and quantitation of metabolites generated upon ingestion of bioactive target compounds;
- mechanistic studies, using relevant compounds at a demonstrated level of purity in appropriate cell-based models, animal trials, or human intervention studies.

Given the complexity of this approach, at least two of these criteria should be met for considering the described work as relevant to the field. In any case, chemical, biochemical, and molecular−biological methods and reproducibility of the work should be the fundamental principle behind the experimental design and should be combined with a biological and/or toxicological evaluation of structure−activity relationsships of the matrix constituents in living organisms related to agriculture and/or food. If the experimental approach is mainly based on individual test systems, the work is likely to remain only observational and descriptive. As a general rule, manuscripts dealing with traditional medicines and herbal remedies or those testing commercially available reference compounds, selected without any convincing rationale, in cell-based in vitro assays to draw conclusions on their impact on disease states (e.g., "anticancer" activity) will generally not be accepted for review. Moreover, it is mandatory that manuscripts reporting on biological properties of individual constituents include information on the purity of the test components and on how it has been determined (e.g., ^{1}H NMR, GC-FID, HPLC-ELSD). Similarly, investigations performed with crude extracts need to present detailed information on the chemical composition of the extracts responsible for the described properties. This means that key representatives of the chemical class investigated (e.g., polyphenols, terpenoids, alkaloids, peptides) should be quantitatively fingerprinted. In general, lack of the unequivocal chemical characterization of the bioactive target components may limit the reproducibility of the results and, as a consequence, such work might not be considered suitable for review.

JAFC has already published a number of good examples of bioactivity research on plants,[5,6,11] pathogens,[12,13] and food/nutrition aspects[14−22] that illustrate the breadth and depth of this field. With the boundaries defined in this perspective, we invite future authors to conform to the highest standards of chemical/biological research on bioactives spanning the range from whole foods to drug-like isolated compounds that are required to best serve the needs of our society.

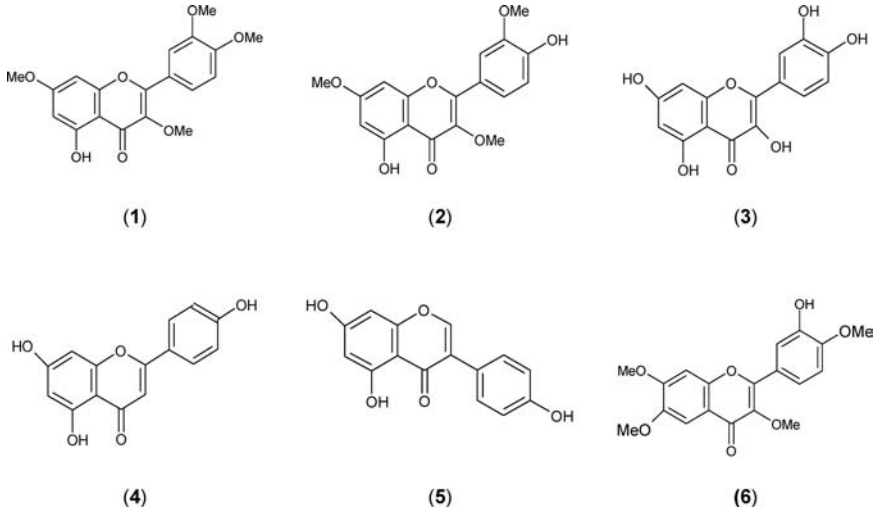

Figure 1. Structures of the evaluated flavonoids: Retusin (**1**), pachypodol (**2**), quercetin (**3**), apigenin (**4**), genistein (**5**), and eupatorin (**6**).

ciliatoglanduliferus Ort. by column chromatography (CC) separation and then were purified by preparative thin-layer chromatography (PTLC) as previously reported.[15] Open column chromatography (silica gel 60, 70−230 mesh, Merck) and PTLC (silica gel 60 F_{254}, 1 mm plates) were used. The identity of compounds **1** and **2** were corroborated by spectroscopic methods and compared with previously reported data.[15] ^{1}H NMR and ^{13}C experiments were recorded on a Varian Unity INOVA at 300 MHz, and EI mass spectra were obtained on a JEOL SX 102A mass spectrometer. Quercetin (**3**), apigenin (**4**), genistein (**5**), and eupatorin (**6**) were purchased from Sigma-Aldrich and used as received (Figure 1).

Chloroplasts Isolation and Chlorophyll Determination. Intact chloroplasts were isolated from market spinach leaves (*Spinacia oleracea* L.) as previously reported.[17,18] Chloroplasts were suspended in a small volume of a solution containing 400 mM sucrose, 5 mM $MgCl_2$, 10 mM KCl, and 30 mM tricine−KOH (pH 8.0), and they were stored as a concentrated suspension in the dark at 4 °C. The chlorophyll (Chl) concentration was measured according to Strain.[19]

Noncyclic Electron Transport Determination. Light-induced noncyclic electron transport determination was performed in the presence of 50 μM methylviologen (MV) as an electron acceptor using a Clark type electrode.[20] Basal electron transport was polarographically determined by illuminating chloroplasts (20 μg chlorophyll/mL) during 1 min in a medium containing 100 mM sorbitol, 10 mM KCl, 5 mM $MgCl_2$, 0.5 mM KCN, 50 μM MV, and 15 mM tricine−KOH (pH 8.0) as previously published.[18,20] Phosphorylating noncyclic electron transport was measured with the basal medium plus 1 mM adenosine diphosphate (ADP) and 3 mM KH_2PO_4.[18,20] Uncoupled electron transport was tested in the basal medium, and 6 mM NH_4Cl was added as an uncoupler.[18,20]

Uncoupled Photosystem II (PSII), Photosystem I (PSI), and Their Partial Electron Flow Determination. These electron flow activities were monitored with an oxygen monitor YSI (Yellow Spring Instruments) model 5300A using a Clark type electrode. The uncoupled electron transport rate was measured from water to 2,5-dichloro-1,4-benzoquinone (DCBQ)[21] using the medium for PSII reactions. This medium is the same for basal measurements without MV but with 100 μM DCBQ, 1 μM 2,5-dibromo-6-isopropyl-3-methyl-1,4-benzoquinone (DBMIB) and 6 mM NH_4Cl. Chloroplasts (20 μg Chl/mL) were then added and illuminated during 1 min.

Uncoupled partial reaction of PSII was measured from water to sodium silicomolybdate (SiMo), determined in the reaction medium for PSII (3 mL), plus 200 μM SiMo[22,23] and 10 μM 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU) before the addition of chloroplasts (20 μg Chl/mL), and then illuminated for 1 min.

The uncoupled PSII partial electron transport rate was measured from DPC (diphenylcarbazide), which is an efficient electron donor to the inactive oxygen-evolving complex of PSII in Mn-depleted thylakoids (thylakoids previously treated with 0.8 M hydroxymethyl aminomethane (Tris) at pH 8.0).[24,25] DPC donates electrons at Z,[26] and the reduction of DCPIP was measured using a Beckman DU 650 spectrophotometer.

The uncoupled PSI electron transport was determined using the basal electron transport medium, plus 10 μM DCMU (to inhibit PSII at Q_B level) and 100 μM dichlorophenol indophenol (DCPIP) reduced with 300 μM ascorbate, and uncoupled with 6 mM NH_4Cl.[27]

All reaction mixtures were illuminated with filtered light (filtered through 5 cm of 1% $CuSO_4$ solution) from a projector lamp (GAF 2660) at room temperature. For each reaction, a blank experiment was performed with the chloroplasts in the reaction medium. The I_{50} value is the concentration producing 50% inhibition of activity and was determined from the plots of activity versus different concentrations of each compound calculated by linear regression analysis by probit.[28]

Chlorophyll *a* (Chl *a*) Fluorescence Determination. Chl *a* fluorescence was measured at room temperature with a Hansatech Fluorescence Handy PEA (plant efficiency analyzer).[29,30] The maximum fluorescence yield from the sample was generated using three red intensity light-emitting diodes (broadband 650 nm) of 3000 μmol m^{-2} s^{-1}. The pulse duration was 2 s. To monitor transients of Chl *a* fluorescence, aliquots of dark-adapted thylakoids containing 20 μg of Chl were transferred to filter paper by gravity and immediately dipped in 3 mL of basal noncyclic electron transport medium at different concentrations of the compounds. Photosynthetic parameters associated with PSII were obtained according to the equations of the O-J-I-P test using the program Biolyzer.[31]

Sample Preparation. Each compound was dissolved in dimethyl sulfoxide (DMSO) to prepare a 20 mM stock solution. For the chlorophyll *a* fluorescence determination, dry biomass, and leaf chlorophyll determination assays, an aliquot of each stock solution was taken to obtain the desired concentration in a deionized aqueous solution (25 mL) containing Tween 20 (0.02% v/v, to avoid the surface tension). The negative control group was sprayed with a solution of deionized water (containing 0.02% v/v of Tween) and DMSO in the same proportion as that used to prepare the one with the major concentration of flavonoid (300 μM). For the positive control, an aliquot of a solution 3 mM DCMU in EtOH was taken to prepare 50 μM DCMU in an aqueous solution containing Tween 20 at 0.02% v/v.

For the germination and seedling growth bioassays, an aliquot of each flavonoid solution was taken to prepare the desired concentration (50 and 100 μM) in an aqueous solution where *T. alexandrinum*, *P. ixocarpa*, and *L. perenne* seeds were grown. To measure the *T. alexandrinum* seedling respiration, test solutions were diluted employing Hoagland medium which consists of 6 mM KNO_3, 4 mM $Ca(NO_3)_2 \cdot 4H_2O$, 1 mM $NH_4H_2PO_4$, 2 mM $MgSO_4 \cdot 7H_2O$, 46 μM H_3BO_3, 13.6 μM Fe−EDTA, 9 μM $MnCl_2 \cdot 4H_2O$, 0.8 μM $ZnSO_4 \cdot 7H_2O$, 0.3 μM $CuSO_4 \cdot 5H_2O$, and 0.1 μM $H_2MoO_4 \cdot H_2O$ (pH = 5.2−5.5).[32]

Plant Material. The seeds of three plant species, green tomato (*Physalis ixocarpa*), clover (*Trifolium alexandrinum*), and grass (*Lolium perenne*), were washed with a 10% sodium hypochlorite solution for 15 min in an orbital shaker (VWR minishaker). After this time, the hypochlorite solution was removed and the seeds were rinsed three times with deionized water. One hundred seeds were placed in 12 cm diameter pots containing a mixture of 50:25:25 v/v soil/peat-moss/agrolita. All pots were watered every third day and maintained in a greenhouse at room temperature (25−30 °C) with a normal day/night (12/12 h) illumination. After 15 days of emergence for *P. ixocarpa* and *L. perenne*, and 20 days for *T. alexandrinum*, the plants were selected by uniformity and similar size and were divided into three groups: (a) the control; (b) the experimental, which was sprayed manually with 25 mL of flavonoid solutions at different concentrations (25, 50, 100, 200, and 300 μM); (c) the positive control (sprayed with 25 mL of 50 μM DCMU).

Chlorophyll *a* Fluorescence Determination in Intact Leaves in Vivo. The chlorophyll *a* (Chl *a*) fluorescence determination was performed at 24, 48 72 and 168 h after treatment of plants and dark adapted for 30 min. The leaves were excited with saturating light as above-mentioned for chloroplasts and processed according to the concept of the JIP-test[29] with the program Biolyzer which executes the JIP test equations for the analysis of the fluorescence transient O-J-I-P.[30]

Leaf Chlorophyll Determination. Leaves of treated species (100 mg) harvested randomly from plants were placed into test tubes and incubated with 5 mL of *N*,*N*-dimethylformamide (DMF) at 4 °C for 24 h in the dark for chlorophyll extraction. The absorbance of each 3.0 mL sample was determined at 664.5 nm for chlorophyll *a* and at 647 nm for chlorophyll *b* using a spectrophotometer (Thermo model G-10S). The extinction coefficients assigned by Inskeep were used to estimate the chlorophyll concentration.[33]

Dry Biomass. After 15 days of treatment with the test compounds, all plants were harvested at ground level and dried in an oven at 65 °C to reach constant weight. Then the dry mass was determined employing an analytical balance.[34]

Germination and Seedling Growth Bioassays. Forty seeds of *P. ixocarpa*, *T. alexandrinum*, and *L. perenne* selected for uniformity (undersized or damaged materials were discarded) were washed and placed in 10 cm Petri dishes using Whatman no. 1 filter paper as support. In each Petri dish 10 mL of deionized water and the aliquot of the stock solution (20 mM) of flavonoid were added; for the negative control, 10 mL of deionized water and the aliquot with the major concentration of solvent used to prepare the test solution were employed. The Petri dishes were incubated at 28 °C in the dark. After 7 days, the values of root and stem lengths as well as the number of germinated seeds were obtained (the number of germinated seeds was determined according to the criteria of 1 mm extrusion of the root). Each assay was conducted in triplicate, and the statistical differences between the treatments were evaluated by Student's *t* test for assessing the statistical significance. Data were presented as the percentage of differences from control in bar graphics. The negative control represents 0%, positive values represent stimulation of the studied parameter, and negative values represent inhibition.

Measurement of the Effect of Flavonoids on the Respiration of *T. alexandrinum* Seedlings. Two hundred seeds of *T. alexandrinum* were placed in 15 cm Petri dishes, 20 mL of a 50% v/v Hoagland medium was added,[32] and flavonoids were added at different concentrations (50, 100, 150, and 200 μM). Then the Petri dishes were incubated in darkness for 7 days at 28 °C. Etiolated seedlings (200 mg) were placed

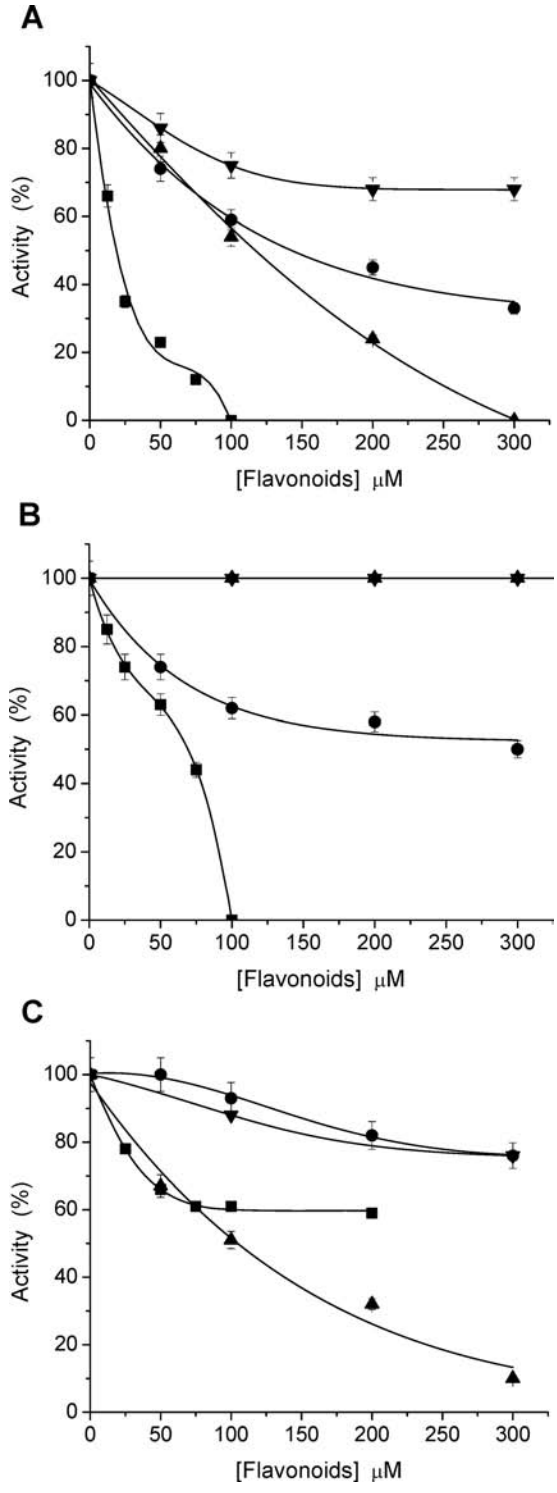

Figure 2. Effect of flavonoids **3** (■), **4** (●), **5** (▲), and **6** (▼) on partial reactions in PSII from H_2O to DCBQ (panel A), from H_2O to SiMo (panel B), and from DPC to DCPIP (panel C). Control value rates for photosystem II from H_2O to DCBQ and from H_2O to SiMo were 520 ± 52 and 110 ± 5 μequiv e^- mg^{-1} Chl h^{-1}, respectively. For the PS II partial reaction measured from DPC to DCPIP, controls for flavonoid **3** and **4** were 80 ± 4 μM DCPIPred mg^{-1} Chl h^{-1}; for **5** and **6**, controls were 96 ± 4.8 μM DCPIPred mg^{-1}. Data are means of three replicates.

in a reaction vessel, and 3 mL of 50% v/v Hoagland medium was added. The seedling respiration was measured as O_2 uptake using a Clark type electrode attached to a Yellow Spring Instruments (YSI) model 5300A oxymeter. The current generated during the O_2 reduction to water was converted to voltage, and the signal was recorded on a Kipp and Zonen chart recorder. The current was stoichiometrically related to the oxygen consumed at the cathode. The consumption rate was calculated with the following equation:

$$\left(\frac{1200\ \text{nmol O}_2}{20\ \text{cm}}\right)\left(\frac{60\ \text{min}}{1\ \text{h}}\right)\left(\frac{y}{1\ \text{min}}\right)\left(\frac{1}{\text{mg seedlings}}\right) = \text{nmol O}_2\ \text{h}^{-1}\ \text{mg}^{-1}$$

The results were reported as nmol O_2 h^{-1} mg^{-1} of seedlings.[35] In the equation, 20 cm on the recorder paper corresponds to 1200 nmol O_2 and y corresponds to the recorded distance in cm when the O_2 uptake of seedlings in aqueous medium occurred.

RESULTS AND DISCUSSION

Isolation of Retusin (1) and Pachypodol (2). The natural flavonoids **1** and **2** were isolated from the hexane extract of the aerial parts of *Croton ciliatoglanduliferus* in approximate 0.5% yield for both compounds, as previously published.[15]

Effect of Flavonoids on the Photosynthetic Electron Transport Chain. Previously, results showed that compound **2** inhibited the photosynthetic electron flow from water to MV on freshly lysed intact spinach chloroplasts.[15] To know the effect of the flavonoids **3**–**6** on the electron transport flow (basal, phosphorylating, and uncoupled), they were assayed under the same conditions as that for **2**. Table 1 shows the I_{50} values for the tested compounds and for each transport. It was found that flavonoid **1** inhibited 20% the electron flow for the three conditions (basal, phosphorylating, and uncoupled) at 300 μM.[15] The most active compound to inhibit the uncoupled electron transport was **2** with an I_{50} value of 74 μM, followed by **3**, **5**, and **6**, with I_{50} values of 114, 200, and 130 μM, respectively. **4** inhibited basal and phosphorylating electron flow; however, at the concentrations evaluated, the I_{50} value for the uncoupled electron flow was not reached (Table 1). Thus, **2**, **5**, and **6** behave as Hill reaction inhibitors and **3** as uncoupler and electron transport inhibitor (Table 1). The most active compounds as uncoupled electron transport inhibitors were **2** and **3**, with I_{50} values of 74 and 114 μM with lower log *P* values of 2.62 and 1.37, respectively.

Localization of Interaction Sites of Flavonoids on PSII, PSI, and Partial Reactions. To localize the inhibition site of flavonoids on the thylakoid electron transport chain, the effects of increasing concentrations of **3**, **4**, **5**, and **6** on PSII, PSI, and the partial reactions were assayed using artificial electron donors and electron acceptors, as well as appropriate inhibitors.[27] Figure 2A shows that flavonoids **3**, **4**, **5**, and **6** inhibit uncoupled PSII from water to $DCBQ_2$ with **3** being the most active followed by **5**. Compound **3** inhibited 100% at 100 μM the electron flow measured from water to SiMo (Figure 2B) and partially (40% at 200 μM) the span from DPC to DCPIP (Figure 2C). Compound **4** also inhibited to a minor degree these partial reactions. Flavonoids **5** and **6** did not affect the electron flow from water to SiMo; however, compound **5** inhibited almost 100% at 300 μM the span from DPC to DCPIP and **6** only did partially. On the other hand, neither one showed inhibitory activity on PSI measured from DCPIP reduced to MV (data not shown).

Chl *a* Fluorescence Determination in Chloroplasts. To corroborate findings by polarography on the interaction site of **3**, **4**, **5**, and **6** at PSII, chlorophyll *a* fluorescence kinetics were determined in freshly lysed spinach chloroplasts incubated for 5 min in the dark at room temperature. The treated chloroplasts contained various concentrations of the flavonoids (25, 150, and 300 μM), and each concentration was measured three times. Control chloroplasts contained the corresponding amount of DMSO used for each treatment. The fluorescence of chlorophyll *a* transients obtained from the treated and control chloroplasts was normalized, and the differences between them revealed an increase in intensity between 2 and 4 ms appearing as a J-band (Figure 3, panels A, C, E, and F). Moreover, experiments with **3** and **4** exhibited lower K-bands (Figure 3, panels B and D).

In samples treated with increasing concentrations of DCMU a single induction phase is observed and the F_M is reached after about 2 ms (J-step).[36] DCMU displaces the secondary quinone acceptor, Q_B, from its binding site at the D1 protein of photosystem II (PSII)[37] and prevents the reoxidation of Q_A^- by forward electron transport. The fluorescence rise is mainly determined by the redox state of Q_A^-.[36]

On the other hand, the appearance of the K-band results from an imbalance in the electron flow between the donor and

J. Agric. Food Chem. 2015, 63, 8106−8115

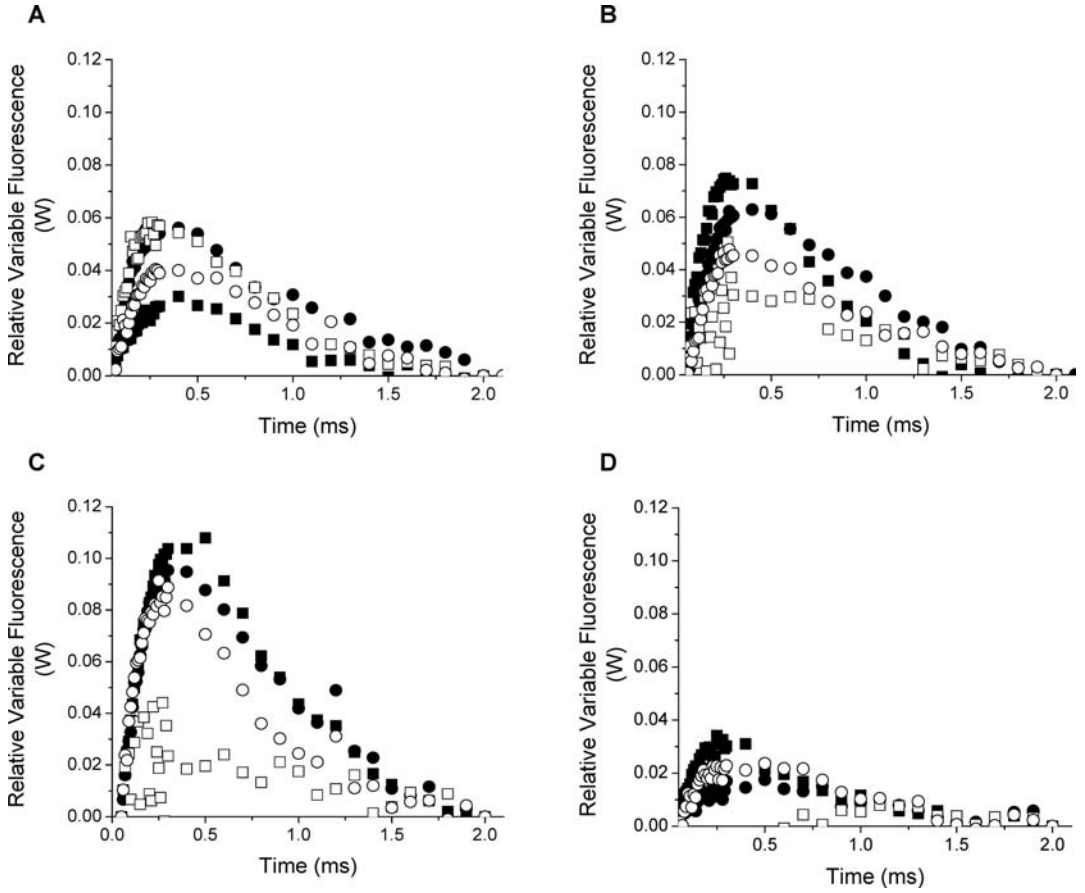

Figure 4. Appearance of the K-band at about 300 μs with the fluorescence of chlorophyll *a* measured in *P. ixocarpa* leaves. The ordinate is the difference between the *W* of the sample minus the *W* of the control, where *W* is the relative variable fluorescence between F_0 and F_J. Therefore, $Wt = V_{0J}(t) = FV_t/(F_J - F_0) = (F_t - F_0)/(F_J - F_0)$. (■) **1**, (●) **2**, (□) **3**, and (○) **5** at 300 μM at 24 (A), 48 (B), 72 (C) h, and 7 days (D).

the acceptor side of PSII. Under this condition, the electron flow from OEC to Z is slower than the electron flow from P_{680} to Q_A. The fast initial fluorescence rise is due to the reduction of Q_A to Q_A^- followed by the reduction of P_{680}^+ by Tyr_Z (a tyrosine residue) without the direct participation of OEC.[37]

Thus, the flavonoids assayed, pachypodol (**2**), quercetin (**3**), genistein (**5**), and eupatorin (**6**), inhibited the electron flow, behaving as Hill reaction inhibitors. The polarographic technique and Chl *a* fluorescence measurements suggested that flavonoids **3** and **4** inhibited the donor side of PSII and partially the acceptor site from P_{680} to Q_A and that **5** and **6** inhibit the acceptor site of PSII probably from P_{680} to Q_B. The potency of these flavonoids is similar to that of other natural products such as siderin[38] and lasiodiplodin[39] among others.

Chl *a* Fluorescence Determination in Leaves. To know if the flavonoids act as postemergent herbicides, plants of *P. ixocarpa* and *L. perenne* were grown for 15 days and 20 days for *T. alexandrinum*, they were treated with the flavonoids, and 24, 48, 72, and 168 h later the chlorophyll *a* fluorescence was measured. The fluorescence curves obtained from these assays showed that compounds **1**, **2**, **3**, and **5** affected *P. ixocarpa* leaves, while **4** and **6** did not show effects. From the chlorophyll *a* transients, the following parameters were obtained: (a) Fluorescence intensity level (F_0) when the electron acceptor (Q_A) is fully oxidized. (b) Fluorescence intensity level (F_M) when Q_A is fully reduced. (c) Fluorescence intensity level at time 0.05 ms (F_1), at 0.1 ms (F_2), at 0.3 ms (F_3), at 2 ms (F_4 or F_J), and at 30 ms (F_5).[40] (d) Area: the area over the curve between F_0 and F_M. It is composed of the area over the OJ-phase, which represents the reduction of the acceptor side of PSII, the area above the transients J-I that is caused by a partial reoxidation of the PQ-pool and electron transfer toward PSI, and the area above the IP-phase, which represents the reduction of the acceptor side of PSI; thus, the total area is a measure of the quantity of electron acceptors between the acceptor side of PSII and the acceptor side of PSI.[41] The values obtained for *P. ixocarpa* leaves treated with **1** are shown in Table 2. The data for the treatments with **2**, **3**, and **5** were similar to that for **1** and are not shown. The transients of fluorescence of chlorophyll *a* obtained with the *P. ixocarpa* leaves control and for the treatments with **1**, **2**, **3**, and **5** were normalized from F_0 to F_4, and the difference between the treated and control normalized transients revealed a band near 0.3 ms (K-band) (Figure 4). As time passed, the K-band intensity was increased; the major K-bands were found at 72 h of treatment (Figure 4C), indicating that the flavonoids **1**, **2**, **3**, and **5** needed time to penetrate the leaves to reach their target. After 7 days of treatment, the bands decreased, indicating that probably the plant metabolized these flavonoids. When the transients were normalized from F_0 and F_5, the difference between the treated and control normalized transients revealed an increase in intensity between 2 and 4 ms, appearing as a J-band (Figure 5). Flavonoids **1**, **2**, **3**, and **5** interact at this site, and the unused energy is dissipated as heat.[30] Besides the appearance of K- and J-bands, F_V/F_M values of the samples treated with **1**, **2**, **3**, and **5** decreased with respect to the control, and TR_0/RC [trapped energy flux per RC (at t = 0)

DOI: 10.1021/acs.jafc.5b02842
J. Agric. Food Chem. 2015, 63, 8106−8115

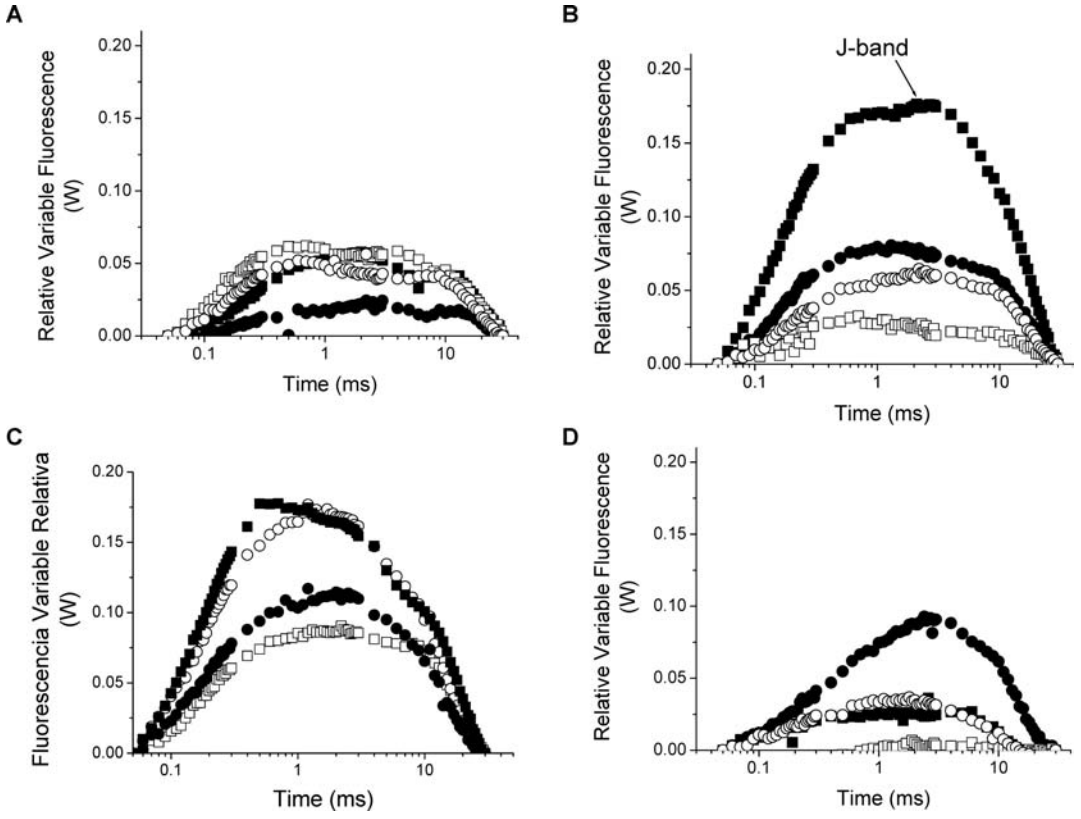

Figure 5. Appearance of the J-band occurs at about 2 ms. The ordinate is the difference between the W of the sample minus the W of the control, where W is the relative variable fluorescence between F_0 and F_I. Therefore, $Wt = V_{0I}(t) = FV_t/(F_I - F_0) = (F_t - F_0)/(F_I - F_0)$. (■) **1**, (●) **2**, (□) **3**, and (○) **5** at 300 μM at 24 (A), 48 (B), 72 (C) h, and 7 days (D).

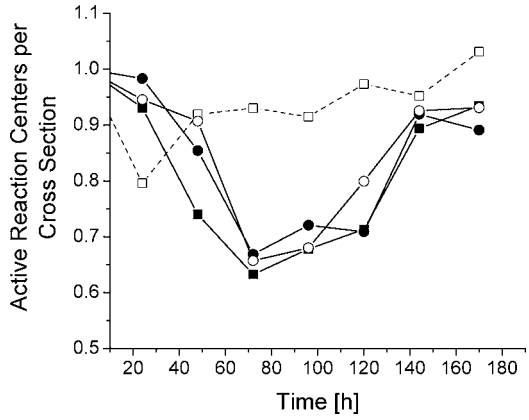

Figure 6. Active reaction centers per cross section of (■) **1**, (●) **2**, (□) **3**, and (○) **5** at 300 μM.

is equal to $M_0(1/V_J)$ where $M_0 = 4(F_{300\,\mu s} - F_0)/(F_M - F_0)$ and $V_J = (F_J - F_0)/(F_M - F_0)$] values were almost stable (Table 2 only shows these values for *P. ixocarpa* leaves treated with compound **1**); these observations suggested[30] that some PSII RCs were transformed to heat sinks or silent reaction centers. These centers cannot reduce Q_A, and their excitation energy is dissipated as heat.[30] The mechanism of action of **1** on *P. ixocarpa* leaves is similar to that observed for other natural products such as robustaflavone on chloroplasts[42] or β-caryophyllene in plants.[35]

Figure 6 shows how the active reaction centers (calculated as $[(ABS/RC)_C/(ABS/RC)_T \times 100]$ for each treatment, where $(ABS/RC)_C$ means the control value and $(ABS/RC)_T$ means the treatment values), decreased as a function of time when plants are treated with 300 μM **1**, **2**, and **5**. After 72 h of treatment, 63% of the reaction centers remained active, indicating that 37% of active reaction centers were transformed to silent reaction centers (RC^{Si}). Treatment with **3** only produced 20% of RC^{Si}; these centers cannot reduce Q_A nor transfer back their excitation energy to the antenna. Hence, the corresponding PSII units do not contribute to the variable fluorescence, whose yield remains constantly low and equal to the units with open RCs.[30] After the 72 h, the RC^{Si} are reactivated (Figure 6), probably as soon as the plant metabolized the flavonoids or these reaction centers are quickly taken apart and repaired.[43] It was observed that **3** only transformed 20% of the active reaction centers to RC^{Si}, and it is known that **3** inhibits electron transport under phosphorylation conditions (ADP + Pi), but it did not inhibit the basal electron transport. This behavior corresponds to an energy transfer inhibition in competition with

Table 4. Dry Biomass of Plants of *Trifolium alexandrinum* (clover) Treated with the Flavonoids[a]

	inhibition (%)					
concn, μM	1	2	3	4	5	6
0	0	0	0	0	0	0
25	33	27	35	8	22	22
50	31	47	38	18	40	38
100	32	44	56	31	59	25
200	34	42	49	12	22	33
300	37	39	39	40	60	36
DCMU, 50	46	46	38	38	42	42

[a]Control value for flavonoids **1** and **2** was 0.712 ± 0.06, 0.663 ± 0.04 for **3** and **4** and 0.775 ± 0.05 g for **5** and **6**.

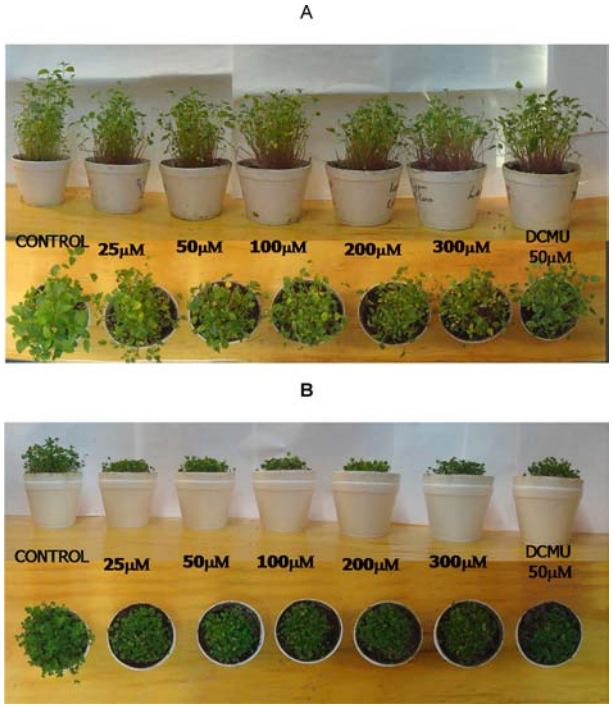

Figure 7. *P. ixocarpa* (A) and *T. alexandrinum* (B) plants treated with different concentrations of compound **1** and compared with 50 μM DCMU (positive control). Control (negative control) plants were sprayed with Tween 0.02% and the major concentration of DMSO used to prepare the flavonoid solutions. The assays were performed in three replicates. For clarity, only one is presented.

the substrate nucleotide, inhibiting the photophosphorylation. Two quercetin molecules cooperatively bind to sites on the β-subunits of CF1 in situ.[44]

Dry Biomass. Flavonoids **1**, **2**, **3**, and **5** decreased the *P. ixocarpa* dry biomass by more than 30% for **1** and **2** and by more than 40% for **3** and **5** (Table 3). Compounds **4** and **6** did not have this effect nor did they affect the chlorophyll *a* fluorescence of this plant. These results suggest that the reduction on dry biomass could be produced because **1**, **2**, **3**, and **5** affected the electron photosynthetic flow in PS II, when transforming the active reaction centers to RC^{Si}. Even if the flavonoids were metabolized 7 days later, the results suggest that their effects in the first 72 h of application are enough to reduce the dry biomass. However, the visual effects on the growth of *P. ixocarpa* and *T. alexandrinum* were observed after 15 days of treatment (Tables 3 and 4). *L. perenne* plants were not affected (data not shown). Figure 7A shows the dramatic effects after 15 days of application of different concentrations of **1** on *P. ixocarpa* plant elongation, compared to DCMU treatment. Table 4 shows the inhibition of the dry biomass in *T. alexandrinum*; in this plant, the six assayed flavonoids decreased the dry biomass by 46% (**1** and **2**), 38% (**3** and **4**), and 42% (**5** and **6**). Figure 7B shows the effect of increasing concentrations of **1** on *T. alexandrinum* after 15 days of treatment; however, the flavonoids did not affect the chlorophyll *a* fluorescence in *T. alexandrinum* plants. Thus, the dry biomass inhibition is not due to their effect on the photosynthetic electron flow.

To know the mechanism of action of flavonoids on dry biomass of *T. alexandrinum* plants, their effects on seedling respiration at different concentrations were assayed. The results (Table 5) showed that compounds **1**−**6** increased the respiration in a concentration-dependent manner, with **3** being the most active; these increments are in agreement with data previously obtained by Takahashi et al.[45] who found that **3** affects the respiratory activity of isolated soybean hypocotyl mitochondria by uncoupling oxidative phosphorylation among other mechanisms.

Chlorophyll Concentration. To know if flavonoids **1**−**6** affect the contents of chlorophyll *a* (Chl *a*) and chlorophyll *b* (Chl *b*), the chlorophyll concentration was measured on treated plants after 15 days. Evaluated flavonoids did not affect the total chlorophyll contents of any plant (data not shown).

Pre-emergence Bioassay Effect on Seed Germination and Seedling Growth. Flavonoids were evaluated to investigate their potential as pre-emergent herbicides, and they were assayed for seed germination and growth (root and shoot lengths) of dicot (*P. ixocarpa* and *T. alexandrinum*) and in monocot (*L. perenne*) seedlings. Figure 8A and 8B shows the effects of **1**−**6** on *P. ixocarpa* and *T. alexandrinum* seeds, respectively. Flavonoids **1**, **3**, and **5** partially inhibited the root elongation of *P. ixocarpa* with significance values ($p < 0.05$), **1** exhibited 39% and 58% inhibition of the roots at 50 and 100 μM respectively; shoot elongation and germination of seeds were not affected by this compound because the p values for the two populations were ≥0.5. *P. ixocarpa* roots decreased 44% and 42% at 50 and 100 μM **3**; **5** decreased the roots 60% and 50% at these same concentrations, and finally **4** and **5** increased slightly the germination (Figure 8A).

Almost all compounds inhibited the root elongation of *T. alexandrinum* seeds at both concentrations (50 and 100 μM)

Table 5. Effect of Increasing Concentrations of Flavonoids 1−6 on *T. alexandrinum* Seed Respiration[a]

concn, μM	1	2	3	4	5	6
0	1720 ± 96	1720 ± 96	1720 ± 96	1720 ± 96	1720 ± 96	1720 ± 96

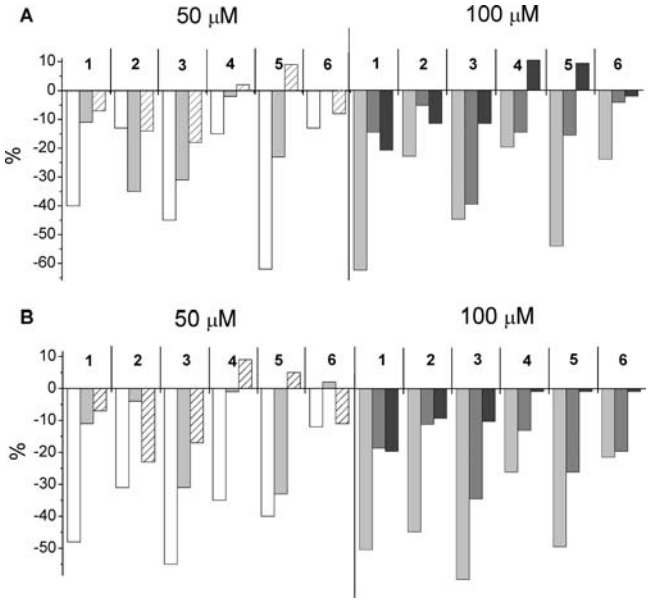

Figure 8. Effect of flavonoids **1**–**6** at 50 μM on root length (white bars) and shoot length (light gray) of seedlings and on germination (diagonal lines), and effect at 100 μM on root length (light gray bars) and shoot length (gray) of seedlings and on germination (dark gray) of *P. ixocarpa* (panel A) and *T. alexandrinum* seeds (panel B). Results are the average of three replicates.

(Figure 8B); the exception was compound **6** with a p value $\geq$0.05. The most active root inhibitor was compound **3** with 55% and 65% inhibition at 50 and 100 μM, respectively. All compounds inhibited shoot elongation, with **1** and **3** being more active as inhibitors of this activity. Figure 9 illustrates the

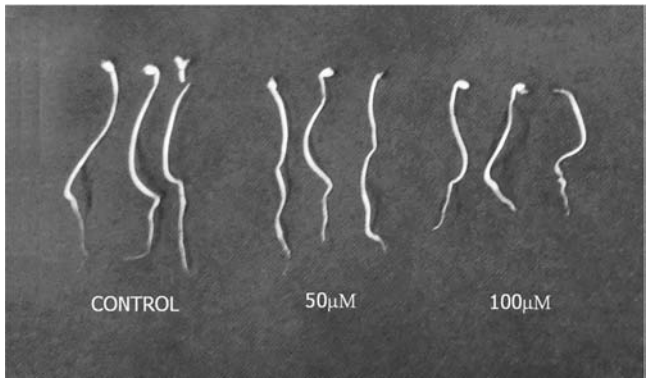

Figure 9. Effect of compound **1** on root and shoot length of *T. alexandrinum* seedlings. The seedlings for this picture were randomly taken from the assays of germination and root and shoot elongation.

inhibition of root and shoot length on *T. alexandrinum* seedlings produced by 50 and 100 μM **3**. *L. perenne* was not affected by any flavonoid (data not shown).

Finally, the flavonoids **1**, **2**, **3**, and **5** behaved as pre- and postemergent herbicides, with **3** and **5** being the most active (an isoflavonoid where the ring B is linked to C-3).

into GC-MS.[3,6,12] Cleanup methods have included using dispersive SPE (as used in QuEChERS with the addition of GCB[4] or with $CaCl_2$ instead of $MgSO_4$[6,12]), using dispersive multiwalled carbon nanotubes,[15] using liquid:liquid extraction (LLE),[5] or using an SPE column containing PSA and GCB.[3,10] Recently, comparisons of three[9,16] or four[6] different extraction and cleanup procedures have been published, although some with mixed conclusions. One suggested that hydration was essential for good recoveries,[6] while another concluded the opposite.[9] A third study concluded that QuEChERS, or a commonly used ethyl acetate extraction, was more effective than a "mini-Luke" procedure based on the older Luke method.[16] In 2008, Lee et al.[17] also compared three extraction and cleanup procedures for 49 pesticides and concluded that QuEChERS[11] gave superior recovery for some pesticides when compared to LLE after hydration or pressurized liquid extraction with acetone for tobacco leaves.

In a prior study in our laboratory with 310 pesticides,[3] a dual-phase GCB/PSA SPE cleanup was shown to provide good results with green tea. In this study, we determined whether two alternative brands of SPE dual-phase cleanup columns (carbon/PSA) could be used in our method without modification.[3] We then employed the method[3] with an alternative SPE brand for measuring 170 pesticides in 62 teas collected from 18 different vendors.

MATERIALS AND METHODS

Materials and Standards Preparation. Pesticide standard mixes (custom-made solutions in acetone at 100 mg/L) were obtained from AccuStandard (New Haven, CT) and prepared at the US FDA pesticide monitoring laboratories for GC-MS analysis. The following 12 custom mixes were used: S-10954-R2, S-10236-R4, S-10238-R4, S-10237A-R3, S-10693B-R1, S-10237B-R2, S-10696B-R1, S-10956-R1, S-10953, S-10952-R1, S-10694-R6, and S-10692A-R3. These custom mixes contained a combined total of 227 pesticides, synergists, isomers, metabolites, flame retardants, and plastizers. The internal standards were hexachlorocyclohexane-D6 (α), methoxychlor-p,p′-D6, and tributyl phosphate-D27 (C/D/N Isotopes Inc., Pointe-Claire, Quebec, Canada), and the mass spectrometry quality standards were acenaphthene-D10, phenanthrene-D10, and chrysene-D12 (Sigma-Aldrich, Milwaukee, WI). The internal standard, tris(1,3-dichloroisopropyl) phosphate, was purchased from TCI America (Portland, OR). Pesticide-grade acetonitrile and toluene, HPLC-grade water, and certified-grade anhydrous sodium sulfate and sodium chloride were purchased from Thermo Fisher Scientific (Pittsburgh, PA). The SPE columns consisted of a dual phase of 250 mg of GCB (top layer) and 500 mg of PSA (bottom layer) with a Teflon frit (p/n ECPSACB256) ("ECPSA" in the tables herein), purchased from United Chemical Technologies (UCT, Bristol, PA). Two alternative SPE columns were the dual-phase Agela "Cleanert" (p/n TPT0006) ("TPT" in the tables herein), consisting of 500 mg of PSA (top layer) and 500 mg of GCB (bottom layer), purchased from Bonna-Agela Technologies Inc. (Wilmington, DE), and dual-phase QuECHERS SPE tubes (p/n 1605349139) from United Sciences (Center City, MN), consisting of columns with 500 mg of carbon X Plus carbon coated on alumina (COA in tables) with 6% synthetic carbon coated to it (top layer) and 500 mg of PSA (bottom layer).

The following types of black, green, Oolong, or white teas (*Camellia sinensis*) were collected: "black", "Ceylon orange pekoe", "decaffeinated green", "decaffeinated Earl Grey", "decaffeinated Lady Grey" "Darjeeling", "English Breakfast", "Earl Grey", "green", "Irish Breakfast", "Jasmine green", "Lady Grey", "Lapsang Souchong", "Oolong", "Organic Green Mint", "Organic Jasmine", "Rose Oolong", "Dao Ren", "Pu-erh", "Rooibos", and "Rooibos red". These tea products were purchased or obtained from retail commercial outlets, including tea marketed as "organic" sources believed to be free of pesticide residues. All products were accepted as being the product indicated by the label, and our selection of products was not intended to be a representative sampling any particular tea product sold in the U.S. nor to represent all tea products sold in the U.S. The black and green teas used for fortification were teas marketed as "organic" and therefore represented to be free of pesticides. Analysis of the unfortified teas did not detect the pesticides monitored in this study.

Twelve AccuStandard custom mixes were combined in a 10 mL volumetric flask by transferring 0.5 mL from each of the 12 mixes. The remaining volume was made up with toluene to produce a stock at 5 mg/L for calibration and fortification standards. The working standards used for quantification were prepared by dilution of this 5 mg/L mixture to give 50 mL of each in a volumetric flask for 0.5, 0.2, 0.1, and 0.05 mg/L in toluene. The resulting standards were then used to prepare lower concentration calibration standards at 0.020, 0.010, 0.005, 0.002, and 0.001 mg/L of the pesticides in toluene. The internal and quality control standards were prepared by dissolving hexachlorocyclohexane-D6, methoxychlor-D6, tris(1,3-dichloroisopropyl) phosphate, and tributyl phosphate-D27 each to a 0.060 mg/L working solution in acetonitrile, and the deuterated polycyclic hydrocarbons to a 0.50 mg/L working solution in toluene.

Tea Leaf Extraction. Tea leaves were ground and homogenized to a fine powder that would pass through an 18-mesh sieve. Dried homogenized tea powder (1.00 ± 0.02 g), 10 mL of water, and 10 mL of extraction solvent (0.060 mg/L of the internal standard, hexachlorocyclohexane-D6 (α), methoxychlor-D6, tris(1,3-dichloroisopropyl) phosphate, or tributyl phosphate-D27, in acetonitrile) were added to a disposable 50 mL centrifuge tube. To ensure complete wetting of the botanical samples, tubes were shaken and allowed to stand for 15 min after the water and the extraction solvent were added. All tea test portions were extracted as previously described.[3]

Solid-Phase Extraction Cleanup. The SPE system consisted of a manifold fitted with 24 conditioned SPE columns, with a rack containing 15 mL glass centrifuge tubes. These SPE cartridges were conditioned with 3 column volumes of acetone and remained wetted with acetone. The collection rack holding the 15 mL disposable centrifuge tubes was inserted in the vacuum manifold. An aliquot (1.25 mL) of the mostly acetonitrile-containing upper layer of the

[a]Mean recoveries (rec) and mean relative standard deviations (RSD) calculated from only the pesticides measured in common to all three SPEs during fortification at any given fortifying concentration. [b]ECPSA = 0.25 g GCB/0.5 g PSA, TPT = 0.5 g PSA/0.5 g GCB, COA = ∼6% carbon-coated alumina (Carbon X)/0.5 g PSA and elution solvent (EA = ethyl acetate, ace = acetone, 3:1 ace/tol =3:1 acetone/toluene).

centrifuged tea leaves/salt/water/acetonitrile mixture was loaded and allowed to percolate onto a tandem SPE column, "ECPSA" topped with anhydrous sodium sulfate. The columns were rinsed with 1 mL of acetone, and eluted and collected with 12 mL of 3:1 acetone/toluene. The cleaned extract was reduced to approximately 100 μL with a gentle nitrogen stream and a water bath (50 °C) using a nitrogen evaporator (N-Evap, Organomation, Associates, Berlin, MA). Toluene (0.5 mL), QC standards (50 μL of deuterated polycyclic aromatic hydrocarbons mixture, 0.5 mg/L), and 25 mg of magnesium sulfate were added, and the extracts were centrifuged[3] at 3000 rpm × 5 min. The toluene extracts were divided between two GC vials with 250 μL vial inserts (Restek Corp., Bellefonte, PA) in order to create a duplicate reserve set of vials.

The TPT SPE columns were operated exactly as the ECPSA columns. The COA SPE columns were operated exactly as described for the ECPSA columns, except the COA columns were eluted with 12 mL of either acetone or ethyl acetate in place of 12 mL of 3:1 acetone/toluene. Incurred teas were cleaned up using the COA column with acetone elution.

Fortification Studies. Black tea and green tea test portions were fortified at 10, 25, 100, and 500 μg/kg. Test portions (1.0 g) were fortified by adding 100 μL of the appropriate fortification solution (0.10, 1.0, and 5.0 mg/L standards prepared in toluene) to the dry test portion, producing a final concentration of 10, 100, and 500 μg/kg, respectively. For the 25 μg/kg fortification, 50 μL of a 0.5 mg/L solution was added. Each centrifuge tube with fortified tea test portion was vigorously vortexed to distribute the pesticides and then allowed to rest for 10 min.

In addition, the entire fortification study for black and green teas was repeated three times from the beginning (i.e., samples were spiked, extracted, and cleaned). The first replication used cleanup on the Agela "Cleanert" (TPT) SPE columns. The second replication used cleanup on the United Science dual-phase QuEChERS Carbon X Plus (COA) column, eluting with acetone. The third replication was identical to the second, but eluting the COA columns with ethyl acetate instead of acetone. Fortification results for COA with black tea and ethyl acetate were not reportable because of laboratory quality assurance issues. Each fortification required two types of tea with five replicates at each of the four concentrations from extraction to cleanup with 20 SPE columns for each tea type, so that in total the fortifications included 160 final fortified extracts, 135 of which were reportable. Blanks are not included in this number. Four blank tea portions were processed with each batch of 20.

Quantification was performed by using the peak area ratio of the responses of analyte to that of the internal standard, tris(1,3-dichloroisopropyl) phosphate or tributyl phosphate-D27, and calculating the concentration by preparing a calibration curve using the peak area ratios of matrix-matched calibration standards to that of the same internal standard. Matrix-matched standards were prepared by extracting tea blanks and fortifying all tea extracts after extraction and cleanup with standards in toluene. Tea standards were prepared at 0.001, 0.002, 0.005, 0.010, 0.02, 0.05, 0.1, 0.2, 0.5, and 1.0 mg/L for use in constructing matrix-matched calibration standards.

GC-QQQ Analysis. A TRACE gas chromatograph coupled with a TSQ Quantum triple-quadrupole mass spectrometer and a TriPlus autosampler (ThermoFisher, San Jose, CA) were employed for sample analysis. Analytes were separated with a 30 m × 0.25 mm i.d. TG-5MS fused silica capillary column (ThermoFisher, San Jose, CA) preceded by a deactivated guard column (5 m × 0.25 mm i.d., Restek Corp., Bellefonte, PA). The column flow rate was 1.4 mL/min, with pressure ramps to maintain a constant flow of helium. Temperature programming, source, transfer-line temperatures, spiltless injection, and multiple reaction monitoring (MRM) optimization were done as previously described.[3] Identifying pesticide residues required the measurement of two precursor/product ion transitions with the correct ion ratio and retention time during the time-dependent MRM window, as previously described.[3] We restricted our screen to the 170 pesticides we had previously optimized[3] that were available in the 12 custom AccuStandard mixtures used in this study. Anthraquinone was weighed out separately, optimized, and added to the mixed standards for the GC-QQQ method. A complete list of pesticide common names, CAS Registry Numbers, structures, molecular weights, retention times, dynamic range, MS/MS transitions, and collision energies is provided in Supporting Table 1.[3]

Statistical Analysis and Calculations. Means and standard deviations from fortification-incurred studies and matrix-dependent instrument quantitation limits (MDIQLs) were determined using Microsoft Excel 2007. Pesticide concentrations were determined by using Thermo Fisher Quanlab Forms 3.0 software to build calibration curves. MDIQLs were estimated for all pesticides through eight measurements, each from one of a series matrix-matched calibration standards for both black tea and green tea (2, 5, 10, and 20 μg/L or 8, 20, 40, and 80 μg/kg in the tea) and from using the standard deviation

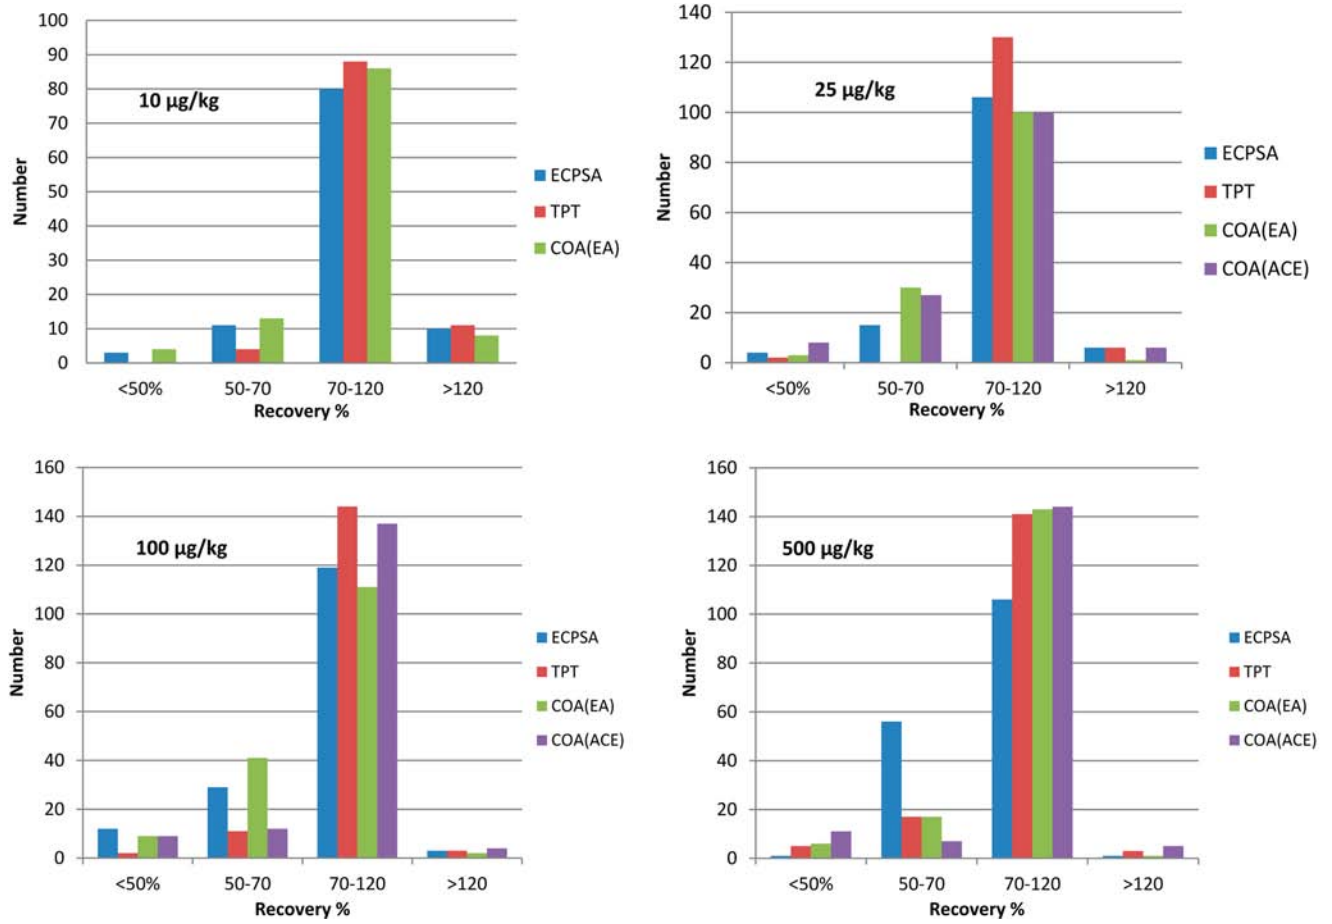

Figure 1. Green tea pesticide recovery profiles at 10, 25, 100, and 500 µg/kg for different SPE carbon/PSA dual-phase SPE columns: ECPSA, TPT, COA(EA), and COA(ACE); EA = ethyl acetate elution and ACE = acetone elution. *Y*-axis is number recovered, and *X*-axis is recovery range.

obtained from 8 quantifications multiplied by 2.998 (*t* test, 1% critical value, degrees of freedom = 7). MDIQLs calculations for each pesticide in both black tea and green tea were verified by manual inspection to ensure sufficient signal-to-noise, repeatability, and the presence of both transitions with the correct ion ratio and retention time. Ion ratios were required to be ±20%, or ±25% for ions <50% of the base peak and >20% of the base peak, or ±30% between 10% and 20% of the base peak, or ±50% for ions <10% of the base peak.[3]

RESULTS AND DISCUSSION

Fortification of Black and Green Teas. Both black and green teas were fortified with the same mixture of standards containing most of the pesticides previously reported on tea by GC-MS, but not dicofol.[3,5,6,11,12,18] Table 2 summarizes the mean recoveries and the mean of their relative standard deviations (RSDs) of the pesticides at each concentration for both green and black teas by SPE column brand. Note the mean recoveries and RSDs in Table 2 reflect the values for only the recoveries of pesticides measured in common across all three columns. Supporting Tables 2 and 3 contain means generated from all measured pesticides fortified on the ECPSA and COA SPE columns. Of the 24 overall mean recoveries reported in Table 2, 13 did not change when only pesticides in common to all SPEs were used for the mean rounded to the nearest 1%. Nine others changed less than 2%, and only two at 10 ppb for black tea went down by 4% or 5% (COA and TPT, respectively). The corresponding RSDs were unchanged, except four at 10 ppb, lower by 1 or 2 percentage points.

Table 2 also reports the total number of pesticides reported at each concentration by SPE column brand and the number with recoveries between 70% and 120%. The fraction of pesticides with recoveries within the desired recovery limits varied from 65% to 95% of the total reported and demonstrated no relationship to SPE column or tea type or the fortifying concentration. Recovery profiles for both green tea and black tea are provided in Figures 1 and 2, respectively, for all three SPE brands. The profiles are quite similar by concentration and SPE brand.

The recovery distributions and RSDs are in general agreement with findings of Pang et al.,[10] except we did not find improved performance with the TPT column with respect to RSDs. Table 3 gives the percentage of the pesticides with RSDs <20% or <10% at 100 or 500 µg/kg spiking concentrations for both green and black teas. The ECPSA and COA columns both demonstrate 97−99% of the pesticide RSDs <20% and 69−85% of the RSDs <10%, while the TPT brand reports 90−95% of the RSDs <20% and 49−81% of the RSDs <10% variously from different spike concentrations or tea type (Table 3).

In 2013, Pang et al.[9,10] established a method using the TPT brand SPE for tea that utilizes twice the volume of toluene for elution as the method used in this study.[10] Sufficient amounts of toluene are reported to be essential for eluting planar pesticides such as hexachlorobenzene completely from GCB.[19] For example, in our study, hexachlorobenzene mean recoveries using TPT were 45% and 34% for the means of all four

Black Tea			
100 μg/kg pesticide			
RSDs <10%	69 ± 7.2	81 ± 6.0	84 ± 5.7
RSDs <20%	97 ± 2.6	93 ± 3.9	99 ± 1.5
500 μg/kg pesticide			
RSDs <10%	69 ± 7.0	49 ± 7.5	85 ± 5.4
RSDs <20%	98 ± 2.1	95 ± 3.3	97 ± 2.6

fortifications in green and black teas, respectively, with mean RSDs of 15% and 17% for green tea and black tea, respectively. The other two brands of SPE had mean recoveries between 50% and 63%, with mean RSDs ranging between 4% and 9%.

The mean recoveries of pesticides at the different fortifying concentrations and SPE brands varied between 73% and 102% (Table 2). Some tea extracts inadvertently reached complete dryness or nearly dry after elution through a specific SPE, which is known to affect recoveries of semivolatile compounds.[9] Lower mean recoveries will result in a smaller fraction of pesticides falling in the desired recovery limits (70−120%), as observed for some fortified concentrations and all SPE brands (Table 2, Figures 1 and 2, and Supporting Tables 2 and 3). The presence in the extracts of four internal standards with differing boiling points from the start of the procedure did not completely compensate for such losses.

No important differences in the mean recoveries or recovery profiles that can be attributed to the use of a specific SPE brand were observed at any concentration or tea type (Table 2, Figures 1 and 2). The accuracy and precision results for all the individual pesticides at each concentration, utilizing either ECPSA or COA SPE columns, can be found in Supporting Table 2 for green tea (COA eluting with ethyl acetate) and Supporting Table 3 for black tea (COA eluting with acetone).

Two examples supporting SPE equivalence were the mean recoveries and mean RSDs for green and black teas fortified at 10 μg/kg. The mean recoveries for green tea were 95%, 102%, and 93%, with mean RSDs of 13%, 10%, and 12% for ECPSA, TPT, and COA (EA), respectively (Table 2). The black tea mean recoveries were also quite similar, at 91%, 83%, and 83%,

[a]Anthraquinone values are estimates due to low and variable recovery. DNQ = detected but not quantified.

with mean RSDs of 15%, 14%, and 11% for ECPSA, TPT, and COA (acetone) SPEs, respectively (Table 2). Mean recovery and mean RSD for green tea using the ECPSA SPE fortified at 10 μg/kg (95% and 13%) were nearly identical to the values previously reported for this method during the validation study that included green tea (91% and 13%).[3]

Other examples supporting SPE equivalency were the fortifications of both black and green teas at 100 μg/kg (Table 2). The mean recoveries pesticides were 90% in black tea for the ECPSA and COA SPEs (Table 2) and 76% in green tea for both brands (Table 2 and Supporting Table 2). The mean RSDs for both black and green tea were 6% and 8% for COA and ECPSA, respectively (Table 2). In addition, >97% of the RSDs were <20%, while 85% were 10% or less for both ECPSA and COA SPE in either green tea or black tea. The total number of pesticides reported at 100 μg/kg fortification for green tea and black tea was identical at 163 and 160, respectively, using ECPSA and COA SPE (Table 2). Matrix-dependent instrument quantitation limits (MDIQLs) resulted in a geometric mean MDIQL of 10 μg/kg for black tea using either ECPSA or COA SPE and 7 μg/kg for green tea (Supporting Tables 2 and 3).

TPT SPE columns showed similar mean recoveries at a 100 μg/kg fortification only with the mean recoveries of 85% for green tea and 77% for black tea, with mean RSDs of 8% for both green and black teas (Table 2). We concluded that no important differences in the accuracy and precision should be anticipated using either the ECPSA or COA brands of SPE column or either elution solvents, and these SPEs are "fit for purpose" with this method.[3] Recovery variability was more related to variability in test portion handling or to a specific pesticide's behavior in GC-MS than their performance on specific SPE brand.

While overall recoveries using the three SPE columns were similar, some differences were observed, as was the case with anthraquinone. Anthraquinone was never validated for this method,[3] but was reported to be on tea.[2] Anthraquinone was almost always not recovered during the fortifications (Supporting Tables 2 and 3) or if measured the recoveries were low (<30%) and reported using the COA SPE. In addition, chlorothalonil, one of the few pesticides known to be quite sensitive to basic character of PSA,[19] was usually not measured at any concentration or recoveries were quite low (<30%). However, chlorothalonil was determined close to the desired recovery range (70–120%) at all four fortifying concentrations in green tea using the TPT SPE (57–71%), at the two highest concentrations using the COA SPE (44% and 55%), and at the higher concentrations in black tea using TPT SPE (66% and 70%).

Incurred Black, Green, Oolong, and White Teas. Pesticides were measured on 41 of the 62 tea leaf products. Before 2007, only one pesticide, glyphosate, had a US EPA tolerance on tea; however, as of December 2013, 18 pesticides have been registered with tolerances on tea (Table 1). Three pesticides (bifenthrin, buprofesin, and cypermethrin) determined on teas in this study are registered for use on tea leaves, tea seeds, or tea oil by US EPA; all samples with these pesticides were below tolerance (Table 1 and Supporting Table

DOI: 10.1021/acs.jafc.5b02860
J. Agric. Food Chem. 2015, 63, 8116–8124

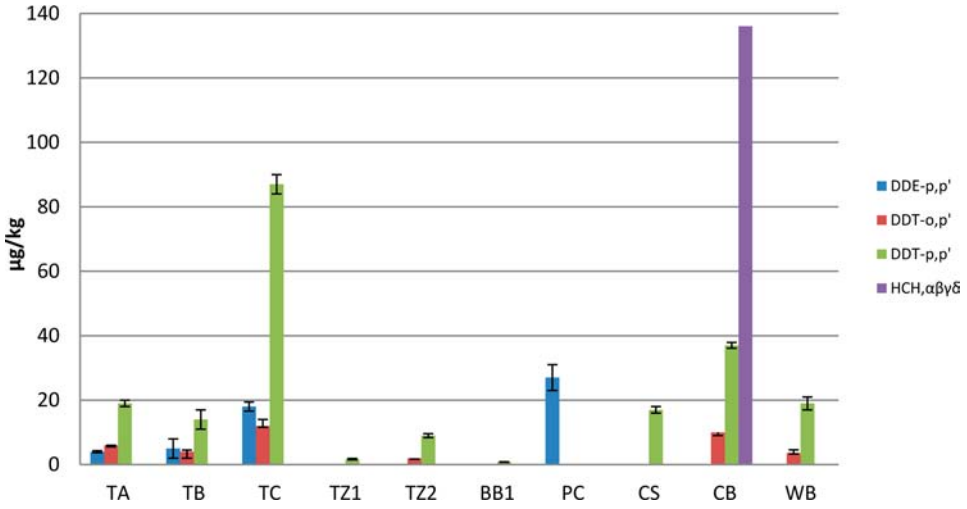

Figure 3. DDT isomer distributions in 10 teas with DDT-p,p′, DDE-p,p′, and isomers along with HCHs found in one sample. Concentrations are in μg/kg dry tea leaves $n = 3$ with error bar = ±SD (HCH is a sum of $\alpha,\beta,\gamma,\delta$). TA, TB, TC, and PC are different Chinese teas, WB is India tea, and the remaining teas are commercial teas purchased in the USA in 2013 (except CB, purchased in 1990) of unknown origins.

4). However, a total of 31 products had pesticide residues having no established tolerance on tea leaves. Those pesticides were anthraquinone, azoxystrobin, chlorpyrifos, cyhalothrin, DDE, DDT, deltamethrin, dicrotophos, fenvalerate, heptachlor, HCH ($\alpha,\beta,\gamma,\delta$), phenylphenol, pyridaben, tebuconazole, tefubenpyrad, and triazophos. Ranges for pesticides and the numbers detected in black, green, white, and Oolong teas are presented in Table 4. Of all pesticides detected in this study, the highest concentrations were for bifenthrin (3200 μg/kg), tebuconazole (1400 μg/kg), deltamethrin (1100 μg/kg), and endosulfans α and β (750 μg/kg) in black, green, white, and black teas, respectively. Although bifenthrin is a pesticide registered for use on tea with a tolerance of 30 000 μg/kg on tea leaves, tebuconazole and deltamethrin have no registered uses on tea. The tolerance for endosulfan has been revoked and will expire in 2016.[18] Endosulfan concentrations did not exceed the revoked tolerance.

Bifenthrin was the most frequently detected pesticide, with residues found on 31 teas (50% of the 62 teas), followed by chlorpyrifos on 12, DDTs on 10, cypermethrin on 9, triazophos on 8, cyhalothrin on 7, endosulfan on 4, deltamethrin on 4, and pyridaben on 3. Seven pesticides were found only on one tea each: azoxystrobin, dicrotophos, fenvalerate, hexachlorocyclohexanes (HCHs), heptachlor, tebuconazole, and tebufenpyrad. In 2012, Lozano et al.[12] reported the highest frequencies for detected pesticides on 75 teas using both GC-MS and LC-MS were acetamiprid (48%) bifenthrin (40%), biphenyl (49%), carbendazim (48%), chloropyrifos (45%), endosulfan (32%), and imidiacloprid (41%).[12] In a 2014 study, Zhu et al.,[18] screening 101 teas using GC-MS, also found high frequencies of detection for bifenthrin (63%), cyhalothrin (55%), cypermethrin (46%), and fenvalerate (25%) and also found higher frequencies of detection for endosulfan (63%), DDTs (56%, ND-400 μg/kg), HCHs (25%), and heptachlor (16%).[18] The concentrations and standard deviations of all identified pesticides on all 62 tea products can be found in Supporting Table 4.

Pesticide usage on tea has increased during the past decade in response to increasing resistance developed by the more than 300 arthropod pests that feed on the tea leaves in northeast India.[20] As a consequence, residue concentrations on tea products increase, resulting in higher frequencies of positive findings for DDT, endosulfan, and synthetic pyrethroids. Although DDT has been banned from use in pest management, increased use in tea growing regions of northeast India results in DDT concentrations as high as 0.2 ppm or more.[20] A large-scale study of selected pesticides used on tea in southern India was conducted in 2006−2008, in which 915 samples were collected.[21] The study using GC and HPLC reported concentrations for dicofol, DDT, ethion, quinalophos, hexaconazole, fenpropathrin, fenvalerate, and propargite and found mainly 0.5−6% of the teas with detectable residues of any pesticide over a three year period above 0.1 mg/kg.[21] Ethion was found in 23% of teas in 2007, but always below the European Union (EU) maximum residue limit of 3 mg/kg. DDTs were screened and not found above a quantitation limit of 0.1 mg/kg in any year.

Ten tea products in this study had measurable amounts of DDT-p,p′, DDT-o,p′ and/or DDE-p,p′, and HCHs (Figure 3) measured on one of the ten. Both DDT and HCHs are listed by the Stockholm Convention as persistent organic pollutants (POPs).[21] The HCHs (α,β,γ) are found in Annex A of ref 22 (designated for elimination), while DDT is listed in Annex B of ref 22 (use restricted to vector control for malaria and as an intermediate for manufacture of dicofol). Nonetheless, we found concentrations for DDTs and HCHs in teas ranging from 1 to 136 μg/kg for DDTs and the sum of the HCHs (Figure 3). The MDIQLs for DDT-p,p′ were between 0.82 and 0.96 μg/kg for green tea and between 0.93 and 1.4 μg/kg for black tea (Supporting Tables 2 and 3). In nine products, DDT-p,p′ dominated the isomer/metabolite pattern, with one tea containing only DDE-p,p′. DDT-o,p′ isomer was measured in 6 of 10 teas always at lower concentration than DDT-p,p′. The ratio between DDT-p,p′ and DDT-o,p′ (3.2−7.3) is in the approximate range found for technical DDT.[23]

DDT has been measured on teas beginning at least in 1969, when it was reported on green tea from Japan with an average of 3.5 mg/kg and concentrations as high as 17 mg/kg.[24] DDT concentrations in green tea fell 10-fold by 1970 when Japan established a 0.5 ppm tolerance for DDT.[24] As early as 1986, a Danish study of 99 black teas from several major tea producing countries found DDT expressed as a sum of DDT-p,p′ + DDE-

p,p′ + DDT-o,p′ + DDD-p, with a range from 20 to 300 μg/kg.[25] DDT detection frequencies varied with the country of origin ranging from 0% (Sri Lanka) to 100% from China.[25] A study of 3 dozen teas sampled in Poland found low μg/kg concentrations of DDTs, HCHs in most teas.[26] In 2002, DDE-p,p′ was reported on four Chinese teas as well as PAHs and PCDD/Fs,[7] but no DDT-p,p′ or DDT-o,p′. In 2004, eight herbal Indian teas (not *Camellia sinensis*) were found with detectable levels of HCHs (20−250 μg/kg) while on one herbal tea had detectable DDT at 6 μg/kg.[27]

One possible source for the DDT currently found on teas is application of dicofol to tea (Table 1).[20,28] Dicofol used on tea leaves typically breaks down or dissipates 95% within about 10 days.[8] Dichlorobenzophenone, a breakdown product of dicofol, could not be found on most teas with DDT measured in this study. However, technical grade dicofol is contaminated with DDT (p,p and o,p), Cl-DDT-p,p′, and DDE-o,p.[28] Directives from US EPA and EU mandate the sum of DDTs must be less than 0.1% in dicofol formulations. The amounts of DDTs and related contaminants were found to vary in dicofol formulations.[28] Dicofol formulations used in China show a trend with DDT-o,p′ ≥ Cl-DDT-p,p′ > DDE,o,p′ > DDT-p′,p, and these products exceeded US EPA and EU mandates.[28] The teas shown in Figure 3 have measurable DDT-p,p′, but do not demonstrate this trend. As we did not include dichlorobenzophenone or Cl-DDT-p,p′ in our tea method; therefore, dicofol as a source of the DDT-p,p′ on teas cannot be excluded. The relatively low amounts of DDT-o,p′ argue against dicofol as the main source.[28]

It has been suggested that higher DDE/DDT ratios found on some teas might originate from GC-MS analysis converting DDT to DDE.[28] Our recovery studies with DDE and DDT did not exhibit evidence for significant conversion in our GC-MS method,[3] yet the teas in our study contain higher DDT concentration in almost all samples (Figure 3). Four of the teas with DDTs originated from China, one was from India, while the rest are of unknown origin. DDT uses on tea have been banned in China since 1983.[28] World-wide contamination in the environment by DDT use over many decades could perhaps be responsible for some contamination.[29]

Pesticides with no US EPA registered tolerance were found on 31 of 62 teas using only GC-QQQ for determinations and a targeted list of only 170 pesticide isomers and metabolites. Additional registered and nonregistered pesticide residues were found on 30 of these teas using LC-MS techniques (manuscript in preparation), similar to reports by other researchers.[4,30] One concern with these residues is that the pesticides may transfer to the brewed tea during the brewing process. DDT, at least by one report, does not show much transfer.[24] A recent study for pesticides in brewed and leaf tea using LC-MS/MS revealed that substantial (>50%) amounts of the 11 pesticides found on incurred teas will transfer during the brewing process.[30] Two recent reports studied transfer of deltamethrin[31] or difenaconazole and azoxystrobin incurred on dry tea leaves by infusion to brewed tea.[32] Both studies suggested transfer would occur to a greater extent if the pesticides were more soluble in water, with lower amounts transferred for the more insoluble pryethroids.[31]

contains only a single chitinase and up to 17 endoglucanase entries.

Despite the intensive research, the study focused on the drought still needs attention.[13,14] We therefore analyzed growth and physiological responses (biomass formation, photosynthetic pigments, mineral nutrients), metabolite profile (amino acids, phenolics), and the isoforms/activity/gene expression of glucanases and chitinases in a new Slovak wheat line after prolonged drought stress.

MATERIAL AND METHODS

Plant Material, Cultivation, and Experimental Design. Wheat (*Triticum aestivum*) plants, line SK-196 that is currently under varietal testing in Slovakia, were sown in plastic pots (32.8 cm diameter and 25.8 cm depth) with commercial substrate BORA (BORA s.r.o., Slovakia) (measured pH of 7.4, 0.17% total N, 25 ppm P and 2.1 ppm Zn). Experiment in randomized complete block design with three replications, 6 pots per condition, was conducted at Faculty of Natural Sciences, University of Constantine the Philosopher in Nitra, Slovakia. A total of 20 seeds were planted per pot. One week after emergence, seedlings were thinned to ten per pot. The plants were grown in a temperature-controlled chamber at 18 °C between 6 p.m. and 6 a.m. and 22 °C between 6 a.m. and 6 p.m., relative humidity of 60% with a 16/8 h photoperiod with light intensity ranging from 300 to 400 μE/m^2/s. When tillering began, the plants were vernalized at 5 °C for 3 weeks in dim light. The pots were regularly irrigated twice a week with 750 mL of distilled water and once in 2 weeks fertilized using standard liquid fertilizer with micronutrients (Akrokompakt NPK 15-10-10, Agrona, Slovakia). The plants were treated preventively with insecticide Karate Zeon 5 CS (in May 2013). Water stress was applied at stage 5 on Feekes growth scale (leaf sheaths strongly erect[15]) by limiting the water supply to 250 mL of water each 48 h, while the control plants were kept well watered. Volumetric soil moisture content was measured for each pot at three different positions using a Theta Probe ML2 (Delta-T Device Ltd.) connected with an Infield 7 Data Logger (UMS GmbH München). The conductivity values measured for stressed plants dropped up to 13% (Figure 1A). Samples were taken 20 days after the start of the experiment. Roots were washed, dried using paper towels, and frozen immediately in liquid nitrogen. Samples were stored at −80 °C until analysis.

Assay of Basic Physiology, Lipid Peroxidation, and Mineral Nutrients. Content of assimilation pigments (chlorophylls and total carotenoids) was determined according to Lichtenthaler and Wellburn[16] on 8−10 leaves that were taken from 5 plants per replicate per treatment. The amount of reducing sugars was determined using the Anthron method.[17] The level of malondialdehyde (MDA) was estimated using the thiobarbituric acid assay.[18]

For the quantification of mineral nutrients, dry samples were mineralized in the mixture of concentrated HNO_3 and water (3 + 3 mL) using microwave decomposition (Ethos Sel Microwave Extraction Labstation, Milestone Inc.) at 200 °C over 1 h. Resulting clear solution was quantitatively placed in glass flasks and diluted to a final volume of 20 mL. All measurements were carried out using an atomic absorption spectrometer AA30 (Varian Ltd.; Mulgrave, Australia) and the air-acetylene flame.[19]

Assay of Chitinase and Glucanase Proteins. Total proteins were extracted from roots and leaves.[20] Aliquots (20 μg)[21] were separated in 12.5% polyacrylamide gels with 0.01% (w/v) glycol chitin as an enzyme substrate. Profiles of total chitinases as well as profiles of acidic/neutral and basic/neutral chitinase isoforms after separation were stained for enzyme activity with 0.01% (w/v) Fluorescent Brightener 28 (Sigma) and subsequent illumination under UV light as described previously.[8] The gels were photographed (BioDoc-It 210 Imaging System, UVP, California, USA) and stained with Coomassie Brilliant Blue R250. The sizes of individual chitinase isoforms were determined based on a co-separated molecular standard (Page Ruler Plus Prestained Protein Ladder, Thermo Scientific) by measuring migration distances of protein bands. Gel images were processed using

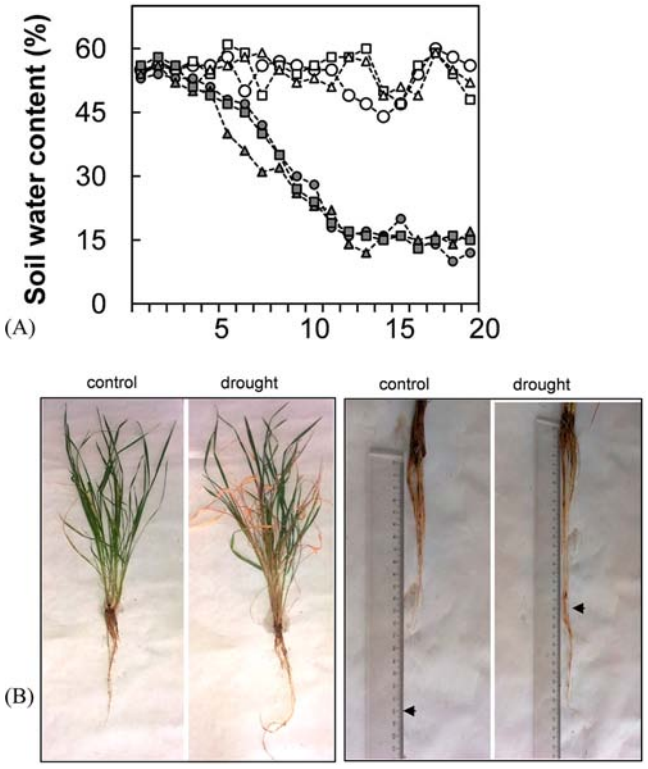

Figure 1. (A) Soil moisture content of the substrate in the pots of control plants (empty symbols) and drought-stressed plants (filled symbols) measured in the period of 20 days (axis x). Three replicates are represented by different symbols, while each symbol indicates average value taken at 3 distinct positions in a pot (respectively). (B) Phenotype of experimental wheat plants watered regularly (controls) and after drought stress (drought) applied by withholding water for the period of 20 days. Lengths of roots were significantly affected; arrows indicate 20 cm on the ruler.

Scion Image software (http://www.scioncorp.com). Background-corrected integrated density (ID) of chitinase bands was calculated in areas of constant size: ID = N*(mean-background) where N is the number of pixels in the selected area and background is the modal gray value (pixels).

Total chitinase activity in samples was measured fluorimetrically using 4-methylumbelliferyl-β-D-N,N',N''-triacetylchitotrioside [4-MU-(GlcNAc)3] as substrate, as described previously.[22]

For the analyses of glucanase enzymes, protein samples were separated in 12.5% polyacrylamide gels containing 0.01% (w/v) laminarin (Sigma), as described above. Activities of individual isoforms in profiles of all active glucanases in samples were detected by boiling of the gels for 10 min in 1 M NaOH containing 0.1% (w/v) 2,3,5-triphenyltetrazolium chloride.[8] The sizes of individual isoforms were determined directly based on a coseparated molecular standard (Page Ruler Plus Prestained Protein Ladder, Thermo Scientific). The gels were scanned; intensity of the bands was taken as a measure of the glucanase activity and determined as described above.

The activity of total β-(1,3)-glucanases in protein samples was measured with DNS method by measuring total reducing sugar content.[23]

Analyses of Gene Expression by qRT-PCR. Total RNA was isolated using the RNease Plant Mini Kit (Quiagen), quantified spectrophotometrically (BioSpec-nano, Shimadzu Biotech), and stored at −80 °C until use. cDNA was made from 1 μg RNA using the Maxima H Minus First Strand cDNA Synthesis Kit and OligodT primers (Thermo Scientific) as per manufacturer's instructions and stored at −20 °C until use. Among the wheat chitinase (6) and glucanase (7) genes available in the NCBI gene bank (to the July 2013), PCR conditions were optimized for those listed in Table S1.

Primers were from the literature or were designed using IDT-PrimerQuest Input (http://eu.idtdna.com/PrimerQuest/Home/Index). Actin (GenBank accession AB181991) and β-tubulin (U76895[24]) were used as internal standards. Reaction mixtures contained 5 μL of 2X SYBR Green PCR Master Mix (Life Technologies), 0.3 μL of 10 μM of both forward and reverse gene specific primers, nuclease-free water, and 1 μL of 1:3 diluted cDNA. The qPCR was carried out in LightCycler Nano (Roche) real-time PCR system in duplicate in 8 well PCR strips. The PCR program started with initial incubation at 50 °C for 2 min, followed by denaturation at 95 °C for 10 min. Forty-five cycles of amplification were performed using a thermal cycling profile of 95 °C for 10 s and 60 °C for 30 s. Subsequently, a melting curve was recorded by holding at 95 °C for 10 s, cooling to 60 °C, and then heating at 0.1 °C/s up to 95 °C. The amplification and melting curve data were collected and analyzed using the LightCycler Nano software 1.0.

Quantification of Metabolites. Soluble phenols were extracted with 80% methanol and quantified using Folin-Ciocalteu method with

DOI: 10.1021/acs.jafc.5b02951
J. Agric. Food Chem. 2015, 63, 8125−8133

gallic acid as standard with detection at 750 nm.[18] In these extracts, selected cinnamic and benzoic acid derivatives were also measured by liquid chromatography with mass spectrometry detection (LC-MS/MS) using device Agilent 1200 Series Rapid Resolution LC system coupled online to Agilent 6460 Triple quadrupole detector with Agilent Jet Stream Technologies: compounds were identified based on the specific m/z values and retention time and quantified using commercially available standards.[25] Flavonoid glycoside isoorientin was also quantified.[26] Thereafter, pellet was 5 times resuspended in 80% methanol followed by centrifugation to remove soluble phenols, dried, and dissolved in 2 M NaOH to release cell wall-bound phenols as reported earlier.[19] Quantifications of the sum of phenols with the Folin-Ciocalteu method and individual metabolites with LC-MS/MS were the same as above.

Free amino acids were extracted with 80% aqueous ethanol and analyses were performed on an HP 1100 liquid chromatograph (Hewlett-Packard, Waldbronn, Germany) with fluorometric detector FLD HP 1100 and using precolumn derivatization with *o*-phtalaldehyde and 9-fluorenylmethyl chloroformate.[25]

Statistical Analyses. Differences between control and drought-stressed plants were evaluated by Student's *t*-test (Microsoft Excel 2003); homogeneity of variance was checked by Levene's test. Number of repetitions in table/figure legends indicates individual plants analyzed for the given parameter.

RESULTS AND DISCUSSION

Drought Affected Wheat Growth and Physiology More Negatively in the Shoots than Roots. The drought evoked in the experimental soil (Figure 1A) suppressed shoot biomass at the level of length and dry weight (Figure 1B and Figure 2). In contrast, a more developed root system was retained in the stressed wheat plants (Figure 1B) due to well-controlled cell expansion for reaching deeper water resources.[27] Leaf necroses were observed and the amount of chlorophylls decreased (Figure 2) as observed by others.[28] The relatively low levels of MDA appeared unaffected by water shortage (Figure 2), contrasting to earlier study.[29] Previously, wheat genotypes with lower MDA content (such as our Slovak wheat line) have been indicated as more tolerant to drought,[30] and it seems that our present wheat line is also tolerant considering duration and intensity of the water deficiency.

The profile of free amino acids revealed a decrease in the majority of detected compounds in the shoot biomass, while the amount of proline increased considerably in response to drought (+160%, Table 1). This is in line with the above-mentioned decrease in assimilation pigments and overall growth. On the other hand, elevated proline accumulation may serve as a protective mechanism aimed at maintaining protein structures and ROS balance. A similar increase in proline has been found in four wheat cultivars under soil drought stress,[29] while application of PEG did not affect it significantly.[31] At the root level, only negligible changes of individual amino acids were observed (significant increase of three compounds, Table 1). The amount of proline was not affected which contradicts data from PEG-treated wheat.[31] Based on the significant increase in root dry biomass (Figure 2) we assume shoot-to-root amino acids translocation aimed at maintaining root growth allowing "search" for water in the soil. On the contrary to previous study with barley exposed to nitrogen deficiency,[26] not only root length but also root dry biomass increased in the present study (Figure 2), indicating investment of metabolites into the growth. Further research focused on phloem exudates is needed to verify this aspect and its regulation by drought.

Mineral nutrients in drought-stressed plants have not been extensively studied yet. Analyses of changes at the level of various macro- and micronutrients showed significant depletion of Ca in the shoots and Na in the roots only (Figure 3). It is evident that despite severe soil water deficiency, tissues retain mineral nutrients effectively.

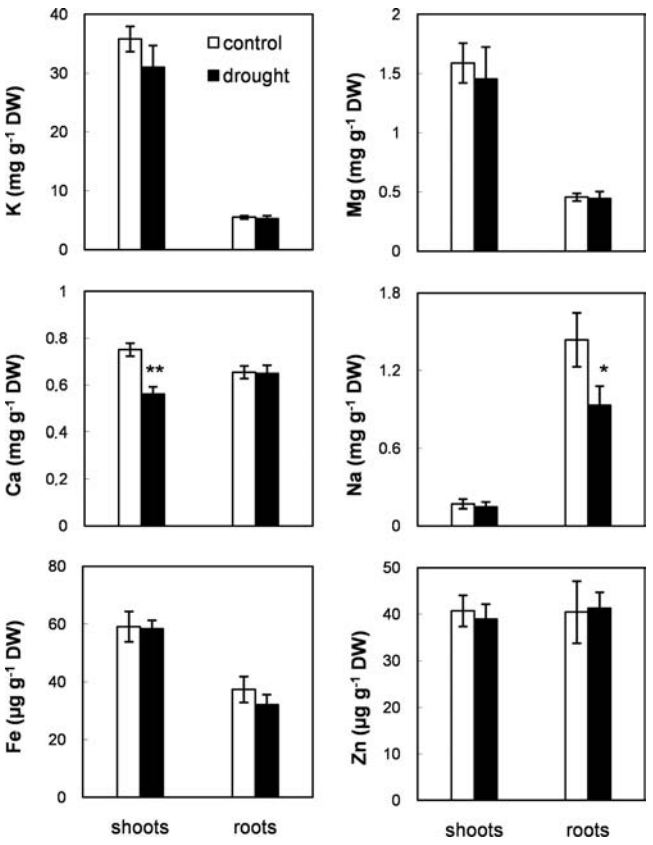

Figure 3. Quantitative changes of selected mineral nutrients in wheat control (watered) plants (white columns) or exposed to drought (black columns) over 20 days. Data are means ± SEM (n = 4). Explanation of statistics is the same as in Figure 2.

Drought Variably Influenced PR Protein Profile. Only a few studies reported the activity of chitinases under abiotic stress.[7,8] Our experiment revealed the presence of at least 7 active chitinase isoforms in wheat (5 acidic and 2 basic ones) in shoots and 10 (6 acidic and 4 basic) isoforms in roots (Figure 4). Previously, up to six different chitinase activity peaks were separated by polyacrylamide gel electrophoresis in wheat plants.[32] In our Slovak wheat line, drought conditions induced chitinases mainly in roots, mainly at the level of acidic isoforms of ~40 kDa (isoforms D and F, Figure 4A). In shoots, small (but significant) induction of a single basic isoform "b" was not reflected into a change of total enzyme activity (Figure 5). No chitinase was newly induced by water shortage in either shoots or roots. These data are in agreement with transcript levels that were elevated for 3 of 4 tested chitinase genes in roots but mostly repressed in shoots (except for a single gene *CD490414*) (Figure 7). In the literature, chitinases are rarely explicitly mentioned in high-throughput drought research. An acidic chitinase has been identified as drought responsive in a proteomic study.[33] Our observations fit well with transcriptomic data of Ergen et al.,[14] who identified 18 chitinase gene representatives differentially expressed in wild emmer

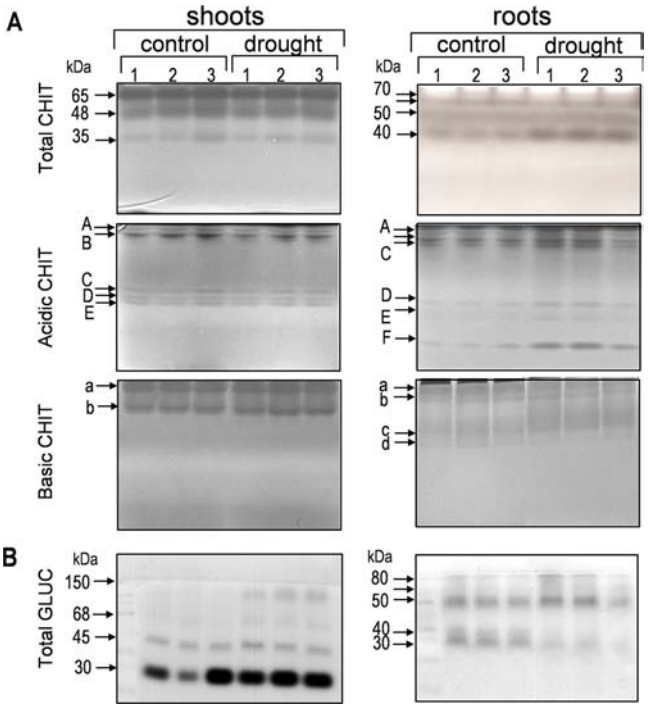

Figure 4. Representative photographs of in-gel detection of the activities of the studied PR proteins in wheat plants grown under normal (control) or drought conditions. Protein extracts from roots and shoots were separated in SDS-PAGE and subsequently renatured for detection of total chitinases (A) and glucanases (B) enzymes profiles (size of isoforms in kDa). Chitinases were also separated for more detailed analysis of acidic- (upper case letters) as well as basic (lower case letters) isoforms, respectively (A). Detected isoforms are indicated with arrows. Size of individual glucanase isoforms was determined by coseparation of a molecular weight standard (Page Ruler Plus Prestained Protein Ladder, Thermo Scientific). Molecular sizes of chitinase isoforms were determined based on Coomassie-stained protein profiles.

wheat upon quick dehydration, mostly in roots. However, the published transcriptomic data on chitinase activity under drought are inconsistent: induction[34,35] or unaffected expression[36] are known. Regulation of individual chitinase genes may depend on genotype, tissue type, and time point.[13,14] Enhanced chitinase activity has been suggested to coincide with drought tolerance of durum wheat[13] and Tibetan wild barley genotypes.[35]

Similarly to chitinases, the profile and activity of glucanases in wheat, especially under abiotic stress, is poorly known.[7,35] Our analyses identified up to 4 different enzyme fractions in wheat tissue. In shoots, each isoform fraction (~30, 45, 68, and 150 kDa) showed an enhanced accumulation by drought (Figure 4B) that resulted in increased overall glucanase activity (Figure 6). Such induction by drought has been reported previously.[14] Only one of the 3 glucanase genes we studied was activated in shoots by drought (*AF112967*), the other was repressed (*DQ090946*), while the third was unaffected (Figure 7). In contrast, in root samples the overall activities of glucanases did not alter markedly (Figure 6), possibly due to differential effect of drought on individual isoforms (Figures 4B and 6) as reported previously.[14,37] Suppression of the activity of some of the glucanase isoforms has been associated with abscisic acid-mediated callose deposition leading to increased water holding capacity.[35]

Comparing the Defense Strategy of Tissues/Organs. The activity of glucanases and chitinases differed in shoot and root tissue (Figures 5 and 6). Furthermore, their often synergistic action described during biotic stress[10] does not seem to be applicable under drought. Roots responded by an activation of chitinases at both enzyme- and gene activity levels and by repression of two glucanase isoforms (Figures 4A and 5). In shoots the glucanase enzyme isoforms were significantly induced, while the examined genes behaved adversely (Figure 4B). Here we note that data can depend not only on organ type or experimental conditions but also might be influenced by the presence of highly similar homologues in the allohexaploid wheat. Genome-specific primers would be very helpful for exploring the gene families of PRs in wheat. At the same time, PR proteins can be constitutively expressed in tissue at very low levels;[10] therefore, their research might be hampered by detection limit of the approach applied, too.

The opposing expression of studied drought-responsive genes in the two organ types might imply specific role of chitinases and glucanases in drought adaptation. It is proposed that chitinases alter the flexibility-elasticity of the cell wall[38] enabling it to withstand the shrinking of cells during dehydration. They also may reduce the risk of plant infection by pathogenic microbes naturally persisting in the soil. On the contrary, the action of glycoside-hydrolyzing, cell wall polysaccharide modifying enzymes like glucanases is suggested to affect accumulation of soluble sugars under water stress.[38] Wheat genotypes with higher concentrations of small organic osmolytes (including sugars released by glucanases) revealed better tolerance to drought.[30] Besides, accumulated PRs can serve as storage proteins under conditions of growth limitations such as reduction of photoperiod, low temperatures, or nutritional/water deficiency.[6,39]

Intriguingly, altered activities of defense proteins in drought-stressed plants are supposed to be associated with overlapping defense responses to water limitation and pathogen attack.[40] Correlation between the isoform banding pattern and activity of chitinases and the genetic resistance of plants to biotic[32] or abiotic[8] stress has been suggested but is not clearly established. Furthermore, kinetics and amplitude of their action has been suggested to contribute to overall susceptibility/resistance of plants.[8] However, though PRs can help plants to endure and recover from mild- or short-term stress, at terminal drought their accumulation can have negative influence on growth,[6] possibly due to additional costs for their synthesis in damaged plants.

Responses of Phenolics to Drought Differed in Shoots and Roots. Phenolic metabolites are abundant plant compounds induced by various stress stimuli.[19,26] In our study, total phenols (Folin-Ciocalteu assay) were affected only in the shoots in the free fraction (Table 2) that is in accordance e.g. with no or slight changes reported in various barley cultivars:[35] we note a strong quantitative discrepancy with our values (10 mg/g DW = ~ 1 mg/g FW) which is physically impossible (ca. 500 mg/g FW, cf. ref 35). In rice grains, prolonged drought even depleted the amount of total phenols,[41] indicating tissue and/or species-specific differences.

Surprisingly, detailed quantification of individual metabolites under drought has only rarely been reported.[42−44] Infusion prepared from peppermint grown at various levels of soil moisture revealed that strong drought (12%) depleted phenolics more than moderate stress.[43] This could be a reason why we observed a relatively slight increase in phenolic acids

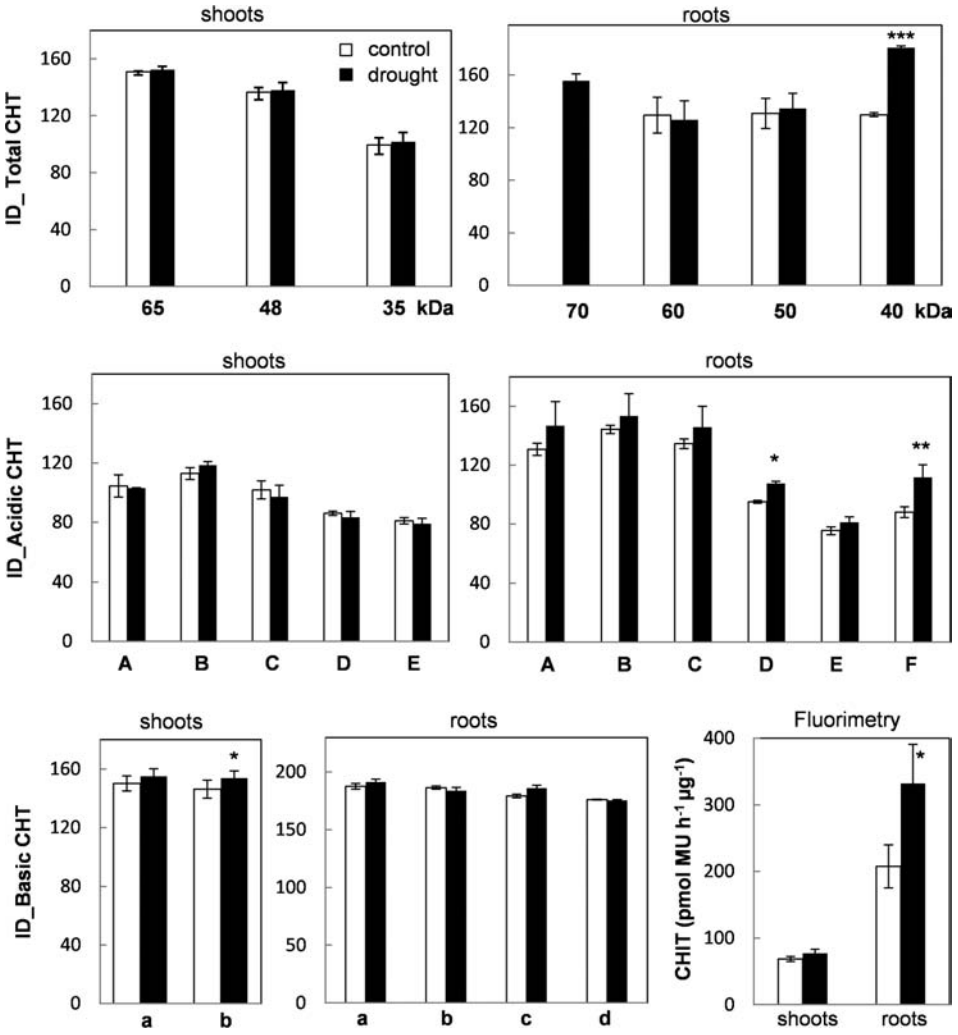

Figure 5. Quantification of the activities of individual chitinase isoforms (total, acidic and basic) in protein extracts from roots and shoots of wheat plants grown under normal and drought conditions. Values are expressed as average raw integrated densities of pixels (ID) ± SE for $n \geq 3$. Total chitinase enzyme activity of samples measured fluorimetrically is also given. Explanation of statistics is the same as in Figure 2 (n.q. − isoform was nonquantifiable due to high background).

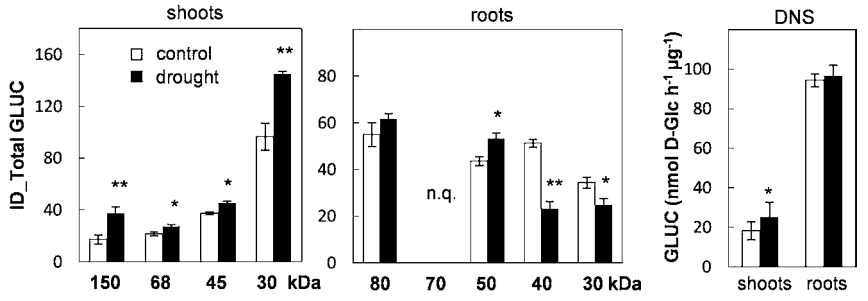

Figure 6. Quantification of activities of individual glucanase isoforms in extracts from roots and shoots of wheat plants grown under normal and drought conditions. Values are expressed as average raw integrated densities of pixels (ID) ± SE for $n \geq 3$. Enzyme activity values in samples measured with DNS method are also shown. Explanation of statistics is the same as in Figure 2 (n.q. − isoform that was nonquantifiable due to high background).

(Table 2) at an ca. 15% soil moisture (Figure 1A). However, stimulation of acids was clearly significant at the level of sum (+44%) and individual metabolites in the shoots but only occasional in the roots. These data fit well with the increase in proline and support, at least partially, a metabolic connection between proline and phenolics: biosynthesis of proline depletes the amount of NADPH, leading to stimulation of pentose phosphate pathway forming not only NADPH but also precursors for phenolics such as erythrose 4-phosphate.[45] This fact was even more visible at the level of isoorientin, a flavonoid glycoside from the luteolin family, which increased 3 times in the shoots but not in the roots (Table 2).

Unlike free phenolic acids serving as a storage pool (for more complex compounds) or as antioxidants, cell wall-bound

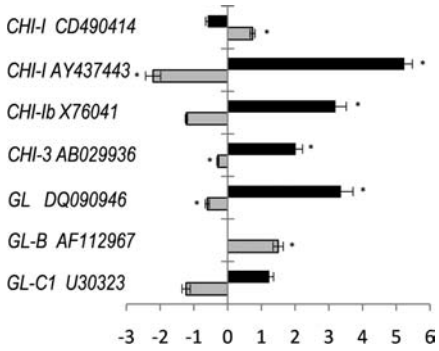

Figure 7. Relative gene expression data by means of the fold change values on a vertical scale for the set of studied PR genes under drought conditions in roots (black columns) and shoots (gray columns). Significant changes ($p \leq 0.05$) are indicated with asterisks. Sequences of primers are shown in Supplementary Table S1.

compounds contribute to fortification by forming bridges with carbohydrates.[4] In agreement with data from drought-stressed triticale,[4] cell wall-bound acids (revealed by alkaline hydrolysis) were quantitatively typically more abundant than respective free counterparts (Table 2). This was mainly visible at the level of lignin precursors including ferulic, *p*-coumaric, and sinapic acids. Overall, our data clearly confirm that synthesis of free and wall-bound phenols in the above-ground biomass of wheat may contribute to protection of photosynthetic organs against oxidative stress and dehydration of the leaves.

In conclusions, prolonged soil drought stress depleted shoot growth and assimilation pigments in wheat, but stimulated root growth and biomass that was also visible at the level of amino acids changes and shoot-to-root translocation is expected. At the same time, mineral nutrients were not affected extensively. Chitinases and glucanases were activated in wheat under drought. Directly as components of defense mechanisms and/or in morphophysiological adjustments of cells during water shortage they contribute to plant capability to survive. Though individual glucanases and chitinases were identified here as drought-responsive, their numbers even under slightly different conditions, another growth stage, and/or using other approaches is likely much larger and requires further research at both genome and proteome levels. Detailed quantification of phenolic metabolites revealed their increase in the free and bound fraction almost exclusively in the shoots, indicating protective action under water deficiency.

response to the pathogen, a molecular method based on a TaqMan quantitative polymerase chain reaction (PCR), was developed to quantitate the fungal presence in the plant tissues.

MATERIALS AND METHODS

Plant Material and Fungal Cultures. Two rice (*O. sativa* L.) cultivars, Selenio and Dorella, were used throughout the experiments. Seed lots of the rice cultivars were provided by the Rice Research Unit of Consiglio per la Ricerca e la Sperimentazione in Agricoltura.

The monoconidial strain VE13 of *F. fujikuroi*,[13] used for artificial inoculation of rice seeds, was stored in potato dextrose agar (PDA) (Merck, Darmstadt, Germany) with 27 mg/L streptomycin (Merck). A small plug was transferred into 500 mL of potato dextrose broth (PDB) (Liofilchem, Roseto degli Abruzzi, Italy) and grown under stirring at 90 rpm and 23 °C for 10 days. The fungal culture was filtered through a sterile gauze to get a conidial suspension at 10^6 conidia/mL. Rice seeds were surface-disinfected in 1% sodium hypochlorite for 2 min and rinsed in sterile distilled water. For each group, 40 seeds per replicate and 3 replicates per experiment were tested. Seeds were soaked in 100 mL of spore suspension and shaken for 30 min at room temperature, while uninoculated seeds for each genotype were soaked in sterile distilled water. The seeds were placed in a sterilized soil in a greenhouse and grown at 24−26 °C during the day and 16−18 °C during the night. Leaves and culms were collected every week for 4 weeks after seed germination (around 7 days after pathogen inoculation). The phenological rice stages at 1, 2, 3, and 4 weeks postgermination (wpg) were V1, V2, V3, and V4, corresponding to the number of leaves with collars on the main stem during vegetative development.[14]

Disease Index. The germination rate and disease index, for three biological replications, were evaluated 28 days after germination using a scale of five distinct classes of symptoms. Each symptom corresponds to a reference number: 0, asymptomatic plants; 25, plants with yellow leaves; 50, plants with long internodes; 75, necrotic plants; 100, dead plants.[15]

Phytohormone and Phytoalexin Extraction and Analysis. *Reagents and Standards.* LC−MS-grade acetonitrile and formic acid used as the mobile phase were purchased from Sigma-Aldrich (St Louis, MO). Methanol, acetonitrile, acetone, ethyl acetate, dichloromethane, and formic acid (HPLC-grade) used for extraction procedures were purchased from Merck (Darmstadt, Germany).

Salicylic acid (purity ≥99%), jasmonic acid (purity ≥95%), abscisic acid (purity ≥98.5%), gibberellic acid (purity ≥95%), naringenin (purity ≥95%), and sakuranetin (purity ≥95%) were purchased from Sigma-Aldrich. Momilactone A and momilactone B were prepared by Prof. Morifumi Hasegawa (College of Agriculture, Ibaraki University, Japan).

Preparation of Standard Solutions. Stock solutions of each analyte were prepared at 1 mg/mL in CH_3OH. Working solutions were prepared by diluting stock solutions in CH_3OH/H_2O (8:2) at different concentrations depending on the range of the calibration curve. A stock solution mixture, made from these individual stock solutions, was prepared in the LC mobile phase and matrixes to obtain calibration curves and to determine the ion suppression, recovery, limit of detection (LOD), and limit of quantitation (LOQ) for each analyte.

Extraction Procedure. Acetone, ethyl acetate, dichloromethane, methanol, acetonitrile, water, and two different mixtures of water/methanol (1:1 and 2:8 pure or containing 0.1% CH_3COOH) were tested. In a second set of analyses, the influence of three extraction times (1 h, 2 h, overnight) and two methods (ultrasonic bath or rotary shaker) on the recovery was evaluated. An analyte-free rice matrix was not available, so for each test two sets of samples, with or without standard additions, were prepared, and each extraction was performed twice for each sample.

A few plants of rice were ground, and 0.2 g of fresh plant material was transferred in 2 mL centrifuge tubes with 1 mL of extraction solution (80% CH_3OH acidified with 0.1% CH_3COOH). The samples were frozen in liquid nitrogen, homogenized by using TissueLyser (Qiagen, Venlo, The Netherlands), and then shaken at 4 °C in the dark overnight. Finally, the samples were centrifuged at 15 000 rpm and 4 °C for 2 min, and the supernatant was analyzed by HPLC−MS/MS.

HPLC−MS/MS Analysis. All analyses were carried out by using a 1260 Agilent Technologies (Santa Clara, CA) system consisting of a binary pump and a vacuum degasser, connected to a Varian model 410 Prostar autosampler (Palo Alto, CA) equipped with a 20 μL loop coupled with a Varian 310-MS TQ mass spectrometer.

HPLC separation of the analytes was performed using a 150 × 2 mm i.d., 3 μm Luna phenyl-hexyl column (Phenomenex, Torrance, CA) under a flow of 200 μL/min. The column temperature was set at 25 °C. Solvent A was H_2O with 0.1% HCOOH, and solvent B was CH_3CN. HPLC analysis was programmed as follows: 40% solvent B for 7 min, followed by a linear gradient from 40% to 100% B in 5 min, and finally holding at 100% B for 4 min.

Samples were ionized using an electrospray (ESI) ion source operating in negative ion mode for salicylic acid, jasmonic acid, abscisic acid, gibberellic acid, naringenin, and sakuranetin and in positive ion mode for momilactone A and momilactone B. For the multiple-reaction monitoring (MRM) experiments, the quantification transitions for each compound were (1) m/z 345 → 239, CE = 14 V, (2) m/z 263 → 153, CE = 12 V, (3) m/z 137 → 93, CE = 16 V, (4) m/z 209 → 59, CE = 14 V, (5) m/z 271 → 151, CE = 18 V, (6) m/z 285 → 119, CE = 30 V, (7) m/z 331 → 269, CE = 25 V, and (8) m/z 315 → 271, CE = 14 V. The collision gas (Ar) pressure was set at 2 mbar for all experiments.

Method Validation. The HPLC−MS/MS method was validated in terms of accuracy, linearity, LOD, and LOQ. The validation was performed on both matrixes using noninoculated samples collected 1 week after germination.

DOI: 10.1021/acs.jafc.5b03018
J. Agric. Food Chem. 2015, 63, 8134−8142

Linearity and Range. The linearity of measurement was evaluated by analyzing different concentrations of the standard solutions of the analytes. Calibration standards were prepared by diluting the stock solutions to obtain specific concentrations.

LOD and LOQ. Usually the LOD and LOQ were established using matrix samples spiked after the extraction procedure with a low amount of standards. An analyte-free matrix was not available, so LOD and LOQ were determined in solvent. The detection and quantification limits were determined on the basis of the standard deviation of the response (σ) and slope of the calibration curve (S) ratio in accordance with the ICH Harmonised Tripartite Guideline[16] expressed as LOD = $3.3\sigma/S$ and LOQ = $10\sigma/S$.

Accuracy. Recovery studies were performed with rice samples spiked at 50%, 100%, and 150% levels with all stock solutions prepared. The accuracy of the method was expressed by [(mean observed concentration)/(spiked concentration)] × 100.

Besides validation, the influence of the components of both rice cultivars on the quantification of every analyte was evaluated. The matrix effect was calculated using the formula ($\text{slope}_{\text{matrix}}/\text{slope}_{\text{solvent}}$) × 100.

Statistical Analysis. Rice samples were harvested at 1, 2, 3, and 4 wpg in three biological replicates. The biological replicates were extracted separately in two technical replicates, and every technical replicate was analyzed twice. The data reported are the average of 12 data points, and the standard deviation is reported as an error bar. Statistical analysis among data of the same analyte was performed using Student's t test at 99% confidence.

Molecular Identification of *F. fujikuroi*. *DNA Extraction.* DNA extraction was performed on 0.1 g of fresh plant material using the commercial EZNA plant DNA kit (Omega Bio-Tek, Norcross, GA), according to the instructions of the manufacturer. For the final elution of DNA, 25 μL of elution buffer was used.

Design of the Real-Time PCR Primers and Probe. The purpose of this work was to identify regions of variability able to discriminate *F. fujikuroi* from other species associated with bakanae disease on rice[5] (*Fusarium proliferatum* and *Fusarium verticilloides*). A part of the elongation factor 1α (TEF) gene was sequenced for different strains. Multiple sequence alignment showed a deletion of six nucleotides in all the strains of *F. fujikuroi* but not in other species.[17] The deletion of *F. fujikuroi* was used as the basis for design of the following primers and probe with the Primer Express 3.0.1 software (Applied Biosystems, Foster City, CA): forward primer FujiF (5′-ATGGGCGCGTTTTGCCCTTT-3′), reverse primer FujiR (5′-GGCGTACTTGAAGGAACCCT-3′), and TaqMan FfujiPq (5′-[FAM]-TTGTCACGTGTCAAACTAAACATTCGAC-[TAMRA]-3′) labeled with the fluorescent reporter dye FAM at the 5′-end and the TAMRA quencher at the 3′-end. The primers and the probe were purchased from Applied Biosystems.

TaqMan Real-Time PCR Assay. The real-time TaqMan PCR assays were conducted using an Applied Biosystems Plus detection system. Twenty microliter reactions containing 12.5 μL of Taqman Master Mix (2×) (Applied Biosystems), PCR primers at a concentration of 10 μM, the TaqMan FfujiPq at 5 μM, and 5 μL of DNA at a concentration of about 30 ng/μL were prepared in triplicate. Amplification and detection were performed in 96-well optical reaction plates (Applied Biosystems) sealed with MicroAmp optical adhesive film (Applied Biosystems) on an ABI Prism 7900HT sequence detection system real-time thermal cycler. The amplification conditions were 2 min at 50 °C and 10 min at 95 °C followed by 15 s at 95 °C and 40 s at 62 °C for 40 cycles.

A standard curve was prepared by serial dilution of known quantities of *F. fujikuroi* DNA to quantitate the fungus inside the rice tissues. In the preparation of the standard curve, the initial concentration of DNA was 386 ng/μL.

Primer and Probe Design, Specificity, and Sensitivity. The primer pair FujiF and FujiR was designed to amplify a 117 bp unique sequence found in the TEF gene of *F. fujikuroi*. For confirmation of the specificity of the amplified product, the TaqMan FfujiPq probe was designed for inclusion in the real-time PCR assay.

The combination of primers FujiF and FujiR with the dual-labeled probe FfujiPq was then tested in real-time PCR with a series of DNA extracts from pure cultures of three species of *Fusarium*. Real-time reactions using this primer−probe combination proved to be specific, and low C_t values were obtained for all *F. fujikuroi* strains and not for isolates of any other *Fusarium* spp.

The sensitivity of the FujiF/FujiR and FfujiPq combination was measured with a six-dilution series of *F. fujikuroi* DNA in deionized DNA-free water, in a range of concentrations from 386 ng/μL down to 0.3 fg/μL. A standard curve was built, and the corresponding amplification efficiency was 96.18%. The results showed a linear relationship between C_t values and concentration, and the correlation coefficient (R^2) was 0.999.

The optimized sequences FujiF/FujiR and FfujiPq permitted the real-time PCR to be run under high-stringency conditions (annealing or elongation at 62 °C), providing maximum specificity without any significant effect on the performance of amplification.

The quantity of the fungus in the plants was measured in nanograms per 100 mg by extraction of DNA from the culm and from the leaves of the cultivars Selenio and Dorella.

RESULTS

Rice Germination and Disease Index. In plants of rice cv. Selenio, symptoms of bakanae were not observed, while typical bakanae-diseased symptoms were observed in plants of cv. Dorella. The disease index calculated for cv. Selenio was 5.0%, while for cv. Dorella it was 72.4%. Also the percentage of germination was different, 72.5% for cv. Dorella and 93.0% for cv. Selenio.

Phytohormone and Phytoalexin Extraction and Analysis. In the first step, authentic standard mixtures were used to evaluate the retention times, m/z values of the corresponding ions, and characteristic MS/MS fragmentation patterns. Each analyte was characterized by two specific precursor−fragment ion combinations and a characteristic retention time. For each analyte, quantification relied on the most intense transition, while the less intense one was used to confirm the assignment.

The choice of the appropriate chromatographic system is the most important factor that influences the sensitivity of HPLC−MS analysis. Samples were analyzed using a phenyl-hexyl column, which allows a good separation of all the analytes in a short time (Figure 2). It was possible to separate the analytes to perform a change of polarity and to detect all the analytes in a single analysis.

Plant hormones and phytoalexins are structurally diverse with different physiochemical properties. The choice of extraction solvent is very important, so during the method optimization, the composition of the extraction solution was first evaluated. Different organic solvents/mixtures and the influence of acidification were tested. A nonpolar extraction solvent extracted a large amount of chlorophyll, and purification was necessary. A mixture of methanol and water provided a high extraction efficiency for all the analytes and did not require purification because a low chlorophyll amount was extracted using an 8:2 ratio.

Validation of the Analytical Method. A validation procedure was carried out to evaluate the applicability of this method. The range of calibration curves was defined for each compound on the basis of the amount in both rice matrixes. The calibration curves showed a good linearity of correlation coefficient ($R^2 > 0.9999$) for all analytes. The LOD for different analytes ranged from 0.87 ng/g for abscisic acid to 20.7 ng/g for salicylic acid, and the LOQ ranged from 2.90 ng/g for abscisic acid to 69.1 ng/g for salicylic acid calculated on the

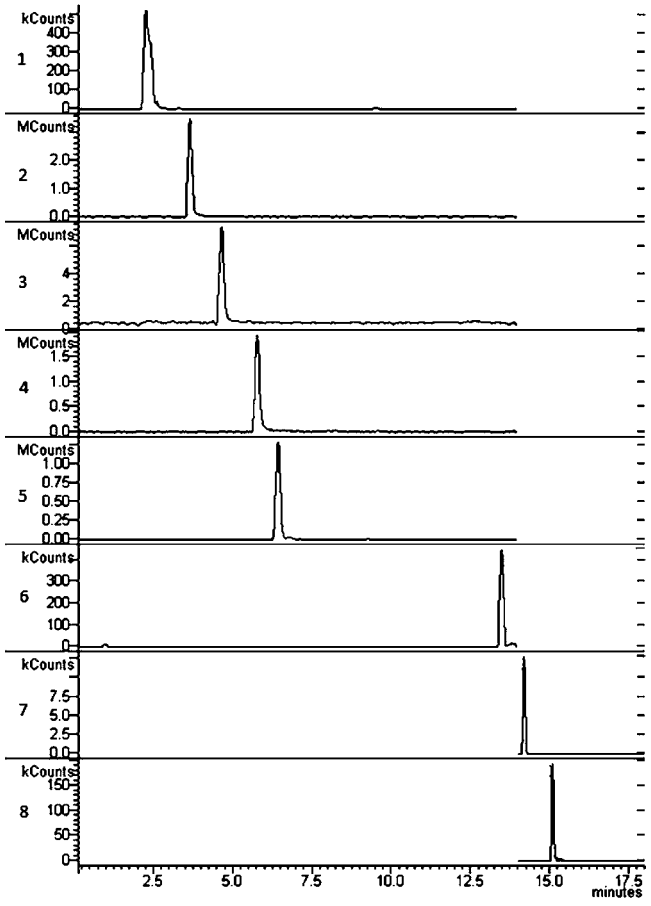

Figure 2. Chromatograms of a standard solution containing a 200 ng/mL concentration of the analytes under MRM conditions.

basis of the fresh weight. For sakuranetin in cv. Selenio and abscisic acid in cv. Dorella, the recovery was very high (around 98%). For the other analytes, recoveries in both cultivars were always higher than 70%. The matrix components can affect the analyte stability, extraction, and ionization. For both cultivars, positive and negative trends were similar; only for naringenin the matrix effect did not affect ionization. The matrixes mostly influenced salicylic acid and momilactone A. The components of the matrix affected the response of each analyte with different intensities. To consider all the effects of the matrix on the quantitative results, a quantitation method developed in the presence of the matrix was used.

Accumulation of Phytohormones. Abscisic acid and gibberellic acid (Figure 3) showed a very different trend in the susceptible cultivar Dorella (D) compared to the resistant one Selenio (S). In the susceptible cultivar, for both phytohormones, it is possible to observe, after *F. fujikuroi* inoculation (D+), an increased concentration in the third (347 ng/g for gibberellic acid and 63.7 ng/g for abscisic acid) and fourth (607 ng/g for gibberellic acid and 82.5 ng/g for abscisic acid) wpg. In the resistant cultivar, abscisic acid was statistically higher in inoculated plants (S+) compared to the uninoculated control (S−) at the four time points. In Selenio, gibberellic acid was not statistically different after pathogen inoculation for the first three wpgs, while it showed a slight increase at 4 wpg.

The trends of jasmonic acid and salicylic acid in the resistant cultivar and in the susceptible cultivar are shown in Figure 4. The trend and the amount of jasmonic acid accumulated in both cultivars were similar during the 4 weeks. For cv. Dorella, the quantity of jasmonic acid in inoculated plants significantly decreased at 3 and 4 wpg compared to that in the uninoculated control (64.8 ng/g for D− and 39.4 ng/g for D+ at 3 wpg, 44.8 ng/g for D− and 23.1 ng/g for D+ at 4 wpg). The accumulation of salicylic acid in both cultivars was quite similar (from 4480 to 7910 ng/g for cv. Selenio and from 5440 to 10700 ng/g for cv. Dorella). Infested rice had a similar trend compared to the control, and the difference of salicylic acid accumulation between them gradually increased with increasing infestation time. In the susceptible cultivar, the concentration of salicylic acid was always higher compared to that in the uninoculated control.

Accumulation of Phytoalexins. An increase of all the phytoalexins in the resistant cultivar was observed. The major

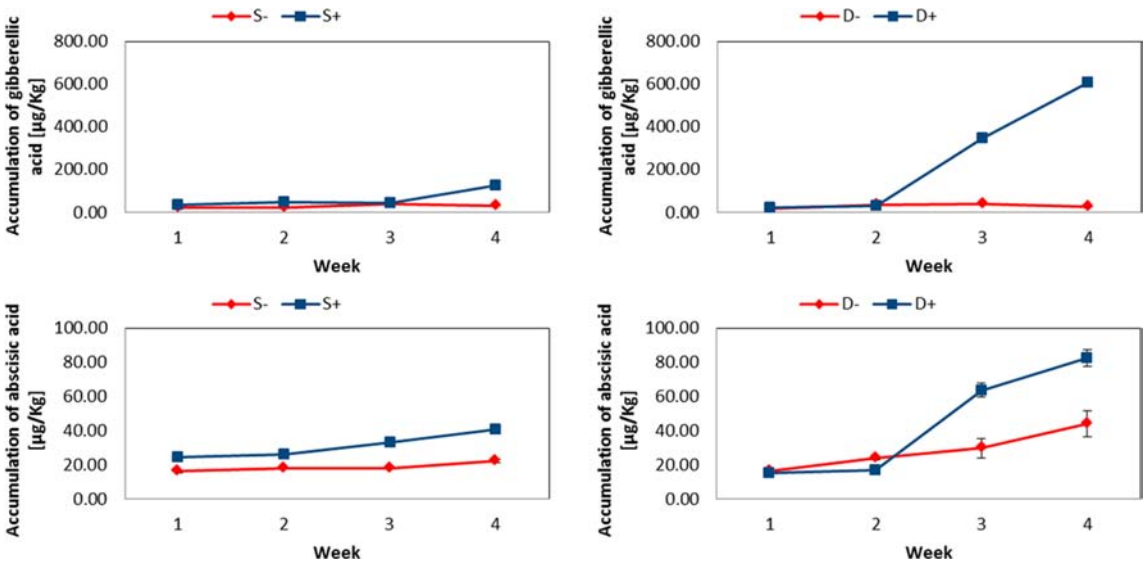

Figure 3. Changes in phytohormone gibberellic acid and abscisic acid accumulation during 4 weeks after germination in resistant (Selenio, S) and susceptible (Dorella, D) rice cultivars, inoculated (+) or not (−) with *F. fujikuroi*. Values are means ± SD (n = 12 independent analyses) in fresh plant tissues (ng/g of fresh weight, FW).

DOI: 10.1021/acs.jafc.5b03018

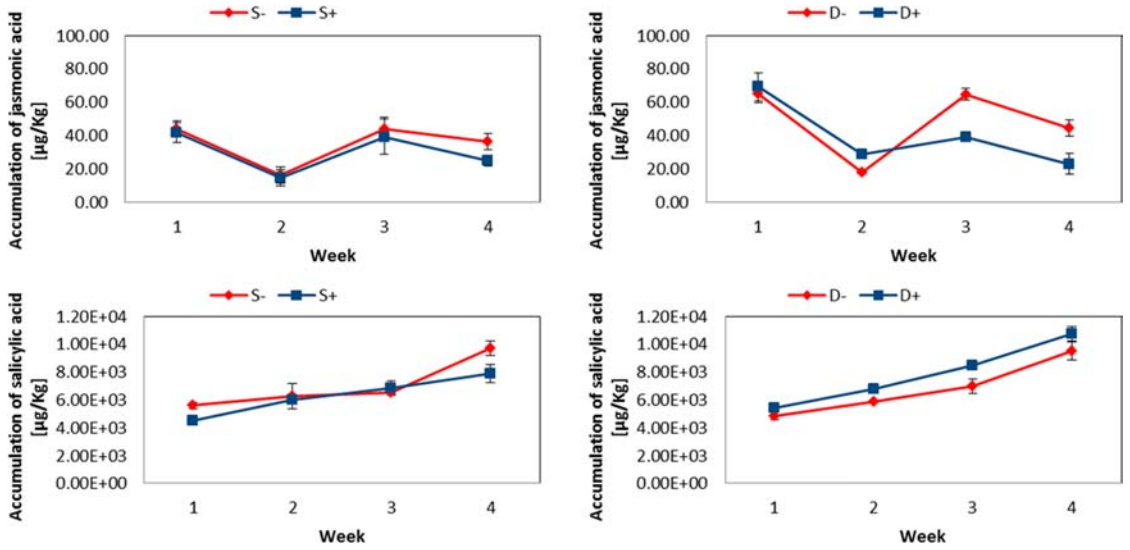

Figure 4. Changes in phytohormone jasmonic acid and salicylic acid accumulation during 4 weeks after germination in resistant (Selenio, S) and susceptible (Dorella, D) rice cultivars, inoculated (+) or not (−) with *F. fujikuroi*. Values are means ± SD (n = 12 independent analyses) in fresh plant tissues (ng/g of fresh weight, FW).

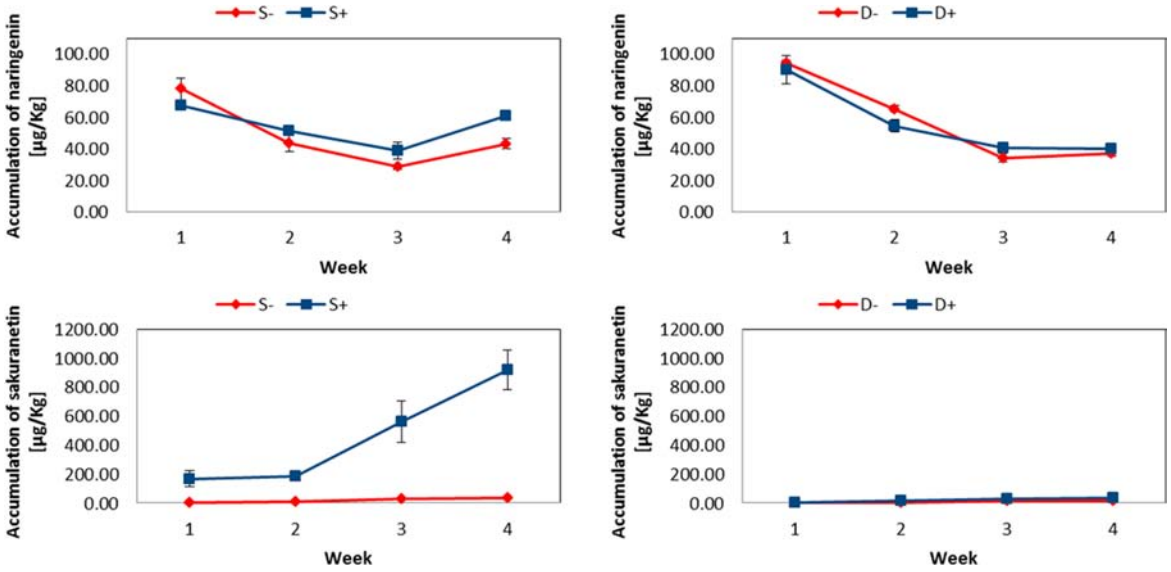

Figure 5. Changes in phytoalexin naringenin and sakuranetin accumulation during 4 weeks after germination in resistant (Selenio, S) and susceptible (Dorella, D) rice cultivars, inoculated (+) or not (−) with *F. fujikuroi*. Values are means ± SD (n = 12 independent analyses) in fresh plant tissues (ng/g of fresh weight, FW).

difference between the two cultivars was found in the accumulation of sakuranetin, which greatly increased (24 times) from the third week in cv. Selenio (Figure 5), while it increased slightly (twice) in the susceptible cultivar. The accumulation of momilactone A (from 1170 to 1960 ng/g for cv. Selenio and from 183 to 1020 ng/g from cv. Dorella) was also higher in the resistant cultivar compared to the susceptible one from 1 wpg (Figure 6). For the other two PAs, differences between the two cultivars are lower: naringenin ranged from 68 to 61 ng/g in cv. Selenio and from 90 to 40 ng/g in cv. Dorella (Figure 5); momilactone B ranged from 115 to 168 ng/g in cv. Selenio and from 66 to 176 ng/g in cv. Dorella (Figure 6).

Quantification of *F. fujikuroi*. The results obtained from real-time PCR allowed the quantification of the fungal DNA and were used to calculate the concentration of *F. fujikuroi* in plants during their growth.

The results showed different trends between the resistant and susceptible cultivars (Figure 7). Inoculated plants of cv. Dorella showed typical bakanae symptoms expressed by abnormal and excessive growth compared to healthy plants. The quantity of *F. fujikuroi* increased during plant growth. At 3 wpg the amount (ng) of fungus was maximum; afterward the quantity of *F. fujikuroi* started to decrease (Figure 7). Conversely, in the inoculated plants of cv. Selenio, symptoms of bakanae were not observed and the quantity of *F. fujikuroi* was steadily lower during 4 weeks (Figure 7). In the uninoculated control of both cultivars, the amount of *F. fujikuroi* was lower throughout the 4 wpg.

DISCUSSION

In this study the differences between the responses of two rice cultivars (Selenio and Dorella) to *F. fujikuroi* were investigated;

DOI: 10.1021/acs.jafc.5b03018
J. Agric. Food Chem. 2015, 63, 8134−8142

different types of analyses, in vivo tests and chemical and molecular analyses, were performed to elucidate the rice resistance mechanism involved.

Several HPLC−MS/MS methods for separation and analysis of free and conjugated phytohormones were developed in plants.[17,18] Liu et al.[19] developed a method for the simultaneous determination of some hormones and phytoalexins to study rice−bacterium interactions. With the same method, Duan et al.[20] studied rice metabolites involved in disease resistance to *M. oryzae*, an agent of rice blast. In this work, a simple and specific method for simultaneous extraction and quantification of metabolites involved in the interaction between rice and *F. fujikuroi* was developed and validated. All the analytes were extracted with a good recovery using a minimal amount of sample.

After pathogen infection or abiotic stress, phytoalexins are produced and accumulated by plants. Changes in phytoalexin concentrations over time may be important in the disease resistance of rice plants.[21] In general, flavonoids in plants have a protective function against stress. Naringenin 7-*O*-methyltransferase (NOMT) catalyzes naringenin methylation to sakuranetin when rice leaves are UV-irradiated[22] or in the presence of an increase of jasmonic acid or a jasmonic acid-related compound.[23] Sakuranetin biosynthesis is rapidly induced by biotic and abiotic stresses and was not found in healthy rice leaves.[24] In this work an increased concentration of sakuranetin was found only in cv. Selenio inoculated plants, not in the uninoculated control or in any sample of susceptible cultivar. It was demonstrated that sakuranetin, during rice−pathogen interaction, was induced in higher quantities in cultivars resistant to blast than in the susceptible ones.[25] Hasegawa et al.[26] established that sakuranetin has a stronger antifungal activity against *M. oryzae* compared with momilactone A, which is the major rice diterpenoid phytoalexin. The main difference observed between the two cultivars is the increase of sakuranetin in resistant inoculated plants. In the interaction of rice with *F. fujikuroi*, sakuranetin is the most important phytoalexin, induced at all the time points.

Momilactones are naturally present in rice plants and are spread in all plant tissues;[27] generally, the content of momilactone A is higher than that of momilactone B. Momilactone A was first isolated from the seed husk of rice and identified as a growth inhibitor,[28] and then it was isolated from rice leaves and characterized as a phytoalexin.[29] The phytoalexin momilactone A was detected in higher levels in cv. Selenio compared to cv. Dorella, from the first week of growth, either in inoculated plants or in uninoculated controls. In inoculated plants the level of momilactone A was always higher

DOI: 10.1021/acs.jafc.5b03018
J. Agric. Food Chem. 2015, 63, 8134−8142

than that in uninoculated controls. MomilactoneA showed a high basal level of production, also without *F. fujikuroi* inoculation, in the resistant rice genotype.

Momilactone B is a potent growth inhibitor and is secreted from the roots throughout the life cycle of the plant,[30] produced in different concentrations depending on the rice cultivars.[31] Generally, stress could induce an increase of the production of allelochemicals, which play an important role in the defense mechanism.[32] In rice, the increased allelopathy with elevated secretion of momilactone B was recorded in different stress conditions.[33] The increase in momilactone B in both cultivars inoculated with *F. fujikuroi* was probably due to a response to stress, but since it also acts as a phytoalexin, momilactone B may play an important role in defense against biotic and abiotic stress. Plant−pathogen interactions produce variations in the level of various phytohormones simultaneously, but each hormone has a characteristic biological effect.[34]

Various plant hormones are often involved in the same biological process with additive, synergistic, or antagonistic action.[35] The rice pathogen *F. fujikuroi* is able to produce large amounts of giberellins, especially the bioactive compound gibberellic acid.[36] Gibberellic acid was significantly detected in cv. Dorella infected with *F. fujikuroi.* At 3 and 4 wpg, increased levels of gibberellic acid were observed and the plants showed typical bakanae symptoms: infected seedlings were elongated, more slender, and slightly chlorotic when compared to healthy seedlings. The increased level of gibberellic acid could be attributed to the presence of the pathogen, which was confirmed by quantitative PCR, only in the susceptible cultivar starting at 2 wpg. Gibberellin A3 production contributes to an increase in the pathogenicity of *F. fujikuroi* on rice.[37] The resistant cultivar Selenio did not show the typical symptoms of bakanae, despite a slight increase of *F. fujikuroi* being observed in inoculated plants at 3 and 4 wpg. Gibberellic acid was observed at low levels in inoculated plants of the resistant cultivar only at 4 wpg.

Jasmonic acid levels had a different trend between infected plants and the uninoculated control for cv. Dorella. At 3 wpg, a decrease of jasmonic acid was observed in inoculated plants of the susceptible cultivar in correspondence with an increase of gibberellic acid, as previously described by Yang et al.[38] Gene expression studies and pathobiological assays suggested that gibberellic acid controls jasmonic acid-responsive gene expression and jasmonic acid-mediated plant immune responses.[39] Gibberellic acid promotes plant growth by regulating the degradation of a class of nuclear growth-repressing proteins called DELLAs. Slender rice 1 (SR1), the only DELLA protein in rice, inhibits JAZ1, the key repressor of jasmonic acid signaling.[40] The increase of gibberellic acid, produced by the fungus, restricts jasmonic acid signaling that is strongly activated during necrotroph infections.[41]

The free salicylic acid level in rice leaves usually ranges from 5 to 30 μg/g of fresh weight.[42,43] A large amount of salicylic acid was accumulated in many plant species (*Arabidopsis*, tobacco) after pathogen inoculation; on the contrary, in rice no significant induction was reported after bacterial or fungal infection.[44] In both uninoculated cultivars, the salicylic acid level was similar, but in cv. Dorella after inoculation the amount of salicylic acid was higher compared to that in cv. Selenio. This is probably due to the role that salicylic acid plays in the modulation of redox balance to protect the plant from oxidative stress and in the defense against pathogen attacks.[45]

Abscisic acid probably compromises rice defense against pathogens. Jiang et al.[46] demonstrated that abscisic acid suppresses the basal resistance of rice when it interacts with the pathogen *M. oryzae* at 3 and 4 wpg. An increased concentration of this phytohormone was observed only in diseased plants of cv. Dorella. A high level of abscisic acid in the susceptible cultivar could be related to the response to biotic stress, as it could antagonize gibberellic acid.[47] Conversely, the concentration of abscisic acid remained constant in the resistant cultivar Selenio; however, the levels of this phytohormone were higher in the inoculated plants compared to the uninoculated control. The role of abscisic acid in disease resistance remains unclear due to its multifaceted function in different tissues and the development stage of the plant. Abscisic acid plays an ambiguous role in the rice immune signaling network; a general pattern suggests that abscisic acid plays a stimulatory role in plant defense during the earlier stages of the pathogen invasion, and vice versa, at later colonization stages, it could have a suppressive role.[48]

The analytical method developed in this paper could be used to study the response of rice to other biotic or abiotic stresses, besides *F. fujikuroi.* The pathogen considered in this work is a seedborne pathogen, and the chemical responses of plants have rarely been studied in relationship to seedborne pathogen infection. Some responses are similar to those activated in response to other rice pathogens, such as *M. oryzae*, which is a foliar fungal pathogen, with the main difference that gibberelins are typically produced by *F. fujikuroi*. The levels of phytohormones and phytoalexins in rice showed that *F. fujikuroi* may behave differently with respect to the cultivar. In the susceptible cultivar, the pathogen could systemically act as a necrotroph destroying the plant cells. On the contrary, in the resistant cultivar, the pathogen is present on rice, though at lower concentration, without damaging the plants, and it triggers salicylic acid and, presumably, a hypersensitive response. Collectively, this information provides important information to elucidate the rice responses occurring during *F. fujikuroi* infection.

DOI: 10.1021/acs.jafc.5b03018
J. Agric. Food Chem. 2015, 63, 8134−8142

of oligopeptides.[15] For example, the antihypertensive oligopeptides VLPVP and HLPLP have been shown to be transported through Caco-2 cell monolayers mainly via the paracellular pathway.[17,18] Additionally, it has been reported that the antihypertensive tripeptide VPP, derived from milk β-casein, is also transported across Caco-2 cell monolayers via the paracellular pathway rather than the PepT1-mediated pathway.[18] However, the molecular mechanism behind the regulation of paracellular transport has not been clearly identified. As such, further studies are needed to assess the transepithelial transport of bioactive peptides, especially oligopeptides, through the human intestine.

As a good protein source for bioactive peptides, chicken egg white, which is composed predominantly of ovalbumin, ovotransferrin, ovomucoid, globulins, and lysozyme, is widely used to prepare antihypertensive peptides.[19] In our previous study, egg-white-derived peptide RVPSL (ovotransferrin 328−332) was identified with in vitro ACE-inhibitory and in vivo antihypertensive activities, making it a prospective functional food candidate and providing an approach for the therapy of hypertension.[20−22] Before studying the bioavailability and pharmacokinetics of the antihypertensive peptide RVPSL in vivo, it is necessary to evaluate its permeability through the intestinal epithelium. Therefore, the objective of this paper was to investigate the resistance to brush border membrane peptidases and the transepithelial transport of RVPSL in the human intestinal Caco-2 cell monolayers. In addition, the structure−transport relationship of RVPSL across Caco-2 cell monolayers was also studied.

MATERIALS AND METHODS

Chemicals. Caco-2 cell lines were purchased from American Type Culture Collection. The antihypertensive peptide RVPSL and other peptides with purity over 95% were synthesized by solid-phase procedures using Fmoc-protected amino acid synthetic methods by ChinaPeptide Co., Ltd. (Shanghai, China). Diprotin A and glycyl-sarcosine (Gly-Sar) were purchased from ChinaPeptide Co., Ltd. (Shanghai, China). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum, penicillin−streptomycin, and Hanks' balanced salt solution (HBSS) were purchased from Gibco BRL Life Technology (Carlsbad, CA). Nonessential amino acid solution, trypsin, L-glutamine, dimethyl sulfoxide (DMSO), ethylenediaminetetraacetic acid (EDTA), collagen type I, cytochalasin D, wortmannin, and sodium azide were all purchased from Sigma−Aldrich (St. Louis, MO). Acetonitrile (ACN), trifluoroacetic acid (TFA), and methanol were purchased from Fisher Scientific (Waltham, MA). All other reagents were analytical-grade.

Cell Culture. The Caco-2 cells were grown in DMEM containing 10% fetal bovine serum, 1% nonessential amino acid solution, 100 units/mL penicillin, 100 μg/mL streptomycin, and 4 mM L-glutamine at 37 °C in an atmosphere of 5% CO_2 and 90% relative humidity. Stock cultures were grown in 75 cm^2 tissue culture flasks and were split at 80−90% confluency with 0.25% trypsin and 0.02% EDTA solution. The cells from passage numbers 30−40 were used and seeded on collagen type I-coated permeable polycarbonate inserts (12 mm diameter, 0.4 μm pore size, 1.12 cm^2 grown surface area; Costar, Corning, NY) in 12 transwell plates at a density of 1×10^5 cells/insert. The culture medium (0.5 mL in the apical side and 1.5 mL in the basolateral side) was replaced every 2 days for the first week and then daily until they were used for experiments 21 days after seeding. The integrity of the cell monolayers was evaluated by measuring transepithelial electrical resistance (TEER) values with an EVOM epithelial volt/ohmmeter (Millicell-ERS, Millipore, Billerica, MA). Only cell monolayers with TEER values higher than 300 $\Omega \cdot cm^2$ were used for transport studies.

Transport Experiments. The bidirectional transepithelial transport of antihypertensive peptide RVPSL in human intestinal Caco-2 cell monolayers was conducted as previously described.[23] Caco-2 cell monolayers were rinsed with HBSS twice and then incubated with HBSS for 30 min at 37 °C in 5% CO_2 prior to transport experiments. Then the HBSS was removed and replaced with 0.5 mL of 5 mM RVPSL (dissolved in HBSS, pH 6.0) on the apical side and 1.5 mL of fresh HBSS on the basolateral side (pH 7.4). Alternatively, to research the efflux of RVPSL, 0.5 mL of fresh HBSS on the apical side (pH 6.0) and 1.5 mL of 5 mM RVPSL (dissolved in HBSS, pH 7.4) on the basolateral side were used. All of the plates were incubated at 37 °C in 5% CO_2 for 2 h. Then the RVPSL concentrations on both the apical and basolateral sides were determined by HPLC analysis.

The resistance of RVPSL to brush border membrane peptidases was studied as described previously by use of diprotin A, an inhibitor of membrane peptidase dipeptidyl peptidase IV (DPPIV, EC 3.4.14.5), which is a major brush border membrane peptidase.[24] Briefly, Caco-2 cell monolayers were preincubated with 1 mM diprotin A at 37 °C in 5% CO_2 for 30 min before transport experiments. Then 0.5 mL of 5 mM RVPSL was added on the apical side. After 2 h of incubation, samples were collected both from apical and basolateral sides and detected by HPLC analysis.

The transepithelial transport mechanism of RVPSL across Caco-2 cell monolayers was investigated by use of transport inhibitors as described previously.[25] Namely, the Caco-2 cell monolayer was preincubated with cytochalasin D (a TJ disruptor, 0.5 μg/mL), wortmannin (a transcytosis inhibitor, 500 nM), sodium azide (an ATP synthesis inhibitor, 10 mM), or Gly-Sar (a peptide transport PepT 1 substrate, 25 mM) for 30 min, followed by addition of 0.5 mL of 5 mM RVPSL to the apical side. Cytochalasin D, wortmannin, and sodium azide were dissolved in DMSO (the final concentration of DMSO in HBSS was 0.044%), and Gly-Sar was dissolved in HBSS. As a control, DMSO was used. After 2 h of incubation, the RVPSL on the basolateral side was detected by HPLC analysis.

The relationship between the structure of RVPSL and transport across Caco-2 cell monolayers was investigated by analyzing the intact transport of a number of peptides, which were re-formed and synthesized based on the structure of RVPSL. These peptides contained two parts: 10 pentapeptides derived from RVPSL by amino acid replacement with Pro residue, and six terminal fragment smaller peptides of RVPSL, including two tetrapeptides, two tripeptides, and two dipeptides. In the transport experiments, peptides (5 mM, pH 6.0) were added on the apical side. After 2 h of incubation, peptide concentrations on the basolateral side were detected by HPLC analysis.

The apparent permeability coefficient (P_{app}, centimeters per second) was calculated as follows:

$$P_{app} = \frac{dC}{dt}\frac{1}{A}\frac{1}{C_0}V$$

where dC/dt is the change of RVPSL concentration in the receiving chamber (micromoles per liter per minute); A is the area of membrane (square centimeters), C_0 iss the initial peptide concentration in donor chamber (millimoles per liter), and V is the volume of the receiving chamber.

Reverse-Phase High-Performance Liquid Chromatography. The peptide was quantified on a Shimadzu HPLC system equipped with LC solution software, a LC-20AD binary gradient pump, a SIL-20AC autosampler, a CTO-20AC column oven, and SPD-20AV UV detector (Shimadzu, Kyoto, Japan). The analytical column was a C18 reverse-phase column (Symmetry C18 column, 250 × 4.6 mm, particle size 5 μm; Waters, Milford, MA). The mobile phases were solvent A (0.1% TFA in water) and solvent B (0.1% TFA in ACN). Samples were eluted with a gradient of solvent B from 10% to 55% in 15 min and held at 55% for 5 min at a flow rate of 0.5 mL/min. The injection volume was 20 μL, and the absorbance detector wavelength was set at 220 nm. The peptide concentration was calculated by a linear regression analysis of the peak area by the method of Lei et al.[16] A calibration curve was constructed over a RVPSL concentration range

DOI: 10.1021/acs.jafc.5b01824
J. Agric. Food Chem. 2015, 63, 8143−8150

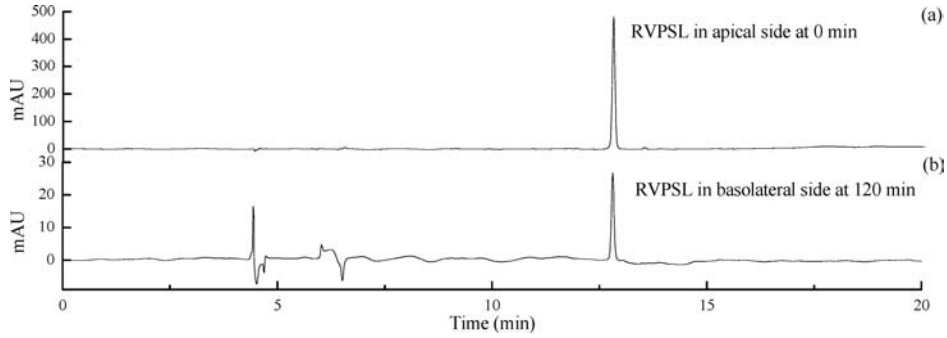

Figure 1. Representative chromatograph of RVPSL with retention time of 12.78 min and total RP-HPLC run time of 20.00 min. (a) RVPSL on the apical side at 0 min (approximately 5 mM); (b) RVPSL on the basolateral side at 120 min (approximately 187 μM) in apical to basolateral transport experiment.

of 10 μM to 5 mM. The HPLC analysis condition was the same as for samples. The peak area of RVPSL was measured, and the calibration curves of peak area versus concentration and the coefficient were then analyzed.

Assay of ACE-Inhibitory Activity. The ACE-inhibitory activity of peptides was determined as described previously.[26] Namely, an aliquot of 30 μL of 4 mM HHL was mixed with 10 μL of sample solutions and then incubated at 37 °C for 5 min. Then, 20 μL of 0.25 unit of ACE was added and the reaction mixture was incubated at 37 °C for an additional 30 min, followed by the addition of 60 μL of 1 M HCl to stop the reaction. The whole assay was conducted in borate buffer (100 mM, pH 8.3) containing 300 mM NaCl. The same buffer was used for solution preparation of the HHL, hippuric acid, peptides, and enzyme dilutions. HPLC analysis was used to quantify the hippuric acid produced by the enzymatic hydrolysis of the substrate hippuryl-L-histidyl-L-leucine (HHL). The analytical column was a C18 reverse-phase column (Symmetry C18 column, 250 × 4.6 mm, particle size 5 μm; Waters, Milford, MA). The isocratic mobile phase consisted of 25% acetonitrile in deionized water (v/v) with 0.5% TFA. The injection volume was 10 μL, and HHL and hippuric acid were detected at 228 nm when the mobile phase was controlled at 0.5 mL/min.

ACE inhibitory activity, as a percentage, was calculated as follows:

$$\text{ACE inhibitory activity} = \frac{(A - B)}{B} \times 100$$

where A is the peak area of the reaction blank, containing the same volume of buffer solution instead of the sample; B is the peak area of the reaction in the presence of both ACE and enzymatic peptide sample; and the IC_{50} value is defined as the concentration of inhibitor inhibiting 50% of the ACE activity under the assayed conditions.

Statistical Analysis. All data were expressed as the mean ± SD (n = 3). The difference between groups was carried out by one-way analysis of variance (ANOVA) followed by least significant difference (LSD) test with the significance level at $P < 0.05$ by use of SPSS 19.0 software.

RESULTS

Validation of RVPSL by RP-HPLC Analysis. As shown in Figure 1, the retention time for RVPSL was 12.78 min out of a total running time of 20.00 min. On both the apical side (Figure 1 a) and basolateral side (Figure 1 b), no matrix-specific interfering peaks were observed. To quantify the RVPSL in the sample, a calibration curve was established over a concentration range of 10 μM to 5 mM. Linear regression analysis of the peak area and concentration of RVPSL revealed a typical equation $y = 446.75x + 31821$ with a mean correlation coefficient $r^2 = 0.9994$, indicating good linearity in this calibration curve and that the equation could be used to determine the concentration of RVPSL in this work. The other peptides used in this study were all previously validated by HPLC analysis.

Transepithelial Flux of RVPSL across Caco-2 Cell Monolayers. In the transepithelial flux experiment, the synthetic peptide RVPSL at a concentration of 5 mM was added to the apical side of Caco-2 cell monolayers and incubated at 37 °C in 5% CO_2 for 2 h. The levels of RVPSL on both the apical and basolateral sides were then determined. As shown in Figure 2, after 2 h of incubation, the accumulated

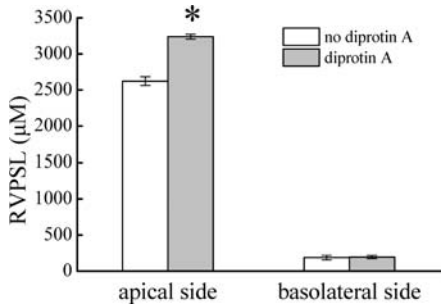

Figure 2. Effect of diprotin A on accumulated amount of RVPSL on the apical and basolateral sides of Caco-2 cell monolayers. In the presence of diprotin A, the RVPSL remaining on the apical side was significantly higher than that without diprotin A ($P < 0.001$). However, no significant increase in the transport of RVPSL to the basolateral side was observed ($P > 0.05$). All values are means ± SD (n = 3). (*) $P < 0.001$ as compared to RVPSL level on the apical side without diprotin A.

concentration of RVPSL on the basolateral side reached 187.46 ± 29.84 μM, and the P_{app} value was found to be (6.97 ± 1.11) × 10^{-6} cm/s, suggesting that the antihypertensive peptide RVPSL could be absorbed intact through the Caco-2 cell monolayers. However, only 2622.20 ± 61.22 μM RVPSL remained on the apical side, indicating that 47.56% ± 1.22% of the initial RVPSL added to the apical side had disappeared. Except for the portion that had been transported, there was 36.31% ± 1.22% of the initial RVPSL that may have been hydrolyzed to shorter fragments or free amino acids by brush border membrane peptidases. However, no other fragments in addition to RVPSL were detected on the basolateral side and in Caco-2 cells under the HPLC conditions used in the present study.

To verify the low resistance of RVPSL to brush border membrane peptidases, the Caco-2 cell monolayer was preincubated with diprotin A, a protease inhibitor, prior to the transport experiment. As a result, the activity of DPPIV, the

DOI: 10.1021/acs.jafc.5b01824
J. Agric. Food Chem. 2015, 63, 8143−8150

main group of brush border membrane peptidases, was restricted. As shown in Figure 2, the amount of intact RVPSL on the basolateral side in the presence and absence of diprotin A was not significantly increased ($P > 0.05$). However, the accumulated RVPSL on the apical side increased to 3238.04 ± 34.11 μM, which was 1.23-fold higher than in the absence of diprotin A ($P < 0.001$), and only 35.24% ± 0.68% of the initial RVPSL had disappeared. Consequently, except for the portion that was transported, degradation of the initial RVPSL by brush border membrane peptidases decreased to 23.49% ± 0.68% ($P < 0.001$).

A bidirectional transport experiment was also designed to determine whether the transepithelial transport of RVPSL was passive or polarized. The permeability coefficient P_{app} for both directions, transport from apical side to basolateral side (AP-BL) and transport from basolateral side to apical side (BL-AP), was tested. As shown in Figure 3, in the absence of diprotin A,

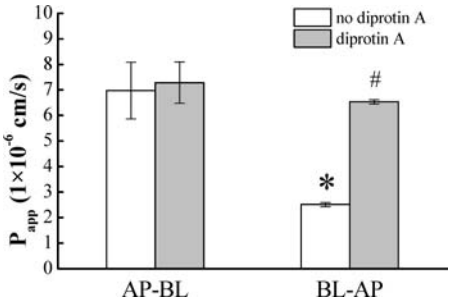

Figure 3. Effects of diprotin A on bidirectional transport of RVPSL across Caco-2 cell monolayers. In the presence of diprotin A, P_{app} for BL-AP increased significantly ($P < 0.001$). However, this was still slightly lower than P_{app} for AP-BL, although the difference was not significant ($P > 0.05$). All values are means ± SD ($n = 3$). (*) $P < 0.001$ as compared to P_{app} for AP-BL in the absence of diprotin A; (#) $P < 0.001$ as compared to P_{app} for BL-AP in the absence of diprotin A.

P_{app} for AP-BL, $(6.97 \pm 1.11) \times 10^{-6}$ cm/s, was approximately 3-fold higher than P_{app} for BL-AP, $(2.52 \pm 0.08) \times 10^{-6}$ cm/s ($P < 0.001$). However, P_{app} for BL-AP increased significantly to $(6.53 \pm 0.08) \times 10^{-6}$ cm/s in the presence of 1 mM diprotin A ($P < 0.001$). It was still slightly lower than P_{app} for AP-BL of $(7.29 \pm 0.81) \times 10^{-6}$ cm/s in the presence of diprotin A; however, no significant difference was observed ($P > 0.05$). These results suggested that the transepithelial transport of RVPSL across Caco-2 cell monolayers was passive and nonpolarized. In addition, the susceptibility of peptides to brush border membrane peptidases might lead to an underestimate of P_{app} for BL-AP.

Effects of Various Compounds on RVPSL Transport. To determine which transport pathways were involved in the transepithelial transport of RVPSL through the intestinal epithelium, Caco-2 cell monolayers were preincubated for 30 min before transport experiment with a range of inhibitors. As shown in Figure 4, in the presence of Gly-Sar, a good substrate for PepT1, the permeability coefficient P_{app} of RVPSL decreased slightly but not significantly ($P > 0.05$), suggesting that the transport of RVPSL across the Caco-2 cell monolayers was not mediated by PepT1. Sodium azide, an ATP synthesis inhibitor, also had little effect on the P_{app} of RVPSL ($P > 0.05$), indicating that transepithelial transport of RVPSL was energy-independent. In addition, the effect of transcytosis, initiated by endocytosis at the apical cell membrane, on RVPSL transport was examined by wortmannin, a transcytosis inhibitor.

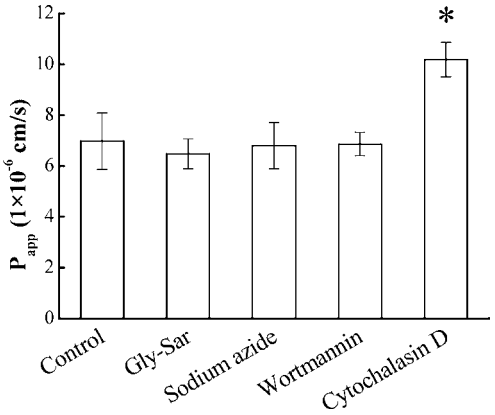

Figure 4. Effects of various compounds on transport of RVPSL across Caco-2 cell monolayers. Gly-Sar, sodium azide, and wortmannin all had little effect on P_{app} of RVPSL ($P > 0.05$). In contrast, cytochalasin D increased the transport of RVPSL significantly ($P < 0.001$), suggesting that RVPSL mainly transported across Caco-2 cell monolayers via the paracellular pathway mediated by TJs. All values are means ± SD ($n = 3$). (*) $P < 0.001$ as compared to the control group.

However, RVPSL transport did not decrease significantly in the presence of wortmannin ($P > 0.05$), indicating that the transcytosis was not involved in RVPSL transport. In contrast, in the presence of cytochalasin D, a TJ disruptor, the permeability coefficient P_{app} of RVPSL across the Caco-2 cell monolayers increased by 46.03%. It was significantly higher than that of the control group ($P < 0.001$), suggesting that RVPSL was transported across the Caco-2 cell monolayers via the paracellular pathway mediated by TJs.

Structure–Transport Relationship of RVPSL Caco-2 Cell Monolayers. To investigate the relationship between RVPSL structure and transport across Caco-2 cell monolayers, Pro was used to replace one or two of the amino acid residues of RVPSL. The P_{app} values of 11 pentapeptides (RVPSL, PVPSL, RPPSL, RVPPL, RVPSP, PVPPL, PVPSP, RPPPL, RPPSP, PPPSL, and RVPPP) varied from $(4.13 \pm 0.62) \times 10^{-6}$ to $(2.08 \pm 2.76) \times 10^{-5}$ cm/s, as shown in Figure 5. The modified pentapeptide RVPSP had the highest P_{app} value at $(2.08 \pm 2.76) \times 10^{-5}$ cm/s. Interestingly, P_{app} values of the other 10 pentapeptides were in the order PPP-X-X > RPP-X-X > PVP-X-X > RVP-X-X (where X represents Pro/P, Leu/L, or Ser/S), suggesting that the N-terminal Pro residue was more beneficial for intact transport of the pentapeptide than Val and Arg residues. Moreover, replacement of N-terminal amino acids was most informative and a high P_{app} arose when the N-terminal Arg residue and Val residue were both replaced by Pro, followed by replacement of Val alone, and then replacement of Arg alone. However, no similar results or other structure–transport relationships were observed at the C-terminus. Furthermore, there was no significant statistical relationship between P_{app} and molecular properties such as molecular weight, log D, molecular volume, molecular surface area, or polar surface area of the 11 pentapeptides. On the other hand, transport of terminal fragments resulting from cleavage of RVPSL was detected as shown in Figure 6. Except for the tetrapeptide VPSL, whose low transport rate might due to a Val residue at the N-terminal first position, all other fragment peptides had higher P_{app} values than the pentapeptide RVPSL, suggesting that the antihypertensive peptide RVPSL could be absorbed more easily through the Caco-2 cell monolayers in

DOI: 10.1021/acs.jafc.5b01824
J. Agric. Food Chem. 2015, 63, 8143–8150

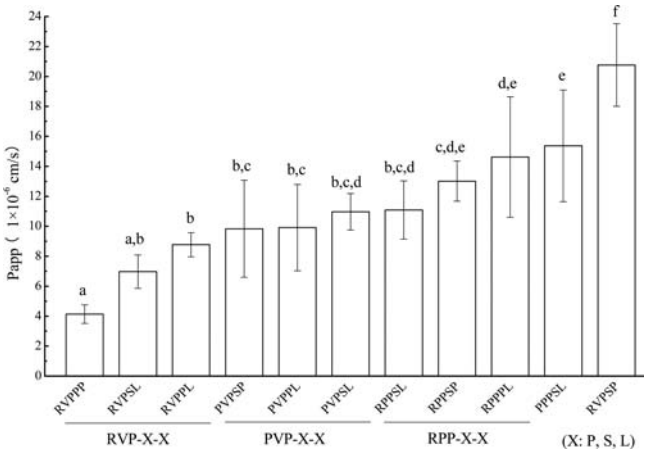

Figure 5. Effects of Pro residue replacement on transport of RVPSL across Caco-2 cell monolayers. Except for RVPSP, with the highest P_{app} value, P_{app} values of the other peptides were in the order PPP-X-X > RPP-X-X > PVP-X-X > RVP-X-X, suggesting that N-terminal Pro residues were more beneficial for intact transport of pentapeptides than Val or Arg residues. However, similar results were not observed at the C-terminus. All values are means ± SD (n = 3). For each measurement, the data marked by different letters are significantly different (P < 0.05).

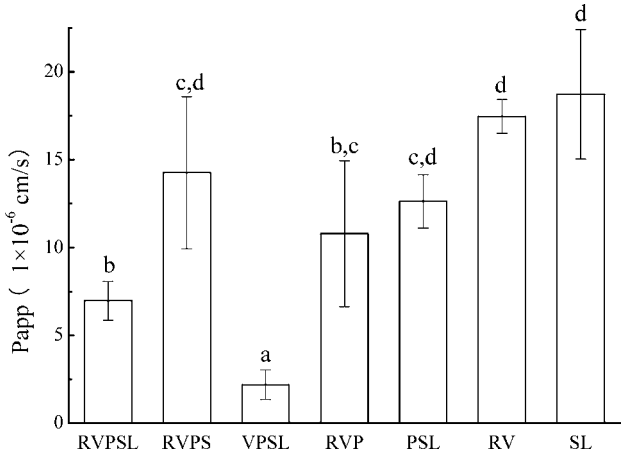

Figure 6. Transport of terminal fragment peptides derived from RVPSL across Caco-2 cell monolayers. Most of the peptide fragments had higher P_{app} values than the pentapeptide RVPSL, suggesting that antihypertensive peptide RVPSL could be more easily absorbed across Caco-2 cell monolayers in smaller fragments, especially in the form of dipeptides and tripeptides. All values are means ± SD (n = 3). For each measurement, the data marked by different letters are significantly different (P < 0.05).

smaller fragments, especially in the form of dipeptides and tripeptides.

Additionally, the ACE-inhibitory activities of the synthetic peptides are shown in Table 1. Besides the precursor peptide sequence RVPSL, which had an ACE-inhibitory IC_{50} value of 20.00 μM, peptides with the sequences PVPSL, RVPPL, RVPSP, PVPSP, RPPPL, RPPSP, and RVP all also exhibited ACE-inhibitory activity. Among these peptides, PVPSL showed the highest ACE-inhibitory activity with an IC_{50} value of 5.51 μM. RVPSP and RPPPL showed ACE-inhibitory activity with IC_{50} values of 51.43 and 47.25 μM, respectively. The remaining peptides all had very low ACE-inhibitory activities with IC_{50} values over 500 μM. However, the peptides PVPSL, RPPPL, and RVPSP all exhibited high permeability through the Caco-2 cell monolayers and genuine ACE-inhibitory activity, suggesting their potential in functional food.

Table 1. ACE-Inhibitory Activities of Synthetic Peptides

no.	peptide sequence	IC_{50} (μM)
1	RVPSL	20.00
2	PVPSL	5.51
3	RPPSL	>500
4	RVPPL	117.43
5	RVPSP	51.43
6	PVPPL	>500
7	PVPSP	152.97
8	RPPPL	47.25
9	RPPSP	357.18
10	PPPSL	>500
11	RVPPP	>500
12	RVPS	>500
13	VPSL	>500
14	RVP	152.39
15	PSL	>500
16	RV	>500
17	SL	>500

DISCUSSION

Food-derived antihypertensive peptides meet the desired properties of modulating physiological health and reducing hypertension through food. However, many of these peptides have limited practical applications due to their instability and low bioavailability in vivo.[27] Thus, it is critical for bioactive peptides to overcome two physiological barriers: extensive enzymatic degradation in the gastrointestinal tract and poor permeability through the intestinal epithelium. In our previous work, the peptide RVPSL, identified from egg white ovotransferrin, had been shown to have ACE-inhibitory activity in vitro and antihypertensive activity in vivo in SHR. In addition, in a simulated gastrointestinal digestion experiment with pepsin and trypsin, 94.42% ± 0.41% of the initial RVPSL remained. From these positive results, in the present study, we investigated the transepithelial transport of RVPSL and its resistance to brush border membrane peptidases using Caco-2 cell monolayers.

It has been demonstrated that Caco-2 cells express at least eight membrane peptidases in their apical surface, and these peptidases exhibit different activities at different growth stages. Among these peptidases, DPPIV has the highest activity, especially when Caco-2 cells are completely differentiated.[28] DPPIV is a member of the prolyl oligopeptidase family of serine proteases and is highly expressed on endothelial cells, differentiated epithelial cells, and lymphocytes. It predominantly cleaves N-terminal dipeptides from proteins containing proline or alanine in the penultimate position.[29] The activity of DPPIV can be specifically inhibited by diprotin A, which transitorily binds to the catalytic site of the enzyme and blocks the degradation of substrates.[30] In the present study, we found that the antihypertensive peptide RVPSL was susceptible to brush border membrane peptidases. Approximately 36.31% ± 1.22% of the initial RVPSL (5 mM) added to the apical chamber was degraded, and this degradation significantly decreased to 23.49% ± 0.68% in the presence of diprotin A. On one hand, although diprotin A is a well-known inhibitor of DPPIV with an IC_{50} value of 1.1 μg/mL (3.22 μM)[31,32] and is

DOI: 10.1021/acs.jafc.5b01824
J. Agric. Food Chem. 2015, 63, 8143−8150

widely used to verify the action of DPPIV, 1 mM diprotin A may be insufficient to fully inhibit the protease. On the other hand, degradation of RVPSL may also be due to the action of other brush border membrane peptidases on the apical surface. The susceptibility of peptides to the membrane peptidases depends on their structural and chemical properties.[33] Some human or bovine milk β-casomorphin-derived peptides have been reported to be very susceptible to DPPIV.[34,35] In general, the N-terminal dipeptide (Xaa-Pro or Xaa-Ala) was regarded as easily cleaved by DPPIV specifically.[29] In addition, N-terminal bulky hydrophobic or basic amino acid residues with an obligate free amino group are good substrates for cleavage by DPPIV.[36] In terms of RVPSL, as the N-terminal Arg is a basic amino acid and contains a free amino group and Val is also a small molecular weight hydrophobic amino acid, these factors may contribute to its degradation by DPPIV. Although Pro residues in the third position are resistant to DPPIV hydrolysis,[36] many natural peptides containing Xaa-Xaa-Pro at the N-terminus have been shown to have high binding affinity for DPPIV without being cleaved.[37] This may also have an influence on the decrease of RVPSL on the apical side, as determined by HPLC.

Caco-2 serves as an in vitro model of the human intestinal epithelium, so the expression of various brush border membrane peptidases in Caco-2 cells is essential. However, it is difficult to evaluate the real transport rate when the tested peptides are susceptible to these membrane peptidases.[24] It has been found that the transport rate of some bioactive peptides increased significantly when membrane peptidases were inhibited by diprotin A.[34,35] In the present study, we also determined the bidirectional transepithelial flux of RVPSL in the presence and absence of diprotin A. The results showed that the P_{app} value for AP-BL was 2.8-fold higher than that for BL-AP in the absence of diprotin A. However, when membrane peptidases were inhibited by diprotin A, there was a significant increase in the amount of RVPSL in the apical chamber in BL-AP transport, leading to a significant increase in P_{app} for BL-AP transport but not AP-BL. As a consequence, no significant difference in the transport rate between AP-BL and BL-AP flux was observed in the presence of diprotin A, suggesting that the permeability of RVPSL across Caco-2 cell monolayers might be nonpolarized and passive. This result was consistent with transport of RVPSL by the paracellular pathway.

Bioactive peptides, especially oligopeptides, are generally thought not to be absorbed intact through the human intestinal epithelium. Previous publications that have focused on the transport of bioactive peptides through in vivo intestine models and in vitro Caco-2 cell monolayers have shown low permeability for these peptides, with permeability coefficients P_{app} ranging from 1×10^{-8} to 1×10^{-6} cm/s. In this work, the antihypertensive pentapeptide RVPSL had good permeability across Caco-2 cell monolayers with a P_{app} value of $(6.97 \pm 1.11) \times 10^{-6}$ cm/s, which is similar to that of human β-casomorphin-7, slightly higher than those of lactoferroxin A,[34] VLPVP[16] and QIGLF,[25] and higher than the values of many other bioactive peptides reported elsewhere, such as KVLPVP,[38] HLPLP,[17] Gly-Ala-Hyp-Gly-Leu-Hyp-Gly-Pro,[39] bovine β-casomorphin-5 and -7, casoxin-6,[35] VYIHPF,[40] and α_{s1}-casein-(f91−97).[41] Moreover, RVPSL even had a higher transport rate than the well-studied tripeptides VPP[18] and YPI.[10] The high permeability of RVPSL across Caco-2 cell monolayers may be due to its structural characteristics and molecular properties. On the other hand, differences in the integrity and tightness of TJs of Caco-2 cell monolayers used in different laboratories may also have important influences on peptide transport. In addition, since Caco-2 cell monolayers have tighter TJs than human intestinal epithelial cells, the paracellular permeability of RVPSL in vivo in human intestinal epithelium is likely to be higher.[42]

There are three possible mechanisms for transport of oligopeptides: transcytosis, paracellular transport and PepT1-mediated transport. There are two types of transcytosis, specific receptor-mediated transport and nonspecific pinocytotic transport, which are mainly responsible for the transport of some proteins and large molecular peptides,[43] such as β-casein (193−209), a 17-residue peptide, which may be absorbed intact through transcytosis via internalized vesicles.[44] In contrast, PepT1 can transport small peptides, including a range of dipeptides and tripeptides, though not all.[13] It is known that PepT1 is a low-affinity, high-capacity transporter and can be inhibited by its substrate glycyl dipeptide.[45] The affinity of peptides for PepT1 depends on the structural characteristics and molecular properties of the peptides, such as charge, hydrophobicity, and side-chain flexibility.[46] However, in the present study, the above two transport pathways were not involved in intact transport of antihypertensive peptide RVPSL across Caco-2 cell monolayers. Another transport mechanism is the paracellular pathway, which is mediated by TJs. The paracellular pathway involves the passive diffusion of water-soluble low molecular mass substances, including oligopeptides.[47] Although TJs, which consist of several proteins such as zonula occludens 1 (ZO-1), occludins, and claudins, form a tight biological barrier against the permeation of exogenous macromolecules or cytotoxic substances, a great number of pores still exist in TJs.[48] The pores usually have a radius no more than 15 Å and selectively allow some minerals and molecules to pass through.[49] Studies have shown that the paracellular pathway is also involved in the transepithelial transport of many bioactive peptides. Again, the properties of peptides such as their molecular size, hydrophilicity, and some molecular surface properties all have important influences on their paracellular flux.[15] In the present study, cytochalasin D, a disruptor of TJs, caused an approximately 1.5-fold increase of the permeability coefficient P_{app} of RVPSL compared to controls, suggesting that the paracellular pathway mediated by TJs might be the major transport route of RVPSL through the intestinal epithelium. This result is similar to that of other previously reported peptides, such as VLPVP,[16] HLPLP,[17] QIGLF,[25] Gly-Ala-Hyp-Gly-Leu-Hyp-Gly-Pro,[39] GGYR,[24] and VPP.[18]

Proline is a key amino acid residue in ACE-inhibitory peptides and is usually found at the C-terminus of a large number of these peptides.[1] In the present study on the relationship between RVPSL structure and transport, Pro was used to replace individual amino acids in RVPSL due to its structure, hydrophobicity, and relatively low molecular weight, which may play important roles in the transport of peptides.[11,12,15] For instance, it had been previously demonstrated that dipeptides with C-terminal Pro residues but not N-terminal Pro residues exhibit high affinity for PepT1.[50,51] However, it was also found that N-terminal, but not C-terminal, Pro residues had important roles on the transport of peptides across Caco-2 cell monolayers in this study. This finding has not been reported elsewhere and will need to be investigated further.

400 spectrometer (^{1}H at 300 MHz), on an Avance III HD 500 MHz Bruker spectrometer (Bruker BioSpin, Rheinstetten, Germany), and/or on a Mercury plus 300 MHz Varian spectrometer (Varian Inc., Palo Alto, CA, USA). $CDCl_3$ was used as solvent, and the chemical shifts are given in parts per million referring to the residual nondeuterated solvent signal ($CDCl_3$ 7.27 and 77.0 ppm for ^{1}H and ^{13}C, respectively). Column chromatography was performed with Si gel (70−230 mesh) from Merck (Darmstadt, Germany). TLC analysis was carried out using Si gel GF-254, 0.2 mm precoated plates (Merck): the spots were visualized either using a UV lamp at 254 nm or by spraying with 2% sulfuric acid in ethanol.

Plant Material. The unripe fruits of *E. umbelliflora* were collected in June 2008 in Itapema, Santa Catarina, Brazil, and identified by Prof. Msc. Oscar Benigno Iza (Universidade do Vale do Itajaí, Itajaí-SC). A voucher specimen (VC Filho 50) was deposited at the Barbosa Rodrigues Herbarium, Itajaí, Santa Catarina, Brazil.

Extraction and Isolation. The unripe fruits, air-dried and cut into small pieces (310.45 g), were extracted twice with methanol (MeOH) at room temperature over a period of 7 days. The combined MeOH extracts were evaporated under reduced pressure with a rotary evaporator at 40 °C to obtain a brown gummy residue, which was suspended in a solution of MeOH/H_2O (4:1) and successively partitioned with *n*-hexane (300 mL), CH_2Cl_2 (300 mL), and ethyl acetate (300 mL) to give three different nonpolar extracts. The residue that remained after partitioning was dried under reduced pressure to give the residual extract. Part of the CH_2Cl_2 extract (8.7 g) was subjected to silica gel 60 (Merck) open column chromatography (4 × 50 cm) and eluted with 400 mL each of a gradient of *n*-hexane/CH_2Cl_2 in ratios to 100:0, 90:10, 80:20, 70:30, 60:40, and 50:50, respectively. On the basis of similar R_f values on TLC developed with the eluent *n*-hexane/CH_2Cl_2 (3:7) and sprayed with 10% sulfuric acid, six fractions (C1−C6) were grouped.

Fraction C3 (0.8 g) was further purified by silica gel 60 open column chromatography (1.5 × 25 cm) and eluted with 200 mL each of mixtures of *n*-hexane/CH_2Cl_2 in ratios 100:0, 90:10, and 80:20 and finally purified by centrifugally accelerated preparative TLC on a Chromatotron (Harrison Research, Palo Alto, CA, USA) on 1 mm plates with hexane/CH_2Cl_2 (9:1), yielding 42 mg of compound **1** and 82 mg of compound **2**.[8]

Fraction C4 (1.2 g) was further purified by silica gel 60 open column chromatography (2 × 30 cm) and eluted with 300 mL each of a mixture of *n*-hexane/CH_2Cl_2 in ratios of 80:20, 70:30, and 60:40, respectively, yielding 125 mg of a white precipitate, which was eugenial C (**3**). Fraction C5 (1.6 g) was purified by centrifugally accelerated preparative TLC and eluted with 500 mL of a gradient of *n*-hexane/CH_2Cl_2 (70:30) to give 45 mg of eugenial D (**4**).

*Eugenial C (**3**):* amorphous white solid; mp 136−138 °C; $[\alpha]_D$ −7 (*c* 0.13, $CHCl_3$); IR (KBr) 3503, 2960, 2884, 1621, 1458, 1380 cm^{-1}; NMR data, see Table 1; EIMS (%) 440 (2), M$^{\bullet+}$ 237 (60) $C_{12}H_{13}O_5$, phloroglucinol, 219 (18), 203 (100) $C_{15}H_{23}$, sesquiterpene; 161 (12), 149 (7), 147 (40), 129 (20), 105 (35). HRESIMS, found 440.2781 (calcd 440.2793 for $C_{27}H_{36}O_5$).

*Eugenial D (**4**):* amorphous white solid; mp 162−165 °C; $[\alpha]_D$ −22 (*c* 0.22, $CHCl_3$); IR (KBr) 3505, 2960, 2875, 1625, 1437, 1380 cm^{-1}; NMR data, see Table 2; EIMS *m*/*z* (%) 440 (30), M$^{\bullet+}$ 237 (100) $C_{12}H_{13}O_5$, phloroglucinol, 219 (21), 203 (95) $C_{15}H_{23}$, sesquiterpene, 161 (25), 149 (24), 147 (55), 129 (30), 105 (40); HRESIMS, found 440.2793 (calcd 440.2787 for $C_{27}H_{36}O_5$).

Microorganisms, Media, and Inocula. For the antimicrobial evaluation, strains of the American Type Culture Collection (ATCC), Rockville, MD, USA, were used, as follows: bacteria, *Bacillus subtilis* ATCC 23858, *Escherichia coli* ATCC 25922, and *Staphylococcus aureus* ATCC 6538P; and yeast *Candida albicans* ATCC 10231. The methicillin-resistant *Staphylococcus aureus* (MRSA) strains (Sa3, Sa4, Sa5, Sa6, Sa8) were obtained from clinical material collected at the Hospital and Maternity Marieta Konder Bornhausen in Itajaí, Santa Catarina, Brazil. The strains were deposited at the Laboratory of Research in Microbiology Univali in Itajaí, Santa Catarina, Brazil.

Quantitative Antimicrobial Evaluation. The minimum inhibitory concentration (MIC) of each compound was determined using broth microdilution techniques, following the guidelines of CLSI[13] M07-A8 for bacteria and CLSI (formerly NCCLS) M27-A2 for yeasts.[14] Stock solutions of compounds diluted in DMSO were added to each medium to give serial 2-fold dilutions, resulting in concentrations ranging from 1000 to 62.5 μg/mL and also from 100 to 0.19 μg/mL. Inocula of 100 μL (5 × 10^5 CFU/mL for bacteria and 10^3−10^4 CFU/mL for yeasts) were added to Mueller−Hinton broth medium (Merck) for bacteria and RPMI-1640 broth medium (Gibco, Grand Island, NY, USA) for yeast. Vancomycin hydrochloride (Sigma, St. Louis, MO, USA) and amphotericin B (Sigma) were used as positive controls. Plates were incubated for 24 h at 35 °C for bacteria and at 30 °C for yeasts. MIC was defined as the lowest concentration of compound capable of causing total inhibition of the growth of microorganism compared with control. All of the antimicrobial assays were tested in duplicate.

Statistical Analysis. The data are reported as mean ± standard error of the mean (SEM) and were compared using one-way analysis of variance (ANOVA), followed by Dunnett's pairwise test, and *p* values <0.05 were considered significant.

RESULTS AND DISCUSSION

Phytochemical analyses of the CH_2Cl_2 fraction of *E. umbelliflora* fruits led to the isolation of four phloroglucinols: **1**, **2**,[11,15] and two new meroterpenoids, **3** and **4** (Figure 1), which were identified (^1H,^{13}C NMR, 1D and 2D-COSY, NOESY, HMQC/HSQC, HMBC experiments, FTIR, and HRESIMS) and compared with those previously reported in the literature for model compounds (Tables 1 and 2).[11,16]

Compound **3** was obtained in the form of a white amorphous solid, mp 136−138 °C; its IR spectrum exhibited a strong carbonyl band at 1621 cm^{-1}. A molecular formula $C_{27}H_{36}O_5$ was inferred from the HRESIMS. The ^1H and ^{13}C NMR data are summarized in Table 1, all of the protons being assigned to the appropriate carbon by HMQC and quaternary carbons by HMBC spectroscopy. The data suggested that the compound consists of two parts: a fully substituted phoroglucinol and a sesquiterpene. The ^{13}C and DEPT spectra of **3** showed 27 carbon signals, including 4 methyls, 8 methylenes, 5 methines, and 10 quaternary carbons. Of these, seven carbons [δ_C 192.1 (d, C-8), 172.7 (s, C-6), 168.0 (s, C-4), 162.1 (s, C-2), 104.4 (s, C-1), 104.1 (s, C-5), and 103.3 (s, C-3)] arose from a typical formylphloroglucinol unit, and signals for a typical linear butyroyl substituent [δ_C 206.9 (s, C-9), 46.1 (t, C-10), 17.8 (t, C-11), and 13.8 (q, C-12)] were observed. In the ^1H NMR spectrum, the phloroglucinol substituents were established by the signal for an aldehyde (δ_H10.10), two hydrogen-bonded hydroxyls (δ_H15.49 and 14.42), a phenolic hydroxyl (δ_H 5.77), and a linear butyroyl group at δ_H 3.12 (t, J = 7.5 Hz), 1.74 (dt, J = 7.5 Hz), and 1.02 (t, J = 7.5 Hz). The relative position of these substituents was proposed on the basis of HMBC connectivities (Figure 2) and showed a close similarity with the phloroglucinol portion of compound **1** (Table 1). The hydroxyl proton 6-OH (δ_H 15.49) showed HMBC correlations with C-1 and C-6 and the hydroxyl proton 4-OH (δ_H 14.42) with C-4 and C-5, whereas the hydroxyl proton 2-OH (δ_H 5.77) was correlated with C-2 and C-3. The HMBC correlations of H-8 (δ_H 10.10) with C-3 and C-4 confirmed that the formyl group was located at carbon C-3.

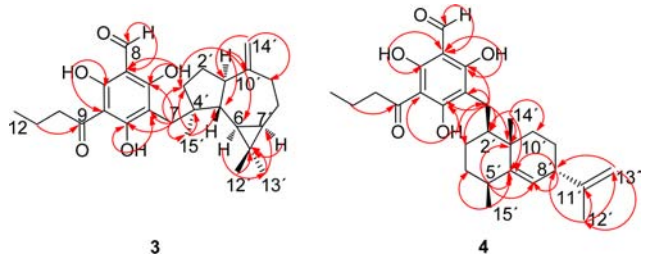

Figure 2. Key HMBC correlations for compounds **3** and **4**.

With respect to the sesquiterpene moiety, it was established as aromadendrene, as shown in structure **3**, from the remaining ^1H and ^{13}C NMR signals and by comparison (Table 1) with the NMR data of model compound macrocarpal C/G (**5**) (Figure 1) isolated from *Eucalyptus macrocarpa*.[16] The aromadendrene skeleton is further supported by HMBC connectivities (Figure 2). The correlations of protons Me-15′ with C-3′, C-4′, and C-5′ allowed the connections of C-3′ and C-5′ to the quaternary carbon C-4′, whereas the correlations of H-1′ with C-5′, C-6′, C-10′, and C-14′, as well as the correlations of H-14′ with C-9′ and C-1′, indicated that the exomethylene group is located at the $\Delta^{10(14)}$ position. The HMBC correlations of protons Me-12′ and Me-13′ to C-11′ and of Me-13′ to C-7′, together with the correlations of H-6′ to C-13′ and H-7′ to C-11′, indicated the connectivity of quaternary carbon C-11′ of the cyclopropane ring to the methine carbons C-6′ and C-7′.

In addition, the HMBC correlations revealed that the two parts of eugenial C are linked by a methylene bridge; the methylene protons in position 7 (δ_H 2.72 and 2.28 d) showed correlations with the carbons C-1, C-2, and C-6 of the phloroglucinol derivative and with C-3′, C-4′, and C-15′ of the aromadendrene skeleton.

The relative configuration of **3** was established on the basis of the NOESY experiments (Figure 3). The NOE correlations of Me-15′ with H-6′ and H-1′ and of H-5′ with H-7 and Me-12′ indicated that H-1′, H-6′, and Me-15′ adopted an α-configuration, whereas H-5′ and Me-12′ adopted a β-configuration, as shown in the previously reported macrocarpals.[17] In addition, the Me-13′ correlated with H-6′ and H-7′. The *trans* relationship among H-5′ and H-1′ was also deduced from the large coupling constants values of the H-5′

J. Agric. Food Chem. 2015, 63, 8151−8155

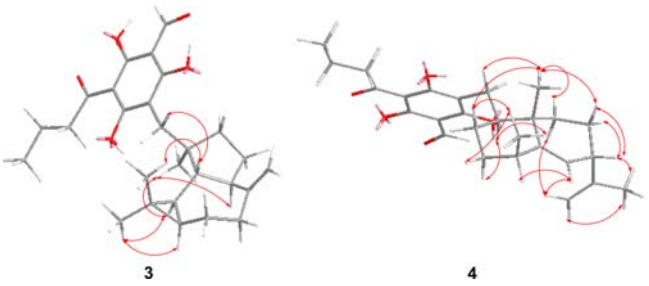

Figure 3. Selected NOESY correlations for compounds **3** and **4**.

(δ_H 1.22, dd, J = 10.5, 10.5 Hz), observed in the ^{1}H NMR spectrum. Therefore, eugenial C was assigned structure **3**.

Compound **4** was obtained in the form of a white amorphous solid (mp 162−165 °C) and exhibited a strong carbonyl bond at 1625 cm^{-1} in the IR spectrum. The molecular formula $C_{27}H_{36}O_5$ was established by HRESIMS and was found to be an isomer of **3**. Structure **4** for eugenial D was assigned on the basis of the following considerations. The EIMS spectrum showed two main fragments at m/z 237 (base peak) and at m/z 203 (95%), which may be attributed, respectively, to the phloroglucinol part ($C_{12}H_{13}O_5$) and to the sesquiterpene moiety ($C_{15}H_{23}$) by C-7/C-2′ cleavage. NMR data enriched by HMBC long-range correlations (Figure 2) are reported in Table 2, and it is evident that eugenial D maintains all of the features exhibited by eugenial C (**3**) (Table 1) for the phloroglucinol moiety, in particular, the ^{1}H NMR signals for the butyroyl chain (δ_H 1.01, 1.73, and 3.10), the aldehyde (δ_H 10.10), and chelated hydroxyls (δ_H 15.35 and 14.35). The correlations observed in HMBC spectra indicated the position of these substituents. The hydroxyl proton 6-OH (δ_H 15.35) showed HMBC correlations with C-5 and C-6 and the hydroxyl proton 4-OH (δ_H 14.35) with C-3 and C-4, whereas the hydroxyl proton 2-OH (δ_H 5.73) was correlated with C-2 and C-3. The H-8 (δ_H 10.10) showed HMBC correlations with C-3 and C-4.

With respect to the sesquiterpene part, the remaining ^{13}C NMR signals of Table 2 were attributed by DEPT and HMQC experiments to two methyls (δ_C 21.3 and 22.3), four methylenes (δ_C 22.4, 22.9, 32.8, and 34.4), three methines (δ_C 38.8, 41.3, and 49.3), and a quartenary carbon (δ_C 38.0). Signals were also present for a trisubstituted double bond (δ_C148.0 and 123.9) and an isopropylene group (δ_C 22.2, 111.6, and 147.9). On the basis of long-range connectives observed in the HMBC spectra (Figure 2) these signals may be collectively assembled in the sesquiterpene with the eudesmane skeleton depicted in structure **4**. The correlations of protons Me-15′ with C-6′ and H-5′ with C-1′, C-6′, and C-7′, as well as of H-8′ to C-6′ and C-7′, linked a trisubstituted double bond $\Delta_{6',7'}$ to C-8′. The correlations of protons Me-14′ with C-1′, C-2′, C-6′, and C-10′ allowed the connections of C-2′, C-6′, and C-10′ to the quaternary carbon C-1′. The correlations of protons Me-12′ with C-8′, C-11′, and C-13′ and of protons Me-13′ with C-12′ and C-8′ established the isopropylene group at C-8′.

Finally, the HMBC correlations of the methylene protons at position 7 (δ_H 2.65 and 2.29) with C-1, C-2, and C-6, as well as with C-1′, C-2′, and C-3′ established the two parts (sesquiterpene and phloroglucinol) of compound **4** are linked.

The relative stereochemistry for **4** was proposed from the NOESY analysis (Figure 3). The NOE correlations of Me-14′ with H-7, H-3′, H-9′, and H-10′ indicated these protons were cofacially oriented, which established Me-14′ as β-oriented. The H-2′ showed correlation with H-4′α and/or H-10′α, indicating that H-2′ was α-oriented. The NOE observed among Me-15′ and H-3′ pointed out Me-15′ as a β-configuration. The H-8′ showed NOE correlations with H-7′, Me-12′, and both H-9′α and H-9′β, which indicated that the isopropylene group at C-8′ adopted the α-axial orientation. In addition, the chemical shifts of C-8′ at δ 41.3 and H-8′ at δ 2.64 (t, J = 5.3 Hz) were in agreement with those reported for the sesquiterpene, which has an isopropylene group at C-8′ with α-axial orientation.[18] The coupling constant of H-8′ (t, J = 5.2 Hz) also was consistent with their equatorial position. Therefore, eugenial D was assigned structure **4**.

It should be emphasized that the meroterpenoids (**1**−**4**) found in *E. umbelliflora* contain, in the phloroglucinol part, both an aldehyde and a butyroyl chain, whereas the analogous compounds widely occurring in the species *Eucalyptus* contain two aldehyde substituents.

Compounds **3** and **4** isolated in the present research were tested against bacteria and yeast. The results showed that both compounds exhibited significant activity against Gram-positive bacteria, including strains of MRSA, which constitute a significant healthcare problem (Table 3).

S. aureus is a versatile and dangerous bacterial pathogen that quickly develops resistance to early antibiotics. Because methicillin is rarely used today, the term "MRSA" is now used to describe strains of *S. aureus* resistant to all β-lactam antibiotics. Therefore, the results against the staphylococci strains were very promising, with MIC values similar to that of vancomycin, which is recognized as the most effective agent for MRSA. However, the compounds were inactive when tested against Gram-negative bacteria and yeasts. This can be explained by the fact that the secondary metabolites from plants often show considerable activity against Gram-positive bacteria, but not against Gram-negative species or yeasts.[19] Both yeasts and Gram-negative bacteria have evolved significant permeability barriers.[20]

The results of antimicrobial activity corroborate the findings of Yamakoshi et al.,[16] who reported that macrocarpals B−G

presented antibacterial activity. The new compound, **3**, also presented a similar antimicrobial profile.

With regard to compounds **3** and **4**, equivalent activity to the antibiotics commonly used in anti-infection therapy was found. Due to their superior activity against *S. aureus* (MIC 3.12 μg/mL), **3** and **4** were also submitted to the test against different strains of MRSA. The results showed that the antibacterial activities of these compounds were similar to that of the standard strain of the bacteria, demonstrating their potential against MRSA (MIC = 0.39−3.12 μg/mL).

Given that nowadays MRSA is a major cause of nosocomial infections worldwide and may be related to exposure to broad-spectrum antibiotics, the discovery of a compound that can be specific to a single bacterium, as described in this study, can contribute to treatment,[21] as it minimizes interference with the host microbial flora.[22]

In conclusion, this study allowed the isolation of two previously unknown phloroglucinols from the fruits of *E. umbelliflora* that showed high antibacterial activity mainly against MRSA standardized and clinical strains, similar to that of antibiotics in clinical use.

m above sea level) were measured by use of a spectroradiometer system (DTM300, Bentham Ltd., Reading, UK) The system is operated by the German Federal Environment Agency as a member of the German Solar UV Monitoring Network, lead-managed by the German Federal Office for Radiation Protection. The duration of each single scan was 6 min,and time was given in Universal Time Coordinated (UTC) defined as Central European Summer Time (CEST) minus 2 h. Time data in the present work are all presented in UTC. The experiments were performed on July 3, 2014, soon after summer solstice with highest natural UV-B irradiance. Sky conditions were cloudless at an outdoor temperature and relative air humidity of 18.0 ± 0.9 °C and 54 ± 3%, respectively.

Experimental Design. The mushroom slices were completely separated from each other on horizontally positioned food trays. The beginning and end pieces of the sliced mushrooms were all placed with their slice plane facing the solar radiation. A temperature sensor was inserted into a representative mushroom slice to monitor the internal temperature. Immediately after their exposure period, the samples were double-sealed in polyethylene zipper bags, labeled, and repacked into EPS boxes with dry ice, which were shipped back to the University Medical Centre Freiburg. Upon receipt at the center, the boxes were stored at −26 °C until replenishment with dry ice and shipment via overnight express delivery to the Danish Technical University, Copenhagen, for the determination of dry matter and vitamin D_2 content.

Different UV-B Doses. To investigate the response of vitamin D_2 content to different UV-B doses, eight different sun exposure times were employed as follows: 0, 15, 30, 45, 60, 120, 240, and 360 min. For logistical reasons and with the aim of exposing the samples to high UV-B doses and attaining a reasonably linear increase in UV-B dose hitting the different dose−response samples (Table 1), all other exposure measurements started at 10:15 a.m. except for the 6 h samples, which started at 8:00 a.m.

Increase in Exposure Surface Area. In a further experiment, both slice sides were exposed successively for 60 min starting at 10:15 a.m., then turned over manually between 11:15 and 11:17 a.m. and exposed for another hour until 12:15 p.m.

Different Slice Thicknesses. In addition to the standard 9 mm thick slices used in the present study, the effect of the ratio of surface area exposed to the solar radiation to mass by two further slice thicknesses (6 and 9 mm) at a sun exposure time of 1 h (10:15−11:15 a.m.) was also assessed.

[a]Abbreviations: DW, dry weight; FW, fresh weight; UV-B, ultraviolet B. [b]Represents mean ± SD values (n = 4). [c]Using moisture content of each sample in the range of 91.5−92.1%. [d]Results of consecutive measurements from ANOVA with LSD post hoc test.

Vitamin D_2 Analysis of Mushroom Slices. The content of vitamin D_2 in mushrooms was quantified in freeze-dried materials by a LC-MS/MS method modified to include vitamin D_2.[17] The standards used were vitamin D_2 (ergocalciferol) (Sigma-Aldrich, Steinheim, Germany) and as internal 26,26,26,27,27,27-d_6-vitamin D_2 (d_6-vitamin D_2) (Chemaphor Inc., Ottawa, ON, Canada). In short, 0.1−0.5 g of freeze-dried mushrooms was saponified using 0.2 g of sodium ascorbate, 9 mL of ethanol, and 3 mL of potassium hydroxide at room temperature for 18 h. The cleanup procedure included liquid−liquid extraction with 10 mL of ethyl acetate in heptane and silica solid phase extraction (Isolute, IST, Hengoed, UK). For detection, vitamin D_2 was derivatized with 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD). The mass spectrometer was operated in positive MRM mode using the following transitions for vitamin D_2 (m/z 603.4 → 298.0) and d_6-vitamin D_2 (m/z 609.4 → 298.0). The validation of the LC-MS/MS method included comparison with the standardized method for vitamin D (HPLC-UV/DAD) performed accredited according to ISO17025.[16,18] For house-reference materials, freeze-dried vitamin D-enriched mushrooms, no differences were found between the LC-MS/MS (n = 5) and the standardized HPLC-UV method (n = 10), 17.0 ± 1.0 and 15.8 ± 1.0 μg vitamin D_2/g DW, respectively.

Statistical Analysis. The study was analyzed using SPSS statistics version 22 (IBM Corp., Armonk, NY, USA). Graphs were created either with SPSS or Microsoft Excel 2010 (Microsoft Corp., Redmond, WA, USA). For descriptive data analyses, values are presented as means ± standard deviations. Group comparisons were analyzed by analysis of variance (ANOVA), and the means were compared using least significant difference (LSD) post hoc test with $P < 0.05$.

RESULTS AND DISCUSSION

Mushroom Samples. In the first hour of sun exposure the internal temperature dramatically increased by 17.8 °C, starting at 10:15 a.m. from a base of 10.4 °C. Thereafter, the temperature increased almost linearly by 2.0 ± 0.7 °C per hour, with the highest temperature of 34.0 °C measured at study end for the 360 min samples.

Solar UV-B Irradiation and Effect of UV-B Doses on Vitamin D_2 Content. The daily dose of solar UV-B measured at the meteorological station Schauinsland and the window in which the various sun exposure times were employed in the present work are shown in Figure 1. The intensity of UV-B wavelengths hitting the mushrooms peaked between 11:00 a.m. and 12:00 p.m., with mean UV-B doses of 0.055 J/cm² during

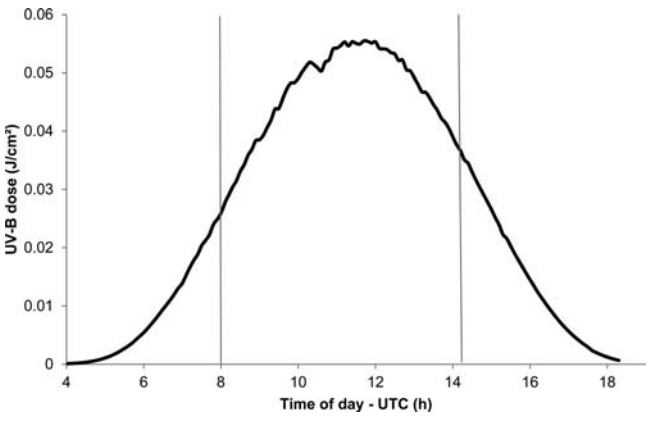

Figure 1. Daily dose of UV-B (280−315 nm), expressed in J/cm², for the 6 min duration of each scan at the meteorological station Schauinsland. The two vertical lines indicate the experimental period, starting at 8:00 a.m. and ending at 4:15 p.m. UTC.

J. Agric. Food Chem. 2015, 63, 8156−8161

each 6 min scan. At the time with the highest UV-B dose, the sun was nearest its zenith: sun rays penetrate the shortest distance through the atmosphere, and the radiant flux on a horizontal surface is at its densest. The doses of UV-B for each exposure time are shown in Table 1.

Cumulative doses of UV-B for the different sun exposure times ranged from 0.13 to 2.80 J/cm^2 (Table 1). As expected, the vitamin D_2 content of the unexposed control mushrooms was negligible (0.03 ± 0.01 μg/g DW). As little as 15 min of sun exposure leading to a UV-B dose of 0.13 J/cm^2 increased significantly the vitamin D_2 content of the mushroom slices (2.2 ± 0.5 μg/g DW; $P < 0.001$). This is equivalent to 17.6 μg of vitamin D_2 per 100 g of fresh mushroom slices exposed to solar radiation for one-fourth of an hour and could contribute 110% of the North American RDA for vitamin D (15 μg/day).[19]

With longer sun exposure times, the vitamin D_2 content increased linearly with the UV-B dose, to 0.53 J/cm^2 after 60 min when the maximum vitamin D_2 content (3.9 ± 0.8 μg/g DW) was attained. Continuing the exposure for >60 min showed no increase but rather a decrease in vitamin D_2 compared to 60 min for 9 mm mushroom slices (Figure 2).

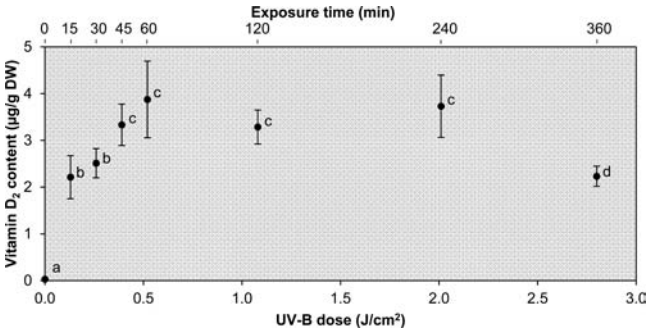

Figure 2. Relationship between vitamin D_2 content in 9 mm sliced white button mushrooms and different sun exposure times, expressed directly in measured UV-B doses. Mean values ($n = 4$) with different lower case letters are significantly different ($P < 0.05$). Error bars represent 2 standard errors. DW, dry weight.

Table 2 summarizes published data from research studies investigating the effect of sun exposure on vitamin D_2 content in harvested mushrooms. The present findings are consistent with the magnitude of vitamin D_2 yields after sun exposure in mushrooms published in two recent papers, however, without data on UV-B doses.[14,15] Simon et al. compared the compositional changes in whole button mushrooms exposed to solar radiation randomly spread on a tarp with those occurring after artificial UV exposure.[14] Sun exposure of 150 min led to a vitamin D_2 content of 27.4 μg/100 g FW, which is almost identical to the contents in the present study after 120 min (24.8 μg/100 g FW).

Phillips and Rasor evaluated the reliability of a consumer-friendly protocol to increase vitamin D_2 in sliced mushrooms by solar radiation at different durations, times of day, and seasons.[15] By choosing results from conditions comparable to those in the present study, they noted a vitamin D_2 content of 36.6 μg/100 g FW attained after 30 min of sun exposure, which was about twice the yield observed in the present study. It should be noted that their study was performed at a lower altitude (633 m), a lower latitude, 37.1° N vs 47.9° N, and hence with more natural UV-B irradiance.

Discrepant results were reported in a further study investigating the effects of solar radiation on the vitamin D_2 content of whole button mushrooms.[16] An UV-B dose of 0.2 J/cm^2 after 20 min of mid-day sun exposure produced a median vitamin D_2 content of only 1.0 μg/100 g FW. Although our study was carried out at seven degrees of lower latitude (47.9 vs 55.4° N) and at almost 1000 m higher altitude, both major factors for more natural UV-B irradiance, the UV-B dose measured by the high-performance spectroradiometer operated by a member of the German Solar UV Monitoring Network in the present study was 0.18 J/cm^2 in 20 min at noon. This may raise some doubt about the accuracy of the portable UV-B photometer used in the study by Kristensen et al.[16] Furthermore, the divergent results between the two studies might be explained by their mushrooms having been exposed to a significantly lower UV-B dose than that measured.

As mentioned above, sun exposure times within the range of 60−240 min produced a plateau in vitamin D_2 content of the mushroom slices, whereas 360 min of UV-B exposure (equivalent to 2.8 J/cm^2) triggered a significant decline in vitamin D_2 content (2.2 ± 0.2 μg/g DW; P = 0.005). These long sun exposure samples, having captured the highest UV-B dose and reached the highest internal temperature of 34.0 °C, had vitamin D_2 contents similar to those in the 15 min samples. In previous dose−response studies with artificial UV exposure of different mushroom species on vitamin D_2 content and various experimental designs, some researchers did find a plateau,[10,13,16,20,21] whereas others described continuous increases in vitamin D_2 with exposure time.[1,8,11,22,23] The sole significant decrease in vitamin D_2 after intensive UV irradiation was found after the artificial irradiation of mushroom powder.[13] All took place under laboratory conditions; moreover, the durations of artificial UV exposure were much shorter than ours, lasting seconds or from several minutes to a maximum of 2 h. It is worth mentioning that the vitamin D_2 contents achieved with artificial UV light were often >10 times higher than in the present study using solar radiation during the drying process.[10,22−25]

Several possible explanatory models are described in the literature for the significant decline of vitamin D_2 after an extended sun exposure period observed in the present study (Figure 2). Provitamin D_2 (ergosterol), its main photoisomer previtamin D_2, and the two major photoisomers of previtamin D_2, lumisterol$_2$ (ring closure) and tachysterol$_2$ (E/Z-isomerization), absorb in the same UV region and, once excited, they can all interconvert by photoisomerizations. Previtamin D_2 can also be isomerized to vitamin D_2 via a thermal reaction.[2,3,26] The ratio of photoisomers at the stationary state is influenced by the irradiation wavelength, with longer wavelengths (>305 nm) favoring the formation of the ring-closed isomers provitamin D and lumisterol.[27] Additionally, prolonged irradiation periods produce irreversible "over-irradiation products" by dimerization and ring cleavage of previtamin D_2 and tachysterol.[28] Furthermore, longer wavelengths of UV-A are able to break down vitamin D.[29] A relevant difference from the studies with artificial UV exposure is the high ratio of UV-A to UV-B in the solar spectrum. During all measurements the energy hitting the mushroom slices in the form of UV-A (315−400 nm) was 41 ± 4 times higher than that of UV-B. UV-B is only a very small part of the total solar UV irradiance on the Earth's surface. A limitation of the present study consists of not having analyzed the samples for ergosterol and some further photoisomerization byproducts.

Sun exposure for only 15 min, which is similar to an UV-B dose of 0.13 J/cm^2, produced a content of vitamin D_2 in sliced button mushrooms at a comparable level to vitamin D_3 levels found in fatty fish suc as Atlantic salmon−the often quoted richest food source of vitamin D.[30]

Effects of Modifying the Exposure Surface Area. By exposing either both slice sides of the mushrooms or slices with different thicknesses to the solar radiation, we investigated the effect of the ratio of the mushrooms' exposed surface area to its mass on vitamin D_2 content (Figures 3 and 4).

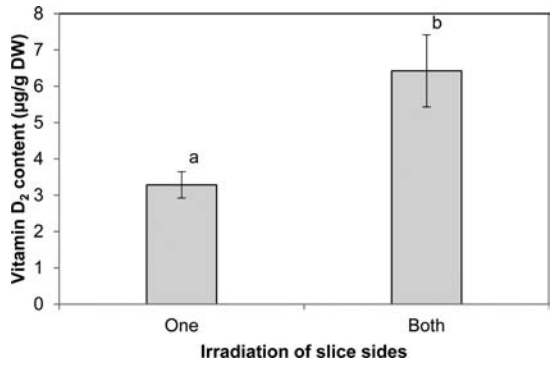

Figure 3. UV-B dose during sun exposure was 1.08 J/cm^2 after 120 min. Samples exposed on both sides were irradiated in the two 60 min periods with 0.53 and 0.55 J/cm^2, respectively. Mean values (n = 4) with different lower case letters are significantly different (P < 0.01). Error bars represent 2 standard errors. Vitamin D_2 content in μg/g DW: one side, 3.3 ± 0.4; both sides, 6.4 ± 1.0.

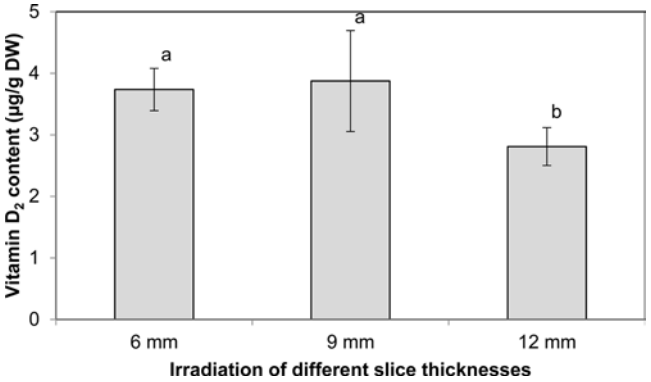

Figure 4. Vitamin D_2 content of different mushroom slice thicknesses after solar irradiation for 60 min with an UV-B dose of 0.53 J/cm^2. Mean values (n = 4) with different lower case letters are significantly different (P < 0.05). Error bars represent 2 standard errors. Vitamin D_2 content in μg/g DW: 6 mm, 3.5 ± 0.3; 9 mm, 3.9 ± 0.8; 12 mm, 2.8 ± 0.3.

After 120 min of sun exposure, the sliced mushroom samples that were turned around and exposed from both sides contained the highest vitamin D_2 of the present study and virtually twice as much as the samples exposed to the total UV-B dose of 1.08 J/cm^2 on only one side (6.4 ± 1.0 vs 3.3 ± 0.4 μg/g DW; P = 0.005).

The highest ratio of exposure area to mass did not lead to higher vitamin D_2 contents than the 9 mm slices. However, the thickest samples (12 mm) contained significantly less vitamin D_2 compared to the 9 mm slices (2.8 ± 0.3 vs 3.9 ± 0.8 μg/g DW; P = 0.05).

DOI: 10.1021/acs.jafc.5b02945
J. Agric. Food Chem. 2015, 63, 8156−8161

The present findings are consistent with data from studies that demonstrated a significantly higher yield of vitamin D_2 in sliced compared to whole mushrooms[20] and data on artificial UV-B exposure of mushroom powder with extremely high yields in vitamin D_2 content (498 μg/g DW),[13] showing the essentiality of the ratio of exposure area to mass.

Sun-Drying. Although the sun-drying process was already well advanced with a water loss of 84% relative to the initial total water content during the longest exposure period (360 min), still the drying process was not completed. The sun-triggered dehydration in the 360 min samples reached a mean water loss of 14% per hour relative to the initial weight. Approximately a minimum of an extra hour of sun exposure would have produced a final moisture content at the recommended level of 4−8% for safe storage.[31]

We found a substantial linear increase up to 1 h of exposure, showing the highest content of 31 μg/100 g FW produced by a UV-B dose of 0.53 J/cm^2. After sun exposure for only 15 min, similar to an UV-B dose of 0.13 J/cm^2, the vitamin D_2 content of sliced button mushrooms was comparable to vitamin D_3 levels found in salmon. This is particularly interesting for vegetarians, because all other dietary sources of vitamin D are of animal origin. In conclusion, the traditional and still practiced method of mushroom dehydration consisting of slicing, sun-drying, and, if needed, final indoor drying, can lead to an underappreciated, unexploited vitamin D-rich food source.

AUTHOR INFORMATION

*(P.U.) Phone: +49-761-2703360. Fax: +49-761-2703334. E-mail: paul.urbain@uniklinik-freiburg.de.

Author Contributions

P.U., study concept, study performance, and statistical analysis; J.J., analytics, critical review; all authors interpreted the data, drafted the manuscript, and saw and approved the final version of the manuscript.

Funding

This project has received funding from the European Union's Seventh Framework Programme (FP7/2007−2013) under Grant Agreement 613977 (ODIN).

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We are grateful to K. Cashman for his critical review, to C. Cuerten for editorial assistance, to J. Valverde from Monaghan Mushrooms Ireland for providing the button mushrooms, to I. Mayer and F. Meinhardt form the German Federal Office for Radiation Protection for receiving real-time UV-B data, to E. Maier, F. Jaeger, and F. Lorenz from University Medical Center's central kitchen for providing material for the experiments and storage of samples, and to K. Saliger and H. Urbain for helping out with sample preparation and experiments.

ABBREVIATIONS USED

EPS, expanded polystyrene; FW, fresh weight; DW, dry weight; LC-MS/MS, liquid chromatography−tandem mass spectrometry; RDA, recommended daily allowance; SEP, solid phase extraction; UTC, Universal Time Coordinated; UV, ultraviolet; UV/DAD, ultraviolet diode array detection

(Lifescan, Inc., Milpitas, CA). Mice with fasting blood glucose levels of ≥16.0 mmol/L were classified as diabetic mice.

General Experimental Procedures. Melting points were determined on an X-4 digital display micromelting point apparatus and are uncorrected. Optical rotations ($[\alpha]_D^{25}$) were measured on a PerkinElmer 341 polarimeter. Infrared (IR) spectra were obtained using a Thermo Nicolet 6700 FTIR spectrometer. Ultraviolet (UV) spectra were recorded on a PerkinElmer Lambda 25 Shimadzu 160 UV/vis spectrometer. The high-resolution electrospray ionization mass spectrometry (HRESIMS) spectra were recorded on an Agilent 6210 series LC/MSD TOF from Agilent Technologies. Nuclear magnetic resonance (NMR) spectra were acquired on a Bruker AVANCE HD III-400 using tetramethylsilane (TMS) as an internal standard. The X-ray diffraction data were collected on a SuperNova, Dual, Eos diffractometer. The structure was solved with the Superflip program using charge flipping and refined with the ShelXL program (using graphite-monochromated Mo Kα radiation). Silica gel (200−300 mesh, Qingdao Marine Chemical Factory, China), macroreticular resin (D-101, Sinopharm Chemical Reagent Co., Ltd., Shanghai, China), Sephadex LH-20 gel (GE Healthcare, Uppsala, Sweden), and MCI gel (CHP20P, 75−150 μm, Mitsubishi Chemical Industries, Ltd., Tokyo, Japan) were used for column chromatography (CC). Preparative high-performance liquid chromatography (HPLC) was carried out on a Shimadzu LC-6AD instrument with a SPD-20A detector, using a YMC-Pack ODS-A column (250 × 20 mm, 5 μm). Thin-layer chromatography (TLC) was performed using Merck precoated plates (Si gel 60 F254, Germany) of 0.25 mm thickness. The spots on TLC were detected with 254 and 365 nm UV light and visualized by spraying with 98% H_2SO_4/C_2H_5OH (5:95, v/v), followed by heating. The absorbances in the enzymatic assay were determined at 405 nm using a Bio-Rad model 680 microplate reader.

Extraction and Isolation. The dried powder of the flower of *E. gardneri* (12.0 kg) was extracted 3 times with MeOH (40 L) for 7 days each at room temperature. The combined extracts were concentrated under reduced pressure, and the residue (862 g) was partitioned into H_2O and extracted with petroleum ether, EtOAc, and *n*-BuOH, successively.

The EtOAc fraction (118 g) was subjected to CC over silica gel (petroleum ether/EtOAc, 40:1, 30:1, 20:1, 15:1, 10:1, 8:1, 5:1, 3:1, 1.5:1, 1:1, and 0:1, v/v) to give nine major fractions (A−I). Fraction A (1.2 g) was chromatographed over MCI (MeOH/H_2O, 9:1) to yield two fractions, A1 and A2. Fraction A2 (231 mg) was subjected to Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to yield compound **6** (22 mg). Fraction B (2 g) was purified by CC over MCI (MeOH/H_2O, 9:1) to yield two major fractions, B1 and B2. Fraction B1 (506 mg) was run again by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to obtain compounds **7** (16 mg), **8** (31 mg), and **9** (27 mg). Fraction B2 (700 mg) was also run again by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to obtain compound **10** (123 mg). Fraction C (1.1 g) was purified by CC over MCI (MeOH/H_2O, 9:1) to yield one fraction C1, and fraction C1 (638 mg) was separated by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to obtain compounds **1** (14 mg), **11** (56 mg), and **12** (21 mg). Fraction E (1.1 g) was purified by CC over MCI (MeOH/H_2O, 9:1) to yield one fraction E1, and fraction E1 was recrystallized from methanol to yield compound **3** (34 mg). Fraction G (1.6 g) was applied to MCI (MeOH/H_2O, 9:1) to give three major fractions (G1−G3). Fraction G1 (300 mg) was subjected to CC over Sephadex LH-20, eluted with MeOH/H_2O (1:1), and finally purified by prep-HPLC (MeOH/H_2O, 4:6) to yield compound **13** (11 mg). Fraction H (1.8 g) was subjected to CC over MCI (MeOH/H_2O, 9:1) to yield three fractions, H1−H3. Fraction H1 (1.5 g) was subjected to CC over Sephadex LH-20, eluted with MeOH/H_2O (1:1) and then purified by prep-HPLC (MeOH/H_2O, 4:6) to yield compound **14** (30 mg). Fraction I (82 g) was chromatographed over MCI (MeOH/H_2O, 9:1) to yield three fractions, I1−I3. Fraction I1 (61 g) was recrystallized from methanol to yield compound **5** (53 g) and a mother liquor (3.6 g). The mother liquor was subjected to CC over silica gel ($CHCl_3$/MeOH, 10:1, 5:1, 3:1, and 0:1) to yield two subfractions, I1.1 and I1.2. Fraction I1.2 (1.4 g) was purified by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to yield compound **15** (18 mg). Fraction I2 (2.3 g) was subjected to CC over Sephadex LH-20 (MeOH/H_2O, 1:1) to yield two subfractions, I2.1 and I2.2. Fraction I2.2 (1.4 g) was purified by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to yield compound **16** (45 mg).

The *n*-BuOH fraction (118 g) was subjected to CC over D-101 macroreticular resin with a H_2O/EtOH gradient (1:0, 8:1, 5:1, 3:1, 1.5:1, 1:1, and 0:1) to yield four major fractions (1−4). Fraction 2 was subjected to CC over silica gel ($CHCl_3$/MeOH, 4:1, 3:1, 2:1, and 0:1) to yield two fractions, 2.1 and 2.2. Fraction 2.2 (2.6 g) was purified by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to obtain compounds **17** (19 mg) and **18** (31 mg). Fraction 3 (42 g) was evaluated by TLC and compared to flavonoid standards, including standards for compounds **5**, **10**, **11**, **15**, and **16**, and the spots were visualized by spraying them with a

5% H_2SO_4/EtOH solution, followed by heating. The TLC results showed that the spots displayed by fraction 3 were similar to those of flavonoids (compounds **5**, **15**, and **16**). Moreover, the content of compound **5** was the highest in this fraction. Fraction 3 (14 g) was subjected to CC over silica gel ($CHCl_3$/MeOH, 4:1, 3:1, 2:1, and 0:1) to yield three fractions, 3.1−3.3. Fraction 3.1 (2.6 g) was purified by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to obtain two subfractions, 3.1.1 and 3.1.2. Fraction 3.1.2 (827 mg) was run again by CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to obtain compounds **17** (19 mg) and **18** (31 mg). Fraction 3.2 (3.1 g) was applied to CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to yield two subfractions, 3.2.1 and 3.2.2. Fraction 3.2.1 (216 mg) was purified by prep-HPLC (MeOH/H_2O, 3:7) to yield compound **4** (22 mg). Fraction 3.2.2 (3.1 g) was chromatographed over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to yield crude **19** (34 mg) and **20** (11 mg), and then they were separately recrystallized from MeOH. Fraction 3.3 (2.9 g) was subjected to CC over Sephadex LH-20 ($CHCl_3$/MeOH, 1:1) to obtain crude **2** (41 mg) and compound **21** (8 mg), and then compound **2** was recrystallized from MeOH.

Structural Elucidation of New Products. Gardnerol A (**1**): colorless crystals (MeOH); melting point (mp), 191−192 °C; IR (KBr) ν_{max}, 3228, 1693, 1589, 1513, 1433, 1031, 836, 792, 456 cm^{-1}; UV (MeOH) λ_{max} (log ε), 208 (4.40), 212 (4.41), 285 (3.90), 322 (4.12) nm; ^{1}H (DMSO-d_6 and methanol-d_4, 400 MHz) and ^{13}C NMR (DMSO-d_6 and methanol-d_4, 100 MHz) data, see Table 1; HRESIMS m/z, 357.0970 $[M + H]^+$ (calcd for $C_{19}H_{17}O_7$, 357.0969).

Gardnerol B (**2**): with powder ($CHCl_3$−MeOH); $[\alpha]_D^{25}$, −10.5 (c 0.38, MeOH); IR (KBr) ν_{max}, 3407, 3078, 2923, 1743, 1721, 1611, 839, 723 cm^{-1}; UV (MeOH) λ_{max} (log ε), 214 (4.26), 252 (3.62), 286 (3.93), 308 (3.98) nm; ^{1}H (DMSO-d_6 and methanol-d_4, 400 MHz) and ^{13}C NMR (DMSO-d_6 and methanol-d_4, 100 MHz) data, see Table 2; HRESIMS m/z, 343.0811 $[M + H]^+$ (calcd for $C_{18}H_{15}O_7$, 343.0812).

X-ray Analysis. The measurement was collected on a SuperNova, Dual, Eos diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). The structure of compound **1** was solved by direct method (SHELXS-2008).

Crystal Data for Compound 1. Gardnerol A (**1**) was crystallized from $CHCl_3$/ CH_3OH (1:1) to give colorless crystals. A single crystal of dimensions 0.35 × 0.31 × 0.24 mm^3 was used for X-ray measurements. Crystal data: $C_{19}H_{16}O_7$, space group P 1 $2_1/c$ 1, a = 14.7352(17) Å, b = 8.7127(9) Å, c = 14.2158(12) Å, α = 90.00°, β = 114.431(12)°, γ = 90.00°, V = 1661.6(3) $Å^3$, Z = 4, D_{calc} = 1.424 g/cm^3, R_1 = 0.0713, and wR_2 = 0.2056.

The supplementary crystallographic data for compound **1** reported in this paper has been deposited at the Cambridge Crystallographic Data Centre, under the reference number CCDC 1403668. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K., fax: +44-1223-336033 or e-mail: data_request@ccdc.cam.ac.uk.

α-Glucosidase Inhibition. The α-glucosidase inhibition was assessed according to the slightly modified method of Jeon et al.[19] The α-glucosidase (0.1 unit/mL) and substrate (*p*-NPG, 1.0 mM) were dissolved in potassium phosphate buffer (0.1 M, pH 6.7), and all samples were dissolved in DMSO. The inhibitor (10 μL) was preincubated with α-glucosidase (40 μL) at 37 °C for 10 min, and then the substrate (50 μL) was added to the reaction mixture. The enzymatic reaction was performed at 37 °C for 30 min. The reaction was then terminated by the addition of Na_2CO_3 (1 M, 100 μL). All samples were analyzed in triplicate with five different concentrations near the IC_{50} values, and the absorbance at 405 nm was determined using a microplate reader. The inhibition percentage (%) was calculated by the following equation:

$$\text{inhibition (\%)} = [(OD_{control} - OD_{control\ blank}) - (OD_{sample} - OD_{sample\ blank}) / (OD_{control} - OD_{control\ blank})] \times 100$$

Type of α-Glucosidase Inhibition. The mode of inhibition of α-glucosidase was investigated with increasing concentrations of substrate (4-nitrophenyl α-D-glucopyranoside) and compound **5**. Then, the inhibition type was determined by a Lineweaver−Burk plot according to Michaelis−Menten kinetics. Origin (version 8.0) software was used for plotting the results.

Oral Sucrose Tolerance Test (OSTT). The fasting normal and STZ-induced diabetic mice were orally administered with compound **5** (150 and 300 mg/kg of body weight), acarbose (5 mg/kg), or the

DOI: 10.1021/acs.jafc.5b03081

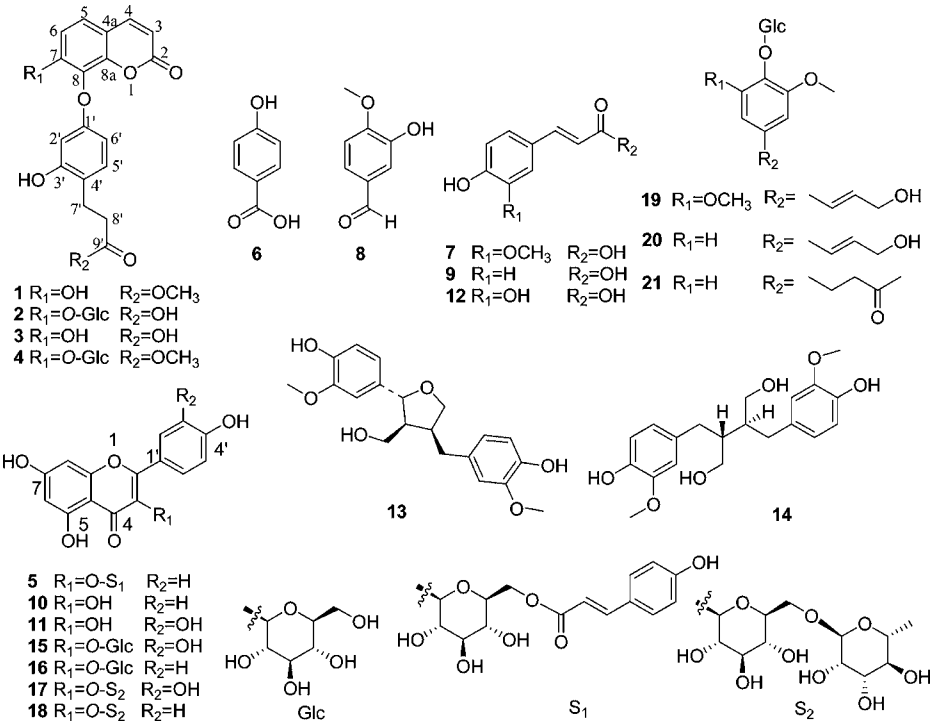

Figure 1. Structures of compounds **1**−**21**.

control and, after 30 min, were given a sucrose solution (3 g/kg of body weight). Each group has six mice. Compound **5** and acarbose were suspended in 0.5% sodium carboxymethyl cellulose (CMC−Na). The control mice were administered with the same volume of 0.5% CMC−Na solution. The tail vein glucose concentrations were measured with a glucometer at 0, 0.5, 1.0, 1.5, 2.0, and 3.0 h after the sucrose load.

Hypoglycemic Activity Assay. The fasting normal and STZ-induced diabetic mice (n = 6 for each group) were orally administered with compound **5** (150 and 300 mg/kg of body weight), glibenclamide (10 mg/kg), or the control (0.5% CMC−Na). The tail vein glucose concentrations were measured with a glucometer at 0, 1.5, 3, 5, 7, and 9 h after administration.

Statistical Analysis. The data were expressed as the mean ± standard error of the mean (SEM) and were analyzed using SPSS (version 19.0) statistical software (SPSS, Chicago, IL). The statistical significance of the differences ($p < 0.05$) between the mean values of the treatment and control groups were obtained from a one-way analysis of variance (ANOVA) followed by Tukey's or Dunnett's test.

RESULTS AND DISCUSSION

Isolation of Compounds from the Flower of *E. gardneri*. The extract was subjected to repeated CC over silica gel, Sephadex LH-20, and octadecyl silica (ODS) to yield 21 compounds (Figure 1). Compounds **1** and **2** were identified as new compounds. The 19 known compounds were identified as edgeworic acid (**3**),[20] 8-(3-(2,4-benzenediol)-propionic acid methyl ester)-coumarin-7-β-D-glucoside (**4**), tiliroside (**5**), 4-hydroxybenzoic acid (**6**), ferulic acid (**7**), 4-hydroxybenzaldehyde (**8**), *trans-p*-hydroxycinnamic acid (**9**), kaempferol (**10**), quercetin (**11**), caffeic acid (**12**), (+)-lariciresinol (**13**), (−)-secoisolariciresinol (**14**), isoquercetin (**15**), kaempferol-3-*O*-β-D-glucoside (**16**), rutin (**17**), kaempferol-3-rutinoside (**18**), syringin (**19**), coniferin (**20**), and zingerone 4-*O*-β-D-glucopyranoside (**21**).

Structure Elucidation of the Two New Compounds. Gardnerol A (**1**) was obtained as colorless crystals after crystallization from $CHCl_3$−CH_3OH. The molecular formula of compound **1** was established as $C_{19}H_{16}O_7$ from the $[M + H]^+$ ion at m/z 357.0907 (calcd. for $C_{19}H_{17}O_7$, 357.0967) in the HRESIMS. The IR spectrum exhibited strong absorption bands at 3228 cm^{-1} (OH), 1693 cm^{-1} (conjugated ester C═O), and 1619, 1582, and 1513 cm^{-1} (aromatic, C═C). The UV spectrum of compound **1** showed the characteristic maxima of a coumarin structure at 231, 252, and 325 nm. The ^1H NMR spectrum exhibited the typical signals in the aromatic region associated with H-3 at δ_H 6.18 (d, J = 9.6 Hz), H-4 at δ_H 7.88 (d, J = 9.6 Hz), H-5 at 7.37 (d, J = 8.8 Hz), and H-6 at δ_H 6.95 (d, J = 8.8 Hz, H-6) of a 7,8-disubstituted coumarin. The heteronuclear multiple-bond correlation (HMBC) correlations from the hydroxy proton at δ_H 10.63 to C-6, C-7, and C-8 confirmed that the hydroxy group was connected to C-7 (Figure 2). Additionally, the aromatic region of the ^1H NMR spectrum clearly showed the presence of an ABX spin system [δ_H 6.35 (d, J = 2.0 Hz, H-2′), δ_H 6.93 (d, J = 8.4 Hz, H-5′), and δ_H 6.27 (dd, J = 8.4, 2.0 Hz, H-6′)], indicative of a tri-substituted aromatic ring, which was confirmed by proton-coupling patterns and ^1H−^1H correlation spectros-

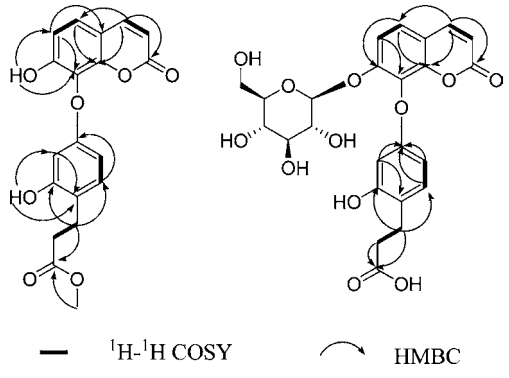

Figure 2. Key ^1H−^1H COSY and HMBC correlations for compounds **1** and **2**.

DOI: 10.1021/acs.jafc.5b03081
J. Agric. Food Chem. 2015, 63, 8162−8169

copy (COSY) correlations (Figure 2). The HMBC correlations of the hydroxy proton at δ_H 9.37 with C-2′, C-3′, and C-4′ supported the assignment that the hydroxy was attached to C-3′. In addition, one singlet at δ_H 3.52 (3H, s, $-COOCH_3$) and two mutually coupled triplets at δ_H 2.66 (2H, t, J = 8.0 Hz, H-7′) and δ_H 2.46 (2H, t, J = 8.0 Hz, H-8′) evidenced the presence of a methyl propionate side chain. The location of this side chain at C-4′ was determined on the basis of cross-peaks from H-7′ to C-3′, C-4′, and C-5′ and from H-4′ to C-7′ in the HMBC spectrum. The linkage of C-1′ to C-8 by one atom of oxygen was deduced from the above-mentioned reasoning and the molecular weight. Thus, the structure of compound **1** was defined as methyl 3-(2-hydroxy-4-*O*-(7-hydroxycoumarinyl)phenyl)propanoate. An X-ray diffraction analysis corroborated this proposed structure (Figure 3).

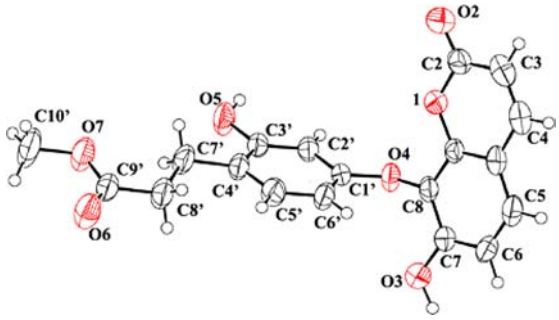

Figure 3. X-ray structure of compound **1**.

Gardnerol B (**2**) was obtained as a white powder. The HRMS data of compound **2** showed a molecular ion at m/z 527.1173 $[M + Na]^+$ (calcd. 527.1160), which was 162 mass units (i.e., $C_6H_{10}O_5$) more than that of compound **3** (m/z 343.0811, $[M + H]^+$). Correspondingly, the ^1H and ^{13}C NMR data of compound **2** were similar to those of compound **3**, except for the presence of an additional glucopyranosyl moiety.[20] The observation of the anomeric proton signal at δ_H 5.09 as a doublet with a coupling constant of 7.6 Hz indicated the presence of the β-glucopyranosyl moiety. The HMBC correlation between the anomeric proton (H-1‴, δ_H 5.09) and C-7 (δ_C 154.7) indicated that the β-glucopyranosyl moiety was attached to C-7 (Figure 2). Furthermore, to confirm the structure of compound **2**, compound **2** was hydrolyzed under acidic conditions. The sugar residue of compound **2** was identified as D-(+)-glucose by TLC comparison to an authentic sample and by its optical rotation value (see the Supporting Information). On the basis of the above analyses, the structure of compound **2** was identified as edgeworic acid-7-*O*-β-D-glucoside.

α-Glucosidase Inhibition. The IC_{50} values of compounds **1**−**21** and extracts from the flower of *E. gardneri* are shown in Table 3. In accordance with the previous report, the flower extract exhibited a significant inhibitory activity with an IC_{50} value of 267 μg/mL. Among these compounds, compound **11** was the most active, with an IC_{50} value of 5.1 μg/mL. Additionally, compound **10** showed a potent inhibitory activity with an IC_{50} value of 56.2 μg/mL. Compound **5**, the most abundant compound in the extract, showed a moderate activity, with an IC_{50} value of 202 μg/mL. Compounds **8**, **12**−**13**, and **16**−**18** also showed moderate activities with IC_{50} values of 486, 957, 279, 179, 272, and 253 μg/mL, respectively. Unfortunately, compounds **2**, **3**, **7**, **14**, and **19**−**21** showed no activities at the maximum concentration tested (3000 μg/mL). Previous

literature reported that flavonoids with 7, 3, 3′, and 4′ hydroxy groups showed significant α-glucosidase inhibitory activity.[21] Our results revealed that the 3′ hydroxy groups are responsible for increased activity because compounds **10** and **11**, with a 3′ hydroxy group, were more active than compounds **5** and **15**−**18**, without a 3′ hydroxy group. Compounds **2** and **3** showed significantly less activity than compounds **1** and **4**. This result suggests that the methyl ester group has an impact on the inhibitory activity. When compound **4** was compared to compound **1**, the inhibitory activity was reduced because of the absence of the hydroxy groups at the C-5 position.

Types of α-Glucosidase Inhibition. To clarify the α-glucosidase inhibition mode of compound **5**, which was the most abundant compound in the extract, Lineweaver−Burk plots were generated (Figure 4).[22] As shown in Figure 4, the value of the vertical axis intercept ($1/V_{max}$) remained unchanged with the increase of the concentrations of compound **5**, indicating that compound **5** was a competitive inhibitor. According to Michaelis−Menten kinetics, the value of the inhibition constant (K_i) is 0.473 mM.

Antihyperglycemic Effects of Compound 5 on Oral Sucrose Tolerance in Normal and STZ-Induced Diabetic Mice. The OSTT is usually performed to evaluate the efficacy of a drug in inhibiting intestinal α-glucosidase *in vivo*.[23] Compound **5** was a major constituent of the extract of *E. gardneri*, and 53 g of compound **5** were obtained from the extract. In addition, compound **5** showed significant α-glucosidase inhibitory activity *in vitro*. Thus, compound **5** was evaluated for its antihyperglycemic effects using an OSTT in both normal and STZ-induced diabetic mice. In comparison to the vehicle, the oral administration of compound **5** at a dose of 300 mg/kg significantly ($p < 0.05$) reduced the postprandial blood glucose level of normal mice (Figure 5A). The antihyperglycemic effect was observed at 30, 60, and 90 min after sucrose loading and was compared to that of acarbose (5 mg/kg). In contrast, the 150 mg/kg dose did not show a significant decrease in glycemia throughout the experiment. The OSTT was repeated in STZ-induced diabetic mice. These results were similar to those for normal mice (Figure 5B). According to the results of the OSTT, compound **5** inhibited the activity of intestinal α-glucosidase.

Hypoglycemic Effect of Compound 5 on Normal and STZ-Induced Diabetic Mice. According to previous methods,[24,25] the hypoglycemic activity of compound **5** was evaluated in both normal and STZ-induced diabetic mice. As shown in

J. Agric. Food Chem. 2015, 63, 8162−8169

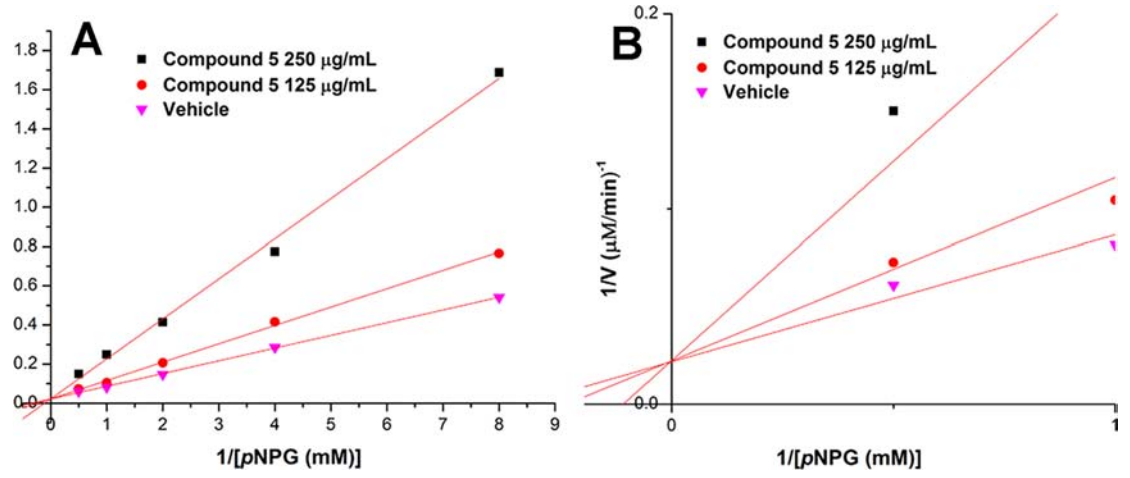

Figure 4. (A) Lineweaver−Burk plots of the reaction of α-glucosidase at different concentrations of substrate and compound **5**. (B) Partially enlarged view of panel A.

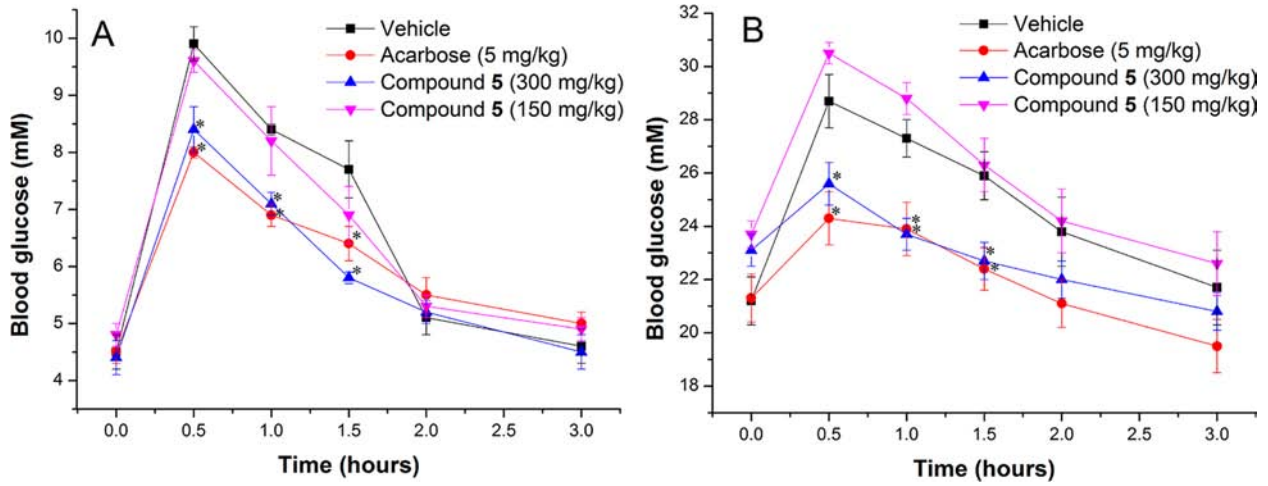

Figure 5. Effects of compound **5** on blood glucose levels in (A) normal and (B) STZ-induced diabetic mice using the OSTT. Data are the means ± SEM for six mice in each group. (∗) $p < 0.05$ by one-way ANOVA with a post-hoc test compared to the control.

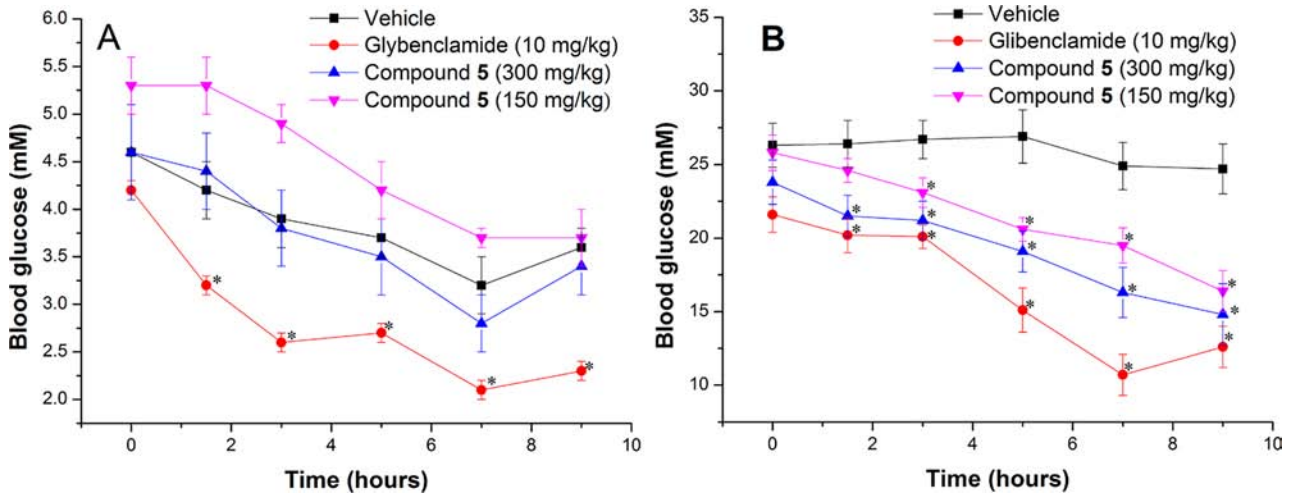

Figure 6. Hypoglycemic effect of compound **5** on (A) normal and (B) STZ-induced diabetic mice. Data are the means ± SEM for six mice in each group. (∗) $p < 0.05$ by one-way ANOVA with a post-hoc test compared to the control.

Figure 6, compound **5**, which had decreased fasting glucose levels in STZ-induced diabetic mice, did not lower the fasting glucose levels in normal mice. In diabetic mice, the oral administration of compound **5** at 150 and 300 mg/kg at both doses significantly decreased the fasting glucose levels when compared to the vehicle-treated groups ($p < 0.05$). The dose at 300 mg/kg

DOI: 10.1021/acs.jafc.5b03081
J. Agric. Food Chem. 2015, 63, 8162−8169

resulted in a significant decrease in the glucose level at 1.5 h (−9.7%), 3 h (−10.9%), 5 h (−18.5%), 7 h (−31.5%), and 9 h (−37.8%). After an administration of 150 mg/kg of compound **5**, the glucose level decreased by 4.7% at 1.5 h, 10.5% at 3 h, 20.2% at 5 h, 24.4% at 7 h, and 36.4% at 9 h. Because compound **5** displayed a hypoglycemic effect in diabetic mice but not in normal mice, in contrast with glibenclamide, these results indicate that compound **5** may not act directly via insulin liberation. Previous studies suggested that kaempferol, the hydrolysis products of compound **5**, improved the chronic hyperglycemia-impaired pancreatic β-cell viability and insulin-secretory function.[26] Therefore, the hypoglycemic action of compound **5** probably involves the protection of pancreatic β-cell survival and function. Further studies are necessary to demonstrate the mechanisms by which compound **5** decreased the fasting glucose levels in STZ-induced diabetic mice.

In summary, two new phenolics, along with 19 known phenolics, were isolated from the flower of *E. gardneri*. Their inhibitory activity against α-glucosidase from *S. cerevisiae* was evaluated, and the data showed that the flower of *E. gardneri* is a rich source of natural α-glucosidase inhibitors. Compound **5**, the most abundant compound in the extract, showed a significant α-glucosidase inhibitory activity and acted as a competitive inhibitor of α-glucosidase. Furthermore, compound **5** is effective *in vivo* for reducing the fasting and postprandial blood glucose levels in STZ-induced diabetic mice. In conclusion, the present study complements the current knowledge about the chemical composition and antihyperglycemic activity of the flower of *E. gardneri*, and it provides scientific evidence to substantiate the use of this flower for traditional therapeutic and dietary uses.

F-127 were purchased from Biotium Inc. (Hayward, CA, USA). HPLC-grade acetonitrile was purchased from Fisher Chemical (Bridgewater, NJ, USA), and HPLC-grade water was prepared using a Milli-Q system (Millipore Ibérica, Madrid, Spain). Trifluoroacetic acid (TFA) of HPLC grade was purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other chemicals employed were of analytical reagent grade, and the water used was double-deionized.

Preparation of Desalted Duck Egg White Peptides (DPs). DPs with molecular weight of <5 kDa were prepared from salted duck egg white as described in our previous work.[13] Salted duck egg white was desalted by electrodialysis equipment, and then the desalted duck egg white was denatured for 30 min in boiling water and cooled to 50 °C. The pH was adjusted to 6.5 prior to the addition of protamex (E:S = 1:25) and maintained at 6.5. After 3.5 h, the hydrolyzed solution was bathed in boiling water for 10 min to inactivate the enzyme. Finally, the mixture was centrifuged at 3000*g* for 10 min, and the supernatant was filtered through a hollow fiber membrane with a molecular weight cutoff of 5 kDa (PLCC, Millipore, Billerica, MA, USA). The filtrate was lyophilized and thereafter referred to as DPs.

Establishment of Caco-2 Cell Monolayers. The Caco-2 cells were used as a model of the intestinal epithelium, and this cell line was purchased from the Cell Bank of Chinese Academy of Sciences (Shanghai, China). The cells were routinely grown in 75 cm^2 plastic flasks (Greiner Bio-One GmbH, Germany) in MEM medium (GIBCO) with 15% fetal bovine serum, supplemented with 1% nonessential amino acids (GIBCO) in the presence of 100 u/mL streptomycin and 100 u/mL penicillin. The cells were then incubated at 37 °C with 5% CO_2. Cell passage numbers of 30−50 were used in this experiment. The culture medium was changed every 2 days until the flasks reached 90% confluence. Cell viability was assessed by the MTT test, and cell morphology was examined through an optical microscope.

At 90% confluence, the Caco-2 cells were detached with trypsin−EDTA treatment (final concentration of 0.005 g/L), followed by seeding of the cells on 12-well millicell cell culture inserts (0.4 μm pore size, 12 mm diameter, Millipore Corp., Billerica, MA, USA) with a cell density of 1.2×10^5 cells/mL and 21 days of incubation. The volume of culture medium was 1.95 mL in the basolateral side and 0.4 mL in the apical side. Transepithelial electric resistance (TEER) values were checked every 2 days by using a Millicell-ERS system (Millipore) to evaluate the tight junction permeability of the Caco-2 cell monolayers.

Calcium Transport Studies. Caco-2 cell monolayers with TEERs exceeding 500 $\Omega \cdot cm^{-2}$ were used for the calcium transport experiments. The monolayers were set in a 12-well plate and washed twice with warm (37 °C) balanced salt solution without calcium and magnesium (HBS) (125 mM NaCl, 4 mM KCl, 4 mM L-Glu, 10 mM glucose, 30 mM HEPES, adjusted to pH 7.4) and incubated at 37 °C for 20 min. The wells were then transferred to a new cluster plate containing 1.95 mL of HBS buffer. Different concentrations of calcium solution (0−20 mM, 0.4 mL) were added to the apical side of the inset, and the calcium transport rates across Caco-2 cell monolayers were measured every hour for 3 h. After the optimum conditions were determined, DPs of different concentrations (0−8 mg/mL) were added to the apical side with the optimum calcium solution. After incubation, samples were collected from the basolateral side for further analysis. The TEERs were monitored before and after the addition of the calcium and DP samples. The calcium contents were measured with an atomic absorption spectrophotometer (AA6300C, Shimadzu, Kyoto, Japan).

Measurement of Ca^{2+} in Caco-2 Cell Population Model. At 90% confluence, the Caco-2 cells were detached with trypsin−EDTA treatment and then washed several times with HBS. About 4×10^6 cells were loaded in HBS with 5 μmol/L Fluo-3/AM and 2.5 μmol/L Pluronic F-127 for 30 min at 37 °C. The loaded cell suspension was rinsed thoroughly two times with calcium-free HBS and then divided into eight portions, each containing 0.5×10^6 cells. Each aliquot was suspended in 1 mL of HBS containing different calcium concentrations (2−6 mM) and then transferred to a cuvette and placed in a Hitachi F-4600 spectrofluorometer (Hitachi, Japan). The cells were stirred continuously during the experiment, and fluorescence excitation/emission wavelengths were set at 488/525 nm for Fluo-3-loaded cells. Then different concentrations of DPs were added into the cuvette through the injection port. To maintain cell viability, the duration of the whole experiment never exceeded 20 min. The results in each case were expressed as Ca^{2+} peak of fluorescence intensity units from baseline.

Everted Rat Intestine Permeation. Wistar male rats in the weight range of 250−300 g were obtained from Hubei Laboratory Animal Research Center and kept under standard environmental conditions. The animals were handled in accordance with the Declaration of Helsinki and the Guiding Principles in the Care and Use of Animals and the Chinese standards (GB 14925-2001). Food was removed about 18 h prior to trial, but water was allowed ad libitum before sacrifice. The entire small intestine was immediately collected via a midline incision of the abdomen and placed into the buffer solution (136 mM NaCl, 8.17 mM KCl, 1.0 mM $MgCl_2$, 11.1 mM glucose, 20 mM HEPES, adjusted to pH 7.4) at 4 °C. The first 15 cm of duodenum was discarded, and the intestine was washed thoroughly with the buffer. The surface liquid was sopped up by the filter paper, and then the intestine was everted. Each everted intestinal segment was about 6 cm in length, and 4 mL of buffer solution (drug free) was then placed into the serosal compartment. The two distal ends were ligatured, and the entire everted intestine segment was placed into the flasks containing 100 mL of buffer with various concentrations of DPs and calcium at 37 °C. Meanwhile, 95% O_2 was constantly bubbled through the buffer. After 120 min of incubation, the serosal solution was collected and the transported calcium was measured with an atomic absorption spectrophotometer (AA6300C, Shimadzu, Kyoto, Japan).

HPLC Analysis Instrumentation. The HPLC analysis was performed on a Waters e2695 HPLC-DAD system (Waters, Milford, MA, USA), equipped with a diode array detector, a vacuum degasser, an autosampler, a binary pump, and a column compartment. DPs (<5 kDa) at a concentration of 10 mg/mL were analyzed on a ZORBAX SB-C18 column (250 mm × 4.6 mm, 5 μm, Agilent Co., Santa Clara, CA, USA) at a flow rate of 1 mL/min, with the temperature of the column maintained at 30 °C. A binary gradient elution system, comprising water (with 0.1% TFA, A) and acetonitrile (with 0.1% TFA, B), was applied as follows: 0.0−20.0 min, 5−15% B; 20.0−35.0 min, 15−20% B; 35.0−40.0 min, 20−30% B; 40.0−50.0 min, 30−40% B. The volume of injection was 10 μL, and the DAD detector was set at 220 nm for analysis.

HPLC-ESI-MS/MS Analysis Instrumentation. For HPLC-ESI-MS/MS analysis, the HPLC system described above was replaced by an Agilent1100 series HPLC-ESI-MS system (Agilent Technologies) but with the same column and gradient elution as in the HPLC analysis. Mass spectrometry conditions were set as follows: ESI^+ ion source; drying gas temperature, 325 °C; nebulizer, 40.00 psi; dry gas flow rate, 10.0 L/min; capillary voltage, 3500 V; scan spectra from m/z 100 to 1000.

The sequences were identified using LCMSD-Trap Data Analysis software and confirmed by searching the online MS database on the UCSF Mass Spectrometry Facility (http://prospector.ucsf.edu/prospector/cgi-bin/msform.cgi?form=mspattern).

Isothermal Titration Calorimetry (ITC). ITC was undertaken with an ITC200 calorimeter (MicroCal, Northampton, MA, USA). The titrant was 10 mM $CaCl_2$, and the sample cell contained 0.5 mM peptides or 0.4 mM EDTA dissolved in double-distilled water (pH 7.8). The titration comprised 20 × 2 μL injections at 25 °C. Data were analyzed with the Origin 5.0 software package (ITC Data Analysis in Origin, MAU130010 REV F-4, MicroCal). The binding constants K, ΔH, and ΔS were calculated.

Statistical Analysis. The sample treatments described in this experiment were conducted in triplicate, and the data were presented as mean values ± SD. Data were calculated using one-way ANOVA of SPSS 18.0 followed by Duncan's multiple-range test. Differences were considered significant at P values <0.05.

RESULTS AND DISCUSSION

Permeability of Caco-2 Cell Monolayers. Native epithelial tissues are traditional subjects for the research of transport processes, but these tissues are complex and contain many different cell types. Caco-2 cells are human intestinal

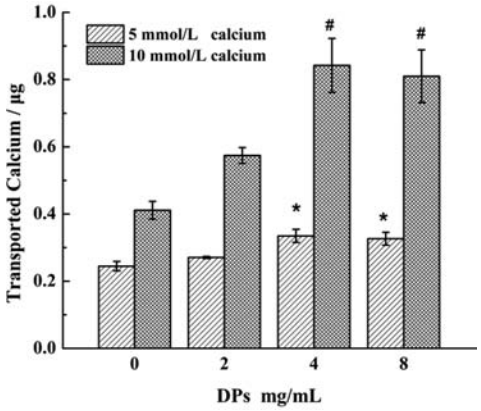

Figure 1. Effects of DPs on calcium transport across Caco-2 monolayers. DPs (0−8 mg/mL) were added to the apical side with calcium solution (5 or 10 mM, 0.4 mL) and then incubated for 120 min. Mean values with different letters are significantly different at $P < 0.05$.

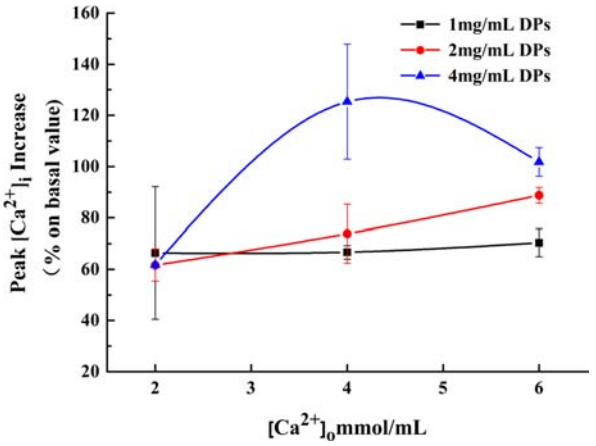

Figure 2. Calcium uptake by Caco-2 cells as influenced by different concentrations of DPs (1−4 mg/mL) and extracellular Ca^{2+} (0−4 mM). Intracellular calcium concentrations are expressed as an increase in fluorescence intensity compared to baseline, which is the original fluorescence intensity before the addition of DPs to the aliquot containing 0.5×10^6 cells.

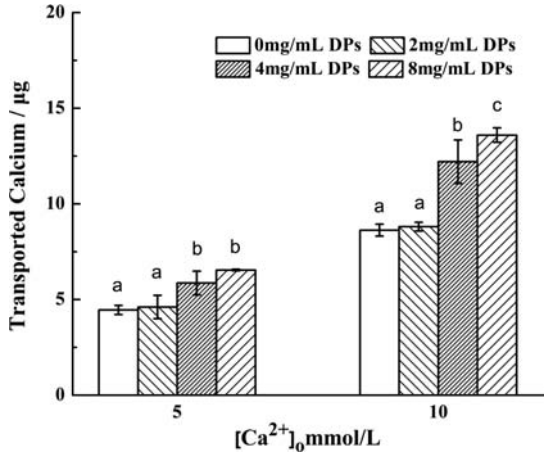

Figure 3. Effects of DPs on calcium transport across everted intestinal sac. DPs (0−8 mg/mL) were added to the mucosal solutions containing 5 or 10 mM Ca^{2+} and then incubated for 120 min. Mean values with different letters are significantly different at $P < 0.05$.

Table 1. Amino Acid Composition (g/100 g Peptides) of DPs (M_w < 5 kDa)

amino acid	DPs (<5 kDa)	amino acid	DPs (<5 kDa)
Asx[a] (D + N)	7.14	Ile (I)	3.3
Thr (T)	5.19	Leu (L)	7.17
Ser (S)	7.44	Tyr (Y)	3
Glx[b] (E + Q)	12.14	Phe (F)	6.17
Gly (G)	2.84	Lys (K)	4.5
Ala (A)	3.95	His (H)	1.54
Cys (C)	1.16	Arg (R)	3.52
Val (V)	4.97	Pro (P)	2.11
Met (M)	5.1	total amino acid	81.24

[a]Asx = Asp + Asn (D + N). [b]Glx = Glu + Gln (E + Q).

adenocarcinoma cells exhibiting enterocyte-like biochemical and morphological characteristics, and they have been reported to be an excellent in vitro model of human enterocytes for absorption studies involving minerals,[14] polyphenols,[15] proteins, and peptides.[16] In the present study, Caco-2 monolayers were used to evaluate the effect of DPs on calcium transport.

After cells had been seeded on 12-well millicell cell culture inserts, different concentrations of calcium were added to the apical compartment and the calcium on the basolateral side was measured. When 5 or 10 mM Ca^{2+} was added, no significant change in calcium transport was observed. When the concentration was increased to 20 mM, the calcium transport showed a 2-fold increase compared to control. As the total Ca^{2+} concentrations in the intestinal lumen may reach 3−4 mM in rats and 7−8 mM in humans after a proper meal,[17] 5 and 10 mM were chosen as suitable Ca^{2+} concentrations for further experiments. The effect of incubation time on calcium transport was then evaluated and found to increase with the extension of incubation time. On the basis of the retention time of food in the intestine (about 120−180 min) and cell viability, an incubation time of 120 min was determined to be the optimum duration for further experiments (data not shown).

Effect of DPs on Calcium Transport in Caco-2 Monolayers. Cell viability was evaluated to be >90% after treatment with different DPs concentrations (0−8 mg/mL). Figure 1 shows the effect of 0−8 mg/mL DPs on calcium transport with 5 and 10 mM Ca^{2+} in Caco-2 cell monolayers. In the presence of 4 and 8 mg/mL DPs, the calcium transport showed increases of 36.77 and 33.33% over that of the control group at the concentration of 5 mM Ca^{2+}. Increasing the concentration of Ca^{2+} to 10 mM increased the calcium transport by 104.88% (4 mg/mL DPs) and 97.01% (8 mg/mL DPs) versus the control group. For a given calcium concentration, the increase in Ca^{2+} transport was roughly equal whether 4 or 8 mg/mL DPs were used, implying that the influence of DPs on the transport process was saturable.

Drugs may be transported across the intestinal epithelium by one or more of four different routes: passive transcellular and paracellular routes, carrier-mediated route, and transcytosis.[18] Because the surface area of the brush border membranes is about 1000-fold larger than the paracellular surface area,[19] drugs can be assumed to be transported mainly by the transcellular route. The TEER value is a highly sensitive measure of membrane permeability, and its variation largely reflects the function of tight junctions that gate the entrance to the paracellular pathway. TEER values showed no significant difference after 120 min of incubation with different concentrations of DPs and calcium. Thus, our results from the Caco-2 cell monolayer experiment

7	36.4	495.2813	LSYL	ovoglobulin

[a]The primary structures of the DPs (<5 kDa) were determined and validated by searching three mass spectrometry databases of SwissProt.2013.6.27, NCBInr.2013.6.17, and UniProtKB.2013.6.17 with the Protein Prospector engine.

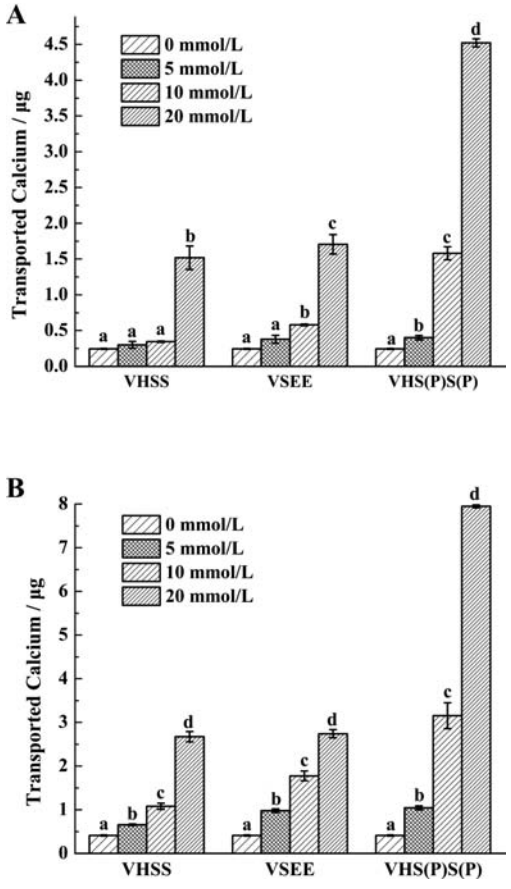

Figure 5. Effects of three pivotal peptides (VHS(p)S(p), VSEE, and VHSS) on calcium transport across Caco-2 monolayers. Peptides (0−20 mM) were added to the apical side with calcium solution (5 mM (A) and 10 mM (B), 0.4 mL) and then incubated for 120 min. Mean values with different letters are significantly different at $P < 0.05$.

confirmed the hypothesis that the paracellular pathway was a minor contributor to calcium transport by DPs. This conclusion is in contrast to the traditional theory holding the paracellular pathway as the major route of calcium transport across Caco-2 cell monolayers.[20] Various mechanisms have been reported to contribute to the absorption of calcium from the intestine, and the paracellular way has been confirmed for many bioactive substances such as vitamin D[21] and CPP.[22] However, the challenge to clearly describe calcium transport at the cellular level remains. Now, our current results provide a new insight into the DPs-mediated calcium transport pathway.

Effect of DPs on Calcium Uptake in Caco-2 Population Model. The effect of DPs (1−4 mg/mL) on the intracellular free calcium concentration, $[Ca^{2+}]_i$, was found to be concentration-dependent in the cell population model with 4 and 6 mM Ca^{2+} (Figure 2). This result is consistent with published studies of CPPs[8] and soluble soybean protein hydrolysate−calcium complex,[2] which may act as calcium carriers and interact with the plasma membrane to transport calcium to the cytosol. This function has been reported to be related to the β-pleated sheet structure of the peptides, which can interact with the plasma membrane to form unregulated Ca^{2+} channels.[23] The β-pleated sheet structure was also found in calreticulin, which is involved in calcium binding in the lumen of the endoplasmic reticulum.[24]

In addition, the optimal DPs/Ca^{2+} ratio for the enhancement of Ca^{2+} uptake was observed to be 4 mM Ca^{2+}/4 mg/mL DPs, indicating the importance of a suitable DPs/Ca^{2+} ratio for promoting calcium absorption. A similar finding was also reported for CPPs in both in vitro cell model[17] and animal models.[25]

Effect of DPs on Calcium Transport in Everted Intestinal Sac Model. Figure 3 shows the amount (μg) of Ca^{2+} absorbed across the everted intestinal sac (6 cm) with mucosal solutions containing 5 or 10 mM Ca^{2+} and 0−8 mg/mL DPs. Using 5 mM Ca^{2+}, calcium transport increased by 31.71% over control with 4 mg/mL DPs and by 46.95% with 8 mg/mL DPs. Similar to the findings in the Caco-2 cell monolayers, the extent of Ca^{2+} transport increase was similar whether 8 or 4 mg/mL DPs was used. At the 10 mM Ca^{2+} concentration, calcium transport exhibited a significant increase over control in the presence of 4 mg/mL DPs (41.45%, $P < 0.05$) and 8 mg/mL DPs (57.59%), but not 2 mg/mL DPs. These results indicate the various Ca^{2+} concentrations are a main driver behind the increase in calcium transport and thus may influence the involvement of the paracellular pathway. Thus, we conclude the paracellular pathway may not be the main transport route in the presence of 5 mM Ca^{2+} concentration. However, when the external concentration of Ca^{2+} was increased to 10 mM, the entrance of the paracellular pathway was opened.

Despite being an in vitro model, the everted intestinal sac model has the advantage of being similar to in vivo intestinal absorption, which has been used in the study of calcium absorption by CPPs.[26] A CPP/Ca ratio of 15 was found to have a significant effect on mineral absorption, and the positive effect of

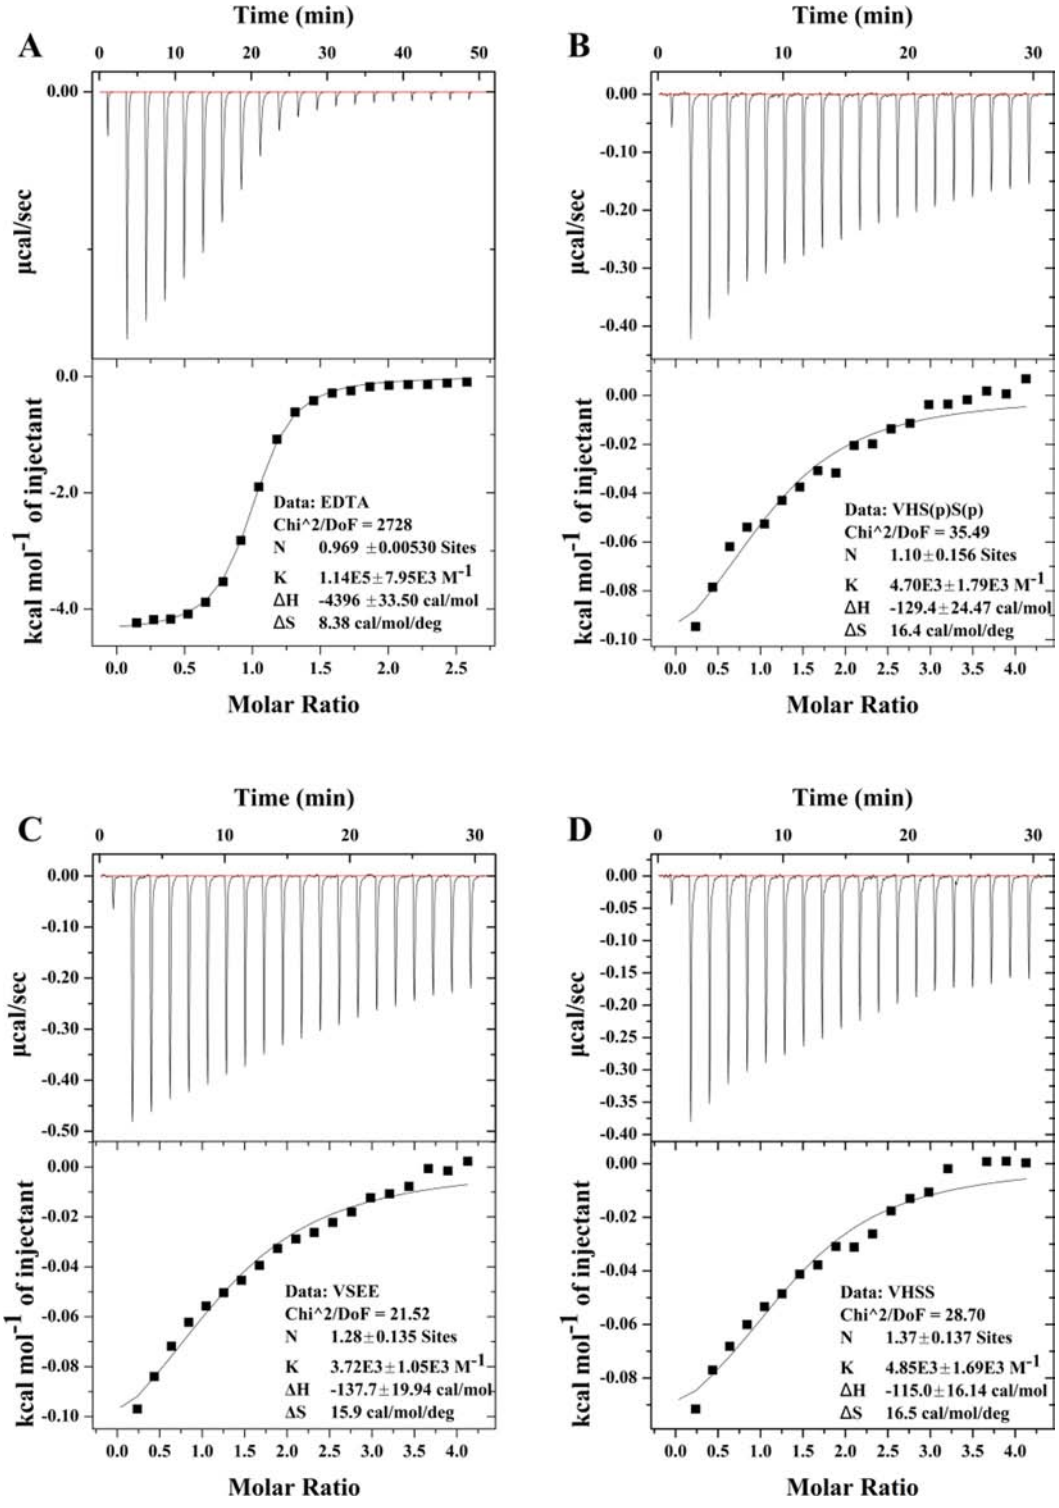

Figure 6. Thermograms and binding isotherms from ITC analysis of the interactions between (A) EDTA and (B) VHS(p)S(p), (C) VSEE, and (D) VHSS at 30 °C.

CPPs on passive Ca absorption seems to depend on the relative amounts of both species in the intestinal lumen. In this study, from both the Caco-2 cell monolayer and everted intestinal sac models, the same conclusion can be drawn: in the presence of DPs, the paracellular pathway is not the main route of calcium absorption.

Identification of High Bioactivity of DPs. The ability of DPs to promote calcium absorption was affected greatly by the amino acid composition of the peptides. The most abundant amino acids in the DPs (<5 kDa) were Glx (Glu + Gln) and Asx (Asp + Asn), accounting for 12.14 and 7.14% of the mass of the peptide, respectively. The contents of Ser, Leu, Phe, Thr, and Met were each also >5% (Table 1). Glu and Ser amino acid residues were also present in the calcium-binding peptides derived from cheese whey protein hydrolysates,[27] porcine blood plasma protein hydrolysates,[28] and Hoki protein hydrolysates.[29]

DOI: 10.1021/acs.jafc.5b03097
J. Agric. Food Chem. 2015, 63, 8170−8176

The carboxyl in some acidic amino acids, the δ-N of the imidazole ring of histidine (His), and N in amidogen of the side chain were the optimal binding sites of Ca^{2+}, and these three amino acids accounted for 35.50% of the total amino acids, which was close to the 37.64% found in soybean peptides.[30]

According to the retention time, seven peaks from DPs with M_w < 5 kDa in the total ion current (TIC) chromatogram were numbered (Figure 4), and the amino acid sequences of the seven peaks were identified as Val-Ser-Glu-Glu (VSEE), Leu-Tyr-Ala-Glu-Glu (LYAEE), Ile-Asn-Glu (INE), Leu-Ser-Tyr-Leu (LSYL), Leu-Asn-Ser-Trp (LNSW), Val-His-Gln (VHQ), and Ile-Leu-Lys-Asn (ILKN) (Table 2). The peptides possess the characteristics of high contents of E, L, N, and S, which is consistent with the result of amino acid composition of DPs. In our previous work, we described a DPs−calcium chelate found using Fourier transform infrared spectroscopy and fluorescence spectroscopy of DPs.[31] The results indicated that the carboxyl groups in some acidic amino acids were the optimal binding sites for Ca^{2+}. The calcium ions caused peptide folding and led to the formation of a DP−calcium chelate. Interestingly, a repeating Glu sequence was found in the C-terminal of VSEE and LYAEE, providing many potential binding sites (the carboxyl groups) for calcium. "Glu-Glu" was also found in the characteristic "acidic motif" Ser(P)-Ser(P)-Ser(P)-Glu-Glu in CPPs.[32] Ser was also found to exist in the peptides LSYL and LNSW, the phosphorylation of which may improve calcium binding, as it has been reported that the phosphorylation of peptides derived from isolated soybean protein could enhance the absorption of calcium in Caco-2 cells.[33] The existence of His in VHQ may contribute considerably to binding calcium due to the δ-N of the imidazole ring. One calcium-binding peptide, Thr-Cys-His, has been identified from a shrimp-processing byproduct hydrolysate, and its high calcium-binding activity may be due to the presence of a His residue.[34] N in amidogen of a side chain of Lys in ILKN was a binding site with calcium, and Lys occupied 4.5% of the mass in DPs (<5 kDa). Lys also been identified in some calcium-binding peptides from tilapia scale protein hydrolysate and bovine serum protein hydrolysates.[4] From the results of those studies, it can be deduced that Glu, Asp, His, and Ser residues may play a crucial role in the chelating of DPs with calcium.

Effect of Three Pivotal Peptides on Calcium Transport in Caco-2 Monolayers. VSEE and VHSS (which had been identified in our laboratory) and phosphorylated VHSS (VHS(p)S(p)) were synthesized by HeFei GuoTai Biology Co., Ltd. (Hefei, China). Figure 5 shows the effect of these three peptides (0−20 mM) on calcium transport, using 5 and 10 mM Ca^{2+}, in Caco-2 cell monolayers. In the presence of 5 mM Ca^{2+}, groups treated with the lower dosage of VHSS and VSEE did not show any significant increase in calcium transport over the control group. As the concentration of peptides was increased to the highest dose (20 mM), the calcium transport increased by >200%. At all doses tested, calcium transport facilitated by VHS(p)S(p) was always higher than that of the other two peptides. In the presence of 10 mM Ca^{2+}, each of the doses tested of VHSS, VSEE, and VHS(p)S(p) stimulated calcium transport.

Figure 6 shows the ITC curves of Ca^{2+} titrated into peptide solutions, as well as the thermodynamic parameters for interaction of peptides with calcium including the stoichiometry (n), association constant (K), change in enthalpy (H), and change in entropy (S). The binding association constants were similar for all peptides, but significantly lower than those for EDTA, which indicates that these three peptides could release calcium easily. The stoichiometry (n) demonstrated a significant difference in how the calcium is bound to peptides. VHS(p)S(p) provides seven binding sites, including an oxygen atom from a hydroxyl in the C-terminal carboxyl, a δ-N atom in the imidazole ring of histidine (His), a N atom of amidogen in the N-terminal, and four oxygen atoms in the phosphate group. Therefore, a small amount of VHS(p)S(p) can bind many calcium ions, which supports the results seen in the Caco-2 monolayers, indicating that the binding activity of peptides is necessary in the process of calcium transport in this cell model. VHSS and VSEE contained three and four functional chelating sites, respectively, so they also could act as calcium-binding peptides. In addition, the three peptides were all detected by HPLC in the basolateral samples, indicating that all three peptides participated in calcium transport, most likely as carriers (data not shown).

On the basis of the mechanisms of calcium uptake in the three models, the amino acid composition, and the sequences of the peptides, the contribution of DPs to calcium absorption may be attributed to two factors: (1) the structure of DPs can ensure high bioactivity is maintained, in order for calcium to interact with the membrane and open the specific calcium channels; and (2) the most suitable DPs structures will not only bind calcium for transport but also release the ion easily.

In summary, the present study provides evidence from three experimental models that DPs (<5 kDa) have a significant effect on calcium absorption. Our results suggest that rather than relying on the paracellular pathway, DPs may facilitate calcium transport by acting as calcium carriers and interacting with the cell membrane to open a special Ca^{2+} channel. Furthermore, our findings shed light on the relationship between amino acid composition and bioactivity. Glu, His, Lys, and Ser in DPs may play crucial roles in the chelation of DPs with calcium, and some peptides containing pivotal amino acid sequences, such as VSEE, have high calcium-binding capability. Future work should focus on the relationship between the bioactivity and structure of DPs to help identify a peptide with the capability of not only binding desired quantities of calcium but also interacting with the plasma membrane to enhance the entrance of Ca^{2+} into cells.

ice. Plasma was separated from blood by centrifugation at 2300×*g* for 10 min at 4 °C, and then frozen at −80 °C until analysis. Plasma acetaminophen concentrations were measured using acetaminophen detection kit (Kanto Chemical Co., Inc., Tokyo, Japan).

In a separate experiment, the effects of various aliphatic compounds having the same carbon chain length as 2,4-decadienal were investigated. 2,4-Decadienal, decanal (saturated aldehyde, Tokyo Chemical Industry Co., Ltd.), decanol (saturated alcohol, Kanto Chemical Co., Inc., Tokyo, Japan), decanoic acid (saturated fatty acid, Tokyo Chemical Industry Co., Ltd.), or vehicle (2% ethanol in saline) was orally administered at a dose of 100 mg/kg body weight; all these solutions contained acetaminophen (100 mg/kg body weight). Tail vein blood samples (60 μL) were collected, and plasma acetaminophen concentrations were measured as described above.

Phenol Red Test. 2,4-Decadienal (100 mg/kg body weight) or its vehicle (1.5% carboxymethyl cellulose and 2% ethanol in saline) was orally administered (10 mL/kg body weight) through a feeding tube (6 Fr, Atom Medical Co., Tokyo, Japan). The suspensions contained phenol red (5 mg/kg body weight), as a nonabsorbable marker, in addition to acetaminophen (100 mg/kg body weight) to assess gastric emptying rate.[10,11] Portal blood was collected into a syringe containing heparin (final concentration 50 IU/mL), aprotinin (final concentration 500 KIU/mL), and dipeptidyl peptidase-IV inhibitor (final concentration 50 μM, Millipore, MA, U.S.A.) 15 min after oral administration from animals under isoflurane anesthesia (MSD K.K., Tokyo, Japan). Plasma was separated and stored as described above. Rats were euthanized by exsanguination immediately after the procedure, and the luminal contents of the stomach, as well as that of the proximal and distal small intestine were collected. The interiors of these tissues were flushed twice with cold saline, and the washout solution was collected. The debris was removed by centrifugation at 8400×*g* for 10 min at 4 °C. After adding 1 N NaOH to the supernatant (1/30 volume of the supernatant), concentration of phenol red was measured spectrophotometrically at 560 nm. The gastric emptying rate was calculated as follows.

Gastric emptying rate (%) = [{the amount of phenol red administrated (mg) − the amount of phenol red remained in the stomach (mg)}/the amount of phenol red administrated (mg)] × 100

Effect of Intraperitoneal Administration of 2,4-Decadienal on Gastric Emptying Rate. We examined the effect of intraperitoneal administration of 2,4-decadienal on gastric emptying. Rats were divided into control, intraperitoneal 2,4-decadienal, and oral 2,4-decadienal groups. Control rats were intraperitoneally administered sterilized saline (10 mL/kg) immediately after oral pretreatment with 10 mL/kg phenol red (5 mg/kg) dissolved in saline containing 1.5% carboxymethyl cellulose. The intraperitoneal 2,4-decadienal group was administered 2,4-decadienal intraperitoneally (100 mg/kg) suspended in sterilized saline immediately after oral pretreatment with phenol red solution. An oral 2,4-decadienal group was administered saline intraperitoneally immediately after oral administration of 2,4-decadienal (100 mg/kg) suspended in the phenol red solution. The gastric content was collected 15 min after intraperitoneal or oral administration, and the gastric emptying rate was determined as described above.

Effect of Duodenal Administration of 2,4-Decadienal on Gastric Emptying Rate. To administer 2,4-decadienal directly into the small intestinal lumen, a catheter was implanted into the duodenum in rats fed with reduced amount of the diet (10 g) on the day before the surgical operation. A middle incision was made under pentobarbital anesthesia (40 mg/kg body weight; Nembutal Injection, Dainippon Sumitomo Pharma, Osaka, Japan or Somnopentyl Injection, Kyoritsu Seiyaku Co., Tokyo, Japan). A silicone catheter (Silascon no. 00; internal diameter 0.5 mm; outer diameter 1.0 mm; Dow Corning Co., Kanagawa, Japan), the tip of which housed a small segment (2−3 mm) of a polyethylene tube (Hibiki Fr No. 4; Kunii Co., Tokyo, Japan), was inserted into the duodenum (2 cm distal to the pyloric part of the stomach) and fixed with a thread. The free end of the catheter was dorsally exteriorized, which allowed the experiment to be carried out in conscious and unrestrained rats. Rats were used for subsequent experiments after a recovery period of 3−4 days. After overnight fasting, 2,4-decadienal (0−25 mg/kg) was administered into the duodenal lumen through the catheter, followed by oral administration of acetaminophen or phenol red solution, as described above.

Statistical Analysis. All results are expressed as mean ± SEM. Significant differences among the groups were determined using Student's *t* test ($P < 0.05$) for two-group comparison or Dunnett's posthoc test ($P < 0.05$) for multiple group comparison as described in the figure legends.

RESULTS AND DISCUSSION

Plasma acetaminophen concentrations in the tail vein blood increased immediately after oral administration of acetaminophen at 100 mg/kg, and then gradually decreased after 45 min (Figure 1A and B). Appearance of acetaminophen in peripheral

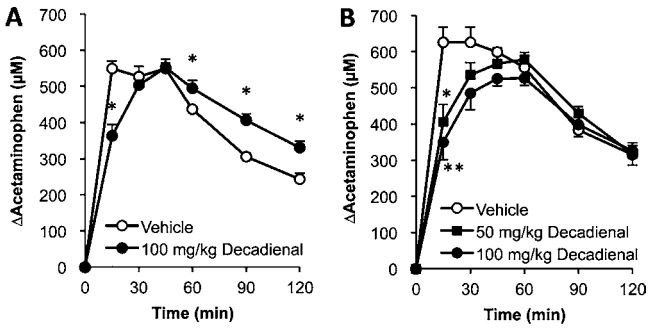

Figure 1. Effects of oral administration of 2,4-decadienal on gastric emptying rate (acetaminophen absorption test). 2,4-Decadienal (decadienal) at 100 mg/kg (A, $n = 6$ in each treatment), or 50 and 100 mg/kg (B, $n = 4$ in each treatment) were orally administered to fasted rats together with acetaminophen. Tail vein blood was collected and acetaminophen concentrations were measured in the plasma. Values are expressed as means ± SEM of changes in acetaminophen concentration from the basal level (0 min). Plots with asterisks (*) have significant difference compared to the value of control group at the same time point ($p < 0.05$, A: Student's *t* test, B: Dunnett's test).

blood was delayed by oral coadministration of 2,4-decadienal (50 and 100 mg/kg), suggesting delayed gastric emptying in the presence of 2,4-decadienal. We used 100 mg/kg dose of 2,4-decadienal in further experiments because of its apparent effect on plasma acetaminophen levels.

To further investigate the inhibitory effect of 2,4-decadienal on gastric emptying rate, we used an unabsorbable marker such as phenol red. In this experiment, luminal contents 15 min after the oral administration were collected, not only from the stomach, but also from the proximal and the distal small intestine, and the remaining amounts of phenol red in the lumen were determined (Figure 2A). The remaining amount of phenol red in the stomach lumen was much higher in the 2,4-decadienal group than the amount in the control group. The gastric emptying rate calculated using the amount of remaining phenol red was significantly lower in the 2,4-decadienal group than the gastric emptying rate of the control group (Figure 2B). Indeed, amounts of luminal phenol red in the proximal and the distal small intestine were lower in the 2,4-decadienal group than that in the control group (Figure 2A). These results confirm the inhibitory effect of orally administered 2,4-decadienal on gastric emptying. Plasma acetaminophen levels in the portal vein were lower in rats treated with oral 2,4-decadienal (Figure 2C), further supporting the gastric inhibitory effect of 2,4-decadienal.

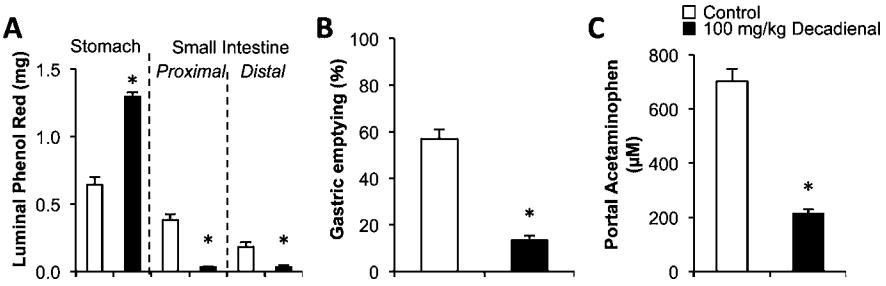

Figure 2. Effects of oral administration of 2,4-decadienal on gastric emptying rate (phenol red recovery method). 2,4-Decadienal (decadienal) at 100 mg/kg was orally administered to fasted rats together with phenol red and acetaminophen (n = 6 in each treatment). Portal blood and luminal contents (stomach and proximal and distal small intestine) were collected 15 min after oral administration. The gastric emptying rate (B) was calculated by using the amount of luminal phenol red in the stomach (A). Portal acetaminophen (C) levels were measured in the plasma. Values are expressed as means ± SEM. Bars with asterisks (*) have significant difference compared to the value of control group (p < 0.05, Student's t test).

In our previous in vitro study, 2,4-decadienal (diunsaturated aldehyde), but not decanal (saturated aldehyde), decanol (saturated alcohol), and decanoic acid (saturated fatty acid), stimulated CCK secretion from enteroendocrine STC-1 cells.[7] In the present study, the effect of the structure−activity relationship on gastric emptying was examined in vivo. As shown in Figure 3, oral administration of 2,4-decadienal

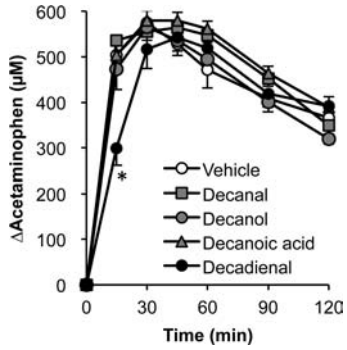

Figure 3. Effects of oral administration of various aliphatic compounds on gastric emptying rate. Aliphatic compounds (decanal, decanol, or decanoic acid) having the same carbon chain length as 2,4-decadienal (decadienal) were orally administered (100 mg/kg) to fasted rats in the acetaminophen absorption test (n = 6 in each treatment). Values are expressed as means ± SEM. Asterisks (*) indicate significant difference compared to the value of control group (p < 0.05, Dunnett's test).

attenuated the elevated plasma acetaminophen levels, but decanal, decanol, or decanoic acid had no effects on plasma acetaminophen levels. The structure−activity relationship consistent with that in our previous in vitro study suggests that 2,4-decadienal acts directly on enteroendocrine cells, rather than after absorption from the intestine.

To determine whether 2,4-decadienal acts in the gastrointestinal lumen or after absorption, gastric emptying rate was measured after oral or intraperitoneal administration of 2,4-decadienal. Gastric emptying rate significantly reduced after oral administration 2,4-decadienal, but not after intraperitoneal administration of 2,4-decadienal, compared to that after control treatment (Figure 4). The result indicates that 2,4-decadienal exerted its inhibitory effects on gastric emptying in the gastrointestinal lumen, and led us to investigate whether the effect was triggered in the small intestinal lumen, by using rats equipped with the duodenal catheter.

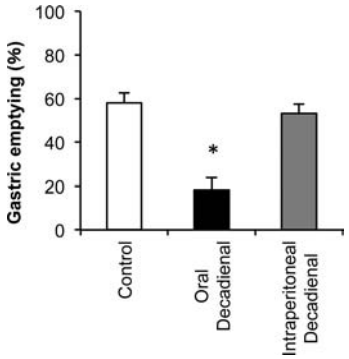

Figure 4. Effect of intraperitoneal administration of 2,4-decadienal, on gastric emptying rate. 2,4-Decadienal solution (decadienal) was orally or intraperitoneally coadministered to fasted rats together with oral phenol red. Gastric emptying rate was determined by measuring luminal phenol red collected from the stomach 15 min after the administration (n = 7−8 in each treatment). Values are expressed as means ± SEM. Asterisks (*) indicate significant difference compared to the value of control group (p < 0.05, Dunnett's test).

Duodenal administration of 2,4-decadienal reduced acetaminophen appearance in plasma of the tail vein in a dose-dependent manner (Figure 5). Compared to control treatment, 10 mg/kg dose of 2,4-decadienal had significantly lower acetaminophen concentration at 15 min, similar to the

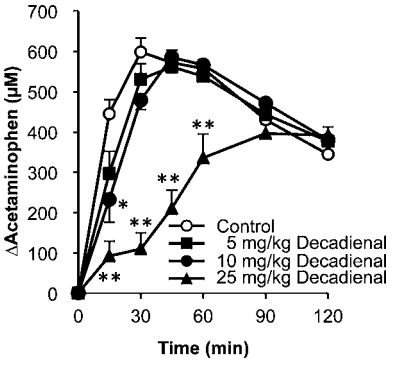

Figure 5. Effect of duodenal administration of 2,4-decadienal on gastric emptying rate. 2,4-Decadienal (decadienal: 0, 5, 10, and 25 mg/kg) was administered into the duodenal lumen through the duodenal catheter followed by oral administration of acetaminophen in fasted rats (n = 6 in each treatment). Values are expressed as means ± SEM. Asterisks (*) indicate significant difference compared to the value of control group at the same time point (p < 0.05, Dunnett's test).

DOI: 10.1021/acs.jafc.5b03126
J. Agric. Food Chem. 2015, 63, 8177−8181

reduction caused by 100 mg/kg dose of oral administration. Duodenal administration of 25 mg/kg dose led to a much greater and sustained (~60 min) reduction in acetaminophen levels. Because the effective duodenal dose (10 mg/kg) is lower than the oral dose (50−100 mg/kg), the result indicates that 2,4-decadienal exerts its gastric inhibitory effect in the small intestinal lumen, rather than in the gastric lumen.

Gut hormones such as CCK, serotonin, and GLP-1 inhibit gastric emptying,[1−5] and 2,4-decadienal potently stimulates CCK secretion in the enteroendocrine STC-1 cells.[7] Because 2,4-decadienal exerts its effects rapidly (~15 min) after oral and duodenal administration, we investigated the involvement of CCK and serotonin that are produced in the proximal small intestine, rather than GLP-1 that is released from the distal small intestine and the large intestine. When a CCK-A receptor antagonist, devazepide was intraperitoneally injected, gastric inhibitory effect of orally administered 2,4-decadienal decreased, but single administration of devazepide accelerated gastric emptying (Figure 6A). Therefore, involvement of CCK signaling has not been clarified in the present study. In contrast, a serotonin type 3 receptor ($5HT_3R$) antagonist, tropisetron, treatment reversed the gastric inhibitory effect of duodenal 2,4-decadienal in the acetaminophen test (Figure 6B). Although a single administration of tropisetron led to significantly higher acetaminophen levels at 15 min compared to control/vehicle treatment, the effect was limited to that time point, and it was smaller than the reversible effect on 2,4-decadienal-reduced gastric emptying. Phenol red test (Figure 6C) confirmed the involvement of serotonin signal, since reduced gastric emptying rate caused by duodenal 2,4-decadienal was clearly attenuated by tropisetron treatment. These results further support the notion that 2,4-decadienal acts directly on serotonin-producing enteroendocrine cells, namely, enterochromaffin cells. We previously demonstrated that 2−4-decadienal stimulated CCK secretion via transient-receptor potential ankyrin 1 (TRPA1).[7] TRPA1 functions in serotonin-producing enteroendocrine cells, not only in CCK-producing cells.[12,13] A recent study in mice demonstrated TRPA1 is expressed in enteoroendocrine cells expressing serotonin and the cells coexpressing serotonin and CCK, but not in the cells only expressing CCK.[14] Thus, compared to CCK secretion, serotonin secretion may be more responsive to TRPA1 activation in the upper small intestine. However, the gastric inhibitory effect of 2,4-decadienal was not completely canceled by the tropisetron treatment (Figure 6B and C), suggesting partial involvement of the TRPA1-CCK signaling pathway. Treatment with the combination of the CCK-A receptor antagonist and the serotonin receptor antagonist may demonstrate the role of CCK secretion in 2,4-decadienal-delayed gastric emptying in the future study. In addition, further studies will be necessary in the future to elucidate the cellular mechanisms that stimulate serotonin secretion from the serotonin-producing enteroendocrine cells.

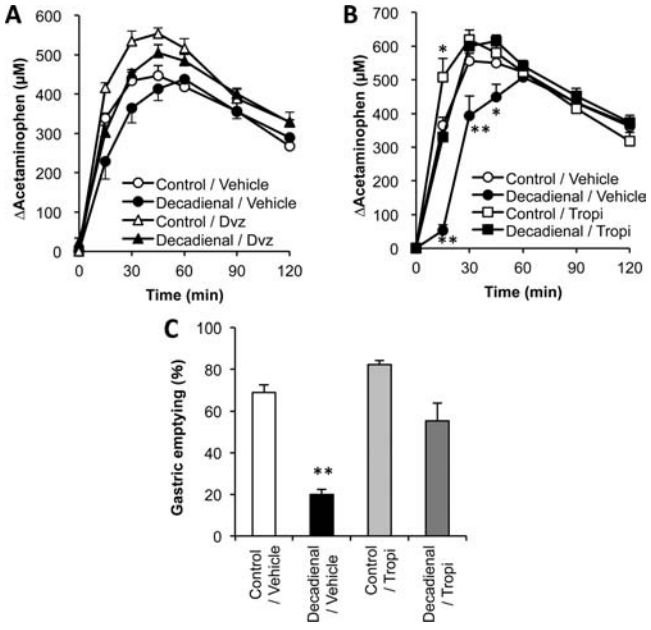

Figure 6. Effect of CCK-A receptor antagonist (devazepide) and 5-HT_3 receptor antagonist (tropisetron) on luminal 2,4-decadienal-induced reduction in gastric emptying rate. (A) Devazepide (Dvz) at 0.5 mg/kg or its vehicle (10% TWEEN80 + 10% DMSO in saline) was intraperitoneally injected 10 min before the oral administration of 2,4-decadienal (decadienal: 100 mg/kg), followed by oral administration of acetaminophen in fasted rats (n = 5−6 in each treatment). (B) Tropisetron (Tropi) at 0.5 mg/kg or its vehicle (saline) was intraperitoneally injected just before the duodenal administration of 2,4-decadienal (decadienal: 0, 10 mg/kg), followed by oral administration of acetaminophen in fasted rats (n = 6−7 in each treatment). Tail vein blood was collected, and acetaminophen concentrations were measured in the plasma. (C) Tropisetron (Tropi) at 0.5 mg/kg or its vehicle (saline) was intraperitoneally injected just before the duodenal administration of 2,4-decadienal (decadienal: 0, 10 mg/kg), followed by oral administration of phenol red in fasted rats (n = 6−7 in each treatment). Gastric emptying rate was determined by measuring luminal phenol red collected from the stomach 15 min after the administration (n = 4−5 in each treatment). Values are expressed as means ± SEM. Asterisks (*) indicate significant difference compared to the value of control/vehicle group (p < 0.05, Dunnett's test).

Gastric emptying decreases in the presence of luminal lipids, proteins, and glucose. In previous studies, duodenal (not oral) administration of lipid (50−100 mg/250−300 g body weight) or glucose (50−100 mg/250−300 g body weight) reduced gastric emptying in rats.[11,15,16] Another study[17] demonstrated that oral administration of peptone or lipid (250−1250 mg/250−300 g body weight) reduced gastric emptying in rats. Although the experimental conditions were different from that employed in the present study, our findings suggest that 2,4-decadienal has more potent inhibitory effect on gastric emptying than these macronutrients.

2,4-Decadienal is one of the flavoring compounds in chicken meat,[18] and is used as a flavoring agent and fragrance, but the physiological effects of orally administered 2,4-decadienal have not been studied. A recent study demonstrated that orally administered 2,4-decadienal was metabolized to 2,4-decadienoic acid and a cysteine-conjugated compound.[19] Unsaturated aldehydes are generated during lipid peroxidation and play critical roles in oxidative stress.[20,21] The structure activity relationship demonstrated in the present study suggests that serotonin-producing enteroendocrine cells sense luminal unsaturated aldehydes to prevent the excess absorption and ingestion of potent peroxides such as unsaturated aldehydes through delaying gastric emptying followed by suppression of appetite. 2,4-Decadienal might be involved in deteriorated lipid-induced appetite suppression or nausea through potent inhibition of gastric emptying. In a previous study investigating the chronic effect of 2,4-decadienal, the no-observed-adverse-effect level was determined to be 100 mg/kg in rats and mice.[22] Although the dose of 100 mg/kg used in the present study was

DOI: 10.1021/acs.jafc.5b03126
J. Agric. Food Chem. 2015, 63, 8177−8181

not found to be very toxic, it is not possible to ingest this dose in a single meal. However, a small amount of 2,4-decadienal ingested together with other macronutrients could potentiate its inhibitory effects on gastric emptying. Because rapid gastric emptying contributes to postprandial hyperglycemia and lipidemia, suppressing gastric emptying is a promising target for preventing or reducing glucose intolerance and dyslipidemia. Although the physiological relevance of structure−activity relationships observed in the present study is still unclear, potent activation of enteroendocrine cells by 2,4-decadienal[7] could explain the potent effect in vivo. Further studies are needed to elucidate the molecular and signaling mechanisms involved in the gastric inhibitory effect of orally administered 2,4-decadienal.

In summary, oral administration of 2,4-decadienal reduced gastric emptying in rats, as assessed by the acetaminophen absorption test and the phenol red recovery method. Structure−activity relationship study revealed the specific potential of 2,4-decadienal to reduce gastric emptying in vivo. Furthermore, duodenal but not intraperitoneal 2,4-decadienal reduced gastric emptying, and the gastric inhibitory effect was mediated via serotonin signaling. These results demonstrate that orally administered 2,4-decadienal has potent inhibitory effect on gastric emptying by acting directly on serotonin-producing enteroendocrine cells.

(D) Column bar graph of apoptosis. ##$P < 0.01$ vs the control group; *$P < 0.05$, **$P < 0.01$ vs HG group.

Disruption of mitochondria changes the permeability of the mitochondrial membrane and leads to apoptosis in endothelial cells, which indicates that mitochondria play a critical role in vascular complications of diabetes.[16] Attention has been focused recently on the role of the mitochondrial permeability transition pore (mPTP) in the regulation of the permeability of the mitochondrial membrane and as a trigger for apoptosis.[17] Opening mPTP increases ROS generation, so mPTP might have an important role in ROS signaling. Hence, mitochondrial targeting of ROS generation or mPTP in mitochondria is emerging as a novel approach in the treatment of diabetic angiopathy.[18,19]

In the present study, we have used an experimental model in which human umbilical vein cells (HUVECs) are exposed to high concentrations of glucose, which partly mimics what happens *in vivo* in diabetic patients.[20] To elucidate the role of PSG-1 in ROS generation and mitochondrial function during hyperglycemia-induced angiopathy, we investigated whether PSG-1 can promote the survival of HUVECs by preventing the overproduction of ROS and mitochondrial dysfunction using the ROS scavengers, the oxidizing agent *tert*-butyl hydroperoxide (tBH), mPTP blockers, and caspase inhibition.

MATERIALS AND METHODS

Reagents. PSG-1 was prepared as previously described.[12] MTT, cyclosporine A (CsA), and *N*-acetyl cysteine (NAC) were purchased from Sigma (St. Louis, MO, USA). Cell culture products were obtained from Life Technologies (Paisley, Scotland, USA). The 5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolcarbocyanine iodide (JC-1) assay kit was purchased from Beyotime Institute of Biotechnology (Shanghai, China). Annexin V-FITC apoptosis detection kits were from BD Biosciences (San Jose, SD, USA); anti-Bcl-2, anti-Bax, anticytochrome *c*, anti-β-actin, and anti-α-tubulin primary antibodies, as well as the HRP-linked secondary antibody, were from Santa Cruz Biotechnology (Santa Cruz, CA, USA). 2′,7′-Dichlorofluorescein diacetate (DCFH-DA) was purchased from Molecular Probes Inc. (Eugene, OR, USA). Anti-VDAC1 rabbit

DOI: 10.1021/acs.jafc.5b03462
J. Agric. Food Chem. 2015, 63, 8182−8191

polyclonal antibody was purchased from Abcam Biotechnology (Abcam, Cambridge, UK). Mitochondria/cytosol fractionation kit and Z-VAD-FMK were obtained from Biovision (Mountain View, CA, USA).

Cells and Cell Culture. HUVECs were purchased from the American Type Culture Collection (ATCC, Catalog No: CRL-1730, US). The cells were seeded in 60 mm Petri dishes and cultured in DMEM supplemented with 10% fetal bovine serum, penicillin (100 U/mL), and streptomycin (100 μg/mL) in a humidified incubator (5% CO2, 37 °C). HUVECs, at 80−90% confluence, were treated with a high concentration of glucose (35.5 mmol/L) for the required time of pretreatment with PSG-1 for 1 h before the high glucose treatment. At the indicated time points, the cells were collected for further evaluation.

Determination of Cell and Mitochondrial Viability. Cell and mitochondrial viability were determined by modification of a previously published protocol.[21] HUVECs were seeded in 96-cell plates at 1×10^4/well for 24 h. The cells were then incubated with high glucose alone or in the presence of PSG-1 for specified times. Cell viability was determined by measuring lactate dehydrogenase (LDH) released from the cells using LDH assay kits (Nanjing Jiancheng Bioengineering Institute, Nanjing, China). Mitochondrial function was determined by measuring NADPH dehydrogenase activity using the MTT assay.

Analysis of Apoptosis. HUVECs were treated with PSG-1 and incubated for prescribed periods. After incubation, HUVECs were harvested and washed with ice-cold PBS, and stained with Annexin V and PI in buffer. Stained cells were analyzed by flow cytometry with a FACSort cell sorter (Becton Dickinson, San Jose, CA, USA).

Determination of ROS Generation. After the incubation period, HUVECs were harvested and washed with ice-cold PBS. Washed cells were further incubated with10 μM DCFH-DA at 37 °C for 20 min in dark. Cells were washed in PBS and analyzed by flow cytometry with a FACSort cell sorter.

Measurement of Mitochondrial Membrane Potential ($\Delta\Psi$m). Flow cytometry with a JC-1 fluorescent probe was used to determine the change of $\Delta\Psi$m in HUVECs. The HUVECs were harvested and washed with 500 μL of culture medium, and then 500 μL of JC-1staining fluids was added to the cells according to the manufacturer's instructions. $\Delta\Psi$m was expressed as a ratio of red fluorescence intensity over green fluorescence intensity.

SDS−PAGE and Western Blot Analyses. SDS−PAGE and Western blot analyses of Bcl-2, Bax, or cytochrome *c* were performed as previously described.[8,22] Anti-α-tubulin and anti-VDAC1 antibodies were used as total control, cytosolic loading control, and mitochondrial loading control, respectively.

Determination of mPTP Opening. The opening of mPTP was determined using the mPTP fluorescence detection kit (Genmed Scientific Inc., USA). After the indicated treatment, the fluorescence intensity of samples was determined by using a Varioskan Flash Multimode Reader (Thermo Electron Corporation, USA).

Assay of Caspase Activities. Caspase activities were measured by a colorimetric assay kit (Biovision, CA, USA). The absorbance at 405 nm of the released ρNA was monitored spectrophotometerically. The protein contents were measured by a BCA kit (Beyotime Company, Nanjing, China).

Statistical Analyses. All data are expressed as the mean ± SEM. Statistical significance was tested by one-way analysis of variance. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS

Effects of PSG-1 on High Glucose-Induced Cytotoxicity in HUVECs. Increase of LDH release is widely used as an index of cellular necrosis.[21] To investigate the effect of PSG-1 on high glucose-induced cell damage, we treated HUVECs for 48 h with a high concentration of glucose (35.5 mmol/L) alone or after pretreatment with PSG-1 (50 μg/mL) for 1 h.[11] HUVECs subjected to high glucose insults induced a significant increase of LDH release. Simultaneous treatment of cells with PSG-1 significantly decreased the amount of LDH released. Such PSG-1 pretreatment caused no significant cytotoxicity in normal cells. To avoid the effect of osmotic pressure on cell injury, mannitol (5.5 mmol/L glucose + 30.0 mmol/L mannitol) was used as a control (Figure 1B). The data showed that mannitol did not protect against high glucose-induced cytotoxicity in HUVECs. These results indicated that PSG-1 was a protective agent against high glucose-induced injury in HUVECs.

Effects of PSG-1 on High Glucose-Induced Apoptosis in HUVECs. Apoptosis was determined by Annexin V and PI double staining. Figure 1C and D showed a significant increase of apoptosis in endothelial cells exposed to high glucose. However, when cells had been pretreated with PSG-1 for 1 h before being subjected to high glucose, a decrease in the number of apoptotic cells was observed. These data suggested that PSG-1 could protect endothelial cells against apoptosis induced by high glucose.

Effects of PSG-1 on High Glucose-Induced ROS Production in HUVECs. Our recent studies have suggested that overproduction of ROS could be attenuated by PSG-1 both *in vivo* and *in vitro*.[9,23] To further analyze the effects of PSG-1 on ROS production, HUVECs were incubated with PSG-1 prior to being exposed to high glucose. It was found that PSG-1 significantly reduced 2′,7′-dichlorofluorescein (DCF) fluorescence, suggesting a significant decrease of ROS production (Figure 2A and B). We considered that this showed a link between the attenuation of intracellular oxidative stress by PSG-1 and its protective effect against hyperglycemia toxicity. To find the relationship between the overproduction of ROS and apoptosis, we used NAC, a ROS scavenger, to investigate the role of ROS in apoptosis after HUVECs had been cultured under elevated glucose concentration conditions. Confirming that glucotoxicity is related to oxidative stress resulting from ROS generation, pretreatment of endothelial cells with 15 mmol/L NAC for 1 h, significantly ameliorates high glucose-induced apoptosis (Figure 1C and D) and ROS generation (Figure 2A and B).

Effects of PSG-1 on High Glucose-Induced Mitochondrial Dysfunction in HUVECs. Mitochondria are believed to play a crucial role in controlling ROS generation, and its dysfunction is one of the prominent phenomenons of ROS-induced cell damage.[24] We further examined the effects of PSG-1 on mitochondrial dysfunction induced by high glucose in HUVECs. As shown in Figure 2C, treatment with high glucose for 48 h induced a significant loss of the activity of mitochondrial dehydrogenase, this points to mitochondrial impairment, which could be significantly attenuated by the addition of PSG-1. The maintenance of the $\Delta\Psi$m is also crucial for mitochondrial functions such as ATP generation and electron transport. Previously, we showed that the bioactivity of PSG-1 is a factor in maintaining $\Delta\Psi$m in cardiomyocytes exposed to anoxia/reoxygenation.[9] In this work, high glucose led to a significant decrease in the red (JC-1 aggregates FL2-H+/FL1-H+)/green (JC-1 monomers FL2-H−/FL2-H+) ratio, suggesting the loss of $\Delta\Psi$m in endothelial cells (Figure 2E and F). Significantly, the loss of $\Delta\Psi$m was blocked by PSG-1 pretreatment, indicating that PSG-1 could alleviate hyperglycemia-promoted mitochondrial dysfunction by both increasing the activity of mitochondrial dehydrogenase and maintaining $\Delta\Psi$m in HUVECs.

production of ROS particularly affects the mitochondria, which causes the collapse of the $\Delta\Psi$), triggering the release of mitochondrial cytochrome *c* to activate the mitochondrial apoptotic pathway.[25,26] The data showed that cytochrome *c* in control mitochondrial cells was highly expressed, with very low expression in cytosol, but cytochrome *c* diffused out of the mitochondria and was significantly accumulated in the cytosol after 48 h of treatment with high glucose. However, cytochrome *c* release from mitochondria into cytosol was significantly reduced when HUVECs were incubated with PSG-1 before high glucose treatment (Figure 2D).

Bax and Bcl-2, the two main members of the Bcl-2 family, act as an upstream checkpoint of mitochondrial dysfunction associated with cytochrome *c* release.[27] Western blotting

analysis showed that Bcl-2 expression was significantly reduced from the mitochondria after high glucose treatment (Figure 2D), but after treatment with high glucose for 48 h, an increased amount of Bax was found in the mitochondrial fraction of HUVECs, whereas the protein of cytosolic Bax was decreased with this treatment. In contrast, PSG-1 alleviated the changes of antiapoptotic Bcl-2 and proapoptotic Bax in HUVECs under high glucose conditions. Meanwhile, PSG-1 inhibited the release of cytochrome *c* into the cytosol and alteration of Bcl-2 paralleled with the increase of $\Delta\Psi$m and the attenuation of apoptosis. The results indicated that high glucose triggered the mitochondrial apoptotic pathway, which was suppressed by PSG-1 in HUVECs.

Effects of PSG-1 on mPTP Opening in HUVECs Subjected to High Glucose. Opening of the mPTP is a mechanism which releases apoptotic factors (such as cytochrome *c*) and mitochondrial membrane permeabilization as occurs during apoptosis.[28] Induction of mPTP opening results in a decrease of calcein fluorescence, and the decrease of fluorescence intensity corresponds to such opening. The results showed that high glucose markedly enhanced the opening of mPTP (Figure 3A). Significantly, PSG-1 inhibited the opening of mPTP, indicating that its effect against apoptosis may be associated with inhibiting the opening of mPTP in HUVECs when exposed to high glucose.

An oxidizing agent, tBH, which is known to cause mPTP opening in living cells,[29] was also used to investigate the opening of mPTP in HUVECs. There was a remarkable increase in apoptosis accompanying the opening of mPTP in HUVECs treated with 500 μmol/L tBH for 45 min. This result confirms that mPTP is an oxidative stress-sensitive channel related to apoptosis (Figure 3B). When HUVECs were subjected to PSG-1 for 1 h, the tBH-induced opening of mPTP decreased significantly in parallel with the attenuation of ROS generation (Figure 3C and D) and apoptosis (Figure 3E and F). These results suggested that PSG-1 may ameliorate oxidative stress-related mPTP opening in HUVECs.

Next, we examined whether manipulation of mPTP opening may alter ROS production. Treatment of the reference mPTP inhibitor CsA resulted in the inhibition of ROS generation (Figure 4Aand B) and also alleviated apoptosis (Figure 4C and D) in HUVECs exposed to high glucose. This would suggest that manipulation of mPTP opening could influence ROS production. Similar results were observed with PSG-1, which was also found to inhibit ROS generation and apoptosis. These findings suggested that mPTP opening was a necessary factor for apoptosis and was closely related to ROS generation. Inhibition of mPTP opening may, therefore, be a means of protecting PSG-1 against hyperglycemia toxicity-induced apoptosis in HUVECs.

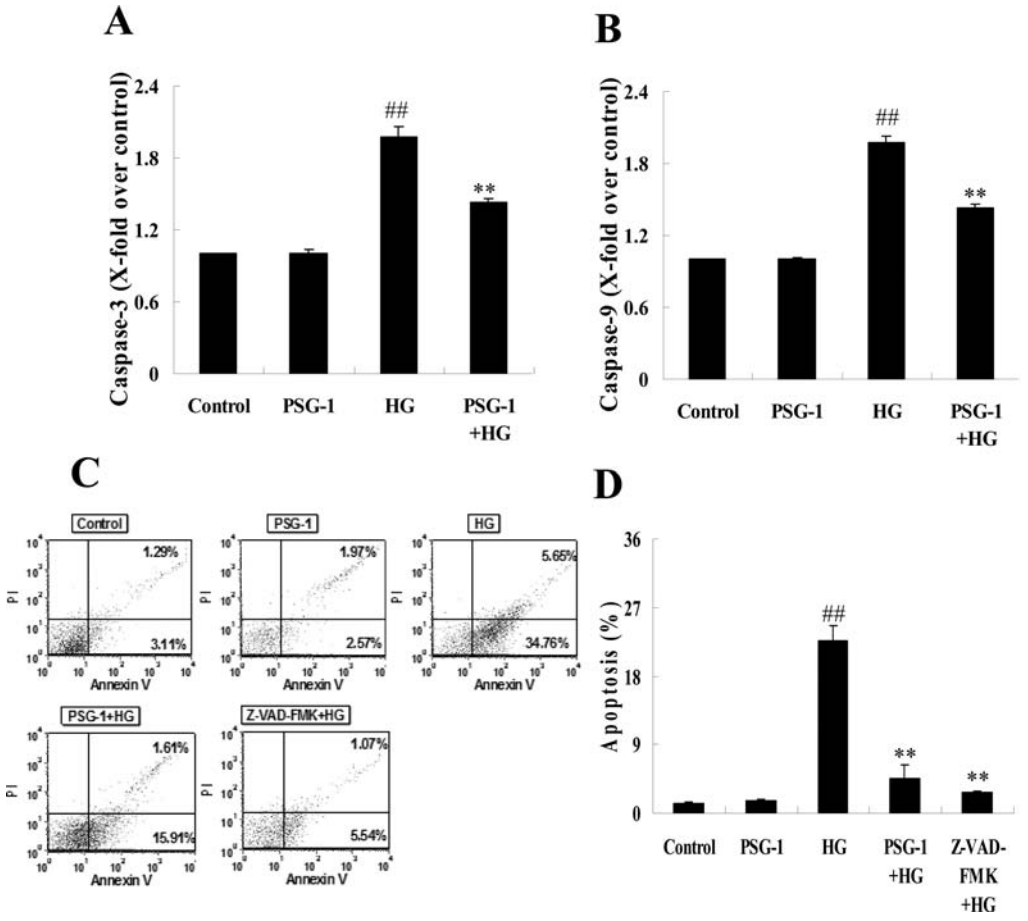

Figure 5. Effects of PSG-1 on caspase activity in HUVECs subjected to high glucose (HG). (A and B) Effects of PSG-1 on the activities of caspase-3 and caspase-9. (C and D) Effects of caspase inhibitor "Z-VAD-FMK" or PSG-1 on apoptosis in HUVECs subjected to HG. ##P < 0.01 vs the control group; *P < 0.05, **P < 0.01 vs the HG group.

Effects of PSG-1 on Caspase Activity in Endothelial Cells. Caspase activation is believed to play an important role in the execution of apoptosis.[30] We found that the activities of caspase-3 and caspase-9 were significantly increased by the high glucose treatment (Figure 5A and B). PSG-1 was found to attenuate the activation of both caspases produced by high glucose. PSG-1 therefore may protect endothelial cells against apoptosis by attenuation of caspase activation. Meanwhile, high glucose-induced apoptosis (Figure 5C and D) was alleviated by treatment with caspase inhibitor "Z-VAD-FMK" (20 μmol/L). These results suggested that high glucose-stimulated apoptosis was caspase-dependent and that PSG-1 could reduce caspase activation.

DISCUSSION

Diabetic angiopathy has been defined as endothelial dysfunction and is recognized as the main complication of diabetes.[31] The present study was designed to investigate the role of a novel *Ganoderma atrum* polysaccharide, PSG-1, in the cell damage of hyperglycemic endothelial cells. We have shown, for the first time, that PSG-1 inhibits endothelial dysfunction by ameliorating mitochondrial damage and apoptosis in high glucose-stimulated endothelial cells.

There is also mounting evidence that hyperglycemia-induced oxidative stress resulting from the overproduction of ROS is a major factor contributing to the development and progression of diabetic angiopathy. Overproduction of ROS is a factor in hyperglycemia-induced angiopathy, but its role in the apoptotic process has not been elucidated. Our results have demonstrated a rapid increase of the ROS levels is associated with a significant increase of apoptosis. This would indicate that enhancement of ROS production is an essential factor for hyperglycemia-induced apoptosis in endothelial cells. Because enhancement of ROS generation can cause apoptosis in high glucose conditions, we have, therefore, examined whether inhibiting ROS production with the potent antioxidant and free radical scavenger NAC can prevent apoptosis in sustained high glucose systems.[32,33] Our results showed that addition of NAC did inhibit apoptosis and added to the evidence that oxidative stress resulting from overproduction of ROS plays a crucial role in hyperglycemia-induced apoptosis. Having demonstrated that PSG-1 did alleviate oxidative stress by the attenuation of ROS generation both *in vitro* and *in vivo*,[9,10] we have therefore further investigated whether endothelial cells are similarly influenced in the context of hyperglycemia. We found that decreased levels of ROS generation led to a reduction in apoptosis and cell injury, indicating that attenuation of ROS generation could enable PSG-1 to be effective against diabetic angiopathy.

The mitochondria generate a steady stream of ROS, which is particularly susceptible to oxidative stress.[34] In the present study, we found that high glucose-treated endothelial cells showed marked changes in several parameters of the mitochondrial function. Interestingly, these changes were

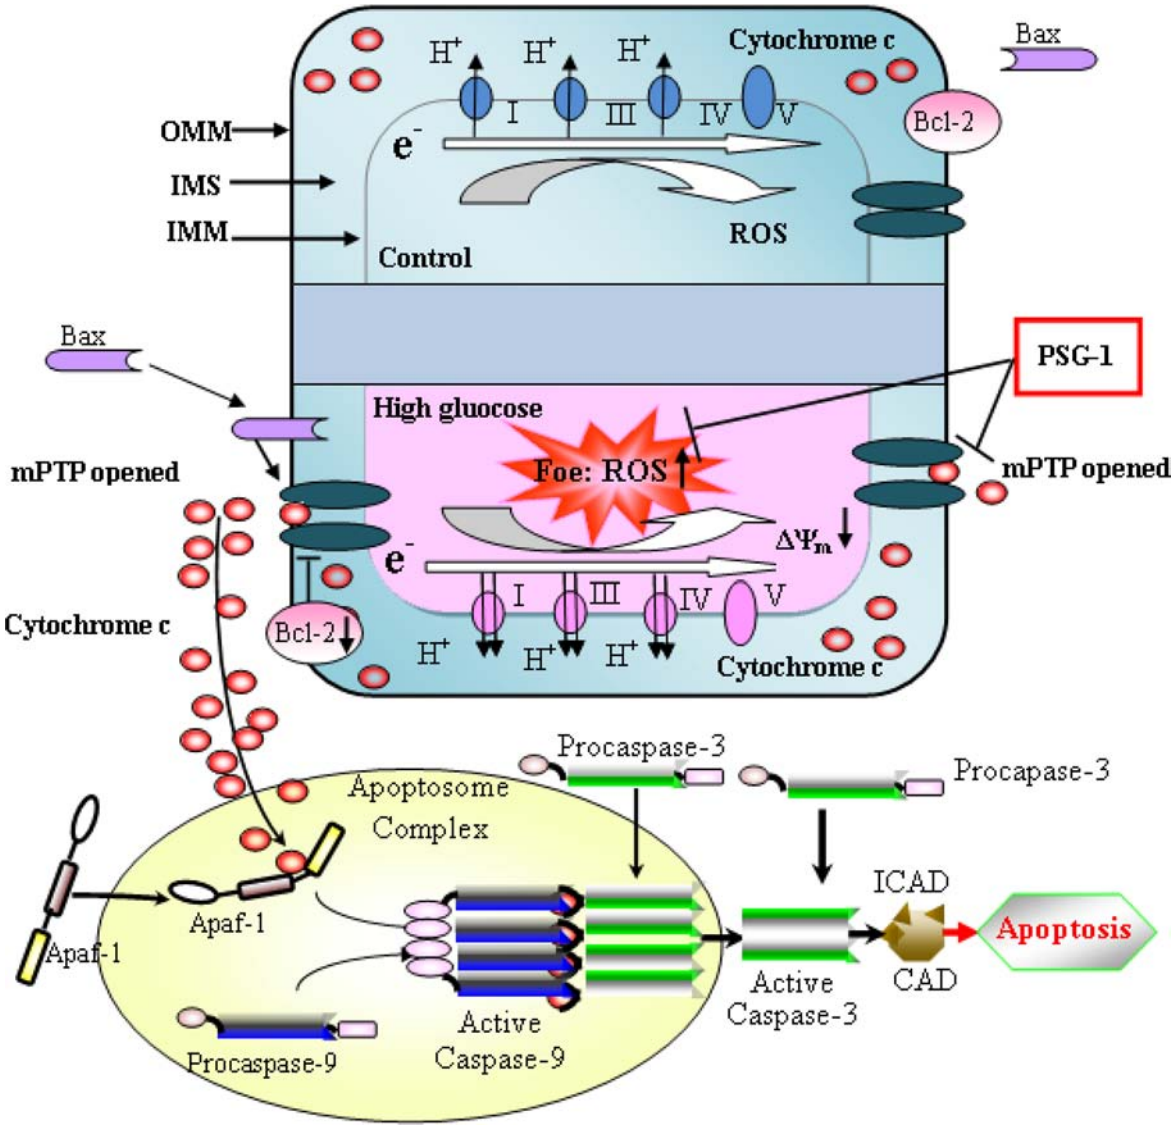

Figure 6. Schematic model for the cellular mechanisms of PSG-1 on the amelioration of apoptosis induced by high glucose in HUVECs. Mitochondria are the primary source of ROS, which are produced by the mitochondrial electron transport chain (ETC). A low level of ROS was generated by the mitochondrial electron transport chain (ETC), and mPTP remains closed under normal conditions. However, under high glucose conditions, ROS are generated in excess and raised to a level that leads to the opening of mPTP. Moreover, the opening of mPTP could trigger the enhancement of ROS generation. These changes coincide with the alteration of Bcl-2 family and the loss of ΔΨm, resulting in cytochrome *c* release and caspase-9 activation. Caspase-9 activation in turn triggers the caspase-3 activation, which subsequently executed apoptosis. Accordingly, PSG-1 could ameliorate endothelial cell damage in response to high glucose via preventing the overproduction of ROS and opening of mPTP. Red circle, cytochrome *c*; IMS, intermembrane space; OMM, outer mitochondrial membrane; IMM, inner mitochondrial membrane; ICAD, inhibitor of caspase-activated deoxyribonuclease; CAD, Caspase-activated deoxyribonuclease.

significantly ameliorated by PSG-1, as evidenced by enhancing the activity of mitochondrial dehydrogenase and maintaining ΔΨm, indicating that PSG-1 may improve mitochondrial function in endothelial cells under high glucose conditions.

In response to overproduction of ROS, the outer mitochondrial membrane becomes permeable, which leads to the loss of ΔΨm, triggers the release of cytochrome *c* from mitochondria to the cytoplasm, and activates the mitochondrial apoptotic pathway.[35] It was consistent therefore that there was a significant decrease in ΔΨm in high glucose conditions in endothelial cells. We also found that release of cytochrome *c* from mitochondria to the cytoplasm was significantly increased. Incubation of endothelial cells with PSG-1 for 1 h significantly attenuated the effect of high glucose on the loss of ΔΨm and release of mitochondrial cytochrome *c*. The Bcl-2 family, which includes both antiapoptotic and proapoptotic proteins, acts as a checkpoint upstream for mitochondrial apoptosis. Antiapoptotic proteins promote cell survival, whereas proapoptotic proteins mediate mitochondria-dependent apoptosis. Bax and Bcl-2, the two main members of this family, influence the permeability of the mitochondrial membrane. Upon apoptotic stimulation, Bax, a pore-forming cytoplasmic protein, translocates to the outer mitochondrial membrane, changes its permeability, and induces cytochrome *c* release from the mitochondria to the cytosol. The antiapoptotic Bcl-2 is associated with the outer mitochondrial membrane where it stabilizes the membrane permeability and thus suppresses the release of cytochrome *c*.[26,35,36] During high glucose-induced apoptosis, a decrease of mitochondrial Bcl-2 expression and distribution of Bax from the cytosol to mitochondria were

DOI: 10.1021/acs.jafc.5b03462
J. Agric. Food Chem. 2015, 63, 8182−8191

observed in endothelial cells. Significantly, the PSG-1 treatment decreased the alteration of Bcl-2 family protein expression in the endothelial cells stimulated by high glucose.

The Bcl-2 family dependent changes in the permeability of the mitochondrial membrane that resulted in the loss of $\Delta\Psi$m and the release of cytochrome *c* are mediated by a high-conductance channel, mPTP. Although Hunter and Haworth in the late 1970s first observed and described mPTP, its function in the vascular complication of diabetes has still not been clarified.[18,37−39] The present study was designed to further explore the role of mPTP in high glucose-induced apoptotic cell death. Our results not only supported the idea of an increase in the opening of mPTP as one of the key events during apoptotic cell death in high glucose but also suggested that mPTP may be an oxidative stress-sensitive channel opened by increased ROS production. Therefore, we have investigated whether inhibition of the opening of mPTP may prevent apoptotic cell death under high glucose conditions. Treatment with CsA significantly inhibited cell death under high glucose conditions, which supported the view that opening of mPTP may play a critical role in high glucose inducing cell death. PSG-1 also inhibited the opening of mPTP with an efficacy similar to that of CsA. PSG-1 can thus influence the oxidative stress-related opening of mPTP, which points to novel insight into the potential therapeutic targets for PSG-1 intervention.

During transduction of an apoptotic signal into the mitochondria, the apoptotic protein of cytochrome *c* is translocated into the cytoplasm, which leads to the activation of caspase-9. Active caspase-9 then activates caspase-3, which contributes to the execution of apoptosis.[40−42] In keeping with these observations, our results showed that high glucose-induced apoptosis was accompanied by a significant increase of caspase-9 and caspase-3 activities, compared with cells under control conditions. Likewise, PSG-1 treatment significantly decreased the high glucose-induced activation of both caspases. Since the final pathway that contributes to the execution of cell death signal is caspase activation, we used a caspase inhibitor Z-VAD-FMK to treat the endothelial cells under high glucose conditions. We found that the caspase inhibitor significantly decreases high glucose-stimulated apoptosis, which suggested that high glucose-induced apoptosis in the endothelial cells might be caspase-dependent, which could be alleviated by PSG-1.

Overall, we have provided *in vitro* evidence about the effects of the *Ganoderma atrum* polysaccharide, PSG-1, on diabetic angiopathy. These interesting findings suggested that PSG-1 alleviated HG-associated cell dysfunction by its effect on the modification of the redox system and implied that antioxidant effects of PSG-1 might be related to its protective effect against vascular dysfunction. On the basis of these results, we have drawn up a schematic model (Figure 6) for the effects of PSG-1 on endothelial cells under high glucose conditions, which describe how ROS production and the opening of mPTP are centrally involved in apoptosis and diabetic angiopathy. Accordingly, PSG-1 could ameliorate endothelial cell damage in response to high glucose via a mitochondria-reactive oxygen species pathway. Meanwhile, factors affecting the permeability of the mitochondrial membrane have a profound influence on cell survival and cell death. Future work is necessary to investigate the molecular basis of the relationship between mPTP and the health benefits of PSG-1 against diabetic angiopathy. Together, these findings make PSG-1 an attractive candidate as a new interventional approach for diabetic angiopathy.

the Iwate University Animal Research Committee and conformed to the Guidelines for Animal Experiments of Iwate University.

Experimental Design and Experimental Diets. *Experiment 1.* A total of 20 rats were allowed free access to tap water and were provided with a 20% (w/w) casein diet based on AIN-93G[11] for 12 days. On day 13, the rats were fasted for 18 h and then fed a control diet (Table 1; 20C, 20% casein diet; 10C, 10% casein diet) or experimental diet (Table 1; 20CK, Lys-rich 20% casein diet; 10CK, Lys-rich 10% casein diet) for 1 h (9:00−10:00). After 3 h of fasting (10:00−13:00), each rat was anesthetized with pentobarbital, then its abdomen was opened, and blood was collected from the inferior vena cava. Each rat was euthanized after the collection of blood. The blood was centrifuged at 3500*g* for 15 min to obtain plasma, which was frozen in liquid nitrogen and stored at −80 °C until analysis. The soleus muscle, extensor digitorum longus (EDL) muscle, and gastrocnemius muscle were removed from the hind leg and weighed.

Table 1. Compositions of the Control and Experimental Diets

	control and experimental diets			
	20C	20CK	10C	10CK
	Ingredient (g/kg of diet)			
milk casein[a]	200	200	100	100
L-lysine[b]	0	6.5	0	6.5
L-cystine[b]	3.0	3.0	3.0	3.0
sucrose[c]	100	100	100	100
α-cornstarch[a]	529.5	523.0	629.5	623.0
soybean oil[c]	70	70	70	70
mineral mixture[a]	35	35	35	35

total Lys[d]	1.30	1.95	0.65	1.30

[a]Obtained from the Oriental Yeast Co., Tokyo, Japan. [b]Obtained from the Ajinomoto Co., Tokyo, Japan. [c]Obtained from the Toyo Sugar Refining Co., Tokyo, Japan. [d]Total Lys was calculated from the sum of Lys contained in casein[11] and the amounts of supplemented Lys with diet.

Experiment 2. A total of 10 rats were allowed free access to tap water and were provided a control (Table 1; 10C, 10% casein diet) or experimental (Table 1; 10CK, Lys-rich 10% casein diet) diet for 15 days. During this period, the food consumption of rats fed the Lys-rich diet was adjusted to that of rats fed the standard 10% casein diet. Excreted urine was collected for 24 h from the morning of the 13th day to the morning of the 14th day; thereafter, the experimental design was the same as for experiment 1. On the 15th day, the rats were fasted for 18 h and then provided a 10% casein diet or Lys-rich 10% casein diet for 1 h and skeletal muscles and blood were collected 3 h later.

Measurement of Myofibrillar Proteolysis. 3-Methylhistidine (MeHis) released from the isolated muscles was measured as described previously[8] by incubating the isolated EDL muscle or soleus muscle in Krebs-Ringer bicarbonate buffer containing 10 mM glucose under 95% O_2/5% CO_2 at 37 °C for 2 h after a 30 min preincubation at 37 °C. The amount of MeHis in the incubation buffer solution was measured using a high-performance liquid chromatography (HPLC) method.[12]

The plasma concentration of MeHis provides an index of myofibrillar proteolysis[13] and was measured by HPLC after derivatization with *o*-phthalaldehyde using the method of Nagasawa et al.,[14] with a slight modification.

The amount of MeHis in urine, commonly used as an index of myofibrillar proteolysis,[15] was measured by HPLC as described by Nagasawa et al.[13,16] It has been proposed that skeletal muscle accounts for 40% of the entire body mass of rats and that 700 nmol of MeHis is present in 1 g of skeletal muscle.[15] Therefore, we expressed our results as a fractional degradation rate (K_d) calculated using the following formula:

$$K_d\ (\%) = 100E/[0.4(W + W_0)700/2]$$

where E (nmol) is the amount of MeHis excretion over 24 h, W_0 (g) is the whole body weight when urine collection started, and W (g) is the whole body weight when urine collection finished.

Measurement of Plasma Amino Acid Concentrations. Plasma was mixed with an equal volume of 3% sulfosalicylic acid during overnight at 4 °C, and then the mixture was centrifuged at 18000*g* for 15 min. Plasma amino acid concentrations in the supernatant were measured using an amino acid autoanalyzer (JLC-500/V, JEOL, Tokyo, Japan).

Measurement of the Plasma Insulin Concentration. The plasma insulin concentration was measured using an enzyme-linked immunosorbent assay (ELISA) according to the protocol (Morinaga Institute of Biological Science, Yokohama, Japan).

Western Blot Analysis. Western blot analysis was performed as reported previously.[8] Gastrocnemius muscle was homogenized in 10 volumes of buffer solution followed by centrifugation at 3800*g*. The supernatant was used as the sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) sample and was separated on a 10% polyacrylamide gel, followed by transfer to a polyvinylidene fluoride (PVDF) membrane (Millipore Corporation, Billerica, MA). The membrane was blocked for 1 h with 5% skim milk in Tris-buffered saline (TBS) containing 0.1% Tween 20 (TBS-T) at room temperature. The membrane was incubated overnight at 4 °C with primary antibodies, and then the membrane was incubated with HRP-conjugated goat anti-rabbit IgG or HRP-conjugated goat anti-mouse IgG in TBS-T. After detection, the membrane was stained with Coomassie Brilliant Blue (CBB) to verify that equal quantities of each protein had been transferred.

Gene Expression of E3 Ubiquitin Ligases. mRNA expression of E3 ubiquitin ligases was assessed by northern blotting as described previously.[8] A total of 10 μg of total RNA extracted from the gastrocnemius muscle were separated on a 1.2% agarose−formaldehyde gel and transferred to a positively charged nylon membrane (Pall Corporation, Port Washington, NY). After ultraviolet (UV) cross-linking, the membranes were hybridized with a digoxigenin-labeled cDNA probe specific to MuRF1, atrogin-1, or glyceraldehyde-3-phosphate dehydrogenase (GAPDH) for 16 h at 50 °C in hybridization solution. Specific hybridization was detected with an anti-digoxigenin antibody conjugated with alkaline phosphatase, and blots were developed with CDP-star reagent (Tropix, Bedford, MA).

Statistical Analysis. Data are expressed as the mean with standard error of the mean (SEM). Data analysis was performed using GraphPad InStat software, version 3.0a (2001, GraphPad Software, Inc., San Diego, CA). Data were analyzed by analysis of variance (ANOVA) and Tukey's post-test in multi-group (more than three groups) comparisons to determine whether there were significant differences ($p < 0.05$) among the groups. Comparisons of two groups were performed using unpaired *t* tests, and the two-tailed *p* value was calculated.

RESULTS

Experiment 1. *Lys-Rich 10% Casein Diet Suppressed the Rate of Proteolysis and Autophagy Activity.* The average food intake for 1 h after 18 h of fasting on the final day did not differ between the groups [20C, 4.4 ± 0.6 g (average ± SE); 20CK, 4.5 ± 0.1 g; 10C, 4.4 ± 0.1 g; and 10CK, 4.3 ± 0.2 g]. The rates of MeHis released from isolated muscles (EDL and soleus muscles) and the plasma MeHis concentration significantly increased in rats fed the standard 10C diet compared to rats fed the 20C diet (panels A and B of Figure 1). However, the values of MeHis in rats fed the 10CK diet were lower than those in the 10C group (panels A and B of Figure 1), whereas

DOI: 10.1021/acs.jafc.5b03811
J. Agric. Food Chem. 2015, 63, 8192−8198

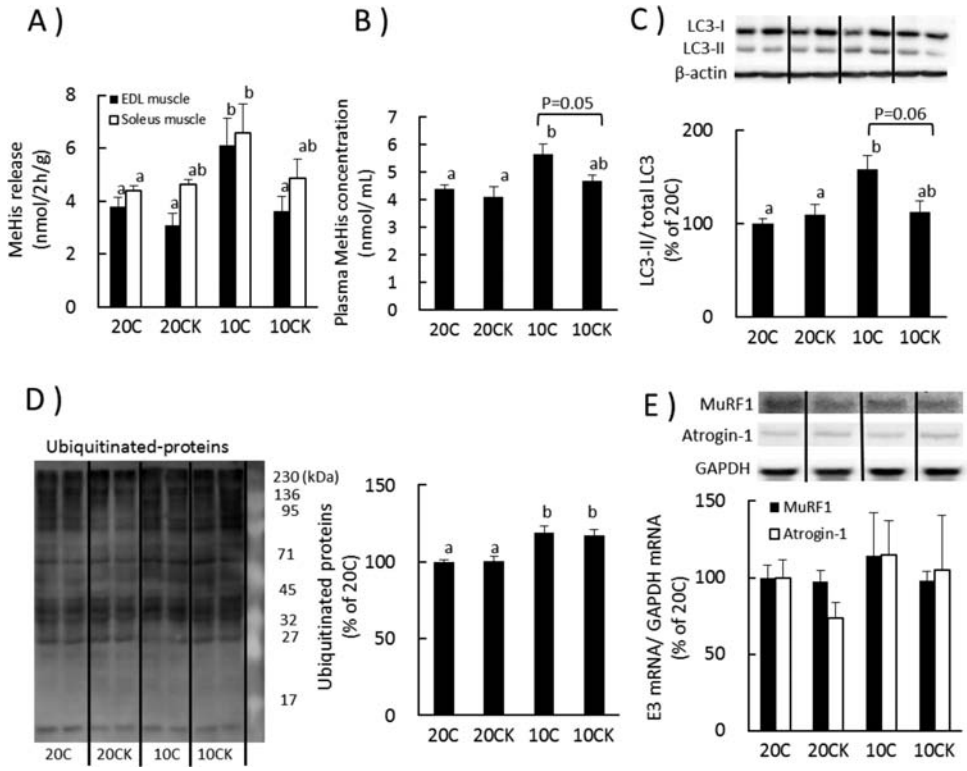

Figure 1. Bolus intake of a Lys-rich 10% casein diet suppresses proteolysis and autophagy. Rats were fed a standard 20% casein diet (20C), Lys-rich 20% casein diet (20CK), standard 10% casein diet (10C), or Lys-rich 10% casein diet (10CK) for 1 h and then fasted for 3 h. (A) Rate of myofibrillar proteolysis was evaluated from the amount of MeHis released from isolated EDL muscle (black bars) or soleus muscle (white bars). (B) Plasma concentration of MeHis was also used as an index of proteolysis. (C) Autophagy activity was evaluated from LC3-II/total LC3 by western blotting. Activity of the ubiquitin−proteasomal system was evaluated from (D) levels of ubiquitinated proteins determined by western blotting and (E) mRNA levels of the E3 ubiquitin ligases, MuRF1 (black bars) and atrogin-1 (white bars), determined by northern blotting. Values are means with SE (n = 5). Different letters indicate significant differences among the groups ($p < 0.05$).

supplementation of Lys to the 20% casein diet did not affect the rate of proteolysis (panels A and B of Figure 1).

We evaluated autophagy activity from the light chain 3 (LC3)-II/total LC3 ratio,[17] and ubiquitin−proteasomal system activity was assessed from the levels of ubiquitinated proteins and the mRNA expression of the E3 ubiquitin ligases, muscle RING-finger protein 1 (MuRF1) and atrogin-1. Consistent with the rate of proteolysis (panels A and B of Figure 1), autophagy activity was suppressed by 45% in rats fed the 10CK diet compared to those fed the standard 10C diet (Figure 1C). The levels of ubiquitinated proteins significantly increased in rats fed the low-protein diets (Figure 1D), despite the same amount of protein being transferred to the membrane for all groups (evaluated by CBB staining; data not shown). Lys supplementation did not suppress ubiquitin−proteasomal activity (panels D and E of Figure 1). These results indicated that supplementing Lys with the 10% casein diet suppresses autophagic proteolysis.

Lys-Rich 10% Casein Diet Stimulated Akt Phosphorylation and Recovered mTOR Signaling Activity. The phosphorylation level of Akt Thr308 increased by 32% in rats fed the 10CK diet compared to rats fed the 10C diet (Figure 2B). A similar increase was observed for Ser473 phosphorylation in Akt (Figure 2B). The mTOR signaling activity was evaluated from the phosphorylation levels of eIF4E-binding protein 1 (4E-BP1) and p70 ribosomal protein S6 kinase 1 (S6K1), which are downstream targets of mTOR. mTOR signaling activity (both of 4E-BP1 and S6K1) in rats fed the 10C diet decreased by 30% compared to rats fed the 20C diet, but supplementation of the 10C diet with Lys restored mTOR signaling activity (panels C and D of Figure 2). This activation effect of Lys on Akt/mTOR signaling was not observed in rats fed the 20CK diet (panels B−D of Figure 2). The phosphorylation level of eukaryotic initiation factor 2 α (eIF2α), which increases in amino-acid-limited conditions and regulates translation and autophagy,[18,19] did not differ among the groups (Figure 2E). These results indicated that supplementing Lys with 10% casein suppressed autophagy through Akt/mTOR signaling activation. On the other hand, the phosphorylation level of eIF2α tended to decrease in 20CK (Figure 2E). Therefore, supplementing Lys with a high-casein diet may stimulate protein synthesis through a mTOR-independent pathway.

Lys-Rich 10% Casein Diet Did Not Affect the Plasma Concentrations of Insulin and Basic Amino Acids Other than Lys. The plasma Lys concentration was significantly higher in rats fed Lys-rich diets (10CK and 20CK) compared to those fed the standard diets (10C and 20C) (Figure 3A). However, the plasma concentrations of two basic amino acids, histidine (His) and arginine (Arg), were unaffected by Lys supplementation of the diet (panels B and C of Figure 3) nor was the plasma insulin concentration affected (Figure 3D). The plasma concentration of amino acids other than Lys did not differ between the standard diet group and the Lys-rich diet group (20C versus 20CK and 10C versus 10CK), whereas the plasma threonine, asparagine, valine, isoleucine, leucine, phenylalanine, and tryptophan concentrations in rats fed the 10C diet were significantly lower than those fed the 20C diet

DOI: 10.1021/acs.jafc.5b03811
J. Agric. Food Chem. 2015, 63, 8192−8198

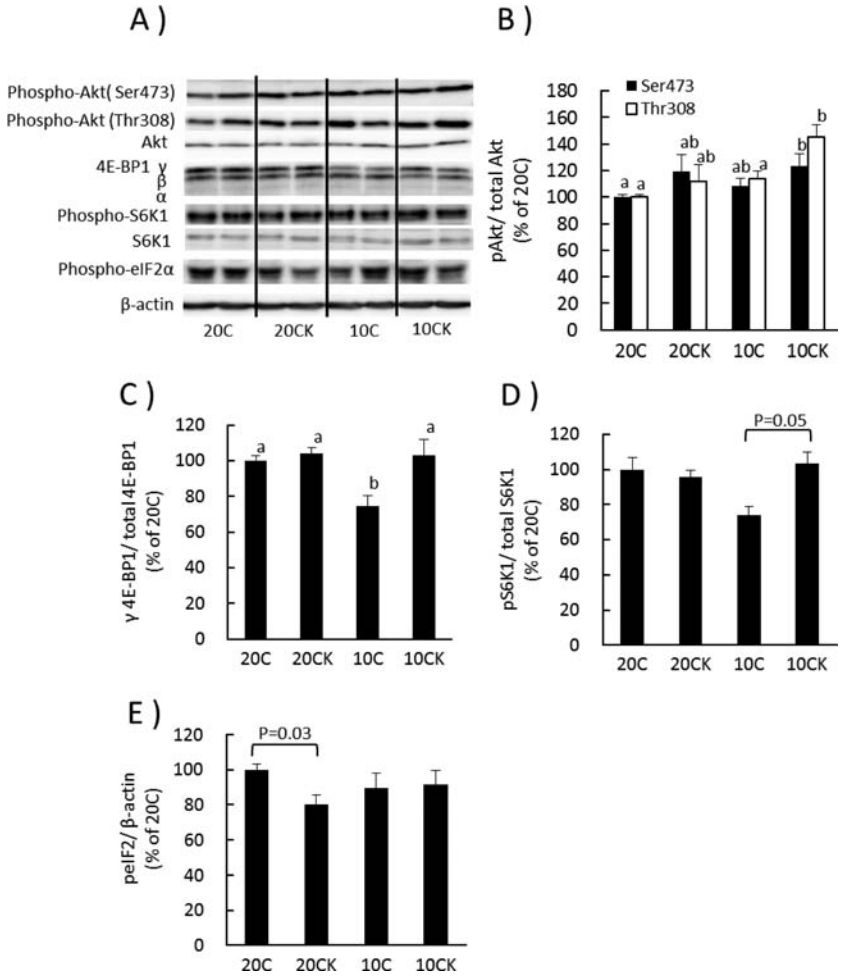

Figure 2. Supplementation of Lys into a 10% casein diet increases Akt phosphorylation and improves the activity of mTOR signaling. Rats were fed a standard 20% casein diet (20C), Lys-rich 20% casein diet (20CK), standard 10% casein diet (10C), or Lys-rich 10% casein diet (10CK) for 1 h and then fasted for 3 h. (A) Representative blots of the detected proteins are shown. Phosphorylation of Akt Ser473(B, black bars), Akt Thr308(B, white bars), (C) 4E-BP1, (D) S6K1, and (E) eIF2α were analyzed by western blotting. Results are expressed as the level relative to the control group. Values are means with SE (n = 5). Different letters indicate significant differences among the groups ($p < 0.05$).

(20C or 20CK versus 10C or 10CK) (panels B and C of Figure 3 and data not shown). These results indicated that the suppressive effect of Lys on autophagy did not depend upon the increase of insulin or other amino acids than Lys.

Experiment 2. *Continuous Intake of the Lys-Rich 10% Casein Diet Increased Skeletal Muscle Mass.* We investigated whether the continuous intake of a Lys-rich diet results in increased skeletal muscle mass in experiment 2, given that bolus intake of a Lys-rich diet suppressed proteolysis (panels A–C of Figure 1) and restored Akt/mTOR signaling activity (panels A–D of Figure 2) in experiment 1. The average food intake per day by rats fed the 10C diet was 9.6 ± 0.6 g (SE) (62 mg of total Lys/day), and those fed the 10CK diet was 9.9 ± 0.6 g (SE) (129 mg of total Lys/day). As expected, 15 days of Lys-rich diet intake significantly increased the masses of the soleus and gastrocnemius muscles, whereas the final body weight and mass of the EDL muscle did not increase (panels A–C of Figure 4). The weights of the soleus and gastrocnemius muscles adjusted for body weight in rats fed the Lys-rich diets also tended to be higher than those of rats fed the corresponding control diet (p = 0.07 and 0.09, respectively). The rate of proteolysis was calculated from the amount of MeHis excreted in the urine and was suppressed by 33% in rats fed Lys-rich diets (Figure 4D). Similarly, autophagy was reduced by 30% in rats fed Lys-rich diets (Figure 4E). These results indicated that continuous intake of the Lys-rich 10% casein diet increased skeletal muscle mass through inhibition of autophagy.

DISCUSSION

A low-protein diet causes loss of skeletal muscle, and Leu has attracted attention as a dietary supplement, which preserves muscle mass in mammals fed a low-protein diet. Yin et al.[20] showed that supplementation of Leu to a low-protein diet (10% whey protein-based diet, 1.88% total Leu) improved protein synthesis in pigs. Similar results have been reported in rats[21] and humans.[22] In addition, it was reported that intake of a 10% whey diet supplemented with Leu (6% total Leu) resulted in increased skeletal muscle mass,[23] although supplementation of Leu to a 20% whey protein diet did not result in increased muscle mass in mice.[24] To our knowledge, there has been no previous study investigating supplementation of a single amino acid other than Leu that diminishes muscle mass loss caused by a low-protein diet.

We previously showed that oral administration of Lys by gavage (114 mg/100 g of body weight) markedly suppressed the rate of proteolysis in fasted rats,[8] and therefore, we

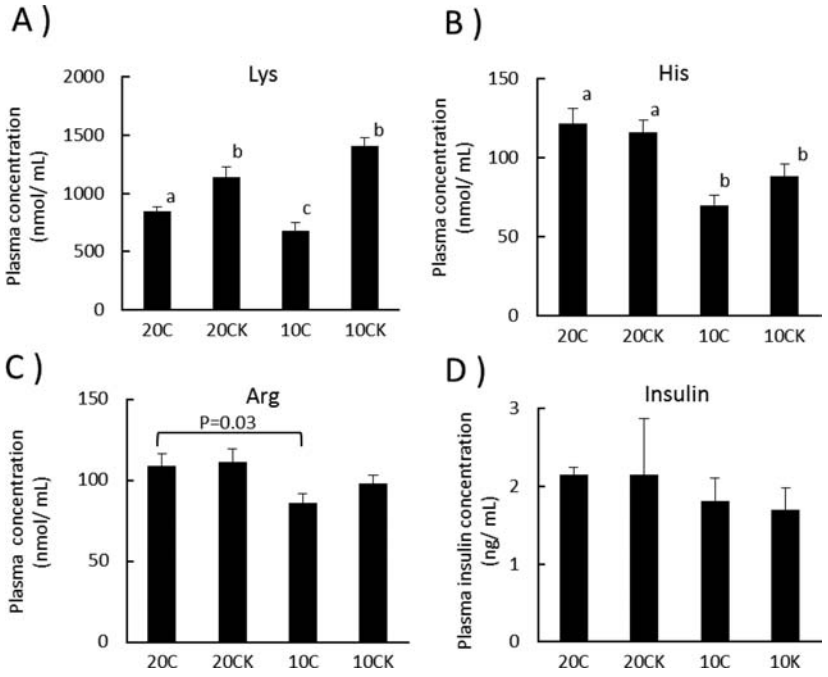

Figure 3. Supplementation of Lys into a 10% casein diet increases the plasma concentration of Lys, but the concentrations of histidine, arginine, and insulin remain unchanged. Rats were fed a standard 20% casein diet (20C), Lys-rich 20% casein diet (20CK), standard 10% casein diet (10C), or Lys-rich 10% casein diet (10CK) for 1 h and then fasted for 3 h. Plasma concentrations of (A) Lys, (B) His, and (C) Arg were measured using an amino acid autoanalyzer, and (D) insulin concentration was measured by ELISA. Values are means with SE (n = 5). Different letters indicate significant differences among the groups ($p < 0.05$).

anticipated that Lys may be a useful dietary supplement for decreasing muscle mass loss. In this study, we supplemented Lys with a low-protein diet and investigated the suppressive effect of dietary Lys on proteolysis, autophagy, and the loss of muscle mass induced by intake of a low-protein diet in rats.

The effect of dietary Lys on proteolysis was evaluated from the rate of proteolysis by measuring MeHis released from isolated muscles (EDL and soleus muscles), the plasma concentration of MeHis, and the amount of MeHis excreted in the urine. In addition, the activity of autophagy, a major proteolytic system,[25] was evaluated from LC3-II/total LC3 (because LC3-II localizes at the autophagosome membrane[17]). First, we investigated the suppressive effect of a bolus intake of a Lys-rich diet on proteolysis and on proteolytic systems (autophagy and the ubiquitin−proteasomal system) after fasting. Supplementation of Lys with the 10% casein diet clearly suppressed the rate of proteolysis and autophagy activity stimulated by the intake of a low-protein diet (Figure 1), whereas the activity of the ubiquitin−proteasomal system[25] was not suppressed by a Lys-rich diet (panels D and E of Figure 1). Therefore, the present results indicate that supplementing Lys with the 10% casein diet would suppress autophagy but not the ubiquitin−proteasomal system, consistent with our previous studies.[8−10] This is the first demonstration that supplementation of Lys to a low-protein diet suppresses proteolysis and autophagy. On the other hand, the supplementation of Lys to the 20% casein diet did not affect the rate of proteolysis or autophagy (panels A−C of Figure 1). The rates of proteolysis and autophagy in rats fed the 20% casein diet were likely suppressed sufficiently, regardless of amino acid supplementation.

We continuously provided a Lys-rich low-protein diet to rats for 15 days and investigated the effect of Lys supplementation into the diet on muscle mass. The continuous feeding of a Lys-rich diet significantly increased the masses of the soleus and gastrocnemius muscles (panels B and C of Figure 4); furthermore, the rate of proteolysis, evaluated from MeHis excreted in the urine, was significantly suppressed by intake of a Lys-rich diet (Figure 4D), as was autophagy (Figure 4E). These results indicate that continuous feeding of a Lys-rich low-protein diet can preserve the mass of skeletal muscle.

Akt is an important regulator of autophagy. Zhao et al.[26] showed that Akt and not mTOR is the central regulator of autophagic proteolysis in skeletal muscle cells. It has been reported that Leu stimulates Akt[9,10,27−31] and that Leu supplementation increased muscle mass and Akt/mTOR signaling activity in rats suffering from malnutrition.[32] We previously demonstrated that Lys suppresses autophagy and activates mTOR signaling, which regulates autophagy through Akt in C2C12 myotubes.[10] In this study, we observed significant phosphorylation of Akt Thr308, which regulates Akt activity,[33−35] in rats fed a Lys-rich diet (Figure 2B). In addition, the activity of mTOR signaling was recovered in rats fed a Lys-rich 10% casein diet, although the activity of mTOR signaling activity decreased in rats fed a standard 10% casein diet (panels C and D of Figure 2). Therefore, a Lys-supplemented diet likely regulates autophagy through the Akt/mTOR signaling pathway in rats fed a low-protein diet.

Akt is phosphorylated through the insulin signaling pathway,[36] and Lys activates the secretion of insulin.[37−39] However, the plasma insulin concentrations of rats fed a Lys-rich diet did not increase (Figure 3D). We previously showed that Lys markedly phosphorylated Akt in the absence of insulin.[9,10] Hence, Akt would be stimulated by an insulin-independent pathway in rats fed a Lys-rich diet.

We previously showed that oral administration of glycine, which is the same nitrogen level of Lys, did not suppress the rate of protein degradation in fasted rats.[8] In addition, we

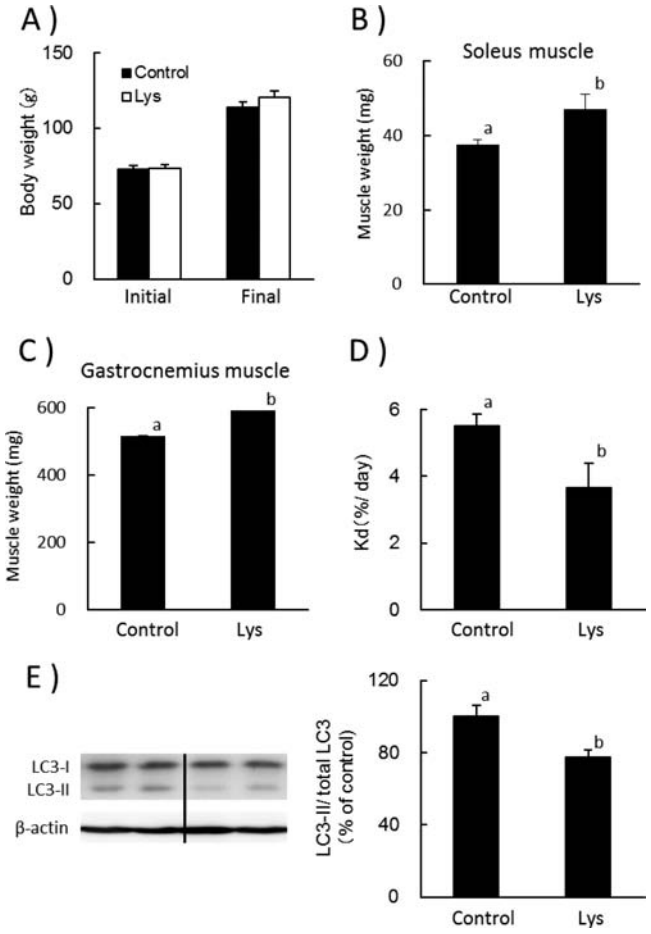

Figure 4. Continuous feeding of a Lys-rich 10% casein diet results in increased muscle mass and suppresses proteolysis and autophagy. Rats were fed a standard 10% casein diet or a Lys-rich 10% casein diet for 15 days. Urine was collected for 24 h, from the morning of the 13th day to the morning of the 14th day. (A) Initial body weight was measured at the start of feeding the control (black bars) or experimental (white bars) diets, and final body weight was measured prior to dissection. The weights of the (B) soleus and (C) gastrocnemius muscles were measured following dissection. (D) Amount of MeHis excreted in urine was measured by HPLC. (E) Autophagy activity evaluated from LC3-II/total LC3 was analyzed by western blotting. Values are means with SE (n = 5). Different letters indicate significant differences among the groups (p < 0.05).

demonstrated that the same molar dose of glycine could not regulate proteolysis, autophagy, and mTOR signaling activity in the C2C12 myotube.[9,10] Therefore, the effect of Lys on proteolysis and autophagy may not depend upon nitrogen uptake.

In conclusion, we demonstrated that supplementation of Lys to a 10% casein diet regulates autophagic proteolysis and Akt/mTOR signaling and continuous feeding of a Lys-rich diet may suppresses muscle mass loss caused by the intake of a low-protein diet. Tesseraud et al. indicated that a Lys-deficient diet induced stimulation of protein degradation in the muscle of chicks.[40] However, they did not show whether supplementing Lys with a diet suppresses proteolysis in skeletal muscle, and the effects of Lys on autophagy and the ubiquitin−proteasomal system were not demonstrated. Therefore, this is the first study that reported supplementing Lys with a low-protein diet suppresses autophagic proteolysis in mammals. Furthermore, we observed recovery of the mTOR signaling activity, which regulates translation in rats fed a Lys-rich low-protein diet compared to rats fed a standard low-protein diet (panels C and D of Figure 2). Therefore, the stimulation of protein synthesis might contribute to the increase of muscle in rats fed a Lys-rich low-protein diet. Supplementing Lys with a low-protein diet might be a beneficial strategy for preventing skeletal muscle loss in chronic kidney disease patients advised to adhere to a low-protein diet. Moreover, the present results may help overcome stunting caused by low-quality dietary protein.

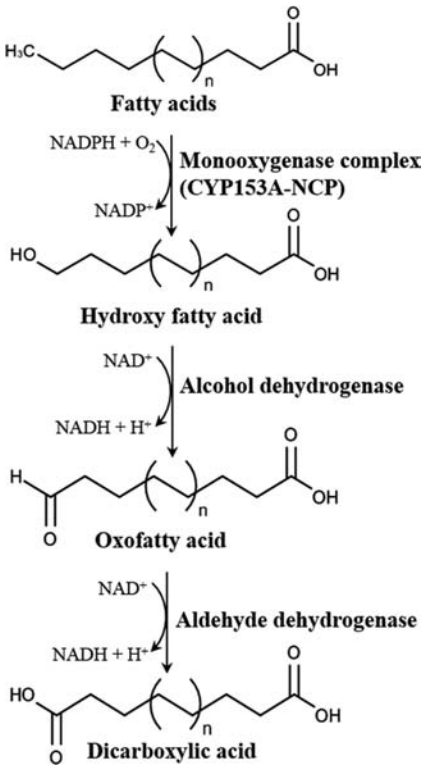

Figure 1. ω-Oxidation pathway. Biotransformation of fatty acids by the sequential oxidation of the terminal methyl group yields the dicarboxylic acid product. Protein ID (Genbank): CYP153A (ABM17701.01); NADPH:cytochrome P450 oxidoreductase (ACZ37122.1); alcohol dehydrogenase (AAA344101.1); and aldehyde dehydrogenase (U.S. Patent no. WO 2013006730 A2).

improve the fatty acid uptake, resulting in high productivity.[18,19] In addition to this, to obtain the maximum yield, the toxicity of accumulated H_2O_2 has to be reduced.[6,16] To the best of our knowledge, to date there are no reports of the production of α,ω-DCAs directly from fatty acid substrates, through utilization of a CYP450-dependent ω-oxidation pathway in *Escherichia coli*, a highly versatile organism that has been widely used for heterologous protein production and for genetic recombination studies because of its rapid growth and potential for high-density cultivation on inexpensive substrates. Additionally, its well-characterized genetics and the availability of an increasingly large number of cloning vectors and mutant host strains make *E. coli* an attractive model for genetic studies.[20] *E. coli* has been demonstrated as a suitable host for heterologous monooxygenase related reactions, including CYP153A, and exhibited higher catalytic activities and product yields when compared to other hosts, such as *Pseudomonas*.[16,21,22] Moreover, using *E. coli* as a host for heterologous expression of CYP450s is advantageous, as *E. coli* lacks endogenous CYP450s that could interfere with heterologous P450 expression. The present study exploits the advantages of the *E. coli* model system to demonstrate a novel biotechnology system that efficiently produces long-chain α,ω-dicarboxylic acids (C12 and C14) from fatty acids by introduction of the ω-oxidation pathway into *E. coli*.

MATERIALS AND METHODS

Microbial Strains and Plasmids. The wild-type *E. coli* MG1655 strain (laboratory stock) was used as the parental strain for all genetic modifications, including gene knockouts and introduction of expression constructs. The *E. coli* DH10B strain (laboratory stock) was used for cloning. *Marinobacter aquaeolei* (DSMZ, DSM 11845), *B. megaterium* (Korean Culture Center of Microorganisms, KCCM 11745), *Saccharomyces cerevisiae* (Korean Collection for Type Cultures, KCTC 7296), and *C. tropicalis* (American Type Culture Collection, ATCC 20336) were procured from the indicated cell culture collection centers. The Biobrick plasmids, pBbA6C and pBbE6K (A = p15A replicon; E = colE1 replicon; 6 = PLlacO promoter; C = chloramphenicol resistance; and K = kanamycin resistance), were used for expression constructs.[23]

Chemicals, Enzymes, and Culture Conditions. All chemicals, including fatty acids and DCAs, were purchased from Sigma-Aldrich (St. Louis, MO). Restriction enzymes (New England Biolabs, Ipswich, MA), DNA ligase (New England Biolabs, Ipswich, MA), and Phusion high-Fidelity DNA polymerase (Thermo Fischer Scientific, Waltham, MA) were used for cloning and plasmid construction. Oligonucleotides were synthesized by Macrogen (Korea). Microbial cells were grown at 37 °C (30 °C for strains carrying temperature-sensitive plasmids) in Luria−Bertani (LB) broth supplemented with suitable antibiotics (kanamycin at 50 μg/mL, ampicillin at 100 μg/mL, or chloramphenicol at 30 μg/mL).

Strain Construction. Knockout of *fadR* and *fadE* in MG 1655 was performed using the lambda Red and FLP-mediated site-specific recombination system as described previously.[24] Primers used for gene deletion and cloning are shown in Table 1. The monooxygenase (CYP153A), NADPH:cytochrome P450 oxidoreductase (NCP), alcohol dehydrogenase, and aldehyde dehydrogenase were amplified using Phusion high-Fidelity DNA polymerase from the genomic DNA of *M. aquaeolei* (DSM 11845), *B. megaterium* (KCCM 11745), *S. cerevisiae* (KCTC 7296), and *C. tropicalis* (ATCC 20336).

First, the fusion construct components of CYP153A from *M. aquaeolei* and NCP from *B. megaterium* were amplified using the primers Maq_F and Maq_R and NCP_F and NCP_R, respectively, and these two genes were linked by overlap extension PCR with a 3xGGS tandem region in the linker between CYP and NCP.[16] The pBbA6C-FP plasmid was constructed by cloning of the fusion construct (CYP-NCP) into the *Bgl*II and *Xho*I site of the pBbA6C plasmid. The *Pseudomonas putida*-alkane transporter gene (*alkL*) was synthesized and cloned into pGEM-B1 by Bioneer (Korea). *AlkL* was then amplified using primers AlkL_F and AlkL_R from the pGEM-B1 plasmid. Subsequently, *Pvu*I- and *Xho*I-digested pBbA6C-FP and *alkL* were ligated to generate the pBbA6C-FP/AlkL plasmid. Alcohol dehydrogenase (*ADH1*) was amplified from *S. cerevisiae* (KCTC 7296) using primers ADH1_F and ADH1_R, and aldehyde dehydrogenase (*ALD5*) was amplified from *C. tropicalis* (ATCC 20336) using primers ALD5_F and ALD5_R. These two genes were linked by overlap extension PCR and cloned into the *Nde*I/*Xho*I site of the pBbE6K plasmid to study the activities of ADH and ALD on the first intermediate of ω-oxidation pathway, ω-hydroxy fatty acid. Subsequently, primers ALD_F and ADH1_R were used to amplify *ADH1* and *ALD5* from the pBbE6K plasmid; these products were then digested with *Xho*I. Finally, the *Xho*I digested pBbA6C-FP/AlkL plasmid and the ALD-ADH PCR product were ligated to yield the final construct, the pBbA6C-ω plasmid. For biotransformation studies, pBbA6C-ω was transformed into MG1655:Δ*fadE* or MG1655:Δ*fadR*:Δ*fadE*, which were designated as Eω and REω, respectively.

Protein Expression and SDS-PAGE Analysis. Protein expression in recombinant cells, grown until OD_{600} reached 0.5, was induced with 0.1 mM of isopropyl β-D-1-thiogalactopyranoside (IPTG). After incubation at 25 °C for 16 h, the cells were collected, sample loading buffer was added, and the mixture was heated at 95 °C for 20 min. The whole cell lysate samples were run on 10% sodium dodecyl sulfate-polyacrylamide gels. Protein bands were visualized by staining with Coomassie Brilliant Blue R-250.

Whole Cell Biotransformation. A single colony of recombinant *E. coli* cells (Eω and REω strains) was selected and grown overnight in 5 mL of Luria−Bertani (LB) medium at 37 °C with rotation at 200 rpm. Five hundred microliters of the culture was inoculated into 50 mL of LB medium and grown overnight at 37 °C with rotation at 200 rpm. Subsequently, this culture was inoculated (1:100) into 1 L of Luria−Bertani (LB) medium, and expression of target genes was induced with 0.1 mM IPTG in addition to 0.25 mM of 5-aminolevulinic acid (ALA) at an OD_{600} of 0.5−0.6. Following the addition of IPTG and ALA, temperature was reduced to 25 °C to facilitate soluble expression of the target genes, with rotation at 200 rpm for 20 h. The recombinant cells were harvested by centrifugation at 12 000*g* for 15 min at 4 °C, washed twice with potassium phosphate buffer (0.1 M, pH 7.4), and used as biocatalysts in the biotransformation studies. The biotransformation was conducted in 250 mL shake flasks by adding a fatty acid (C12 or C14) substrate stock solution containing 20% of FA in DMSO to a final concentration of 1g/L into 0.1 M potassium phosphate buffer (pH 7.4) containing the following: 50 g_{cww}/L of the induced resting cells, 0.5% Tween 80, 1X filter sterilized trace element solution[25] (g/L: 2.4 g of $FeCl_3 \cdot 6H_2O$, 0.3 g of $CoCl_2 \cdot H_2O$, 0.15 g of $CuCl_2 \cdot 2H_2O$, 0.3 g of $ZnCl_2$, 0.3 g of $Na_2MO_4 \cdot 2H_2O$, 0.075 g of H_3BO_3, and 0.495 g of $MnCl_2 \cdot 4H_2O$), and 30 μg/mL of chloramphenicol. The biotransformation was carried out in the presence and absence of cosubstrates (1% (w/v) glycerol and 0.4% (w/v) D-glucose). The biotransformations were conducted in a shaking incubator (30 °C and 200 rpm), and samples were collected at different time points for product quantification and identification by (gas chromatography) GC.

Effects of Temperature on DCA Production. To examine the effect of temperature on DCA production, the biotransformation was conducted at 25, 30, and 37 °C using the engineered *E. coli* strain, REω. Biotransformations were conducted in a shaking incubator (200 rpm), samples were collected at different time points, and products were quantified using GC.

Biotransformations in Mini-Bioreactor. Because REω performed better in shake flask conditions than did Eω, REω was used for further biotransformation studies that were carried out in a homemade, mini-bioreactor (250 mL capacity) that had precise monitoring and control systems for pH, temperature, and agitation speed. The biotransformation medium and conditions were maintained as for the shake flask experiments. Agitation speed was set at 1200 rpm. The biotransformations were conducted at 30 °C, and samples were collected every 2 h for product quantification by GC.

Effects of 5-Aminolevulinic Acid and Thiourea on DCA Production. To determine the effect of heme precursors, such as 5-aminolevulinic acid (ALA), on the production of DCA, 0.25 mM ALA and 0.1 mM IPTG were added at the time of heterologous gene induction in REω. For analyzing the effects of thiourea, thiourea was added to the biotransformation reaction for a final concentration of 1 mM.[6] The biotransformations were conducted in a shaking incubator (30 °C and 200 rpm), and samples were collected at different time points for product quantification by GC.

Production of LDCAs from Coconut Oil Hydrolysate. Coconut oil was hydrolyzed according to the method described by Chua et al.[26] with slight modifications. Briefly, the reaction mixture contained 10 mL of coconut oil (Samchun, Korea), 1.75 mL of distilled water, 13.25 mL of hexane, and 0.25 g of lipase lipozyme from *Mucor miehei* (Sigma-Aldrich, St. Louis, MO). The mixture was incubated at 40 °C with rotation at 200 rpm for 12 h. After hydrolysis, water and hexane were removed by rotary evaporation at 60 °C. The resulting residue was used for biotransformation studies with REω. The biotransformation medium and conditions were maintained as described in a previous section. The biotransformations were conducted in a shaking incubator (30 °C and 200 rpm), and samples were collected for product identification by GC.

Product and Data Analysis. For the quantification and identification of α,ω-DCAs, the cell-free supernatant from the culture media of recombinant *E. coli* was acidified with HCl. DCAs produced through biotransformation were extracted twice with an equal volume of ethyl acetate containing 1 g/L methyl nonadecanoate (C19 FA) as an internal standard and then subjected to derivatization with (trimethylsilyl) diazomethane solution (TMS). The silylated derivatives were analyzed and quantified by a gas chromatograph (GC) (Agilent 7890A, U.S.) equipped with a flame ionization detector (FID) and an Agilent capillary column-DB WAX (30 m length, 0.320 mm internal diameter, 0.50 μm film thickness). The temperature program employed was 120 °C for 2 min, followed by a linear temperature gradient, increasing 10 °C/min to 220 °C. The concentration of biotransformation products was determined using calibration curves (R^2 > 0.99). Identification was performed on GC (Agilent 7890A) equipped with a mass selective detector (MSD, Agilent 5975C). Samples were prepared as for GC/FID. Mass spectra were obtained by electron impact ionization at 70 eV. The expected reaction products were identified by their characteristic mass fragmentation pattern and compared to authentic standards. All of the experimental data were subjected to one-way analysis of variance (ANOVA) or multivariate analysis of variance (MANOVA) followed by Tukey's test using SPSS (Version 11) software to determine levels of significance. Probability (P) values of <0.01 or <0.05 were considered significant.

RESULTS AND DISCUSSION

Strain Engineering. Two molecular modifications may increase DCA product yield by the ω-oxidation pathway: (1) increasing fatty acid uptake efficiency and (2) inhibition of substrate degradation by alternative pathways. Fatty acid

DOI: 10.1021/acs.jafc.5b03833
J. Agric. Food Chem. 2015, 63, 8199−8208

degradation (β-oxidation) in *E. coli* is catalyzed by enzymes encoded by the *fad* regulon, which are responsible for the transport and activation of long-chain fatty acids and their β-oxidative cleavage into acetyl-CoAs. Genes in the regulon encode for the outer-membrane-bound fatty acid transport protein FadL[27] and inner-membrane-associated protein FadD,[28] which are responsible for transport of exogenous long-chain fatty acids into the cell by a specific transport process. Genes in the *fad* regulon are repressed by *fadR*.[29] Cho et al.[30] found that the expression levels of fadL and fadD were elevated 4- and 3-fold, respectively, in the ΔfadR mutant. The degradation of imported fatty acids is avoided by deleting the critical conversion step carried out by acyl-CoA dehydrogenase (*fadE*), thus preventing the β-oxidation pathway. For this study, in the parental strain, MG1655, *fadR*, and/or *fadE* were successfully knocked out.

Additionally, the pBbA6C-ω construct was made by fusion of genes responsible for the direct conversion of fatty acids into the corresponding DCAs. The highly ω-regioselective (>95%) and catalytically active fusion construct that consists of CYP of *M. aquaeolei* and NCP of *B. megaterium*, generated by Scheps et al.,[16] was used in the present study. The linker region between CYP and NCP domains contained a native linker, found between the heme and NCP domains in self-sufficient CYP450 of *B. megaterium*. A 3xGGS region preceded the native linker, as this sequence was found to be conducive for linkage of different protein domains.[16,31] The AlkL gene of *P. putida* was engineered into the final construct to improve the fatty acid uptake efficiency.[18,19] Alcohol dehydrogenase (ADH) of *S. cerevisiae* and aldehyde dehydrogenase (ALD) of *C. tropicalis* were employed to oxidize the product of the fusion construct (ω-hydroxy fatty acids) into DCA. The activities of both ADH and ALD on the pBbE6K plasmid were analyzed by expressing them in the Δ*fadE* strain when the strain was fed with 12-hydroxydodecanoic acid (ω-hydroxy fatty acid); the product was confirmed to be 1,12-dodecanedioic acid (C12 DCA) by GC−MS (data not shown). The various genes inserted into the final construct, pBbA6C-ω, were PCR amplified and confirmed by gene sequencing (Macrogen, Korea). All of the inserted genes were expressed well and visualized as clear bands by SDS-PAGE analysis (Figure 2).

Production of Dodecanedioic Acid (C12 DCA) and Tetradecanedioic Acid (C14 DCA). Both Eω and REω *E. coli* strains were used for the production of dodecanedioic acid (C12 DCA) and tetradecanedioic acid (C14 DCA), with the supplementation of cosubstrates (glycerol or glucose), from C12 FA and C14 FA (Figure 3a). In REω, in the presence of cosubstrates, a maximum of 76 mg/L C12 DCA and 157 mg/L C14 DCA was produced in 48 h of biotransformation. REω produced 142% more C12 DCA and 204% more C14 DCA than Eω during 48 h of biotransformation. This result suggests that *fadR* deletion facilitates the transport of fatty acids into the cell via increased expression of *fadL* and *fadD*, which are responsible for FA import. REω began producing DCAs earlier in the course of biotransformation as compared to Eω. Additionally, REω produced a higher concentration of C14 DCA when compared to C12 DCA concentration ($P < 0.5$). Glycerol and glucose had inhibitory effects on the induction of alkane-degrading and DCA-producing enzymes in yeasts.[32,33] Expression of the fad regulon genes is strongly repressed by glucose via Crp, in both the presence and the absence of oleate.[30] In contrast, ω-hydroxy fatty acid (C12) was synthesized in engineered *E. coli* containing engineered CYP153A/AlkL with cosubstrates (glycerol−glucose) in biotransformation.[16]

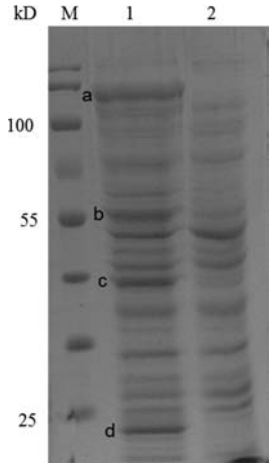

Figure 2. Expression of ω-oxidation genes. Lane M, marker; lanes 1 and 2, total fractions of REω and wild type, respectively; a, fusion protein (CYP-NCP, 120 kD); b, aldehyde dehydrogenase (ALD1, 54 kD); c, alcohol dehydrogenase (ADH5, 37 kD); and d, alkane transporter (AlkL, 25 kD). The molecular mass of each enzyme was calculated on the basis of their sequence by the online ExPasy tool.

Because REω performed better than Eω in terms of DCA production, subsequent biotransformations were carried out in REω strains without cosubstrates. REω synthesized a maximum of 150 mg/L C12 DCA and 308 mg/L C14 DCA (Figure 3b). The conversion efficiency of REω was 15% and 31% for C12 DCA and C14 DCA respectively. Notably, the final amount of DCA was about 2-fold higher than that of cosubstrate fed REω. Moreover, this concentration was already reached after just 12 h as compared to 48 h in cosubstrates fed biotransformations. This strategy is consistent with that of Song et al.,[34] wherein no cosubstrates were added for the synthesis of DCA by Baeyer−Villiger monooxygenase/esterase-based whole cell biotransformation. Jeon et al.[5] observed that the maximum product formation rate and final product concentration were greater when glucose was excluded from the biotransformation, indicating that glucose did not help convert oleic acid into 10-hydroxystearic acid. Therefore, further experiments were conducted employing REω strains without any cosubstrates.

Fasan et al.[35] previously listed the following factors as impacting the final yield in whole-cell biotransformations using P450-containing resting cells: accessibility of substrate and oxygen; toxicity of substrate, oxygen, and product; and ability of the cells to regenerate NAD(P)H. In the present study, no glucose or glycerol was used; however, these molecules are considered important for the regeneration of cofactors.[21,36] Therefore, further investigations are underway to construct a cofactor regeneration system that will circumvent the redox balance issue. In the future, this system could be effectively used along with the system presented here to achieve higher product yield.

Effects of Temperature on DCA Production. After the addition of IPTG, the temperature was reduced from 37 to 25 °C, as lower temperatures serve to control metabolic fluctuations and improve both protein solubility and activity; this therefore reduces the formation of insoluble fractions of proteins (inclusion bodies).[37] Heterologous gene expression can influence the biotransformation performance of the *E. coli*-based biocatalyst.[5] This study used three different temperatures

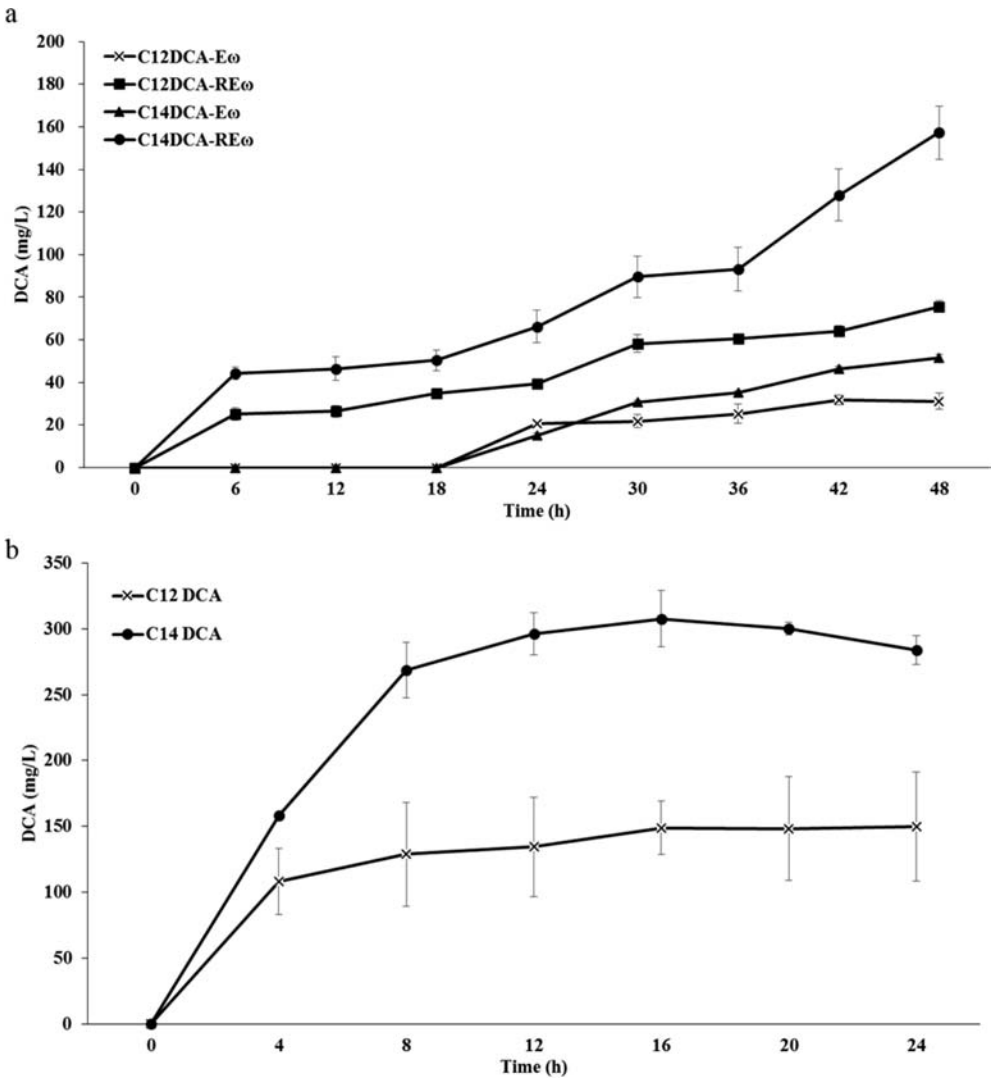

Figure 3. Production of DCAs by Eω and REω. (a) Production of C12 and C14 DCA by Eω and REω supplemented with cosubstrates. Cosubstrate mixture contains 0.4% (w/v) glucose and 1% (w/v) glycerol. (b) Production of C12 and C14 DCA by REω without cosubstrates. No product was formed in the wild-type strain. Data represent the means of three different experiments, and error bars represent standard deviation.

for biotransformations: preparation of starter cultures was performed at 37 °C, enzyme expression after induction was at 25 °C, and biotransformation occurred at 30 °C. The effect of temperature on DCA production during biotransformation was evaluated at 25, 30, and 37 °C using the engineered strain, REω. The results presented in Figure 4 show that 30 °C was the optimum temperature for biotransformation, producing the maximum titer. It was found that a maximum of 3.99- and 3.54-fold increased C12 DCA and 2.11- and 2.70-fold increased C14 DCA was obtained at 30 °C when compared to that of 25 and 37 °C, respectively. Many studies involving *E. coli* whole cell biotransformation by CYP450s are performed at 30 °C, to achieve the maximum yield.[16,38] In the present study, REω ($P < 0.05$) produced significantly more C12 DCA and C14 DCA at 30 °C than at 25 or 37 °C, confirming that 30 °C was the optimum temperature for catalytic action of ω-pathway enzymes.

Biotransformations in Mini-Bioreactor. To increase productivity, transformations were carried out in a mini-bioreactor, providing efficient mixing with an impeller at high speed. The formation of fatty acid droplets is speculated to cause inefficient transportation of the fatty acids inside the cells.[5] Efficient mixing allows improved fatty acid transport and dispersal of fatty acid droplets. The data suggest that the bioconversion rate was rapid and the level of DCA production stabilized after 8−10 h (Figure 3b). Therefore, samples were withdrawn every 2 h for 10 h. Bioreactor efficiency in regard to DCA production was compared to that in the shake flask condition (Figure 5). DCA production was improved in bioreactor when compared to the shake flask. A maximum increase of 2.61-fold C12 DCA and 1.70-fold C14 DCA production was observed in the mini-bioreactor when compared to the shake flask. The maximum titer was achieved in the bioreactor in a shorter period of time (6 h), when compared to the shake flask condition (8−10 h).

Effects of 5-Aminolevulinic Acid and Thiourea on DCA Production. In addition to the productive catalytic cycle in the monooxygenase enzyme complex, some unproductive reactions occur, as P450 inefficiency and oxidative stress yield H_2O_2 as a side-product.[17,39] In *E. coli*, accumulation of H_2O_2 is toxic and causes growth defects.[40] It has been reported that exposing *E. coli* to reactive oxygen species (ROS) such as H_2O_2 causes damage to all macromolecules, potentially damaging enzymes by oxidizing sulfhydryl and iron−sulfur moieties.

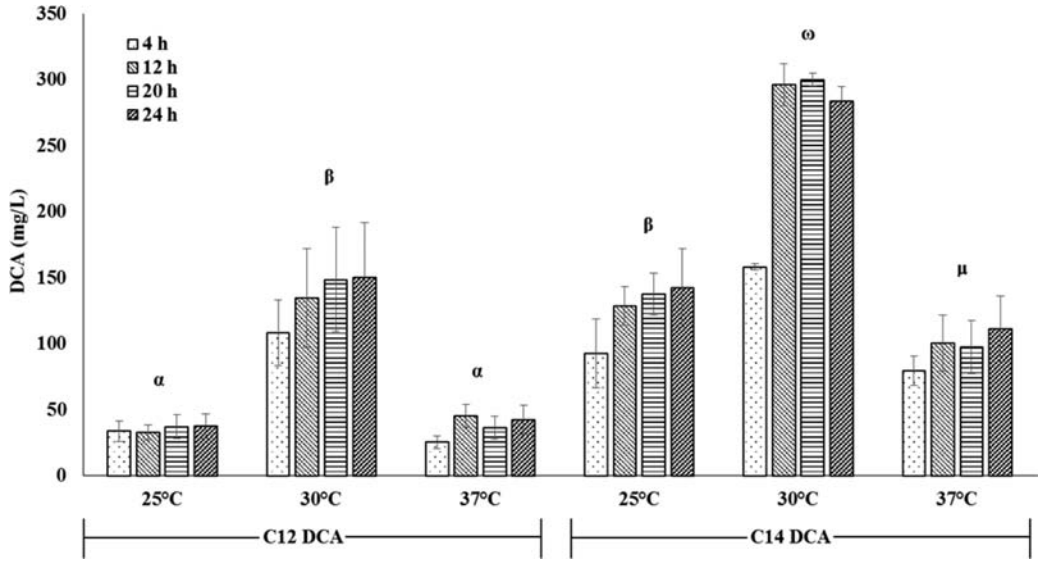

Figure 4. Effects of temperature on biotransformation of C12 and C14 FA to corresponding DCAs by REω. Temperature of 30 °C was determined to be the optimum for this biotransformation. Data represent the means of two different experiments. and error bars represent standard deviation. Different symbols above each set of bars indicate significant difference ($P < 0.05$) according to Tukey's test.

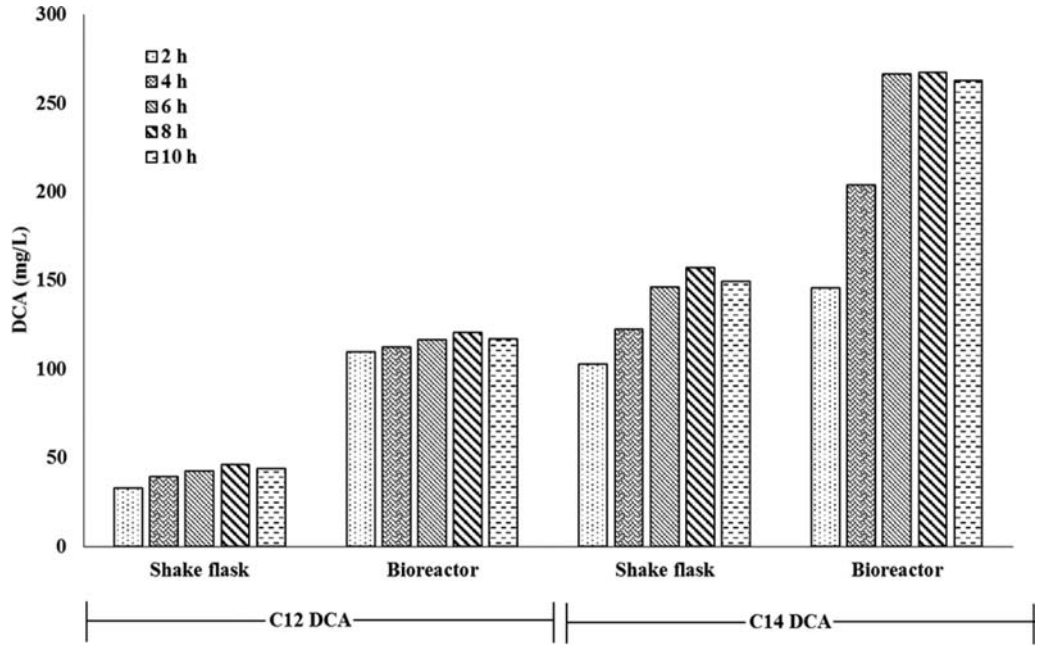

Figure 5. Production of DCAs in a mini-bioreactor by REω. C12 and C14 DCA product concentrations were increased by performing the biotransformation in the mini-bioreactor. Temperature was maintained at 30 °C and agitation speed was maintained at 1200 rpm throughout the biotransformation process.

Conversion of H_2O_2 to a hydroxyl radical can produce mutagenic and lethal lesions.[41] Scheps et al.[16] observed that a concentration of 274 μM of H_2O_2 was produced by CYP153A during production of 12-hydroxy fatty acid after 20 h of biotransformation. They also claimed that reduction in the final DCA concentration could be due to the toxicity of accumulated H_2O_2, as well as acetate. Therefore, to obtain the maximum production, the process can be equipped with a scavenging system for H_2O_2. We investigated the effect of the antioxidant reagent thiourea, which has been shown to decrease intracellular H_2O_2 concentrations, reduce the damage caused by free radicals generated from H_2O_2, and promote fatty acid utilization.[6,42] Figure 6a depicts the effect of addition of thiourea on the production of C12 and C14 DCAs. Addition of 1 mM thiourea showed an at least 7% increased C12 DCA and 33% increased C14 DCA production as compared to that of respective controls. Our results are consistent with the findings of Doi et al.,[6] wherein the authors obtained an 8.3% increase in product formation from fatty acid substrates on supplementation with thiourea.

Because the constructed CYP153A is a heme-dependent monooxygenase, the effect of heme precursors was investigated. *E. coli* does not tend to accumulate heme beyond its metabolic requirement, as free heme is toxic.[43] The effect of the heme precursor 5-aminolevulinic acid (ALA) on product concentration was evaluated by inducing the REω cells with 0.25 mM

DOI: 10.1021/acs.jafc.5b03833
J. Agric. Food Chem. 2015, 63, 8199−8208

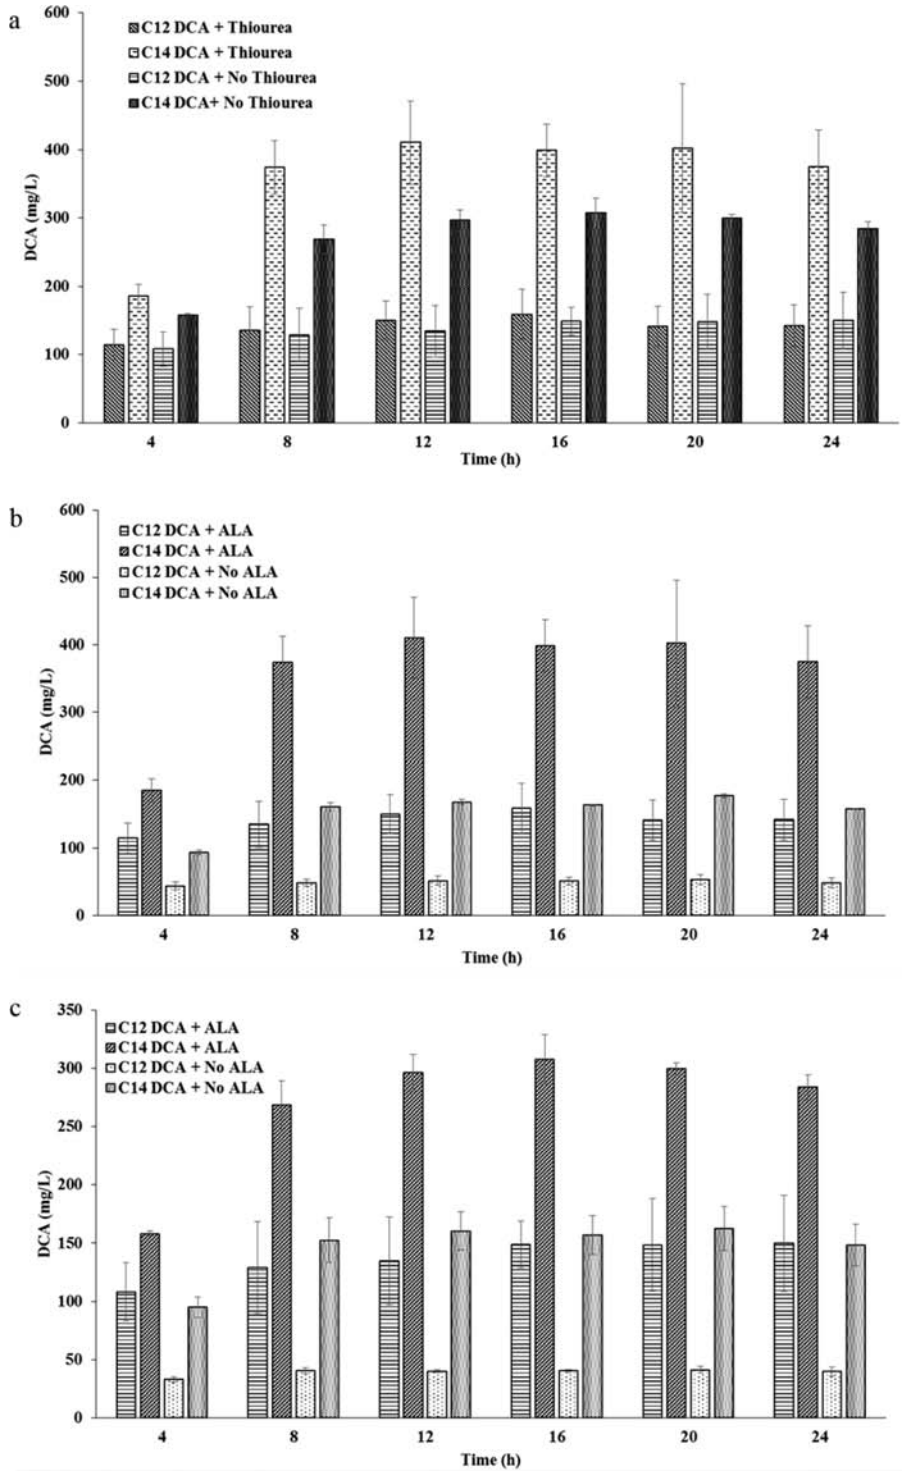

Figure 6. Effects of thiourea and 5-aminolevulinic acid (ALA) supplement on DCA production. (a) Thiourea was added to a final concentration of 1 mM during the biotransformation. Thiourea significantly ($P < 0.01$) increased the concentration of C14 DCA by REω but not C12 DCA. ALA supplementation increased product concentration in the presence (b) and absence (c) of thiourea. REω cells were induced with 0.25 mM of ALA and 0.1 mM of IPTG to induce expression of ω-oxidation pathway genes. Addition of ALA resulted in a significant difference ($P < 0.01$) in the concentration of C12 and C14 DCA when compared to the non-ALA supplemented REω. Data represent the means of three different experiments, and error bars represent standard deviation.

of ALA alongside 0.1 mM of IPTG. Figure 6b and c shows that, regardless of thiourea supplementation, addition of ALA resulted in a significant difference ($P < 0.01$) in the concentration of C12 DCA and C14 DCA when compared to the non-ALA supplemented REω. C12 DCA and C14 DCA increased by 2.98- and 2.44-fold, respectively, following addition of ALA.

Under the optimized condition, engineered *E. coli* produced a maximum of 159 mg/L C12 DCA and 410 mg/L C14 DCA, respectively, in 4−8 h shorter than corresponding controls by

J. Agric. Food Chem. 2015, 63, 8199−8208

whole cell biotransformation from fatty acids. Table 2 consolidates all of the data on the production of C12 DCA and C14 DCA under different growth conditions. We suggest that, by employing our direct synthesis of DCA system, it is possible to produce DCAs with various chain-lengths in a single reactor simply by changing the substrates. Even when increased monooxygenase expression and activity occurred following supplementation of ALA and thiourea, the amount of C12 DCA was comparatively less than that of C14 DCA. This may be due to limitation in substrate conversion efficiency during C12 DCA formation. CYP153A possessed higher substrate conversion efficiency for C14 fatty acids (80−85%) than C12 fatty acids (60−65%).[15] Apparently, high CYP450 content in biomass does not necessitate higher product yield.[36] To increase CYP450 monooxygenase-based whole cell biotransformation cost-effectiveness and feasibility for industrial production, methods for circumventing H_2O_2-dependent issues [such as overexpression of oxidative-stress regulator (OxyS)][6] and combinatorial overexpression of heme biosynthesis genes (such as *hemALDF*)[44] should be explored.

Table 2. Consolidated Data on the Production of Dodecanedioic Acid (C12 DCA) and Tetradecanedioic Acid (C14 DCA) under Different Growth Conditions[a]

	growth condition			maximum concentration of the product (mg/L)			
strain	cosubstrates	ALA	thiourea	C_{12} DCA	time (h)	C_{14} DCA	time (h)
Eω	+	+	−	32	48	52	48
REω	+	+	−	77	48	157	48
	−	−	−	41	20	163	20
	−	−	+	53	20	177	20
	−	+	−	150	24	308	16
	−	+	+	159	16	410	12
	−	−	+	121	8	267	6

[a]REω strain was selected for its efficiency over Eω strain. All of the experiments were carried out in a shake flask except the last row that was performed in a mini-bioreactor. Values are rounded off to the nearest one. Cosubstrates, 1% (w/v) glycerol and 0.4% (w/v) D-glucose; ALA, 5-aminolevulinic acid (0.25 mM); thiourea, 1 mM.

Production of LDCAs from a Fatty Acid-Rich Feedstock-Coconut Oil Hydrolysate. Plant oils are available from various oilseeds in large quantities. Various vegetable oil feedstock, including corn oil, palm oil, coconut oil, sunflower oil, olive oil, and palm kernel oil, have been evaluated for the production of one of the Bioplastic monomers, polyhydroxyalkanoate (PHA).[45] Conversion of fatty acids from renewable feedstock to specialty chemicals is an attractive commercial opportunity.[4,11] Notably, oils from nonedible crops could be used for DCA production. In the present study, the constructed synthetic biocatalytic system (REω) in *E. coli* was evaluated for production of DCAs of various chain lengths, using coconut oil as a substrate. The main purpose of using this oil was simply to demonstrate the capability and applicability of our engineered system to produce DCAs from a fatty acid-rich renewable biomass source. The routine usage of coconut oil in terms of culinary and medicinal properties likely precludes large-scale usage in DCA production; however, other plant-based oils could easily be employed using the system presented here. It was found that the coconut oil hydrolysate contained the following FAs (% w/w): C8 (5.4%), C10 (5.1%), C12 (47.68%), C14 (15.18%), C16 (7.02%), C18 (5.62%), C18.1 (7.74%). The remaining lysate portions may contain other saturated FAs and unsaturated FAs or be accounted for by incomplete enzyme digestion of oil. Subsequently, the hydrolysate was subjected to the constructed ω-oxidation pathway system (REω). The data show that the system can synthesize decanedioic acid (C10 DCA), dodecanedioic acid (C12 DCA), tetradecanedioic acid (C14 DCA), and hexadecanedioic acid (C16 DCA) from the coconut oil hydrolysate (Figure 7). Therefore, our system could be used for the production of DCAs from any plant oils high in fatty acids, including the nonedible vegetable oils.

To conclude, we engineered an *E. coli* strain capable of producing α,ω-dicarboxylic acids directly from fatty acid substrates. The constructed system could be extended to produce high value LDCAs from cost-effective renewable plant oils. Further improvements in construction of self-sufficient

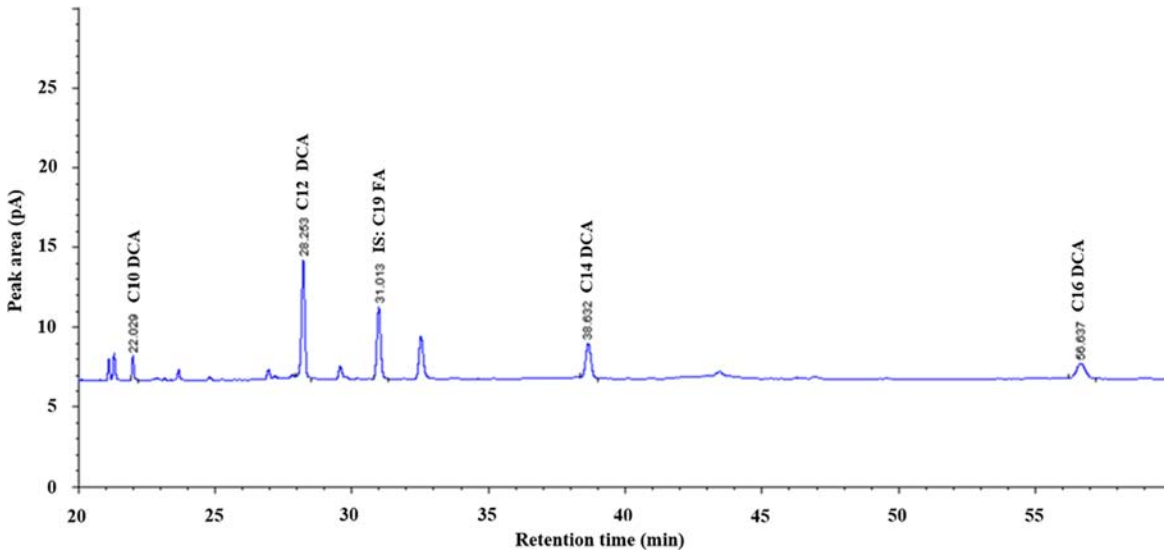

Figure 7. Gas chromatographic analysis patterns of different chain length of DCAs produced from coconut oil using the engineered *E. coli* strain REω.

DOI: 10.1021/acs.jafc.5b03833
J. Agric. Food Chem. 2015, 63, 8199−8208

strains could make the process more economically feasible. Although the utilization of fats and oils for the production of industrial chemicals/monomers is an emerging field, the process has to be industrialized and scaled up to cope with product cost, environmental concerns, available feedstock, and sustainable industrial processes. We suggest that the engineered microbial system presented here could serve as an efficient platform for the industrial production of α,ω-dicarboxylic acids.

According to sequence analysis, OVMG contains 13 potential N-glycosylation sites,[17,20] but this has not been confirmed experimentally yet. The present study explored the glycosylation of OVMG using mass spectrometry and two-dimensional electrophoresis (2-DE). OVMG was purified from fresh egg white, and the molecular weight of the OVMG subunit was measured by MALDI-TOF MS; thus, the mass of carbohydrate moieties was calculated. Then, OVMG was deglycosylated by PNGase F and subsequently digested by proteases, and the N-glycosylation sites were identified using HPLC-ESI-MS/MS. Finally, 2-DE analysis of OVMG was performed to display the heterogeneity of glycosylation of OVMG.

MATERIALS AND METHODS

Preparation of OVMG. Fresh hen eggs laid within 24 h from White Leghorns were used for the purification of OVMG. The operation was performed as previously described.[21] Briefly, fresh hen egg white (100 mL) was diluted with an equal volume of distilled water, followed by two-step PEG (polyethylene glycol 8000) precipitation (5−9%, w/v) to obtain OVMG-rich precipitate (P_{5-9}). Then the precipitate was dissolved in PBS and further purified by gel filtration chromatography (Sephacryl S-200 HR, GE Healthcare Biosciences AB, Uppsala, Sweden) at a flow rate of 0.75 mL/min with an automatic liquid chromatography system (JiaPeng Technology, Shanghai, China). The first peak of eluent was collected and desalted with distilled water using an Amicon Ultra-15 centrifugal filter device (100 kDa NMWL, Millipore, Bedford, MA, USA) and then stored at 4 °C. The purity of OVMG was tested by HPLC using a TSK gel G2000SWXL column (7.8 × 300 mm; TOSOH, Tokyo, Japan) with a Waters 2695 separations module (Waters, Milford, MA, USA) as previously described,[21] and the result is shown in Figure S1.

Measurement of the Molecular Weight of OVMG Subunit by MALDI-TOF MS. The molecular weight of the OVMG subunit was measured by a Bruker Reflex III MALDI-TOF mass spectrometer (Bruker Daltonik GmbH, Bremen, Germany) working in positive ion mode. A saturated solution of α-cyano-4-hydroxycinnamic acid in acetonitrile and 0.1% TFA was used for the matrix.[22,23] Purified OVMG (about 2 μM) was reduced with 10 mmol/L DTT, and then 1 μL of sample solution was mixed with 1 μL of matrix solution. The mixed solution was deposited on the stainless steel target plate and dried at room temperature. The ions were ionized under a laser intensity of 80% and accelerated with an acceleration voltage of 20 kV, then measured in a linear mode and m/z range of 40000−220000.[22]

PNGase F Deglycosylation and Protease Digestion. PNGase F digestion was performed following the instructions of the manufacturer. OVMG was dissolved in distilled water to 1.5 mg/mL and the pH adjusted to 8.0 by 100 mM NH_4HCO_3. Denatured OVMG was prepared by adding 30 μL of 0.15% SDS with 80 mM 2-mercaptoethanol to 255 μL of OVMG solution and incubating for 20 min at 95 °C. After that, the solution was kept at room temperature to cool, 15 μL of PNGase F enzyme solution (500 U/mL, Sigma-Aldrich) was then added and incubated at 37 °C overnight to release asparagine-linked oligosaccharides.[11]

Deglycosylated OVMG solution (300 μL) was alkylated with 50 mM iodoacetamide for 30 min at room temperature. Then the solution was equally divided into three parts and separately digested with trypsin, chymotrypsin, and endoproteinase Glu-C (Sigma-Aldrich) at an enzyme-to-substrate ratio of 1:50 w/w overnight at 37 °C; the reaction was then stopped by heating to 100 °C for 5 min. The samples were then lyophilized for subsequent LC-MS/MS analysis.

Identification of the N-Glycosylation Sites of OVMG Using HPLC-ESI-MS/MS. The digests (by trypsin, chymotrypsin, and Glu-C) of deglycosylated OVMG were analyzed separately to identify the N-glycosylation sites. Mass spectrometric measurements were performed by HPLC-ESI-MS/MS using an LTQ mass spectrometer (Thermo-Fisher Science, Bremen, Germany) equipped with a nanospray source and Eksigent RP-HPLC (Eksigent Technologies, Dublin, CA, USA). Ten microliters of the digests was loaded onto a PepMap C18 analytical column (75 μm × 15 cm, Dionex), and separation was carried out at a flow rate of 300 nL/min using a gradient constructed from solution A (2% ACN, 0.1% formic acid) and solution B (80% ACN, 0.1% formic acid): 2−40% B for 90 min; 40−100% B for 15 min; 100% B for 15 min. The spray voltage was set as 2.2 kV, and the temperature of the ion transfer capillary was 200 °C. The mass rangesfor the MS scan was set to m/z 200−2000. For MS/MS analysis, peptides were subjected to fragmentation by collision-induced decomposition (CID), and normalized collision energy was 35%.

For the identification of N-glycosylation sites, a matching search was performed against a local database containing the OVMG FASTA file (P20740-OVOS_CHICK) using the MASCOT search engine (Matrix Science). Types of searches were MS/MS ion search, with either trypsin, chymotrypsin, or Glu-C as the enzyme allowing up to two missed cleavages. Carbamidomethylation (C) was set as a fixed modification; deamidation (NQ) and oxidation (M) were specified as variable modifications. The data were searched with a peptide ion mass tolerance and a fragment ion mass tolerance of ±0.25 Da. Only peptides with Mascot ion score >23 ($p < 0.005$) and containing the PNGase consensus sequence (N-X-S/T, X ≠ P) were considered for further analysis.[24]

Two-Dimensional Electrophoresis and Protein Identification. 2-DE analysis was carried out with the Ettan IPGphor 3 System for the first-dimension isoelectric focusing (IEF) and the Ettan DALTSix System (GE Healthcare) for the second-dimension SDS-PAGE. Sample (100 μL, 80 μg of protein) was loaded onto DryStrip IPG strips (24 cm; pH 4−7) and isoelectrically focused for a total of 64000 Vh per gel using the same conditions previously described (20 °C; 300 V for 0.5 h, 700 V for 0.5 h, 1500 V for 1.5 h, 9000 V for 3 h, and 9000 V for 5 h).[25] After equilibration to resolubilize proteins and reduce disulfide bonds, the second-dimension electrophoresis was performed using a 10% SDS-PAGE. The gels were run at 2 W per gel for 40 min and followed by 17 W per gel for approximately 4 h. Protein spots on 2-DE gels were visualized by Coomassie Brilliant Blue staining. Gel evaluation and data analysis were carried out using the Image Master V 7.0 program (GE Healthcare).[25] For identification, the candidate protein spots were excised manually from the stained gels and digested with trypsin (Promega, Madison, WI, USA). The digested peptides were extracted and then identified using a MALDI-TOF MS/MS (Bruker, Karlsruhe, Germany). Data were searched against the protein database (NCBInr, *Gallus gallus*) via the MASCOT program (http://www.matrixscience.com).[26]

Bioinformatics Analysis. To compare the N-glycosylation sites of chicken OVMG (UniProtKB accession P20740) with its homologous proteins, another nine egg macroglobulins (OVMGs) from *Aves* were selected: common turkey (G1NMI3, *Meleagris gallopavo*), duck (R0J9X6, *Anas platyrhynchos*), emperor penguin (A0A087R4G8, *Aptenodytes forsteri*), adelie penguin (A0A093NQZ9, *Pygoscelis adeliae*), dalmatian pelican (A0A091SNW1, *Pelecanus crispus*), flamingo (A0A091V5J9, *Phoenicopterus ruber*), red-legged seriema (A0A091M0T0, *Cariama cristata*), white-tailed sea-eagle (A0A091P9X7, *Haliaeetus albicilla*), and hoatzin (A0A091VDK9, *Opisthocomus hoazin*). The sequences of OVMGs were obtained from the UniProt database, and N-glycosylation sites were predicted by NetNGlyc 1.0 Server (http://www.cbs.dtu.dk/services/NetNGlyc/). Alignment of the 10 sequences was performed online (http://www.uniprot.org/align). Finally, the comparison of three representative OVMGs (chicken, P20740; turkey, G1NMI3; duck, R0J9X6) was visualized and presented by Illustrator for Biological Sequences (IBS, version 1.0).[27]

RESULTS AND DISCUSSION

Molecular Mass of Glycan Moiety in OVMG. OVMG includes a 36-residue signal peptide and a 1437-residue main chain.[17] The molecular weight (MW) of the main chain is 162.2 kDa,[20] but the measured MW of the subunit was reported from

DOI: 10.1021/acs.jafc.5b02618
J. Agric. Food Chem. 2015, 63, 8209−8215

165 to 195 kDa by different methods.[28−30] In the present study, the MW of OVMG subunit was measured by MALDI-TOF MS. As shown in Figure 1, four ion signal peaks were observed at m/z 44791, 62154, 92203, and 183297, which respectively correspond to ($[M + 4H]^{4+}$), ($[M + 3H]^{3+}$), ($[M + 2H]^{2+}$), and ($[M + H]^{+}$). Thereby, the MW of OVMG subunit is 183.3 kDa, and the MW of the glycan moiety was calculated as 21.1 kDa, accounting for 11.5% of the whole OVMG molecular.

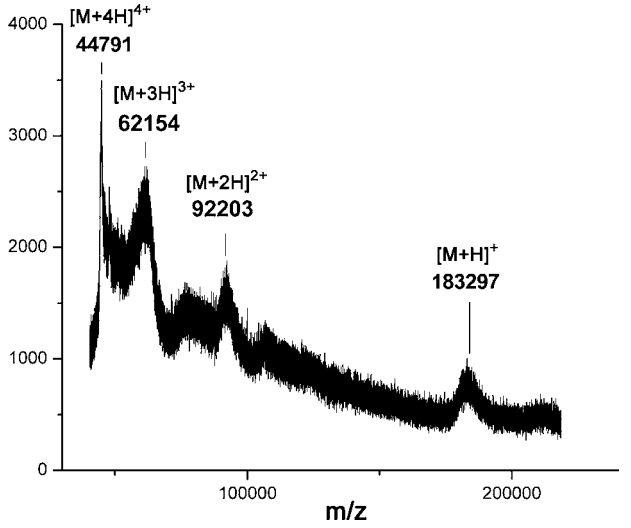

Figure 1. MALDI-TOF-MS analysis of OVMG subunit. OVMG was reduced by DTT and mixed with matrix solution, then ionized under a laser and measured by TOF MS in a linear mode. Four ion signals peaks were observed at m/z 44791, 62154, 92203, and 183297, which respectively correspond to ($[M + 4H]^{4+}$), ($[M + 3H]^{3+}$), ($[M + 2H]^{2+}$), and ($[M + H]^{+}$) of OVMG; thereby, the MW of OVMG subunit is 183.3 kDa.

This result provided a more accurate MW of OVMG and was consistent with those of sequence speculation[17] and experimental analysis.[31,32] Additionally, the full width at half-maximum (fwhm) of the molecular ion peak of OVMG subunit ($[M + H]^{+}$) was approximately 6000 (m/z), indicating the glycosylation of OVMG is not homogeneous.

By comparison with other egg white glycoproteins, the proportion of OVMG glycan is higher than those of ovalbumin, ovotransferrin, and lysozyme, but lower than those of ovomucin and ovomucoid.[10,33] Because glycans play an important role in the recognition of allergens by the immune system,[34] such a high proportion of glycans in OVMG strongly suggests that OVMG should be considered as a suspected allergen, and its potential allergenicity needs to be confirmed in future studies.

N-Glycosylation Sites of OVMG. To identify the N-glycosylation sites, OVMG was deglycosylated by PNGase F and subsequently digested by proteinase, and then the digests were analyzed by HPLC-ESI MS/MS. PNGase F cleaves N-linked oligosaccharides from glycoproteins and results in a transfer of the originally glycosylated asparagine to aspartic acid with a 0.98 Da increase in molecular weight. The mass change of peptide fragments in which the glycosylated asparagine is converted to aspartic acid can be exploited to identify N-glycosylation sites.

Table 1. N-Glycosylation Sites of OVMG Identified by HPLC-ESI MS/MS

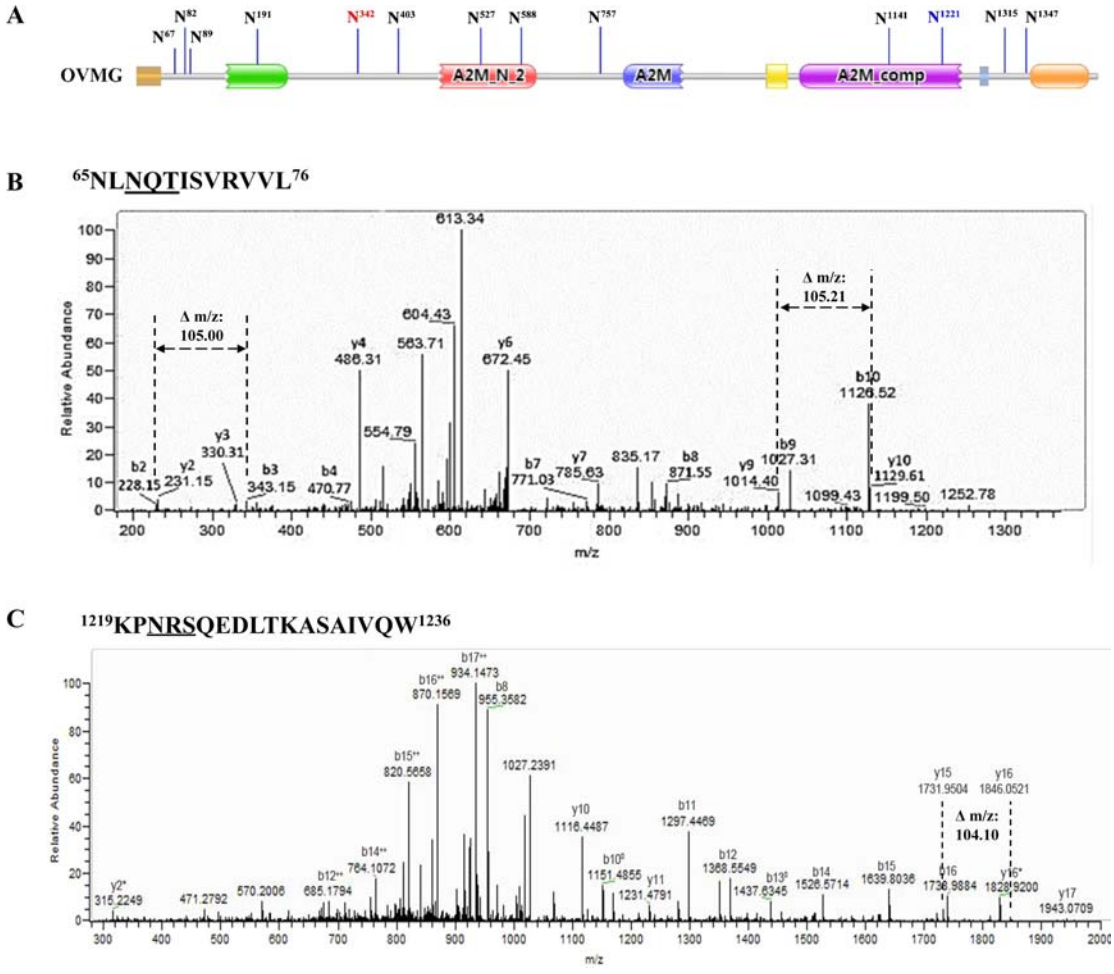

Figure 2. Location of N-glycosylation sites on OVMG and two representative MS/MS spectrums of peptides that contain the PNGase consensus sequence. (A) Location of identified N-glycosylation sites on the sequence of OVMG. Domains of OVMG were assigned by Pfam (http://pfam.xfam.org/); N^{1221} was partly glycosylated, and N^{342} was not covered in the analysis. (B) MS/MS spectrum of peptide ^{65}NLNQTISVRVVL^{76}, in which the glycosylated asparagine (Asn, N^{67}) is converted to aspartic acid (Asp); the mass difference between y10 and y9 (or b3 and b2) is 115 Da. (C) MS/MS spectrum of peptide ^{1219}KPNRSQEDLTKASAIVQW^{1236}, which does not glycosylate on its potential site (N^{1221}); the mass difference between y15 and y16 is 114 Da.

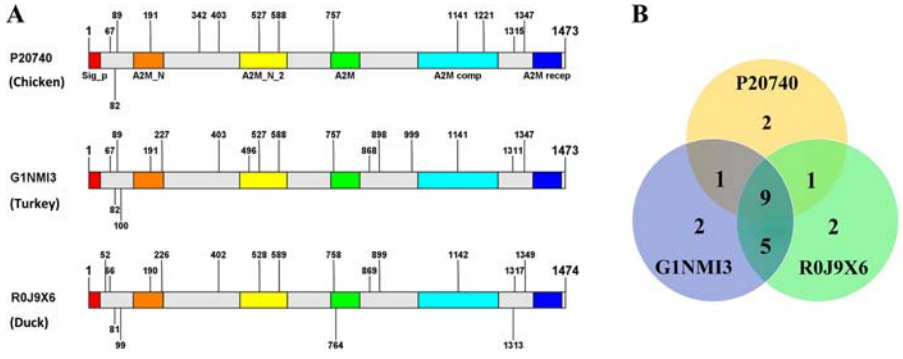

Figure 3. Comparison of OVMG N-glycosylation sites with its homologous proteins: (A) location of N-glycosylation sites on the sequence of OVMGs from chicken (P20740, *Gallus gallus*), turkey (G1NMI3, *Meleagris gallopavo*), and duck (R0J9X6, *Anas platyrhynchos*); (B) Venn diagram illustrating the number of conserved N-glycosylation sites in the three proteins.

For getting higher sequence coverage, deglycosylated OVMG was digested by three different proteases (trypsin, chymotrypsin, and Glu-C), and then digests were subjected to HPLC-ESI MS/MS. The MS/MS data were searched against a local database containing the OVMG FASTA file by the Mascot engine to identify peptides containing deglycosylated asparagines. A total of 439 peptides (Table S1) were found by the following conditions: Mascot ion score >23 ($p < 0.005$) and including PNGase consensus sequence. These peptides contain 12 N-glycosylation sites, among them, only 1 site (N^{1221}) existed in both glycosylated and not glycosylated forms, whereas all other 11 sites were glycosylated (Table 1 and

DOI: 10.1021/acs.jafc.5b02618
J. Agric. Food Chem. 2015, 63, 8209−8215

Figure 2A). Another potential glycosylation site (N^{342}) was not covered in the MS/MS analysis. Two representative MS/MS spectra of the N-glycosylation sites, N^{67} and N^{1221}, are presented in Figure 2, and other spectra of N-glycosylation sites are shown in Figure S2.

Alignment of OVMG N-Glycosylation Sites with Their Homologous Proteins. Glycosylation has an important impact on the folding, structure, and function of protein and results in the diversity of glycoproteins. To understand well the role of glycosylation in the function of a protein, glycosylated sites are indispensable information. The macroglobulin family is ancient and conservative; the BLAST protein sequence of OVMG against the UniProtKB database (http://www.uniprot.org/blast/) showed that the sequence identity between OVMGs from different species of *Aves* is >80%. Two representative bird OVMGs (G1NMI3, from common turkey; and R0J9X6, from duck) were selected, and their sequence, structural domain, and N-glycosylation sites were compared with chicken OVMG (P20740). The results were visualized and are shown in Figure 3. It was observed that the domains of these three proteins are highly conserved (Figure 3A), suggesting that they possess structural similarities. The numbers of predicted N-glycosylation sites of these three proteins are 13 (P20740), 17 (G1NMI3), and 17 (R0J9X6), respectively, and the alignment results revealed that a total of 9 predicted N-glycosylation sites were located at identical positions among all three proteins.

Interestingly, G1NMI3 has a higher sequence identity with P20740, but shares more predicted N-glycosylation sites with R0J9X6 (Figure 3B). To further explore this finding, another seven sequences of OVMGs from birds (*Aves*) were selected, and their predicted N-glycosylation sites were compared with the above three OVMGs. Results showed that total numbers of predicted N-glycosylation sites of the ten OVMGs are between 13 and 17, and chicken OVMG possesses the fewest sites (Table S2). For further analysis, we define a "conserved site" to be the N-glycosylation site that exists in more than six sequences. The alignment results revealed that the total number of conserved N-glycosylation sites of the ten OVMGs is 15. Chicken OVMG (P20740) has 10, common turkey OVMG (G1NMI3) and mallard OVMG (R0J9X6) have 13, and the other seven OVMGs have 14−15 conserved N-glycosylation sites.

The above results showed that chicken OVMG has some differences with other OVMGs with respect to N-glycosylation sites. The fewest total and conserved N-glycosylation sites indicated that chicken OVMG loses some of them, but the reason is not clear yet. Because the sequence identity of the ten OVMGs is >83%, there should be some other reasons besides the genetic factors. Among these ten species, only chicken, turkey, and duck are domesticated. The domestication of chicken began approximately 5400 BCE,[35] much earlier than that of duck (500 BCE) and turkey (300 BCE−100 CE).[36,37] Therefore, the domestication processes might play a certain role in the loss of OVMG N-glycosylation sites. Because most food allergens are glycoproteins, the loss of glycosylation sites may result in reduced food allergenicity. Recently, transcriptome analyses of carrot also suggested the human selection to reduce allergy: compared with wild carrot roots, putative allergen-related protein genes were silenced in cultivated carrot roots.[38] A systematic bioinformatics analysis is needed to confirm whether the loss of N-glycosylation sites is widespread in other domesticated animals and plants. The study of this phenomenon will provide important information for the research of food allergenicity.

The sequence identity between OVMG and mammalian macroglobulin is 39−44%.[17] Comparison of OVMG and human A2MG showed that the cysteine residues are highly conserved between these two proteins. Twenty-four of the total 27 cysteine residues of OVMG are placed at identical positions in the sequence compared with A2MG, suggesting these two proteins share a similar folding pattern and tertiary structure. In contrast, the alignment results revealed that OVMG and A2MG share only three N-glycosylation sites at positions N^{67}, N^{82}, and N^{403}. The few conserved sites implied that the differences between OVMG and A2MG, as reported in the previous research,[28,29,39] might be partly due to their difference in glycosylation sites.

Heterogeneity of OVMG Glycosylation. Glycoproteins usually exist in multiple glycoforms, and the heterogeneity is considered to affect the physical and chemical properties of the protein, immunogenicity, and biology functions. Results of MW of glycan moiety and N-glycosylation sites had revealed the heterogeneity of OVMG glycosylation. Moreover, an intuitive demonstration of the heterogeneity of OVMG was also achieved by 2-DE assay.

After expanding in 2-DE gel, OVMG showed two series of spots around the molecular weight of 170 kDa (Figure 4).

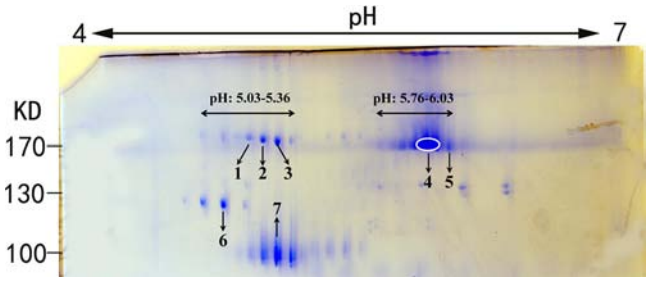

Figure 4. Visual illustration of the heterogeneity of OVMG glycosylation using 2-DE. OVMG was separated by 2-DE using 24 cm (pH 4−7) IEF strips and 10% SDS-PAGE gels. Spots were identified using MALDI-TOF MS/MS. Spots 1−5 and 7 were identified as OVMG; spot 6 was identified as ovalbumin.

Spots 1, 2, and 3 were relatively separate with p*I* values ranging from 5.18 to 5.30; spots 4 and 5 were undivided spots with a train of vertical streaks and p*I* values ranging from 5.90 to 6.05. All five spots were identified as OVMG (gil45382565, ovostatin [*Gallus gallus*]; Table 2). Spot 7, which has a molecular weight of about 100 kDa and a p*I* value range of 5.30, also was identified as OVMG, corresponding to the degradation fragment of OVMG.[28,39] The wide range of p*I* and vertical streaks could be considered as evidence of the heterogeneity of OVMG glycosylation.

The heterogeneity of glycoprotein occurs at glycosylation sites (macroheterogeneity) with variable occupancy of glycosylation sites, and the glycan profile (microheterogeneity) on each site occupied more than one kind of glycan. Combined with the N-glycosylation site results, it was initially speculated that OVMG has a low heterogeneity in N-glycan sites, but a high heterogeneity in glycan profiles.

Interestingly, spot 6, which has a MW of 123.2 kDa and a p*I* of 5.07, was identified as ovalbumin. The MW is approximately 3 times that of normal ovalbumin, indicating that ovalbumin might self-cross-link by non-disulfide covalent bonds. This kind

[a]Ovomacroglobulin also named "ovostatin".

of ovalbumin covalent aggregate also appeared in the previous comparative proteomic research of egg white proteins,[26] but how they are formed has not been studied yet. A hypothesis is that ovalbumin is oxidized during the purification process or storage, resulting in the covalent cross-linking of ovalbumin.

This study experimentally confirmed the glycosylation of chicken OVMG and reported the N-glycosylation sites for the first time. The data also demonstrated the heterogeneity of OVMG glycosylation. These results will provide valuable information to understand the bioactivity function and identify potential allergenic sites of OVMG. However, to fully characterize the glycosylation of OVMG, the glycan profile and glycopeptide structure should be investigated in the future.

emerging elicitation technology has been applied to generate fruits, vegetables, and herbs enriched with valuable phytochemicals either for fresh consumption or as a source for functional foods and nutraceuticals, causing the increased ingestion of these health-beneficial substances.[22−26] Additionally, UV radiation is a promising and clean elicitation approach that does not taint the production system and that, moreover, can be easily manipulated. Therefore, an interesting possibility is to exploit UV radiation for enhancing isoflavonoid accumulation in AMHRCs. This can satisfy consumer demand for these naturally derived health-promoting products.

The main objective of this work was to improve isoflavonoid production in AMHRCs through UV (UV-A, UV-B, and UV-C) elicitation and to obtain extracts with higher antioxidant activity for possible use in ther food, nutraceutical, pharmaceutic, and cosmetic industries. Moreover, the transcriptional expressions of genes involved in isoflavonoid biosynthetic pathway were examined to shed light on the molecular changes that took place in the elicited AMHRCs and the possible bottlenecks that controlled isoflavonoid biosynthesis. To the best of our knowledge, no information about the effect of UV elicitation on isoflavonoid accumulation, biosynthetic gene expression, and antioxidant activity in AMHRCs is currently available.

MATERIALS AND METHODS

Plant Materials and Reagents. All experiments were conducted with a highly productive *A. membranaceus* hairy root line II (AMHRL II) established previously by our laboratory.[4] Stock cultures of AMHRL II were maintained on Murashige and Skoog (MS)-based solid medium supplemented with 30 g/L sucrose and 1 g/L casein hydrolysate but without NH_4NO_3, at 25 ± 1 °C in the dark. Standard compounds including CAG, ON, ASG, CA, and FO were purchased from Weikeqi Biological Technology Co. Ltd. (Sichuan province, China). MiniBEST Plant RNA Extraction Kit, PrimeScript RT Reagent Kit, and SYBR Premix Ex *Taq*II Kit were provided by TaKaRa (Dalian, China). Ascorbic acid (VC), 2,2-diphenyl-1-picrylhydrazyl-hydrate (DPPH), linoleic acid, butylated hydroxytoluene (BHT), and β-carotene were obtained from Sigma-Aldrich Co. (Steinheim, Germany). Lamps (40 W) of UV-A, UV-B, and UV-C were bought from Beijing Institute of Electric Light Source (Beijing, China). Other reagents of either analytical or optical grade were purchased from Beijing Chemical Reagents Co. (Beijing, China).

UV Elicitation Treatments to AMHRCs. After AMHRCs were cultured under the optimal conditions described previously,[4] the spent media were then renewed. The distance of UV lamps from AMHRCs was adjusted to obtain a low intensity (3 W/m^2) monitored by a DRC-100X photometer (Spectronics, Westbury, NY, USA). The UV elicitation dose (typically in kJ/m^2) was calculated as 3 W/m^2 multiplied by the irradiation time. During elicitation experiments, cultures were divided into four groups: one being used as control at 28 ± 1 °C in the dark and the others being irradiated by UV-A (λ_{max} = 365 nm), UV-B (λ_{max} = 313 nm), and UV-C (λ_{max} = 254 nm) at 28 ± 1 °C for 4 h, that is, 43.2 kJ/m^2, respectively. Moreover, AMHRCs were harvested under a series of UV-B doses (0, 5.4, 10.8, 21.6, 43.2, 64.8, 75.6, 86.4, 97.2, 129.6, and 172.8, kJ/m^2) that were calculated as 3 W/m^2 multiplied by different exposure durations (0, 0.5, 1, 2, 4, 6, 7, 8, 9, 12, and 16, h). After elicitation treatments, parts of UV-elicited and control root samples were placed into aluminum foil packets, frozen immediately with liquid nitrogen, and stored at −80 °C for further RNA isolation. The remaining root samples were rinsed with tap and distilled water, dry-blotted on filter paper, and dried in a vacuum oven at 50 °C to a constant dry weight (DW) for liquid−solid extraction of isoflavonoids. Meanwhile, the medium samples were also collected for liquid−liquid extraction of isoflavonoids.

RNA Isolation and cDNA Preparation. Total RNA was isolated from frozen hairy roots (250 mg, fresh weight) using a MiniBEST Plant RNA Extraction Kit (TaKaRa) in accordance with the manufacturer's protocols. The quality and quantity of RNA were assessed by agarose gel electrophoresis and determined by a GeneQuant II RNA/DNA calculator (Pharmacia Biotech, Cambridge, UK), respectively. Subsequently, total RNA (500 ng) was reverse-transcribed to cDNA using a PrimeScript RT reagent Kit (TaKaRa) following the manufacturer's instructions. Finally, the synthesized cDNA (20 μL) was diluted to 200 μL with sterile water and used as the template for the subsequent molecular experiments.

Quantitative Real-Time PCR Analysis. Quantitative real-time PCR (qRT-PCR) was performed with a Stratagene Mx3000P Real-Time PCR system (Agilent Technologies, Santa Clara, CA, USA). Specific primers for genes (Table 1) involved in isoflavonoid biosynthetic pathway were designed as suggested previously.[27] The reaction solution (20 μL) for qRT-PCR assay contained 10 μL of SYBR Premix Ex *Taq*II (TaKaRa), 0.8 μL of each specific primer (10 μM), 2 μL of the above cDNA template, and 6.4 μL of sterile water. The amplification procedure for all investigated genes was set as follows: initial denaturation at 95 °C for 3 min, followed by 40 cycles of denaturation at 95 °C for 15 s, annealing at 55 °C for 30 s, and extension at 72 °C for 20 s. The relative expression level of each gene

was calculated using the *18S* gene as the internal reference. Results were analyzed by Mxpro-Mx3000P software according to the delta CT method.[28]

Isoflavonoid Extraction and LC-MS/MS Analysis. The complete extraction of isoflavonoids from root samples was performed as described previously.[4] To extract isoflavonoids from liquid media, samples were partitioned twice with ethyl acetate in a separatory funnel. The organic phases were combined and then evaporated to dryness at 45 °C using a rotary evaporator. All extracts obtained from both root and medium samples were redissolved in 25 mL of methanol (HPLC grade) and then filtered through a 0.45 μm membrane for LC-MS/MS analysis.

An Agilent 1100 series HPLC (Agilent Technologies, San Jose, CA, USA) coupled to an API 3000 triple tandem quadrupole MS (Applied Biosystems, Concord, ON, Canada) with a Phenomenex Gemini C18 110A reversed-phase column (250 mm × 4.6 mm i.d., 5 μm) was used for the determination of five target isoflavonoids. According to our previous research,[4] the mass spectra of selected reaction monitoring at m/z 445.2 → 283.0, 428.8 → 266.9, 463.2 → 301.1, 283.0 → 268.0, and 267.0 → 252.0 were chosen for the identification and quantification of CAG, ON, ASG, CA, and FO, respectively. The content of each target compound was calculated by the calibration curve and reported as micrograms per gram based on the DW of roots.

Determination of Antioxidant Activities. Antiradical activities and antilipid peroxidation capacities of extracts from AMHRCs were respectively determined by DPPH radical-scavenging assay and β-carotene/linoleic acid bleaching test.[4] Antioxidant properties of samples were expressed as IC_{50} values, which were calculated through the logarithmic regression curves for DPPH radical scavenging ratio (%) or β-carotene bleaching inhibition percentages (%) versus sample concentration (mg/mL). The higher antioxidant activity was corresponding to the lower IC_{50} value. Activities of antioxidant enzymes including superoxide dismutases (SOD, EC 1.15.1.1), catalase (CAT, EC 1.11.1.6), ascorbate peroxidase (APX, EC 1.11.1.11), and glutathione reductase (GR, EC 1.6.4.2) were determined according to the previously reported methods.[29]

Statistical Analysis. All experiments were conducted three times. Results were expressed as means ± standard deviations. The data were statistically analyzed using the SPSS statistical software (version 17.0, SPSS Inc., Chicago, IL, USA). Differences between means were determined by analysis of variance with Tukey's test on the level of significance declared at $P < 0.05$.

RESULTS

Effect of Different Types of UV radiation on Isoflavonoid Accumulation. Under the optimal culture conditions described previously,[4] 34-day-old AMHRCs are capable of achieving the maximum isoflavonoid accumulation and biomass production. Therefore, 34-day-old AMHRCs adopted in this work were elicited by UV radiation for further enhancing isoflavonoid biosynthesis without affecting biomass productivity. Nevertheless, whether UV elicitation can promote isoflavonoid biosynthesis in AMHRCs was still unknown. Accordingly, 34-day-old AMHRCs were individually exposed to UV-A, UV-B, and UV-C at a fixed radiation dose (43.2 kJ/m^2) to assess their effects on the yield of total target isoflavonoids (sum amount of CAG, ON, ASG, CA, and FO). As shown in Figure 1, the elicitation treatment regardless of UV type increased isoflavonoid yields in the range of 362.15−443.04 μg/g DW relative to the control (231.88 μg/g DW). The results demonstrated that UV elicitation was indeed beneficial for promoting isoflavonoid (usually acting as phytoalexins/phytoanticipins) accumulation in AMHRCs as a consequence of countering unfavorable environmental stresses. Moreover, the isoflavonoid yield decreased in the order UV-B (443.04 ± 15.38 μg/g DW) > UV-C (417.66 ± 8.16 μg/g DW) > UV-A

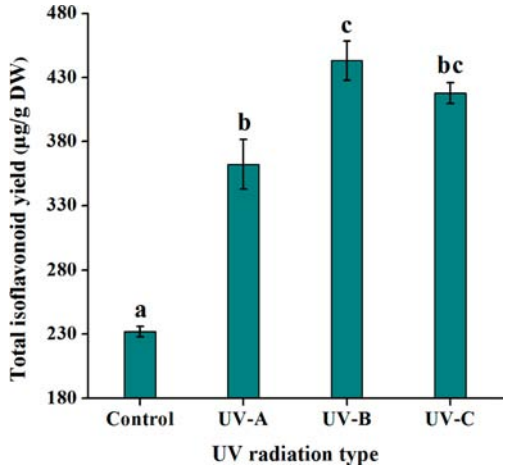

Figure 1. Effects of UV-A, UV-B, and UV-C treatments (43.2 kJ/m^2, i.e., 4 h) on the yield of total target isoflavonoids in 34-day-old AMHRCs. Control: nontreated AMHRCs. Mean ± SD values not sharing the same lower case letters are significantly different ($P < 0.05$).

(362.15 ± 19.42 μg/g DW). Overall, UV-B was screened as the best elicitor that was adopted for the subsequent experiments.

Effect of Elicitation Dose of UV-B on Isoflavonoid Accumulation. The effect of an elicitor on the yield of secondary metabolites for a specific plant in vitro culture primarily depends on the elicitation dose.[9,14−16] Thus, it is of great necessity to investigate the effects of different UV-B radiation doses on the yield of total target isoflavonoids in 34-day-old AMHRCs. As exhibited in Figure 2A, it is obviously demonstrated that the mild-dose UV-B radiation (86.4 kJ/m^2) was the most favorable for isoflavonoid accumulation. The decrease of isoflavonoid amount under high-dose UV-B treatments (97.2−129.8 kJ/m^2) might be associated with the irreversible damage of cellular macromolecules such as proteins, nucleic acids, and lipids due to the absorption of the energy-rich radiation.[20,30] Additionally, it is worth mentioning that UV-B-elicited AMHRCs (Figure 2C) showed a significant indication of stress (browning color in root tissues) in comparison with the corresponding control cultures (Figure 2B).

Isoflavonoid Profiles in Response to UV-B Elicitation. Isoflavonoid profiles in AMHRCs treated by different UV-B radiation doses are presented in Table 2. Under the optimal elicitation dose (86.4 kJ/m^2), UV-B-treated AMHRCs were capable of yielding 533.54 ± 13.61 μg/g DW of total isoflavonoids, which was 2.29-fold higher as against that of control (232.93 ± 3.08 μg/g DW). In detail, the contents of CAG, ON, ASG, CA, and FO in the elicited AMHRCs were 14.57 ± 0.87, 5.83 ± 0.46, 119.59 ± 6.72, 225.01 ± 8.28, and 168.54 ± 5.36 μg/g DW, respectively, which were correspondingly 1.61-, 1.42-, 1.87-, 2.35-, and 2.90-fold higher as compared to those in the control (9.06 ± 0.13 μg/g DW CAG, 4.12 ± 0.19 μg/g DW ON, 64.95 ± 3.77 μg/g ASG, 95.64 ± 2.80 μg/g CA, and 59.16 ± 1.65 μg/g DW FO). These differences could be appreciated by comparing the LC-MS/MS chromatograms of extracts from different treated AMHRCs (Figure 3).

Putative Isoflavonoid Biosynthetic Pathway. To elucidate the transcriptional regulation of isoflavonoid biosynthesis upon UV-B elicitation, a better understanding of the isoflavonoid biosynthetic pathway is essential. On the basis of current ideas,[17,27,31,32] a putative biosynthetic scheme of target

isoflavonoids is proposed in this study (Figure 4). Overall, the pathway consists of 10 metabolic steps, beginning with phenylalanine ammonia-lyase (PAL) that catalyzes the deamination of phenylalanine into cinnamic acid. Consecutively, cinnamate-4-hydroxylase (C4H) catalyzes the hydroxylation of cinnamic acid into *p*-coumaric acid. Afterward, 4-coumarate coenzyme A ligase (4CL) catalyzes the conversion of *p*-coumarate into its CoA ester. Subsequently, chalcone synthase (CHS) and chalcone reductase (CHR) co-catalyze the condensation of *p*-coumaryl CoA with three malonyl-CoA molecules toward the formation of an isoflavonoid skeleton, isoliquritigenin, which can be further converted into liquiritigenin with the catalysis of chalcone isomerase (CHI). After

that, liquiritigenin is catalyzed by isoflavone synthase (IFS) to form daidzein, which is then converted into FO under the catalytic action of isoflavone *O*-methyltransferase (IOMT). The subsequent hydroxylation at the 3′-position of the B-ring in FO leads to the formation of CA through the catalysis of isoflavone 3′-hydroxylase (I3′H). Eventually, FO and CA are transformed into their glycosides (ON and CAG) via the catalysis of uridine diphosphate-dependent glycosyltransferases (UGTs). Due to the large enzyme families with significant functional diversity, the last glycosylation steps remain to be identified.

Biosynthetic Gene Expressions in Response to UV-B Elicitation. With the aim of clarifying the molecular mechanism underlying isoflavonoid enhancement in the presence of UV-B elicitation, the transcriptional profiles of isoflavonoid biosynthetic genes (*PAL*, *C4H*, *4CL*, *CHS*, *CHR*, *CHI*, *IFS*, and *I3′H*; Figure 4) were determined by qRT-PCR. In this study, samples from UV-B-treated AMHRCs were taken for analysis at three different elicitation doses (43.2, 86.4, and 129.6, kJ/m^2). Gene expression levels were normalized using the reference *18S* gene as internal standard, and the transcripts of all related genes in control were set as 1.

As presented in Figure 5, the expression levels of all investigated genes were significantly promoted following UV-B elicitation, which suggested that the enhanced isoflavonoid accumulation was a result of the improved expressions of these

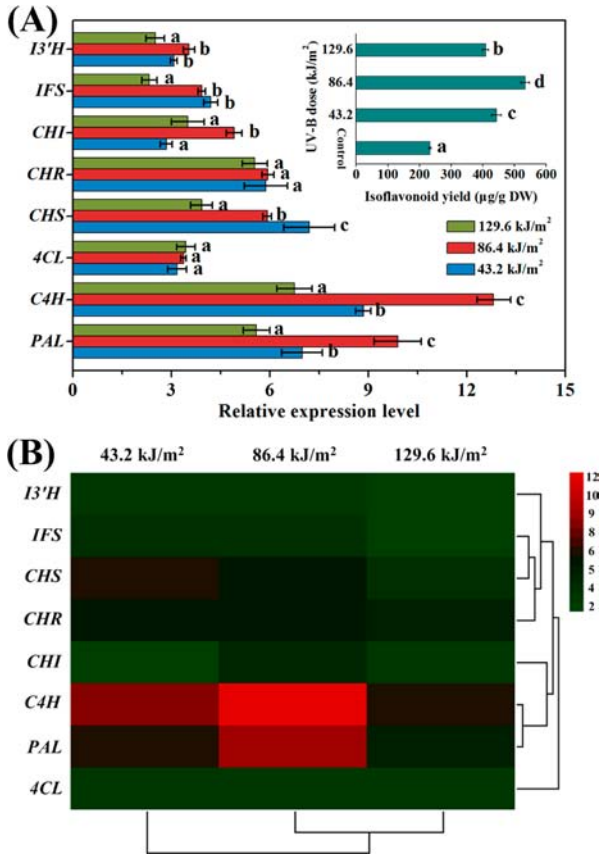

Figure 5. (A) Total isoflavonoid yields and transcriptional levels of isoflavonoid biosynthetic genes in 34-day-old AMHRCs exposed to three different UV-B elicitation doses (43.2, 86.4, and 129.6, kJ/m^2, i.e., 4, 8, and 12 h). (B) Hierarchical analyses of gene expressions in samples. Control, nontreated AMHRCs. Mean ± SD values not sharing the same lower case letters are significantly different (P < 0.05).

biosynthetic genes. Interestingly, not all genes displayed the highest expression levels at the optimal elicitation dose (86.4 kJ/m^2) where isoflavonoid amount was the maximum. The transcriptional levels of *PAL*, *C4H*, *CHI*, and *I3′H* genes were observed to be gradually stimulated and reached their individual peak values at 86.4 kJ/m^2, with expression levels of 9.90-, 12.83-, 4.92-, and 3.54-fold higher as against control, respectively. However, the maximum transcriptional levels of *4CL*, *CHS*, *CHR*, and *IFS* genes were not observed at the optimal elicitation dose necessary for the highest isoflavonoid yield. The expression levels of *CHS* and *IFS* genes were highest at 43.2 kJ/m^2, where they were 7.20- and 4.25-fold higher as compared to control, respectively, but decreased gradually afterward. Moreover, the transcriptional profiles of *4CL* and *CHR* genes had no significant changes during the elicitation period and remained approximately 3- and 6-fold higher relative to control, respectively.

Antioxidant Activities in Response to UV-B Elicitation. As shown in Figure 6, activities of antioxidant enzymes

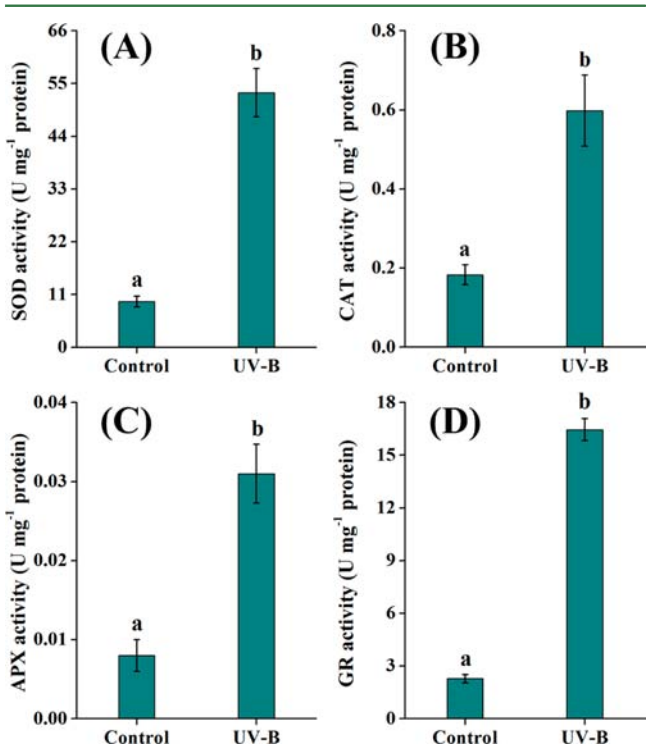

Figure 6. Activities of antioxidant enzymes including (A) SOD, (B) CAT, (C) APX, and (D) GR in control and UV-B-treated AMHRCs. Control, nontreated AMHRCs.

including SOD, CAT, APX, and GR in UV-B-treated AMHRCs were significantly higher than those in control, indicating that antioxidant enzymes were indeed activated to protect AMHRCs from UV-B damage. With the purpose of studying the antioxidant response of AMHRCs to UV-B elicitation and investigating if a correlation exists with the levels of isoflavonoids in extracts, DPPH radical-scavenging assay and *β*-carotene/linoleic acid bleaching test were respectively applied to determine antiradical activities and antilipid peroxidation capacities of extracts from differently treated AMHRCs. Obviously, the observations with extracts from both control and UV-B-elicited AMHRCs exhibited dose-dependent relationships in antioxidant properties (Figure 7). As expected from the quantified levels of isoflavonoids, the UV-B-treated samples

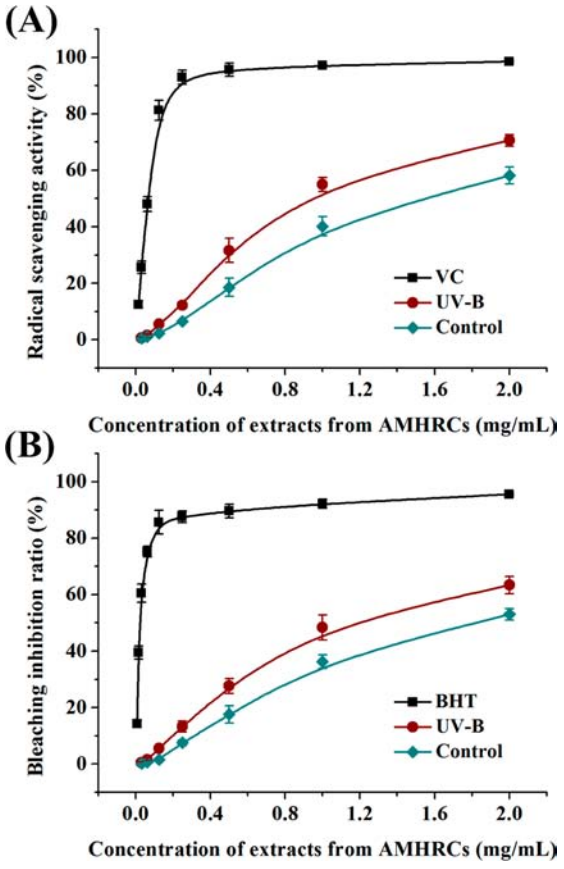

Figure 7. Antioxidant activities of extracts from control and UV-B-treated AMHRCs as assessed by (A) DPPH radical scavenging assay and (B) β-carotene/linoleic acid bleaching test. Control, nontreated AMHRCs. *X* axis, concentration of extracts from AMHRCs (mg/mL); *Y* axis, antioxidant activities (inhibition percentage/ratio, %) in DPPH radical scavenging assay and β-carotene/linoleic acid bleaching test.

showed much higher antioxidant efficacies in terms of antiradical (IC_{50} value of 0.85 mg/mL) and lipid peroxidation inhibition (IC_{50} value of 1.08 mg/mL), as compared to the corresponding values of control samples (1.38 and 1.71 mg/mL).

DISCUSSION

It is well documented that three classes of UV radiation (UV-A, UV-B, and UV-C) are important regulators of plant's secondary metabolism, triggering the biosynthesis of various phytochemicals (e.g., phenolic compounds, alkaloids, terpenes, carotenoids, and glucosinolates) that can play an important role in a plant's defense systems.[19−21] Obviously, the three types of UV radiation exhibited distinct influences on isoflavonoid yield in AMHRCs (Figure 1). Due to the various wavelengths of UV-A, UV-B, and UV-C, the perceptions of diverse UV photons and the subsequent signal transductions in plant cells are different.[33,34] The consequence of a given radiation dose of UV-A, UV-B, and UV-C can result in different damaging effects on DNA, proteins, lipids, and membranes and/or physiological processes of plant cells, which can induce diverse influences on a plant's secondary metabolism,[23,24,35,36] thus promoting the synthesis of distinct levels of isofavonoids to protect AMHRCs from UV damage. In this work, UV-B offering the highest isoflavonoid yield was adopted as the appropriate elicitor.

Generally, plant tissues exposed to an elicitor (or stressor) can cause reversible and elastic "eustress" (an activating, temporal, and constructive elicitation/stress through predisposing plant cells/organs to a state of low alert via stimuli-specific signaling pathways that leads to the activation of defense secondary metabolisms), and once the exposure exceeds a tolerance-limit dose, an irreversible and plastic "distress" (a strong elicitation/stress event under severely unfavorable environment conditions that results in metabolic damage or, in extreme cases, the death of plant cells/organs) takes place.[30,37] In this work, the appropriate UV-B exposure dose (86.4 kJ/m^2) could realize the balance between "eustress" and "distress" for maximally inducing isoflavonoid accumulation in AMHRCs (Figure 2A).

UV-B radiation has been extensively demonstrated to cause multiple cellular injuries in plants than can activate various signaling pathways involving nonspecific DNA damage, reactive oxygen species (ROS), wound/defense signaling, and specific photomorphogenic signaling.[20,38] It is evident that the existence of these signaling pathways can contribute to stimulating the expression of genes involved in the biosynthesis of various secondary metabolites.[19−24,26] Molecular studies were able to clarify the transcriptional expressions of genes involved in isoflavonoid biosynthetic pathway in response to UV-B elicitation. This could be helpful in discovering and exploring those genes which were the possible bottlenecks that controlled isoflavonoid biosynthesis and provide useful information for isoflavonoid production via engineering manipulation in the future.

It is reported that the promoters of a series of genes involved in flavonoid biosynthetic pathway contain a specially recognized domain that can interact with MYB family transcriptional factors with light-responsive elements.[23,24,39,40] As inferred, these transcriptional factors could be activated by UV-B radiation, thus leading to the transcriptional activation of all investigated isoflavonoid biosynthetic genes in this work (Figure 5). Additionally, a positive correlation was observed between the expression profiles of *PAL*, *C4H*, *CHI*, and *I3′H* genes and the accumulation patterns of isoflavonoids (Figure 5A), which indicated that the boosted isoflavonoid biosynthesis in AMHRCs might be activated by the simultaneous up-regulation of these genes following UV-B elicitation. Moreover, *PAL* and *C4H* genes exhibited significantly higher expression levels than those of other genes (Figure 5B). These results suggested that *PAL* and *C4H* genes might be more sensitive and critical than other genes for isoflavonoid biosynthesis in UV-B-elicited AMHRCs. Factually, the promoter of *PAL* gene contains similar light-responsive elements with G-box sequence, which can significantly up-regulate the expression of *PAL* gene in response to UV induction.[23,24] Generally, *PAL* and *C4H* genes have been proposed as two dominant control points of phenylpropanoid, flavonoid, and isoflavonoid biosynthesis in response to various biotic and abiotic stresses, inclusive of pathogen attack, UV radiation, and mechanical wounding.[22,31,41−44] Moreover, *PAL* and *C4H* encoding enzymes are thought to be physically associated with each other in organized multienzyme complexes exhibiting coordinated expression.[41] Similarly, *PAL* (a smart gene switch) and *C4H* genes play a key role in controlling the accumulation of CAG and CA in *A. membranaceus* plants during low-temperature treatment.[32] Cumulatively, the results of this study confirmed that *PAL* and *C4H* genes were crucial regulatory points controlling

isoflavonoid biosynthesis in AMHRCs responsive to UV-B elicitation.

Factually, plants exposed to UV-B stress can greatly enhance the generation of ROS, resulting in an oxidative disturbance (i.e., imbalances between ROS production and antioxidant scavenging capacity).[20,30] Generally, plants utilize antioxidant enzymes as representing the first line of defense against ROS overproduction, preventing oxidative damage of cell membrane systems, nucleic acids, lipids, and proteins, and maintaining the stability of their functions.[45,46] In the present study, the activities of antioxidant enzymes (SOD, CAT, APX, and GR) in AMHRCs were significantly stimulated by UV-B radiation (Figure 6). However, the action of antioxidant enzymes needs to be complemented by that of nonenzymatic ROS scavenging systems in plants suffering from stress conditions.[45] Flavonoids have been proposed as constituting a secondary antioxidant system that is activated as a consequence of the depletion of antioxidant enzyme activity.[45−47] Moreover, there is a growing body of evidence that flavonoids can screen harmful UV-B radiation and especially scavenge ROS formed under stressful conditions, thus protecting plant cells from oxidative damages.[48,49]

In this study, the significantly induced isoflavonoids (2.29-fold higher than control) might actively balance the cell redox status of AMHRCs under UV-B-mediated oxidative stress through their antioxidant and free radical scavenging abilities. In addition, the intake of isoflavonoids is vitally important for human health (e.g., prevention of cancer, inflammation, and cardiovascular and age-related diseases), which is believed to be related to their antioxidant activities.[2,4,50] Currently, natural products containing isoflavonoids are of great interest in the food, cosmetic, and pharmaceutical fields for their possible use as antioxidant additives to replace toxic synthetic ones.[51,52] From this point of view, the isoflavonoid enhancement driven by UV-B possesses benefits for both ends of the biobased food chain, that is, for plants themselves as well as for human health.

Previously, several in vitro antioxidant assays have shown that CAG, ASG, CA, and FO were the primary antioxidant contributors acting as hydrogen/electron donors to neutralize peroxyl free radicals.[4−6,53] The better antioxidant activities of the UV-B-treated samples as against control (Figure 7) might be partly ascribed to the higher levels of these antioxidant compounds. However, antioxidant capacities of plant extracts are not dependent on some single molecules, due to the synergistic and redox interactions among multiple components that are present. Factually, UV-B radiation can induce the accumulation of many cellular antioxidants, such as ascorbic acid, glutathione, proline, tocopherol, flavonols, phenolics, and carotenoids.[19−21,45] Herein, it was inferred that the possible synergistic effects of these antioxidant constituents contributed to the tremendous increase in antioxidant activity of UV-B-treated samples. Anyway, the results of this study confirmed that UV-B-elicited AMHRCs could offer health-promoting extracts with higher antioxidant activity as natural additives in functional foods and nutraceuticals.

Overall, the present study established an effective, convenient, and feasible UV-B elicitation approach to enhance isoflavonoid biosynthesis in AMHRCs. We found that UV-B radiation as elicitor possessed the potential to induce the transcriptional activation of biosynthetic genes that ultimately boosted isoflavonoid accumulation in AMHRCs. This investigation also opened a gate to clarify the crucial regulatory points (*PAL* and *C4H* genes) in the isoflavonoid biosynthetic pathway of *A. membranaceus*.

crystallography. The crystal of the WT was obtained from a solution containing PEG 8000. The unit cell was relatively large, and 10 protein subunits were likely to be present in the asymmetric unit.[32] Molecular replacement using various available structures was not successful. Consequently, we solved the structure of M6 using experimental phasing with CsCl as the anomalous scatterer. The aim of this study was to improve the thermostability of EstF27 by directed evolution and also provide useful information about the structure−function relationship.

MATERIALS AND METHODS

Materials. *E. coli* DH5α and pUC19 (TaKaRa, Dalian, China) were used for the construction of the random mutagenesis libraries. The *E. coli* strain BL21(DE3) and the pET-28a (+) plasmid (Novagen, Madison, WI) were used for protein expression. Restriction endonucleases, DNA polymerase, and T4 DNA ligase were purchased from Thermo Fisher Scientific (Hudson, NH). FA was purchased from Sigma-Aldrich (St. Louis, MO). 4-Nitrophenyl ferulate (pNPF) was procured from the Slovak Academy of Sciences (Bratislava, Slovakia). All other chemicals and reagents were of analytical grade and were purchased from commercial sources, unless indicated otherwise.

Construction and Screening of a Random Mutagenesis Library. The plasmid pUC19-*estF27* (GenBank accession number HQ241478) was used as the template for the first round of mutagenesis and gave rise to a stable mutant with four mutations (named M4, T27I/S84L/V161I/G243C). Then the plasmid pUC19-*M4* was further used as the template for the second round of mutagenesis. The random mutagenesis was performed with the GeneMorph II random mutagenesis kit (Stratagene, La Jolla, CA) following the manufacture's protocol with the primers 5′-TATAACAGCTATGACCATGATTACGCCAAGCTTATG-3′ (forward) and 5′-GAATTCGAGCTCGGTACCCGGGGATCC-3′ (reverse). The error-prone polymerase chain reaction (epPCR) product was recovered and digested with *Bam*HI and *Hin*dIII and then ligated into pUC19, which had been previously digested with the same restriction enzymes. The ligation product was transformed into *E. coli* DH5α via electroporation, and the transformants were cultured on LB-agar plates containing 100 μg/mL ampicillin, 0.1% (v/v) tributyrin, 0.3% (w/v) poly(vinyl alcohol), 80 μg/mL rhodamine B, and 0.1 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) at 37 °C overnight. Single colonies that formed a transparent zone were picked, transferred on duplicate LB-agar plates containing 100 μg/mL ampicillin and 0.02 mM IPTG, and cultivated at 37 °C for 48 h. One plate was incubated for 50 min at 60 °C for the first round of mutagenesis or 25 min at 85 °C for the second round of mutagenesis. After the plate was cooled to room temperature, about 5 mL of a mixture containing 0.3 mg/mL 1-naphthyl acetate and 1.3 mg/mL Fast Blue B salt was added to it. Positive colonies were confirmed by the brown halos formed around the colonies. The plasmid of the transformants expressing the mutants with improved thermostability was subsequently extracted for sequence analysis.

Site-Directed Mutagenesis. In vitro site-directed mutagenesis was performed with the TaKaRa MutanBEST kit (TaKaRa, Dalian, China) following the instructions of the manufacturer by using the plasmid pET-28a(+) as the template. The primers used are listed in Table S1. The correctness of the mutants was confirmed by sequencing.

Overexpression and Purification of the Target Proteins. The full-length EstF27 gene was PCR-amplified using the primers 5′-GATAGGGCCATATGACCCCCGAATTGCGCGCCAA-3′ and 5′-TTGCACTTCTCGAGTCACCGCGTACCCTGCGCAC-3′. After double digestion by the *Xho*I and *Nde*I restriction enzymes, the digested PCR product was ligated into a modified pET28a(+) vector in which the thrombin site (recognition peptide LVPRGS) was replaced by a Tobacco etch virus (TEV) protease cleavage site (recognition peptide ENLYFQG). The plasmids encoding the target proteins contain a 6× histidine tag at the N-terminus, and were transformed into *E. coli* BL21(DE3) for overexpression.

The cells carrying pET28a/EstF27 plasmids were grown at 37 °C and 190 rpm overnight in LB medium containing 30 μg/mL kanamycin. A 500 mL volume of fresh culture medium was then inoculated with 5 mL of the overnight culture. When the absorbance at 600 nm (OD_{600}) reached 0.6−0.8, 1 mM IPTG was added to the culture and the cells were subsequently induced overnight at 37 °C. Then the cells were harvested by centrifugation at 5000*g* for 15 min and resuspended in prechilled nickel−nitrilotriacetic acid (Ni−NTA) buffer A containing 40 mM Tris−HCl (pH 8.0), 250 mM NaCl, 10 mM imidazole, 1 mM phenylmethanesulfonyl fluoride (PMSF), and 1 mM β-mercaptoethanol. After sonication, the cell lysate was cleared by centrifugation at 14000*g* for 1 h at 4 °C. The resulting supernatant was mixed with Ni−NTA (Qiagen) resin at 4 °C for 1 h. The bound protein was washed with 10 column volumes of buffer A. The target protein was then eluted with Ni−NTA buffer B containing 40 mM Tris−HCl (pH 8.0), 250 mM NaCl, 250 mM imidazole, 1 mM PMSF, and 1 mM β-mercaptoethanol. The protein was pooled, concentrated, loaded onto a Superdex 200 column (GE Healthcare), and eluted with a buffer containing 20 mM Tris−HCl (pH 8.0), 150 mM NaCl, and 1 mM DTT. The eluted protein displayed a symmetric peak on the Superdex 200 column and was concentrated to 15 mg/mL before being flash frozen and stored at −80 °C for further crystallization experiments.

The recombinant proteins used for activity analysis were purified according to the same method without the addition of PMSF in Ni−NTA buffers. The enzymes in buffer B were further dialyzed three times in phosphate buffer (100 mM, pH 7.0) and then stored at 4 °C for further study.

The molecular mass of the recombinant protein was determined by using sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) with suitably sized protein markers (Thermo Fisher Scientific, Waltham, MA) as standards. The protein concentration was determined by using the CoomassiePlus (Bradford) assay kit (Thermo Fisher Scientific) according to the product manual.

Determination of the Thermostability and Kinetic Parameters. The optimal pH values and optimal temperatures of EstF27 and the mutants were determined by using pNPF as the substrate. The concentration of pNP released was determined by measuring the absorbance of the solution at 405 nm. The reaction mixture contained 10 μL of the diluted enzyme solution and 490 μL of the substrate solution. The substrate solution was prepared according to Mastihuba et al.[33] The pH buffers included 100 mM citric acid−sodium citrate buffer (pH 5.0−6.0), phosphate buffer (pH 6.0−8.0), Tris−HCl buffer (pH 8.0−9.0), and glycine−NaOH buffer (pH 9.0−10.0). The optimal temperature was determined by measuring the initial reaction rates in the temperature range of 30−70 °C in phosphate buffer (100 mM, pH 7.0).

Two parameters were measured to evaluate the thermostability of EstF27 and the mutants. One is the half-life ($t_{1/2}$), which is defined as the incubation time needed to inactivate 50% of the initial enzyme activity. The purified enzymes (0.1 mg/mL) were incubated at 55, 65, or 70 °C in 100 mM phosphate buffer (pH 7.0). Samples were collected at various time intervals, cooled in ice, and assayed at 40 °C using pNPF as the substrate. The other one is the average size of the protein particles (*z*-average), measured by dynamic light scattering. The measurements were carried out with a photogoniometer as the plate reader (Wyatt Technology, Goleta, CA).[34] The WT protein and different mutants (1 mg/mL, 100 mM phosphate buffer, pH 7.0) were centrifuged at 14000*g* for 10 min, and the supernatant was transferred to the 384-well plates. Mineral oil was added on top to prevent evaporation during the heating process. The plate was subjected to a 2000*g* centrifugation for 2 min to remove air bubbles before readout in the temperature-controlled DynaPro plate reader. The temperature range was set to 25−75 °C, and the temperature increase rate was 0.35 °C/min. Each sample was run in triplicate, and each well was measured five times, with a 5 s acquisition time.

The storage stability of EstF27 and the mutant M6 was determined at 25 °C in 100 mM phosphate buffer (pH 7.0). After different storage times (0−150 days), the residual activities were tested. The initial activity of the enzymes was defined as 100%.

The kinetic parameters (K_{cat} and K_m) of EstF27 and the mutant M6 were determined by assaying the activity in 100 mM phosphate buffer (pH 7.0) at 40 and 65 °C with seven different concentrations (0.5K_m to 5.0K_m) of pNPF as the substrate. The kinetic data were fitted to a

DOI: 10.1021/acs.jafc.5b03424
J. Agric. Food Chem. 2015, 63, 8225−8233

Lineweaver−Burk curve using the SigmaPlot software (Systat Software, Chicago, IL).

Release of FA from DSWB. The wild-type EstF27 and the thermostable mutant M6 were each applied to degrade DSWB synergistically with xylanase from *Thermomyces lanuginosus* (Sigma-Aldrich, St. Louis, MO). The reactions were performed at 40 and 65 °C in 1 mL of phosphate buffer (100 mM, pH 7.0) containing 50 mg of DSWB. The enzyme loads were 10 U/mL for xylanase and 0.5 mg/mL for EstF27 and M6. Samples were collected at different time intervals, boiled for 5 min, and filtered. The concentration of FA released was determined by high-performance liquid chromatography (HPLC). A C18 reversed-phase column (8.0 × 300 mm, 5 μm, ODS, Japan) was used for the HPLC analysis. A mixture of methanol/HPLC-grade water containing 1% (w/v) acetic acid (30:70, v/v) was used as the mobile phase at a flow rate of 1.0 mL/min at 30 °C. The injection volume was 10 μL, and the absorbance at 280 and 320 nm was recorded. The wheat bran was destarched on the basis of the method described by Topakas et al.[35] The total FA content in the DSWB was determined according to the method of Garcia et al.[36]

Crystallization and Data Collection. The mutant M6 was crystallized using the sitting-drop vapor-diffusion method in 96-well plates. The commercial screens Index and Crystal Screen and a home-made PEG/ammonium sulfate-based screen were used for initial crystallization screening. Crystals of M6 grew to optimal sizes in 5−7 days at 25 °C in 1.2 M ammonium sulfate and 100 mM HEPES (pH 7.5). A single crystal was flash-frozen in liquid nitrogen using 20% glycerol (v/v) plus the crystallization solution as a cryoprotectant.

A native X-ray diffraction data set (a total of 214 frames) was collected at 100 K using an in-house Oxford Diffraction Xcalibur Nova diffractometer operating at 50 kV and 0.8 mA. The rotation was 0.75° per frame, and the crystal-to-detector distance was 60 mm. The exposure time was 30 s, and the data were recorded with a 165 mm Onyx CCD detector. To determine the phase, derivative crystals were obtained by soaking the native crystals in the above cryoprotectant with 1 M CsCl for 15 min. The soaked crystals had no apparent decay, and a data set of 180 frames was collected afterward, with a rotation of 1° per frame. The crystal-to-detector distance was 65 mm, and the exposure time was 90 s.

Accession Numbers. The atomic coordinates and structure factors have been deposited in the Protein Data Bank with the accession code 4ZRS.

RESULTS AND DISCUSSION

Screening for Mutants with Improved Thermostability. Two epPCR libraries were successfully constructed for screening mutants with improved thermostability, which contained about 30000 and 25000 clones, respectively. Twenty clones of each library were randomly picked and sequenced to estimate the diversity of the library. The results showed that the error rates of the libraries were 0.95 and 1.2 nucleotide changes/kb, respectively. About 45% of the clones were identified to be active by the transparent zone formed around the colonies. Then they were transformed to duplicate LB-agar plates for further screening the mutants with enhanced thermostability.

To avoid significant changes of the protein expression on the transformed plates, a low induction concentration of IPTG (0.02 mM) was applied (Figure S1). After a heat treatment for 50 min at 60 °C, the WT completely lost activity (Figure S2A). Four positive clones were identified out of nearly 13,500 clones after the first library was screened. Sequence analysis identified that the mutations were T27I, S84L, G243C, and V161I/G243C, respectively. The individual contribution of each mutation to the thermostabilization was subsequently determined (Table 1). The combination of four such mutations resulted in the mutant M4 with a half-life of 4 h at 65 °C. To further improve the thermostability, a second random library was constructed on the basis of M4. The screening was performed after the heat treatment for 25 min at 85 °C (Figure S2B). Two more mutants, H195L and A259V, were identified. Combination of all the beneficial mutations gave rise to the mutant M6.

Table 1. Half-Lives of EstF27 and the Mutants

enzyme	$T_{1/2}$ at 55 °C (h)	$T_{1/2}$ at 65 °C (h)	$T_{1/2}$ at 70 °C (h)
EstF27	0.5[a]	ND[b]	ND
EstF27-T27I	30	ND	ND
EstF27-S84L	6	ND	ND
EstF27-V161I	1.5	ND	ND
EstF27-G243C	45	ND	ND
M4	70	4	ND
M4-H195L	430	30	ND
M4-A259V	330	20	ND
M4-H195L/A259V (M6)	1680	140	3

[a]Different from that in the previous report[31] because the fusion tag was different. [b]ND = not determined.

Enzymatic Characterization. The optimal temperature (T_{opt}) of EstF27 is 40 °C (Figure 1A). The mutations increase the optimal temperatures to 60 °C (M4) and 65 °C (M6), which are 20 and 25 °C higher than that of the WT, respectively (Figure 1A). Meanwhile, the optimal pH values of the recombinant protein shift 0.5−1.0 unit toward the alkaline direction by the mutations (Figure 1B). The half-life of EstF27 at 55 °C is 0.5 h (Table 1), different from that in the previous report, in which EstF27 remained at only 25% activity after incubation for 10 min at 55 °C.[31] The discrepancy may be due to the effects of the fusion tags present in the different expression vectors. Four mutations (T27I, S84L, V161I, and G243C) were identified after the first round of screening, resulting in 3−30-fold improvement of the half-life (Table 1). Combination of the four thermostabilizing mutations results in the mutant M4 with a half-life of 70 h at 55 °C, which is an about 140-fold improvement over that of the WT. The combination of another two mutations (H195L and A259V) obtained from the second random library further extends the half-life from 70 h (M4) to 1680 h (M6).

Dynamic light scattering (DLS) is a useful method for monitoring the presence of aggregated protein as has been used to monitor the change in the dimensions of the protein during denaturation and renaturation.[37,38] The effects of temperature on the protein particle sizes measured by DLS are shown in Figure 2. The temperatures that significantly changed the protein particle size of M4 and M6 are 63 and 68 °C, which are 7 and 12 °C higher than that of the WT (56 °C), respectively. These critical temperatures at which the protein particle sizes change dramatically are an indication of formation of aggregates in solution, which may lead to further denaturation.[39] The increase in these temperatures suggests improvement in enzymatic thermostability, consistent with the trend observed by the half-life measurements.

The storage stability of EstF27 and the mutant M6 was also determined. After storage at 25 °C for 150 days, the activity of M6 was almost constant (100.5 ± 2.1%), whereas that of the WT was only 21.2 ± 2.7% (Table 2). This result again showed the better thermostability of mutant M6 than that of the WT.

The measured kinetic parameters of EstF27 and the mutant M6 are listed in Table 3. The catalytic efficiency of the protein was increased by the mutations. The K_{cat}/K_m value of M6 at its T_{opt} of 65 °C is about 1.9-fold higher that of WT at its T_{opt} of 40 °C. Previous studies on directed evolution of enzymes have suggested that increased thermostability of enzymes may come at the cost of their activities at low temperature.[40,41] However, the

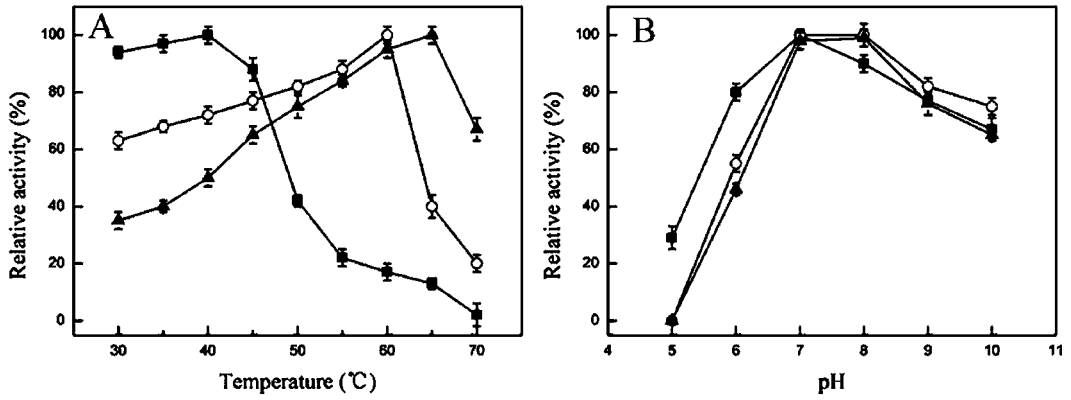

Figure 1. Effects of the temperature (A) and pH (B) on the initial reaction rates of EstF27 (■), M4 (○), and M6 (▲). The data points are the average of triplicate measurements, and the error bars represent the standard deviation.

mutations identified in this work significantly enhanced the thermostability of EstF27 while maintaining its activity at 40 °C. A reasonable explanation is that only the clones that showed transparent zones at 37 °C were picked for further screening, and the positive clones were identified at room temperature after heat treatment. Thus, both properties of thermostability and activity at low temperature were constrained during the directed evolution process.[24]

Releasing FA from DSWB. Wheat bran is one of the major byproducts of the milling industries and a good source of FA.[4,42] FAEs usually work synergistically with xylanases to degrade such natural substrates. To investigate the effects of enhanced thermostability on the hydrolysis of DSWB, such reactions were performed at both 40 and 65 °C. The total FA present in DSWB was determined to be 0.49% (w/w). No FA was detected when only xylanase was added (Figure 3, Figure S4). During a hydrolysis of 10 h at 40 °C, the concentrations of FA released by EstF27 and M6 were 223.2 ± 6.8 and 273.3 ± 8.1 μM, representing 17.7% and 21.6% of the total FA. At 65 °C, the concentration of FA released by M6 in 10 h was 464.8 ± 11.9 μM, representing 36.8% of the total FA, whereas EstF27 appeared to have completely lost its activity quickly as little FA was detected (Figure 3). M6 released 2-fold more ferulic acid at its T_{opt} of 65 °C than EstF27 at its T_{opt} of 40 °C. These results show the advantage of the thermostable mutant M6 over EstF27 in releasing ferulic acid at high temperature.

Structure of the Mutant M6 and Comparison to Other Structural Homologues. To further understand the structural basis of the enhanced thermostability, we seek to solve the crystal structure of the thermostable mutant M6. EstF27 belongs to a distant family of carboxylesterase, and its closest orthologue in sequence is a phenmedipham hydrolase from *Altererythrobacter atlanticus* (AKH43926), which shares 72% sequence identity with EstF27. The molecular replacement with several homologous structures as the search probes using the native data did not yield a plausible solution. To solve the structure, experimental phasing was pursued using CsCl as the anomalous scatterer. Cesium has an f'' of 7.9 e^- at 1.54 Å (the Cu Kα wavelength), which is higher than that of iodine (6.8 e^-). The crystals did not show apparent morphology changes after 15 min of CsCl soaking, and a complete SAD data set was collected at this wavelength to a resolution of 2.4 Å at the home X-ray source. Surprisingly, cell content analyses indicated that the asymmetric unit contains only one molecule, in contrast to the original two in the native data set. Therefore, the quick-soaking procedure still induced significant changes in the unit cells. Experimental phasing by Phaser generated a high-quality map, in which seven cesium sites were found. Of these, one cesium ion is bound to the dimer interface and most likely disrupts the association of the two monomers (data not shown). The Cs-bound derivative structure was built using the autobuild option of Phenix followed by manual rebuilding. The structure of the mutant M6 was subsequently solved at a resolution of 2.0 Å using molecular replacement with the SAD solution as the search probe.

The crystals of the mutant M6 belong to an orthorhombic system with the space group $P2_1$, and each asymmetric unit contains two monomers with 54.6% solvent content. Both chains are completely intact from G-1 to R290 with no internal disorders and of excellent electron density (Table S2). The spherical protein displays the α/β hydrolase fold, featuring a central eight-stranded mixed β-sheet sandwiched by five helices on each side (Figure 4A). Among these, only the β2 strand is antiparallel to the other strands, while the remainder of the strands are all parallel to each other.

A DALI search shows that the closest structural homologues for this protein are a putative carboxylesterase from *Lactobacillus plantarum* (PDB code 3BJR) and a cloned carboxylesterase, EstE1, from a metagenomic library (PDB code 2C7B).[43] The basic α/β hydrolase fold is conserved as indicated by structure overlay. The rms deviation values are 2.6 Å over 223 Cα atoms and 3.2 Å over 248 Cα atoms between the M6 structure and the above two structures, respectively (Figure 4B). While the central eight-stranded sheet structures align well, noticeable local structural differences are also observed. For example, as shown in Figure S5, when compared to that of EstE1, the N-terminus of EstF27 resolves more residues and forms two helices instead of a single helix; in addition, regions between β6 and β7 display substantial rearrangements: the β6−α6 loop is shorter and forms only one helix (α6), as compared to the two helices in EstE1, and the Cα trace of the α6−α7 helices in EstF27 also has significant shifts. These structural changes may be related to the substrate specificity that each enzyme catalyzes.

Additionally, most of the essential residues are conserved as demonstrated by the multiple sequence alignment (Figure S6). A catalytic triad formed by Ser, His, and Asp/Glu residues has been reported to be critical to the activity of α/β hydrolases.[44,45] At the active site, the catalytic triad Ser151−His263−Asp230 is well conserved, suggesting that these proteins share a common catalytic mechanism. The OD1 atom of the carboxylate group in Asp230 forms a hydrogen bond with the ND1 atom of the His263 imidazole ring and constitutes part of the proton-shuffling network. Interestingly, we found that extra density was

connected to the side chain of S151. After careful inspection, a sulfamoyl moiety was built into the density successfully (Figure S7). The most possible scenario was that S151 acts as a nucleophile and attacks PMSF (intended for protease inhibition) during the course of protein purification, leading to the covalent linkage. Additionally, the four-residue motif 73HGGG76, a signature of the hormone-sensitive esterase/lipase (HSL) family,[46,47] is located in a loop, flanking the other side of the S151 nucleophile.

EstF27 exists as a dimer in solution as indicated by size-exclusion chromatography studies, and this observation is

consistent with two monomers being in the asymmetric unit. However, we have encountered problems in assigning the dimer interface. In the current structure, the two subunits dimerize through a C-terminal helix, α8 (dimer type I). Alternatively, they could provide intermolecular contacts and result in another type of dimer via interactions using α2 and α6 (dimer type II) (Figure S8). Interestingly, both types of dimers are reasonable in terms of dimer interface as well as free energy according to the PISA server: the buried surface area is 2570 and 2380 Å^2, and ΔG^{int} is −16.8 and −19.7 kcal/mol, respectively. To find the physiological dimer interface, we examined the structure and discovered that C243, a residue at the dimer interface, forms a disulfide bond with its counterpart from the other subunit in the electron density map (Figure 5A). The S−S bond formation is supported by the extra band at ∼70 kDa on an SDS−PAGE gel under a nonreducing environment. Upon reduction, this band disappears and the monomeric-form band appears (Figure 5B), indicating the interface as shown in the crystal structure is the genuine biological dimerization mode. We also tested the mutant

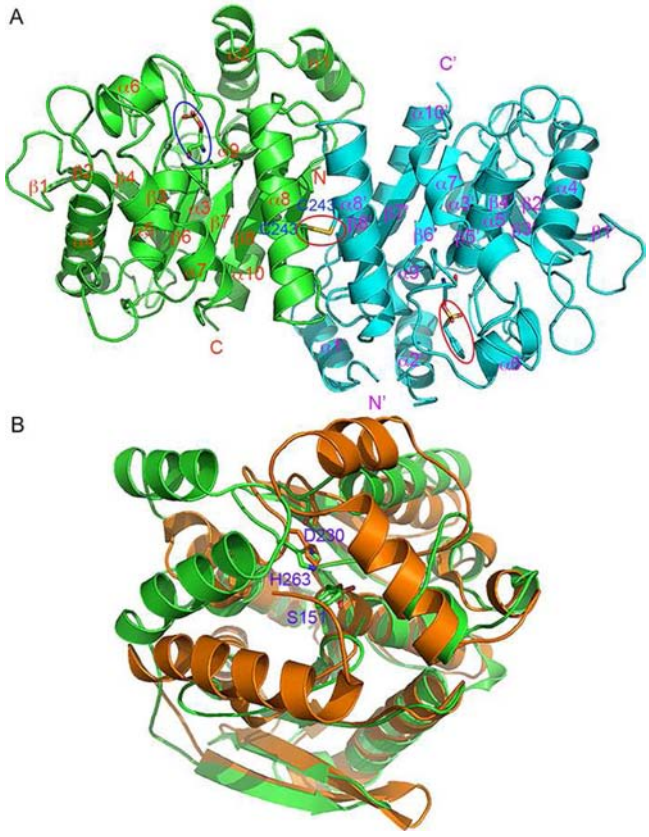

Figure 4. Overall structure of EstF27 and comparison with the orthologues. (A) The two subunits are colored in cyan and in green. The major secondary elements and the N- and C-termini are labeled. The intersubunit C243−C243′ disulfide bond is shown as a ball-and-stick model and circled. The modified S151 on each subunit is also circled. (B) Structure overlay of Cα traces of EstF27 (green) and a cloned carboxylesterase from a metagenomic library (PDB code 2C7B). The catalytic triad is shown as a ball-and-stick model.

C243G, which reverts the cysteine residue back to the original glycine, and the extra band was not observed, further strengthening our argument (Figure 5B). Coincidentally, C243 is also one of the resulting mutants obtained from our first-round mutagenesis screen, and the disulfide bridge enhances the stability of the dimer.

Another interesting discovery is that K164−G172, a fragment connecting α5 and β6, adopts different paths in each subunit (Figure S9). This region is at least 16 Å from the nucleophile S151, and the cause of different conformations and their biological significance are unclear.

Rationalization of the Mutations. We generated a series of mutants through random mutagenesis that greatly promote the thermostability of EstF27. We subsequently determined the crystal structure of the most stable mutant M6 at high resolution, and the crystal structure reveals that G243C, a mutant at the dimer interface, forms a disulfide bridge with C243′ and presumably stabilizes the dimer through the S−S covalent bond. Examination of the other mutant sites on the structure suggests that most of the mutations tend to increase the hydrophobicity of the protein, and several of them besides C243 are located at the dimer interface. For an example, the mutations T27I, H195L, and S84L all change polar residues to hydrophobic residues, while the mutations V161I and A259V tend to increase the hydrophobicity of EstF27. Hydrophobic interactions may play a very important

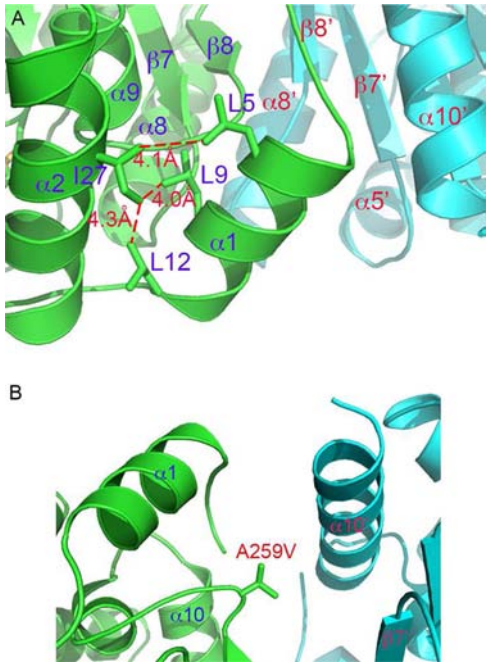

Figure 6. Details of the hydrophobic interaction. (A) Local environment of I27, which could possibly form hydrophobic interactions with L5, L9, and L12 residues from α1 (close to the interface). (B) Local environment of V259, which could possibly form hydrophobic interactions with α10′ from the other subunit. The residues of interest are shown as a ball-and-stick model, and the major secondary elements are labeled.

role in forming the inner core of the enzyme, and these mutations turn out to boost the thermostability. Specifically, T27I may form hydrophobic interactions with L5 (the closest distance between the two residues is 4.94 Å), L9 (4.0 Å), and L12 (4.3 Å) of α1, which is close to the dimer interface (Figure 6A). Similarly A259V may promote the stability of the dimer interface by increasing the hydrophobic interactions with α10′ from the other monomer (Figure 6B). Byun et al.[43] discovered that the thermostability of EstE1, an EstF27 homologue, correlates with its ability to form a dimer. In contrast, disruption of the hydrophobic interactions between the two monomers destabilizes its stability, which supports our current data. Furthermore, after mutation, L195 is in a hydrophobic environment formed by Y199, F77, W206, and I183. The closest distances between the δC atoms of L195 and the aromatic rings of the former three residues are 3.7−3.9 Å. Similarly, L84 is in close range to F89 and Y90. I161 is also in a hydrophobic pocket, and within 5.0 Å, it is surrounded by residues L222, L215, I220, I157, I179, and I174 (Figure S10). These findings provide an explanation for the contribution of the P195L, S84L, and V161I mutations. One must realize that the crystal structure could not provide a perfect explanation for the role of every mutant, because the crystal structure only reflects a static state of the mutant M6 in the crystal lattice. The thermostability evaluation, performed at a temperature as high as 70 °C (Table 1), is a combined result of both thermodynamic and dynamic properties of each mutant. Ideally, the crystal structure of each mutant and detailed solution studies using NMR etc. will greatly help to elucidate the structural basis of the thermostability and enzymatic behavior.

In conclusion, the thermostability of EstF27 was significantly enhanced by the substitutions of six amino acids. The mutations also enhanced the storage stability and improved the catalysis efficiency. The thermostable mutant M6 released 2-fold more ferulic acid at its T_{opt} of 65 °C than the wild type at its T_{opt} of 40 °C in a 10 h hydrolysis of destarched wheat bran. The crystal structure of M6 was determined at 2.0 Å, and structural analysis showed that a new disulfide bond, as well as hydrophobic interactions formed by the mutations, may play an important role in stabilizing the protein. These results may provide useful information for the further engineering of EstF27 in a subsequent study.

Figure 1. Effect of moisture on color development before and after roasting at 120 °C for 90 min in (a) raw and roasted almonds exposed to 5% moisture (control) and (b) raw and roasted almonds exposed to 11% moisture.

Little information is available regarding the chemical changes that occur in raw almonds with CD as most experimental data are derived on roasted nuts where the defect can be seen. However, information on the chemical changes that occur in the raw almonds is critical for developing screening methods and for optimizing drying, roasting, and storage conditions to decrease product loss related to CD. The specific objectives of this study were to (1) develop a colorimetric method based upon CIE *LCh* color values to identify CD in raw almonds; (2) evaluate the influence of temperature and moisture on the development of CD in raw almonds; and (3) evaluate the volatile profiles of raw almonds with CD to further identify the chemical changes that occur with the development of CD.

MATERIALS AND METHODS

Chemicals and Reagents. Reagents were purchased from either Sigma-Aldrich (St. Louis, MO, USA) or Fisher Scientific (Pittsburgh, PA, USA) and included C_7−C_{40} saturated alkanes standard (1000 μg/mL in hexane), ethanol (HPLC/spectrophotometric grade), and 2-methyl-1-propanol, 1-butanol, 3-methyl-1-butanol, 1-pentanol, 1-hexanol, heptanol, 1-octanol, 1-nonanol, benzyl alcohol, phenylethyl alcohol, hexanal, nonanal, and benzaldehyde. Octanal-d_{16}, 2-methylpyrazine-d_6, and *n*-hexyl-d_{13} alcohol were used as stable isotope internal standards for three major categories of identified compounds (i.e., aldehydes, pyrazines, and alcohols). Stable isotopes were purchased from C/D/N Isotopes Inc. (Quebec, Canada).

Experimental Design. Dehulled raw kernels (100 lb, var. Nonpareil) were supplied by the Nickels Soil Laboratory (Arbuckle, CA, USA) in September 2012. Twenty-seven vessels each containing 100 almond kernels were exposed to conditions that produced an internal kernel moisture content of 5% (actual 4.75 ± 0.4%), 8% (actual 8.4 ± 0.35%), or 11% (actual 11.55 ± 0.35%) moisture in a controlled-atmosphere incubator (Thermo Scientific, Marietta, OH, USA) at 35 ± 2 °C. Three individual vessels were removed every other day, and samples were evaluated for moisture, CIE *LCh* color, and volatile analysis by HS-SPME-GC/MS. Almonds treated at 5 and 8% moisture were monitored for 18 days. Almonds treated with 11% moisture were monitored for 7 days. The same procedure was repeated at 45 ± 2 °C.

Moisture Determination. The moisture content of the almonds was determined gravimetrically by drying homogenized samples (~1 g) at 95−105 °C under vacuum for 48 h. Moisture was determined in triplicate, and the results were averaged.

Colorimetric Measurements. Raw almond kernels (420) were split in half along the natural seam, and each half was placed into one of two identical racks with individual identifying slots. One rack of the split kernels was roasted at 120 °C for 90 min, whereas the other rack was not roasted. Almonds with visual apparent darkening after roasting (i.e., those with CD) were grouped separately from the nondarkened kernels (i.e., those without CD), and the surface color of each individual kernel was measured using a LabScan XE spectrophotometer (HunterLab, Reston, VA, USA). The color values *L** (lightness), *C* (chroma), and *h* (hue), according to the CIE *LCh* color scale, were recorded using a port size of 0.4 in. with a D65 optical sensor, 0° geometry, and 10° angle of vision.

As CD is apparent only after heat treatment, raw almond half-kernels with CD were identified by matching the half-kernels that developed CD upon roasting with the corresponding raw half-kernels. Color measurement of raw kernels was made as described above. Evaluations were performed in triplicate and the results averaged.

HS-SPME-GC/MS Analysis. Volatiles were analyzed using a previously reported method, with a smaller sample size (200 mg versus 5 g).[16] Briefly, ground almonds (200 mg) were added to a 2 mL crimp-top vial with 5 μL of mixture of internal standard (10 μg/mL, octanal-d_6, 2-methylpyrazine-d_6, and *n*-hexyl-d_{13} alcohol) and sealed with an aluminum seal (PTFE/silicone liner, Fisherbrand, Fisher Scientific, USA). The samples were incubated for 60 min at room temperature. Samples were exposed to a previously conditioned 1 cm 50/30 μm DVB/CAR/PDMS solid phase microextraction (SPME) fiber (Supelco, Inc., Bellefonte, PA, USA) over the headspace (HS) of the sample for 60 min at ambient temperature. The SPME fiber was immediately injected for 10 min into a Hewlett-Packard 6890 series gas chromatography (GC) system coupled with a HP 5973 mass selective detector (MS; Agilent Technologies, Palo Alto, CA, USA). An Agilent DB-Wax column (30 m length, 0.25 mm i.d., 0.25 μm film) was used to separate compounds. The oven temperature program started with an initial setting of 40 °C for 1 min, followed by a ramp of 5 °C/min to 180 °C, then 10 °C/min to 210 °C with a hold time of 3 min. The injector temperature was set at 240 °C. Helium was used as the carrier gas at a flow at 0.7 mL/min. MS transfer line temperature was set at 250 °C. The temperatures of MS quadrupole and MS source were 150 and 230 °C, respectively. Total ion chromatograms (TICs) were collected by scanning from *m*/*z* 30 to 180 at a rate of 2.48 scans/s.

Identification and Relative Quantitation. Volatile compounds were identified by comparison of their MS spectra and retention times with those of authentic standards. Volatile compounds without authentic standards were tentatively identified by comparing the Kovats' retention indices (KI) and/or mass spectrum with those reported in the NIST Mass Spectral Search Program (version 2.0 a) with >80% as a cutoff to match compounds. The KIs were calculated from the retention times of C_7−C_{40} *n*-alkanes.

Relative quantitation of each volatile compound was performed by comparing the total peak area at of each compound to the total peak area of one of three internal standards (IS) (i.e., octanal-d_{16}, 2-methylpyrazine-d_6, and *n*-hexyl-d_{13} alcohol, for aldehydes, pyrazines, and alcohols, respectively). Relative concentration was determined using eq 1 according to Baek et al.[17] and Hopfer et al.:[18]

$$\text{rel concn}\left(\frac{\text{ng}}{\text{g}}\right) = \frac{\left(\frac{\text{peak area}}{\text{IS peak area}}\right)}{\text{sample wt}} \times \text{IS added} \quad (1)$$

Statistical Analysis. All statistical analyses were performed using Graphpad Pism version 6.01 (GraphPad Software, Inc.). All data sets were tested for significance (p value < 0.05) using a t test for

Table 1. CIE *LCh* (Lightness, Chroma, and Hue) Color Values for Raw and Roasted Almonds with Concealed Damage (CD) and without Concealed Damage (NCD)[a]

	raw almonds		roasted almonds	
	NCD	CD	NCD	CD
lightness (L)	79.46 ± 2.97	70.62 ± 6.40	78.71 ± 3.69	58.82 ± 8.22
chroma (C)	16.65 ± 2.26	20.69 ± 2.32	20.55 ± 3.32	31.82 ± 4.48
hue (h)	87.24 ± 1.15	86.24 ± 1.52	82.73 ± 12.45	71.20 ± 4.11

[a]All values are significant at the $p < 0.05$ level.

comparing temperature (35 and 45 °C), moisture content (5, 8, and 11%), and group (NCD and CD).

Values given in Table 3 were calculated as follows. The mean (18 day average) was calculated for each volatile at 5 and 8% moisture, in each group (i.e., CD and NCD) at 35 °C (data not shown). The difference between the means was determined (CD − NCD) and is given in column (a) (5% moisture) or column (b) (8% moisture). A positive value indicates that the volatile is higher in the CD group as compared to the NCD group. The value reported in column (c) (% relative change) was obtained using eq 2.

$$\text{rel \% change} = \frac{(\text{mean at 8\%} - \text{mean at 5\%})}{\text{mean at 5\%}} \times 100 \quad (2)$$

A positive value indicates that there was an increase in this volatile in the 8% moisture group relative to the 5% moisture group. Values for Table 4 were calculated as above but using data obtained at 45 °C.

Values given in Table 5 were calculated as follows. The mean (18 day average) was calculated for each volatile at 35 and 45 °C, at 5 or 8% moisture (data not shown). The difference between the group means (45 − 35 °C) for each volatile was calculated, and data are given in column (a) for 5% moisture or in column (b) for 8% moisture. A positive value indicates that there was an increase in the volatile at 45 °C relative to that at 35 °C. The value reported in column (c) (% relative change) was obtained using eq 3.

$$\text{rel \% change} = \frac{(\text{mean at 45 °C} - \text{mean at 35 °C})}{\text{mean at 35 °C}} \times 100 \quad (3)$$

RESULTS AND DISCUSSION

Although CD is defined by the almond industry as a "dark" brown color covering ~50% of the kernel after heat treatment, this definition varies among processors and identification relies on a subjective visual inspection of the roasted kernels.[19] To date, processors have tried several methods to identify the extent of CD before roasting, including blanching raw almonds and splitting open the kernels and visually determining the number of kernels with CD. Currently, there are no reliable methods for measuring CD in raw almonds, and a lack of screening methods can result in considerable production losses. Herein the CIE lightness (L), chroma (C), and hue (h) color values were measured in raw and roasted almonds with the goal of identifying a numerical color value corresponding to CD in both raw and roasted almonds. As CD is not visible in raw almonds, kernels were first split in half along the natural seam, and half of the kernel was roasted at 120 °C for 90 min, whereas the other half was not. CIE color values were measured in the roasted kernel halves with visual discoloration over ≥50% of the kernel (i.e., those with visible CD; Figure 1b) and in roasted kernels without visual discoloration (those with no visible CD (NCD); Figure 1a), and the results are given in Table 1. The means of the lightness (L) color value had the greatest difference (78.71 ± 3.69 for NCD and 58.82 ± 8.22 for CD) as compared to hue (h) and chroma (C) and allowed for the separation of CD and NCD almonds using an L color value cutoff of 70.00 (Table 1). More than 400 almonds were evaluated in this way to establish this relationship. Therefore, for the purpose of this study, roasted almonds with CD are defined as those with an L color value of ≤70.0, whereas those with an L color value of ≥70.0 are defined as having no concealed damage (NCD).

Using this definition, the roasted kernel halves were matched to their corresponding raw kernel halves, and the CIE *LCh* color values were measured in the raw kernels. In the raw kernels, the mean L color value was significantly lower in almonds with CD (70.62 ± 6.40) as compared to almonds with NCD (79.46 ± 2.97). The mean C color value was significantly higher in almonds with CD (20.69 ± 2.32) as compared to the NCD almonds (16.65 ± 2.26), and the mean h color value was significantly higher in NCD almonds (87.24 ± 1.15) as compared to the almonds with CD (86.98 ± 1.52). Although color values were significantly different at the $p < 0.05$ level in the raw almonds, there is not enough difference (±2 SD) for these values to be used as a robust screening tool for detecting CD in raw almonds by colorimetry. Therefore, all studies investigating the influence of moisture and temperature on volatiles relied on splitting almond kernels in half, roasting half, and identifying the roasted half kernels with CD using an L color value of ≤70.0. These were then matched with the corresponding raw kernel half to identify the raw kernels with CD.

In raw almonds exposed to 5% moisture and 45 °C, only 2–3% of the kernels formed CD over the 18 days of the study (Figure 2). These almonds were considered the control group for all comparisons. An approximately 20% increase in CD was observed in almonds exposed to 8% moisture at 35 °C. These levels remained consistent at ~25% over the 18 days. At 45 °C, the trend was similar and approximately 20% of the almonds

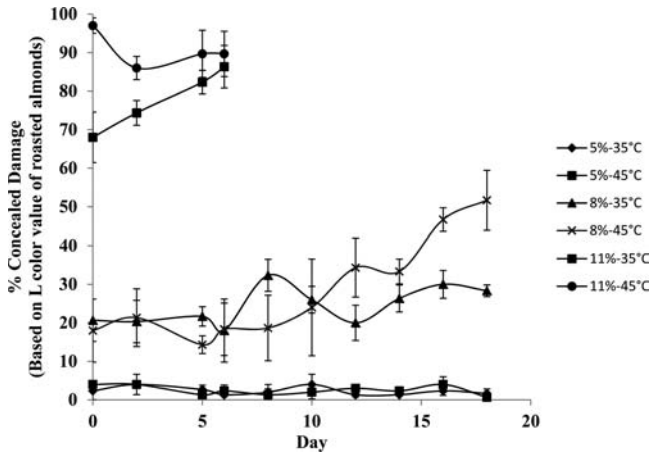

Figure 2. Percent concealed damage (CD) as measured by the CIE L color value in raw almonds held at 5, 8, and 11% moisture and stored at 35 and 45 °C for 18 days.

J. Agric. Food Chem. 2015, 63, 8234–8240

had CD until day 10. After the 10th day, CD increased, reaching 52% on the 18th day of the study. In comparison, almonds exposed to 11% moisture displayed a significant level of CD beginning the first day of the experiment. For example, 68 ± 7% of the almonds stored at 35 °C displayed CD on the first day of this study and levels increased to ∼100% by day 5, whereas 97 ± 2% of the almonds stored at 45 °C displayed CD on the first day of the study (Figure 2). As so many of the almond kernels exposed to 11% moisture developed CD immediately, we were unable to make reliable comparisons between the CD and NCD almonds in this group. Walton et al.[8] demonstrated a similar result in raw macadamia nuts exposed to a moisture content >20% for 5 days at temperatures ≥30 °C; after 5 days, discoloration affected 90% of the kernels.

The profile of volatile compounds was measured in raw almond kernels using HS-SPME-GC/MS.[16] The main volatiles identified include 19 alcohols, 3 aldehydes, 3 lactones, and 3 organic acids (Table 2). Volatiles identified herein were similar to volatiles reported in Monterey and a Greek variety of almond (name not provided)[20−22] and include 3-methyl-butanol, 3-methyl-3-buten-1-ol, 1-pentanol, 1-hexanol, benzyl alcohol, phenylethyl alcohol, hexanal, nonanal, benzaldehyde, butyrolactone, γ-hexalactone, and acetic acid. Herein, 1-nonanol was identified in almonds for the first time, whereas the following compounds were tentatively identified: 1-propanol, 2-methyl-2,3-pentanediol, 3-methyl-2-butanol, 2-methyl-3-pentanol, 2-methyl-2-buten-1-ol, γ-pentalactone, pentanoic acid, and hexanoic acid.

Almonds exposed to 5% moisture and stored at 35 °C showed little significant difference in the volatile composition between the CD and NCD groups (Table 3, column a). More significant differences were observed when CD and NCD almonds from the 8% moisture group (Table 3, column (b)) were compared. In general, increasing the moisture content from 5 to 8% significantly increased levels of most volatiles (Table 3, column (c)) with the exceptions of hexanal and 3-methyl-1-butanol, which decreased. A decrease in hexanal could be due to increased dehydrogenase activity at the higher moisture level.

In contrast, at 45 °C and either 5 or 8% moisture, significant differences were observed for numerous volatile compounds (Table 4, columns (a) and (b)). Significant increases ($p < 0.05$) were observed in the aldehydes (i.e., hexanal, nonanal, and benzaldehyde) and lactones (i.e., γ-pentalactone, butyrolactone, and γ-hexalactone) at 45 °C as compared to 35 °C. In general, increases in temperature enhance the rate at which many reactions (chemical, enzymatic, and metabolic) occur,[23] which could explain the higher levels of volatile found in both the 5 and 8% moisture groups at 45 °C as compared to 35 °C. Increasing moisture from 5 to 8% at 45 °C also produced a significant increase in the relative concentrations of almost all volatiles (Table 4, column (c)). Volatiles that increased can be broadly categorized as byproducts of lipid oxidation (3−9 carbon alcohols, aldehydes, and organic acids), lipid metabolism (lactones), and compounds resulting from increases in enzymatic activities (benzaldehyde, phenylethyl alcohol, benzyl alcohol). These findings agree with results reported by Mira et al.,[24] who characterized the volatiles in lettuce seeds stored at 35 °C with water contents ranging from 3 to 9% moisture. Seeds stored at a water content >6% moisture showed an increase in volatiles related with lipid peroxidation (4−7 carbon alkanes, alcohols, aldehydes, and ketones). When the effect of just temperature (Table 5) is considered, it is apparent that increases in temperature enhanced the levels of most volatiles measured. Greater than 90% increases were observed with compounds primarily related with lipid oxidation and include hexanal, nonanal, acetic acid, 2-ethyl-1-hexanol, γ-pentalactone, and pentanoic and hexanoic acid.

Although benzaldehyde and benzyl alcohol are important flavor components in bitter almonds, the levels appear to be

relatively low in sweet almond varities.[16,18] The opposite appears to be true with 2,3-butanediol, for which levels are relatively higher in some sweet varieties as compared to bitter varieties.[25] To date, little information is available with respect to the content and relationships of these compounds in different varieties of sweet almonds. Herein, we show that benzyl alcohol and 2,3-butanediol are influenced by moisture but not temperature and that levels of benzaldehyde are influenced by temperature at low moisture levels (<5%).

In conclusion, we demonstrate that CIE *LCh* colorimetric measurement of raw almond kernels, for routine screening for CD, is not possible using the conditions described herein. However, CIE *LCh* colorimetric measurements of roasted almonds can be used to identify CD in roasted almonds and have potential as a post-roasting screening tool. Studies of volatiles indicate that although the profiles are similar between CD and NCD almonds, the levels of volatiles related to lipid peroxidation and amino acid degradation are higher in the CD group. These studies suggest that postharvest moisture exposure resulting in a kernel moisture content ≥8% is a key factor in the development of CD in almonds and that increases in temperature will accelerate this process. Future studies should focus on investigating if CD can be reduced by drying almonds with moisture levels ≥8% to <6% prior to roasting, evaluating the impact of CD on storage and shelf life of almonds, and alternative screening methods (e.g., near infrared reflectance spectroscopy, NIR) for detecting CD in raw almonds.

Present Address

#(J.L.) Department of Food Science and Technology, Chung-Ang University, Anseong 456-756, South Korea. E-mail: jihlee@cau.ac.kr.

Funding

The Almond Board of California provided financial support for this study. We also acknowledge the support of the John Kinsella Endowed Chair in food, nutrition, and health.

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We thank Dr. Thomas Gradziel (Plant Science, UC Davis) and Franz Niederholzer (UC Farm Advisor Colusa/Sutter/Yuba Counties) for many thoughtful conversations on almond flavor and breeding and for providing almond samples. Additionally, we thank Dr. Susan Ebeler and Anna Hjelmeland from the UC Davis Food Safety and Measurement Facility.

ABBREVIATIONS USED

CD, concealed damage; NCD, no concealed damage; HS-SPME-GC/MS, headspace solid phase microextraction gas chromatography/mass spectrometry

method to the quantitative and enantioselective analysis of **2a** in young and old white and red wines as well as some juice samples. Studies of the fate of glucose ester **2b** during fermentation were also conducted to determine whether menthiafolic acid (**2a**) could be formed from **2b** during vinification. Finally, the chirality of wine lactone (**1**) and menthiafolic acid (**2a**) in an older wine was also investigated to see whether the isomeric distribution of **1a** and **1b** in the wine was that expected if **1** was formed primarily from **2a**.

MATERIALS AND METHODS

General. All reagents used were purchased from Sigma-Aldrich (Australia). Solvents for GC/MS were CHROMASOLV Plus (Sigma-Aldrich, Australia) or Pest-grade, purchased from Asis Scientific (Hindmarsh, South Australia), and dispensed using a Puresolv solvent purification system (Innovative Technologies, Massachusetts, USA). Other solvents used were OmniSolv HPLC-grade from VWR (Murrarie, QLD, Australia), with the exception of ethanol that was fractionally distilled food-grade ethanol. The water used was purified by a Milli-Q system. Racemic and (6*R*)-(*E*)-2,6-dimethyl-6-hydroxyocta-2,7-dienoic acid (menthiafolic acid, **2a**), menthiafolic acid glucose ester **2b**, racemic d_5-menthiafolic acid, racemic and (3*S*,3a*S*,7a*R*)-3a,4,5,7a-tetrahydro-3,6-dimethylbenzofuran-2-one (wine lactone) were synthesized as described previously.[8,14,17] Commercial wine samples were bottled products obtained from local retail outlets. Juice samples were prepared by homogenizing grape samples (ca. 500 g), centrifuging them at 4 °C at 10 000 rpm (17 666 g) for 30 min, and taking the supernatant to be used for further analyses. The pH of Maggie Beer verjuice (a commercial juice product) was adjusted to 3.2 with potassium hydroxide (aqueous, 1 M). Model wine was redistilled ethanol in Milli-Q water (10 + 90, v/v), saturated with potassium hydrogen tartrate and pH-adjusted to pH 3.2 with L-(+)-tartaric acid (10% w/v in water). Chemically defined grape juice medium (CDGJM) was prepared as described by Ugliano et al.[18] The prepared CDGJM was sterilized by filtration with a 0.22 μm membrane. Synthetic wine was produced by fermentation of CDGJM (3 L) which was inoculated with 4 × 10^6 cells/mL of *Saccharomyces cerevisiae* AWRI 838 cells preadapted in 50:50 YM/CDGJM (60 mL) as described below and incubated at 22.5 °C for 14 days. Progress of fermentations was assessed by weight, and completion was confirmed when residual glucose and fructose concentration was <2g/L. The wine was cold-settled for 5 days at 4 °C and was sterilized by filtration with a 0.22 μm Stericap (Millipore, MA, USA) bottle-top filter device. For gas chromatography−mass spectrometry (GC-MS), positive-ion electron impact (EI) mass spectra were recorded on an Agilent 6890 gas chromatograph (GC) coupled to an Agilent 5973N mass spectrometer (MS) with a GERSTEL MPS2Multi Purpose Sampler. Details of GC-MS operating parameters for quantitative and enantioselective analysis of menthiafolic acid and for enantioselective and nonenantioselective analysis of wine lactone have been given previously.[14,17]

Sample Preparation. For analysis of menthiafolic acid in white wines and grape juices, samples were prepared as described in Giaccio et al.[17] for white wines. Red wine samples (100 mL) were spiked with a solution of d_5-2,6-dimethyl-6-hydroxyocta-2,7-dienoic acid (250 μL, 0.10 mg/mL in ethanol) and then stirred with PVPP (ca. 5 g) under nitrogen for 16 h. The wines were then centrifuged at 10 000 rpm (17 666 g) at 4 °C for 25 min and the supernatant then treated in the same way as the white wine and grape juice samples. For enantioselective analysis of wine lactone in Chardonnay E, the wine (250 mL) containing added sodium chloride (25 g) was continuously extracted with dichloromethane (150 mL) over 24 h. The organic layer was washed with brine (2 × 100 mL), dried ($MgSO_4$), and concentrated to 100 mL through a Vigreux column. The concentrate was then washed with aqueous sodium bicarbonate solution (0.5 M, 2 × 200 mL), dried ($MgSO_4$), and further concentrated to 5 mL. The concentrated extract was then purified by column chromatography on silica gel 60 (30 × 2 cm^2 column, filled to 20 cm). Elution was carried out using pentane/ether (95:5, 200 mL, collected as fraction 1; 90:10, 200 mL, fraction 2; 70:30, 100 mL, fraction 3; 70:30 100 mL, fraction 4; 60:40, 200 mL, fraction 5; and 0:100, 200 mL, fraction 6). All fractions were concentrated to 5 mL as above and further concentrated to 200 μL under a stream of nitrogen. Samples were then transferred into a 2 mL GC/MS vial fitted with a 250 μL insert ready for analysis by GC-MS. Wine lactone was detected in fractions 3 and 4.

Method Validation for Quantitative Analysis of Menthiafolic Acid in Wine and Grape Juice. Calibration curves for menthiafolic acid (**2a**) were obtained with spiked standard additions to model wine (pH 3.3), white wine, and grape juice. The analyte (**2a**) was added to afford the following concentrations: in model wine, 0, 5, 10, 50, 100, 250, 500, and 2000 μg/L; in white wine, 0, 5, 10, 50, 100, 150, 250, 500, 1000, and 2000 μg/L; and in grape juice, 0, 5, 10, 150, 250, 500, and 2000 μg/L. All spiked samples were prepared, extracted, and analyzed in duplicate as previously described.[17] For the white wine, six replicates of the 10 and 500 μg/L spiked wine samples were prepared, extracted, and analyzed to test the repeatability of the method. The calibration curves were linear throughout the concentration range, with correlation coefficients (r^2) for **2a** of 0.9998, 0.9987, and 0.9993 for the model wine, white wine, and grape juice, respectively. For the white wine, the standard deviations were 6.5 and 3.5% at 10 and 500 μg/L, respectively. The slopes of the calibration curves were virtually identical. The LOD was 5 μg/L, and LOQ was 15 μg/L on the basis of visual evaluation. On the day of each set of analyses of the commercial wine and juice samples and of the various ferments described below, a minicurve was prepared in model wine. Three concentration points were prepared in duplicate at 5, 500, and 2000 μg/L and extracted simultaneously with the wine samples. QC's with additions of 10 and 500 μg/L were also prepared in duplicate and analyzed along with the wine, juice, and fermentation samples, each of which were also analyzed in duplicate.

Fermentation Studies with Menthiafolic Acid Glucose Ester (2b). All fermentation treatments were conducted in triplicate with either CDGJM (150 mL) or synthetic wine (150 mL) containing glucose ester **2b** at a concentration of 1.32 mg/L. Triplicate control experiments were carried out (a) with inoculated medium (150 mL) containing no glucose ester **2b** and (b) with noninoculated medium (150 mL) spiked with glucose ester **2b** and stored for the same time and temperature as the ferments. Starter cultures were prepared as follows: *S. cerevisiae* strain AWRI 838 and *Dekkera bruxellensis* strain AWRI 1499 were both obtained from the Australian Wine Research Institute culture collection maintained on yeast malt (YM) medium (Amyl Media, Dandenong Australia) supplemented with 1.5% agar and stored at 5 °C. Starter cultures were prepared by adding a loopful of yeast cells to YM (10 mL) and incubating at 28 °C with shaking for 48 h (*Saccharomyces*) or 72 h (*Dekkera*). Preadaptation of the cells to the fermentation medium was carried out by inoculating 600 μL (*Saccharomyces*) or 1 mL (*Dekkera*) of the starter culture into a 50:50 solution of CDGJM/YM (30 mL) and incubating at 28 °C overnight (*Saccharomyces*) or for 48 h (*Dekkera*). *Oenococcus oeni* (Lallemand VP-41) was reconstituted from a commercial preparation according to manufacturers instructions by addition of the freeze-dried bacteria (0.15 g) to sterilized water (30 mL) at 20 °C, which was then allowed to stand for 15 min with occasional stirring.

Alcoholic Fermentations. *S. cerevisiae* strain AWRI 838 (300 μL of a ca. 2 × 10^8 cell count culture) in 1:1 YM/CDGJM was inoculated into CDGJM (150 mL) containing glucose ester **2b**. Fermentations were incubated at 22 °C for 9 days and were shaken constantly at 120 rpm. Fermentation progress was monitored by weight, and ferments were deemed complete when no further weight loss was recorded. This was verified by analysis of residual glucose and fructose, which showed an average final total sugar content of 6.4 g/L.

Malolactic Fermentations. *O. oeni* (Lallemand VP-41) in sterile water (300 μL) was inoculated into synthetic wine (150 mL), containing the glucose ester **2b**, that had previously been stored in an anaerobic chamber to remove all oxygen. The fermentations were incubated under anaerobic conditions for 13 days at 22 °C. Fermentation progress was monitored by malic acid content, which was an average of 0.48 g/L at the end of fermentation.

DOI: 10.1021/acs.jafc.5b03147
J. Agric. Food Chem. 2015, 63, 8241−8246

***Dekkera* Fermentations.** *D. bruxellensis* AWRI 1499 was inoculated at 2×10^6 cfu/mL into synthetic wine (150 mL, adjusted to 5 g/L fructose) containing the glucose ester **2b** that had previously been stored in an anaerobic chamber to remove all oxygen. Fermentations were incubated under anaerobic conditions at 22 °C for 13 days before analysis for **2a**. Ferments were monitored by glucose plus fructose content. The fermentation did not go to completion and had average sugar levels of 13.1 g/L after 14 days.

RESULTS

Quantitative Analysis of Grape and Wine Samples for Menthiafolic Acid (2a). A total of 28 white wines, 4 Shiraz wines, and 6 white grape juice samples were analyzed for menthiafolic acid (**2a**) using a previously described stable isotope dilution assay that determines **2a** as the corresponding methyl ester.[17] The results of these analyses are shown in Tables 1 and 2. Menthiafolic acid was detected in all but one of the wine samples at concentrations ranging from 26 to 342 μg/L. The highest concentrations were found in a Chardonnay (234 μg/L), Gewürztraminer (272 μg/L), and Lexia (342 μg/L) wine. On the basis of the hydrolysis kinetics we reported earlier,[14] these quantities of **2a** would be sufficient to generate wine lactone at a concentration above its reported odor detection threshold after one to two years of aging, provided that the wine lactone (**1**) formed is predominantly the same enantiomer (**1a**) as that reported by Guth.[6] Lexia, a monoterpene-dependent variety, showed the highest concentration of **2a** of all the wines analyzed. Lexia is produced from Muscat grapes and can be aged from 5 to 8 years. Chardonnay wines can also sometimes undergo aging, albeit for shorter periods. The Shiraz wines, which are most often aged for a few years prior to drinking, also had significant quantities of **2a**.

Semillon	13.6	16	1.8
Viognier	13.8	27	2.6

The grape juice samples analyzed contained **2a** at variable concentrations (Table 2). To our knowledge, this is the first report of the occurrence of menthiafolic acid (**2a**) in grape juice. The Gewürztraminer had the highest concentration of **2a** (235 μg/L), whereas the other juices contained significantly less. Although the concentration of **2a** in half of the juice samples was lower than in most of the wines, we note that the sample numbers were relatively small, the variation in concentration is large, and the wines were not made from these juices so a direct comparison of the two sets of data ought not to be made.

Formation of Menthiafolic Acid (2a) from the Corresponding Glucose Ester 2b during Fermentation with *Saccharomyces*, *Oenococcus*, and *Dekkera* spp. The analyses demonstrate that menthiafolic acid (**2a**) is a component of at least some grape juices, but it is possible that additional quantities of **2a** could be produced from other precursors such as glucose ester **2b** by microbiological processes occurring during various winemaking steps such as fermentation and barrel aging. This possibility was therefore investigated by conducting a series of replicated model fermentations in which the media were spiked with synthetic **2b**. CDGJM was inoculated with *S. cerevisiae* (strain AWRI 838) for alcoholic fermentation, whereas secondary ferments were conducted with model wines (produced from fermented CDGJM) inoculated with either *O. oeni* commercial preparation VP-41 from Lallemand or *D. bruxellensis* strain AWRI 1499. These strains are among the most commonly used for or (for *D. bruxellensis*) encountered during winemaking in Australia.

In all fermentation treatments to which glucose ester **2b** was added, menthiafolic acid (**2a**) was detected at the end of fermentation, although the amounts found in the *D. bruxellensis* treatments were below the limit of quantification (15 μg/L, equivalent to 2% conversion). No menthiafolic acid was detected in the control ferments to which no glucose ester had been added or in uninoculated control samples containing the glucose ester. This suggests that the menthiafolic acid was formed by biological transformation of **2b**. The proportion of ester converted to acid is shown in Table 3.

In these experiments, the greatest degree of release of **2a** by wine microorganisms was during alcoholic fermentation, whereas a smaller amount was also released during subsequent malolactic fermentation. Together, these fermentations were

J. Agric. Food Chem. 2015, 63, 8241−8246

Table 3. Percent Conversion of Glucose Ester (2b) to Menthiafolic Acid (2a)

inoculating organism	% conversion	% sd
Saccharomyces cerevisiae AWRI 978	14.7	1.7
Oenococcus oeni VP-41	4.7	2.8
Dekkera bruxellensis AWRI 1499	<2	

able to convert around 20% of the added glucose ester **2b** to menthiafolic acid **2a**. Of course, commercial wine production encompasses a whole range of winemaking conditions and practices, including addition of exogenous enzymes, and the extent to which menthiafolic acid can be formed from its glucose ester is likely to be highly variable. Whether this formation is important to the final concentration of menthiafolic acid in wine will also depend on the proportions of this acid and its glucose ester in the corresponding must. There is not yet, however, a method for quantifying ester **2b** in juice or wine. In addition, it is possible that juice contains other, as yet unidentified, conjugates of menthiafolic acid that can also be converted to **2b** during vinification.[9]

Enantioselective Analysis of Menthiafolic Acid and Wine Lactone. Although grape juices can contain menthiafolic acid (**2a**) in significant concentration and this concentration can be augmented through the action of some wine microorganisms with esterase activity, an assessment of the importance of **2a** as a precursor to the odor-active form of wine lactone **1a** requires a determination of the chirality of **2a**. Several of the wine and juice samples listed in Tables 1 and 2 were therefore reanalyzed by enantioselective chromatography. The results are shown in Table 4.

Table 4. Percentage of (*R*)- and (*S*)-Menthiafolic Acid 2a in Various Samples

	% (*R*)[a]	% (*S*)[a]	SD (%)
	Wine Sample		
Chardonnay E	11	89	1.1
Gewürztraminer	23	77	0.5
Shiraz A	17.5	82.5	0.2
Shiraz B	19.5	80.5	2.8
	Grape Juice Sample		
Gewürztraminer	15	85	0.8

[a]Percentage of total menthiafolic acid **2** present. Samples are the same as those for Tables 1 and 2.

Each sample contained **2a** in both *R*- and *S*-forms. When samples were spiked with synthetic *R*-menthiafolic acid, only the peak assigned as the *R*-methyl ester of **2a** on gas chromatography was symmetrically enhanced, confirming the assignments. The *S*-isomer predominated in all samples. This result was earlier suggested by Luan et al. because both linalool and its oxidation products were found to have mainly *S*-configuration.[15] On the basis of the observed stereochemistry of wine lactone formation,[14,15] if wine lactone in wine is formed primarily from acid-catalyzed rearrangement of menthiafolic acid, then wine lactone in the wines studied here would be expected to comprise mostly the relatively odorless enantiomer **1b** not the potent odorant **1a** reported by Guth.[1,6]

The method reported by Guth for measuring wine lactone in wine was a time-consuming process involving salting, continuous liquid–liquid extraction, concentration, washing, and column chromatography.[1,2] We therefore trialed various other methods for enantioselective analysis of wine lactone in wine. Although ethyl acetate extraction of model wine solutions of wine lactone in relatively high concentration was satisfactory for the model studies described previously,[14] a more sensitive method was required for real wines. Initially, we examined extraction methods for model wine solutions of wine lactone at a concentration of 5 μg/L. Recoveries by organic solvent extraction were poor, and solid-phase microextraction with a variety of fibers failed to detect any wine lactone at all. Salting out solutions did not improve these results. When a dichloromethane solution of wine lactone was back-washed with a single volume of model wine equivalent to the volume used for the extraction experiments, some 85% of the wine lactone was lost from the organic phase in a single extraction, indicating the hydrophilic nature of the analyte and that partitioning of wine lactone between organic and aqueous ethanolic solutions would only favor solution in the former when used in a relatively high volume. Partial dealcoholization of model wine solutions of wine lactone under alkaline conditions (in which the wine lactone was converted to the open-chain salt form), followed by reacidification and extraction with organic solvents, gave no improvement of extraction efficiency, and freeze-drying of solutions resulted in total loss of wine lactone.

The use of solid-phase extraction (SPE) sorbents gave variable results with model wine solutions of wine lactone. Optimal recovery of wine lactone, as indicated by GC peak intensity, was achieved with LiChrolutEN sorbent. The model wine solutions were first salted out, then percolated through the sorbent, and eluted with dichloromethane giving a recovery of 54%. However, when this technique was applied to a commercial white wine spiked with 10 μg/L of wine lactone, the recovered analyte was barely detectable by GC-MS. It appears that wine lactone was not efficiently adsorbed onto the solid phase when other wine components were present.

Isolation of wine lactone from white wine following a method similar to that used by Guth was ultimately successful.[1,2] A white wine (250 mL) spiked with **1** (5 μg/L) was extracted continuously with dichloromethane over 16 h. The extract was concentrated and analyzed by GC-MS showing wine lactone **1** as a significant peak. However, other peaks coeluting with **1** were also present, and these could not be resolved on a range of available GC-MS columns. When the dichloromethane extract was washed with base, evaporated, and subjected to column chromatography on silica, a much cleaner extract was obtained, with wine lactone (**1**) being easily observed free of coeluters by GC-MS. Although this method was not practical for large sample numbers because of its cumbersome and time-consuming steps, it was adequate to examine the chirality of wine lactone in a wine (Chardonnay E from Table 1) containing a high concentration of menthiafolic acid (**2a**). This wine was four years old at the time of analysis.

Chardonnay E contained both enantiomers of wine lactone **1a** and **1b**. To our knowledge, this is the first reported occurrence of the relatively odorless form **1b** as a wine constituent. Furthermore, and in contrast to the report of Guth who studied young white wines, **1b** was the dominant enantiomer, with a ratio of **1a**/**1b** = 31:69. On the basis of the enantioselectivity of the hydrolytic conversion of menthiafolic acid (**2a**) to wine lactone at pH 3.0 determined previously[14] and the relative proportions (Table 4) of (*R*)- and (*S*)-menthiafolic acid in Chardonnay E (which had a pH of 3.06), the predicted ratio of **1a**/**1b** that would be formed from

J. Agric. Food Chem. 2015, 63, 8241−8246

hydrolysis, at ambient temperature, of **2a** present in this wine would be 38:62, a result close to the ratio measured.

DISCUSSION

Ever since wine lactone was observed as a wine component, researchers have sought to understand the origin of this powerful and pleasant odorant that is present in young wine but can increase in concentration during bottle aging.[7] Bonnländer et al. proposed the monoterpene acid **2a**, commonly known as menthiafolic acid and found in numerous conjugated forms in a variety of plants,[9] as one possible precursor to wine lactone.[8] However, three separate studies have shown that enantiomerically pure menthiafolic acid gives two enantiomers of wine lactone on mild acid hydrolysis and not just the single enantiomer observed by Guth in his study of young white wines.

On the basis of our observations that menthiafolic acid (**2a**) in five grape and wine samples was always present mainly as the (*S*)-form and that the wine lactone in an aged Chardonnay wine was mainly the relatively odorless **1b** enantiomer, it seems unlikely that the **1a** enantiomer of wine lactone observed by Guth in young wines was formed from **2a**. It is possible that the additional wine lactone that Guth observed to be formed during bottle aging was indeed formed by hydrolysis of **2a** but was in fact partially, or even mostly, **1b**. If this was the case, then the enantiomerically pure **1a** in the younger wines must have had a biogenetic origin different from that formed from **2a** in older wine.

The ratio of **1a**/**1b** in wine probably varies from one sample to another, but wines that are more than a year old presumably contain at least some of the weakly odorous **1b** enantiomer. This being the case, simple nonenantioselective analysis of wine samples for wine lactone could lead to an overestimation of the impact of wine lactone on the aroma and flavor of wine. Such an assessment requires quantitative enantioselective analysis of samples. However, since the original studies by Guth, quantitative data for wine lactone in any form in wine samples has been lacking, presumably because of the difficulty in obtaining reference standards and because wine lactone is not easily extracted from wine using the most commonly employed techniques such as SPME. This poor extractability could also explain why wine lactone does not normally feature in lists of important wine odorants as determined by aroma extract dilution analyses.

The laborious method used by Guth to quantify wine lactone in his wine samples was adopted by us for enantioselective analysis of wine lactone in Chardonnay E after a variety of ultimately futile attempts to develop a streamlined analytical method. This more laborious procedure was adequate for individual samples but not for screening larger sample numbers. A more rapid procedure, suitable for larger sample numbers will probably require the sensitivity and resolving power of, for example, GC/GC/MS, to overcome problems of poor analyte recovery and coelution with other wine components.

Samples. Four hop samples were kindly supplied by Yakima Chief (Louvain-la-Neuve, Belgium): Amarillo, Citra, Mosaic, and Warrior (harvest 2013). Saaz hop (harvest 2013) and Hallertau Blanc were provided by Hopsteiner (Mainburg, Hallertau, Germany). A brown beer, bought at a local supermarket and stored for two years in a dark room at 20 °C for natural aging, was used for beer investigation.

Theaspirane Chemical Oxidation. A 0.485 g sample of commercial theaspirane (85% purity, final concentration 0.05 M), 50 mL of Milli-Q water, and 1 mL of hydrogen peroxide solution were mixed in the presence of 60 mg of iron chloride, used as catalyst. The reaction medium was heated at 100 °C for 3 h. After three diethyl ether extractions (3 × 20 mL), the extract was dried with anhydrous sodium sulfate. Dodecane was added as external standard, and the mixture was concentrated to 10 mL in a Kuderna-Danish apparatus at 39 °C (total concentration factor, 5; final EST concentration, 7 mg/L). The final extract was stored at −80 °C and analyzed by gas chromatography−mass spectrometry (GC-MS), gas chromatography−high-resolution mass spectrometry (GC-HRMS), and gas chromatography−olfactometric detection (GC-O).

Hop and Beer XAD 2 Extraction Procedure with or without Glucoside Enzymatic Release. For hop extraction, 20 g of finely ground hop and 1000 μL of internal standard (IST, 1 g/L octyl-glucopyranoside) were added to 250 mL of water/methanol (80:20 v/v) and mixed thoroughly with an Omni Mixer (Omni international, Kennesaw, GA) for ten 30 s periods interrupted by ten 30 s resting periods. The mixture was then centrifuged for 10 min at 10000 rpm; the upper phase was recovered, whereas the lower one was re-extracted in the same way. Both fractions were filtered with a Büchner funnel, and methanol was removed with a Rotavapor to a final volume of 300 mL. Polyphenols were eliminated by treatment for 1 h under agitation with 6 g of polyvinylpolypyrrolidone (AEB, Brescia, Italy). After a second Büchner filtration, the hop extract was divided into two 250 mL Schott flasks.

In the case of beer extraction, 150 mL of degassed beer and 500 μL of internal standard (IST, 1 g/L octyl-glucopyranoside) were poured into a Schott flask.

Six grams of Amberlite XAD 2 resin thoroughly rinsed with Milli-Q water (approximately 400 mL) were poured into each hop or beer flask. After being shaken in a dark room for 2 h, the mixtures were poured into a glass column for separation. After natural elution from the XAD 2 resin, 50 mL of water and 25 mL of diethyl ether were consecutively poured for resin washing. Glucosides were finally eluted with 25 mL of methanol. The extract was evaporated to dryness and resuspended in 25 mL of acetate buffer (pH 5). Enzymatically treated samples and controls (giving also free amounts of theaspirane analogs) were incubated at 35 °C for 2 h, with or without β-glucosidase (14 mg). Both were extracted three times with 15 mL of diethyl ether

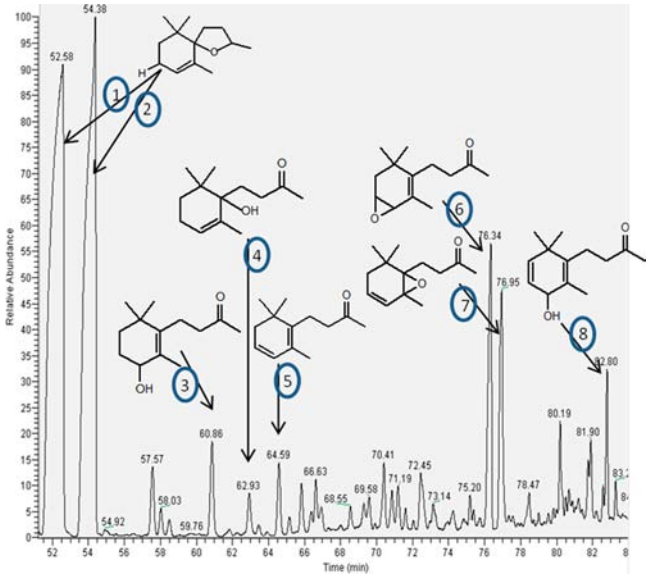

Figure 1. Total ion MS chromatogram of the theaspirane chemical oxidation media. (**1**) Theaspirane A, (**2**) theaspirane B, (**3**) 4-hydroxy-7,8-dihydro-β-ionone, (**4**) 6-hydroxy-7,8-dihydro-α-ionone, (**5**) dihydro-dehydro-β-ionone, (**6**) 3,4-epoxy-5,6-dehydro-7,8-dihydro-β-ionone, (**7**) 3,4-dehydro-5,6-epoxy-7,8-dihydro-β-ionone, and (**8**) 4-hydroxy-2,3-dehydro-7,8-dihydro-β-ionone.

(10 min, 1000 rpm). The combined organic phase was dried with anhydrous sodium sulfate, and 0.5 mL of EST (20 mg/L dodecane; final EST concentration, 20 mg/L) was added to the extract before concentration to 0.5 mL in a Danish-Kuderna apparatus at 39 °C. The final extracts were stored at −80 °C and analyzed by GC-MS.

Gas Chromatography−Mass Spectrometry. A 1 μL sample of hop, beer, or model extract was analyzed with a ThermoFinnigan Trace GC 2000 gas chromatograph equipped with a low-bleed MS capillary column (CP-Sil5-CB, 50 m × 0.32 mm i.d., 1.2 μm film thickness) and a splitless injector (250 °C). The split vent was opened 0.5 min postinjection. The oven temperature was programmed to rise from 36 to 85 °C at 20 °C/min, then to 145 °C at 1 °C/min, and finally to 250 °C at 3 °C/min. The carrier gas was helium, and the pressure was set at 100 kPa. Electronic impact (EI) mass spectra were recorded at 70 eV (full scan with a mass range from 40 to 380 m/z, or SIM mode on m/z = 70/84 for octanol; 57/71 for dodecane; 82/138 for theaspirane; 126/158 for 4-hydroxy-7,8-dihydro-β-ionone and

J. Agric. Food Chem. 2015, 63, 8247−8253

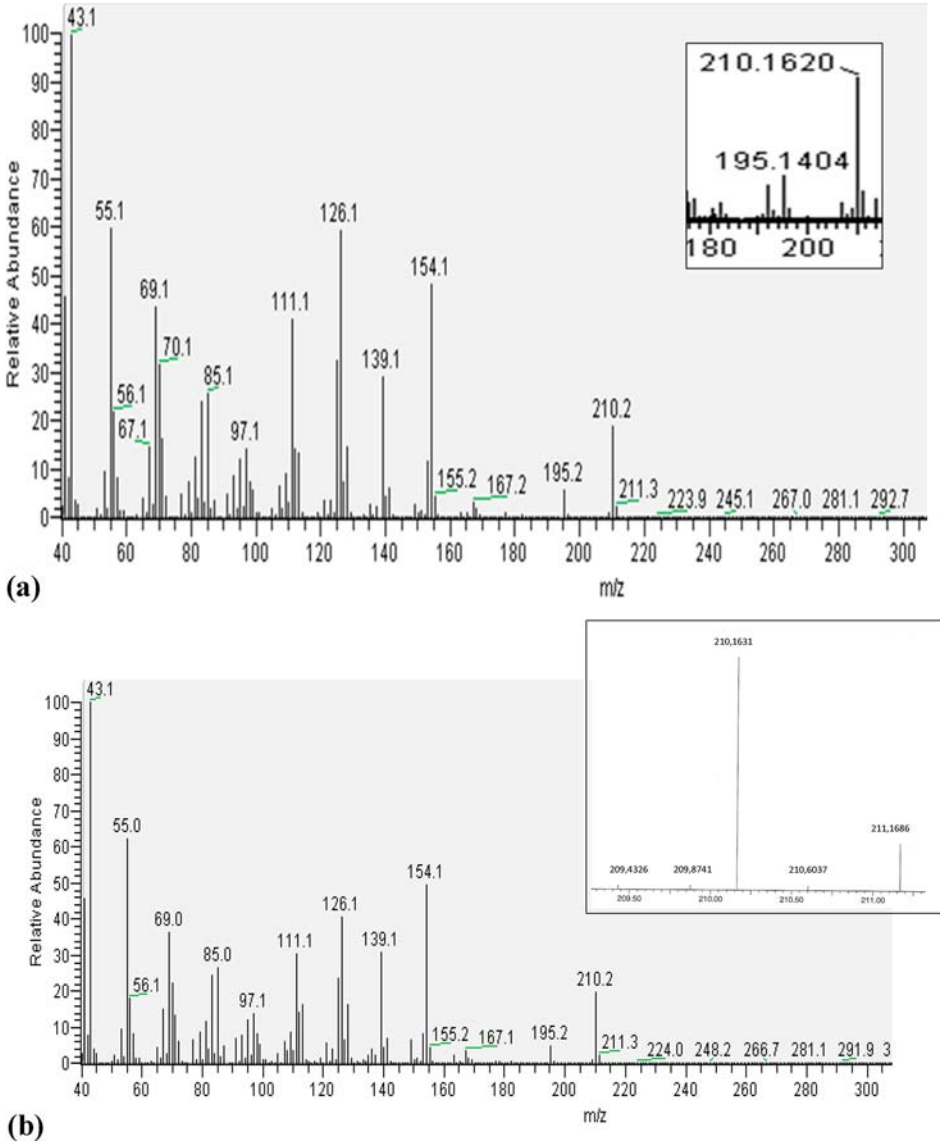

Figure 2. MS and HRMS spectra of 4-hydroxy-7,8-dihydro-β-ionone (a) and 6- hydroxy-7,8-dihydro-α-ionone (b).

6-hydroxy-7,8-dihydro-α−ionone; 119/134 for dihydrodehydro-β-ionone; 110/152 for 3,4-epoxy-5,6-dehydro-7,8-dihydro-β-ionone; 191/209 for 3,4-dehydro-5,6-epoxy-7,8-dihydro-β-ionone; and 165/137 for 4-hydroxy-2,3-dehydro-7,8-dihydro-β-ionone) on a ThermoFinnigan Trace MS simple quadrupole mass spectrometer. Spectral recording was automatic throughout separation (Xcalibur software was used, NIST databank).

Gas Chromatography−High-Resolution Mass Spectrometry. The apolar column described above for GC-MS was connected to a GC-HR mass spectrometer from Waters (HRMS, GCT Premier, ToF). Perfluorotributylamine was injected on line as MS standard (the ions 69 and 131 were found in all spectra). Electron ionization (EI) mass spectra were recorded at 70 eV (trap current, 200 IA; emission current, 400 IA). Spectral recording was automatic throughout separation (Xcalibur software was used, NIST databank).

Gas Chromatography−Olfactometric Detection. A 1 μL sample of hop, beer, or model extract was analyzed with a Chrompack CP9001 gas chromatograph equipped with a splitless injector maintained at 250 °C; the split vent was opened 0.5 min postinjection. Compounds were analyzed with the wall-coated open tubular (WCOT) apolar CP-Sil5-CB column (50 m × 0.32 mm i.d., 1.2 μm film thickness). The carrier gas was nitrogen, and the pressure was set at 60 kPa (CP-Sil5-CB). The oven temperature was programmed to rise from 36 to 85 °C at 20 °C/min, then to 145 °C at 1 °C/min, and finally to 250 °C at 3 °C/min. In order to assess the olfactory potential of the extracts, the column was connected to a GC-O port (Chrompack) maintained at 250 °C. The effluent was diluted with a large volume of air (20 mL/min) prehumidified with an aqueous copper(II) sulfate solution.

Statistical Analyses. All analyses were carried out in duplicate. Multiple comparisons of means were performed by means of Tukey's test, with SAS software version 9.2 (SAS Institute, Inc., Cary, NC). Values in Table 1 that do not share a common letter are significantly different ($p < 0.05$).

RESULTS AND DISCUSSION

Investigation of Theaspirane Degradation Media. In order to study theaspirane oxidation products, theaspirane degradation medium was analyzed by GC-HRMS. Besides 4-hydroxy-7,8-dihydro-β-ionone ($RI_{CPSil5CB}$ = 1373, peak 3, Figure 1), having a nice grenadine-like flavor, and dihydrodehydro-β-ionone ($RI_{CPSil5CB}$ = 1419, peak 5, Figure 1), exhaling a dried fruit/Sauternes aroma, already identified by Collin et al. (2012)[6] in the same oxidation medium, four major compounds (**4** ($RI_{CPSil5CB}$ = 1493), **6** ($RI_{CPSil5CB}$ = 1657), **7** ($RI_{CPSil5CB}$ = 1667), and **8** ($RI_{CPSil5CB}$ = 1774)) were evidenced (Figure 1). As depicted

in Figure 2, compound **4** exhibits the same mass spectrum as 4-hydroxy-7,8-dihydro-β-ionone (compound **3**), but no odor was detected at the GC-O sniffing port in the theaspirane degradation medium. Compound **4** is here tentatively identified as 6-hydroxy-7,8-dihydro-α-ionone by GC-HRMS (Figure 2 b) (experimental m/z = 210.1631; calculated m/z = 210.1620; δ = 5.2 ppm). Upon fragmentation, peaks 6 and 7 yielded the same mass spectrum, as illustrated in Figure 3a,b. These compounds appeared to be the

issued from degradation of compound **5**. Another compound (**8**), with an experimental m/z of 208.1521 but without any 152 fragment, was most probably issued from epoxide opening in compound **6**, leading to 4-hydroxy-2,3-dehydro-7,8-dihydro-β-ionone (fragmentation pattern proposed in Figure 4). Figure 5 gives a hypothetical succession of degradations (including oxidation, hydration, epoxidation, epoxide opening), starting from theaspirane or its preprecursor and giving rise to compounds **3**–**8**.

Investigation of Free and Bound Precursors of Theaspirane and Derived Compounds in Hop. The existence of a theaspirane glucosidic precursor has been mentioned by Daenen et al. (2008)[4] for the Saaz hop variety. Therefore, theaspirane and its degradation products were here investigated in six hop varieties before and after enzymatic treatment. The GC-MS chromatogram of Mosaic XAD-2 extract (Figure 6) revealed, for the first time, the existence of huge quantities of free theaspirane (**1** and **2**) in hop (7.3 and 6.3 mg/kg,respectively), together with 4-hydroxy-7,8-dihydro-β-ionone (**3**), 6-hydroxy-7,8-dihydro-α-ionone (**4**), dihydrodehydro-β-ionone (**5**), and both monoepoxides (**6** and **7**). Yet Mosaic emerged as the only variety among those investigated here to contain these compounds mainly in free form. Citra and Amarillo proved to be much more interesting sources of the theaspirane preprecursor (111 and 2290 mg/kg enzymatically released, respectively; Table 1). Together with theaspirane, 4-hydroxy-7,8-dihydro-β-ionone was also found in hop extracts subjected to β-glucosidase treatment, especially for the hop Amarillo (10 mg/kg). Although containing only 26 mg/kg theaspirane, the dual hop variety Hallertau Blanc emerged as the best source of the nice dried-fruit-like dihydrodehydro-β-ionone (4 mg/kg from bound form, Table 1). From the brewer's standpoint, we can suspect free compounds to be massively lost through volatilization during boiling, while glucosides should be able to release an unexpected range of flavors through enzymatic or chemical hydrolysis during fermentation or beer aging. The enzymatic treatment applied to conventional hops (the aromatic Saaz and the bitter Warrior) yielded much less interesting profiles (<2 mg/kg theaspirane and no derived compounds detected). The four dual hops investigated here have also been described, recently, to be of particular interest for their citrus-like potential, brought by very delicate polyfunctional thiols and terpenols.[13]

Investigation of Theaspirane Degradation Products in Fresh and Aged Beer. Scholtes et al. (2012)[5] have recently shown that glucosides, partially hydrolyzed and oxidized during hop or beer aging, can release theaspirane analogs in Gueuze beers. This mechanism, although less favored in usual unoxidized lager and special beers, could also be a source of interesting flavors.Theaspirane and its oxidation-derived compounds were next investigated in a Belgian top-fermentation beer, both fresh and allowed to age for two years. For the first time in a top-fermentation beer, theaspirane A (**1**), theaspirane B (**2**), 4-hydroxy-7,8-dihydro-β-ionone (**3**), 6-hydroxy-7,8-dihydro-α-ionone (**4**), and both monoepoxides (**6** and **7**) were all evidenced by GC-MS in the fresh beer samples (Figure 7).

Despite unavoidable oxidation in the bottle, analysis of the 2-year-aged beer samples revealed the presence of theaspiranes A and B in the same concentration range as found in the fresh samples (3.6 μg/L theaspirane A in fresh beer and 4.4 μg/L after 2 years; 2.4 μg/L theaspirane B in fresh beer and 2.7 μg/L after 2 years). This supports the hypothesis of a balance due to glucoside hydrolysis. Of course, complementary data are still needed to confirm the occurrence of glucosidic forms in fresh beer, and their ability to be enzymatically or chemically hydrolyzed through aging. On the other hand, 4-hydroxy-7,8-dihydro-β-ionone (**3**), 6-hydroxy-7,8-dihydro-α-ionone, and both monoepoxides (**6** and **7**), present in fresh samples (0.7, 0.2, 4.7, and 2.8 μg/L, respectively), proved to be degraded to unquantifiable levels after 2 years.

place in beer based mainly on following the rate of oxygen consumption. Oxygen is a central reactant in oxidative reactions, and the amount of consumed oxygen is therefore an excellent measure of the overall extent of oxidation. However, this technique has so far not been used for mechanistic studies of oxidative reactions in beer, despite its successful use in mechanistic studies of oxidation mechanisms in wine.[17] The focus of this study has been characterization of the interactions between compounds that are important for the formation of radicals by metal-catalyzed oxidation reactions. This has included studies of intermediary radicals detected by ESR and characterization of the antioxidant properties of sulfite and thiols in beer.

MATERIALS AND METHODS

Chemicals. ThioGlo 1 fluorescent thiol reagent was obtained from Berry & Associates, Inc. (Dexter, MI, U.S.A.). Acetonitrile, glutathione (GSH), $FeSO_4{\cdot}7H_2O$, H_2O_2, N-*tert*-butyl-α-nitrone (PBN), 1-octanol, hydrochloric acid (37%), and 2,2,6,6-tetramethylpiperidine-1-oxy (TEMPO) were purchased from Sigma-Aldrich (St. Louis, MO, U.S.A.). Tris(hydroxymethyl)amino methane (tris), $Fe_2(SO_4)_3{\cdot}H_2O$, trifluoroacetic acid (TFA, > 99.8%), and sodium ascorbate were obtained from Merck (Darmstadt, Germany). Sodium sulfite was obtained from J.T. Baker, Deventer, The Netherlands. All chemicals were of analytical grade or highest possible purity. Water was purified through a Milli-Q water purification system (Millipore, Billerica, U.S.A.).

An all-malt pilsner beer (bottled with crown corks, 4.6% vol. alcohol) was obtained from a local supermarket and stored at 4 °C in the dark. All bottles were from one production batch and replicate analyses were performed by using different bottles. Before experiments, 150 mL beer was degassed by stirring 5 min in a Blue Cap bottle. Excessive foaming was prevented by addition of 15 μL 1-octanol.

Forced Aging of Beer. Forced aging was conducted by incubating the beer at elevated temperatures or by addition of Fenton reagents (Fe(II) or Fe(III) and H_2O_2 either alone or in combination) at different concentrations. All reagents were prepared fresh every day. The specific conditions and concentrations are given in the figure texts of each figure.

Measurement of Oxygen Consumption. Experiments studying the effects of addition of Fenton reagents were carried out using a 150 mL two-necked, round-bottomed flask equipped with a magnetic stirring bar placed in a water bath at 26 °C. One neck was closed with a rubber septum, and a HQ 30d Luminescent Dissolved Oxygen (LDO) sensor (Hach Lange, Düsseldorf, Germany) was placed in the other neck. The flask was completely filled with degassed beer, which had been freshly saturated with atmospheric air by bubbling for 2 min. The oxygen measurements were started immediately after the flask was filled. The oxygen concentration was recorded every 10 s, and the sensor had initially been calibrated against air saturated water at 26 °C. The oxygen consumptions were typically measured during 8 h. Solutions of Fenton reagents (Fe(II), Fe(III), or H_2O_2) were added during the experiments through the rubber septa using syringes and needles.

In experiments where effects of temperature were studied, a set up using a Clark electrode (Unisense NR-sensor, Aarhus, Denmark) was used. Aliquots of 50 mL of degassed beer were air saturated by flushing with atmospheric air for 2 min in a preheated water bath adjusted to the desired temperature (26 °C, 40 °C, and 60 °C). Subsequently, the sample was quickly transferred to a 2 mL chamber (MR-chamber, Unisense, Aarhus, Denmark) leaving no headspace of air. Aliquots of 20 μL of 0.36 mM Fe solution was added immediately before closing the chamber in experiments testing the effects of iron. The filled chamber was placed in a thermostated water bath adjusted to the same temperature as that for the air saturation and equipped with a Clark electrode. The measurement was started immediately. The oxygen concentration was recorded every 10 s using an oxygen analyzer (Picoammeter PA 2000, Unisense, Aarhus, Denmark). The electrode and oxygen analyzer were calibrated by a two-point calibration using air saturated water and oxygen-free solutions of 0.1 M sodium ascorbate in 0.1 M NaOH at the same temperatures as those in the experiments. The calibrations were performed before each analysis. The molar concentrations of oxygen in air saturated beer at the different temperatures were calculated from Ostwald coefficients for oxygen solubility in alcohol−water solutions at 4, 12, 25, and 50 °C, as reported by Shchukarev and Tolmacheva.[18] The Ostwald coefficient (I) describes the solubility of a gas in a liquid and is defined according to eq 1, where V_G is the volume of absorbed gas, and V_L is the volume of absorbed liquid:[19]

$$I = \frac{V_G}{V_L} \tag{1}$$

The Ostwald coefficients are reported by Shchukarev and Tolmacheva as a function of the alcohol concentration as mass %. The beer used in this study had a density of 1.01 g/mL, resulting in an alcohol content equal to 3.6 mass %. The Ostwald coefficients for water and 3.6% ethanol in water at 26 and 40 °C were obtained from interpolation of second order polynomial fits of Van't Hoff plots of Shchukarev and Tolmacheva's data, whereas the coefficients for water and 3.6% ethanol in water at 60 °C were obtained by equivalent second order polynomial extrapolation (Table 1). The Ostwald coefficients were converted to molar concentrations using the ideal gas law, eq 2.

Table 1. Ostwald Coefficients and Oxygen Concentrations in Water and in 3.6%(w/w) Ethanol in Water in Contact with Atmospheric Air[a]

	Ostwald coefficient		oxygen concentration (μM)	
T (°C)	in water	in 3.6% (w/w) ethanol	in water	in 3.6% (w/w) ethanol
4	0.0451[b]	0.0468	416	432

40	0.0259	0.0264	212	215
50	0.0238[b]	0.0239	189	189
60	0.0223	0.0222	172	170

[a]The values are calculated from data reported by Shchukarev & Tolmacheva (1968) as described in Materials and Methods. [b]Data from Shchukarev & Tolmacheva (1968).

$$n = \frac{p{\cdot}V_G}{R{\cdot}T} \tag{2}$$

where p is the atmospheric pressure of gas, R the universal gas constant, and T is the temperature.

From the loss of oxygen concentration over time, the rate constants of oxygen consumption were calculated at 26 °C, 40 °C, and 60 °C and plotted in order to determine the temperature dependency according to the Arrhenius eq 3, where k is the rate constant, E_a is the activation energy, A is the preexponential factor, R the universal gas constant, and T is the temperature:

$$\ln k = \ln A - \frac{E_a}{R}{\cdot}\frac{1}{T} \tag{3}$$

The slope of the Arrhenius plot (E_a/R) is used for the calculation of the temperature coefficient (Q_{10}) by eq 4:

$$\log Q_{10} = \frac{10{\cdot}E_a}{2.3{\cdot}R{\cdot}T^2} \tag{4}$$

where the Q_{10} value indicates the increase in reaction rates when the temperature is increased by 10 °C.

ESR Lag Phase Measurements during Forced Aging. Measurements of lag phases for radical formation were performed by ESR according to Uchida et al.[9] Beer was degassed by stirring on a magnetic stirrer for 5 min. Degassed beer containing 30 mM PBN was heated at 60 °C in closed Blue Cap bottles with a headspace of atmospheric air. Samples were analyzed at given time intervals. ESR spectra were recorded at room temperature with a JES-FR30 ESR spectrometer (Jeol, Tachikawa, Japan) using a quartz capillary (ID 0.75 mm) sample cell (Wilmad Glass, Buena, NJ). The settings were as follows: Microwave power, 4 mW; sweep width, 50.0 G; sweep time, 2 min; modulation amplitude 1.25 G; time constant 0.3 s. Intensities of the ESR signals were calculated relative to an internal Mn(II) standard attached to the ESR cavity. All ESR measurements were performed in duplicate as a minimum.

Sulfite and Thiol Analysis. Quantification of sulfite and thiols was performed according to Abrahamsson et al.[20] and Hoff et al.[21] based on derivatization of sulfite and thiols with ThioGlo 1 fluorescent reagent followed by separation with Reversed Phase High Performance Liquid Chromatography (RP-HPLC) and fluorescence detection. Sulfite and thiol determinations were performed in duplicate as a minimum.

Data Analysis. Statistical analysis was performed using SAS 9.2 package, SAS Institute, Inc., U.S.A. Data were analyzed by analysis of variance using proc glm. Means were used to compare differences and LSD was applied to compare the mean values. The significance level was $p < 0.05$.

RESULTS

Effects of Iron and Hydrogen Peroxide on Oxygen Consumption. Oxygen is a central reactant in various oxidative reactions, and the rate of oxygen consumption is therefore expected to provide quantitative information about the overall rate of oxidation reactions in the tested beer. Experiments were carried out at temperatures from 25 to 60 °C using degassed beer that had been quickly saturated with atmospheric air immediately before the oxygen measurements were initiated. The oxygen concentration in 3.6% (w/w) ethanol in water, which is equivalent to the alcohol concentration of the applied lager beer, was calculated at different temperatures as described in the Materials and Methods section from Ostwald coefficients reported by Shchukarev and Tolmacheva for oxygen solubility in ethanol–water mixtures (Table 1).[18] The results showed that ethanol concentration of 3.6% (w/w) only had a minor influence on the oxygen solubility as compared to pure water.

Oxygen consumption in the lager beer that was saturated by atmospheric air was measured at 26 °C, and within the first 10 min of the measurements, the oxygen concentration decreased quickly, followed by a slower linear decrease during the following 8 h (Figure 1). Only about 25% of the initial amount of oxygen was consumed during the experiment. The addition of Fe(II) or Fe(III) after 2 h was found to have a major effect on the rate and extent of oxygen consumption at high concentrations (36 μM). The subsequent addition of H_2O_2 after 4 h significantly increased the rate of oxygen consumption, and the rate increase was larger when 36 μM Fe had been added in advance as compared to addition of only 3.6 μM Fe. Surprisingly, the additions of Fe(II) or Fe(III) had very similar effects. This may be due to the rapid conversion of Fe(III) to Fe(II) by reducing compounds in beer, in agreement with the findings of Kunz et al.[21] Further addition of H_2O_2 after 6 h did not affect the rate of oxygen consumption, which suggests the system had already been saturated after the first addition of H_2O_2. The addition of H_2O_2 alone did not result in any significant increase in the rate of oxygen consumption as compared to the control (data not shown). This demonstrates that the combination of Fe and H_2O_2 increases the rate of oxygen consumption in beer to a greater extent than the individual compounds alone.

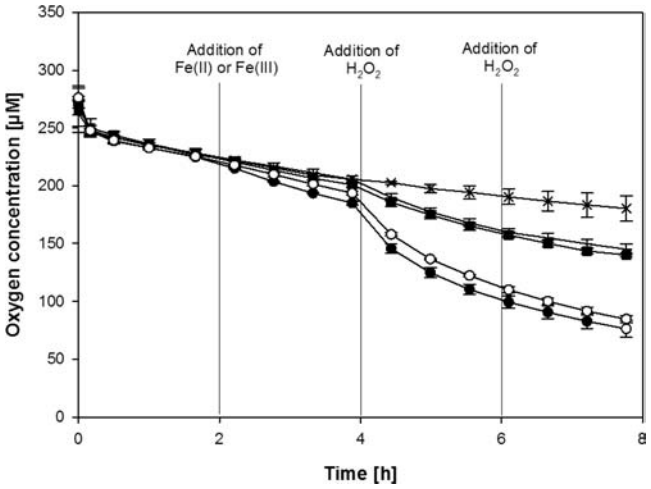

Figure 1. Oxygen consumption in beer, in which 3.6 μM Fe(II) (−), 3.6 μM Fe(III) (■), 36 μM Fe(II) (●), or 36 μM Fe(III) (○) were added after 2 h, and 180 μM H_2O_2 was added after 4 and 6 h at 26 °C. The control beer (x) was studied without addition of the Fenton reagents. Means are presented, and standard deviations are shown as error bars, $n = 2$.

The rates of oxygen consumption in air saturated lager beer were determined at 26 °C, 40 °C, and 60 °C, with and without the addition of 3.6 μM Fe(II), in order to establish the temperature dependency of the oxidation processes. The oxygen consumption was found to be linear with time and with slightly increasing rates for increasing temperatures both with and without added Fe(II). An Arrhenius plot of the rates of oxygen consumption gave linear correlations with activation energies equal to 26.6 and 22.4 kJ/mol with added Fe(II) (Figure 2). The temperature coefficient (Q_{10}), which describes the ratio by which reaction rates are increased when the temperature is increased 10 °C, was determined from the

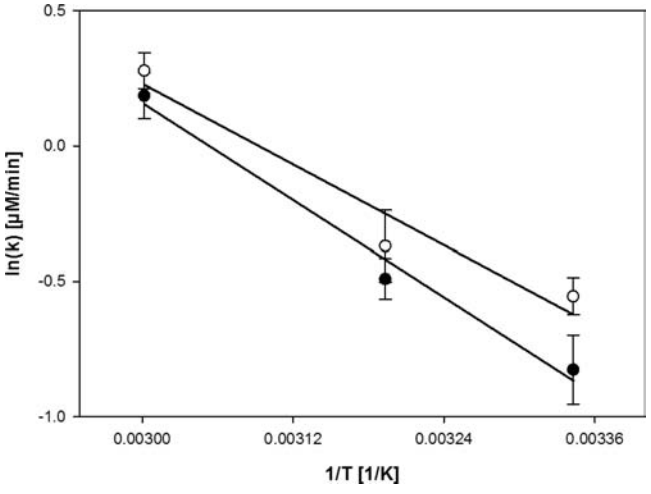

Figure 2. Arrhenius plot of the rate constants for oxygen consumption obtained at 26 °C, 40 °C, and 60 °C for fresh beer (●) and beer mixed with 3.6 μM Fe(II) (○). Means are presented and standard deviations are shown as error bars, $n = 3$.

DOI: 10.1021/acs.jafc.5b02617
J. Agric. Food Chem. 2015, 63, 8254–8261

activation energies by eq 4. Q_{10} was 1.4 ± 0.1 for beer and 1.3 ± 0.1 for beer with added of Fe(II). The addition of Fe(II) had no significant influence on the temperature dependency of the oxygen consumption. For most biological reactions, the Q_{10} is between 2 and 3.[22] Thus, the temperature dependency of oxygen consumption in beer is low, which may be due to a low enthalpy of reaction for the initial binding of dioxygen.

Formation of Radicals in Beer Determined by ESR Spectroscopy. The effects of the oxygen consumption on the formation of radicals were investigated by measuring the ESR lag phase. Beers were heated for different periods of time at 50 or 60 °C in the presence of atmospheric air. Subsequently, the spin trap PBN was added, and the lag phase measurements were initiated. Preincubation of the beer for up to 120 min at 50 °C was found to have no significant effect on the length of the lag phase (Figure 3). Increasing the preincubation

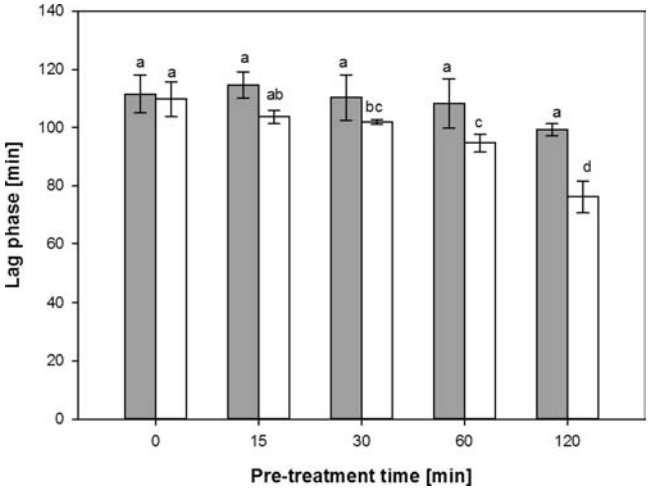

Figure 3. Lag phases determined by ESR spectroscopy of fresh beer and of beer preincubated at 50 °C (gray bars) and 60 °C (white bars) for 15 min, 30 min, 60 and 120 min. Means are presented and standard deviations are shown as error bars, n = 3. Different letters above bars indicate significantly different values (p < 0.05).

temperature to 60 °C decreased the lag phase slightly, and significantly more after 30 min preincubation, and the effects were more pronounced after 60 and 120 min of preincubation time. It is noteworthy that the lag phase of the fresh beer was 110 min, whereas incubation of the beer without the presence of the spin trap PBN at 60 °C for 120 min only reduced the lag phase by about 30 min. This suggests that the spin trap plays a more active role in the radical generating mechanisms in beer than by only trapping radicals. The moderate effect of preincubation on the length of the lag phase is in good agreement with the oxygen consumption measurements. Clearly, the beer still contained active antioxidants even after 120 min at 60 °C in the presence of atmospheric air. Addition of 3.6 μM of Fe(II) or Fe(III) to the beer and incubating for 15 min at room temperature decreased the ESR lag phase by about 30 min. Incubating the beer with added iron for longer times did not further shorten the lag phase (data not shown). Also, in these experiments, the addition of Fe(II) and Fe (III) had similar effects on the length of the lag phases.

The combined addition of Fe(II) and increasing concentrations of H_2O_2 15 min before the ESR lag phase measurements had two effects: (1) The length of the lag phase decreased, and (2) at the same time the initial level of trapped radicals increased (Figure 4A). Adding H_2O_2 in increasing concentrations (50−130 μM) without addition of

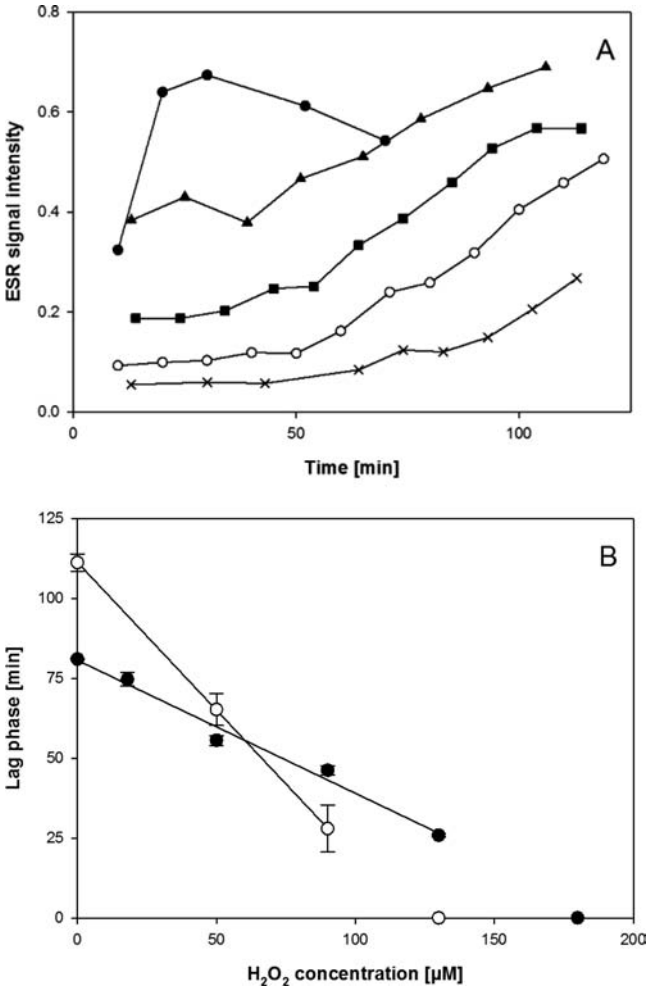

Figure 4. (A) Radical formation measured by ESR in beer at 60 °C with added 3.6 μM Fe(II) and H_2O_2 in the concentrations 18 μM (x), 50 μM (○), 90 μM (■), 130 μM (▲), and 180 μM (●) 15 min prior to analysis. Samples were run in duplicates and representative single measurements are presented. (B) Plot of ESR lag phases of beer with 3.6 μM Fe(II) added (●) and without 3.6 μM Fe(II) added (○) as a function of H_2O_2 concentration. Means are presented, and standard deviations are shown as error bars, n = 2.

Fe(II) only decreased the lag phases and did not influence the initial level of detected radicals (data not shown). Similar experiments have been performed by Uchida & Ono,[10] who observed a complete loss of lag phase by adding H_2O_2, which is likely due to the fact that they used much higher H_2O_2 concentrations (300−900 μM). According to Uchida & Ono,[23] H_2O_2 can accumulate in concentrations up to 15 μM at 60 °C in beer. The lag phase was found to decrease linearly with increasing H_2O_2 concentration, and the addition of Fe(II) decreased the slope of the linear dependence (Figure 4B).

Consumption of Sulfite and Thiols in Beer during Forced Aging. Sulfite is known to be an important antioxidant in beer and the concentration of sulfite is often found to correlate with the ESR lag phase.[10,12] Thus, the sulfite concentration was also quantified in beer during forced aging. Incubation of the beer with 50 μM H_2O_2 for 15 min at 26 °C caused a decrease in sulfite concentration of ca. 40 μM

DOI: 10.1021/acs.jafc.5b02617
J. Agric. Food Chem. 2015, 63, 8254−8261

independent of the addition of 3.6 μM Fe(II) (Figure 5). This suggests that sulfite mainly reacts with H_2O_2 in beer. Increasing

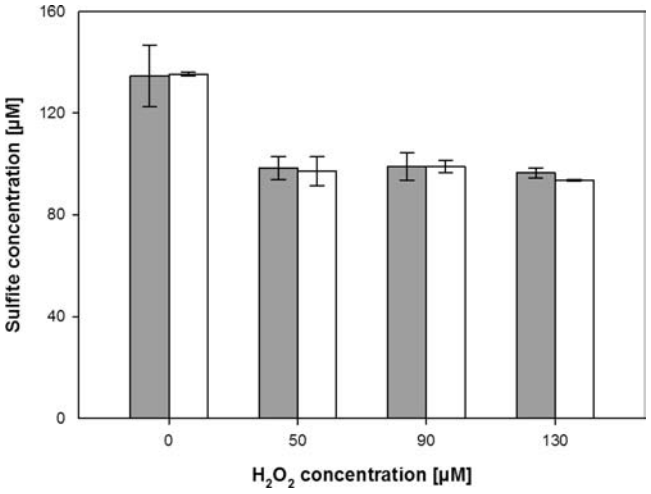

Figure 5. Sulfite concentrations in beer treated with different concentrations of H_2O_2. The beer either contained no additional Fe(II) (gray bars), or was added 3.6 μM Fe(II) (white bars). The beers were kept for 15 min at 26 °C before sulfite concentrations were determined. Means are presented, and standard deviations are shown as error bars, n = 2.

the H_2O_2 concentration did not result in further consumption of sulfite (Figure 5). Incubating the beer at 26 °C with only 3.6 μM Fe(II) did not affect the sulfite concentration. Similarly, the sulfite concentration was unaffected by addition of 36 μM Fe(II) or Fe(III) (3.6 μM and 36 μM) in the absence of of H_2O_2 (data not shown), which indicates that sulfite alone cannot protect the beer from oxidative processes during forced aging.

The consumption of sulfite was further investigated by incubating the beer at 26 °C for 8 h and at 60 °C for 1 and 8 h. Sulfite consumption was found to be highly temperature dependent; incubation at 26 °C for 8 h without addition of either Fe(II) or H_2O_2 resulted in a loss of about 40%, while incubation at 60 °C for 8 h caused a complete depletion of sulfite (Figure 6A). By incubation at 26 °C, the addition of 36 μM Fe(II) did not influence the sulfite concentration, whereas addition of 180 μM H_2O_2 caused an almost complete depletion of sulfite, proving the direct reaction between H_2O_2 and sulfite. Addition of 3.6 μM Fe(II) in combination with 180 μM H_2O_2 resulted in a similar sulfite consumption as without addition of Fe(II). Again, this observation confirms the ability of sulfite to remove H_2O_2 in beer. Surprisingly, addition of 36 μM Fe(II) in combination with 180 μM H_2O_2 resulted in a higher final sulfite concentration as compared with the addition of 3.6 μM Fe(II).

To clarify the role and reaction mechanism of protein thiols as antioxidants in beer, thiols were also quantified in the same samples as described above. Consumption of thiols was clearly not as temperature dependent as that of sulfite, as the consumption patterns were very similar at 26 and 60 °C (Figure 6B). When incubating the beer for 8 h at 60 °C, only approximately 50% of the thiols were consumed, whereas sulfite was depleted (Figure 6, parts A and B). In beer without additives, all incubation conditions caused a loss of thiols, whereas addition of Fe(II) and/or H_2O_2 caused an additional loss of thiols. Addition of a combination of Fe(II) and H_2O_2 caused the greatest loss of thiols, indicating that thiols primarily

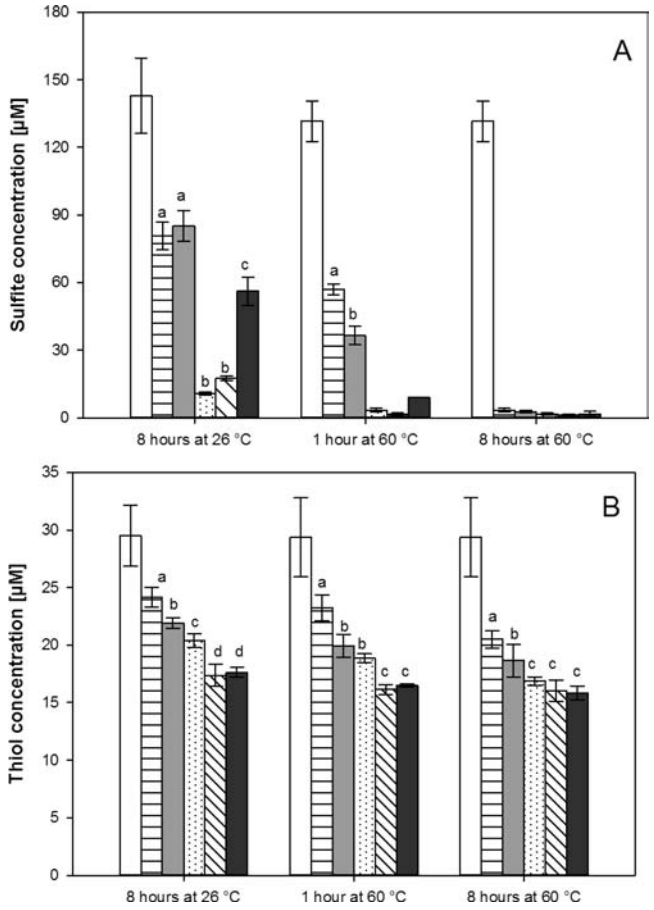

Figure 6. Sulfite (A) and thiol (B) concentrations in fresh beer (white bars) and incubated beers with no additives (horizontal striped bars) and with addition of 36 μm Fe(II) (gray bars), 180 μM H_2O_2 (dotted bars), 3.6 μM Fe(II) + 180 μM H_2O_2 (slanting striped bars), and 36 μM Fe(II) + 180 μM H_2O_2 (black bars) as determined by RP-HPLC with ThioGlo 1 after incubation for the specified periods and temperatures. Means are presented, and standard deviations are shown as error bars, n = 3. The different letters above the bars indicate significantly different values ($p < 0.05$).

react with 1-hydroxyethyl radicals formed via the Fenton reaction. Considering the observed preservation of sulfite in beer with added 36 μM Fe(II) and 180 μM H_2O_2 compared to addition of 3.6 μM Fe(II) and 180 μM H_2O_2 (Figure 6A), it can be ruled out that thiols protect sulfite from consumption, as no additional loss of thiols happened by addition of the high concentration of Fe(II) in combination with H_2O_2.

DISCUSSION

The early oxidative reactions in beer can be described by the mechanism shown in Scheme 1, which is based on iron catalyzed trapping of oxygen leading to the initial formation of hydrogen peroxide, which then initiates ethanol oxidation driven by the Fenton reaction. In this study, the focus has been on iron as the prooxidative catalyst; however, trace levels of copper are expected to play a similar role as that of iron. Similar mechanisms have been suggested for metal catalyzed oxidations in wine based on model studies, and they may therefore be of general relevance for a broad range of alcoholic beverages.[17,24] Oxygen is consumed both by the initial formation of hydrogen peroxide and also during the ethanol oxidation cycle, and the rates of oxygen consumption are therefore a combined measure

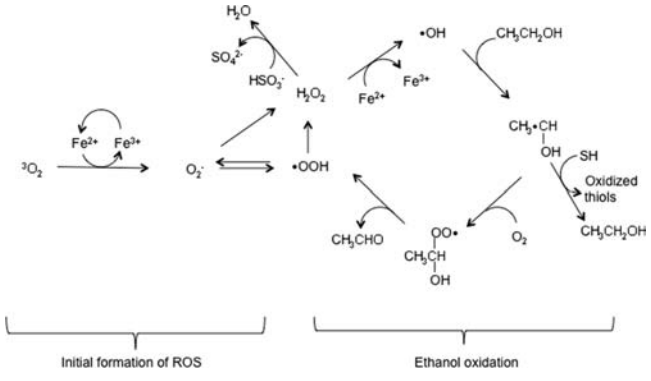
J. Agric. Food Chem. 2015, 63, 8254−8261

Scheme 1. Early Stages of Oxidative Reactions in Beer



of both parts of the oxidation scheme. The ESR lag phase measurements are based on trapping the 1-hydroxyethyl radical, which is a central intermediate in ethanol oxidation.

The ethanol oxidation involves the formation of hydroperoxyl radicals, $HOO^{\bullet}$, which disproportionate and generate oxygen and hydrogen peroxide reaction 4. The overall stoichiometry of the ethanol oxidation is therefore equivalent to reaction 5, which emphasizes that hydrogen peroxide and Fe(II) are consumed together with oxygen.

$$2HOO^{\bullet} \rightarrow H_2O_2 + O_2 \quad (4)$$

$$2CH_3CH_2OH + O_2 + H_2O_2 + 2Fe^{2+} + 2H^+ \rightarrow 2CH_3CHO + 4H_2O + 2Fe^{3+} \quad (5)$$

$$H_2O_2 + HSO_3^- \rightarrow H_2O + SO_4^{2-} + H^+ \quad (6)$$

Hydrogen peroxide is a central intermediate in Scheme 1 linking the initial trapping of oxygen to the ethanol oxidation. However, hydrogen peroxide may also react with sulfite reaction 6, and the competition between this reaction and the Fenton reaction, reaction 1, determines the amount of ethanol being oxidized. In wine, a similar competition between the Fenton reaction and the direct reaction of H_2O_2 with sulfite has been demonstrated.[25] The beer in this study contained 140 μM sulfite. Keeping the beer for 8 h under atmospheric air resulted in a linear consumption of 92 μM oxygen (Figure 1). Under the same conditions, only approximately 60 μM sulfite was consumed (Figure 6), which indicates that ethanol oxidation occurred to some extent together with the reaction with sulfite, resulting in extra oxygen being consumed according to reaction 5. Consumption of sulfite was found to depend mainly on the addition of H_2O_2 and not on the addition of Fe (Figure 5), which supports a direct reaction between sulfite and hydrogen peroxide. In the beer used in the present study, this competition was also observed, as shorter ESR lag phases were seen when increasing H_2O_2 concentrations were added, whereas in the presence of Fe(II), the initial level of radicals formed in the beer also increased with increasing H_2O_2 concentrations (Figure 4A).

The competition of H_2O_2 reacting in the Fenton reaction, resulting in ethanol oxidation, or reacting with sulfite depends on the kinetics of the two reaction routes. The rate constant for the reaction between H_2O_2 and sulfite is around 10^3 M^{-1} s^{-1},[8] whereas rate constants for the Fenton reaction vary from 60 M^{-1} s^{-1} to 10^5 M^{-1} s^{-1} depending on the Fe(II) ligands.[26−28] Consequently, the ratio of the concentrations sulfite and with Fe(II) determine which reaction route that will dominate, and hydrogen peroxide is consumed by the Fenton reaction when a high level of Fe is present, while the reaction with sulfite is the major route at low iron concentrations. The depletion of sulfite and its efficiency as antioxidant will therefore be directly linked to the relative amounts of iron and copper ions that are present.

The addition of iron alone had only minor effects on the rates of oxygen consumption and the consumption of sulfite, indicating a negligible effect on the initial trapping of oxygen. However, the iron addition had an effect when hydrogen peroxide was also added, which according to Scheme 1 will directly initiate the oxidation of ethanol. Interestingly, additions of either Fe(III) or Fe(II) had the same effects on the oxygen consumption, the radical formation and lag phases as determined by ESR spectroscopy, and the decrease of sulfite concentrations during forced aging of beer. Uchida & Ono[10] have demonstrated that Fe(II) has prooxidative activity in beer by decreasing the ESR lag phase, but in their study Fe(III) was not included. Recently, it was shown by Kunz et al.[21] that intermediate Maillard reaction products with an enediol structure are capable of reducing Fe(III) to Fe(II) in beer. Assuming fast redox equilibria between Fe(II) and Fe(III) species in beer may explain the similar effects of adding the two species. Polyphenols and sulfite have been shown to efficiently reduce Fe(III) to Fe(II) in wine.[17,25] However, a similar role of polyphenols in beer is less likely as they neither inhibit nor increase radical formation.[29] In this study, we observed that addition of Fe(III) did not affect the sulfite concentrations, suggesting that sulfite is not able to reduce Fe(III) in beer in contrast to wine. This may be due to the differences in pH as well as the different types of ligands that are present in beer and wine. In wine, Fe ions are coordinated to tartaric and malic acid.[30] In beer, iron is found as a mixture of negatively charged, positively charged, and neutral species, suggesting coordination to a variety of ligands.[31]

The concentrations of thiols in beer decreased during incubation at different conditions (Figure 6B), but not to the same extent as that observed for sulfite. This suggests that thiols play a secondary role as antioxidants in beer. Thiols are not expected to efficiently react with H_2O_2 due to the low rate constant of 10^{-2} to 10^{-3} M^{-1} s^{-1} as observed for cysteine.[32] Accordingly, the addition of 180 μM H_2O_2 had a smaller effect on the thiol concentrations than on the sulfite concentrations (Figure 6). It is hypothesized that once sulfite is depleted in beer, thiols act as secondary antioxidants by removing 1-hydroxyethyl radicals (Scheme 1). This is supported by the high rate constant of 10^9 M^{-1} s^{-1} for this reaction.[16] However, the thiols will be competing with hop-derived bitter acids which also react with 1-hydroxyethyl radicals with similar high rate constants.[33] Recently, it has been suggested that sulfite and thiols in beer may reversibly bind staling aldehydes as adducts, and that these aldehydes may be released during beer aging.[34] On the basis of the present results, the aldehydes bound to sulfite would be the first to be released, followed by the thiol adducts at later stages of beer oxidation. Furthermore, a major fraction of the thiols seemed to be resistant to oxidation, suggesting that beer thiols have widely different redox properties. Interestingly, thiol consumption was not observed to be as temperature dependent as sulfite consumption. This observation is in agreement with a previous storage experiment of beers performed at 22 and 35 °C, where sulfite was depleted more rapidly at 35 °C, while thiol depletion was less temperature dependent.[35] This may suggest that beers exposed to heat, e.g., during long distance shipment will be depleted in

J. Agric. Food Chem. 2015, 63, 8254−8261

their content of sulfite (the primary antioxidant), but may still contain thiols as secondary antioxidants.

A remarkably low temperature dependency of oxygen consumption in beer was found with a Q_{10} of 1.3, which is most likely due to a low enthalpy of reaction for the initial reactions trapping oxygen. Addition of a combination of iron and H_2O_2 to beer caused an increased rate of oxidation as determined by oxygen consumption and increased radical formation as determined by ESR spectroscopy in comparison to addition of either iron or H_2O_2 alone, which is consistent with Fenton-mediated oxidation in beer leading to ethanol oxidation and the formation of 1-hydroxyethyl radicals. Sulfite was found to compete with the Fenton reaction for H_2O_2, and the primary antioxidative mechanism of sulfite was found to be through the direct reaction with H_2O_2, while protein thiols are suggested to play a secondary role as antioxidants in beer by removing 1-hydroxyethyl radicals. On the basis of these results, it will be possible to develop quantitative kinetic models that can potentially be used for predicting the shelf life of beer as well as the effect of various combinations of intrinsic and extrinsic factors.

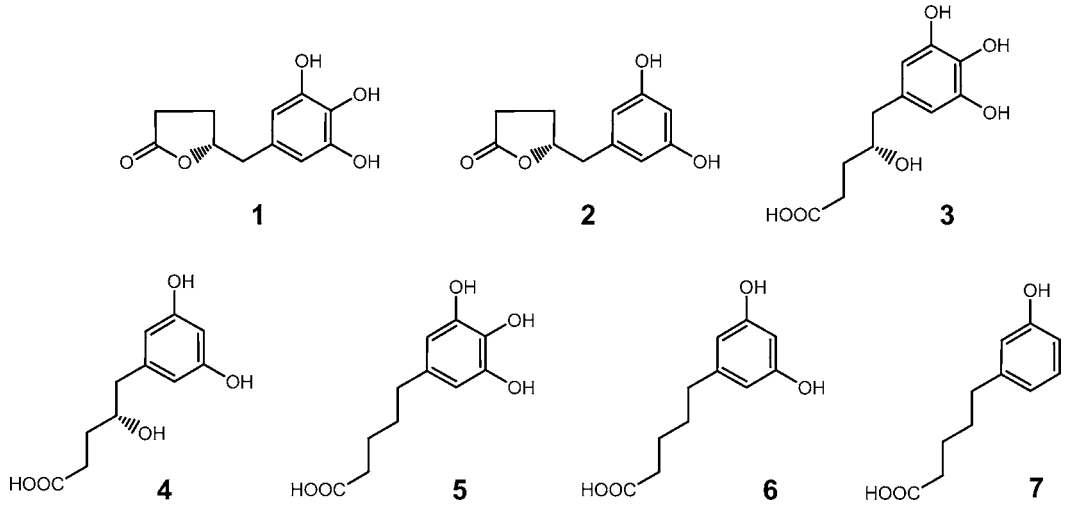

Figure 1. Chemical structures of EGCG metabolites.

Furthermore, two intestinal bacteria (*Adlercreutzia equolifaciens* MT4s-5 and *Flavonifractor plautii* MT42) capable of degrading EGC were isolated and identified.[25] In this study, we found that *A. equolifaciens* MT4s-5 catalyzed the conversion of EGC into 1-(3,4,5-trihydroxyphenyl)-3-(2,4,6-trihydroxyphenyl)propan-2-ol and then *F. plautii* MT42 converted the propan-2-ol into 5-(3,4,5-trihydroxyphenyl)-γ-valerolactone (**1**) and 4-hydroxy-5-(3,4,5-trihydroxyphenyl)valeric acid simultaneously. In a similar way, 5-(3,5-dihydroxyphenyl)-γ-valerolactone (**2**) was produced from 1-(3,5-dihydroxyphenyl)-3-(2,4,6-trihydroxyphenyl)propan-2-ol, which was formed from EGC by *A. equolifaciens* MT4s-5 in the presence of hydrogen. These developments made it possible to prepare enough intestinal EGCG or EGC metabolites to be able to examine their physiological activity in vivo.

Thus, in the context as described above, we attempted to investigate the hypotensive activity of intestinal metabolites derived from EGCG or EGC. The metabolites were first screened for their ACE inhibitory activities, and major metabolites **1** and **2** excreted in human and rat urine were then examined for their blood pressure lowering activity in SHR.

MATERIALS AND METHODS

Materials. EC, EGC, EGCG, and (−)-epicatechin gallate (ECG) were purchased from Sigma-Aldrich Japan (Tokyo). (−)-Catechin (C), (−)-gallocatechin gallate (GCG), and (−)-catechin gallate (CG) were prepared according to the method previously described.[26] EGCG metabolites, 5-(3,4,5-trihydroxyphenyl)-γ-valerolactone (**1**), 5-(3,5-dihydroxyphenyl)-γ-valerolactone (**2**), 4-hydroxy-5-(3,4,5-trihydroxyphenyl)valeric acid (**3**), 4-hydroxy-5-(3,5-dihydroxyphenyl)-valeric acid (**4**), 5-(3,4,5-trihydroxyphenyl)valeric acid (**5**), 5-(3,5-dihydroxyphenyl)valeric acid (**6**), and 5-(3-hydroxyphenyl)valeric acid (**7**), were prepared according to our previous papers.[18,24,26] The chemical structures of EGCG metabolites (**1**−**7**) are illustrated in Figure 1. ACE from rabbit lung, hippuryl-His-Leu (HHL), and hippuric acid were obtained from Sigma-Aldrich Japan (Tokyo). All other reagents were available products of analytical or HPLC grade.

Assay of ACE Inhibitory Activity. EGCG metabolites (**1**−**7**) and catechins (C, EC, EGC, ECG, CG, EGCG, and GCG) were individually dissolved in 10 mM citrate−phosphate buffer (pH 4.0) containing 5% methanol, and each solution was adequately diluted with distilled water to give final concentrations of 100 mM for metabolites **2** and **4**, C, and EC, 75 mM for EGC, 50 mM for metabolites **1** and **3**, 25 mM for metabolites **5**−**7**, and 10 mM for ECG, CG, EGCG, and GCG. The sample solution prepared above was used as stock solution. To measure ACE inhibitory activity, an adequate volume of distilled water was added to each stock solution, ranging from 10 to 70 μL, to make a total volume of 70 μL. To the solution (70 μL) was added 200 μL of 150 mM HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) buffer (pH 8.3) containing 450 mM NaCl and 6 mM hippuryl-His-Leu (HHL) and 30 μL of ACE solution (0.1 U/mL). The mixture was incubated for 30 min at 37 °C. The reaction was stopped by the addition of 200 μL of 1 M acetate buffer (pH 4.0). After centrifugation, hippuric acid in the supernatant was analyzed by an LC-MS system. The LC-MS analysis was performed by a Surveyor HPLC and an LCQ Deca XPplus system (Thermo Fisher Scientific K.K., Yokohama, Japan). HPLC was carried out with a 100 mm × 2 mm i.d., 5 mm, CAPCELL PAK C18 MG column (Shiseido Co. Ltd., Tokyo, Japan) at a flow rate of 0.2 mL/min and 40 °C. The column was eluted with solvent A (10% (v/v) acetonitrile aqueous solution containing 0.2% (v/v) formic acid) for 3 min, followed by a linear gradient in solvent B (40% acetonitrile aqueous solution containing 0.2% formic acid) from 0 to 50% for 3−15 min and then a linear gradient from 50% B to 100% A for 15−20 min. Quantification of hippuric acid liberated from HHL by ACE was performed with the selected ion monitoring (SIM) mode. The separated $[M + H]^+$ ion chromatogram was selected at m/z 180 for the specific parent ion of hippuric acid. The concentration of the hippuric acid was determined on the basis of the standard calibration curve of authentic sample. ACE inhibitory activities were calculated as follows: ACE inhibitory activity (%) = 100 × (ACE activity of the control − ACE activity of the sample)/ACE activity of the control. Then, concentrations of the sample versus ACE inhibitory activities were plotted, and IC_{50} was calculated from the resulting curves.

Animals. Male SHR (14 weeks of age) were purchased from Charles Liver Laboratories Japan, Inc. (Yokohama) and housed in a room at 23 ± 3 °C and 60 ± 5% relative humidity, with a 12 h light−dark cycle. The rats were fed a pelleted diet (Rodent Labo Diet EQ, Japan SLC) for a week. All experimental procedures were in accordance with the guidelines for animal experiments of Food Research Laboratories, Mitsui Norin Co., Ltd.

Measurement of Systolic Blood Pressure (SBP) after Oral Administration of Metabolites 1 and 2 to SHR. Male SHR at 15 weeks of age were divided into two groups (n = 6−8) with almost the same average values of SBP. After a 16 h fast, 100 or 150 mg/kg of 5-(3,4,5-trihydroxyphenyl)-γ-valerolactone (**1**) dissolved in saline (1 mL) was administered orally to SHR with a gastric metal probe. Only saline (1 mL) was administered to the control group. In the same way, 150 or 200 mg/kg of 5-(3,5-dihydroxyphenyl)-γ-valerolactone (**2**) was orally administered. SBP was measured before and 2 and 4 h after dosage by the tail cuff method using a pneumatic pulse transducer (BP-98A; Softron, Tokyo, Japan).

DOI: 10.1021/acs.jafc.5b03676
J. Agric. Food Chem. 2015, 63, 8262−8266

Statistical Analysis. All values of SBP are expressed as means ± SEM. Statistical comparisons of the SBP values 2 and 4 h after the single administration between control and test substance-treated groups were performed by using Student's *t* test with the Bonferroni correction. The statistical differences between SBP before (basal SBP) and after administration of the metabolites were analyzed by using Dunnett's *t* test. The statistical calculations were done with IBM SPSS Statistics 19 computer software (IBM Japan, Tokyo). Differences are considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

ACE Inhibitory Activity of EGCG Metabolites. ACE inhibitory activities of EGCG metabolites (**1**−**7**) produced by intestinal bacteria were evaluated. In addition, the inhibitory activities of catechins (C, EC, EGC, ECG, CG, EGCG, and GCG) were also measured for the purpose of reference. IC_{50} values of the compounds tested are indicated in Table 1. All of the EGCG metabolites showed ACE inhibitory activities and the order of IC_{50} was hydroxyphenyl valeric acids (**5** ≥ **6** > **7**) > trihydroxyphenyl-γ-valerolactone (**1**) > trihydroxyphenyl 4-hydroxyvaleric acid (**3**) ≫ dihydroxyphenyl 4-hydroxyvaleric acid (**4**) ≫ dihydroxyphenyl-γ-valerolactone (**2**). With regard to ACE inhibitory activities of the catechins, galloylated catechins (EGCG, GCG, CG, and ECG) showed stronger inhibitory activities than nongalloylated catechins (EGC, EC, and C).

Table 1. ACE Inhibitory Activity (IC_{50}) of EGCG Metabolites and Catechins

metabolite	IC_{50} (mM)	catechin	IC_{50} (mM)
1	2.89	EC	4.96
2	19.59	C	5.29
3	5.41	EGC	5.05
4	12.12	ECG	0.70
5	1.51	CG	0.35
6	2.38	EGCG	0.38
7	3.00	GCG	0.55

Hypotensive Activities of Metabolites 1 and 2 after a Single Oral Dosage to SHR. All of the EGCG metabolites tested showed ACE inhibitory activity, although their activity was of varying degrees. To examine the hypotensive activity of these metabolites after a single oral administration to SHR, we selected 5-(3,4,5-trihydroxyphenyl)-γ-valerolactone (**1**) and 5-(3,5-dihydroxyphenyl)-γ-valerolactone (**2**) because they are reported to be not only the dominant metabolites in the gut tract[18] but also the major urinary metabolites in humans and rats,[16,17,19,27] whereas the other metabolites were scarcely found in urine, if at all.

Metabolite **1** was orally administered to SHR at a dosage of 100 or 150 mg/kg. Basal SBP values (mm of Hg) were 189.0 ± 4.7 for the control group versus 192.1 ± 3.7 for the 100 mg/kg dosage group and 193.9 ± 4.7 for the control group versus 193.4 ± 2.4 for the 150 mg/kg dosage group. The administration of 100 mg/kg of **1** brought about no significant decrease in SBP as compared with the control group. However, a significant decrease in SBP was observed between basal SBP (SBP before administration) and SBP 4 h after administration (−14.9 ± 5.6 mm of Hg, $p = 0.029$, Dunnett's *t* test) in the 100 mg/kg dose group, but no significant change was observed in the control group as shown in Table 2. On the other hand, as shown in Figure 2A SBP significantly reduced 2 h after oral dosage of 150 mg/kg of **1** as compared with the control group ($p = 0.002$, Student's *t* test with the Bonferroni correction), although no significant decrease in SBP was observed 4 h after administration. Significant decrease in SBP of the 150 mg/kg dose group was also observed between basal SBP and SBP 2 h after dosage (−13.7 ± 5.0 mm of Hg, $p = 0.024$, Dunnett's *t*-test) but not between basal SBP and SBP 4 h after dosage. There was no significant change in SBP in the control group.

Table 2. Change in Systolic Blood Pressure after Oral Administration of Metabolites 1 and 2 to SHR[a]

	metabolite **1**		metabolite **2**	
	control	100 mg/kg dosage	control	150 mg/kg dosage
0 h	189.0 ± 4.7	192.1 ± 3.7	195.9 ± 6.7	197.7 ± 3.5
2 h	186.0 ± 4.6	186.1 ± 3.9	180.0 ± 4.2[a]	179.3 ± 2.8*[2]
4 h	184.4 ± 3.5	177.3 ± 4.3*[1]	180.4 ± 4.0[b]	181.7 ± 6.7*[3]

[a]Each SBP value (mm of Hg) represents the mean ± SEM. Statistical differences within each group were conducted using Dunnett's *t* test. Differences from basal SBP value (0 h) within each group are considered significant at $p < 0.05$: *[1], $p = 0.029$; *[2], $p = 0.023$; *[3], $p = 0.049$; [a], $p = 0.076$; [b], $p = 0.085$. Statistical differences between the control and the dosage groups were performed with Student's *t* test. There were no significant differences ($p < 0.05$) between the two groups.

In the case of metabolite **2**, 150 or 200 mg/kg was administered and changes in SBP were measured. No significant reduction in SBP at the 150 mg dose of **2** was observed as compared with the control group. A significant reduction of SBP was detected both between basal SBP and SBP 2 h after the administration of the 150 mg/kg dosage (−18.4 ± 6.6 mm of Hg, $p = 0.023$, Dunnett's *t* test) and between basal SBP and SBP 4 h after the same dosage (−16.0 ± 6.6 mm of Hg, $p = 0.049$, Dunnett's *t* test) as indicated in Table 2. While there was found to be a decreasing trend but no significant reduction of SBP was observed either between basal SBP and SBP after 2 h (−15.9 ± 7.3 mm of Hg, $p = 0.076$, Dunnett's *t* test) or between basal SBP and SBP after 4 h (−15.4 ± 7.3 mm of Hg, $p = 0.085$, Dunnett's *t* test) in the control group (Table 2). Accordingly, SBP-decreasing effects of the 150 mg/kg dosage of metabolite **2** were unclear. Figure 2B shows the time course changes in SBP after a 200 mg/kg administration of **2** and saline (control group). Basal SBP was 197.0 ± 5.2 for the control group and 198.7 ± 5.6 for the 200 mg/kg of dose. Metabolite **2** (200 mg/kg) showed hypotensive effects 4 h after oral intake ($p = 0.044$, Student's *t* test with the Bonferroni correction) as compared with the control group (after 4 h). A significant decrease in SBP change of the 200 mg/kg dose group was also observed between basal SBP and SBP 4 h after dosage (−30.3 ± 11.4 mm of Hg, $p = 0.033$, Dunnett's *t* test).

There are some reports on the physiological activities of intestinal catechin metabolites including 5-(3,4,5-trihydroxyphenyl)-γ-valerolactone (**1**) and 5-(3,5-dihydroxyphenyl)-γ-valerolactone (**2**), which are the major metabolites detected in rat and human urine.[20−23] However, no information is available on their blood pressure lowering effects. In this study, we revealed that intestinal EGCG metabolites possessed ACE inhibitory activity in vitro, although their activities were estimated to be about $^1/_4$ to $^1/_{50}$ of those of EGCG. As far as metabolites **1** and **2** are concerned, the ACE inhibitory activities were about $^1/_8$ for **1** and $^1/_{50}$ for **2** as compared with those of EGCG (Table 1), whereas the absorptivity of metabolites **1** and **2** is calculated to be about 10−85 times

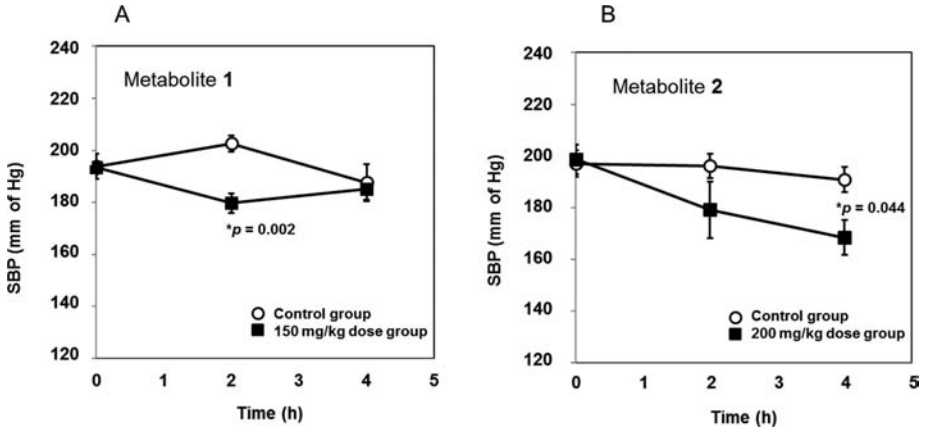

Figure 2. Effects of a single oral administration of metabolites **1** and **2** on systolic blood pressure in SHR. SBP values are expressed as means ± SEM. Statistical analysis was performed using Student's *t* test with the Bonferroni correction. Significant difference (*p* value) from the control group is shown.

higher than that of EGCG based on their urinary excretion amounts.[15−17,19] From the above observations, it was expected that these metabolites could show hypotensive effects in vivo. Accordingly, we examined hypotensive effects of metabolites **1** and **2** in in vivo experiments with SHR. The experiments clearly demonstrated hypotensive effects were observed after a single oral administration of the metabolites to SHR. In addition, our preliminary study on the metabolism of compound **1** showed that after a single oral administration of 5 mg/rat to SHR the compound peaked at 1 h, then decreased gradually, and at >4 h after dosage had almost disappeared from the rat plasma. During this period of time only a slight amount of degraded products derived from **1** was detected in plasma (data not shown). In the case of metabolite **2**, we did not examine its metabolism, but it is presumed that results similar to those for metabolite **1** would be obtained, judging from the similarity of their chemical structures and results of our previous study.[16] Therefore, it is likely that the two metabolites do actually possess hypotensive effects in vivo.

With respect to the mechanism for hypotensive activity of metabolites **1** and **2** in vivo, we found that these metabolites possessed ACE inhibitory activity. Although a direct relationship between the ACE inhibitory activity and hypotensive effects of the metabolites has not yet been proven and the mechanism remains unclear, the possibility cannot be denied that ACE inhibitory activities may be associated with their hypotensive effects. Apart from the mechanism proposed above, nitric oxide (NO) released from endothelium is considered to function as an important factor for vasodilation and consequently to reduce blood pressure.[13,14] Hence, the reduction of NO bioavailability by active oxygen species would cause endothelial dysfunction and, in the worst case, cardiovascular complications. Accordingly, antioxidants are thought to play an important role in the suppression of hypertension by preventing the reduction of NO bioavailability in arteries.[11,14] Our previous study revealed that intestinal catechin metabolites including metabolites **1** and **2** possessed antioxidative activities and their activities were stronger than or nearly equal to those of Trolox, a vitamin E derivative.[20] It is therefore possible that the metabolites may contribute as antioxidants, at least in part, to suppress the increase in blood pressure through the prevention of NO reduction by active oxygen species. As discussed above, the question of how mechanisms responsible for the hypotensive effects of metabolites **1** and **2** are at work remains unanswered. Further study is needed to clarify the mechanism of their hypotensive activity in vivo.

It is well recognized that EGCG has a variety of physiological activities including suppression of cholesterol and triglyceride in the blood,[5] suppression of glucose level in the blood,[6] antihypertensive activity,[8−10] antioxidant activity,[1−4] and chemopreventive activity.[7] Among the physiological activities, it is explainable to some extent that suppression of cholesterol in blood may be due to the prevention of cholesterol absorption through the small intestine by intact EGCG[28] and that suppression of glucose levels in the blood may be due to the inhibition of α-amylase and sucrase by intact EGCG in the small intestine.[29,30] However, it is doubtful in some cases whether intact EGCG actually acts as a major bioactive substance, because it has been reported to be poorly absorbed in the body.[15−17] On the other hand, intestinal metabolites such as 5-(3,4,5-trihydroxyphenyl)-γ-valerolactone (**1**) and 5-(3,5-dihydroxyphenyl)-γ-valerolactone (**2**) have been reported to be absorbed in large amounts in the body,[16,17,19] leading us to suppose that the metabolites may act as in vivo bioactive substances. In this context, we previously examined the antioxidative activity of EGCG metabolites and demonstrated they possessed antioxidative activity at least equivalent to that of Trolox, although their activities were weaker than those of their original catechins.[20] Among them, metabolites **1** and **2** may be the main antioxidant contributors in the body due to their good absorptivity. In this study, we observed that the EGCG metabolites had ACE inhibitory activity in vitro and that two major metabolites **1** and **2** had hypotensive effects in in vivo experiments. However, the relationship between ACE inhibitory activity and hypotensive effects remains to be investigated. Therefore, it seems reasonable to surmise that blood pressure lowering effects by catechin intake may be due, in part, to the hypotensive effects of metabolites **1** and **2**. Thus, study on the biological activity of intestinal metabolites such as **1** and **2** likely makes it possible to explain some of the health beneficial effects of tea catechins in the body. Accordingly, further in vivo studies on the physiological activity of the metabolites will be required.

Table 1. Purified Enzymes Used in This Study

name	supplier	catalogue name	description	declared activity
Pect	Sigma-Aldrich	Pectinase	Pectolytic enzyme preparation: contains mainly pectintranseliminase, polygalacturonase, pectin esterase, and small amounts of hemicellulases and cellulases.	19 U/mg
EPG	Megazyme	E-PGALS	Endopolygalacturonase from *A. niger*, contains minor levels of endogalactanase, endoarabinase, pectin transeliminase, arabinofuranosidase, and β-galactosidase activity.	280 U/mg protein, polygalacturonic acid as substrate
EG	Megazyme	E-CELTR	Endo-1,4-β-glucanase with minor levels of endo-1,4-β-xylanase, endo-1,4-β-mannanase, α-glucosidase, β-glucosidase, β-xylosidase, α- and β-galactosidase, β-mannosidase, and α-L-arabinofuranosidase activities.	19−71[a] U/mg, assumed 40 U/mg for this study
XG	Megazyme	E-XEGP	Xyloglucan-specific endo-1,4-β-glucanase, recombinant enzyme.	104 U/mg
EA	Megazyme	E-EARAB	Endoarabinase with α-L-arabinofuranosidase <0.01% (on beet arabinan); endogalactanase <0.01%.	15 U/mg

[a]Depending on substrate.
