
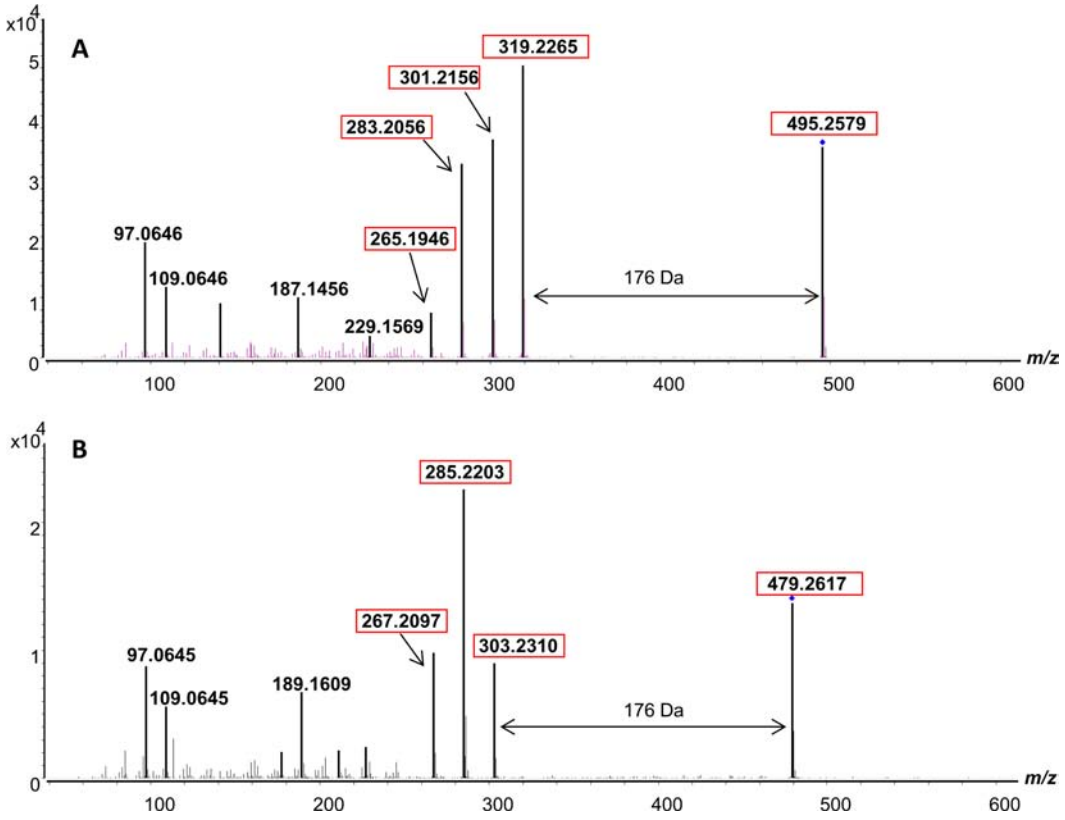

Figure 2. MS/MS of OHMT-glu (A) and MS/MS of MT-glu (B), CE 30.

acetate (EtOAc) were of high-performance liquid chromatography (HPLC) grade (Burdick & Jackson, Muskegon, MI). Ammonium Hydroxide (NH_4OH), potassium dihydrogen phosphate (KH_2PO_4), dipotassium hydrogen phosphate (K_2HPO_4), and formic acid were of reagent grade supplied by Fisher Scientific (Pittsburgh, PA). Oasis MAX strong anion exchange (3 mL, 60 mg) solid-phase extraction (SPE) cartridges were obtained from Waters Corp. (Milford, MA). The lyophilized enzyme β-glucuronidase type VII A from *Escherichia coli* (20 000U) was purchased from Sigma Chemical Co. (St. Louis, MO).

Fish Dosing. Fish were dosed with MT at the Center for Veterinary Medicine aquaculture facility. Tilapia (*Oreochromis* species, not sex reversed) was obtained from Aquasafra Inc. (Bradenton, FL) as ∼1 g fry. Fish were raised in freshwater recirculating systems consisting of two 500 gal tanks at a temperature range of 20−30 °C until they reached a suitable size for dosing (400−700 g). Tilapia were given a single oral dose of 60 mg/kg body weight MT and sacrificed at 1, 3, 7, and 14 days after the dose. One fish was used for each time point. Bile samples were removed and stored at −80 °C until analysis. Control bile was also removed from a fish that was not fed with MT. The experimental protocol was approved by the Animal Care and Use Committee at the Office of Research, Center for Veterinary Medicine, U.S. Food and Drug Administration, and all procedures were conducted in accordance with the principles stated in the Guide for the Care and Use of Laboratory Animals (2011) and the Animal Welfare Act of 1966 (P.L. 89-544), as amended.

Sample Preparation. Bile from dosed and control fish were weighed (∼100 mg each) into 15 mL polypropylene centrifuge tubes. A 1 mL sample of 5% aqueous ammonium hydroxide solution was added to each sample and vortexed for 30 s. The extracts were subjected to SPE cleanup by an automated SPE system (RapidTrace workstation by Caliper Life Science, Hopkinton, MA). Waters Oasis MAX, SPE cartridges were preconditioned with 2.5 mL of MeOH (42 mL/min) followed by 2.5 mL of water (42 mL/min). After the samples were loaded (1 mL/min), cartridges were rinsed successively with 2 mL of 0.5 M NH_4OH in 5% MeOH (42 mL/min) followed by 2 mL of 20% MeOH (42 mL/min). Cartridges were dried by passing 6 mL of air (42 mL/min). Glucuronides were eluted with 2 mL of freshly prepared 2% formic acid in MeOH (1 mL/min). The eluents were evaporated to dryness by blowing N_2 at 40 °C. Samples were reconstituted to 200 μL with MeOH/water (60/40 v/v) and transferred to autosampler vials for mass spectral analysis after filtering through a 0.2 μm nylon syringe filter.

Enzymatic Hydrolysis of Bile from Dosed Fish with β-Glucuronidase from *E. coli*. Glucuronide enriched fraction from SPE of control and dosed fish bile (3 days) was evaporated to dryness and dissolved in 200 μL of 0.25 M potassium phosphate buffer (pH ∼ 6.8). A 40 μL (1000U) of β-glucuronidase enzyme from *E. coli* in 0.25 M phosphate buffer was added. The phosphate buffer was prepared by mixing 55 mL of 0.5 M dipotassium hydrogen phosphate and 45 mL of 0.5 M potassium dihydrogen phosphate. The sample was incubated overnight in a shaking water bath at 37 °C and was extracted twice with 300 μL of ethyl acetate. The combined ethyl acetate extract was evaporated to dryness under nitrogen in a TurboVap evaporator at 40 °C. The residue was reconstituted in 200 μL of 60:40 methanol:water. The sample was transferred to autosampler vial after filtering through a 0.2 μm nylon syringe filter for mass spectral analysis.

Liquid Chromatography−Quadrupole Time-of-Flight Mass Spectrometry (LC-QTOFMS) Analysis. Chromatographic separation was carried out using a HPLC system (Agilent Series 1100 or 1290 Palo Alto, CA) equipped with a reversed phase C18 analytical column of 150 × 2.0 mm, 3 μm particle size (Phenomenex Luna C18) with a guard column of the same packing. The column oven was held at 40 °C, and the autosampler tray was maintained at 20 °C. The injection volume was 5 or 10 μL. Mobile phase A and B were 0.1% aqueous formic acid and ACN with 0.1% formic acid, respectively. The optimized chromatographic method on the Agilent 1290 pump was a linear gradient of 40−90% ACN in 10 min, hold at 90% ACN for 2 min, linear gradient of 90-40% ACN in 1 min, followed by equilibration at 40% ACN for 12 min before the next injection. The optimized method for Agilent 1100 pump was a linear gradient of 30−90% ACN in 10 min, hold at 90% ACN for 5 min, linear gradient of 90−30% ACN in 1 min, followed by equilibration at 30% ACN for 9 min before the next injection. Flow rate was 0.2 mL/min for both gradients. The HPLC system was connected to a

quadrupole time-of-flight mass spectrometer model 6530 from Agilent (Agilent Technologies, Palo Alto, CA) equipped with electrospray jet stream technology operating in the positive ion mode, using the following operation parameters: capillary voltage 3500 V; nebulizer pressure, 50 psi; drying gas, 12 L/min; gas temperature, 325 °C; nozzle voltage, 1000 V; fragmentor voltage, 165 V; skimmer voltage, 65 V; and octapole RF, 750 V. LC/MS accurate mass spectra were recorded across the range of m/z 50−1000 at 4 GHz high resolution. Data were collected in both centroid and profile formats and processed with Mass Hunter software. Accurate mass measurements of each peak from the extracted ion chromatograms were obtained by means of a calibrant solution delivered by an external isocratic pump. This solution contains the internal reference masses of purine ($C_5H_4N_4$) at m/z 121.0509 and HP-921 [hexakis-(1H, 1H, 3H-tetrafluoro-pentoxy) phosphazene] ($C_{18}H_{18}O_6N_3P_3F_{24}$) at m/z 922.009. The OHMT-glu ion at calculated exact mass of m/z 495.2589 was extracted from the total ion

chromatogram and selected as the precursor ion for collision-induced dissociation (CID) experiment. For targeted tandem mass spectrometry (MS/MS) analysis, product ion scan range was 50−500 Da. A retention time window was set at ±0.5 min, and the isolation width was set at medium (~4 m/z). Collision energy of 30 eV was used for MS/MS experiments to obtain maximum intensity of fragments at m/z 319.2265, 301.2156, and 283.2056.

RESULTS AND DISCUSSION

We utilized the MFE algorithm in the Q-TOF Mass Hunter qualitative analysis software to detect the molecular features in the glucuronide-rich extract of dosed tilapia bile. For the extraction of molecular features, we used a peak height filter of >15 000 in the compounds filter tab. The charge state was limited to 1. Ion species were limited to the positive ions H^+ and Na^+. The 523 molecular features extracted under these criteria were then searched against our in-house database of MT metabolites. We used the criteria of mass and a mass accuracy tolerance of 5 ppm for the library search to identify OHMT-glu of the correct formula $C_{26}H_{38}O_9$ at m/z 495.2579 with a mass accuracy of 2 ppm. The in-house MT metabolite database was constructed to include the exact masses and the molecular formulas of mono-, di-, and tri-hydroxylated MT and their glucuronides.

According to the formula $C_{26}H_{38}O_9$, OHMT-glu has an additional hydroxyl function. The QTOF high-resolution mass spectrometry (HRMS) approach utilized provided us with exact masses of good mass accuracy to determine the chemical formula of OHMT-glu as well as its fragment ions. The correct formula generated for the fragment ions enabled us to propose structures for them. We took advantage of published literature of steroid fragmentation pathways and compared them with our experimental observations. This is a difficult strategy because small differences in chemical structure such as additional double bonds and methyl groups can result in a significantly different fragmentation pathway of steroids.[10]

The MS/MS analysis of OHMT-glu at a collision energy (CE) of 30 eV (Figure 2A) showed an abundant peak at m/z 319.2265 ($C_{20}H_{31}O_3$) $[M + H - 176\ Da]^+$ due to the loss of a dehydrated glucuronide molecule (176 Da). Successive losses of water from m/z 319 were observed at m/z 301.2156 ($C_{20}H_{29}O_2$), 283.2056 ($C_{20}H_{27}O$), and 265.1946 ($C_{20}H_{25}$) for $[M + H - glu - H_2O]^+$, $[M + H - glu - 2H_2O]^+$, and $[M + H - glu - 3H_2O]^+$, respectively, indicating three oxygens in OHMT-glu structure. The MS/MS spectrum of our previously synthesized MT-glu showed corresponding losses of dehydrated glucuronide molecule followed by only two consecutive water losses (Figure 2B). This further confirms that OHMT-glu bears an additional hydroxyl group in the aglycone in comparison to MT-glu. We designate the aglycone of OHMT-glu as OHMT. Our challenge was to place the additional hydroxyl group in OHMT.

Hydroxylation is a common metabolic pathway of anabolic steroids. Therefore, an understanding of fragmentation of hydroxylated steroids is very important in their structure elucidation. Also, an in-depth comparison of fragmentation of known related hydroxylated MT analogs with that of OHMT is a useful strategy for structure elucidation. The hydroxylation can be at any of the ring carbons or one of the three methyl groups. Hydroxylation has been reported previously at C6, 7, 11, 15, and

16 of MT and related compounds.[7,11−13] To simplify the discussion, the nominal masses are sometimes used in this paper.

To find further structural information on OHMT, we optimized the fragmentation voltage at 200 V in the MS1 experiment to produce in-source generated fragment ion at *m/z* 319 (protonated OHMT) from precursor ion at *m/z* 495 (the protonated OHMT-Glu). We then recorded the MS/MS spectrum of the in-source generated OHMT (*m/z* 319) (Figure 3) and compared it with those generated from the three commercially available standards C-6*α*, -6*β*, and -11*α* hydroxy-MT (Figure 4).

Mass spectra of hydroxylated MT standards and OHMT showed significant ions at *m/z* 301, 283, and 265 indicating three sequential losses of water (Figures 3 and 4). In addition, two other common ions were observed at *m/z* 243 and 225. These can be attributed to the loss of 58 Da (acetone) from fragment ions at *m/z* 301 and 283, respectively.[14]

However, the lower *m/z* region of product ion spectra of the three standards looked quite different from that of OHMT. We observed very prominent ions at *m/z* 97.0630 (C_6H_9O) and 109.0642 (C_7H_9O) in the MS/MS spectra of OHMT (Figure 3). In fact, these two ions were the most abundant ions in its MS/MS spectrum. However, these ions were either absent or of very low abundance in the MS/MS spectra of the 3 hydroxylated MT standards (Figure 4).

Williams et al.[15] extensively studied the abundance of *m/z* 97 and 109 ions in monohydroxylated testosterones. According to their study, the hydroxylation of testosterone at C-2, C-6, C-7, C-11, and C-19 positions greatly reduces the relative abundances of the *m/z* 97 and 109 ions. Therefore, the presence of intense fragment ions at *m/z* 97 and 109 in the MS/MS spectra of OHMT provides strong support to rule out hydroxylation at C-2, C-6, C-7, C-11, and C-19 positions.

In an attempt to characterize the aglycone OHMT further, the glucuronide extract from the anion exchange SPE of bile was successfully hydrolyzed by *β*-glucuronidase enzyme from *E. coli* in 0.25 M phosphate buffer (pH ∼6.8) to produce hydroxylated MT analogs. One major and a few other minor isomeric hydroxylated MT analogs were detected in the hydrolysis reaction (Figure 5). They were less polar, and their retention times did not match with that of commercially available hydroxy MT standards C-6*α*, C-6*β*, and C-11*α* (Figure 5). Therefore, the additional hydroxyl group cannot be on either C-6 or C-11*α* of the OHMT.

Moreover, hydroxylation of methyl groups at C-17, C-18, and C-19 can also be ruled out because of the absence of a characteristic 30 Da (formaldehyde) loss in the spectrum of OHMT.[14,16]

As reported previously, 17-alkyl steroids (MT, ethisterone, oxymestrone, and mibolerone) show a neutral loss of 58 Da corresponding to a loss of acetone molecule due to

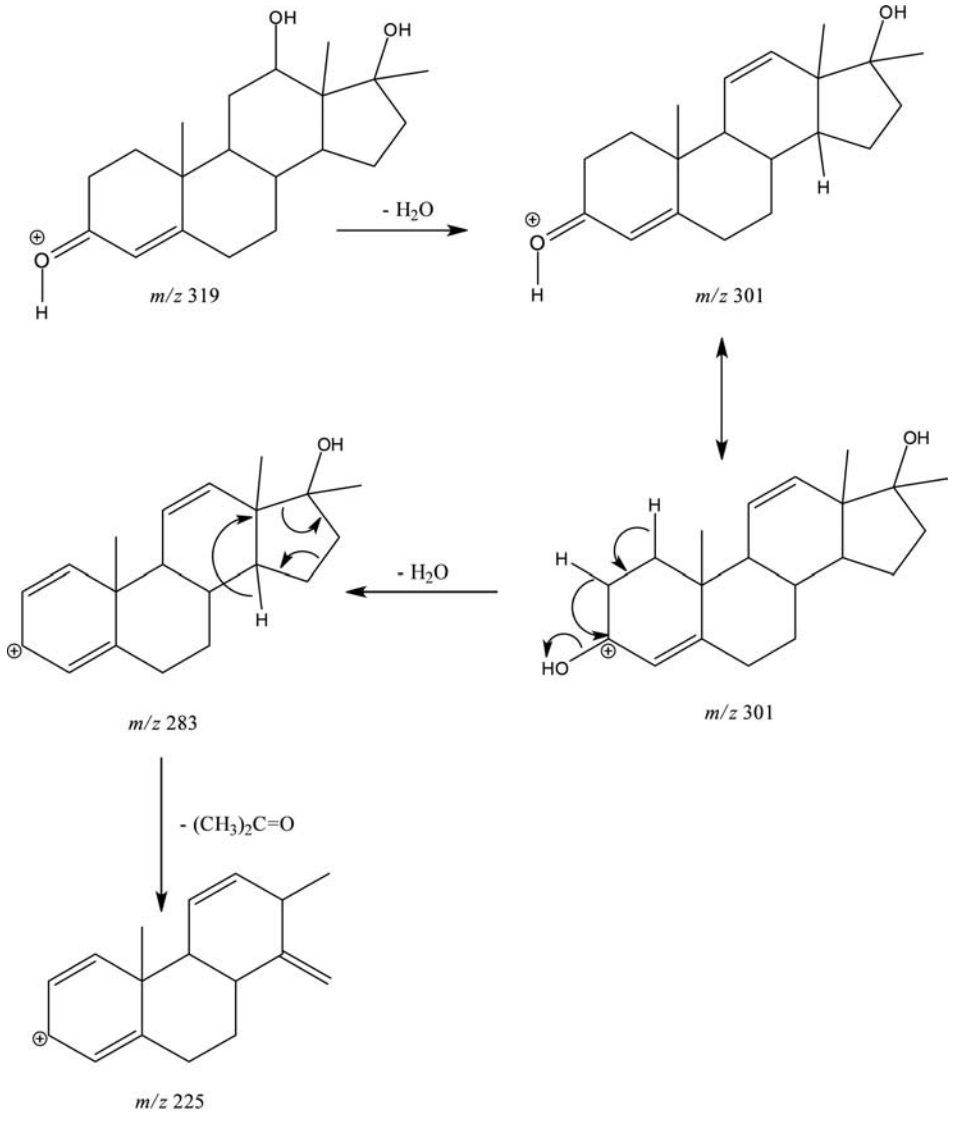
Scheme 2. Proposed Alternative Mechanism for the Formation of *m/z* 225



fragmentation of the D ring. Also, it has been stated that this neutral loss can be seen after losing a water molecule from the molecular ion.[14] According to the proposed mechanism (Schemes 1 and 2), the molecular ion at *m/z* 319 loses a water molecule to generate an ion at *m/z* 301 followed by a loss of a neutral acetone molecule to generate the ion at *m/z* 243. On the basis of this mechanism, C-16 cannot be substituted with a hydroxyl group because we see a significant D ring fragment at *m/z* 243 in OHMT.

A careful in-depth analysis and comparison of our mass spectrometric data against published literature has enabled us to eliminate hydroxylation of most of the carbons in OHMT except for the 15 and 12 positions of the nucleus. As postulated in the proposed pathways (Schemes 1 and 2), formation of the two ions we observe at *m/z* 243 and 225 can be better explained by locating the new hydroxyl group at C-12 than at C-15 in OHMT. Similar mechanisms have been proposed by Pozo et al. in a study to elucidate urinary metabolites of fluoxymesterone.[14] The *m/z* 225 ion can originate from *m/z* 243 (Scheme 1) or the ion at *m/z* 283 (Scheme 2). Therefore, we are proposing C-12 as the most probable position for the hydroxyl group in OHMT (Figure 1). The glucuronidation can be at C-17 or on the new hydroxyl moiety, which generates ambiguity about positioning of the glucuronide in OHMT-glu. To confirm the structure of OHMT-glu we need to compare the mass spectrometric and LC data (retention time) with a standard. Unfortunately, there are no commercial standards available for OHMT-glu or OH-MT for comparison purposes. The multistep procedure to synthesize OHMT-glu was beyond the scope of our study. We were also limited by the minute amount of OHMT-glu present in the bile to purify sufficient quantity to get NMR data to support the structure elucidation. However, by a careful study of the steroid fragmentation pathways, we were able to propose a tentative structure for OHMT-glu to best fit all our experimental data. This is a useful strategy in cases in which a chemical standard is not available.

Typical extracted ion chromatograms of the parent ion at *m/z* 495.2589 for $[M + H]^+$ in bile of dosed fish over a 14 day period are shown in Figure 6. All bile samples from dosed fish contained OHMT-glu. The control bile was confirmed negative. A rough estimate of the OHMT-glu concentrations in bile as compared to a MT-glu standard over 14 days are reported in Table 1.

The previously reported MT-Glu is not detected 7 days after administration.[9] However, the OHMT-glu stays in the bile for at

least up to 14 days after administration. Because it persists in bile longer, OHMT-Glu is a better metabolite to monitor in bile than the previously reported MT-glu. MT is not approved for use in aquaculture in the United States. Therefore, this method can be used for monitoring its illegal use and for surveillance purposes.

In this paper we have attempted to show the strength of HRMS in providing the exact mass of OHMT-glu with high mass accuracy to arrive at the correct molecular formula for structure elucidation purposes. In addition, utilization of retrospective analysis of data generated in the past to discover other unknown metabolites is also highlighted.

chemistry move toward the simplification and miniaturization of sample preparation. This can be simply achieved by scaling down the size of previous systems or by developing new setups and techniques.[21] Different extraction methods to accelerate and miniaturize the process (sample size and organic solvent volumes) in the search for cost-effective solutions have been evaluated.[22] Despite these benefits, few protocols[23] have been developed in human milk matrices to cover this demand.

With regard to TAG determination in milk, several techniques such as thin-layer chromatography (TLC),[7,24] silver ion adsorption−TLC,[25] RP-HPLC,[16,23,26−28] or with silver ions (Ag-HPLC),[14,29] two-dimensional LC,[30] gas chromatography (GC),[25] and tandem MS with ammonia negative ion chemical ionization[31] have been employed. From all of these techniques, RP-HPLC has been widely used, because it provides a better resolution of individual TAG molecules. Thus, these compounds are separated according to both chain length and degree of unsaturation of the FAs.[32] However, RP-HPLC for TAGs separation has been usually performed using a binary gradient of acetonitrile (ACN)−isopropanol[14,27] or a linear ternary gradient of ACN−dichloromethane−acetone.[16,23,28] These latter gradients led to low resolution of TAGs peaks, and the first-mentioned gave a long analysis time (90 min).

To improve chromatographic performance in terms of throughput and/or resolution, particularly when numerous complex food extracts have to be analyzed, recent advances in LC instrumentation could be beneficial.[33] In this context several analytical strategies related to column technology have been developed in HPLC, including the use of monolithic supports packed columns with sub-2-μm particles operating at ultrahigh pressure (UHPLC) or with core−shell or fused-core particles. These latter core−shell particle columns are capable of maintaining high efficiencies at increasing flow rates with the subsequent reduction of analysis time. Also, these columns operate comfortably within the pressure limits of conventional LC instruments, rivaling the performance obtained with sub-2-μm columns on UHPLC instruments. However, the use of these columns in conventional LC systems for TAG separation in human milk samples has not been reported to date.

Multivariate data analysis can be used to obtain more information on major, minor, and trace components in foods.[34,35] Within these statistical tools, linear discriminant analysis (LDA) is probably one of the best known methods, and it has been successfully used for the identification/differentiation of several foods, such as dairy products, oils, wines, and others.[36,37]

In this work, the development of analytical conditions for the extraction and RP-HPLC separation of milk fat TAGs is described. For this purpose, a small-scale fat extraction protocol (with reduced consumption of reagents and processing time, consistent with the recent trends in green chemistry) and in combination with the use of a fused-core HPLC column is presented and compared. In addition, on the basis of TAG profiles of milk samples from different mammalian species (human, bovine, caprine, and ovine), a LDA model is applied to differentiate these matrices according to their species origin.

MATERIALS AND METHODS

Chemicals. TAG standards including trilaurin (LaLaLa), trimyristin (MMM), tripalmitin (PPP), tripalmitolein (PaPaPa), and triolein (OOO) from Sigma (St. Louis, MO, USA) were employed. The following analytical grade reagents were also used: HPLC grade ACN and methanol (MeOH) were purchased from VWR Chemicals (Barcelona, Spain); reagent grade dichloromethane, *n*-pentanol, and *n*-hexane, HPLC grade 2-propanol and *n*-butanol, and anhydrous sodium sulfate were supplied by Scharlau (Barcelona, Spain). Butylhydroxytoluene (BHT) was purchased from Fluka (Buchs SG, Switzerland).

Samples. Human milk samples (n = 15) were kindly donated by healthy well-nourished mothers in different stages of lactation (3 colostrum (1−5 days); 5 transitional milk (6−15 days); 7 mature milk (after 16 days)). All mothers, who were Caucasian, middle-class, and lived within the urban area of Valencia, consumed an unrestricted omnivorous diet. The samples were collected between the baby's feed by manual expression using a Medela Harmony Breastpump (Zug, Switzerland).

Bulk raw milk samples of Holstein-Friesian cows (n = 20) were collected by milking machines, whereas milk samples of Cartera goats (n = 20) and Murciano-Granadina sheep (n = 20) were collected by manual expression from animals in midlactation stage. All of these samples were kindly donated by different farms located at La Comunitat Valenciana, Spain. All animals were free from mastitis or any other inflammatory diseases. They were grazed in the morning and in the afternoon were reared in stables and fed hay, fodder grass, and vegetables. After collection, milk samples were rapidly heated to 80 °C and held at this temperature for 1.5 min to inactivate the lipases and to avoid TAG hydrolysis.[38]

Sample Preparation. A lipid extraction method (method I) was developed in this study. It consisted of a modification of the traditional gravimetric method.[16] Briefly, a well-mixed milk aliquot (150 μL) was placed in a centrifuge tube and 2.5 mL of a dichloromethane−MeOH solution (2:1, v/v), containing 5 μg mL^{-1} BHT to prevent lipid oxidation,[24] was added. The mixture was sonicated for 10 min, vortexed for 1 min, placed in the refrigerator (4 °C) for 15 min, and centrifuged at 10000 rpm for 8 min. Then, 800 μL of distilled water was added, sonicated for 10 min, mixed for 1 min in the vortex, and centrifuged at 10000 rpm for 8 min. The organic layer was washed with 800 μL of a saturated solution of sodium chloride, sonicated for 10 min, vortexed for 1 min, and centrifuged 8 min at 10000 rpm. The organic fraction was dried with anhydrous sodium sulfate, and the fat solution was then filtered with a syringe through a 0.45 μm filter, collected in a preweighed HPLC vial, and dried under a nitrogen stream. The fat was dissolved in a 2:2:1 ACN/2-propanol/*n*-hexane (v/v/v) ternary mixture and injected in the LC system. This method was compared with that described by Morera et al.[16] (method II).

High-Performance Liquid Chromatography and Mass Spectrometry. An 1100 series liquid chromatograph (Agilent Technologies, Waldbronn, Germany) provided with a quaternary pump, a degasser, a thermostated column compartment, an automatic sampler, and a UV−vis diode array detector online coupled to an Agilent 385-ELSD was employed. Separation was carried out with a Kinetex C18 100 Å column (150 mm × 4.6 mm, 2.6 μm; Phenomenex, Torrance, CA, USA). The optimized separation conditions were as follows: isocratic elution with an 80:20 ACN/*n*-pentanol mixture for 45 min, followed by a gradient of ACN/*n*-pentanol up to ratio of 60:40 in 20 min; column temperature, 10 °C; flow rate, 1.0 mL min^{-1}; and injection volume, 10 μL. UV detection was performed at 205 ± 10 nm (360 ± 60 nm as reference). The ELSD parameters were as follows: evaporation and nebulization temperature, 55 °C; gas flow rate, 1.2 standard liters per minute (SLM); gain factor, 1.

For TAG identification, a UPLC binary pump system (Acquity, Waters, Milford, MA, USA) was interfaced to a triple-quadrupole mass spectrometer (TQD, Waters, Manchester, UK) through an atmospheric pressure chemical ionization (APCI) source. The MS working conditions were as follows: probe temperature, 600 °C; corona discharge current, 20 μA; source temperature, 120 °C; desolvation gas flow, 800 L h^{-1}; cone gas flow, 60 L h^{-1}. Drying as well as nebulizing gas was nitrogen (Praxair, Valencia, Spain). The mass spectrometer scanned within the m/z 150−1000 range in the positive ionization mode at one scan per second.

Data Treatment and Statistical Analysis. The area of selected TAG peaks was measured from the ELSD detector, and a data matrix

DOI: 10.1021/acs.jafc.5b01158
J. Agric. Food Chem. 2015, 63, 5761−5770

was constructed (see Results and Discussion). After normalization of the variables, statistical data treatment was performed using SPSS (v. 15.0, Statistical Package for the Social Sciences, Chicago, IL, USA). Using a stepwise algorithm, the predictors to be included in the LDA model were selected. According to this algorithm, a predictor is considered eligible for its inclusion in the model if the significance of its F test exceeds the specified probability level given by the entrance threshold, F_{in}. However, the entrance of a new predictor modifies the significance of those predictors that are already present in the model. For this reason, after the inclusion of a new predictor, a rejection threshold, F_{out}, is used to decide if one of the other predictors should be removed from the model. This sequential process continues until no more predictors are eligible for entrance or removal from the model. The default probability values of F_{in} and F_{out}, 0.05 and 0.10, respectively, were adopted.

RESULTS AND DISCUSSION

Optimization of the Separation of TAGs. The initial separation conditions were adapted from a previous work for TAG separation in vegetable oils.[39] The optimization study was performed using human milk samples. Using a flow rate of 1.5 mL min^{-1} and a column temperature of 10 °C, a similar optimization study of mobile phase, including several binary mixtures of ACN with different alcohols (2-propanol, *n*-butanol, and *n*-pentanol) at 70:30 ratio, was conducted. Using 2-propanol, poor resolution and relatively long analysis times (ca. 50 min) were obtained. Using *n*-butanol and *n*-pentanol, analysis time and resolution improved significantly, although most peaks still overlapped. Despite this overlapping, the ACN/*n*-pentanol mixture gave shorter analysis time with respect to *n*-butanol and, therefore, *n*-pentanol was selected for the following studies.

Next, the influence of the content of *n*-pentanol in the 20−30% range on TAGs separation was studied. As shown in Figure S1 (see the Supporting Information), resolution was improved with decreasing *n*-pentanol content. Broad peaks with separation times longer than 45 min were obtained with <20% *n*-pentanol. Thus, an 80:20 (v/v) ACN/*n*-pentanol mixture was selected. This mobile phase also provided a satisfactory response in ELSD. Then, the effect of column temperature on TAG separation and detection response of UV (Figure S2, left) and ELSD (Figure S2, right) detectors was performed under isocratic conditions. As it can be seen, the TAG resolution increased when the temperature decreased, with a concomitant increase in both backpressure (from 22.4 to 25.4 MPa along the 5−20 °C range) and analysis time. Within the studied temperature interval, the TAG peaks showed satisfactory peak widths (measured at 50% peak height) ranging between 6.3 and 53.0 s (Figure S2, left) and 6.2−42.2 s (Figure S2, right). With regard to detector response, neither UV nor ELSD detection showed significant changes in the response (measured as peak area) over the temperature range investigated. These observations in ELSD response were different from those reported in the literature, where a positive[40] or negative[41] correlation with column temperature for peak area could be found. This behavior could be explained by the narrow temperature interval (5−20 °C) considered in this study. Thus, a column temperature of 10 °C provided the highest number of resolved peaks (30) (with peak widths ranging between 5.4 and 29.1 s) in <50 min with a reasonable backpressure (24.1 MPa), being selected for further studies.

Next, the influence of flow rate on TAG separation was also studied. A flow rate decrease from 1.5 to 1.0 mL min^{-1} led to an improvement in the resolution at the expense of an increase of analysis time. Lower flow rates (<1.0 mL min^{-1}) provided a significant peak broadening (peak widths ranged between 10.2 and 80.3 s and asymmetry factors comprised between 0.85 and 1.60) at very long separation time (>100 min). In addition, a decrease of the ELSD response with increasing flow rate was found, which was consistent with findings reported by several authors.[40,42] As a result, a flow rate of 1.0 mL min^{-1} was selected for further studies. Under these conditions, the late-eluting compounds were barely distinguished from baseline. To decrease the retention time and improve detection (peak shape), a solvent gradient step was established. Thus, the *n*-pentanol content was increased from 20 to 40% in 20 min after the first 45 min of isocratic elution with 80:20 ACN/*n*-pentanol. Figure 1 shows the ELSD chromatogram obtained under these conditions, where satisfactory peak shapes for highly retained TAGs were obtained.

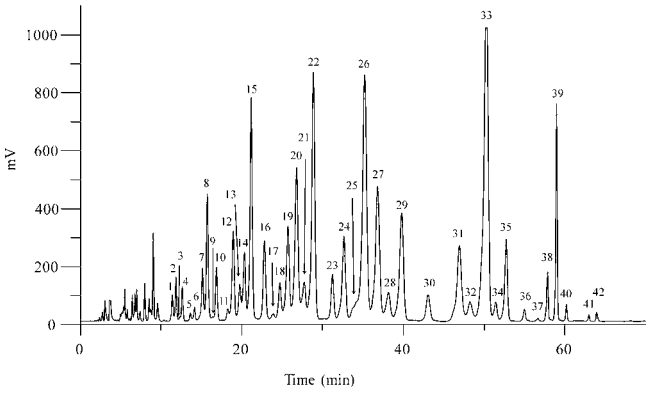

Figure 1. TAG profile of mature human milk. Chromatographic conditions: isocratic elution for 45 min at 80:20 ACN/*n*-pentanol followed by a linear gradient to 60:40 ACN/*n*-pentanol in 20 min; column temperature, 10 °C; flow rate, 1.0 mL min^{-1}.

The performance of the developed RPLC method was compared to those previously reported for analysis of TAGs in human milk. Most of these studies were usually conducted using conventional microparticulate columns packed with 5 μm silica particles;[23,27,28] however, it should be mentioned that data of efficiency or other analytical parameters were not provided. In any case, an estimation of the number of resolved peaks of some of these works was done. These values were between 17 and 22,[23,27,28] which were significantly lower than those obtained in this work (35). Also, packed columns of sub-2-μm particles operating at UPLC conditions have been applied to these samples.[43,44] To our knowledge, the work of Beccaria et al.[43] is the only one that has reported performance data (peak capacities values up to 170 for 114 min gradient) using three serially coupled core−shell type C18 columns. However, the number of resolved peaks was similar to our method, which is accomplished in shorter analysis (<65 min) using a RP column in a conventional high-pressure system.

Identification of TAGs. Generally, the elution of TAGs in RP-HPLC occurs according to the partition number (PN).[32,45] The PN for each individual TAG can be calculated as follows: PN = CN − 2ND, where CN is the number of carbon atoms and ND is the number of double bonds in the FAs attached to the glycerol molecule (see Table 1). However, the procedure for identifying the TAGs based on the PN is complicated due to the large number of FA constituents and rather limited to the coincidence of this parameter for several TAGs. For this reason,

[a]Peak identification number according to Figure 2; TAGs identified according to protonated molecule ($[M + H]^+$) and diacylglycerol ions ($[M + H - R_{1,2,3}COOH]^+$) observed in the APCI mass spectrum and to the relative order of PN. [b]Structure indicated by FA composition (e.g., OOO for triolein) using the following abbreviations: Ca, capric acid (C10.0); La, lauric acid (C12:0); M, myristic acid (C14:0); P, palmitic acid (C16.0); Pa, palmitoleic acid (C16:1); S, stearic acid (C18:0); O, oleic acid (C18:1); L, linoleic acid (C18:2); Ln, linolenic acid (C18:3); Ara, arachidic acid (C20:0); ETE, eicosatrienoic acid (C20:3).

to achieve a reliable TAG identification, a fragmentation study resulting from the APCI-MS analysis of TAGs in the positive ionization mode was performed.[46,47] The APCI mass spectra of TAGs exhibited a protonated molecule, $[M + H]^+$, the intensity of which depends on the degree of unsaturation of the TAG molecule, and $[M + H - R_{1,2,3}COOH]^+$ ions resulting from the loss of fatty acyl moieties (diacylglycerol (DAG) ions). The intensities of the protonated molecules $[M + H]^+$ formed from saturated TAGs were low or even undetected (for fully saturated TAGs), and their identification was performed according to their respective DAG ions. These results were consistent with those previously reported.[45,48] Table 1 shows the m/z values of the protonated molecules and DAG ions found in the human milk samples studied. No distinction was made between the *sn*-1, *sn*-2, and *sn*-3 positions in the TAG species identified. It should be noted that despite the satisfactory resolution achieved in this work, some cases of coelution of TAGs were observed (see Table 1 and Figure 1).

With regard to the number of TAGs here identified, this can be favorably compared to that reported in previous human milk studies. For example, in the work of Morera et al.[16] up to 43 different TAGs were reported, whereas in recent studies of Linderborg et al.[44] and Mondello's group,[43] 37 and 51 different TAGs, respectively, were positively identified. However, these values were lower than those reported by Haddad et al.;[49] where up to 98 TAGs were identified by using two serially coupled C18 columns in combination with tandem ESI-MS and subsequently confirmed by GC-MS.

Small-Scale Extraction Method and Quantification. First, the evaluation of fat content using the proposed small-scale extraction method was performed. To evaluate the efficiency of fat extraction, the method developed here (method I) was compared to the conventional protocol (method II). Thus, fat was extracted and gravimetrically determined[25,26,41,42] from 12 mature human milk aliquots, 6 by method I and 6 by method II. The fat content obtained by methods I and II ranged between 0.021 and 0.029 g mL^{-1} and between 0.025 and 0.029 g mL^{-1}, respectively. Table 2 shows the fat content

Table 2. Fat Content in Human Milk Obtained Gravimetrically by Methods I and II

	fat (g mL^{-1})	
human milk aliquot	method I	method II
1	0.0231	0.0270
2	0.0246	0.0249
3	0.0294	0.0258
4	0.0252	0.0256
5	0.0258	0.0279
6	0.0207	0.0291
mean ± SD	0.0248 ± 0.0029	0.0267 ± 0.0016

(expressed as mean ± SD) obtained for both methods. No significant differences in the fat milk content between both extraction procedures were observed ($p > 0.05$, Student's t test), and the results found were consistent with those described in the literature.[3,23] After these results had been obtained, the evaluation of TAG content was next considered.

When performing quantification in ELSD, several authors have established that its response is linear for a wide range of

concentrations.[38,50] However, some studies[51,52] have demonstrated that the response from HPLC-ELSD follows a nonlinear empirical model: $A = am^b$, where A is the area of chromatographic peak, m the mass of analyte, and a and b two experimental parameters related to the ELSD configuration. Thus, each change in the instrumental working conditions would require a new estimation of these parameters. This equation can be easily linearized as follows: $\log A = b \log m + \log a$. However, the application of this equation requires the availability of each TAG identified in the target sample, which is not commercially feasible. To overcome this limitation, Heron et al.[52] have developed an empirical methodology to evaluate the TAG content in vegetable oils based on the previous equation using a reduced number of standards. However, the method provided a high variability (between 1 and 40%) with respect to the real mass percentage. Another approach proposed by several authors[28,51] is based on the application of the internal normalization method as measurement of mass percentage, where a similarity in the response factors of TAGs (relative response factors, RRF) with respect to triolein (OOO) ranged between 0.83 and 1.21) was assumed. To confirm this assumption, calibration curves of homologous TAG standards were performed and fitting equations of both linear and power models to detector response (area) versus mass of lipid injected were obtained. As shown in Table 3, the peak areas were well-fitted by power model equations in the mass range studied (0.5−100 μg). The limits of detection (LOD) and limits of quantification (LOQ) were also estimated for signal-to-noise ratios of 3 and 10, respectively. The results obtained for homogeneous TAG standards were LOD (9.2−13.1) ng and LOQ (30.6−43.3) ng (see Table 3). Then, the RRF calculated for pure homogeneous TAG standards in relation to OOO were obtained, giving values close to unity, which allows a quantitative estimation of TAGs on the basis of the percentage peak area. The relative content of each TAG (expressed as mean ± SD) obtained is given in Table 4. As shown in Table 4, no significant differences ($p > 0.05$, Student's t test) were observed between results obtained with both methods for >85% of the TAGs. From this study, it can be derived that method I provided satisfactory results, both in the total fat content and in the quantitative analysis of representative TAGs. Moreover, method I has several advantages over method II. Table 5 summarizes the essential features of both sample preparation methods. Method I uses much smaller volumes of the sample and chemical solutions (90% reduction); thus, the expense and chemical hazards are greatly reduced. Although other operational steps for both methods were quite similar, the small-scale protocol requires the use of materials such as micropipets or small syringes, which simplifies the handling of more samples simultaneously and speeds the isolation process of fat. In particular, method I allowed processing 120 samples per day (in an 8 h working day), whereas a rate of 30 samples per day could be achieved with method II. A comparison between our method and the traditional Folch method for milk samples[43,49] was also done. In this protocol, the extraction step employs larger volumes of solvents (40−180 mL of chloroform/methanol (2:1, v/v), followed by several re-extractions and washings, which results in larger experimental effort, longer time, and greater amounts of residues of harmful solvents generated than the developed protocol. Consequently, the present procedure is suitable to be applied to systematic and routine characterization of lipid composition in human milk samples. Additionally, due to the small sample volume required, the proposed method offers the possibility of analyzing separate individual milk sample portions from within one feeding, allowing the characterization of possible fluctuations in the TAG composition.

As shown in Table 4, from 69 TAG molecular species identified, the major TAGs found in the lipid fraction in both protocols were POO, POL, LaPO + MMO, MOO, and PSO (see Table 1 for abbreviations) at 20, 10, 7, 6, and 5%, respectively. The amounts of these most abundant TAGs were similar to those obtained in the literature.[16,27,49] For example, the studies of Zou et al.,[27] in milk from Danish women pointed out that the TAGs were mainly composed of POO (21.52%) and POL (16.93%). These small discrepancies can be attributed to natural factors such as randomization in human milk, the physiological stage,[16] and the susceptibility of human milk TAGs to dietary habits.[5,44] It is also important to remark that the molecular weight distribution of TAGs (expressed as CN:ND groups[44]) in human milk reported in this work (see Figure S3) is in agreement with the findings of studies previously reported.[44,49]

Taking into account the advantages described above for method I, it was extended to the milk of other mammalian species (cow, sheep, and goat). Thus, the total fat content varied within the ranges 0.023−0.046, 0.046−0.057, and 0.034−0.076 g mL^{-1} for cow, sheep, and goat milks, respectively. These milk samples were also analyzed using the developed LC method with an excellent resolution/elution time ratio compared to those previously reported[14,16,23,27,28] (Figure 2). TAG profiles (particularly for the main TAG peaks) similar to those reported in the literature were found for these samples.[14] From these profiles, 22 common peaks, which could be easily integrated, were selected for the four mammalian species and used for statistical treatment.

Classification of Mammalian Milks Using TAG Profiles with LDA Model. First, to reduce the variability associated with total amount of TAGs recovered from milk samples and to minimize the sources of variance also affecting the sum of the areas of all peaks, normalized rather than absolute peak area

[a]Data obtained from three extractions performed the same day for each extraction method. [b]Peak identification number, TAG information, and abbreviations as indicated in Table 1.

Table 5. Comparison of Sample Preparation Protocols

	method I (small scale)	method II[16]
sample volume (mL)	0.15	1.5
extraction		
(i) CH_2Cl_2/MeOH (2:1, v/v) (mL)	2.5	25
(ii) water (mL)	0.8	8
(iii) saline solution (mL)	0.8	8
material required	10 mL centrifuge tubes, syringes, syringe filters, micropipets	Falcon 50 mL conical centrifuge tubes, separating funnels, filter funnels, filter paper, pipettes, Pasteur pipets
samples per day	120	30

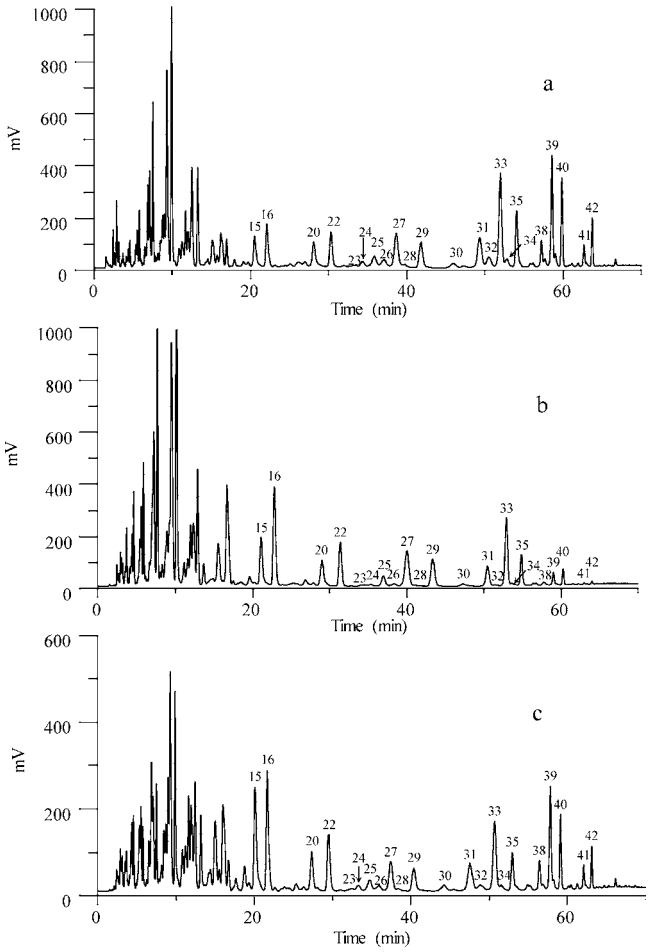

Figure 2. TAG profile of milk from different mammalian species: cow (a); sheep (b); goat (c). Chromatographic conditions were as in Figure 1.

was used. To normalize the variables, the area of each peak was divided by each of the areas of the other 21 peaks; in this way, and taking into account that each pair of peaks should be considered only once, (22 × 21)/2 = 231 non-redundant peak area ratios were obtained to be used as predictors. Using the normalized variables, an LDA model capable of classifying the milk samples according to their respective mammalian species was constructed. A matrix containing 75 objects that corresponded to all of the milk samples analyzed was constructed. Thus, this matrix was divided into two groups of objects to constitute the training and evaluation sets. The training set was composed by 67 objects (18 milks × 3 animal mammalian species + 13 human milk samples), whereas the evaluation set was constituted by the remaining samples (8 objects). A response column, containing the categories corresponding to the four mammalian species, was added to these matrices. When the LDA model was constructed, an excellent resolution between all of the category pairs was

J. Agric. Food Chem. 2015, 63, 5761−5770

achieved (Wilks' lambda, $\lambda_w < 0.01$). The variables selected by the SPSS stepwise algorithm, and the corresponding standardized coefficients of the model, showing the predictors with large discriminant capabilities, are given in Table 6. As shown in Figure 3a, a large resolution between the human milk from the other mammalian milks was achieved along the first discriminant function (df). As deduced from Table 6, the first df was mainly constructed with the peak area ratios OOL/PaOO and POO/(POAra + SSO) (peaks labeled 24/25 and 33/41, respectively). The projection on the second df shows a lack of capability to resolve between cow and goat milks. However, both milks were clearly distinguished from sheep and human milks. In this case, the second df was mainly constructed with the peak area ratios (CaMS + CaPP + LaLaS + LaMP + MMM + OLL)/(MOO + PPaO) and (LaPO + MMO)/PSO (peaks labeled 16/27 and 22/39, respectively). According to Figure 3b, along the third df, it is not possible to distinguish between sheep and human milk, but both were markedly differentiated from cow and goat milks. As shown in Table 6, the third df was mainly constituted with the peak area ratios (CaPO + LaMO)/(CaPS + LaMS + LaPP + MMP) and (CaMS + CaPP + LaLaS + LaMP + MMM + OLL) (peaks labeled 15/23 and 16/24, respectively). Finally, as illustrated in Figure 3c, by using a plane oblique to the three first discriminant functions, all of the possible pairs of categories were very well resolved from each other.

Table 6. Predictors Selected and Corresponding Standardized Coefficients of the LDA Model Constructed To Discriminate between Milks Obtained from Different Mammalian Species

predictor[a]	first df	second df	third df
peak 15/peak 23	−0.466	0.219	2.275
peak 16/peak 24	0.700	−0.302	−2.742
peak 16/peak 27	0.075	−2.114	2.020
peak 16/peak 35	−0.262	0.126	1.306
peak 16/peak 41	−0.395	1.559	0.128
peak 22/peak 39	−0.284	2.067	0.067
peak 23/peak 41	−0.230	−1.282	0.055
peak 24/peak 25	2.748	0.463	−0.143
peak 26/peak 40	0.949	0.263	0.243
peak 30/peak 33	−0.115	0.693	1.016
peak 33/peak 41	1.662	0.724	0.812

[a]See Table 1 for peak identification.

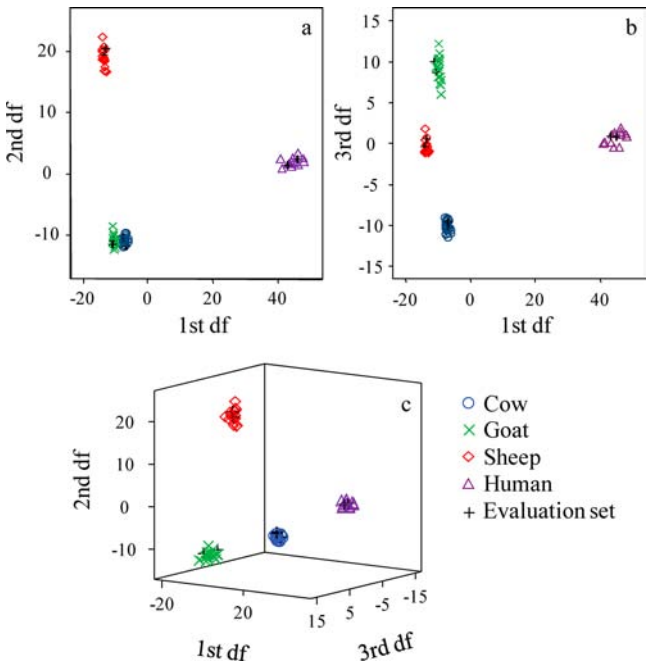

Figure 3. Score plots on the planes of the first and second (a) and second and third discriminant functions (df) (b) and on an oblique plane of the 3-D space defined by the three discriminant functions (c) of the LDA model constructed to discriminate between different mammalian milk species. Evaluation set samples are labeled as indicated in the legend.

Using this model and leave-one-out validation, all of the objects of the training set were correctly classified. On the other hand, the prediction capability of the model was evaluated using the evaluation set. In this case, all of the objects (represented with a cross symbol in Figure 3) were correctly assigned within 95% probability level. It should be pointed out that in the case of human milk samples, different periods of lactation were taken, and in all cases, an excellent classification within this category was accomplished, which supports the robustness of the developed LDA model.

In summary, a highly efficient RP-HPLC-UV-ELSD method of TAGs in human milk samples has been developed. Also, a small-scale sample preparation method has been established, being particularly important for human milk samples. The combination of this sample extraction protocol with HPLC-UV-ELSD technique could provide a methodology highly recommended in studies on breastfeeding and its contribution to infant growth and development. Finally, the possibility of classifying milks according to their mammalian origin by using TAG profiles obtained by HPLC-ELSD has been successfully demonstrated.

laboratory has demonstrated that this process did not introduce significant metal contamination, and all subsequent stages of handling were performed using metal-free materials. Approximately 10−15 g of coarsely ground coffee was taken for a pretreatment study and for caffeine extraction. The remainder was ground with a zirconium oxide ball mill (Fritsch, Idar-Oberstein, Germany) to produce a fine, visibly homogeneous powder. This sample was divided between two sterile, acid-washed containers for stable isotope and elemental analysis.

Sample Pretreatment. As an initial study, six samples (samples 1, 10, 27, 33, 35, and 50), from diverse geographical origins, were extracted with water and with hexane to determine whether these pretreatments could increase the discrimination of isotopic analysis by removing some complexity from the analyte. Approximately 5 g of coarsely ground samples was extracted with approximately 150 mL of high-purity water or hexane using conventional Soxhlet apparatus for 5 h. Aqueous extracts were heated in wide beakers at 102 °C until visibly dry. Hexane extracts were dried by rotary evaporation. The dried extracts were analyzed by FT-infrared spectroscopy to determine the chemical composition, and both the extracted samples and the dried extracts were analyzed to determine the carbon and nitrogen isotopic composition.

Extraction of the samples with water or hexane were considered to represent the extremes of what might be removed or recovered from the coffee beans, that is, by polar, aqueous, or nonpolar, organic, solvents. The aqueous extracts of the coffee were found to have infrared spectra consistent with mixtures of sugars and proteins, whereas the solvent extracts were found to have infrared spectra consistent with vegetable oil. The results of the isotopic analysis of the extracts and residues are summarized in Table 2. Extraction with water was found to have a negligible effect on either the δ^{13}C or δ^{15}N composition of the residual coffee, whereas the aqueous extracts were somewhat enriched in both isotopes. In contrast, extraction with organic solvent produced a significant depletion in the δ^{13}C composition of the residual coffee with a concomitant large enrichment in the extract. The solvent extracts did not contain sufficient nitrogen to permit δ^{15}N determination, and the extracted coffee was not significantly changed in nitrogen isotopic composition (data not shown).

When considering the patterns and relationships within these data, it was concluded that the pretreatments did not enhance the discriminatory power of isotopic analysis (based on δ^{13}C and δ^{15}N measurements), and all subsequent analyses were performed on untreated samples.

Stable Isotope Analysis. All isotope ratio measurements were performed using a Thermo Scientific (Bremen, Germany) Delta V^{Plus} isotope ratio mass spectrometer (IRMS) coupled to a ConFlo IV interface for working gas introduction and sample dilution.

Carbon and nitrogen isotopic compositions were determined using a Thermo Scientific Flash 2000 HT elemental analyzer (EA) configured for flash combustion at 950 °C with a helium flow of 100 mL/min. The reactor comprised a single quartz tube containing chrome oxide, reduced copper, and silver/cobaltous oxide. A chemical trap containing magnesium perchlorate was inserted between the reactor and the IRMS. Each sample was analyzed in triplicate with median standard deviations of 0.09 and 0.13‰ for carbon and nitrogen measurements, respectively.

Hydrogen and oxygen isotopic compositions were determined using a Thermo Scientific Flash 2000 HT EA configured for thermal conversion (TC/EA) operating at 1400 °C with a helium flow of 100 mL/min introduced via a bottom-feed adaptor. Samples were measured into silver capsules (4 × 3.2 mm, IVA Analysentechnik, Meerbursch, Germany) and equilibrated with purified Brisbane tap water (with a well-characterized isotopic composition) for 3 days. Samples were then dried over phosphorus pentoxide for 3 days, under vacuum. Encapsulated samples were introduced into the reactor via a Zero blank autosampler (Costech Analytical Technologies Inc., Valencia, CA, USA). Each sample was analyzed in triplicate with median standard deviations of 1.3 and 0.10‰ for hydrogen and oxygen measurements, respectively.

Data were normalized to the international isotope scales (VPDB-LSVEC or VSMOW-SLAP) by two-point calibration; a list of the reference materials and quality control (QC) materials used is given in the Supporting Information (supplement 1).

The δ values of the nonexchangeable hydrogen content were estimated from the measured values of the sample and the equilibration water by mass balance:

DOI: 10.1021/acs.jafc.5b01526
J. Agric. Food Chem. 2015, 63, 5771−5779

$$R_{nex} = R_{meas} - (R_{water} \times \alpha \times f_{ex})/(1 - f_{ex})$$

R_{nex} is the nonexchangable H isotope ratio, R_{meas} is the measured H isotope ratio, and R_{water} is the equilibration water H isotope ratio.

The fraction of exchangeable H atoms (f_{ex}) was taken as 0.25,[22] and the fractionation factor (α) between H atoms in the equilibration water and samples was taken as 1. This estimate of nonexchangeable hydrogen was considered appropriate for a comparative study.

Caffeine Extraction. Caffeine was isolated from an aqueous extract of coffee by supported liquid−liquid extraction using a method previously described to isolate active pharmaceutical ingredients.[21] This method was reported to have no significant effect on isotopic composition. Coarsely ground coffee was extracted with high-purity water as described above. When cooled, 0.6 mL of the extracts was loaded onto ChemElute 1 mL unbuffered liquid extraction cartridges (Agilent Australia, Victoria, Australia) and allowed to permeate for 15 min. The cartridges were then eluted with 3.5 mL of high-purity chloroform, yielding 1.5 mL of extract directly into a 2 mL autosampler vial. The method was shown to recover >98% of the caffeine present in the sample.

Caffeine Analysis. Extracted caffeine was characterized using a 7819A (Agilent Australia) gas chromatograph (GC) coupled to a Thermo Scientific ISQ MS. The injector was maintained at 280 °C with a constant helium flow of 1 mL/min and a split ratio of 10:1. Caffeine was separated using a DB-5 column (30 m × 0.25 mm × 0.25 μm) (Agilent Australia) with the following temperature program: 120 °C (2 min) raised at 15 °C/min to 280 °C (2 min). The carbon isotopic composition of extracted caffeine was determined using the analytical conditions above, with the GC column coupled to a Thermo Scientific GC-IsoLink interface with the combustion reactor operated at 1030 °C. Data were normalized to the VPDB-LSVEC scale using a certified sample of natural caffeine (IAEA-600; $\delta^{13}C_{VPDB}$ −27.77 ‰) and a sample of synthetic caffeine ($\delta^{13}C_{VPDB}$ −38.40 ‰) calibrated in-house using the methodology described above.

Elemental Analysis. The methods of analysis have been previously described.[23,24] In summary, approximately 0.3 g samples were accurately weighed into PTFE vessels and digested with high-purity nitric acid (69% Seastar Chemicals, Canada) using a Mars Xpress microwave digestion system (CEM Corp., Matthews, NC, USA).

Digested samples were analyzed using a Vista Pro ICP-OES (Varian Australia) and a 7700 ICP-MS (Agilent Australia) with autosampler and Integrated Sample Introduction System (ISIS). Appropriate reference materials were used for quality control (Supporting Information supplement 1).

Data Pretreatment. All elemental concentration data that were below the limit of detection (LoD) for more than 50% of the samples were removed from the overall data. Any of the remaining data that were below the LoD were replaced with the numerical value of the LoD for a given element and are presented as such. Data are reported for 13 elements (Ca, K, P, Mg, Al, Ti, Mn, Fe, Ni, Cu, Zn, Sr, Ba), together with the δ^2H, δ^{13}C, δ^{15}N, and δ^{18}O compositions (Supporting Information supplement 2).

To constrain the data further, the median and interquartile range (IRQ) were calculated for each measured parameter, and data were considered to be outliers if an individual value fell beyond

$$\text{median} - (1.5 \times \text{IQR}) \text{ or } \text{median} + (1.5 \times \text{IQR})$$

Outliers were substituted with the median value for the measured parameter and are presented in the Supporting Information (supplement 2, highlighted in green). In total approximately 6% of the elemental concentration data were substituted by this process, although notably, 22% of the aluminum concentration data and 33% of the nickel concentration data were considered to be outliers. These elevated metal concentrations did not appear to be associated with particular countries of origin, suppliers, or style of coffee (beans vs ground) and may have resulted from contact with metal surfaces during storage. None of the isotopic data were classified as outliers.

None of the measured parameters showed significant differences between coffees purchased ground or as beans or between *arabica* and blends of *arabica* and *robusta*.

Statistical Analysis. Data were analyzed and plotted using the R 3.0.1 software environment for statistical computing and graphics.[25] Two-tailed *t* tests were used to compare coffees purchased ground versus beans and *arabica* versus blends of *arabica* and *robusta*. Least absolute deviation (LAD) regression was applied to the data to determine the equation of robust fit and the correlation, R^2 (observed vs predicted). Principal component analysis (PCA) was performed on the elemental data to determine which parameters accounted for the largest differences between samples. This was performed using the L_1-norm to increase robustness to outliers compared to traditional PCA.[26] Discriminant analysis (DA) was applied to both elemental and isotopic data to determine to what extent these parameters distinguished between the different regions or countries of origin. Stepwise DA, using the Mahalanobis distance, was used to find the optimum set of discriminant functions (DFs), and once these parameters were established, the classifications were calculated using jackknife tests. The results of conventional DA represent the recognition ability based on the samples used to generate the model, whereas the jackknife approach assesses the external validity and is considered a good approach when, as in this case, sample sizes are small. In these tests, one case is eliminated from the original data set and the DFs are computed using the remaining observations. This procedure is repeated with each individual observation in turn omitted, and the values are averaged to provide a *jackknifed* estimate of the DFs.

RESULTS AND DISCUSSION

Samples were grouped according to their region of origin: Africa (A), Australia (Au), Central America (CA), Indonesia (Ind), India (In), Papua New Guinea (PNG), and South America (SA), as shown in Table 1. When discriminant analysis was performed, the data for PNG were grouped with the close geographical neighbor Australia, so as not to include a group with a single member. Because of wide geographical differences, Indonesia and India were treated as separate entities rather than as a single "Asia" grouping.

Correlation. A Pearson correlation matrix was calculated for all measured parameters in which few significant relationships were observed. Strong correlations were observed between δ^2H and δ^{18}O compositions and between δ^{18}O composition and the δ^{13}C compositions of both the coffee and the extracted caffeine (see below). The only strong correlation observed within the elemental concentration data was between the concentrations of strontium and barium, both group II metals.

Principal Component and Discriminant Analysis. PCA was applied to the elemental concentration data to determine which parameters accounted for the largest differences between samples. The loading factors for PC1 were dominated by potassium concentration, the loading factors for PC2 by the concentrations of calcium and magnesium, and the loading factors of PC3 by phosphorus. PCA did not provide clear discrimination between the regions of origin.

Stepwise DA reduced the elemental concentration data to 5 variables (Ca, Ti, Fe, Ni, Zn) from the original 13, the major contributions to the DFs being the concentrations of calcium and titanium. Stepwise DA reduced the isotopic data to three variables, (δ^2H, δ^{13}C, δ^{18}O) from the original five, δ^{13}C and δ^{18}O being the major contributors to the DFs. This reduced data set can be explained by the strong covariance between δ^2H and δ^{18}O and between $\delta^{13}C_{coffee}$ and $\delta^{13}C_{caffeine}$. Combining the elemental and isotopic data, stepwise DA identified eight variables, consistent with the results above (δ^2H, δ^{13}C, δ^{18}O,

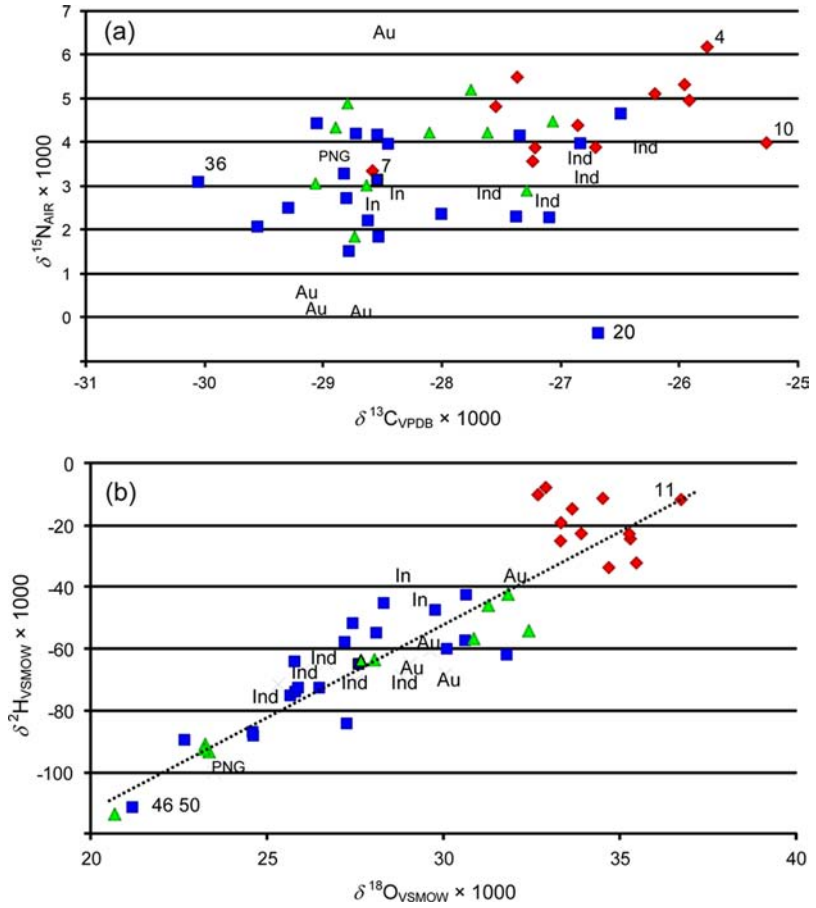

Figure 1. Plots of (a) carbon versus nitrogen isotopic composition and (b) hydrogen versus oxygen isotopic composition of roasted coffee beans: Africa (diamonds, red), Central America (squares, blue), South America (triangles, green); other countries are identified by letters (see Table 1). Dashed line shows the LAD regression ($Y = 5.93X - 229$; $R^2 = 0.83$).

Ca, P, Ti, Ni, Zn) with the major contributions to the DFs being the isotopic data.

Stepwise DA was also applied to distinguish between countries within Central/Douth America. Both the elemental concentrations (Ca, K, Ti, Fe, Ni, Cu, Zn, Ba) and isotopic compositions (δ^2H, δ^{13}C, δ^{15}N) identified as major contributors to the DFs were different from those that contributed to global variations. When elemental concentration and isotopic data were combined, stepwise DA removed only the concentrations of strontium and barium from the data, confirming that climatic and geological variations are more subtle on a regional scale than globally.

The same approach was applied to distinguish between countries within the African continent. Stepwise DA identified variables within the isotopic data (δ^2H/δ^{18}O) and within the elemental concentration data (Ca, K, Mg, P, Al, Mn, Fe), which were quite different from those selected for global data or for the Central/South America region. Again, this finding suggests that regional variations are driven by different factors from global variations and from variations within other regions.

Carbon and Nitrogen Isotopes. Figure 1a shows an $X-Y$ scatter plot of δ^{15}N versus δ^{13}C compositions of the coffee samples. Overall, the δ^{13}C data spanned a wide range (from −30.0 to −25.2‰); the most enriched samples originated from Ethiopia or Kenya (samples 4 and 10) and the most depleted sample (sample 36) from Bolivia. The δ^{15}N compositions spanned a similar range (from −0.3 to +6.4‰); the most enriched samples originated in Australia (sample 16) or Ethiopia (sample 4) and the most depleted samples originated from Australia (samples 13−15) or El Salvador (sample 20).

The variation in δ^{13}C composition of roasted coffees measured in this study (from −30.0 to −25.2‰) was in agreement with those determined in earlier studies of green coffee beans: from −29.9 to −24.6 to‰[17] and from −28.1 to −23.8‰.[18] The variation in δ^{15}N composition spanned a slightly wider range (from −0.3 to +6.4‰) than reported in these earlier studies: from +1.5 to +3.3[17] and from +1.2 to +5.6.[18] These findings suggest that, akin to elemental composition, there was little change in the isotopic composition of green and roasted coffee with respect to δ^{13}C and δ^{15}N.

The large variation in the data presented in Figure 1 suggested that many factors influence the isotopic composition such as water and nutrient availability, light intensity, and temperature.[27] Despite the large number of environmental factors that may control these data, some trends were apparent. In general, the samples most enriched in both ^{13}C and ^{15}N came from Africa and the most depleted samples came from Central/South America. The one exception to this trend was sample 7, which was purchased as ground coffee from a large supermarket chain and claimed to be a product of Ethiopia. Coffees from Indonesia formed a cluster with little variation in carbon and nitrogen composition. Coffees from Australia, Papua New Guinea, and India had similar δ^{13}C compositions, typical of C_3 plants (approximately −28.7‰), but had δ^{15}N compositions that spanned the entire range observed in this study.

DOI: 10.1021/acs.jafc.5b01526
J. Agric. Food Chem. 2015, 63, 5771−5779

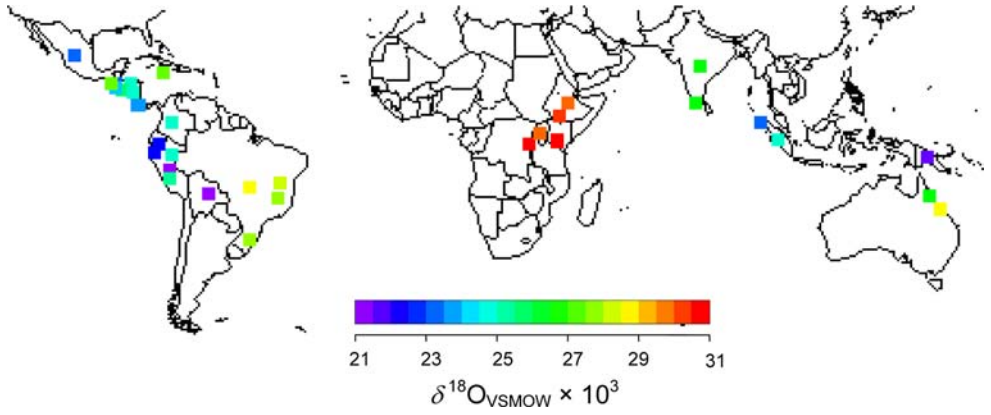

Figure 2. Isoscape of the oxygen isotopic composition of coffee samples.

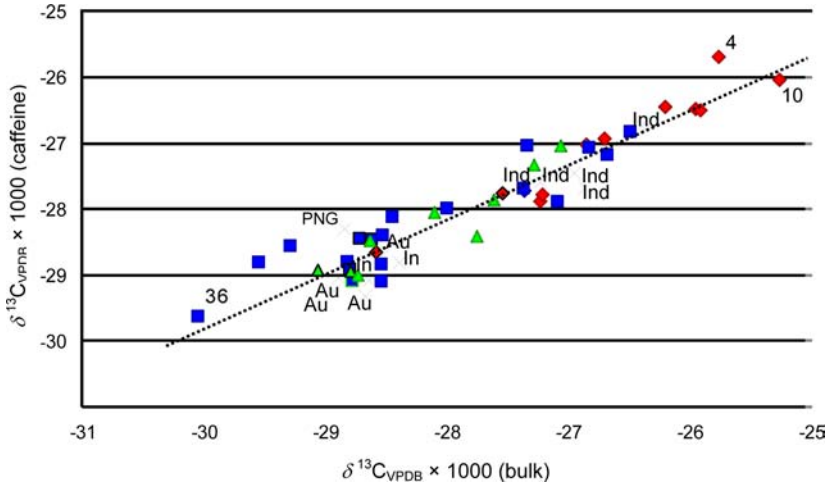

Figure 3. Carbon isotopic composition of extracted caffeine versus carbon isotopic composition of roasted beans: Africa (diamonds, red), Central America (squares, blue), South America (triangles, green); other countries are identified by letters (see Table 1). Dashed line shows the LAD regression ($Y = 0.81X - 5.3$; $R^2 = 0.81$).

In common with earlier studies of green coffee beans[18] it was apparent that a combination of carbon and nitrogen isotopic composition allowed some degree of discrimination between Africa, Asia, and Central/South America regions but not intracontinent.

Three Australian coffees had $\delta^{15}N$ compositions close to that of atmospheric nitrogen (0‰), whereas the fourth (sample 16) was the most enriched sample in this study (+6.4‰), claiming to be organic, as did sample **4**. Nitrogen stable isotopic composition has been used to distinguish organic and conventional cultivation methods for a range of fruits[28−31] on the basis that inorganic fertilizers have $\delta^{15}N$ compositions close to atmospheric nitrogen (from −6 to +6‰), whereas manure and other organic fertilizers can be greatly enriched (from +1 to +37‰). From the limited data available in this study it appeared that $\delta^{15}N$ composition may be extended to the authentication of organic coffee beans. This principle would also support the fact that African countries, in which natural fertilizers predominate, are typically enriched in ^{15}N with respect to countries that favor the use of inorganic fertilizers.

Hydrogen and Oxygen Isotopes. Figure 1b shows an $X-Y$ scatter plot of the δ^2H versus $\delta^{18}O$ compositions of the coffee samples with a relationship defined by

$$\delta^2H = \delta^{18}O \times 5.9 - 229$$

The hydrogen isotopic composition spanned a range from −113 to −8‰, and the oxygen isotopic composition spanned a range from +20.6 to +36.7‰. The most enriched sample (sample 11) originated from Rwanda and the most depleted samples (samples 46 and 50) from Colombia and Peru. The range of $\delta^{18}O$ compositions (from +20.6 to +32.4‰) was somewhat smaller than previously reported for green coffee beans (from +18.7 to +34.8‰).[17] Although the $\delta^{18}O$ composition of plant material is attributed mainly to precipitation at different latitudes and altitudes,[32] the data in this study showed no correlation with latitude. This may reflect little variation, as a majority of coffee is grown between latitudes 23°26′ north and south of the equator.

The relationship between δ^2H and $\delta^{18}O$ was characterized by a slope that was typical neither of meteoric water (typical slope 8)[33] or of evaporation-enriched water in fruits (typical slope 4).[34] It is likely that the observed relationship contained contributions from both of these processes and/or water loss through roasting. During roasting, green coffee beans are progressively heated to 230 °C, losing approximately 13% of their weight,[35] the majority of which is likely to be water.

The pattern of data presented in Figure 1b for $\delta^2H/\delta^{18}O$ broadly reflected those observed from $\delta^{13}C/\delta^{15}N$, samples from Africa being the most isotopically enriched and samples from Central/South America being the most depleted. For $\delta^2H/\delta^{18}O$

DOI: 10.1021/acs.jafc.5b01526
J. Agric. Food Chem. 2015, 63, 5771−5779

data there was a clear delineation of African countries, including sample 7, which had ambiguous $\delta^{13}C/\delta^{15}N$ characteristics. Samples from low-coffee-producing nations (Australia, India, and Indonesia) formed discrete groupings within the data, with the exception of Australian sample 16, which was an organic product. On the basis of Figure 1b it is likely that $\delta^{2}H/\delta^{18}O$ composition was also characteristic of organic production methods, organic and African samples being the most enriched.

Figure 2 presents a simple geo-spatial map (*isoscape*) showing the distribution of $\delta^{18}O$ of the coffee samples from this study. The isotopic data were ranked into 20 groups, assigned a color according to the palette shown in Figure 3, and plotted on a global map using the longitude and latitude of each sample (Supporting Information supplement 2). Very similar patterns were observed for plots of $\delta^{2}H$ and $\delta^{13}C$ as might be expected given the strong correlations between these variables. Although the data shown in Figure 2 were relatively sparse, there was a marked similarity to isoscapes predicting plant $\delta^{18}O$ composition derived from global precipitation.[36] By plotting data in this way it becomes possible to answer the question, "is the isotopic composition consistent with the claimed geographical origin?", removing the need for comparative samples.

Caffeine. Figure 3 shows an $X-Y$ scatter plot of the $\delta^{13}C$ composition of the extracted caffeine versus that of the whole coffee with a relationship defined by

$$\delta^{13}C_{caffeine} = \delta^{13}C_{coffee} \times 0.8 - 5.3$$

The isotopic compositions of the extracted caffeine spanned a slightly smaller range (from −29.6 to −25.7‰) than previously reported (from −29.9 to −25.1‰),[20] and there was a strong correlation between $\delta^{13}C_{caffeine}$ and $\delta^{13}C_{coffee}$ (R^2 = 0.81). The small difference between $\delta^{13}C_{caffeine}$ and $\delta^{13}C_{coffee}$ (median difference = −0.22‰; range from −0.80 to +0.77‰) was in agreement with a study of the biosynthesis of purine alkaloids (specifically caffeine), which predicted a small depletion in the carbon isotopic composition of caffeine with respect to cellulose.[37]

The general trends observed in Figure 1 were also apparent in Figure 3, African samples being the most isotopically enriched, Central/South American samples being the most depleted, and low-coffee-producing regions (Australia, India, and Indonesia) forming discrete groupings within the data. The strong correlation between $\delta^{13}C_{caffeine}$ and $\delta^{13}C_{coffee}$ may provide a limited means to determine the authenticity of caffeinated beverages by reference to Figure 3. However, such an approach may be limited by the technical complexity of GC-IRMS measurements for elements other than carbon.

Country of Origin. Table 3 summarizes the results of DA applied to the analytical data obtained in this study. A reduced data set of elemental concentrations (Ca, Ti, Fe, Ni, Zn) provided a reasonable basis to discriminate between regions of production (63% overall correct). A reduced data set of isotopic composition ($\delta^{2}H$, $\delta^{13}C$, $\delta^{18}O$) provided somewhat better discrimination for some regions but misclassified samples from Central/South America and India, leading to similar overall success (65% correct). Combining elemental and isotopic data improved the discrimination between Central and South America and the overall correct classification (77% correct). Although the degree of correct classification was lower than reported by previous studies,[16−19] we find that the current results represent a realistic estimate of what is possible with a limited number of samples.

Table 3. Results of Discriminant Analysis Applied to Regions and Countries of Origin Showing the Percentage Correct Classification Obtained by Jackknifed and Conventional (Non-jackknifed) Methods

DA was also applied independently to data from Central/South America and from Africa (Table 3). These tests failed to correctly classify coffee from any of the countries, with the possible exceptions of Guatemala/Honduras and Rwanda/Uganda. As only a single sample from each country was analyzed, it is not possible to conclude if this finding reflects that these countries were characterized by a unique elemental composition.

DA results can be explained with reference to Figures 1 and 2; countries from Africa were clearly delineated by enriched isotopic compositions, whereas data for Central/South America and low-coffee-producing countries (Australia, India, and Indonesia) were encompassed in a broad band of values. Isotopic composition appeared to be driven by factors such as precipitation, more than national or continental boundaries. Consequently, in South America there was a distinction between the ^{18}O compositions of coffees from the east and west coasts, which was more pronounced than any difference between Central/South America; that is, intraregion differences were similar to, or greater than, inter-region differences. For this reason, assigning countries to broad, man-made groupings such as "Asia" as a basis for DA may not be appropriate.

DOI: 10.1021/acs.jafc.5b01526
J. Agric. Food Chem. 2015, 63, 5771−5779

Although DA was successfully applied to assess numerically the region of origin, it was apparent (Table 3) that the level of discrimination provided by DA was greatly overestimated when compared to the results obtained using a jackknifed approach. We recommend caution in the haphazard use of DA; specifically, the number of observations must be significantly greater than the number of independent variables (>5:1), and the number of observations in the smallest group must be greater than the number of independent variables. In the absence of such large sample sets, simpler $X-Y$ and geo-spatial plots (Figures 1−2) provide a simple and robust approach to narrow the range of possible origins.

The isotopic composition of a coffee can be compared against the data presented in Figure 1 to determine if the combinations of both $\delta^{13}C/\delta^{15}N$ and $\delta^{2}H/\delta^{18}O$ are consistent with a single geographical origin in Africa, Australia, India, Indonesia, or Papua New Guinea. The elemental composition of a sample can then act as a further point of comparison, and an analyst may have reasonable confidence in reporting such a result. The use of kernel density estimation (kde) has been applied to stable isotope data to calculate a quantitative weight of evidence that a sample belongs to one group rather than another.[38] This approach may be extended to food forensic applications but is beyond the scope of the current work. The wide spread and overlap of isotopic data for Central and South American coffees may preclude such comparisons but, as noted above, the presentation of isotopic data in the form of a geo-spatial map or isoscape (Figure 2) provides a means by which to consider whether the isotopic composition of a sample is consistent with the proposed region of origin. Increasing the value of such comparisons will require large data sets and/or models linking our data to existing databases such as global precipitation.[36]

■ ACKNOWLEDGMENTS

We are grateful to the editorial staff for their patience and to the reviewers for identifying a number of flaws in the original drafts of the manuscript. We acknowledge the support of Queensland Health Forensic and Scientific Services in completing this work. We are also grateful to and apologize to the specialty coffee roasters of Brisbane who enthusiastically sold us their finest single-origin coffee without realizing that it would never be drunk. We extend special thanks to Prof. Brian Fry of Griffith University for many mutually valuable discussions on the appropriate use of discriminant analysis.

epoxide groups, where a variety of internal standards were used.[13,14] In one of these studies,[13] the nondeuterated chloroform present in the deuterated chloroform was used as an internal reference for quantitative purposes. Generally, the main benefit of using the residual solvent signal as an internal standard is that it allows the sample to be recovered because the solvents are volatile and therefore easy to remove. However, the residual solvent content was found to vary from batch to batch, and its use for quantitative purposes requires external calibrants to determine its content in the deuterated solvent.[15] Therefore, frequent calibrations are required when using the deuterated solvent as an internal standard. Moreover, because chloroform is easily evaporated, when it is used as an internal standard for quantification, special care must be taken in handling the samples and the solvents. In the other study,[14] signals from methyl groups were used as the internal standard for quantification, but the applicability of this method to oxidized oils needs to be verified, because alkanes can be formed when oils undergo lipid oxidation,[16] especially at high temperatures. Glycerol protons were found to be constant during oxidation in the absence of water;[17] therefore, they can be used as alternative internal standards for ^{1}H NMR quantification, which will allow rapid sample preparation and easy handling.

In this study, a quantitative NMR method of measuring epoxides was developed and validated using soybean oil. This method represents significant improvement over other methods[12−14] in that partially epoxidized oils are synthesized and used for quantification, instead of using epoxy fatty acid standards, so that signals are generated to mimic those that would be encountered in oxidized oils. Specifically, synthetic epoxidized soybean oils were made to establish a calibration curve, and used to validate the proposed method. The one-step sample preparation allowed rapid determination of epoxides at low levels without any addition of external references. As the objective of this study was to develop a method to monitor epoxides during lipid oxidation, the application of the proposed method to thermally oxidized soybean oils was also verified by conducting an accelerated study of oxidative stability.

MATERIALS AND METHODS

Materials. Commercial soybean oil was obtained from Clic International Inc. (Montreal, Canada). Hydrogen bromide−acetic acid solution (33 wt % in acetic acid) and deuterated chloroform were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Hydrogen peroxide (50%) was from Fisher Scientific (Ottawa, Canada). All chemicals were of analytical grade.

GC Analysis of Fresh Soybean Oil. The fatty acid profile of soybean oil was analyzed using gas chromatography with flame ionization detection (GC-FID). A modified version of the Global Organization for EPA and DHA Voluntary Monograph for Omega-3 was followed to convert triacylglycerols to fatty acid methyl esters (FAME).[18] FAME were separated on a DB-23 column ((50%-cyanopropyl)methylpolysiloxane, 30 m, 0.25 mm i.d., 0.25 μm thickness) using helium as the carrier gas. The GC conditions were as follows: the initial temperature of the oven was held at 153 °C for 2 min and increased to 205 °C at 2.3 °C/min and held for 8.3 min; the FID was set to 270 °C, whereas the injector was operated in split mode (100:1) at 250 °C.[19] The fatty acid profile was reported as percent of total mass.

Epoxidation. The fatty acid profile of the commercial soybean oil was obtained by GC-FID and the concentration of double bonds was therefore calculated using fatty acid proportional data. To prepare epoxidized soybean oil for characterization of epoxides, a molar ratio of 1:0.5:1.5 double bonds/formic acid/hydrogen peroxide was used for epoxidation. The mixture of formic acid, hydrogen peroxide, and soybean oil was heated at 38 °C for 6 h.[20,21]

To establish a calibration curve, epoxidized soybean oils with a range of different concentrations of epoxides were prepared by reducing the amount of the reagents (formic acid and hydrogen peroxide) used for epoxidation while maintaining the molar ratios of formic acid and hydrogen peroxide at 0.5:1.5 (1:3). As the amount of epoxides generated from lipid oxidation is usually small, much lower amounts (<10% of the original amount) of epoxidation reagents were used. For converting <2% double bonds in soybean oils to epoxy groups, 2 h instead of 6 h was used with heating at 38 °C. Ethyl acetate was used to recover the epoxidized oil, following the procedures in a previous study,[22] and was then dried with anhydrous sodium sulfate. The solvent in the oil layer was evaporated under nitrogen, and the remaining oil was collected as the epoxidized soybean oil.

^{1}H NMR Analysis. The ^{1}H NMR spectra were recorded on a Bruker Avance 500 MHz spectrometer. All of the oil samples were prepared for ^{1}H NMR analysis by dissolving 0.1 g of sample in 2.0 mL of deuterated chloroform and placing 750 μL of the solution in a NMR tube (5 mm diameter, 8 in. in length, Wilmad-LabGlass, Vineland, NJ, USA). The acquisition parameters were modified from a previous study:[23] spectral width, 10080 Hz; relaxation delay, 3 s; number of scans, 64; acquisition time, 3.25 s; with a total acquisition time of 6.9 min for each sample. The signal of nondeuterated chloroform present in the deuterated chloroform was used as a reference for chemical shifts, and the signals associated with the *sn*-1,3 glycerol protons (4.18, 4.33 ppm) on the glycerol backbone were taken as an internal standard for quantification. All of the integrations for quantitative NMR were conducted using Topspin 2.1.

Epoxide Content Determined by the HBr Method. The concentration of epoxides in synthetic epoxidized soybean oil was determined by a modified AOCS Method Cd 9-57 using hydrogen bromide (HBr).[2] To accurately determine the low epoxide concentrations, diluted HBr−acetic acid solution and increased sample size were used. As HBr is sensitive to air and light, the HBr−acetic acid solution was standardized each time before use. Crystal violet solution (0.001 g/mL in acetic acid) was used as the indicator, and the samples were titrated to a blue-green end point. This determination was performed in triplicate for each sample.

To facilitate comparison with PV, the concentration of epoxides was reported as millimoles of epoxy groups per kilogram of oil (mmol/kg)

$$\text{epoxide content (mmol/kg)} = (V \times N \times 1000)/M$$

where V is the volume of HBr to titrate the sample in mL, N is the normality of the HBr solution in mol/L, and M is the mass of sample in g.

Characterization of Epoxides by ^{1}H NMR. The fresh and the epoxidized soybean oils were analyzed by ^{1}H NMR for characterization of epoxides. The signals were assigned by taking into account the descriptions of the chemical shifts from the previous work.[13]

Quantification of Epoxides by ^{1}H NMR. A standard curve is usually established by analyzing a series of standard solutions and plotting the signal responses versus the concentrations. However, when using NMR, this may contribute to large deviations from a linear relationship over a variety of concentration, as observed in previous work.[24] Therefore, rather than establishing a standard curve by making serial dilutions of a stock solution, a calibration curve method was used to keep the NMR samples at the same total lipid concentration of ∼50 mM but with various epoxide contents.

A set of 20 synthetic epoxidized soybean oil samples were analyzed by ^{1}H NMR. The signals of the *sn*-1 and *sn*-3 glycerol protons (4.18, 4.33 ppm) were taken as an internal standard for quantification because they were well separated from other signals and remained constant during both epoxidation and oxidation. The area of the signal of epoxides was obtained by calibrating the area of the internal standard as 4.0000. The integrations were performed in triplicate. A calibration curve was established by plotting the epoxide area versus the epoxide concentration determined by using the modified AOCS Method Cd 9-57 described.[2]

Table 1. Test of Accuracy and Precision of the Proposed Method, Evaluated by the *p* Values of the Two-Sample *t* Test and the Acceptable Horwitz %RSDs, Respectively

	epoxide content (HBr method)		epoxide content (^{1}H NMR)			
sample	mean ± SD (mmol/kg)	%RSD	mean ± SD (mmol/kg)	%RSD	two-sample *t* test *p* value	acceptable Horwitz %RSD
1	666.1 ± 4.7	0.71	660.7 ± 8.8	1.33	>0.10	2.65
2	325.9 ± 5.4	1.66	320.8 ± 5.8	1.81	>0.10	2.96
3	54.6 ± 0.8	1.49	55.6 ± 1.4	2.61	>0.10	3.87
4	11.7 ± 0.3	2.26	12.2 ± 0.5	3.73	>0.05	4.88

The validation of this quantitative NMR technique included the testing of linearity, parameters of accuracy, and repeatability.[25] Thus, the validation process was conducted following the guidelines previously addressed by the International Union of Pure and Applied Chemistry (IUPAC).[26] The statistical tests were conducted by Minitab 17. For the test of linearity, the regression and the residuals of the calibration curve were analyzed. For the estimation of accuracy and precision, four epoxidized samples were analyzed by ^{1}H NMR in five replicates. The average epoxide content of each sample was compared to the value determined according to AOCS Method Cd 9-57 for the test of trueness or bias, using a two-sample *t* test (Table 1). The precision was described by the relative standard deviation (%RSD) of the quintuplet results (Table 1) and characterized by the Horwitz equation.[27] According to the Horwitz equation, an acceptable Horwitz %RSD was calculated as

$$\%\mathrm{RSD} = \frac{2}{3} \times 2^{(1-0.5 \log C)}$$

where *C* was the mass concentration of epoxides in decimal fraction. % RSD falling below this level indicated sufficient precision.[27]

To assess precision using the Horwitz equation,[27] the epoxide content was calculated as mass fraction of the oxirane oxygen in the oil[2]

$$\text{epoxide content} = (V \times N \times 0.016)/M$$

where *V* is the volume of HBr to titrate the sample in mL, *N* is the normality of the HBr solution in mol/L, and *M* is the mass of sample in g.

The precision of the method was also evaluated using thermally oxidized soybean oils. Five soybean oil samples were incubated in open test tubes at 100 °C for 4, 8, 12, 16, and 20 days. Each sample was tested for its PV (AOCS Method Cd 8-53)[2] and epoxide content (the proposed method). The tests were conducted for each sample in triplicate (Table 2). The precision was described by the %RSD of the triplicate results.

Table 2. Peroxide Value and Epoxide Content Measured for Soybean Oil Heated at 100 °C for the Test of Repeatability, Expressed by %RSD

	peroxide value		epoxide content	
sample	mean ± SD (mmol/kg)	%RSD	mean ± SD (mmol/kg)	%RSD
1	47.2 ± 0.3	0.61	8.4 ± 0.4	4.15
2	48.3 ± 1.4	2.80	17.2 ± 0.6	3.58
3	89.1 ± 0.7	0.79	29.2 ± 1.1	3.85
4	87.6 ± 0.6	0.64	55.7 ± 1.5	2.69
5	60.0 ± 0.6	1.02	90.7 ± 2.0	2.20

Stability Studies of Soybean Oil. A stability study of soybean oil was conducted to monitor the changes in PV and epoxide content over the course of oxidation. Three open amber containers (125 mL) were used for incubations at 100 °C with each initially containing 30 g of soybean oil. Every 2 days, 2.5 g of oil was sampled from each container for analysis of its PV (AOCS Method Cd 8-53)[2] and epoxides (the proposed method). The tests of each oil sample were performed in triplicate. PV and epoxide content were plotted over time for comparison.

RESULTS AND DISCUSSION

Characterization of Epoxides Derived from Soybean Oil. The initial soybean oil contained 10.2 ± 0.1% palmitic acid (16:0), 21.9 ± 0.3% oleic acid (18:1n-9), 52.5 ± 0.8% linoleic acid (18:2n-6), and 7.7 ± 0.2% linolenic acid (18:3n-3). Therefore, the total unsaturation was estimated to be 5.46 mol of double bonds per kilogram of oil. The signals of epoxides derived from soybean oil were between 2.90 and 3.24 ppm; as the size of those signals increased, the size of the signals due to double bonds (~5.40 ppm) decreased correspondingly (Figure 1; Supplementary Table 1 in the Supporting Information). Thus, the epoxidation method used here was successful in epoxidizing the commercial soybean oil, generating obvious signals of epoxides in the ^{1}H NMR spectra.

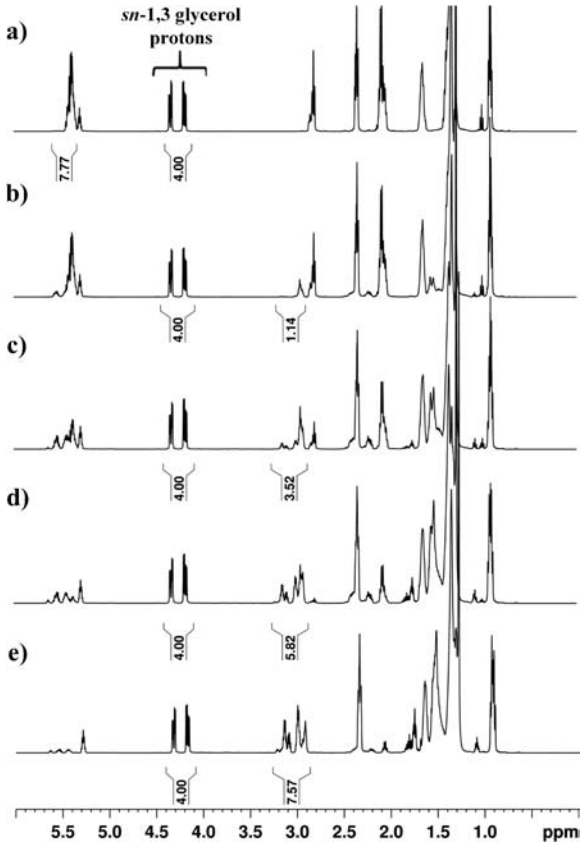

Figure 1. ^{1}H NMR spectrum of (a) fresh soybean oil and epoxidized soybean oils with epoxide contents of (b) 0.70 mol/kg, (c) 2.06 mol/kg, (d) 3.41 mol/kg, and (e) 4.16 mol/kg. The integrations of the double bonds (5.40−5.60 ppm in (a)) and the epoxides (2.90−3.24 ppm in (b−e)) were made by taking the signals of *sn*-1 and *sn*-3 glycerol protons (4.18 and 4.33 ppm) as internal standards. The area of the internal standard was calibrated as 4.00 as the number of *sn*-1 and *sn*-3 glycerol protons is 4.

J. Agric. Food Chem. 2015, 63, 5780−5786

On the basis of previous publications[13,14] and our observation of the ^{1}H NMR spectra in Figure 1, we made the assignments as follows, where −CHOCH− represents an epoxy group: δ 1.45−1.60 (−C**H**$_2$—CHOCH−), 1.70−1.85 (−CHOCH—C**H**$_2$—CHOCH−), 2.00−2.10 (−C**H**$_2$—CH═CH−), 2.80−2.85 (−CH═CH—C**H**$_2$—CH═CH−), 2.90−2.95 (−C**H**OC**H**−), 2.90−2.95 (−C**H**OC**H**−CH$_2$−CH═CH−), 3.00 (−C**H**OCH−CH$_2$−CHOC**H**−), 3.06−3.24 (−CHOC**H**−CH$_2$−C**H**OCH−), 5.35−5.45 (−C**H**═C**H**−), 5.40−5.60 (−C**H**═C**H**—CH$_2$—CHOCH−), 5.60−5.65 (−CHOCH—CH$_2$—C**H**═C**H**—CH$_2$—CHOCH−) (Supplementary Table 1). The range of chemical shifts of epoxides increased with the concentration of epoxides in the oil (Figure 1). For oils with a low epoxide content (Figure 1b), the signals of epoxides appeared around 2.90−2.95 ppm, which was likely related to the formation of the partially epoxidized linoleic acid and linolenic acid (−C**H**OC**H**—CH$_2$—CH═CH−), and overlapped with the less intense signal of epoxy oleic acid at 2.90−2.95 ppm (−CH$_2$—C**H**OC**H**—CH$_2$−). For oil samples with higher epoxide content (Figure 1c), the signals associated with diepoxides appeared at ∼3.00 ppm (−C**H**OCH—CH$_2$—CHOC**H**−) and 3.09 and 3.16 ppm (−CHOC**H**—CH$_2$—C**H**OCH−), and their intensities increased with increasing concentration. The signal that indicated the presence of triepoxides appeared at 3.20 ppm, when ∼62% of the original double bonds had been converted into epoxy groups (Figure 1d). In Figure 1e, the epoxidized soybean oil gave five signals between 2.90 and 3.24 ppm, with small signals due to double bonds remaining between 5.40 and 5.60 ppm, which indicated that ∼76% of the double bonds were converted into epoxy groups.

Lipid oxidation is a relatively complex autoxidation process, so the structure of epoxy products may vary with the conditions of oxidation. Although the chromatography method employs common GC-FID instrumentation,[28] making it an accessible technique to many analysts, it does rely on the use of epoxy fatty acid methyl ester (FAME) standards for identification of the signals on the chromatograms. Any epoxide structures that vary from the standards may be overlooked during identification and cause underestimations of epoxide concentration. Moreover, the selectivity of quantitative NMR did not depend on the structure of epoxides, and therefore it gave an overview of all the epoxy groups formed in the oil. The chemical shifts of epoxides (2.90−3.24 ppm) were distinct from other oxidation products including alcohols (3.43−3.62 ppm), conjugated dienes (5.40−6.58 ppm), double bonds conjugated with carbonyls (6.08−6.82 ppm), hydroperoxides (8.30−8.90 ppm), and aldehydes (9.49−9.79 ppm).[29] In summary, ^{1}H NMR can be used to detect epoxides in oxidized soybean oils with superior selectivity, which is a major advantage over the chromatography method.

Quantification of Epoxides. Although fully epoxidized soybean oil gave signals between 2.90 and 3.24 ppm, oxidized oils, with relatively low epoxide content, gave signals between 2.90 and 3.10 ppm, mostly due to monoepoxides with or without adjacent double bonds (Supplementary Table 1). The epoxy protons were monitored for quantitative purposes because the size of the signals between 2.90 and 3.24 ppm was proportional to the amount of epoxy groups generated in the oil, regardless of the presence of saturated/unsaturated mono- and diepoxides. Although the signals at 1.45−1.60 ppm (−C**H**$_2$—CHOCH−) and 2.00−2.10 ppm (−C**H**$_2$—CH═CH−) were related to the generation of epoxides (Figure 1), the change in size of the signals was not proportional to the amount of epoxy groups; therefore, the epoxy protons were the best indicators of formation of epoxides.

When signal response versus concentration was plotted, a calibration curve was established for epoxides in soybean oil with a good linear relationship. The regression equation was $y = 0.0151 + 0.0016x$ with an R^2 of 99.96%, where y represented the signal response and x was the concentration of epoxides (Figure 2). To our knowledge, this is the first demonstration of

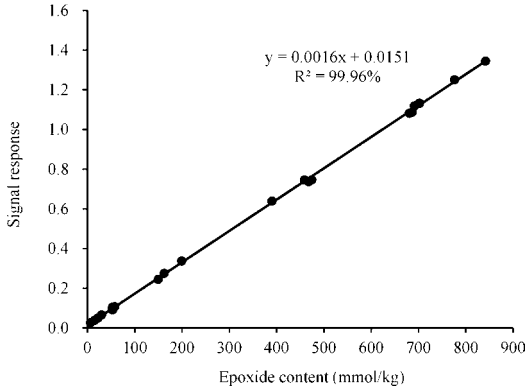

Figure 2. Fitted linear relationship by plotting signal response (y) versus the epoxide concentration (x) measured by the HBr method. Each point represents a single epoxidized soybean oil sample.

agreement between the ^{1}H NMR method and the HBr method for low epoxide concentrations. Residual analysis of all calibration points did not reveal any trends relating to the concentration of epoxides. The residuals passed the Anderson−Darling test and followed a normal distribution with a p value of 0.148. Thus, the linear relationship between the signal response and the epoxide content did not depend on the concentration of epoxides in the experimental range of concentrations (6.7−841.6 mmol/kg). A linear fit was found for the calibration curve ($F = 7.63$, $p < 0.001$). Therefore, the area ratio of the signals of epoxides/internal reference increased linearly with the epoxide content. Because epoxides were not found in the fresh soybean oil using the HBr method, the fresh soybean oil was considered a blank. The limit of quantification (LOQ) was therefore determined to be 6.3 mmol/kg by taking into account the standard deviation (σ) of the blank and the slope (s) of the calibration curve (LOQ = $10\sigma/s$).[30]

Accuracy testing was conducted on four epoxidized samples with different concentrations. As shown in Table 1, the proposed method gave results similar to those measured by AOCS Method Cd 9-57 (HBr method), with little bias and two-sample t tests showing no difference between the mean values determined by the HBr method and the proposed method for each sample (p value > 0.05). The precision of the proposed method (%RSD 1.33−3.73) was slightly poorer than that of the HBr method (%RSD 0.71−2.26), which was likely due to the errors introduced by manual integration of the ^{1}H NMR signals. The precision of both methods varied with concentration. Compared to the acceptable Horwitz %RSD values (2.65−4.88), the proposed method provided good precision (%RSD 1.33−3.73). Thus, quantitative NMR was shown to provide reliable results.

The objective of this work was to develop a quantitative method to determine epoxide content in oxidized oils for the study of lipid oxidation. Therefore, it was important to verify

DOI: 10.1021/acs.jafc.5b01719
J. Agric. Food Chem. 2015, 63, 5780−5786

the applicability of this method to thermally oxidized oils. The test of repeatability of the method was performed on five thermally oxidized soybean oil samples, which were heated at 100 °C for 4, 8, 12, 16, and 20 days (Table 2). There were contrasting patterns of PV and epoxide content with samples 1 and 2 (Table 2) having similar PVs (47.2 and 48.3 mmol/kg) but different epoxide contents (8.4 and 17.2 mmol/kg). Similarly, samples 3 and 4 (Table 2) had comparable PVs (89.1 and 87.6 mmol/kg) but very different epoxide contents (29.2 and 55.7 mmol/kg). The differing epoxide concentrations indicate that the two samples had undergone different oxidation processes, an observation that would be overlooked with just examination of PV. Thus, epoxide content provided a different evaluation of the extent of lipid oxidation compared to PV.

Compared to the HBr method,[2] the proposed method overcomes the problem of the interferences caused by other lipid oxidation products (α- or β-unsaturated carbonyls and conjugated dienes) when using the HBr method. Additionally, much less organic solvent is required for NMR analysis, because standardization of HBr solution is required before use of the reagent; the HBr method is also time-consuming. Compared to the previous methods of measuring epoxides, such as the NBP,[10] DTC,[11] and transmethylation[31] methods, the major advantage of quantitative NMR is its convenience. No derivatization is needed for analysis of epoxy compounds, and the preparation of an NMR sample is simple and rapid, making NMR a competitive approach to determine epoxides.

In this study, the *sn*-1,3 glycerol protons were taken as the internal standards instead of using the signals due to the residual chloroform[13] or the methyl protons.[14] As described earlier, methyl protons have limited applications as internal standards for oxidized oils, whereas the use of the residual solvent as standard may require external calibrants and special handling of the samples. Therefore, taking the signals related to the structure of triacylglycerol as internal standards can overcome these problems and still allow the sample to be recovered in its pure form, because no extra standard material is added. Unfortunately, information describing LOQ, accuracy, or precision was not provided in those previous studies,[13,14] so it is impossible to compare the performance of the proposed method with the previous methods in those aspects.

The method described here is an original approach; rather than spiking fully epoxidized soybean oil or epoxy fatty acid standards into samples, synthetic partially epoxidized oils (<10% double bonds were converted into epoxy groups) were used to establish a calibration curve. The synthetic epoxidized oils with low epoxide levels gave signals (2.90−3.10 ppm) similar to those derived from the oxidation process, making it possible to establish a calibration curve mimicking the real situation. The use of synthetic epoxidized oils as calibration standards has a number of advantages. First, commercial unsaturated epoxy fatty acid standards and diepoxide standards are only available as a limited number of structures. The proposed method utilizes commonly used reagents, hydrogen peroxide and formic acid, to synthesize partially epoxidized oils with remaining double bonds, which avoids the limitation of the commercially available standards. Second, the extent of epoxidation can be controlled by the amount of reagents used; therefore, the range of the concentrations encompassed by the calibration curve is adjustable. When epoxides are expected at a relatively low level, epoxy groups are likely surrounded by double bonds, and only a small amount of reagents is needed. When epoxides are expected at a high level, diepoxides can be synthesized by increasing the amount of epoxidation reagents. Third, the current epoxidation method can be easily applied to other kinds of oils,[20,22] so this method will have a wide range of applications.

Stability Study of Soybean Oil. To further study the formation of epoxides during lipid oxidation, a stability study of soybean oil was performed at 100 °C for 12 days. The curves representing PV and epoxide content showed different patterns over time, although deviations were observed between the three samples determined at each test point (RSD between 1.62 and 10.63% for PV and between 0.61 and 8.69% for epoxide content; Figure 3). PV increased quickly in the first 8 days and

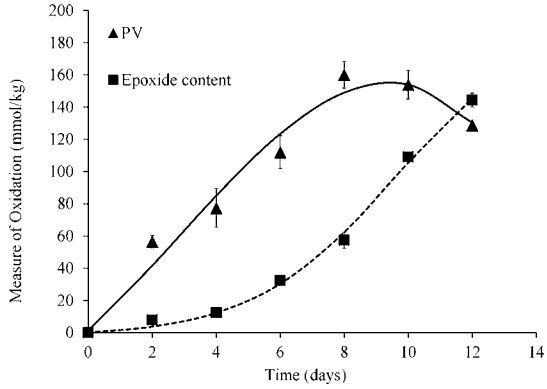

Figure 3. Peroxide value (PV) and epoxide content (mean ± standard deviation, n = 3 for each point) in the stability study of soybean oil performed at 100 °C with model 2 shown for PV and with model 3 for the epoxide content. See Table 3 for model parameters.

then reached a peak, followed by a slow decline. However, no significant increase was found for the epoxide content in the first 4 days. Epoxide content increased drastically after the lag time (days 0−4) and was not observed to decrease in the experimental period. Compared to the stability study of sunflower oil at 100 °C in the previous study,[13] lower amounts of epoxides were found in the soybean oil in this work. The two oils would have had different fatty acid compositions, which are well-known to influence the rate of formation and structure of lipid oxidation products. The surface area of oil during oxidation was also much greater in the previous work,[13] likely leading to a faster oxidation process.[32]

The PV and epoxide content were fitted by three selected models using the least-squares method (Table 3), including a second-order polynomial function, a third-order polynomial function, and a phenomenological model,[9] all in the variable t, which represented the days of thermal oxidation. The polynomial functions were selected because PV showed a significant decrease after the peak value. The phenomenological model was previously introduced for modeling PV because hydroperoxides are known as intermediates, forming and decomposing at the same time. The parameters of the phenomenological model, $a(T)$, $k_f(T)$, and $t_{cf}(T)$, were temperature dependent, related to the formation and decomposition of hydroperoxides as intermediate products of lipid oxidation.[9] In this work, this model was extensively fitted to the epoxide data because epoxides have also been considered as important intermediates.[7] The mean square error (MSE) of each regression was used as a measure of the goodness of fit (Table 3). Specifically, PV was fitted by the second-order model $y(t) = -1.44t^2 + 28.83t + 1.32$ with an MSE of 163.94,

DOI: 10.1021/acs.jafc.5b01719
J. Agric. Food Chem. 2015, 63, 5780−5786

Table 3. Fit of the Selected Mdels to PV and Epoxide Content Observed in the Stability Study of the Soybean Oil

model 1:	$y(t) = at^2 + bt + c$			
	a	b	c^a	MSE
PV	−1.44	28.83	1.32	163.94
epoxide content	1.10	−0.93	0.00	23.86
model 2:	$y(t) = at^3 + bt^2 + ct + d$			
	a	b	c	d^a	MSE
PV	−0.16	1.35	18.12	1.32	88.26
epoxide content	0.00[b]	1.08	−0.84	0.00	23.86
model 3:[c]	$y(t) = y_0 + [a(T) - y_0] \times \left\{\frac{1}{1+\exp\{k_f(T)[t_{cf}(T)-t]\}} - \frac{1}{1+\exp[k_f(T)t_{cf}(T)]}\right\}$			
	$a(T)$	$k_f(T)$	$t_{cf}(T)$	MSE
PV	204.15	0.47	2.17	220.47
epoxide content	199.37	0.45	9.62	10.31

[a]This constant was determined by the PV or epoxide content measured on the initial day (day 0). [b]The value was 0.0014 in four

whereas the epoxide content was fitted by $y = 1.10t^2 - 0.93t$ with an MSE of 23.86. Increased order of polynomial function contributed to the lowest MSE for PV (MSE of 88.26 for the third-order model) but resulted in the same MSE for epoxide content (MSE of 23.86 for the third-order model) so a third-order model was not necessary for epoxides. In addition, PV and epoxide content were fitted by the phenomenological model (model 3 in Table 3), where the fit of PV gave a large MSE (MSE of 220.47), but the best fit was observed for the epoxide content (MSE of 10.31). Therefore, model 2, employing a third-order polynomial, was suggested for PV, whereas model 3, the phenomenological model, was best for epoxides (Figure 3). Further studies can be conducted to allow the model to be adapted to the formation of epoxides at different temperatures.

Although the physical meanings of these models are not discussed here, it is obvious that the curves of epoxide concentrations and PV show very different trends, indicating that the rearrangement of radicals is an important reaction during lipid oxidation and should be taken into consideration when monitoring the oxidation process. Epoxides are important lipid oxidation products, produced in large concentrations under the condition of this study, and their formation has a lag time in the initial period of lipid oxidation. As an additional indicator of oxidation, epoxide content provided more information about the extent of the process, which may enable a more comprehensive understanding of the mechanisms of lipid oxidation. With appropriate validation, this ^{1}H NMR technique should be easily applied to other oils.

oxide could be detected in areca nut extract (ANE)-treated oral cells. We therefore chemically synthesized arecoline *N*-oxide and investigated its effects on normal human cells and immunodeficient NOD/SCID mice. Our study unearthed clues about how areca nut induces OMPD. This study also increases our understanding of the mechanism by which betel chewing may lead to tumorigenesis.

MATERIALS AND METHODS

Cell Culture and Treatment. Normal human gingival fibroblast cells (HGF-1, CRL-2014) were obtained from American Type Culture Collection (ATCC, Manassas, VA, USA)/Bioresource Collection and Research Center (BCRC, Taipei, Taiwan). Cells were grown and maintained in Dulbecco's modified Eagle's medium (DMEM), supplemented with 10% fetal bovine serum, at 37 °C in a 5% CO_2 incubator. Normal human oral keratinocyte HOK cells purchased from ScienCell Research Laboratories (Carlsbad, CA, USA) were cultured in the oral keratinocyte growth medium (ScienCell Research Laboratories). For identifying the protein adducts of the areca nut in HOK cells, equal amounts of cells were treated with 200 μg/mL ANE or saliva-contained ANE for 24 h. For determination of DNA damage or fibrotic related genes, equal amounts of HGF-1 cells were seeded and grown until confluent for chemical treatment, avoiding strong cytotoxicity via arecoline or arecoline *N*-oxide. Cells were then treated with arecoline or arecoline *N*-oxide for 7 days. The culture medium was refreshed every 2 days during the experiment.

Chemicals. ANE or saliva-contained ANE were prepared as previously described.[11] Arecoline hydrobromide was purchased from Sigma-Aldrich (St. Louis, MO, USA). Arecoline *N*-oxide was synthesized as previously described.[10a] In brief, a solution of arecoline in ether was treated with aqueous 3 M peroxyacetic acid (1.95 g in 13 mL of H_2O) dropwise during 30 min at 0 °C. After 2 h, the oily lower layer was separated and then precipitated three times by the addition of ether, which concentrated under reduced pressure to afford arecoline *N*-oxide as a pale yellow viscous oil. The synthesized chemical has been confirmed by high-resolution mass spectrometry and NMR analysis. The used arecoline *N*-oxide was dissolved in 0.1% DMSO/deionized water.

Identification of Protein Adducts in HOK Cells. Protein adducts from ANE-exposed cells were identified using the LC-MS/MS system (LTQ Orbitrap Discovery hybrid Fourier transform mass spectrometer; Thermo Fisher Scientific Inc., Germany) as previously described.[12] The raw data files from each treated cell were processed with Proteome Discoverer 1.1 software (Thermo Scientific) to gain the file of peak lists. Protein identification was analyzed by an in-house Mascot server.

Cytotoxicity Detection. To measure the cytotoxicity, 10^4 HGF-1 cells were seeded into 96-well culture plates and cultured for 24 h for arecoline or arecoline *N*-oxide treatment. The released lactate dehydrogenase (LDH) in the culture medium was assessed using a LDH assay (CytoTox-ONE Homogeneous Membrane Integrity Assay, Promega, Madison, WI, USA).

Animals and Experimental Protocol. In this study, the experimental animals used were 10-week-old NOD.CB17-*Prkdc*^{scid}/NcrCrl (NOD SCID Mouse) animals purchased from LASCO Charles River Technology (Taiwan) and then maintained in a specific pathogen-free environment. In the present study, animal procedures conformed to the guidelines published by the National Institutes of Health (NIH Publication No. 85-23) and were approved by the Institutional Animal Care and Use Committee (IACUC) of China Medical University (CMU). The mice (each weighing approximately 28 g) were randomly divided into two groups. Group 1 (the control group, $n = 8$) was treated with 0.1% DMSO/deionized water by cotton swab smearing the oral cavity once daily, 5 days per week. Group 2 ($n = 12$) was treated with 500 μg/mL arecoline *N*-oxide dissolved in 0.1% DMSO/deionized water in the same manner. During treatment, a standard laboratory diet and water were offered to all mice.

Real-Time Quantitative PCR (RT-qPCR). Total RNA was isolated from treated cells using TRIzol reagent (Invitrogen Corp., Carlsbad, CA, USA) according to the manufacturer's protocol. The cDNA templates were produced by reverse transcription of the total RNA with random primer and a high-capacity cDNA reverse transcription kit (Applied Biosystems, Foster City, CA, USA). The products were then subjected to RT-qPCR analysis with the specific primer pairs using the ABI StepOnePlus Real-Time PCR Systems (Applied Biosystems) with Power SYBR Green PCR Master Mix (Invitrogen Corp.). The primer sequences are listed in Table S1.

Western Blotting. To detect H2A.X phosphorylation, the cells were lysed in lysis buffer A (50 mM Tris-HCl, pH 7.4, 100 mM NaCl, 1 mM EDTA, 10 mM magnesium acetate, and 1% NP-40) containing a cocktail of protease inhibitors (Roche, Germany) on ice for 10 min. The extracts were centrifuged at 15600*g* for 5 min at 4 °C to sediment the insoluble fraction. The pellet was resuspended in lysis buffer A and mixed with an equal volume of 4× Laemmli's sample buffer. Sample loading of the insoluble fraction was normalized by protein concentration of the soluble fraction. Protein samples from both the soluble (for GAPDH) and insoluble (for H2A.X phosphorylation) fractions were separated by SDS−polyacrylamide gel and electro-transferred to polyvinylidene fluoride membranes (Millipore, Bedford, MA, USA). The membranes were incubated with primary antibodies as indicated and peroxidase-conjugated secondary antibodies, and protein signals were detected by enhanced chemiluminescence reagent (Millipore). For detection of collagen 1, cell lysates were prepared in lysis buffer B (50 mM Tris-HCl, pH 7.4, 100 mM NaCl, 1 mM EDTA, 10 mM magnesium acetate, 1% Triton X-100, and protease inhibitors cocktail). Monomeric collagen 1 was detected using a denaturing polyacrylamide gel electrophoresis (PAGE). To ensure equal loading, Western blotting was performed by using a denatured PAGE with double layers (6 and 9%) for separation. For detection of polymeric collagen, total protein (120 μg) was separated by nonreducing PAGE. The primary antibodies used were antiphospho-histone H2A.X (Ser139; Cell Signaling Technology), anticollagen 1 (St. John's Laboratories, United Kingdom), and anti-GAPDH (GeneTex Inc., Taiwan).

Immunohistochemistry Analysis. Tongue tissue samples from all 20 treated mice of 21 weeks were fixed with 4% paraformaldehyde for 3 days, embedded in paraffin. The 3−5 μm sections were stained with hematoxylin and eosin (H&E), specific antibodies, and Masson's trichrome for histological evaluation and scoring. Immunohistochemical detection of mouse H2A.X phosphorylation (gamma-H2A.X) was performed using the antiphospho-histone H2A.X (Ser139; Cell Signaling Technology) antibody. The protein signal was detected using the appropriate primary antibody amplifier, horseradish peroxidase (HRP)-conjugated polymer, and DAB chromogen/substrate. The positive signals of gamma-H2A.X were counted in a high-power field (200× magnification) in five mice from each group. The results were averaged, the numbers from 60 cells per fS randomly selected sublingual positions each mouse. A trichrome stain for assessment of fibrosis was performed by using a Trichrome Modified Masson's Stain Kit (Scytek Laboratories, Logan, UT, USA) according to the manufacturer's instructions. Tongue fibrosis sections were counted and scored under 50× magnification of five separated fields of three mice per group. The quantification was used by the Fovea Pro 3.0 and OptiPix 2.0 free Wide Histogram Photoshop plug-in software. In this study, results of all immunohistochemical were interpreted by two pathologists.

RESULTS

Detection of Arecoline *N*-Oxide Protein Adduct in Cultured Oral Keratinocytes. Diseases caused by chemical exposure have been demonstrated through the metabolism of chemically bound products, such as DNA or protein adducts.[9a] To confirm the possibility of arecoline *N*-oxide presence in oral cells exposed to areca nuts, normal HOK cells were stimulated with ANE or saliva-contained ANE, and protein samples from the cell lysate were assayed to identify protein adducts (Table 1). The protein adduct of arecoline *N*-oxide-bound annexin A1

[a]Chemically bound amino acids are shown in bold and underlined. [b]Both arecaidine *N*-oxide bound leucine 215 and cysteine 216 of beta-actin were identified.

was identified in the saliva-contained ANE-treated HOK cells. Products of arecaidine and arecaidine *N*-oxide bound proteins were also detected. These results indicated the presence of arecoline *N*-oxide in oral cells exposed to areca nuts.

Arecoline *N*-Oxide Increased Oral Collagen Deposition in Mice. Protein or DNA targets of arecoline *N*-oxide remain uncharacterized. Because the effects of arecoline *N*-oxide might result from multiple DNA or protein adducts in vivo, we investigated its effects by treating it directly. Commercial arecoline *N*-oxide is rarely obtained. Hence, we produced arecoline *N*-oxide chemically. We tested whether arecoline *N*-oxide can cause oral pathological changes in NOD/SCID mice. The immunodeficiency NOD/SCID mice were used as a model to avoid antitumor immune response.

The average body weight of the mice, in both arecoline *N*-oxide and control groups, slightly increased during the 21 weeks of treatment. The average increases in body weight in the control and arecoline *N*-oxide-treated mice were 1.08 and 1.1%, respectively. No tumor formation was observed in the exterior alimentary canal. An increase in collagen synthesis is a main cause of OSF.[13] To assess whether arecoline *N*-oxide enhanced collagen expression, tongue specimens were examined, and collagen deposition was found to be significantly higher in arecoline *N*-oxide-treated mice than in control mice with obvious observation in sublingual tongue (Figure 1A,B and Figure S1). Quantitative analysis of staining intensity and percentage indicated that arecoline *N*-oxide-treated mice showed a 1.97-fold increase in collagen deposition on the tongue. These results suggest that oral fibrotic potential is shown in arecoline *N*-oxide-treated mice.

Pathologic changes in all mouse tongues were observed by H&E staining (Figure 1C,D). The arecoline *N*-oxide-treated group showed significant pathologic hyperplastic lesions in the epithelium of the sublingual tongue (Figure 1D). In contrast, control groups showed mild pathologic change of hyperplasia (Figure 1C), which might be due to long-term exposure to a low concentration of DMSO. No pathologic changes were observed in the upper surface of the tongue in both groups. These results indicate that arecoline *N*-oxide increased the severity of squamous hyperplasia in the sublingual tongue.

Arecoline *N*-Oxide Increased Expression of Collagen 1. Our mouse experiment indicated that arecoline *N*-oxide induced oral collagen deposition, which implies that arecoline *N*-oxide has fibrotic potential.[7a] Next, we tested the fibrotic related effects of arecoline *N*-oxide in cultured HGF-1 cells. During betel chewing, the concentration of arecoline in saliva can reach as much as 97.39 μg/mL (about 600 μM).[14] First, we compared the cytotoxicity between arecoline and arecoline *N*-oxide by determining the LDH release in cells treated with various concentrations of arecoline or arecoline *N*-oxide. Indeed, cytotoxicity was induced in both treatment groups (Figure 2A). Arecoline *N*-oxide induced higher LDH release than arecoline, with a significant effect observed at a concentration of 400 μM (1.44-fold, $p < 0.05$, vs arecoline). Taken together, these results indicate that arecoline *N*-oxide induced stronger cytotoxicity than arecoline.

To ascertain if arecoline *N*-oxide stimulation increases collagen 1 production, confluent HGF-1 cells were treated with arecoline *N*-oxide for 7 days and then analyzed for levels of collagen 1 mRNA (Figure 2B) and protein (Figure 2C,D). Arecoline *N*-oxide significantly increased the expression of collagen 1 mRNA and protein, and significant induction was observed at both 200 and 400 μM concentrations, respectively. These results indicate that arecoline *N*-oxide increased collagen 1 production in HGF-1 cells, which corresponded to the observations of our mouse study.

Arecoline *N*-Oxide Increases the Expression of Oral Fibrotic Related Genes. TGF-beta 1 is a well-known fibrotic signaling molecule that is increased in OSF tissues.[15] The effects of arecoline *N*-oxide on *TGF-beta1* induction in HGF-1 cells were estimated by RT-qPCR. Both arecoline and arecoline *N*-oxide significantly increased the mRNA of *TGF-beta1* (Figure 3 **A**). The effect of arecoline *N*-oxide was significantly higher than that of arecoline (at both 200 and 400 μM, $p < 0.05$). A series of oral precancerous related gene transcripts were also examined. These genes included *S100A4*,[16] *matrix metalloproteinase-9* (*MMP-9*),[17] *interleukin-6* (*IL-6*),[18] *fibronectin*,[19] *E-cadherin*,[20] and *alpha-smooth muscle actin* (*alpha-SMA*)[21] (Figure 3B−F and Figure S3). Arecoline *N*-oxide significantly stimulated increased expression of *S100A4, MMP-9, IL-6, fibronectin*, and *alpha-SMA*. It also reduced the level of *E-cadherin* mRNA. These results correlate with previous observations of genetic regulation in OSF. Arecoline *N*-oxide showed higher activity than arecoline in its effects on the expression of these genes expect *alpha-SMA* (at 400 μM, $p < 0.05$, vs arecoline). Thus, arecoline *N*-oxide may be a causative agent of OSF.

Arecoline *N*-Oxide Increased H2A.X Phosphorylation. DNA damage is triggered early in tumorigenesis. To compare the effect on DNA damage, phosphorylation of histone H2A.X at serine (Ser) 139 (also called gamma-H2A.X), a marker of DNA double-strand breaks,[22] was determined in confluent cells after 7 days of treatment. Whereas a slight effect of arecoline was observed, arecoline *N*-oxide significantly induced gamma-H2A.X (Figure 4A,B). At arecoline *N*-oxide concentrations of 200 and 400 μM, levels of gamma-H2A.X increased 4.32- and 5.13-fold, respectively, as compared with the control. Arecoline *N*-oxide showed higher activity than arecoline at an equal concentration (at both 200 and 400 μM, $p < 0.05$). Similar results were shown when we measured 8-OHdG, another

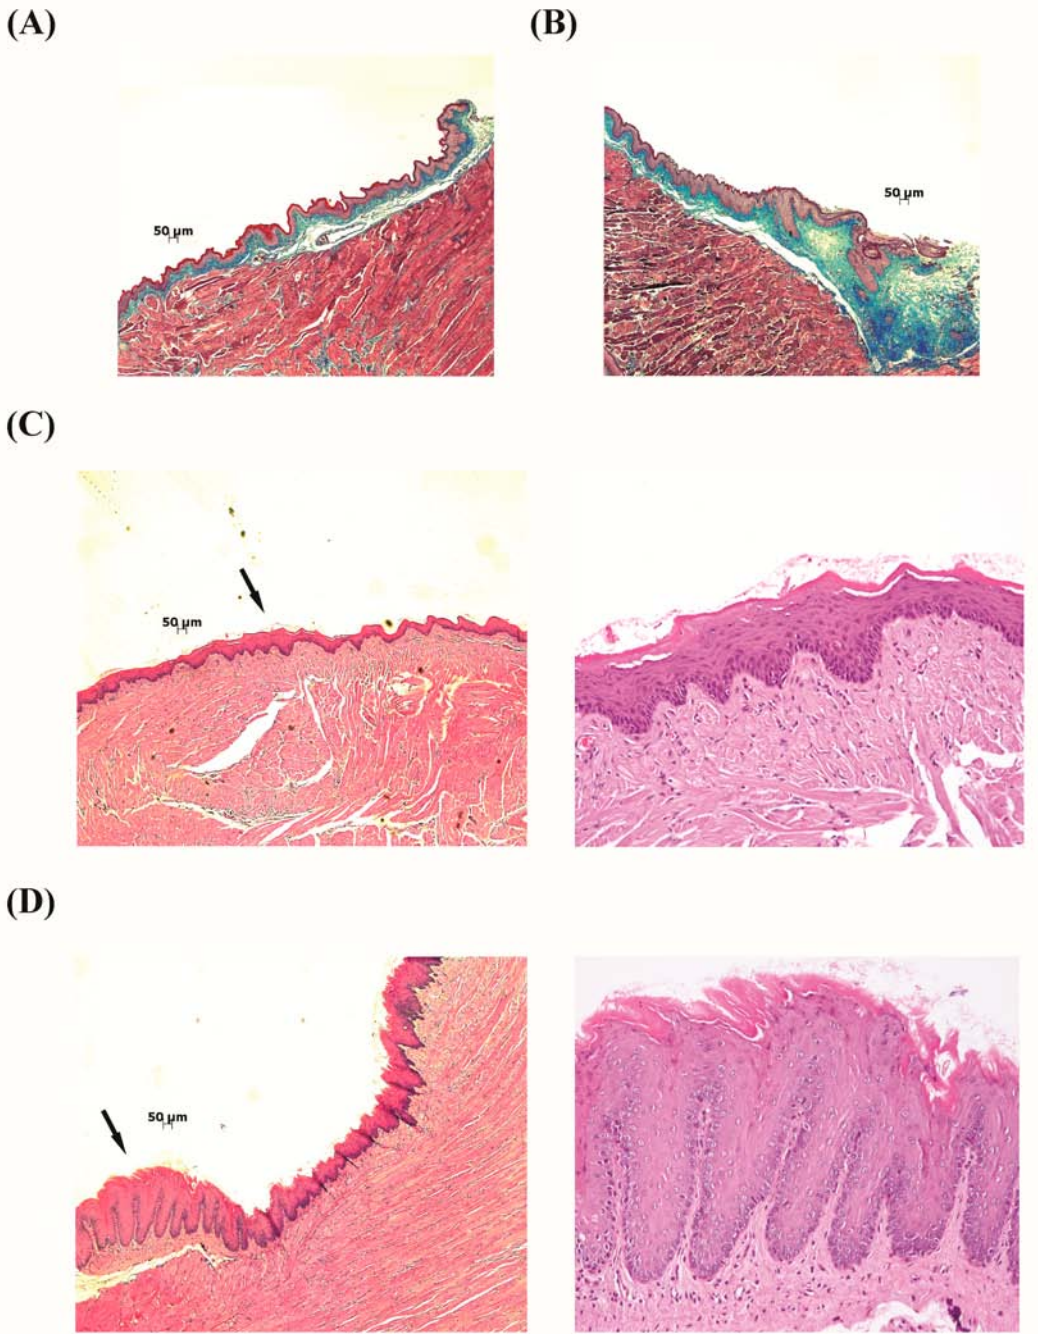

Figure 1. Arecoline *N*-oxide increased collagen deposition and severity of squamous hyperplasia in mouse tongue. Mice were consecutively treated with arecoline *N*-oxide (500 μg/mL) for 21 weeks. Tongues were stained with Masson's trichrome staining in control (A) and arecoline *N*-oxide groups (B). Sublingual tongues are shown (magnification, 50×; scale bar, 50 μm). Pathological changes of sublingual tongue samples from the control (C) and arecoline *N*-oxide groups (D) were visualized by H&E staining. Indicated areas in left panels (black arrowheads, magnification, 50×) were observed under higher magnification (200×). Scale bar, 50 μm.

marker for oxidative stress and DNA damage (Figure S2). Our data indicated that arecoline *N*-oxide induced gamma-H2A.X in HGF-1 cells. Therefore, immunostaining of tongue sections from each mouse group using the anti-gamma-H2A.X antibody was performed (Figure 4C,D). Significant expression of gamma-H2A.X was detected in the cells of the sublingual tongue in the arecoline *N*-oxide group (10.93-fold, $p < 0.05$, vs the control group), indicating that DNA damage occurred in this region. Taken together, these data indicate that arecoline *N*-oxide induced DNA damage response in vitro and in vivo.

DISCUSSION

Arecoline *N*-oxide was first identified as a metabolite of arecoline in rat urine in 1971.[10a] A later study also identified it in mouse urine, which indicates that it is a major metabolite of arecoline.[23] The metabolic interconversion between arecoline, arecaidine, arecoline *N*-oxide, and arecaidine *N*-oxide has been suggested.[10b,23] Previous study showed that arecoline was converted to arecoline *N*-oxide by the human flavin-containing monooxygenases FMO1 and FMO3.[10b] The FMO1 and FMO3 are predominantly expressed in kidney or liver.[24] In the present study, we identified arecoline *N*-oxide in ANE-treated human

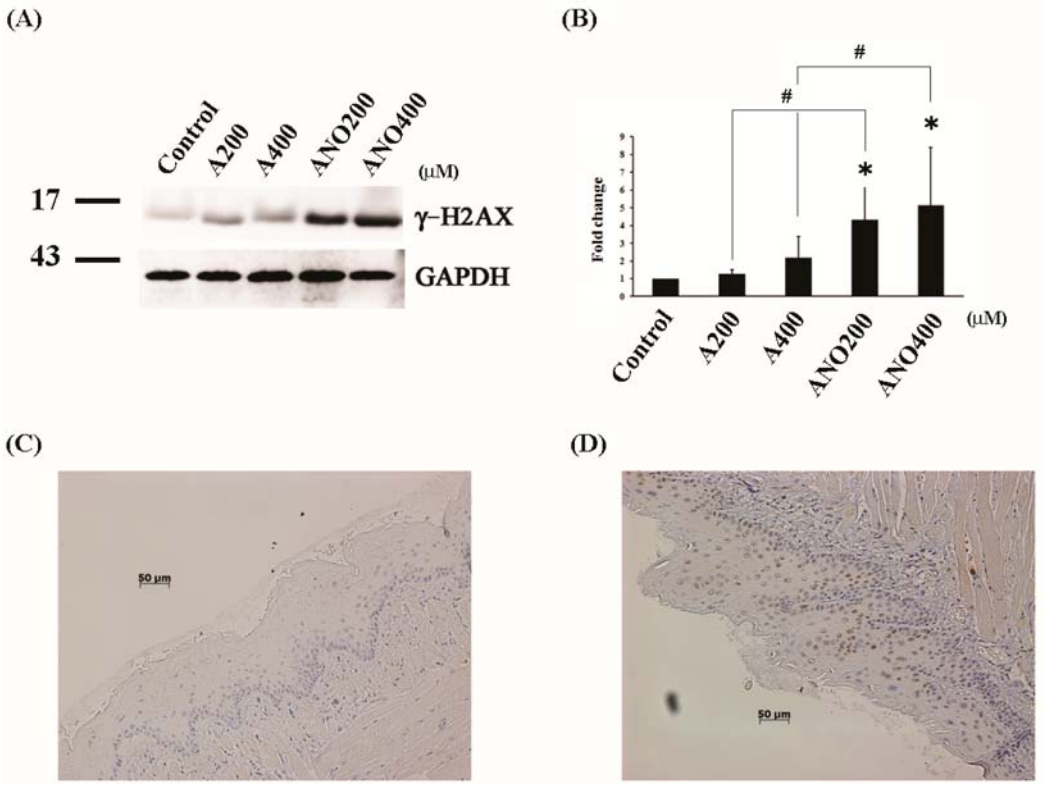

Figure 4. Arecoline *N*-oxide induced gamma-H2A.X in HGF-1 cells and mice. (A) Gamma-H2A.X (γ-H2AX) protein expression was detected by Western blotting in confluent cells treated with arecoline or arecoline *N*-oxide for 7 days. (B) Induction effect on gamma-H2A.X is plotted on a bar graph. Signals of gamma-H2A.X were quantified by densitometry analysis and expressed as average percentage of respective control cells. Results depict mean (±SD) of three independent experiments. (∗) $p < 0.05$ compared with cells without arecoline or arecoline *N*-oxide stimulation; (#) $p < 0.05$, arecoline *N*-oxide group versus arecoline. Arecoline *N*-oxide induced expression of gamma-H2A.X in mice. Immunohistochemical expression of gamma-H2A.X in sublingual tongue samples from the control (C) and arecoline *N*-oxide groups (D). Magnification, 200×.

oral cells. Our data indicated effective cytotoxicity, genotoxicity, and fibrotic gene regulation and increased pathological changes induced by arecoline *N*-oxide. Because arecoline *N*-oxide showed a potential influence on tumorigenesis, it is reasonable to suspect that the toxicity of the areca nut on oral tumorigenesis might be dependent on the cellular amount of its metabolites. Hence, cellular conditions affecting the metabolism of areca nut might play a key role in the occurrence of oral carcinogenesis via betel chewing.

To test whether the constituents of the areca nut enhance oral tumorigenesis or cause precancerous lesions in vivo, numerous studies have treated experimental animals with areca nut or arecoline through diet, drinking water, or intraperitoneal injection. Mice treated with areca nut or arecoline showed higher gene mutation frequency and mutations in *BRCA1*.[25] Lung adenocarcinoma, stomach squamous cell carcinoma, testicular lymphoma, and liver hemeangioma induced in areca nut-stimulated animals have also been studied.[26] In one study focused on the induction of oral lesions or tumor formation, cotreatment with arecoline and 4-NQO of tobacco-related carcinogen induced tongue tumors in mice; however, arecoline alone did not induce any oral pathological lesions.[27] In addition, 3-(methymitrosamino)propionitriIe (MNPN) and *N*-(nitrosomethylamino)propionitrile (NMAP), lime-enhancing synthesized derivatives from the areca nut in saliva, showed lower effects on tumor induction in the oral cavity of rats.[28] Although a strong association between oral precancer or cancer and betel chewing has been demonstrated,[3] the results from multiple animal studies have not proven that there is a link. Differences affecting the metabolism of areca nut, such as oral condition or genetic background, might lead to different outcomes in humans and other experimental animals during areca nut exposure. Areca nut might show a higher potential for oral tumorigenesis in humans than in other experimental animals.

It has been reported that *N*-oxide derivatives of various chemicals show DNA binding activity or reaction with cellular ion containing enzymes. Formation of DNA and protein adducts is central to tumorigenesis via environmental chemicals, such as tobacco or alcohol.[29] Recently, we established a screening platform for identifying protein adducts in samples exposed to arecoline and arecaidine.[12] In this study, protein adducts of ANE in culture keratinocytes were identified (Table 1). Myosin and beta-actin are abundantly expressed in most types of cells, which might be easy binding targets for chemicals. In contrast, they are important cell regulators. It has been shown that some adducts to abundantly expressed proteins, such as antibodies or tubulins, are involved in the immune response or drug sensitivity.[30] Most importantly, the *N*-oxide derivatives from the areca nut, arecoline *N*-oxide and arecaidine *N*-oxide, exist in areca nut exposed oral cells. The influence of those metabolites on diseases requires further investigation.

Both the areca nut and arecoline have been reported to induce DNA damage. Both of these molecules have been suggested as a cause of oral cell carcinogenesis.[6c] In this study, we used gamma-H2A.X as a marker to determine genotoxicity via arecoline *N*-oxide (Figure 4). When DNA damage occurs,

J. Agric. Food Chem. 2015, 63, 5787−5794

the histone H2AX is rapidly phosphorylated at Ser 139 (gamma-H2A.X). This process is involved in the DNA double-strand break repair pathway.[22b] Oxidative stress via the areca nut and arecoline is the main pathway causing DNA damage.[6c] Therefore, *N*-oxide derivatives of the areca nut might induce strong oxidative stress. Gamma-H2A.X was reported as an independent prognostic marker in oral squamous cell carcinoma, which is associated with reduced overall survival time.[22a] Here, we suggest that it might be a marker of the incidence of malignant transformation in OPMD. To avoid strong side effects via other solvents, we used a lower concentration (0.1%) of DMSO to dissolve the arecoline *N*-oxide. However, our results suggested that arecoline *N*-oxide increased the severity of hyperplasia (Figure 1), which is based on the observation of mild hyperplasia in the 0.1% DMSO treated group (the control group). DMSO induced the proliferation of human gingival fibroblasts[31] and sebaceous hyperplasia.[32] Thus, the trace of hyperplasia in the control group is most likely due to DMSO. OSF is a precancerous condition with high collagen expression in oral carcinogenesis. It is a chronically insidious oral mucosal condition, with submucosal fibrosis affecting the oral cavity, pharynx, and esophagus.[13] TGF-beta is well-known as a potent stimulator of the production and deposition of collagen.[33] The areca nut increases collagen accumulation and activates the TGF-beta signaling pathway. Our data also showed an increase in collagen and TGF-beta production by arecoline *N*-oxide, which suggests that arecoline *N*-oxide may be an inducer of OSF. Interestingly, most of the effects of arecoline *N*-oxide were observed in the regions located in the sublingual space below the tongue, possibly due to longer chemical exposure time in that area than in other areas of mouth. In addition, these chemicals might also react with saliva for longer periods of time, which implies that there are more toxic derivatives being produced.

The presence of arecoline *N*-oxide in saliva during betel chewing has not been studied to our knowledge. Arecoline concentration in the saliva can reach around 600 μM.[14] Although the cellular concentration of arecoline *N*-oxide is unclear, our results indicate that fibrotic gene regulation was induced by 200 μM arecoline *N*-oxide (Figure 3). In addition to arecoline, other alkaloids of the areca nut might also metabolically convert to *N*-oxide products, which can also induce oral fibrosis or tumorigenesis. The inhibitory effects on mutagenicity of arecoline *N*-oxide by sulfhydryl compounds and titanium trichloride in bacteria were cited by Lin et al.[6b] Therefore, uptake of inhibitors against those chemicals during betel chewing might be a way to prevent related oral diseases.

Although oral tumors were not induced by arecoline *N*-oxide in our study, this compound may still enhance tumorigenicity. Exposure to arecoline *N*-oxide in an increasing frequency for longer periods might be required for tumor formation. Because the immunodeficient mice are prone to spontaneous cancer and other diseases, further study using wild-type mice is required. Further investigation is also necessary to reveal arecoline *N*-oxide-targeted DNA or protein adducts that lead to tumorigenicity. In conclusion, our study showed the oral fibrotic potential of arecoline *N*-oxide in vitro and in vivo. Our findings provide new insights into the mechanism of carcinogenesis of the areca nut.

gastrointestinal tract, its bioavailability tends to be highly variable and low.[21]

A possible way of slowing osteoporosis is to increase the absorption and bioavailability of calcium by using absorption enhancers or reducing the size of the compounds from microscale to nanoscale. The surface area of the nanoparticles increases, and the properties of the more reactive surface molecules lead to the new properties of the nanoparticles.[22] Whereas nanodelivery systems can increase the absorption and bioavailability of nutrients, they also can change the distribution of the substances in the body.[23] Previous studies by Mohanty et al.[24] and Thakkar et al.[25] on the effect of nanoparticle size, delivery system, and bioavailability revealed that particle size reduction is one of the most important factors to enhance absorption and bioavailability. These combined effects, namely, using suitable composition and nano-size reduction, can help to protect against the development of osteoporosis.

There are different experimental techniques for measuring calcium bioavailability. One of these techniques is the use of in vivo assay. Particularly, small animals such as rats are used as their bones respond quickly to changes, in a human-like fashion, and they are easy to use and inexpensive. The ovariectomized (OVX) rat model is a widely used animal model to simulate estrogen deficiency induced bone loss and is commonly used to test calcium bioavailability for the treatment of postmenopausal osteoporosis.

The current study developed a fortified milk powder containing calcium citrate and some calcium bioavailability enhancers (i.e., inulin, water-soluble and fat-soluble vitamins including B_6, K_1, and D_3, and DHA as well as EPA). To improve the absorption and bioavailability of dietary calcium, two types of fortified milk powder have been developed and compared in vivo by OVX and OVX-OS rats as a model of menopause and menopause-OS women, respectively. It has been hypothesized that the fortified milk with specific composition and optimum preparation condition improves the absorption and bioavailability of calcium in OVX and OVX-OS rats. It is accepted that adequate amounts of calcium, vitamins D_3, K_1, B_6, inulin, DHA, and EPA are key elements for healthy bone development, maintenance of bone density and bone strength, and prevention of osteoporosis, but fortification with micro calcium particles results in lower absorption efficiency than nano calcium particles. Among various sources of fortified foods, little information is available about nanoparticles. Therefore, for the purpose of finding another type of fortified food, we have compared nanofortified milk powder with micro- and non-fortified milk on calcium absorption and bioavailability in OVX and OVX-OS rats as a model of menopause and menopause-OS women, respectively.

MATERIALS AND METHODS

Chemicals and Materials. Skim milk powder (T1) was provided by Fonterra (Kuala Lumpur, Malaysia). Food grade calcium citrate, inulin, vitamins D_3, K_1, and B_6, EPA, and DHA were procured from Finuco (Sankyo Seifun Co, Ltd., Chugoku/Okayama, Japan). A Sartorius stedim biotech system (GmbH, 37070 Gottingen, Germany) was used to obtain deionized water for all procedures.

Milk Fortification. The fortified milk powder contained calcium citrate, EPA and DHA (1:1), vitamins D_3, K_1, and B_6, and inulin based on the North American and Western European recommended dietary allowance (Table 1).[10] These compounds were added to skim milk powder and mixed for 5 min with a mixer (Bachiller, Barcelona, Spain) (Table 1). The samples were kept in airtight glass bottles and stored in a refrigerator.

[a]Gold Coin Animal Feed (702P-Pellet). [b]T1. [c]T2 and T2-nano.

Phase 1: Optimization of Preparation Condition of Calcium Nanofortified Milk Powder. *High-Pressure Homogenization.* Sample preparation was achieved by dispersing milk powder in deionized water (20% w/v). A mixer (Silverson L4R, Buckinghamshire, UK) was used for 5 min at 1000 rpm as prehomogenizer to prepare coarse sample. Then, the sample passed through a high-pressure homogenizer (APV, Crawley, UK) with different homogenization condition (i.e. cycle, 3−5; pressure, 200−400 bar) to produce calcium citrate nanofortified milk sample (T2-nano).

Polydispersity Index (PDI) and Average Particle Size (APS). A dynamic light-scattering particle analyzer (Malvern Series ZEN 1600, Malvern Instruments Ltd., Worcester, UK) was used to analyze APS and PDI of fortified milk powder. A laser ray passed through the sample and was scattered by the particles in a distinctive pattern. A photodiode array detector measured the APS. The measurement scale of APS was reported in micrometers. The experiment was carried out in triplicate for each diluted sample. The system reported a measure of particle size distribution as PDI. PDI values range from 0, for a completely monodisperse system, to 1.0, for a polydisperse particle dispersion.

Response Surface Analysis. Response surface methodology (RSM) evaluated the effect of two independent variables, namely, x_1 (cycle (3, 4, and 5)) and x_2 (pressure (200, 300, and 400 bar)), on the response variables, Y_1 (PDI) and Y_2 (particle size (nm)). A central composite design (CCD) consisting of 14 treatments, including 6 center points, was created to optimize the preparation condition of nano calcium citrate fortified milk powder prepared by high-pressure homogenization and simultaneously study the main, interaction, and quadratic effects of independent variables on the dependent variables.[26]

Optimization and Validation Procedure. To determine the optimum level of preparation parameters leading to minimum particle size and minimum PDI, graphical (three-dimensional response surface) and numerical optimization[27] were carried out (Minitab v.16, Minitab Inc., State College, PA, USA). To predict the exact optimum level of independent variables, response optimizer (Minitab v. 16) was used for numerical optimization leading to the desired response goals. The adequacy of RSM (model validation) was evaluated using the t test.

Particle Morphology. The nanoparticle structure and morphology were examined using energy filtered transmission electron microscopy (EFTEM; LEO 912 AB Omega, LEO Electron Optics, Oberkochen, Germany). Air-dried samples on a copper grid were negatively stained with 2% phosphotungstic acid solution (2 min) and air-dried before being observed under EFTEM.[27] The diameters of the particles were determined using the scale bar on the electron micrographs. Reproducibility of the EFTEM images was assured by taking at least four pictures of each sample.

Phase 2: In Vivo Study. The ultimate test of success of a formula depends on its in vivo performance, which was conducted in a suitable animal model (refer to graphical abstract). Approval to carry out in vivo study was obtained from the Animal Care and Use Committee of Faculty of Veterinary Medicine of Universiti Putra Malaysia (UPM, Selangor, Malaysia). The animals used for in vivo experiments were female Sprague–Dawley rats (n = 96, 7 weeks old) weighing ∼250 g obtained from UPM veterinary hospital (Serdang, Selangor, Malaysia). The animals were kept under standard laboratory condition at a temperature of 22 ± 2 °C and relative humidity of 50 ± 5%. The animals were housed in metabolic cages (a conventional, circular metabolic cage made of clear plastic was used), one per cage, with free access to standard laboratory feed (Gold Coin animal feed, Kuala Lumpur, Malaysia) (Table 1) and distilled water ad libitum.

The experimental diets contained the nonfortified milk powder (T1, 850 mg/100 g) as the main protein source. Ovariectomy was performed by excising the ovaries. The animals were anesthetized with a combination of ketamine (80 mg/kg) and xylazine (10 mg/kg), intraperitoneally.[28] Briefly, hair was cut over the surgical area and scrubbed with iodine. A small incision (∼1.0 cm) was made in the skin between the middle of the back, starting at the last rib. The skin was moved to one lateral side, and a small incision was made through the peritoneal lining. The entire ovary was removed with a single cut between the uterine horn and oviduct on each side. The skin was then recovered with a surgical staple.[29] Sham surgery consisted of the skin incision and staple procedures only.[30] After 1 week postsurgery treatment, the rats were randomly assigned to three main groups (sham, OVX, and OVX-OS). Each group of rats was randomized into four different subgroups including eight rats each and maintained for a period of 8 weeks as an experimental period.

The first and second groups included sham and OVX rats that were fed treatment diets (1, basal diet, standard rat chow diet as a control diet; 2: T1; 3, T2; and 4, T2-nano). The third group included OVX rats that were fed a low-calcium diet for 6 weeks prior to experimental diets. The idea was to induce osteoporosis in the OVX rats and change them to OVX-OS rats. To ensure all groups were fed treatment diets similarly, during that 6 week period the other two groups (sham and OVX rats) were kept on basal diet. After 6 weeks of low-calcium diet feeding, the OVX-OS rats were randomly divided into four subgroups. Then they received experimental diets for 8 weeks the same as sham and OVX rats. During the 8 week experimental period, the treatment diets were given (5 mL) orally by gavage twice daily.

Sample Collection. After an 8 week feeding period, following overnight fasting, rats were anesthetized with a 1:2 (v/v) mixture of ketamine (10 mg/kg) and xylazine (25 mg/kg) and sacrificed.[31] Blood collected by cardiac puncture was centrifuged (Hettich EBA 20 centrifuge, Andreas Hettich GmbH & Co. KG, Tuttlingen, Germany) at 5000 rpm (2850g) for 8 min at 4 °C to separate serum that was maintained at −20 °C for further chemical analysis. Feces were collected for each individual rat in the last 6 days of the experiment. Then, the feces were air-dried, finely ground, stored in a plastic tube, and kept at 4 °C until further use for calcium analysis. The bones (femurs) were cleaned by eliminating the soft tissue. However, they were initially soaked in saline solution prior to sealing in plastic bags and storing at −20 °C.[32] They were saved for calcium determination, bone strength (maximum load) measurement, and bone morphology.

Experimental Analysis. *Mechanical Assays.* Femurs were subjected to an Instron universal testing instrument (5kN model 3365, Norwood, MA, USA) for evaluation of biomechanical function of bones. Femurs were brought to room temperature before breaking in the exact center of the bones. To analyze the maximum load, the bone was placed on two supporting bars (2 mm in diameter) with a span of 15 mm, and an upper crosshead roller (6 mm diameter) was applied in the middle of the bone and advanced at 0.5 mm/min until the rupture was automatically determined by the apparatus. The midpoints of the femurs were determined by measuring the length of each bone and dividing the length using a Vernier caliper. The crosshead compressed the middle of the femur with linearly increasing force, until fracture occurred. The load deformation curve was recorded. The test results provided values for maximum load (N).[32]

Calcium Analysis. To measure serum calcium, an automatic blood chemical analyzer with Roche testing kits (Roche COBAS MIRA PLUS, Basel, Switzerland) was used. Total concentration of calcium in the diet, feces, and bone calcium contents were measured by an atomic absorption spectrophotometry (Thermo Scientific, S series, Waltham, MA, USA) using a standard procedure.[32]

Morphology Structure. Fractured surfaces of the femurs obtained from the mechanical strength test were processed for scanning electron microscopy (SEM) (LEO 1455VPSEM, London, UK). Briefly, bone was fixed (2.5% glutaraldehyde for 72 h and postfixation

in 1% osmium tetroxide for 24 h), then dehydrated in ethanol, and dried with CO_2 at critical point. Finally, it was attached to aluminum specimen holders with colloidal silver. This process provided a conducting path to remove charges that would result from the incident electron beam of SEM striking the specimen. The mounting stubs were placed in an oven at 70 °C for 15 min to allow evaporation of volatile solvents from the carbon element and silver paint. Then sputter was coated with palladium−gold using a sputter coater. Finally, the processed bone was analyzed at 25 kV accelerating voltage by SEM.[32] Three micrographs at final magnifications (×450) were taken from each animal.

Absorption and Bioavailability. Apparent calcium absorption and relative bioavailability values were calculated using consumed calcium in the diets, fecal calcium, and total calcium in bones as explained previously.[20]

Statistical Analysis. Data analysis was carried out using Minitab software (version 16, Minitab Inc., State College, PA, USA). A completely randomized design was employed to generate all treatments. In each experiment, a comparison was made using one-way ANOVA within and between groups receiving the same diets. Significant ($p < 0.05$) differences were determined among treatment groups with Tukey's multiple-range tests.

RESULTS

Response Surface Analysis. RSM is an experimental design method useful in optimization processes. The ability to experimentally explore the main and interaction effects and the relationship between several independent and dependent variables are the advantages of RSM over the conventional optimization process, where one factor is varied while the others remain constant. Using RSM reveals that just a few experimental runs are required to generate a vast amount of information for optimization, which reduces the time and cost required to obtain the optimized parameters. According to Table 2, the arrangement of CCD permits the progress of the suitable empirical equations.[26]

The estimated regression coefficients of two high-pressure variables, along with the corresponding R^2, p values, lack of fit test, significant probability of each parameter, and their F ratios, are shown in Table 3. The final reduced models (FRMs) fitted for PDI and APS showed high coefficients of determination (0.953 and 0.965, respectively), which indicated the satisfactory adjustment of the reduced response surface models employed for describing the variation of dependent variables as a function of the main preparation parameters.[33]

The analyses of PDI and APS of T2-nano were significantly ($p < 0.05$) influenced by cycle and pressure (Table 3). Both response variables were significantly ($p < 0.05$) fitted by a second-order regression equation. In fact, the variability of PDI was significantly ($p < 0.05$) defined as a function of linear and interaction effects of both homogenization variables (Table 3). In addition, the variability of APS was significantly ($p < 0.05$) defined as a function of linear effects of pressure variable ($p = 0.00$) and interaction as well as quadratic effects of both homogenization variables (Table 3).

In the present study, both high-pressure variables had the same negative (b_1 and b_2) significant ($p < 0.05$) effect on APS and PDI (Table 3). It was concluded that the APS and PDI of the fortified milk powder were significantly ($p < 0.05$) decreased with increasing pressure and cycle (Table 3).

Effect of Homogenization Condition on Characteristics of Fortified Milk Powder. Figure 1 demonstrates the APS of T1, T2, and T2-nano. Lower PDI values for T2-nano compared with T2 and T1 are clearly presented in the figure. Figure 2 exhibits the significant ($p = 0.00$) interaction effects of high-pressure variables on APS and PDI of the fortified milk powder. The interaction effect of cycle and pressure decreased the APS of the fortified milk powder. This observation confirmed that the presence of the interaction effects improved the fitness of the FRM to the experimental data for the APS. The interaction between cycle and pressure had equal significant ($p = 0.00$) effects on the APS and PDI of the fortified milk powder (Table 3).

Optimization and Validation of Homogenization Process. The multiple response optimizations leading to the minimum APS and PDI of the T2-nano were carried out. The overall optimal condition leading to the minimum PDI and APS was predicted to be obtained at the combined level of four cycles and ~300 bar pressure (Figure 3). The average cycle and pressure led to the minimum PDI. Moreover, the region resulting in the smallest average size was predicted to be obtained by the average cycle and pressure. Under corresponding optimum condition, the desirable fortified milk powder with the predicted optimum PDI and APS was prepared to verify the accuracy of the reduced models. Thus, PDI and APS of the

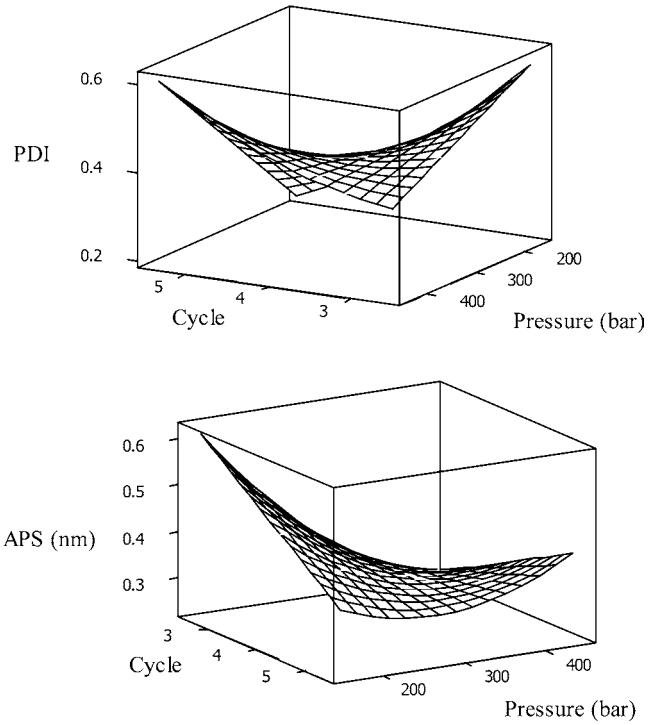

Figure 2. Response surface plots showing the interaction effect of independent variables on polydispersity index (PDI) and average particle size (APS) of the fortified milk powder.

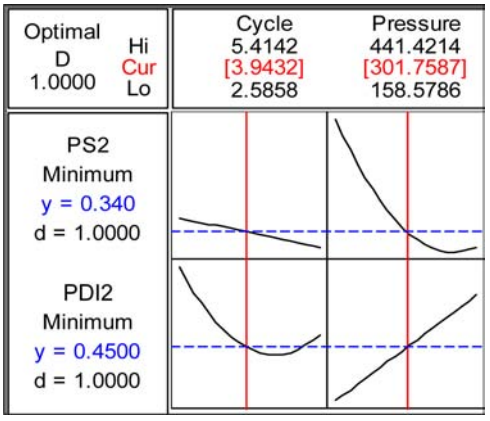

Figure 3. Response optimization, parameters, predicted responses (y), and desirability (d). PS, particle size; PDI, polydispersity index.

prepared fortified milk powder were determined and subsequently compared with the predicted values. The corresponding response values obtained from the experimental data and the ones predicted by the reduced models were observed to be close together (Table 4), and no significant ($p = 0.63$) difference was observed between the experimental and predicted values (Table 4), thus indicating the adequacy of the FRMs fitted by RSM. Briefly, the optimization of high-pressure homogenization of the calcium citrate fortified milk powder resulting in nanoparticles (100−1000 nm) was targeted. In this study, either increase or decrease of the pressure from 300 to 200 bar or from 300 to 400 bar resulted in the larger particle size and higher PDI. The same undesirable particle size and PDI were obtained with the application of more or fewer than four cycles.

Particle Morphology. The transmission electron microscopy (TEM) images of T1, T2, and T2-nano are shown in Figure 4. Nanoparticles are generally characterized by their size and morphology using such advanced microscopic techniques as TEM. As Figure 4 shows, the size of particles was significantly reduced in nanofortified milk powder (C) compared with fortified milk (B) and skim milk (A) powders. The results of TEM were in agreement with particle size analyzer for all milk powders.

Effect of Experimental Diets on Serum Calcium in Sham, OVX, and OVX-OS Rats. Blood was collected at the beginning of the experiment showing the serum calcium content of 2.54 mmol/L. Table 5 compares the experimental data on total serum calcium concentration of sham, OVX, and OVX-OS rats at the end of experiments. It is apparent from this table that, although the highest amount of total serum calcium was fournd for T2-nano, regardless of treatments, no significant ($p = 0.21$) difference was found among the experimental diets and between the groups (sham, OVX, and OVX-OS).

Effect of Experimental Diets on Bone Calcium in Sham, OVX, and OVX-OS Rats. The results obtained from the analysis of bone calcium are shown in Table 5. To assess calcium bioavailability, bone calcium content was tested. In Table 5 there is a clear trend of decreasing bone calcium in T2-nano, T2, T1, and basal diet in both OVX and OVX-OS rats. Indeed, bone calcium content was significantly ($p = 0.00$) higher in both OVX and OVX-OS groups fed T2 compared to those in basal diets and T1. Moreover, significant difference ($p = 0.00$) was observed between T1 and basal diet in OVX rats. On the other hand, there was no significant ($p = 0.18$) difference between T1 and basal diet in OVX-OS rats. It is apparent from this table that the T2-nano group had the greatest femur calcium content compared with other groups in both OVX and OVX-OS rats. Furthermore, the femoral calcium in OVX rats was significantly ($p = 0.00$) higher than in OVX-OS rats (Table 5), therefore indicating higher femoral bone mineral density. Moreover, the results in Table 5 show that the amount of bone calcium in the sham group was significantly ($p = 0.00$) higher than in OVX and OVX-OS rats.

Effect of Experimental Diets on Mechanical Properties of Bones in Sham, OVX, and OVX-OS Rats. Maximum load (bone strength) was used to evaluate calcium bioavailability. Table 5 presents the results of maximum load in sham, OVX, and OVX-OS rats. The strength test revealed a significant ($p = 0.02$) positive effect for the fortified diet on the rat femurs. As the results show, the T2 intake in sham, OVX, and OVX-OS rats significantly ($p = 0.02$) enhanced the maximum load in femurs compared with basal diet and T1 groups. In the mechanical testing, the maximum load of T1 groups slightly increased in comparison with basal diet groups. However, there was no significant ($p = 0.09$) difference in maximum load between these groups after 8 weeks of feeding in sham and OVX rats, whereas there was a significant ($p = 0.00$) difference between T1 and basal diet groups in OVX-OS rats. There was no significant difference ($p = 0.08$) between the bone strength of OVX and OVX-OS rats receiving T2 during the experiment, but the present results (Table 5) demonstrated significant improvement in bone strength and maximum load in the sham group fed with fortified milk powder compared to the rest. The results obtained from this study indicated that fortified milk powder may have a preventive effect on bone loss in rats.

In addition, rats in the T2-nano groups had significantly ($p = 0.01$) higher bone stiffness and bone strength compared with other groups in all sham, OVX, and OVX-OS rats (Table 5). Therefore, particle size reduction in the diets could increase maximum load and affect bone strength. As shown in Table 5, it was found that the bone strength of OVX rats receiving T2-nano significantly ($p = 0.01$) increased compared with OVX-OS rats. Interestingly, it was found that OVX rats fed T2-nano had similar maximum load with T2-nano sham group with no significant difference ($p = 0.23$).

Effect of Experimental Diets on Bone Morphology of Sham, OVX, and OVX-OS Rats. Alterations of bone morphology can be compared among all experimental diets in Figure 5. The SEM images of basal diet groups (as control diet) of sham, OVX, and OVX-OS rats clearly showed severe reduction of bone mass in the femurs (Figure 5A,E,I). SEM of

[a]Means with different lower case letters (a−d) in a column are significantly ($p < 0.05$) different. Means with different upper case letters (A−C) in a row are significantly ($p < 0.05$) different. T1, skim milk; T2, fortified milk powder containing calcium citrate + vitamins (D_3 + K_1 + B_6) + EPA and DHA + inulin.

rat femurs receiving T1 illustrated no immense cracks resulting from increasing bone mass (Figure 5B,F,J). It was found that the bone morphology of T1 groups had an improvement compared to basal diet in sham, OVX, and OVX-OS rats. Treatment with T2 restored the morphological abnormalities (Figure 5C,G,K) in the groups. As compared with T2, treatment with T2-nano demonstrated better status of bones. It can be seen from Figure 5D,H,L that femur morphology and canal openings had a great improvement in T2-nano groups. After 8 weeks of feeding with experimental diets, the SEM images of the rat femurs showed that bone morphology was better improved in the OVX groups compared with the OVX-OS groups. In all sham, OVX, and OVX-OS rats, T2-nano showed better bone morphology than the rest of the diet groups.

Effect of Experimental Diets on Absorption and Bioavailability of Calcium in Sham, OVX, and OVX-OS Rats. The results obtained from the calcium absorption and bioavailability analysis of sham, OVX, and OVX-OS rats are shown in Figure 6. It can be seen from the data in Figure 6a that the T2 groups had significantly (p = 0.00) more absorption than the T1 groups in both OVX and OVX-OS rats; however, the difference between T2 and T1 was not significant (p = 0.11) in the sham group. In addition, calcium absorption in T2-nano was significantly (p = 0.00) higher than T2 in all groups. As a result, the percentage of calcium absorption in the T2-nano group was at the highest level compared with the other groups for sham, OVX, and OVX-OS rats. Under experimental conditions, the absorption of calcium for T2-nano had a significant (p = 0.00) increase in sham and OVX rats compared to OVX-OS rats. On the other hand, the opposite trend was observed in calcium absorption for T2 (Figure 6a).

From the data in Figure 6b, the same trends as calcium absorption were observed for the bioavailability of calcium with significant differences (p = 0.00) among the groups in sham, OVX, and OVX-OS rats. Similar to the calcium absorption, in all groups of rats, calcium bioavailability of T2 was higher than T1. Moreover, the percentage of calcium bioavailability in T2-nano was significantly (p = 0.00) higher than in T2. As clearly displayed in Figure 6b, the amount of calcium bioavailability had a positive significant (p = 0.00) impact in sham and OVX compared with OVX-OS rats.

■ DISCUSSION

This study set out with the aim of assessing the importance of suitable formula and reducing particle size in improving calcium absorption and calcium bioavailability. With respect to calcium, the average intakes among postmenopausal women are below the current recommended value. Some researchers[34,35] have mainly been interested in calcium fortification, which is an important source of dietary calcium and a basic defense against osteoporosis. The results of the present study showed that fortification with calcium and suitable enhancers had a positive effect on femur morphology, bone strength, and bone calcium. Results of SEM are in agreement with previous findings,[36] which showed that improved calcium absorption could decrease the occurrence of bone fracture and osteoporosis.

The current study developed a calcium citrate fortified milk powder to improve the calcium absorption and bioavailability and to decrease the occurrences of bone fracture as well as osteoporosis. For instance, researchers have previously demonstrated that calcium absorption is determined by the chemical form of the calcium compound, other components of

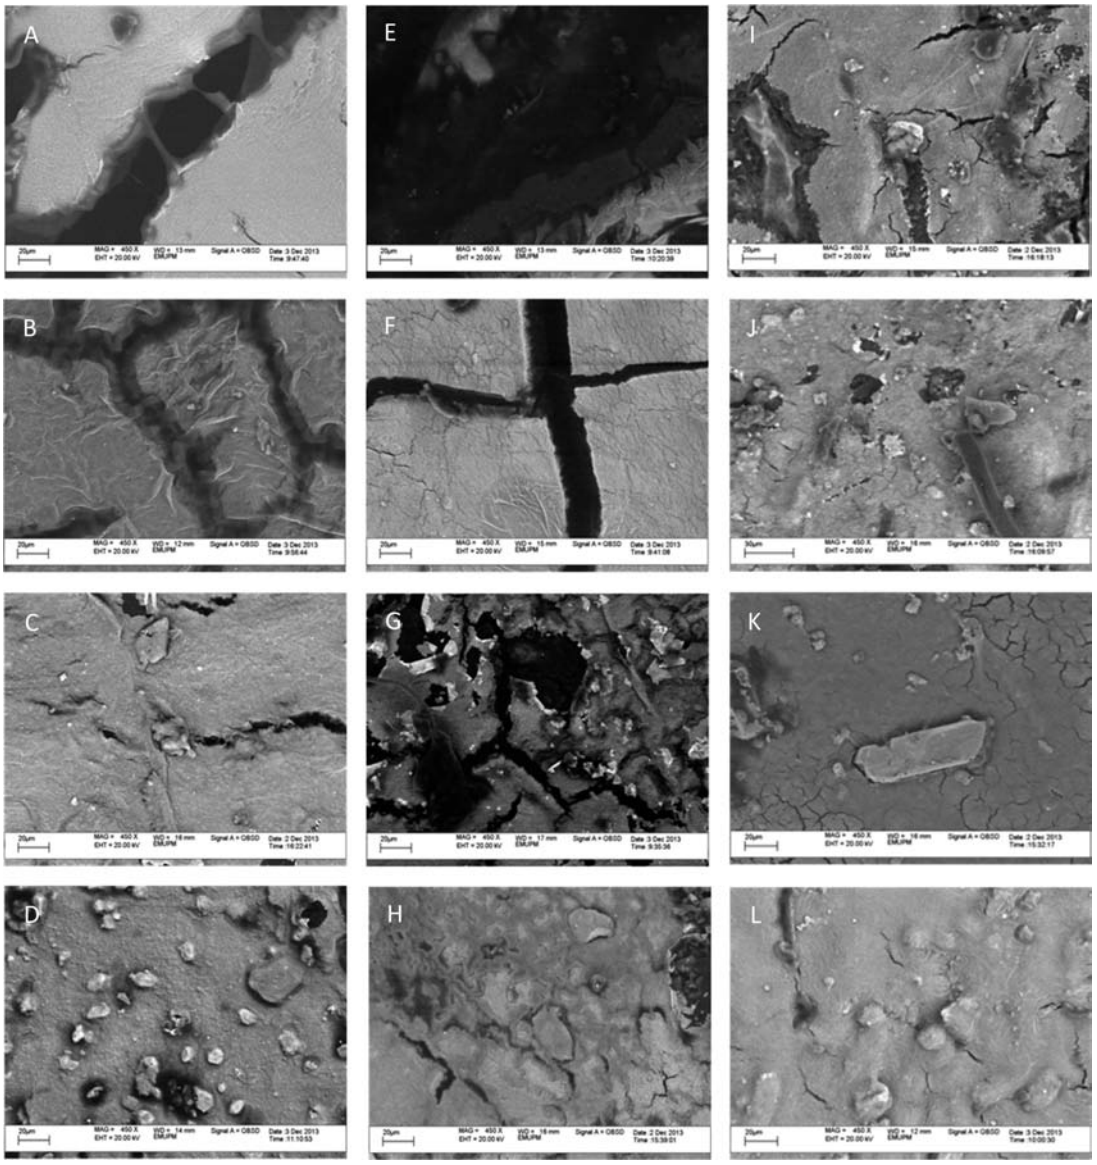

Figure 5. Bone SEM images of OVX rats (A–D), OVX-OS rats (E–H), and sham (I–L): basal diet (A, E, and I), T1 (B, F, and J), T2 (C, G, and K); calcium citrate + vitamins (D_3 + K_1 + B_6) + EPA + DHA + inulin and T2-nano (D, H, and L).

the diet, and the absorption capacity of the intestines.[37] The first important mentioned factor was the chemical form of the calcium compound. Calcium citrate with 21% of elemental calcium is widely used in calcium supplements and fortified foods.[38] In addition, calcium citrate is absorbed equally well when taken with or without food.[39] It is also the best choice for people with inflammatory bowel disease and other conditions that hamper calcium absorption.[40] Therefore, it was chosen as the preferred source for fortification of skim milk powder.

It has also been reported that there was difference in the bioavailability of calcium from milk and that from calcium salts.[16] In the present study, observations showed that the fortified milk powder had more absorption and bioavailability compared to the skim milk powder. These differences might be due to the added absorption enhancers as the components of the diet. In fact, mineral bioavailability could be influenced by several factors in the diet. The magnitude of this influence depends on inhibitors and promoters contained in meal and the diet composition.

Some researchers observed positive effects of inulin and the other compounds (omega-3, vitamins D_3, K_1, and B_6) on calcium absorption and bioavailability.[41−45] The present results indicated that when calcium absorption enhancers were used in combination, absorption and bioavailability of calcium increased (Figure 6). These observations confirmed that bone loss caused via osteoporosis is preventable by effective calcium absorption enhancers.

Furthermore, some researchers concluded that hormonal status and an adequate intake of calcium are major factors in determining calcium and bone status, whereas the particle size of the calcium supplement is not significant in this relation.[46] On the other hand, Cho et al.[47] demonstrated that nanoparticles had higher absorption and more extensive organ distribution when administered orally. Furthermore, Wegmüller et al.[48] stated that decreasing the particle size of elemental iron powders increases iron absorption. Moreover, Singh et al.[49] studied the effect of different-sized cerium oxide nanoparticles on the decomposition and hydrogen absorption kinetics of magnesium hydride. Their results showed nanoparticles had 1.5 times better absorption kinetics with respect to pure

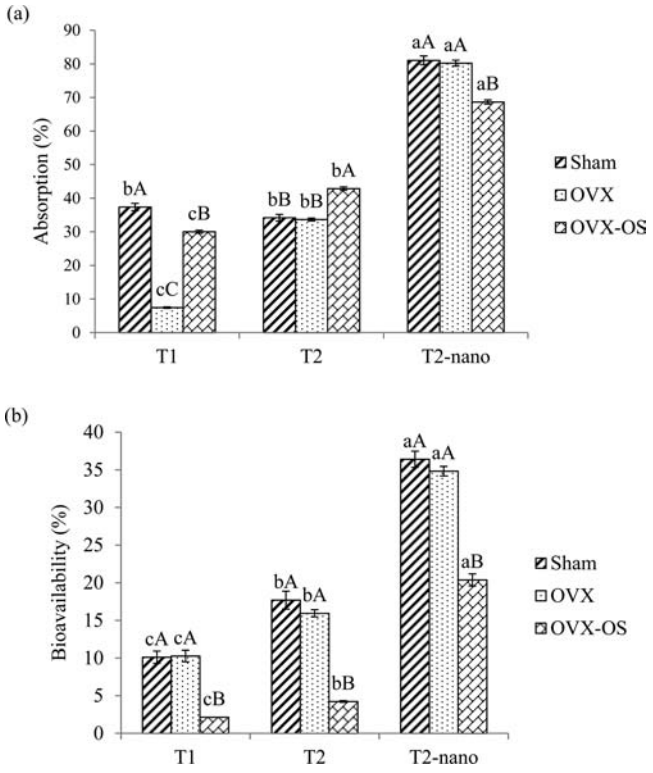

Figure 6. (a) Absorption and (b) bioavailability of calcium for sham, OVX rats, and OVX-OS rats. Different lower case letters show significant difference ($p < 0.05$) between rats fed different diets. Different upper case letters show significant difference ($p < 0.05$) among rats fed the same diet.

magnesium hydride. Similarly, the results of the present study revealed that using a suitable composition and particle size reduction to nanoscale may induce high intestinal calcium absorption and decrease bone loss by ovariectomy and osteoporosis.

The findings of the current study are also consistent with those of Kruger et al.,[43] who indicated that improved calcium absorption could decrease the occurrences of bone fracture and osteoporosis. Thus, the data on the absorption and bioavailability indicated the importance of suitable formulation and preparation conditions in high intestinal absorption and high bioavailability of calcium in rats. Although, the current findings demonstrate the efficacy of nutrients and reducing particle size in the treatment of osteoporosis in rats, further experimental investigations are required to clarify the mechanism of this system in the human body.

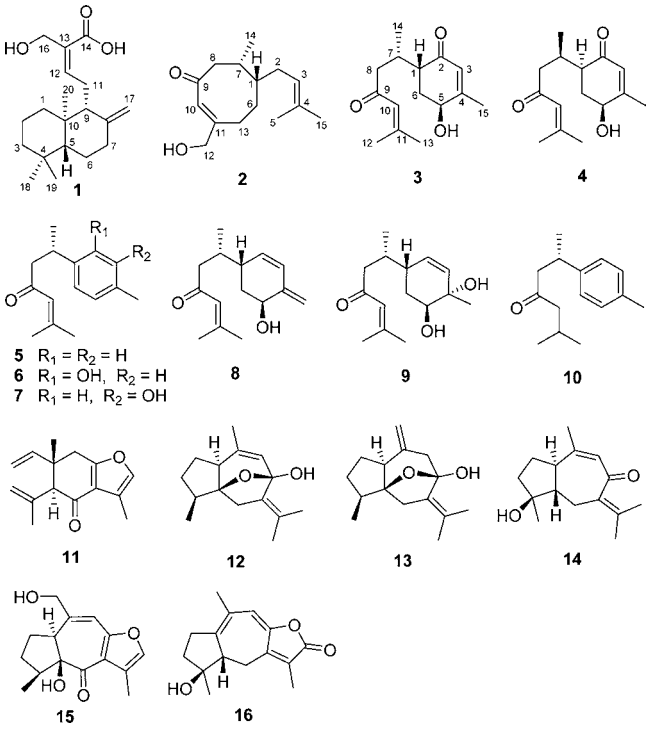

Figure 1. Structures of compounds **1**–**16** from *C. longa*.

Ltd., Kyoto, Japan). The flow rate of HPLC was 5.5 mL/min. Silica gel (100–200 mesh) was used for column chromatography (Qingdao Haiyang Chemical Group Co. Ltd., Qingdao, People's Republic of China). Chemical reagents for isolation were of analytical grade and purchased from Tianjin Chemical Reagent Co. (Tianjin, People's Republic of China). Biological reagents were from Sigma Chemical Co. The murine microglial BV-2 cell line was from Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences (Shanghai, People's Republic of China).

Plant Material. The rhizomes of *C. longa* were purchased in July 2009 from Anguo Materia Medica Market, Hebei province, People's Republic of China. The plant material was identified by one of the authors (Dr. Yuanqiang Guo), and a voucher specimen (no. 20090871) was deposited at the laboratory of the Research Department of Natural Medicine, College of Pharmacy, Nankai University.

Extraction and Isolation. The air-dried rhizomes of *C. longa* (6.0 kg) were powdered and extracted with MeOH (3 × 48 L) under reflux. The organic solvent was removed to give a crude residue (750 g). This residue was suspended in H_2O (0.8 L) and partitioned with EtOAc (3 × 0.8 L). The EtOAc-soluble portion (245.0 g) was fractionated by silica gel column chromatography (silica gel, 1.0 kg; column, 9 × 70 cm), using a gradient solvent system of petroleum ether/acetone (100:0, 100:1, 100:2, 100:3, 100:5, 100:8, 100:11, 100:16, 100:23, and 100:30; 21 L for each gradient elution), to yield eight fractions (F_1–F_8) based on TLC analyses. Fraction F_7 was subjected to MPLC over ODS eluting with a step gradient from 73–93% MeOH in H_2O to give four subfractions ($F_{7\text{-}1}$–$F_{7\text{-}4}$). Subfraction $F_{7\text{-}3}$ was further isolated by preparative HPLC (78% MeOH in H_2O) to give compound **1** (t_R = 27 min, 16.9 mg). The purification of subfraction $F_{7\text{-}2}$ with the same HPLC (74% MeOH in H_2O) yielded compound **9** (t_R = 24 min, 13.7 mg). Fraction F_5, with the same procedures as for F_7, gave four subfractions $F_{5\text{-}1}$–$F_{5\text{-}4}$, and compounds **2** (t_R = 26 min, 13.2 mg) and **14** (t_R = 21 min, 13.1 mg) were obtained from $F_{5\text{-}2}$ (82% MeOH in H_2O) with the same HPLC system. Fraction F_6 was fractionated by the above MPLC to yield three subfractions $F_{6\text{-}1}$–$F_{6\text{-}3}$, and the purification of subfraction $F_{6\text{-}1}$ (80% MeOH in H_2O) with the same HPLC system afforded compounds **3** (t_R = 21 min, 11.9 mg), **4** (t_R = 23 min, 9.9 mg), **15** (t_R = 35 min, 14.1 mg), and **16** (t_R = 39 min, 13.7 mg). Using the same MPLC system as for the above fractions, F_2, F_3, and F_4 afforded their subfractions $F_{2\text{-}1}$–$F_{2\text{-}5}$, $F_{3\text{-}1}$–$F_{3\text{-}4}$, and $F_{4\text{-}1}$–$F_{4\text{-}6}$, respectively. The following purification of subfractions $F_{2\text{-}5}$ (88% MeOH in H_2O), $F_{2\text{-}1}$ (85% MeOH in H_2O), and $F_{2\text{-}3}$ (86% MeOH in H_2O) yielded compounds **5** (t_R = 25 min, 15.0 mg), **6** (t_R = 26 min, 18.1 mg), and **11** (t_R = 29 min, 10.1 mg), respectively. Compounds **7** (t_R = 41 min, 20.9 mg) and **8** (t_R = 33 min, 14.6 mg) were obtained from subfraction $F_{4\text{-}3}$ with the same HPLC system (80% MeOH in H_2O). Compounds **10** (t_R = 36 min, 8.9 mg) and **12** (t_R = 28 min, 12.7 mg) were isolated from $F_{3\text{-}2}$ (82% MeOH in H_2O) and the purification of $F_{3\text{-}4}$ (84% MeOH in H_2O) to afford compound **13** (t_R = 29 min, 19.2 mg).

Computational Methods. Starting from the conformation of every compound deduced from NOESY spectrum and Chem3D modeling, conformational searches were performed first using MOE software[17] and conformers were selected for geometry optimizations. Geometry optimizations and reoptimizations on the B3LYP/6-31+G(d,p) level were finished by the Gaussian 09 package.[18] TDDFT ECD calculations[19−21] for the optimized conformers were performed at the CAM-B3LYP/SVP level with a CPCM solvent model in acetonitrile, and the calculated ECD spectra of different conformers were simulated with a half bandwidth of ∼0.4 eV. The CD curves were extracted by SpecDis 1.62 software.[22] The overall ECD curves of all the compounds were weighted by Boltzmann distribution after UV correction.

Bioassay for NO production. The bioassay for NO production was performed according to the reported method.[16]

RESULTS AND DISCUSSION

The ethyl acetate-soluble part of the methanol extract of the rhizomes of *C. longa* was fractionated by silica gel column chromatography and MPLC and further purified by HPLC to afford 2 new and 14 known terpenoids, **1**−**16**.

Compound **1** was obtained as a colorless oil. Its HR-ESIMS provided the molecular formula $C_{19}H_{30}O_3$, which was supported by the NMR data (Tables 1 and 2). The molecular formula suggested five unsaturation degrees for **1**. The ^{1}H NMR spectrum of **1** indicated three methyl groups [δ_H 0.89 (3H, H_3-18), 0.83 (3H, s, H_3-19), and 0.74 (3H, s, H_3-20)], three olefinic protons [δ_H 6.97 (1H, t, J = 6.7 Hz, H-12), 4.42 (1H, s, H-17a), and 4.84 (1H, s, H-17b)], and two hydroxymethyl protons [δ_H 4.39 (2H, s, H_2-16)]. The ^{13}C NMR spectrum of **1** showed 19 carbon signals, which were sorted as three methyls [δ_C 33.6 (C-18), 21.7 (C-19), and 14.4 (C-20)], eight methylenes [δ_C 39.2 (C-1), 19.3 (C-2), 42.0 (C-3), 24.1 (C-6), 37.9 (C-7), 23.8 (C-11), 57.2 (C-16), and 107.9 (C-17)], three methines [δ_C 55.4 (C-5), 56.7 (C-9), and 150.1 (C-12)], and five quaternary carbons [δ_C 33.6 (C-4), 148.0 (C-8), 39.6 (C-10), 129.5 (C-13), and 172.2 (C-14)] with the aid of DEPT and HMQC spectra. On the basis of the total unsaturation degrees, the aforementioned spectroscopic features, and the reported terpenoids from the genus *Curcuma*,[23−26] compound **1** might be a norditerpene with two rings. Comparison of the chemical shifts of C-1−C-10, and C-17−C-20 of compound **1** with those of reported labdane-type diterpenes[23−25] showed the occurrence of a structural fragment, two fused six-membered rings. To corroborate the above deductions and elucidate the structure, HMBC and ^{1}H−^{1}H COSY experiments were performed. The following interpretation of HMQC, HMBC, and ^{1}H−^{1}H COSY spectra (Figure 2) resulted in the confirmation of the above structural moiety of two fused six-membered rings, where the olefinic

J. Agric. Food Chem. 2015, 63, 5805−5812

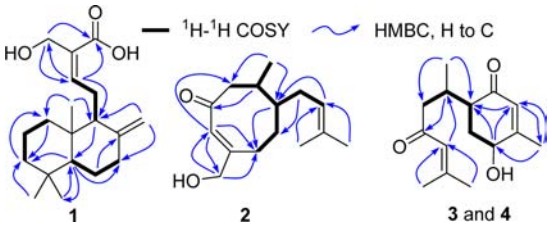

Figure 2. ^{1}H−^{1}H COSY and key HMBC correlations of compounds **1**−**4**.

carbons of the terminal double bond at δ_C 148.0 and 107.9 were assigned to C-8 and C-17, and the three methyls (C-18, C-19, and C-20) were demonstrated to be attached at C-4, C-4, and C-10, respectively. The residual five carbons at δ_C 23.8, 150.1, 129.5, 172.2, and 57.2 were assigned to C-11−C-16 by the HMBC correlations of H-12 to C-9, C-11, C-13, C-14, and C-16 and H_2-16 to C-12, C-13, and C-14. On the basis of the above evidence and further detailed analyses of HMQC, HMBC, and ^{1}H−^{1}H COSY spectra, the planar structure of compound **1** was elucidated as a 15-nor labdane diterpene.[23,24]

The relative configuration of compound **1** was deduced from NOESY spectrum and Chem3D modeling (Figure 3). NOESY correlations observed for H-1β/H-3β, H-1β/H-5, H-1β/H-9, H-3β/H_3-19 H-3β/H-5, H-2α/H_3-18, H_3-18/H_3-20, H_3-18/H-6α, H_3-20/H-7α, H-7α/H-11b, H-9/H-17a, H-9/H-12, H-17a/H-12, H-12/H_2-16, H-17b/H-7β, and H-11a/H-1α, together with Chem3D modeling, implied a conformation for compound **1** as shown in Figure 3, where the two six-membered rings A and B were *trans*-fused and existed in a chair and a twisted boat conformation, respectively, the H-5 proton was found to be β-axially oriented, the methyl groups Me-18 and Me-20 were both in an α-axial position, and the double bond of C-12 and C-13 was *Z*-configuration. After finishing the elucidation of the relative configuration, the absolute configuration of **1** was established by comparing the experimental and calculated ECD spectra.[19] The calculated ECD spectra were obtained as follows. Starting from the conformation of **1** deduced from NOESY correlations and Chem3D modeling, conformational searches by MOE software[17] and the final geometry optimization on the B3LYP/6-31+G(d,p) level by the Gaussian 09 package[18] were performed. Then, the ECD spectra were calculated at the CAM-B3LYP/SVP level with the CPCM model in acetonitrile. The obtained ECD spectrum of **1a** (Figure 4) matched the experimental

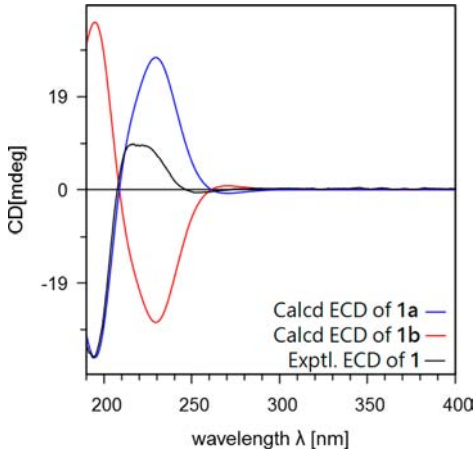

Figure 4. Calculated ECD spectra of **1a** (5*R*,9*R*,10*R*)-isomer and **1b** (5*S*,9*S*,10*S*)-isomer and the experimental ECD spectrum of **1** in acetonitrile.

results closely. All of the above evidence allowed the structure of **1** to be elucidated as (5*R*,9*R*,10*R*,12*Z*)-15-norlabda-8(17),11-diene-14-oic acid, which has been named longpene A.

DOI: 10.1021/acs.jafc.5b01584
J. Agric. Food Chem. 2015, 63, 5805−5812

The molecular formula of compound **2** was determined as $C_{15}H_{24}O_2$ on the basis of the HR-ESIMS. The IR spectrum showed an absorption band (1658 cm^{-1}) of an α,β-unsaturated ketone moiety. From the ^1H NMR spectrum of **2**, the typical signals of three methyl groups, two olefinic protons, and two methylene protons were observed (Table 2). The ^{13}C NMR spectrum of **2** exhibited 15 carbon resonances, comprising three quaternary carbons (C-4, C-9, and C-11), four methines (C-1, C-3, C-7, and C-10), five methylenes (C-2, C-6, C-8, C-12, and C-13), and three methyls (C-5, C-14, and C-15) indicated by DEPT and HMQC spectra. On the basis of the unsaturation degrees from the molecular formula and the above spectroscopic characteristics, compound **2** might be a monocyclic sesquiterpene. To verify this deduction, the following HMBC and $^1H-^1H$ COSY experiments were performed. In the HMBC spectrum, the correlations of the olefinic proton H-10 with the carbons C-8, C-9, C-11, C-12, and C-13, the methyl protons H_3-14 with the carbons C-1, C-7, and C-8, and the methylene protons H_2-12 with the carbons C-10, C-11, and C-13 disclosed the presence of an eight-membered ring, which was supported by the cross signals in the $^1H-^1H$ COSY spectrum. In addition to this eight-membered ring, a 3-methyl-2-butenyl fragment was also disclosed by interpretation of the HMBC spectrum, which showed the long-range couplings of the olefinic proton H-3 to the carbons C-1, C-2, C-4, C-5, and C-15 and the methyl protons H_3-5 (H_3-15) to the carbons C-4 and C-3. This 3-methyl-2-butenyl moiety was demonstrated to be linked to C-1 of the eight-membered ring by the corresponding HMBC and $^1H-^1H$ COSY correlations (Figure 2). Further analyses of the HMQC, HMBC, and $^1H-^1H$ COSY spectroscopic data resulted in the assignments of all the protons and carbons. Hence, the planar structure for **2** could be established, which possesses an eight-membered ring.

The stereochemistry of **2** was elucidated by interpretation of the NOESY spectrum. NOESY correlations observed for H-1/H-7, H-1/H-3, H-1/H-6b, H-2b/H-7, H-2a/H_3-14, H-3/H_3-5, H-7/H-8b, H_3-14/H-8b, H-8a/H-13a, and H-10/H_2-12, together with Chem3D modeling, implied a molecular arrangement for compound **2** as shown in Figure 3, in which the C-14 methyl group was in an α-position, the H-1 proton was in a β-position, and the double bond between C-10 and C-11 was found to be in *E*-configuration. After definition of the relative configuration, the same energy minimization, geometry optimizations, and TDDFT ECD calculations as for compound **1** were performed to confirm the absolute configuration. The obtained ECD spectra calculated at the CAM-B3LYP/SVP level with the CPCM model in acetonitrile for **2a** (1*S*,7*S*) and **2b** (1*R*,7*R*) are shown in Figure 5. By comparison of the experimental and calculated ECD spectra, the absolute configuration of **2** was determined to be 1*S* and 7*S*. Thus, compound **2** (longpene B) was elucidated as a skeletally novel sesquiterpene with an eight-membered ring, which may be derived from bisabolane sesquiterpenes through the cleavage of C-6 and C-5 and the cyclization of C-6 and C-13.

Compound **3**, a colorless oil, possessed a molecular formula of $C_{15}H_{22}O_3$ as supported by the HR-ESIMS. From the ^1H NMR spectrum of **3**, four methyl groups, two olefinic protons, and one oxygenated methine proton were displayed (Table 2). The ^{13}C NMR spectrum of **3** exhibited 15 carbon resonances. With the aid of DEPT and HMQC spectra, these 15 carbons were sorted as 4 methyls, 5 methines, 2 methylenes, and 4 quaternary carbons including 2 ketone carbonyl carbons

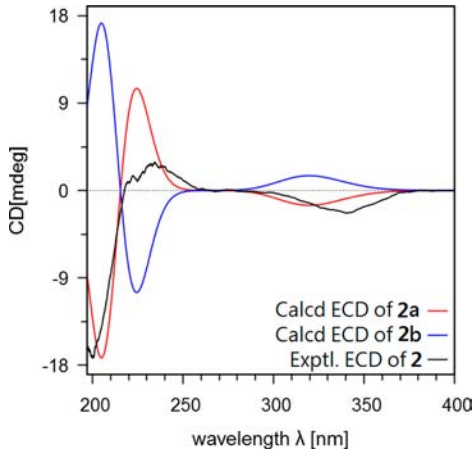

Figure 5. Calculated ECD spectra of **2a** (1*S*,7*S*)-isomer and **2b** (1*R*,7*R*)-isomer and the experimental ECD spectrum of **2** in acetonitrile.

conjugated with double bonds. The above spectroscopic features disclosed compound **3** should be a sesquiterpne with two ketone carbonyls.[3,5,26−28] To elucidate the sesquiterpene skeleton and accomplish the assignments of proton and carbon signals, an HMBC experiment was carried out. From the HMBC spectrum, the long-range correlations of the olefinic H-3 proton [δ_H 5.74 (1H, d, J = 1.2 Hz)] with carbons C-1, C-2, C-4, C-5, and C-15 and of the oxygenated H-5 proton [δ_H 4.32 (1H, t, J = 4.5 Hz)] with carbons C-1, C-3, C-4, C-6, and C-15 revealed the presence of a six-membered ring, which was supported by the $^1H-^1H$ COSY correlations (Figure 2). Furthermore, the side chain comprising C-7−C-14 was deduced from the HMBC correlations of H_3-14 to C-1, C-7, and C-8, H-10 to C-8, C-9, C-11, C-12, and C-13, and the corresponding $^1H-^1H$ COSY correlations. The linkage of the six-membered ring and the side chain allowed the establishment of planar structure for compound **3**, which was a bisabolane-type sesquiterpene.[26,27] This planar structure of **3** was the same as that of 5α-hydroxyl-1β-bisabolon-9-one reported in the literature,[29] and the NMR data for these two compounds were almost identical. However, the orientation of C-14 methyl in 5α-hydroxyl-1β-bisabolon-9-one was not assigned, and the absolute configuration of this compound was also unknown. To elucidate the configuration of **3**, a NOESY experiment and TDDFT ECD calculations were performed.

The NOESY correlations of H-1/H_3-14, H-3/H_3-15, H-5/H_3-15, H-5/H-6α, H-6β/H-7, H-8a/H_3-14, H-8b/H-10, and H-8a/H-10 and a Chem3D modeling revealed a conformation as shown in Figure 3. In this arrangement for compound **3**, the unsaturated six-membered ring was found to be a twist-chair preferential conformation, the side chain C-7−C-10 was α-equatorially oriented, and the hydroxy group at C-5 was β-axially oriented, which was supported by a triplet peak for H-5 and the coupling constant ($J_{5,6\alpha/6\beta}$ = 4.5 Hz). According to this arrangement inferred from the NOESY spectrum, the C-14 methyl group was determined to be in an α-position. The relative configuration of compound **3** was therefore characterized. On the basis of the relative configuration of **3** deduced from the above analyses, an energy minimization of this conformation was performed. Furthermore, the geometry optimizations were carried out and the calculated ECD spectra at the CAM-B3LYP/SVP level were obtained. A comparison of these ECD spectra revealed that the calculated ECD spectrum

DOI: 10.1021/acs.jafc.5b01584
J. Agric. Food Chem. 2015, 63, 5805−5812

of (1*R*,5*S*,7*S*)-**3** (Figure 6) was in good agreement with the experimental spectrum. Therefore, the absolute configuration of

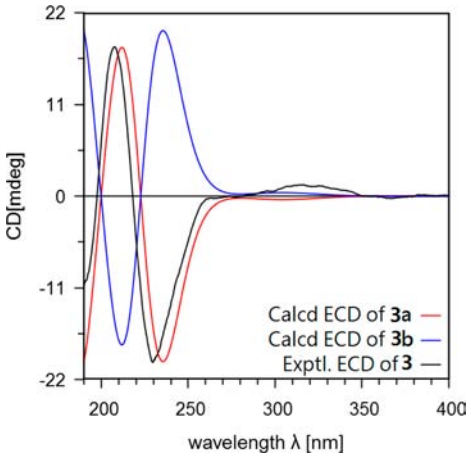

Figure 6. Calculated ECD spectra of **3a** (1*R*,5*S*,7*S*)-isomer and **3b** (1*S*,5*R*,7*R*)-isomer and the experimental ECD spectrum of **3** in acetonitrile.

3 was assigned as 1*R*, 5*S*, and 7*S*. Thus, the structure of **3** was assigned as shown and given the trivial name longpene C.

Compound **4** had the same molecular formula of $C_{15}H_{22}O_3$ as **3** on the basis of their HR-ESIMS data. The ^{13}C and ^{1}H NMR spectra (Tables 1 and 2) of compound **4** were almost identical with those of **3**, which implied that **4** should also be a similar bisabolane-type sesquiterpene. This bisabolane-type sesquiterpene structure was verified by the following HMQC, HMBC, and $^{1}H-^{1}H$ COSY experiments, and the two carbonyl carbons at δ_C 199.6 and 201.1, four olefinic carbons at δ_C 127.3, 163.9, 123.8, and 155.7, and one oxygenated carbon at δ_C 70.2 were attributed to C-2, C-9, C-3, C-4, C-10, C-11, and C-5, respectively. By further analyses of 2D NMR spectra, the planar structure of **4** was established, which was the same as that of **3**, whereas compound **4** was also found to almost have the same NMR data as 5β-hydroxyl-1β-bisabolon-9-one reported in the above-mentioned literature,[29] where the relative configuration of C-14 methyl and the absolute configuration were not determined. Using the same NOESY experiment and TDDFT ECD calculations, the configuration of **4** was elucidated as follows. NOESY correlations observed for H-1/H-5, H-1/H_3-14, H-3/H_3-15, H-5/H-6α, H-6β/H-7, H-8a/H_3-14, and H-8a/H-10, together with Chem3D modeling, implied a conformation for **4** as shown in Figure 3, where the protons H-1 and H-5 were both in an α-position with an axial orientation, and the C-14 methyl group was found to be in a β-position. On the basis of the relative configuration of **4**, the calculated ECD spectra were obtained using TDDFT method, of which the calculated ECD spectrum for (1*S*,5*S*,7*R*)-**4** (Figure 7) matched the experimental spectrum closely. The absolute configuration of **4** was therefore determined as 1*S*, 5*S*, and 7*R*, and compound **4** was given the trivial name longpene D.

By analyses of the NMR spectroscopic data and comparison with the literature, the remaining known compounds were elucidated as *ar*-tumerone, **5**;[27] turmeronol B, **6**;[28] turmeronol A, **7**;[28] intermedin B, **8**;[30] bisacurone, **9**;[31] *ar*-dihydroturmerone, **10**;[27] curzerenone, **11**;[32] curcumenol, **12**;[33] isocurcumenol, **13**;[34] procurcumenol, **14**;[35] zedoardiol, **15**;[36,37] and zedoalactone F, **16**.[38]

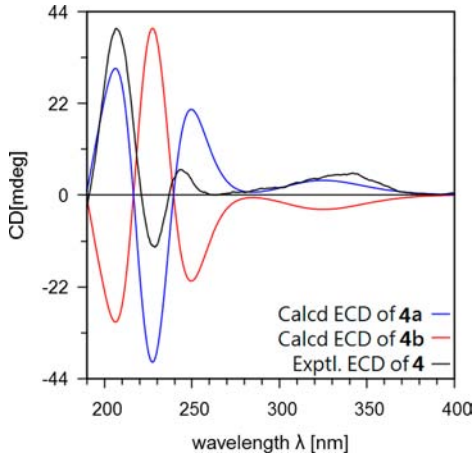

Figure 7. Calculated ECD spectra of **4a** (1*S*,5*S*,7*R*)-isomer and **4b** (1*R*,5*R*,7*S*)-isomer and the experimental ECD spectrum of **4** in acetonitrile.

To explore the potential pharmacological activities of these terpenoids and search for NO inhibitors as candidates for inflammatory diseases,[39] terpenoids **1**−**16** isolated from the rhizomes of *C. longa* were assayed for their NO inhibitory effects in murine microglial BV-2 cells according to a method previously reported.[40] 2-Methyl-2-thiopseudourea sulfate (SMT) was used as a positive control (IC_{50} = 2.8 μM). All of the isolated terpenoids exhibited inhibitory activities on LPS-induced NO production, and the IC_{50} values are shown in Table 3. The (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay showed that these compounds had no significant cytotoxicity to the BV-2 cells at their effective concentrations for the inhibition of NO production (data not shown).

Table 3. IC_{50} Values of Compounds 1−16 Inhibiting NO Production in BV-2 Cells

compound	IC_{50} (μM)	compound	IC_{50} (μM)
1	74.0	**10**	>100
2	>100	**11**	>100
3	87.3	**12**	>100
4	98.1	**13**	23.6
5	92.1	**14**	97.0
6	49.0	**15**	37.1
7	>100	**16**	95.4
8	30.0	SMT[a]	2.8
9	29.8		

[a]SMT (2-methyl-2-thiopseudourea, sulfate) was used as a positive control. Data are presented on the basis of three experiments.

In conclusion, the present phytochemical investigation on *C. longa* has led to the isolation and characterization of 2 new and 14 known terpenoids, **1**−**16**. Their structures, especially the absolute configurations of **1**−**4**, were elucidated by analyses of their NMR spectroscopic data and comparison of their calculated and experimental ECD spectra. Among them, compound **1** is a rare norditerpene with an *ent*-labdane skeleton, and **2** is a skeletally novel sesquiterpene having an eight-membered ring. In the biological screening executed, all of the isolated terpenoids displayed NO inhibitory effects, and compound **13** exerted the most inhibition against LPS-induced NO production in BV-2 cells. The discovery of two new

compounds further elucidated the chemical components of *C. longa* used a food spice, and these bioactive terpenoids with NO inhibitory activities implied that the natural spice *C. longa* may be potentially promotive to human health.[39]

24.03	217	xylose	29.8
26.16	204	mannose	5.6
30.45	217	galactose	5.6
31.74	204	glucose	10.0

new way to apply the polyphenols and soluble polysaccharide fibers for biomedical or food preservation based on their medical function,[12] excellent film-forming potential, and homogeneous dispersion in water.[27,28]

MATERIALS AND METHODS

Materials and Reagent. *Phyllanthus emblica* residues were obtained from South Subtropical Experimental Station (Jingdong), Research Institute of Resource Insects, Chinese Academy of Forestry, located in Yunnan. Hydrochloric acid and 95% ethanol were purchased from Guanghua Technologies Co. Ltd. (Guangzhou, Guangdong, China). Tannin, anhydrous calcium chloride, and gelatin were from Crystal Pure Industrial Co. Ltd. (Shanghai, China).

Fabrication of SDF. SDF was extracted according to the modified previous method.[29,30] The residue of *P. emblica* was dried in a vacuum drying oven (VOS-300VD, Tokyo Chemical Equipment, Tokyo, Japan) at 105 °C and smashed into an 80 mesh sieve. SDF was extracted from 30 g of residue of *P. emblica*, and then residue was digested with 500 mL of hydrochloric acid (5%, volume fraction) at 80 °C for 8 h to extract SDF. After these treatments, the sample was filtered to remove solid. Remaining liquid was suspended in 4 times volumes of 95% ethanol to precipitate SDF. The precipitate was allowed to form at room temperature for 0.5 h, followed by centrifugation at 8000 rpm for 15 min. The residue was washed twice with 78% ethanol and 95% ethanol, respectively, and was dried in a vacuum drying oven to constant weight at 60 °C. Then, SDF was stored at 4 °C for further use.

Fabrication of SDF−Tannin Self-Assembled Film. At first, the SDF−tannin self-assembled nanoscale clusters were prepared by dissolving 1 g of SDF in 50 mL of deionized water at 60 °C. The solid of tannin (1, 2, 3, and 4 g) and $CaCl_2$ were put in SDF solution to be stirred for 1 h before cooling to room temperature, followed by centrifugation at 8000 rpm for 30 min. The residue cluster was washed several times with deionized water to take away unchelated component and dried at 60 °C for further use.[31,32] Ten grams of gelatin was placed in a 150 mL beaker, followed by the addition of 100 mL of deionized water at 60 °C for 2 h. The gelatin solution was not stirred and allowed to cool to room temperature to form a hydrogel. A certain amount of the SDF−tannin self-assembled nanoscale clusters was dispersed in deionized water after sonication for 30 min and then added in this beaker to observe the phenomenon of gelatin hydrogel surface.

Characterizations. *Fiber Quality Analysis of SDF.* The size distribution analysis of individual SDFs was performed using a fiber quality analyzer (FQA) (Lda02, Optest, Ontario, Canada).[33] The quantity of SDF was maintained from 25 to 40 roots per second. Equal fiber length and width were measured.

Zeta Potential Analysis. Zeta potential was measured with a Lazer Zee microelectrophoresis analyzer from Mutek. Dilute SDF suspensions of interest were placed into the chambers of the capillary cell of this device. Looking through a microscope, the voltage was adjusted until the SDF particles appeared stationary.

Gel Point Determination. Gel point was determined according to viscosity change. One gram of SDF and 4 g of tannin were dissolved in 100 mL of deionized water. Then the viscosity value was recorded while calcium ion was gradually added. To equilibrate the solution, each sample was allowed to settle at room temperature for 30 min. The measurement was done using a rheometer (N1000, Eyela, Tokyo, Japan) at 20 °C.

Fourier Transfer Infrared Spectroscopy (FT-IR). The sample was placed in FT-IR (Tenson 27, Brook, MI, USA), with the scanning range set from 4000 to 400 cm^{-1} with a resolution ratio of 4 cm^{-1} to observe typical functional absorption peak.

Wide-Angle X-ray Diffraction (WAXD). WAXD measurements were carried out on a WAXD diffractometer (D8-Advance, Bruker, Madison, WI, USA) in reflection mode. The X-ray used was Ni-filtered Cu Kα radiation with a wavelength of 1.5418 Å. The voltage was set at 40 kV and the current was set at 40 mA. Measurement was done by 2θ = 2° min^{-1} scan over a 2θ range of 8−40°.[16]

Differential Scanning Calorimetry (DSC). The samples were investigated by DSC instrument (DSC200, Netzsch, Bavaria, Germany) under the protection of nitrogen. The test temperature ranged from 35 to 500 °C, with a heating rate of 10 °C/min, under which condition the endothermic peak of the DSC curve was observed.

Transmission Electron Microscope (TEM). TEM observations were performed using a Philips CM30 operated at 100 kV. A droplet of sample suspension was placed on a copper grid covered by a thin SDF film and allowed to dry at 80 °C overnight.

Scanning Electron Microscope (SEM). The sample was evenly dispersed on conducting paper, to separate the superficial and

DOI: 10.1021/acs.jafc.5b00192
J. Agric. Food Chem. 2015, 63, 5813−5820

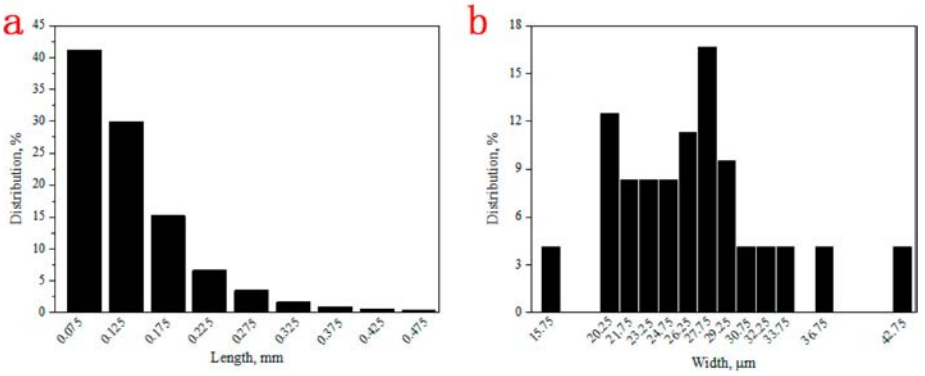

Figure 1. Length distribution of SDF (a); width distribution of SDF (b).

nonadherent part. The sample was placed in the SEM (IGMA, Zeiss, Oberkochen, Germany) for observation of its appearance.

Controllable Film Thickness. Film thickness was determined by using a thin film measurement system. The samples for microscope (VHX-1000, Keyence, Tokyo, Japan) observation were scraped by using a sharp razor blade and placed on a glass slide.[17] The proportion of SDF to tannin ranged from 1:1 to 1:4, all of which were applied to the same amount of calcium ion. The film thickness was measured by image-processing software.

In Vitro Cytotoxicity Test. The MTT method was used to test the in vitro cytotoxicity. In brief, 1×10^4 cells per well were seeded in 96-well plates and exposed to different types of film. After the exposure was complete, the culture medium was removed from each well and replaced with 100 mL of new medium containing MTT (0.5 mg/mL) and incubated for 3 h at 37 °C. The resulting formation product was dissolved by adding an equal amount of acidified isopropanol. Ninety-six-well plates were centrifuged at 2500 rpm for 10 min. Then, a 100 mL supernatant was transferred to other fresh wells of a mictotiter plate and absorbance was measured at 570 nm by using a microplate reader (Varioskan Flash, ThermoFisher, Foster City, CA, USA). This value corresponds to a 0% decrease in MTT conversion activity and represents 100% cell viability.

Antibacterial Activity Test. The antibacterial activity of film against Gram-positive bacteria including *Staphylococcus aureus*, flavobacterium, *Bacillus subtilis*, and Gram-negative bacteria involving *Pseudomonas aeruginosa* was determined using the modified disk diffusion method. Bacteria were incubated at 37 °C for 36 h before films were pasted onto agar plates. The surface of self-assembled films was observed and recorded.[34]

Alcohol Insulation Test. Alcohol solution (60 wt %) dyed by melanin was poured onto SDF−tannin self-assembled film to observe if the alcohol infiltrated into the gelatin hydrogel. The optical microscope (VHX-1000, Keyence) and SEM (IGMA, Zeiss) were employed to observe changes of the film (SDF/tannin = 1:2) after soaking in a 60 wt % alcohol solution.

RESULTS AND DISCUSSION

Determination of SDF. As we know, comprehensive utilization of residue resource has potent economic value and exploitation prospects. Preparation of SDF could realize *P. emblica* residue value. *P. emblica* SDF properties were not found in existing papers, so it was necessary for us to characterize the physical and chemical properties of SDF extracted from *P. emblica* residue. As Table 1 shows, the main components of the SDF was pectin, representing approximately 45 wt %. There was 27 wt % hemicellulose and other water-soluble polysaccharides in the SDF exacted from *P. emblica* residue. The high pectin content may be attributed to the high pulp content of the *P. emblica* residue. The monosaccharide composition of SDF was determined by our previous experiment.[35] The monosaccharide composition was determined by GC-MS and is shown in Table 1; SDF was mainly composed of ribose, arabinose, rhamnose, xylose, mannose, galactose, and glucose, which bears a certain similarity to hemicellulose.[36] Hemicellulose could be easily incorporated with physical or chemical cross-linking in forming special property clusters, film, and hydrogel, and so did SDF.[37] FT-IR spectra of the SDF showed strong adsorption peaks at 1744 and 3418 cm^{-1}, which were attributed to the −CO− of the carboxyl group and the ionizable −OH group due to the high pectin content of the SDF. Meanwhile, the value of the zeta potential test was −14.2 mV, which was an important factor to estimate sample stability and to judge opposite charge. It can indicate that the SDF aggregates are negatively charged and relatively stably dispered in aqueous solution. Fiber length and width distribution of SDF were determined by fiber quality analyzer as shown in Figure 1. The length distribution of SDF ranged from 0.075 to 0.475 mm. The lengths of the main distributions at 0.075 and 0.125 mm were 41.20 and 29.89%, respectively. In the present investigation, the length of SDF was much bigger compared to rod-like hemicellulose.[38] The main width distribution was 20.25−29.25 μm. These SDF showed good properties of film-forming ability due to their large geometrical size. The result of the dietary fiber analysis indicated that the SDF extracted from *P. emblica* residue could fairly stably disperse in water by the ionized carboxyl groups of the different kinds of monosaccharide.[8] In addition, reagent labels of hydrolyzable tannins show its formula is $C_{76}H_{52}O_{46}$, corresponding to a combination of 10 mol of gallic acid and 1 mol of glucose. All molecules were connected by ester bonds. A large number of phenolic hydroxyl groups are exposed on the surface of the molecule.

Preparation and Characteristics of Nanoclusters. Figure 2 shows the system viscosity at the gelation point as a function of the weight of calcium ion. The curve of viscosity of the SDF−tannin complex system showed the gel−sol transition behavior. With the increase of calcium ion, the viscosity of the system increased first. The cross-linked clusters were prepared with calcium ion, which functioned as contact phenolic hydroxyl group (tannin) and carboxylic group (SDF) by coordinate bond.[39] The complex system changed from solution to dispersed nanoparticle at the gel point (calcium ion, 19.2 mg) as the TEM images of Figure 3 show. Subsequently, the cross-linked clusters formed with calcium ion increased while the value of viscosity declined until constant. Major differences in the shape distribution and the internal structure of sample were visualized in the TEM images (Figure 3). Without calcium ion, the sample SDF−tannin mixture, which remained clear,

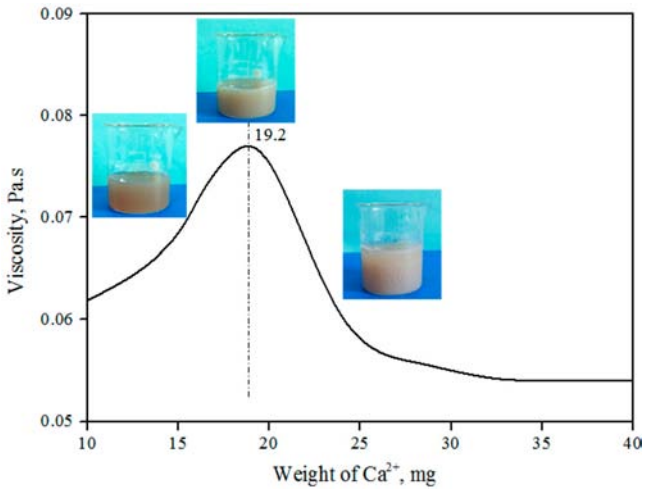

Figure 2. Weight of calcium ion dependence of SDF−tannin complex system viscosity.

could form a micrometer-scale film on the surface of the copper grid. On the contrary, the structure of SDF−tannin clusters after cross-linking was a series of nanoscale sphere (d < 50 nm), which could homogeneously disperse in solution. This proved that tannin and SDF were aggregated by cross-linking to form nanoscale particles.

We employed the FT-IR, XRD, and DSC tests to investigate the interaction between the SDF and tannins before and after cross-linking induced by calcium ion. FT-IR is used as an analytical tool to characterize the chemical change of the functional groups. The nanoclusters showed a wider hydroxyl association peak than SDF, and narrower than that of tannin. Because tannin contained a large number of phenolic hydroxyls, only a part of phenolic groups were coordinated by calcium ion, whereas the remaining part was involved in hydrogen bond formation with itself and hydrogel of SDF.[40] Figure 4 shows the adsorption intensity of SDF−tannin nanoclusters decreased obviously at approximately 2930 cm^{-1}, which belonged to sugar C−H stretching vibration; therefore, the configuration of SDF and tannin was changed after chelating with tannin and calcium ion.[41] Meanwhile, because the carboxyl group of the carbohydrate was mainly calcium cross-linked, the shift of these peaks from 1744 to 1736 cm^{-1} was likely to result from the electrostatic interaction between SDF and divalent cations. The peaks at 1708, 1536, and 1200 cm^{-1} belonged to the C═O stretch of esters, the stretch of aromatic rings, and C—OH stretches of phenols, respectively, the intensity of which decreased remarkably.[42] This can be attributed to the metal−ligand coordination restricting the movement of the tannin molecule.

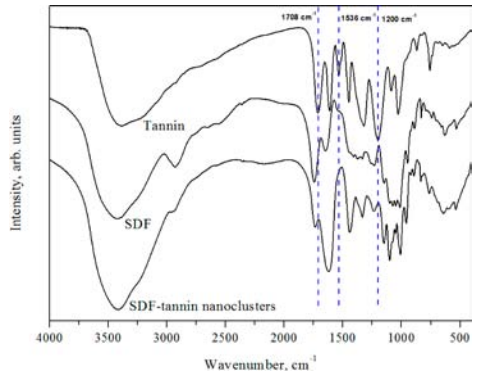

Figure 4. FT-IR spectra of tannin, SDF, and SDF−tannin nanoclusters.

Figure 5 shows the XRD patterns of the tannin, SDF, and SDF−tannin nanoclusters. XRD was used to determine the crystallinity changes to detect the aggregation state of the molecule. On the basis of multipeak fitting, the noncrystallinity peak of tannin was at 25°. SDF had two noncrystallinity peaks and crystallinity peaks at 13°, 21°, and 34°, respectively. Remarkably, there was no obvious peak at the curve of SDF−tannin nanoclusters. The characteristic peak of SDF disappeared. Its features demonstrated that crystallization of the SDF was severely restricted by the interaction between SDF and calcium ion.

J. Agric. Food Chem. 2015, 63, 5813−5820

Following the literature studied, we used DSC to elucidate the effect of chelation on the thermal transition. Figure 6 shows

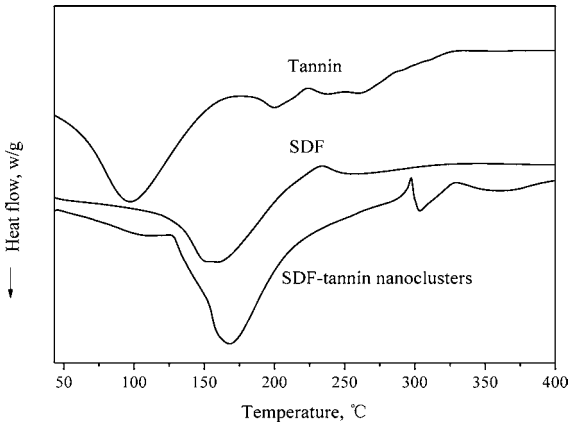

Figure 6. DSC thermograms of the tannin, SDF, and SDF−tannin nanoclusters.

the DSC curves of tannin, SDF, and SDF−tannin nanoclusters. There were two obviously endothermic peaks of tannin, SDF, and SDF−tannin nanoclusters. The low-temperature peak was ascribed to endotherm and the high-temperature one to restricted decomposition or melting state. The endotherm of SDF−tannin nanoclusters (168.2 °C) was significantly higher than that of SDF (157.5 °C) or tannin (96.8 °C). SDF−tannin nanoclusters showed the highest melting state temperature (303.4 °C) followed by SDF (250.9 °C) and tannin (157.5 °C). Compared to SDF, the endothermic peak of SDF−tannin nanoclusters was increased by 11.3 °C and decomposition temperature was elevated by 52.5 °C. The exothermic transition was shifted to the high temperature. From the above analysis, this behavior is another demonstration of the strong interaction between calcium and SDF−tannin aqueous dispersion.

Self-Assembly Behavior of SDF−Tannin Nanoclusters on the Protein Surface. Four kinds of film are shown in Figure 7. When the weight proportion of SDF to tannin was 1:1, the film was thin and uneven. The appearance of the other three (1:2, 1:3, and 1:4) films was more homogeneous and dense. This demonstrated that the amount of tannin would affect its ability to adhere to gelatin. As the proportion of tannin

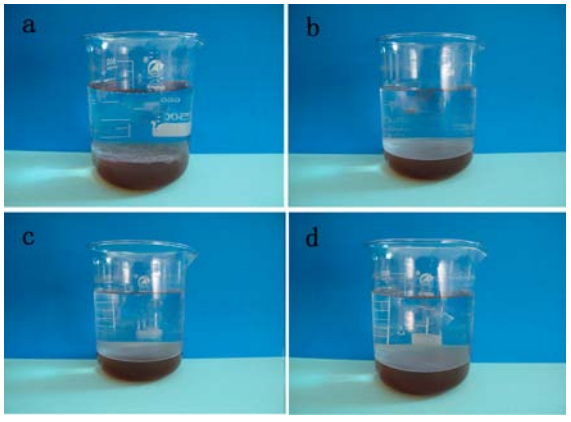

Figure 7. Films prepared at different tannin and SDF proportions: ratios 1:1 (a), 1:2 (b), 1:3 (c), and 1:4 (d).

increased, more uncovered phenolic hydroxyl groups were retained to form more hydrogen bonds with the protein on the surface of gelatin. The attractive force between SDF−tannin nanoclusters and gelatin was enhanced, and the formed film was more stable. The thickness of the SDF−tannin self-assembled films could be controlled by changing the tannin concentration. In Figure 8, the thickness of the film was 144 μm

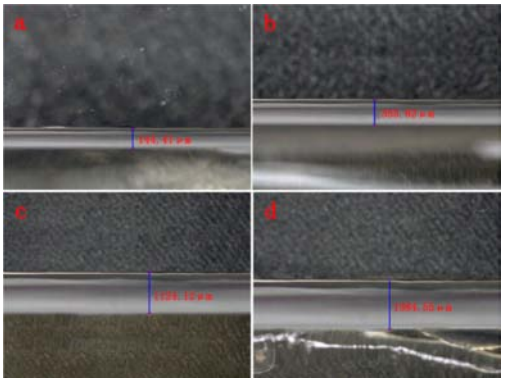

Figure 8. Photographs of SDF−tannin self-assembled films with different proportion of SDF to tannin: ratios 1:1 (a), 1:2 (b), 1:3 (c), and 1:4 (d).

at the ratio of 1:1. It increased as the proportion of tannin rose, with the maximum reaching 1384 μm at a ratio of 1:4. It is quite evident that film thickness could be changed by controlling the proportion of tannin.

Figure 9 shows SEM recorded for SDF and SDF−tannin self-assembled film specimens. The SDF micrograph depicted

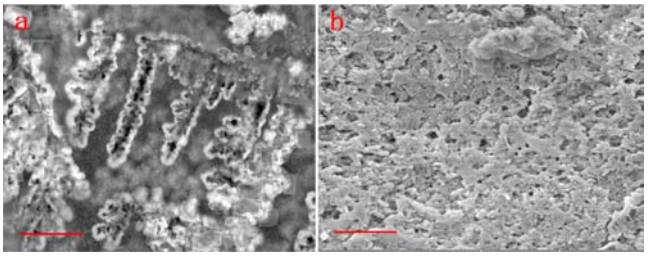

Figure 9. SEM images of SDF (a) (bar = 30 μm) and SDF−tannin self-assembled film (b). (Bar = 200 nm.)

apparent features of rod-like microscale. According to the TEM and SEM results, the formation process of self-assembly film was evidently confirmed. First, the nanoclusters were fabricated by the electrostatic interaction between calcium ion and SDF−tannin mixed system. Calcium ion as an initiator was an ionic compound that could combine with SDF and tannin through metal−ligand coordination. Then, SDF and tannin were cross-linked to gel and aggregated to form nanoclusters. These nanoclusters had phenolic hydroxyl groups and showed properties of tannins, which could adhere to the surface of protein.[43] Finally, the smooth film was formed by the hydrogen-bonding actions of −OH (tannin) and $-NH_2$ (the protein surface of gelatin hydrogel).[15] The process mechanism is given in Figure 10.

Properties of the Self-Assembled Film. Similar to other biomedical materials, the toxicity of film should be evaluated. Figure 11 shows the cell tended to grow more rapidly on the surface of the film. Of the four types of film, the toxicity was

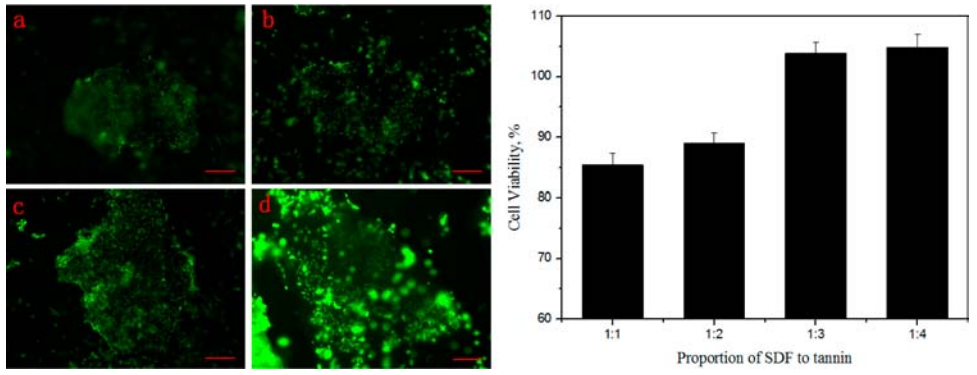

Figure 11. Photographs of cell growth on the surface of the films with different proportions of SDF to tannin: ratios 1:1 (a), 1:2 (b), 1:3 (c), and 1:4 (d). (Bar = 100 μm.) Histogram shows the cell viability of the films.

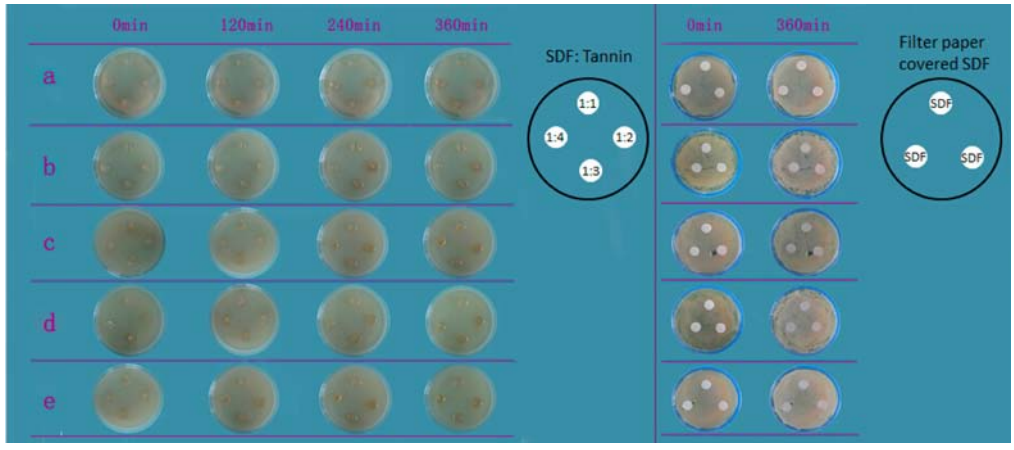

Figure 12. Antimicrobial activity of SDF−tannin self-assembled film and the filter paper covered SDF at different reaction times against *Staphylococcus aureus* (a), flavobacterium (b), *Bacillus subtilis* (c), *Pseudomonas aeruginosa* (d), and *Escherichia coli* (e).

decreased as tannin increased. Film a showed the cell viability value was 85.40% followed by film b (89.04%), film c (103.90%), and film d (104.90%). It could be assumed that the SDF−tannin self-assembled film could be considered to be safe under normal conditions. All of the films exhibited great cell viability and adhesion, which could be attributed to the protein attachment properties of tannin. The results showed that SDF−tannin self-assembled film had good biocompatibility as well as application potential for wound recovery. Figure 12 shows the antibacterial activity of the film against flavobacterium, *Bacillus subtilis*, Gram *Pseudomonas aeruginosa*, and *Escherichia coli*. Five types of bacteria could not grow on the surface of four films with the proportion of SDF to tannin ranging from 1:1 to 1:4. The broad-spectrum antibacterial property of SDF−tannin self-assembled film was mainly attributed to the tannin component. The result also indicates that the activity of tannins as natural antimicrobials for food preservation are also retained after the cross-linking process.[44] In addition, there was no inhibition zone because tannin was fastened to the film. This demonstrated that the SDF−tannin self-assembled film could be applied in the field of food preservation and biomedical wound dressing to inhibit bacterial growth.

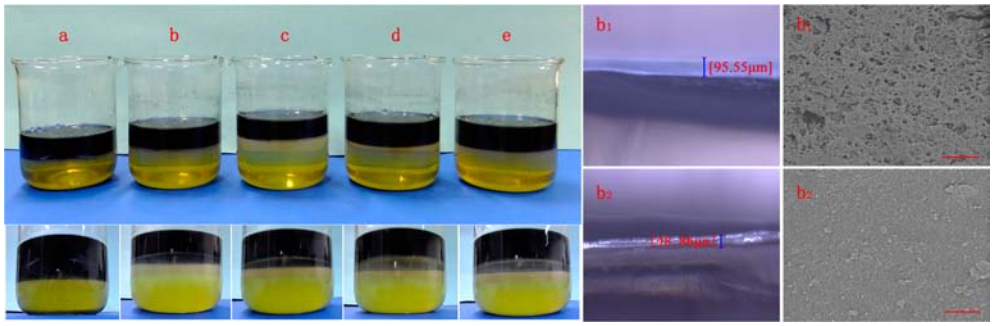

Figure 13. Films with different proportions of SDF to tannin (a, 0:1; b, 1:1; c, 1:2; d, 1:3; e, 1:4) were used to defend alcohol; cross-section image and SEM image of the film (SDF/tannin = 1:2) before (b1) and after (b2) soaking in 60 wt % alcohol solution. (Bar = 10 μm.)

Gelatin was used to imitate human gastric mucosa in this experiment, which helped evaluate if SDF−tannin self-assembled film could prevent alcohol passing to reduce gastric mucosa damage from alcohol. Alcohol (50 mL) was added into the system to simulate drinking to test if it had any impact on the film-covered gelation surface. It turned out that the film was well attached at gelatin and maintained stability even in the presence of high concentrations of alcohol (Figure 13). We have tested the four kinds of proportion of SDF to tannin film as the alcohol insulation. Simple SDF could not be tested because they cannot form membrane structure by themselves. The film containing only tannin cannot prevent alcohol passing. In contrast, tannin film with any proportion of SDF added could served as an alcohol barrier. This can be attributed to the special alcohol insolubility of SDF. In Figure 13, we find that film thickness shrank from 95.5 to 48.8 μm after soaking in alcohol solution for 12 h. As the film shrank, a dense structure without holes was formed that can prevent alcohol passing, as the SEM images showed. Thus, SDF−tannin self-assembled film could prevent gastric mucosa damage from alcohol and is applicable in the pharmaceutical area.[45]

In this work, we successfully developed a facile route to prepare SDF−tannin nanoclusters by using calcium ion as a bridging cross-linking agent. The appearance of SDF−tannin nanoclusters was a series of nanoscale microspheres. Meanwhile, we found there was a strong hydrogen interaction between the tannin component of nanoclusters and protein, through which the SDF−tannin nanoclusters could self-assemble on the surface of the protein to form a dense film. The SDF−tannin self-assembled film, the thickness of which could be controlled by the concentration of tannin, showed nontoxic and broad-spectrum antimicrobial properties. It is worth noting that the SDF−tannin self-assembled film could well attach to gelatin and prevent damage to gastric mucosa from alcohol because the film shrank due to the special alcohol insolubility of SDF. In conclusion, this work provided a novel strategy to develop the application of SDF and tannin for the food preservation and biomedical wound-dressing fields.

and aqueous phases to see if the mode of addition affected AOX efficacy in a low-moisture system. The AOX efficacy was related to cracker structure and AOX partitioning via imaging with confocal microscopy. Commercial AOX of varying hydrophobicities were also used to evaluate the relationship between hydrophobicity and AOX efficacy.

Improving our understanding of AOX mechanisms has broad and long-lasting implications. Development of new, tailored AOX that can extend product quality, thereby reducing industry loss and supporting development of foods with extended shelf life, can have benefits to consumers as well as meals for space and military programs. Improved AOX technologies will also improve the health and wellness of the food supply by allowing greater utilization of heart-healthy polyunsaturated fats and other bioactive lipids susceptible to oxidation.

MATERIALS AND METHODS

Materials. Baking soda (Arm & Hammer), iodized table salt (Morton), and all-purpose flour (Gold Medal) were purchased from local grocery stores. Interesterified soybean oil 762420 (henceforth referred to as ISO) was provided by Archer Daniels Midland Co. (Decatur, IL, USA). Dry goods were stored in closeable freezer bags to prevent moisture sorption; ISO was kept frozen (−20 °C) until use. Dodecyl and eicosyl rosmarinate esters were prepared as described previously (structures in original publication).[11] Rosmarinic acid, the fluorescent probe Nile Red, and all other chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA). All solutions were prepared using double-distilled water.

General Sample Manufacture and Preparation. Crackers were prepared as previously described[12] by premixing dry ingredients (sifted flour, baking soda, and salt) and then blending with the ISO until the fat was homogeneously cut into the flour; all mixing was done with a KitchenAid model KSM95 (Mississauga, ON, Canada) and associated attachments. Water was then added to form a dough, which was briefly kneaded by hand until all flour was visibly incorporated (∼30 s). Ten grams of additional flour was sprinkled on the surface of a baking mat to prevent sticking; all of this flour was incorporated during kneading. The dough was flattened by twice sheeting it through a pasta roller (KitchenAid KPSA attachment; thickness setting 2). Crackers (2.5 cm × 2.5 cm) were cut from the dough with a pizza cutter and baked on an ungreased cookie sheet at 163 °C for 21 min in an electric oven (General Electric model JB350DFWW; Fairfield, CT, USA). After baking, crackers were coarsely crushed using a mortar and pestle, and 0.5 g was placed into acid-washed, 10 mL glass GC vials (Supelco Analytical, Bellefonte, PA, USA). The vials were closed with aluminum caps containing PTFE/silicone septa (Supelco Analytical) and stored at 55 °C in the dark for 30−75 days depending upon lag phase. Crackers for confocal image analysis were stored in closeable freezer bags in the dark at ∼4 °C and imaged within 3 days of manufacture.

AOX and Dye Incorporation into the Crackers. One hundred and fifty-nine micromoles of rosmarinic acid (R0) or its 12- (R12) and 20- (R20) carbon esters (henceforth collectively referred to as "rosemary AOX") or 344 μmol of synthetic antioxidants [propyl gallate (PG), *tert*-butylhydroquinone (TBHQ), and butylhydroxy toluene (BHT)] were dissolved in 1.0 mL of ethanol and mixed with ISO in the KitchenAid mixer (model KSM95) for 1 min before the dry ingredients were added. Alternatively, rosmarininc acid esters in 1.0 mL of ethanol were mixed with water before dough formation in some experiments. In all cases, the same volume of ethanol was added to control (no AOX) treatments. Nile Red in ethanol (0.5 mL) was added to the ISO prior to mixing in the rosemary AOX and control treatments.

Measurement of Lipid Oxidation. Lipid hydroperoxides, the primary oxidation products, were measured in triplicate using a modified version of the International Dairy Federation method as previously described by Shantha and Decker.[13] In short, coarsely crushed crackers (0.105 g) were pulverized using a mortar and pestle and added to a mixture of chloroform and methanol (5 mL; 2:1 v/v), vortexed briefly, and centrifuged (3400*g*) for 10 min to extract the hydroperoxide-containing lipid fraction. This extract (200 μL) was mixed with (1) 16.7 μL of a 50:50 solution of ferrous sulfate (66 mM in double-distilled water) and barium chloride (38 mM in 0.4 N HCl) and (2) 16.7 μL of ammonium thiocyanate (3.9 M in double-distilled water). The final mixture was vortexed, covered to prevent evaporation, and incubated 20 min at ambient temperature as color developed. Absorbance was measured at 500 nm on a Genesys 20 spectrophotometer (ThermoSpectronic, Waltham, MA, USA). The concentration of hydroperoxides was calculated from a cumene hydroperoxide standard curve.

Headspace hexanal, the secondary oxidation product, was measured in triplicate with a GC-2014 Shimadzu gas chromatograph equipped with an AOC-5000 autosampler (Shimadzu, Kyoto, Japan) based on the solid phase microextraction (SPME) method of Panya et al.[8] Specifically, a 50/30 μm divinylbenzene/carboxen/polydimethylsiloxane (DVB/Carboxen/PDMS) SPME fiber (Supelco, Bellefonte, PA, USA) was inserted through the vial septum and exposed to the sample headspace for 10 min at 55 °C. The SPME fiber was desorbed at 250 °C for 3 min in the gas chromatograph detector at a split ratio of 1:7. The temperatures of the oven, injector, and flame ionization detector were 65, 250, and 250 °C, respectively, and samples ran for 6 min. Volatile aldehydes were separated on a fused-silica capillary column (30 m × 0.32 mm i.d. × 1 μm) coated with 100% poly(dimethylsiloxane) (Equity-1, Supelco), and peak integration was calculated using Shimadzu EZstart (version 7.4) software. A standard curve made from crushed cracker spiked with known hexanal concentrations (hexanal was diluted in methanol with a range from 0 to 136 mmol hexanal per kilogram of cracker) was used to determine hexanal concentrations in the samples.

Measurement of Rosemary AOX. To prepare samples for high-performance liquid chromatography (HPLC), 0.150 ± 0.005 g of pulverized crushed cracker was mixed with 1 mL of methanol, sonicated for 30 min, and filtered (0.45 μm syringe filter Millex-FH, Millipore Corp., Bedford, MA, USA) into amber vials with polyethylene snap caps (Waters, Milford, MA, USA). HPLC determination of rosmarinic acid and its esters was carried out with a Hypersil gold C18 reversed phase column (250 mm × 4.6 mm, 5 μm) equipped with a Hypersil gold guard column (10 mm × 4 mm, 5 μm) (Thermo Scientific, USA) using an LC-10ATvp HPLC system (Shimadzu, USA). Samples were injected into the HPLC at a flow rate of 1 mL/min at room temperature using a mobile phase of either methanol (to detect rosemary antioxidants) or acetonitrile (to detect caffeic acid). Pure rosmarinic acid and its alkyl esters and caffeic acid were dissolved in methanol and used as standards. R0 and its esters were detected with a photodiode array detector (SPD-M10Avp, Shimadzu, USA) at 328 nm. Peak integration was performed using Shimadzu EZstart (version 7.4).

Confocal Microscopy. A Nikon confocal microscope (C1 Digital Eclipse, Tokyo, Japan) with a PL FLUOTAR ELWD 20.0 × 0.45 objective lens was used to capture the confocal images. Whole crackers were glued to a slide and imaged by quadrants, with at least four images taken in each quadrant. A 408 nm laser was used to excite the R0 and esters, and a 488 nm laser was used to excite Nile Red. Emission spectra were collected from 415 to 485 nm for the R0 and esters and from 485 to 545 nm for the Nile Red, and the resulting images were overlaid. Detector pinhole size was 150 μm. All resulting images consisted of 512 × 512 pixels, with a pixel size of 414 nm, and a pixel dwell time of 10.40 μs. Images were analyzed using EZ-CS1 (version 3.8) software (Nikon, Melville, NY, USA).

Statistical Analysis. Differences between treatments were determined by differences in the laboratory phase of lipid hydroperoxide and hexanal formation. The cutoff for the end of the oxidation lag phase was marked by the first datum point that was significantly greater than the time-zero value with all subsequent data points also being significantly greater than the time-zero value. Means were compared using analysis of variance (General Linear Model with Tukey's Honestly Significant Difference test as a post hoc test for multiple comparisons). Statistical difference was set at $p < 0.05$. All

DOI: 10.1021/acs.jafc.5b01085
J. Agric. Food Chem. 2015, 63, 5821−5827

calculations were performed using XLSTAT statistical software (version 2006.3, Addinsoft, New York, NY, USA).

RESULTS

Sample Quality. To ensure consistent production, all crackers were made by one individual, trained for >8 h before experimentation, and all samples were consistent both visually and in final moisture content. To ensure reproducibility, cracker production steps were carefully controlled; two batches were freshly prepared for every treatment, and all treatments presented in a single figure were prepared the same day, including fresh control treatments.

Homologous AOX Series. R0 and its alkyl esters were selected as a means of varying hydrophobicity while keeping the AOX portion of the molecule constant.[11] The activity of each antioxidant was tested at 159 μmol because it corresponded to 500 ppm of R0, a concentration typically used by industry for AOX applications. R0 and its alkyl esters naturally fluoresce (blue region of Figure 1), allowing their location to be determined with confocal microscopy without the use of additional probes. Nile Red was used as a lipid-soluble confocal probe to view the lipids (green region of Figure 1) in the cracker. In all treatments, the ISO formed a continuous lipid phase surrounding the starch granules (data not shown), as was seen in a previous study.[12] AOX were first added by incorporating them in the lipid prior to dough formation.

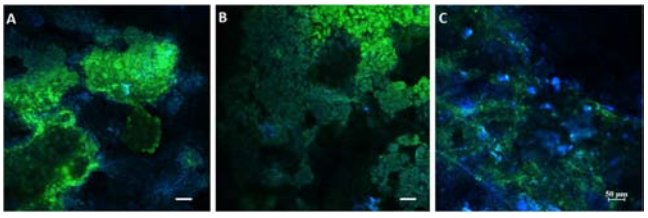

Figure 1. Fluorescence of Nile Red dye (green) and either (A) rosmarinic acid, (B) dodecyl (R12) rosmarinate ester, or eicosyl (R20) rosmarinate ester (blue) in crackers at day 0. Antioxidants were incorporated by mixing with the lipid phase prior to dough formation. Scale bars: 20 μm in panels A and B; 50 μm in panel C.

Confocal microscopy can provide useful information about the location of different components in foods, but it does have its limitations due to limits in resolutions and variations in focusing depths in foods with rough textures. Therefore, we attempted to keep our discussion of the confocal results as general and conservative as possible and realize that the images can be difficult to interpret. Figure 1A shows crackers containing free R0. In this system, the blue R0 tended to partition separately from the green lipid region. This is likely due to the low lipid solubility of R0, which agrees with findings by Panya et al.[8] in which <15% of R0 was found in the lipid phase of oil-in-water emulsions. In contrast, Figure 1B shows that the R12 ester of rosmarinic acid tended to overlap with the lipid, thereby creating more regions of turquoise areas in the confocal images and suggesting that the R12 ester was associated with the lipid more than R0. This would also be in agreement with Panya et al.,[8] who found that >90% of R12 was in the lipid phase of oil-in-water emulsions. The partitioning behavior of R20 is shown in Figure 1C. It differs from R0 and R12 in that it formed distinct regions of blue scattered throughout the cracker. It is unclear why this would occur because R20 is the most hydrophobic and would be soluble in the lipid. However, these images suggest that instead of forming a homogeneous mixture with the ISO, some of the R20 is self-aggregating apart from the ISO. This could occur if the concentration of the R20 used in these experiments exceeded its solubility in the ISO.

The difference in AOX partitioning observed via confocal microscopy was compared to the actual AOX efficacy. The esterified rosemary esters, which showed greater overlap with the lipid in the confocal images, significantly extended the lag phase of both hydroperoxide (Figure 2A) and hexanal (Figure 2B) development when the AOX was incorporated into the lipid phase prior to dough formation. R0 was the least effective. It extended the hydroperoxide lag phase only a few days compared to the control, but it actually increased the formation of headspace hexanal compared to the control, decreasing the hexanal headspace lag phase from 40 days (control) to 21 days (R0) (Figure 2B). This suggests the polar R0 destabilized hydroperoxides, perhaps by binding and solubilizing prooxidant metals or by reducing metals to their more reactive state, causing increased lipid hydroperoxide decomposition into secondary lipid oxidation products such as hexanal. In contrast, R20 and R12 both delayed hydroperoxide generation and extended the headspace hexanal lag phase, for R12 to 48 days and for R20 to 55 days.

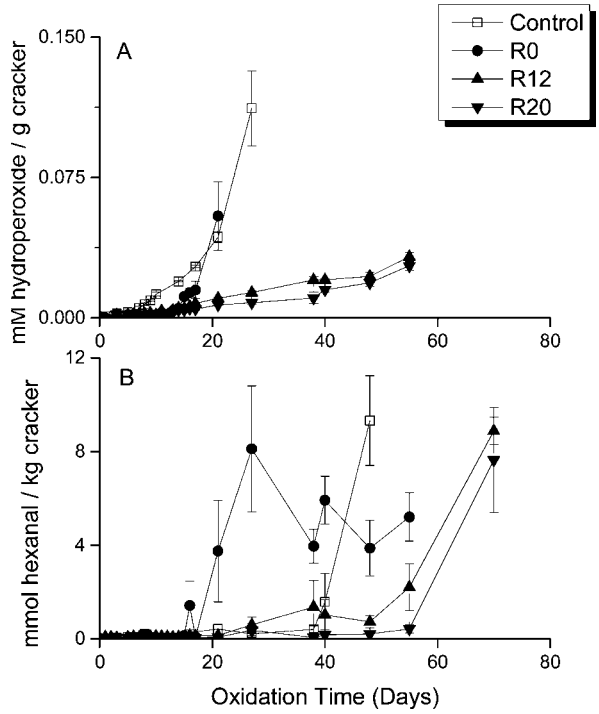

Figure 2. (A) Lipid hydroperoxides and (B) headspace hexanal in crackers with rosmarinic and its esters (chain lengths = 0, 12, or 20 carbons) incorporated into the lipid prior to dough formation. Crackers were stored in the dark at 55 °C. Standard error bars are smaller than data points in some instances.

To determine how AOX partitioning and efficacy were affected by the mode of incorporation, R0 and its alkyl esters (R12 and R20) were also dissolved in ethanol and added to the water phase prior to formation of the dough (Figure 3). Addition of the AOXs to the water altered AOX activity because none of the treatments extended the hydroperoxide lag phase compared to the control, although hydroperoxide

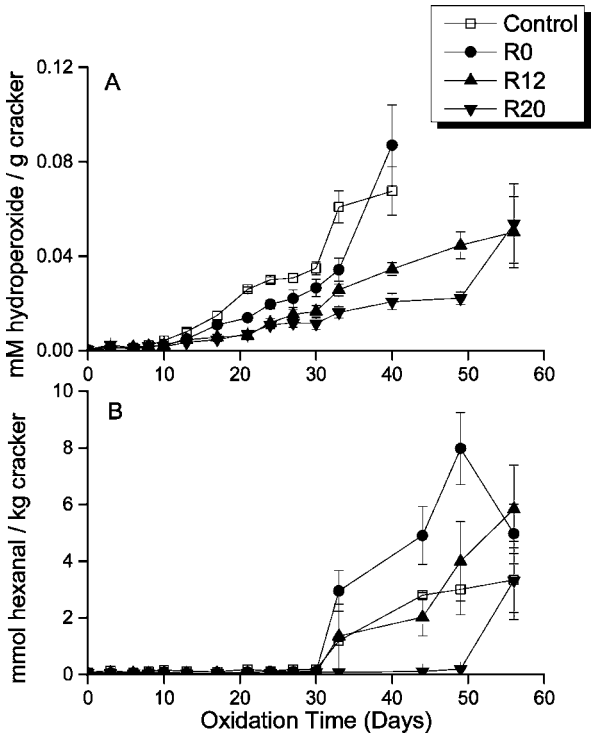

Figure 3. (A) Lipid hydroperoxide and (B) headspace hexanal formation in crackers made by incorporating rosmarinic ester antioxidants (chain lengths = 0, 12, or 20 carbons) into the aqueous phase prior to dough formation. Crackers were stored in the dark at 55 °C. Standard error bars are smaller than data points in some instances.

generation was slower in all three rosemary treatments (Figure 3A). However, R20 was considerably more effective than R12 at inhibiting hexanal formation by extending the lag phase almost 20 days (Figure 3B). That means R12 increased the lag phase of hexanal formation when added to the lipid phase but was ineffective compared to the control when added to the aqueous phase. R20 produced similar hexanal lag phases when added to the lipid (54 days) or aqueous (49 days) phases. Finally, R0 did not increase hexanal formation when added to the water phase, again suggesting that AOX activity was altered by mode of addition.

Lipid oxidation data (Figure 3) were again related to physical structure. Confocal images of the crackers where the AOX were added to the water suggested that R20 still formed distinct regions of blue scattered throughout the lipid regions as it did when added to the lipid, which likely explains its continued efficacy (Figure 4C). Previously (Figure 1A), we showed that

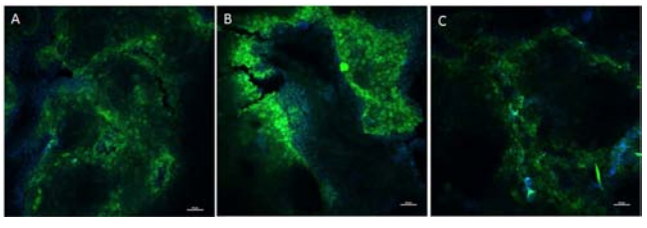

Figure 4. Fluorescence of Nile Red dye (green) and either (A) rosmarinic acid, (B) dodecyl (R12) rosmarinate ester, or (R20) eicosyl rosmarinate ester (blue) phase partitioning of lipid and antioxidant, respectively, in crackers at day 0. Antioxidants were incorporated by mixing with the aqueous phase. Scale bars: 50 μm.

R0, when added to the lipid phase, was not highly associated with the lipid phase. This trend also occurred when the R0 was added to the aqueous phase (Figure 4A). When R12 was added to the lipid phase, areas of AOX overlapped with the lipid created turquoise zones (Figure 1B). However, fewer of these types of overlap were observed when R12 was added to the aqueous phase (Figure 4B). Few differences were observed in the confocal images between R0 and R20 when they were added to the water, which could help explain why their AOX activity was similar (Figure 3). The change in R12 partitioning could be due to its inability to solubilize in the solid fat when added to the water phase. It is also theoretically possible that R12 uniquely interacted with starch and that these interactions were increased when it was added to the water phase. The unbranched $\alpha(1\rightarrow4)$ glucan chains of starch are known to form a helical structure with a hydrophobic interior that interacts with other nonpolar molecules and residues.[14] Many published studies show that lauric acid (C12:0) is commonly complexed with starch.[15−17] The 12-carbon alkyl chain of R12 may have behaved like lauric acid, readily forming complexes with the helical starch. In either case, this would partition R12 away from the lipid, thereby decreasing its ability to inhibit lipid oxidation.

Free radical scavenging AOX are degraded during lipid oxidation reactions, so their concentrations during storage can be used as a measure of oxidation reactions. HPLC was used to monitor the loss of R0 and its esters during storage when they were added to the lipid phase. The loss was in the order R0 > R12 > R20 (Figure 5). In all cases, the rosmarinic acid

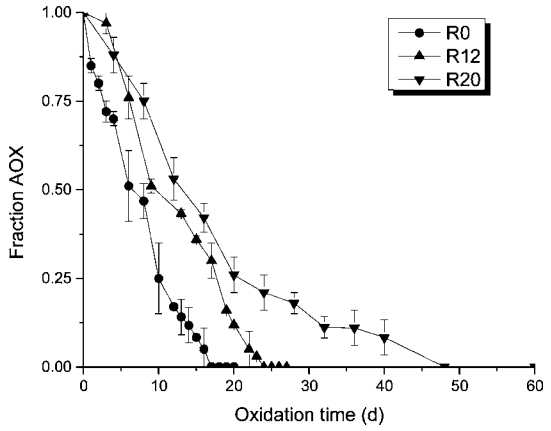

Figure 5. Loss of rosmarinic ester antioxidants (chain lengths = 0, 12, or 20 carbons) added to the lipid phase during storage at 55 °C in the dark as determined by HPLC. Vertical lines indicate standard error for each point.

homologues were completely lost prior to the formation of hexanal (Figure 2B). HPLC was also used to monitor the loss of R0 and its esters during storage when they were added to the water. In that case, loss was in the order R0 ≅ R12 > R20 (Figure 6). Again, the rosmarinic acid homologues were completely lost prior to formation of hexanal (Figure 3B). The similarity of R0 and R12 degradation rates when they were added to the aqueous phase again supports the observation that these two AOX were behaving similarly.

It is unclear what made the R20 ester oxidize more slowly. Previous research has shown that the rosmarinate esters in oil-in-water emulsions degraded into caffeic acid in the presence of α-tocopherol. Because caffeic acid also has AOX activity, its

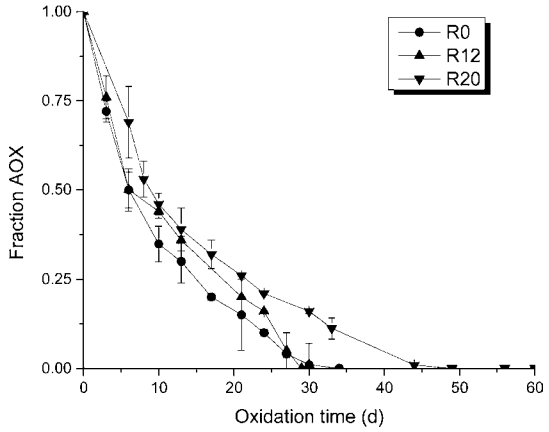

Figure 6. Loss of rosmarinic ester antioxidants (chain lengths = 0, 12, or 20 carbons) added to the aqueous phase during storage at 55 °C in the dark as determined by HPLC. Vertical lines indicate standard error for each point.

formation decreased the rate of R20 degradation and further decreased lipid oxidation.[10] The formation of caffeic acid in the crackers was determined by HPLC as described by Panya et al.[10] In the cracker systems, no quantifiable caffeic acid was measured by HPLC regardless of alkyl chain length. This could be because the crackers contained no quantifiable amounts of tocopherols from the ISO.

Another possibility for the decreased degradation rate of R20 compared to R0 and R12 could be due to interactions with other food components. Phenolic AOX can interact with transition metals, resulting in the reduction of the metal and the degradation of the antioxidant.[18] Therefore, it is possible that the R0 and R12 could interact with metal more when they partition separately from the lipid, thereby causing them to degrade more quickly. The R20, which partitioned in the lipid and formed concentrated pockets outside the lipid, could have fewer interactions with metals and thus degrade more slowly, leaving more R20 for scavenging free radicals. Finally, it is important to note that AOX efficacy is linked to concentration: as the concentrations of AOX such as tocopherols are increased, their effectiveness can decrease.[19] Therefore, a third possibility is that the R20 concentration in the lipid phase produced optimal AOX activity. As the R20 decomposed during oxidation, it is possible it moved from its discrete pockets outside the lipid back into the lipid phase. This could keep R20 concentrations in the ISO at optimal levels, thus enhancing efficacy.

Commercial AOX. The homologous series of rosmarinate esters are an excellent research tool to study AOX properties because they vary in hydrophobicity and yet their AOX functionalities are very similar.[11] However, rosmarinate esters are not approved food grade ingredients. Hence, the activity of approved food additives with various hydrophobicities was also investigated. This study tested the efficacy of PG (least hydrophobic), TBHQ, and BHT (most hydrophobic) in the model cracker system by incorporating the AOX into the lipid phase; all were added at a molar equivalent to 500 ppm of TBHQ. PG was prooxidative as determined by both lipid hydroperoxides and headspace hexanal (Figure 7). This is similar to what was observed with the hydrophilic R0, which had little effect on lipid hydroperoxide formation and accelerated headspace hexanal formation when added to the lipid phase (Figure 2). TBHQ and BHT are both more

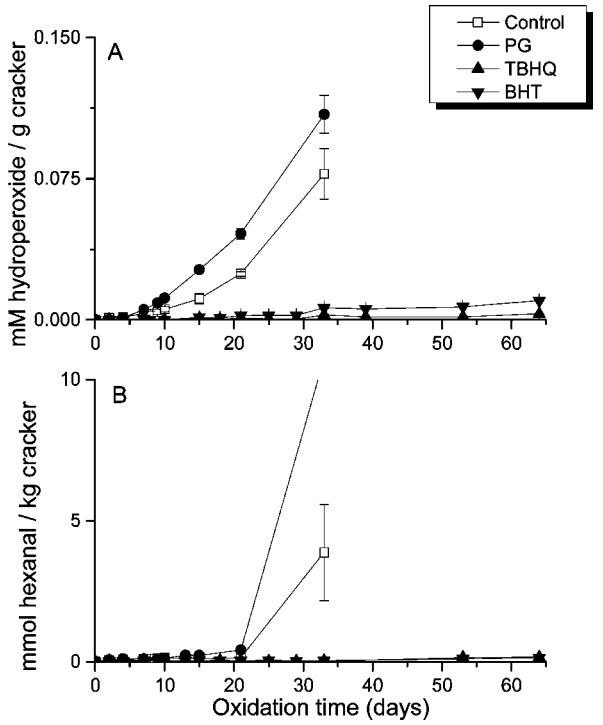

Figure 7. (A) Lipid hydroperoxide and (B) headspace hexanal in crackers made by incorporating propyl gallate (PG), *tert*-butylhydroquinone (TBHQ), or butylhydroxytoluene (BHT) into the lipid phase. Crackers were stored at 55 °C in darkness. Standard error bars are smaller than data points in some instances.

hydrophobic than PG and exhibited greater antioxidant efficacy. Figure 7A shows that, after 33 days, both TBHQ and BHT treatments were still in the lag phase of hydroperoxide formation. Analysis of headspace hexanal formation led to the same conclusion: the hydrophobic antioxidants BHT and TBHQ were more effective than PG treatments and similar to each other at limiting lipid oxidation. This again agrees with the rosmarinate ester experiments in that AOX efficacy increases with increasing hydrophobicity. However, it should also be noted that unlike the rosmarinic acid esters, the free radical scavenging effects of PG, BHT, and TBHQ are not equal, and thus the observed differences would also be due to differences in chemical reactivity. Both BHT and TBHQ (at 344 μmol) were more effective than the R20 rosmarinate esters (at 159 μmol).

DISCUSSION

These results suggest that AOX efficacy in crackers increases with increasing hydrophobicity, meaning that crackers follow markedly different trends from bulk oils and oil-in-water emulsions.[3,4,6,8−10,18,20] Much of this likely relates to the unique physical structure of low-moisture foods, which affects the physical location of the AOX. AOX should be most effective when they partition at the site of oxidation, which in both oil-in-water emulsions and bulk oils containing association colloids is oil−water interfaces.[3,19] The ISO used in the model crackers formed a continuous lipid phase that surrounds starch granules (Figure 1). In addition, the crackers are very low in water and, as in other low-moisture foods, the water that is in the crackers is likely associated with molecules such as starch and proteins and therefore does not exist as dispersed droplets.[21,22] This means that that there will be very few water−lipid interfaces

DOI: 10.1021/acs.jafc.5b01085
J. Agric. Food Chem. 2015, 63, 5821−5827

where lipids and water-soluble prooxidant would interact as would be seen in oil-in-water emulsions and bulk oils with association colloids.

The inability of highly polar R0 to inhibit lipid oxidation could be due to its exclusion from the lipid phase, meaning it is physically separated from lipid oxidation reactions, as suggested by the confocal microscopy. The R12 ester had inconsistent activity given that it was effective when added to the lipid phase prior to dough formation but ineffective when added to the aqueous phase. R12 has intermediate solubility characteristics of the three rosmarinates tested,[8] suggesting that the method of introduction into dough could impact its partitioning. For example, when added to the ISO, it might be better retained in the lipid phase compared to when it is added to the aqueous phase, where it might interact with other molecules in the flour, thereby preventing it from partitioning into the lipid phase. The consistent ability of R20 to inhibit lipid oxidation suggests that it partitions at the site of lipid oxidation regardless of the method used to introduce it into the dough.

Overall, the ability of AOX to inhibit lipid oxidation in low-moisture crackers is very different from bulk oils and oil-in-water emulsions. R0 is effective in bulk oils[23] but was prooxidative in the crackers. In oil-in-water emulsions, rosmarinate esters follow the "cutoff effect" in which the activity of AOX esters increases with increasing hydrophobicity up to 8−12 carbon alkyl chain length, after which AOX activity decreases dramatically with increasing chain length, with R20 having essentially no activity.[6−11] In the crackers, R20, the most hydrophobic ester, had the most activity. In addition, results with the synthetic AOX support the notion that highly hydrophobic AOX are the most effective in the crackers. Thus, the physical properties of low-moisture crackers have a much different impact on the activity of AOX from bulk oils and oil-in-water emulsions, and they therefore may require a different class of AOX than other types of foods.

Extending the lag phase of lipid oxidation correlates directly to extended shelf life and maximizing nutritional benefits by inhibiting the degradation of vitamins susceptible to oxidation. This research suggests that the lag phase of lipid oxidation can be extended in low-moisture crackers by using the most hydrophobic AOX option available. Such an AOX selection is unique to low-moisture foods compared to oil-in-water emulsions and bulk oils. These AOX could be used in combination with other AOX strategies such as control of transition metals and elimination of oxygen and light exposure to maximize the shelf life of low-moisture foods.

involved in amino acid decarboxylation could be the results of a horizontal gene transfer (possibly from Gram-negative bacteria) and could be located in genomic islands, as already demonstrated for tyrosine decarboxylase operon.[18,19]

The presence of relevant amounts of BAs in food is associated with a massive growth of decarboxylating bacteria. Then, in unfermented foods, BA concentration has been considered as a spoilage index.[10] By contrast, in fermented foods the presence of complex microbial communities necessary for their production is often associated with high BA (among which is PUT) accumulation. According to a report of the EFSA,[10] PUT was found at median values of 26.9 mg/kg in fermented sausages and 82 mg/kg in fish sauce, whereas in dairy products this value was <50 mg/kg; higher PUT contents were found in fermented vegetables.

LAB are common components of the microbial population responsible for the production of several fermented foods. Their use in competitive strategies has been deeply studied in recent decades,[20−22] and recently the effect of the relationships between bioprotective LAB and decarboxylative bacteria has been described.[23−25] They can produce a wide range of metabolites, such as organic acids, diacetyl, acetoin, hydrogen peroxide, antifungal peptides, and bacteriocins, which are often able to inhibit or kill other microorganisms without safety implications.[26,27] During growth, LAB produce these antimicrobial substances, which are released and accumulated in the medium. Thus, the separation of cells from the cultural broth produces cell free supernatants (CFSs), which may exert interesting antimicrobial activity. The effects of CFSs from specific LAB on TYR and other BA production by common foodborne pathogens (FBPs) have been studied.[28] From this perspective, this work has the aim to investigate the impact of CFSs from some LAB strains on PUT and other monoamine and polyamine formation by FBPs in a specific decarboxylase medium. In particular, the effects of CFSs on the decarboxylase activities of *Salmonella* Paratyphi A, *Listeria monocytogenes*, *Staphylococcus aureus*, and *Escherichia coli* were assessed in ornithine decarboxylase broth (ODB).

MATERIALS AND METHODS

Bacterial Strains and Culture Conditions. LAB strains, which are *Lactococcus lactis* subsp. *lactis* IL 1403 (*Lc. lactis* subsp. *lactis*), *Leuconostoc mesenteroides* subsp. *cremoris* DSMZ 20346 (*Leuc. mesenteroides* subs. *cremoris*), *Pediococcus acidilactici* ATCC 25741 (*Pc. acidilactici*), and *Streptococcus thermophilus* NCFB 2392 (*Str. thermophilus*) were obtained from Sutcu Imam University (Kahramanmaraş, Turkey) in BGML stock culture.

The four selected foodborne pathogens were *Staphylococcus aureus* ATCC 29213 (*Staph. aureus*), *Escherichia coli* ATCC 25922 (*E. coli*), *Listeria monocytogenes* ATCC 7677 (*L. monocytogenes*), which were bought from American Type Culture Collection (Rockville, MD, USA), and *Salmonella* Paratyphi A NCTC 13 (*S.* Paratyphi A), which was purchased from National Collections of Industrial Food and Marine Bacteria (Aberdeen, UK).

Preparation of Cell-free Supernatants from Lactic Acid Bacteria. The CFSs were prepared using the medium in which LAB strains grew. In particular, LAB were pregrown in 10 mL of De Man, Rogosa, and Sharpe (MRS; Merck) medium (1%, v/v) with overnight incubation at 37 °C, and then 7.5 mL of the bacterial culture was added aseptically to 750 mL of MRS medium in a sterile 1000 mL bottle. Bacteria in the bottle were incubated at 37 °C for 16 h without shaking. A cell-free supernatant was taken by centrifuging at 9000 rpm for 20 min under refrigeration (at 4 °C) from bacterial suspension. The cell-free supernatant was sterilized using a Sartorius membrane filter (0.22 μm).

Determination of Antimicrobial Assay of LAB Strains. The antimicrobial activity of CFSs from the LAB against *E. coli*, *Staph. aureus*, *L. monocytogenes*, and *S.* Paratyphi A was achieved by using the well diffusion assay. More information about determination of antimicrobial activity has been reported by Toy et al.[28]

Foodborne Pathogen Growth in Ornithine Decarboxylase Medium. The production of PUT by all foodborne pathogen strains used in this work was monitored using ornithine decarboxylase broth (ODB) as proposed by Klausen and Huss.[29] ODB contains 2 g/L peptone, 1 g/L Lab-Lemco powder (Oxoid CM0017, Hampshire, UK), 5 g/L NaCl (Merck 1.06404.1000, Darmstadt, Germany), 8.02 g/L L-ornithine HCl (Sigma H8125), and 5 mg/L pyridoxal HCl (Sigma P9130, Steinheim, Germany). The ODB also contains glutamic acid, arginine, lysine, tyrosine, and tryptophan that come from peptone and beef extract, which are calculated as 304, 170, 132, 14, and 16 mg/L, respectively.

The broth pH was adjusted at 7.0 according to their optimum growth pH with 1 M NaOH or 6% trichloroacetic acid (Riedel-de Haen 27242, Seelze, Germany). The ODB was pipetted in 10, 7.5, and 5 mL bottles and then autoclaved at 121 °C for 15 min prior to use. Two different concentrations, which are 50% (5 mL of CFS + 5 mL of ODB) and 25% (2.5 mL of CFS + 7.5 mL of ODB) of CFS, were prepared. The control was prepared as only ODB without CFS.

Foodborne pathogen strains were grown in nutrient broth (Merck 1.05443.0500, Darmstadt, Germany). Each precultured foodborne pathogen strain was inoculated 1% (v/v) in ODB for each CFS concentration and control. All of them were incubated at their optimum growth temperature for 72 h. After that, 5 mL of the bacterial cultures was removed to separate bottles, and then 2 mL trichloroacetic acid was added. They were centrifuged at 3000*g* for 10 min and then filtered through a filter paper (Millipore). Finally, 4 mL of filtrate was taken for derivatization stage to analyze BAs using HPLC.

Derivatization of Bacterial Supernatant. For derivatization of standard and bacterial supernatant, a stock solution (2%) of benzoyl chloride dissolved in acetonitrile was used. For derivatization of standard amine solutions, 100 μL was taken (4 mL of bacterial supernatant) from each free base standard solution (10 mg/mL). One milliliter of 2 M NaOH was added, followed by 1 mL of 2% benzoyl chloride and the solution mixed on a vortex mixer for 1 min. The reaction mixture was left at room temperature for 5 min and then centrifuged (3000*g*) for 10 min. After that, the benzoylation was stopped by adding 2 mL of saturated NaCI mixture, and the mixture was extracted twice with 2 mL of diethyl ether. The upper organic layer was moved into a clean tube after mixing. Afterward, the organic layer was evaporated to dryness in a stream of nitrogen. Finally, the residue was dissolved in 1 mL of acetonitrile, and 10 μL aliquots were injected into the HPLC for BA determination.

Analytical Method. Biogenic amine analysis was achieved according to the method of Ozogul et al.[30] and measured in milligram amines per liter of broth. The confirmation of BA production was accomplished using a rapid HPLC method with a reversed phase column by using a gradient elution program. Ammonia and trimethylamine separations were done using the same injection of the BA determination.

A Shimadzu Prominence HPLC apparatus (Shimadzu, Kyoto, Japan) equipped with an SPD-M20A diode array detector and two binary gradient pumps (Shimadzu LC-10AT), an autosampler (SIL 20AC), a column oven (CTO-20AC), and a communication bus module (CBM-20A) with valve unit FCV-11AL was used. The column was ODS Hypersil (5 μm, 250 × 4.6 mm) for the BA analyses, and it was purchased from Phenomenex (Macclesfield, Cheshire, UK).

Chromatographic separation was done by continuous gradient elution with acetonitrile and HPLC grade water. The gradient started at 60% HPLC grade water and was then decreased to 40% in 20 min. The total separation time was <20 min, and the gradient was run for 25 min to ensure full separation. The injection volume was 10 μL and detection was monitored at 254 nm.

Statistical Analysis. The data gathered from CFS of LAB strains were processed using one-way analysis of variance (ANOVA), SPSS 15.0 for Windows (SPSS Inc., Chicago, IL, USA). The level of

[a]The data are reported as mean values ($n = 4$); standard deviation is given in parentheses. Values in the same row followed by different letters (a–d) are significantly different ($p < 0.05$). [b]PUT, putrescine; CAD, cadaverine; SPD, spermidine; SPN, spermine; AGM, agmatine.

significance was set at $p < 0.05$. Means were compared by Duncan t tests.

RESULTS AND DISCUSSION

pH Values of CFSs and Antimicrobial Activity of LAB Strains. The pH values of CFSs of *Str. thermophilus*, *Lc. lactis* subsp. *lactis*, *Leuc. mesenteroides* subsp. *cremoris*, and *Pc. acidilactici* were 4.06, 4.15, 4.06, and 4.35, respectively, in accordance with the data previously reported by Toy et al.[28] The initial pH of the ODB medium was 7. The pH values of the media obtained by adding, respectively, 25 and 50% of CFS to ODB were 4.86 and 5.66 for *Str. thermophilus*, 4.91 and 5.75 for *Lc. lactis* subsp. *lactis*, 4.93 and 5.68 for *Leuc. mesenteroides* subsp. *cremoris*, and 5.15 and 5.97 for *Pc. acidilactici*.

All of the CFSs resulting from the tested LAB strains' growth showed antimicrobial effect against *E. coli*, *Staph. aureus*, *L. monocytogenes*, and *S.* Paratyphi A according to the well diffusion assay employed. In fact, all of the inhibition zones were >8 mm of diameter, with the highest effect by CFS of *Str. thermophilus* against *Staph. aureus* (data not shown).

Putrescine and Other Polyamines Produced by Foodborne Pathogens. Putrescine-forming FBPs produced not only PUT but also other polyamines, that is, CAD, SPD, SPN, and AGM, besides other BAs. Although lysine and other amino acids were not added directly into ODB, the medium contained peptone and beef extract. For this reason, the observed quantity of other BAs derived from the transformation of amino acids was made available from these protein sources.

Polyamines produced by *S.* Paratyphi A, *E. coli*, *L. monocytogenes*, and *Staph. aureus* in ODB are presented in Table 1. Significant differences ($p < 0.05$) among the species for each amine were observed. With regard to PUT, *L. monocytogenes* and *S.* Paratyphi A were responsible for the highest accumulation, producing 5902 and 4991 mg/L, respectively. The PUT amount produced by *S.* Paratyphi is slightly higher than the theoretical maximum allowed by the ornithine added to the medium (5330 mg/L). The excess of production can be partially attributed to the biodegradative pathway, due to the presence of other sources of precursors (ornithine but also arginine) in the other medium constituents (peptone and Lab-Lemco powder). In any case, also the contribution of the biosynthetic pathway to PUT accumulation cannot be excluded, even if this contribution cannot be quantified under the adopted conditions. Also, the other two species were able to accumulate high levels of PUT, because a high source of free ornithine is available in the decarboxylase broth. Furthermore, SPD was accumulated in high level by all of the species studied (ranging from 228.1 to 399.3 mg/L). PUT can be converted into SPD through the action of several enzymes, the most important of which are methionine adenosyltrasferase, *S*-adenosyl methionine decarboxylase, and spermidine synthase,[11] and then it is not surprising that SPD is produced proportionally to the amounts of PUT. *L. monocytogenes* ATCC 7677 was the highest producer of CAD, SPD, and SPN, whereas *Staph. aureus* accumulated the higher quantity of AGM. These amines have a key role in the response of *E. coli* to oxidative and acidic stresses.[31,32] Similar mechanisms were observed in *Salmonella enterica* and *Vibrio vulnificus*.[33,34] Furthermore, many recent works demonstrated that polyamine biosynthesis and transport mechanisms are involved in classical virulence factors responsible for bacterial pathogenesis. These aspects have been elucidated in *Shigella*[35] and *Helicobacter pylori*.[36]

Effects of CFSs on Putrescine Production by Foodborne Pathogens. The effects of CFSs of LAB strains on PUT accumulation by foodborne pathogens were studied by adding 25 or 50% of supernatants to ODB. The LAB strains employed in this study were previously tested for their decarboxylating potential in MRS broth, and only traces of BAs were found (data not reported).

PUT accumulations in CFS-added samples are reported in Figure 1 for the four foodborne pathogens. In the evaluation of

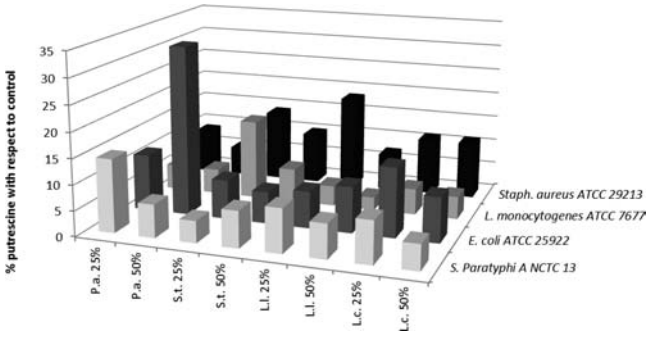

Figure 1. Percentage of putrescine produced by FBPs with respect to control effected by the addition of 25 or 50% of CFSs from LAB.

these data it has to be considered that the dilution rate between CFS and ODB necessarily modified the amount of ornithine available for the decarboxylation, which decreased to 4.0 mg/L in the samples with a 50:50 ratio (ODB/CFS) and to 6 mg/L in the samples with a 75:25 ratio. For this reason, the data are expressed as percentage of PUT accumulated with respect to the control samples (foodborne pathogens in ODB without the addition of CFSs). All of the CFSs reduced the accumulation of PUT by ≥65%. In general, all of the 50% CFSs samples resulted in a lower PUT concentration if compared to the correspondent 25% CFSs samples, with the exception of *E. coli* in the presence of *Pc. acidilactici* and *Lc. lactis* subsp. *lactis* CFSs and *S.* Paratyphi A in the presence of *Str. thermophilus* CFSs. *Salmonella* Paratyphi A and *L. monocytogenes* showed the most relevant inhibition of PUT accumulation. In the samples

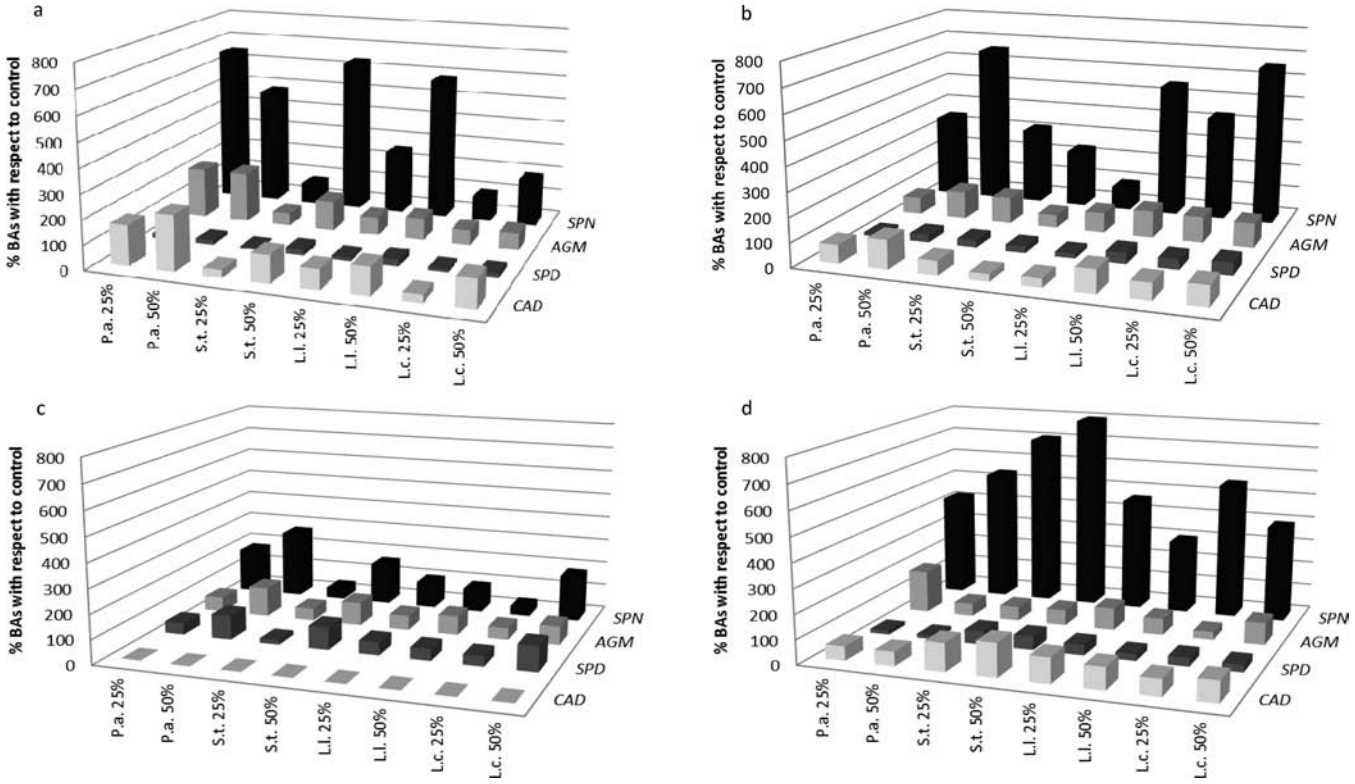

Figure 2. Percentage of cadaverine (CAD), spermine (SPN), spermidine (SPD), and agmatine (AGM) produced by FBPs with respect to control effected by the addition of 25 or 50% of CFSs from LAB: (a) *S.* Paratyphi A NCTC 13; (b) *E. coli* ATCC 25922; (c) *L. monocytogenes* ATCC 7677; (d) *Staph. aureus* ATCC 29213.

inoculated with this strain, PUT amount was between 5 and 10% of the amount found in the control (ODB). On the contrary, the decarboxylating activities of *Staph. aureus* and *E. coli* were less inhibited by CFSs. All of the strains tested in CFS had a decrease in PUT accumulation which was higher than that expected considering only the dilution effect of ODB. On the other hand, also the CFSs contained peptides and amino acids that could act as precursors for the decarboxylating activity. The reduction in the yield of ornithine decarboxylation was the result of the inhibiting effect of the CFS. Undoubtedly, the presence of lactic acid played a major role in this inhibition, even if the pH of the media added with CFSs was not prohibitive for the growth of the species tested in these trials.

Ozogul[23] observed that in histidine decarboxylase broth (in the absence of ornithine added) the growth in coculture of the same foodborne pathogen strains with *Lc. lactis* subsp. *lactis* and *Str. thermophilus* determined an increase of PUT, justifying the protective role exerted by this BA, which confers to cells a competitive advantage.[6] By contrast, adjunct of CFSs determined an opposite trend in ODB in which, however, the concentration of precursor was very high, independent of the dilution effect of the addition of CFSs. The same trend was observed for the same strains in tyramine decarboxylase broth.[22] These data reflected an inhibition or a modification of the foodborne pathogen metabolism due to the presence of antibacterial compounds produced by LAB during their growth.[26]

Effects of CFSs on Other Polyamine Production by Foodborne Pathogens. The protective role of polyamines was well evidenced by the fact that the sum of CAD, SPN, SPD, and AGM increased in the samples with added CFSs. In fact, this trend is often opposite to PUT accumulation. This discrepancy was probably related to the amount of precursor for these BAs. In effect, the presence of extremely high ornithine concentration can mask some metabolic response of the cells. The variation in polyamine accumulation with respect to the control samples is reported in Figure 2. Some differences can be found in the behavior of these BAs in relation to the foodborne pathogens. SPD was produced in lower amount with respect to control in many samples, especially by Gram-negative foodborne pathogens, whereas SPN increased drastically in the major part of the samples with respect to the control. This increase was particularly evident in *Staph. aureus* and less marked in *L. monocytogenes*. This latter species was characterized by the lower increase of polyamines. PUT is the precursor for the synthesis of SPD and SPN, which were obtained by successive addition of aminopropyl group to this BA,[11] and this may explain the relevant increase of SPD in all samples. SPN and SPD can have a strong protective effect, especially for nucleic acids, and their production is regulated by the cells under stress conditions.[11,37]

The production of CAD, which derives from the decarboxylation of lysine, is scarcely affected by the presence of CFSs, with the exception of the samples inoculated with *L. monocytogenes* in which CAD accumulation was drastically reduced, whereas in *S.* Parathyphi A in the presence of *Pc. acidilactici* a higher increment of CAD was observed.

Finally, AGM, which derives from decarboxylation of arginine, increased in all of the samples. This BA can be also a precursor for the production of PUT, following the agmatine deiminase pathway in the Gram-positive bacteria[38] or the agmatinase pathway in Gram-negative bacteria.[6] This pathway strengthened the hypothesis that the extremely high production

of PUT observed in some species can be based on sources different from the ornithine added to ODB.

The results regarding these other BAs are reported in Tables 2 and 3 for Gram-negative and Gram-positive foodborne pathogens, respectively. Some common trends can be found in these data. HIS was characterized by a marked concentration decrease in all samples. This trend was particularly evident in the samples of *L. monocytogenes*. This strain produced 673.9 mg/L of HIS in the control and amounts variable between 2.7 and 120.2 mg/L in the presence of LAB CFSs. Similar behavior was observed also for 2-phenylethylamine, deriving from decarboxylation of phenylalanine, even if the decrease was less pronounced. By contrast, tyramine, which was accumulated in very low concentrations in the controls (between 3.5 and 7.5 mg/L), showed in all the CFS adjunct broths a marked increase. These behaviors can be probably attributed to the different availabilities of precursors in the CFSs.

The results of this study showed that all of the CFSs employed reduced the accumulation of PUT by ≥65%. This could be due to the production of antimicrobial substances or the presence of the weak organic acids, contained in CFSs, that, decreasing pH quickly, inhibited microbial growth. On the other hand, the other polyamines increased in the samples with added CFSs, due to their cell protective role. For this reason, the use of CFSs in the food sector can have a double role. In fact, it can reduce the accumulation of some BAs, but it seems to increase the presence of others. To prevent the growth of pathogenic bacteria and its unfavorable compounds' formation in fermented food, bacteriocinogenic LAB strains may be used as starter cultures, cocultures, or bioprotective cultures to improve food quality and safety. Further studies aimed to a deep understanding of the metabolic pathways that bring about BA production are needed.

different in samples, depending on the relative source of nitrogen.

Perini et al.[3] report the use of stable isotope ratio analysis to verify the authenticity of *Passito* wine. The effect of the grape's withering process on the variability of the $(D/H)_I$, $(D/H)_{II}$, and $\delta^{13}C$ of wine ethanol and the $\delta^{18}O$ of wine water were monitored. The production of PDO Erbaluce di Caluso Passito at five different vineyards in the Piedmont (Italy) was considered in two successive years. The results show that the isotopic parameters $(D/H)_I$, $(D/H)_{II}$, and $\delta^{13}C$ of ethanol did not change during the withering period, whereas the $\delta^{18}O$ of water and ethanol tended to decrease.

However, to better define univocal parameters, isotope ratios, expressed as $\delta^{13}C$, are preferably determined by the use of gas chromatography−combustion isotope ratio mass spectrometry (GC-C-IRMS) to fix a variable number of $\delta^{13}C$ values relative to pure compounds in the food investigated. The approach allows the preseparation of the components of interest in a capillary column, with the aim of directly determining the $\delta^{13}C$ value, through a combustion chamber followed by the isotope ratio MS instrument section. Different analytical approaches to GC-C-IRMS analyses applied to several food types such as coffee samples of different geographic origins and fatty acids (methyl esters) of different natural sources will be proposed, as well as specific examples of the characterization of various natural compounds.

NEW METHODS FOR QUALITY AND SAFETY CONTROL

Food quality and safety have been highly topical for the past 10 years in the public debate, in food policy, in industry, and, last but not least, in research. To ensure quality and food safety for consumers, it is essential develop analytical methods that are fast, sensitive, solventless, inexpensive, and suitable for automation and more transferable at industrial scale, ensuring control over the whole food chain.

One of the main problems in ensuring food safety is the presence of contaminants, and several papers in this issue have developed new methods for the determination of food toxins.

OTA is the only mycotoxin with legal limits in the European Union (EU) for wine; in contrast, there is no EU legislation imposed for aflatoxins and ochratoxin B (OTB). A study was focused on the development, by using immunoaffinity column cleanup and HPLC-FLD method in 57 red wines produced in Sicily, of a reproducible and sensitive analytical method for six mycotoxins: OTA, OTB, aflatoxin B_1 (AFB_1), aflatoxin B_2 (AFB_2), aflatoxin G_1 (AFG_1), and aflatoxin G_2 (AFG_2).

This study is the first report of OTA, OTB, and the main aflatoxins content in red Sicilian wines. The analytical method reported represents a real advantage in the field of mycotoxin surveillance in foods and shows that there is a real risk of contamination in wine.

The use of noninvasive tools for food processing and quality control is highly recommendable. In this respect, the detection of food flavors via gas sensing is surely a valuable option; in fact, flavors depend on the volatile molecules present in food and on their release, which is strongly influenced by the composition of the matrix. In one of the presented works was developed a gas sensor array based on quartz crystal microbalances (QCMs) modified with gold nanoparticles bearing peptide moieties. Results demonstrated the ability of the QCM gas sensor array under development to be used in the discrimination of food samples with different aroma patterns.

A simple and fast HPAEC-PAD analytical method with good sensitivity has been developed for the determination and quantification of carbohydrates in honey. The technique allows the simultaneous determination of minor and major saccharides without pretreatment of sample that, always, causes the loss of minor sugars. The analytical method was applied to honeys of different botanical origins, and the performance of this method was validated according to range, linearity, calibration curves, limit of detection, and limit of quantification.

In comparison with HPLC-RI, which is used as an official method, HPAEC-PAD was more sensitive and faster, with high specificity and improved peak resolution.

In one study was reported an optimized analytical method for the evaluation of fatty acid composition in lentils by using GC-FID. The results showed that there are five main fatty acids in lentils (palmitic, stearic, oleic, linoleic, and linolenic acids) and that unsaturated fatty acids are prevalent with respect to saturated ones. Indeed, in all types of lentil samples analyzed, the predominant fatty acid was linoleic acid, whereas the least concentrated one was stearic acid. Finally, it is very interesting that in lentils the ratio between omega-6 and omega-3 fatty acids coincides with that in the Recommended Dietary Allowances (RDA).

BOTANICAL AND NUTRACEUTICAL PRODUCTS

Nutraceuticals are foods or food ingredients that have defined physiological effects. They do not easily fall into the legal categories of food or drug and often inhabit a gray area between the two. These products in general terms cover health promotion and "optimal nutrition"; the concept of enhanced performance, both physically and mentally; and reduction of disease risk factors.

Botanical extracts represent a large segment of nutraceuticals and present additional problems relating to the complex nature and composition of these products. The term "botanicals", in this context, can represent the whole plant but also parts of plants, such as algae, fungi, and lichens. This word includes also specific preparations from these materials involving extraction, distillation, fractionation, purification, concentration, and fermentation processes. All of these botanicals need to be first recognized by the botanical name of the plant according to the binomial system (genus, species, variety, and author) and the part used (e.g., leaf, root, and fruit).[4]

The wide diffusion of these products requires new analytical methods to control their quality, guarantee their safety, and contribute to the scientific studies aimed to evaluate their beneficial effects.

In the X Italian Congress of Food Chemistry a whole day was dedicated to this hot topic, and different results were presented aimed in particular to control the quality of the vegetal matrix.

A chromatographic method for the qualitative and quantitative characterization of peel of different species of citrus was developed to obtain a total evaluation of the phytocomplex and to verify the eventual content of protoalkaloids such as synephrine. Twenty-four constituents comprising flavones, flavanones, polymethoxyflavonoids, and protoalkaloids were fully identified. Fourteen major constituents were quantified using a validated HPLC method with UV−vis. Synephrine was present in all samples except grapefruit.

Another work reported a study on Limone dell'Etna, a brand recently launched by citrus growers for lemon fruits produced in that area with the aim of enhancing and promoting Limone

DOI: 10.1021/acs.jafc.5b00324
J. Agric. Food Chem. 2015, 63, 5837−5840

dell'Etna production and contributing to an increase in the value of a product that, due to its peculiar qualities, could be awarded with a European certified label. Qualitative parameters (total soluble solids, titratable acidity, pH) and health-promoting components such as ascorbic acid, flavanones, and hydroxycinnamic acids of the two different varieties have been determined at fruit maturity.

Also, the stigmas from different samples of *Crocus sativus* cultivated in Italy (Tuscany and Umbria) have been analyzed to characterize this product from a quality point of view. The identification and quantification of crocins, safranal, picrocrocin, and flavonols were mainly carried out by applying an integrated approach by HPLC-DAD and NMR to control the hydroalcoholic and aqueous extracts, respectively.

The term "nutraceuticals" can be applied also to new formulations proposed for celiac patients to improve the quality of their diet. In the presented study, the chemical characterization and the quality evaluation of two different gluten-free breads with added chestnut flour were performed. In particular, protein and fat contents, fatty acid and volatile profiles, antioxidant capacity, and glycemic index were measured for each sample, and the results obtained for gluten-free breads were compared with those obtained for breads with added chestnut flour. The results showed that the addition of chestnut flour leads to a product with a higher nutritional profile.

NEW METHODS TO DETECT BIOACTIVE METABOLITES IN FOODS

A more accurate determination of the bioactive compounds in foods is a hot topic of recent years. At the same time, the development of innovative analytical methods more suitable to this aim is one of the targets of the *Journal of Agricultural and Food Chemistry*.

The presence of significant amounts of bioactive molecules may provide health benefits and play an important role in the prevention and risk reduction of some chronic diseases. Among these, the stilbenes, a class of compounds present in small fruits such as grapes and berries, act as natural protective agents to defend the plant against viral and microbial attack, excessive ultraviolet exposure, and disease. A work of this Congress applied HRGC equipped with FID and MS detectors, operating in selected ion monitoring (SIM) mode, to quantify *trans*-resveratrol and *trans*-pterostilbene in commercial blueberry samples, considering both the free and conjugated forms. Another work reports the characterization of the anthocyanin fraction of nine sweet cherry cultivars, grown in an experimental field of Vignola (Emilia Romagna). For this purpose was developed an extraction and purification method by SPE, and then the recovered anthocyanin fraction was characterized by HPLC-MS and MS-MS. This study aims to give some parameters suitable to evaluate cherry fruit quality, focusing on healthy compounds, especially considering the achievement of the Protected Geographical Indication (PGI) obtained in 2012 for this fruit. An optimization of the extraction procedure for the simultaneous recovery of anthocyanins, flavonols, flavan-3-ols, and stilbenes by HPLC-DAD-MS for the characterization of cv. Apulia Rose seedless table grape was also reported. The grape skins (cv. Apulia Rose) were extracted by means of three technologies (namely, solid to liquid, ultrasonic-assisted, and microwave-assisted extractions) under various different experimental conditions (namely, solvent type, solvent-to-solid ratio, and time contact) to determine the effect of these conditions on the yield of phenolic compounds. On the basis of quantitative HPLC-MS/MS analyses, ultrasonic-assisted extraction in methanol appeared to be the most efficient condition to extract the aforementioned compounds simultaneously. In addition, the solvent-to-solid ratio was found to have a critical role in extraction efficiency.

The coffee plant not only is a source to produce the well-known drink but also has a large floral display with strong scent and produces more fruits and seeds when pollinated by bees. In view of these aspects it is not surprising to encounter coffee honey as a side-product of coffee production, albeit rare and almost unexploited to date. By an integrated analytical approach the authors gave an overview of the composition of this product, evidencing the main differences with respect to citrus honeys. Even if further studies need to be done, the authors suggest caffeine and theobromine as reliable markers to trace coffee honey authenticity.[5]

Di Lorenzo et al.[6] reported the use of HPLC-PDA-ESI-MS^n and NMR methodologies to evaluate the chemical composition of five Sicilian unifloral honeys produced in purity by the local black honeybees. In detail, the analyzed honeys were lemon and orange honeys (*Citrus limon* and *Citrus aurantium*), sulla honey (*Hedysarum coronarium*), dill honey (*Anethum graveolens*), and loquat honey (*Eriobotrya japonica*).

This analysis allowed the description of the phytochemical composition of each type of honey and the identification of many compounds that were found in these types of honey for the first time.

EFFECTS OF STORAGE AND TECHNOLOGICAL PROCESSES ON FOODS

During food storage the primary goal is to prevent the proliferation of bacteria, fungi, molds, and other microorganisms that, inside the food, can produce undesirable or toxic substances and to retard the oxidation of the edible oils and fat. Indubitably, the availability of specific strategies designed to inhibit the aging or degradation that may occur during storage is of great relevance in food chemistry.

A study focused on the investigation of the effects of different drying technologies on the volatile fraction of three Italian rice cultivars coupling headspace solid phase microextraction (HS-SPME) to gas chromatography−mass spectrometry (GC-MS) was also reported. Paddy rice from selected cultivars was treated both with traditional hot air technology and with static microwave drying. Analytical results on differently processed rice, after home-cooking, showed changes in the volatile fraction profile, in particular between aroma compounds. The results give information on the actual distribution of aroma precursor as a function of the progressive drying process and can be correlated to the sensory quality of the final product.

Due to the presence of an amino group on the side chain, modifications on lysine residues, N^{ϵ}-(2-furoylmethyl)-L-lysine (furosine), N^{ϵ}-(carboxymethyl)-L-lysine (CML), N^{ϵ}-(carboxyethyl)-L-lysine (CEL), are the most widely used marker to monitor the thermal damage on proteic constituents. The authors propose a method suitable to achieve not only a simultaneous detection of the main markers but also characterization by high sensitivity, good reproducibility, and repeatability in several food matrices through stable isotope dilution assay and ESI-MS. The possibility of selectively recovering the external parts of barley by a process of progressive pearling has been investigated for production of functional breads. The authors used three different series of substituted flours, adding increasing percentages (from 5 to 25%) of external parts to

DOI: 10.1021/acs.jafc.5b00324
J. Agric. Food Chem. 2015, 63, 5837−5840

prepare the breads. As expected, the use of enriched flours improved the functional properties of the breads, in accord with the original properties of the barley fractions.[7]

CONCLUSIONS

This special issue of *Journal of Agricultural and Food Chemistry* contains a selection of papers that were presented at the X Italian Congress of Food Chemistry (CHIMALI 2014) in Florence, Italy, July 6−10, 2014. There are many papers derived from collaborations between different universities and also some papers obtained from cooperation with important Italian companies.

We thank all contributors for making available their experience in food research and devoting their time to making this special issue a volume containing information of great interest to researchers working in food chemistry and food analysis. We also thank all of the companies that, by their sponsorship, have contributed to the good performance of this national event.

We are also grateful to the Editorial Board of *Journal of Agricultural and Food Chemistry* for giving us the opportunity to publish this special issue. We give special thanks to the previous Editor in Chief, James Seiber, who accepted our proposal to dedicate an issue to the X Italian Congress of Food Chemistry. Finally, our thanks to the new Editor in Chief, Thomas Hofmann, and his editorial assistant, Ivonne Hofmann-Sellier, who helped us to carefully supervise the final version of this special issue. We believe this issue will be useful to improve the cross-fertilization of ideas in the fascinating area of food and nutraceutical products.

history of organic plants. This has partly been addressed by compound-specific isotope analysis of N and O of plant-derived nitrate, which has proven promising for organic authentication of vegetables.[1,13] However, due to the inherently low nitrate contents of most generative plant tissue, it remains unclear if stable isotope analysis of nitrate from cereal grains is feasible. Consequently, this calls for the development of novel analytical methods for authenticity testing of organic crops.

The stable isotope ratio of carbon $^{13}C/^{12}C$ (expressed as $\delta^{13}C$) has also been investigated as well for organic authentication. In C3 plants, $\delta^{13}C$ is affected by water availability and drought stress, but also shows significant interactions with nutrient availability and fertilization,[14,15] which frequently can be systematically different between organic and conventional systems. Additionally, $\delta^{13}C$ values can be related to a different contribution and isotopic ratio of CO_2 from soil respiration or from other sources (e.g., a CO_2-enriched atmosphere in the greenhouse) to plant photosynthesis.[16−18] The soil management practices used in organic systems and the use of green manure may lead to higher microbial activity in organic soils compared to conventionally grown.

Traditionally, stable isotope analysis has relied on measurements of bulk plant tissue, but emerging methods aimed at individual chemical compounds provide a means of obtaining a more in-depth understanding.[19] GC-C-IRMS has been utilized for examining the effects of land use and fertilizer practices on $\delta^{15}N$ value of individual amino acids in soil.[20] Previous studies[21] also showed that the $\delta^{15}N$ signatures of individual amino acids (e.g., histidine and phenylalanine) can be used to discriminate between different plant species in relation to the acquisition of available N sources. Amino acids are indeed the dominant low molecular weight nitrogen-bearing biomolecules in plants, and the pattern of isotopic fractionation during synthesis of these compounds records a range of information about the growth environment, such as the form of plant-available nitrogen in the soil.

New and more sensitive markers are needed to verify the authenticity of organically grown plants, and this study is thus timely and of practical relevance. We investigated the feasibility of using compound-specific nitrogen and carbon isotope analysis of plant-derived amino acids for differentiation between organically and conventionally grown wheat. The study was conducted on common wheat from Danish field trials and on durum wheat from Italian on-farm studies.

MATERIALS AND METHODS

Reagents and Reference Materials. L-Amino acid standards at ≥98% purity (alanine, aspartic acid, glutamic acid, glycine, isoleucine, norleucine, leucine, phenylalanine, proline, and valine) and analytical grade cation-exchange resin (Amberlite IR120 hydrogen form) were purchased from Sigma-Aldrich. All other solvents (dichloromethane, isopropanol, acetone, and ethyl acetate) and reagents (triethylamine and acetic anhydride) used were of analytical grade and purchased from Sigma-Aldrich and VWR (Milan, Italy).

Plant Materials and Sampling. Eighteen samples of winter wheat (*Triticum aestivum* L. cv. Tommi) were grown at three different Danish geographical locations: Flakkebjerg (FL), Foulum (FO), and Jyndevad (JY). The plants were grown in three systems (one conventional and two organic) under controlled conditions in a long-term field trial and were sampled in 2007 and 2008. The conventional system (CS) relied on the use of pesticides and synthetic fertilizers, whereas the organic systems (OSA and OSB) were managed in full compliance with the guidelines for organic farming (European Community Council Regulation EEC 2091/91 and EC 834/2007). The two organic systems OSA and OSB differed with regard to nutrient input. In the OSA system pig manure was imported from conventional farms, whereas the OSB system relied on nutrient input from green manures originating from cover crops being mixtures of grasses and N_2-fixing legumes. Fertilizer application rates as well as the percentage content of C and N in wheat samples are shown in Table 1. A map of the locations, soil characteristics, further details regarding field trials, climatic conditions, sampling of wheat grains and sample preparation are described elsewhere.[22]

[a]CS, conventional; OSA, organic with animal manure; OSB, organic with green manures.

In addition to the 18 samples from Denmark, 17 samples of durum wheat (*Triticum turgidum* ssp. durum cv. Khorasan, Senatore Cappelli, Simeto, or Levante) were collected from commercial farms in 2012 in the main wheat-producing regions of Italy (Basilicata, $n = 7$; Molise, $n = 7$; and Emilia-Romagna, $n = 3$). Wheat was grown in each location in either a conventional system (CS, with mineral fertilizer) or an organic system (with organic fertilizer, OSA; or after 5 years of legumes, OSB; or without any fertilizer). The organic systems were managed in full compliance with the guidelines for organic farming (European Community Council Regulation EC 834/2007) for at least 8 years prior to the sample production. The systems were all based on stockless crop production but were managed differently depending on soil characteristics, climate, and farm structure. In the conventional system, pesticides and inorganic fertilizers were used according to usual farming practice. Nutrient supply in the organic system was based on the crop rotation built fertility and in some cases addition of commercial pelleted organic fertilizers. No irrigation was used for any of the organic and conventional fields. Information about location, cropping system, variety, and fertilizers used as well as the percentage content of C and N in wheat samples is reported in Table 2. All durum wheat samples were harvested at maturity and consequently on different days in the different regions (from mid-June until mid-July).

EA-IRMS Analysis. The $\delta^{15}N$ and $\delta^{13}C$ values of pure non-derivatized single amino acids and of bulk samples were measured using an elemental analyzer (Flash EA 1112, Thermo Scientific, Bremen, Germany), equipped with an autosampler (Finnigan AS 200, Thermo Scientific) and interfaced through a ConFlo IV dilutor device (Thermo Finnigan, Bremen, Germany) with a DELTA V isotope ratio mass spectrometer (Thermo Scientific). The isotopic values were calculated against L-glutamic acid USGS 40 (IAEA-International Atomic Energy Agency, Vienna, Austria), fuel oil NBS-22 (IAEA), and sugar IAEA-CH-6

[a]Conv, conventional; Org, organic.

for $^{13}C/^{12}C$ and against L-glutamic acid USGS 40 and potassium nitrate IAEA-NO3 for $^{15}N/^{14}N$.

The content of N and C was measured using IRMS (ANCA-SL elemental analyzer coupled to a 20-20 Tracermass mass spectrometer, Sercon Ltd., Crewe, UK). Quality assurance was performed by duplicate measurements of all samples as well as analysis of Certified Reference Materials (NIST 1515, NIST 8436, and 141d acetanilide $CH_3CONHC_6H_5$, National Institute of Standards and Technology) as previously described.[22]

Hydrolysis of Protein and Purification. Wheat samples were defatted three times with petroleum ether/ethyl ether (2:1 v/v, 30 mL) homogenizing with an Ultraturrax device (model X-620, Staufen, Germany; 11500 rpm for 3 min) and using a centrifuge (ALC PK 131R, Thermo Electron Corp., Germany; 4100 rpm for 6 min) to separate the ether from the residue. The defatted powdered samples were left open to air-dry and then stored at room temperature until analysis.

Acid hydrolysis was conducted to obtain individual amino acids from protein: 250 mg of lipid-extracted sample was digested with 2 mL of 6 M HCl at 110 °C for 24 h in a PTFE-capped Pyrex vial. After cooling, the hydrolyzed solution was filtered on glass wool, and the solution was blown to dryness under N_2 and redissolved in 2 mL of 0.1 M HCl. A known quantity of norleucine (8 mg mL^{-1} in 0.1 M HCl) was added as internal standard, and the solution was stored at −20 °C.

Amino acids were purified through ion-exchange chromatography on an Amberlite IR120 cation-exchange resin, previously saturated with H^+ on all exchange sites. This was accomplished by soaking the resin overnight in 3 M NaOH, followed by washing in distilled water and soaking overnight in 6 M HCl, after washing with distilled water. The H^+ saturated resin was pipetted into a glass pipet column fitted with a quartz wool plug, and a fraction of the hydrolyzed sample (500 μL) was added to the column. Salts were removed with distilled water and the amino acids eluted with NH_4OH (10 wt %) and then dried under N_2 before derivatization. Under those conditions, the resin does not cause any isotopic fractionation.[23,24]

Derivatization. Amino acids were analyzed after *N*-acetylisopropyl derivatization based on the method reported elsewhere.[25] Samples were first esterified in 1 mL of acidified isopropanol (1:4 acetyl chloride/isopropanol) at 100 °C for 1 h. Esterifying reagents were evaporated under a gentle stream of nitrogen at 40 °C, and dried esters were rinsed with two sequential 250 μL aliquots of dichloromethane to remove reagents in excess. Amino acid esters were acylated with 1 mL of acetic anhydride/triethylamine/acetone solution (1:2:5 v/v) at 60 °C for 10 min. The reagents were evaporated under a N_2 stream at room temperature, and dried derivatives were dissolved in 1 mL of saturated NaCl−water solution and 1 mL of ethyl acetate and mixed vigorously. The organic phase containing the amino acids was collected and dried under nitrogen at room temperature. Residual water was removed with two sequential 250 μL aliquots of dichloromethane. Finally, samples were dissolved in 200 μL of ethyl acetate and stored at −20 °C until analysis.

GC-C-IRMS Analysis. The isotopic values of 10 amino acids, alanine (Ala), aspartate (Asx), glutamate (Glx), glycine (Gly), isoleucine (Ile), leucine (Leu), phenylalanine (Phe), proline (Pro), threonine (Thr), and valine (Val), were determined by GC-C-IRMS (Figure 1).

Due to the acid hydrolysis, asparagine (Asn) and glutamine (Gln), present in wheat, are converted into aspartic acid (Asp) and glutamic acid (Glu), respectively. Therefore, the $\delta^{15}N$ and $\delta^{13}C$ values determined of Asx and Glx represent the nitrogen and carbon isotopic value of both aspartate + asparagine and glutamate + glutamine, respectively.[24]

Individual amino acid isotopic analysis was carried out using a Trace GC Ultra (GC IsoLink + ConFlo IV, Thermo Scientific) interfaced with an IRMS (DELTA V, Thermo Scientific) through an open split interface and with a single-quadrupole GC-MS (ISQ Thermo Scientific) to identify the compounds. For $\delta^{15}N$ analysis 0.8−1.0 μL of each sample was injected in splitless mode by an autosampler (Triplus, Thermo Scientific). A HP-INNOWAX capillary column (60 m × 0.32 mm i.d. × 0.25 μm film thickness; Agilent) with He as carrier gas (at a flow of 1.4 mL/min) was used. The injector temperature was set at 250 °C, and the oven temperature of the GC started at 40 °C, at which it was held for 2 min before heating at 40 °C/min to 140 °C, at 2.5 °C/min to 180 °C, at 6 °C/min to 220 °C, and finally at 40 °C/min to 250 °C and held for 15 min. For $\delta^{13}C$ analysis 1.0 μL of each sample was injected in split mode and a stronger polar column was used to obtain higher and sharper peaks (ZB-FFAP capillary column, 30 m × 0.25 mm i.d. × 0.25 μm film thickness; Phenomenex). The oven temperature of the GC started at 40 °C, at which it was held for 1 min before heating at 15 °C/min to 120 °C, at 3 °C/min to 190 °C, and finally at 5 °C/min to 250 °C and held for 7 min.

The eluted compound was combusted into N_2, CO_2, and H_2O in a combustion furnace reactor operated at 1030 °C and composed of a nonporous alumina tube (320 mm length) containing three wires

J. Agric. Food Chem. 2015, 63, 5841−5850

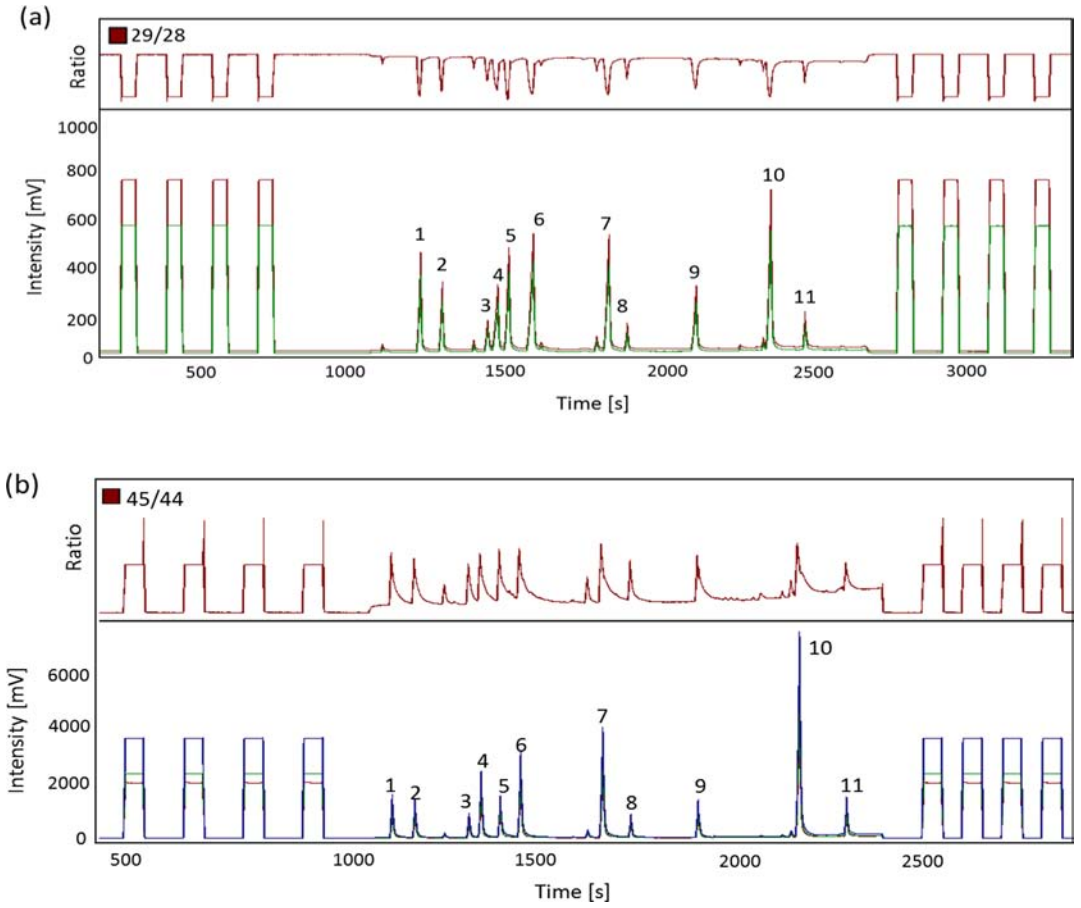

Figure 1. GC-C-IRMS chromatogram of *N*-acetyl-isopropyl derivatives of amino acids in a wheat sample (nitrogen isotopic ratio (a) and carbon isotopic ratio (b)). Peaks: 1, Ala; 2, Val; 3, Ile; 4, Leu; 5, Gly; 6, Nleu (internal standard); 7, Pro; 8, Thr; 9, Asx; 10, Glx; 11, Phe. The four first and last peaks of each panel are reference gas signals.

(Ni/Cu/Pt, 0.125 mm diameter, 240 mm identical length) braided and centered end-to-end within the tube. Water vapor was removed by a water-removing trap, consisting of a Nafion membrane. During $\delta^{15}N$ analysis a liquid nitrogen trap was added after the combustion oxidation reactor to remove CO_2 from the oxidized and reduced analyte.

To monitor instrumental performance a mixture of L-amino acid standards was derivatized and the $\delta^{15}N$ and $\delta^{13}C$ values were measured by GC-C-IRMS before each analytical run. Moreover, the isotopic value of the internal standard norleucine added to each sample was checked. Norleucine was chosen as internal standard because it is not naturally present in wheat. The $\delta^{15}N$ and $\delta^{13}C$ values of pure norleucine (+14.0 and −27.6‰, respectively) and of the pure L-amino acids (see below) were determined by EA-IRMS. The analytical run was accepted when the differences between GC-C-IRMS and EA-IRMS values were, at most, ± 1.0 and ±1.5‰, respectively, for $\delta^{15}N$ and $\delta^{13}C$.

Data Analysis and Corrections. All of the $\delta^{15}N$ and $\delta^{13}C$ values are reported relative to reference N_2 and CO_2 of known nitrogen and carbon isotopic composition, respectively, introduced directly into the ion source at the beginning and end of each run (Figure 1). All samples were measured in triplicate, and the isotope ratios were expressed in δ‰ versus atmospheric nitrogen for $\delta^{15}N$ and V-PDB (Vienna − Pee Dee Belemnite) for $\delta^{13}C$ according to eq 1

$$\delta = \left[\frac{(R_s - R_{std})}{R_{std}}\right] \quad (1)$$

where R_s is the isotope ratio measured for the sample and R_{std} is the isotope ratio of the internationally accepted standard.

Measured $\delta^{13}C$ values for derivatized amino acids are the product of both the carbon native to the molecule and the contribution from the reagents used for derivatization. The $\delta^{13}C$ values of the mixture of standard amino acids measured by EA-IRMS and their respective *N*-acetylisopropyl esters obtained with GC-C-IRMS are presented in the Supporting Information (SI 1). Therefore, an empirical correction[26] was applied to determine the effective carbon isotope value. Correction factors were calculated by determining the $\delta^{13}C$ values of the underivatized amino acid standards (EA-IRMS) and the derivatized amino acid standards (GC-C-IRMS):

$$n_{cd}\delta^{13}C_{cd} = n_c\delta^{13}C_c + n_d\delta^{13}C_d \quad (2)$$

n is the number of moles of carbon, and the subscripts c, d, and cd represent the compounds of interest, the derivative group, and the derivatized compound, respectively.

When calculating the uncertainty of $\delta^{13}C$ measurement (see below), we considered measurement errors as well as the total analytical error, which arises from the different derivatization steps:

$$\sigma_c^2 = \sigma_s^2\left(\frac{n_s}{n_c}\right)^2 + \sigma_{sd}^2\left(\frac{n_s + n_d}{n_c}\right)^2 + \sigma_{cd}^2\left(\frac{n_c + n_d}{n_c}\right)^2 \quad (3)$$

n is the number of moles of carbon, and the subscripts c, cd, d, s, and sd, represent the underivatized compound, the derivatized compound, the derivatizing reagent, the underivatized standard, and the derivatized standard, respectively.

Accuracy and Precision of GC-C-IRMS. To test the accuracy of the determination of amino acid isotopic values, we compared the $\delta^{15}N$ and $\delta^{13}C$ values of the mixture of standard amino acids measured by GC-C-IRMS with the isotopic values of pure nonderivatized single amino acids obtained with EA-IRMS. The $\delta^{15}N$ and $\delta^{13}C$ values determined by EA-IRMS were the mean of two measurements, whereas the $\delta^{15}N$ and $\delta^{13}C$ values determined by GC-C-IRMS were the average of three runs. Both

DOI: 10.1021/acs.jafc.5b00662
J. Agric. Food Chem. 2015, 63, 5841−5850

$\delta^{15}N$ and $\delta^{13}C$ values obtained from EA-IRMS were linearly correlated with those from GC-C-IRMS after derivatization, as shown in the Supporting Information (SI 2 and SI 3), and the difference between the values measured by EA-IRMS and by GC-C-IRMS after empirical correction was not higher than ±0.5 and ±1.6‰ for $\delta^{15}N$ and $\delta^{13}C$, respectively (SI 1).

To evaluate the precision, 10 replicates of the reference amino acid mixture were derivatized, and each of them was analyzed by GC-C-IRMS in triplicate. The precision (1σ) of GC-C-IRMS determinations was on average ±0.4‰ for $\delta^{15}N$ and ±0.8‰ for $\delta^{13}C$.

To evaluate the uncertainty of measurements for all of the processes, a wheat sample was hydrolyzed and derivatized 10 times, and each of the samples was analyzed by GC-C-IRMS. The standard deviation obtained (1σ) was on average ±0.3‰ for $\delta^{15}N$ and ±1.0‰ for $\delta^{13}C$ (Supporting Information (SI 4).

Statistical Analysis. The data were statistically evaluated using Statistica v 9 (StatSoft Italia srl, Padua, Italy).

RESULTS AND DISCUSSION

Wheat Amino Acid $\delta^{15}N$ and $\delta^{13}C$ Values. The $\delta^{15}N$ and $\delta^{13}C$ values of the amino acids Ala, Val, Ile, Leu, Gly, Pro, Thr, Asx, Glx, and Phe from the 18 Danish and from the 17 Italian wheat grain samples are shown in the Supporting Information (SI 5 and SI 6), whereas the mean and standard deviation (SD) values across agricultural systems are reported in Tables 3 and 4.

From the $\delta^{15}N$ values it is evident that the ^{15}N content between different amino acids can vary significantly due to isotopic fractionation occurring during N metabolism within the plant. Ammonium (NH_4^+) from soil is assimilated directly into plant amino acid metabolism via the enzyme glutamine synthetase, whereas nitrate (NO_3^-) undergoes sequential reduction to nitrite and then subsequently to ammonia via the nitrate and nitrite reductase enzymes.[27] The first amino acid produced by ammonia assimilation is glutamine, which therefore plays a central role in the amino acid metabolism. Glutamate and then other amino acids are produced by the transfer of the amide of glutamine to keto acids and by transamination.[28] It follows that in our case the $\delta^{15}N$ of glutamic acid derived from acid hydrolysates of glutamic acid and glutamine (Glx) represents the main source of imported nitrogen being a product of the net flux of N entering and leaving the Gln and Glu pools.

Figure 2a shows mean values of differences between the $\delta^{15}N$ values of Ala, Val, Ileu, Leu, Gly, Pro, Thr, Asx, and Phe and that of Glx across all 35 wheat samples. This allows comparison of the $\delta^{15}N$ value of single amino acids normalizing the possible variation caused by the external nitrogen source (e.g., fertilizer practices, soil composition, location). The $\delta^{15}N$ relative trend among amino acids is in agreement with the results reported in other studies.[29] As compared to the $\delta^{15}N$ value of Glx (Figure 2a), the $\delta^{15}N$ values of Phe (+4.4 ± 1.4‰) and Pro (+1.0 ± 0.8‰) are higher. The relative ^{15}N enrichment of Phe and Pro compared to the other amino acids in cereal grains is in agreement with the scientific literature on the subject, concluding that there is an isotopic fractionation associated with this enzymatic reaction.[29] Phenylalanine ammonia-lyase catalyzes the deamination of Phe, and the kinetic isotope effect associated with this reaction leaves the residual Phe enriched in ^{15}N, whereas the ^{15}N enrichment of Pro is caused by a kinetic isotope effect associated with the enzymes (proline dehydrogenase and Δ^1-pyrrolidine-5-carboxylate dehydrogenase) involved in its catabolism.[29,30]

The $\delta^{15}N$ values of Ala (−3.1 ± 1.5‰), Val (−1.4 ± 1.4‰), Ileu (−4.1 ± 1.8‰), Leu (−5.7 ± 1.3‰), Gly (−5.0 ± 1.8‰), Thr (−9.8 ± 2.5‰), and Asx (−2.9 ± 1.6‰) are lower than the

[a]Values are the means of three analytical replicates. CS, conventional; OSB, organic with green manure; OSA, organic with animal manure; nothing, organic without fertilizer treatment; SD, standard deviation. Significantly different mean values (HSD Tukey's, $p < 0.05$) between groups are indicated with letters "a" and "b".

$\delta^{15}N_{Glx}$ value. These amino acids are principally produced during transamination of precursors, amino acids (e.g., glutamic acid), and keto acids. Previous studies[31] have reported that enzymatic reactions of transamination involved in plant metabolism induced a kinetic isotope effect leading to the lower $\delta^{15}N$ values in NH_2 of product amino acid and that the extent of isotopic fractionation may vary depending on the reaction rates.

The mean $\delta^{13}C$ value of plant material is fixed by that of the primary carbon source (CO_2) and by the kinetic isotope effect of the CO_2-binding reaction (RuBP-carboxylase and PEP-carboxylase, respectively). The pattern of aliphatic amino acids and aromatic amino acids derived from glucose and shikimic acid, respectively, reflects the resulting ^{13}C distribution of these precursors, and it is supplemented by the introduction of additional C atoms depleted by the kinetic isotope effect on the PEP−carboxylase reaction.[32] Figure 2b shows mean values of differences between the $\delta^{13}C$ values of Ala, Val, Ileu, Leu, Gly, Pro, Thr, Asx, and Phe and that of Glx across all 35 wheat samples from all three agricultural systems and locations. $\delta^{13}C$ values of Gly (+9.6 ± 3.3‰) and Thr (+11.6 ± 2.7‰) were higher than the $\delta^{13}C_{Glx}$ value, whereas the $\delta^{13}C$ values of Val (−6.1 ± 2.2‰), Ileu (−2.0 ± 2.1‰), Leu (−9.6 ± 2.1‰), Pro (−2.1 ± 2.2‰), and Phe (−2.7 ± 4.0‰) were lower. The measured $\delta^{13}C$ values of Ala and Asx were very similar to that of Glx (within ±2.5 and ±2.4‰, respectively) in all of the wheat samples.

$\delta^{15}N$ and $\delta^{13}C$ Amino Acid Values for Organic Authentication. In Tables 3 and 4 the mean and standard deviation of the data grouped according to agricultural system across locations in Denmark and Italy, respectively, as well as the results of the honestly significantly difference (HSD) for unequal N Tukey's test are reported.

Grouping the Danish samples according to the agricultural systems, Tukey's test results (Table 3) showed that conventionally grown wheat had significantly lower $\delta^{15}N$ values than the organic wheat OSA, whereas it was not distinguishable from the organic wheat fertilized with green manure (OSB). This corresponds with results from bulk tissue analysis in previous studies.[1] This finding clearly highlights the limitation of $\delta^{15}N$ as a marker of organic production when plant fertilization is based on N_2-fixing green manures. On the other hand, the $\delta^{13}C$ value of Glx was significantly ($p < 0.05$) lower in the conventional wheat compared to both organic systems (OSA and OSB). $\delta^{15}N$ values of plant amino acids are clearly affected by the nitrogen source, which in this case results in similar $\delta^{15}N$ values for CS and OSB samples. In contrast, $\delta^{13}C$ is more linked to the different characteristics of the field under conventional and organic regimens in terms of water availability, drought stress, and nutrient availability, which influence the photosynthetic activity and stomatal conductance of leaves.[14−18] Here we found lower $\delta^{13}C$ values in the conventional wheat, which is expected to be due to a higher stomatal conductance in these plants due to the higher nitrogen content (as reported in Tables 1 and 2). Indeed, previous studies[33] showed that the maximum CO_2 assimilation rates and maximum stomatal conductance, when measured under higher N availability conditions, as typically observed in conventional crops, did lead to a higher discrimination of RuBisCo against $^{13}CO_2$. In contrast, N deficiency, as in the case of organic crops, can induce stomatal closure, which is caused by a lower ratio of the N-regulated plant hormones cytokinin and abscisic acid. This leads to a reduced discrimination against $^{13}CO_2$ and thereby higher $\delta^{13}C$ values. Lower $\delta^{13}C$ values were also observed in proteins extracted from conventional apples,[34]

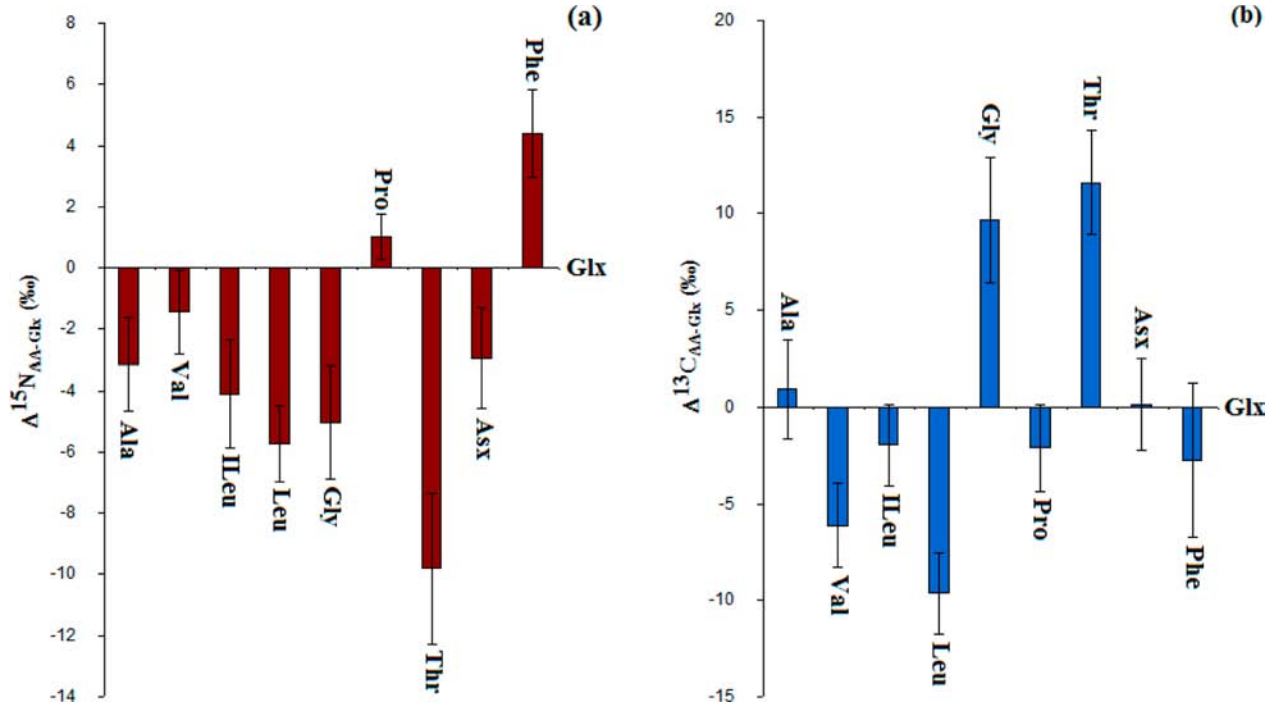

Figure 2. Differences between the δ^{15}N (a) and δ^{13}C (b) values of Ala, Val, Ileu, Leu, Gly, Pro, Thr, Asx, and Phe and the δ^{15}N and δ^{13}C of Glx for all of the Danish and Italian wheat samples. Bars represent mean values ± SD (n = 35).

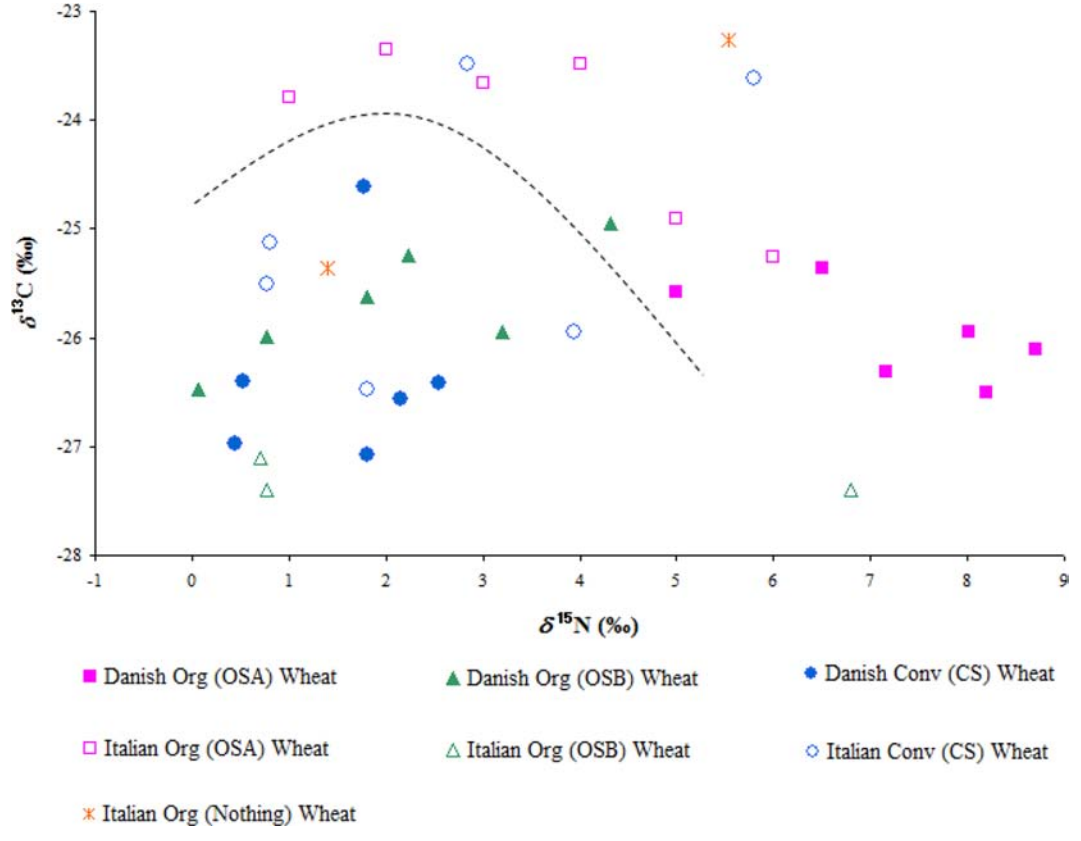

Figure 3. δ^{15}N plotted against δ^{13}C in bulk tissue samples of Danish and Italian wheat samples. Circles are CS (conventional), squares are OSA (organic with animal manure), triangles are OSB (organic with green manure), and stars are nothing (organic without fertilizer treatment). Solid and open symbols indicate Danish and Italian samples, respectively. Please note that the dashed line is only for illustrative purposes and does not represent statistical analysis.

but not in conventional onions and cabbages[15] or in soil of conventional grassland.[35]

Applying Tukey's test on δ^{15}N amino acid values of the Italian durum wheat samples grouped according to the agricultural

DOI: 10.1021/acs.jafc.5b00662
J. Agric. Food Chem. 2015, 63, 5841−5850

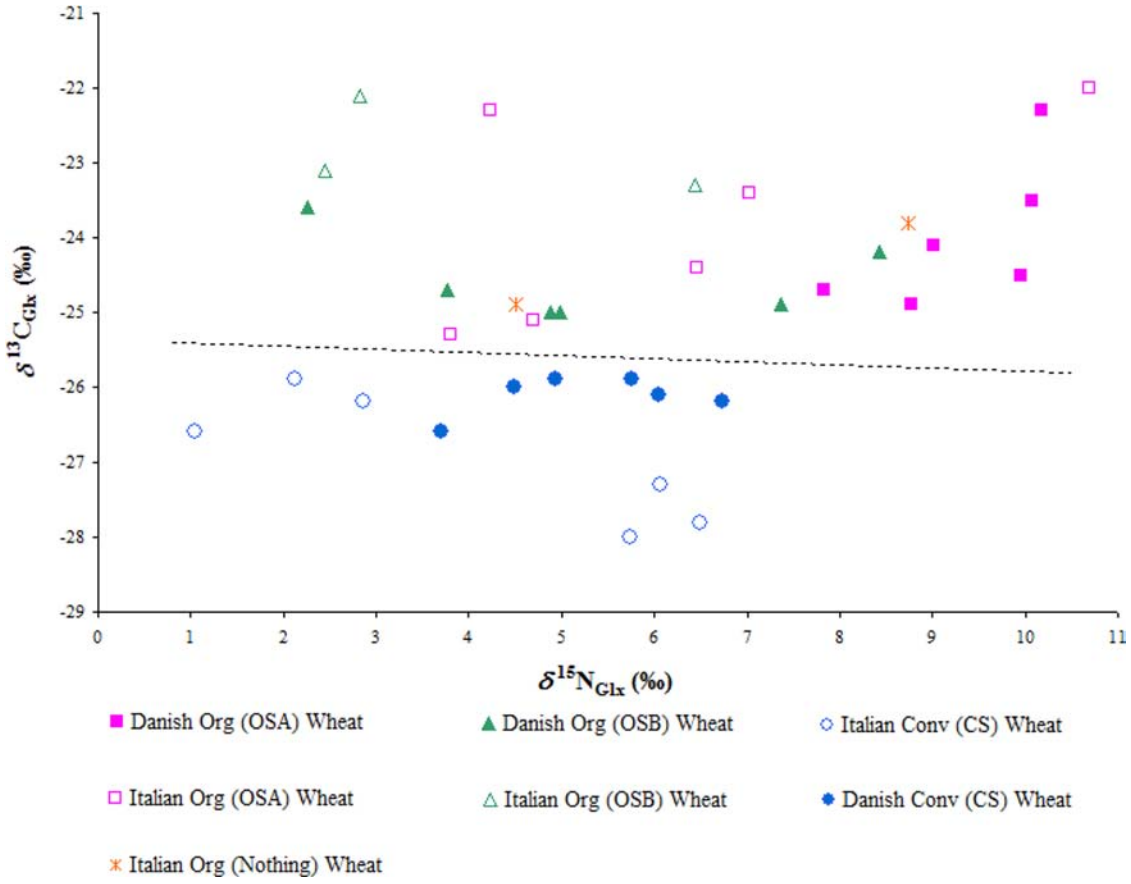

Figure 4. δ^{15}N in Glx plotted against δ^{13}C in Glx of Danish and Italian wheat samples. Circles are CS (conventional), squares are OSA (organic with organic fertilizer), triangles are OSB (organic with green manure), and stars are nothing (organic without fertilizer treatment). Solid and open symbols indicate Danish and Italian samples, respectively. Please note that the dashed line is only for illustrative purposes and does not represent statistical analysis.

regimen, no significant differences between the four groups were observed (Table 4). Conventionally cultivated durum wheat was not distinguishable from either the organic wheat OSA (fertilized with organic fertilizer) or OSB (fertilized with green manure) or organic wheat grown without fertilization. The main reason for this finding is that we considered samples produced in different Italian regions (Emilia Romagna, Basilicata, Molise) potentially characterized by different δ^{15}N values of the soil.

As observed for Danish wheat and also for Italian durum, the δ^{13}C values of some amino acids were significantly different between agricultural regimens. In particular the δ^{13}C of Glx was significantly lower ($p < 0.05$) in the conventional samples compared to organic systems (OSA, OSB, nothing) as for Danish samples.

On the basis of Tukey's test results we decided to consider all Danish and Italian samples together focusing on δ^{15}N and δ^{13}C values of Glx for discriminating between the agricultural systems. Moreover, we considered δ^{15}N and δ^{13}C values of bulk tissue wheat grain samples, taking the data from the literature for Denmark[1] and measuring the samples from Italy to conduct a direct comparison with the compound-specific data. Figure 3 shows the distribution of δ^{15}N and δ^{13}C values of Danish and Italian bulk tissue samples, whereas Figure 4 shows the same distribution for δ^{15}N and δ^{13}C values of Glx. The bulk tissue analysis allowed separation of wheat samples grown with the use of animal manure (OSA) from samples grown using synthetic fertilizers (CS), but it was impossible to distinguish the agricultural system based on legumes as green manures (OSB) from the conventional one, as discussed above.

However, the δ^{15}N and δ^{13}C values of Glx (Figure 4) improved the discrimination between the conventional and organic agricultural systems. In particular, the δ^{13}C value of Glx was able to distinguish organic samples from those grown in the conventional agricultural system—even when including the variations caused by wheat species, variety, harvest period, geographical location, etc.

Previous studies[36] have shown that multivariate statistical analysis can be a tool to improve the discrimination between different foods (e.g., organic and conventional). Linear discriminant analysis (LDA) is probably the most frequently used supervised pattern recognition method, which is based on maximization of the ratio of between-class variance and minimization of the ratio of within-class variance. LDA was performed using the data set composed by all wheat samples (35 organic and conventional samples) and 20 variables (δ^{15}N and δ^{13}C amino acid values) to establish if it is possible to enhance the separation between agricultural regimens. After application of LDA, three discriminant functions were calculated, and Figure 5 shows the score plot of the wheat samples using as axes the first two functions that explain 91.2% of total variance.

The three categories of wheat (OSA, OSB, and CS) were well separated across the principal component Rad 1. The latter correlates negatively with δ^{15}N Pro (−2.849) and δ^{13}C Val (−2.158) and positively with δ^{15}N Phe (3.436) and δ^{15}N Glx (2.622). Rad 2 improves the separation between OSA and the

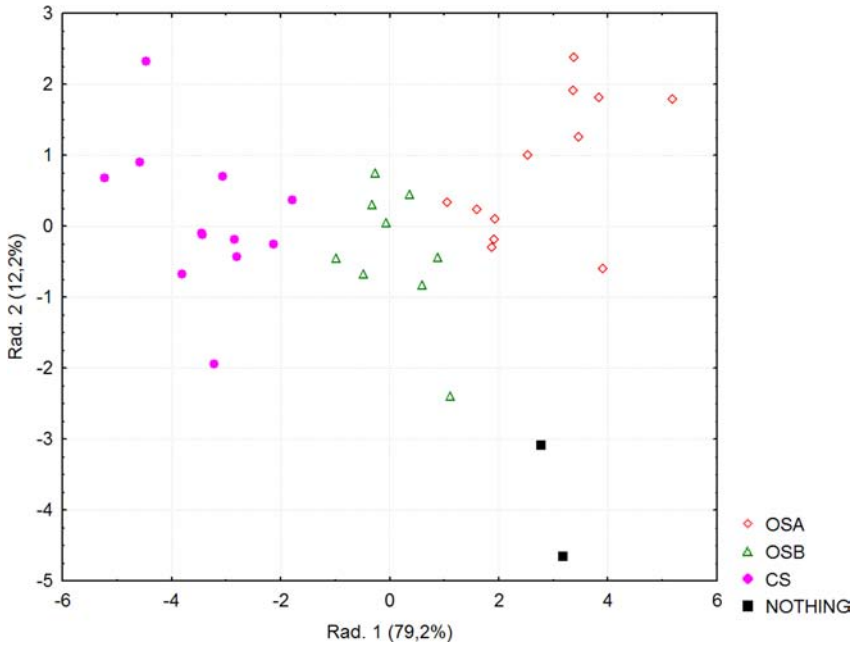

Figure 5. LDA scores plot of nitrogen and carbon isotope analysis of amino acids for organic and conventional wheat samples.

"nothing" group and correlates negatively with δ^{15}N Leu (−1.339), δ^{15}N ILeu (−1.036), and δ^{15}N Glx (−1.018), whereas it correlates positively with δ^{15}N Ala (1.314). δ^{13}C Glx did not correlate significantly with Rad 1 and Rad 2 because it is capable of separating organic from conventional samples but not the three types of organic agricultural systems.

We can conclude that compound-specific δ^{15}N and δ^{13}C analysis of plant-derived amino acids represents a promising tool for verification of the fertilization history of crops. δ^{13}C of glutamic acid and glutamine, in particular, but also the combination of δ^{15}N and δ^{13}C of the 10 amino acids Ala, Val, Ile, Leu, Gly, Pro, Thr, Asx, Glx, and Phe did improve the separation between organic and conventional wheat, even when organic wheat production was based on fertilization and crop rotation using N_2-fixing plants. It is recommended that the novel method is tested on a larger set of samples and across different plant species and locations to further evaluate the applicability of compound-specific stable isotope analysis of amino acids for organic authentication.

[a]For the *Ramandolo Passito* different withering procedures were adopted in the three years.

with hanging of the grapes) were considered in two successive years. Moreover, numerous samples of different traditional Italian *passito* wines from grapes taken at different stages of withering and withered in different conditions were taken into account, focusing on the $\delta^{18}O$ of water.

The final aim was to define the isotopic characteristics of Italian *passito* wines and to check whether isotopic methods can be used for authenticity verification for this type of wine.

The novelty of this study lies in the fact that for the first time, the effect of grape withering processes (up to 5 months) on the variability of the $(D/H)_I$, $(D/H)_{II}$, $\delta^{13}C$, and $\delta^{18}O$ of wine ethanol and the $\delta^{18}O$ of wine and must water was monitored during the production of *passito* wines considering different types of withering and different years. The monitoring carried out becomes very important, because variations in the isotopic values with withering can lead to wrong interpretation of the data and therefore to false conclusions about the authenticity of the samples.

MATERIALS AND METHODS

Grape Samples. The study focused on *Erbaluce di Caluso Passito* DOC, a wine produced with Erbaluce white grapes grown in the province of Turin (Piedmont, northwestern Italy) during 2011 and 2012.[21] The grape samples were withered in five different cellars with fruit-drying rooms (*fruttaio*) located in Caluso (N 45.301045, E 7.894921), identified as ER-A, ER-B, and ER-C, in San Giorgio Canavese (N 45.333054, E 7.798944), ER-D, and in Piverone, ER-E (N 45.445302, E 8.006088), and the producers guaranteed respect of the procedural guidelines (G.U no. 248). ER-A withered the grapes by hanging them, ER-B put the product on wicker trellises, ER-C and ER-D withered the grapes in small boxes (holding about 5 kg), and ER-E used big boxes (holding about 20 kg), both in single layers. Two tons of Erbaluce grapes were withered for all cellars and years. During withering, relative humidity and temperature were monitored in each cellar using a Hobo data logger (Onset, Bourne, MA, USA). In 2011, the withering process was faster due to specific climatic conditions. In particular, the relative humidity percentage (RH%) in the first period of withering was low (60−65%) and the sugar increment achieved was about 10 °Brix. In 2012, the RH% in the first period of dehydration was 70−82%, with a low sugar concentration (+3 °Brix) in some cellars (EC-A, EC-D, EC-D). In this case, a longer processing time was necessary to obtain the minimum sugar content for the production of *Erbaluce di Caluso Passito* wine in accordance with its production discipline. In 2012 one sample of fresh grapes from ER-C was also withered in controlled climatic conditions (25 °C; 55 RH%) in a controlled chamber (ER-F).

Moreover, 78 grape samples used to produce 17 different traditional Italian *passito* wines (Table 1) were sampled in 2011, 2012, and 2013 by inspectors of the Italian Ministry of Agriculture. For each product, the grapes were collected immediately after harvesting and at the end of withering. In some cases an intermediate sample was also collected. We can identify two large groups (samples withered in the *fruttaio* and *en plein air*) and, within these, particular types of withering (e.g., on trellises, in boxes, or hung).

Vinification. For the study focused on *Erbaluce di Caluso*, a sample of about 10 kg of fresh and dried berries was used for must and wine production and analysis, with an interval of 4−5 weeks during the withering processes.

For the other traditional *passito* wines (Table 1), about 10 kg of fresh and dried berries was used for the must.

All samples of fresh and dried grapes were manually crushed and pressed, and the must was clarified with static decantation for 24 h, without adjuvants. In the must sample fermentation was arrested with sodium metabisulfite (800 mg/L).

For wine production each sample of must was inoculated with *Saccharomyces cerevisiae* (Uvaferm BC strain, Lallemand, Verona, Italy) rehydrated in each must and 1 g/L of yeast nutrient (Fermaind, Lallemand). Alcoholic fermentation took place at 25 °C in glass bottles with a bubbler valve in the cap.

Analysis. The D/H and $^{13}C/^{12}C$ isotope ratios of the alcohol obtained by distillation using Cadiot columns were determined following the official methods established by the International Organization of Vine and Wine (OIV), MA-AS-311-05 MA-AS-312-06, using site-specific natural isotope fractionation-nuclear magnetic resonance (SNIF-NMR) (FT-NMR AVANCE III 400, Bruker BioSpin GmbH, Karlsruhe, Germany) and isotope ratio mass spectrometry (IRMS) (SIRA II-VG ISOGAS, FISIONS, Rodano, Milano, Italy) interfaced with an elemental analyzer (Flash 1112, Carlo Erba, Milano, Italy). The D/H values were measured site-specifically in the methyl and methylene positions of ethanol [$(D/H)_I$ and $(D/H)_{II}$].

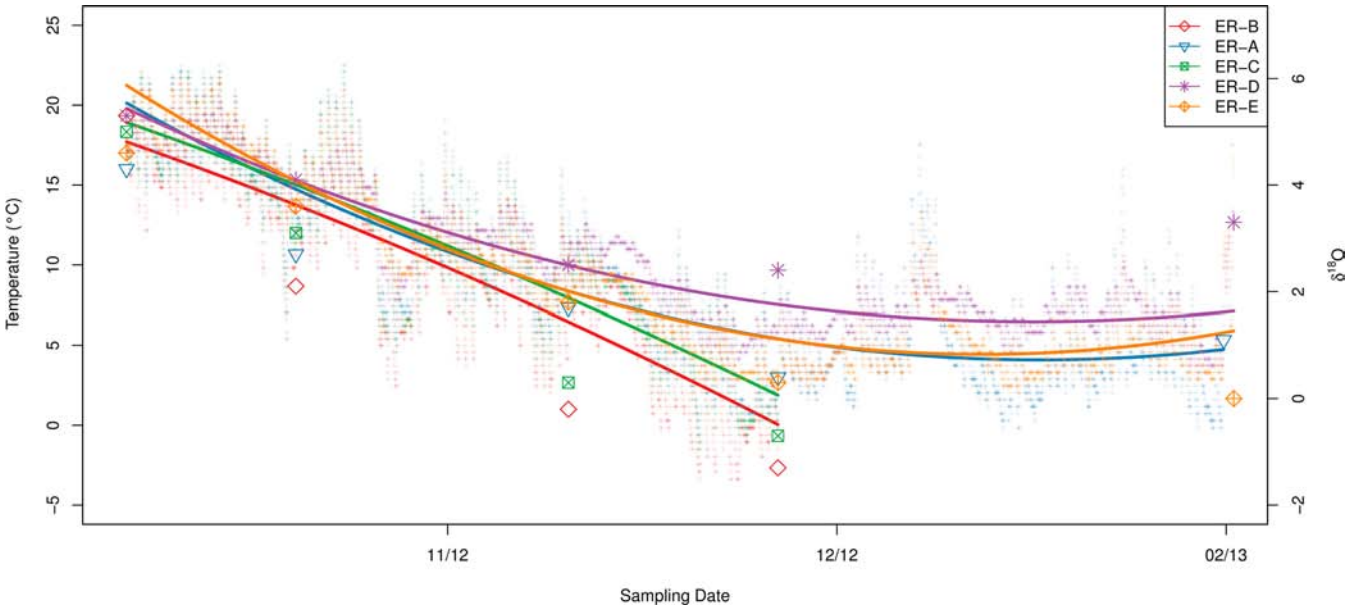

Figure 1. Variation in $\delta^{18}O$ with temperature in the *fruttaio*.

$^{18}O/^{16}O$ ratio analysis of wine and must water was performed using a SIRA II (VG Fisons, Middlewich, UK) connected to a water/CO_2 equilibration system Isoprep 1 (VG Fisons). The procedure is described in the OIV-MA-AS2-12 method (2009).

A DeltaPlus-XP isotope ratio mass spectrometer (IRMS) coupled to a thermal conversion/elemental analyzer (TC/EA) (both Thermo Scientific, Bremen, Germany) was used for $^{18}O/^{16}O$ analysis of ethanol samples following the procedure reported by Perini and Camin.[16]

The $^{13}C/^{12}C$ and $^{18}O/^{16}O$ values are denoted in delta in relation to the international V-PDB (Vienna-Pee Dee Belemnite) and V-SMOW (Vienna-Standard Mean Ocean Water) standards according to the general equation

$$\delta i\ \mathrm{E} = \frac{(i\ \mathrm{RSA} - i\ \mathrm{RREF})}{i\ \mathrm{RREF}}$$

where i is the mass number of the heavier isotope of element E (for example, ^{13}C); RSA is the respective isotope number ratio of a sample (such as for C, number of ^{13}C atoms/number of ^{12}C atoms or as $^{13}C/^{12}C$ approximation);[22,23] and RREF is the respective isotope number ratio of internationally recognized reference materials (see above).

The delta values are multiplied by 1000 and are expressed in units "per mil" (‰).

The working reference materials are specified in the OIV methods. A sample of wine was used to validate the whole analysis (distillation + measurement). With one sample of must we also allowed for fermentation. The final value was reported in a control chart, and if it was within the tolerance range, the whole session was validated.

The analytical uncertainties (estimated by combining within-laboratory reproducibility standard deviation with estimates of method and laboratory bias using proficiency test data)[24] of the measurements were 0.3‰, 0.6‰, 0.8 ppm, and 1.2 ppm for $\delta^{13}C$, $\delta^{18}O$, $(D/H)_I$, and $(D/H)_{II}$ in ethanol, respectively. For the $\delta^{18}O$ of water, the value was 0.3‰.

The alcohol content and residual sugar content were analyzed following the OIV-MA-AS312-01A and OIV MA-AS311-02 official methods.

Total soluble solid concentration (°Brix, as SSC) was measured with an Atago 0−32 °Brix temperature compensating refractometer (Atago Corp., Tokyo, Japan), and pH was determined with potentiometry, using a Crison electrode (Carpi, Italy). Titratable acidity (TA), expressed as grams of tartaric acid per liter, and ethanol expressed in % (v/v) were estimated using the OIV method. Glucose, fructose, and glycerol were quantified (as g/L) using a high-performance liquid chromatography system.[4]

Statistical Analysis. All statistical analysis was performed in R [R]. Linear modeling was applied to identify significant relationships between the $\delta^{18}O$ and temperature/humidity profiles recorded during withering. To account for differences in the initial conditions in the five different fruit-drying rooms, the initial conditions were subtracted from the $\delta^{18}O$, temperature, and humidity profiles before modeling. Modeling was then performed on the variation in temperature, humidity, and $\delta^{18}O$ shift. Stepwise model selection was performed using the MASS R package, freely available at the CRAN Web site (http://cran.r-project.org/),[25] and the best model was identified with the Akaike information criterion (AIC).

RESULTS AND DISCUSSION

Effect of Withering in Fruit Rooms (*Erbaluce di Caluso Passito*). In Table 2 the $\delta^{18}O$ values of must and wine water and the $(D/H)_I$, $(D/H)_{II}$, R, $\delta^{13}C$, and $\delta^{18}O$ values of wine ethanol are shown, together with some quality data for must and wine. Samples are grouped by cellar and year.

As expected, the sugar content in the grape increased with the degree of withering. The acidity of Erbaluce in the grape was normally very high. During the withering process the decrease in titratable acidity could be attributed to the concentration of cations, in particular K^+, caused by higher weight loss with salification of part of the tartaric acid, and to malic and citric acid depletion.[7] The must for *passito* production has a high sugar content and complete fermentation with *S. cerevisiae* is not possible. The alcohol content and yield generally depend on the initial sugar content in must, which influences yeast metabolism such as the production of glycerol.[26]

Of the isotopic parameters, $\delta^{18}O$ was most influenced by the degree of withering. In each of the five cellars, $\delta^{18}O$ decreased significantly from the starting value (from grapes immediately after harvesting) to the final value (grapes with a higher sugar content), with differences from −2 to −6‰ in must and wine water and from −2 to −10‰ in wine ethanol. As expected, the $\delta^{18}O$ of must was not different from that of wine.

The O stable isotope composition of grape juice is initially controlled by that of the source water and, as the grape berries

DOI: 10.1021/acs.jafc.5b02127
J. Agric. Food Chem. 2015, 63, 5851−5857

mature and approach harvest, by environmental conditions such as temperature and relative humidity, which control the degree of evapotranspiration, tending to enrich the grape water in ^{18}O.[20,27,28] Moreover, the $\delta^{18}O$ of grape water is affected by precipitation during the final development of the grape, with a relatively rapid response, due to stable isotope exchange with water vapor.[17]

Hermann et al. assumed that isotope fractionation takes place at leaf level and that isotopically modified water is transported into the grapes, where its isotopic signature should be preserved.[28] Other authors state that this fractionation takes place particularly in the leaves and also in the berry.[17,29] In a more recent paper,[30] isotope fractionation was also observed in a grape juice exposed to the atmosphere for several days, but protected from rain and snow.

In our study it is evident that grape water is also subject to isotopic fractionation after harvesting in grapes separated from the vines, when dehydration occurs. The decrease in $\delta^{18}O$ was coherent with the decrease in temperature recorded automatically every hour in the different fruit-drying rooms (Figure 1), but not with the variation in relative humidity (Supporting Information Figure S1).

To statistically evaluate the significance of relationships between $\delta^{18}O$ and temperature and humidity, a statistical modeling approach was applied. The rationale behind this is that the actual value for $\delta^{18}O$ shift is determined by the preceding average environmental conditions. By taking into account relative data (see Materials and Methods) the five different fruit-drying rooms can be considered as independent replicates of the same phenomenon.

The modeling was performed by considering the average temperature and humidity values in the period before each $\delta^{18}O$ analysis. To better characterize the process, three scenarios were examined, calculating the average temperature and humidity 1, 2, and 3 weeks before each $\delta^{18}O$ analysis. Each scenario was then modeled separately. In all cases a general linear model of the form $\delta^{18}O = A \times \text{temperature} + B \times \text{humidity} + C \times (\text{temperature} \times \text{humidity}) + D + \varepsilon$ was considered. This form is able to capture the separate effect of changes in temperature and humidity, the implicit contribution of time, and also the possible presence of an interaction effect between the two predictors. This separate modeling approach was preferred to a more complex linear model taking into account all of the possible factors and their interactions for two reasons: (a) the very small number of experimental points (only five time-resolved measurements of the isotopic ratios); (b) high correlations between the averages of temperature and humidity at the 1, 2, and 3 week intervals. In all three cases, the best model was found by stepwise model selection. For all three scenarios, stepwise selection indicated that the interaction term is not necessary to model the $\delta^{18}O$ shift during withering. In all cases, the optimal model had the form $\delta^{18}O = A \times \text{temperature} + B \times \text{humidity} + C + \varepsilon$, the level of significance for the two predictors in the three models being summarized in Table 3.

The results confirmed that temperature is the most significant parameter able to predict $\delta^{18}O$ variations in *passito* wine. By comparison of the adjusted R^2 for the three models (0.71 for week 1, 0.62 for week 2, and 0.57 for week 3, see Table 3), it is also possible to identify the model that shows the best fit with the experimental data. Considering that the 1 week model shows the highest adjusted R^2, it is possible to conclude that the average temperature and humidity in that period were better able to predict the isotopic shifts observed.

Table 3. Levels of Significance for the Modeling of $\delta^{18}O$ on the Basis of Temperature and Humidity

	estimate	std error	P value	signif level[a]

[a]***, <0.0001; **, <0.001; *, < 0.1; ns, not significant.

It is interesting to note that by withering one of the grape samples (ER-F, 2012) in a temperature-controlled room with specific and constant temperature (25 °C) and humidity (55.5%), the grapes were dehydrated to about 49 °Brix in a short time (22 days) and the $\delta^{18}O$ value of wine increased from 4.9 to 9.6‰ (Table 2).

One reason for this is that in this case kinetic isotope fractionation takes place, as described by Ingraham et al. for wines obtained from grapes subjected to extreme evapotranspiration processes due to high daily temperatures and low humidity.[17] To simplify, kinetic or equilibrium isotope fractionation can occur in nature. Kinetic fractionation is a process that separates stable isotopes from one another by their mass during unidirectional processes. One naturally occurring example of kinetic fractionation is the evaporation of seawater to form clouds or the process of evapotranspiration observed in plants. Isotopically lighter water molecules (i.e., those with ^{16}O) evaporate more easily than the isotopically heavier ones, with ^{18}O. During this process the vapor becomes enriched with ^{16}O, whereas water becomes enriched in ^{18}O. Equilibrium isotope fractionation is the partial separation of isotopes between two or more compounds or phases in the thermodynamic equilibrium. Most equilibrium fractionation results from the reduction in vibrational energy (especially zero-point energy) when a heavier isotope is substituted for a lighter one.[31] An example of equilibrium isotope fractionation is the concentration of heavy isotopes of oxygen in liquid water compared with water vapor at low temperature (see Raleigh fractionation).[32]

It is possible to surmise that in the case of withering in the *fruttaio*, in the particular environmental conditions in the drying room, with low temperature and high humidity causing slow withering (up to 4 months and over), there is competition between at least two different processes: diffusive transport of water from the grape, but also isotopic exchange between the grape water and air humidity in the boundary layer at the interface between the skin and atmosphere, until an isotopic equilibrium is reached. The final result in this type of samples is a decrease in the $\delta^{18}O$ of grape water.

The $\delta^{18}O$ of ethanol obtained after distillation of *passito* samples showed good correlation with the $\delta^{18}O$ of *passito* wine water (R^2 = 0.78), as already observed.[16]

In contrast with $\delta^{18}O$, the $(DH)_I$ values of wine ethanol did not change during the experiment in either of the years considered ($P < 0.05$), also in the temperature-controlled room,

DOI: 10.1021/acs.jafc.5b02127
J. Agric. Food Chem. 2015, 63, 5851−5857

whereas the $(DH)_{II}$ and $\delta^{13}C$ values did change, but without any clear trend (Table 2). At all events, in most cases, both $(DH)_{II}$ and $\delta^{13}C$ tended to decrease with withering time (up to 1‰ for $\delta^{13}C$). This may be due to the fact that *passito* wines have a high sugar content, which can obstruct fermentation, in a similar way to sweet wines subject to the stopping of fermentation, with a subsequent decrease in $(DH)_{II}$ and $\delta^{13}C$.[33]

SURVEY OF ITALIAN *PASSITO* WINES

In this section we consider the $\delta^{18}O$ of must water for 78 samples of 17 different traditional Italian *passito* wines (Table 1), including *Erbaluce di Caluso*. For each sample we measured only the $\delta^{18}O$ of must water (Supporting Information Table S1), as this is the official parameter most influenced by withering, as described above.

The samples from northern Italian regions Piedmont, Lombardy, Emilia Romagna, Veneto, and Friuli Venezia Giulia (Figure 2a), subjected to postharvest drying of grapes in

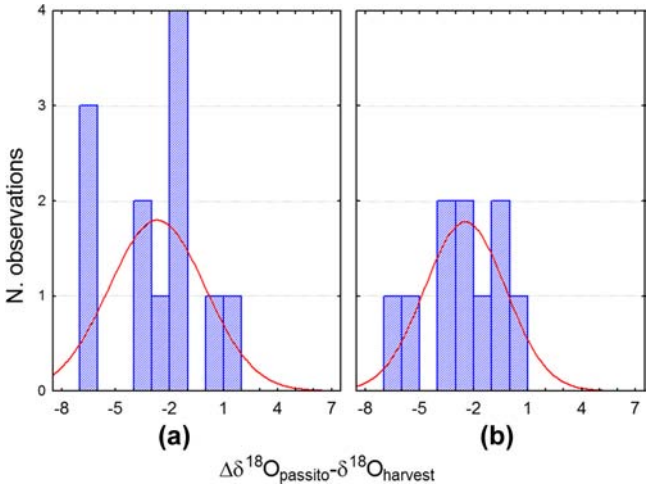

Figure 2. Difference between $\delta^{18}O$ of must water at the end of withering ($\delta^{18}O_{passito}$) and at harvest ($\delta^{18}O_{harvest}$). Withering was performed in northern (a) and central (b) Italy using *fruttaio*.

dedicated fruit rooms (*fruttaio*), showed a change in the $\delta^{18}O$ of water by −6.5‰, as observed above. In two cases (Figure 2a), Ramandolo 2013 (withering on trellises with forced ventilation) and Picolit 2011 (in boxes with controlled temperature) the $\delta^{18}O$ value increased by around 1‰, probably because withering took place in a shorter time (<1 month), which caused kinetic isotopic fractionation.

For the *passito* samples of regions in central Italy (Figure 2b), Tuscany, Marche, and Umbria, which also adopted withering in the *fruttaio*, $\delta^{18}O$ decreased up to −6‰.

For *passito* produced *en plein air* in the northern regions (Friuli Venezia Giulia and Emilia Romagna) (Figure 3a), climatic conditions caused equilibrium isotope fractionation, as in the *fruttaio*. Indeed a decrease in $\delta^{18}O$ was observed. In the southern regions of Apulia, Sicily, and Sardinia, in most cases $\delta^{18}O$ increased with withering (Figure 3b). Indeed, normally in these regions the grapes overripen on the plants in autumn, and due to the relatively higher temperature in these areas, kinetic evapotranspiration takes place. In two cases (*Passito di Manduria* and *Moscato di Trani*, both 2012) $\delta^{18}O$ decreased up to −4.6‰, probably because of precipitation, which could exchange with grape water.

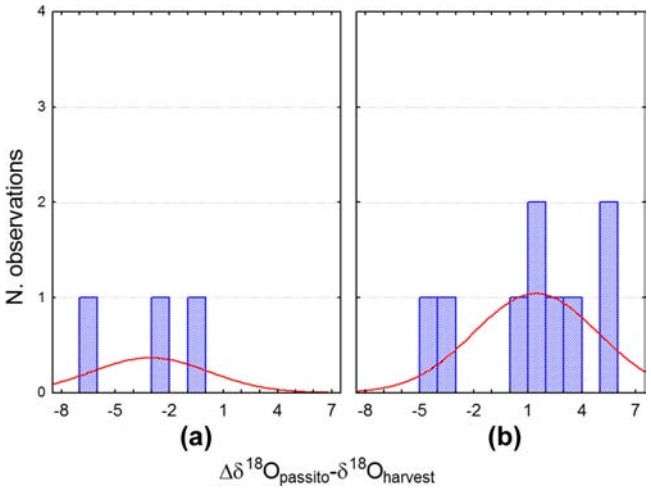

Figure 3. Difference between $\delta^{18}O$ of must water at the end of withering ($\delta^{18}O_{passito}$) and at harvest ($\delta^{18}O_{harvest}$). Withering was performed in northern (a) and southern Italy (b) *en plein air*.

The significant variation in the $\delta^{18}O$ of must and wine water and wine ethanol observed during withering have never previously been reported in the literature. This variation can lead to problems when interpreting data for detecting authenticity, if referring to an official wine databank based only on fresh grape wines. Indeed, decreases or increases of up to 6‰ can make the $\delta^{18}O$ values fall outside the limits defined by the European wine databank for an authentic wine for the declared origin,[34] with consequent false declaration of watering down or mislabeling. Furthermore, the ethanol $\delta^{18}O$ values of final samples were sometimes (ER-B, ER-C, and ER-E) outside the range proposed for authentic wine samples (from +24 to +36‰).[16] Particular attention must be therefore paid when the $\delta^{18}O$ data of *passito* wines is evaluated for fraud detection.

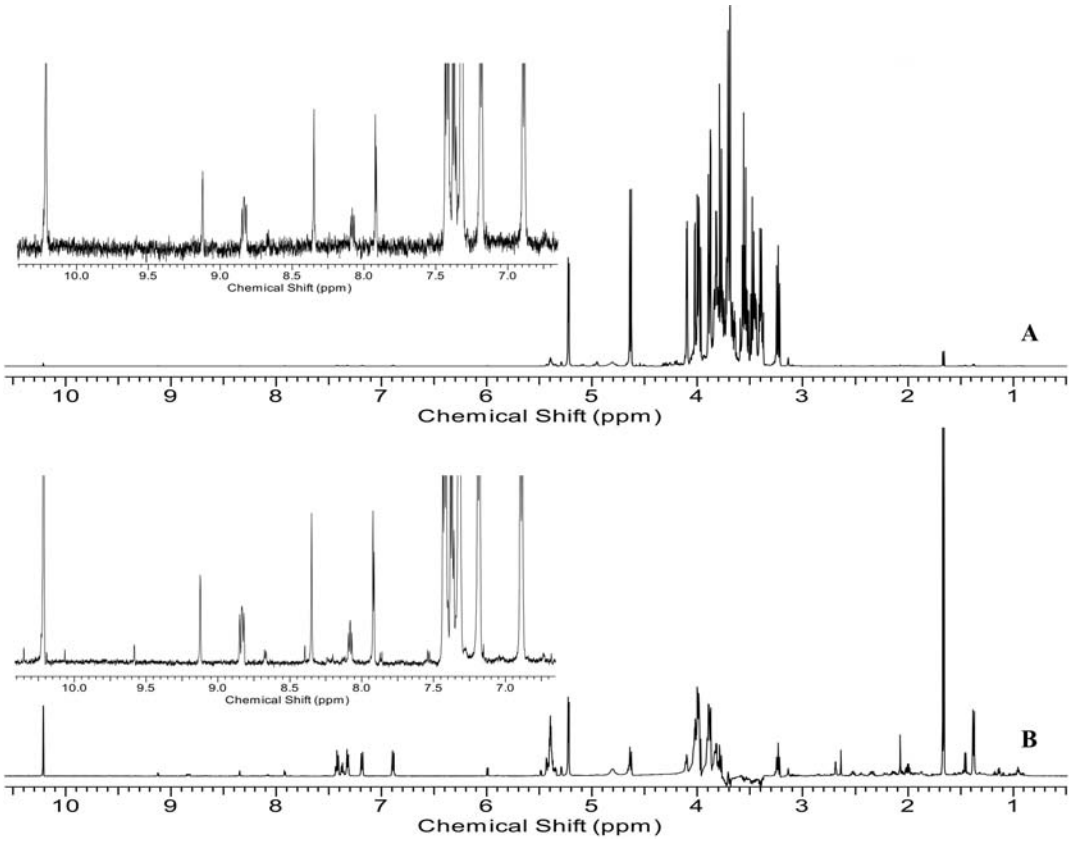

Figure 1. ^{1}H NMR spectra of coffee honey dissolved in D_2O and expansion of the aromatic region: (A) spectrum acquired with a one pulse sequence with presaturation of the water signal; (B) spectrum acquired with the modified DPFGSE sequence (see text).

99.9% *d*, Sigma-Aldrich, Milan, Italy), isobutyraldehyde (≥99%, Sigma-Aldrich, Milan, Italy), *N*,*N*-dimethylformamide (DMF, ≥99.99% (GC), Fluka-Sigma-Aldrich, Milan, Italy), calcium formate (standard for quantitative NMR, TraceCERT, Fluka-Sigma-Aldrich, Milan, Italy) were acquired as noted. Five millimeter precision glass NMR tubes 535-pp-7 and coaxial insert wgs-5bl were obtained from Wilmad (purchased through Sigma-Aldrich, Milan, Italy).

Honey Samples. Three different *Coffea* spp. honey samples were analyzed, two from Colombia and one from Honduras. The honey from Honduras (Capucas Miel) was purchased in a local market; the sample named Colombia 1 was produced by Apicalarama (Calarama Group) in the municipality of Chaparral, Department of Tolima, and the sample named Colombia 2 was produced on the farm Edén in the municipality of Apia, Department of Risaralda, both under the supervision of Jhon Ever Cardona (La Promotora de Bienes y Servicios Apicolas Proapis s.a.s.). These two honeys were obtained using an African species (*Apis mellifera scutellata*) known to be very aggressive; the bees that were used were duly selected and bred by J. E. Cardona for their limited aggressiveness.

Sample Preparation. About 180 mg of honey was dissolved in 550 μL of D_2O, precisely weighed. The volume obtained was measured, and 450 μL of the solution was transferred to 5 mm precision glass NMR tubes (Wilmad 535-pp).

NMR Spectroscopy. NMR experiments were recorded at 298 K using a Bruker Avance DMX600 spectrometer (Bruker Biospin GmbH Rheinstetten, Karlsruhe, Germany) operating at 599.90 MHz for ^{1}H and equipped with a 5 mm TXI xyz-triple gradient probe. The spectra were acquired using a double pulsed field gradient spin echo (DPFGSE) sequence,[11] modified by the addition of an inversion hard pulse after the first gradient in the G-S-G cluster, to obtain a G-π-S-G (G is a pulsed field gradient and S is a soft π pulse).[12] As a soft pulse, we used an inversion Reburp sequence of 1.2 kHz sweep width and 3867 ms duration centered at 4.00 ppm. All gradient pulses were followed by a 100 μs recovery delay. The relaxation delay was 65 s, and 72−256 scans were collected, resulting in acquisition times between 1 h and 30 min and 4 h and 55 min.

ACD software (ACD Laboratories 12.0, Toronto, ON, Canada) was used to process the spectra. An exponential window function with line broadenings of 0.3−0.5 Hz was applied before Fourier transformation. Phase and baseline corrections were performed manually, and the signal of the α H1 proton of glucose at 5.22 ppm was used as chemical shift reference.

Quantitative Analysis. To quantify absolute concentrations, a coaxial tube filled with an isobutyraldehyde solution in DMSO-d_6 was inserted in the NMR tube. This standard was chosen because its aldehydic proton resonates in our region of interest, not overlapping with any other signal. The solution was prepared by accurately weighing isobutyraldehyde and the DMSO-d_6 solvent, for a final concentration of the standard of 0.023 M. The accuracy of our quantitative analysis was demonstrated by the quantification of the formate signal in the spectrum of one of the aqueous honey samples using the standard addition method (weighed quantities of a standard solution of calcium formate in D_2O were added directly into the NMR tube and its concentration in the original sample extrapolated).

To calculate the concentration of the analytes, a scale factor of 0.108 was considered, corresponding to the ratio between the volume of the coaxial insert (V_c) and the volume occupied by the sample in the outer part of the NMR tube (V_s) calculated as reported by Rastrelli et al.[11] The absolute concentration of analytes (C_a) was determined by comparing the integral value of the area of the corresponding proton signal (I_a) and that of the aldehydic proton of isobutyraldehyde at 10.21 ppm (I_s), using the relationship C_a (mol/L) = $(I_a/I_s)(V_c/V_s)C_s$, where C_s is the concentration of the external standard.

The following formula gives the concentration of the analytes (in mg/kg): C_a (mg/kg) = C_a (mol/L) × MW_a × V_a (mL)/m_{honey}(kg), where MW_a is the molecular weight of the considered analyte, V_a is the volume of the honey solution in D_2O, and m_{honey} is the weight of the honey sample.

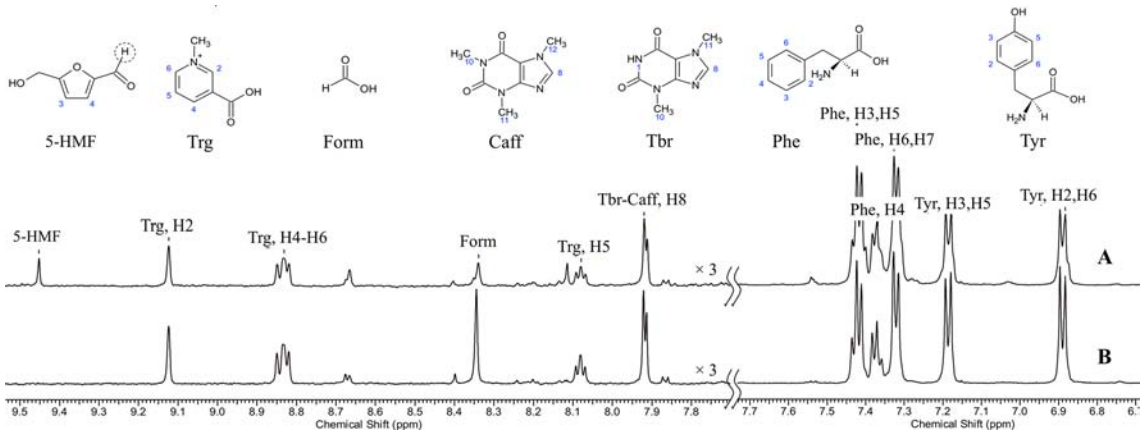

Figure 2. Aromatic region of Colombia 1 (A) and Colombia 2 (B) honey samples dissolved in D_2O. The chemical structures of the identified compounds and the corresponding assignments of the peaks are reported. 5-HMF, 5-hydroxymethylfurfural; Trg, trigonelline; Form, formic acid; Tbr, theobromine; Caff, caffeine; Phe, phenylalanine; Tyr, tyrosine.

The longitudinal relaxation time T_1 of all signals of interest, in the matrices and in the standard solutions, was determined using the inversion−recovery sequence. To produce quantitative data, the relaxation delay was at least 5 times the longest measured T_1, corresponding to the aldehydic signal of isobutyraldehyde in DMSO-d_6, determining a relaxation delay of 65 s.

Every sample was analyzed in duplicate, the spectra were processed four times, and data are reported as the mean ± standard deviation expressed as milligrams per kilogram of honey.

Pollen Analysis. Qualitative and quantitative melissopalynological analyses were carried out according to the UNI 11299:2008 method[13] by a specialized Italian laboratory.

RESULTS AND DISCUSSION

Optimization of the ^{1}H NMR Parameters. The metabolites that we wanted to quantify are present in up to hundreds of parts per million in coffee honey. ^{1}H NMR spectra of honey samples dissolved in water are dominated by the intense signals of sugar protons, which limit the value of the receiver gain (RG) that can be used and consequently the digitalization of very small signals. To overcome this problem, we utilized a DPFGSE sequence, modified with the insertion of a hard π pulse in the cluster [G-S-G] to obtain a G-π-S-G block.[12] As a result, the resonances in the sugar proton region are further defocused by the second gradient pulse, which allowed us to increase the RG by a factor of 128. The outcome of this approach is shown in Figure 1, where a normal spectrum obtained only with water presaturation is compared with a spectrum obtained with the modified DPFGSE sequence in the same amount of time. The improvement in S/N ratio is almost 4-fold.

To verify that the intensity of the signals of interest is not affected by the soft pulse, a 9 h long experiment was performed on one of the samples using the water presaturation sequence. The integral ratio of the signals of interest was the same as in the spectrum obtained with the modified sequence (not shown).

Spectral Analysis. Figure 2 displays the aromatic region of the ^{1}H NMR spectra (6.8−10 ppm) of Colombia 1 and Colombia 2 samples. A similar spectrum was obtained with the Honduras sample. The chemical formulas of the seven identified compounds and relative assignments are also shown.

For quantitative determination purposes, the integrals of the following signals were chosen: the sum of the three signals of phenylalanine divided by 5 (7.32, 7.36, and 7.42 ppm), the sum of the two signals of tyrosine divided by 4 (6.88 and 7.18 ppm), the singlet at 8.35 ppm for formic acid; the peak of the aldehydic proton at 9.45 ppm for 5-HMF; and the signal at 9.12 ppm for trigonelline. The signals of caffeine (7.91 ppm) and theobromine (7.92 ppm) are partially overlapped, and the integral values were extracted by deconvolution of the peaks. Table 1 shows the results of this quantification.

Table 1. Quantities of the Identified Metabolites in *Coffea* Honey Dissolved in D_2O

	concentration ± SD (mg/kg)		
	Honduras	Colombia 1	Colombia 2
caffeine	15.0 ± 0.6	52.0 ± 1.6	97.8 ± 1.4
theobromine	24.9 ± 0.9	99.9 ± 1.3	159.2 ± 6.2
trigonelline	23.0 ± 0.4	55.4 ± 2.2	85.7 ± 2.7
phenylalanine	220.1 ± 11.5	819.7 ± 12.4	795.4 ± 17.2
tyrosine	161.8 ± 4.0	499.5 ± 8.3	701.7 ± 18.9
formic acid	40.2 ± 0.8	11.3 ± 0.1	45.2 ± 0.6
5-HMF	23.7 ± 0.5	26.2 ± 2.9	not detected
Tbr/Caff molar ratio	1.79	2.01	1.75

The signals from phenylalanine and tyrosine are the strongest in this region of the spectrum. Amino acids are present in all types of honey and can have both plant and animal origins, the major source being pollen.[14,15] Several studies have demonstrated that amino acid composition is not sufficient to distinguish the botanical origin of honey samples, because rather high variability among honeys from the same botanical source and between honeys from different floral origin was found.[15,16] The content of phenylalanine and tyrosine we found is in the range reported in the literature.[4,15]

Formic acid is a natural component of honey and, together with the other organic acids present, contributes to honey's antibacterial and antioxidant activities. It presents high variability depending on the floral and geographical origins of the honey, and the values found in *Coffea* honey, reported in Table 1, are in the lower range reported in previous studies.[17]

5-HMF is present in only two samples, and in each case its concentration is well below the maximum values defined by the European Directive[18,19] (80 mg/kg for honeys of declared origin from regions with tropical climate).

Table 2. Honey Pollen Content

honey sample	*Coffea* pollen (%)	other pollens (%)
Colombia 1	64	Anacardiaceae (16); Myrtaceae (11); unknown (4), Verbenaceae (3); Labiatae (1); Compositae H (1); *Cordia* (1); *Stachys*; and Bombacaceae (present)
Colombia 2	95	Melastomataceae (3); Myrtaceae (1); Mimosaceae, *Senecio*, Compositae H, *Croton*, and Lauraceae (present)
Honduras	36	Compositae H (33); Melastomataceae (9); unknown (8); *Borreria* (3); Myrtaceae (2); Umbelliferae (1); Compositae T (1); *Liquidambar* (1); *Vernonia* (1); Anacardiaceae, *Citrus limon*, *Cordia*, and Sapindaceae (present)

The three purine and pyridine alkaloids, caffeine, theobromine, and trigonelline, are present in all of the analyzed samples and, until now, these had never been reported to be simultaneously present in any type of honey. Our data suggest that these compounds might be considered as chemical markers of *Coffea* as botanical origin. Caffeine is also present in other monofloral honeys, in particular, in *Citrus* spp. honeys but in much smaller amounts compared to the results of the current study on *Coffea* honey.[2,20] High amounts of caffeine (we found up to 98 ppm) are somewhat surprising because of the well-known toxic[21] and repellent effect of caffeine at high concentrations on honeybees.[22] It was recently reported that honeybees are deterred from drinking sucrose solutions containing caffeine at concentrations >100 ppm, although they preferred slightly caffeinated sucrose solutions over the control without caffeine.[23] Caffeine concentration in nectar does not exceed 58 ppm, even though levels of caffeine in vegetative and seed tissues of *Coffea* up to 24×10^3 ppm have been reported.[24] At the nectar level, caffeine does not exceed the bees' bitter taste threshold, implying that pollinators select pharmacologically active nectar (it enhances memories of reward) but not repellent. In fact, honeybees rewarded with caffeine were 3 times as likely to remember a learned floral scent as were honeybees rewarded with sucrose alone.[25]

For the first time, trigonelline was identified and quantified in *Coffea* honey samples; this compound had previously been identified in orange honey produced in Corsica.[3] Paraxanthine and theophylline were not found in our NMR spectra, probably because their concentrations were too low.

Theobromine has previously been reported in traces amounts in citrus honey.[2] The amounts of theobromine we determined were higher than those of caffeine. In fact, the amount of theobromine found in monofloral coffee honey seems too high considering its levels in coffee flowers. It has been reported that *C. arabica* flower parts (petals, stamens, and gynoecium) contain caffeine as the main purine alkaloid.[26] The gynoecium also contains theobromine (10−20% of caffeine) and no theophylline, whereas the other organs contain remarkably high values of theophylline (4−12% of caffeine) and <1% theobromine.[26] Moreover, although the absolute amounts of caffeine and theobromine vary in the three honey samples, their molar ratio remains fairly constant. These results suggest a possible role played by honeybee metabolism more than plant metabolism. The first step in metabolic degradation of caffeine in mammals is its demethylation, mainly to paraxantine (>80%),[27] whereas in plants, theophilline is the most important first metabolite.[28] We were not able to confirm this finding with the existing literature, but our data can be explained if theobromine is the main metabolic derivative in honeybees.

Blossom honey essentially consists of nectar concentrated by the activities of specialized bees in the hive. In the case of *Citrus* spp., during honey production, one should expect a much higher caffeine concentration in citrus honey than found in nectar; however, it has been calculated that about 95% of the nectar caffeine is removed or degraded by a still unknown mechanism.[2] In the present study, we found much higher amounts of caffeine in the honey, although the caffeine content in *Coffea* nectar is not much higher than in *Citrus* nectar. A possible explanation is that the strain of African bees used to produce *Coffea* honey and the *Apis mellifera* commonly used to produce *Citrus* honey metabolize caffeine in different ways. The remarkably high content of theobromine found in coffee honey could also be related to differing bee metabolisms. In our previous work, we compared honey produced by *A. mellifera* and by stingless bees; we detected differences clearly attributable to the different metabolism of the two species.[29]

Pollen Analysis. The percentage of *Coffea* pollen found in the three samples is reported in Table 2. For the two samples from Colombia, *Coffea* pollen >50%[30] makes the products "monofloral", whereas the Honduras sample can be classified as "multifloral".

We found an excellent correlation between the specific markers, caffeine, theobromine, and trigonelline, and the relative amount of specific *Coffea* pollen measured in the same sample. In Figure 3, the linear equations and the R^2 values

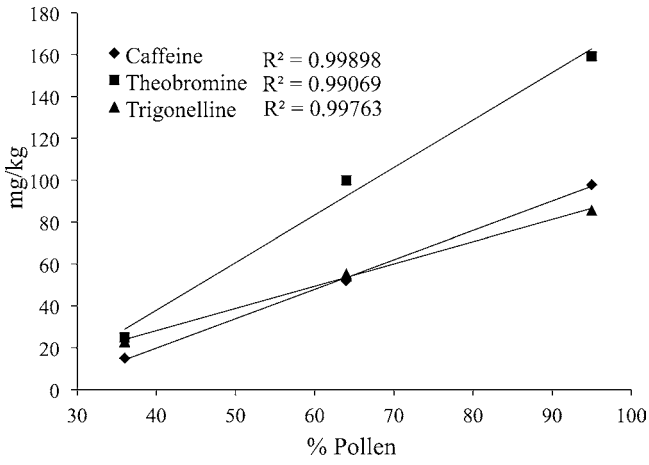

Figure 3. Linear correlation between marker content and the percentage of specific *Coffea* pollen measured in the three analyzed samples.

are reported. No correlation was found for phenylalanine (R^2 = 0.69), tyrosine (R^2 = 0.95), and formic acid (R^2 = 0.84). This is in line with our proposal that the former derivatives are specific for coffee honey, and the latter ones are not.

This result is important because it offers a way to validate our proposed method through comparison with an existing, accepted one. Indeed, melissopalynological analysis is universally recognized as the official technique to classify monofloral honey, although numerous drawbacks are associated with it. Among these are the time required and the need for experienced analysts. Many attempts have been put forth to

DOI: 10.1021/jf506359u
J. Agric. Food Chem. 2015, 63, 5858−5863

develop more objective methods, based on physical−chemical parameters, to certify the botanical origin of honey,[31−36] and NMR is emerging as a powerful technique in this regard.[37,38] The linear relationship between these two independent parameters might offer, for the first time in honey analysis, a sound and objective alternative to pollen determination.

The obvious limitation of the current study is that only three samples were analyzed. The reason for the small number of samples is also fairly understandable: coffee honey is not at all a common product; on the contrary, it is quite rare. The two monofloral samples we studied derive from a pilot project funded by the Ernesto Illy Foundation to promote beekeeping as an additional support to coffee cultivation activities in Colombia; the third sample was commercially available and was bought as "coffee honey", but the amount of *Coffea* pollen present was not sufficient to make it a monofloral product. Despite this limitation, the findings of the present study led to interesting hypotheses. To confirm these relevant hypotheses, our next study will be conducted with a higher number of samples, different origins, and different bee species.

This preliminary work also has a methodological value because it emphasizes the power of NMR in the characterization of complex mixtures, in the determination of botanical origin of honey, and in the simultaneous quantification of several compounds without the need for separation or derivatization. Moreover, the modified DPFGSE pulse sequence we used successfully suppressed the intense sugar signals, allowing the quantification of minor components in honey.

ACKNOWLEDGMENTS

We gratefully acknowledge the contribution of Jhon Ever Cardona (La Promotora de Bienes y Servicios Apicolas Proapis s.a.s.) in the technical supervision of the production of the honey samples from Colombia. We warmly thank Luca Turello and Stefano Scanferla (illycaffè spa) for their valuable technical support.

honey (*Eriobotrya japonica* (Thunb.) Lindl.), and almond honey (*Prunus dulcis* Mill. ex Rchb.).[10] The results showed that the tested honey samples presented higher phenolic content and antioxidant capacity than those produced by other honeybee subspecies from Sicily, other different Italian regions, and abroad.[10−14] Moreover, all tested honeys showed good antimicrobial activity against a broad spectrum of microorganisms.

Honey chemical characterization is generally studied with high-performance liquid chromatography coupled with diode array detection or electrospray ionization tandem mass spectrometry (HPLC-PDA or HPLC-ESI-MS/MS). These techniques are useful to reveal the presence of botanical biomarkers, α-dicarbonyl and phenolic compounds,[3,15] and contaminants.[16] Nevertheless, matrix interference, especially in the analysis of carbohydrates and peptides, and low sensitivity require the application of solid phase extraction (SPE) sample treatment before the analysis of the sugar- and peptide-derived fractions. Therefore, in most investigations carbohydrates are not determined or are evaluated as total sugar content according to spectrophotometric methods with a lack of specific knowledge on these components.[17−19] Given this scarce information about the chemical composition of *A. mellifera* ssp. *sicula* honeys, especially regarding carbohydrates and polyphenols, the present investigation represents an extension of our previous research[10] and is aimed to (1) investigate the chemical composition of two further honeys, sulla honey (*Hedysarum coronarium* L.) and dill honey (*Anethum graveolens* L.), with a multimethodological approach that consists of HPLC-PDA-ESI-MS^n and NMR spectroscopy; and (2) to extend the study of lemon, orange, and medlar honeys with NMR spectroscopy, to deepen the knowledge about their sugar and amino acid compositions. The combination of these techniques combines the advantages of liquid chromatography coupled with MS to those of NMR spectroscopy, which is a technique that has been recently employed in the field of food analysis, because it can lead both to "high-throughput" and simultaneous structural information on a wide range of metabolites and to the identification of specific metabolites or their classes. This approach allowed us to describe the phytochemical composition of each type of honey and identify many compounds that were found in these types of honeys for the first time. In addition, we could compare the metabolic profiles obtained by our analysis with those already reported in the literature and provide a first phytochemical composition for that kind of honey for which no chemical data are available in the literature.

MATERIALS AND METHODS

Chemicals and Materials. Millipore grade water was obtained with a Milli-Q water purification system (Millipore Corp., Billerica, MA, USA); formic acid, (−)-catechin, and luteolin were purchased from Sigma-Aldrich (Milan, Italy); LC-MS grade methanol was obtained from VWR International PBI srl (Milan, Italy). D_2O 99.9%D was purchased from EURISO-TOP (Saint-Aubin, France).

Honey Samples. *A. mellifera* ssp. *sicula* honey samples of different botanical origin, that is, sulla (*H. coronarium*), dill (*A. graveolens*), lemon (*C. limon*), orange (*C. arantium*), and medlar honeys (*E. japonica*), were obtained from an Italian independent apiarist (Carlo Amodeo, Termini Imerese, Palermo, Italy). Honey samples were harvested in 2014 by individual apiarists in the area of Termini Imerese (37°98′ N, 13°70′ E, Palermo, Italy). Samples were classified following the melissopalynological analysis[10] according to which the floral source was confirmed if the pollen content in the honeys was not lower than 10% (this percentage ranged between 27 and 61%). During the experiments, three samples for each botanical source were kept at 5 °C in the dark in airtight containers for <5 months until the analysis.

Sample Preparation for RP-HPLC-PDA-ESI-MS^n Analysis. One gram of each honey sample was added to 2 mL of Millipore grade water acidified with 0.1% formic acid. Each sample was purified with SPE, using an RP Sep-Pak Vac 6 cm^3 (1g) tC18 cartridge (Waters, Milford, MA, USA). After wetting the cartridge with methanol (10 mL) and conditioning it with 0.1% formic acid (10 mL), the polyphenol-enriched fraction (SPE_2 fraction) was eluted with 2 mL of a solution composed of methanol and 0.1% formic acid, 90:10% v/v, at a flow rate of 0.4 mL/min. The SPE_2 fraction was concentrated under a nitrogen stream until the volume of 130 μL, corresponding to a concentration of 7.69 mg/mL. After filtration with 0.45 and 0.20 μm nonsterile syringe filters, the concentrated SPE_2 fraction was submitted to RP-HPLC-PDA-ESI-MS^n analysis.

RP-HPLC-PDA-ESI-MS^n Analysis. All experiments were performed using a Thermo Finnigan Surveyor Plus HPLC, equipped with a quaternary pump, a Surveyor UV−vis diode array detector, and a LCQ Advantage Max ion trap mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA), connected through an ESI source.

The separation was carried out on a Gemini C18 110 Å (150 × 2 mm, 5 μm), equipped with an Ultra Cartridge C18 Peptide Security Guard Column, both from Phenomenex (Torrance, CA, USA). The mobile phase consisted of water acidified with 0.1% of formic acid (A) and methanol (B) and was eluted with the following gradient: from 2 to 5% B in 10 min, from 5 to 40% B in 50 min, from 40 to 60% B in 10 min, from 60 to 100% B in 10 min, followed by a 10 min isocratic run of 100% B. Total run time was 115 min, including column reconditioning. The flow rate was maintained at 0.3 mL/min, the autosampler and column temperatures were maintained at 4 and 25 °C, respectively. Chromatograms were monitored at 210, 254, and 280 nm; spectral data were collected within the range of 200−800 nm for all peaks. The ion trap was operated in data-dependent, full scan (m/z 100−1000), zoom scan, and MS^n mode. To obtain MS^2 data, a 35% collision energy and an isolation width of 2 m/z were applied. ESI source parameters had previously been optimized by flow injection analysis using (−)-catechin (10 ppm, in 0.1% formic acid and methanol, 50:50, v/v) and luteolin (5 ppm, in 0.1% formic acid and methanol, 50:50, v/v), for negative and positive ionization, respectively, to a ionization voltage of 3.5 kV, a capillary temperature of 200 °C, a sheath gas flow of 45 arbitrary units, and an auxiliary gas flow of 20 arbitrary units.

Sample Preparation for NMR Analysis. The samples were prepared dissolving 20 mg of honey in 700 μL of D_2O containing 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid sodium salt (TSP, 2 mM) as internal standard. Once a homogeneous solution was achieved using a vortex rotor, 700 μL of honey solution was transferred into a standard 5 mm NMR tube and subjected to NMR analysis.

NMR Analysis. The NMR spectra were recorded at 27 °C on a Bruker AVANCE 600 NMR spectrometer operating at the proton frequency of 600.13 MHz and equipped with a Bruker multinuclear z-gradient inverse probehead capable of producing gradients with a strength of 55 G cm^{-1} in the z-direction. ^{1}H spectra were referenced to methyl group signals of TSP (δ = 0.00 ppm) in D_2O. ^{1}H spectra were acquired by adding 64 transients with a recycle delay of 3 s. The residual HDO signal was suppressed using presaturation with a single soft pulse on the HDO resonance frequency applied during the relaxation delay followed by a strong observation pulse.

2D NMR experiments, namely, ^{1}H−^{1}H TOCSY, ^{1}H−^{13}C HSQC, and ^{1}H−^{13}C HMBC, were performed using the same experimental conditions previously reported.[20] The mixing time for the ^{1}H−^{1}H TOCSY was 80 ms, and the spin lock field was 6250 Hz. The HSQC experiments were performed using a coupling constant $^1J_{C-H}$ of 150 Hz, and the ^{1}H−^{13}C HMBC experiments were performed using a delay for the evolution of long-range couplings of 80 ms.

[a]Compound identified in sulla honey. [b]Cmpound identified in dill honey. [c]Compound revealed by positive ionization mode.

RESULTS AND DISCUSSION

RP-HPLC-PDA-ESI-MS^n Analysis. RP-HPLC-PDA-ESI-MS^n analysis of sulla and dill honeys allowed the identification of 22 compounds, some of which were present in both honey samples. The chromatograms obtained from sulla and dill honey analyses are reported in Figure 1. The identification of these compounds was performed on the basis of their chromatographic behaviors; UV−vis, MS, and MS/MS spectra; and comparisons with literature data. The results obtained are summarized in Tables 1 and 2. For each compound, the retention time, the wavelength of maximum absorbance, m/z values of molecular ion, and its fragment ions are reported.

Nine flavonoids, among which were four flavonols (quercetin hexosyl rutinoside, quercetin rhamnosyl-hexosyl-rhamnoside, quercetin rutinoside, and kaempferol rutinoside), four flavanonols (dihydroflavonols, i.e. pinobanksin methyl ether, pinobanksin, pinobanksin acetate, and pinobanksin butyrate), and one flavanone (pinocembrin), were identified. Moreover, the analysis showed the presence of four organic acids (citric

acid, kynurenic acid, phenyllactic acid, and 4-methoxyphenyllactic acid), three phenolic acids and derivatives (*p*-hydroxybenzoic acid, caffeic acid isoprenyl ester, and methyl syringate), one vitamin and its main metabolite (riboflavin and lumichrome), one norisoprenoid (abscisic acid), one amino acid (phenylalanine), dehydrovomifoliol ((±)-1′-hydroxy-4′-keto-α-ionone), and 3-hydroxy-1-(2-methoxyphenyl)penta-1,4-dione.

As far as flavonoids are concerned, RP-HPLC-PDA-ESI-MS^n analysis of sulla honey showed the presence of flavonols, flavanonols, and a flavanone. In contrast, in dill honey just a flavanonol and a flavanone were detected. Peaks 11, 12, and 14 were identified as quercetin derivatives, because all of their MS^2 spectra showed the presence of quercetin aglycone at m/z 301. Peak 11 was assigned to quercetin hexosyl-rutinoside (MW 772) because the parent ion at m/z 771 produced fragment ions at m/z 609, due to the loss of a hexosyl moiety $[M - 162]^-$, and at m/z 463, corresponding to a hexosylated quercetin, due to the loss of the rutinoside group. Peak 12 was identified as quercetin-rhamnosyl-hexosyl-rhamnoside (MW 756) because its MS^2 spectrum showed the presence of a significant fragment ion at m/z 609, due to the loss of 146 Da that corresponded to a rhamnosyl unit. Moreover, the produced fragment ion corresponded to quercetin linked to a rhamnosyl moiety and a hexosyl one, $[301 + 146 + 162]^-$. Peak 14 was assigned to quercetin rutinoside (MW 610) on the basis of a comparison with literature data.[21] In fact, the pseudomolecular ion at m/z 609 produced a fragment ion at m/z 301, corresponding to the aglycone, due to the loss of the rutinoside moiety, $[M - 308]^-$. Peak 17 was assigned to kaempferol rutinoside (MW 594) because it produced a parent ion at m/z 593 and a fragment ion at m/z 285, corresponding to kaempferol aglycone and obtained by the loss of the rutinoside group.[21]

Of the flavanonols, peak 18 was identified as pinobanksin (MW 272) because the parent ion at m/z 271 produced the typical MS^2 spectrum already known in the literature,[22] characterized by the presence of fragment ions at m/z 253, due to the loss of H_2O, at m/z 243, corresponding to $[M - H - CO]^-$, at m/z 165, corresponding to $[M - H - H_2O - 2CO_2]^-$, at m/z 151 corresponding to the ion $[^{1,3}A]^-$, which derives from the cleavage of the C ring of the aglycone that undergoes retro-Diels–Alder scission. Peaks 16, 21, and 22 were assigned to pinobanksin derivatives. In more detail, peak 16 was identified as pinobanksin methyl ether (MW 286) because its MS/MS spectrum showed the presence of ions at m/z 252, due to the loss of the methyl group and a water molecule, at m/z 271, corresponding to the aglycone obtained by the loss of the methyl group, and at m/z 239 and 224 as previously reported.[23] Peak 21 was identified as pinobanksin acetate (MW 314). The assignment was possible by comparing the MS^2 spectrum with data already available in the literature.[23] The parent ion at m/z 313 produced fragment ions at m/z 271, corresponding to pinobanksin aglycone, obtained by the loss of the acetate (− 42 Da), and at m/z 253, due to the loss of a water molecule from the aglycone. Pinobanksin methyl ether and pinobanksin acetate were detected only in sulla honey, whereas pinobanksin butyrate, identified as peak 22, was found in both honey samples. The assignment was possible due to the fact that pinobanksin butyrate (MW 342) parent ion at m/z 343 produced a MS/MS spectrum as already reported by Chua et al.[24]

The flavanone, peak 19, was detected in both sulla and dill honeys and was identified as pinocembrin because the molecular ion at m/z 255 produced fragment ions at m/z 213, due to the loss of $[M - C_2H_2O^-]^-$, and at m/z 151, corresponding to the ion $[^{1,3}A]^-$, which derives from C ring cleavage by RDA scission, as reported by Ristivojević et al.[23]

The chemical structures of flavonoids detected in sulla and dill honeys are reported in Figure 2.

The presence of flavonoids in sulla honey is in agreement with earlier studies carried out on an Italian sulla honey sample in which quercetin and kaempferol aglycones were identified.[11] For the other flavonoids, this is the first report on the isolation and identification of flavanonols and a flavanone in sulla honey, to date. With regard to the absence of flavonols in dill honey, Ortan et al.[25] showed the presence of quercetin in *A. graveolens* flowers, leaves, and fruits, but no literature data have been reported on the potential content of these compounds in nectar and honey. Also in this case, this is the first report on the isolation and identification of pinobanksin butyrate and pinocembrin in dill honey.

J. Agric. Food Chem. 2015, 63, 5864−5874

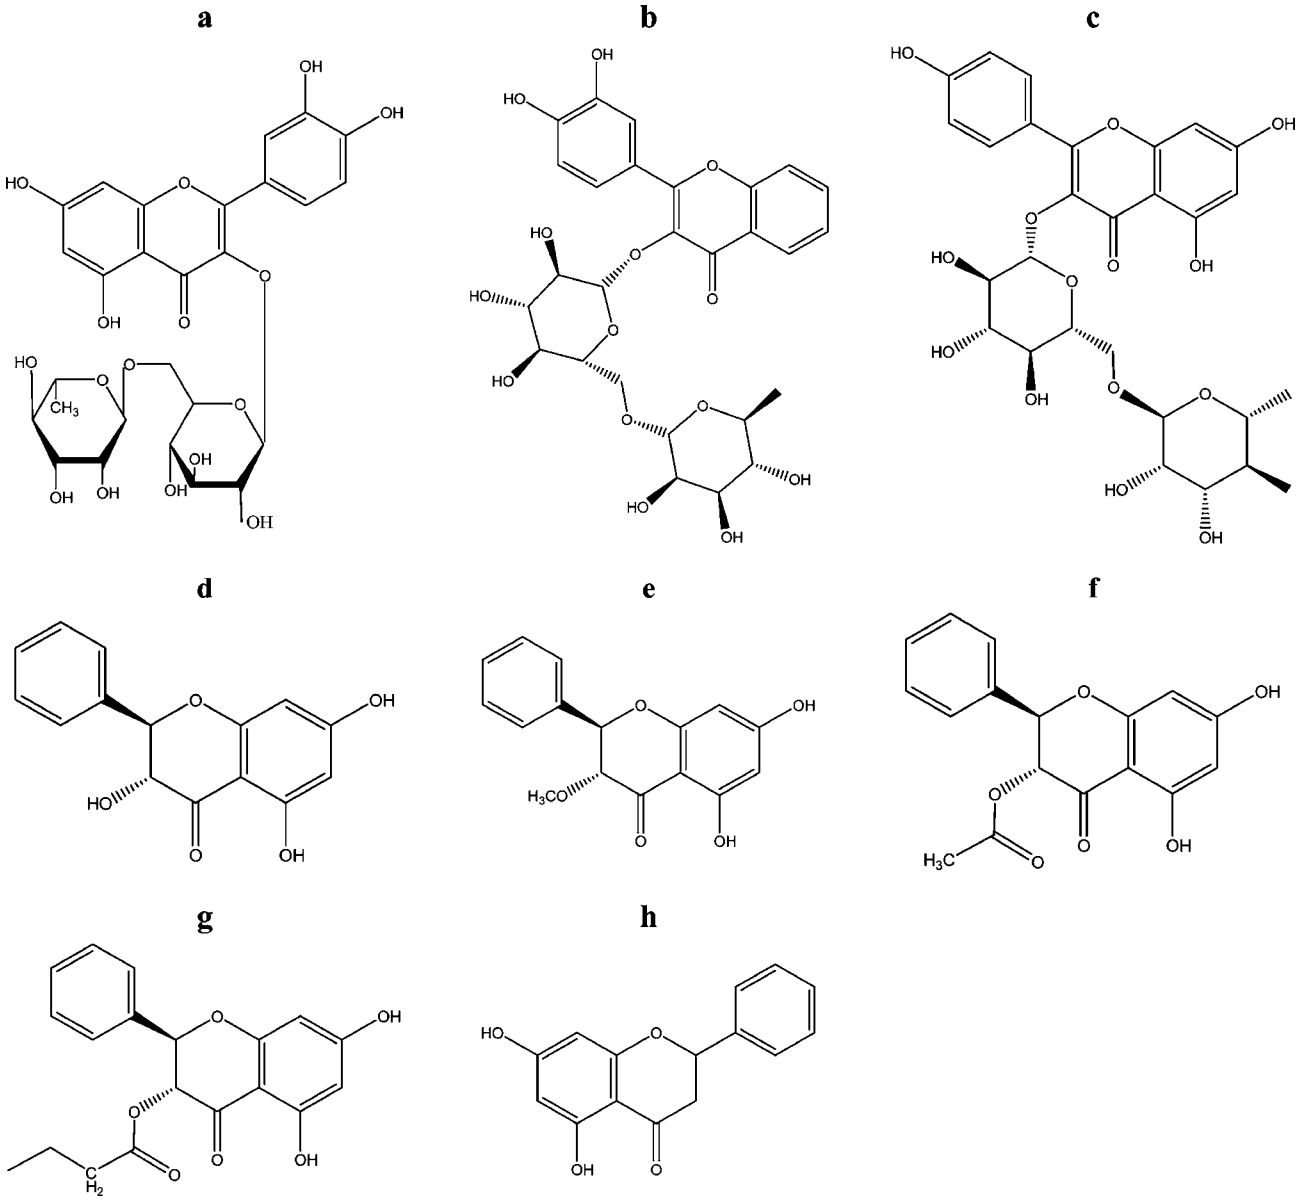

Figure 2. Chemical structures of flavonoids detected in sulla and dill honeys.

With regard to organic acids, the analysis showed the presence of four compounds belonging to this chemical class. In more detail, peak 2, detected in both sulla and dill honeys, was identified as citric acid (MW 192) because the parent ion $[M - H]^-$ at m/z 191 produced a fragment ion at m/z 129, corresponding to $[M - H - H_2O - CO_2]^-$, and another ion at m/z 111, due to the consequent loss of H_2O. Peaks 1 and 5 were identified as 4-methoxyphenyllactic acid (MW 196) and phenyllactic acid (MW 164), respectively. They were found in both sulla and dill honeys. In more detail, peak 1 was assigned to 4-methoxyphenyllactic acid because in the negative ionization mode the pseudomolecular ion at m/z 195 produced a MS/MS spectrum as previously reported in the literature by Oelschlaegel et al.[7] Peak 5 was identified as phenyllactic acid (MW 166) because its parent ion $[M - H]^-$ at m/z 165 produced fragment ions at m/z 147 and 119, corresponding to the neutral loss of H_2O and HCO_2H, respectively.[7] Peak 9, detected only in dill honey, was assigned to kynurenic acid (MW 189). Its parent ion $[M + H]^+$ at m/z 190 produced fragment ions at m/z 173 and 162, due to the loss of OH and a carbonyl group, respectively.

Phenyllactic acid is a common compound found in honeys. Its concentration ranges from several hundreds of millgrams per kilogram to <1 mg/kg and is strongly correlated to the typical honey sensorial properties.[5] Kynurenic acid derives from the tryptophan metabolic pathway and is the precursor of kynurenine and xanthurenic acid. Its presence in honey could be of interest due its biological and biochemical properties. Soto et al. showed the presence of kynurenic acid and derivatives in different botanical origin honeys. The highest kynurenic acid amounts were found in chestnut, blackberry, and multifloral honeys, with concentrations ranging from 103 to 141 to 3 mg/kg. Other kinds of honeys, such as oak, heather, orange, eucalyptus, thyme, sunflower, and acacia, were shown to contain lesser amounts (concentration <1 mg/kg) of this quinolone alkaloid. Nevertheless, no data are available on the presence of kynurenic acid in dill honey to date.[26]

J. Agric. Food Chem. 2015, 63, 5864−5874

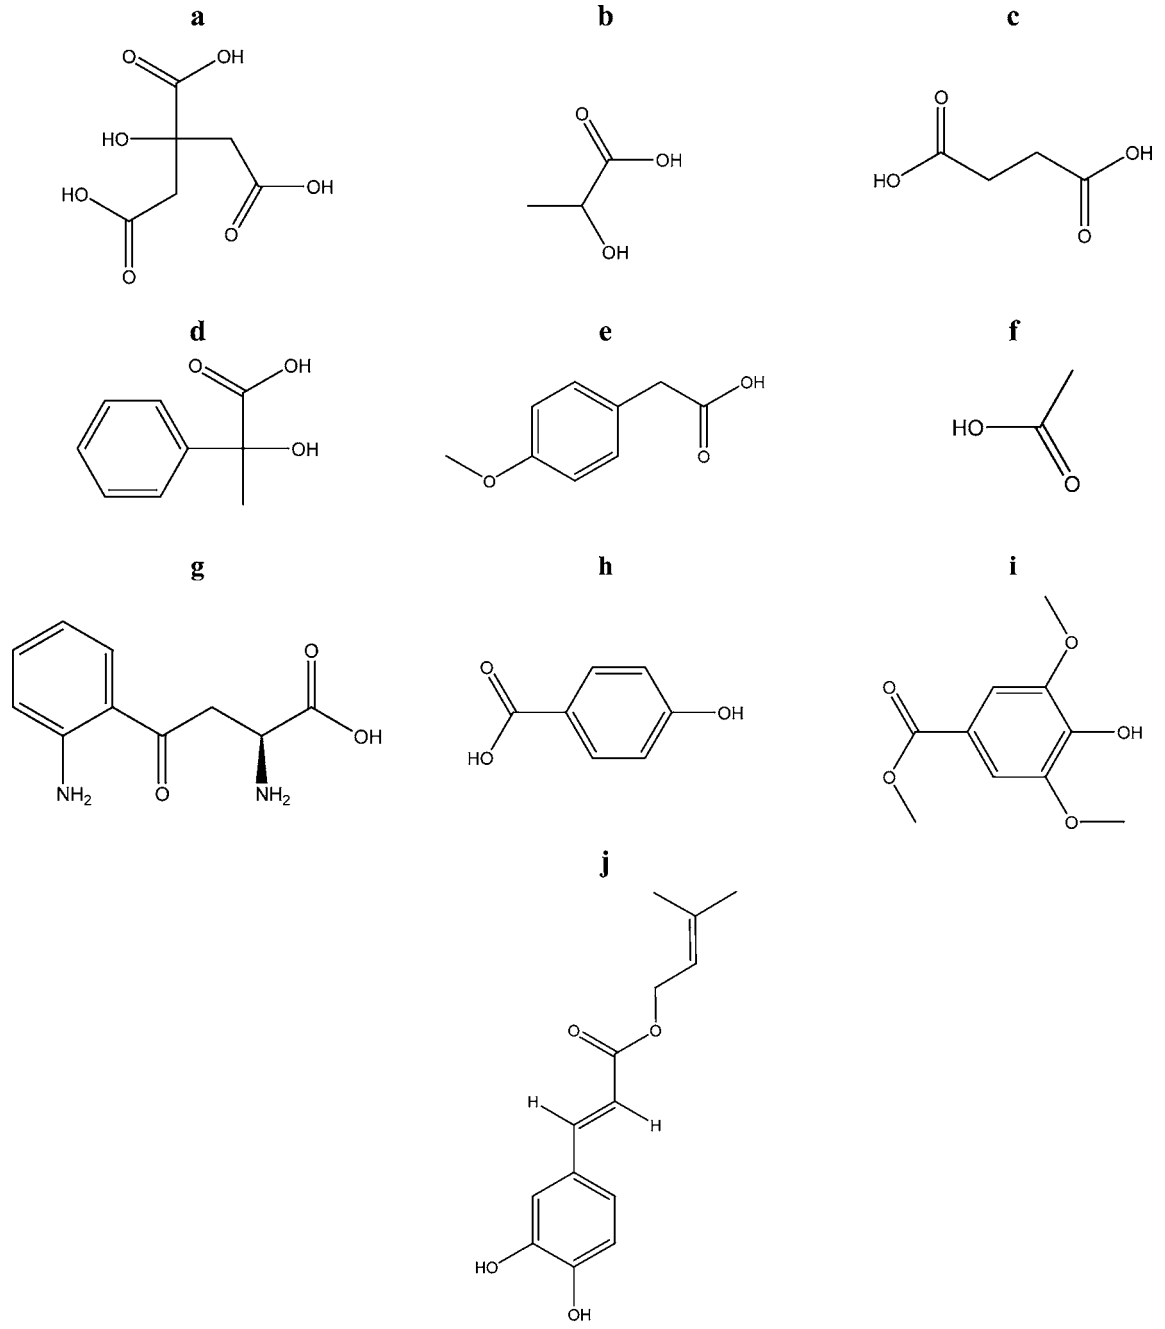

Figure 3. Chemical structures of organic acids, phenolic acids, and their derivatives detected in sulla and dill honeys.

As far as phenolic acids and derivatives are concerned, three substances were determined. Peak 7, detected only in dill honey, was identified as *p*-hydroxybenzoic acid (MW 138) because it presented a pseudomolecular ion $[M - H]^-$ at m/z 137, which produced a fragment ion at m/z 93, obtained by the loss of the carboxylic moiety. Peak 10, present only in dill honey, was assigned to methyl syringate (MW 212) because its parent ion $[M + H]^+$ at m/z 213 produced fragment ions at m/z 181, due to the loss of a carboxymethyl group, at m/z 154, corresponding to $[M - OCH_3CO]^+$, and at m/z 121, corresponding to $[M - (OCH_3)_2CO]^+$. Peak 20, identified only in sulla honey, was assigned to caffeic acid isoprenyl ester (MW 248). Its MS spectrum showed the presence of a parent ion $[M - H]^-$ at m/z 247, whereas its MS/MS spectrum presented ions at m/z 179, due to the loss of the isoprenyl group, and at m/z 135, obtained by the consequent loss of the carboxylic moiety.[27]

The chemical structures of organic acids, phenolic acids, and their derivatives detected in sulla and dill honeys are reported in Figure 3. Methyl syringate is a common phenolic derivative that was already detected in many honeys of different botanical origins such as robinia, rape, chestnut, clover, linden blossom, daendelion, sunflower, thyme, and manuka honeys.[28] The presence of this compound in sulla honey is in agreement with Jerković et al., who determined this compound by GC-MS analysis.[28] With regard to the other phenolic and hydroxycin-

DOI: 10.1021/jf506192s
J. Agric. Food Chem. 2015, 63, 5864−5874

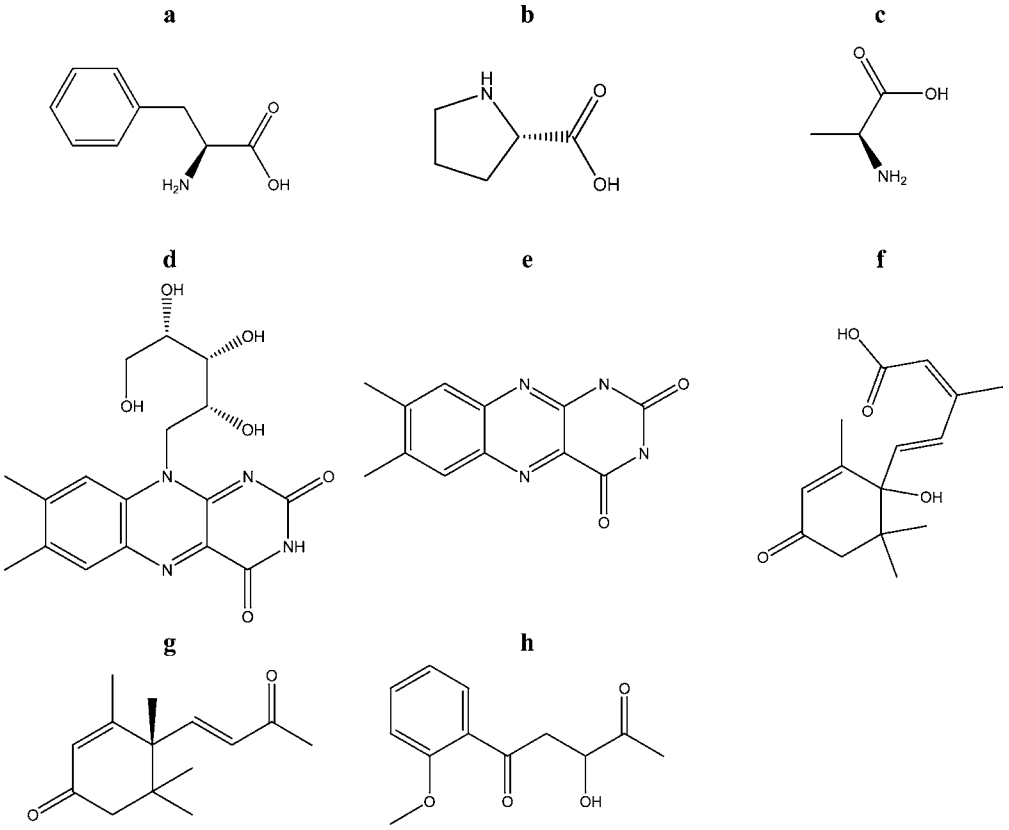

Figure 4. Chemical structures of other metabolites detected in sulla and dill honeys.

namic acids found in sulla and dill honeys, these compounds are typical secondary metabolites of plants,[29] widely distributed in many parts of the plants including flowers and nectars, and are identified in many different floral origin honeys.[10,15,30]

With regard to the other identified compounds, peak 3, found only in dill honey, was assigned to phenylalanine (MW 165) because its pseudomolecular ion at *m*/*z* 166 produced a fragment ion at *m*/*z* 120, due to the neutral loss of 46 Da, corresponding to HCOOH.

It is known that amino acids in honey are attributable to both animal and plant origin. The most abundant honey amino acid is proline, followed by phenylalanine, alanine, and glutamic acid. Phenylalanine content seems to be correlated to geographical origin, even if its presence is not always confirmed in honey, as reported by Kelly et al.[31]

In dill honey LC-MS/MS analysis showed also the presence of a riboflavin and lumichrome (7,8-dimethylalloxazin). The positive ionization mode allowed the identification of riboflavin (MW 376) as peak 8 because its MS/MS spectrum presented an intense fragment ion at *m*/*z* 243, corresponding to lumichrome, obtained from the partial loss of the ribitol moiety. Moreover, peak 13 was assigned to lumichrome (MW 242), because its MS^2 spectrum showed the presence of the same fragment ions as previously reported by Tuberoso et al.[5]

Lumichrome is a degradation product of riboflavin formed via a photochemical-induced cleavage of the ribityl group under neutral and acidic conditions. The presence of lumichrome was reported for the first time in 2011 by Tuberoso et al.[5] in thistle (*Galactites tomentosa* Moench) honey samples collected in different areas of Sardinia (Italy). More recently, the same authors reported that lumichrome occurs also in Dalmatian sage (*Salvia officinalis* L.) honey samples.[32] Our results show the occurrence of lumichrome in dill honey for the first time.

The present analysis allowed us to identify abscisic acid (MW 264), a norisoprenoid compound, derived from carotenoid degradation.[30] Abscisic acid was identified in dill honey as peak 15 because it showed fragment ions, derived from a parent ion $[M - H]^-$, at *m*/*z* 263, at *m*/*z* 219, due to the loss of the carboxylic group, and at *m*/*z* 201, corresponding to $[M - CO_3H]^-$.[33]

Abscisic acid acts as a plant hormone, inhibiting growth and helping plants to control stressful conditions. The presence of this compound in dill honey is not surprising as it is widely distributed in many honey varieties. With regard to sulla honey, the absence of abscisic acid confirms the results obtained by Jerković et al., who did not find this compound but revealed the presence of vomifoliol, a degradation product of abscisic acid.[28] On the other hand, we determined dehydrovomifoliol in both sulla and dill honeys.[7] In fact, LC-MS/MS analysis showed the presence of dehydrovomifoliol (detected in both sulla and dill honeys) and 3-hydroxy-1-(2-methoxyphenyl)penta-1,4-dione (found only in dill honey), which were previously identified in manuka honey (*Leptospermum scoparium* R.Forst. & G.Forst.) and were considered specific markers of this kind of honey.[7] The assignment was possible due to the presence in the literature of MS/MS spectra of these compounds that allowed a comparison.[7] Both compounds were identified in positive ionization mode, giving fragment ions at *m*/*z* 205 and 121 for dehydrovomifoliol (MW 222, peak 5) and at *m*/*z* 205 and 135 for 3-hydroxy-1-(2-methoxyphenyl)penta-1,4-dione (MW 222, peak 6), respectively.

The chemical structures of the other metabolites detected in sulla and dill honeys are reported in Figure 4.

J. Agric. Food Chem. 2015, 63, 5864−5874

NMR Analysis. In accordance with literature data,[34] the ^{1}H NMR spectrum of honey in an aqueous solution is dominated by the intense signals of glucose and fructose anomeric forms (Figure 5 is an example) where total ^{1}H NMR spectra of dill and sulla honeys are compared.

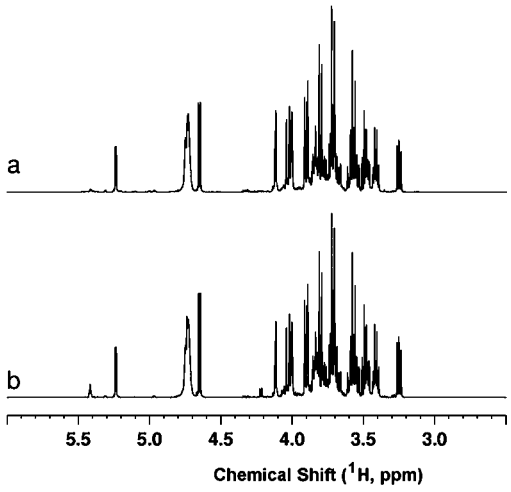

Figure 5. ^{1}H NMR spectra of dill (a) and sulla (b) honeys solutions in D_2O.

Apart from the signals of the principal components of the saccharide fraction, glucose and fructose, the signals of minor components are also observed in ^{1}H spectra. In Figure 6 the spectral region of anomeric protons (5.5−4.4 ppm) is reported not only for dill and sulla honeys but also for lemon, orange, and medlar ones. The complete assignment of these signals to individual compounds requires the application of $^{1}H-^{13}C$ HSQC-NMR with enhanced resolution in the ^{13}C dimension,[35] to overcome the overlapping of their ^{1}H and ^{13}C resonances,[34] the use of literature databases, and, in some cases, addition of standard compounds. The partial assignment obtained using 2D NMR experiments and literature data[34−36] was focused on ^{1}H signals not overlapped with other resonances. In this case the direct quantification by integration of corresponding ^{1}H signals was possible. Raffinose, kojiobiose, turanose, and nigerose were identified by virtue of their characteristic anomeric signals (Figure 6). The multiplet signal at 5.42 ppm showed a marked variation in the intensity among the five honeys. The structure of this multiplet (two doublets at 5.419 and 5.412 ppm partially overlapped) together with the corresponding ^{13}C correlations (a double spot in $^{1}H-^{13}C$ HSQC spectrum at 92.7 and 100.3 ppm) proves that it belongs to at least two different components. A detailed analysis of the literature data[34−36] revealed that at least seven di- and oligosaccharides have the anomeric CH group giving the signal with very similar ^{1}H (i.e., 5.42 ppm) and ^{13}C chemical shifts and usually present in honey: erlose, kestose, raffinose, sucrose, maltose, maltotriose, and maltotetraose. As verified by the direct addition of raffinose in our solution, the anomeric proton from the α-D-glucopyranose ring of raffinose gave a doublet signal at 5.435 ppm, and so raffinose can be excluded. The analysis of other ^{1}H and ^{13}C resonances including those outside the anomeric region indicated that kestose did not contribute to the signals at 5.419 and 5.412 ppm. Among the remaining sugars, sucrose and erlose were responsible for the doublet at

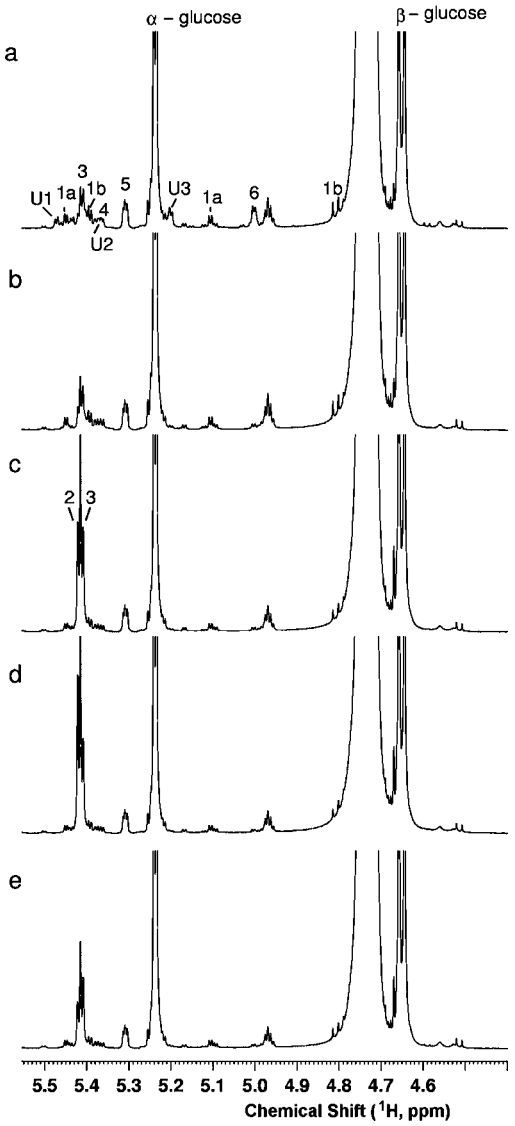

Figure 6. 5.5−4.4 ppm ^{1}H NMR spectral region of dill (a), medlar (b), sulla (c), orange (d), and lemon (e) honey solutions in D_2O. Assignments: 1a and 1b, kojibiose; 2, sucrose; 3, maltooligosaccharides; 4, nigerose; 5, turanose; 6, raffinose; U1, U2, U3, unassigned signals.

5.419 ppm, whereas erlose and maltose (according to $^{1}H-^{13}C$ HSQC experiment) contributed to the doublet at 5.412 ppm.

The quantification of raffinose, kojibiose, turanose, and nigerose in the five honeys has been performed by the integration of selected signals and normalization of integrals with respect to an internal standard (TSP) (Table 3). In the case of kojibiose and turanose, one of the anomeric forms (*O*-α-D-glucopyranosyl-(1→2)-β-D-glucopyranose and 3-*O*-α-D-glucopyranosyl-α-D-fructofuranose, respectively) was not quantified due to the absence of specific resonances not overlapped with the signals of the other sugars. As a consequence, the absolute content of kojibiose and turanose in honeys was underestimated. Nevertheless, taking into account that all of the anomeric forms were in equilibrium under the experimental conditions, the contents of kojibiose and turanose reported in Table 3 can be considered as relative values that can be compared between different samples.

Table 3. Sugar Concentrations in Sulla, Dill, Lemon, Orange, and Medlar Honeys According to NMR Analysis

	concentration (mg/g)				
sugar	sulla	dill	lemon	orange	medlar
raffinose	2.8 ± 0.1	25.7 ± 0.8	2.6 ± 0.1	2.2 ± 0.1	4.1 ± 0.1
kojibiose[a]	4.2 ± 0.1	6.7 ± 0.1	3.9 ± 0.1	3.9 ± 0.1	6.6 ± 0.1
turanose[b]	20.6 ± 0.4	22.6 ± 0.5	17.9 ± 0.2	18.0 ± 0.3	22.9 ± 0.4
nigerose	7.4 ± 0.1	nd	6.7 ± 0.2	6.8 ± 0.1	10.2 ± 0.3

[a]Only *O*-*α*-D-glucopyranosyl-(1→2)-*α*-D-glucolpyranose anomer. [b]Only 3-*O*-*α*-D-glucopyranosyl-*β*-D-fructofuranose and 3-*O*-*α*-D-glucopyranosyl-*β*-D-fructopyranose.

The values reported in Table 3 evidence the marked differences in the content of minor components of the saccharide fraction in the honeys of different botanical origins. Raffinose content showed a noticeable variation, whereas the contents of turanose were quite similar in all five honeys as well as to some extent the contents of kojibiose. The content of raffinose was particularly high in dill honey with respect to other honeys. The content of nigerose in dill honey was not determined due to overlapping of its signals with those of an unassigned compound (U2). It is noteworthy that dill honey contains still unidentified saccharides (denoted U1, U2, and U3 in Figure 6a) absent in the other four honeys, as suggested by ^{1}H NMR signals.

Especially in dill honey, the occurrence of carbohydrates such as kojibiose, turanose, and nigerose (Figure 7), which were shown to possess prebiotic effects in experimental animal studies, suggests that these honeys may exert prebiotic effects. These compounds have been found to show a large number of physiologic effects, such as increasing bifidobacteria numbers in the colon. This effect has been connected to other positive effects for human health such as the production of compounds able to inhibit potential pathogen growth, reduce blood ammonia levels, and produce vitamins and digestive enzymes. Moreover, the carbohydrates reported above showed also the capacity to increase calcium absorption and fecal weight and to decrease gastrointestinal transit time and blood lipid levels.[37,38]

Finally, in the region between 3 and 0.5 ppm (Figure 8a,b) characteristic signals of organic acids and amino acids are present. The signals of proline and lactic, acetic, and succinic acids were identified in this region in all honeys, but the intensity of proline and lactic and succinic acids resonances was much higher in dill compared to sulla honey. Another amino acid, phenylalanine, was identified only in dill (Figure 6c) and lemon honeys, whereas its content was too low to be detected in sulla (Figure 6d), medlar, and orange honeys. According to the literature, proline is the most abundant amino acid in honey followed by phenylalanine.[39] Moreover, alanine traces were observed only in the dill honey spectrum (Figure 8).

In conclusion, this investigation represents the first study of the chemical composition of sulla and dill honeys obtained in purity by Sicilian black honeybees performed with a combined method that includes HPLC-PAD-ESI-MS^n and NMR spectroscopy analyses. LC-MS/MS analysis allowed the identification of 22 compounds. In sulla honey, 14 compounds were identified, among which were 3 organic acids, 1 derivative of a phenolic acid, 4 flavonols, 1 flavanon, 4 flavanonols, and dehydrovomifoliol. In dill honey, 14 compounds were detected, among which were 4 organic acids, 2 phenolic acids and derivatives, 1 flavanonol, 1 flavanon, 1 B2 vitamin and its metabolite, 1 amino acid, 1 norisoprenoid compound, dehydrovomifoliol, and 3-hydroxy-1-(2-methoxyphenyl)penta-1,4-dione. Some compounds were previously detected in other

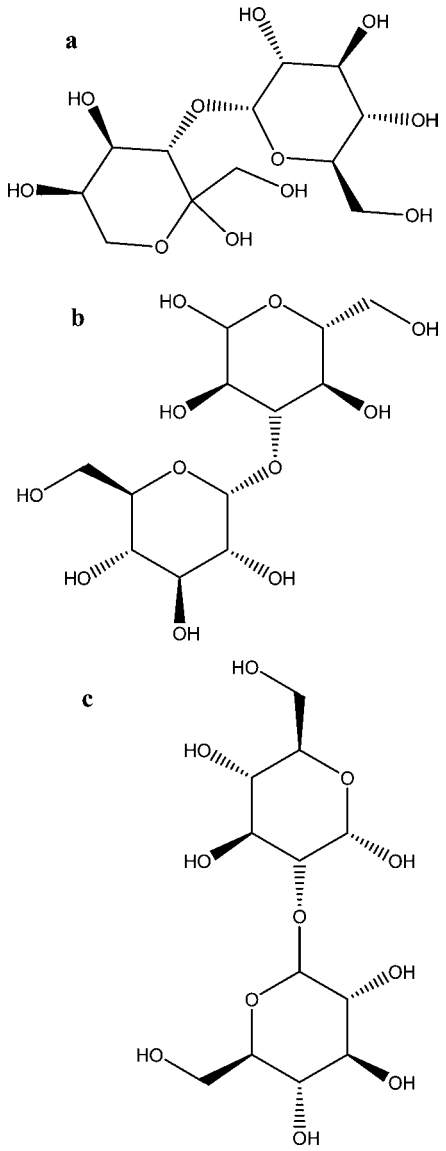

Figure 7. Chemical structures of (a) turanose (3-*O*-*α*-D-glucopyranosyl-*β*-D-fructopyranose), (b) nigerose (3-*O*-*α*-D-glucopyranosyl-D-glucose), and (c) kojibiose (2-*O*-*α*-D-glucopyranosyl-D-glucopyranose).

A. mellifera ssp. *sicula* honey samples of different botanical origins,[10] but for many other substances, this research represents the first report on their identification in these particular kinds of honey. NMR spectroscopy allowed the identification and quantification of several carbohydrates such as raffinose, kojibiose, turanose, and nigerose, the beneficial effects of which on nonpathogenic gut microorganism growth

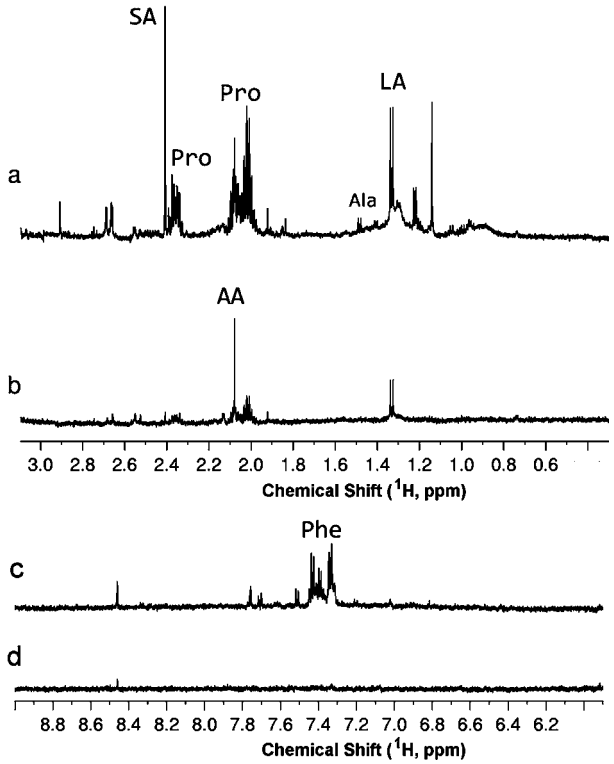

Figure 8. Two selected regions of ^{1}H NMR spectra of dill (a, c) and sulla (b, d) honey solutions in D_2O. Assignments: AA, acetic acid; Ala, alanine; LA, lactic acid; Phe, phenylalanine; Pro, proline; SA, succinic acid.

are well documented. Especially, the finding of the high content of turanose in all tested honeys and raffinose in dill honey justifies the prebiotic effect ascribed to honey.

The combination of these two methodologies allowed us to describe the phytochemical composition of each type of honey and identify many compounds that were found in these types of honey for the first time. In addition, we could compare the metabolic profiles obtained by our analysis with those already reported in the literature and provide the first phytochemical composition for that kind of honey for which no chemical data are available in the literature. On the basis of the obtained results, this combined approach can be applied conveniently for future honey analyses.

source of phytochemicals.[13] The main challenge of adding these byproducts to bakery products is to find new processing strategies to incorporate more of the bioactive compounds in flour while still removing those parts of grain that confer inferior technological quality or affect safety.[3] In general, DF additions to baking lead to important reductions in the loaf volume, and a different texture of the breads is obtained; thus, the optimal proportion of DF addition to each different food should also be determined on the basis of sensory attributes.

The cereal grain fractionation technology, which could also be applied easily with a selective dry pearling process, is receiving a great deal of attention because of its capacity to efficiently separate negative and positive aspects, to produce new ingredients and flour mixes with technologically optimized functional and nutritional attributes.[14,15] The sequential pearling of wheat kernel and the incorporation of selected pearled fractions into the bread formula were studied in previous works.[16,17]

The effects of the inclusion of barley whole grain or bran fractions were previously reported by several authors, who focused separately on the nutritional benefits[18−22] or the technological consequences.[23−26] However, the addition of intermediate pearled barley fractions to breadmaking has not yet been considered.

The aims of this study were (i) to analyze the bioactive compound contents and detrimental factors in barley kernels, through a sequential pearling process, in order to use them as functional food ingredients; and (ii) to comprehensively evaluate the nutritional enhancement and the technological impact of the incorporation, at different replacement levels, of an intermediate pearled barley fraction into bread formulations.

MATERIALS AND METHODS

Field Barley Production. Two commercial winter barley varieties were cultivated side by side in the same field, in a medium-texture fertile soil in Carignano, northwestern Italy (44°53′8.69″ N, 7°41′16.75″ E, 232 m asl), during the 2011−2012 growing season, according to the normal crop management program applied in the growing area.

The compared barley varieties were Trasimeno (Geo Seed, Grinzano di Cervere, CN, Italy), a two-row cultivar, and Ketos (Limagrain Italia Spa, Busseto, PR, Italy), a six-row cultivar. Both cultivars have hulled grains.

Planting was conducted in 12 cm wide rows at a seeding rate of 450 seeds m^{-2} on October 24, 2011. The previous crop was maize for grain, and the seed bed was set after plowing (30 cm) and harrowing. A total of 130 kg N ha^{-1} was applied as a granular ammonium nitrate fertilizer, split equally between the tillering and stem elongation stages. Harvest was conducted with a combine-harvester on June 23, 2012. Kernel samples of each cultivar were stored at 4 °C until the beginning of the pearling tests.

Sequential Grain Pearling. Nine fractions of kernels from each cultivar were obtained through incremental pearling, following the approach proposed by Beta et al.[27] The pearling consisted of consecutive passages of barley whole grain and pearled grain in an abrasive-type grain testing mill (TM-05C model, Satake, Tokyo, Japan) at a constant speed of 1100 rpm and a frequency of 55 Hz. The pearling process was monitored by time control. After each assay, the laboratory pearler was cleaned thoroughly by means of dust aspiration and compressed air, to minimize equipment contamination. Initially, a 500 g portion of each unprocessed barley was subsampled from a 5 kg sample, and the remaining 4.5 kg was pearled. Starting with unprocessed grain, kernels were initially pearled to remove 5% of the original grain weight, and this resulted in a first fraction (0−5% w/w). The remaining kernels were then pearled to remove a second fraction of 5% (5−10% w/w). The pearling process was continued until another six fractions (designated 10−15, 15−20, 20−25, 25−30, 30−35, and 35−40%, respectively) plus a residual 60% of the kernel (40−100%) had been collected.

The whole grain samples and the residual 60% of the unprocessed kernels were milled using a laboratory centrifugal mill (ZM-100; Retsch, Haan, Germany) with a 1 mm opening. Then, both the milled and pearled samples (500 g) were ground to pass through a 0.5 mm sieve and stored at −25 °C until the chemical analyses.

Substitution of Flour with Barley Pearled Fraction in the Breadmaking Procedure. A functional ingredient was obtained from the barley pearling, following the approach proposed in a previous study focused on wheat.[17] The two-row Trasimeno barley, which showed the lower deoxynivalenol (DON) content and the higher β-glucan content, was chosen to prepare an intermediate pearled fraction, to obtain a functional ingredient that would preserve a high functional role, but without those parts of grain that could confer inferior technological quality or affect safety. Considering that the fiber, proteins, minerals, and antioxidant compounds are concentrated in the most external layers, but β-glucans are present in a greater concentration in the inner part of the barley kernel, the best compromise to preserve all of these functional compounds appeared to be the 15−25% (w/w) fraction. In fact, the total and insoluble DF in the selected pearled fraction was still high, and although the more external coarse fiber, located in the hull, and the more external endosperm layers were removed, a good β-glucan content was still provided.

Starting from unprocessed grain, the barley kernels were initially pearled to remove 15% of the original grain weight, according to the previously reported procedure, and this most external fraction was discarded. The remaining kernels were then pearled to remove a second 10% fraction of the original grain weight (15−25%), and this fraction was used to replace refined commercial breadmaking flour at different percentages.

Five mixtures of refined commercial breadmaking flour, with increasing replacement rates (5, 10, 15, 20, and 25%) of the selected pearled barley fraction, were obtained and employed for breadmaking. Refined flour and the selected pearled barley fraction were accurately mixed using a rotary laboratory blender (Beccaria S.r.l., Cuneo, Italy). The Chopin alveograph parameters of the commercial refined flour were deformation energy (W) = 325 J 10^{-4} and curve configuration ratio (P/L) 0.52. The particle size of the selected pearling fraction was similar to that of the refined commercial flour: in both cases, >80% of the particles were <200 μm.

The breads were made according to AACCI Method 10-10.03 for 3 kg of flour.[28] The formula contained salt (2% of flour weight), brewer's yeast (3% of flour weight), and the optimal water absorption, which was previously determined through a Mixolab rheological analysis. The dough was then mixed in a spiral mixer (Esmach, Bonpard Group, Vicenza, Italy) and divided into three pieces of approximately 400 g/piece, to obtain three loaves, which were placed in baking tins (10.5 × 6 cm^2, 6.5 cm deep). The mixing times were different for the refined commercial and the selected pearled barley fraction mixtures, to obtain an equivalent dough development. After fermentation (at 30 °C and a relative humidity of 85% for 120 min), the loaves were baked at 215 °C for 45 min.

The three composite loaves for each replacement level were used as replicates for chemical and technological analyses.

Chemicals. The total DF and mixed-linkage β-glucan kits for enzymatic determinations were supplied by Megazyme (Megazyme International Ireland Ltd., Wicklow, Ireland). The solvents (HPLC grade) and formic acid (50%, LC-MS grade) were purchased from Sigma-Aldrich (Milan, Italy). The water was obtained from a Milli-Q instrument (Millipore Corp., Bedford, MA, USA). The antibody-based immunoaffinity columns were supplied by VICAM (Waters Corp., Watertown, MA, USA). The analytical standards (purity ≥ 95%) and all other chemicals (reagent grade level) were purchased from Sigma-Aldrich.

Chemical Analyses on Pearling Fractions and Breads. *Sample Preparation.* Bread samples were ground in a laboratory mill (ZM-100; Retsch, Haan, Germany), and in the case of DF, total

phenolic content (TPC), and total antioxidant activity (TAA) determinations, they were further freeze-dried (Heto Drywinner 8, Copenhagen, Denmark) and ground in an oscillatory mill (Mixer Mill MM440, Retsch GmbH). The pearled barley fractions, the whole flours, and the freeze-dried ground breads were sieved (particles size < 250 μm) prior to the TAA analyses.

Proximate Composition. Moisture, total proteins, ashes, dietary fiber (both total and insoluble), and β-glucan contents were determined as previously described.[16,17] The conversion factors employed to calculate the total protein content were 5.83 and 5.70 for barley and for wheat flour and bread, respectively.

Total Phenolic Content. TPC was determined on composite breads and on the flours employed to prepare the loaves. Phenolic extracts were prepared as previously reported,[17] and then 30−100 μL (according to the expected concentration) was made to react with 100 μL of Folin−Ciocalteu reagent and 350 μL of sodium carbonate (5%), adding distilled water to obtain a total volume of 2900 μL. After 1 h of incubation, the absorbance was measured at 760 nm (Evolution 60S spectrophotometer, Thermo Scientific, Milan, Italy). The results were expressed as ferulic acid equivalents through a calibration curve ($y = 0.0105x - 0.0563$; $R^2 = 0.994$; linearity range = 10−80 μg).

Total Antioxidant Activity. TAA was determined by employing DPPH$^•$ and ABTS$^{•+}$ methods (direct measurement on solid samples), as previously described.[16,17,29] DPPH$^•$ antiradical activity was determined in both methanolic (DPPH MeOH) and hydroalcoholic (DPPH H_2O) solutions.

As far as the DPPH MeOH method is concerned, the samples were opportunely weighed (0.5−20 mg, to obtain final inhibition percentage values <70%), and then 700 μL of methanol and 700 μL of a 100 μM DPPH$^•$ methanolic solution were added. The reaction was carried out in the dark under stirring for 25 min, and then the samples were promptly centrifuged for 1 min at 14000 rpm (Microcentrifuge 5417 R, Eppendorf Italia, Milan, Italy) and the absorbance was measured at 515 nm after exactly 30 min of reaction (Evolution 60S spectrophotometer, Thermo Scientific, Milan, Italy). A control solution (without sample) was tested under the same conditions to calculate the DPPH$^•$ inhibition percentage.

The DPPH H_2O method was performed as described for DPPH in the methanolic solution, but with the addition of 1400 μL of water and 1400 μL of the DPPH$^•$ methanolic solution to the solid samples.

ABTS$^{•+}$ reagent was prepared as described by Re et al.[30] and further diluted in a mixture of ethanol/water (50:50, v/v) to obtain an absorbance of 0.700 ± 0.020 at 734 nm. Samples were tested in the ratio of 0.5−10 mg per 6 mL of ABTS$^{•+}$ solution (inhibition percentage values < 70%). The reaction solutions were stirred for 25 min and then centrifuged at 14000 rpm for 1 min (Microcentrifuge 5417 R, Eppendorf Italia). Absorbance of the samples and control solutions was performed after exactly 30 min, and then the inhibition percentage values were calculated.

For all of the methods, the final results were expressed as millimoles of trolox equivalents (TE) per kilogram of sample (dw) through a calibration curve (DPPH, $y = 11.267x - 4.3171$, $R^2 = 0.982$, linearity range = 1−15 μg; ABTS, $y = 2.666x - 1.9208$, $R^2 = 0.986$, linearity range = 5−35 μg).

Deoxynivalenol Contamination. The DON content was analyzed on barley fractions obtained from the sequential pearling using a high-performance liquid chromatography (HPLC-MS-MS) method (range = 80−4000 μg kg^{-1}), as previously described by Sovrani et al.[16] The percentage of recovery, obtained using Certified Reference Materials (CRM Trilogy Analytical Laboratory, 2.1 mg kg^{-1} ± 0.2 mg kg^{-1}), was 79% (relative standard deviation = 6%). The limit of detection (LOD) and the limit of quantification (LOQ) were 5 and 16 μg kg^{-1}, respectively.

Breadmaking Technological Quality Analyses. *Rheological Properties of the Flour.* The mixing and pasting behaviors of the control and different replaced flours were studied using a Mixolab analyzer (Chopin Technologies, Paris, France), according to ICC Standard Method 173.[31] This instrument allows specific information to be obtained about the behavior of dough constituents (starch, protein, water) by continuously measuring the torque (Nm) produced by the passage of the dough between two mixing blades, subject to the dual stress of mixing and temperature changes.

Bread Crust and Crumb Color. The chromatic characteristics of the bread crust and crumb were determined using a Minolta Chroma Meter reflectance spectrophotometer (model CR-400, Minolta Co., Osaka, Japan). Standard illuminant C was used as the reference. The analysis was performed in triplicate at three different points for each loaf, for both the bread crust and crumb. The color values of *L**, *a**, and *b** were determined directly by the instrument, according to Commission Internationale de L'Eclairage methods.[32]

Combined Acoustic−Mechanical Analysis of the Bread Crust. A penetration test was carried out to assess the mechanical and acoustic properties of the bread crust, using a TA-XT Plus Texture Analyzer (SMS-Stable Micro Systems, Surrey, UK), combined with an AED Acoustic Envelope Detector supplied by the same manufacturer. Force and acoustic emission acquisitions were made simultaneously using the Texture Exponent software (Stable Micro Systems), with a data rate of 500 points per second during a compression/penetration test.[33] Each loaf was penetrated by a P/6 6 mm steel cylindrical probe, a deformation of 20 mm was applied with a test speed of 1 mm s^{-1}, and an instrumental trigger of 0.05 N was used. The microphone was placed at a fixed distance of 10 mm from the sample for the acoustic measurements. To minimize the noise, the acoustic measurements were filtered through an integrated 1 kHz high-pass filter, and a 24 dB instrumental gain was applied.

The analysis was performed in triplicate at three different points for each loaf. The following mechanical and acoustic parameters were determined from the force−distance and acoustic spectra according to the method of Piazza et al.:[33] total energy (mJ), maximum acoustic emission (dB (SPL)), and number of acoustic emission peaks using 15 dB (SPL) as the peak threshold value.[17]

Bread Volume. Loaf volume was determined 1 h after baking, by means of the rapeseed displacement method AACCI Standard 10-05.01.[34]

Bread Crumb Texture Profile Analysis. Texture measurements were performed on two slices (20 mm thick), cut from the central part of the three replicated loaves for each mixture of refined flour and pearled fraction, 4 h after baking. The bread slices were compressed in the central area using an SMS P/35 flat probe (Stable Micro Systems) for a 50% deformation of the slice with a waiting time between two bites of 30 s, using 1 mm s^{-1} as the speed test.[17] An instrumental trigger of 0.05 N was applied. The typical texture profile analysis parameters were determined from the force−distance curves and calculated by the software: hardness (N), cohesiveness (adimensional), gumminess (N), springiness (mm), chewiness (mJ), and resilience (adimensional).[35]

Statistical Analysis. All of the analyses were performed at least in triplicate. The results of the bread samples were reported as the means

of the three loaf replicates. The analysis of variance (ANOVA) was used to compare the samples. The residual normal distribution was verified using the Kolmogorov−Smirnov test, whereas variance homogeneity was verified using the Levene test. Multiple-comparison tests were performed according to the REGW-Q test on treatment means. The SPSS for Windows, version 20.0 statistical package (SPSS Inc., Chicago, IL, USA), was used for the statistical analysis.

RESULTS AND DISCUSSION

Bioactive Compounds in the Whole Barley Kernel. The ash, protein, total and insoluble DF, and β-glucan contents, the DON contamination, and the TAA determined for the whole grain kernels are reported in Table 1. Except for the TAA obtained with the DPPH methods, ANOVA showed significant differences between the barley varieties used in this study. Trasimeno (two-row cultivar) reported a higher content of ash (+0.3%) and above all of β-glucans (+1.6%) than Ketos (six-row). Conversely, cv. Ketos had higher total and insoluble DF (+7%) and TAA, obtained through the ABTS method (+8%). As expected, the protein content was higher in the six-row barley (+1%). The DON content was under the LOQ for cv. Trasimeno, whereas the average contamination of this mycotoxin in the cv. Ketos kernel was 178 μg kg^{-1}.

The greatest difference between the compared cultivars is related to the almost double β-glucan content recorded in the two-row cultivar compared to the six-row one, thus confirming previous information.[36,37]

Even though the relative content of some compounds is genetically regulated (as in the case of β-glucans), their final absolute concentration is closely dependent on pedoclimatic and agronomic factors. For this reason, and considering that the observed varietal differences referred to a single year and a single cultivation location, further investigations should be conducted to improve the characterization of these barley cultivars.

Bioactive Compounds of the Pearled Barley Fractions. A total of 10 samples were obtained from each barley variety: the whole unprocessed grain and the 0−5, 5−10, 10−15, 15−20, 20−25, 25−30, 30−35, 35−40, and 40−100% fractions, obtained through the pearling process. The two first pearling passages (0−5 and 5−10%) led to an almost complete visual dehulling of the barley kernel, according to previous works.[15] The bioactive compound content in the fractions obtained from the sequential barley pearling is reported in Table 2. In both varieties, ANOVA showed highly significant differences ($P < 0.001$) between the kernel pearling fractions for all of the considered parameters. The first pearling fraction (0−5%) resulted in the highest content of the total and insoluble DF. Sequential pearling has shown that both the total and insoluble fibers decreased progressively from the external to the internal layers, whereas the β-glucan content increased going toward the inner kernel layers in both varieties, in agreement with the results of several authors.[38−40] According to Liu et al.,[15] the inner part of the barley kernel, after removal of 60% of the grain weight, showed a 27% higher β-glucan content than the whole kernel. In the cultivars considered in our study, the β-glucan contents of the residual part of the kernels after pearling (40−100%) were 79 and 38% higher than that of whole kernel, for the six-row and two-row barleys, respectively.

Comparing the β-glucan contents of the milling fractions of whole grain or pearled barley, Sullivan et al.[39] found the highest concentration in the middling fractions, followed by flour and, finally, by bran. Moreover, the authors reported that barley pearling (10% w/w) clearly affected the soluble and insoluble fiber contents in the milling fractions: the total DF of the grain

[a]Mixolab parameters: water absorption, amount of water required for dough development; DDT, dough development time; stability, time of dough stability at a constant temperature; amplitude, dough elasticity; C2, protein weakness; C3, starch gelatinization; C4, hot gel stability; C5, starch retrogradation in the cooling phase; C2, C3, C4, and C5, end points of the corresponding mixing phases. Means followed by different letters are significantly different (the level of significance is shown in table). [b]SEM, standard error of means.

was decreased considerably by the pearling process. Conversely, there was little difference in the β-glucan content. In the study carried out by Marconi et al.,[41] the abrasive pearling fractions of barley hulled by approximately 10, 25, and 40% showed DF removals of 35, 55, and 71%, respectively, and β-glucan content removals of 5, 19, and 37%, respectively.

A progressive decrease in the percentage of ash was observed, because the mineral components are mainly distributed in the outer layers of the kernel.[41] Because useful elements and heavy metals, such as cadmium and lead, are included in ash, it could be useful to preserve the good mineral form present in cereals and remove the more contaminated fractions. In a previous experiment on wheat sequential pearling, heavy metals were found only in the most external fractions.[16]

The protein content was the lowest in the initial surface removal layer, which corresponded to the coarse hull fraction, whereas the highest content was observed in the 15−25 and 10−20% fractions, for Ketos and Trasimeno cultivars, respectively.

The 10−15 and 15−20% pearling fractions were those with the highest TAA. The next external layers (0−5 and 5−10%), consisting mainly of hull, and the next internal layers (20−25 and 25−30%) showed 48 and 44% lower TAA, respectively.

DON Contamination of the Pearled Barley Fractions. DON contamination in the barley fractions is reported in Table 2. The content of this mycotoxin was under the LOQ in all of the compared pearling fractions of cv. Trasimeno, thus confirming the data from whole grain kernels, whereas, for cv. Ketos, the outermost kernel layers had the highest DON contamination, which was 6 and 3 times higher than that of the whole kernel for the 0−5 and 5−10% fractions, respectively. These findings confirm that large concentrations of DON accumulate in the hulls of barley and that the application of processing strategies able to carefully remove the hull can lead to a significant reduction in the DON levels.[42]

As previously reported for wheat,[16] DON showed a decrease, going from the external to the internal layers, that followed a biphasic type pattern: a remarkable reduction was observed in the first pearling steps, and this was followed by a slower decrease. No significant differences were observed for DON contamination for the 25−30, 30−35, and 35−40% fractions. House et al.[43] reported that a grain mass loss of 15% through barley pearling reduced DON contamination by 34%.

Characterization of the Wheat Flour and Pearled Barley Fraction. The two-row Trasimeno barley, which showed the lower DON content and the higher β-glucan content, was chosen to prepare an intermediate pearled fraction, so as to obtain a functional ingredient that would preserve a high functional role, but without those parts of the grain that could confer inferior technological quality or affect safety. Considering that the fiber, proteins, minerals, and antioxidant compounds are concentrated in the most external layers, but β-glucans are present in a greater concentration in the inner part of the barley kernel, the best compromise to preserve all of these functional compounds appeared to be the 15−25% (w/w) fraction. In fact, the total and insoluble DF in the selected pearled fraction was still high, and although the more external coarse fiber, located in the hull, and the more external endosperm layers were removed, a good β-glucan content was still provided.

The refined commercial wheat flour and the selected pearled barley fraction were characterized for their chemical composition (ash, protein, DF, β-glucan, TPC content) and TAA (Table 3). The pearled barley fraction had 10, 1.5, 11, 14, and 8 times higher contents of ash, protein, DF, β-glucans, and TPC, respectively, than the refined commercial flour. Taking into account the different methods, the TAA of the pearled barley

fraction was from 10 to 73 times higher than in the refined wheat flour.

Rheological Parameters of the Replaced Flours. Five mixtures of refined breadmaking flour, with an increasing replacement of the selected pearled barley fraction (5, 10, 15, 20, and 25%), were obtained and characterized for their rheological properties (Table 4); the refined flour (no replacement) was analyzed as the control.

The progressive replacement of flour with the pearled barley fraction significantly increased the amount of water required for the flour hydration process, although no differences were observed for the dough development time (DDT) at any replacement level. Compared to the control without the addition of the pearled fraction, the replacement at a 5% level significantly reduced dough stability and the C2 point (protein strength) by 26 and 20%, respectively. A further reduction was observed at the 10% level, of 40 and 31% for both parameters, respectively. Conversely, these parameters both increased slightly at higher replacement levels. Comparing the addition of bran from different cereals at different replacement levels to white flour, Sudha et al.[23] reported that barley bran (DF = 45%) led to the highest increase in water absorption (from 64 to 76%) and the greatest reduction in dough stability (from 7.0 to 3.5 min), whereas the DDT increased more for wheat, rice, and oat bran. According to Rosell et al.,[24] these differences are mainly related to the competition for water of the added barley fibers with the flour proteins and starch and to the negative physical and mechanical effects of fiber on the formation of the gluten network. Moreover, the increase in water absorption of the dough is also related to the nonstarch polysaccharide contents and β-glucans in particular.[44]

The dough amplitude was affected significantly only at the 25% level, whereas the starch gelatinization (C3 point) and amylase activity (C4) were already affected at 5% of substitution. A further significant reduction in the C3 value was observed for a 15% level of replacement. Conversely, increasing the replacement level of refined flour with the pearled barley fraction did not affect the C5 point (starch retrogradation). Dough resistant to extension, elasticity, and starch pasting properties has been reported to be affected significantly by the 15% inclusion of barley middlings in the bread formulation.[18]

Overall, compared to literature data referring to the addition of whole grain barley flour or other byproducts of barley processing,[18,19,25] the substitution of wheat flour with the selected intermediate pearling fraction has led to less dough weakening and, thus, a more contained reduction of dough stability.

Bread Technology Properties. The previously described composite flours were employed to prepare 5-, 10-, 15-, 20-, and 25%-substituted breads; a control bread was also prepared using the refined flour (without replacement) for comparison purposes. Bread samples were first analyzed for their technology properties: crust color, bread crunchiness and volume, and TPA test.

Bread Crust Color and Crunchiness. ANOVA showed significant differences in the L^* and b^* values for the crusts of bread made with different replacement levels of the refined flour with the pearled barley fraction (Table 5). An increase in the pearled fraction substitution resulted in a moderate reduction in the L^* (lightness) and the blue−yellow components (b^*). No significant changes were found for the redness (a^*) values.

In a previous work, no significant differences in crust color were observed for up to 10% blending with whole grain barley flour.[20] Sumner et al.[38] reported that the removal of the outer kernel layers resulted in an increase in lightness (L^*) of pearled barley grain and a reduction in the red (a^*) and yellow (b^*) values and showed intermediate values of L^*, a^*, and b^* between the hull and the inner pearled fractions for an intermediate pearling fraction similar to that used in the present study (15−24% w/w). In the breads obtained at replacement levels of 5 and 10%, the lightness (L^*) of the crust was reduced by 7 and 11%, respectively, compared to the control test. In the previous study based on pearled wheat fractions,[17] the reduction in crust lightness was found at the same replacement levels of 6 and 12%.

The results of the mechanical and acoustic property tests of the composite bread crust are reported in Table 5. The total break energy, which is the energy necessary to break the crust and to continue the compression until 20 mm of penetration, was already significantly reduced at the 5% replacement level, and a descending trend was observed as the flour replacement level was increased. A decreasing trend was also evidenced for both of the acoustic parameters that were evaluated (maximum acoustic emission and number of acoustic emission peaks, using a threshold value of 15 dB (SPL)) while increasing the replacement percentage. The maximum acoustic emission detected during compression was lower at each substitution, with significant differences from the 15% replacement level with respect to the control. A steep decrease in the parameter pertaining to the number of acoustic emission peaks was found between the control and the 10% replacement level samples,

DOI: 10.1021/jf506193p
J. Agric. Food Chem. 2015, 63, 5875−5884

which pointed out the loss of crust crunchiness in the substituted samples. The mechanical and acoustic crust evaluations showed a possible variation in the microstructure of the breads: this was also shown in extruded breads and was related to the water activity content and production parameters.[45,46]

Bread Volume, Bread Crumb Texture Profile Analysis, and Color. The increasing percentage of refined flour replacement with the pearled barley fraction led to a significant decrease in the bread volume (Figure 1). This effect already

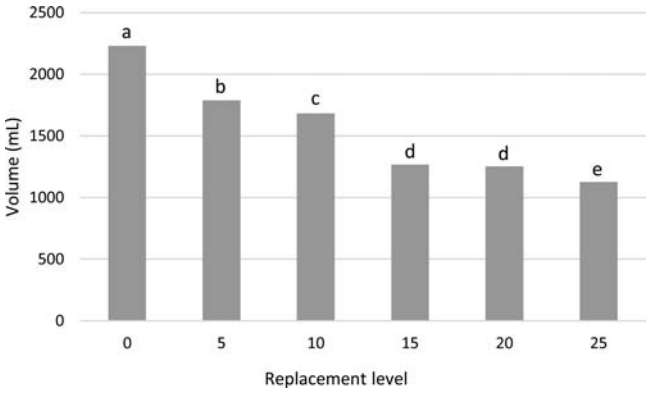

Figure 1. Volume of composite bread with refined flour and enriched fractions obtained through barley kernel pearling.

began at the 5% replacement of refined flour with the pearled fraction. At a 10% replacement level, the bread volume was reduced by 24%, compared to the control made with only refined wheat flour. The same reduction was reported by Gill et al.,[26,47] who included barley flour. At the same level of replacement, but using an intermediate pearled fraction obtained from wheat, the volume was reduced by 8% compared to the control.[17] A higher impact, on bread volume, of the inclusion of barley and other cereals, compared to wheat, was reported by Ragaee et al.:[21] the inclusion of 20% rye, barley, and oat whole grain flour led to reductions in loaf volume of 18, 27, and 28%, respectively. Conversely, the authors did not find any significant difference between a control bread and a 20% replacement of whole grain wheat flour. Gujral et al.[48] reported a reduction in loaf volume of 65% when 20% w/w of barley flour was incorporated in wheat bread.

The TPA parameters obtained during the analysis of the bread crumbs (Table 6) pointed out a variation in all of the parameters, excluding resilience, when the replacement level was increased. In particular, the force-related hardness parameter increased following the substitution increase, and the cohesiveness and springiness decreased slightly. In general, the variation in hardness predominated over cohesiveness and springiness in the variations of the derived parameters, such as gumminess and chewiness, thus evidencing a harder, gummier, and more difficult crumb to bite with the increased replacements. The differences are particularly clear for the 10% substitution.

The lower loaf volume and firmer crumb texture (hardness, gumminess, chewiness) with the inclusion of the pearled barley fraction may be attributed to gluten dilution caused by the addition of DF, which interfered with the optimal gluten matrix formation during fermentation and baking.[47] Moreover, no-starch polysaccharides could also have a profound impact on dough properties during breadmaking and could lead to a lower loaf volume and increasing bread firmness.[49] When added to wheat flour, β-glucans from barley could tightly bind to high amounts of water in the dough, suppress the availability of water to develop a gluten network, and cause rupture of the gas cells.[26,44]

Compared to the crust, for which an evolution in the lightness and some variations in the yellow color were perceived, the color of the bread crumbs was different. The evaluation of the bread crumb color showed an increase in both the a^* (red) and b^* (yellow) color components with an increase in the flour replacement, whereas the L^* (lightness) value showed a nonhomogeneous trend for the substitutions. A similar reduction in crumb brightness was observed for an increase in the whole flour barley substitution.[26]

Chemical Characterization of the Bread. The moisture, ash, DF, β-glucan, and TPC contents and the TAA of the bread increased linearly and significantly as the refined flour was replaced with the selected pearled barley fraction, whereas the protein content did not show a clear tendency (Table 7). In fact, although the pearled barley fraction presented much higher values than the refined commercial flour for the other parameters, the protein content was only 1.5 times higher. These results suggest that the contribution of the barley fraction alone is not sufficient to significantly improve the protein content of breads; for this reason, a linear increase, as in the case of the other parameters, was not observed.

Compared to the control (0% of replacement), the 5%-substituted bread showed a more than double content of insoluble DF, β-glucans, and TPC and, in the case of the DPPH

methods, also of TAA. Moreover, at this replacement level, a significant increase in the moisture (+0.9%) and ash (+0.14%) contents was observed compared to the refined control. A further significant increase in ashes, total and insoluble DF, β-glucans, and TAA was observed at a 10% replacement level, and a bread classified as a "source of fiber" (DF > 3%) and very close to being a "good source of fiber" (DF > 6%) was obtained.[50]

The supplementation of hulled barley whole grain flour led to a generally lower increase in DF compared to that reported in the present study: at a 15% level of substitution, Dhingra and Jood[20] reported increases of 10 and 7% in the total and insoluble fiber of bread, compared to a control, whereas no changes were observed for the ash content. Compared to whole grain barley flour, the intermediate pearled fraction also led to clearly higher increases in TPC and TAA. Compared to the control recipe, the bread enriched with 40% w/w of barley flour[26] presented TPC and TAA increases similar to those obtained in this study at a 5% replacement level. This is consistent with the fact that the external layers of barley kernels and, particularly, the selected pearled fraction employed for bread preparation have higher TAA than whole barley.

In conclusion, the results obtained in this work show that selected byproducts of barley pearling could be proposed as potential ingredients for the manufacture of functional foods rich in DF and antioxidant compounds. However, considering the technological impact on dough and bread properties, their amounts in the formulation of bakery products need to be considered carefully, taking into account the sensory acceptability of consumers and also the possible application strategies that could be introduced to mitigate these undesirable effects.

The inclusion of this pearled fraction could probably easily be applied to other bakery products that require lower leavening, such as biscuits, and this could result in the necessity of introducing fewer technological changes. However, to obtain enriched bread using these pearled barley fractions, it could be interesting to perform specific enzymatic or physical treatments or to modify the breadmaking process through the use of additives or sourdough fermentation.

stitutions of $Pro_{182}Thr$ and $Tyr_{310}Cys$ in the *EPSPS* gene were recently reported in glyphosate-resistant sourgrass (*Digitaria insularis*).[31] The level of resistance due to these target site mutations is relatively low, ranging from 2- to 4-fold.[32]

Two other glyphosate resistance mechanisms have been reported more recently. Horseweed[33] and *Lolium* species[34] reduced the amount of glyphosate that reaches the target site by rapidly sequestering glyphosate into the vacuole. This mechanism has conferred 14-fold resistance to glyphosate.[34] A high level of resistance to glyphosate in Palmer amaranth (*Amaranthus palmeri*) and Italian ryegrass results from *EPSPS* gene amplification.[35,36] *EPSPS* gene amplification is heritable and correlates with glyphosate resistance in the F2 population.[35] How rare these resistance mechanisms are is not yet known. The case with Palmer amaranth indicates gene amplification could confer high levels of resistance.

Starting in the mid-2000s, some Italian ryegrass populations have been surviving the spring vegetation desiccation treatments in Arkansas (United States) about the same period it was reported in neighboring Mississippi.[16,37] The severity of escapes and reduction in weed control has been escalating. *Lolium* is the major weed problem in wheat in the southern United States. This is also a problem in corn and cotton as these crops are planted in the spring when Italian ryegrass is actively growing. Off-season application of glyphosate has historically been effective in reducing *Lolium* infestation. It also has already evolved resistance to acetyl-CoA carboxylase (ACCase) and acetolactate synthase (ALS) herbicides used in wheat.[38−43] The evolution of resistance to glyphosate has compromised preplant weed management options as well and has increased the risk of economic losses in crop production. The objectives of this study were to determine the level of resistance to glyphosate in the Arkansas *Lolium* populations and to investigate the mechanisms by which selected populations survive a previously lethal dose of glyphosate.

MATERIALS AND METHODS

Plant Materials. Mature panicles from suspected glyphosate-resistant Italian ryegrass were collected in Desha County, Arkansas, in 2009 and 2010. Des05, Des09, and D8 populations were collected from cotton fields; D4 and Des13 were from fallow fields; Des14 and Des15 populations were from soybean fields. Seeds were grown in a greenhouse maintained at 24/18 °C day/night temperatures with a 12 h photoperiod. Plants were watered daily and fertilized with Miracle-Gro, a water-soluble all-purpose plant food containing 15−30−15% NPK, every 2 weeks. Seedlings at three-leaf stage were sprayed with a discriminating dose of 870 g ae ha^{-1} glyphosate. The surviving plants were grown to maturity for seed increase, and seeds from all plants in the same population were bulked at harvest. Populations grown for seed increase were placed either in the greenhouse (8 m apart, with other species in between as physical barriers) or outdoors (25 m apart). Multiple plants from one population were grouped together to cross-pollinate. Seeds generated were used for the subsequent experiments. A susceptible population (98-3) that was not exposed to glyphosate selection was used as the susceptible standard (reference) in all experiments.

Experiment 1. Population Dose−Response Bioassay. Seeds were planted into flats (25 × 25 × 5 cm) filled with Sunshine Mix LC1 soil (Sun Gro Horticulture Canada Ltd., Vancouver, BC, Canada). Flats were equally divided in two greenhouses because of space limitations; one was maintained at 24/18 °C and the other at 30/25 °C day/night temperatures at 12 h photoperiod. Following emergence, plants were thinned to 15 seedlings per flat. Three- to four-leaf seedlings (98-3, Des05, Des14, D4, D8, and D13) were treated with eight doses of glyphosate from 0 to 13920 g ae ha^{-1}, which corresponds to 0−16 times the commercial dose of 870 g ae ha^{-1}. Treatments for 98-3 included a nontreated check and 11 doses of glyphosate from 13 to 3480 g ae ha^{-1} corresponding to $^1/_{64}$−4 times the commercial dose of glyphosate. MON 78623 (58% v/w potassium salt of *N*-(phosphonomethyl)glycine; Monsanto Co., St. Louis, MO, USA) was applied with 0.25% nonionic surfactant (NIS). Glyphosate treatments were applied using a laboratory sprayer equipped with a flat fan spray nozzle (TeeJet spray nozzles, Spraying Systems Co., Wheaton, IL, USA) delivering 187 L ha^{-1}. The experiment was conducted in a randomized complete block design with two replications. Each replication consisted of one tray (50 × 25 × 5 cm) accommodating two flats and placed in two greenhouses by replication.

The number of survivors was recorded at 28 days after treatment (28 DAT). Plants were cut at the soil surface and stored in a dryer for 3 days, and the dry weight was recorded. Data were expressed as percentage of biomass reduction relative to the nontreated control. Regression analysis was conducted using SAS JMP v. 10. The percent biomass reduction and percent mortality were fitted to a nonlinear, sigmoid, three-parameter logistic regression model defined by (eq 1)

$$Y = c/[1 + \exp(-a \times (X - b))] \quad (1)$$

where Y is the biomass reduction or mortality expressed as a percentage of the nontreated control, a is the growth rate, b is the inflection point, c is the asymptote, and X is the glyphosate dose. The dose needed to kill 50% (LD_{50}) of the population or cause 50% biomass reduction (GR_{50}) was calculated from the above equation.

Experiment 2. Single-Plant Dose−Response Bioassay. To determine the relationship of the *EPSPS* copy number in glyphosate-resistant plants and resistance level, dose−response assays were conducted using clones of 14 total individual plants from Des05, Des09, Des13, Des14, Des15, and D8 (Table 1). Enough clones were propagated for each plant to accommodate the dose range tested and calculate the resistance factor of each plant. Four plants from the susceptible standard 98-3 were used as reference. The dose−response assay was conducted in the greenhouse, maintained at 24/18 °C at 12 h photoperiod. To accomplish this, tillers (adventitious shoots at the base of grasses) of each plant were separated and planted in 15 cm pots to obtain 24 clones per plant that were sprayed with eight herbicide doses in three replicates. Resistant plants were treated with glyphosate at 0, 218, 435, 870, 1740, 3480, 6960, and 13920 g ae ha^{-1}, using a laboratory sprayer calibrated to deliver 187 L ha^{-1}. The susceptible plants were sprayed with seven doses of glyphosate at 0, 54, 109, 218, 435, 653, 870, and 1740 g ae/ha^{-1}. Glyphosate was

applied with 0.25% NIS. The overall effects of glyphosate such as chlorosis, stunting, and desiccation were visually assessed at 28 DAT relative to the nontreated control, using a scale of 0−100 where 0 = no visible injury and 100 = complete death. Visible injury was regressed against glyphosate dose and modeled with a sigmoid, three-parameter, logistic function in SAS JMP ver.11 (eq 1). The amount of glyphosate needed to incur 50% injury (GR_{50}) was obtained from the regression equation.

Experiment 3. Absorption and Translocation of Glyphosate. Seeds from Des05, Des14, and 98-3 populations (Table 1) were planted in 2.5 cm pots in the greenhouse maintained at 24/18 °C day/night temperatures at 12 h photoperiod. Three weeks from emergence, when seedlings were 7.5−10 cm tall, formulated glyphosate (MON 78623) containing 0.25% NIS (Kinetic HV, Helena Chemical Co., Memphis, TN, USA) was sprayed at 870 g ae ha^{-1} in 187 L ha^{-1} spray volume and then spotted with 4 μL of herbicide solution containing 1.776 kBq ^{14}C-glyphosate. Plants were harvested at 24 and 48 h after treatment (HAT) and sectioned into four parts: treated leaf, above treated leaf, below treated leaf, and roots. To remove nonabsorbed glyphosate, the treated 5 cm portion of the treated leaf was rinsed for 15 s with 1 mL of a methanol/water (1:1 v/v) solution containing 0.25% v/v NIS. The rinsate was collected in a 20 mL scintillation vial, mixed with 10 mL of scintillation cocktail, and radioassayed by liquid scintillation spectroscopy (LSS) (Packard Tri-Carb 2100TR Liquid Scintillation Spectrometer, Packard Instrument Co., Downers Grove, IL, USA) to determine the amount of nonabsorbed ^{14}C. After rinsing dissection of the treated leaf, all plant parts were dried for 48 h at 50 °C. Individual plant parts were oxidized (Biological Oxidizer OX500, R. J. Harvey Instrument Corp., Tappan, NY, USA), and the released CO_2 was trapped in 15 mL of scintillation cocktail and radioassayed using LSS. Absorbed glyphosate was calculated by dividing the amount of ^{14}C recovered from the oxidized plant parts by the sum of the radioactivity contained in the leaf wash and that recovered from the oxidized plant parts. The distribution of ^{14}C-glyphosate in plant tissues was expressed as a percentage of absorbed radioactivity. The experiments were arranged in a completely randomized block design with four replicates. In the absorption experiment, a factorial scheme with two factors (population and harvest time) was tested by ANOVA. The translocation experiment, which had three factors (population, plant section, and harvest time), was also analyzed by ANOVA in SAS JMP Pro v.11.

Experiment 4. *EPSPS* Gene Sequencing. Two populations were randomly chosen for *EPSPS* gene sequencing (Table 1). Seeds from Des05 and Des14 populations were planted in 4.5 cm pots filled with Sunshine Mix LC potting soil. Tillers of 12 plants from Des05 and of 13 from Des14 were divided and transplanted into two pots. One set of clones was cut to 8 cm, allowed to regrow to 12 cm, and then sprayed with glyphosate at 870 g ae ha^{-1}. Clones that survived at 28 DAT were classified as resistant (R); otherwise, they were susceptible (S). Clones of all 13 plants from the Des14 population survived, whereas only 7 clones from the Des05 population remained alive at 28 DAT. The corresponding nontreated clones of verified R plants were used for sequencing of the *EPSPS* gene.

Young leaf tissues of 7 and 13 confirmed R plants from Des05 and Des14 populations, respectively, were harvested and stored at −80 °C for RNA extraction. In addition, leaf tissues of 5 and 10 S plants, respectively, from Des05 and 98-3 populations also were harvested. Leaf tissues were ground into fine powder in liquid nitrogen using a mortar and pestle. Total RNA was extracted using PureLink RNA Mini kit (Life Technologies, Carlsbad, CA, USA). First-strand complementary DNA (cDNA) was synthesized using Oligo$(dT)_{20}$ supplied in the Improm-II Reverse Transcription System first-strand cDNA synthesis kit (Promega, Madison, WI, USA). Forward primer LPM2F (5′-TSCAGCCCATCARGGAGATCT-3′) designed by Perez-Jones et al.[44] and reverse primer LPM2R1 (5′-CTAGTTCTT-CACGAAGGTGCTTA-3′) designed by Salas et al.[36] were used to amplify the *EPSPS* gene. The primer pair amplified a 915 bp fragment of the *EPSPS* region encompassing codon 106 where the known resistance-conferring point mutation occurs.

The polymerase chain reaction (PCR) was performed in a 25 μL reaction mixture consisting of 4 μL of cDNA, 0 0.4 μM of both forward and reverse primers, 12.5 μL of Taq2x master mix (New England Biolabs Inc., Ipswich, MA, USA), and nuclease-free water. The reaction mixture was loaded in a thermal cycler (PTC-200, MJ Research, Inc., Watertown, MA, USA) programmed for the following temperature profile: initial denaturation at 94 °C for 3 min, 35 cycles of 94 °C for 30 s; annealing at 57.5 °C for 30 s; elongation at 72 °C for 90 s, and final extension at 72 °C for 10 min. PCR products were cleaned using Wizard SV Gel and PCR Clean-Up System (Promega) before sequencing. The resulting DNA sequences were cleaned, aligned using the *EPSPS* sequence of Italian ryegrass as reference, and analyzed for polymorphisms using Sequencher v.5 and Bioedit v.7 software.

Experiment 5. *EPSPS* Copy Number Determination. Leaf tissues from 10 confirmed R plants of selected populations (Des05, Des14, and D8) and 10 plants of the S population 98-3 (Table 1) were harvested and stored at −80 °C. Plants used for whole-plant dose−response assays, glyphosate translocation studies, and gene sequence analysis were among those analyzed for gene copy number. Genomic DNA was extracted using the hexadecyltrimethylammonium bromide (CTAB) method[45] following the modification of Sales et al.[46] Approximately 100 mg of leaf tissue from each plant was ground to a fine powder in liquid nitrogen, transferred to a 1.5 mL centrifuge tube, and suspended in 500 mL of CTAB extraction buffer (100 mM Tris-HCl, pH 8.0, 20 mM ethylenediaminetetraacetic acid (EDTA), pH 8.0, 2 M NaCl, 2% CTAB, 2% polyvinylpyrrolidone-40, 1 mM phenanthroline, and 0.3% β-mercaptoethanol). The aqueous extracts were incubated in a water bath at 55 °C for 40 min, treated with RNase solution, and extracted with an equal volume of phenol/chloroform/isoamyl alcohol solution (25:24:1). Total nucleic acids were precipitated from the supernatant by the addition of an equal volume of isopropanol. The DNA pellet was washed with 500 μL of absolute ethanol, dried in a vacufuge for 5 min, and resuspended in 30 mL of Tris-EDTA buffer (10 mM Tris-HCl, pH 8.0, 1 mM EDTA). Genomic DNA was quantified using a NanoDrop spectrophotometer model ND-1000 (Thermo Scientific, Wilmington, DE, USA) and checked for quality by agarose gel electrophoresis.

Quantitative real-time PCR was used to measure the genomic copy number of *EPSPS* relative to cinnamoyl-CoA reductase (*CCR*) genomic copy number in Italian ryegrass. Primer sets and qPCR conditions were described previously.[36] Triplicate genomic DNA templates (10 ng) were amplified in a 25 μL reaction mixture using Bio-Rad iQ SYBR Green Supermix by the following thermoprofile on a Bio-Rad CFX96 Real-Time System PCR machine: 10 min at 94 °C, 40 cycles of 94 °C for 15 s, and 60 °C for 1 min then increasing the temperature by 0.5 °C every 5 s to generate the product melt-curve. Data were analyzed using CFX manager software (version 1.5). Primer efficiency and slope were 101.8% and −3.279 for *EPSPS* and were 98.64% and −3.355 for *CCR*, respectively. Negative controls did not have amplification products. Relative quantification of *EPSPS* was calculated as Δ^{Ct} = (Ct, *CCR* − Ct, *EPSPS*) according to the method described by Gaines et al.[35] Increase in *EPSPS* copy number was expressed as $2^{\Delta Ct}$. Each sample was run in three technical replicates to calculate the mean and standard error of the increase in *EPSPS* copy number. Results were expressed as fold increase in *EPSPS* copy number relative to *CCR*.

RESULTS AND DISCUSSION

Population Dose−Response Bioassay. Dose−response bioassay confirmed the resistance of Des05, Des13, Des14, D5, and D8 Italian ryegrass populations to glyphosate. The glyphosate dose that caused 50% growth reduction (GR_{50}) of the S population (98-3) was 101 g ae ha^{-1} glyphosate, whereas those of R populations ranged from 726 to 1264 g ae ha^{-1} glyphosate (Table 2 and Figure 1). Resistant populations Des05, Des14, Des13, D8, and D4 were, respectively, 7, 8, 9, 13, and 19 times less sensitive to glyphosate than the S

[a]Resistance level (R/S) calculated using the GR_{50} of the resistant population relative to the susceptible standard. [b]Resistance level (R/S) calculated using the LD_{50} of the resistant population relative to the susceptible standard. [c]Glyphosate-resistant population. [d]Glyphosate-susceptible population. [e]Lower, 95%; upper, 95%.

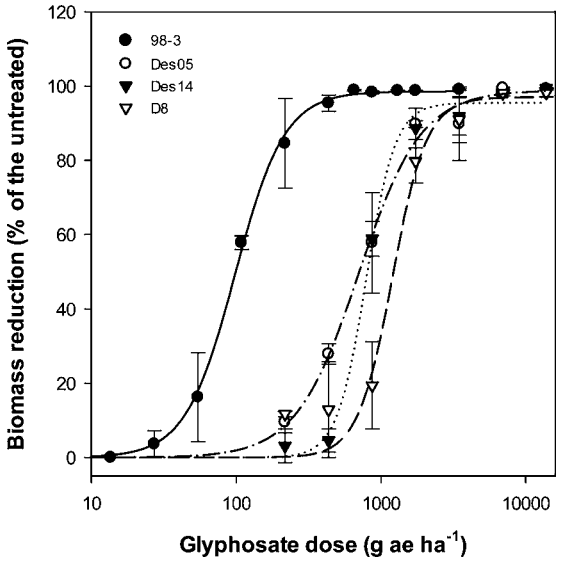

Figure 1. Shoot biomass reduction of selected *L. perenne* ssp. *multiflorum* populations, 28 days after treatment. Error bars are standard errors of the mean. Des05, Des14, and D8 had estimated 50% biomass reductions (GR_{50}) of 726, 831, and 1264 g ae ha^{-1} glyphosate, respectively. The susceptible 98-3 population had an estimated GR_{50} of 101 g ae ha^{-1} glyphosate.

population based on the R/S ratio calculated from GR_{50} values. The recommended field dose of glyphosate is 870 g ae ha^{-1}; thus, the R populations required 0.8−1.5 times the normal field dose of glyphosate to reduce aboveground biomass or ryegrass by 50%. The herbicide dose that caused 50% mortality (LD_{50}) of the 98-3 population was 184 g ae ha^{-1}, whereas those of the R populations ranged from 1524 to 2719 g ae ha^{-1} (Table 2 and Figure 2). On the basis of LD_{50} values, Des13, Des05, Des14, D8, and D4 populations had 8-, 9-, 9-, 12-, and 15-fold resistance relative to the 98-3 population (Table 2). These resistance levels are similar to the resistance levels calculated from the GR_{50} values. More than 1.8−3.1 times the commercial dose of glyphosate was needed to kill 50% of the resistant populations. Thus, growers would have to apply at least double these LD_{50} amounts to achieve 100% control in the corresponding fields; however, applying twice the normal dose is not recommended in commercial practice. The use of a higher dose also increases selection pressure and will accelerate the evolution of resistant populations.[47]

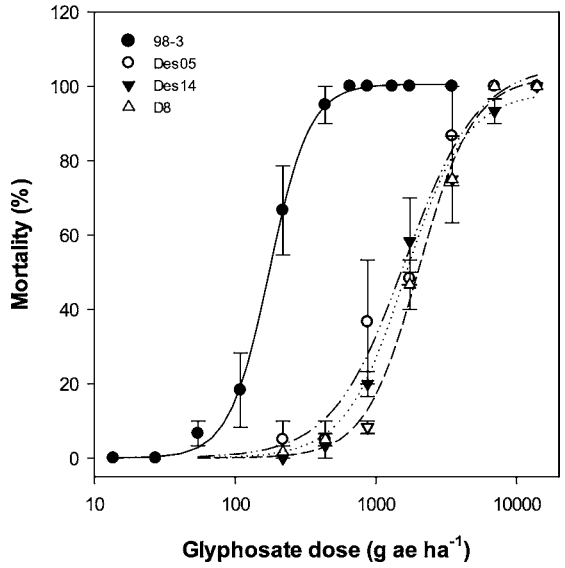

Figure 2. Mortality of selected glyphosate-resistant and -susceptible *L. perenne* ssp. *multiflorum* populations, 28 days after treatment. Error bars are standard errors of the mean. Des05, Des14, and D8 populations had estimated LD_{50} values of 1702, 1587, and 2245 g ae ha^{-1} glyphosate, respectively. The susceptible 98-3 population had an estimated LD_{50} of 184 g ae ha^{-1} glyphosate. LD_{50} is the amount of herbicide that kills 50% of the population.

The survival rate of populations is indicated by the LD_{50} values, which allows prediction of seed deposits into the soil seed bank or potential patch expansion of the resistant plants.[48] The GR_{50} values may differ slightly from the LD_{50} values, but together, these provide a better picture of population response to glyphosate. These inform us on the proportion of plants that are expected to survive a glyphosate application and how healthy these remaining plants are. The GR_{50} and LD_{50} values indicate that D4 and D8 populations are more resistant than Des05, Des14, and D13. The full dose of glyphosate at 870 g ae ha^{-1} is no longer sufficient to control these five R populations. The failure of glyphosate to control Italian ryegrass calls for alternative weed management approaches to mitigate the evolution of resistance.[37] The use of other herbicides, or the addition of other herbicides to glyphosate, is needed for complete weed control during field preparations prior to planting the crop. Resistance to glyphosate in these populations was lower than that of the first glyphosate-resistance population previously tested (Des03), which showed 23-fold resistance to glyphosate and required 3,880 g ae ha^{-1} glyphosate for 50% biomass reduction.[37] Nevertheless, the proportion of plants that escape glyphosate application in these populations already cause ecological concerns (of continuing resistance evolution) and economic detriment due to either yield loss from competition or additional costs for controlling escapes.

Uptake and Translocation of Glyphosate. Glyphosate is a potent herbicide because of its ability to translocate in the plant to the apical meristems, root, and underground reproductive organs of perennial plants via xylem and phloem.[49] It is possible that changes in the translocation pattern of glyphosate could endow resistance in plants. Glyphosate absorption was almost 60% in both S and R plants (Table 3). This result was similar to what was reported for glyphosate-R and -S Italian ryegrass from Mississippi[16] but differs from those in Chile,[50] where R and S plants absorbed >90% of ^{14}C-glyphosate at 48 HAT. On average 40 and 56% of

Table 3. ^{14}C Glyphosate Absorption and Distribution in Various Plant Tissues of Resistant and Susceptible *Lolium perenne* ssp. *multiflorum* Populations from Arkansas (United States)

	^{14}C-glyphosate absorption[a] (% of applied)		^{14}C-glyphosate distribution[a] (% of absorbed)							
			treated leaf		above treated leaf		below treated leaf		roots	
population	24 HAT[b]	48 HAT	24 HAT	48 HAT	24 HAT	48 HAT	24 HAT	48 HAT	24 HAT	48 HAT
Des05[c]	38	51	80	65	1	2	11	17	8	15
Des14[c]	44	59	79	68	1	1	12	19	8	12
98-3[d]	37	57	77	71	1	3	14	16	8	11

[a]Values are the average of four plants. [b]HAT, hours after treatment. [c]Resistant population. [d]Susceptible population.

applied glyphosate was absorbed by R and S plants at 24 and 48 HAT, respectively, and this response was not significantly different between R (Des05 and Des14) and S populations ($P > 0.05$).

Radioactivity recovered from the treated leaf represented glyphosate loaded into the leaf, but not translocated. The quantity of ^{14}C-glyphosate recovered from the treated leaf at 48 HAT was not different between R (65−68% of absorbed) and S (71% of absorbed) plants (Table 3). Translocation of ^{14}C-glyphosate into the roots and below the treated leaf was low, ranging from only 11 to 19%; the radioactivity accumulated above the treated leaf was nil (1−3% of absorbed). The proportion of ^{14}C-glyphosate recovered above the treated leaf, below the treated leaf, and in the roots increased between 24 and 48 HAT; however, no significant difference was detected between R and S populations in any plant sections at any harvest time. These results were similar to what was reported on *Lolium* populations from Australia[51] and California,[52] where the distribution patterns of ^{14}C-glyphosate did not differ between resistant and susceptible plants. On the contrary, glyphosate-resistant Italian ryegrass populations from Mississippi,[16] Oregon,[14] and Chile[50] showed reduced translocation of glyphosate. Among the Arkansas populations, however, resistance to glyphosate was not due to differences in uptake and translocation.

Partial *EPSPS* Gene Sequencing. A 915 bp PCR fragment of the *EPSPS* gene was amplified from cDNA of the R and S Italian ryegrass plants. This fragment encompassed amino acid positions 77−381 in the 444 amino acid long, mature EPSPS. The sequenced region included the domain where point mutations are known to confer resistance to glyphosate, for example, in corn at Pro_{106},[22−30] Gly_{101},[53] and Thr_{102}.[54] Mutations at Pro_{182} and Tyr_{310} were also observed in glyphosate-resistant sourgrass,[31] although the impact of these mutations on EPSPS enzyme activity has not been verified. Some nucleotide polymorphisms were detected in our recent research on Italian ryegrass; however, none was associated with resistance to glyphosate (data not shown). A mutation of Gly_{162}Ser was detected in one resistant Des14 plant, but this mutation was also found in a susceptible plant from Des05. Comparison of the *EPSPS* sequence between glyphosate-R and -S plants revealed both synonymous and nonsynonymous polymorphisms, but there were no amino acid changes in the catalytic sites that are known to confer resistance to glyphosate (data not shown). Therefore, mutations in the *EPSPS* gene known to endow resistance to glyphosate are not present in Des05 and Des14 Italian ryegrass populations or in the highly resistant population Des03.[37]

The absence of point mutations in the *EPSPS* gene that are exclusive to the R plants and the absence of other mutations previously associated with resistance to glyphosate indicate that target-site alteration is not the resistance mechanism in Des05 and Des14 populations. Considering that target-site mutation was also not found in the highly glyphosate-resistant population Des03,[36] it can be deduced that target-site mutation is not the mechanism of resistance among these tested glyphosate-resistant populations in Arkansas. It could also be that target-site mutation is a rare resistance mechanism among Arkansas Italian ryegrass populations for reasons not yet known. The rarity of target-site mutation as resistance mechanism to glyphosate is associated with the strong conservation of the catalytic site where glyphosate binds.[32] Glyphosate interacts with 17 invariant amino acids in the active site of the EPSPS protein[55] and mimics the transition state in the enol transfer reaction.[56] Because the active site of the EPSPS protein is highly conserved, any mutation at this site is deleterious and causes significant fitness penalty.[56] Single-site mutation at Thr_{97} to Ile or Pro_{101} to Ser[54] or Gly_{96} to Ala[53] in *Escherichia coli* impairs the binding of glyphosate but at the same time reduces affinity for the substrate phosphoenolpyruvate. Deleterious mutations of critical catalytic sites are not exclusive to EPSPS. Mutation in the *psbA* gene, which confers resistance to triazine herbicide, results in reduced agroecological fitness.[57] On the other hand, some mutations endowing target-site-based resistance to ACCase and ALS herbicides have little or no fitness costs.[12] Studies comparing glyphosate-resistant goosegrass with Pro_{106}Ser mutation versus susceptible population show some differences, but it is not yet evident whether there are any fitness costs associated with EPSPS-binding-site-based resistance.[58,59] Sammons et al.[32] reported that glyphosate has a very low risk for target-site resistance and this holds true to date. Thus, we are starting to find glyphosate-resistant populations that display resistance mechanisms other than target-site mutation.

***EPSPS* Genomic Copy Number Relative to *CCR*.** The degree of *EPSPS* gene amplification differed greatly among the resistant plants within each population, indicating high intrapopulation genetic variability. Genomic *EPSPS* copy number relative to *CCR* was 1 for S plants (n =10), whereas the relative *EPSPS* copy numbers for R plants (n = 30) were higher, ranging from 11 to 151 (Table 4 and Figure 3). The *EPSPS* copy number in Des05, Des14, and D8 resistant plants ranged from 11 to 121, from 24 to 97, and from 18 to 151, respectively. Italian ryegrass is an outcrossing species;[60] thus, a high degree of genetic diversity would be expected within a population. A broad range of *EPSPS* copy numbers also was detected in glyphosate-resistant Palmer amaranth, which is an obligate outcrossing species.[61] Individual plants that were subjected to both dose−response assay and *EPSPS* copy number analysis showed that the increase in copy number strongly correlated with the level of resistance to glyphosate (r = 0.80) (Figure 4). Plants with higher GR_{50} values had higher

Table 4. Summary Statistics of the Relative *EPSPS* Copy Number in Glyphosate-Resistant *L. perenne* ssp. *multiflorum* Populations, Arkansas (United States)

	EPSPS:CCR copy no.[a]					
population	mean	median	SD	CV	min	max
Des05	45	39	33	73	11	122
Des14	48	48	23	47	24	97
D8	80	84	47	59	18	151
98-3	1	1	0.2	20	0.8	1.4

[a]Values are averages of 10 plants.

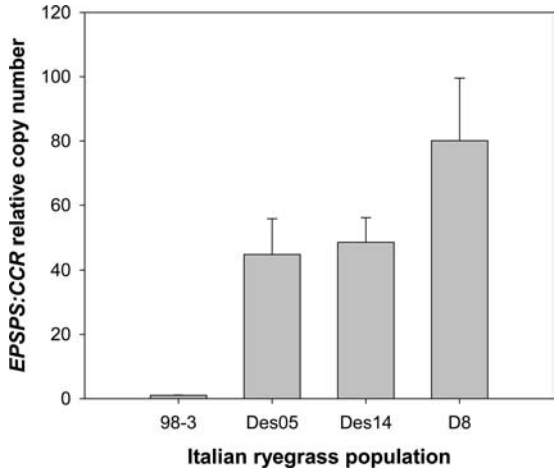

Figure 3. *EPSPS* relative genomic copy number in glyphosate-resistant and -susceptible *L. perenne* ssp. *multiflorum* plants. Relative copy number of *EPSPS* in resistant populations (D8, Des05, and Des14) ranged from 11 to 151 (n = 30), whereas the susceptible standard (98-3) contained a single copy (n = 10). Values are averages of 10 plants per population, with 3 technical replicates. Vertical bars represent the standard error of the mean.

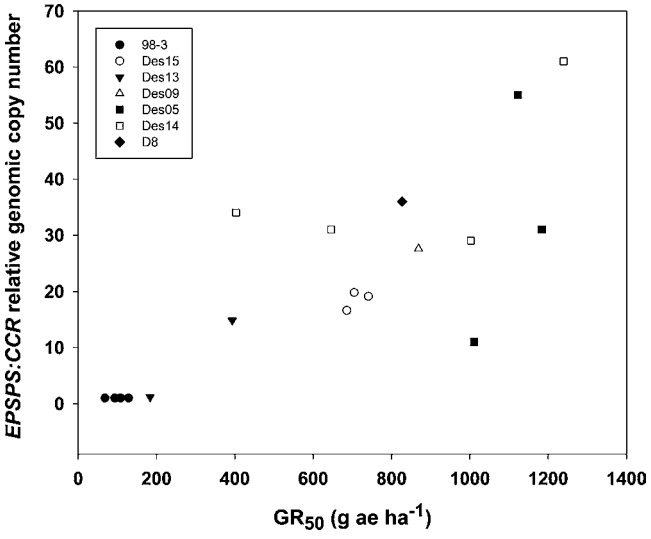

Figure 4. Relationship between the amount of glyphosate needed to incur 50% injury (GR_{50}) and the relative *EPSPS* genomic copy number (r = 0.80). Susceptible plants (98-3) had the lowest GR_{50} and *EPSPS* copy number.

EPSPS copy number (Figure 4). Other studies in Italian ryegrass[36] and Palmer amaranth[62,63] populations also reported positive correlation between *EPSPS* copy number and the level of resistance to glyphosate. The observation that plants with higher resistance levels to glyphosate had higher copies of *EPSPS* suggests that additional *EPSPS* gene copies have additive effects in conferring resistance to glyphosate.[61] Our data suggest that >10 *EPSPS* copies are necessary to survive the recommended field dose of glyphosate. Gaines et al.[61] reported that between 30 and 50 *EPSPS* genomic copies enabled *Amaranthus palmeri* to withstand the toxic effects of glyphosate. The EPSPS enzyme activity was not determined in this study; however, previous research[36,61] revealed that increased *EPSPS* copy number resulted in elevated EPSPS activity. Not all of the amplified genes may translate to increased level of protein (e.g., EPSPS) expression because transcriptional, post-transcriptional, and translational regulatory elements also play a crucial role in gene expression.[64] Salas et al.[36] observed that Italian ryegrass with similar *EPSPS* copy number did not show the same level of resistance. This could be a manifestation of some gene copies not resulting in a protein product or the involvement of other resistance mechanisms.

Amplification of the native, glyphosate-sensitive form of EPSPS enzymes had conferred resistance to glyphosate in chicory (*Cichorium intybus*), rock harlequin (*Capnoides sempervirens*), soybean (*Glycine max*), alfalfa (*Medicago sativa*), and tobacco (*Nicotiana tabacum*) in plant tissue culture with glyphosate selection.[65] Resistance to glyphosate in alfalfa, soybean, and tobacco from progressive selection in plant cell cultures is attributed to amplification of the *EPSPS* gene within the genome.[66] In addition, a glyphosate-tolerant wild carrot (*Daucus carota*) cell line generated by stepwise selection with glyphosate contained a 4−25-fold increase in *EPSPS*.[67] Similarly, a glyphosate-resistant petunia (*Petunia hybrida*) cell line contained a 20-fold increase in *EPSPS* gene copies.[68] Amplification of the *EPSPS* gene in Palmer amaranth from Georgia (United States) was recently reported by Gaines et al.[35] in which genomes of glyphosate-resistant plants contained from 5- to >160-fold more copies of the *EPSPS* gene, resulting in a 40-fold EPSPS overexpression. This Palmer amaranth population showed 6−8-fold resistance to glyphosate at the population level.[69] Although the EPSPS enzyme activity was not investigated in our study, various studies indicated that *EPSPS* gene amplification results in increased EPSPS enzyme activity in glyphosate-resistant plants.[65−67] Gene amplification can produce an abundant supply of EPSPS enzymes that are able to counteract the loss of metabolic function of enzyme molecules that are inhibited by glyphosate.[70] This affords the plant continued synthesis of aromatic acids for normal physiological function in the presence of glyphosate.

Given the lethal consequence of mutations in the binding site of the *EPSPS* gene, the selected glyphosate-resistant plants harbor other mechanisms of survival, such as *EPSPS* gene amplification. Gene duplication serves as a mechanism of adaptation to a changing environment such as environmental stresses.[71,72] Intense glyphosate usage as a selector will favor survival of plants with elevated copies of the glyphosate target gene *EPSPS*.[36] Amplification of *EPSPS* provides a certain level of glyphosate resistance in plants;[65] however, the stability of *EPSPS* gene amplification and the contribution of each additional copy are not clearly understood. *EPSPS* gene amplification in Palmer amaranth is heritable,[35] but the manner by which it is inherited is complex. Inheritance of *EPSPS* amplification in Palmer amaranth from North Carolina and Georgia was consistent with polygenic inheritance.[63,73] However, studies on plant cell culture revealed that gene

DOI: 10.1021/acs.jafc.5b00018
J. Agric. Food Chem. 2015, 63, 5885−5893

amplification varied considerably for different cell cultures.[65] Stable resistance was achieved with chicory,[74] tomato,[75] and tobacco,[76] but resistance to glyphosate was slowly reduced or lost entirely when glyphosate selection was removed in Madagascar periwinkle (*Catharanthus roseus*)[77] and wild carrot cell cultures.[78] In the absence of glyphosate selection pressure, resistance may be reduced, suggesting a fitness penalty for cells containing amplified genes.[65] However, the massive amplification of *EPSPS* gene in glyphosate-resistant Palmer amaranth did not cause any fitness cost.[79] Other than endowing resistance to glyphosate, no physiological advantage has been documented thus far as a consequence of *EPSPS* gene amplification.

In conclusion, the resistance to glyphosate in all Italian ryegrass populations analyzed is conferred by amplification of the *EPSPS* gene. This is the primary mechanism for resistance to glyphosate among Italian ryegrass populations in Arkansas. *EPSPS* copy number correlated positively with resistance level to glyphosate. The mechanism of *EPSPS* gene amplification and the nature of its heritability are not yet known. Information on the mechanism of amplification, stability, and genetic inheritance of copy number and fitness penalty that may be associated with *EPSPS* gene amplification is necessary to fully understand the novel mechanism of resistance to glyphosate due to *EPSPS* gene amplification in Italian ryegrass.

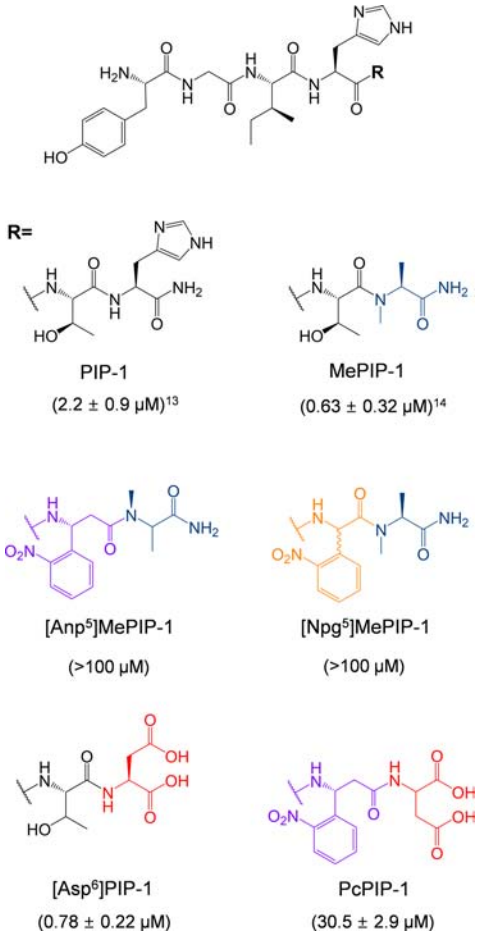

Figure 1. Structure of PIP-1 and its analogs. Anp, (*R*)-3-amino-3-(2-nitrophenyl)propionic acid; Npg, (*RS*)-(2-nitro)phenylglycine. Values in parentheses indicate EC_{50} for H_2O_2 generation.

at G1 phase and was rapidly inactivated by UV irradiation. This inactivation reactivated the cell cycle in all cells in a homogeneous and synchronous manner, allowing analysis of the cell cycle progress in detail.

In the present study, we designed a photocleavable PIP-1 analog to investigate the mechanisms underlying the stimulation period-dependent induction of late immune responses such as phytoalexin biosynthesis. The introduction of a photocleavable amino acid into PIP-1 successfully provided an analog, the activity of which can be "switched off" by UV irradiation. Using this analog, we explored key components that are associated with the initiation of phytoalexin biosynthesis in response to continuous stimulation with PIP-1.

MATERIALS AND METHODS

Plant Cell Culture. Tobacco cells (*Nicotiana tabacum* cv. Xanthi) were maintained as suspension cultures in 25 mL of liquid Linsmaier and Skoog (LS) medium at pH 5.75 containing 1-naphthalenacetic acid (10 μM), 5-benzyladenine (1 μM), and 3% of sucrose in a 100 mL Erlenmeyer flask. The cells were grown at 25 °C under continuous illumination on a rotary shaker (100 rpm) and subcultured every 2 weeks. The experiments were conducted using 9- and 10-day old subcultured tobacco cells.

Chemicals. *N*-(9-Fluorenylmethoxycarbonyl) (Fmoc)-NH-SAL resin, Cl-Trt(2-Cl)-Resin, and general Fmoc-protected amino acids were purchased from Watanabe Chemical Industries (Hiroshima, Japan). Fmoc-(*R*)-3-amino-3-(2-nitrophenyl)propionic acid was purchased from PepTech Corporation (Bedford, MA) and Fmoc-(*RS*)-(2-nitro)phenylglycine was synthesized as described by Rodenko et al.[20] (Carboxymethylaminocarbonyl)-4,4′-bis(dimethylamino)-diphenylamine sodium salt (DA-64), cycloheximide (CHX), and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) were purchased from Wako Pure Chemical Industries (Osaka, Japan), Nacalai Tesque (Kyoto, Japan), and Santa Cruz Biotechnology (Dallas, TX), respectively.

Synthesis of Photocleavable Analogs. An Fmoc solid-phase peptide synthesis strategy was used to synthesize photocleavable analogs. Deprotection of the Fmoc protecting group was conducted using 20% piperidine in DMF 3 times for 3, 3, and 20 min. Coupling of Fmoc-protected amino acids (3 equiv) was performed in the presence of *O*-(benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) (3 equiv), 1-hydroxybenzotriazole (HOBt) (3 equiv), and *N*,*N*-diisopropylethylamine (DIPEA) (6 equiv) in *N*,*N*-dimethylformamide (DMF). Completion of the reaction was checked by Kaiser test.[22] After completion of all coupling reactions, the resin was washed with DMF, diethyl ether, and methanol and subsequently vacuum-dried. Peptide cleavage and removal of side-chain protecting groups were conducted using cleavage cocktails [TFA/triisopropylsilane/1,3-dimethoxybenzene (92.5:2.5:5) for Fmoc-SAL-resin attached peptides and TFA/triisopropylsilane/H_2O (95:2.5:2.5) for Cl-Trt(2-Cl)-resin attached peptides] for 2 h at room temperature. The reaction mixture was filtered, and the filtrate was mixed with cold diethyl ether to precipitate the peptides. The peptides were then vacuum-dried. For analogs containing (2-nitro)phenylglycine, dichloromethane was used instead of DMF throughout the process. Peptide purification was conducted by RP-HPLC using a 250 mm × 10 mm i.d., 5 μm, protein and peptide C18 semipreparative column (Grace, Columbia, MD), and lyophilized. Purified peptides were identified by electrospray ionization liquid chromatography−mass spectrometry (ESI-LC/MS) on an LCMS-2010 instrument (Shimadzu, Kyoto, Japan).

Measurement of H_2O_2 Generation. H_2O_2 generation was measured as described previously.[23] Suspension-cultured tobacco cells (0.2 g) were resuspended in 1 mL of assay buffer (175 mM mannitol, 0.5 mM $CaCl_2$, 0.5 mM K_2SO_4, 2.0 mM MES, pH 5.75) and incubated for 1 h at 25 °C using a tube rotator. Peptide samples were added to tobacco cell suspensions, and the cells were reincubated for 15 min at 25 °C. The supernatants (60 μL) were added to a 96-well microplate containing an H_2O_2 indicator solution (140 μL, 100 mM DA-64, 1 U/mL horseradish peroxidase, 100 mM PIPES, pH 7.0). This microplate was incubated for 10 min at 37 °C. The absorbance at 727 nm was observed using a Benchmark microplate reader (Bio-Rad, Hercules, CA). The amount of H_2O_2 was calculated using a calibration curve based on pure H_2O_2. As an index of activity, the concentration required for half-maximal responses (EC_{50}) was calculated using PRISM (GraphPad Software, La Jolla, CA).

Peptide Photolysis. The photocleavable analogs were dissolved in distilled water at 100 μM of final concentration. The solution was irradiated with UV light (365 nm, 10 mW/cm^2) using a Blak-ray B-100A UV lamp (UVP, Upland, CA). The UV-irradiated solution was analyzed with LCMS-2020 and LCMS-IT-TOF (Shimadzu) equipped with a 150 mm × 2.1 mm i.d., 3.6 μm, Aeris PEPTIDE XB-C18 reverse phase column (Phenomenex, Torrance, CA).

Cell Death Assay. Cell death was measured as described previously with modifications.[24] Cells (0.2 g) were treated with peptide samples and incubated for 24 h at 25 °C using a tube rotator. After incubation, the cell suspension was reincubated in Evans blue solution (Wako Pure Chemical Industries) at a final concentration of 0.01% for 15 min and then washed with distilled water 3 times to remove any unabsorbed dye. The washed cells were transferred into a new microtube containing 50% methanol and 1% SDS to extract the dye in dead cells and incubated for 1 h at 60 °C. The solution was centrifuged for 15 min at 1900*g*. Absorbance of the supernatant at 595 nm was measured on a microplate reader (Bio-Rad).

Quantitation of Capsidiol. Capsidiol content was quantitated as described previously.[13] Tobacco cells (0.6 g) resuspended in 3 mL of LS medium were incubated for 1 h. The cells were then treated with peptide samples and incubated for 24 h at 25 °C on a rotary shaker under continuous illumination. After incubation, capsidiol was

DOI: 10.1021/acs.jafc.5b01910
J. Agric. Food Chem. 2015, 63, 5894−5901

extracted from the culture medium using 4 mL of ethyl acetate twice and vacuum-dried. The residue was then dissolved in 1 mL of ethyl acetate and subjected to QP-2010 GC/MS analysis (Shimadzu), equipped with a 30 m × 0.25 mm, 0.25 μm phase thickness, DB-5MS capillary column (J & W Scientific, Folsom, CA). Other GC/MS conditions were described previously.[14] The amount of capsidiol was quantitated from the peak areas obtained in the total ion chromatogram, using a calibration curve based on an authentic standard purified from *Capsicum annuum* fruit.[25]

In-Gel Kinase Assay. In-gel kinase assay was performed as described previously with modifications.[26] Tobacco cells (0.6 g) resuspended in 3 mL of LS medium were incubated for 1 h at 25 °C. The cells were then treated with peptide samples and reincubated for 3 h. After all medium was removed, tobacco cells were ground in liquid nitrogen using a mortar and pestle. Powdered tobacco cells were homogenized using 1.5 mL of extraction buffer [50 mM HEPES, pH 7.4, 5 mM EDTA, 5 mM EGTA, 5 mM DTT, 10 mM NaF, 10 mM Na_3VO_4, 50 mM β-glycerophosphate, 1 mM 4-(2-aminoethyl)-benzenesulfonyl fluoride, 2 μg/mL antipain, 2 μg/mL aprotinin, and 2 μg/mL leupeptin] and centrifuged at 16 000*g* for 30 min at 4 °C. Protein extracts (10 μg) were electrophoresed on 12% SDS-polyacrylamide gels embedded with 0.25 mg/mL myelin basic protein (MBP) (Sigma, St. Louis, MO) as a kinase substrate. After electrophoresis, the gel was washed with washing buffer (20% 2-propanol, 50 mM Tris, pH 8.0) three times for 20 min each at room temperature to remove SDS and incubated with buffer A (50 mM Tris, pH 8.0, 5 mM DTT) for 1 h. The proteins in the gel were denatured using denaturation buffer (50 mM Tris−HCl, pH 8.0, 6 M guanidine·HCl, 20 mM DTT, 2 mM EDTA) twice for 30 min each. The kinases were allowed to renature by incubations in buffer A containing 0.04% of Tween 20 overnight at 4 °C with 5 changes of buffer. After equilibration in assay buffer (50 mM HEPES, pH 8.0, 2.0 mM DTT, 0.1 mM EGTA, and 20 mM $MgCl_2$) for 30 min at room temperature, the gel was incubated in 20 mL of assay buffer containing 30 μM ATP and 1.85 MBq of [γ-^{32}P]-ATP (111 TBq/mmol) (PerkinElmer, Waltham, MA) for 1 h at room temperature. The reaction was stopped by transferring the gel into a solution containing 10% trichloroacetic acid (w/v) and 1% sodium phosphate (w/v). The gel was washed five times with the same solution for 20 min each to remove any unincorporated [γ-^{32}P]-ATP and dried on filter paper using a vacuum gel-dryer. The dried gel was then exposed to BAS-MS 2040 imaging plates (Fujifilm, Tokyo, Japan) and analyzed using BAS-2500 (Fujifilm). Prestained size markers (Nacalai Tesque) were used to estimate the size of the kinases.

Gene Expression. Tobacco cells (0.6 g) suspended in 3 mL of LS medium were treated with peptide samples and incubated for 4 h at 25 °C. Incubated cells were collected by filtration and ground in liquid nitrogen using a mortar and pestle. Total RNA was extracted from powdered tobacco cells using TRIzol reagent (Life Technologies, Carlsbad, CA) according to the manufacturer's instructions. The RNA was then incubated with 10 U of RQ1 RNase-Free DNase (Promega, Madison, WI) for 30 min at 37 °C to degrade the DNA. cDNA was synthesized from 1 μg of total RNA using a PrimeScript RT reagent kit (Takara Bio, Otsu, Japan) according to the manufacturer's instructions. Quantitative reverse transcription polymerase chain reaction (qRT-PCR) was performed by Thermal Cycler Dice (Takara Bio) with amplification buffer (25 μL of final volume) containing 2 μL of cDNA template, SYBR *Premix Ex Taq* II (Takara Bio), and 0.4 μM of the following forward and reverse primer; *HMGR2*: 5′-GAGGG-GAGAGGAAAGTCTGTAG-3′ and 5′-TCTCTATGTTCTGAGCT-GGGTC-3′. *Actin* (5′-CCATTGGCTCAGAGAGGTTC-3′ and 5′-GTTGGAAGGTGCTGAGAG-3′) was used as a reference gene.[27]

Enzyme Assay. 3-Hydroxy-3-methylglutaryl coenzyme A reductase (HMGR) activity was measured as described previously.[28] In brief, tobacco cells (0.6 g) treated with peptide samples for 4 h were used for crude enzyme extraction. Tobacco cells were ground in liquid nitrogen using a mortar and pestle and homogenized using extraction buffer (50 mM Tris-HCl, 10 mM β-mercaptoethanol, 1% (w/v) PVP, pH 7.5). The mixture was centrifuged at 16 000*g* at 4 °C for 30 min, and the supernatant was used for measurement of HMGR activity after determining protein concentrations using a Bio-Rad protein assay reagent. The crude extract was added to the assay buffer (50 mM Tris-HCl, 0.3 mM HMG-CoA, 0.2 mM NADPH, and 4 mM DTT, pH 7.0), and NADPH oxidation was measured by monitoring a decrease in absorbance at 340 nm. One unit of HMGR enzyme is equivalent to the oxidation of 1 mM NADPH per minute. Elicitor-inducible HMGR activity was estimated by subtracting the constitutive activity in the absence of the elicitor from the activity in the presence of the elicitor.

RESULTS AND DISCUSSION

Design of Photocleavable PIP-1 Analogs and Evaluation of Their Elicitor Activity. In a previous contribution, we reported that PIP-1 can be rapidly hydrolyzed from its C-terminal end in the presence of tobacco cells and that no elicitor activity was observed when the C-terminal two residues were deleted.[14] The degradation-resistant analog MePIP-1 was obtained by attaching an *N*-methyl group to the amide bond between Thr and Ala residues (Figure 1). This analog exhibited elicitor activity higher than that of PIP-1 in terms of phytoalexin production. To obtain photocleavable PIP-1 analogs whose activity can be switched off by UV irradiation, the analogs must be stable against enzymatic degradation unless UV-irradiated. In this regard, MePIP-1 was suitable as a starting compound for development of photocleavable PIP-1 analogs. Therefore, we first substituted the Thr residue of MePIP-1 with a photocleavable amino acid (Anp) (Figure 1, [Anp^5]MePIP-1) because cleavage of the amide bond between His and Anp by UV irradiation was expected to produce inactive peptides. However, this analog did not show any measurable activity, even before UV irradiation (Figure 1). This lack of activity could be associated with the β-amino acid structure of Anp, which adds an additional carbon atom to the main peptide chain, possibly causing unfavorable structural changes preventing the interaction between the peptide and the receptor. Subsequently, we attempted to substitute the Thr residue with a photocleavable α-amino acid (Npg) (Figure 1, [Npg^5]MePIP-1), although substitution also resulted in loss of biological activity (Figure 1). In this case, the steric interaction between the 2-nitrobenzyl group and the neighboring terminal *N*-methyl group might have influence on the activity by changing the overall molecular conformation into the inactive form. Therefore, we explored different strategies to obtain new degradation-resistant PIP-1 analogs that could be suitable for designing photocleavable analogs.

While studying the relationship between structure and enzymatic degradation of PIP-1, it became apparent that the basic character of the C-terminal His residue could be important for the recognition by proteases derived from tobacco cells (data not published). Accordingly, we substituted the C-terminal His residue with an acidic amino acid, Asp, and replaced the C-terminal amide group with a carboxy group, which is known to increase PIP-1 elicitor activity (Figure 1, [Asp^6]PIP-1).[13] As expected, [Asp^6]PIP-1 displayed higher degradation resistance compared with that of PIP-1 without affecting elicitor activity (Figure 1 and Figure S1 in the Supporting Information). On the basis of the structure of [Asp^6]PIP-1, we designed a photocleavable analog as shown above. After substitution of the Thr residue of [Asp^6]PIP-1 with Anp (Figure 1, PcPIP-1), the resulting compound retained the elicitor activity and was resistant to degradation (Figures 1 and 2). In the following sections, we examine whether photocontrol of the elicitor activity of this analog is possible.

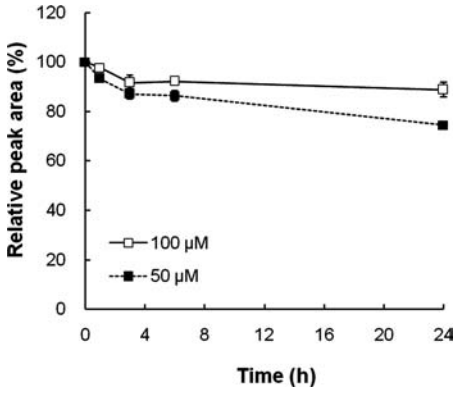

Figure 2. Degradation resistance of PcPIP-1 in the presence of tobacco cells. Relative amounts of PcPIP-1 in the cell culture medium after treatment are plotted (n = 2).

Photolysis of the Photocleavable PIP-1 Analog. We evaluated the reactivity of the photocleavable analog PcPIP-1 in aqueous solution under UV irradiation. ESI-LC/MS was used to monitor the degradation of PcPIP-1. When PcPIP-1 (m/z observed for $[M+2H]^{2+}$, 398.68; retention time, 15.1 min) was irradiated at 365 nm for 5 min, approximately 10% of the initial concentration was detected (Figure 3). Instead, several new peaks appeared in the chromatogram. The molecular masses of two peaks detected at 3.7 min (m/z 488.27 for $[M + H]^+$) and 6.3 min (m/z 489.26 for $[M + H]^+$) of retention time corresponded with those of YGIH-NH_2 and YGIH-OH, respectively, identified by comparing with synthesized standards. These peptides were considered to be produced by photolysis of the Anp residue, although the formation mechanism of the latter was not clear. The molecular mass of the other two peaks detected at 13.0 and 13.5 min of retention times was similar to that of the original peptide (m/z observed for $[M+2H]^{2+}$, 398.67; calculated, 398.66). These peaks were still detected after irradiation with UV light for an additional 10 min; however, only marginal levels of the original peptide were detected at that stage. MS/MS analysis showed that whereas fragment ions related to the amino acid sequence were regularly observed for the case of the original peptide, the two unknown peaks gave only two major fragment ions (Figure S2 in the Supporting Information). MS^3 analysis suggested that these fragment ions correspond to YGIH-NH_2 and 3-(2-nitrosophenyl)-3-oxopropanoyl aspartic acid, the expected photolyzed products of PcPIP-1. On the basis of these results, we assumed that these two unknown peaks observed after photolysis can be the structural isomers of an intermediate produced during photolysis of PcPIP-1. Previous studies have proposed that the photolysis of 2-nitrobenzyl compounds is a multistep process, and the decay of *aci*-nitro intermediates (Figure S3 in the Supporting Information) is considered to be rate-limiting.[29,30] By analogy, the photolysis of PcPIP-1 might involve the formation of relatively long-lived α-hydroxybenzyl intermediates;[31−33] therefore, it seems likely that the unknown peaks detected were associated with the 3-hydroxy-3-(2-nitrosophenyl) intermediate product, as shown in Figure S3 in the Supporting Information. The possible epimerization of this intermediate can account for the occurrence of two peaks with the same molecular mass.

Photocontrol of Activity of the Photocleavable PIP-1 Analog. To confirm that PcPIP-1 can be inactivated by UV irradiation, we first compared the defense-inducing activity of PcPIP-1 with and without UV irradiation. Regarding early-phase immune responses, treating cells with intact PcPIP-1 at 50 or 100 μM significantly increased the level of H_2O_2 generated (Figure 4A). Exposing PcPIP-1 to UV irradiation in the absence of tobacco cells reduced markedly its elicitor activity. When cells were treated with UV-irradiated PcPIP-1 at 50 and 100 μM, the level of H_2O_2 generated decreased by 6- and 2-fold, respectively. Exposing PcPIP-1 to UV irradiation also significantly affected the induction of the late-phase immune responses, such as HR-like cell death and phytoalexin production, compared with that by intact PcPIP-1. The levels of cell death induced by UV-irradiated PcPIP-1 were evidently lower than those induced by intact PcPIP-1 (Figure 4B). The production of capsidiol, the major phytoalexin in tobacco, also markedly differed between UV-irradiated and intact PcPIP-1; in this case, the activity was nearly entirely repressed by UV irradiation both at 50 and 100 μM (Figure 4C). These results indicated that UV-irradiated PcPIP-1, a mixture of the photolyzed products and intermediates, presents a level of elicitor activity sufficiently lower than that of intact PcPIP-1.

We then examined whether PcPIP-1 can be also inactivated by UV irradiation in the presence of tobacco cells. As shown in Figure 5A, when tobacco cells were UV-irradiated for 5, 10, or 15 min following treatment with PcPIP-1 at 100 μM for 1 h, a time-dependent decrease in capsidiol production was observed,

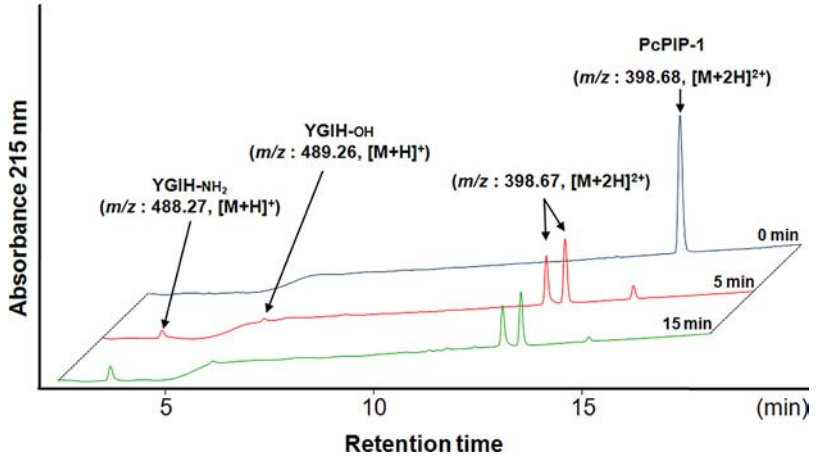

Figure 3. HPLC profile of photolyzed products of PcPIP-1 at 100 μM.

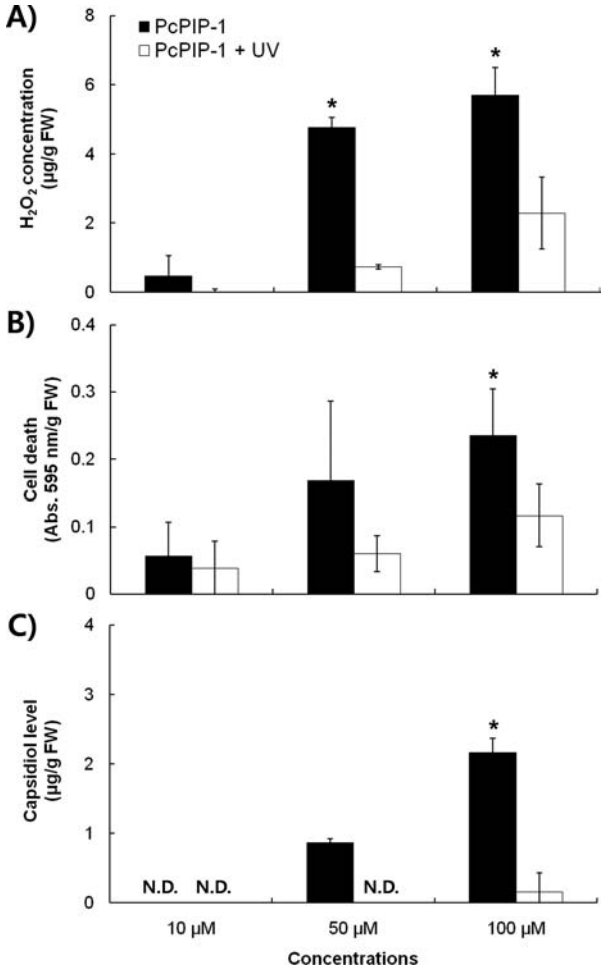

Figure 4. Comparisons of immune responses induced by PcPIP-1 between those with and without UV irradiation in the presence of tobacco cells. (A) H_2O_2 generation, (B) HR-like cell death, and (C) capsidiol production. Asterisks indicate significant difference at $P < 0.05$ according to the Student's paired *t*-test. Vertical bars indicate ±SD of three independent replicates. N.D.: not detected.

indicating that photolysis of PcPIP-1 occurred in the presence of tobacco cells similar to the process observed for aqueous solution in the absence of tobacco cells. These results were consistent with those from a previous study in which wash-out of PIP-1 from the cells 1 h after treatment resulted in no capsidiol production.[14] Therefore, our results confirmed that exposing PcPIP-1 to UV irradiation for 15 min was effective to inactivate it to entirely repress its action on tobacco cells. Capsidiol production after treatment with 100 μM of PIP-1 was not affected by 15 min of UV irradiation, indicating that UV irradiation per se had no negative effect on tobacco cells in relation to phytoalexin production.

Next, we investigated the stimulation period required to initiate capsidiol production in tobacco cells using PcPIP-1. Tobacco cells were treated with PcPIP-1 at 100 μM and irradiated with UV light for 15 min after 1, 3, 6, and 9 h. Capsidiol production was measured 24 h after treatment with PcPIP-1. Significant levels of capsidiol were detected when the cells were UV-irradiated 6 or 9 h after elicitation. By contrast, no capsidiol was detected when UV-irradiated 1 or 3 h after elicitation (Figure 5B). These results indicated that the continuous stimulation with PcPIP-1 for a time period between 3 and 6 h is required to induce phytoalexin production. These results were consistent with those from a previous study that used the cell-washing method to remove treated PIP-1 from the culture medium, where 3−6 h of continuous stimulation was required for capsidiol production.[14] However, the amount of capsidiol detected when PcPIP-1 was inactivated 6 or 9 h after elicitation by UV irradiation was much larger than that observed in the experiments using the cell-washing method. This is probably due to the difference in the degree of stresses placed on the tobacco cells. Cell-washing is more likely to damage cells than irradiation with UV light, possibly affecting negatively capsidiol biosynthesis. Moreover, the amount of the capsidiol accumulated in the extracellular fluid up to the time of cell-washing could have been lost, resulting in an underestimation of capsidiol production. Thus, our results showed that photocleavable PcPIP-1 presents several advantages as a tool to study phytoalexin induction mechanisms by elicitors because of its ability to stop the stimulation of the immune system rapidly but not aggressively, without damaging the cells or losing the phytoalexin accumulated in the medium.

Effect of PIP-1 Stimulation Period on Activation of Signaling Pathways and Biosynthesis Enzymes Important for Capsidiol Production. Following the recognition of pathogens or elicitors, MAP kinase cascades mediate the

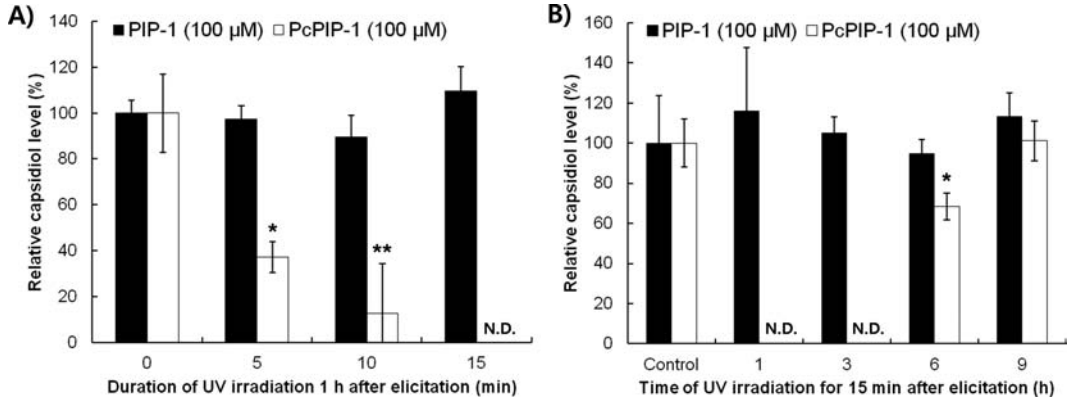

Figure 5. Comparisons of capsidiol production after treatment with PIP-1 and PcPIP-1 at 100 μM. (A) Effect of UV-irradiation period. signaling pathway invoking late-phase immune responses.[9] In a previous study, we showed that PIP-1 induces activation of a 48 kDa kinase in tobacco cells,[14] which corresponds to a salicylic acid-induced protein kinase (SIPK).[26] From our previous study on the relationship between SIPK activation and capsidiol production, we concluded that a prolonged activation of SIPK induced by continuous elicitor stimulation is likely to be involved in the induction of capsidiol biosynthesis. However, which key components directly control capsidiol production in response to continuous stimulation with PIP-1 remains unknown.

3-Hydroxy-3-methylglutaryl CoA reductase (HMGR) acts as an upstream rate-limiting enzyme in the mevalonate pathway, and it plays an important role in the synthesis of isoprenoids essential for plant growth and development via constitutive activity that is likely to be regulated by *HMGR1*.[34] It was shown that the elicitor-inducible HMGR activity is considered to be responsible for capsidiol biosynthesis in tobacco cells,[35,36] which seems to be associated with *HMGR2*, an elicitor-inducible HMGR isogene in Solanaceae plants.[37,38] However, the mechanisms underlying the regulation of HMGR activity in response to elicitor treatment are poorly understood. In a previous study, we showed that short-term stimulation with PIP-1 induced the accumulation of *HMGR2* transcripts,[14] whereas no production of capsidiol was observed. In this regard, it is possible that HMGR activity is "switched on" only after continuous stimulation with PIP-1 via translational and/or post-translational regulatory mechanisms, leading to capsidiol production. Therefore, we investigated the relationship between the duration of stimulation with PIP-1 and the induction of HMGR activity along with the activation of SIPK using PcPIP-1.

We first examined the effect of the duration of stimulation with PIP-1 on SIPK activation. As shown in Figure 6A, SIPK activity increased significantly after 3 h of treatment with PcPIP-1. This enhancement of SIPK activity was much weaker when PcPIP-1 was inactivated by UV irradiation 1 h after elicitation. This result was consistent with our previous results obtained using the cell-washing method, where the enhanced SIPK activity decreased after washing out the elicitor.[14] However, the decrease in the SIPK activity was much sharper in the present study, compared to that observed using the cell-washing method. In the latter, high levels of the SIPK activity were still detected even after washing out the elicitor, probably due to physical stress or damage caused to the cells during washing operations. Our results here showed that the use of the photocleavable analog can effectively "switch off" elicitor-mediated MAP kinase activation including downstream responses, such as phosphorylation of its substrates. Thus, this method appears to be particularly advantageous for investigating key components important for capsidiol production in response to continuous stimulation with PIP-1 through MAP kinase signaling.

We then examined the effect of the duration of the stimulation with PIP-1 on the induction of *HMGR2* expression. Following treatment with either PIP-1 or PcPIP-1, *HMGR2* transcripts increased significantly regardless of UV irradiation (Figure 6B). This result clearly indicated that the short-term elicitor stimulation is enough for induction of the expression of *HMGR2*, as previously observed.[14] Treatment of protein synthesis inhibitor (CHX) did not suppress *HMGR2* expression induced by PcPIP-1, suggesting that de novo protein synthesis is not involved in this gene expression. Next, the effect of the

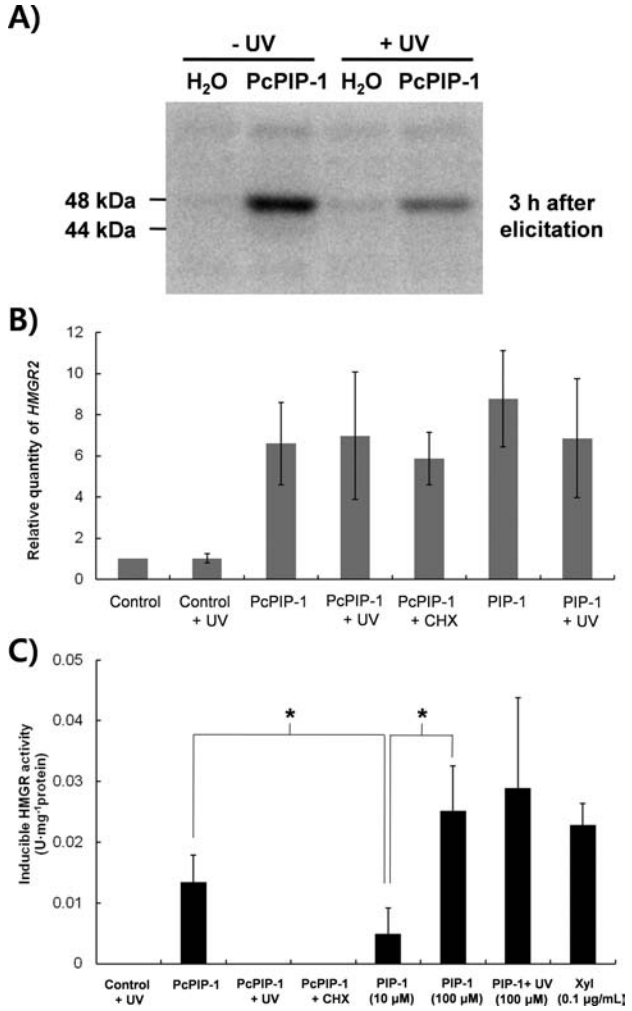

Figure 6. Effect of stimulation period on MAP kinase and HMGR activation. (A) Comparison of MAP kinase activity induced by PcPIP-1 (100 μM) between those with and without UV irradiation. UV irradiation (15 min) was applied 1 h after treatment with PcPIP-1. The activity of MAP kinase was measured 3 h after sample treatment by the in-gel kinase assay using MBP as a substrate. (B) Comparison of relative quantity of *HMGR2* transcripts. Suspension cultured tobacco cells were treated with 100 μM of PIP-1 or PcPIP-1. (C) Comparison of the elicitor-inducible HMGR activity. Suspension cultured tobacco cells were treated with xylanase (Xyl, 0.1 μg/mL), PIP-1 (10 and 100 μM), or PcPIP-1 (100 μM). Distilled water was used as a control. Increases in the activity from that of the control were shown as the inducible HMGR activity. +UV: UV irradiation for 15 min at 1 h after elicitation. +CHX: cycloheximide (10 μg/mL) treatment. The total RNA and crude enzyme were extracted 4 h after elicitation. Asterisks indicate significant difference at $P < 0.05$ according to the Student's paired *t*-test. Vertical bars indicate ±SD of three independent replicates.

duration of the stimulation with PIP-1 on the elicitor-inducible HMGR activity was examined. When a fungal elicitor xylanase, which is known to induce capsidiol production,[13,39,40] was treated, significant enhancement of the HMGR activity was observed (Figure 6C). Similar enhancement was observed after treatment with PIP-1 at 100 μM, which induces capsidiol production. This enhancement was not affected by UV irradiation, indicating that UV irradiation at this wavelength has no adverse effect on enhancement of the HMGR activity. Moreover, treatment with PIP-1 at 10 μM, which induces only

J. Agric. Food Chem. 2015, 63, 5894−5901

low levels of capsidiol production due to enzymatic degradation by tobacco cells, did not show significant enhancement of the HMGR activity. In the case of PcPIP-1, an increase in the HMGR activity was observed after treatment at 100 μM, where capsidiol production was induced. However, this enhancement was not induced when PcPIP-1 was inactivated by UV irradiation 1 h after treatment, where no capsidiol production was observed. Thus, production of capsidiol correlated well with enhancement of the HMGR activity. This suggests that the elicitor-inducible HMGR activity, which is switched on in response to continuous stimulation with PIP-1, is closely associated with the initiation of capsidiol biosynthesis, although the involvement of other factors cannot be ruled out. In addition, because CHX suppressed the enhancement of the HMGR activity, it is possible that de novo protein synthesis is involved in induction of the HMGR activity through translational or post-translational regulation mechanisms.

In a previous study, we showed that transient activation of SIPK induces only the accumulation of *HMGR2* transcripts and does not lead to capsidiol production, and that capsidiol production requires an increase in SIPK activity for at least 3 h.[14] In the present study, we showed that the increase in HMGR activity was also associated with the prolonged activation of SIPK activity. Therefore, it is possible that SIPK plays a dual role in immune response signaling pathways: induction of defense-related genes at an early phase and translational and/or post-translational activation of enzymes at a late phase. In fact, as shown in *Nicotiana benthamiana*, the expression of *HMGR2* is regulated by MAPK-mediated phosphorylation of WRKY8 transcription factors in response to pathogen inoculation.[41] Regarding translational or post-translational regulation of HMGR activity, recombinant HMGR1 from *Arabidopsis* has been shown to be inactivated in vitro by *Brassica oleracea* HMGR kinase A through phosphorylation of serine residues present in the catalytic domain.[42] In addition, HMGR activity has been demonstrated to be negatively regulated by protein phosphatase 2A that is considered to be a post-translational regulator of HMGR activity under stress conditions in *Arabidopsis*, and it was suggested that both active and inactive phosphorylation sites may exist in HMGR.[43] Thus, continuous stimulation with PIP-1 might influence phosphorylation of either these regulatory proteins or HMGR via kinase cascades including SIPK. Further investigations on variations in phosphorylation of regulatory proteins through continuous stimulation with PIP-1 would help understanding the regulatory mechanisms involved in phytoalexin biosynthesis in response to elicitors.

In summary, we designed photocleavable analogs to investigate which factors are involved in the initiation of phytoalexin production induced by PIP-1. An analog containing 3-amino-3-(2-nitrophenyl)propionic acid as the photocleavable residue exhibited a significant elicitor activity and was able to induce both early- and late-phase immune responses. This analog (PcPIP-1) was highly resistant to enzymatic degradation by tobacco cells, although it was easily inactivated through exposure to UV irradiation. Using this analog, we found that an increase in HMGR activity necessary for capsidiol production was significantly regulated by the stimulation period of PIP-1. To our knowledge, this study is the first report demonstrating that the continuous action of elicitor is required for activation of HMGR necessary for capsidiol production in tobacco cells.

TMS as an internal standard. ESIMS spectra were acquired on a Thermo Finnigan LCQ-Advantage mass spectrometer (Finnigan Co., Ltd., San Jose, CA, USA). HR-ESIMS were recorded by an IonSpec 7.0 T FTICR MS (IonSpec Co., Ltd., Lake Forest, CA, USA). HPLC purifications were finished on a CXTH system, equipped with a UV3000 detector at 210 nm (Beijing Chuangxintongheng Instruments Co., Ltd., Beijing, People's Republic of China). The HPLC column used was a 20 × 250 mm i.d., 5 μm, YMC-pack ODS-AM (YMC Co., Ltd., Kyoto, Japan). Silica gel (100−200 mesh) was used for column chromatography (Qingdao Haiyang Chemical Group Co., Ltd., Qingdao, People's Republic of China). Chemical reagents for isolation were of analytical grade and purchased from Tianjin Chemical Reagent Co. (Tianjin, People's Republic of China). Biological reagents were from Sigma Chemical Co.

Plant Material. The roots of *E. prolifera* were collected in July 2010 from Kunming, Yunnan province, People's Republic of China. The botanical identification was made by one of the authors (Y.G.), and a voucher specimen (No. 20100705) was deposited at the laboratory of the Research Department of Natural Medicine, College of Pharmacy, Nankai University, People's Republic of China.

Extraction and Isolation. The air-dried roots of *E. prolifera* (3.8 kg) were extracted with methanol three times (3 × 20 L) under reflux. The organic solvent was evaporated to afford a crude extract (900 g), which was suspended in H_2O (0.9 L) and then partitioned with ethyl acetate (3 × 0.9 L) to give the EtOAc-soluble portion (150 g). This portion was fractionated by silica gel column chromatography (silica gel, 1.0 kg; column, 9 × 70 cm), using a gradient solvent system of petroleum ether/acetone (100:0, 100:2, 100:4, 100:7, 100:11, 100:16, 100:23, 100:30, 100:40, and 0:100, 21 L for each gradient elution), to afford nine fractions (F_1−F_9) according to the TLC analyses. Fraction F_8 (eluted by petroleum ether/acetone, 100:30 and 100:40) was subjected to medium-pressure liquid chromatography (MPLC) over octadecylsilyl (ODS) eluting with a step gradient from 60 to 90% MeOH in H_2O to give four subfractions ($F_{8\text{-}1}$−$F_{8\text{-}4}$). Subfraction $F_{8\text{-}3}$ was further purified by preparative HPLC (YMC-pack ODS-AM, 250 × 20 mm i.d., 77% MeOH in H_2O) to afford compound **1** (t_R = 23

[a]Assignments of ^{1}H NMR data are based on ^{1}H−^{1}H COSY, HMQC, and HMBC experiments. [b]Signals were in overlapped regions of the spectra, and the multiplicities could not be discerned.

min, 7.2 mg), and the purification of F_{8-4} by the same HPLC system (82% MeOH in H_2O) yielded compound **5** (t_R = 27 min, 11.5 mg). Fraction F_9 (eluted by petroleum ether/acetone, 100:40 and 0:100), using the above MPLC (60−90% MeOH in H_2O), provided four subfractions F_{9-1}−F_{9-4}. Compounds **2** (t_R = 32 min, 13.6 mg) and **8** (t_R = 21 min, 13.1 mg) were obtained from subfraction F_{9-2} by using the same HPLC system (73% MeOH in H_2O), and the following purification of subfraction F_{9-4} (77% MeOH in H_2O) afforded compound **4** (t_R = 24 min, 13.2 mg). Using the same MPLC system as for the above fractions, F_7 gave subfractions F_{7-1}−F_{7-4}. The following purification of subfraction F_{7-3} (73% MeOH in H_2O) produced compounds **3** (t_R = 35 min, 13.1 mg), **6** (t_R = 30 min, 13.8 mg), and **7** (t_R = 26 min, 15.0 mg).

Computational Methods. The ECD calculations were performed according to the reported method.[29]

Antifungal Activity Assay. The antifungal activities of the isolated compounds were assayed against three pathogenic fungi (*Physalospora piricola*, *Alternaria solani*, and *Gibberella zeae*) using a mycelium growth inhibition method, the details of which have been previously reported.[30] The commercially available agricultural fungicides chlorothalonil and carbendazol were used as the corresponding positive controls. Compounds possessing good activities (inhibitory rate > 50% at 50 μg/mL) were further evaluated using the above-mentioned method with different concentrations.

RESULTS AND DISCUSSION

The ethyl acetate-soluble part of the methanol extract of the roots parts of *E. prolifera* was fractionated by silica gel column chromatography and MPLC and further purified by HPLC to afford six new (**1**–**6**) and two known (**7** and **8**) diterpenoids (Figure 1). The known compounds were identified by comparison of spectroscopic data with those reported in the literature as 2α,5α,7β,15β-tetra-*O*-acetyl-3β-*O*-propinoyl-14α-*O*-benzoyl-14-deoxomyrsinol, **7**,[31] and 3β-*O*-propionyl-5α,10,15β-tri-*O*-acetyl-14β-*O*-nicotinoyl-7-oxo-10,18-dihydromyrsinol, **8**.[14]

Compound **1** was obtained as a white powder. Its molecular formula was assigned as $C_{35}H_{43}NO_{13}$ on the basis of HR-ESIMS. The ^1H NMR spectrum of **1** exhibited four oxygenated methine protons [δ_H 5.53 (1H, t, *J* = 3.8 Hz, H-3), 5.90 (1H, d, *J* = 11.1 Hz, H-5), 3.91 (1H, d, *J* = 5.5 Hz, H-8), and 5.35 (1H, br s, H-14)], four aromatic protons [δ_H 8.36 (1H, d, *J* = 7.9 Hz), 7.40 (1H, dd, *J* = 7.9, 4.9 Hz), 8.79 (1H, d, *J* = 4.9 Hz), and 9.22 (1H, br s)], and a pair of oxygenated methylene protons [δ_H 4.17, and 3.66 (each 1H, d, *J* = 9.8 Hz, H_2-17)]. Additionally, seven methyl signals were also exhibited in the ^1H NMR spectrum. The ^{13}C NMR spectrum of **1** showed 35 carbon resonances (Table 1). From the ^1H and ^{13}C NMR spectra of **1**, three acetyl groups were apparent from the methyl singlets (δ_H 2.24, 2.01, and 1.90 s) and the corresponding carbons (Table 1). The above-mentioned four aromatic proton signals (Table 2), together with the typical carbon resonances, revealed the presence of one nicotinoyl group.[14] In addition to these substituent groups, a propionyl moiety (Tables 1 and 2) was deduced and defined from the methyl and methylene proton signals and the observation of the corresponding carbon signals (Tables 1 and 2).[13] Apart from the above 15 carbon signals for the substituent groups, there were additional 20 carbons displayed in the ^{13}C NMR spectrum, including 3 methyls, 3 methylenes, 9 methines, and 5 quaternary carbons based on the DEPT and HMQC spectra. These 20 typically skeletal carbons implied that compound **1** possessed a characteristic cyclomyrsinol-type diterpene skeleton according to the reported related diterpenes from the genus *Euphorbia*.[32−36] This skeleton of cyclomyrsinol-type diterpene was further confirmed by HMBC and ^1H–^1H COSY experiments,

DOI: 10.1021/acs.jafc.5b02021
J. Agric. Food Chem. 2015, 63, 5902−5910

in which the carbonyl signal at δ_C 211.2 was assigned to C-7, and the oxygenated carbon signals at δ_C 77.3, 71.7, 72.1, 78.2, 89.6, 84.1, 90.2, and 66.9 were attributed to C-3, C-5, C-8, C-10, C-13, C-14, C-15, and C-17, respectively. The positions of the acyloxy groups were deduced from the HMBC spectrum. The HMBC correlation of the carbonyl signal at δ_C 173.2 with the proton signal at δ_H 5.53 (H-3) demonstrated that one acetoxy group was attached at C-3. Similarly, the long-range couplings of the carbonyl carbon signals at δ_C 173.5 and 166.3 with the proton signals at δ_H 5.90 (H-5) and 5.35 (H-14) disclosed the presence of the propionyloxy group and the nicotinoyloxy group at C-5 and C-14, respectively. Because there were no long-range correlations of the skeletal protons with the carbonyl carbons of the two remaining acetoxy groups, it was therefore concluded that the two acetoxy groups were attached to quaternary carbons of the cyclomyrsinol skeleton. On the basis of the chemical shifts of skeletally oxygenated carbons and similar cyclomyrsinol diterpenes in the literature,[35,36] the residual acetoxy groups could only be located at C-10 and C-15, of which the C-10 acetoxy group was assigned by a NOESY experiment, indicating the NOESY correlations of H_3-19 (δ_H 1.59) to the methyl protons (δ_H 1.90) of the C-10 acetoxy group. Consequently, the other remaining acetoxy was assigned to C-15. By further analyzing the HMQC, HMBC, and $^1H-^1H$ COSY spectra (Figure 2), all of the proton and carbon signals were assigned unambiguously. Thus, the planar structure of **1** was established.

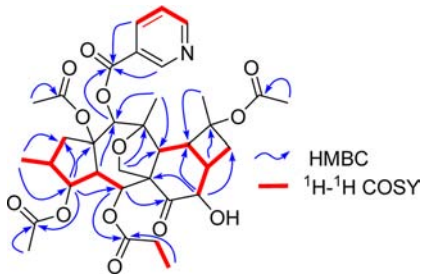

Figure 2. $^1H-^1H$ COSY and selected HMBC correlations of compound **1**.

The stereochemistry of **1** was elucidated as follows. The NOESY correlations of H-2/H-4, H-4/H-14, H-4/H_2-17, H-5/H-12, H-12/H_3-20, H-8/H-9, H_3-19/H-11, and H_3-19/H-9, but not of H-3/H-5, together with a Chem3D modeling revealed a conformation as shown in Figure 2. In this arrangement for compound **1**, the three rings, A, B, and C (5/7/6), were *trans*-fused with each other, H-12 proton and the C-15 acetoxy group were found to be in a β-position, and H-4 and C-17 were in an α-position. Another four-membered ring in the skeleton was *cis*-fused with ring C, and the H-9 and H-11 protons were assigned to be α-oriented correspondingly. In turn, the three methyl groups, Me-16, Me-19, and Me-20, were determined as β-, α-, and β-oriented, the acetoxy groups at C-3 and C-10 and the C-8 hydroxy group were all β-oriented, and the C-5 propionyloxy group was in an α-position according to this conformation of **1** and the above NOESY correlations. The relative configuration of **1** was therefore designated as shown in Figure 3.

The absolute configuration of **1** was established by the TDDFT ECD calculations[37−39] and substantiated by the octant rule. Starting from the conformation of **1** deduced from the NOESY correlations and Chem3D modeling, conformational

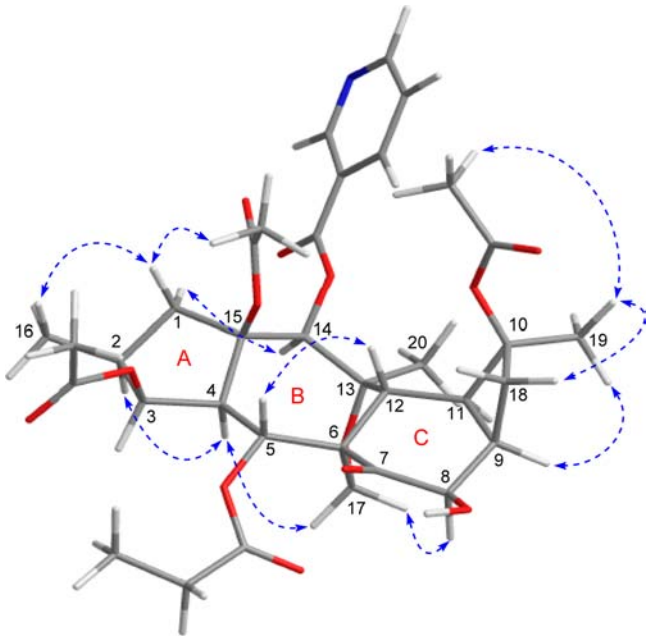

Figure 3. Conformation and key NOESY correlations of compound **1**.

searches with the MMFF94 force field by MOE software[40] and geometry optimizations by the Gaussian 09 package[41] were performed. Then, the ECD spectra were calculated at the CAM-B3LYP/SVP level with the CPCM model in acetonitrile. The obtained ECD spectrum of **1** (Figure 4) matched the experimental results closely, which suggested an absolute configuration of 2*S*,3*S*,4*R*,5*R*,6*S*,8*R*,9*R*,10*S*,11*S*,12*R*,13*R*,14*S*,-15*R* for compound **1**. The experimental ECD spectrum of **1** displayed a positive Cotton effect at 311 nm ($\Delta\varepsilon$ +9.42), corresponding to the n−π* transition of the cyclohexanone chromophore, which confirmed the absolute configuration of 2*S*,3*S*,4*R*,5*R*,6*S*,8*R*,9*R*,10*S*,11*S*,12*R*,13*R*,14*S*,15*R* unequivocally according to the octant rule.[42] On the basis of the above evidence, the structure of **1** was established as (2*S*,3*S*,4*R*,-5*R*,6*S*,8*R*,9*R*,10*S*,11*S*,12*R*,13*R*,14*S*,15*R*)-3β,10β,15-tri-*O*-acetyl-5α-*O*-propionyl-14β-*O*-nicotinoylcyclomyrsinol, which has been named prolifepene A.

Compound **2** had a molecular formula of $C_{39}H_{47}NO_{11}$ based on the HR-ESIMS. From the ^1H NMR spectrum of **2**, three oxygenated methine protons, a set of oxygenated methylene protons, nine aromatic protons, and six methyl signals were observed (Table 2). The ^{13}C NMR spectrum of **2** exhibited 39 carbon resonances. From the ^1H and ^{13}C NMR spectra, the methyl singlet (δ_H 1.88 s), together with the corresponding carbon signals (Table 1), implied the occurrence of one acetyl group, and the aromatic proton signals and the corresponding carbon resonaces (Table 1) revealed the presence of one nicotinoyl and one benzoyl group.[14,16] In addition, a butyryl group was also deduced and defined from the observation of the carbon signals (δ_C 170.1, 35.7, 17.7, and 13.5) and the corresponding proton signals (Table 2) based on those reported diterpenes with acyl groups in the literature.[13] Apart from the above 19 resonances for the substituent groups, the remaining 20 skeletal carbons in the ^{13}C NMR spectrum constituted a characteristic premyrsinol-type diterpene skeleton.[35,36]

To confirm the above deduction and position these substituent groups, the following HMQC, HMBC, and

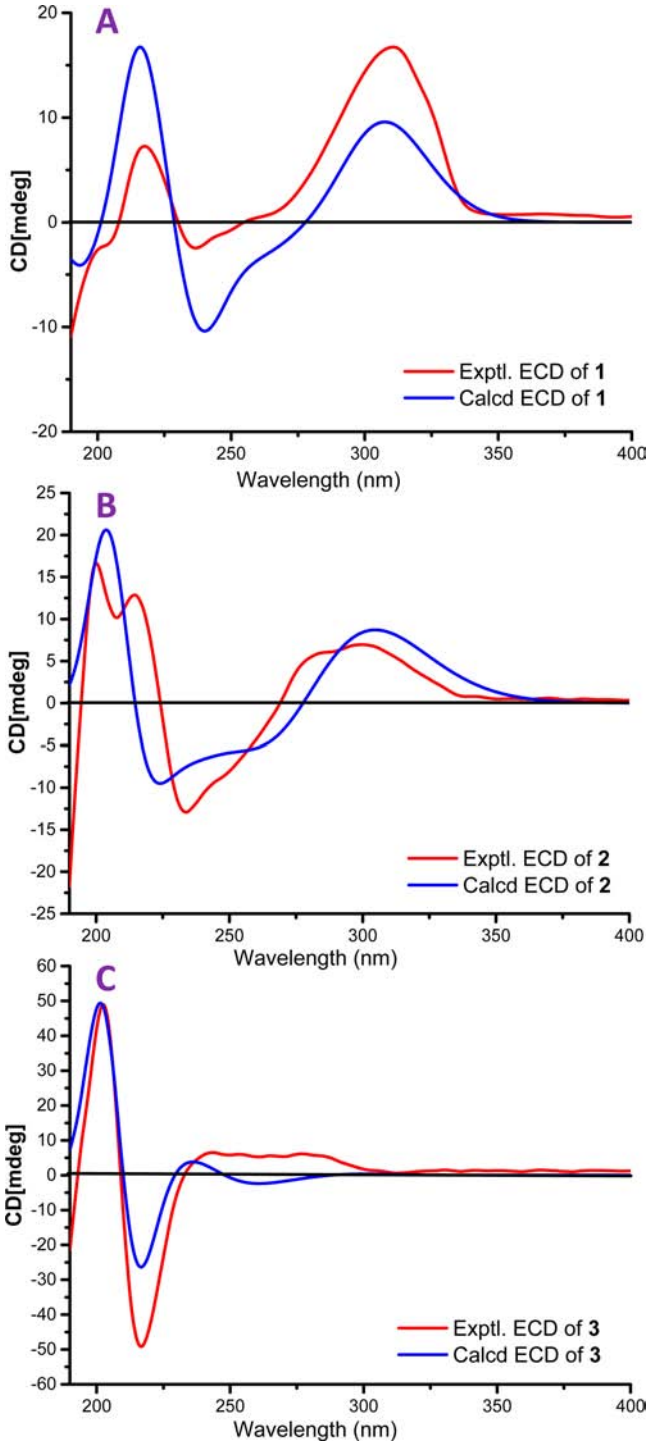

Figure 4. Calculated and experimental ECD spectra for compounds **1** (A), **2** (B), and **3** (C) in acetonitrile.

^{1}H−^{1}H COSY experiments were performed. By interpretation of the 2D NMR spectra, the presence of the above deduced acyl groups was substantiated and the characteristic premyrsinol-type diterpene skeleton was elucidated unequivocally, where the oxygenated carbons at δ_C 78.2, 69.2, 70.3, 79.6, 84.3, and 62.3 were attributed to C-3, C-5, C-7, C-13, C-15, and C-17, respectively. The locations of these acyloxy groups were determined by HMBC correlations. The long-range couplings of the protons H-3 (δ_H 5.61), H-5 (δ_H 6.07), H-7 (δ_H 5.06), and H_2-17 (δ_H 5.33 and 4.57) with the carbonyl carbons at δ_C 170.1, 165.0, 171.8, and 165.0 demonstrated that the butyryloxy group was located at C-3, the benzoyloxy group at C-5, the acetoxy group at C-7, and the nicotinoyloxy group at C-17, respectively. There were no additional acyloxy groups in compound **2**, indicating that the substituent groups at C-13 and C-15 could only be hydroxy groups, which was verified by the HR-ESIMS data. Further analyses of the HMQC, HMBC, and ^{1}H−^{1}H COSY data led to the assignments of all the proton and carbon signals. The planar structure with a premyrsinol-type diterpene skeleton for **2** was therefore elucidated. The relative configuration was elucidated on the basis of NOESY spectrum, which disclosed the correlations of H-2/H-4, H-3/H-4, H-4/H_3-20, H-5/H-12, H-7/H_2-17, H-9/H-11, H_2-17/H_3-20, and H-11/H_3-20. These NOESY correlations and the Chem3D modeling revealed that the three rings (5/7/6) forming the premyrsinol-type skeleton were *trans*-fused as those in **1**, the C-15 hydroxy group and H-12 proton were in a β-position, and C-17 and H-4 were in an α-position. Consequently, the C-3 butyryloxy, C-7 acetoxy, and C-13 hydroxy groups were assigned to be β-oriented, and the C-5 benzoyloxy group and H-9 and H-11 protons were determined as α-oriented according to the NOESY correlations. The relative configuration of compound **2** was therefore established. On the basis of the relative configuration of **2** deduced from the NOESY spectrum, the same procedures, conformational searches, geometry optimizations, and calculated ECD spectra as in the case of **1** were performed to determine the absolute configuration of **2**. As shown in Figure 5, the calculated ECD

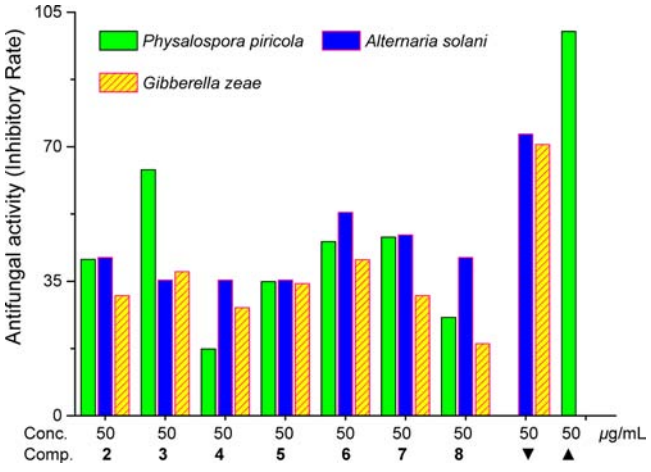

Figure 5. Antifungal effects of compounds **2**−**8** against three pathogenic fungi. Three common pathogenic fungi (*P. piricola*, *A. solani*, and *G. zeae*) were selected to evaluate the antifungal activities of compounds **2**−**8**. The biological data presented are the mean scores for each treatment across replicates. The symbols ▼ and ▲ indicate the positive controls chlorothalonil and carbendazol, respectively.

spectrum for (2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,9*S*,11*S*,12*R*,13*S*,15*R*)-**2** was in good agreement with the experimental one. Therefore, the absolute configuration of **2** was assigned as 2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,-9*S*,11*S*,12*R*,13*S*,15*R*. Thus, compound **2** was characterized as (2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,9*S*,11*S*,12*R*,13*S*,15*R*)-3β-*O*-butyryl-5α-*O*-benzoyl-7β-*O*-acetyl-17-*O*-nicotinoylpremyrsinol and was given the trivial name prolifepene B.

Compound **3** was obtained as a white powder. Its HR-ESIMS corresponded to the molecular formula $C_{36}H_{45}NO_{11}$. From the ^{1}H and ^{13}C NMR spectra, three acetyl, one butyryl, and one nicotinoyl group were evident on the basis of those acyl groups

DOI: 10.1021/acs.jafc.5b02021
J. Agric. Food Chem. 2015, 63, 5902−5910

in compounds **1** and **2**. Apart from these carbon resonances for the acyl groups, there were 20 residual ones present in the ^{13}C NMR spectrum. The 20 skeletal carbons were sorted into 3 methyls, 3 methylenes, 10 methines, and 4 quaternary carbons with the aid of DEPT and HMQC spectra. According to these spectroscopic features, especially the terminal double bond (C-10 and C-18), and the diterpenoids isolated from the genus *Euphorbia*,[13,14] it could be deduced that compound **3** had a 14-deoxomyrsinol-type skeleton, which was confirmed by the following HMBC and $^{1}H-^{1}H$ COSY experiments. Correspondingly, the skeletal olefinic and oxygenated carbon signals at δ_C 123.1, 133.1, 147.2, 112.8, 76.5, 69.0, 63.6, 89.1, 82.0, 89.6, and 69.2 were assigned to C-8, C-9, C-10, C-18, C-3, C-5, C-7, C-13, C-14, C-15, and C-17, respectively. The locations of acyloxy groups were deduced from the HMBC spectrum, exhibiting the correlations of the protons H-3 (δ_H 5.31), H-5 (δ_H 5.95), H-7 (δ_H 4.86), and H-14 (δ_H 5.25) with the corresponding carbonyl carbons at δ_C 173.4, 169.2, 170.4, and 164.4. These HMBC correlations demonstrated the two acetoxy, one butyryloxy, and one nicotinoyl group to be attached at C-5, C-7, C-3, and C-14, respectively. The residual acetxoy group should be attached to quaternary carbons of the myrsinol skeleton due to the lack of long-range correlations of skeletal protons to the carbonyl carbon of the acyloxy moiety. On the basis of the chemical shifts of skeletally oxygenated carbons, this residual acetoxy group could only be located at C-15.[13,16] By further analyzing the 2D NMR spectra, the planar structure of **3** was elucidated.

The relative configuration of compound **3** was established by analyses of the NOESY spectrum, which showed the correlations of H-2/H-4, H-3/H-4, H-4/H-14, H-4/H_2-17, H-5/H-12, H-7/H-11, and H-12/H_3-20. According to these NOESY correlations, the relative configuration of **3** was as depicted in Figure 1, where the three rings (5/7/6) were similarly *trans*-fused with each other as those in compounds **1** and **2**; H-4 and H-11 protons and C-17 were found to be in an α-position, the C-3 butyryloxy, the C-7 and C-15 acetoxy, and the C-14 nicotinoyloxy group were all in a β-position, and the C-5 acetoxy was assigned as α-oriented. After definition of the relative configuration of **3**, the absolute configuration was assigned as 2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,11*S*,12*R*,13*R*,14*S*,15*R*, by comparison of its experimental and calculated ECD spectra (Figure 4) using TDDFT method. On the basis of the above evidence, the structure of compound **3** (prolifepene C) was established as (2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,11*S*,12*R*,13*R*,14*S*,15*R*)-3β-*O*-butyryl-5α,7β,15β-tri-*O*-acetyl-14β-*O*-nicotinoyl-14-deoxomyrsinol.

The ^{1}H and ^{13}C NMR spectra of compounds **4**–**6** were found to be similar to each other. Analyses of the ^{13}C and ^{1}H NMR spectra of the three compounds indicated that compounds **4**–**6** all possess the same 14-deoxomyrsinol-type diterpene scaffold as compound **3**.[35,36] The main differences between compounds **4**–**6** were found to be in the different substituent groups that occurred in each case. For compound **4**, five acyl groups (two acetyl, two nicotinoyl, and one benzoyl group) were deduced and determined according to its ^{13}C and ^{1}H NMR spectra. Using the same HMBC and NOESY experiments as for compounds **1**–**3**, the positions of these substituent groups and the relative configuration of compound **4** were determined, where one acetoxy group was located at C-5 with an α-orientation, the other acetoxy group was at C-15 with a β-orientation, the benzoyloxy group was at C-7 with a β-orientation, and the two nicotinoyloxy groups were at C-3 and C-14, both in a β-position. For compound **5**, besides the same three acetoxy groups and one nicotinoyloxy group as present in compound **3**, a propionyloxy moiety was deduced and defined on the basis of its ^{13}C and ^{1}H NMR data, which was located at C-3, replacing the butyryloxy group in compound **3**. Compound **6** was found to have the same acyl groups (three acetyl, one nicotinoyl, and one butyryl group) as compound **3**. From the evidence of the HMBC spectrum, the butyryloxy group was found to be located at C-3, the nicotinoyloxy group was at C-7, and the three acetoxy groups were at C-5, C-14, and C-15, respectively. The same relative configuration for all of compounds **3**–**6** was validated by the careful comparison of their NOESY spectra. On the basis of the above spectroscopic evidence, biosynthetic considerations, and absolute configuration of **3** elucidated by the TDDFT ECD method, the structures of compounds **4**–**6** were therefore elucidated as (2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,11*S*,12*R*,13*R*,14*S*,15*R*)-3β,14β-di-*O*-nicotinoyl-5α,15β-di-*O*-acetyl-7β-*O*-benzoyl-14-deoxomyrsinol, (2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,11*S*,12*R*,13*R*,14*S*,15*R*)-3β-*O*-propinoyl-5α,7β,15β-tri-*O*-acetyl-14β-*O*-nicotinoyl-14-deoxomyrsinol, and (2*S*,3*S*,4*R*,5*R*,6*R*,7*R*,11*S*,12*R*,13*R*,14*S*,15*R*)-3β-*O*-butyryl-5α,14α,15β-tri-*O*-acetyl-7β-*O*-nicotinoyl-14-deoxomyrsinol, which have been named prolifepenes D, E, and F, respectively.

E. prolifera is a poisonous plant, and its chemical constituents may be useful for the agricultural and medical industries.[27,28] To explore the potential biological effects of these diterpenes to serve agriculture, these isolated compounds from *E. prolifera* were preliminarily investigated for their antifungal activities against three pathogenic fungi (*G. zeae*, *P. piricola*, *A. solani*), which commonly infect crops, leading to severe crop yield reduction and dramatic economic losses in agriculture.[1] Carbendazol was used as a positive control and had an EC_{50} value of 0.43 μg/mL against *P. piricola*, and the other positive control, chlorothalonil, gave the corresponding EC_{50} values of 27.34 and 10.10 μg/mL against *A. solani* and *G. zeae*, respectively. At the concentration of 50 μg/mL, all of the evaluated compounds exhibited antifungal activities. Their preliminary antifungal activities are shown in Figure 5 (compound **1** was not assayed for antifungal effects because of inadequate amounts). For the pathogenic fungus *G. zeae*, all of the compounds showed weak or moderate antifungal effects at the concentration of 50 μg/mL. For the fungus *A. solani*, compound **6** showed a strong activity with an inhibitory rate of 53% and an EC_{50} value of 29.60 μg/mL. For the fungus *P. piricola*, compound **3** had a stronger activity than other compounds with an inhibitory rate of 64% and an EC_{50} value of 28.26 μg/mL.

In conclusion, six new and two known diterpenes were obtained from the roots of the plant *E. prolifera*. Their structures including the absolute configurations were elucidated by the NMR data analyses, the TDDFT ECD calculations, and the octant rule. The subsequent biological screenings indicated that these isolated compounds had antifungal activities against three phytopathogenic fungi. The results of our phytochemical investigation further revealed the chemical components of *E. prolifera* make it a poisonous and medicinal plant, and the biological screenings suggested that *E. prolifera* may be potentially useful to protect crops against phytopathogenic fungi; the bioactive compounds may probably be considered as candidate agents of antifungal agrochemicals for crop protection products.

N-Trimethylsilylimidazole (TMSI), *N*-methyl-*N*-trimethylsilylacetamide (MSA), *N*-trimethylsilyldiethylamine (TMSDEA), *N*-trimethylsilyldimethylamine (TMSDMA), *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA), *N*,*O*-bis(trimethylsilyl)-acetamide (BSA), and *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) have also been used as silylation agents.[21] MSTFA was found to be superior in comparison to other reagents, giving better results for a broader range of analytes and producing fewer byproducts, especially when preceded with alkoxyamine treatment to prevent the formation of cyclic anomers.[22] This two-step procedure was further extended to other polar compounds present in multicomponent extracts, being now a gold standard in GC-MS-based metabolomics.[23]

However, as in vitro glycation mixtures often contain 50−200 mmol/L phosphate, that is, concentrations dramatically exceeding its dynamic range,[6,11,12] their analyses by GC-MS can be challenging. Additionally, peptides or proteins present in the mixture might also affect both method and instrument performance. Here we describe a new approach for the analysis of carbohydrates in heated model phosphate-buffered glycation systems containing D-glucose and peptide. The method relied on the removal of the phosphate component by SPE on polymer-based ion exchange cartridges followed by two-step derivatization with methoxyamine hydrochloride (MOA) and MSTFA and subsequent GC-MS analysis.

MATERIALS AND METHODS

Chemicals. Fmoc-rinkamide AM resin and Fmoc-L-Arg(Pbf)-OH (peptide synthesis grade) were bought from Iris Biotech GmbH (Marktredwitz, Germany). All other Fmoc-protected L-amino acids (peptide synthesis grade) were from ORPEGEN Pharma (Heidelberg, Germany). *N*,*N*′-Dimethylformamide (DMF, ≥99.8%), piperidine (≥99.5%), and dichloromethane (DCM, ≥99.9%) were purchased from Biosolve (Valkenswaard, The Netherlands). Trifluoroacetic acid (≥99.9%), α-D-glucose monohydrate (≥99.5%), D-(−)-fructose (≥99.5%), methanol (HPLC grade, ≥99.9%), 2-propanol (UV/IR grade, ≥99.9%), and D-(+)-sucrose (≥99.5%) were from Carl Roth GmbH & Co (Karlsruhe, Germany). L-(+)-Arabinose (≥99%), D-(+)-maltose monohydrate (≥98%), and D-(+)-mannose (≥98%) were from Merck KGaA (Darmstadt, Germany). MSTFA (≥95%) was bought from Macherey-Nagel (Düren, Germany). D-(+)-Galactose, D-(−)-ribose, D-(−)-mannitol, *myo*-inositol, diethyl ether (99%), and acetonitrile (≥99.9%, HPLC grade) were bought from VWR International GmbH (Dresden, Germany). 3-Deoxyglucosone (95%; 3-DG) was from Santa Cruz Biotechnology (Heidelberg, Germany). Ammonia solution (∼25% p.a.) was bought from KMF Laborchemie Handles GmbH (Lohmar, Germany). All other chemicals were purchased in required purities from Sigma-Aldrich Chemie GmbH (Taufkirchen, Germany). Water was purified in-house (resistance = 18 mΩ) on a PureLab Ultra Analytic System (ELGA Lab Water, Celle, Germany).

Peptide Synthesis. The sequence Ac-AFGSARASGA-NH_2 was synthesized on a Syro2000 multiple-peptide synthesizer (MultiSynTech GmbH, Witten, Germany) by 9-fluorenylmethoxycarbonyl/*tert*-butyl (Fmoc/^{t}Bu)-chemistry using 8 equiv (eq) of Fmoc-amino acid derivatives activated with 1,3-diisopropylcarbodiimide/hydroxybenzotriazol (DIC/HOBt) in DMF. N-Terminal acetylation was implemented in the automated synthesis by using 8 eq of acetic acid. After cleavage from the resin and removal of all protecting groups, the peptide was purified by RP-HPLC using 0.1% (v/v) aqueous trifluoroacetic acid (TFA) as ion pair reagent added to water (eluent A) and 60% (v/v) aqueous acetonitrile (eluent B) in 1% eluent B/min gradient (22−42% eluent B in 20 min). The purified peptide was reconstituted in 20% aqueous acetonitrile and split into aliquots of 50 nmol in 0.5 mL polypropylene tubes (Eppendorf AG, Hamburg, Germany). The solvent was removed under reduced pressure, and residues were stored at −20 °C.

In Vitro Glycation of the Model Peptide. The dried peptide aliquots were reconstituted in 100 μL of 100 mmol/L sodium phosphate buffer (pH 7.4) containing 18 μmol/L iron(II) sulfate in the presence or absence of 25 mmol/L D-glucose and incubated for 0, 30, 60, and 120 min at 95 °C under continuous shaking at 550 rpm. The incubated samples were cooled on ice, allowing the gas phase to condense completely and centrifuged (2 min at 2500*g*), and the reaction was quenched by the addition of 20 μL of a 6 mmol/L diethylenetriaminepentaacetic acid (DTPA) solution. Afterward, the samples were dried under vacuum and stored at −80 °C prior to GC-EI-MS analysis. The incubations performed in the absence of peptide served as controls.

Solid Phase Extraction. Ion exchange cartridges (mixed mode anion/cation exchanger CHROMABOND PSMix, 1 mL/100 mg, Macherey-Nagel), strong anion (CHROMABOND PSOH$^-$, 1 mL/100 mg, Macherey-Nagel), and weak anion exchanger (CHROMABOND HR-XAW, 45 μm, 1 mL/30 mg, Macherey-Nage) were conditioned with 3 mL of methanol and equilibrated with 3 mL of water. After the sample application, elution was performed in five steps: 1 mL of 5% (v/v) aqueous ammonia (E1), 1 mL of 5% (v/v) aqeuous acetic acid (E2), 1 mL of 50% (v/v) aqeuous methanol containing 10% (v/v) ammonia (E3), 1 mL of 50% aqeuous methanol containing 10% acetic acid (E4), and 1 mL of 20% methanol in acetone (E5). The individual fractions were dried under vacuum, and the carbohydrates and phosphate were analyzed by GC-MS after methoximation/trimethylsilylation.

For analysis of glycation mixtures, polymer-based mixed mode ion exchange SPE cartridges (CHROMABOND PSMix, 1 mL/100 mg, Macherey-Nagel) were conditioned and equilibrated with 3 mL (3 × 1 mL) of methanol and water, respectively. A 50 μL sample (n = 3) was diluted 20-fold with water and loaded, and carbohydrates were eluted with 10 mL of water. The eluates were lyophilized and reconstituted with 500 μL of 30% aqueous methanol. Eighty-five microliters of each diluted fraction was transferred to a 0.5 mL polypropylene tube, dried under vacuum, and stored at −20 °C prior to derivatization and GC-EI-MS analysis.

Method Standardization and Validation. Standardization and validation of the method was performed by a serial dilution (2−2.5-fold increment) of the authentic standard mixture (100 pmol/L−1 mmol/L each, 20 calibration levels, n = 3) in 30% aqueous methanol. The calibration mixtures were dried and derivatized directly or subjected to SPE (when spiked to the glycation matrix) before derivatization as described above. The experimentally determined limits of detection (LODs) were defined as 3.3 SD/m, where m is the slope of the calibration curve and SD is its standard deviation (calculated from the residual standard deviation of the relevant points in LDR).[24] The limits of quantitation (LOQs) were defined as the lower limit of the linear dynamic range, but not smaller that S/N = 10/1. The linear dynamic ranges (LDRs) were determined with 12 and 20 calibration levels (n = 3, increment 2.0−2.5) in the presence and absence of matrix, respectively. The accuracies were assessed using three calibration levels within the LDRs considering the SPE procedure. The uncertainty of the analysis was determined at the LOD for each analyte.

Derivatization Procedure and GC-MS. The samples were derivatized by employing a modification of the protocol described by Fiehn and co-workers.[22] In detail, 30 μL of freshly prepared 20 mg/mL MOA in pyridine solution was added to the dried sample and shaken at 600 rpm for 90 min at 30 °C. Then, 55 μL of MSTFA was added, and the sample was incubated for 30 min at 37 °C under continuous shaking at 600 rpm. The derivatized sample was transferred to a GC autosampler glass vial with micro inserts (NeoLab, Heidelberg, Germany) and subjected to GC-EI-MS analysis. One microliter of sample was injected by an A200S autosampler (CTC Analytics, Zwingen, Switzerland) into a Trace GC Ultra chromatograph equipped with a standard split/splitless injector (Thermo-Fisher Scientific, Bremen, Germany) as described in the Supporting Information (protocol S-1).

RESULTS

GC-EI-MS of Carbohydrate Derivatives. GC-MS analysis of the standard mixture containing 22 TMS-methoxime carbohydrate derivatives resulted in rich signal patterns in the corresponding total ion current (TIC) chromatograms (Figure 1). Individual analytes were typically represented by two well-resolved

J. Agric. Food Chem. 2015, 63, 5911−5919

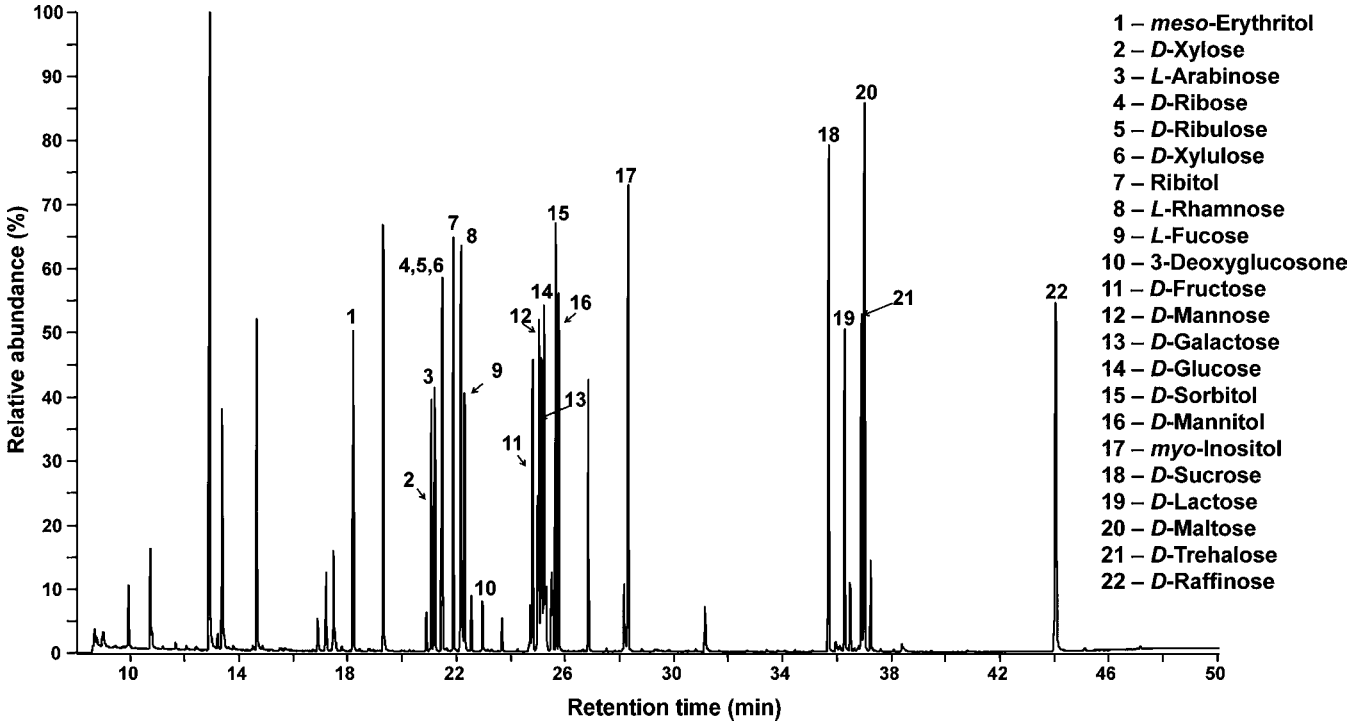

Figure 1. Total ion current chromatogram of TMS derivatives of carbohydrate methoximes identified in a 25 μmol/L carbohydrate standard mixture.

chromatographic peaks corresponding to *syn*- and *anti*-isomers of the TMS-methoximes. All carbohydrates were annotated by t_R and their characteristic MS fragmentation patterns. The numbers and intensities of the signals observed in the EI spectra (and, hence, obtained matches in spectra similarity search) were sufficient for unambiguous identification of analytes by spectra similarity (NIST database) or manual interpretation with a reversed match >900. Moreover, the annotation was confirmed by experiments performed with individual authentic standards. Extracted ion chromatograms (XICs) of the most intense and characteristic m/z values ($m/z \pm 0.5$) were integrated at specific retention times for relative and absolute quantitation.

When the temperature gradient from 40 to 350 °C was applied, baseline separation could be achieved for the majority of the sugars (Figure 1). However, some sugars, namely, D-ribose, D-ribulose, and D-xylulose (a diastereomer of D-ribulose), showed a strong coelution under these conditions (Figure S-1A). Moreover, the EI spectra of these analytes demonstrated a high similarity and absence of characteristic signals that made distinguishing these sugars impossible (Figure S-1B–D). Unfortunately, further optimization of the GC temperature gradient did not improve the separation of these three analytes. Therefore, in sugar mixtures, these unresolved signals were annotated as "ribose equivalents".

To assess the potential of our method for carbohydrate quantitation, we determined LODs and LOQs as well as LDRs for all analytes (Table S-1). For most of the analytes LODs were between 10 and 500 fmol (only L-fucose showed LOD of 1 pmol). The LOQs were in the range of 50–500 fmol, being higher only for L-rhamnose and L-fucose (1 and 2.5 pmol, respectively). The method showed a good linearity: the LDRs typically covered 3 orders of magnitude, whereas two analytes (D-sucrose and ribitol) produced linear GC-MS response over only 2 orders of magnitude. Only for two sugars, namely, L-rhamnose and L-fucose, the LDRs were $<10^2$.

Effects of Peptide and Phosphate on GC-MS Performance. Prior to application of our approach to the investigation of the protein/peptide Maillard reaction, it was necessary to characterize the effect of the glycation mixture components on the GC-MS responses of carbohydrates. For this, on the basis of the literature data,[6,11] we modeled a typical in vitro glycation reaction, based on 100 mmol/L phosphate buffer (pH 7.4), 18 μmol/L $FeSO_4$, and 0.5 mmol/L synthetic peptide Ac-AFGSARASGA-NH_2 simulating protein component. As this reaction was expected to be accompanied by the formation of multiple sugar intermediates, it contained three other carbohydrates besides glucose (D-mannose, D-fructose, and L-arabinose, each 20 μmol/L). Our results clearly demonstrated the absence of an essential effect of peptide Ac-AFGSARASGA-NH_2 on the recovery of carbohydrates (data not shown). However, in the presence of 100 mmol/L phosphate buffer, the GC-MS responses of all analytes were significantly decreased (Figure 2): up to a 57% reduction of signal intensities in comparison to the phosphate-free control was observed.

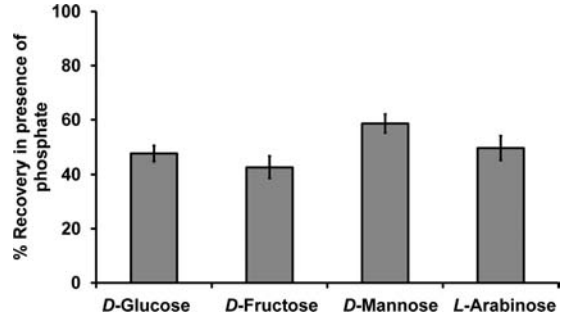

Figure 2. Effect of 100 mmol/L phosphate buffer (pH 7.4) on the intensity of characteristic chromatographic signals (peak areas) of the TMS-methoximes of D-glucose (m/z 319 ± 0.5), D-fructose (m/z 307 ± 0.5), D-mannose (m/z 319 ± 0.5), and L-arabinose (m/z 307 ± 0.5) obtained by GC-MS analysis of glycation mixtures. Recoveries were calculated in comparison to phosphate-free control.

Phosphate Removal by Ion Exchange SPE. To avoid this signal suppression, that is, to make our approach compatible with in vitro glycation systems, it was necessary to remove excess phosphate from the samples prior to derivatization and GC-MS analysis. For this, the same mixture of four carbohydrates, spiked to the above-mentioned phosphate-containing model glycation system, was depleted for phosphate anions by means of three polymeric ion exchange SPE materials (Figure 3). The analysis of the fractions revealed that total recoveries of all sugars from a strong cation/anion exchanger (PS-Mix) were higher than from the strong anion (PS-OH^-) and weak anion (HR-XAW) exchangers. Remarkably, the latter two phases demonstrated high variability of recovery for different sugars and generally lower recovery rates. The distribution of analyte between different SPE fractions was clearly favored for the flow-through fraction (72.3%), although 14% of recovered D-glucose was detected in the first elution fraction (5% aqueous ammonia, Figure 4A). In contrast, only a small portion of phosphate was recovered in the flow-through fraction, whereas most of this anion was eluted in the first three elution steps (5% aqueous ammonia, 5% aqeuous acetic acid, 50% aqeuous methanol containing 10% ammonia, Figure 4). Thereby, the weak anion exchanger had much lower phosphate removal efficiency than the other two tested phases. On the basis of these results, further method development was performed with the PS-Mix stationary phase.

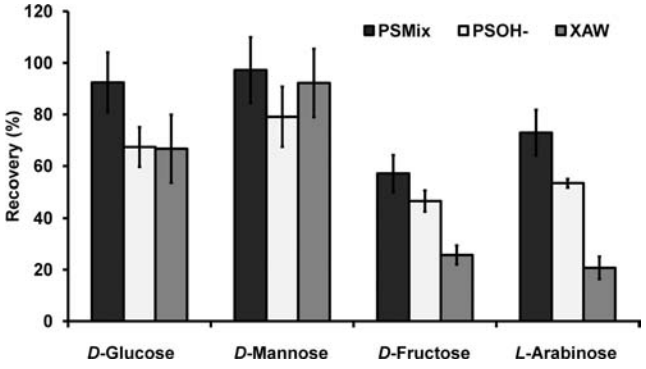

Figure 3. Total recoveries of D-glucose, D-mannose, D-fructose, and L-arabinose from mixed mode anion/cation exchange (PSMix), strong and weak anion exchange (PS-OH^- and HR-XAW, respectively) SPE cartridges (n = 5) after application of the 20 μmol/L carbohydrate mixture (D-glucose, D-fructose, D-mannose, and L-arabinose) in 100 mmol/L phosphate buffer (pH 7.4) containing 0.5 mmol/L synthetic peptide and 18 μmol/L $FeSO_4$. The eluates were dried and analyzed by GC-EI-MS after methoximation/trimethylsilylation.

In the next step, elution was optimized in terms of analyte recovery and degree of phosphate removal. As the abundance of phosphate was very high in the first three elution fractions and negligible in the flow-through fraction (Figure 4B), we replaced the elution steps with water (collected with the flow through) and 5% aqeuous formic acid. Indeed, when the mixture of four sugars (D-glucose, D-mannose, D-fructose, and L-arabinose, 20 μmol/L each) loaded on the PS-Mix cartridges was eluted with 0.9 mL of water, up to 85% of the total sugar recoveries were obtained (Figure S-2A). Moreover, even 0.9 mL of 5% aqueous formic acid resulted in enhanced elution of phosphate, whereas <0.5% of the total applied phosphate was recovered when elution was performed by the same volume of water (Figure S-2B). To increase the analyte recoveries, we applied higher elution volumes. Thereby, about a 30% increase in sugar recoveries was achieved when using 10 mL of water (Figure S-2A). Remarkably, it did not enhance the recovery of phosphate (Figure S-2B). Therefore, in further experiments elution was performed with 10 mL of water.

Finally, we verified the applicability of the established sample preparation scheme to the matrix used for in vitro glycation. For this, a solution of synthetic peptide Ac-AFGSARASGA-NH_2 (0.5 mmol/L) in 100 mmol/L phosphate buffer (pH 7.4) containing 18 μmol/L $FeSO_4$ was 20-fold diluted with water and spiked with the mixture of 22 carbohydrates (25 μmol/L). Fifty microliters of this mixture was subjected to the optimized SPE procedure, derivatized, and analyzed by GC-MS. In parallel, the same mixture was analyzed without SPE. Absolute quantitation of phosphate in the eluate fractions revealed >99% phosphate removal efficiency. Thereby, recoveries of the sugars were in the range of 60−95%, which was sufficient for quantitation.

Method Validation. The experimental procedure presented here was validated in terms of sensitivity, linearity, recovery, and precision. For the determination of method LODs, LOQs, and LDRs, serially diluted mixtures of 22 carbohydrates (n = 3) with analyte concentrations ranging from 1 nmol/L to 1 mmol/L were derivatized and analyzed by GC-MS after the SPE procedure. The method LODs (LOD_m) ranged from 10 to 210 fmol (Table 1). For most of the carbohydrates, the method LOQs (LOQ_m) were between 100 and 500 fmol, although for L-fucose it

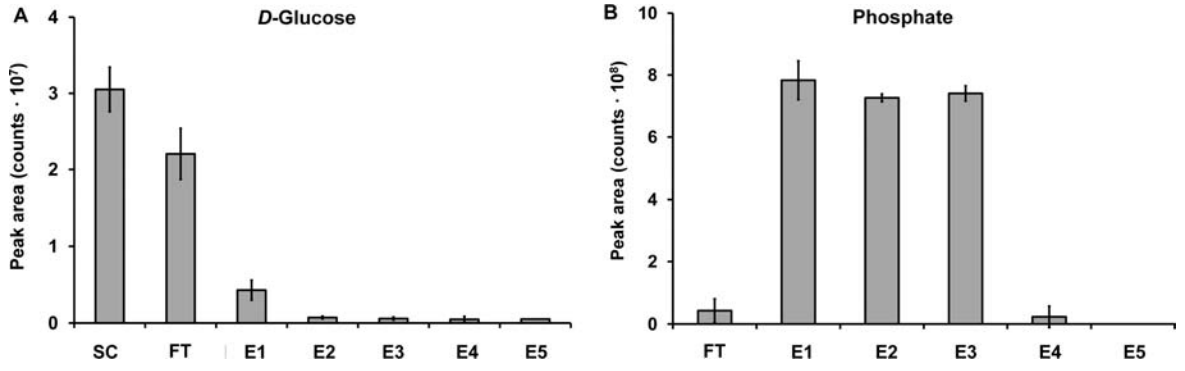

Figure 4. Intensities of D-glucose and phosphate signals (peak areas at m/z 319 ± 0.5 and 314 ± 0.5, respectively) in individual SPE (mixed mode anion/cation exchange, PSMix) fractions (n = 5): flow through (FT) and elution 1−5 (E1−E5). The carbohydrate mixture containing 20 μmol/L D-glucose, D-fructose, D-mannose, and L-arabinose was applied in 100 mmol/L phosphate buffer (pH 7.4) containing 0.5 mmol/L synthetic peptide and 18 μmol/L $FeSO_4$. The fractions were dried and analyzed by GC-EI-MS after methoximation/trimethylsilylation in parallel to sugars-only control (SC).

[a]All parameters were determined in independent dilution series ($n = 3$). [b]LODs and LOQs are given as fmol on column. [c]Sugar recoveries were calculated as the ratios of the calibration curve slopes obtained without and with SPE procedure. [d]Accuracy was determined using three calibration levels covering the lower, middle, and higher part of the LDRs. [e]Uncertainty was calculated at the LOD of each analyte. [f]Parameters determined for L-arabinose. [g]D-Ribose, D-ribulose, and D-xylulose were quantified as D-ribose equivalents.

was 2.5 pmol. Thus, for some analytes, the introduction of the SPE procedure resulted in an up to 5-fold decrease in their LODs and/or LOQs (Tables 1 and S-1). Moreover, for the majority of analytes an essential reduction of LDRs (defined for $R^2 \geq 0.99$) was observed; these values were typically 1 order of magnitude lower when the SPE procedure was applied (Tables 1 and S-1). The recoveries of the carbohydrates, calculated as the ratios of the calibration curve slopes obtained without and with the SPE procedure, were for most of the analytes >74%, although for three of them, namely, D-mannitol, D-glucose, and D-fructose, they were 63.8, 66.2, and 69.0%, respectively.

For the determination of intraday and interday precision, glycation mixtures ($n = 5$) were incubated for 60 min as described under Materials and Methods on three nonconsecutive days and analyzed by the workflow presented in Figure 5. The method demonstrated a high precision: for concentration determination neither intraday nor interday relative standard deviation (RSD%) exceeded 10%, whereas for retention times these values did not exceed 1% (Table S-2).

Quantitation of Sugar Intermediates in Model Glycation Mixtures. The established method was applied for the absolute quantitation of carbohydrate intermediates of the Maillard reaction. For this, D-glucose (25 mmol/L) was incubated in the absence and presence of synthetic peptide as described under Materials and Methods. GC-MS analysis of the glycation mixtures, performed after phosphate removal, revealed the formation of at least eight pentose and hexose monosaccharides present at least at one time point of incubation at concentrations exceeding LOQ_m, identified by characteristic retention times and similarity of EI mass spectra (Table 2). Peak areas were derived by integration of corresponding extracted ion chromatograms at retention times specific for each sugar. Quantitation relied on external calibration in authentic matrix. For this, the standard mixture was serially diluted with glycation medium and subjected to the ion exchange-based SPE procedure prior to GC-MS.

One of the detected sugars was D-glucose, whereas the rest were intermediates of Maillard reaction, demonstrating a characteristic kinetic behavior. The formation of two of them, D-mannose and D-fructose, increased over the incubation period. In the beginning of the reaction, the concentration of D-fructose increased more quickly in comparison to D-mannose. However, after 60 min of reaction, both hexoses showed a similar kinetic behavior (Table 3), achieving maximal concentrations after 120 min of incubation (up to 10.8% of initial D-glucose concentration). Similar kinetics was observed for D-ribose (and, probably, coeluting D-ribulose and D-xylulose), although it was below the LOQ up to 60 min of incubation both in the glycation mixtures and in controls. The maximal concentration of D-ribose in the reaction mixture (0.9% of initial D-glucose concentration) was observed in the absence of peptide after 2 h of incubation. Another pentose, arabinose, showed different kinetics: its maximal concentration (0.85 mmol/L, i.e., 3.4% of the initial D-glucose concentration) was achieved after 60 min of incubation and then decreased. As GC-MS analyses of the TMS-methoximes of D- and L-arabinose individually and in a mixture showed the same chromatographic behavior for both isomers (Figure S-3), most probably arabinose formed in the incubated samples was represented with the D-isomer. 3-Deoxyglucosone, *myo*-inositol, and D-xylose were also found both in the absence and in the presence of synthetic peptide. However, their concentrations at these reaction times were below corresponding LOQs; therefore, these sugars could not be absolutely quantified in this system.

DISCUSSION

Model reactions are known to be a convenient tool for the study of the Maillard reaction in protein systems. Typically, to

[a] D-Ribose, D-ribulose, and D-xylulose were quantified as D-ribose equivalents. For all analytes, the boldfaced selective m/z and peak 1 were used for quantitation; 3-DG, 3-deoxyglucosone.

characterize the patterns of glycoxidative protein modifications, biologically relevant polypeptides, such as collagen,[25] bovine or human serum albumins (BSA and HSA, respectively),[26] were used. However, due to the large number of potential glycation sites, such mixtures are often too complex for efficient analysis of reaction pathways and mechanisms. Therefore, in the past decades, model peptide-based systems for the glycation of amino groups with selected glycation agents were established.[27] Recently we have described an advanced glycation model system based on arginine-containing peptides.[6] This approach provided adequate information about the peptide modifications and the kinetics of their formation. However, to reveal the underlying reaction mechanisms, this information needs to be complemented with knowledge about α-dicarbonyl and sugar profiles. As methods for comprehensive α-dicarbonyl analysis are well-established and reported elsewhere,[28] here we focused on carbohydrate profiling.

In the whole workflow of carbohydrate analysis, complete separation of all monosaccharides seems to be the most challenging task. Indeed, the differences in the structures of isomeric sugars are obviously too small to affect the chromatographic behavior of the analytes, and in this study, that was the case for D-ribose, D-ribulose, and D-xylulose (Figure S-1A). These three sugars could not be separated under any chromatographic conditions tested, without loss of selectivity in other sections of the chromatogram. Although Medeiros and Simoneit[29] recently separated ribose and xylulose TMS derivatives obtained without a methoximation step on a 5% phenyl-methylpolysiloxane column, their method suffered from coelution of fucose and xylose, galactose, and altrose, as well as arabitol and xylitol. Application of liquid chromatography (LC)-based techniques (LC-MS) resulted in compromised selectivity[30] and sensitivity,[31] although it can be successfully applied for the analysis of specific compound groups (e.g., dicarbonyls).[32] Remarkably, the LODs observed in this study for some monosaccharides (e.g., **1**, **3**, **7**, **11**, **12**, **13**, **15**, and **16**) and for all oligosaccharides (**18**–**22**) were lower than those observed with LC-MS,[33] GC-flame ionization detection (FID),[34] GC-MS,[23] and GC-MS/MS[35] methods. The values obtained here were also advantageous in comparison to those obtained with soft ionization techniques: ESI-MS,[36] MELDI-MS,[37] and MALDI-TOF-MS.[38] The lower method LODs and LOQs in comparison to the corresponding instrument values can be explained by different drying procedures: freeze-drying versus Speedvac. Additionally, reconstitution of dried SPE eluates in a low volume of derivatization mixture provided further increase of sensitivity due to the concentration effect (Tables 1 and S-1). Thus, in terms of both analyte coverage and selectivity, our method is, to the best of our knowledge, superior in comparison to those reported before. The sensitivity improvement can be also attributed to the double-focusing sector field mass analyzer used here, which is known for its high sensitivity.

Another challenge of multicomponent analysis is the interference between analytes and sample matrix (i.e., undefined compounds behind the scope of analysis) directly affecting

[a]D-Glucose was heated in 100 mmol/L phosphate buffer (pH 7.4) containing 18 μmol/L $FeSO_4$ in the absence and presence of synthetic peptide Ac-AFGSARASGA-NH_2 at 95 °C during 2 h. The incubated samples were subjected to mixed mode anion/cation exchange (PSMix) SPE, derivatized with MOA/MSTFA, and analyzed by GC-EI-MS. [b]Initial D-glucose concentration. [c]Percentage of the initial glucose concentration. Data are expressed as mean ± SD; blq, below the limit of quantitation. [d]3-DG, 3-deoxyglucosone. [e]D-Ribose, D-ribulose, and D-xylulose were quantified as D-ribose equivalents.

analyte signal intensities. These events, generally denoted as matrix effects, result in signal enhancement or suppression and represent thereby an essential challenge in instrumental analyses.[39] Thus, this phenomenon was described for sugars: for example, glucose was reported to enhance the signals of lysine and fumaric and citric acids in plant samples.[19] Here, we observed that sugar-derived signals themselves could be suppressed in the presence of high (100 mmol/L) phosphate concentrations (Figure 2). Indeed, as this inorganic anion can be readily derivatized with MSTFA and converted into its volatile 3-TMS ether, it is involved in retention and separation, and, when present in concentrations exceeding column capacity, might interfere with analytes. Commonly, suppression effects within the GC-MS system can be explained by the formation of active sites in the analytical system.[40] Typically, the injector is the preferred part where these active sites can emerge. This might occur when a highly abundant analyte does not undergo quantitative derivatization and, due to compromised volatility, deposits in the liner. In such cases, subsequent injections with MSTFA as the solvent can furthermore provoke an in situ derivatization of these deposited remainders yielding irreproducible memory peaks in the corresponding chromatograms. Indeed, we observed such signals in MSTFA blank runs analyzed after the samples overloaded with phosphate (data not shown). This clearly indicated that formation of active sites could be responsible for the observed suppression effect (Figure 2).

Obviously, removal of phosphate from the samples before derivatization was the only way to escape this problem. Typically, SPE is the method of choice for this. As both analytes (i.e., sugars) and contaminating phosphate anions are polar substances, our strategy relied on the use of ion exchange cartridges. Surprisingly, a comparison of the three tested materials, that is, mixed mode anion/cation exchanger (PS-Mix), strong anion (PS-OH^-), and weak anion (HR-XAW) exchangers, applied to four carbohydrates dissolved in 100 mmol/L sodium phosphate buffer, revealed a consistently better recovery from the PS-Mix material in comparison to the other two phases (Figure 3). This improvement related to additional PS-H^+ functionality of the PS-Mix cartridges most probably can be attributed to the binding of iron and sodium cations, removing them from the mobile phase, where they otherwise could induce dipoles in the carbohydrate molecules that may lead to a more anionic character of the carbohydrates increasing the interaction with the $PSOH^-$ column material.

High analyte recoveries and method precision allowed the application of our approach to in vitro glycation reactions performed with arginine-containing peptide.[6] As early glycation was not described for arginine side chains yet, this peptide can be subjected exclusively to advanced glycation, that is, interaction with α-dicarbonyls, first of all glyoxal and methylglyoxal.[41] According to our results, the detected intermediates of dicarbonyl formation were mostly hexoses and pentoses (Table 2). In most cases, their origin can be explained by known pathways of the protein Maillard reaction or simple interconversion of monosaccharides (e.g., Lobry de Bruyn–Alberda van Ekenstein rearrangement driven by proton abstraction).[42] Thus, mannose and 3-deoxyglucosone can be generated from glucose via 1,2-endiol intermediate.[42] As the presence of the peptide did not influence fructose concentrations in the reaction mixture (Table 3), it can be concluded that this monosaccharide was generated solely from free glucose. Most probably, mannose was rather reactive toward the model peptide or its degradation was catalyzed by the peptide: its abundance was much lower when incubations were performed in the presence of peptide (Table 3). The formation of *myo*-inositol (even in trace amounts) apparently identified (Figure S-4) under the conditions of incubation seems to be confusing. In animals, this polyol is synthesized from glucose-6-phosphate in two enzymatic steps.[43] However, its nonenzymatic generation, to the best of our knowledge, was not described so far.

Generally, pentoses are well-known intermediates of protein Maillard reaction and typically generated in glucose-based glycation mixtures via retroaldolization.[44] All of them, especially aldoses, are potent glycation agents and readily react with free amino groups.[45] It can be assumed that, although ribose is much less abundant in the reaction mixtures (Table 3), it has an essentially higher reactivity in comparison to arabinose (represented here, most probably, with a D-isomer (Figure S-3)). Indeed, the concentration of ribose is significantly decreased in the presence of peptide, which might indicate its enhanced autoxidation. This enhancement, in turn, can be explained by the shift of chemical equilibrium due to the reaction of sugar autoxidation products with arginine residues. The same was observed for mannose, which is known to have a relatively low glycation potential.

In conclusion, our method allowed simultaneous quantitation of carbohydrates present in model glycation systems. Gas chromatographic analyses of sugars after two-step derivatization

with MOA and MSTFA showed very good performance and can be applied to the analysis of carbohydrate patterns in Maillard reaction mixtures. The method provided high sensitivity and precision for more than 10 relevant carbohydrates. After removal of >99% phosphate with mixed-mode ion exchange SPE, at least seven sugars (Maillard reaction intermediates) were identified by GC-MS and reproducibly quantified (RSD < 10%) using the peak areas of the corresponding extracted ion chromatograms. The method for the analysis of carbohydrates in model glycation mixtures established here can be used to get better insights into the mechanisms of protein Maillard reaction and pathways of AGE formation.

providing a relatively high resolution for plant species discrimination.[17] However, the high level of sequence divergence is at the expense of sites conserved enough to standardize universal primers. In contrast, another widely utilized chloroplastic barcode, *rbcL* (large subunit of the ribulose-1,5-bisphosphate carboxylase/oxygenase gene), enables robust PCR amplification due to a high level of sequence conservation, but provides relatively poor resolution for discriminating plants at low taxonomic levels.[17,18] As a result, no single genomic region has yet been identified as the ultimate barcode, and it is often recommended that barcode regions be used in combination to meet specific research needs.[19,20]

In the present work, two noncoding regions from the chloroplast genome, the *trnL* (UAA) intron and the intergenic spacer between the *trnL* (UAA) 3′ exon and *trnF* (GAA) genes,[21] were used as DNA-barcodes for the discrimination of herbal species. Primers that anneal at conserved flanking coding regions and amplify variable noncoding sequences have long been available for these two barcode regions, and their universality has been shown with successful PCR amplifications from a wide range of taxonomic groups.[21,22,16] The rate of insertions/deletions (indels) in the two noncoding regions is at least as high as that of nucleotide substitutions.[22] The accumulation of indels is reflected by amplified fragment length polymorphisms that enable the discrimination of species based on size separation of the barcode amplicons. Such a discrimination capacity is remarkably useful in food authenticity analyses, because in the presence of multiple species in a food commodity, sequence analyses may fail to produce clean, reliable peaks from a mixture of divergent amplicons.[17] The length polymorphisms in the *trnL* (UAA) intron region of the chloroplast genome have been utilized for botanical origin authentication in food products in several studies. James and Schmidt[23] were successful in developing a simple, PCR-based assay that detects the presence of potential allergen food crops based on *trnL* (UAA) intron length polymorphisms. By taking advantage of the high fragment size resolution feature of capillary electrophoresis systems, Spaniolas et al.[24,25] displayed the potential of the *trnL* (UAA) intron length polymorphisms to identify the botanical origin of plant oils. When high-resolution melting (HRM) analysis was employed as the genotyping strategy, melting curves generated by the *trnL* (UAA) intron amplicons were sufficient to discriminate 11 nut species and detect hazelnut contamination in food products.[9] HRM analysis of the *trnL* (UAA) intron amplicons provided sufficient resolution to discriminate 13 legume species and allowed the detection of soybean (*Glycine max*)−lupine (*Lupinus* spp.) admixtures.[26] In addition, *trnL* (UAA) intron barcode-HRM analysis was successful in authenticating the Protected Designation of Origin (PDO) of legume species *Lathryus cleymenum*.[27] Utilization of a similar approach for species discrimination was also demonstrated in fruit juices.[28] With the present work, we propose a fast and reliable PCR-capillary electrophoresis (PCR-CE) barcode assay that involves the use of two plastid noncoding regions and test its efficiency to authenticate botanical origin on a set of 26 commercial herbal tea products that represent eight species that are common in herbal teas.

MATERIALS AND METHODS

Herbal Tea Samples and Reference Tissue. The herbal tea samples used in this work included 26 commercial herbal tea products in the form of tea bags. The sample set represented seven types of herbal teas commonly found in retail stores, including three single-ingredient products (sage tea, chamomile tea, and linden tea) and four blends of two herbal species (rose hip−hibiscus tea, peppermint−linden tea, peppermint−fennel tea, and anise−fennel tea). Each type of herbal tea was represented by four different commercial products from four different companies, except for peppermint−linden tea, which was represented by products from two companies. Herbal tea samples were purchased from retail stores. Because the aim of this study was to evaluate the performance of the plastid DNA-barcodes and not the herbal tea brands, company names are not provided. Samples of each herbal tea type were randomly assigned numbers (samples 1−4) regardless of the brand names.

Reference tissue samples of sage (*Salvia officinalis* L.), chamomile (*Matricaria chamomilla* L.), linden (*Tilia cordata* Mill.), rose hip (*Rosa canina* L.), hibiscus (*Hibiscus sabdariffa* L.), peppermint (*Mentha piperita* L.), fennel (*Foeniculum vulgare* Mill.), and anise (*Pimpinella anisum* L.) were obtained from Aegean University Botanical Garden and Herbarium Research and Application Center (Izmir, Turkey).

DNA Isolation. All DNA isolations were performed using a NucleoSpin Plant II Kit (Macherey Nagel, Duren, Germany) according to the manufacturer's instructions. For sample preparation, silica-dried tissue samples of reference herbal species were ground using a mortar and pestle, and 100 mg of ground tissue was used to isolate DNA. In-house admixtures of two, three, and four herbal species, prepared by mixing ground tissue from relevant reference samples, were also used for DNA extraction. Four different admixtures of pairs of herbal species (linden:peppermint; sage:anise; rose hip:chamomile; sage:linden) were prepared in two different admixing ratios of 95:5% and 99:1%. Admixtures of three (sage:anise:chamomile and linden:peppermint:chamomile) and four (chamomile:peppermint:anise:linden) herbal species were also prepared by mixing equal weights of ground reference tissue from all participant species. In the case of commercial products, the contents of multiple tea bags from each package were combined prior to sampling 100 mg of dried tissue. All DNA extractions (from reference tissue and commercial samples) were performed in two replicates. The concentration of DNA was measured using a Qubit 2.0 Fluorometer (Life Technologies, Thermo Fisher Scientific Inc., Waltham, MA, USA) with a dsDNA BR Assay Kit (Life Technologies). DNA integrity was checked on a 1.5% agarose gel.

PCR-CE Barcode Analysis. Primers that amplify the plastid *trnL* (UAA) intron (primers c and d) and the intergenic spacer between *trnL* (UAA) 3′ exon and *trnF* (GAA) gene (primers e and f) were introduced by Taberlet et al.[21] Primer sequences from the 5′ to 3′ direction are as follows: primer c, CGAAATCGGTAGACGCTACG; primer d, GGGGATAGAGGGACTTGAAC; primer e, GGTTCAAGTCCCTCTATCCC; and primer f, ATTTGAACTGGTGACACGAG. For simplicity, the two plastid barcodes are here named after the amplification primers as plastid-cd (Pl-cd) and plastid-ef (Pl-ef). Barcode regions were amplified in 20 μL reaction mixtures containing 1× Colorless GoTaq Flexi PCR buffer, 1.5 mM $MgCl_2$, 0.25 mM of each deoxyribonucleotide triphosphate (dNTP) (Promega Corp., Madison, WI, USA), 1 U of GoTaq G2 Flexi DNA Polymerase (Promega Corp.), 0.25 μM of each primer, and 5 ng of template DNA. Thermal cycling conditions consisted of one cycle of initial denaturation for 10 min at 94 °C, followed by 35 cycles of 94 °C for 30 s, 62 °C for 30 s, and 72 °C for 60 s, with a final extension step of 10 min at 72 °C. PCR mixtures with an alternative DNA polymerase [Q5 High-Fidelity DNA Polymerase (New England Biolabs Inc., Ipswich, MA, USA)] were prepared in a volume of 25 μL and contained 1× Q5 Reaction Buffer, 0.2 mM of each deoxyribonucleotide triphosphate (dNTP) (Promega Corp.), 0.5 U of Q5 High-Fidelity DNA Polymerase (New England Biolabs Inc.), 0.50 μM of each primer, and 5 ng of template DNA. Thermal cycling conditions consisted of one cycle of initial denaturation for 30 s at 98 °C, followed by 35 cycles of 98 °C for 10 s, 62 °C for 20 s, and 72 °C for 30 s, with a final extension step of 2 min at 72 °C. Barcode amplicons in the 96-well microtiter plates used for PCR amplification were directly loaded on a Qiaxcel Advanced capillary electrophoresis system (Qiagen, Valencia, CA, USA). No postamplification treatment was

Table 1. Barcode Amplicon Sizes of the Eight Herbal Species Used in This Study

herbal species	barcode Pl-cd [*trnL* (UAA) intron]	barcode Pl-ef (*trnL*−*trnF* intergenic spacer)	GenBank accession no.
Foeniculum vulgare	340 bp and 582 bp	434 bp	KT003613
Hibiscus sabdariffa	573 bp	260 bp and 469 bp	KT003612
Matricaria chamomilla	488 bp	442 bp	KT003608
Mentha piperita	580 bp	368 bp	KT003610
Pimpinella anisum	602 bp	432 bp	KT003611
Rosa canina	614 bp	472 bp	KT003614
Salvia officinalis	558 bp	370 bp	KT003607
Tilia cordata	628 bp	459 bp	KT003609

applied to the samples. The sample loading procedure did not involve a post-PCR labeling step, as the capillary cartridges provided with Qiaxcel DNA High Resolution Kits (Qiagen) are ready-to-use and filled with the staining dye−gel mixture. QX DNA Size Marker 50−800 bp, v2.0 (Qiagen) was used as the size standard, and QX Alignment Marker 15 bp/1000 bp (Qiagen) was used for aligning the size standard fragments. The high-resolution run method OM800 was applied with a sample injection time of 10 s. QIAxcel ScreenGel Software (Qiagen) was used for visualization of the barcode profiles. PCR-CE barcode assays were performed in three replicates for each DNA sample, and capillary electrophoresis runs were performed in two replicates.

Barcode DNA Sequencing. Primers that amplify the two barcodes, Pl-cd and Pl-ef, were used for dye-terminator sequencing. Sequencing targets were amplified in 20 μL reaction mixtures containing 1× Colorless GoTaq Flexi PCR buffer, 1.5 mM $MgCl_2$, 0.25 mM of each deoxyribonucleotide triphosphate (dNTP) (Promega Corp.), 1 U of GoTaq G2 Flexi DNA Polymerase (Promega Corp.), 0.25 μM of each primer, and 5 ng of template DNA. Thermal cycling conditions consisted of one cycle of initial denaturation for 10 min at 94 °C, followed by 35 cycles of 94 °C for 30 s, 62 °C for 30 s, and 72 °C for 45 s, with a final extension step of 10 min at 72 °C. For each reference/herbal tea sample, PCR reactions were performed in five replicates and combined during the purification step with the DNA Clean & Concentrator-5 Kit (Zymo Research, Irvine, CA, USA). Purified PCR products were used as template in dye-terminator sequencing reactions, prepared using GenomeLab DTCS Quick Start Kit (Beckman Coulter, Brea, CA, USA) according to the manufacturer's instructions. Sequencing reaction thermal cycling conditions were 30 cycles of 96 °C for 20 s, 50 °C for 20 s, and 60 °C for 4 min. The reaction mixture for each amplicon was then purified using ZR DNA Sequencing Clean-up Kit (Zymo Research), resuspended in 30 μL of sample loading solution (Beckman Coulter), and run on a Beckman CEQ8800 capillary electrophoresis device using the LFR-b method (injection voltage 2.0 kV for 10−15 s, separation temperature of 57 °C, separation voltage of 6.0 kV, separation time of 60 min). Sequence peaks were visualized with the "Sequencing" module of Beckman CEQ8800 software version 8.0 (Beckman Coulter). Alignment and assembly of sequences from forward and reverse directions and alignment of reference and sample sequences were performed using the "Investigator" module of the CEQ 8800 (Beckman Coulter) software. The MEGA V6.0 computer program[29] was used for cross-species sequence alignments with the ClustalW method. Homology search in GenBank Nucleotide Collection was carried out using "nucleotide blast" as the BLAST program with the "megablast" option optimized for identifying highly similar sequences. BankIt sequence submission tool (http://www.ncbi.nlm.nih.gov/WebSub/?form=history&tool=genbank) was used for sequence submission to the GenBank database.

RESULTS

Identification of Species Origin in Herbal Tea Products Using the PCR-CE Barcode Assays. The two plastid barcodes (barcode Pl-cd and barcode Pl-ef) were amplified using the DNA from the 8 reference samples and 26 commercial herbal tea products. Barcode amplicons were directly loaded on the capillary electrophoresis system without any post-PCR treatment. Because amplicons from the reference samples constituted the standards in the analysis, they were run simultaneously with the amplicons from the commercial tea samples. Sizes of the barcode amplicons are given in Table 1. A single fragment amplification pattern was observed for all of the species except for fennel and hibiscus, which yielded double bands for barcodes Pl-cd and Pl-ef, respectively. All eight herbal species displayed distinctive fragments with no two species yielding fragments of identical size for either of the two barcodes. The amplicon size of barcode Pl-cd ranged between 340 and 614 bp, whereas barcode Pl-ef amplicons ranged between 260 and 472 bp for the eight species. For barcode Pl-cd, the minimum fragment size difference (2 bp) was observed between fennel and peppermint, which produced fragments of 582 and 580 bp, respectively. However, fennel also displayed an additional 340 bp fragment in its barcode Pl-cd profile. For barcode Pl-ef, the minimum fragment size difference was 2 bp and was observed for fennel (434 bp) and anise (432 bp) and also sage (370 bp) and peppermint (368 bp) (Table 1). Similarly, rose hip and hibiscus produced barcode Pl-ef fragments of similar, but not identical, size (472 and 469 bp), with the latter yielding an additional band of 260 bp in its profile.

For the sage reference sample, the fragment sizes of the two barcodes were 558 and 370 bp for barcodes Pl-cd and Pl-ef, respectively (Table 1). Barcode sizes of all four commercial sage tea samples matched those of the standard reference (Figure 1), and no additional, unexpected fragments were observed for any of the samples in any of the replicate experiments. Therefore, we concluded that the botanical origins of the tested commercial sage tea products were true-to-label.

The chamomile reference sample gave Barcode Pl-cd and Pl-ef fragment sizes of 488 and 442 bp, respectively (Table 1). Barcode Pl-cd and Barcode Pl-ef profiles of three commercial chamomile tea samples (Figure 2, panels II−IV) perfectly matched with those of the reference sample, proving their identity as authentic chamomile tea. However, sample 4 (Figure 2, panel V) produced profiles that were inconsistent with the reference for both barcodes. In addition to the single 488 bp band expected for chamomile tea, sample 4 yielded an additional band of 564 bp length for barcode Pl-cd (Figure 2A, panel V). The barcode Pl-ef assay also produced an extra 359 bp band from sample 4, which was not expected for chamomile (Figure 2B, panel V). Similar results were obtained in all three replicate experiments with the two barcodes. Therefore, results of both barcode assays were in agreement and implied that sample 4 was either adulterated or contaminated with a plant species other than chamomile.

For the linden reference sample, the barcode Pl-cd and Pl-ef fragment lengths were 628 and 459 bp, respectively (Table 1).

Sample order is the same for rows A and B: I, sage reference sample; II, sage tea sample 1; III, sage tea sample 2; IV, sage tea sample 3; V, sage tea sample 4.

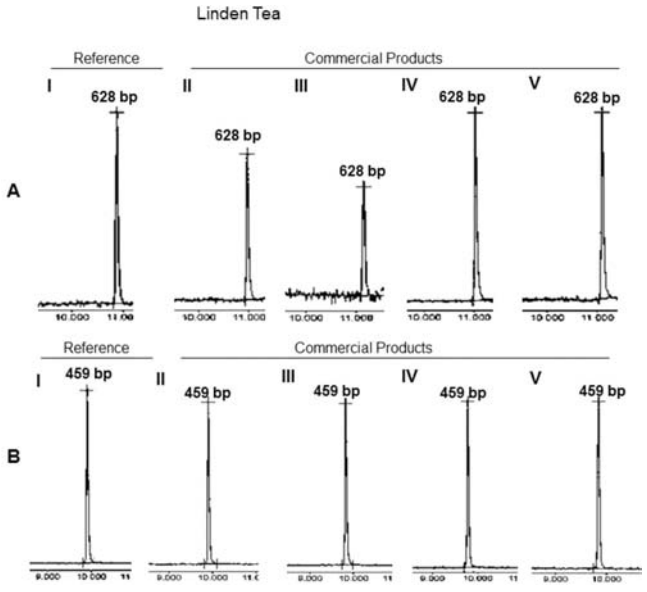

Figure 3. Capillary electropherograms displaying the results of the PCR-CE barcode assays applied on linden tea samples: (A) barcode Pl-cd assay; (B) barcode Pl-ef assay. Sample order is the same for rows A and B: I, linden reference sample; II, linden flower tea sample 1; III, linden flower tea sample 2; IV, linden flower tea sample 3; V, linden flower tea sample 4.

PCR-CE barcode analysis results of the reference and the four commercial linden flower tea samples were in concordance in all three replicate experiments, identifying the commercial samples as authentic linden tea (Figure 3). Peppermint−linden blends were also examined. According to the product labels, the ratio of peppermint in peppermint−linden blends was 20% for sample 1 and 30% in sample 2. The peppermint reference amplicons were 580 and 368 bp for barcodes Pl-cd and Pl-ef, respectively (Table 1). The two peppermint−linden commercial samples were successfully resolved by both barcodes with each barcode electropherogram displaying double bands of

sizes identical to the references (Figure 4). In addition, no unexpected band other than the two species-specific fragments was observed in any of the replicate experiments with the two barcodes; therefore, the botanical origin of the two commercial products was identified as a blend of peppermint and linden as indicated on the labels.

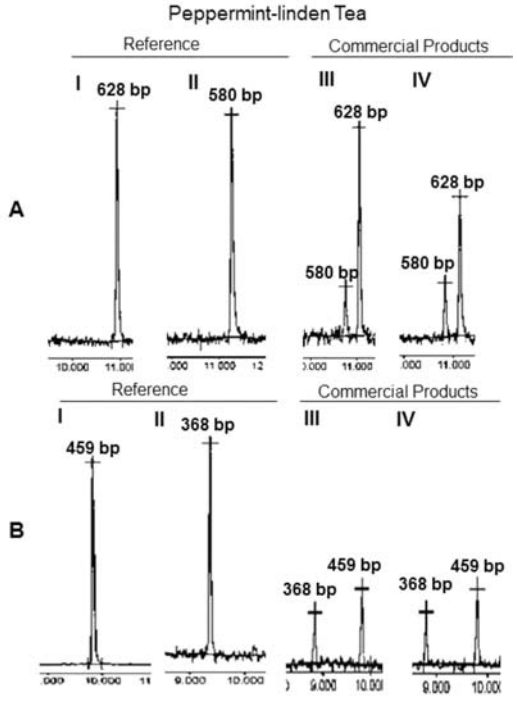

Figure 4. Capillary electropherograms displaying the results of the PCR-CE barcode assays applied on peppermint−linden tea samples: (A) barcode Pl-cd assay; (B) barcode Pl-ef assay. Sample order is the same for rows A and B: I, linden reference sample; II, peppermint reference sample; III, peppermint−linden tea sample 1; IV, peppermint−linden tea sample 2.

All four rose hip tea samples included in this work were blends of rose hip and hibiscus. The ratios of rose hip:hibiscus blends declared on the product labels were 70:30% for samples 1 and 3 and 60:40% for samples 2 and 4. Rose hip and hibiscus reference samples yielded barcode Pl-cd fragments of 614 and 573 bp, respectively (Table 1). Barcode Pl-cd analysis of the four commercial products was successful in clearly identifying both rose hip- and hibiscus-specific fragments (Figure 5A), and no additional band was observed to suspect the presence of undeclared plant material in the samples. The barcode Pl-ef profile of the hibiscus reference had two bands of 260 and 469 bp, whereas the rose hip reference produced a single 472 bp fragment (Table 1). When the commercial products were analyzed, the hibiscus-specific 260 bp fragment was readily identifiable in all four samples. However, the second, larger fragment could not be resolved by the capillary electrophoresis system in any of the replicate experiments because of the size similarity between the rose hip- and hibiscus-specific fragments (472 vs 469 bp) (Figure 5B, ,panels III−VI). As a result, whereas the presence of hibiscus in the samples was apparent by the presence of the 260 bp fragment, the mixture of the 472 and 469 bp fragments was identified as a single band within a size range of 470−472 bp. Nevertheless, barcode Pl-cd alone allowed distinguishing of species-specific amplification profiles when tested on rose hip−hibiscus blends.

Two types of fennel tea blends (anise−fennel tea and peppermint−fennel tea) were included in our analyses. Commercial samples of anise−fennel blends were labeled as either "fennel tea" or "anise−fennel tea" but always included anise in the list of ingredients. The ratio of anise in the blend was declared on the label of one product (sample 2) as 10%,

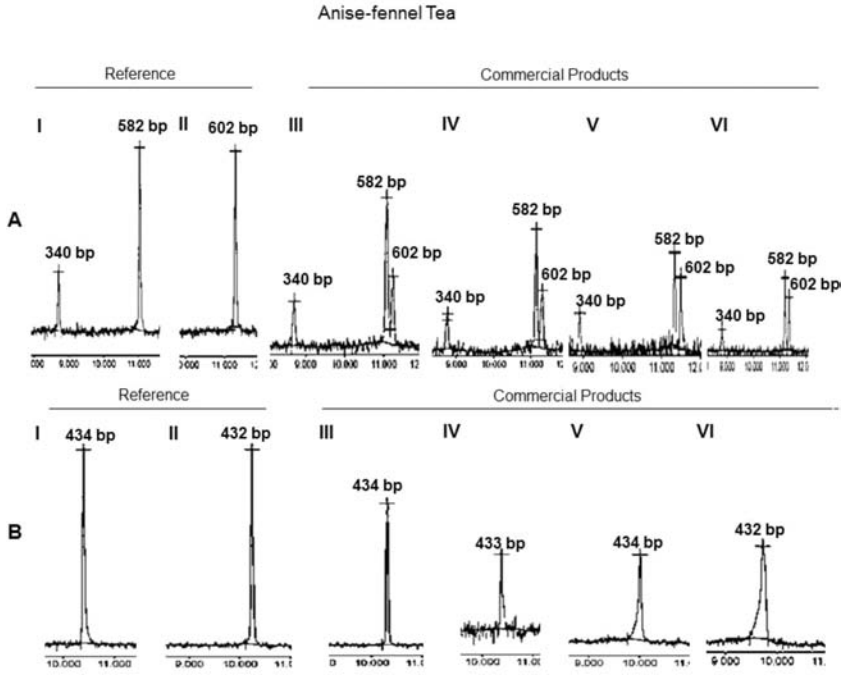

Figure 6. Capillary electropherograms displaying the results of the PCR-CE barcode assays applied on anise−fennel tea samples: (A) barcode Pl-cd assay; (B) barcode Pl-ef assay. Sample order is the same for rows A and B: I, fennel reference sample; II, anise reference sample; III, anise−fennel tea sample 1; IV, anise−fennel tea sample 2; V, anise−fennel tea sample 3; VI, anise−fennel tea sample 4.

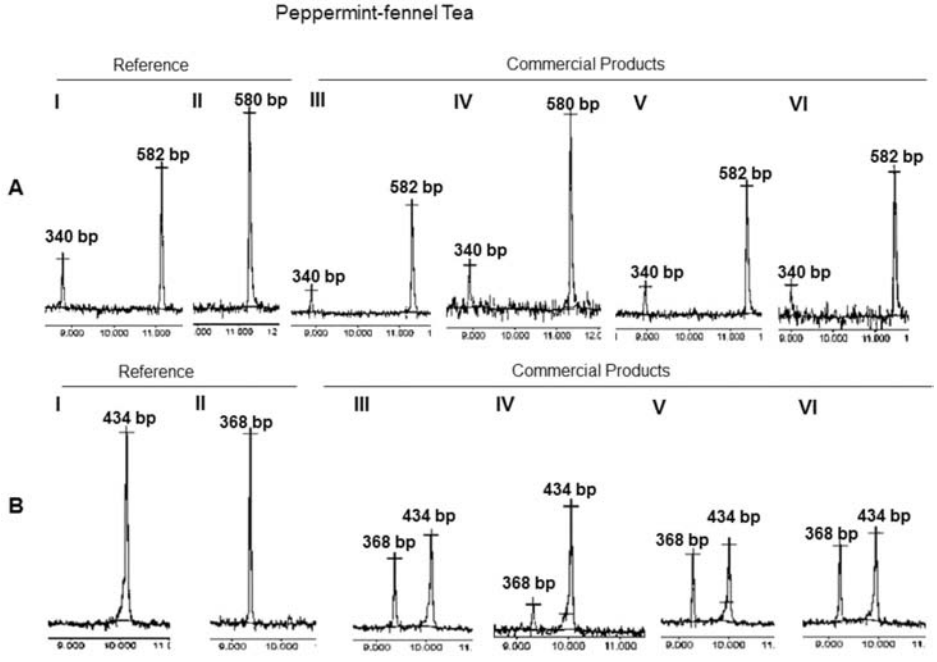

Figure 7. Capillary electropherograms displaying the results of the PCR-CE barcode assays applied on peppermint−fennel tea samples: (A) barcode Pl-cd assay; (B) barcode Pl-ef assay. Sample order is the same for rows A and B: I, fennel reference sample; II, peppermint reference sample; III, peppermint−fennel tea sample 1; IV, peppermint−fennel tea sample 2; V, peppermint−fennel tea sample 3; VI, peppermint−fennel tea sample 4.

but no ratio information was included in the ingredients list for the remaining three samples. The barcode Pl-cd amplification profile of fennel reference sample produced two bands of 340 and 582 bp, and the anise reference yielded a single 602 bp fragment (Table 1). All three fragments representing the two species were resolved by the capillary electrophoresis system, clearly displaying the presence of both species in the samples (Figure 6A). In addition, there were no unexpected amplicons in the profiles of the commercial samples to suspect contamination or adulteration. Fennel and anise references produced barcode Pl-ef amplicons of similar size (434 and 432 bp) (Table 1). Although we were able to reproducibly distinguish the two species from each other when amplicons from individual reference samples were run simultaneously, fennel- and anise-specific barcode Pl-ef fragments could not be resolved when amplified from the tea blends. Such samples had

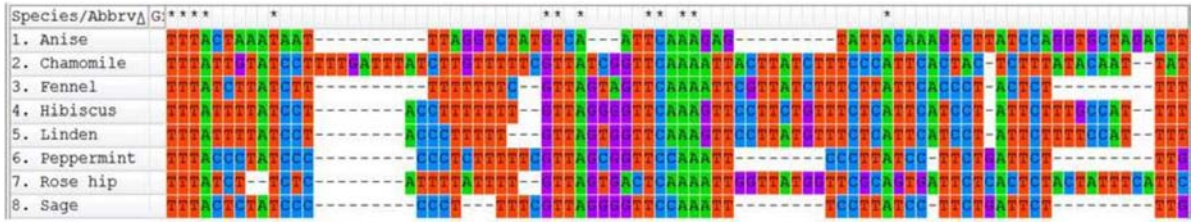

Figure 8. Portion of the alignment of plastid intergenic spacer (*trnL* (UAA) 3′ exon−*trnF* (GAA) gene) nucleotide sequences displaying indels and substitutions among eight herbal species.

single fragments of 432, 433, or 434 bp (Figure 6B, panels III−VI). Hence, barcode Pl-cd analysis was required to correctly identify the fennel−anise tea blends. For peppermint−fennel teas, blend ratio information was supplied on the labels of samples 1 and 2 as 90% fennel:10% peppermint. Barcode Pl-cd and Pl-ef amplicon sizes of the peppermint reference sample were 580 and 368 bp, respectively (Table 1). Because the 582 bp fragment from fennel and 580 bp fragment from peppermint could not be resolved, a two-fragment pattern with the 340 bp fennel-specific band and a larger band of either 580 (Figure 7A, panel IV) or 582 bp (Figure 7A, panels III, V, and VI) was observed for the peppermint−fennel tea samples as a result of barcode Pl-cd analysis. On the other hand, barcode Pl-ef was successful in clearly identifying the species-specific fragments of 434 bp (fennel) and 368 bp (peppermint) (Figure 7B). No unexpected barcode amplicon was observed in any of the replicate experiments to suspect the authenticity of the peppermint−fennel tea samples.

Sequencing Barcode Amplicons from Reference and Commercial Herbal Tea Samples. The two noncoding plastid barcodes used in this work represent single-copy sequences, as they are intended for use in plant phylogenetic inference.[21] Therefore, amplification profiles of both barcodes should have single fragments, and additional bands of lower intensity are regarded as nonspecific. Because the barcode Pl-ef amplification profile of hibiscus involved two fragments, only the larger fragment (469 bp), which was of comparable size with those from the remaining herbal species, was isolated from agarose gel for sequencing. Similarly, Spaniolas et al.[24] reported extra fragments in the *trnL* (UAA) intron amplification profiles of soybean (*Glycine max*) and corn (*Zea mays*), which they regarded as unspecific PCR byproducts. Alignment of barcode Pl-ef sequences from reference samples revealed several insertions/deletions of variable size among the sequences from the eight species, which resulted in the length polymorphisms among the barcode amplicons (Figure 8).

To verify the sequence identity between barcode amplicons from the reference samples and the commercial products, barcode fragments from the commercial tea samples were also sequenced. For the three single-ingredient herbal teas (sage, linden, and chamomile), barcode-Pl-ef sequences from the tea samples perfectly matched those from the references (data not shown). To identify the contaminant/adulterant species in chamomile tea sample 4, the extra fragments that appeared in the barcode Pl-cd (Figure 2A, panel V) and Pl-ef (Figure 2B, panel V) profiles of the sample were isolated from agarose gel and sequenced. Genbank database search identified the highest identity scores for homologous sequences from the *Rosmarinus officinalis* (rosemary) plastid genome for both barcodes. According to the BLAST homology search results, barcode Pl-cd sequence from the contaminant/adulterant species displayed an identity score of 96% with the rosemary sequence deposited under GenBank accession no. AY540465.1. Similarly, a 99% identity score was displayed for the barcode Pl-ef sequence and a rosemary plastid sequence entry (GenBank accession no. FJ490792.1). As a result, we predicted that rosemary was the source of the unexpected barcode fragments in the chamomile tea. Barcode Pl-ef PCR products from the commercial peppermint−fennel and peppermint−linden tea samples were separated by agarose gel electrophoresis to isolate species-specific fragments separately for sequencing. In concordance with the results of the PCR-CE barcode assays, sequences obtained from the commercial samples exactly matched the peppermint, fennel, and linden reference barcode sequences. Because barcode Pl-ef amplicons of rose hip and hibiscus (Figure 5B) and fennel and anise (Figure 6B) could not be resolved due to their size similarity, species-specific fragments of barcode Pl-cd were isolated and sequenced for the rose hip−hibiscus and anise−fennel commercial tea samples. Alignment of the sequence electropherograms showed that barcode sequences from the commercial tea samples were identical with the reference sequences for all four herbal species, thereby validating the results of the PCR-CE barcode analyses.

Determining the Threshold of Admixture Detection. To test the efficiency of the proposed methodology to identify blends of more than two herbal species and set a threshold of admixture detection, barcode Pl-cd assay was applied on in-house blends prepared using reference herbal samples (Figures 9 and 10). To improve the confidence in assessing the performance of the proposed methodology, experiments were carried out using two different types of DNA polymerases. The two admixtures prepared with tissue from three herbal species contained 33% of each species in the blends. The barcode Pl-cd assay was successful in identifying the botanical origin of the two blends as admixtures of sage, anise, and chamomile (Figure

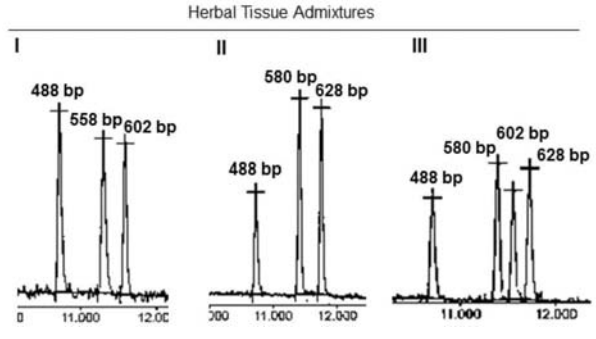

Figure 9. Capillary electropherograms displaying the results of the barcode Pl-cd assay applied on reference tissue admixtures of three and four herbal species. I, chamomile, sage, anise; II, chamomile, peppermint, linden; III, chamomile, peppermint, anise, linden.

DOI: 10.1021/acs.jafc.5b01255

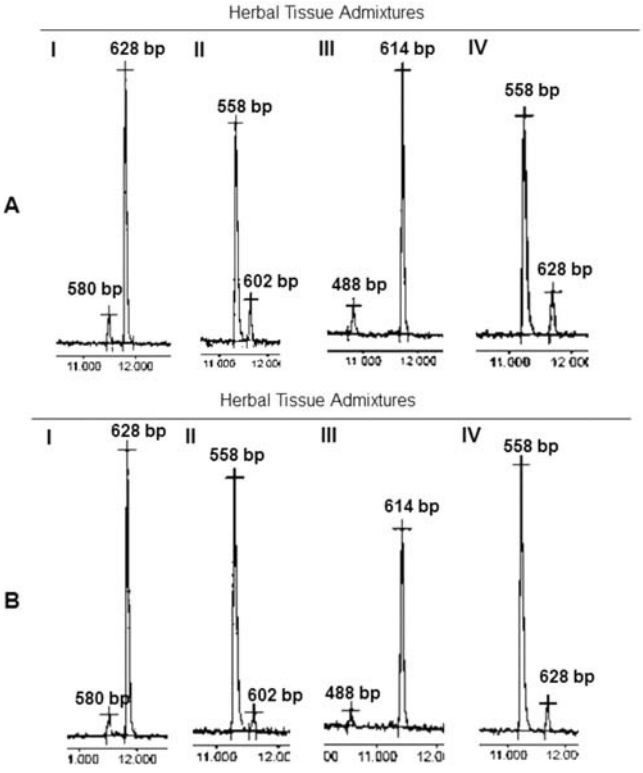

Figure 10. Capillary electropherograms displaying the results of the barcode Pl-cd assay applied on reference tissue admixtures of two herbal species: (A) 95:5% blends; (B) 99:1% blends. (A) I, 95% linden:5% peppermint; II, 95% sage:5% anise; III, 95% rose hip:5% chamomile; IV, 95% sage:5% linden. (B) I, 99% linden:1% peppermint; II, 99% sage:1% anise; III, 99% rose hip:1% chamomile; IV, 99% sage:1% linden.

9, panel I) and linden, peppermint, and chamomile (Figure 9, panel II). The admixture of four herbal species contained 25% of each species in the blend. When the barcode Pl-cd assay was applied on the admixture, barcode fragments of all four species (chamomile, peppermint, anise, and linden) were successfully resolved. Thus, the sample was correctly identified as a blend of four different species (Figure 9, panel III). Linden:peppermint, sage:anise, rose hip:chamomile, and sage:linden admixtures were prepared in two sets that contained the minor constituent at ratios of 5 and 1% in the blends. When the barcode Pl-cd assay was applied on these admixtures, barcode amplicons from the minor constituents (peppermint, anise, chamomile, and linden, respectively) were readily identifiable in all of the samples for both admixing ratios (Figure 10). Parallel experiments with both DNA polymerases (GoTaq G2 Flexi DNA Polymerase, Promega Corp.; and Q5 High-Fidelity DNA Polymerase, New England Biolabs Inc.) produced similar results with similar barcode amplicon peak heights obtained from the minor constituents (data not shown). As a result, the threshold of admixture detection of the proposed methodology was set as 1%.

DISCUSSION

It is almost impossible to identify substitution or contamination in herbal products because morphological features are lost during the processing of herbs into powders or fragmented products.[2] Identification often requires sophisticated analytical chemistry methods or diagnostic molecular approaches. In addition, substitution can easily be masked with food colorants and aromatics, resulting in products with indistinguishable color, taste, and smell. As a result, herbal products constitute an easy target for fraud or mislabeling, as evidenced by recent DNA-based studies that report a high frequency of substitution in herbal teas[1] and supplements.[2,14,15]

In this work, we tested the performance of plastid noncoding DNA length polymorphisms to authenticate the botanical origin of herbal teas. The plastid *trnL* (UAA) intron used in this work (barcode Pl-cd) was reported as a region of significant size variation, when sequences flanked by primers c and d[21] were compared for 706 plant species corresponding to 366 genera and 116 families.[16] Similarly, interspecific length polymorphisms that allowed species discrimination even within the same genus were shown for the plastid intergenic spacer [*trnL* (UAA) 3′ exon−*trnF* (GAA) gene],[21] which was used as the second barcode (barcode Pl-ef) in our study. By taking advantage of the length polymorphisms in the two noncoding barcode regions, we were able to verify the botanical origin and detect the presence of undeclared plant material in the tested herbal tea samples. For our sample set, the lowest ratio of an ingredient (10%) was declared for anise and peppermint in anise−fennel and peppermint−fennel blends. Our results showed that we could clearly detect the presence of a minor ingredient in a commercial sample with the PCR-CE assays (Figures 6A, panel IV, and 7B, panels III and IV). When the barcode Pl-cd assay was applied on herbal tissue admixtures of more than two species, all herbal constituents in the blends were correctly identified. Moreover, herbal ingredients present in minor quantities as low as 1% were readily detected in the tested blends. In addition, two different DNA polymerases were equally efficient in amplifying the barcode fragment from minor constituents to detectable quantities. As a result, the limit of the proposed methodology to identify herbal tissue admixtures was identified as 1%. We attribute this result to our barcode choice. Due to its high copy number in plant cells, the plastid genome is an ideal target for working with mixed samples of multiple species origin or highly processed samples with degraded DNA.[16]

Following a similar PCR-CE approach, Spaniolas et al.[24,25] used *trnL* (UAA) intron length polymorphisms for the authentication of the botanical origin of plant oils. While they were able to obtain barcode fragments of identical size as the references when they applied the PCR-CE assay on DNA from single plant species, amplicons with small size differences could not be resolved by the capillary electrophoresis system when PCR fragments from multiple species were analyzed. We also observed the problem of resolving small fragment size differences of 2−3 bp with barcode Pl-ef (Figure 5) and barcode Pl-cd (Figure 7A), when barcode amplicons from tea blends were analyzed. However, the use of a second barcode solved this problem in all three cases (Figures 5A, 6A, and 7B), resulting in the successful identification of herbal species in the tea blends. Thus, our results highlight the importance of using a combination of barcode regions to achieve sufficient species resolution. The use of barcode combinations is also valid when sample genotyping is based on sequencing. For example, Stoeckle et al.[1] investigated the authenticity of commercial herbal teas based on *rbcL* and *matK* sequences and reported that readable sequences could be obtained from 77 and 79% of the samples when *rbcL* and *matK* regions were sequenced, respectively. However, the success rate for sequencing either of the markers was much higher (90%). In our study, we

DOI: 10.1021/acs.jafc.5b01255
J. Agric. Food Chem. 2015, 63, 5920−5929

established reference barcode fragment length profiles and reference barcode sequences using reference tissue samples of the eight herbal species. We assessed the authenticity of the commercial samples by running reference and sample barcode amplicons simultaneously on the capillary electrophoresis. Thus, we were able to compare the electrophoretic mobility of the barcode amplicons from samples and references with high confidence. In addition, we verified our PCR-CE analysis results by comparing the reference and sample barcode sequences. Because we performed reference sequencing in our study, we did not face the problem of finding barcode sequences from the relevant species in public databases. When a reference sample set is not employed, the success of identifying the botanical origin of a sample depends on the availability of sequence for the species in the databases. For example, Stoeckle et al.[1] reported that barcode sequence records were missing in the GenBank database for about one-third of the herbal species listed on the labels of the tea samples they examined. In addition, it should be noted that, even when a sequence match is identified from a database, there is no certainty that the sequence entry is from a correctly identified plant.[2]

In this work, we used plastid DNA length polymorphisms for the authentication of botanical origin in herbal teas. While species identification based on barcode sequencing works well with single-ingredient samples, sequencing reactions may fail to produce clean, reliable sequences from samples of multiple species due to sequence divergence.[17] In that respect, barcode size variations improve the success rate in sequencing by enabling fragment isolation from a mixture of amplicons. By taking advantage of mitochondrial DNA length polymorphisms, Pun et al.[30] proposed a methodology that involved PCR fragment separation followed by sequencing for the identification of species from mixed samples of unknown identity. Barcode fragment size-based tests are especially suitable for food analyses, because species origin authentication of food products aims at identifying whether a sample is true-to-label or not. Therefore, it is feasible to set standards by analyzing sample barcode fragments with respect to barcode profiles of ingredients listed on the product label. Any deviation from the standards (i.e., reference profiles of the listed ingredients) can be further investigated by taking advantage of barcode length polymorphisms to separate and isolate the alien fragment for sequencing. By following such an approach, we were able to isolate and sequence contaminant/adulterant barcode amplicons from the suspected chamomile tea sample and search public databases for homologous sequence matches. On the basis of our results, we predicted that chamomile tea sample 4 contained rosemary and was mislabeled as a single-ingredient product.

It is important to note that the utility of the PCR-CE barcode assays proposed in this work is not limited to herbal teas but can be extended to authenticate all types of processed herbal products or raw material. When an appropriate genomic region with sufficient interspecific size variation is selected as the analyte, capillary electrophoresis analysis is a faster, more cost-efficient, less equipment and labor/expertise demanding, and relatively simple alternative to sequencing for herbal product authenticity analyses. PCR-CE assays can be standardized for individual products by employing references based on the ingredients list and applied as routine tests for the verification of botanical origin. PCR-CE assays can also be coupled with sequencing any time adulteration is suspected in a sample.

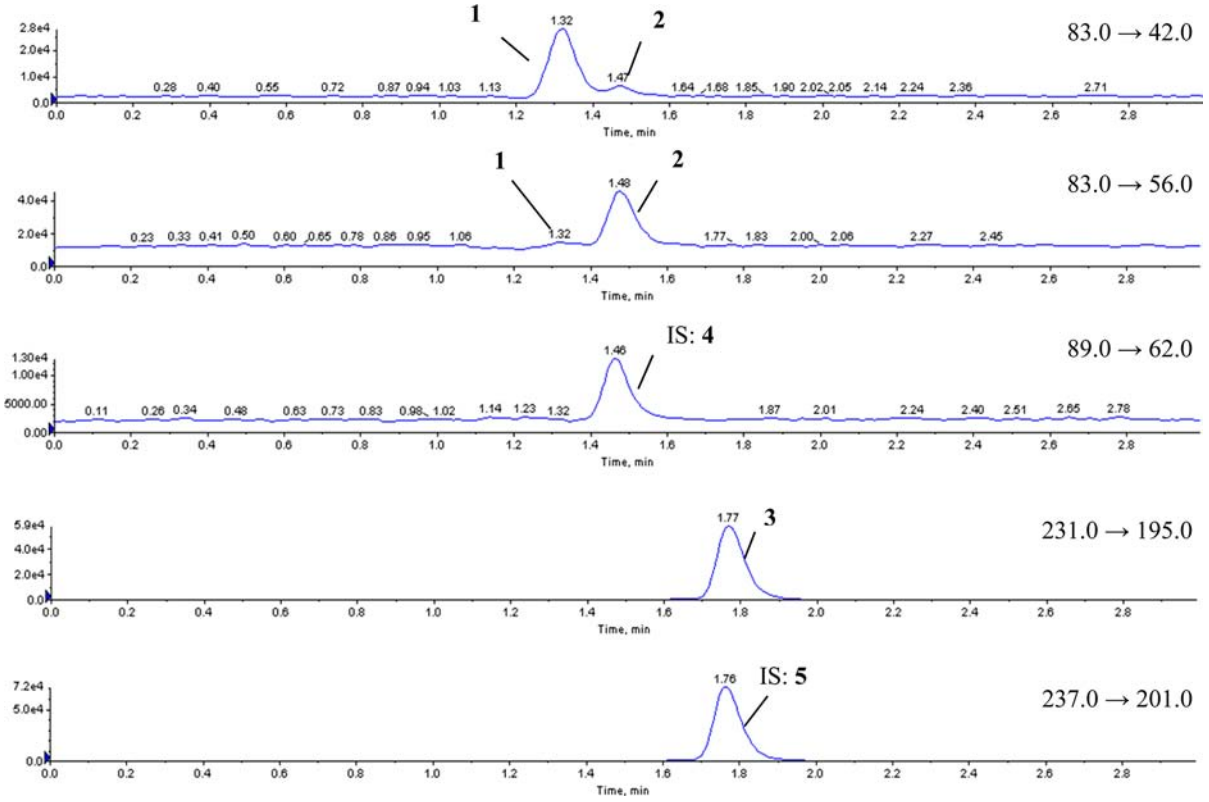

Figure 2. LC-MS/MS mass traces of the calibration standard solution at concentration levels of 0.51 ng/mL for 2-methylimidazole (**1**), 0.50 ng/mL for 4-methylimidazole (**2**), and 0.94 ng/mL for 2-acetyl-4-(1,2,3,4-tetrahydroxybutyl)imidazole (**3**).

ammonium chloride as a source of nitrogen, even though the high temperatures of 120−160 °C applied for the production of caramel food colorings would not be reached. This question was addressed in this study.

Analysis of the considered imidazoles is typically carried out by liquid chromatography−tandem mass spectrometry (LC-MS/MS) as their analysis by gas chromatography usually involves laborious derivatization reactions.[8,9] The available literature describes various methods for the determination of **1**−**3** in different matrices; however, only a few published methods exist for their simultaneous quantitation.[10,11] For example, Wang and Schnute described a UHPLC-MS/MS methodology using 4-methylimidazole-d_3 as an internal standard for their simultaneous determination in beverages using basic eluents under isocratic conditions on a C_{30} separation phase.[10] Schlee et al. published a method for the quantitation of **1**−**3** in caramel food colorings and cola beverages by LC-MS/MS with gradient elution under basic condition on a common C_{18} column without the use of an internal standard.[11]

Here we present an analytical method for the simultaneous and selective determination of the imidazoles **1**−**3** in licorice and other foodstuffs by high-performance liquid chromatography−tandem mass spectrometry applying stable-isotope dilution analysis (SIDA).[12,13] Chromatographic separation was achieved on a common C_{18} reversed-phase column within 3 min. Detection was carried out with the MS/MS system operating in multiple reaction monitoring (MRM) mode.

MATERIALS AND METHODS

Chemicals and Reagents. **1** and **2** were obtained from Sigma-Aldrich (Taufkirchen, Germany), **3** and [$^{13}C_6$]-2-acetyl-4-(1,2,3,4-tetrahydroxybutyl)imidazole (**5**, see Figure 1) were from ELFI Analytik GbR (Neufahrn, Germany), and 4-methylimidazole-d_6 (**4**, see Figure 1) was from Dr. Ehrenstorfer (Augsburg, Germany). HPLC grade methanol was purchased from Bernd Kraft (Duisburg, Germany), whereas formic acid, ammonia, potassium hexacyanoferrate(II) trihydrate, and zinc sulfate heptahydrate of analytical grade were from Merck (Darmstadt, Germany). Licorice samples (ammonium chloride content ≤2%) were purchased in local retail stores. Licorice products for the model assay were provided by the testing facility of a major German licorice manufacturer.

Stock Solutions. Stock solutions of **1**, **2**, and **4** were prepared by dissolving a suitable amount of the respective chemical in a mixture of methanol and purified water (MeOH/H_2O, 50:50 v/v) to obtain a concentration of 1 mg/mL. Stock solutions of **3** and **5** were prepared by dissolving a suitable amount of the respective substance in 0.1 M hydrochloric acid. Calibration levels of all analytes and internal standards were prepared by dilution of the respective stock solution with MeOH/H_2O (50:50 v/v) to obtain a respective concentration of 5 μg/mL. A calibration standard solution was prepared by mixing the standard solutions of **1**−**5** in MeOH/H_2O (50:50 v/v) and contained 5 ng/mL of **1**, **2**, and **4** as well as 10 ng/mL of **3** and **5**. This solution was further diluted with purified water (1:10). Internal standard solutions of **4** and **5** were prepared by appropriate dilution of the stock solutions with MeOH/H_2O (50:50 v/v) to a final concentration of 100 μg/mL.

Sample Preparation. All samples were finely ground and stored at room temperature prior to analysis. For equilibration, each sample (4 g) was placed in a 100 mL iodine determination flask, spiked with **4** (5 ng/mL, 200 μL) and **5** (10 ng/mL, 150 μL), and incubated at room temperature for 30 min. For extraction of the imidazoles methanol/water (50:50 v/v, 50 mL) was added, and the mixture was stirred for 30 min, followed by another volume of methanol/water (50:50 v/v, 50 mL) and subsequent sonication for 15 min at room temperature. Removal of proteins was achieved following the procedure of Carrez (150 g potassium hexacyanoferrate(II) trihydrate/L, 300 g zinc sulfate heptahydrate/L; 500 μL each). Finally, after filtration through a folded filter (Whatman, Germany), the obtained filtrates were diluted (for

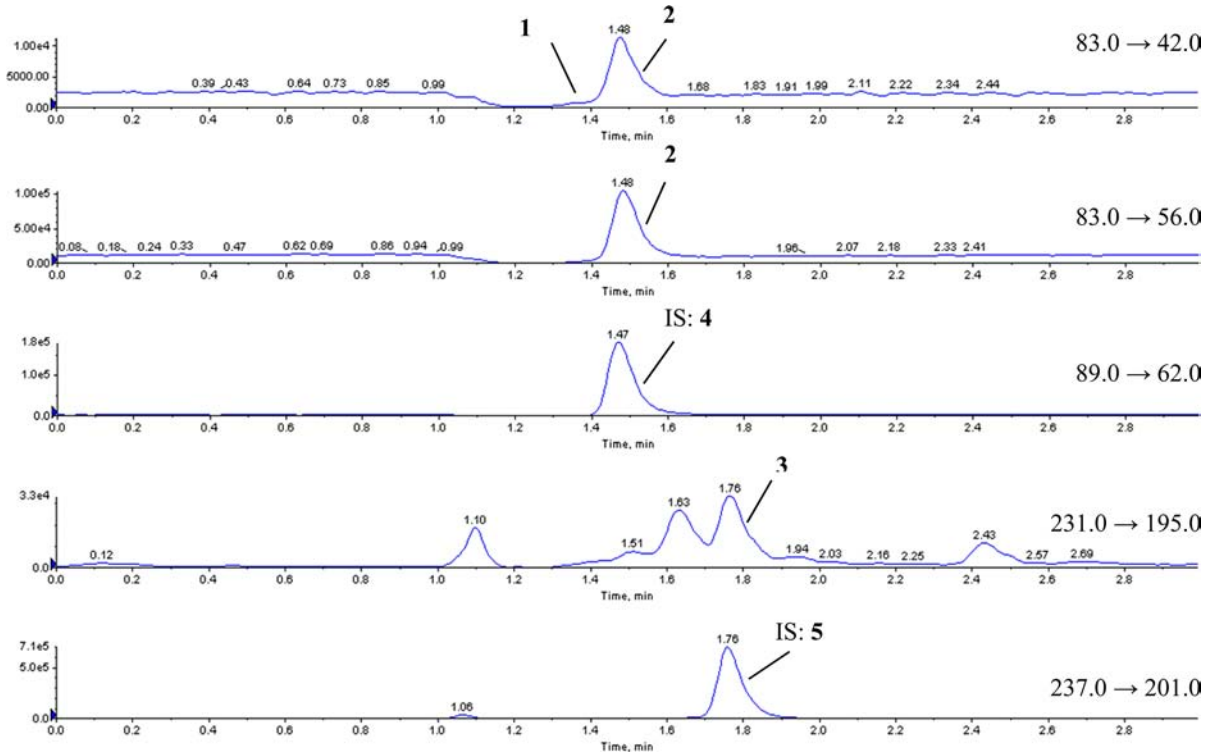

Figure 3. Example chromatogram of a licorice sample: 2-methylimidazole (**1**) ≤ LOD, 4-methylimidazole (**2**) = 1.09 mg/kg, and 2-acetyl-4-(1,2,3,4-tetrahydroxybutyl)imidazole (**3**) = 0.12 mg/kg.

analysis of **2** and **3**, with purified water 1:10; for analysis of **1**, with MeOH/H_2O 50:50 v/v 1:200) into HPLC vials.

LC-MS/MS Conditions. The LC-MS/MS system consisted of a 1260 Infinity HPLC from Agilent (Waldbronn, Germany) coupled to a TripleQuad 4500 tandem mass spectrometer from ABSCIEX (Darmstadt, Germany) through an electrospray ionization (ESI) interface in positive ionization mode (spray voltage, 3.0 kV; vaporizer temperature, 450 °C; curtain gas, 25 psi of N_2; collision energy, 25 V; Turbo V, ABSCIEX). Chromatographic separation was achieved on a Poroshell 120 EC-C_{18} (4.6 × 50 mm, 2.7 μm particle size, Agilent) under isocratic conditions (A/B, 50:50 v/v); A, 0.1% formic acid/methanol (99.5:0.5 v/v); B, 0.05% ammonia solution/methanol (90:10 v/v). The injection volume was 20 μL, and the flow rate was set to 0.45 mL/min. The following MRM transitions were used for analyte detection: **1**, m/z 83.0 → 42.0 (target), m/z 83.0 → 56.0 (qualifier); **2**, m/z 83.0 → 56.0 (target), m/z 83.0 → 42.0 (qualifier); **4**, m/z 89.0 → 62.0 (target), m/z 89.0 → 48.0 (qualifier); **3**, m/z 231.0 → 195.0 (target), m/z 231.0 → 153.0 (qualifier); **5**, m/z 237.0 → 201.0 (target), m/z 237.0 → 159.0 (qualifier).

Method Validation. Linearity was assessed by spiking a blank sample (licorice-free candy) at 10 different levels (0.005, 0.01, 0.025, 0.05, 0.10, 0.50, 1.00, 1.50, 2.50, and 5.00 mg/kg of **1**−**3**). LODs and LOQs of **1**−**3** were derived according to DIN 32645 by 10-fold analysis of a blank sample (direct method according to 5.3 of DIN 32645).[15] Total recovery was evaluated by spiking a blank sample to a final content of 1 mg/kg **1**−**3** followed by 6-fold analysis.[12,13] For the determination of intraday accuracy and interday precision, a licorice sample obtained from a local retail store was used.

RESULTS AND DISCUSSION

Method Development. One objective of this study was to develop and validate a method for the sensitive and simultaneous quantitation of the imidazoles **1**−**3**. Quantitative determination was carried out using commercially available **4** and **5** as internal standards (Figure 1). To achieve baseline separation of the **1** and **2** regioisomers, various parameters such as eluent composition, flow rate, temperature, and column material were evaluated. Separation of the analytes was tested on a C_{18} (Poroshell 120 EC-C18, Agilent) or a C_{30} (Acclaim C30, Thermo Scientific, Dreieich, Germany) reversed-phase column as well as on a porous graphitic carbon phase (Hypercarb, Thermo Scientific) while using a two-component eluent composed of A (0.05% aqueous ammonia solution, 100%, 0−2 min) and B (methanol, 100%, 2−3 min) at a flow of 0.45 mL/min. In addition, an isocratic eluent made from acidic and alkaline components (0.1% formic acid/methanol 99.5:0.5 v/v; 0.05% ammonia solution/methanol, 90:10 v/v) was evaluated, which, when used in combination with the Poroshell 120 EC-C18 column, provided an excellent baseline separation of **1**−**3** (Figure 2). Hence, the Poroshell 120 EC-C18 column and an eluent composed of acidic and basic components were used for further method development.

When complex licorice matrices were analyzed, ion suppression was observed for **1** when compared to the aqueous samples used for chromatography development. To remove the interfering matrix components a common Carrez clarification was introduced, and several dilution steps (1:10, 1:100, 1:200 v/v) of the sample solution injected into the LC-MS/MS system were evaluated to eliminate any remaining matrix effects. A recovery for **1** of 86% with acceptable sensitivity was finally achieved at a dilution of 1:200.

Although baseline-separated, the **1** and **2** regioisomers can also be distinguished from differences in their fragmentation behavior. Whereas **1** shows higher relative intensities at mass transition m/z 83 → 42, **2** shows higher intensity at mass transition m/z 83 → 56 (Figure 2). Figure 3 shows a typical chromatogram of a licorice sample recorded using the optimized LC-MS/MS conditions described above.

Method Validation. Following the guidelines laid out by Kromidas,[14] method validation included the following

DOI: 10.1021/acs.jafc.5b01493
J. Agric. Food Chem. 2015, 63, 5930−5934

Table 1. Method Validation Data

	2-methylimidazole	4-methylimidazole	2-acetyl-4-(1,2,3,4-tetrahydroxybutyl)imidazole
calibration range (mg/kg)	0.05−5.00 ($r^2 \geq 0.999$)	0.02−5.00 ($r^2 \geq 0.999$)	0.01−5.00 ($r^2 \geq 0.999$)
recovery (%)	86.1	99.4	99.5
limit of detection (LOD, mg/kg)	0.05	0.02	0.01
limit of quantitation (LOQ, mg/kg)	0.16	0.07	0.03
intraday accuracy (n = 12, %)		2.2	5.5
interday precision (n = 12, %)		9.3	10.2

parameters: intraday accuracy, interday precision, recovery, linearity, limit of detection (LOD), and limit of quantitation (LOQ). Validation data are summarized in Table 1.

Limits of detection and quantitation were estimated according to DIN 32645 and were 0.05 mg/kg for **1**, 0.02 mg/kg for **2**, and 0.01 mg/kg for **3** (LOD) as well as 0.03−0.16 mg/kg for all analytes (LOQ).[15] Linearity was evaluated by plotting the concentration of each analyte against the respective analyte/internal standard ratio (**2** was calibrated using **4** as the internal standard). Linearity in the range of LOD−5 mg/kg of licorice was shown for all 3 analytes by a coefficient of determination of ≥0.999. Intraday accuracies and interday precisions were calculated from 12 separate measurements and showed standard deviations ≤10.2% (Table 1). The developed methodology provided efficient recovery rates, which are in accordance with available literature data: **1**, 86%; **2**, 99%; **3**, 100%.[10,11]

Endogenous Formation. To check for endogenous formation of the imidazoles **1**−**3** in licorice in the presence of ammonium chloride, a model assay was conducted examining several coloring-free licorice products (n = 20; five levels of ammonium chloride in duplicate: 1, 2, 4, 6, and 8%). Depending on their manufacture, samples were further grouped into in-house types A, B, and C, where ammonium chloride had been added to the cooking mass either before (type A) or after (type B) the cooking process, whereas type C (here not under consideration) was simply dredged in solid ammonium chloride (see also Supporting Information, Figure S1). All model assays were conducted under typical industrial conditions at a testing facility of a major German licorice manufacturer, and samples were analyzed in our laboratory.

The results show a linear correlation (r^2 = 0.937) between the levels of endogenously formed **2** and the amount of added and concomitantly heated ammonium chloride when the ammonium chloride was added to the cooking mass before the cooking process (type A). The determined absolute levels of **2** (relative to the dry mass) were in the range from 0.02 (LOD) to 1.5 mg/kg. In type B licorice products, where ammonium chloride is added after the cooking process, most of the samples showed levels of **2** below the LOQ of 0.07 mg/kg. Only those products with 8% ammonium chloride showed levels at 0.09 mg/kg, just above the LOQ.

Endogenous formation of **3** in type A licorice products again depends on the amount of added and concomitantly heated ammonium chloride. A linear correlation between the endogenously generated amounts of **3** and the added ammonium chloride was derived with a coefficient of determination of r^2 = 0.909. The determined levels of **3** (relative to the dry mass) were in the range from 0.01 (LOD) to 0.17 mg/kg. In the case of type B licorice products all samples showed levels below an LOQ of 0.03 mg/kg.

Monitoring. Monitoring assays were subsequently carried out to examine the endogenous formation of **1**−**3** in 29 coloring-free licorice products. **1** was not observed in any of the samples, whereas levels of **2** and **3** were in the range of LOD−1.30 mg/kg (median, ≤LOQ) and LOD−0.10 mg/kg (median, ≤LOQ), respectively.

Maximum limits for **2** and **3** have not been defined for end products but are available for the caramel food colorings ammonia caramel E150c and sulfite ammonia caramel E150d (E150c, 200 mg/kg **2**, 10 mg/kg **3**; E150d, 250 mg/kg **2**).[5] Assuming that an amount of caramel food colorings of up to 2% is usually added to certain licorice products, the resultant carry-over produces a still acceptable content level for **2** of 4 mg/kg and a content level of 0.2 mg/kg for **3**. However, the determined levels of **2** and **3** formed in commercial licorice products by the addition of ammonium chloride were well below these theoretically derived maximum levels. The licorice products reviewed in this study can thus be judged safe with respect to a possible contamination by any of the imidazoles **1**−**3**.

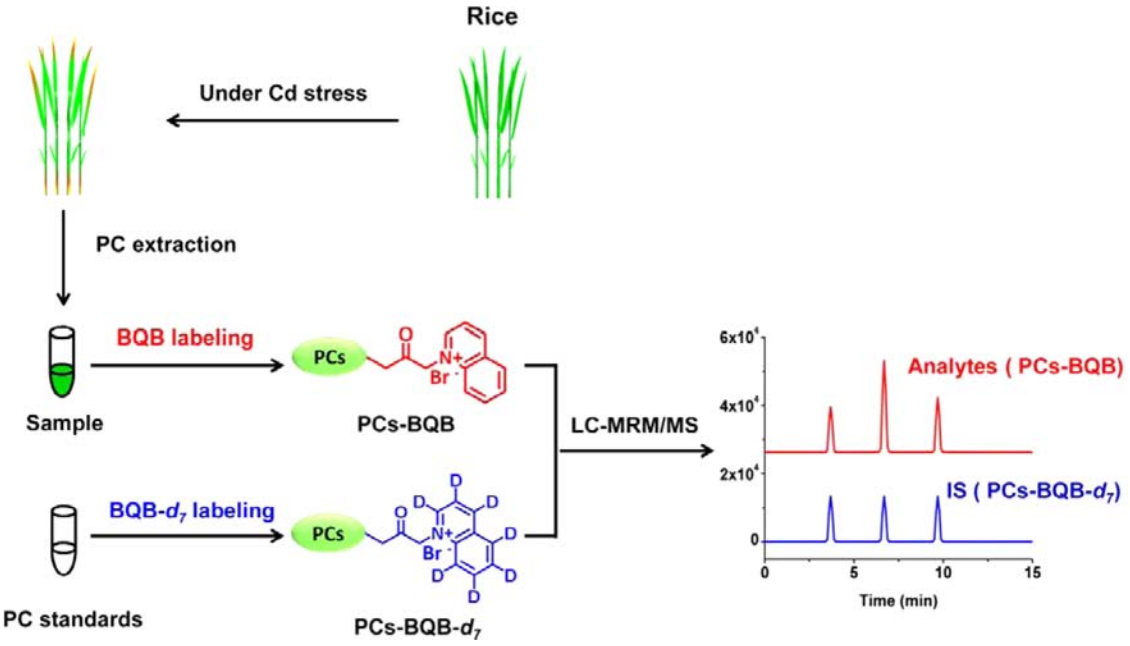

Figure 1. Schematic diagram of the principle of stable isotope labeling coupled with LC/MS analysis for PC determination.

analysis for the determination of phytohormones and carboxyl- and thiol-containing metabolites in plant and human urine samples.[20,24,25]

In this work, we developed a novel strategy by combing stable isotope labeling with LC/MS analysis to improve the identification and quantitation of PCs in rice samples. The schematic diagram of the principle of this method was shown in Figure 1. A pair of isotope-labeling reagents of ω-bromoacetonylquinolinium bromide (BQB) and BQB-d^7 were used to label the analytes in sample and PC standards, respectively, and then combined before LC/MS analysis. In this respect, the heavy labeled standards were used as the ISs for quantitation to minimize the matrix and ion suppression effect in MS analysis. In addition, the ionization efficiency of PCs was also greatly enhanced through the introduction of a permanently charged moiety of quaternary ammonium of BQB into the analytes. The established method was successfully applied to the sensitive quantitation of endogenous PCs in rice under Cd stress with different Cd concentrations and treatment time.

MATERIALS AND METHODS

Chemicals and Reagents. PCs (PC_2, PC_3, PC_4, PC_5, and PC_6) were purchased from Anaspec (Fremont, CA). Glycine and tris(2-carboxyethyl)phosphine hydrochloride salt (TCEP) were purchased from Sigma (St. Louis, MO). Formic acid and ethylenediaminetetraacetic acid (EDTA) were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Chromatographic-grade acetonitrile (ACN) was purchased from TEDIA Co., Inc. (Fairfield, OH). All other solvents and chemicals used were of analytical grade. The water used throughout the study was purified by a Milli-Q apparatus (Millipore, Bedford, MA). Stock standard solutions of PCs were prepared in 1.0 mM EDTA solution containing 0.05% formic acid at a concentration of 1.0 mM.

Rice Culture and Treatments. Rice seedings (*Oryza sativa* L. cv. Zhenghan No. 2) were germinated and grown by hydroponic culture in Hoagland's nutrient solution in a growth chamber with 70−80% relative humidity under a 16 h light (28 °C)/8 h dark (25 °C) photoperiod according to a previously described method, with some modifications.[26] Hoagland's nutrient solution contains 1.425 mM NH_4NO_3, 0.323 mM NaH_2PO_4, 0.513 mM K_2SO_4, 0.998 mM $CaCl_2$, 1.643 mM $MgSO_4$, 0.008 mM $MnCl_2$, 0.062 μM $(NH_4)_6Mo_7O_{24}$, 0.015 mM H_3BO_3, 0.122 μM $ZnSO_4$, 0.124 μM $CuSO_4$, 0.038 mM $FeCl_2$, and 0.062 mM citric acid. After 10 days of growing, the seedings with uniform size were subjected to Cd stress with different concentrations of $CdNO_3$ (0, 10, 100, 500, and 1000 μM). Rice seedings were harvested after Cd stress for 3 h, 3 days, and 7 days, then weighted, immediately frozen in liquid nitrogen, and stored at −80 °C.

Sample Preparation. Sample extraction was carried out according to a previously described method, with slight modifications.[7] Plant tissues (leafs and stems) were frozen in liquid nitrogen and ground into fine powder with a mortar and pestle. Then, 5 mg of plant powder was transferred into a 0.6 mL centrifuge tube and extracted with 50 μL of 0.1 M cold HCl (4 °C) containing 1 mM EDTA for 30 min. The exacted sample was centrifuged at 12 000 rpm for 30 min under 4 °C. Then, 30 μL of supernatant was added with 1 M NaOH (2 μL) to adjust the pH to 2 and then treated with 10 nmol of TCEP (10 mM, 1 μL) under 45 °C for 60 min.

Chemical Labeling. The chemical-labeling procedure was performed according to our previous work.[27] Briefly, 20 nmol of BQB (1 mM, 20 μL) was added to a 1.5 mL tube and dried under nitrogen gas. Subsequently, 90 μL of glycine−HCl buffer solution (5.0 mmol/L, pH 3.5) and 10 μL of treated plant extracts were added. The mixture was incubated at 60 °C for 60 min with shaking at 1500 rpm. The BQB-d_7-labeled PCs were added to serve as ISs for the quantitation. Then, 20 μL of samples were subjected to LC/MS analysis.

Liquid Chromatography−Electrospray Ionization−Tandem Mass Spectrometry (LC−ESI−MS/MS) Analysis. Analysis of samples was performed on the LC−ESI−MS/MS system consisting of an AB 3200 QTRAP mass spectrometer (Applied Biosystems, Foster City, CA) with an electrospray ionization source (Turbo Ionspray) and Shimadzu LC-20AD high-performance liquid chromatography (HPLC) (Tokyo, Japan) with two LC-20AD pumps, a SIL-20A auto sampler, a CTO-20AC thermostated column compartment, and a DGU-20A3 degasser. Data acquisition and processing were performed using AB SCIEX Analyst 1.5 software (Applied Biosystems, Foster City, CA). The HPLC separation was performed on a Shimadzu VP-ODS column (150 × 2.0 mm inner diameter, 5 μm, Tokyo, Japan) with a flow rate of 0.2 mL/min at 30 °C. Formic acid in water (0.1%, v/v, solvent A) and acetonitrile (solvent B) were employed as mobile phases. A gradient of 0−20 min from 5 to 40% B,

Figure 2. Chemical-labeling reaction for PCs using BQB.

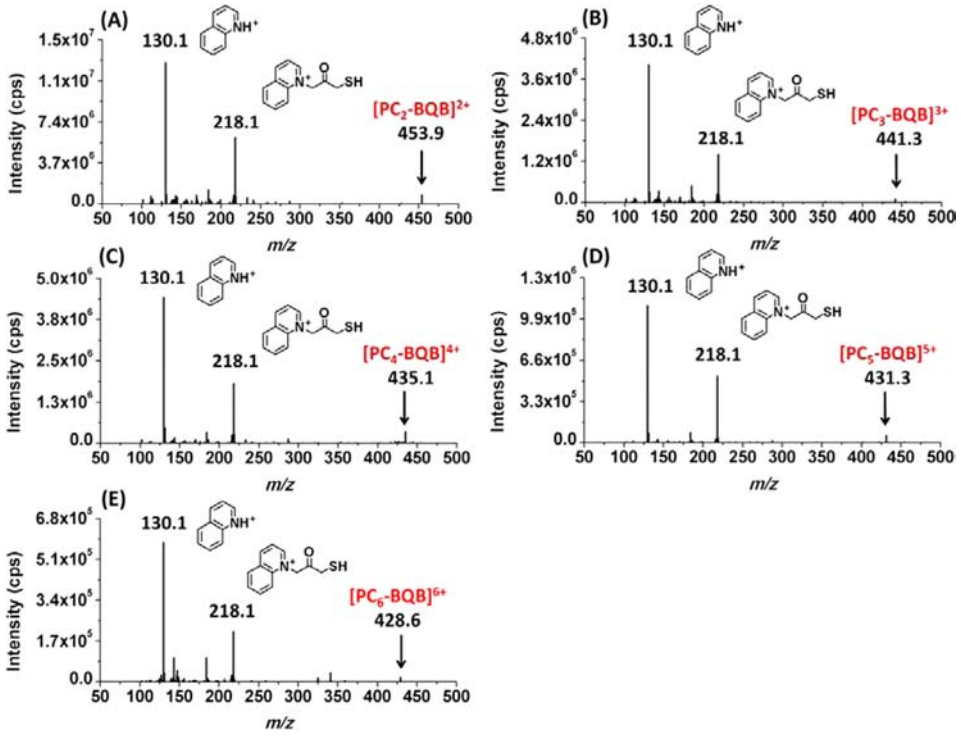

Figure 3. MS/MS spectra of the BQB-labeled PCs: (A) PC_2–BQB, (B) PC_3–BQB, (C) PC_4–BQB, (D) PC_5–BQB, and (E) PC_6–BQB.

20–25 min from 40 to 60% B, 25–26 min from 60 to 5% B, and 26–40 min at 5% B was used.

All BQB-labeled PCs were quantitated by multiple reaction monitoring (MRM) mode in positive mode. The optimal electrospray ionization (ESI) source conditions were as follows: turbo heater temperature (TEM), 550 °C; ion spray voltage, 4500 V; curtain gas, 30 psi; nebulizing gas (gas 1), 40 psi; and heated gas (gas 2), 60 psi.

Method Validation. To evaluate the linearity of the method, standards of PC–BQB at concentrations of 1, 2, 5, 10, 20, 50, 100, 200, and 500 nM fixed amounts of ISs ($PC_{2,3,4,6}$–BQB-d_7, 50 nM; PC_5–BQB-d_7, 10 nM) were used to construct calibration curves by plotting the peak area ratio (analyte/IS) against the PC–BQB concentrations with triplicate measurements. The residual plots were also considered, and the Durbin–Watson test was applied to prove linearity. The limits of detection (LODs) and limits of quantitation (LOQs) were determined at a concentration where the S/N ratios were 3 and 10, respectively.

The accuracy and precision of the developed method were assessed by the recoveries and the intra- and interday relative standard deviations (RSDs). Both recoveries and intra- and interday RSDs were calculated with PC standards spiked in rice tissue samples at three different concentrations. For each concentration, triplicate measurements were performed. The intraday variation was evaluated by repeating the process 3 times within 1 day, and the interday variation was investigated on 3 successive days.

RESULTS AND DISCUSSION

MS Behavior of BQB-Labeled PCs. The typical chemical labeling of PCs by BQB was shown in Figure 2. The results show that all of the thiol groups from the PCs could react with BQB, and the derivatives had several parent molecule ions with different charge states in the positive ESI–MS (see Figure S1 of the Supporting Information). This phenomenon might be attributed to the fact that the carboxy groups released the protons of derivatives during the ionization process and which then results in the derivatives containing one or several negative charges. It is benificial in identifying metabolites by multi-peaks in one analysis. Meanwhile, we found that the intensity of ions from derivatives with the most charge states were highest among the multiple parent molecule ions.

All of the parent molecule ions were subjected to ESI–MS/MS analysis to investigate the fragmentation behavior of BQB-labeled PCs. Figure 3 depicts the fragment ion spectra of BQB-labeled PC_2 ($[M]^{2+}$), PC_3 ($[M]^{3+}$), PC_4 ($[M]^{4+}$), PC_5 ($[M]^{5+}$), and PC_6 ($[M]^{6+}$). The results show that two common product ions at m/z 130.1 and 218.1 were observed for all of the derivatives. The product ion of m/z 130.1 was assigned to the fragment ion generated from the quinoline moiety of BQB, and

DOI: 10.1021/acs.jafc.5b01797
J. Agric. Food Chem. 2015, 63, 5935–5942

m/z 218.1 was assigned to the fragmentation of the C−S bond in derivatives. However, in comparison to the BQB-labeled PCs, the fragment ion spectra of unlabeled PCs were more complex (see Figure S2 of the Supporting Information).

Enhancement of Detection Sensitivity upon Chemical Labeling. The PCs can be ionized in ESI−MS with positive-ion mode. The MRM transitions of 540.1 → 336.0, 772.2 → 233.2, 1004.3 → 233.1, 1236.4 → 464.9, and 1468.4 → 772.0 for unlabeled PC_2, PC_3, PC_4, PC_5, and PC_6 were extracted, respectively, as a result of the highest signal intensity in the LC−MS analysis (Figure 4A). However, the ionization

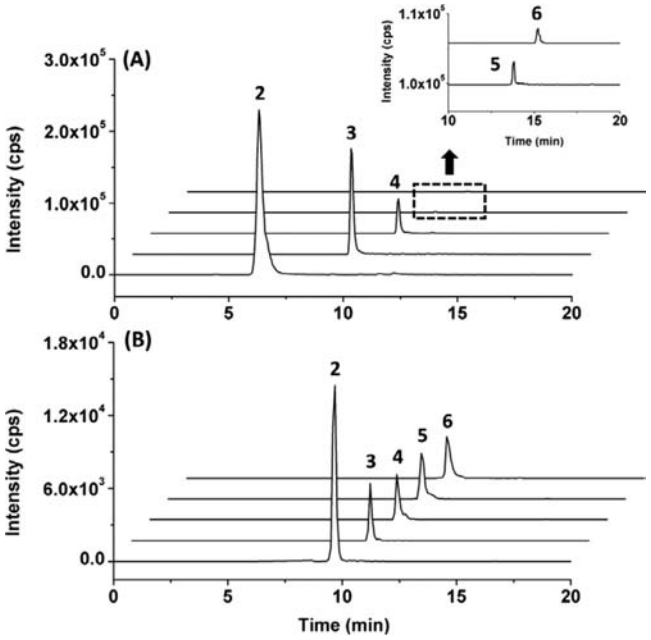

Figure 4. Extracted-ion chromatograms between unlabeled and BQB-labeled PC standards: (A) unlabeled PC_{2-5}, 10 μM; PC_6, 50 μM, 10 μL and (B) BQB-labeled PC_{2-5}, 0.1 μM; PC_6, 0.5 μM, 10 μL.

efficiency is normally poor, and the ionization efficiency dropped from PC_2 to PC_6. Previous studies demonstrated that introducion of an easily ionizable group into target componds by chemical labeling could obviously increase the detection sensitivities of analytes during ESI−MS analysis.[28−33] In this respect, chemical labeling of PCs by BQB that has a permanent charged moiety of quaternary ammonium may also largely enhance the ionization efficiencies of thiol compounds during ESI−MS analysis.

Here, we used the PC standards (PC_2, PC_3, PC_4, PC_5, and PC_6) to evaluate the enhancement of detection sensitivity upon chemical labeling by BQB under MRM mode. The detailed MRM conditions of BQB-labeled and unlabeled PCs were shown in Table 1 and Table S1 of the Supporting Information, respectively. Figure 4B shows the extracted ion chromatograms of BQB-labeled PC standards under MRM transitions. The transitions of $[M]^{n+}$ → 218.1 for BQB-labeled PCs were extracted because of the high signal intensity and low matrix interferences (Figure 4B). Although the PC concentrations labeled with BQB were 100-fold lower than unlabeled PCs, MS responses of BQB-labeled PCs were much more improved. We calculated the LODs of the unlabeled and BQB-labeled PCs under their own optimized MRM conditions, and the results show that the signal intensities of BQB-labeled PCs improved by 14.3−750.0-fold compared to the unlabeled PCs (Table 2). As shown in Figure 4B, the higher PC derivatives exhibited a strong peak tailing. The phenomenon may be due to the residue Si−OH of the silica-based stationary phase, which may strongly interact with the positively charged group(s) of derivatives. The higher PCs of derivatives have more numbers of the charged groups that lead to the strong peak tailing. We also found that the addition of formic acid at a higher concentration in the mobile phase could inhibit the tailing; however, it also caused the MS intensities to decrease. Taking the good peak shape and high intensities into consideration, we selected the formic acid concentration in the mobile phase as 0.1% (v/v).

Stability of BQB-Labeled PCs. The stability of the derivatives may greatly influence the reproducibility and sensitivity in determination of PCs. To examine the stability of the derivatives, the derivatives were left for 4 °C and determined every 24 h. The results indicated that the BQB derivatives of PCs could be stored at 4 °C for at least 1 week without a decrease of signal intensities (see Figure S3 of the Supporting Information). The RSDs were 2.2, 5.9, 3.3, 5.1, and 1.4 for the BQB-labeled PC_2, PC_3, PC_4, PC_5, and PC_6, respectively. It is worth noting that the PC−BQB derivatives should be placed in the vial of polyethylene to avoid the adsorption by the glass (Si−OH) vial.

Optimization of the TCEP and BQB. We investigated the effects of the contents of TCEP and BQB on the efficiencies of reduction of disulfide bonds and chemical labeling. Plant extract (without Cd stress) spiked with PCs (PC_{2-5}, 0.1 μM; PC_6, 0.5 μM) was used as the samples. To minimize the effect of instrumental variation, the same amounts of BQB-d_7-labeled PCs (PC_{2-5}, 0.1 μM; PC_6, 0.5 μM) were used as ISs and added to the samples prior to LC/MS analysis.

PCs are sensitive to oxidation during plant sample preparation and storage. The oxidation can occur in both inter- and intramolecular reactions via disulfide bond formation. El-Zohri et al. found intermolecular-oxidized PC_2 at m/z 1077 and PC_3 at m/z 1543,[16] and the intramolecular-oxidized PC_2 at m/z 770 were also observed in a previous study.[3] Thus, in the current study, the reducing agent was added to avoid the oxidation of PCs before chemical labeling. The reducing agent of TCEP ranging from 0 to 50 nmol was investigated, and the content of BQB was fixed at 30 nmol. As shown in Figure S4A of the Supporting Information, the peak intensity ratio (analyte/IS) of PC derivatives did not obvisouly change with the increase of TCEP from 0 to 10 nmol. We reason that the PC standards added in the plant extracts were all reduced PCs and were labeled with BQB immediately. However, the peak intensity ratio (analyte/IS) dropped with the increase of the TCEP amounts from 10 to 50 nmol, especially for PC_6, indicating that the efficiencies of chemical labeling may be suppressed by the excess content of TCEP. Consequently, 10 nmol of TCEP was used in the following experiments.

Because the plant sample mixture was much more complex than pure standards and BQB would be consumed by the target compounds as well as other thiol-containing interferents in the plant matrix, the amounts of labeling reagent were further optimized in the range of 1−30 nmol. As shown in Figure S4B of the Supporting Information, the peak intensity ratio (analyte/IS) of derivatives increased with the increase of the BQB content from 1 to 10 nmol and then reached a plateau when BQB contents exceeded 10 nmol. The highest chemical-labeling efficiencies of PC were achieved using 10 nmol of

BQB. For more reliable quantitation of PCs in plant tissue, we used 20 nmol of BQB in the following experiments.

Method Validation. A series of experiments, including linearity, LODs and LOQs, recoveries, and precisions, were performed to validate the proposed method under optimized conditions. The results show that good linearity was obtained with a regression coefficient (R^2) higher than 0.9931 (see Table S2 of the Supporting Information). The residual plots show that a plot of the standardized residual versus the standardized predicted value revealed no particular pattern (i.e., data were randomly distributed around 0), no more than 5% of cases had

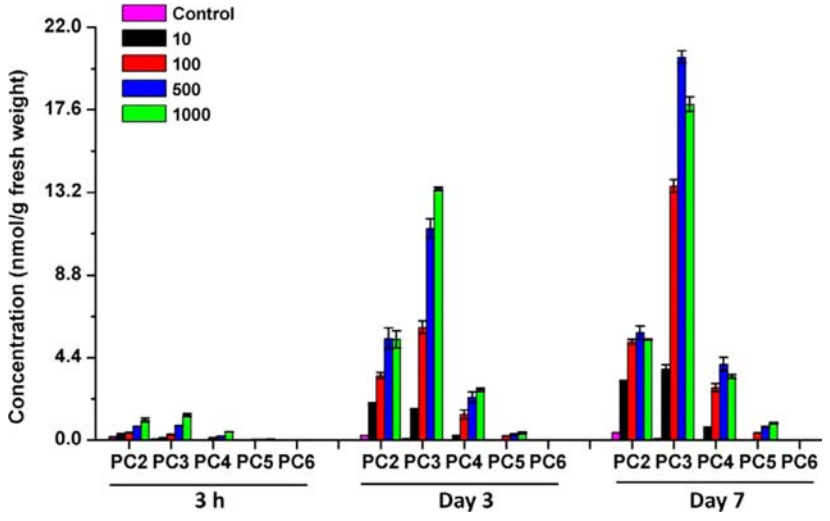

Figure 6. Content change of PCs in rice with Cd stress at different concentrations and time.

a standardized residual absolute value above 2, and the Durbin–Watson statistics were 2.1, 2.2, 1.2, 2.3, and 2.3 for PC_2, PC_3, PC_4, PC_5, and PC_6, respectively (between 1.5 and 2.5), indicating that the residuals were uncorrelated (see Figure S5 of the Supporting Information).[34] The LODs and LOQs for five PCs were in the range of 0.1–1.6 and 0.4–5.0 nM, respectively. Table 3 shows the comparison of the LODs obtained between our method and other methods reported in the literature.[3,11,15,17−19] Generally, the LODs obtained by the current method are much lower than those given in the literature, especially for the LODs of PC_4, PC_5, and PC_6, which were about 7–17 times lower than the lowest values reported in previous studies.[3,15,18]

The recoveries of five PCs were in the range of 71.6–93.1%, and the intra- and interday RSDs were less than 9.8 and 16.3%, respectively (see Table S3 of the Supporting Information), indicating that the accuracy and precision of the proposed method were satisfactory for the determination of PCs in plant samples.

Quantitation of Endogenous PCs in Plant Samples. In the present work, after 10 days of growing, rice samples were treated with Cd at different concentrations (0, 10, 100, 500, and 1000 μM) and collected after Cd stress for 3 h, 3 days, and 7 days. The real rice pictures under Cd stress with different concentrations and time were shown in Figure S6 of the Supporting Information. As seen, the rice under all of the Cd concentrations show the same appearance (green) at the Cd treatment time of 3 h and 3 days. However, at the treatment time of 7 days, the rice leaves turned yellow, starting from the 100 μM Cd concentration, and the inhibitory effects in plant

DOI: 10.1021/acs.jafc.5b01797
J. Agric. Food Chem. 2015, 63, 5935–5942

growth were also observed at the Cd concentrations of 500 and 1000 μM.

The concentrations of the PCs in those rice tissues were determined by the developed method. Figure 5 shows the typical extracted ion chromatogram of five PCs and their respective ISs from the plant treated with 100 μM Cd (3 days). As seen, the BQB-labeled PCs and the ISs (BQB-d_7-labeled PCs) were co-eluted on the chromatography, and the chromatographic isotope effect of BQB- and BQB-d_7-labeled standards was about 0.1 min.

The quantitation results (Figure 6 and Table S4 in Supporting Information) show that only PC_2 and PC_3 were observed in the control samples (0 μM Cd), indicating that PC_2 and PC_3 can be synthesized in plants even without heavy metal stress. For the rice under Cd stress, in comparison to the control samples, the contents of PC_2 and PC_3 under Cd stress at the concentrations of 10−1000 μM dramatically increased.

PC_4 and PC_5 were also detected in Cd-stressed rice. It is worth noting that PC_5 was first detected in the rice tissues in our study. PC_4 and PC_5 were induced by the Cd concentration greater than 10 μM, and PC_4 could also be found in rice under 10 μM Cd at the treatment time of 3 and 7 days. The results indicate that PC_4 was more easily synthesized than PC_5 in rice. The concentrations of PC_2, PC_3, and PC_4 in rice at 100 μM Cd stress (7 days) were consistent with previous work for the measurements of PCs in rice stems with 50 μM Cd stress for 7 days.[3] Generally, the contents of PCs in rice increased with the increase of the concentration and treatment time of Cd, indicating that the PCs have the role of detoxification for plants under Cd stress.[1]

Comparison of the Developed Method to Previous Methods. In comparison to previously published methods, our method has two major advantages. First, the detection sensitivity was significantly improved. As seen in Table 3, the LODs of PC_4, PC_5, and PC_6 obtained by the current method were 7, 8, and 17 times lower than the lowest values reported in the previous studies, respectively, and the LODs of PC_2 and PC_3 were also comparable to those lowest values. Because of the high detection sensitivity, PCs can be easily quantitated using only 5 mg of rice tissues and PC_5 was first detected in the rice tissues. Second, the accuracy for the identification and quantitation of PCs was also enhanced. The PC standards labeled with BQB-d_7 were used as the isotope ISs, which can calibrate the ion signal variation caused by matrix and ion suppression effects in MS analysis (Figure 5). Taken together, the method can significantly improve the detection sensitivity and accuracy for the identification and quantitation of PCs in plants.

In conclusion, we developed a stable isotope-labeling method combined with LC/MS analysis for the sensitive detection of PCs in rice. The plant samples and PC standards were labeled with BQB and BQB-d_7, respectively, then mixed, and analyzed by LC/MS. The BQB labeling improves the detection sensitivities of PCs by 14−750-fold because of the introduction of a permanent charged moiety of quaternary ammonium, and the BQB-d_7-labeled standards were used as the ISs for quantitation to minimize the severe matrix effect. Using the developed method, four endogenous PCs (PC_2, PC_3, PC_4, and PC_5) were successfully identified and quantitated in only 5 mg of rice samples under Cd stress, and PC_5 was first reported to exist in rice tissues by this method. The contents of PCs dramatically increased as the Cd concentrations and treatment time increased, suggesting that PCs have the role of detoxification in plants under Cd stress. This highly sensitive and reliable method can also be extended for the identification and quantitation of PCs in other samples.

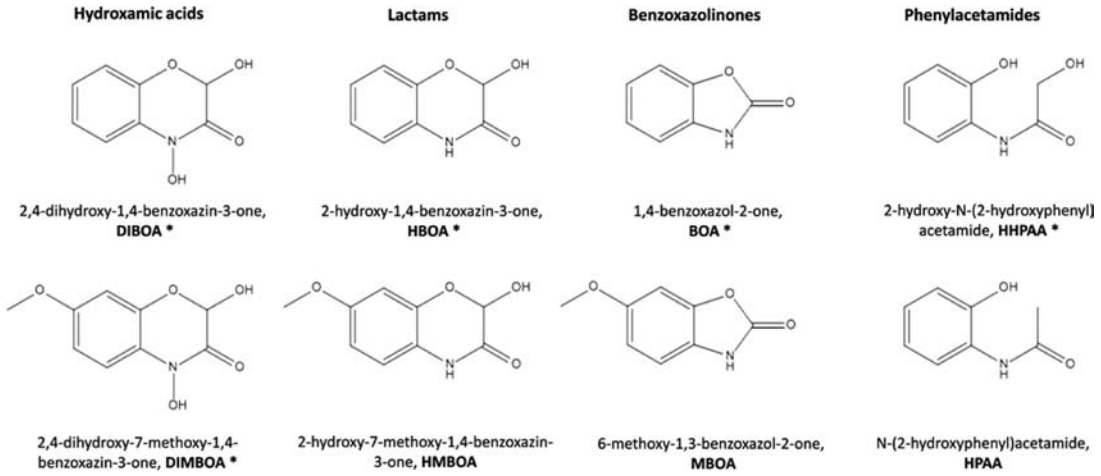

Figure 1. Molecular structures of the different benzoxazinoids exemplified with the most common compounds of each chemical class The asterisk (∗) indicates the compounds found in this study. In addition to aglycone forms, also the diglycoside and glucoside forms of DIBOA, DIMBOA, and HBOA were identified and analyzed in this study.

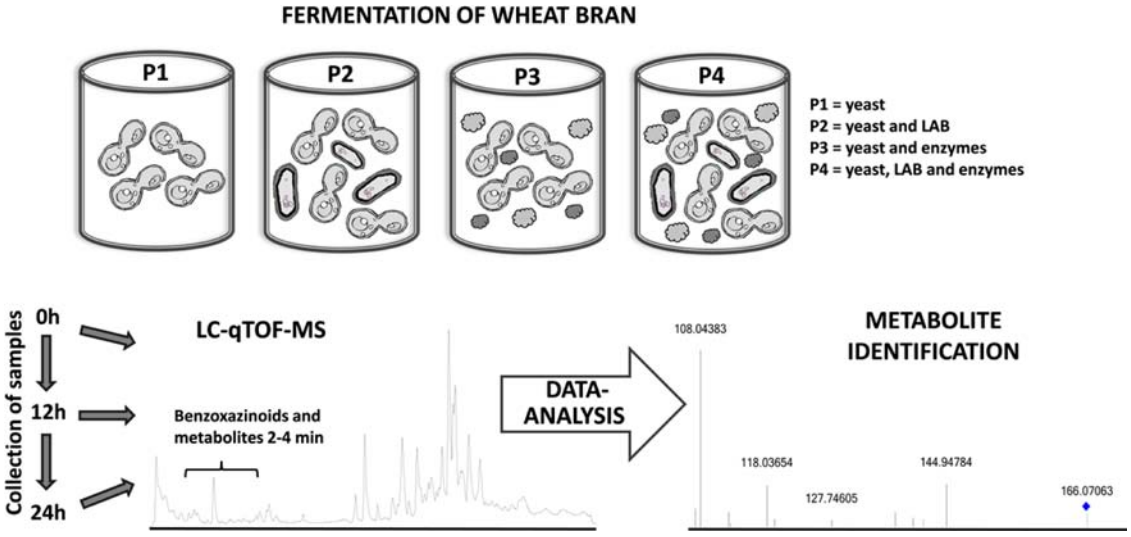

Figure 2. Schematic illustration of the study setup. Ground wheat bran was fermented in four different conditions (P1−P4). All conditions included equal amounts of yeast (*Kazachstania exigua*) at the start. In addition, conditions P2 and P4 included added lactic acid bacteria (*Lactobacillus brevis*), and conditions P3 and P4 had mixture of enzymes with cellulase, xylanase, β-glucanase, and α-amylase activity. Samples were collected at the start (0 h) and after 12 and 24 h of fermentation. LC-qTOF-MS analytics was used to study the effects of different fermentation conditions on the resulting benzoxazinoid metabolite profile.

Benzoxazinoids are highly bioactive compounds that have been suggested to even have pharmaceutical potential and may therefore have implications on health as part of the diet, as has been reviewed recently.[15] For example, benzoxazinoids have been reported to have antiallergenic and anti-inflammatory, as well as appetite suppressing effects in humans.[3,4,16−18] Additionally, benzoxazinoids may reduce cellular glucose uptake.[19] On the other hand, benzoxazinoids have also been found to be potent polyploidy-inducing agents in human-derived cell lines (HepG2 and HeLa), which has raised concern for their potential adverse health effects.[20,21] For phenylacetamides, no reports on bioactivity and potential effects on health are found. Whereas it is unclear whether benzoxazinoids, or potentially their metabolized forms, for example, phenylacetamides, have an impact on human metabolism, there is a need to understand the effect of different food-processing technologies on their content. It is known that soaking and boiling can considerably change the content of benzoxazinoids and their glycosides in grains or flakes and that they are released into water in notable amounts during such processing.[8] Sourdough fermentation combined with baking has been shown to effectively degrade DIBOA diglycoside and increase the amount of BOA and benzoxazinoid-related metabolite HPAA,[11,14] but whether the degradation was due to fermentation or baking is not known.

In the current study, we used a nontargeted liquid chromatography quadrupole time-of-flight mass spectrometry (LC-qTOF-MS) metabolite profiling approach with the aim of examining the effects of different fermentation conditions on the benzoxazinoid profile of wheat bran sourdoughs. The effect of different microbial contents (yeast, and yeast with lactic acid bacteria) as well as impact of cell wall degrading enzymes was evaluated.

MATERIALS AND METHODS

Materials. Commercial wheat bran (Fazer Mills, Lahti, Finland) was ground using a TurboRotor mill (Mahltechnik Görgens GmbH,

Dormagen, Germany) to a median particle size of 160 μm. Enzymes used in fermentations 3 and 4 were Depol 740l (Biocatalyst Ltd., UK) and Grindamyl A1000 (Danisco, Denmark). Their enzyme activities are presented in Supporting Information Table 1. The yeast used in all fermentations was *Kazachstania exigua* (VTT C-81116), and the lactic acid bacteria (LAB) starter used in fermentations 2 and 4 was *Lactobacillus brevis* (VTT E-95612).

Bran Fermentations. Four different liquid fermentations (P1, yeast; P2, yeast + LAB; P3, yeast + enzymes; and P4, yeast + LAB + enzymes), containing bran and water (10:90 w/w) with an initial inoculum of ca. 10^6−10^7 cfu/mL for both starter cultures employed, were made as duplicates. The fermentations were performed in 1 L BIOSTAT QPlus bioreactors (Sartorius Stedim Biotech GmbH, Germany) in an anaerobic environment, which was created by a flow of nitrogen into the bottom of the fermentor. Preparation of the sourdoughs and process parameters can be found in the Supporting Information (Tables 2 and 3). Samples (285 g) were taken at 0, 12, and 24 h, freeze-dried (Lyovac GT 2, Steris GmbH, Germany; or Epsilon 2-25DS, Christ, Germany), and milled (Bamix, Switzerland and Retsch ZM 200, Retsch GmbH, Germany) to pass a 0.5 mm sieve. The process scheme for fermentations and sampling is illustrated in Figure 2.

Acidification. Acidity (pH and total titratable acids (TTA)) of the bioprocessed bran was determined from a suspension containing 5 g of bran sample and 50 mL of distilled water in an automatic titrator (Mettler Toledo titrator T50). After pH measurement, the suspension was titrated with 0.1 M NaOH to a final pH of 8.5. TTA value was expressed as the amount of NaOH used in milliliters per 10 g of sample.

Sample Preparation and LC-qTOF-MS Analyses. For LC-qTOF-MS analyses 100 mg of each freeze-dried and ground fermentation sample was weighed. The samples were extracted by vigorous shaking with 80% methanol for 30 min at room temperature using a Multi Reax shaker (Heidolph Instruments GmbH, Germany), centrifuged for 10 min at 6708*g* (7 °C), and filtered through a 0.2 μm PTFE membrane (PALL Corp., USA). Prior to analysis, samples were stored for 12 h at 6 °C. Metabolite profiling was carried out on an LC-qTOF-MS system consisting of a 1290 ultrahigh-performance liquid chromatograph (UHPLC) with a 6540 ultrahigh-definition (UHD) accurate-mass qTOF mass spectrometer (Agilent Technologies, USA). Separation of metabolites was performed using a 2.1 × 100 mm 1.8 μm particle size Agilent ZORBAX Eclipse XDB-C18 column (Agilent Technologies) thermostated at 50 °C. The mobile phase consisted of 0.1% of formic acid in water (phase A) and 0.1% of formic acid in methanol (phase B). The gradient program was as follows: 2−100% of B in 10 min, held at 100% of B for 4.5 min, 100−2% of B in 0.01 min, and held at 2% of B for 1.99 min. The mobile phase flow rate was 0.4 mL/min, and the sample injection volume was 1 μL. The instrument was equipped with an Agilent Jet Stream electrospray source and was operated in negative ionization mode with the following source parameters: drying gas flow rate, 11 L/min; gas temperature, 325 °C; pressure of nebulizer gas, 45 psi; Vcap, 3500 V; fragmentor, 100 V; skimmer, 45 V. The mass scan range was m/z 50−1600. For tandem mass spectrometry (MS/MS) analyses three different collision energies (10, 20, and 40 V) were used. The mass-axis was calibrated online during the analyses with two reference mass ions. Data acquisition was conducted with MassHunter Acquisition B.04.00 (Agilent Technologies).

Data Processing. Data were extracted using MassHunter Qualitative analysis B.05.00 (Agilent Technologies) using the "Find Compounds by Molecular Feature" function. Peaks were extracted by combining isotopes, sodium adducts, and dimers for specific "compounds". For compound alignment data were output into the Mass Profiler Professional software (version 2.2, Agilent Technologies, Santa Clara, CA, USA). Main emphasis on data analysis was laid on analyzing the benzoxazinoids, which typically elute at 2−4 min in our chromatographic conditions; therefore, the collection of signals for the data analysis was focused on this region. Compounds were identified on the basis of their accurate mass, molecular formula, and MS/MS fragmentation pattern. A heatmap chart was generated with Multi-experiment Viewer (MeV) software.[22,23]

RESULTS AND DISCUSSION

Identification of the Benzoxazinoid Compounds. Tentatively identified benzoxazinoids in wheat bran ferments included DIBOA diglycoside, DIBOA glycoside, HBOA diglycoside, HBOA glycoside, DIMBOA diglycoside, and BOA aglycone. All reported compounds were detected in negative electrospray ionization as molecular ions. The recorded MS/MS fragments of detected benzoxazinoid glycosides and metabolites are presented in Table 1, as well as references used for confirmation of identification. MS/MS fragmentation spectra for DIBOA and HBOA diglycoside and HHPAA with extracted ion chromatograms are presented in Figure 3. The fragmentation pattern of benzoxazinoid glycosides was analogical to that found earlier (Table 1; Figure 3).[6] Identification of the phenylacetamide HHPAA, a potential microbial conversion product of benzoxazinoids, was based on the fragmentation pattern showing major fragments at m/z 118.0453 and 108.0422 (Figure 3), which is in accordance with that reported earlier.[11] There were two signals (m/z 150.055 with retention time (rt) of 3.0 and 3.2 min) exhibiting the molecular mass and MS/MS fragmentation corresponding to phenylacetamide HPAA as reported earlier.[11] However, the structural difference between these two compounds could not be resolved, and therefore they are reported as unknowns (Table 1). Additionally, the data were searched for other earlier reported conversion products of benzoxazinoids,[24] but none were found. However, there were two metabolites formed

during the fermentation (m/z 189.092 at 3.67 min and m/z 224.055 at 2.75 min), which had fragmentation pattern and retention time referring potentially to benzoxazinoid derived metabolites (Table 1). The ion with m/z 189.092 gave several fragment ions including m/z 118.037, 107.114, and 108.051, which were observed also for the benzoxazinoid compounds eluting in this same chromatographic region. Additionally, the unknown compound with m/z 224.055 resulted in MS/MS fragments of m/z 162.053, 134.024, 118.042, and 108.055, which are very close in mass to the ions observed for other

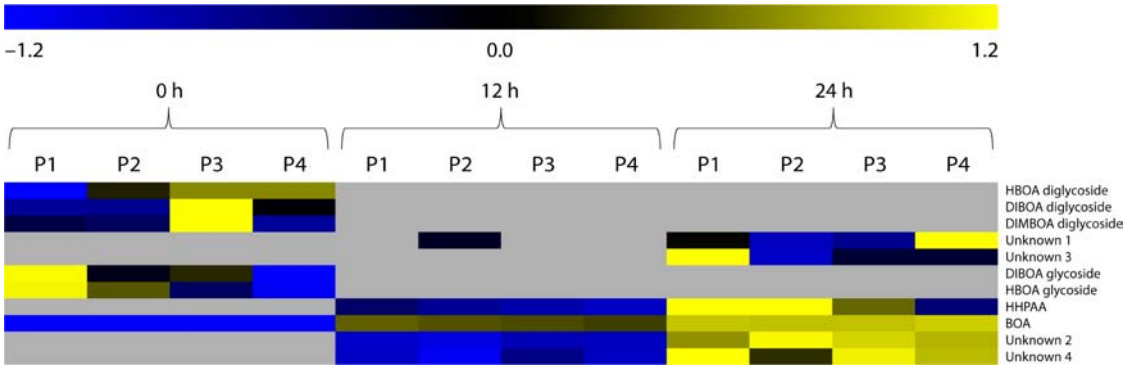

Figure 4. Heatmap representation of the tentatively identified benzoxazinoids and their conversion products in the different bioprocesses (P1−P4) during fermentation (0, 12, and 24 h). The signal abundances were row-wise normalized. The color coding indicates the abundance of each metabolite: yellow, high abundance; blue, low abundance; gray, no value.

benzoxazinoid compounds, including DIMBOA and HHPAA. We have recently observed this same unknown compound to be excreted in urine of mice after feeding with rye bran and, intriguingly, this compound was excreted in significantly higher levels when rye bran was fermented with yeast.[25]

Effects of Fermentation on the Benzoxazinoid Compounds. The relative intensities of the identified compounds had major differences during all four bioprocesses as visualized in a heatmap chart (Figure 4). Prior to fermentation (0 h), both the mono- and diglycoside derivatives of DIBOA, DIMBOA, and HBOA were found in all four fermentation conditions. Although our analytical method was not quantitative, it is worth mentioning that at the onset of fermentation we detected the largest peak areas for DIBOA and HBOA diglycosides (Figure 5), which have been shown to be

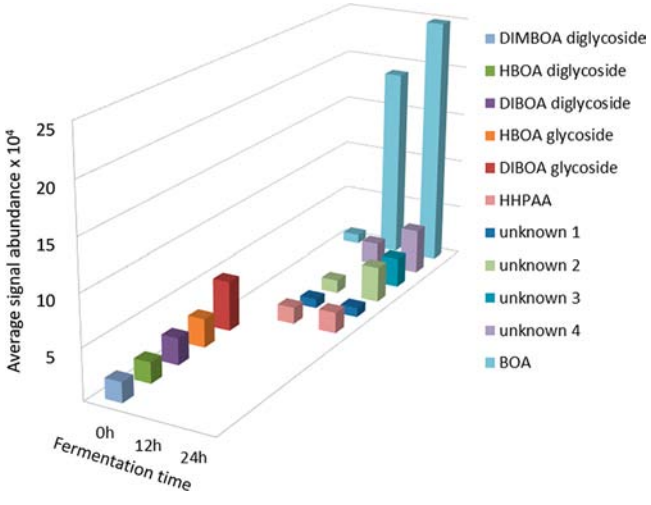

Figure 5. Average abundance of benzoxanoid derivatives and metabolites as relative peak areas plotted against fermentation time. The abundances from the different bioprocesses were combined.

the most abundant benzoxazinoids in wheat bran.[8] There were no benzoxazinoid aglycones or any of the potential degradation products detected prior to fermentation in any of the samples, except for a minor signal for BOA. Between 0 and 12 h of fermentation all di- and monoglycoside derivatives of benzoxazinoids were degraded in all of the tested fermentation conditions. In contrast, the breakdown products of DIBOA and HBOA, namely, BOA and HHPAA, as well as the several unknown compounds potentially derived from benzoxazinoids, were detected only from 12 h onward, showing highest accumulation at 24 h (Figures 4 and 5). One potential mediator for the compound conversion in the fermentation is the microbial metabolism in the bioprocess. Of the four fermentation methods used, P1 and P3 did not contain added lactic acid bacteria (LAB) but only the yeast, whereas in fermentations P2 and P4 a LAB starter was included. However, despite the differential bacterial regime, the fermentation method did not affect the degradation of glycosides and formation of other compounds including BOA and HHPAA (Figure 4). The pH decreased in all fermentations from 6.7 to an average of 4.8 during 24 h, and the use of LAB starter (P2 and P4) had only a slight additional 0.5 unit decrease in pH (Supporting Information (Table 4)). This slight difference in pH had no effect on the metabolic conversions. The lowered pH in fermentations without added LAB is most likely due to the growth of naturally occurring bacteria in the bran as has been demonstrated earlier.[26] Thus, the degradation of benzoxazinoid glycosides or formation of BOA and HHPAA was quite similar after two different types of fermentation irrespective of the microbial content. There were two unknown metabolites, which were produced mainly in either the fermentation containing yeast solely (P1; unknown 3, m/z 188.092) or after the fermentation with yeast, LAB, and enzymes (P4; unknown 1, m/z 150.055) referring to differential impact of the fermentation regime to the metabolic conversion (Figure 4). However, these two compounds remained unknown, similarly as two compounds that were produced in all of the fermentation conditions, which highlights the necessity of further structural analysis to understand the metabolic conversions of benzoxazinoid compounds during food processing.

In fermentations P3 and P4 enzyme preparations with cellulase, xylanase, β-glucanase, and α-amylase activities (Supporting Information (Table 1)) were used to modify the cereal cell wall structure and to release phytochemicals into the fermentation matrix.[27] With the application of enzymes in fermentation, the amount of phytochemicals in the dough can be modified; for example, the phenolic acids can be released from arabinoxylan.[27] This can further improve the bioaccessibility and bioavailability of these compounds.[28,29] Even when the sampling procedure was maintained as similar as possible for the four different fermentation conditions, the metabolic conversions seem to start rapidly after mixing the constituents of the fermentation mixture, as was suggested by the differences in the metabolite levels at the onset of the fermentation (0 h).

J. Agric. Food Chem. 2015, 63, 5943−5949

Interestingly, the fermentation together with yeast and the mixture of enzymes had the highest amount of the diglycoside conjugates of DIBOA, DIMBOA, and HBOA. This could be due to the enzymatic processing of the bran structure resulting in increased release of diglycoside conjugates to the fermentation media. In fermentation mixture P4 the mixture of enzymes was also added, but together with the LAB starter, which could boost the subsequent conversion of the digycosides and hence result in lower abundances of diglycosides when compared to the fermentation without the addition of LAB. However, the exact location of benzoxazinoids in the bran matrix is not yet studied, and thus the potential to increase their release by enzymatic treatment is only speculative. Detailed kinetic study would require quantitative targeted methods, which is currently not possible as not all of the detected compounds are available as commercial standards, and at the end of the fermentation process the levels of the main end products were relatively similar without striking differences between the different fermentation conditions.

In previous studies it has been demonstrated that boiling and soaking affect both the profile and the apparent concentration of benzoxazinoids in wheat.[8] Whereas it has been speculated that sourdough fermentation may be involved in altering the benzoxazinoid concentration in whole grain bread,[11] it was still unclear if this was due to the fermentation or the baking process. Our results clearly show that extensive structural conversions occur on benzoxazinoids during fermentation without baking, including degradation of benzoxazinoid glycosides and formation of HHPAA. The earlier finding of HHPAA glucuronide and sulfate as one of the most discriminatory signals for whole grain sourdough rye bread intake[11] suggests that HHPAA is bioavailable, as has also been shown in a postprandial study involving rye bran enriched diets.[14] Conversion of HHPAA was suggested to be postabsorptive metabolism,[11] although on the basis of our results this could equally be due to direct absorption of the metabolite present in sourdough bread. However, focused quantitative analyses are required to resolve the kinetics and dose−response relationship of this metabolite.

In our analysis, two signals potentially corresponding to HPAA were detected in the fermented products, but detailed identification could not be accomplished. HPAA has been previously detected in bread and was suggested to be a result from degradation of benzoxazinoid glycosides.[11] However, an alternative way of formation could be due to thermal processing during baking from HHPAA via dehydroxylation. Additionally, in our analysis, we observed unknown metabolites emerging in the sourdough process, which could potentially be of benzoxazinoid origin based on similarity in MS/MS fragments when compared with the identified metabolites. Therefore, it is possible that other, yet unknown, metabolized forms of benzoxazinoids are present in products involving sourdough fermentation and interestingly, as we recently observed, some of these seem to be also bioavailable and excreted in urine of mice after feeding with rye bran.[25]

In conclusion, we showed for the first time in a controlled fermentation that benzoxazinoid glycosides are degraded during fermentation and that HHPAA and BOA, conversion products of benzoxazinoids, alongside other potential metabolites of benzoxazinoid origin, are formed in sourdough. We also showed that the conversion was not remarkably affected by using lactic acid bacteria or enxymes in the fermentation in addition to yeast starter. This result emphasizes the potential of fermentation to modify the composition of phytochemicals embedded in the cereal matrix and the need to examine the effects of food processing on the phytochemical composition to be able to evaluate dietary effects at the molecular level.

J. Agric. Food Chem. 2015, 63, 5943−5949

In vitro models using cultured human intestinal cells have been shown to be useful for a more focused investigation of the absorption of dietary compounds. One such model, Caco-2 cultured intestinal cells, has been successfully used to study the characteristics of transepithelial transport of a variety of nutrients and dietary components.[23] This system has been adapted for use in iron uptake research[24] and has been used extensively to study iron nutritional qualities of a range of foods and food products. An advantage of the Caco-2 system is that it confers the ability to study Fe uptake effects of individual food components apart from other dietary factors. Using this in vitro system, Hu et al.[25] reported that flavonoid polyphenols in colored bean seed coats strongly inhibited Fe bioavailability in bean digests. Thus, polyphenols have been implicated in reduced iron nutrition, specifically in beans, by studies using a range of experimental systems.

In Fe bioavailability studies, polyphenols have commonly been grouped as Fe uptake inhibitors, with the implication that all members of this class of phytochemicals act in a similar manner. The generalized nature of the presumed inhibitory effect is illustrated by the way that polyphenols are typically measured. Most studies use the Folin−Ciocalteu method,[26] and results are reported as gallic acid equivalents.[27] Little information has been established concerning the effects of specific individual polyphenols on Fe bioavailability. This work set out to identify polyphenolic compounds present in black and white bean and to examine the relative Fe-inhibition properties of specific polyphenols using a Caco-2 cell assay.

MATERIALS AND METHODS

Chemicals. LC-MS grade acetonitrile, LC-MS grade methanol, LC-MS grade formic acid, quercetin 3-glucoside, kaempferol 3-glucoside, 3,4-dihydroxybenzoic acid, catechin, myricetin, quercetin, kaempferol, dimethyl sulfoxide (DMSO), glucose, hydrocortisone, insulin, selenium, triiodothyronine, and epidermal growth factor were purchased from Sigma-Aldrich (St. Louis, MO, USA). Myricetin 3-glucoside was purchased from Extrasynthese (Genay, France). Sodium bicarbonate and PIPES were from Fisher Scientific (Waltham, MA, USA). Fe standard (1000 μg/mL in 2% HCl) was from High-Purity Standards (Charleston, SC, USA). Modified Eagle's medium (MEM), Dulbecco's modified Eagle's medium (DMEM), and 1% antibiotic−antimycotic solution were purchased from Gibco (Grand Island, NY, USA).

Bean Sample Preparation. Dried black and "Great Northern" white beans (Goya Foods, Inc., Secaucus, NJ, USA) were purchased at a local market. Isolated seed coats were prepared by wrapping whole black and white beans in deionized water-soaked paper towels until seed coats began to wrinkle and separate from cotyledons. Seed coats were then removed with forceps, dried, and ground to a coarse powder with a mortar and pestle. Whole beans were rinsed with deionized water, autoclaved for 30 min, lyophilized, and ground with a coffee grinder. To 1 g of ground bean material (cooked whole beans or isolated seed coats) was added 5 mL of methanol/water (50:50 v/v). The slurry was vortexed for 1 min, placed in a 24 °C sonication water bath for 15 min, vortexed again for 1 min, and centrifuged at 4000*g* for 15 min. The supernatant was filtered with a 0.45 μm Teflon syringe filter and stored for later use in a −20 °C freezer. For use in Caco-2 assays, whole bean methanol/water extracts were dried in a rotary evaporator, weighed, and redissolved in an appropriate volume of pH 2 medium (140 mM NaCl and 5 mM KCl, pH adjusted with HCl) to achieve the desired extract concentration.

Preparation of Fe and Polyphenol Solutions. Fe stock solutions were prepared from 1000 mg/mL Fe standard in pH 2 medium. For use in Caco-2 assays, polyphenols were dissolved to a concentration of 1.6 mM in DMSO and diluted with pH 2 medium to achieve 400 μM stock solutions containing 25% DMSO. Stock solutions were further diluted with pH 2 medium to appropriate concentrations for use in Caco-2 assays. Maximum DMSO concentration in the highest polyphenol concentration treatments (30 μM) was 3.1%. For use as LC-MS standards, polyphenols were dissolved to a concentration of 4 mM in DMSO and diluted to 1 mM with MeOH/H_2O (50:50 v/v). These stock solutions were further diluted with 50:50 MeOH/H_2O for use in standard curves.

Caco-2 Assays. Assays were performed with Caco-2 cells cultured on the bottom surface of wells in 24-well culture plates (Costar 24 Well Clear TC-Treated Multiple Well Plates). Cells were grown in DMEM supplemented with 3.7 g/L sodium bicarbonate, 25 mM HEPES (pH 7.2), and 10% fetal bovine serum. Cells were seeded at passages 29−38, at a density of 50000 cells/cm^2 on collagen-treated plates. Under these culture conditions, the cells were confluent by day 4 postseeding and formed highly reproducible, differentiated cell monolayers with consistent protein concentrations over the course of numerous experiments. Cells were used in experiments 13 days postseeding.

Solutions containing bean extract and/or polyphenol(s) were prepared in 150 μL of pH 2 medium. Fifty microliters of iron standard diluted in the same medium was added to extract or polyphenol solutions to achieve 4 or 10 μM Fe final concentration, and combined solutions (200 μL) were incubated at room temperature for 15 min before addition of 1 mL of MEM, supplemented with 3.5 g/L glucose, 2.2 g/L sodium bicarbonate, 10 mmol/L piperazine-*N*,*N*′-bis[2-ethanesulfonic acid] (PIPES) (pH 7.0), 1% antibiotic−antimycotic solution, hydrocortisone (4 mg/L), insulin (5 mg/L), selenium (5 μg/L), triiodothyronine (34 μg/L), and epidermal growth factor (20 μg/L). A half milliliter of this combined solution was applied directly onto Caco-2 cell monolayers in 24-well plates. After overnight incubation at 37 °C, cells were washed twice with a buffered saline solution (130 mM NaCl, 5 mM KCl, 5 mM PIPES, pH 6.7) and then lysed by the addition of 500 μL of 18 MΩ water. Lysed cells were measured for ferritin and protein concentrations as described previously[24,25] with modifications. Ferritin data in Figures 1−4 were acquired using an immunoradiometric assay (FER-IRON II), and data in Figure 5 used an enzyme immunoassay (SPECTRO FERRITIN, both from RAMCO Laboratories, Stafford, TX, USA). Ferritin formation was used as a measure of iron uptake and was expressed in nanograms of ferritin per milligram of cell protein. Cell protein was quantified using the Bio-Rad DC protein assay kit (Bio-Rad Laboratories). Means and standard errors of three replications were calculated for both protein and ferritin concentrations.

LC-MS Analysis. Extracts and standards were analyzed with a Waters Acquity UPLC. Five microliter samples were injected and passed through an Acquity UPLC BEH Shield RP18, 1.7 μm, 2.1 × 100 mm, column (Waters) at 0.5 mL/min. The column was temperature-controlled at 40 °C. The mobile phase consisted of water with 0.1% formic acid (solvent A) and acetonitrile with 0.1% formic acid (solvent B). Polyphenols were eluted using linear gradients of 86.7−84.4% A in 1.5 min, 84.4−81.5% A in 0.2 min, 81.5−77% A in 2.8 min, 77−55% A in 0.5 min, 55−46% A in 1 min, and 46−86.7% A in 0.2 min and a 0.8 min hold at 86.7% A for a total 7 min run time. From the column, flow was directed into a Waters Acquity photodiode array detector set at 300−400 nm and a sampling rate of 20/s. Flow was then directed into the source of a Xevo G2 QTOF mass spectrometer (Waters Corp.), and ESI mass spectrometry was performed in negative ionization mode with a scan speed of 5/s in the mass range from 50 to 1200 Da. Capillary and cone gas voltages were set at 2.3 kV and 30 V, respectively. Desolvation gas flow was 800 L/h, and desolvation gas temperature was 400 °C. Source temperature was 140 °C. Lock-mass correction was used, with leucine enkephalin as the lock-mass standard and a scan frequency of 25 s. Instrumentation and data acquisition were controlled by MassLynx software. Individual polyphenols in bean samples were tentatively determined by mass using MarkerLynx software, and their identities were confirmed by comparison of LC retention times with authentic standards. Polyphenol standard curves for flavonoids were derived from integrated areas under UV absorption peaks from 10 replications.

Standard curves for catechin and 3,4-dihydroxybenzoic acid were constructed from MS ion intensities using 10 replications.

Statistical Analysis. Data are presented as the mean ± standard error of the mean (SEM) in Caco-2 assays of nanograms of ferritin per milligram of protein (Figures 1–5) and as the mean ± standard deviation (SD) for polyphenol concentrations (Table 1).

Table 1. Concentrations of Polyphenols Present in Extracts from Black Bean Seed Coats[a]

polyphenol	rt (min)	*m/z*	mean ± SD (μM)	p/i
myricetin 3-*O*-glucoside	2.80	479.0820	100.6 ± 5.1	i
quercetin 3-*O*-glucoside	3.69	463.0870	33.2 ± 1.6	i
kaempferol 3-*O*-glucoside	4.54	447.0919	17.6 ± 0.9	p
3,4-dihydroxybenzoic acid	1.03	153.0179	14.3 ± 2.5[b]	p
catechin	1.35	289.0706	10.2 ± 0.9[b]	p
myricetin	5.39	317.0292	7.4 ± 0.4	i
quercetin	5.80	301.0344	1.8 ± 0.1	i
kaempferol	6.26	285.0399	1.5 ± 0.1	p

[a]rt, retention time; p/i, promoter or inhibitor of iron uptake in Caco-2 assays. [b]Quantified by MS ion intensity. Other concentrations were determined by integration of UV absorption peak areas.

RESULTS

Increasing concentrations of extracts from whole white or black beans applied to Caco-2 cells in the presence of 10 μM Fe induced an increase in ferritin formation, reaching a maximum at extract concentrations of 0.1–0.2 mg/mL (Figure 1). At higher extract concentrations, ferritin formation declined, with a greater decrease observed in black bean extracts. In the absence of added Fe, ferritin formation remained around baseline levels in both white bean and black bean.

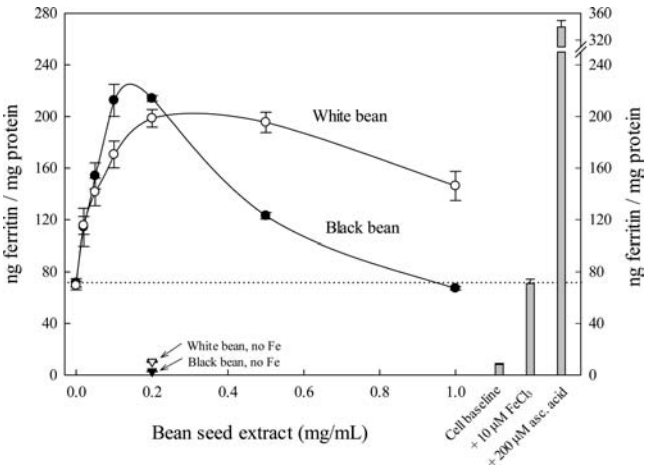

Figure 1. Ferritin formation in Caco-2 cells in response to various concentrations of extracts from whole white and black beans. Dotted line indicates ferritin response to 10 μM Fe alone. Error bars represent standard error of the mean and do not extend outside some data points.

When extracts from seed coats isolated from both black and white beans were applied to Caco-2 cells, the ferritin formation responses to the two types of bean were very different. The presence of white bean seed coats promoted ferritin formation at all extract concentrations, whereas seed coat extracts from black bean inhibited ferritin formation at all concentrations (Figure 2). In white bean seed coats, at extract concentrations of ≥0.2 mg/mL, ferritin production was double that of 10 μM Fe applied alone. Baseline levels of ferritin production were observed in the presence of both white and black bean seed coat extracts when Fe was withheld, demonstrating that enhanced ferritin production by white bean seed coats was not associated with higher endogenous Fe concentration in white bean seed coats. In striking contrast to the response to white bean seed coat extracts, black bean seed coat extracts strongly inhibited ferritin formation to nearly cell baseline levels at extract concentrations of ≥0.2 mg/mL (Figure 2).

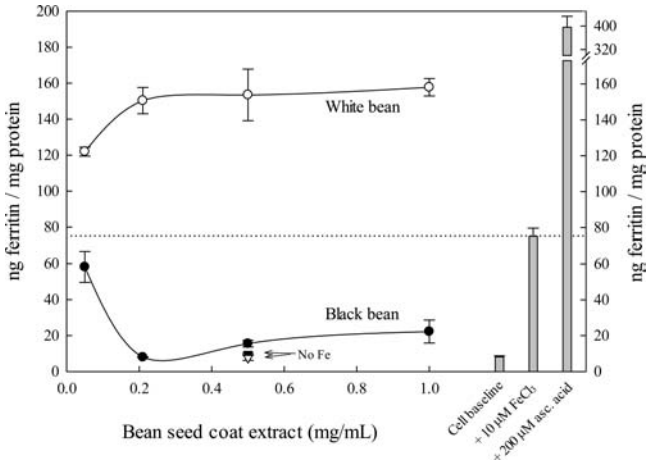

Figure 2. Ferritin formation in Caco-2 cells in response to various concentrations of extracts from white and black bean seed coats. Dotted line indicates ferritin response to 10 μM Fe alone. Error bars represent standard error of the mean and do not extend outside some data points.

Because it has been reported that polyphenols inhibit iron absorption in Caco-2 cells,[25,28] we investigated the effects of individual polyphenols on ferritin formation. Various concentrations of the flavonol myricetin, a polyphenol known to be present in black beans,[8] were added to whole black and white bean extracts (0.2 mg/mL) in a Caco-2 ferritin assay to test the response. Ferritin formation was inhibited in both black and white beans in the presence of myricetin at concentrations ≥10 μM Fe (Figure 3). In the absence of bean extract, 20 μM myricetin plus 10 μM inhibited ferritin formation down to cell baseline levels.

When supplied alone to Caco-2 cells, specific polyphenols had markedly varying effects on ferritin formation. At concentrations equimolar and greater than that of Fe, myricetin strongly inhibited ferritin formation (Figure 4). At higher myricetin concentrations, ferritin formation declined to cell baseline levels. The flavanol epicatechin induced a strong promotional effect on ferritin formation at all concentrations (Figure 4). The increase in ferritin production in the presence of epicatechin was Fe-dependent, as indicated by the low (cell baseline) level of ferritin formed when cells were supplied with 20 μM epicatechin in the absence of Fe (Figure 4).

To identify specific polyphenol composition, black and white bean seed coat extracts were analyzed by LC-MS. In black bean, the most abundant identifiable polyphenol was myricetin 3-*O*-glucoside, followed by lesser amounts of quercetin 3-*O*-glucoside and kaempferol 3-*O*-glucoside (Table 1). The benzoic acid, 3,4-dihydroxybenzoic acid, and the flavanol catechin were also present, followed by aglycones of the most abundant glycosylated flavonols (Table 1). White bean seed coat extracts contained no detectable amounts of these

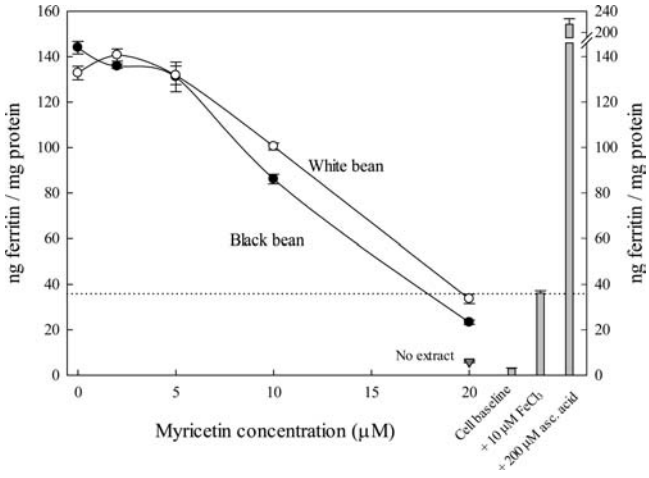

Figure 3. Ferritin formation in Caco-2 cells in response to various concentrations of myricetin plus 0.2 mg/mL extracts from whole white and black beans. Dotted line indicates ferritin response to 10 μM Fe alone. Error bars represent standard error of the mean and do not extend outside some data points.

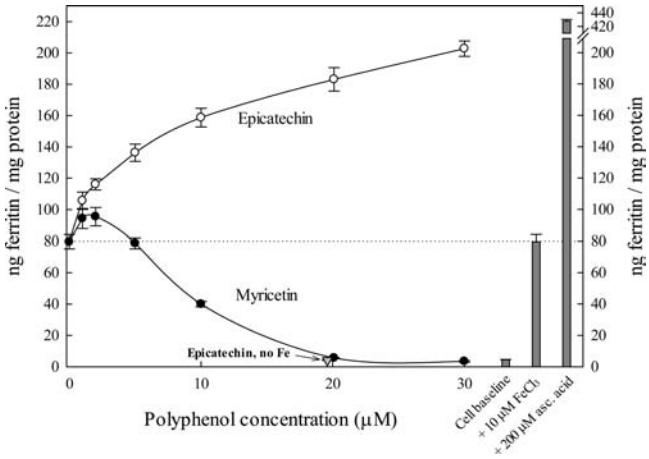

Figure 4. Ferritin formation in Caco-2 cells in response to various concentrations of epicatechin and myricetin, without bean extract. Dotted line indicates ferritin response to 10 μM Fe alone. Error bars represent standard error of the mean and do not extend outside some data points.

compounds. Anthocyanidins and anthocyanins, although present in black bean, were not considered in this study.

To examine the Fe bioavailability effects of the most abundant polyphenols present in black bean seed coats, each of the eight compounds listed in Table 1 was tested for its effect on ferritin formation with the Caco-2 assay. Kaempferol 3-*O*-glucoside, kaempferol, catechin, and 3,4-dihydroxybenzoic acid promoted ferritin production, whereas myricetin 3-*O*-glucoside, quercetin 3-*O*-glucoside, quercetin, and myricetin inhibited the formation of ferritin in a concentration-dependent manner (Figure 5). For all eight compounds, withholding Fe resulted in cell baseline levels of ferritin production. Relative Caco-2 ferritin responses varied somewhat among experiments as shown by slightly different values of Fe-alone and Fe plus ascorbic acid treatments. This is normal for Caco-2 bioassays, and it is important to note that in all cases, polyphenols showing either promotional or inhibitory effect on Fe bioavailability did so consistently. Experiments with individual polyphenols were repeated several times to confirm those observations.

DISCUSSION

In both in vitro and in vivo studies, whole colored beans and the seed coats from colored beans have consistently been shown to inhibit Fe bioavailability, and this inhibition has been demonstrated to be due to the presence of polyphenols in the seed coat.[2,15,22,29] As expected, in the present study, extracts of black bean whole seeds or seed coats inhibited ferritin production (i.e., cell Fe uptake) in Caco-2 cells to a much greater degree than similar extracts from white bean (Figures 1 and 2). The results clearly show that when the black bean seed coat is present, either as an extract from seed coats or whole seeds, the relative effect is one of inhibition of Fe uptake.

It should be noted that, although the primary focus of this study was the effects of polyphenols on Fe uptake, extracts from whole black and white beans and seed coats of white bean produced an enhancement of Fe uptake compared with supplying Caco-2 cells with Fe alone (Figures 1 and 2). The factor(s) present in cotyledons or seed coats responsible for increased ferritin formation cannot be determined from these results, but we can speculate that proteins and possibly phytate and/or other compounds present in extracts could help to solubilize Fe and make it available for absorption. This effect was concentration-dependent, with a maximum Fe uptake at about 0.2 mg/mL in both whole white and black bean extracts (Figure 1). This effect may be due, at least in part, to the presence of phytic acid in cotyledons. Under some conditions, low levels of phytic acid can actually promote Fe uptake in vitro,[30] whereas higher levels like those normally found in crops such as beans inhibit Fe uptake. As expected, the addition of ascorbic acid to Fe in controls (Figures 1−5) clearly demonstrated the power of this reducing agent to increase Fe uptake in Caco-2 assays.

It is also important to note that the low (near cell baseline) level of ferritin production in the absence of added Fe indicates that the compounds extracted from whole beans or seed coats (Figures 1 and 2) or individual polyphenols applied alone to Caco-2 cells (Figures 4 and 5) did not by themselves cause the ferritin formation response. Also, given that the extracts contained negligible amounts of Fe, it is very likely that the ferritin formation responses observed in these experiments were due to the interaction of extracted compounds with exogenously added Fe. Therefore, we can be confident that the in vitro conditions used in this work are suitable for characterizing both promotional and inhibitory effects of extractable compounds on Caco-2 cell Fe uptake.

There has been a consistent general assertion in the literature that all polyphenols inhibit Fe bioavailability.[31] This assumption is countered, however, by the results of the present study. Clearly, the addition of the flavonoid myricetin, a polyphenol known to be present in black beans,[8] to whole black and white bean extracts brought about a concentration-dependent decrease in Fe bioavailability (Figure 3). At myricetin concentrations >5 μM, the ferritin-promoting effects of whole bean extracts seen in Figure 1 were reversed by the addition of this individual polyphenol. Similarly, direct application of myricetin alone to Caco-2 cells brought about a strong decrease in Fe uptake at concentrations >5 μM (Figure 4).

On the other hand, the strong, concentration-dependent promotion of ferritin formation by epicatechin and catechin (Figures 4 and 5) and the moderate enhancement of Fe uptake

DOI: 10.1021/acs.jafc.5b00531
J. Agric. Food Chem. 2015, 63, 5950−5956

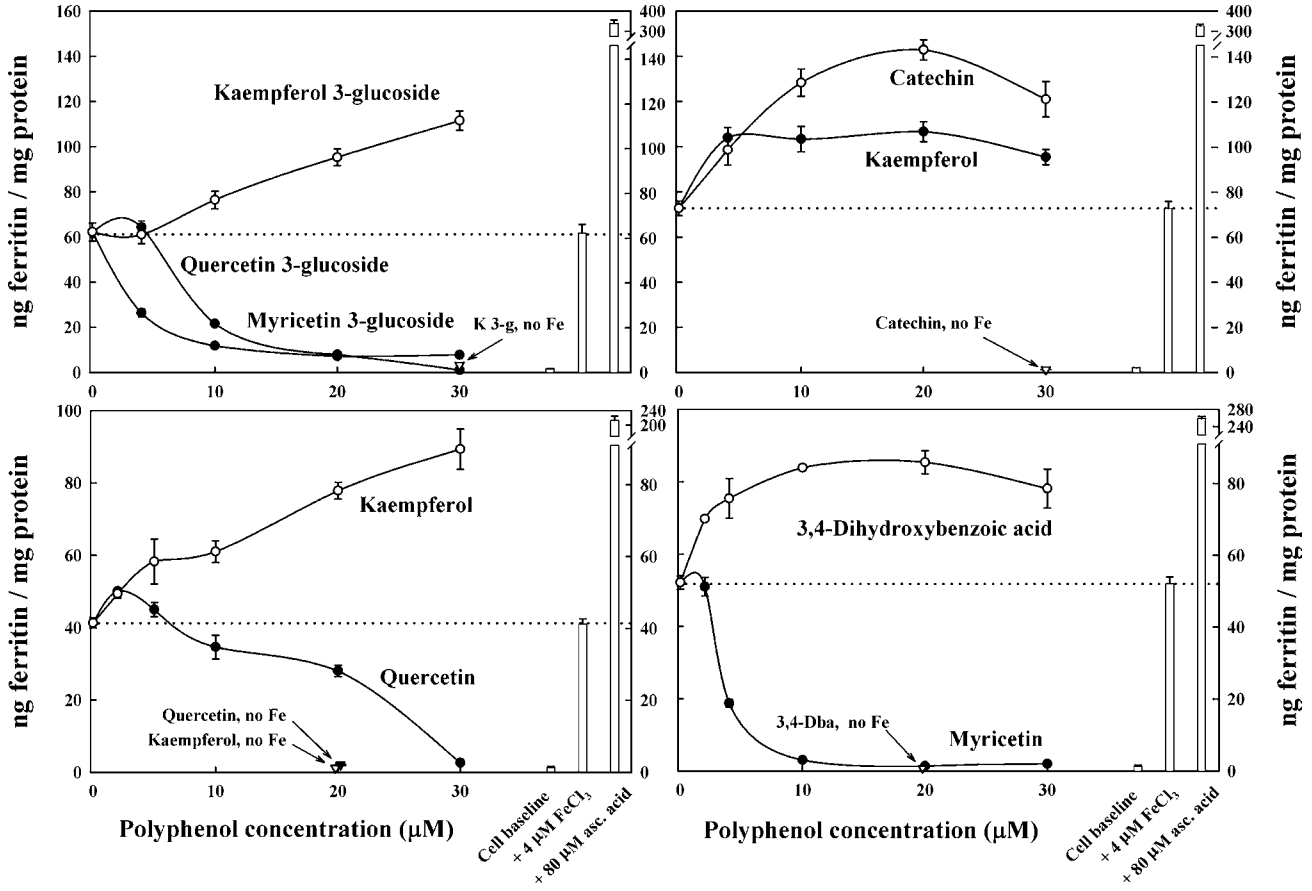

Figure 5. Ferritin formation in Caco-2 cells in response to various concentrations of eight polyphenols determined to be present in black bean seed coat extracts. Dotted line indicates ferritin response to 4 μM Fe alone. Error bars represent standard error of the mean and do not extend outside some data points.

by kaempferol, kaempferol 3-glucoside, and 3,4-dihydroxybenzoic acid (Figure 5), all applied directly to Caco-2 cells, are in contrast to the general assumption that polyphenols inhibit Fe uptake. As summarized in Table 1, of the eight most abundant non-anthocyanin polyphenols present in black bean seed coats, four were shown to be promoters of iron uptake in Caco-2 cells and four were shown to be inhibitors (Figure 5). This appears to be the first study to clearly show both inhibitory and promotional effects on Fe uptake by specific polyphenols. It is important to note that these cell culture experiments are relatively easy to carry out. Thus, we believe that this approach can be applied to characterize the effects of the multitude of other compounds present in staple food crops (and their interactions) that can influence Fe bioavailability.

The mechanism by which epicatechin and catechin promote Fe uptake is not known. One possible mechanism that may be involved with promotion is increased solubility of iron−epicatechin/catechin complexes coupled with favorable exchange kinetics at membrane-bound iron transport sites. This would tend to increase the amount of iron available for uptake by Caco-2 cells.

Another possible mechanism with some support in the literature is reduction of Fe^{3+} to Fe^{2+} by epicatechin. As shown in Figures 1−5, iron reduction by ascorbic acid had a strongly promoting effect on iron uptake in our Caco-2 system. If it occurs, iron reduction by epicatechin should also have a promoting effect. As reviewed by Perron et al.,[13] reduction of Fe^{3+} to Fe^{2+} by some polyphenols can occur, especially at low pH. Catechol[32] and epicatechin[33,34] have been demonstrated to reduce Fe^{3+} to Fe^{2+} at pH 2−3. In our experiments, polyphenols were incubated with Fe in pH 2 solution for 15 min and then added to pH 7-buffered MEM and quickly placed on Caco-2 cell monolayers. It is conceivable that this protocol was capable of generating sufficient Fe^{2+} to cause promotion of iron uptake before re-oxidation of Fe^{2+} to Fe^{3+} occurred. Re-oxidation of Fe^{2+} has been reported to occur with an increase in pH, but the kinetics with which this may occur is not well characterized.[32]

Iron reduction via the catecholate configuration on the B ring of epicatechin and catechin may be involved with increased Fe uptake.[13] Another promoter of iron uptake in our study, 3,4-dihydroxybenzoic acid, also contains a catecholate substructure. However, the promoters kaempferol and kaempferol 3-glucoside do not have either catecholate or gallate substructures, so their Fe-uptake promotional properties may proceed through another mechanism. On the other hand, the inhibitors quercetin, myricetin, and their glucosides do contain catecholate and gallate ligands, respectively. The inhibitory properties of those four polyphenols may occur simply by strongly binding iron and making it unavailable for uptake. Thus, a consistent polyphenol structure/iron bioavailability functional relationship influencing Fe bioavailability is not apparent in the major black bean polyphenols identified in this study.

We can speculate on the concentration-dependent inhibitory activity of myricetin on iron uptake (Figure 4) on the basis of

DOI: 10.1021/acs.jafc.5b00531
J. Agric. Food Chem. 2015, 63, 5950−5956

the well-documented ability of phenolic compounds to chelate iron.[35−37] Stability constant values for Fe^{3+}−myricetin complexes in the range of 10^5−10^9 have been reported,[9] and inhibition of iron uptake due to binding by polyphenols has been demonstrated in Caco-2 cells.[28,38] Thus, the iron uptake inhibition by myricetin shown in Figure 4 is consistent with previously published reports and suggests that it is due to iron−myricetin complexation and subsequent Fe uptake inhibition.

In black bean seed coats, the total concentration of the four iron uptake inhibitors was >3 times higher than the concentration of the four promoters (Table 1). Thus, it is not surprising that the net effect of black bean seed coat extracts containing all eight major polyphenols is a strong inhibition of iron uptake (Figure 2). However, implicit in this calculation is that the polyphenols studied here have a similar concentration effect on promotion or inhibition. In fact, examination of the curves in Figure 5 suggests that this assumption may not be true. For example, myricetin appears to be a more effective inhibitor than quercetin at a given concentration and catechin, a more effective promoter than kaempferol. It is not possible to deduce from the data in Figure 5 the net effect of combining promoters and inhibitors. Additional studies will be needed to establish the relative effectiveness of individual polyphenols and their interactions to promote or inhibit iron bioavailability.

It would appear that identification of polyphenols that can promote iron bioavailability raises the possibility of producing breeding lines with enhanced nutritional quality. The results reported here were obtained using an in vitro cell culture system, and it is not clear that the promotional effects observed using this system would extend to in vivo systems. Experiments with animal models or human feeding trials will be necessary to test the possibility. It is interesting that a human study of the effects of several polyphenols determined that, whereas gallic acid and tannic acid inhibited iron absorption, catechin produced no such inhibition.[39] This observation suggests that, even if polyphenol promotion of iron uptake in cell culture does not translate to promotion in vivo, breeding for reduced levels of inhibitory polyphenols as well as enhanced levels of promoting polyphenols may yield more nutritious staple foods.

this food after oral administration to rats. We used an ether derivative compound with one OH (tyrosol ethyl ether, TEE), one with two OH (hydroxytyrosol ethyl ether, HTEE), and one with no OH in its structure (3,4-di-*o*-methylidene-hydroxytyrosol ethyl ether, MHTEE). Although MHTEE is a related phenolic compound not present in VOO, it was tested here as a "negative control" for antioxidant effects. Ethyl ether derivatives were used because of their greater lipid solubility and metabolic stability than natural compounds.[15,16] We chose the ethyl derivative with a short hydrocarbon chain for testing, because this made it more likely that the differences we observed between compounds were related to their basic chemical structure and the possible influence of the side chain. Moreover, by using different hydrocarbon chain lengths in the same experimental model, we aimed to show that the neuroprotective effect of the ethyl derivative was similar to that of the nonetherified compound.[17]

The sequence of our experiments was designed to answer the following questions: (1) Is the presence of OH important for the antioxidant effect of VOO polyphenols after oral administration? (2) Is there a relationship between the OH-antioxidant effect of VOO polyphenols and their neuroprotective effect after oral administration in rats? (3) Are the neuroprotective mechanisms of these compounds directly related to their antioxidant effects, and are the latter related to the OH groups, or are their neuroprotective effects explainable by other mechanisms?

MATERIALS AND METHODS

Chemicals. Lactate dehydrogenase reagent kits were obtained from Biosystem SA (Barcelona, Spain). HTEE (two OH in the chemical structure), TEE (one OH in the chemical structure), and MHTEE (no OH in the chemical structure) (Figure 1) were chemically synthesized

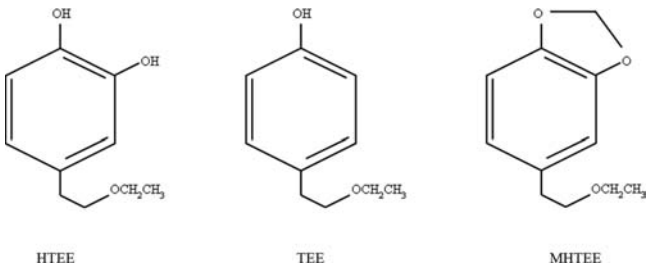

Figure 1. Chemical structures of hydroxytyrosol and hydroxytyrosyl alkyl ethers.

according to the methods of Madrona et al.[18] We chose the ethyl derivative to a long hydrocarbon chain in order not to interfere with the essential chemical structure in our explanation of how a known antioxidant affects these polyphenols. This approach allowed us to ascribe the differences between compounds to the basic chemical structure and the possible influence of the side chain. Moreover, research with different hydrocarbon chain lengths in the same experimental model showed that the ethyl derivative had a neuroprotective effect very similar to that of the nonetherified compound.[17]

Study Design. The animals (10 per group) were 2-month-old adult male Wistar rats (body weight 200−250 g). All rats were used in accordance with current Spanish legislation for animal care, use, and housing (EDL 2013/80847. BOE-A-2013-6271). The recommendations in the *Guide for the Care and Use of Laboratory Animals* (NIH publication 86-23, revised 1985) were followed, as well the Spanish Law on the Protection of Animals, where applicable. The study protocol was approved by the University of Malaga Ethics Committee for the Use of Animals.

Animals (10 rats per group) were distributed in seven groups: (1) control rats treated with saline, (2) rats treated with 10 mg/kg/day po (HTEE), (3) rats treated with 20 mg/kg/day po HTEE, (4) rats treated with 10 mg/kg/day po TEE, (5) rats treated with 20 mg/kg/day po TEE, (6) rats treated with 10 mg/kg/day po MHTEE, and (7) rats treated with 20 mg/kg/day po MHTEE. These doses were chosen according to results obtained in a previous study with HTEE, HTEE acetate, and HTEE ethyl ether in the same experimental model.[19,20] All compounds were given once per day for 7 days via an endogastric cannula at 10:00 a.m. The last dose was given 1 h before the animals were killed.

All rats were anesthetized with pentobarbital sodium (40 mg/kg ip) and were then decapitated with a guillotine.

In Vitro Model of Rat Brain Hypoxia−Reoxygenation. We used a previously described in vitro method of hypoxia−reoxygenation in brain slices.[21] The cortex and midbrain were cut coronally into 1 mm slices with a vibrating microtome (Capdem Instruments, San Francisco, CA, USA). The slices were placed in buffer (composition in mmol/L: 100 NaCl, 0.05 KCl, 24 $NaHCO_3$, 0.55 KH_2PO_4, 0.005 $CaCl_2$, 2 $MgSO_4$, 9.8 glucose, pH 7.4) and perfused with a mixture of 95% O_2 and 5% CO_2. After 30 min to reach equilibrium, the slices were placed in fresh buffer of the same composition except that the concentration of $CaCl_2$ was 3 mmol/L, that of $MgSO_4$ was 0.001 mmol/L, and no glucose was included. This solution was perfused with a mixture of 95% N_2 and 5% CO_2 for 20 min (hypoxia). Then the slices were placed in fresh buffer containing glucose, and the solution was perfused with a mixture of 95% O_2 and 5% CO_2 (reoxygenation).

Brain slices and/or incubation buffer were analyzed (1) after 30 min of incubation and before N_2 perfusion, (2) after 20 min of perfusion with N_2, and (3) after 180 min of reoxygenation. For all studies the tissues were quickly frozen in liquid nitrogen and stored at −80 °C until the day of the experiment, which was done not more than 7 days after the sample was frozen.

Analytical Techniques. All techniques were run in a single-blind manner; that is, the persons who did the assays were unaware of the origin and nature of the samples.

Lipid Peroxidation. To quantify lipid peroxidation, we measured thiobarbituric acid reactive substances (TBARS) in brain cell membrane-enriched fractions.[22] Absorbance was determined spectrophotometrically at 532 nm (FLUOstar-POLAEstar, BMG Labtechnologies. Offenburg, Germany). The results were expressed as nanomoles of TBARS per milligram of protein.

Glutathione Levels. Total glutathione was measured spectrofluorometrically.[23] Brain tissue was homogenized in 0.1 M sodium phosphate buffer (pH 8.0) with 25% phosphoric acid at a proportion of 1:20 and then centrifuged at 13000*g* for 15 min at 4 °C to obtain the supernatant. Cuvettes were prepared for spectrofluorometry with sodium phosphate buffer, the supernatant for each sample, and *o*-phthaldehyde. To determine the proportions of oxidized and reduced glutathione, we incubated the supernatant from each sample with 4-vinylpyridine and then proceeded as for as total glutathione.

Lactate Dehydrogenase Assay. Tissue damage was measured as lactate dehydrogenase (LDH) efflux. Enzyme activity was measured spectrophotometrically at 340 nm with a commercial kit (Cytotoxicity Detection Kit, Roche Applied Science, Barcelona, Spain) according to the manufacturer's instructions.

3-Nitrotyrosine. Brain tissue was homogenized (1:10 w/v) in a buffer containing 100 mM KH_2PO_4/K_2HPO_4 and 0.1% digitonin (pH 7.4). Then the homogenate was centrifuged at 5000*g* for 10 min at 4 °C. The amount of 3-nitrotyrosine in the supernatant was measured according to the manufacturer's instructions for the enzyme immunoassay kit.

Prostaglandin E_2. Brain tissues were snap-frozen in liquid nitrogen and stored until analysis. The samples were homogenized (1:10 w/v) in 15% methanol with 0.1 N phosphate-buffered saline (pH 7.5), then centrifuged at 37000*g* for 15 min at 4 °C. The supernatant was run through a C18 column (Bio-Rad Laboratories, Hercules, CA, USA) that had been activated with absolute methanol, followed by washing

[a]TBARS, thiobarbituric acid reactive substances; GSH, reduced glutathione; GSSG, oxidized glutathione. [b]$p < 0.001$ with respect to control group.

with distilled water. After the sample had been assayed, the column was washed with 15% methanol in distilled water followed by petroleum ether. Prostaglandins were eluted with methyl formate. The samples were then dried at room temperature under a nitrogen current and reconstituted with phosphate-buffered saline. The concentration of prostaglandin E_2 was measured with a commercial enzyme immunoassay (GE Healthcare UK Limited, Little Chalfont, Buckinghamshire, UK).

Interleukin 1β (IL1β). The tissue was homogenized in a volume of 1 mL of a buffer (4 °C, pH 7.2) containing 50 mM Tris, 1 mM EDTA, 6 mM $MgCl_2$, 1 mM phenylmethanesufonyl fluoride, 5 μg/mL leupeptin, 1 mg/mL antipain, 1 mg/mL aprotinin, and 1 mg/mL soybean trypsin inhibitor. After mixing, the samples were transferred to silicone tubes, then sonicated (VC-50T Vibracell, Sonics Materials, Newtown, CT, USA) for 5−10 s, and centrifuged at 14000*g* for 10 min at 4 °C. Then the supernatant was collected and processed according to the instructions for commercial kits for IL1β determination.

Statistical Methods. The data in the text, tables, and figures are expressed as the mean ± standard deviation of 15 animals or measurements. All statistical analyses were done with the Statistical Package for Social Sciences v. 19.0 (SPSS Co., Chicago, IL, USA). One-way analysis of variance followed by Bonferroni transformation and unpaired Student's t tests were used. To establish a possible relationship between cell death (LDH efflux) and other biochemical variables, Pearson correlation coefficients were calculated. In all cases, statistical significance was assumed at a value of $p < 0.05$.

RESULTS AND DISCUSSION

There were no statistically significant differences between control samples and samples from rats treated with HTEE, TEE, or MHTEE in the mean value of TBARS or reduced (GSH) or oxidized (GSSG) glutathione in oxygenated brain slices (Table 1). After the oxygenation period in brain slices tested with the hypoxia−reoxygenation experimental model, TBARS production increased from 2.3 ± 0.6 nmol/mg protein before anoxia to 5.0 ± 1.6 nmol/mg protein after reoxygenation ($p < 0.0001$). After ex vivo treatment with HTEE, TBARS production was inhibited, whereas TEE showed significant inhibition only at 20 mg/kg/day and MHTEE did not produce significant changes (Table 2).

In the experiments with brain hypoxia−reoxygenation, GSH decreased from 12.9 ± 4.6 to 6.5 ± 2.2 μmol/g tissue ($p < 0.0001$), and the percentage of GSSG with respect to GSH +GSSG increased from 16.1 ± 4.1 to 22.5 ± 5.3% ($p < 0.01$). None of the compounds modified GSH concentration or the percentage of GSSG with respect to GSH+GSSG (Table 2).

The antioxidant effect of hydroxytyrosol (two OH groups) and some esterified and etherified derivatives has been reported (see reviews by Raederstorff and Granados-Principal)[5,24] in chemical matrices, in cell culture, and in whole animal organs including rat brain tissue.[7,19,25,26] This effect has also been demonstrated in ex vivo experiments.[17] Tyrosol (one OH group) has demonstrated a weak antioxidant effect[27] that was approximately 25% of the effect of hydroxytyrosol in cell cultures.[28] The results of the present study confirmed these differences, because the antioxidant effect of TEE was about 20−22% that of HTEE.

The present study demonstrates the relationship between the antiperoxidative effect of these compounds and the presence of OH groups in brain tissue after oral administration to rats. Our results are further supported by the absence of an antioxidant effect of MHTEE, which lacks OH groups. Therefore, two phenolic compounds in VOO exhibited very different antioxidant potencies: one (HTEE) had a clear antioxidant effect, whereas the other (TEE) had little effect on oxidative stress in brain tissue.

Therefore, the catechol group influences the antioxidant effect of VOO polyphenols in rat brain tissue after oral administration.

In our hypoxia−reoxygenation experiments, LDH efflux increased from 0.2 ± 0.04 to 2.9 ± 0.7 arbitrary units/mg tissue ($p < 0.0001$). All three compounds reduced LDH efflux after

DOI: 10.1021/acs.jafc.5b00627
J. Agric. Food Chem. 2015, 63, 5957−5963

oral treatment for 7 days in comparison to control group (Figure 2).

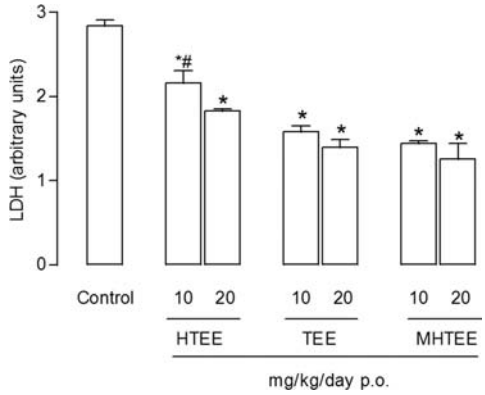

Figure 2. Lactate dehydrogenase efflux (LDH) measured after reoxygenation of brain slices in animals (N = 10 per group) treated for 7 days po with saline (control), hydroxytyrosol ethyl ether (HTEE) (two OH in the chemical structure), tyrosol ethyl ether (TEE) (one OH), or 3,4-di-*o*-methylidene-hydroxytyrosol ethyl ether (MHTEE) (no OH). (∗) $p < 0.001$ with respect to control group; (#) $p < 0.05$ with respect to HTEE 20 mg/kg/day and to TEE and MHTEE 10 and 20 mg/kg/day.

These results confirm the neuroprotective effect of hydroxytyrosol, HTEE acetate, and HTEE ethyl ether reported previously with the same experimental method as we used here.[7,17,19,20] Oxidative stress plays an important role in the process of neuronal death in brain ischemia,[29,30] and antioxidant compounds have thus been postulated to act as neuroprotective agents.[29] According to this hypothesis the polyphenolic compound with the greatest antioxidant potency (HTEE, with two OH) should have a greater neuroprotective effect than TEE (with one OH and a weak antioxidant effect). By this reasoning MHTEE, which lacks OH in its structure and has no antioxidant effect in brain tissue, would be expected to have little or no neuroprotective effect. In our experimental model, however, this prediction was not fully met, because TEE and MHTEE in fact showed greater neuroprotective potency than HTEE.

Tyrosol ethyl ether has shown neuroprotective effects in vitro[31] and in vivo.[10,32] In our experiments the antioxidant effect of TEE was proportionatey lower than its cytoprotective effect.

The antioxidant effect of these compounds influences only part of their neuroprotective action. This makes it necessary to consider other pathways of brain damage that might explain the overall neuroprotective effect of VOO polyphenols, particularly those involving TEE. In this study we explored two main neurotoxic pathways: nitrosative stress and some inflammatory mediators. The concentration of 3-nitrotyrosine, as an index of peroxynitrite formation in brain slices, increased from 1.2 ± 0.3 nmol/100 mg tissue before anoxia to 3.7 ± 0.8 nmol/100 mg tissue ($p < 0.001$) after reoxygenation. All three compounds inhibited 3-nitrotyrosine production at a dose of 20 mg/kg/day (Figure 3). There was no relationship between 3-nitrotyrosine inhibition and the number of OH groups in the chemical structure of the compounds we compared here.

The inhibition of nitrosative stress by olive oil polyphenols has been reported previously,[25,32] and hydroxytyrosol reduces the neuronal cytotoxicity induced by nitric oxide donors.[33]

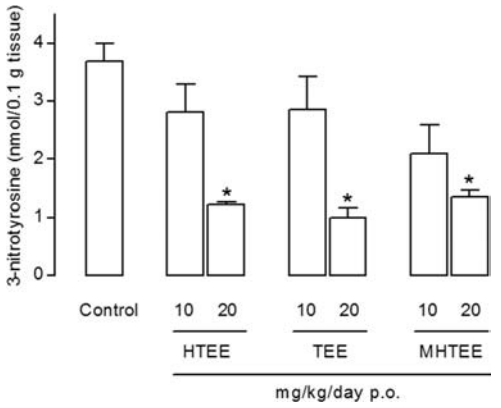

Figure 3. Peroxynitrite concentration (3-nitrotyrosine) measured after reoxygenation of brain slices in animals (N = 10 per group) treated for 7 days po with saline (control), hydroxytyrosol ethyl ether (HTEE) (two OH in the chemical structure), tyrosol ethyl ether (TEE) (one OH), or 3,4-di-*o*-methylidene -hydroxytyrosol ethyl ether (MHTEE) (no OH). (∗) $p < 0.0001$ with respect to control group and with respect to each 10 mg/kg/day group.

Moreover, hydroxytyrosol and tyrosol are known to act as nitrogen radical scavengers[34] and to prevent protein nitration induced by peroxynitrites.[35] This effect seems to be independent of their antioxidant effect, because their inhibitory profiles differ for oxidative and nitrosative stress in this experimental model with rat brain slices. Moreover, MHTEE (which had no antioxidant effect) had an inhibitory effect on 3-nitrotyrosine concentration after reoxygenation in brain slices.

With regard to inflammatory mediators, prostaglandin E_2 concentration in brain slices increased from 15.1 ± 6.2 pg/100 g tissue before anoxia to 57.0 ± 24.7 pg/100 mg tissue after reoxygenation ($p < 0.0001$). In this experimental model IL1β increased from 10.1 ± 4.1 pg/100 mg tissue before anoxia to 34.5 ± 12.7 pg/100 mg tissue after reoxygenation ($p < 0.0001$). All three polyphenol compounds inhibited prostaglandin E_2 production, whereas only HTEE inhibited IL1β production (Figure 4).

Hydroxytyrosol was previously found to inhibit type-2 cyclooxygenase (COX-2) in peripheral human blood cells.[25,36] Activation of the inducible isoform of COX in brain tissue and the prostaglandin synthesis resulting from this activation have been related to some aspects of ischemic damage,[37] and the inhibition of COX-2 correlated with a neuroprotective effect of some nonsteroidal anti-inflammatory drugs in the same experimental model as we used in this study.[21] This effect seems to be independent of the antioxidant effect because exposure to TEE (weak antioxidant effect) and MHTEE (no antioxidant effect) had an even greater effect than exposure to HTEE.

With regard to our results for IL1β inhibition, research with cultured human leukocytes showed that hydroxytyrosol inhibited the expression of stimulatory factors for cytokine synthesis (NF, STAT-1α, IRF-1) and, in general, the majority of inflammatory mediators.[32,38−40] Specifically, Rosignoli et al.[40] reported the importance for this effect of two OH groups at the ortho position, because other derivatives without these groups (dialdehyde elenolic acid) had no anti-inflammatory activity in activated human monocytes.

According to these results, TEE may exert its neuroprotective effect through mechanisms other than a (weak) antioxidant

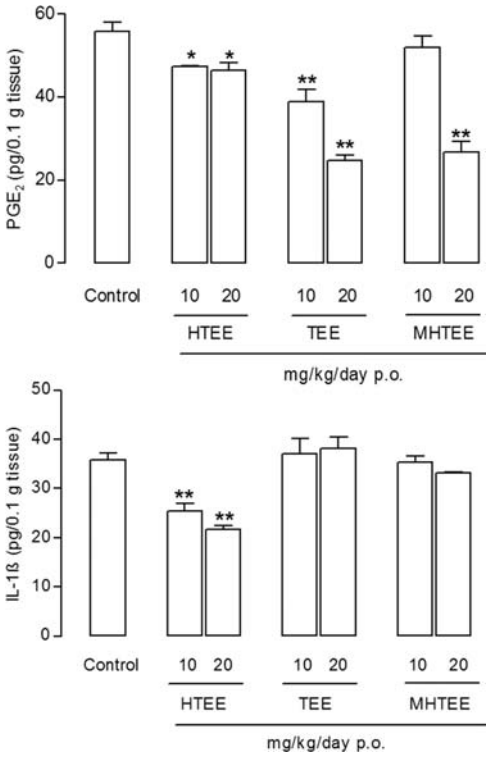

Figure 4. Prostaglandin E_2 (PGE_2) and interleukin 1β (IL1β) concentrations measured after reoxygenation of brain slices in animals (N = 10 per group) treated for 7 days po with saline (control), hydroxytyrosol ethyl ether (HTEE) (two OH in the chemical structure), tyrosol ethyl ether (TEE) (one OH), or 3,4-di-*o*-methylidene-hydroxytyrosol ethyl ether (MHTEE) (no OH). (*) $p < 0.01$; (**) $p < 0.001$ with respect to control group.

effect, for example, by inhibiting nitrosative stress or prostaglandin production.

To determine the possible contribution of each of these biochemical pathways to the neuroprotective effect of these compounds and to determine whether the presence of OH groups influenced this effect, we calculated Pearson correlation coefficients for the relationship between LDH efflux and variables identified in the hypoxia−reoxygenation model (Table 3). This analysis suggested that two types of mechanism may be responsible for the neuroprotective effect of VOO polyphenols: (1) an antioxidant effect, probably related to the presence of catechol groups (the neuroprotective effect of TEE and MHTEE was not significantly related to their effect on brain oxidative stress); (2) other effects (inhibition of nitrosative stress and inflammatory mediators) independent of their antioxidant effect and unrelated to the presence of catechol groups (TEE and MHTEE exerted these inhibitory effects).

Table 3. Pearson Correlation Coefficients between LDH Efflux and Oxidative and Nitrosative Stress and Inflammatory Mediators[a]

relationship between LDH and:	HTEE (two OH)	TEE (one OH)	MHTEE (no OH)
TBARS	0.72[b]	0.45	0.08

In conclusion, this study demonstrates that the presence of the catechol group in the chemical structure of VOO polyphenols is an important factor that contributes to their antioxidant effect in rat brain tissue, and that partly explains their neuroprotective effect. Inhibition of oxidative stress in the model of cerebral hypoxia−reoxygenation is not the only neuroprotective mechanism in which these compounds are involved. Other components of olive oil with a weak antioxidant effect, such as tyrosol, might also have a neuroprotective effect by modifying other biochemical pathways, for example, by inhibiting nitrosative stress or prostaglandin production. The neuroprotective effect of VOO in our experimental model may be the result of a combination of these mechanisms for HTEE and TEE, among other compounds. Further experiments designed to test combinations of these polyphenols will be needed to fully characterize the mechanisms behind their neuroprotective effect.

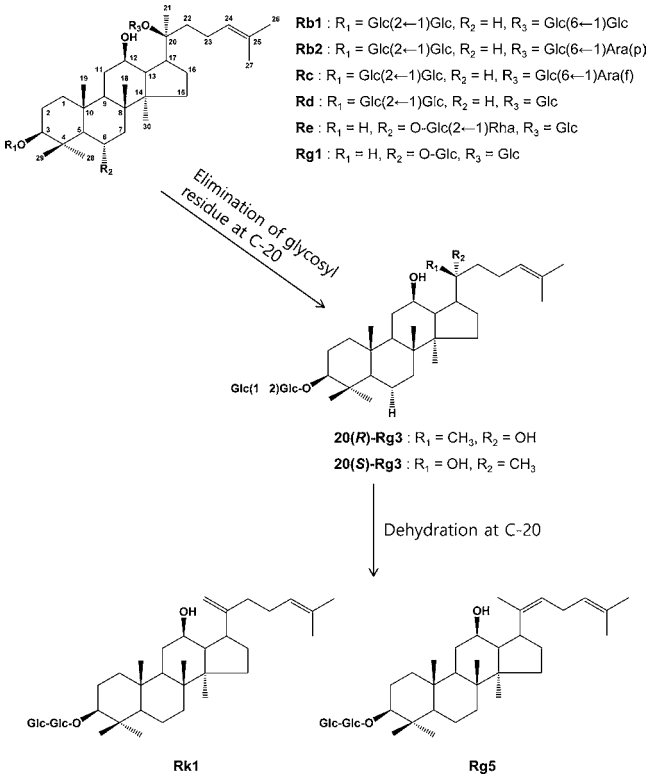

Figure 1. Structures of ginsenosides: −Glc, D-glucopyranosyl; −Rha, L-rhamnopyranosyl; −Ara(f), L-arabinofuranosyl; and −Ara(p): L-arabinopyranosyl.

MATERIALS AND METHODS

Chemicals and Reagents. Standard ginsenosides, including Rb1, Rb2, Rc, Rd, Re, Rg3, Rk1, and Rg5 (purity of 98−100%) were purchased from Ambo Institute (South Korea). Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum (FBS) were purchased from Invitrogen Co. (Grand Island, NY). Primary antibodies for c-Jun N-terminal kinase (JNK), phospho-JNK, p53, and cleaved caspase-3 as well as all secondary antibodies were obtained from Cell Signaling Technology, Inc. (Danvers, MA). The EZ-Cytox cell viability assay kit was purchased from ITSBIO (Seoul, South Korea). Acetonitrile and water used were of high-performance liquid chromatography (HPLC) grade, obtained from Fisher Scientific (Pittsburgh, PA), and glacial acetic acid was of analytical grade, purchased from Sigma-Aldrich (St. Louis, MO).

Preparation of Processed Ginseng Using Microwave Irradiation. White ginseng (WG) was processed using microwave irradiation as reported previously.[16] In brief, aliquots (200 mg) of the dry extract of WG were added to 1 mL of water in a 10 mL container of a microwave irradiator (model 908005) manufactured by CEM Company. WG was irradiated with microwaves in the sealed container at a temperature of 150 °C and power of 100 W (2455 MHz frequency) for 60 min. Microwave-irradiated dry extracts of ginseng (MG) were freeze-dried to obtain microwave-irradiated process products. Microwave irradiation was performed at a pressure of 20 atm. Vessel pressure was automatically controlled by the microwave irradiator.

Purification of Ginsenoside-Containing Fractions. MG extract (50 g) was subjected to open-column chromatography on a Diaion HP-20 (Mitsubishi Chemical Co., Ltd., Tokyo, Japan) and eluted stepwise with 5 L of distilled water and MeOH. The respective fractions were evaporated to yield the water eluate (MG−H_2O, 38 g) and the MeOH eluate (MG−MeOH, 10 g).

Analysis of Ginsenosides. Ginsenosides were identified and quantified using a previously reported method.[13] An analytical reversed-phase HPLC system comprised of a solvent degasser (Agilent, G1322A), binary pump (Agilent, G1312C), and model 380 evaporative light scattering detector (ELSD, Agilent) was used in the analysis. The standard solutions containing 1−100 μg of each ginsenoside were injected onto the HPLC column, with all calibration curves showing good linearity (R^2 > 0.995). The analysis was repeated 2 times for the assessment of repeatability.

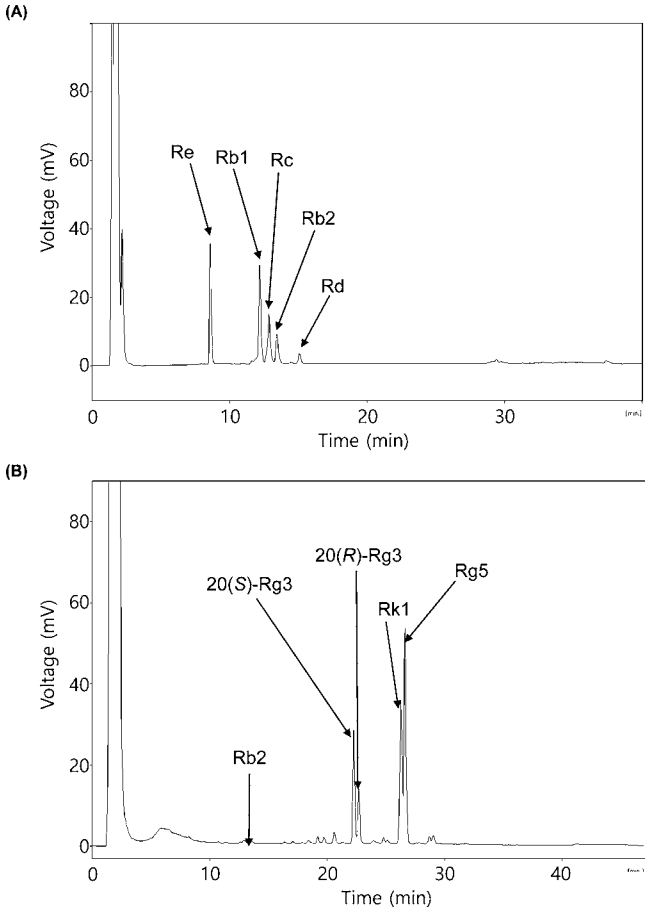

Figure 2. Structural changes in ginsenosides present in ginseng extract induced by microwave irradiation. (A) HPLC chromatogram presenting peaks corresponding to ginsenosides (Re, Rb1, Rc, Rb2, and Rd) present in raw ginseng. (B) HPLC chromatogram presenting peaks corresponding to ginsenosides [20(*S*)-Rg3, 20(*R*)-Rg3, Rk1, and Rg5] present in microwave-processed ginseng.

Protective Effect against Oxidative Damage in Kidney Cells. The protective effect against oxidative nephrotoxicity was evaluated in LLC-PK1 cells.[17] LLC-PK1 (pig kidney epithelium, CL-101) cells were cultured in DMEM supplemented with 10% FBS, 1% penicillin/streptomycin, and 4 mM L-glutamine at 37 °C with 5% CO_2 in air. Cells were seeded in 96-well culture plates at 1 × 10^4 cells/well and allowed to adhere for 24 h. Thereafter, test samples with or without cisplatin (25 μM) were added to the culture medium. Epigallocatechin gallate (EGCG) was used as a positive control. After 24 h of incubation, the cell viability was evaluated using the EZ-Cytox cell viability assay kit.

Protective Effect against Cisplatin-Induced Nephrotoxicity in Mice. All procedures involving the use of live animals as described in this study were approved in May 2013 by the Institutional Animal Care and Use Committee of the Korea Institute of Science and Technology and strictly followed the National Institutes of Health (NIH) guidelines for humane treatment of animals. Male C57/BL6 mice, 9−10 weeks of age, were obtained from Orient Bio Co., Ltd. (Seongnam, South Korea). They were kept on a 12 h light/dark cycle and given free access to water and a normal diet. The mice were subsequently divided into 6 groups that were similar in their initial body weights and assigned to the following treatment groups: group 1, vehicle-treated mice received water alone (no ginseng treatment; n = 4); group 2, cisplatin-treated mice received water alone (no ginseng treatment; n = 4); group 3, cisplatin-treated mice received WG extract (100 mg/kg) in aqueous

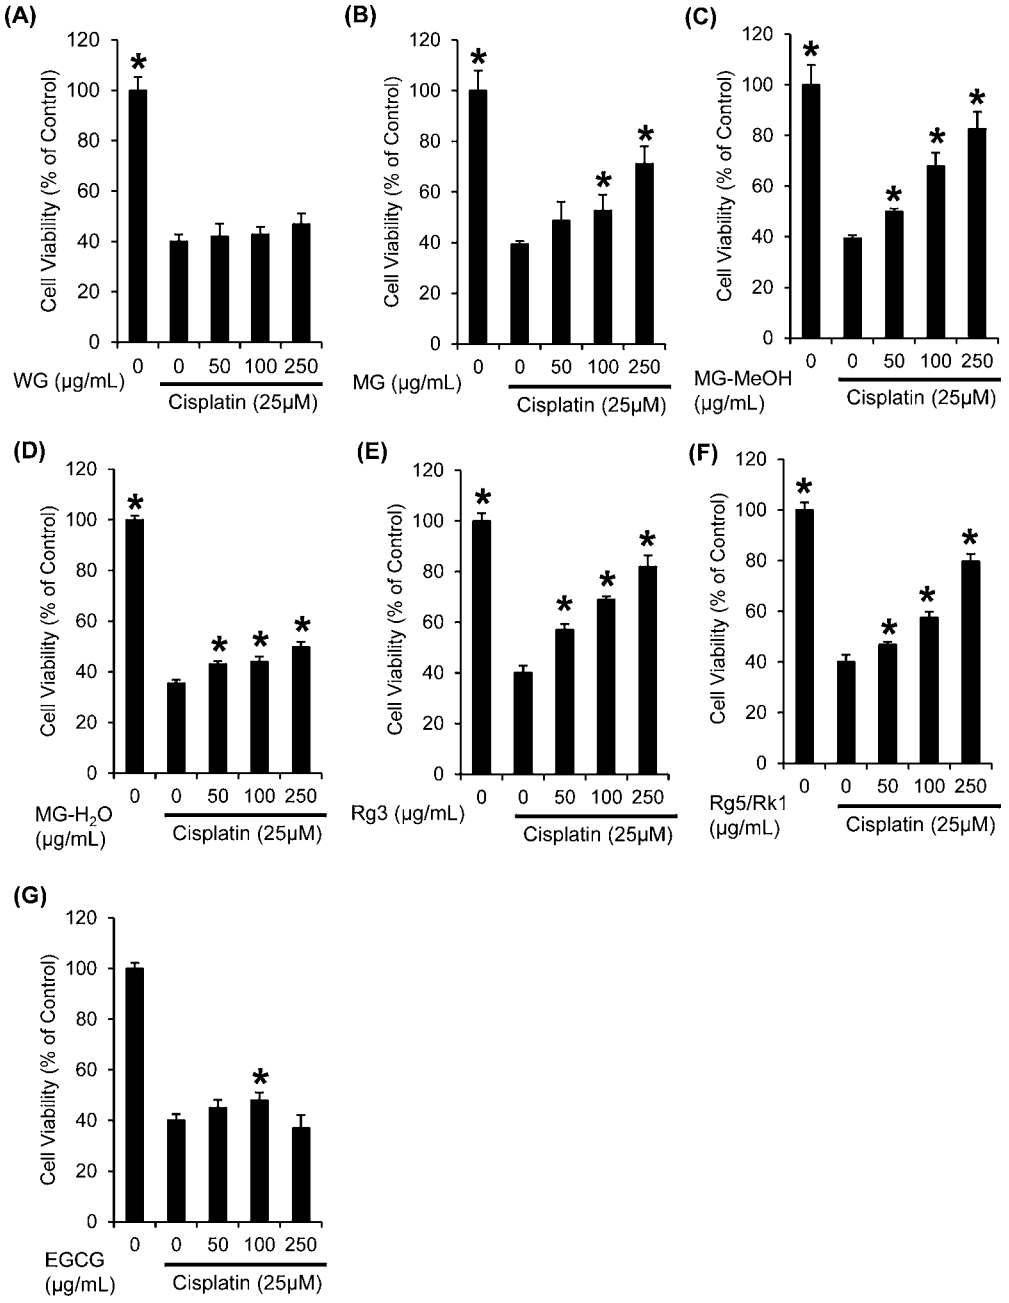

Figure 3. Comparison of the protective effects of WG, MG, MG−MeOH, MG−H_2O, Rg3, Rg5/Rk1, and EGCG against cisplatin-induced cytotoxicity in LLC-PK1 cells. (∗) $p < 0.05$ compared to the cisplatin-treated control value.

solution orally for 10 days (cisplatin + WG; $n = 4$); group 4, cisplatin-treated mice received MG extract (100 mg/kg) in aqueous solution orally for 10 days (cisplatin + MG; $n = 4$); group 5, cisplatin-treated mice received MG−MeOH (25 mg/kg) in aqueous solution orally for 10 days (cisplatin + MG−MeOH; $n = 4$); and group 6, cisplatin-treated mice received NAC (100 mg/kg) in aqueous solution orally for 10 days (cisplatin + NAC; $n = 4$). Samples were orally administered daily, while vehicle-treated rats were given water. After 10 days, mice in the five treatment groups (cisplatin, cisplatin + WG, cisplatin + MG, cisplatin + MG−MeOH, and cisplatin + NAC) were intraperitoneally administered a single dose of cisplatin (16 mg/kg of body weight) in 0.9% saline. Mice were sacrificed 3 days after cisplatin administration under light ether anesthesia. Blood samples were collected in tubes containing 0.18 M ethylenediaminetetraacetic acid (EDTA) from the abdominal aorta.

Analyses of Plasma Biomarkers. Blood samples were centrifuged at 3000*g* for 10 min at 4 °C. The plasma creatinine levels were measured by a rate-blanked kinetic Jaffe method.

Western Blotting Analysis. Whole-cell extracts were then prepared according to the instructions of the manufacturer using RIPA buffer (Cell Signaling Technology, Danvers, MA) supplemented with 1× protease inhibitor cocktail and 1 mM phenylmethylsulfonyl fluoride. Proteins were separated by electrophoresis, blotted onto polyvinylidene fluoride (PVDF) transfer membrane, and analyzed with epitope-specific primary and secondary antibodies.

Statistical Analysis. Statistical significance was determined through the one-way analysis of variance (ANOVA), followed by a multiple-comparison test with Bonferroni adjustment. p values lower than 0.05 were considered statistically significant (SPSS 11.5 software).

3. RESULTS AND DISCUSSION

The chromatograms for each of the prepared ginseng extracts are shown in panels A and B of Figure 2. The processing conditions for microwave treatment of ginseng extracts were optimized,[16]

DOI: 10.1021/acs.jafc.5b00782
J. Agric. Food Chem. 2015, 63, 5964−5969

and conditions resulting in the highest amounts of ginsenosides Rg3, Rg5, and Rk1 were selected. Ginsenosides were identified and quantified as reported previously.[13,16] As shown in panels A and B of Figure 2, each of the ginsenosides Re (114 μg), Rb1 (158 μg), Rc (94 μg), Rb2 (74 μg), and Rd (8 μg) content was decreased in WG, while the ginsenosides Rg3 (105 μg), Rk1 (151 μg), and Rg5 (275 μg) content increased in MG by microwave irradiation at 150 °C for 60 min. Ginsenosides 20(*S*)-Rg3 and 20(*R*)-Rg3 are produced by the elimination of the glycosyl residue at carbon-20 of protopanaxadiol-type saponins, such as ginsenosides Rb1, Rb2, Rc, and Rd during the steaming process.[11,18,19] Ginsenoside Rg3 is converted to Rg5 and Rk1 by further dehydration at the carbon-20 position by high pressure and temperature.[13,19]

Using LLC-PK1 renal epithelial cells as the *in vitro* model, we compared the protective activities of WG, MG, MG−MeOH, MG−H_2O, ginsenoside Rg3 epimers, and ginsenoside Rg5/Rk1 against cisplatin-induced oxidative renal damage. The ginsenoside stereoisomers were used as mixtures because of the difficulty in preparing a single ingredient with high purity. On the basis of previously collected data, 25 μM cisplatin, which results in approximately 60% cell death, was selected for further study. Loss of cell viability was noted after 24 h incubations of samples at a range of ginsenoside concentrations (0, 50, 100, and 250 μg/mL) with cisplatin (25 μM). The renoprotective effect of MG was observed to be stronger than that of WG (panels A and B of Figure 3). Additionally, we have assessed the renoprotective effects of the water and MeOH elution fractions of MG (MG−H_2O and MG−MeOH) to identify the main active components. On the basis of our observations, the MeOH fraction increased cell viability at a concentration of 50 μg/mL, while no amelioration in cell viability was observed following treatment with MG−H_2O (panels C and D of Figure 3). High concentrations of ginsenosides-20(*S*)-protopanaxadiol (ginsenosides Rb1, Rb2, Rc, Rd, Rg3, Rg5, and Rk1) and 20(*S*)-protopanaxatriol (ginsenosides Re and Rg1) are already known to be eluted in the MeOH fraction,[11] suggesting that the observed renoprotective activity of the MeOH elute is likely due to ginsenosides. Consequently, we investigated the renoprotective effects using ginsenosides Rg3 and Rg5/Rk1, the content of which was increased by microwave processing. Ginsenosides Rg3 and Rg5/Rk1 were found to significantly ameliorate cisplatin-induced reduction in cell viability in a dose-dependent manner (panels E and F of Figure 3). This protective effect was stronger than that of EGCG (Figure 3). We have also confirmed that MG and its active components did not affect the anticancer activity of cisplatin (see Figure S1 of the Supporting Information).

Figure 4 presents the protein expression levels of P-JNK, JNK, p53, and cleaved caspase-3 in the control and treated (WG, MG, and MG−MeOH) cells. The blocking of JNK−p53−caspase-3 signaling cascade plays a vital role in mediating the protective effect of renoprotectants against oxidative cytotoxicity in cultured LLC-PK1 cells.[20−22] Cisplatin-induced nephrotoxicity was previously correlated with the formation of oxidative stress, which can activate JNK.[23,24] Treatments with antioxidants and caspase inhibitors were shown to ameliorate cisplatin-related nephrotoxicity.[25] The important roles of JNK activation have emphasized the regulation of apoptosis pathways as well as inflammation.[26−28] In LLC-PK1 cells, p53 is activated by cisplatin, and p53 inhibition by pharmacological and molecular approaches reduces cisplatin-induced apoptosis.[29,30] Expression of JNK and p53 proteins in LLC-PK1 cells recovered markedly after treatments with MG and MG−MeOH but not with WG

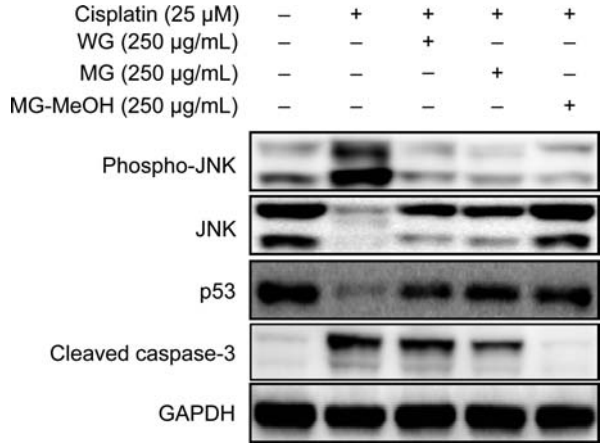

Figure 4. Comparison of the effects of WG, MG, and MG−MeOH on the expression of proteins P-JNK (46 and 54 kDa), JNK (46 and 54 kDa), p53 (53 kDa), and cleaved caspase-3 (17 and 19 kDa) in LLC-PK1 cells. Western blot assays were performed in triplicate for each protein and were repeated at least 3 times. The presence or absence of samples is indicated by a plus or minus sign, respectively.

(Figure 4). To further investigate the ability of MG and MG−MeOH to prevent apoptosis, the renal expression of cleaved caspase-3 was measured. In these experiments, MG significantly reduced the expression of cleaved caspase-3 (Figure 4). Figure 5 presents the expression of proteins P-JNK, JNK, p53,

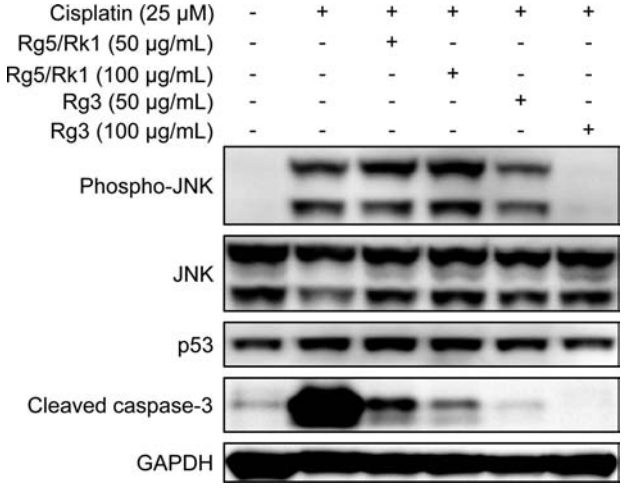

Figure 5. Comparison of the effect of ginsenosides Rg3 (50 and 100 μg/mL) and Rg5/Rk1 (50 and 100 μg/mL) on the expression of proteins P-JNK (46 and 54 kDa), JNK (46 and 54 kDa), p53 (53 kDa), and cleaved caspase-3 (17 and 19 kDa) in LLC-PK1 cells. Western blot assays were performed in triplicate for each protein and were repeated at least 3 times. The presence or absence of samples is indicated by a plus or minus sign, respectively.

and cleaved caspase-3 in control and experimental cells treated with ginsenoside Rg3 (at 50 and 100 μg/mL) or Rg5/Rk1 (50 and 100 μg/mL). Expression of JNK and p53 proteins in LLC-PK1 cells was markedly increased following treatment with Rg3 and Rg5/Rk1. Additionally, the elevated expression of cleaved caspase-3 following cisplatin treatment was significantly attenuated by ginsenosides Rg5/Rk1 and, more potently, by ginsenoside Rg3 co-treatments (Figure 5).

To determine whether MG and its ginsenoside fraction elicit renoprotective effects *in vivo*, we used cisplatin-induced renal

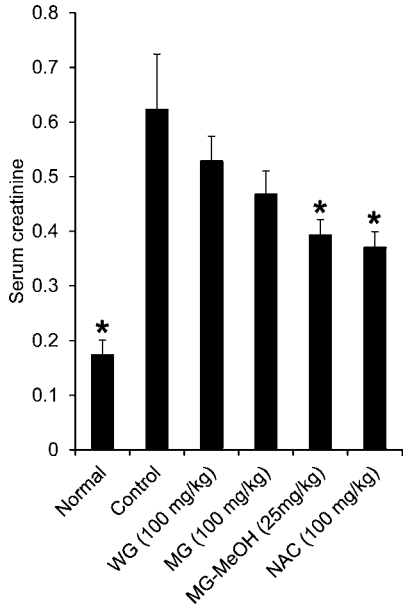

Figure 6. Protective effects of microwave-processed ginseng extract against cisplatin-induced renal damage in mice. (*) $p < 0.05$ compared to the cisplatin-treated control value.

oxidative-damaged mice as an *in vivo* model. Cisplatin-injected mice exhibited increased serum levels of creatinine compared to the vehicle-treated animals (Figure 6). Serum creatinine is a tried and true marker of kidney injury.[31,32] Elevated serum creatinine levels in cisplatin-treated mice were slightly attenuated by co-treatment with WG. In particular, increased serum creatinine levels were significantly reduced by administration of MG and, more potently, MG−MeOH, which contains ginsenosides Rg3, Rg5, and Rk1 (Figure 6). The renoprotective effect of MG−MeOH was as strong as that of NAC, which has been found to be effective in attenuating nephrotoxicity induced by cisplatin.[33] Therefore, co-treatment with MG and its active ginsenosides afforded significant protection against cisplatin-induced nephrotoxicity in mice.

In summary, we demonstrated that MG and its active ginsenosides Rg3, Rg5, and Rk1 showed a protective effect against cisplatin-induced nephrotoxicity in cultured kidney cells and mice. We found that ginsenosides Rg3, Rg5, and Rk1, generated during the heat treatment of ginseng, ameliorate renal damage by regulating inflammation and apoptosis. The experimental results provide convincing evidence for kidney protection effects of MG and its active ginsenosides, both *in vitro* and *in vivo*, supporting its therapeutic potential. Future studies will focus on the effect of MG and its active ginsenosides on unexplored areas, such as diabetic nephropathy.

suppression at higher DP. MS detection is more sensitive, but also more expensive, and typical MS approaches (e.g., electrospray ionization) do not have the molecular weight range to directly measure higher DP proanthocyanidins. Moreover, at higher DP, proanthocyanidins may form ions with multiple charges and/or undergo fragmentation. Due to the redox properties of polyphenols in cocoa, HPLC with electrochemical detection (ECD) could be employed for the identification and separation of a wide array of compounds in a single run. Our laboratory and others have successfully used this technique for the separation and detection of flavan-3-ol monomers.[18,19] The underlying unique redox chemistry of compounds makes ECD typically more selective and sensitive than UV and fluorescence detectors.[20] To our knowledge, proanthocyanidins of DP > 3 have not previously been analyzed by reversed-phase HPLC-ECD.

Polyphenols play an important role in the sensory characteristics of cocoa and chocolate products. With both bitter and astringent properties, these compounds in excess can negatively affect consumer acceptability.[21] Cocoa alkalization ("Dutching") is a process during which cocoa powder or nibs are exposed to a basic solution at increased temperatures. Resulting products are often darker in color, less astringent and bitter, and more dispersible compared to their unalkalized counterparts. Previous studies have reported that commercially available cocoa powders that had been subjected to "heavy alkalization" had up to 90% loss of total polyphenols (TP) and significantly reduced levels of proanthocyanidins.[22] Although suggestive, this study is limited by the fact that the authors did not alkalize the cocoa powder samples themselves, and no information regarding time, temperature, and concentration of alkali was provided. Instead, the degree of alkalization was based on the pH and color of the commercial product with lighter colored and lower pH products considered less alkalized. This approach discounts variability in the native pH of cocoa beans as well as differences in the levels of proanthocyanidins based on country of origin, harvest time, etc. In the absence of a direct examination of the effect of alkali treatment on proanthocyanidin content as a function of time, it is difficult to develop a predictive model to balance desirable sensory and ingredient functionality with retention of putative bioactive molecules.

Studies that have evaluated the direct effect of alkalization have focused on monomeric polyphenols or proanthocyanidin dimers, and few data are available regarding the effect of alkalization on proanthocyanidins of high DP. Due to the biological significance of high DP proanthocyanidins, such data are critical for understanding the potential bioactivity differences in various cocoa products.[14,23] In the present study we developed a new reversed phase HPLC-ECD method to separate and quantitate flavan-3-ol monomers and proanthocyanidins of DP 2−7. We demonstrate the usefulness of this new method by examining the effects of alkalization on individual flavan-3-ol monomers and proanthocyanidins of DP up to 7 and use the data to develop an initial predictive model of alkali-induced proanthocyanidin degradation.

MATERIALS AND METHODS

Materials. Commercial cocoa powder with a single batch code was sourced locally from a supermarket. Total polyphenols were estimated using the Folin−Ciocalteu reagent (Sigma-Aldrich, St. Louis, MO, USA). Cocoa proanthocyanidin standards were provided by the Hershey Co. (Hershey, PA, USA). All other chemicals were of the highest grade commercially available.

Alkalization of Cocoa Samples. Cocoa powder (15 g) was combined with 135 mL of ultrapure water and a stir bar in a 250 mL. The mixture was stirred at 400 rpm until the cocoa powder was dispersed. While stirring, samples were heated to 92 °C and a predetermined volume of 4.0 M sodium hydroxide solution was added to bring the starting pH of the solution to pH 8. Samples were removed at seven time points: heating onset, when the solution reached 92 °C (6 min after application of heat), and 0.5, 5, 15, 30, and 60 min after base addition. Upon removal, samples were poured into preweighed tubes and cooled in an ice−water bath prior to storage at −80 °C. Samples were freeze-dried to obtain a dry cocoa powder. Alkalization was repeated twice (overall $n = 7$ per treatment and time point).

Sample Preparation. After alkalization, the lipids were removed from cocoa samples by extraction three times with 10 volumes of hexane with continuous agitation for 10 min. After each extraction, the solvent was decanted. Lipid-free cocoa powder was air-dried for 24 h, and the defatted mass was recorded. A polyphenol-enriched fraction was prepared by sequentially extracting the defatted cocoa material with 30 mL of acetone/water (70:30, v/v) and 30 mL of methanol/water (50:50, v/v) with continuous agitation for 10 min. Following each extraction, the mixture was centrifuged at 1776*g* for 4 min. The supernatant from each extraction was then combined, the organic solvent was removed under vacuum, and the remaining water was frozen at −80 °C and lyophilized under 0.1 Pa vacuum. Extracts were stored at −80 °C until later use. Prior to analysis, cocoa extracts were redissolved in DMSO at 10 mg/mL.

HPLC Analysis. Cocoa flavan-3-ols and proanthocyanidins were analyzed using an HPLC system consisting of two LC-20AD pumps, an SIL-20AC refrigerated autosampler (Shimadzu Scientific, Kyoto, Japan), and an ESA 5500 coulochem electrode array system (CESA; Chelmsford, MA, USA). The potentials of the CEAS were set at −100, 100, 300, and 500 mV. A 150 mm × 4.6 mm, 5 μm, Supelcosil LC-18 column (Supelco, Bellefonte, PA, USA) was used for chromatographic separation. The mobile phases consisted of solvent A (30 mM sodium phosphate monobasic buffer, 1.75% acetonitrile, and 0.125% tetrahydrofuran, pH 3.35) and solvent B (15 mM sodium phosphate monophosphate buffer, 58.5% acetonitrile, and 12.5% tetrahydrofuran, pH 3.45). Mobile phase conditions started at 4% B with isocratic flow for 7 min. The concentration of B increased linearly to 17% at 25 min, to 33% B at 45 min, and to 98% B at 60 min. Mobile phase conditions were held at 98% B for 3 min prior to re-equilibration to 4% B. The flow rate was 1.0 mL/min, and the column temperature was maintained at 35 °C. For HPLC analysis, cocoa extracts (10 mg/mL in DMSO) were diluted 10-fold in 0.2% ascorbic acid in deionized water and filtered through a 0.45 μM PTFE filter (VWR International, Radnor, PA, USA). Injection volume was 30 μL. Samples were normalized to a standardized extract. Quantitation of **1** and **2** was based on a detector potential of 100 mV. Quantitation of **3**−**8** was based on a detector potential of 300 mV.

Kinetic Analysis. Kinetic analyses were carried out using GraphPad Prism (La Jolla, CA, USA). Data were fitted to a two-phase exponential decay model described by

$$Y = \text{span}\,\beta \times e^{-K\beta \times X} + \text{span}\,\alpha \times e^{-K\alpha \times X} + \text{plateau}$$

Y is concentration; span β and span α are constants that indicate the portions of the concentration−time curve in the slow and fast decay portions, respectively; K_β and K_α are the rate constants for the slow and fast portions, respectively, of the concentration−time curve; and plateau is the concentration at infinity. Initial and terminal half-lives ($t_{1/2\alpha}$ and $t_{1/2\beta}$) are equivalent to $0.6392/K$.

Color and pH Analysis. Sample pH was determined using a pH meter. Color was analyzed by L, a, b values using a CR400 Hunter colorimeter (Minolta, Osaka, Japan) calibrated to a white standard provided with the instrument. Samples were equilibrated to 25 °C, 10 mL of sample was placed in a clear plastic sample tray, and the L, a, b

[a]Within-day and between-day relative standard deviation (%RSD) was determined using a standard cocoa powder with known amounts of proanthocyanidins.

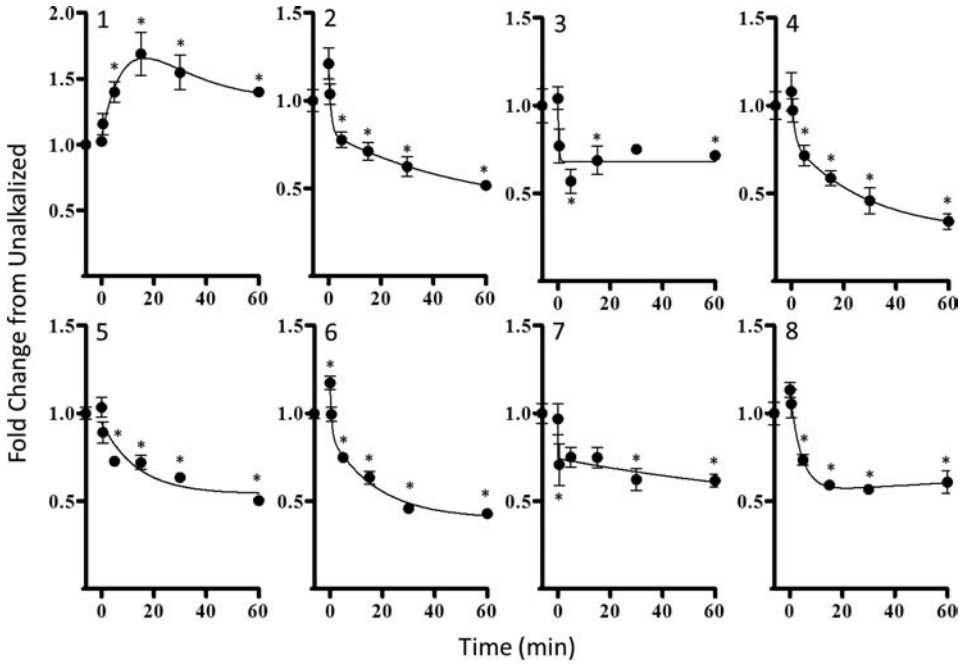

Figure 3. Effect of alkalization on the levels of individual flavan-3-ols and proanthocyanidins in cocoa powder. Data were fitted to a two-phase exponential decay model. Data represent the mean ± SEM. ∗ indicates $p < 0.05$ compared to unalkalized control.

values were measured. Color difference (ΔE) from unalkalized control was calculated as previously reported.[26]

$$\Delta E = \sqrt{(\Delta L^2 + \Delta a^2 + \Delta b^2)}$$

J. Agric. Food Chem. 2015, 63, 5970−5975

Total Phenolics Determination. Total phenolics were measured as previously described.[14] For total phenolic analysis, cocoa extract was dissolved in DMSO (final concentration = 10 mg/mL). The extract was then combined with 79 volumes of deionized water and 5 volumes of of Folin−Ciocalteu reagent and mixed for 5 min. The reaction was stopped by the addition of 15 volumes of 1.9 M sodium carbonate. After 30 min of incubation at 37 °C, the absorbance at λ 765 nm was measured and compared to a standard curve of gallic acid.

Statistical Analysis. All statistical analyses were carried out using GraphPad Prism (La Jolla, CA, USA). Mean ± standard error of the mean (SEM) was reported for HPLC-ECD data (flavan-3-ol monomers and proanthocyanidin content). Relative percent standard deviation (RSD) was calculated for within- and between-day variations from three replicate samples each run on three separate days. Mean ± SEM was reported for pH and color analysis. ΔE was calculated using unalkalized sample as the control. When applicable, comparison between treatments was calculated using one-way ANOVA with Tukey's HSD test. Significance was achieved at $p < 0.05$.

RESULTS AND DISCUSSION

In the present study, we developed a new reversed phase HPLC-ECD for the analysis of cocoa polyphenols and used that method to monitor alkali-induced changes in the content and composition of polyphenols in cocoa powder. To our knowledge, this is the first report of separation and quantitation of proanthocyanidins by HPLC-ECD.

The present chromatographic separation resulted in well-resolved peaks with high signal-to-noise ratio. Compounds **1** and **2** eluted at 16.4 and 22 min, respectively (Figure 2). Proanthocyanidin retention time was directly proportional to DP (Figure 2). The ECD response was greater for **1** and **2** compared to the proanthocyanidins. The ECD response was linear with respect to concentration of the individual flavan-3-ols and proanthocyanidins over a range of 1.5−15 μg (R^2 = 0.956−0.999). Within- and between-day variations of the new method are shown in Table 1. All compounds had between-day RSD values <10% except for **1** (11.4%).

In addition to the peaks that were identified with authenticated standards, several peaks that eluted after 41.2 min were well resolved. These peaks could represent higher DP proanthocyanidins, but a lack of high-quality, authenticated standards precluded their identification. Additional studies with such standards may increase the usefulness of the method.

All treatments resulted in a significant increase in the content of **1** compared to unalkalized cocoa ($p < 0.05$) (Figure 3). Concentrations of **1** increased by 69% during the first 15 min of alkalization and then began to slowly decline. Concentrations of **2** were significantly reduced after the first 5 min of alkalization, and treatment for 60 min resulted in a 47% reduction. These results are consistent with those previously reported.[24,25] Two potential mechanisms underlie these opposite trends. First, **2** may undergo epimerization to **1**.[24,25] Second, there is evidence that **2** may be preferentially added to proanthocyanidins during polymerization. Although **1** could act as a nucleophilic unit for attack, previous research has shown that 75−81% of terminal proanthocyanidin subunits are **2**.[26,27]

The concentration of **3**−**8** decreased as a function of alkalization time (Figure 3). The proanthocyanidins showed an initial rapid decay, likely due to condensation to form compounds with higher DP, followed by a slowing of the decay function. The levels of **4**, **5**, **6**, and **8** were significantly reduced after 5 min of alkalization. Interestingly, **3** deviated from the general trend of the other proanthocyanidins. Alkalization for 5 and 15 min significantly reduced **3** to its lowest value; however, upon further alkalization, the content **3** increased to levels comparable to that of the unroasted control. This increase could be a result of the formation of new dimers from flavan-3-ol subunits.

Degradation kinetics of proanthocyanidins were best modeled by a two-phase exponential decay model. Half-lives and R^2 values are shown (Table 2). A two-phase exponential decay model may best predict changes in cocoa proanthocyanidins during alkaline processing due to the continual degradation and formation of proanthocyanidins of various degrees of polymerization. It is interesting to note the model fits relatively well for proanthocyanidins composed of an odd number of flavan-3-ol subunits, whereas the changes in proanthocyanidins with an even number of subunits are not well explained by the model. Because of the poor fit of the model to **3** and **7**, the predicted half-lives are suspect. Similarly, because **1** initially increased, the model fit the data poorly and half-lives were not determined. More research is needed to better understand the mechanism behind proanthocyanidin condensation and the stability of individual proanthocyanidins under basic conditions to further refine this model.

Table 2. Half-Lives of Cocoa Flavan-3-ols and Proanthocyanidins[a]

	$t_{1/2\alpha}$ (min)	$t_{1/2\beta}$ (min)	R^2
1	n/a	n/a	0.458
2	0.62	37.73	0.749
3	0.25	5.62×10^{15}	0.379
4	0.82	20.09	0.705
5	9.43	9.43	0.640
6	0.44	12.49	0.917
7	7.60×10^{-33}	80.78	0.268
8	2.98	769.50	0.780

[a]Half-lives were derived by fitting concentration vs time data to a two-phase exponential decay model. R^2 represents the goodness of fit of the model to the data. n/a indicates that the concentration increased rather than decreased with time.

To provide context for the changes observed in individual compounds, we determined the effect of alkali treatment on cocoa powder color and total phenolic content. Alkalization increased cocoa pH compared to unalkalized cocoa powder (7.48−8.03 vs 5.57) (Table 3). As expected, alkaline treatment resulted in a time-dependent darkening (Figure 4). These pH changes and color changes are within the range of commercially available cocoa powders reported previously and correspond to "medium" to "heavily" alkalized cocoa powders as defined in that study.[22] To evaluate the differences between overall color of the samples, ΔE was calculated, using unalkalized averages for L, a, and b as the control. The human eye can perceive a difference in color if ΔE exceeds a value of 1.[28] All treatments resulted in a $\Delta E > 1$ and were significantly different from the unalkalized samples ($p < 0.05$), and all treatments with base addition were significantly different from samples that were preheated with no alkali. L, a, and b values all followed an inverse trend with increasing degree of alkalinization. Lower L values correspond with a darker appearance, whereas lower a and b values correspond with less red and less yellow, respectively (Table 3).[28] These results are important because one of the primary uses of alkalization today is to modify the color of cocoa, which was successfully achieved in this study.[22]

Table 3. Effect of Alkalization on pH and Color[a]

treatment	final pH	color			
		L	*a*	*b*	Δ*E*
unalkalized	5.57 ± 0.04	32.9 ± 0.6	9.3 ± 0.3	12.0 ± 0.5	0.00
preheat (92 °C, 6 min, no alkali)	5.57 ± 0.01	31.3 ± 0.1	8.6 ± 0.0	10.0 ± 0.2	2.62
time postalkali addition (min)					
0.5	8.03 ± 0.02*	28.6 ± 0.6	7.0 ± 0.4	8.2 ± 0.4	6.18
5	7.89 ± 0.06*	28.9 ± 0.2	7.5 ± 0.3	8.5 ± 0.3	5.59
15	7.70 ± 0.04*	29.3 ± 0.2	7.6 ± 0.2	8.6 ± 0.4	5.20
30	7.71 ± 0.01*	29.2 ± 0.5	7.6 ± 0.4	8.6 ± 1.0	5.28
60	7.48 ± 0.06*	28.7 ± 0.3	7.1 ± 0.1	7.9 ± 0.4	6.30

[a]All time points postalkali addition were significantly different from the unalkalized and preheated samples in terms of *L*, *a*, *b*, and Δ*E* values.

Figure 4. Representative images of the effect of alkalization on cocoa color.

Total phenolics were significantly reduced compared to the unalkalized control for all treatments ($p < 0.05$) (Figure 5). At 60 min, alkalization resulted in a 20.4% loss of phenolic compounds. Our results are consistent with trials in a previous study that reported a 26% loss in total polyphenols after alkalization at 1% NaOH for 20 min at 0.02 MPa.[29] The findings, although significant, are much less dramatic than those previously reported in the literature. Previous studies have reported a 60.5% decrease in total phenolics at similar final pH value.[22] The authors characterized this cocoa as a "medium alkalized" product. Another study reported a 60% loss in total flavonoids as quantified by LC-UV for cocoa with a pH ≤7.2.[10] These differences may be due to the fact that previous studies used commercially obtained products rather than samples alkalized in-house.

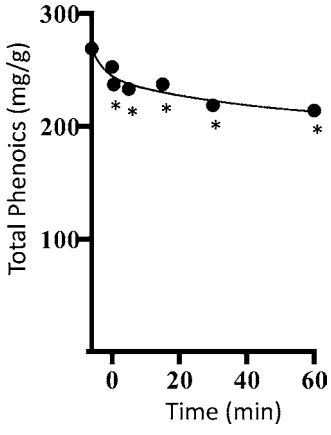

Figure 5. Effect of alkalization on the total polyphenol content in cocoa. Data represent the mean ± SEM. ∗ indicates $p < 0.05$ compared to unalkalized cocoa.

In the setting of a cocoa-processing facility, it is likely that large batches of alkalized cocoa are stored at room temperature for longer periods of time prior to use. In the present study, we extracted cocoa samples immediately after alkalization and stored the extracts at −80 °C to prevent further loss. These differences in postalkalization handling may account in part for the differences in total polyphenolics observed. In addition, because the panels of products used in previous studies are likely of different geographic origin and may have undergone different postharvest processing (i.e., fermentation and roasting), they likely have differences in polyphenol content and composition that are independent of alkalization.

Overall, the present study demonstrates the usefulness of HPLC-ECD for the analysis of flavan-3-ols as well as proanthocyanidins up to DP 7. Furthermore, although alkalization at pH 8 for 1 h, which resulted in a significant color change, reduced total phenolics by 20%, this reduction does not fully explain changes in individual polyphenols. We propose two-phase exponential decay as an initial model to predict alkali-induced polyphenol loss. Future mechanistic studies on proanthocyanidin polymerization could greatly improve the field and lead to improved prediction of proanthocyanidin composition based on processing conditions.

Neu5Gc should not be used in human food because of potential immunological problems.[27]

Galacto-oligosaccharide mixtures (GOS) with degrees of polymerization (DP) from 2 to 9, which are synthesized from lactose by enzymatic transgalactosylation using specific microbial β-galactosidases, have shown to be functional food products with excellent prebiotic functions.[28] These ingredients are broadly applied in the infant food sector. Depending on the enzyme used, GOS contains an array of linear and branched $(Gal)_nGlc$ oligosaccharides with different substitution patterns. For one of these products, prepared with *Bacillus circulans* β-galactosidase, the ensemble up to DP5 comprises >40 components.[29−34]

In view of reported functions of both GOS and sialylated oligosaccharides, taking into account the low amounts of sialyl-oligosaccharides in cow's milk, it is hypothesized that partial sialylation of GOS (Sia-GOS) will generate mixtures of compounds that combine the different properties, meaning novel products with broad functionalities both for the food (Sia = Neu5Ac) and feed (Sia = Neu5Gc) industries. To this end we have chosen *Trypanosoma cruzi trans*-sialidase (TcTS), recombinantly produced in *E. coli* and capable of transferring sialic acid from various artificial and natural Sia(α2−3)Gal(β1−x)-glycans (sialogalactoglycans) to Gal(β1−x)-glycans (asialogalactoglycans), as the biocatalyst (for a review, see ref 35). For the aimed for food and feed products, bovine κ-casein-derived glycomacropeptide (GMP) (>99% Neu5Ac; <1% Neu5Gc) and bovine blood plasma glycoprotein mixture (BPG) (45% Neu5Ac; 55% Neu5Gc) were selected, respectively, as sialic acid donor substrates. Using the sialic acid acceptor substrates GOS and specific DP GOS, analytical information was collected about the formed Sia-GOS mixtures and patented.[36,37] A related study, but without analytical details, to such an approach has been patented earlier for the system GOS/GMP/*Trypanosoma congolense trans*-sialidase.[38] Parallel to our work some sialyltransfer studies have appeared on the sialylation of GOS with GMP using TcTS, *Trypanosoma rangeli trans*-sialidase, and *Pasteurella multocida trans*-sialidase.[39−41]

Recently, we have reported a basic study focused on the reaction kinetics, efficiency, and specificity of the (α2−3)-sialylation of terminal Gal residues of the GOS components 3′-galactosyl-lactose, 4′-galactosyl-lactose, and 6′-galactosyl-lactose, using TcTS combined with the donors 2-*O*-(4-methylumbelliferyl)-α-*N*-acetylneuraminic acid (4-MU-Neu5Ac) and GMP. Interestingly, also the internal Gal residue of 6′-galactosyl-lactose turned out to be sialylated.[42] In a further study, of importance for the exploration of potential food and feed applications, here, we present our detailed results, including matrix-assisted laser-desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) and nuclear magnetic resonance (NMR) studies, on the sialylation of Vivinal GOS and GOS DP with the sialic acid donors GMP (Neu5Ac donor) and BPG (Neu5Ac/Neu5Gc donor) and the biocatalyst TcTS.

MATERIALS AND METHODS

Chemicals. Vivinal GOS was obtained from FrieslandCampina Domo (Borculo, The Netherlands). Bovine κ-casein-derived glycomacropeptide (GMP) was provided by FrieslandCampina Innovation Center (Wageningen, The Netherlands). Bovine blood plasma glycoprotein (BPG) preparations were supplied by Darling Ingredients Nederland BV (Son, The Netherlands). *N*-Acetylneuraminic acid (Neu5Ac), *N*-glycolylneuraminic acid (Neu5Gc), 2-*O*-(4-methylumbelliferyl)-α-*N*-acetylneuraminic acid (4MU-Neu5Ac), and *N*-acetylneuraminyl(α2−3)lactose (3′-SL) were obtained from Carbosynth Ltd. (Compton, UK). *N*-Glycolylneuraminyl(α2−3)lactose was a gift of Prof. Dr. T. Urashima (Obihiro, Japan). D_2O (99.9 atom % D) was acquired from Cambridge Isotope Laboratories Ltd. (Andover, MA, USA).

TcTS Production and Purification. Recombinant TcTS enzyme batches were produced in *E. coli* BL21(DE3) (Invitrogen, Carlsbad, CA, USA) using plasmid pTrcTS611/2[43] (a gift of Prof. Dr. A. C. C. Frasch, Buenos Aires, Argentina), as previously described.[42] The specific transglycosylation activity of TcTS was determined as 1.0 μmol/min/mg using 4MU-Neu5Ac and lactose as substrates and quantitative detection of *N*-acetylneuraminyl(α2−3)lactose using high-pH anion-exchange chromatography with pulsed-amperometric detection (HPAEC-PAD) analysis.

Isolation of Vivinal GOS DP Fractions by Size Exclusion Chromatography. Vivinal GOS was fractionated on a Bio-Gel P-2 Fine (45−90 μm) column (60 × 5 cm) using demineralized water as eluent at a flow rate of 1 mL/min and 40 °C. The separation was followed by an RI-101 Shodex refractive index detector (Showa Denko Europe GmbH, Munich, Germany). Carbohydrate-containing fractions (5 mL) were screened with MALDI-TOF-MS and pooled according to DP.

Analysis of Sialic Acid Content and Linkage Type of Bovine κ-Casein-Derived GMP and Bovine BPG. To determine the total sialic acid content of GMP and BPG, samples were incubated with 0.1 M HCl for 1 h at 80 °C, then neutralized with 1 M NaOH, and, after dilution with dimethyl sulfoxide, subjected to HPAEC-PAD analysis. For quantification of released Neu5Ac and Neu5Gc, use was made of calibration curves of known concentrations of both sialic acids. Following the same analysis protocol, the ratios of (α2−3)- and (α2−6)-linked sialic acid in GMP and BPG were determined by comparing the release of sialic acid by linkage-type nonspecific sialidase A (Prozyme, Hayward, CA, USA) and (α2−3)-specific sialidase S (Prozyme). Enzymatic incubations were carried out according to the manufacturer's protocols.

Enzyme Incubations. All TcTS incubations were performed in 50 mM sodium citrate buffer (pH 5.0) containing 30 mM NaCl at 25 °C. Reactions were stopped by placing on ice or at −20 °C until further processing. Samples for HPAEC-PAD analysis were diluted with 95% dimethyl sulfoxide.

TcTS incubations with 3.5 mg/mL Vivinal GOS (DP1−DP9; average DP of 3, corresponding to 2 mM) and 67.5 mg/mL GMP [corresponding to 5 mM (α2−3)-linked Neu5Ac] were carried out for 24 h. Sample aliquots were evaluated by HPAEC-PAD and MALDI-TOF-MS.

TcTS incubations with different GOS DPs (each at 3 mM) and 85 mg/mL GMP [corresponding to 6 mM (α2−3)-linked Neu5Ac] were carried out for various times, depending on the application. Sample aliquots were evaluated by HPAEC-PAD, and incubation mixtures were further subjected to weak anion-exchange chromatography (AEX) on Resource Q, followed by ^{1}H NMR analysis, MALDI-TOF-MS, or $NaBH_4$ reduction, as described below.

TcTS incubations with 65 mg/mL BPG (corresponding to 2 mM total sialic acid) and 4 mM lactose, GOS DP3, or GOS DP4 were carried out for various times, and samples were taken for evaluation by HPAEC-PAD. Obtained sialyl-lactose mixtures (24 h) were subjected to preparative HPAEC-PAD analysis to yield pure Neu5Ac(α2−3)lactose and Neu5Gc(α2−3)lactose. Obtained Sia-GOS products (48 h) were separated into mono-Sia-GOS and di-Sia-GOS fractions by AEX on Resource Q, and purified sialylated products were desalted prior to ^{1}H NMR analysis, as described below.

Isolation of Sialylated GOS Products by Weak AEX. To remove sialic acid donor glycoconjugates, incubation mixtures were filtered on Amicon Ultra 15 mL filters (10000 NMWL membrane) (Millipore) following the manufacturer's protocol. Then, samples were desalted on CarboGraph solid-phase extraction (SPE) columns (300 mg; Grace, Breda, The Netherlands). After washing with 0.1% trifluoroacetic acid, oligosaccharides were eluted with 25% aqueous acetonitrile, containing 0.1% trifluoroacetic acid as eluent, and

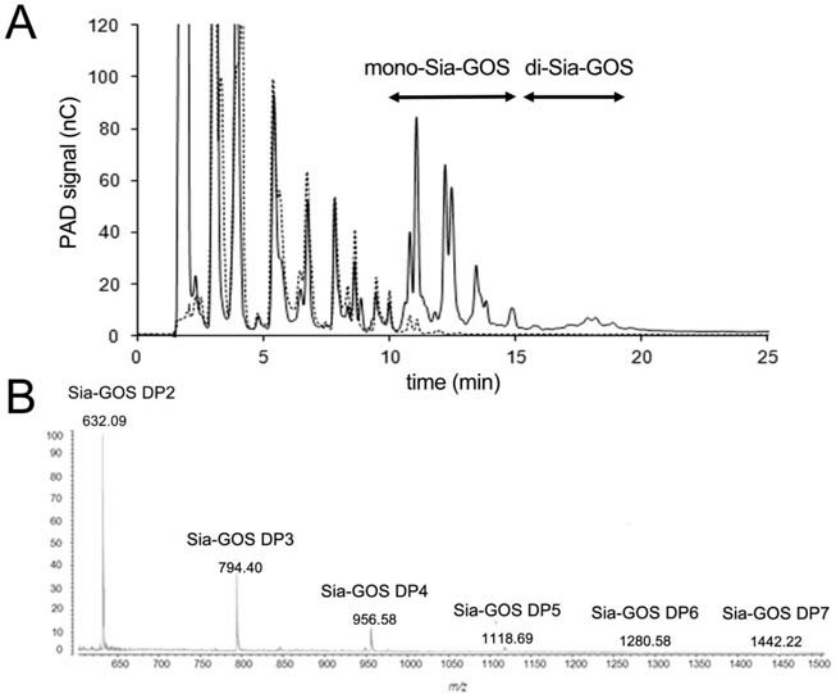

Figure 1. (A) HPAEC-PAD profile on CarboPac PA-1 of compounds in the Vivinal GOS/GMP/TcTS reaction mixture (incubation at 25 °C and pH 5.0) at t = 0 h (dotted line) and t = 24 h (solid line). The regions of formed mono-Sia-GOS and di-Sia-GOS are marked. (B) MALDI-TOF-MS spectrum (negative-ion mode) of the monocharged fraction of the Vivinal GOS/GMP/TcTS reaction mixture, showing $[M - H]^-$ quasi-molecular ions for mono-Sia-GOS DP2−DP7.

lyophilized. (Sialylated) oligosaccharide mixtures were fractionated on a 1 mL Resource Q anion-exchange column (GE Healthcare, Uppsala, Sweden) fitted in an Äkta Performance Fast Protein Liquid Chromatography system (GE Healthcare), equipped with a UV detector (214 and 280 nm) and a conductivity cell. The column was subsequently eluted with 3 mL of water, a linear gradient of 0−8% 0.5 M NaCl over 5 min, and a linear gradient of 8−50% 0.5 M NaCl in 6 min, at a flow rate of 1 mL/min. Neutral, monocharged, and dicharged oligosaccharide fractions were collected, desalted on CarboGraph columns (see above for conditions), and subjected to structural analysis.

Reduction of Disialylated GOS Fractions. Resource Q disialylated GOS fractions were treated with $NaBH_4$ (10 mg/mL) for 2 h at room temperature, followed by neutralization by dropwise addition of 4 M acetic acid (pH paper check). Formed boric acid was removed in vacuo by coevaporation with methanol. After lyophilization from water, the samples were subjected to MALDI-TOF-MS and HPAEC-PAD analyses.

High-pH Anion-Exchange Chromatography−Pulsed Amperometric Detection. Analytical analyses of oligosaccharides were carried out by HPAEC-PAD on a Dionex ICS-3000 system (Thermo Scientific, Amsterdam, The Netherlands), equipped with a CarboPac PA-1 column, as previously described.[42] Preparative isolation of Neu5Ac(α2−3)lactose and Neu5Gc(α2−3)lactose was performed on a Dionex ICS-5000 system, equipped with a CarboPac PA-1 guard column (50 × 4 mm) and a CarboPac PA-1 column (250 × 9 mm), using a gradient of 30−600 mM sodium acetate in 0.1 M NaOH (1 mL/min). Desalting was performed on CarboGraph columns (see above for conditions).

MALDI-TOF-MS. MALDI-TOF-MS experiments were performed on an Axima mass spectrometer (Shimadzu Kratos Inc., Manchester, UK), as previously described.[42]

NMR Spectroscopy. ^{1}H NMR spectra were recorded at a probe temperature of 298 K on a Varian Inova 600 spectrometer (NMR Center, University of Groningen) or on a Bruker DRX-500 spectrometer (Bijvoet Center, Department of NMR Spectroscopy, Utrecht University). Samples were exchanged twice with D_2O with intermediate lyophilization and then dissolved in 650 μL of D_2O. Proton chemical shifts are expressed in parts per million in reference to internal acetone (δ^1H 2.225). Suppression of the HOD signal was achieved by applying a WET1D pulse (600 MHz spectra) or a WEFT pulse (500 MHz spectra).

RESULTS AND DISCUSSION

TcTS Catalyzed Formation of Sia-GOS from GMP and Vivinal GOS. For the sialylation reaction of Vivinal GOS, the following characteristics of the donor GMP and the acceptor GOS have been recently documented. The used GMP preparation (MW 10 kDa) has a total sialic acid content of 3.6% (w/w), corresponding to 0.12 mmol/g dry matter; the ratio of Neu5Ac and Neu5Gc is 99:1.[42] The *O*-glycans of GMP contain both (α2−3)-linked and (α2−6)-linked Neu5Ac; the percentage of (α2−3)-linked Neu5Ac is 59% (w/w).[42] The used Vivinal GOS preparation contains free Glc (18.5%), free Gal (1.7%), DP2 products (42.5%), DP3 products (23.6%), DP4 products (10.2%), DP5 products (3.0%), and DP6−DP9 products (<0.5%). At present, the structures of >40 components have been elucidated (>98% of the oligosaccharides), being mainly linear and branched reducing (major) and linear nonreducing (minor) $(Gal)_nGlc$ oligosaccharides (Supporting Information Scheme S1). The common small basic structural fragments, which are nearly only elongated by Gal(β1−4) residues, are five disaccharides, namely, Gal(β1−2)Glc, Gal(β1−3)Glc, Gal(β1−4)Glc, Gal(β1−6)Glc, and Glc(α1−1β)Gal, and four branched trisaccharides, namely, Gal(β1−2)[Gal(β1−6)]Glc, Gal(β1−3)[Gal(β1−6)]Glc, Gal-(β1−4)[Gal(β1−6)]Glc, and Gal(β1−2)[Gal(β1−4)]Glc.[33,34]

A mixture of GOS (3 mM) and GMP (80 mg/mL; containing 6 mM (α2−3)-linked Neu5Ac) was incubated with TcTS (1 μg/mL) for 24 h at 25 °C and pH 5.0. The chosen time, temperature, and pH are based on the optimal

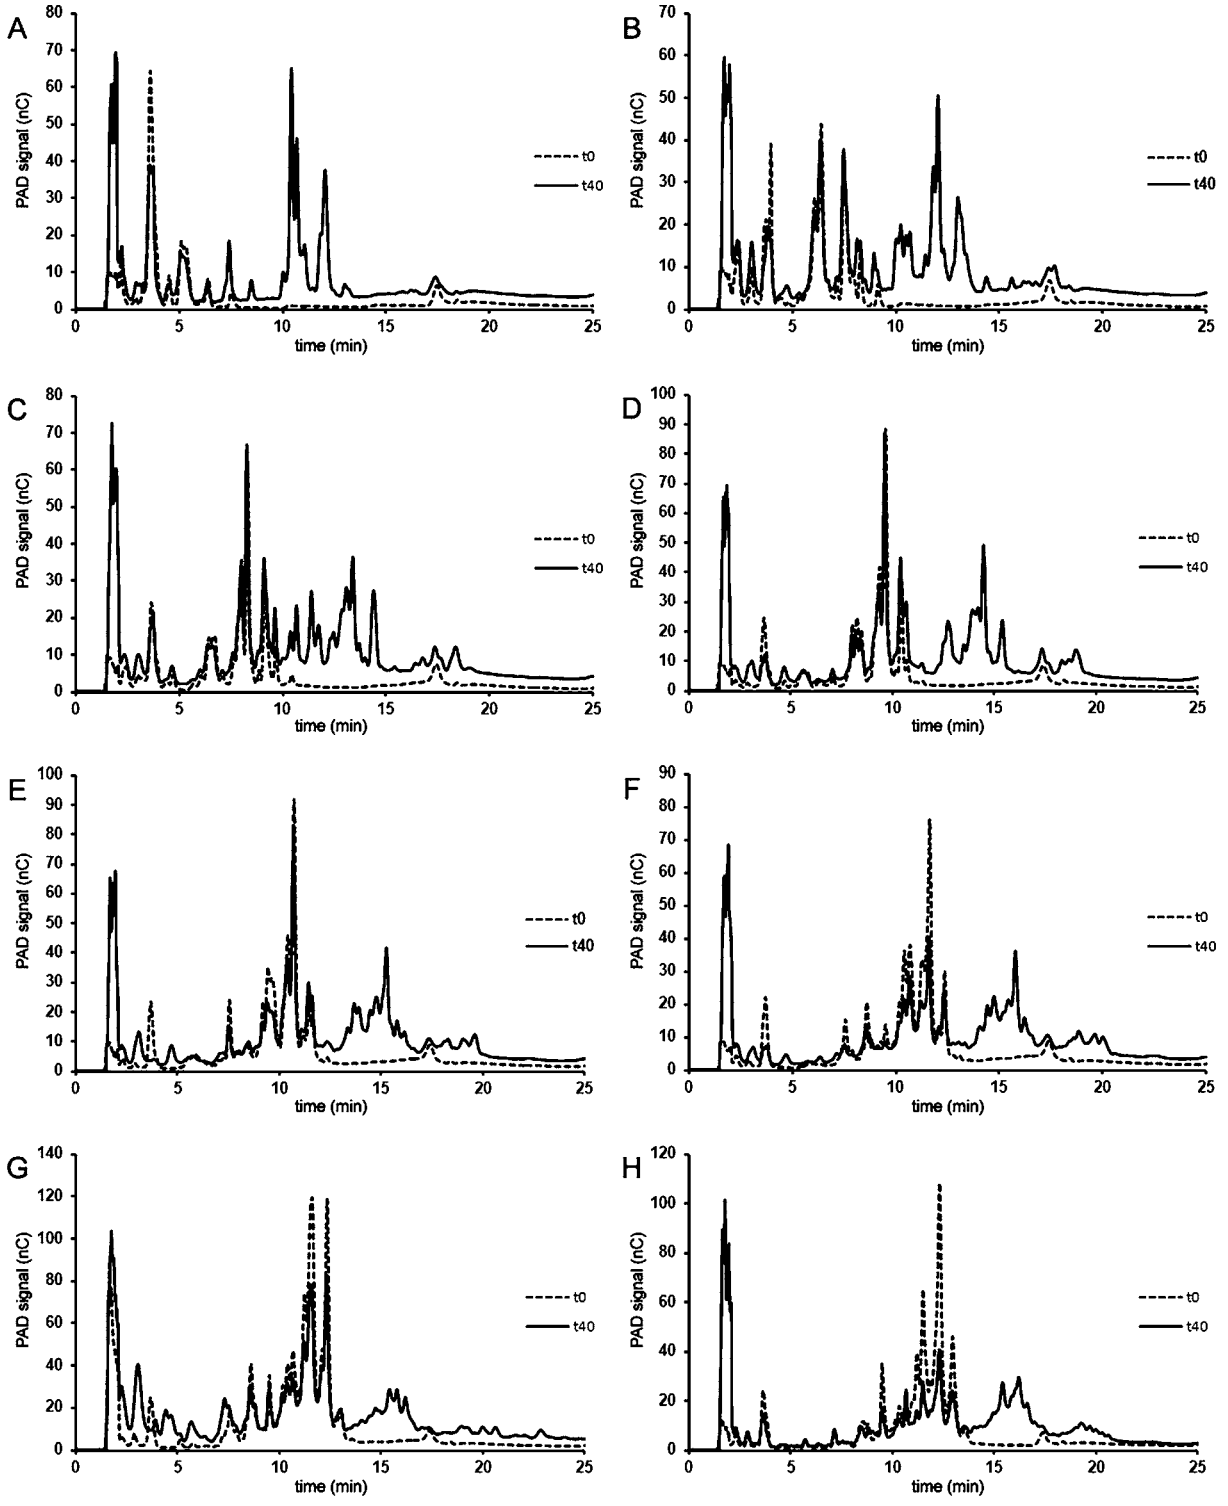

Figure 2. HPAEC-PAD profiles on CarboPac PA-1 of compounds in GOS DP2−DP9/GMP/TcTS reaction mixtures (incubation at 25 °C and pH 5.0) at t = 0 h (dotted line) and t = 40 h (solid line): (A) GOS DP2; (B) GOS DP3; (C) GOS DP4; (D) GOS DP5; (E) GOS DP6; (F) GOS DP7; (G) GOS DP8; (H) GOS DP9.

conditions established earlier for the transfer of Neu5Ac from 4MU-Neu5Ac to lactose, yielding Neu5Ac(α2−3)lactose.[42] Comparison of the HPAEC profile on CarboPac PA-1 (PAD detection) of the obtained reaction mixture after t = 24 h with that of GOS at t = 0 h showed a quite different peak pattern, reflecting a complex mixture of GOS and Sia-GOS components (Figure 1A). Clearly, the peaks in the higher retention time region reflect negatively charged Sia-GOS components. Closer inspection of the HPAEC profile of the reaction mixture revealed that two product pools were distinguishable on the basis of their retention times: a major pool of products with retention times between 10 and 15 min, expected to be mono-Sia-GOS components, and a minor pool of products with retention times between 16 and 20 min, expected to be

DP9	20 ± 3	79 ± 2	21 ± 2

[a]Conversion percentages were determined in duplicate. [b]Mono- and di-Sia-GOS percentages were measured in triplicate (DP3−DP6) and duplicate (DP7−DP9).

disialylated-GOS (di-Sia-GOS) components. The latter structures can be formed from GOS components containing two terminal Gal units, which are both targets for sialylation by TcTS or from 6′-galactosyl-lactose (here terminal and internal Gal can be sialylated) present in GOS.[33,34,42] Note that mono-Sia-GOS components can originate from GOS structures with one and two terminal Gal units (and from 6′-galactosyl-lactose). After working up the reaction mixture, indeed AEX on Resource Q (UV detection at 214 nm) yielded a peak in the monocharged and in the dicharged region of sialylated oligosaccharides (data not shown). MALDI-TOF-MS analysis (negative-ion mode) of the monocharged fraction revealed a series of quasi-molecular $[M - H]^-$ ions for monosialylated GOS (mono-Sia-GOS) of GOS DP2−DP7 (m/z 632.09, 794.40, 956.58, 1118.69, 1280.58, 1442.22) (Figure 1B). The molar ratio of mono-Sia-GOS and di-Sia-GOS, based on the UV detection of C═O in Neu5Ac at 214 nm, taking into account the number of Neu5Ac units (one or two) in the detected molecules, was determined to be 97:3. The relatively low percentage of di-Sia-GOS is caused by the relatively high percentage of GOS DP2 (42.5%, w/v; i.e., lactose and other GOS DP2 components), which cannot form di-Sia-GOS structures.

TcTS Incubations of GMP with GOS DP2−DP9 Fractions. As is evident from the above experiment, incubation of GOS with GMP and TcTS leads to a highly complex mixture of GOS + Sia-GOS components with concomitant overlap in retention times on CarboPac PA-1 using HPAEC-PAD. Therefore, it was decided to separate GOS in its DP fractions and to incubate them separately with GMP and TcTS. To this end Vivinal GOS was fractionated on Bio-Gel P-2, yielding GOS fractions ranging from DP1 to DP9 (Supporting Information Figure S1). Each GOS DP fraction (3 mM), except DP1, was incubated with GMP [80 mg/mL; containing 6 mM (α2−3)-linked Neu5Ac] and TcTS (1 μg/mL) for 40 h at 25 °C and pH 5.0. HPAEC-PAD analysis on Carbo-Pac PA-1 (Figure 2) showed for all DP fractions the formation of product peaks with increased retention times, indicating that GOS DP2−DP9 were all suitable acceptor substrates for TcTS.

Separation of the reaction mixtures by AEX on Resource Q (UV detection at 214 nm) yielded two charged fractions for all DPs ≥3 (for DP4, see Figure S2). MALDI-TOF-MS analysis (negative-ion mode) of the charged fractions prepared from GOS DP2−DP6 confirmed in each case, except DP2 (only mono-Sia-GOS), the presence of both mono-Sia-GOS and di-Sia-GOS components (Table 1). When incubation experiments were followed over time, the total Sia-GOS and di-Sia-GOS formations were found to be maximal after 32 h of incubation at 25 °C (Table 2). The conversion of GOS to Sia-GOS was the highest for DP2 (about 56%), about 36% for medium-length GOS chains (DP3−DP6), and about 17% for long-chain GOS (DP7−DP9), respectively, indicating that TcTS has a preference for shorter GOS acceptors.

As the GOS preparation contains reducing linear (one terminal Gal unit) and branched (two terminal Gal units) oligosaccharides and nonreducing linear oligosaccharides (two terminal Gal units), di-Sia-GOS can originate from reducing branched as well as from nonreducing linear oligosaccharides. To make these two groups of di-Sia-GOS components visible, the di-Sia-GOS fractions obtained from GOS DP4 and DP5 were incubated with $NaBH_4$, whereby the reducing branched oligosaccharides were converted into their corresponding oligosaccharide-alditols. In HPAEC-PAD analyses on CarboPac PA-1, oligosaccharide-alditols have shorter retention times than their reducing oligosaccharide analogues,[44] but nonreducing oligosaccharides will retain their retention times. Inspection of the HPAEC-PAD profiles (Figure S3) before and after reduction, together with MALDI-TOF-MS analysis (data not

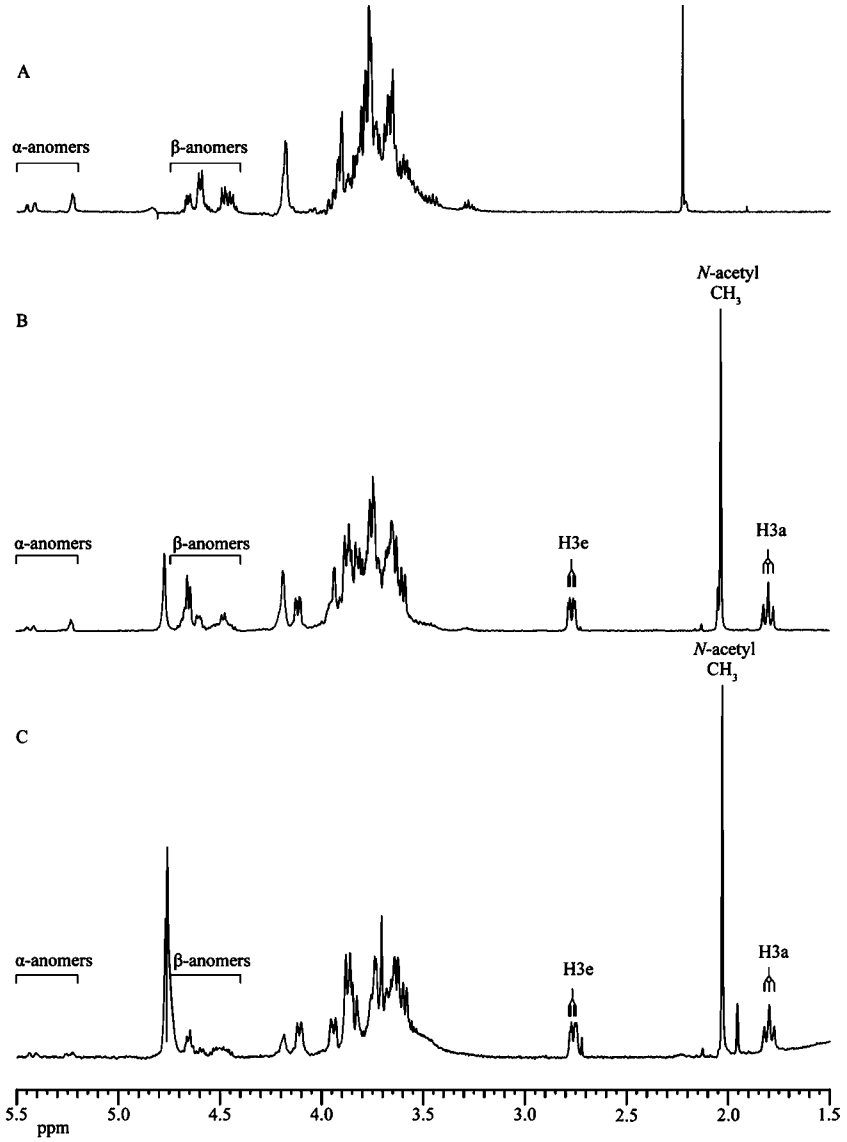

Figure 3. 500 MHz ^{1}H NMR spectra, recorded in D_2O at 298 K, of (A) GOS DP4, (B) DP4 mono-Sia-GOS, and (C) DP4 di-Sia-GOS. The sialylated GOS DP4 fractions were obtained from the incubation of GOS DP4 with GMP and TcTS.

shown), showed that the majority of the di-Sia peaks shifted to shorter retention times, in agreement with the finding that nonreducing oligosaccharides form only a very minor part of GOS.[34]

As a typical example of the NMR analysis of the different Sia-GOS DP fractions, a short discussion of the spectra of mono-Sia-GOS DP4 (MALDI-TOF-MS: $[M - H]^-$, 956.60) and di-Sia-GOS DP4 (MALDI-TOF-MS: $[M - H]^-$, 1247.38) is presented. The ^{1}H NMR spectrum of the DP4 GOS acceptor [a mixture of at least 15 DP4 structures in which the D-Glc*p* unit is mono or disubstituted by D-Gal*p* residues (monomeric, dimeric, or trimeric fragments); see Scheme S1[34]] is shown in Figure 3A. It shows α-anomeric peaks at δ 5.449 and 5.406, reflecting the GOS DP4 components with 2-, 2,4-, 2,6-, and 1,2-O-substituted α-D-Glc*p* residues; the α-anomeric signals in the range δ 5.25−5.22 reflect the GOS DP4 components with 1-, 3-, 4-, 6-, 3,6-, and 4,6-O-substituted α-D-Glc*p* residues, whereas the signals at δ 4.221 and 4.164 correspond with H-6a signals of 6-O-substituted D-Glc*p* residues (i.e., β- and α-anomeric forms of reducing D-Glc*p*, respectively) present in part of the GOS DP4 ensemble. The signals in the range of δ 4.75−4.40 stem from β-D-Glc*p* and β-D-Gal*p* H-1 atoms, and those in the range of δ 4.20−4.17 from β-D-Gal*p* H-4 atoms of GOS DP4 components containing 3- (very minor) and/or 4-O-substituted (major) β-D-Gal*p* residues.[33,34] Comparison of the ^{1}H NMR spectrum of mono-Sia-GOS DP4 (Figure 3B) with that of GOS DP4 (Figure 3A) shows, besides several signals shifting in the β-anomeric region, three clear additional signals that have similar peak areas. The new signals at δ 2.763 and 1.799 belong to the Neu5Ac H-3e and H-3a atoms of Neu5Ac(α2−3) residues [Neu5Ac(α2−3)Gal regions: H-3e, δ 2.75−2.76; H-3a, δ 1.79−1.80[45]] and the new signal at δ 4.112 is the Gal H-3 signal of 3-O-substituted β-D-Gal*p* units (a terminal Gal residue in GOS), in accordance with the Neu5Ac(α2−3)Gal sequence. Note that Neu5Ac(α2−6) H-3e and H-3a atoms of the Neu5Ac(α2−6)Gal sequence resonate in the regions δ 2.67 and 1.70−1.72, respectively.[45] The monosialylation follows from a comparison of the H-1 surface areas of the α-and β-anomeric Glc/Gal residues with those of the Neu5Ac H-3e signal, showing a 3.4:1 ratio for Glc/

DOI: 10.1021/acs.jafc.5b01505
J. Agric. Food Chem. 2015, 63, 5976−5984

Gal:Neu5Ac, fitting to a monosialylation of DP4 structures. Following a similar reasoning, the ^{1}H NMR spectrum of di-Sia-GOS (Figure 3C) can be interpreted [Neu5Ac(α2−3) H-3e, δ 2.760; H-3a, δ 1.794]. The disialylation is reflected by a 1.6:1 ratio for Glc/Gal:Neu5Ac, fitting to disialylated DP4 structures. Note that β-anomeric signals close to the HOD peak suffer from cosuppression, resulting in underestimation of the Glc/Gal amount in this approach.

Sialylation of Lactose with BPG as Sialic Acid Donor and TcTS as Catalyst. For the decoration of GOS with both Neu5Ac and Neu5Gc, a bovine BPG preparation was selected as sialic acid donor. Blood plasma glycoprotein preparations are a rich source of *N*- and *O*-glycans terminated by (α2→3)- and (α2→6)-linked sialic acids.[25,46,47] Total sialic acid analysis of BPG, after mild acid hydrolysis, by HPAEC-PAD yielded a content of 0.7% (w/w), corresponding to 23.4 μmol/g dry matter (w/w), of which 45% was Neu5Ac and 55% Neu5Gc. By comparing the amount of sialic acid released by the linkage-type nonspecific sialidase A and the (α2−3)-specific sialidase S, the percentages of (α2−3)-linked Neu5Ac and Neu5Gc in BPG were determined to be 60 and 40%, respectively.

To test the sialic acid transfer reaction with BPG as donor, first lactose was applied as acceptor. To this end BPG [65 mg/mL; corresponding with 0.54 and 0.44 mM (α2−3)-linked Neu5Ac and Neu5Gc, respectively] was incubated with TcTS (1 μg/mL) and lactose (4 mM) for 24 h at 25 °C and pH 5.0, and the products Neu5Ac(α2−3)lactose and Neu5Gc(α2−3)lactose were quantified by HPAEC-PAD on CarboPac PA-1 [Figure 4; the relative response factor of Neu5Gc(α2−3)lactose

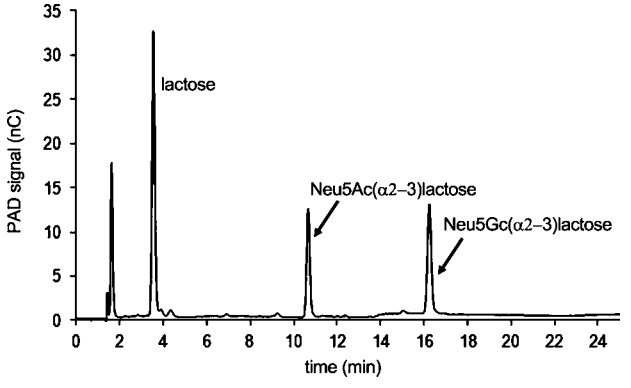

Figure 4. HPAEC-PAD profile on CarboPac PA-1 of the product mixture obtained from the incubation of lactose with BPG (24 h, 25 °C, pH 5.0), showing the formation of Neu5Ac(α2−3)lactose and Neu5Gc(α2−3)lactose.

is 1.2 times that of Neu5Ac(α2−3)lactose]. MALDI-TOF-MS analysis of the mixture revealed quasi-molecular ions $[M - H]^-$ at m/z 631.88 (Neu5Ac product) and m/z 647.87 (Neu5Gc product). Both products were isolated on CarboPac PA-1 and subjected to ^{1}H NMR analysis, showing the typical ^{1}H NMR parameters for (α2−3)-linked Neu5Ac (H-3e, δ 2.759; H-3a, δ 1.801; NAc, δ 2.030) and (α2−3)-linked Neu5Gc (H-3e, δ 2.777; H-3a, δ 1.820; NGc, δ 4.121).[45] Under the applied conditions, it was found that 33% of total Neu5Ac and 20% of total Neu5Gc could be transferred to lactose, which means that the percentage of transfer of (α2−3)-linked Neu5Ac and (α2−3)-linked Neu5Gc amounted to 55 and 50%, respectively.

Sia-GOS Obtained from TcTS Incubations with BPG and GOS DP3 and DP4. As incubations with GOS would lead to highly complex mixtures of Sia-GOS, built from components of different DP with only Neu5Ac, only Neu5Gc, and in the case of reducing branched oligosaccharides and nonreducing linear oligosaccharides also with both Neu5Ac and Neu5Gc, pilot experiments were carried out with GOS DP3 and DP4.

Both GOS DP fractions (4 mM) were incubated with BPG [65 mg/mL; corresponding with 0.54 and 0.44 mM (α2−3)-linked Neu5Ac and Neu5Gc, respectively] and TcTS (1 μg/mL) for 48 h at 25 °C and pH 5.0. When compared with the HPAEC profiles of the starting materials, HPAEC-PAD analysis showed in both cases above 10 min the formation of two nearly identical product pools, suggesting that both Neu5Ac(α2−3)GOS and Neu5Gc(α2−3)GOS were formed in similar ratios [Figure 5; compare with Figure 2B (DP3) and 2C (DP4) for

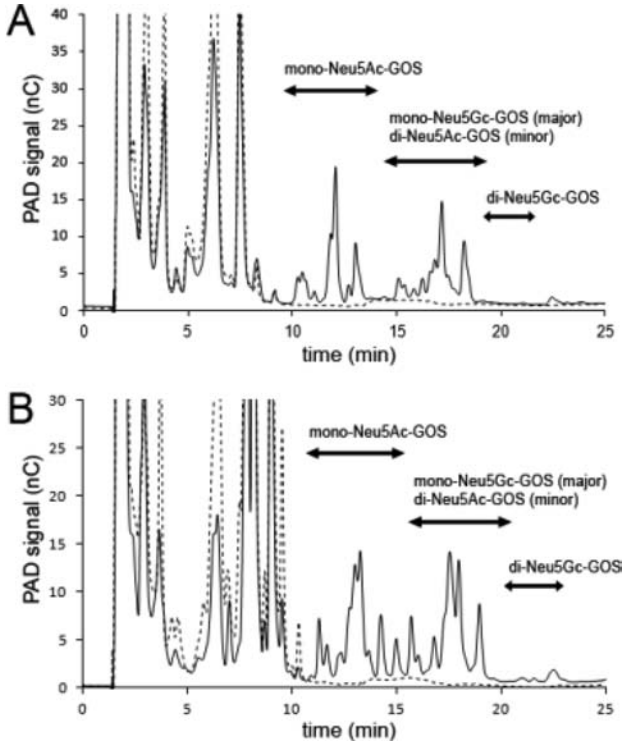

Figure 5. HPAEC-PAD profiles on CarboPac PA-1 of compounds in GOS DP3/BPG/TcTS and GOS DP4/BPG/TcTS reaction mixtures (incubation at 25 °C and pH 5.0 for 48 h): (A) GOS DP3; (B) GOS DP4.

only Neu5Ac(α2−3)GOS]. The sialylated GOS DP3 and DP4 reaction mixtures were separated by AEX on Resource Q, and the ratios of the mono-Sia-GOS and di-Sia-GOS fractions were determined to be 97:3 and 98:2, respectively (not optimized). The mono-Sia-GOS fractions were collected and subjected to ^{1}H NMR analysis (Figure S4). The NMR spectra showed overlap of the Neu5Ac and Neu5Gc signals; assignment of the chemical shifts led to the conclusion that both mono-Sia-GOS fractions contain (α2−3)-linked Neu5Ac (H-3e, δ 2.761; H-3a, δ 1.798) and (α2−3)-linked Neu5Gc (H-3e, δ 2.782; H-3a, δ 1.814) (^{1}H NMR data for Sia-GOS of DP3 are shown). Also, the presence of both *N*-acetyl and *N*-glycolyl signals at δ 2.031 and 4.122 was consistent with the presence of Neu5Ac and Neu5Gc in the products.

Conclusions. The presented data show that the *trans*-sialidase of *T. cruzi* is capable of transferring (α2−3)-linked sialic acid from the low-cost naturally available bovine donor

DOI: 10.1021/acs.jafc.5b01505
J. Agric. Food Chem. 2015, 63, 5976−5984

substrates GMP and BPG to GOS (total Vivinal GOS or derived specific GOS DPs), thus forming novel sialylated oligosaccharide mixtures (Sia-GOS) in excellent yields. Detailed analytical data for these complex mono-Sia-GOS and di-Sia-GOS mixtures were collected, substantiating the course of the decoration reactions. As the used donors contain the two basic members of the sialic acid family, Neu5Ac and Neu5Gc, nearly only (Neu5Ac in GMP) or in an attractive ratio, when focused on Neu5Gc (55% Neu5Gc) (BPG), they are highly suitable to be further explored for potential applications in both the food and feed industry, respectively. The protocols developed in this study are currently upgraded for the generation of larger batches of Sia-GOS products. When available, these products can be evaluated for food (GOS + Neu5Ac-GOS) and feed (GOS + Neu5Ac/Neu5Gc-GOS) applications in terms of combined prebiotic/antiadhesive properties. This holds for preparations obtained from both total GOS or from specific DP fractions of GOS. Moreover, separation of mono- and di-Sia-GOS fractions generates possibilities for testing them individually.

world-leading contributors to the development of methods for positional analysis of glycerolipids: "the assays of stereo- and regioisomers are more demanding than conventional lipid analyses...All of the methods are subject to improvement".[19]

Attempts to solve these problems include a comprehensive procedure employing an off-line two-dimensional HPLC-MS technique.[20−23] Its advantage is an ability to identify and quantitate a number of TG regioisomers (e.g., the data for 11 TG species were presented in one study).[20] However, with MS-based detection other issues arise: some TG species in the sample present linear calibration plots, whereas others possess nonlinear plots, complicating the data processing.[24] Here, it was concluded that linearity should not be assumed as nonlinear calibration plots may be obscured by scatter in the data or by plots where there is only slight curvature. Additional care and processing of the data are thus required to ensure the highest confidence in the results. Indeed, different MS detectors are known to give different ratios of isomeric TGs.[23] For example, when ionizing OOP, the OO/OP ratio of fragment ions varies from 51 with a Thermo Orbitrap to 64 with a Bruker Ion trap, whereas ionization of OPO with the same instruments provides OO/OP ratios of 16 and 21, respectively. Similarly, ionization of SOO provides OO/SO ratios ranging from 50 for a Bruker Ion trap to 70 for a Bruker QqTOF instrument, whereas OSO provides OO/SO ratios of 17 and 22, respectively, for the same instruments. Another recently reported study uses off-line two-dimensional chromatography by applying nonaqueous reversed phase (RP)-HPLC followed by Ag^+-HPLC of the selected fractions using evaporative light scattering detection (ELSD).[25] When two-dimensional chromatography is not used, separation of isomers and potential contaminants remains problematic, and the resulting chromatograms can be complex and unresolved;[22,23] among others, the separation of the OPO/POO pair has not been solved.

The goal of this work was to establish a convenient and reliable method by which to separate structurally similar TGs, with the targeted quantitation of OPO. A range of techniques was investigated with a view to comparing the advantages and limitations of each. This paper details efforts to provide a robust separation and analytical method that provides data with a high level of confidence and for which a range of potential contaminants were considered.

MATERIALS AND METHODS

Chemicals and Materials. Oleic, linoleic, elaidic, and stearic acids and glycerol were purchased from Sigma-Aldrich (USA). 1-Monopalmitoylglycerol, 1,3-dipalmitoylglycerol, 1,2-dipalmitoylglycerol, 1,3-dioleoyl 2-palmitoylglycerol (OPO), *rac* 1,2-dioleoyl-3-palmitoylglycerol (OOP), 1,2-dipalmitoyl-3-oleoylglycerol (PPO), 1,3-dipalmitoyl-2-oleoylglycerol (POP), tripalmitin (PPP), triheptadecanoin (HHH), triolein (OOO), trielaidin (EEE), trilaurin, trimyristin, tristearin, triarachidin, tribehenin, tripalmitolein, tripetroselinin, trielaidin, tri-11-eicosenoin, trierucin, trilinolein, and trilinolenin were purchased from Sigma-Aldrich (St. Louis, MO, USA). The triglyceride mix TG2-TG10 was from Supelco (Sigma-Aldrich, St. Louis, MO, USA). Commercial samples for analysis included sample 1, a dietary ingredient comprising dairy milk solids blended with OPO-containing oil; sample 2, OPO oil; sample 3, OPO oil (samples, 1, 2 and 3 were kind donations of industrial food grade products from a New Zealand company); and sample 4, infant formula.

POP and PPO were synthesized from 1,3-dipalmitoylglycerol and 1,2-dipalmitoylglycerol, respectively, and oleic acid, with dicyclohexylcarbodiimide (DCC) as the coupling agent.[26] A mixture of 1-palmitoyl-2,3-distearoyl-, 1-stearoyl-2-linoleoyl-3-palmitoyl-, 1-linoleoyl-2-stearoyl-3-palmitoyl-, and 1,2-dilinoleoyl-3-palmitoylglycerols was prepared from 1-monopalmitoylglycerol and a mixture of stearic and linoleic acids (1.00:1.03 mol/mol) using the same method. Similarly, a mixture of tristearin, triolein, 1-stearoyl-2,3-dioleoyl-, 1,3-dioleoyl-2-stearoyl-, 1,2-distearoyl-3-oleoyl-, and 1,3-distearoyl-2-oleoylglycerols was prepared from glycerol and a mixture of stearic and oleic acids (1.00:1.00 mol/mol). Synthetic samples were purified by column chromatography on Merck silica gel 70−230 mesh 100 Å grade 10184 (Sigma-Aldrich, St. Louis, MO, USA) with the consecutive use of hexane, hexane/dimethyl ether (99:1, by v/v), and hexane/diethyl ether (95:5, by v/v) solvent systems and controlled by TLC using Merck HPTLC silica gel 60 10 × 10 cm (Darmstadt, Germany) in hexane/diethyl ether/formic acid (80:20:2, v/v/v) with detection by iodine vapor. The composition of the samples was assessed by GC-FID. The regiospecific distribution of the saturated, monounsaturated, and diunsaturated fatty acids in triacylglycerols was assessed using NMR spectroscopy,[27] with the spectrum acquisition parameters modified as presented under NMR Spectroscopy below. DCC was from Acros Organics (Fisher Scientific, Pittsburgh, PA, USA). The same approach was used to synthesize a mixture of OOO, OOE, OEO, OEE, EOE, and EEE starting from oleic and elaidic acids (1.00:1.04 mol/mol) and glycerol. HPLC solvents (acetone, acetonitrile, *n*-hexane) were Merck LiChrosolv solvents for liquid chromatography (Sigma-Aldrich).

Extraction of TGs from Infant Formula. A 2 g sample of the infant formula powder (sample 4) was extracted using a modification of the method of Svennerholm and Fredman[28] to ensure that polar lipids (required for other assays, not related to this work) were also extracted. The original method was modified as follows: 2 g of powder was combined with 6 mL of water and mixed with 16 mL of methanol. This solution was then extracted sequentially with chloroform (8 mL) and 1:1 chloroform/methanol (16 mL) and twice with 2:1 chloroform/methanol (12 mL) with the use of ultrasonication (5 min/extraction). The centrifuged lipid extracts from each extraction were combined and transferred to a separating funnel and washed with water (23 mL) and then with 10% aqueous KCl (3 mL). The lower (organic, chloroform-rich) layer was dried and constituted the crude lipid extract. A portion (40 mg) of the crude lipid extract was dissolved in $CHCl_3$ (2 mL) and purified by passage through a Phenomenex Strata 500 mg silica SPE column (Torrance, CA, USA). Elution with chloroform (4 mL) produced a TG-rich fraction, which was dried under a stream of nitrogen gas and used directly for RP-HPLC.

GC-FID. Fatty acid methyl esters (FAMEs) were prepared from samples 1−3 by direct transmethylation without prior lipid extraction. Sample 4 was extracted as described above and converted into FAMEs.[29] GC analysis of the FAMEs was performed on a Trace GC Ultra gas chromatograph (Thermo Fisher Scientific, Waltham, MA, USA) equipped with a flame ionization detector (FID) and TraceGold TG-WaxMS capillary column of dimensions 30 m × 0.25 mm i.d., 0.25 μm (Thermo Fisher Scientific, Waltham, MA, USA). Helium (99.99%) was used as carrier gas (Air Products, Allentown, PA, USA), and a split ratio of 100:1 was maintained. Injector and detector temperatures were both set at 280 °C, and the oven was held at 190 °C for 50 min. Individual peaks of FAME were identified by comparison with standards of FAME and by equivalent chain length values.[30]

GC-FID analysis of acylglycerols was performed on the same gas chromatograph equipped with a CP-TAP CB UniMetal capillary column of dimensions 25 m × 0.25 mm i.d., 0.1 μm, supplied by Agilent (Santa Clara, CA, USA). Samples were injected in splitless mode. Helium (99.99%) was used as carrier gas (Air Products). Injector and detector temperatures were set to 350 and 370 °C, respectively. The oven temperature was raised from 60 to 200 °C at a rate of 120 °C/min, then increased to 320 °C at a rate of 20 °C/min, followed by a rise to 360 °C at a rate of 1 °C/min, and was maintained at that temperature for 6 min.

NMR Spectroscopy. In a typical experiment 20−45 mg of a sample was dissolved in 0.75 mL of $CDCl_3$. ^{13}C NMR spectra were recorded at 125.7 MHz with WALTZ16 proton composite pulse decoupling on a Bruker Avance III NMR spectrometer (Bruker, Billerica, MA, USA) equipped with an automatic tuning 5 mm multinuclear probe at 303 K. The pulse program ZGIG, which was

DOI: 10.1021/acs.jafc.5b01835
J. Agric. Food Chem. 2015, 63, 5985−5992

supplied with Bruker TopSpin2.6 spectrometer software, was used for suppression of nuclear Overhauser effects via inverse gate proton decoupling. Acquisition parameters were as follows: 90° ^{13}C observe pulse, 11.0 μs; spectral width, 2011 Hz (16 ppm) centered on the carbonyl region at 171 ppm; 32768 real and imaginary FID data points collected during the 8.146 s FID data acquisition time, followed by a 22 s recovery delay time to ensure a pulse repetition time of >5 times the longest expected longitudinal relaxation time T1. A total of 800 scans were collected, requiring almost 7 h per spectrum.

Because this part of the study involved quantitation, some comments on digital handling at the receiver stage are warranted. Although analog to digital converter oversampling and the standard Bruker "sharp" digital filter were used in conjunction with a 125 kHz analog filter, routine "on the fly" linear prediction (as implemented by the Bruker "baseopt" parameter) was not used to correct the initial FID data points to align them to the true time zero of the FID near the center of the excitation observe pulse. The FID was zero filled once to 32768 real data points, and a 0.06 Hz exponential weighting function was applied before Fourier transformation.

RP-HPLC. Semipreparative nonaqueous RP-HPLC was performed using a Gilson HPLC system (Middleton, MI, USA) comprising two Gilson 306 pumps and a Gilson 811C dynamic mixer. The mobile phase was 70:30 acetone/acetonitrile run under isocratic conditions at a flow rate of 4 mL/min for a duration of 72 min. The column, a Phenomenex Prodigy 5 μm 100A 250 × 10 mm ODS column, was operated at room temperature. Detection was at 210 nm using a Gilson UV−vis 156 detector. Because the methods employed isocratic elution, no further column conditioning was necessary between samples. Nevertheless, 80 mL of solvent was allowed to flow through the column between runs, at 4 mL/min. Samples of the oil were prepared by dissolving approximately 100 mg of the oil in 1 mL of the mobile phase. Three injections of 300 μL were made for each sample, and the collected fractions were pooled for subsequent analysis. For the infant formula, 30−40 mg of the extracted TG sample was dissolved in 300 μL of acetone and injected in one dose. Fractions were evaporated using a rotary evaporator and transferred to a vial using hexane. The hexane was evaporated under a stream of nitrogen, the sample weighed, and the solution made up with an accurately measured volume of hexane or isooctane.

Ag$^+$-HPLC. Analytical silver ion HPLC was performed on a Waters H-class Acquity UHPLC system (Milford, MA, USA) with UV at 205 nm (PDA) and ELSD detectors in series, using Agilent ChromSpher 5 Lipids columns (Santa Clara, CA, USA).[31,32] The Waters Acquity ELS detector settings were as follows: detector gain, 500; gas pressure (compressed air), 240 kPa; nebulizer set to cooling; and drift tube temperature, 60 °C. Three columns (250 × 4.6 mm) were connected in series and maintained at 25 °C. The mobile phase was 0.5% acetonitrile in *n*-hexane (sonicated to ensure complete mixing), and the flow rate was 1.0 mL/min. Samples were prepared at 10 mg/mL in hexane, and injection volumes of 2−5 μL were used for the high OPO samples and UV detection. Lower concentrations were employed when the ELSD was used for detection (approximately 2 mg/mL).

For high OPO samples, the method involving preparative nonaqueous RP-HPLC to generate an OPO-enriched fraction with analysis by Ag$^+$-HPLC with UV detection at 205 nm was the most effective. For the low OPO samples (<1% OPO), a weighed amount of the extracted TG fraction was used for the nonaqueous RP-HPLC, and an amount of 40 mg proved useful. There was no need to weigh the recovered fraction, which was dried of solvent and made up in 500 μL of *n*-hexane for Ag$^+$-HPLC using ELSD as the detector. A standard curve could be prepared using OPO at 0.2 mg/mL in *n*-hexane. Injections of between 1 and 10 μL were sufficient to prepare a standard curve, using the syringe on board the HPLC apparatus. Similar volumes were found appropriate for injection of samples in both the high OPO and low OPO procedures. For the work described here the UV-based standard curve for OPO was linear for the range from 3 to 16 μg injected. The ELSD standard curve conformed to a power curve in the range 0.2−1.2 μg of OPO injected.[33]

RESULTS AND DISCUSSION

^{13}C NMR Spectroscopy. The use of ^{13}C NMR spectroscopy of carboxyl carbons is accurate and convenient to determine the regiospecific distribution of saturated, *cis*-9 and *cis*-11 monounsaturated and polyunsaturated fatty acids in TGs.[27] Although this method was unable to provide data sufficient to detail the regiospecific distribution of individual fatty acids in complex mixtures, it was helpful to determine the ratio of saturated fatty acids in the α-positions (*sn*-1,3) of triacylglycerols to those in the β-position (*sn*-2). The optimal conditions for recording the spectra and securing details on the allocation of the signals to link those with the identity of the responsible compound were facilitated by the use of TG standards, both as discrete individual components and in mixtures of molecules. Dairy-derived samples (sample 1) afforded a distinctive set of signals for the carboxyl carbon atoms of the saturated fatty acids, in both the *sn*-1,3 and *sn*-2 positions. This was attributed to the presence of short-chain saturated fatty acids in the dairy TGs (Figure 1).

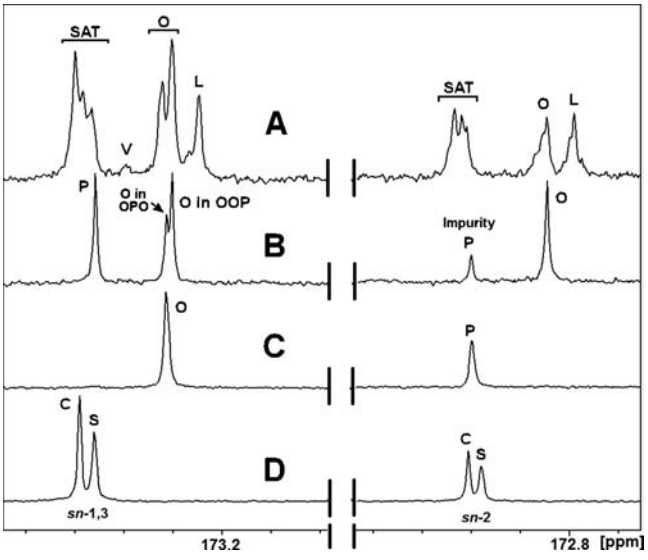

Figure 1. ^{13}C NMR spectra: (A) sample 1 (dietary ingredient); (B) OOP; (C) OPO standard; (D) mixture of tricaproin (CCC) with tristearin (SSS), with peak allocations. Note that the commercially obtained reference sample of OOP in fact contained 19.7% of an impurity, identified as OPO, with a saturated acid in the β-position.

If it is beneficial to have saturated fatty acids (any) in the middle of the TG molecule and unsaturated acids (any) at the side carbons of a glycerol moiety, then ^{13}C NMR spectroscopy is seemingly the best option to provide the relevant data for such indiscriminate requirements. For example, using the data from a previous study,[34] one may calculate that in human milk triacylglycerols, 47.1 mol % of colostrum-derived saturated fatty acids are located in the *sn*-2 position (72.0 ± 2.6% of total fatty acids in the *sn*-2 position are saturated), ignoring the identity of the fatty acids concerned. In transitional milk 45.9 mol % of the saturated fatty acids are located in the *sn*-2 position (77.1 ± 8.8% of *sn*-2 fatty acids are saturated), and in mature milk 45.5 mol % of the saturated fatty acids are located in the *sn*-2 position (79.1 ± 1.3% of *sn*-2 fatty acids are saturated). There is evidently very little variation in the level of saturated fatty acids in the *sn*-2 position between colostrum, transitional milk, and mature milk. Our data on saturated fatty acids in the *sn*-2

DOI: 10.1021/acs.jafc.5b01835
J. Agric. Food Chem. 2015, 63, 5985−5992

position of the samples investigated in the present study, given in mole percent of total saturated fatty acids present in the sample, are as follows: sample 1, 34.9 mol % (46.0% of *sn*-2 fatty acids are saturated); sample 2, 52.9 mol % (72.6% of *sn*-2 fatty acids are saturated); and sample 3, 52.4 mol % (80.3% of *sn*-2 fatty acids are saturated).

Given the data presented above, it would seem reasonable to use total "*sn*-2 saturates" as one of the parameters when infant formulas are compared to human milk. Although limited, the method is appealing and may provide sufficient information when dealing with infant constipation issues. Specifically, the work of Quinlan et al.,[7] published before OPO-enriched formulas started to gain popularity, leads to the identification of some interesting trends. Using data from that study it was possible to calculate that the amount of insoluble calcium salts of saturated fatty acids in the stools of formula-fed infants was substantially higher than that in breast milk-fed infants. Between formula-fed and breast milk-fed infants, the difference was approximately 36 times higher for lauric, 33 times for myristic, 24 times for palmitic, and 8 times for stearic acid, excreted in the form of calcium salts. These elevated levels of insoluble soaps, seemingly produced from triacylglycerols with saturated fatty acids in *sn*-1 and/or *sn*-3 positions, were linked to an increased incidence of hard stools and constipation in infants. An advantage of the use of the ^{13}C NMR spectroscopic method was that the results were produced as mole percent, making it easy to estimate the potential loss of calcium due to the formation of calcium soaps from non-*sn*-2-linked fatty acids in dietary TGs.

A downside of the method was in its low throughput, because the time required for recording a spectrum is 6−7 h using a sample size of 20−30 mg. It is possible that the use of larger samples with different NMR probes may reduce the time required for analysis while retaining the accuracy of the method. A recent publication shows that optimization of the parameters reduces the recording time even in the case of complex mixtures of triacylglycerols from fish oils.[35]

Other signals in ^{13}C NMR spectra, for example, those of α-CH_2 carbon atoms or of olefinic carbons, may also be helpful in providing information about the regiospecific distribution of fatty acids in triacylglycerols.[36] An alternative HSQC-TOCSY NMR method[37] was employed for the analysis of palmitoyl- and oleoyl-containing standards of triacylglycerols, but cannot resolve the present analytical problem.

GC-FID and GC-MS analysis. In contrast to ^{13}C NMR spectroscopy, GC-based analysis of TGs provides information on molecular species composition but no data on the regiospecific distribution of fatty acids. Due to the difficulties faced in volatilizing TGs, a high-temperature methylsilicone phase presented an obvious choice. This allows the separation of the compounds according to the number of carbon atoms in the molecule. An improved option would be medium-polarity phenyl-methylpolysiloxane phases that allow separation according to the number of the double bonds within a group of TGs with the same carbon number.[38]

The target compound, OPO, is a triacylglycerol with 52 carbon atoms in the fatty acid moieties containing two double bonds, TG52:2 in shorthand notation. The column employed in the present study allowed the baseline separation of TG52:0, TG52:1, TG52:3, and TG52:4 (see Figure 2). Despite this ability to separate isomers, OPO remained indistinguishable from its regioisomer, OOP, when this column was used (Figure 2). Incomplete separation of OPO/OOP from stearoyl-linoleyl-

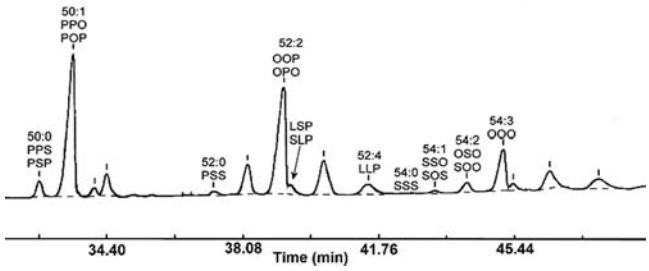

Figure 2. GC separation of sample 1 triacylglycerols in the area of interest according to the number of carbon atoms and unsaturation in the fatty acid residues. Only the peaks with retention times identical to those of the reference TG samples used are labeled.

palmitoyl (SLP) glycerols present in both human milk and some infant formulas[10] was also seen (marked with an arrow in Figure 2).

There are a number of questions yet to be addressed in the GC analysis of TGs, one being the applicability of different injectors to various types of oils.[39] An observation made in one study[39] is that, at least for some oils, a common split/splitless injector may produce results as good as more sophisticated programmed temperature injectors. The study also shows the importance of determining and using the response factors for individual TGs. For example, the difference in relative response between TG50:1 (POP) and TG54:2 (SOO) varied by almost 50%. In our experiments the difference in relative response between POP and OPO was approximately 15%. If average common values were used instead of specific values for response factors, the error can be significant, leading to unreliable data. Attempts in the present study to add a MS dimension by using a Shimadzu GCMS-QP2010-FID instrument were unsuccessful due to the upper temperature limit for the heated GC-MS interface being too low (350 °C) for a reliable transfer of the TGs of interest and were thus not pursued.

HPLC. Initial attempts to analyze TG mixtures by Ag^+-HPLC alone, even with two or three Ag^+ columns in line, yielded poor results. The sample being injected was thus simplified by adding a semipreparative RP-HPLC step and collecting the group of TGs that would contain the target OPO (Figure 3). Obviously, if other TGs are also of interest for regiospecific analysis, the relevant fractions may be collected during the same run. This "TG52:2" fraction (outlined area in

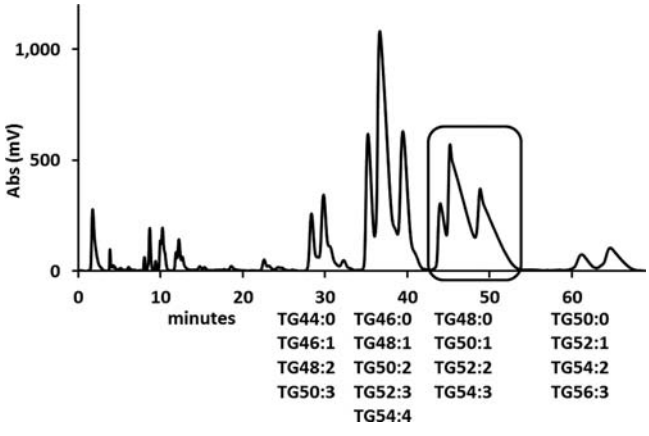

Figure 3. RP-HPLC trace of sample 3. Detection was by UV at 210 nm. The fraction collected for Ag^+-HPLC assay is identified.

DOI: 10.1021/acs.jafc.5b01835
J. Agric. Food Chem. 2015, 63, 5985−5992

Figure 3) produced by RP-HPLC could, apart from OPO, theoretically contain TGs 48:0, 50:1, 52:2, 53:4, 56:4, 58:5, 60:6, 62:7, 64:8, 66:9, etc., because these species demonstrate chromatographically similar behavior under the conditions employed. Of these, the following have been reported in analyses of human milk and infant formulas: 48:0 (PPP), 50:1 (PPO, POP, SMO and its isomers), TG52:2 (OOP, OPO, SLP), and 54:3 (OOO, SOL, SLnS).[10]

Ag^+-HPLC of an OPO/OOP mixture demonstrated that these isomers are clearly separable using this type of chromatography (Figure 4, trace A). Saturated, monounsaturated, and triunsaturated TGs are not expected to overlap with OPO and/or OOP in Ag^+-HPLC. It was still important to exclude the possibility of OPO/OOP overlapping with other diunsaturated TGs that might be present in the sample, namely, SLP and its regioisomers. Accordingly, a mixture of SLP isomers was prepared, and it was confirmed that those are clearly separated from OPO in Ag^+-HPLC under the conditions used (Figure 4, trace B). Under these conditions, OPO and OOP were also distinct from POP and PPO (Figure 4, trace C). Although the complete separation of LSP and OOP was not achieved (Figure 4, trace D), LSP is not reported among the TGs found in human milk and its substitutes[10] and is therefore unlikely to interfere if OOP content is to be determined. Confirmation of the peak identity was obtained by collection of the putative OPO peak and subsequent FAME analysis thereof by GC after hydrolysis and conversion of the free fatty acids into their methyl esters. Additionally, a sample spiked with authentic OPO showed coelution of the OPO peaks. Sample-derived OOP was also found to coelute with authentic OOP. Adlof[40] reported that silver ion HPLC also allows the separation of saturated TGs possessing shorter homologues due to their higher retention times. In the present experiments with three Ag^+-HPLC columns connected in series, good separation of monounsaturated homologues (SSO and PPO) was achieved, whereas diunsaturated TGs (SOO, OOP, OSO, and OPO) demonstrated good but incomplete separation (Figure 5).

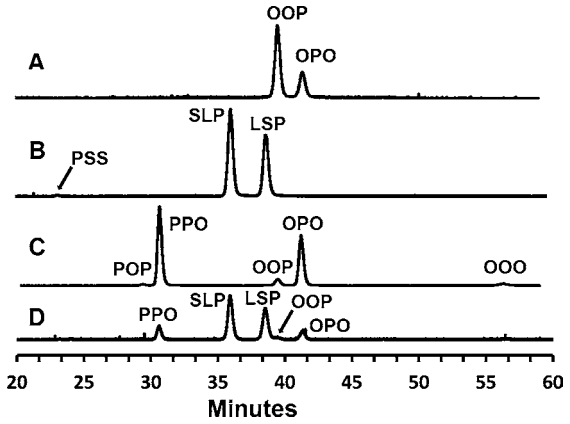

Figure 4. Ag^+-HPLC separation of OPO from the other TGs that may be present in the RP-HPLC "TG52:2" fraction: (A) OOP/OPO mixture; (B) SLP/LSP mixture; (C) sample 2 "TG52:2" fraction; (D) sample 2 "TG52:2" fraction + SLP/LSP mixture.

Although it was tempting to try to improve the separation by increasing the number of columns (e.g., four in line) in the hope that the RP-HPLC fractionation step might be omitted, a significant increase in the time required for analysis would be incurred. Additionally, the danger that polyunsaturated TGs with higher retention times will accumulate in the columns and interfere with subsequent assays made the RP-HPLC/Ag^+-HPLC option more attractive. Moreover, due to the low loading capacity of analytical Ag^+-HPLC columns, the RP-HPLC step was beneficial, because it allowed an increase in the relative content of all "TG52:2" components, thus increasing the sensitivity and accuracy of the method. An extra advantage of employing the two-step HPLC is that there was no need to prepare high-purity triacylglycerols for injection, because contaminants that might be present in oils or lipid extracts (e.g., phospholipids, sterol esters, etc.) were either rejected at the RP-HPLC step or did not fit into the OPO window in Ag^+-HPLC. Also, potential overlap with OSO was avoided by the two-step method.

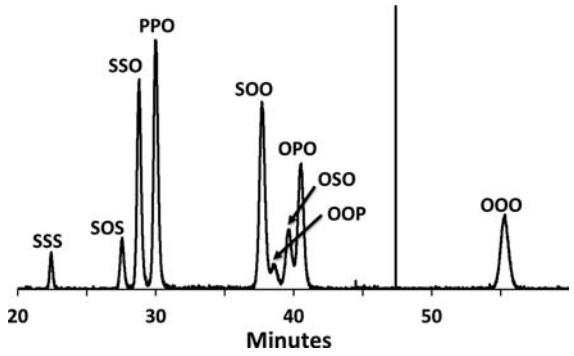

Figure 5. Separation of homologous unsaturated TGs by Ag^+-HPLC: SSO and PPO, SOO and OOP, and OSO and OPO. Detection was by ELSD.

Two more possibilities exist in which the OPO fraction may be contaminated with triacylglycerols of similar mobility during Ag^+ chromatography. The first was that dairy fats are known to contain *trans* fatty acids,[41] which demonstrate higher mobility than their *cis* isomers in Ag^+ chromatography.[42] It was consequently possible that triacylglycerols, which contain shorter chain fatty acids, and *trans* fatty acids may have retention times similar to that of OPO. Approximations have been made from analyses of trielaidin (EEE) versus OOO behavior, and the effect of chain-shortening on the behavior of saturated TGs has been investigated.[40] These observations suggest that, to compensate for an increase in mobility due to one *trans* double bond present, the triacylglycerol in question must have a lower number of carbon atoms. It would therefore be rejected at the RP-HPLC step in the present method and cause no problems during Ag^+ chromatography. In the second, it was possible that entities with the same or even higher number of carbon atoms and higher levels of unsaturation than OPO and containing a *trans* fatty acid (e.g., a TG54:3) may be a source of contamination in the "TG52:2" fraction from the RP-HPLC step. It was anticipated that the chromatographic behavior of one or more of EEE, EEO, EOE, EOO, OEO, and OOO may overlap with OPO. To address this possibility a mixture of TG54:3 containing oleic and elaidic acids was prepared and subjected to Ag^+-HPLC. Pleasingly, OPO was clearly separated from its nearest neighbor EEO (Figure 6).

A reversed-order approach (compared to ours) two-dimensional for analysis of TGs has been reported. Online Ag^+-HPLC and RP-HPLC with detection by UV, ELSD, and PI-APCI-MS was employed.[43] Both UV and ELSD methods of detection performed poorly (probably due to a low loading capacity of

the column used for the separation in the first dimension (a cation exchanger coated with silver nitrate).

As ELSD detectors are in common use in many analytical laboratories, the application of either UV or ELSD for the detection of a range of molecules is now routine. In this work a UV detector and ELSD in series were used for optimum reliability of the data. It was clear that UV detection was only useful for the high OPO samples. The limit of detection with UV at 205 nm was approximately 1.5 μg of OPO injected (at this level the ELSD peak was above scale). Using ELSD, the limit of detection was an order of magnitude lower at around 0.2 μg of OPO injected. Lipid samples with low levels of OPO such as the infant formula used in this work would be difficult to analyze using UV detection. Whereas ELSD was particularly useful for low OPO samples, the range of detection was narrower and the detector quickly moved off scale with samples containing higher levels of OPO; this would require sample dilution to obtain accurate data. For this reason, the use of an UV detector for those samples where the OPO level is high remained the method of choice. The UV standard curve for OPO was found to be linear for the range from 3 to 16 μg injected, whereas the ELSD standard curve conformed to a power curve in the range of 0.2−1.0 μg of OPO injected. The nondestructive nature of UV detection was also useful for collection of fractions from Ag^+-HPLC for any subsequent analysis (e.g., GC-FID of FAMEs). The combined results produced by different approaches to the analysis of OPO-containing mixtures are presented in Table 1.

Calibration and Statistical Data. For ELSD, good linearity (R^2 = 0.999 over nine discrete calibration curves set up over a period of 3 days using freshly prepared samples) was shown between 0.2 and 1.0 μg injected when using a log curve of the response. This also demonstrated the good repeatability of the method. For UV detection, good linearity (R^2 = 0.999) was obtained between 3 and 16 μg injected. The method was found to be reproducible when using three individual lipid samples (extracted from the infant formula as described above). For n = 13, the average content of OPO in the lipid was found to be 5.77 ± 0.24 mg/g of lipid, with RSD = 4.1%. The median was 5.72 mg/g and the range, 0.90 mg/g. For ELSD, the LOD was calculated as 0.1 μg injected weight of OPO, whereas the LOQ was calculated as 0.3 μg injected weight of OPO.[44]

In summary, the results demonstrate that ^{13}C NMR spectroscopy was useful to provide high-level "rough" data relating to the level of saturated fatty acids in the *sn*-2 position of TGs, but lacked the power (with the protocols employed) to provide structural information on those saturated fatty acids. The combination of RP-HPLC with UV detection at 210 nm, followed by Ag^+-HPLC of the selected OPO-containing fraction with either UV detection or ELSD, presented a reliable and robust method by which quantitative data for OPO content could be generated from complex matrices. Usefully, OPO was well separated from all other likely diunsaturated and/or *trans* triunsaturated TGs, thereby avoiding signals from non-OPO TGs that would give falsely elevated readings for OPO. The UV and ELSD detection methods provide complementary ranges for detection as indicated by their respective calibration curves. The method presented allowed good limits of detection and of quantitation. Because the combination of techniques draws together a set of procedures that are designed to specifically deal with complex matrices, the applicability of the method is likely to be wide-ranging and, thus, readily transferrable to other complex matrices and foodstuffs. It is expected, however, that some fine-tuning of one or both of the HPLC methods would be required, depending on the analytes of interest.

[a]Only the most selective ion products are shown.

agents.[21,22] For example, in the presence of acids or bases, the highly strained β-lactam ring opens to give an array of products (metabolites) such as penicilloic acid, penicillinic acid, penicillamine, penilloaldehyde, aminopenicillanic acid, penaldic acid, penamaldic acid, isopenicillic acid, penillic acid, and penilloic acid. Of these, the most abundant are penillic acid, **2**, and penilloic acid, **3**.[22−29] The instability of penicillin G emphasizes the importance of designing an analytical method that identifies not only penicillin G but also potential metabolites.

To the best of our knowledge, no method has been reported for the analysis of penicillin G and its metabolites in citrus matrices. In this paper, we present a sensitive method to quantitate penicillin G and its metabolites (penillic and penilloic acids) with high selectivity in a variety of citrus matrices using ultra-high performance liquid chromatography coupled with triple-quadrupole tandem mass spectrometry (UHPLC-MS/MS). Throughout method development, we systematically investigated the extraction process and matrix effects to optimize quantitative accuracy and precision. Because of the potential use of penicillin G to treat citrus greening disease, it is necessary to develop a reliable method for the extraction and identification of penicillin G residues. This method is useful to quantitatively monitor the presence of penicillin G and its metabolites in citrus fruits post-treatment.

MATERIALS AND METHODS

Reagents. Penicillin G potassium salt (99.4%) and internal standard (penicillin G-d_5 potassium salt) (98.4%) were provided by o2si Smart Solutions (Charleston, SC, USA). Penilloic acid (96.3%) and penillic acid (99.3%) were purchased from LGC Standards (Wesel, Germany). HPLC grade hexane, acetonitrile (with and without 1% formic acid), methanol, and water (with and without 1% formic acid) were provided by Fisher Scientific (Pittsburgh, PA, USA). Anhydrous monosodium phosphate, disodium phopshate, and ammonium acetate were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Buffer Solution Preparation. The phosphate buffer solution (PBS) (0.1 M, pH 7) was prepared by dissolving anhydrous NaH_2PO_4 (5.8 g, 0.0483 mol) and Na_2HPO_4 (8.15 g, 0.0574 mol) in 1 L of deionized (DI) water. Ammonium acetate ($NH_4C_2H_3O_2$) buffer (0.05 M, pH 6.7) was prepared by dissolving ammonium acetate (4.0 g, 0.0519 mol) in 1 L of DI water.

Preparation of Standard Stock Solutions. Individual stock solutions of penicillin G potassium salt, penilloic acid, penillic acid, and internal standard penicillin G-d_5 at 1000 μg/mL were made by dissolving the standard (after adjusting for salt content and purity) in a mixture of water and acetonitrile (1:1, v/v). These stock standard solutions were stored at −20 °C for an extended period of time (>5 months) with no issues.

Preparation of Mixed Intermediate Standard Solutions (Int-A) (1 μg/mL = 1 ng/μL). The above stock solutions, each at 1000 μg/mL, were used to prepare a mixed standard solution (Int-A) containing penicillin G, penillic acid, and penilloic acid, each at a concentration of 1 μg/mL. These were prepared by adding 100 μL of each standard stock solution into the same 100 mL volumetric flask. The flask was filled to the mark with phosphate buffer (0.1 M, pH 7). Preparation of intermediate solutions at concentrations of 2, 5, 20, 100, 200, and 300 ng/mL was carried out on each day of batch extraction/analysis by further diluting Int-A. The intermediate internal standard solution containing 1 μg/mL penicillin G-d_5 was prepared by adding 100 μL of the penicillin G-d_5 stock solution (1000 μg/mL) into a 100 mL volumetric flask, which was subsequently filled to the mark with phosphate buffer (0.1 M, pH 7). This was further diluted with

J. Agric. Food Chem. 2015, 63, 5993−6000

phosphate buffer to make an internal standard intermediate solution at a concentration of 40 ng/mL.

Calibration Curve Preparation. To prepare 800 μL of the individual calibration standards, 100 μL of the penicillin G-d_5 internal standard intermediate standard (40 ng/mL) was added to each of six different autosampler vials. Then to each vial was added 100 μL of each intermediate standard (2, 5, 20, 100, 200, 300 ng/mL). This was followed by the addition of 600 μL of ammonium acetate buffer. It should be noted that the calibration curve was prepared out of matrix for the quantitation of penicillin G because an internal standard was used to compensate for ion suppression and recovery losses during the extraction procedure. Because no isotopically labeled standards are available for penillic or penilloic acids, a calibration curve in matrix was used. The in-matrix curve was prepared by carrying six separate 2 g samples of matrix through the extraction process. The extracted matrix samples were evaporated in 50 mL centrifuge tubes and labeled 1−6. To each sample of dried matrix was added 100 μL of the correspondingly labeled mixed intermediate standard (2, 5, 20, 100, 200, 300 ng/mL) along with 700 μL of ammonium acetate buffer.

Sample Fortification. The fortified samples were made by spiking 2 g of the different citrus matrices (lemon, orange, and grapefruit) with 100 μL of four intermediate mixed standard solutions (2, 5, 20, and 200 ng/mL) and 100 μL of the internal standard intermediate solution (40 ng/mL). Overall, four spikes were made for each matrix to reach final concentrations of 0.1, 0.25, 1, and 10 ng/g of penicillin G, penillic acid, and penilloic acid in each spike. The concentration of the internal standard spiked into the matrix was constant in all samples (2 ng/g). Reagent (2 g of water) and matrix blanks were not fortified with internal standard and were used as negative controls.

Penicillin G Extraction from Citrus Matrices. Citrus fruit samples were purchased (from retail stores) and immediately stored at −80 °C. The entire frozen fruits were then homogenized to a powder-like consistency using a robot coupe with a 7 mm thick stainless steel blade (Robot Coupe, Ridgeland, MS, USA), and a 2 g portion was immediately weighed into a 50 mL polypropylene centrifuge tube. Then, 4 mL of PBS buffer (0.1 M, pH 7) was added, and the samples were fortified with 100 μL of internal standard. Each of four separate samples was then spiked with the intermediate standards, in triplicate, as shown in Table 1. The samples were shaken using a vortex mixer for 10 min at 1100 rpm. Four milliliters of hexane was added to the mixture followed by additional shaking in the vortex mixer (10 min at 1100 rpm). Then, the samples were centrifuged at 4000 rpm for 15 min to separate the aqueous and organic layers. The hexane layer was then discarded using a Pasteur pipette, and the aqueous layer was then transferred to an Amicon Ultra 50000 M_w membrane filtration device (Millipore, Darmstadt, Germany). Centrifugation at 4000 rpm for 15 min filtered solids and residual hexane from the aqueous layer. The filtrate was washed with 2 mL of phosphate buffer followed by further centrifugation (15 min, 4000 rpm) resulting in a filtered aqueous solution containing extracted penicillin G and its metabolites.

SPE Cleanup of Penicillin G. Oasis HLB, 6 cc, 200 mg SPE extraction cartridges (Waters, Milford, MA, USA) were prewashed sequentially with 3 mL of methanol, 3 mL of H_2O, and 3 mL of PBS buffer. The sample extract was loaded onto the SPE column, and the column was washed with 2 mL of phosphate buffer. Then, a slight vacuum was applied to dry the SPE columns. Penicillin G and metabolites were eluted from the SPE columns with 3 mL of acetonitrile into clean 50 mL polypropylene centrifuge tubes. The eluate was evaporated to dryness using a stream of N_2 at 40 °C for 1 h. Ammonium acetate buffer (800 μL) was then immediately added. The extract was mixed by vortexing for 20 s and followed by filtration through a 0.2 μm PVDF filter for LC-MS/MS analysis.

LC-MS/MS Method. The LC-MS/MS included an ACQUITY UPLC I-Class System (Waters) connected to an API 6500 Qtrap (AB Sciex, Toronto, ON, Canada) triple-quadrupole mass spectrometer. Analyses were carried out using electrospray ionization (ESI) in positive-ion mode using multiple reactions monitoring (MRM). Optimized mass spectrometer parameters for the detection of penicillin G and its metabolites were obtained through infusion studies. The parameters optimized were declustering potential (DP), entrance potential (EP), collision energy (CE), and collision cell exit potential (CXP). The MS/MS product ion spectra of the standards and experimental samples were obtained using a target-oriented screening approach in enhanced product ion (EPI) scan mode. The source parameters (ion source voltage (4500 V), curtain gas (30 psi), heater gas (45 psi), and ion source temperature (400 °C)) were identical in MRM and EPI scan modes. Separation of the test compounds was achieved using a 150 mm × 2.1 mm i.d., 1.7 μm, Acquity C18 column. The mobile phase composition was (A) water with 0.1% formic acid and (B) acetonitrile with 0.1% formic acid. The column temperature was maintained at 40 (±1) °C. The gradient began at 95:5 of A:B with a flow of 0.2 mL/min. The gradient was changed to 5:95 of A:B over a course of 10 min followed by a 5 min hold at 5:95 of A:B. Over 0.1 min, the gradient was changed to 95:5 of A:B with a concomitant change in flow rate to 0.4 mL/min. After 4 min, the flow was reduced to 0.2 mL/min over the course of 0.1 min. This was held for 0.8 min to complete the LC gradient (20 min total run time).

Method Validation. This analytical method was validated by independently analyzing three different matrices (lemon, orange, and grapefruit); each matrix was studied in triplicate. A multipoint, in-matrix calibration curve was used to calculate the concentration of penillic acid and penilloic acid in the spikes. The penicillin G is calculated from a multipoint, in-solvent calibration curve with an isotopically labeled internal standard (penicillin G-d_5). Calibrants were used at levels ranging from 0.25 ng/g (equivalent to 0.1 ng/g in sample) through 37.5 ng/g (equivalent to 15 ng/g in sample). A minimum of five data points for linear and quadratic regression lines were required, but any combination of standards may be used for quantitation. Curves were fit with $1/x$ weighting with an R^2 value >0.99. It is the policy of the laboratory to set limit of detection (LOD) and limit of quantitation (LOQ) values at levels greater than the minimum 3× and 10× general requirements, respectively, such that daily instrument variance, matrix effects, procedural errors, etc., do not result in failures to meet validated LODs and LOQs for studies taking place over extended periods of time. It is also the policy of the laboratory to verify LOD and LOQ reporting levels using spiked sample matrix. In short, the laboratory may set LOD and LOQ values to levels greater than the minimum detected signal at 3× or 10× on the instrument on the basis of the needs of the method and the desired ruggedness of the method. The LOD for this method was set to the lowest concentration validated in this study at 0.1 ng/g in matrix, whereas the LOQ was set at 0.25 ng/g. Both of these levels exceed the 3× and 10× requirements for the primary transition. Values below the LOD are reported as not detected (ND). Values between the LOD and LOQ are reported as below the quantitation limit (BQL). Values at and above the LOQ are reported as actual values.

RESULTS AND DISCUSSION

Citrus matrices contain a variety of compounds including sugars, citric acid, vitamin C, folic acid, potassium, phytochemicals (e.g., limonoids, flavanoids, etc.), and essential oils (e.g., limonene, octanal, copaene, dodecanal, etc.).[30−33] These various products are distinct in their structures and properties; this must be taken into consideration when attempts are made to extract specific molecules of interest such as penicillin G and its metabolites (penillic acid and penilloic acid) (Figure 1). These products are amphiphilic, containing a benzyl group at one end and one or two carboxylic acids at the other. The presence of carboxylic acid groups increases the polarity of these molecules, which makes them highly soluble in water and easily extracted using an aqueous medium. It is worth noting that penicillin G contains a fused β-lactam ring system, which is susceptible to ring-opening under acidic and alkaline conditions, as well as under enzymatic activity. It can easily be transformed or isomerized into many other compounds such as penillic, penilloic, and penaldic acids, penicillamine, and

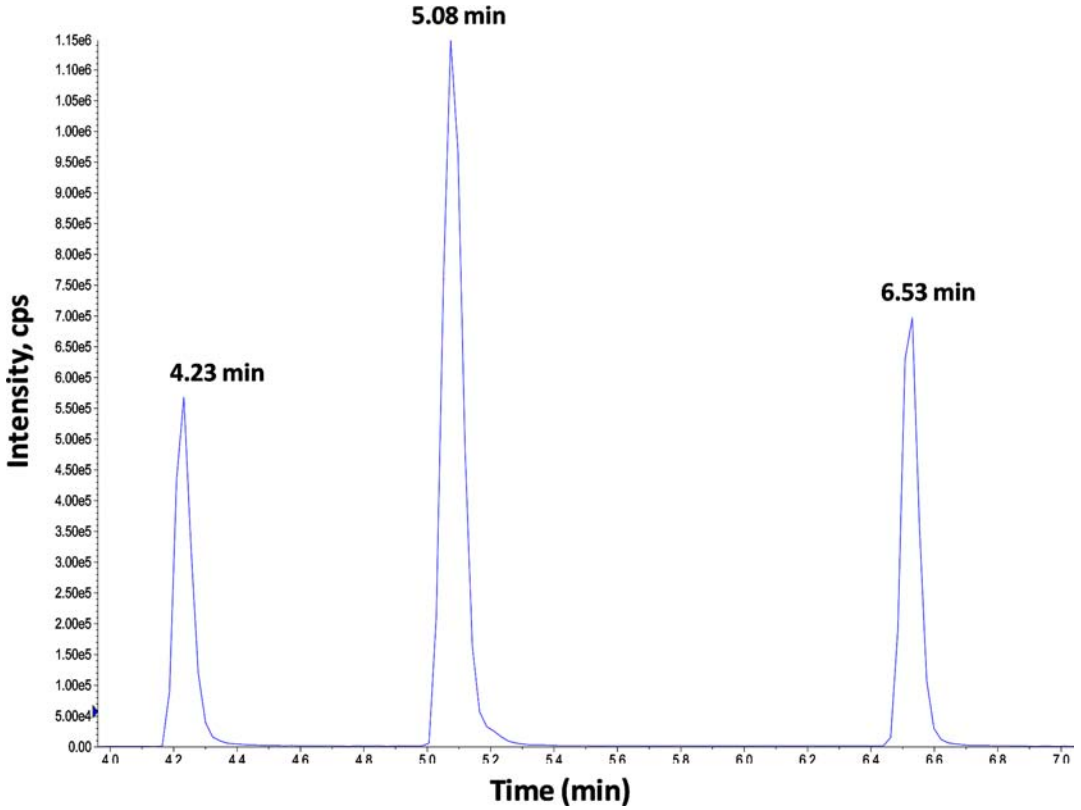

Figure 2. LC chromatogram of the three analytes showing their retention times with 6.53 min for penicillin G, 5.08 min for penilloic acid, and 4.23 min for penillic acid.

penilloaldehyde. Once infected citrus trees are treated with penicillin G, we believe various environmental conditions including heat, rain, sunlight, and contact with biological nucleophiles, acids, or bases might lead to the decomposition of penicillin G and formation of penicillin metabolites.[21] Therefore, it is important to identify these metabolites when fully assessing the treatment of citrus trees with penicillin G. This motivated us to incorporate penilloic acid and penillic acid metabolites (commercially available) into our extraction and analytical method because they may be present even after penicillin G has fully decomposed. This information guided us in the development of our method for the extraction of penicillin G and its metabolites from citrus matrices as observed by LC-MS/MS analysis.

Extraction Method Optimization. Samples were fortified with an internal standard solution containing only penicillin G-d_5 as well as an intermediate mixed standard solution containing penicillin G, penilloic acid, and penillic acid. After fortification, liquid/liquid extraction using a phosphate buffer (pH 7) and hexane solvent was carried out. The buffer helps to prevent degradation of penicillin G because it is more stable at pH 7, whereas the hexane removes nonpolar components from the sample. This increases the longevity of the C18 columns used on the liquid chromatograph instruments and decreases the probability of ion enhancement or suppression. Next, the aqueous phase was cleaned using a membrane filtration device to remove completely insoluble components. Finally, we used an amphiphilic OASIS HLB column to trap and purify the analytes from hydrophilic contaminants. The analytes were then eluted with acetonitrile, dried, reconstituted with an organic buffer (ammonium acetate), and injected in the LC-MS instrument. This method of extraction has been successfully used to extract penicillin G, penillic acid, and penilloic acid with absolute recoveries ranging from 35 to 70% depending on the matrix used, the compound of interest, and the fortification level. Recoveries as calculated for penicillin G using the internal standard had a range of 77−118% (Table 1).

LC-MS/MS Analysis. Solutions (1 ng/μL) of penicillin G, penicillin G-d_5, penillic acid, and penilloic acid were independently infused into the AB Sciex 6500 mass spectrometer to verify precursor/product ion masses. A Q1MS scan mode was used to identify the precursor ion of each compound. Once identified, the DP was optimized for each precursor ion. Then, product ion scan mode was used to find the product ions. A scan range from 100 to 340 Da was used to allow for observation of low mass product ions as well as the precursor ion. A collision energy ramp (5−80 eV) allowed for determination of the best confirming product ions for each precursor in terms of sensitivity and unique mass values. Using a MRM scan mode, in conjunction with automated compound optimization mode, the DP, CE, EP, and CXP were optimized for each product ion. The precursor to product ion transitions were found to be 335 → 176, 335 → 160, and 335 → 114 (amu) for penicillin G, 309 → 263, 309 → 174, and 309 → 128 (amu) for penilloic acid, 335 → 289, 335 → 243, 335 → 176, and 335 → 128 (amu) for penillic acid, and 335 → 181, 335 → 160, and 335 → 114 (amu) for penicillin G-d_5. Using the optimized parameters, subjection of the standards to LC-MS analysis allowed for observation of retention times and ion ratios between precursor and product ions. Penicillin G and its metabolites were separated on a reversed-phase LC column under the given gradient conditions within 20 min. Figure 2 shows the LC chromatogram of these three compounds. Typical retention times of 6.53, 5.08, and 4.23

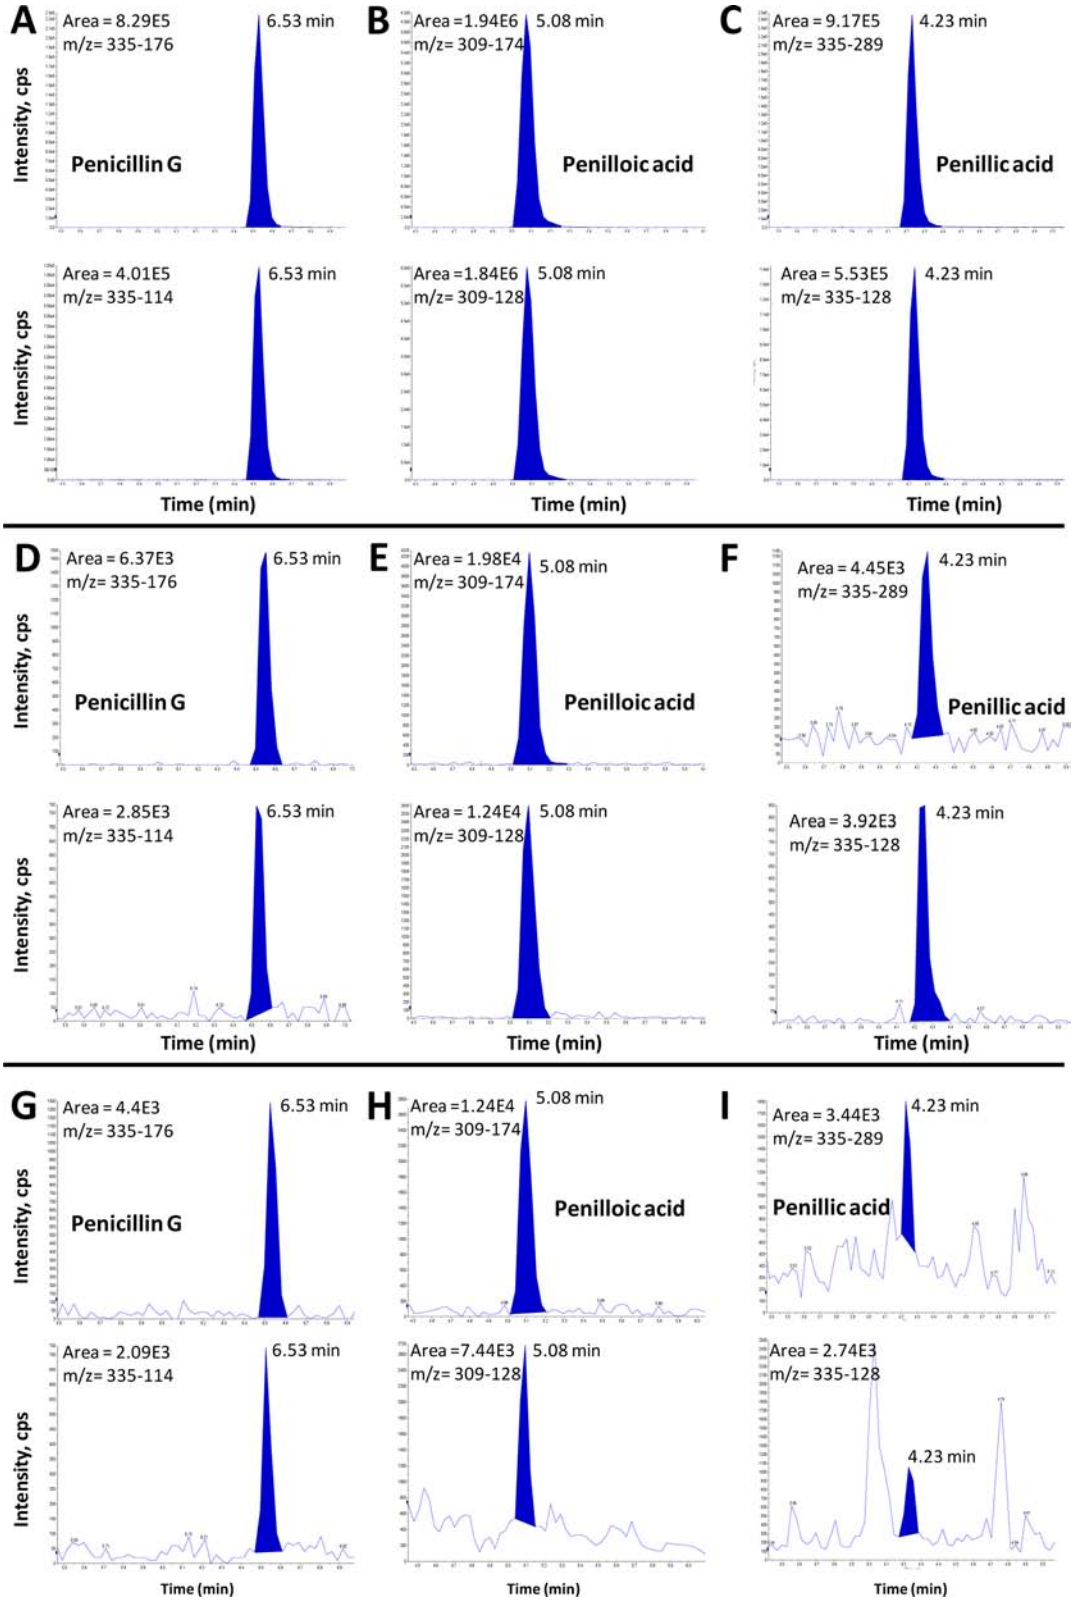

Figure 3. Extracted ion chromatograms collected at standard concentrations of 15 ng/mL in solvent (A–C), 0.1 ng/mL in solvent (D–F), and 0.1 ng/mL in grapefruit matrix (G–I) for penicillin G (*m/z* 176 and 114), penilloic acid (*m/z* 174 and 128), and penillic acid (*m/z* 289 and 128), respectively. These ion products were used for quantitation and precursor confirmation.

min were observed for penicillin G, penilloic acid, and penillic acid, respectively. These retention times reflect expectations based on the chemical structures (i.e., polarity) of these compounds. On one hand, the shortest retention (for penillic acid) can be explained by the high polarity of the two carboxylic acid groups along with the imidazoline heterocycle. Penicillin G, on the other hand, features only one carboxylic acid group along with a nonpolar benzyl group contributing to its longer

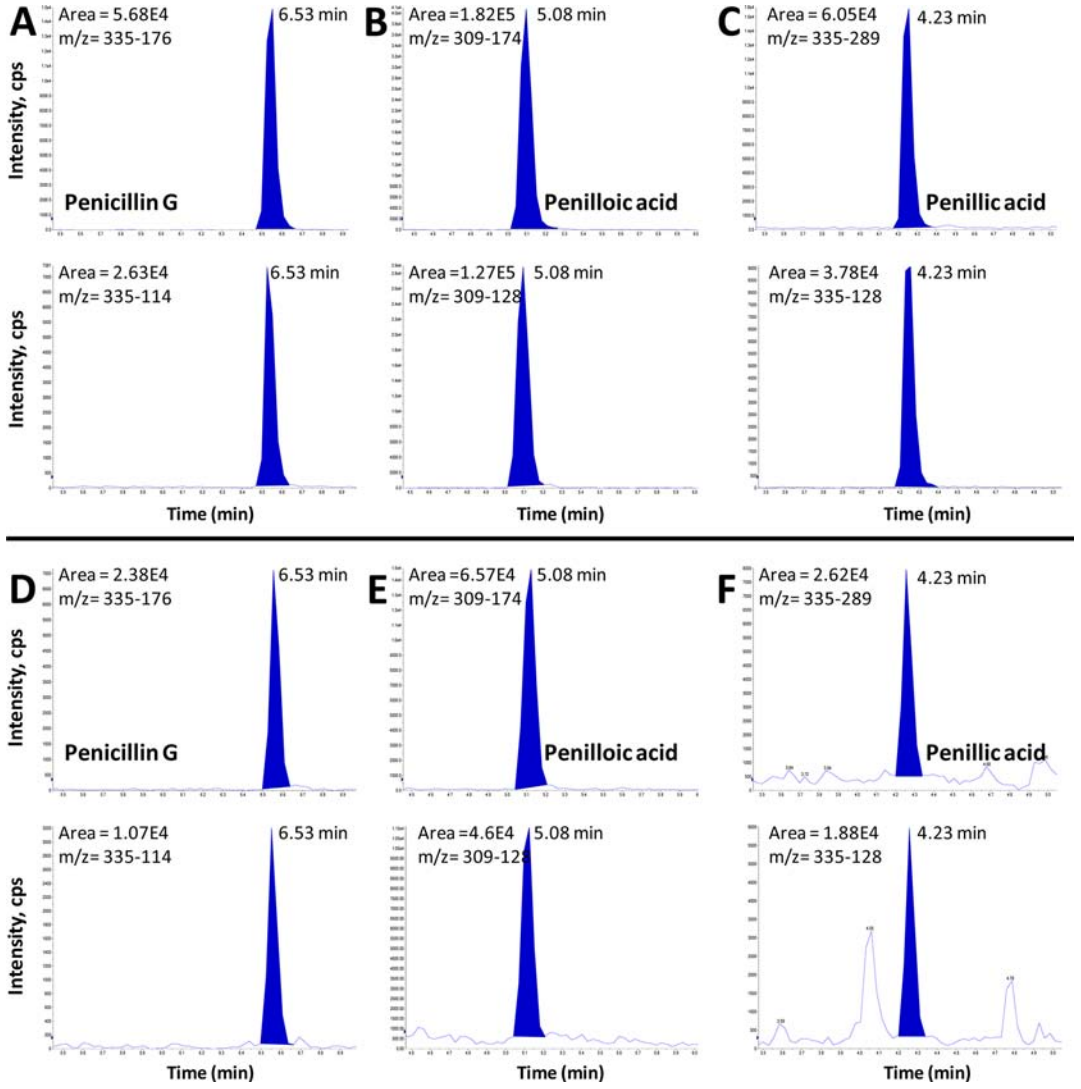

Figure 4. Chromatograms of two product ions of standards in solvent (A–C) and of fortified (spiked) samples in grapefruit matrix (D–F), each at a concentration of 1 ng/mL. The absolute difference in ion ratios between standards in solvent and fortified grapefruit matrix were found to be 1.3, 0.2, and 9% for penicillin G, penilloic acid, and penillic acid, respectively.

retention time of 6.53 min (Figure 1). Panels A–C of Figure 3 show representative LC-MS chromatograms of the most sensitive two product ion signals at a concentration of 15 ng/mL sample in solvent. To demonstrate the ability of this method to function at the LOD, the same chromatograms are shown in Figure 3D–F and in Figure 3G–I at a concentration of 0.1 ng/mL in solvent and grapefruit matrix, respectively. At the LOD level (100 ppt), matrix interference is clearly observed; however, detection of the product ions is still possible (Figure 3I). The product ion transitions used for quantitation purposes were selected on the basis of both the sensitivity and the presence of a clean background. The transitions used for quantitation are 335 → 114, 309 → 174, and 335 → 128 for penicillin G, penillic acid, and penilloic acid, respectively.

Fortifications and Recoveries Results. The method was tested in triplicate to determine its accuracy and precision, and the results are shown in Table 1. Penicillin G, penilloic acid, and penillic acid were each examined in three different citrus commodities (orange, grapefruit, and lemon) at four different concentrations (0.1, 0.25, 1, and 10 ng/g of matrix). The commodities were extracted within the same day to limit the extent of penicillin G degradation in the citrus matrices. The three analytes were then extracted and analyzed by UHPLC/ESI-MS/MS along with a set of samples prepared in solvent at identical concentrations. Preliminary experiments indicated that the instrumental response varies with the absence or presence of citrus matrix. Therefore, to compensate for the effects of the matrix suppression, matrix-matched calibration standard curves (in-matrix curves) were used to quantitate the analytes and obtain what we call absolute recovery. Because of the availability of the standard, penicillin G can be quantified using isotopically labeled penicillin G-d_5 internal standard, which accounts for recovery losses, ion suppression, and degradation of the analytes during the extraction process. Absolute recoveries of the three analytes used in this study from fortified citrus were calculated using a matrix-matched calibration standard curve, and the correlation of coefficient values (R^2) were consistently >0.99. To generate these curves, standards were dissolved in a solution (containing the matrix components) at concentrations varying from 0.1 to 15 ng/g. To quantitate the absolute recoveries of the analytes, chromato-

DOI: 10.1021/acs.jafc.5b02030
J. Agric. Food Chem. 2015, 63, 5993–6000

grams were used to plot the in-matrix calibration points, which were fitted using a $1/x$ weighted quadratic curve. On the other hand, the calibration curve obtained using the isotopically labeled internal standard, penicillin G-d_5, was fitted using $1/x$ linear regression.

The effect of matrix on the area counts for all of the analytes in the three matrices was also investigated. We determined the effect of ion suppression on the signal in all of the citrus matrices. The matrix ion suppression was found to be about 18, 39, and 19% in lemon, 25, 42, and 32% in orange, and 32, 42, and 28% in grapefruit for penicillin G, penilloic acid, and penillic acid, respectively. These data indicate that there is a slight difference in the ion suppression when the matrix is varied. Table 1 shows the absolute recoveries of penicillin G, penillic acid, and penilloic acid along with their relative standard deviations (RSD). Samples were analyzed in triplicate for each matrix as measured by the in-matrix curve. It also shows the recovery of penicillin G as calculated by the internal standard. The recoveries of penilloic acid and penillic acid at each of the four concentrations ranged from 50 to 73% with an average RSD value of <10%. However, the matrix seems to affect the recovery of penicillin G with an average of 70, 50, and 38% recovery in orange, grapefruit, and lemon, respectively. This is probably due to the instability of penicillin G at low pH during the extraction process. We anticipated having lower pH in the lemon matrix than in the grapefruit and orange matrices. To confirm this, we measured the pH of each matrix after stabilization with 4 mL of phosphate buffer and found the pH to be 4.0 for lemon, 5.5 for grapefruit, and 6.0 for orange. Furthermore, we studied the stability of penicillin G and penicillin G-d_5 in the final extract from lemon over the course of 1 week. The final extract, with a pH 7.0 after reconstitution with ammonium acetate buffer, was stored at 10 °C in the LC autosampler. Under these conditions, no significant changes were observed in the concentrations of penicillin G and penicillin G-d_5.

The recovery of penicillin G obtained when corrected with internal standard was nearly 100%. Low recoveries were observed in grapefruit and lemon (about 70−80%) at low levels of fortification (0.1 and 0.25 ppb). Differing matrices did not affect ion ratios, which closely corresponded to the ion ratios observed for in-solvent standards (Figure 4). Figure 4 shows an example of the chromatograms of two ion products of penicillin G, penillic acid, and penilloic acid dissolved in solvent and in fortified/extracted samples (spikes) at 1 ng/mL. These chromatograms demonstrate the consistency of ion ratios (RSD < 10%). The recoveries and RSDs indicate that our method provides good accuracy and precision for the determination of penicillin G and its metabolites in citrus.

In conclusion, an efficient method for the extraction, identification, and quantitation of penicillin G and its metabolites in a variety of citrus fruits (lemon, orange, and grapefruit) has been developed and optimized using UHPLC-MS/MS. Combining liquid/liquid extraction with solid phase extraction cartridges served as a simple and rapid technique for the extraction of penicillin G and the metabolites of interest (penilloic acid and penillic acid). Two product ion transitions per analyte, along with the ion ratios, were used for data acquisition and analyte confirmation, resulting in a highly selective method. Penicillin G and its metabolites can be detected with a limit of detection (LOD) of 0.1 ng/g when 2 g of citrus is extracted. This method is currently used by the Florida Department of Agriculture and Consumer Services to test actual citrus for the presence of penicillin G and its metabolites from trees that have been affected by the greening disease and treated with penicillin G.

concert with the UGT enzymes to eliminate foreign compounds from the body.[20] Contribution of MRP2 to excretion of glucuronides has been well established.[21−24] However, the role of MRP4 in transporting glucuronides remains elusive despite the fact that estradiol 17-β-D-glucuronide is shown to be a substrate for transport by MRP4.[25]

In our previous study, it was shown that cellular glucuronidation was altered by inhibiting the exporter activity or decreasing exporter expression.[26,27] However, the mechanisms underlying the dependence of UGT metabolism on glucuronide efflux remain elusive. The objective of the present study was to explore the role of futile recycling (or deglucuronidation) in the disposition of two flavonoids (i.e., genistein and apigenin) using UGT1A1-overexpressing HeLa cells (or HeLa1A1 cells). Deglucuronidation refers to the β-glucuronidase (GUSB)-mediated hydrolysis reaction in which glucuronidated metabolites were converted back to the parent compounds. The pharmacokinetics of both aglycone and glucuronide in HeLa1A1 and MRP4 knocked-down cells were determined and compared after administration of the aglycone. A two-compartment pharmacokinetic model incorporating the deglucuronidation process was established and used to describe the data. Our result revealed that the effect of glucuronide efflux on total glucuronidation was through a futile recycling mechanism.

CHEMICALS AND METHODS

Chemicals. The pLVX-mCMV-ZsGreen-PGK-Puro vector was purchased from BioWit Technologies (Shenzhen, China). The anti-GUSB (human β-glucuronidase) and anti-GAPDH antibodies were purchased from Abcam (Cambridge, MA, USA). Uridine diphosphoglucuronic acid (UDPGA), alamethicin, and D-saccharic-1,4-lactone monohydrate were purchased from Sigma-Aldrich (St. Louis, MO, USA). Apigenin and genistein were purchased from Aladdin Reagents (Shanghai, China). Apigenin-7-*O*-glucuronide (or apigenin glucuronide (AG)) and genistein-7-*O*-glucuronide (or genistein glucuronide (GG)) were synthesized in our laboratory using rat liver microsomes as described.[28]

Cell Culture. HeLa1A1 cells and MRP4 knock-down HeLa1A1 cells (referred to as HeLa1A1-MRP4-shRNA cells) were seeded into six-well plates at a density of 4.0×10^5 cells/well and were grown using Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS). On day 2 post seeding, the cells were used for the glucuronide excretion experiments. The procedures for establishment of HeLa1A1 and HeLa1A1-MRP4-shRNA cells have been detailed in our previous publications.[26,27] In HeLa1A1-MRP4-shRNA cells, the protein level of MRP4 was reduced to 35% as compared to HeLa1A1 cells.[27]

Development of GUSB Transfected HeLa Cells. HeLa cells were stably transfected with the cDNA of human GUSB using the lentiviral approach following our published procedures.[26] In brief, the full-length cDNA (1956 bp) of GUSB was PCR-amplified from the commercial pMD18-T plasmid (Sino Biologic Inc., Beijing, China). After purification, GUSB cDNA was ligated into the pLVX-mCMV-ZsGreen-PGK-Puro vector. The recombinant vector was then incorporated in the generation of lentiviral particles that were used to transduce the HeLa cells. Stably transfected cells were obtained by puromycin selection and named HeLa-GUSB cells.

Detection of GUSB mRNA by Reverse Transcription-Polymerase Chain Reaction (RT-PCR). Cells were collected, and total RNA isolation was performed using the TRIzol extraction method. The total RNA was converted to cDNA using the iScript cDNA synthesis kit according to the manufacturer's protocol (Bio-Rad, Hercules, CA, USA). The PCR conditions were as follows: 3 min of denaturation at 95 °C followed by 30 cycles of 20 s at 95 °C, 30 s at 55 °C, and 30 s at 72 °C and a final step of 72 °C for 5 min using Taq DNA polymerase (TransGen Biotech, Beijing, China). The forward primer was 5′-GTCGCGGGAGTGCAAGGAG-3′, and the reverse primer was 5′-TGTTGATGGCGATAGTGATT-3′. After RT-PCR, agarose gel electrophoresis was performed, and DNA bands were visualized under UV light.

Glucuronidation Assay. The aglycones (i.e., genistein and apigenin) were incubated with HeLa1A1 cell lysate to determine the rates of glucuronidation as described in our publications.[29−31] In brief, in addition to the aglycone (substrate), the incubation medium contained the lysate (26.5 μg/mL), $MgCl_2$ (0.88 mM), saccharolactone (4.4 mM), alamethicin (22 μg/mL), and UDPGA (3.5 mM) in 50 mM potassium phosphate (pH 7.4). The reaction was terminated by adding ice-cold acetonitrile (containing the internal standard biochanin A). The samples were vortexed and centrifuged at 18000*g* for 15 min. The supernatant was subjected to UPLC analysis. All experiments were performed in triplicate.

Modeling of Enzyme Kinetics. Kinetic parameters were derived by fitting the substrate inhibition equation (eq 1) to the data of reaction rates versus substrate concentrations.[32,33] Substrate inhibition refers to inhibition of enzyme activity at high substrate concentrations. Parameter estimation was performed using Graphpad Prism (San Diego, CA, USA).

$$V = \frac{V_{max} \times [S]}{K_m + [S]\left(1 + \frac{[S]}{K_{si}}\right)} \quad (1)$$

K_m is the Michaelis constant, V_{max} is the maximal velocity, and K_{si} is the substrate inhibition constant.

Glucuronide Excretion Experiments. The excretion experiment was performed essentially as described.[26,27] In brief, all culture wells were washed twice with 37 °C HBSS (pH 7.4). Then, the cells were incubated at 37 °C with HBSS (2 mL) containing the aglycone (i.e., genistein or apigenin). At each time point (i.e., 0.5, 1, 1.5, and 2 h), a 200 μL aliquot of extracellular medium was sampled and immediately replaced with the same volume of dosing solution. With the addition of 100 μL of acetonitrile (containing the internal standard biochanin A), the concentrations of glucuronides were measured by UPLC. After sampling at the last time point, the medium was rapidly removed by suction. The cells were processed, and intracellular aglycone and glucuronide were measured following our published procedures.[27]

A different set of experiments was performed to obtain the aglycone/glucuronide levels (both extracellular and intracellular) versus time profiles. The cells in culture wells were incubated with the aglycone at a dose of 2.5 nmol. At each time point (i.e., 10, 20, and 30 min and 1, 1.5, and 2 h), the incubation medium was sampled from the culture wells ($n = 3$). The residual medium was rapidly removed by suction. The cells were processed, and intracellular aglycone and glucuronide were measured following our published procedures.[27]

The excretion rate (ER) of intracellular glucuronide was calculated according to eq 2

$$ER = V\frac{dC}{dt} \quad (2)$$

where V is the volume of the incubation medium, C is the cumulative concentration of the glucuronide, and t is the incubation time.

The fraction of dose metabolized (f_{met}), an indicator of the extent of drug glucuronidation, was calculated exactly as described (eq 3).[27]

$$f_{met} = \frac{\text{excreted glucuronide} + \text{intracelluar glucuronide}}{\text{dosed aglycone}} \quad (3)$$

Pharmacokinetic Modeling and Data Fitting. A two-compartment model (Figure 1), consisting of the (incubation/extracellular) medium and the cell compartments, was used to describe the transport and glucuronidation in HeLa1A1 cells. The mass balance equations are shown (eqs 4−7). Transport of the aglycone (A) across the cell membrane occurred with the clearance CL_d, representing passive diffusion. Glucuronide (G) formation followed substrate inhibition kinetics described by V_{max}, K_m, and K_{si}. Excretion of glucuronide followed linear kinetics with the first-order rate constant K_{ef}. Similarly,

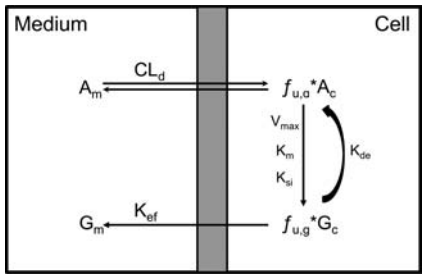

Figure 1. Schematic representation of a two-compartment model that describes the glucuronidation of flavonoids and excretion of their glucuronides in HeLa1A1 cells. Please refer to the text for the definition of each parameter.

conversion of glucuronide back to the aglycone (futile recycling or deglucuronidation) obeyed the linear kinetics (K_{de}). $f_{u,a}$ and $f_{u,g}$ denote the unbound fractions of aglycone and conjugate in the cell compartment, respectively. The model assumed (1) glucuronidation was the only metabolic pathway and (2) transport of aglycone across the membrane was a nonsaturable (linear) process.

Modeling and data fitting were performed using MATLAB (The Mathworks Inc., Natick, MA, USA). In data fitting, the protein binding of glucuronide was assumed to be unity ($f_{u,g} = 1$). Also the K_m and K_{si} were fixed as the corresponding values derived from the in vitro glucuronidation assays.

$$\frac{dA_m}{dt} = -\frac{CL_d}{V_m}A_m + \frac{CL_d}{V_c}f_{u,a}A_c \quad (4)$$

$$\frac{dA_c}{dt} = \frac{CL_d}{V_m}A_m - \frac{CL_d}{V_c}f_{u,a}A_c - \frac{f_{u,a}A_cV_{max}}{V_cK_m + f_{u,a}A_c + \frac{(f_{u,a}A_c)^2}{V_cK_{si}}} + K_{de}f_{u,g}G_c \quad (5)$$

$$\frac{dG_m}{dt} = K_{ef}f_{u,g}G_c \quad (6)$$

$$\frac{dG_c}{dt} = \frac{f_{u,a}A_cV_{max}}{V_cK_m + f_{u,a}A_c + \frac{(f_{u,a}A_c)^2}{V_cK_{si}}} - K_{ef}f_{u,g}G_c - K_{de}f_{u,g}G_c \quad (7)$$

Preparation of Cell Lysate. Cells collected in 50 mM potassium phosphate buffer (pH 7.4) were disrupted by sonication for 15 min in an ice-cold water bath. Cell lysate was obtained by centrifugation (4 °C) at 1000*g* for 5 min. Protein concentration was determined by Bio-Rad protein assay kit using bovine serum albumin as a standard.

Protein Binding Assay. Binding of the aglycones (genistein and apigenin) to cell lysate was measured using the rapid equilibrium dialysis system (RED) (Thermo Scientific, Rockford, IL, USA) as described.[34] In brief, the sample chamber was filled with 400 μL of the aglycone in HBSS (pH 7.4) containing the cell lysate (0.4 mg/mL). The buffer chamber was filled with 600 μL of blank buffer. The filled RED device was incubated at 100 rpm at 37 °C for 4 h (sufficient for reaching equilibrium) using an Eppendorf E24 incubator shaker (Hamburg, Germany). After incubation, a 50 μL aliquot from each chamber was mixed with 200 μL of acetonitrile, vortexed, and centrifuged for 15 min at 18000*g*, and the concentration of aglycone in the supernatant was determined by UPLC. The unbound fraction (fu) was calculated using the equation

$$fu = \frac{[S]_{buffer\ chamber}}{[S]_{sample\ chamber}}$$

where $[S]_{buffer\ chamber}$ and $[S]_{sample\ chamber}$ are the concentrations of aglycone in the respective chambers at the end of the incubation.

The fraction of unbound (fu) values versus genistein concentration was fitted to a Michaelis–Menten-like equation (eq 8) using the Graphpad Prism v5 software

$$fu = \frac{f_{u\text{-}max}[S]}{K_s + [S]} \quad (8)$$

where $f_{u\text{-}max}$ is the maximal fraction unbound and K_s is the concentration of genistein at half $f_{u\text{-}max}$.

Hydrolysis of Glucuronides by GUSB. The HeLa-GUSB or HeLa cell lysate was incubated with glucuronides (GG and AG) to determine the rates of glucuronide hydrolysis as described.[27] The assayed concentration ranges for GG and AG were 2.5–160 and 3.75–120 μM, respectively. The hydrolysis rate of GUBS was derived by subtracting the hydrolysis rate of HeLa cell lysate from that of HeLa-GUSB cell lysate.

Quantification of Aglycones and Glucuronides by UPLC Analysis. Concentrations of aglycones and their glucuronides were determined by using a Waters ACQUITY UPLC system equipped with a BEH column (2.1 × 50 mm, 1.7 μm; Waters). Elution was performed using a gradient of 2.5 mM ammonium acetate in water (mobile phase A) versus acetonitrile (mobile phase B) at a flow rate of 0.45 mL/min. The gradient program was 5% B at 0–0.5 min, 5–40% B at 0.5–1.2 min, 40% B at 1.2–1.5 min, 40–95% B at 1.5–2.8 min, 95% B at 2.8–3.3 min, and 95–5% B at 3.3–4 min. The detection wavelengths were 258 and 340 nm for genistein/GG and apigenin/AG, respectively.

Western Blotting. The cell lysate (40 μg of total protein) was analyzed by SDS-PAGE (8% acrylamide gels), and the proteins were transferred onto PVDF membranes (Millipore, Bedford, MA, USA). Blots were probed with the anti-GUSB antibody and the anti-GAPDH antibody (as internal loading control) followed by horseradish peroxidase-conjugated rabbit anti-goat IgG (Santa Cruz Biotechnology, Santa Cruz, CA, USA). Protein bands were detected by enhanced chemiluminescence (ECL).

Statistical Analysis. Data are expressed as the mean ± SD (standard deviation). Mean differences between treatment and control groups were analyzed by Student's *t* test. The level of significance was set at $p < 0.05$ (*) or $p < 0.01$ (**) or $p < 0.001$ (***).

RESULTS

Binding of Genistein and Apigenin to HeLa1A1 Cell Lysate. Protein binding of genistein to cell lysate was concentration dependent (Figure 2A). The unbound fraction (fu) showed a hyperbolic curve with respect to the genistein concentration (Figure 2A). The data were well characterized by a Michaelis–Menten-like equation (eq 8) with a $f_{u\text{-}max}$ value of 0.84 and a K_s value of 0.39 μM. By contrast, protein binding of apigenin to cell lysate was concentration independent, showing an average fu value of 0.37 (Figure 2B). The results suggested that there was a high possibility that genistein and apigenin bound to intracellular proteins once inside the cells.

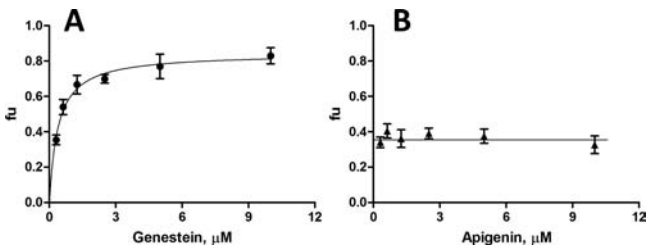

Figure 2. Protein binding of (A) genistein (0.31–10 μM) to HeLa1A1 cell lysate and (B) apigenin (0.31–10 μM) to HeLa1A1 cell lysate. Each data point is the average of three determinations with error bar representing the standard deviation.

J. Agric. Food Chem. 2015, 63, 6001–6008

Glucuronidation of Genistein and Apigenin by HeLa1A1 Cell Lysate. The HeLa1A1 cell lysate was able to generate glucuronides from the aglycones genistein and apigenin. Glucuronidation of the two compounds consistently obeyed substrate inhibition kinetics (V_{max} = 0.10 nmol/min/mg, K_m = 0.54 μM, and K_{si} = 2.0 μM for genistein; V_{max} = 0.19 nmol/min/mg, K_m = 0.56 μM, and K_{si} = 3.7 μM for apigenin) (Figure 3). Compared to genistein, glucuronidation of apigenin showed a higher intrinsic clearance value ($CL_{int} = V_{max}/K_m$). This suggested that apigenin was glucuronidated more efficiently by cell lysate.

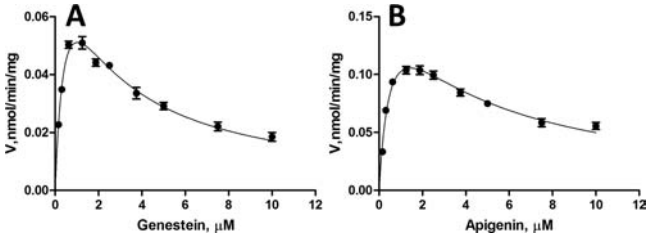

Figure 3. Kinetic profile of (A) glucuronidation derived from incubation of genistein with HeLa1A1 cell lysate and (B) glucuronidation derived from incubation of apigenin with HeLa1A1 cell lysate. Each data point is the average of three determinations with error bar representing the standard deviation.

Excretion of GG and AG in HeLa1A1 Cells. Genistein glucuronide (GG) was efficiently generated and excreted after incubation of the aglycone (loading doses of 1.25−20 nmol) with the cells. The excretion rates of GG ranged from 0.40 to 0.69 nmol/min/mg. Of note, the excretion rate of GG decreased ($p < 0.05$) significantly with an increase in the loading dose of genistein (Figure 4A). In response to dose escalation, the intracellular level of GG also decreased ($p < 0.05$), whereas the intracellular level of genistein increased ($p < 0.01$) (Figure 4B,C).

Likewise, apigenin glucuronide (AG) was efficiently generated and excreted after incubation of the aglycone (loading doses of 1.25−20 nmol) with the cells. The excretion rates ranged from 0.84 to 1.1 nmol/min/mg. Interestingly, the excretion rate of AG was highest at the intermediate dose of 5 nmol (Figure 5A). Dose escalation from 1.25 to 5 nmol caused a substantial increase in the intracellular level of AG ($p < 0.001$) (Figure 5B). However, further increase of the dose from 5 to 20 nmol did not alter the intracellular level of AG (Figure 5B). By contrast, the intracellular level of apigenin markedly rose as the loading dose increased ($p < 0.001$) (Figure 5C).

Expression of GUSB in HeLa, HeLa1A1, and HeLa1A1-MRP4-shRNA Cells. Expression of GUSB in HeLa and the modified cells was determined at both mRNA and protein levels (Figure 6). The mRNA of GUSB was found significantly in three cell lines (Figure 6A). Also, all three cell lines expressed the GUSB proteins at an identical level (Figure 6B). Clearly, transfection of HeLa cells did not alter protein expression of GUSB. The results suggested that GUBS within the cells may be involved in cellular glucuronidation.

Hydrolysis of Glucuronides (GG and AG) by GUSB. The hydrolysis kinetics of GG and AG by the GUSB enzyme were determined and compared. GUSB catalyzed the hydrolysis of two glucuronides at a wide range of concentrations (Figure 7). Determination of the kinetic parameters such K_m and V_{max} was unlikely because the reaction rates were linearly related to the tested substrate concentrations (Figure 7). However, we were able to estimate the intrinsic clearance (CL_{int}) by performing linear regression. The estimated CL_{int} values were 115 and 151 μL/h/mg for GG and AG, respectively (Figure 7). The CL_{int} value for AG was higher than that for GG ($p < 0.05$), suggesting that AG was more efficiently hydrolyzed by GUSB compared to GG.

Disposition of Genistein in HeLa1A1 versus HeLa1A1-MRP4-shRNA Cells. The concentration−time profiles were determined for extracellular genistein and GG and for intracellular genistein and GG in control versus MRP4 knocked-down (shRNA-MRP4) cells at a dose of 2.5 nmol of genistein (Figure 8). Knock-down of MRP4 led to a substantial decrease in excretion of GG (30.2%, $p < 0.01$) (Figure 8A) and in the f_{met} value (29.6%, $p < 0.01$) (Figure 8A,B). A reduction in cellular glucuronidation caused by MRP4 silencing was accompanied by elevations in both extracellular and intracellular levels of the aglycone (genistein) (Figure 8C,D). The two-compartment pharmacokinetic model featuring a futile recycling or deglucuronidation process (K_{de}) was well fitted to the data (Table 1 and Figure 8). The derived K_{ef} values were 20 and 9.1 1/h for control and shRNA-MRP4 cells, respectively (Table 1). A significant decrease (54.5%, $p < 0.01$) in the rate constant for glucuronide efflux was well consistent with decreased expression of MRP4 due to gene silencing.

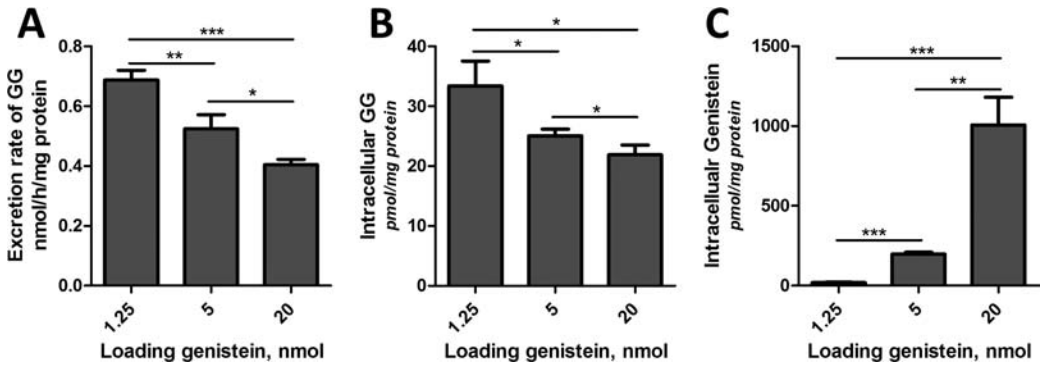

Figure 4. Disposition of genistein in HeLa1A1 cells at different doses: (A) excretion rates of genistein glucuronide (GG) at different loading doses; (B) intracellular amounts of GG at 2 h under different loading doses; (C) intracellular amounts of genistein at 2 h under different loading doses. Each data point is the average of three determinations with error bar representing the standard deviation (n = 3). (*) $p < 0.05$; (**) $p < 0.01$; (***) $p < 0.001$.

DOI: 10.1021/acs.jafc.5b00983
J. Agric. Food Chem. 2015, 63, 6001−6008

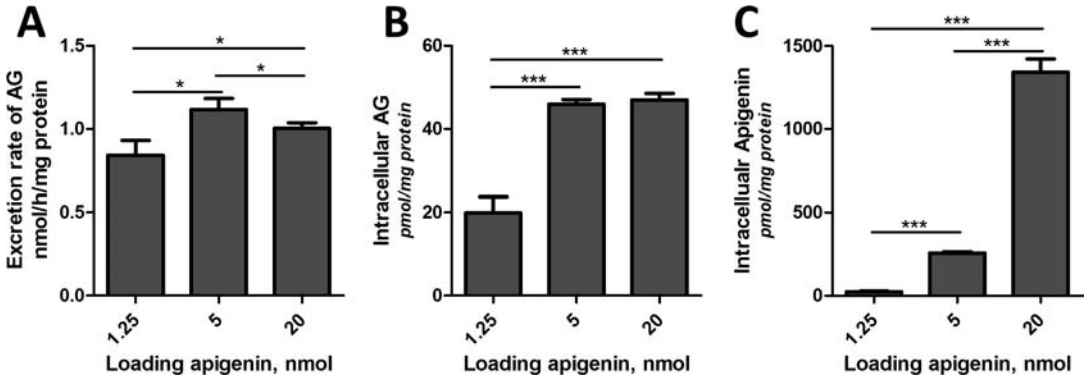

Figure 5. Disposition of apigenin in HeLa1A1 cells at different doses: (A) excretion rates of apigenin glucuronide (AG) at different loading doses; (B) intracellular amounts of AG at 2 h under different loading doses; (C) intracellular amounts of apigenin at 2 h under different loading doses. Each data point is the average of three determinations with error bar representing the standard deviation (n = 3). (*) $p < 0.05$; (***) $p < 0.001$.

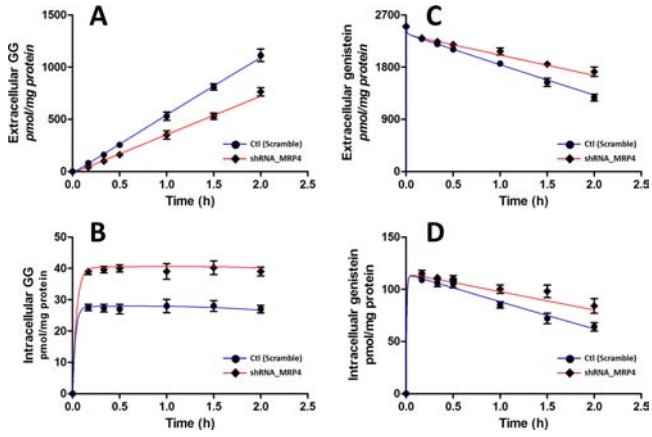

Figure 8. Pharmacokinetic profiles for genistein disposition in HeLa1A1 and shRNA-MRP4 transfected cells at the dose of 2.5 nmol: (A) extracellular GG−time profile; (B) intracellular GG−time profile; (C) extracellular genistein−time profile; (D) intracellular genistein−time profile. Solid lines are predicted data from the pharmacokinetic model depicted in Figure 1.

Disposition of Apigenin in HeLa1A1 versus HeLa1A1-MRP4-shRNA Cells. The concentration−time profiles were determined for extracellular apigenin and AG and for intracellular apigenin and AG in control versus shRNA-MRP4 cells at a dose of 2.5 nmol of apigenin (Figure 9). As observed for genistein, MRP4 silencing resulted in significant decreases in excretion of AG (30.5%, $p < 0.01$) (Figure 9A) and in the f_{met} value (27.7%, $p < 0.01$) (Figure 9A,B). Reduced glucuronidation in the shRNA-MRP4 cells was accompanied by elevations in both extracellular and intracellular levels of the aglycone (apigenin) (Figure 9C,D). Similarly, the data were well described by the two-compartment pharmacokinetic model incorporating the futile recycling process (Table 1 and Figure 9). The derived K_{ef} values were 23 and 12 1/h for control and shRNA-MRP4 cells, respectively (Table 1). A significant reduction (47.8%, $p < 0.01$) in the efflux rate constant was well consistent with a compromised efflux capacity due to decreased expression of MRP4.

DISCUSSION

In this study, the pharmacokinetics of both flavonoid (genistein or apigenin) and generated glucuronide in HeLa1A1 and MRP4 knocked-down cells were determined and compared after administration of the flavonoid. Consistent with our

[a]Assigned values from in vitro metabolism kinetics.

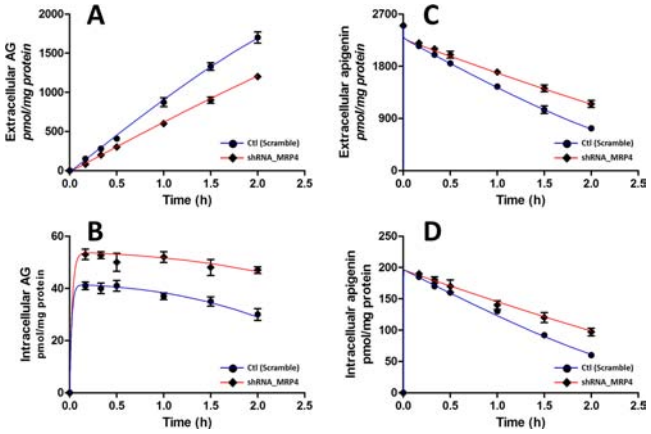

Figure 9. Pharmacokinetic profiles for apigenin disposition in HeLa1A1 and shRNA-MRP4 transfected cells at the dose of 2.5 nmol: (A) extracellular AG−time profile; (B) intracellular AG−time profile; (C) extracellular apigenin−time profile; (D) intracellular apigenin−time profile. Solid lines are predicted data from the pharmacokinetic model depicted in Figure 1.

previous study,[27] knock-down of MRP4 led to significant reductions in glucuronide excretion and total glucuronidation (representing one aspect of glucuronidation−efflux interplay). In addition, the pharmacokinetic data (in the control versus shRNA-MRP4 cells) were well described by a two-compartment model incorporating the futile recycling process (characterized by the rate constant K_{de}) (Figures 8 and 9). Furthermore, we showed that the GUSB enzyme was expressed in HeLa and the modified cells (Figure 6). Also, GUSB enzyme was capable of catalyzing efficient hydrolysis of the flavonoid glucuronides back to their parent compounds. Taken together, our results indicated that the futile recycling (enabled by GUSB-mediated deglucuronidation) was essential for the occurrence of glucuronidation−efflux interplay.

Glucuronidation of the two model flavonoids (i.e., genistein and apigenin) followed substrate inhibition kinetics (Figure 3). It should be noted that glucuronidation of many other flavonoids by UGT1A1 displays substrate inhibition.[32,35,36] The mechanisms for substrate inhibition in glucuronidation reactions remain elusive.[32] Nevertheless, the substrate inhibition may be attributable to an allosteric (inhibitory) binding site within the enzyme and/or formation of a ternary dead-end enzyme complex.[32] The substrate inhibition kinetics can be used to explain why the excretion rates of GG decreased as the loading dose of genistein increased (Figure 4A). The loading dose ranged from 1.25 to 20 nmol, corresponding to an incubation concentration range of 0.625−10 μM. Within the range of 0.625−10 μM, the rate of glucuronidation decreased with an increase in the substrate concentration (Figure 3A). Likewise, a decrease in the rate of AG excretion when loading apigenin was increased from 5 to 20 nmol (i.e., from 2.5 to 10 μM in terms of incubation concentration) can be well explained by the substrate inhibition kinetics wherein the glucuronidation rate at 10 μM was smaller than that at 2.5 μM (Figures 5A and 3B).

In vitro protein binding assays showed that genistein and apigenin bound significantly to cell lysate at a high protein concentration of 0.4 mg/mL, indicating that intracellular binding of the two compounds to proteins may be substantial (Figure 2). This was well consistent with the low values of derived fu values (0.040 and 0.023 for genistein and apigenin, respectively) from pharmacokinetic modeling (Table 1). On the other hand, the derived kinetic parameters for glucuronidation reactions were not corrected using protein binding (Figure 3). This was because binding of the aglycones (log P = 1.7−2.7) to cell lysate (at a low protein concentration of 26.5 μg/mL) in the glucuronidation assays was negligible (fu > 0.99) based on the Hallifax and Houston model. This model has been shown to accurately predict the fu values for the compounds with intermediate lipophilicity.[37]

Flavonoids are a large class of compounds with many types of health benefits such as anticancer and anti-inflammatory effects.[38−40] However, extensive glucuronidation is a significant barrier to the bioavailability of flavonoids, limiting their therapeutic uses. Therefore, a better understanding of the factors that govern glucuronidation of flavonoids would contribute to solving the problem of low bioavailability. The current study and our previous ones showed that reduced glucuronidation of flavonoids was attained by inhibiting exporter activity and decreasing exporter expression.[26,27] Hence, it represented a promising approach to modulate the bioavailability of flavonoids by manipulating the activities of efflux transporters such as MRP4.

Disposition of genistein and apigenin in HeLa1A1 cells (and MRP4 knocked-down cells) was adequately characterized by the two-compartment pharmacokinetic model (Figure 1). The pharmacokinetic model assumed that the aglycones passed the cell membranes freely by passive diffusion. This assumption was valid as passive diffusion was the predominant mechanism for transport of the two flavonoids.[41,42] The model also assumed that efflux of glucuronides followed a linear (nonsaturable) kinetics described by the first-order rate constant K_{ef}. The linear transport kinetics appeared to be valid because saturation of the efflux transporters was not observed for intracellular glucuronides of up to 60 pmol/mg protein (data not shown). In addition, protein binding of glucuronides was not considered (i.e., $f_{u,g}$ = 1) in data fitting; this was reasonable as binding of

J. Agric. Food Chem. 2015, 63, 6001−6008

polar glucuronides to cellular proteins was negligible or nonexistent.

Knock-down of the efflux transporter MRP4 leading to reduced glucuronidation of flavonoids represented one aspect of glucuronidation−efflux interplay, as also noted previously.[27] In the current study, we provided the first experimental evidence that the futile recycling (deglucuronidation) enabled by GUSB was necessary for this interplay of glucuronidation with glucuronide efflux to occur. Futile recycling appeared to bridge the two processes (i.e., glucuronide formation and excretion), making the interplay of glucuronidation−efflux feasible.[19] Impaired glucuronide efflux (due to decreased transporter expression) led to an elevation in the intracellular level of glucuronide (Figures 8 and 9). A rise in intracellular glucuronide was associated with an increase in the rate of futile recycling according to the first-order kinetics (the conversion rate = K_{de} × intracellular glucuronide) (Figure 1). As a consequence, total formation of glucuronide was altered (i.e., reduced) in the cells. On the contrary, in the absence of futile recycling, glucuronide formation was independent of its downstream process excretion; thus, impact of glucuronide excretion on its formation was impossible.[19]

Use of HeLa1A1 cells (and transporter knock-down cell lines) for glucuronide transport studies was more advantageous compared to the membrane vesicles or the monolayer cells (e.g., MDCK) overexpressing a single transporter. This was because the HeLa1A1 cells expressing an array of transporters were a closer mimic of the in vivo situations. In addition, synthesis of glucuronide (lacking in commercial availability) was avoided as glucuronide can be generated from dosed aglycone by the cells. Moreover, the HeLa1A1 cells were free of concerns raised in identification studies of glucuronide transporters using membrane vesicle or monolayer cells.[22] First, drug glucuronides poorly cross cellular membranes by passive diffusion. Therefore, use of polarized monolayers (expressing a transporter) with administration of glucuronide can be problematic. This was because the glucuronide will not enter the cells.[22] Second, studies with inside-out vesicles are time-consuming and challenging.[22]

In summary, glucuronidation of two flavonoids (i.e., genistein and apigenin) and excretion of their glucuronides were investigated using HeLa1A1 cells. Glucuronidation of these two flavonoids by cell lysate consistently followed substrate inhibition kinetics. GG or AG was efficiently generated and excreted after incubation of the aglycone with the cells. Knock-down of MRP4 resulted in a substantial reduction in the excretion of GG and AG. A significant reduction was also observed for cellular glucuronidation of genistein and apigenin. The alterations in glucuronide excretion and cellular glucuronidation were well characterized by a two-compartment pharmacokinetic model incorporating the process of futile recycling. This study provided the first experimental evidence that the effect of glucuronide efflux on total glucuronidation was through a futile recycling mechanism.

antagonistic mechanism, can satisfy long-term concerns over food safety and the environment in the mushroom industry.

The objectives of this study were to search for a new biological control agent against mushroom red bread mold disease from the *A. bisporus* mushroom cultivation substrate obtained from a commercial mushroom operation and to isolate and investigate the biological properties of the antimicrobial lipopeptide from the antagonistic *Bacillus* sp. strain.

MATERIALS AND METHODS

Fungi. The pathogenic fungus strain M21 (*N. sitophila*) was isolated from a contaminated *A. bisporus* compost-based cultivation substrate in a commercial *Agricus* mushroom factory in Shandong, China. Primers ITS1 (5′- TCCGTAGGTGAACCTGCGC-3′) and ITS4 (5′- TCCTCCGCTTATTGATATGC-3′) were used to amplify the internal transcribed space regions (ITS) of 18S rDNA sequences of M21.[15] PCR sequences were aligned and compared with those available in the GenBank database using the BLAST program.[16] Then the homology of the sequence was determined. A phylogenetic tree was constructed according to the neighbor-joining method using MEGA 4.0 based on the 18S rDNA sequence. Nucleotide sequence data for the pathogenic fungus have been submitted to GenBank database under accession number KM588213.

The fungi *Trichoderma harzianum* (ACCC30371), *Fusarium solani* (ACCC36223), *F. graminearum* (ACCC37686), *Botrytis cinerea* (ACCC36028), and *F. incarnatum* (CFCC 84580) were supplied by the Agricultural Culture Collection of China and the China Forestry Culture Collection Center.

Bacteria. A total of 600 colonies of bacteria were separated from *A. bisporus* mushroom composts by the serial dilution method.[17] Bacteria thus isolated were tested for their antifungal activity against the pathogenic fungus *N. sitophila* M21.

The bacterium B154, one of the antifungal strains, was characterized using the API 50 CHB system (BioMerieux, Marcy l'Etoile, France). Microscopic observation and biochemical features were tested as described previously.[18,19] To confirm biochemical identification, a partial sequence analysis of the 16S rDNA was performed. PCR amplification of the 16S rDNA gene of strain B154 with universal forward (5′-AGAGTTTGATCCTGGCTCAG-3′) and reverse (5′-GGCTACCTTGTTACGACTT-3′) primers was carried out.[20] The 16S sequence for B154 was deposited in GenBank (KM588212). A neighbor-joining tree was constructed based on the 16S rDNA sequences of bacterial strains. A *gyrA* fragment corresponding to *Bacillus subtilis gyrA* positions 42 to 1066 was PCR amplified by using primers *gyrA*-forward (5′-CAGTCAGGAAATGCGTACGTCCTT-3′) and *gyrA*-reverse (5′-CAAGGTAATGCTCCAGGCATTGCT-3′).[21] The *gyrA* sequence for B154 was deposited in GenBank (KR296983).

In Vitro Antagonism Experiments. The ability of the B154 strain to inhibit the growth of various fungal pathogens was tested in Petri dishes containing a potato dextrose agar (PDA) medium. The mycelial plugs of *N. sitophila*, *T. harzianum*, *F. incarnatum*, *F. solani*, *F. graminearum*, and *B. cinerea* were cultivated in the center of the plates at 28 °C, and the bacteria were inoculated on the edges. The slow growth fungi were inoculated on the plate 24−48 h prior to the bacteria. The inhibition of fungal growth was evaluated by the percentage of reduction of mycelium expansion compared to control plates without bacteria. The mycelial growth inhibition (MGI) percentage was calculated according to the equation MGI = $(A_0 - A_1)/A_0 \times 100$, where A_0 is the area of mycelium on control plates and A_1 is the area of mycelium on plates inoculated with B154.[22] The antagonism assay was conducted three times, and all treatments in each assay contained three replicates.

Selection of the Best Medium for Production of Antifungal Activity. To select the best culture medium for optimal production of antifungal activity, several broth media were tested: tryptic soya broth (TSB), Luria−Bertani broth (LB), nutrient broth (NB), and tryptic yeast (TY).[23] Incubation was performed at 30 °C with shaking at 150 rpm/min for 24 h. Cell growth was monitored by optical density measurement at 600 nm, and any secreted antifungal activity found in the culture supernatant was described by the diameter of the clear zone.

Fermentation and Kinetic Production of Antifungal Compounds. Bacterial fermentation was carried out in a gyratory shaker (150 rpm/min) at 30 °C. Antifungal activity was detected after incubating the producer strain in TSB medium for 56 h. We collected 10 mL of the culture at an interval of 4 h for the determination of cell growth, and the anti-*N. sitophila* activity in the supernatant was obtained by measuring the diameter of the clear zone. The pH of the medium was monitored regularly throughout the culture period.[24]

Antifungal Activity of the Compound. The activity of the antifungal compound produced by B154 was measured by the disc diffusion assay on all purification extracts and by using high-performance liquid chromatography (HPLC) fractions to determine where the antifungal compounds were eluted.[25] Arbitrary units (AU) of antifungal activity were calculated by the reciprocal of the highest dilution showing inhibition per milliliter of antifungal compound fraction. The antagonism assay was conducted three times, and all treatments in each assay contained three replicates.

Isolation and Purification of Antifungal Compound by Ion Exchange Chromatography. The antifungal compound was recovered by 20% ammonium sulfate precipitation of the B154 culture supernatant.[12] The precipitate was collected and dialyzed by distilled water in 3.5 kDa dialysis tubing. The resulting solution was concentrated by lyophilization, and the solid was dissolved in sterile milli-Q water to obtain the crude bioactive substance (1.0 mg/mL).

The crude extract (10 mL) was loaded onto a DEAE-Sephadex A50 (1.5 cm × 15 cm i.d.) column (GE Healthcare, Uppsala, Sweden) previously equilibrated with Tris-HCl buffer (25 mM, pH 8.0). A gradient of 0−1 M NaCl in buffer was run through the column at 0.5 mL/min.[26] The eluent was monitored at 280 nm using an HD5 spectrophotometer (Huxi Analysis, Shanghai, China), and fractions were collected every 5 min. All samples were assayed for antifungal activity, and the antifungal fractions were collected and concentrated by ultrafiltration with an Ultra-15 centrifugal filter concentrator (Millipore, Darmstadt, Germany).

Ultraviolet Spectrum. The ultraviolet absorption spectrum of the antibiotic collected from the ion exchange column was measured using a UV-1800 recording spectrophotometer (Shimadzu, Kyoto, Japan) from 200 to 600 nm.[27]

Detection of Antifungal Activity in Tricine-SDS-PAGE Gel. Tricine sodium dodecyl sulfate-polyacrylamide gel electrophoresis (Tricine-SDS-PAGE) was performed with active fractions from each purification step using a Mini Protean tetra cell vertical gel electrophoresis unit (Bio-Rad, Hercules, CA).[25] TSB medium, culture supernatant, dialyzed 20% ammonium sulfate fraction, and the antifungal fraction that had been purified by ion exchange chromatography were loaded onto the gel; ultra low molecular weight protein markers (Sigma-Aldrich, St Louis, MO) were used for size reference.

After electrophoresis, three duplicate gels were fixed in 500 mL of 50% (v/v) methanol/10% (v/v) acetic acid for 30 min and stained with 0.025% Coomassie brilliant blue G-250 (Bio-Rad, Hercules, CA) in 10% acetic acid/45% ethanol.

pH and Heat Stability. The concentrated antifungal fractions collected from ion exchange column were filter-sterilized using 0.22 μm filters (Millipore, Darmstadt, Germany) and lyophilized. Each aliquot was dissolved in 200 μL of buffer within the range of pH 2−12 adjusted with diluted HCl or NaOH. After incubation for 2 h at 25 °C and neutralization to pH 7, residual activity against *N. sitophila* was tested.

We evaluated thermal stability after incubation of antifungal fractions at different temperatures for 30 min or after autoclaving at 121 °C for 20 min. After the samples were cooled at room temperature, we quantitated residual inhibitory antifungal activity.

Effect of Proteolytic Enzymes. The effect of the proteolytic enzymes proteinase K, pepsin, trypsin, and papain on antifungal activity was investigated. Enzymes were dissolved in Tris-HCl buffer

J. Agric. Food Chem. 2015, 63, 6009−6018

(50 mM, pH 7.8) and were added to the antifungal fraction at a mass ratio of 1:10 and 1:5. After incubation at 37 °C for 2 h, solutions were incubated at 90 °C for 5 min and cooled at room temperature. The residual antifungal activity in the supernatant was tested. The untreated antifungal fraction and the enzymes alone in buffer were used as controls.

Conidial Germination Inhibition Assays. We examined the inhibitory effect of the purified antifungal fractions on conidial spore germination of *N. sitophila*.[28,29] The antifungal fractions were serially diluted with PDA to a final concentration of 30, 20, or 10 μg/mL. Sterile phosphate buffer (20 mM, pH 6.8) was used as a control. A 10 mL sample of the mixture was added into Petri dishes, and the *N. sitophila* spore suspension at a concentration of 10^5 cfu/mL was prepared and inoculated by spreading in the Petri dishes. After 6 h of incubation at 25 °C, the plates were observed by optical microscopy. When the length of the germ tube was longer than the radius of the spore, the spore was rated as germinated. At least 200 spores were counted on each plate. Each treatment was conducted in triplicate, and the experiments were repeated twice. The relative germination inhibition (RI) of the treatment compared to the control was calculated by percentage, using the following formula:

$$RI = (N_0 - N) \times 100/N_0$$

where RI is the relative inhibition, N_0 the number of germinated spores on the control plates, and N the number of germinated spores on the treatment plates.

Slices of pathogenic fungal spores were dyed by lactophenol cotton blue and observed using a B203 LED microscope (Optec instrument, Chongqing, China).

SEM Analyses. The effect of antifungal extracts from B154 on *N. sitophila* hyphae and spores was examined by scanning electron microscopy (SEM).[10] The antifungal fractions were diluted with potato dextrose broth (PDB) to a final concentration of 30 μg/mL. Spore suspension (10^5 cfu/mL) and the hyphae were added to the PDB medium. After incubation at 28 °C for 24 h in a shaker at 50 rpm/min, the spore and hyphae were harvested for SEM. Samples were sputter-coated with gold palladium in an IB-3 nanotech sputter-coating apparatus (EIKO, Osaka, Japan) and then examined using an S-3400N SEM (Hitachi, Tokyo, Japan).

Antifungal Activity of Bacteria B154 on *A. bisporus* Mushrooms. We studied the in vivo effect of the antifungal bacterium B154 against the pathogen fungus *N. sitophila* in the mushroom beds and recorded the associated yields of *A. bisporus*. The experimental cultivation trials of *A. bisporus* were conducted at the JiuFa Mushroom Test Demonstration Factory in cooperation with China Agricultural University. Suspensions of the fungus *N. sitophila* (10^3 cfu/mL) were mixed with the spawned compost (1 L suspension/m^2 of compost) on mushroom beds. One liter each of B154 fermentation broth (fermented for 24, 48, or 72 h) was mixed thoroughly with compost to inhibit the fungal pathogen. For comparison, there were two controls. In one control, only the pathogen fungus was mixed with compost (negative control); in the other (positive control), neither the pathogen nor the antagonistic bacteria B154 was used. Closed mushrooms were harvested, counted, and weighed daily. At the end of the third flush, yields were determined and expressed as kilograms per square meter. Each treatment was replicated three times, and these experiments were repeated twice.

Purification of Antifungal Active Compounds. The antifungal compounds collected through the DEAE-Sephadex A50 column from *B. subtilis* B154 were purified by a 1200 series HPLC system (Agilent Technologies, Wilmington, DE) using a ODS-A reverse phase (RP) C18 column, 4.6 mm × 250 mm i.d., 120 A (YMC, Allentown, PA) with a linear gradient elution of deionized water and acetonitrile.[30] Mobile phase: 0.05% trifluoroacetic acid water solution (A), acetonitrile (B). Flow rate: 0.8 mL/min. Gradient program: 30% B in 0−5 min; 30−45% B in 5−10 min; 45−80% B in 10−60 min; 80−100% B in 60−80 min; 100% B in 80−90 min. This step was repeated several times, and peaks with the same retention time were collected for determination of activity. The final active collection was dried, weighed, and used for studies of chemical characterization.

Analysis of Antifungal Conpound by MALDI-TOF MS Analysis. The HPLC-purified compound was analyzed on a 4800 Plus matrix-associated laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) system (Applied Biosystems, Foster, CA).[31,32] For MALDI-TOF-MS analysis, HPLC fractions extracted from *B. subtilis* B154 were mixed with α-cyano-4-hydroxycinnamic acid (α-CHCA) saturated in 50% (v/v) acetonitrile containing 0.1% trifluoroacetic acid in equal amounts, applied to the MALDI sample plate, and left to air-dry.

ESI-MS/MS Analysis. Electrospray ionization tandem mass spectrometry (ESI-MS/MS) analysis of antifungal compound was performed on a SYNAPT G2-Si quadrupole time-of-flight (Q-TOF) mass spectrometry system (Waters MS Technologies, Manchester, UK).[31,33] MS survey scans in a mass range of m/z 100−2000 and of 30 s duration were run. The electrospray source was operated at a spray cone voltage of 80 V, a capillary voltage of 3 kV, and a source temperature of 100 °C. For the ESI experiment, the nanoflow gas pressure was set at the 0.5 bar, and the purge gas flow was set at 10 mL/min. Helium was used as the collision gas.

Statistical Analysis. All data were presented as the mean ± standard deviation (SD). One-way analysis of variance (ANOVA) and Duncan's multiple range tests were used to determine significant differences ($p < 0.05$) between the means using the statistical software SPSS 18.0 (IBM Corp., Armonk, NY).

RESULTS AND DISCUSSION

Identification of Pathogenic Fungus M21 and Antifungal Bacterium B154. The BLAST results based on the ITS sequence showed M21 had the highest similarity (100%) with *Neurospora sitophila* (GU192459.1) The phylogenetic tree constructed based on the ITS sequence indicated M21 closely clustered with *N. sitophila* as well. Mycelium of M21 was white and villiform (Figure 1A). After growing on PDA medium for 3

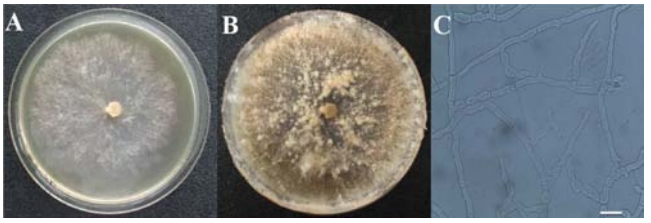

Figure 1. Colonial morphology (A), spore (B), and hyphal characteristics (C) of *N. sitophila* M21. Mycelia of *N. sitophila* M21 were amplified 40 times. Scale bar is 20 μm.

d, several orange spores formed (Figure 1B). M21 mycelium amplified 40 times showed that the diameter of its hypha was about 10−12 μm, and many hypha branches formed (Figure 1C). The combination of colony traits, mycelium morphological traits, and molecular characteristics allowed us to identify pathogenic fungus M21 as *N. sitophila*. The red bread mold (*N. sitophila*) is one of the major diseases threatening mushroom production.[3,34] *N. sitophila* became epidemic rapidly, when the room temperature and humidity were relatively high, leading to inhibition of primordial formation and reduction in yield.

Strain B154 isolated from the *A. bisporus* mushroom compost had the highest activity against the strain M21 (Figure 2A). Therefore, strain B154 was used in the subsequent investigation. The colonies of bacterial strain B154 were white, and its morphology was irregular (Figure 2B). A preliminary identification of this strain through phenotypical and

J. Agric. Food Chem. 2015, 63, 6009−6018

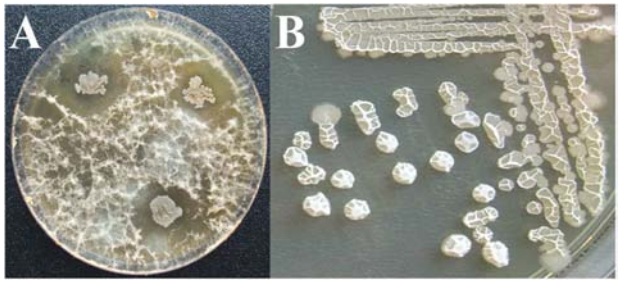

Figure 2. Growth inhibition of *N. sitophila* by the bacterial strain B154 (A) and the morphology of the colonies of B154 (B).

biochemical characteristics showed that this isolate belonged to the genus *Bacillus*. It is a Gram-positive bacillus, motile spore-forming organism and is catalase- and oxidase-positive. The tests of hydrogen sulfide, indole production, and Voges–Proskauer were positive. The use of an API 50 CHB kit with the APILAB Plus software indicated 99.6% identity with *B. subtilis*.

The BLAST results indicated that strain B154 had 100% similarity with *Bacillus subtilis* (NCDO1769) according to the sequence of the 16S rDNA gene. Phylogenetic trees constructed based on the 16S rDNA gene also indicated that B154 closely clustered with *B. subtilis*.

Because strain B154 identified as *B. subtilis* group on the basis of 16S rDNA sequence analysis is not satisfactory, we applied another method to obtain more reliable species identification. We performed *gyrA* sequencing preliminarily identified as *B. subtilis* on the basis of 16S rDNA sequencing. Cluster analysis of the *gyrA* sequence of B154 with those from the study of Chun and Bae[35] showed that strain B154 was identified as *B. subtilis* subsp. *subtilis*.

Antifungal Activity Spectrum. When tested in vitro against two fungal species of mushroom pathogens (*N. sitophila* and *T. harzianum*) and four phytopathogens (*F. incarnatum*, *F. solani*, *F. graminearum*, and *B. cinerea*), *B. subtilis* strain B154 could inhibit the mycelia growth of all of the fungi (Table 1).

Table 1. Antagonism Developed by *B. subtilis* Strain B154 on PDA Plates Against Various Fungal Pathogens

fungal pathogen	MGI (%)[a]
Neurospora sitophila	7.5 ± 0.4
Trichoderma harzianum	26.7 ± 0.6
Fusarium incarnatum	4.3 ± 0.2
Fusarium solani	7.1 ± 0.5
Fusarium graminearum	7.6 ± 0.3
Botrytis cinerea	38.3 ± 0.4

[a]MGI: relative mycelia growth inhibition percentage per bacterial colony. Data are expressed as the mean ± SD, $n = 9$.

The MGI of B154 on *N. sitophila* was 7.5%, and the MGI on *T. harzianum* was 26.7%. *B. subtilis* had inhibitory ability against various plant fungal pathogens, such as *Fusarium oxysporum*, *Exserohilum turcicum*,[12] and *Alternaria alternate*.[30] Our study indicated that strain B154 isolated from *A. bisporus* mushroom compost provided a broad spectrum of antifungal activities against both plant and mushroom pathogenic fungi; thus, it would be a potential effective alternative to chemical fungicides, especially in the mushroom industry.

Kinetic Production of the Antifungal Activity in the Optimized Medium. The antagonism potential of B154 could play a major role in biocontrol because of the production of antifungal compounds. Variation in the composition of the culture medium was shown previously to affect the production of antimicrobial activity.[23,36] The production of antifungal activity by strain B154 was tested in various media (Figure 3A).

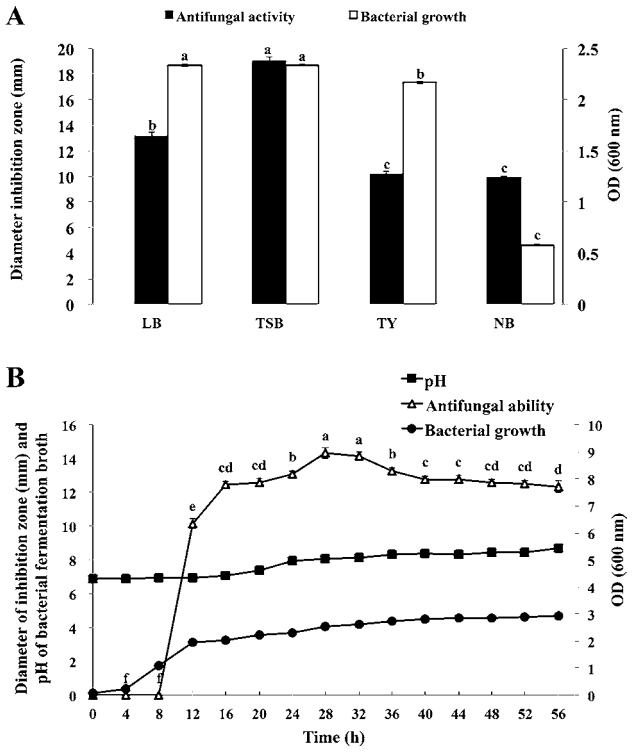

Figure 3. Effect of various growth media (A) and the kinetic study (B) of biomass and antifungal activity produced by *Bacillus* strain B154. Bacterial growth was evaluated by optical density measurement at 600 nm. Antifungal activity against *N. sitophila* was expressed as the diameter of the inhibition zone (in millimeters). Columns in the graph marked by different lower case letters for each mean are significantly different at $p < 0.05$ using Duncan's multiple-range tests. Data are expressed as mean ± SD of triplicate assays.

The TSB medium allowed maximum biomass accumulation and the highest antifungal activity against *N. sitophila*. The activity obtained by culturing in LB medium dropped significantly compared to TSB medium ($p < 0.05$), while the biomass in these two kinds of media was the same.

Synthesis of antimicrobial compounds by *Bacillus* species generally starts at the end of the exponential phase and reaches its maximum level during the stationary phase.[37,38] During the growth period of B154 in TSB medium, antifungal activity against *N. sitophila* (diameter of inhibition zone was 10.17 mm) was detected during the exponential growth phase (12 h after inoculation), and maximum antifungal activity (inhibition zone was 14.33 mm) was attained during the stationary phase (28 h after inoculation) (Figure 3B). This meant that the bacterium could produce high levels of the bioactive substance within a short period. Medium pH was monitored throughout the experiment and increased from 7 to 8.7 at 56 h.

Ultraviolet Spectrum and Tricine-SDS-PAGE Gel Detection of Antifungal Compound Purified by Ion Exchange Chromatography. Ion exchange chromatography of B154 culture extract on a DEAE-Sephadex A50 column contained one unadsorbed fraction and one adsorbed fraction

DOI: 10.1021/acs.jafc.5b02218
J. Agric. Food Chem. 2015, 63, 6009–6018

(**1** and **2**). Of these fractions, only fraction **2** showed strong antifungal activity (Figure 4A). The antibiotic was eluted from the DEAE-Sephadex matrix in 0.55−0.6 M NaCl.

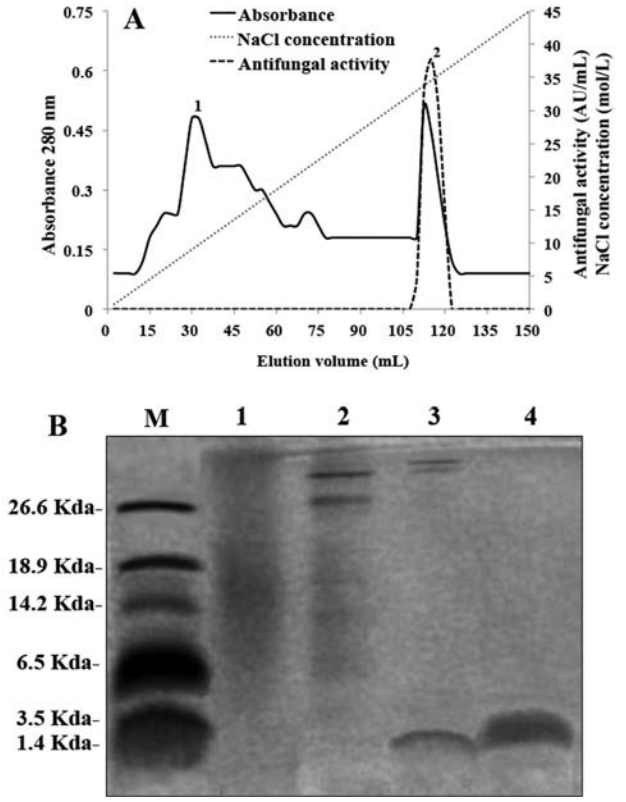

Figure 4. Ion exchange chromatography on a DEAE-Sephadex A50 column (A) and tricine-SDS-PAGE (B) of peptide antibiotic purification fraction. Slanting line across the chromatography indicates linear NaCl concentration gradient (0−0.75 M) employed to elute the adsorbed fractions **1** and **2**. Data are expressed as the mean, $n = 9$. Tricine-SDS-PAGE: (lane M) polypeptide SDS-PAGE standards; (lane 1) TSB medium; (lane 2) culture supernatant; (lane 3) dialyzed 20% ammonium sulfate precipitate; (lane 4) antifungal peptide purified by ion exchange chromatography.

Purification of the biologically active component from the culture medium is summarized in Table 2. The initial 20% ammonium sulfate precipitation yielded 47.2% of the original activity, and 25.5% of the initial activity was recovered by ion exchange chromatography.

Table 2. Yields of Chromatographic Fractions with Antifungal Activity Obtained at Different Stages of Purification from Culture Supernatant of *B. subtilis* B154

	volume (mL)	total protein (mg)	total activity[a] (AU)	activity recovery[b] (%)
culture supernatant	200.0	3712.6 ± 19.7	7522 ± 23.1	−
$(NH_4)_2SO_4$ precipitate	25.0	55.6 ± 2.9	3552.1 ± 53.2	47.2
ion exchange peak	12.5	12.7 ± 0.1	1917.7 ± 38.6	25.5

[a]Activity is expressed as activity units (AU) against *N. sitophila*. [b]Activity recovery indicates the percentage of initial activity. Data are expressed as the mean ± SD, $n = 9$.

The absorbance spectrum for the antibiotic measured in milli-Q water showed absorbance maxima at 236 and 275 nm, and there was no appreciable absorbance above 300 nm. *B. subtilis* is the producer of cyclic lipopeptides, for example, molecules of seven amino acids with a β-fatty acid.[26,39] The ultraviolet spectrum of the antibiotic suggested that our strain might be a producer of cyclic lipopeptides with antifungal activity. The absorbance maximum between 220 and 240 nm was due to the presence of tyrosine.[27]

The active fraction that was purified by ion exchange column, the TSB medium, the culture supernatant, and 20% ammonium sulfate precipitate were loaded onto a tricine gel containing 16.5% separating gel. The active bands were visualized with Coomassie brilliant blue G-250 solution (Figure 4B). Compared to the polypeptide marker, the molecular mass of purified peptide (lane 4) was estimated to be approximately 1.4 kDa. Tricine-SDS-PAGE confirmed the purity of the antibiotic preparation. The culture supernatant (lane 2) produced many bands of stained contaminated material. Evidently, almost all of this contaminated material was removed by the purification protocol (lane 4). Although ion exchange extraction actually decreased antibiotic activity relative to the previous step (ammonium sulfate precipitate) (Table 2), the ion exchange protocol was very effective at eliminating colored material contaminating the sample, and it separated the antibiotic peak from other peaks seen in the chromatogram.

pH, Heat Stability, and Effect of Proteolytic Enzymes on Antifungal Peptide. The antifungal activity of the purified peptide from the ion exchange column was conserved until 90 °C. In addition, it was stable within a wide range of pH (4−10). The antifungal activity was severely reduced at pH 2−3 and at a pH higher than 10 ($p < 0.5$). This heat-stable property was also observed in other antimicrobial metabolites produced by *Bacillus* species.[40,41] Temperature and pH stability of the antifungal peptide can provide greater application for the food and agrochemical industries.

The treatment of the antifungal peptide with different proteases, such as proteinase K, pepsin, papain, and trypsin, in enzyme/peptide mass ratios of 1:10 and 1:5 (w/w) for 2 h at 37 °C, did not affect its antifungal activity. The resistance of the antifungal peptide to the proteases might be attributed to the cyclic structure of the peptide, which inhibits the enzymatic action of proteases on peptides.[25]

Effect of *B. subtilis* B154 Antifungal Compound upon *N. sitophila* Conidia and Hyphae. We evaluated the ability of the B154 antibiotic compound purified by ion exchange column on arresting the germination of *N. sitophila* conidia by an in vitro bioassay (Figure 5). The RI rate for conidial germination increased with an increase in the antibiotic peptide concentration (Figure 5A). At 10 μg/mL, *B. subtilis* B154 antibiotic peptide reduced the number of germinated spores by 7.7%, at 20 μg/mL by 28.4%, and at 30 μg/mL by 83.4%. The subsequent development of branched mycelia in untreated (Figure 5B,a) or antifungal peptide treated (Figure 5B,b−d) discs observed by light microscopy showed that the development of *N. sitophila* conidia was arrested at the stage of the germ tube. Conidial germination represents the first step in triggering an asexual life cycle of aerial pathogenic fungi and the spread of the disease.[29] Therefore, the use of micro-organisms that produce antifungal compounds that inhibit conidial germination is a potential means of biocontrol for fungal disease.[42]

DOI: 10.1021/acs.jafc.5b02218
J. Agric. Food Chem. 2015, 63, 6009−6018

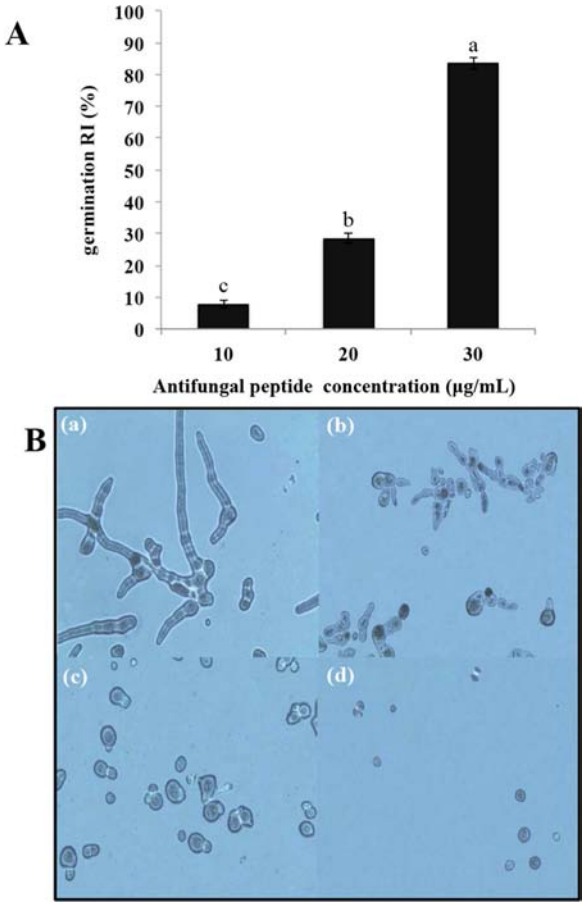

Figure 5. Influence of *B. subtilis* B154 antibiotic peptide on *N. sitophila* conidial germination. Columns in the graph marked by different lower case letters for each mean are significantly different at $p < 0.05$ using Duncan's multiple-range tests. Data are expressed as mean ± SD (n = 6). (B, a) Germination of control conidial spores; (B, b) spores in the presence of 10 μg/mL antifungal peptide; (B, c) spores treated with 20 μg/mL antifungal peptide; (B, d) the same effect produced by 30 μg/mL antifungal peptide extract from strain B154.

The surface appearance of hyphae and spores observed by SEM showed that the control hyphae and conidia of *N. sitophila* grew normally and were smooth with no breakage (Figure 6A,C), while the structures of hyphae and spores treated with B154 antifungal peptide were damaged and irregular (Figure 6B,D). When treated with antifungal peptide, the hyphae were deformed, distorted, wilted on the surface, and cavitated, and the conidia displayed a collapsed morphology characterized by distortion, shrinking, and loss of turgor. These findings support the hypothesis that the secretion of antifungal compounds, such as lipopeptides, is the primary mechanism contributing to the deleterious effect of the *B. subtilis* strain against conidial germination and hyphae growth of fungi.[43]

Antifungal Activity of Bacteria B154 on *A. bisporus* Mushrooms. B154, which was effective against the particular pathogen *N. sitophila* M21 in vitro, was selected to test for *A. bisporus* mushroom yield. B154 notably enhanced the yield of *A. bisporus* ($p < 0.05$) compared to a negative control (Figure 7). Among the three fermentation times (24, 48, and 72 h) during which the bacteria inoculum was tested in the *N. sitophila*-contaminated mushroom beds, 72 h was shown to be best in terms of mushroom yield.

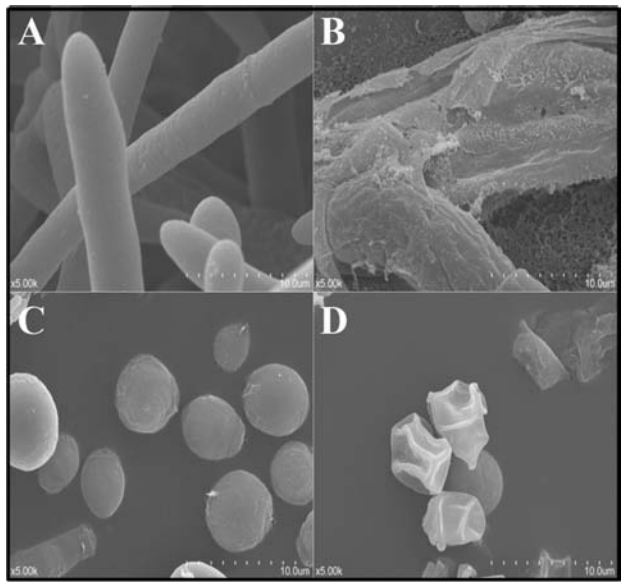

Figure 6. SEM of *N. sitophila* spores and hyphae after the antifungal peptide treatment: A, the control hyphae; B, hyphae treated with antifungal peptide; C, control spores; D, spores treated with antifungal peptide. Bars represent 10 μm.

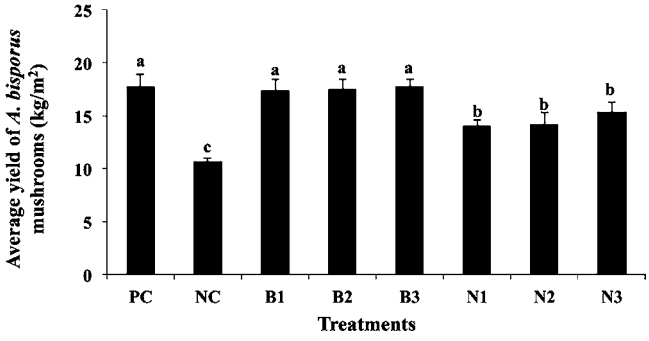

Figure 7. Results of *B. subtilis* B154 inhibition of *N. sitophila* in the compost of *A. bisporus* mushrooms. PC, positive control; NC, negative control; B1, inoculated with bacteria inoculum at 24 h; B2, bacteria inoculum at 48 h; B3, bacteria inoculum at 72 h; N1, inoculated with both fungal and bacteria inoculum at 24 h; N2, fungal and bacteria inoculum at 48 h; N3, fungal and bacteria inoculum at 72 h. Columns marked by different lower case letters for each mean are significantly different at $p < 0.05$ using Duncan's multiple-range tests. Data are expressed as mean ± SD (n = 6).

Few reports on controlling the phyto-pathogens using antibiotics produced by *B. subtilis* in vivo appear in the literature. The lipopeptide bacillomycin D derived from *B. subtilis* could inhibit the growth of *Aspergillus flavus* on corn.[10] However, antibiotics have not yet been commercialized extensively because of low production yields and high purification costs.[44] We inoculated the fermentation broth of *B. subtilis* B154 directly in the *A. bisporus* mushroom cultivation substrate to investigate the biocontrol ability of B154 on fungal pathogen *N. sitophila* in vivo. Our results indicated that *B. subtilis* B154 isolated from the *A. bisporus* mushroom compost might be a potential safety control agent against red bread mold, as it could colonize and proliferate in the mushroom cultivation substrates to compete with the fungal pathogens.

Isolation and Mass Spectrometry Analysis of the Active Compound. Using reverse phase HPLC, six pure

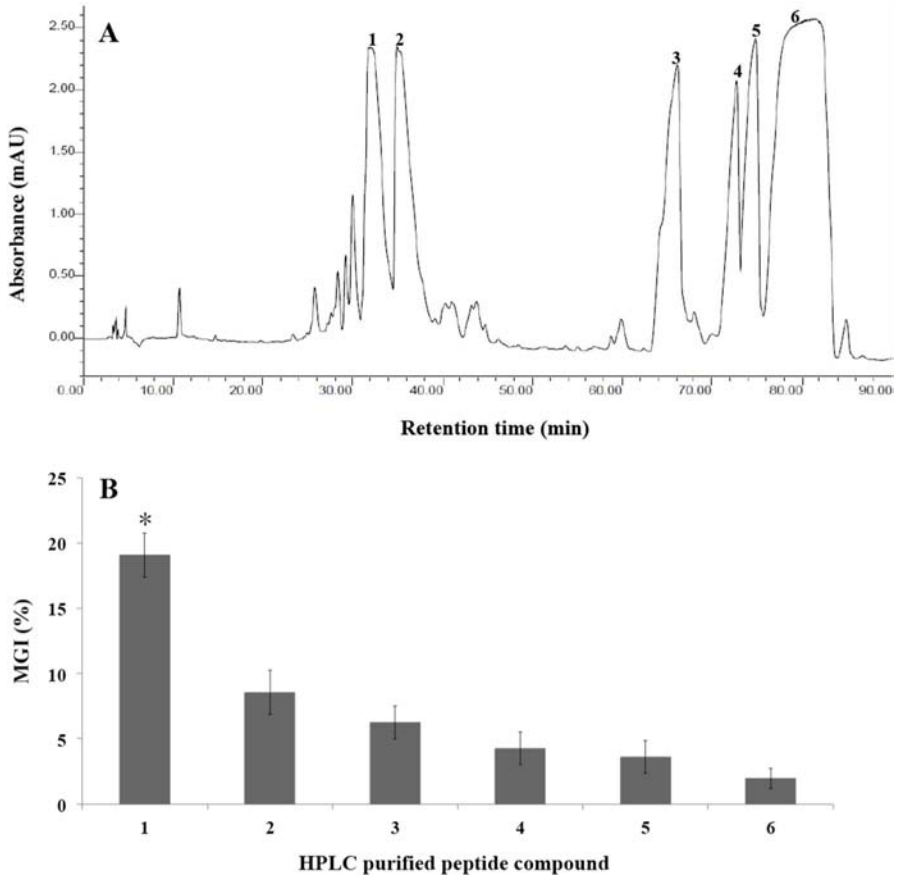

Figure 8. Reverse phase HPLC chromatogram (A) and anti-*N. sitophila* activity (B) of antifungal compounds. Six antifungal compounds were labeled compounds **1**−**6**. The column marked by a star for the mean is significantly different at $p < 0.05$ using Duncan's multiple-range tests. Data are expressed as mean ± SD ($n = 3$).

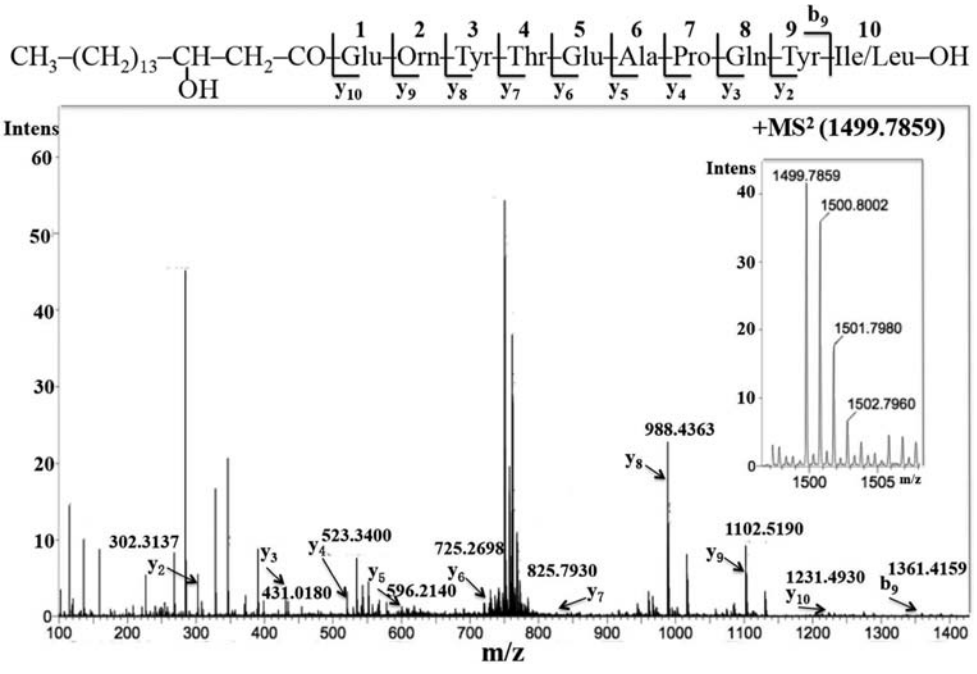

Figure 9. ESI-MS/MS spectra of the purified antifungal compound **1** against *N. sitophila* from *B. subtilis* B154.

antifungal compounds (labeled compounds **1**−**6**) were obtained (Figure 8A). Compound **1** had the highest antifungal activity against the mushroom pathogen *N. sitophila* (Figure 8B).

DOI: 10.1021/acs.jafc.5b02218
J. Agric. Food Chem. 2015, 63, 6009−6018

Compound **1** was further purified with RP-HPLC and then analyzed by MALDI-TOF-MS and ESI-MS/MS. The molecular weight of the purified chemical having antifungal activity was elucidated by MALDI-TOF-MS spectrometry. Data from the positive ion mass spectrum analysis showed that $[M + H]^+$ ion peak was 1499.7633; therefore, the molecular weight of compound **1** was 1498.7633 Da. Many strains of *Bacillus* species were reported to secrete antimicrobial lipopeptides, such as surfactin (m/z 994−1065), iturins (m/z 1028−1073), and fengycin (m/z 1421−1566), which can play important roles in the control of plant diseases.[10,45,46] The fengycin family could be readily distinguished by its distinctly higher masses in the m/z range of 1421−1566.[31,45,47,48] Compound **1** yielded a mass at 1499.7633; therefore, this compound was probably fengycin.

Fengycins are cyclic depsipeptides formed by lactonization involving the side chain −OH of Tyr_3 and C-terminal −COOH of Ile_{10}. The fengycins also possess a three-residue tail segment, and the N-terminal of the decapeptide segment is acylated with a β-hydroxy fatty acid.[49] The peptide sequences of fengycin variants from various *Bacilli* strains have been determined by MALDI-MS and LC-ESI-MS. Two classes of fengycins, A and B, have been reported thus far. Fengycin A has ^{D}Ala at position 6, while fengycin B has ^{D}Val in that position. Within each class, further heterogeneity was observed corresponding to the presence of a β−OH fatty acid, with the chain length varying from C_{14}−C_{19}.[47,48] Under collision-induced dissociation conditions, intense product ions corresponding to cleavage of Glu_1-Orn_2 (m/z 1066 or 1094) and Orn_2-Tyr_3 (m/z 952 or 980) are readily observed and have been used as diagnostics for identifying fengycin variants with the amino acids replacement within the macrocyclic moiety.[47,48] ESI-MS/MS spectrometry analysis of $[M + H]^+$ (m/z 1499.7633) was conducted further to confirm the structure of compound **1**. The ESI-MS/MS spectrum of the compound **1** ion (m/z 1499.7859) yielded two key product ions (y_9 m/z 1102.5.5, and y_8 m/z 988.4), which were not indicative of either of these two classes, demonstrating that compound **1** was a potential new fengycin type lipopeptide (Figure 9).

In the present study, specific residues have been inferred at the individual residue positions based on the mass shifts observed upon fragmentation. For example, a shift of 71 Da has been assigned to an Ala while a shift of 129 Da is assigned to a Glu residue. However, assignments based exclusively on the basis of mass spectrometry may not readily distinguish between isomeric residues like Ile (113 Da) and Leu (113 Da).[31] Based on the product ions (y_2−y_{10}, b_9) of the ESI-MS/MS spectrum of compound **1** (Figure 9), the composition of the amino acid residue was (Glu_1-Orn_2-Tyr_3-Thr_4-Glu_5-Ala_6-Pro_7-Gln_8-Tyr_9-Ile/Leu_{10}), a C_{17} β-hydroxy fatty acid chain connected with the N-terminal of Glu_1.

Fengycins exhibit antifungal activity against some filamentous fungi in vitro;[12] however, to date, no investigator has reported the antifungal application of fengycins in the control of mushroom mold. This work opens the possibility for biocontrol of red bread mold disease in commercial mushroom crops.

In conclusion, the new fengycin type lipopeptide is a potent antifungal component isolated from the *B. subtilis* B154, providing a valuable tool for resistance against pathogenic fungi in mushroom compost. In addition, the management of the microbial community in substrate during *A. bisporus* cultivation, such as inoculation of *Bacillus* spp., can be a way to optimize the growth of *A. bisporus* by increasing the competitive ability against the red bread mold *N. sitophila*. The bacterium B154 can act as a potential alternative to fungistats that inhibit fast-growing fungal antagonists. These findings are of great importance because peptide produced by bacteria or antagonistic microbe would be a way to help *Agaricus* compete with other fungal antagonists and thus to improve edible mushroom production and food safety.

	antisense	CCGAGAGAGGTGGAAAAACA	
GSK-3β	sense	TCGTCCATCGATGTGTGGTC	202
	antisense	TTGTCCAGGGGTGAGCTTTG	
GS	sense	TTGCCAGAATGCACGCAGAA	125
	antisense	TGCCTGCATCATCTGTTGAC	
β-actin	sense	GATCGATGCCGGTGCTAAGA	367
	antisense	TCCTATGGGAGAACGGCAGA	

[a]Primer sets designed for RT-PCR to evaluate the expressions of PI3K, Akt, GSK-3β, and GS at gene level. The specific primers, which include both sense and antisense, were designed separately and followed the designing principles.

environment for 7 days. Then the animals were randomly divided into normal control group (NC) and diabetic control group (DC). The NC group, consisting of 20 rats, was fed a normal chow diet during the whole study, whereas the other group was fed a high-fat diet (HFD). After a month, the HFD rats were injected intraperitoneally with STZ solution at a dose of 30 mg/(kg·body weight (bw)). The STZ was dissolved in citrate buffer at pH 4.2−4.5. The rats in the NC group were injected with the citrate buffer vehicle. Seventy-two hours after injection, the rats in the DC group with blood glucose level ≥11.1 mmol/L were considered as T2DM rats and would be used in future experiments. These T2DM rats were fed the HFD throughout the whole study. Then the T2DM rats were randomly divided into three groups with 10 animals each. The first group (low-dosage group, LD) received D-pinitol at 30 mg/(kg·bw·day), the second group (high-dosage group, HD) received D-pinitol at 60 mg/(kg·bw·day), and the last one received distilled water only (diabetes control group, DC). Ten rats were chosen from the normal control group to receive D-pinitol at 60 mg/(kg·bw·day) as the normal high-dosage control group (NH).

Oral Glucose Tolerance Test (OGTT) and Insulin Tolerance Test (ITT). OGTT was performed in overnight-fasted rats from every group. Vehicle (distilled water) was orally administered to NC and DC groups. Doses of 30, 60, and 60 mg/kg D-pinitol were orally administered to LD, HD, and NH groups, respectively. Twenty minutes later, all of the rats were orally administered glucose at a dose of 2 g/kg. Blood was withdrawn from the tip of the tail at 0, 30, 60, and 120 min from all five groups to measure the blood glucose level.

ITT were performed in overnight-fasted rats from all groups 3 days after the OGTT. Twenty minutes after administration of the vehicle (distilled water) and D-pinitol, the rats were injected with insulin intraperitoneally at a dose of 0.15 U/kg. Similar to the procedure for OGTT, blood samples were withdrawn at 0, 30, 60, and 120 min after the injection of insulin, and the blood glucose level was measured.

Biochemical Analysis. The fasting blood glucose (FBG) level was determined by using the blood glucose meter and test strips each week. The fasting serum insulin (FINS) was determined by ELISA kit. The insulin sensitivity index (ISI) was calculated following the formula ISI = Ln (1/FINS × FBG). The homeostasis model assessment-β (HOMA-β) was calculated following the formula HOMA-β = (20 × FINS)/(FBG − 3.5). All of the parameters were performed according to the manufacturer's instructions. The blood samples and viscera organs were stored at −80 °C in the refrigerator for future research.

Real-Time Polymerase Chain Reaction (RT-PCR) Analysis. RT-PCR was operated to determine the expression levels of the genes. Total RNA was extracted from liver using Trizol reagent, and the concentration of the total RNA was determined by the ultraviolet spectrophotometer. It was converted to DNA by using a RT-PCR kit, and the reaction was performed according to the manufacturer's instructions. The specific primers, which include both sense and antisense, were used for the amplification of DNA (Table1).

Western Blot Analysis. The expression of protein including PI3Kp85 (85 kDa), PI3Kp110 (110 kDa), Akt (60 kDa), p-Akt (60 kDa), GSK-3β (46 kDa), and GS (81−85 kDa) was analyzed by Western blot. In brief, 100 mg of liver was homogenized in RIPA buffer for 10 min, followed by centrifugation at 10000 rpm for 5 min at 4 °C. The supernatant was transferred to a new clean centrifuge tube, and the Bradford colorimetric method was used to determine the concentration of the total protein. The tissue protein (50−70 μg) was subjected to 10% SDS-PAGE for 0.5 h at 80 V and for 2.5 h at 100 V, to separate the target protein from the others. Proteins were transferred to a nitrocellulose membrane for 3 h at 300 mA by wet transfer equipment. The membrane was incubated in blocking solution containing 5% nonfat dried milk for 2 h at room temperature. Subsequently, the membrane was exposed to the desired primary antibodies, PBS containing PI3Kp85 antibody (1:1000), PI3Kp110 antibody (1:1000), Akt antibody (1:1000), p-Akt (Ser473) antibody (1:2000), GSK-3β (1:1000), and GS (1:1000), incubated with the membrane at 4 °C overnight; β-actin (43 kDa) was used as control protein. After incubation with the secondary antibody for 2 h at room temperature, the membrane was exposed to chemiluminescent reagent (ECL) for about 5−10 min. The expressions of the proteins on the membranes with fluorescence were exposed to X-ray photographic films in a darkroom, and the band densities were quantified.

Immunohistochemistry. Liver tissues embedded in paraffin were performed on 5 μm paraffin sections for immunohistochemical staining. The paraffin sections were dewaxed and rehydrated before being dipped into 0.01 M citrate buffer (pH 6.0) with a boiling water reaction to retrieve antigen. The paraffin sections were incubated with 3% H_2O_2 to quench the activity of endogenous peroxidase. Then the sections were incubated in the solution containing 3% BSA to block nonspecific binding sites, whereas endogenous avidin-binding activity was inhibited by continuous treatment with avidin−biotin. The following steps of the immunodetection experiment were operated according to the manufacturer's instruction for the SABC (rabbit IgG)−POD Kit. For each antibody, a negative control was included in which the primary antibody was replaced with phosphate buffer saline (PBS).

Table 2. Effect of D-Pinitol on Body Weight of Experimental Rats[a]

	body weight (g)			
group	0 weeks	1 week	3 weeks	5 weeks
NC	425.50 ± 14.12	456.50 ± 24.01**	478.50 ± 21.60**	496.50 ± 27.18**
DC	420.00 ± 28.55	368.63 ± 31.92	375.00 ± 26.01	380.75 ± 30.73
LD	413.60 ± 15.63	380.80 ± 16.19	366.20 ± 12.48	385.00 ± 14.76
HD	433.20 ± 29.75	393.80 ± 30.72	408.80 ± 25.55*	424.20 ± 17.87*
NH	417.80 ± 32.51	435.20 ± 19.72	477.00 ± 30.94	492.00 ± 34.26

[a]The effect of D-pinitol on body weight is exhibited in this table. The rats in DC group were significantly lighter than the normal ones. After treatment with D-pinitol, body weight of the rats in HD group was significantly higher than the ones in DC group. We evaluated (*)$p < 0.05$ as significant and (**) $p < 0.01$ as very significant. Values are the means ± SD, and each group contained 10 rats.

Table 3. Effect of D-Pinitol on Fasting Blood Glucose of Experimental Rats[a]

	fasting blood glucose (mmol/L)				
group	0 weeks	1 week	3 weeks	5 weeks	reduction rate (%)
NC	5.0 ± 0.57**	4.6 ± 0.57**	5.0 ± 0.56**	4.8 ± 1.18**	
DC	18.6 ± 3.00	20.2 ± 2.95	23.1 ± 6.26	21.1 ± 4.31	
LD	18.7 ± 5.35	21.3 ± 6.03	19.9 ± 4.13	16.9 ± 3.02**	9.63
HD	19.0 ± 2.20	18.5 ± 2.58	18.6 ± 3.01*	16.6 ± 2.56**	12.63
NH	4.7 ± 0.30	4.3 ± 0.38	4.5 ± 0.72	4.2 ± 0.44	

[a]Data in this table show the effect of D-pinitol on FBG. The FBG levels of the rats in LD and HD groups had a tendency to reduce during the treatment. Both LD and HD groups had very significant differences compared with DC group in FBG after 5 weeks of treatment. We evaluated (*) $p < 0.05$ as significant and (**) $p < 0.01$ as very significant. Values are the means ± SD, and each group contained 10 rats.

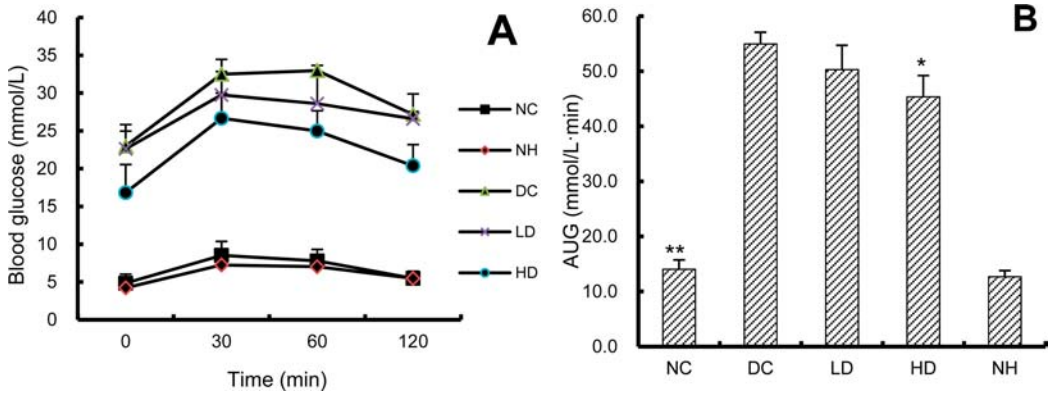

Figure 1. OGTT was performed after 4 weeks of treatment in all experimental rats. Animals in LD, HD, and NH groups received D-pinitol orally; rats in NC and DC groups received vehicle only. Twenty minutes after that, all groups received oral glucose at dosage of 2 g/kg. Blood samples were collected at 0, 30, 60, and 120 min after administration of glucose. Each point is the mean ± SD of 10 separate rats. The area under curve of panel A was calculated and exhibited in panel B). (*) $p < 0.05$ compared with the DC group was considered as significant difference. (**) $p < 0.01$ was very significantly different compared with the DC group.

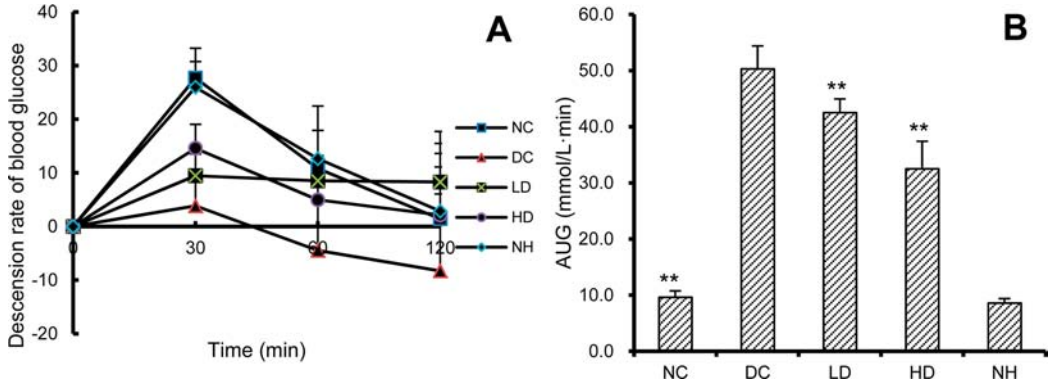

Figure 2. ITT was performed in all experimental rats 3 days after OGTT. Rats in the LD, HD, and NH groups received D-pinitol orally, whereas NC and DC groups received vehicle only. Rats were injected with insulin at 0.15 U/kg intraperitoneally, and blood samples were withdrawn at 0, 30, 60, and 120 min after injection. Each point is the mean ± SD of 10 separate rats. The area under curve of panel A was calculated and exhibited in panel B. (**) $p < 0.01$ was very significantly different compared with the DC group.

Statistical Analysis. All of the data were presented as means ± SD. The *t* test was used to exhibit the significance of differences between samples. These differences were considered significant when $p < 0.05$, whereas $p < 0.01$ was regarded as very significant (SPSS version 20.0, Statistical Package for the Social Sciences Software, SPSS Inc., Chicago, IL, USA).

RESULTS

D-Pinitol Increased Body Weight and Reduced Fasting Blood Glucose. Body weight and FBG of all the experimental rats were measured each week, and Table 2 reveals the body weight of all groups. There was a remarkable difference in body weight between normal rats and diabetic rats ($p < 0.01$). The body weight of the DC group was significantly lower than that of the NC group during the whole experiment ($p < 0.05$). Supplementation of D-pinitol to the diabetic rats showed a significant increase in body weight after 5 weeks of treatment compared to the DC group ($p < 0.05$).

Table 3 shows the level of FBG of all rats. The level of FBG of diabetic rats was significantly higher than that of the normal rats. D-Pinitol exhibited a positive effect on hypoglycemic activity in diabetic rats. The reduction rates of FBG in LD and HD groups were 9.63 and 12.63% separately. The LD group and HD group

Table 4. Effect of D-Pinitol on Insulin Sensitivity of Experimental Rats[a]

	insulin sensitivity		
group	FINS (mIU/L)	ISI	HOMA-β
NC	13.11 ± 1.55**	−4.06 ± 0.19**	260.88 ± 150.43**
DC	20.07 ± 3.17	−6.13 ± 0.15	20.77 ± 5.07
LD	18.29 ± 2.56	−5.89 ± 0.18	23.04 ± 6.91
HD	14.18 ± 2.14*	−5.40 ± 0.17*	24.55 ± 9.77
NH	13.86 ± 1.75	−4.10 ± 0.20	301.39 ± 128.29

[a]Data in this table suggested that rats in the DC group had a higher concentration of insulin in serum than that in normal groups. D-Pinitol helped to lower the contents of FINS and increased ISI of the rats in the LD and HD groups. (*) $p < 0.05$ was considered as significant and (**) $p < 0.01$ as very significant. Values are the means ± SD, and each group contained 10 rats.

both showed very significant decrease compared with the DC group ($p < 0.01$).

On the basis of the data, it can be concluded that D-pinitol is useful to increase the body weight and decrease FBG level in HFD/STZ-induced diabetic rats.

D-Pinitol Improved OGTT and ITT of Diabetic Rats. After 4 weeks of treatment with D-pinitol, overnight-fasted rats were subjected to an OGTT. Oral supplementation of glucose (2 g/kg) increased blood glucose level within 30 min, and it remained at a high level over the next 90 min in DC rats. The blood glucose level rose to the peak as well in NC rats, but dropped to the initial level after 120 min. Treatment with D-pinitol (60 mg/(kg·bw)) in diabetic rats inhibited the rise in blood glucose levels significantly after oral glucose administration (Figure 1A). The results of OGTT were expressed as overall area under curve of glucose (AUG) over 120 min, and the AUG of the HD group was markedly less than that of DC group (Figure 1B, $p < 0.05$).

Three days after OGTT, all rats were evaluated for ITT after an overnight fast. After intraperitoneally injected insulin at 0.5 U/kg, the blood glucose levels at 30, 60, and 120 min revealed that normal rats took more advantage of insulin than the diabetic rats (Figure 2A). Significant differences between the DC group ($p < 0.05$) and D-pinitol dosage groups suggested that D-pinitol increased the utilization of insulin and improved the insulin sensitivity of the diabetic rats as well (Figure 2B).

D-Pinitol Enhanced Insulin Sensitivity of T2DM Rats. The investigation studied whether D-pinitol could exert an insulin-sensitizing activity in T2DM rats. As Table 4 illustrates, treatment with D-pinitol increased ISI. Fasting blood insulin content stayed at a high level in DC and LD groups, whereas the HD group showed a significant decrease compared with the DC group ($p < 0.05$). When treated with D-pinitol, the diabetic rats showed a tendency of HOMA-β enhancement.

D-Pinitol Ameliorated Insulin Resistance through the PI3K/Akt Pathway. In this investigation we evaluated the effects of D-pinitol on PI3K, Akt, GSK-3β, and GS at the gene level with RT-PCR, inquiring into the molecular mechanism of D-pinitol in improving insulin resistance. The RT-PCR consequences in Figure 3 indicated that D-pinitol-treated groups increased the expression of PI3K, Akt, and GS at the gene level with the relativity of β-actin. The expression of GSK-3β was decreased in LD and HD groups, which were both very significantly different to the DC group ($p < 0.01$).

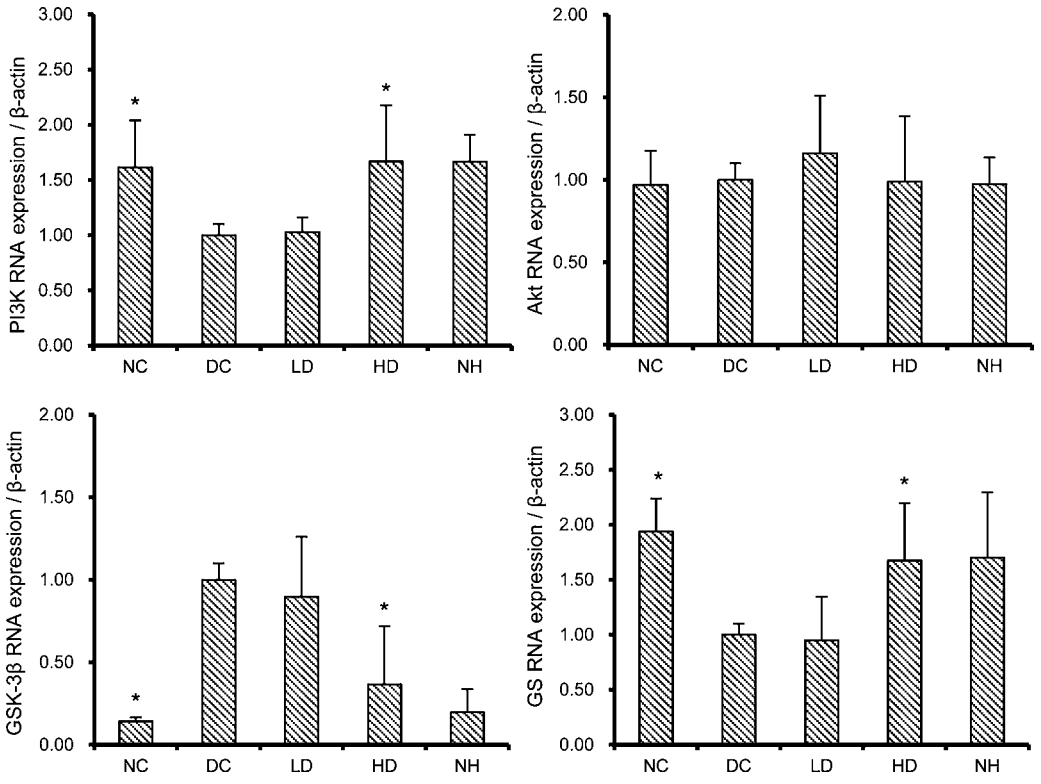

Figure 3. Total RNA was extracted from liver using Trizol reagent, and the concentration of the total RNA was determined by the ultraviolet spectrophotometer. RT-PCR was operated according to the manufacturer's instructions of the RT-PCR kits, and the results in this figure demonstrate the effect of D-pinitol on the genes in the PI3K/Akt pathway. (*) $p < 0.05$ compared with the DC group was considered as significantly different. Values are the means ± SD, and each group contained 10 samples.

DOI: 10.1021/acs.jafc.5b01238
J. Agric. Food Chem. 2015, 63, 6019−6026

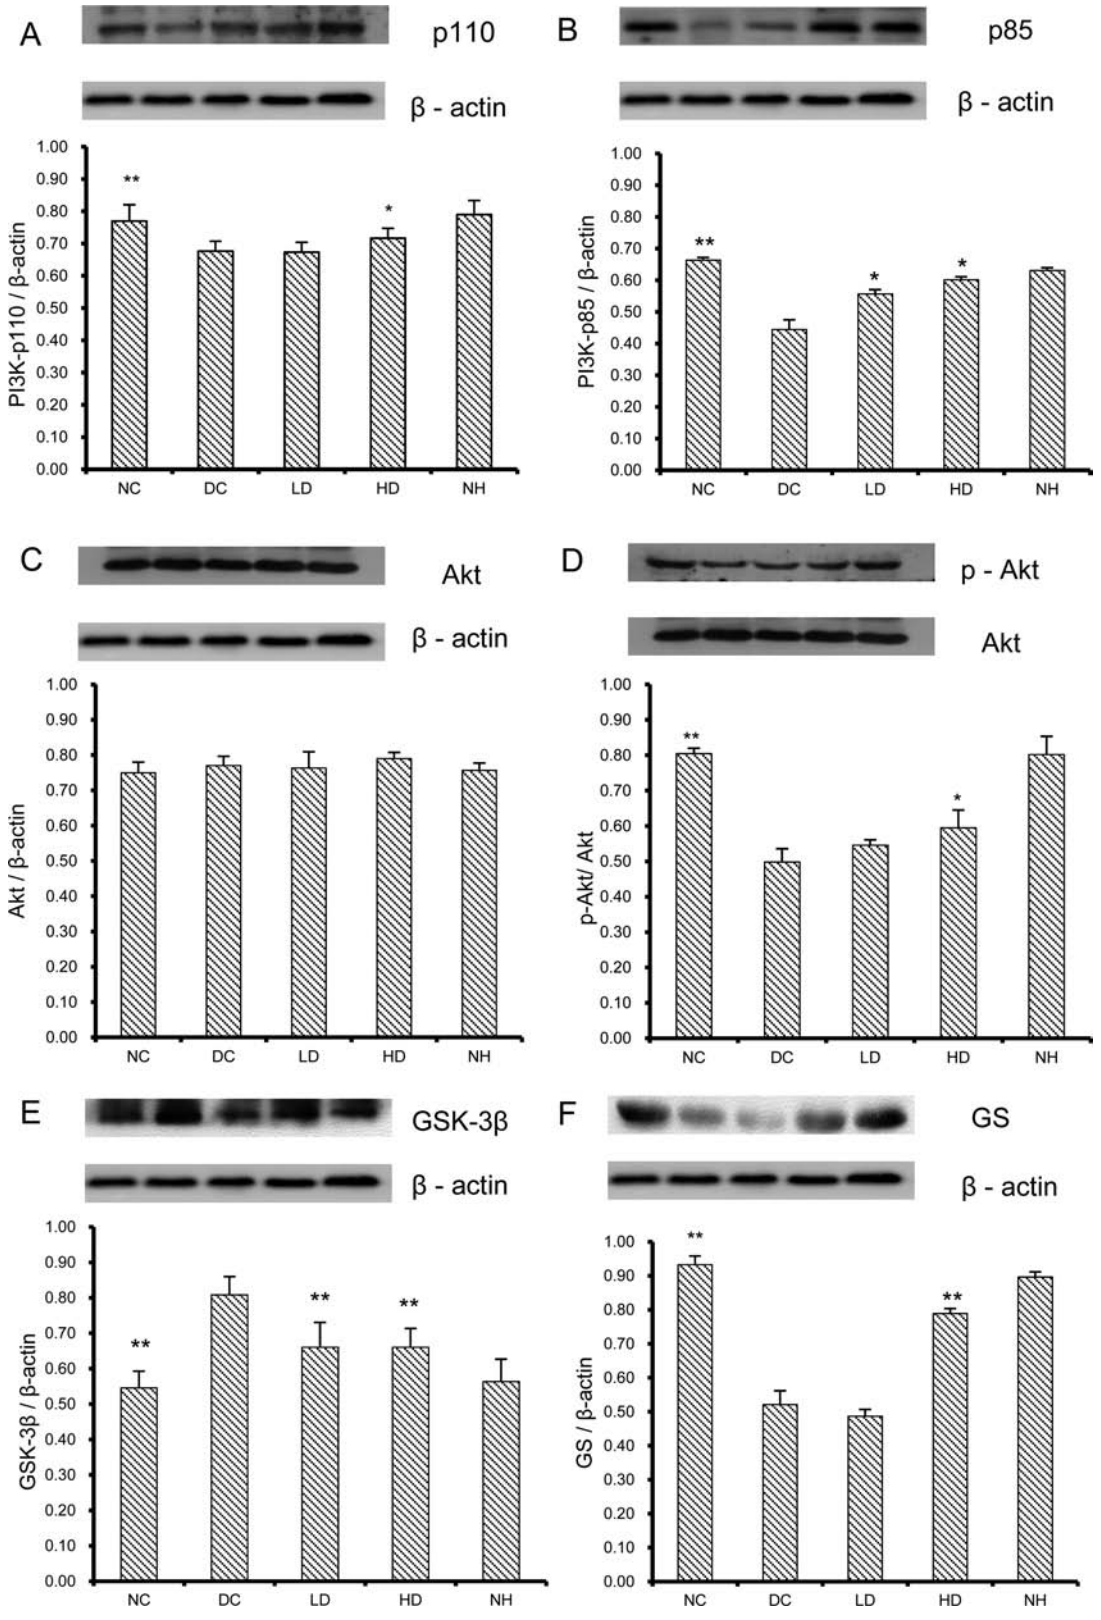

Figure 4. Western blot was used to express the effect of D-pinitol on the key proteins in PI3K/Akt pathway. The proteins of p85, p110, Akt, p-Akt, GSK-3β, and GS in liver tissue were extracted by RIPA and separated by 10% SDS-PAGE. Similar results were obtained in three independent experiments. Photos are representative images. Values are the means ± SD. (*) $p < 0.05$ compared with the DC group was considered as significantly different. (**) $p < 0.01$ was very significantly different compared with the DC group.

We also evaluated the expression of the main proteins in the PI3K/Akt pathway. PI3K is a kind of phosphatidylinositol kinase, which comprises a catalytic subunit (p110) and a regulatory subunit (p85). The p85 subunit is coupled with tyrosine-phosphorylated receptor tyrosine kinases, and the p110 subunit is required for G-protein-mediated activation of PI3K. D-Pinitol

DOI: 10.1021/acs.jafc.5b01238
J. Agric. Food Chem. 2015, 63, 6019−6026

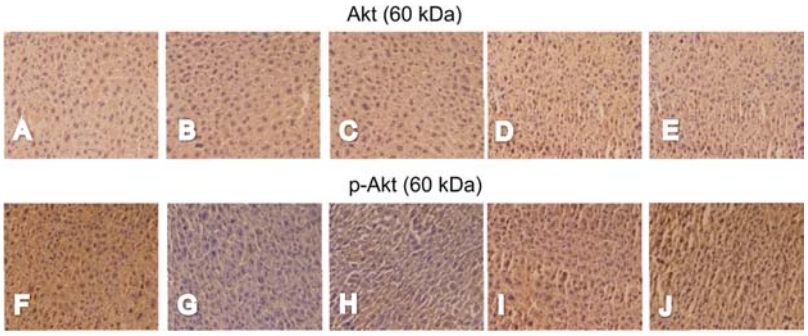

Figure 5. Immunohistochemical staining was performed on the 5 μm paraffin sections embedded with liver tissues. All staining steps were performed according to the manufacturer's instruction of SABC (rabbit IgG)−POD Kit. The staining outcomes were observed by microscope at 200 times magnification.

significantly increased the expression of p110 and p85 in diabetic rats (Figure 4A,B, $p < 0.05$). Akt and p-Akt were measured in this study to determine whether PI3K downstream signaling was affected by D-pinitol in diabetic rats. The results in Figure 4C,D suggested that D-pinitol treatment was associated with a significant increase in phosphorylation of Akt in liver tissue compared with the DC ($p < 0.05$). To gain some insight into the molecular mechanism for the effect of D-pinitol on glycogen synthesis, we assessed the levels of GSK-3β protein and GS protein (Figure 4E,F); the expression quantity of GSK-3β protein was decreased remarkably in D-pinitol-treated groups, and the expression of GS protein was increased.

The results showed that D-pinitol treatment significantly enhanced the expression of the main proteins in the PI3K/Akt pathway and then indicated that D-pinitol had a positive effect on liver insulin transduction.

Immunohistochemistry Test on Paraffin Sections. Immunohistochemistry staining of Akt and p-Akt suggested that liver tissues were completely stained in each group (Figure 5). There was no obvious difference in the staining of Akt in all groups. Increased immunostaining of p-Akt was observed in liver tissues of normal control rats, whereas the staining of p-Akt was markedly diminished in the DC group. Greater immunostaining for p-Akt in the HD group was presented in the tissues compared with diabetic control, whereas the LD group showed no obvious difference compared with the DC group.

DISCUSSION

T2DM is one of the most complicated worldwide epidemics in recent decades. T2DM, caused by insulin resistance, is associated with both hyperglycemic and hyperlipidemia. An imbalance of insulin sensitivity between the liver and peripheral tissue as well as endocrine pancreatic function damage may lead to T2DM.[14] Besides, T2DM is always the original reason causing many chronic diseases. Therefore, it is very important to find an appropriate way for better treatments and precaution strategies of T2DM. There are numerous investigations establishing animal models to mimicking T2DM. On the basis of the experimental characteristics, we chose SD rats as our experimental animals, which more easily obtain the pathological features resembling T2DM.[15] The rats were fed a HFD for 4 weeks and then injected with low-dose STZ, which would closely mimic the metabolic characteristic of human T2DM.[16,17] The liver plays a significant role in glycemic control between meals because it is the main organ that regulates glucose transformation.[18] In traditional medicines, along with the antidiabetic activity, negative consequences appeared and puzzled the patients. Some herbs and natural compounds were found to have hypoglycemic effect in recent studies.[19] D-Pinitol is a natural compound extracted from Pinaceae plants or Leguminosae and was reported as having a hypoglycemic effect.[20]

In summary, on the basis of our results, D-pinitol showed dose-dependent reduction of FBG and improvement of body weight, oral glucose tolerance, and insulin tolerance of T2DM rats. D-Pinitol lowered the concentration of FINS in diabetic rats, which meant it is helpful to enhance the insulin sensitivity of the body, and relieved the symptom of insulin resistance. D-Pinitol treatment also enhanced ISI, which meant D-pinitol increased the ability of the body to take advantage of insulin to accelerate glucose metabolism. We considered HOMA-β as the indicator to evaluate the function of pancreatic β-cells. However, D-pinitol showed a weak effect on pancreatic β-cells in this investigation. These results proved the positive effects of D-pinitol on relieving hyperglycemia and insulin resistance in T2DM rats. It also strengthened the ability of the body in glucose tolerance and the sensitivity to insulin. The PI3K/Akt pathway plays an important role in the metabolic effect of insulin,[21,22] and Akt/PKB is a critical node downstream of the PI3K/Akt pathway. Any fluctuation of Akt activation causes the pathophysiological properties of various complex diseases.[23,24] D-Pinitol, in this research, had favorable effects on mediating the activation of PI3K/Akt pathway signaling and alleviating insulin resistance of T2DM rats. The expressions of PI3Kp85 and PI3Kp110 subunits in D-pinitol-treated groups showed a dose-dependent increasing tendency. During the experiment, stimulation with high-density insulin can cause up-regulation of PI3Kp85 protein, which would give a negative feedback on insulin sensitivity in return and affect the activity of downstream molecules to inhibit the continuous conduction of signal.[25]

D-Pinitol also increased the amounts of phosphorylated Akt at Ser473 in a dose-dependent manner, and p-Akt inhibited the GSK-3β protein directly. GSK-3β activity can be acutely inactivated by insulin signaling through insulin receptor substrate-1 (IRS-1), PI3K, and the action of Akt to phosphorylate specific serine residues on the enzyme. An additional substrate of GSK-3β is IRS-1, and phosphorylation of IRS-1 on serine/threonine residues leads to impairment of insulin signaling.[26] Therefore, GSK-3β can negatively modulate the insulin action on GS protein and, potentially, on glucose transport activity.

Besides, according to the data, rats in the NH group exhibited no difference from the NC group, which explained that D-pinitol has no negative effect on normal rats.

J. Agric. Food Chem. 2015, 63, 6019−6026

In conclusion, D-pinitol relieves insulin resistance through the PI3K/Akt pathway, thereby reducing the concentration of blood glucose. We confirmed that this study investigated the probable mechanism of D-pinitol in relieving symptoms of T2DM, and D-pinitol can be developed into an effective drug for the treatment of T2DM when sufficient further research on D-pinitol can be performed.

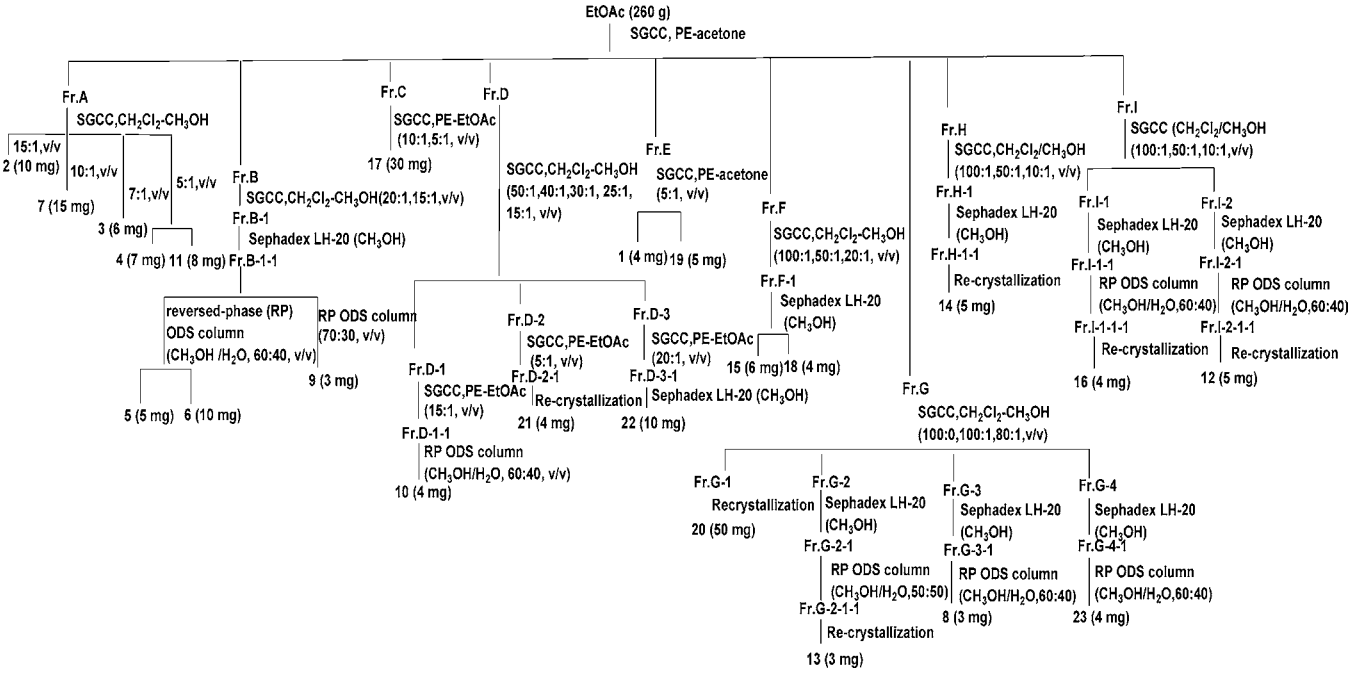

Figure 1. Schematic representation of the extraction and isolation procedure.

voucher specimen was deposited in Shenyang Pharmaceutical University.

General Experimental Procedures. Column chromatography (CC) was performed with silica gel (SiO_2 300−400 mesh, Qingdao Marine Chemical Group, Co. Qingdao, Shandong, China), reversed phase ODS (300−400 mesh, Agela Technologies Co. Tianjin, China), and Sephadex LH-20 (Pharmacia, Co. Tokyo, Japan). NMR spectra were recorded with a Bruker ARX-600 (^{1}H, 600 MHz; ^{13}C, 150 MHz) spectrometer in DMSO-d_6 or $CDCl_3$ with tetramethylsilane as internal standard. All other chemical agents, including CH_3OH, ethanol, petroleum ether, ethyl acetate, and *n*-butanol, were of analytical grade and were obtained from Tianjin DaMao Chemical Reagents Co. (Tianjin, China)

Extraction and Isolation. To obtain the active constituents, the stems of green asparagus (30 kg) were extracted with 75% EtOH (bp 78.1 °C) under reflux at 80 °C, on the basis of the results of several published references.[9,10] After evaporation of the alcohol, the residual aqueous solution was subsequently extracted with water, petroleum ether (PE, 388 g), ethyl acetate (EtOAc, 260 g), and *n*-butanol (*n*-BuOH, 200 g). The extraction and isolation scheme is shown in Figure 1.

Phytochemical study of green asparagus led to the isolation of 23 compounds, including 7 steroids (**1**−**7**), 2 esters (**8**, **11**), 3 arynes (**9**, **10**, **12**), 1 lignin (**13**), 3 flavonoids (**14**−**16**), 4 alkaloids (**17**−**20**), and 3 aliphatic series (**21**−**23**): 24(*R*)-24-ethyl-5α-cholestane-3β,5,6β-triol (**1**),[11] stigmasterol (**2**),[12] (22*E*,24*S*)-5α,8α-epidioxy-24-methylcholesta-6,22-dien-3β-ol (**3**),[13] 5α,8α-epidioxy-(20*S*,22*E*,24*R*)-ergosta-6,22-dien-3β-ol (**4**),[14] 24(*S*)-cycloart-25-ene-3β,24-diol (**5**),[15] α-spinasterol (**6**),[16] yamogenin (**7**),[17] 1,3-*O*-diferuloylglycerol (**8**),[18] methyl *p*-hydroxycinnamate (**11**),[19] 4-[5-(4-methoxyphenoxy)-3-penten-1-ynyl] phenol (**9**),[20] 4-[5-(4-hydroxyphenoxy)-3-penten-1-ynyl]phenol (**10**),[20] 4,4-dihydroxy-2-methyl-3-[(4-hydroxyphenyl)ethynyl]biphene (**12**),[21] syringaressinol (**13**),[22] quercetin (**14**),[23] kaempferol (**15**),[24] quercitrin (**16**),[25] aurantiamide acetate (**17**),[26] neoechinulin A (**18**),[27] 3-pyridinecarboxylic acid, 1,6-dihydro-6-oxo-methyl ester (**19**), 2-(2-hydroxytetracosanoylmino)-1,3,4-octadecanetriol (**20**),[28] hexadecanoic acid, 2,3-dihydroxypropyl ester (**21**),[29] 12,13,15-trihydroxy-9-octadecenoic acid (**22**),[30] and 2-octadecendioic acid (**23**).[31] The known compounds **1**−**23** (Figure 2) were identified by comparison of their NMR data with those reported in the literature. The purity of each compound ranged from 95 to 98%, as determined by HPLC analysis. Furthermore, compounds **1**, **3**, **5**, **11**, **12**, and **17**−**20** were extracted from the *Asparagus* genus for the first time.

Cell Culture. Murine hepatic stellate cells (t-HSC/Cl-6) were routinely maintained in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% heat-inactivated fetal bovine serum and antibiotics (100 U/mL penicillin and streptomycin) in a humidified atmosphere containing 5% CO_2 at 37 °C.

Cell Viability Assay. t-HSC/Cl-6 cells were cultured in 96-well plates (1×10^4 cells/well) overnight and then treated with the individual compounds at various concentrations with or without TNF-α for another 48 h. Cell viability was then assessed by the MTT assay. After removal of all of the remaining liquid in the wells, 100 μL of fresh medium containing MTT reagent (5 μg/mL) was added to each well and incubated for 3 h at 37 °C. After that, the formazan crystals were dissolved with dimethyl sulfoxide, and the reduction of cell viability was determined by measuring the absorbance at 490 nm using a microplate reader. For this experiment, each of the 23 compounds was dissolved in dimethyl sulfoxide to give a 0.1 M stock solution.

RNA Extraction and Quantitative RT-PCR. Total RNA was extracted from the treated cells. The quality and quantity of RNA were determined. Quantitative real-time PCR was carried out using the ABI Prism 7900-HT sequence detection system (96 wells) as described.[32] The following primers were designed for mouse cytokine analysis: tumor necrosis factor-α (TNF-α), forward 5′-CCCTCACACTCAGATCATCTTCT-3′ and reverse 5′-GCTACGACGTGGGCTACAG-3′; IL-6, forward 5′-TAGTCCTTCCTACCCCAATTTCC-3′ and reverse 5′-TTGGTCCTTAGCCACTCCTTC-3′; TGF-β1, forward 5′-ACCTGCAAGACCATCGACAT-3′ and reverse 5′-GGTTTTCTCATAGATGGCGT-3′; activin C, forward 5′-CCGTGAGATTGGCTGGAAT-3′ and reverse 5′-GCGTTGGCTTTGAGCAGAT-3′. β-Actin was used as internal control.

Western Blotting Analyses. In addition to RNA, total protein was also extracted from the treated cells. In brief, the cells were lysed in RIPA buffer (Cell Signaling Technology, USA) for 15 min on water ice. After brief sonication, the cell lysate was centrifuged at 14000*g* for 15 min at 4 °C. The supernatant was resolved by SDS-PAGE using 12% gel. The proteins in the gel were then transferred to a nitrocellulose membrane. The following primary antibodies were used for immunoblotting: anti-TGF-β1 (1:1000), anti-p-Smad2 (1:1000), anti-activin C (1:1000), anti-p-ERK (1:1000), anti-p-JNK (1:1000), anti-c-Jun (1:1000), anti-c-Fos (1:1000), and anti-β-actin

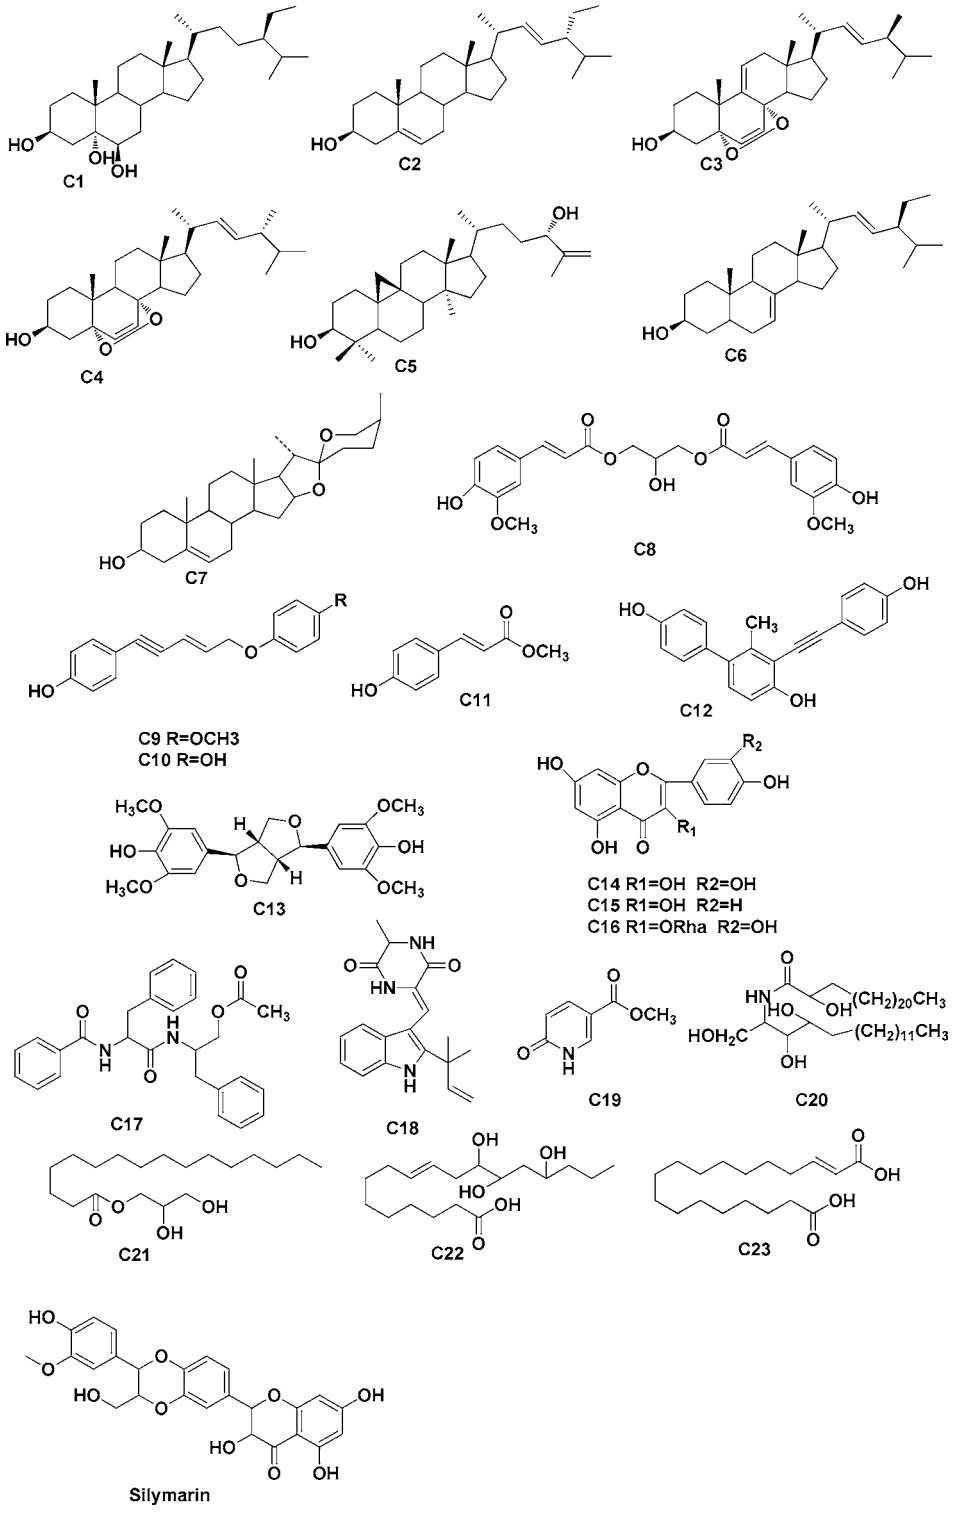

Figure 2. Chemical structures of isolated compounds **1**−**23** and silymarin.

(1:3000). Signals were detected by an enhanced chemiluminescence technique (Amersham Life Science, USA).

Quantification of the Active Compounds from Green Asparagus. For HPLC analysis, the top four active compounds (**3**, **4**, **10**, **12**) were analyzed using a HPLC system (LC3000, Beijing ChuangXinTongHeng Science & Technology Co., Ltd., Beijing, China) equipped with a UV lamp (Beijing ChuangXinTongHeng Science & Technology Co., Ltd.) and a C_{18} reversed-phase analytical column (Agilent HC-C18, 4.6 × 250 mm, 5 μm; Agilent Technologies Inc., Santa Clara, CA, USA). The HPLC mobile phase was composed of methanol (solvent A) and water (solvent B). The linear gradient elution system was as follows: 0−20 min, 53−65% (v/v) A; 20−30 min, 65−80% (v/v) A; 30−45 min, 80−90% (v/v) A; 45−60 min, 90−100% (v/v) A, and 60−90 min, 100% (v/v) A, at a flow rate of 1 mL/min. The quantification of the top four active compounds by UV was performed at 210 nm. The column temperature was maintained at 30 °C, and the injection volume was 20 μL. In addition, to quantitate the top four active compounds, namely, (22*E*,24*S*)-5α,8α-epidioxy-24-methylcholesta-6,22-dien-3β-ol, 5α,8α-epidioxy-(20*S*,22*E*,24*R*)-ergosta-6,22-dien-3β-ol, 4-[5-(4-hydroxyphenoxy)-3-penten-1-ynyl]phenol,

DOI: 10.1021/acs.jafc.5b01490
J. Agric. Food Chem. 2015, 63, 6027−6034

and 4,4-dihydroxy-2-methyl-3-[(4-hydroxyphenyl)ethynyl]biphene, were measured at concentrations of 0.025, 0.05, 0.1, 0.2, and 0.5 g/L to prepare a calibration curve for each compound. The percentage of the top four active compounds was calculated using eq 1:

$$\%\ \text{of compd} = A(\text{peak area of compd}) / A(\text{total peak areas of compd}) \times 100 \quad (1)$$

Statistical Analysis. All of the results were expressed as means ± SDs of three determinations at each concentration for each sample. Analysis of variance (ANOVA) was performed, and the mean separation was done by LSD ($p \leq 0.05$) using the SPSS 16.0 program for Windows (SPSS Inc., Chicago, IL, USA).

The HPLC chromatograms were recorded and analyzed using a CXTH-3000 Data Station (CXTH Co., Ltd., Beijing, China), and the results were calculated using Windows Excel 2010.

RESULTS

Phytochemical Characterization. Phytochemical investigation of the stem of green asparagus resulted in the isolation of 23 compounds, including 7 steroids, 2 esters, 3 arynes, 1 lignan, 3 flavonoids, 4 alkaloids, and 3 aliphatic series. Among these, compounds **1**, **3**, **5**, **11**, **12**, and **17**−**20** were obtained from this genus for the first time. The structures of compounds **1**−**23** were determined using a combination of NMR spectra and then identified by comparison of the spectral data with those reported in the literature (Table 1).

Among the tested compounds, compounds **3**, **4**, **7**, **8**, **10**−**12**, **16**, and **20** showed potent antihepatic fibrosis activity, and the relative order of potency was **10** > **12** > **3** > **8** > **4** > **20** > **16** > **7** > **11** as depicted in Table 2. We concluded that the high activity of compounds **10** and **12** could be due to their acetylenic bonds, whereas a significant difference was observed between the activity of compounds **9** and **10**, both of which had the same skeleton, except for the 16-hydroxyl (**10**) or methoxyl (**9**), suggesting that the hydroxyls may be more important for the antihepatic fibrosis activity. In addition, comparison of compounds **1**−**7** showed that the antihepatic fibrosis capacities of steroidal compounds may be influenced by the ring containing oxygen.

Quantification of the Top Four Active Compounds. The contents of **3**, **4**, **10**, and **12** in *A. officinalis* L. were determined by HPLC-UV analysis and are shown in Table 3.

Preliminary Screening of Inhibitory Activity against Self-Activated t-HSC/Cl-6 Cells. All of the extracts and compounds isolated were assayed for their inhibitory activities against self-activated t-HSC/Cl-6 cells, and the results are shown in Table 2. The PE- and EtOAc-extracted fractions greatly inhibited the activation of t-HSC/Cl-6 cells, with IC_{50} values of 87.77 and 45.52 μg/mL, respectively. At the same time, compounds **3**, **4**, **7**, **8**, **10**−**12**, **16**, and **20** isolated from the EtOAc-extracted fraction were more potent than the positive control drug silymarin (IC_{50} = 352.11 μM) or Fufang BiejiaRuangan Pian (IC_{50} = 212.34 μg/mL) at inhibiting the activation of t-HSC/Cl-6 cells, with IC_{50} values of 76.70, 111.08, 172.70, 95.22, 36.65, 196.30, 56.04, 166.34, and 125.11 μM, respectively. The inhibitory activity of these compounds against the activation of t-HSC/Cl-6 cells suggested that they might contribute to the inhibitory activity of the EtOAc-extracted fraction against hepatic fibrosis. Furthermore, the strong inhibitory activity of compounds **10** and **12** toward the activated t-HSC/Cl-6 cells could possibly be related to their different phytochemical properties.

Table 1. Compounds Isolated from the Stems of Green Asparagus

kind	compd	name	ref
steroids	**1**	24(*R*)-24-ethyl-5α-cholestane-3β,5,6β-triol	11

	20	2-(2-hydroxytetracosanoylmino)-1,3,4-octadecanetriol	28
aliphatic series	**21**	hexadecanoic acid, 2,3-dihydroxypropyl ester	29
	22	12,13,15-trihydroxy-9-octadecenoic acid	30
	23	2-octadecenedioic acid	31

Growth Inhibitory Effects of Compounds 3, 4, 10, and 12 toward TNF-α-Activated t-HSC/Cl-6 Cells. HSC activation, which includes initiation and perpetuation, is an early event in liver fibrogenesis. The activation of HSCs converts normal, quiescent vitamin A-rich cells into myofibroblast-like cells characterized by proliferation, chemotaxis, fibrogenesis, contractility, matrix degradation, retinoid loss, and the release of white blood cell chemoattractant/cytokine.[33−37] On the basis of the preliminary growth inhibitory screening data and considering the yield of phytochemical isolation, compounds **3**, **4**, **10**, and **12** were subjected to further investigation (Figure 3); **8** was not evaluated due to its low yield, although it also has better inhibitory activity on self-activated t-HSC/Cl-6 cells. t-HSC/Cl-6 cells were treated with these compounds (one at a time) plus TNF-α for 48 h, and the growth of the t-HSC/Cl-6 cells was determined. According to the data shown in Figure 3, compounds **3**, **4**, and **10**, but not **12**, could significantly decrease the growth of activated t-HSC/Cl-6 in a dose-dependent manner, and the extents of growth inhibition exerted by these compounds were even greater than that exerted by the positive control silymarin.

[a]IC_{50} values, expressed as means ± SDs, were calculated from the least-squares regression equations in the plot of the logarithm of three graded concentrations vs % inhibition using SPSS 16.0 program for Windows (SPSS Inc., Chicago, IL, USA). [b]Significant differences with respect to positive control (silymarin) at the $p < 0.01$ level. [c]The concentration unit of these extracts is μg/mL. [d]Significant differences with respect to positive control (Fufang Biejia Ruangan Pian) at the $p < 0.01$ level.

Table 3. Retention Times and Contents of 3, 4, 10, and 12 As Resolved by HPLC Analysis

compd	regression eq	R^2	retention time (min)	%
3	$y = 36.95x - 0.062$	0.999	57.048	0.012
4	$y = 14.94x + 0.132$	0.999	62.043	0.016
10	$y = 436.4x - 1.865$	0.999	33.848	0.069
12	$y = 161.2x - 0.112$	0.999	14.385	0.016

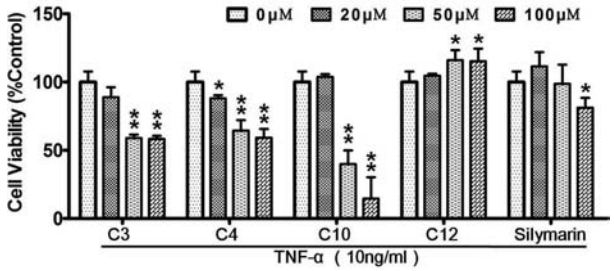

Figure 3. Effects of compounds **3**, **4**, **10**, and **12** on the viability of murine hepatic stellate cells (t-HSC/Cl-6). t-HSC/Cl-6 cells were seeded in 96-well plates (1×10^4 cells/well) for 24 h and then treated with TNF-α (10 ng/mL) and the four compounds at various concentrations for 48 h. Silymarin with TNF-α (10 ng/mL) was used as positive control. Viable cell numbers were estimated via MTT assay. Data represent the means ± SDs of three independent experiments, each performed in triplicate. (*) $p \leq 0.05$; (**) $p \leq 0.01$.

Compounds 3, 4, 10, and 12 Decrease Cytokine Released by TNF-α-Activated t-HSC/Cl-6 Cells. Besides HSC activation, ECM deposition and other events like oxidative stress, inflammation, and immune responses are also involved in the fibrogenic response. The levels of transforming growth factor beta 1 (TGF-β1) and activin C (Figure 4), both of which are HSC activation-associated factors, were increased in TNF-α activated t-HSC/Cl-6 cells. In addition, the levels of TNF-α and IL-6 were also increased in these cells. However, treatment of these cells with compounds **3**, **4**, **10**, and **12** decreased the transcript levels of both TGF-β1 and activin C, as well as inhibiting the release of TNF-α, while having no effect on the level of IL-6.

Compounds 3, 4, 10, and 12 Change the Expression Levels of HSC Activation-Associated Genes. TGF-β1 produced by HSCs acts as a potent fibrogenic signal as it increases the production of collagen I and other matrix constituents such as fibronectin and proteoglycans.[35,38] These effects are induced by the interaction between TGF-β1 and the membrane receptor complex formed by TβRI and TβRII, leading to the phosphorylation of intracellular mediators, namely, Smad proteins (Figure 5). The antifibrotic mechanism is mainly the result of the down-regulation of the TGF-β1/Smad signaling pathway. To further investigate the antifibrotic mechanism of the tested compounds, changes in the expression levels of genes associated with TGF-β1/Smad signaling pathway and its downstream target genes were determined. Upon stimulation with TNF-α, the expression levels of TGF-β1, activin C, and p-Smad2 were increased. At the same time, increased levels of phosphorylated extracellular signal-regulated kinsase (ERK) and c-Jun N-terminal kinases (JNKs) were also detected. Down-regulation of the expression of TGF-β1 and activin C and modulation of its intracellular mediators Smad2 by **3**, **4**, **10**, and **12** were observed in the present study. The above-mentioned compounds attenuated TNF-α-induced ERK and JNK phosphorylations and also the expression level of c-Fos and c-Jun, the downstream targets of JNK.

DISCUSSION

In present study, 23 compounds (purity > 95%, % is referred to HPLC analysis) were isolated from green asparagus, and 9 of them were obtained from this genus for the first time. The structures of compounds **1**−**23** were determined using a combination of ^{1}H and ^{13}C NMR spectra and then identified by comparison of the spectral data with those reported previously in the literature.

During chronic liver injury, HSCs are activated, and their subsequent proliferation can cause ECM deposition, leading to scar formation and fibrosis. During the early stages of liver disease and hepatic fibrosis, the infiltrated immune cells produce and release high levels of TNF-α and IL-1β. Therefore, TNF-α has been implicated as a key effector molecule in the activation of HSCs through regulating the levels of cytokines, chemokines, and other adhesion molecules. Medicinal plants are often safe, cost-effective, and versatile and are therefore popular potential antifibrotic agents. There are two ways by which medicinal plants and their bioactive compounds and extracts could reduce liver fibrosis: inhibition of HSC activation and reduction of ECM deposition. In the present study, we investigated the effect of the crude extract of green asparagus as well as of the pure compounds isolated from the extract on TNF-α-activated quiescent HSCs.

Perpetuation of HSC activation results in the maintenance of the activated phenotype and therefore the generation of fibrosis.[39] Scars are formed through changes in HSC behavior, such as proliferation, fibrogenesis, contractility, chemotaxis, retinoid loss, white blood cell chemoattractant/cytokine release,

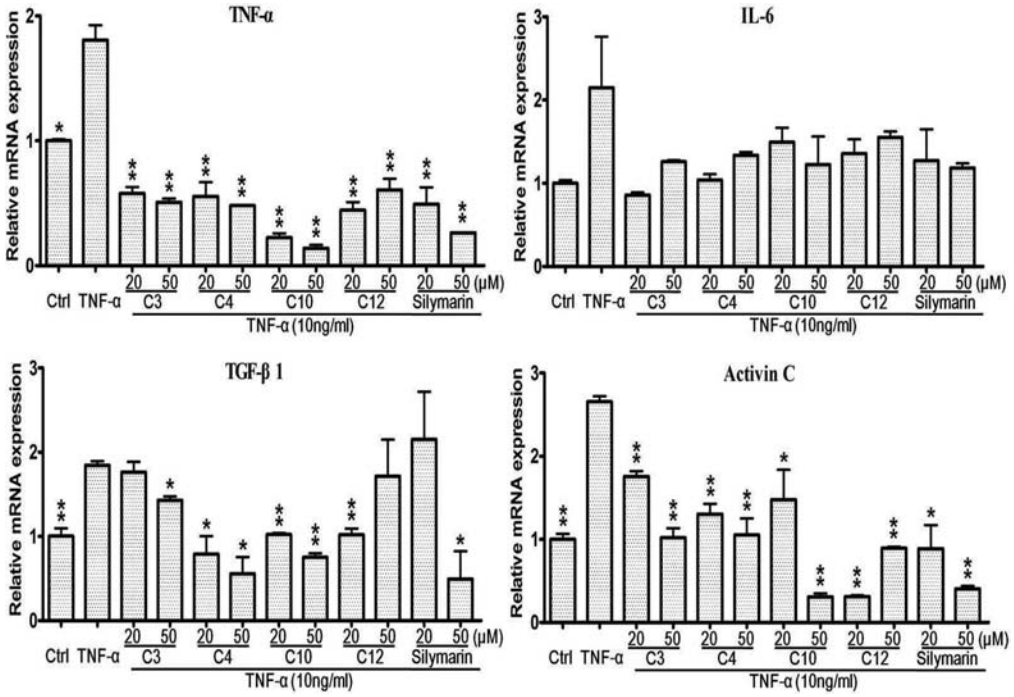

Figure 4. Changes in the expression levels of marker genes involved in inflammation (TNF-α, IL-6) and fibrosis (TGF-β1, activin C) in t-HSC/Cl-6 cells induced by the four compounds (**3**, **4**, **10**, and **12**). RNA was extracted from t-HSC/Cl-6 cells with or without TNF-α (10 ng/mL) and the four compounds or silymarin (positive control) at different concentrations for 48 h and subjected to real-time PCR analysis. Asterisks indicate significant differences in mRNA levels of TNF-α, IL-6, TGF-β1, or activin C with respect to TNF-α treatment only at the (*) $p \leq 0.05$ and (**) $p \leq 0.01$ levels, respectively.

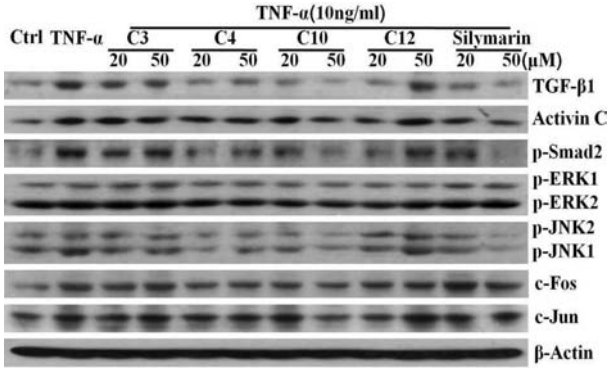

Figure 5. Inhibition of TGF-β/Smad-signaling-associated proteins mediated by the four compounds (**3**, **4**, **10**, and **12**) in t-HSC/Cl-6 cells. The levels of TGF-β/Smad signaling-associated proteins in t-HSC/Cl-6 cells activated with TNF-α (10 ng/mL) with or without the compounds for 48 h were determined and compared. β-Actin was used as a loading control. All experiments were performed three times. Representative data are shown.

and matrix degradation.[35] Cell proliferation further promotes liver fibrosis by increasing the number of collagen-producing cells. However, the growth of TNF-α-activated t-HSC/Cl-6 cells was significantly inhibited by compounds **3**, **4**, and **10**, and in dose-dependent manner, which suggested that bioactive compounds from green asparagus could improve liver fibrosis via inhibition of the proliferation of activated HSCs.

Inflammation and immune responses are involved in the initiation and perpetuation of fibrosis.[33,34,36,37] These pathways are potential targets for therapy aiming to reduce hepatic fibrosis. High levels of TNF-α released by immune cells are usually detected during the early stages of liver disease and hepatic fibrosis. The compounds from green asparagus could reduce TNF-α level in a time- and dose-dependent manner. This suggested that the inhibition of HSC activation by the compounds purified from green asparagus were probably due to their anti-inflammation capacity, stemming from the suppression of TNF-α expression.

Activation of TGF-β1/Smad signaling is one of the most important pro-fibrogenic pathways.[40] The disruption of this pathway is a common mode of action exerted by antifibrotic plants. Our findings were consistent with findings reported by other investigators. The compounds from green asparagus could decrease the level TGF-β1 and the phosphorylation of Smad2. Meanwhile, the phosphorylated forms of ERK and JNK, as well as the expression levels of c-Fos and c-Jun, the downstream targets of JNK, were also decreased. Impressively, activin C, a closely related member of the TGF-β superfamily of growth and differentiation factors, has been shown to inhibit regenerative DNA synthesis in hepatic cells and liver regeneration and to induce apoptosis.[41−45] In direct contrast, Wada et al. reported that overexpression or recombinant activin C stimulates DNA synthesis and growth of AML12 and AML12tAR cells and accelerates liver regeneration.[46,47] The present data showed that in TNF-α-activated t-HSC/Cl-6 cells, the level of activin C was increased, and after treatment with the compounds, it was reduced, but only at certain concentrations of the compounds.

In summary, our results demonstrated that compounds from green asparagus could inhibit HSC activation by inhibiting the proliferation of activated HSCs and attenuating TNF-α level. Moreover, TGF-β1/Smad signaling and MAPKs (ERK and JNK) signaling pathways were also involved in the antifibrosis mechanism of the tested compounds. Therefore, the current tested compounds from green asparagus may prove to be good

DOI: 10.1021/acs.jafc.5b01490
J. Agric. Food Chem. 2015, 63, 6027−6034

potential agents for the therapy of hepatic fibrosis. However, it should be noted that liver fibrosis treatment should take into account the versatility of its pathogenesis and should act upon all pathways involved, beginning with HSC activation and ECM deposition.

As a widely consumed vegetable worldwide, the current findings will no doubt have a positive effect on the search for protection against hepatic fibrosis, However, considering the contents analysis results in the current study, it may be difficult to acquire the necessary amount of the active compounds to protect against hepatic fibrosis unless a sufficient intake of asparagus can be ensured. It may therefore be necessary to produce green asparagus extracts or compounds and use them as a food supplement. Further study of the bioactive components from green asparagus on suppressing the development of hepatic fibrosis in vivo and at the clinical level will be necessary.

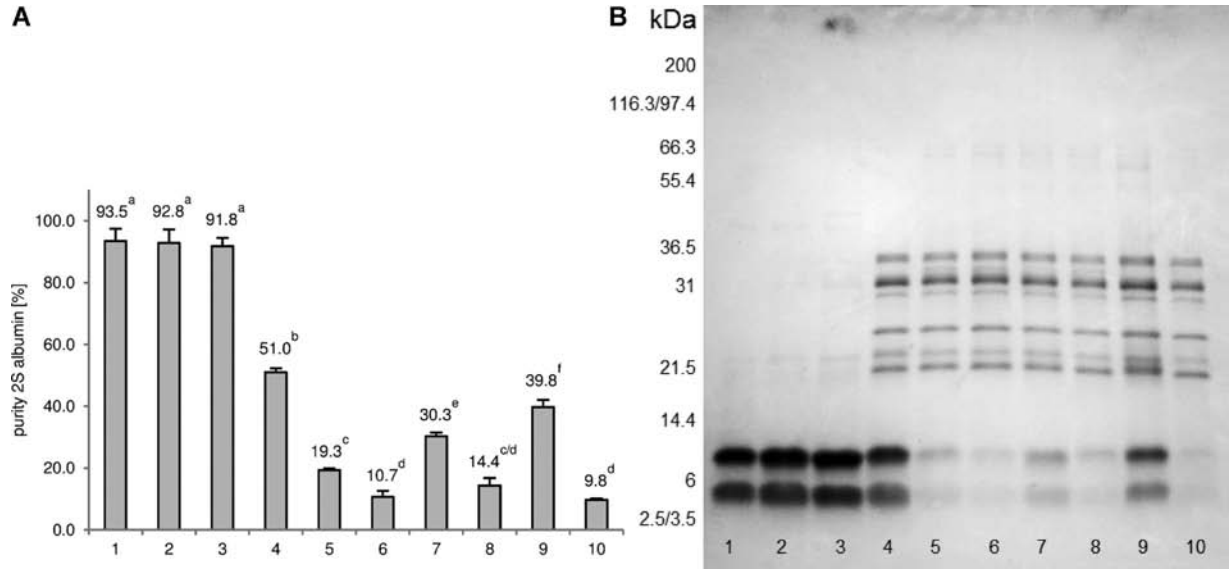

Figure 1. Effect of buffer system on 2S extraction. (A) Purity of 2S albumin extracts from mustard given as percentage of the total extracted protein in different buffer systems. Superscript letters indicate significance groups ($p \leq 0.05$): 1, glycine (100 mM, pH 2.5); 2, acetate (100 mM, pH 3.6); 3, citrate (100 mM, pH 4.0); 4, citrate (100 mM, pH 5.0); 5, MES (100 mM, pH 6.0); 6, MOPS (100 mM, pH 7.0); 7, Tris (100 mM, pH 8.0); 8, glycine (100 mM, pH 9.0); 9, bicarbonate (100 mM, pH 11.0); 10, Millipore H_2O. (B) Representative SDS-PAGE gel. Numbering is according to (A).

Preparation of Defatted Seed and Nut Flour. All seeds and nuts containing more than ∼40% fat (sunflower seeds, hazel nuts, pistachio seeds, Brazil nut seeds, sesame seeds, pecan seeds, cashew seeds, walnuts, and peanut seeds) were defatted twice prior to analysis. Seeds and nuts were crushed for 2−3 s in a knife mill (Grindomix GM 100, Retsch, Haan, Germany), resulting in a coarse flour. The first defatting step was performed by adding *n*-pentane (1 g/10 mL) and continuous stirring for 2 h at room temperature. The slurry was sieved and air-dried overnight. All seeds and nuts containing <40% fat (mustard seeds, buckwheat seeds, chickpea seeds, soybean seeds) as well as the pre-defatted material were separately milled to a fine powder using a nitrogen-cooled rotor-mill (Pulverisette, 1 mm mesh width, Fritsch, Idar Oberstein, Germany). Subsequently, the powder was defatted using *n*-pentane as described above. The defatted flour was stored at −20 ± 2 °C.

Extraction of Proteins. Proteins were extracted from the defatted flour by vigorous shaking (Mini shaker, VWR, 550 rpm) for 2 h in a 10-fold excess of different buffers (150 mg flour/1.5 mL buffer) at different temperatures. The slurry was centrifuged for 30 min at 9000*g* (Universal 16, Hettich, Spenge, Germany), and the supernatant was used for subsequent SDS-PAGE analysis immediately to avoid protein precipitation.

Optimization of Extraction. Four different parameters were systematically optimized to obtain optimal conditions for extraction: the buffer system (a), the extraction temperature (b), the molarity of the extraction buffer (c), and the pH of the extraction buffer (d). All experiments were carried out in biological triplicates using mustard seeds, and results were transferred to the other seeds and nuts. The pH was adjusted with an accuracy of ±0.03.

Experiment a included the following buffer systems: glycine−HCl buffer (100 mM, pH 2.5), sodium acetate−acetic acid buffer (100 mM, pH 3.6), sodium citrate−HCl buffer (100 mM, pH 4.0), sodium citrate−HCl buffer (100 mM, pH 5.0), MES−HCl buffer (100 mM, pH 6.0), MOPS−HCl buffer (100 mM, pH 7.0), Tris−HCl buffer (100 mM, pH 8.0), glycine−HCl buffer (100 mM, pH 9.0), sodium bicarbonate−HCl buffer (100 mM, pH 11.0). In this first experiment the molarity of all buffer solutions was 100 mM, and the pH was in the optimal buffering range of the respective buffer system. As 2S albumins are traditionally extracted using water, extraction with Millipore H_2O was in addition included in this study.

Experiment b was performed at extraction temperatures of 4, 23, and 60 °C, respectively. Molarity and pH values were not modified compared to experiment a.

Experiment c was performed using buffer molarities of 20, 50, 100, 200, 500, and 1000 mM, respectively. The pH value was not modified.

Experiment d was performed to assess extraction performance over the complete pH range of the respective buffer systems. For that purpose the lower limit of the pH range was increased in steps of ∼0.5 pH unit until the upper limit was reached.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE). Protein samples were separated by Tris−glycine SDS-PAGE using precast gels (Any kD Mini-PROTEAN TGX Gels, 15 well, 15 μL) and a Mini-PROTEAN Tetra cell (Bio-Rad). Protein solutions (10 μL) were diluted with Millipore H_2O to a volume of 150 μL and mixed with 50 μL pf 4× reducing sample loading buffer (2-ME in Bio-Rad 4× Laemmli Sample Buffer according to the manual). After the samples had been heated at 95 °C for 5 min, a volume of 10 μL per lane was loaded. Gels were run for 30 min at 200 V and stained for 2 h with Coomassie blue staining solution (500 mg of Coomassie brilliant blue R-250, 400 mL of methanol, 100 μL of acetic acid, filled to 1 L). After destaining, the gels were documented with a Chemidoc XRS system (Bio-Rad) and analyzed with the software ImageJ 1.48v (National Institutes of Health, Bethesda, MD, USA).

Buffer Exchange. Buffer exchange was performed using PD-10 desalting columns containing 8.3 mL of Sephadex G-25 medium (GE Healthcare, Uppsala, Sweden) according to the gravity protocol of the manufacturer. The column was equilibrated with 30 mL of phosphate buffered saline (1× PBS, 12 mM phosphate), and the flow-through was discarded. A sample volume of 0.5 mL was applied to the column, and 2.0 mL of equilibration buffer was added after the sample had entered the packed bed. Again, the flow-through was discarded. The elution was carried out with 5 mL of phosphate buffered saline (1× PBS, 12 mM phosphate), and the eluate was manually fractionated into ∼0.5 mL fractions. A qualitative protein test of all fractions was performed with protein assay reagent (Protein Assay, Bio-Rad) according to the method of Bradford using 20 μL of sample, 40 μL of Bradford reagent, and 140 μL of H_2O.[12] All fractions containing protein (indicated by blue color) were combined and used for further analyses.

Circular Dichroism (CD) Spectroscopy. CD studies were carried out by recording data in the far-UV region (250−200 nm) on a Jasco

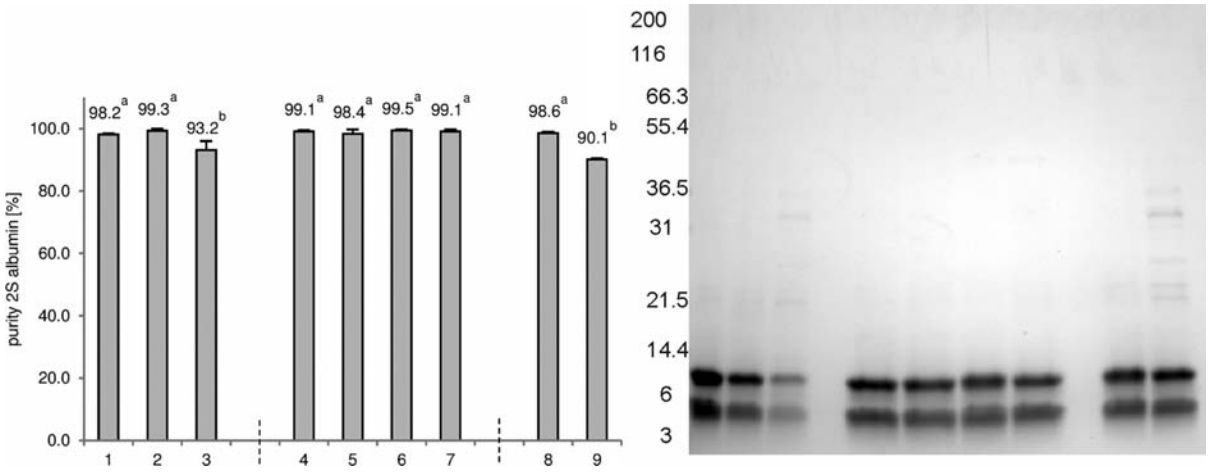

Figure 4. Effect of pH on mustard 2S albumin extraction; purity of 2S albumin extract at various pH values. Superscript letters indicate significance groups ($p \leq 0.05$): 1, glycine (100 mM, pH 2.5, 60 °C); 2, glycine (100 mM, pH 3.0, 60 °C); 3, glycine (100 mM, pH 3.5, 60 °C); 4, citrate (100 mM, pH 2.5, 60 °C); 5, citrate (100 mM, pH 3.0, 60 °C); 6, citrate (100 mM, pH 3.5, 60 °C); 7, citrate (100 mM, pH 4.0, 60 °C); 8, acetate (100 mM, pH 3.6, 60 °C); 9, acetate (100 mM, pH 4.0, 60 °C).

J810 spectropolarimeter in a 1 mm pathlength quartz cuvette (4 mL) at room temperature. The protein concentration was determined by Nanodrop 1000 (Thermo Scientific, Dreieich, Germany) and adjusted to 100 μg/mL. Spectra were recorded with a scanning speed of 100 nm/min and accumulated over four measurements. All samples were analyzed in 1× PBS (12 mM phosphate) after buffer exchange.

SDS-PAGE Gel Analysis. To exclude gel-to-gel differences due to staining/destaining interferences and limited linearity of Coomassie brilliant blue dye, we performed relative quantitation of single gel lanes. The protein purity given in the results are described by relative signal intensities of 2S albumin signals compared to other proteins in the same lane of the respective gel and represent the 2S albumin content as a percentage of the total protein extracted in a single sample. Using the software ImageJ 1.48v (National Institutes of Health, USA), the background of the gel was subtracted and every lane was plotted individually. The relative protein content was calculated as the sum of 2S albumin signals (large and small subunit) divided by the summarized peak areas of the sample (defined as 100%). The analysis is exemplified in the Supporting Information (Figure S1).

Statistical Analysis. All experiments were carried out as biological triplicates, and SPSS Statistics version 22 (IBM, Ehningen, Germany) was used to compare means. A one-way analysis of variances (ANOVA) was performed to evaluate the relationship between extraction conditions (independent variable) and the change in the 2S albumin percentage (dependent variable). A Tukey HSD post hoc test with a 95% confidence interval was used to evaluate pairwise differences among means.

RESULTS AND DISCUSSION

Effect of Buffer System. Ten different buffer systems were used to survey selective extraction of 2S albumins from mustard seeds (results are summarized in Figure 1 and Table S1). With regard to the 2S albumin yield, we observed considerable differences. The use of very acidic buffer systems (glycine (100 mM, pH 2.5), acetate (100 mM, pH 3.6), and citrate (100 mM, pH 4.0)) results in efficient and selective 2S albumin extraction with purities >90% and no significant differences between these three buffer systems. All remaining buffers gave only poor 2S albumin purities between 9.8 and 51.0% and a strongly reduced yield as demonstrated by SDS-PAGE (Figure 1B). Notably, the lowest purity and yield were observed for water (Figure 1, sample 10). This is of particular interest, as current methods in place for 2S albumin isolation mainly use water for the extraction. Garino et al. purified hazelnut 2S albumins by extraction with water at 4 °C and subsequent purification with SEC and RP-HPLC.[10] On the basis of our initial results, not only 2S albumin purity but also total protein yield can be improved by systematic optimization of extraction conditions. Furthermore, additional chromatographic purification is not necessary for most downstream applications.

Effect of Extraction Temperature. For further optimization, we chose the three most promising buffer systems (glycine (100 mM, pH 2.5), acetate (100 mM, pH 3.6), and citrate (100 mM, pH 4.0)) and assessed effects of different extraction temperatures (4, 23, and 60 °C, respectively). The molarity of all buffers was 100 mM, and the pH was set to 2.5 for glycine buffer, 3.6 for acetate buffer, and 4.0 for citrate buffer. An overview of the results is given in Table S1 and Figure 2. The statistical classification into significance groups demonstrates that 2S albumin purities were not affected by the extraction temperature in the above-mentioned three buffer systems. Increasing temperatures resulted, however, in higher total protein yield for all three buffers, leading to enhanced extraction efficiency at 60 °C compared to extraction at 23 and 4 °C (Figure 2, not statistically evaluated). Therefore, extraction at 60 °C was chosen for further experiments.

Effect of Molarity. Molarities between 20 and 1000 mM were tested for the three most promising buffer systems, glycine, acetate, and citrate, and the extraction was carried out at 60 °C. It has to be noted that 2S albumins are highly thermostable, and we did not observe relevant structural modifications (see also CD Spectroscopy; Supporting Information). The pH was set to 2.5 for glycine buffer, 3.6 for acetate buffer, and 4.0 for citrate buffer, respectively, and the effects of molarity on extraction are shown in Table S1 and Figure 3.

For the glycine buffer system, no significant difference in 2S albumin purity is observed when buffer molarities are modified from 20 to 1000 mM. For the acetate and citrate buffer no significant difference in purity is observed between 20 and 500 mM. For both buffers, purity is significantly reduced when using a buffer molarity of 1000 mM (Figure 3). Obviously a high buffer molarity, on the one hand, favors the extraction of high total protein amounts but, on the other hand, results in reduced selectivity and thus decreasing 2S purity. As high amounts of buffer salts are not beneficial for many analytical

DOI: 10.1021/acs.jafc.5b01634
J. Agric. Food Chem. 2015, 63, 6035−6040

routines, an intermediate buffer molarity of 100 mM was chosen for further experiments.

Effect of pH. As the pH of the buffer system was the most critical parameter in the initial experiment, we further assessed the influence of different pH values for the three most promising acidic buffers (glycine, acetate, and citrate) at molar buffer concentrations of 100 mM and 60 °C. Extraction of 2S albumins was analyzed for the three buffers over the respective buffering pH range in steps of ~0.5 pH unit. Results are summarized in Table S1 and Figure 4.

For the glycine buffer, an increase in pH to 3.5 resulted in reduced purity compared to extraction at pH 2.5 or 3.0. The citrate buffer showed equal purity of extracted 2S albumins over the complete pH range between 2.5 and 4.0. In contrast, an increase of pH of the acetate buffer from 3.6 to 4.0 led to a significant decrease in purity.

Optimized Buffer Conditions. We demonstrate that not a single optimal buffer system exists, but the extraction must comply with certain conditions: In our approach the most important parameter is the acidic pH of the buffer system and consequently glycine, acetate, or citrate buffers that have optimal buffering capacity between pH 2.5 and 4.0 resulted in the highest 2S albumin purity and high protein yield. The extraction temperature had no significant influence on purity, but elevated temperatures resulted in increased 2S albumin yield. This is especially interesting as 2S albumins are highly thermostable.[9] Optimal results with respect to buffer molarity are obtained in a broad range between 20 and 500 mM. Notably, the purity of 2S extracts is reduced when buffer molarity is further increased.

Performance Control and Transferability. As the optimized acidic buffer conditions are not common for protein extraction, we analyzed the secondary structure of the acidic protein extract and compared it to a 2S albumin fraction extracted in 100 mM Tris-HCl, pH 8.0, and purified by SEC. Extractions with three different acidic buffer systems (100 mM glycine, pH 2.5, 60 °C; 100 mM acetate, pH 3.6, 60 °C; and 100 mM citrate, pH 4.0, 60 °C) were compared with the SEC-purified 2S albumins using CD spectroscopy. To eliminate the influence of different buffers on CD spectra, a buffer exchange step to 12 mM phosphate buffer was included for all samples prior to CD spectroscopy. For all samples, we obtained CD spectra typical for 2S albumins (which mainly consist of α-helical structures), and no significant differences between the acidic extracts and the SEC-purified 2S albumins extracted with Tris buffer were observed (Figure 5), demonstrating that acidic extraction conditions do not interfere with 2S albumin structure.

As it is intended to provide a method generally applicable for the extraction of 2S albumins, we assessed the transferability from mustard to further seeds and nuts (see Materials and Methods). For 9 of 13 matrices included in this study, we observed excellent purity of 2S albumin extract and very good yield as exemplified in Figure 6. The crude protein was extracted with 100 mM Tris-HCl, pH 8.0, 23 °C (with an addition of 2 M NaCl for extraction of walnut according to the method of Sathe et al.[13]) and was compared to the extraction with 100 mM glycine, pH 2.5, 60 °C. Notably, selective 2S albumin extraction was not obtained for food matrices from legumes (peanut, chickpea, and soybean), and sunflower showed significantly reduced selectivity (Figure 6). As we did not observe phylogenetic clustering of extractable and "non-extractable" 2S albumin sequences (data not shown), we assume that differences in food matrices underlie reduced selectivity of the extraction for peanut, chickpea, soybean, and sunflower 2S albumins.

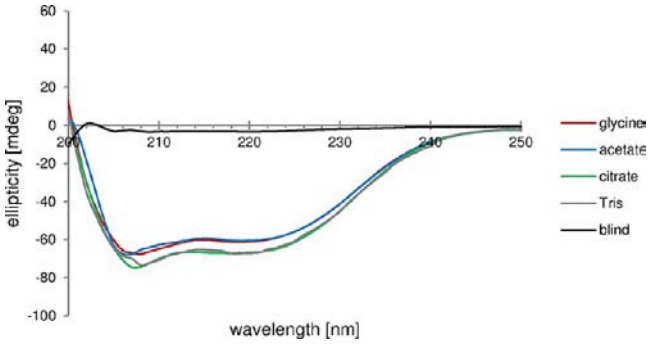

Figure 5. Circular dichroism spectroscopy of acidic buffers (glycine, acetate, and citrate) at 60 °C and 2S albumin preparation purified with GPC after Tris extraction at 20 °C. No significant differences in spectra are observed, and all obtained spectra are typical for 2S albumins, which are rich in α-helical secondary structure.

In our study we present a simple, rapid, and selective method for the isolation of 2S albumins from different seeds and nuts. We achieved 2S albumin purities up to 99% and excellent yield for our model protein Sin a 1 from mustard seeds and demonstrate excellent transferability to other allergenic seeds and nuts. In comparison to conventional chromatography-based purification methods (IEX, SEC, RP-HPLC), the newly developed method requires only minimal laboratory equipment and allows in principle unlimited protein yield with higher protein concentration compared to currently used chromatographic methods.

The purification of 2S albumins is relevant for different fields of interest in allergen research. With the selective extraction presented in this study, the production of allergen extracts from different natural sources that contain a single allergen with its natural variants and isoforms is feasible. Due to the pronounced stability of 2S albumins, neither acidic pH nor elevated extraction temperature influences the structure as demonstrated by CD spectroscopy.

Consequently, component-resolved diagnostic (CRD) of natural allergens might become possible. Today, allergen preparations for CRD are derived from recombinant expression as crude allergen extracts from natural sources are too complex and might not be reproducible.[14] Using selective extraction of 2S albumins results in the high yield of an isolated allergen with its isoforms and variants that might be employed (after a further purification step if necessary) for CRD. Although crude natural extracts are too complex for allergen diagnosis, isolated recombinant single isoforms of allergens do not reflect the natural complexity of allergens such as 2S albumins. Selective extraction might be an alternative for 2S albumins. It has to be noted that we did not investigate the immunological properties of the 2S extracts obtained in this study, which would be an essential prerequisite when aiming to use such extracts for CRD. Trace amounts of residual further allergens such as 11S legumins or 7S vicilins might influence the immunological properties, and this interference has to be ruled out. However, the high yield of 2S allows for efficient further downstream purification if necessary.

of Trp-His in the gut using the intestinal epithelial cell line HT-29.

MATERIALS AND METHODS

Materials. Trp-His was purchased from GL Biochem (Shanghai, China). His-Trp was purchased from Kokusan Chemical (Osaka, Japan). Nifedipine (a dihydropyridine (DHP) L-type Ca^{2+} channel blocker) and verapamil (a phenylalkylamine (PAA) L-type Ca^{2+} channel blocker) were obtained from Sigma-Aldrich (St. Louis, MO, USA). (*S*)-(−)-Bay K 8644, a specific L-type Ca^{2+} channel agonist, was purchased from Santa Crutz Biotechnology (Dallas, TX, USA).

Induction of Colitis in Vivo and Treatment with Trp-His. All animal experiments were approved by the University of Guelph Animal Care Committee and carried out in accordance with the Canadian Council of Animal Care Guide to the Care and Use of Experimental Animals (eAUP no. 1536). The experiments for induction of DSS-induced colitis in mice were performed as previously described.[7] Briefly, female BALB/c mice (6−8 weeks, 18−20 g; Charles River Laboratories, Montreal, QC, Canada) were group housed with a 12 h light/dark cycle and allowed unrestricted access to standard food and water. Trp-His (100 or 250 mg/kg body weight (BW)/day) or vehicle (sterilized water) was given to mice via oral administration for 14 days. On the seventh day, 5% (w/v) DSS (MW 36−50 kDa; MP Biomedicals, Solon, OH, USA) was added to drinking water to induce acute colitis and continued for the following 7 days. The negative control mice received water only, and the positive group received water with DSS for 7 days. BWs were measured on a daily basis, and the daily weight changes were expressed as mean percentage change relative to the initial weight. Mice were humanely euthanized on day 14. Colons were collected and sectioned longitudinally, and tissue samples were flash frozen and stored at −80 °C for further analysis.

Clinical Evaluation of Colitis. Mice were inspected daily for stool consistency, presence of blood in stool, or general appearance. The clinical scoring was calculated as described by Maxwell et al.[23] and defined as follows: stool score, 0 = normal, 1 = moist/sticky stool, 2 = soft stool, 3 = diarrhea; stool blood score, 0 = no blood, 1 = evidence of blood in stool or around anus, 2 = severe bleeding; mouse appearance, 0 = normal, 1 = ruffled fur or altered gait, 2 = lethargic or moribund.

Measurement of Cytokine Concentrations in Colon. Measurement of tumor necrosis factor (TNF)-α and interleukin (IL)-6 in mouse colon tissues was carried out as previously described.[7] Briefly, tissue samples were homogenized in ice-cold PBS containing proteinase inhibitors (1 mM phenylmethanesulfonyl fluoride (PMSF), 0.1 mM ethylenediaminetetraacetic acid (EDTA), 10 μg/mL aprotinin, 10 μg/mL leupeptin, and 10 μg/mL pepstatin A; Sigma-Aldrich) using a Polytron homogenizer (PT 1200, Kinematica AG, Luzern, Switzerland) for 3 min and centrifuged at 10000*g* for 10 min. Protein concentration of the homogenate supernatant was measured by DC protein assay (Bio-Rad Laboratories, Hercules, CA, USA), according to the manufacturer's instructions. The supernatants and cytokine standards were added to an anti-mouse TNF-α antibody (1:500; BD Bioscience, Mississauga, ON, Canada) or IL-6 antibody (1:250; BD Bioscience)-coated plate and incubated for 2 h at 37 °C. Next, a biotinylated anti-mouse TNF-α antibody (1:500; BD Bioscience) or IL-6 antibody (1:500; BD Bioscience) was incubated for 1 h at 37 °C. Avidin−horseradish peroxidase (Av-HRP, 1:2000; BD Bioscience) was added for 0.5 h at 37 °C. Then, 100 μL of 3,3′,5,5′-tetramethylbenzidine (TMB) and 25 μL of 0.25 M H_2SO_4 were added to each well. The absorbance was measured at 450 nm by a plate reader (iMark model 550, Bio-Rad).

RNA Isolation, cDNA Synthesis, and RT-PCR. The colons were homogenized in Trizol reagent (Life Technologies, Carlsbad, CA, USA), and total RNA was extracted from the aqueous phase by using an Aurum Total RNA Mini Kit (Bio-Rad) according to the manufacturer's instructions. The quantity and quality of the total RNA were verified by Nano Drop ND-1000 (Thermo Scientific, Waltham, MA, USA). RNA (1 μg) was reverse transcribed using a qScript cDNA Synthesis Kit (Quanta BioSciences, Gaithersburg, MD, USA), and real-time quantitative PCR was carried out using PerfeCTa SYBR Green Supermix (Quanta Biosciences) on a MyiQ single-color real-time PCR detection system (Bio-Rad) as previously described.[9] The primer sequences used were follows: β-actin, forward, 5′-GAAATCGTGCGTGACATCAAAG-3′, reverse, 5′-TGTAGTTCATGGATGCCACAG-3′; TNF-α, forward, 5′-CCCCAAAGGGATGAGAAGTT-3′, reverse, 5′-CACTTGGTGGTTTGCTACGA-3′; IL-6, forward, 5′-CCGGAGAGGAGACTTCACAG-3′, reverse, 5′-CAGAATTGCCATTGCACAAC-3′; IL-1β, forward, 5′-GGATGAGGACATGAGCACCT-3′, reverse, 5′-AGCTCATATGGGTCCGACAG-3′; interferon (IFN)-γ, forward, 5′-GCTCTTCCTCATGGCTGTTT-3′, reverse, 5′-GTCACCATCCTTTTGCCAGT-3′; monocyte chemoattractant protein (MCP)-1, forward, 5′-CCCAATGAGTAGGCTGGAGA-3′, reverse, 5′-TCTGGACCCATTCCTTCTTG-3′, IL-10, forward, 5′-GCCTTATCGGAAATGATCCA-3′, reverse, 5′-AGGGGAGAAATCGATGACAG-3′. These primers were obtained from the University of Guelph Laboratory Services Molecular Biology Section (Guelph, ON, Canada). Results are presented as fold expression change relative to negative control. Relative gene expression was calculated according to the $2^{-\Delta\Delta Ct}$ method[24] using mouse β-actin as reference gene.

Cell Culture ant Treatment. Human intestinal epithelial cell line HT-29 (HTB-38; American Type Culture Collection, Manassas, VA, USA), was grown in McCoy's 5A medium (Sigma-Aldrich) supplemented with 100 units/mL penicillin−streptomycin and 10% fetal bovine serum (FBS; Life Technologies). HT-29 cells (2.0×10^5 cells/well) were grown in 12- or 24-well tissue culture plates (Corning, Corning, NY, USA) until confluent monolayers were obtained. The confluent monolayers were rinsed with Hank's balanced salt solution (HBSS) and incubated for 2 h with peptides (Trp-His or His-Trp), L-type Ca^{2+} channel blocker, or agonist at the indicated concentrations in McCoy's 5A medium containing 5% FBS. The negative and positive control cells were treated with medium alone for 2 h. After peptide treatment, TNF-α (2 ng/mL; Life Technologies) was added and cells were incubated for 2 h. For the competitive assay, an L-type Ca^{2+} channel agonist, Bay K 8644, was added to the cells 1 h after the addition of peptide/blocker and incubated along with the peptide/blocker for 1 h before the addition of TNF-α. The culture supernatants were collected, and IL-8 concentrations were measured by ELISA as described previously[25] with minor modification. Briefly, the supernatants and IL-8 standards were added to an anti-human IL-8 antibody (1:1000; BD Bioscience)-coated plate and incubated for 2 h at 37 °C. Next, a biotinylated anti-human IL-8 antibody (1:2000; BD Bioscience) was incubated for 1 h at 37 °C. Av-HRP (1:2000) was added for 0.5 h at 37 °C, and then 50 μL of TMB and 25 μL of 0.25 M H_2SO_4 were added to each well. The absorbance was measured at 450 nm as mentioned above.

Cell Viability. Cell viability during peptide/TNF-α treatment was measured using the WST-1 Cell Proliferation Reagent (Roche Applied Science, Indianapolis, IN, USA) according to the manufacturer's instructions, and viability was calculated as a percent relative to untreated cells.

Western Blot Analysis. Cell monolayers were rinsed with HBSS and incubated for 2 h with peptide or medium, followed by TNF-α (2 ng/mL) for 1 or 2 h. Cells were then washed twice with ice-cold PBS and lysed in 100 μL of ice-cold radio-immunoprecipitation assay (RIPA) buffer containing Halt Protease and Phosphatase Inhibitor Cocktail and 0.5 M EDTA (Thermo Scientific). The supernatants were collected following centrifugation at 10000*g* for 25 min. The protein concentration was measured by a DC protein assay. An aliquot of sample was mixed with NuPAGE LDS Sample Buffer (4×) (Life Technologies) and incubated for 5 min at 95 °C. The samples (containing 30 μg of total protein) were separated on a 10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) gel and transferred to a polyvinylidene difluoride (PVDF) membrane (Pall Corp., Port Washington, NY, USA). The membrane was probed with primary antibody (1:1000) overnight at 4 °C. The antibodies used were rabbit monoclonal antiphospho-c-jun N-terminal kinase (JNK) (Thr^{183}/Tyr^{185}), JNK, phospho-IκBα (Ser^{32}) (Cell Signaling Tech-

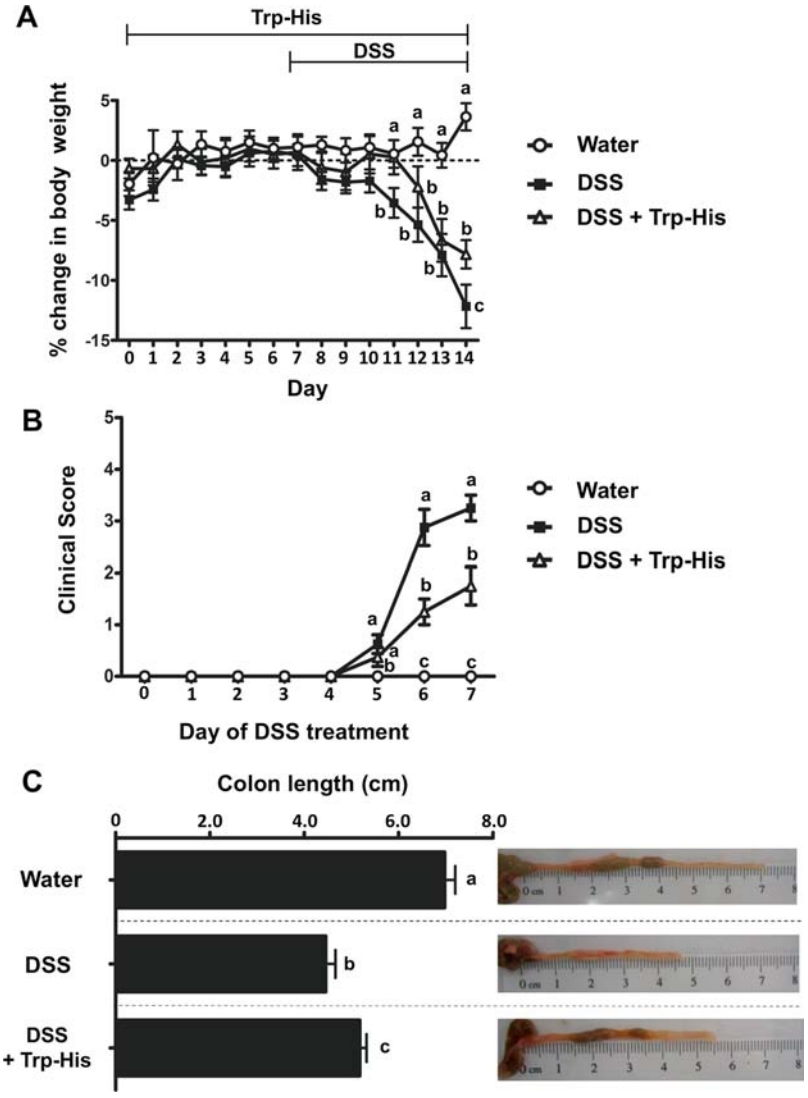

Figure 1. Effect of Trp-His on DSS-induced colitis signs and weight loss. Mice were given 100 mg/kg BW Trp-His for 14 days. On the seventh day, colitis was induced with 5% (w/v) DSS added to drinking water. (A) Mice were weighed daily, and changes in body weight are reported as percent change relative to the initial weight. (B) Mice were scored daily for clinical signs of DSS-induced colitis. (C) After 14 days, colons were removed and measured from the end of the cecum to the anus. Data represent means ± SEM (n = 8/group). Unless indicated, no significant difference was observed between groups. Values without a common letter are significantly different at $P < 0.05$.

nology, Danvers, MA, USA); and mouse monoclonal antiphospho-p38 (Tyr^{182}), p38, extracellular signal-related kinase 1/2 (ERK), IκBα, and rabbit monoclonal anti-phospho-ERK (Thr^{177}) (Santa Crutz Biotechnology). The membrane was washed and incubated with HRP-conjugated anti-mouse or anti-rabbit IgG (1:2000; GE Healthcare, Mississauga, ON, Canada) for 1 h at room temperature. Proteins were detected with ECL Plus Western Blotting Detection Reagent using a Typhoon FLA 9500 scanner (GE Healthcare). Densitometry was performed using NIH ImageJ software (Image Processing and Analysis in Java, National Institutes of Health, http://rsbweb.nih.gov/ij/).

Statistical Analysis. The results are expressed as the mean ± SEM. Statistical analyses were performed using GraphPad Prism version 5.0 (GraphPad, San Diego, CA, USA). Statistical differences between curves were analyzed using two-way analysis of variance (ANOVA) followed by Tukey's multiple-comparison test. Statistical differences between individual groups were determined using one-way ANOVA followed by Tukey's multiple-comparison test. $P < 0.05$ was considered statistically significant.

RESULTS

Preventative Effects of Trp-His on DSS-Induced Colitis in Mice. Administration of DSS in mice causes symptoms of colitis similar to those seen in human ulcerative colitis, including weight loss, diarrhea, bloody stool, and colon shortening.[26] On the fourth day of DSS treatment (day 11 of the study) (Figure 1A), the positive control mice (DSS) began to lose weight when compared with the negative control mice (water). Mice receiving Trp-His for 14 days (DSS + Trp-His) attenuated significantly ($P < 0.05$) DSS-induced weight loss on the seventh day of DSS treatment (day 14) (Figure 1A). An increase in clinical scores was also observed in DSS-treated groups beginning on the fifth day of DSS treatment, and the administration of Trp-His significantly ($P < 0.01$) reduced the severity of DSS-induced clinical signs on the sixth and seventh days (Figure 1B). No clinical signs were observed in mice before the start of DSS treatment (data not shown). As shown in Figure 1C, shortening of colon length, which is a typical sign of DSS-induced colitis, was significantly ($P < 0.05$) attenuated

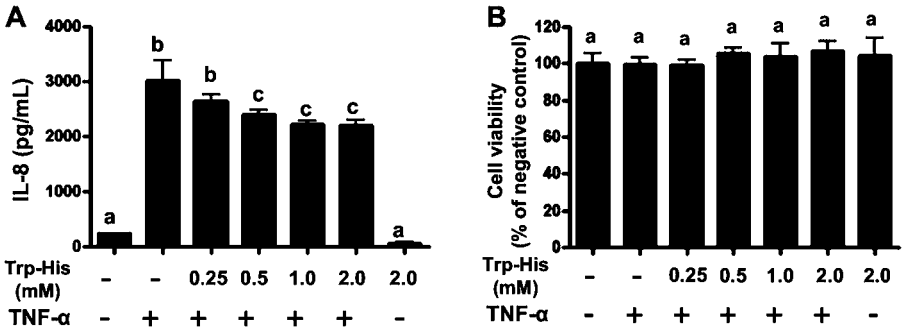

Figure 4. Effect of peptides on IL-8 secretion in HT-29 cells. (A) HT-29 cells were pretreated with medium or Trp-His at indicated concentrations for 2 h followed by TNF-α (2 ng/mL) for 2 h. IL-8 concentrations in the supernatants were measured by ELISA. Results are expressed as cytokine picograms per milliliter. (B) The viability of cells treated with Trp-His and/or TNF-α was analyzed by WST-1. Data represent means ± SEM of at least three independent tests. Values without a common letter are significantly different at $P < 0.05$.

expression of inflammatory mediators in the colonic tissues. As shown in Figure 2, treatment with Trp-His markedly ($P < 0.01$) attenuated the production of TNF-α and IL-6 when compared with the DSS mice (TNF-α, water, 229.2 ± 40.1 pg/mg protein, DSS, 527.6 ± 52.2 pg/mg protein, DSS + Trp-His, 198.5 ± 60.5 pg/mg protein; IL-6, water, 121.1 ± 22.8 pg/mg protein, DSS, 225.0 ± 32.3 pg/mg protein, DSS + Trp-His, 69.5 ± 27.4 pg/mg protein). In addition, Trp-His significantly inhibited the mRNA expression of pro-inflammatory cytokines and chemokines, including TNF-α ($P < 0.05$), IL-6 ($P < 0.01$), IL-1β ($P < 0.01$), IFN-γ ($P < 0.01$), and MCP-1 ($P < 0.01$) when compared with the DSS mice (Figure 3). There was no significant difference in the expression of anti-inflammatory cytokine IL-10. These findings suggested that Trp-His can exert potent anti-inflammatory effects in the colon of DSS-treated mice.

Effect of Trp-His on IL-8 Production in TNF-α-Stimulated HT-29 Cells. We explored the underlying mechanisms of anti-inflammatory effect of Trp-His using an intestinal epithelial cell line HT-29. TNF-α (2 ng/mL) was used to induce cellular inflammatory responses in HT-29 cells, and IL-8, a predominant pro-inflammatory chemokine produced in TNF-α-stimulated HT-29 cells,[27] was measured as an indicator of intestinal inflammation. As shown in Figure 4A, Trp-His significantly ($P < 0.05$) inhibited TNF-α-induced IL-8 secretion in HT-29 cells. Trp-His alone had no effect on IL-8 secretion. It was confirmed that Trp-His had no toxic effect at all concentrations used here (Figure 4B). The lowest concentration that significantly suppressed IL-8 production, 0.5 mM, was selected for further in vitro study.

Blocking Effect of L-Type Ca^{2+} Channels by Trp-His on TNF-α-Induced IL-8 Secretion. To clarify the structural requirement of Trp-His to exert an anti-inflammatory effect in HT-29 cells, the reverse sequence peptide of Trp-His, that is, His-Trp was used. Interestingly, His-Trp also significantly ($P < 0.01$) inhibited TNF-α-induced IL-8 secretion, and its inhibitory potential was to a similar degree as Trp-His (Figure 5A). As noted in our previous study, Trp-His can prevent an intracellular Ca^{2+}-mediated signaling via the blockade of L-type Ca^{2+} channels, and this blocking effect is similar to that of the reverse sequence peptide His-Trp.[18] This evidence allowed us to consider the involvement of L-type Ca^{2+} channels blocking in the regulation of IL-8 secretion induced by TNF-α. As specific inhibitors/activators of L-type Ca^{2+} channels, nifedipine, which binds to an extracellular side of the Ca^{2+} channel protein, verapamil (inhibitor), which binds to an intracellular side of the Ca^{2+} channel protein, and Bay K 8644 (activator) were selected. As shown in Figure 5B, both inhibitors

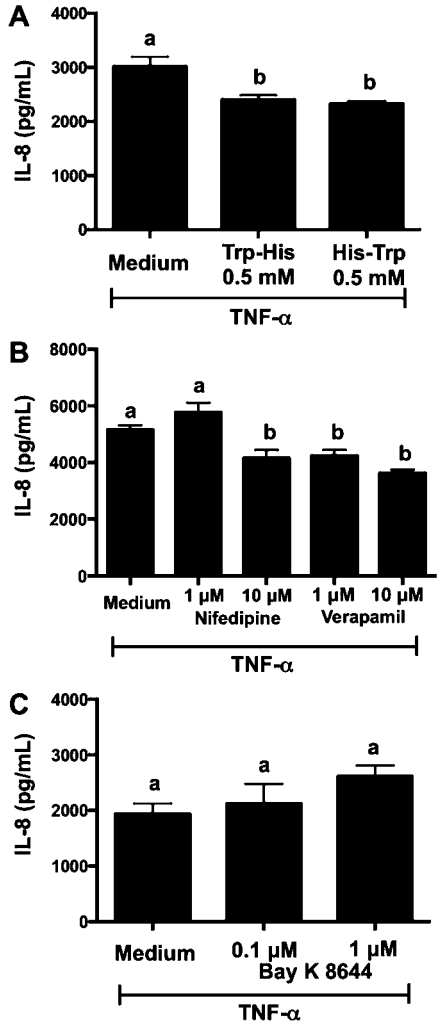

Figure 5. Effect of L-type Ca^{2+} channel blockers/agonist on IL-8 secretion in HT-29 cells. HT-29 cells were pretreated for 2 h with medium ((A) Trp-His or His-Trp, (B) nifedipine or verapamil, (C) Bay K 8644) at indicated concentrations followed by TNF-α (2 ng/mL) for 2 h. IL-8 concentrations in the supernatants were measured by ELISA. Results are expressed as cytokine picograms per milliliter. Data represent means ± SEM of at least three independent tests. Values without a common letter are significantly different at $P < 0.05$.

J. Agric. Food Chem. 2015, 63, 6041−6050

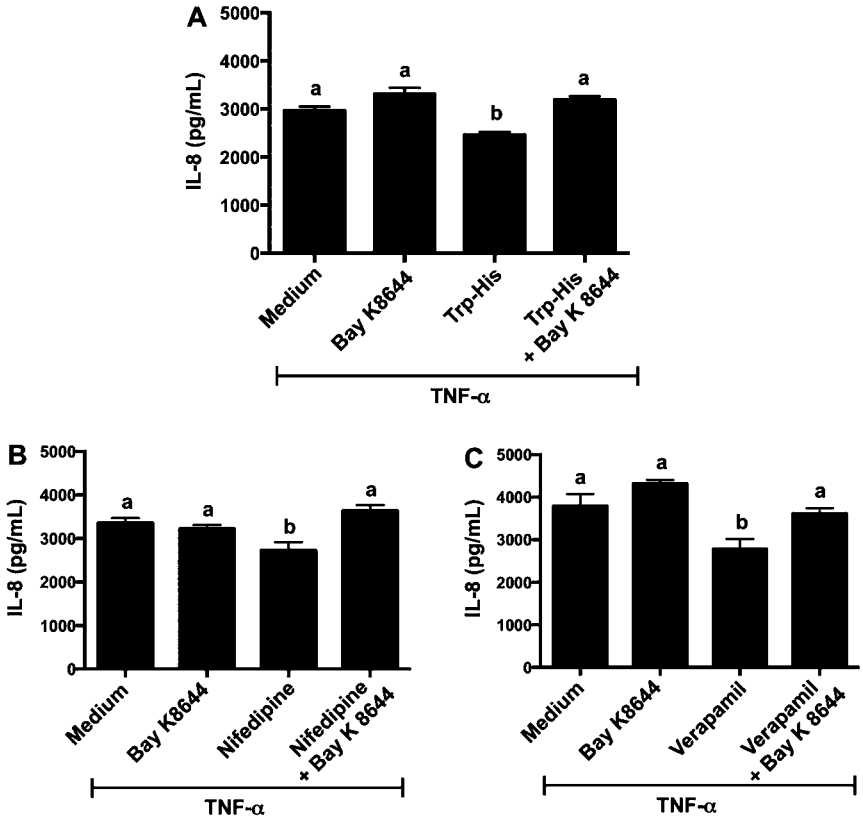

Figure 6. Effect of the combination of Trp-His or Ca^{2+} channel blockers with Bay K 8644. HT-29 cells were pretreated with medium, Bay K 8644 (0.1 μM), (A) Trp-His (0.5 mM), (B) nifedipine (10 μM), or (C) verapamil (1 μM). Bay K 8644 was added to the cells 1 h after the addition of Trp-His/blocker and incubated along with the peptide/blocker for 1 h before the addition of TNF-α (2 ng/mL). IL-8 concentrations in the supernatants were measured by ELISA. Results are expressed as cytokine picograms per milliliter. Data represent means ± SEM of at least three independent tests. Values without a common letter are significantly different at $P < 0.05$.

significantly ($P < 0.05$) reduced TNF-α-induced IL-8 production. In contrast, Bay K 8644 did not seem to affect the IL-8 secretion (Figure 5C), suggesting that the blockade of L-type Ca^{2+} channels may contribute to the decrease in IL-8 secretion observed here. To investigate whether the blockade of L-type Ca^{2+} channels by Ca^{2+} channel-blocking peptide Trp-His was similarly involved in the reduction of IL-8 production, cells were pretreated with Bay K 8644 (0.1 μM) in the presence of Trp-His (0.5 mM), followed by TNF-α treatment. The inhibitory effect of Trp-His on IL-8 secretion was completely abolished in the presence of Bay K 8644 (Figure 6A). Likewise, the inhibitory potential of nifedipine (10 μM) or verapamil (1 μM) was also abolished by Bay K 8644 (Figure 6B,C). These results indicate that the blocking effect of Trp-His on L-type Ca^{2+} channels is involved in the inhibition of IL-8 secretion in TNF-α-stimulated HT-29 cells. To further elucidate the anti-inflammatory effects of Trp-His on the TNF-α-mediated signals that control cytokine/chemokine production, we examined the effect of Trp-His on TNF-α-induced activation of mitogen-activated protein kinases (MAPKs) and nuclear factor (NF)-κB pathways. HT-29 cells were first treated with Trp-His, followed by stimulation with TNF-α for 1 or 2 h. Western blot analysis of total cell lysates using anti-phospho-MAPKs antibodies revealed that Trp-His significantly ($P < 0.05$) decreased TNF-α-induced phosphorylation of p38 and ERK after TNF-α stimulation for 2 h and that of JNK after 1 h stimulation when compared with TNF-α-treated cells (Figure 7A-C). Since phosphorylation of IκBα leads to the activation of NF-κB in TNF-α-stimulated HT-29 cells,[28] the involvement of Trp-His in the phosphorylation of IκBα was also investigated. As shown in Figure 7D, the phosphorylation level of IκBα was significantly ($P < 0.05$) increased after TNF-α stimulation for 1 h, and this was significantly ($P < 0.05$) reduced by treatment with Trp-His. These findings demonstrate that Trp-His can regulate TNF-α-mediated MAPKs/NF-κB signaling pathways in HT-29 cells.

DISCUSSION

The present study demonstrated that oral administration of Trp-His (100 mg/kg BW/day) significantly reduced the typical DSS-induced colitis symptoms and exerted anti-inflammatory effects in the mouse model of colitis. In vitro, the blocking effect of Trp-His on L-type Ca^{2+} channels contributed to the attenuation of TNF-α-induced IL-8 secretion in intestinal epithelial cell line HT-29. We further elucidated that Trp-His inhibited the activation of p38, ERK, JNK, and IκBα, which control pro-inflammatory mediator production.

Although the etiology of IBD is still unclear, overproduction of pro-inflammatory cytokines and chemokines has been shown to play an important role in the progression of colitis. TNF-α, IL-6, and IL-1β have been reported as key cytokines to amplify mucosal immune responses in IBD patients.[29] Current evidence suggests that IFN-γ and TNF-α are involved in the dysfunction of intestinal epithelial barrier, leading to the excessive entry of antigens, which initiates the inflammatory responses.[30] Chemokines such as MCP-1 promote the infiltration/migration of immune cells to areas of inflammation.[31] Our previous studies have demonstrated that dietary di/tripeptides could attenuate

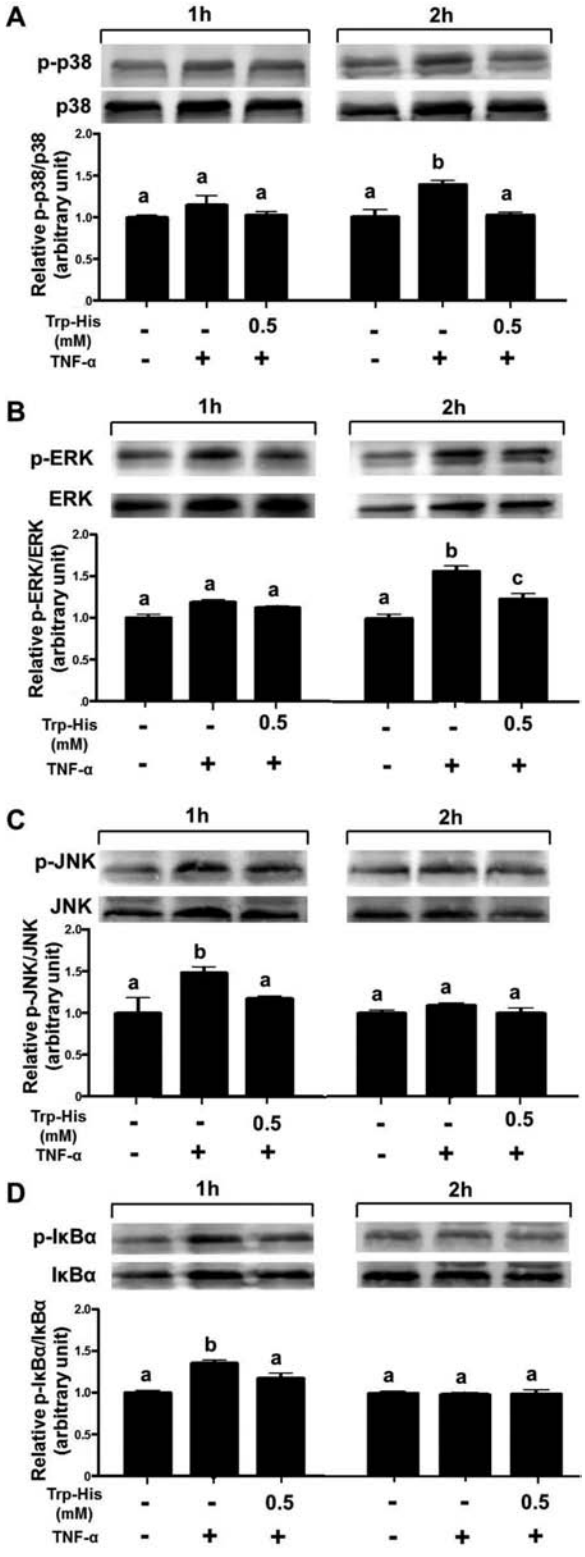

Figure 7. Effect of Trp-His on the phosphorylation of MAPKs and IκBα. HT-29 cells were pretreated with Trp-His followed by TNF-α (2 ng/mL) for 1 or 2 h. The expression of phosphorylated or total MAPKs in HT-29 cells was determined by Western blotting. The respective means of (A) p-p38/p38, (B) p-ERK/ERK, (C) p-JNK/JNK, and (D) p-IκBα/IκBα are reported as a ratio relative to the negative control. Data represent means ± SEM of at least three independent tests. Values without a common letter are significantly different at $P < 0.05$.

the development of colitis via down-regulating the expression of pro-inflammatory mediators in animal models of colitis.[8,9,12] Here, we observed that Trp-His reduced DSS-induced colitis signs, including BW loss, colon shortening, and diarrhea, and attenuated the local expression of TNF-α, IL-6, IL-1β, IFN-γ, and MCP-1 in the colon of DSS-treated mice. These results are consistent with a previous study which demonstrated that tripeptide Val-Pro-Tyr[9] at a similar dose could lessen the severity of colitis in DSS-treated mice. This would suggest that Trp-His may exert its anti-inflammatory effects by regulating the local expression of cytokines/chemokines, thereby contributing to the prevention of DSS-induced colitis development.

To elucidate the underlying mechanisms of anti-colitis by Trp-His, we further examined the anti-inflammatory effect of Trp-His in vitro. The HT-29 human colon carcinoma cell line has been shown to be a useful model for studying the physiology and immune function of intestinal epithelial cells, and the pattern of secretion of cytokines such as IL-8 by TNF-α stimulation was found to be similar in HT-29 cells and freshly isolated human colon epithelial cells.[32,33] Cho et al.[34] reported that the phytochemical arvelexin (4-methoxyindole-3-acetonitrile) inhibited TNF-α-mediated IL-8 production via NF-κB inactivation in HT-29 cells, and its anti-inflammatory potential was correlated with anti-colitis activity in DSS-treated mice. Here, we observed that Trp-His reduced TNF-α-induced IL-8 secretion by HT-29 cells. Interestingly, His-Trp, a Ca^{2+} channel-blocking peptide,[18] and L-type Ca^{2+} channel blockers (nifedipine and verapamil) also exert the inhibitory potential of TNF-α-induced IL-8 production. The expression of L-type Ca^{2+} channels, not other N- or P-type, has been confirmed in the same cell line, HT-29.[35] Furthermore, the elevation of $[Ca^{2+}]_i$ promotes the intracellular inflammatory signaling, leading to the production of IL-8 in an intestinal epithelial cell.[36] These reports imply that L-type Ca^{2+} channels may be a potential target for controlling inflammatory responses in HT-29 cells. The specific L-type Ca^{2+} channel agonist Bay K 8644 was employed here to confirm whether the anti-inflammatory effects of Trp-His were mediated via blockade of L-type Ca^{2+} channels. As expected, the combination treatment of Trp-His with Bay K 8644 completely abolished the inhibitory effect of Trp-His on TNF-α-induced IL-8 production. Similarly, the inhibitory effect of nifedipine (DHP type blocker) or verapamil (PAA type blocker) on IL-8 production was also abolished by Bay K 8644. These results are consistent with the paper by Zahradnikova et al.[37] which showed that the presence of Bay K 8644 reduced the inhibitory potency of the Ca^{2+} channel by a DHP-type blocker (in a competitive manner) or a PAA-type blocker (in a negative allosteric interaction). This would suggest that the blockade of L-type Ca^{2+} channels by Trp-His may contribute to the regulation of the TNF-α-induced inflammatory responses in HT-29 cells.

The activation of p38, ERK, JNK, and NF-κB was involved in the TNF-α-induced IL-8 secretion in HT-29 cells.[38] Western blot analysis in our present study demonstrated that the phosphorylation of MAPKs and IκBα was reduced by Trp-His in TNF-α-stimulated HT-29 cells. These results are consistent with studies which demonstrated that anti-inflammatory polyphenols can exert their effect by attenuating MAPKs activation after 1 h of stimulation with TNF-α in a human intestinal epithelial cell line,[39] and the NF-κB activation in TNF-α-stimulated HT-29 cells was shown to be induced without the degradation of IκBα.[40] These data suggest that Trp-His could exert anti-inflammatory effects via the inhibition

J. Agric. Food Chem. 2015, 63, 6041−6050

of MAPKs and NF-κB activation in TNF-α-mediated signaling pathways. The binding of TNF-α to TNF receptors initiates the forming of a signaling complex with TNF receptor-associated factors (TRAFs), thereby the complex activating MAPK kinase kinases (MAPKKKs), resulting in the subsequent activation of Ca^{2+}-dependent MAPKs and NF-κB.[41] In addition, activation of Ca^{2+}/CaM-dependent protein kinase II (CaMK II) also contributes to NF-κB activation in TNF-α-mediated inflammatory responses.[42] The activated CaMK II is involved in the facilitation of Ca^{2+} entry by phosphorylating the intracellular site of L-type Ca^{2+} channel.[43] In our previous study, Trp-His suppressed the phosphorylation of L-type Ca^{2+} channel via the inhibition of CaMK II activation in VSMCs.[19] Moreover, we recently demonstrated that the CaMK II inhibition by Trp-His would be caused by the inhibition of Ca^{2+}−CaM formation with the binding free energy of −49.1 kJ/mol in in silico analysis.[44] We successfully determined that Trp-His was absorbed as the peptide form into Sprague−Dawley rat blood, showing a maximal level at 1 h after single oral administration at 10 mg/kg BW (maximal concentration, 28.7 ± 8.9 pmol/mL plasma), and the peptide was preferably transported across the intestinal membrane by a proton-coupled peptide transporter 1 (PepT1).[15] Thus, these findings allow us to consider that the underlying mechanisms of the anti-inflammatory effect by Trp-His may be involved in the regulation of the CaMK II-related signaling through the blockade of L-type Ca^{2+} channels and/or the inhibition of Ca^{2+}−CaM formation on the intestine (Figure 8). Further studies are needed for clarifying whether Trp-His and other Ca^{2+} channel-blocking peptides can regulate Ca^{2+}−CaM/CaMK II-mediated inflammatory signaling so as to attenuate inflammatory responses.

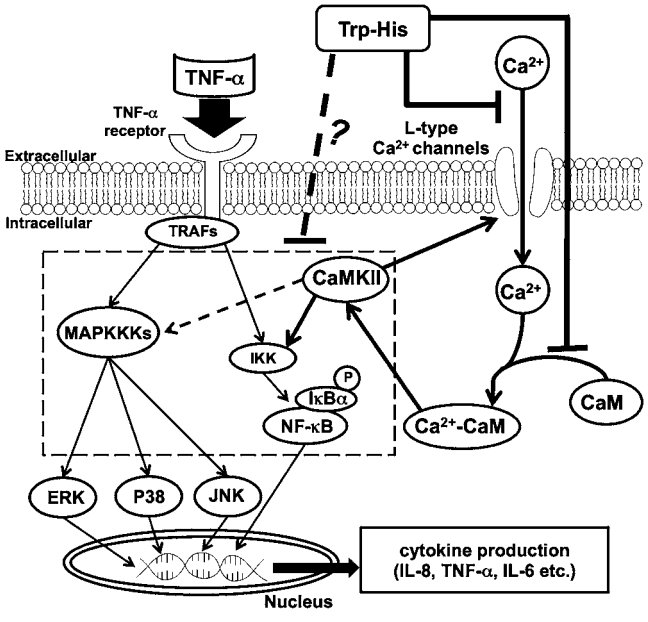

Figure 8. Possible role of Trp-His on the regulation of TNF-α-induced inflammatory signaling pathways in the intestine. The present study provides the first evidence that Trp-His reduces the TNF-α-induced IL-8 secretion through the blockade of L-type Ca^{2+} channels and inhibits the activation of MAPKs/NF-κB in HT-29 cells. Trp-His would attenuate the phosphorylation of L-type Ca^{2+} channels via the inhibition of CaMK II[19] and inhibit the formation of Ca^{2+}−CaM complex that is required for CaMK II activation.[44] Considering that the activated CaMK II is involved in the regulation of the subsequent TNF-α-mediated inflammatory signaling pathways, these data suggest that Trp-His may play a potential role in the inhibition of Ca^{2+}−CaM/CaMK II pathways.

In conclusion, the present study demonstrated that the anti-atherosclerotic peptide Trp-His prevented the development of DSS-induced colitis in mice in part by down-regulating the expression of pro-inflammatory cytokines. Trp-His significantly reduced TNF-α-induced IL-8 secretion through the blockade of L-type Ca^{2+} channels in HT-29 intestinal epithelial cells, which suggests that the blockade of L-type Ca^{2+} channels may play a beneficial role in attenuating the intestinal inflammatory responses. The anti-inflammatory activity of Trp-His was also associated with the inhibition of Ca^{2+} signaling pathway-mediated activation of MAPKs (p38, JNK, and ERK) and IκBα. Therefore, L-type Ca^{2+} channel blocking peptides such as Trp-His would be a potential preventative peptide for the amelioration of intestinal inflammation.

assess host responses to the implantation of biomaterials and the exposure of ionizing radiation.[17,18] It has been used to evaluate the anti-inflammatory potentials of vanillin and ginger extract on experimental colitis.[16] It also has been utilized to monitor the anti-inflammatory effects of medicinal herbs on LPS-induced acute systemic inflammation and carbon tetrachloride-induced chronic hepatitis.[19,20] Immunohistochemical (IHC) staining was further performed to elucidate the anti-inflammatory mechanisms of ginger and zingerone. Our findings suggested that ginger and zingerone were likely to be broad-spectrum anti-inflammatory agents in most organs that suppressed the activation of NF-κB, the production of interleukin-1β (IL-1β), and the infiltration of inflammatory cells.

MATERIALS AND METHODS

Chemicals. LPS (from *Escherichia coli* 055:B5), zingerone, and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) were purchased from Sigma (St. Louis, MO). MG-132, a NF-κB inhibitor, was purchased from Santa Cruz (Dallas, TX). D-Luciferin was purchased from Xenogen (Hopkinton, MA). Mouse monoclonal antibody against p65 was purchased from Chemicon (Temecula, CA). Rabbit polyclonal antibodies against IL-1β and CD11b were purchased from Santa Cruz (Dallas, TX) and Abcam (Cambridge, UK), respectively.

Preparation of Ginger Extract. Dried ginger was purchased from Xin Lung Chinese Herbal Medicine Pharmacy (Taichung, Taiwan). The voucher specimen has been deposited in Graduate Institute of Chinese Medicine, China Medical University. Ginger was ground to a fine powder and extracted by mixing 20 g of powder with 100 mL of ethanol at room temperature with shaking. Three days later, the supernatant was collected and stored at −30 °C for further analysis.

Cell Culture. Recombinant HepG2/NF-κB cells, which carried NF-κB-driven luciferase genes, were constructed previously.[19] HepG2/NF-κB cells were maintained in Dulbecco's modified Eagle's medium (Life Technologies, Gaithersburg, MD) supplemented with 10% fetal bovine serum (Hyclone, Logan, Utah) and incubated at 37 °C with 5% CO_2.

Luciferase Assay and Cell Viability Assay. HepG2/NF-κB cells (2×10^7 cells) were seeded in a 96-well plate and incubated at 37 °C overnight. LPS (100 ng/mL), MG-132 (5 μM), or various amounts of ginger and zingerone were then added to cells and incubated at 37 °C for 24 h. Cell viability was analyzed by MTT colorimetric assay as described previously.[19] Luciferase assay was performed as described previously.[19] Relative NF-κB activity was calculated by dividing the relative luciferase units (RLUs) of compound-treated cells by the RLUs of solvent-treated cells.

Animal Experiments. Transgenic mice carrying the luciferase genes driven by NF-κB-responsive elements were constructed as described previously.[17] Mouse experiments were conducted under ethics approval from China Medical University Animal Care and Use Committee (Permit No. 97-28-N).

Six-week-old female transgenic mice were randomly divided into four groups of five mice: (1) mock, no treatment; (2) LPS, (3) LPS/ginger, and (4) LPS/zingerone. Mice were challenged intraperitoneally with 1 mg/kg LPS and then orally with 100 mg/kg ginger extract or zingerone 10 min later. Four hours later, mice were imaged for the luciferase activity and subsequently sacrificed for *ex vivo* imaging and IHC staining.

***In Vivo* and *ex Vivo* Bioluminescence Imaging.** Bioluminescence imaging was performed as described previously.[17] Briefly, for *in vivo* imaging, mice were injected intraperitoneally with 150 mg/kg D-luciferin, placed in the IVIS Imaging System 200 Series chamber (Xenogen, Hopkinton, MA) 5 min later, and imaged for 1 min. Photons emitted from bodies were quantified using Living Image software (Xenogen, Hopkinton, MA).The intensity of the signal from bodies was quantified as the sum of all photon counts per second and presented as photon/s. For *ex vivo* imaging, mice were injected with D-luciferin and sacrificed 5 min later. The organs were removed immediately, placed in the IVIS chamber, and imaged for 1 min. The intensity of signal was quantified as the sum of all detected photon counts per second with the region of interest and presented as photon/(s·cm^2·steradian (sr)).

Cytokine Enzyme-Linked Immunosorbent Assay (ELISA). The amounts of proinflammatory cytokines, including IL-1β and tumor necrosis factor-α (TNF-α), in sera were quantified using Quantikine Mouse ELISA kits (R&D Systems, Minneapolis, MN). Briefly, mouse sera were added to wells coated with anti-IL-1β or anti-TNF-α antibodies and incubated at room temperature for 2 h. Biotinylated anti-mouse IL-1β or TNF-α antibodies, and avidin-horseradish peroxidase were added sequentially to wells. After a final wash, chromogenic substrate (tetramethylbenzidine) was added, and the reaction was stopped with 2 N H_2SO_4. The absorbance at 450 nm was measured using an ELISA reader (Multiskan GO, Thermo Scientific, Waltham, MA).

IHC Staining. Parafilm-embedded small intestines were cut into 5-μm-thick sections, deparaffinized in xylene, and rehydrated in graded ethanol. Sections were incubated with anti-p65, anti-IL-1β, or anti-CD11b antibodies overnight at 4 °C and then incubated with a biotinylated secondary antibody (Zymed Laboratories, Carlsbad, CA) for 20 min at room temperature. Finally, the sections were incubated with avidin−biotin complex reagent and stained with 3,3′-diaminobenzidine according to manufacturer's protocol (Histostain-Plus, Zymed Laboratories, Carlsbad, CA).

Statistics Analysis. Data were presented as mean ± standard error. Student's *t*-test was used for the comparison between two experiments. A value of $p < 0.05$ was considered statistically significant.

RESULTS

Ginger and Zingerone Suppressed LPS-Induced NF-κB Activities in Cells. Zingerone is a phenolic alkanone of ginger extract (Figure 1), and the content of zingerone was approximately 0.01 mg/mL in ethanolic extract of ginger by high-performance liquid chromatography analysis (see Supplementary Figure 1 of the Supporting Information). We first analyzed the effects of ginger and zingerone on LPS-induced NF-κB activation in cells. HepG2/NF-κB cells were treated with LPS, followed by MG-132 or various amounts of ginger and zingerone. As shown in Figure 2, LPS increased the NF-κB activity by 4-fold, compared with mock-treated cells. MG-132, a well-known NF-κB inhibitor, significantly suppressed LPS-

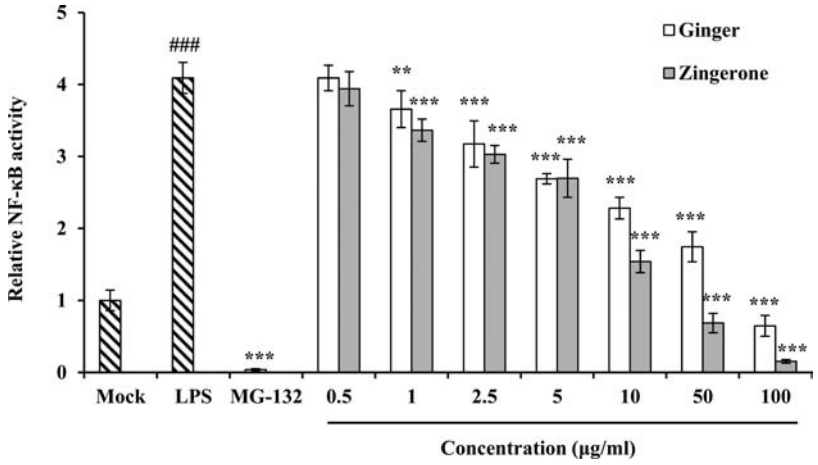

Figure 2. Effects of ginger and zingerone on LPS-induced NF-κB activities in cells. HepG2/NF-κB cells were treated with 100 ng/mL LPS and various amounts of ginger extract and zingerone. MG-132 (5 μM) was used as a positive control. NF-κB activity was measured 24 h later by luciferase assay. Results are expressed as relative NF-κB activity, which is presented as the comparison with RLU relative to solvent-treated cells. Values are mean ± standard error (n = 6). $^{###}p < 0.001$, compared with mock. $^{**}p < 0.01$, $^{***}p < 0.001$, compared with LPS.

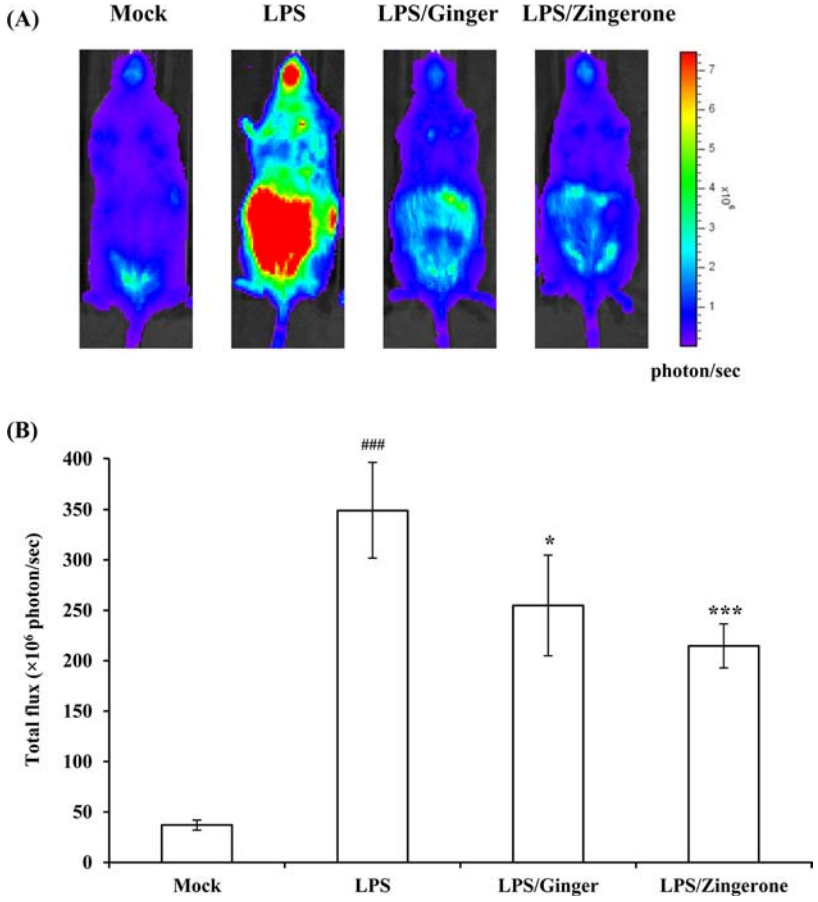

Figure 3. NF-κB-driven luminescence in living mice. (A) *In vivo* image. Transgenic mice were administered 1 mg/kg LPS and then treated with 100 mg/kg ginger or zingerone. Four hours later, mice were injected intraperitoneally with D-luciferin and imaged for 1 min. The color overlay on the image represents the photons per second emitted from mice, as indicated by the color scale. Photos are representative images (n = 5/group). (B) Quantification of photon emission from the whole body. Values are mean ± standard error. $^{###}p < 0.001$, compared with mock. $^{*}p < 0.05$, $^{***}p < 0.001$, compared with LPS.

induced NF-κB activities. Ginger and zingerone decreased NF-κB activities induced by LPS, and the decrease displayed a dose-dependency. The maximal inhibition (84.5% ± 3.5% and 96.2% ± 0.6%) was observed at 100 μg/mL ginger and zingerone, respectively. Moreover, zingerone was more effective than ginger in the inhibition of LPS-induced NF-κB activity. No visible cytotoxic effects were observed, judged by MTT assay (data not shown). These findings suggested that ginger and zingerone significantly suppressed NF-κB activities induced by LPS in cells.

J. Agric. Food Chem. 2015, 63, 6051−6058

Ginger and Zingerone Suppressed LPS-Induced Inflammation in Mice. The *in vivo* anti-inflammatory effects of ginger and zingerone were then analyzed by NF-κB bioluminescent imaging. Ginger extract or zingerone was orally given to transgenic mice, which had been challenged with 1 mg/kg LPS. The NF-κB-dependent bioluminescence was monitored 4 h later. As shown in Figure 3, LPS induced an approximately 4-fold increase in NF-κB-driven luminescent intensity, compared with mock-treated animals. The induced luminescence was observed over the whole body, and the strongest luminescence appeared in the abdominal region. Ginger and zingerone significantly decreased the LPS-induced luminescent intensity by 26.9% ± 14.3% and 38.5% ± 6.2%, respectively. These findings suggested that ginger and zingerone suppressed LPS-induced NF-κB-dependent luminescence in mice.

NF-κB plays a crucial role in the regulation of immunity. We wondered whether the intensity of NF-κB-driven luminescence was correlated with inflammation. The amount of proinflammatory cytokines, including IL-1β and TNF-α, in sera were therefore quantified by ELISA. As shown in Figure 4, LPS

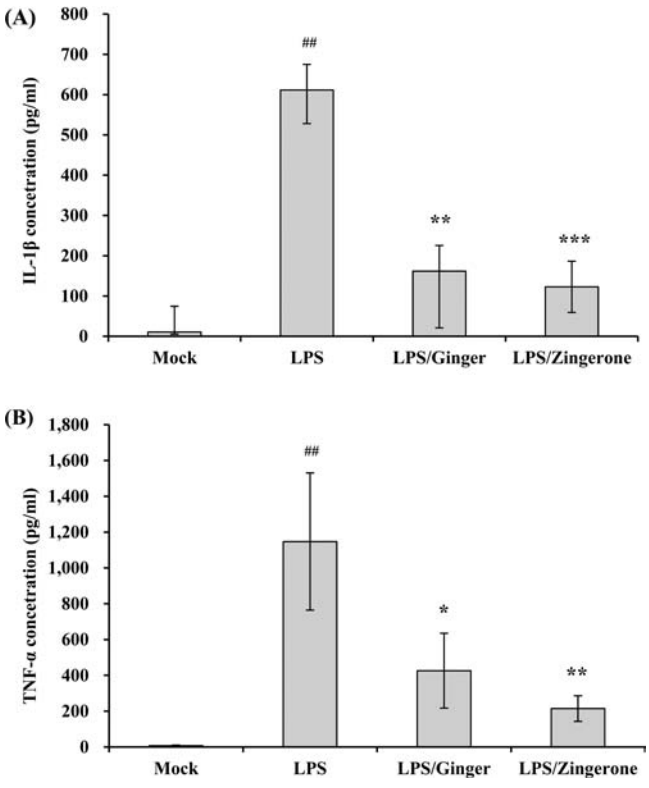

Figure 4. Effects of ginger and zingerone on LPS-induced IL-1β and TNF-α production in sera. Transgenic mice were challenged with 1 mg/kg LPS and then given with 100 mg/kg ginger or zingerone. Four hours later, mice were sacrificed, and the amount of IL-1β (A) and TNF-α (B) in sera was quantified by ELISA. Values are mean ± standard error (n = 5/group). ##p < 0.01, compared with mock. *p < 0.05, **p < 0.01, ***p < 0.001, compared with LPS.

significantly increased the amount of IL-1β and TNF-α in sera by 55.6 ± 7.6 and 172 ± 57.5 fold, respectively. However, ginger and zingerone significantly decreased LPS-induced IL-1β and TNF-α production in sera. Ginger reduced the production of IL-1β and TNF-α by 73.5% ± 23% and 63.9% ± 18.2%, respectively, while zingerone decreased IL-1β and TNF-α production by 79.9% ± 10.4% and 81.3% ± 6.2%, respectively. These data suggested that ginger and zingerone suppressed LPS-induced systemic inflammation in mice. Moreover, the correlation between NF-κB-dependent luminescent intensity and cytokine production indicated the representative of NF-κB-driven luminescence on the degree of inflammation.

Ginger and Zingerone Suppressed LPS-Induced Inflammation in Most Organs. Previous studies have shown that ginger or zingerone displayed anti-inflammatory efficacies in individual organs, such as liver, lung, brain, and colon. We would like to know whether ginger and zingerone exhibited broad-spectrum anti-inflammatory actions in most organs. Transgenic mice were therefore challenged with LPS and orally administered ginger extract and zingerone, and NF-κB-driven luminescence in organs was monitored 4 h later. As shown in Figure 5, luminescent intensities of organs were increased by LPS, suggesting that intraperitoneal injection of LPS induced inflammation in most organs. The maximal induction of luminescence by LPS was observed in kidney (15.9 ± 8 fold), followed by intestine (15.2 ± 6 fold), brain (10.4 ± 1.4 fold), heart (5.7 ± 1.5 fold), liver (4.7 ± 1.9 fold), spleen (4.7 ± 1.2 fold), lung (3.7 ± 1.4 fold), and stomach (2.7 ± 0.7 fold). Administration of ginger and zingerone significantly decreased LPS-induced NF-κB-driven luminescence in most organs. The maximal inhibition of LPS-induced luminescence by ginger and zingerone was observed in intestine, followed by kidney, liver, heart, and brain. Zingerone significantly decreased LPS-induced luminescence in lung, while ginger slightly decreased luminescent signals in lung. Moreover, both ginger and zingerone slightly decreased LPS-induced luminescent intensities in spleen.

We further analyzed the anti-inflammatory effects of ginger and zingerone in different segments of small intestine. We divided the small intestine into 35 segments, and the length ratio of duodenum, jejunum, and ileum was 1:3:2. The intensity of signal from each segment was quantified as photon/s. The suppression of LPS-induced luminescent signal by ginger or zingerone was further represented as the inhibitory percentage. As shown in Figure 6, LPS increased NF-κB-driven luminescence in whole small intestine, and strong luminescence was observed from segment 17 to 30, which corresponded to the region between midjejunum and midileum. Both ginger and zingerone suppressed LPS-induced bioluminescent intensity in whole small intestine, and the inhibition from segment 14 to 35 was >50% by ginger and zingerone. Overall, these data suggested that ginger and zingerone displayed broad-spectrum anti-inflammatory activities in most organs. Additionally, *ex vivo* imaging first showed that LPS induced a more severe inflammation in the region spanning from midjejunum to midileum. Moreover, LPS-induced luminescent signal in the junction of jejunum and ileum was suppressed efficiently by ginger and zingerone.

Ginger and Zingerone Inhibited LPS-Induced NF-κB Activation, IL-1β Production, and Inflammatory Cell Infiltration in Small Intestine. IHC staining was further performed to analyze the anti-inflammatory effects and mechanisms of ginger and zingerone in small intestine. As shown in Figure 7, the number of IL-1β-positive cells was increased by LPS, compared with mock. However, the expression of IL-1β-positive area was decreased by ginger and zingerone. In addition, LPS increased the number of CD11b-positive cells, including monocytes and granulocytes, while ginger and zingerone inhibited the expression of CD11b-

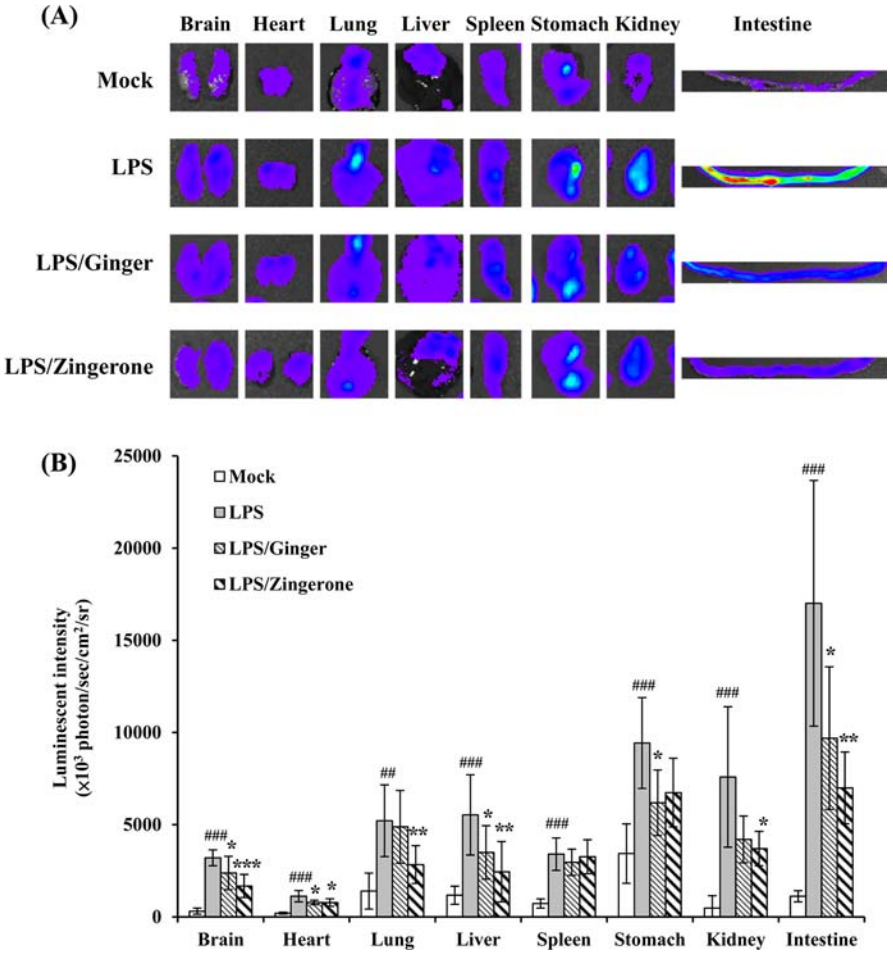

Figure 5. NF-κB-dependent luminescence in individual organs. (A) *Ex vivo* imaging. Transgenic mice were administered 1 mg/kg LPS and then treated with 100 mg/kg ginger or zingerone. Four hours later, mice were injected intraperitoneally with D-luciferin. Five minutes later, mice were sacrificed, and organs were excised rapidly and subjected to imaging (n = 5/group). (B) Quantification of photon emissions from organs. Values are mean ± standard error. ##p < 0.01, ###p < 0.001, compared with mock. *p < 0.05, **p < 0.01, ***p < 0.001, compared with LPS.

positive area. These data suggested that ginger and zingerone suppressed the production of IL-1β and the infiltration of inflammatory cells, resulting in the amelioration of LPS-inflammation in small intestine.

Because NF-κB plays a critical role in inflammation, we analyzed the level of NF-κB activity by IHC staining. The monoclonal antibody used here was against p65 nuclear localization sequence, which was blocked by inhibitory IκB when NF-κB was inactivated. LPS increased the number of p65-positive cells, while ginger and zingerone decreased the p65-positive area. These findings suggested the inhibition of LPS-induced inflammation byginger and zingerone might be through NF-κB signaling pathway.

DISCUSSION

In this study, we comprehensively evaluated the anti-inflammatory effects of ginger and zingerone by NF-κB bioluminescent imaging. Because of the light absorption by pigmented molecules and the low spatial resolution of bioluminescent imaging, we performed *ex vivo* imaging to monitor the effects of ginger and zingerone on individual organs.[21] Previous studies have shown that ginger extract and zingerone display anti-inflammatory activities in specific organs. For example, ginger extracts ameliorate LPS-induced hepatic injury and experimental colitis in mice.[16,22] Administration of ginger extracts significantly represses paw and joint swelling in rats with severe chronic adjuvant arthritis.[23] Ginger also exhibits a protective role on the diabetic brain by modulating the astroglial response to the injury in rats.[24] Moreover, zingerone attenuates LPS-induced lung injury in mice.[15] By NF-κB bioluminescent imaging, we found that administration of ginger and zingerone inhibited LPS-induced NF-κB-driven luminescence in brain, lung, liver, and colon. However, we newly identified that ginger and zingerone reduced LPS-induced luminescent intensities in heart, stomach, kidney, and small intestine. In addition, the maximal inhibition of LPS-induced luminescent signal by ginger and zingerone was observed in intestines, followed by kidney. The *in vivo* metabolism or pharmacokinetics of ginger and zingerone has been reported. After oral administration of 2 g of ginger extract in human, the glucuronide and sulfate metabolites of ginger components, such as gingerols and shogaol, are detected in plasma and gastrointestinal tract.[25] Oral dosage (100 mg/kg) of zingerone in rats results in the urinary excretion of glucuronide and sulfate conjugates of zingerone.[26] The distribution of ginger extract and zingerone in gastrointestinal tract and kidney might explain their anti-inflammatory effects in small intestine and kidney. Because of the correlation between NF-κB-driven luminescent signals and inflammation, we speculated that ginger and zingerone exhibited broad-spectrum anti-inflammatory activities

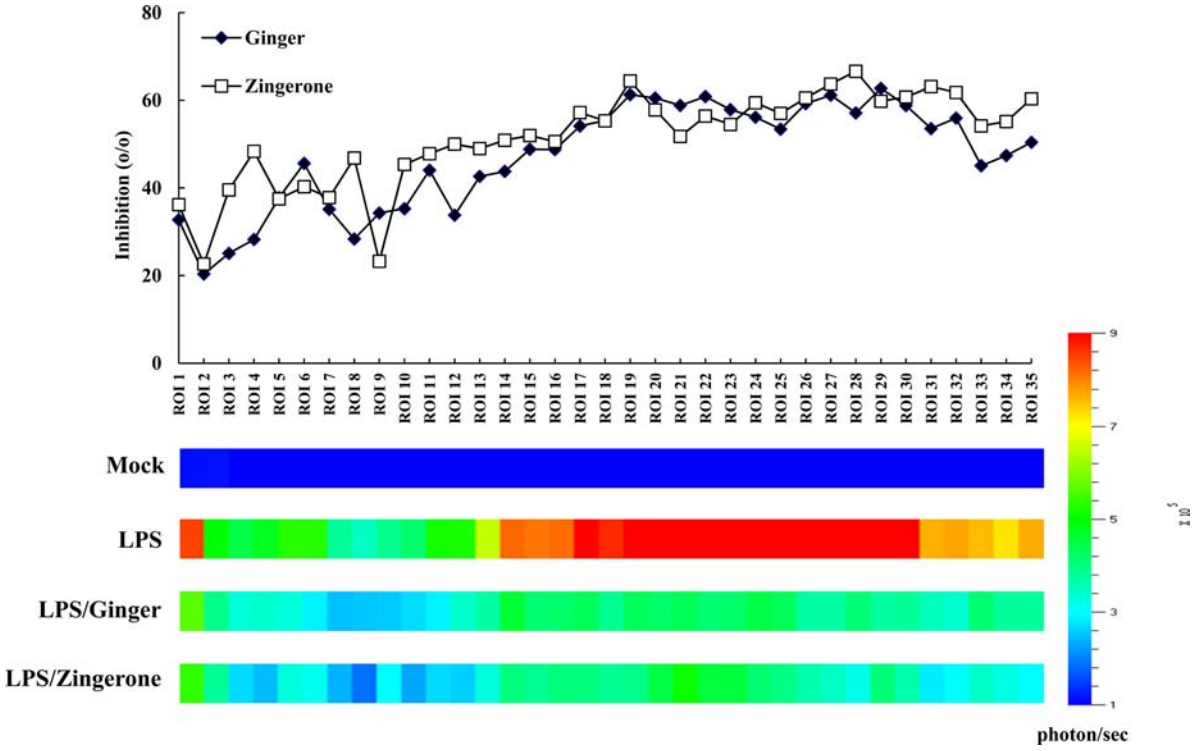

Figure 6. Anti-inflammatory effects of ginger and zingerone in various segments of small intestine. Transgenic mice were challenged with 1 mg/kg LPS and then given 100 mg/kg ginger or zingerone. Four hours later, mice were injected intraperitoneally with D-luciferin. Five minutes later, mice were sacrificed, and organs were excised rapidly and subjected to image. Small intestine was divided equally into 35 segments, and the photon emission from each segment was quantitated. Results are expressed as inhibition (%). Heatmap of small intestine is shown on the bottom. The color overlay on the heatmap represents the photons per second emitted from each segment of small intestine, as indicated by the color scale.

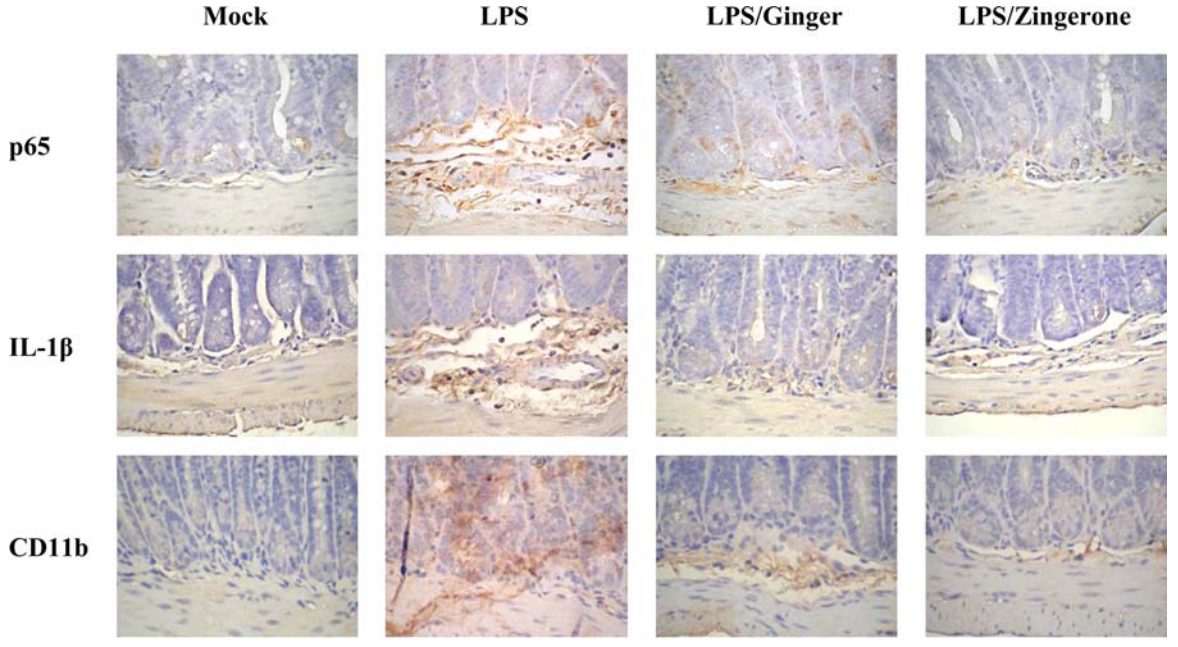

Figure 7. IHC staining analysis of p65, IL-1β, and CD11b in jejunum. Transgenic mice were challenged with 1 mg/kg LPS and then given 100 mg/kg ginger or zingerone. Four hours later, mice were sacrificed. Section of midjejunum was stained with antibodies against p65, IL-1β, and CD11b (400× magnification). Photos are representative images (n = 5/group).

that suppressed the LPS-induced inflammation in various organs.

Anti-inflammatory mechanisms of ginger and its constituents have been analyzed in *in vitro* and *in vivo* studies. For instance, ginger extract ameliorates LPS-induced hepatic injury via inhibiting the production of proinflammatory cytokines and attenuating the mitogen-activated protein kinases and NF-κB signaling pathways.[22] It also inhibits the activities of cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS) and thus inhibits the synthesis of prostaglandins and

DOI: 10.1021/acs.jafc.5b01801
J. Agric. Food Chem. 2015, 63, 6051−6058

NO, mediators of inflammation.[27] Ginger derivatives, such as 6-shogaol, reduce osteoarthritis symptoms by inhibiting toll-like receptor 4 (TLR-4)-mediated innate immunity and cathepsin-k activity.[28] 6-Shogaol also displays a neuroprotective effect via inhibiting iNOS, COX-2, proinflammatory cytokines, and NF-κB activities in LPS-treated microglial cells.[14] In addition, 1-dehydro-10-gingerdione inhibits TLR-4-mediated signaling cascades and cytokine expression via blockade of LPS binding to myeloid differentiation protein 2, a coreceptor of TLR-4 in macrophages.[29] In this study, we found that ginger and zingerone inhibited LPS-induced NF-κB activities in various organs in mice. Ginger and zingerone also suppressed the nuclear translocation of NF-κB subunit p65, the production of IL-1β, and the infiltration of granulocytes in small intestine. Overall, this study suggested that ginger and zingerone shared a common anti-inflammatory mechanism by inhibiting NF-κB activities and proinflammatory cytokine production in LPS-induced systemic inflammation. Moreover, ginger exhibits a nonsteroidal anti-inflammatory activity via inhibiting the activities of COX-2 and iNOS in other studies, probably explaining why ginger displayed a broad-spectrum anti-inflammatory activity in various organs in this study.

Detailed anti-inflammatory effects of ginger and zingerone in small intestine were evaluated here. It is interesting to find that LPS increased NF-κB-driven luminescence in the entire small intestine, especially from the middle portion of jejunum to the end of ileum. It is known that LPS activates macrophages, neutrophils, and dendritic cells via binding to TLR-4 and activating downstream NF-κB activity. The activated immune cells then initiate the inflammatory response and present antigens to lymphocytes in lymph nodes.[30] In comparison with duodenum, jejunum and ileum have abundant Peyer's patches, organized lymphoid nodules, in mice. Thus, we speculated that LPS induced maximal NF-κB-driven luminescence in jejunum and ileum might result from the abundance of Peyer's patches. We also found that ginger and zingerone suppressed LPS-induced NF-κB-dependent bioluminescent signals in the entire small intestine, especially in the region between midjejunum and midileum. Zingerone possesses the vanillyl moiety, which is considered important for the activation of vanilloid receptor 1 (VR1) expressed in nociceptive sensory neurons.[31] A recent study shows that activated VR1 protects against LPS-mediated renal injury possibly via reducing renal inflammation responses.[32] In addition, sensory VR1 has been found to modulate cytokine response to LPS and thereby induce the subsequent anti-inflammatory effect in the gut mucosa.[33] VR1 nerve fibers are observed within enteric ganglia of jejunum and ileum,[34] probably explaining why zingerone displayed more activities in jejunum and ileum than in duodenum.

In conclusion, we comprehensively evaluated the anti-inflammatory effects of ginger and zingerone on LPS-induced systemic inflammation via NF-κB bioluminescent imaging. Our data showed for the first time that ginger and zingerone suppressed NF-κB-driven luminescence in most organs. In addition, our findings suggested that ginger and zingerone are likely to be broad-spectrum anti-inflammatory agents that suppress the activation of NF-κB, the production of IL-1β, and the infiltration of inflammatory cells in most organs.

Figure 1. Structures of carotenoids from red mamey and related compounds.

DRX Avance II (500/125 MHz for $^{1}H/^{13}C$) spectrometer (Bruker Corp., Billerica, MA, USA). Chemical shifts are referenced to internal TMS (^{1}H) or to the residual solvent signals (^{13}C).

MS Analysis. Samples were dissolved in MeOH and infused directly using a Fusion 100 T syringe pump (Thermo Fisher, Waltham, MA, USA) to a Q-Exactive quadrupole-orbitrap hybrid mass spectrometer (Thermo Fisher) with HESI source operated in positive ion mode. Data acquisition and analysis were performed by using Xcalibur (version 2.2 SP1.48). The source was operated with a spray voltage of 3500 V. Both sheath and auxiliary gases were nitrogen delivered at 10 and 2 L/min, respectively. The capillary temperature was set to 200 °C, whereas the ESI source heater was set to 40 °C. The RF level of the S-lenses was set to 70. For full MS experiments aimed at exact mass identification, we used the isolation window of m/z 50−750. By MS/MS experiments performed with the aim of structural elucidation of the β-cryptoxanthin-epoxides, we used the precursor ion isolation window of m/z 567.4−569.4. High-energy collision cell was used for fragmentation at four different collision energy levels, 10, 15, 20, and 25%. In the lists of MS results the first value is always the m/z of the corresponding compound; all other ions are products of fragmentation.

The exact mass measurements (HRESITOFMS) were performed using a Waters Q-TOF Premier mass spectrometer (Waters Corp., Milford, MA, USA). The sample was dissolved in MeOH and measured in positive electrospray ionization mode.

HPLC-DAD Analysis. A Dionex P680 gradient pump with a Dionex PDA-100 detector and Chromeleon 6.70 software was used. The analytical HPLC separation was carried out on an end-capped C30 column with 250 mm × 4.6 mm i.d., 5 μm, YMC C30 (YMC Co. Ltd.). Eluents were (A) MeOH/methyl *tert*-butyl ether (MTBE)/H_2O (81:15:4) and (B) MeOH/MTBE/H_2O (6:90:4). The chromatography was performed in linear gradient from 100% A eluent to 50% B mixture in 45 min, with a 1 mL/min flow.

The chiral HPLC-DAD separation was carried out on a 250 × 4.6 mm i.d., 3 μm, Chiralcel OD column (Daicel, Chemical Industries, Ltd.). Eluents were (A) MeOH/EtOH (1:1) and (B) MeCN/EtOH (1:1). The chromatography was performed in linear gradient from 100% A eluent to 100% B mixture in 30 min, with a 1 mL/min flow. HPLC-DAD analysis was performed with a Dionex HPLC system (Thermo Fisher Scientific).

Semipreparative HPLC. A model 1050 Hewlett-Packard chromatograph (Hewlett-Packard Development Co., Palo Alto, CA, USA) equipped with a diode array detector and HP ChemStation software was used. The separation was carried out on an end-capped C30 column with a 250 mm × 4.6 mm i.d., 5 μm, YMC C30 with an isocratic system of MeOH/MTBE/H_2O (7:16:4), with 2.5 mL/min flow, monitored at 450 nm.

HPLC-ECD analysis. Chiral HPLC separations were performed with a Jasco HPLC system using Chiralpak IA column with 250 mm × 4.6 mm i.d., 5 μm (Daicel, Chemical Industries, Ltd.) and *n*-hexane/propan-2-ol (9:1) eluent at a flow rate of 1.0 mL/min for **4** and **7** (Figure 1). HPLC-UV and OR chromatograms of the stereoisomeric mixtures were recorded with Jasco MD-910 multiwavelength and OR-2090Plus chiral detector, respectively. The online ECD and UV spectra were measured simultaneously by stopping the flow at the UV absorption maximum of each peak. The values of the ECD ellipticity (ϕ) were not corrected for the concentration. Three consecutive scans were recorded and averaged for an HPLC-ECD spectrum with standard sensitivity, 2 nm bandwidth and 1 s response. The background HPLC-ECD spectrum of the eluent was recorded in the same way.

Plant Material. Matured fruits were purchased at the Metropolitan public market in Panama City, Panama.

Extraction and Isolation. The pulp of red mamey (500 g) was homogenized in a porcelain mortar with 50 g of $NaHCO_3$ and extracted with acetone until no more color was observed. The extract was diluted with a mixture of Et_2O/*n*/hexane (1:1), washed with H_2O to remove acetone, dried (Na_2SO_4), and evaporated. The residue was dissolved in Et_2O and saponified with methanolic KOH. After saponification, the ethereal solution was washed to remove alkali and evaporated. The residue was subjected to open column chromatography (Al_2O_3 Brockman grade III) using an increasing percentage of ether in *n*-hexane.

The mixture of β-cryptoxanthin 5,6- and 5′,6′-epoxide was contained in the fraction that eluted with 15−25% diethyl ether. The specific epoxides were isolated by semiprepative HPLC, with several consecutive injections.

Cryptocapsin, **8**, was isolated from the fraction that eluted with 50% ether. This fraction was submitted to open column chromatography on

DOI: 10.1021/acs.jafc.5b01936
J. Agric. Food Chem. 2015, 63, 6059−6065

$CaCO_3$ (Merck) with toluene/hexane (30:70). Five colored zones could be separated: zone 1, 10 mm brick red band (mixture of cryptocapsin 5,8-epoxides[29] and 3′-deoxycapsorubin;[30] zone 2, 10 mm pink band, cryptocapsin 5,6-epoxide;[29] zone 3, 20 mm red band of cryptocapsin, **8**; zone 4, 10 mm pink band, 3′-deoxycapsanthin 5,6-epoxide;[29] zone 5, 3 mm yellow band of cryptoxanthin 5,6,5′,6′-diepoxide.[29] After processing (cutting the column into pieces and extracting), zones 2−5 were crystallized from benzene by the addition of hexane, yielding 4 mg of cryptocapsin 5,6-epoxide, 8 mg of cryptocapsin, **8**, 0.5 mg of 3′-deoxycapsanthin 5,6-epoxide, and 0.5 mg of cryptoxanthin 5,6,5′,6′-diepoxide.[29]

3′-Deoxycapsanthin, **9**, was isolated in pure form by additional column chromatography of a fraction eluted with 30% ether. This fraction was submitted to open column chromatography on $CaCO_3$ with toluene/hexane (20:80). After development, three zones were visible: zone 1, 6 mm pale yellow band, unidentified mixture; zone 2, 50 mm yellow band, mixture of β-cryptoxanthin 5,8- and 5′,8′-epoxides; zone 3, 20 mm pink band, 3′-deoxy-capsanthin, **9**. After processing, zone 3 was crystallized from benzene by the addition of hexane, yielding 2 mg of 3′-deoxy-capsanthin, **9**.

Preparation of Semisynthetic β-Cryptoxanthin-5′,6′-epoxides. To a solution of β-cryptoxanthin acetate (108 mg) in Et_2O (360 mL) at room temperature was added 9.2 mL of 0.339 M concentration monoperoxyphthalic acid (Et_2O solution). The mixture was kept under N_2, in the dark. After 12 h, the mixture was washed with 5% aqueous $NaHCO_3$ solution, the organic phase was dried (Na_2SO_4), and a 30% KOH/MeOH solution (∼100 mL) was added. After 16 h, the solution was washed with H_2O until neutral and dried (Na_2SO_4), and the solvent was evaporated.

Column Chromatography of β-Cryptoxanthin-epoxide Mixture. The residue was dissolved in hexane and submitted to open column chromatography on $CaCO_3$ (Biogal, Debrecen, Hungary) with eluent toluene/hexane (20:80). Picture after development: 5 mm bright yellow (zone 1, not identified); 10 mm intermediate zone; 60 mm bright yellow (zone 2, mixture of β-cryptoxanthin-diepoxides and -5,6-epoxides); 10 mm pale ochre (zone 3, β-cryptoxanthin 5′,6′-epoxides). After processing, zone 3 was crystallized from benzene by the addition of hexane yielding 6 mg of mixture of β-cryptoxanthin-5′,6′-epoxides, **4** and **7**.

(3*S*,5*R*,6*S*)-β-Cryptoxanthin-5,6-epoxide [(3*S*,5*R*,6*S*)-3-Hydroxy-5,6-dihydro-5,6-epoxy-β,β-caroten-3-ol, 1]: orange crystals, UV−vis (benzene) λ_{max} 434 (sh), 457, 487 nm, λ_{max} after acid treatment, 418, 438, 465 nm; UV−vis (hexane) λ_{max} (log ε) 475sh (3.93), 447 (4.00), 423sh (3.84), 398sh (3.58), 377sh (3.30), 330 (3.03), 267 (3.33); ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.98 (3H, s, H-16), 1.03 (6H, s, H-16′, H-17′), 1.15 (3H, s, H-17), 1.19 (3H, s, H-18), 1.26 (2H, overlapping, H_{ax}-2, OH), 1.46 (2H, m, H-2′), 1.63 (4H, overlapping, H_{eq}-2, H_{ax}-4, H-3′), 1.72 (3H, s, H-18′), 1.93 (3H, s, H-19), 1.96 (3H, s, H-19′), 1.97 (6H, s, H-20, H-20′), 2.02 (2H, t, J = 6.8 Hz, H-4′), 2.39 (1H, m, H_{eq}-4), 3.90 (1H, s, H-3), 5.88 (1H, d, J = 15.4 Hz, H-7), 6.16 (1H, m, H-7′), ∼6.25 (8H, overlapped, H-8, H-10, H-12, H-14, H-8′, H-10′, H-12′, H-14′), ∼6.63 (4H, overlapped, H-11, H-15, H-11′, H-15′); ECD [hexane, λ (nm) (Δε), $c = 1.98 \times 10^{-4}$ M] 472sh (1.27), 444 (1.38), 418sh (1.06), 333 (1.82), 270 (−5.41), 238 (1.78), 215 (−4.53), 199 (0.48), negative below 197 nm; MS m/z 568.43 $[M]^+$, 553.40 $[M - 16 + H]^+$, 488.36 $[M - C_6H_8]^+$, 476.36 $[M - C_7H_8]^+$, 461.34 $[M - C_7H_8O]^+$, 415.30 $[M - 153]^+$; t_R = 17.5 min on a C30 column.

RESULTS AND DISCUSSION

The extraction of red mamey was performed as described previously.[28] Column chromatography of the extract on aluminum oxide and calcium carbonate resulted in 1 mg of β-cryptoxanthin-5,6-epoxide, **1**, 1.5 mg of β-cryptoxanthin-5′,6′-epoxide, **4**, 2 mg of 3′-deoxycapsanthin, **9**, and 8 mg of cryptocapsin, **8**.

Structure Elucidation of Natural β-Cryptoxanthin 5,6- and 5′,6′-Epoxides. The β-cryptoxanthin monoepoxides, **1** and **4** exhibited UV−vis maxima at (434), 457, and 487 nm in benzene, which was in accordance with the 5,6- or 5′,6′-epoxy group. Upon acidification with dilute HCl solution, a 20 nm hypsochromic shift of the above transition was observed, which was characteristic of the conversion to the corresponding furanoid oxide.

Mass spectrometry helped to identify the location of the epoxide groups unequivocally. The compound eluted at the retention time of 14.5 min had the molecular ion at (m/z) 568.43. Fragmentation of this mass even with relatively low fragmentation energies produced a large number of ions. The fragmentation profile was very similar to that reported earlier for β-cryptoxanthin.[31] Characteristic ions were observed at values of m/z 553.40 ($[M - 16 + H]^+$ or protonated β-cryptoxanthin), 488.36 ($[M - C_6H_8]^+$), 476.36 ($[M - C_7H_8]^+$), 461.34 ($[M - C_7H_8O]^+$), and 415.30 ($[M - 153]^+$), loss of the hydroxylated ring with cleavage at the 7,8 carbon−carbon bond from the protonated molecule, and several fragment ions corresponding to cleavages of the polyene chain.

The other compound eluting at the retention time of 17.5 min had the molecular ion at (m/z) 568.43, as well. The fragmentation of this compound seemed to be almost identical to the fragmentation of the other compound with the retention time of 14.5 min. It contained the same high abundant ions, but the most intensive differed. To clarify the position of the epoxidation we calculated the theoretical masses of two ions (169.12340 and 171.13769), which contain the six-membered ring, four methyl groups, the epoxide, and the hydroxyl groups as they all together could occur in the tandem spectra only if the position of the epoxidation is 5,6. All of the tandem spectra were analyzed using mass isolation ranges of 169.11−169.13 and 171.13−171.15, and these two ions (Figure 2) were observed only in the spectra of the compound with the retention time of 17.5 min. Their intensities applying 25% HCD cell energy were 3 and 6% of the intensity of the precursor ion (568.43) or 0.01 and 0.02% of the total ion chromatogram.

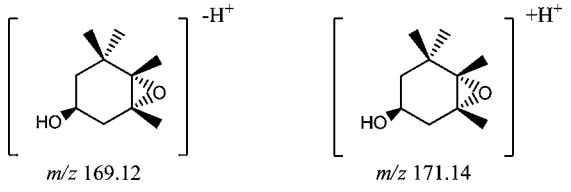

Figure 2. Two ions, m/z 169.12 and 171.14, used for the differentiation of 5,6- and 5′,6′-epoxides.

In the ^{1}H NMR spectrum of compound **1**, methyl group signals were observed at 1.03 ppm (six protons) and 1.72 ppm (three protons) due to the C-16′, C-17′, and C-18′ methyl groups of the unsubstituted β-ring and at 0.98 and 1.15 ppm (C-16, C-17) and 1.19 ppm (C-18) of the 3-hydroxy-5,6-epoxy-5,6-dihydro-β-ring.[32]

The structural elucidation of compounds **1** and **4** was supported by the ^{1}H and ^{13}C NMR measurements, which were in good agreement with the literature data.[18,32]

In the 3-hydroxy β-end group, the δ(H) of CH_2(4) differed significantly for the *cis*- and *trans*-epoxide (relative to OH) and, therefore, proved the (3*S*,5*R*,6*S*)-configuration of **1**. Because the (5′*S*,6′*R*)- or (5′*R*,6′*S*)-configuration of the epoxy β-end groups cannot be distinguished in the ^{1}H NMR spectra, the elucidation of the configuration at the nonhydroxylated end group was achieved by electronic circular dichroism (ECD) measurements.

Carotenoid-5,6-epoxides exhibit strongly conservative ECD spectra comparable to those of other carotenoids with a substituted β-end group. The influence of additional substituents such as a OH group at C(3) or C(3′) is rather small,[33] and thus ECD spectra of the epoxides are governed by the absolute configuration of the epoxy group. The ECD spectra of **1** showed positive Cotton effects (CEs) at 472, 444, 418, 333, 238, and 199 nm and negative ones at 270 and 215 nm. The ECD spectrum of **1** (Figure 3) was compared with those of the related (5*R*,6*S*)- and (5*S*,6*R*)-5,6-epoxy-β-carotene,[34,35] which allowed the assignment of the absolute configuration of **1** as (3*S*,5*R*,6*S*).

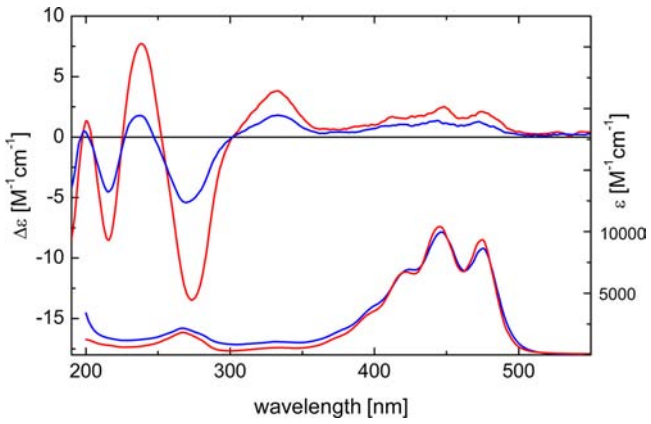

Figure 3. ECD and UV−vis spectra of (3*S*,5*R*,6*S*)-β-cryptoxanthin-5,6-epoxide, **1** (blue curves), and (3*R*,5′*R*,6′*S*)-β-cryptoxanthin-5′,6′-epoxide, **4** (red curves), in acetonitrile.

Although the β-cryptoxanthin-5′,6′-epoxide, **4**, contained the epoxide moiety in the other end group, its ECD spectrum showed the same CEs for the corresponding transitions as the β-cyryptoxanthin 5,6-epoxide, **1**, which determined the absolute configuration as (3*R*,5′*R*,6′*S*). In this way, the compound eluted at 14.5 min was identified as (3*R*,5′*R*,6′*S*)-β-cryptoxanthin 5′,6′-epoxide, **3**, whereas the compound eluted at 17.4 min was (3*S*,5*R*,6*S*)-β-cryptoxanthin 5,6-epoxide, **1**.

Investigation of Semisynthetic β-Cryptoxanthin-5′,6′-epoxides. Earlier, from a mixture of synthetic epoxidation products of β-cryptoxanthin, we could isolate and crystallize a

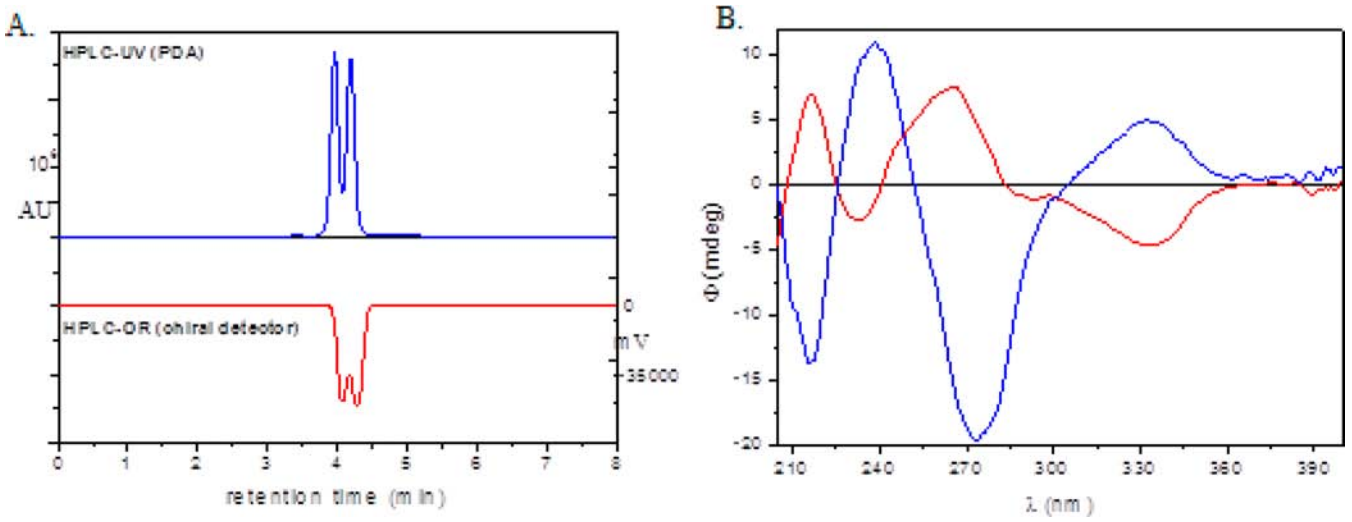

Figure 4. (A) HPLC-UV and HPLC-OR chromatograms of a mixture of (3*R*,5′*R*,6′*S*)- and (3*R*,5′*S*,6′*R*)-cryptoxanthin-5′,6′-epoxide diastereomers, **4** and **7**, on a Chiralpak IA column (hexane/isopropanol 9:1). (B) HPLC-ECD spectra of cryptoxanthin-5′,6′-epoxide diastereomers (3*R*,5′*R*,6′*S*)-, **4** (blue curve), and (3*R*,5′*S*,6′*R*)-, **7** (red curve), in hexane/isopropanol 9:1.

5′,6′-epoxide derivative, which had been reported as the (3*R*,5′*R*,6′*S*)-epoxide, **4**.[18]

To have a further identification aid of the *β*-cryptoxanthin 5′,6′-epoxide, the compound was prepared again semisynthetically from *β*-cryptoxanthin by oxidation with monoperoxy phthalic acid. This furnished the necessary amount for the NMR investigations. After isolation of the mixture of the *syn*- and *anti*-mono-5′,6′-epoxides, which are nondistinguishable by nuclear magnetic resonance, the assignment of the ^{1}H and ^{13}C signals furnished by 2D techniques ($^{1}H-^{13}C$ HSQC, $^{1}H-^{13}C$ HMBC measurements, $^{1}H-^{1}H$ COSY) was possible. The end-group carrying the epoxide moiety has shown the known ambivalent behavior considering the assignment of the proton signals, whereas the signal of the 3-OH-*β* end-group was assigned unequivocally. However, the resulting chemical shifts were in good accordance with the published data.[18] The identification of *β*-cryptoxanthin 5′,6′-epoxide of natural origin was confirmed by semisynthetic counterpart in the further analytical investigations.

HPLC reinvestigation of this semisynthetic compound with a chiral stationary phase showed that this sample contains two components with identical UV−vis spectra and sign of optical rotation. The epoxidation of *β*-cryptoxanthin could produce two diastereomeric 5′,6′-epoxy derivatives, which could not be separated by column chromatography using calcium carbonate or HPLC using C18 or C30 columns. However, separation of (5′*R*,6′*S*)- and (5′*S*,6′*R*)-cryptoxanthin-5′,6′-epoxide diastereomers, **4** and **7**, respectively, was achieved on Chiralcel OD and Chiralpak IA HPLC columns, which showed approximately equal amounts of the two diastereomers (Figure 4). Comparison of the retention times of the semisynthetic compounds with that of natural *β*-cryptoxanthin-5′,6′-epoxide, **4**, on Chiralcel OD column showed that the first-eluting diastereomer was the natural one. On the Chiralpak IA column, this elution order was apparently reversed. The HPLC-ECD spectra of the diastereomeric (3*R*,5′*R*,6′*S*)-, **4**, and (3*R*,5′*S*,6′*R*)-, **7**, showed opposite CEs for the corresponding ECD transitions, but they were not mirror image curves (Figure 4B). On the basis of the ECD spectra of natural (3*R*,5′*R*,6′*S*)-, **4**, the (3*R*,5′*R*,6′*S*) absolute configuration was assigned to the second-eluting diastereomer.

Structure Elucidation of Cryptocapsin 8 and 3′-Deoxycapsanthin 9. The isolation of cryptocapsin was described earlier from red mamey.[29] All of the spectroscopic data of the isolated compound were identical with the data reported in the literature.[31,32]

The UV−vis spectrum of 3′-deoxycapsanthin, **9** (λ_{max} 484 nm in benzene, 498 and 469 nm in hexane) was in agreement with the chromophore conjugated with a carbonyl group. Reduction of **9** with $NaBH_4$ gave an approximately 1:1 mixture of the corresponding diastereomeric alcohols. The UV−vis spectrum of this mixture showed the expected fine structure and a hypsochromic shift (λ_{max} 434, 457, 487 nm in benzene). The molecular formula of **9** was determined to be $C_{40}H_{56}O_2$ by HPLC-MS. The ^{13}C and ^{1}H NMR assignments for **9** were made on the basis of 1D (^{1}H) and 2D (COSY, HSQC) experiments and by comparison with capsanthin and sapotexanthin. In compound **9**, methyl group signals could be attributed to an unsubstituted *κ*-ring. The ^{13}C and ^{1}H NMR data of **9** were similar to those of sapotexanthin, except for the *β*-end group signals (*δ* H-3, *δ* C-3).[28] The ^{1}H signal at *δ* 4.02 and the ^{13}C signal at *δ* 65.0 indicated that the hydroxy group is attached to the cyclohexane and not the *κ*-ring.[32,36] The connection of H-2, H-3, and H-4 protons from the *β*-end group and the connection of H-2′, H-3′, and H-4′ protons from the *κ*-end group were confirmed on the basis of COSY measurements. All other ^{1}H and ^{13}C data and *all-E* polyene chain were in good accordance with literature data.[32,36]

The ECD spectrum of **9** showed positive CEs at 347, 253, and 205 nm and negative ones at 294 and 225 nm with pronounced shoulders (Figure 5). These ECD transitions are governed by the C-5′ chirality center, which is adjacent to the carbonyl group conjugating with the decaene moiety. On the basis of the ECD spectrum, the absolute configuration of **9** could be determined as (3*R*,5′*R*).[36]

If *β*-cryptoxanthin-5,6,5′,6′-diepoxide is present in high amounts in a plant, it usually triggers the production of cryptocapsin-5,6-epoxide and 3′-deoxycapsanthin-5,6-epoxide. The 3-hydroxy *κ*-end group forms from a 3-hydroxy-5,6-epoxy-*β* end group by pinacol rearrangement, which is a common process in carotenoid biosynthesis. In this way the cryptocapsin, **8**, could be formed from *β*-cryptoxanthin 5,6-epoxide, **1**, in red

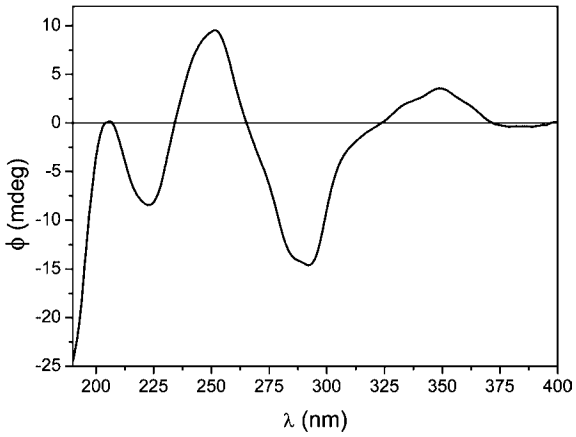

Figure 5. ECD spectrum of **9** in hexane.

mamey. Similarly, the nonhydroxylated 5,6-epoxy-β-ring could result in the nonhydroxylated κ-ring, for example, 3′-deoxycapsanthin **9** forms from β-cryptoxanthin 5′,6′-epoxide **4** (Figure 6).

Our results confirm recently published observations: In red mamey, both the enzyme responsible for the epoxidation of the nonhydroxylated rings and the enzyme that catalyzes the rearrangement of the epoxides should be highly active to produce the detected carotenoids in such a high concentration.[21,28,29] It has been also confirmed that natural 5,6-epoxy carotenoids bear the 5*R*,6*S* configuration independent of the presence or absence of the hydroxyl group on the six-membered ring. During the synthesis of semisynthetic epoxides the compound with 5*S*,6*R* configuration is obtained, as well. Our study has also shown that the two epoxide isomers can be separated only on a chiral column if the ring is not hydroxylated. In the light of these new findings old data about similar compounds should be rechecked.

have on the choice of the main parameters of the malaxation process, when coupled with a flash thermal treatment of the olive paste using a tubular heat exchanger with the common purpose of producing high-quality VOOs. The objectives of this study were to investigate the influence that the new technology could have on the quantitative and qualitative release of phenolic and volatile compounds into VOOs extracted from five Italian olive cultivars simultaneously to an interesting impact on the reduction of the time required for a traditional virgin olive oil mechanical extraction process.

MATERIALS AND METHODS

Chemicals. (3,4-Dihydroxyphenyl)ethanol (3,4-DHPEA) was obtained from Cayman Chemicals Ltd. (Ann Arbor, MI, USA), whereas (*p*-hydroxyphenyl)ethanol (*p*-HPEA) was obtained from Janssen Chemical Co. (Beerse, Belgium). The dialdehydic forms of elenolic acid linked to 3,4-DHPEA and *p*-HPEA (3,4-DHPEA-EDA and *p*-HPEA-EDA, respectively), the isomer of oleuropein aglycon (3,4-DHPEA-EA), (+)-1-acetoxypinoresinol, and (+)-pinoresinol were extracted from the VOO according to the method developed by Montedoro et al.[25] In short, the phenols were extracted from the oil (1 kg) using methanol/water 80:20 v/v (2 L). The mixture made of olive oil (1 kg) and methanol/water (500 mL) was homogenized for 3 min at 25 °C. Then, it was centrifuged at 3000 rpm for 20 min. After the recovery of the supernatant, that procedure was repeated three more times. After solvent evaporation and partial purification of the crude extract obtained from the olive fruit and VOO, phenolic separation was performed by semipreparative high-performance liquid chromatography (HPLC) analysis using a 9.4 mm i.d. × 500 mm Whatman Partisil 10 ODS-2 semipreparative column; the mobile phase was 0.2% acetic acid in water (pH 3.1) (A)/methanol (B) at a flow rate of 6.5 mL/min, whereas detection of the phenols was performed using a diode array detector (DAD).[25] The purity of all the substances obtained from direct extraction was tested by HPLC, and their chemical structures were verified by nuclear magnetic resonance (NMR), using the same operative conditions reported in previous papers.[25,26] Pure analytical standards of volatile compounds were purchased from Fluka and Aldrich (Milan, Italy).

Mechanical VOO Extraction Process. In this research, the VOOs were extracted from olives of the Ottobratica, Cellina di Nardò, Peranzana, Coratina, and Moraiolo cultivars. The Coratina olives, on the one hand, and the Peranzana olives, on the other, were harvested in the Apulia region, in the province of Bari, and in the province of Foggia, respectively, whereas the Cellina di Nardò originated from the Salento area of the Apulia region. The growing area of Ottobratica olive trees was the province of Reggio Calabria (Calabria), whereas Moraiolo trees are typical of the region of Umbria. All cultivars were harvested during the period between the end of October and the last week of November 2013, and the ripening stage of these olives, evaluated on the basis of the pigmentation index according to the method of Pannelli et al.,[24] was 0.95. The olives were processed within 48 h after harvesting. About 150 kg of each olive cultivar was processed using an industrial plant TEM 200 system (Toscana Enologica Mori, Tavarnelle Val di Pesa, Florence, Italy) consisting of a hammer mill, a malaxer with a gas controller system and a working capacity of 200 kg of olives, and a two-phase decanter; a UVPX 305 AGT 14 centrifuge (Alfa Laval S.p.A., Tavarnelle Val di Pesa, Florence, Italy) was used to separate the olive oil.

The control trial malaxation was carried out for 30 min at 25 or 30 °C.

The other tests were conducted using an EVO-Line heat exchanger (Alfa Laval S.p.A.) placed after the same hammer crusher used in the control trial. This was able to determine a flash thermal conditioning (FTC) of olive paste, and heated hot water to 35 and 40 °C to bring the pastes to 25 or 30 °C, respectively. The instantaneous heating of the paste was performed with a counter current, hot water flow, automatically regulated by specifically regulated valves, controlled by a programmable logic controller (PLC). Heated paste was sent to a covered malaxer, and the oil was extracted using the same industrial plant used for the control, following the flowchart illustrated by Esposto et al.[22]

The trials were performed to test two flash conditioning temperatures (25 and 30 °C) for 15 and 20 min of malaxation and, in addition, each experimental condition was repeated twice. Those times were calculated from the moment the inoperative malaxer was completely full.

VOO samples were stored in the dark at 13 °C until analysis. Samples of pomaces were stored at −25 °C until analysis. Two analytical replicates were performed in all of the samples.

VOO Analyses. *Legal Quality Parameters.* Free acidity, peroxide value, and UV absorption characteristics at 232 and 270 nm of oils obtained were measured in accordance with the European Union Official Methods.[27]

Oil Content. Foss-Let 15310 (A/S N. Foss Electric Denmark) was used for the quantitative evaluation of pomace oil content. Dry pomaces (22.5 g) were homogenized (Homogenizer, A/S N. Foss Electric

[a]The data are the mean values of two independent experiments analyzed in duplicate, and the standard deviation is reported in parentheses. Values in each row having different letters (a–d) are significantly different from one another ($p < 0.05$). [b]FTC, flash thermal conditioning.

Denmark) with 120 mL of tetrachloroethylene with the addition of a small amount of anhydrous sodium sulfate for 2 min and estimated.

Phenolic Compounds. The analysis of VOO was conducted with direct injection dissolving 1 g of oil in 5 mL of acetone, and then the solution was filtered through a polyvinylidene fluoride (PVDF) syringe filter (0.2 μm). As described by Selvaggini et al.,[28] HPLC analysis was performed using an Agilent Technologies system, model 1100, consisting of a vacuum degasser, a quaternary pump, an autosampler, a thermostated column compartment, a DAD, and a fluorescence detector (FLD), controlled by ChemStation (Agilent Technologies, Palo Alto, CA. USA), and used to process the chromatographic data. A Spherisorb ODS-1 250 mm × 4.6 mm with a particle size of 5 μm (Waters, Milford, MA, USA) column was used to evaluate the phenolic compounds. The mobile phase consisted of 0.2% acetic acid (pH 3.1) in water (solvent A)/ methanol (solvent B) at a flow rate of 1 mL/min, and the gradient changed as follows: 95% A for 2 min, 75% A in 8 min, 60% A in 10 min, 50% A in 16 min, 0% A in 14 min, and maintained for 10 min. Following the re-equilibration of the initial condition, equilibration was reached in 13 min; the total running time was 73 min. All phenolic compounds, except lignans, which were detected by FLD

operated at an excitation wavelength of 280 nm and emission at 339 nm,[29] were detected by DAD at 278 nm.

Volatile Compounds. Evaluation and quantification of volatile compounds in VOOs were performed by headspace solid-phase microextraction, followed by gas chromatography−mass spectrometry (HS-SPME/GC-MS), according to the method of Servili et al.[30] Six grams of oil with the addition of 50 μL of a standard methanolic solution, consisting of butanal, isobutyl acetate, and 1-nonanol, were mixed with vortex for 1 min, and then 3 g was placed into a 10 mL vial. To sample the headspace volatile compounds, solid-phase microextraction (SPME) was applied as follows: all of the vials were held at 35 °C, and then the SPME fiber (a 50/30 μm 1 cm long DVB/Carboxen/PDMS, Stableflex; Supelco, Inc., Bellefonte, PA, USA) was exposed to the vapor phase for 30 min to sample the volatile compounds. The fiber was then inserted into the gas chromatograph (GC) injector, set in splitless mode, using a splitless inlet liner of 0.75 mm i.d. for thermal desorption, where it was left for 10 min. All of the SPME operations were automated through the Varian CP 8410 autoinjector (Varian, Walnut Creek, CA, USA).

GC-MS Analysis. A Varian 4000 GC-MS equipped with a 1079 split/splitless injector (Varian) was used. A fused-silica capillary column was employed (DB-Wax-ETR, 50 m, 0.32 mm i.d., 1 μm film thickness; J&W Scientific, Folsom, CA, USA). The column was operated with helium at a constant flow rate of 1.7 mL/min, maintained with an electronic flow controller (EFC). The GC oven heating program began at 35 °C. This temperature was maintained for 8 min and then increased to 45 °C at a rate of 1.5 °C/min. This was then increased to 150 °C at a rate of 3 °C/min, to 180 °C at a rate of 4 °C/min, and finally to 210 °C at a rate of 3.6 °C/min. This temperature was held for 14.5 min. The total analysis time was 80 min. The injector temperature was maintained at 250 °C, the temperature for the transfer line was fixed at 170 °C, and the mass spectrometer was operated in the electron ionization (EI) mode at an ionization energy of 70 eV, with scanning in the mass range of m/z 25−350 at a scan rate of 0.79 s/scan and a manifold temperature of 150 °C. The GC-MS was operated with Varian MS Workstation Software, version 6.6. The volatile compounds were identified by comparing their mass spectra and retention times

with those of authentic reference compounds. Integration of all the chromatographic peaks was performed by choosing the three masses with the highest intensities from among those specific for each compound, to selectively discriminate them from their nearest neighbors. The results of the peak areas were calculated on the basis of the relative calibration curve for each compound and expressed in g/kg of oil.[30]

Statistical Analysis. *Analysis of Variance (ANOVA).* The statistically significant differences of data were evaluated by one-way ANOVA. The SigmaPlot 12.3 was used (Systat Software Inc., San Jose, CA, USA).

Principal Component Analysis (PCA). The PCA model was built with 30 objects (6 oils for each cultivar analyzed) and 28 variables (legal quality parameters, acidity, peroxide value, K_{232}, K_{270}, ΔK; phenolic compounds, 3,4-DHPEA, *p*-HPEA, 3,4-DHPEA-EDA, *p*-HPEA-EDA, (+)-1-acetoxypinoresinol, (+)-pinoresinol, 3,4-DHPEA-EA, total phenol; volatile compounds, (*E*)-2-pentenal, hexanal, (*E*) 2-hexenal, (*E*,*E*)-2,4-hexadienal, sum of aldehydes, 1-penten-3-ol, (*E*)-2-penten-1-ol, 1-hexanol, (*Z*)-3-hexen-1-ol, (*E*)-2-hexen-1-ol, sum of alcohols, hexyl acetate, (*Z*)-3-hexenyl acetate, sum of esters, 1-penten-3-one) to analyze the influence of processing parameters on the analytical data of VOO. The SIMCA 13.0 chemometric package was used (Umetrics AB, Umeå, Sweden). The raw data of each variable were centered, with the subtraction of the mean, and autoscaled to unit variance, dividing these results by the standard deviation. The number of significant components was found by applying cross-validation.

RESULTS AND DISCUSSION

The impact of the flash thermal conditioning of the olive pastes was tested on five Italian olive cultivars (Ottobratica, Cellina di Nardò, Peranzana, Coratina, and Moraiolo) characterized by various origin areas.

Instead of heating it with the traditional malaxation processes, the first step was to analyze the effects of the FTC of the olive

[a]The data are the mean values of two independent experiments analyzed in duplicate, and the standard deviation is reported in parentheses. Values in each row having different letters (a−d) are significantly different from one another ($p < 0.05$). [b]FTC, flash thermal conditioning.

paste on the parameters associated with the yield extraction. The FTC treatment, coupled with 15 and 20 min of malaxation time, longer than the time investigated by Esposto et al.,[22] corresponding to 10 min, determined a similar oil yield during the mechanical extraction process of the virgin olive oil, in comparison to the control trial. The differences between the control and the FTC trials, expressed as residual pomace oil, are not significant for any of the cultivars analyzed (Table 1).

Marketable parameters, free acidity, and peroxide values were unaffected by the FTC treatment of the paste for both the temperatures and malaxation times analyzed, showing that the thermal modification applied to the mechanical extraction process does not modify the normal chemical and biochemical processes of fat degradation, with a specific reference to residual lipase activities (data not shown).

The evaluation of K_{232}, K_{270}, and ΔK did not show significant modification due to the use of FTC in the olive paste in all of the cultivars studied (data not shown). Therefore, as already reported in a previous paper,[22] there are no negative effects on the legal quality parameters of virgin olive oil FTC at the two different temperatures and malaxation times compared to the respective control.

The data analysis of the phenolic composition of VOOs (Table 2) showed a strong variation depending on the cultivar processed. In all of the cultivars studied, the phenolic concentration of the oils, obtained with the FTC treatment, was always higher than those extracted by the traditional process. The increase of phenolic compounds was influenced by the processing parameters such as the temperature and time of malaxation applied after FTC. Indeed, an increase in the mixing time, post rapid thermal conditioning, corresponds to an increase of phenols released in the VOOs. The mixing time used, lower than in the control trials, already determined an improvement in the phenolic concentration after 15 min of malaxation, even though the main differences were observed in the oils extracted 20 min after FTC of the olive pastes at both temperatures tested.

In a previous study,[22] 10 min of malaxation applied after the FTC treatment of the olive pastes in cv. Peranzana was unable to enhance the phenolic concentration of VOOs compared with the traditional extraction process, highlighting the correct time of malaxation paste after an FTC treatment is at least 15 min. As a result, 15 min can be considered the minimum time required to improve cell wall degradation by the endogenous depolymerizing enzymes, which promote the release of phenols in the VOOs and in the vegetation waters.[31,32]

The most important differences in terms of phenolic compounds are mainly related to the oleuropein derivatives such as 3,4-DHPEA-EDA and 3,4-DHPEA-EA and, to a lesser extent, to the ligstroside derivatives that include *p*-HPEA and *p*-HPEA-EDA; these increases appear to be affected not only by the thermal treatment but also by the genetic origins of the Italian cultivars analyzed, confirming that the distribution of the values obtained under different extraction process conditions is strictly cultivar-dependent.[10] The results from the combinations of 30 °C and 20 min of malaxing time applied after FTC treatment, which enabled the highest concentrations of phenolic compounds to be extracted, indeed showed a great variation between the cultivars, with increases in the total phenols of 9.9, 17.5, 18.5, 25.5, and 37.3% for cultivars Cellina di Nardò, Peranzana, Moraiolo, Ottobratica, and Coratina, respectively. On the contrary, lignans such as (+)-1-acetoxypinoresinol and (+)-pinoresinol showed the lowest variability under the different operative conditions applied, validating a general stability of these compounds to almost all of the technological parameters involved in the mechanical extraction process of VOOs.[10,17,22]

The results relating to the volatile compounds (Tables 3−7) are interesting because they show a differentiated impact on the generation of aroma, of the operative conditions applied during the olive FTC, associated with the cultivar. As shown in Table 5, the use of flash heating produces an increase in esters, related to a "floral" sensory note in cv. Peranzana,[12] when the treatment was applied to the olive pastes at the times and temperatures tested; C_6 aldehydes, (*E*)-2-hexenal in particular, increase in the oils from cv. Peranzana malaxed for 15 min at 25 and 30 °C, whereas C_6 alcohols did not show a specific trend that can be associated with the paste treatment. Those results confirm, as reported in a previous paper,[22] the positive impact of FTC on the volatile composition of VOOs from cv. Peranzana but, at the same time, show that the FTC effect on the volatile compounds of VOO was strongly affected by the

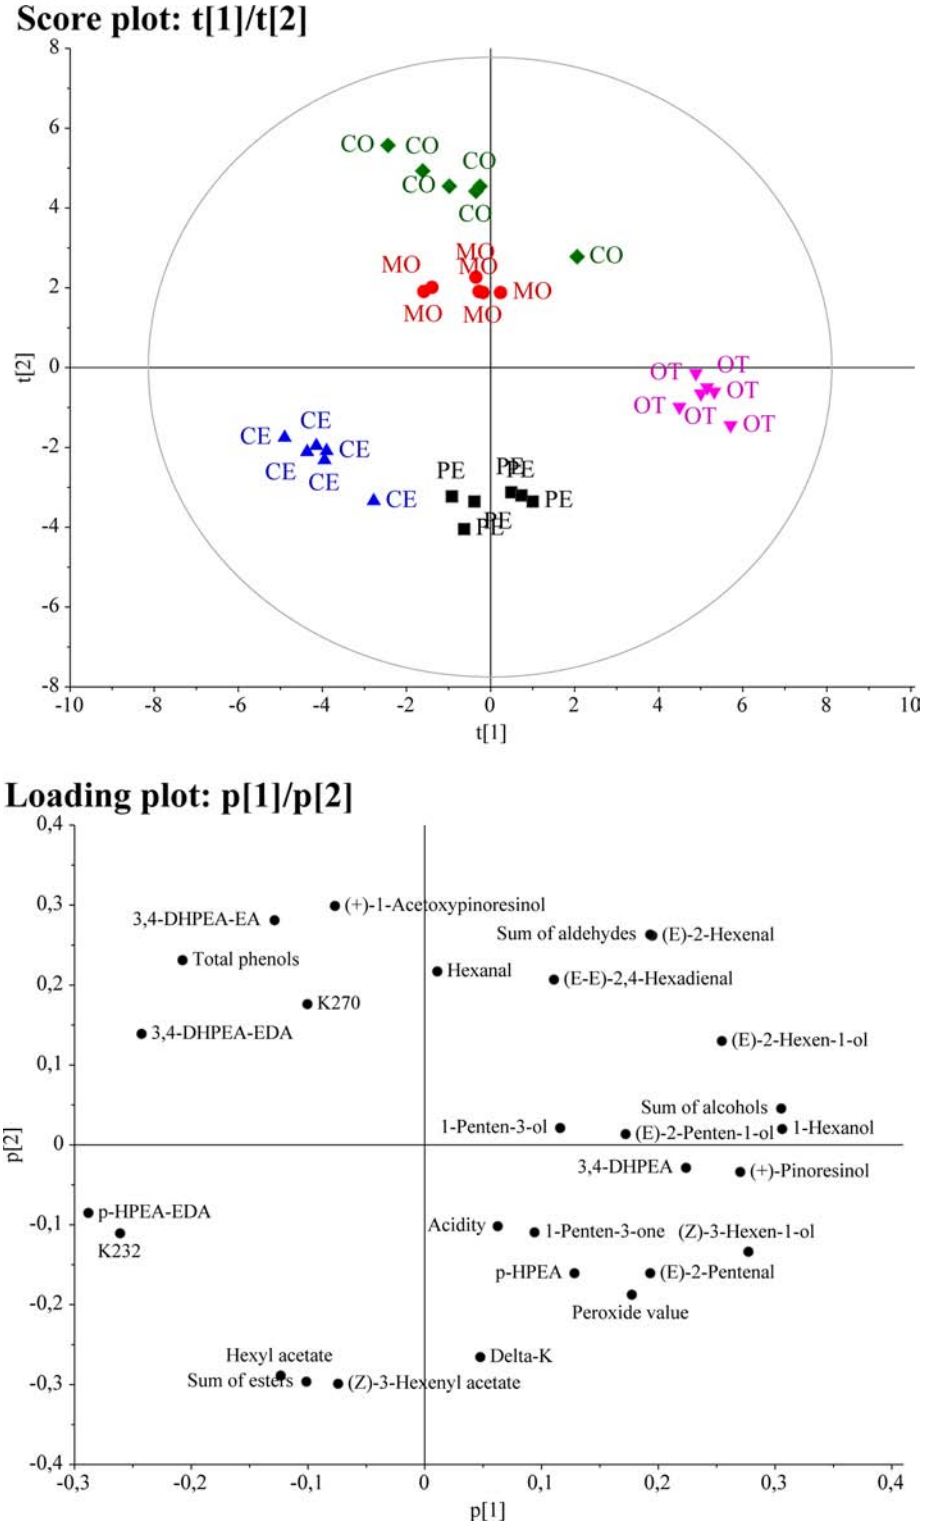

Figure 1. Score plot and loading plot of the first two principal components (explaining 34 and 31% of the total variance, respectively) of the PCA model built with VOOs obtained from five Italian olive cultivars under different malaxation conditions. CE, Cellina di Nardò; CO, Coratina; MO, Moraiolo; OT, Ottobratica; PE, Peranzana.

olive cultivar. VOOs from cultivars Coratina and Cellina di Nardò showed a restricted reduction in esters, whereas the C_6 unsaturated aldehydes did not show any significant modification (Tables 4 and 6). The C_6 alcohols, on the contrary, demonstrated a significant reduction in cv. Coratina, due to the FTC at both temperatures, whereas the VOO from cv. Cellina di Nardò showed no significant differences associated with the paste treatment. A reduction in esters, associated with the FTC, was also found in VOO from cv. Ottobratica and demonstrated at 25 °C that C_6 aldehydes were not affected by the application of flash heating treatment and that C_6 alcohols improved at 30 °C depending on the malaxation time, whereas no significant differences were found at 25 °C except for (*E*)-2-hexen-1-ol (Table 3). The oil obtained from cv. Moraiolo showed a

DOI: 10.1021/acs.jafc.5b01666
J. Agric. Food Chem. 2015, 63, 6066−6074

significant reduction in C_6 alcohols in all of the oils obtained by flash heating treatment of the olive pastes excluding (*Z*)-3-hexen-1-ol. A minor modification was observed, on the contrary, for the other volatile compounds (Table 7).

The reported results demonstrate that the impact of the flash heating treatment of the olive pastes on the phenolic composition of the VOO shows the same behavior characterized by a higher phenolic concentration in VOO obtained after FTC treatment in all of the cultivars. Those results can be explained by the improved activity of the thermal treatment on the endogenous enzymes, which catalyze the depolymerization of the cell walls and improve the release of phenols in the oil. The impact of FTC treatment on the lipoxygenase pathway appears to be cultivar-dependent. The genetic origin of the raw material affects not only the absolute activity of each enzyme involved in the lipoxygenase pathway but also their distribution in the constituent parts of the fruit.[12,33−35] Both of these aspects could explain the differences in the generation of aroma, observed using the same operative condition in various cultivars.

The PCA model reported in Figure 1, built with 30 objects and 28 variables, explains with five significant principal components 92% of the total variance (explaining each 34, 31, 17, 7, and 3%, respectively), summarizes the differences observed in previously reported results, and clearly highlights a discrimination of the VOO samples according to the cultivar origin. The first component put in evidence a discrimination of VOOs of cultivars Cellina di Nardò and Ottobratica, and the loading plot shows that this separation is mainly due to the secoiridoid derivatives, such as 3,4-DHPEA-EDA and *p*-HPEA-EDA, present in greater concentrations in the first cultivar, and saturated and unsaturated C_6 alcohols and (+)-pinoresinol, higher in cv. Ottobratica and, as indicated in Tables 3 and 4, the content of these compounds for this cultivar are about 4 times higher than for cv. Cellina di Nardò. VOOs from cultivars Coratina and Moraiolo, characterized by high concentrations of the phenolic compounds and a volatile profile with high contents of (+)-1-acetoxypinoresinol, 3,4-DHPEA-EA, (*E*)-2-hexenal, and hexanal by a side and a low concentration of esters by the other, are located in the upper side of the second component and discriminated by VOOs from cultivars Peranzana and Cellina di Nardò, which are positioned on the opposite side. The concentrations of the phenolic compound (+)-1-acetoxypinoresinol is about 5-fold, whereas 3,4-DHPEA-EA is more than twice in cv. Coratina with respect to cv. Peranzana; also, the values found for the aldehydes above-mentioned are 2-fold higher in the objects present in the upper side of the second principal component.

via the Maillard reaction followed by a self-assembly method; that is, the Maillard dry-heat conjugates were heated in a water bath at the isoelectric point of β-conglycinin, where it showed the lowest polydispersity index value. The size distribution, turbidity, morphology, ζ-potential, and conformation of nanogels were investigated to characterize the nanogels. The mechanism of nanogel formation was systematically analyzed, and the stability of nanogels was also observed.

MATERIALS AND METHODS

Materials. Soy β-conglycinin was separated from defatted soybean flour (obtained from Shandong Gaotang Lanshan Group Corp., Shandong, China) on the basis of the method of Nagano et al.[19] The protein content of β-conglycinin was 84.03% (Kjeldahl, N × 5.71). Dextran (molecular weight 48−90 kDa) and 8-anilino-1-naphthalenesulfonic acid (ANS) were supplied by Sigma (St. Louis, MO, USA). All reagents were of analytical grade unless specified. All solutions were prepared by using deionized water.

Synthesis of Soy β-Conglycinin−Dextran Conjugates. Soy β-conglycinin and dextran powder mixtures with weight ratios of 1:1 were dissolved in distilled water and lyophilized. The lyophilized powder was dry-heated at 60 °C with a relative humidity of 79% in a desiccators containing saturated KBr in the bottom for 4 days. The resultant samples were dissolved in distilled water and centrifuged (10000*g*, 15 min, 25 °C). The supernatant was then freeze-dried, and the products were soy β-conglycinin−dextran conjugates.

Fabrication of Soy β-Conglycinin−Dextran Nanogels. The Maillard conjugates were dispersed in double-distilled water to reach a soy β-conglycinin concentration of 1 mg/mL. The pH of the completely solubilized conjugate solution was acidified to 4.8 by stepwise addition of 0.1 mol/L HCl. The solution was then placed in a water bath without stirring at a temperature of 95 °C for 50 min. The resultant soy β-conglycinin−dextran nanogels solution was either kept at 4 °C or freeze-dried.

To evaluate the effect of pH on the size distributions of nanogels, the conjugates were acidified to pH 3.8, 4.3, 4.8, 5.3, or 5.8 and subsequently incubated in water baths at 80 °C for 30 min. Other steps were as described above. To study the effect of protein concentration, conjugate solutions at concentrations ranging from 0.5 to 10 mg/mL were used and heated at 80 °C for 30 min. Other steps were as described above. To investigate the effect of the heating temperature, the conjugate solutions were heated at 75, 80, 85, 90, or 95 °C for 30 min. Other steps were as described above. To observe the effect of heating time on size distributions of nanogels, the Maillard products were heated in water baths at 95 °C for 5−60 min. Other steps were as described above.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was performed according to the methodology of Laemmli[20] with a 12% acrylamide separating gel and a 5% stacking gel. The samples were dissolved in 0.125 mol/L Tris-HCl buffer that contained 1% (w/v) sodium dodecyl sulfate, 2% (v/v) 2-mercaptoethanol, 5% (v/v) glycerol, and 0.025% (w/v) bromophenol blue. The sample solutions (5 mg/mL, 10 μL) were heated for 5 min in boiling water before electrophoresis. After electrophoresis, the gels were stained for protein for 2.5 h and for carbohydrate for 16 h with Coomassie brilliant blue R-250 and periodate−Schiff solution, respectively.[21] The gel stained for protein was then destained with 10% (v/v) methanol and 10% (v/v) acetic acid.

Degree of Glycation (DG). The DG of soy β-conglycinin−dextran conjugates was estimated using trinitrobenzenesulfonic acid (TNBS) reaction according to Adler-Nissen with some modifications.[22] A sample solution (1 mg/mL, 0.5 mL) was mixed with $NaHCO_3$ (4 wt %, 0.5 mL), sodium dodecyl sulfate (0.1 wt %, 0.5 mL), and TNBS (0.1 wt %, 0.5 mL). The solution was then incubated at 40 °C for 2 h, followed by the addition of 0.25 mL of 1 N HCl to quench the reaction. The absorbance of the solution was measured by using a UV2300 ultraviolet−visible spectrophotometer (Tianmei Ltd., Shanghai, China) at a wavelength of 340 nm. DG was determined as

$$DG = [(A_0 - A_1)/A_0] \times 100\%$$

where A_0 and A_1 were the absorbance of solutions before and after glycation, respectively.

Dynamic Light Scattering Measurements. The size distributions of the samples were conducted on a Zetasizer Nano-ZS instrument (Malvern Instruments, Worcestershire, UK) with a fixed scattering angle of 173° equipped with a 4 mW He−Ne laser (633 nm wavelength). The sample was placed in a 1 cm × 1 cm cuvette (PCS8501) and analyzed three times at 25 °C. The apparent average hydrodynamic diameter (D_h) and polydispersity index (PDI) were obtained.

ζ-Potential Measurements. The ζ-potentials of samples were also examined on the Zetasizer Nano-ZS instrument. ζ-Potentials were calculated by using Dispersion Technology software according to the Smoluchowski approximation in an automatic mode.[23] Each sample was analyzed in triplicate.

Turbidity Measurements. Native β-conglycinin, β-conglycinin/dextran mixtures, and β-conglycinin−dextran conjugate powders were dissolved in distilled water to achieve the final protein concentration of 1 mg/mL. The pH values of the solutions were acidified to 4.8 using 0.1 mol/L HCl. The solutions were then placed in a water bath at 95 °C for different times (0−60 min).The turbidity of each sample was assessed by measuring the transmittance of sample solution at a wavelength of 540 nm on a UV2300 ultraviolet−visible spectrophotometer (Tianmei Ltd.).[24]

Surface Hydrophobicity (H_0) Measurements. Surface hydrophobicity was obtained by using the ANS as fluorescence probe following the method described by Haskard and Li-Chan[25] with some modifications. Briefly, samples were dissolved in buffer solutions (0.01 mol/L, pH 7.0) to reach desired protein concentrations (0.02−0.2 mg/mL). Aliquots of ANS stock solution (8×10^{-3} mol/L, 20 μL) were mixed with each sample solution (4 mL). The mixtures were then shaken fully on a vortex mixer and stored in the dark for 3 min before measurements. Fluorescence intensity (FI) was analyzed on an F7000 fluorescence spectrophotometer (Hitachi Co., Tokyo, Japan) with wavelengths of 390 nm (excitation) and 470 nm (emission) at 25 °C. The FI value at each concentration minus the FI value of the blank (without added ANS) was calculated as the final FI value. The initial slope of the final FI value versus protein concentration (mg/mL) was obtained by a linear regression analysis and used as an index of H_0. Each sample was conducted three times.

Circular Dichroism (CD) Spectroscopy. CD spectra were recorded on an MOS-450 spectropolarimeter (BioLogic Science Instrument, Grenoble, France). The far-UV CD spectrum probed the secondary structures. Each sample was placed in a 2 mm quartz cuvette with the protein concentration of 0.1 mg/mL and scanned from 180 to 260 nm. The near-UV CD spectrum probed the tertiary structures. Each sample was placed in a 10 mm quartz cuvette with a protein concentration of 2 mg/mL and scanned over a wavelength range from 260 to 340 nm. For each measurement, the spectrum was an average of eight scans. All determinations were carried out in triplicate.

Atomic Force Microscopy (AFM). AFM images were captured in tapping mode on a Multimode 8 scanning probe microscope (Bruker Inc., Billerica, MA, USA) equipped with a silicon cantilever (FESPA, Bruker Corp, Santa Barbara, CA, USA) of 125 μm length. Aliquots (2 μL) of sample previously diluted to 5 μg/mL with deionized water were deposited on a freshly cleaved mica substrate and air-dried for overnight before imaging.

Scanning Electron Microscopy (SEM). SEM image was acquired on a Nova NanoSEM 430 (FEI NanoPorts, Eindhoven, The Netherlands) at 10 kV accelerating voltage. The preparation of specimen for SEM was the same as AFM. The specimen was coated with gold followed by imaging.

Transmission Electron Microscopy (TEM). TEM image was recorded on a JEM-2100F electron microscopy at an accelerating voltage of 80 kV. Aliquots (10 μL) of dispersions (diluted to 3 μg/μL with deionized water, previously) were dropped on the carbon membrane support copper grid. Excessive dispersions were removed by filter paper and dried for 5 min. Ten microliters of 1% (w/v)

DOI: 10.1021/acs.jafc.5b01778
J. Agric. Food Chem. 2015, 63, 6075−6083

phosphotungstic acid was placed on the copper grid and stained for 5 min before removing it with filter paper, and the grid was dried overnight at ambient temperature.

Data Analysis. All measurements were performed in triplicate if not specified. Significance of difference was analyzed using analysis of variance (ANOVA) and Tukey's test at 5% level of probability (SPSS 17.0 for Windows statistical software).

RESULTS AND DISCUSSION

Characteristics of Soy β-Conglycinin−Dextran Conjugates Formed by Maillard Dry-Heating Reaction. The process of Maillard conjugation involves three stages.[26] In the initial stage, an amino group was condensed with a carbonyl group to synthesize a Schiff base, which then cyclizes to an N-substituted glycosylamine. It subsequently goes through Amadori rearrangement to produce a more stable Amadori rearrangement product (ARP, 1-amino-1-deoxy-2-ketose).[27] The ARP undergoes a complex series of reactions to form multiple colored compounds in the following stages.[28] The reaction is often limited to the initial stage to prevent the occurrence of highly colored and poorly characterized products.

The formation of Maillard-type protein−polysaccharide complexes was confirmed by SDS-PAGE and TNBS test. Figure 1A exhibits the protein staining SDS-PAGE pattern; the

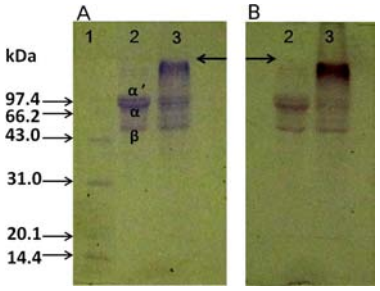

Figure 1. SDS-PAGE patterns for β-conglycinin/dextran samples: (A) protein stain; (B) carbohydrate stain. Lanes: 1, protein marker; 2, native β-conglycinin; 3, β-conglycinin−dextran conjugates. Arrows indicate the boundary between the stacking and separating gels.

characteristic bands of β-conglycinin (subunits of α′, α, and β) were detected in lane 2, which is consistent with Zhang.[29] However, when it comes to lane 3, a shift of bands toward the top of separating gels was visualized after the Maillard reaction, which is clear evidence that compounds with high molecular weight were developed. The migration of dextran can be elided because it carries no charge, the effect of noncovalent interactions on SDS-PAGE may be ignored because they were disrupted in the reducing condition, and an intense bank accumulated on the top of separating gels in carbohydrate staining pattern (Figure 1B, lane 3), all of which strongly verified the covalent attachment of dextran to β-conglycinin.

The degree of glycation was evaluated by quantifying the loss of available amino groups of β-conglycinin after Maillard reaction using the TNBS method. The DG of the Maillard dry-heating products prepared by us was around 16.7%.

Characteristics of Soy β-Conglycinin−Dextran Nanogels Fabricated by Self-Assembly Approach. DLS is a quantitative and effective tool to investigate the particle size and size distribution of nanogels.

As mentioned above, Schmitt and co-workers reported spherical microgels exhibiting colloidal stability were formed in a narrow pH range near the isoelectric point (p*I*) of β-lactoglobulin. The p*I* of β-conglycinin is 4.8.[30] Therefore, in this study, the effect of pH on the formation of nanogels was studied by heating (80 °C) the soy β-conglycinin−dextran conjugates (1 mg/mL) at the pH range of 3.3−5.8. As shown in Figure 2, when the pH was shifted toward the p*I*, the mean

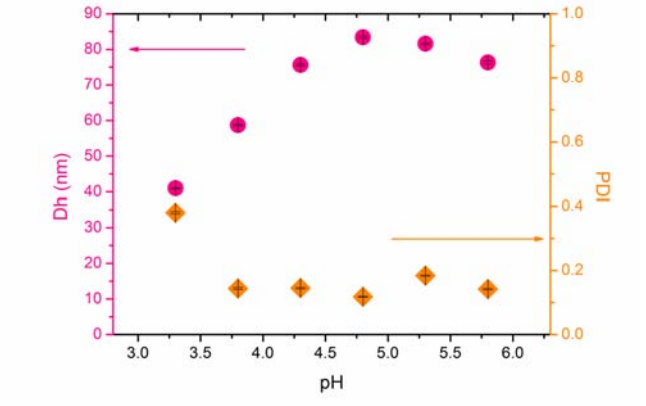

Figure 2. D_h and PDI of nanogels prepared by heating the β-conglycinin−dextran conjugates (1 mg/mL) in a water bath at 80 °C for 30 min at different pH values.

hydrodynamic diameter (D_h) increased, whereas the polydispersity index (PDI) decreased, implying that the nanoparticles were more uniform at p*I*. There was a dominant interaction, electrostatic repulsion, and hydrophobic attraction during the heat-induced gelating process. When the pH decreased from 4.3 to 3.3 or increased from 5.3 to 5.8, β-conglycinin carried more charges, resulting in stronger long-range electrostatic repulsion and weaker short-range hydrophobic aggregation. Therefore, the β-conglycinin molecules were separated from each other, which may weaken the gelation ability of protein and make it unfavorable to the formation of homogeneous nanogels. On the other hand, at the isoelectric point where β-conglycinin carried zero net charge and nanogels displayed the lowest PDI value, the electrostatic repulsion can be ignored and hydrophobic attraction was strong enough to construct well-defined nanonetwork hydrogels.

Figure 3 exhibits the influence of β-conglycinin concentration on the DLS result of nanogels, which were prepared by heating (80 °C) the conjugates (0.5−10 mg/mL) at pH 4.8. The increment of β-conglycinin gradually increased the D_h and PDI values of nanogels (from 79.26 to 123.65 nm and from 0.189 to 0.276, separately). A higher concentration of β-conglycinin brings molecules closer together. As a consequence, the mean particle size increased as the concentration increased. Furthermore, when the protein concentration was increased to ≥8 mg/mL, the turbidity of the solution markedly increased and the mobility of the solution sharply diminished. In the following study we adopted 1 mg/mL as the optimal protein concentration to form nanogels.

A heat treatment of proteins above their denaturation temperature is a prerequisite for unfolding the hydrophobic groups and forming gels.[31] Because the denaturation temperature of β-conglycinin is 60−75 °C,[32] a heating temperature range of 75−95 °C was used to study the formation of nanogels. As shown in Figure 4, the D_h and PDI of nanogels did not change significantly when the heating temperature

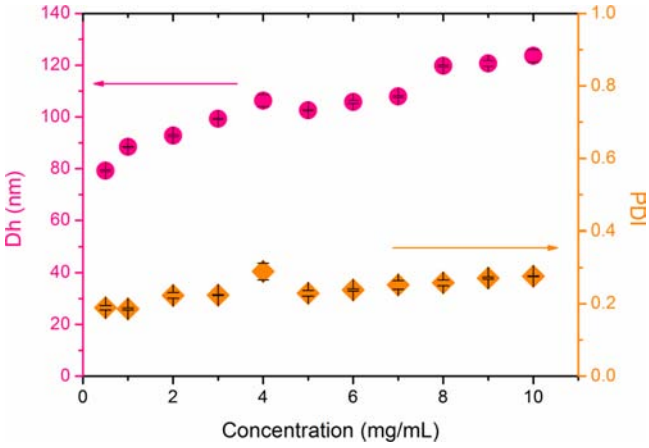

Figure 3. DLS results of nanogels prepared by heating the β-conglycinin–dextran conjugates with different concentrations at 80 °C for 30 min.

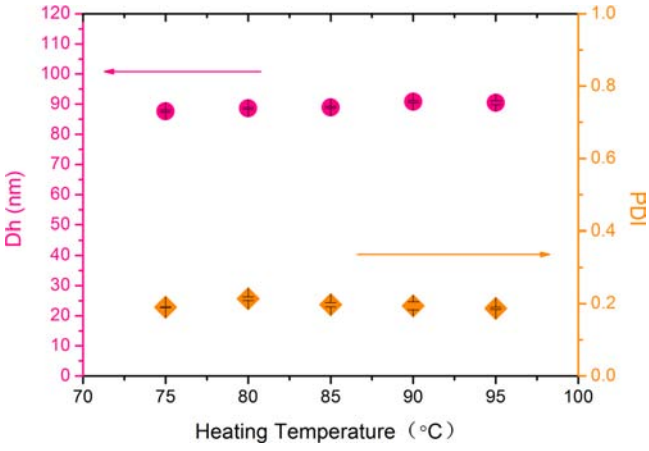

Figure 4. D_h and PDI of nanogels prepared by heating 1 mg/mL β-conglycinin–dextran conjugates at different temperatures for 30 min.

improved. Because the lowest PDI value appeared at 95 °C, we chose a heating temperature of 95 °C for nanogel synthesis.

The size distribution of nanogels (Figure 5) and the turbidity of native β-conglycinin and β-conglycinin/dextran mixture as well as nanogels (Figure 6) as a function of heating time were

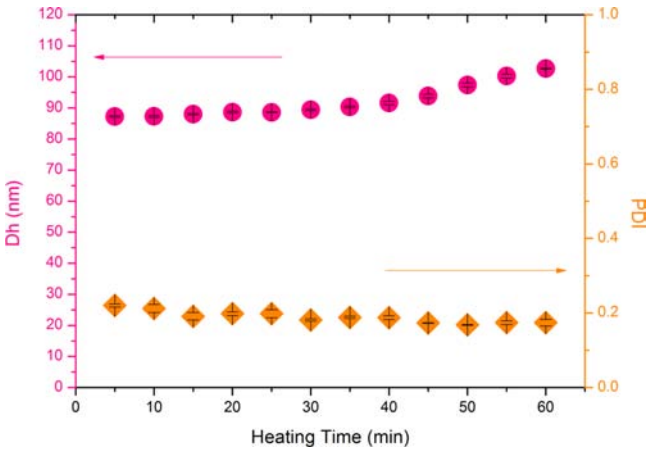

Figure 5. D_h and PDI of nanogels prepared by heating 1 mg/mL β-conglycinin–dextran conjugates at 95 °C for different times.

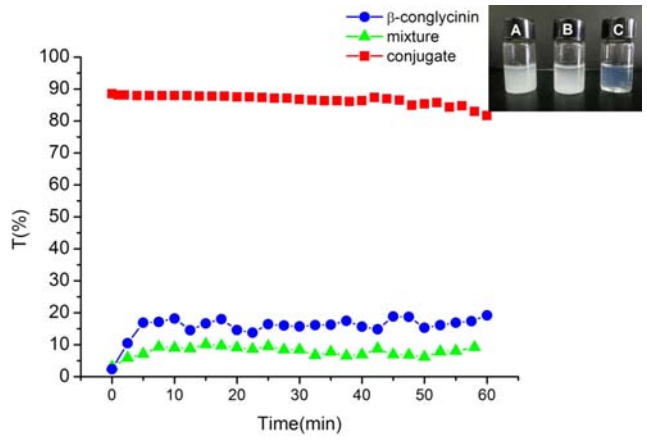

Figure 6. Turbidity of β-conglycinin, β-conglycinin/dextran mixture, and β-conglycinin–dextran conjugates incubated in a water bath at 95 °C for 0–60 min. (Inset) Photographs of β-conglycinin (A), β-conglycinin/dextran mixture (B), and β-conglycinin–dextran conjugates (C) heated in a water bath at 95 °C for 60 min.

investigated. As shown in Figure 5, when the heating time increased, the particle size did not grow markedly and PDI dropped slightly. It is notable that the PDI value fell below 0.2 after 15 min of heating, indicating that homogeneous dispersed nanogels were formed in a broad heating time range of 15–60 min. We used a 50 min heat treatment to the conjugates in the following study. As shown in Figure 6, depletion flocculation appeared after a heat treatment to β-conglycinin, and a similar phenomenon was found by Chen and co-workers.[33] Precipitation was also observed in the presence of free dextran, indicating that the individual dextran molecules cannot prevent the β-conglycinin molecules from aggregating. However, when the conjugates were heated, no coagula were found and the solution was translucent. Therefore, the dextran grafted to β-conglycinin not only can suppress the protein coagulation but also can improve the solubility of protein.

Taken together, heating 1 mg/mL soy β-conglycinin–dextran conjugates at pH 4.8 in a water bath at 95 °C for 50 min was chosen to prepare nanogels in the following study.

Morphology, Formation Mechanism, and Structure of Soy β-Conglycinin–Dextran Nanogels. *Morphology and Formation Mechanism.* Atomic force microscopy has been proved to be helpful for detecting 3D information on nanoscale particles.[34] Scanning electron microscopy is available to obtain 2D information by examining the surfaces of samples,[35] whereas transmission electron microscopy is valuable for investigating the structures of specimens,[36] both of which produce 2D images.

DLS and AFM were carried out to determine the dimensions and morphology of β-conglycinin–dextran conjugates and nanogels as well as to probe the effect of self-assembly on the aggregation of protein. DLS data show that after self-assembly, the D_h of particles increased from 73.21 to 83.33 nm, whereas the polydispersity index reduced from 0.184 to 0.096, which indicates that the particles in nanogel solution were more homogeneous. The AFM images exhibit that the conjugates (Figure 7A) were irregular aggregations and the nanogels (Figure 7B) were approximately spherical in shape. In comparison, there were far fewer aggregates and more uniform globules in the nanogels than conjugates. The DLS and AFM analyses imply that self-assembly of the amphiphilic conjugates

DOI: 10.1021/acs.jafc.5b01778
J. Agric. Food Chem. 2015, 63, 6075–6083

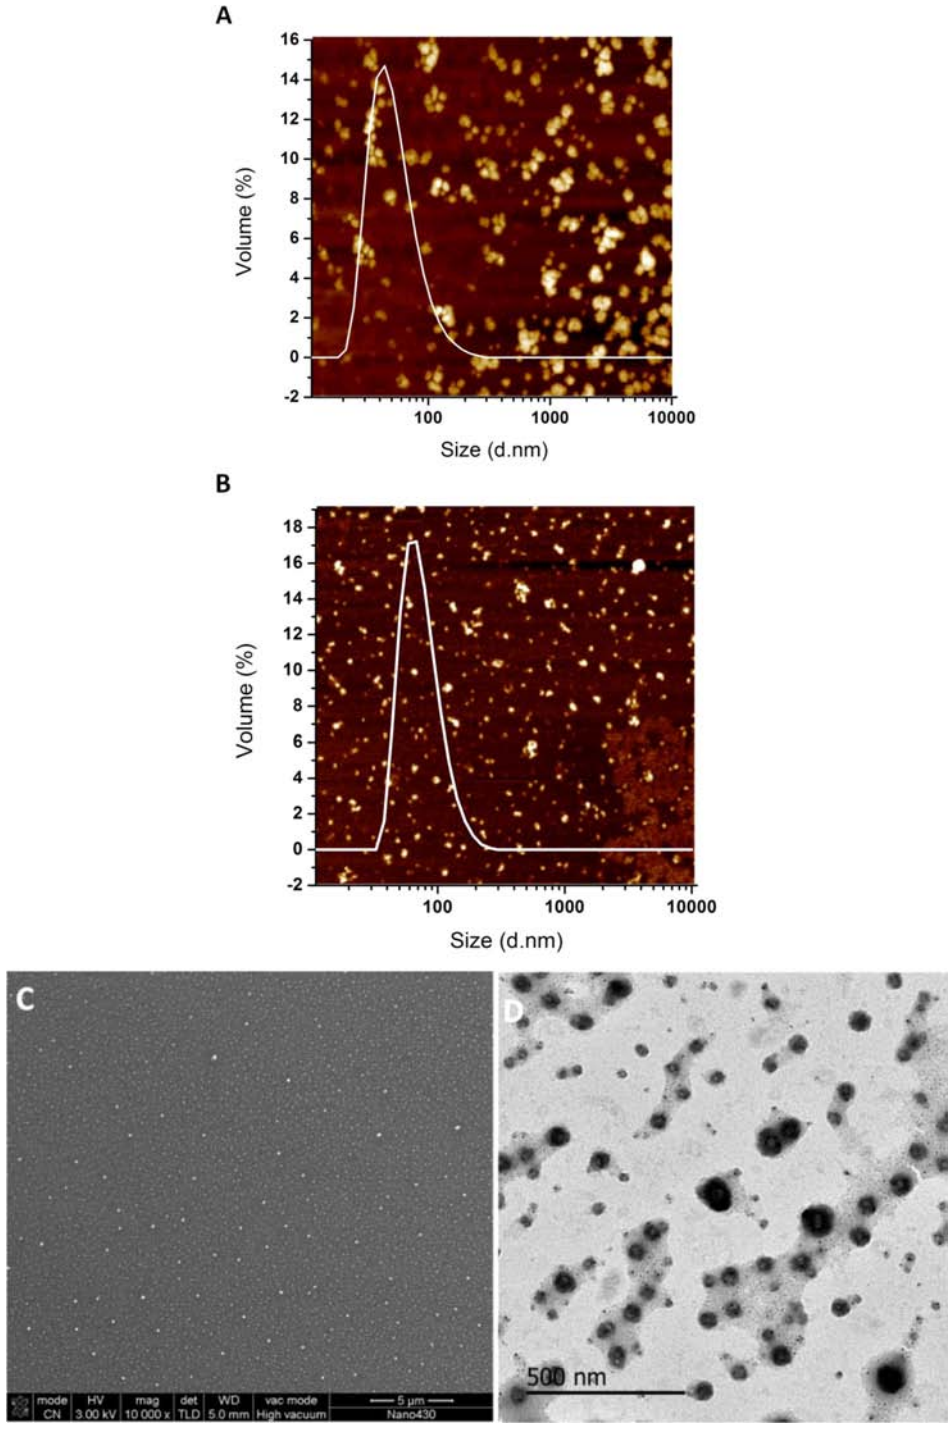

Figure 7. AFM images and size distribution of β-conglycinin−dextran conjugates (A) and nanogels (B); SEM image (C) and TEM image (D) of β-conglycinin−dextran nanogels.

can form spherical particles and deplete self-aggregates of β-conglycinin.

The SEM image presented in Figure 7C illustrates that the well-dispersed nanogels were of globular shape with narrow particle distribution. The TEM image (Figure 7D) verifies that the nanogels were characterized by spherical shapes with core−shell structure having a dark shell and a light core. The phenomenon found in the TEM image may be rationalized by the following mechanism: a heat treatment to conjugates could cause the β-conglycinin to unfold, promote macroscopic aggregates, and form macro gels, but the dextran covalently attached to the β-conglycinin through Maillard reaction restrained the β-conglycinin from aggregating due to the steric hindrance of dextran; it, therefore, served as the barrier for the inner β-conglycinin molecules, which cross-linked with each other by attractive forces (e.g., hydrophobic, disulfide bonds).[37] Hence, the flexible and hydrophilic dextran chains constituted the dark shell region, whereas the hydrophobic cross-linked β-conglycinins constituted the light core region (Figure 7D).

ζ-Potential. The ζ-potential of β-conglycinin, β-conglycinin/dextran mixture, and β-conglycinin−dextran nanogels was monitored at various pH values (Figure 8). The samples

DOI: 10.1021/acs.jafc.5b01778
J. Agric. Food Chem. 2015, 63, 6075−6083

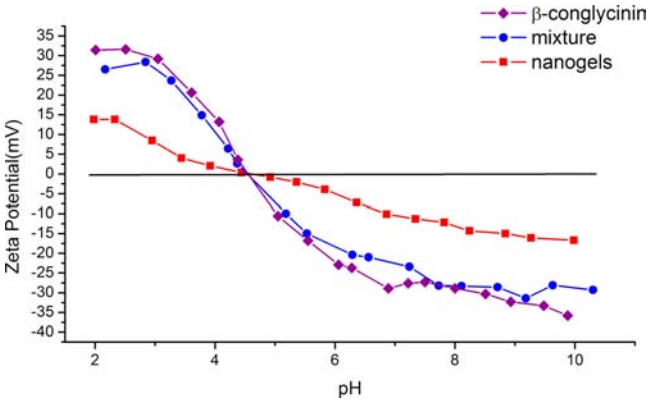

Figure 8. Zeta potential of native β-conglycinin, β-conglycinin/dextran mixture, and β-conglycinin−dextran nanogels at different pH values.

were positively or negatively charged at the pH above or below p*I*, and they carried zero net charge near the p*I*. It is worth noting that the ζ-potential of nanogels was pronouncedly lower in magnitude compared with native β-conglycinin as well as mixture, and the difference was even larger when the pH was farther from the p*I*. Harada and Kataoka synthesized core−shell-like polyion complex micelles developed from lysozyme and poly(ethylene glycol)−poly(aspartic acid) block copolymer (PEG−P (ASP)).[38] The ζ-potential of these associates was about zero because the PEG corona could sterically stabilize the micelles. Riley and co-workers reported that the ζ-potential of nanoparticles prepared from poly(lactic acid) (PLA)−PEG copolymers was negligible when compared with PLA nanoparticles, and they attributed this phenomenon to the PEG segment that shielded the carboxyl acid end groups of the PLA chains.[39] Likewise, the ζ-potential profile of nanogels in Figure 8 further confirmed the aforementioned finding that β-conglycinin cores were covered with nonionic dextran blocks. The coated dextran shielded the inner protein and, therefore, it weakened the electrostatic repulsion of protein in different cores. However, the nanogel solution still carried several net charges at the pH farther from the p*I*. This phenomenon may be attributed to the presence of native β-conglycinin in the solution, which neither conjugated with dextran nor fabricated nanogels.

Circular Dichroism Spectroscopy. CD spectroscopy has been proved as a reliable method to reveal the conformational structure of protein.[40] The far-UV spectrum (in the region of 190−250 nm) estimates the secondary conformation of protein, whereas the near-UV fingerprint (in the region of 260−340 nm) exhibits the tertiary structure of protein.

The far-UV curves of native β-conglycinin, β-conglycinin/dextran mixture, β-conglycinin−dextran conjugates, and nanogels were presented in Figure 9A. The spectrum of native β-conglycinin showed two negative dichroic peaks around 208 and 217 nm, a positive bank in the vicinity of 195 nm, and a zero-crossing near 200 nm, suggesting that the secondary composition of native β-conglycinin was mainly β-sheet.[41] There was no significant difference in secondary structure among the native protein, mixture, and conjugates. However, as to nanogels, the mean residue ellipticity at 208 and 217 nm largely decreased, which indicated that the secondary conformation of nanogels changed and the β-sheet content increased.

The near-UV spectra are shown in Figure 9B. The native β-conglycinin exhibited a positive peak at 270 nm, and the

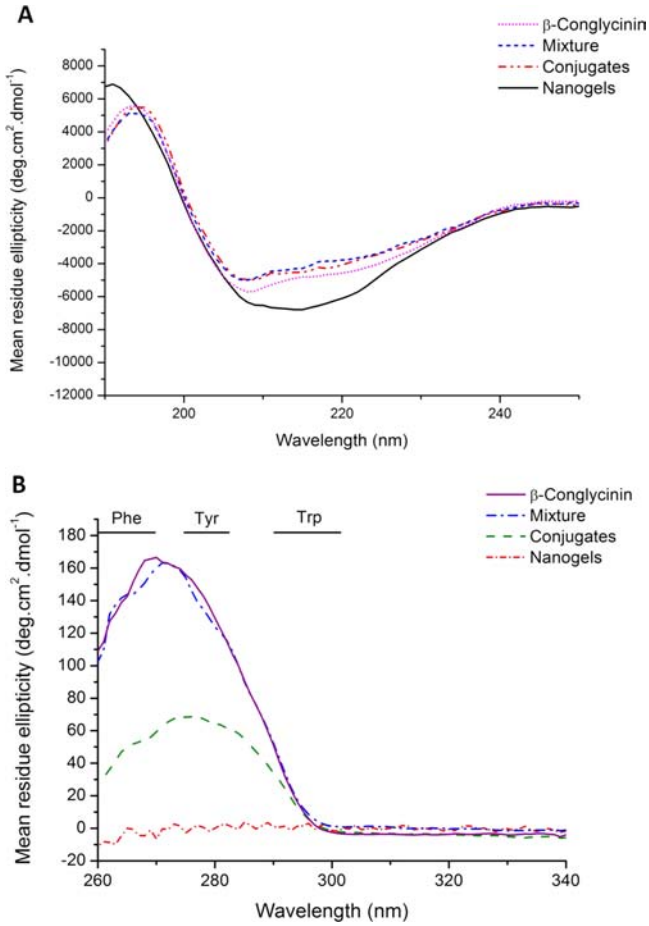

Figure 9. Far-UV CD spectra (A) and near-UV CD spectra (B) of native β-conglycinin, β-conglycinin/dextran mixture, and β-conglycinin−dextran conjugates and nanogels.

dichroic curve of mixture was similar to that of β-conglycinin. However, a decrease in the magnitude of the bank was observed after glycation, demonstrating that aromatic side chains were exposed to some extent during Maillard reaction.[42] It is worth noting that the positive peak of nanogels disappeared and the intensity of the spectrum was relatively low, clearly indicating that the tertiary structure of protein was totally destroyed after further heating of the Maillard dry-heat conjugates.

Surface Hydrophobicity. H_0 was determined by fluorescence probe methods using the ANS probe, which can access the hydrophobic groups on the surface of proteins and bind with the aromatic amino acid residues. H_0 has been used to reflect the 3D structure and conformational changes of protein.[25] Figure 10 exhibits the changes of H_0 at pH 7.0 with various specimens. The surface hydrophobicity of the mixture decreased slightly compared with the native β-conglycinin, suggesting that the free dextran had little effect on the H_0 of protein. Moreover, there was no substantial difference ($P < 0.05$) in H_0 between the conjugates and native β-conglycinin. This phenomenon might be attributed to the conjecture that H_0 is determined not only on the degree of partial denaturation of β-conglycinin during the Maillard dry-heat process, which is prone to increase it, but also on the degree of glycation, which is prone to decrease it. However, further heat treatment of conjugates caused a pronounced enhancement in H_0 of the nanogels. It is well-known that heat treatment will lead to the

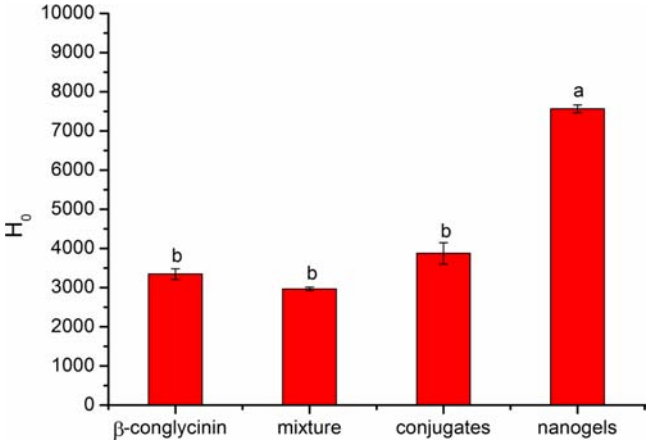

Figure 10. Surface hydrophobicity (H_0) of native β-conglycinin, β-conglycinin/dextran mixture, β-conglycinin–dextran conjugates, and nanogels. Different letters (a, b) above columns indicate significant differences ($P < 0.05$).

thermal denaturation of protein and subsequent exposure of nonpolar amino acids. Consequently, the surface hydrophobicity of β-conglycinin in nanogels was higher than that of the native protein and conjugates. The result indicates that the tertiary structure of nanogels was changed, which is consistent with the previous CD study.

Because the core of nanogels was composed of cross-linked β-conglycinins, the hydrophobic groups of which were exposed to the surface of protein, it is likely that several well-defined hydrophobic compartments were developed inside the core of nanogels, which might be available to deliver hydrophobic compounds due to the hydrophobic attraction between β-conglycinins and compounds.

Stability of Soy β-Conglycinin–Dextran Nanogels. The nanogels prepared at pH 4.8 were then incubated at various pH values. Figure 11A illustrates that the particle size and size distribution of nanogels did not change significantly from pH 2 to 12, suggesting that the nanogels were resistant to pH change. When the pH was farther from the p*I*, the β-conglycinins in the core were prone to separate from each other, but the cross-linking structure of β-conglycinins, which were formed in the heating process, made the nanogels remain stable in solution. On the other hand, when the pH was at/around the p*I*, the β-conglycinins in different cores tended to aggregate due to the lack of electrostatic repulsion; however, the glucan shells acted as shields to prevent the proteins from aggregating owing to the hydrophilicity and steric hindrance of dextrans. The results were in accordance with the aforementioned self-assembly mechanism of nanogels.

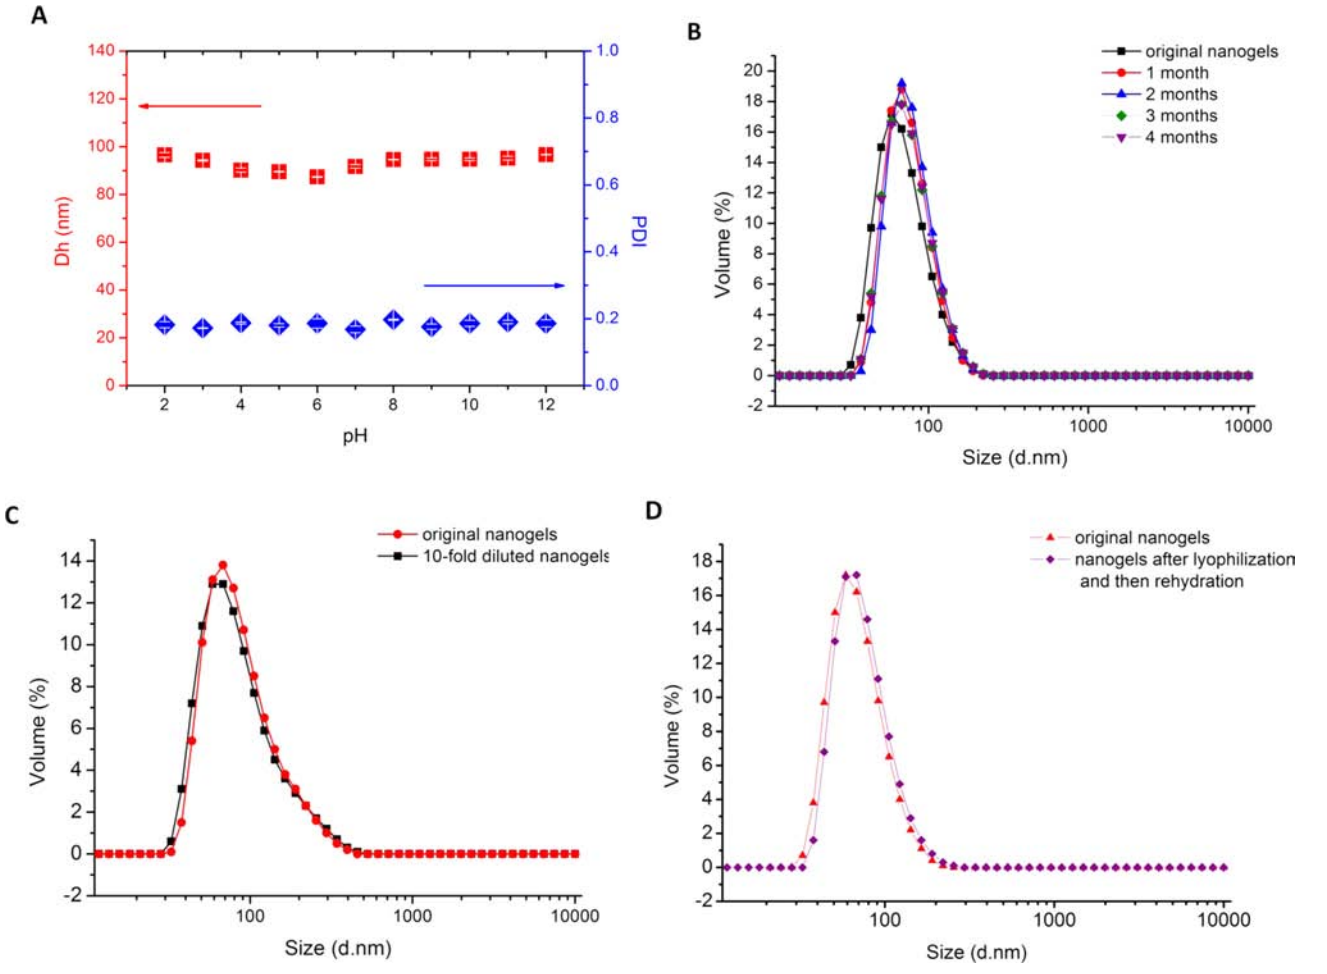

Figure 11. (A) D_h and PDI of nanogels under different pH conditions; (B) size distribution of freshly prepared nanogels and after storage for 1, 2, 3, or 4 months; (C) size distribution of nanogels as prepared and diluted to 0.1 mg/mL; (D) size distribution of nanogels as prepared and freeze-dried followed by rehydration.

DOI: 10.1021/acs.jafc.5b01778
J. Agric. Food Chem. 2015, 63, 6075–6083

No aggregates were found in the nanogel solution and, together with the particle size and polydispersity values (Figure 11B), were maintained after 4 months of storage at 4 °C without antiseptics, indicating that the nanogels were initially in thermodynamic equilibrium.[38] The narrow Gaussian fit of nanogels (Figure 11C), which were diluted to 0.1 mg/mL (10-fold), reconfirms that the cross-linking structures of nanogels are fairly stable. Furthermore, the lyophilized nanogels were water-dispersible, and there is no considerable change in the particle size of nanogels that were freeze-dried followed by rehydrating versus the original ones (Figure 11D). All of these outstanding properties are favorable to the practical application of nanogels in the food industry.

The synthesis of nanogels was illustrated in Figure 12. Amphiphilic soy β-conglycinin−dextran conjugates were formed by dextran covalently attaching to protein via the Maillard reaction. The amphiphilic graft copolymers subsequently self-assembled to fabricate core−shell nanogels. The grafted dextran afforded a shell to the inner cross-linked β-conglycinins and in turn improved the stability of nanogels. The formerly buried hydrophobic groups were exposed to the surface of β-conglycinin and constructed several hydrophobic compartments in the core, which may offer great potential to deliver hydrophobic compounds due to the hydrophobic interaction between the nanogels and the compounds.

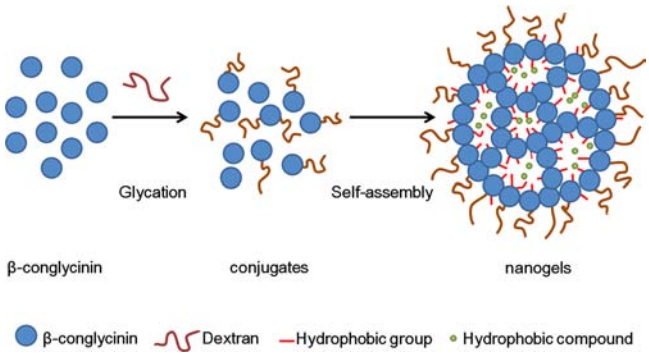

Figure 12. Illustration of the synthesis of β-conglycinin−dextran nanogels.

In conclusion, soy β-conglycinin−dextran nanogels were successfully produced via a self-assembly method at the isoelectric point of β-conglycinin. The nanogels were spherical with core−shell structures, as evidenced by AFM, SEM, and TEM as well as ζ-potential studies, and the hydrodynamic diameter was around 90 nm. Surface hydrophobicity and CD analyses clearly indicated that the structures of β-conglycinins were destroyed and the hydrophobic groups were exposed to the surface of protein to form hydrophobic compartments in the cores. The nanogels were fairly stable against long-term storage, pH change, lyophilization, or dilution. These valuable properties and the low toxicity of nanogels may provide a promising way to deliver hydrophobic compounds, and further research will emphasize the loading and unloading bioactive substance.

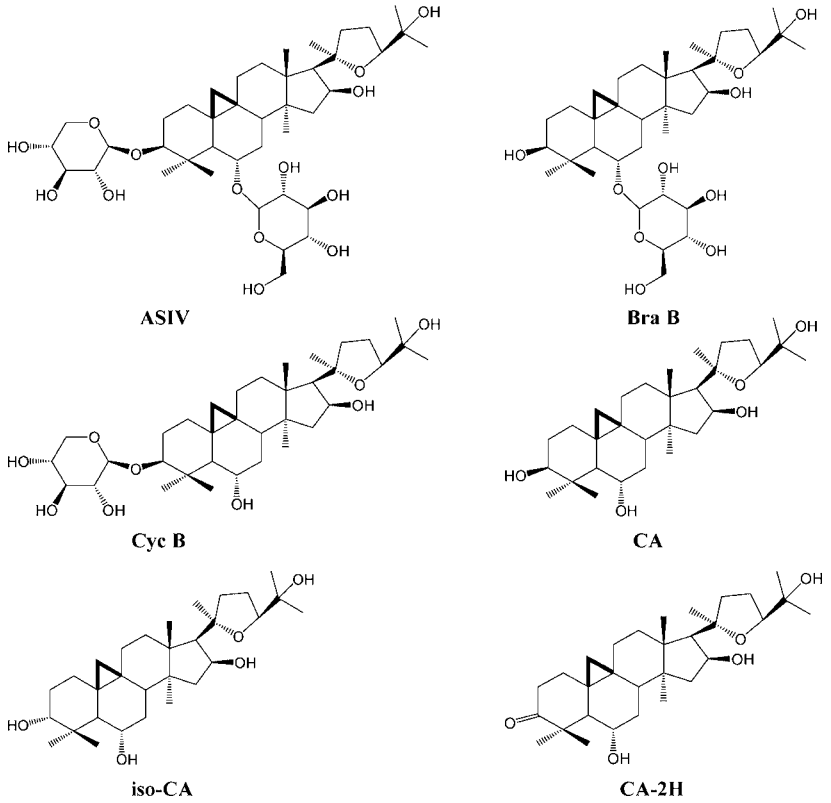

Figure 1. Chemical structures of ASIV and its metabolites. ASIV, astragaloside; Bra B, brachyoside B; Cyc B, cyclogaleginoside B; CA, cycloastragenol; iso-CA, iso-cycloastragenol; CA-2H, dehydrogenated metabolite of CA.

the disposition of ASIV is still missing. In addition, the activity of intestinal microbiota is predicted to change enterohepatic circulation of metabolites secreted from the liver and affect the *in vivo* distribution of xenobiotics. Elucidation of the effect of the intestinal microbiome on the disposition of ASIV will be a great help in understanding its bioactivities and bioavailability. Therefore, the present study aimed to investigate the enterohepatic circulation of ASIV and assess the impact of the activity of the intestinal microbiome on the disposition of ASIV.

MATERIALS AND METHODS

Chemicals. ASIV (purity > 98%) and CA (purity > 98%) were supplied by Shanghai Winherb Medical Technology Co. Ltd. (Shanghai, China). Ketoconazole (the internal standard, IS, purity > 99%) was obtained from the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Solutol HS 15 was provided by BASF Co. (Ludwigshafen, Germany). BBL brain−heart infusion (BHI) and rat liver S9 were purchased from Becton Dickinson Co. (Franklin Lakes, NJ, USA). Hemin bovine and vitamin K1 were supplied by Shanghai Yuanye Biotech Co. (Shanghai, Chaina). L-Cystine was provided by Biosharp Co. (Anhui, China). β-Nicotinamine adenine dinucleotide phosphate (reduced form, NADPH) was purchased from Xinjingke Biotechnology Co. (Beijing, China). HPLC grade acetonitrile was obtained from Fisher Chemicals (Fair Lawn, NJ, USA). Distilled water, prepared from demineralized water, was used throughout the study. All other chemicals and solvents were of analytical grade and used without further purification.

Animals. Male Sprague−Dawley (SD) rats (200 ± 10 g) were obtained from Laboratory Animal Center of Shenyang Pharmaceutical University (Shenyang, China). They were kept in a temperature- and humidity-controlled (temperature, 25 ± 2 °C; humidity, 52.6 ± 5.3%) environment with a reverse 12 h light/dark cycle. After a week of acclimation, the animals were fasted 12 h before experiments. During the period of experiment, animals had free access to food and autoclaved distilled water except those under anesthesia with urethane. All experimental procedures were performed in accordance with the guidelines of the Experimental Animal Care and Use Committee of Shenyang Pharmaceutical University (Shenyang, China). The experimental animal ethic review approval number was SYPU-IACUC-2014-0039.

Pharmacokinetic Study. *Oral Administration.* Six male rats were given a single intragastrical (ig) administration of 10 mg/kg ASIV dissolved in 0.5% sodium carboxymethyl cellulose (CMC-Na). The dosage was selected according to the published literature[12] as well as the clinical dosage of Radix Astragali (20−100 g/day) and the content of ASIV in Radix Astragali (≥0.04%). The rats were slightly anesthetized by diethyl ether before blood collection. Blood samples (200 μL) of rats obtained from the periorbital sinus vein were collected into heparinized tubes before administration (0 h) and at 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, 10, and 12 h after administration. Plasma was separated by centrifugation at 4000*g* for 5 min and stored at −70 °C until analysis.

Intravenous Administration. Six male rats were treated with a dose of 1.5 mg/kg ASIV from the caudal vein on the basis of reported documents.[11,17,29] The injection solution is prepared in 10% (w/v) Solutol HS 15 in saline. After the rats were slightly anesthetized by diethyl ether, blood samples (200 μL) were collected from the periorbital sinus vein into heparinized tubes before administration (0 h) and at 0.083, 0.167, 0.33, 0.5, 1.0, 2.0, 4.0, 6.0, 8.0, 10, and 12 h after dosing. Plasma was separated by centrifugation at 4000*g* for 5 min and stored at −70 °C until analysis.

Enterohepatic Circulation Experiments in Bile Duct Cannulation Rat Model. *Oral Administration Experimental Design.* Twelve male rats were randomly divided into two groups. One group of rats (n = 6) received bile duct cannulation surgery before being given a dosage of 10 mg/kg ASIV from the duodenum. In brief, the animals were anesthetized by an intraperitoneal (ip) injection of urethane (1 g/kg). A 1 cm cut was made to expose the jugular vein for each rat. Then the vein was cut, and a cannula made of polyethylene-

DOI: 10.1021/acs.jafc.5b00168
J. Agric. Food Chem. 2015, 63, 6084−6093

20 tubing was inserted. After the cannula and the vein were tied with sterilized suture, a 4 cm cut was made to open the abdominal cavity of the rat. The bile duct was separated from the surrounding tissue, and a polyethylene-10 tubing was inserted into the duct. When bile flow out of the cannulation was seen without restriction, the cannula was secured with sutures. After that, ASIV solution (1 mg/mL in 0.5% CMC-Na) in a syringe was slowly injected into the duodenum through an intravenous infusion needle at about 6 cm below pylorus. The injection rate was controlled at 0.1 mL/min by a syringe pump. Another six control rats were treated with the same procedure except bile duct drainage.

With the tolerance of rats to surgery and the pharmacokinetic profiles of ASIV and its metabolites after an ig administration of ASIV taken into consideration, blood samples (200 μL) of bile duct-cannulated rats and control rats were collected from the jugular vein at only four time points: before administration (0 h) and at 2.0, 8.0, and 10 h after administration. Plasma was separated by centrifugation at 4000*g* for 5 min. Bile samples were collected into 1.5 mL centrifuge tubes in 30 min before administration and every 30 min after administration until 10 h. Plasma and bile samples were stored at −70 °C until analysis.

Intravenous Administration Experimental Design. Six male rats having bile duct and jugular vein cannulation surgery (by the same method as described above) were given an injection of ASIV at a dose of 1.5 mg/kg from the caudal vein. Another six rats having only jugular vein cannulation surgery were labeled as controls. The control rats also received an iv injection of 1.5 mg/kg ASIV from the caudal vein after surgery. Blood samples (200 μL) of rats in both groups were obtained from the jugular vein and collected into heparinized tubes before administration (0 h) and at 2.0, 8.0, and 10 h after administration. Plasma was separated by centrifugation at 4000*g* for 5 min. Bile samples were collected into 1.5 mL centrifuge tubes in 30 min before administration and every 30 min after administration until 10 h. Plasma and bile samples were stored at −70 °C until analysis.

Rat Intestinal S9 Fraction Preparation. Rat intestinal S9 fraction was prepared from male SD rats according to a published procedure with a slight modification.[30] In brief, rats were anesthetized with urethane (1 g/kg), and then rat whole intestines were cut out and flushed with ice-cold saline containing 1 mM dithiothreitol. After the intestines were pooled from six rats, they were washed twice with the ice-cold washing solution (consisting of 8 mM KH_2PO_4, 5.6 mM Na_2HPO_4, 1.5 mM KCl, 96 mM NaCl, 27 mM sodium citrate, and 0.04 mg/mL phenylmethanesulfonyl fluoride (PMSF)). After they had been dried with paper, the intestinal strips were cut open, and mucosal cells were scraped off in a 4 °C cold room. The mucosal cells were centrifuged at 900*g* for 5 min at 4 °C and washed twice in 50 mL of the homogenization buffer (consisting of 10 mM, pH 7.4, KH_2PO_4, 250 mM sucrose, 1 mM EDTA, and 0.04 mg/mL PMSF). The cells were resuspended in 15 mL of the homogenization buffer. After 15 min of centrifugation at 9000*g* and 4 °C, the supernatant was collected, aliquoted, and stored at −70 °C until use. Protein concentration was determined by using the Coomassie brilliant blue colorimetric method.

In Vitro Metabolism of ASIV and CA by Rat Liver and Intestinal S9 Fraction. ASIV (1 μM) or CA (1 μM) was mixed with liver or intestinal S9 fraction (the final protein concentrations were 1 mg/mL), potassium chloride (10 mM), magnesium chloride (10 mM), and 1.0 mM NADPH in 50 mM potassium phosphate buffer (pH 7.4). The total volume was 200 μL. The reaction was initiated by the addition of a solution of NADPH after 5 min of pre-incubation. After incubation at 37 °C for 0 and 1 h, the reaction was terminated by the addition 200 μL of cold methanol (0 °C). The mixture was centrifuged at 4000*g* for 5 min, and the supernatant was stored at −20 °C until analysis. Controls were prepared in the same manner, except for the presence of NADPH. Blank samples were assayed without substrate to exclude analytical interference by the matrix.

In Vitro Metabolism of ASIV and CA by Rat Intestinal Microbiota. Five healthy male rats were housed in individual steel metabolism cages. Fresh feces were collected and immediately stored at −70 °C until use. Pooled feces (2.5 g from five rats, 0.5 g/rat) were mixed with 20 mL of culture medium of BHI containing 37 μg/mL BHI, 5 μg/mL hemin bovine, 0.5 mg/mL L-cystine, and 0.02% vitamin K1.[31] The fecal suspension was centrifuged at 300*g* for 5 min. The resultant supernatant was transferred into another clean tube and centrifuged at 4000*g* for 10 min; then the residue was resuspended in 15 mL of culture medium of BHI to produce intestinal bacteria solution. ASIV (20 μM) or CA (1 μM) was mixed with 20 μL of intestinal bacteria solution and 180 μL of culture medium of BHI. The total volume was 200 μL. The mixture was incubated at 37 °C under anaerobic conditions for 0, 2, 4, 8, 12, 24, 36, and 48 h. The reaction was stopped by the addition of 200 μL of cold methanol (0 °C). The mixture was centrifuged at 4000*g* for 5 min, and the supernatant was stored at −20 °C until analysis. Control and blank samples were prepared in the same manner without bacteria solution and substrate, respectively.

Effect of Activity of Intestine Microbiota on the Disposition of ASIV. *Comparison of Metabolism of ASIV by Intestinal Microbiota from Rats Pretreated with and without Antibiotics.* Five male rats were given a mixture solution of streptomycin sulfate and bacitracin (1:1, w/w; 200 mg/kg) dissolved in sterilized water through gavage twice daily for 6 days to inhibit the activity of intestinal microbiome. Another five rats without the treatment of antibiotics were used as controls. Fresh fecal samples from five control rats and those from five antibiotic-pretreated rats were collected individually and pooled separately. Then intestinal bacteria solutions from the two different fecal samples were prepared and incubated with 20 μM ASIV by the corresponding methods as described above. After incubation at 37 °C for 0, 4, 8, 12, and 24 h, the reaction was stopped by the addition of 200 μL of cold methanol (0 °C). The mixture was centrifuged at 4000*g* for 5 min, and the supernatant was stored at −20 °C until analysis. Control and blank samples were prepared in the same manner without bacteria solution and substrate, respectively.

Antibiotics used to inhibit the activity of gut microbiota may interact with the analyte, which might interfere with the study result. Therefore, we determined the potential interference of antibiotics to the biotransformation ASIV in intestinal microbiota. ASIV (20 μM) in the presence of streptomycin sulfate and bacitracin (1:1, w/w; 0.08, 0.4, or 2 mg/mL) was mixed with 20 μL of intestinal bacteria solution and 180 μL of culture medium of BHI. After incubation at 37 °C for 0 and 4 h, the reaction was stopped by the addition of 200 μL of cold methanol (0 °C). The mixture was centrifuged at 4000*g* for 5 min, and the supernatant was stored at −20 °C until analysis. Control and blank samples were prepared in the same manner without bacteria solution and substrate, respectively.

Comparison of Pharmacokinetics of ASIV in Rats Pretreated with and without Antibiotics. Six male rats were treated with antibiotics according to the same method as mentioned above. After an overnight fast, antibiotic-pretreated rats received an ig dose of 10 mg/kg ASIV dissolved in 0.5% CMC-Na. The rats were under light diethyl ether anesthesia before blood collection. Blood samples (200 μL) were collected from the periorbital sinus vein into heparinized tubes before administration (0 h) and at 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, 10, and 12 h after administration. Plasma was separated by centrifugation at 4000*g* for 5 min and stored at −70 °C until analysis. The rats given an ig dose of ASIV in pharmacokinetic study were used as controls.

Sample Preparation. For plasma and bile samples, a 10 μL aliquot of the IS solution (4.0 μM ketoconazole in methanol) and a 100 μL aliquot of methanol were added into a 50 μL aliquot of sample. The mixture was vortex-mixed for 1 min. After being centrifuged at 15000*g* for 5 min, a 5 μL aliquot of the supernatant of each sample was injected for LC-MS/MS analysis.

For the samples in in vitro metabolism studies, a 10 μL aliquot of the IS solution (4.0 μM ketoconazole in methanol) and a 50 μL aliquot of methanol were added into 100 μL of sample. Then the mixture was prepared according to the same method as that for plasma and bile samples.

LC-MS/MS Analysis. The chromatographic separation was performed on a Venusil ASB C18 column (150 × 4.6 mm, 5 μm, Agela, Tianjin, China). Methanol (A) and 5 mM ammonium acetic acid (B) were used as mobile phase for elution. The gradient was controlled as follows: 0−1.0 min, 60% A; 1.0−2.0 min, 60−90% A;

DOI: 10.1021/acs.jafc.5b00168
J. Agric. Food Chem. 2015, 63, 6084−6093

2.0−5.5 min, 90% A; 5.5−6.0 min, 90−60% A; 6.0−8.0 min, 60% A. The retention times of ASIV, Bra B, Cyc B, CA, iso-CA, CA-2H, and IS were around 4.5, 4.8, 4.7, 5.1, 6.0, 5.3, and 4.2 min, respectively.

An API 4000 triple-quadrupole tandem mass spectrometer (Applied Biosystem/MDS SCIEX, Foster City, CA, USA) with Turboionspray source (TIS) was operated in positive ion mode. Quantification was performed using the multiple reactions monitoring (MRM) method. The MRM transitions and compound-dependent parameters for ASIV and its metabolites are listed in Table 1. The main working parameters

Table 1. MRM Transitions and Compound-Dependent Parameters for ASIV and Its Metabolites

compound	MRM transition	DP	EP	CE	CXP
ASIV	m/z 785 → 143	44	10	16	10
CA and iso-CA	m/z 491 → 143	33	10	16	15
CA-2H[a]	m/z 489 → 143	33	10	16	15
Bra B[a]	m/z 653 → 143	44	10	16	10
Cyc B[a]	m/z 623 → 143	44	10	16	10
ketoconazole (IS)	m/z 531 → 489	120	10	55	15

[a]Without the standards of CA-2H, Bra B, and Cyc B, the compound-dependent parameters of CA were adopted for the determination of CA-2H and those of ASIV were used for the quantification of Bra B and Cyc B because of similarity in chemical structure.

were set as follows: ionspray voltage, 4.5 kV; ion source temperature, 350 °C; gas 1, 40 psi; gas 2, 45 psi; curtain gas, 15 psi. Analyte concentrations were determined using the software Analyst 1.5.

The assay of ASIV and CA was validated according to the guidance for bioanalytical method validation.[32] The calibration curves were constructed in concentration ranges of 2.55−510 nM for ASIV and 1.02−204 nM for CA with good linearity showing correlation coefficients (r) better than 0.993. Without the standard of iso-CA, the amount of iso-CA was calculated from the standard curves of CA. The same method was applied by Zhou et al. to investigate the pharmacokinetics of iso-CA in rats after an oral dose of 40 mg/kg ASIV.[13] The intra- and interday precisions were lower than 13.6% for ASIV and CA, and the accuracy was within ±12.1% deviation from the nominal values of the analytes. Due to the lack of standards of Bra B and Cyc B, their concentrations were expressed as peak area ratios of analyte/IS in the study.

Data Analysis. The pharmacokinetic parameters of ASIV, CA, and iso-CA were estimated by noncompartmental method using the DAS 3.2.0 pharmacokinetic program (Chinese Pharmacology Society) because the noncompartmental model is a robust population model and it provides additional information on the random variation component existing between animals. The maximum plasma concentrations (C_{max}) and the corresponding peak time (t_{max}) were observed from the individual drug plasma concentration−time profile. The terminal elimination rate constant (k_e) was estimated by log−linear regression of concentrations observed during the terminal phase of elimination. The elimination half-life ($t_{1/2}$) was calculated as 0.693/k_e. The area under the plasma concentration−time curve was calculated by the linear trapezoidal rule.

Data are reported as the mean ± SD. Independent Student t tests and one-way ANOVA with Tukey−Kramer multiple-comparison (post hoc) tests (Minitab, version 14) were used to evaluate statistical differences. Differences were considered statistically significant when p values were <0.05.

RESULTS AND DISCUSSION

Pharmacokinetic Study. *Oral Administration.* The mean plasma concentration−time curves of ASIV, CA, and iso-CA in rats after an ig dose of 10 mg/kg ASIV are shown in Figure 2A. The main pharmacokinetic parameters of ASIV, CA, and iso-CA are presented in Table 2. ASIV reached the maximum level (C_{max}) of 34.5 ± 20.6 nM at 2.0 h, whereas its metabolites, CA

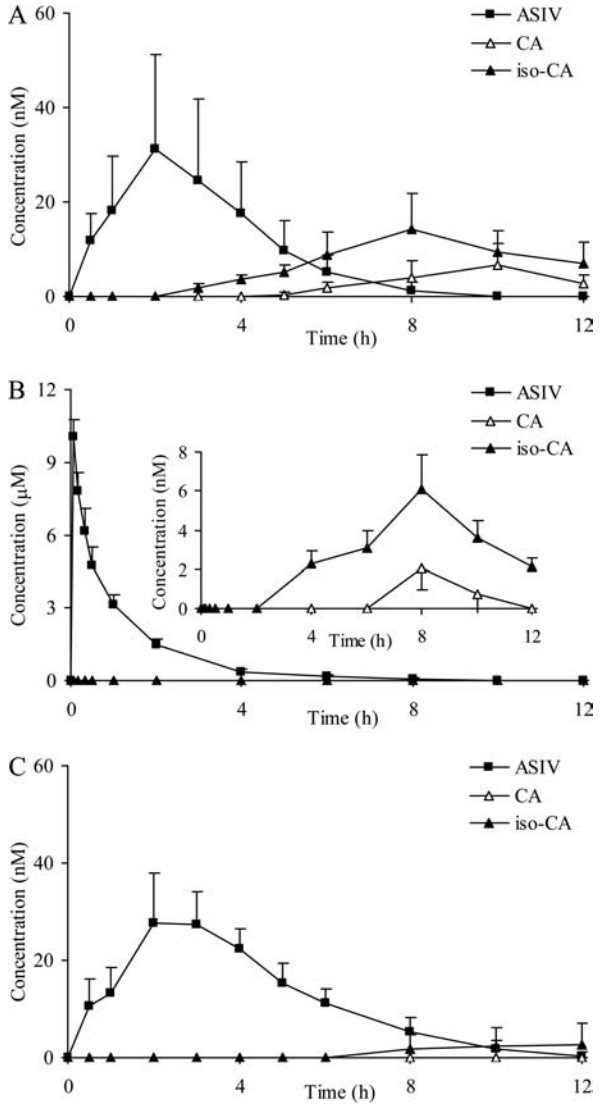

Figure 2. Mean plasma concentration−time curves of ASIV, CA,and iso-CA in control rats after an intragastrical (ig) administration of 10 mg/kg ASIV (A) or an intravenous (iv) administration of 1.5 mg/kg ASIV (B) and in antibiotic-pretreated rats after an ig administration of 10 mg/kg ASIV (C). Each point represents the mean ± SD (n = 6).

and iso-CA, achieved their maximum concentrations comparatively late at approximately 8 h. As reported by Zhou et al.,[13] ASIV predominated in the forms circulated in blood after ingestion. The contributions of ASIV, CA, and iso-CA to the total exposure (the sum of AUC values of ASIV, CA, and iso-CA) were 51.0, 12.5, and 36.5%, respectively (Table 2). No other metabolites of ASIV were observed in rat plasma.

Multiple peaks often appear in plasma concentration−time curves of xenobiotics with enterohepatic circulation. However, there was not a secondary peak in the concentration−time curve of ASIV. This phenomenon probably resulted from the slow and approximately uniform absorption of ASIV from the small intestine, because ASIV showed similar low absorption rates in rat duodenum, jejunum, and ileum.[32]

Intravenous Administration. Pharmacokinetics of ASIV and its metabolites in rats were studied after an iv injection of 1.5 mg/kg ASIV. The mean plasma concentration−time curves of ASIV, CA, and iso-CA are shown in Figure 2B. The corresponding pharmacokinetic parameters are summarized in

		CA[c]				
		iso-CA[a]		4.41 ± 4.01[d]	11.0 ± 1.2	16.4 ± 15.0[d]

[a]The valid time points were not enough for the calculation of $t_{1/2}$. [b]The C_{max} data were obtained from the plasma samples collected at 0.083 h after injection. [c]The concentration of CA in antibiotic-pretreated rats after an ig dose of ASIV was too low to be detected. [d]The data obtained in antibiotic-pretreated rats were significantly different from those obtained in control rats after ig administration of ASIV according to Student's t test ($p < 0.05$).

Table 2. When rats received an iv injection of ASIV, ASIV traveled in rat systemic circulation mainly as itself. Very tiny amounts of CA and iso-CA were detected in rat plasma from 4 h after administration. The contributions of ASIV, CA, and iso-CA to the total exposure were 99.7, 0.05, and 0.3%, respectively (Table 2). Compared with the corresponding data obtained after ig administration, the contribution of CA and iso-CA to the total exposure decreased >100 times after iv injection (0.05 vs 12.5% for CA and 0.3 vs 36.5% for iso-CA), suggesting that the intestinal tract might contribute more than the liver to the biotransformation of ASIV.

Enterohepatic Circulation Experiment in Bile-Duct Cannulation Rat Model. *Oral Administration Experiment.* To investigate the effect of enterohepatic circulation on the disposition of ASIV, we compared the plasma distribution of ASIV and its metabolites between rats with and without bile-duct cannulation (control) at 2, 8, and 10 h after administration of ASIV from the duodenum. Time points of 2, 8, and 10 h were the t_{max} values of ASIV, iso-CA, and CA, respectively, as shown in the pharmacokinetic study of ASIV after oral administration (Figure 2A and Table 2).

The plasma concentrations of ASIV, CA, and iso-CA in control rats at 2 h were 29.5 ± 10.1 nM, undetectable, and undetectable, respectively; at 8 h they were 2.68 ± 2.26 nM, undetectable, and 2.64 ± 0.89 nM, respectively; and at 10 h they were undetectable, 5.05 ± 2.53 nM, and 9.37 ± 4.23 nM, respectively. After rats received bile-duct drainage surgery, the plasma amount of ASIV at 2 h (8.51 ± 3.91 nM) was significantly lower than that in control rats at the same point (Figure 3). Moreover, the amounts of CA and iso-CA in bile-duct cannulated rats became immeasurable at 8 and 10 h (Figure 3). These data declared that enterohepatic circulation played an important role in the disposition of ASIV after oral administration.

Biliary excretion of ASIV and its metabolites was assayed to partly profile the enterohepatic circulation process of ASIV. Figure 4 shows the bile excretion of ASIV, Bra B, and Cyc B in rats after duodenal administration of ASIV. Due to the lack of standards of Bra B and Cyc B, their excretion concentrations were expressed as peak area ratio of analyte/IS (Figure 4B). The biliary excretion of ASIV reached a plateau at 3 h after dosing (Figure 4A). The accumulative bile excretion of ASIV in

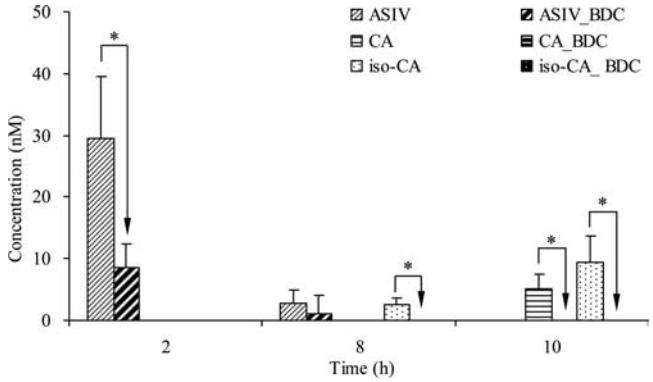

Figure 3. Comparison of plasma concentrations of ASIV, CA, and iso-CA between rats treated with and without bile-duct cannulation after administration of 10 mg/kg ASIV from the duodenum. The concentrations of ASIV, CA, and iso-CA in control rats are labeled "ASIV", "CA", and "iso-CA", respectively; those in cannulated rats are labeled "ASIV_BDC", "CA_BDC", and "iso-CA_BDC", respectively. Each point represents the mean ± SD (n = 6). The asterisk (*) indicates the differences of plasma concentration between control and cannulated rats are significant according to Student's t test ($p < 0.05$).

10 h, calculated as [(amount of ASIV in bile/dose) × 100], was 0.015%.

Although obvious amounts of ASIV, Bra B, and Cyc B were excreted from bile after rats received ASIV from the duodenum, the biliary excretion amounts of CA, iso-CA, and CA-2H were not detectable. Zhou et al. found that when 5 μM ASIV was incubated with rat intestinal bacteria, Bra B and Cyc B were formed after 0.5 and 8 h of incubation, respectively, whereas CA, iso-CA, and CA-2H were not found in the first 8 h.[13] This result suggested that the formation rates of Bra B and Cyc B from ASIV by intestinal microbiota were faster than those of CA, iso-CA, and CA-2H. The undetectable biliary excretion of CA, iso-CA, and CA-2H probably resulted from the slow hydrolysis of ASIV, Bra B, and Cyc B in the intestine and/or liver.

Intravenous Administration Experiment. In the present study, we also compared the plasma distribution of ASIV and its metabolites between bile-duct cannulated rats and control rats after iv injection. Neither CA nor iso-CA was found in

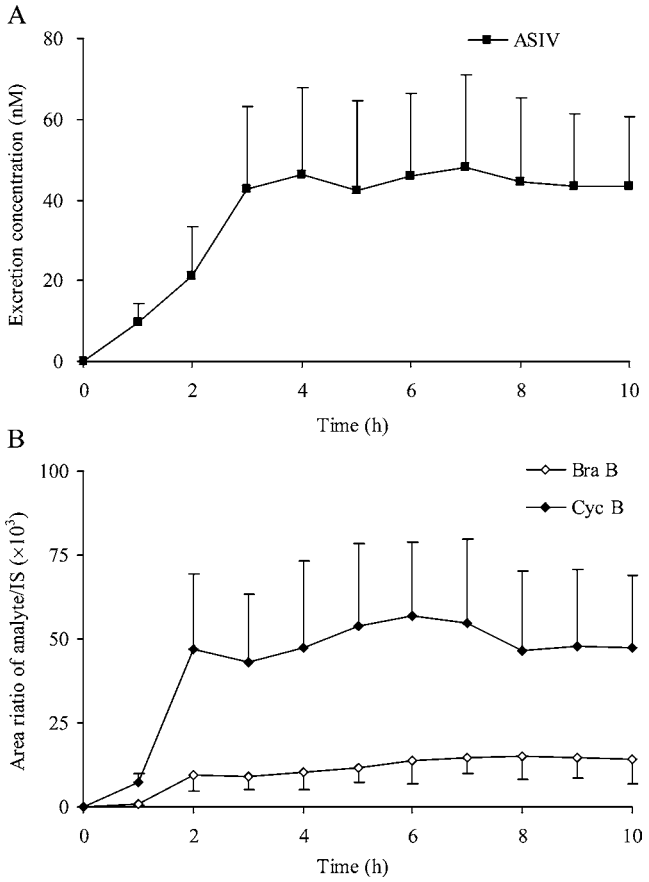

Figure 4. Bile excretion profiles of ASIV (A) and its metabolites (B) in rats following a dose of 10 mg/kg ASIV through the duodenum. In panel B, the excretion amounts of Bra B and Cyc B are expressed as peak area ratio of analyte/IS without the standards of Bra B and Cyc B. Each point represents the mean ± SD (n = 6).

control and bile-duct cannulated rats at 2, 8, and 10 h after iv injection. The plasma concentrations of ASIV in control rats at 2, 8, and 10 h were 1292 ± 198, 133 ± 26, and 36.5 ± 10.9 nM, respectively. The amount of ASIV in the bile-duct cannulation group of rats was kept at a level similar to that in the control group at the same time point, which was 1263 ± 230 nM at 2 h, 136 ± 19 nM at 8 h, and 37.2 ± 9.8 nM at 10 h.

Bile sample assay revealed that no metabolites (including Bra B, Cyc B, CA, iso-CA, and CA-2H) except ASIV were excreted from bile after iv injection of ASIV. The accumulative bile excretion of ASIV in 10 h after iv adminstration was 27.4%. Although more than one-fourth of the dosage was excreted from bile in 10 h, the plasma level of ASIV after iv injection was not affected by bile-duct drainage surgery. These data were further proof for the limited adsorption of ASIV in the intestine. In addition, the low cumulative bile excretion of ASIV after duodenal administration (0.015%) was also believed to come from the poor intestinal absorption of ASIV. Bra B and Cyc B, two deglycosylated metabolites of ASIV, were secreted from bile when rats received ASIV through the duodenum (Figure 3); however, they were not found in bile when rats were given ASIV intravenously. This result indicated that intestinal hydrolysis of ASIV was critical for the formation of Bra B and Cyc B.

After summarizing the results of enterohepatic circulation experiments, we proposed that ASIV was first slowly hydrolyzed to Bra B and Cyc B by gut microbiota; these compounds then distributed in the liver via portal vein and were quickly excreted with bile. CA was formed from the repeated hydrolysis of ASIV, Bra B, and Cyc B by gut microbiota via enterohepatic circulation, and iso-CA was generated from CA by gut microbiota and/or hepatic enzymes (Figure 5). To test and supplement our hypotheses, we investigated the metabolism of ASIV and CA by rat liver S9 fraction, intestinal S9 fraction, and intestinal microbiota.

In Vitro Metabolism of ASIV and CA by Rat Liver and Intestinal S9 Fraction. In vitro hepatic and intestinal enzyme metabolism of ASIV and CA was studied using rat liver and intestinal S9 fraction in the presence of NADPH. ASIV was comparatively stable to rat liver and intestinal S9 fraction. After ASIV (1 μM) was incubated with rat liver or intestinal S9 fraction at 37 °C for 1 h, none of the metabolites, such as Bra B, Cyc B, CA, iso-CA, and CA-2H, was observed in the incubation samples, which agreed with the reported data obtained from rat liver microsome.[13]

Iso-CA was one of the major components circulating in rat blood after oral administration of ASIV. It was generated from CA via CA-2H.[13] Therefore, we investigated the metabolism of CA in rat liver and intestinal S9 fraction to illuminate the role of liver and intestine in the formation of iso-CA. It was reported that CA was extensively metabolized by rat liver microsome and produced several monohydroxylated metabolites as well as a few hydroxylated and dehydrogenated metabolites.[24] In our study, CA underwent moderate metabolism in rat liver S9 fraction but was hardly biotransformed by intestinal S9 fraction. When CA was incubated with rat liver S9 fraction at 37 °C for 1 h, approximately 25% of CA was metabolized, of which 6% was converted to iso-CA. CA-2H as well as two hydroxylated metabolites of CA and two hydroxylated and dehydrogenated

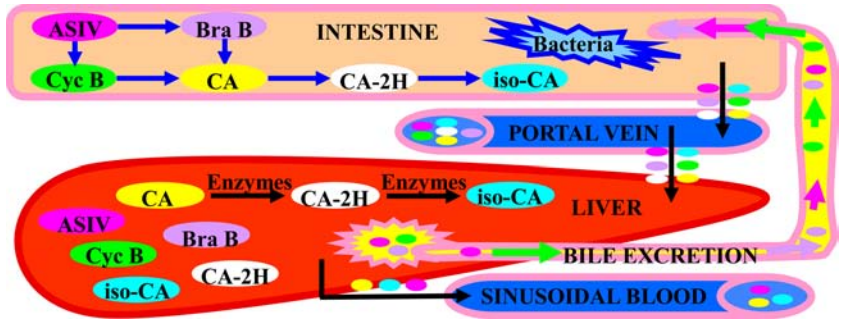

Figure 5. Schematic representation of disposition pathways of ASIV in enterohepatic circulation. Pink, purple, green, yellow, blue, and white particles stand for ASIV, Bra B, Cyc B, CA, iso-CA, and CA-2H, respectively.

metabolites of CA was also observed in rat liver S9 fraction (data not shown).

In Vitro Metabolism of ASIV and CA by Rat Intestinal Bacteria. The metabolic profile of ASIV against incubation time in rat intestinal bacteria is plotted in Figure 6. To

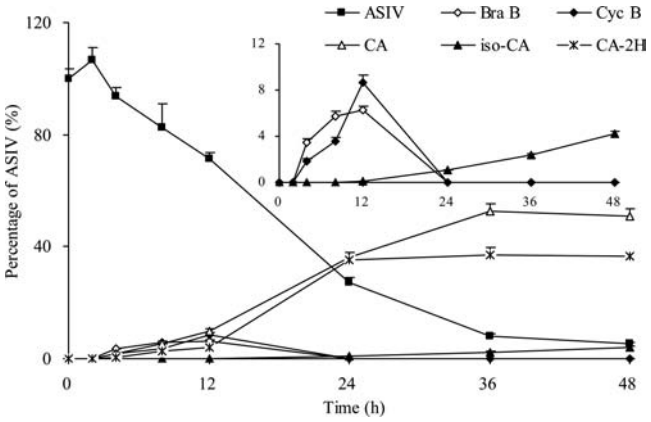

Figure 6. Remaining amount of ASIV and the formation amounts of Bra B, Cyc B, CA, iso-CA, and CA-2H after incubation of 20 μM ASIV with rat intestinal bacteria at 37 °C. The amounts of ASIV, Bra B, Cyc B, CA, iso-CA, and CA-2H were calculated as percentages of the initial amount of ASIV before incubation. Each point represents the mean ± SD (n = 3).

intuitively compare the metabolism rate of substrate and the generation rates of metabolites, the remaining amount of ASIV and the formation amounts of Bra B, Cyc B, CA, iso-CA, and CA-2H in incubation solution were expressed as percentages of the initial amount of ASIV before incubation. Despite the lack of standards of Bra B, Cyc B and CA-2H, we calculated their amounts by the following method based on the observation that there were no other metabolites of ASIV after incubation except Bra B, Cyc B, CA, iso-CA, and CA-2H, and hence the metabolized amount of ASIV equaled the total generation amount of the five metabolites. After 24 h of incubation, only ASIV, CA, iso-CA, and CA-2H were detected in incubation solution. The amounts of ASIV, CA, and iso-CA were determined from the calibration curves of ASIV and CA, respectively. The formation amount of CA-2H at this time point (24 h) was calculated by (100% − remaining amount of ASIV% − formation amount of CA% − formation amount of iso-CA%), which was 36.3%. Then the formation amounts of CA-2H at other time points were calculated by comparing their peak area ratio to the peak area ratio at 24 h. By a similar method, we figured out the generation amounts of Bra B and Cyc B at each time point. The generation curves of Bra B, Cyc B, and CA-2H plotted by this way were not very accurate because of measurement and calculation errors, but this method was convenient to illuminate the metabolic behavior of ASIV in gut bacteria.

ASIV was slowly metabolized by the intestinal microbiome. After 4 h of incubation, ASIV began to be converted to Bra B, Cyc B, CA, and CA-2H by intestinal bacteria. The formation rates of Bra B, Cyc B, CA, and CA-2H after 4 h of incubation were 3.47 ± 0.29, 1.87 ± 0.19, 1.69 ± 0.15, and 0.59 ± 0.06%, respectively, suggesting that ASIV was metabolized to Bra B by intestinal bacteria more quickly than to other metabolites. This result was coincident with the observation of Zhou et al.[13] The remaining amount of ASIV in incubation solution linearly declined along with time from 4 to 24 h. After 24 h of incubation, about 72% of ASIV was metabolized by gut bacteria, among which 36% was converted to CA, 35% to CA-2H, and 1% to iso-CA%. Given that iso-CA was generated from CA via CA-2H, formation time courses of the metabolites of ASIV indicated that the conversion from CA-2H to iso-CA seemed to be the rate-limiting step for the generation of iso-CA in the intestine.

When 1 μM CA reacted with intestinal bacteria, its metabolism rate was much slower than that of ASIV (Figure 7). No other metabolites except CA-2H and iso-CA were found

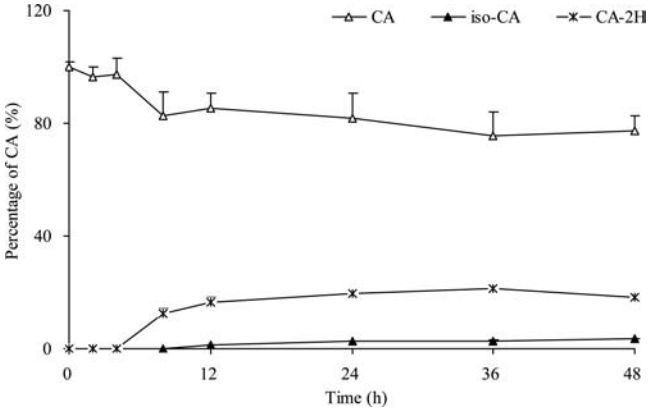

Figure 7. Remaining amount of CA and the formation amounts of iso-CA and CA-2H after incubation of 1 μM CA with rat intestinal bacteria at 37 °C. The amounts of CA, iso-CA, and CA-2H were calculated as percentages of the initial amount of CA before incubation. Each point represents the mean ± SD (n = 3).

in the intestinal bacteria incubation samples of CA. The total biotransformation amount of CA was <30% after 48 h of incubation, of which around 3.5% was converted to iso-CA (Figure 7). The amount of CA-2H generated was obtained by (100% − remaining amount of CA% − formation amount of iso-CA%). Although the production amount of CA-2H was >15% after 12 h of incubation, the formation amount of iso-CA was <1.5%, which further confirmed that the formation rate of iso-CA in the intestine depends on the conversion rate of CA-2H.

Taken together, in vitro metabolism of ASIV in S9 fraction and in gut microbiota showed that ASIV was not metabolized by the liver and intestinal S9 fraction but was slowly hydrolyzed by gut bacteria. This result demonstrated that deglycosylation of ASIV in the intestinal tract was a crucial step for the formation of CA. Although the intestine is likely to be the more important organ responsible for the disposition of ASIV, in vitro metabolism data of CA suggested that the liver might have a bigger role in the generation of iso-CA because the formation rate of iso-CA from CA was faster in the liver S9 fraction (6% in 1 h) than that in the intestinal microbiome (3.5% in 48 h).

Effect of Activity of Intestine Microbiota on the Disposition of ASIV. *Comparation of Metabolism of ASIV by Intestinal Microbiota from Rats Pretreated with and without Antibiotics.* Hydrolysis of ASIV by gut microbiota is a key factor in the disposition of ASIV after oral administration. To investigate the influence of the activity of the intestinal microbiota on the deglycosylation of ASIV, in vitro gut microbial conversion of ASIV was compared between the intestinal microbiota obtained from antibiotic-pretreated rats and that from control rats by the method as described under

DOI: 10.1021/acs.jafc.5b00168
J. Agric. Food Chem. 2015, 63, 6084−6093

Materials and Methods. Antibiotic-pretreated models represent one relatively simple strategy to study the role of intestinal bacteria in xenobiotic metabolism, although antibiotics cannot eliminate all microorganisms from the intestine. Streptomycin sulfate and bacitracin are the common antibiotics applied to attenuate the activity of intestinal bacteria.[33,34]

The metabolic behaviors of ASIV in control gut bacteria and antibiotic-pretreated intestinal bacteria are shown in Figure 8.

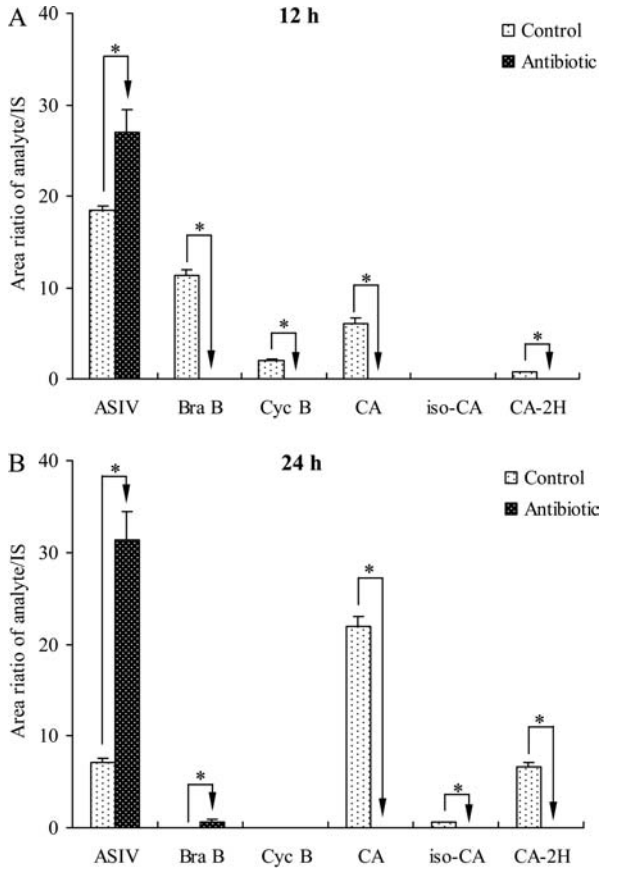

Figure 8. Remaining amount of ASIV and the formation amounts of Bra B, Cyc B, CA, iso-CA, and CA-2H after incubation of 20 μM ASIV with rat intestinal bacteria obtained from control rats (control) and from antibiotic-pretreated rats (antibiotic) at 37 °C for 12 h (A) and 24 h (B). The amounts of ASIV, Bra B, Cyc B, CA, iso-CA, and CA-2H were expressed as peak area ratio of analyte/IS. Each point represents the mean ± SD (n = 3). The asterisk (∗) indicates the differences are significant according to Student's t test ($p < 0.05$).

To intuitively contrast the difference in the metabolism of ASIV between control and antibiotic-pretreated gut microbiota, the amounts of ASIV, Bra B, Cyc B, CA, iso-CA, and CA-2H were expressed as peak area ratio of analyte/IS. When ASIV (20 μM) was incubated with control gut bacteria at 37 °C for 12 h, around 30% of ASIV was metabolized (Figure 6). Antibiotics obviously inhibited the metabolism of ASIV by intestinal microbiome. No metabolites of ASIV were observed in antibiotic-pretreated gut microbiota samples over the same time period (12 h, Figure 8A). After 24 h of incubation, >70% of ASIV was converted in control intestinal microbiota (Figure 6), whereas only a trace of Bra B was produced from ASIV by antibiotic-pretreated gut bacteria (Figure 8B).

To assess the potential interference of antibiotics to the hydrolysis of ASIV by intestinal microbiota, ASIV was simultaneously incubated with low, middle, and high concentrations of streptomycin sulfate and bacitracin (1:1, w/w) in control gut bacteria at 37 °C for 4 h. The generated amounts of Bra B, Cyc B, and CA were concentration-independently decreased by antibiotics (Figure 9). It seemed

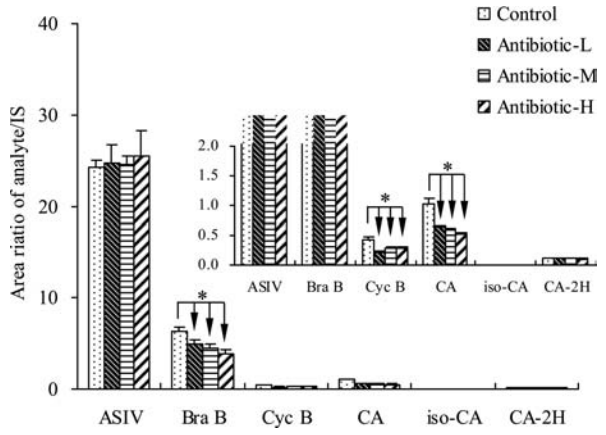

Figure 9. Remaining amount of ASIV and the formation amounts of Bra B, Cyc B, CA, iso-CA, and CA-2H after 20 μM ASIV was incubated with and without antibiotics in control rat intestinal bacteria at 37 °C for 4 h. The final concentrations of antibiotics (streptomycin sulfate/bacitracin = 1:1, w/w) in incubation solution were 0 (control), 0.08 (antibiotic-L), 0.4 (antibiotic-M), or 2 mg/mL (antibiotic-H), respectively. The amounts of ASIV, Bra B, Cyc B, CA, iso-CA, and CA-2H are expressed as peak area ratio of analyte/IS. Each point represents the mean ± SD (n = 3). The asterisk (∗) indicates the differences are significant according to one-way ANOVA test ($p < 0.05$).

that antibiotics interfered with the hydrolysis of ASIV. However, with further investigation, we believed that the decreased generation by antibiotics mainly resulted from the bacteriostasis action of antibiotics rather than its interference with the biotransformation of ASIV, because the microbial culture experiment showed that the colony amount of gut bacteria in the presence of antibiotics was obviously less than that in the absence of antibiotics after 4 h of incubation (data not shown). As shown in Figure 9, the formation rate of CA-2H was not affected by antibiotics. It is well-known that there are a lot of species of microorganisms existing in mammal intestines. The unchanged formation rate of CA-2H was probably caused by the fact that the microbiotas responsible for the biotransformation from CA to CA-2H were not suppressed by streptomycin sulfate and bacitracin.

Comparative Disposition of ASIV in Rats Pretreated with and without Antibiotics. An in vivo experiment is the ultimate model to study the effect of intestinal microbiota on xenobiotic disposition. In the present study, we compared the pharmacokinetics of ASIV and its metabolites in rats treated with and without antibiotics. After rats received antibiotics for 6 days, they were given 10 mg/kg ASIV through gavage. The mean plasma concentration−time curves of ASIV, CA, and iso-CA in antibiotic-pretreated rats are shown in Figure 2C. The C_{max}, t_{max}, $t_{1/2}$, and AUC_{0-t} values of ASIV in antibiotic-pretreated rats were 32.4 ± 7.8 nM, 2.83 ± 0.98 h, 1.99 ± 0.33 h, and 135 ± 30 nM·h, respectively (Table 2). The pharmacokinetic profile of ASIV in antibiotic-pretreated rats was similar to that in control rats (Figure 2A,C), which might be caused by passive diffusion of ASIV in intestinal

DOI: 10.1021/acs.jafc.5b00168
J. Agric. Food Chem. 2015, 63, 6084−6093

absorption.[16] Nevertheless, the plasma concentrations of CA in antibiotic-pretreated rats were immeasurable. Moreover, the C_{max} (4.41 ± 4.01 nM) and AUC_{0-t} (16.4 ± 15.0 nM·h) values of iso-CA in antibiotic-pretreated rats were significantly less than the corresponding data obtained from control rats (Table 2). The result indicated that the disposition of ASIV was obviously affected by the activity of intestinal bacteria after oral administration. Antibiotic treatments altered the intestinal microbiota composition of rodents.[35,36] Streptomycin and bacitracin inhibited the activity of Lactobacillaceae, which includes species capable of hydrolyzing saponins.[37,38] This might be one reason why the exposure of CA and iso-CA in antibiotic-pretreated rats was lower than in control rats. The alteration in rat microbial composition caused by streptomycin and bacitracin and the bacteria species involved in the hydrolysis of ASIV need to be further investigated.

Genetics, infant feeding patterns, antibiotic usage, sanitary living conditions, and long-term dietary habits are known to shape the composition of the gut microbiome.[39] Gut microbiota affects the metabolism of some natural compounds and synthetic drugs and resultantly affects their bioactivity or toxicity.[18,19,40−42] Our study shows that the metabolism of ASIV by intestinal microbiome was a crucial step in the disposition of ASIV, rather than that by hepatic and intestinal enzymes. Variations in intestinal microbiota induced by physiological or pathological conditions may change the disposition of ASIV and subsequently influence the potential health benefits of ASIV. Therefore, gut microbiota should be considered as a critical factor for understanding the bioactivities of ASIV.

diseases, and oxidative stress has been shown to activate extracellular signal-regulated kinases (ERK) 1/2 simultaneously.[25,26] Interestingly, previous results also show that antioxidants (e.g., *N*-acetyl-L-cysteine, NAC) added before other toxin treatment can rescue cells from cytotoxicity induced by the toxin through decreased oxidative damage.[27] In addition, the ERK signaling pathway is one of the major pathways of T lymphocyte proliferation and IL-2 production.[28−30] Until now, the interaction of AFB_1-induced immunotoxicity and the ERK1/2 pathway in T lymphocyte proliferation is relatively unexplored.

Because a lot of research shows AFB_1 exposure could exert oxidative stress in cell culture model,[31] we hypothesize that (i) AFB_1 could induce immunotoxicity in primary porcine splenocytes and (ii) AFB_1 induced decreases of porcine splenocyte proliferation and IL-2 production by oxidative stress mediated ERK1/2 MAPK signaling pathway. Thus, our objective was to evaluate the effect of different concentrations of AFB_1 on the anti-CD3-induced primary porcine splenocytes proliferation and IL-2 production, intracellular redox status, and expression of p-ERK1/2 MARK protein and to determine whether intracellular oxidative stress and the phosphorylation of the ERK1/2 MARK pathway are novel mechanisms involved in AFB_1-induced immunotoxic properties in primary porcine splenocytes.

MATERIALS AND METHODS

Animal and Cell Culture. The use of experimental animals and the following procedures were approved by the Nanjing Agricultural University Animal Care Committee. Fifty normal Meishan pigs (half males and half females), aged 30 days and weighing 8 ± 2 kg, were collected from the breeding center of Jiangsu Polytechnic College of Agriculture and Forestry and killed. The spleens were removed and placed in Hanks' solution and then disrupted mechanically under a clean bench, after which they were carefully layered on the surface of lymphocyte separation medium (Tianjin Hematology Institute, Chinese Academy of Medical Sciences, China). Isolated spleen lymphocytes were adjusted and supplemented with enriched RPMI-1640 medium (Invitrogen, USA), which was added with 10% fetal bovine serum (FBS), penicillin (20 mg/mL), and streptomycin (20 mg/mL) and cultivated at 37 °C in the incubator with 5% CO_2, and subsequently evaluated for the viability of isolated spleen lymphocyte by 0.4% trypan blue dye exclusion. We detected lymphocyte proliferation at 24, 36, 48, 60, and 72 h in the beginning stage of the experiment. However, we found that cell proliferation at 60 h had the best results by flow cytometry, so we detected cell proliferation only at 60 h in the following experiment. In previous literature, the antigen-specific response is more sensitive to AFB_1 exposure than the mitogen-specific response in pigs, so we selected only anti-CD3 stimulation rather than mitogen stimulation in the present experiment.

AFB_1 (Sigma, USA) was dissolved in DMSO (1 mg/mL), and final mycotoxin concentrations were diluted in the culture medium. Cells without any AFB_1 and with 0.4% final concentration of DMSO were used as the control group.

Spleen Lymphocyte Proliferation Assay. Spleen lymphocytes (1×10^6 cells/well) were treated with various concentrations of AFB_1 in the absence or presence of anti-pig-CD3 mAb (clone PPT3, Abcam, UK) and cultivated in 96-well plates for 60 h. In the splenocyte viability experiment, AFB_1 was exposed at 0, 0.5, 1, 2, 4, 8, 10, and 20 μg/mL concentrations. In cell proliferation analysis, AFB_1 was treated at 0, 1, 2, 4, and 8 μg/mL concentrations. Subsequently, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) solution (Sigma, USA) was added at 5 mg/mL concentration, and the plate was oscillated for 10 min by enzyme-labeled instrument (Bio-Rad, USA). Finally, the optical density (OD) value was assessed as absorbance at 490 nm. All samples were assayed in quadruplicate.

To assess T-cell proliferation, 1×10^6 cells/well CFSE-stained splenocytes were cultivated in 24-well plates accompanied by RPMI-1640 medium to a final volume of 1 mL. After 60 h, splenocytes were centrifuged and wash with phosphate buffered saline (PBS) once, then stained with anti-CD3-PEcy5 (Abcam, UK) and prepared for flow cytometry analysis. Flow cytometry was used and enabled by FACSCalibur (BD Biosciences, USA). Color compensation was achieved using an appropriate single fluorochrome-labeled sample. Data were analyzed using FlowJo 7.6.5 (TreeStar).

Determination of IL-2 in Splenocytes. Splenocytes (1×10^6 cells/well) were seeded in 96-well plates and treated with various concentrations of AFB_1 (0, 1, 2, 4, and 8 μg/mL) in the absence (controls) or presence of anti-pig-CD3 mAb for 60 h. The cell supernatants were then collected and assayed for IL-2 by ELISA (R&D Systems, USA). All samples were assayed in triplicate.

Oxidative Stress Analysis. Primary porcine splenocytes at a density of 2×10^6/well in 6-well plates were treated with AFB_1 at 0, 1, 2, 4, and 8 μg/mL for 60 h in the presence of anti-pig-CD3 mAb.

Intracellular glutathione (GSH) in splenocyte cytosol was measured as previously described,[32] using commercially available kits (Jiancheng, China), which are based on the reaction of 5,5′-dithiobis(2-nitrobenzoic acid) and GSH to 5-thio-2-nitrobenzoic acid. Cell extracts were prepared, and GSH was measured spectrophotometrically (412 nm). Protein concentration was determined according to the BCA method using commercially available kits (Beyotime, Jiangsu, China). Data were expressed as micromoles of GSH per gram of protein. All samples were assayed in triplicate.

Assessment of T-SOD enzymatic activity was performed according to a previously described method,[33] using commercially available kits (Jiancheng, China). The absorbance was measured at 525 nm for 10 min. One unit of T-SOD was defined as the enzyme amount responsible for 50% of the inhibition of epinephrine oxidation. T-SOD enzymatic activity was expressed as units (U) per milligram of protein. All samples were assayed in triplicate.

Intracellular malondialdehyde (MDA) in splenocyte cytosol was measured as previously described,[34] using commercially available kits (Jiancheng, China). All samples were assayed in triplicate.

Western Blot Analysis. Spleen lymphocyte suspension was cultured in a 6-well plate at a density of 2×10^6/well for 60 h with a density of 2×10^6 cells/well. After separation by SDS-PAGE, protein molecules on the gel were transferred onto a PVDF membrane and then probed using a specific antibody to quantitatively detect ERK (1/1000) (Cell Signaling Technology, USA) and p-ERK (1/2000) protein (Cell Signaling Technology, USA). After the first antibody reaction overnight, the PVDF membrane was washed by TBST three times and incubated for 60 min with horseradish peroxidase (HRP)-labeled anti-rabbit secondary antibody (Cell Signaling Technology, USA), diluted 1/5000 (v/v) in 5% (w/v) BSA TBST. Finally, the result of Western blot was detected by electrochemiluminescence (ECL) using the Amersham Hyperfilm ECL reagent.

Short Interfering RNA (siRNA) Transfection. Double-stranded RNA sequences were designed according to the sequence of ERK-specific siRNAs using Invitrogen BlockiT RNAi designer and were synthesized by Invitrogen. The ERK-specific siRNAs sequence was sense 5′-CUCCAAAGCUCUGGAUUUAtt-3′ and antisense 5′-UAA-AUCCAGAGCUUUGGAGtt-3′. The control siRNA had the sequence 5′-UUCUCCGAACGUGUCACGUTT-3′. Duplexes were resuspended in DEPC-treated water to obtain 20 mM solutions before use. T cells in RPMI-1640 medium without FBS or antibiotics were seeded in 6-well plates, 24-well plates, and 96-well plates after spleen lymphocytes were separated, and siRNA was introduced using the X-tremeGene siRNA transfection reagent (Roche, USA) according to the manufacturer's protocol.

Statistical Analysis. All of the data were analyzed statistically using the SPSS 18.0 for Windows statistical software package (Statistical Product and Service Solutions, Inc., USA). All results are presented as the mean ± SEM. We also performed a one-way ANOVA on the statistical analysis. Tukey's b (K) post-test was used to compare means of each group, and a *P* value was considered significant at 0.05.

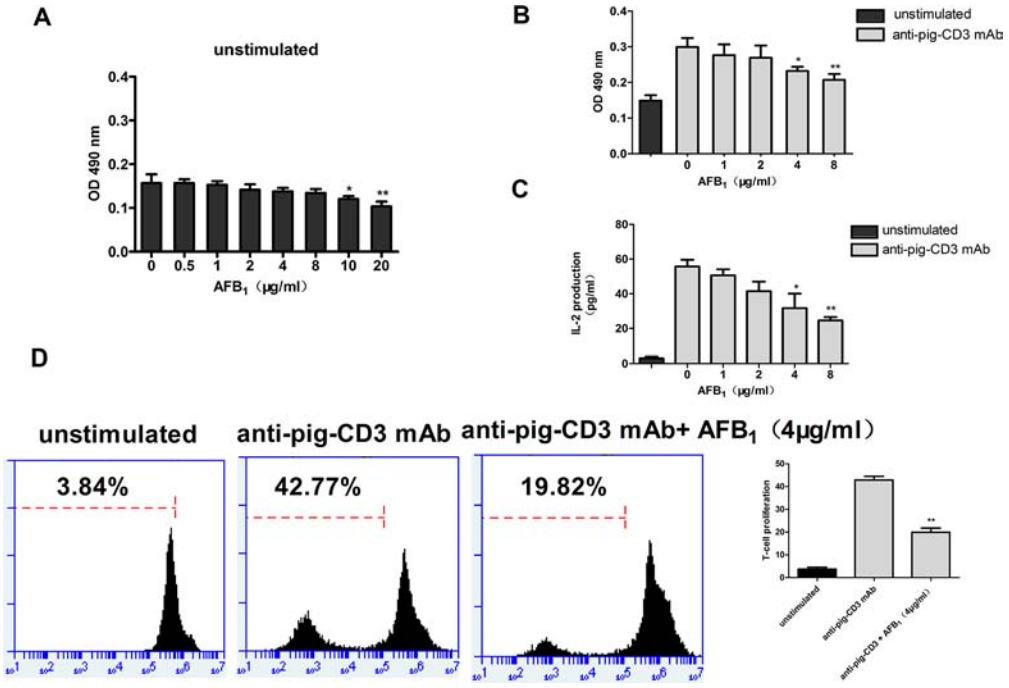

Figure 1. Effects of AFB_1 on the viability, cell proliferation, and IL-2 production in primary porcine splenocytes. Primary porcine splenocytes (1×10^6 cells/well) were treated with different concentrations of AFB_1 for 60 h without any stimulus (A) or stimulated by 2 μg/mL anti-pig-CD3 mAb (B) and were assayed by the MTT method. The values are presented as means ± SEM ($n = 4$). IL-2 production in splenocytes treated with different concentrations of AFB_1 and IL-2 concentrations was determined by ELISA (C). The values are presented as means ± SEM ($n = 3$). Significant differences with control were designated as $* P < 0.05$ and $** P < 0.01$. CD3+T-cell proliferation was monitored using CFSE labeling (D). Cells were stained with anti-CD3-PEcy5. CD3+T cells from the entire well were analyzed for proliferation by flow cytometry. The percentage of proliferating cells for each culture is indicated. A representative experiment from two separate experiments is shown.

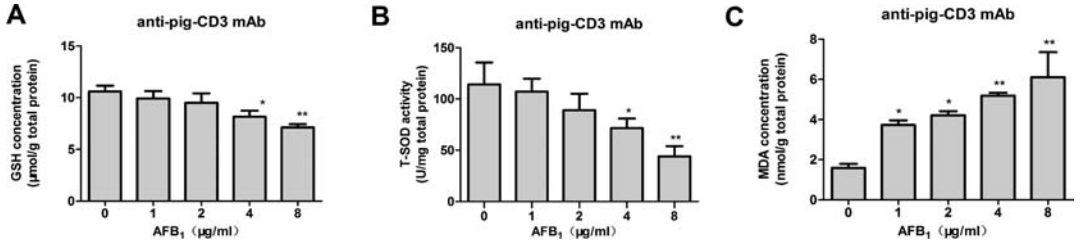

Figure 2. Effects of AFB_1 supplementation on oxidative stress capacity. Primary porcine splenocytes at a density of 2×10^6/well in 6-well plates were treated with AFB_1 at 1, 2, 4, and 8 μg/mL for 60 h in the presence of anti-CD3. Changed levels of GSH (A), T-SOD (B), and MDA (C) were assayed as described under Materials and Methods. The values are presented as means ± SEM ($n = 3$). Significant differences with control were designated as $*P < 0.05$ and $** P < 0.01$.

Supplementary Information. Primary porcine splenocytes were stimulated with 2 μg/mL anti-pig-CD3 mAb in the absence or presence of 5 mmol/L of NAC for 24 h, washed with PBS once, and then treated with AFB_1 (4 μg/mL) or not for another 36 h. Moreover, control and NAC treatment group were treated at the final concentration of 0.4% DMSO.

RESULTS

Effects of AFB_1 on Viability, Cell Proliferation, and IL-2 Production in Primary Porcine Splenocytes. To investigate the effect of AFB_1 treatment on the antigen-stimulated lymphocyte proliferation, we examined the effects of AFB_1 at various concentrations on splenocyte proliferation and IL-2 production. As shown in Figure 1, DMSO, the solvent of AFB_1, does not have a significant effect on splenocyte viability and proliferation of lymphocytes. However, the higher doses of AFB_1 (10 and 20 μg/mL) showed significant cytotoxic effect on the viability ($P < 0.05$) (Figure 1A). On the basis of this observation, the higher dose was excluded during our experiments. Over the range of concentrations of AFB_1 used, the proliferation of cells was significantly lowered by AFB_1 at 4 and 8 μg/mL in a dose-dependent manner ($P < 0.05$) (Figure 1B). A significant reduction in IL-2 production by anti-pig-CD3 stimulation was observed at concentrations of 4 and 8 μg/mL ($P < 0.05$). The inhibition indicates dose dependency (Figure 1C).

To confirm whether the proliferation evaluated by cell counting assay was due to T lymphocytes or total cells or any other cell type, CD3+T-cell proliferation was estimated by CFSE labeling of splenocytes and following anti-pig-CD3-PEcy5 staining. The T-cell proliferation measured by CFSE showed a pattern similar to that of MTT. Total CD3+T cells proliferated less in the toxin exposure group than in the control group with anti-pig-CD3 mAb regulated and treated (19.82 versus 42.77%, Figure 1D).

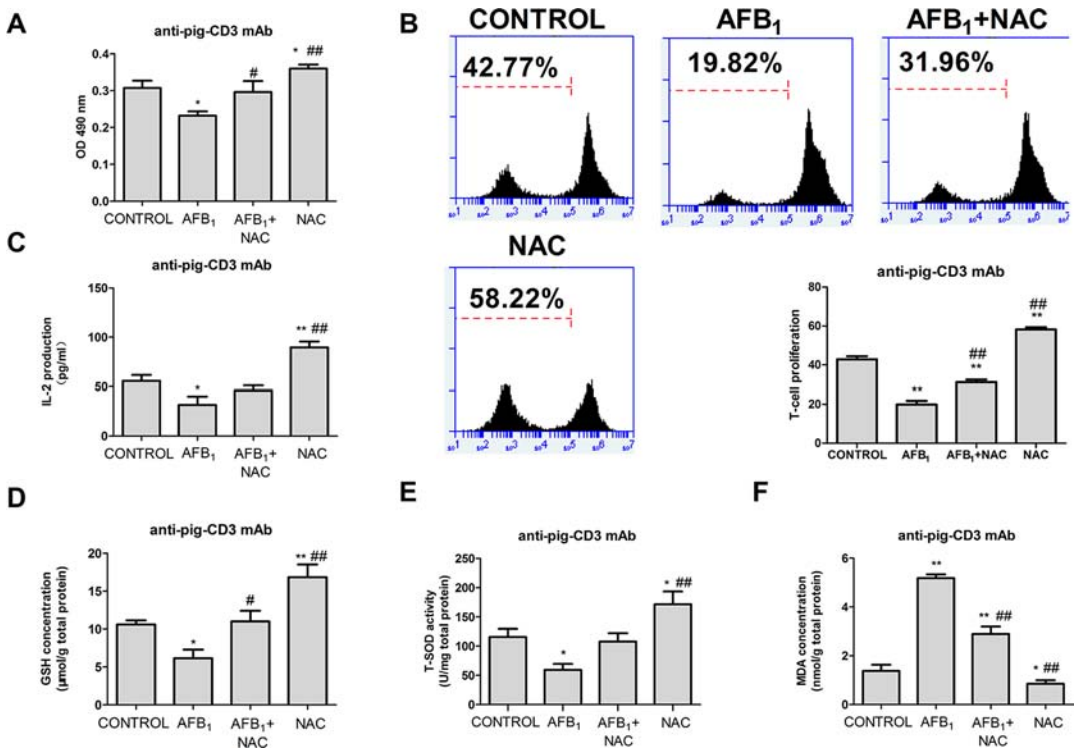

Figure 3. Effects of NAC on cell proliferation, IL-2, and redox activity induced by AFB_1 in primary porcine splenocytes. Primary porcine splenocytes were stimulated with anti-CD3 in the absence or presence of 5 mmol/L of NAC for 24 h and then inoculated with or without AFB_1 at 4 μg/mL for a further 36 h treatment. Cells were assayed for cell proliferation (A), IL-2 production (C), levels of GSH (D), T-SOD (E), and MDA (F). Data are presented as means ± SE of three independent experiments: ∗ $P < 0.05$ and ∗∗ $P < 0.01$ are statistically significant compared to control cells; # $P < 0.05$ and ## $P < 0.01$ are statistically significant compared to 4 μg/mL AFB_1-treated T cells. CD3+T-cell proliferation was monitored using CFSE labeling (B). Cells were stained with anti-CD3-PEcy5. CD3+T cells from the entire well were analyzed for proliferation by flow cytometry. The percentage of proliferating cells for each culture is indicated. A representative experiment from two separate experiments is shown.

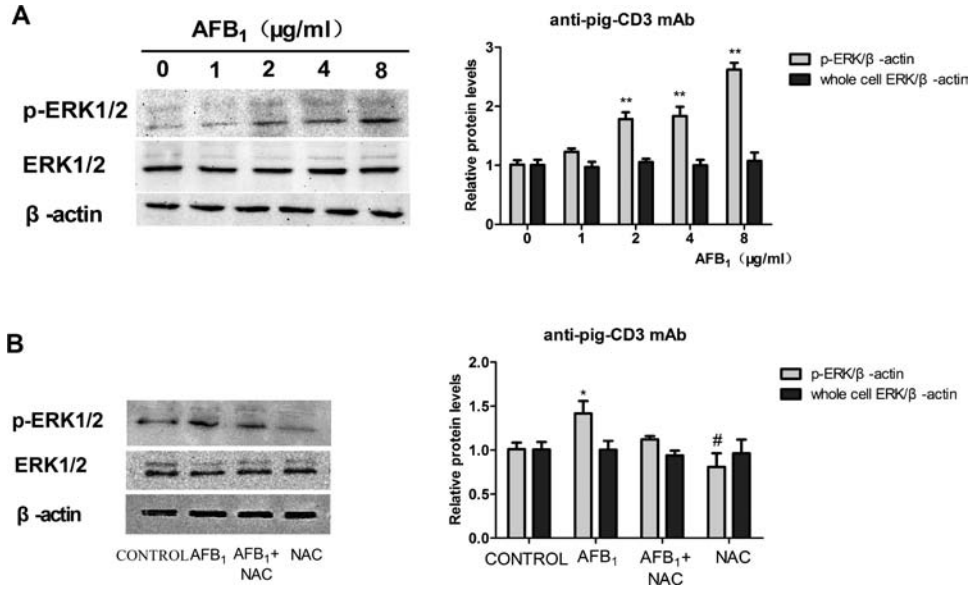

Figure 4. Western blot and densitometric analysis of ERK1/2 expression. Primary porcine splenocytes were treated with AFB_1 at 1, 2, 4, and 8 μg/mL for 60 h in the presence of anti-CD3 (A). Primary porcine splenocytes were stimulated with anti-CD3 in the absence or presence of 5 mmol/L of NAC for 24 h and then inoculated with or without AFB_1 at 4 μg/mL for a further 36 h treatment (B). Whole cell ERK expression/β-actin was used as a control. Densitometric analysis results are expressed as the ratio of phosphorylated ERK to β-actin and the whole cell ERK expression to β-actin. Graphical results are represented the mean ± SEM of three independent experiments: ∗ $P < 0.05$ and ∗∗ $P < 0.01$ are tatistically significant compared to control cells; # $P < 0.05$ and ## $P < 0.01$ are statistically significant compared to 4 μg/mL AFB_1-treated T cells.

Effects of AFB_1 Supplementation on Oxidative Stress Capacity. To investigate the effect of AFB_1 exposure on the parameters of oxidative stress, GSH, T-SOD, and MDA levels were measured in the splenocytes. Cells treated with AFB_1

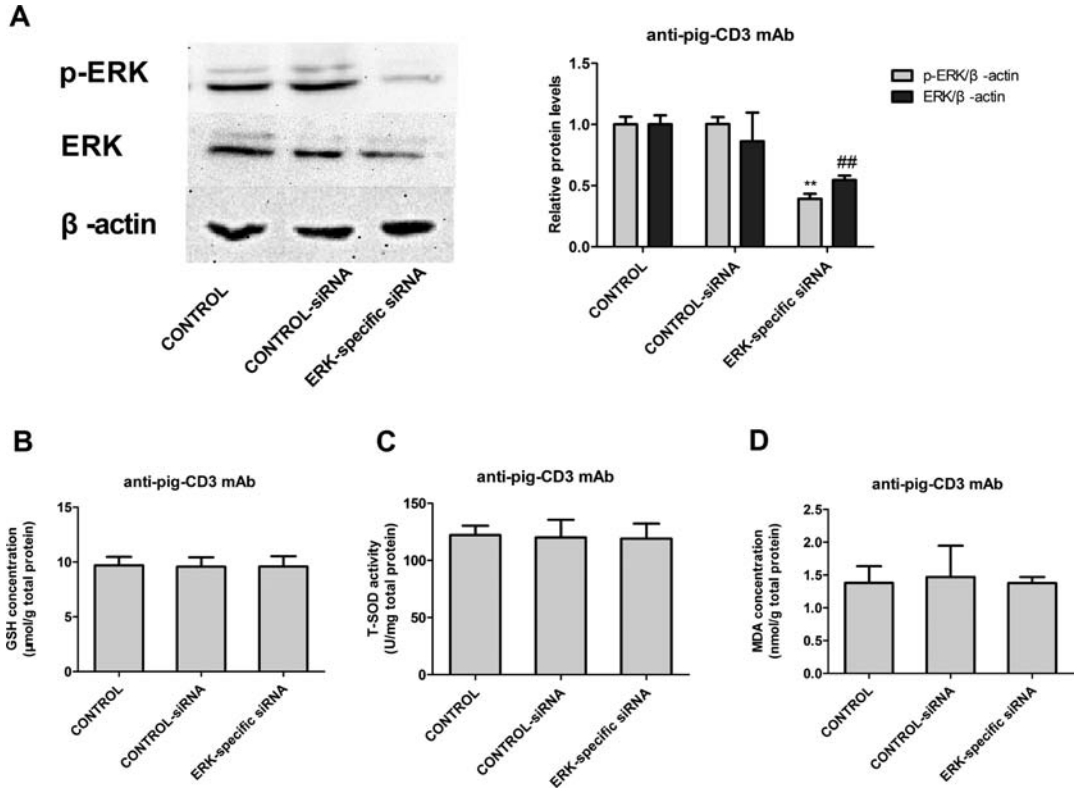

Figure 5. Effect of ERK-knockdown on ERK1/2 and p-ERK1/2 expression and oxidative stress in primary porcine splenocytes. Cell were transfected with either an ERK-specific siRNA or a control siRNA and cultured for 5 h before 4 μg/mL AFB_1 and 2 μg/mL anti-CD3 treatment. Cell samples were assayed for p-ERK and ERK protein levels (A) and GSH (B), T-SOD (C), and MDA (D) levels as described under Materials and Methods. Whole cell ERK expression/β-actin was used as a control. Densitometric analysis results are expressed as the ratio of phosphorylated ERK to β-actin and the whole cell ERK expression to β-actin. Graphical results are represented the mean ± SEM of three independent experiments: * and # indicate statistically significant difference from control (* and #, $P < 0.05$; ** and ##, $P < 0.01$).

showed a dose-dependent decrease in the intracellular concentrations of GSH. The minimal decreases of GSH levels appeared in activated splenocytes exposed to 8 μg/mL AFB_1 (Figure 2A) and GSH concentrations in the 4 μg/mL AFB_1 show a significant decrease compared with control splenocytes, whereas T-SOD presents the same trend (Figure 2B). To assess the MDA levels in primary porcine splenocytes, which is a marker of oxidative stress, we measured the results as shown in Figure 2C. In 0−8 μg/mL AFB_1-treated groups, MDA concentrations exhibit a dose-dependent increase. MDA concentrations in the 1 μg/mL AFB_1 show a significant enhancement compared with control splenocytes. The maximal increases of MDA level were observed in activated splenocytes incubated with 8 μg/mL AFB_1.

Effects of NAC on Cell Proliferation, IL-2, and Redox Activity Induced by AFB_1 in Primary Porcine Splenocytes. To determine whether a change of oxidative stress could affect T-cell proliferation, primary porcine splenocytes were stimulated with 2 μg/mL anti-pig-CD3 mAb in the absence or presence of 5 mmol/L of NAC for 24 h. As shown in Figure 3A, AFB_1 treatment exhibited significant toxicity, which was suppressed in NAC-treated cells ($P < 0.05$). The T-cell proliferation measured by CFSE showed a pattern similar to that of MTT (Figure 3B). Total CD3+T cells proliferated more in the NAC exposure group and the NAC and AFB_1 group than in the AFB_1 group with anti-pig-CD3 mAb treatment (58.22 and 31.96 versus 19.82%). We found that NAC alleviated AFB_1-induced cytotoxicity as demonstrated by increasing intracellular concentrations of GSH levels (Figure 3D) and decreasing MDA levels (Figure 3F), respectively, compared with the AFB_1 group ($P < 0.05$). However, NAC together with AFB_1 did not produce a significant increase in the IL-2 production and intracellular concentrations of T-SOD levels (Figure 3C,E).

Western Blot and Densitometric Analysis of p-ERK1/2 and ERK1/2 Expression. To determine if the AFB_1 treatment of primary porcine splenocytes affects expression of extracellular signal-regulated kinases, Western blot was used to measure protein levels of ERK1/2 protein in activated splenocytes. The significant change in p-ERK1/2 expression was associated with a dose-dependent increase in gray value. As shown in Figure 4A, in the cells exposed to various concentrations of AFB_1 (1−8 μg/mL), AFB_1 at a concentration of 2 μg/mL showed significantly higher ERK1/2 phosphorylation compared to the no-toxin group ($P < 0.01$). It has been assumed that the influence of AFB_1 on cell proliferation shows connections with p-ERK1/2 protein expression in T lymphocytes. As shown in Figure 4B, expression of p-ERK1/2 protein in activated splenocytes was decreased in NAC interaction with the AFB_1 group compared to the AFB_1 group.

Effect of ERK-Knockdown on ERK1/2 Expression and Oxidative Stress in Primary Porcine Splenocytes. The extent of ERK-knockdown was evaluated by determination of ERK1/2 protein levels after primary porcine splenocyte cells were transfected with either an ERK1/2-specific or a control siRNA. As shown in Figure 5, transfection of primary porcine splenocytes cells with ERK-specific siRNA led to a decrease in ERK1/2 protein levels compared with control cells, there being

DOI: 10.1021/acs.jafc.5b00433
J. Agric. Food Chem. 2015, 63, 6094−6101

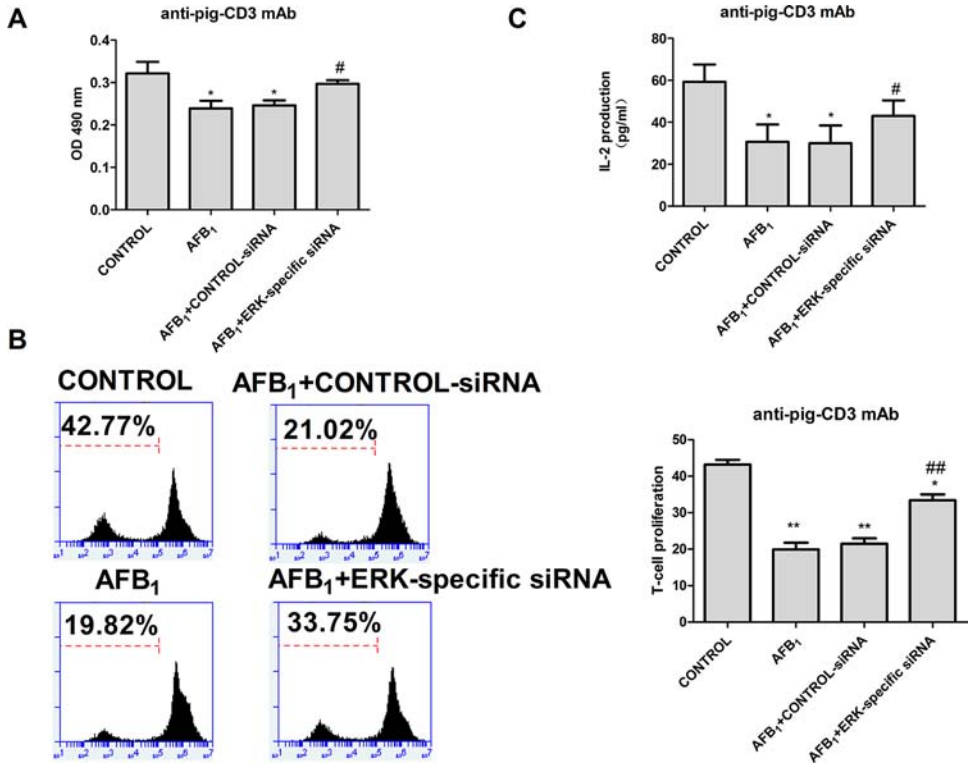

Figure 6. Alleviative effects of ERK1/2 knockdown on immunosuppression induced by AFB_1 in primary porcine splenocytes. Cells were transfected with either an ERK-specific siRNA or a control siRNA and cultured for 5 h before 4 μg/mL AFB_1 and 2 μg/mL anti-CD3 treatment. The transfected cells were assayed for proliferation by MTT (A) and IL-2 concentration by ELISA (C). Cells with only stimulus were used as control. Data are presented as means ± SE of three independent experiments: * $P < 0.05$, statistically significant compared to control cells; # $P < 0.05$, statistically significant compared to 4 μg/mL AFB_1-treated T cells. CD3+T-cell proliferation was monitored using CFSE labeling (B). Cells were stained with anti-CD3-PEcy5. CD3+T cells from the entire well were analyzed for proliferation by flow cytometry. The percentage of proliferating cells for each culture is indicated. A representative experiment from two separate experiments is shown.

a 65% decrease in p-ERK1/2 protein levels and a 55% decrease in whole cell ERK1/2, respectively (Figure 5A). Transfection of primary porcine splenocytes with siRNA targeted against ERK had no effects on the redox status as measured by intracellular GSH levels, T-SOD levels, and MDA levels (Figure 5B–D).

Alleviative Effects of ERK-Knockdown on Immunosuppression Induced by AFB_1 in Primary Porcine Splenocytes. To address whether ERK1/2 plays a key role in reducing the cytotoxicity of AFB_1 in primary porcine splenocytes, cells were cultured and then transfected with ERK-specific or control siRNA. After 5 h of transfection treatment, the medium was removed. Transfected cells were then cultured with AFB_1 at 4 μg/mL in the presence of anti-pig-CD3 mAb for a further 55 h. As shown in Figure 6, ERK-specific siRNA alleviated the immune toxicity of AFB_1, as demonstrated by increasing T-cell proliferation (Figure 6A) and IL-2 production (Figure 6C) ($P < 0.05$), but not in cells transfected with the siRNA control. The T-cell proliferation measured by CFSE showed a pattern similar to that of MTT (Figure 6B). Total CD3+T cells proliferated more in the ERK-specific siRNA group than in the AFB_1 exposure group and control siRNA group with anti-pig-CD3 mAb treatment (33.75 versus 19.82 and 21.02%).

DISCUSSION

Previous studies have indicated that an AFB_1-contaminated diet has been widely documented in many parts of the world and exposure to the toxin affects the immune response in pigs.[35,36] However, the detailed mechanisms of the immunotoxicity induced by AFB_1 have not been reported in pigs until now. The present work is the first to investigate the relationship of cell signaling pathway and the immunotoxicity induced by AFB_1. The present data showed that the effects of AFB_1-induced immunotoxicity were associated with oxidative damage and the ERK1/2 MAPK signaling pathway.

Costello et al. demonstrated an overall higher activation status achieved with CD3i/CD28i than with PHA.[37] Meissonnier et al.[8] supplied results that the antigen-specific response is more sensitive to AFB_1 than the mitogen-specific response in blood lymphocytes exposed to dietary AFB_1 from pigs. Therefore, we chose anti-CD3 stimulation rather than mitogen stimulation in the present experiment. Lymphocyte proliferation and IL-2 production were considered as measures to evaluate T-cell function in an in vitro experiment.[38] Our results showed that the vitality of AFB_1-induced unstimulated T cells was decreased dose dependently, but relatively insensitively, compared to the active T cells, which was consistent with a previous study that AFB_1 decreases lymphoid cell populations, especially activated lymphocytes.[8] In anti-CD3-induced T cells, 4–8 μg/mL AFB_1 exposures significantly inhibited T-cell proliferation and IL-2 production in the present work. Actually, concentrations of >8 μg/mL had been detected and had a continued declining trend (data not shown). To ensure the accuracy of the results, both MTT and flow cytometry were used as effective methods to measure the proliferation of T cells in the present experiment.

To our knowledge, reactive oxygen species (ROS) not only result from normal cellular metabolism but also are related to

DOI: 10.1021/acs.jafc.5b00433
J. Agric. Food Chem. 2015, 63, 6094–6101

the treatment of the drugs or environment pollutants.[39] Parveen et al. showed that 0.25 μg/mL AFB_1 caused a significant increase in oxidative stress in MDCK cells, which was demonstrated by a significant increase of MDA level and reduction of intracellular GSH level, as well as GPX1 activity and mRNA level.[40] Our results showed that AFB_1 treatment induced intracellular oxidative stress in the splenocyte, which is consistent with previous studies.[41]

The results from the NAC treatment experiments provided further evidence that AFB_1-induced T-cell inhibition is associated with cellular oxidative stress in splenocytes. NAC is a pharmacological antioxidant. Treatment of NAC in splenocytes reduced oxidative stress and resulted in an alleviation of T-cell proliferation. Xiao et al. confirmed that the significant toxicity induced by 4-ClBQ could be suppressed after NAC treatment in human keratinocytes.[27] Our study showed that NAC alleviated the immunotoxic effects of AFB_1, which indicated that the AFB_1-induced immunotoxic effects were due to an increase of redox status.

In previous research, ERK1 and ERK2 have been demonstrated as ultimately phosphorylated products from MAPK families, and the activated ERKs translocate to the nucleus and transcription factors, changing gene expression to promote growth, differentiation, or mitosis.[42] Also, the ERK signaling pathway is one of the major pathways of T-lymphocyte proliferation.[43] However, there is little research available on the relationship with the ERK pathway and immunosuppression of AFB_1. In our experiment, T cells were exposed to various concentrations of AFB_1 (1−8 μg/mL), and expression of ERK1/2 was increased at 2, 4, and 8 μg/mL in a dose-dependent manner. Our current results strongly indicated that AFB_1 exposure could activate the ERK1/2 signaling pathway in primary porcine splenocytes.

Above all, hypotheses were formulated that the change of phosphorylation of ERK1/2 seems likely correlated with ROS generation in certain aspects. In the previous study, Keshari et al. demonstrated ROS resulted in activation of ERK in PMNs, which is an important component of the innate immune system.[44] To examine oxidative stress as a function in the MAPK signaling pathway, NAC was added before AFB_1 exposure. The finding that NAC, a nonspecific antioxidant, down-regulated the phosphorylation of the ERK1/2-MAPK pathway in primary porcine splenocytes (Figure 4 B) further certified this hypothesis.

To further determine the specificity of the ERK1/2−MAPK pathway regulating AFB_1-induced oxidative stress and immune toxicity, experiments were repeated using ERK-specific siRNA, which can specifically block ERK1/2 expression (Figure 6). O'Connell et al. made a key contribution to the inhibition of the MAPK pathway resulting in attenuation of the CsA-induced mesangial cell alterations caused by oxidative stress.[45] Our results are consistent with the previous studies, which strongly indicate that ERK1/2-knockdown mitigates AFB_1-induced cellular immunity toxicity and the ERK pathway maybe is a key mechanism of T-cell suppression induced by AFB_1. It seems that AFB_1 exposure produced oxidative stress, and then oxidative stress activated the ERK signal pathway and resulted in the suppression of T-cell proliferation. The mechanisms by which oxidative stress and ERK1/2 phosphorylation correlated with interaction are relatively unexplored but undoubtedly important areas for future investigation.

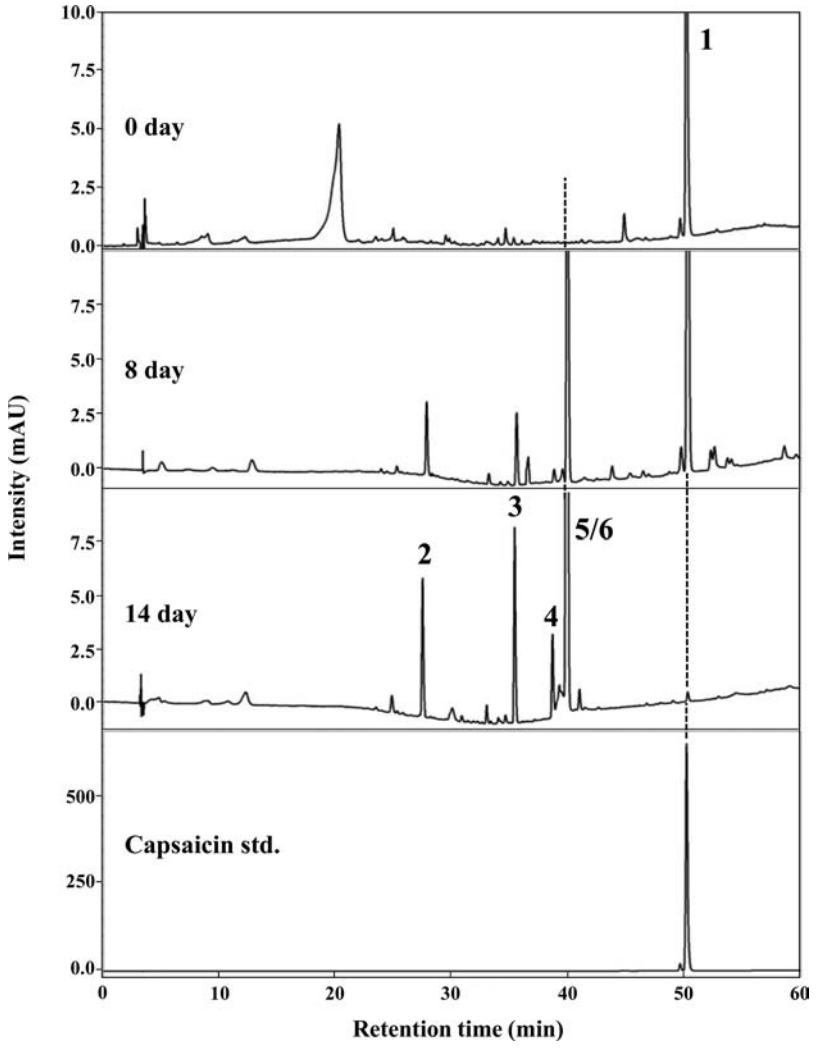

Figure 1. High-performance liquid chromatography chromatograms of capsaicin culture during incubation.

September 2014. The main ingredients were listed as red pepper powder, starch syrup, wheat flour, glutinous rice, *meju* made with soybean, and calcium. Capsaicin (purity, 50%) was obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA) and was purified as follows: Commercial capsaicin (purity, 50%) was dissolved in MeOH (0.3 mL). An aliquot of the capsaicin solution was subjected to preparative HPLC equipped with a Shim pack prep-ODS(H)KIT column (20 i.d. × 250 mm, 10 μm) (Shimadzu, Kyoto, Japan). Capsaicin was detected at 280 nm at a flow rate of 9.9 mL/min. Elution was achieved using a solvent mixture of MeOH/H_2O (7:3, v/v) as the mobile phase. Capsaicin (t_R 18.7 min, 240.6 mg, white powder) was collected, subjected to NMR and MS analyses, and used as a standard. The purity of capsaicin was >98.0%. *A. oryzae* KCCM 11372 was obtained from the Korean Culture Center for Microorganism (Seoul, Korea). Potato dextrose agar (PDA) and potato dextrose broth (PDB) were purchased from Difco Co. (Detroit, MI, USA). All solvents used for analyses were of HPLC grade. All other chemicals used were of reagent grade.

Incubation of Capsaicin with *A. oryzae*. Purified capsaicin (10 mg) was added to PDB (100 mL), inoculated with a 5% (v/w) spore suspension of *A. oryzae* and incubated for 14 days at 30 °C and 120 rpm in an incubator. The samples were collected at intervals of 0, 2, 4, 6, 8, 10, 12, and 14 days during the incubation and were stored immediately at −70 °C until analysis. *A. oryzae* was grown on PDA and maintained at 30 °C. The spores were inoculated to PDB and maintained in a shaker incubator at 30 °C and 120 rpm for 48 h. The cells were collected by centrifugation (890*g*, 15 min, at 4 °C), and starter culture was obtained.

HPLC Profile of Capsaicin Metabolites. The cultured capsaicin broth (1 mL) was centrifuged for 15 min, at 4 °C and 890*g*. The supernatant was extracted with EtOAc (6 mL, twice). The EtOAc fractions were combined and concentrated under vacuum. The EtOAc fraction was dissolved in 0.5 mL of 90% MeOH and subjected to reversed-phase-HPLC containing a photodiode array system operating at 200−800 nm. The capsaicin metabolites were separated on a Capcell Pak C18 column (UG-120, 4.6 mm i.d. × 250 mm, 5 μm) (Shisheido, Tokyo, Japan) at 40 °C using a gradient consisting of 100% H_2O (solvent A) to 100% MeOH (solvent B). The gradient was started with 50% B for 30 min, increased to 80% B at 50 min, and held at 100% B until 60 min. The flow rate was 1.0 mL/min.

Purification and Isolation of Capsaicin Metabolites. Purified capsaicin (200 mg) was added to PDB (2.0 L) and incubated for 14 days under the same conditions described above. Samples were collected at intervals of 0, 2, 4, 6, 8, 10, 12, and 14 days during the incubation. The cultured capsaicin broth was centrifuged for 15 min, at 4 °C and 890*g*. The supernatant was extracted with EtOAc (4 L, twice), and then the EtOAc fractions were combined and concentrated under vacuum. The EtOAc fraction was fractionated by octadecylsilane (ODS, 70−230 mesh) (YMC, Kyoto, Japan) column (3.0 cm × 80 cm i.d.) chromatography eluted with H_2O/MeOH (7:3−0:10, v/v, stepwise elution, each 300 mL). The fractions were subjected to TLC and grouped into 13 fractions (A−M). Each fraction was analyzed by HPLC under the conditions described above. The HPLC

chromatograms showed high purity of fractions J (**3**, t_R 24.5 min, 4.5 mg), K (**4**, t_R 25.5 min, 93.6 mg), and L (a mixture of **5** and **6**, t_R 28.7 min, 12.8 mg). Fraction H (10.6 mg) was purified by HPLC equipped with a μBondapak C18 column (10 μm, 7.8 i.d. × 300 mm) (Waters, Milford, MA, USA) (flow rate, 5.0 mL/min; wavelength, 210 nm; elution, from 50 to 80% MeOH for 40 min) to give **2** (t_R 17.7 min, 1.0 mg). Thin-layer chromatography (TLC) was carried out by using silica gel TLC plates (0.25 mm thickness) (Merck, Rahway, NJ, USA) and developed using a mixture of EtOAc/HOAc/$CHCl_3$ (5:1:2, v/v/v). The spots were detected by UV light (254 nm) and 1% cerium(IV) sulfate ethanol solution spray.

Structural Analysis. NMR spectra were obtained with a ^{unit}INOVA 500 spectrometer (Varian, Walnut Creek, CA, USA). Methanol-d_4 (CD_3OD) (Acros Organics, Morris Plains, NJ, USA) containing tetramethylsilane was used as an analytical solvent. The mass spectra were acquired on a SYNAPT G2 hybrid (Waters, Cambridge, UK) and LCMS-8030 (Shimadzu, Kyoto, Japan) equipped with an electrospray ionization source (ESI-MS).

HPLC ESI MS/MS Analysis of the Capsaicin Metabolites Identified in Gochujang. Freeze-dried gochujang (1 g) was homogenized in MeOH (20 mL, twice). The mixture was filtered under vacuum through no. 2 filter paper (Whatman, Maidenstone, UK). The MeOH solutions were combined and concentrated under vacuum at 38 °C. The extracts were suspended in distilled water (10 mL) and partitioned with EtOAc (10 mL, three times). The EtOAc fraction was evaporated under vacuum at 38 °C and dissolved in MeOH/$CHCl_3$ (1:1, v/v, 4 mL), and then the fraction was analyzed using a high-performance liquid chromatography/electrospray ionization tandem mass spectrometer (HPLC-ESI/MS) (Shimadzu). Capsaicin and its metabolites (**1**−**6**) were separated under the chosen HPLC conditions [column, MG III (C18, 3 μm, 3.0 i.d. × 100 mm) (Shiseido); column temperature, 35 °C; flow rate, 0.3 mL/min (Shimadzu)]. The sample was eluted using a gradient system of H_2O (solvent A) to MeCN (solvent B) (both containing 0.3% formic acid), starting with 100% B, increasing to 20% A for 8 min, holding to 20% A for 16 min, increasing to 50% A for 30 min, increasing to 80% A for 35 min, increasing to 100% A for 40 min, and holding at 100% A for 45 min. The mass spectrometer was set up respectively for multiple reaction monitoring (MRM) with a dwell time of 0.1 s per transition to monitor the capsaicin metabolites: m/z 304.1 $[M - H]^-$ → 168.2 for **1**; m/z 268.3 $[M + H]^+$ → 137.1 for **2**, m/z 310.1$[M + H]^+$ → 174.3 for **3**, m/z 320.1$[M - H]^-$ → 184.1 for **4**, m/z 334.0 $[M - H]^-$→ 154.2 for **5** and **6**. The optimal MS conditions for **1**−**6** were employed: ESI source voltage, 3.5 kV; detector voltage, 45 V; heat block temperature, 400 °C; desolvation line temperature, 250 °C. Nebulizing gas and drying gas flows were 3.0 and 15.0 L/min, respectively. Argon was used as the collision gas at a pressure of 230 kPa. The optimized collision energies for **1**−**4** and **5** and/or **6** were 13.0, −16.0, −11.0, 13.0, and 19.0 V, respectively.

The contents of **1**−**6** in gochujang were quantitatively analyzed by HPLC ESI MS/MS analysis. Sample and standard solutions were prepared just before analysis. The calibration curves (n = 6) were constructed using **1**−**6** (0.1−50 ng) that were isolated from capsaicin broth incubated with *A. oryzae*. Accuracy and reproducibility were evaluated using the standard spike method. External standards of capsaicin and **1**−**6** were added to aliquots of gochujang at three

DOI: 10.1021/acs.jafc.5b01730
J. Agric. Food Chem. 2015, 63, 6102−6108

concentrations to determine their precision. The quantification and quantitation of capsaicin and its metabolites **1**−**6** in gochujang were performed in triplicate.

RESULTS AND DISCUSSION

Changes in Capsaicin and Its Metabolites in the Medium during *A. oryzae* Incubation. *A. oryzae* was incubated with capsaicin in PDB at 30 °C for 14 days. The supernatants (1 mL) obtained with the passage of time were extracted with EtOAc, and the H_2O and EtOAc fractions were analyzed by reversed-phase-HPLC. In the EtOAc fraction, the capsaicin peak decreased gradually depending on the incubation period (Figure 1). New metabolites were detected from 6 days of incubation, and then capsaicin was detected at detection limit concentration (100 pmol) at 14 days of incubation. No chemical transition was observed from H_2O fraction (data not shown), suggesting that capsaicin metabolites converted by *A. oryzae* were extracted in the EtOAc fraction. However, no chemical change of capsaicin was observed in PDB without *A. oryzae* at 30 °C for 14 days (data not shown).

Isolation and Identification of the Capsaicin Metabolites Converted by *A. oryzae*. Capsaicin was incubated with *A. oryzae* for 14 days, and the culture was solvent-fractionated to obtain the EtOAc fraction. Five converted metabolites **2**−**6** were purified and isolated from the EtOAc fraction of the capsaicin culture by ODS open-column chromatography and ODS-HPLC. The structures of the converted compounds were determined by NMR and ESI-MS analyses.

The molecular weight of metabolite **2** was determined to be 267, as established by a pseudomolecular ion peak at m/z 268.3 $[M + H]^+$ in the ESI-MS (positive) spectrum. The ^1H NMR spectrum of **2** was partially similar to that of **1**.[16] The ^1H NMR spectrum exhibited three trisubstituted benzene ring proton signals at δ 6.87 (1H, br s, H-2′), 6.73 (1H, d, J = 8.0 Hz, H-5′), and 6.73 (1H, d, J = 8.0 Hz, H-6′), one methoxyl proton signal at δ 3.84 (3H, s, $-OCH_3$), and one nitrogen-bearing methylene proton signal at δ 4.26 (2H, s, H-7′) (Table 1), indicating a vanillylamine moiety as a partial capsaicin structure. In addition, three sp^3 methylene carbon protons at δ 2.28 (2H, m, H-2), 1.91 (2H, m, H-3), and 2.32 (2H, m, H-4) were observed in the ^1H NMR spectrum. This result was also supported by the ^{13}C NMR spectrum, which contained 13 carbon signals including 7 sp^2 carbons with 5 quaternary carbons at δ 177.0−112.5 and 4 sp^3 carbons at δ 56.5−12.8 (Table 2). Considering the molecular weight of **2**, the chemical shifts in five sp^2 quaternary carbons indicated that one was a nitrogen-bearing carbonyl carbon at δ 175.3 (C-1) with evidence of a carbonyl carbon at δ 177.0 (C-4). Metabolite **2** was suggested to be *N*-vanillylcarbamoylbutanoic acid based on the ESI-MS and 1D NMR spectra. The complete NMR assignment and connectivity of **2** were further studied by $^1H-^1H$ correlation spectroscopy ($^1H-^1H$ COSY), heteronuclear single-quantum correlation (HSQC), and heteronuclear multiple-bond correlation (HMBC) experiments. Vanillyl and carbamoylbutanoic acid moieties were confirmed by the 2D NMR spectra. In particular, H-7′ was correlated with C-1 in the HMBC spectrum (Figure 3), indicating a vanillyl group was connected to the C-1 position of carbamoylbutanoic acid. Consequently, the structure of metabolite **2** was unambiguously determined to be *N*-vanillylcarbamoylbutanoic acid (Figure 2).

The molecular weight of metabolite **3** was 309 based on the pseudomolecular ion peaks detected at m/z 332.1 $[M + Na]^+$ and 310.1 $[M + H]^+$ in the ESI-MS (positive) spectrum, and the molecular formula ($C_{17}H_{27}NO_4$) was established by the HRESI-MS data (m/z 310.2021 $[M + H]^+$, calculated for $C_{17}H_{28}NO_4$, m/z 310.2018, +0.3 mDa). The ^1H NMR spectrum of **3** was related to that of **1**.[18] However, the ^1H NMR spectrum of **3** exhibited two upfield-shifted sp^3 methylene proton signals at δ 1.30 (2H, m, H-6) and 1.56 (1H, m, H-7) and one downfield-shifted sp^3 oxygenated methylene proton signal at δ 3.34 (2H, m, H-9′) (Table 1), compared to the proton signals of the olefinic double bond and the methyl group in capsaicin. The ^{13}C NMR spectrum revealed the presence of 17 carbon signals, including 7 sp^2 carbons with 4 quaternary carbons at δ 176.2−112.6 and 10 sp^3 carbons at δ 68.5−17.2 (Table 2). The side chain of **3** was suggested to be hydroxymethyloctanamide on the basis of the ESI-MS and 1D NMR spectra. The complete NMR assignment and connectivity of **3** were further determined by 2D NMR. The important correlations observed from the HMBC experiment are shown in Figure 3. In particular, correlations between H-9 and C-7 and C-8 were observed in the HMBC spectrum, indicating that the side chain of **3** was 8-hydroxy-7-methyloctanamide (Figure 3). Therefore, the structure of metabolite **3** was *N*-vanillyl-9-hydroxy-8-methyloctanamide (Figure 2), which is a new compound.

The molecular weight of metabolite **4** was 321 on the basis of the pseudomolecular ion peak detected at m/z 320.1 $[M - H]^-$ in the ESI-MS (negative) spectrum. The ^1H and ^{13}C NMR spectra of **4** were similar to those of **1**, except for an oxygenated methylene group. An oxygenated methylene proton and carbon signals were detected at δ 3.34 (2H, m, H-9) in the ^1H NMR spectrum (Table 1) and at δ 68.5 (C-9) in the ^{13}C NMR spectrum (Table 2), suggesting that **4** is a hydroxylated capsaicin (ω-hydroxycapsaicin). The ^1H and ^{13}C NMR spectra of **4** were consistent with those of ω-hydroxycapsaicin, which was isolated from *Capsicum annuum* (Banshou) previously.[19] Therefore, **4** was identified as ω-hydroxycapsaicin (Figure 2).

The molecular weight of fraction L was 335 on the basis of the pseudomolecular ion peak detected at m/z 334.2 $[M - H]^-$ in the ESI-MS (negative) spectrum, and the molecular formula ($C_{18}H_{25}NO_5$) was established by the HRESI-MS data (m/z

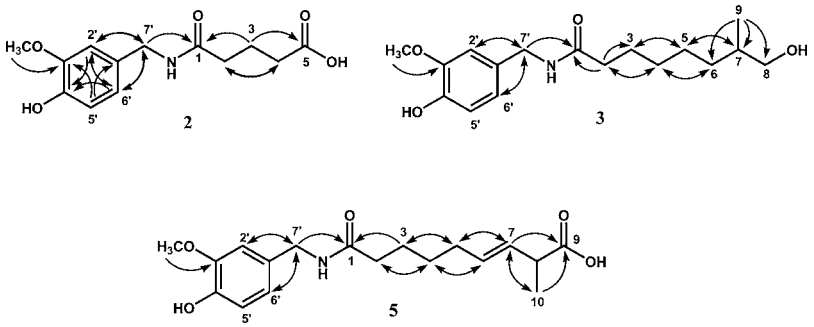

Figure 3. Heteronuclear multiple-bond correlation (HMBC) correlations (arrows) for **2**, **3**, and **5**.

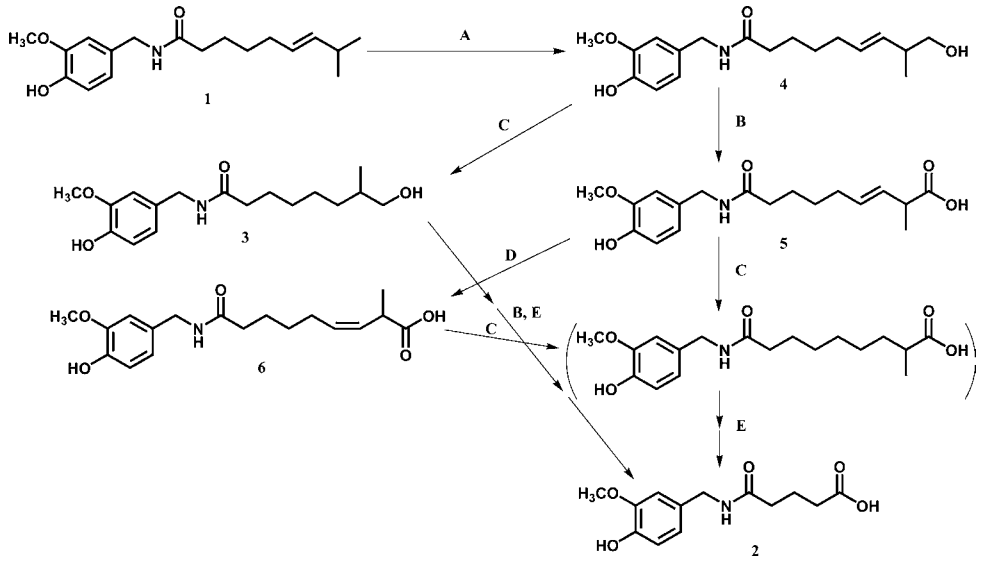

Figure 4. Proposed bioconversion mechanisms of the metabolite conversion from capsaicin by *A. oryzae*: (A) ω-hydroxylation; (B) alcohol oxidation; (C) hydrogenation; (D) isomerization; (E) α- and β-oxidations.

334.1655 $[M - H]^-$, calculated for $C_{18}H_{24}NO_5$, m/z 334.1654, +0.1 mDa). The ^1H and ^{13}C NMR spectra of fraction L showed evidence of a mixture of two compounds. These data suggest that the skeletal structure was similar, but the olefinic double bond differed. The ^1H NMR spectrum of fraction L had unequal methine proton signal intensity at a ratio of 2.5:1 (the main metabolite, **5**; the minor metabolite, **6**). The ^1H and ^{13}C NMR spectra of **5** were related to those of **1** and **4**, except for a carbonyl group. A carbonyl carbon signal at δ 179.0 (C-9) was observed in the ^{13}C NMR spectrum (Table 2), indicating that **5** contained a carboxylic group rather than a methyl alcohol group contained in **4**. The ESI-MS and 1D NMR results suggested that **5** was methyl-*N*-vanillylcarbamoyloctenoic acid. The complete NMR assignment and connectivity of **5** were further determined by 2D NMR. The olefinic double-bond position was side chain C-6 and C-7, based on the proton−proton correlations in the $^1H-^1H$ COSY experiment and the proton−carbon correlations in the HMBC experiment. In particular, correlations (Figure 3) of H-10 and H-7 to C-9 and of H-10 to C-7 were observed in the HMBC spectrum, indicating that the side chain of **5** was determined to be 8-methylcarbamoyl-6-octenoic acid (Figure 2). The olefinic double-bond signals of **5** overlapped with those of **6**. The olefinic double-bond signals of **5** were confirmed by the NOE experiment. The proton signals of the methyl group at δ 1.20 (H-10) and the olefinic double bond at δ 5.48−5.54 (H-6 and H-7) were enhanced when the proton signal of H-8 at δ 3.11was irradiated. The geometry of the olefinic double bond at C-6 and C-7 was the *trans* form, on the basis of their coupling constant value (15.5 Hz). Therefore, the structure of metabolite **5** was 8-methyl-*N*-vanillylcarbamoyl-6(*E*)-octenoic acid (Figure 2).

The ^1H and ^{13}C NMR spectra of metabolite **6** were closely related to those of metabolite **5**, except for different chemical shifts in the methine proton and olefinic double-bond carbon signals (Table 1). In particular, methine proton signals at δ 3.02 (H-8) were observed at 0.09 ppm upfield, the C-7 signal at δ 133.0 was shifted by 0.3 ppm, and the signals of C-6 at δ 130.6 and of C-9 at δ 177.3 were shifted by above 0.4 ppm compared to the ^1H and ^{13}C NMR spectra of **5**. The complete NMR assignment and connectivity of **6** were further confirmed by the $^1H-^1H$ COSY, HSQC, and HMBC experiments. The geometry of the olefinic double bond at C-6 and C-7 was the *cis* form, based on the NOE data and their coupling constant value (12.5 Hz). Consequently, the structure of metabolite **6** was 2-methyl-*N*-vanillylcarbamoyl-6(*Z*)-octenoic acid (Figure 2).

The structures of five metabolites converted from capsaicin by *A. oryzae* were determined by NMR and MS analyses. Metabolites **2**, **4**, and **5** have already been reported as capsaicin metabolites converted by *A. niger*.[15,16] However, the NMR study for the capsaicin metabolites **2** and **5** converted by *A. niger* was insufficient. Therefore, we performed complete assignments of them using NMR analysis to provide data as models for establishing the structures of the capsaicin

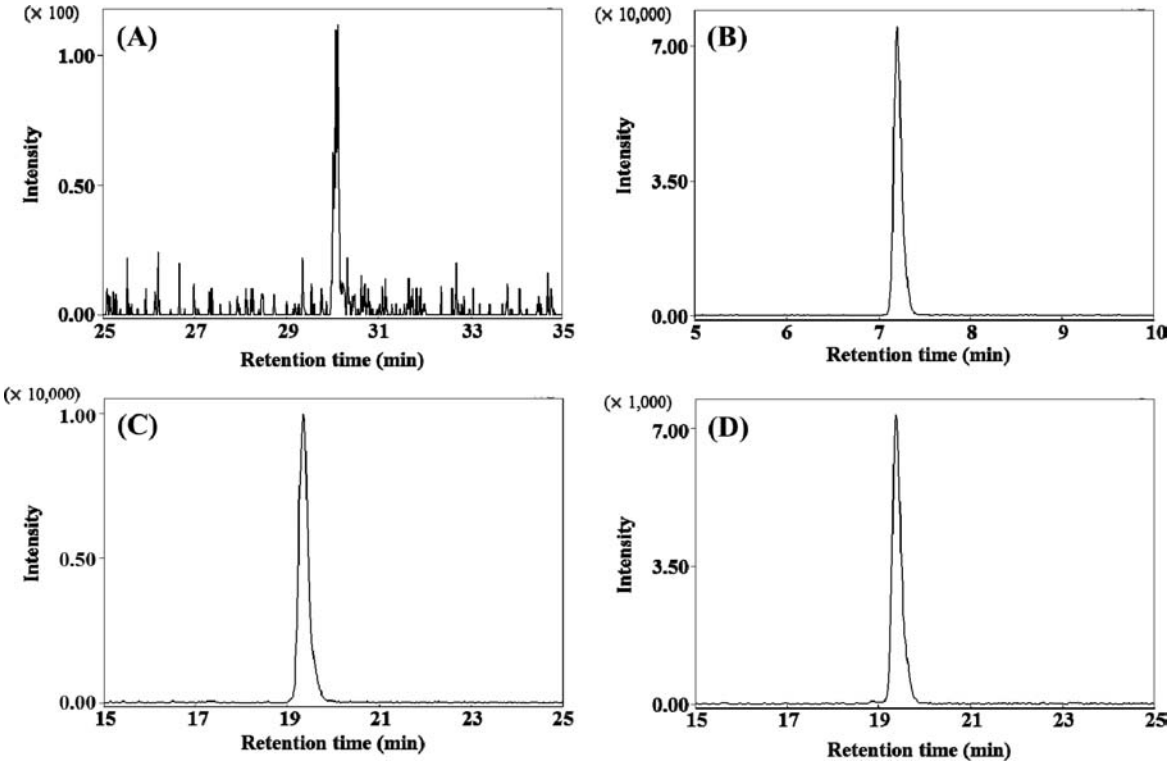

Figure 5. Multiple reaction monitoring chromatograms of (A) **1**, (B) **2**, (C) **4**, and (D) **5** and/or **6** in gochujang. Capsaicin and its metabolites were analyzed by LC-ESI-MS/MS. Capsaicin metabolites were detected by selective multiple reaction monitoring (MRM): m/z 304.1 $[M - H]^-$ → 168.2 for **1**; m/z 268.3 $[M + H]^+$ → 137.1 for **2**; m/z 320.1 $[M - H]^-$ → 184.1 for **4**; m/z 334.0 $[M - H]^-$→ 154.2 for **5** and **6**. Detailed procedures for LC-ESI-MS/MS analysis have been described under Materials and Methods.

metabolites in future research. Among the five metabolites, **3** and **6** are new capsaicin metabolites first reported in this study. *Streptomyces mobaraensis* and *Actinoplanes utahensis* hydrolyze capsaicin to vanillylamine and *trans*-8-methyl-6-nonenoic acid.[10−14] However, capsaicin hydrolysates (vanillylamine and *trans*-8-methyl-6-nonenoic acid) were not identified in this study. These observations indicate that capsaicin hydrolysis may not be a predominant pathway in *A. oryzae*. The conversion mechanisms by *A. oryzae* of capsaicin metabolites are proposed in Figure 4. Metabolite **4** was produced by the hydroxylation of capsaicin and was converted to **3** and **5** by β-oxidation and alcoholic oxidation, respectively. In addition, metabolite **6** was probably degraded from **5** by α- and β-oxidations via isomerization and/or hydrogenation, and **2** was likely produced from **3** by α- and β-oxidations.

Qualitative and Quantitative Analyses of the Capsaicin Metabolites in Gochujang. Capsaicin and its metabolites **1**−**6** in gochujang were quantitated by HPLC-ESI-MS using the isolated compounds as external standards. The EtOAc fraction obtained after solvent fractionation from gochujang MeOH extracts was analyzed by selective MRM detection and MS/MS. The capsaicin metabolites **1**, **2**, **4**, and **5** and/or **6** were detected at t_R 30.8, 7.2, 19.3, and 19.4 min on the MRM chromatogram of gochujang (Figure 5). The metabolites were identified using the retention times of authentic compounds **1**, **2**, **4**, and **5** and/or **6**. In this study, the identity of **5** and **6** on the EtOAc fraction MRM chromatogram could not be determined because **5** and **6** were a mixture when they were purified, suggesting that **5** and **6** are present in gochujang. However, metabolite **3** (t_R 16.0 min; limit of detection, 0.5 ng) was not detected on the MRM chromatogram of gochujang, suggesting no production of it or rapid conversion to other capsaicin metabolites, although this compound is produced during fermentation of gochujang. These results indicate that capsaicin metabolites **2**, **4**, and **5** and/or **6** are unambiguously present in gochujang.

Capsaicin and its metabolites **1**, **2**, **4**, and **5** and/or **6** were also analyzed quantitatively by selective MRM detection and MS/MS. The external calibration curve of each compound at a concentration range of 0.1−50 ng produced a good linear correlation ($R^2 > 0.99$). The dilution ratio of gochujang extract in MeOH/$CHCl_3$ was 1:800 (w/v). The repeatability of each metabolite ranged from 1.1 to 2.6%: **1**, 1.1%; **2**, 1.9%; **4**, 2.6%; and **5** and/or **6**, 2.4%. The recoveries of **1** (99.0 ± 1.1%), **2** (99.5 ± 1.9%), **4** (100.3 ± 2.6%), and **5** and/or **6** (101.0 ± 2.4%) ranged from 99.0 to 101.1%. Of the capsaicin metabolites, **5** and **6** (5607.8 ± 53.0 μg/100 g dry wt) were most abundantly found in gochujang, yet the abundance was lower than that of capsaicin (7671.4 ± 278.6 μg/100 g dry wt) (Table 3). Metabolites **2** (74.8 ± 1.4 μg/100 g dry wt) and **4**

(38.1 ± 0.9 μg/100 g dry wt) were present in small amounts in gochujang compared to **5** and/or **6**. In this study, most capsaicin was converted when *A. oryzae* was incubated with capsaicin in PDB at 30 °C for 14 days. However, capsaicin was found at greater content than capsaicin metabolites in gochujang product. It is considered because gochujang is a high viscous paste that is fermented from a primary mixture of red hot pepper powder, waxy rice flour, fermented soybean, and koji. Although capsaicin metabolite-related enzymes were secreted from *A. oryzae* during the fermentation of gochujang, the amounts and activities of the secreted enzymes may be relatively lower than those in PDB culture. Therefore, capsaicin may be converted slowly to capsaicin metabolites during the fermentation of gochujang. The varieties and contents of capsaicin metabolites in gochujang may be dependent upon the fermentation microorganisms and the extent of fermentation.

The contents of capsaicinoids in hot pepper were 46−77% for capsaicin, 21−40% for dihydrocapsaicin, 2−12% for nordihydrocapsaicin, and >2% for other capsaicin derivatives.[1,18] According to the results of a capsaicinoid sensory evaluation, the pungent intensity decreases in the order **1** (100) = dihydrocapsaicin (100) > nordihydrocapsaicin (57) > homodihydrocapsaicin (50) > homocapsaicin (43).[20] In addition, *N*-nonanoylvanillylamide, which contains a nine-carbon side chain, has the most pungent taste.[21] However, the pungency of capsaicin derivatives, which have more variable carbon side chains than that of *N*-nonanoylvanyllylamide, is lower.[22,23] Thus, the pungency of capsaicin derivatives may depend on the amide acylation and carbon side chain length. In addition, ω-hydroxycapsaicin has slightly weaker pungency than **1**.[19] All capsaicin metabolites identified in this study contain the carboxylic acid or hydroxyl groups, and **2** and **3** had fewer carbons in their side chain than **1**. Therefore, capsaicin metabolites are likely to be less pungent than capsaicin, although pungency was not evaluated in this study.

The five capsaicin metabolites converted by *A. oryzae* were elucidated by NMR and MS analyses. Also, the capsaicin metabolites in gochujang were all found except for **3**. Therefore, the capsaicin metabolites are likely produced from **1** during gochujang fermentation, and the product becomes less pungent than red hot pepper. These results will provide useful information to improve the quality and biological activity of gochujang to control pungency during fermentation. New alternatives for capsaicin products in food and pharmaceutical applications can be suggested for future study.

and 5 days. Samples for Nano-PALDI MSI were cut from the fruit using a blade, and the frozen samples were set axially in a cryostat (CM-3050S; Leica, USA) at −25 °C. Samples were cut into serial sections (50 μm) and thaw-mounted on indium tin oxide glass slides for MSI.

MSI of Procymidone in Cucumbers. Standard procymidone dissolved in 70% methanol (Dr Ehrenstorfer, Germany) was used for the standards. Standard procymidone was desalted before MS measurement to detect a definite protonated ion. Standard procymidone (10 ppm) was dropped on an iron oxide nanoparticle-coated target MS plate. After drying the solution, ice water was dropped on the target position and immediately removed. High solubility sali-ions were almost purged from the procymidone sample. MSI was achieved by a Fourier-transform ion cyclotron resonance (FT-ICR) MS (SolariX, Bruker, Germany). An iron oxide nanoparticle (1 mg/mL) suspension was dispersed in methanolic solution and was sprayed on glass slides with an airbrush on some sections (nozzle caliber, 0.2 mm). The section surface was irradiated with 1000 laser shots in the positive ion detection mode of the mass spectrometer. To detect the laser spot area, the sections were scanned and a spot-to-spot center distance of 100 μm in each direction at the center and the pericarp of the cucumber was measured. For the pericarp, flesh, and seed regions, the related intensities were processed by discarding background peaks. The remaining intensities formed the set of variables that were used for imaging and semiquantitative analysis.

RESULTS AND DISCUSSION

Detection of Procymidone by GC-MS and Nano-PALDI-FT-ICR MS. GC-MS was used for the quantitative analysis of the pericarp, flesh, and whole fruit. The total ion chromatogram showed that the signal at 21.5 min corresponded to procymidone, which was consistent with the database value. We monitored the procymidone ion at m/z 283 and prepared a calibration curve over the range of 0.01−10 ppm. Selected ion monitoring of m/z 283 showed m/z 255, 212, 96, 67, and 53 as fragment ions.[9] The whole sample showed the same amount of procymidone residue regardless of the time stored, indicating that the amount of procymidone residue did not decrease during storage. In the pericarp region, the amount of procymidone decreased over time. There was a substantial decrease in the amount of procymidone residue between days 0 and 1 and subsequent days, whereas it did not change between days 1, 3, and 5. In contrast, the flesh showed a substantial increase in the amount of procymidone (Figure 1).

We investigated whether the increase in the concentration of the procymidone residue was caused by changes in the weight of the cucumber through the evaporation of water. The weight of the cucumbers did not change over time. Thus, the GC-MS results quantitatively showed the amount of procymidone in cucumbers.

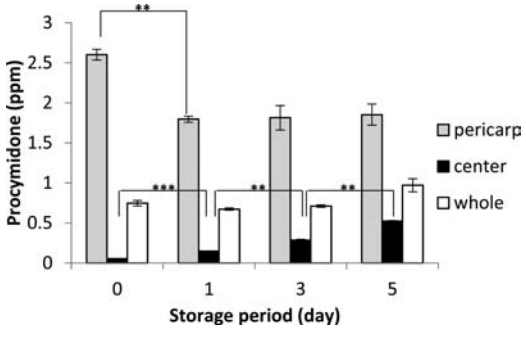

Figure 1. GC results for the concentration of procymidone in the pericarp, flesh, and whole cucumber. The values are expressed as the standard error of mean. (**) $p < 0.01$, and (***) $p < 0.001$ by Student's t test.

FT-ICR MS offers high resolution ($R = 10^5-10^6$) and accuracy ($\Delta m = 10^{-4}-10^{-3}$ u).[10−12] Thus, we could classify the molecular species from the exact mass (M_e) without tandem mass spectrometry. To confirm the ionization of procymidone by Nano-PALDI, a procymidone standard was ionized using an iron oxide nanoparticle ionization-assisting reagent. Procymidone ions at m/z 284.025, 306.007, and 321.981 corresponded to the protonated ion and the sodium and potassium adducts, respectively (Figure 2). The same signals were detected from the section of cucumber sample containing the procymidone standard, indicating that iron oxide-based Nano-PALDI ionized the procymidone in the cucumber sections (Figure 3).

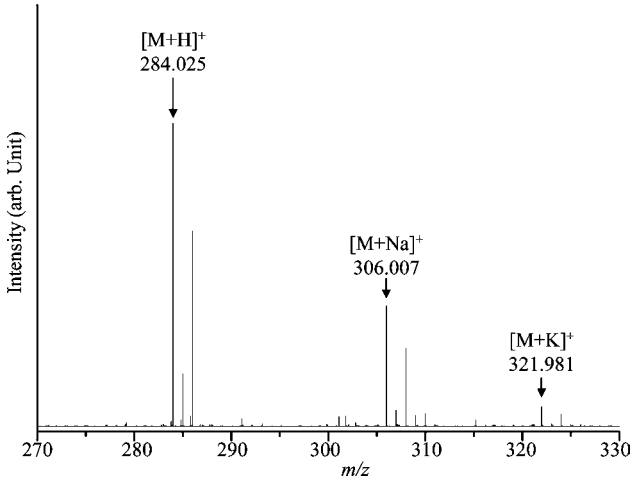

Figure 2. Nano-PALDI MS spectra of procymidone standard. m/z 284.025, 306.007, and 321.981 correspond to the protonated ion and sodium and potassium adducts of procymidone, respectively.

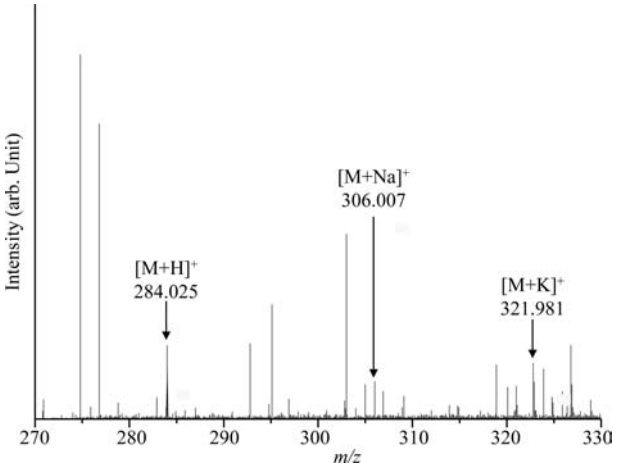

Figure 3. Mass spectrum of cucumber section containing procymidone.

Comparison of Storage Period. We imaged the localization of procymidone in cucumbers by MSI at a resolution of 100 μm to show whether procymidone was localized in any of the regions. The protonated ion signal was chosen as the procymidone target in the cucumber section because the images of the sodium and potassium adducts reflected the

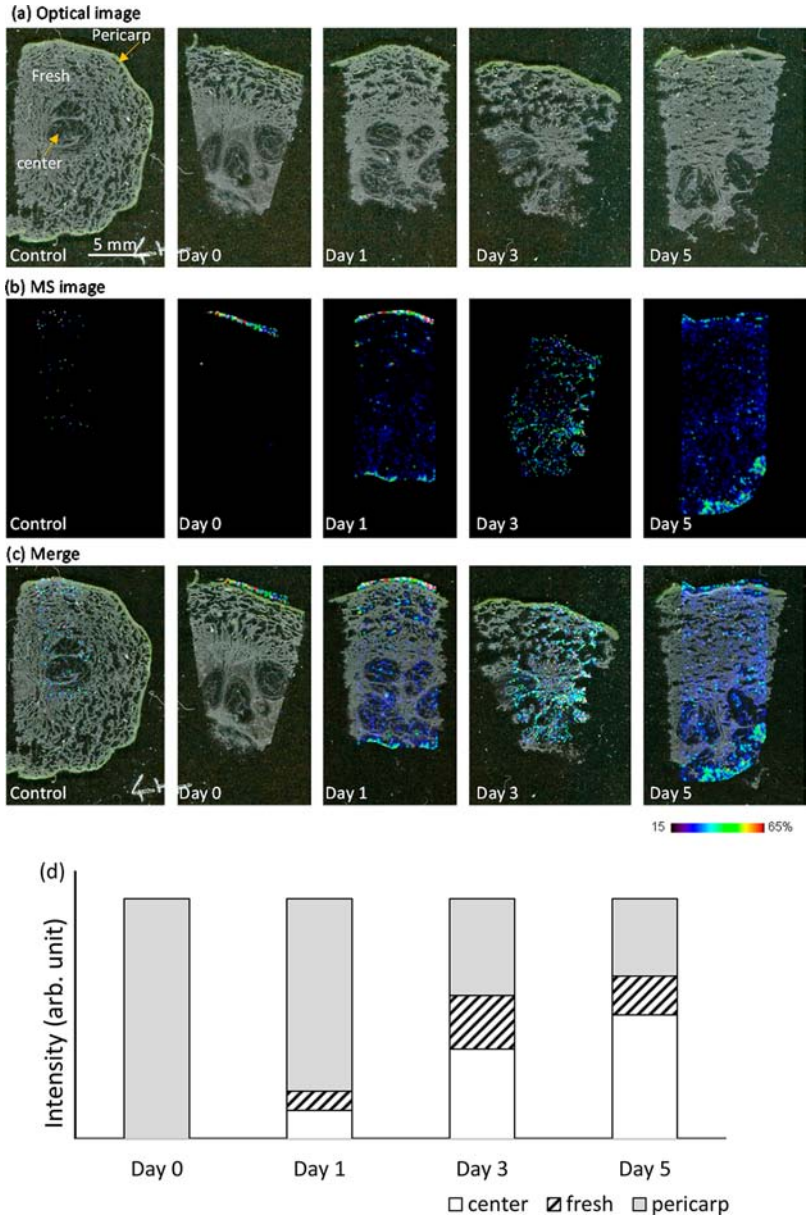

Figure 4. Procymidone distribution in cucumber control samples and samples sprayed with procymidone 0, 1, 3, and 5 days after harvest: optical image of cucumber sections (a); MSI of procymidone (b); merged optical and ion image (c); stacked bar chart of procymidone in the samples, reconstructed from the MSI data by binarization (d).

localization of the salt rather than that of the procymidone. A number of high-intensity signals were detected in the mass spectrum obtained from the samples containing procymidone. Thus, we could analyze the localization of procymidone from cucumber sample by MSI.

The optical image of the cucumber sections was used to determine the pericarp, flesh, and center regions of the tissue (Figure 4a). The control sample did not show the presence of procymidone. The cucumber samples that were sprayed with procymidone after harvest on day 0 showed procymidone in only the pericarp region and procymidone had not reached the inner region.

The image of the cucumber sample 1 day after harvest showed procymidone in the pericarp region in a ladder pattern. Procymidone migrated toward the inner region. Three days after harvest, procymidone was mainly present from the premedial flesh to the center region. Five days after harvest, procymidone was found in the center region. These images were not obtained on the same day; thus, we constructed the ion images by normalizing the signal intensity of m/z 284.025 (Figure 4b,c).

Semiquantitative regional analysis was performed by matching the MS intensities with the pericarp, flesh, and seed regions. The values were converted to the intensity per unit area. The total intensity ratios for samples 0, 1, 3, and 5 days after harvest were 3:2:1:1, 0:1:2:3, and 0:1:3:5 in the pericarp, flesh, and seed regions, respectively.

In the pericarp, the intensity for the day 0 sample was 3-fold higher than that for the day 3 and 5 samples. The intensity of the samples decreased over time. However, for the flesh the intensity increased in the day 1−3 samples and decreased in the day 5 sample. In contrast, the intensity of the center region gradually increased with time, indicating that procymidone reached the inner region and ended up in the center region

J. Agric. Food Chem. 2015, 63, 6109−6112

(Figure 4d). Penetration of procymidone occurred from day 1, and it was present in all sections of the cucumber by day 3 and became concentrated in the center, although some procymidone remained in the pericarp. These data show only relative comparison, although it was in good agreement with quantitative GC-MS data (Figure 1).We performed MSI of the localization of procymidone in cross sections of cucumbers. Nano-PALDI enabled imaging of the low molecular weight pesticide. MSI showed that procymidone migrated toward the center of the cucumber over 5 days. Visualization of pesticide gives us the time-dependent permeation aspect. MSI is a powerful tool for fundamental science, agricultural chemistry, food hygiene, and pesticide science.

dissolution in NaOH/urea aqueous solution. The effects of acid pretreatment time on DP, carbohydrate composition, kappa numbers, crystallinity indices, morphology, and dissolved proportions of lignocellulose were studied.

MATERIALS AND METHODS

Materials. Softwood unbleached kraft pulp (UKP) with a kappa number of about 28, another softwood unbleached kraft pulp (UKP′) with a higher lignin content, and a softwood thermomechanical pulp (TMP) were used as the wood pulp samples, which were kindly provided by Oji Paper Co., Ltd., Japan. $NaClO_2$ was purchased from Sigma-Aldrich Co. Other reagents and solvents were of laboratory grade and were used as received from Wako Pure Chemicals, Tokyo, Japan.

Chlorite Delignification. The UKP or TMP with a weight of 5 g was delignified by a mixture of 1 g of $NaClO_2$, 0.3 mL of acetic acid, and 160 g of water four times. The mixture was kept at room temperature. It took 40 min each time. The mixture was occasionally shaken by hand. Softwood bleached kraft pulp (BKP) with low lignin content and bleached TMP (BTMP) were finally obtained after filtration.

Dilute Acid Hydrolysis. Three grams of dried original pulp (UKP, UKP′, and TMP) or bleached pulp (BKP and BTMP) was dispersed in 100 g of 3% H_2SO_4 aqueous solution. The mixture was heated by water bath at 80 °C for different times (0.5, 1, 2, 3, or 4 h). After the acid hydrolysis, the pulps were separated by filtration and kept without drying. The pulp samples were coded as UKP-hydrolysis time (UKP-0.5, UKP-1, UKP-2, UKP-3, or UKP-4), UKP′-hydrolysis time (UKP′-4 or UKP′-8), TMP-hydrolysis time (TMP-4 or TMP-8), BKP-hydrolysis time (BKP-0.5, BKP-1, BKP-2, BKP-3, or BKP-4), and BTMP-hydrolysis time (BTMP-4), respectively. The pulps without acid treatment were coded UKP-0, BKP-0, UKP′-0, TMP-0, and BTMP-0, respectively.

Dissolution. The original pulp or acid-treated pulp was dispersed in a 7 wt % NaOH/12 wt % urea/81 wt % H_2O solution with pulp content of 1 wt %, and then the pulp dispersion was frozen and thawed. The resulting mixture was centrifuged at 10000 rpm for 10 min at 5 °C and then filtered.[16] The remaining undissolved fractions were washed by 7 wt % NaOH/12 wt % urea/81 wt % H_2O three times and further washed by water until they were neutral. Then they were dried in a vacuum oven with P_2O_5 at 40 °C for 48 h and weighed. The dissolved proportion of the pulp was calculated according to the equation

$$\text{dissolved proportion} = \frac{m_0 - m_1}{m_0} \times 100\% \quad (1)$$

where m_0 is the dry mass of the pulp before dissolution and m_1 is the dry mass of the residual undissolved pulp. The dissolved proportion measurements were repeated more than three times, and their average was obtained.

Film Preparation. UKP′-4 was dissolved in NaOH/urea solvent to obtain a lignocellulose solution with 4 wt % lignocellulose content. After centrifugation, the solution was cast on a glass plate and soaked in 5 wt % aqueous H_2SO_4 for 5 min, following the previously reported method.[19] The regenerated lignocellulose gel was washed thoroughly with water and air-dried at 23 °C and 50% relative humidity for more than 1 day to obtain the lignocellulose film.

Lignin Content Determination. The Klason method and kappa number method were used to determine the lignin content of the samples.[36]

Sugar Analysis. The carbohydrate compositions of the samples were determined by the alditol−acetate method.[37] Sulfuric acid (72 wt %, 1 mL) was added to 100 mg samples, kept at room temperature for 4 h, and then diluted with water to adjust the concentration of sulfuric acid at 4 wt %. Hydrolysis of the samples in 4 wt % sulfuric acid was performed in an autoclave at 120 °C for 1 h. After cooling to room temperature, the hydrolyzed solution was filtered by glass filter, and the filtrate was adjusted to 100 mL with water. As the internal standard, 1.00 mL of *myo*-inositol aqueous solution (1.00 mg/mL) was added into 5.00 mL of the cooled solution obtained above. The solution was neutralized by aqueous barium hydroxide solution to pH 5.5. After removal of the precipitate, about 20 mg of $NaBH_4$ was added to the filtrate, and the reaction mixture was kept at room temperature for 24 h. Excess $NaBH_4$ was degraded by acetic acid. After the mixture was evaporated to dryness, a small amount of methanol was added and dried. This was repeated several times, and then the mixture was heated in an oven at 105 °C for 15 min to ensure complete removal of the water. The dry residue was acetylated by 1 mL of acetic anhydride below 120 °C for 3 h and then analyzed by gas chromatography GC-14b with FID (Shimadzu Co., Kyoto, Japan) using a column TC-17 (fused-silica capillary column, 30 m, 0.25 mm i.d, GL Science Inc., Tokyo, Japan) with a temperature program of 20 min at 220 °C, injection temperature of 220 °C, and detector temperature of 230 °C.

X-ray Diffraction (XRD). The samples were dried in a vacuum oven with P_2O_5 at 40 °C for 48 h. XRD patterns of the samples were acquired in reflection mode using a RINT 2000 diffractometer (Rigaku, Tokyo, Japan) with monochromator-filtered Cu Kα radiation (λ = 0.15418 nm) at 40 kV and 40 mA. Scans were obtained from 4 to 40° 2θ at a speed of 1° per minute. The crystallinity index (CI) was calculated from the height ratio between the intensity of the crystalline region and total region according to Segal's method.[38,39]

Scanning Electron Microscopy (SEM). The surfaces of the wood pulps were coated with osmium using a Meiwafosis Neo osmium coater at 10 mA for 10 s and observed with a Hitachi S4800 field-emission SEM at 2 kV.

Optical Microscopy. The pulps were dispersed in the 7 wt % NaOH/12 wt % urea/81 wt % H_2O solutions with pulp content of 1 wt %, and then the pulp dispersions were frozen and thawed. The images of the final dispersions (or solutions) were observed by using an optical microscope (BX-50 with a digital camera DP-20, Olympus, Japan).

Viscosity-Average Degree of Polymerization (DP_v) measurement. The samples (0.04 g) were dissolved in 0.5 M copper ethylenediamine (20 mL) for 30 min. The intrinsic viscosity of the solution was obtained by using a Cannon−Fenske capillary viscometer, and the value was converted to DP_v values using the Mark−Houwink−Sakurada equation, $[\eta] = 0.57 \times DP_v$.[40]

Tensile Test. The tensile test of the lignocellulose film was performed using a Shimadzu EZ-TEST instrument equipped with a 500 N load cell. Rectangular strips 2 × 30 mm in size were cut from the lignocellulose film and tested with a span length of 10 mm at a rate of 1.0 mm min^{-1}. The film was conditioned at 23 °C and 50% relative humidity for 2 days before the test.

RESULTS AND DISCUSSION

Effect of Acid Treatment on Characteristics of Pulps. Figure 1 shows the yields of the wood pulps after acid

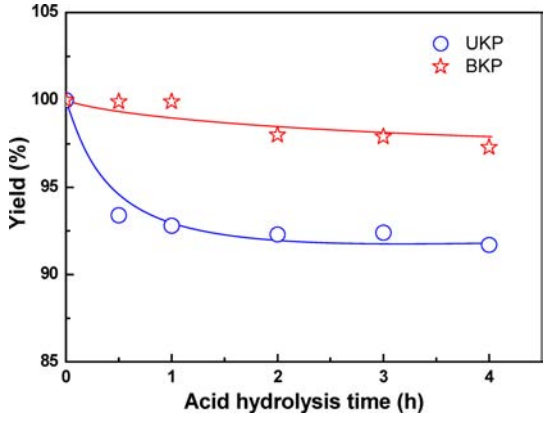

Figure 1. Effects of acid hydrolysis time on the yields of the wood pulps. Yield is based on the weight of the samples before acid hydrolysis.

DOI: 10.1021/acs.jafc.5b01714
J. Agric. Food Chem. 2015, 63, 6113−6119

hydrolysis based on the weight of the wood pulps before acid hydrolysis. The yields decreased only a little after acid hydrolysis. Even after 4 h of acid hydrolysis, the yield of softwood BKP was still high (97.3%) and slightly higher than 91.7% of softwood UKP. This was probably because BKP contains less acid soluble components, such as lignin and hemicellulose, after delignification compared with UKP. Especially, the yields of the wood pulps with different acid-treated times (0.5−4 h) were almost the same. As will be seen later, the amounts of the main components (cellulose, hemicellulose, and lignin) of the wood pulps barely changed under the mild dilute acid hydrolysis condition, which is the reason for the high yields of UKP and BKP after acid hydrolysis.

The kappa numbers of the wood pulps are shown in Figure 2. After acid hydrolysis, the kappa numbers of UKP and BKP slightly decreased and kept a similar level with different acid-treated times (0.5−4 h). Table 1 shows the carbohydrate compositions of the wood pulps before and after dilute sulfuric acid treatment. The results indicated that the hemicellulose contents of the pulps barely changed under the different acid treatment times (0.5−4 h). The results of carbohydrate compositions together with the kappa numbers (Figure 2) and yields of the pulps (Figure 1) confirmed that the amounts of the main components (cellulose, hemicellulose, and lignin) of UKP and BKP were almost unchanged for the different acid hydrolysis times, and in this case their influence on the dissolution of wood pulp in NaOH/urea system could be excluded.

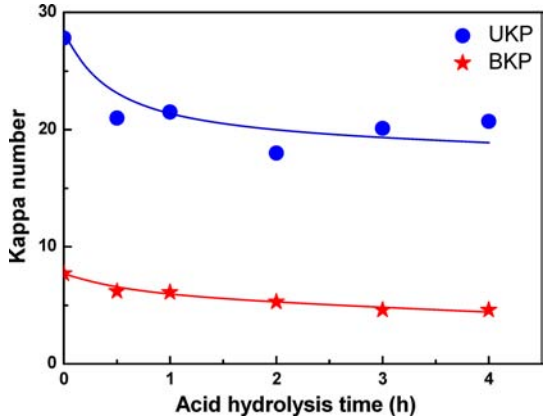

Figure 2. Effects of acid hydrolysis time on the kappa numbers of the wood pulps.

Table 1. Carbohydrate Compositions of the Wood Pulps before and after Pretreatment by Sulfuric Acid Hydrolysis

sample	glucose (%)	xylose (%)	mannose (%)	galactose (%)
UKP-0	71.1	6.5	5.0	0.8
UKP-0.5	78.3	6.5	6.8	0.8
UKP-1	83.1	7.3	5.4	0.2
UKP-2	84.7	7.2	5.7	0.6
UKP-3	81.1	7.2	3.8	0.5
UKP-4	84.1	6.9	5.4	0.4
BKP-0	82.1	7.4	5.6	0.8
BKP-0.5	83.3	7.4	5.6	0.5
BKP-1	84.8	7.5	5.5	0.5
BKP-2	85.4	7.2	6.0	0.6
BKP-3	85.9	6.8	5.5	0.5
BKP-4	86.9	7.2	5.5	0.5

Figure 3 shows the XRD patterns of the wood pulps before and after acid hydrolysis, and the effects of acid hydrolysis time on the crystallinity indices (CI) of the wood pulps are shown in Figure S1. Compared with the original wood pulp, the crystallinity indices of the acid hydrolysis pulps increased. The crystallinity indices of UKP increased from 66 to 77% and that of BKP increased from 73 to 79%, with the increase in acid hydrolysis time from 0 to 4 h. Moreover, the increase in the crystallinity index of UKP after 1 h of acid hydrolysis was more than that of BKP; this was probably due to there being more amorphous components present in UKP-0 than in BKP-0, such as lignin, hemicellulose, and amorphous cellulose.

SEM images of the wood pulps before and after acid hydrolysis are shown in Figure 4. UKP-0 and BKP-0 show relatively smooth and flat surfaces, and many random microfibril bundles were present on the surface of UKP-0, probably owing to the S1 layer of the wood fiber. However, after acid hydrolysis, these random microfibril bundles disappeared and some oriented fiber bundles appeared, forming a rough surface. This change in morphology of wood fiber was probably due to the S1 layer of the wood fiber having been removed by acid hydrolysis and the secondary wall of the wood fiber appearing.[34] Moreover, compared with UKP, the change in morphology of BKP after acid hydrolysis was more obvious. The surface of BKP became very rough, and some microfibril bundles were stripped from the surface of the wood fiber after acid hydrolysis. This may have been because lignin exerted a preventative influence on the acid hydrolysis of wood fiber, and the lower lignin content of BKP compared with UKP led to a greater change in morphology after the acid hydrolysis.

Dissolution of Acid-Treated Unbleached Kraft Pulp and Bleached Kraft Pulp. Figure 5 shows the photos of different UKP/NaOH/urea solutions and BKP/NaOH/urea solutions after freezing and thawing. The UKP-0/NaOH/urea solution and BKP-0/NaOH/urea solution were not transparent. However, after 2 h of acid pretreatment, UKP and BKP gave transparent NaOH/urea solution, suggesting that most of the UKP-2 and BKP-2 was dissolved in the NaOH/urea solution.

The effect of acid pretreatments on the dissolution of wood pulps was also studied by optical microscopy. The relevant optical microscope images of different UKP/NaOH/urea solutions after freezing and thawing are shown in Figure 6. In the case of the UKP-0/NaOH/urea dispersion, most of the wood fibers kept their original morphology, although some of the wood fibers were swollen. However, even after 0.5 h of acid hydrolysis, the morphology of UKP-0.5 changed obviously. Most pulps were dissolved or became highly swollen fibers, fragments, balloons, or flat rings in the insoluble fractions. Moreover, with increasing acid hydrolysis time, the insoluble fractions were reduced. UKP-3/NaOH/urea shows a clear solution image, indicating that after 3 h of acid hydrolysis, the wood pulp almost completely dissolved in the NaOH/urea aqueous solution.

Figure 7 shows the dissolved proportions and DP_v of wood pulps pretreated by dilute sulfuric acid. After 4 h of acid hydrolysis, DP_v of UKP and BKP decreased from 1150 to 550 and from 1300 to 520, respectively, whereas the dissolved proportions of UKP and BKP increased from 20.7 to 94.7% and

DOI: 10.1021/acs.jafc.5b01714
J. Agric. Food Chem. 2015, 63, 6113−6119

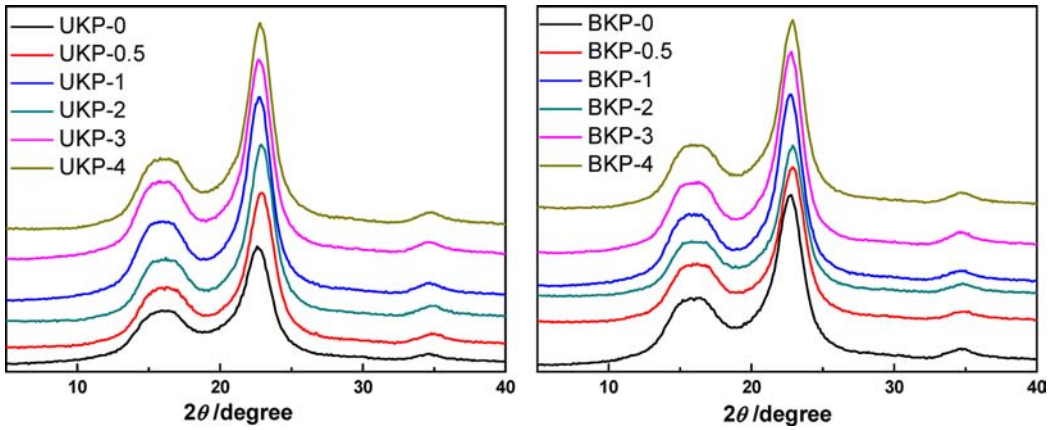

Figure 3. XRD patterns of the wood pulps before and after acid hydrolysis.

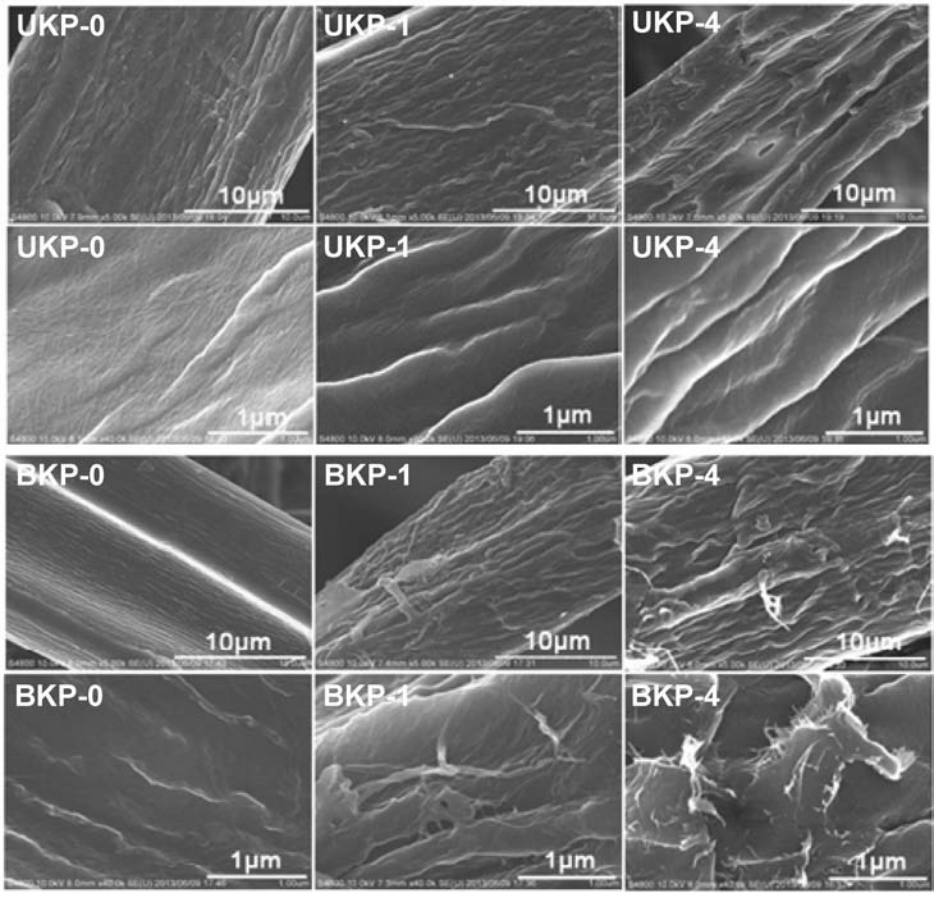

Figure 4. SEM images of the wood pulps before and after acid hydrolysis.

from 20.5 to 96.3%, respectively. It was indicated that the wood pulps with lower DP had higher dissolved proportions in the NaOH/urea solvent system, which was similar to the dissolution of cotton linters cellulose in this solvent system.[24] In fact, even though the acid hydrolysis time was only 2 h, the dissolved proportions of UKP-2 and BKP-2 had already increased to about 90%, which was much better than those of the untreated UKP-0 and BKP-0. Moreover, the dilute acid-treated wood pulps still kept a relatively high DP_v of about 600. Furthermore, this figure also shows that under the same acid hydrolysis conditions, the dissolved proportions of UKP and BKP were similar. This indicated that the main factor influencing the dissolved proportion of the wood pulp in this case is the molecular weight of the wood pulp, and the effect of lignin content could be neglected. However, it does not mean that the presence of lignin does not affect the dissolution of the pulps into this solvent. After acid hydrolysis, the lignin molecule must be cut into smaller fragments even though they are not removed from the pulp.[41] This fragmentation of lignin must affect the interaction between lignin and polysaccharide. The results of dissolved proportions of the wood pulps were in good agreement with the results of their appearances (Figure 5) and optical microscope images (Figure 6).

DOI: 10.1021/acs.jafc.5b01714
J. Agric. Food Chem. 2015, 63, 6113−6119

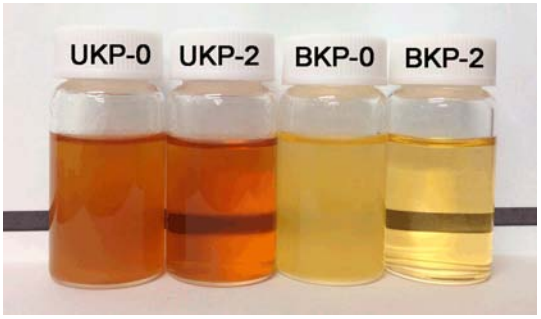

Figure 5. Photographs of different UKP/NaOH/urea solutions and BKP/NaOH/urea solutions after freeze and thaw.

To further confirm that wood pulp with low molecular weight was easily dissolved in NaOH/urea solvent, regenerated wood pulps were prepared by regeneration of once-dissolved pulp with ethanol. DP_v values of the original wood pulp samples and the regenerated wood pulp samples are shown in Figure 8. BKP-3 with a low DP_v of 530 almost completely dissolved in NaOH/urea solvent (Figure 7). After dissolution and regeneration, DP_v of the regenerated BKP-3 was about 400, not much lower than that of the original BKP-3. This result indicated that the dissolution of wood pulp in NaOH/urea solvent followed by regeneration resulted in only a slight degradation of cellulose. Furthermore, UKP-1 and BKP-1 could not completely dissolve in the NaOH/urea solvent. The DP_v of the regenerated UKP-1 was about 410, which was much lower than that of the original UKP-1 (700). The DP_v of the regenerated BKP-1 was about 390, also much lower than that of the original BKP-1 (730). This indicates again that the low molecular weight fraction of pulp was easy to dissolve in the NaOH/urea solvent, which is consistent with the results of the dissolved proportions shown in Figure 7.

Dissolution of Wood Pulps with High Lignin Contents. To study whether the acid-treated pulp with high lignin content (>3%) could dissolve in NaOH/urea solvent or not, the different acid hydrolysis pulps with relatively high lignin contents were dissolved, and their relevant dissolved proportions are shown in Table 2. UKP′ had a lignin content of 6.1%. After acid hydrolysis for 4 h, it could dissolve well in NaOH/urea solvent, and its dissolved proportion increased from 20 to 93%. The dissolved proportion of the original TMP was very low (about 10%), probably due to its high lignin content (about 29%). After acid hydrolysis for 4 h, the dissolved proportion of TMP increased to 33%, although the dissolved proportion was still very low. Even after acid hydrolysis for 8 h, TMP still could not completely dissolve and the dissolved proportion was <40%. After delignification of TMP by $NaClO_2$, the obtained BTMP had a lignin content of about 13.5%. After 4 h of acid hydrolysis of BTMP, the dissolved proportion of the obtained BTMP-4 increased from 45 to 96%, which indicated that, even though the lignin content of BTMP-4 was still as high as 14.2%, it could dissolve well in NaOH/urea solvent.

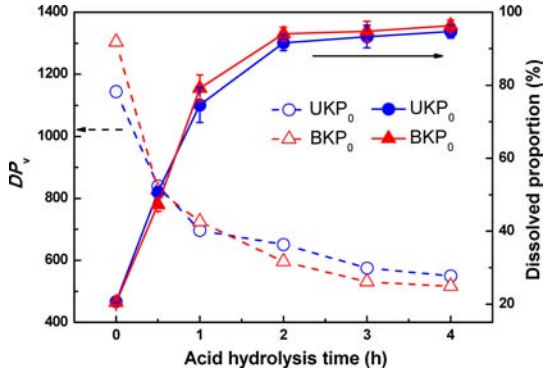

Figure 7. Effects of acid hydrolysis time on the dissolved proportions and viscosity-average degrees of polymerization (DP_v) of the wood pulps.

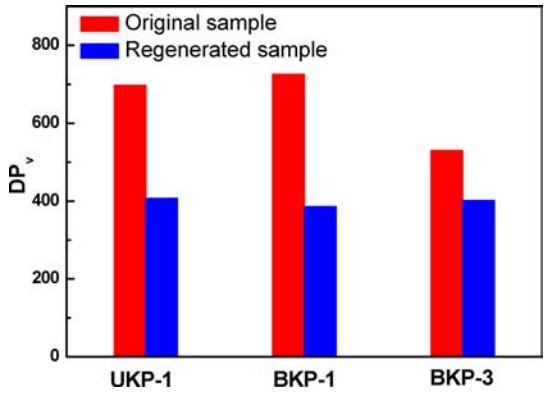

Figure 8. Viscosity-average degrees of polymerization (DP_v) of the wood pulps (UKP-1, BKP-1, and BKP-3) and their relevant regenerated samples prepared by dissolution in NaOH/urea solution followed by regeneration with ethanol.

Table 2. Dissolved Proportions of Different Pulp Species before and after Acid Treatment

sample	Klason lignin content (%)	dissolved proportion (%)
UKP′-0	6.1	19.7 ± 0.7
UKP′-4	6.9	93.4 ± 2.1
TMP-0	28.7	10.5 ± 0.2
TMP-4	32.3	33.3 ± 0.1
TMP-8	33.3	37.6 ± 0.8
BTMP-0	13.5	42.8 ± 2.8
BTMP-4	14.2	95.6 ± 3.6

J. Agric. Food Chem. 2015, 63, 6113−6119

The dissolution of wood pulps in NaOH/urea solvent can be visualized as a map plotted along the DP_v and lignin contents of the wood pulps (Figure 9). This map shows how both the DP_v and lignin contents influenced the dissolved proportions of wood pulps. When DP_v was as high as 1300, the wood pulp, even though it had a low lignin content of 1.2%, could not dissolve well. On the other hand, when the lignin content was too high (e.g., 33.3%), the wood pulp, even though it had a relatively low DP_v of about 400, still could not dissolve well. However, when both the DP_v and lignin content were not so high, as shown in the green region of Figure 9, the wood pulps could almost completely dissolve in NaOH/urea solvent with dissolved proportions >90%. For instance, the UKP′-4 pulp with DP_v of about 500 and lignin content of 6.9% could dissolve in NaOH/urea solvent and achieve a maximum pulp concentration of 4 wt % in the obtained lignocellulose solution. Moreover, lignocellulose materials could be prepared from these wood pulp/NaOH/urea solutions. Figure 10 shows appearances of the UKP′-4 pulp, the relevant lignocellulose film, and the stress−strain curve of the lignocellulose film. The film with yellow color exhibited good transparency and bendability. It possessed a tensile strength of 82 MPa, Young's modulus of 3.7 GPa, and elongation at break of 10.3%. These lignocellulose films are promising as new biobased materials and the applications of lignocellulose would be widely expanded. This may promote the creation of new material and chemical streams from nonfood agriculture to high-tech industry. Meanwhile, the enhanced utilization of these wood resources, together with adequate artificial management of forests and tree plantations, would help to create a sustainable and low-carbon society.

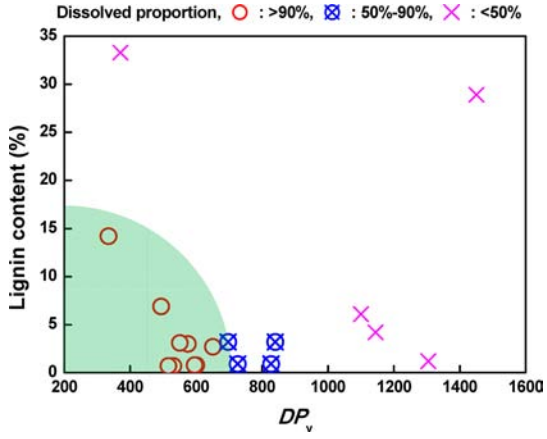

Figure 9. Dissolved proportion map of wood pulps in NaOH/urea solvent in terms of their DP_v and lignin contents.

compounds (VOCs) contributing to the reduction of the ozone layer and overall leading to poor air quality. These facts led to new agricultural practices such as anaerobic soil disinfestation and biofumigation. Both techniques involve incorporating in the soil large quantities of fresh organic material. To qualify as a good cover crop for the management of plant-parasitic nematodes, the crop should be a poor host for the nematodes and lower the population after incorporation into the soil.[19] *E. sativa* cv. Nemat was found to be a poor host for *M. incognita*, *Meloidogyne javanica*, and *Meloidogyne hapla* when tested as a cover crop in a greenhouse treatment.[20]

Much of the scientific research on rucola extracts deals with their biological activities, but to the best of our knowledge, there are no reports on the nematicidal activity of *E. sativa* and its volatile phytochemicals on *M. incognita*. In the present study we investigated (1) the chemical characterization of the volatilome of *E. sativa* by means of solid phase microextraction (SPME) followed by GC-MS analysis, (2) the synthesis of the most abundant compound present in volatilome and the nematocidal activity (EC_{50}) of the secondary metabolites of rucola, (3) the disruption of the parasites' biological cycle in host roots treated with fresh rucola powder, and (4) the efficacy of field-grown rucola, incorporated in situ, on root-knot nematodes.

MATERIALS AND METHODS

Chemicals. Carbon disulfide, erucin, iberin, and sulforaphane were obtained from Santa Cruz Biotechnology (Dallas, TX, USA); butyl isothiocyanate, isobutyl isothiocyanate, 2-ethylfuran, (*E*)-2-hexenal, pentyl isothiocyanate, hexyl isothiocyanate, (*E*)-3-hexen-1-ol, (*Z*)-3-hexen-1-ol, 2-furoic acid, ethyl 2-furoate, 2-furanacetic acid, tetrahydrothiophene, 3-pentanone, dimethyl sulfoxide, and *β*-cyclocitral were obtained from Sigma-Aldrich (Milano, Italy). Methanol was of high-performance liquid chromatography grade.

General Procedure for the Synthesis of (*E*)- and (*Z*)-3-Hexenyl Acetate. (*Z*)-3-Hexenyl acetate and (*E*)-3-hexenyl acetate were prepared as reported in the literature, with slight modifications.[21] (*Z*)- or (*E*)-3-hexen-1-ol (0.3 g, 2.99 mmol) and 4-(*N*,*N*-dimethylamino)pyridine (DMAP) (0.44 g, 3.59 mmol) were dissolved in 7.5 mL of diethyl ether. Acetic anhydride (0.37 g, 3.59 mmol) was then added dropwise with stirring, rapidly producing a white precipitate. The reaction mixture was warmed to 40 °C and stirred for 4 h. The crude mixture was then diluted with diethyl ether and washed with water (10 mL), 10% HCl (3 × 8 mL) and saturated $NaHCO_3$ (3 × 10 mL). The combined organic phase was dried over Na_2SO_4 and then concentrated under vacuum to provide the desired acetate as a pale yellow oil.^{1}H spectra, recorded on a UnitInova 500 MHz spectrometer (Varian, Walnut Creek, CA, USA), are consistent with those reported in the literature.[21]

Plant Material. Commercial *E. sativa* was obtained from a local market in Cagliari (Sardinia, Italy) on March 2014. Samples were used fresh and a voucher specimen was deposited at the Department of Life and Environmental Sciences, University of Cagliari, Cagliari, Italy, for species identification.

GC-MS Analysis. SPME analysis was performed following the method proposed by Jirovetz et al.[22] with minor modifications. Prior to analysis, the aerial parts of a sample of *E. sativa* were first ground to a paste in a mortar; 3 g of this paste was then placed into a 20 mL SPME vial, 75.5 × 22.5 mm, which was tightly closed with a septum and allowed to equilibrate for 5 min at 60 °C, and then the fiber was exposed to the headspace.

The extraction was carried out on a 1 cm DVB/CAR/PDMS 50/30 Stableflex (Supelco, Milano, Italy) SPME fiber. The fiber was preconditioned at 270 °C for 1 h in a Gerstel MPS bake-out station, according to the manufacturer's instructions. Prior to and after each analysis, the fiber underwent a further bake-out step for 5 min at 250 °C. The extraction time was fixed to 30 min, based on a previous optimization. After the extraction, the fiber was desorbed for 2 min into a Gerstel CIS6 PTV injector operating at 250 °C in a splitless mode.

Compound separation and identification was first performed on an Agilent 7890 GC equipped with a Gerstel MPS autosampler, coupled with an Agilent 7000C MSD detector. The chromatographic separation was performed on a VF-Wax 60 m × 0.25 mm i.d., 0.5 μm (J&W Scientific, Folsom, CA, USA), with the following temperature program: 40 °C for 4 min, then increased to 150 °C at a rate of 5.0 °C/min, held for 3 min, then increased to 240 °C at a rate of 10 °C/min, and held for 12 min. Helium was used as the carrier gas at a constant flow of 1 mL/min. The MS detector was set as follows: EI ion source operating at 70 eV, full scan acquisition range between *m*/*z* 40 and 650, scan rate of 7.1 cycles/s. Source and quadrupole temperatures were respectively 230 and 150 °C; He and N_2 were used respectively as quenching and collision gas at flows of 2.5 and 1 mL/min, respectively. Further injections were performed, as a confirmation, on a 3800 gas chromatograph directly coupled with a 2000 ion trap mass detector (Varian, Milano, Italy). The separation was achieved on an HP-5MS column of 30 m, 0.25 mm i.d., 0.25 μm (J&W Scientific), with the following temperature program: 50 °C for 5 min, then increased to 250 at a rate of 3.0 °C/min, held for 10 min, and then increased to 300 °C at a rate of 10.0 °C/min. The MS detector was programmed as follows: EI ion source operating at 70 eV, acquisition range between *m*/*z* 40 and 650, scan rate of 1 scan/s. The trap, manifold, and transfer line temperature were set to 200, 80, and 200 °C, respectively. Compounds were identified using their MS data (Mass Spectral Library NIST08 MS), the linear retention indices, and comparison with authentic standard (when available). The data were processed using a MassHunter Workstation B.06.00 SP1.

Nematode Paralysis Bioassays. A population of *M. incognita* of Italian origin was reared on tomato (*Solanum lycopersicum* Mill.) cv. Roma VF for 2 months in a glasshouse at 25 ± 5 °C. Batches of 30 egg masses (averaging 4500 eggs/batch) were collected from infected tomato roots and placed on 2 cm sieves (215 μm diameter), positioned on a 3.5 cm Petri dish. Distilled water was used as a natural hatching agent.[23]The eggs were then incubated in a growth chamber at 25 ± 2 °C, in the dark. First-emerging second-stage juveniles (J2) were discarded, and only second-stage juveniles collected after 2 days were used for the experiments. Compounds identified in rucola, including carbon disulfide and erucin, were tested on nematodes in a dose range of 1−1000 mg/L using fosthiazate as a chemical control. As part of this study, we also tested a series of structurally related isothiocyanates such as methyl isothiocyanate, butyl isothiocyanate, isobutyl isothiocyanate, pentyl isothiocyanate, hexyl isothiocyanate, benzyl isothiocyanate, phenyl isothiocyanate, and allyl isothiocyanate. Stock solutions of pure compounds were prepared in methanol to overcome insolubility, using aqueous Tween 20 (0.3% v/v) for further dilutions. The final concentration of methanol in each well never exceeded 1% (v/v) because preliminary experiments showed that this concentration was not toxic to the nematodes.[23] Distilled water as well as a mixture of methanol and aqueous Tween 20 at 0.3% (v/v) served as controls. In all cases, working solutions were prepared containing twice the test concentration and mixed in 96-well cell culture plates at a ratio of 1:1 (v/v) with a suspension of 25 nematodes added to each well. Multiwell plates were covered to avoid evaporation and maintained in the dark at 20 °C. Juveniles were observed with the aid of an inverted microscope (Zeiss, Gottingen, Germany) at 20× after 1 and 3 days for pure compounds and extracts of *E. sativa*, respectively. The nematodes were at this point moved to plain water after washing through a 20 μm sieve to remove the excess test compounds. Numbers of motile and paralyzed nematodes were assessed by pricking the juvenile body with a needle, and they were counted. Paralysis experiments were performed three times, and every treatment was replicated six times.

Experiment with Containerized Plants. For this experiment we used a clay loam soil, free of root-knot nematodes, with 1.3% organic matter and a pH of 7.8 that was collected from a noncultivated field at the Aristotle University of Thessaloniki Farm (Greece). The soil was sieved through a 3 mm sieve and partially air-dried overnight. The soil was mixed with sand at a ratio of 2:1 to obtain the mixture used for the

bioassays. It was separated into seven plastic bags, which received appropriate amounts of fresh rucola paste to achieve concentrations from 4 to 100 mg/g, whereas a treatment with plain water was used as control. Each soil sample was then inoculated with 2500 nematodes of *M. incognita* and was used for transplanting 7-week-old, at the six-leaf stage, tomato plants, cv. Belladonna, into plastic pots containing 200 g of soil, which were maintained at 27 °C and 60% relative humidity for a 16 h photoperiod; each pot received 20 mL of water every 3 days. Forty days later, root samples were stained with acid fuchsin,[24] and the following variables were assessed: fresh root and shoot weight and total number of females and galls of nematodes per gram of root at 10×, under uniform illumination by transparent light within tissue sample. The experiment was conducted twice, and the treatments were always arranged in a completely randomized design with five replicates.

Field Experiment. To verify the efficacy under field conditions *E. sativa* was planted in the field and, after having reached full growth, it was incorporated in soil that subsequently was planted with tomatoes. Specifically, the experiment consisted of two treatments, namely (1) rucola seeds planted in full field surface at a concentration of 5 g/m^2 and (2) an untreated control. Each treatment consisted of four replicates, and each plot area was 10 m^2. One month later when rucola had reached full growth, it was mechanically incorporated in the soil. A week later 7-week-old, at the six-leaf stage, tomato plants, cv. Belladonna, were transplanted. No other treatments were performed for nematode control during the culture period, and the efficacy was assessed 73 days post transplanting by uprooting the plants and categorizing with root index for RKN infection. Successively, the weight of roots and aerial parts was recorded.

Statistical Analysis. For containerized bioassays, data were expressed as a percentage decrease in the number of females and galls per gram of root corrected for the control, according to Abbott's formula:

$$\text{corrected \%} = 100 \times \left(1 - \frac{\text{no. of females in treated plot}}{\text{no. of females in control pot}}\right)$$

It was fitted in the log−logistic model[25] to estimate the concentration causing a 50% decrease in females per gram of root (EC_{50} value). In this regression equation, the rucola paste concentration (mg/g) was the independent variable (x) and the number of females and galls of nematodes (percentage decrease over water control) was the dependent variable (y). Additionally, Tuckey's test was used to

DOI: 10.1021/acs.jafc.5b02425
J. Agric. Food Chem. 2015, 63, 6120−6125

separate treatment differences and root or shoot fresh weight, $P \leq 0.05$. Because ANOVA indicated no significant treatment by time interaction (between runs of experiments), means were averaged over experiments.

Because paralysis in solvent (methanol, Tween-20) did not significantly differ from that observed in distilled water, the percentages of paralyzed nematodes were corrected by eliminating the natural paralysis in the water control (0−5% of total number of nematodes) according to the Schneider−Orelli formula[26]

$$\text{corrected \%} = [(\%\ \text{mortality in treatment} - \%\ \text{mortality in control}) / (100 - \%\ \text{mortality in control})] \times 100$$

and they were analyzed (ANOVA) combined over time. Because ANOVA indicated no significant treatment by time interaction, means were averaged over experiments. Corrected percentages of paralyzed nematodes treated with tested compounds were subjected to nonlinear regression analysis using the log−logistic equation proposed by Seefeldt et al.:[25]

$$Y = C + (D - C)/\{1 + \exp[b(\log(x) - \log(EC_{50}))]\}$$

C = lower limit, D = upper limit, b = slope at EC_{50}, and EC_{50} = test substances' concentration required for 50% death/paralysis of nematodes after elimination of the control (natural death/paralysis). In the regression equation, the test substances' concentration was the independent variable (x) and the paralyzed nematodes (percentage increase over water control) was the dependent variable (y). The mean value of the six replicates per test substance concentration and immersion period was used to calculate the EC_{50} value. Mean data values were reported with the respective standard deviations.

RESULTS AND DISCUSSION

SPME is a useful analytical technique for the semiquantitation of volatile compounds in different matrices, whereas GC-MS is used for compound identification. With these techniques, we identified 32 compounds in *E. sativa* paste; (*Z*)-3-hexenyl acetate was the most abundant, followed by (*Z*)-3-hexen-1-ol, with relative percentages of 22.7 ± 1.6 and 15.9 ± 2.3, respectively (Table 1). Stereoisomers of (*E*)- and (*Z*)-3-hexen-1-ol are produced by plants when mechanical damage occurs and may have indirect plant defense signaling properties.[27] The level of the isothiocyanate erucin in the *E. sativa* volatilome was 8.6 ± 1.3%, although Jirovetz et al.[22] reported levels of approximately 14.2%.

According to Cataldi et al.,[28] the most abundant glucosinolates isolated from rucola leaves are glucoerucin, 4-methylpentyl glucosinolate, 1-hexyl glucosinolate, glucoraphanin, 4-mercaptobutyl glucosinolate, progoitrin, sinigrin, and glucobrassicin.[28] In fact, three of the isothiocyanates deriving from the three first mentioned glucosinolates reported above were identified in *E. sativa* after GC-MS analysis (Table 1).

When we tested the nematicidal activity of rucola volatile compounds, we found that erucin, pentyl isothiocyanate, hexyl isothiocyanate, 2-(*E*)-hexenal, 2-ethylfuran, and methyl thiocyanate were the most active, with EC_{50} values of 3.2 ± 1.7, 11.1 ± 5.0, 11.3 ± 2.6, 15.0 ± 3.3, 16 ± 5.0, and 18.1 ± 0.6 mg/L after 24 h of incubation with nematodes, whereas the EC_{50} for (*Z*)-3-hexen-1-ol was 323 ± 91 mg/L (Table 2). Figure 1 reports the chemical structures of the most active compounds tested. On the other hand, furan derivatives such as 2-furoic acid, ethyl 2-furoate, and 2-furanacetic acid were not active at 100 mg/L (Table 2). Furthermore, β-cyclocitral found in trace amounts in leaves of *E. sativa*[29] was not active at 100 mg/L. Interestingly, acetates of (*E*)- and (*Z*)-3-hexen-1-ol were not

Table 2. EC_{50} Values (n = 4) of Tested Compounds against *M. incognita* Calculated after 1 Day of Nematode Immersion in Test Solutions

compound	$EC_{50/1day}$ (mg/L ± SD)
(**1**) erucin	3.2 ± 1.7
(**2**) methyl isothiocyanate	7.9 ± 3.1
(**3**) pentyl isothiocyanate	11.1 ± 5.0
(**4**) hexyl isothiocyanate	11.3 ± 2.6
(**5**) (*E*)-2-hexenal	15.0 ± 3.3
(**6**) 2-ethylfuran	16 ± 5.0
(**7**) methyl thiocyanate	18.1 ± 0.6
(**8**) (*Z*)-3-hexen-1-ol	323 ± 91
(**9**) 3-pentanone	>100
(**10**) tetrahydrothiophene	>100
(**11**) (*Z*)-3-hexenyl acetate	>400
(**12**) (*E*)-3-hexenyl acetate	>400
(**13**) carbon disulfide	>500
(**14**) (*E*)-3-hexen-1-ol	>700
(**15**) benzyl isothiocyanate[a]	1.9 ± 0.3

active at concentrations >400 mg/L. Among isothiocyanate derivatives, not found in the *E. sativa* volatilome, the most effective in paralyzing *M. incognita* was benzyl isothiocyanate, followed by allyl isothiocyanate and butyl isothiocyanate, exhibiting $EC_{50/1day}$ values of 1.9 ± 0.3, 6.6 ± 2.5, and 12 ± 8 mg/L, respectively. It is noteworthy that isobutyl isothiocyanate and phenyl isothiocyanate were not active at concentrations >200 and >1000 mg/L, respectively. Sulforaphane was 50 times less active if compared with its reduced isothiocyanate analogue erucin (EC_{50} = 152 ± 35 mg/L), whereas iberin showed an EC_{50} of 180 ± 21 mg/L. Finally, carbon disulfide and (*E*)-3-hexen-1-ol were not found active at concentrations >500 and >700 mg/L, respectively. Interestingly, in our in vitro conditions, butyl isothiocyanate showed a fumigant activity at 160 mg/L (data not shown). Slight structural differences among isothiocyanates conferred significantly different nematicidal effects. This suggests that the biological activity is not only a concentration-dependent function but also related to the alkyl chain characteristics. Notably, Caboni et al.[7] observed that nematodes treated with different isothiocyanates were paralyzed in a straight shape with evident internal vacuolization (Figure 2). The same evidence

Figure 2. *M. incognita* J2 before (A) and after (B) a 24 h immersion in erucin at 10 mg/L. After treatment, nematodes were paralyzed in a straight shape, and internal vacuoles were evident.

was observed when nematodes were treated with some V-ATPase inhibitors such as α,β,γ,δ-unsaturated aldehydes and pyocyanin.[30,31] Conversely, nematodes treated with the organophosphorous fosthiazate were paralyzed in a coiling shape.[7] When the methanolic extract of fresh rucola paste was tested against *M. incognita*, a clear dose−response relationship was established and significant paralysis/death of nematodes was evident after 3 days of exposure with a calculated EC_{50} value of 93 ± 59 mg/L (data not shown). According to the results of our experiment with containerized tomato plants infested with *M. incognita*, when *E. sativa* paste was incorporated to the growing medium, it decreased root infestation and increased plant growth in a dose-response manner. The EC_{50} values based on the numbers of females and galls were calculated at 20.02 ± 1.65 (95% CI, 16.64−23.41) and 20.75 ± 1.65 (95% CI, 16.99−24.53) mg/g, respectively. The treatment of tomato plants with rucola paste induced fresh shoot weight increase (Table 3), whereas no root weight increase was observed.

Most interestingly, rucola used as a soil amendant fully controlled RKN under our field conditions. Specifically, on the basis of the galling index, all roots were severely knotted in control plants and the root system was absent (root index 10) due to secondary infections by soil pathogens, whereas in rucola-treated plants no knots were evident (root index 1).

Table 3. Weight Increase of Aerial Parts after Treatment with Rucola Paste in Nematode-Infested Tomato Plants

E. sativa paste (mg/g)	aerial part weight[a] (g)
0	4.45 ± 0.24c
4	4.99 ± 0.15cb
8	5.61 ± 0.05cbd
16	6.23 ± 0.36cbd
32	7.35 ± 0.26d
64	7.14 ± 0.16d
128	6.95 ± 0.15bd

[a]Data are presented as means of five replicates with standard deviations. Means followed by the same letter are not significantly different according to Tukey's test ($P \leq 0.05$).

In the literature reporting on the use of soil amendants in RKN management, the family Brassicaceae is probably the most cited due to the isothiocyanate levels observed in its members.[32] This is the first study on the nematicidal properties of the volatilome of *E. sativa* on *M. incognita*, which shows the possibility of its potential use as an intercrop plant. Intercropping, being a cost-effective, environmentally friendly pest management method, can be easily used in developing countries.

In our previous works, we largely stressed the importance of compound volatility in the nematicidal character of various botanical extracts.[5] This feature is essential for delivering the active substance to the inner parts of the soil infested by nematodes. Herein we report the high activity in containerized and field experiments of rocket and attribute it to its isothiocyanates contents. Nevertheless, under field conditions the efficacy of the isothiocyanates decreases due to their short half-life, making mandatory the repetition of applications,[8] a fact that should not be underestimated. The fate in soil of pure isothiocyanates is to be studied with regard to their half-life as ingredients in complex botanical soil amendments. This together with the cost effectiveness of respective treatments could establish a nematode control method suitable for integrated crop management.

J. Agric. Food Chem. 2015, 63, 6120−6125

Recently, several artificial diets and in vitro rearing techniques have been developed for *A. mellifera* larvae.[18,22−25] On the basis of these new diets and rearing methods, we here describe a dietary exposure assay for assessing the direct toxicity of insecticidal compounds to *A. mellifera* larvae. We then used the dietary exposure assay to evaluate the potential toxicity of Cry1C and Cry2A to *A. mellifera* larvae. These Cry proteins have been expressed in rice and other plants for the control of lepidopteran rice pests, such as *Chilo suppressalis* (Walker) (Lepidoptera: Crambidae) and *Scirpophaga incertulas* (Walker) (Lepidoptera: Pyralidae).[26,27] In addition, biochemical and histopathological experiments were conducted to further evaluate the potential toxicity of the two Cry proteins on this species.

MATERIALS AND METHODS

Insects. Worker larvae of *A. mellifera* were obtained from three colonies at the Institute of Plant Protection, CAAS. The queens were individually confined in cages (45 × 55 × 65 cm) with an empty comb, where they were permitted to lay eggs for 24 h. On the second day after the eggs hatched, the combs were transferred to the laboratory, and the 1.5−2.0 day old larvae were used for experiments.

Larvae of a *Bt*-susceptible strain of *C. suppressalis* were obtained from a colony that had been maintained on an artificial diet for over 50 generations in our laboratory. The *C. suppressalis* larvae were used to test the bioactivity of the Cry proteins (as described later).

Chemical Compounds. Commercial royal jelly and yeast extract were purchased from China-Bee Science & Technology Development Co., Ltd. (Beijing, People's Republic of China) and Oxoid Ltd. (Hampshire, England), respectively. D-(+)-glucose, D-(+)-fructose, bovine serum albumin (BSA), and soybean trypsin inhibitor (SBTI) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Cry1C and Cry2A proteins were purchased from Envirotest-China (agent for Envirologix Inc., Portland, MA, USA; www.envirotestchina.com). The *Bt* proteins were produced and purified at the Department of Biochemistry, Case Western Reserve University (Cleveland, OH, USA; contact person Dr. Marianne Pusztai-Carey). The protoxins from *Bt* had been expressed as single-gene products in *Escherichia coli*. The *E. coli* expressed protoxin inclusion bodies were dissolved and trypsinized and then isolated and purified by ion exchange HPLC; the pure fractions were finally desalted and lyophilized. Purity was about 94−96%. The bioactivity of the Cry proteins was verified in a sensitive-insect bioassay using neonate larvae of *C. suppressalis* that were reared for 7 days with artificial diet containing a range of Cry protein concentrations (see Bioactivity of Cry Protein in Diets). The EC_{50} (toxin concentration resulting in 50% weight reduction in comparison to the control) values of our protein batches were estimated to be 18.1 and 1310 ng/mL for Cry1C and Cry2A, respectively.[50]

Artificial Diet and Rearing Technique for *A. mellifera* Larvae. Diet making and rearing techniques have been described in more detail elsewhere.[25] The artificial diet for *A. mellifera* larvae contained 50% royal jelly, 4% glucose, 8% fructose, 37% double-distilled water, and 1% yeast extract. The sugars and the yeast extract were dissolved in distilled water, and freshly thawed royal jelly was added to the mixture and mixed thoroughly by hand. The prepared diets were added to 5 mL centrifuge tubes and stored at −20 °C until they were used. Before they were provided to *A. mellifera* larvae, the diets were thawed and brought to 34 °C in a water bath.

A plastic grafting tool for bee larva was used to gently and individually transfer *A. mellifera* larvae (1.5−2.0 days old) to cells (diameter 1.6 cm) of 24-well cell culture plates (Corning Inc., Corning, NY, USA). After they were transferred, the larvae were examined with a stereo microscope to confirm that they were alive. An Eppendorf pipet was used to carefully add artificial diet to each cell such that the bee larvae floated on the food. The plates were covered with lids and placed in a desiccator containing 10% sulfuric acid (resulting in 90% RH) and incubated in a climatic chamber at 34 ± 1 °C in darkness. New diet was added daily after unconsumed diet in each cell was gently removed with a vacuum pump. Each larva was provided with 100 μL of diet per day for the first 2 days and then with 200 μL per day until defecation. Defecation was determined to have occurred when yellow, stringy material or uric acid crystals were observed. Once defecation occurred (i.e., once the larvae were mature), each larva was removed from the cell, gently blotted on tissue papers to remove the food on the body surface, weighed, and then transferred to a new 24-cell plate, the cells of which were lined with tissue paper on the bottoms and walls. The plates were then placed in a desiccator containing a saturated NaCl−water solution (resulting in 70% RH) in a climatic chamber at 34 ± 1 °C in darkness until adult emergence. Larvae were observed every 12 h (9:00 am and 9:00 pm) for development and mortality.

Response of *A. mellifera* Larvae to SBTI in the Dietary Assay. Previous studies have confirmed that SBTI is toxic to *A. mellifera*.[7,9,23,28] Therefore, SBTI was used as a positive control to verify that the artificial diet and our dietary exposure assay could be used to detect toxicity.

A stock solution of SBTI was diluted with distilled water and mixed into the *A. mellifera* larval artificial diet to give concentrations of 0, 0.1, 1, and 10 mg/g FW of diet. The experimental system and the provision of diets were the same as those described in the previous section. There were 3 replicates per treatment, and each replicate contained 24 larvae. The larvae were examined for development and mortality every 12 h. When the larvae matured (as indicated by the occurrence of defecation), they were weighed.

Toxicity of *Bt* Proteins to *A. mellifera* Larvae. *Effects on Life Table Parameters.* Larvae were fed one of five diets, which were prepared by treating the artificial diet with (1) Cry1C (50 μg/g FW of diet), (2) Cry2A (400 μg/g FW of diet), (3) BSA (400 μg/g FW of diet; negative control), (4) SBTI (1 mg/g FW diet; positive control), or (5) no added protein (blank control). The experimental conditions and the feeding system were the same as those described earlier. Diets were prepared 3 days before initiation of this experiment and were stored at −20 °C until used. BSA was used here as a nontoxic protein control, because a previous study showed that feeding of BSA does not affect the survival and development of honey bees and a parasitoid Hymenoptera.[23,29] There were 5 replicates pre treatment, and each replicate contained 15 larvae. Insect development and mortality were recorded twice per day (9:00 am and 9:00 pm), and the mature larvae were weighed.

Uptake of Cry Protein by A. mellifera Larvae. *A. mellifera* larvae were fed artificial diet containing no toxin (the control), Cry1C at 50 μg/g FW of diet, or Cry2A at 400 μg/g FW of diet as described in the previous section. After 2 and 4 days of feeding, six larvae were collected per treatment. Additional larvae were allowed to pupate before six pupae were collected per treatment. The larvae and pupae were stored at −20 °C until Cry concentrations were measured.

The concentrations of Cry proteins in individual larvae and pupae were measured by double-antibody sandwich enzyme-link immunosorbent assay (DAS-ELISA) using Cry1C and Cry2A detection kits from EnviroLogix (Portland, MA, USA). The insects were washed in phosphate buffered saline Tween-20 (PBST) (provided with the kit) to remove Cry proteins from body surfaces before analysis. Cry protein was extracted and ELISA measurements were performed following the manufacturer's instructions. Optical density (OD) values were read with a microplate spectrophotometer (PowerWave XS2, BioTek, Winooski, VT, USA). The concentrations of Cry proteins were calculated by calibrating the OD values to a range of concentrations of Cry protein standards provided with the kit.

Bioactivity of Cry Protein in Diets. The bioactivity of Cry proteins in *A. mellifera* larval diets was assessed in three subsamples that were collected from the pure diet (untreated with Cry protein) or diets containing Cry1C (at 50 μg/g FW of diet) or Cry2A (at 400 μg/g FW of diet) that had been exposed to bee larvae for 1 day. The bioactivity of Cry proteins was determined with a sensitive-insect bioassay that used *C. suppressalis* larvae. For Cry protein extraction, a 50 mg sample of each of the three diets was homogenized with 2 mL of PBST buffer (provided with the ELISA kit as described above). After the preparations were centrifuged at 15.8*g*, the supernatants were

DOI: 10.1021/acs.jafc.5b01662
J. Agric. Food Chem. 2015, 63, 6126−6132

appropriately diluted and thoroughly incorporated into the artificial diet for *C. suppressalis* larvae.[30] The artificial diets were cut into slices and placed in Petri dishes (6 cm diameter, 1 cm height) with neonate larvae of *C. suppressalis* (one slice and one larva per dish). The Petri dishes were then sealed with Parafilm. Each treatment was represented by 30 replicate dishes. After 7 days, the *C. suppressalis* larvae were weighed.

Enzyme Activity Analysis. *A. mellifera* worker larvae (1.5−2.0 days old) were fed pure diets or diets containing BSA (at 400 μg/g FW of diet), Cry1C (at 50 μg/g FW of diet), Cry2A (at 400 μg/g FW of diet), or SBTI (at 1 mg/g FW of diet) as described earlier. After 4 days of feeding exposure, seven larvae were collected per treatment and stored at −20 °C before the activity levels of four gut enzymes (the total protease, tryptase, aminopeptidase, and α-naphthyl acetate esterase (α-NAE)) were measured using ELISA kits from Beijing Luyuan Bode Biotechnology Co., Ltd. (Beijing, People's Republic of China). Samples were homogenized at 4 °C in 300 μL of 0.15 mol/L NaCl.[31] The homogenates were then centrifuged at 3000*g* for 10 min at 4 °C, and the resulting supernatants were used for analysis of the enzymatic activities following the manufacturer's instructions. The optical density (OD) values were read with a microplate spectrophotometer (PowerWave XS2, BioTek, Winooski, VT, USA). The activity levels of test enzymes were calculated by calibrating the OD values to a range of concentrations of standards provided with the kits.

Histopathology. *A. mellifera* larvae (1.5−2.0 days old) were fed artificial diet containing no added protein, BSA at 400 μg/g FW of diet, Cry1C at 50 μg/g FW of diet, Cry2A at 400 μg/g FW of diet, or SBTI at 1 mg/g FW of diet. After 4 days of feeding exposure, five larvae were collected per treatment. The midguts of the larvae were fixed in a 10% (v/v) paraformaldehyde solution for at least 24 h at 4 °C. Tissues were sectioned at 4 μm thickness with a microtome (Leica, R2235, Wetzlar, Germany). The sections were stained with hematoxylin-eosin stain, and images were captured with a digital camera (Olympus, DP73, Japan) mounted on a microscope (Olympus, BX63, Japan).

Data Analysis. In the bioassays with SBTI or Cry proteins, statistical comparisons were made between each treatment and the control (pure artificial diet) by Dunnett's tests after one-way ANOVAs showed a significant effect for any life table parameter. Student's *t* tests were used to compare the weights of *C. suppressalis* larvae that were fed artificial diets containing the extract from untreated diet vs extracts from diets containing Cry proteins. One-way ANOVAs were used to compare enzyme activities among treatments, and Dunnett's tests were used to separate the means between each toxin treatment and the control.

All statistical analyses were conducted using the software package SPSS (version 13 for Windows, 2004).

RESULTS

Response of *A. mellifera* Larvae to SBTI. In the diet-only control treatment, >95% of the worker larvae developed to pupae (Figure 1A), and >90% developed to adults (Figure 1B). With an increasing concentration of SBTI in the diet, the survival rates of *A. mellifera* were steadily reduced (Figure 1), and no larvae survived to the pupal stage at the highest SBTI concentration of 10 mg/g fresh weight (FW) of diet (data not shown). Pupal and adult development and larval weight were not significantly affected by SBTI at 0.1 mg/g FW diet (Dunnett's test; $P > 0.05$) (Figure 1A−D), but SBTI at 1.0 mg/g FW diet significantly decreased the pupation rate (Dunnett's test; $P = 0.006$) (Figure 1A), eclosion rate ($P = 0.012$) (Figure 1B), and mature larvae fresh weight ($P = 0.003$) (Figure 1D) and significantly prolonged larval development time (days to defecation) (Dunnett's test; $P = 0.023$) (Figure 1C).

Toxicity of *Bt* Proteins to *A. mellifera* Larvae. *Effects on Life Table Parameters.* *A. mellifera* pupation rate, eclosion rate, larval development time (days to defecation), days to the adult stage, mature larval weight, and adult weight did not significantly differ among the untreated control diet and diets containing BSA, Cry1C, or Cry2A proteins (Dunnett's test: BSA, $P = 0.999$, 0.837, 0.711, 1.000, 0.999, and 0.998, respectively; Cry1C, $P = 0.999$, 1.000, 0.351, 0.421, 0.998, and 0.983, respectively; Cry2A, $P = 0.999$, 0.999, 0.405, 0.699, and 0.788, respectively) (Table 1). *A. mellifera* pupation rate and eclosion rate were decreased by feeding the diet containing SBTI in comparison to those fed control diet (by 13.3 and 17.3%, respectively), although the differences were not significant (Dunnett's test; $P = 0.058$ and 0.054 for pupation rate and eclosion rate, respectively). The developmental time of *A. mellifera* larvae (days to defecation and to adult) were also not significantly affected by the diet containing SBTI (Dunnett's test: $P = 0.12$ for larval development time, $P = 0.68$ for days to adult) (Table 1). In contrast, the mean weights of mature larvae and of newly emerged adults were significantly reduced by SBTI (Dunnett's test, $P < 0.001$) (Table 1).

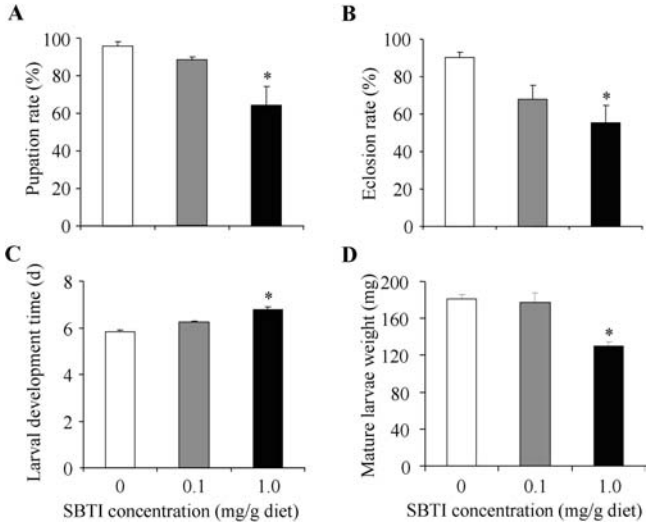

Figure 1. Life-table parameters of *Apis mellifera* larvae fed an artificial diet containing different concentrations of SBTI. An asterisk denotes a significant difference between the treatment and the control ($P < 0.05$). No larva reached the pupal stage at the highest SBTI concentration of 10 mg/g diet (data not shown). Values are means + SE, $n = 3$.

Uptake of Bt Proteins by A. mellifera Worker Larvae. ELISA measurements revealed that all *A. mellifera* larvae contained considerable amounts of Cry1C or Cry2A, but no Cry protein was detected in pupae when they were fed diets containing the corresponding *Bt* proteins. After 2 and 4 days of feeding, the mean ± SE concentrations of Cry1C in *A. mellifera* larvae were 0.61 ± 0.04 and 0.82 ± 0.14 μg/g of FW insect, respectively. For Cry2A, the concentrations detected after 2 and 4 days of feeding were 29.11 ± 2.01 and 18.70 ± 1.02 μg/g FW insects, respectively. No Cry protein was detected in larvae or pupae fed with control diet.

Bioactivity of Bt Proteins. After *C. suppressalis* larvae were fed for 7 days in the sensitive-insect bioassay, the mean ± SE weights per larva were 1.71 ± 0.12, 0.92 ± 0.11, and 0.19 ± 0.11 mg when the artificial diet contained extract from the control bee diet, extract from the bee diet containing Cry1C protein, and extract from the bee diet containing Cry2A, respectively (Figure 2). According to the Student's *t* test, the difference relative to the diet containing control extract was

time to adult (days)	18.68 ± 0.21	18.66 ± 0.28	18.59 ± 0.05	18.46 ± 0.10	18.96 ± 0.20
mature larval weight (mg)	199.02 ± 3.35	200.34 ± 4.98	190.70 ± 5.39	197.15 ± 3.65	151.43 ± 9.31*
emergence weight of adults (mg)	137.06 ± 4.73	138.56 ± 5.11	131.17 ± 4.96	134.39 ± 2.84	101.80 ± 5.41*

[a]Each protein treatment was compared to the control. Dunnett's test was used for all comparisons. An asterisk denotes a significant difference between a treatment and the untreated control ($P < 0.001$). Values are means ± SE, $n = 5$.

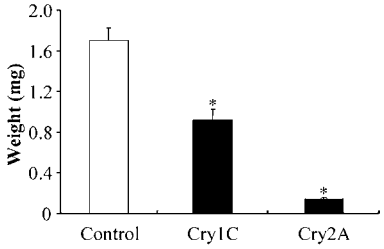

Figure 2. Weight of *Chilo suppressalis* larvae fed for 2 days on an artificial diet that contained an extract from pure bee artificial diet (control) or extracts from bee diets containing Cry1C or Cry2A. An asterisk denotes a significant difference between the treatment and the control ($P < 0.05$). Values are means + SE, $n = 30$.

significant for the diet containing Cry1C extract ($t = 4.91$, $df = 57$, $P < 0.001$) and for the diet containing Cry2A extract ($t = 11.91$, $df = 54$, $P < 0.001$) (Figure 2).

Enzyme Activity in A. mellifera Worker Larvae. The activities of the total protease, tryptase, aminopeptidase, and α-naphthyl acetate esterase (α-NAE) were similar when *A. mellifera* larvae were fed the untreated control diet or diets containing BSA, Cry1C, or Cry2A protein (Dunnett's test; $P > 0.1$) (Table 2). When *A. mellifera* larvae were fed a diet containing SBTI, the activity levels of all test enzymes were significantly increased relative to the control (Dunnett's test; all $P < 0.001$).

Histopathology of A. mellifera Larvae after Ingestion of Cry Proteins. Midgut sections from *A. mellifera* larvae that had ingested BSA, Cry1C, Cry2A, or SBTI, as well as midguts from control larvae that had not been exposed to the toxins, were examined microscopically for histopathological effects. Midguts of *A. mellifera* larvae had a monolayer epithelial cell structure (Figure 3). For larvae fed pure diet or diet containing BSA or

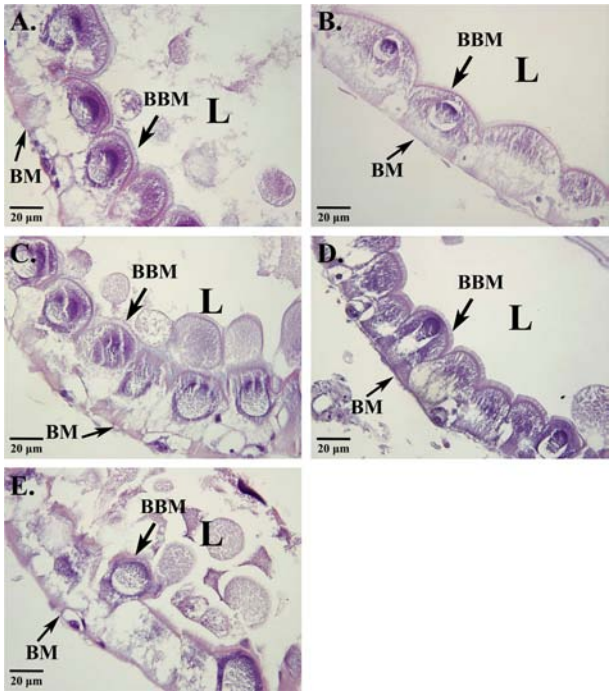

Figure 3. Light micrographs of midgut sections of *Apis mellifera* larvae fed for 4 days on artificial diets containing no toxin (A), BSA at 400 μg/g diet (B), Cry1C at 50 μg/g diet (C), Cry2A at 400 μg/g diet (D), or SBTI at 1 mg/g diet (E). Note that the brush border membranes (BBM) of the epithelial cells (ECs) are clear and that the ECs are homogeneous and intact in the midguts of larvae that consumed a diet without toxin or a diet with BSA, Cry1C, or Cry2A. For larvae that consumed a diet with SBTI, however, the BBMs are lysed and the ECs showed signs of degeneration. BM = base membrane, L = lumen.

Cry proteins, the epithelial cells (ECs) were intact and aligned, and their brush border membranes (BBMs) were clearly visible (Figure 3A–D). There was no apparent difference between midgut sections from control larvae and from larvae fed Cry1C or Cry2A protein. For the larvae fed on a diet containing SBTI, however, the ECs showed signs of degeneration and had separated from the basal membrane (BM) and the BBM of ECs lysed (Figure 3E).

DISCUSSION

Evaluating the potential adverse effects of IRGE plants on valued nontarget organisms typically starts with laboratory experiments that measure the potential toxicity of the insecticidal proteins produced by IRGE plants.[4,32−34] These experiments are referred to as tier 1 studies and are conducted under controlled, worst-case exposure conditions. In the tier 1 assays, purified insecticidal proteins are normally delivered directly to test species by incorporating them into artificial diets at high concentrations. These concentrations are much higher than those encountered in the field and thus yield conservative results: i.e., they tend to overestimate adverse effects.[33−35] Tier 1 assays require a suitable method for delivering insecticidal compounds to the test organism and arriving at conclusive results.[33,34,36]

Artificial diets and in vitro rearing techniques for *A. mellifera* larvae have been developed, and these are useful for conducting dietary exposure assays that assess the potential toxicity of insecticidal compounds.[18−20,22−25,37−39] The artificial diet and the procedure for feeding *A. mellifera* larvae used in the present study were the same as those described by Huang.[25] The >90% survival rate with this diet satisfies the basic criterion of >80% survival for diets used for tier 1 assays.[32−34] In addition to the untreated pure diet control, diet containing the nontoxic protein BSA was included as a negative control treatment in our experiments for further evaluation of how the test system and test conditions, including the diet used in the study, affect the mortality and development of *A. mellifera* larvae. This negative control treatment could ensure nutritional equivalence between dietary treatments, and it assisted in determining whether observed effects are related to the test compounds.[33] Likewise, the survival rate of *A. mellifera* larvae in this negative control treatment was >90%, suggesting that there was no apparent background effect with the diet used in the current dietary testing system.

Positive control treatments are particularly useful in dietary exposure assays with the purposes of indicating whether the test compound is actually ingested and confirming the sensitivity of the testing system. In addition, positive controls may function as useful references to permit comparison to other test results.[33,34] Compounds used as a positive control should be readily accepted and toxic to the test organism and have properties similar to those of the test compounds in terms of their route of toxicity.[33,34] SBTI was used to determine the ability of our dietary exposure assay because it is known to be readily accepted and toxic to bees[23] and is an orally active compound, as are the tested Cry proteins. Dose-dependent responses to dietary SBTI were observed for all of the measured life table parameters for worker larvae. This demonstrated that the test system used in the current study was capable of efficiently detecting dietary effects of insecticidal compounds. In addition, these results indicated that artificial diet containing SBTI at 1 mg/g FW of diet is a useful positive control.

After validating the dietary exposure assay described in the present study, we evaluated the potential toxicities of purified Cry1C at 50 μg/g diet and Cry2A at 400 μg/g diet to *A. mellifera* worker larvae. These can be regarded as worst-case exposure scenarios, because these concentrations in the diet are >10 times higher than the Cry protein concentrations in pollen of the current *Bt* rice lines (mean concentrations of Cry1C and Cry2A are 2.6 μg/g dry weight of T1C-19B pollen and 33.5 μg/g dry weight in T2A-1 pollen, respectively[40,41]). Pollen is the only route by which honeybee larvae would be exposed to Cry proteins, because rice does not produce nectar. Considering that *A. mellifera* larvae ingest only small amounts of plant pollen,[8] the concentrations of Cry proteins used in this study are much higher than the Cry protein levels likely encountered by *A. mellifera* under natural conditions. Our results indicate that *A. mellifera* larvae were not negatively affected when fed a diet containing Cry1C or Cry2A proteins. Feeding on diets containing SBTI at 1 mg/g FW, in contrast, significantly reduced the survival and weight of *A. mellifera* larvae. The results also demonstrated that *A. mellifera* larvae did ingest the insecticidal compounds that were incorporated in the diet of our assay and that our experimental system was capable of detecting the adverse dietary effects caused by toxic compounds.

To further determine the quantity of Cry proteins ingested by *A. mellifera* worker larvae, the contents of Cry proteins were measured by ELISA in larvae fed for 2 or 4 days on diets that contained Cry protein. High concentrations of both Cry proteins were detected in *A. mellifera* larvae, confirming that the larvae did ingest the Cry proteins. Interestingly, no Cry protein was detected in pupae that had developed from larvae that had fed on both Cry protein treatments. The likely reason for the absence of Cry protein in the pupae is the fact that the bee larvae empty their gut before pupation. The absence of Cry proteins in pupae developing from larvae that had consumed Cry protein containing diet was also documented for the ladybird beetles *Stethorus punctillum* and *Propylea japonica* (Coleoptera: Coccinellidae),[42,43] suggesting that those insects also empty their guts before pupation. This is not the case for lacewings (Neuroptera: Chrysopidae), however, because insecticidal proteins such as *Galanthus nivalis* agglutinin and Cry proteins could still be detected in lacewing pupae or adults that developed from larvae that ingested these compounds.[30,44,45]

To have confidence in the findings that Cry1C and Cry2A do not affect larval *A. mellifera*, the bioactivity of the test compounds during the feeding assay needs to be confirmed.[33,34] A bioassay with the *Bt* protein sensitive species *C. suppressalis* was conducted to test the bioactivity of the Cry1C and Cry2A proteins in the artificial bee diet. The 7 day larval weight was selected as the measurement end point because it has been proven to be a credible and sensitive parameter for assessing the possible impact of *Bt* toxins on this sensitive test insect.[30,42,46] The results demonstrated that *A. mellifera* larvae had ingested large amounts of bioactive Cry1C or Cry2A protein. We therefore conclude that *A. mellifera* larvae are not sensitive to Cry1C or Cry2A at concentrations that are much higher than those potentially encountered under natural conditions.

The activities of four gut enzymes (the total protease, tryptase, aminopeptidase, and α-naphthyl acetate esterase) have been widely used to indicate the potential toxicity of insecticidal compounds.[21,28] Our results showed that consumption of

DOI: 10.1021/acs.jafc.5b01662
J. Agric. Food Chem. 2015, 63, 6126−6132

Cry1C or Cry2A did not affect the activity of these enzymes in *A. mellifera* larvae, while the activity levels of all analyzed enzymes were significantly increased in *A. mellifera* larvae fed on a diet containing SBTI in comparison to those fed control diet. A similar pattern of change in the activity of these enzymes has been observed for *Folsomia candida* (Collembola: Isotomidae) fed purified Cry1C and Cry2A.[47] These results further demonstrate that Cry1C and Cry2A do not affect *A. mellifera* larvae. In addition, microscopy revealed that the midgut brush border membranes of *A. mellifera* larvae were not damaged after ingestion of Cry1C or Cry2A protein. Because the BBM is the locus of Cry protein activity in sensitive organisms,[28,31] this provided additional evidence that neither Cry protein is toxic to *A. mellifera* larvae.

In summary, we used toxicological, biochemical, and histopathological techniques to assess the toxicity of Cry1C and Cry2A proteins to *A. mellifera* worker larvae. These techniques have been widely used in previous studies to evaluate the potential toxicity of insecticidal compounds on arthropods.[21,28,48] With the integrated application of these techniques, a convincing conclusion can be drawn that Cry1C and Cry2A have no acute toxicity to *A. mellifera* larvae at concentrations that are more than 10 times higher than those detected in pollen from *Bt*-transgenic plants. The results are consistent with previous studies in which the purified *Bt* proteins Cry1Ac, Cry1Ab, Cry1A.105, Cry2A, and Cry3Bb1 were found to be nontoxic to *A. mellifera* larvae or adults.[14,17,20,49] Thus, we conclude that the planting of GE crops including *Bt* rice expressing such *Bt* proteins poses a negligible risk to *A. mellifera*.

ODAP, β-isoxazolinon-alanine, and found that there was no difference in the incorporation of the precursor in seeds of high- and low-β-ODAP genotypes, suggesting that the differences in β-ODAP among genotypes was likely the result of differences in the biosynthesis and amount of the precursor of β-ODAP near maturity. It is therefore not clear whether the accumulation or catabolism of β-ODAP at vegetative and reproductive stages is associated with the final concentration of β-ODAP in seeds at maturity.

As the basis for genotypic variation in the amount and concentration of β-ODAP in seeds and the effect of water stress on this genotypic variation is not known, an experiment on the accumulation and catabolism of β-ODAP in vegetative and reproductive tissues of seven grass pea genotypes varying in seed β-ODAP concentration was conducted at three levels of water availability. We hypothesized that variation in amount and concentration of β-ODAP in seeds is determined by the accumulation and/or catabolism of β-ODAP in vegetative and reproductive tissues at the early reproductive phase and that the variation in the amount and concentration of β-ODAP in seeds with varying water availability is determined as a result of the processes of accumulation and catabolism in these tissues. The purpose of the present study was to (1) track the variation in β-ODAP concentration and amount in leaves and pods of seven grass pea genotypes at flowering, podding, and maturity; (2) examine whether water stress affected the distribution of β-ODAP at these stages; and (3) determine the relationship between amount and concentration of β-ODAP in seeds in the vegetative and early reproductive stages at three levels of water availability.

MATERIALS AND METHODS

Plant Materials and Growth Conditions. Seven genotypes of grass pea (six genotypes from the International Centre for Agricultural Research in Dry Areas and one local cultivar, Dingxi, from China) were planted on April 4, 2013 at the Yuzhong Experiment Station of Lanzhou University, Yuzhong, Gansu province, China (35°51′ N, 104°07′S; altitude, 1620 m). The genotypes had similar phenologies, differing by 6 days in time to flowering; plant height varied from 320 to 420 mm; seed coat color varied from cream to dark brown; and seed β-ODAP concentration varied more than 200% when the genotypes were planted in the field at the Yuzhong Experiment Station of Lanzhou University in 2012 (Table 1). The experimental site has a typical semiarid climate with an accumulated rainfall of 202.5 mm, a mean temperature of 14.5 °C, and a mean relative humidity of 58% during the growing season (March−July). Ten uniform seeds of the seven genotypes were each sown in 45 plastic pots (0.26 m diameter, 0.30 m high) containing 8.0 kg of a dry silty-loam loess soil (haplic greyxems[34]) and vermiculite mixture (soil:vermiculite = 2:1, v/v) with a field capacity (FC, the percentage of water in the soil when the soil is fully saturated, then allowed to drain for 48 h) of 30.8%; the pots were placed in a rainout shelter that was open when rain was not forecast. Ten DAS, the plants were thinned to five seedlings per pot. Nitrogen (0.68 g of NH_4NO_3) and phosphorus (1.58 g of KH_2PO_4) were supplied as a solution to each pot before sowing. Three water treatments were imposed: (1) Well-watered (WW): pots were watered daily in the late afternoon to 80% FC throughout the growing period. (2) Moderate water-stressed (WS): pots were kept at 80% FC until 35 DAS when soil water content (SWC) was allowed to fall to 50% FC and maintained at 50% FC to maturity by daily watering in the late afternoon until maturity. (3) Severe WS: pots were kept at 80% FC until 35 DAS when the SWC was allowed to fall to 35% FC and maintained at 35% FC by daily watering in the late afternoon to maturity.

Days to 50% flowering and maturity were recorded and dry matter of different organs measured at flowering (54 DAS), early podding (75 DAS), and maturity (103 DAS). At flowering and podding, plants were cut off at soil level and separated into stems and leaves at flowering and leaves, stems, and pods at early podding. They were then dried in a forced-draft oven at 80 °C for 24 h, and dry weights (DW) were recorded. Fresh leaf (0.5 g) and pod (0.5 g) material at flowering and podding stages were sampled for measurement of β-ODAP concentration. At maturity, plants were cut off at soil level and separated into stems, leaves, pod walls and grain and then dried in a forced-draft oven at 80 °C for 24 h; DW was then recorded. Total grain number was counted and individual grain DW (seed size) was calculated as grain DW/total grain number. A subsample (about 1.0 g) of air-dried seeds was collected at maturity to measure β-ODAP concentration. β-ODAP amount for each plant organ was calculated as product of the β-ODAP concentration and the DW of each organ.

There were 21 different treatment combinations (7 genotypes, each with 3 water treatments), with 15 pots per treatment, giving a total of 315 pots. At both flowering (54 DAS) and early podding (75 DAS), 3 of the 15 pots per treatment were harvested for DW measurements and 3 for β-ODAP concentration, while at maturity the three remaining pots were harvested. The experiment was arranged as a complete randomized block design with three replicate blocks.

β-ODAP Concentration. β-ODAP concentration was analyzed using the methods of Wang et al.[35] and Yan et al.[36] Dry seeds (0.5 g) were ground to powder using a mini ball mill (FZ102, Zhongxing Ltd. Beijing, China) or fresh leaves (0.5 g) or fresh pods (0.5 g) were homogenized with 4.5 mL of ethanol/water (7:3, v/v) and extracted for 24 h at room temperature. The mixture was centrifuged for 0.25 h at 150 000*g* with 0.5 mL of supernatant dried under vacuum. A 100 μL of 0.5 M $NaHCO_3$ solution was used to dissolve the residue, and then 100 μL of the reagent (100 mg of 1-fluoro-2,4-dinitrobenzene in 10 mL of acetonitrile) was added to the mixture for derivatization which was completed in 0.75 h at 60 °C. After the mixture was cooled to room temperature, 0.8 mL of 0.01 M KH_2PO_4 solution was added to the above reaction mixture; then the mixture was vortexed for 10 s and filtered through a 0.45 μm membrane filter. A 20 μL sample of the product was taken for high-performance liquic chromatography (HPLC) analysis using a HPLC system (Agilent 1200, Waldbronn, Germany) to detect β-ODAP concentration. The chromatographic conditions were set as follows: Phenomenex C 18 column of 3.9 × 150 mm; mobile phase, acetonitritle/0.1 M KH_2PO_4, 17/83 (v/v); column temperature, 40 °C; flow rate, 1/60 mL/s; detection wave, 360 nm. The mobile solutions were filtered through a 0.45 μm membrane filter and degassed before use in the HPLC system. ODAP (containing 80% β-ODAP, and 20% α-

[a]Least significant differences (LSD) for each column are given: $LSD_{0.05(W)}$ for water treatments, $LSD_{0.05(G)}$ for genotypes, $LSD_{0.05(W\times G)}$ for water treatment by genotype interactions (n.s., no significant difference; *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$).

ODAP, provided by Prof. Zhixiao Li, School of Chemistry and Chemical Engineering, Lanzhou University, Lanzhou, Gansu Province, China) was used as a standard for quantitative analysis.

Statistical Analyses. Data were analyzed by two-way ANOVA (water treatments and genotypes) using Genstat 12.1 (VSN International Ltd., Hemel Hempstead, UK). Where significant effects were found, least significant difference (LSD) values at $P = 0.05$ are presented. Linear regressions between the amount or concentration of β-ODAP in the seeds and the amount of β-ODAP in the leaves and pods during growth were analyzed by Origin 8.0 (Microcal Software Inc. Northampton, Massachusetts, United States). Ordinary least-squares (OLS) regression analysis was used to test linear Y − linear X relationships, and OLS slope heterogeneity among water treatments was tested using the Standardized Major Axis Tests and Routines (SMATR) (version 2.0, NSW, Australia).[37]

RESULTS

Phenology. In the WW treatment, the seven genotypes reached 50% flowering in 43−55 DAS (mean, 47 DAS) with IF 2156, IF 1942, and IF 1312 flowering first and the local cultivar, Dingxi, flowering last (Table 2). Water stress reduced the time to 50% flowering by 1−2 days at both 50% FC and 35% FC (Table 2). In the WW treatment, maturity varied from 91 DAS in the early flowering genotypes to 103 DAS in Dingxi (mean, 95 DAS); at 50% FC, the time to maturity decreased by 5 days, and at 35% FC it decreased by a further 4 days (Table 2).

Plant Dry Weight, Grain Yield, and Yield Components. In the WW treatment (80% FC), the local cultivar, Dingxi, had the most aboveground DW and grain DW at maturity with 9.9 and 4.5 g/plant, respectively, of the seven grass pea genotypes, followed by IF 1312 and IF 225 (aboveground DW 6.9−7.9 g/plant and grain DW 3.1−3.2 g/plant); then IF 1942, IF 1310, and IF 1347 (aboveground DW 5.0−5.9 g/plant and grain DW 2.7−2.9 g/plant); with the least aboveground DW and grain DW at maturity observed in IF 2156 (4.1 and 2.2 g/plant, respectively) (Table 2). In the WW treatment, the seven genotypes ranked differently for pod DW (including seed) at early podding (75 DAS), leaf DW at flowering (54 DAS), and early podding (75 DAS) when compared to the seed DW at maturity (Table 2). Reducing available water to 50% FC significantly decreased aboveground DW and seed DW at maturity by 40% and 33%, respectively, on average across genotypes, and reducing of available water to 35% FC reduced aboveground DW and seed DW by a further 41% and 45%, respectively (62−65% less than in the WW treatment) (Table 2). There was a highly significant interaction between genotypes and water treatments, with aboveground DW and seed DW of the local cultivar, Dingxi,

J. Agric. Food Chem. 2015, 63, 6133−6141

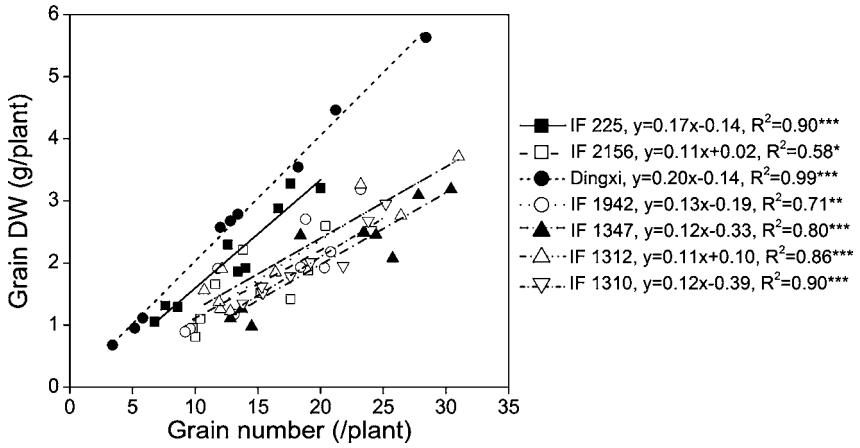

Figure 1. Relationship between grain dry weight (DW) and grain number in seven grass pea (*Lathyrus sativus* L.) genotypes. The lines are the fitted ordinary least-squares (linear) regressions (regression data shown).

decreasing by 40−43% at 50% FC and by 77−80% at 35% FC, compared to 30−39% and 44−50% at 50% FC and 35% FC, respectively, in genotype IF 1310 (Table 2). Leaf and pod DW at podding decreased with decreasing water availability in a similar manner and percentage to seed DW (Table 2). The reduction in leaf and pod DW in the local cultivar, Dingxi, was greater than that in IF 1310 as water availability decreased from 80% FC to 35% FC (Table 2). The large reduction in seed DW with water stress in Dingxi (Table 2) was associated with a large decrease (44% at 50% FC and 79% at 35% FC) in seed number (Table 2). This contrasts with the smaller decrease in seed numbers in IF 1310 (20% at 50% FC and 39% at 35% FC) with water stress (Table 2). The reduction in seed DW with water stress was associated with a decrease in grain number in all genotypes (Table 2, Figure 1). Seed size (individual grain DW) decreased in all genotypes when the water treatment decreased from 80% FC to 50% FC, but it increased in some genotypes when the water stress treatment decreased to 35% FC (Table 2), such that the reduction in seed DW with WS was not associated with individual grain DW (data not shown).

***β*-ODAP Concentration in Leaves, Pods, and Seeds.** *β*-ODAP concentration in leaves at flowering varied significantly among genotypes, from 0.79% in IF 1310 to 1.58% in IF 1347 in the WW treatment (Table 3). In all genotypes the concentration of *β*-ODAP in the leaves decreased between flowering and podding, which varied with genotype (Table 3). Water stress increased *β*-ODAP concentration in the leaves at both flowering and early podding, but the only significant interaction was at flowering when the severe stress treatment (35% FC) induced a significant increase in *β*-ODAP concentration in IF 225, IF 2156, and IF 1347 (Table 3).

At maturity when plants senesce, *β*-ODAP can be detected only in seeds and not in the leaves, stems, roots, or pod walls.[27,32] Therefore, we measured *β*-ODAP concentration in whole pods (including developing seeds) at early podding but only in seeds at maturity. In the WW treatment, IF 1312 had the highest pod *β*-ODAP concentration at 2.51%, while IF 1310 had the lowest at 0.65% at podding; there was a significant reduction (more than 1% decrease on average across genotypes) in *β*-ODAP concentration in seeds at maturity compared with pods at early podding (Table 3). The concentration of *β*-ODAP in seeds varied from 0.85% in IF 1312 to 0.22% in IF 1310 in the WW treatment (Table 3). In all genotypes except IF 1312, water stress (50% FC) significantly increased *β*-ODAP concentration in pods

Table 3. Leaf *β*-ODAP Concentration [% Dry Weight (DW)] at Flowering [54 Days after Sowing (DAS)] and Early Podding (75 DAS), Pod *β*-ODAP Concentration (% DW) at Early Podding (75 DAS), and Seed *β*-ODAP Concentration (% DW) at Maturity (103 DAS) in Seven Grass Pea (*Lathyrus sativus* L.) at early podding and increased it further at 35% FC (Table 3). Similarly, water stress increased the concentration of β-ODAP in seeds at maturity, but the low seed β-ODAP genotype, IF 1310, was consistently low in all three water treatments (Table 3). It is notable that the ranking for seed β-ODAP concentration in the seven genotypes in the moderate WS (50% FC) treatment (Table 3) was the same as that observed in the field in 2012 (Table 1).

Contrary to previous observations,[38−40] there was no association between seed size (individual grain weight, Table 2) or seed color (Table 1) with the β-ODAP concentration in the seed (Table 3) in the limited number of genotypes used in this study.

β-ODAP Amount in Leaves, Pods, and Seeds. As the amount of β-ODAP in the tissues is a product of β-ODAP concentration and tissue DW, it is a measure of the net accumulation, synthesis minus catabolism, and redistribution of β-ODAP by the plant. In the WW treatment, IF 225 had the greatest, while IF 1310 had the least, amount of β-ODAP in the leaves at flowering (Table 4). Over all the genotypes, water shortage significantly reduced the amount of β-ODAP in the leaves at flowering from 15.6 mg/plant at 80% FC to 14.1 mg/plant at 50% FC to 12.4 mg/plant at 35% FC, and there was a significant genotype by water interaction in the leaves of IF 1942 that had more β-ODAP at 50% FC than at 80% FC (Table 4). Nevertheless, IF 225 had the most and IF 1310 had the least β-ODAP in the leaves at flowering in all three levels of water supply (Table 4). Generally, the amount of β-ODAP decreased in the leaves between flowering and early podding, more so at 35% FC than 50% FC and less so at 80% FC (Table 4).

In the WW treatment, IF 1312 had the most and IF 1310 had the least β-ODAP in pods at early podding and in seeds at maturity (Table 4). The amount of β-ODAP in pods at early podding generally increased from 80% FC to 50% FC to 35% FC, except in IF 2156, Dingxi, IF 1312, and IF 1310 (Table 4), but the amount of β-ODAP in seeds at maturity decreased with increasing water stress such that the amount of β-ODAP in mature seeds was about 54% of that in pods at podding at 80% FC, 36% at 50% FC, and 23% at 35% FC (Table 4). IF 1310 had the least β-ODAP in seeds at maturity in all soil water treatments (Table 4).

Changes in β-ODAP Amount in Leaves and Pods between Different Stages of Growth. In the WW treatment (80% FC), there was a significant reduction in β-ODAP in the leaves between flowering and early podding in IF 225, IF 2156, IF 1942, and IF 1312 (Table 5). The average reduction across the seven genotypes was greater for all genotypes at 50% (5.9 mg/plant) and 35% FC (6.5 mg/plant) than at 80% FC (3.6 mg/plant) (Table 5). In contrast, the amount of β-ODAP in the pods at early podding increased relative to the amount in the leaves at flowering in all seven genotypes and all three water treatments (Table 5). The increase in β-ODAP in pods was greater with decreased water availability; the mean increase for all grass pea genotypes was 19.2 mg/plant at 80% FC, 24.9 mg/plant at 50% FC, and 28.0 mg/plant at 35% FC (Table 5). The amount of β-ODAP in pods decreased from early podding to maturity (at maturity, the seed β-ODAP amount is the same as pod β-ODAP amount as there is no β-ODAP in the pod wall) in all seven genotypes in all water treatments (Table 5). The reduction in β-ODAP in pods increased as the water deficit became more severe; the mean reduction for the seven genotypes was 16.1 mg/plant at 80% FC, 24.9 mg/plant at 50% FC, and 31.2 mg/plant at 35% FC (Table 5). Water shortage did not significantly affect the sum of β-ODAP in leaves and pods at the early podding stage, but there was significant variation among genotypes from 68.2 mg/plant in IF 1312 to 23.7 mg/plant in IF 1310 in the WW treatment (Table 5). IF 1310 consistently had the least β-ODAP in leaves and pods at 23.7 to 27.7 mg/plant, while the genotype with the greatest amount varied from IF 1312 at 80% FC to Dingxi at 50% FC to Dingxi and IF 1347 at 35% FC (Table 5).

relationship between the amount of β-ODAP in seeds at maturity and the sum of leaf and pod β-ODAP amounts at 80% FC and 50% FC, but not at 35% FC, with no increase in the amount of β-ODAP in seeds relative to the amount of β-ODAP in leaves and pods at podding in severely stressed plants (Figure 2b). There was also a significant ($P < 0.05$) positive association between the change in β-ODAP amount between leaves at flowering and pods at early podding, and seed β-ODAP concentration at maturity in all three water treatments (Figure 3a), and with the amount of β-ODAP in seeds at maturity in the WW and moderate WS (50% FC) treatments (Figure 3b). There was no significant ($P > 0.05$) relationship between the change in leaf β-ODAP between flowering and podding, nor in the change in β-ODAP amount in the pods between podding and maturity and the seed β-ODAP concentration and amount at maturity (Table 6).

DISCUSSION

Grass pea differs genotypically in the concentration of β-ODAP in seeds at maturity. In this study we confirmed this and showed that the concentration of β-ODAP in seeds increased with water shortage but that a low β-ODAP genotype maintained the lowest β-ODAP concentration at all levels of water availability. We have shown that the variation in seed β-ODAP concentration at maturity is associated with the net (synthesis minus catabolism) amount of β-ODAP in pods and leaves at early podding in all three water treatments. This was associated with a marked increase in the amount of β-ODAP in pods at early podding compared with leaves at flowering, but not with the marked reduction in the amount of β-ODAP in seeds at maturity compared with pods at early podding, suggesting that the concentration of β-ODAP in seeds is likely the result of synthesis of β-ODAP or its precursor, β-isoxazolinon-alanine, in the early reproductive phase and the possible transfer of β-ODAP from leaves to pods and seeds. Genotypes ranked on the basis of their seed β-ODAP concentration in the field in 2012 had the same ranking as the ranking at the moderate stress (50% FC) treatment in the rainout shelter. However, the concentration of β-ODAP in seeds showed a genotype by environment interaction in that the rankings differed in the WW (80% FC) and severe WS (35% FC) treatments.

Effect of Water Stress on Biomass Accumulation, Grain Yield, and Yield Components. Reducing water supply to 50% FC and 35% FC had a marked effect on the growth of grass pea plants, reducing leaf DW at flowering and early podding as well as aboveground DW and seed DW at maturity by 40% and 33%, respectively, at 50% FC, and by 65% and 62%, respectively, at 35% FC. The reduction in grain DW by water stress in the seven genotypes was largely due to a reduction in grain number, with grain size largely unaffected; grain size even increased in the large-seeded genotype Dingxi which had a large reduction in grain number under severe water shortage. This result is consistent with other results with grass pea; water stress reduced

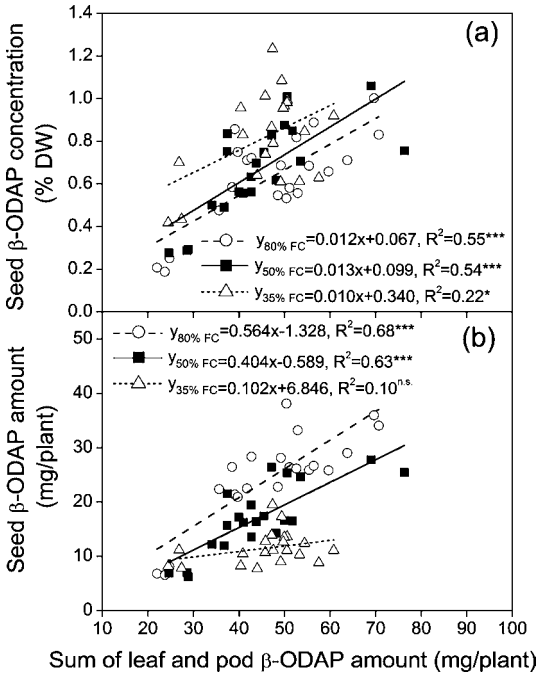

Figure 2. Relationship between (a) seed β-ODAP concentration and (b) seed β-ODAP amount at maturity and sum of leaf and pod β-ODAP amounts at podding in seven grass pea genotypes maintained at three water regimes: well-watered (80% field capacity, FC), moderate water stress (50% FC), and severe water stress (35% FC). The line is the fitted ordinary least-squares (linear) regression (regression data shown).

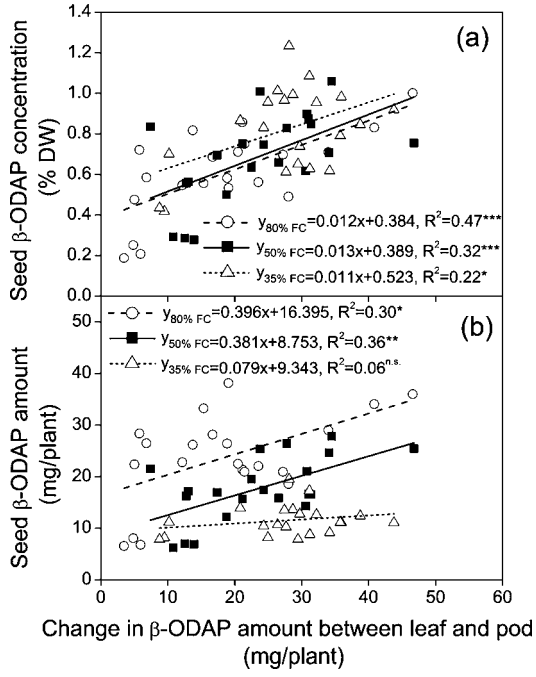

Figure 3. Relationship between (a) seed β-ODAP concentration and (b) seed β-ODAP amount at maturity and the change in β-ODAP amount between leaves at flowering and pods at early podding in seven grass pea cultivars maintained at three water regimes: well-watered (80% field capacity, FC), moderate water stress (50% FC), and severe water stress (35% FC). The line is the fitted ordinary least-squares (linear) regression (regression data shown).

the number of filled pods, grain number, grain DW, pod length, and pod wall DW, but not individual grain DW in the large-seeded (0.18 g/seed) *Lathyrus sativus* L. genotype Dingxi.[41] On the other hand, *Lathyrus sativus* L. cv. Ceora which has small seeds at 0.12 g/seed, produced smaller seeds (0.09 g/seed) and fewer seeds (from 269.5 to 124.0 per plant) when subjected to terminal water stress.[31] These results are consistent with those of Cocks et al.[28] who showed that a large-seeded (0.19 g/seed) grass pea accession, SEL 526, maintained its seed size, while a small-seeded (0.12 g/seed) accession had smaller seeds (0.09 g/seed) with increasing severe water stress.

Effect of Water Stress on β-ODAP Concentration and Amount. In this study, water stress increased β-ODAP concentration in leaves, pods, and seeds in all seven genotypes, more so with lower water supply. This result is consistent with previous results showing that water shortage increased β-ODAP concentration in different tissues of grass pea[28,29,42] but does not agree with observations by Gusmao et al.[30] and Kong et al.[31] that terminal drought induced no change in β-ODAP concentration of seeds. However, while the concentration of β-ODAP increased in this study, the amount of β-ODAP in the leaves at flowering and podding, and in the seeds at maturity, significantly decreased when the water supply decreased from 80% FC to 35% FC because of the reduction in DW in leaves, pods, and seeds with water shortage.

Accumulation and Catabolism of β-ODAP during the Vegetative and Reproductive Period. Jiao et al.[27] showed that the concentration of β-ODAP in leaves gradually declined with age. In the present study, leaf β-ODAP concentration also decreased from flowering to early podding. As there was little change in leaf DW over this period, this represents a loss in β-ODAP by either catabolism or translocation to the developing pods. The concentration of β-ODAP in seeds at maturity was lower than that in pods (containing seeds) at podding in all seven grass pea genotypes. This loss in β-ODAP concentration was associated with a large loss in the amount of β-ODAP in seeds at maturity relative to that in pods at podding, particularly in the severe WS treatment (35% FC). This suggests that there was considerable catabolism of β-ODAP in the senescing and maturing grass pea plants.

The reduction in the amount of β-ODAP in leaves from flowering to early podding was not associated ($P > 0.05$) with the concentration of β-ODAP in seeds at maturity, but there was a significant positive relationship between the increased amount of β-ODAP in leaves at flowering and pods at early podding, suggesting that variation in seed β-ODAP concentration may be related to differences in synthesis of new β-ODAP in pods at early podding rather than any transfer from leaves to pods, particularly as the amount of β-ODAP in pods at the podding stage was far higher than the amount of β-ODAP in leaves at flowering or podding.

The amount and concentration of β-ODAP in seeds at maturity was positively associated with the sum of leaf and pod β-ODAP amounts at podding, further suggesting that the amount of leaf and pod β-ODAP at this early reproductive stage jointly affected the final β-ODAP concentration in seeds. This was true in the genotype, IF 1310, which had the lowest amount and concentration of β-ODAP in seeds amount at maturity and the lowest amount of β-ODAP in leaves and pods at podding of seven grass pea genotypes. This is consistent with the observations by Kuo et al.[33] that genotypes differing in seed β-ODAP concentration differ in the biosynthesis of its precursor, not in the conversion of the precursor to β-ODAP; we suggest that the synthesis and accumulation of β-ODAP and its precursor in the vegetative and early reproductive stages determines the

[a]n.s., not significant ($P > 0.05$).

concentration in seeds at maturity. The strong association between the sum of β-ODAP in leaves and pods at early podding and final concentration in seeds at maturity could also be used to predict final β-ODAP concentration in the seed by measuring the β-ODAP level in the vegetative tissues at the early reproductive stage. Water stress did not significantly affect the relationship between seed β-ODAP concentration and the sum of leaf and pod β-ODAP at podding. However, severe water stress significantly reduced the slope between the amount of β-ODAP in seeds and the sum of leaf and pod β-ODAP amounts compared to the WW treatment, indicating that the severe WS treatment reduced the transfer of β-ODAP from leaves and pods at the early reproductive stage to seeds at maturity.

In summary, the variation among genotypes in seed β-ODAP concentration is a result of variation in the net accumulation (synthesis and catabolism) of β-ODAP during both the vegetative and reproductive phases. Water shortage affects this accumulation of β-ODAP in leaves and pods at podding differently among genotypes and hence induces differences in β-ODAP concentration in seeds at maturity. While the genotype by water supply interaction has been observed previously, the present study provides evidence that the differences among genotypes starts in the vegetative stage and is not simply determined by differences in synthesis in the late reproductive phase.

a final concentration of 10 U mL^{-1}. Phytic acid dodecasodium salt, pancreatin from porcine pancreas (4 × USP), and pepsin from porcine gastric mucosa (>250 U mg^{-1}) were obtained from Sigma (Steinheim, Germany). Ultrasep ES 100 RP18 was purchased from Bischoff (Leonberg, Germany) and AG1 X-4, 100−200 mesh, resin from Bio-Rad (München, Germany). All reagents were of analytical grade.

Standard Phytase Activity Assay. The phytase activity assay was performed according to the method of Greiner et al.[9] Briefly, 10 μL of an appropriately diluted phytase preparation was incubated with 350 μL of phytate solution (2.5 mM of sodium phytate in 100 mM sodium acetate−acetic acid buffer, pH 5.5) at 37 °C. After an incubation time of 30 min, the liberated inorganic phosphate was measured by using a modification of the ammonium molybdate method.[10] One unit of phytase activity was defined as 1 μmol of P released in 1 min at test conditions. Blanks were performed by adding stop solution prior to enzyme addition.

Biochemical Characterization of the Phytases. To study the pH dependency of the phytase activity, the following buffers were used: pH 2.0−3.5, glycine−HCl; pH 4.0−5.5, sodium acetate−acetic acid; pH 6.0−7.0, sodium acetate−HCl; and pH 8.0−9.0, Tris−HCl.

To determine kinetic constants, the incubation mixture consisted of 350 μL of incubation buffer (100 mM glycine−HCl, pH 3.0, or 100 mM sodium acetate−acetic acid, pH 5.0) containing sodium phytate in a serial dilution of a concentrated stock solution (20 mM). Kinetic constants (K_M, k_{cat}) were calculated from Michaelis−Menten plots of the data. For the calculation of k_{cat}, the molecular masses of the nonglycosylated phytases were used: 42 kDa for the phytase from *Escherichia coli*,[9] 45 kDa for the phytases from *Peniophora lycii*[11] and *Buttiauxella*,[12] 47 kDa for the *Citrobacter braakii* phytase,[13] and 49 kDa for the *Aspergillus niger* phytase.[14]

Phytase inactivation by pepsin was determined by incubating 20 mU of the different phytase preparations in 100 mM glycine−HCl, pH 3.0, containing 3000 U of pepsin for 45 min at 37 °C. As a control the pH stability of the different phytases was determined under the same conditions. After incubation, residual phytase activity was determined using the standard phytase assay.

To study the dependency of phytase activity by ionic strength, 50 mM sodium acetate−acetic acid buffer (pH 4−5.5) was used and ionic strength was increased by adding NaCl to 600 mM.

Simulation of Poultry Digestive Tract. A simple in vitro degradation model was used to simulate the digestive tract of poultry, respectively, the crop, stomach (proventriculus and gizzard), and small intestine.[15] Because poultry diets are usually corn−soybean-based, ground wheat was used as a model feed in this study. The intrinsic wheat phytase was inactivated by microwave treatment of the ground wheat. One gram of ground wheat was incubated with 3 or 6 mL of 50 mM sodium acetate−acetic acid buffer, pH 5.0, buffer containing different amounts of phytase activity (0, 250, 500, 750, and 1000 U kg^{-1}) at 40 °C for 30 min. Subsequent stomach simulations were performed by adding 280 μL of 1 M HCl and 520 μL of 50 mM sodium acetate−acetic acid buffer, pH 3, containing 21 mg mL^{-1} pepsin to the crop digesta. The entire mixture was incubated at 40 °C for 45 min under continuous shaking at 100 rpm on a rotary shaker to guarantee a homogeneous distribution of all ingredients. Simulations of the small intestine were performed by adding 650 μL of 1 M $NaHCO_3$ and 650 μL of 14.8 mg mL^{-1} aqueous pancreatin solution to the stomach digesta. The entire mixture was incubated at 40 °C for 60 min. Inorganic P release and *myo*-inositol phosphate (IP_6−IP_3) quantification were used to follow phytate dephosphorylation throughout the simulated digestion. The samples obtained from the simulated digestion studies were freeze-dried overnight, and 1 g of the freeze-dried samples was extracted with 20 mL of 2.4% HCl for 3 h at room temperature. The resulting suspensions were centrifuged (30 min, 10000 rpm). The supernatants were collected and used for inorganic phosphate determination[10] and *myo*-inositol phosphate quantification.[16]

Quantification of the Liberated Inorganic Phosphate. The liberated phosphate was quantified by using a modification of the ammonium molybdate method.[10] One and a half milliliters of a freshly prepared solution of acetone/2.5 M sulfuric acid/10 mM ammonium molybdate (2:1:1 v/v) and thereafter 100 μL of 1.0 M citric acid were added to 400 μL of the suitably diluted supernatants or to the mixtures of the phytase activity assays. Any cloudiness was removed by centrifugation prior to the measurement of absorbance at 355 nm. To quantify the released phosphate, a calibration curve was produced over the range of 5−600 nmol of phosphate.

Quantification of *myo*-Inositol Phosphates. Two milliliter aliquots of the supernatants were diluted with water to give a final volume of 60 mL. The entire solution was applied to a column (0.7 × 15 cm) containing 0.5 g of AG 1-X4 200−400-mesh resin. The column was washed with 25 mL of water and 25 mL of 25 mM HCl. Then *myo*-inositol phosphates were eluted with 25 mL of 2 M HCl. The eluates obtained were concentrated in a vacuum evaporator and dissolved in 1 mL of water. Then 20 μL of the samples was chromatographed on Ultrasep ES 100 RP18 (2 × 250 mm). The column was run at 45 °C and 0.2 mL min^{-1} of an eluant consisting of formic acid/methanol/water/tetrabutylammonium hydroxide (44:56:5:1.5 v/v), pH 4.25, as described by Sandberg and Ahderinne.[17] A mixture of the individual *myo*-inositol phosphate esters (IP_3−IP_6) was used as a standard.

RESULTS AND DISCUSSION

Biochemical Properties of the Phytases Used in the in Vitro Degradation Model. Some enzymatic properties of seven commercially available phytase products were determined under identical assay conditions. All phytases have been produced in genetically modified microorganisms. Therefore, it is assumed that the major constituent of the phytase products analyzed is the respective phytase, and the enzymatic properties determined reflect those of the enzyme in question. Phytases from five different donor organisms have been used in this study (Table 1). Two are of fungal (*A. niger*, *P. lycii*) and three of bacterial origin (*E. coli*, *C. braakii*, *Buttiauxella* sp.). On the basis of the carbon in the *myo*-inositol ring of phytate at which hydrolysis is initiated, the commercial phytase products consist either of a 3-phytase (*A. niger*) or a 6-phytase (*E. coli*, *P. lycii*, *C. braakii*, *Buttiauxella* sp.). Furthermore, variants of the above-mentioned phytases with significant improvements over the

[a]Phytase activity at pH 5.5 was taken as 100%.

parent enzymes through selective molecular modifications have found their way to the marketplace.[2] In addition, the expression system used for phytase production has an effect on the enzymatic character of the phytase. Last but not least, postfermentation activities such as product formulation and optimization can influence the properties of the final phytase preparation.[2] Therefore, phytases of the same origin might exhibit differences in their enzymatic properties as also shown for the *E. coli* phytases in this study (Table 2; Figure 1).

With respect to phytate dephosphorylation in the gastrointestinal tract of poultry, the low pH (pH 4−5) in the forestomach (crop) as well as in the proventriculus and gizzard (pH 2−5) has to be considered.[2,15] The small intestine of poultry, however, presents a neutral pH environment (pH 6.5−7.5).[15] Thus, pH optima and pH activity profile of supplementary phytases generally determine their ability to develop catalytic activity in the aforementioned gastrointestinal compartments.[18] All phytase preparations studied showed an acid pH optimum for phytate dephosphorylation and were shown to be virtually inactive above pH 7.0 (Figure 1A,B; Table 2). Thus, the phytase preparations included in the study are expected to act most efficiently under the conditions present in the forestomach, proventriculus, and gizzard of poultry. Under intestinal pH conditions the phytases exhibit almost no phytate-degrading capability. However, considerable differences in their pH activity profiles have been observed. Even if the site of phytase action in the gastrointestinal tract of poultry has received little attention so far, the crop was reported to be very likely the primary site of phytate dephosphorylation by supplementary phytase.[19] With regard to the bioefficacy of supplementary phytase, it has also to be considered that phytases are in general supplemented according to their activity determined at standard conditions (pH 5.5, 37 °C, 5 mmol/L sodium phytate).[20] Therefore, their phytate-degrading activity will differ at other pH conditions. In Table 2, the relative phytate-degrading activities of the phytase preparations included in the studies at pH 3.0 (represents the pH conditions in the proventriculus and gizzard of the birds) and pH 7.0 (represents the pH conditions in the small intestine of the birds) are displayed. Compared to their phytate-degrading activities at pH 5.5, some of the phytase preparation studied exhibited a similar (EC1, EC2, EC3), a significantly higher (BSP, CB), or a significantly lower (PL, AN) phytate-degrading capability at pH 3.0. The lowest relative activity was determined for PL (12.5%) and the highest for BSP (235.1%). At pH 7.0 all phytase preparations included in the study showed a very low phytate-degrading capability compared to that at pH 5.5. The phytate-degrading activity at pH 7.0 of all enzymes has been found to be below 8% compared to the activity at pH 5.5.

Furthermore, it must be considered that bioefficacy is not only determined by the pH activity profile of the phytase but, among others, by its kinetic constants for phytate hydrolysis, its stability under the pH conditions of the crop or stomach, and its susceptibility to pepsin degradation and the electrostatic environment in the crop or stomach.[18] Even if so far not proven by animal studies, a high affinity for phytate and *myo*-inositol pentakisphosphate, high turnover numbers with both compounds, and narrow substrate specificity are concluded to be desirable properties for phytases used as feed additives.[18] In Table 2, the kinetic constants (K_M, k_{cat}) of the phytase preparations included in the studies for phytate dephosphorylation at pH 5.0 (represents the pH conditions in the crop of the birds) and pH 3.0 (represents the pH conditions in the proventriculus and gizzard of the birds) are given. For all phytase products the turnover numbers (k_{cat}) were lower and the Michaelis−Menten constants (K_M) higher at pH 3.0 than at pH 5.0. Thus, all phytases acted more rapidly on and exhibited a higher affinity toward phytate at pH 5.0 compared to pH 3.0. Relatively low K_M values have been found for AN and PL at pH 5.0 and for PL at pH 3.0. However, AN also exhibited relatively low turnover number at both pH values. A higher affinity toward sodium phytate of *A. niger*[14] and *P. lycii*[11,14] phytases compared to the phytases from *E. coli*,[9] *C. braakii*,[13] and *Buttiauxella*[12] has already been reported.

With the exception of PL all phytase products included in the study showed a remarkable stability at pH values representing the conditions of the proventriculus and gizzard of the birds (Table 2). PL exhibited 58% residual phytase activity after exposure at pH 3.0 and 37 °C for 45 min, whereas with all other phytase products residual activities >80% have been observed. These data are in good agreement with already published data on the pH stability of the phytases studied.[9,12,13,21] The effectiveness and limitations of feed supplementation with phytases may also depend on their susceptibility to proteolytic cleavage. By incubating the phytase products with pepsin at pH 3.0, differences in their ability to withstand degradation by this digestive protease were observed (Table 2). The bacterial phytases seem to be pepsin tolerant (residual activity >85%), whereas the fungal phytases retained only 34% (PL) and 47% (AN) of their initial activity after pepsin digestion. These data are in good agreement with already published data on the susceptibility of phytases to proteolytic cleavage by pepsin.[13,22−25]

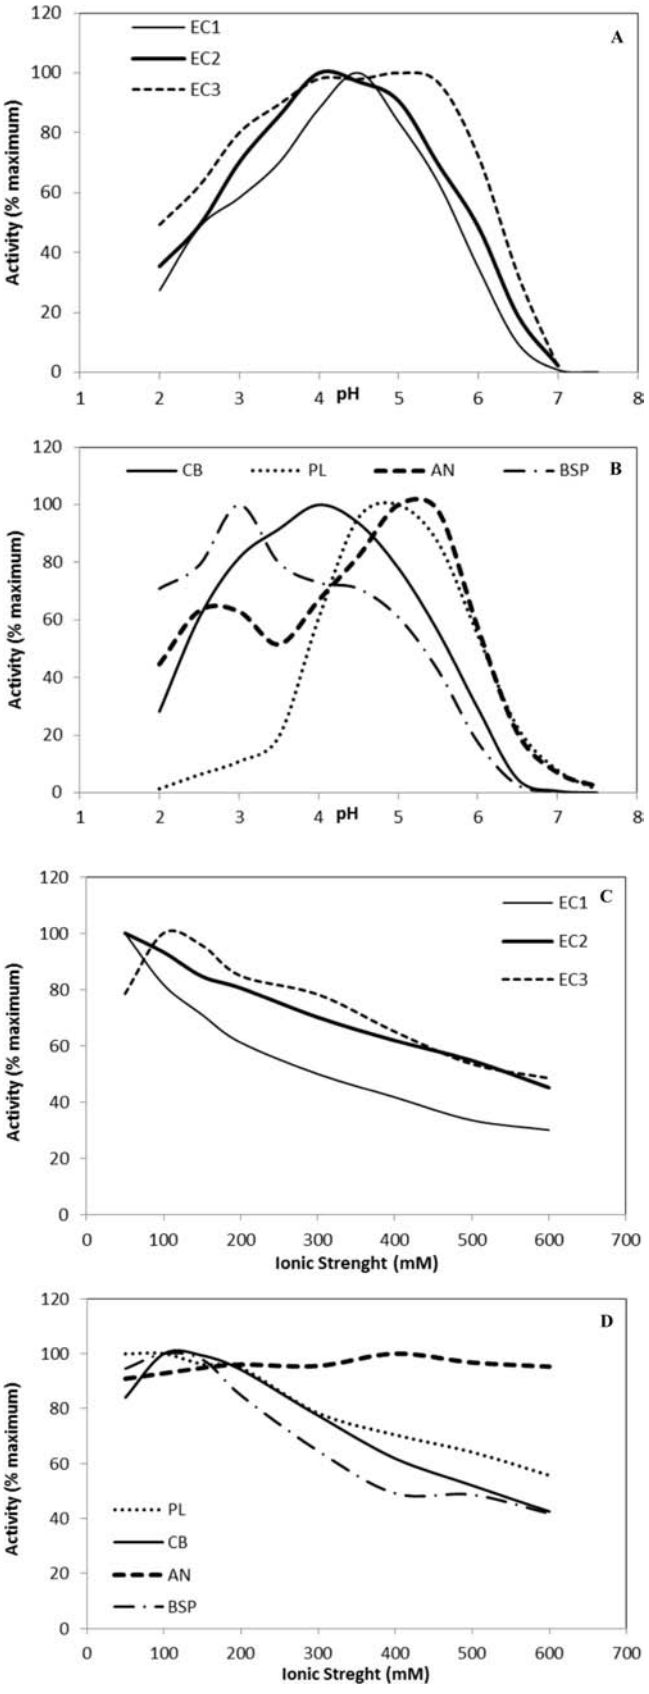

Figure 1. Effect of pH (A, B) and ionic strength (C, D) on phytase activity of the phytase products used in the in vitro degradation model.

In addition, it was already shown that the electrostatic environment could have an effect on phytase activity. The pH profiles of the phytases from *A. niger* and *E. coli*, for example, have been modified by both the buffer and the introduction of salt (NaCl, $CaCl_2$).[26] Addition of NaCl up to 600 mM to increase the ionic strength of the phytase environment resulted in a strong inhibition of all phytase products with the exception of AN (Figure 1C,D).

No clear conclusion about the bioefficacy of the phytase products could be drawn from the enzymatic properties determined. Some enzymatic properties would point to a certain phytase product as better suited for application as an animal feed supplement; some other enzymatic properties would give preference to a different phytase product (Table 2). Furthermore, there is no evidence that a single property is more important with respect to bioefficacy. A better performance in vivo is a conjunction of all enzymatic properties as well as the interaction with phosphatase activity occurring in the gastrointestinal tract.[18] Thus, enzymatic properties could only be guidelines on potential functionality of phytases in animal feeds and digestive systems.

Phytase Performance in an in Vitro Simulation of Poultry Digestive Tract. The effect of seven commercial phytase products on phytate dephosphorylation was studied in an in vitro simulation of the digestive tract of poultry based on that of Zyla and co-workers.[15] The simulation included some key conditions of the crop, stomach (proventriculus and gizzard), and small intestine of the birds. In general, supplementation of animal feed with 250−1000 U kg^{-1} is recommended by the phytase suppliers.[27−29] Therefore, 250, 500, 750, and 1000 U kg^{-1} were used in this simulation study. Whole wheat flour (ground wheat grains) was used as a feed matrix. The intrinsic wheat phytase activity was reduced to 27.6 ± 2.1 U kg^{-1} dry matter by microwave treatment. Thus, the residual activity of the intrinsic wheat phytase corresponds to 11% of the phytase activity added to the simulation at the lowest dose. A complete inactivation of the intrinsic wheat phytase could not be achieved by microwave treatment, and structural changes of the wheat by microwave treatment could not be avoided. To simulate the crop two different volumes of buffer were used. The lower volume (3 mL per gram of wheat flour) represented much better the conditions in the digestive track of the birds with respect to viscosity. However, it was extremely difficult to homogeneously distribute the phytase added throughout the entire crop content by mixing, because the mixture had a pasty consistency. To overcome this problem, 6 mL of buffer per gram of microwave-treated wheat flour was used in a second setup. Phytate dephosphorylation was followed by quantification of phytate (IP_6) and partly phosphorylated *myo*-inositol phosphates (IP_5−IP_3) as well as the inorganic phosphate (P_i) released. The variation of the analytical methods applied was determined using 10 replicates of the artificial crop, stomach, and intestine digesta without phytase addition. The standard deviation of P_i, IP_6, and IP_{total} (IP_6 + IP_5 + IP_4 + IP_3) represented 5−15% of the average (coefficient of variation; CV), whereas the standard deviation of the partly phosphorylated *myo*-inositol phosphates represented 30−100% of average. The high CVs for IP_3, IP_4, and IP_5 can be explained by the fact that these are transient forms in the phytate degradation pathway and occur in a significantly lower concentration compared to IP_6 and P_i. Conclusions drawn from the simulated digestion studies were therefore based only on IP_6, IP_{total}, and P_i.

The following trends in the simulated gastrointestinal degradation studies have been observed: IP_6 as well as IP_{total}

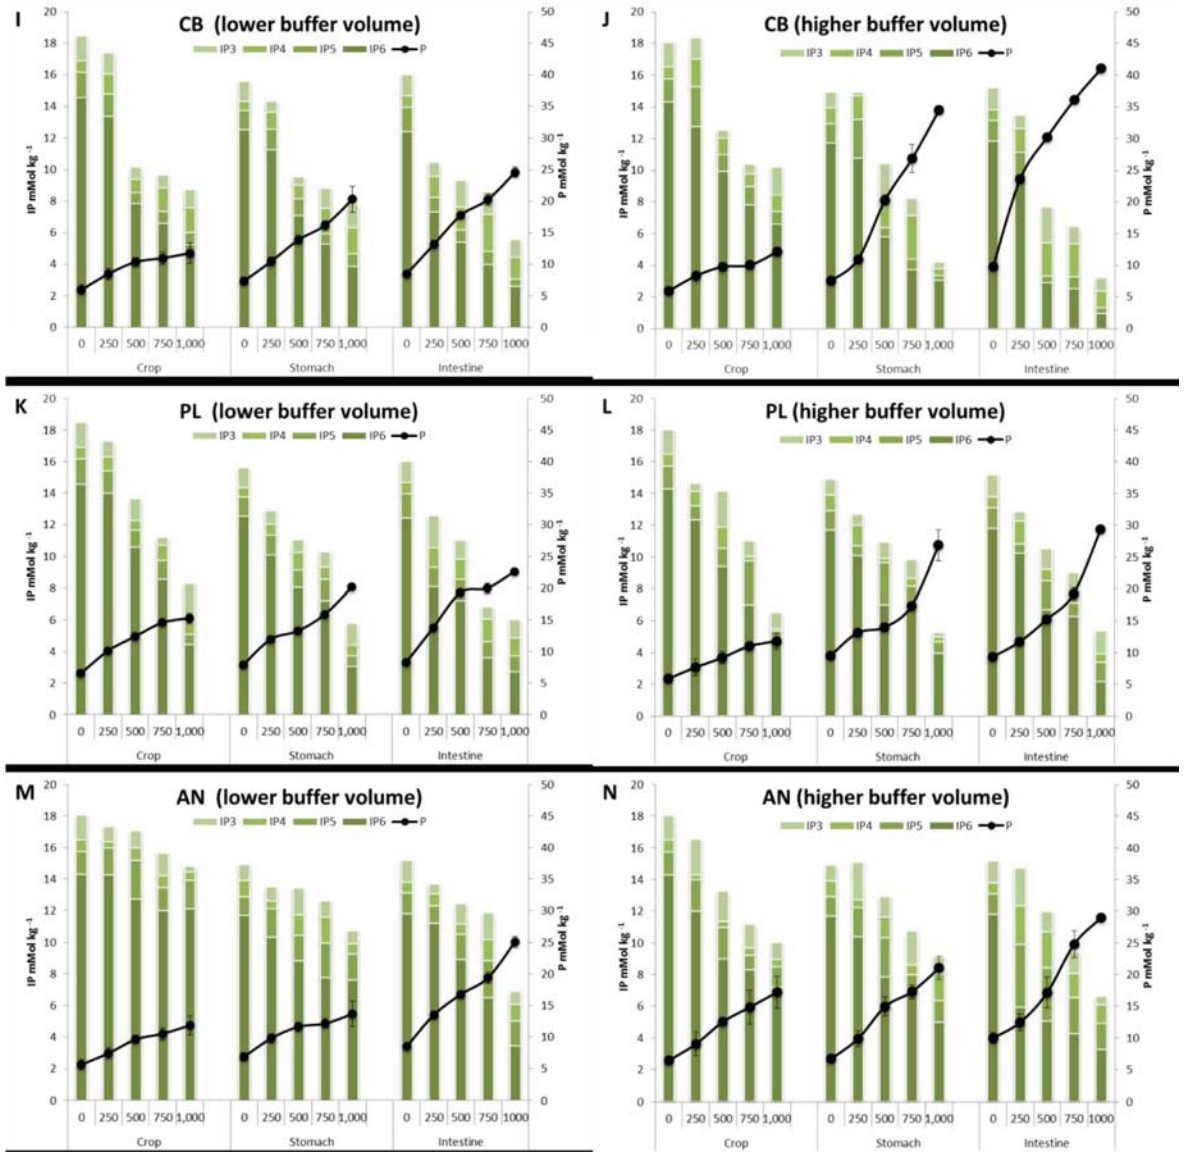

Figure 2. Enzymatic phytate dephosphorylation during in vitro simulation of poultry digestive tract quantified by reversed-phase high-performance liquid chromatography of *myo*-inositol phosphates (columns: IP_6 to IP_3) and P_i (dots and black lines). In the individual graphs the data obtained for the phytase products EC1, EC2, EC3, BSP, CB, PL, and AN are shown. A, C, E, G, I, K, and M represent the lower buffer volume, whereas B, D, F, H, J, L, and N the higher buffer volume. For every enzyme and buffer system samples were analyzed after simulation of the crop, crop and stomach, as well as crop, stomach, and small intestine at increasing phytase doses (0−1000 U kg^{-1}).

decreased, whereas P_i increased with increasing phytase supplementation (Figure 2). This result was expected, because phytases were added to release the organically bound phosphate in the phytate molecule. Histidine acid phytases (HAP) as used in this study are capable of releasing up to five phosphate moieties from the phytate molecule.[18] However, P_i release determined experimentally and P_i release calculated from the HPLC data of *myo*-inositol phosphate turnover did not match. The calculated values were always higher. The impossibility to quantify IP_2 and IP_1 with the HPLC method applied might explain this observation at least in part, because the difference in IP_{total} during in vitro digestion compared to IP_{total} in the diets was taken as IP_1 for P_i release calculations. The experimentally determined P_i release in the in vitro degradation system was comparable to values already available in the literature. In poultry, P availability was reported to increase up to 1 g P kg^{-1} of feed when feeds are supplemented with 766 U kg^{-1} of HAP phytase.[30,31] P_i release in the in vitro degradation system at 750 U kg^{-1} phytase was determined to be 0.83 ± 0.24 g P kg^{-1} (lower buffer volume) and 0.93 ± 0.31 g P kg^{-1} (higher buffer volume), respectively. Selle et al.[31] reported that 42% of the organically bound phosphate from phytate was released under the conditions mentioned above, whereas the corresponding values in the in vitro degradation system were 72.7 ± 6.8% (lower buffer volume) and 85.6 ± 9.7% (higher buffer volume), respectively. However, this study was performed with microwave-treated ground wheat, whereas Selle et al.[31] used a complete feed. A higher buffer volume and, respectively, a lower viscosity in the in vitro digestion studies resulted in general in improved IP_6 dephosphorylation and in lower IP_{total} and higher P_i amounts (Figure 2). The extent of the improvement in the release of the organically bound phosphate dephosphorylation was dependent on the phytase used. EC1 and EC2 were most sensitive to modification of the

buffer volume, whereas BSP, CB, and EC3 were moderately sensitive and PL as well as AN showed similar behaviors at both buffer volumes. Apparently, bacterial phytases were more affected by the modification in buffer volume during in vitro digestion, which may suggest that viscosity is of more concern regarding bioefficacy of bacterial compared to fungal phytases. In contrast to the enzymatic dephosphorylation of phytate in a buffered system, no real accumulation of partially phosphorylated *myo*-inositol phosphates such as IP_4 or IP_3 has been observed in the in vitro digestion system (Figure 2). A reduced mobility of the phytase and the *myo*-inositol phosphate molecules due to the higher viscosity in the in vitro digestion compared to the buffered system seems to result in the preference of the phytase to act upon the just released *myo*-inositol phosphate instead of binding a different phytate molecule into its active site. As expected from their pH profiles (Table 2; Figure 1), the major site of action of the different phytase products used was determined to be the stomach, but a significant *myo*-inositol phosphate dephosphorylation was also observed in the crop (Figure 2). About 80−90% of the enzymatic *myo*-inositol phosphates dephosphorylation occurred in the stomach and crop.

All phytase products included in the study were capable of releasing the organically bound phosphate from *myo*-inositol phosphate moiety. Their relative performances, however, were remarkably different (Figure 2). When the enzymatic properties of the different phytases (Table 2) as well as incubation time in the different parts of the intestinal tract and the phytate concentration in the microwave-treated ground wheat are taken into consideration, all phytases should be able to dephosphorylate all phytate accessible in the wheat to *myo*-inositol monophosphate, the final phytate dephosphorylation product of histidine acid phytases, even at the lowest dose (250 U kg^{-1}) used. Because IP_6, IP_5, IP_4, and IP_3 were still present in the intestinal samples of the in vitro degradation system, further parameters need to affect phytase performance. An attempt was made to explain enzyme performance in the in vitro degradation system by considering incubation time and substrate concentrations in the different parts of the digestive tract as well as pH dependence of enzymatic activity individually and in combination. Neither correlation tables nor component analysis or regression plots were able to explain the differences in phytase performance (data not shown). Therefore, further parameters such as lower catalytic activity toward precipitated forms of phytate, product inhibition (P_i) of enzymatic activity, reduction in enzymatic activity due to adsorption processes, and limited access of the phytase to phytate because of mobility and physical constraints may affect phytase performance.

Due to the vast number of parameters affecting phytase performance in the in vitro degradation system used as well as in animal studies, an in vitro system will hardly be able to fully mimic the in vivo situation. Besides determination of the enzymatic properties of a phytase, however, in vitro simulation is considered as a good complementary tool to preselect promising phytase candidates as a feed supplement. To compare the different enzyme products used in the study, the phytase activity needed to achieve a 50% reduction in IP_6 and a 50% release of the P_i bound to the *myo*-inositol ring was estimated using nonlinear fit of a negative exponential model of the observed data (Table 3). According to the model, between 319 and 581 U phytase per kilogram of microwave-treated ground wheat was needed to achieve a 50% reduction in IP_6, whereas between 952 and 2606 U phytase per kilogram of ground wheat was required to release 50% of the P_i bound to the *myo*-inositol ring when the lower buffer volume was used. With the higher buffer volume, the corresponding values were estimated to be 129−503 and 636−1791 U per kilogram of microwave-treated ground wheat, respectively. Thus, significantly lower phytase activity values were calculated to achieve a 50% reduction in IP_6 compared to a 50% release of the organically bound P_i. This result was expected because in the former case more or less 50% of the IP_6 present in the microwave-treated ground wheat was converted to IP_5, and in the latter case all IP_6 was enzymatically dephosphorylated to IP_3. In addition, it must be considered that partially phosphorylated *myo*-inositol phosphates are dephosphorylated with a different velocity compared to IP_6 and that the rate of phosphate release decreases progressively as the enzymatic reaction proceeds.

The differences in the behavior of the different commercially available phytase products in the in vitro degradation model system do not precisely reflect their performance in the animal. Therefore, the model cannot be used to rank phytases with respect to their bioefficacy, but it is considered as a simple and useful tool to evaluate the suitability of a phytase to be used as a feed supplement. Although relevant factors such as dietary P levels, intestinal phytase, and P absorption are not implemented in the system, this approach might help to reduce the number of feeding trials when searching for a better suited phytase for animal feed application in the initial screening phase. Based on of the phytase activity needed to achieve either a 50% reduction in IP_6 or a 50% release of the organically bound P_i, studies are currently carried out to establish a threshold value for the need to conduct animal feeding trials with the phytase in question. Furthermore, these studies should answer the question of whether the in vitro model will prove satisfactory when only the higher buffer volume is used and only P_i is quantified. In that case, the model system is more easily handled; the in vitro studies are less time-consuming and need less analytical effort. Further research work is in progress to study the value of in

J. Agric. Food Chem. 2015, 63, 6142−6149

The solubility of chlorpyrifos in water is very low, and the analysis has to be carried out in toxic solvents such as DMF. The reduction potential of chlorpyrifos on mercury-based electrodes is almost close to the hydrogen evolution potential, which complicates the estimation of sensing currents (peak currents). In this work we tried to overcome these disadvantages by developing a newer modified electrode for the sensing of chlorpyrifos.

Due to the high affinity of nano-TiO_2 on phosphate groups, it was used as a sensor probe along with nafion for the electrochemical sensing of the organophosphate pesticide fenitrothion.[19] Cellulose acetate (CA) is a porous material that is used to immobilize the enzymes, bacteria, and metal nanoparticles. The advantages of CA membrane are good stability in alcohol-based electrolyte, biocompatibility, easy film-forming properties, and low cost.[20,21] Titanium dioxide immobilized on a cellulose acetate membrane, a hybrid material, shows a very attractive electrocatalytic property and stability in sensor applications.[22,23] Nano-TiO_2/cellulose acetate is a complex material with no chemical interaction between TiO_2 particles and cellulose acetate, which are only physically mixed. However, very few studies were available in the literature using this composite modified electrode in sensor applications. Studies on the analysis of pesticides on this composite modified electrode were not reported in the literature.

In this paper, we report the preparation, characterization, and application of a nano-TiO_2/cellulose acetate modified glassy carbon electrode (n-TiO_2/CA/GCE) for the electrochemical sensing of chlorpyrifos. SEM was used for surface characterization. Cyclic voltammetry, differential pulse voltammetry, and amperometry were used as sensing techniques.

EXPERIMENTAL PROCEDURES

Apparatus. Cyclic votammetry (CV), differential pulse votammetry (DPV), and amperometry were performed with the computer-controlled Autolab PGSTAT 30 (Eco Chemie, Utrecht, The Netherlands) electrochemical system. DPV was recorded with the following optimized instrumental settings: modulation amplitude, 40 mV; modulation step, 4 mV; and set scan rate, 8 mV s^{-1}. For electrochemical experiments, a 10 mL glass cell with a TiO_2/cellulose acetate coated glassy carbon electrode (GCE Alfa Aesar, 3 mm diameter) as the working electrode, platinum foil as the counter electrode, and saturated calomel electrode (SCE) as the reference electrode was used. SEM analysis was done with a Hitachi model S-3000H with 20 kV acceleration voltage. HPLC analysis was carried out with an LC-10AT pump and an SPD-10A detector (Shimadzu, Kyoto, Japan) at 254 nm with a Shimpack CLC ODS-18 column. Prior to electrochemical measurements, the solution was deareated by purging with pure nitrogen for 15 min. All electrochemical experiments were carried out at 30 ± 1 °C.

Reagents and Chemicals. Chlorpyrifos was purchased from AccuStandard, New Haven, CT, USA. A stock solution of chlorpyrifos (2424 μM) was prepared in methanol. Tetra-*n*-butyl ammonium bromide was purchased from Alfa Aesar, and its 0.05 M solution was prepared in 60:40 methanol/water (v/v). It was used as the solvent−supporting electrolyte system. The nano-TiO_2 powder was prepared as follows, and the details are available in the literature.[24] Titanium(IV) butoxide (10 g) was dissolved in cyclohexanol solvent. To this solution a premixed solution containing water, cyclohexanol, and hexadecyltrimethylammonium bromide was added at room temperature. After 12 h, triethylamine was added to precipitate TiO_2 powder. The TiO_2 powder was separated, washed with acetone, and dried in air at 353 K for 2 h. The dried powder was calcined at 773 K to give nano-TiO_2 powder. Other reagents used were of analytical reagent grade.

Preparation of n-TiO_2 /CA/GCE. The GC electrode was hand polished with fine emery papers (1/0, 2/0, 3/0, 4/0), rinsed thoroughly with Millipore water, cleaned successively in 10% NaOH solution, 1:1 HNO_3/water (v/v), and MeOH, each for 2 min, and dried in air.[25] Before modification of the GC electrode, the reproducibility of the bare GC electrode was checked with the recording of cyclic voltammetric responses of a potassium ferrocyanide/ferricyanide redox system in 0.1 M KCl as reported in the literature.[26]

Cellulose acetate solution was prepared by following the procedure available in the literature.[27,28] Cellulose acetate (0.2 g) was dissolved in solvents containing 12.7 mL of acetone and 10.6 mL of cyclohexanone and stirred for 3 h to get a homogeneous solution.

The modifier solution n-TiO_2/CA was prepared by mixing 4 mg of nano-TiO_2 powder into 4 mL of the above prepared cellulose acetate solution and stirred for 1 h. This solution was used for modification of the GC electrode. The GC electrode was coated with 8 μL of n-TiO_2/CA solution by the drop−dry method. This 8 μL modifier solution contains 4.36 μL of acetone, 3.64 μL of cyclohexanone, 8 ng of TiO_2 powder, and 0.05264 ng of cellulose acetate. The coated GC electrode was dried in air for 3 h. A very thin film was seen on the GC surface. This modified n-TiO_2/CA/GCE was used for electrochemical measurements.

RESULTS AND DISCUSSION

Surface Morphology of n-TiO_2/CA/GCE. An SEM image of the composite modified GCE is shown in Figure 1. From the figure, it can be seen that the composite film uniformly covered the surface of the GCE with pores and shrinking of the film. The nano-titania particles are spread on the surface.

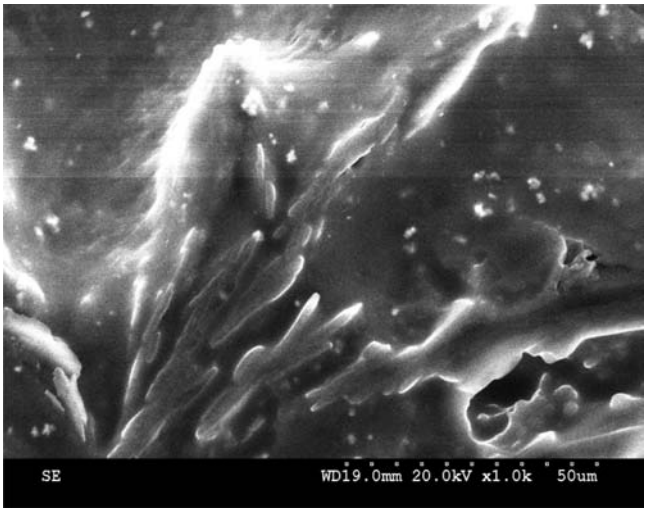

Figure 1. SEM image of n-TiO_2/CA/GCE.

Optimization of Modified Electrode Preparation. The volume of nano-TiO_2/cellulose acetate solution used for modification of the GCE surface was optimized by recording cyclic voltammetry of 50 μM chlorpyrifos in 0.05 M on n-TiO_2/CA/GCE in TBAB 60:40 methanol/water (Figure 2). The peak current increases with the increase in the volume of nano-TiO_2/cellulose acetate solution up to 8 μL. A further increase in the volume of nano-TiO_2/cellulose composite solution on GCE results in a decrease in the peak current value. This may be due to the formation of thicker films, which may render the mass transport difficult, so the optimum volume of 8 μL was used to modify the electrode surface.

Cyclic Voltammetric Analysis. Figure 3 shows the cyclic voltammetric response of 50 μM chlorpyrifos at n-TiO_2/CA/

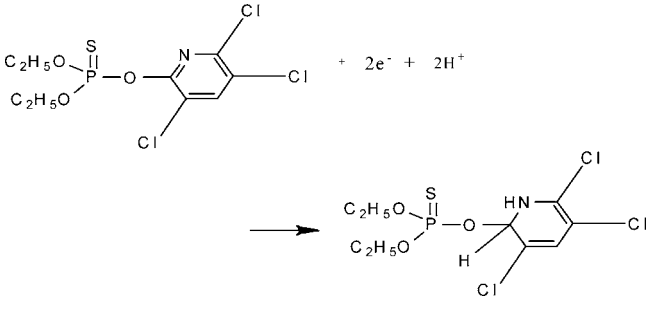
GCE. The reduction peak is observed at around −1.55 V. This peak is due to the electroreduction of −C═N of the pyridine ring of the chlorpyrifos via a $2e^-$ transfer step as reported earlier.[11−13]



No peaks are observed on the reverse scan, which means that the reduction process is irreversible. The peak current increases with the increase in the scan rates and the concentrations. A linear relationship between the peak currents and the square root of the scan rates reveals that the reduction process is diffusion controlled. The reduction of C═N of the pyridine ring is difficult and occurs very close to the hydrogen evolution region and sometimes completely overlaps with the background reduction, that is, hydrogen evolution. However, the attachment of three chlorine atoms in the pyridine ring delocalizes the electrons at the −C═N− bond and, consequently, enhances the reduction of the −C═N− bond of the pyridine ring at lesser negative potentials.[11] However, studies on the direct reduction of chlorpyrifos are limited. The reduction of chlorpyrifos was carried out on the bare glassy carbon electrode (Figure 3a), cellulose acetate modified GCE (Figure 3b), and n-TiO_2/CA/GCE (Figure 3c). The n-TiO_2/CA/GCE gives a high sensing current when compared to the CA/GCE and bare GCE. The presence of TiO_2 nanoparticles in the cellulose acetate matrix leads to the shift of hydrogen evolution nearly by 200 mV more cathodic region, which improves the measurement of true sensing current of chlorpyrifos. The peak observed on bare GCE is close to the hydrogen evolution potential. Cellulose acetate is a negatively charged membrane, which is a good matrix for the incorporation of TiO_2 nanoparticles due to the physical interaction of TiO_2 nanoparticles with cellulose acetate,[29] which was confirmed by FT-IR analysis. Figure 4

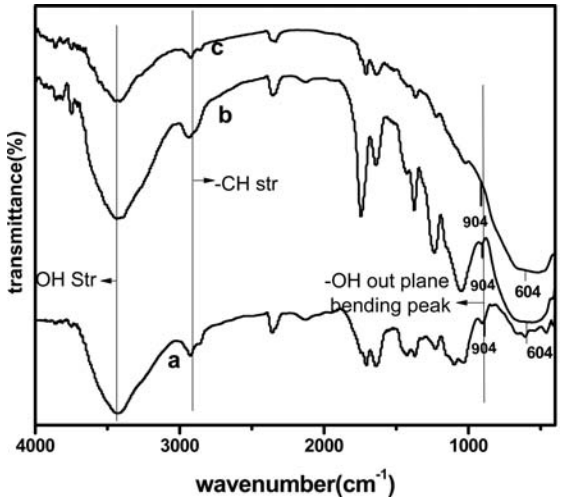


Figure 4. FTIR spectra of (a) cellulose acetate, (b) nano-TiO_2, and (c) nano-TiO_2/cellulose acetate composite.

shows the FTIR spectra of the CA, nano-TiO_2, and n-TiO_2/CA composites. The peaks are identified as follows: The broad peak at 3430 cm^{-1} is due to the −OH stretching frequencies. The broad peak around 2900 cm^{-1} is due to the −C−H stretching frequencies. The absorption peak around 1700 cm^{-1} is due to the C═O stretching frequencies.[30,31] The −C−H bending vibration peak around 904 cm^{-1} and the −OH out-of-plane bending peak around 600 cm^{-1} are of low intensity in the composite film (Figure 4c). The IR absorption peaks above 2000 cm^{-1} are intense and are composition dependent. All three IR spectra show similar characteristics, which demonstrates that the interaction between titania particles and cellulose acetate film matrix is through physical adsorption and not chemical bonding.

The presence of TiO_2 in the cellulose acetate increases the sensing current of chlorpyrifos, which is due to the electrocatalytic activity of TiO_2 nanoparticles. The pores in the film may also contribute to the increase in the peak currents. Figure

5 shows the effect of various concentrations of chlorpyrifos on the peak current of chlorpyrifos. The peak current increases

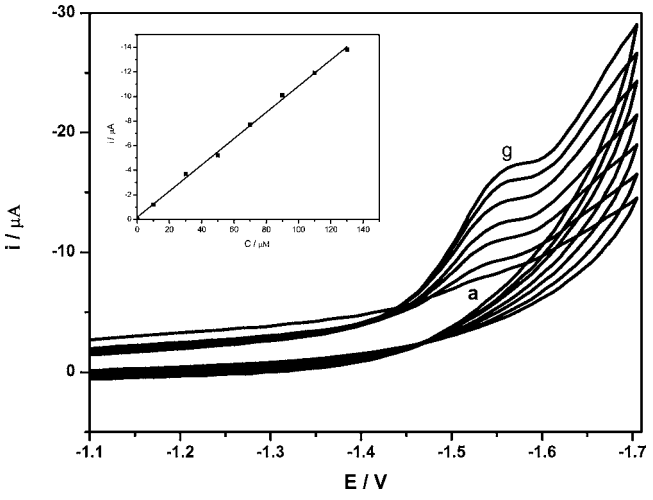

Figure 5. Influence of various concentrations of chlorpyrifos on the peak current, (a) 10, (b) 30, (c) 50, (d) 70, (e) 90, (f) 110, (g) 130 μM, at nano-TiO_2/cellulose acetate modified GCE in 60:40 (v/v) methanol/water containing 0.05 M TBAB at 100 mV s^{-1}. (Inset) Calibration graph.

with the increase in the concentrations of chlorpyrifos ranging from 10 to 130 μM (inset graph in Figure 5). The limit of detection (LOD) and limit of quantitation (LOQ) were calculated from the calibration graph constructed with concentration of chlorpyrifos on the *x*-axis and reduction current on the *y*-axis using the relationships LOD = $3s/m$ and LOQ = $10s/m$, where *s* is the standard deviation of the intercept and *m* is the slope of the calibration curve.[32] The LOD is 4.4 μM, and the LOQ is 14.7 μM.

Differential Pulse Voltammetric Analysis. Typical DPV curves at various concentrations of chlorpyrifos are shown in Figure 6. The peak current obtained after subtracting the background current increases with the increase in the

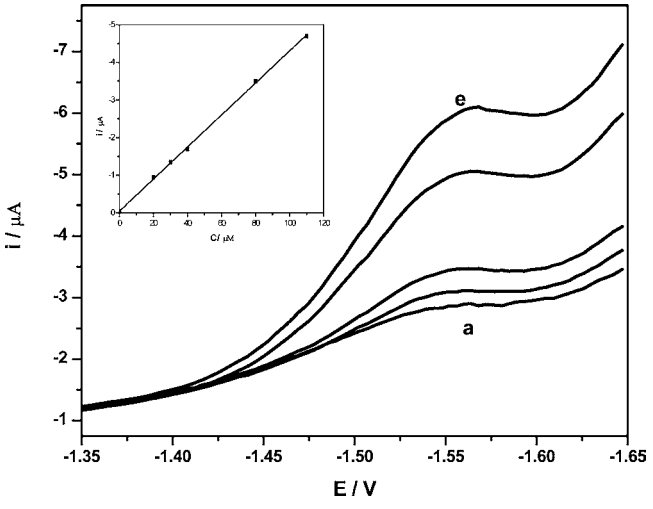

Figure 6. Differential pulse voltammetric response of various concentrations of chlorpyrifos, (a) 20, (b) 30, (c) 40, (d) 50, (e) 80, and (f) 110 μM, at nano-TiO_2/cellulose acetate modified GCE in 60:40 (v/v) methanol/water containing 0.05 M TBAB. (Inset) Calibration graph.

concentration of chlorpyrifos. The peak current varies linearly with an increase in the concentration of chlorpyrifos from 20 to 110 μM (inset in Figure 6). The LOD and the LOQ values are 3.5 and 11.7 μM, respectively. The analytical parameters obtained on various electrodes reported in the literature are presented in Table 1. Although the reduction potential of chlorpyrifos on nano-TiO_2/cellulose acetate modified GCE is higher than the values reported on mercury-based electrodes, from an environmental point of view, mercury is not a suitable material for sensing. The reduction potentials are comparable with the PEDOT modified and carbon paste modified electrodes. The nano-TiO_2/cellulose acetate modified GCE presented in this work is stable, reproducible, and biocompatible and, moreover, the preparation of the modified electrode is simple.

Amperometric Analysis. Figure 7 shows the amperometric response of chlorpyrifos at nano-TiO_2/cellulose acetate modified GCE. It was recorded at a constant potential of −1.5 V. The reduction current increases for each addition of chlorpyrifos, and the steady state current was measured. The peak current varies linearly with the increase in concentration of chlorpyrifos from 20 to 340 μM (inset in Figure 7). The LOD and the LOQ values are 11.8 and 39.2 μM, respectively.

Reproducibility and Stability of n-TiO_2/CA/GCE. The electrochemical responses are affected by the surface chemistry of carbon−oxygen functionalities present on the GC electrode and cleanliness, that is, the absence of adsorbed impurities.[33−36] In the present work GC was hand polished with finer emery papers to remove the oxide layers and adsorbed impurities on the electrode surface. Then the GC electrode was throughouly washed with Millipore water to remove the loosely adsorbed particles on the GC surface. The GC electrode was further chemically cleaned with NaOH, HNO_3, and MeOH. The electron transfer rates of redox reactions and reproducibility on the GC electrode are controlled by the distribution of surface oxides. The distribution of surface oxides was modified by exposing the GC electrode to NaOH and HNO_3. The surface of GC contains C—OH and C═O functional groups. The relative density of these species varies with the chemical treatments with NaOH and HNO_3. Treatment with NaOH increases the surface coverage of C—OH and with HNO_3 increases the surface coverage of C═O. Methanol is a less aggressive cleaning agent, which desorbs the solution impurities.[37,38] Bare GC electrodes pretreated by the above methods gave reproducible voltammetric responses for the ferrocyanide/ferricyanide redox system in 0.1 M KCl. Hence, the above pretreatment procedures were adopted in the present work.

First, the reproducibility of the bare GC electrode pretreated with emery papers and chemical agents such as NaOH, HNO_3, and MeOH was established by recording the cyclic voltammetric responses of ferricyanide/ferrocyanide in 0.1 M KCl.[26] The pretreatment procedures used in this work were sufficient to give reproducible CV responses. The pretreated GC electrode was used for modification with n-TiO_2/CA composite film. The modified GC electrode was potentiostatically cycled from the rest potential to the hydrogen evolution potential at slow sweep rates, for example, 10 mV s^{-1} in supporting electrolyte solution. After a few cycles, the background current was stable and reproducible. Then cyclic voltammograms were recorded for the reduction of chlorpyrifos on n-TiO_2/CA/GCE.

DPAdSV	CMCPE (−1.2 V)	2.8×10^{-10}–5.7×10^{-6} M	2.2×10^{-10} M		14
cyclic voltammetry	TiO_2/CA/GCE (−1.5 V)	$(10.0–30) \times 10^{-6}$ M	4.4×10^{-6} M	14.7×10^{-6} M	present work
DPV	TiO_2/CA/GCE (−1.5 V)	$(20.0–110) \times 10^{-6}$ M	3.5×10^{-6} M	11.7×10^{-6} M	present work
amperometry	TiO_2/CA/GCE	$(20.0–340) \times 10^{-6}$ M	11.8×10^{-6} M	39.2×10^{-6} M	present work

[a]The value given in parentheses is the reduction potential.

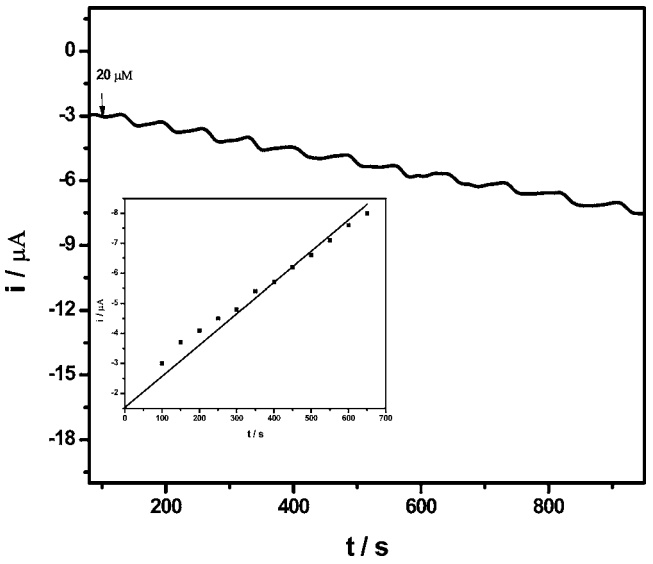

Figure 7. Amperometric response of chlorpyrifos for the constant addition of 20 μM at nano-TiO_2/cellulose acetate modified GCE in 60:40 (v/v) methanol/water containing 0.05 M TBAB. (Inset) Calibration graph.

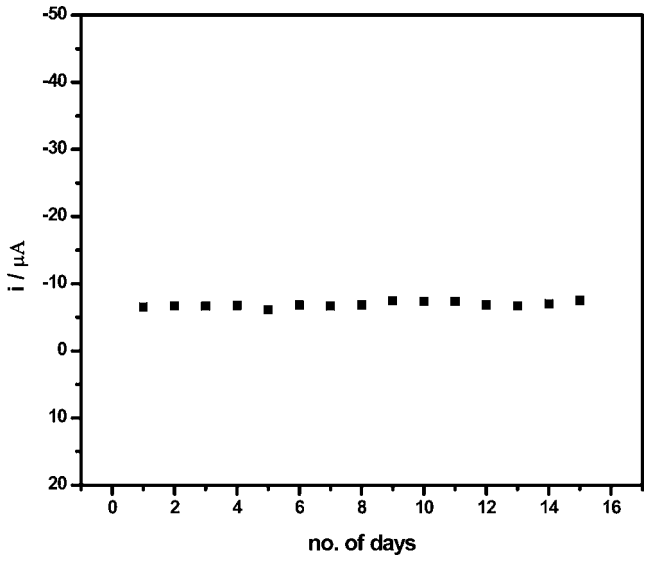

Figure 8. Stability of the n-TiO_2/CA/GCE electrode over time for the addition of 50 μM chlorpyrifos in 60:40 (v/v) methanol/water containing 0.05 M TBAB at 100 mV s^{-1}.

Reproducibility of the electrochemical response of this electrode was checked by carrying out a series of seven repetitive experiments for the fixed concentration of 50 μM chlorpyrifos. The peak currents are reproducible with the relative standard deviation of 2.54%. The reproducible response of the modified electrode with respect to time was checked (Figure 8). After the modification, the same electrode was used for the sensing of chlorpyrifos for 15 days successively. The peak currents are reproducible with the relative standard deviation of 5.3%. The stability of the electrode was also checked. After 40 cycles of cyclic voltammetric scans, the peak current variation from the initial current was 2.8% only. This shows that the nano-TiO_2/cellulose acetate film is highly stable and reproducible.

Interference Study. The interference study of several inorganic species and pesticides on the reduction signal of 50 μM chlorpyrifos was carried out using cyclic voltammetry. The concentration of the pesticides and the interfering ions were taken in 1:1 ratio. The inorganic ions such as Ca^{2+}, Mg^{2+}, Na^+, NH_4^+, and K^+ do not interfere with the chlorpyrifos reduction signal. Possible interferences with the other nitroaromatic pesticides such as methyl parathion and fenitrothion were also checked. These pesticides are reduced at around −700 mV on n-TiO_2/CA/GCE, whereas chlorpyrifos is reduced at around −1.55 V. The wide variation in the reduction potential makes it possible to determine chlorpyrifos even in the presence of these nitropesticides. The possible interference of chlorocompounds such as chlorophenol, chloroaniline, and chlorobenzene was also analyzed. The reduction of these chlorocompounds is not observed on this electrode under the present experimental conditions, and these chlorocompounds do not show any interference in the sensing signal of chlorpyrifos (Figure 9).

Real Sample Analysis. *Chlorpyrifos-Spiked Water Analysis.* The analytical utility of the above methods was checked with the water sample, which was collected at the Central Electrochemical Research Institute (CECRI) premises. It was tested for the presence of chlorpyrifos. Chlorpyrifos was absent in the water sample. Therefore, a 100 μM concentration of chlorpyrifos was spiked into the water sample and was thoroughly shaken for 1 h. Then it was extracted by using dichloromethane. A small amount of anhydrous sodium sulfate was added to the extracted sample to remove traces of water. The solvent was slowly evaporated to get the residue. The chlorpyrifos residue was dissolved in solvent supporting electrolyte and was used as analyte for electrochemical experiments. The recovery rates obtained in electrochemical techniques are summarized in Table 2. The results are compared with the HPLC method.

Commercial Sample Analysis. The commercial chlorpyrifos sample was analyzed using nano-TiO_2/cellulose acetate modified GCE as a sensor probe. One hundred milliliters of commercial chlorpyrifos was purchased from the local market, which contains approximately 20% (v/v) chlorpyrifos. The

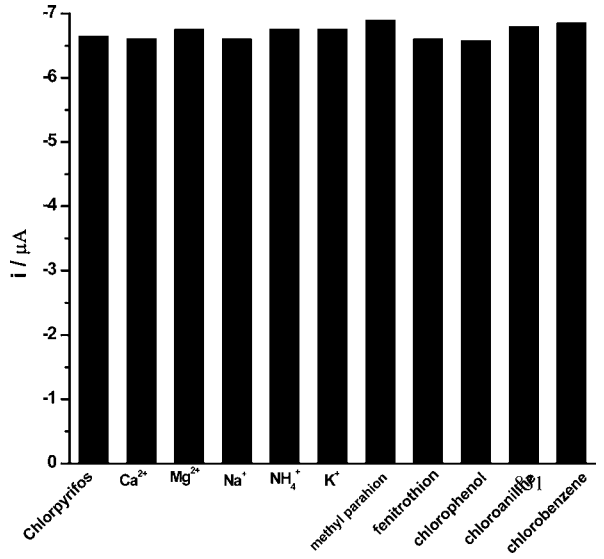

Figure 9. Interference study of various inorganic metal ions and pesticides on the reduction signal of 50 μM chlorpyrifos at n-TiO_2/CA/GCE in 60:40 (v/v) methanol/water containing 0.05 M TBAB at 100 mV s^{-1}.

Table 2. Recovery Study of Chlorpyrifos in Spiked Water Samples

method	amount added (μM)	amount recovered[a] (μM) ± SD	recovery rate (%)
cyclic voltammetry	100	91.84 ± 0.18	91.84
differential pulse voltammetry	100	96.28 ± 0.11	96.28
amperometry	100	96.46 ± 0.01	96.46
HPLC	100	98.80 ± 0.08	98.80

[a]Number of samples analyzed was 6.

actual concentration of the commercial samples was determined using an HPLC technique and was taken as reference value. It was diluted to 100 μM. Then it was used as an analyte in cyclic voltammetry, differential pulse voltammetry, and amperometry to verify the concentrations specified by the manufacturer. The concentration obtained in electroanalytical techniques is given in Table 3. The results obtained with electroanalytical techniques are comparable with the results obtained in the HPLC method.

Table 3. Commercial Sample Analysis

method	concn (%)[a,b] (v/v)
cyclic voltammetry	17.5 ± 0.50
differential pulse voltammetry	18.00 ± 0.09
amperometry	16.5 ± 0.08
HPLC	18.61 ± 0.10

[a]Concentration specified by the manufacturer is approximately 20% (v/v). [b]Number of samples assayed was 6.

Soil Analysis. Ten milliliters of chlorpyrifos was taken from the 100 mL commercial chlorpyrifos pack, which contains 20% (v/v) chlorpyrifos, and it was diluted to 1000 mL. Then this pesticide was sprayed on a pomegranate tree using an air sprayer. After 1 week, 112.6 g of soil under the pomegranate plant was collected and thoroughly ground. Then it was extracted as per the procedure explained above. The extracted sample was analyzed by electroanalytical techniques and HPLC measurements. The numer obtained in HPLC measurements is taken as reference value. The results obtained in electrochemical techniques are well comparable with the HPLC techniques (Table 4), so the electrochemical sensor using this nano-TiO_2-cellulose acetate modified electrode is promising for the analysis of environmental samples.

Table 4. Soil Sample Analysis

electroanalytical technique	concn (μM)[a,b]
cyclic voltammetry	91.62 ± 0.31
differential pulse voltammetry	91.64 ± 0.23
amperometry	102 ± 0.12
HPLC	99.6 ± 0.08

[a]Number of samples analyzed was 6. [b]Total weight of the soil was 112.6 g.

In this study a stable, reproducible, and biocompatible nano-TiO_2/cellulose acetate modified electrode was developed and used for the analysis of chlorpyrifos. The presence of TiO_2 nanoparticles increases the sensing current of chlorpyrifos, which enhances the sensitivity of the sensor. Moreover, the presence of TiO_2 nanoparticles in the cellulose acetate matrix shifts the hydrogen evolution markedly, which improves the measurement of true sensing current of chlorpyrifos. The modified electrode is highly stable with respect to time so that the electrode once modified can be used many times for the sensing of chlorpyrifos. The electrode modification procedure outlined in this work is also simple. The nano-TiO_2/cellulose acetate film on the glassy carbon electrode surface is highly stable in alcoholic medium, which makes this physically mixed composite material suitable for the determination of chlorpyrifos in alcoholic medium. This modified electrode replaces the mercury sensing electrode in the determination of chlorpyrifos. The materials used in the preparation of the modified electrode are cheap. The modified electrode can easily be renewed for subsequent analysis. The analytical utility of the proposed method was checked in the spiked water sample and the commercial sample.

Recently, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS)-based approaches have been developed for biological fluid profiling, showing their potential in the quali-quantitative analysis of milk proteins and peptides.[8] MALDI-TOF-MS has the advantage of requiring small amounts of even heterogeneous samples, permitting their analysis in a very short time. In particular, detection of α-lactalbumin, β-lactoglobulin, and $\gamma 2/\gamma 3$-casein isoforms during protein profiling (PR-P) of whey and skimmed milk samples has been used to reveal definite species-associated milk frauds.[9−13] Linear regression analysis of the resulting mass spectra quantified nondeclared milk material even in low amounts.[13] Recently, MALDI-TOF-MS PR-P of skimmed samples combined with multivariate calculation techniques allowed an accurate estimate of the levels of adulteration in bovine−goat−sheep milk mixtures.[14] No similar applications were developed to assess fraudulent addition of powdered material to fresh milk. Direct serum or skimmed milk PR-P applications did not find a counterpart at the peptide level. In fact, peptide profiling (PE-P) approaches were developed only when contemplating additional experimental steps consisting of the enzymatic digestion (with trypsin or plasmin) of the whole milk samples or of selected proteins preventively resolved by electrophoresis.[4,5,15−20] This experimental setup severely affected the time necessary for entire analysis and highly complicated the nature of the resulting MALDI-TOF spectra, generally determining the need for additional chromatographic steps for an accurate quantification of the adulteration percentages.

In this study, an integrated platform for the combined peptidomic and proteomic profiling of milk samples has been developed to rapidly reveal illegal adulterations due to the addition of either nondeclared bovine material to water buffalo, goat, and ovine milks or of powdered bovine material to the fresh counterpart. To this purpose, specific peptide and protein markers of fresh bovine milk (BM), water buffalo milk (WM), ovine milk (OM), and goat milk (GM) were identified after direct analysis of skimmed samples. Markers of TT were characterized in fresh bovine milk (BM), pasteurized milk (PM), ultra-high-temperature (UHT) milk (UM), and powdered milk (IM) samples. Principal components (PCs) scores of ad hoc prepared species- or TT-associated adulterated milk samples were subjected to partial least-squares (PLS) regression, allowing an accurate estimate of the fraud extents in test samples at either protein and peptide level.

EXPERIMENTAL PROCEDURES

Sample Preparation. Fresh raw BM, WM, OM, and GM samples were collected from local farms after morning milking, stored at 4 °C, and assayed within 5 h. Bovine PM, UM, and IM samples from different (20 in number) commercial brands were purchased from supermarkets and used before their expiration date (Supporting Information Table S2). In all cases, 25 different samples were analyzed for each type of milk.

For adulteration studies, binary mixtures of BM in WM, OM, and GM counterparts or IM in BM were prepared at 1, 2, 5, 10, 15, 20, 30, 40, and 50% v/v values. Three independent samples were prepared for each specific binary mixture.

All milk samples or their binary mixtures were defatted by centrifugation at 3000 rpm, for 30 min, at 4 °C. A part of the corresponding skimmed material (20 μL) was directly analyzed by MALDI-TOF-MS for the generation of the corresponding protein profiles. The remaining material (200 μL) was diluted 1:1 v/v with water, transferred onto Amicon Ultra devices (3 kDa cutoff) (Millipore), and filtered by centrifugation at 10000 rpm, at 4 °C. Two technical replicates were prepared for each filtrate. Peptides from filtrates were directly analyzed by MALDI-TOF-MS or extracted with C_{18}ZipTip devices (Millipore) and then subjected to MS analysis.

MALDI-TOF-MS Profiling Measurements. Before MALDI-TOF-MS PR-P, skimmed milk samples were diluted 1:100 with water. Each sample (0.5 μL) was mixed with 0.5 μL of a solution of sinapinic acid (10 mg/mL) (Bruker Daltonics, Bremen, Germany) in 0.1% v/v trifluoroacetic acid (TFA) and 30% v/v acetonitrile (ACN), placed onto a Ground Steel Target (Bruker Daltonics), and dried at room temperature. Before MALDI-TOF-MS PE-P, peptide samples (0.5 μL) were mixed with 0.5 μL of a solution of α-cyano-4-hydroxycinnamic acid (25 mg/mL) (Bruker Daltonics) in 0.1% v/v TFA and 30% v/v ACN, placed onto the instrument target reported above, and dried at room temperature.

Protein and peptide samples were analyzed by MALDI-TOF-MS using an UltraflexExtreme mass spectrometer (Bruker Daltonics) equipped with the FlexControl software package (version 3.4, Bruker Daltonics).[21] In all cases, spectral acquisition methods were developed to maximize the number of signals present in the mass spectra and the corresponding signal-to-noise ratios. In the case of PR-P measurements, spectra were recorded in the positive linear mode (LM) (laser frequency, 1000 Hz; ion source 1 voltage, 25.19 kV; ion source 2 voltage, 23.59 kV; lens voltage, 7.50 kV; sample rate, 0.31; mass range, 5000−20000 Da). Five independent spectra (1000 shots at random positions on the same target place, for spectrum) were automatically collected, calibrated externally by using the Protein Calibration Standard 1 (Bruker Daltonics), and subsequently analyzed. In the case of PE-P measurements, spectra were recorded both in the positive LM (laser frequency, 1000 Hz; ion source 1 voltage, 25.19 kV; ion source 2 voltage, 23.94 kV; lens voltage, 6.50 kV; sample rate, 0.16; mass range, 500−5000 Da) and in the positive reflector mode (RM) (laser frequency, 1000 Hz; ion source 1 voltage, 25.19 kV; ion source 2 voltage, 22.50 kV; lens voltage, 8.50 kV; reflector, 26.83 kV; reflector 2, 13.75 kV; sample rate, 0.63; mass range, 500−5000 Da). Ten independent spectra (500 shots at random positions on the same target place, for spectrum) for each peptide mixture were automatically collected, externally calibrated by using Peptide Calibration Standard 2 (Bruker Daltonics), and subsequently analyzed.

Bioinformatics and Statistics. FlexAnalysis (version 3.4) and ClinProt Tools (version 2.2) software packages (Bruker Daltonics) were used for the analysis of all MALDI-TOF-MS data, which included spectral mass adjustment (compression by a factor of 10 in the total mass range), optional smoothing (using the Savitsky−Golay algorithm with a frame size of 25 Da), spectral baseline subtraction, normalization, internal peak alignment, and peak picking. Pretreated data were then subjected to visualization and statistical analysis. Peptides or proteins showing a statistically significant difference in signal intensity or mass value were determined by means of Wilcoxon (PWKW), Anderson−Darling (PAD,) and t (PTTA) tests. A class prediction model was set up by Genetic Alghorithms (GA). Discriminant peaks were considered those presenting at least a p value <0.000001 among the PWKW, PAD, and PTTA ones. Finally, a principal components analysis (PCA) of the spectra was performed, which was carried out by an external MATLAB software tool integrated into ClinPro Tools software.

With regard to adulterated milk, corresponding PCs scores were subjected to PLS regression by XLSTAT software (Microsoft). Adulteration prediction at two points (5 and 15% v/v) was obtained by the forecast function of Excel software (Microsoft), using PLS results as matrix reference data.

RESULTS AND DISCUSSION

To define an optimal method for the suitable discrimination of milk samples by MALDI-TOF-MS profiling, dedicated procedures were set up for the combined analysis of the corresponding protein and peptide components. Due to the composition complexity of each milk type, various experimental protocols were developed for this purpose, which were

DOI: 10.1021/acs.jafc.5b02384
J. Agric. Food Chem. 2015, 63, 6157−6171

compared a posteriori for their discrimination performances. PR-P assays were performed directly on diluted skimmed milk samples.[9−14] On the other hand, PE-P measurements were realized on diluted low molecular mass skimmed milk filtrates that were then straightly analyzed by MALDI-TOF-MS or extracted with concentration devices before MS analysis. Attempts to assay peptides directly in diluted skimmed milk samples were unsuccessful in terms of recognition performances (data not shown). Different instrument acquisition ranges were assessed for protein and peptide analysis; in the latter case, the effect of a spectral acquisition in LM and RM was also evaluated (see below). Optimized procedures were used for milk speciation, for the characterization of commercial bovine milk samples subjected to various TTs, and finally for the detection of adulterated test samples as result of the addition of nondeclared material.

On the whole, a data set of 3500 MALDI-TOF mass spectra was recorded for the speciation of raw milk from four animal species. In particular, 500 mass spectra were acquired for the corresponding PR-P (5 spectral replicas for 25 milk samples from totally different individuals of each animal species); a representative example is reported in Figure 1. A thousand mass spectra were acquired for the corresponding PE-P of milk filtrates (10 spectral replicas for 25 milk samples from totally different individuals of each animal species) either in LM and in RM; representative examples are reported in Supporting Information Figures S1 and S2. Five hundred mass spectra were acquired for the corresponding PE-P of milk filtrates subjected to C_{18}ZipTip enrichment (5 spectral replicas for 25 milk samples from totally different individuals of each animal species) either in LM or in RM; representative examples are reported in Supporting Information Figure S3 and in Figure 2.

A data set analogous to that reported above was recorded in the case of BM and commercial thermally treated PM, UM, and IM samples. A representative example of the corresponding PR-P spectra is reported in Figure 3. Similarly, exemplificative PE-P spectra of milk filtrates acquired either in LM or in RM are shown in Supporting Information Figures S4 and S5, respectively. Peptide MALDI-TOF spectra of milk filtrates subjected to C_{18}ZipTip enrichment recorded either in LM or in RM are presented in Supporting Information Figure S6 and in Figure 4, respectively.

Finally, a data set of 3780 MALDI-TOF mass spectra was recorded for the detection of adulterated milk samples as a result of the addition of nondeclared material. Experiments were performed to identify adulteration either from raw BM added to WM, OM, or GM, and from IM added to BM. In particular, 540 mass spectra were acquired for the corresponding PR-P (5 spectral replicas of the 9 percentage values assayed for each kind of adulteration; experiments were performed on triplicate samples) (data not shown); 1080 mass spectra were acquired for the corresponding PE-P of milk filtrates (10 spectral replicas of the 9 percentage values assayed for each kind of adulteration; experiments were performed on triplicate samples) either in LM or in RM (data not shown); 540 mass spectra were acquired for the corresponding PE-P of milk filtrates subjected to C_{18}ZipTip enrichment (5 spectral replicas of the 9 percentage values assayed for each kind of adulteration; experiments were performed on triplicate samples) either in LM or in RM (data not shown).

In each case, statistical analysis of mass spectra of pure milk samples allowed the identification of discriminant signals on the basis of intensity and/or mass values. Class prediction model

was set up by GA; marker proteins or peptides were identified by means of their PWKW, PAD, and PTTA p values. Corresponding data for milk speciation are shown in Supporting Information Table S3 (PR-P, 23 markers), Supporting Information Table S4 (PE-P in LM, 65 markers), Supporting Information Table S5 (PE-P in RM, 106 markers), Supporting Information Table S6 (PE-P in LM after C_{18}ZipTip enrichment, 63 markers), and Supporting Information Table S7 (PE-P in RM after C_{18}ZipTip enrichment, 95 markers), together with additional statistical parameters. Corresponding data for the characterization of thermally treated commercial bovine milks are shown in Supporting Information Table S8

(PR-P, 10 markers), Supporting Information Table S9 (PE-P in LM, 27 markers), Supporting Information Table S10 (PE-P in RM, 47 markers), Supporting Information Table S11 (PE-P in LM after C_{18}ZipTip enrichment, 46 markers), and Supporting Information Table S12 (PE-P in RM after C_{18}ZipTip enrichment, 53 markers), together with additional statistical parameters. As expected, a number of common peptide markers occurred between analyses performed in LM and RM. In particular, 43, 39, 18, and 23 common peptide markers were observed during PE-P on milk filtrates for speciation, on C_{18}ZipTip-enriched milk samples for speciation, on milk filtrates for TT characterization, and on C_{18}ZipTip-enriched milk samples for TT characterization, respectively. Importantly, data from PWKW, PAD, and PTTA analyses defined the recognition capability of each specific assay; corresponding results are reported in Tables 1 and 2. They demonstrate that milk speciation (100% recognition capability) was guaranteed in the case of MALDI-TOF-MS profiling measurements performed either on proteins from milk filtrates, on peptides from milk filtrates analyzed in RM, or on peptides from C_{18}ZipTip-enriched milk filtrates analyzed in both LM and RM, notwithstanding the heterogeneous polypeptide composition of

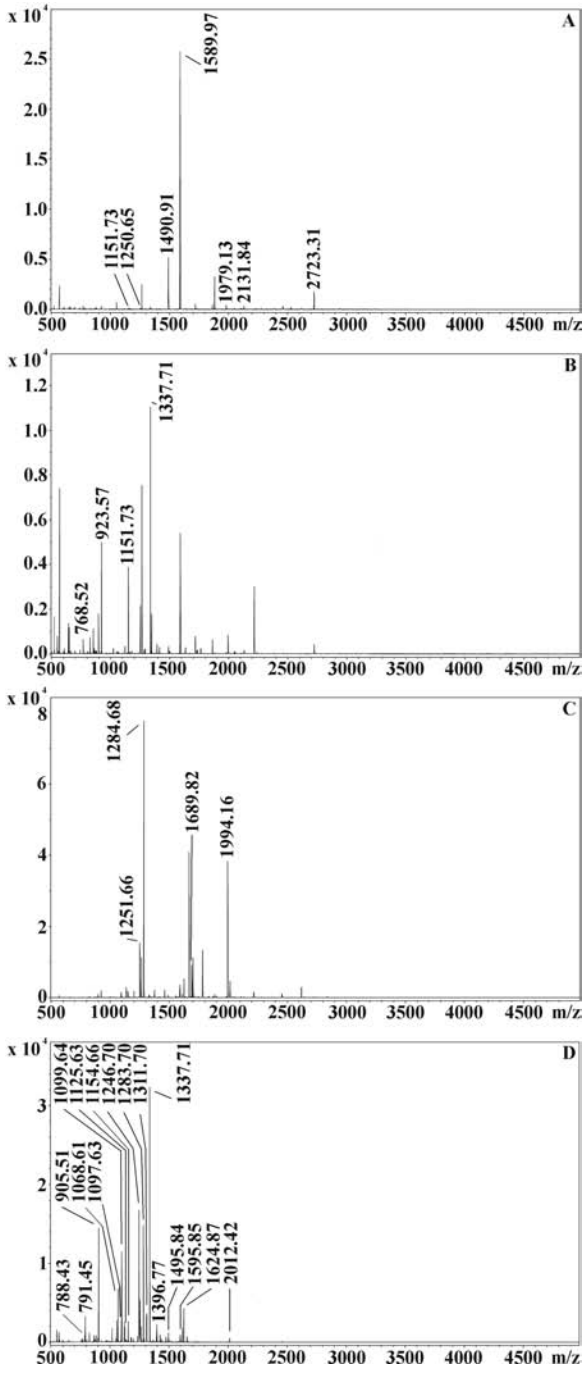

Figure 4. MALDI-TOF-MS PE-P in RM of milk filtrates subjected to C_{18}ZipTip enrichment from thermally treated commercial milk samples. Spectra refer to fresh BM (A), PM (B), UM (C), and IM (D). MH^+ signals corresponding to identified marker molecules are highlighted by reporting the associated mass values.

this biological fluid[16,18,22] (Table 1). Conversely, the characterization of the TT of commercial bovine milks was ensured only in the case of peptides from C_{18}ZipTip-enriched milk filtrates analyzed in RM (Table 2). The latter result is probably dependent on the higher complexity of the protein and peptide mixtures present in commercial milk samples;[5,15,17,19,20,23−26] it also emphasizes that the method used for spectral acquisition can highly affect the recognition capability of the whole platform. On this basis, particular care is necessary for the initial setup of the PR-P and PE-P experimental conditions to

Table 1. ClinProt Model Generation Report for the Speciation of Milk Samples from Different Animal Species (Cow, Buffalo, Goat, and Sheep)

molecular targets/acquisition method	cross validation (%)	recognition capability (%)
proteins from diluted samples/LM	95.11	100.00
peptides from C_{18}ZipTip-enriched diluted milk filtrates/RM	89.43	100.00
peptides from diluted milk filtrates/RM	90.10	100.00
peptides from C_{18}ZipTip-enriched diluted milk filtrates/LM	89.11	100.00
peptides from diluted milk filtrates/LM	77.47	97.39

Table 2. ClinProt Model Generation Report for the Recognition of Thermally Treated Commercial Milk Samples (Raw, Pasteurized, Ultrahigh-Temperature, and Powdered)

molecular targets/acquisition method	cross validation (%)	recognition capability (%)
proteins from diluted samples/LM	87.82	97.19
peptides from C_{18}ZipTip-enriched diluted milk filtrates/RM	89.69	100.00
peptides from diluted milk filtrates/RM	90.07	96.46
peptides from C_{18}ZipTip-enriched diluted milk filtrates/LM	86.94	98.04
peptides from diluted milk filtrates/LM	82.44	98.00

guarantee the maximum number of signals present in the mass spectra and of the corresponding signal-to-noise ratios. These instrumental settings have to be maintained during the whole analysis of the different milk samples with the aim of not compromising the recognition capability of the whole platform.

As expected, PCA of the data reported in Supporting Information Tables S3−S12 was in line with the recognition capability values reported in Tables 1 and 2. For example, panels A and B of Figure 5 show the PCA 3D scatter plots of results from BM, WM, GM, and OM proteins analyzed in LM and from BM, WM, GM, and OM C_{18}ZipTip-enriched peptides in RM, respectively, which were used for milk speciation. A good separation of the colored spots was evident in both cases. Similarly, panels A and B of Figure 6 show the PCA 3D scatter plots of results from BM, PM, UM, and IM proteins analyzed in LM and from BM, PM, UM and IM C_{18}ZipTip-enriched peptides in RM, respectively, which were used for the recognition of the material thermal treatment. Although more appreciable in a three-dimensional representation, well-resolved colored spots were evident also in these cases. Best dot separation occurred in the case of peptides. Less-resolved PCA 3D scatter plots were obtained in the case of the remaining methods used for milk speciation (Supporting Information Figure S7) and for the recognition of milk TT (Supporting Information Figure S8).

On the basis of the data reported in Tables 1 and 2, Figures 5 and 6, and Supporting Information Figure S7 and S8 and the capability of this MS platform to perform independent analyses on different molecules (proteins and peptides), we conclude that complementary information associated with the highest recognition capability values for milk speciation and for thermal treatment characterization are obtained when diluted skimmed milk samples and C_{18}ZipTip-enriched diluted skimmed milk filtrates are analyzed for the respective protein and peptide content in LM and RM, respectively.

MALDI-TOF-MS PE-P experiments were performed in RM on diluted milk filtrates subjected to C_{18}ZipTip enrichment.

Marker Assignment. Marker protein signals recognized for milk speciation (Supporting Information Table S3 and Figure 1) and for TT recognition (Supporting Information Table S8 and Figure 3) were associated with specific components on the basis of literature data[9−14,17] and mass calculations. As expected, most of the signals were assigned to α-lactalbumin and β-lactoglobulin, as well as to γ2/γ3-caseins and proteoso peptones resulting from the activity of milk plasmin on β-casein.[17,27−29] In particular, γ2-caseins and γ3-caseins were identified as marker signals in BM, WM, GM, and OM; α-lactalbumins were assigned markers in BM, WM, and GM; β-CN fragments (98−207) were discriminant signals in GM and OM; β-lactoglobulin, proteoso peptones p.p.8.I., and β-casein fragments (1−68) and (69−209) were discriminant molecules in GM, BM, and WM, respectively (Table 3). The latter complementary peptides originated after specific proteolysis at K_{68}; this lysine is exclusively present within the water buffalo β-casein sequence.[4,17]

When compared to data reported above, PR-P of thermally treated milk samples identified a reduced number of protein markers, that is, proteoso peptones p.p.8.I. (BM, PM, and UM), β-lactoglobulin (BM and PM), α-lactalbumin adduct with lactose (Δm = +324) (IF), γ2-casein (UM), and its adduct with lactose (IM) (Table 4). Various nonassigned marker species were specific for UM and IM; the corresponding hypothetical lactose adducts were present only in IM.

Finally, marker peptide signals from C_{18}ZipTip-enriched diluted skimmed milk filtrates recognized for speciation (Supporting Information Table S7 and Figure 2) and for TT recognition (Supporting Information Table S12 and Figure 4) were associated with specific components based on MALDI-

[a]MS experiments were performed in reflectron mode as reported under Experimental Procedures. Most intense MH^+ signals reported in Supporting Information Table S7 were subjected to fragmentation analysis for structural assignment (see Supporting Information for experimental details). Difference value between the maximal and the minimal average peak/area intensity of all classes (DAve) (see ClinProt Tools software for details), UniProt/NCBI sequence code (the latter highlighted in *italics*), protein name, experimental/theoretical MH^+ (monoisotopic) value, modifications(s), mass error (in Da), peptide sequence, MASCOT/SEQUEST score (the latter highlighted in *italics*), and the mass spectrometry method used for peptide assignment (LIFT or CID) are reported. Theoretical MH^+ values were calculated according to the indicated UniProt/NCBI sequence entries. nd, not determined.

[a]MS experiments were performed in reflectron mode as reported under Experimental Procedures. Most intense MH^+ signals reported in Supporting Information Table S12 were subjected to fragmentation analysis for structural assignment (see Supporting Information for experimental details). Difference value between the maximal and the minimal average peak/area intensity of all classes (DAve) (see ClinProt Tools software for details), UniProt/NCBI sequence code (the latter highlighted in *italics*), protein name, experimental/theoretical MH^+ (monoisotopic) value, modifications(s), mass error (in Da), peptide sequence, MASCOT/SEQUEST score (the latter highlighted in *italics*), and the mass spectrometry method used for peptide assignment (LIFT or CID) are reported. Theoretical MH^+ values were calculated according to the indicated UniProt/NCBI sequence entries. nd, not determined.

TOF/TOF and nanoLC-ESI-LIT-MS/MS analyses (see Supporting Information for experimental details). Fragmentation data were obtained from peptide mixtures loaded on the MALDI plates also used for PE-P experiments and directly analyzed by nanoLC-ESI-LIT-MS/MS analysis; in the latter case, specific data searching for peptides having a mass value coincident with that of the marker species was realized. This combined approach identified 38 marker peptides for milk speciation as deriving from β-casein (BM, WM, GM, and OM), α_{S1}-casein (BM and OM), α_{S2}-casein (GM), glycosylation-dependent cell adhesion molecule 1 (BM and WM), κ-casein (WM, GM, and OM), cytoglobin isoform X1 (WM), serum amyloid A protein (GM and OM), butyrophilin subfamily 1 member A1 (GM), lactoperoxidase (GM), and cohesin subunit SA-3 (OM), some of which bear specific modifications (Table 5). Similarly, 28 marker peptides for TT recognition were

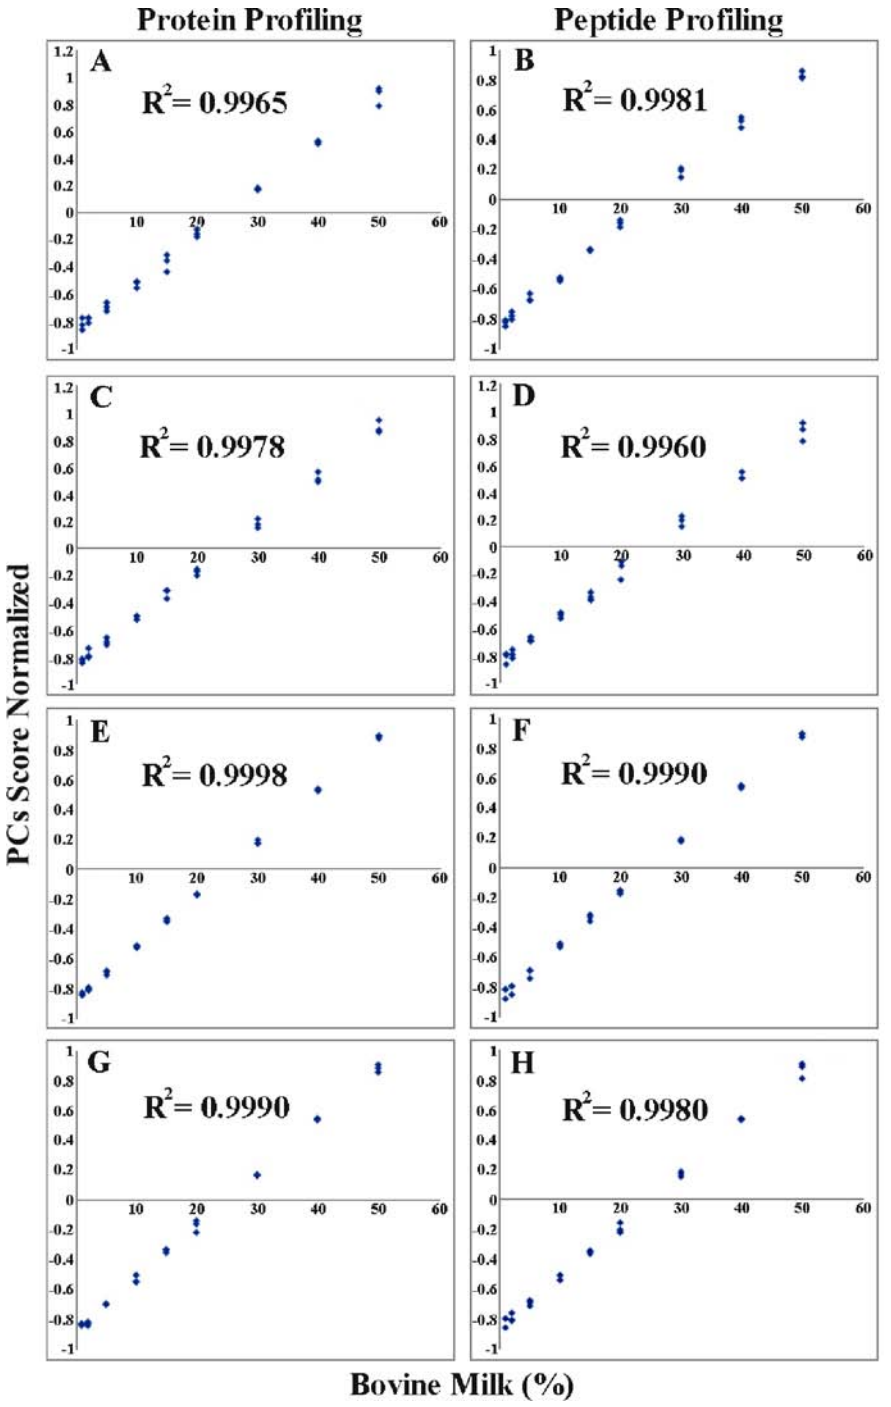

Figure 7. PLS plot of MALDI-TOF-MS data deriving from protein (A, C, E, and G) and peptide (B, D, F, and H) profiling experiments on adulterated milk samples resulting from the addition of BM to WM (A, B), GM (C, D), and OM (E, F) or of fresh BM to IM (G, H). MALDI-TOF-MS PR-P experiments were performed in LM on diluted milk samples. MALDI-TOF-MS PE-P experiments were performed in RM on diluted milk filtrates subjected to C_{18}ZipTip enrichment. The different dots show the concentration of BM in the mixture in relation to the normalized PC scores.

identified as deriving from β-casein (BM, PM, UM, and IM), α_{S1}-casein (BM, PM, UM, and IM), α_{S2}-casein (PM, UM, and IM), glycosylation-dependent cell adhesion molecule 1 (BM), and polymeric immunoglobulin receptor (PM) (Table 6). In the case of either milk speciation or thermal treatment recognition, the slight difference in the nature of the marker molecules identified with PR-P and PE-P experiments should be associated with the molecular mass value of intact proteins, which may exceed the instrument mass range we used, and the resistance of specific proteins to proteases that may hamper the production of the corresponding peptides.

Adulteration. Platform capability to recognize milk adulteration due to the addition of either nondeclared BM to WM, GM, and OM or IM to fresh BM was verified with PR-P and PE-P by analyzing nine impure milk samples, which were prepared in triplicate following the addition of different BM volumes into WM, GM, and OM to generate 1, 2, 5, 10, 15, 20, 30, 40, and 50% v/v binary mixtures. Similarly, adulterated samples having identical mixed concentrations were prepared

DOI: 10.1021/acs.jafc.5b02384
J. Agric. Food Chem. 2015, 63, 6157−6171

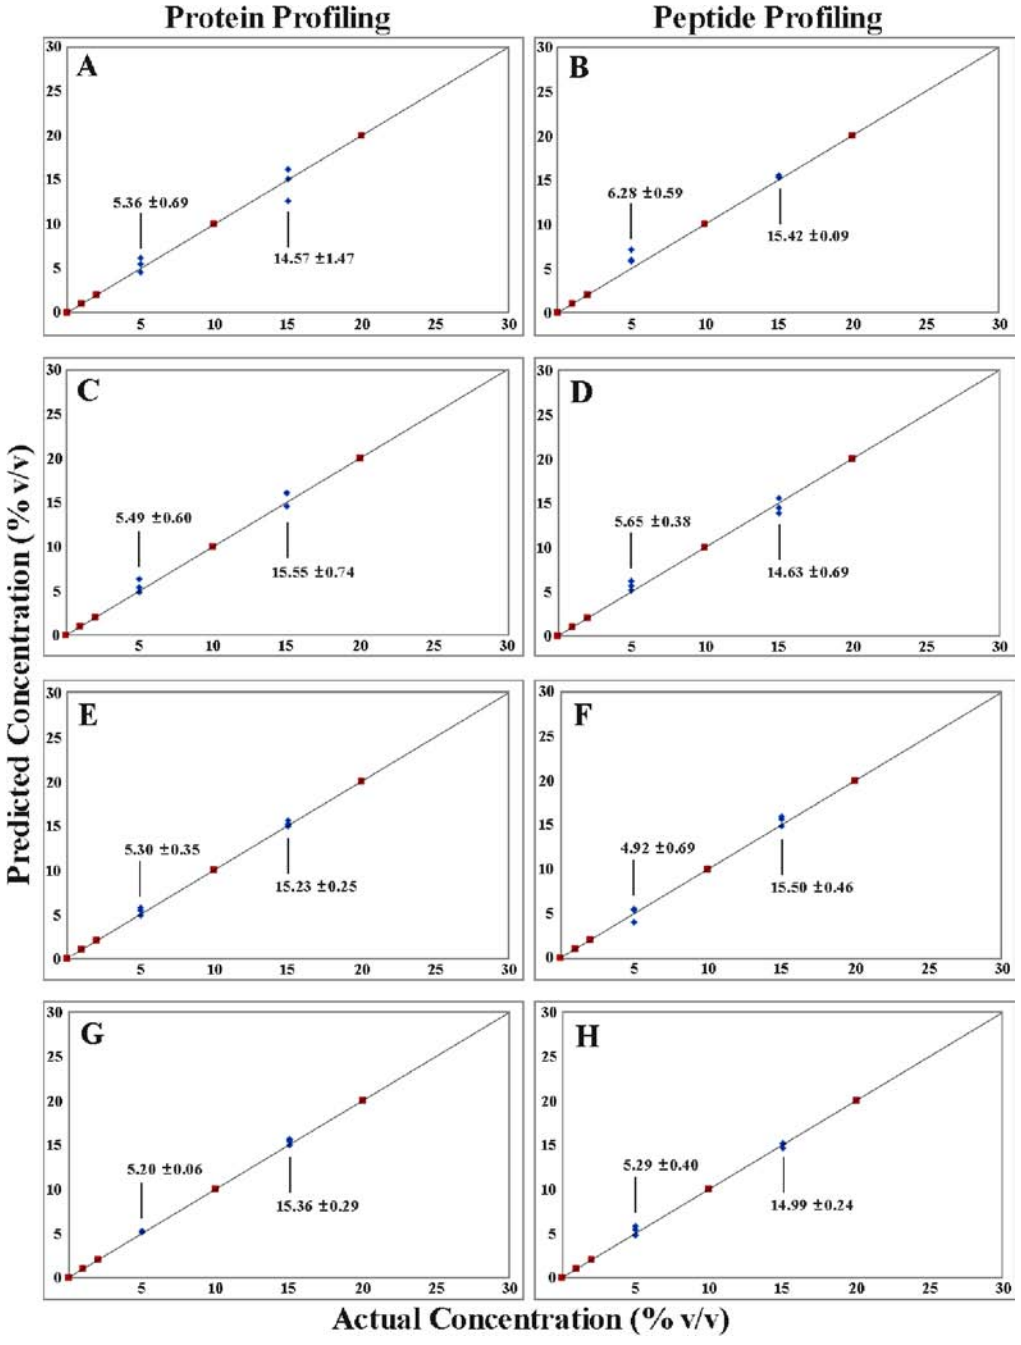

Figure 8. Plots showing the predicted levels of milk adulteration after MALDI-TOF-MS protein (A, C, E, and G) and peptide (B, D, F, and H) profiling experiments. The different panels represent data for adulterated samples resulting from the addition of BM to WM (A, B), GM (C, D), and OM (E, F). Data for adulterated samples resulting from the addition of fresh BM to IM are also shown (G, H). MALDI-TOF-MS PR-P experiments were performed in LM on diluted milk samples. MALDI-TOF-MS PE-P experiments were performed in RM on diluted milk filtrates subjected to C_{18}ZipTip enrichment. Blue squares represent the training data set, whereas the red rhombuses indicate the test set. The predicted levels of milk adulteration are reported ± SD.

when IM was added to BM. After spectral processing according to the procedures already set up for pure materials, MALDI-TOF-MS data of these binary mixtures were subjected to PCA. Resulting PCA data also included variance, PC score, and coefficient values. These data were then used for PLS regression calculations. Figure 7 shows the PLS regression plot of each binary mixture, as deriving from PR-P and PE-P analyses. An optimal linearity of the data was observed in each case. Normalized values for two adulterated test samples analyzed in triplicate were then used to get a prediction of the corresponding percentages of adulteration. Plots of the predicted adulteration levels, as estimated from the above-mentioned PLS model on the basis of the corresponding PR-P and PE-P data, are reported in Figure 8. Data from PR-P and PE-P analyses matched each other and were in good agreement with real adulteration percentages (5 and 15%) within experimental error. These results demonstrated the good capability of this platform to predict illegal adulteration levels of unknown milk samples when they are processed together with proper adulteration standards. They also demonstrated the

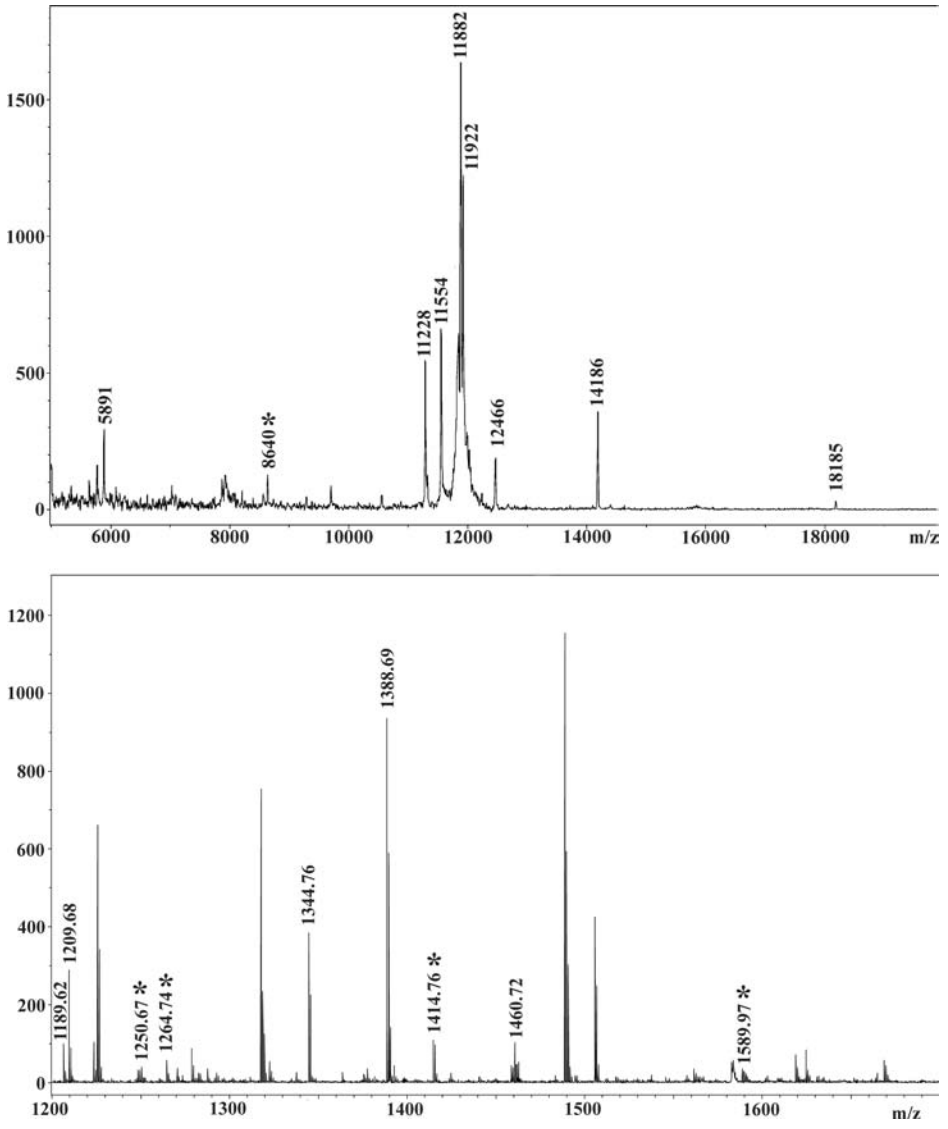

Figure 9. Cropped regions of the MALDI-TOF-MS PR-P and PE-P spectra of a GM sample containing 5% v/v BM. MALDI-TOF-MS PR-P was performed in LM on diluted milk samples. MALDI-TOF-MS PE-P was performed in RM on diluted milk filtrates subjected to C_{18}ZipTip enrichment. MH^+ signals corresponding to GM and BM marker molecules are highlighted by reporting the associated mass values; those associated with BM adulteration are marked with an asterisk.

importance of having an analytical system that provides simultaneously two independent adulteration measurements realized on diluted skimmed milk samples and C_{18}ZipTip-enriched diluted skimmed milk filtrates, which are analyzed for the respective protein and peptide contents, respectively. As an example, Figure 9 shows the simultaneous detection of bovine protein and peptide markers in the PR-P and PE-P spectra of an adulterated GM sample containing 5% v/v BM.

Conclusions. The development of a versatile and fast method for the detection of fraudulent adulterations in milk is a very important issue, due to the economic impact that these frauds have in dairy productions.[6] As mentioned before, a number of analytical methods have been developed for this purpose, which have the disadvantage of being sometimes time-consuming, suitable only for a specific milk assay (speciation or TT analysis), useful for a unique animal species to animal species milk discrimination, and/or eventually not adaptable for global screening of milk samples (Supporting Information Table S1). To overcome these limits and take advantage of previous applications of the ClinProt technology for biomarker recognition and disease prediction in humans,[30,31] a MALDI-TOF-MS platform for combined PR-P and PE-P of milk samples has been here developed, which recognizes markers either for speciation in BM, WM, GM, and OM or for thermal treatment in BM, PM, UM, and IM, quickly assigning the nature of a pure unknown material. This platform was developed by taking advantage of other applicable studies in the biomedical research field.[32−34] Platform capability to recognize milk adulteration due to the addition of small volumes either of nondeclared BM to WM, GM, and OM or of IM to fresh BM was verified by analyzing different ad hoc prepared binary mixtures and specific test samples. In the latter case, concentration values were predicted according to independent PR-P and PE-P analyses and verified a posteriori to be coincident with real data.

With respect to previous papers describing the use of PR-P analysis on diluted skimmed samples for milk speciation,[9−14] this study extends this method to the analysis of TT and

DOI: 10.1021/acs.jafc.5b02384
J. Agric. Food Chem. 2015, 63, 6157−6171

introduces an independent, complementary measurement based on an ad hoc developed PE-P approach that has been set up to integrate protein data with additional information on other molecules, that is, peptides, validating final results. When coupled to a robust statistical evaluation of the resulting data, this platform ultimately permits the typing of milk and the correlation of MALDI spectra with quantitative adulteration values. By introducing PE-P analysis in the sample-processing pipeline, this integrated profiling approach also permits the detection of adulterations due to the addition of powdered material into fresh milk, broadening the applicative scenario of the MALDI profiling techniques in dairy science. The high-throughput character of the MALDI ionization technique and its versatility in answering a number of issues related to the certification of raw materials used in dairy industry suggest the massive use of this platform in milk analysis with the aim to preserve product tradition and value.

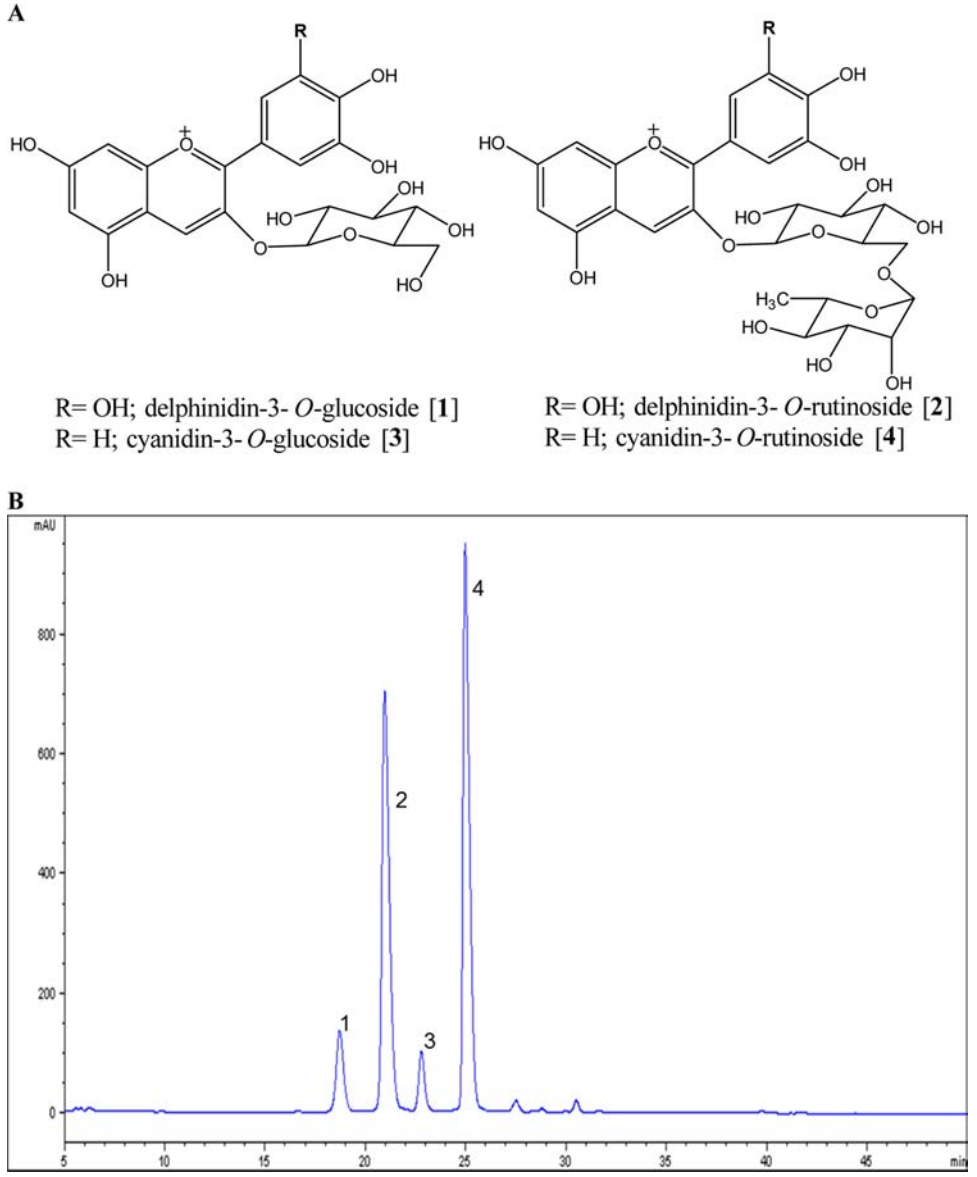

Figure 1. Chemical structures of black currant anthocyanins (A) and their respective HPLC-DAD chromatogram peaks. Peak numbers correspond to Table 1 and 2 labels.

equally distributed between cyanidin and delphinidin aglycones[24] and, therefore, provides an attractive model to investigate these differences. Moreover, anthocyanins represent the most abundant phenolic compounds in black currants, with other minor phenolics contributing to <5% of black currant powdered extract.[25] Protocatechuic and gallic acids are major breakdown metabolites of cyanidin- and delphinidin-type anthocyanins, respectively.[26]

The present study was designed to examine the preventive effect of anthocyanin-rich black currant extract on the development of obesity and hyperglycemia induced by feeding a high-fat diet in C57BL/6 mouse polygenic obesity model with intact and antibiotic-disrupted gut microbiome. Major anthocyanins and their phenolic acid metabolites were identified in feces and gastrointestinal tissue samples from these animals.

MATERIALS AND METHODS

Chemicals. The anthocyanins cyanidin- and delphinidin- 3-*O*-β-glucosides (HPLC grade standards) were purchased from Polyphenols Laboratories AS (Sandnes, Norway). All other chemical reagents and solvents were purchased from Sigma (St. Louis, MO, USA). A commercial black currant powdered extract (Active Cassis Extract 30) was kindly provided by Eddie Shiojima (Just the Berries, Palmerston North, New Zealand). Total anthocyanin content of the black currant powdered extract was 32.4%, and its anthocyanin composition was 41.4% delphinidin-3-*O*-rutinoside, 11.2% delphinidin-3-*O*-glucoside, 42.4% cyanidin-3-*O*-rutinoside, and 5.0% cyanidin-3-*O*-glucoside according to the manufacturer's certificate of analysis (Figure 1).

Animals and Diets. All animal experiments were performed according to procedures approved by the NC Research Campus Institutional Animal Care and Use Committee in the David H. Murdock Research Institute, an AAALAC accredited animal care facility.

Male, 6-week-old, C57BL/6J mice were purchased from Jackson Laboratory (Bar Harbor, ME, USA) and housed four animals per cage under controlled temperature (24 ± 2 °C) and light (12 h light−dark cycle, lights on at 7:00 a.m.). Immediately upon arrival, animals were

DOI: 10.1021/acs.jafc.5b00963
J. Agric. Food Chem. 2015, 63, 6172−6180

allowed to adapt to the new conditions for 7 days, and handling the animals was performed daily during this time to reduce the stress of physical manipulation. Mice were then randomized into ad libitum access to Research Diets (New Brunwick, NJ, USA) low 10 kcal% fat diet D12450J (LFD, 3.85 kcal/g, n = 24) or high 60 kcal% fat diet D12492 (HFD, 5.24 kcal/g, n = 24) and tap water for 6 weeks (weeks 1−6).

Lean and obese mice were further randomized to control low-fat diet (LFD, n = 8), control high-fat diet (HFD, n = 8), and the respective low-fat (LFD+C, n = 16) and high-fat (HFD+C, n = 16) black currant-supplemented treatment groups (1% black currant powdered extract, weight on g/kcal basis, incorporated in LFD or HFD diet by Research Diets). Because typical 24 h food intake for a C57BL/6 mouse is 2.5−3.0 g or 10−12 kcal/g body weight,[27] the animals were expected to consume an average of 25 mg/day of black currant powdered extract or 8 mg/day of black currant anthocyanins. Mice were kept on the respective diets for an additional 8 weeks (weeks 7−14). Animal weight and food intake (accounting for spillage) were recorded weekly for the duration of the study. All animal diets were kept at −80 °C for long-term storage and stability, and freshly thawed food was dispensed to animals every 3−4 days to limit phytochemical degradation in food matrix.

Antibiotic Knockdown of Endogenous Gut Microbiome. An antibiotic cocktail (0.5 g/L vancomycin, 1 g/L neomycin sulfate, 1 g/L metronidazole, 1 g/L ampicillin) previously shown to be sufficient to deplete all detectable commensal bacteria[28] was administered in drinking water ad libitum to half of the animals on LFD+C and HFD +C supplemented with black currant powdered extract (n = 8, LFD +CA and HFD+CA groups, respectively) for the entire duration of the black currant feeding study (weeks 7−14).

Oral Glucose and Insulin Tolerance Tests. For the oral glucose tolerance test, mice were fasted overnight (16 h) and received an oral gavage of D-glucose (1.5 g/kg body weight, Sigma). For the insulin tolerance test, mice were fasted for 4 h and received an intraperitoneal injection of insulin (0.75 U/kg body weight, Santa Cruz Biotechnology). Blood glucose concentrations were measured at 0, 15, 30, 60, and 120 min after glucose or insulin challenge in blood samples obtained from tail-tip bleedings, using a glucometer (Lifescan, Johnson and Johnson).

Sample Collection. Fecal samples from mice were collected, weighed, and pooled by cage midway (week 10) and at the end of the black currant feeding study (week 14) and stored at −80 °C. At the end of the experiment, blood was collected by heart puncture after CO_2 inhalation. Gastrointestinal tissues (stomach, duodenum, jejunum, ileum, cecum, and colon) and luminal digesta were collected and stored at −80 °C to determine the temporal sequence and signaling events that are responsible for changes in physiology and metabolism.

Anthocyanin and Metabolite Extraction. Anthocyanins were extracted from feces, gastrointestinal digesta, and gastrointestinal wall tissue using 60% aqueous methanol (1% trifluoroacetic acid acid) following a previously reported method for the rapid analysis of various anthocyanins in rats.[29]

HPLC and LC-MS Analysis. The phytochemical composition of ACE30 black currant powdered extract was analyzed in triplicate by LC-MS in positive mode (Agilent G1312B-1200 series Infinity Quaternary HPLC system coupled with Agilent 6530A accurate-mass quadrupole time-of-flight MS with Agilent Jet Stream source). Dry samples were reconstituted with 500 μL of 80% methanol, and 5 μL was injected onto an Agilent ZORBAX Eclipse Plus C18 column (3 × 100 mm, 1.8 μm). A gradient from 30% acetonitrile in 0.1% formic acid to 90% acetonitrile in 0.1% formic acid was used for HPLC separation. Mass data were acquired with the following parameters: drying gas temperature, 300 °C; drying gas flow, 7 L/min; nebulizer pressure, 40 psi; sheath gas temperature, 350 °C; sheath gas flow, 10 L/min; capillary voltage, 3500 V; nozzle voltage, 500 V; fragmentor voltage, 150 V; skimmer voltage, 65 V; octopole RF peak voltage, 750 V. Standard curves for compounds of interest were obtained in a linear dynamic range of 10−50000 pg and used for quantitative analysis. Peak area was determined by Agilent MassHunter Qualitative Analysis (version B.05.00) software.

Individual anthocyanins and phenolic acids were quantified by HPLC as described in our previous publication.[30] Briefly, filtered samples were injected (10 μL) into a 1200 HPLC system (Agilent Technologies) equipped with a UV−vis diode array detector (DAD), controlled-temperature autosampler (4 °C), and column compartment (30 °C) using a reversed-phase Supelcosil LC-18 column, 25 mm × 4.6 mm × 5 μm (Supelco, Bellefonte, PA, USA). Standard curves were calculated using peak areas at UV of 520 or 325 nm for anthocyanins (as cyanidin 3-O-glucoside or delphinidin 3-O-glucoside equivalents) or phenolic acids, respectively, and the known injected concentrations for the standards.

Statistics. Data were analyzed by one-way ANOVA followed by Dunnett's multiple-range tests using Prism 6.0 (GraphPad Software, San Diego, CA, USA). Body weight gain and glucose tolerance were analyzed by two-factor repeated-measures ANOVA, with time and treatment as independent variables. All data are presented as means ± SEM. Significant differences were accepted when the P value was <0.05.

RESULTS

Characterization of Black Currant Powdered Extract and Diets. The LC/JS-ESI/Q-TOF/MS was used for initial untargeted characterization and quantification of the major phytochemicals in ACE30 black currant powdered extract prior to food incorporation studies. Five major phytochemicals were identified in the extract (Table 1). Citric acid was a major weak organic acid present in the powdered extract in the amount of 279 mg/g. Total anthocyanin content of the extract was 323 mg/g, together with citric acid this accounted for 60% of components present in the ACE30 extract. Four anthocyanins were routinely quantified in the powdered extracts and tissue samples by subsequent HPLC-DAD analysis (Figure 1). ACE30 extract contained two cyanidin-based anthocyanins and two delphinidin-based anthocyanins in approximately equal amounts (153 vs 170 mg/g). On the other hand, 3-O-rutinosides were 5 times more abundant in the powdered extract as compared to their 3-O-glucoside counterparts (271 vs 52 mg/g). Anthocyanins represented the most abundant phenolic compounds in black currants, with other minor phenolics contributing to <5% of black currant powdered extract as shown by us previously.[25]

Table 1. Characterization and Quantification of Major Components in ACE30 Black Currant Powdered Extract Using LC-MS

peak	phytochemical composition	other name	m/z $[M]^+$	concentration (mg/g extract)
	citric acid		192	279
1	delphinidin-3-O-glucoside	mirtillin	465	36
2	delphinidin-3-O-rutinoside	tulipanin	611	134
3	cyanidin-3-O-glucoside	chrysanthemin	449	16
4	cyanidin-3-O-rutinoside	antirrhinin	595	137

Incorporation of ACE30 extract in animal food at the 1% level was performed at the same grams per kilocalorie basis (Table 2). Anthocyanin levels in the diet remained stable for at least 4 days at room temperature and for the duration of the study when diets were stored at −80 °C (data not shown).

[a]LFD, low-fat diet; HFD, high-fat diet.

Changes of Body Weight, Food Intake, and Food Efficiency. Six-week-old mice were fed LFD or HFD for 6 weeks to initiate development of obesity in the HFD animals (Figure 2). Next, the treatment groups were presented with anthocyanin-enriched diets and control (tap water) or antibiotic-supplemented tap water for an additional 8 weeks. There were no abnormal clinical signs throughout the entire study. After 14 weeks, mice fed HFD developed 48% larger body weights as compared to their LFD controls (30.8 vs 45.6 g, Figure 2A). Incorporation of 1% black currant powdered extract into the respective diets for 8 weeks resulted in 8−10% smaller body weights in animals receiving anthocyanin treatment, irrespective of fat content of the diet (LDF+C and HFD+C groups). However, body weight loss was absent in anthocyanin-treated animals with disrupted gut microbiome due to the addition of antibiotic cocktail to their drinking water (LFD+CA and HFD+CA groups, Figure 2B).

Food intake was not significantly different among all treatment groups and varied in the range of 2.4−3.0 g/mouse/day (Figure 2C). The caloric intake was significantly higher in HFD animals; however, neither supplementation with the black currant extract nor antibiotic cocktail affected food intake of the treatment animals respective to their controls (Figure 2D). Therefore, the data suggest that anthocyanin supplementation decreased mouse body weight without affecting the food or caloric intake.

Feed efficiency (%), calculated as (body weight gain/food intake) × 100 ratio, was higher in HFD groups (Figure 3). Supplementation with black currant powdered extract decreased feed efficiency in LFD+C and HFD+C mice. Upon disruption of gut microbiome with antibiotic cocktail in the drinking water, a trend to increase feed efficiency was observed in HFD+CA but not LFD+CA mice.

Anthocyanins in Fecal Samples. We observed the intense red/purple coloration of the small intestine, cecal, and fecal content samples only from anthocyanin-fed mice. HFD diet alone was responsible for a 20% increase in fecal pellet weight as compared to LFD controls. Neither anthocyanin treatment nor antibiotic cocktail supplementation changed the number or size of fecal pellet output in treated animals as compared to the respective LFD or HFD controls (Figure 4). Relative anthocyanins and their phenolic acid metabolite concentrations found in fecal samples after 4 and 8 weeks of treatment are summarized in Table 3.

No significant differences in metabolism or fecal output of anthocyanins or their respective phenolic acids were observed

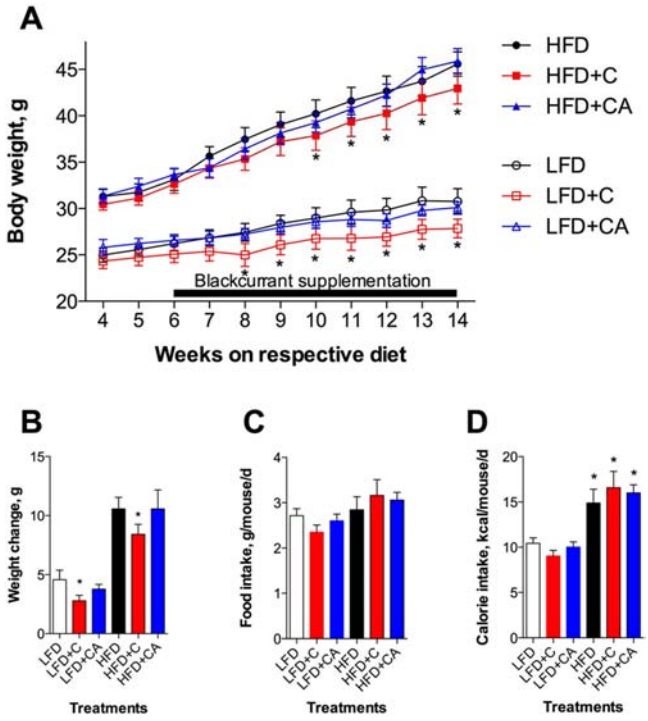

Figure 2. Effects of black currant and gut microbiome on body weight (A), body weight gain (B), food intake (C), and calorie intake (D) in the C57BL/6J mice. Six-week-old male mice were fed a low- or high-fat diet for 6 weeks. Lean and obese mice were further randomized to control low-fat diet (LFD), control high-fat diet (HFD), and the respective low-fat (LFD+C) and high-fat (HFD+C) black currant-supplemented treatment groups (1% black currant powdered extract incorporated in LFD or HFD) and kept on the same diet for an additional 8 weeks. An antibiotic cocktail was administered in drinking water ad libitum to half of the animals on black currant-supplemented treatment groups (LFD+CA and HFD+CA groups, respectively) for the entire duration of the black currant feeding study (weeks 7−14). Animal weight and food intake were recorded weekly for the duration of the study. Results are expressed as means ± SEM, $n = 8$. Body weight gain was analyzed by two-factor repeated-measures ANOVA, with time and treatment as independent variables. (∗) $P < 0.05$ versus respective LFD or HFD control. One-way ANOVA, Dunnett's post hoc test. Body weight gain was analyzed by two-factor, repeated-measures ANOVA, with time and treatment as independent variables.

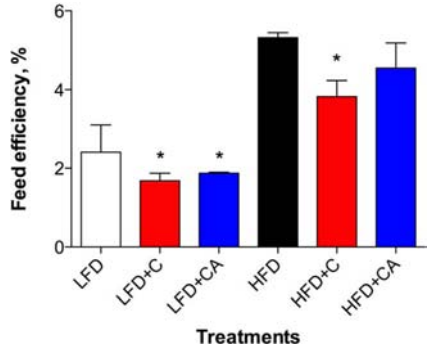

Figure 3. Effects of black currant and gut microbiome on feed efficiency in the C57BL/6J mice fed low- and high-fat diets. Animals received low-fat diet (LFD) or high-fat diet (HFD) or black currant-supplemented treatment groups (1% black currant extract) LFD+C or HFD+C for 8 weeks. Feed efficiency was calculated as (body weight gain/food intake) × 100 ratio. (∗) $P < 0.05$ versus respective LFD or HFD control. One-way ANOVA, Dunnett's post hoc test.

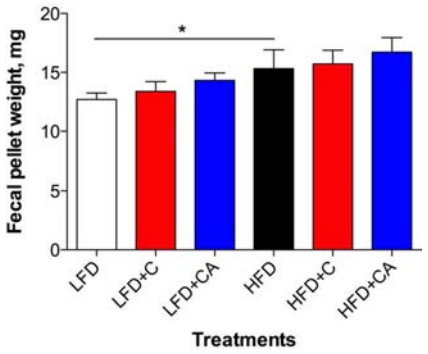

Figure 4. Effects of black currant and gut microbiome on fecal excretion in the C57BL/6J mice fed low- and high-fat diets. Animals received low-fat diet (LFD) or high-fat diet (HFD) or black currant-supplemented treatment groups (1% black currant extract incorporated in LFD or HFD; LFD+C or HFD+C) for 8 weeks. Results are expressed as means ± SEM. (*) $P < 0.05$ versus respective LFD or HFD control. One-way ANOVA, Dunnett's post hoc test.

between LFD+C and HFD+C treatments. Administration of antibiotic cocktail to LFD+CA and HFD+CA groups resulted in marked 16−25-fold increases in anthocyanin content of feces. The effect was more pronounced in lean animals, suggesting that the gut microbiome was more active at biotransformation of anthocyanins than in their obese counterparts. The 3-*O*-rutinosides seemed to be the most susceptible to microbial biotransformation (24−55-fold increases in lean and 16−28-fold increase in obese animals receiving antibiotic cocktail in drinking water for week 10 of the study). Among all molecules tested, cyanidin-type anthocyanins showed the most dramatic increase in fecal content upon disruption of gut microbiome (28−55-fold for week 10; 32−51-fold for week 14 of treatment).

We also observed a parallel decrease in phenolic acid metabolites in feces of antibiotic-treated animals. Both gallic acid (delphinidin-derived metabolite) and protocatechuic acid (cyanidin-derived metabolite) fecal contents decreased 2−4-fold depending on the time of analysis (Table 3).

Anthocyanins in Gastrointestinal Wall Tissues. Jejunum, cecum, and colon gastrointestinal wall tissues collected from each diet group were analyzed to compare anthocyanin and phenolic acid profiles. Anthocyanin ratio profiles from jejunum tissues were very similar to those in the original extract (Table 4). Administration of antibiotic cocktail to LFD+CA and HFD+CA groups resulted in marked 2−5-fold increases in anthocyanin content of jejunum tissues. The effect was more pronounced in lean animals (4−5-fold) versus obese mice (1.5−2-fold), suggesting that, once again, the intact gut microbiome was more active at biotransformation of anthocyanins. Even though cyanidin- and delphinidin-type anthocyanins were present in black currant powdered extract and diet in almost equal concentrations (Tables 1 and 2), a strong preference for selective absorption of gallic acid (delphinidin-derived metabolite) was evident as compared to protocatechuic acid (cyanidin-derived metabolite) levels in the jejunum walls (Table 4). An approximately 3-fold enrichment in gallic acid over protocatechuic acid was observed in the jejunum of lean LFD+C and LFD+CA mice, and this ratio dropped to <2-fold in obese HFD+C and HFD+CA animals. Because similar ratios were observed in both intact and antibiotic-treated animals, this effect was likely independent of gut microbiome.

Smaller amounts of anthocyanins were also observed in cecum (Table 5) and colon (Table 6) walls. A small parallel increase in anthocyanin and phenolic acid metabolite content was observed in the colon as animals LFD+CA and HFD+CA were treated with antibiotic cocktail; however, generally lower amounts of tissue metabolites suggested that these tissues were less likely to absorb the bioactive anthocyanins from diet. Phenolic acid content was increased in cecum tissue compared to jejunum tissue (with the exception of HFD+CA animals)

[a]n/d, not detected LFD+C, low-fat diet supplemented with black currant extract; LFD+CA, low-fat diet supplemented with black currant extract and antibiotic cocktail; HFD+C, high-fat diet supplemented with black currant extract; HFD+CA, high-fat diet supplemented with black currant extract and antibiotic cocktail.

and diminished below detection levels in the colon tissue. These data may reflect increased biotransformation of anthocyanins in the cecum and further degradation of phenolic acid metabolites into simple phenols in the colon.[23]

Effect on Glucose Metabolism and Insulin Sensitivity. Baseline blood glucose levels were measured at week 14 of the study after an overnight fast (Figure 5, time point 0 min). Black currant supplementation or gut microbiome disruption had no effect on blood glucose in animals on LFD (Figure 5A). Baseline blood glucose levels did not differ for HFD and HFD +C groups as well (Figure 5B). However, HFD+CA mice without functional gut microbiome showed a 45% increase in baseline blood glucose (284 mg/dL) versus HFD controls or HFD+C animals with black currant supplementation (193 mg/dL). The HFD group blood glucose levels were significantly higher at 30, 60, and 120 min after oral gavage as compared with the LFD mice, whereas the anthocyanin treatment (HFD +C) significantly reversed peak blood glucose concentration at 60 min (Figure 5B). Despite black currant supplementation, mice with disrupted gut microbiome (HFD+CA) showed high peak blood glucose values similar to those of untreated HFD controls (Figure 5B).

Insulin sensitivity was enhanced in LFD animals receiving black currant supplementation, even when their gut microbiome was suppressed by antibiotic cocktail (Figure 5C). HFD mice developed insulin resistance as expected, whereas black currant-supplemented HFD+C mice showed improved insulin sensitivity at 30, 60, and 120 min after insulin injection (Figure 5D). Suppression of gut microbiome had a dramatic negative effect on insulin sensitivity in HFD+CA animals: despite black

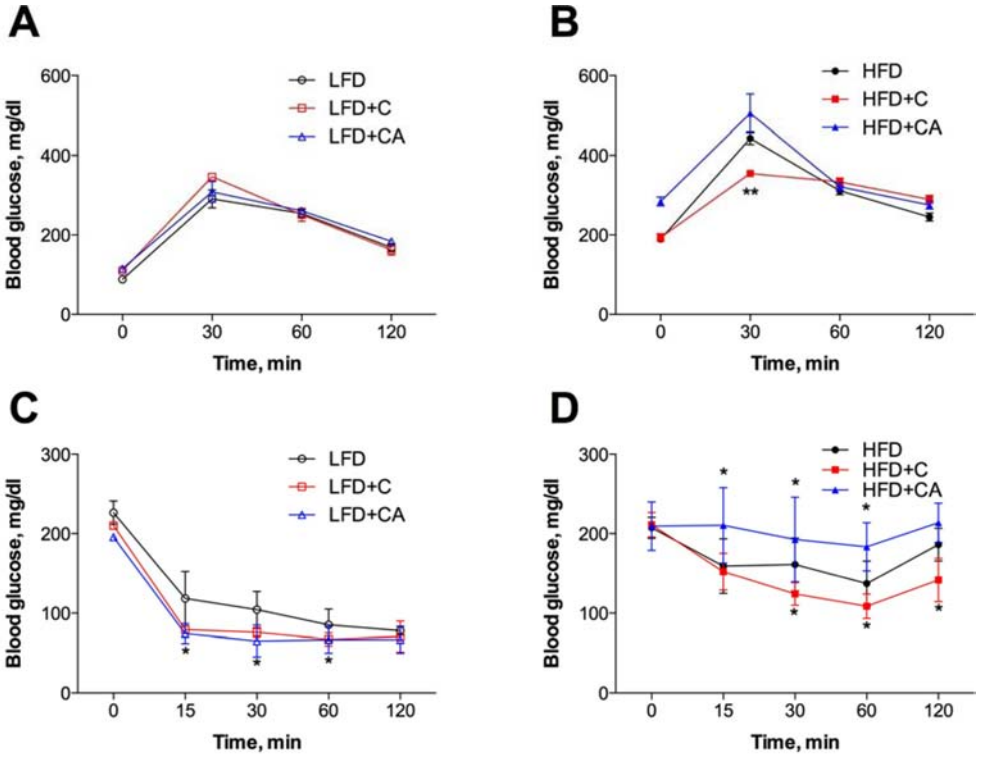

Figure 5. Chronic insulin-sensitizing effect of black currant supplementation on oral glucose tolerance test on low-fat diets (A) and high-fat diets (B) and insulin tolerance test on low-fat diets (C) and high-fat diets (D) in the C57BL/6J mice. Eight-week-old male mice were fed a low- or high-fat diet for 6 weeks. Lean and obese mice were further randomized to control low-fat diet (LFD), control high-fat diet (HFD), and the respective low-fat (LFD+C) and high-fat (HFD+C) black currant-supplemented treatment groups (1% black currant extract incorporated in LFD or HFD diet) and kept on the same diet for an additional 8 weeks. An antibiotic cocktail was administered in drinking water ad libitum to half of the animals on black currant-supplemented treatment groups (LFD+CA and HFD+CA groups, respectively) for the entire duration of the black currant feeding study (weeks 7−14). For oral glucose tolerance test, mice were fasted overnight (16 h) and received oral gavage of D-glucose (1.5 g/kg body weight). For insulin tolerance test, mice were fasted for 4 h and received intraperitoneal injection of insulin (0.75 U/kg body weight). Blood glucose concentrations were measured at 0, 15, 30, 60, and 120 min after glucose or insulin challenge in blood samples obtained from tail-tip bleedings, using a glucometer. Values are means ± SEM. (*) $P < 0.05$ and (**) $P < 0.01$ when compared with LFD or HFD control by one-way ANOVA followed by Dunnett's post hoc test.

currant supplementation, the insulin tolerance curve remained virtually flat for the duration of the testing, showing significant degree of insulin resistance at all time points tested (15−120 min).

DISCUSSION

Bioactive anthocyanins are of substantial health-promoting interest as their daily intake is 180−200 mg in the United States and may be significantly higher in other countries where more fruits and vegetables are consumed on a regular basis.[31] A single serving of anthocyanin-rich berries may contribute in excess of 100−200 mg of anthocyanins to a regular diet,[32] which is 5−10-fold higher than the daily intake of other flavonoids, such as quercetin or apigenin.[33] Anthocyanins are structurally diverse compounds that are present in plants in different concentrations and have various degrees of hydroxylation, methylation, glycosylation, and acylation.[3] This inherent diversity may be responsible for the lack of equivocal results from animal and human studies, because predominantly delphinidin- and malvidin-containing fruits are more likely to improve metabolic and cardiovascular disease risk biomarkers (i.e blueberry,[16] black currant and bilberry,[17,18] or grapes[19]), whereas cyanidin-based supplementation strategies offer less protection (i.e., elderberry,[20] blood orange,[21] or purple carrot[22]). In this study, we focused on the effects of black currant powdered extract on glucose metabolism and insulin sensitivity in diet-induced obese mice with intact and antibiotic-disrupted gut microbiome. The predominant flavonoids in the extract (Tables 1 and 2) were four anthocyanins that are equally distributed between cyanidin and delphinidin aglycones (Figure 1), in agreement with previously published data.[24] Anthocyanins represented the most abundant phenolic compounds in black currants, with other minor phenolics contributing to <5% of black currant powdered extract as shown by our previous work.[25]

Reduced body weight associated with 1% black currant powdered extract supplementation was observed together with no change in food intake (Figure 2). In this study mice consumed on average between 2.5 and 3.0 g food/animal/day, which is equal to ingestion of 8−10 mg/animal/day (300−400 mg/kg/day) of black currant anthocyanins. The human equivalent dose for this study was estimated at 25 mg/kg/day or 1.5 g/day of total anthocyanins for an average adult.[34] This dose was 8 times larger than an average anthocyanin intake in a regular U.S. diet[31] and could be achieved by incorporating 3−4 cups of fresh black currants (250−750 mg anthocyanins/100 g fruit)[35,36] or wild blueberries (350−550 mg anthocyanins/100 g fruit)[37] in the diet. Citric acid present in the black currant powdered extract was not likely to contribute to beneficial effects of black currant anthocyanin supplementation on obesity and metabolic disease, as obese patients show significantly

DOI: 10.1021/acs.jafc.5b00963
J. Agric. Food Chem. 2015, 63, 6172−6180

higher values in the level of citric acid as a result of natural changes in intermediate metabolism components associated with obesity.[38]

The majority of studies focusing on anthocyanin absorption have shown that the bioavailability of anthocyanins is low. The maximum black currant anthocyanin concentration in plasma reached 0.4 μM (t_{max} = 15 min) and returned to baseline after 7 h.[24] Gastrointestinal tissues, however, receive longer exposure time to anthocyanins that could increase their absorption in the tissue walls. Indeed, in this study we observed concentrations up to 35 and 111 μg/g anthocyanins in the jejunum tissue of LFD and HFD mice, respectively, and these levels increased to 154 and 195 μg/g tissue in antibiotic-treated animals (Table 4).

Anthocyanin concentrations were much lower in cecum and colon tissues, suggesting that black currant anthocyanins are maximally absorbed in the jejunum—a conclusion that is consistent with previous observations.[24] On the other hand, gallic and protocatechuic acid levels were highest in cecum and largely undetectable in colon tissues (Table 5). Even though cyanidin- and delphinidin-type anthocyanins were present in black currant extract and diet in almost equal concentrations, a strong preference for selective absorption of gallic acid was evident as compared to protocatechuic acid in the jejunum (Table 4). Because similar ratios were observed in both intact and antibiotic-treated animals, this effect was likely independent of gut microbiome.

We observed that the gut microbiome was crucial for the protective effect of black currant anthocyanins against obesity and associated insulin resistance (Figure 5). Indeed, germ-free HFD mice gained more weight than controls.[39] At the same time, addition of antibiotic cocktail to drinking water decreased anthocyanin biotransformation in the gut, which resulted in higher anthocyanin concentrations in the gastrointestinal tissues (Tables 4−6) and feces (Table 3). Cyanidin-based anthocyanins showed the most dramatic increase in fecal content upon disruption of gut microbiome, suggesting their high susceptibility to microbial degradation in the gut. At the same time, an approximately 3-fold enrichment in gallic acid (major delphinidin-derived metabolite) over protocatechuic acid (major cyanidin-derived metabolite) was observed in the jejunum of both intact and antibiotic-treated animals. These observations may explain why plants or foods rich in cyanidin-type anthocyanins are less effective in preventing metabolic and inflammatory disorders in animal and human studies. Higher gastrointestinal tissue levels of anthocyanins in antibiotic-treated animals, however, did not correlate with metabolic health outcomes, possibly indicating that not intact anthocyanins but their gut microbiome metabolites are partially responsible for these effects.

In conclusion, consumption of black currant powdered extract decreases weight gain of the LFD and HFD fed C57Bl/6J mice with healthy gut microbiome. Feces of gut microbiome-deficient mice showed an increase in anthocyanins and a decrease in their phenolic acid metabolites, whereas a corresponding increase was observed in the jejunum tissue. Cyanidin-type anthocyanins were much more sensitive to gut microbiome metabolism than delphinidins. Thus, gut microbiome was crucial for the protective effect of black currant anthocyanins against obesity and associated insulin resistance.
