Figure 1. CoMPP analysis of the CDTA (pectin) and NaOH (hemicellulose) fractions extracted from Pinotage skin AIR hydrolyzed with pure enzymes. The values in the heat map are the average of three biological samples and show the relative abundance of the different epitopes normalized to the highest signal in the data set, which was set to 100. The boxed sections indicate enzymes that caused extensive enzymatic hydrolysis. The enzymes that were used are described in Table 1, and the monoclonal antibodies are listed in the Supporting Information (Table S1).

MATERIALS AND METHODS

Pinotage Skin Cell Wall Preparation. *Vitis vinifera* cv Pinotage grapes were harvested in 2012 in the Boland wine-producing area of South Africa. The sugar concentration of the grapes was established from three random juice samples (50 mL each) to be 22.7 °B by using Fourier transform infrared (FT-IR) spectroscopy with a WineScan FT120 Basic (FOSS Analytical, Hillerød, Denmark) instrument. The scans were done in duplicate. Berries were sampled from bunches randomly selected from different harvest crates, and the berries were picked from the top, middle, and bottom of a bunch. The grapes were frozen at −20 °C before the skins were manually peeled with a scalpel and flash frozen with liquid nitrogen in 20 10 g (wet weight) batches. The frozen skins were kept at −80 °C and then freeze-dried. The freeze-dried skins were dry milled and homogenized with a Retsch MM400 mixer mill (Retsch, Haan, Germany) at 30 Hz for 30 s, and from the resulting powder, the cell wall or alcohol insoluble residue (AIR) was extracted. The AIR extraction method described by Ortega-Regules et al.[17] was followed except that the first acetone step after the buffered phenol extraction was omitted and after the third acetone wash, the AIR was air-dried, mixed with an equal volume of Milli-Q water, frozen at −80 °C, and then freeze-dried and stored for further analysis.

Enzymatic Hydrolysis of Pinotage AIR Using Purified Enzymes. A representative sample of AIR was obtained by mixing together 200 mg from each of the 20 AIR samples. From this pooled sample, 50 mg were used per reaction or biological repeat. The AIR was suspended in citrate phosphate buffer, pH 5 to form a 7.5% (w/v) suspension, and sodium azide was added at a final concentration of 0.02% (w/v) to prevent bacterial growth. The enzymes used in the experiment (Pect, EPG, EG, EA, and XG) are described in Table 1. A Thermo Scientific Pierce BCA Protein Assay (Thermo Fisher Scientific Inc., Waltham, MA) kit was used to determine the protein concentration of each enzyme. Enzymes were added in excess to ensure a potentially complete hydrolysis. Therefore, a dosage of 180 U/g dry matter of pectinase-containing enzymes (Pect and EPG) and 40 U/g of all other enzymes (EG, EA, and XG) were added individually or in combinations (EPG−EG; EPG−EG−EA; Pect−XG; Pect−EG). The reactions, performed in triplicate, were incubated at 40 °C for 48 h; after the

residual solids were washed with sterile distilled water, they were finally freeze-dried.

Cell Wall Profiling of AIR Samples. The monosaccharide composition of the AIR collected before and after enzyme hydrolysis was analyzed as described in ref 8. The acid hydrolysis was performed with 2 M TFA at 110 °C for 2 h. The monosaccharide composition was expressed as pM/mg AIR, and each biological repeat was analyzed twice with standard deviations in the tables representing the average of three biological samples.

One sample for each biological repeat (enzyme hydrolysis reaction) was analyzed with the CoMPP technique and entailed the sequential extracted of the pectin- and hemicellulose-rich fractions from 10 mg of AIR per sample, using the solvents diamino-cyclo-hexane-tetra-acetic acid (CDTA) and NaOH respectively.[13,18] The different fractions were printed on nitrocellulose membranes and probed individually with 26 different monoclonal antibodies (mAbs) and carbohydrate binding modules (CBMs) as previously described[18] and listed in Table S1 in the Supporting Information. A mean spot signal was calculated after it was normalized to the highest signal (set as 100) in the data set, and a cutoff value of 5 was used.

Univariate and Multivariate Data Analysis. Statistical significant differences in the results were determined with the unpaired *t*-test (95% confidence level). The patterns and main trends within the data were investigated with principal component analysis (PCA)[19] and partial least-squares projections to latent structures (PLS)[20] using SIMCA 13 software (Umetrics, Umeå, Sweden).

RESULTS AND DISCUSSION

The cell walls or AIR isolated from fresh, ripe Pinotage grape berry skins were incubated with a collection of purified enzymes (Table 1) under buffered conditions favoring the enzymes (pH 5, 40 °C) to evaluate the (maximum) potential and impact of hydrolysis on this matrix. By using isolated cell walls as substrate, the aim was to eliminate any potential interfering substances (e.g., high sugar concentrations, phenolics, tannins and organic acids present in grape juice) and improve the accessibility of enzymes to the target polysaccharides. The enzymes were chosen to degrade different polysaccharide targets, namely pectins, celluloses, and hemicelluloses, and the purified enzyme preparations exhibited these main activities, although most (except the xyloglucanase) also contained some lesser side activities (Table 1).

The AIR was analyzed using CoMPP analysis, and the results are presented as a heat map in Figure 1. The relative abundance of specific cell wall polysaccharides, extracted with either CDTA or NaOH, is presented as a percentage of the whole data set. The CDTA fraction of the control samples (no enzyme added) contained an abundance of pectin-type polymers (Figure 1), but as expected,[8] some xyloglucan (mAb LM25), arabinogalactan proteins (AGPs), and extensins were also present. The NaOH extraction of the control samples mainly dissolved hemicelluloses, with some cellulose (mAb CBM3a) and some unbranched rhamnogalacturonan-I (RG-I) also present. The monosaccharide composition (Table 2) of the control samples confirmed the abundance of galacturonic acid (GalA) followed by arabinose, a profile previously also shown in other grape cultivars.[9]

It was hypothesized that all the enzymes that were used would be able to depolymerize and/or fragment the grape cell wall polymers, leading to fragments diffusing out into the incubation buffer and therefore an overall reduction in levels of polymers and monosaccharides recorded by the different methods. However, such a universal reduction was not seen; some of the enzyme-treated samples showed an increase and others a decrease in relative abundance of polymers (evaluated with CoMPP analysis). Strikingly, in all the reactions in which the Pect enzyme was involved (CDTA fraction) there was a drastic decrease in the values for homogalacturonan (HG) epitopes (mAbs JIM5 and JIM7, LM19, and to a lesser degree LM18) compared to the control samples. The HG with very low methylesterification, recognized by mAb PAM1, was an exception with the values staying more or less stable with or without enzyme addition. On the other hand, enzyme treatments lead to a complete removal of RG-I (mAbs INRA-RU1 and INRA-RU2) and xyloglucan (mAb LM25). In contrast, all the other enzymes (EPG, EG, EA, XG, and combinations of these) nearly doubled the levels of HG (specifically mAbs JIM5 and JIM7) that could be extracted with CDTA from the AIR (Figure 1, CDTA fraction). The XG treatment delivered the highest values in HG (mAbs JIM5, JIM7, LM18, and LM19) compared to the control samples, possibly indicating that the hydrolysis of the xyloglucan that cross-links the cellulose microfibrils has an influence on the release of polymers from within the cell wall. The levels of unbranched RG-I (mAbs INRA-RU1 and INRA-RU2), xyloglucan (mAb LM25), and AGPs (mAb JIM13) were not altered by these enzymes (in contrast with Pect). The major epitopes recognized in the NaOH fraction were xyloglucan (mAbs LM15 and mAbs LM25), cellulose (mAb CBM3a), and extensins (mAb JIM20). Although all of the mAb INRA-RU2 labeled RG-I were removed, either by enzyme hydrolysis or during CDTA extraction, low quantities of mAb INRA-RU1 labeled RG-I could be extracted with NaOH (Figure 1, NaOH fraction). This was seen in the control as well as the EPG-, EG-, EA-, and XG-treated samples. Moreover, all enzyme treatments

J. Agric. Food Chem. 2015, 63, 8267−8274

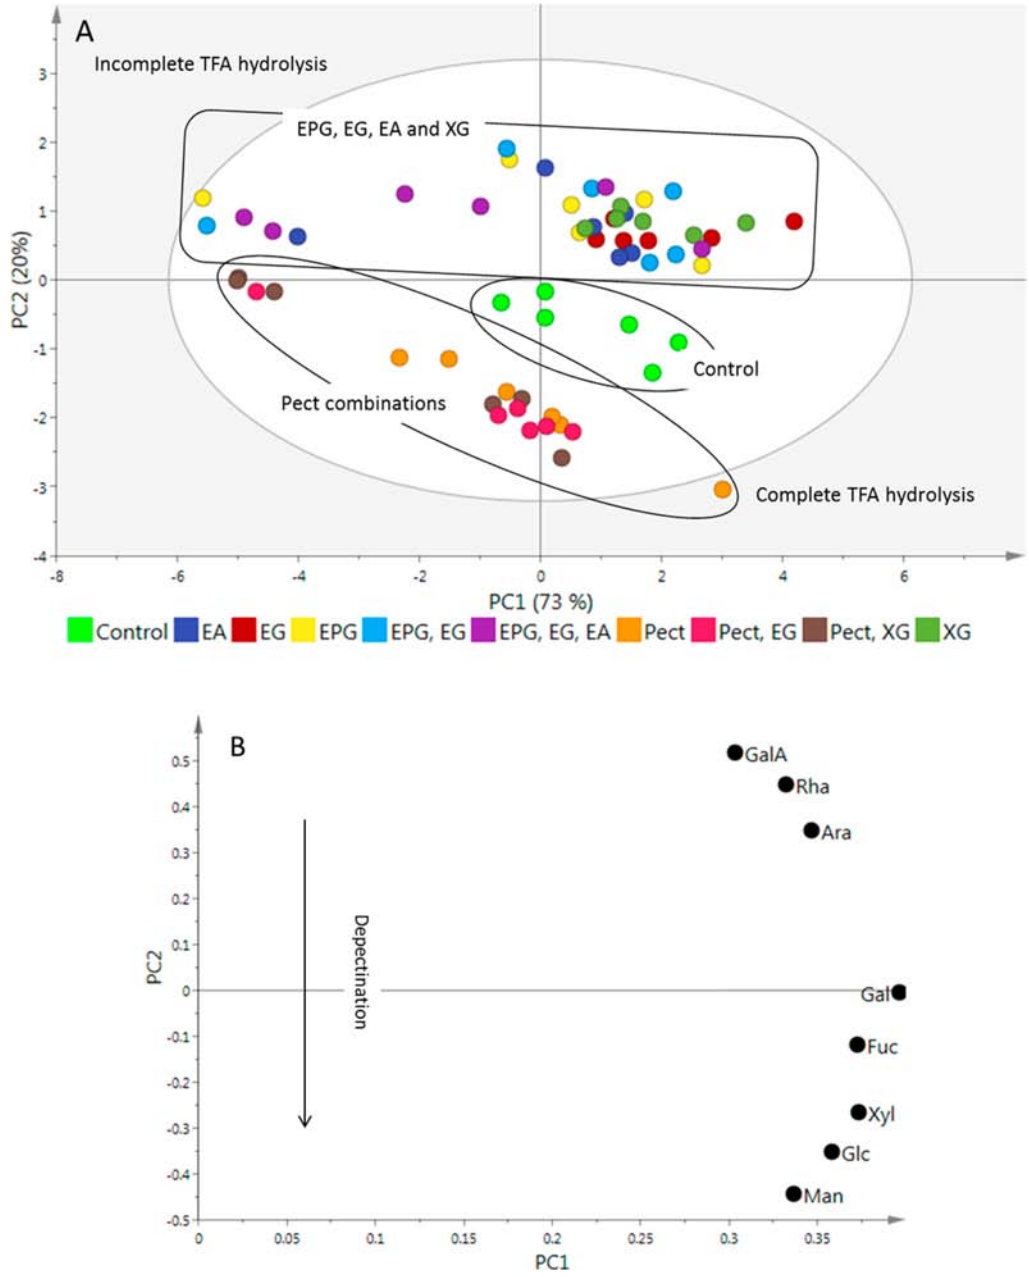

Figure 2. Principal component analysis (PCA) of the monosaccharide analysis on Pinotage AIR treated with pure enzymes. The score (A) and loading (B) plots show the variability in the efficiency of the TFA hydrolysis. The enzymes are described in Table 1.

increased the signal for extensins (mAb JIM20) compared to the control. These observations lead to two main conclusions (contextualized and discussed below): certain enzymes cause more complete hydrolysis than others, and some of the enzyme combinations have synergistic effects.

Synergistic Actions and Associations between Cell Wall Polymers, As Shown by the CoMPP Technique. Almost all the enzymes decreased the xyloglucan signals, presumably by removing some surface-exposed, pectin-associated xyloglucan due to pectin hydrolysis (EPG, Pect, and Pect–EG) or by direct xyloglucan hydrolysis (XG). The Pect–XG combination was the only treatment that increased both mAbs LM15 and LM25 labeling in the NaOH fraction compared to the control (Figure 1). Neither the XG nor the Pect enzymes on their own could show the same effect, confirming a synergism between the two enzymes under these conditions. Depectination by Pect probably facilitated better access for the XG enzyme to its target, leading to xyloglucan hydrolysis and an increased extraction (with NaOH) of partially degraded xyloglucan from within the hemicellulose–cellulose structure. We know plant cell wall xyloglucan is shielded by pectin,[21] but this synergistic effect between pectinases and xylanases has not been shown previously (to our knowledge) in grape tissues, and it is the first time that CoMPP was used to demonstrate such synergism. This interesting aspect could benefit from further investigation because according to a study by Hu et al.[22] synergistic effects are highly substrate-specific and also depend on the substrate preparation.

The enzyme hydrolysis in combination with the sequential extraction steps, as used in CoMPP analysis, provided the ability to identify possible associations between the cell wall polymers of the grape berry skins. For example, AGPs recognized by mAb

DOI: 10.1021/acs.jafc.5b02847
J. Agric. Food Chem. 2015, 63, 8267–8274

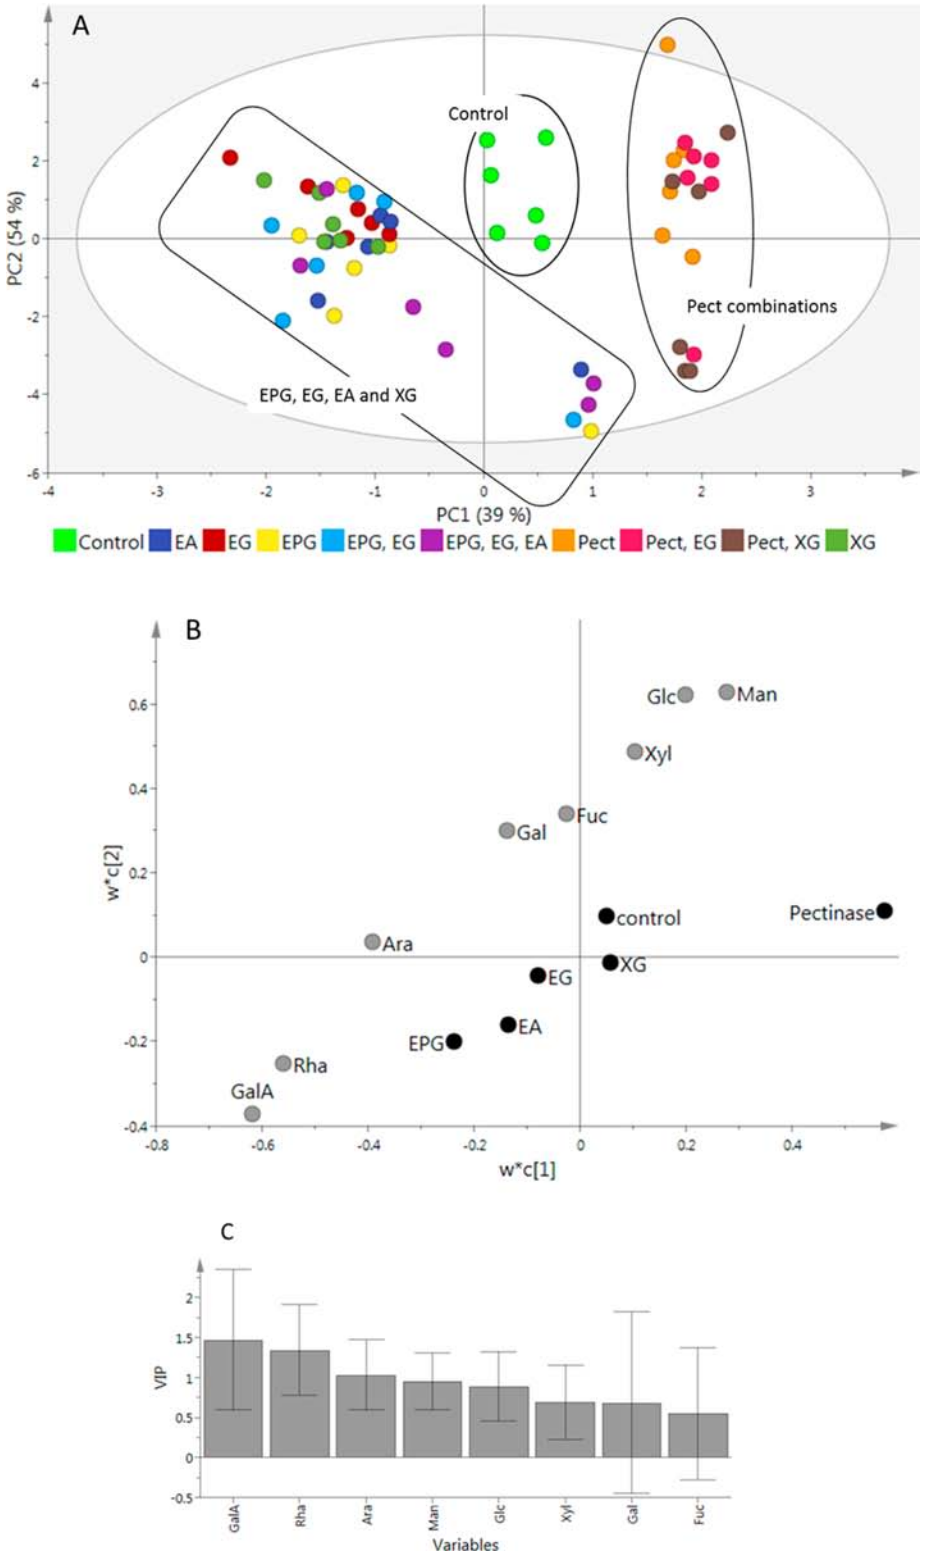

Figure 3. PLS (partial least-squares projections to latent structures) score (A) and loading plot (B) of the monosaccharide analysis of Pinotage AIR treated with pure enzymes show the Pect-treated samples separating from the other samples because of an abundance of Man and Glc and a scarcity of GalA, Rha, and GlcA. (C) VIP plot (variable importance for the projection) is an interpretation tool that summarizes the importance of variables in a PLS model, and a VIP value grater than 1 indicates that a variable has an above average influence on the model. The VIP plot indicated that GalA, followed by Rha and Ara were the most important contributors toward the configuration of the samples in the PLS plot.

JIM13 were reduced by Pect action (Figure 1), and the labeling pattern was similar to mAb INRA-RU1. This can indicate that these AGPs are bound to pectin polymers (as previously reported in other plants[23−25]) and subsequently removed during pectin hydrolysis. It might also just confirm the hydrolysis of RG-I because it should be noted that mAb JIM13 showed cross reactivity with RG-I of sycamore maple.[26] Another example is the association between the RG-I (specifically mAb INRA-RU1) and

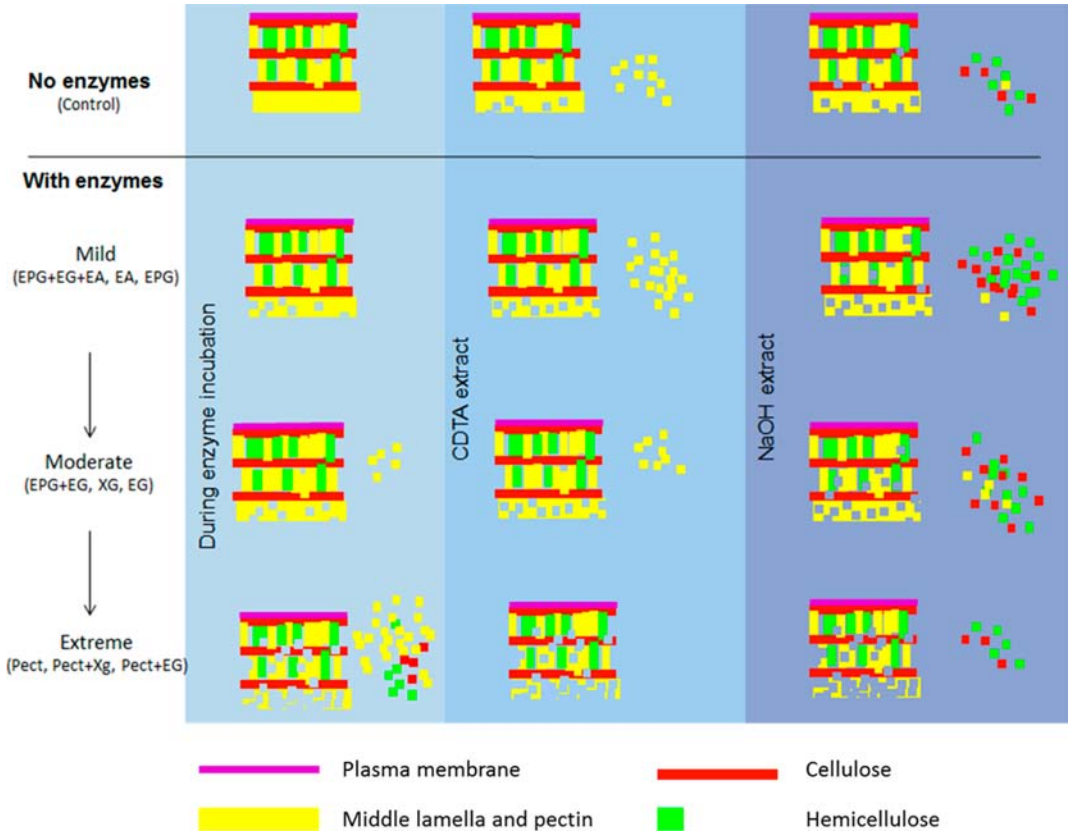

Figure 4. Schematic presentation (not to scale) of a section of the grape skin cell wall showing the presumed changes to the cell wall composition during enzyme hydrolysis and extraction with CDTA and NaOH. The colored blocks represent the polymers removed by enzymes and/or extraction solutions. Mild degradation is typified by pore formation and is seen with CoMPP analysis as an enhancement in the CDTA extract. As the degradation advances (longer incubation or more effective enzymes), smaller degradation products were removed during the enzyme hydrolysis step, resulting in a decrease in polymers that could be extracted. With moderate degradation, the pores presumably became large enough for the enzymes to penetrate the cell wall and break up hemicellulose polymers. At first those partially degraded polymers could only be removed from within the cell wall framework by extraction with NaOH. If the degradation proceeds far enough (pores are large enough and/or polymer size reduction went far enough), those partially degraded polymers will diffuse out unassisted during the enzymatic hydrolysis step.

xyloglucan; xyloglucan (specifically mAb LM25) is found in the pectin fraction, and similarly a signal for mAb INRA-RU1 was detectable in the NaOH fraction (even after enzyme hydrolysis and extraction with CDTA) which was probably a confirmation of the xyloglucan−pectin association found in grape[27] and other plant cell walls.[28,29] Similar results were also obtained in a profiling and fractionation study on berry cell wall extracts from pomace of Cabernet Sauvignon under wine-fermentation conditions.[30] Interestingly, the RG-I labeled by mAb INRA-RU2 (that has more galactosyl side chains than INRA-RU1 labeled RG-I) were absent in the NaOH fraction. Furthermore, the relative abundance of xyloglucan (mAb LM25) and RG-I (mAbs INRA-RU1 and INRA-RU2) was similarly influenced by the different enzyme treatments and concomitantly removed, but there was no resemblance between mAb LM25 and HG labeling patterns, which is an additional indication of a xyloglucan−RG-I specific association in grape berry tissue.

The Degree or Extent of Enzymatic Hydrolysis Influences the Cell Wall Composition. The monosaccharide compositional analysis of the AIR samples after enzyme hydrolysis revealed some interesting results (Table 2). Compared to the control samples, Pect−XG hydrolysis led to a decrease (statistically significant, 95% confidence interval) in Ara (arabinose) while Pect−XG and Pect−EG decreased the Rha (rhamnose) values. This corresponded well with the decrease in unbranched RG-I and AGPs (CoMPP analysis, Figure 1) of the Pect enzyme-treated samples. In addition, the Pect and Pect combination treatments caused a decrease in GalA (galacturonic acid) which could be attributed to depectination, and this was confirmed by the decrease in the signal for all the HG polymers (except mAb PAM1). In contrast, all the other enzymes caused an increase in GalA monosaccharides. An increase (compared to the control samples) in the monosaccharide concentration is only possible if it is accepted that incomplete TFA hydrolysis took place during the preparation steps prior to gas chromatography−mass spectrometry (GC-MS) monosaccharide analysis. Acid hydrolysis conditions for pectin-rich samples present a compromise between GalA and neutral sugar yields because of the difference in the susceptibility to acids demonstrated by different glycoside bonds.[31]

This incomplete acid hydrolysis took place in the control samples, but in contrast, the AIR samples treated with EPG, EG, EA, and XG were already partially hydrolyzed or unravelled. This led to a more complete acid hydrolysis by allowing better access for the TFA to penetrate the AIR particles, delivering quantities of monosaccharides that were higher than those of the control samples. This unravelling and rendering of access to the inner cell wall spaces by the action of the EPG, EG, EA, and XG enzymes were also demonstrated with the CoMPP results (Figure 1). In the case of the Pect-treated samples, the enzymatic hydrolysis

DOI: 10.1021/acs.jafc.5b02847
J. Agric. Food Chem. 2015, 63, 8267−8274

already removed a large fraction of the pectin cell wall polymers (HG and RG-I), which was probably enhanced by the presence of pectin esterase activity in the Pect preparation (Table 1). The residue remaining after enzyme hydrolysis thus contained less GalA. We therefore presume that complete acid hydrolysis could take place in the Pect samples by virtue of extensive enzymatic degradation and unravelling. Our findings are supported by the results of Wikiera et al.[32] who compared the GalA yields from apple pomace when using acid hydrolysis (2 M TFA, 100 °C, 2 h) against an enzyme and acid hydrolysis combination (0.2 M TFA, 80 °C, 72 h) and found that the latter resulted in higher yields of GalA.

Multivariate data analysis of monosaccharide composition of the samples revealed (PCA plot, Figure 2) the Pect-treated samples loosely grouped in the bottom half of the plot. The control samples formed a second group in the middle, and the rest of the samples were spread out along the top half of the plot. The spread of all the samples along the first component axis (PC1, 73%) illustrates the variation in the efficiency of the TFA hydrolysis which led to differences in the monosaccharide values (pM/mg AIR) recorded. Further analyses were done using a partial least squares (PLS)[20] (Figure 3) plot, which is a regression technique for modeling the association between two sets of variables and has the ability to analyze noisy, collinear, and incomplete sets of variables. The PLS analysis confirms the depectination that took place because of the influence of the Pect enzyme preparation with the latter being on opposite sides of the loading plot (Figure 3B) from GalA and Rha. This is supported by variable importance for the projection (VIP) plot (Figure 3C) that identified GalA followed by Rha as the principal influence for the configuration of the variables in the PLS plot.

The CoMPP results in combination with the monosaccharide analysis allowed "a view" of the cell walls (AIR) of Pinotage grape skins in which there were some HG, unbranched RG-I, xyloglucan (mAb LM25-binding motifs only), AGPs, and extensins exposed on the surface of the AIR particles (as confirmed with the results of the no enzyme treatment). During the CDTA extraction, the pectins and associated compounds were removed from the surface area of the AIR particles. When the extraction was preceded by enzymatic hydrolysis, the composition of the extracted fraction depended on the extent of the hydrolysis that took place (Figure 4). Extensive hydrolysis (as seen with Pect-treated samples), removed some AGPs and more or less all pectin polymers except some HG (labeled by mAbs PAM1, LM18, and LM19), which correlates with the low levels of GalA and Rha measured in these samples. This implies that the polymers were enzymatically reduced in size to the extent that the fragments could diffuse out from within the AIR particles and were subsequently removed at the end of the enzyme hydrolysis period. With less extensive enzyme hydrolysis (EPG, EG, EA, XG, and combinations of these enzymes), some of the bonds between the cell wall polysaccharides were broken but not enough to allow the removal of polymers into the hydrolysis buffer, as was seen with the Pect enzymes. Instead, it is better described as an "opening up" action, or unravelling and partial degradation of the AIR structure to allow better access for the CDTA in the subsequent extraction step to dissolve the pectins (HG extraction is enhanced) from the surface and subsurface layers of the particle leading to an increase in the abundance of these polymers in the CDTA extract. This is in contrast with the control samples in which only the outer pectin-rich layers were dissolved. This unravelling action is similar to our previous results[8] in the cell walls from Pinotage skins retrieved from fermentations supplemented with commercial maceration enzymes. The results indicate (Table 2, Figure 1) that depectination by both extreme and mild enzymatic hydrolysis unmasked the core hemicellulose−cellulose framework, and this presumably enabled cellulases and hemicellulases to remove some of the xyloglucan and cellulose (lower values than the control samples in the NaOH fraction (Figure 1) (except Pect−XG as discussed previously). This demonstration (Figure 4) of the different levels of enzymatic hydrolysis on grape skin cell walls provides a unique perspective, also confirming CoMPP as an effective method to evaluate different enzyme combinations and enzyme types for grape tissue degradation.

In summary, The CoMPP analyses proved to be a valuable, sensitive, and high-throughput method to trace modifications in the polymers of grape berries' cell walls. It highlighted synergism between different enzymes and gave indications of polymer associations. Furthermore, we could distinguish different levels of enzymatic hydrolysis and provide a "view" of how the skin cell walls are impacted by these hydrolyses. For future work it might be informative to use different enzyme-to-AIR ratios to study the effect of enzyme loading and improve the observation of subtle differences. It would also be valuable to repeat this study under winemaking conditions (pH 3−4, 18−25 °C) to determine the extent and influence of enzyme inhibition on the results. This study provided us with a new method for evaluating different enzymes or enzyme combinations as well as tests the effect of enzymes on different substrates or different incubation conditions. It could be a valuable tool to use not only in the development of enzyme preparations for the wine industry but also in industries in which enzymes are used for the degradation of plant tissues.

bonds of their substrates, thus being capable of giving rise to a variety of analogous volatile norisoprenoids.[13,22,30] Plant CCDs can be classified into six subfamilies according to the cleavage position and/or their substrate preferences: CCD1, CCD2, CCD4, CCD7, CCD8, and 9-cis-epoxy-carotenoid dioxygenases (NCEDs).[13,14,22,31] Plant CCD1 and CCD4 appear to be primarily functioning in the biosynthesis of norisoprenoid components of flavor, aroma, and pigmentation of fruits and flowers.[32] Recently, a novel CCD2 was identified and characterized from *Crocus sativus* that catalyzes the first dedicated step in crocin biosynthesis.[22] Conversely, CCD7 and CCD8 appear to be dedicated to the biosynthesis of strigolactones, plant growth regulators impacting several important physiological processes such as shoot branching and development of arbuscular mycorrhizae.[18−20] Finally, all NCEDs, which are only distantly related to CCDs, play a role in the biosynthesis of abscisic acid by producing its C15-precursor xanthotoxin from the 9-*cis* isomers of epoxy-carotenoids.[33]

The present study describes the carotenoid accumulation, norisoprenoid content, transcript level, and the isolation of a *CCD1* gene from fruits of *L. nobilis* (*LnCCD1*). To characterize the catalytic activity of *LnCCD1*, the gene was isolated and functionally expressed in *Escherichia coli*. The recombinant protein was assayed for cleavage activity with a variety of carotenoid substrates. To study the possible involvement of LnCCD1 in the synthesis of norisoprenoids flavor compounds, the expression pattern of this gene was determined in the fruit of *L. nobilis* by real-time-PCR.

MATERIALS AND METHODS

Chemicals. HPLC-grade acetonitrile, methanol, acetone, α-ionone, β-ionone, lycopene, lutein, and α- and β-carotenes were purchased from Sigma-Aldrich.

Plant Material. *Laurus nobilis* plants were grown in the "Newe Yaar" Research Center in northern Israel, under standard field irrigation and fertigation conditions. Pericarps of freshly harvested green and black fruits were crushed in liquid nitrogen and stored at −80 °C for analysis of carotenoids, norisoprenoid volatiles, and transcripts.

Carotenoid Extraction. Carotenoids were extracted by grinding fresh *L. nobilis* pericarp of green and black fruits (100 mg) in acetone. The solvent was collected and filtered and the grinding and collecting of solvent repeated until the solvent was colorless. Acetone was dried under a stream of N_2 and then redissolved in 1 mL of acetone. 100 μL of the sample in acetone was diluted 10 times and spared for spectroscopic quantification. The rest of the sample was again dried under a stream of N_2 and redissolved in acetone for further analysis by HPLC.

HPLC Analyses and Carotenoid Quantification. HPLC analysis was performed on a Waters HPLC system equipped with a Waters 600 pump, a Waters PDA detector 996, and a Waters 717 plus autosampler. A Spherisorb ODS2 C18 column (Waters, 5 μm, 4.6 × 250 mm) coupled to a guard cartridge system SecurityGuard (Phenomenex) was used. Gradient was applied at a constant flow of 1.6 mL/min with acetonitrile:water (9:1; A) and ethyl acetate (B) as described in Isaacson et al. (2004).[34] Data were collected in the range of 250−600 nm, and analyzed using the Empower software. Quantification of carotenoids was done spectroscopically on the diluted carotenoid sample in acetone.[35] Phytoene quantification was done by normalizing its integrated peak at 286 nm to correct for its specific mass extinction coefficient relative to β-carotene (factor of 2.074).

Extraction of Volatile Compounds from Fruits of *L. nobilis*. Three replicates of fresh *L. nobilis* pericarp of green and black fruits (1 g) were ground into a homogeneous powder under liquid nitrogen using mortar and pestle. The fine powders were placed in a 20 mL DuPont autosampler vial (DuPont Performance Elastomers, http://www.dupontelastomers.com) with a white solid-top polypropylene cap (Alltech, http://www.alltech.com). Samples were overlaid with 5 mL of NaCl (25%) solution and 1 g of NaCl (for inhibition of enzyme activity). To each sample, the internal standard 2-heptenone was added to produce a final concentration of 1 mg/kg (1 ppm). After incubation at room temperature (25 °C) for 1 h, the volatile compounds were collected with a solid phase micro extraction (SPME) device PDMS-100 with a polydimethylsiloxane fiber (Sigma-Aldrich) by inserting the fiber into the tube and leaving it in place for 20 min at room temperature. After this incubation step, the SPME fiber was injected directly into the GC−MS.

Auto-HS-SPME-GC−MS Analysis of Volatile Compounds. Volatile compounds were analyzed on a GC−MS apparatus (Agilent Technologies, CA) equipped with an Rtx-5SIL MS (30 m × 0.25 mm × 0.25 μm) fused-silica capillary column essentially as described by Yahyaa et al. (2015).[36] Briefly, He_2 (1 mL min^{-1}) was used as a carrier gas. The injector temperature was 250 °C, set for splitless injection. The oven was set to 50 °C for 1 min, and then the temperature was increased to 220 °C at a rate of 5 °C min^{-1}. For SPME analysis, thermal desorption was allowed for 40 min. The detector temperature was 280 °C. The mass range was recorded from 41 to 450 m/z, with electron energy of 70 eV. Identification of the main components was done by comparison of mass spectra and retention times with those of authentic standards and supplemented with a Wiley GC−MS library.

Isolation and Characterization of *L. nobilis* Fruit Carotenoid Cleavage Dioxygenase-1. Putative *L. nobilis* CCD encoding genes were searched for using a homology-based algorithm in the transcriptome database of *L. nobilis*, which has been assembled on the basis of available GenBank sequence data entries. A single full-length gene was tentatively identified as *L. nobilis* carotenoid cleavage dioxygenase-1 (*Ln*CCD1). Two specific primers corresponding to the *LnCCD1* protein-coding sequence 5′-end (5′-ATG GAG AAG GAA AAT GGA A-3′) and 3′-end (5′-CTT TCC CTG TTG TTG AAG TTG TTC C-3′) were designed. RNA from *L. nobilis* pericarp of the green and black fruits was isolated using the Spectrum Plant Total RNA Kit (Sigma-Adlich). For producing a cDNA clone, 5 μg of total RNA from fruits of *L. nobilis* was reverse transcribed using the SuperScript One-Step RT-PCR with Platinum *Taq* DNA polymerase (Invitrogen) used for amplification, yielding a 1650 bp specific fragment. The cDNA was inserted into the pEXP5-CT/TOPO TA expression vector (Invitrogen Corporation, Carlsbad, CA), yielding pEXP-*LnCCD1* in which the LnCCD1 coding sequence was fused with a His tag-coding extension at the C-terminus. The construct was introduced into *E. coli* Top10 cells. The constructs' fidelity and orientation of the inset in the vector were verified by DNA sequencing.

Functional Expression Experiments and Determination of Volatiles from Bacterial Headspace. *E. coli* strains engineered to accumulate phytoene (pBCAR-EB), lycopene (pBCAR-EBI), β-carotene (pBCAR-EBIY), δ-carotene (pDCAR), and zeaxanthin (pZEAX) were transformed with the expression construct pEXP-*LnCCD1*.[37,38]

Production of the recombinant protein was induced by IPTG, and the volatiles were collected by SPME and analyzed by GC−MS, respectively, as described by Yahyaa et al., 2013.[39]

***LnCCD1* Transcript Analysis.** For real-time RT-PCR analysis of *LnCCD1*, total RNA (5 μg) from *L. nobilis* pericarp of green and black fruits was extracted (Spectrum Plant Total RNA Kit, Sigma-Aldrich) and reverse transcribed using an oligo$(dT)_{12-18}$ primer and the SuperScript II first-strand system (Invitrogen). RNA quality and quantity were determined by using agarose gel electrophoresis, and the concentrations were measured using the NanoDrop ND-1000 spectrophotometer (Bargal Analytical Instruments). To remove the trace amounts of genomic DNA during RNA purification from RNA preparations, On-Column DNase I Digest Set was applied (Sigma-Aldrich).

Real-time RT-PCR was performed on an Applied Biosystem StepOnePlus Real-Time PCR System (Life technology) using ABsolute Blue qPCR SYBR Green ROX Mix (Tamar Laboratory

DOI: 10.1021/acs.jafc.5b02941
J. Agric. Food Chem. 2015, 63, 8275−8282

Supplies Ltd., Israel), using 5 ng of reverse-translated total RNA and 100 ng of primers.

Primers for *LnCCD1* were LnCCD1_F_qPCR (5′-AGT CTT ACA CAG GCA GGA AAC-3′) and LnCCD1_R_qPCR (5′-CAA ACT TGA TGA TGC CCT TCA C-3′). A relative quantification of gene expression was performed using actin from *L. nobilis* as a reference gene. The following actin primers were used as positive controls: Actin-F-qPCR (5′- GTG AGC TGA GGC TTG ATT GA-3′) and Actin-R-qPCR (5′- TCG ACC CAA GTA CAC AGA CTA-3′). Differences in relative expression levels of LnCCD1 were calculated from 2-ΔΔCt value after normalization of LnCCD1 data to actin. All analyses were performed using three biological replicates.

RESULTS AND DISCUSSION

Carotenoid Pigmentation Patterns of *L. nobilis* Influence Fruit Norisoprenoid Volatile Composition. We previously demonstrated that variation in terpenoid volatiles accumulation in different *L. nobilis* tissues is organ and gender dependent.[9] Also, variation in total content of *L. nobilis* green and black fruits terpenes has been reported.[8,9] However, to the best of our knowledge, the influence of carotenoid composition on volatile norisoprenoid accumulation in fresh *L. nobilis* pericarp of green and black fruits has never been shown. Therefore, it was of interest to analyze the carotenoid content of fresh *L. nobilis* pericarp of green and black fruits and the norisoprenoid volatiles using HPLC and GC−MS, respectively. The main carotenoid found in *L. nobilis* pericarp of the green and black fruits is lutein (Table 1). The content of β-carotene, zeaxanthin, antherexanthin, violaxanthin, and neoxanthin was different in pericarp of the green and black bay laurel fruits. The total carotenoid level in green fruits of *L. nobilis* was 2-fold higher than that found in the black fruits (Table 1). A drastic and marked decrease of the β-carotene and lutein contents was found during fruit development (in the black fruit). In accordance, our analyses showed that norisoprenoid volatiles such as 6-methyl-5-hepten-2-one (MHO), pseudoionone, and β-ionone are present only in the fresh pericarp of the black *L. nobilis* fruits (Table 1). Of particular interest is the fact that the levels of MHO, pseudoionone, and β-ionone, which could be derived from the breakdown of lycopene, α-carotene, and β-carotene, were correlated with the β-carotene content in the black fruits (Table 1).

Table 1. Carotenoids and Norisoprenoid Volatiles in *Laurus nobilis* Fruits

	green fruits	black fruits
Carotenoid[a] Content (μg g^{-1} of FW)		
β-carotene	38.51 ± 0.54	13.70 ± 1.4
zeaxanthin	0.42 ± 0.09	0.20 ± 0.05
lutein	83.25 ± 0.95	33.07 ± 3.67
antheraxanthin	8.88 ± 1.45	9.59 ± 2.47
violaxanthin	6.65 ± 0.50	4.92 ± 0.34
neoxanthin	7.58 ± 0.28	7.36 ± 1.05
total	145.29 ± 0.63	68.84 ± 1.49
Norisoprenoid[b] Compounds (ng g^{-1} of FW)		
6-methyl-5-hepten-2-one	nd	51.2 ± 5.1
pseudoionone	nd	48.7 ± 14.9
β-ionone	nd	31.6 ± 0.9

[a]Carotenoid standards were identified by HPLC on the basis of commercial standards. [b]Norisoprenoid compounds were identified by GC−MS on the basis of reference volatiles. The results shown are an average and standard errors of at least three biological replicates. nd = not detected.

Many volatiles are produced in plant tissues at specific developmental stages, for example, during flowering, ripening, or maturation. Although a single fruit synthesizes several hundred volatiles, only a small subset generates the "flavor fingerprint" that helps animals and humans recognize appropriate foods and avoid poor or dangerous food choices.[40]

β-Ionone is widely distributed in plants and is considered an important and potent flavor contributor in many fruits and fruit-based foods, due to its extremely low odor thresholds (0.007 ppb).[28,39,41] MHO is also an important flavor and aroma volatile found in a number of fruits such as tomato.[42] MHO is present as a component of the floral scent of numerous plants, occurring in over 50% of 991 species of flowering plants that had their floral scent analyzed.[43]

Our data presented above indicate that norisoprenoid volatiles found in the fresh *L. nobilis* pericarp black fruits indeed originate from the oxidative degradation of carotenoids as the main route, as it also is in many other plants, for example, in carrots and melon,[28,39] in watermelon and tomato,[29,44] in strawberry,[45] in *Rosa damascena*,[46] in pepper,[27] and in *Crocus sativus*.[22] Also, the function of fruit volatiles as a signal of ripeness and as an attractant for seed-dispersing organisms is supported by the fact that some substances are specifically formed by ripe fruits but are absent in vegetative tissues and nonripe fruit (Table 1). Unlike ripe fruits and flowers, vegetative tissues often produce and release many of the volatiles sensed as flavors only after their cells are disrupted.

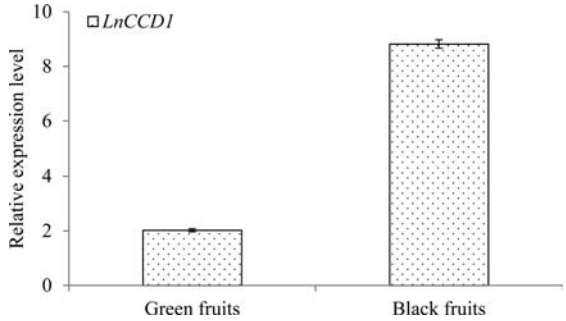

Figure 1. Expression patterns of *LnCCD1* in green and black fruits of *L. nobilis*. Quantification of *LnCCD1* transcript levels by real-time RT-PCR analysis normalized to actin transcripts. All analyses were performed using three biological replicates.

Expression Patterns of *LnCCD1* in Fruits of *L. nobilis*. The expression pattern of the *LnCCD1* gene along fruit development (green and black fruits) was examined by real-time RT-PCR (Figure 1). The expression level of the *LnCCD1* gene in black fruits was 6-fold higher than that found in the green fruits (Figure 1). Moreover, a significant correlation was observed between increase of the expression level of *LnCCD1* and the accumulation of norisoprenoids during fruits development and the decrease of β-carotene content (Table 1 and Figure 1).

In our analysis of norisoprenoid volatiles in *L. nobilis* green and black fruits, we were not able to detect volatile norisoprenoids in the green fruits (Table 1). Thus, we cannot conclude that the *LnCCD1* gene expression in *L. nobilis* green fruits is related to the production of norisoprenoids. However, a lag between CCD1 gene expression and norisoprenoid volatiles

DOI: 10.1021/acs.jafc.5b02941
J. Agric. Food Chem. 2015, 63, 8275−8282

production has been reported,[47,48] which could be explained by the different cellular localization of carotenoids and CCD1 enzymes.[21,47,49] Although there is a temporal delay in volatile emission in relation to gene expression, in tomato the silencing of both *LeCCD1A* and *LeCCD1B* genes generates a reduction in β-ionone and geranylacetone. This provides a cause-and-effect relationship between *LeCCD1* gene expression and the formation of those important flavor volatiles in vivo.[47]

Identification of LnDcCCD1. The role of CCDs in the formation of norisoprenoids and their flavor properties in *L. nobilis* fruits has not been reported. In attempts to identify a gene responsible for norisoprenoid formation in *L. nobilis* fruits, we examined the recently created *L. nobilis* transcriptome database[9] for genes exhibiting similarity to known CCD sequences from other plants.

Data mining of the *L. nobilis* database resulted in identification of one full length cDNA clone (Figure S1), displaying high sequence similarity to other plant carotenoid cleavage dioxygenases. The clone, designated *LnCCD1*, originated from a leaves expressed sequence tagged (EST) library of *L. nobilis*. The predicted LnCCD1 protein sequence consists of 550 amino acids, with a calculated molecular mass of 61.9 kDa. The deduced amino acid sequence of LnCCD1 contains two conserved domains, which are typically found in enzymes involved in the biosynthesis of norisoprenoids.[50]

LnCCD1 protein displays a high sequence similarity (86%) to the CCD from *Phoenix dactylifera* (date plum), and (84%) to CCD1 from *Nelumbo nucifera* (sacred lotus). LnCCD1 is also similar to the *Vitis vinifera* VvCCD1 (84%) that cleaves zeaxanthin symmetrically yielding 3-hydroxy-β-ionone, a C13-norisoprenoidic compound, and a C14-dialdehyde.[51] LnCCD1 is also similar to CCD1 from *Prunus mume* (chinese plum) (82%), to CCD1 from *Cucumis melo* (melon) (82%),[28] to *Malus* × *domestica* (apple) (81%), to CCD1 from *Osmanthus fragrans* (fragrant olive) (80%), and to DcCCD1 from *Daucus carota* (carrot) (80% identity), which encodes enzyme that cleaves only cyclic carotenoids to generate α- and β-ionone.[39] Phylogenetic analyses show that the protein encoded by this cDNA clusters with other plant CCD1 enzymes (Figure 2).

LnCCD1 Cleaves Multiple Carotenoids To Generate Norisoprenoids Volatiles Derived from 9,10 and 5,6 Double Bond Cleavage. To determine the substrate specificities and bond cleavage position preferences of the *LnCCD1*, the cDNA was cloned into bacterial expression vector pEXP5-CT/Topo, and the recombinant LnCCD1 protein was expressed in *E. coli* strains that accumulate various carotenoids biosynthesis enzymes.[37,38] Except for phytoene that is colorless, the carotenoids that accumulate in these strains provide a specific color to the cells depending on the carotenoid accumulated, and a loss of color indicates that the carotenoids could be metabolized to colorless compounds. Cultures expressing LnCCD1 and accumulating various carotenoids were grown in darkness, induced with IPTG, and grown for a further 12 h at room temperature. The norisoprenoid volatiles were collected by auto-HS-SPME and analyzed by GC−MS.

No isoprenoid-derived volatiles were identified in the culture synthesizing the acyclic carotenoids phytoene by GC−MS headspace analyses (Figure 3 and Table 2). To ensure that LnCCD1 did not cleave these acyclic carotenoids and generate nonvolatile products, the phytoene-accumulating *E. coli* cultures expressing the LnCCD1 were extracted and analyzed by HPLC. The phytoene carotenoid levels of the LnCCD1-expressing cultures were identical to controls harboring empty vectors and

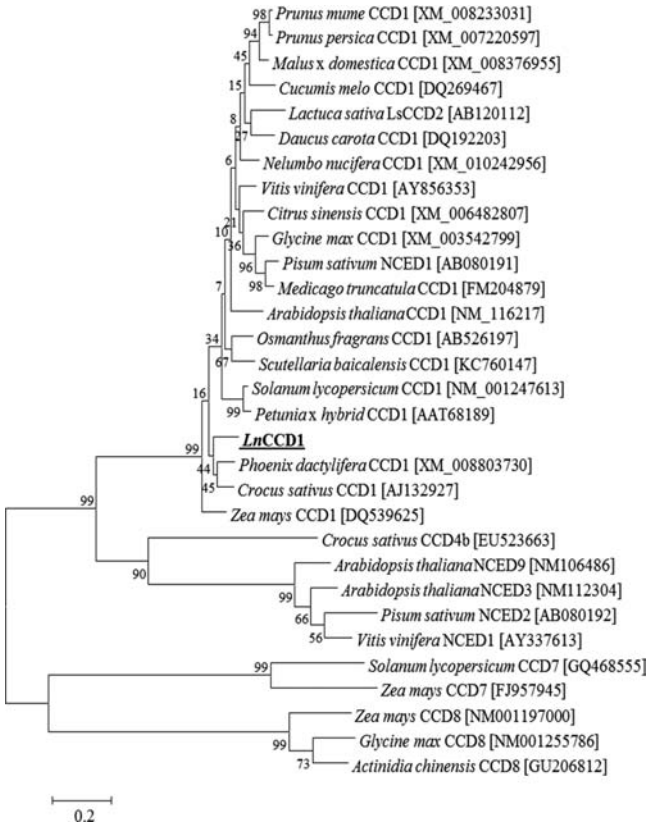

Figure 2. Phylogenetic tree of deduced amino acid sequences of carotenoid cleavage oxygenases from *L. nobilis* and other plant species. The tree was generated using Phylogeny Analysis MEGA6.1 program.[54] The resulting tree was bootstrap analyzed with 1000 replicates. The black bold underline indicates the *L. nobilis LnCCD1* gene identified in this study. Accession numbers are indicated in parentheses.

not overexpressing LnCCD1 (data not shown). Moreover, no new nonvolatile products were found, as compared to the control (data not shown), confirming that LnCCD1 did not cleave phytoene at a detectable rate. Similarly, Yahyaa et al. (2013)[39] reported that DcCCD1, a CCD isolated from *Daucus carota* roots, did not cleave the acyclic carotenoids phytoene. Also, similar results were reported by Vogel et al. (2008)[52] that ZmCCD1, a CCD isolated from maize, did not cleave phytoene.

Norisoprenoid volatiles were identified in vitro during coexpression of *LnCCD1* in different carotenoid producing *E. coli* strains (Table 2 and Figure 3). Pseudoionone and MHO were detected in lycopene-accumulating *E. coli* strain (Table 2 and Figure 4A). Pseudoionone is generated by 9,10 or 9′,10′ bond cleavage of lycopene, whereas MHO is generated by 5,6 or 5′,6′ bond cleavage. The presence of MHO and pseudoionone was unequivocally confirmed by a comparison of their retention indices (RI) and a mass spectra to that of authentic MHO and pseudoionone. Both pseudoionone and MHO were not detected in *E. coli* cells transformed with control plasmids devoid of the *LnCCD1* gene (Table 2 and Figure 4B). These results indicate that the *L. nobilis* CCD1 enzyme, like the *Arabidopsis*, maize, tomato, and *Rosa damascena* CCD1, cleaves lycopene at 9,10 (9′,10′) and 5,6 (5′,6′) bonds to generate pseudoionone and MHO.[46,52]

The norisoprenoid volatiles derived from δ- and β-carotene-accumulating *E. coli* strains revealed a similar pattern (Table 2,

DOI: 10.1021/acs.jafc.5b02941
J. Agric. Food Chem. 2015, 63, 8275−8282

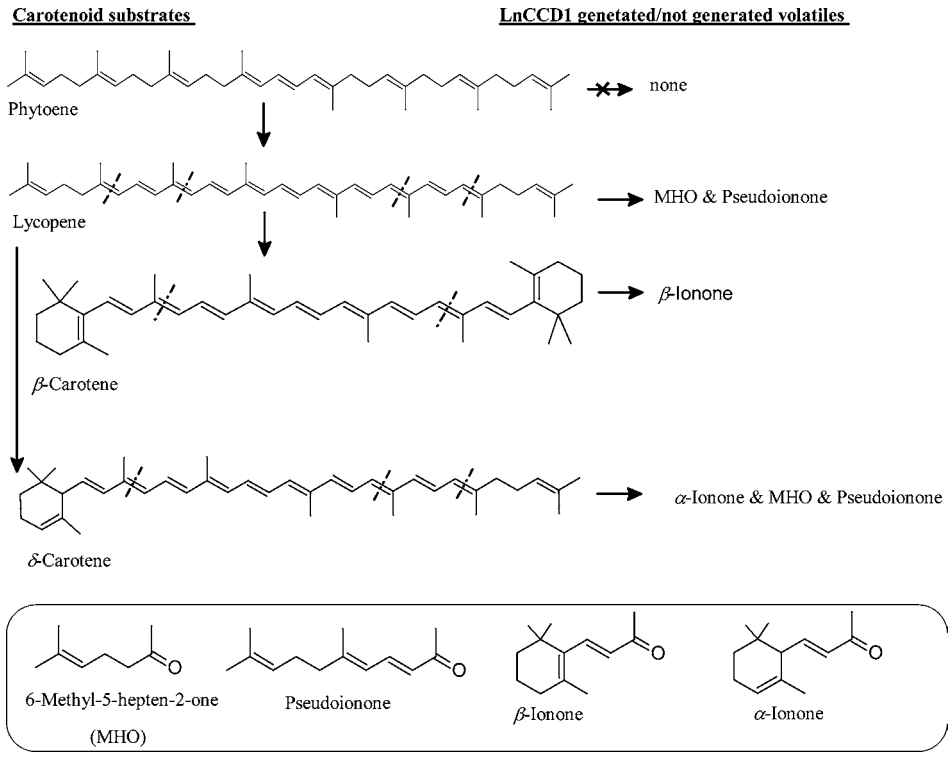

Figure 3. Proposed sites of LnCCD1 bond cleavage and the volatiles generated. An abbreviated version of the carotenoid biosynthetic pathway in higher plants is shown. Carotenoid substrates (left) are oxidatively cleaved by LnCCD1 to yield the norisoprenoid derivatives (right).

Table 2. Norisoprenoids Formed in Vitro during Coexpression of *LnCCD1* in Carotenoid Producing *E. coli* Strains

		norisoprenoids[a] present in headspaces of bacterial cultures (ng/mL)			
plasmid	carotenoid	6-methyl-5-hepten-2-one	pseudoionone	β-ionone	α-ionone
pBCAR-EB	phytoene				
pBCAR-EB + *LnCCD1*					
pBCAR-EBI	lycopene				
pBCAR-EBI + *LnCCD1*		36.05 ± 3.17	26.57 ± 1.08		
pBCAR-EBIY	β-carotene

[a]Norisoprenoid compounds were identified by GC−MS on the basis of mass spectra matching with the standard NIST-98.L and Wiley 7N.I library (ms), comparison of retention index (RI) with literature data (RI), comparison with standard. The results shown are an average and standard errors of at least three biological replicates.

Figure 5A, and Figure S2). β-Ionone was detected from β-carotene-accumulating culture, and α-ionone was detected in the δ-carotene-accumulating culture, as evidenced by their retention index (RI) and a mass spectrum identical to that of authentic α- and β-ionone (Table 2, Figure 5A, and Figure S2). Both α- and β-ionone are indicative of 9,10 (9′10′) bond cleavage. Additionally, pseudoionone and MHO also were detected in both cultures expressing LnCCD1 enzyme, indicating cleavage of δ- and β-carotene precursor carotenoids at 9,10 (9′,10′) and 5,6 (5′,6′) bonds. Pseudoionone, MHO, and α- and β-ionone were absent in *E. coli* cells transformed with control plasmids devoid of the *LnCCD1* gene (Table 2, Figure 5B, and Figure S2).

LnCCD1 was also overexpressed in an *E. coli* strain accumulating the yellow-orange colored xanthophyll zeaxanthin, resulting in colorless colonies. The putative volatile enzymatic reaction products of the cleavage of zeaxanthin were further analyzed by auto-HS-SPME-GC−MS. MHO, pseudoionone, and β-ionone were identified in the head space of the *E. coli* strain accumulating zeaxanthin and expressing *LnCCD1* (Table 2 and Figure S3). 3-Hydroxy-β-ionone, the expected oxidative cleavage product of zeaxanthin, could not be detected in the headspace of these cultures (Table 2). MHO, pseudoionone, and β-ionone are breakdown products of lycopene and β-carotene, respectively, which are intermediate in zeaxanthin biosynthesis, suggesting that LnCCD1 may compete for the lycopene and β-carotenoid substrate with the β-carotene cyclase and the β-carotene hydroxylases (respectively) that are expressed in the zeaxanthin accumulating *E. coli* strain carrying that gene, the hydroxylase that catalyzes the formation of zeaxanthin in these cultures.[37,38] Similar observations (presence of β-ionone and not 3-hydroxy β-

(E) The inset shows the structure and the mass spectrum of the enzymatic reaction product identified as *β*-ionone by matching the retention time and the MS pattern with an authentic standard. The identity of the cleavage products (peaks marked) was confirmed using authentic standards.

ionone) have been noted in previous studies of expression of the *DcCCD1* gene from carrot roots,[39] *RdCCD1* and *RdCCD4* genes from *Rosa damascena*, *MdCCD4* gene from *Malus* × *domestica*, *CmCCD4a* gene from *Chrysanthemum* × *morifolium*, and *OfCCD4* gene from *Osmanthus fragrans*.[46,53]

In each carotenoid accumulating *E. coli* strain tested in this study, additional norisoprenoid volatiles consistent with the cleavage of precursor carotenoids were observed, indicating that LnCCD1 cleaves precursor carotenoids before they can be converted into the final product. Similar results were reported by Vogel et al. (2008) and Huang et al. (2009),[46,52] who reported that ZmCCD1 and RdCCD1, CCDs isolated from maize and *Rosa damascena*, respectively, have a broad substrate specificity and cleaved multiple carotenoids at two different double bond positions (9,10, 9′10′, 5,6, and 5′6′).

One of the most significant findings of this work is that LnCCD1 can cleave lycopene at 9,10 (9′,10′) and 5,6 (5′,6′) double bonds to produce pseudoionone and MHO. Cleaving lycopene by LnCCD1 provides a biological route to synthesize MHO, an important flavor and aroma volatile found in a number of fruits such as tomato.[42] Accordingly, the bulk of the volatile norisoprenoid products detected in the recombinant *E. coli* overexpressing the *LnCCD1* gene apparently result from the 9,10 (9′,10′) and 5,6 (5′,6′) cleavage of different carotenoids. We therefore conclude that *LnCCD1* encodes a protein that displays 9,10 and 5,6-carotenoid cleavage

J. Agric. Food Chem. 2015, 63, 8275−8282

dioxygenase activity and can accept a wide range of carotenoids as a substrates. LnCCD1 is able to release MHO, pseudoionone, β-ionone, and α-ionone depending on the carotenoid substrate offered.

In conclusion, several carotenoids and norisoprenoid volatile compounds, for example, MHO, pseudoionone, and β-ionone, were detected in the *L. nobilis* pericarp of the black fruit. LnCCD1 was found to have a broad substrate specificity and to cleave multiple carotenoids at two different double bond positions (9,10, 9′10′, 5,6, and 5′6′). On the basis of the pattern of norisoprenoid volatiles detected by auto-HS-SPME-GC−MS analysis, and their odor thresholds, we suggest that LnCCD1 cleavage products may contribute to *L. nobilis* fruit flavor and aroma.

■ ACKNOWLEDGMENTS

We are grateful to Professor Eran Pichersky for critical reading of the manuscript and many discussions during the preparation of this work. We are grateful to Professor Nativ Dudai and Doya Sa'adi for taking care of the *Laurus nobilis* plants. We also thank Professor Joseph Hirschberg for providing the following plasmids: pBCAR-EB, pBCAR-EBI, pBCAR-EBIY, pDCAR, and pZEAX.

■ ABBREVIATIONS USED

CCD, carotenoid cleavage dioxygenase; LnCCD, *Laurus nobilis* carotenoid cleavage dioxygenase; FW, fresh weight; GC−MS, gas chromatography mass spectrometry; HPLC, high performance liquid chromatography; IPTG, isopropyl-1-thio-β-D-galactopyranoside; MHO, 6-methyl-5-hepten-2-one; HS-SPME, head-space-solid phase micro extraction

mostly composed of salts, proteins, lipids, and carbohydrates.[18] Despite the low content of lipids, they remain an indispensable component in jellyfish. For example, phosphonolipid (PnL), commonly present in the jellyfish, is a structural element of cell membranes and plays a special role in stabilizing cell membranes and protecting membrane lipids from hydrolytic enzymes.[19]

Sphingophosphonolipid (SPnL) and phospholipid (PL) from jellyfish *Aurelia Aurelia* and *Pelagia noctiluca* have been analyzed.[20,21] However, no assignment of fatty acids (FAs) to the *sn*-1 and *sn*-2 positions of the glycerol backbone has been achieved. Furthermore, traditional lipid analytical methods are complex and time-consuming. For instance, the confirmation of FA compositions in each lipid class needs the separation by thin layer chromatography (TLC), fraction collection, hydrolysis by lipase, derivatization, and identification of derivatized FAs by gas chromatography (GC) or gas chromatography coupled with mass spectrometry (GC-MS). Nuclear magnetic resonance (NMR) and electrospray ionization mass spectroscopy (ESI-MS) have been also used to characterize glycolipids and SPnL in *Phyllorhiza punctata*.[22] Even though detailed structural information on monogalactosyldiacylglycerol (MGDG), sulfoquinovosyldiacylglycerol (SQDG), and ceramide 2-aminoethylphosphonate (CAEP) has been obtained, a series of complex steps are still required to separate lipids by TLC. In addition, the infusion of crude lipid extracts into ESI-MS could result in a significant loss of ion signals from those low-abundance components.[23] Fortunately, this problem can be avoided by the separation of crude lipids using chromatography. Recently, the comprehensive characterization of a variety of lipids in marine organisms has been achieved by using UPLC coupled with Q-TOF MS in a MS^E data collection mode[24,25] without the requirement of preseparation. In the present study, the comprehensive characterization and semiquantification of lipid profile in different parts of jellyfish *R. esculentum* were conducted by ultraperformance liquid chromatography−electrospray ionization−quadrupole time-of-flight mass spectrometry (UPLC-ESI-Q-TOF-MS), which will facilitate the evaluation of the nutritional value of *R. esculentum* as a healthy food for humans or as a diet supplement for commercial fish.

MATERIALS AND METHODS

Sampling Method. Jellyfish *R. esculentum* were randomly caught from the coast of Ningbo by using a fishnet and dissected into three distinct body parts including umbrella, oral arms, and mouth stalk. These body parts of *R. esculentum* were freeze-dried, ground to fine powder in the presence of liquid nitrogen, and individually stored at −20 °C for future use.

Total Lipid (TL) Extraction and Lipid Standards. Briefly, 50 mg of different freeze-dried body parts of *R. esculentum* was extracted with chloroform/methanol (1:1, v/v) containing 0.05% butylated hydroxytoluene (BHT). The combined lipid extracts were evaporated on a rotary evaporator (IKA, Germany), and the residue was stored at −20 °C. Lipid standards including phosphatidylethanolamine (PE; 16:0−18:1), phosphatidylcholine (PC; 18:1−14:0), phosphatidylinositol (PI; 16:0−18:1), phosphatidylserine (PS; 16:0−18:1), ceramide (Cer; d18:1−16:0), and sphingosyl phosphoethanolamine (Cer-PE; d17:1−12:0) were purchased from Avanti Polar Lipids (Alabaster, AL, USA). triacylglycerol (TAG) (18:3−18:3−18:3) was purchased from Larodan (Limhamn, Sweden). All extraction procedures were performed in triplicate, and the data were expressed as the mean ± SD.

UPLC Analysis. Reversed-phase analysis was carried out on a Waters ACQUITY Ultra Performance LC system (UPLC) using an ACQUITY UPLC BEH C_8 analytical column (2.1 × 100 mm, 1.7 μm). The flow rate was 0.5 mL/min with mobile phase A composed of acetonitrile/isopropanol/tetrahydrofuran (1:1:1, v/v/v) and mobile phase B composed of water/acetonitrile (1:2, v/v), both containing 0.1% formic acid as well as 0.01% lithium acetate. Efficient separation of lipids was achieved with a gradient elution: 0−3 min, 2% A; 3.0−5.0 min, 2−30% A; 5−12 min, 30−50% A; 12−22 min, 50−80% A; 22−25 min, 80% A; 25−27 min, returning to initial 2% A; 27−30 min, 2% A. The temperature of the sample chamber was set at 6 °C, the column temperature was set at 40 °C, and the injection volume was 3 μL for each analysis. Before injection, samples were filtered with a 0.22 μm ultrafiltration membrane (Millipore, Bedford, MA, USA).

Mass Spectrometric Analysis. Mass spectrometric analysis was performed on a Waters Q-TOF Premier mass spectrometer in both positive and negative ion modes. The mass range was from 150 to 1200 with a scanning duration of 0.3 s. The nebulization gas was set at a constant flow rate of 600 L/h at 400 °C, and the source temperature was set at 120 °C. Compositions and contents of TLs were detected in both positive and negative modes. For positive mode, the capillary voltage was set at 3.0 kV; the sampling cone voltage was set at a ramp of 25−40 V, whereas for negative mode, the capillary voltage was set at 2.6 kV and the sampling cone voltage was set at a ramp of 25−40 V. MS^E analysis was performed on the mass spectrometer with the setting at 6 kV for low collision energy and a ramp of 25−50 kV for high collision energy. The time-of-flight analyzer was used in V mode and tuned for maximum resolution (>10000 resolving power at m/z 1000). The instrument was previously calibrated with sodium formate, and the lock mass spray for precise mass determination was set by leucine enkephalin ($[M + H]^+$ at m/z 556.2771 and $[M - H]^-$ at m/z 554.2615) at a concentration 0.2 ng/mL, which makes the maximum relative error up to 5 ppm.

Identification of Lipids by ESI-MS. The exact masses (the mass difference was <5 ppm) of lipids were determined on the Q-TOF MS system, which allowed for the possible elemental composition calculation of empirical chemical formula. The freely accessible databases of HMDB (http://www.hmdb.ca), MAPS (http://www.lipidmaps.org), and METLINE (http://metlin.Scripps.edu) were further used to elucidate the putative structures of lipids. The structural identification of each lipid species was carried out by UPLC-MS/MS analysis through comparison of the molecular compositions, retention times (RT), and specific fragmentation behaviors with lipid standards that are biologically relevant and commercially available. The fragmentation patterns of PC, PE, PI, PS, Cer, and TAG have been previously described.[26−29] Furthermore, the fragmentation pattern of PE (18:0/22:4) is shown in the Supporting Information for better illustrating the structural elucidation process of these lipids in *R. esculentum*. ESI-MS/MS information for the determination and structural elucidation of CAEP is also available.[22]

Semiquantitative Analysis of Lipids. Internal standards were spiked into samples for semiquantitative analysis of lipids in *R. esculentum*. It is noted that these internal standards were not detected in *R. esculentum* during pre-experiments. The TLs extracted from 50 mg of dried *R. esculentum* were dissolved in 1000 μL of methanol, ensuring a final concerntration of 5 nmol/mL for each lipid standard. An extracted ion chromatogram (EIC) of each lipid class was obtained from the low collision energy scan (6 V), and the peak area was integrated, respectively. After the variable ionization efficiencies in different proportions of mobile phase were calibrated, the semiquantitative analysis was carried out according to the area ratio of each lipid to that of the corresponding internal standard. Because CAEP standard is not commercially available,[20] the semiquantitative analysis of CAEP was performed according to the area ratio of CAEP to that of the Cer-PE internal standard, which has a structure remarkably similar to that of CAEP.

Meanwhile, semiquantitative analysis of FAs was also performed from liquid chromatography coupled with mass spectrometry (LC-MS) data by a normalization method. To obtain the contents of total FAs, a calculation factor was applied to each lipid species: 1 for Lysophophatidylcholine (LPC), lysophophatidylethanolamine (LPE), and lysophosphatidylinositol (LPI), CAEP, and Cer; 2 for PC, PE, PS and PI; and 3 for TAG.

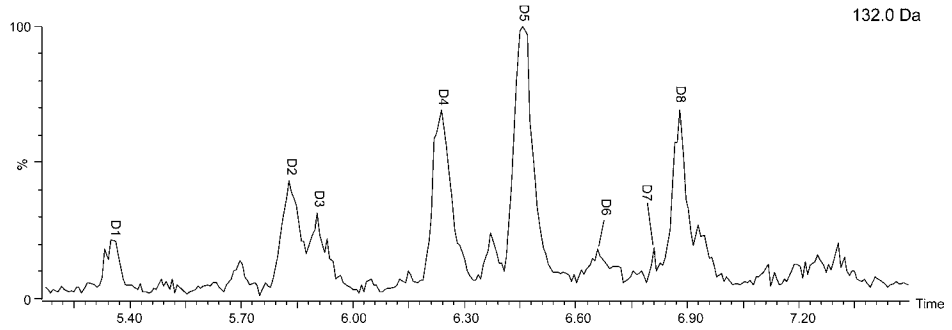

Figure 1. EIC for the characteristic ion of CAEP at m/z 132.0 from the high collsion energy scans. The marked peaks are consistent with the identified CAEP shown in Supporting Information Tables 1, 2, and 3.

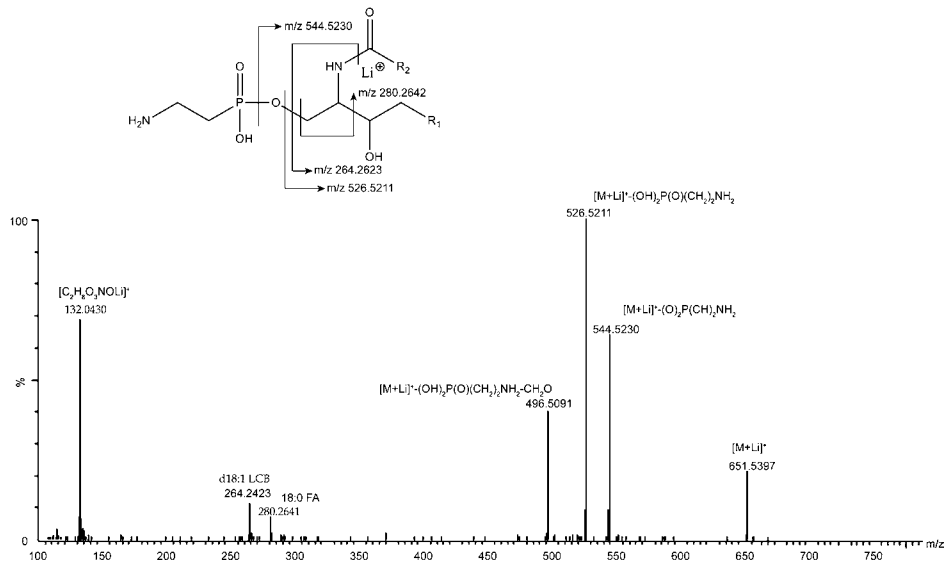

Figure 2. MS/MS spectrum and fragmentation pathways of the $[M + Li]^+$ at m/z 651.5397 of CAEP (d18:1/16:0).

Data Processing. The raw LC-MS data from both ESI^+ and ESI^- were acquired in the centroid mode by the UPLC-Q-TOF-MS system and analyzed using MassLynx (v4.1) software (Waters, Milford, MA, USA).

Phospholipase A2 (PLA2) Activity Assay. For PLA2 activity assay, 50 mg freeze-dried samples were homogenized with 1 mL of chilled 0.9% sodium chloride, and thereafter the samples were centrifuged at 12000 rpm for 10 min at 4 °C; finally, the supernatants were stored at −20 °C until assay. After thawing, the PLA2 catalytic activity of the extracts was assayed by a photometric method.[30] Briefly, bovine pancreatic PLA2 (Sigma-Aldrich, Madison, WI, USA) was used as the standard, and 7.9 mM 18:0−20:4 PC (Avanti) was used as the substrate in buffer containing 125 mM Tris-HCL, 4 mM calcium chloride, 1 mM deoxycholate, and 2.5 g/L Triton X-100 at pH 8.0. In total, 10 μL of PLA2 standard solution or sample was incubated with 50 μL of substrate mixture in a 96-well microplate at 37 °C for 20 min. Color reagents of the NEFA C Kit (Wako Chemical, Osaka, Japan) were added and incubated according to the manufacturer's instructions. Absorbance was measured at 550 nm (Microplate reader, Thermo Fisher, USA). The unit of PLA2 activity is defined as the activity for the release of 1 μmol of FA per minute. The protein concentration of the extract was measured as previously described[31] by using bovine serum albumin (Sigma-Aldrich) as the standard. The results were expressed as units per liter (u/L) and units per gram of protein (u/g) for the extract.

RESULTS AND DISCUSSION

In the negative mode, LPE, PE, LPI, PI, and PS were detected as the $[M - H]^-$ ion, and LPC and PC as $[M + HCOO]^-$.[27,28] The precursor ion $[M - H]^-$ of PE formed the characteristic fragment ions $[C_2H_7O_4NP]^-$ at m/z 140 and $[C_5H_{11}O_5NP]^-$ at m/z 196. The parent ion $[M - H]^-$ of PI produced the fragment ion $[C_6H_{10}O_8P]^-$ at m/z 241 that was unique to PI. The precursor ion $[M - H]^-$ of PS formed the ion $[M - H - 87]^-$ due to neutral loss of its headgroup $C_3H_5O_2N$. In addition, the parent ion $[M + HCOO]^-$ of PC produced the fragment ion $[M - CH_3]^-$ as the result of the loss of $C_2H_4O_2$, along with the unique ion $[C_4H_{11}O_4NP]^-$ at m/z 168. In addition, the compositions and positions of fatty acyl residues in those glycerophospholipids (GPLs) were identified by ESI-MS/MS in a negative mode.[28,32]

TAG and Cer were detected as $[M + Li]^+$ in positive mode.[22,26,29] For TAG, the MS/MS spectra of $[M + Li]^+$ produced fragment ions such as $[R_nCO\text{-}18]^+$, $[R_nCO]^+$, $[R_2CH{=}CHCOOH + Li]^+$, $[RnCOOH + Li]^+$, $[M + Li - R_nCOOH{-}R_2CH{=}CHCOOH]^+$, $[M + Li - R_nCOOLi]^+$, and $[M + Li - R_nCOOH]^+$ that were used for analysis of TAG, whereas for Cer, the precursor ion of $[M + Li]^+$ produced an abundant fragment ion that is the representative of long-chain base (LCB), *N*-acyl, and polar headgroup from the ESI-MS/MS spectrum, which allowed for the unequivocal identification of the structures for these lipids.

Identification of CAEP was performed on the basis of the MS fragmentation pattern provided by de Souza[22] with some modification. As has been reported, the MS/MS spectra of $[M + H]^+$ yielded fragment ion representing LCB. Ion reflecting

DOI: 10.1021/acs.jafc.5b03145
J. Agric. Food Chem. 2015, 63, 8283−8291

the FA constituents was not observed. In contrast, the product ion of $[M + Li]^+$ produced structurally informative fragment ions representing both LCB and FA in our work. Furthermore, abundant fragment ion $[C_2H_8O_3NPLi]^+$ at m/z 132.0, representing lithiated aminoethylphosphonate(AEP) headgroup, was generated in the MS/MS spectra of $[M + Li]^+$ rather than in the MS/MS spectra of $[M + H]^+$, which could be used as the characteristic fragment ion of CAEP.

From the EIC of the characteristic fragment ion at m/z 132.0 referred to above, a series of signal peaks representing CAEP were obtained at retention times between 5.0 and 7.0 min (Figure 1). The peak (D8) at the retention time of 6.9 min (Figure 1) was used as an example to illustrate the structural elucidation process in detail. A group of ions at m/z 645.5353 and 651.5397 were obtained in the mass spectra at the retention time of 6.9 min in the total ion chromatogram (TIC) of the low collision energy scan. Thus, the $[M + Li]^+$ ion of the CAEP was at m/z 651.5397 and the elemental composition was $C_{36}H_{73}O_5N_2PLi$. The MS/MS spectrum of the precursor ion $[M + Li]^+$ at m/z 651.5397 (Figure 2) produced a fragment ion at m/z 526.5211, corresponding to neutral loss of the headgroup-AEP $[(OH)_2P(O)-(CH_2)_2NH_2]$, along with the ion at m/z 544.5230, by eliminating $[(O)_2P-(CH_2)_2NH_2]$. Further elimination of CH_2O from m/z 526.5211 via charge-remote fragmentation produced an ion at m/z 496.5091, followed by neutral loss of LCB as the terminal conjugated diene or neutral loss of the FA as the ketene to produce ions at m/z 280.2642 and 264.2423 that reflect the 16:0 FA and d18:1 LCB in the molecule. Thus, the structure of CAEP at the retention time of 6.9 min could be easily determined as d18:1−16:0.

Compositions of Each Lipid Species from Different Parts of *R. esculentum*. Utilizing the method described above in both positive and negative modes, more than 87 species from 10 major lipid classes including LPC, PC, LPE, PE, LPI, PI, PS, Cer, CAEP, and TAG were identified (Supporting Information Tables 1, 2, and 3). Concerning the compositions and locations of FAs in these lipid species, several interesting observations were achieved in all parts of *R. esculentum*. First, longer and more unsaturated fatty acids (UFAs), such as 22:6ω-3 (docosahexenoic acid, DHA), 20:5ω-3 (eicosapentaenoic acid, EPA), and 20:4ω-6 (arachidonic acid, AA), were mainly located in the *sn*-2 position of GPLs, whereas relatively short saturated fatty acids (SFAs) and monounsaturated fatty acids (MUFAs) were primarily located at the *sn*-1 position of GPLs. For example, PCs were mainly composed of 20:4, 20:5, and 22:6 FA at the *sn*-2 position and SFAs with 13C−18C at the *sn*-1 position. PEs were composed of 20:4 and 20:5 FA at the *sn*-2 position and MUFAs of 15C−17C at the *sn*-1 position. PS and PI were composed of 18:0 at the *sn*-1 position and of 22:4, 22:5, 22:6, 24:5 and 24:6 FA at the *sn*-2 position. Second, the compositions of LCB and *N*-acyl chain in Cer were consistent with those in CAEP. Both contained d18:1 (sphingosine) and d18:2 (sphingadienine) LCB, along with *N*-acyl chains composed of SFAs with 14C−16C and MUFAs with 16C−18C. The compositions of CAEP in jellyfish *R. esculentum* were partly comparable to those obtained previously from jellyfish *Aurelia aurita*, which consisted primarily of dihydroxyl LCB with 16C−18C and trihydroxyl LCB, combined with SFAs with 14C−18C.[20] Previous studies have reported that the compositions of major CAEP from different jellyfish species do not reveal the specificity, whereas the compositions of minor CAEP reveal specificity to each jellyfish species.[21] Thus, one possible explanation for such a difference in CAEP compositions between jellyfish *R. esculentum* and *Aurelia aurita* could be associated with the species. Third, TAGs identified in all parts of *R. esculentum* were mainly composed of 22:6 FA at the *sn*-1/*sn*-3 position and 16:0 FA at the *sn*-2 position.

A total of 6 Cer species were identified from *R. esculentum*, with the predominant species composed of d18:2−16:0. LCB portions of Cer were composed of d18:1 and d18:2. The *N*-acyl chains of Cer were composed of SFAs with 15C and 16C and MUFAs with 17C and 18C. According to our current knowledge, the presence of Cer is first observed in jellyfish. Cer consisting of LCB linked to the FA via an amide bond was particularly important in triggering apoptosis and the activation of a variety of protein kinase cascades.[33] It is well-known that many diseases including cancer, atherosclerosis, neuropathies, diabetes, Parkinson's disease, and Alzheimer's disease could be induced when the organism failed to regulate apoptosis.[34] They were rarely found as such at greater than trace levels in tissues. Thus, one probable reason could be that the concentration of Cer in jellyfish was too low to be detected by using traditional methods such as TLC, which requires a large amount of lipids and gains poor separation. In contrast, UPLC-ESI-Q-TOF-MS could result in rapid separation and precise characterization of complex lipids with only a very small amount of samples. However, neither MGDG nor SQDG, previously detected from jellyfish *Phyllorhiza punctata*,[22] is detected in *R. esculentum* by using the method established by Xu.[35] The presence of MGDG and SQDG in jellyfish *Phyllorhiza punctata* seems to be the result of an endosymbiotic association with microalgae, because these glycerolipids are commonly detected in thylakoid membranes of photosynthetic tissues. Therefore, the absence of these glycerolipids in *R. esculentum* is probably due to the absence of endosymbiotic microalgae.

Contents of Each Lipid Species from Different Parts of *R. esculentum*. It is reported that the ion response is linear in a biologically relevant range for a great amount of different lipids on ESI-Q-TOF-MS, and internal lipid standards are spiked into the samples for the semiquantitative analysis.[36] In the present study, the dynamic range/linearity of total lipids is determined on the basis of concentration of mixed standard lipids up to 5 nmol/mL and reveals good linearity. Therefore, the lipid profile is semiquantified in comparison with the internal lipid standards.

On the basis of the method discussed above, the contents of each lipid species from different parts of *R. esculentum* were obtained and are partly shown in Tables 1, 2, and 3 (see Supporting Information Tables 1, 2, and 3 for the contents of all lipid species present in different parts of *R. esculentum*). Results showed that GPLs and sphingolipids (SPLs) were the major lipid classes in all parts of *R. esculentum*, accounting for 54−63 and 23−28% of TLs, respectively (Figure 3). Furthermore, GPLs were dominantly composed of PC and PE, accounting for 44.6−86.9% of GPLs (Figure 3). It is well-known that PC and PE are the essential constituents of the bilayer membrane, which plays an important role in the growth and metabolism of organisms. For example, PC, once named "lecithin", could significantly improve the performance of the brain and accelerate signal transfer among neurons.[37] Previous studies have confirmed that foods containing PC are critical for brain development in infants and children.[38] PE, once named "cephalin", is the second most abundant PL in animals and is particularly enriched in the brain. PE plays an important role in

heart and contractile ring disassembly at the cleavage furrow during cytokinesis of mammalian cells.[39]

PC and PE in *R. esculentum* are characteristics of high levels of AA, EPA, and DHA. The sum of these acids in PC reveals the variation from 46 to 49%. AA and EPA are predominant FAs in PE, accounting for 52−64 and 33−47% of total FAs in PE, respectively. The benefits of diets containing ω-3 and ω-6 FAs for humans are well proven.[40,41] These essential FAs can be incorporated into cell membranes when they are available, and the deficiency of these essential FAs is associated with

impaired brain function;[42] ω-3 and ω-6 FAs are available only from dietary sources in humans.[43] Besides, extensive studies have demonstrated that ω-3 FAs, especially EPA and AA, are highly required for optimum growth and survival of some commercial fish and crustaceans, because these species have a limited capability to elongate shorter chain precursors such as 18:3 and 18:2 FAs to longer ω-3 highly unsaturated fatty acids (HUFAs) such as EPA and DHA. Therefore, these essential FAs must be obtained from feed.[44−46]

Low levels of PS and PI were also detected in *R. esculentum*, accounting for 3.5−4.3 and 3% of GPLs (Figure 3). Although PS and PI are minor portions of GPLs, they are vitally important signing molecules. For instance, PI can regulate the functions of innumerable proteins integral to membranes by binding to cytosolic proteins or cytosolic domains of membrane proteins.[47] PS is not only a component of membranes for the precursor of other PLs but also an essential cofactor for binding to and activating a large number of proteins, especially proteins with signaling activities.[48] As described above, the FA located at the *sn*-1 position of PS and PI is 18:0 FA. PS and PI have longer and more UFAs at the *sn*-2 position. These unusual FAs include docosatetraenoic acid (22:4), docosapentenoic acid (22:5), tetracosapentaenoic acid (24:5), and tetracosahexaenoic acid (24:6). Despite the low concentrations of these FAs, they have many important functions, such as reducing blood lipid and enhancing memory.[49]

SPLs, the second most abundant lipid in *R. esculentum*, are composed of CAEP and Cer. The former PnL is relatively abundant in some invertebrates, and it has been reported in jellyfish *Aurelia aurita* and *Phyllorhiza punctata*.[20,22] High levels of CAEP have also been detected in jellyfish *R. esculentum* with variation from 20 to 25.6% of TLs (Figure 3). CAEP, composed of an ethanolamine headgroup linked to ceramide via a phosphono group (O−P−C), is different from the commonly encountered sphingomyelin (SM) that is composed of a choline polar head linked to a ceramide via a phosphate group (O−P−O). Previous studies suggest that the C−P bond could provide the molecule with a relative resistance to chemical hydrolysis and thermal decomposition when

J. Agric. Food Chem. 2015, 63, 8283−8291

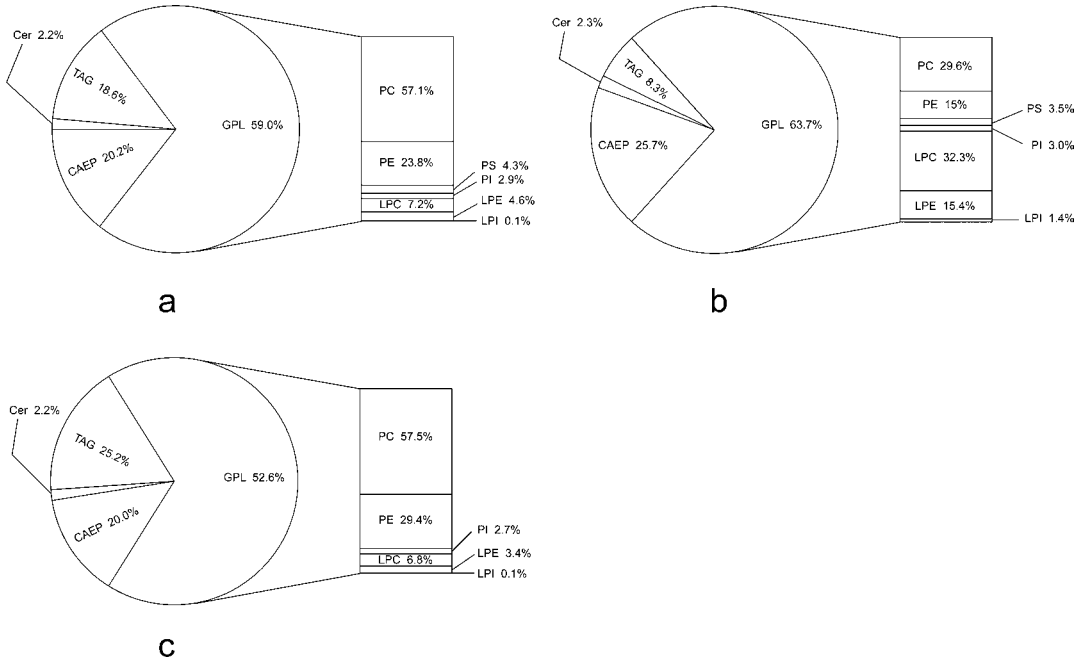

Figure 3. Relative contents of GPLs, CAEP, Cer, and TAG to TLs and the relative contents of PC, PE, PS, PI, LPC, LPE, and LPI to GPLs in oral arms (a), umbrella (b), and mouth stalk (c) of jellyfish *Rhopilema esculentum*.

compared with the common O−P bond.[50] Thus, CAEP could contribute to membrane stabilization, thus protecting membrane lipids from hydrolytic enzymes. Similarly, previous studies have demonstrated that cnidaria contains many hydrolytic enzymes. Therefore, the cell membrane of jellyfish *R. esculentum* may be benefit from the presence of CAEP. High CAEP proportions may also play an important role in the survival of jellyfish in an eutrophic environment where other organisms cannot survive.[51] Because "invertebrate" CAEP is thought to replace the "vertebrate" SM, the potential functions of CAEP may be similar to those of SM in vertebrates, such as endocytosis, virus budding, or immune cell signaling.[52] In addition, extensive studies have been conducted to evaluate the safety of CAEP to cell lines for applications in health foods and supplements. The results suggest that CAEP can effectively protect the liver from the damage caused by microcystin-LR, a cyclic peptide released by several bloom-forming toxic cyanobacteria, and complete the maintenance and promotion of human health.[53]

The contents of Cer were 3.8% in umbrella, 3.9% in oral arms, and 4.1% in mouth stalk (Figure 3). Despite the low concentration of Cer in membrane, it could exert important biological functions including cell differentiation, transformation, and proliferation as well as the regulation of apoptosis.[33] Cer is generally regarded as the precursor of SPLs in vertebrates and can be converted rapidly to more SPLs including SM and various glycosylceramides.[54] As mentioned above, LCB and *N*-acyl chain compositions of Cer were in agreement with those of CAEP. Thus, a hypothesis that Cer may also be the precursor of CAEP in invertebrates has been proposed. Further investigations are highly required for confirming this hypothesis.

Difference in Lipid Contents from Different Parts of Jellyfish *R. esculentum*. When the content of each lipid species in different parts of *R. esculentum* was analyzed, it was obvious that Lysophospholipid (LPL) contents in oral arms (LPC, 1.682 ± 0.010 nmol/mg; LPE, 0.801 ± 0.030 nmol/mg; LPI, 0.075 ± 0.005 nmol/mg) were much higher than those in umbrella (LPC, 0.270 ± 0.019 nmol/mg; LPE, 0.169 ± 0.009 nmol/mg; LPI, 0.005 ± 0.001 nmol/mg) and those in mouth stalk (LPC, 0.101 ± 0.007 nmol/mg; LPE, 0.052 ± 0.003 nmol/mg; LPI, 0.002 ± 0.001 nmol/mg) (Figure 4). Because

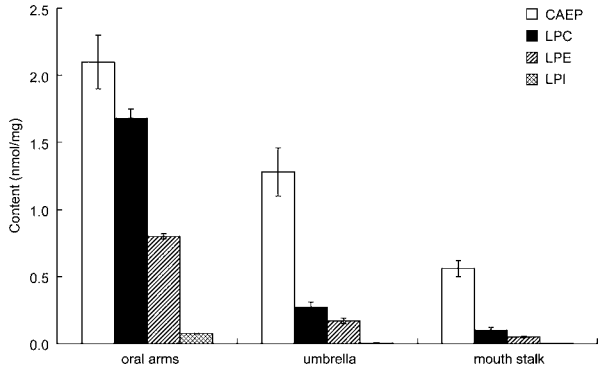

Figure 4. CAEP, LPC, LPE, and LPI contents in oral arms, umbrella, and mouth stalk of jellyfish *Rhopilema esculentum*.

these LPLs are commonly produced by the hydrolysis of GPLs in the presence of hydrolytic enzymes, PLA2[55] with the release of *sn*-2 FA and LPL, a high content of LPL may reflect the presence of PLA2 in large amounts. Therefore, the catalytic activity of PLA2 in different parts of *R. esculentum* was further measured, and a higher PLA2 level was determined in oral arms (149.5 ± 4.2 u/g protein) when compared that in umbrella (81.6 ± 2.7 u/g protein) and mouth stalk (21.3 ± 1.2 u/g protein) (Figure 5), which is in good agreement with the high proportion of LPL in oral arms.

Similar to LPC, LPE, and LPI, abundant CAEP (2.101 ± 0.031 nmol/mg) detected in oral arms was higher than that in umbrella (1.280 ± 0.020 nmol/mg) and mouth stalk (0.563 ± 0.009 nmol/mg) (Figure 4). According to the discussion above, CAEP can provide cell membranes relative resistance to

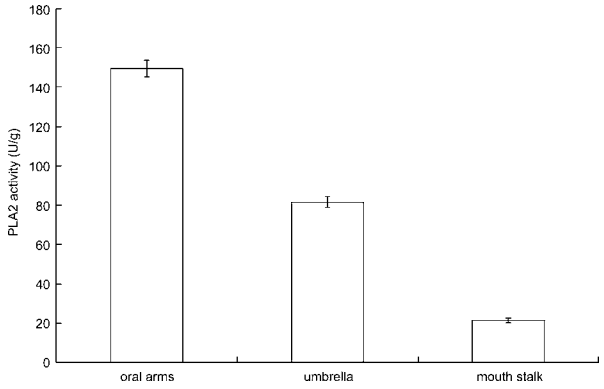

Figure 5. PLA2 activity in oral arms, umbrella, and mouth stalk of jellyfish *Rhopilema esculentum*.

chemical hydrolysis and thermal decomposition in the presence of hydrolytic enzymes such as PLA2. Therefore, cell membranes of oral arms containing high PLA2 may be benefit from the presence of CAEP.

Despite the high contents of LPC, LPE, LPI, and CAEP, oral arms contained a relatively lower proportion of TAG (8.3% of TLs) when compared with umbrella (18.6% of TLs) and mouth stalk (25.2% of TLs) (Figure 3). TAG containing three FAs with glycerol is usually regarded as an energy store. Previous studies have demonstrated that exercise will lead to the consumption of TAG.[56] Because the major functions of oral arms are food intake and movement with high requirement of large amount of energy, the relatively low TAG content detected in oral arms can be associated with the specific functions of oral arms.

In conclusion, considering the high level of GPLs and FA compositions in GPLs, the edible jellyfish *R. esculentum* has extensive potential as a health-promoting food for humans or as a supplemental feed for some commercial fish and crustaceans. Meanwhile, higher LPC, LPE, LPI, and CAEP in oral arms can be well explained due to the abundant PLA2 in oral arms. On the other hand, food intake and movement will lead to the consumption of TAG in oral arms.

and DM were suspended in aqueous 0.15 M NaCl before administration in mice.

Animals and Treatment. Male mice (21 ± 1 g, 7 weeks old) were obtained from Kunming Institute of Zoology. The mice were treated as described previously.[30] All animal experiments were done in compliance with Animal Ethical Committee of University of Science and Technology of China. Sixty male mice were divided randomly into six groups: one control group (0.15 M NaCl) and five experimental groups (50 mg/kg BW nano ZnO, 50 mg/kg BW bulk ZnO, 15 mg/kg BW DM, 50 mg/kg BW nano ZnO + 15 mg/kg BW DM, and 50 mg/kg BW bulk ZnO + 15 mg/kg BW DM). The animals were intragastrically administered with chemicals at a dose of 0.1 mL/10 g BW, respectively, for 14 consecutive days. After 2 weeks, the samples of blood were collected from the tail vein after the mice were anaesthetized by ether. The brain, heart, lung, liver, kidney, and spleen were excised, washed with 0.15 M NaCl, and weighed for determination of the coefficients of organs.

Serum Biochemical Parameters Assay. Liver function was determined by the serum levels of lactate dehydrogenase (LDH), alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBIL), alkaline phosphatase (ALP), total protein (TP), albumin protein (ALB), and albumin/globulin (A/G). Nephrotoxicity was evaluated with creatinine (CRE) and blood urea nitrogen (BUN). All of the biochemical parameters were determined by an automatic biochemical analyzer (Roche Modular DPP System) using commercial kits (Roche Diagnostics, Mannheim, Germany).

Histopathological Examination. Tissues of the kidney, liver, heart, lung, brain, and spleen were recovered from the necropsy. Their histological examinations were performed using an optical microscope as described previously.[30]

Measurement of Oxidative Stress Makers. The kidney and liver tissues were assayed for the malondialdehyde (MDA) level and the activities of superoxide dismutase (SOD), catalase (CAT), and glutathione peroxide (GPx) using the commercial kits (Nanjing Jiancheng Bioeng Inst.) as described previously.[30]

Measurement of ChE Activity. ChE activity was determined in liver tissue by the hydroxylamine–ferric chloride method using acetylcholine as a substrate.[31] The rate of acetylcholine hydrolysis was determined through the measurement of the remaining acetylcholine after hydrolysis catalyzed by ChE. The remaining acetylcholine reacted with NH_2OH to form acethydroximic acid, which reacted with Fe^{3+} to produce the purple-brown color of the ferric–acethydroximic acid compound. This compound could be spectrophotometrically determined at 520 nm. One unit of ChE activity is the amount of protein that decomposes 60 μmol of acetylcholine per hour at 37 °C.

Analysis of Biodistributions of Zn and DM. The liver, kidney, heart, lung, brain, or spleen tissue (~0.2 g) was digested with ultrapure HNO_3 solution for 12 h. The solutions were then mixed with 0.5 mL of H_2O_2 and heated at 130 °C to remove the remaining HNO_3. The remaining solutions were diluted to 5 mL with 2% (v/v) HNO_3. The Zn contents in the solutions were measured by inductively coupled plasma-atomic emission spectrometry (ICP-AES) (Optima 7300 DV, PerkinElmer Corp.). The DM contents in the organs were measured by gas chromatography–mass spectrometry (GC–MS).[32] The liver, kidney, heart, lung, brain, or spleen tissue (0.1–0.2 g) was homogenized and centrifuged at 4500 rpm for 25 min at 4 °C. The supernatant was added to a CNWBOND C18 SPE column. The column was washed with 10 mL of 5% CH_3OH and then eluted with 10 mL of CH_3OH. The eluate was evaporated to dryness by a nitrogen stream at 25 °C. The dry extract was dissolved in 50 μL of CH_3OH, and 1 μL of the solution was injected into a Thermo Trace GC-ISQ MS system (Thermo Fisher Scientific).

Assays for Stability of Nanoparticles. To evaluate the stability of nanoparticles in the stomach of mice, 5–40 mg of nano ZnO or bulk ZnO was incubated with 5 mL of artificial gastric fluid (AGF) (0.32% pepsin, 0.2% NaCl, pH 1.5) with gentle shaking for up to 4 h at 37 °C. Supernatants were collected after centrifugation at 12 000*g* for 20 min. The Zn concentration in supernatants was determined by ICP-AES.

Statistical Analysis. Data were analyzed by one-way analysis of variance (ANOVA) test by using SPSS 18.0 software (SPSS Inc.). The statistical significance was set at $p < 0.05$ for all tests.

RESULTS AND DISCUSSION

Coefficients of Organs. No abnormal daily behaviors were seen in the control, nano ZnO, and bulk ZnO groups during the entire experimental period. A few signs of acute organophosphate poisoning, including anorexia and reduced activity, were observed in the DM group. The mice coadministrated with DM and nano or bulk ZnO showed varying degrees of signs such as loss of appetite, mild tremor, and piloerection. As shown in Figure 1, the body weights of the mice in the nano and bulk ZnO groups increased a little more slowly than those in the control group, whereas the body weight of mice administrated with DM increased much more slowly, as compared with the control. Co-administration of DM with nano or bulk ZnO had a significantly enhanced adverse effect on the weight gain. As shown in Table 1, compared with the control, the coefficients of the liver of the nano and bulk ZnO groups did not change significantly, but a significantly higher coefficient of the liver was observed in the DM group ($p < 0.05$). In the nano ZnO + DM group, a significant increase was seen in the coefficient ($p < 0.05$) of the liver compared with either the nano ZnO or the DM group, revealing that nano ZnO and DM enhanced each other in affecting the coefficient of the liver. Similarly, co-administration of DM with bulk ZnO also had an enhanced influence on the coefficient of the liver. Compared with the control, the coefficients of the brain, kidney, heart, lung, and spleen of all exposure groups did not change significantly.

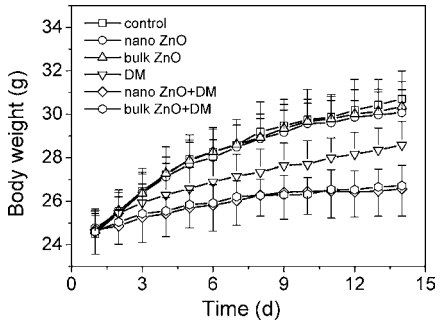

Figure 1. Changes of the body weight in mice ($n = 10$) during the administration period.

Combined Effects on Biodistributions of Zn and DM. Figure 2A shows the biodistribution of Zn in the mice after administration with nano or bulk ZnO and/or DM. A major percentage of Zn accumulated in the liver, lung, and spleen of mice after oral administration with nano or bulk ZnO. The biodistribution of Zn in the DM group was similar to that in the control group. Co-administration with nano ZnO and DM significantly increased the biodistribution densities of Zn in the liver and lung ($p < 0.05$) compared to the nano ZnO group. Similarly, co-administration with bulk ZnO and DM also significantly increased the biodistribution densities of Zn in the liver and lung compared to the bulk ZnO group. DM is lipophilic in nature and prone to interacting with the cell membrane, which results in a disturbance in the phospholipids bilayer structure,[33] allowing Zn^{2+} to easily pass through the membrane and distribute into the tissues. As a result, DM

[a]The mice were intragastrically administered with nano or bulk ZnO and/or DM for 14 days. Data shown are means ± SD (n = 10). [b]$p < 0.05$ vs the control. [c]$p < 0.05$ vs the nano ZnO group. [d]$p < 0.05$ vs the DM group. [e]$p < 0.05$ vs the bulk ZnO.

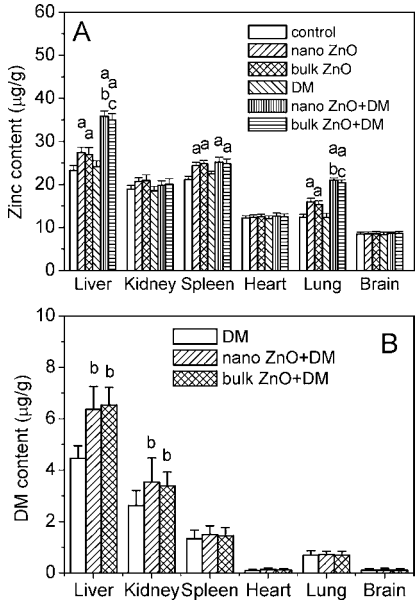

Figure 2. Biodistributions of DM and Zn in the mice tissues determined by GC−MS and ICP-AES. The male mice were intragastrically administered with nano or bulk ZnO and/or DM for 14 days. (A) The Zn contents in the different tissues of the mice. (B) The DM contents in different tissues of mice. Statistical significance: a, $p < 0.05$ vs the control; b, $p < 0.05$ vs the nano ZnO (A) or DM (B) group. Values represent means ± SD, n = 10.

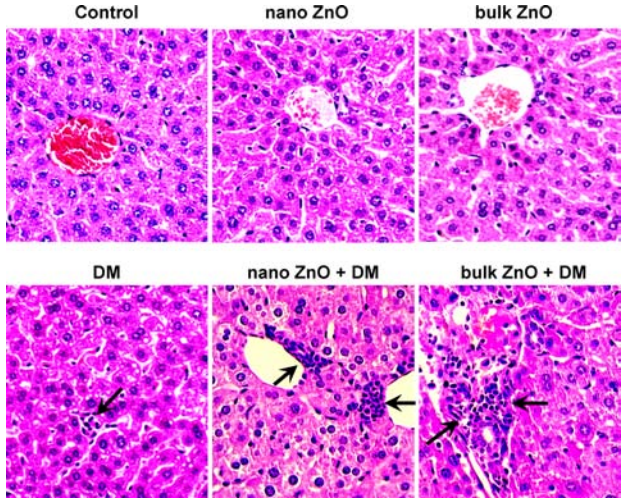

Figure 3. Pathological images of the mice liver tissue following daily intragastrical administrations of nano or bulk ZnO and/or DM for 14 days. No abnormalities were seen in the control, bulk ZnO, and nano ZnO groups. In the DM group, the infiltration of inflammatory cells (arrow) was seen around the central vein. In the nano ZnO + DM and bulk ZnO + DM groups, multiple areas of spotty necrosis (arrows) were induced around the central vein.

significantly increases the biodistribution density of Zn in mice liver.

As shown in Figure 2B, the majority of DM was accumulated in the liver, kidney, and spleen after administration with DM. Interestingly, co-administration with nano ZnO and DM significantly increased DM accumulation in the liver and kidney compared to the DM group. Similarly, coexposure to bulk ZnO and DM also significantly increased DM accumulation in the liver and kidney compared to the DM group. These results together indicate that co-administration of DM and nano or bulk ZnO results in the enhanced accumulation of Zn and DM in the liver.

Effects of Co-Administration on Pathological Changes in Tissues. As shown in Figure 3, in the nano and bulk ZnO groups, no abnormalities were observed in the liver. In the DM group, the infiltration of inflammatory cells around the central vein was observed in the liver. In the nano ZnO + DM group, multiple areas of spotty necrosis were found in the liver. These results indicate that co-administration with nano ZnO and DM induces more pathological damage in the liver than administration of either nano ZnO or DM alone, which is attributed to the co-administration-induced increases in the accumulation of DM and Zn in the liver. Similarly, multiple areas of spotty necrosis were also found in the liver in the bulk ZnO + DM group, indicating that co-administration with bulk ZnO and DM also increased DM-induced pathological damages in the liver. Compared with the control, no apparent abnormal changes were found in the cellular structures of heart, spleen, kidney, brain, and lung tissues in all administrated mice (Figure S2, SI).

Effects of Co-Administration on Liver and Kidney Functions. The combined toxicity of nano ZnO and DM in mice was analyzed by a blood biochemical assay. As shown in Table 2, administration with nano or bulk ZnO did not significantly effect the serum biochemical parameters of mice, except that their LDH that significantly increased ($p < 0.05$) compared with the control value, revealing that nano or bulk ZnO did not influence the kidney function but slightly influenced the liver function. On the contrary, administration with DM significantly increased the AST, ALP, LDH, and TBIL levels compared with the control ($p < 0.05$), indicating DM-induced liver dysfunction. Co-administration with nano ZnO and DM significantly increased the AST, ALT, ALP, LDH, and TBIL levels ($p < 0.05$), compared with either the nano ZnO or the DM group, suggesting that co-administration with nano ZnO and DM had an enhanced influence on the liver dysfunction, which is attributed to the co-administration-induced synergistic accumulation of DM and Zn in the liver.

Table 2. Changes in Biochemical Parameters in Mice Serum[a]

index	control	nano ZnO	bulk ZnO	DM	nano ZnO + DM	bulk ZnO + DM
AST (U/L)	93 ± 10	112 ± 9	109 ± 9	135 ± 14[b]	158 ± 16[b,c,e]	153 ± 12[b,d,e]
ALT (U/L)	31.2 ± 2.8	33.2 ± 4.8	31.9 ± 5.6	34.9 ± 7.1	62.0 ± 11.9[b,c,e]	60.3 ± 10.2[b,d,e]
ALP (U/L)	136 ± 15	139 ± 11	133 ± 17	174 ± 23[b]	218 ± 28[b,c,e]	226 ± 12[b,d,e]
LDH (U/L)	613 ± 23	809 ± 27[b]	797 ± 33[b]	838 ± 36[b]	987 ± 52[b,c,e]	973 ± 37[b,d,e]
TBIL (μmol/L)	0.98 ± 0.13	1.08 ± 0.11	1.03 ± 0.09	1.39 ± 0.12[b]	1.61 ± 0.08[b,c,e]	1.58 ± 0.16[b,d,e]
ALB (g/L)	36.4 ± 2.5	37.8 ± 1.9	36.9 ± 2.6	40.4 ± 2.3	39.5 ± 3.5	38.8 ± 3.4
TP (g/L)	52.4 ± 3.5	51.6 ± 2.9	52.8 ± 2.8	54.5 ± 3.9	52.6 ± 4.4	53.8 ± 3.1
CRE (μmol/L)	51.2 ± 3.2	50.8 ± 3.0	50.2 ± 2.2	49.5 ± 4.7	49.1 ± 2.8	50.7 ± 4.0
BUN (mmol/L)	8.63 ± 0.58	8.26 ± 0.36	8.94 ± 0.44	8.57 ± 0.39	8.73 ± 0.66	8.51 ± 0.45

[a]The mice were intragastrically administered with nano or bulk ZnO and/or DM for 14 days. Data shown are means ± SD (n = 10). [b]$p < 0.05$ vs the control. [c]$p < 0.05$ vs the nano ZnO group. [d]$p < 0.05$ vs the bulk ZnO group. [e]$p < 0.05$ vs the DM group.

Similarly, co-administration with bulk ZnO and DM also had an enhanced influence on the liver dysfunction. The significant increase in the LDH level was caused by hepatocellular necrosis after co-administration of nano or bulk ZnO with DM. The kidney function markers CRE and BUN did not change obviously in all administrated mice, suggesting that co-administration with nano or bulk ZnO and/or DM did not significantly influence the renal function.

Effects of Co-Administration on ChE Activity. The combined toxicity of nano ZnO and DM in mice was investigated by ChE assay. As reported previously, DM is a ChE inhibitor.[26,34] Figure 4 shows the ChE activities in the liver

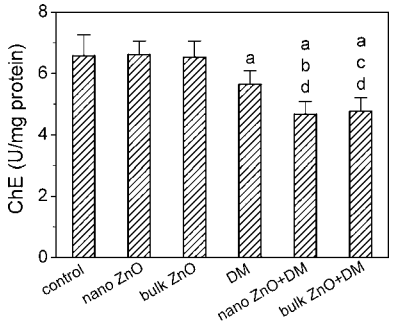

Figure 4. ChE activity of mice liver following daily intragastrical administrations of nano or bulk ZnO and/or DM for 14 days. Statistical significance: a, $p < 0.05$ vs the control; b, $p < 0.05$ vs the nano ZnO group; c, $p < 0.05$ vs the bulk ZnO; d, $p < 0.05$ vs the DM group. Values represent means ± SD, n = 10.

of the mice after administration with nano or bulk ZnO and/or DM. In the nano and bulk ZnO groups, the ChE activity did not significantly change compared with the control value. Administration with DM resulted in marked inhibition in the ChE activity in the liver. In the nano ZnO + DM group, ChE activity in the liver was significantly inhibited compared to either the nano ZnO or the DM group, revealing that nano ZnO significantly enhances the inhibition of the ChE activity by DM, which is attributed to an increase in DM and/or nano ZnO accumulation in the liver after co-administration with nano ZnO and DM. Similarly, co-administration with bulk ZnO and DM also significantly enhanced the inhibition of the ChE activity by DM.

Effects of Co-Administration on Oxidative Stress in Liver. The combined effect of co-administration of nano ZnO with DM on the oxidative damage in mice liver was investigated by analysis of the endogenous antioxidative enzymes, GPx, SOD, and CAT. Previous studies revealed that a decreased level of antioxidative enzyme is related to increased oxidative stress.[35] Figure 5 shows that administration with nano or bulk ZnO did not induce apparent oxidative stress in mice liver. On the contrary, administration with DM caused significant decreases in GPx and CAT activities in mice liver, indicating that DM induced significant oxidative stress in the liver. The oxidative stress is owing to a high accumulation of DM in the liver after administration with DM. It is worthwhile to note that administration with DM caused an increase of SOD activity in mice liver. The increased SOD activity is accounted for by a DM-activated compensatory mechanism.[36] Co-administration with nano ZnO and DM led to significant decreases ($p < 0.05$) in GPx, CAT, and SOD activities in mice liver compared to that in either nano ZnO or DM group, revealing that co-administration with nano ZnO and DM causes more severe oxidative stress in mice liver than administration with either nano ZnO or DM alone, which is attributed to the co-administration-induced enhanced accumulation of DM and Zn in the liver. Similarly, co-administration with bulk ZnO and DM also significantly enhanced the DM-caused oxidative stress in mice liver.

MDA is the final product of lipid peroxidation, and the MDA level indicates the level of oxidative damage in organs. Figure 5D shows that administration with nano or bulk ZnO did not significantly effect on the level of MDA in mice liver, compared to that in the control. By contrast, administration with DM induced a significant increase of the MDA level in mice liver ($p < 0.05$) than that in control group, indicating that the lipid peroxidation of the liver was induced by DM. The oxidative damage in mice liver resulted in its pathological change (Figure 3) and dysfunction (Table 2). Co-treatment with nano ZnO and DM resulted in a significantly higher concentration of MDA ($p < 0.05$) in mice liver compared to that in either the nano ZnO or the DM group, indicating an enhanced influence of nano ZnO and DM on lipid peroxidation in mice liver, which may be explained by the fact that DM and nano ZnO significantly enhanced the accumulation of each other in the liver. Similarly, co-administration with bulk ZnO and DM also significantly enhanced the DM-induced lipid peroxidation in the liver.

Stability of Nano or Bulk ZnO in Artificial Gastric Fluid. When nanoparticles are administrated orally to animals, the dissolution behaviors in gastric fluid should be checked. However, there are several conflicting results on the dissolution of nano ZnO in AGF. Seok et al. reported that around 98% of nano ZnO (40 nm) had dissolved in AGF (pH 1.7).[4] Cho et al. showed that all nano ZnO (89.3 nm) dissolved in AGF (pH 1.5) within 5 min.[8] However, Wang et al. found that only 3.3%

J. Agric. Food Chem. 2015, 63, 8292−8298

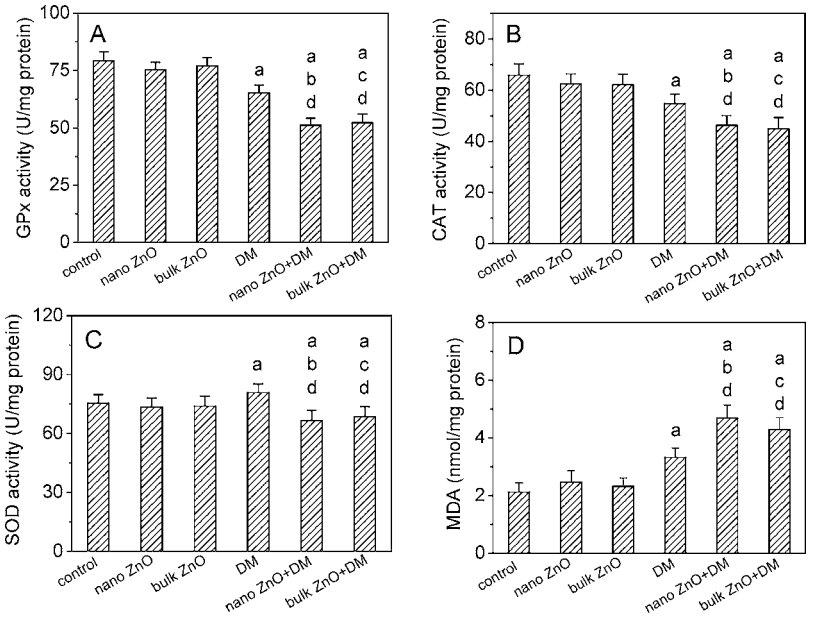

Figure 5. Activities of GPx, CAT, and SOD and the MDA level in the mice liver after daily intragastrical administrations with nano or bulk ZnO and/or DM for 14 days. Statistical significance: a, $p < 0.05$ vs the control; b, $p < 0.05$ vs the nano ZnO group; c, $p < 0.05$ vs the DM group; d, $p < 0.05$ vs the bulk ZnO. Data were shown as means ± SD ($n = 10$).

of nano ZnO (20 nm) had dissolved in AGF (pH 1.2).[37] Paek et al. demonstrated that about 13−14% of zinc ions in nano ZnO (20 and 70 nm) was released into the AGF (pH 1.5), and the release level was not influenced by size.[38] To analyze the stability of nano or bulk ZnO in gastric fluid, different amounts of bulk ZnO or nano ZnO were incubated with acidic AGF. When the concentration of bulk or nano ZnO was less than or equal to 5 mg/mL, the milk-white nano or bulk ZnO solution became clear within a few minutes after incubation with the AGF, indicating that all of nano or bulk ZnO mass had dissolved in the AGF. The ICP-AES data show that 98.4% of Zn^{2+} ions in nano ZnO and 97.8% of Zn^{2+} ions in bulk ZnO were released into supernatant after incubation of nano or bulk ZnO (5 mg/mL) with the AGF for 4 h (Figure 6B), further confirming that almost all of the nano or bulk ZnO dissolved in the AGF. However, when the concentration of nano or bulk ZnO exceeded 5 mg/mL, the milk-white nano or bulk ZnO solutions were still unclear after incubation with the AGF for 4 h, suggesting that only part of nano or bulk ZnO dissolved in the AGF. As shown in Figure 6A, the concentration of Zn^{2+} in AGF was almost constant with the increases of the concentrations of nano or bulk ZnO from 5 to 8 mg/mL, indicating that the dissolved Zn^{2+} concentration tended to equilibrium. These results reveal that the dissolution of bulk ZnO in AGF was similar to that of nano ZnO. Nano or bulk ZnO at low concentration (≤5 mg/mL) almost completely dissolved in the AGF. However, nano or bulk ZnO at high concentration (>5 mg/mL) partly dissolved in the AGF. The previous conflicting results on the dissolution of nano ZnO in AGF should be due to the concentrations of nano ZnO used in each experiment being different.[4,8,37,38]

In the present study, the concentration of administered nano or bulk ZnO was 0.5 mg/mL, which was much less than 5 mg/mL. After administration, the solution of nano or bulk ZnO was diluted with the gastric fluid and its concentration should further decrease. It appears that both bulk and nano ZnO administered by the oral route must dissolve completely in the

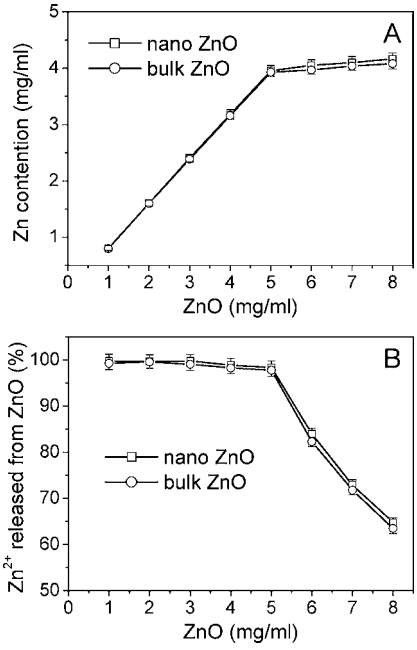

Figure 6. Zn^{2+} ions released from nano or bulk ZnO in AGF. The content of Zn^{2+} in AGF (A) and the percentage of dissolution of Zn^{2+} ion (B) were measured using ICP-AES after incubation of nano or bulk ZnO with the artificial gastric fluid (0.32% pepsin, 0.2% NaCl, pH 1.5) for 4 h. Data shown are means ± SD ($n = 3$).

stomach of mice. The dissolved Zn^{2+} ions will be absorbed through the small intestine and then enter into the systemic circulation.[39] The fast dissolution of both bulk and nano ZnO in acidic gastric fluid results in that bulk ZnO and nano ZnO have the nearly identical, slight effects on the liver function in the mice after oral administration, regardless of particle size. In addition, the results of the function and histopathology of mice liver show that both nano and bulk ZnO have nearly identical enhancement effects on the DM toxicity in the liver after oral

DOI: 10.1021/acs.jafc.5b01979
J. Agric. Food Chem. 2015, 63, 8292−8298

co-administration with DM. The data from the oxidative stress measurement and ChE activity assay also confirm that both nano and bulk ZnO have the nearly identical enhanced effects on DM-induced toxicity in mice liver.

Nano ZnO represents an important class of toxicant, because nano ZnO is unstable in aqueous solutions and releases Zn^{2+} and the high level of Zn^{2+} can induce oxidative stress inside cells.[40,41] It is well-known that free Zn^{2+} is highly reactive and toxic.[4] Our results demonstrated that oral administration of nano ZnO (30.1 nm) at a dose of 50 mg/kg BW for 14 days did not cause observable injury in mice, suggesting that most Zn^{2+} ions released from nano ZnO may form compounds with biomolecules and the amount of free Zn^{2+} is insufficient to cause injury in mice. However, Sharma et al. showed that oral administration of nano ZnO (30 nm) at a dose of 300 mg/kg BW for 14 consecutive days caused significant injury in mice liver.[27] Similarly, Esmaeillou et al. reported that exposure of nano ZnO (20−30 nm) through oral gavage at a single dose (333.33 mg/kg BW) had severe toxicological effects on the liver, kidney, and lung of mice.[42] These findings together with present results indicate that the low amount of nano ZnO is biocompatible; however, nano ZnO at high doses displays hazardous effects. Therefore, the content of nano ZnO in food and food supplements is the critical matter for its safe application.

Nano ZnO at low dose is safe for application in food and food supplements. However, in the case of coexposure with DM, our findings demonstrate that nano ZnO significantly enhances DM-induced damage in mice liver, which is attributed to the enhanced accumulation of Zn and DM in the liver. People may be exposed to nano ZnO and/or DM at different doses in different situations. The dose of nano ZnO or DM used in our experiments do not necessarily reflect the actual concentration of nano ZnO or DM found in real situations; however, the data can be used to assess the health risks from coexposure to nano ZnO and DM. In the present study, we have made the first attempt to evaluate the effect of nano ZnO on DM-induced toxicity in mice. Further evaluation of the combined toxicity of nano ZnO and DM in animals at various doses is needed.

In summary, although nano ZnO at a dose of 50 mg/kg BW is of low toxicity to male mice, co-administration with nano ZnO and DM significantly enhances DM-induced injury in mice liver, which is due to the enhanced accumulation of Zn and DM in mice liver. The increased accumulation of Zn and DM causes marked oxidative stress in mice liver, which results in severe liver damage. These findings suggest that close attention should be paid to the combined toxicity of nanoparticles and pesticides with the increasing use of nanomaterials in the world.

an important task to ameliorate the condition of allergic patients.

The selection of wheat varieties expressing low or no concentrations of allergens is presently underway.[8] This is favored by the wide biodiversity of the genus *Triticum*. Indeed, differences in the IgE-binding capacity of certain wheat varieties have been observed in patients affected by baker's asthma[9−11] and food allergy,[10,12−14] including WDEIA. Although a certain degree of variability in the allergenic potency of the various cultivars was shown, previous works failed to find reliable hypoallergenic candidates. With regard to baker's asthma, the polysensitization profile of patients is one of the limiting factors.[15] Although sensitization is usually limited to ω-5 gliadins,[16] as far as food allergy is concerned, no wheat varieties expressing this allergen have been identified thus far, except for a translocated wheat, in which part of the short arm of the 1B chromosome was replaced with a portion of the short arm of the 1R chromosome of rye.[12] Finally, no study has specifically evaluated the immunoreactivity of different wheat varieties *in vivo* [i.e., by skin prick test (SPT)].

ω-5 gliadins, which are encoded at the Gli-B1 locus present in the B chromosome, are inevitably associated with durum and bread wheats. For this reason, the diploid wheat *Triticum monococcum* (*T.m.*), known also as "einkorn", might represent a potential alternative to conventionally used wheat. Indeed, the genome of *T.m.* is A^mA^m, very close to the A^uA^u present in modern wheat; thus, the only ω gliadins expressed are those associated with the locus Gli-A1, never related to WDEIA thus far.[12] Corbellini et al.[17] demonstrated that some einkorn accessions possessing good bread-making characteristics do not present the typical electrophoretic bands of *T.a.* ω gliadins, which would support the possible use of this cereal as a hypoallergenic option for WDEIA patients. The aim of this study was to assess the immunoreactivity of *T.m.* proteins among patients suffering from WDEIA, by immunochemical techniques and SPT, and to evaluate the suitability of this cereal in the future development of hypoallergenic flours.

MATERIALS AND METHODS

Wheat Extraction. Four einkorn wheat accessions cultivated at the Istituto Sperimentale della Cerealicoltura in Sant'Angelo Lodigiano, Lodi, Italy (ID109, ID358, ID1331, and Monlis) were selected. These accessions are characterized by good bread-making characteristics.[17,19,20] *T.a.* cv. Bologna was used as a wheat reference. A total of 1 g of seeds of each sample was milled in a mortar and extracted in phosphate-buffered saline (PBS, pH 7.2, 1:10, w/v) as previously described[21] for 2 h at room temperature (RT). After centrifugation at 12000*g*, the supernatants were collected and stored at −20 °C and the pellets were subsequently washed with PBS and distilled water. The supernatants obtained after these washing steps were discarded. The pellets were finally extracted with 40% ethanol (1:5) for 2 h and centrifuged. The supernatants containing the PBS-insoluble gliadins (mainly) and glutenins (to a lesser extent) were collected and stored at −20 °C.

Preparation of Prick Test Diagnostic Solutions. Diagnostic solutions were produced by diluting the protein extracts (accessions ID109, ID358, ID1331, and Bologna) in a storage solution containing 40% glycerol and 0.4% phenol for commercial preparations. The protein concentrations were 1.5 mg/mL for the PBS-soluble proteins and 0.5 mg/mL for the PBS-insoluble proteins. The concentration of ω-5 gliadin was 0.1 mg/mL. Diagnostic solutions were filtered at 0.20 μm in sterile conditions.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS−PAGE) and IgE Immunoblotting. The protein extracts from the different wheat samples were mixed with 2× loading buffer (62.5 mM Tris−HCl at pH 6.8, 1.3% (w/v) SDS, 10% (w/v) glycerol, and 4% β-mercaptoethanol) and heated at 100 °C for 5 min. Proteins (50 μg/cm of lane width) were separated in 16% SDS−PAGE at 20 mA current by means of a Mini Protean III apparatus (Bio-Rad, Hercules, CA) in 25 mM Tris−192 mM glycine and 0.1% SDS (pH 8.4). The gels were stained with Coomassie R250.

Alternatively, proteins were electroblotted onto nitrocellulose (Millipore, Schwalbach, Germany) at 50 V for 150 min. The membrane was blocked with 1% BSA and 0.05% Tween 20 in PBS (PTB) and probed with the sera of patients at 1:10 dilution. Bound IgE was detected by a monoclonal horseradish peroxidase (HRP)-conjugated anti-IgE antibody (Southern Biotech, Birmingham, AL) at 1:1500 dilution, followed by chemiluminescence reaction with Immobilon Western Chemiluminescent HRP Substrate (Millipore) and image acquisition by a Chemidoc XRS apparatus (Bio-Rad).

Purification of ω-5 Gliadin. A *T.a.* extract from 20 g of seeds was used to purify ω-5 gliadin. The ethanol-soluble protein fraction was concentrated by adding 2 volumes of 1.5 M NaCl and leaving the solution overnight at 4 °C. After the centrifugation at 10000*g* for 15 min, the supernatant was discarded and the gluten proteins in the pellet were solubilized in 6 M guanidine HCl, adjusted to pH 8 with Tris−HCl + 50 mM dithiothreitol (DTT). Purification was carried out by reversed-phase high-performance liquid chromatography (RP-HPLC) on a Vydac 218TP C18 semi-preparative column (10 × 250 mm, 5 μm particle size) and separated at a 5 mL/min flow rate in 0.05% trifluoroacetic acid with a 10−70% acetonitrile gradient in 65 min and 70−90% acetonitrile gradient in 10 min as described previously.[22] Peaks were collected, lyophilized, and analyzed by immunoblotting with the sera of patients to identify the immunoreactive ω-5 gliadin.

HPLC−Tandem Mass Spectrometry (MS/MS) Analysis of the Purified ω-5 Gliadin. A protein amount of 3 μg of putative ω-5 gliadin isolated by HPLC was lyophilized and diluted in 50 μL of 0.084 N HCl. Pepsin from porcine pancreas (Sigma-Aldrich, St. Louis, MO) was added in a 1:60 enzyme/protein ratio. After 2 h, the digest underwent ZipTip cleaning (Millipore) following the procedure of the manufacturer and then lyophilized.

Peptides were separated by reversed-phase nano-HPLC-Chip technology (Agilent Technologies, Palo Alto, CA) online coupled with a three-dimensional (3D) ion trap mass spectrometer (model Esquire 6000, Bruker Daltonics, Bremen, Germany). The chip was composed of a Zorbax 300SB-C18 (150 mm × 75 μm, with a 5 μm particle size) analytical column and a Zorbax 300SB-C18 (40 nL, 5 μm) enrichment column. The complete system was fully controlled by ChemStation (Agilent Technologies) and EsquireControl (Bruker Daltonics) softwares. The scan range used was from m/z 300 to 1800. For MS/MS experiments, the system was operated with automatic switching between MS and MS/MS modes. The three most abundant peptides of each m/z were selected to be further isolated and fragmented. The MS/MS scanning was performed in the normal-resolution mode at a scan rate of m/z 13.000 per second. A total of five scans were averaged to obtain a MS/MS spectrum. Database searches were conducted using the MS/MS ion search of Mascot against all entries of the non-redundant National Center for Biotechnology Information (NCBI) database with the following parameters: specific pepsin digestion, up to two missed cleavage; fixed and variable modifications, carbamidomethyl-Cys and oxidated Met, respectively; peptide and fragment tolerances, ±0.9 and ±0.9 Da, respectively; and peptide charges, +1, +2, and +3. For positive identification, the score of the result of $[-10 \log(P)]$ had to be over the significance threshold level ($p < 0.05$).

Patients and Diagnosis. A total of 14 patients [mean age of 42 years, with a standard deviation (SD) of 12.2; 10 male] attending the Verona Allergy Unit between January 2012 and January 2014 with an unequivocal clinical history of WDEIA (allergic symptoms after exercise within 4 h of ingestion of wheat-based products) and positive serum ω-5 gliadin-specific IgE were studied in the standard diagnostic setting. All of the participants were informed about the study by the medical team and signed an informed consent approved by the ethics

committee. The clinical characteristics of patients and the results of diagnostic workup are summarized in Table 1.

A total of 11 patients had a history of severe systemic reactions (urticaria angioedema, dyspnea, and/or hypotension), while 3 patients experienced only urticaria after exercise within 4 h of wheat product ingestion.

A total of 7 patients reported symptoms also in the case of exposure to co-factors other than exercise: 3 after NSAIDs intake, 3 with concomitant alcohol ingestion, and 1 with both.

The allergic patients underwent SPTs with a commercial wheat extract (Lofarma, Milano, Italy), solutions of PBS-soluble and -insoluble protein fractions of *T.a.*, three different accessions of *T.m.* (ID109, ID358, and ID1331), and purified ω-5 gliadin following standard procedures.[18] Results were considered positive if the mean wheal diameter was 3 mm or larger after 15 min. Histamine dihydrochloride (10 mg/mL, Alk-Abellò, Copenhagen, Denmark) and physiological saline were used for positive and negative controls.

Serum-specific IgE to wheat, gluten, and recombinant ω-5 gliadin were assayed with ImmunoCAP (Thermo Fisher Diagnostics, Uppsala, Sweden). Concentrations of ≥0.35 kU/L were considered positive.

Enzyme-Linked Immunosorbent Assay (ELISA) for Wheat-Specific IgE Detection. ELISA was performed on Maxisorp 96 well microplates (Nunc A/S, Roskilde, Denmark). Purified ω-5 gliadin (50 ng per well) or the ethanol extract from the different wheat accessions (0.1 mg/mL) was diluted in PBS and non-covalently coated for 30 min at RT. After washing with PBS and 0.05% Tween 20, the wells were blocked with PTB for 30 min at RT. The sera of patients were incubated at 1:10 dilution in PTB overnight. For ELISA inhibition performed on ω-5 gliadin-coated wells, sera were co-incubated with ethanol extracts from *T.a.* and *T.m.* accessions diluted in PTB (100 μg/mL final concentration). A buffer control was considered (no serum incubation), while the 100% signal was given by the omission of the inhibitor. Bound IgE was detected by incubation with an unlabeled mouse monoclonal anti-human IgE antibody (1:500, Southern Biotech, Birmingham, AL) for 1 h, followed by a HRP-conjugated anti-mouse immunoglobulin G (IgG) antibody (1:2000, Sigma-Aldrich) for 1 h, both diluted in PTB. Tetramethylbenzidine (TMB, Sigma-Aldrich) was used as the chromogenic substrate. Optical density (OD) was monitored at 450 nm by a Power Wave microplate reader (Bio-Tek, Winnoski, VT).

Statistics. Statistical analysis was performed by one-way, within subject, analysis of variation (ANOVA) test, followed by a post-hoc pairwise *t* test, with adjusted *p* values using the Holm method. Calculations were carried out using the R statistical computing platform. The Pearson coefficient was computed to test the correlations between the same data. All immunochemical analyses were performed in triplicate.

RESULTS

Purification of ω-5 Gliadin. The elution from HPLC revealed two main peaks in the region of the chromatogram, where ω gliadin was expected to elute as previously described.[22] MS/MS analysis identified the first peak as ω-5 gliadin, and SDS–PAGE confirmed the purity of the protein. The results are reported in Figure S1 and Table S1 of the Supporting Information.

***T.m.* Extracts Showed No Immunoreactivity by SPTs.** SPTs with the commercial wheat extract were positive only in six patients (42.8%), while 100% of tested patients were positive to the insoluble fraction of *T.a.* and purified ω-5 gliadin. Wheal diameters observed for the *T.a.*-insoluble fraction (8.1 ± 3.6 mm, with a range of 4–17 mm) and purified ω-5 gliadin (10.3 ± 3.3 mm, with a range of 7–16 mm) were larger than those obtained with the commercial wheat extract (1.6 ± 2.1 mm, with a range of 3–6 mm). These results are in agreement with previous data, showing a low sensitivity of commercial wheat SPTs[4,23] for patients affected by WDEIA. These findings might be a consequence of a low concentration of the responsible allergens (insoluble fraction) in wheat commercial extracts. Interestingly, 12 of 13 tested patients were also positive to *T.a.* salt-soluble extract (4.38 ± 2.2 mm, with a range of 2–9 mm).

A completely different pattern was observed for *T.m.* extracts. Both soluble and insoluble protein extracts of each *T.m.* accession failed to induce reactivity in almost all tested patients (Table 1). Only patient BT09 showed a positive signal with the insoluble fraction of ID109.

IgE of Patients React Mainly to Gluten Proteins. Specific IgE to wheat, gluten, and recombinant ω-5 gliadin measured by CAP were present in 8 (57.1%), 10 (71%), and 14 (100%) of the tested patients with a mean of 1.25, 3.98, and 14.06 kU_A/L, respectively. No significant correlations where found among the CAP values and SPT wheal diameters.

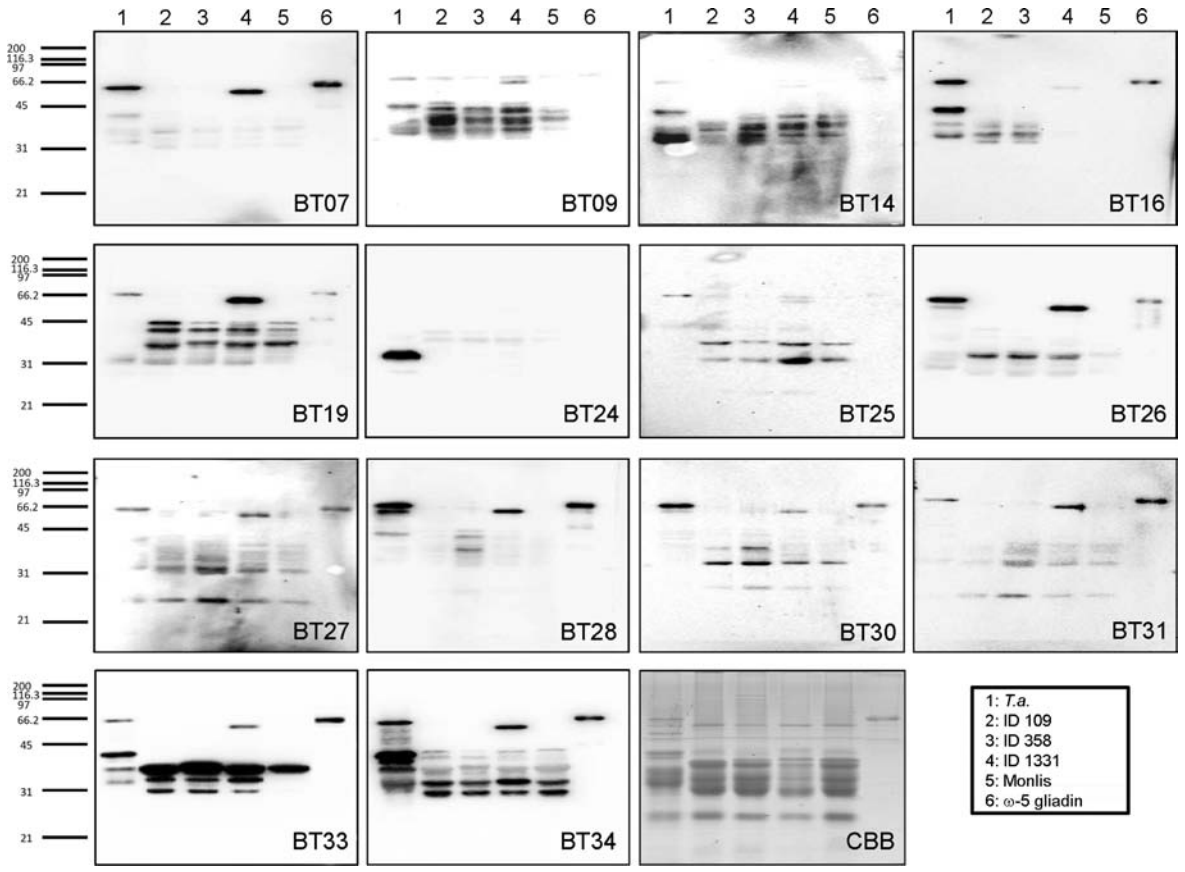

Figure 1. IgE immunoblotting of *T.a.* and *T.m.* PBS-insoluble extracts. Each panel corresponds with an immunoblotting developed with the serum of a specific patient. CBB = Coomassie Brilliant Blue staining.

Protein extracts from *T.a.*, ID109, ID358, ID1331, and Monlis were assayed with the sera of patients by immunoblotting to evaluate their IgE-binding capacity. In these experiments, we included *T.m.* Monlis, which, different from the other accessions, is registered as a marketable variety. Immunoblotting showed positive signals mainly for PBS-insoluble proteins (Figure 1), while the PBS-soluble proteins generated often faint signals and, in some cases, tested negative. This suggests that soluble proteins are scarcely involved in the pathogenesis of this disease. The results obtained for the PBS-soluble fraction are presented in Figure S2 of the Supporting Information. No significant correlations where found among the signals detected by immunoblotting and SPT wheal diameters. Concerning the immunoblotting carried out with the PBS-insoluble fraction (Figure 1), IgE-binding proteins were detected at 65 kDa in *T.a.* samples for 92% of the recruited patients, confirming that they possess IgE antibodies specific to ω-5 gliadin. The patient serum BT24 did not recognize ω-5 gliadin, despite a high CAP value to the same allergen. No patient resulted sensitized to HMW glutenins.

As far as *T.m.* accessions are concerned, in almost all patients, IgE bound proteins with lower molecular mass if compared to *T.a.*, and they are, therefore, reminiscent of α/β gliadins and LMW glutenins. In addition, ID1331 presents a protein band comigrating to ω-5 gliadin. This is in agreement with previous findings showing that ID1331, different from other *T.m.* accessions, possesses ω gliadins compatible with those of *T.a.*[17]

No IgE-binding protein was detected by immunoblotting with the sera of healthy volunteers (data not shown).

Einkorn Storage Proteins Show Partial Cross-Reactivity with ω-5 Gliadin Epitopes. A first set of direct ELISA experiments with the sera of patients was performed using insoluble protein extracts as coating (Figure 2). This demonstrated a general lower immunoreactivity of *T.m.* extracts in comparison to *T.a.*, except for the sera of four patients, i.e., BT14, BT24, BT27, and BT33, which showed rather similar immunoreactivity to all of the samples. ELISA experiments carried out with the sera of healthy volunteers showed negligible signals (data not shown). Measurements obtained by direct ELISA with the sera of individual patients on extracts from each wheat sample were grouped (Figure 3A), and differences between groups were analyzed statistically. *T.a.* extracts provided data significantly different from those obtained with the other wheats (Figure 3B; $p < 0.01$), whereas no differences were observed between the three *T.m.* accessions. Data from all samples were correlated (Figure 3C; Pearson coefficient > 0.90).

Because all patients are sensitized to ω-5 gliadin and given its role as a major allergen, we carried out ELISA inhibition experiments with purified ω-5 gliadin as coating. The results showed a limited cross-reactivity among *T.a.*- and *T.m.*-insoluble proteins (Figure 4). Indeed, the inhibition levels of *T.m.* accessions were generally lower than the *T.a.* auto-inhibition values, and for some patients (e.g., BT30 and BT31), no cross-reactivity was appreciable at all. Figure 5 summarizes the whole set of data. The percent inhibition values of *T.m.* accessions distributed differently (Figure 5A), with median values of 16% for ID109, 16% for ID358, and 23% for ID1331, with respect to 68% of *T.a.* Values measured for *T.a.* were

significantly different from those of *T.m.* accessions ($p < 0.01$; Figure 5B). Among the *T.m.* accessions, ID109 and ID358 showed the highest correlation level (Pearson coefficient = 0.92; Figure 5C), in agreement with the identical percent inhibition value calculated by ELISA. The higher percent inhibition value calculated for ID1331 correlates with the presence of the 65 kDa *ω*-5 gliadin-like band detected by IgE immunoblotting (Figure 1). The reason for the lack of total (i.e., 100%) autoinhibition of the IgE binding of *T.a.* proteins to the coated *ω*-5 gliadin is probably due to the low concentration of *ω*-5 gliadin in the *T.a.* protein extract. Notably, the sera of patients BT14 and BT33, despite a high immunoreactivity to *T.m.* accessions (Figure 2), showed low cross-reactivity with *ω*-5 gliadin. Patient BT24 showed higher cross-reactivity for all *T.m.* accessions.

DISCUSSION

The rationale of our work was to evaluate the immunoreactivity of wheat accessions whose genotype lacks B genome but, at the same time, possess good bread-making characteristics. A previous paper by Corbellini et al.[17] showed that some accessions of *T.m.* (A^mA^m) did not present typical *ω* gliadin electrophoretic bands. In addition, the accessions with this specific pattern showed good rheological traits, comparable to

T.a., giving better results in the SDS-sedimentation test than *T.m.* accessions with ω gliadin-like bands. This represents an important point because the main reason for the low exploitation of einkorn with respect to modern wheat, besides the lower production yield, is its poor dough quality.[24]

In a previous publication,[21] we evaluated different quality traits of several einkorn accessions that could make this wheat suitable for the production of functional foods. In particular, we found that *T.m.* lacks α-amylase inhibition activity, which, together with its high content in nutraceutical molecules, such as carotenoids, represents an interesting and attractive characteristic. The patients recruited for the present study were selected on the basis of clinical history and presence of ω-5 gliadin-specific IgE. Western blotting results confirmed immunoCAP results; the sera of all patients but one (BT24) contained IgE specific for a 65 kDa band identified as ω-5 gliadin by MS.

SPTs performed with in-house gluten-containing extracts (*T.a.*-insoluble protein extract) appeared definitely more sensitive than SPTs performed with the commercial wheat

DOI: 10.1021/acs.jafc.5b02648
J. Agric. Food Chem. 2015, 63, 8299−8306

extract. Moreover, positive SPT responses to gluten solution agreed with positive specific IgE to ω-5 gliadin in 100% of patients, while only 76.9% of patients positive to gluten SPTs displayed gluten-specific IgE, as measured by ImmunoCAP. This means that, for SPTs with *T.a.*, the insoluble protein fraction appears to be an excellent screening test for the disease. SPT with PBS-soluble proteins tested positive in 92.3% of the patients, but the immunoblotting carried out with this protein fraction failed to detect any IgE binding proteins in several patients (Figure. S2); the denaturing conditions of SDS−PAGE possibly affected the epitopes present in the PBS-soluble protein fraction. If so, this would lead us to question the real contribution of such epitopes in allergic manifestations after ingestion of transformed foods, such as bread, where proteins normally undergo strong thermal denaturation. The same line of reasoning could help in interpreting the results obtained with the serum of the patient BT24 that showed reactivity toward ω-5 gliadin by ImmunoCAP, ELISA, and SPT but not by immunoblotting.

Once the sera were used to probe the storage proteins of the three *T.m.* accessions, different IgE-binding patterns were obtained in comparison to *T.a.* The 65 kDa band was not recognized in accessions ID109, ID358, and Monlis, confirming the initial hypothesis, namely, that these wheats do not possess ω-5 gliadin; instead, lower molecular mass proteins were detected suggesting that either certain epitopes harbored in these proteins could cross-react with ω-5 gliadins or recognition could be mediated by different epitopes.

To quantify the immunoreactivity of *T.m.*-insoluble proteins and to evaluate their possible cross-reactivity with ω-5 gliadin expressed in modern *T.a.*, we followed an ELISA approach based on the detection of IgE-binding epitopes (1) in the insoluble protein extracts and (2) after the co-incubation of the sera of patients with the insoluble protein extracts from the three *T.m.* accessions on a coating of ω-5 gliadin. While the first results showed a certain degree of reduction in the IgE-binding capacity toward the insoluble proteins of *T.m.* accessions in comparison to *T.a.*, the inhibition approach showed that, for the majority of the patients, the cross-reactivity level between *T.m.*-insoluble proteins and ω-5 gliadin is rather low, less than 20%. It is of note that, despite this cross-reactivity, SPT performed with extracts of the three *T.m.* accessions was negative for almost all of the tested patients. Because it is acknowledged that the negative predictive value (NPV) for SPT is relatively high,[25] our results indicate that, despite a limited cross-reactivity to modern ω-5 gliadin, there is a reasonable possibility that the recruited patients might tolerate *T.m.*-based foods.

Taken together, these results suggest that *T.m.* accessions might represent a potential candidate for the production of hypoallergenic bakery goods for patients sensitized to ω-5 gliadin. Further analyses, such as oral provocation with *T.m.*-based products, should be carried out to investigate their safety.

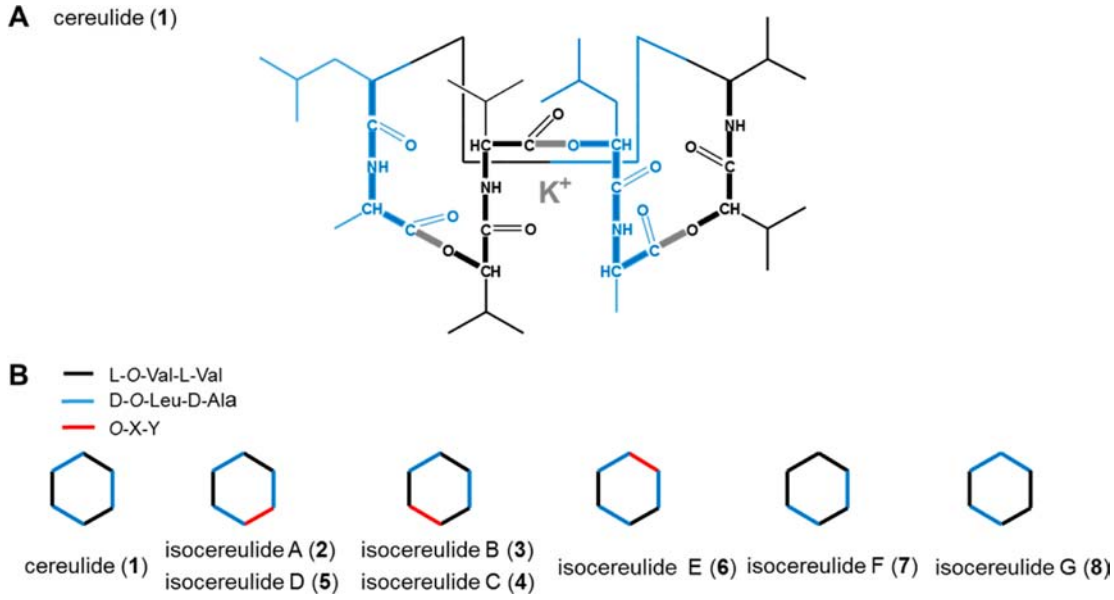

Figure 1. (A) Chemical structure of the cyclic dodecadepsipeptide cereulide (**1**), [D-*O*-Leu-D-Ala-L-*O*-Val-L-Val]$_3$; (B) chemical structure of isocereulides A (**2**) to G (**8**); *O*-X-Y indicates the position of the dipeptides L-*O*-Leu-L-Val (isocereulide A, **2**), D-*O*-Val-D-Ala (isocereulide B, **3**), D-*O*-Leu-D-Ser (isocereulide C, **4**), L-*O*-Val-L-Ala (isocereulide D, **5**), and D-*O*-Ile-D-Ala (isocereulide E, **6**).

A–G (**2**–**8**, Figure 1) were unequivocally determined in their chemical structure.[29,30] Most intriguingly, the isocereulides were found to differ widely in their cell toxicity correlating with their ionophoric properties; for example, purified isocereulide A showed about an 8-fold higher cytotoxicity than purified cereulide in the HEp-2 assay and induced an immediate breakdown of bilayer membranes.[30] As differences in the bioactivity of these dodecadepsipeptides and various concentrations might be correlated to gastrointestinal diseases ranging from acute and limited periods of vomiting to deadly intoxications, the knowledge-based risk assessment of *B. cereus* toxins in food and feed products requires more comprehensive quantitative tools to accurately analyze the major isocereulides along with cereulide. The objective of the present investigation was, therefore, to develop a rapid, sensitive, and robust stable isotope dilution assay for the combined quantitation of cereulide (**1**) and isocereulides A–G (**2**–**8**) by means of ultraperformance liquid chromatography–mass spectrometry (UPLC-MS/MS).

MATERIALS AND METHODS

Chemicals. Water for chromatographic separations was purified with an integral 5 system (Millipore, Schwalbach, Germany), and solvents used were of HPLC or LC-MS grade, respectively (J. T. Baker, Deventer, The Netherlands). For cultivation of bacteria strains, the following compounds were obtained commercially: MeOH and EtOH (Mallinckrodt Baker B.V., Deventer, The Netherlands); pepton tryptone, yeast extract (Oxoid, Hamphsire, UK); NaCl (Carl Roth, Karlsruhe, Germany); D-glucose monohydrate (Fluka, Sigma-Aldrich, Steinheim, Germany); and $^{13}C_1$-L-valine (Cambridge Isotope Laboratories, Inc., Andover, MA, USA). Eleven dairy-based desserts, five rice puddings, three cereals, two rice samples, two baby foods, and two animal feed products were purchased from a local supermarket (Freising, Germany). In addition, two suspicious noodle samples, each causing intoxications in child daycare facilities, were obtained from the German Health and Food Safety Authority.

UPLC-TOF-MS Profiling of Bacterial Strain Panel. A total of 78 representative *B. cereus* strains were collected on the basis of the following criteria as recently reported:[29] (i) source, clinical isolates from patients (associated with food poisoning/associated with other clinical infections), isolates from food (associated with food poisoning/not associated with food poisoning), environmental isolates; (ii) diversity in geographical origins; and (iii) diverse toxin gene profiles representing different subtypes. Strains were grown on Luria–Bertani (LB) agar plates or in LB broth (5 g/L NaCl, 5 g/L yeast extract, 10 g/L tryptone) at 24 °C for 24 h and were labeled with a designation number (1–78).

For UPLC-TOF-MS strain profiling, LB broth (100 mL) supplemented with D-glucose (0.2%) and NaCl (0.5%) was inoculated with an overnight preculture (10^3 cfu/mL) and incubated (24 h, 24 °C) in baffled flasks (500 mL) while rotary shaking (120 rpm). The optical density of the cell cultures was measured at 600 nm (OD_{600}) against LB medium (reference) using a GeneQuant pro spectrophotometer (Biochrom, UK). Cell cultures were diluted 1:20 in LB if the OD_{600} was >1.0. The cultures were autoclaved (15 min, 121 °C) and centrifuged (7800*g*, 20 °C, 12 min, Sigma 3-18 K), and the pellet obtained was extracted with ethanol (10 mL) by shaking for 15 h. After centrifugation (7800*g*, 12 min), the supernatant was centrifuged (18600*g*, 5 min) again and membrane filtered (0.2 μm; Phenomenex, Aschaffenburg, Germany), and aliquots (3 μL) were analyzed by UPLC-TOF MS.

Biosynthetic Production of Cereulide, Isocereulides, and $^{13}C_6$-Cereulide. For production of reference materials of cereulide (**1**), isocereulides A–G (**2**–**8**), and $^{13}C_6$-cereulide ($^{13}C_6$-**1**), the *B. cereus* strains F4810/72 and WSBC 10925 were cultivated for 24 h at 24 °C in LB broth supplemented with D-glucose (0.2%) and MOD medium,[31] modified by adding sucrose (20 mM) and adjusting the final concentration of L-valine or $^{13}C_1$-L-valine (for $^{13}C_6$-**1**) to 20 mM while omitting L-isoleucine as reported previously.[28–30,32] After EtOH extraction, the target compounds were purified by C18 SPE cleanup, followed by preparative RP-HPLC, and their chemical structures were verified by means of UPLC-TOF MS and NMR experiments.[28,30]

UPLC-MS/MS-SIDA Quantitation of Cereulide (1) and Isocereulides A–G (2–8). For the preparation of an ethanolic stock solution of the target analytes, purified cereulide (**1**) and isocereulides A–G (**2**–**8**) were solubilized in ethanol and the exact individual concentrations determined by UPLC-MS/MS quantitation of **1**–**8** using $^{13}C_6$-cereulide as internal standard (triplicate analysis): cereulide (**1**; 89.35 ng/mL); isocereulide A (**2**; 99.35 ng/mL); isocereulide B (**3**; 90.66 ng/mL); isocereulide C (**4**; 14.51 ng/mL); isocereulide D (**5**; 67.19 ng/mL); isocereulide E (**6**; 78.01 ng/mL); isocereulide F (**7**; 67.37 ng/mL); and isocereulide G (**8**; 161.20 ng/

[a]Concentrations are given as the mean of three independent sample preparations with triple injection. [b]Reproducibility (interday precision as RSD in % and amount in ng/g) of three independent sample preparations analyzed at three different days (triple injection, each). [c]Repeatability (intraday precision as RSD in %) was determined using three replicates for each concentration in 1 day. [d]Limits of detection (LOD) and quantitation (LOQ) were calculated by analyzing spiked rice blank samples and were determined as the lowest concentrations of analyte for which signal-to-noise ratios were 3 and 10.

mL). Homogenized food samples (0.25 g) were weighed into a centrifuge tube (15 mL, Sigma-Aldrich, Germany) and spiked with a solution of $^{13}C_6$-cereulide (1.72 ng/mL in EtOH) as internal standard. For validation experiments, aliquots of the ethanolic stock solution of analytes **1–8** were spiked at different concentrations to a rice sample. After vortexing for 30 s and equilibration for 30 min at room temperature, extraction with MeCN (3 mL) was performed by shaking tubes for 1 h horizontally on a rocking table (250 rpm; Gesellschaft für Labortechnik mbH, Germany). The mixture was then centrifuged for 10 min (4.4 rpm, Eppendorf AG, Germany), and the supernatant was membrane filtered (0.45 μm; Schleicher & Schuell, Germany) and then directly analyzed by means of UPLC-MS/MS. Quantitation of the analytes was performed by means of a calibration curve using cereulide as analyte and $^{13}C_6$-cereulide as internal standard. Standard solutions of cereulide (0.04, 0.08, 0.41, 0.83, 1.65, 4.13, 8.25, 10.32, 12.38, 16.51, and 20.63 ng/mL in MeCN) and $^{13}C_6$-cereulide (1.72 ng/mL) were mixed and analyzed in triplicates by means of UPLC-MS/MS. A calibration curve was prepared by plotting peak area ratios of analyte to internal standard against concentration ratios of each analyte to the internal standard using linear regression (origin excluded). The equation for the quantifier mass transition (m/z 1170.7 → 357.2) obtained was $y = 1.4017x - 0.0475$ (cereulide/[$^{13}C_6$]-cereulide, $R^2 = 0.9998$).

Method Validation. The trueness and accuracy of the method were studied by recovery experiments by spiking a cooked rice sample with cereulide (**1**) and isocereulides A–G (**2–8**) at two concentration levels, each in three replicates, and triple UPLC-MS/MS injection (Table 1). Reproducibility and repeatability were determined to evaluate the robustness of the method. To study reproducibility, the rice sample was spiked with analytes **1–8** (Table 1), two replicates each, and analyzed in triplicates on three different days. Technical repeatability was studied by evaluation of results from triplicates received through quantitation of three independent sample replicates prepared with two different concentrations of analytes **1–8** (Table 1). To determine the limit of detection (LOD) and the limit of quantitation (LOQ), blank rice samples were spiked with different concentrations of cereulide and isocereulides A–G (Table 1) and equilibrated for 24 h at room temperature, and, after addition of the internal standard $^{13}C_6$-cereulide, quantitation was performed by UPLC-MS/MS as detailed above. LOD and LOQ were calculated as the concentrations equaling signal-to-noise ratios of 3 and 10, respectively.

Ultraperformance Liquid Chromatography–Mass Spectrometry. Mass spectrometric analyses were performed on a Waters Xevo TQ-S mass spectrometer (Waters, Manchester, UK) coupled to an Acquity UPLC i-class core system (Waters, Milford, MA, USA) consisting of a binary solvent manager, sample manager, and column oven. Aliquots (2 μL) of prepared samples were injected into the UPLC/MS-MS system equipped with a 2.1 × 150 mm, 1.7 μm, UPLC CSH C18 column (Waters, Manchester, UK). Operated with a flow rate of 0.7 mL/min at a temperature of 55 °C, the following gradient was used for chromatography: starting with a mixture (85:15, v/v) of MeCN (0.25% HCOOH) as solvent A and $HCOONH_4$ (10 mmol, 0.1% HCOOH) as solvent B, solvent A was increased to 95% within 8.0 min, increased to 99% within 0.1 min, kept constant for 0.9 min, decreased within 0.1 min to 85%, and followed by re-equilibration on starting conditions for 0.9 min. Measurements were performed using positive electrospray ionization (ESI) and the quantitative calibration mode consisting of the following ion source parameters: capillary voltage, +3.6 kV; sampling cone, 50 V; source offset, 35 V; source temperature, 150 °C; desolvation temperature, 650 °C; cone gas, 250 L/h; desolvation gas, 1100 L/h; collision gas flow, 0.15 mL/min; and nebulizer gas flow, 7.0 bar. Calibration of the mass spectrometer in the range from m/z 40 to 1963 was performed using a solution of

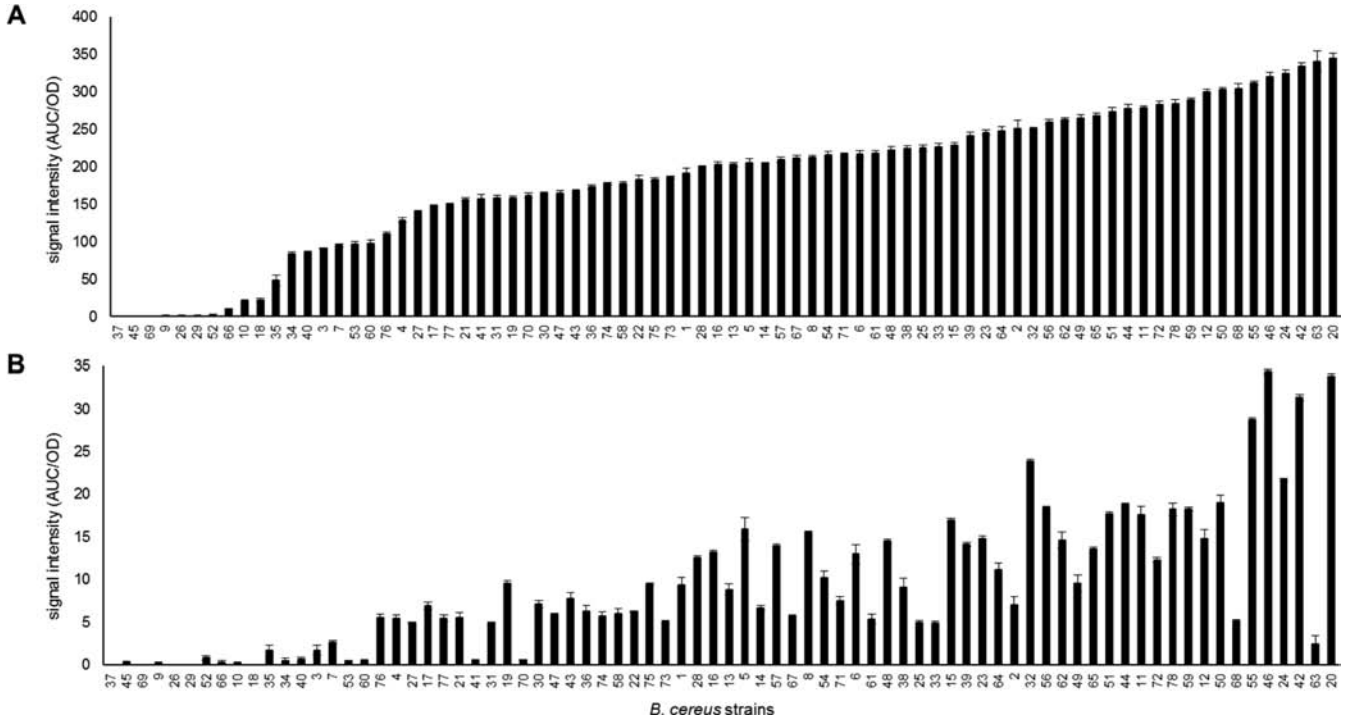

Figure 2. UPLC-ESI-TOF MS analysis of (A) cereulide and (B) isocereulides A–G (**2**–**8**) in 78 *B. cereus* strains.

phosphoric acid (0.1% in MeCN). The UPLC Xevo TQ-S system was operated with MassLynx 4.1 SCN 813 (Waters), and data processing and analysis were performed using TargetLynx (Waters). By means of the multiple reaction monitoring (MRM) mode, the ammonium adducts of cereulide and isocereulide G (m/z 1170.7 → qualifier, m/z 172.2, 314.2; quantifier, m/z 357.2), isocereulides A and F (m/z 1184.7 → qualifier, m/z 172.2, 314.2; quantifier, m/z 357.2), isocereulides B and E (m/z 1156.6 → qualifier, m/z 172.2, 314.2; quantifier, m/z 357.2), isocereulide C (m/z 1186.6 → qualifier, m/z 172.2, 314.2; quantifier, m/z 357.2), isocereulide D (m/z 1142.6 → qualifier, m/z 172.2, 314.2; quantifier, m/z 357.2) and $^{13}C_6$-cereulide (m/z 1176.7 → m/z qualifier, 173.2, 316.2; quantifier, m/z 358.2) were analyzed using the mass transitions (given in parentheses) monitored for a duration of 25 ms. ESI^+ mass and product ion spectra were acquired with direct flow infusion using IntelliStart. The MS/MS parameters were tuned for each individual compound, detecting the fragmentation of the $[M + NH_4]^+$ molecular ions into specific product ions after collision with argon.

High-Resolution Mass Spectrometry. UPLC-ESI-TOF-MS analyses were performed on a Waters Synapt G2 HDMS spectrometer that was coupled to an Acquity UPLC core system (Waters) equipped with a 2 × 150 mm, 1.8 μm, HSS T3 C18 column (Waters, Manchester, UK). Chromatographic and mass spectrometric parameters were identical with those reported recently.[29] The raw data obtained from UPLC-TOF-MS analysis were processed with MarkerLynx XS using ApexTrack peak integration to detect chromatographic peaks. Marker intensity threshold was set to 2000 cps, mass window was 0.02 Da, retention time window was 0.1 s, and data were deisotoped.

RESULTS AND DISCUSSION

Recent mass spectrometric screening demonstrated a high chemodiversity of the emetic toxin cereulide (**1**) and indicated a series of at least 18 cereulide variants, among which the major isocereulides A–G (**2**–**8**) were determined in their chemical structures (Figure 1).[29,30]

***B. cereus* Strain Profiling.** To answer the question of whether cereulide production by *B. cereus* strains is coupled to the generation of isocereulides A–G, 78 *B. cereus* strains representative for different sources (clinic, food intoxications, food, environment) and derived from diverse geographical origins were grown under defined conditions for 24 h at 24 °C in LB broth supplemented with 0.2% glucose (10^3 cfu/mL), extracted with ethanol and, then, analyzed by means of UPLC-TOF-MS.[29] To consider possible variations of the cereulide content due to different growth behaviors of *B. cereus* strains, the optical density of the cultures was determined after 24 h of incubation. The optical density (OD_{600}) of the various *B. cereus* cultures, each incubated under identical conditions, was in a rather narrow range between 14 and 19 (16.5 ± 1.8 relative standard deviation, RSD). The frequency of the $[M + Na]^+$ ion (area under the curve, AUC) recorded for cereulide (Figure 2A) and isocereulides A–G (Figure 2B) was then normalized for the optical density measured for each strain. No/low cereulide-producing *B. cereus* strains with AUC/OD ratios below 50 produced no or only low amounts of isocereulides A–G (Figure 2A). Most of the medium (AUC/OD ratios of 50–250) and high cereulide producers (AUC/OD > 250) generated also medium to high amounts of isocereulides (Figure 2B). Exceptions such as *B. cereus* strains 63, 68, and 70 might be due to variations in the strains' genetic backgrounds because isocereulide biosynthesis involves the relaxed substrate specificity of the A domains, an inefficient proofreading by Ces T, and a different peptide assembly compared to cereulide.[30,33] Although isocereulides A–G seem to be produced in about 10 times lower amounts when compared to cereulide, the ∼8 times increased cytotoxic activity found for isocereulide A requires an accurate quantitation of all these depsipeptides to enable a profound knowledge-based risk assessment of *B. cereus* toxins in foods.[30]

Development of a Stable Isotope Dilution Analysis. To develop a fast and robust SIDA for the combined quantitation of cereulide (**1**) and isocereulides A–G (**2**–**8**) by means of UPLC-MS/MS, first, reference material of the analytes **1**–**8** and $^{13}C_6$-cereulide to be used as the internal

J. Agric. Food Chem. 2015, 63, 8307–8313

standard were biosynthetically produced by cultivating *B. cereus* under optimized conditions in the presence of L-valine and $^{13}C_6$-L-valine, respectively, followed by straightforward downstream purification as reported recently.[28,30]

To evaluate the suitability of $^{13}C_6$-cereulide as internal standard for quantitation of analytes **1**–**8**, $^{13}C_6$-cereulide and the analytes were individually infused into the mass spectrometer using a syringe pump. Optimum intensities of pseudomolecular ions and respective fragments were obtained by software-assisted ramping of the declustering potential, the cell entrance potential, and the collision energy, as well as the cell exit potential, respectively. As the ion $[M + NH_4]^+$ of cereulide and isocereulides A–G was the most predominant pseudomolecular ion, these were selected for the optimization. Tuning of the ammonium adducts and the pseudomolecular ions $[M + H]^+$ revealed similar fragment patterns and fragment intensities.

Fast chromatographic baseline separation of the analytes **1**–**8** was achieved within 10 min using a RP-UPLC CSH C18 column (Figure 3A). For analysis of cereulide (**1**; *m/z* 1170.7),

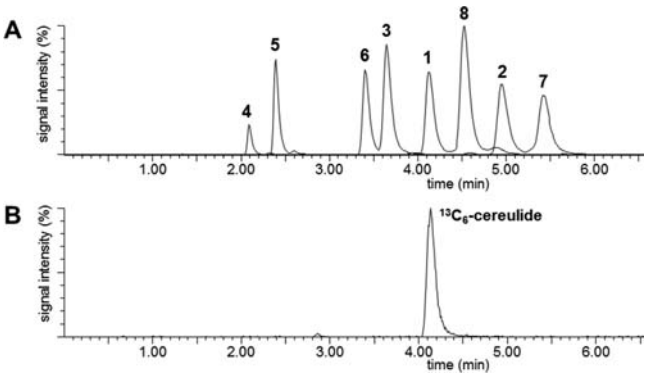

Figure 3. UPLC-ESI-MS/MS mass chromatogram of (A) cereulide (**1**) and isocereulides A–G (**2**–**8**) and (B) the internal standard $^{13}C_6$-cereulide.

isocereulide G (**8**; *m/z* 1170.7), isocereulides A (**2**) and F (**7**) (*m/z* 1184.7), isocereulides B (**3**) and E (**6**) (*m/z* 1156.6), isocereulide C (**4**; *m/z* 1186.6), and isocereulide D (**5**; *m/z* 1142.6), the same fragment ions were selected as qualifier (*m/z* 172.2, 314.2) and quantifier (*m/z* 357.2). For the internal standard $^{13}C_6$-cereulide (*m/z* 1176.7), the qualifier fragments *m/z* 173.2 and 316.2 and the quantifier ion *m/z* 358.2 were selected (Figure 3B).

Performance of the developed UPLC-MS/MS SIDA method was checked by using boiled rice as matrix and a mixture containing defined amounts of the analytes cereulide (**1**) and isocereulides A–G (**2**–**8**) in a range of 14.51–161.20 ng/mL for spiking experiments. Calibration over 2.5 order of magnitudes revealed good linearity for the analysis of cereulide using $^{13}C_6$-cereulide as internal standard with a correlation coefficient >0.999. The obtained calibration curve was used to check the performance of the developed UPLC-MS/MS method for a combined quantitation of cereulide and isocereulides A–G.

The trueness of the analytical method was studied by recovery experiments. To achieve this, a blank rice sample was spiked with analytes **1**–**8** at two different concentration levels and, then, analyzed by UPLC-MS/MS SIDA. The determined recovery rates ranged between 107% (**1**, **8**) and 125% (**4**) with RSD ranging from 1 to 4%, thus demonstrating appropriate trueness and precision of the developed UPLC-MS/MS method.

To evaluate the robustness of the SIDA method, repeatability and reproducibility were determined. Technical repeatability (intraday precision) of the analytical method was evaluated by considering the quantitative data obtained from triple injections of three sample replicates prepared with two concentrations of cereulide and isocereulides A–G (Table 1). For all analytes, the relative standard deviation was <3%. To study the reproducibility (interday precision) of the analytical method, three independent sample preparations with one concentration of cereulide and isocereulides A–G (Table 1), two replicates each, were analyzed in triplicates at three different days. Relative standard deviation of the analytes ranged from 3% (**2**) to 8% (**5**).

LOD and LOQ were determined in boiled rice as the concentration at which the peak height of cereulide and isocereulides A–G was at least 3 and 10 times, respectively, above the noise level. To achieve this, different concentrations of **1**–**8** were spiked to boiled rice and UPLC-MS/MS quantitation was performed using $^{13}C_6$-cereulide as internal standard. On average, LOD and LOQ were found to be 0.1 and 0.5 ng/g for cereulide and isocereulides A–G, respectively, thus indicating high sensitivity for the developed UPLC-MS/MS method.

To apply the UPLC-MS/MS SIDA quantitation of **1**–**8** to real food samples, a total of 25 randomly selected commercial food and feed samples (rice, puddings, desserts, cereals, baby foods, animal feeds) and two suspicious noodle samples, which were assumed to have caused intoxications in five child daycare facilities and were obtained from the German Health and Food Safety Authority, were analyzed. Whereas cereulide (**1**) and isocereulides A–G (**2**–**8**) could not be detected in amounts >0.1 ng/g (LOD) in any of the 25 commercial food and feed samples, both suspicious noodle samples showed elevated levels of cereulide (**1**) and isocereulides A–G (**2**–**8**) ranging from 0.59 ng/g (**7**) to 189.08 ng/g (**1**) in noodle sample 1 and from 5.77 ng/g (**7**) to 6198.17 ng/g (**1**) in sample 2 (Table 2).

Table 2. Concentrations of Cereulide (1) and Isocereulides A–G (2–8) in Suspicious Cooked Noodles

	concn[a] (ng/g) in	
analyte	sample 1	sample 2
cereulide (**1**)	189.08 (±28.88)	6198.17 (±162.09)
isocereulide A (**2**)	11.81 (±1.82)	268.28 (±9.56)
isocereulide B (**3**)	1.12 (±0.09)	15.40 (±0.79)
isocereulide C (**4**)	1.02 (±0.06)	10.13 (±0.33)
isocereulide D (**5**)	0.77 (±0.04)	9.34 (±0.31)
isocereulide E (**6**)	0.95 (±0.05)	9.61 (±0.45)
isocereulide F (**7**)	0.59 (±0.01)	5.77 (±0.09)
isocereulide G (**8**)	3.40 (±0.39)	84.56 (±3.48)

[a]Results are given as the mean of two independent cleanups with triple injection.

Because symptoms of intoxication caused by cereulide (**1**) are reported to be observable at concentrations of ≥10 μg/kg body weight, the detected cereulide concentration in both noodle samples indicates the potential to cause food poisoning in 2–6-year-old children, which have about 10–30 kg body weight.[5,34] Interestingly, isocereulide A (**2**) was detected in both noodle samples as the most predominant variant among the isocereulides. Although isocereulide A was found in both

noodle samples in 16 and 23 times lower concentrations when compared to cereulide (**1**), the ~8-fold increased cytotoxicity of **2** indicates isocereulide A as a potential key toxic component in *B. cereus*-contaminated food.[30]

In summary, a rapid, sensitive, and robust SIDA for the combined quantification of cereulide (**1**) and isocereulides A–G (**2**–**8**) by means of UPLC-MS/MS was developed. On average, trueness and precision of the method were 112.5% (±1.8 RSD), repeatability and reproducibility were 2 and 4% for cereulide and isocereulides A–G, and the LOD and LOQ of 0.1 and 0.5 ng/g demonstrated a high sensitivity for the developed SIDA method in the range or even better than the LOQ of 4.1 and 1.0 ng/g reported recently for cereulide,[26,35] thus supporting a knowledge-based risk assessment of the entire set of *B. cereus* toxins in foods. The observation that isocereulide A (**2**), showing an ~8-fold increased cytotoxicity when compared to cereulide (**1**), was present in *B. cereus*-contaminated noodle samples as the major isocereulide indicates isocereulide A as a potential key toxic component in *B. cereus*-contaminated food. These findings urge further studies to explore potential synergistic cocktail effects of cereulide and isocereulides on the biological function of these depsipeptides.

J. Agric. Food Chem. 2015, 63, 8307−8313

(QTOF) and ion trap or quadrupole orbital ion trap (Q-orbital trap) MS, can be used for screening for chemical contaminants in full-scan mode and aid in the structural elucidation, identification, and characterization of the chemical on the basis of high-resolution and -accuracy mass results in MS/MS mode with improved method performance and precision and accuracy of analytical data.[11−16]

This study reports the development and testing of a UHPLC/Q-orbital trap MS method for the simultaneous determination of common mycotoxins, including the major classes such as aflatoxins, ergot alkaloids, fumonisins, ochratoxins, and trichothecenes. The performance and practical applicability of UHPLC/Q-orbital trap MS will be assessed by evaluating a validated procedure used to analyze, quantitate, and identify 26 mycotoxins in commercially available finished grain and nut products and reference grain materials by LC-MS/MS.[17] This hybrid technology has already been applied to screening mycotoxins in dairy products in full-scan mode.[18] Finished samples will be screened using full-scan MS, and identification of mycotoxins is achieved by data-dependent MS/MS experiment (DDMS^2) using the hybrid Q-orbital trap MS technology. The high-resolution and -accuracy mass results generated will also be evaluated with results generated in previous work using LC-MS/MS. High mass accuracy results of the product ions generated from MS/MS fragmentation can be used to propose structural information on the products and will provide further confidence in the identification of mycotoxins in finished grain and nut samples.

MATERIALS AND METHODS

Safety. Mycotoxins are toxic chemical compounds that may be fatal if inhaled, absorbed through the skin, or swallowed and must be treated with extreme caution and care. All laboratory safety rules including wearing of safety goggles and gloves must be strictly followed at all times. All mycotoxin waste should be properly disposed of in a designated waste container to prevent the possible spread of these chemicals. All sample vials, vial caps, and other glassware used to prepare, contain, or make contact with the mycotoxin standards were soaked in a 1% minimum bleach solution for at least 72 h before proper disposal.

Chemicals and Materials. Aflatoxin B_1, aflatoxin B_2, aflatoxin G_1, aflatoxin G_2, beauvericin, deoxynivalenol, diacetoxyscirpenol, 15-acetyldeoxynivalenol, fumonisin B_1, fumonisin B_2, fusarenon-X, HT-2 toxin, neosolaniol, ochratoxin A, ochratoxin B, T-2 toxin, and zearalenone standards were purchased in neat form from Romer Laboratories, Inc. (Union, MO). Ergot alkaloids (ergocornine, ercocristine, ergocryptine, ergometrine, ergosine, ergotamine) were provided as a mixture, also purchased from Romer Laboratories. Citrinin, sterigmatocystin, and verrucarin A standards were purchased from Sigma-Aldrich (St. Louis, MO).

Stable isotope-labeled internal standards, $^{13}C_{17}$-aflatoxin B_1 (0.5 μg/mL), $^{13}C_{20}$-ochratoxin A (10 μg/mL), $^{13}C_{18}$-zearalenone (25 μg/mL), $^{13}C_{34}$-fumonisin B_1 (25 μg/mL), and $^{13}C_{24}$-T-2 toxin (25 μg/mL), and two reference materials, aflatoxin in maize and zearalenone in maize, were purchased from Romer Laboratories, Inc. (Union, MO). Native and isotope-labeled mycotoxins, CAS numbers, molecular formulas, molecular weight, and other relevant UHPLC and MS information are provided in the Supporting Information, Table S1. Nine reference materials (aflatoxin, deoxynivalenol, and zearalenone in corn and wheat) were generously provided by the United States Department of Agriculture, Grain Inspection, Packers and Stockyards Administration, Technology and Science Division (USDA-GIPSA-TSD, Kansas City, MO). Rice, wheat, corn, peanut, pistachio, and almond samples and finished grain (i.e., pasta) and nut (i.e., peanut butter) products were purchased from commercially available sources.

LC-grade acetonitrile, methanol, and water and MS-grade formic acid and ammonium formate were purchased from Fisher Scientific (Pittsburgh, PA). Plastic syringes (3 mL) and 13 mm × 0.2 μm PTFE syringe filters were purchased from Pall Life Sciences (Ann Arbor, MI). Positive- and negative-ion solutions used to calibrate the Q-orbital trap MS were purchased through ThermoFisher Scientific Inc. (San Jose, CA).

Standards Preparation. Stock standard solutions (200 μg/mL) of each of the 26 mycotoxin standards were prepared by dissolving 5.0 mg of the mycotoxin in 25 mL of acetonitrile. As previously described, two working standard solutions were used: groups A and B. Group A consisted of aflatoxin B_1, aflatoxin B_2, aflatoxin G_1, aflatoxin G_2, beauvericin, diacetoxyscirpenol, ergot alkaloids, HT-2 toxin, neosolaniol, ochratoxin A, ochratoxin B, sterigmatocystin, T-2 toxin, and verrucarin A, prepared to a concentration of 1.0 μg/mL by transferring 0.5 mL of the diluted individual stock standard solution (20 μg/mL) to a 10 mL volumetric flask, and then bringing the mixture up to volume with acetonitrile/water (50:50, v/v). Group B consisted of citrinin, deoxynivalenol, 15-acetyldeoxynivalenol, fumonisin B_1, fumonisin B_2, fusarenon-X, and zearalenone, prepared to a concentration of 10 μg/mL by delivering 0.5 mL of each individual stock standard (200 μg/mL) to a 10 mL volumetric flask and then bringing the mixture up to volume with acetonitrile/water (50:50, v/v). Stock solutions and working standard solutions used in the preparation of solvent-only calibration standards, matrix-matched calibration standards, and method recovery studies were stored at −20 °C.

Solvent-only calibration standards (SOCS) were prepared from the working standard solutions by diluting the group A and B working standard solutions to 500 and 5000 ng/mL, respectively. Eight SOCSs (0.5, 1.0, 2.5, 5.0, 10, 25, 50, and 100 ng/mL for group A; 5.0, 10, 25, 50, 100, 250, 500, and 1000 ng/mL for group B) were prepared by successive dilution of the group A and group B mixed working standard solutions with acetonitrile/water (50:50, v/v). The mixed isotope labeled internal standards solution was prepared by mixing 0.1 mL each of $^{13}C_{17}$-aflatoxin B_1 (0.5 μg/mL), $^{13}C_{20}$-ochratoxin A (2.5 μg/mL), $^{13}C_{18}$-zearalenone (5 μg/mL), $^{13}C_{34}$-fumonisin B_1 (25 μg/mL), and $^{13}C_{24}$-T-2 toxin (5 μg/mL) with 0.5 mL acetonitrile/water (50:50, v/v). These mixed isotope labeled internal standards solution was added (20 μL) to the SOCS and brought to volume at 1.0 mL, resulting in concentration levels of 1.0, 5.0, 10, 50, and 10 ng/mL, respectively.

Sample Preparation. As previously described, packaged grains and nuts (shells removed) were homogenized with dry ice in a RobotCoupe blender (Ridgeland, MS) until powdery consistencies were obtained.[11] The homogenized samples were transferred to polypropylene freezer bags stored in a −20 °C freezer, and the bags were left open to allow the carbon dioxide to sublime before being sealed until further use.

A volume of 5 mL of extraction solvent (acetonitrile/water, 85/15, v/v) was added to 1.00 ± 0.02 g of ground sample in 15 mL disposable screw capped polypropylene centrifuge tubes (Corning Inc., Corning, NY).[17] Samples were extracted for 30 min using a high-speed shaker with pulsation (Glas-Col, Terre Haute, IN) using a motor speed setting of 75 (1540−1560 rpm as measured by a DPM5 digital photo tachometer (Universal Enterprises, Inc. Beaverton, OR) and pulser frequency set at the middle mark of the dial (∼30−35 pulsations/min), followed by centrifugation for 5 min at 4500 rpm (4200*g*) (ThermoElectro Corp., Milford, MA). A 500 μL portion of the extract was transferred to a clean test tube, followed by the addition of 20 μL of the internal standard solution and 480 μL of 20 mM ammonium formate, and then the tube was vortexed for 15 s. Samples were filtered through 13 mm × 0.2 μm PTFE syringe filters (Pall Life Sciences, Ann Arbor, MI) and added via a 3 mL disposable syringe directly into an autosampler vial (National Scientific, Rockwood, TN).

Recovery Studies. Method recovery samples were prepared in quadruplicates from the homogenized sample matrices at three spiking concentrations (10, 50, and 100 μg/kg for group A; 100, 500, and 1000 μg/kg for group B). Method blank samples were also prepared in each sample batch as quality control samples, and also for matrix effect studies. For group A recovery studies, the spiking solution volumes of 100 μL (0.1 μg/mL), 50 μL (1 μg/mL) or 100 μL (1 μg/mL) was added to the sample tubes containing 1.00 ± 0.02 g of ground samples

J. Agric. Food Chem. 2015, 63, 8314−8332

to achieve fortification levels of 10, 50, or 100 μg/kg, respectively. For group B recovery studies, spiking solution volumes of 100 μL (1 μg/mL), 50 μL (10 μg/mL) or 100 μL (10 μg/mL) were added into sample tubes containing 1.00 ± 0.02 g of ground samples to achieve fortification levels of 100, 500, or 1000 μg/kg, respectively. After addition of 5 mL of extraction solvent (acetonitrile/water, 85/15, v/v), the sample tubes were placed on the high-speed shaker and extracted as described in the previous section.

Quantitation was performed by matching the peak area ratio responses of the analyte and calibration standards to that of the internal standard. For those native compounds without labeled internal standards, quantitation was performed by the external standard method; the concentration of the analyte was determined using the curve based on the peak areas of matrix-matched calibration standards. Matrix-matched standards were prepared by extracting rice, wheat, corn, peanut, pistachio, and almond blanks (matrices were determined blanks by analysis) and then fortifying the extracts with calibration standards to the appropriate concentrations. Calibration curves consisted of the eight calibration standards from the two mycotoxin groups (A and B) and were constructed using least-squares regression.

Analysis of Reference Materials and Commercial Products. Reference materials obtained from Romer Laboratories and USDA-GIPSA-TSD, and commercial finished grain and nut products were prepared in triplicates using procedures described in the Sample Preparation section. Whole samples were homogenized, while finished commercial products that were already in homogeneous form were used as provided. The samples were quantitated using matrix-matched standards prepared from matrices that were screened and determined to be free of the mycotoxins of interest using the internal standard calibration method.

Limits of Detection and Quantitation Studies. The matrix-dependent instrument limits of detection and quantitation (MD-ILD and MD-ILQ) for each analyte were obtained using procedures similar to those described by the U.S. Environmental Protection Agency's (EPA) protocol.[19] Matrix-matched LOD/Q can provide an estimate of the method LOD/Q as well as assess the sensitivity of the instrument and allow comparisons to other platforms in the presence of the matrix. The MD-ILD was determined from replicate (n = 8) analyses of the estimated detection limit using the lowest (or fortifying with a lower) concentration of a matrix-matched calibration standard (MMCS) that is statistically different from the matrix-matched blank and multiplying the standard deviation (SD) by 2.998 (critical $t_{0.010}$ = 2.998 for degrees of freedom (d_f) of 7). The MD-ILQ was calculated by multiplying the MD-IDL by a factor of 3.3.

UHPLC/Q-orbital Trap MS Analysis. An Accela ultrahigh-performance chromatograph coupled with a quadrupole orbital trap mass spectrometer (Q-orbital trap, QExactive, ThermoFisher Scientific, San Jose, CA) equipped with an electrospray ionization (ESI) interface source and controlled by Xcalibur software 2.2 was employed for all method validations. The UHPLC method validation was performed on a Hypersil GOLD aQ polar end-capped C18 column of dimensions 2.1 × 100 mm and a 2.1 × 10 mm guard column of the same stationary phase (ThermoFisher Scientific, San Jose, CA) using a flow rate of 0.3 mL/min. The mobile phases used were HPLC-grade water containing 0.1% formic acid and 5 mM ammonium formate (A) and HPLC-grade methanol containing 0.1% formic acid and 5 mM ammonium formate (B). After an initial time of 1 min at 100% A, the proportion of B was increased linearly to 100% in the following 8 min, followed by a hold time of 4 min at 100% B. The mobile phase was returned to the initial conditions in 0.5 min, and the column was equilibrated for 5.5 min. The total chromatographic run time was 18 min. The column was at room temperature (typically 27 °C), and the injection volume was set at 5 μL.

The Q-orbital trap MS was equipped with a heated electrospray ionization (HESI) probe and a collision cell to carry out higher-energy collision dissociation (HCD)-based tandem MS (MS/MS or MS^2) experiments. The Q-orbital trap MS was operated in either full-scan MS or full-scan $DDMS^2$ mode. The $DDMS^2$ mode uses the quadrupole to select target molecular ions from an inclusion list and then carries out HCD experiments using normalized collision energies (NCEs) in the collision cell to generate high-resolution, accurate mass spectra of precursor and/or product ions. In-house nitrogen gas was used for the shealth, auxiliary, and sweep gases with flow rates set at 30, 15, and 0 L/min, respectively, while the HESI spray voltage (positive), capillary temperature, S-lens level, and heater temperature were set at +4.0 kV, 350 °C, 50 kV, and 350 °C, respectively. Samples were analyzed in batches of about 50 and consisted of quality control samples (i.e., glassware rinses, blanks, calibration standards, and fortified samples) and field incurred samples. The commercially available calibration solutions were used to tune and calibrate the instrument in both positive and negative electrospray modes.

In full-scan MS mode, the Q-orbital trap performed without the HCD fragmentation, and the scan range was set from 100 to 900 m/z from 0 to 12 min during LC analysis. Optimized mass resolution (full width at half maximum, R_{FWHM}) of 70 000 at m/z = 200 was used along with one microscan. Automated gain control (AGC), the maximal number of ions allowed in the C-trap and consequent orbital trap MS analysis, was set at 1×10^6 with a maximum inject time of 250 ms to enhance the linearity of the orbital trap MS system. For $DDMS^2$ scan, the Q-orbital trap MS used prescan R_{FWHM}, AGC, maximum inject time, and isolation window settings of 17 500, 2×10^5, 50 ms, and 4.0 m/z, respectively. Based on previous NCE experiments, where the NCE ranged from 10 to 100 an overall NCE setting of 35 was selected. The masses of the precursor ions ($[M + H]^+$ or $[M + NH_4]^+$) for the 26 native mycotoxins and the 5 isotopically labeled mycotoxins listed the Supporting Information, Table S1 were provided in the inclusion list. Other $DDMS^2$ settings include an underfill ratio of 5.0%, an intensity threshold of 8.3×10^4, apex trigger of 3−6 s, and dynamic exclusion of 10.0 s, while the charge exclusion and peptide match options were not used.

Data Analysis. Mycotoxins were initially identified by their retention time (t_R) from the extraction ion chromatogram (XIC) of target ion m/z for each mycotoxin using full-scan accurate mass data collected in $DDMS^2$ mode. Calculations of the theoretical mono-isotopic m/z of precursor and product ions and A, A+1, and A+2 isotopes, as well as prediction of molecular composition using experimental m/z, were performed using the Xcalibur Qual Browser (V. 2.2 SP1.48) with a mass accuracy (δ_M) tolerance of 5 ppm and mass precision set to five decimal places. The mass accuracy δ_M for a measured ion is calculated by dividing the difference between the theoretical and measured m/z by the theoretical m/z and expressed as part-per-million (ppm):

$$\delta_M \text{ (ppm)} = 1 \times 10^6 \times \frac{(m/z_{measured} - m/z_{theoretical})}{m/z_{theoretical}}$$

Qualitative analyses to determine the mycotoxin and corresponding accurate m/z were based on molecular formula using TOXID 2.1.2, while Mass Frontier (V. 7.01 SR1) software was used to propose molecular structures from the $DDMS^2$ fragmentation studies. Quantitative determination of mycotoxins for recovery and incurred samples experiments, as well as detection and quantitation limits, were determined by LC Quan 2.7 software. All software packages were obtained from ThermoFisher Scientific (San Jose, CA). Results from the analysis were exported to Microsoft Excel 2007 (Microsoft Co., Redmond, WA), to process averages, standard deviations (SD), and relative standard deviations (RSD).

RESULTS AND DISCUSSION

Optimization of UHPLC/Q-Orbital Trap MS in Full-Scan Mode. The "dilute-and-shoot" procedure used for the UHPLC/Q-orbital trap MS multianalysis of mycotoxins had been previously applied to and validated using HPLC-MS/MS.[17] To determine the optimal resolution setting, native mycotoxins were fortified in solvent (acetonitrile/water) and extracts obtained from acetonitrile/water extracts of mycotoxin-free peanut and wheat samples at 1, 10, and 100 ng/mL. Replicate measurements (n = 9) of these solutions were performed by operating the UHPLC/Q-orbital trap MS in full-scan mode and using R_{FWHM} settings of 17 500, 35,000, 70 000, and 140 000.

[a]Additional information on the specific mycotoxin is provided in Supporting Information, Table S5.

The experimental m/z values of the precursor ion ($[M+H]^+$ or $[M+NH_4]^+$) extracted from full-scan MS spectra, the theoretical m/z values, and the δ_M values for each mycotoxin are summarized in the Supporting Information, Tables S2−S4, for solvent, peanut, and wheat matrices. The average and standard deviation of δ_M values of the mycotoxins at each resolution in the three matrices were determined from the results in the Supporting Information tables and summarized in Table 1.

The resolution studies reveal the averages and standard deviations of δ_M values to be within a desirable range[20] of ±2.5 ppm and <2 ppm at R_{FWHM} = 17 500 and 35 000, respectively. At R_{FWHM} = 70 000 and 140 000, the average δ_M and SD improved to ±1.0 ppm and <1 ppm, respectively. These results are consistent with other studies using single-stage or hybrid (quadrupole and ion trap) orbital trap MS analyzers at various R_{FWHM} settings, ranging 10 000−100 000 for analyzing drugs in dried blood spots[21] and pesticides in fresh produce[22] as well as mycotoxins and other chemical contaminants in food commodities[23] and baby food.[24] The δ_M values from the solvent and wheat matrix at 1.0 ng/mL decrease, with increasing R_{FWHM}, but no significant trend was observed with the peanut matrix. Although neosolaniol could not be detected at 1.0 ng/mL at R_{FWHM} = 17 500 in the solvent or matrices, it was detected at the three higher R_{FWHM} settings. While the two lower and two higher R_{FWHM} settings provided δ_M < 2.5 and 1 ppm, respectively, and would meet the criterion for positive identification (i.e., <5 ppm with mass tolerance setting at 5 ppm),[20] the ability to analyze neosolaniol becomes a determining factor in selecting an optimal R_{FWHM} for routine analysis of mycotoxins. R_{FWHM} = 70 000 was selected for data acquisition because this setting can provide more data points from R_{FWHM} = 140 000 due to scan speeds (3 versus 1.5 Hz/s), allowing for better definition of extracted ion chromatogram (XIC) for quantitation.

Studies using R_{FWHM} 70 000 were conducted to evaluate δ_M and the measured % relative abundances ($\%_{RA}$) of the carbon-based A peak[25] (where A is a carbon-based organic compound which include $[M+H]^+$ and $[M+NH_4]^+$) and the A+1 and A+2 (and A+3 for Cl-containing ochratoxin A) isotope peaks for identification of the mycotoxins. Table 2 presents the number of mycotoxins identified with different ranges of δ_M of these three peaks; Supporting Information, Table S5 provides the measured $\%_{RA}$ of A+1 and A+2 to the A peak in solvent, peanut, and wheat matrices fortified at 1, 10, and 100 ng/mL. The δ_M values of the A base peak for each mycotoxin were within ±1 ppm and could be detected at 1 ng/mL or higher in the solvent and sample matrices. The RSD and $\%_{RA}$ of the A base peak and A+1 measured were generally <20%, allowing the use of the A+1 with δ_M = ±2 ppm, retention time window of ±30 s, and $\%_{RA}$ of ±20% as reliable criterion for identifying the targeted compounds.[26] The A+1 isotopes of the five trichlothecene mycotoxins could not be detected due to inferior ionization of neosolaniol and interferences from co-extractives present in the wheat matrix for 15-acetyl deoxynivalenol, deoxynivalenol, fusarenon-X, and HT-2.

The measured values of the A+2 isotopes generated higher RSD, lower $\%_{RA}$, and higher δ_M values when compared to their theoretically available values. It appears that the A+2 isotope, along with the use of retention time window and δ_M < 5 ppm

[a]Detailed procedures and materials are described in the Materials and Methods section. Percent difference is calculated as the difference between the measured and certified concentration (measured − certified) divided by the certified concentration, and the result multiplied by 100%. N = 21 for GIPSA reference materials. Total aflatoxins ($B_1 + B_2 + G_1 + G_2$) and total fumonisins ($B_1 + B_2$) are given; n is not provided for these sets of reference materials.

identification criteria, at best can be used as a reference rather than a reliable identification parameter. In some cases, chromatography could probably be refined to separate the interfering matrix components from the isotope masses of the mycotoxin analytes of interest. Five A+2 isotopes, including ergometrine, the ergot alkaloid in this study with the lowest molecular weight, could not be detected at 1 ng/mL. In contrast, ochratoxin A, the only mycotoxin in this study consisting of ^{35}Cl and ^{37}Cl isotopes, produced a fourth molecular isotope that could be reliably identified at all three concentration levels.

Results of Method Validation. *Matrix-Dependent Instrument Limits of Detection and Quantitation (MD-ILD and MD-ILQ).* The MD-ILDs for each mycotoxin in each of the six matrices, calculated using the procedures of the U.S. Environmental Protection Agency's protocol[19] based on the quantitative results obtained from the precursor ion of the mycotoxin obtained in full-scan mode, along with the MD-ILQ (3 × MD-ILD), are provided in Table 3. The EPA protocol provides a consistent and reliable metric other laboratories can use to carry out follow-up experiments for comparison purposes because statistical calculations rather than the subjective estimation of signal-to-noise ratios are used to determine the detection limits. The MD-ILDs and MD-ILQs were compound-dependent and independent of matrix type, as fusarenon-X, deoxynvalenol, and 15-acetyldeoxynivalenol were consistently higher than the other mycotoxins in the six matrices. The MD-ILQs of aflatoxins, sterigmatocystin, ochratoxins, diacetoxyscirpenol, neosolaniol, beauvericin, and ergot alkaloids were less than 0.3 μg/kg for all six matrices evaluated, whereas citrinin, deoxynivalenol, fusarenon-X, 15-acetyldeoxynivalenol, verrucarin A, HT-2, zearalenone, and fumonisins were determined to have MD-ILQs in the range of 1.4−9.8 μg/kg. These results indicate that the orbital trap in full-scan MS mode is sensitive enough to analyze grain and nut products in low (<10 μg/kg) to sub-μg/kg levels. Electrospray ionization in positive mode was used to ionize the mycotoxins and is the determining factor for detection since the orbital trap MS results were comparable to previous HPLC-MS/MS results using the same mycotoxins, matrices, and method.[17] Regulatory limits of deoxynivalenol and fumonisins determined by most countries and the European Union are in the 500−1000 μg/kg range, whereas aflatoxins and ochratoxin A limits are set at 20 and 50 μg/kg, respectively, in most grains and nut products.[28] As shown in Table 3, the method can achieve MD-ILQs a factor of at least 50 times lower than the MRLs required by the published regulatory requirements, which can be applied for screening purposes.

Recovery Studies. Method validation was performed using three grain (rice, wheat, and corn) and three nut matrices (peanut, pistachio, and almond). These recovery studies were performed by adding fortification standards to blank grain, and nut samples at three concentration levels, 10, 50, and 100 μg/kg and 100, 500, and 1000 μg/kg for groups A and B mycotoxin mixes (n = 4 at each fortification level), respectively, as listed in Table 4. The identification was achieved using criteria discussed above while the quantitation was performed using matrix-matched calibration curves (r^2 > 0.99 and calibration ranges provided in Table 3) and the precursor molecular ion, i.e., $[M+H]^+$ or $[M+NH_4]^+$. The linearity criterion using r^2 > 0.99 was achieved for all of the mycotoxins in all six sample matrix as the r^2 values of the mycotoxin calibration range are provided in Table 3, indicating that the Q-orbital trap MS in full-scan mode can be used for quantitative determination. The mean recoveries (n = 12, ± RSD) of all mycotoxins at the three fortification levels were 91 ± 10, 94 ± 10, 98 ± 12, 91 ± 13, 99 ± 15, and 93 ± 17% for corn, rice, wheat, almond, peanut, and pistachio, respectively. Most of the mycotoxins were recovered in the 70−120% recovery range in all six matrices, with the notable exception of fumonisin B_1 and B_2 in the nut matrices. The lower recoveries of the more polar fumonisins (49−73%) compared to the other mycotoxins (72−129%) in multimycotoxin procedures are attributed to the higher organic content of the extraction solvent, resulting in lower extraction efficiencies, which had been observed in previous studies.[27] In general, the multimycotoxin procedure is applicable to screening and determining the mycotoxin levels in a variety of cereal and nut products.

Method Accuracy in the Analysis of Reference Materials. The ability of this method to provide accurate analytical results is demonstrated by triplicate (n = 3) analysis of 11 corn and wheat reference materials obtained from USDA-GIPSA and Romer Laboratories. Results of the reference materials provided in Table 5 list concentration levels from 6.31 ± 0.31 μg/kg (n = 21) of ochratoxin A to as high as 2310 ± 110 μg/kg (n = 21) of fumonisins in corn. There was no statistical difference

[a]The range of contamination levels of each mycotoxin and each concentration listed is an average of three replicates (n = 3).

between the certified and measured values of these reference materials, with the exception of ochratoxin A in wheat, consistent with LC-MS/MS results.[17] The % difference ranged from +1.9% (zearalone in wheat) to −19.2% (ochratoxin A in wheat) with eight of the 11 reference materials ≤10% (absolute % difference) even though the reference values of the certified materials had been analyzed by a different combination of mycotoxin procedures for extraction and different analytical instrumentation, such as HPLC equipped with fluororescence or ultraviolet and mass spectrometric detection. The experimentally determined concentrations of target analytes were within the satisfactory range for the tested mycotoxins (aflatoxins, DON, fumonisins, ochratoxin A, zearalenone), indicating this validated method can accurately provide quantitative results.

Sample Analysis. The method was used to analyze finished cereal and nut products purchased from local markets and online stores in the United States in August 2011 to January 2012. A total of 70 commercial products were analyzed, which included six rice, 16 wheat, 18 corn, 11 peanut, ten pistachio and nine almond-based finished samples. Table 6 summarizes the frequency of mycotoxins present and the range of their concentrations in these finished products (Supporting Information, Table S6 provides additional and detailed information about these products and their mycotoxin concentrations). Of the grain products, rice contained the least number of mycotoxins, as only one rice flour sample contained sterigmatocystin and ochratoxin A at levels of 0.8 ± 0.2 and 2.6 ± 0.5 μg/kg (n = 3), respectively. Wheat products (wheat flour and dried pasta) were found to contain mycotoxins (deoxynivalenol, sterigmatocystin, ochratoxin A, T-2 toxin, ergometrine, ergosine, ergocornine, ergocryptin, ergotamine, ergocristine, and beauvericin) at concentration levels ranging from 1.1 (1.1 ± 0.3 μg/kg for ergosine, 1.1 ± 0.4 μg/kg for T2 toxin), to 90 ± 15 μg/kg (deoxynivalenol) (n = 3). Ochratoxin A was present in five wheat samples at concentrations <3 μg/kg, below the 3−50 μg/kg maximum tolerance levels set by most governments. Among the 18 corn meal, and flour samples, 16 were shown to be contaminated with various mycotoxins, such as beauvericin (14/18), ochratoxin A (1/18), T-2 toxin (1/18), fumonisin B_1 (11/18), fumonisin B_2 (8/18), zearalenone (4/18), and deoxynivalenol (3/18), at concentrations levels ranging from 0.8 ± 0.2 (beauvericin) to 1175 ± 182 (fumonisin B_1) μg/kg (n = 3). All levels of fumonisins analyzed were below the maximum levels of 2000−4000 μg/kg for degermed or partially degermed dry-milled corn products established by the U.S. Food and Drug Administration.[28]

Fewer mycotoxins were detected and at lower concentrations in finished nut products than grains. Five of the 11 peanut products (peanut flour, peanut butter, and raw peanut) surveyed were contaminated with aflatoxin B_1 at concentrations less than 0.6 μg/kg; two of those peanut products also contained beauvericin at concentrations of 4.5 ± 1.1 and 0.8 ± 0.2 μg/kg (n = 3, each). Pistachio products (roasted pistachio, pistachio butter, and pistachio flour) were found to contain a total of seven mycotoxins distributed among four of the ten samples studied. One pistachio product was cocontaminated with five mycotoxins, aflatoxin B_1, aflatoxin B_2, aflatoxin G_1, ochratoxin A, and ochratoxin B at levels <7 μg/kg. Of the nine almond samples studied, only one almond flour sample was found to contain aflatoxin B_1 at 0.3 ± 0.1 μg/kg. These results compared well with those obtained in a previous study in which the same 70 grain and nut samples were analyzed using HPLC-MS/MS[17] (both UHPLC-Orbitrap MS and HPLC-MS/MS are shown and compared in Supporting Information, Table S6) demonstrating that UHPLC/Q-Orbitrap MS in full-scan results can be used in routine quantitative analysis, providing enhanced data quality via accurate mass measurement of the precursor ions.

Identification of Mycotoxins by UHPLC/Q-Orbital Trap MS Using Data-Dependent Tandem Mass Spectrometry (DDMS²). LC-MS/MS, based on triple-quadrupole mass spectrometry, has been a reliable, proven procedure providing acceptable quantitative and qualitative results based on the retention time of the analyte and two precursor-to-product ion transitions based on nominal masses. The dominant primary

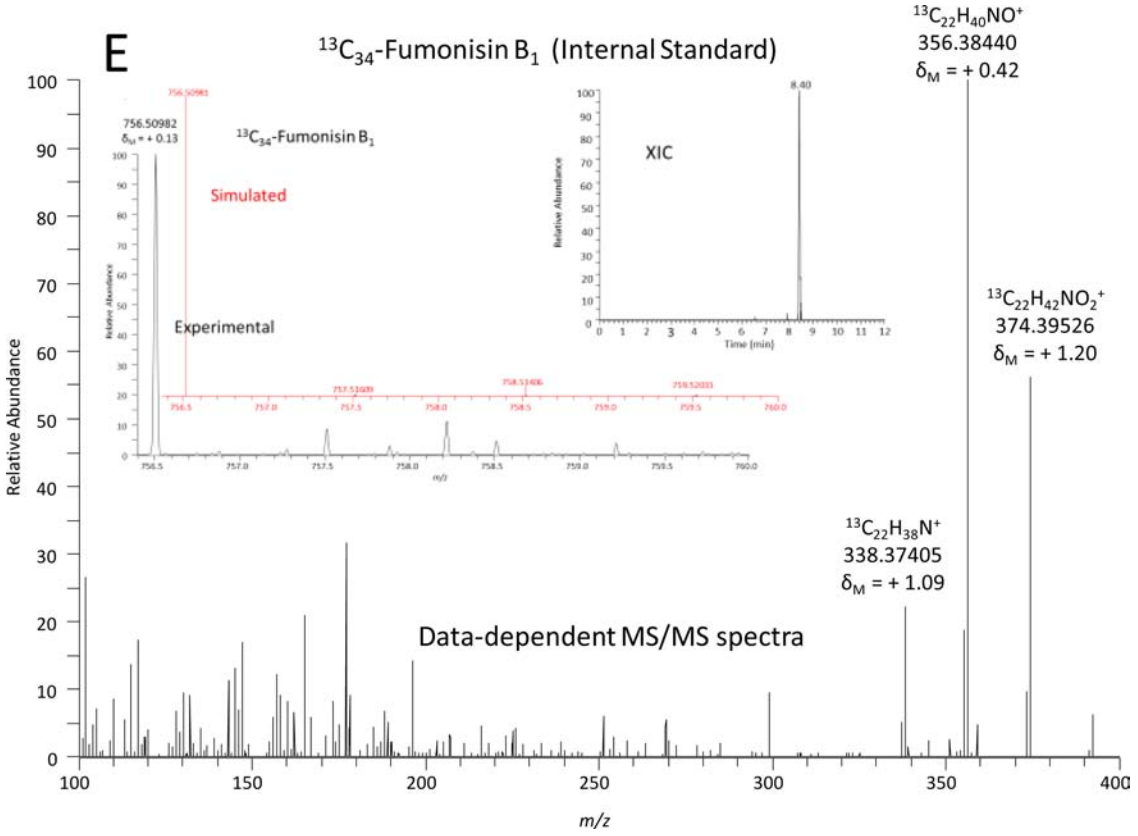

Figure 1. UHPLC-quadrupole orbital trap mass spectrometry analysis of a corn reference material (GIPSA-MRM2010-021) used for the analysis of fumonisins (FB1, FB2, FB3). (A) Total ion chromatogram (TIC) of a corn extract and resulting extracted ion chromatograms (XIC) of fumonisins using *m/z* 722.39575 (fumonisin B_1) and 706.40083 (fumonisins B_2 and B_3). The reason for the question mark for FB3 was that no reference standard was used for identifying fumonisin B_3. (B–D) Experimental and simulated mass spectra for $[M + H]^+$, $[M+1+H]^+$, and $[M+2+H]^+$ isotope peaks extracted from the TICs in full-scan mode (inset) and data-dependent MS/MS (DD-MS^2) spectra of FB1, FB2, and FB3, respectively, revealing fragments generated from collision experiments (NCE = 35). Only FB1 and FB2 were confirmed with reference standards in acetonitrile/water. (E) XIC, isotope mass spectra, and DD-MS^2 spectra of labeled $^{13}C_{34}$–FB1 used as an internal standard in the corn extract.

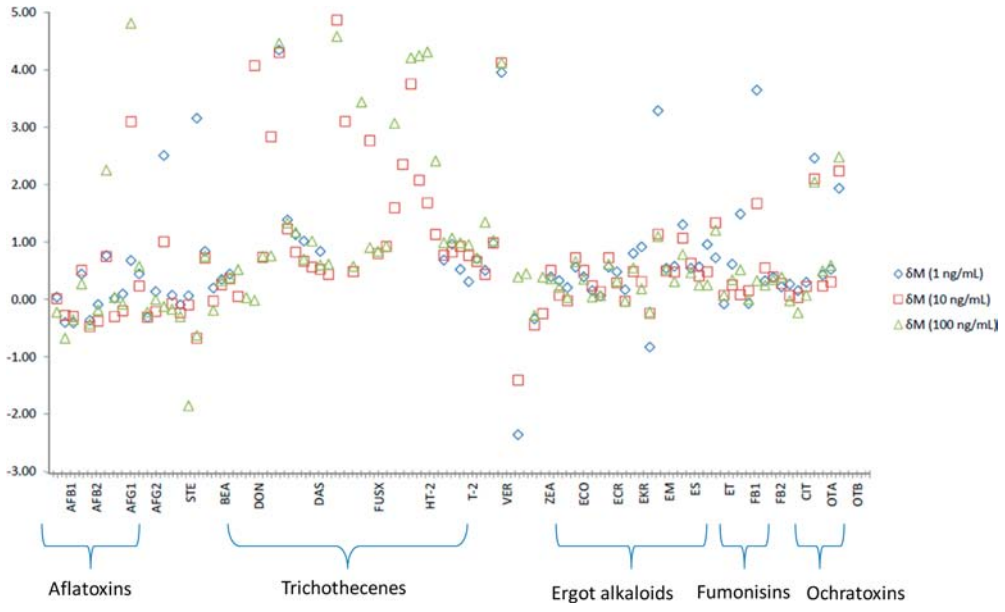

Figure 2. Mass accuracy distributions, δ_M (1 ng/mL), δ_M (10 ng/mL), and δ_M (100 ng/mL) of mycotoxin fragments extract from solvent (acetonitrile/water) and acetonitrile/water extracts of peanut and wheat matrices at concentration levels of 1, 10, and 100 ng/mL. Refer to Table 7 for a complete listing of mass ion fragments for each mycotoxin.

[a]Average ion ratios (% avg) and relative standard deviations (RSD) based on triplicate results each of the mycotoxins fortified in solvent (acetonitrile/water) and acetonitrile/water extracts from peanut and wheat matrices at 1, 10, and 100 ng/mL. The % ion ratio was determined by the ratio of the ion signal responses extracted of the ion to the response with the signal of the molecular ion (indicated in bold) of the highest signal intensity.

and the lesser abundant secondary transitions are typically used for quantitation and identification, respectively, of the analyte.[29,30] The Q-orbital trap operating in DDMS^2 mode provides accurate masses (δ_M < 5 ppm) of the precursor and product ions and offers a higher level of confidence in analyte identification than a triple-quadrupole mass analyzer in MS/MS mode. The DDMS^2 spectra of native mycotoxins can provide accurate masses, resulting in the probable molecular formulas of product ions (DDMS^2 spectra of native mycotoxins are provided in Supporting Information, Figure S1). Figure 1 reveals a wealth of information gained from UHPLC/Q-orbital trap MS in full and DDMS^2 scan modes of fumonisins from a corn reference sample. Extracted ion masses of 722.39575 and 706.40083 and retention times were able to determine the presence of fumonisin B_1 and B_2 (FB1 and FB2), respectively, as well as an additional peak consistent with the presence of fumonisin B_3 (FB3, Figure 1), though identification was incomplete without a reference standard. The three native fumonisin species could be identified by characteristic products (Figure 1B−E) that were resolved chromatographically or by mass (Figure 1E), such in the case of the isotope-labeled internal standard (Figure 1E) using DDMS^2. The DDMS^2 spectra were also used to identify aflatoxins, fumonisins, ochratoxins, and ergot alkaloids for the grain and nut samples in the survey because spectra could be triggered at levels of >10 ng/mL (>50 μg/kg) for these mycotoxin classes. Identification could not be achieved for most of the trichlothecene mycotoxins because the concentrations measured did not trigger the DDMS^2 response but the concentrations reported were significantly below the tolerance or regulatory levels. The available information provided by DDMS^2 spectra was used for identification by providing the characteristic product ions of the mycotoxin in the incurred or fortified food samples as well as additional product information that allows for advanced data interpretation to enhance the confidence of analysis and to carry out retrospective nontargeted analysis.

Figure 2 summarizes the δ_M values of products obtained from individual mycotoxins in the presence of solvent, wheat, and peanut matrices at 1, 10, and 100 ng/mL using a generalized NCE setting of 35 (the numerical δ_M results shown in Figure 2 at each level in solvent, peanut, and wheat matrices are provided in Supporting Information, Tables S7−S10, respectively). The products were selected and consistent with various MS/MS studies of aflatoxins,[31−33] ergot alkaloids,[34−37] fumonisins,[38] ochratoxins,[39,40] trichothecenes,[41,42] and others[43,44] produced by *Fusarium* species. Average δ_M values of products were typically within ±1 ppm, independent of the matrix and dependent on the relative abundances of the precursors and products. DDMS^2 spectra were not generated for 15-acetyl deoxynivalenol (15-acetyl DON), HT-2, T2, DON, DAS, fusarenon-X, and neosolaniol at 1 ng/mL and for 15-acetyl DON and neosolaniol at 10 and 100 ng/mL because either spectra could not be triggered at the lowest concentration level or the experimental m/z values could not be confidently matched with structures using a mass tolerance δ_M < 5 ppm. Further improvements in identification can be achieved by optimizing the intensity threshold and/or individual or step NCEs for individual mycotoxins rather than using the generalized NCE = 35 value used in this study. However, the ionization of trichlothecene mycotoxins generates excessive products, and the lack of any prominent products can result in lower abundances and signal intensities.

Ion ratios of the primary and secondary transitions are typically used in targeted MS/MS analysis for confirmation purposes and are evaluated for their reliability in the orbital trap MS analysis of mycotoxins. To provide additional guidelines, account for differences in the % ion ratios, and improve the confidence in identification, fortification studies of mycotoxins in various matrices at different concentrations were conducted. As shown in Table 7 (with additional information available in Supporting Information, Table S11), the ion ratios for most of the mycotoxins (aflatoxins, beauvreicin, ergot alkaloids, fumonisins, ochratoxins, trichothecenes, verrucarin, and zearalenone) were not influenced by either analyte concentration or sample matrix. The mass ion ratio for citrinin based on m/z 251.09140 (quasi molecular ion) and 233.08084 (resulting from the loss of the hydroxyl group from the molecular ion) listed in Table 7 (and Supporting Information, Table S11) were shown to be influenced by the matrix and its concentration in the matrix. The ion ratios were significantly different in nut and grain matrices and the solvent standard at each fortification level. The products generated from DDMS^2 Q-orbital trap MS signify an important distinction from triple-quadrupole MS/MS results because the high mass accuracy results obtained from the DDMS^2 Q-orbital trap provide the confidence that the products generated can be easily extracted or distinguished from artifacts of the same nominal masses. For example, the theoretical m/z ions of 283.13827 and 203.07027 from zearalenone were found at 10 and 100 ng/mL levels in solvent and matrix with δ_M < 2.5 ppm and were clearly distinguishable from the experimental artifact masses of 283.13722 (δ_M = 15.36) and 203.06904 (δ_M = −6.08) that are present at 1 ng/mL (results of δ_M > 5 ppm were not shown because the mass tolerance of 5 ppm was exceeded). These results in Table 7 also show that the differences of the % ion ratio responses of zearalenone and the other mycotoxins are concentration-dependent and well behaved and consistent within the presence of the matrix. However, differences in the average and standard deviation of ion responses are observed due to variability

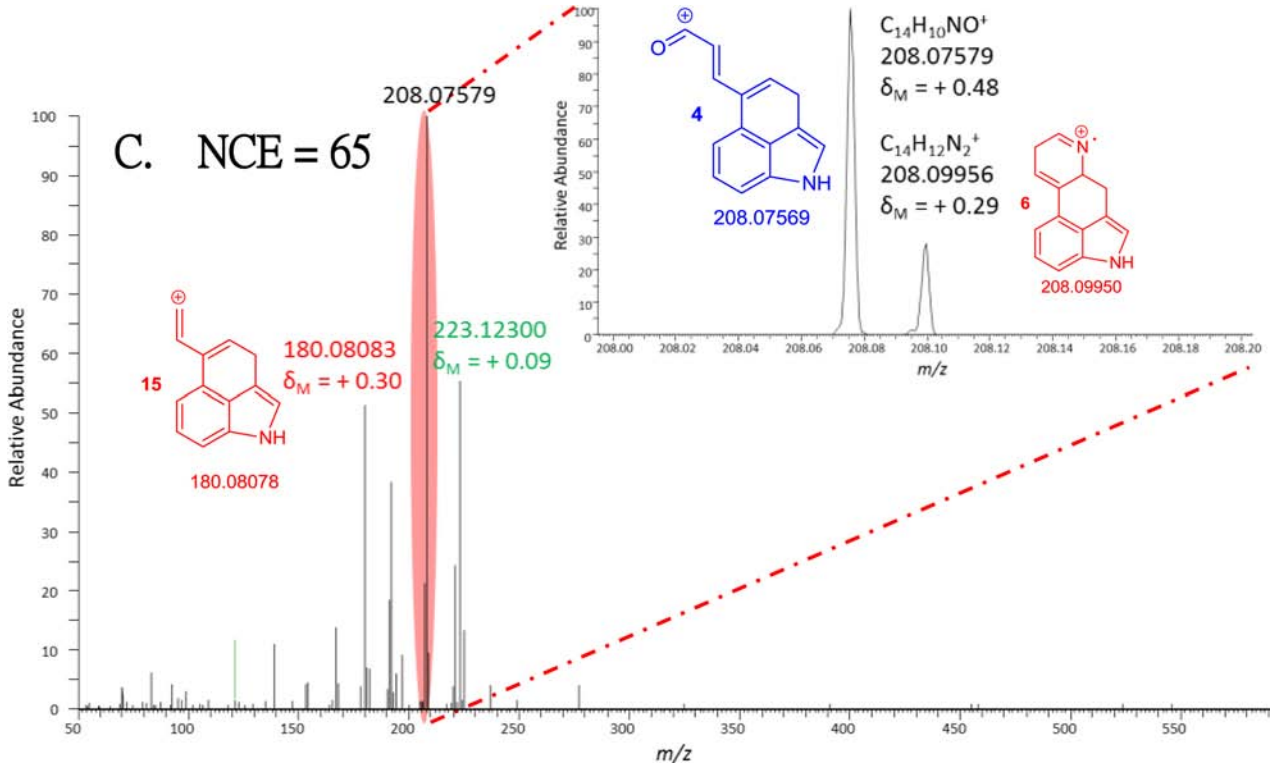

Figure 3. Data-data MS/MS (DDMS^2) spectra of the ergot alkaloid mycotoxin, ergocornine, generated using UHPLC-quadrupole orbital trap mass spectrometry at different normalized collision energies (NCEs): (A) 10, (B) 35 (inset: ion chromatogram of ergocornine (major peak) and −inine (minor peak) epimer extracted using its protonated adduct m/z 562.30240), and (C) 65. DDMS^2 spectra of ergocornine were determined at half peak height and refer to Figure 4 for product structures and numerical assignments.

between matrices (as indicated by peanut and wheat results provided in Supporting Information, Table S11).

High-Resolution Accurate Mass DDMS^2 Fragmentation Studies of Mycotoxins. The benefits of full-scan, high-resolution, accurate mass measurements are further demonstrated by comparing m/z of product ions obtained from LC-MS/MS and UHPLC/Q-orbital trap MS in DDMS^2 mode for the analysis of ergot alkaloid mycotoxins. DDMS^2 spectra are illustrated in Figure 3, revealing the accurate masses (δ_M < 5 ppm) of product ions obtained from HCD experiment of the dominant epimer (Figure 4B, inset) of ergocornine at three NCE levels of 10, 35, and 65. Previous LC-MS/MS studies have provided detailed fragmentation schemes of these peptide-like indole alkaloids, resulting in the formation of two characteristic lysergic acid moiety products (m/z 223 and 208), typically used for quantitation and identification. A possible fragmentation pathway from the precursor ion, ergocornine, to its various products is illustrated in Figure 4, based on previous LC-MS/MS studies[34,35] and supported by high-resolution/high-mass-accuracy DDMS^2 analysis. Fragmentation begins by protonation of the amide bond in **1A** (m/z 562.30240), leading to two possible pathways involving α- and β-cleavage of the amide bond, and then the formation of the ergoline products **2** (m/z 268.14435) and **12**, and **3A** (m/z 251.11789), respectively. Product **2** can also be fragmented directly to **3A** from the loss of $-NH_3$. Product **3A** can be further fragmented and either lose −CO via rearrangement to **3B** to form a lysergic acid derivative cation **5** (m/z 223.12298) or undergo further rearrangement to lose $-C_2H_3N$ to form cation **4** (m/z 208.07569). The current study supports the presence of lysergic acid derivative product ions, **5** $[C_{15}H_{15}N_2]^+$ (m/z 223.12298) and **4** $[C_{14}H_{10}NO]^+$ (m/z 208.07569), but not the formation of the radical **6** $[C_{14}H_{12}N_2^{\bullet}]^+$ ion (m/z 208.09950) due to the loss of the $-CH_3^{\bullet}$ group, as suggested by LC-MS/MS results.[34,35] Low (10) and medium (35) NCEs resulted in no and little product formation of the radical ion **6** (Figure 3A,B), indicating the loss of a methyl cation from the stable **5** product is highly unlikely. A higher NCE (65) (Figure 3C) is required to form the radical product ion **6**, but its signal intensity is still approximately one-third of that of product **5**. The formation of a product ion at m/z 180.08083 (and δ_M = 0.30 Figure 3**C**) indicating loss of −CO further supports the presence of product ion **4** (m/z 180.08078). The presence of one or both of these product masses observed by DDMS^2 results was also determined experimentally using HPLC coupled to a high-resolution mass analyzer consisting of an ion trap/orbital trap hybrid or single-stage orbital trap mass analyzers.[36,37] Other products based on results obtained from LC-MS/MS and UHPLC/Q-orbital trap DDMS^2 can be postulated by protonation of the hydroxide moiety in **1B** resulting in the loss of $-H_2O$ (**7**, m/z = 544.29183), followed by a number of rearrangement and fragmentation steps of the peptide moiety that forms the lysergic acid or the substituted indole cation products **10** (m/z 348.17065) and **11** (m/z 305.12845), respectively. The formation of products **14** (m/z 277.15467) is believed to be a result of a rearrangement and loss of $-H_2O$ of the peptide moiety **12**, formed as a fragmentation result of β-cleavage of the amide bond in **1A**.

Due to the full-scan capability of orbital trap MS, one can carry out MS/MS experiments using DDMS^2 mode, in which the quadrupole will select those coeluting precursor ions, and then carry out the HCD using an optimized or three-step NCE, such that targeted product ions can be measured in a single

J. Agric. Food Chem. 2015, 63, 8314−8332

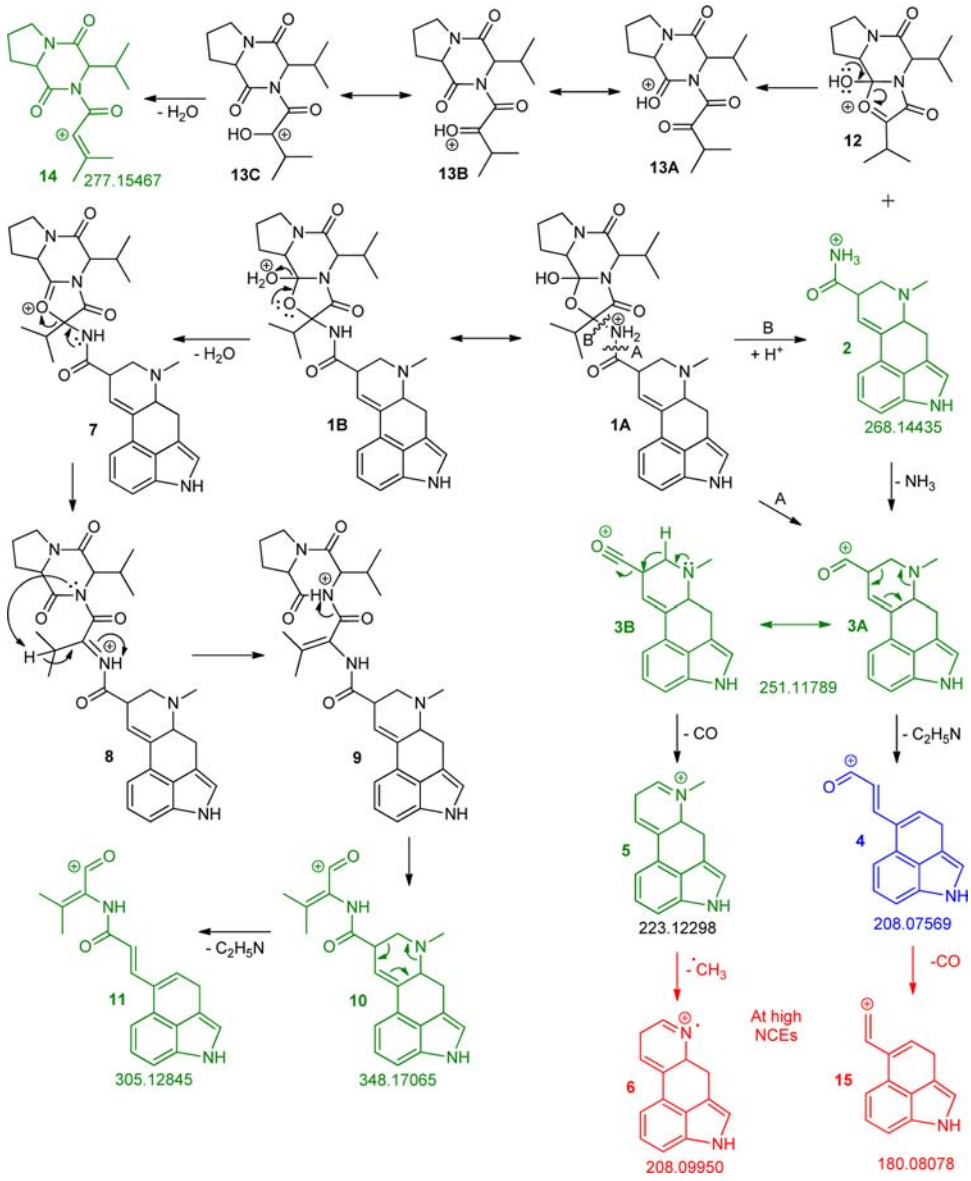

Figure 4. Possible fragmentation mechanism of ergocornine, as provided by LC-MS/MS studies of Lehner et al.[30] and Mohammed et al.[31] with experimental agreement and some modifications by studies performed in this work as well as by Mulac et al.[32] and Arroyo-Manzanares et al.[35] If protonation occurs at the amide bond **1A**, two fragmentation pathways (A,B) are possible: (A) α-cleavage of the amide bond to form **3A**, **3B**, or (B) β-cleavage of the amide bond in **2**, which can lose NH_3 to form **3A**, **3B**. Structures **3A**, **3B** can either lose CO to **5** or undergo rearrangement to **4**. The LC-MS/MS prediction of **6** (as indicated in red) is not consistent with the experimental result obtained from UHPLC-Quadrupole/orbital trap in data-dependent MS/MS experiments unless a higher NCE is used. High-resolution and high-accuracy studies indicate the formation of **4** is the more likely structure present (as indicated in blue and subsequent formation of **15** at a higher NCE) in the MS/MS spectrum in Figure 3. Protonation at the hydroxide moiety **1B** would result in the loss of H_2O followed by a number of steps to promote the formation of **10**, which can undergo rearrangement to **11**. Structure **14** is a result of the fragmentation of the peptide moiety **12** resulting from β-cleavage of the amide linkage in **1A**.

composite MS spectrum. The data acquisition duty cycle will increase when additional mycotoxins are added to the inclusion list to perform $DDMS^2$ analysis. This will limit the number of data points required to accurately define an extracted ion chromatogram peak for consistent quantitative analysis. Therefore, to ensure the data acquisition duty cycle would not adversely affect the use of both full MS and $DDMS^2$ scanning modes, UHPLC separation and intensity thresholds will need to be further evaluated and optimized for quantitative and qualitative analysis. Studies will be required to extract both quantitative and qualitative information from a single $DDMS^2$ analysis to determine whether the quality of such quantitative results will be acceptable for multianalyte procedures that are becoming popular due to cost and time effectiveness and efficiency.[22]

This validated method for analyzing finished and nut products was shown to be easy, efficient, and rugged for routine multi-mycotoxin sample analyses and could be modified and expanded to include other mycotoxins and fungal metabolites, if certified standards become available. The use of Q-orbital trap MS technology has been evaluated thoroughly by applying a validation for mycotoxins in grain and nut products comparable to a previous LC-MS/MS study, evaluating reference and actual food samples, and providing high-accuracy mass fragmentation information that was useful for mycotoxin identification. Future research will include

expanding and modifying this method to analyze additional chemical contaminants, optimize $DDMS^2$ conditions, evaluate other types of full-scan collision experiments such as data-independent acquisition,[45−47] and perform analyses using other food and agricultural matrices.

loading, sample cross-contamination, and the requirement for solvent washing between samples.

Because of these issues, indirect stoichiometric FTIR methods are generally a better approach to quantitation,[10−15] with a variety of bases having been used to convert FFAs to their salts. In these methods, the COO^-X^+ salts formed can be measured spectroscopically or, alternatively, the conjugate acid (X^-H^+) if it is infrared active and measurable. In all cases, solvents are used to reduce viscosity and facilitate sample handling. A complicating factor in the indirect stoichiometric procedures is how the samples are handled spectroscopically, in terms of being either split-sample or single-sample analyses. The distinction here is that in the split-sample approach, paired spectroscopic analyses are required, one of the oil samples with the reagent added (S_R) and the other the oil sample with only the solvent (S_S) added. By spectroscopically subtracting S_S from S_R, the differential spectrum ($\Delta S = S_R - S_S$) contains only the spectroscopic contributions related to the chemical changes taking place, the other spectroscopic contributions having been ratioed out. Although this is the more ideal approach from the standpoint of quantification, it also requires the analysis of two samples to obtain a single result. This requirement is generally considered impractical from a sample preparation and handling perspective by commercial laboratories when considering an automated method.[15] Most of these issues have been overcome by using sodium phenolate in 1-propanol (phenolate/1-PrOH) as the reagent in the single-sample mode, providing for oil−solvent miscibility as well as suitably located conjugated acid (phenol) absorption. By measuring the phenol formed at ∼1569 cm^{-1}, an accurate, single-sample, automated turnkey method has been implemented to deliver ASTM-identical AN (AV) results for the mineral-based lubricants.[15] To date, the $FTIR_{phenolate}$ procedure has only been applied to mineral-based oils with the objective of producing ASTM-identical AN results for lubricants.[11] As such, turnkey, autosampler-based FTIR instrumentation equipped with custom ancillary software designed for commercial lubricant laboratory use is required rather than a conventional, standard benchtop FTIR spectrometer.

This work was designed to develop and validate a generic, semiautomatable FTIR method capable of rapidly determining the acidity of ester-based oils using any basic FTIR spectrometer to produce results as, or more than, accurate as standard titration procedures.

MATERIALS AND METHODS

Materials. All reagents were of analytical grade, with sodium phenolate (phenolate), oleic acid, and *p*-toluenesulfonic acid (*p*-TSA) obtained from Aladdin Inc. (Shanghai, China) and 1-propanol (1-PrOH) obtained from Ling Feng Inc. (Shanghai, China). Vegetable oils, including soy, sunflower seed, peanut, palm, were obtained from local Chinese retailers. Freshly prepared phenolate/1-PrOH was stored in and delivered from a bottle dispenser; inlet air passed through a solution of $Ca(OH)_2$ (Sinopharm Chemical Reagent Co., Shanghai, China) to prevent atmospheric CO_2 ingression, which leads to carbonic acid formation and consumption of the phenolate. Any oil used for calibration or as reference oil (O_R) was passed through activated silica gel to remove any FFA, the silica gel (60−100 mesh) being preactivated at 280 °C for 4 h before use.

Instrumentation. The instrument used was a Tensor 27 FTIR spectrometer (Bruker Inc., Bremen, Germany) controlled by OPUS software (Bruker Inc.), with all spectra collected at a resolution of 4 cm^{-1} using 16 scans (∼30 s scanning) over a spectroscopic range of 400−4000 cm^{-1}. General spectroscopic processing, including spectroscopic subtraction, obtaining second-derivative spectra, region selection, and baselines for calibration and validation, was carried out using Omnic (Nicolet, Madison, WI, USA) software. Analyses were carried out using a 100 μm CaF_2 transmission flow cell equipped with Luer lock fittings, with the cell loaded by aspiration using a long stainless steel Leur-Lock needle connected via Tygon tubing to the cell and a three-way control valve, sample trap, and then vacuum.

Sample Preparation. For spectroscopic analysis, a standardized sample preparation protocol was used, requiring the dispensing of 10 mL of 1% phenolate dissolved in 1-PrOH from a calibrated bottle-topped dispenser into a 25 mL glass vial containing 5 g (±0.01) of oil. After reagent addition, the vial was capped and shaken until the solution was clear, after which it was ready for spectroscopic analysis. The sample can be taken either by opening the vial and aspirating the sample into the cell via the needle while using the valve or, if a septum cap is used, puncturing the septum with the needle and loading the cell.

Calibration. Acid-free oil is required for calibration, with any refined oil serving this purpose if treated with activated silica gel to ensure that all polar constituents have been removed. Using this acid-free oil, oleic acid-spiked calibration standards ($C_{0\rightarrow n}$) were prepared, the base oil to which no oleic acid had been added serving as the calibration reference oil (C_0). Using calibration samples prepared as above, a single-beam air spectrum was first taken, the cell loaded by aspiration, followed by a single-beam spectrum of the C_0 solution to produce its absorption spectrum (AC_0) and stored. The cell was then emptied by aspirating air through the cell, flushed with 1-PrOH, emptied again, and loaded with the next standard, the cell flushing step depending on whether any significant sample carry-over is encountered. Using the same air background, the single-beam spectrum of each of the subsequent spiked calibration standards was collected to produce the absorption spectrum of each standard ($AC_{1\rightarrow n}$). Differential spectra were then produced by subtracting AC_0 from each spectrum of the standards and its 5-5 gap-segment second-derivative taken ($\Delta^2AC_{1\rightarrow n}$) and multiplied by 100 to magnify the small absolute peak height obtained to more workable values. For calibration, the peak height of the $\nu_{phenolate^-}$ absorption (∼1588 cm^{-1}) and the ν_{COO^-} of the FFA salt (∼1569 cm^{-1}) in the $\Delta^2AC_{1\rightarrow n}$ spectra were measured relative to a zero baseline. These responses are related by linear regression to AV and %FFA, respectively, calculated from the oleic added standard to produce the calibrations.

Sample Analysis. The analysis of unknowns requires that a representative acid-free reference oil (O_R), which is analogous to CA_0 of the calibration set, be available, which is readily prepared by passing an oil through an activated silica gel column. Sample analysis parallels the calibration procedure by collecting the spectrum of the reagent-reacted reference oil, O_R, to produce AO_R, which was stored. The cell was then loaded with the first reagent-reacted oil sample to obtain its absorption spectrum (AO_{S1}); its differential spectrum was calculated ($\Delta AS_1 = AO_{S1} - AO_R$) and its 5-5 gap-segment second-derivative taken (Δ^2AS_1) and multiplied by 100; the second-derivative calibration equations derived for FFA and/or AV were used to predict the respective values.

Analytical Spectroscopy. A set of 11 calibration standards (C_0−C_{11}) were prepared covering a range 0−4% FFA_{oleic} (0−7.96 mg KOH/g as AV) by the gravimetric addition of pure oleic acid (±0.1 mg) to a refined, silica gel-treated peanut oil (acid-free). Using the second-derivative calibrations, a set of representative oils (soy, peanut, and sunflower), spiked with known amounts of oleic acid, were prepared and analyzed by FTIR in duplicate for their AV/FFA content. These samples were also analyzed in duplicate according to AOCS Cd 3d-63/Cd 5a-40. Both the AOCS and FTIR results were compared to the gravimetrically added AV/FFA oleic acid values in terms of accuracy and reproducibility; the gravimetric data were considered to reflect the true acidity of the samples. Three additional sets of samples were prepared in another acid-free oil, one gravimetrically spiked with *p*-TSA, a second with oleic acid, individually, and a third with mixtures of two acids to determine whether carboxylic and noncarboxylic acid contributions could be differentiated and quantified properly. Subsequently, FTIR and AOCS predictions were compared by analyzing used oils of unknown

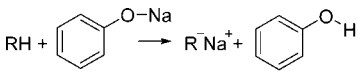
DOI: 10.1021/acs.jafc.5b02738
J. Agric. Food Chem. 2015, 63, 8333−8338

provenance obtained from local vendors to validate the overall performance of the FTIR method. For these analyses, two spectroscopically divergent oils were used as O_R to determine if oil-type and/or other matrix effects affect the FTIR predictions relative to the AOCS results.

Validation Analysis. The spectra obtained were analyzed using TurboQuant (version 7.2.0) (Thermo-Electron Corp., Madison, WI, USA), a spectral analytical and chemometrics package providing for region selection, spectroscopic transformations, calibration development, and concurrent prediction of validation samples relative to known or chemically determined values as well as facilitating statistical analysis of the results.

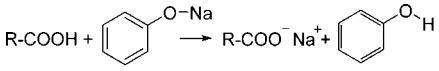
RESULTS AND DISCUSSION

Calibration. As noted, the indirect phenolate-based FTIR method ($FTIR_{phenolate}$) has been applied only to mineral-based oils as a single-sample, automated procedure to determine AN with the objective of obtaining ASTM-identical results. In this work, the objective was to simplify and assess the performance of the $FTIR_{phenolate}$ procedure for its ability to analyze non-phosphate ester-based oils so as to make the FTIR procedure more generic and utilitarian. The phenolate stoichiometric reaction used for the analysis for AV in hydrophobic matrices can be generalized as



(1)

In the case of ester-based oils, carboxylic acids are effectively the only source of acidity:



(2)

In eqs 1 and 2, all acidity with a pK_a value 1 order greater than that of phenolate should be readily measurable via the spectroscopic loss of the $\nu_{phenolate}$ absorption, whereas in eq 2, one may have the option of measuring acidity using either the $\nu_{phenolate}$, ν_{COO^-}, or both as a measure of FFAs. By using acid-free oil to calibrate and pure oleic acid as the acid source, a calibration devised in this manner should produce an identical response regardless of the mode of measurement. However, when acidity other than FFAs is present, AV and %FFA results will differ and a conversion ratio of FFA to AV (1.99 as oleic) will produce a lower result.

Figure 1 illustrates the simple differential and 5-5 gap-segment second-derivative spectra obtained for phenolate-reacted, oleic acid-spiked peanut oil calibration standards after subtraction of the spectrum of acid-free AC_0. The changes in the differential spectra reflect the loss of phenolate and the formation of COO^-Na^+, but are spectroscopically difficult to interpret due to spectroscopic overlap. However, after taking the gap-segment second-derivative, these absorption changes are more clearly parsed out, with the negative phenolate band at ~1588 cm^{-1} becoming smaller with acid concentration, whereas the positive oleate band at ~1569 cm^{-1} grows proportionately, thus providing means of differentiating between carboxylate (FFA) acidity and total acidity contributions (AV). Figure 2 presents calibration plots devised on the basis of the second-derivative spectra by measuring the minimum and maximum, respectively, of the COO^- and phenolate bands in each spectrum and relating the peak height to the %FFA and AV, respectively.

The calibration equations obtained for the $\Delta^2AC_{1\rightarrow n}$ spectra in terms of AV and FFA based solely on oleic acid being present are

$$FTIR_{AV} = 13.636 \times Abs_{(1588cm^{-1})} + 0.230 \quad (3)$$

$$R^2 = 0.9975, SD = 0.1441$$

$$FTIR_{FFA} = -5.454 \times Abs_{(1569cm^{-1})} + 0.047 \quad (4)$$

$$R^2 = 0.9989, SD = 0.0469$$

Both of these calibrations are highly linear and their respective SD values reflect a coefficient of variation (CV) of ~2.0 and 3.5%, respectively.

Validation. With these calibration relationships in hand, one can theoretically differentiate between carboxylate and other forms of acidity using the carboxyl (%FFA) and phenolate (AV) response at 1569 and 1588 cm^{-1}, respectively. To test this as well as the overall reproducibility and accuracy of FTIR method in determining acidity relative to the AOCS titrimetric method, soybean oil was gravimetrically spiked with oleic acid as well as with *p*-TSA, one set of each acid spiked into the oil alone, with another set where the two acids were present

together; all were also analyzed according to the AOCS method. In addition, a series of used oils of unknown provenance were analyzed according to the AOCS method and FTIR to compare their performance to gravimetric addition. The second-derivative spectra obtained for the calibration and validation samples were combined, a new calibration was derived, and the validation samples were predicted and compared to the known added acid amounts and/or chemically determined values using TurboQuant. All analyses were carried out in duplicate, including the reference titrimetric procedure, so as to obtain a comparative baseline in terms of accuracy (a) and reproducibility (r). On the basis of these duplicate analyses the mean difference (MD_r) and standard deviation of the difference (SDD_r) for reproducibility were determined to be 0.032 and 0.077 mg KOH/g for AV and 0.008 and 0.022% for FFA, respectively. Both the gravimetrically prepared calibration standards and the oleic/*p*-TSA samples can serve as a measure of the accuracy (a) of the titration procedure, with the MD_a and SDD_a obtained being 0.071 and 0.122 mg KOH/g oil, respectively, for AV, using the mean value of the duplicate analyses. Figure 3 presents a

J. Agric. Food Chem. 2015, 63, 8333−8338

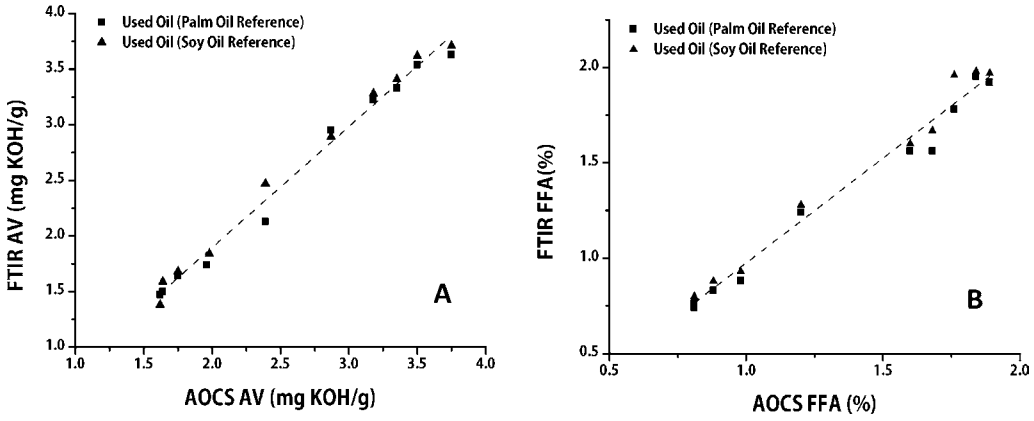

Figure 5. (A) Comparison plot of AV results obtained by AOCS and FTIR methods for used oil. (B) Similar plot for %FFA results.

composite grouping of all the validation second-derivative spectra collected.

These spectra are somewhat similar to the calibration spectra presented in Figure 1 but demonstrate substantially more variability in the phenolate band maxima. The COO^- band is more uniform, but confounded to some extent as some oils contain only *p*-TSA, which lacks the COO^- absorption. Even so, AV, defined as a measure of all acid contributions, carboxylic acids as well as noncarboxylic acids, can still be accurately measured via the loss of the phenolate band as seen in Figure 4A, which compares the FTIR predictions against the mean of the AOCS titration results for the same samples.

The ability to predict acids other than carboxylic acids correctly using the COO^- absorbance is by definition not possible and is confirmed in Figure 4B, where ⊗ represents only *p*-TSA-containing oils. Although this is an extreme example and unlikely to occur in reality, it demonstrates that, should acids other than carboxylic acids exist, the %FFA prediction will be erroneous relative to the titrimetrically determined value in such circumstances. Included in both of these assessments are used oils of unknown provenance in terms of oil type, requiring the use of an arbitrarily selected, acid-free reference oil (O_R). To assess whether the oil used as O_R affects the FTIR results significantly relative to the AOCS data, two chemically and spectroscopically divergent oils (soybean and palm oils), differing significantly in their saponification number (SN) and iodine values (IV) were used as O_R so as to generate their respective differential spectra. The FTIR AV and %FFA predictions of these used oils are compared to their mean AOCS AV and FFA results and illustrated in Figure 5, panels A and B, respectively, linear regression producing the following relationships:

$$AV_{FTIR} = 1.088 \times AV_{AOCS} - 0.280 \quad (5)$$

$$SD = 0.097, R^2 = 0.989$$

$$\%\,FFA_{FTIR} = 1.099 \times \%FFA_{AOCS} - 0.124 \quad (6)$$

$$SD = 0.070, R^2 = 0.980$$

On the basis of these results, there is minor oil-dependent bias introduced depending on which oil is used as O_R; however, as long as one consistently uses a particular oil as O_R, the results will track consistently.

Table 1 presents the overall performance of the methods relative to Figure 4 in terms of mean differences (MD_r) and standard deviation of the difference (SDD_r) between duplicates as well as in terms of accuracy (MD_a and SDD_a) of the AOCS and FTIR results relative to the amounts of acid added.

Table 1. MD and SDD for Reproducibility (r) and Accuracy (a) for Acidity of Oleic Acid and *p*-Toluenesulfonic Acid-Spiked Oils

	AV_{AOCS}	$AV_{FTIR\ C18:1}$	$AV_{FTIR p\text{-}TSA}$	$FFA_{FTIR\ C18:1}$	$FFA_{FTIR p\text{-}TSA}$
MD_r	0.032[a]	0.012[a]	0.018	0.008	NA[b]
SDD_r	0.077	0.028	0.041	0.022	NA
MD_a	0.071	0.025	0.088	0.056	NA
SDD_a	0.122	0.107	0.166	0.032	NA

[a]Absolute AV and COOH measurements from which these statistics are derived differ by a factor of ∼2, which affects their relative magnitudes. [b]NA, not applicable by definition to FTIR quantitation of FFA.

Comparison of both the AV and FFA results illustrates that the $FTIR_{phenolate}$ procedure consistently produces results statistically closer to the gravimetrically added acidity for COOH from the standpoint of either accuracy or reproducibility relative to the AOCS reference method. This confirms that the method is on firm ground in being considered a primary method in its own right. In the case of the *p*-TSA measurement, the accuracy is slightly lower, but of similar magnitude. Although one gains the impression that the COOH measure is significantly superior to that of the AV measurement on the basis of these comparative statistics, these differences are to a large degree a result of the relative magnitude of the measurements when the conversion ratio of FFA to AV is 1.99 rather than analytical differences.

As structured, the $FTIR_{phenolate}$ method performs well in determining the acidity of ester-based oils, expressed either as %FFA or as AV. Like the standard AOCS methods, this FTIR method is a primary, rather than a secondary, method. Calibration simply requires the standard addition of oleic acid to any refined, activated silica gel treated ester-based oil to ensure no residual inherent acidity exists to bias the calibration. For the analysis of unknown samples, any reasonably representative, acid-free oil can serve as reference oil, again, readily prepared by treating it with activated silica gel. Oil-type effects on quantification are minimal and consistent, with optimal results achieved using second 5-5 gap-segment derivative differential spectra. As configured, sample handling is facile, and accurate results can be obtained for all ester-based oils, other than phosphate esters, making the method of general utility even if the oil type or provenance is undefined. Because

DOI: 10.1021/acs.jafc.5b02738
J. Agric. Food Chem. 2015, 63, 8333−8338

the method uses an oil-miscible solvent as the phenolate carrier, sample handling issues associated with the high viscosity oils are minimized, facilitating rapid, even semiautomated, analysis. To the extent that a spectrometer and its attendant software allow one to program the spectroscopic data processing steps, it is possible to provide results directly in terms of %FFA or AV.

As configured, the $FTIR_{phenolate}$ method differs significantly from its specialized automated counterpart used to determine AN in mineral-based lubricants, which requires more sophisticated chemometrics to ensure delivery of ASTM-identical results. As such, this method is a hybrid procedure, combining elements of both the split-sample and the single-sample approaches, capable of ratioing out (subtracting) the oil spectrum, on the one hand, while avoiding the need for paired analysis, on the other. The sensitivity of the method can be increased or decreased simply by varying the path length proportionately. Although the method as developed here is based on a fixed oil-reagent ratio, one can develop a more generalized procedure by including an oil concentration calibration using the CH overtone region in the near IR portion of the spectrum (4500−4000 cm^{-1}). Using this approach one can spectroscopically determine the oil content of the sample prepared and dynamically normalize the differential spectra to vary the sensitivity. As designed, this simple FTIR procedure uses minimal amounts of solvent and sample, handles multiple samples readily, and provides accurate acidity results for ester-based oils, making it a utilitarian alternative to titrimetric procedures if a basic FTIR spectrometer is available.

antifungal activity by nuclear magnetic resonance (NMR) spectroscopy.

At present, an increasing importance is given to this technique[10] because it is able to point out different classes of chemical compounds, both endogenous and exogenous, at the same time, in a single spectrum, and it was successfully applied to several complex food matrices.[11−16] In particular, the comparison by NMR spectroscopy of cultivars of the same species with different degrees of resistance toward external attacks has already proven to be a reliable tool to detect molecules involved in fruit defense as well as their precursors.[12]

Because metabolites of flesh are closely related to fruit quality while those of peel are important in plant defense against fungal attacks, with the skin being a barrier between the fruit and the environment, hydroalcoholic and chloroformic extracts of both flesh and peel of the two apple cultivars were characterized by NMR spectroscopy.

MATERIALS AND METHODS

Sampling. Eight fruits of the Almagold cultivar (scab-resistant apple) and eight of the Golden Delicious cultivar (scab-susceptible apple) were hand-harvested in an organic farm orchard, located in Scurelle (Trento) in the northern Italian region Trentino-Alto Adige/Südtirol. The climate is temperate with significant rainfall during the year (annual average of 850 mm). The trees were 9 years old, grafted on M26 roostock, planted at a distance of 2.5 × 4.5 m, trained as "spindle", and irrigated with a drip irrigation system. The soil is classified sandy loam, sub-acid with a normal content of macro- and microelements. The harvest of fruits was made in the third decade of September at the stage of commercial maturity for both cultivars, which was assessed according to the following parameters: firmness of 6.4−6.9 kg/cm^2, soluble solid of 12.4−12.8 °Brix, and starch index of 2.5−3.0. These measurements were carried out following the official guidance on objective tests to determinate the quality of fruits.[17] The fruits, having a diameter of 70−75 mm, were taken from a single plant, in parts of the canopy well exposed to light to ensure higher and uniform quality characteristics. The yield has been regulated by manual thinning, leaving 70−80 fruits per tree. All apples were sampled in arbitrary order within a total time of 7 days, which were stored at 277 K before use. The selected fruits were without any apparent injury.

Sample Preparation. Slices of fresh cut flesh (about 1.2 g of fresh weight) were frozen in liquid nitrogen, finely powdered, and extracted according to the modified Bligh−Dyer methodology,[18] with a 2:2:1 methanol/chloroform/water final volumetric ratio. The sample was kept at 277 K for 1 h and then centrifuged for 20 min at 10000*g* at the same temperature. The upper hydroalcoholic phase and the lower organic phase were carefully separated and dried. The dried phases were stored at 193 K until the NMR analysis.

The peel was carefully separated from the flesh with the aid of a scalpel, pooled to acquire about 1.5 g of fresh material, and then underwent to the same extraction and drying procedures as the flesh.

Dry Matter Measurement. Dry matter was determined[17] by drying the apple sample in a oven at 70 °C until consecutive weightings made at 2 h intervals vary by less than 3 mg.

NMR Experiments. Each dry extract of the hydroalcoholic phase was dissolved in 0.6 mL of D_2O containing 2 mM 3-(trimethylsilyl)-propionic-2,2,3,3-d_4 acid sodium salt as the chemical shift and concentration reference.

Each chloroformic phase sample was resuspended in 0.6 mL of $CDCl_3$ containing 2 mM cyclohexamethyltrisiloxane as the chemical shift and concentration reference.

All solvents and standards were purchased from Sigma-Aldrich (St. Louis, MO).

All spectra were recorded at 298 K on a Bruker AVANCE III spectrometer operating at the proton frequency of 400.13 MHz and equipped with a Bruker multinuclear *z*-gradient inverse probehead.

Aqueous extract ^{1}H spectra were acquired employing the standard presat pulse sequence for solvent suppression with 64 transients, a spectral width of 6000 Hz, and 64 000 data points for an acquisition time of 5.5 s. The recycle delay was set to achieve a 15 s total acquisition time to avoid relaxation effects.

^{1}H spectra of the chloroformic phase samples were acquired with 64 transients with a spectral width of 6000 Hz and 32 000 data points for an acquisition time of 2.62 s. The recycle delay was set to achieve a 13 s total acquisition time to avoid relaxation effects.

Total correlation spectroscopy (TOCSY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC) two-dimensional spectra were acquired on a selection of samples to univocally assign ^{1}H and ^{13}C resonances. TOCSY experiments were acquired with a spectral width of 6000 Hz in both dimensions, a data matrix of 4000 × 256 points, a mixing time of 110 ms, and a relaxation delay of 2 s.

HSQC experiments were performed with a spectral width of 6000 and 25 500 Hz for the proton and carbon, respectively, a data matrix of 4000 × 256 points, an average $^1J_{C-H}$ of 145 Hz, and a recycle delay of 2 s.

Several HMBC spectra were acquired with a spectral width of 6000 and 25 500 Hz for the proton and carbon, respectively, a data matrix of 4000 × 256 points, long-range constants $^nJ_{C-H}$ of 4, 8, and 12 Hz, and a recycle delay of 2 s.

Quantification of the metabolites was performed by comparison of the signal integral to the reference integral, and quantities were expressed in milligrams per gram of fresh weight.

Statistical Analysis. The signals that could be clearly identified and had no overlap with neighboring signals were integrated for each sample. The resulting data set was submitted to analysis of variance (ANOVA) for the evaluation of statistical differences between the cultivars to point out the molecules responsible for the separation.

Data are presented as the mean ± standard deviation (SD). Univariate ANOVA was performed with Sigmaplot 11.0 software (Systat Software, Inc., San Jose, CA). A Shapiro−Wilk test was performed on each variable to assess their normality prior one-way ANOVA analysis. On the variables positive to ANOVA, a Holm−Sidak test, an all pairwise multiple comparison test, was applied to determinate which categories were discriminated by these metabolites ($p < 0.05$). Pearson correlation (Pearson product moment correlation) was carried out using Sigma stat software to observe the correlation between the quantified metabolites. The threshold value for correlation significance was $r = 0.765$. This value was chosen according to the sample population ($n = 8$) and α level = 0.05. Therefore, in this work, only the correlations with $r < -0.765$ and $r > 0.765$ were considered.

RESULTS AND DISCUSSION

Metabolic Profile. The comprehensive metabolic profile analysis of the two apple cultivars was carried out by ^{1}H NMR spectroscopy of hydroalcoholic and chloroformic extracts of both skin and flesh. Panels A and B of Figure 1 show representative ^{1}H NMR spectra (of aqueous and organic flesh and skin apple extracts) used for this purpose and the major NMR peaks that have contributed to the discrimination between the two cultivars. A total of 26 and 34 metabolites in flesh and skin, respectively, were identified. Their ^{1}H chemical shifts, multiplicity, and ^{13}C chemical shifts are reported in the Supporting Information.

Several NMR signals were identified by ^{1}H and ^{13}C NMR characteristic and cross-correlated signals in two-dimensional (2D) spectra as well as a comparison to literature data.[19,20] The assignment of the ^{1}H spectrum will be discussed for a class of compounds.

Hydroalcoholic Phase. Organic Acids. In the ^{1}H spectrum of aqueous flesh and skin apple extracts, acetic acid (AA), citric acid (CA), malic acid (MA), citramalic acid (CmA), succinic acid (SA), and quinic acid (QA) were identified by means of their diagnostic peaks and, with the exception of AA and SA,

DOI: 10.1021/acs.jafc.5b03311
J. Agric. Food Chem. 2015, 63, 8339−8347

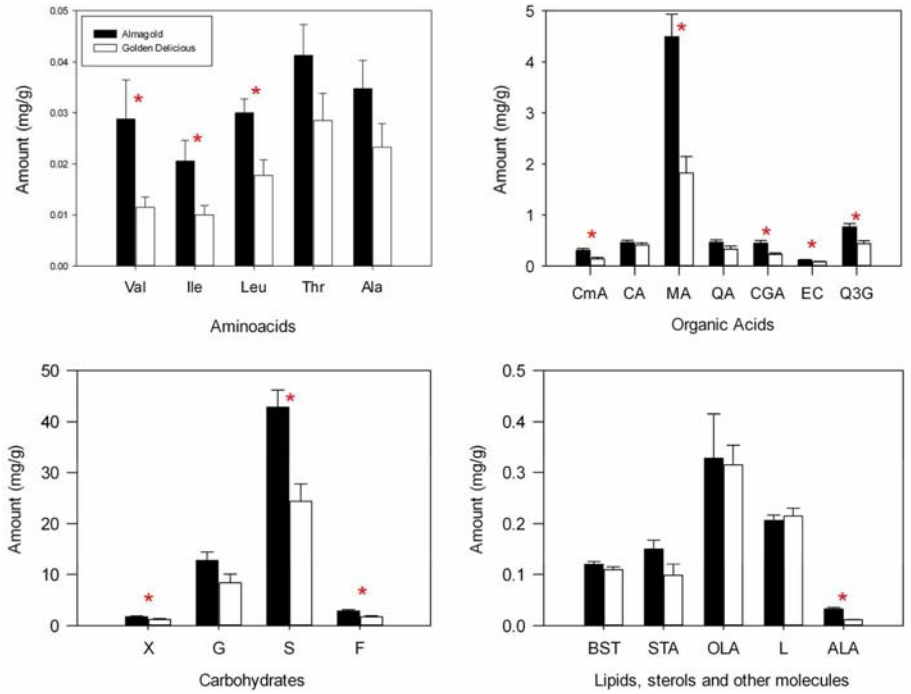

Figure 2. Amount of metabolites quantified by ^{1}H NMR in the flesh of Almagold (black bars) and Golden Delicious (white bars) apples. The metabolites positive to ANOVA ($p < 0.05$) are evidenced by an asterisk.

their TOCSY correlation patterns. CmA was univocally identified on the basis of its diagnostic singlet at 1.41 ppm (CH_3) and its doublets at 2.42 and 2.72 ppm (CH_2). The QA TOCSY spectrum showed scalar correlation among the signals at 1.89 and 2.09 ppm (CH_2-1), 2.00 and 2.06 ppm (CH_2-5), 3.55 (CH-3), 4.02 ppm (CH-2), and 4.15 ppm (CH-4).

Carbohydrates. The main carbohydrates detected in the ^{1}H spectrum of aqueous flesh and skin apple extracts were α- and β-glucose (G), α- and β-xylose (X), fructose (F), and sucrose (S). These molecules were identified on the basis of their diagnostic proton CH-1 anomeric doublets: α- and β-G at 5.25 and 4.69 ppm, respectively, α- and β-X at 5.18 and 4.57 ppm, S at 5.42 ppm, and CH-3 of F at 4.22 ppm. The remaining protons of the aforementioned spin systems were confirmed by means of 2D TOCSY experiments.

Free Amino Acids. The free amino acids leucine (Leu), isoleucine (Ile), valine (Val), threonine (Thr), and alanine (Ala) were identified by 2D TOCSY experiments of aqueous flesh and skin apple extracts. Their characteristic resonances are a multiplet at 0.97 ppm for Leu (δ,δ'-CH_3), a doublet at 1.02 ppm for Ile (γ-CH_3), a doublet at 1.05 ppm for Val (γ'-CH_3), a doublet at 1.33 ppm for Thr (γ-CH_3), and another doublet at 1.49 ppm for Ala (β-CH_3).

Phenolic Compounds. In the ^{1}H NMR spectrum of aqueous apple extracts, epicatechin (EC), chlorogenic acid (CGA), quercetin-3-*O*-galactoside (Q3G), and phloridzin (PRZ) were identified on the basis of their diagnostic spin systems. EC was identified through the TOCSY correlations between the resonances at 6.12 ppm (CH-6) and 6.14 ppm (CH-8), among the signals at 6.68 ppm (CH-6′), 6.75 ppm (CH-5′), and 6.95 ppm (CH-2′), and among the signals at 2.49 and 2.82 ppm (CH_2-4″), 3.97 ppm (CH-3″), and 4.56 ppm (CH-2″).

The caffeoyl moiety of CGA was univocally assigned as a result of the diagnostic doublets at 6.41 ppm (=CH−CO_2−) and 7.62 ppm (−CH=), while the QA moiety was assigned thanks to the TOCSY correlation pattern among the resonances at 2.07 and 2.22 ppm (CH_2-1′), 2.09 and 2.24 ppm (CH_2-5′), 3.88 ppm (CH-3′), 4.24 ppm (CH-4′), and 5.32 ppm (CH-2′).

Q3G aglycone was identified by TOCSY cross-peaks between the aromatic resonances at 6.20 ppm (CH-6) and 6.41 ppm (CH-8) and among the resonances at 7.69 ppm (CH-5′), 7.55 ppm (CH-6′), and 6.91 ppm (CH-2′) and its glycone was identified by the diagnostic doublet at 5.48 ppm (CH-1″).

PRZ was identified by TOCSY correlations between the resonances at 6.88 ppm (CH-3,5) and 7.15 ppm (CH-2,6) and the singlets at 6.05 ppm (CH-5′) and 6.21 ppm (CH-3′).

Organic Phase. Lipids. In the ^{1}H NMR spectrum of flesh and skin chloroformic phase, several lipid species were identified on the basis of TOCSY correlation patterns among the broad resonances at about 0.9 ppm (CH_3), 1.2 ppm (*n*-CH_2), 1.6 ppm (CO−CH_2−$C\underline{H}_2$), 2.0 ppm ($C\underline{H}_2$-CH=), 2.3 ppm (CO−$C\underline{H}_2$), 2.8 ppm (=CH−$C\underline{H}_2$−CH=), and 5.2 ppm (CH=CH). In comparison of the signals rising from CH_2 in α to the carboxyl group (2.3 ppm) to the signal from CH_2 in α to the unsaturations (2.0 ppm), it was possible to evaluate both the saturated and total unsaturated fatty acid contents. The amount of polyunsaturated fatty acids (PUFAs) was determined on the basis of linoleic (L) and linolenic (ALA) lipid diagnostic resonances at 2.77 and 2.82 ppm, respectively.

On the basis of the integrals of the aliphatic chain CH_2 and their ratio with the other fatty acid chain resonances, it was possible to assess that the average length of the chains is 18 carbon atoms. Therefore, the fatty acids were quantified in equivalents of stearic acid (STA), oleic acid (OLA), linoleic acid (L), and linolenic acid (ALA).

Arachidonic acid (ARA) was detected and quantified as a result of its diagnostic resonance at 2.92 ppm.

Sterols. β-Sitosterol (β-ST) was univocally assigned on the basis of the HSQCs between hydrogen at 0.68 ppm (CH_3-18) and carbon at 12.2 ppm and between the resonances at 1.01

DOI: 10.1021/acs.jafc.5b03311
J. Agric. Food Chem. 2015, 63, 8339−8347

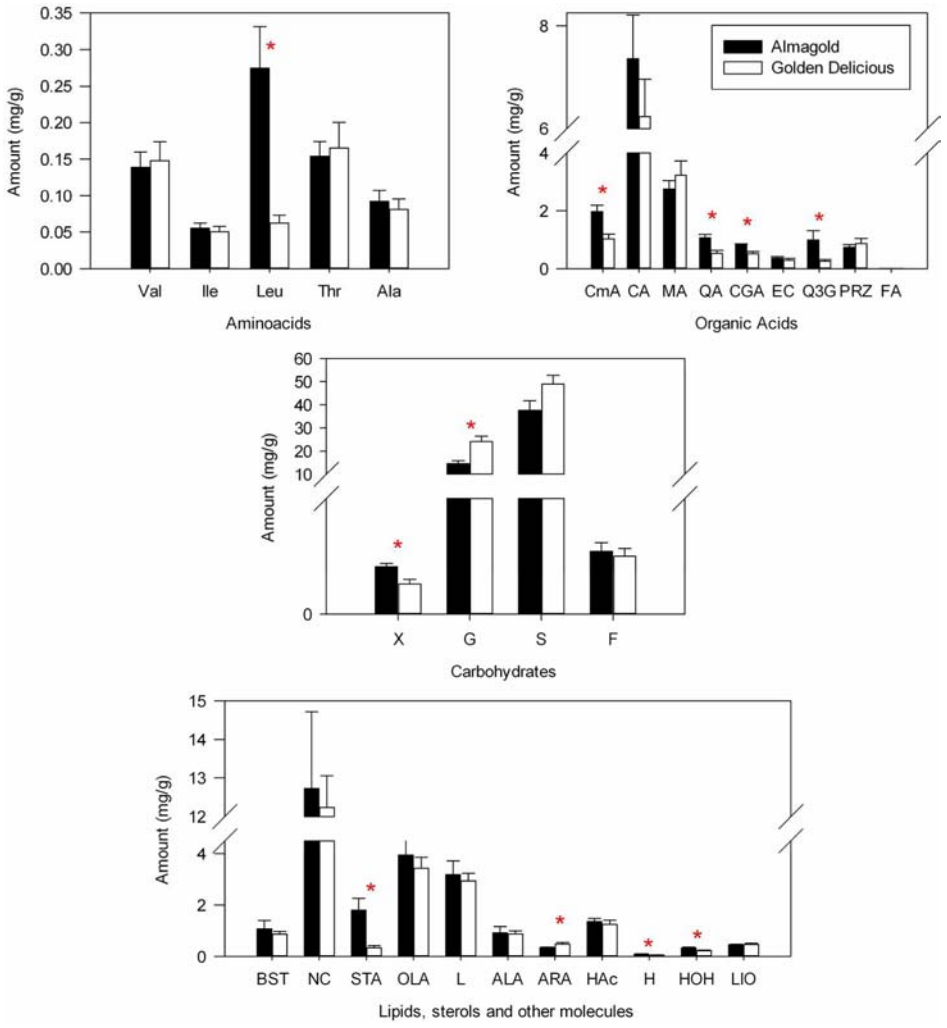

Figure 3. Amount of metabolites quantified by ^{1}H NMR in the skin of Almagold (black bars) and Golden Delicious (white bars) apples. The metabolites positive to ANOVA ($p < 0.05$) are evidenced by an asterisk.

ppm (CH_3-25) and 19.1 ppm. Other molecule resonances were identified on the basis of the TOCSY correlation pattern among the resonances at 5.34 ppm (CH-6), 1.98 and 1.52 ppm (CH_2-7), 1.46 ppm (CH-8), 0.99 ppm (CH-14), 1.57 ppm (CH_2-15), and 1.85 and 1.26 ppm (CH_2-16). Another TOCSY pattern that was attributed to the A ring of this sterol was formed by the proton signals at 3.52 ppm (CH−OH-3), 2.28 ppm (CH_2-4), 1.84 and 1.51 ppm (CH_2-2), and 1.85 and 1.08 ppm (CH_2-1).

Ursolic acid (UA) was univocally identified by HSQC and HMBC experiments. Some of the most diagnostic correlations were detected between the singlet at 5.49 ppm and the carbon signal at 125.7 ppm (CH-12), between hydrogen at 1.97 ppm and carbon at 37.4 ppm (CH_2-22), and between the protons at 1.61 ppm and carbon at 31.1 ppm (CH_2-21). Moreover, long-range correlations were observed between the protons 21 and 15 and carbon at 179.7 ppm (C-28).

Miscellaneous. Along with the aforementioned lipid species, several long-chain aliphatic molecules, such as nonadecane (NC), were observed in the ^{1}H NMR spectrum of the apple skin chloroformic phase. Their resonances were observed at 0.89 ppm (ω-CH_3) and 1.27 ppm (n-CH_2) and were distinguished from the similar lipid signals by their HSQCs as well as the absence of TOCSY correlations with the proton resonances of CH_2 in α and β positions with respect to the carboxyl group. These molecules are one of the main constituents of the waxy cuticle coating the apple skin and, along with other analogue linear olefins, are responsible for the relative adhesion of water, pesticides, fungal spores, and other airborne deposits on the fruit surface.

Linalool (LIO), hexanol (HOH), hexyl acetate (HAc), and hexanal (H) were detected only in the skin. LIO was identified on the basis of its diagnostic vinyl moiety resonance at 6.33 ppm (dd, =CH-2) and TOCSY correlation pattern with the resonances at 5.10 and 5.35 ppm (CH_2= 1a and 1b, respectively). Their complete assignment was performed by HSQC and HMBC experiments. Long-range HMBCs were observed between the H-2 and carbon in position 3 at 72.1 ppm, between this carbon and hydrogen at 0.96 and 1.21 ppm (CH_3-9 and CH_2-4, respectively), and between the quaternary carbon at 130.9 ppm (C-7) and the protons at 1.61, 1.68, and 5.08 ppm (CH_3-8, CH_3-10, and =CH-6, respectively). The resonance of proton in position 5 was univocally assigned on the basis of HSQC between its signal at 2.08 ppm and the carbon signal at 39.5 ppm and by HMBC between the aforementioned proton resonance and the carbon at 124 ppm (C-6).

J. Agric. Food Chem. 2015, 63, 8339−8347

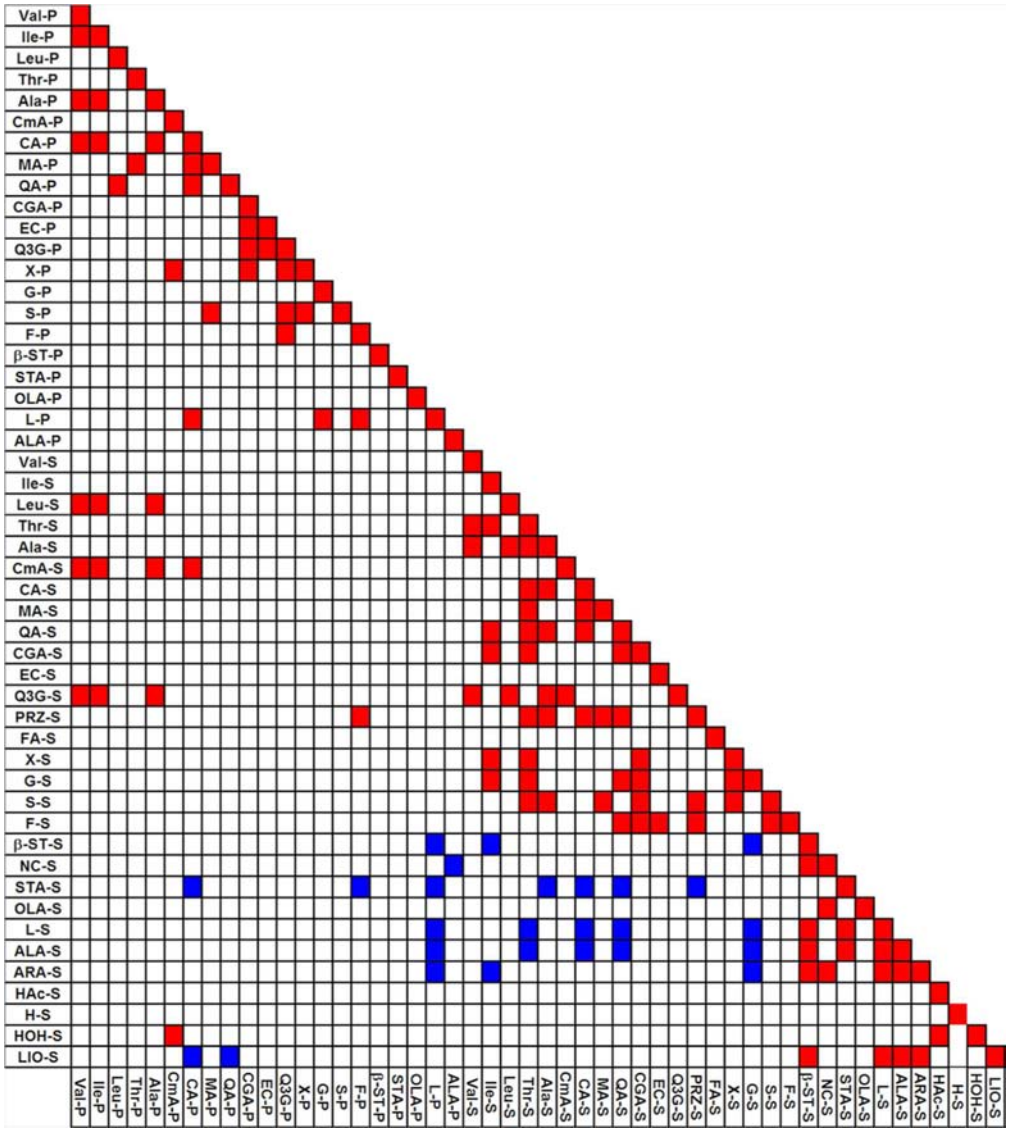

Figure 4. Pearson's correlation map of Almagold metabolites. Positive correlations are in red, while negative correlations are in blue. The correlation threshold is ±0.765.

The quantitative analysis is reported in Figures 2 and 3 for the flesh and peel metabolites, respectively.

Dry Matter Measurement. The measured dry matter content for Almagold samples was 16.7 ± 0.2%, while for Golden Delicious samples, it was 14.8 ± 0.3%. These data are in good agreement with NMR measurements for the apple flesh (Figure 2), because the metabolites present in Almagold are generally more abundant than those in the other cultivar.

Statistical Analysis. With regard to flesh analysis, the Almagold showed statistically ($p \leq 0.05$) larger amounts of Val, Ile, Leu, CmA, MA, CGA, Q3G, X, S, F, and ALA. With regard to peel analysis, the Almagold showed statistically ($p \leq 0.05$) larger amounts of Leu, CmA, QA, CGA, Q3G, X, and STA, while Golden Delicious contained larger amounts of G and ARA (Figures 2 and 3).

Because ANOVA is an univariate statistical analysis tool, this technique is unable to evidence correlations between the variables. These correlations are an important source of information because the ratios between the metabolites in a vegetal or animal sample are influenced by the metabolic network that is characteristic of each species or cultivar.

To quantify these correlations, Pearson coefficients were calculated and reported in Figures 4 and 5 for Almagold and Golden Delicious, respectively.

Comparison between Almagold and Golden Delicious. The metabolic profile comparison between the two apple varieties showed only quantitative differences (Figures 2 and 3) between metabolites, while both qualitative and quantitative differences were clearly highlighted between flesh and skin.

Most fruits and plants react to external attacks and pathogens producing several secondary metabolites to repel infections only after the first contact.[21] Nevertheless, it was observed that some fruits are able to resist against fungal attacks during quiescence not only on the basis of the synthesis of these defense metabolites after the infection but also because of the presence of preformed antifungal compounds.[22] Moreover, another benefit of pre-existent antimycotic metabolites is that, even in the case of a successful infection, those molecules were observed to reduce the secretion of fungal pathogenicity factors occurring during quiescent infections.[23]

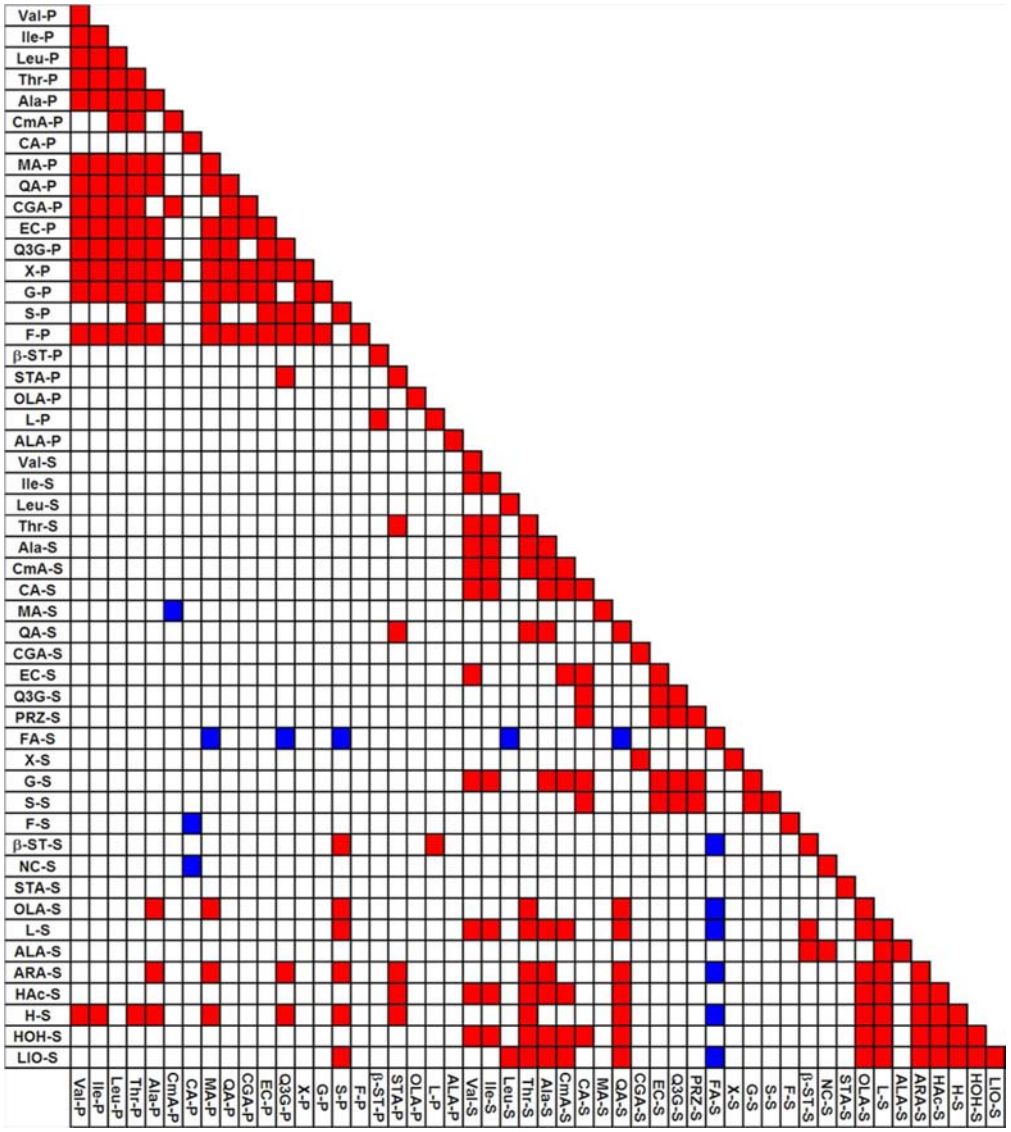

Figure 5. Pearson's correlation map of Golden Delicious metabolites. Positive correlations are in red, while negative correlations are in blue. The correlation threshold is ±0.765.

Skin Hydroalcoholic Phase. As stated before, statistical analysis performed on the skin metabolites shows that the Almagold cultivar, which is resistant to *V. inaequalis*, has a higher amount of Leu, CmA, QA, CGA, Q3G, and X and a lower amount of G (Figure 3), while metabolites such as EC and PRZ are not discriminant between the two cultivars. Among these molecules, QA, Q3G, and CGA play an important role in fruit defense against external threats, such as fungi attacks. In particular, QA is an intermediate of the phenylpropanoid pathway,[24] and it could be transformed into several different secondary metabolites according to external stimuli.

Q3G, the most abundant aromatic compound in both cultivars, is a flavonoid with a potent and non-specific antifungal activity found in many fruits and leaves,[24] was shown to be able to reduce the growth of several fungal species up to 99%, yet was never tested on *Venturia* strains specifically.

CGA is a powerful antioxidant, and high concentrations of this molecule in immature fruits were reported to aid the plant in repelling brown rot infection by interfering with fungal melanin production.[25] The same defense mechanism could be effective against other types of fungal attacks.

PRZ, detected only in the skin, is a glycosylated flavonoid that is involved in defense against herbivores and fungi attacks.[26] Nevertheless, this metabolite is present in almost the same amount in both cultivars (Figure 3), suggesting that this molecule is not directly involved in the protection against *V. inaequalis*.

In comparison of the skin metabolites of the two cultivars, it is also possible to observe that the total carbohydrate amount of Almagold is statistically lower than the total carbohydrate amount present in the Golden Delicious skin and that the sensible variety is especially rich in glucose. Fungi are unable to photosynthesize carbohydrates as a result of the lack of chloroplasts, and they need to absorb nutrients from other plants. Because the cultivar more vulnerable to *V. inaequalis* attacks, the Golden Delicious, is the cultivar with more carbohydrates in the skin, it is possible that the presence of readily available nutrients for the fungi could increase the infection diffusion in the fruit.

Skin Organic Phase. Several molecules, in particular, UA, LIO, NC, ARA, HOH, HAc, and H, were observed to be present only in the fruit skin.

DOI: 10.1021/acs.jafc.5b03311
J. Agric. Food Chem. 2015, 63, 8339−8347

Quantitative differences were detected between the two cultivars, in particular, the Almagold is richer in H, HOH, and STA, while the Golden Delicious has greater amounts of ARA.

UA is a pentacyclic triterpene whose biological role is the protection against microbial and fungi attacks.[27] LIO is a monoterpene found in many flowers and greatly contributes to the pleasant scent.[28] NC, other analogue linear olefins, and to a lesser extent, ARA are some of the main constituents of the waxy cuticle coating the apple skin, and they are responsible for the adhesion of water, pesticides, fungal spores, and other airborne deposits on the fruit surface. Moreover, PUFAs are also known to act as antimycotic agents because they fluidize the fungi cell membrane[29] and sensitize them against other antifungal agents. Because ARA is more abundant in the more sensible cultivar, it is possible that this defense mechanism is not viable against the *V. inaequalis* strain or that its antifungal efficiency is lower that the efficiency observed for L and ALA fatty acids.

Among the observed *n*-hexane derivatives, H possesses antifungal activity,[30] and its presence in the fruit skin can lead to a faster response toward detected fungi attacks.

Flesh Hydroalcoholic Phase. With regard to the flesh hydroalcoholic phase, the more resistant cultivar possesses a higher amount of CmA, MA, CGA, and Q3G, but only the last two molecules are known to be involved in the protection against fungal attacks. Their presence in the flesh of Almagold could be important because some defense compounds are produced in flesh,[31] with the purpose of a "last ditch defense" against damages, such as the damages produced by a successful *V. inaequalis* infection.

With regard to other molecules with known antifungal activity, it is interesting to observe that the amount of QA is statistically higher in the skin than in the flesh of both cultivars, but while, in the skin, it was more abundant in Almagold apples, in the flesh, there were no statistical differences between the two species.

Flesh Organic Phase. In comparison of the composition of flesh organic phases, the main difference between the two cultivars is that Almagold has a higher amount of ALA fatty acids. In addition to their aforementioned direct antifungal activity, it is worth noting that PUFAs are the precursors for the biosynthesis of volatile linear chain molecules and the main type of volatiles in apples are C_6 linear and branched alcohols, aldehydes, and acids.[32]

Pearson Correlations. The comparison of the Pearson's correlation maps of the two cultivars highlights several interesting differences regarding the metabolic correlations of the molecules with defensive roles. First of all, correlations of the same metabolite between the two locations (i.e., Ala in the flesh and Ala in the skin) were not observed in either cultivar. The absence of a direct correlation between the concentration of a metabolite in the flesh with the same in the skin suggests that no exchange occurs between the two molecule pools. This hypothesis implies that the metabolites involved in the defense from external attacks, which are those found in the skin, are synthesized *in loco*.

Moreover, it can also be observed that, in the peel of Golden Delicious (Figure 5) variety, PRZ, CGA, Q3G, and EC correlate only with molecules located in the skin and not with the molecules of the flesh, whereas in the Almagold (Figure 4) variety, PRZ, Q3G, and EC correlate with molecules located in both flesh and peel. These metabolites are involved in several defense mechanisms and, as reported before, are synthesized both prior and after an external stimulus.[21,22] Other molecules, in the peel, that show different correlations between the two cultivars are QA and CGA. This is important because variations in Pearson's correlation patterns could suggest that the metabolic pathways involved in their synthesis and their following reactions are different between the two cultivars.

This study, given its general approach, shows how the NMR-based characterization of the metabolic profile is a promising tool for the rational choice of cultivars for selective cross-breeding aimed to the development of disease-resisting fruit varieties. In particular, it is possible to attribute the resistance toward *V. inaequalis* to higher contents of QA, CGA, and Q3G and a minor amount of free carbohydrates in the peel of the fruit. Nevertheless, it is important to highlight that another major difference between the resistant and vulnerable cultivars lies in the correlation patterns among the levels of the molecules responsible for defense; this indicates that their biosynthetic pathways are different between the two cultivars, and this difference could also contribute to the different degrees of reaction to fungi attacks.

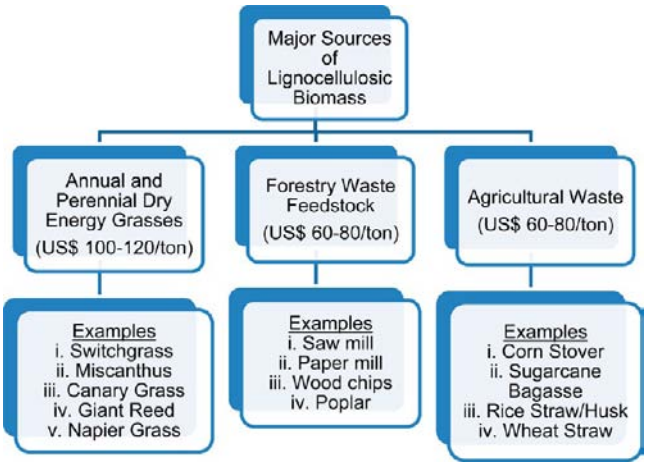

Figure 1. Major sources of lignocellulosic biomass.

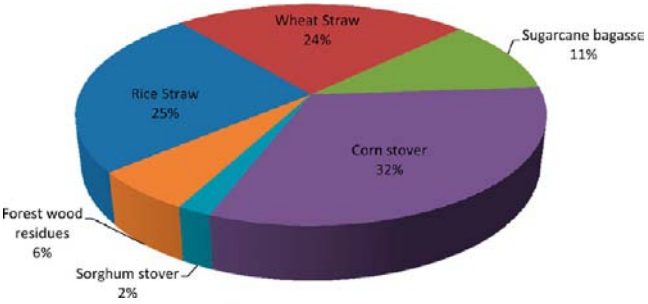

Figure 2. Global production of potentially available lignocellulosic biomass.

agricultural wastes contribute to the yearly global yield of lignocellulosic biomass.[46] For example, approximately 400 million tons of rice and wheat straw along with corn stalks are harvested in the United States each year. In mainland China, 700−800 million tons of agricultural residues are produced annually, and half of that amount is used as bioresources in the production of fuels and chemicals.[1,47,48] Brazil, which is the largest producer of sugar cane globally, generates 185 million tons of sugar cane bagasse per harvest.[49] Agricultural residues such as rice husks are used to produce electricity in gasification units and have been scrutinized intensely for use in silica production.[47] Additionally, rice husks were reported to be a potential source of biofertilizer after undergoing a biodegradation process.[50,51] Moreover, agricultural residues could be reprocessed into animal feed and used for farm cultivation.[48] However, agricultural residues are still underutilized because a large portion of this biomass is discarded as waste.[46] For instance, 10% of the corn straw in United States is collected for reuse purposes such as mulching, but most of the rice straw is disposed of by burning, which results in air pollution.[2,49,52,53] Rocha et al. also highlighted that certain components of agricultural residues such as sugar cane bagasse are still underutilized, although these residue components could potentially serve 40 different applications.[49]

Annual and Perennial Dry Energy Grasses. Annual and perennial energy crops are produced mainly to serve as raw materials in the production of biofuel due to their prominent characteristic of being low-cost and low-maintenance, which leads to economic and environmental advantages over other various forms of biomass.[40] For instance, these crops, which are normally densely planted, have the distinctive trait of high yields

Table 1. Breakdown of Worldwide Major Crops[44,45]

crop	world production (tonnes)	major producing country (tonnes) (% of world total production)	other countries (tonnes)
cassava	2.77×10^8	Nigeria: 5.3×10^7 (19.1%)	Thailand: 3.02×10^7 Indonesia: 2.39×10^7 Brazil: 2.15×10^7

and do not require annual reseeding once established.[54] Some of the common forms of energy crop biomass are illustrated in Table 2, where switchgrass and *Miscanthus* straw are among the

Table 2. Biomass Yields of Different Energy Crops[42]

energy crop	establishment time (years)	dry matter biomass yield (tons/ha/year)
willow	3+	5−11
poplar	3+	2−10
eucalyptus	4+	10−12
Miscanthus	3+	5−43
switchgrass	2−3	5−19
reed canary grass	1−2	2−10
alfalfa	1−2	1−17
fiber sorghum	1−2	16−43

main contributors annually, at 5−19 and 5−43 tons/ha/year, respectively.[42] Similarly, the cost of both maintenance and investment are low for these perennial grasses because they require less harvesting and fertilizers, which account for the major portion of the total cost.[43] Energy crops are able to grow under poor soil conditions without compromising the energy yield. A steady supply flow of these perennial crops could be obtained, thus avoiding the concern of requirement for costly storage for large biomass volumes.[42] In both the United States and Canada, switchgrass serves as a major crop due to its abundant availability and its ability to resist both disease and harsh environments.[42] The effective growth of *Miscanthus* is well-known in Asia, whereas in European regions, *Miscanthus* is grown as a source of combustible energy.[19] In African grasslands, minimal amounts of nutrients are required for growing Napier grasses, which can swiftly be harvested and yield high amounts of lignocellulosic biomass.

Forestry Waste. Woody raw materials such as sawmill residues and wood chips are more flexible in terms of harvesting times. Thus, long latency periods for forestry waste storage can also be avoided.[43] Conventionally, the lignin content in woody feedstock is greater and contains less ash,[40] and woody raw materials are thus used in the manufacture of paper and pulp.[43] Because of these characteristics, high densities of woody biomass are considered to be more attractive for cost-effective transportation. In China, approximately 900 million tons of forestry wastes and products are produced annually, and one-third of the entire amount of waste could be converted into renewable energy sources.[1] Correspondingly, short-rotation forest crops are cultivated for the production of wood chips to serve as a substitute for fossil fuels and other products such as geotextiles and building materials in Europe.[55]

COMPOSITIONAL AND STRUCTURAL CHARACTERISTICS OF LIGNOCELLULOSIC BIOMASS

Lignocellulosic biomass is basically composed of different layers of plant cell wall (Figure 3).[56] First, the primary wall is formed, followed by the secondary wall layers, through the deposition of wall substances into the primary wall, where most cells are elongated and stretched during differentiation. The chemical composition of the cell walls is dependent on the species of the plants. Some cells contain only nonlignified primary cell wall, whereas others possess a thickened secondary cell wall that is normally lignified. This lignified secondary cell wall consists of a multilayered structure. As shown in Figure 4,[57] the outer part of a softwood bleached kraft pulp (SBKP) is the highly lignified compound that consists of middle lamellae and primary wall, followed by a thin S1 layer; a thick, less lignified middle S2 layer; a thin inner S3 later; and, finally, a warty layer formed by lignin precursors.[58] This lignified secondary wall accounts for the majority of the plant biomass and usually comprises 40−50, 15−25, 20−25, and 5−10% of cellulose, hemicellulose, lignin, and other components, respectively.[57,59] Other minor nonstructural components, such as proteins, ash, extractives, and pectin, are

dependent on factors such as the different species, tissues, plant maturity, harvest times, and method of storage and environmental factors. Extractives are usually complex mixtures that consist of sugars, terpenoid compounds, and monolignols.[60] Every plant has its own floral cell walls with different amounts of specific compounds.[59] Some of the components of lignocellulosic biomass that consist primarily of agricultural residues are summarized in Table 3.[59−63]

Cellulose. Normally, cellulose accounted for 30−40% of floral cell walls. Cellulose is a β-1,4-linked glucose polysaccharide that comprises the larger portion of the cell wall that is common to all plants. Cellulose is long, consists of oriented microfibrils, and has the ability to coalesce into larger and longer fibrils. These fibrils are hydrophobic and highly crystalline, which enhances the recalcitrance of biomass.[60] The field emission scanning electron microscopy (FE-SEM) image of microfibrils (Figure 5) can be seen clearly from the untreated SBKP.[57] Therefore, the fibril is difficult to be decomposed hydrolytically because of its connected area of crystalline and amorphous structures.[59] Generally, cellulose can withstand higher decomposition temperatures than hemicellulose and lignin, with decomposition occurring at a temperature of approximately 320−356 °C.[61]

Hemicellulose. Hemicellulose is known as the second most abundant polymer on earth, with an estimated production of 60 billion tons annually, and it comprises 30−35% of floral cell walls.[59,62] Hemicellulose chains usually interact with one or more cellulose fibrils to form noncovalent cross-links between cellulose bundles. As an example, hardwood species are composed mainly of glucuronoarabinoxylans, which are formed by the complex pentose sugar chain. Conversely, softwood species are the combination of galactoglucomannans with a backbone of β-1,4-linked D-mannopyranose and D-glucopyranose units.[60] Furthermore, hemicellulose consists of different branches of complex carbohydrate structures (xylose, arabinose, mannose, glucose, and galactose) that are not recalcitrant to conversion to monomeric sugars because of their amorphous, branched, and single-chain polysaccharides. Therefore, hemicellulose is more favored for the hydrolysis process than cellulose is.[59,60] The processing step of extraction of the hemicellulose from biomass can produce or liberate compounds such as acetic acid, which eventually will help in autohydrolysis pretreatment.

However, acetic acid may inhibit subsequent fermentation steps, thereby lowering the production of ethanol and other compounds.[62]

Lignin. Lignin accounted for 11−25% of floral cell walls. Lignin is known as an amorphous phenolic macromolecule that can be found only in the secondary cell wall. Three primary units, namely, guaiacyl (G), sinapyl (S), and *p*-hydroxyphenyl (H), are linked by aryl ether or C−C bonds to form lignin.[58] The high level of heterogeneity of lignin is synthesized through the oxidative coupling of 4-hydrophenylpropanoids during secondary cell wall deposition, which results in layers of lignin in different monomers. Lignin acts as a protective barrier with impermeability and immunity to prevent an attack from microorganisms and chemical degradation by restricting the accessibility of efficient saccharification of cellulosic microfibils.[56,59,60] Additionally, lignin provides mechanical support and water transport for the cell.[61]

Overall, cellulose provides strength over the cell walls, whereas hemicellulose acts as a wire mesh that circulates around the cellulose and provides enhancement to the strength and linkage. Lignin fills the remaining space and sets everything in place and excludes water from the polysaccharide environment. This unique combination results in the high resistance of lignocellulosic biomass to mechanical and biological degradation.[60]

ROLE AND GOAL OF LIGNOCELLULOSIC BIOMASS PRETREATMENTS

Pretreatment is necessary in the bioconversion process to overcome the complex recalcitrant biomass structure. Pretreatment provides higher accessibility for the enzymes to convert cellulose and hemicellulose into useful fermentable sugars during the enzymatic hydrolysis process. When biomass is exposed to pretreatment, several operations, such as the increase in the surface area and porosity, modification of the lignin structure, removal of lignin, partial depolymerization of hemicellulose, and reduction of cellulose crystallinity, can be accomplished. These operations result in the improvement of the hydrolysis process such that a higher percentage of fermentable sugars can be recovered.[64,65] According to Singhvi et al.,[66] only 20% of the sugar can be recovered without introducing pretreatment, but 80−83% of the fermentable sugar can be recovered with introduction of a pretreatment process.[67] Generally, pretreatment can be categorized into three areas: mechanical, chemical, and biological pretreatments. Mechanical pretreatment such as milling, grinding, and chipping reduces the size of the biomass and therefore provides higher surface area and porosity.[64] Another important example of mechanical pretreatment is ultrasound pretreatment. Ultrasound pretreatment applies the principle of cavitation that forms millions of microscopic vapor bubbles. The explosion of these bubbles will create high temperature (1700−4700 °C) and pressure (1800 bar) in a microsecond, thus producing shockwaves that induce mechanical effects such as breaking larger molecules into smaller fractions with particle size reduction.[68,69] Chemical pretreatment involves the disruption of biomass recalcitrance by means of chemical reactions. Some of the conventional methods are liquid hot water, dilute and concentrated acid hydrolysis, alkaline hydrolysis, organosolv, oxidative delignification, and room temperature ionic liquids.[70] Moreover, certain methods are termed "physicochemical" pretreatments because they involve the integration of both mechanical and chemical pretreatments, such as steam explosion and CO_2 explosion.[64] Biological pretreatment involves the use of environmentally friendly enzymes such as cellulase and hemicellulase to break down complex carbohydrates into simple sugars.[70] However, enzymatic hydrolysis is usually inefficient if it is applied directly to biomass, unless the biomass has already undergone the aforementioned mechanical or chemical pretreatments. The advantages/disadvantages of some common biomass pretreatments are provided in Table 4.[3−18,20,21,35,38,70−75]

Table 4. Comparison of Different Biomass Pretreatments

pretreatment	advantages	disadvantages	refs
dilute acid hydrolysis	obtain high yields of fermentable sugars	produces inhibitory byproducts, corrosive, requires acid neutralization	3−7, 72
concentrated acid hydrolysis	obtain high yields of fermentable sugars	sugar recovery rate is slow, highly corrosive, requires acid recovery system for feasibility	71, 73
autohydrolysis (liquid hot water)	produces less inhibitors, simple operation	high-temperature operation, high energy and water input; dissolved pentose appeared mainly in oligomeric form, which required further post-hydrolysis step to obtain monomeric sugar	13−15, 20, 21
sodium hydroxide (NaOH)	effectively removes lignin, low temperature and pressure operation, low inhibitor production	long pretreatment time, expensive chemical, complex recovery process	8, 9
ammonia fiber expansion (AFEX)	low enzyme demands during enzymatic hydrolysis, low inhibitor production	produces high amounts of oligomers which cannot be fermented by microorganism, safety and environmental issues of ammonia	10, 21, 70
ammonia recycle percolation (ARP)	effectively removes lignin, low inhibitor production	can handle only low solid loadings	11, 12, 20
ionic liquid	effectively dissolves cellulose, minimal environmental impacts	high costs of reagents, regeneration requirements, lack of knowledge regarding toxicity and causticity of reagent	18, 20, 71, 74, 75
inorganic salt	less corrosive, low enzyme demands	little understanding of salt residues effect on downstream processing	35, 38, 71
steam explosion	low enzyme dosages demand, low energy demand.	formation of degradation product that inhibits subsequent hydrolysis and fermentation	16, 17
enzymatic hydrolysis	environmentally friendly, low energy demand	inefficient without other pretreatment beforehand, slow process	70

USE OF INORGANIC SALTS FOR BIOMASS PRETREATMENT

One of the most novel pretreatment technologies that has attracted interest is the use of inorganic salts either as aqueous solutions in an acid-free environment or as catalysts in an acid pretreatment system.[22] The integration of inorganic salts has also been implemented with organosolv[23,24] and microwave irradiation.[25] This inorganic salt pretreatment method has been used to pretreat various types of lignocellulosic biomass, as shown in Table 5.[22−24,26−38] Some examples of inorganic salts are NaCl, KCl, $CaCl_2$, $MgCl_2$, $Fe_2(SO_4)_3$, $FeCl_2$, $FeSO_4$, and $FeCl_3$, which have been proven to increase the hydrolysis rate and yield of cellulose or hemicelluloses.[27,30,31] Among all of the inorganic salts, $FeCl_3$ has been proven to be the most effective inorganic salt and could be used to replace acid for biomass hydrolysis.[70] $FeCl_3$ has the capability of solubilizing hemicelluloses into monomeric and oligomeric sugars in liquid hydrolysate with large amounts of xylose while producing a cellulose-rich solid substrate that is highly useful in enzymatic hydrolysis for producing glucose at a later stage.[28,32] Therefore, inorganic salts possess potential for the production of both cellulosic bioethanol and value-added chemicals from hemicellulose-derived sugars.

Hemicellulosic Sugar Recoveries. Pretreatment of biomass is carried out mostly to produce cellulosic bioethanol via fermentation. However, only limited studies have shown a remarkable recovery of hemicellulosic sugars from the biomass. One of the pretreatments that has been extensively studied is dilute acid hydrolysis, where Fields and Wilson[76] found that temperatures between 100 and 150 °C were usually preferred in xylose production. To compare the performance of inorganic salts with dilute acid in the aforementioned temperature range, Marcotullio et al.[38] investigated the selective production of hemicellulose-derived carbohydrates using $FeCl_3$. At 120 °C and 120 min, $FeCl_3$ achieved a performance comparable to that of HCl, with a total monomeric xylose yield of 20.6 wt % of the initial wheat straw in the hydrolysate. Dilute acid hydrolysis of hemicelluloses and cellulose also produced higher amounts of fermentable sugar yields when the biomass was first impregnated with $FeSO_4$, again proving the positive effect of an inorganic salt in the pretreatment of lignocellulosic biomass.[39] Nevertheless, the optimal operating conditions reported for hemicellulosic sugar recovery by using inorganic salt pretreatment have been somewhat contradictory. According to Linares et al.,[33] the use of 0.26 mol/L of $FeCl_3$ at 153 °C and 30 min produced a maximum of 63.2% total hemicellulosic sugar recovery from olive tree biomass. Liu et al.[27] reported 89.0% xylose recovery when corn stover was pretreated with 0.1 mol/L of $FeCl_3$ under conditions almost similar (140 °C, 20 min) to those of Linares et al.[33] Thus, it can be concluded that the optimal operating conditions for inorganic salt pretreatment vary depending on the biomass and the inorganic salt used. Generally, more severe operating conditions are not suggested for sugar recovery from the biomass because the conditions may cause sugar degradation to furfurals and/or other degradation products. Nevertheless, it is important to achieve a balance between pretreatment severity and reducing sugar production by using eq 1.[29,77]

$$\mathrm{CS} = \log R - \mathrm{pH}$$

$$\mathrm{CS} = \log\left[t \times \exp\left\{\frac{(T_H - T_R)}{14.75}\right\}\right] - \mathrm{pH} \quad (1)$$

CS (unitless) is the combined severity parameter, R (unitless) is the severity factor, t (min) is the pretreatment time, T_H (°C) is the reaction temperature, T_R (100 °C) is the reference temperature, and pH is the acidity of the aqueous solution after the pretreatment process of biomass.

At low severity, hemicelluloses could not be degraded, whereas at high severity, the yield of xylose was minimal due to the degradation of xylose into inhibitors, although up to 100% of hemicellulose degradation was achieved.[29,71] As a case in point, a high $FeCl_3$ concentration >0.10 mol/L accelerated the dissolution of oligomeric xylose to monomeric xylose and then monomeric xylose to degradation products, but not the transformation from xylan into oligomeric xylose.[27] At a temperature of 180 °C, the degradation of xylose and xylotriose was increased by 6- and 49-fold, respectively, when the xylose monomer and oligomer mixture were pretreated with 0.8% of $FeCl_3$ compared with using pressurized hot water.[78] However,

the hemicellulose structure generally forms chemical bonds with cellulose and lignin that are more complicated than the pure monomer and oligomer interactions in the synthetic mixture.[32] Less severe parameters may be incapable of breaking down the hemicellulose structure, despite degrading the monomer and oligomer into inhibitors. Sun et al.[29] obtained the highest sugar content and a low inhibitor concentration at a moderate combined severity of 0.32, but when the combined severity was increased from 1.22 to 1.81, the concentration of total sugars dropped swiftly. The efficient solubilization of hemicellulose by using inorganic salts could be attributed to the reduced activation energy requirements for biomass hydrolysis.[39] Hence, in the case of pentose-oriented pretreatment, operating at mild temperatures and nearly atmospheric pressure could be a realistic option.[38]

Cellulosic Sugar Recoveries. In the context of glucose recovery, the removal of hemicelluloses and lignin fractions of the lignocellulosic biomass is essential during the pretreatment process. $FeSO_4$ was able to selectively hydrolyze up to 95.0% of the hemicelluloses into a liquid fraction, with the cellulose remaining in the biomass residue.[22] As a result of removing hemicellulose from the solid fraction, the subsequent enzymatic hydrolysis was enhanced by promoting cellulose exposure and enzymatic activity of cellulase.[22] Liu et al.[28] achieved a high enzymatic hydrolysis of 98.0% for the solid residue after undergoing a pretreatment process using 0.1 mol/L of $FeCl_3$, which contributed to 93.0% of the glucose recovery. In another notable study, Zhang et al.[37] achieved a satisfactory glucose yield of 61.7% via the enzymatic hydrolysis of pretreated cattail solid residue. Remarkably, the addition of 0.1 mol/L of $FeCl_3$ during the organosolv pretreatment also removed all hemicelluloses while conserving approximately 90% of the initial cellulose in the residue for subsequent enzymatic saccharification.[23]

The improvement of enzymatic digestibility and the subsequent increase in the cellulosic sugar recoveries from the biomass residue was attributed to the effects of the inorganic salt pretreatment on the biomass structure. Specifically, the smooth continuous surface of the cellulose was damaged for better enzyme access, and the amorphous hemicelluloses existing as irregular clumps were almost completely removed from the solid residue after the introduction of $Fe(NO_3)_3$ pretreatment, as shown in Figure 6.[29] Similar changes to the surface morphology of the biomass were also observed when NH_4Cl or $MgCl_2$ was used to pretreat *Miscanthus* straw, as shown in Figure 7.[31] According to Kang et al.,[31] both NH_4Cl and $MgCl_2$ caused damage to the compact structure of *Miscanthus* straw, but further studies to determine the cause of the different morphology were apparently inconclusive. An application of $FeCl_3$ also exhibited a disruption of the recalcitrant structures of the crystalline cellulose that are normally observed in the biomass. According to Liu et al.,[27] the exposure of the cell internal structure and an improved surface area and porosity made the material softer and more readily able to be digested. Hence, the enzymatic digestibility of the solid residue pretreated with 0.1 mol/L of $FeCl_3$ and 50% (w/w) ethanol was observed to reach as high as 89%.[23] Moreover, Yu et al.[36] managed to enhance the enzymatic digestibility to approximately 86.0% by applying $CuCl_2$ in the flow-through mode. The increase in the crystallinity index could possibly be explained by the fact that high amounts of hemicelluloses were removed without much alteration to the cellulosic structure due to the milder pretreatment conditions.[38] Thus, the crystalline structure of the cellulose core was exposed.

Production of Inhibitors. When lignocellulosic biomass is pretreated with inorganic salts, low generation of fermentation inhibitors might occur due to pentose dehydration.[23,24] Some studies have suggested that inorganic salts might generate fewer inhibitory coproducts compared with the acid hydrolysis pretreatments that are well-known to produce high amounts of toxic degradation compounds, primarily acetic acid, furfural, and 5-hydroxymethylfurfural (HMF).[20] For instance, low concentrations of furfural (0.011 g/L) and HMF (0.148 g/L) were achieved when organosolv was used together with $FeCl_3$.[23] The results were in agreement with the results of Kamireddy et al.,[26] who found that corn stover produced lower amounts of inhibitors when it was pretreated with $CuCl_2$ or $FeCl_3$ compared with H_2SO_4 using the same conditions (160 °C, 10 min). Specifically, $CuCl_2$ obtained approximately 0.42 g/L HMF and 1.50 g/L furfural, and $FeCl_3$ produced 0.52 g/L HMF and 1.19 g/L furfural. The HMF and furfural produced during H_2SO_4 hydrolysis were 1.10 and 2.40 g/L, respectively. Nonetheless, the production of inhibitors is heavily dependent on inorganic salt characteristics and pretreatment harshness. Increases in the $Fe(NO_3)_3$ concentration and pretreatment time were proven to intensify furfural production.[30] The trend of xylose monomer degradation was observed to accelerate significantly when the $FeCl_3$ concentration was increased from 0.1 to 0.4%.[27] When the concentration of $FeCl_3$ was increased from 100 to 200 mmol/L, Marcotullio et al.[38] observed a growth in acetic acid formation from 1.6 to 2.6 wt % during the pretreatment of wheat straw at 100 °C. Furthermore, temperature had a profound effect on

inhibitor production,[29,30] in which temperature >160 °C favored the conversion of xylose to furfural.[23] The increase in pretreatment temperature from 100 to 120 °C also caused the concentration of acetic acid to rise from 1.6 to 3.2 wt %, although the $FeCl_3$ concentration was maintained.[38]

Nonetheless, some previous studies were also done to test whether inorganic salts could be used for intentional conversion of sugars to furfural.[78−80] $FeCl_3$ was found to have a peculiar catalytic effect on xylose and xylotriose degradation, with the rate constants being 3- and 7-fold greater than those of dilute H_2SO_4 at the same pH.[78] Zhang et al.[80] noted that an isomerization of xylose for accelerating sugar dehydration and furfural production was promoted by metal chlorides at 185 °C and 100 min. The degradation rates of carbohydrates using inorganic salts were faster than those using dilute H_2SO_4 at the same pH.[78] Thus, this phenomenon suggests that the inorganic salts contributed to more efficient carbohydrate dehydration into the furfural compound, which is desirable in the context of using the furfural compound in the fields of chemical industry and liquid fuel production.

REACTION MECHANISM FOR INORGANIC SALT PRETREATMENT

Although some studies have reported the effects of inorganic salts on lignocellulosic biomass pretreatment, little is known about the reaction mechanism involved. To date, several mechanisms have been proposed to explain the behavior of inorganic salts. First, metal salts act as Lewis acid by dissolving in aqueous solvents to produce complex cations. A Lewis acid can be defined as a molecular body that serves as an electron pair acceptor that can react with a Lewis base to form a Lewis adduct.[71] Accordingly, coordinate covalent bonds with six water molecules as monodentate ligands are formed around the central metal cation. Leshkov and Davis[81] proposed the general expression of these metal ion ligand complexes as $[M(H_2O)_n]^{z+}$ (where M is the metal ion, z is the cation oxidation state, and n is the solvation number, typically ranging between 4 and 9). Hence, metal chlorides such as Al^{3+} and Fe^{3+} are presumed to follow this reaction mechanism to form six coordinate covalent bonds with water molecules, whereas Cu^{2+} achieves a stable complex ion by coordinating as a tetradentate ligand.[26,36]

The formation of the metal cations ultimately acting as Lewis acids would then aid in the cleavage of the glycosidic linkages. The coordinated water molecules from the hydrated cation play a pivotal role in xylose formation by participating as nucleophiles.[82,83] Similarly, the conversion of cellulose to glucose mediated by $ZnCl_2$ has also been examined to understand the mechanism of formation of inorganic salts as Lewis acids. First, the zinc was found to coordinate to the glycosidic oxygen to help break down the glycosidic linkage, resulting in the reduction of reaction energy. Then, in the second step of the mechanism, the coordinated water molecules of the metal cation complex participated as nucleophiles to yield D-glucose, as shown in Figure 8.[84] The same Lewis acid mechanism pathway can be observed for $AlCl_3$[83] and $FeCl_3$ salts.[85]

Second, metal ions can undergo hydrolysis when they are mixed with water to produce the H_3O^+ ion. The hydrolysis reactions are represented by eqs 2 and 3[86]

$$[M(H_2O)_6]^{2+} + H_2O \rightleftharpoons [M(H_2O)_5OH]^{+} + H_3O^{+} \quad (2)$$

$$[M(H_2O)_6]^{3+} + H_2O \rightleftharpoons [M(H_2O)_5OH]^{2+} + H_3O^{+} \quad (3)$$

where M is the metal ion.

Therefore, the aqueous metal salt solutions present a Brønsted acid character similar to that of HCl to depolymerize hemicelluloses into monosaccharides,[38,85] as shown in Figure 9.[26] Interestingly, $FeSO_4$ was proposed to facilitate the breakdown of the glycosidic linkage due to the adsorption of Fe^{2+} to the hydroxyl oxygen atoms and the oxygen of the cellulose pyran ring to form a carbohydrate complex.[22] In the dilute acid pretreatment, each proton pairs with one electron to

weaken the bond energy for easier bond rupture. Thus, Zhao et al.[22] suggested that metal ions could be playing the same role and may possibly be even more effective in assisting bond rupture because they have more positive charges to pair with more electrons.

However, the capability of metal salts to accept electrons and the different ionic radii of metal ions contribute to the various stabilities of the carbohydrate complexes.[32] The effect of the inorganic salts on the decomposition of hemicellulose seems to follow this particular order: transition metal chlorides ($FeCl_2$, $FeCl_3$, $CuCl_2$, $ZnCl_2$) > alkaline earth metal chlorides ($MgCl_2$, $CaCl_2$) > alkaline metal chlorides (KCl, NaCl). Transition metal ions such as Fe^{3+} and Fe^{2+} make good electron acceptors compared with the alkaline metal ions, namely K^+ and Na^+,[32] because transition metal ions are able to coordinate with the oxygen donor atoms of carbohydrates and their derivatives without losing the protons that make up the hydroxyl groups of the ligand.[36] Alkaline metal cations are weak electron acceptors and are unable to coordinate with carbohydrates, thus providing an explanation for the relatively low sugar recovery compared with the sugar recovery observed for transition and alkaline earth metals. Hence, the dissimilar arrangements of extranuclear electrons in the metal elements and the saccharide−metal cation intermediate complex between inorganic salts result in contrasting performance in hemicellulose hydrolysis.[36] According to Marcotullio et al.,[38] $FeCl_3$ produced filtrates with the pH lower than the HCl pretreatment (1.73−1.81 and 2.25−2.46, respectively). The results concur with those of Liu et al.,[27] where the pH after $FeCl_3$ pretreatment reached as low as 1.68. Pretreatment with other inorganic salts, namely NaCl, KCl, $CaCl_2$, and $MgCl_2$, produced filtrates with pH close to 7. When the pH approached neutral, hemicelluloses were mainly solubilized as oligomers, despite the lesser degradation of the hemicelluloses into toxic inhibitors.[22] With respect to the findings of Kang et al., the effect of a trivalent salt was reported to be greater than the effect of a di- or monovalent salt during biomass hydrolysis.[31] For example, $FeCl_3$ generated 71.6% enzymatic digestibility and almost 100% xylan removal from biomass, which were at least 26.7 and 31.8% higher than those of di- and monovalent metal salts, respectively.[31] Hence, Fe^{3+} apparently formed a stronger acid in aqueous solution than did other cations because of its pK_a (acid dissociation constant) value of 2.46, which was significantly lower than those of Al^{3+} (4.85), Cu^{2+} (6.50), Fe^{2+} (9.49), Mg^{2+} (11.4), Ca^{2+} (12.7), and Na^+ (14.1).[26]

PROSPECTS AND CHALLENGES OF THE INORGANIC SALT PRETREATMENT

Reduction in Operational Cost. Generally, inorganic salts have several advantages over the "current technology" of lignocellulosic biomass pretreatment, such as dilute acid hydrolysis. The dilute acid hydrolysis pretreatment method has been known to cause corrosion issues and requires expensive materials for equipment construction.[22] Corrosion occurs easily because inorganic acids such as H_2SO_4, which is commonly used in dilute acid hydrolysis, produces a strong electrolyte during the pretreatment process. An inorganic salt is less corrosive than an inorganic acid[35] because the former undergoes hydrolysis to release hydrogen ions as a weak electrolyte to provide a steadier reactive environment.[32] Moreover, Liu et al.[27] discovered that certain inorganic salts (NaCl, KCl, $MgCl_2$, $CaCl_2$) generated a hydrolysate with a pH that was more suitable for downstream fermentation. The need for high neutralization requirements may therefore be eliminated. However, stronger inorganic salts such as $FeCl_3$ and $Fe_2(SO_4)_3$ demonstrated higher xylose recovery, despite a low pH of ∼2.0 that may require additional

DOI: 10.1021/acs.jafc.5b01813
J. Agric. Food Chem. 2015, 63, 8349−8363

neutralization.[27] The inorganic salts can be recovered in the form of metal hydroxides via ultrafiltration, and the treatment with conjugated acids is able to convert the metal hydroxides back to metal chlorides, which could be recycled and reused in the later part of the biomass pretreatment process.[26]

Associated Limitations. However, some concerns arise regarding the use of inorganic salts for lignocellulosic biomass pretreatment. In particular, the effect of different inorganic salts on the cellulase hydrolysis is not well understood.[71] For instance, excessive Fe and Cl proportions left in the solid fraction might affect the microorganisms or enzymes during bioconversion at the later stage.[38] In a study to identify the inhibitory effects of metal ions, Fe^{3+} and Fe^{2+} were thought to target cellulose and cause undesirable impacts on cellulolysis.[87] Heavy metal elements such as chromium even caused the denaturing and inactivation of cellulase, which led to the unsatisfactory enzymatic hydrolysis of Cr^{3+}-pretreated sugar cane bagasse.[35] Kamireddy et al.[26] reported contradictory results, in which the enzymatic hydrolysis was improved due to the presence of metal complexes that formed lignin−metal complexes. This occurrence eliminated lignin inhibition and granted access to more cellulose sites. This result may explain the huge fluctuation of enzymatic hydrolysis yield, which ranged from 36.6 to 98.0%,[28,33] as well as other factors such as biomass characteristics, pretreatment severity, and enzymatic loadings. Kim et al.[23] argued that $FeCl_3$ could be removed via a washing/filtration process to a point where it was undetected. A novel approach has been developed to generate electricity while removing Fe^{2+} from the liquid fraction by using a fuel cell system.[88] Nevertheless, further investigations are required to analyze the mechanism of inorganic salt pretreatments and the effects on downstream applications caused by metal ions in the biomass residues and liquid hydrolysate.

Economic Feasibility. At present, the development of second-generation fuels and chemicals from lignocellulosic biomass via a biochemical route may present greater cost reduction potential than the thermochemical route because the latter involves extremely energy-intensive processes. The biotechnological conversion of biomass to second-generation products has not been intensively commercialized, although the subject has been studied for decades, mainly due to the uncertainty of the techno-economic feasibility of large-scale production.[46,66] Pretreatment of lignocellulosic biomass, which is necessary to achieve high sugar yields in biotechnological operation, has been singled out as the most expensive step, as it represents approximately 20% of the total cost of the whole process.[65] Among the available pretreatment technologies, those that employ chemicals currently offer better yields at lower costs, which are essential for economic viability. As part of an initiative of the U.S. Department of Agriculture, Eggeman and Elander performed a comprehensive economic analysis to evaluate various biomass pretreatment methods (dilute acid, hot water, ARP, AFEX, and lime).[89] They concluded that low-cost pretreatment reactors were often counterbalanced by the higher costs associated with catalysts/solvents and product recovery, which resulted in little difference in economic performance among the pretreatments investigated. To date, no literature is available regarding the economics of biomass pretreatment using inorganic salts. Generally, inorganic salts such as $FeCl_3$ and $AlCl_3$ are expensive.[90] Nonetheless, the application of inorganic salt has showed promising opportunities for reduced costs because of its less corrosive nature, which allow for the use of cheaper construction materials.[35] Furthermore, a recent study conducted by Liu et al.[27] proved that inorganic salts could be used directly as an aqueous solution for biomass pretreatment without an addition of acid, which reduced neutralization requirements. Additionally, Marcotullio et al.[38] successfully carried out pretreatment of biomass at mild temperatures and at approximately atmospheric pressure using an inorganic salt. Hence, scale-up issues concerning continuous biomass feeding at high pressures and material resistance could be avoided. Silva and Chandel[70] also stated that inorganic salts allowed simple process conditions that would reduce operational costs and energy consumption.

In conclusion, further research is necessary to investigate the physicochemical changes and mechanisms involved during not only inorganic salt pretreatment but also other lignocellulose pretreatment methods in general on a cellular scale. With an advancement in the field of analytical chemistry, better optimization studies could be performed to develop more cost-effective pretreatment technologies in the future.

[a]Quantifier ion.

MATERIALS AND METHODS

Chemicals and Instruments. Oil samples were purchased from local markets in Beijing in October−November 2013 and stored at normal atmospheric temperature. LC-MS grade acetonitrile and methanol were obtained from the Merck (Darmstadt, Germany), and HPLC grade formic acid (99.7%) and ammonium acetate (99.5%) were obtained from Dikma Technology Inc. (Richmond, VA, USA). Primary secondary amine (PSA), octadecyl (C_{18}), and graphitized carbon black (GCB) sorbents were obtained from Agela Technologies (Tianjin, China). Ultrapure water was produced using a Milli-Q RC apparatus (Millipore, Bedford, MA, USA).

The purities of most standard PFCs were ≥98%, with a minority of purity ≥92%. PFOS, PFOA, perfluoro-*n*-dodecanoic (PFDoA), perfluoruodecanesulfonic acid (PFDS), perfluoro-*n*-undecanoic acid (PFUdA), perfluoro-*n*-nonanoic acid (PFNA), perfluoro-*n*-hexanoic acid (PFHxA), perfluoro-*n*-hexadecanoic acid (PFHxDA), perfluoro-*n*-tetradecanoic acid (PFTeDA), perfluoro-*n*-tridecanoic acid (PFTrDA), perfluoro-*n*-heptanoic acid (PFHpA), perfluorohexanesulfonic acid (PFHxS), perfluoro-*n*-decanoic acid (PFDA), perfluoro-*n*-heptanesulfonate (PFHpS), perfluoro-*n*-butanoic acid (PFBA), perfluorooctanesulfonamide (PFOSA), sodium perfluoro-1-butanesulfonate (PFBuS), and trifluoromethanesulfonic acid (TFMSA), and isotopically labeled standards, namely, sodium perfluoro-1-[1,2,3,4-$^{13}C_4$]-octanesulfonate ($^{13}C_4$-PFOS), perfluoro-*n*-[1,2,3,4-$^{13}C_4$]-butanoic acid ($^{13}C_4$-PFBA), perfluoro-*n*-[1,2-$^{13}C_2$]-hexanoic acid ($^{13}C_2$-PFHxA), sodium perfluoro-1-hexane-[$^{18}O_2$]-sulfonate

DOI: 10.1021/acs.jafc.5b03903
J. Agric. Food Chem. 2015, 63, 8364−8371

($^{18}O_2$-PFHxS), and perfluoro-*n*-[1,2,3,4-$^{13}C_4$]-octanoic acid ($^{13}C_4$-PFOA), were purchased from Wellington Laboratory (Ontario, Canada). A cocktail solvent containing all 18 PFCs with respective concentrations of 10 μg/mL was prepared by diluting the standards with methanol. Working standard solvents for calibration were freshly prepared with methanol. Isotopic standard working solutions containing $^{13}C_4$-PFOA, $^{13}C_4$-PFOS, $^{13}C_4$-PFBA, $^{13}C_2$-PFHxA, and $^{18}O_2$-PFHxS with respective concentrations of 200 μg/mL were prepared by diluting the ISs with methanol. All solutions were stored at −20 °C.

HPLC Conditions. Chromatographic analyses were conducted using an Agilent series 1200 HPLC system (Agilent, Santa Clara, CA, USA) equipped with a binary pump, column oven, and autosampler. PFCs were separated using an XBridge C_{18} column (150 mm × 2.1 mm × 3.5 μm; Waters, Ireland) at 40 °C, with an injection volume of 5 μL. Mobile phases A (aqueous buffer with 5 mM ammonium acetate and 0.1% formic acid) and B (methanol with 5 mM ammonium acetate and 0.1% formic acid) were used, with a gradient elution of A:B = 40:60 (0−0.5 min), 20:80 (0.5−4 min), 5:95 (4−8 min, held 2 min), and 40:60 (10−13 min, held 7 min) at flow rates of 0.20 (0−0.5 min), 0.30 (0.5−8 min), 0.25 (8−10 min), and 0.20 (10−20 min) mL/min (see Table S1).

Tandem Mass Spectrometer Conditions. Mass spectrometric detection was performed using an API 5000 tandem quadrupole mass spectrometer (Applied Biosystems, Foster City, CA, USA) in negative electrospray ionization mode with multiple-reaction monitoring (MRM). Typical parameters of the electrospray ionization source were as follows: ion spray voltage, − 4500 V; curtain gas pressure (CUR), 35 psi; collision gas (CAD), 4 V; atomization air pressure (GS1), 60 psi; auxiliary gas pressure (GS2), 70 psi; dwell time, 200 ms; resolution Q1, low; resolution Q2, unit. The MRM transitions and collision energy (CE), declustering potential (DP), entrance potential (EP), and collision cell exit potential (CXP) used are summarized in Table 1. All system control, data acquisition, and data analysis were performed using AB Sciex Analyst 1.4.2 software (Applied Bioscience).

Sample Preparation. A homogenized edible oil sample (5 g) was weighed and placed into a 50 mL polypropylene (PP) centrifuge tube. Internal standards (ISs) containing $^{13}C_4$-PFOA, $^{13}C_4$-PFOS, $^{13}C_4$-PFBA, $^{13}C_2$-PFHxA, and $^{18}O_2$-PFHxS (100 μL, 20 μg/L) were spiked to the sample. After equilibrium for 20 min, acetonitrile (10 mL) was added and the tube was shaken vigorously for 3 min and centrifuged for 6 min (6000 rpm and 4 °C). The supernatant was transferred to a 50 mL bottle, and these procedures were performed twice. The combined supernatants were rotoevaporated (15 kPa, 110 rpm, and 30 °C), and the residues were reconstituted with cyclohexane:ethyl acetate (1:1 v/v, 10 mL) solvent for purification by an Accuprep MPS-GPC System (J2 Scientific, Columbia, MO, USA). This system comprised an autosampler, a solvent delivery module, an ultraviolet (UV) detector, a fraction collector, and a GPC column (400 mm × 30 mm) containing 50 g of polymer resin styrene−divinylbenzene Biobead SX-3 (Bio-Rad, Irvine, CA, USA). Ethyl acetate−cyclohexane (1:1, v/v) was used as the mobile phase at a flow rate of 4.7 mL/min. The fraction containing target compounds was collected over 20−60 min in a 250 mL tube. After GPC, the eluate was evaporated to dryness using a rotary evaporator (Heidolph, Schwabach, Germany) at 150 rpm and 30 °C. The residue was reconstituted in methanol (1 mL) and then transferred to a centrifuge tube containing

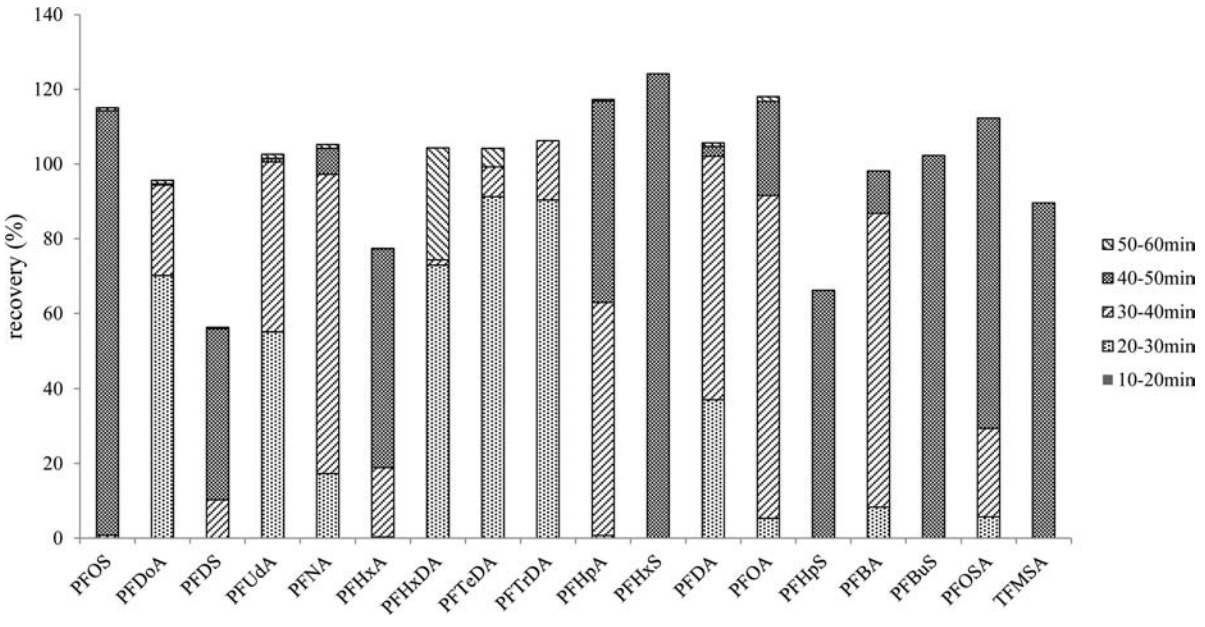

Figure 1. Recoveries of target PFCs at different time periods using GPC with cyclohexane:ethyl acetate (v/v, 1:1) as the mobile phase, at a flow rate of 4.7 mL/min.

DOI: 10.1021/acs.jafc.5b03903
J. Agric. Food Chem. 2015, 63, 8364−8371

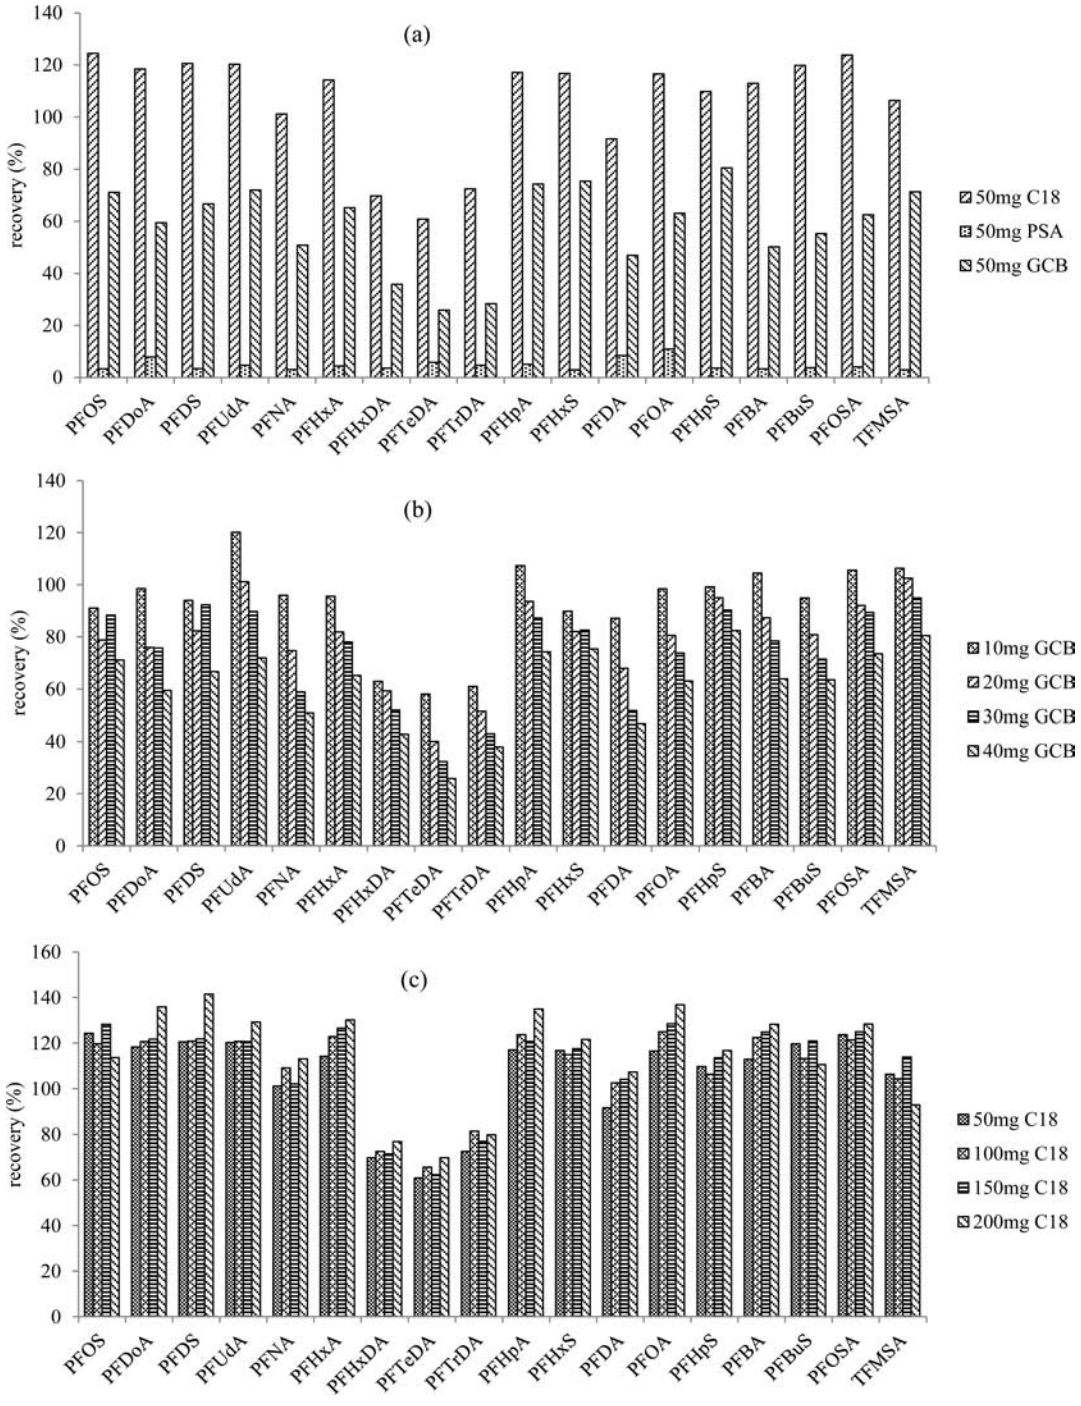

Figure 2. Recoveries of target PFCs spiked at 5 μg/kg in blank edible oil samples using (a) various DSPE sorbents, (b) different amounts of GCB, and (c) different amounts of C_{18}.

C_{18} (150 mg) and GCB (10 mg) as DSPE sorbents. The mixture was shaken for 2 min, centrifuged for 6 min (3000 rpm and 4 °C), and filtered through a 0.22 μm membrane prior to LC-MS/MS analysis.

Quality Assurance and Quality Control. The identification was based on retention time, the transitions, and their ion ratio by using SRMs of PFCs.[30,31] Concentrations of all target PFCs were quantified by the internal standard isotope method. Concentrations of PFOS, PFDS, and PFOSA in edible oil samples were quantified relative to $^{13}C_4$-PFOS; PFDoA, PFUdA, PFNA, PFHxDA, PFTeDA, PFTrDA, PFHpA, PFDA, and PFOA relative to $^{13}C_4$-PFOA; PFHxA relative to $^{13}C_2$-PFHxA; PFHxS, PFHpS, PFBuS, and TFMSA relative to $^{18}O_2$-PFHxS; and PFBA relative to $^{13}C_4$-PFBA. All equipment rinses were carried out with LC-MS grade methanol and pure water before use to avoid sample contamination. Procedural blanks were measured throughout the study, and low levels of PFOS, PFDS, PFHxDA, and PFTeDA (<0.004–0.027 μg/kg) were detected in the procedural blanks (see Table S2). During the sample analysis, a procedural blank and matrix spike were incorporated in the analytical procedures for every batch of 6 samples. The recoveries were evaluated using olive oil samples spiked with target compounds at three concentration levels including 0.1, 1, and 10 μg/kg. Trace amounts of PFOS, PFDS, PFUdA, PFHxDA, and PFTeDA in method blank were controlled at 0.03, 0.01, 0.004, 0.02, and 0.005 μg/kg with an acceptable RSD lower than 7% (n = 5) (see Figure S1), whereas other PFC background contamination was much lower. According to the regulation of ISO 25101 and EPA Method 573, a sample concentration that was 10-fold

higher than the blank value would be considered to be validated and reported.[32,33] All results were blank corrected by subtracting the mean concentrations of the corresponding compounds in the procedural blanks of the batch. The instrument detection limits (IDLs) were defined as the concentration at a peak with a signal/noise (S/N) ratio of 3. The method detection limits (MDLs) were set to be the mean of the concentration plus three times the standard deviation in the blank samples, in which PFOS, PFDS, PFUdA, PFHxDA, and PFTeDA were detected. The MDLs for the other compounds, which were not detected in blank samples, were set to be the instrumental minimum detectable amounts.[34,35]

RESULTS AND DISCUSSION

Optimization of Extraction Solvent. The most commonly used solvents (acetonitrile and methanol) have been applied with regard to the extraction of PFCs in lipid matrices.[16−18,23] The extraction efficiencies of PFCs from edible oils were evaluated for the solvents. As shown in Table 2, the recoveries of PFCs ranged from 74% to 129% by using acetonitrile as the extraction solvent. However, relatively low extraction efficiencies with high deviation were observed (23−166%) when methanol was used for extraction. Considering that PFCAs contain acidic groups, it is expected that strongly acidic extraction solvents may exhibit relatively high extraction efficiencies.[36−38] Therefore, we also assessed the recoveries of PFCs extracted with acetonitrile containing 0.1% formic acid. The recoveries of PFCs by acidified acetonitrile ranged from 103 to 347% (except for a PFHxDA, 51%), which were much higher than those of extraction by acetonitrile. A similar phenomenon was also observed by Young et al. and Yeung et al. in analysis of PFCs in blood and milk samples.[36,39] The possible reason could be that formic acid extraction would introduce more interference, resulting in high recoveries.[36,39] Therefore, acetonitrile was chosen as the extraction solvent in this study.

Optimization of GPC. GPC is an effective procedure for removing high-molecular-weight interference on the basis of different molecular size from the target compounds, and it is appropriate for both polar and nonpolar compounds. In this study, the purification effect and recoveries of all target PFCs using GPC were evaluated by collecting the eluate at different time periods, and calculated by olive oil matrix-matched standards with ISs used for correction. In the first 10 min, all target PFCs were not detected in the eluate. Only less than 0.3% of PFCs was obtained in the eluates collected between 10 and 20 min; meanwhile, most of the large molecule interference such as fat and proteins eluted out (Figure 1). In the time period between 20 and 50 min, large amounts of PFCs were eluted out with recoveries ranging from 56% to 124%. Finally, the remaining 30% of PFHxDA was collected in eluates between 50 and 60 min. Therefore, about 180 μL of eluates, which discarded most of the lipids and gave satisfactory recoveries, was collected between 20 and 60 min for analysis of PFCs in the present study.

Optimization of DSPE. After purification by GPC, small amounts of pigment and free fatty acids in some oil samples with similar molecular masses as target compounds coeluted with the analytes. DSPE was further conducted after GPC to solve this problem. The cleanup effects of various DSPE sorbents, i.e., PSA, GCB, and C_{18}, were evaluated in a blank olive oil matrix extract, respectively.

As shown in Figure 2a, the recoveries of all target PFCs were only 3−11% when 50 mg of PSA DSPE sorbent was used, suggesting strong electrostatic interactions between PSA and PFCs, although PSA is a common sorbent for removing various polar impurities.[40,41] In comparison, the recoveries of samples using GCB (50 mg) and C_{18} (50 mg) DSPE sorbents were improved to 26−75% and 61−124%, respectively. While relatively low recoveries were found for samples using GCB DSPE sorbents, the extract solution became much clearer in GCB treated samples compared with samples treated with C_{18} DSPE sorbents. The observation is consistent with the fact that GCB sorbents are known to remove hydrophobic interaction-based compounds such as pigments which the C_{18} and PSA cannot completely remove.[42−45]

The amount of DSPE sorbents was further optimized for GCB and C_{18} sorbents, respectively. As shown in Figure 2b, the recoveries of PFCs decreased with the increase of the amount of GCB sorbent from 10 to 50 mg, which probably originated from the absorption enhancing by adding increasing amount of

DOI: 10.1021/acs.jafc.5b03903
J. Agric. Food Chem. 2015, 63, 8364−8371

GCB sorbent with special configuration of hexatomic ring. Thus, only a small amount of GCB sorbent could be applied to the cleanup of oil extracts to get sufficient recoveries of target PFCs. As for C_{18} sorbents, the recoveries of all target PFCs were 61−124%, 66−125%, 62−129%, and 70−142% when 50, 100, 150, and 200 mg of C_{18} sorbent were used, respectively (Figure 2c), thus no obvious variation was found for recoveries of PFCs at different amounts of C_{18}. Although a large amount of C_{18} DSPE sorbents could be applied to the cleanup, the sorbents might not as good as GCB sorbent in removing the pigments in oil samples. As shown in Figure S3, the extract solution became clearer and shallower by using a mixture of GCB and C18 DSPE sorbent compared with that only using C18 DSPE sorbent. To remove most interference in the sample extracts, we used a combination of 150 mg of C_{18} and 10 mg of GCB as the DSPE sorbent in this study, which greatly helped to remove the pigments and other interference in the elutes after GPC fractionations.

Matrix Effects. Matrix effects were determined by comparing slopes of calibration curves (n = 6) constructed by equal concentrations of standard solution and isotopic internal PFCs in pure methanol and different blank matrix extracts (seven kinds of oil). As shown in Table 3, significant suppression matrix effects for all 18 target PFCs were observed in sunflower seed oil, sesame oil, and olive oil samples. The slopes of calibration curves in the matrix extracts relative to those in the solvent ranged from 0.63 to 0.99. Both suppression and enhancement matrix effects were observed for various PFC isomers in the four other types of plant oil, namely, blend oil, soybean oil, peanut oil, and corn oil. The slope ratios of calibration curves between matrix and blank samples ranged from 1.02 to 1.39 for most target PFCs in blend oil except for PFDS and PFHpA, whose slope ratios were 0.99 and 0.97 respectively. In soybean oil matrix samples, most PFCs were suppressed as their slope ratio ranged from 0.74 to 1.0, except for PFDoA (1.01), PFHxDA (1.09), and PFTrDA (1.26). The same phenomenon was also observed in peanut oil: most PFCs were suppressed as their slope ratio ranged from 0.53 to 0.93 except for PFTrDA (1.18). Similarly, most PFCs were also suppressed in corn oil matrix samples as their slope ratio ranged from 0.72 to 0.96 except for PFUdA (1.86), PFHxDA (1.24), and PFHpA (1.11). Therefore, calibration curves were built by spiking blank extracts of the corresponding matrix with ISs to reduce the influence of the matrix for the quantification of samples.

Method Validation. The compound-specific matrix spiking recoveries were determined by spiking high level (1 μg/kg and 10 μg/kg) and lower level (0.1 μg/kg and 0.01 μg/kg) near to those limits of quantitation of the olive oil samples (n = 3). All recoveries for the entire method are shown in Table S3. Mean recoveries of each compound ranged from 60% to 129% with the RSDs no more than 20% at each fortification level for each compound in olive oil, demonstrating good extraction efficiency of the method. As shown in Table 1, the IDLs ranged from 0.004 to 0.4 μg/kg for all target PFCs on the basis of the peak-to-peak S/N (>3). The MDLs of all target PFCs were in the range from 0.004 to 0.4 μg/kg. It should be noted that the MDLs were almost 10 times lower than that obtained for milk by Young et al.,[39] and the results indicate that the method had relatively high sensitivities to the determination of trace concentrations of PFCs in edible oils.

Application to Edible Oils. Six types of edible plant oils with different manufacturing processes and brands purchased

from supermarkets in Beijing were analyzed with the developed method in 2013. As shown in Table 4, the detected PFC concentrations in the oils ranged from below the MDL to 4.64 μg/kg with acceptable RSDs less than 25% (n = 3), and these values are lower than those detected in fish[6,46−48] and eggs[15] and similar to those in milk.[21,49] The PFOA detection rate was the highest (92%) among the 18 PFCs with concentrations from below the MDL to 0.50 μg/kg, and the possible reason could be its widespread use as a processing agent in industrial products; 1.8 μg/kg of PFOA was also detected by Schecter et al. in olive oil.[50] Second to PFOA, the detection rates of PFHxA, PFNA, and PFDA were 67%, 58%, and 50%, respectively. It should be noted that the highest concentration detected was 4.64 μg/kg of PFNA in blend oil, and this is probably due to PFNA not being globally regulated. A similar result was reported by Van et al. in polar-bear liver.[51] PFHpA and PFHpS were detected at rates of 25%, with concentrations below the MDL to 0.50 μg/kg in all six types of edible oils. In general, C_6−C_{10} PFCAs and PFSAs were found extensively in the edible oils, which is similar to the findings reported by Chung et al. for fatty food.[52]

δ^{15}N values of egg albumen as hens can roam and forage freely in pasture and soils, picking up insects, seeds, and grass. These dietary components also take on higher δ^{15}N values due to the ongoing deposition of poultry manure and the use of these nutrients for pasture growth over time. When analyzed for stable isotopes, these higher protein dietary inputs and nutrient transfers from poultry manure may confound eggs sampled from conventional free range farming systems with eggs from organic farming systems by increasing the overall δ^{15}N values, giving δ^{15}N values similar to those of organic eggs. However, when the δ^{15}N values of organic eggs are lower than expected, it is usually due to a nonorganic diet, unless the hen's diet is composed mainly of N-fixing plants (i.e., lucerne, alfalfa, or peas) or plants grown on green composts used to fertilize feed crops.

New Zealand organic eggs sampled in a previous study[7] showed a wide range of δ^{15}N values suggesting the likelihood of fraudulently labeled eggs. Several organic egg producers were found to be supplying organic eggs with much lower δ^{15}N values than other organic farms. Their isotope values were similar to those of eggs from conventional farming regimens, suggesting that the hens were not receiving an organic diet and/or they were not free ranging or had very limited outdoor access.

Organic farming practices worldwide aim to enhance biodiversity, biological cycles, and soil biological activity to achieve economically and ecologically sustainable systems. As yet there are no recognized scientific testing standards to distinguish free range and organic laid eggs (with outdoor access) from caged or barn laid eggs (indoor access only).[11] Evaluation frameworks by organic bodies use compliance and auditing systems to ensure eggs and commercial feed comply with regulations.[9] However, with the high price of compliance systems, some producers and distributors self-regulate and do not adopt any national certification standards, leaving the opportunity for misinterpretation of regulations or mislabeling to arise. Although past verification of egg products using stable isotopes[7] or carotenoid profiling[8,10] has been shown to identify cases that do not entirely fit within normal data sets, these can be more rigorously evaluated if they meet certain specifications. This screening potential holds great promise for the egg industry, especially if it can be shown to be applicable on an international, country, or regional scale.[8−10,12]

We investigate for the first time a large training set of poultry feed and corresponding egg albumen from barn, free range, and organic hens collected in The Netherlands in 2009 to understand isotopic feed variation, trophic transfer to egg albumen and provide guidelines for egg verification specific to Dutch farming systems. Data from a previous study of New Zealand eggs[7] and critical feed ingredients[4] are compared to new isotope data of eggs acquired in 2010 and 2014 to investigate if any significant feeding changes have occurred during this time. Finally, stable isotope egg profiles from barn, free range, and organic farmed egg albumen from both countries are compared to determine if isotope ranges used to verify and authenticate country-specific farming regimens are internationally applicable.

MATERIALS AND METHODS

Dutch Training Set. A training set of eggs and corresponding feed were collected from 49 Dutch layer hen farms in May 2009. Organic (24), free range (12), and barn (13) farms were selected with the help of the Dutch poultry and egg product board and the Dutch organic produce certification body SKAL. The selection was balanced with regard to sampling a range of geographical locations (north, east, south, west) and farm size per production system. Organic farm groups consisted of farm sizes of <5000, 5000−10000, and 10000−20000 hens; the conventional farm groups consisted of farm sizes of 10000−20000, 20000−50000, and >50000 hens. The differences in categories between organic and conventional productions reflect the particular farm populations; organic farms are usually smaller sized than conventional farms. Information on the breed and age of the laying hen flock, as well feed samples (type and supplier), was collected along with eggs. Fresh eggs and feed were stored at 4 °C until analysis.

New Zealand Test Set. Thirty different brands of (7 caged, 7 barn, 12 free range, and 4 organic) eggs were purchased from local poultry farmers and several grocery stores in Lower Hutt, New Zealand, in 2010. They were integrated with published results from 18 brands of eggs (5 caged, 3 barn, 6 free range, and 4 organic) sampled in 2008[7] to monitor changes within the egg industry during this time. A further 4 brands of organic eggs were sampled in 2014 to provide a final check on organic labeling practices. The eggs represented a range of producers from small cottage industries with 20−30 hens to large industrial operations with 20000−50000 hens.

Sample Preparation and Analyses. Nine eggs from each farm or egg brand were sampled for isotope analyses. Albumen from three eggs was separated from yolks, pooled in triplicate to avoid single anomalous results (i.e., if a particular hen was less free ranging than others), and freeze-dried. Egg albumen and feed samples were homogenized, ground, and weighed in duplicate. Approximately 1.5 mg of albumen and 3−10 mg of feed were transferred into 6 × 4 mm tin capsules. Carbon and nitrogen content and isotopic composition of Dutch and New Zealand egg albumen and feed samples were analyzed at the GNS Science Stable Isotope Laboratory, Lower Hutt, New Zealand, using a Europa Geo 20/20 (PDZ Europa Ltd. U.K.) isotope ratio mass spectrometer, interfaced to an ANCA-SL elemental analyzer (PDZ Europa Ltd. U.K.) in continuous flow mode (EA-IRMS). The carbon dioxide gas was resolved from nitrogen gas using gas chromatographic separation on a column at 65 °C and analyzed simultaneously for isotopic abundance as well as total organic carbon and nitrogen. International and working reference standards (NIST-N1, IAEA-CH_6, leucine, wheat flour, and beet sugar) and blanks were included during each run for calibration.

Isotopic ratios ($^{13}C/^{12}C$ and $^{15}N/^{14}N$) are expressed as isotopic deviations δ defined as

$$\delta\ (‰) = \frac{R_S - R_{Ref}}{R_{Ref}} \times 1000$$

where R_s is the isotopic ratio measured for the sample and R_{ref} that of the international standards. The δ^{13}C value is relative to the international Vienna Pee Dee Belemnite (VPDB) standard, and the δ^{15}N value is relative to atmospheric air. Results are expressed in δ (‰) versus the specific reference. Analytical precision (standard deviation, SD) of standards and samples are within ±0.1‰ for carbon and ±0.2‰ for nitrogen (1σ).

Statistical Analysis. Nitrogen and carbon isotopic data of Dutch and New Zealand eggs were subjected to multifactor analysis of variance (MANOVA; including country, farming regimen, farm, replicate analyses, year factors) to investigate the effects of two or more independent variables for significant effects on two or more metric dependents (in this case, nitrogen and carbon isotope ratio values). It allows a joint analysis of each dependent rather than requiring several univariate tests to be performed, thus avoiding multiple testing risks. Fisher's least significant difference (LSD) tests were carried out to determine significant differences among groups using XLSTAT 2014.3.02 (Addinsoft, Paris, France). A significance level of $p < 0.05$ was used throughout the study.

RESULTS

Dutch Poultry Feed. Feeds from 49 poultry farms were investigated using carbon and nitrogen isotopes. Values ranged

DOI: 10.1021/acs.jafc.5b01975
J. Agric. Food Chem. 2015, 63, 8372−8380

from −16.3 to −22.3‰ for δ^{13}C and from 1.5 to 4.0‰ for δ^{15}N. The 24 organic poultry feeds were completely distinguishable from 13 barn (conventional) feeds on the basis of δ^{15}N values (Figure 1). Organic poultry feeds had δ^{15}N values ranging between 2.8 and 4.0‰, whereas barn feeds (including omega-3-enriched feed) had δ^{15}N values ranging from 1.5 to 2.7‰. Free range feeds are expected to be similar to barn feeds as they are also grown conventionally. However, the free range feeds in this study had δ^{15}N values that spanned the range of both barn and organic farm feeds, ranging from 1.8 to 3.8‰, with 5 of 12 free range poultry feeds (FR2, FR 3, FR4, FR5, FR7) having δ^{15}N values >2.7‰. Poor isotopic separation between some free range and organic feeds suggested that some free range farms may be using organic feeds, even though their farming system is not labeled organic, and/or there was some other significant source of ^{15}N-enriched protein (plant, animal, or inorganic supplement) component included in feeds.[5,13−18]

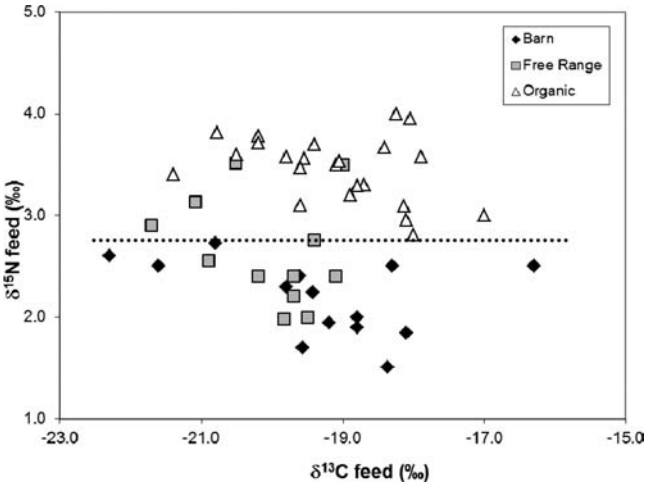

Figure 1. Distribution of carbon and nitrogen isotopes of feeds across different Dutch farming regimens.

Carbon isotopes gave an indication of the level of C_3 and C_4 feed components,[18] with more positive δ^{13}C values (< −18‰) suggesting a higher proportion of C_4 plants (i.e., maize) in the feed, where

$$\delta^{13}\text{C feed} = X(\delta^{13}\text{C } C_3 \text{ plants} + \text{additives}) + Y(\delta^{13}\text{C } C_4 \text{ plants})$$

$X + Y = 1$, δ^{13}C C_3 plants varies from −25 to −28‰, and δ^{13}C C_4 plants varies from −10 to −12‰. The feeds all showed a wide range of δ^{13}C values from −16.3 to −22.3‰, and using the above mixing model suggests feeds comprise between 20 and 70% C_4 plants (i.e., maize). Although barn feeds had the widest range of values of the three groups of feed, barn and free range feeds are farmed conventionally, suggesting the δ^{13}C isotopic feed differences are mostly determined by different combinations of feed. When feeds had more positive δ^{13}C values, it is likely that there was a higher C_4 plant component (i.e., maize) contained in the feed and a lower reliance on C_3 plant components (i.e., wheat and soy),[18,19] although the most positive feed δ^{13}C value was an omega-3-enriched barn feed at −16.3‰. Given that another omega-3-enriched feed had a δ^{13}C value of −20.2‰, the variation in δ^{13}C values is most likely due to a variation in C3 and C4 plant feed components than the dominance of specific omega-3-enriched additives. The δ^{13}C value of conventional and organic feeds will most likely vary seasonally as the use of C_3 and C_4 plants in poultry feed is usually indexed to the price of these feed components in any one year. Barn and free range eggs sell for lower prices than organic eggs and are likely to be produced usung the cheapest ingredients obtainable at the time while retaining a balanced diet.

Dutch Egg Albumen. The carbon and nitrogen isotope values of egg whites from 49 farms (13 barn, including 2 omega-3-enriched egg farms, 12 free range, and 24 organic farms) were investigated. Values ranged from −22.5 to −17.3‰ for δ^{13}C and from 3.4 to 6.2‰ for δ^{15}N (Figure 2; Table 1). Isotopic discrimination between organic and barn egg whites was feasible using δ^{15}N values, although discrimination between all three groups (organic, barn, and free range egg whites) or between free range and organic eggs was not clear (Table 1).

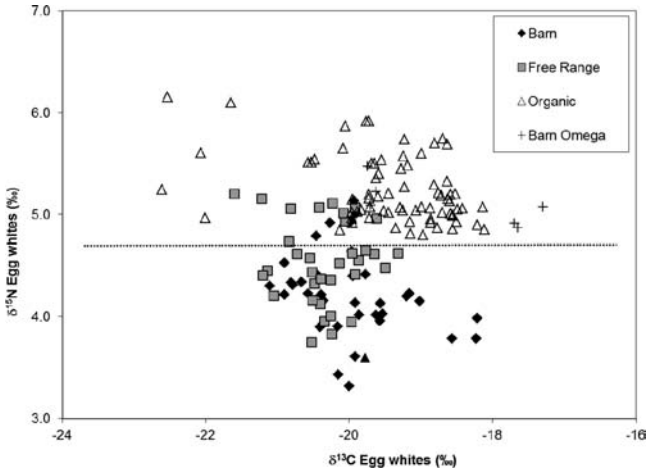

Figure 2. Distribution of carbon and nitrogen isotopes of egg whites across different Dutch farming regimens (including three composite samples measured from 49 different farms).

Table 1. Comparison of δ^{15}N and δ^{13}C Values of Dutch Poultry Feed and Egg Whites from 49 Farms Including 3 Farming Regimens (Mean ± SD)[a]

	farm type		
	barn (n = 13)	free range (n = 12)	organic (n = 24)
δ^{15}N feed	2.2 ± 0.4	2.7 ± 0.7	3.4 ± 0.4
δ^{13}C feed	−19.4 ± 1.6	−20.0 ± 1.0	−19.1 ± 1.1
δ^{15}N egg whites	4.3 ± 0.5^{B}	4.5 ± 0.4^{B}	5.3 ± 0.3^{A}
δ^{13}C egg whites	−19.8 ± 0.9^{A}	−20.3 ± 0.4^{B}	−19.5 ± 0.9^{A}

[a]Values with different letters in a row are significantly different (MANOVA, Fisher LSD test P < 0.05).

A histogram was constructed to demonstrate the frequency distribution of Dutch egg white δ^{15}N values from different farming regimens (Figure 3). All Dutch organic egg whites tested in this study had δ^{15}N values >4.8‰. This contrasted with barn and free range egg whites, for which the majority had δ^{15}N values below 4.8‰, apart from four barn and three free range farms, which had slightly higher values ranging between 4.8 and 5.2‰. Higher δ^{15}N values in egg whites from the three

DOI: 10.1021/acs.jafc.5b01975
J. Agric. Food Chem. 2015, 63, 8372−8380

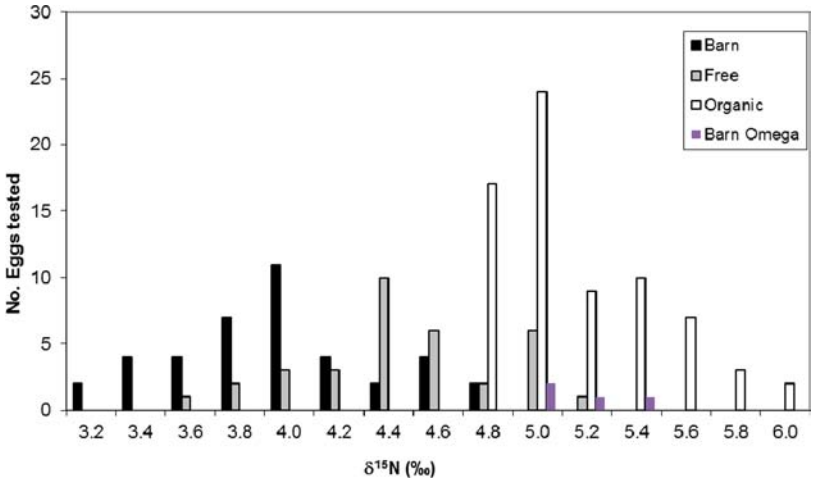

Figure 3. Frequency distribution of nitrogen isotopes of egg whites across different Dutch farming regimens.

free range farms may be due to use of organic feeds, increased ^{15}N from foraging in manured fields, or some other higher protein feed supplement not usually included in conventional feeds. The wide range of free range egg $\delta^{15}N$ values (from 3.6 to 5.2 ‰) may indicate poultry feed composition differences, but, on the basis of feedback from farmers, would more likely indicate that some hens are experiencing more opportunity to range freely than others.

Two barn farms supplemented their feed with omega-3 products to produce omega-3-enriched eggs. These egg whites also had a tight range of $\delta^{15}N$ values (ca. 5.1‰), although in this training set, only two farms (six composites of three eggs) were sampled. These values are above the usual range for barn-raised eggs possibly due to the added omega-3 supplement, which is usually derived from flaxseed or fish oil (increased ^{15}N from protein). However, their corresponding feeds do not indicate any noticeable enrichment in ^{15}N ($\delta^{15}N$ values of feeds for hens laying omega-3 eggs were 2.5 and 2.4‰, respectively) values expected with fish oil, so either there is a further omega-3 supplement included in their diet that was not tested or these hens are acquiring enriched dietary nitrogen from an unknown source, not typically used in conventional feeds.[7] The inclusion of barn omega-3 eggs in the data set (Table 1) skews the barn egg white $\delta^{15}N$ values from 4‰ (without omega-3 eggs) to 4.3‰ (with omega-3 eggs), also providing a higher SD than the other farming regimens.

It was not possible to discriminate between farming regimens on the basis of $\delta^{13}C$ values alone. Barn and free range egg whites had a narrower range of $\delta^{13}C$ values than organic egg whites. A large majority of organic egg whites had more positive $\delta^{13}C$ values than barn and free range egg whites due to a larger maize (C4) component in the feeds. Maize is a commonly grown organic crop and is frequently diverted into animal feeds. Two organic farms had egg whites with significantly more negative $\delta^{13}C$ values than all other samples. The hens that laid these eggs may have had a higher proportion of C3 components in their feed (i.e., wheat or soybeans) or significant access to fresh vegetation (grass or other green crops).[5,7]

Trophic effects (TE) or $\Delta^{15}N$ (egg−feed) values were examined across different Dutch farming regimens (Figures 4 and 5) to investigate differences between feeds and feeding regimens on the resultant egg products from each farm. Barn, free range, and organic raised eggs have an average TE of 2.1, 1.9, and 1.8‰, respectively (Table 1), consistent with strict

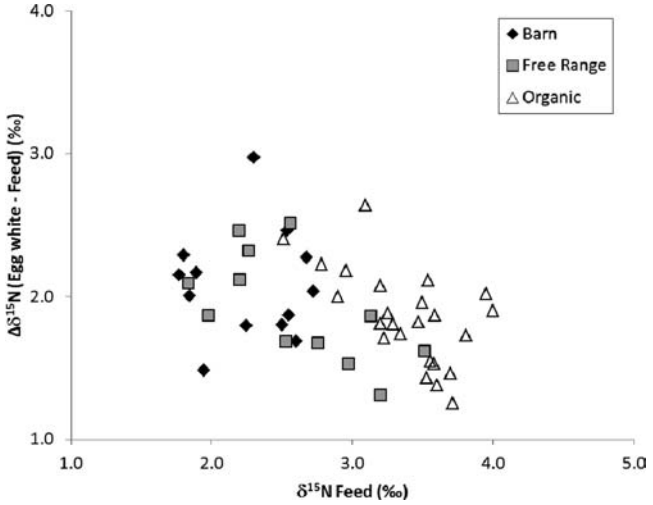

Figure 4. Trophic effect between Dutch poultry feeds and egg whites across different farming regimens.

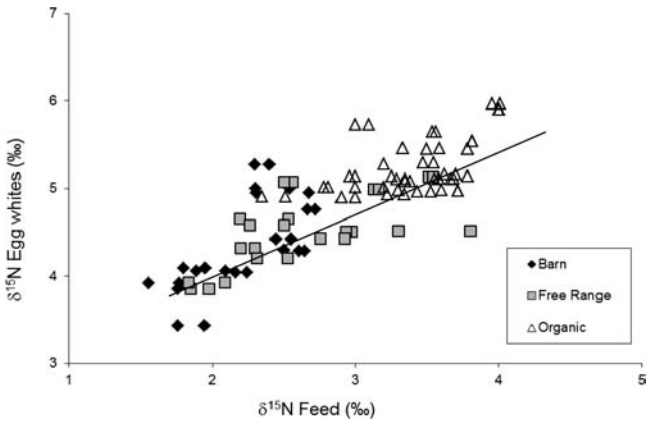

Figure 5. Isotopic correlation between $\delta^{15}N$ values feeding regimen (excluding omega-3 eggs) of Dutch egg whites where $y = 0.71x + 2.77$, $r^2 = 0.66$.

herbivores, which have TE values <2‰.[20−22] The slightly elevated TE in barn-raised eggs (from farm size E, Table 2) is due to the skew from the two barn omega-3 egg farms, which have TEs of 2.5 and 2.8‰, respectively. When the omega-3 egg data are removed, barn eggs have an average TE of 2.0‰.

av	1.6	1.9	1.9			1.8 (0.3)

[a]Farm size: A, <5000 hens; B, 5000−10000 hens; C, 10000−20000 hens; D, 20000−50000 hens; E >50000 hens. [b]Omega-3 eggs.

Higher TE values (TE > 2‰) in omega-3 eggs may be due to added dietary omega-3-derived protein (such as algae or flax oil), rather than foraged worms and insects, which would contribute only a fraction of the daily protein intake.

Elevated TE values occur in all farming regimens (Table 2), although 60% of farms producing barn-raised eggs had a TE > 2‰, whereas free range and organic farms only had 25 and 17%, respectively. Higher TE may be caused by cannibalism, which can occur more frequently in barn-raised poultry due to their enclosed habitat, lack of outside foraging opportunities, and the obvious lack of animal protein in their diet. In this study, cannibalism is a more plausible explanation for higher TEs than the inclusion of added animal protein in feed due to strict regulations around MBM in European (EU) animal feeds. A meat product ban in EU poultry feed was instigated in the mid-1990s due to the bovine spongiform encephalopathy (BSE) or "mad cow disease" crisis in Europe, when more than 200 people (mainly in the UK) died of Creutzfeldt−Jacob disease.

It is also interesting to note that the dietary feed difference of 1.2‰ between average δ^{15}N (organic-barn feed) is almost fully retained in the egg whites, as the average δ^{15}N (organic-barn egg whites) is 1.0‰. On the basis of these similarities between TEs, it is possible to confirm δ^{15}N values of egg whites from its corresponding feed (excluding omega-3 feeds, Figure 5).

New Zealand Eggs. Egg whites from four egg farming regimens studied in New Zealand in 2008[7] were compared with a new suite of eggs collected in New Zealand in 2010 and 2014 to monitor changes of egg white δ^{15}N values. The previous 2008 study suggested that some hens producing free range and organic eggs had diets that were no different from those of cage or barn hens on the basis of δ^{15}N values, and the consumer was being misled. These conclusions were based on the small (1.4‰) difference between δ^{15}N (average cage-average organic) egg values, although cage and organic egg farming regimens had much bigger SDs (Table 3).

An evaluation of eggs from 2010 showed the difference between mean cage and organic eggs δ^{15}N values had increased only slightly from 1.4‰ (in 2008) to 1.6‰ (in 2010, Table 3). However, a stepwise change in feed composition had occurred over this time, and each farming regimen was more enriched relative to their 2008 mean values (up to 1.2‰ for caged eggs, 1.7‰ for barn eggs, 0.1‰ for free range eggs, and 1.3‰ for organic eggs; Table 3; Figure 6), reflecting a significant dietary composition shift of New Zealand poultry feeds.

In 2008, New Zealand poultry feeds would have consisted of mostly plant-derived products (similar to The Netherlands), yet by 2010 this study shows the isotopic composition of New Zealand eggs from cage, barn, and organic hens had both higher δ^{15}N and δ^{13}C values than those from 2008 due to a trophic level increase from leguminous proteins[23] to animal protein[18] (where estimated δ^{15}N and δ^{13}C values of grass-fed beef are ca. 8‰[22] and ca. −20‰,[24] respectively). Feed manufacturers have confirmed that up to 15% MBM (from conventionally raised animal origin) has been included in New Zealand organic poultry feeds since 2010. The addition of MBM can be attributed to economic and practical changes affecting New Zealand poultry farmers and feed growers over this time. Anecdotally, cannibalism frequently occurs in flocks that suffer protein deficiency, and personal accounts from several New Zealand farmers indicated the need for poultry feed manufacturers to include more animal protein in feeds to counteract this unwanted trait in noncaged farming systems.

Table 3. Comparison of δ^{15}N and δ^{13}C Values of New Zealand Egg Whites According to Farming Regimen and Year Sampled in 2008 (Rogers, 2009), 2010, and 2014 (Mean ± SD)[a]

	farm type			
	cage	barn	free range	organic
δ^{15}N whites 2008	4.3 ± 1.5^{D}	4.4 ± 0.9^{E}	5.7 ± 1.2^{BC}	5.8 ± 1.7^{BC}
δ^{15}N whites 2010	5.5 ± 0.6^{C}	6.1 ± 0.8^{B}	5.8 ± 0.9^{BC}	7.1 ± 1.0^{A}
δ^{15}N whites 2014	NA	NA	NA	6.9 ± 1.2^{A}

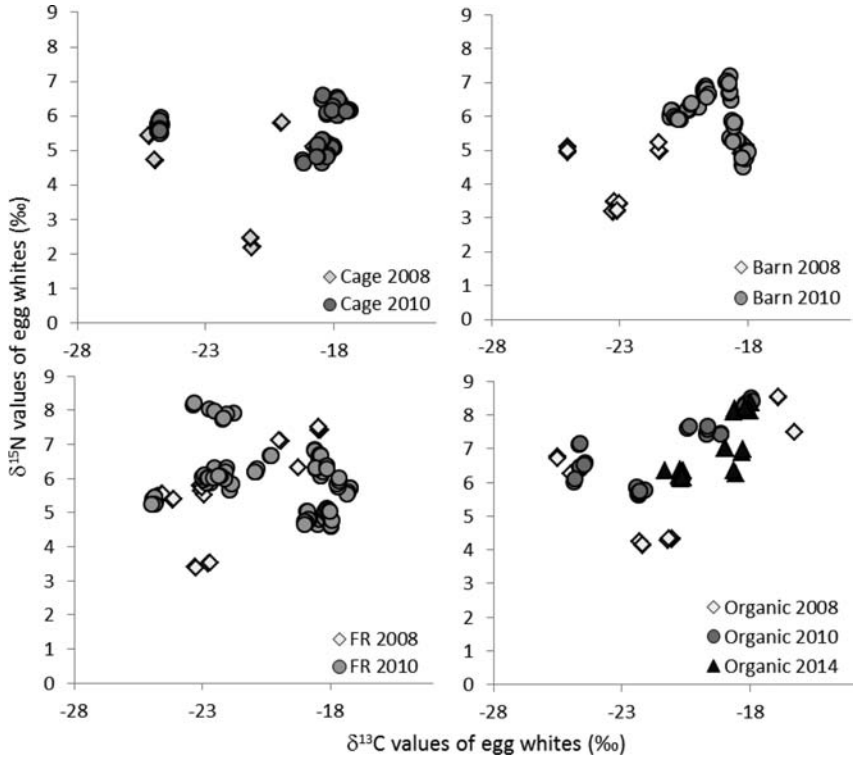

Figure 6. Comparison of carbon and nitrogen values of cage, barn, free range (FR), and organic egg whites from New Zealand sampled in 2008,[7] 2010, and 2014.

Table 4. Comparison of All δ^{15}N and δ^{13}C Values of New Zealand Egg Whites According to Farming Regimen Sampled from 2008 to 2014 (Rogers, 2009) (Mean ± SD)[a]

	farm type			
	cage	barn	free range	organic
all δ^{15}N whites 2008–2014	5.3^{C}	5.7^{B}	5.8^{B}	6.7^{A}
all δ^{13}C whites 2008–2014	-20.5^{A}	-19.8^{A}	-20.5^{A}	-20.7^{A}

[a]Values with different superscript letters in a row are significantly different (MANOVA, Fisher LSD test $P < 0.05$).

A further four brands of organic eggs were rechecked in 2014 to confirm the ^{15}N increase found in 2010. The δ^{15}N values of organic eggs sampled in 2014 were found to be very similar to those from 2010, although the δ^{13}C values were found to be slightly more positive (−19.6‰) than both the 2008 and 2010 values (−21.3 and −21.2‰ respectively). The variance (SD) of all δ^{13}C organic egg values decreased from 3.0 and 2.9‰ (in 2008 and 2010, $n = 4$ for each year) to 1.2‰ (in 2014, $n = 4$), suggesting a more uniform feed is now being used by egg producers. Nonetheless, as organic plant-only poultry feeds are significantly more expensive than conventional feed, the use of nonorganic dietary MBM included in New Zealand organic feeds conveniently lowers feed costs for organic poultry farmers, although the undisclosed use of MBM in organic poultry feed may be of interest to organic vegetarian egg consumers.

When the three New Zealand sampling events between 2008 and 2014 were taken into account (Table 4), key trends between farming regimens were observed for the δ^{15}N values but not for the δ^{13}C values. Organic eggs presented highest δ^{15}N values, followed by barn and free range eggs, which did not differ significantly, and finally cage eggs.

In 2008, organic egg whites had a δ^{15}N value of 5.8‰. and an SD of 1.7‰. Even though only four organic brands were sampled at this time, it was noted that two organic egg farms had considerably lower δ^{15}N values than the others. We compare these values with the average δ^{15}N value and SD of organic egg whites sampled in 2010 and 2014: 7.1‰ in 2010 and 6.9‰ in 2014, compared to 5.7‰ in 2008; and 1.0‰ in 2010 and 1.2‰ in 2014, compared to 1.7‰ in 2008. Organic eggs sampled in 2010 and 2014 have δ^{15}N values that are consistently higher and their SDs are smaller than 2008 values, confirming discrepancies in the integrity of some organic eggs sampled in 2008 and indicating potentially fraudulent labeling of organic eggs.

This observation was further supported by a MANOVA test of the organic egg white data (Table 3) with conventional (cage, barn, and free range) egg whites. The Fisher LSD test showed only small differences between δ^{15}N values of conventional (cage, barn, and free range) egg whites from 2008 compared to 2010. The Fisher LSD test results also showed a complete overlap between δ^{15}N values of organic and free range egg whites sampled in 2008 (Table 3).

Comparison between δ^{15}N Values of Dutch and New Zealand Egg Whites. A comparison between the δ^{13}C and δ^{15}N isotopic compositions of Dutch and New Zealand eggs under different farming systems was undertaken using MANOVA. Statistical analyses focused on the data per country.

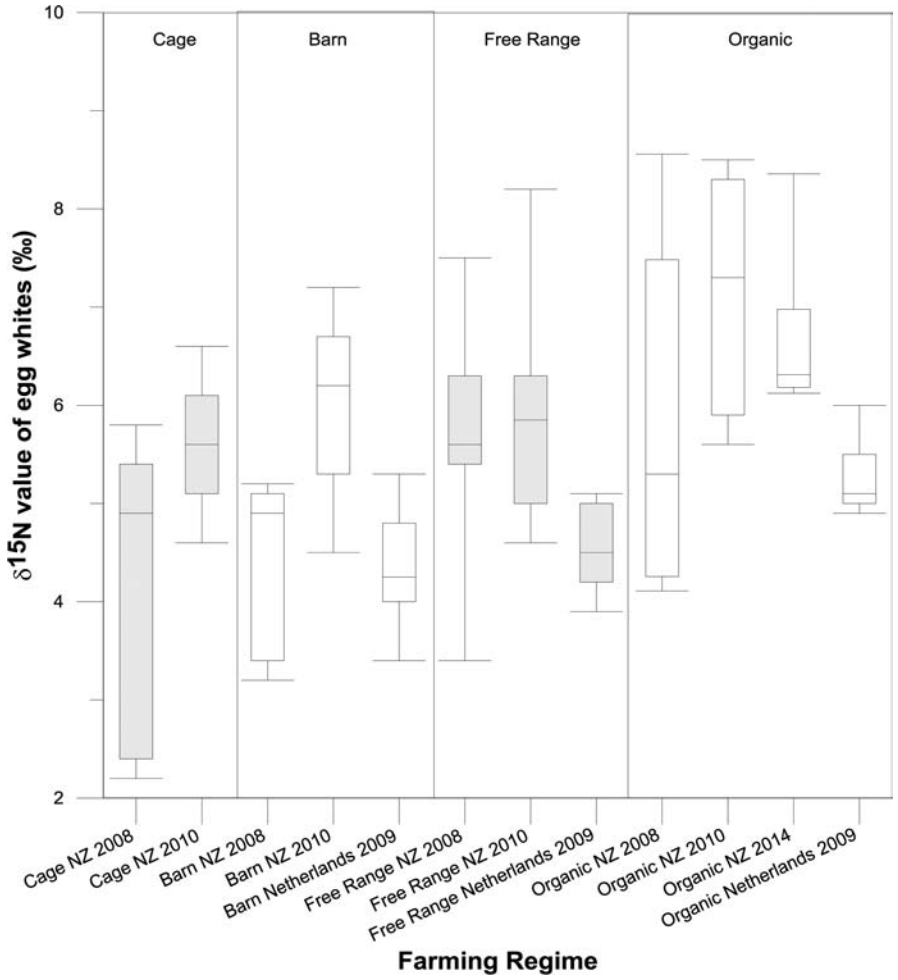

Figure 7. Box and whisker plot of δ^{15}N values of New Zealand and Dutch egg whites. The end whiskers represent the minimum and maximum range of δ^{15}N values, and the box indicates the first and third quartiles, with the whisker inside the box indicating the median value.

Table 5. *t* Test (Independence) and *p* Variance of Dutch Egg Whites Compared to New Zealand Egg Whites

	Dutch barn	Dutch free range	Dutch organic
barn 2008	0.12 (0.90)		
barn 2010	10.91 ($p < 0.001$)		
free range 2008		4.51 ($p < 0.001$)	
free range 2010		6.71 ($p < 0.001$)	
organic 2008			1.92 (0.06)
organic 2010			11.11 ($p < 0.001$)
organic 2014			11.05 ($p < 0.001$)

For the Dutch egg whites a significant difference in δ^{15}N values was observed between organic eggs and barn/free range eggs (Table 1). The δ^{13}C values of the Dutch egg whites showed significant differences between free range eggs and organic/barn eggs (Table 1).

A comparison between δ^{15}N values of egg whites from The Netherlands and New Zealand was made, including the three sets of New Zealand eggs sampled in 2008, 2010, and 2014 (Figure 7). Dutch egg whites (sampled in 2009) corresponded more closely with New Zealand egg whites sampled from 2008 (Figure 7; Table 5) rather than those from 2010 and 2014. Dutch barn and organic egg whites did not differ significantly from their respective New Zealand counterparts sampled in 2008 ($P < 0.05$), but Dutch free range egg whites differed significantly from the New Zealand free range egg whites sampled in 2008 ($P < 0.05$). New Zealand egg whites analyzed in 2010 and 2014 showed a significant increase in δ^{15}N values compared to New Zealand egg whites from 2008. Dutch eggs sampled in 2009 and New Zealand egg whites sampled in 2010 and 2014 demonstrated significant differences ($P < 0.05$) between their respective groups. The differences observed between the New Zealand egg whites (sampled in 2010 and 2014) and Dutch egg whites suggested that poultry feeds from these two countries comprised different components. From this study, δ^{15}N values showed that New Zealand hens from barn, free range, and organic farming systems in 2010 and from organic farming systems in 2014 were receiving a diet that was ^{15}N-enriched compared to hens from The Netherlands. Comparison of δ^{15}N values of New Zealand egg whites sampled in 2010 and 2014 to the initial data set of New

DOI: 10.1021/acs.jafc.5b01975
J. Agric. Food Chem. 2015, 63, 8372−8380

Zealand eggs sampled in 2008[7] also suggested an increase in δ^{15}N values of poultry feeds over this time, consistent with a higher level of dietary protein consumption by New Zealand hens. New Zealand egg whites analyzed in 2010 and 2014 also had more negative δ^{13}C values than the Dutch eggs (Tables 2 and 3), due to a preferential use of C3 plants (due to lower cost and a more suitable growing climate) in poultry feeds rather than the common usage of C4 plants (corn) in Dutch feeds.

The isotopic range and SD range of conventional and organic poultry egg whites sampled from the Dutch farms were smaller than corresponding isotopic and SD ranges of conventional and organic egg whites from New Zealand (2008−2014) and suggested that Dutch conventional and organic poultry feeds are more homogeneous, with similar dietary components, than those from New Zealand.

This study provides an isotopic comparison of δ^{15}N and δ^{13}C values of egg whites from The Netherlands and New Zealand to investigate whether it is possible to use isotopes as an internationally applicable verification and authentication tool for egg farming regimens across countries, continents, or hemispheres. Although the results showed there were significant isotopic differences in feeding regimens between Dutch egg whites and New Zealand egg whites sampled in 2010 and 2014, within a country or regional basis, δ^{15}N values of egg whites are shown to be a promising tool to authenticate and monitor truthfulness of labeling within markets using similar feeding systems and to identify instances when feeding practices may not be consistent with a specified farming regimen. This study found several key differences between New Zealand and Dutch eggs. New Zealand barn, free range, and organic eggs tend to be more enriched in ^{15}N and more depleted in ^{13}C than Dutch eggs, particularly for barn and organic farmed systems. Dutch egg whites had lower δ^{15}N values (<6‰) than New Zealand egg whites (up to 8.4‰) and confirmed an entirely plant based diet rather than one that contains supplementary MBM (commonly used in New Zealand but not permitted in EU countries).

Dutch organic eggs were easily discriminated from barn eggs using isotope analysis, but showed overlap with free range eggs. New Zealand free range and organic eggs showed considerable overlap for the eggs sampled in 2008, and some minor overlap was seen in 2010, but New Zealand organic eggs sampled in 2014 are generally distinguishable from cage, barn, and free range eggs sampled in 2010 and 2008. The shift in lowest New Zealand organic egg δ^{15}N value from 4.2‰ in 2008 to 6.1‰ in 2014 indicates that there was a significant change in feed composition. A smaller stepwise shift was also seen in cage, barn, and free range eggs between 2008 and 2010.

Feed manufacturers confirmed that up to 15% MBM can be found in organic feeds, although MBM is less frequently used in conventional feeds (personal communication). For countries that import eggs, a multi-isotope approach (C, S, H) might also be useful not only to verify farming regimen but also as a traceability tool, where country of origin labeling may an issue. Uptake of this research by verification authorities should be directed at auditing egg whites from organic and free range farms to assess and compare their ^{15}N variability and isotopic range. Given the range of egg white δ^{15}N values reported in this study, each farming regimen has a range of expected δ^{15}N values. On the basis of this study, Dutch organic egg whites presented a minimum δ^{15}N value of 4.8‰. New Zealand organic eggs derived from authentic organic feeds that incorporate up to 15% MBM, but are primarily from organic plant feeds, have a minimum δ^{15}N value of 6.0‰. In instances when this value is lower, further investigation into feeding practices of the specific farms is recommended.

MATERIALS AND METHODS

Chemicals, Media, Strains, and Plasmids. Alachlor (≥99.4%), metolachlor (≥98.0%), acetochlor (≥98.2%), pretilachlor (≥95.6%), and butachlor (≥99.6%) were purchased from Beijing Qinchengyixin Technolog Co., Ltd. (China). All other chemicals used in this study were of analytical grade and obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Inorganic salt medium (ISM, pH 7.0) contained (g/L) KH_2PO_4, 3.0; K_2HPO_4, 1.5; NH_4NO_3, 2.0; $MgSO_4{\cdot}7H_2O$, 0.1; $CaCl_2$, 0.01; and EDTA-2Na, 0.01. Luria−Bertani (LB, pH 7.0) medium contained (g/L) yeast extract, 5.0; tryptone, 10.0; and NaCl, 10.0. For solid medium, 20.0 g/L agar was added. Media were sterilized at 121 °C for 30 min. ISM and LB, which were purchased from Qingdao Hope Bio-Technology Co., Ltd., were used to isolate and culture the strains.

The primers and enzymes used for DNA amplification were purchased from the supplier (Shanghai SANGON Biological Engineering Co., Ltd., China). *E. coli* DH5α and *E. coli* BL21 (DE3) were used as hosts for constructing heterologous expression of protein. The plasmid pET-29a (+) was used for gene cloning and expression. *E. coli* strains were cultured in LB medium with the appropriate antibiotics at 37 °C.

Enrichment, Isolation, and Identification of Butachlor-Degrading Strain. The activated sludge used for the isolation of butachlor-degrading strain was obtained from Hangzhou Qingfeng Agro-chemical Co., Ltd., a pesticide manufacturer in Zhejiang province, China. Ten grams of activated sludge was added into a 250 mL Erlenmeyer flask containing 100 mL of ISM with 20 mg/L butachlor as the sole carbon source. The medium was incubated in a rotary shaker at 30 °C and 150 rpm for 7 days. Ten milliliters of the enrichment culture was transferred into another 100 mL of fresh ISM medium containing 50 mg/L butachlor and incubated at 30 °C and 150 rpm for another 7 days. The transfer was conducted weekly until the butachlor concentration gradually increased to 100 mg/L. Dilutions of the enrichment were spread onto LB agar plates containing 100 mg/L butachlor. After incubation at 30 °C for 7 days, the colonies were selected and purified to verify their degrading capabilities. The ability of isolates to degrade butachlor was determined by HPLC.

The isolate with high butachlor degradation rate was selected for further analysis. The physiological and biochemical characteristics of the strain were studied by using BioMerieux API 50 CHB/E reagent, which was purchased from Hangzhou Yidan Bio-Technology Co., Ltd. The 16S rRNA gene was amplified by PCR using the following primers: 27F (5′-AGAGTTTGATCCTGGCTCAG-3′) as the forward and 1492R (5′-TACGGTTACCTTGTTACGACTT-3′) as the reverse.[17] The PCR product was purified and cloned. The cloned insert was sequenced by Shanghai SANGON Biological Engineering Co., Ltd. The sequencing result was submitted to GenBank and compared with known 16S rRNA gene sequences in the GenBank database by BLAST.[18] Phylogenetic analysis was conducted using the neighbor-joining method with Clustal X[19] and MEGA 4.0 software.[20] Finally, this isolate was identified on the basis of its morphological and biochemical properties as well as phylogenetic analysis.

Biodegradation Experiment of Butachlor by Strain. The isolate was precultured in LB medium and incubated at 30 °C and 150 rpm for 24 h. Cells were harvested by centrifugation (5000*g*, 5 min) at 4 °C and washed twice with fresh ISM. Finally, cells were resuspended in fresh ISM at a concentration equivalent to an OD_{600} of 1.0. An inoculum (2%, v/v) was inoculated into a 250 mL Erlenmeyer flask containing 100 mL of ISM with 100 mg/L butachlor as the sole carbon source. Under optimal conditions (30 °C, pH 7.0), the medium was incubated on a rotary shaker at 150 rpm. Control experiment, which was incubated with inactivated cells, was carried out under the same condition. Each treatment was performed in three replicates. At 24 h intervals, sample aliquots were collected from the cultures. The residual concentration of butachlor was determined by HPLC, and the growth of cells was recorded by measuring the absorbance at 600 nm using a UV−vis spectrophotometer. The degradation rate was calculated according to the equation

$$\rho = \frac{X_0 - X_1}{X_0} \times 100\%$$

in which X_1 is the concentration of butachlor with cells inoculation and X_0 is the concentration of butachlor with inactivated cells inoculation.

Assays for Enzymatic Activitiy with Crude Cell Extracts. To prepare the crude cell extracts, strain hys-1 was cultured in LB medium with 100 mg/L butachlor to exponential phase in a rotary shaker at 30 °C and 150 rpm. The cells were harvested by centrifugation at 5000*g* for 10 min (Eppendorf centrifuge 5810R, Germany) at 4 °C. Precipitates were washed twice and resuspended with 20 mM sodium phosphate buffer solution (PBS, pH 7.0). Finally, the cell concentration was adjusted to the density of 5.0 (OD_{600}). The cells were then disrupted by sonication (Scientz-IID, Ningbo, China) for 30 min, and cell suspensions were centrifuged at 12000*g* for 20 min at 4 °C to remove cell debris. After being passed through a cellulose acetate filter with a pore size of 0.2 mm, the clear supernatants were referred to as crude cell extracts. Protein concentrations of the supernatants were determined by using the Bradford method[21] with bovine serum albumin (Sigma) as standard.

Enzyme activity of crude cell extracts against butachlor and other tested chloroacetamide herbicides was investigated in this study. Assays were performed by adding 0.5 mL of crude cell extracts to 4.5 mL of 50 mM PBS buffer (pH 7.0) containing 1.0 mM NADH and 0.5 mM substrates. The mixtures were incubated at 30 °C for 15 min. The reactions were terminated by adding 0.1 mL of 30% HNO_3. Then, the mixtures were centrifuged at 12000*g* for 15 min at 4 °C. The supernatants were then freeze-dried and redissolved in 1.0 mL of acetonitrile. The samples were filtered through a 0.22 μm Millipore membrane filter and subjected to HPLC analysis, which was used to determine the substrate concentration. One unit (U) of enzyme activity was defined as the amount of enzyme that consumed 1 μmol of substrate per minute. The specific activity (U/mg) of enzyme was defined as the consumption of 1 μmol of substrate per minute per milligram of protein. Control experiments without enzyme were also analyzed in parallel, and no spontaneous activity was detected. All experiments were repeated in triplicate.

Cloning, Expression, and Sequence Analysis of the Debutoxylase Gene. The Dbo gene was cloned from genomic DNA of strain hys-1 by PCR. Nucleotide sequences of esterase genes reported in the literature[22−24] were retrieved from NCBI (http://www.ncbi.nlm.nih.gov), and multiple pairs of primers were designed. Through final screening, the primer sequences 5′-ggtcgacatgatgaaattagcatct-3′ and 5′-gtcgacttaccaatctagttgctcc-3′ (the underlining indicates the *Sal*I restriction site) were designed for the PCR amplification. The PCR product was cloned into the *pEASY*-T1 (cloning vector). Plasmids were checked for inclusion of the desired insert and subsequently purified with a UNIQ-10 Gel Extraction Kit. The positive plasmid was subjected to DNA sequencing by SANGON Biotech Co. Ltd. (Shanghai, China). BlastN and BlastP were used for searching related nucleotide sequences and deducing amino acids (www.ncbi.nlm.nih.gov/Blast), respectively.

To remove the phosphate group to obtain a neutral sugar chain, pET-29a (+) undigested vector was digested with *Sal*I and was treated with calf intestinal alkaline phosphatase. Then the target fragment was cloned into the *Sal*I site by using the treated pET-29a (+) to obtain the plasmid pET-29a harboring genes and transformed into *E. coli* DH5α. The transformants were grown in LB medium at 37 °C until the OD_{600} of 0.5 and then spread onto LB selection plates supplemented with 100 mg/L kanamycin. The primer sequences, 5′-taatacgactcactataggg-3′ (T7 primer sequences) and 5′-gtcgacttaccaatctagttgctcc-3′ were used to identify the recombinant plasmid.

Then the positive plasmid was transformed into *E. coli* BL21 (DE3). The transformants were grown in LB medium at 37 °C until the OD_{600} of 0.5 and then were induced in the addition of isopropyl-β-D-thiogalactopyranoside (IPTG) to a final concentration of 1 mM. After growing for 18 h, cells were spread onto LB selection plates supplemented with 100 mg/L kanamycin and 200 mg/L butachlor. Kanamycin-resistant transformants were selected, and colonies with a clear transparent halo could be taken as the positive transformants. Such colonies were screened and further tested for the ability to degrade butachlor by HPLC analysis.

The phylogenetic analysis of Dbo with the closely related enzyme was performed using MEGA 4.0 software.[20] The Kimura two-parameter

DOI: 10.1021/acs.jafc.5b03326
J. Agric. Food Chem. 2015, 63, 8381−8390

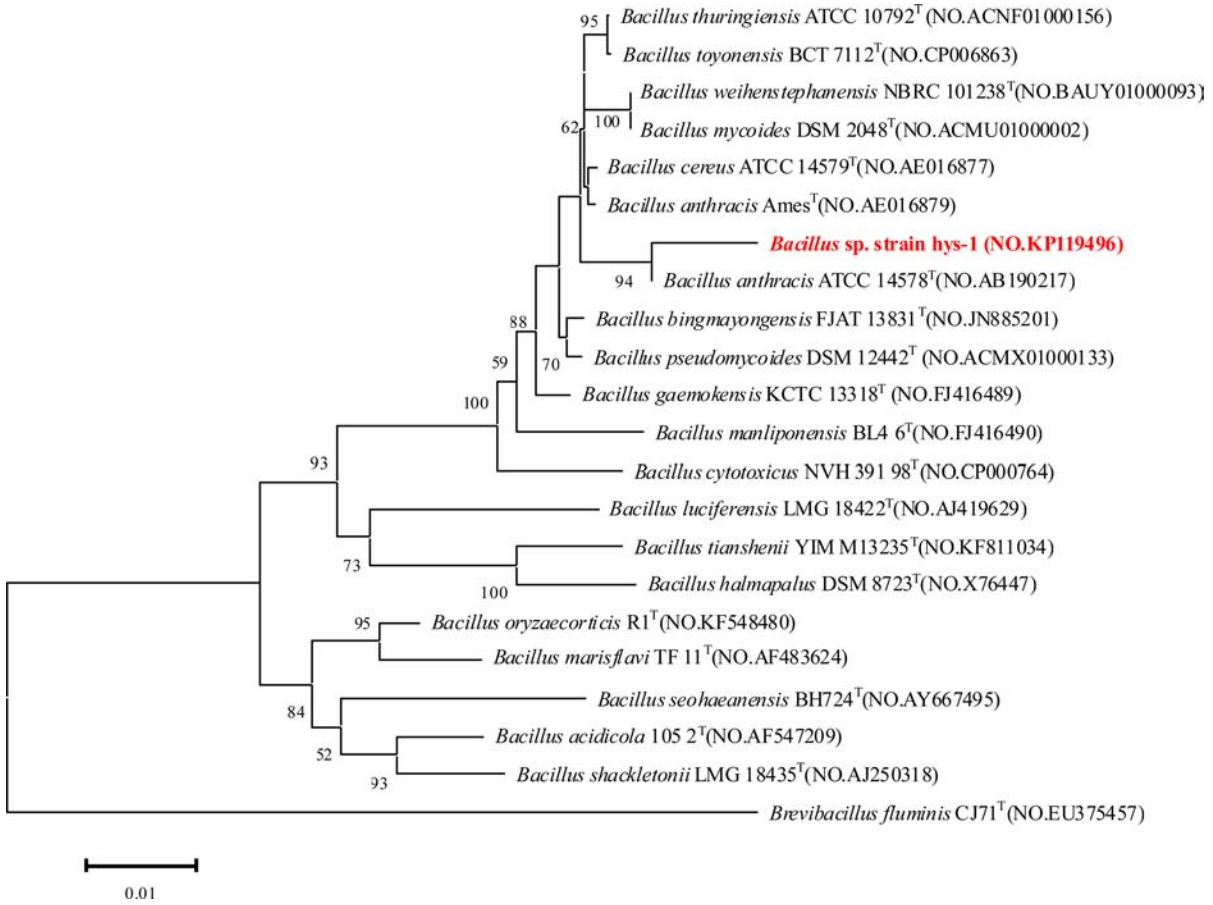

Figure 1. Neighbor-joining phylogenetic tree of 16S rRNA genes of strain hys-1. Bootstrap values above 50% (based on 1000 replications) are represented at the branch points. Bar = 0.01 substitution per nucleotide position.

distance model was used to calculate the distances, and the tree topology was evaluated on the basis of bootstrap analysis of 1000 times.

Purification and Characteristics of the Recombinant Enzymes. The positive recombinants of *E. coli* BL21 were incubated in LB medium containing 50 mg/L kanamycin until the OD_{600} of 0.5 at 37 °C and then were induced by adding 1 mM IPTG. After incubation at 18 °C for 10 h, the cells were harvested by centrifugation at 5000*g* for 10 min at 4 °C, washed twice, and resuspended with 50 mM PBS (pH 7.0). Cell suspensions were disrupted by sonication for 15 min and then centrifuged at 12000*g* for 15 min at 4 °C to remove the cell debris. The supernatant was used for further enzyme purification. The purification of the recombinant enzyme was carried out according to the methods described by Nguyen et al.[25] Protein concentrations were quantified via the Bradford method[21] using bovine serum albumin as the standard.

To determine the optimal pH, enzyme reaction was performed in various buffers at 30 °C. The following buffers were used: 20 mM citrate buffer (pH 3.0, 4.0, 5.0, 6.0); 20 mM PBS (pH 6.0, 6.5, 7.0, 7.5, 8.0, 8.5); and 0.1 M sodium bicarbonate buffer (pH 8.5, 9.0, 9.5, 10.0). To determine optimal temperature, enzyme reaction was conducted in 20 mM PBS (pH 7.0) at various temperatures from 20 to 50 °C. The effects of different metal ions on the enzymatic activity were determined by incubating 1 mM of various metal salts in 20 mM PBS buffer (pH 7.0) at 30 °C. PBS without additional metal salts was used as the control (100%). Enzyme activity was measured using the enzyme assay conditions described above, and butachlor was used as the substrate for the enzyme reaction assay. Three replicates were used for each sample.

Analytical Methods. To analyze butachlor and other chloroacetamide herbicides, the culture sample was centrifuged at 12000*g* for 20 min at room temperature. Then, the supernatants were freeze-dried, redissolved in 1.0 mL of acetonitrile, and filtered through a 0.22 μm Millipore membrane filter. Residual chloroacetamide herbicides were analyzed with HPLC (Waters e2695) equipped with a UV−vis detector (Waters 2489) and an XBridge C_{18} column (inner diameter, 4.6 mm; length, 25 cm; particle size, 5.0 μm). The temperature of the separation column was 35 °C. Mobile phase was acetonitrile/water (80:20, v/v), and the flow rate was 0.8 mL/min. The injection volume was 20 μL, and the column elution was monitored by measuring at 230 and 215 nm. The concentration was calculated on the basis of a peak area from calibration curve.

The reaction products were analyzed by LC-MS. The analyses were performed by a time-of-flight mass spectrometry (Waters Xevo G2 Q-TOF, USA) equipped with an electrospray ionization (ESI). The positive mode was set at a source temperature of 110 °C, a desolvation temperature of 450 °C, and a capillary voltage of 2.5 kV. The cone gas flow and desolvation gas flow were 50 and 1000 L/h, respectively. Nitrogen was used as the desolvation gas, and argon was used as the collision gas. The compounds were ionized in the positive electrospray ionization (ESI^+) ion source and were detected in high-resolution mode. Full scan signals were recorded from m/z 50 to 600. Finally, the data were collected and analyzed by Masslynx V 4.1 (Waters, USA). Structures of products were analyzed with formula weight matching software (*MassFragment*).

GenBank Accession Numbers. The GenBank accession numbers of the Dbo gene and the 16S rRNA gene sequence of strain hys-1 were KT121406 and KP119496, respectively.

RESULTS AND DISCUSSION

Isolation and Identification of hys-1. After 2 months of enrichment and screening, a single strain was isolated from the active sludge and designated hys-1. The strain was selected on the basis of its ability to use butachlor as the sole carbon source.

DOI: 10.1021/acs.jafc.5b03326
J. Agric. Food Chem. 2015, 63, 8381−8390

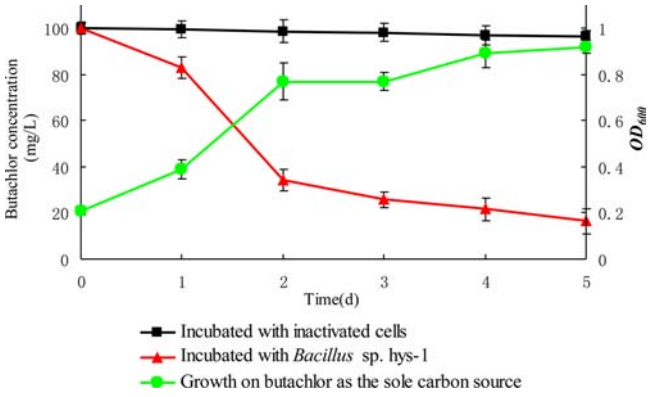

Figure 2. Utilization of butachlor during growth of hys-1. Error bars represent the standard error of three replicates.

Strain hys-1 degraded approximately 84% of butachlor within 5 days and >90% after 7 days if used at concentration of 100 mg/L in ISM. Strain hys-1 was an aerobic and Gram-positive bacterium. The electron micrograph of hys-1 cells showed that the bacterium was rod shaped (4.4−4.5 μm × 1.2−1.3 μm), spore-bearing, and atrichosis. Colonies grown on LB agar plates at 30 °C for 36 h were white, circular, and 2.0−3.0 mm in diameter. Strain hys-1 was able to grow within a temperature range of 25−40 °C, the optimal temperature being 30−37 °C. Growth occurred at pH 6.0−9.0, with optimal growth at pH 7.0−8.0. Growth of strain hys-1 was observed at NaCl concentrations between 5 and 12%, with an optimum of 8%. BioMerieux API 50 CHB/E reagent was used to determine the activities of constitutive enzymes and other physiological properties according to the manufacturer's instructions (data not shown). The 16S rRNA gene (1458) of strain hys-1 was sequenced and deposited in the GenBank database with the accession no. KP119496. Analysis of 16S rRNA gene sequences revealed the

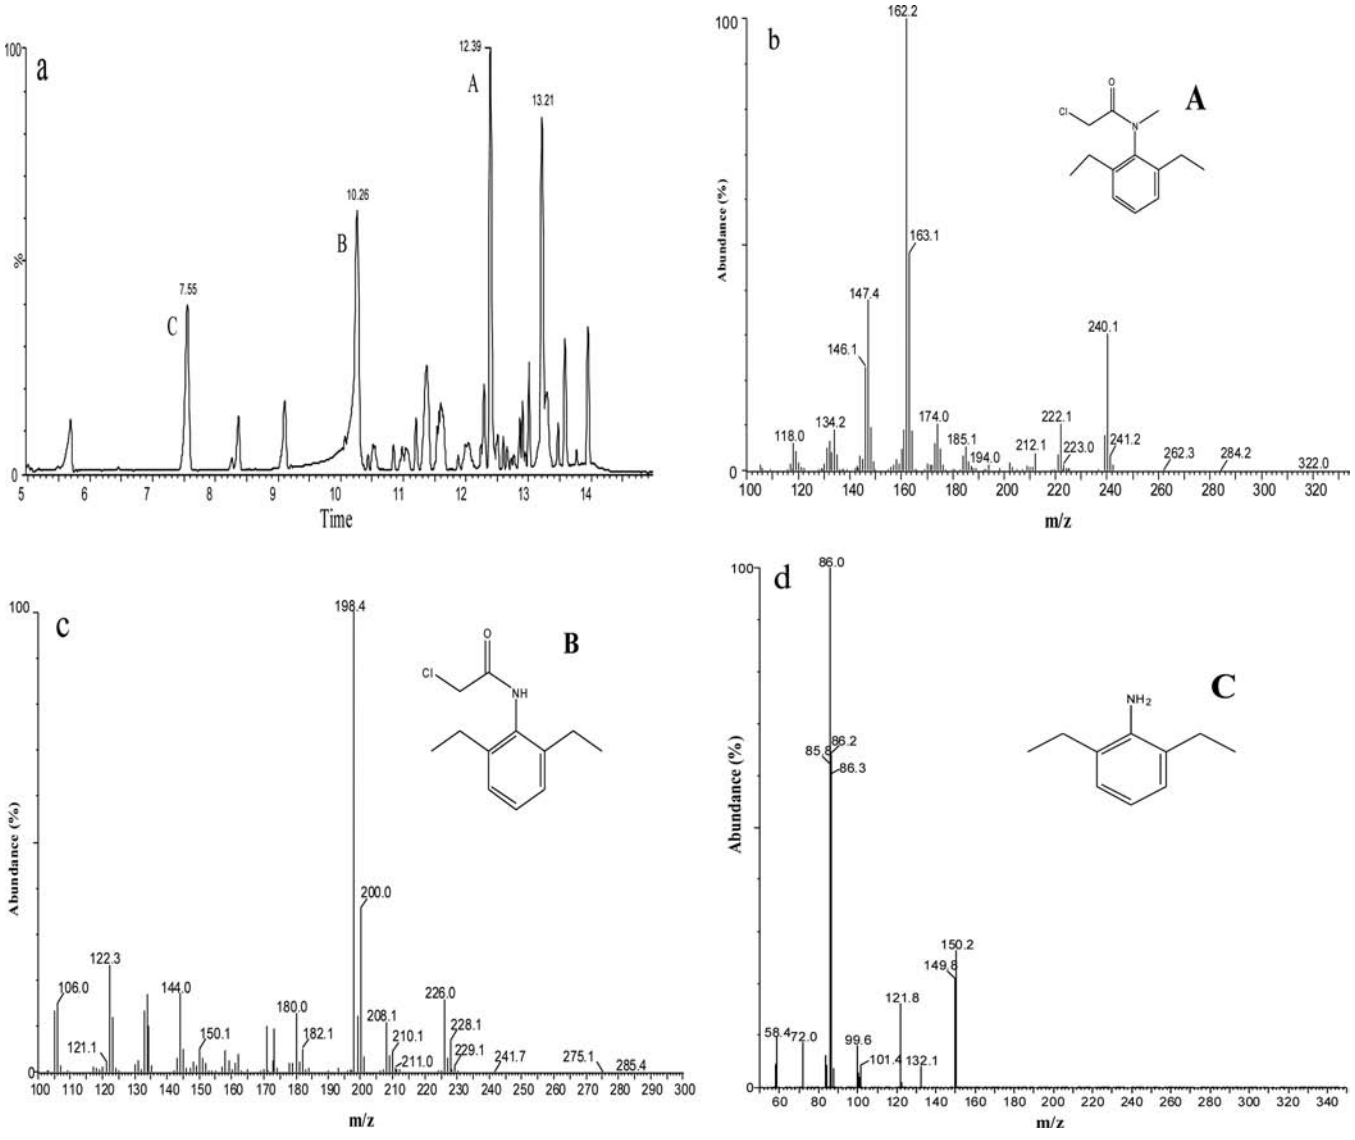

Figure 3. Mass spectrum analysis of the butachlor intermediates degraded by hys-1: (a) Total ion chromatogram (TIC) for intermediates A, B, and C. The retention time of each compounds was 12.39, 10.26, and 7.55 min, respectively. (b−d) The mass spectrum of characteristic ions for compounds A, B, and C. They were identified as 2-chloro-*N*-(2,6-diethylphenyl)-*N*-methylacetamide, 2-chloro-*N*-(2,6-diethylphenyl)-acetamide, and 2,6-diethylaniline, respectively.

highest sequence identity (99%) with the 16S rRNA gene of *Bacillus anthracis* ATCC 14578^T (no. AB190217), and phylogenetic analysis showed that the two strains share the closest relationship (Figure 1). Thus, on the basis of the results of phenotypic and physiological characteristics and genotypic and phylogenetic analyses, strain hys-1 was considered as a *Bacillus* sp.

So far, various studies showed that many bacteria were able to degrade butachlor, including *Sphingomonas* sp.,[26] *Paracoccus* sp.,[13] *Pseudomonas* sp.,[27] *Catellibacterium caeni* sp.,[9] *Rhodococcus*

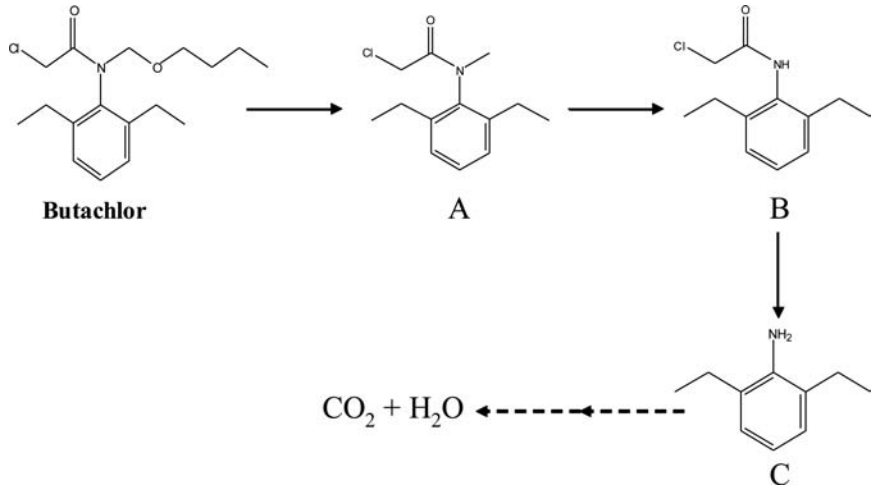

Figure 4. Complete biodegradation pathway of butachlor by strain hys-1.

Table 2. Specific Activities of Crude Cell Extracts[a]

substrate	specific activity (μmol min^{-1} mg^{-1})
alachlor	38.46 ± 1.27*
acetochlor	32.81 ± 1.04*
butachlor	27.35 ± 1.31*
metolachlor	−
pretilachlor	−

[a]Data in the table are shown as means ± SE. −, no activity was detected. The asterisk (*) indicates significant difference ($p < 0.05$, ANOVA test).

sp.,[15] *Acinetobacter* sp.,[28] *Mycobacterium* sp.,[14] and *Sphingobium* sp.[14,29] Members of *Bacillus* are widespread in nature and play an important role in the ecosystem. Tuo et al.[30] isolated a *Bacillus* sp. Q2 that could degrade 500 mg/L quinoline completely within 30 h under optimal conditions. Li et al.[31] obtained a *Bacillus* sp. GZB capable of effectively degrading bisphenol A (BPA) under anaerobic and aerobic conditions. Lu et al.[32] found that *Bacillus cereus* JP12 could use decabromodiphenyl ether (BDE-209) as the sole carbon and energy source for growth in mineral salt medium. Moreover, Zu et al.[33] isolated a *Bacillus* sp. GZT that had an excellent ability to simultaneously debrominate and mineralize 2,4,6-tribromophenol (TBP). All of this suggested that the *Bacillus* sp. strains could have a great potential application value in biodegradation of organic contaminants and remediation of water and soil. This study obtained a *Bacillus* sp. hys-1 from activated sludge, which was capable of degrading butachlor as the sole carbon, nitrogen, and energy source. The results expanded the application range of *Bacillus* sp. in the field of environmental pollution remediation.

Biodegradation Experiment of Butachlor by Strain hys-1. The butachlor degradation and growth patterns of strain hys-1 were studied in ISM with butachlor as the sole carbon source. Under optimal conditions (temperature, 30 °C; pH 7.0; butachlor concentration, 100 mg/L), hys-1 degraded butachlor rapidly, with 83.6% of the initial dose degraded within 5 days (Figure 2). At the beginning of the incubation period, strain hys-1 did not adapt to the environment quickly and the most efficient degradation was obtained the next day. No significant change of butachlor concentration was observed in the cultures incubated with inactivated cells. Butachlor degradation was associated with a concomitant increase in cell density from 0.21 to 0.92 (OD_{600}). These results indicated that butachlor served as the carbon source for strain hys-1 growth.

Identification of Metabolites and Butachlor Biodegradation Pathway. To elucidate the butachlor biodegradation pathway and the interaction with cell metabolism, the intermediates of butachlor degradation by strain hys-1 were identified with HPLC-ESI-MS/MS. Three metabolites, designated metabolites A, B, and C, were obtained with different retention times (Figure 3). For the first 3 days of butachlor degradation, metabolites A and B were determined with high concentration levels by HPLC. In positive-ion chemical ionization, metabolite A showed a protonated molecular ion peak at m/z 240.1 $[M + H]^+$ and characteristic fragment ion peaks at m/z 174.0, 162.2, 147.4, and 134.2. With the formula weight matching software (*MassFragment*), structures of characteristic fragments were matched and are shown in Table 1. On the basis of these results, product A was identified as 2-chloro-*N*-(2,6-diethylphenyl)-*N*-methylacetamide. The positive-ion chemical ionization of metabolite B showed a molecular ion peak m/z 226.0 $[M + H]^+$, and its characteristic fragment ion peaks were m/z 208.1, 198.4, 180.0, and 122.3. Furthermore, the matching results of characteristic fragments are shown in Table 1. According to these data, product B was identified as 2-chloro-*N*-(2,6-diethylphenyl)acetamide. In addition, the concentration of metabolite C increased after incubation for 5 days, and the mass spectrum gave a base peak at m/z 150.2 $[M + H]^+$ with the characteristic fragment ion peaks at m/z 132.1, 121.8, and 105.1. On the basis of these data, product C was identified as 2,6-diethylaniline. It should be noted that although the sample gave a peak at RT = 13.21 min, its molecular ion peak showed a higher molecular weight compared with butachlor, and its characteristic fragment ion peaks could not be detected by MS/MS. Therefore, we inferred it was an impurity peak. Moreover, these metabolites (A, B, and C) could hardly be detected after butachlor degradation for 10 days. Thus, we deduced that butachlor was completely degraded by strain hys-1.

Until now, few studies[9,13,14,34] have reported the possible aerobic and anaerobic degradation pathways of butachlor by microorganisms. In general, the major methods for butachlor degradation include dechlorination, hydroxylation, dehydrogenation, debutoxylation, debutoxymethylation, N-dealkylation, O-dealkylation, cyclization, etc.[35−37] Liu et al.[15] reported that butachlor was only hydrolyzed by strain B1 through N-dealkylation, which resulted in the production of butoxymetha-

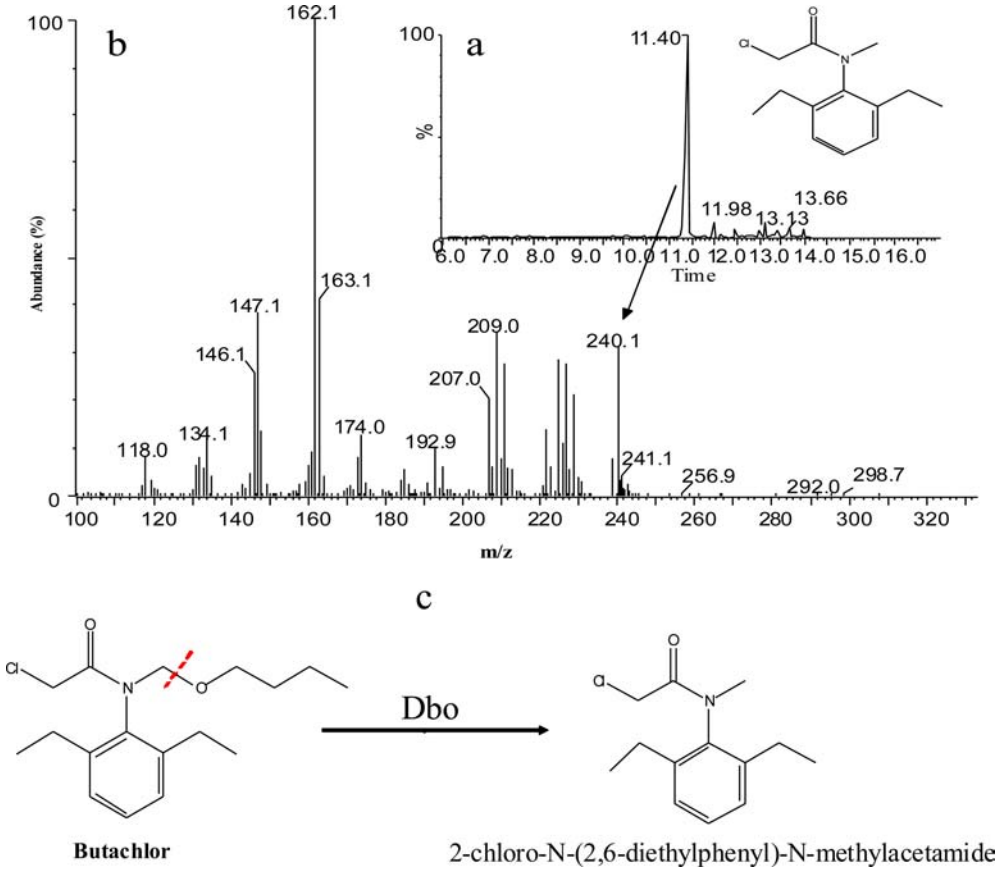

Figure 5. Mass spectrum of metabolite and proposed metabolic pathway: (a) Total ion chromatogram (TIC) for metabolite. The retention time was 11.40 min. (b) Mass spectrum of characteristic ions for the metabolite (RT = 11.40 min) identified as 2-chloro-*N*-(2,6-diethylphenyl)-*N*-methylacetamide. (c) Proposed metabolic pathway of butachlor by the positive clone. Butachlor was transformed into 2-chloro-*N*-(2,6-diethylphenyl)-*N*-methylacetamide by debutoxylation.

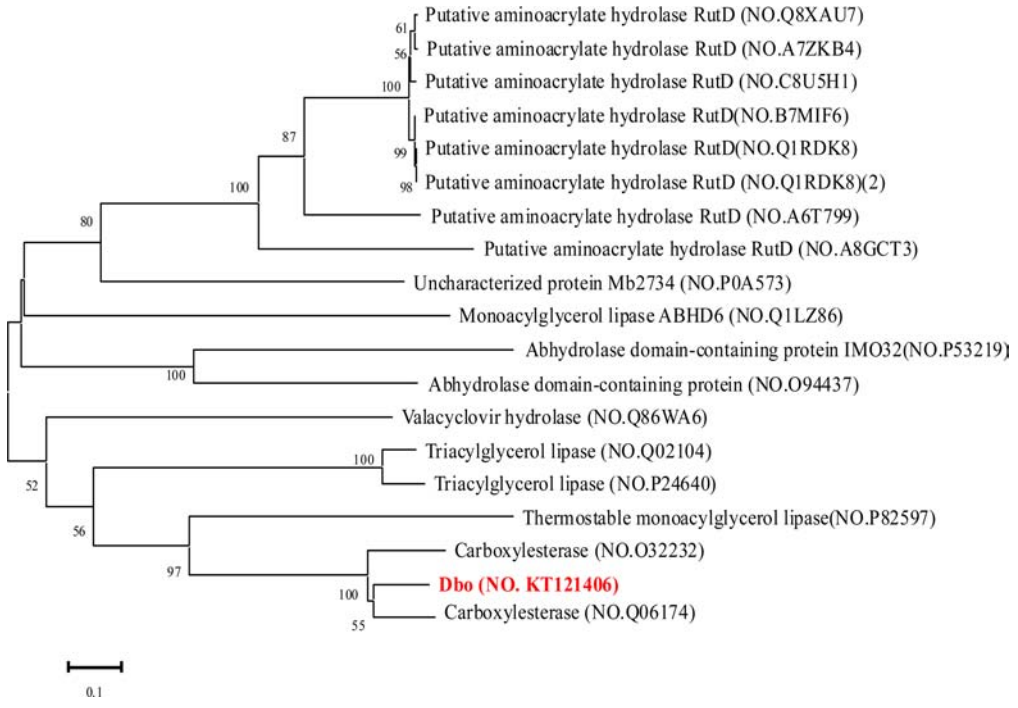

Figure 6. Phylogenetic relationships of butachlor debutoxylase amino acid sequences (Dbo).

nol and 2-chloro-*N*-(2,6-dimethylphenyl)acetamide. Analogously, a study by Chen et al.[16] also showed that sphingomonads DC-6 and DC-2 degraded butachlor via N-dealkylation. Otherwise, Zheng et al.[9] found that five metabolites were

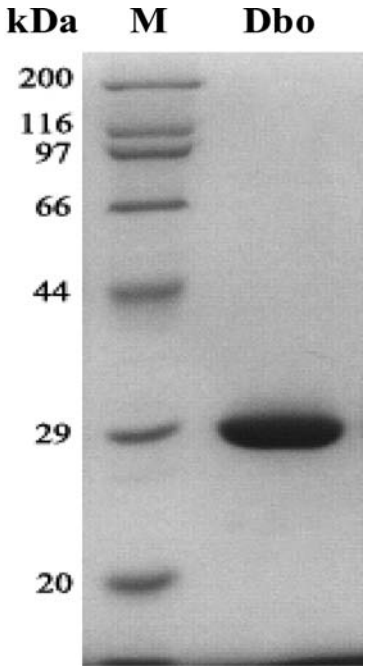

Figure 7. SDS-PAGE analysis of the purified enzymes. Lanes: M, protein marker; Dbo, purified recombinant Dbo.

produced during butachlor degradation by strain DCA-1^T, but three macromolecular degradation products remained in the culture medium, while not being further degraded. In addition, Kim et al.[14] reported that butachlor was completely degraded by the two isolates (*Mycobacterium* sp. J7A and *Sphingobium* sp. J7B) by syntrophic metabolism, whereas each isolate alone was not able to completely degrade butachlor. In a recent study, Zhang et al.[13] observed a plausible complete mineralization pathway of butachlor by *Paracoccus* sp. FLY-8. First, butachlor was degraded to alachlor by partial C-dealkylation and then through N-dealkylation to form 2-chloro-*N*-(2,6-dimethylphenyl)acetamide, which was further cleaved to 2,6-diethylaniline. 2,6-Diethylaniline was subsequently degraded via the metabolites aniline and catechol. In the end, catechol was oxidized through an ortho-cleavage pathway.

On the basis of all of the above results, the complete degradation pathway of butachlor by strain hys-1 is also proposed in Figure 4. Butachlor was initially metabolized to 2-chloro-*N*-(2,6-diethylphenyl)-*N*-methylacetamide by debutoxylation and then transformed to form 2-chloro-*N*-(2,6-diethylphenyl)-acetamide by N-demethylation. Subsequently, it was converted to 2,6-diethylaniline and further mineralized into CO_2 and H_2O. Butachlor was completely degraded by strain hys-1 finally, which was different from the reported butachlor mineralization pathway.[13] Thus, a new mineralization pathway by strain hys-1 was found as a novel metabolic mechanism of butachlor

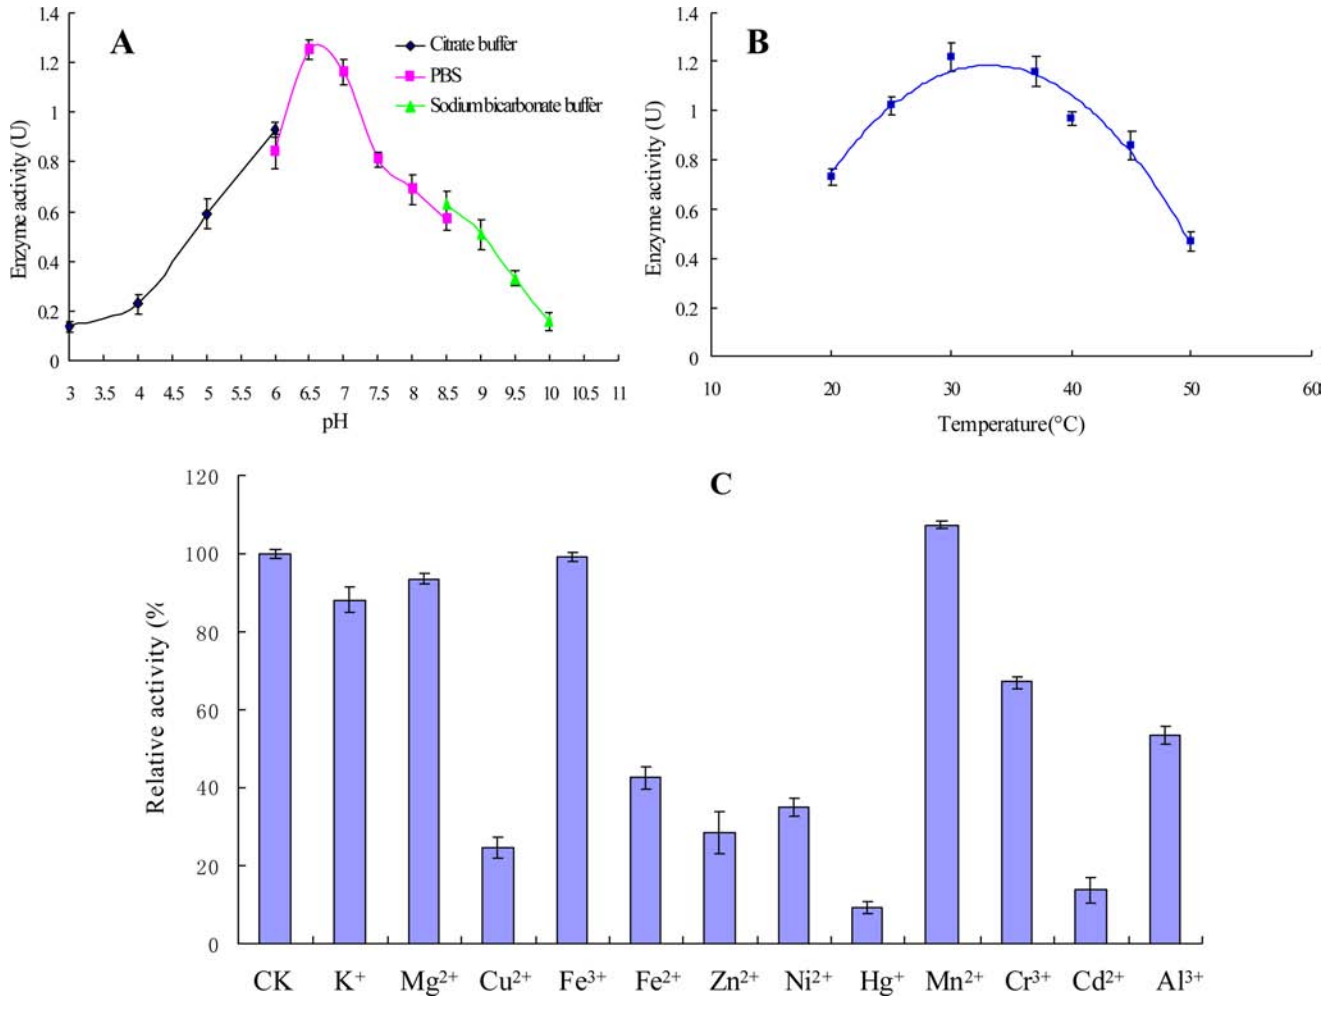

Figure 8. Effects of pH (A), temperature (B), and different metal ions (C) on Dbo activity. Error bars represent the standard error of three replicates.

J. Agric. Food Chem. 2015, 63, 8381−8390

biodegradation. In conclusion, strain hys-1 could degrade butachlor completely, which effectively reduce the secondary contamination caused by butachlor metabolites. Furthermore, the efficiency of butachlor degradation by strain hys-1 is much higher than that by *Paracoccus* sp. FLY-8.[13]

Substrate Specificity of the Enzyme. The substrate specificity of crude cell extracts was investigated using five chloroacetamide herbicides (Table 2). The results revealed that the crude cell extracts were able to catalyze alachlor, acetochlor, and butachlor degradation, with specific activities of 38.46, 32.81, 27.35 μmol min^{-1} mg^{-1} protein, respectively. No activity was detectable in the case of metolachlor and pretilachlor. This difference of reactivity may be related to the enzyme selectivity. Moreover, it was shown that the hydrolysis efficiency descended as alachlor > acetochlor > butachlor, which indicated that the hydrolysis activities decreased with the increase of the alkoxy chain length.

Dbo Gene Cloning, Expression, and Sequence Analysis. To clone the Dbo gene from strain hys-1, the gene was amplified by the primers as described previously. Next, the recombination genes were constructed and then transformed into *E. coli* BL21 (DE3). After growth on LB selection plates at 37 °C for 18 h, a positive clone was screened and the ability to degrade butachlor was confirmed by HPLC. In addition, the metabolites were further identified by LC-MS. The results indicated that the positive clone could transform butachlor into 2-chloro-*N*-(2,6-diethylphenyl)-*N*-methylacetamide by debutoxylation (Figure 5). Thus, it was subjected to gene sequencing. Finally, a continuous gene (744 bp in length) was obtained and deposited in the GenBank database with the accession no. KT121406. The gene encoding butachlor debutoxylase was designated Dbo.

Sequence analysis indicated that the GC content of Dbo was 38.31 mol % and a protein of 247 amino acids was encoded. Proteomic predictions showed that the molecular weight of Dbo is 28282.43 Da. The phylogenetic relationship of amino acid sequences is shown in Figure 6. The results showed the highest protein sequence identity (99%) with carboxylesterase (no. Q06174) and 97% identity with thermostable monoacylglycerol lipase (no. P82597). Both carboxylesterase and lipase are members of the esterase family. Thus, we speculated that Dbo could be a *Bacillus* esterase homologue that had the capability of realizing butachlor debutoxylation.

Purification and Characteristics of Dbo. To study the enzymatic properties, Dbo was expressed in *E. coli* BL21 and purified using Ni−nitrilotriacetic acid affinity chromatography. The purified enzyme was analyzed by SDS-PAGE and gave a single band (Figure 7). The molecular mass of the denatured enzyme was approximately 28 kDa, which is consistent with the molecular mass predicted from the amino acid sequence (28282.43 Da). Dbo could catalyze the debutoxylation of butachlor into 2-chloro-*N*-(2,6-diethylphenyl)-*N*-methylacetamide. Above all, Dbo involved in the degradation of butachlor was reported for the first time.

The effects of pH, temperature, and metal ions on Dbo activity were assayed with the purified enzyme. Dbo showed high activity at pH 6.5−7.0, with an optimum pH of 6.5, and the activity was inhibited under acidic (<5.0) or alkaline (>8.0) condition (Figure 8A). The enzyme showed relatively high activity at temperatures ranging from 25 to 40 °C, retaining >50% activity at 20 and 45 °C, yet 38% activity at 50 °C. The highest activity appeared at 30 °C (Figure 8B). Metal ions play an important role in Dbo activity (Figure 8C). Cu^{2+}, Fe^{2+}, Zn^{2+}, Ni^{2+}, Hg^{+}, and Cd^{2+} significantly inhibited the Dbo activity, whereas K^{+}, Mg^{2+}, and Fe^{3+} influenced enzyme activity indistinctively. Approximately 30−50% of Dbo activity was inhibited by Cr^{3+} and Al^{3+} ions. Furthermore, Mn^{2+} slightly activated Dbo activity at the tested concentration. The present study showed that Dbo could carry out the debutoxylation of butachlor and may possess potential to be used in bioremediation of butachlor-contaminated environments.

water treatment to removal organic pollutants and heavy metals have been extensively tested,[17,18] studies on the use of biosorbents in the preparation of CRFs have emerged in recent years.[19,20]

The main objective of this research was the development of azadirachtin alginate-based CRFs using biosorbents as modifying agents not only to control the release rate of azadirachtin but also to stabilize this botanical insecticide against degradation.

To achieve this objective, the following tasks were performed: (i) preparation of azadirachtin alginate-based formulations using biosorbents like kraft lignin, olive pomace, and humic acid, (ii) characterization of prepared formulations, and (iii) evaluation of azadirachtin formulations through kinetic and photodegradation studies.

MATERIALS AND METHODS

Materials. Azadirachtin from a neem tree (17.7%) was provided from The Indian Neem Tree Company, Mumbai, India. The chemical structure of azadirachtin is shown in Figure 1.

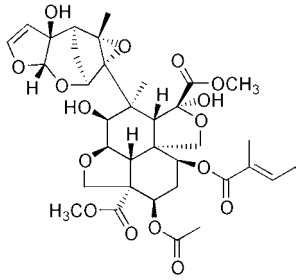

Figure 1. Chemical structure of azadirachtin.

Alginic acid was used as sodium salt obtained from *Macrocystis pyrifera*, and calcium chloride (97%) and sodium tripolyphospate (90%) were provided by Sigma-Aldrich Co LLC.

The lignin used in this study was a commercially available pine kraft lignin, Indulin AT (Westvaco Corp., Charleston, SC, USA). The olive pomace used in this study was obtained from a three phases extraction procedure on olive oil by the company Almazara de Felix S.C.A. The humic acid was provided by the company Sigma-Aldrich Co., LLC.

Chemical Analysis of Modifying Agents. The elemental analyses of lignin, humic acid, and olive pomace were performed for C, H, N, O, and S in an elemental analyzer from Elementar, model Vario Micro CHNS-O.

All of these characteristics of the modifying agents are shown in Table 1.

The total surface acidity (R-COOH, Ar-COOH, and Ar-OH groups) of humic acid and olive pomace was determined using the Schnitzer and Gupta method.[21] The total amount of carboxylic groups was determined using the method proposed by Schnitzer and Wright.[21,22] The total amount of phenolic hydroxyl groups was determined following the method proposed by Schnitzer,[22] that is

$$(\text{total surface acidity}) - (\text{carboxylic groups}) = \text{phenolic hydroxyl groups (meq g}^{-1})$$

These data are given in Table 1. The organic matter content of lignin, humic acid, and olive pomace was determined by the Walkley-Black method.[23] These data are given in Table 1.

Preparation of the Azadirachtin CRFs. The prepared CRFs were based on the gelling properties of the alginate in the presence of divalent cations. It was made up of formulations in water containing different percentages of technical grade azadirachtin (Az), sodium alginate (A), lignin (L), humic acid (H), and olive pomace (O) (shown in Table 2). These mixtures were vigorously stirred for 1 h.

Table 2. Percentage (by Weight) of the Components of CR Formulations Containing Azadirachtin

formulation[a]	azadirachtin	alginate	lignin	humic acid	olive pomace	water
AAz	0.28	1.47				98.25
AOAz	1.17	1.40			4.75	92.69
AHAz	1.17	1.40		4.75		92.69
ALAz	1.17	1.40	4.75			92.69

[a]AAz: alginate-azadirachtin. AOAz: alginate-olive pomace-azadirachtin. AHAz: alginate-humic acid-azadirachtin. ALAz: alginate-lignin-azadirachtin.

The alginate mixtures (100 g) were dropwise added to a 250 mL gellant bath of 0.25 M $CaCl_2$, as was described previously.[14] The resulting beads were allowed to gel in the 0.25 M $CaCl_2$ solution for a total of 20 min, then they were filtered and dried first at room temperature and then in an oven (40 °C) to constant weight. CRF granules were maintained in an oven at controlled environment (40 °C) before experiments were carried out. The resulting products are labeled in the text as AAz, ALAz, AHAz, and AOAz.

Azadirachtin CRFs Characterization. *Determination of Azadirachtin Content in CRFs.* The concentration of azadirachtin in the CRFs was determined by dissolving 20 mg of the dry granules in a 0.03 M tripolyphosphate solution (5 mL). This solution was placed in stoppered conical flasks and shaken in a thermostatic bath at 25 °C ± 0.1 °C for 2 h. After that, 80 mL of a methanol/water mixture (80:20 v/v) was added, and the solutions were left in the thermostatic bath at the same conditions for 24 h. The resulting extract was made up to 100 mL with methanol/water mixture (80:20 v/v) and filtered using 0.20 μm syringe nylon filters (Millex GN, Millipore Co., Billerica, MA USA). The insecticide concentration was determined by HPLC, using a Beckman Coulter Inc., System Gold HPLC (Fullerton, CA, USA) equipped with a diode-array detector and 32 Karat data station. HPLC operating conditions to analyze azadirachtin were described previously by other authors.[24−26] The mobile phase was an acetonitrile−water mixture 40:60, the flow rate was 1 mL/min, and the column used was a Nova-Pak C18 4 μm 3.9 × 150 mm supplied by Waters Assoc. (Massachusetts, USA). The analysis was performed at the wavelength of 217 nm by injecting a volume of 50 μL. External standard calibration was used, and three replicates were carried out for each formulation.

Mean Granule Size and Average Granule Mass. The average diameter of CR granules was determined using a Stereoscopic Zoom Microscope from Nikon, model SMZ1000, provided with a camera

Table 1. Physicochemical Characteristics of Modifying Agents

	elemental analysis (%)					total surface acidity (meq g^{-1})			organic matter content (%)

PixelLINK (Megapixel FireWire Camera) model PL-A662. Each measure was taken through the analysis of a basis of 20 particles using the software Image Pro-Plus 6.0.

To determine the average mass of the granules, an analytical balance Mettler Toledo model AG245 was used. Different populations of 10 granules were weighed 5 times to calculate the average mass per granule.

Morphological Study. The morphological and structural surface of the formulations was examined using a Hitachi S-3500-N scanning electron microscope (SEM) at the required magnification at room temperature. The granules were deposited on brass holds and sputtered with a thin coat of gold under vacuum. The acceleration voltage used was 10 kV with secondary electron image as a detector. To examine the internal morphology, the granules were carefully cut with the aid of a chisel, and their cross-sections were photomicrographed.

Water Uptake Tests. The water uptake was measured for granules using the method of Franson and Peppas.[27] Granules were immersed in water using stoppered conical flasks and shaken in a thermostatic bath at 25 °C ± 0.1 °C. Then, they were removed periodically (see Results and Discussion for intervals). The excess water was blotted from the surface of the granules using filter paper, and after that, granules were weighed. Three replicates (10 granules in each replicate) were carried out. The granules were then dried, first at room temperature and then in an oven (40 °C), to constant weight. The water uptake (g g^{-1} dry granule) was calculated.

Water Release Kinetics. For each formulation and technical azadirachtin (two replicates), an accurately weighed quantity of granules containing 8 mg of azadirachtin was added to 500 mL of distilled water and placed into stoppered conical flasks. Flasks were kept in a thermostatic bath at 25 (±0.1) °C. At different time intervals, aliquots of 0.5 mL were removed to determine azadirachtin concentration, and 0.5 mL of fresh water was added to the flasks to maintain sinking conditions.

Photodegradation Study. Photodegradation studies were carried out at 25 °C using a solar simulator Xenoterm model 1500RA from SECCI (Barcelona, Spain) provided with a xenon lamp (1500 W). An accurately weighed quantity of the different formulations (AAz and ALAz) and technical grade azadirachtin, containing about 1.5 mg of azadirachtin, were placed in Pyrex glass Petri dishes. The samples were placed in the solar simulator and were taken off the apparatus at different time intervals. These samples were extracted by the method described Azadirachtin CRFs Characterization section to determine the remaining amount of azadirachtin in each formulation. Dark controls of all experiments were conducted keeping Pyrex glass Petri dishes containing the different formulations at 25 °C. All experiments were carried out in duplicate.

RESULTS AND DISCUSSION

Azadirachtin CRF Characterization. Characteristics of alginate-based CR granules (dry products) containing azadirachtin are shown in Table 3. The results of practical azadirachtin loading and entrapment efficiency (EE) were calculated using eqs 1 and 2.

Table 3. Characteristics of Controlled Release Granules Containing Azadirachtin

formulation	theoretical azadirachtin loading (%)[a]	practical azadirachtin loading (%)	EE (%)	mean granule size (mm)	average granule mass (mg)
AAz	2.83	1.17	41.34	1.06	0.456
AOAz	2.83	2.55	90.10	1.93	4.234
AHAz	2.83	2.31	81.62	1.59	1.552
ALAz	2.83	2.81	99.50	1.96	1.379

[a]Theoretical azadirachtin loading (%) = (total amount of azadirachtin used to prepare the formulation/total amount of solid components used in the formulation process) × 100.

$$\text{practical azadirachtin loading (\%)} = \left(\frac{\text{amount of azadirachtin in CR granules}}{\text{amount of CR granules}}\right) \times 100 \quad (1)$$

$$\text{entrapment efficiency (\%)} = \left(\frac{\text{practical azadirachtin loading}}{\text{theoretical azadirachtin loading}}\right) \times 100 \quad (2)$$

The practical azadirachtin loadings ranged between 1.17% for AAz formulation and 2.81% for ALAz formulation. This insecticide content is suitable for a practical agricultural application.[28] The granules were generally spherically shaped, and the technical grade azadirachtin was readily incorporated in the alginate matrix, obtaining granules of size between 1.06 for AAz formulation mm and 1.96 mm for ALAz formulation. The addition of lignin, humic acid, and olive pomace to the alginate formulations led to larger and heavier granules that were spherical and dried with less aggregation. The addition of lignin to the alginate formulation led to the largest granules. The average mass of these granules oscillated between 0.456 mg/granule for the formulation AAz and 4.234 mg/granule for the formulation AOAz. The values of entrapment efficiency ranged between 41.43% for the formulation AAz and 99.50% for the formulation ALAz. In the granules containing modifying agents, the entrapment efficiency was higher than 81.62%, the highest value corresponding to the formulation prepared with lignin as modifying agent (99.50%), which may be attributed to the difference of the molecular structure among lignin, olive pomace, and humic acid. These data show the validity of the used method for the encapsulation of azadirachtin, mainly in the presence of modifying agents. Previous studies of encapsulation of synthetic pesticides with alginate and sorbents like bentonite, activated carbon and anthracite used as modifying agents showed higher entrapment efficiency values using these sorbents.[12−14]

Morphological Study. SEM pictures from the external morphology of the different azadirachtin controlled release formulations prepared are shown in Figure 2. A spherical shape for all the formulations that contain a modifying agent can be observed. From these formulations, the one that obtains a higher homogeneity is that modified with lignin (Figure 2b). An irregular morphology is shown by the formulation prepared without a modifying agent (Figure 2a).

SEM pictures with a higher resolution (×500) were also taken (Figure 3). The above-mentioned observations were confirmed, showing that the formulation AAz had some cracks (Figure 3a) that will affect the release of azadirachtin from the granules.

Water Uptake Test. The amount of water uptake by the different alginate-modifying sorbent granules is presented in Figure 4. Water uptake curves were characterized by a fast initial uptake of water followed by an apparent equilibrium or a slow water uptake. The plot of the water uptake versus time showed that the granules containing humic acid or olive pomace reached the water uptake equilibrium in approximately 2 h, with at least 24 h being necessary for lignin-based granules. The highest water absorption quantity is reached by the formulation modified by lignin, followed by the one modified with humic acid, showing the one modified with olive pomace had the lowest water uptake. Moreover, the granules retained their spherical morphology throughout the study without any disruptions.

The addition of olive pomace to the alginate formulation generated a greater density of the granules which can be due to

DOI: 10.1021/acs.jafc.5b03255
J. Agric. Food Chem. 2015, 63, 8391−8398

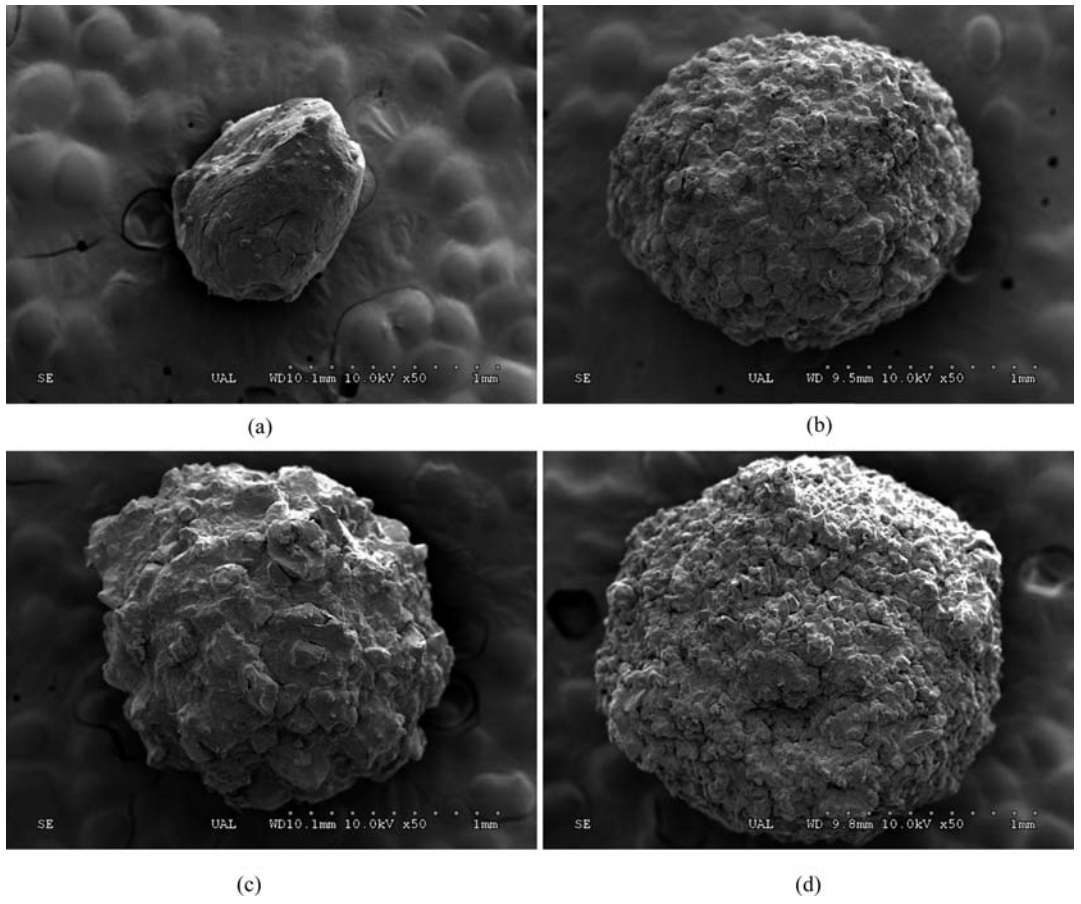

Figure 2. SEM of the shape and external morphology (×50 magnification): AAz (a), ALAz (b), AHAz (c), and AOAz (d).

the higher cross-linking between this sorbent and the hydrophilic groups of alginate chains. Consequently, the water uptake for olive pomace granules was lower than that obtained for granules prepared with lignin or humic acid as sorbents.[29] Thus, water uptake and intensity of interactions of the azadirachtin with lignin, humic acid, and olive pomace could affect the diffusion through the granules and hence the release of the active ingredient.

Water Release Kinetics. The effect of modifying agents on the release of azadirachtin from alginate granules was investigated. When the polymer matrix was placed in water, the granules swelled because of the absorption of water, and then, azadirachtin in the swollen part diffused out of the polymer matrix. In vitro release profiles of alginate CRFs and technical grade azadirachtin are shown in Figure 5.

From this figure, we can deduce that the granules made with alginate and azadirachtin (AAz) produced a slower release rate than the technical grade azadirachtin. It can be appreciated that 80% of technical grade azadirachtin was dissolved in less than 6 h but that it was necessary to have at least 192 h to release the same percentage of azadirachtin from the alginate-based CR formulation AAz.

The influence of the modifying agents such as lignin, humic acid, and olive pomace, appeared clearly defined for all CR formulations prepared. In this sense, the presence of the modifiers produced a slower release rate in comparison to the CRFs prepared without these modifiers (AAz) as is shown in Figure 4. It is observed that the addition of modifying sorbents produced a decrease in the release rate of active ingredient, which was higher for lignin than those prepared with humic acid and olive pomace, according to the difference observed between the release profiles. From Figure 5, it can be seen that approximately 58%, 78%, and 99% of azadirachtin is released in 550 h for the formulations ALAz, AHAz, and AOAz, respectively.

For all formulations, a decrease in the release rate of insecticide over time was observed. This result is probably due to an increase in the distance where dissolved molecules have to diffuse as the depleted zone advances to the center of the matrix. In diffusion-controlled matrix systems, this usually means that the release is proportional to the square root of time.[30] The formulations of this research are described as systems containing finely divided solute particles, which are uniformly dispersed within the matrix phase. Higuchi[31] originally analyzed analogous systems, such as drugs dispersed in a stationary matrix. In these spherical monoliths systems, Higuchi suggested the following equation assuming Fickian diffusion ($y = kt^{1/2}$):[31]

$$\left[\frac{1-\left(1-\frac{M_t}{M_0}\right)^{2/3}-\frac{2}{3}\frac{M_t}{M_0}}{2}\right]^{1/2} = K_H t^{1/2};$$

$$K_H = \left(\frac{1}{C_0 r^2}P\right)^{1/2} \quad (3)$$

where M_t/M_0 is the fraction of active ingredient released at time t, and K_H is a constant that depends on the radius of the sphere (r), the initial concentration of the active ingredient (C_0), and the permeability of the matrix (P). The K_H values and correlation

coefficients were obtained by applying the model proposed by Higuchi to release data, using the nonlinear curve-fitting utility of SigmaPlot software (version 9.0, Systat Software, Inc.). These values are presented in Table 4 together with values of *P*. The Higuchi model gave values of r^2 higher than 0.91, indicating that this model was suitable to describe the release of the azadirachtin from CRFs. For all formulations, the values of K_H were in the order of 10^{-2} $h^{-1/2}$.

Table 4. Constants from Fitting the Higuchi Equation to Release Data of Azadirachtin in Water and the Matrix Permeability Parameter

formulation	$K_H \times 10^2$ ($h^{-1/2}$)	R^2	$P \times 10^7$ (g $h^{-1}cm^{-1}$)
AAz	1.89	0.918	0.0977
AOAz	1.31	0.919	0.5222
AHAz	1.02	0.975	0.1277
ALAz	0.84	0.934	7.599

DOI: 10.1021/acs.jafc.5b03255
J. Agric. Food Chem. 2015, 63, 8391−8398

The variation order for K_H values was ALAz < AHAz < AOAz < AAz.

This variation order suggests that the factors which affect the K_H parameter and the release of active ingredient from the different granules studied should be the same and therefore produced by the presence of modifying agents as lignin, humic acid, and olive pomace. The variation observed for P values can be explained according to the different masses and sizes of the prepared granules that affect the C_0 values.

To simplify the analysis of curves from three-dimensional devices, the release data were analyzed by applying the empirical equation proposed by Ritger and Peppas:[32]

$$\frac{M_t}{M_0} = Kt^n \quad (4)$$

where M_t/M_0 is the percentage of active ingredient released at time t, K is a constant that incorporates characteristics of the macromolecular network system and the active ingredient, and n is a diffusional parameter, which is indicative of the transport mechanism.

The values of K and n obtained from 90% of maximum azadirachtin released, in each curve (Figure 4), were obtained using the nonlinear curve-fitting utility of SigmaPlot software. These values and the correlations coefficients are presented in Table 5. According to correlation coefficients, we can deduce that

Table 5. Constants from Fitting the Empirical Equation $M_t/M_o = Kt^n$ to Release Data of Azadirachtin in Water

formulation	$K \times 10^2$	n	r^2	T_{50} (h)
AAz	10.11	0.408	0.89	50.29
AOAz	1.55	0.697	0.99	146.25
AHAz	2.02	0.626	0.99	168.35
ALAz	2.49	0.569	0.99	194.79

the release profiles of insecticide azadirachtin fit well to the empirical equation. The n values ranged from 0.408 for AAz formulation up to 0.697 for AOAz formulation. Values of n close to 0.43 are indicative of Fickian diffusion in spherical monolithic matrixes.[32] The fact is that slightly different values of n equal to 0.43 could be explained by the complexity of the heterogeneous system involved together with the capacity of the modifying agents, olive pomace, humic acid, and lignin, to interact with the active ingredient. That is the reason why in these special cases, diffusion is not the only factor to consider in the release process.

The K values range between 10.11×10^{-2} h^{-n} for AAz and 1.55×10^{-2} h^{-n} for AOAz. After the analysis of these data, it was found that the use of modifying agents leads to lower K parameter values.

In general, the monolith systems in this study consist of a hydrophilic network of alginate and calcium ions with the active ingredient azadirachtin dispersed in it, which makes up water quickly as indicated in the water uptake section. These systems were changed in some cases by the addition of olive pomace, humic acid, and lignin. All of them made an alginate hydrogel with a continuous membrane around the insecticide and modifying agents. In this situation, the solid active ingredient was dissolved, spread through the macromolecular network, and released to the environment. Considering the molecular weight of azadirachtin (720.7 g mol^{-1}), it was not probably that steric impediments were produced by the alginate hydrogel. However, the crossing areas of alginate could make the movement of the active ingredient difficult.[33] In fact, the presence of modifying agents such as olive pomace, humic acid, and lignin increased the centers of interaction with azadirachtin. Additionally, the time taken for 50% of the insecticide to be released (T_{50}) was calculated from K and n constants and also presented in Table 5. The order of variation if this was the parameter for the prepared CRFs was AAz ≪ AOAz < AHAz < ALAz.

The lowest value of T_{50} means that this CRF produced the fastest azadirachtin release in water. The addition of biosorbents, olive pomace, humic acid, and lignin to the basic alginate formulation reduced the release rate. The formulation prepared with lignin as modifying agent produced the slowest release rate. So, the T_{50} values obtained could be explained if we take into account the different O. M. content and aromaticity of the biosorbent used in each case and the extent of the interactions between insecticide and biosorbents. These interactions will affect the diffusing process and thus the release rate of azadirachtin from the alginate-based granules.

Photodegradation Study. The aim of this experiment was to compare the efficiency of CRFs to improve the stability of azadirachtin against to photodegradation. For that, AAz, ALAz, and technical grade azadirachtin were tested under simulated sunlight.

In Figure 6, the stability of azadirachtin-loaded alginate granules and technical grade azadirachtin subjected to sunlight

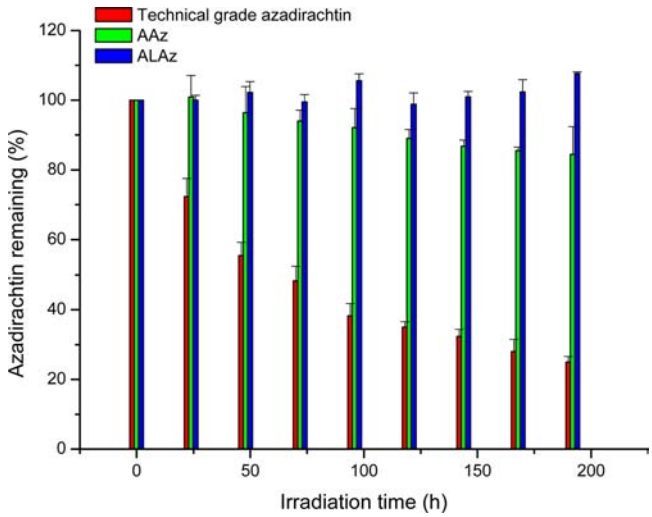

Figure 6. Percentage of remaining azadirachtin after simulated sunlight exposure.

irradiation is reported in terms of the percentage of azadirachtin remaining versus irradiation time. As shown in Figure 6, the azadirachtin remaining for AAz granules was 84.4% and 100% for ALAz granules after irradiating by sunlight for 192 h. In the case of technical grade azadirachtin, the azadirachtin remaining was 27.7% after 192 h irradiation time.

According to these values, the order of photostability of the formulations investigated under the experimental conditions was

technical grade azadirachtin < AAz < ALAz

These results showed that AAz formulation provided a moderate degree of azadirachtin photoprotection while the lignin-based formulation provided complete protection against simulated sunlight over the whole experiment. This can be explained if we consider that lignin is a biopolymer with different functional groups able to absorb UV radiation due to the presence of aromatic rings and "π" bonds in their structure.[34]

DOI: 10.1021/acs.jafc.5b03255
J. Agric. Food Chem. 2015, 63, 8391−8398

Thus, lignin was suitable to stabilize azadirachtin against photodegradation by absorption of UV radiation by the chromophores. Besides, the alginate-derived oligosaccharides have been used as potential UV protector in the areas of functional foods[35,36] and biological control.[37]

Some natural ultraviolet light absorbers such as ferulic acid, gallic acid, aloin, and rutin have been researched as photostabilizers of azadirachtin. These natural products showed a moderate degree of azadirachtin photostabilization with dissipation half-life ranging between 14.41 and 20.21 h.[5]

This study demonstrates that the use of natural polymers such as lignin and alginate to encapsulate azadirachtin improve its stability against photodegradation. These biosorbents can be selected and matched to stabilize UV-labile biopesticides. Therefore, this encapsulation method could be used to enhance the storage period of azadirachtin under conditions that cause photodegradation.

In conclusion, alginate and biosorbents have been used to optimize hybrid hydrogel-based CRFs for the botanical insecticide azadirachtin. High EE values for azadirachtin have been obtained using biosorbents as modifying agents, reaching a value of 99.5% for the lignin alginate-based formulation. SEM studies demonstrated that the use of modifying agents improves the formulation's homogeneity. The kinetic experiments of release in water have shown that the use of lignin, olive pomace, and humic acid as modifying agents of the alginate formulations reduces the release rate of the azadirachtin in comparison with that of the technical product and with alginate formulations without modifying agents and shows the highest decrease in release rate corresponding to the formulation prepared with lignin. The data obtained from photodegradation experiments indicated that natural polymers such as kraft lignin and alginate can be used to protect azadirachtin against photodegradation.

Therefore, these new formulations could be used to improve the delivery of the azadirachtin to its site of action and also to improve its photostability, developing new procedures to encapsulate botanical pesticides.

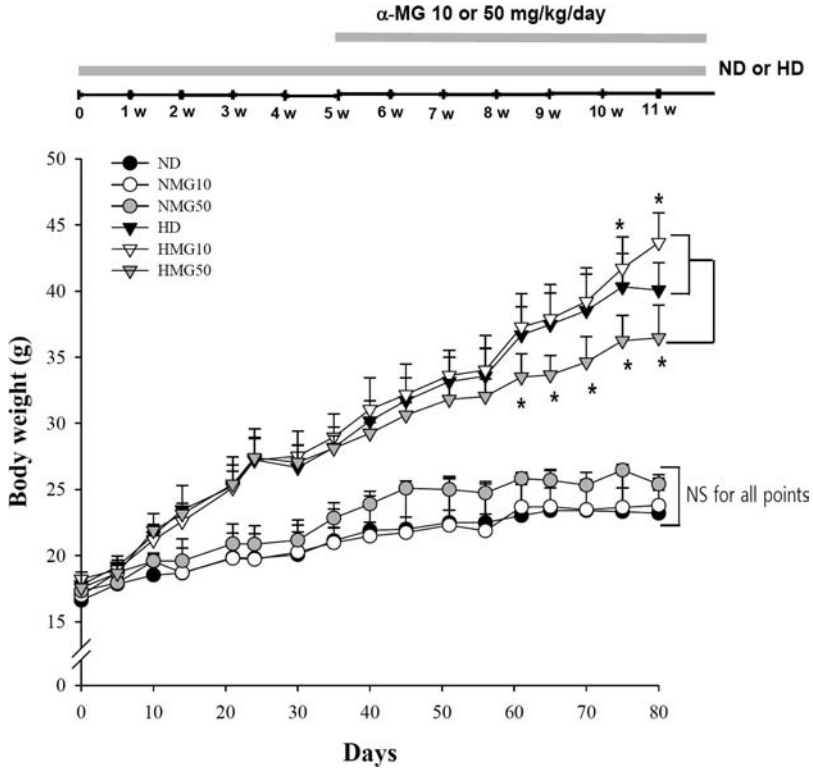

Figure 1. Effects of α-MG on body weight gain in ND, NMG10, NMG50, HD, HMG10, and HMG50 groups. (∗) Significantly different from ND group; (#) significantly different from HD group; (†) significantly different between MG10 and MG50 groups.

the previously reported protocol.[14] Polyethylene glycol 400 (PEG 400) was from Showa Chemical Co. (Tokyo, Japan). Antibodies against β-actin, SirT1, p-AMPK, AMPK, PPARγ, and RXRα were purchased from Cell Signaling Technology, Inc. (Danvers, MA, USA).

Animals. The protocols for the animal studies were approved by the Institute of Laboratory Animal Resources of Dongguk University, Seoul, South Korea (2012-0673; July 25, 2012). Male C57BL/6 mice were obtained from Charles River Orient (Seoul, South Korea) and acclimated for 1 week before the study was begun. Upon arrival, animals were randomized and housed at three per cage under strictly controlled environmental conditions (20−25 °C and 48−52% relative humidity). A 12 h light/dark cycle was used at an intensity of 150−300 Lux. C57BL/6 mice were started on either a normal diet (ND, 10% of kilocalories as fat; Pproduct N12450B) or a high-fat diet (HD, 60% of kilocalories as fat; product D12592, Research Diets, New Brunswick, NJ, USA) for 80 days. After 5 weeks (at day 35) of ND or HD, the mice were distributed into six treatment groups. α-MG (10 or 50 mg/kg/day) dissolved in PEG 400 and distilled water (6:4, v/v) was orally administered to mice with ND (NMG10 and NMG50 groups, respectively; n = 8 for each) or HD (HMG10 and HMG50 groups, respectively; n = 8 for each) every day during the last 6 weeks of diet feeding. ND and HD groups (n = 8 for each) were orally administered a vehicle instead of α-MG.

Measurement of Liver, Fats, and Kidney Weights and Triglyceride (TG) Levels in the Liver. At the end of the experimental period, the liver, fats, and kidney were extracted and the weights were measured. In the case of fats, the weights of total, epididymal, and retroperitoneal fats were measured separately. For the measurement of hepatic TG, 0.3 g of liver was homogenized in 0.1 M Tris-acetate buffer (pH 7.4), and 6 volumes of chloroform/methanol (2:1) was added. After vigorous stirring, the mixtures were incubated on ice for 1 h and centrifuged at 800g for 3 min. The resulting lower phase was aspirated. The hepatic TG content was determined using an Enzychrom TG assay kit.

Blood Chemistry. At the end of the experimental period, plasma samples were collected and total protein, albumin, aspartate aminotransferase (AST), alanine aminotransaminase (ALT), creatinine, total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), TG, free fatty acid (FFA), glucose, blood urea nitrogen (BUN), and creatinine levels were analyzed (analyzed by Green Cross Reference Laboratory, Seoul, South Korea).

Hematoxylin and Eosin Staining in the Liver and Various Sites of Fat. The left lateral lobe of the liver and epididymal and retroperitoneal fats were excised,[19] fixed in 10% formalin, and embedded in paraffin. Four micrometer thick sections of liver and epididymal and retroperitoneal fats were obtained and stained with hematoxylin and eosin (H&E) for the histological examination of adipocytes, as previously described.[19]

Immunoblotting Analysis. Protein expression of hepatic SirT1, AMPK, p-AMPK, PPARγ, and RXRα were assessed by Western blotting analysis according to the manufacturer's instructions. After the determination of protein concentration, 20 μg of protein was mixed 1:1 with 2× sample buffer (20% glycerol, 4% SDS, 10% 2-ME, 0.05% bromophenol blue, and 1.25 M Tris-buffer, pH 6.8), loaded onto an SDS-PAGE gel (8 or 15%), and run at 150 V for 90 min. The tissue proteins were transferred to an ImmunoBlot polyvinylidene difluoride membrane using a Bio-Rad semidry transfer system. Following blocking, membranes were incubated with primary antibody at dilutions of 1:500−1:1000 at 4 °C overnight, washed three times in PBS, and further incubated with a HRP-conjugated secondary anti-IgG antibody at dilutions of 1:2000−1:20000 for 1 h. After three washings, the immunoreactive proteins were visualized by ECL chemiluminescence detection (Amersham Biosciences, Piscataway, NJ, USA). Equal loading of proteins was verified by β-actin immunoblotting.

Statistical Analysis. A P value <0.05 was deemed to be statistically significant using Duncan's multiple-range test of the Social Package of Statistical Sciences (SPSS) posteriori analysis of variance (ANOVA). All data are expressed as the mean ± standard error.

RESULTS

Effects of α-MG on Body Weight Gain and Food Intake. Effects of α-MG on body weight changes in C57BL/6

DOI: 10.1021/acs.jafc.5b01637
J. Agric. Food Chem. 2015, 63, 8399−8406

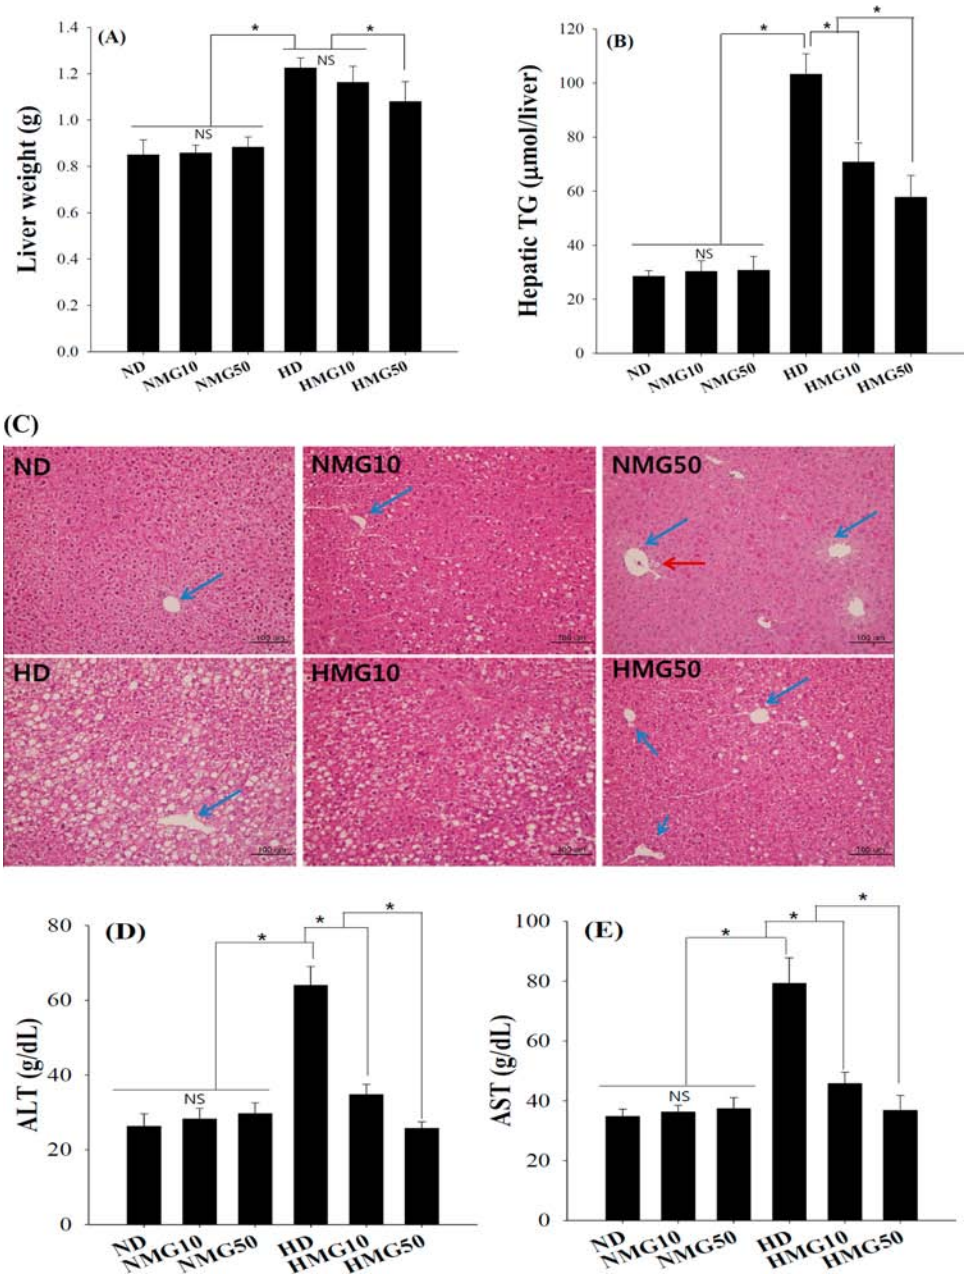

Figure 2. Effects of α-MG on liver from ND, NMG10, NMG50, HD, HMG10, and HMG50 groups. The weights of liver and hepatic TG contents were measured (A, B). Also, the histology of liver was compared after H&E staining: vein (blue arrow); bile duct (red arrow) (C). The liver functions were determined by ALT and AST in serum (D, E). (*) Means not sharing a common symbol differ, $P < 0.05$.

mice fed a normal diet (ND) or a high-fat diet (HD) are shown in Figure 1. The body weight gains in the high-fat diet groups were significantly greater than those in the normal diet groups from day 14 to the end of this experiment (e.g., body weight gain compared with initial body weight: 12.3 vs 28.8% at day 14 and 39.6 vs 130% at day 80, respectively, for the ND and HD groups). The body weight loss appeared 26 days after starting the treatment with 50 mg/kg α-MG (at day 61 after the start of the HD) in the HMG50 group compared with the HD group. However, a body weight loss did not appear in the HMG10 group compared with the HD group. The mean value of body weight in the NMG50 group seemed to be greater than in the ND or NMG10 group; however, there was no significant difference. The food intakes were comparable among all groups of mice (data not shown).

Effects of α-MG on Hepatic Steatosis. In an effort to assess the effect of α-MG on hepatic steatosis, measurements of liver weight and hepatic TG level and histopathological analysis of the liver were conducted. In the HMG50 group, the high-fat diet induced an increase in liver weight and hepatic TG level in the HD group (by 44.1 and 262% increase for liver weight and hepatic TG, respectively, vs the ND group), and the increase in liver weight and hepatic TG level was restored (by 12.2 and 44.1% decrease, respectively, vs the HD group) (Figure 2A,B). As shown in Figure 2C, the histopathological analysis of the liver revealed that HD caused the accumulation of fat droplets in the liver, accompanying hepatic steatosis. Arrestingly, the hepatic fat accumulation decreased in the HMG50 group according to liver histology. The conditions of liver weight, hepatic TG level, and hepatic steatosis in the HMG10 group

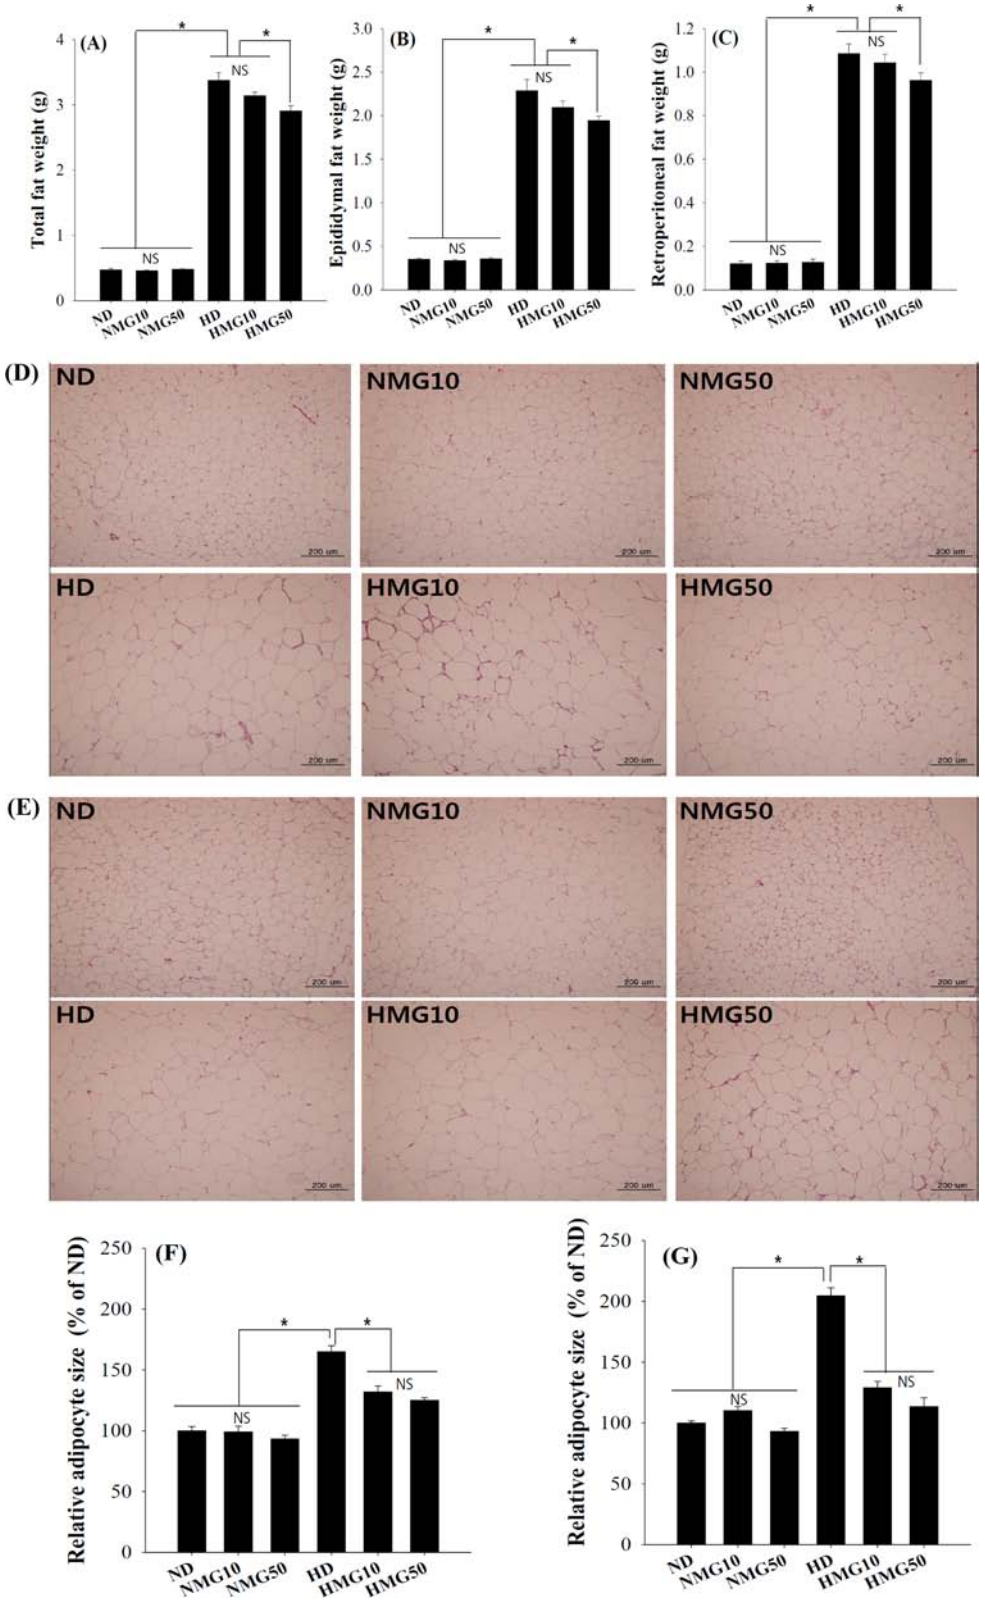

Figure 3. Effects of α-MG on fat from ND, NMG10, NMG50, HD, HMG10, and HMG50 groups. The weights of total fat, epididymal fat, and retroperitoneal fat were measured (A−C). The histologies of epididymal and retroperitoneal fats were compared after H&E staining (D, E). Adipocyte size of epididymal fat (F) and retroperitoneal fat (G) was measured. (∗) Means not sharing a common symbol differ, $P < 0.05$.

were still abnormal and similar to the HD group. According to Figure 2D,E for the measurement of liver functions, the serum ALT and AST levels were significantly higher in the HD group (by 144 and 128% increases respectively, vs the ND group), but were recovered to control levels in the HMG10 (by 45.7 and 42.3% decreases respectively, vs the HD group) and HMG50 (by 59.8 and 53.6% decreases respectively, vs HD group) groups. The albumin levels were comparable among the three

J. Agric. Food Chem. 2015, 63, 8399−8406

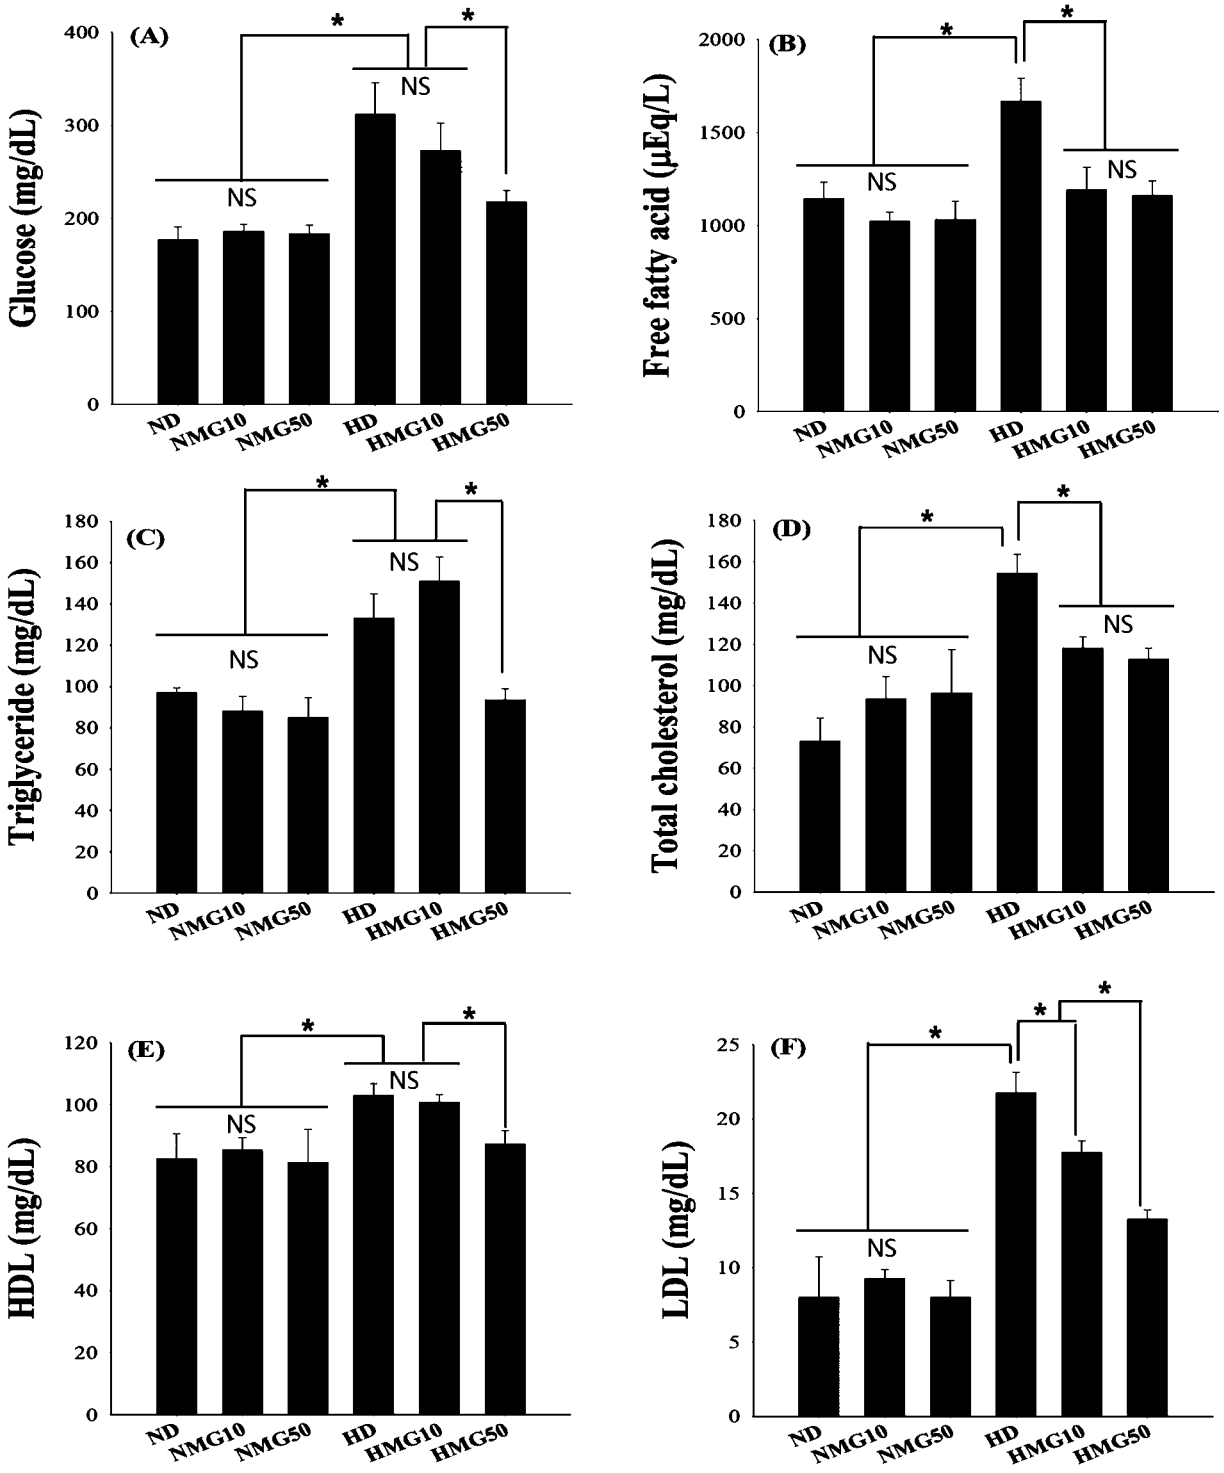

Figure 4. Effects of α-MG on serum profiles in ND, NMG10, NMG50, HD, HMG10, and HMG50 groups. Glucose (A), free fatty acid (B), triglyceride (C), total cholesterol (D), high-density lipoprotein cholesterol (HDL-C) (E), and low-density lipoprotein cholesterol (LDL-C) (F) were assayed. (*) Means not sharing a common symbol differ, $P < 0.05$.

groups of mice fed HD (data not shown). With the ND, in both the NMG10 and NMG50 groups, all conditions of the liver maintained a normal state. Collectively, these results demonstrate that 50 mg/kg α-MG treatment attenuated hepatic steatosis in high-fat diet-fed mice.

Effects of α-MG on Fat Accumulation. To investigate whether α-MG regulated the fat accumulation in adipose tissues, the weight and size of epididymal and retroperitoneal fats were examined. The weights of total, epididymal, and retroperitoneal fats were increased in the HD group (by 614, 549, and 804% increases respectively, vs the ND group), which were significantly reduced (by 13.8, 15.0, and 11.3% decreases respectively, vs HD group) in the HMG50 group (Figure 3A−). As shown in Figure 3D,E, the sizes of epididymal and retroperitoneal fats in the HD group were significantly increased, by 64.9 and 104.6%, respectively, compared with

DOI: 10.1021/acs.jafc.5b01637
J. Agric. Food Chem. 2015, 63, 8399−8406

those of the ND group. In the HMG50 group, the sizes of adipose tissue were slightly reduced, by 24.2 and 44.5% in both epididymal and retroperitoneal fats, respectively, as compared with the HD group (Figure 3F). However, 10 mg/kg α-MG treatment did not significantly affect the fat weights and sizes from the HD group. In normal diet groups (ND, NMG10,and NMG50), there were no changes in fat weights or sizes regardless of treatment with α-MG.

Effects of α-MG on Lipid Metabolism. To determine whether α-MG improved lipid metabolism, the serum glucose, FFA, TG, TC, HDL-C, and LDL-C levels were measured (Figure 4). All parameters in the HD group were higher (by 76.6, 45.7, 37.1, 111, 24.8, and 172% increases respectively) than in the ND group, and all of them were decreased in the HMG50 group (by 30.2, 30.3, 29.7, 26.9, 15.3, and 39.1% decreases respectively, vs the HD group). In the HMG10 group, FFA, TC, and LDL-C levels were reduced (by 28.5, 23.3, and 18.4% decrease, respectively, vs the HD group). In particular, in the HMG50 group, the reduction in the LDL-C level was greater than that of the HDL-C level (by 39.1 and 15.3% decreasesfor LDL-C and HDL-C levels, respectively, vs the HD group). The ratio of HDL-C/LDL-C in the HMG50 group was significantly increased (by 38.5%) compared with the HD group. These results suggest that α-MG improved the serum lipid profile, which may result from the decrease in lipogenesis.

Effects of α-MG on Hepatic Fatty Acid Metabolism through the SirT1-AMPK Pathway. To investigate the involvement of α-MG in hepatic fatty acid metabolism, Western blotting analysis was performed as shown in Figure 5. First, the

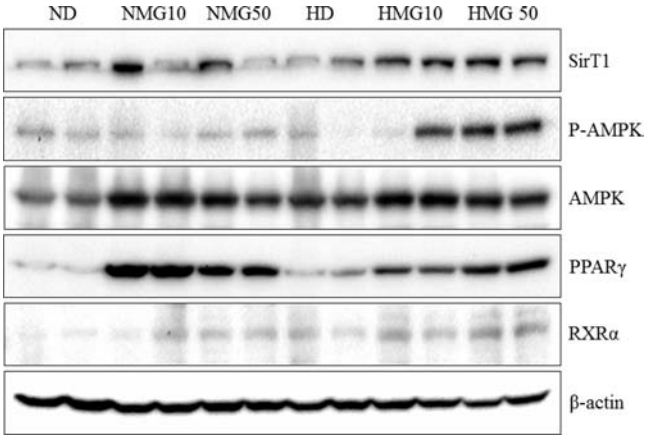

Figure 5. Protein levels of hepatic SirT1, phosphorylated AMPK, AMPK, PPARγ, and RXRα in liver were measured. SirT1, AMPK, PPARγ, and RXRα pathways regulate energy metabolism and hepatic lipid homeostasis.

protein levels of hepatic PPARγ and AMPK were increased in the HD group (vs the ND group); however, those of hepatic SirT1 and phosphorylated AMPK were much the same in the ND and HD groups. When ND-fed mice were supplied with 10 or 50 mg/kg α-MG, the protein levels of hepatic PPARγ and AMPK were remarkably amplified; however, α-MG seemed to negligibly affect the level of SirT1 and phosphorylated AMPK proteins. In HD-fed mice, an α-MG supplement up-regulated the hepatic PPARγ protein level in HD-fed mice, suggesting that α-MG acted as a hepatic PPARγ agonist. Interestingly, the protein levels of hepatic SirT1 and phosphorylated AMPK showed a different phenomenon with the α-MG supplement between ND- and HD-fed mice. In the HMG10 and HMG50 groups, protein levels of both hepatic SirT1 and phosphorylated AMPK were outstandingly increased compared with the HD group, suggesting that the hepatic SirT1 and AMPK axis was implicated in changes in fat accumulation in the liver, in parallel with the induction of hepatic PPARγ by α-MG. On the basis of these results, α-MG regulated the hepatic fatty acid metabolism through the SirT1 and AMPK pathways. Subsequently, the effects of α-MG treatment on the levels of lipogenic genes involved in fatty acid oxidation were determined in the liver. The protein expression of RXRα was stimulated in the HMG10 and HMG50 groups compared with the HD group, suggesting that the activated PPARγ and RXRα may form a heterodimer and bind to responsive DNA elements more effectively, thereby stimulating the transcription of genes related to lipid metabolism in the liver.

DISCUSSION

The present study provides the first in vivo evidence that α-MG attenuated hepatic steatosis through hepatic SirT1-AMPK and PPARγ pathways. As found in the experimental data, the hepatic fat accumulation was significantly attenuated, and the increase in hepatic TG content was decreased by α-MG compared with the HD group. All of these results were consistent with the changes in metabolic parameters.

A metabolic syndrome is defined as the combination of various symptoms of abdominal obesity, dyslipidemia, impaired glucose metabolism, hypertension, inflammatory responses,[18] and hepatic steatosis, the latter of which is referred to as a representative hepatic component of metabolic syndrome.[2,20] Typically, the high-fat diet is emerging as the most common cause for the overproduction and accumulation of lipids (mostly TG) within hepatocytes, which evolves into a line of diagnostic symptoms in hepatic steatosis with obesity patients.[19−22] Hepatic steatosis leads to the elevated influx of fatty acids, hepatic fat accumulation, and impaired export of TG and other cytotoxic factors, including oxidative stress, lipid peroxidation, and inflammatory cytokines[19] after excess intake of nutrients. Thus, the hepatic steatosis model in obese mice induced by a high-fat diet was utilized in this study.

The gross inspection of the HMG50 group indicates a clear recovery in body weight, fat mass, hepatic steatosis, and serum biochemical profiles relevant to lipid metabolism. The average values of food intake for 80 days were comparable among all groups, indicating that α-MG did not control appetite, but had a beneficial influence on fatty acid oxidation or cholesterol homeostasis.[20,23] In particular, the up-regulated serum glucose, FFA, TC, LDL-C, and TG were gradually reduced by α-MG in the HMG10 and HMG50 groups, and notably a significantly increased HDL-C and HDL/LDL-C ratio were observed. Moreover, the decreased TG content may result from decreased lipid synthesis. Because the high HDL-C/LDL-C ratio showed a positive correlation with a lower risk of cardiovascular disease, the 50 mg/kg α-MG treatment showed potential efficacy to ameliorate metabolic diseases.[24,25] In the HMG50 group, hepatic steatosis and abnormal liver function seemed to be recovered by 50 mg/kg α-MG supplementation, but 10 mg/kg α-MG seemed to reduce hepatic steatosis negligibly. The elevated ALT and AST levels in the HD groups were restored in the HMG10 and HMG50 groups, indicating that a high-fat diet resulted in abnormal liver function, and α-MG attenuated hepatic injury. With supplementation of 10 and 50 mg/kg α-MG with the ND, the normal liver state was

DOI: 10.1021/acs.jafc.5b01637
J. Agric. Food Chem. 2015, 63, 8399−8406

maintained, suggesting that α-MG itself did not cause liver injury. In addition, hepatic steatosis was recovered in the HMG50 group with respect to morphological aspects. Furthermore, no renal injuries were observed in any group of mice (Supporting Information 1). Taken together with body weight changes, hepatic steatosis, fat accumulation, and/or lipid metabolism, α-MG seemed to regulate hepatic steatosis and obesity. In particular, the body weight and liver weight changes seemed to be dose-dependent, because 50 mg/kg α-MG treatment significantly decreased body and liver weights, but there was no significant decrease at 10 mg/kg α-MG treatment compared to those in the HD group. A dose of 50 mg/kg of α-MG administered to mice is equivalent to approximately 320 mg/kg in the human adult, according to the interspecies dose conversions of NOAELs and previous reports.[26−28]

The Western blotting results clearly indicate that the hepatic SirT1 and phosphorylated AMPK levels were activated by α-MG in the HMG10 and HMG50 groups. Moreover, the protein expression of hepatic PPARγ and RXRα was stimulated by α-MG in the HMG10 and HMG50 groups.

AMPK, a downstream component of a protein kinase cascade, acts as an intracellular energy sensor to maintain energy balance. This pivotal role of AMPK makes it an ideal candidate for regulating whole-body energy metabolism such as glucose homeostasis and lipid metabolism, and additionally AMPK may play a role in protecting the body from metabolic diseases with obesity.[29,30] Along with AMPK phosphorylation, SirT1, a nuclear protein, plays a key role in controlling the transcription factors related to energy metabolism.[31] The specific SirT1 activator enhances oxidative metabolism in liver and skeletal muscle,[29] which may regulate whole-body glucose metabolism both systemically and locally.[31,32] Activation of SirT1 mimics several metabolic aspects of calorie restriction that enhance selective nutrient utilization and mitochondrial oxidative function.[32] The AMPK/SirT1 signaling pathway is, furthermore, the mechanism by which hormones enhance mitochondrial metabolism.[32,33] Regulation of AMPK and SirT1 is a potential therapeutic target for attenuation of fatty acid oxidation in liver.[33] The functions of these enzymes are like a fuel gauge: they are activated under conditions of high-energy depletion.[33] Phosphorylation of AMPK leads to the down-regulation of lipid biosynthesis by phosphorylating of acetyl-CoA carboxylase, which decreases the amount of malonyl-CoA and, in turn, suppresses carnitine palmitoyl-CoA transferase, resulting in an increase of fatty acid oxidation.[34] In addition, PPARγ forms heterodimers with the RXR that regulate the lipid metabolism.[35,36] SirT1 and PPARγ might coordinate the regulation of adipogenesis.[37−39] We have found that α-MG suppressed lipid accumulation in the mouse model. Although α-MG has also been found to be effective in fatty liver by PPARγ activation, the interplay between the AMPK signaling pathway and regulation of lipid disorders remains unclear.

The administration of α-MG to HF-induced obese mice reduced body-weight gain, adipose mass, serum triglyceride, total cholesterol, and low-density lipoprotein concentration. Our results suggest that α-MG exerts antiobesity effects in HF-induced obese mice by activating hepatic AMPK, SirT1, and PPARγ expression. The antiobesity effect of α-MG in HF-induced mice may support the potential of α-MG to reduce the risks of metabolic diseases.

study was to evaluate whether EGCG attenuates aging-associated metabolic disorders through modulation of the insulin signaling pathway, mitochondrial function, and lipid metabolism in skeletal muscle and liver using SAMR1 and SAMP8 models.

MATERIALS AND METHODS

Materials. EGCG (TEAVIGO, DSM), a highly purified extract from green tea leaves (*Camellia sinensis*) containing >94% EGCG and <5% other catechins,[16] was a gift from Gemfont Corp. (Taipei, Taiwan). For Western blotting, primary antibodies Akt, phospho-Akt (Thr308), phospho-AS160 (Thr642), AMP-activated protein kinase α (AMPKα), phospho-AMPKα (Thr172), GLUT4, mammalian target of rapamycin (mTOR), phospho-mTOR (Ser2448), and peroxisome proliferator-activated receptor gamma coactivator 1-α (PGC1α) were purchased from Cell Signaling Technology (Danvers, MA, USA). Akt substrate of 160 kDa (AS160) was from Millipore (Billerica, MA, USA), and GAPDH was from GeneTex (Hsinchu City, Taiwan). Secondary antibodies goat anti-rabbit and sheep anti-mouse HRP conjugated antibodies were purchased from Bio-Rad (Hercules, CA, USA) and GE Healthcare Life Sciences (Pittsburgh, PA, USA), respectively.

Animals. The senescence-accelerated mouse-prone 8 (SAMP8, n = 30) and senescence-accelerated mouse-resistant 1 (SAMR1, n = 9) mice were obtained from Providence University (Taichung, Taiwan). Animal experiments were approved by the Institutional Animal Care and Use Committee of National Cheng Kung University. Mice were individually caged in an air-conditioned animal facility at 20 ± 2 °C on a 12 h light/dark cycle and were maintained with free access to water and normal chow diet (LabDiet 5010, St. Louis, MO, USA). Body weight and food intake were measured weekly. At the age of 28 weeks, SAMP8 mice were divided into two groups: SAMP8 mice (n = 15) were fed chow diet; SAMP8 mice administered 0.32% EGCG (n = 15) were fed chow diet consisting of 0.32% EGCG (3.2 g EGCG/kg chow diet) for 12 weeks. The presently used dose of EGCG has been reported to effectively inhibit obesity, metabolic syndrome, and fatty liver disease in high-fat-fed mice.[17] At the age of 40 weeks, animals were fasted overnight and then euthanized. After decapitation, blood was immediately collected and centrifuged at 3000 rpm, and the supernatant was collected. Tissues were isolated immediately and stored at −80 °C for further analysis.

Glucose, Insulin, and Free Fatty Acid Measurement. Serum glucose levels were measured by ACCU-CHEK (Roche, Switzerland). Serum insulin levels were measured by mouse insulin ELISA kit (Mercodia, Uppsala, Sweden) according to the manufacturer's instructions. Serum FFA levels were measured by colorimetric kit (BioVision, Milpitas, CA, USA) according to the manufacturer's instructions.

ALT and AST Activities and TG Measurement. For ALT and AST activities, liver samples (~10 mg) were measured by colorimetric assay kit (BioVision) according to the manufacturer's instructions.

To solubilize TG, liver samples (~50 mg) were homogenized in 5% NP-40. The samples were slowly heated to 100 °C for 5 min and then cooled, and the heating procedure was repeated once more. Samples were centrifuged for 2 min at top speed to remove any insoluble material and were diluted 10-fold with distilled water followed by the manufacturer's instructions (BioVision).

Liver Histology and Oil Red O Staining. Fresh liver tissues were fixed in 10% buffered formaldehyde solution and embedded in paraffin. Embedded liver tissue blocks from SAMP8 and SAMR1 mice were cut into 5 μm sections and stained with hematoxylin and eosin. For oil red O (ORO) staining, frozen liver tissues were embedded in OCT compounds and were cut into 20 μm sections. The sections were stained with 0.4% ORO solution (Sigma, St. Louis, MO, USA) for 5 min and then rinsed in tap water. Images were observed under a microscope (Zeiss, Germany) and captured with a digital camera (Nikon, Japan). Quantification of neutral lipids by ORO analysis in liver was performed using ImageJ.[18]

Western Blot. Skeletal muscle and liver samples were homogenized in ice-cold RIPA buffer (Cell Signaling Technology) containing 1 mM phenylmethanesulfonyl fluoride, and the supernatant was obtained by centrifugation. Total protein in the supernatant was measured by the BCA method (Bio-Rad), and the supernatant was obtained by centrifugation. An equal amount of protein for each preparation was added to 6× Laemmli sample buffer, separated by SDS-PAGE, transferred to PVDF membrane, blocked with 5% nonfat dry milk in 0.1% Tween-Tris buffered saline, and incubated in 5% dry milk Tween-Tris buffered saline with different primary antibodies. Membranes were then washed and incubated with horseradish peroxidase-conjugated secondary antibodies in Tween-Tris buffered saline with 5% nonfat dry milk. Protein bands were visualized using a Chemiluminescence kit (Millipore, Billerica, MA, USA). Quantitative results of Western blotting were performed using the LAS-4000 mini biomolecular imager (GE HealthCare Life Sciences).

RNA Extraction and Real-Time PCR. Total RNA was extracted from skeletal muscle and liver samples by using Trizol/chloroform procedure (Gibco BRL, Rockville, MD, USA) and quantified by using a NanoDrop meter. Total RNA (1 μg) was reverse transcribed into cDNAs by using the kit (Invitrogen, Grand Island, NY, USA) according to the manufacturer's instructions. mRNA levels were quantified using StepOnePlus Real-Time systems (Applied Biosystems, Foster City, CA, USA). Primer sequences are shown in Table 1. Real-time PCR was performed using Fast Start SYBR Green master mix kit (Applied Biosystems). Each cDNA sample was run in triplicate, and GAPDH as an internal control gene was included in each run to correct sample-to-sample variation and to normalize mRNA levels.

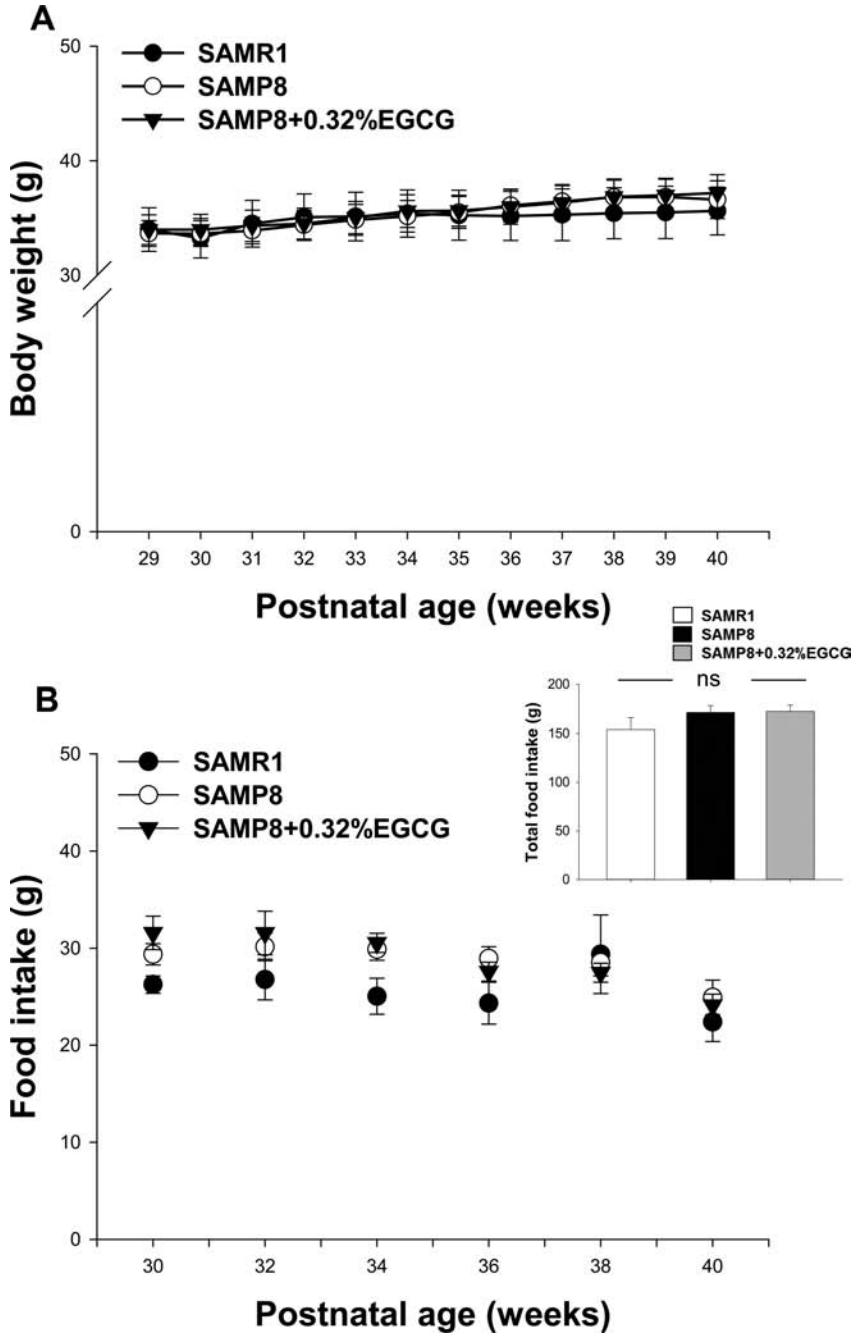

Figure 1. (A) Body weight and (B) mean weekly food intake and total food intake of SAMR1, SAMP8, and SAMP8 + 0.32 EGCG mice. Results are expressed as means ± SEM.

The relative mRNA level was calculated according to the comparative ΔΔCt method.

DNA Extraction and Quantification. Genomic DNA from skeletal muscle and liver samples was prepared using a commercial kit according to the manufacturer's instructions (Zymo Research, Irvine, CA, USA). The relative copy numbers of mitochondrial and nuclear DNA were determined by real-time PCR with specific primers. Ct values were determined for MTCO2 gene encoded by mitochondrial DNA and 18S rRNA gene encoded by the nuclear DNA. The relative mtDNA copy number was calculated by normalizing to 18S rRNA gene copy number.[19] Primer sequences are shown in Table 1.

Statistical Analysis. Results are expressed as means ± SEM. The one-way ANOVA was used to determine the statistical significance of the differences among the groups and following post hoc assessment by Student−Newman−Keuls method correction for multiple comparisons (SigmaPlot 12.0). Different lower case letters indicate significant differences among groups at a P of ≤0.05 by one-way ANOVA.

RESULTS

Body Weight, Food Intake, and Metabolic Parameters. No significant differences in body weight and food intake were observed between SAMR1 and SAMP8 mice (Figure 1). Administration of EGCG for 12 weeks did not affect body weight and food intake of SAMP8 mice. The levels of fasting glucose, insulin, and FFA were significantly increased in SAMP8 mice compared with age-matched SAMR1 at 40 weeks old (Table 2). After administration of EGCG for 12 weeks, the levels of fasting glucose and insulin in SAMP8 mice were similar to those in SAMR1 mice (Table 2).

Table 2. Fasting Serum Glucose, Insulin, and FFA after 12 Weeks of EGCG Treatment[a]

	Glucose (mg/dL)	Insulin (pmol)	FFA (μmol)
SAMR1	246.6 ± 14.9[a]	62.2 ± 19.9[a]	4.12 ± 0.57[a]
SAMP8	286.0 ± 6.7[b]	129.5 ± 9.7[b]	6.42 ± 0.45[b]
SAMP8 + 0.32% EGCG	254.7 ± 7.5[a]	99.1 ± 13.5[ab]	6.76 ± 0.48[b]

[a]Serum samples were collected from 40-week-old SAMR1, SAMP8, and SAMP8+EGCG mice after overnight fasting. Data are means ± SEM (n = 8−14/group). Significance (P < 0.05) among groups is denoted by different letters.

Effects of EGCG on Insulin Signaling Pathway and AMPKα in Skeletal Muscle. The levels of key proteins involved in the insulin signaling pathway (Akt, pAkt, AS160, pAS160, and GLUT4) were measured by Western blotting. Significantly decreased Akt activity, increased AS160 activity, and decreased protein expression of GLUT4 were observed in SAMP8 mice compared with age-matched SAMR1 (Figure 2A−D), supporting insulin-resistant conditions observed in skeletal muscle of SAMP8 mice. EGCG normalized Akt activity and promoted the protein expression of GLUT4 (123%) in SAMP8 mice compared with age-matched SAMR1. AMPK is a key molecule responsible for non-insulin-mediated glucose uptake. A marked increase in AMPKα activity (146%) was observed in SAMP8 mice after 12 weeks administration of 0.32% EGCG (Figure 2E).

Effects of EGCG on Mitochondrial Function in Skeletal Muscle. Mitochondrial dysfunction in skeletal muscle is highly associated with insulin resistance. PGC1α is a master regulator involved in mitochondrial biogenesis and function. Nuclear respiratory factor 1 (Nrf1), a downstream target of PGC1α and an important transcription factor, stimulates the expression of mitochondrial proteins such as oxidative phosphorylation components and regulates the expression of mitochondrial transcription factor A (Tfam), thereby affecting mitochondrial DNA (mtDNA) replication and expression. Significantly decreased PGC1α protein expression (Figure 3A,B) and mtDNA/nuclear DNA ratio (Figure 3C) were observed in SAMP8 mice compared to age-matched SAMR1 mice. EGCG restored mtDNA/nuclear DNA ratio in SAMP8 mice to the level observed in SAMR1 mice (Figure 3C). EGCG did not affect PGC1α protein expression after 12 weeks of administration. Significantly decreased SIRT1 mRNA expression in SAMP8 mice was restored by EGCG (Figure 3D). EGCG resulted in a marked increase in Nrf1 mRNA expression (267%), thereby stimulating gene expression of downstream targets including Tfam (330%), mitochondrial complex I Ndufs8 (178%), and complex IV Cox5b (127%) mRNA expression in comparison with SAMR1 mice and SAMP8 mice without EGCG feeding (Figure 3D).

Effects of EGCG on Histopathology and Function of Liver. As shown in Figure 4B, SAMP8 mice displayed fatty infiltration with macro- and microvesicles in the liver. Staining neutral lipids and lipid droplets with ORO further demonstrated fatty liver in SAMP8 mice (Figure 4E,G). In contrast, lipid droplets were rarely observed in SAMR1 mice (Figure 4D,G). In line with morphological observation, hepatic TG was significantly increased in SAMP8 mice (Figure 4H), which demonstrated excess lipid accumulation in liver of SAMP8 mice. After 12 weeks of EGCG treatment, a marked reduction in hepatocyte ballooning and fewer lipid droplets were observed (Figure 4C,F). Normalization of hepatic TG to the level of SAMR1 mice was also observed after 12 weeks of EGCG treatment (Figure 4H). Significantly increased ALT activity was observed in SAMP8 mice compared with age-matched SAMR1 mice (Figure 4I). EGCG normalized hepatic ALT activity to the level of SAMR1 mice after 12 weeks of treatment (Figure 4I). No significant difference in hepatic AST activity was observed among three groups (Figure 4J).

Effects of EGCG on Lipid Metabolism, Inflammation, and Mitochondrial Function in Liver. Promoted de novo lipogenesis through up-regulated transcription factors by insulin and glucose results in increased hepatic lipid accumulation in liver of SAMP8 mice. Marked increases in sterol regulatory element-binding proteins-1c (SREBP-1c) (277%) and carbohydrate-responsive element-binding protein (ChREBP) (224%), transcription factors involved in the biosynthesis of fatty acids, in conjunction with significant decreased adipose triglyceride lipase (ATGL) gene expression, a rate-limiting enzyme in TG hydrolysis, were observed in liver of SAMP8 mice (Figure 5A). These results indicate that accelerated aging-associated lipid accumulation in liver is through reduced hepatic TG hydrolysis and increased hepatic TG biosynthesis. Furthermore, NFκB, a master regulator of pro-inflammatory signaling pathway, was significantly increased at mRNA level in SAMP8 mice. EGCG significantly suppressed SREBP-1c and attenuated NFκB mRNA expression, but did not affect ChREBP and ATGL mRNA expression (Figure 5A). The mTOR pathway has been shown to activate SREBP-1c expression. Therefore, normalization of SREBP-1c mRNA to the level of SAMR1 (Figure 5A) was, at least in part, attributed to inhibition of mTOR activity via suppressing the positive regulator, Akt, and activating the negative regulator, AMPK, by EGCG (Figure 5B−E). Significantly decreased PGC1α protein expression and mtDNA/nuclear DNA ratio were observed in the liver of SAMP8 mice compared to those of age-matched SAMR1 mice (Figure 6A−C). EGCG did not affect these two at the present dose. No differences in SIRT1, PGC1α, Nrf1, Tfam, mitochondrial complex I, and complex IV at mRNA levels were observed in liver among the three groups (Figure 6D).

DISCUSSION

Aging per se is an independent risk factor for the development of insulin resistance. As a result, impairment of glucose homeostasis in peripheral tissues such as skeletal muscle occurs during the aging progress.[20] In this study, higher levels of glucose and insulin observed in SAMP8 mice compared to the normal aging group, SAMR1 mice, suggest that the accelerated aging mouse model is suitable for studying the underlying mechanism of aging-associated insulin resistance. EGCG, the most abundant component in green tea, improves insulin sensitivity in different rodent models.[16,17,21] In this study, EGCG successfully attenuated aging-associated insulin resistance in SAMP8 mice.

In the present study, hyperglycemia and hyperinsulinemia were observed in SAMP8 mice at the age of 40 weeks. In line with our data, elevated insulin levels and increased insulin resistance index (HOMA-IR) in SAMP8 mice at similar age were reported by another group.[9] Postreceptor defects in skeletal muscle of SAMP8 mice may impair glucose homeostasis, because it is the major peripheral tissue responsible for insulin-mediated glucose uptake.[22] Defective insulin signaling pathway including inhibition of PI3K/Akt pathway and decreased GLUT4 expression, which have been considered as

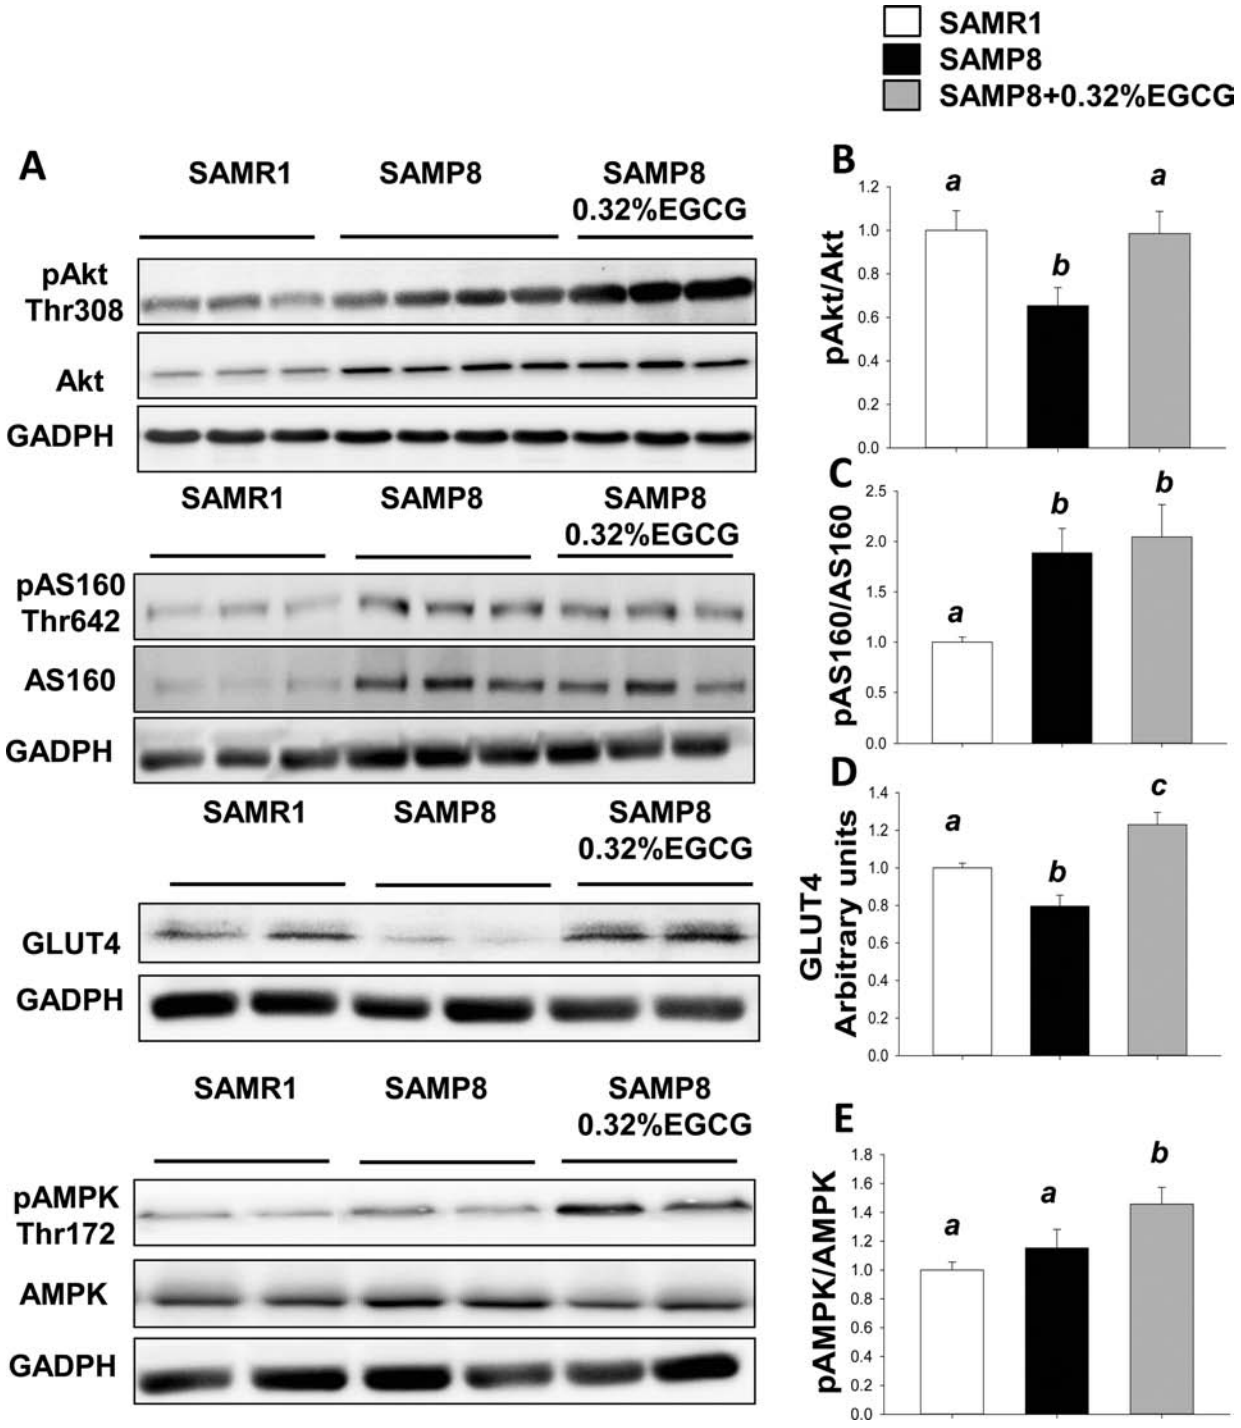

Figure 2. Insulin signaling pathway and AMPKα in skeletal muscle: (A) Representative blots are shown. (B−E) Values presented are means ± SEM (n = 6−8/group). Equal amounts of mouse tissue lysates were analyzed using Western blotting with anti-phospho-Akt (Thr308), anti-Akt, anti-phospho-AS160 (Thr642), anti-AS160, anti-GLUT4, anti-phospho-AMPKα (Thr172), and anti-AMPKα antibodies. Statistical analysis was performed using ANOVA followed by post hoc analysis using Student−Newman−Keuls method. Significance (P < 0.05) among groups is denoted by different letters.

the pathophysiology of skeletal muscle insulin resistance,[23,24] were observed in SAMP8 mice of the present study. In the search for popular natural products, EGCG reveals beneficial effects on obesity and diabetes ranging from in vitro cell models[12,25] to in vivo studies by using different diabetic and/or obese rodent models.[16,17,21,26,27] The underlying mechanism of alleviating FFAs-induced insulin resistance by EGCG was reported to suppress serine phosphorylation of PKCθ and IRS1, enhance AMPK activity, and stimulate GLUT4 translocation in rats.[28] Here, we demonstrated that EGCG exhibited beneficial effects on aging-associated insulin resistance in SAMP8 mice via not only enhanced AMPK activity but also restored Akt activity and stimulated GLUT4 protein expression. Restored GLUT4 expression by EGCG in SAMP8 mice could be attributed to AMPK activation, because AMPK directly

regulates the GLUT4 expression through phosphorylation of histone deacetylase 5.[29]

Distinct from the insulin signaling pathway, perturbation in mitochondrial function has been considered as a novel mechanism involved in the development of insulin resistance, especially in the older age groups.[30,31] Significantly decreased PGC1α and mtDNA copy number in skeletal muscle of SMAP8 mice reveal mechanisms linking defective mitochondrial biogenesis to insulin resistance. Beyond insulin resistance, mitochondrial dysfunction occurred in SAMP8 mice contributes to the shorter lifespan of these mice.[32] Pharmacological and nutritional agents have been used to promote AMPK and SIRT1 activities and subsequently activate PGC1α function and boost mitochondrial biogenesis.[31,33,34] With regard to the effect of EGCG on mitochondrial biogenesis in SAMP8 mice, it restored SIRT1 gene expression and stimulated AMPK activity, leading to enhanced transcription factors such as Tfam and NRF1 accompanied by restored mtDNA copy number and promoted mitochondrial complex I and IV at mRNA levels in the present study.

Fatty liver, including hepatocellular ballooning and lipid accumulation, was observed in SAMP8 mice of our and others' studies.[11,35] The underlying mechanism of spontaneous fatty liver in SAMP8 mice could be due to an imbalance between

J. Agric. Food Chem. 2015, 63, 8407−8417

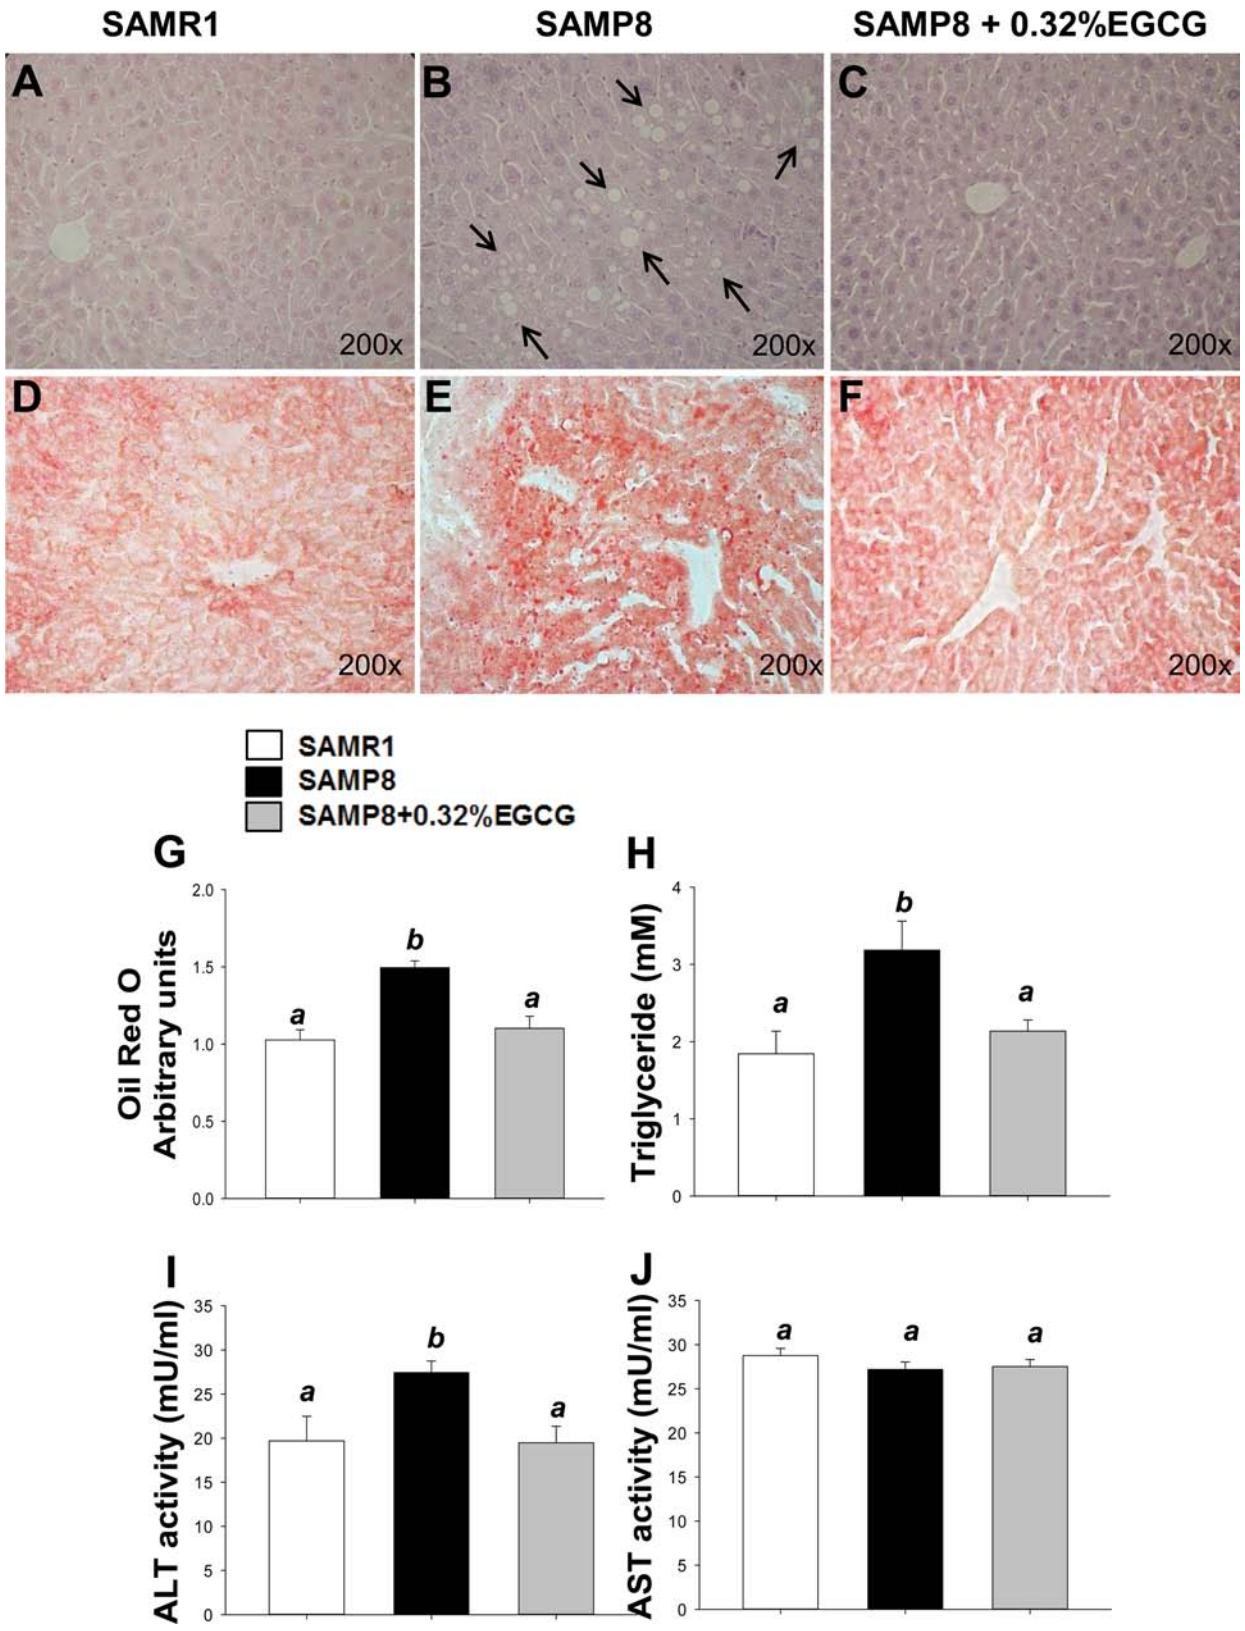

Figure 4. Fatty liver in SAMR1, SAMP8, and SAMP8 + 0.32% EGCG mice: hepatic histological analysis (A–C) stained with hematoxylin and eosin (200×) (arrows indicate the accumulation of TG as macro- or microvesicles (B)); visualization (D–F) and quantification (G) of neutral lipids stained with ORO solution in liver; TG concentration, ALT activity, and AST activity in liver (n = 6–11/group) (H–J).

lipid supply and demand during aging. At the age of 40 weeks, SAMP8 mice elevated serum FFA levels because enhanced TG lipolysis and reduced FFA esterification in adipose tissue result in rising circulating FFA levels under insulin-resistant conditions.[36] It is reasonably assumed that elevated circulating FFA entered hepatocytes and were subsequently esterified into

TG, leading to excessive accumulation of TG in the liver of SAMP8 mice. Up-regulation of nuclear transcription factors including SREBP-1c and ChREBP, responsible for de novo fatty acid synthesis, was observed in SAMP8 mice. Promoted de novo lipogenesis via the activation of two transcription factors in the liver is attributed to higher levels of insulin and glucose.[10] TG hydrolysis and fatty acid oxidation are essential processes to prevent excessive TG accumulation in the liver. Decreased TG hydrolysis was observed by ATGL knockdown in vitro.[37] Here, we found a marked decrease in ATGL gene expression of SAMP8 mice. Suppressed ATGL expression, the key enzyme for the breakdown of TG, could attenuate intrahepatic TG hydrolysis, thus preventing fatty acid oxidation. Loss of mitochondrial function and impaired fatty acid oxidation are causative factors in excessive TG accumulation in the liver of Otsuka Long-Evans Tokushima Fatty rats.[38] In agreement with the previous study,[38] decreased PGC1α protein expression and mtDNA copy number in SAMP8 mice were correlated with a decrease in mitochondrial biogenesis, which could result in a reduced rate of mitochondrial fatty acid oxidation and consequently cause excessive TG accumulation. Up-regulation of mitochondrial biogenesis was not observed in EGCG treated mice. Meng et al. reported that administration of EGCG (500 mg/kg diet) for 6 months protected mitochondrial integrity

Statistical analysis was performed using ANOVA followed by post hoc analysis using Student−Newman−Keuls method. Significance (P < 0.05) among groups is denoted by different letters.

including restored mitochondrial membrane potential of lymphocytes and increased mitochondrial DNA deletion in the liver of rats.[39] The main discrepancy between their study and ours could be attributed to the duration of administration (6 months vs 12 weeks). In another study, SAMP8 administered melatonin, a direct free radical scavenger and an indirect antioxidant, from 7 to 12 months of age (6 months), led to a significant increase in mitochondrial complex I and IV activities in the liver of melatonin-treated SAMP8 mice.[40] Taken together, these results indicate that the protective effects may depend on the duration of treatment.

Reduced hepatic TG contents by EGCG in SMAP8 mice are consistent with an earlier study using high-fat-fed rodent models.[17] Beneficial effects of EGCG on lowering hepatic TG

DOI: 10.1021/acs.jafc.5b02501
J. Agric. Food Chem. 2015, 63, 8407−8417

levels in SMAP8 mice are attributed to modulation of SREBP-1c expression via inhibiting mTOR activity and/or decreasing insulin levels. Inhibition of mTOR by rapamycin, an mTOR inhibitor, leads to repressed SREBP-1c protein expression and subsequently inhibits lipid accumulation in orotic acid-induced fatty liver.[41] Furthermore, Akt and AMPK, two major upstream regulators of mTOR, were down- and up-regulated by EGCG in SAMP8 mice, respectively. Akt, the positive regulator of mTOR, was suppressed by EGCG within physiologically relevant concentrations;[42] on the other hand, AMPK activation results in the inhibition of mTOR.[41] Therefore, the molecular mechanism underlying the reduction of fatty acid synthesis by EGCG was attributed to suppression of SREBP-1c at mRNA level via inhibiting the mTOR pathway. In addition to mTOR, insulin is a well-known stimulator of lipogenesis and activates hepatic SREBP-1c expression at the transcriptional level.[43] For this reason, it is likely that the restoration of SREBP-1c mRNA in SAMP8 back to the level of SAMR1 mice was due to lower insulin levels by EGCG. Decreased ALT and NFκB activities by EGCG have been reported in NAFLD rodent models.[14,17] In accordance with these studies, we found that EGCG reduced liver injury and inflammatory status, such as decreased ALT activity and attenuated NFκB gene expression in SAMP8 mice. Reduced liver damage via inhibiting the NFκB-induced inflammatory signaling pathway in healthy rats is thought to be the potential mechanism in the extension of lifespan after long-term administration of EGCG.[15]

Decreased respiratory quotient by EGCG has been observed in obese mice, suggesting that EGCG stimulates fatty acid oxidation.[44] Results from the present study indicate that EGCG up-regulates genes related to mitochondrial function in skeletal muscle of SAMP8 mice. Therefore, it is speculated that the increased FFA influx to skeletal muscle, together with the activation of key enzymes in lipid catabolism by EGCG, leads a marked increase in muscle fatty acid oxidation. Simultaneously, fewer FFA are taken up by the liver thereby preventing lipid accumulation in liver. Taken together, it is suggested that skeletal muscle participated in preventing TG accumulation in the liver of SMAP8 mice.

In conclusion, SAMP8 mice exhibited higher levels of insulin, glucose, and FFA, and defective insulin signaling and mitochondrial dysfunction in skeletal muscle are suitable models for the investigation of aging-associated insulin resistance. Increased SREBP-1c and ChREBP involved in lipogenesis and decreased gene responsible for TG hydrolysis result in lipid accumulation leading to the development of fatty liver in SAMP8 mice. Dietary supplementation of SAMP8 mice with EGCG for 12 weeks alleviates aging-associated skeletal muscle insulin resistance via stimulating AMPKα activity, restoring Akt activity and GLUT4 protein expression, and enhancing mitochondrial biogenesis. EGCG prevents fat accumulation in the liver, at least in part, through inhibition of mTOR activity and down-regulation of SREBP-1c mRNA. Overall, our results indicate that EGCG as an antiaging agent is beneficial for aging-associated metabolic disorders.

ABBREVIATIONS USED

AMPKα: AMP-activated protein kinase α
ATGL: adipose triglyceride lipase
ChREBP: carbohydrate-responsive element-binding protein
EGCG: (−)-epigallocatechin-3-gallate
FFA: free fatty acids
GLUT4: glucose transporter 4
IRS1: insulin receptor substrate 1
mTOR: mammalian target of rapamycin
NAFLD: nonalcoholic fatty liver disease
NFκB: nuclear factor-κB
Nrf1: nuclear respiratory factor 1
ORO: oil red O
PGC1α: proxisome proliferator-activated receptor gamma coactivator 1-α
PI3K: phosphatidylinositol-3-kinases
PKC: protein kinase C
SAM: senescence-accelerated mice
SIRT1: sirtuin1
SREBP-1c: sterol regulatory element binding proteins-1c
Tfam: mitochondrial transcription factor A
TG: triglycerides

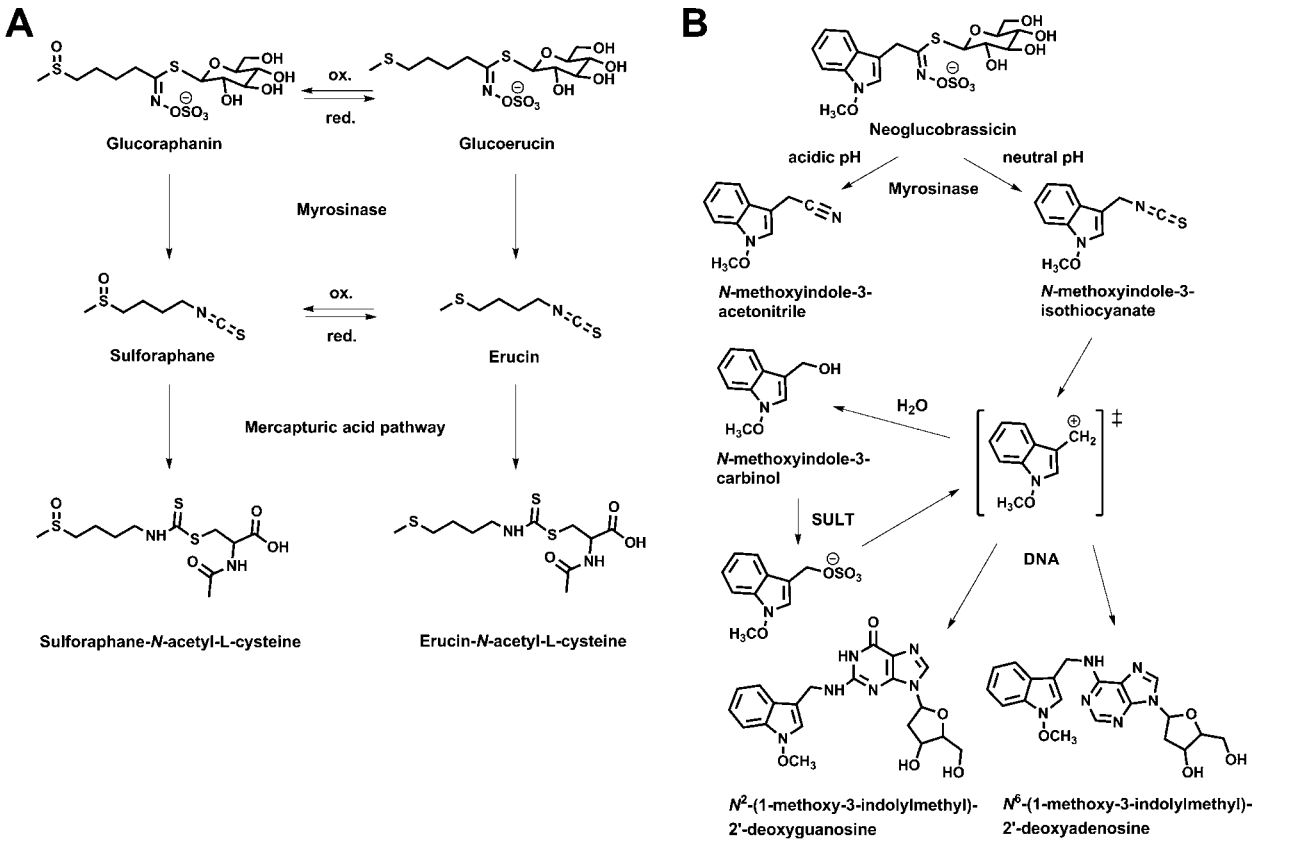

Figure 1. Chemical structures of (A) glucoraphanin, (B) neoglucobrassicin, and their metabolites following myrosinase-catalyzed hydrolysis and further reaction products (mercapturic acids, DNA adducts) investigated in the present study. SULT, sulfotransferase.

(methylthio)butyl glucosinolate, GER] was from Phytolab GmbH & Co. KG (Vestenbergsgreuth, Germany). NGBS was isolated from Pak Choi with a purity of >99% according to Baasanjav-Gerber et al.[3] *N*-Methoxyindole-3-carbinol (NI3C) and *N*-methoxyindole-3-acetonitrile were synthesized and provided by Dr. Albrecht Seidel (Biochemical Institute for Environmental Carcinogens, Professor Dr. Gernot Grimmer-Foundation, Germany) as described previously.[13] Myrosinase, *N*-(*tert*-butoxycarbonyl)-L-cysteine methyl ester (*N*-*t*Boc-Cys-ME), cysteinylglycine, *N*-acetyl-L-cysteine, L-glutathione, and trifluoroacetic acid were purchased from Sigma-Aldrich (Steinheim, Germany). Potassium dihydrogen phosphate, dipotassium hydrogen phosphate, ethyl acetate, L-cysteine, acetonitrile, and MeOH (both HPLC-grade) were obtained from Roth (Karlsruhe, Germany). Ethanol (HPLC-grade) was obtained from VWR (Darmstadt, Germany). All aqueous solutions were prepared with ultrapure water purified with Ultra Clear UV UF (Barsbüttel, Germany). *N*-*t*Boc-Cys-ME stock solution (1.068 M in MeOH) was prepared fresh daily with 100% MeOH and was further diluted to a 427 mM working solution with 60% MeOH (v/v).

Mercapturic acid conjugates of SFN and ERU were prepared as reference substances for the detection and quantification as described by Kassahun[14] and Vermeulen.[15] Briefly, isothiocyanates were dissolved in ethanol and gradually added to the corresponding reagent solution (*N*-acetyl-L-cysteine, L-cysteine, cysteinylglycine, or L-glutathione). The mixture was allowed to react during 24 h of stirring at room temperature. After removal of the solvents using a vacuum centrifuge (Jouan SpeedVac RC 1020, Saint Herblain, France), the structure and purity of all analytical standards were investigated by HPLC-flow-inject electrospray ionization mass spectrometry and nuclear magnetic resonance spectroscopy.

Animals and Treatments. To investigate the role of human gut bacteria in the bioactivation of GRA and NGBS in vivo, animal experiments were carried out using HMA mice in comparison to germ free mice. Animal experiments were conducted in accordance with the institutional and national guidelines for the care and use of laboratory animals. All experimental procedures were approved by the Animal Welfare Committee of the local authority (Landesamt für Verbraucherschutz, Landwirtschaft and Flurneuordnung, Frankfurt/Oder, Germany) under approval number 23-2347-4-2010. The mice were housed in isolators under controlled temperature and lighting conditions (23 °C, 12 h light/dark cycle) and had free access to irradiated food (50 kGy) and autoclaved water.

Eight week old germ free mice were associated with fecal microbiota from a healthy human female donor. A fresh fecal sample was transferred to an anaerobic hood, diluted 1:10 with reduced phosphate buffer (PBS, in g/L: NaCl 8.5, KH_2PO_4 0.3, Na_2HPO_4 0.6, cysteine × HCl × H_2O 0.25, Bacto peptone 0.1, and resazurine 0.001, pH 7) and the resulting slurry subsequently diluted 1:5 with glycerol and stored at −80 °C until use. For association of the germ free mice, 200 μL of the suspension was applied to each animal by gavage. The ability of the donor's microbiota to activate GLS was not affected by this procedure as cecal and colonic contents of the recipient mice displayed similar activities (data not shown).

For practical reasons, animal experiments were carried out consecutively. Inoculation with frozen material ensured the same composition and quality of inoculation material for all experiments, as it is known that the microbial composition of a human donor changes over time.[16] We previously demonstrated that fecal material for inoculation can be stored after freezing and be transferred to germ free rodents by inoculation of the frozen fecal material. Counts of bacterial strains in cecal, colonic, and fecal material were comparable to those of gnotobiotic animals that received the bacteria live.[17]

The stability of the intestinal microbiota composition in mice was monitored throughout the study by PCR-coupled denaturing gradient gel electrophoresis as described previously.[18] The microbiological status of germ free mice was confirmed as described previously.[19] Throughout the study, the fecal microbiota of the HMA mice had up to 51% similarity to that of the human fecal donor sample. Similarity of

DOI: 10.1021/acs.jafc.5b02948
J. Agric. Food Chem. 2015, 63, 8418−8428

fecal microbiota within a human individual usually varies between 65 and 88% within a certain time frame.[16] Similarities did not differ significantly between time points. These data correspond to those reported in a previous long-term study with rats.[20]

Glucoraphanin Treatment. Male, 8-week-old germ free C3H/HeOuJ mice (Charles River Laboratories International, Sulzfeld, Germany, $n = 30$) were associated with human intestinal microbiota by intragastric application of a human fecal suspension (diluted 1:50 in reduced phosphate buffer, pH 7, containing in g/L of 80% glycerol: NaCl 8.5, KH_2PO_4 0.3, Na_2HPO_4 0.6, cysteine × HCl × H_2O 0.25, Bacto peptone 0.1, resazurine 0.001) or water as a control. We investigated fecal samples from several human donors for their glucosinolate-degrading activity in relation to their habitual Brassica intake. However, we did not observe any correlation between the intake of Brassica vegetables and the rate of glucosinolate hydrolysis in their fecal slurries. The animals were fed the standard diet (Altromin, Lage, Germany) for 2 weeks after association to allow bacteria to colonize the animals' gut. Thereafter, they were switched to a GLS-free semisynthetic diet (Altromin C1000f, Lage, Germany).

After 2 weeks on this diet, at 12 weeks of age, 10 mice per group received once an oral dose of glucoraphanin (172 mg/kg body weight) or glucoraphanin in combination with myrosinase (17 U/kg body weight) as a positive control or water as a negative control. The latter served to assess the absorbance by proteins in the sample. For application, glucoraphanin and myrosinase were dissolved in autoclaved ultrapure water and sterilized by membrane filtration (0.22 μm pore diameter). The GRA dose of 7.2 μmol corresponds to approximately 35 or 60% of the total daily GLS dose administered in a recent study to mice in the form of GLS-enriched broccoli or pak choi.[21] The activity of myrosinase administered together with GRA was sufficient to cleave the GRA completely within 22 min in vitro (data not shown).

Urine and feces were collected using metabolic cages (Tecniplast, Hohenpeißenberg, Germany) over 48 h after application. The collected samples were pooled for every 12 h. Urine samples were centrifuged for 5 min at 20.000*g* and 5 °C. The resulting supernatants and the feces were frozen at −80 °C until further analysis. Finally, mice were anesthetized, and blood was taken by cardiac puncture. The blood was centrifuged at 2.000*g* for 10 min at 4 °C, and the resulting plasma was stored at −80 °C. The gastrointestinal tract was removed and divided into three segments: cecum, small intestine, and colon. The tissue and contents from each segment were collected and immediately frozen at −80 °C until further analysis.

Neoglucobrassicin Treatment. The NGBS experiment was conducted in the same way as the GRA experiment but with the following modifications: Since NGBS was not commercially available and isolation from plant material was very time-consuming, the number of animals was reduced to $n = 5$ per group. NGBS (297 mg/kg body weight) or water as a negative control was orally administered to HMA and germ free animals. The latter served to assess the absorbance of proteins in the sample. To identify a dose that causes detectable adduct levels in colonic and cecal tissue of mice in response to the oral administration of neoglucobrassicin, we performed preliminary experiments. We tested doses of 60, 200, and 600 μmol/kg body weight, and the latter dose was considered to be most suitable. The germ free animals received NGBS in combination with myrosinase (29 U/kg body weight) as a positive control. For HMA mice, the positive control was omitted. The activity of myrosinase administered together with NGBS was sufficient to cleave the NGBS completely within 22 min in vitro (data not shown). The mice were killed 8 h after NGBS application, and urine and feces were pooled during this period. Cecal and colonic tissues were shock-frozen in liquid nitrogen and stored at −80 °C until DNA adduct analysis.

Analysis of Glucosinolates and Their Metabolites in Biological Samples. *Glucoraphanin.* The analysis of GRA and its potential metabolites GER, SFN, and ERU was performed as described previously.[22] Briefly, each sample was analyzed twice: SFN and ERU were determined directly after derivatization with *N*-*t*Boc-Cys-ME. GRA and GER were determined indirectly after enzymatic hydrolysis to SFN and ERU, respectively. The GRA and GER contents of a sample were calculated from the difference of the concentrations of the SFN-*N*-*t*Boc-Cys-ME derivative or the ERU-*N*-*t*Boc-Cys-ME derivative before and after myrosinase treatment. The latter represented the sum of the initial GLS and isothiocyanate content, and the former represented the initial sulforaphane or erucin content.

Neoglucobrassicin. For analysis of intact NGBS and its metabolites NI3C and *N*-methoxyindole-3-acetonitrile, urine (30 μL) and plasma (30 μL) were diluted 1:2 (v/v) with phosphate buffer (1 M, pH 6.7) and briefly vortexed. The diluted samples were extracted three times with 300 μL of 1-butanol. After adding 1-butanol, samples were vortexed for 5 min at room temperature and centrifuged at 3.000*g* and 4 °C for 10 min. Feces and intestinal contents (each 30 mg) were diluted 1:10 (w/v) with phosphate buffer (0.1 M, pH 6.7), vortexed for 5 min at room temperature, and then centrifuged for 10 min at 24.652*g* and 4 °C. The resulting supernatants were extracted three times with 900 μL of 1-butanol, vortexed three times, and centrifuged at 3.000*g* at 4 °C for 10 min. The pellets were extracted three times with 300 μL of 20% MeOH in water (v/v), vortexed for 5 min at room temperature, and subsequently centrifuged at 20.000*g* at 4 °C for 10 min. Every supernatant obtained was evaporated until dryness using a vacuum centrifuge. The residue was suspended in 30 μL of 60% acetonitrile in water (v/v), vortexed for 5 min at room temperature, centrifuged at 20.000*g* and 4 °C for 5 min, and the supernatant subjected to HPLC analysis.

Mercapturic Acid Conjugates in Urine. For the analysis of mercapturic acids, urine samples were centrifuged at 20.000*g* and 4 °C for 5 min. Supernatants were diluted with water (1:5, v/v), centrifuged again at 20.000*g* and 4 °C for 5 min, and analyzed immediately by HPLC/DAD. The analysis of potential mercapturic acid conjugates of NGBS was not performed due to the unavailability of reference substances.

DNA-Adduct Analysis. DNA adducts are formed by reaction of nucleophilic sites of the DNA with exogenous or endogenous electrophilic metabolites. Such a highly reactive electrophile, precisely a benzylic carbocation, can be formed after NGBS hydrolysis either from the resulting short-lived isothiocyanate or from an also unstable sulfoconjugate, whose formation from NI3C is catalyzed by sulfotransferase.[13] Adducts in DNA isolated from cecum and colon tissues were determined using isotope-dilution ultraperformance liquid chromatography−electrospray ionization−tandem mass spectrometry (UPLC-ESI-MS/MS) as described previously.[23,24] Briefly, DNA samples (25 μg) were spiked with [$^{15}N_5$]N^2-(1-methoxy-3-indolylmethyl)-2′-deoxyguanosine ([$^{15}N_5$]N^2-(1-MIM)-dG) and [$^{15}N_5$]N^6-(1-methoxy-3-indolylmethyl)-2′-deoxyadenosine ([$^{15}N_5$]N^6-(1-MIM)-dA) as internal adduct standards, hydrolyzed to 2′-deoxynucleosides, and quantified by isotope-dilution multiple reaction monitoring (MRM). The use of a standard DNA isolation protocol[25] resulted in considerable contamination with RNA despite RNase treatment. Therefore, dG was quantified in the DNA hydrolysate by UPLC-ESI-MS/MS using [$^{15}N_5$]dG as an internal standard, and the actual DNA content of the samples was subsequently determined knowing that dG constitutes 21% of all nucleosides in the murine genome.[26]

HPLC and UPLC-ESI-MS/MS Apparatus and Conditions. Metabolites were separated and quantified with a Summit HPLC system (Dionex, Idstein, Germany) consisting of a pump (P680A LPG), an autosampler (ASI-100T), a column oven (TCC-100), and a diode-array detector (UVD 340U PDA). The HPLC was equipped with an analytical C18 LiChrospher reversed-phase column (5 μm, 4.6 × 250 mm, Merck, Darmstadt, Germany) and a C18 LiChrospher guard column (5 μm). The autosampler temperature was set at 5 °C, the flow rate was 1.0 mL/min, and the column temperature was 30 °C. Instrument control, data acquisition, and peak area analysis were done using the Chromeleon 6.40 Chromatography data system (Dionex, Idstein, Germany). GLS and their metabolites were identified by their retention times, and their UV-spectra in comparison to reference substances and calibration curves were used for their quantification.

For the analysis of isothiocyanate-*N*-(*tert*-butoxycarbonyl)-L-cysteine methyl ester (ITC-*N*-*t*Boc-Cys-ME) derivatives, NGBS and its metabolites, the mobile phase consisted of potassium dihydrogen phosphate (50 mM) acidified with phosphoric acid to pH 2.3 (solvent

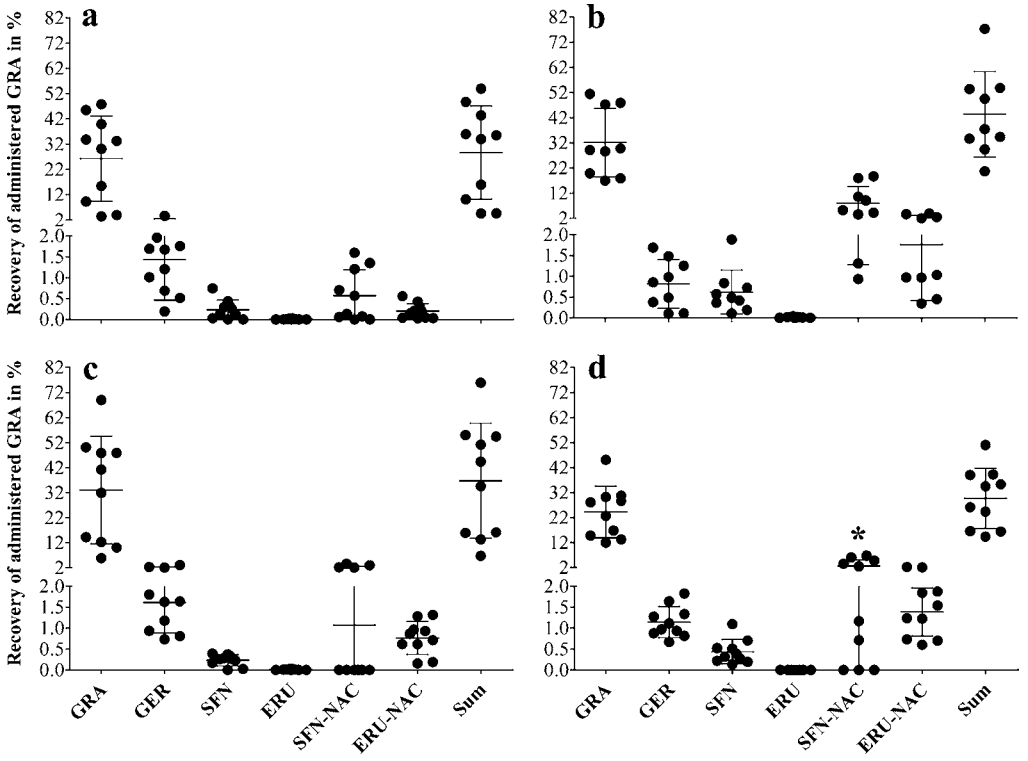

Figure 2. Renal excretion of glucoraphanin (GRA) and its potential metabolites glucoerucin (GER), sulforaphane (SFN), erucin (ERU), sulforaphane-*N*-acetyl-L-cysteine (SFN-NAC), and erucin-*N*-acetyl-L-cysteine (ERU-NAC) within 48 h after GRA application (172 mg/kg body weight) depicted as % recovery of applied GRA in germ free mice without (a) and with (b) myrosinase application and human microbiota-associated (HMA) mice without (c) and with (d) myrosinase application. Each point represents an experimental animal (n = 9 to 10 per group). Depicted are the mean and standard deviation. * translates into the significant difference ($p < 0.05$) between germ free and HMA mice.

A), acetonitrile (solvent B), and ultrapure water (solvent C). ITC-*N*-*t*Boc-Cys-ME derivatives were analyzed as described previously.[22] For the measurement of NGBS and its metabolites, the gradient started with 100% A, changed to 3% B within 4.5 min, from 3% to 25% B within 20.5 min, and from 25% to 60% B within 20 min. The gradient was subsequently switched from 60% B to 100% C and held for 5 min. Then, the column was rinsed with 100% C for 5 min. Finally, the mobile phase returned to the initial solvent composition for 5 min for re-equilibration of the column between single runs.

For the analysis of mercapturic acid conjugates, which were detected at 254 nm, the mobile phase consisted of 0.05% (v/v) trifluoroacetic acid in water (A), 0.1% (v/v) trifluoroacetic acid in acetonitrile (B) and ultrapure water (C). A linear gradient from 0% B to 20% B within 10 min, which was held for 5 min, changed to 35% B within 7.5 min and to 100% B within 5 min, which was held for 5 min. Finally, the mobile phase returned to the initial composition for 5 min for re-equilibration of the column between single runs.

The analysis of the DNA adducts formed from NGBS metabolites was conducted using an Acquity UPLC system equipped with an Acquity UPLC BEH Phenyl column (1.7 μm, 2.1 × 100 mm) coupled to a Xevo TQ triple quadrupole mass spectrometer (all from Waters, Eschborn, Germany) operating in the positive ion mode (ESI+). Conditions for LC separation and MS/MS detection of the analytes have been published previously.[23]

Statistical Analysis. The excretion of GRA, NGBS, and their metabolites via urine, feces, and gut contents of mice was calculated for each animal as percentage recovery of the ingested GLS dose based on molar amount of GLS applied. Statistical analysis was performed using the software SPSS 20.0 (IBM, NY, USA). Values were tested for normal distribution using the Kolmogorov−Smirnov test.[27] Differences were analyzed for normally distributed data on their statistical significance using the unpaired t test and for dependent measurements using the paired t test. Differences of non-normally distributed data were checked for significance using the Mann−Whitney-U-test for unpaired data and the Wilcoxon-test for paired data. Differences in excretion between HMA and germ free mice were considered significant at $p < 0.05$, and a trend was defined as $p < 0.1$. Data are presented as mean values.

RESULTS

Glucoraphanin Is Absorbed Intact and Mainly Excreted via Urine. *Plasma and Urine.* Forty-eight hours after application of GRA with or without myrosinase, no GRA-derived metabolites could be detected in plasma from germ free or HMA mice. Instead, approximately 30% of the applied GRA was excreted in urine in its intact form, mainly within 24 h. The application of GRA (172 mg/kg body weight, corresponding to 362 μmol/kg body weight) to germ free and HMA mice resulted within 12 h in the total renal excretion of GRA and its metabolites in amounts that corresponded to 24 (±17) and 29 (±19)% of administered dose of GRA, respectively, when no myrosinase had additionally been applied and 22 (±17) and 21 (±12)%, respectively, when myrosinase had been applied. When the observation time was extended to 48 h, these values were only slightly increased; they were 29 (±18) and 37 (±23)% in germ free and HMA mice, respectively, without myrosinase, and 43 (±17) and 30 (±12)%, respectively, with myrosinase (Figures 2a−d). Thus, GRA was absorbed intact regardless of the colonization status of the mice and whether myrosinase had been applied. In contrast to the procedure used in our study, Lai et al. administered GRA or SFN directly to the cecal lumen of anesthetized rats using a surgical procedure. In this way, these substances bypassed the small intestine where absorption of GRA preferentially takes place as may be deduced from the appearance of intact GRA in the animals' urine within

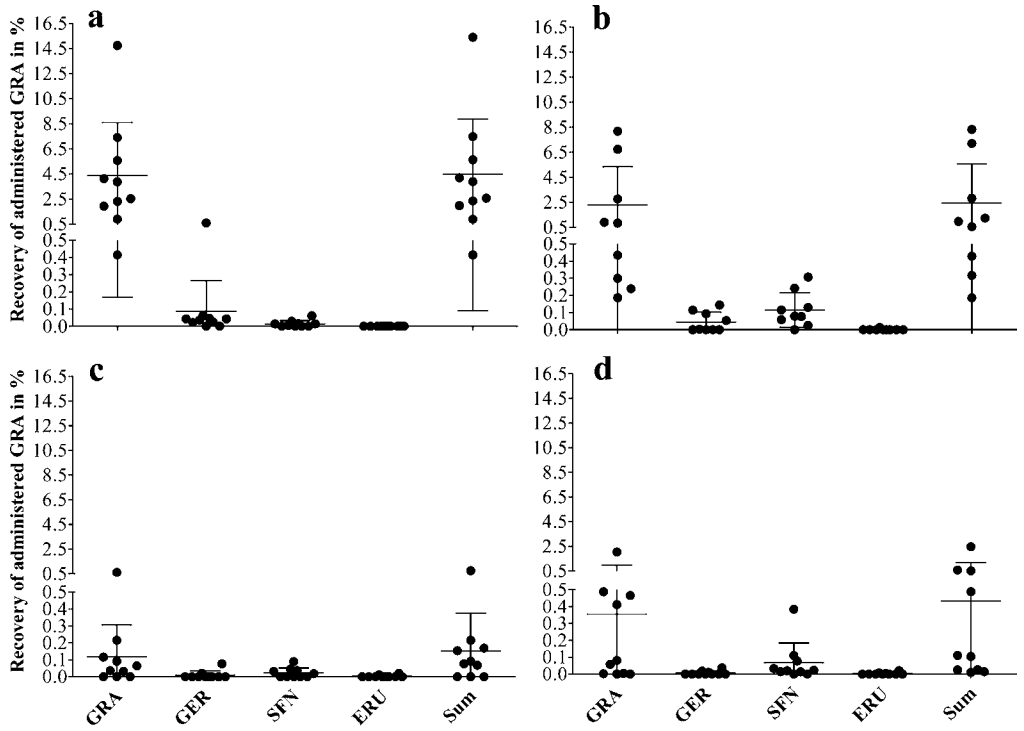

Figure 3. Fecal excretion of glucoraphanin (GRA) and its potential metabolites glucoerucin (GER), sulforaphane (SFN), and erucin (ERU) within 48 h after its application (172 mg/kg body weight) depicted as % recovery of applied GRA in germ free mice without (a) and with (b) myrosinase application and human microbiota-associated (HMA) mice without (c) and with (d) myrosinase application. Each point represents an experimental animal (n = 9 to 10 per group). Depicted are the mean and standard deviation.

12 h after application.[28] A small amount of GER was detected in all groups (the mean varying from 0.8 to 1.6% recovery within 48 h after GRA application, based on the dose of GRA applied to the animals), which suggests that GRA was reduced to GER by the animals' metabolism. The isothiocyanates, SFN and ERU, were excreted in the urine of germ free and HMA mice. However, renal excretion was low for SFN and almost negligible for ERU. The amount of SFN recovered within 48 h after GRA application in germ free and HMA mice corresponded to 0.23 (±0.23) and 0.24 (±0.13)% of the applied GRA dose, when no myrosinase had been applied, and to 0.62 (±0.53) and 0.44 (±0.29)%, respectively, when myrosinase had been applied. Thus, GLS underwent hydrolysis to isothiocyanates in the animals irrespective of the presence or absence of myrosinase. ERU may have been formed either by the reduction of SFN or by hydrolysis of GER, the reduction product of GRA.

SFN and ERU excreted in urine within the first 12 h after application of GRA were mainly present as *N*-acetyl-L-cysteine (NAC) conjugates, also referred to as mercapturic acids. Glutathione or cysteine conjugates were not detected. The amount of NAC-conjugates excreted by the experimental groups differed: Within 48 h after the application of GRA, germ free mice and HMA mice excreted SFN-NAC in amounts corresponding to 0.57 (±0.62) and 1.1 (±1.4)% of the initial administered GRA dose, respectively, as well as ERU-NAC in amounts corresponding to 0.20 (±0.18) and 0.76 (±0.39)% of the initial administered GRA dose. Thus, germ free animals excreted significantly less ERU-NAC than HMA mice (p < 0.05). As expected, the application of myrosinase resulted in increased amounts of SFN-NAC and ERU-NAC excreted by germ free mice and HMA mice: 7.9 (±6.7)% of the GRA dose was recovered within 48 h as SFN-NAC and 1.8 (±1.3)% as ERU-NAC in germ free mice as well as 2.5 (±2.6)% as SFN-NAC and 1.4 (±0.6)% as ERU-NAC in HMA mice (p < 0.05 for SFN-NAC).

Gut Contents and Feces. Neither intact GRA nor its metabolites were detectable in small intestinal, cecal, and colonic contents of HMA mice 48 h after GRA application. However, they were present at low concentrations in small intestinal, cecal, and colonic contents of germ free animals corresponding to 0.05 (±0.03)% with myrosinase and 0.64 (±0.41)% without myrosinase of the applied GRA dose (p < 0.05). Thus, in germ free mice, myrosinase reduced the GRA content in the small intestine, cecum, and colon. In HMA mice, the absence of GRA or isothiocyanates from gut contents was unrelated to the application of myrosinase. Thus, the presence of myrosinase, whether administered orally or as a consequence of bacterial colonization, led to a reduced recovery of GRA in the gut contents. From a total of 10 animals per experimental group, SFN was only detected in the intestinal contents of two germ free animals without and one germ free animal with myrosinase administration (0.004, 0.006 and 0.024%, respectively, of the initial dose of GRA applied to the animals were recovered as SFN).

Fecal excretion of GRA and its metabolites over 48 h was determined for both mouse groups (Figures 3a–d). The germ free mice excreted more intact GRA in their feces than HMA mice, namely, 4.4 (±4.2)% versus 0.12 (±0.19)% of the initial dose of GRA, p < 0.001, without myrosinase supplementation, as well as 2.3 (±3.1)% versus 0.36 (±0.63)% with myrosinase supplementation. As observed for the gut contents, myrosinase administered orally or provided by intestinal bacteria, resulted in an overall reduced recovery of GRA in the feces. GER was detected at very low levels in all groups (the mean varying from

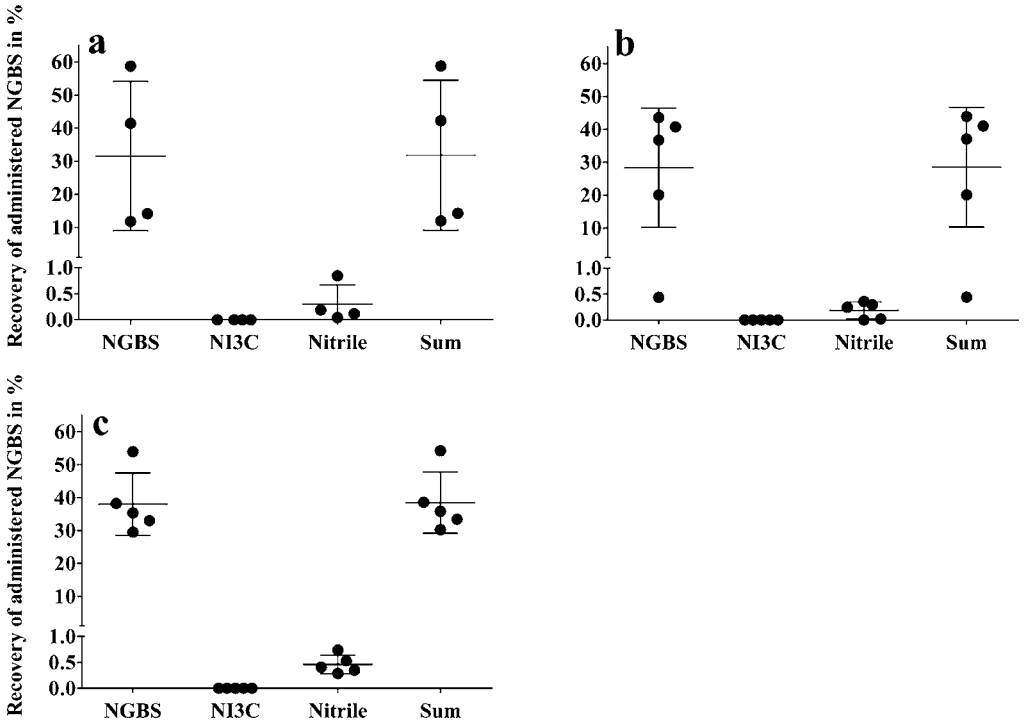

Figure 4. Renal excretion of neoglucobrassicin (NGBS) and its potential metabolites *N*-methoxyindole-3-carbinol (NI3C) and *N*-methoxyindole-3-acetonitrile (Nitrile) within 8 h after its application (297 mg/kg body weight) depicted as % recovery of applied NGBS in germ free mice without (a) and with (b) myrosinase application and in human microbiota-associated (HMA) mice (c). Each point represents an experimental animal (n = 5 per group). Depicted are the mean and standard deviation.

0.007 to 0.09% recovery within 48 h after GRA application, based on the dose of GRA applied to the animals).

Fecal excretion of SFN and ERU by HMA mice corresponded for both isothiocyanates together to 0.07 (±0.12) and 0.025 (±0.035)% of the initial GRA dose, with or without oral myrosinase application, respectively. In germ free mice that received myrosinase, the proportion of orally applied GRA recovered as SFN and ERU was 0.12 (±0.10)%. SFN was also detected in germ free animals, which did not receive myrosinase, but only in very low amounts, corresponding to 0.014 (±0.019)% of the initial GRA dose applied to the animals. Overall, the recovery of GRA and its metabolites in the feces 48 h after its oral administration was low, independent of bacterial colonization of the animals: in germ free and HMA mice, 4.5 (±4.4) and 0.15 (±0.22)% of the applied GRA dose, when no myrosinase had been applied, and 2.5 (±3.1) and 0.43 (±0.75)%, respectively, when myrosinase had been applied.

Neoglucobrassicin Is Also Absorbed Intact and Mainly Excreted via Urine. *Urine and Plasma.* Eight hours after its oral application, NGBS was detected in the plasma of mice from all groups and hence, similar to GRA, was also absorbed intact. The recovery of NGBS in plasma was higher in germ free mice that did not receive myrosinase than in germ free animals that received myrosinase, namely, 0.022 (±0.015) versus 0.005 (±0.004)% of the administered NGBS dose, $p < 0.05$. The recovery of NGBS in the plasma of HMA mice was 0.007%. However, the detection of NGBS was overall low, and metabolites derived from NGBS, i.e., NI3C and *N*-methoxyindole-3-acetonitrile, were not observed.

Independent from bacterial colonization and the application of myrosinase, NGBS was excreted in urine intact. The recovery in urine of germ free animals with and without myrosinase application was 28 (±18) and 32 (±23)% of the administered NGBS dose, respectively, and 38 (±9)% in the urine of HMA mice (Figures 4a–c). NI3C, a stable degradation product of NGBS, which under neutral pH conditions is formed from the respective isothiocyanate, was not detected in urine samples. *N*-Methoxyindole-3-acetonitrile, which is formed under acidic conditions from the isothiocyanate of NGBS, was excreted in very small amounts in all experimental groups. Germfree animals with and without myrosinase application excreted the nitrile at concentrations that correspond to 0.18 (±0.16) and 0.30 (±0.37)% of the administered NGBS dose, respectively, and HMA animals to 0.46 (±0.18)%. Thus, renal excretion of *N*-methoxyindole-3-acetonitrile was higher in HMA mice than in germ free animals that received myrosinase ($p < 0.05$).

Gut Contents and Feces. The recovery of NGBS in gut contents of HMA mice was very low and corresponded to only 0.01 (±0.005)% of the administered NGBS dose. The combined gut contents of germ free mice contained NGBS mainly in its intact form, no matter whether myrosinase had been applied (2.5 ± 5.5% of applied dose) or not (4.2 ± 4.5, $p < 0.05$, Figures 5a–c). Germfree mice contained only small amounts of NI3C in their intestines, corresponding to 0.12 (±0.05) and 0.03 (±0.04)% of the administered NGBS dose, with and without myrosinase application, respectively. However, HMA mice contained even less NI3C in their intestines, corresponding to 0.0002 (±0.0002)% of the applied NGBS dose ($p < 0.05$). *N*-Methoxyindole-3-acetonitrile contents in the cecum and colon of germ free animals were low and corresponded to 0.01 (±0.02)% of the administered NGBS dose with myrosinase application and 0.02 (±0.02)% without, while it was not detected in HMA mice.

Neither NGBS nor its metabolites were detected in feces from HMA mice within 8 h after its application. Independent from the application of myrosinase, fecal excretion of NGBS by

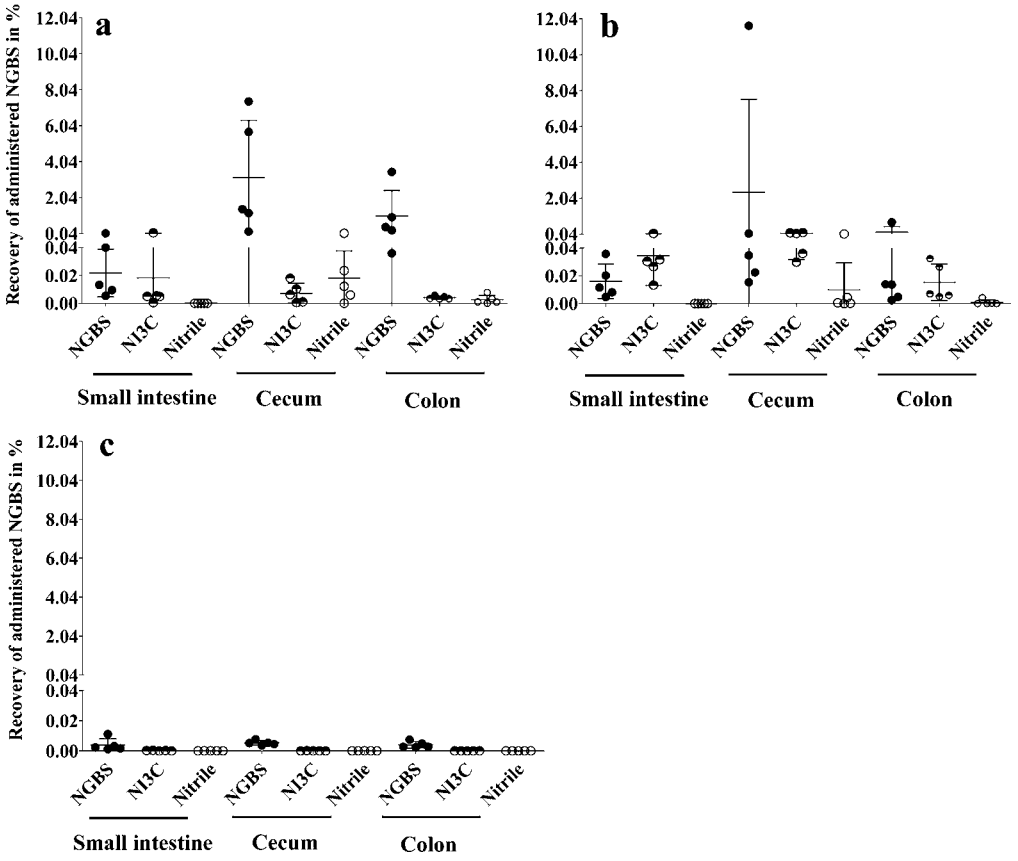

Figure 5. Recovery of neoglucobrassicin (NGBS) and its metabolites *N*-methoxyindole-3-carbinol (NI3C) and *N*-methoxyindole-3-acetonitrile (Nitrile) in gut contents of germ free mice without (a) and with (b) myrosinase application and of human microbiota-associated (HMA) mice (c) 8 h after its application (297 mg/kg body weight). Each point represents an experimental animal (n = 5 per group). Depicted are the mean and standard deviation.

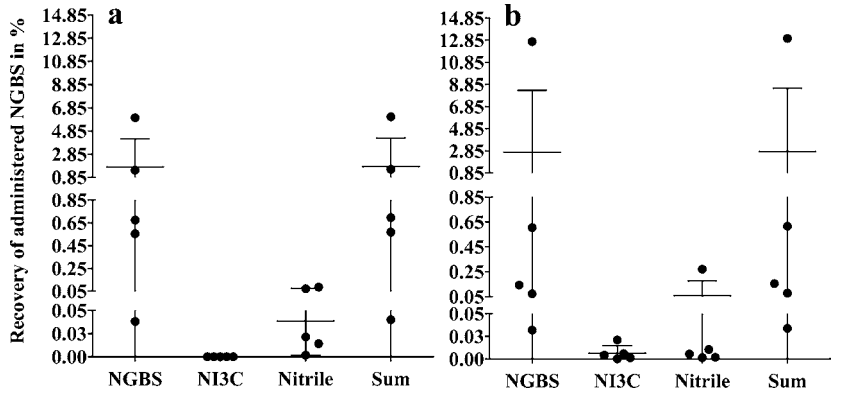

Figure 6. Fecal excretion of neoglucobrassicin (NGBS) and its potential metabolites *N*-methoxyindole-3-carbinol (NI3C) and *N*-methoxyindole-3-acetonitrile (Nitrile) within 8 h after its application (297 mg/kg body weight) depicted as % recovery of applied NGBS in germ free mice without (a) and with (b) myrosinase application. Data from human microbiota-associated (HMA) mice are not depicted as neither NGBS nor its metabolites were detected in their feces. Each point represents an experimental animal (n = 5 per group). Depicted are the mean and standard deviation.

germ free mice in its intact form was low and corresponded to 2.7 (±5.9)% of the administered NGBS dose with myrosinase treatment and 1.7 (±2.4)% without (Figure 6a–b). NI3C was excreted in very small quantities in the myrosinase-treated germ free animals, corresponding to 0.006 (±0.008)% of the applied NGBS dose. Germfree mice also contained very small fecal amounts of *N*-methoxyindole-3-acetonitrile corresponding to 0.06 (±0.12)% of the NGBS dose applied to mice with myrosinase application and 0.04 (±0.04)% without.

DNA Adducts. The genotoxic activity of NGBS depending on the colonization status and/or the myrosinase treatment was studied by LC-MS/MS analysis of adducts in DNA isolated from murine cecum and colon 8 h after administration of NGBS. DNA adducts were detected in the cecum and colon of all NGBS-treated HMA and germ free mice: HMA, 78 (±49) and 54 (±45) DNA adducts (sum of dA- and dG-adducts) per 10^8 nucleotides, respectively. They were also detected in the cecum and colon of germ free mice: 441 (±625) and 333 (±547) DNA adducts per 10^8 nucleotides, respectively, with

DOI: 10.1021/acs.jafc.5b02948
J. Agric. Food Chem. 2015, 63, 8418–8428

myrosinase, and 55 (±51) and 33 (±26) DNA adducts per 10^8 nucleotides, respectively, without myrosinase. Control animals, germ free or HMA, that received the vehicle only showed no DNA adducts originating from NGBS. Thus, without oral application of myrosinase, germ free and HMA mice did not differ from each other with respect to the amount of DNA adducts formed. It may be concluded that the oral application of myrosinase to germ free mice was responsible for the increased numbers of cecal and colonic DNA adducts ($p < 0.05$ and $p < 0.1$, respectively). However, as the amount of DNA adducts formed in the cecum and colon of HMA mice was not significantly different from that of germ free mice not treated with myrosinase (Figure 7), a role of the human-derived bacteria colonizing the gut of HMA mice in NGBS activation is negligible.

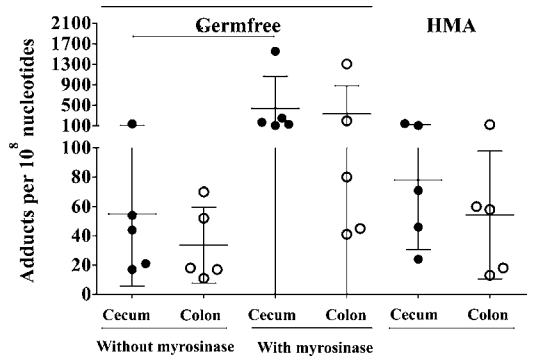

Figure 7. DNA adduct levels (sum of N^6-(1-MIM)-dA and N^2-(1-MIM)-dG) in cecum and colon of germ free mice with and without myrosinase application and of human microbiota-associated (HMA) mice 8 h after application of neoglucobrassicin (297 mg/kg body weight). Each point represents an experimental animal ($n = 5$ per group). Depicted are the mean and standard deviation. *$p < 0.05$.

DISCUSSION

Glucosinolates Are Absorbed Intact and Mainly Excreted via Urine. Mice excreted approximately one-quarter to one-third of orally applied GLS, GRA, and NGBS, intact in their urine. Thus, the amount of hydrolysis products recovered was lower than expected. This finding may be of importance as potential health effects of GLS have mainly been attributed to the hydrolysis products of GLS.

Intact GLS were detected not only in the urine of mice following their application but also in plasma. For example, intact NGBS appeared in the plasma of mice 8 h after NGBS had been administered confirming the absorption of intact GLS into the circulation. Until now, only a few studies have addressed the absorption of intact GLS: intact GRA was observed in plasma of dogs and rats.[29] Rats were also reported to excrete intact GRA, but the proportion of GRA recovered in urine was only 5% of the administered dose.[30] Following the consumption of broccoli, GRA and sinigrin were detected in human urine and plasma, respectively.[31,32,35,36] Studies on everted intestinal sacs of rats provided evidence for a passive transport of intact GLS from the mucosal to the serosal side of the epithelial cells in the small intestine and colon.[33] The transport rate of GLS depends on their chemical structure: transport of the aromatic GLS glucotropaeolin was slightly faster than that of the aliphatic GLS sinigrin. This has been attributed to the lipophilic side chain of sinigrin.[33] However, in the present study urinary excretion of indolic NGBS 8 h after its application was similar to that of aliphatic GRA after 12 h. This indicates a rather fast absorption, distribution, and excretion for both GLS. This is in agreement with data obtained in rats, in which 95% of the total excretion of GRA was observed in urine within 8 h after its application.[30]

Detection of intact GLS in plasma and urine in the present study possibly indicates that physiological effects previously reported for GLS may be at least in part exerted by GLS itself rather than by its degradation products. This has not been studied to any great extent, and the results are in part contradictory. For example, GRA induces chemoprotective phase II enzymes[34] and has shown cytotoxic and genotoxic properties in vitro.[35]

Isothiocyanates Are Excreted in Urine Mainly as Mercapturic Acid Conjugates. After the application of GRA, SFN and ERU appeared in the urine of germ free and HMA mice. ERU is formed either by the reduction of SFN or hydrolysis of GER. The latter is formed by the reduction of GRA.[36] Urinary SFN and ERU were mainly excreted as their NAC-conjugates within 12 h after GRA application. A rapid renal excretion of mercapturic acid conjugates was also reported for humans; it occurred within the first 8 h after the ingestion of broccoli sprouts.[37] However, whereas in humans 40% of the applied GRA dose was detected as SFN-NAC,[6] the excretion of NAC-conjugates in the present mouse study was low, unless myrosinase was given to the mice. These differences might be due to differences between animal species in the catalytic activity and specificity of xenobiotic metabolizing enzymes or to the fact that in the present study GRA was applied as a pure substance, whereas in human studies broccoli or other GLS-containing vegetables were given, in which GRA is embedded in a plant matrix.[38] Studies of the metabolism of isothiocyanate in various species have shown differences in the metabolite profile. The cyclic mercaptopyruvic acid (4-hydroxy-4-carboxy-3-benzylthiazolidin-2-thione) occurred in the urine from guinea-pigs and rabbits after the oral or intravenous administration of benzyl isothiocyanate or its cysteine metabolite.[39] In human individuals, the isothiocyanates are mainly metabolized via the mercapturic acid pathway.[40] However, to the best of our knowledge, mercaptopyruvic acid has not been observed in human intervention studies up to now, and we also did not detect it in our study.

Interindividual Differences in Metabolism of the Glucosinolates. In the present study, considerable differences in the excreted amounts of GRA, NGBS, and their metabolites were observed between individual animals. High interindividual variation in excretion was also observed in human studies after the intake of GLS via *Brassica* vegetables.[41,42] The interindividual differences in the excretion of GLS metabolites observed in the present study may be due to different times of feed intake, as the amount of feed in the stomach varies when animals are fed ad libitum, which in turn would affect transit time and thereby the metabolism of GLS.[43]

Impact of Intestinal Microbiota on the Bioactivation of Glucosinolates Is Low. This is the first study that examines the impact of human intestinal bacteria on the bioavailability of GLS in vivo using HMA mice and germ free animals as a control. As a positive control, myrosinase was applied orally to the mice to achieve enzymatic cleavage of GLS in the animals' digestive tract. This is the first time that intact GLS are reported to be present in feces and gut contents after their oral application, even though in low amounts. Germ free

DOI: 10.1021/acs.jafc.5b02948
J. Agric. Food Chem. 2015, 63, 8418−8428

mice had higher amounts of intact GLS in their feces and gut contents than HMA mice. This difference may result from an increased hydrolysis or a higher absorption of GLS in HMA animals and supports the hypothesis that human intestinal bacteria convert GLS. However, these differences may also be the result of a shortened intestinal transit time reported for colonized animals in comparison to that of their germ free counterparts.[44] The intestinal microbiota modulates the intestinal nervous system and thus stimulates the motility of the intestine[45] such that GLS would stay longer in the intestinal tract of germ free animals.

Only very small amounts of metabolites derived from orally applied GRA or NGBS were detected in plasma, urine, or feces. Unexpectedly, HMA and germ free mice did not differ substantially in the spectra of GLS metabolites formed and hence in their ability to hydrolyze GLS into their respective metabolites. Basal GLS activation in germ free animals was only slightly increased by oral myrosinase application or by bacterial colonization with HMA. This is in agreement with a gnotobiotic rat study, in which intestinal microbiota in contrast to plant myrosinase hardly contributed to the hydrolysis of GLS, which was adminstered as freeze-dried Brussels sprouts (mainly sinigrin).[46] On the basis of these results and the outcome of our study, the impact of human intestinal bacteria on activation of GLS appears to be rather weak in vivo, at least in HMA rodents.

Other factors that could possibly account for GLS hydrolysis in germ free mice were investigated and excluded: an in vitro incubation of GLS with synthetic gastric and intestinal juices and various mouse tissues did not lead to their hydrolysis (data not shown). The detection of intact GRA and NGBS in intestinal contents and feces of mice also argues in favor of a considerable stability of GLS during gastrointestinal passage. Moreover, GRA and NGBS preparations used in the animal experiments remained stable for at least 24 h of incubation at 37 °C (data not shown). A spontaneous cleavage of GLS in germ free mice is therefore unlikely. There was also no indication that the germ free mice investigated in the present study were contaminated with bacteria. Their germ free status was confirmed by Gram staining and checking fecal samples from these animals for growth (data not shown). Thus, the presented results indicate a thioglucosidase activity of the host, which is in contradiction to the literature to date.

However, it cannot be excluded that the HMA animal model is not well suited for studying the bacterial hydrolysis of GLS in vivo. This conclusion may be drawn from the fact that the number of DNA adducts detected in the intestinal tissue did not differ significantly between HMA and germ free mice after the application of NGBS and overall were very low. In contrast, conventional C3H and FVB/N mice treated in the same way as the HMA and germ free C3H mice in the present study showed 5- to 8-fold higher numbers of DNA adducts in the cecum compared to the HMA mice of the present study (conventional C3H mice, 392 (±43) DNA adducts per 10^8 nucleotides (n = 5); conventional FVB/N mice, 616 (±283) DNA adducts per 10^8 nucleotides (n = 10)). This indicates that bacterial hydrolysis of NGBS was higher in conventionally colonized mice than in HMA mice.[4] This difference between conventional and HMA mice indicates that the human microbiota transferred to germ free mice may have lost its ability to hydrolyze GLS following colonization. However, the fact that the fecal samples from both the human donor and the recipient mice efficiently hydrolyzed GRA and NGBS in vitro indicates that the microbial community had not lost this activity (data not shown). Communication between host and microbiota plays an important role in this ecosystem.[47] Therefore, the bacterial metabolism of GLS may have been affected in vivo by the specific host environment. The composition of the intestinal microbiota and the catalytic activity of selected enzymes in the gut of HMA mice are largely comparable to those of the human donor. Therefore, comparing HMA mice with germ free mice is a suitable experimental approach to investigate the complex human gut microbiota in vivo.[48] However, it should be kept in mind that not all human bacteria are able to establish in the mouse gut[49] and that the digestive tract of humans differs from that of mice. Owing to these limitations, the results obtained in this mouse study cannot simply be extrapolated to humans without additional experiments. Nevertheless, our experiments clearly show that the intestinal microbiota plays a minor role in the bioactivation of GLS in HMA mice.

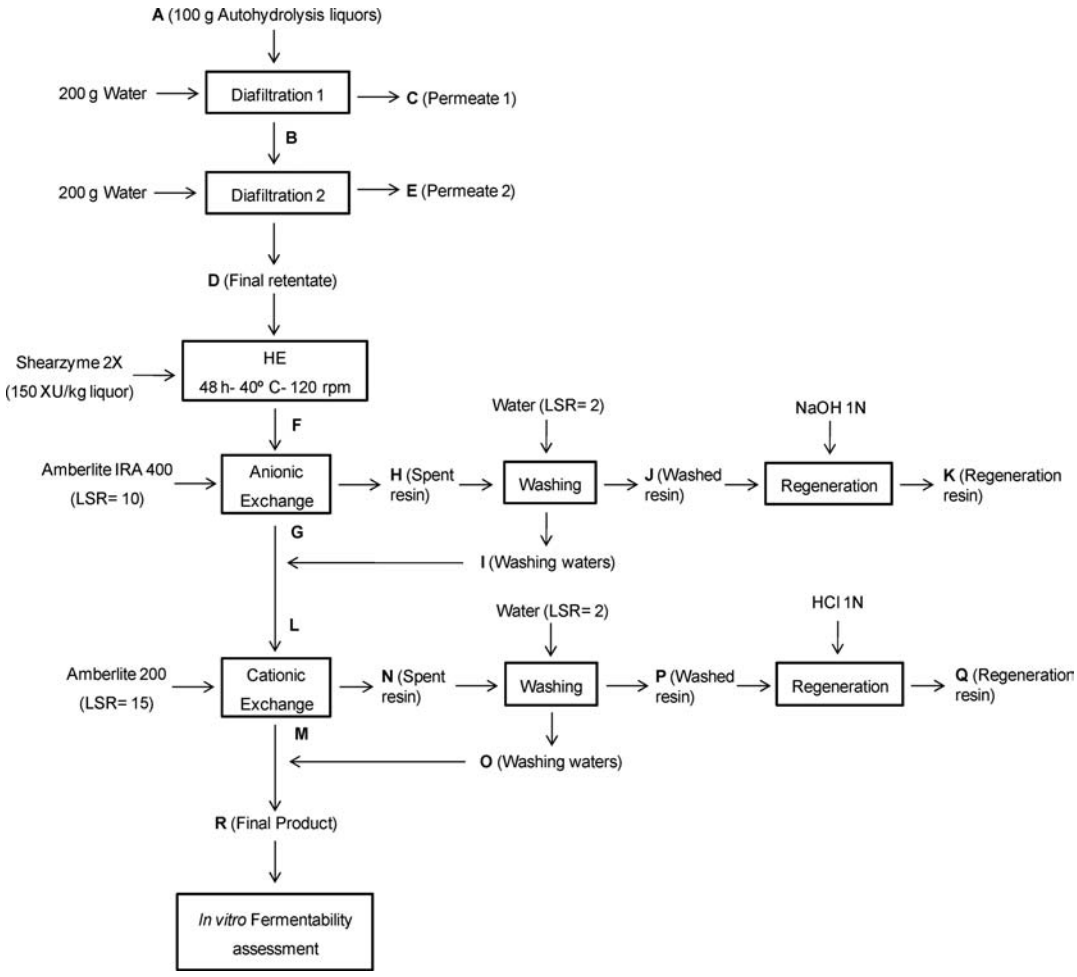

Figure 1. Scheme of the process after obtaining the optimal autohydrolysis conditions.

When BSG is subjected to hydrothermal treatment under selected conditions, hemicelluloses are mainly broken down into oligosaccharides (OS) with a variable degree of polymerization.[16−18] Afterward, if AXOS with a low degree of polimerization (DP) are desired, the enzymatic hydrolysis is a suitable alternative because it is possible to control the reaction, limiting the formation of undesirable products. In addition, no chemicals are used in the process, which is in line with the green chemistry perspective.[11]

However, in addition to AXOS production, other effects occur during the process (including extractives solubilization, monosaccharides production, sugar decomposition product generation, and lignin depolymerization). Because of this, if the AXOS are to be used for food purposes, then the autohydrolysis liquors need to be refined to remove these nondesired impurities. This goal can be achieved by a variety of technologies including liquid−liquid extraction, membrane filtration, or ion exchange.[18−20]

The aims of this work were (1) to evaluate the production of AXOS from BSG by hydrothermal treatment, (2) to modify and refine the AXOS obtained by a combined process of enzymatic hydrolysis, membrane filtration, and ion exchange, and (3) to evaluate the effects of the final purified product on the composition of the colonic microbiota and organic acids production (SCFA and lactate) using fecal inoculum from elderly.

MATERIALS AND METHODS

Raw Material. BSG samples were provided by Customdrinks (Galicia, Spain), dried at room temperature, homogenized in a single lot, and stored.

Starch Extraction and Hydrothermal Processing. Two types of pretreatments were assayed to remove or, at least, to reduce the starch content of BSG: (i) an aqueous treatment at 100 °C for 30 min and (ii) a nonisothermal water extraction (from 60 to 130 °C in 9.3 min).

In both cases, BSG was mixed with distilled water at a liquid−solid mass ratio of 8:1 g/g (oven-dry basis) and introduced into a stirred, stainless-steel reactor (Parr Instr. Co., Moline, IL, USA). Then, the reactor was heated up to achieve the desired temperature, and when the treatment was finished, the suspension was cooled and centrifuged. The solid phases from this first treatment were air-dried and stored until use.

Solids resulting from starch extraction were mixed with distilled water at a liquid−solid mass ratio of 8:1 g/g and subjected to a hydrothermal treatment under nonisothermal operation up to maximum temperatures of 180, 190, 195, 200, 210, or 220 °C. Once the temperature was achieved, the reactor was cooled and opened, and the liquors recovered by centrifugation were analyzed and processed as described below.

With the aim of facilitating the comparison between different reaction conditions, the severity factor (R_0) of each treatment was calculated according to Overend and Chornet.[21] This parameter combines the effects of time and temperature caused by isothermal or nonisothermal processing; it is defined as

DOI: 10.1021/acs.jafc.5b03132
J. Agric. Food Chem. 2015, 63, 8429−8438

$$R_0 = \int_0^t \exp\left[\frac{T(t) - 100}{14.75}\right] dt \quad \text{(eq 1)}$$

(where t and $T(t)$ are the reaction time and the temperature, respectively) and gives a simplified, empirical interpretation of the complex chemistry of polysaccharide degradation in aqueous media.[22]

Because treatments with similar R_0 values should provoke similar effects on the reaction products, a treatment was carried out under isothermal conditions at T = 180 °C and t = 12.2 min, a set of operational conditions that corresponds to a severity factor = 4439.8 min, a value identical to the one calculated for the experiment carried out under selected nonisothermal conditions where the T_{max} was 195 °C.

Processing of Autohydrolysis Liquors. Liquors from the hydrothermal treatment were subjected to membrane filtration (Amicon stirred cell, model 8400, Millipore, Darmstadt, Germany) using the experimental device described by Gómez et al.[23] However, in this work, the operation was carried out only in diafiltration mode (two stages) at room temperature using a transmembrane pressure of 3 bar, as indicated in Figure 1.

Retentate from the second diafiltration stage (stream D in Figure 1) was treated with a commercial endoxylanase (Shearzyme 2×) kindly provided by Novozymes-Spain (more details in Gullón et al.).[24] The xylanases were added to the retentate at the desired enzyme loading (150 XU/kg of liquor), and the solution was kept at 40 °C in an agitated vessel (120 rpm). Hydrolysis was carried out for 48 h, and no buffer was added to the medium.

Liquors from the enzymatic hydrolysis (Figure 1) were treated with Amberlite IRA 400 (a strong-anion-exchange resin) and Amberlite 200 (an acidic cation-exchange resin) to reduce the content of ionic impurities. Both resins were supplied by Sigma-Aldrich (St. Louis, MO, USA). In both cases, liquors and resin were contacted for 24 h with gentle agitation at room temperature using a liquor/resin mass ratio of 10:1 g/g (Amberlite IRA 400) and 15:1 g/g (Amberlite 200). At the end of treatment, the spent resins (streams H and N) were washed with distilled water using a RLS of 2 g of water per gram of resin in order to recover those compounds that could have been retained. The resulting stream (denoted as R) was freeze-dried and stored until use in fermentation experiments.

Fermentation of AXOS Mixtures. Samples of AXOS were fermented using fecal inocula obtained from three healthy elder volunteers (age > 60 years). Fecal samples were collected in sterile vials, kept in an anaerobic cabinet, and used within a maximum of 2 h after the collection. The fecal inoculum (FI) was prepared by dilution in a reduced physiological salt solution (RPS; cysteine-HCl 0.5 g/L and NaCl 8.5 g/L) ratio of 100 g of feces to 1 L of RPS at pH 6.8.

FOS (Sigma-Aldrich, St. Louis, MO, USA) and a medium without any carbon source were included in the study as positive and negative controls, respectively.

The fermentation process was developed according to Gullón et al.[20] An assay was carried out per donor for each substrate (FOS or AXOS), and the data shown correspond to an average of the results from the three different donors (n = 3).

Changes in human fecal bacterial populations were assessed by FISH using the following 16S rRNA probes: Lab158 (*Lactobacillus/Enterococcus* group), Bif164 (*Bifidobacterium* genus), Bac303 (*Bacteroides/Prevotella* group), and His150 (clusters I and II of *Clostridium*), all of which were purchased from Tib Molbiol, Berlin, Germany. For the total cell counting, samples were stained with 4′,6-diamidino-2-phenylindole (DAPI) from Sigma-Aldrich (St. Louis, MO, USA). Bacterial counts were carried out at fixed fermentation times using a fluorescence microscope (Olympus BX41, Tokyo, Japan). One hybridization was made per analyzed sample (one sample was obtained per donor, substrate, and time) and a minimum of 15 fields were counted per hybridized sample.

Differences between bacterial populations and organic acid concentrations were tested using one-way analysis of variance (ANOVA) and Tukey's post hoc test. Differences were considered significant when $p < 0.05$.

Analytical Methods. Aliquots from BSG and spent solids from hydrothermal treatments were subjected to moisture and ash determinations (methods ISO 638 and ISO 776, respectively) and to quantitative acid hydrolysis (method TAPPI T13m). The HPLC analysis of liquors was carried out using a 1100 series Hewlett-Packard chromatograph fitted with a refractive index detector and a Aminex HPX- 87H column from Biorad (Hercules, CA, USA) operating at 50 °C and using as mobile phase H_2SO_4 0.003 M (flow rate = 0.6 mL/min). In addition, uronic acids (UA) were determined by the method of Blumenkrantz and Asboe-Hansen[25] using galacturonic acid (Fluka, parent company of Sigma-Aldrich, St. Louis, MO, USA) as a standard for quantification. Elemental nitrogen was determined with a Thermo Finnegan Flash EATM 1112 analyzer, using 130 and 100 mL/min of He and O_2 and an oven temperature of 50 °C. Protein content was obtained by multiplying the elemental N content by 6.25. The starch content was quantified with an enzymatic kit (Boheringer-Mannheim, R-Biopharm, Darmstadt, Germany). All determinations were made in triplicate.

In contrast, samples of liquors were filtered through 0.45 μm cellulose acetate membranes and assayed for the glucose, xylose, arabinose, acetic acid, formic acid, hydroxymethylfurfural (HMF), and furfural content by HPLC following the method described above. Moreover, an aliquot of the liquors were subjected to quantitative posthydrolysis (with 4% sulfuric acid at 121 °C for 20 min) before HPLC analysis in order to determine the concentrations of oligomers (GlcOS, XOS, and AraOS) present in the media. (The increase in the concentrations of monosaccharides caused by the posthydrolysis is a measure of the oligomers content.) In a similar way, the increase in acetic acid concentration allows us to measure the amount of acetyl groups (AcO) linked to oligosaccharides. Additionally, uronyl substituents were determined by the same method already cited for the raw material, using galacturonic acid as a standard for quantification. Nonvolatile compounds (NVC) were measured by oven-drying at 100 °C until constant weight, whereas the content of impurities (other nonvolatile compounds, ONVC) were calculated as follows: ONVC = (NVC − MS − OS)/ NVC. All the analyses were made by triplicate.

The structural characterization of the refined product (stream R in Figure 1) was carried out by high-performance size-exclusion chromatography (HPSEC) using an Ultimate 3000 system (Dionex Corp., Sunnyvale, CA, USA) and by matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry (MALDI-TOF MS) using an Ultraflex workstation (Bruker Daltonics, Bremen, Germany). More details can be found in the article by Gómez et al.[23]

Cells were harvested by centrifugation (10 000 rpm), and the supernatants were filtered through 0.20 μm cellulose acetate membranes (Sartorius Stedim Biotech, Germany) before HPLC analysis for monosaccharides, oligosaccharides, formate, lactate, succinate, and SCFA (acetic, propionic, and butyric acids) as well as pH measurement. Cell pellets were used for counting the selected bacterial groups by FISH.[20]

RESULTS AND DISCUSSION

Aqueous Extraction and Autohydrolysis. Starch lacks prebiotic potential, and its presence in liquors is a drawback if a high-purity final product is desired. Therefore, a pretreatment is needed to remove it or, at least, to reduce its content in the raw material.[26] Moreover, starch could be used for a variety of processes. Two alternatives (isothermal and nonisothermal aqueous treatment) were assayed, resulting in similar solid yields (~76%) and starch removal percentages (85%), although small losses of target compounds were also found to occur.

Taking this into account, an isothermal pretreatment at 100 °C for 30 min was chosen because lower energy consumption was expected. The composition of both BSG and pretreated solid is shown Table 1. As can be seen, glucan, xylan, acid insoluble residue (AIR), and protein were the major components in both untreated and pretreated solids. As a

DOI: 10.1021/acs.jafc.5b03132
J. Agric. Food Chem. 2015, 63, 8429−8438

Table 1. Chemical Composition of BSG and the Pretreated Solid Obtained by Aqueous Extraction at 100 °C for 30 min

component	BSG (%)	pretreated solid (%)
glucan	24.91	19.73
xylan	13.94	17.43
arabinan	6.68	7.99
acetyl groups	0.80	0.88
UA	6.45	6.13
AIR	22.82	20.77
starch	9.42	2
protein	26.77	24.10
ashes	2.98	

result of the aqueous extraction, a solid enriched in xylan and arabinan with lower starch content was obtained.

Following the process scheme (Figure 1), pretreated solids were subjected to hydrothermal processing, first under nonisothermal conditions (until reaching a temperature of 180, 190, 200, 210, or 220 °C) and second under isothermal conditions (at 180 °C), as explained above.

Figure 2 shows the dependence of monosaccharide and oligosaccharide concentrations on the maximum temperature of the treatment. As can be seen, the xylose concentration increased significantly from 195 to 210 °C, as a result of hydrolysis of oligomers, whereas arabinose showed a maximum at 200 °C and decreased rapidly. The evolution of the oligosaccharides content with temperature is shown in Figure 2b, and maxima of XOS content and their main substituents (uronic acids and acetyl groups) were observed near T_{max}= 200 °C. At 200 °C, up to 77% of the xylan was hydrolyzed into XOS, whereas the percentage of acetyl groups remaining as substituents of XOS exceeded the 60%. Regarding the total OS yield (excluding GlcOS), a maximum of 13.7 g per 100 g of dry BSG was achieved at 195 °C. This value was then selected as the optimum, and it is in agreement with the results published by Carvalheiro et al.[16]

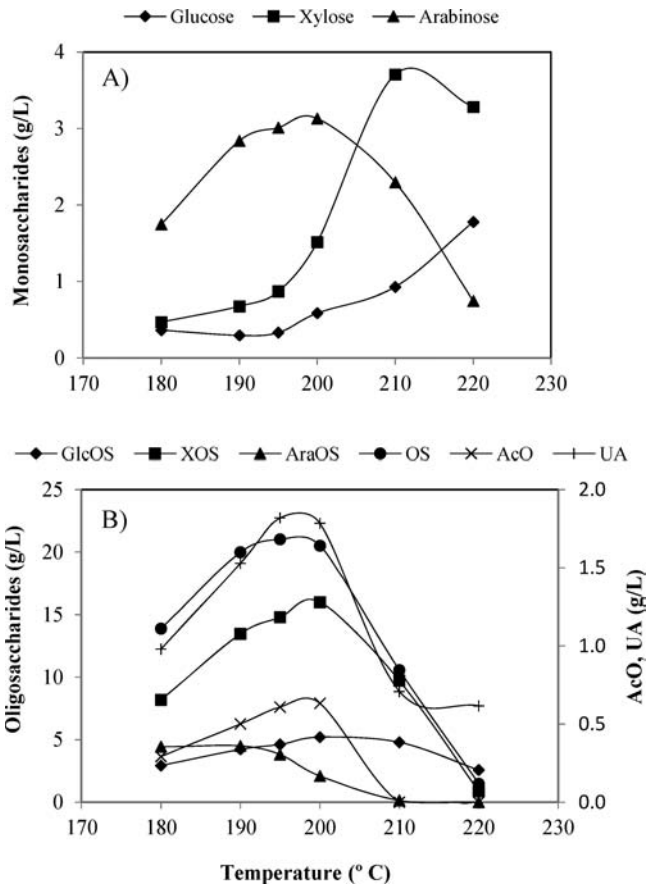

Figure 2. Effect of temperature on the composition of autohydrolysis liquors: (A) monomers expressed in g/L and (B) oligomers expressed in g/L.

Figure 3a shows a fast increase in the acetic acid, formic acid, furfural, and HMF concentrations, which starts at 195 °C and is partially due to the sugar decomposition. As a consequence of the increased severity, a rapid increase in the ONVC impurities concentration can be observed in Figure 3b. Meanwhile, the NVC content shows a maximum at 200 °C (0.048 g/g of liquor) and then decreases because of the decomposition reactions that give volatile compounds as products. These results compared favorably with the ones obtained from barley husks and wheat straw by Garrote et al.[27] and Carvalheiro et al.,[28] respectively.

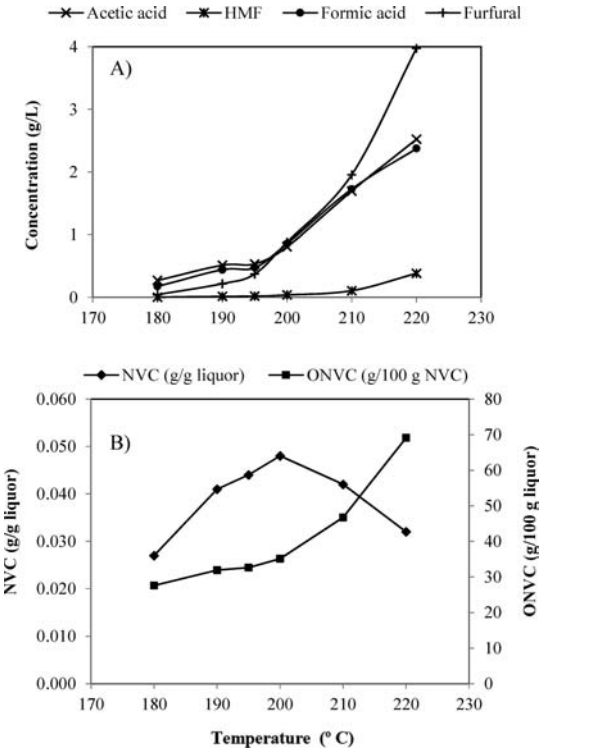

Figure 3. (A) Dependence of the concentrations of organic acids and furans in autohydrolysis liquors. (B) Temperature dependence of the concentrations of NVC and ONVC in reaction liquors (NVC, nonvolatile compounds; ONVC, other nonvolatile compounds or impurities).

Operating under isothermal conditions at the same severity (T = 180 °C and t = 12.2 min), 12.8 g of OS (OS = XOS + AraOS + AcO + UA) were obtained from 100 g of dry BSG. As indicated in Table 2, these liquors (stream A) contained 8% of MS, 61% of OS (including GlcOS), and 31% of ONVC. Most of the ONVC could correspond to products derived from the protein fraction, being necessary to develop a refining process.

Purification of Liquors. Figure 1 shows the purification scheme proposed for reducing the average DP of AXOS and to increase the purity of the final product. Membrane filtration is a

[a]MS, monosaccharides; OS, total oligosaccharides including acetyl groups and uronic substituents. [b]Expressed as mass fractions (kg NVC/kg stream), except for NVC, which is expressed as kg NVC/100 kg stream. [c]On the basis of 100 kg of autohydrolysis liquors obtained under optimal conditions: 180 °C and 12.2 min.

simple technology that has many advantages: it is energetically efficient, not harmful solvents are needed, it is easily scaled-up, and it was even employed successfully for the purification, fractionation, and/or concentration of oligosaccharides.[18,23] In contrast, ion exchange allows change of the ionic composition of a certain solution without introducing undesirable substances. Even though these resins are expensive, they can be reutilized after a simple regeneration with NaOH or HCl and distilled water. The scaling-up of this technique is not difficult, and it is used in several industrial applications. Moreover, ion exchange was also successfully applied to the purification of autohydrolysis liquors.[19,26]

Table 2 lists compositional data of the streams involved in the process as well as the mass balances.

Diafiltration. First, autohydrolysis liquors were diluted with distilled water and concentrated to their original volume using a 1 kDa molecular weight cutoff membrane. This sequence was repeated twice. As a result of this treatment, the concentrations of unwanted compounds (monosaccharides and ONVC) decreased to 79.4 and 28.5%, respectively. In contrast, high recoveries were achieved for oligomers and substituents (83.6% for XOS, 75.7% for AraOS, 81.6% for AcO, and 84.2% for UA). These results confirm the suitability of this technology for refining autohydrolysis liquors as mentioned in the literature.[29−31] Nevertheless, a higher degree of purity is desired because the ONVC content of the stream D is still 30%.

Enzymatic Hydrolysis. Because the DP distribution of AXOS is an important factor affecting their biological properties, the aim of the second step was to reduce the average DP of the oligomers by partial enzymatic hydrolysis using endoxylanases. As can be seen in Table 2, the content of the main part of the components remained almost constant. Some variations were observed for GlcOS and glucose concentrations, demonstrating the presence of cellulase activity in the enzymatic preparation.

Ion Exchange. As observed in previous studies, significant removal of impurities can be reached when XOS-containing liquors are treated by ion-exchange resins.[26,29,32] Taking this into account, an aliquot of stream F (liquors from the enzymatic hydrolysis) was subjected to ion exchange using Amberlite IRA400 (an anion exchange resin) under the conditions mentioned above. As a result of the treatment, a decrease of the ONVC by >50% and losses below 10% of total OS were achieved. The OS losses could be reduced to a value of 6% if the washing waters generated during the resin regeneration stage were recovered and added to the stream G to give stream L.

To increase the purity of the final product, stream L was treated with a cationic exchange resin generating stream M, which was joined with stream O to give the final refined product (stream R, Table 2). The percentages of product recovery in stream R were 80.3% for GlcOS, 89.9% for XOS,

DOI: 10.1021/acs.jafc.5b03132
J. Agric. Food Chem. 2015, 63, 8429−8438

89.9% for AraOS, 93.0% for AcO, and 95.8% for UA, but were just 32.6% for ONVC. As can be seen in Table 2, a final product containing 84% of substituted oligosaccharides (XOS, 56.2%; AraOS, 15.3%) and 8% of nonvolatile impurities was obtained by applying this processing scheme. These results are in agreement with other previous related studies.[29,32]

Structural and Chemical Characterization of the Final Product (Stream R). As a result of the process reflected in Figure 1, AXOS-enriched samples were obtained and freeze-dried in order to obtain a solid product that was evaluated for their prebiotic potential. However, in order to obtain more information about the composition of the product, samples of stream R were further characterized by HPSEC and MALDI-TOF MS. It must be taken into account that the structural features of OS affect their prebiotic potential as confirmed in the literature. Sarbini et al.[33] indicated that low-molecular-mass OS are often more selectively fermented by bifidobacteria and lactobacilli than are their parent high-molecular-weight carbohydrates. According to Sanchez et al.,[34] who used a human colon model system, the chain length of the AXOS is critical in determining the site of fermentation because shorter-chain-length molecules are fermented in the proximal colon, whereas longer molecules (average DP = 29) reach the distal colon and increase SCFA concentrations in all the compartments.

HPSEC analysis (Figure 4) proved the presence of large amounts of OS, including those with DP > 40 (molecular

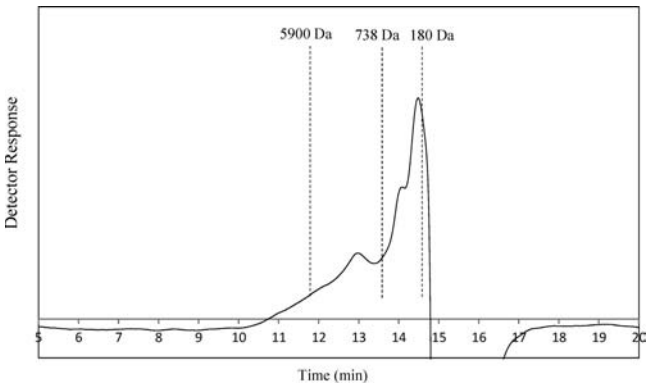

Figure 4. HPSEC chromatogram (including pullulan standards) of stream R.

weight >5900 Da), but the highest area was the one observed in the range 180−738 Da (using pullulan standards), namely, DP ≈ 2−6. This is interesting data taking into account that according to Moura et al.[35] a decrease in XOS consumption by species such as *Bifidobacterium adolescentis* was observed when DP was increased. Moreover, *L. brevis* showed preference for the commercial preparation, which basically constituted of xylobiose.

Likewise, the MALDI-TOF MS analysis data (Figure 5) confirmed the presence of a wide range of OS made up of both unsubstituted (DP = 3−16) and acetyl-substituted (DP = 3−10) pentoses. In accordance with the compositional information shown in Table 2 (XOS/AraOS = 3.67), the oligomers present in the refined product correspond not only to XOS but also to AXOS.

In Vitro Fermentability of the Refined Final Product. To assess the effects of AXOS consumption on the stimulation of four bacterial groups, an in vitro fermentation study was carried out using fecal samples obtained from three volunteers over 60 years old.

SCFA production and pH Evolution in the Fecal Cultures. As is well-known, a variety of the beneficial effects of prebiotics are related to SCFA production and pH reduction in the gut. As shown in Table 3, almost no differences were found between the pH values observed with FOS and AXOS. The decrease of pH was more pronounced during the first 11 h of fermentation, in concordance with the increases in the concentrations of SCFA and with the largest percentage of total OS consumption (Table 4), especially for GlcOS that were consumed up to 90% of their initial amount. In contrast, longer fermentation times resulted in slow decreases in the concentration of substrates, suggesting that some products could have low fermentability and, as a consequence, could reach distal parts of the colon. In fact, some oligomers (10.7 and 17.3% of the initial XOS and AraOS, respectively) remained in the media at the end of fermentation time assayed (45 h). In agreement with our results, a recent study on the prebiotic activity of refined AXOS[26] reported that some XOS and AraOS were not depleted at the end of fermentations (33 h). The incomplete consumption of these compounds could be attributed to the presence of high-DP linear chains because the acetyl groups were metabolized after 7 h, and according to Reis et al.,[36] smaller and highly ramified arabinoxilooligosaccharides are preferably consumed to linear fragments. However, this was not confirmed in this work, and it also should be taken into account that the fermentation pattern adopted by gut microbiota not only depends on the substrate structure but also on the composition of the initial microbiota.

Furthermore, Table 3 also details the generation profiles of SCFA (acetate, propionate, and butyrate), lactate, and formate.

As can be seen, the evolution of the total SCFA content in media containing AXOS was similar to that observed with FOS, and their production mainly took place along the period of 0−11 h (as a result of consumption of the OS). At 29 h, the total organic acids production observed for AXOS was basically acetic acid ≫ butyric acid > propionic acid. In a previous work using XOS derived from rice husks, fermentation times longer than 9 h also resulted in increased SCFA production and a similar product profile.[29] By contrast, a different profile was observed for commercial FOS because lower amounts of acetic acid and significant amounts of lactate (11.6 mM) and formate (19.1 mM) were achieved in the medium. Lactate was usually detected at low concentrations in cultures containing OS, even disappearing in a second fermentation stage (from 11 h), but it is often found at higher concentrations in FOS cultures.[23,37,38] Specifically, the maximum significant amount of lactic acid quantified in this study was 13.96 mM using FOS at 11 h. It has been described as behaving as an intermediary product rapidly converted into SCFAs by the cross-feeding of other bacteria,[36,39,40] which is the likely cause of its decreasing concentration.

In addition to the differences in the organic acids profile, a significant difference (125.04 vs 104.32 mM) was found in total acid concentrations between both substrates at the last time assayed. This fact is in agreement with previous studies; for instance, Reis et al.[36] obtained SCFA average values of 108.4 and 80.6 mM when using arabinoxylan from BSG and FOS, respectively. In the same way, Gullón et al.[26] determined after 33 h of fermentation an average total content of SCFA of 95.0 and 75.6 mM when employing as substrates AXOS from wheat bran and FOS, respectively.

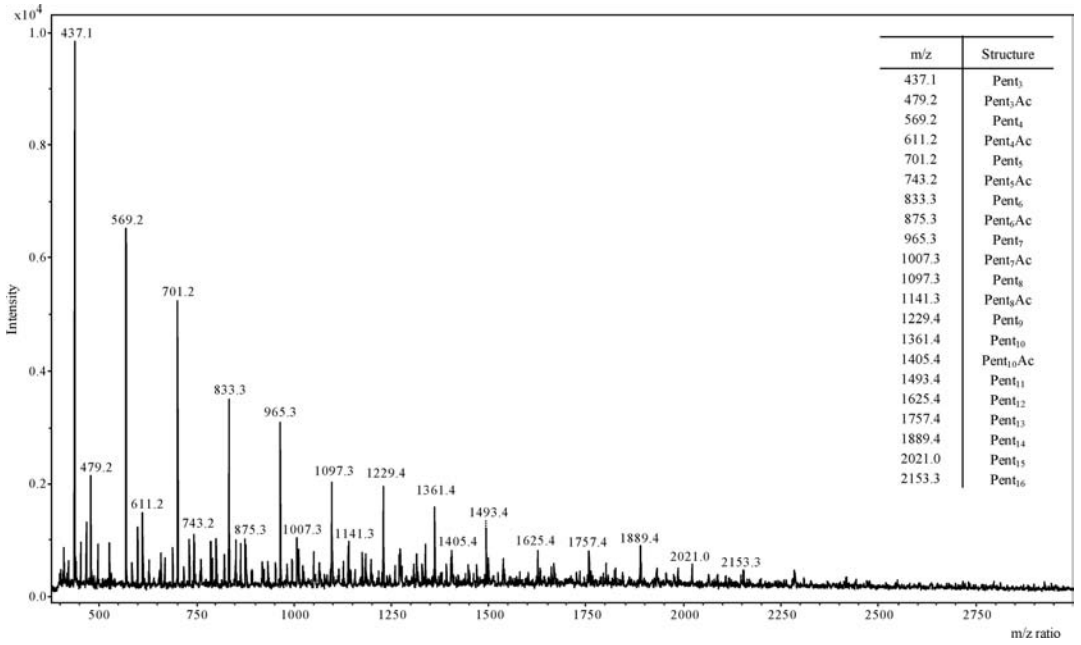

Figure 5. MALDI-TOF mass spectrum of stream R.

Acetate was the main acid in all the experiments, reaching the highest values when AXOS were used as substrate. In fact, observing the data obtained for this acid, significant differences were found between the three substrates assayed from 11 h to the end of fermentation. The acetate proportions (with respect to total acids) and its concentrations obtained at 45 h with AXOS, FOS, and the negative control were 70.7, 42.8, and 70.5% and 88.4, 44.7, 30.9 mM, respectively. This acetogenic potential of XOS was previously observed by Gullón et al.[29] using rice husks as raw material or by Gullón et al.[26] with AXOS from wheat bran. Similarly, the highest propionate concentrations were found in media containing AXOS, which is in agreement with the results reported by Hughes et al.[41] and Gullón et al.,[26] ranging from 6.6 mM in the control assay until to 14.8 mM with AXOS at 45 h. Propionate generation has been associated with the presence of side chains in XOS,[42] and it is utilized primarily by the liver. Its role as a potential modulator of cholesterol synthesis has been proposed.[43]

By comparison, butyrate levels were found in similar amounts in both AXOS and FOS cultures (Table 3), being slightly higher in experiments with FOS. These results were similar to those reported by Gullón et al.[26] with hemicellulose-derived soluble AXOS or by Rivas et al.[44] employing saccharides derived from wood mannan. The butyrate accumulation leads to potent effects on a variety of colonic mucosal functions and may promote satiety.[45] In the case of the negative control, the SCFA generation is associated with the protein degradation, which consequently also lead to increases of the ammonia and phenols (generated in putrefactive processes) levels in the gut.

Dynamics of the Bacterial Populations. Nowadays, potential prebiotic consumers expect from these products the promotion of the growth of specific groups able to enhance their health. Many investigations have focused only on the stimulation of *Bifidobacterium* and *Lactobacillus* species.[46] However, in addition to these two bacterial groups, *Bacteroides* and *Clostridium* also are of great interest and should be included in all the studies. Following the Figure 6 and regarding the number of bifidobacteria, increases in this genus were higher for AXOS, in comparison with commercial FOS, so it can be stated that they have a similar or even greater bifidogenic effect than FOS. On the contrary, the increases in the number of lactobacilli were significantly higher than the ones observed in the control assay but lower than the ones achieved with FOS. This is in agreement with the lactic acid generation in the experiments assayed with FOS, as well as with other studies that demonstrated the potential of FOS to promote the growth of lactobacilli.[23,47,48]

Moreover, the increases in clostridia numbers (often considered harmful bacteria because of their capacity to produce branched-chain fatty acids and a variety of nitrogen- and sulfur-containing compounds) were, in general, lower than those observed in the other bacterial groups, and when AXOS are used as substrate, these increases were slightly lower than those achieved with FOS and similar to the ones observed in the control assays. This means that the growth of clostridia numbers observed in these assays could partially be due to the components of the basal medium. Gullón et al.[20] observed a similar effect on the clostridia population with fermented oligosaccharide mixtures derived from apple pomace using the same nutrient medium.

Meanwhile, the rise in the bacteroides counts was similar in both AXOS and FOS assays after 20 h of fermentation, but almost the same increases were also observed in control experiments because this group of bacteria has saccharolytic and peptolytic activity. Rycroft et al.[48] obtained similar results for *Bacteroides* populations when FOS and XOS were used as substrates, and Jaskari et al.[49] reported that oat xylooligomers were not selectively used by bifidobacteria because *Bacteroides* sp. or *C. difficile* also showed moderate growth on these substrates. By contrast, Yamada et al.[50] reported that wheat arabinoxylan hydrolysates (arabinosylxylobiose, arabinosylxylotriose, arabinosylxylotetraose, and diarabinosylxylotetraose) were utilized by *B. adolescentis* and *Bifidobacterium longum* but not by *Bacteroides* sp.

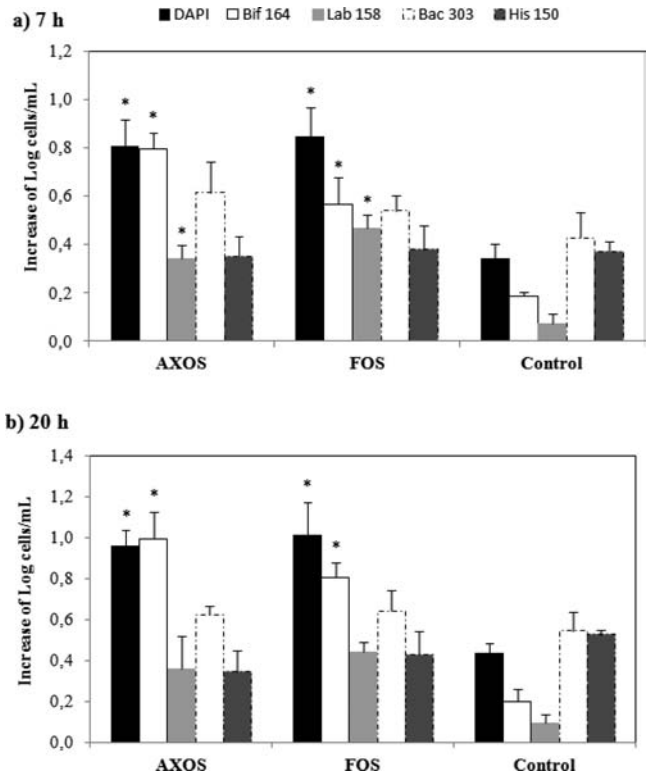

Figure 6. Increase of bacterial populations (expressed as log cells/mL) in fecal batch cultures using three different human inoculums and various substrates: (a) 7 h and (b) 20 h. Error bars indicate standard error (n = 3). Asterisks indicate significant differences (Tukey's test, p < 0.05) between different carbon sources. DAPI: 4′,6-diamidino-2-phenylindole; Bif164: *Bifidobacterium*; Lab158: *Lactobacillus/Enterococcus*; Bac303: *Bacteroides/Prevotella*; and His150: *Clostridium histolyticum* clusters I and II.

This influence of AXOS on the growth of the four bacterial groups (Figure 6) presented a pattern in close correspondence with the substrate consumption because the largest increase in total cell counts took place within the first 7 h of fermentation, coinciding with the largest decrease in the concentration of OS and with the pH decreasing. Also, the highest production of lactic or acetic acids correlated with changes in the numbers of bifidobacteria and lactobacilli. These results are in agreement with Mussatto et al.,[13] who indicated that germinated barley foodstuff is considered to be a mild anti-inflammatory through increases in colonic butyrate concentration and the number of *Bifidobacterium* sp., or with Jaskari et al.,[49] who proved that most of the intestinal bacteria tested (*Bacteroides thetaiotaomicron*, *Bacteroides vulgatus*, *Bacteroides fragilis*, and *C. diffcile*) were able to degrade at least some xylooligomers from oat spelt xylan. In addition, the data obtained by Falck et al.[11] from batch fermentation experiments showed that XOS hydrolysates from cereal xylan (rye flour) and hardwood (birchwood) were fermented by both *B. adolescentis* and *L. brevis*, whereas nontreated polymeric xylans were not fermented by any of the strains. However, Finegold et al.[1] reported that XOS increases the counts of *Bifidodobacterium* without increasing the counts of *Lactobacillus* in healthy adults. Another study assessing the effects of a 4 g per day of XOS on the intestinal microbiota, gastrointestinal function, and nutritional

DOI: 10.1021/acs.jafc.5b03132
J. Agric. Food Chem. 2015, 63, 8429−8438

parameters in elderly patients over a 21 day period concluded that XOS supplementation promoted intestinal health and showed no adverse effects on the elderly study population.[51] This is an important point because a requirement for an effective prebiotic would be the absence of gastrointestinal side effects.

CONCLUSIONS

Brewer's spent grain (BSG) was evaluated as a raw material for obtaining a mixture of arabinoxylooligosaccharides (AXOS) suitable to be use as prebiotics for elderly. After hydrothermal treatment of BSG, AXOS were refined by membrane filtration and ion exchange and modified by enzymatic hydrolysis.

The presence of both substituted (DP = 2−10) and unsubstituted (DP = 2−16) oligosaccharides made up of xylose and arabinose were confirmed in purified mixtures (OS content = 84% w/w) by MALDI-TOF MS. Finally, AXOS were evaluated for their prebiotic activity by in vitro fermentation assays using fecal inocula from elderly people. Experimental results showed that AXOS fermentation resulted in increased bifidobacteria and lactobacilli populations with respect to the negative control cultures as well as the accumulation of SCFA, confirming a stimulatory effect. Moreover, taking into account the variations in the bacterial populations and the production of organic acids, it can be concluded that the results obtained with AXOS are slightly better than the ones achieved with FOS.

Therefore, the intake of this kind of AXOS could enable the improvement of intestinal microbiota and their functions and, as a consequence, the health of the elderly.

AUTHOR INFORMATION

Funding

We are grateful to Xunta de Galicia (project ref GRC2014/018 and "INBIOMED" Project) for the financial support of this work. Both projects were partially funded by the FEDER Program of the European Union ("Unha maneira de facer Europa"). B.G. thanks the Spanish Ministry of Education, Culture, and Sports for her FPU research grant.

bone loss preventive, and osteoclastogenesis suppressing.[19] For these reasons, efforts toward efficient synthesis of compounds **2** and **3** by a chemoenzymatic approach have recently been reported.[20]

To gain a deeper insight into this subject and to establish which are the main metabolites present in *C. sativus* petals, we analyzed them by high-resolution magic-angle-spinning nuclear magnetic resonance (HR-MAS NMR) and their ethanol (95%) extract by HR-NMR. HR-MAS NMR spectroscopy allows for the derivation of the biochemical profile of intact (human, animal, or plant) tissues[21] formed by fast-moving small metabolites that give rise to narrow resonances. Through HR-MAS NMR, we tried to have a look inside a complex row matrix without disrupting its structure and avoiding hydrolytic processes that can flank extraction. The purpose of this paper is to contribute to the utilization of *C. sativus* petals directly after the separation from saffron. To the best of our knowledge, this is the first HR-MAS NMR study of petals.

EXPERIMENTAL SECTION

Plant Materials. *C. sativus* flowers were collected in Abruzzo (Italy), in the Aquila Saffron Protected Designation of Origin (PDO) status, at the Farm "Vigna di More" located in Tione degli Abruzzi, in autumn 2011. The flowers grew at 700 m above sea level. The bulbs were planted in August on a ground prepared 1 year before (the soil is employed every 5 years), and the flowers were harvested in October. The bulbs were put at 2−3 cm distance from each other, at least 8 cm depth in rows of two or three, according to the space and land available. Flowers were hand-picked early in the morning, before sunrise before perianth opening, and were placed in traditional wicker baskets. After collection, they were stored at 5 °C and send to the lab, where intact petals were used for HR-MAS NMR measurements within 3 days after collection.

Extraction. Fresh petals (10 g) were extracted with 95% ethanol (Sigma-Aldrich), and the extract was vacuum-evaporated (150 mg). The whole process was carried out quickly at room temperature (about 1 h). The extracts were analyzed in HR-NMR and mass spectrometry (MS).

NMR Measurements. ^{1}H HR-MAS NMR spectra were recorded with a Bruker Avance 400 (Bruker BioSpin) spectrometer operating at a frequency of 400.13 MHz. The instrument was equipped with a ^{1}H,^{13}C HR-MAS probe for semi-solids and with a broadband inverse (BBI) probe for liquids. Before HR-MAS examination, intact saffron petals were introduced in a MAS zirconia rotor (4 mm outer diameter) and 10 μL of D_2O was added to provide deuterium for the lock system, fitted with a 50 μL cylindrical insert to increase sample homogeneity, and then transferred into the probe cooled to 5 °C. Experiments were performed at a temperature of 5 °C controlled by a Bruker cooling unit.

Samples were spun at 4000 Hz, and one-dimensional (1D) and two-dimensional (2D) spectra were acquired using the sequences implemented in the Bruker software. The same experiments were carried out on D_2O extract solution at 25 °C, with a lower number of scans. To record ^{1}H water-presaturated spectrum, a composite pulse sequence (zgcppr) with 2 s water presaturation during the relaxation delay, 8 kHz spectral width, 32 000 data points, and 16−8 scans were used. The 2D correlation spectroscopy (COSY) spectra were acquired using a standard pulse sequence (cosygpprqf), 1 s water presaturation during relaxation delay, 2−4 kHz spectral width, 2000 data points, 4 scans per increment, and 128 increments. The 2D total correlation spectroscopy (TOCSY) spectra were acquired using a standard pulse sequence (mlevgpph19), 1 s water presaturation during relaxation delay, 100 ms mixing (spin-lock) time, 2−4 kHz spectral width, 4000 data points, 4 scans per increment, and 512 increments. The 2D heteronuclear single-quantum coherence (HSQC)-edited spectra were acquired using a standard pulse sequence echo−antiecho phase sensitive (hsqcedetgp), 0.5 s relaxation delay, 1.725 ms evolution time, 2−4 kHz spectral width in f2, 2000 data points, 16−8 scans per increment, 15 kHz spectral width in f1, and 256 increments. The 2D heteronuclear multiple-bond coherence (HMBC) spectra were acquired using a standard pulse sequence (hmbcgplpndqf), 0.5 s relaxation delay, 50 ms evolution time, 2−4 kHz spectral width in f2, 2000 data points, 128−32 scans per increment, 22 kHz spectral width in f1, and 256 increments.

Deconvolution of ^{1}H NMR-selected signals was run with MestReNova 9.1 (2014 Mestrelab Research S.L.).

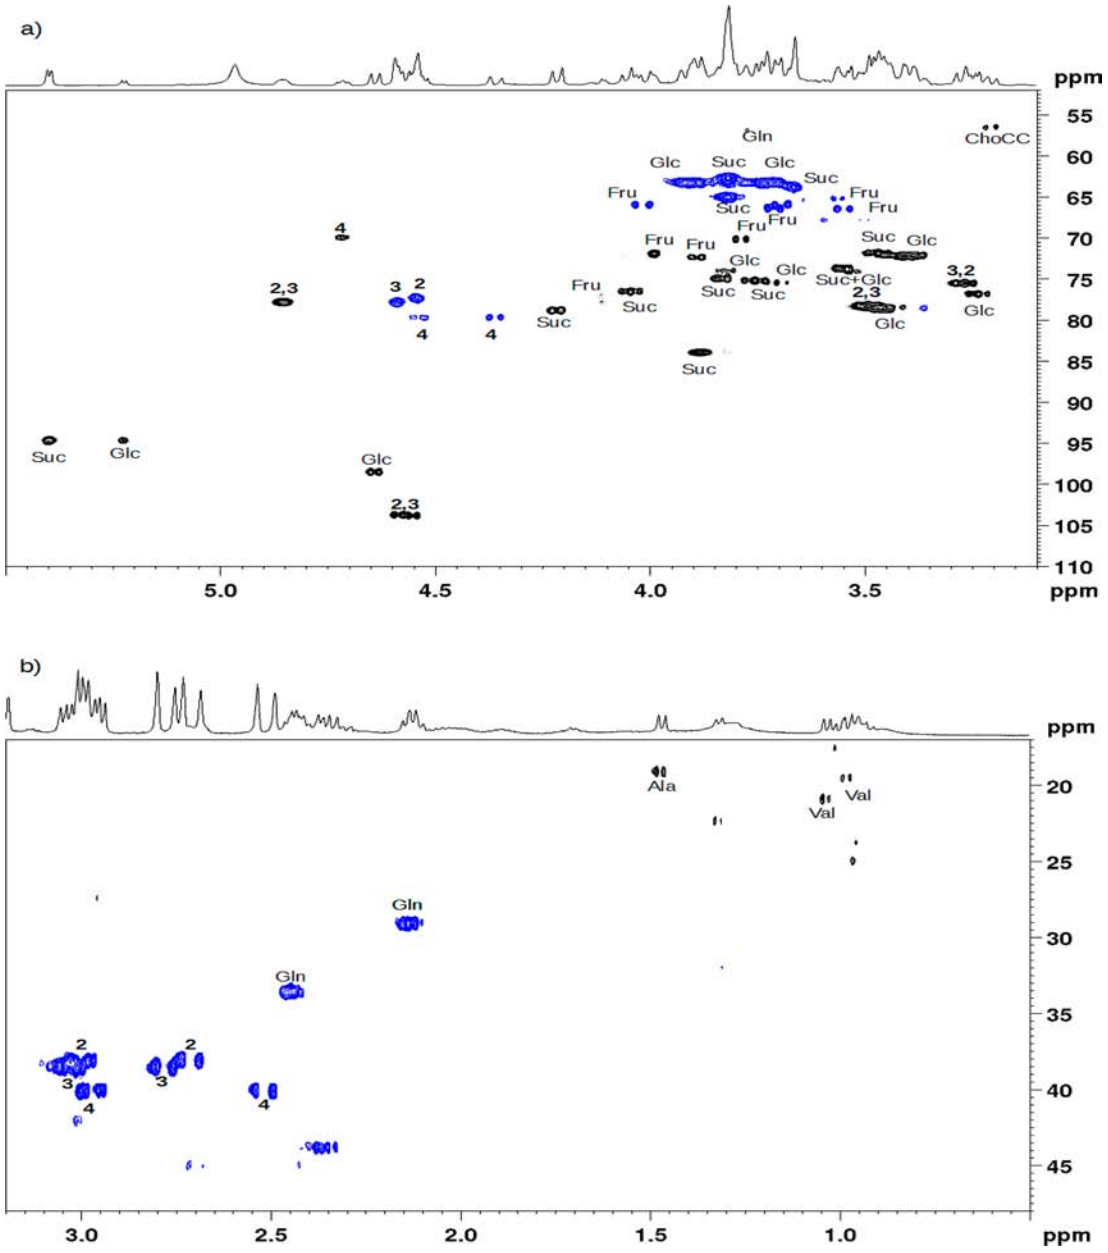

Figure 3. Enlarged (a) carbohydrate and (b) aliphatic regions of the HSQC HR-MAS NMR spectrum of fresh saffron petals. ChoCC = choline-containing compounds.

Electrospray Ionization (ESI) Ion-Trap (IT) MS Measurements. The negative-ion ESI mass spectra and ESI−MS/MS data (collision energies of 10, 15, 20, or 35 eV) were acquired with a LC−MS(n) IT 6310A (Agilent Technologies) coupled with a HPLC Agilent Series 1200 equipped with a Zorbax SB-C18 column, 30 × 2.1 mm inner diameter, 3.5 μm particle size (Agilent). Eluents were acetonitrile, H_2O, and 1% formic acid. Chromatographic runs were performed using a gradient of 1% formic acid in acetonitrile (98 → 10%) and 1% formic acid in water (2 → 90%). The solvent flow rate was 0.2 mL/min; the temperature kept at 25 °C; and the injector volume selected was 2 μL. Total ion current (TIC) chromatograms were acquired in both positive and negative mode in the mass range between m/z 100 and 1400. He was used as the collision gas in MS^2 experiments.

RESULTS AND DISCUSSION

The water-presaturated ^{1}H HR-MAS NMR spectrum of saffron petals (Figure 2a) shows the overlapped signals from a number of metabolites, mainly in the carbohydrate region, whereas only broad and weak signals are found in the aromatic region, at about 6.9 and 7.7 ppm, where multiplets from kaempferol derivatives are expected. These two broad resonances are sometimes assigned to polyphenols, but they have also been attributed to NH protons.[22] On the other hand, some multiplets in the range of 3.1−2.5 ppm, outside the common carbohydrate region, are detected, and other low signals mainly attributable to free amino acids and lipids are present at lower parts per million (ppm).

To disentangle the complex spectral pattern, it was necessary to use 2D NMR homo- and heterocorrelated experiments, such as COSY, TOCSY, HSQC, and HMBC. We were thus able to reconstruct molecular skeletons and compare the chemical shifts and the correlation patterns to those reported in the literature and in NMR databanks, such as the Human Metabolome Database (HMDB; http://www.hmdb.ca/). Using this approach, we found that the majority of signals in the ^{1}H spectrum are due

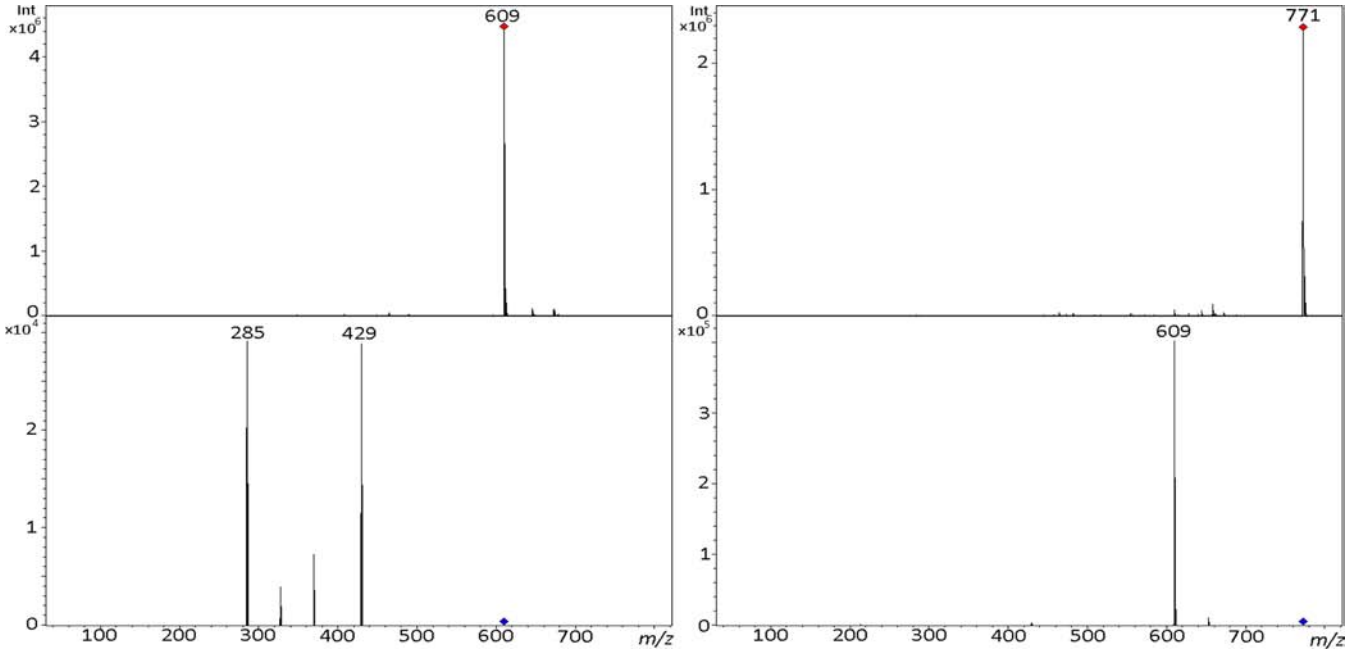

Figure 4. ESI−IT MS/MS spectra of (left) compound **1** and (right) minor kaempferol derivative.

to sucrose (Suc), glucose (Glc), and fructose (Fru), as can be better seen observing HSQC correlations (Figure 3). Apart from those sugars, other resonances as a result of compounds **2**−**4** are detected and assigned, through 2D experiments, as reported in Table 1. The chemical shifts determined by us on intact petals were parallel to those reported in pyridine-d_5 by Zhang et al.[20] Remarkably, even 2D NMR spectra did not highlight signals from kaempferol or its derivatives in the aromatic region, meaning that, in the cell environment of fresh petals, these molecules are not freely tumbling but are probably associated with rigid structures within the cell. Other minor resonances were confirmed to derive from free amino acids (mainly alanine, Ala, glutamine, Gln, and valine, Val).

The molar ratio of total **2**−**4** derivatives relative to the water signal, estimated through deconvolution of 2-H signals of compounds **2**−**4** at 2.8−2.5 ppm and H_2O at 4.97 ppm in the not presaturated ^{1}H NMR spectrum, resulted in around 0.3 mol %. It can be roughly converted to 0.8% in weight with respect to water and then, considering 75% water in petals, to 0.6% of compounds **2**−**4** in intact petals.

Fresh petals were then extracted rapidly with 95% ethanol; the vacuum-evaporated residue was solubilized in D_2O; and 1D and 2D NMR and ESI MS/MS spectra were acquired.

The ^{1}H NMR spectrum of the extract is reported in Figure 2b, and it clearly displays signals in the aromatic region that compare well to those reported by Wolfram et al.[23] and were assigned, together with other resonances in the carbohydrate region, to kaempferol 3-*O*-sophoroside (**1**; Table 1) and to a minor derivative that differs mainly for the 2′,6′-H signals that are found at 8.09 ppm, 8-H at 6.78 ppm (d, 2.2 Hz), 6-H at 6.50 ppm (d, 2.2 Hz), and 1-H_{Glc} at 5.48 ppm (d, 7.6 Hz) and could be a 7-substituted derivative of compound **1**.

Apart from differences in the chemical shifts, as a result of a change from the cell environment to D_2O solution, resonances from compounds **2**−**4** were also detected in the ethanol extract, even though in a ratio different with respect to that observed in intact petals: the (**2** + **3**)/**4** molar ratio passes from 2.5:1 in intact petals to less that 1:1 in the extracts, and at the same time, the free glucose signals enhance with respect to those of sucrose (1-$H_{\alpha\text{-Glc}}$/1-H_{suc} passes from 0.4 to 1.2). Hence, the extraction process, even though carried out rapidly and without acidic conditions, promoted hydrolysis of compounds **2** and **3** to compound **4** and free Glc.

ESI−IT MS was finally employed to confirm the presence of compound **1** and to clarify the structure of the minor flavonol detected in the ethanol extract (Figure 4). The two major peaks detected in negative mode correspond to *m*/*z* 609 and 771 $[M - H]^-$ pseudo-molecular ions. The collision-induced dissociation (CID) with He gas of *m*/*z* 609 (highest) peak gave *m*/*z* 429 $[M - C_6H_{12}O_6 - H]^-$ and *m*/*z* 285 $[\text{kaempferol} - H]^-$ as expected for two subsequent hexose losses starting from compound **1**. On the other hand, CID of *m*/*z* 771 gave *m*/*z* 609, corresponding to a loss of $C_6H_{10}O_5$, demonstrating that this derivative contains a further hexose unit. Minor peaks, corresponding to pseudo-molecular species of *m*/*z* 625 (which decomposes to *m*/*z* 463 through hexose loss) and *m*/*z* 651 (which gives *m*/*z* 471 and 285 under CID), were also detected. The former could be due to quercetin sophoroside, and the latter is probably an acetylated derivative.

In conclusion, this work shows that HR-MAS NMR can be employed to monitor bioactive compounds freely tumbling in the cell environment, directly on intact petals. HR-MAS NMR allows for detection of the presence of compounds **2**, **3**, and **4** directly on intact *C. sativus* petals, without the need of extraction processes. Their content was estimated by HR-MAS NMR to be roughly 0.6%. HR-MAS NMR does not detect instead flavonols, especially compound **1**, that are still contained in petals in a not negligible amount, as demonstrated by ^{1}H NMR analysis of the ethanol extract. This implies that flavonol derivatives in saffron petals have low tumbling rates, which could be due to their close association to macromolecular species in cell walls.[24]

The 3-hydroxybutyrolactone derivatives **2**−**4** contained in *C. sativus* petals are biologically active species that, together with compound **1**, probably contribute to confer hepatoprotective, antihyperglycemic, anti-inflammatory, and other effects to petal

DOI: 10.1021/acs.jafc.5b03284
J. Agric. Food Chem. 2015, 63, 8439−8444

extracts. The extraction process leads to partial hydrolysis of petal constituents; hence, it could be useful to evaluate the direct employment of saffron petals for phytopharmaceutical and nutraceutical purposes, to better exploit a waste product of massive production of commercial saffron.

The data presented in this study strongly support the idea that petals of *C. sativus* are not a waste but can be used for their biological activity in specific foods as well as in herbalist products. This can have a major impact for the community of saffron, the cultivation of which represents an opportunity to improve and develop the economy of the agricultural sector in poor European regions. The exploitation of not only stigmas but also petals as raw material for health-enhancing products would further enhance the economical value of this activity and reduce waste production.

sulfate, 50 ppm) at 25 °C in the dark. After 90 h of incubation, the monocolonies on the surface of the plates were transferred onto KMV^+ medium several times to purify the strains. These isolated strains were kept on a KMV^+ medium (without antibiotics) as monoclonal cultures, and then we determined their squalene content using gas chromatography.

Molecular and Phylogenetic Analyses. The genomic DNA of selected strains was extracted using a Universal Genomic DNA extraction kit (Takara DV811A, Dalian, China), according to the protocol of the manufacturer. The internal transcribed spacer (ITS) region was amplified using the ITS4 primer P1 (5′-TCCTCCGCTTATTGATATGC-3′) and the ITS5 primer P2 (5′-GGAAGTAAAAGTCGTAACAAGG-3′). The polymerase chain reaction (PCR) products were visualized by agarose gel electrophoresis and purified using the TIANgel Midi Purification Kit (TIANGEN DP209, Beijing, China). The purified PCR products were cloned into the pGEM-T Easy vector (Promega) and then were sequenced by Takara Co., Ltd.

The resulting sequence data were searched using NCBI BLAST, and the sequences were aligned with the ClustalX program. A phylogenetic tree was inferred using the Minimum Evolution method of MEGA, version 5.0. The tree reliability was evaluated by bootstrap analysis of 1000 replicates.

Strains and Cultivation. Strain SD301 was isolated by the methods mentioned above and cultivated in 50 mL of GPY medium (6% glucose, 1% peptone, and 1% yeast extract) containing 1.5% artificial sea salt in a 250 mL flask shaken at 200 rpm and 25 °C.

Optimization of Culture Conditions. To investigate the effects of various cultivation media, eight carbon sources (6% of glucose, D-fructose, D-xylose, maltose, sucrose, lactose, glycerol, and starch) and seven nitrogen sources (2% of yeast extract, peptone, tryptone, urea, ammonium sulfate, sodium glutamate, and sodium nitrate) were tested. Tryptone (2%) was used as the nitrogen source for the carbon source testing, while glucose (6%) was consistently used as the carbon source when the nitrogen source testing was carried out. To investigate the C/N ratio effect on the cell growth and squalene yield of strain SD301, the constant concentration of the C source of 6% and various N source concentrations were used.

The effects of varying concentrations (0−60 g L^{-1}) of sea salt were also studied using the optimized medium. To examine the effects of various growth parameters, various pH values (pH 4.0, 5.0, 6.0, 7.0, 8.0, and 9.0) and different temperatures (15, 20, 25, 30, and 35 °C) were used to cultivate *Pseudozyma* sp. SD301.

All tests were carried out in 250 mL flasks with 50 mL medium shaken at 200 rpm and 25 °C for 5 days.

Batch and Fed-Batch Fermentation Experiments for Squalene Production. A batch fermentation experiment was performed in a 5 L Biostat B plus bioreactor, which was equipped with controllers for pH, temperature, agitation, and dissolved oxygen (DO) concentration. Batch cultures were carried out in 3.5 L of production medium. The temperature was maintained at 25 °C. The agitation speed automatically varied from 300 to 800 rpm at a fixed air flow rate of 1.2 vessel volumes per minute (vvm) to maintain the DO at 20% air saturation. The pH was maintained at 6.0 by adding 2 mol L^{-1} NaOH or 2 mol L^{-1} HCl. To control foam formation, 1 mL of antifoam was added at the beginning of the run. Samples for off-line determination of the glucose concentration, biomass, and squalene yield were withdrawn every 6 h until the end of the fermentation (48 h).

Another fed-batch fermentation experiment was also performed in the 5 L Biostat B plus bioreactor, with the same conditions of the batch fermentation, except that intermittent glucose feeding was supplied to maintain the residual glucose concentration at approximately 5 to 25 g L^{-1} by feeding a 40% (w/v) glucose stock solution. The samples were withdrawn every 10 h until the end of the fermentation (100 h).

The initial fermentation medium contained 60 g L^{-1} glucose and 20 g L^{-1} yeast extract in artificial seawater (artificial sea salt concentration of 15 g L^{-1}). This medium also contained a vitamin solution (2 mL L^{-1}). The vitamin solution was filter-sterilized (0.22 μm) and contained 100 mg/L thiamine, 10 mg/L biotin, and 50 mg/L cyanocobalamin.

Biomass Determination and Glucose Assay. The biomass of *Pseudozyma* sp. SD301 was expressed as DCW. Samples (5 mL) were collected and centrifuged at 7000*g* at 4 °C for 10 min, and they were then freeze-dried to a constant weight at −50 °C for approximately 60 h. The residual glucose in the fermentation medium was analyzed by a biosensor equipped with a glucose oxidase electrode (SBA-40E, Institute of Biology, Shandong Academy of Sciences, Jinan, China).

Observation Using Confocal Laser Scanning Microscopy (CLSM). To investigate the intracellular localization of squalene in *Pseudozyma* sp. SD301, the observation of *in vivo* fluorescence imaging of the cells were carried out using CLSM (FluoView FV1000, Olympus, Tokyo, Japan). First, the cells were dyed by nile red using the method mentioned by Morita et al.[24] In details, 500 μg mL^{-1} nile red was prepared in acetone and stored at 4 °C as the stock solution. Then, the stock solution was added to the culture with a final concentration of 0.1 μg mL^{-1} and incubated at 37 °C for 15 min. Second, the stained cells were observed by CLSM, and the excitation and emission wavelengths were 559 and 612 nm, respectively. The fluorescent images were obtained at 1000× magnification.

Lipid Extraction and Fatty Acid and Squalene Content Analyses. The total lipid content was estimated using a modified miniaturized Bligh−Dyer method.[25] The harvested cells were extracted into 30 mL of chloroform/methanol (2:1, v/v) at room temperature. The lipid extract was dried over anhydrous Na_2SO_4, and the solvent was removed by evaporation.

The total lipid was converted into fatty acid methyl esters (FAMEs), and the fatty acid composition was analyzed using an Agilent 7890-5975 gas chromatography−mass spectrometry (GC−MS) system (Agilent Technologies, Inc., Santa Clara, CA).[26]

Squalene was isolated from the total lipid by saponification,[27] with some modifications. Samples (5 mL, V_1) were freeze-dried and used to extract the total lipid by the methods mentioned above. The extracted total lipid was transferred into 10 mL of 10% KOH−ethanol solution and incubated at 60 °C for 1 h with refluxing for saponification. Then, 4 mL of distilled water was added, and the unsaponifiable compositions were extracted with 2 mL (V_2) of *n*-hexane. Afterward, squalene was separated by Agilent 7890A GC with a 7650A automatic liquid sampler using a HP-5, 30 m × 320 μm × 0.25 μm column; meanwhile, nitrogen was used as a carrier gas. The initial oven temperature was 100 °C and was maintained for 1 min, and then the temperature was raised to 300 °C for 15 °C min^{-1} and, finally, maintained at 300 °C for another minute. Peak detection was performed by a flame ionization detector. The temperature of the injection port and flame ionization port was 300 °C. The injection volume was 1 μL, and the split ratio was 1:10. The squalene concentration (X, μg mL^{-1}) was further quantified using an external standard method. The standard curve (Figure S1) was made from a set of concentrations of commercial squalene standard (>99% squalene, J&K Chemical) by GC analysis. The squalene production (P, g L^{-1}) was calculated by eq 1.

$$P = X\frac{V_2}{V_1} \times 10^{-3} \quad (1)$$

RESULTS AND DISCUSSION

Isolation and Identification of *Pseudozyma* sp. SD301. Samples obtained from a mangrove ecosystem were screened for squalene-producing microorganisms. Almost 100 purified strains were isolated as colonies on the KMV^+ medium plates and microscopically observed. The biomass (DCW) of the strains ranged from 5.29 to 27.61 g L^{-1} when cultivated in the GPY medium, and the squalene contents (percent of DCW) and squalene yields ranged from 0.4 to 5.6% DCW and from 0.1 to 0.9 g L^{-1}, respectively.

Among these tested strains, SD301 showed the highest levels of squalene content and yield. On the basis of morphological

DOI: 10.1021/acs.jafc.5b03539
J. Agric. Food Chem. 2015, 63, 8445−8451

observations, SD301 formed a yeast-like vegetative cell that was ovoid to cylindrical and produced fusiform blastoconidia (Figure 1). These morphological characteristics were common features of the genus *Pseudozyma*.[28] Subsequently, the ITS region of this strain was determined, and SD301 was confirmed to be a *Pseudozyma* strain by phylogenetic analysis using the minimum-evolution (ME) tree (Figure 2). Hence, the newly isolated strain was termed *Pseudozyma* sp. SD301. To find the optimal conditions for squalene production, we further investigated the cell growth and squalene production on various carbon and nitrogen sources and under various temperatures, pH, and osmotic stresses, all of which are necessary for the optimization of the culture conditions.

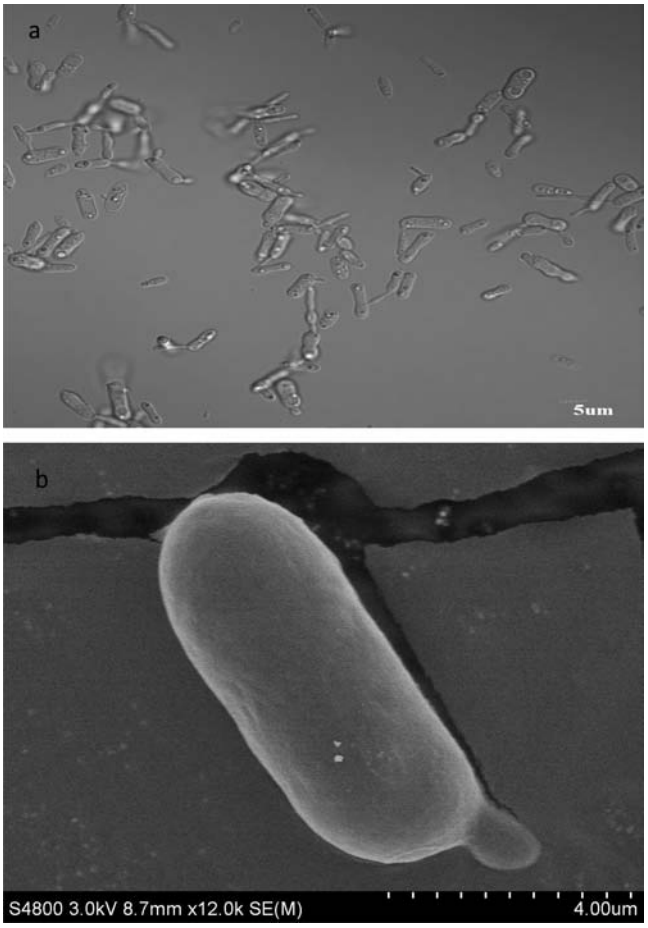

Figure 1. Morphology of *Pseudozyma* sp. SD301 (a, light microscope, 400× magnification; b, scanning electron microscope, 3500× magnification).

Cell Growth and Squalene Production on Various Carbon and Nitrogen Sources. As shown in Figure 3a, glucose, fructose, xylose, maltose, sucrose, starch, glycerol, and lactose were used as carbon sources to investigate the cell growth and squalene yield of *Pseudozyma* sp. SD301. The monosaccharide hexoses, such as glucose and fructose, could be well used by *Pseudozyma* sp. SD301 with a biomass of 24.06 and 19.09 g L^{-1}, respectively, but pentoses (such as xylose) and polysaccharides (e.g., starch) were not efficient substrates for cell growth. Sucrose was a good carbon source for *Pseudozyma* sp. SD301 growth, while maltose, another disaccharide, was not optimal. At the same time, glycerol and lactose were also very suitable for its growth. In contrast, only three carbon sources, glucose, sucrose, and lactose, were fit for optimal squalene production by *Pseudozyma* sp. SD301, with the best squalene yield of 0.79 g L^{-1} (Figure 3a). These results were in agreement with previous data obtained for *Pseudozyma* sp. JCC207.[15]

Peptone, yeast extract, tryptone, urea, sodium glutamate, ammonium sulfate, and sodium nitrate were tested as organic or inorganic nitrogen sources for the growth of *Pseudozyma* sp. SD301 (Figure 3b). When yeast extract was used as a nitrogen source, the highest biomass and squalene production (28.32 and 0.788 g L^{-1}, respectively) were obtained, followed by tryptone, peptone, sodium glutamate, ammonium sulfate, urea, and sodium nitrate. According to our results, organic nitrogen sources, such as yeast extract, tryptone, and peptone, were more suitable for the cell growth and squalene production than inorganic nitrogen sources because these organic nitrogen sources had, in contrast to inorganic nitrogen sources,

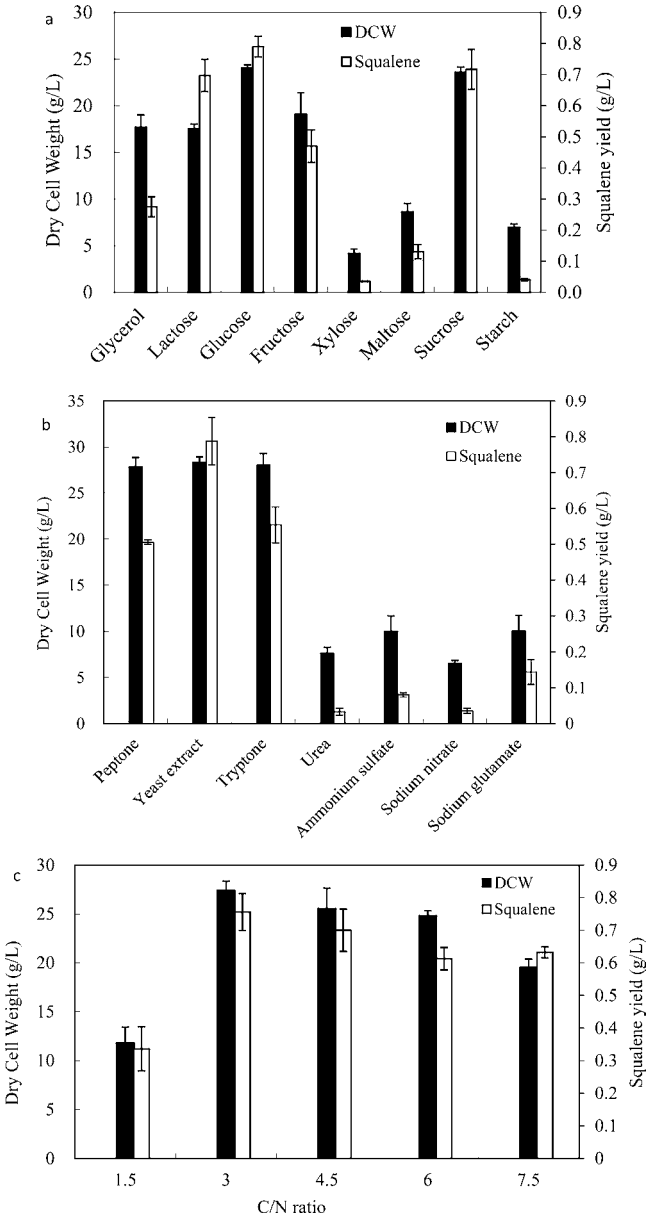

Figure 3. Effects of (a) carbon sources, (b) nitrogen sources, and (c) C/N ratio on the cell growth and squalene yield in *Pseudozyma* sp. SD301.

additional growth factors, such as vitamins and coenzymes, which might be necessary for squalene biosynthesis. These results were slightly different from the results of *Pseudozyma* sp. JCC207,[15] which could also produce squalene with inorganic nitrogen sources.

It is well-known that the C/N ratio of the culture medium dramatically affects the growth of microorganisms. A high C/N ratio is effective for increasing the lipid content in cells.[29] Therefore, the effects of the C/N ratio on the cell growth and squalene yield of strain SD301 were examined (Figure 3c). The cell growth increased to the maximum level by increasing the C/N ratio to 3. The highest squalene yield of 0.756 g L^{-1} was also obtained at this C/N ratio. A further increase of the C/N radio showed a negative effect on both the cell growth and squalene yield. When the C/N ratio reached 7.5, the biomass and squalene production decreased to 19.53 and 0.632 g L^{-1}, respectively. This phenomenon could be explained by the fact that the high C/N ratio might lead to relative nitrogen hunger (or other nutrient hunger, e.g., phosphorus and sulfur), which limits cell growth and increases the biosynthesis of other lipids (such as fatty acids and triglyceride).

Effects of the Sea Salt Concentration and Culture Temperature on Cell Growth. The effects of the sea salt concentration on cell growth and squalene production were examined in a range of 0−6%. *Pseudozyma* sp. SD301 showed a wide salinity tolerance. As shown in Figure 4a, the optimum salt

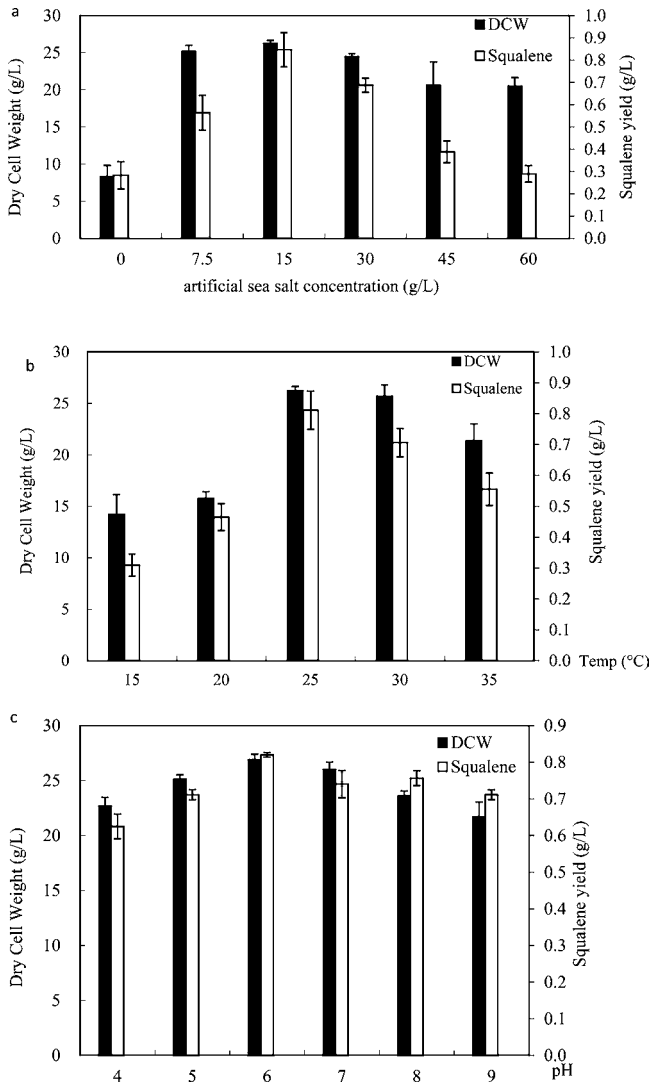

Figure 4. Effect of (a) artificial sea salt concentration, (b) temperature, and (c) initial pH on cell growth and squalene yield in *Pseudozyma* sp. SD301.

concentration was 15 g L^{-1}, with a biomass and squalene yield of 26.25 and 0.847 g L^{-1}, respectively. A slight change in the cell growth was observed in the range of 0.75−3%. Many microorganisms living in the mangrove ecosystem show euryhalinity[30,31] because the salinity of this area often sharply changes as a result of the afflux of fresh water and evaporation.

The effects of the temperature on biomass and squalene yield were tested from 15 to 35 °C. As shown in Figure 4b, there were only slight fluctuations in biomass and squalene yield between the temperatures of 25 and 30 °C. The biomass production was the highest (26.23 g L^{-1}) at 25 °C. However, when the temperature was raised to 35 °C, the biomass

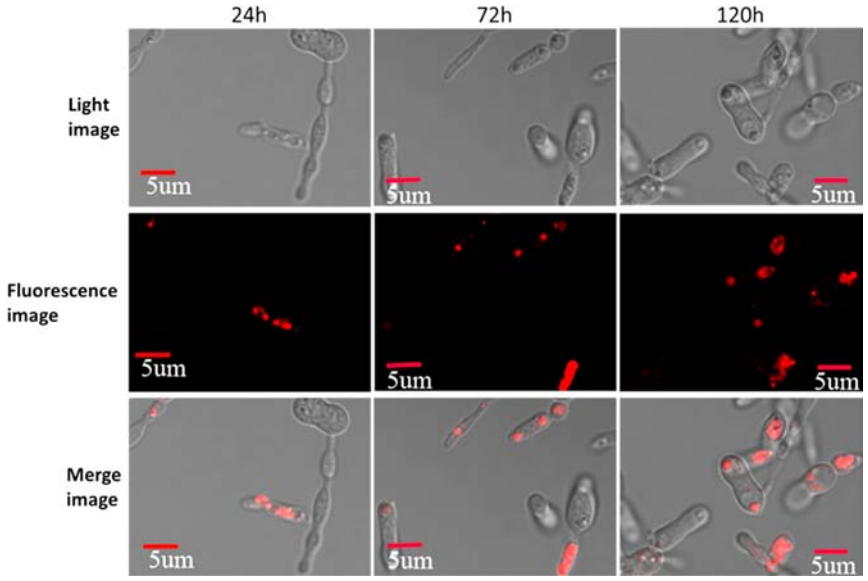

Figure 5. Observation of *Pseudozyma* sp. SD301 using CLSM for locating the lipid droplets and squalene accumulation during cultivation.

decreased to 21.37 g L^{-1} and the squalene yield also decreased significantly, from 0.811 g L^{-1} at 25 °C to 0.555 g L^{-1} at 35 °C. The variation in squalene yields may be the result of the biosynthesis of ergosterol and steroids, which are vital structural and regulatory components in eukaryotic cells.

Effects of Initial pH on Cell Growth. Because the pH value of the medium profoundly affects cell membrane functions, cell metabolism, and the uptake of nutrients and product biosynthesis, the initial pH values of the medium tested in this study ranged from 4.0 to 9.0. The results showed that strain SD301 had a wide adaptability of initial pH (4.0−9.0) for growth and squalene accumulation (Figure 4c). The variation of biomass and squalene yields in the tested pH ranges ranged from 21.70 g L^{-1} (pH 9.0) to 26.90 g L^{-1} (pH 6.0) and from 0.625 g L^{-1} (pH 4.0) to 0.820 g L^{-1} (pH 6.0), respectively. The optimal pH for biomass and squalene yield was 6.0. The wide pH adaptability of *Pseudozyma* sp. SD301 may due to its adaptation to the mangrove ecosystem, in which the pH is constantly changing with tidal actions.

Microscopic Observation and the Fatty Acid Composition of *Pseudozyma* sp. SD301. From the fluorescence imaging of the cells (Figure 5), the lipid droplets containing squalene were distinctly observed at the both ends of the cells and were accumulated along with the cell growth. This phenomenon was coincident with that in *Saccharomyces cerevisiae*.[16,17] The fatty acid composition of SD301 was shown in Table 1, and the main ingredients were the fatty acids with 16 or 18 carbons, such as C16:0, C18:0, C18:1, and C18:2. Along with the cell growth, the content of saturated fatty acids in cells decreased and the content of unsaturated fatty acids reached up to over 51%.

Table 1. Fatty Acid Profiles of *Pseudozyma* sp. SD301

	content (% TFA)		
fatty acid	24 h	72 h	120 h
C14:0	2.03	1.57	1.34
C16:0	30.06	26.46	24.89
C16:1	2.32	2.09	1.45
C17:0	2.44	2.77	1.51
C18:0	24.12	20.99	15.97
C18:1	23.21	29.22	35.94
C18:2	13.87	14.58	16.74
C20:0	1.83	2.28	2.14

Batch and Fed-Batch Fermentation Experiments for Squalene Production. Using the optimized culture conditions described above, the biomass, squalene production, and glucose consumption were examined during batch and fed-batch cultivation.

Glucose was exhausted after 42 h of batch fermentation, reaching the highest biomass and squalene production of 30.24 and 1.649 g L^{-1}, respectively (Figure 6a). The conversion rate from glucose to biomass was approximately 50.4%, and the squalene productivity reached 0.039 g L^{-1} h^{-1}. In contrast, for the fed-batch fermentation, a total glucose concentration of 143 g L^{-1} was consumed and the maximum DCW was 71.53 g L^{-1} with a squalene yield of 2.445 g L^{-1} at 80 h (Figure 6b). In comparison to the batch fermentation, both the glucose conversion rate and the squalene productivity were slightly decreased. This result might be caused by the increasing C/N ratio during glucose feeding, which could influence cell growth and increase fatty acid and triglyceride biosynthesis.

Some strains of *Aurantiochytrium* (*Schizochytrium* or *Thraustochytrium*) were used to produce squalene with the final yield of approximately 1 g during 96 h of fermentation. In comparison to these strains, *Pseudozyma* sp. SD301 had superior squalene productivity and higher squalene yield (Table 2). The squalene yield of 2.445 g L^{-1} by *Pseudozyma* sp. SD301 was 2 times greater than the reported highest yield of *Aurantiochytrium* sp. 18W-13a (1.29 g L^{-1}), and the squalene productivity was approximately 3 times higher than that of *Aurantiochytrium* strains.

In summary, this study characterized a newly isolated yeast-like strain, *Pseudozyma* sp. SD301, which is a promising candidate for commercial squalene production. The results illustrated that the optimized medium for squalene production should contain 60 g L^{-1} glucose, 20 g L^{-1} yeast extract, and 15 g L^{-1} artificial sea salt concentration, with the appropriate cultivation conditions of pH 6.0 and 25 °C.

Figure 1. Isogarcinol decreased proteinuria and reduced the histopathological changes caused by cGVHD. Chronic GVHD mouse model was induced as mentioned in Materials and Methods. Mice were placed in metabolic cages for urine collection and proteinuria was measured using the Bradford assay. Mice were sacrificed at week 10 to evaluate the histological scores in the kidney with H&E stain. (A) Chemical structure of isogarcinol. (B) Proteinuria during the development of cGVHD. (C) Isogarcinol reduced proteinuria at week 10. (D) Renal histopathology in different groups at week 10. A, glomerulus, and B, tubules. (E) Isogarcinol lowered the histological score in the kidneys. **, $p < 0.01$ versus control; #, $p < 0.05$ versus cGVHD.

allogeneic skin transplantation.[19] In addition, isogarcinol showed a desirable effect on rheumatoid arthritis and its anti-inflammatory effect has also been reported.[20] Furthermore, isogarcinol had lower toxicity on liver and kidney function than did CsA in experimental animals.[19,20] On the basis of our previous study, we hypothesized that isogarcinol can inhibit the stimulation of CD4 T cells and exhibit an anti-inflammatory effect in the cGVHD mouse model, and we aimed both to determine whether orally administered isogarcinol could be a novel and effective agent for the treatment of SLE and to elucidate the potential underlying mechanisms.

MATERIALS AND METHODS

Six- to eight-week-old female DBA/2 and BDF1 (C57BL/6 × DBA/2) mice were purchased from Beijing Vital River. The mice were housed in a controlled environment (12 h light/12 h dark period, 25 ± 1 °C) in the Animal Center of Beijing Normal University for 1 week before gaining access to standard food and water for mice. All animal experimental procedures were conducted according to protocols approved by Ethic and Animal Welfare Committee (NO.CLS-EAW-2013-015) and were conducted in strict accordance with institutional guidelines. Isogarcinol (purity >95%) was extracted and purified in our lab by J.C.

Bradford assay kit was purchased from Bioteke (Beijing, China). Blood urea nitrogen, creatinine, triglyceride, and cholesterol test kits were brought from Reegen (Beijing, China). Calf thymus DNA, 3,3′-5,5′-tetramethylbenzidine (TMB), rabbit antibody against mouse IgG, goat anti-mouse IgG1, lipopolysaccharide (LPS, L2880), phorbol, 12-myristate 13-acetate (PMA), and ionomysin were purchased from Sigma (St. Louis, MO USA). HRP-conjugated rabbit anti-goat IgG and HRP-conjugated goat anti-mouse IgG were brought from CST (Danvers, MA, USA). TRIzol reagent, DMEM, and fetal bovine serum (FBS) were from Life Technologies (Carlsbad, CA, USA). RNA and quantitative real-time PCR (qRT-PCR) reagents such as oligodT primers, TaqMan Reverse Transcription Reagents, and SYBR Premix Ex Taqkit were from TaKaRa Bio (Kusatsu, Shiga, Japan). Flow cytometry antibodies such as FITC-conjugated anti-mouse CD4, PE-conjugated CD8, IFN-γ, and IL-4 and Golgi Stop were brought from BD biosciences (San Jose, CA, USA). Tumor necrosis factor-α (TNF-α), IL-1β, and IL-6 ELISA kits were from Neobioscience (Shenzheng, China).

Murine Model of cGVHD. DBA/2 mice were sacrificed, and spleen cells were filtered through sterile mesh, lysed in hemolysis buffer, washed, and processed into single-cell suspensions. Either 0.9% NaCl (control group) or 6×10^7 DBA/2 spleen cells (other groups) per mouse were twice injected into the tail vein of a BDF1 mouse at day −7 and day 0. For the drug effect study, the mice were divided into 5 groups ($n = 7$): control, cGVHD, isogarcinol 30 mg/kg, isogarcinol 60 mg/kg, and CsA 30 mg/kg. For further mechanism study, the mice were divided into 3 groups ($n = 4–6$): control, cGVHD, and isogarcinol 60 mg/kg group. Isogarcinol is insoluble in water, so isogarcinol and CsA were dissolved in 20% DMSO and 80% distilled water. Isogarcinol and CsA were continuously given daily by gavage from day 1 until the end of the experiment. The control and the cGVHD groups received the same dose of the vehicle (20% DMSO + 80% distilled water, total of 0.2 mL per mouse per day). Animal experiments were repeated twice.

Determination of Proteinuria, Serum Blood Urea Nitrogen, Triglyceride, Creatinine, and Cholesterol Content. Serum and urine were collected every 2 weeks. The mice were placed in metabolic cages for urine collection. Proteinuria was tested using the Bradford assay kit. The serum blood urea nitrogen (BUN), creatinine, triglyceride, and cholesterol levels were measured using an automatic biochemical analyzer (Olympus AU400,Tokyo, Japan).

J. Agric. Food Chem. 2015, 63, 8452−8459

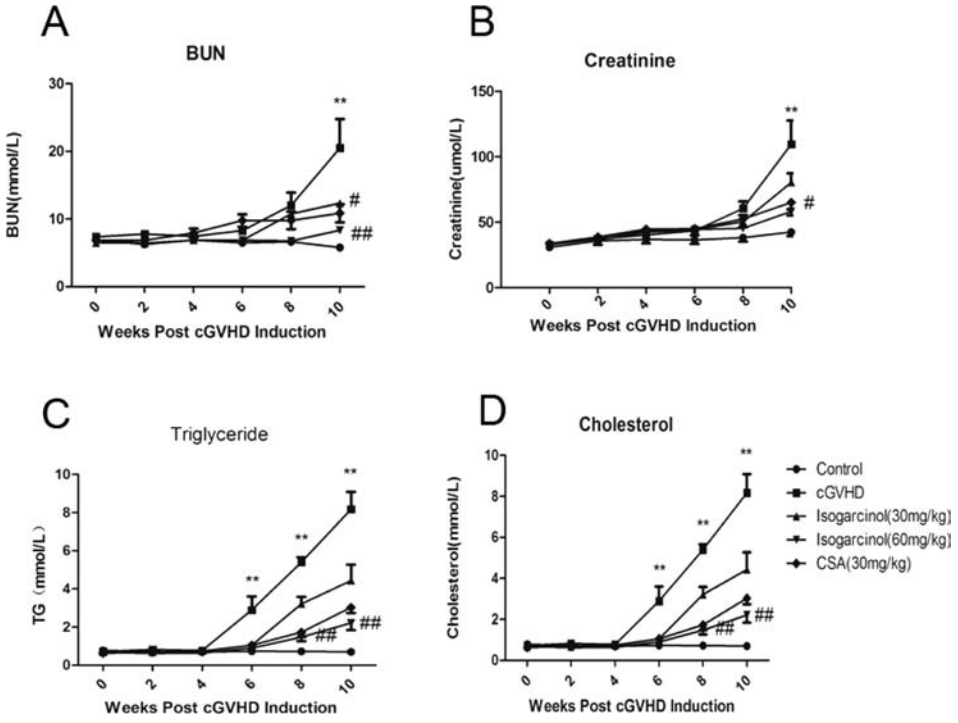

Figure 2. Isogarcinol corrected abnormal serum indices in the cGVHD mice. Chronic GVHD mouse model was induced as mentioned in Materials and Methods. Serum was collected every 2 weeks, and the serum indices were measured by an automatic biochemical analyzer. Isogarcinol lowered (A) blood urea nitrogen, (B) creatinine, (C) triglyceride, and (D) cholesterol in the cGVHD mouse model. The bars show the mean ± SEM ($n = 7$). **, $p < 0.01$ versus control; # and ##, $p < 0.05$ and $p < 0.01$ versus cGVHD, respectively.

Determination of Serum Antibody Production. The serum anti-double-stranded DNA (anti-dsDNA) or total antibody was tested by ELISA as follows: Microtiter plates were coated with calf thymus DNA. Then, HRP-conjugated goat anti-mouse IgG was added, followed by TMB. The reaction was stopped with 2 M H_2SO_4, and the plates were read at 450 nm in a Polarstar Omega (BMG labtech, Cary, NC, USA). Serum IgG1 was measured as follows: Microtiter plates were coated with rabbit antibody against mouse IgG. Goat anti-mouse IgG1 was used as primary antibody. The HRP-conjugated rabbit anti-goat IgG was then added as the secondary antibody. TMB and H_2SO_4 were added in order, and the plates were read at 450 nm. The samples were diluted 1:250.

Real-Time PCR. Mice were sacrificed at the end of the experiment, and total RNA was isolated from the fresh spleen and kidney using TRIzol reagent. Then, cDNA synthesis was initiated by adding oligodT primers and TaqMan Reverse Transcription Reagents. qRT-PCR was performed according to the instructions of SYBR Premix Ex Taqkit in an Applied Biosystems 7500 fast Real-Time PCR system (Thermo Fisher, Grand Island, NY, USA). β-actin was used for normalization, and the sequences of the primers used are as follows: T-bet, gttcaaccagcaccagacagag (forward), tggtccaccaagaccacatc (reverse); GATA-3, ggatgtaagtcgaggcccaag (forward), attgcaaaggtagtgcccggta (reverse); IFN-γ cggcacagtcattgaaagccta (forward), gttgctgatggcctgatt-gtc (reverse); IL-4 acggagatggatgtgccaaac (forward), agcaccttggaa-gccctacaga (reverse), TNF-α, actccaggcggtgcctatgt (forward), gtgagg-gtctgggccatagaa (reverse); IL-1β tccaggatgaggacatgagcac (forward), gaacgtcacacaccagcaggtta (reverse); IL-6 caacgatgatgcacttgcaga (forward), ctccaggtagctatggtactccaga (reverse); β-actin, agagggaaatcg-tgcgtgac (forward), caatagtgatgacctggccgt (reverse).

Flow Cytometry. BDF1 mice were sacrificed at week 8, and spleen cells were filtered through sterile mesh, lysed in hemolysis buffer, washed, and processed into single-cell suspensions. To determine the content of CD4 and CD8, single-cell suspensions were directly used without stimulation of PMA and ionomysin. FITC-conjugated anti-mouse CD4 and PE-conjugated CD8 were used for the flow cytometry assay.

To determine the intracellular cytokine staining, the cells were cultured in 20% FBS DMEM for 2 h. Then, 100 ng/mL PMA and 1000 ng/mL ionomycin together with Golgi Stop were added for an additional 4 h. Next, the cells were harvested, blocked, and stained with FITC-conjugated anti-mouse CD4, PE-conjugated anti-mouse IFN-γ, and PE-conjugated anti-mouse IL-4 according to the respective manufacturer's protocol. Finally, the cells were analyzed on a FACS Calibur flow cytometer system with CellQuest software (BD, San Jose, CA, USA).

Macrophage Preparation and Cytokine Measurement. At the end of the experiment, macrophages of every group of mice were collected and adjusted to 1×10^6/mL in plates. Then, cells were cultured in 20% FBS DMEM at 37 °C for 2 h. Then, cells were stimulated by 10 μg/mL LPS for an additional 12 h before culture supernatants were harvested. Cytokines in culture supernatants, such as TNF-α, IL-1β, and IL-6, were determined using ELISA kits.

Renal Histopathology. The mice were sacrificed at week 10 to evaluate the histological scores in the kidney. After being fixed in 4% formalin and embedded in paraffin, the kidney was sectioned, mounted on slides, and stained with H&E. Each observer was blinded when evaluating each section, scoring the glomeruli, and classifying the lesion.[21] The following scale was applied: 0, normal morphology; 1, moderate expansion of the glomerular matrix without glomerulonephritis; 2, mild glomerulonephritis with mesangial hypercellularity and/or segmental necrosis; 3, moderate glomerulonephritis with extensive sclerosis and/or loop necrosis and/or cellular crescent; 4, severe glomerulonephritis with large area of loop necrosis and cellular crescent.

Statistical Analyses. The results are expressed as the means ± standard error of the mean (SEM). One-way analysis of variation (ANOVA) followed by Bonferroni's multiple comparison test was used to compare experimental groups and the control groups. The statistical analyses were performed in GraphPad Prism 5.0 software. The level of statistical significance was set at $p < 0.05$.

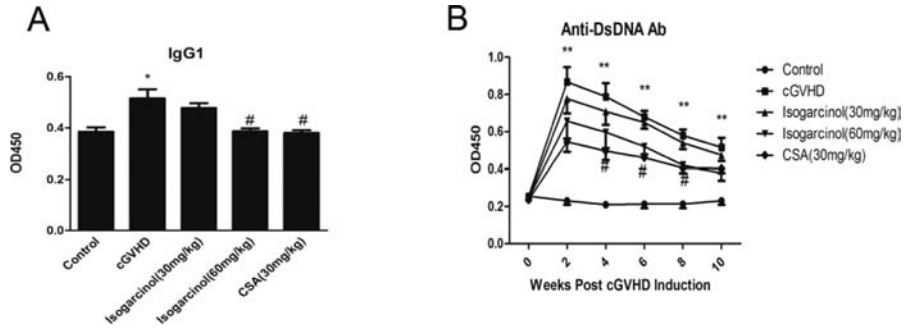

Figure 3. Isogarcinol decreases serum autoantibodies in cGVHD mouse model. Chronic GVHD mouse model was induced as mentioned in Materials and Methods. Serum was collected every 2 weeks and ELISA assay was used to determine the content of serum IgG1 and anti-dsDNA antibody. (A) Isogarcinol reduced the content of serum IgG1 at week 10 ; (B) Isogarcinol reduced the content of serum anti-dsDNA antibody. The bars show the mean ± SEM (n = 7). **, $p < 0.01$ versus control; #, $p < 0.05$ versus cGVHD.

RESULTS

Isogarcinol Reduced Proteinuria and Ameliorated Histopathological Changes Caused by cGVHD. Nephritis is a notable characteristic in both human SLE and the animal SLE model.[10,12] During the experiment, increased proteinuria was observed in cGVHD mice at week 6 and continued to increase in the following weeks. Daily treatment with 30 and 60 mg/kg isogarcinol significantly decreased proteinuria (Figure 1B,C). Renal histopathology was evaluated at week 10 after cGVHD induction with H&E stain (Figure 1D). Severe glomerulonephritis with extensive sclerosis was observed in cGVHD mice, and the renal histopathology score was significantly higher in the cGVHD group compared to that in the control group (3.3 versus 0.2, $p < 0.01$). Treatment with 60 mg/kg isogarcinol lowered the score to 2.0 ($p < 0.05$) (Figure 2E).

Isogarcinol Corrected Abnormal Serum Triglyceride, Creatinine, Blood Urea Nitrogen and Cholesterol in cGVHD Mice. SLE is a systemic autoimmue disease that affects many internal organs in the body. It is reported that during the experiment the biochemical indices such as triglyceride, creatinine, blood urea nitrogen, and cholesterol in serum were increased in similar models.[10,13,22] We measured the concentration of these indices every 2 weeks with an automatic biochemical analyzer and found that the indices of cGVHD group mice exhibited a significant high level. Treatment with 60 mg/kg isogarcinol and 30 mg/kg CsA significantly lowered these indices (Figure 2).

Isogarcinol Reduced Serum anti-dsDNA Antibody and IgG1 Concentrations. Anti-dsDNA antibody is the signature antibody in the cGVHD mouse model and in human SLE. It is documented that IgG1 was also upregulated in this model.[10] Serum was collected every 2 weeks, and levels of anti-dsDNA antibody as well as of IgG1 were determined using ELISA assay. The results manifested that after treatment with isogarcinol the anti-dsDNA and IgG1 antibodies were inhibited (Figure 3A,B). Treatment with 60 mg/kg isogarcinol and 30 mg/kg CsA were equally effective in preventing anti-dsDNA and IgG1 antibody.

Isogarcinol Alleviated the CD4 Activation in the cGVHD Mouse Model. From all of the above results, the new immunosuppressant isogarcinol displayed an outstanding effect in the cGVHD mouse model. Next, we divided the mice into 3 groups: control, cGVHD, and 60 mg/kg isogarcinol for the further mechanism studies (n = 4−6). CD4 T cell activation and interaction with CD8 T cells, together with the antibody-producing B cells, have been a major focus of investigation in SLE-cGVHD, and both CD4 T cell expansion and ineffective CD8 T cells play a role in the model.[23] Flow cytometry was applied to measure the proportion of CD4/spleen cells and the ratio of CD4/CD8. The experimental results exhibited that both were increased in the cGVHD mice, whereas isogarcinol lowered them (Figure 4A,B). These results suggest that isogarcinol might alleviate CD4 activation during the development of cGVHD. Furthermore, we extracted RNA directly from spleen cells, and the gene expression levels of Th1 (T-bet) and Th2 (GATA-3) and their key cytokines IFN-γ and IL-4 were determined. All four genes were significantly upregulated in spleen cells, whereas isogarcinol decreased their expression (Figure 4C−E).

Next, we tried to evaluate the activation form of CD4 T cells. After stimulation by 100 ng/mL PMA and 1000 ng/mL ionomycin and together with Golgi stop for another 4 h, the spleen cells were intracellularly strained for IFN-γ and IL-4. Flow cytometry was used to determine the content of CD4+IFN+ and CD4+IL4+ in spleen cells. We found that both cytokines of CD4 T cells, IFN-γ and IL-4, were increased in the cGVHD mice (Figure 5A). We also calculated the absolute content of IFN-γ+CD4+ and IL-4+CD4+ cells, and treatment with isogarcinol markedly reduced the secretion (Figure 5B). Furthermore, the relative content of the cells was also measured, and the ratio of IFN-γ+ and IL-4+ in CD4+ T cells also decreased after isogarcinol treatment (Figure 5C). In total, these results suggest that isogarcinol alleviated CD4 activation in both inactivated form and under activated condition.

Isogarcinol Exhibited Anti-Inflammatory Effects in the cGVHD Mouse Model. After stimulation with various agents such as LPS, macrophages participate in quite a few autoimmune diseases through a number of mechanisms. A variety of signal pathways are involved in the action of macrophages such as secretion of cytokines. Finally, at week 8 peritoneal macrophages were collected and cultured in vitro for the ELISA test. The levels of inflammatory cytokines TNF-α, IL-1β, and IL-6 were determined after stimulation with LPS. We found that the expression of three kinds of inflammatory cytokines was increased in cGVHD mice, yet the treatment of isogarcinol lowered these levels (Figure 6A).

The overproduction of autoantibodies assembled in kidney and deposition of immune complexes results in inflammation, then finally renal failure. In the process, inflammatory cytokines play a crucial role in the effect of inflammation. At week 8,

J. Agric. Food Chem. 2015, 63, 8452−8459

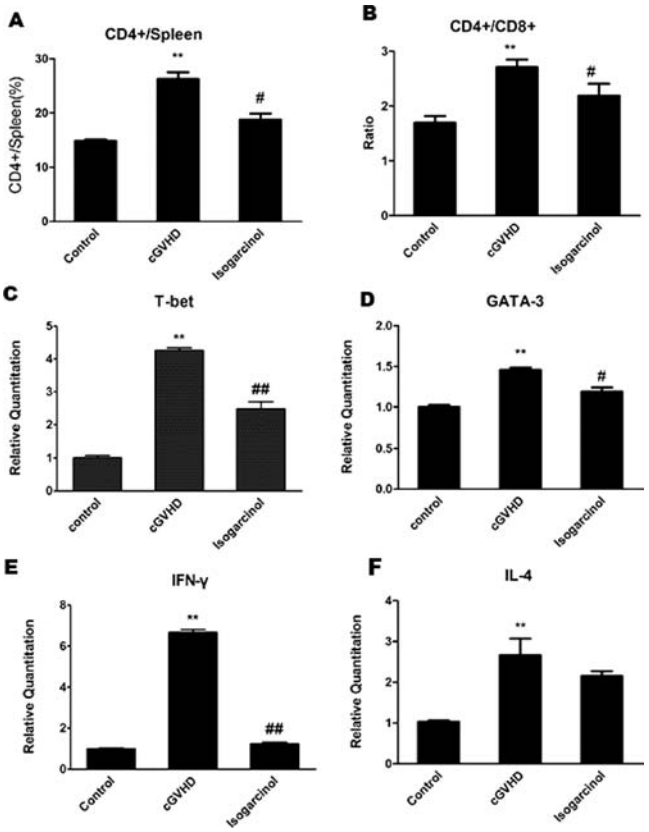

Figure 4. Isogarcinol alleviated the CD4 activation in cGVHD mouse model. At week 8, spleen cells of BDF1 mice were processed into single-cell suspensions and directly stained for flow cytometry test without stimulation. (A) Isogarcinol decreased the CD4 in spleen cells. (B) Isogarcinol reduced the ratio of CD4/CD8. In contrast, total RNA of fresh spleen tissues was extracted, and the expressions of relevant genes were measured using qRT-PCR. The expression levels of (C) T-bet, (D) GATA-3, (E) IFN-γ, and (F) IL-4 were lowered by isogarcinol. The bars show the mean ± SEM (n = 4–6). **, $p < 0.01$ versus control; # and ##, $p < 0.05$ and $p < 0.01$ versus cGVHD, respectively.

mRNA was directly extracted from the kidneys, and qRT-PCR was performed to analyze the inflammatory gene factors. The mRNA expression of TNF-α and IL-6 were prominently reduced in the isogarcinol group compared to expression in the cGVHD group, but we did not find any differences of IL-1β among the groups (Figure 6B). Together, these results suggest that the anti-inflammatory effects of isogarcinol might protect against the disease.

DISCUSSION

Injecting DBA/2 spleen cells into the tail vein of a BDF1 mouse can lead to an SLE-like disease resembling human SLE.[24−26] Compared to the traditional gene SLE models, such as (NZB × NZW) F1 and MRL/lpr mouse models, chronic GVHD models are easier to control, more adjustable, and have a shorter period that are widely used in studying the mechanism of quite a few chronic diseases. In our SLE model, the female donor will make the female host more vulnerable to SLE than a male, which is similar to human SLE.[27] All of these reasons make our mouse model a favorable model for the lupus study. In our present work, we proved that the immunosuppressant isogarcinol (especially 60 mg/kg group) markedly prevented the development of proteinuria and ameliorated lethal renal injury (Figure 1), corrected the abnormal biochemical index in serum (Figure 2), and significantly lowered the serum antibody (Figure 3). Further work with 60 mg/kg isogarcinol treatment inhibited the activation of CD4 T cells (Figures 4 and 5) and inflammation in kidneys and macrophages (Figure 6). The therapeutic effect of isogarcinol may at least partially contribute to the inhibition of CD4 T cells and the inflammation effect. In our further work with 60 mg/kg isogarcinol treatment, we picked week 3 (day 21) and week 8 (day 56) to evaluate the CD4 expansion and inflammatory cytokine secretion. However, we did not find any differences among the groups at week 3 (data not shown).

Recognition of the foreign MHC of the F1 host by parental spleen cells leads to a GVH disease. There are two major types of GVHD: acute and chronic.[28] Compared to acute GVHD, which is more likely to reflect apoptosis and necrosis, chronic GVHD is characterized by inflammatory and fibrotic processes.[29,30] During the development of cGVHD, stimulation of CD4 T cells plays an paramount role in SLE-cGVHD, and both CD4 T cell expansion and ineffective CD8 T cells play a role in this model. Similar reports demonstrated that genetic lupus mice displayed increased CD4 T cell activation at a higher CD4/CD8 ratio.[31,32] In our present study, we compared the ratio of CD4/CD8 and CD4/spleen cells, and we found that treatment with 60 mg/kg isogarcinol could alleviate the activation of CD4 cells.

Depending on the pattern of cytokine production, CD4+ T cells can be divided into at least three different subsets: Th1, Th2, and Th17 cells. Th1 cells preferentially produce IFN-γ and IL-2, which activate macrophages and stimulate production of IgG2a in mice. Th2 cells preferentially produce IL-4 and IL-10, which provide potent B cells and help induce IgG1 production in mice. It has been traditionally reported that the cytokines produced during acute GVHD are Th1 cells, whereas those produced during cGVHD are Th2 cytokines. However, recent studies have suggested that cGVHD could be caused by cytokines secreted by Th1 cells.[33,34] The mechanisms leading to the development of cGVHD are still not completely understood. In similar models, there was a significant expansion of Th2 cells in the early phase (week 2) of the model,[35] whereas some reported that both Th1 and Th2 cells were increased but that the increase of Th2 cells was more significant.[8,12] In our experiment, we found serum IgG1 (Figure 3) and IL-4 (data not shown) increased in cGVHD mice at week 10. These results suggest that there might be Th2 cell expansion in this model. However, the gene expressions of Th1 (T-bet) and Th2 (GATA-3) and their key cytokines IFN-γ and IL-4 were all increased in spleen cells before stimulation (Figure 4). Furthermore, after the stimulation with PMA and ionomysin, we compared the absolute content and relative content of Th1 and Th2 cells, and the results were similar to the inactivated experiments (Figure 5). In addition, we did not find any differences of Th17 cells at week 8 (data not shown). In our previous work, we have reported that isogarcinol significantly inhibited the proliferation of murine spleen T-lymphocytes induced by ConA.[19] These results indicate to us that isogarcinol downregulates both Th1 and Th2 cells and alleviates CD4 activation resulting in attenuation of lupus-like disease.

We also found isogarcinol significantly decreased NO production and inducible nitric oxide synthase mRNA expression in the LPS-stimulated RAW 264.7 macrophages and the anti-inflammatory effect associated with isogarcinol in

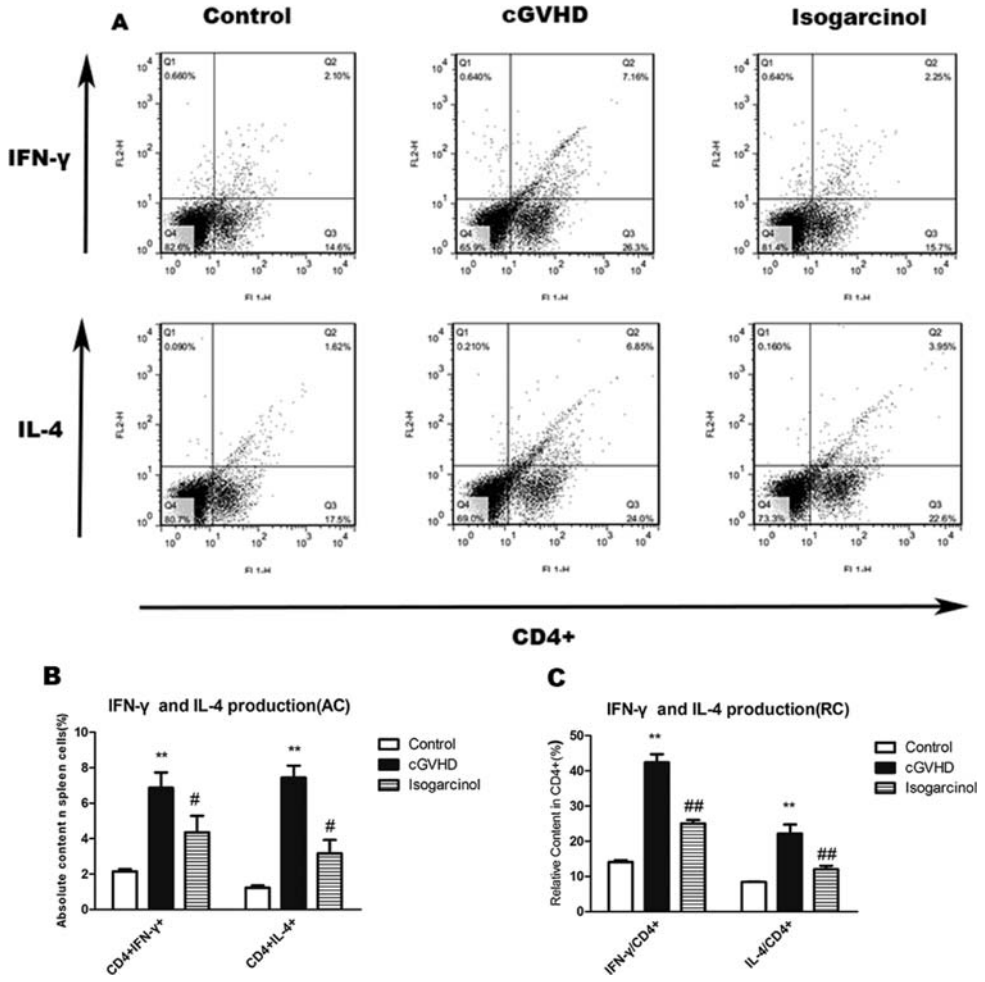

Figure 5. Isogarcinol alleviated PMA/ionomycin induced CD4 activation in cGVHD mouse model. At week 8, spleen cells of BDF1 mice were processed into single-cell suspensions and were cultured in 20% FBS DMEM for 2 h. After stimulatation by 100 ng/mL of PMA and 1000 ng/mL ionomycin and together with Golgi stop for another 4 h, the spleen cells were harvested and then intracellularly strained with IFN-γ and IL-4 on CD4 T cells. Flow cytometry was used to determine the content of CD4+IFN+ and CD4+IL4+ in spleen cells. (A) The content of CD4+IFN+ and CD4+IL4+ cells in the different groups. (B) Isogarcinol lowered the absolute content (AC) of spleen cells. (C) Isogarcinol lowered relative content (RC) of CD4+ cells. AC = IFN-γ+CD4+(IL-4+CD4+)/spleen cells; RC = IFN-γ+CD4+(IL4+CD4+)/Total CD4+ cells. The bars show the mean ± SEM (n = 4–6). **, $p < 0.01$ versus control; # and ##, $p < 0.05$ and $p < 0.01$ versus cGVHD, respectively.

chronic inflammatory arthritis.[19,20] The inflammatory cytokines TNF-α, IL-1β, and IL-6 produced by macrophages play an essential role in responding to infection and inflammation. Moreover, the kidney mRNA levels of TNF-α and IL-1β as well as protein levels in lupus-prone MRL/lpr mice have been found to increase.[36] We first tested the cytokines of the macrophages and found the inflammatory cytokines, such as TNF-α, IL-6, and IL-1β, were highly expressed in cGVHD mice. The gene expression in kidneys of two inflammatory cytokines, TNF-α and IL-6, displayed a similar result (Figure 6). Treatment with 60 mg/kg isogarcinol can effectively reduce inflammatory cytokine secretion and finally protect the injury of the kidneys and prevent proteinuria (Figure 1). These results suggest that the anti-inflammatory effects of isogarcinol may protect from the GVH response.

Antibody- and immune-complex-mediated inflammation in SLE can trigger the development of glomerulonephritis, arthritis, and serositis. The most common cause of death in SLE is renal failure, and the 5-year survival rate is approximately 77%. Current therapies for lupus are broad-spectrum, including steroids and immunosuppressants, which are compromised by toxicity and side effects in the medications. Immunosuppressants, such as CsA, can inhibit the CN pathway and target T cells to regulate GVH responses. In our present research, we found a similar effective therapy between daily oral 60 mg/kg isogarcinol and 30 mg/kg CsA in preventing proteinuria, autoantibodies, and abnormal serum indicators. However, the CsA group manifested a higher renal histological score than did the isogarcinol group (Figure 1). In addition, during the experiment, a significant body weight change in the CsA treatment mice and abdominal edema was observed during the experiment (data not shown), and because of edema, the CsA group mice showed less activity than the other mice group. All of these may have to do with the toxicity of CsA with daily oral treatment. Moreover, we compared the toxicity of CsA and isogarcinol for both in vitro and in vivo experiments. Isogarcinol exhibited a better viability of spleen cells, and the serum indices, such as glutamic-pyruvic transaminase, glytamic-oxalacetic transaminease, total bilirubin, urea nitrogen, and creatinine, were abnormally high in the CsA group compared with the isogarcinol group.[19] Similar experiments regarding the toxicity of CsA were found in the collagen-induced arthritis

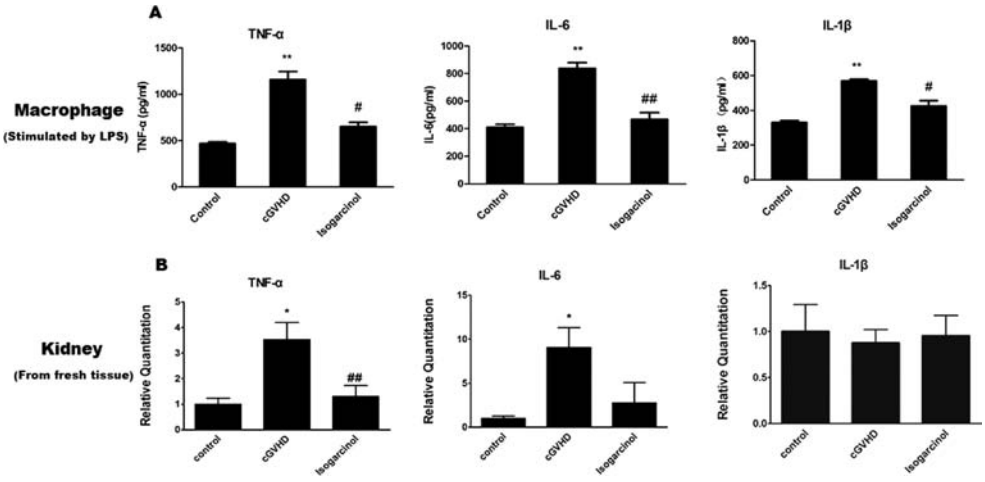

Figure 6. Isogarcinol exhibited an anti-inflammatory effect in the cGVHD mouse model. At week 8, macrophages of BDF1 mice were collected and adjusted to 1×10^6/mL in plates. Cells were cultured in 20% FBS DMEM for 2 h then stimulated with LPS in vitro for 12 h. The supernatants were harvested for the ELISA assay. (A) Isogarcinol reduced the content of TNF-α, IL-1β, and IL-6 expression. Messenger RNA of kidney tissue was directly extracted, and relevant genes were measured using qRT-PCR. (B) The effect of Isogarcinol on gene expression of TNF-α, IL-6, and IL-1β in the kidneys. The bars show the mean ± SEM (n = 4–6). **, $p < 0.01$ versus control; # and ##, $p < 0.05$ and $p < 0.01$ versus cGVHD, respectively.

mouse model.[37] These results all link with the severe hepatotoxicity and nephrotoxicity of CsA. In our present work, we found an immunosuppression and anti-inflammatory effect of isogarcinol extracted from mangosteen fruit. Therefore, we have reason to expect it will become a potential candidate drug in the future.

Isogarcinol is a low-toxicity, peroral compound we extracted from mangosteen fruit. Experimental data in this study elucidated that it is effective against SLE-like disease, and the therapeutic effect was associated with the downregulation of the activation of CD4 T cells and the inflammatory effect.

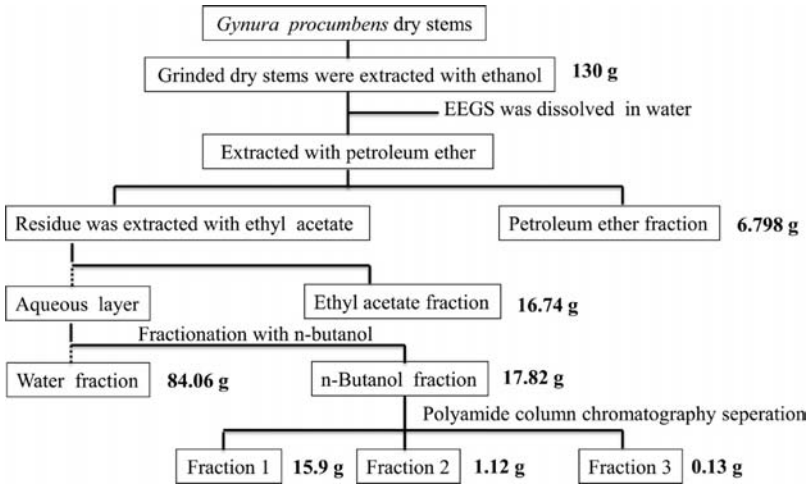

Figure 1. Schematic diagram of the bioguided fractions of *G. procumbens* on alcohol-induced liver injury.

molecular mechanisms underlying the protective effects of *G. procumbens* against ALD.

MATERIALS AND METHODS

Reagents. *G. procumbens* was produced in Shantou, Guangdong, China (identified by Prof. Bingkun Zhang, Wuhan Botany, Chinese Academy of Sciences). P44/42 MAPK (Erk1/2), phospho-p44/42 MAPK (Thr202/Tyr204), p38 MAPK, phospho-p38 MAPK (Thr180/Tyr182), acetyl-CoA carboxylase, phospho-acetyl-CoA carboxylase (Ser79) antibodies were purchased from Cell Signaling Technology (Beverly, MA). SREBP-1 antibody was purchased from Abcam (Cambridge, UK). AMPK1/2 and phospho-AMPK1/2 (Thr172) antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). The GAPDH antibody was purchased from AB CLONAL Biotechnology (Wuhan, Hubei, China). Chlorogenic acid and silymarin were purchased from Sigma-Aldrich (St. Louis, MO). All other chemicals purchased were of the purest form commercially available.

Animals, Grouping, Treatment, and Sampling. *Preparation of the Ethanol Extract from G. procumbens Stems (EEGS) and Its Subfractions.* Fresh stems were minced, dried in the sun, and powdered for the experiments. The extract was prepared from 1000 g of powder extracted by heat reflux in 10 L of 80% ethanol at 85 °C for 1 h and filtered. The extraction was repeated three times. The filters were combined and evaporated under reduced pressure at 50 °C to remove the solvent. Then, the extract was lyophilized to obtain EEGS with a yield of 18.5%. The yield in the present study is always calculated using the following formula: yield = (weight of the dried extract/weight of sample used for extraction) × 100%.

EEGS was further fractionated according to the schematic diagram shown in Figure 1. EEGS was dissolved in 500 mL of water, and the solution was successively extracted by the same volumes of petroleum, ethyl acetate, and water-saturated *n*-butyl alcohol. Each solvent extraction was repeated three times. The extracts of each solvent were combined and then evaporated under reduced pressure at 50 °C. The crude extracts of the four fractions were classed, yielding petroleum, ethyl acetate, *n*-butyl alcohol, and water at 5.4%, 14.2%, 13.3%, and 67.0%, respectively.

The *n*-butyl alcohol extract was further fractionated on a polyamide glass column (custom-made, inner diameter 2 cm, packing height 40 cm). Elution was started with distilled water followed by 60% ethanol and ending with 95% ethanol, 375 mL each, 2.5 mL/min. The eluted fractions were evaporated under reduced pressure at 50 °C to give fraction 1 (yield 92.74%), fraction 2 (yield 6.49%), and fraction 3 (yield 0.76%).

Analysis of Chlorogenic Acids by HPLC-UV. Five chlorogenic acids—neochlorogenic acid, chlorogenic acid, isochlorogenic acid A, isochlorogenic acid B, and isochlorogenic acid C—have been isolated and identified in EEGS in our previous study. HPLC analysis was carried out with a U3000-Dionex instrument with a 5 μm Acclaim C-18 column (4.6 × 250 mm, Thermo Fisher Scientific, Inc., Waltham, MA). Detection was carried out at 326 nm with a 70 min gradient. Solvent A was acetonitrile, and solvent B was a 0.1% aqueous phosphoric acid solution. The gradient system was A-B (v/v) = 19/81 (0 min) → 27/73 (65 min) → 19/81 (70 min). The flow rate of the mobile phase was 1 mL/min (Figure 2). The contents of neochlorogenic acid, chlorogenic acid, isochlorogenic acid A, isochlorogenic acid B, and isochlorogenic acid C in EEGS as calculated by external standard method were 0.01%, 0.27%, 0.28%, 0.051%, and 0.12%, respectively. The contents of chlorogenic acid in petroleum extract, ethyl acetate extract, *n*-butyl alcohol extract, water extract, fraction 1, fraction 2, and fraction 3 were 0.0078%, 0.38%, 1.0%, 0.03%, 0% (not detectable), 13.6%, and 42.0%, respectively.

Screening of the Active Fraction(s) of EEGS in the Acute Alcohol Exposure Model. The acute alcohol exposure model designed by Carson and Pruett[17] is particularly valuable when used to screen the efficacy of agents that may offer clinical benefits and for the mechanistic and predictive analysis of therapeutic compounds.[18] In the current study, male Kunming mice (body weight 18−22 g) were used, and all experiments followed the WHO Guidance of Humane Care and Use of Laboratory Animals. Ethanol (5 g/kg) was given orally (by gavage) every 12 h for a total of three doses to induce liver injury in the acute alcohol exposure model. EEGS and its fractions were suspended in the ethanol solution so that the mice received ethanol and EEGS or its fractions at the same time. The mice were sacrificed 4 h after the last ethanol treatment, and their blood samples and whole livers were immediately collected. Blood samples were used to test for alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activity. Serum levels of ALT and AST were determined using commercial spectrophotometric kits (Nanjing Jiancheng Bioengineering Institute, Nanjing, Jiangsu, China) according to the manufacturer's instructions. Liver samples were used for RT-PCR, Western blot, triglyceride (TG) content analysis, and histological examination. We performed three rounds of screening with the acute ALD model to evaluate the active fraction(s) of *G. procumbens*. One round of screening was to determine the optimal EEGS dose, and the other two were to screen the active fraction(s) of the EEGS and *n*-butyl alcohol extract.

Estimation of the Effect of EEGS and Fraction 2 in the Chronic Alcohol Exposure. Because acute alcohol exposure in mice induces hepatic steatosis in a manner similar to chronic ethanol administration, the acute model is useful as a screening tool and/or a mechanistic and predictive analysis for agents against liver disease induced by chronic alcohol intake.[18] However, negative health consequences of alcohol use vary according to the drinking pattern, such as acute or chronic.[1] The acute model with three binge-drinking episodes did not evoke the full range of symptoms of chronic alcohol consumption in the liver.[19]

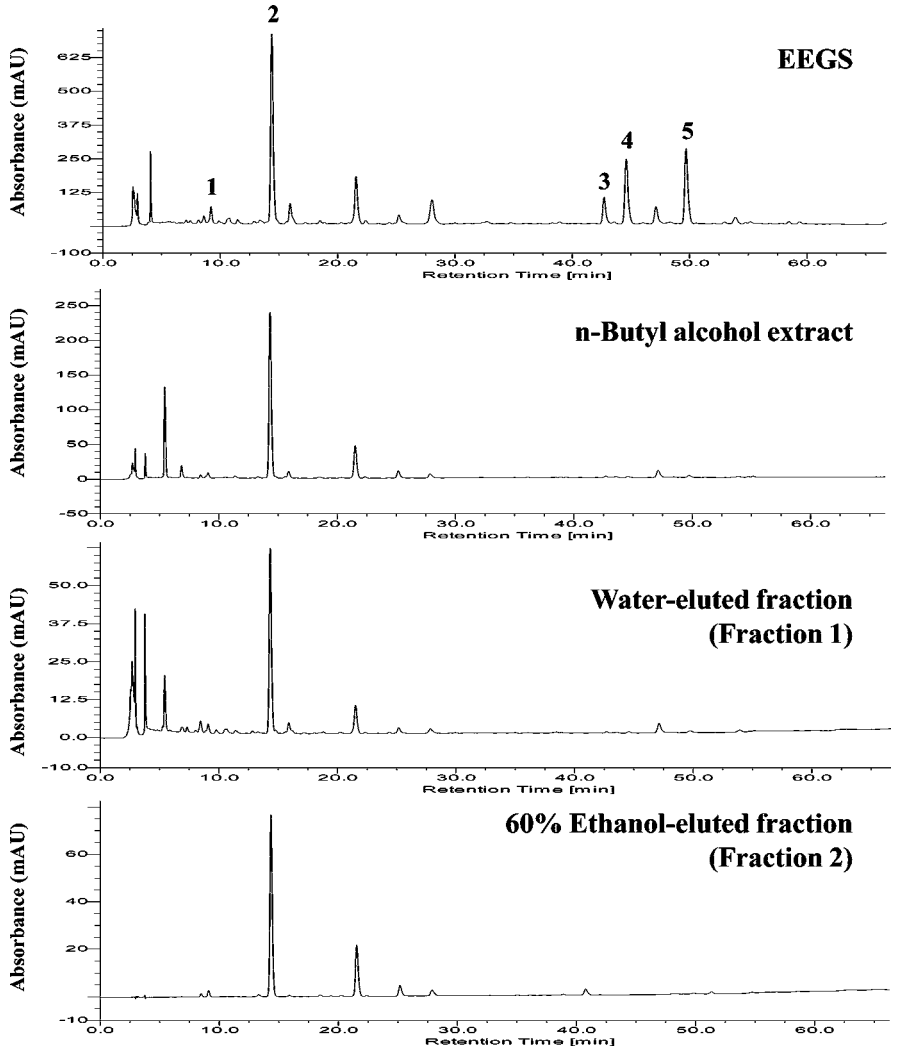

Figure 2. Representative HPLC-UV chromatograms of EEGS and its subfractions. HPLC analysis was carried out with a U3000-Dionex instrument with a 5 μm Acclaim C-18 column (4.6 × 250 mm) (Thermo Fisher Scientific, Inc. Waltham, MA). Detection was carried out at 326 nm with a 70 min gradient. Solvent A was acetonitrile, and solvent B was 0.1% aqueous phosphoric acid solution. The gradient system was A-B (v/v) = 19/81 (0 min) → 27/73 (65 min) → 19/81 (70 min). The flow rate of the mobile phase was 1 mL/min. Peaks: 1, neochlorogenic acid; 2, chlorogenic acid; 3, isochlorogenic acid B; 4, isochlorogenic acid A; and 5, isochlorogenic acid C.

Thus, we also evaluated the protective effect of *G. procubens* on chronic ethanol-induced liver steatosis. Liquid diets were based on the Lieber−DeCarli formulation (Dyets, Inc., Bethlehem, PA). Each mouse was housed in an individual cage and allowed ad libitum access to ethanol-containing diet. Control animals were pair-fed the same diet but with maltodextrin isocalorically substituted for ethanol.[20] Either the ethanol-containing diet or the isocaloric maltose-dextrin (control) diet was fed to the animals for 8 weeks. The ethanol content began at 2.5% and was increased in a stepwise manner 0.5% every 2 days until the end of the first week and then 0.5% every 4 days until 5% was achieved. This level was maintained until the end of the experiment.

Silymarin, a mixture of flavonolignans with anti-oxidant and anti-inflammatory features, is extracted from the seed of *Silybum marianum* and protects against both acute[21] and chronic[22] ethanol-induced liver injury.[2] In view of its nontoxic nature, easy availability, and well-studied quality standard, silymarin was used as the positive control in the present experiment. Blood ethanol concentrations were measured using gas chromatography as previously described.[23,24] Blood alcohol levels ranged between 66 and 186 mg/dL and were similar among the groups.

Histological Assay. Liver tissues were fixed in 4% paraformaldehyde and then embedded in paraffin. Three-micrometer sections were stained with hematoxylin and eosin (H&E) by standard methods and then studied by light microscopy. Hepatic lipids were determined by staining 16 μm thick frozen liver sections with oil red O. Multispectral imaging was performed using the Nuance Multispectral Imaging System (Cambridge Research and Instrumentation Inc., Woburn, MA) as described in our previous study.[25] Briefly, spectral optical density data were automatically acquired from 420 to 720 nm in 10 nm increments. Spectral unmixing was accomplished using Nuance software v1.42 with pure spectral libraries of oil red O (slide stained with only oil red O). For the quantification, three equal-sized fields of each photograph were randomly chosen for each experiment.

Measurement of Liver TG Content. Hepatic levels of TG in mice were measured using a commercially available Tissue Triglyceride Assay kit (Applygen Technologies Inc., Beijing, China). A 20-fold volume of lysate was added to the 40 mg liver preparations. Supernatants were collected after centrifugation at 2000 rpm for 5 min and analyzed for TG content according to the manufacturer's protocol. The TG concentrations were normalized to protein concentrations and expressed as mg of TG/g of protein.

Real-Time PCR Assay. Total RNA was extracted from the stored frozen liver tissues using RNAiso Plus (TaKaRa Bio, Dalian, Liaoning, China) according to the manufacturer's protocol. The isolated RNA was converted into complementary DNA using Advantage RT-for-PCR Kit (TaKaRa Bio, Dalian, Liaoning, China). RT-PCR was

performed on the Thermal Cycler Dice TP800 system (TaKaRa Bio, Otsu, Shiga Prefecture, Japan) using SYBR Premix Ex *Taq*II (TaKaRa Bio, Dalian, Liaoning, China) with 30−40 cycles of denaturation at 95 °C for 5 s, annealing, and extension at 60 °C for 30 s. GAPDH was used as an internal standard, and the mRNA expression levels of the target genes were normalized to that of GAPDH. The sequences of both forward and reverse primers are listed in Table 1.

Western Blotting Assay. Total proteins were extracted from liver using Cell Lysis Buffer for Western and IP (Beyotime Institute of Biotechnology, Haimen, Jiangsu, China) containing 1% phenylmethanesulfonyl fluoride (Beyotime Institute of Biotechnology, Haimen, Jiangsu, China) and 1% phosphatase inhibitor cocktail (Roche Diagnostics GmbH, Mannheim, Germany). Protein concentrations were determined by the Lowry method.[26] Twenty micrograms of protein was separated by electrophoresis on a 6%, 8%, or 12% sodium dodecyl sulfate-polyacrylamide gel, and electrophoretically transferred to polyvinylidene difluoride membranes. The blots were incubated with specific primary antibodies for 1 h at room temperature: rabbit anti-AMPKα1/2 antibodies, rabbit anti-phospho-p44/42 MAPK, rabbit p44/42 MAPK, rabbit anti-phospho-p38 MAPK, and rabbit p38 MAPK antibodies (1:200 dilution); mouse anti-SREBP-1 and rabbit anti-phospho-AMPKα1/2 (1:750 dilution); rabbit anti-acetyl-CoA carboxylase and rabbit anti-phospho-acetyl-CoA carboxylase antibodies (1:2000 dilution); and mouse anti-GAPDH antibody (1:10000 dilution) overnight at 4 °C. They were then incubated with a secondary antibody: rabbit polyclonal anti-immunoglobulin G (IgG), or mouse or rabbit monoclonal anti-IgG (1:2000 dilution). Antibody binding was detected using an enhanced chemiluminescence kit with hyper-enhanced chemiluminescence film.

Statistical Analysis. All results were expressed as the mean ± standard deviation (SD). Statistical comparisons were performed using one way analysis of variance (ANOVA) with Dunnett's multiple comparison test or unpaired Student's *t* test. The analyses were performed with SPSS software (version 16.0, SPSS Inc., Chicago, IL). A p value less than 0.05 was considered to be statistically significant. The Western blot and optical histological results were obtained from at least three independent experiments, and the analysis was carried out with triplicate samples.

RESULTS

EEGS Attenuated Acute Ethanol-Induced Lipid Accumulation in the Liver. ALT is released from the cytoplasm of impaired hepatocytes. Its serum activity is most commonly used in clinical practice as a reliable primary indicator for ALD.[5,27] As shown in Figure 3A, acute alcohol gavage significantly increased serum activities of ALT (37.9 ± 6.0 U/L vs 30.5 ± 4.2 U/L); this elevation was significantly diminished by treatment with EEGS at a dose of 50 mg/kg. EEGS at a dose of 25 mg/kg also prevented the increase in ALT activity to a certain extent but with no significant difference compared with Group IB. As shown in Figure 3B, acute alcohol gavage increased serum activities of AST. This elevation was significantly diminished by treatment with 50 mg/kg EEGS. EEGS at a dose of 25 mg/kg also slightly prevented the increase in AST activity, but with no significant difference compared with Group IB. According to the above ALT and AST results, the suppressive effect on ethanol-induced injury occurred in a dose-dependent manner.

To assess the effect of EEGS on hepatic steatosis induced by acute ethanol intake, hepatic lipid accumulation was qualitatively examined by oil red O staining and quantitatively determined by a TG quantification kit. After three doses of ethanol administration via oral gavage, mice from both the ethanol group and ethanol plus EEGS groups exhibited obvious accumulation of neutral lipid droplets in their livers compared with the control group, as illustrated by oil red O staining (Figure 3D,E). The lipid droplets in the livers of the EEGS-treated groups were much fewer than those in the model group. Quantitative analysis (Figure 3F) confirmed the histological results by demonstrating that acute ethanol gavage dramatically increased the hepatic TG content in mice, and this elevation was significantly diminished by treatment of EEGS at doses of 12.5 and 50 mg/kg. These data clearly indicated that EEGS could effectively reverse acute ethanol-induced hepatic lipid accumulation. Although the data from the H&E staining and oil red O staining (Figure 3C−E) indicated the treatment with EEGS at dose of 25 mg/kg exerted a protective effect, the data in Figure 3F showed a tendency without statistical significance. In view of significant effect of both 12.5 and 50 mg/kg EEGS, the medium dose of 25 mg/kg was considered to be a turning point, and EEGS exerted bidirectional regulation in a dose-dependent manner, which usually indicates the involvement of complex active ingredients and multiple pathways. Therefore,

the medium dose of 25 mg/kg was selected as an optimal dose for further study as specified below.

The *n*-Butanol Fraction Extracted from EEGS Was the Active Fraction of EEGS. Serum ALT activity and hepatic lipid accumulation were used as assessment criteria to screen the active fraction(s) of EEGS. Hepatic lipid accumulation was evaluated by vacuolation in H&E stained sections and quantitatively determined by a TG quantification kit.

As shown in Figure 4B, acute alcohol gavage increased serum ALT activity to a certain extent, and this elevation was significantly diminished by treatment with the *n*-butyl alcohol fraction from EEGS. In addition, the *n*-butyl alcohol fraction significantly reduced the ethanol-induced hepatic lipid accumulation as shown in Figure 4A,C. Again, treatment with EEGS only showed a tendency without statistical significance (Figure 4C), which was consistent with the data in Figure 3F. Moreover, these data provide a further evidence for the existence of bidirectional regulation in protective effect of EEGS against ethanol-induced liver steatosis. Together, the *n*-butanol fraction was determined to be the most active fraction of EEGS and was selected for further fractionation by the polyamide glass column.

Fraction 2 Was the Active Fraction of the *n*-Butyl Alcohol Extract. As shown in Figure 5B, acute alcohol gavage significantly increased serum ALT activity, and this elevation was diminished by treatment of fraction 1, 2, or 3 to a certain extent. In addition, fractions 1 and 2 significantly reduced the ethanol-induced hepatic lipid accumulation as shown in Figure 5A,C. Thus, fractions 1 and 2 were determined to be the active fractions of the *n*-butyl alcohol extract according to the screening criteria mentioned above. Compared with fraction 1, fraction 2 had fewer compounds (Figure 2) and required a lower dose to achieve similar activity. Thus, fraction 2 was selected for further study.

EEGS, Fraction 2, and Chlorogenic Acid Attenuated Chronic Ethanol-Induced Hepatic Lipid Accumulation. As shown in Figure 6D, chronic alcohol treatment increased serum ALT activity, and this elevation was significantly

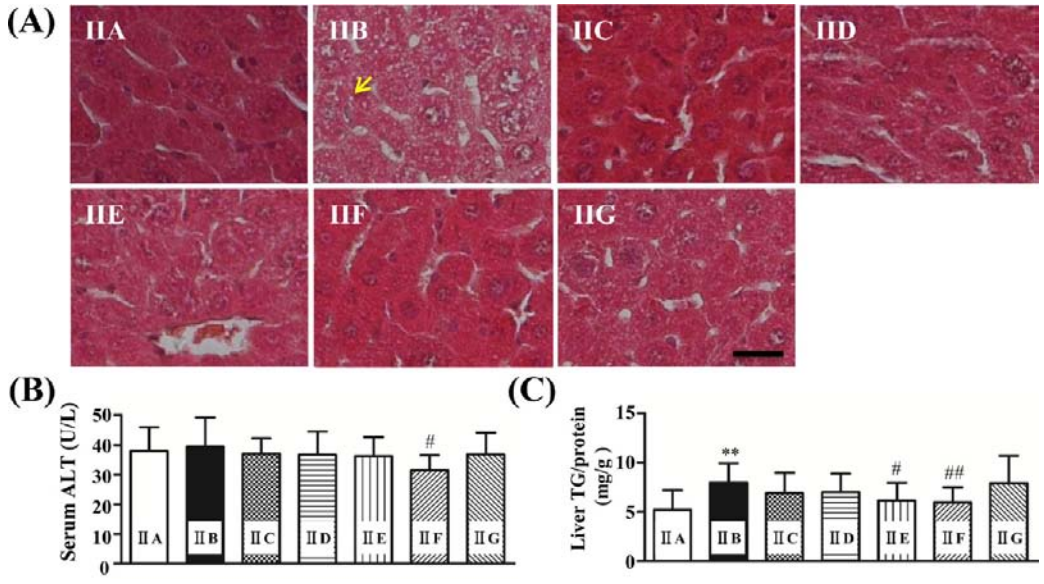

Figure 4. The *n*-butanol fraction was the active fraction of EEGS. Animals were randomly divided into seven groups: Group IIA, control (normal saline treated); Group IIB was treated with 5 g/kg ethanol only; Groups IIC, IID, IIE, IIF, and IIG received oral administration with 5 g/kg ethanol plus EEGS (25 mg/kg), petroleum ether fraction (1.35 mg/kg), ethyl acetate fraction (3.55 mg/kg), *n*-butanol fraction (3.33 mg/kg), or water fraction (16.75 mg/kg), respectively, every 12 h for a total of three doses. (A) Representative photomicrographs of H&E staining of liver sections. The arrow indicates vacuolated hepatocytes. (B) Serum alanine aminotransferase (ALT) activity. (C) Quantitation of hepatic triglyceride (TG) content. Data are expressed as the mean ± SD, $n = 12$; $^{**}P < 0.01$ vs control; $^{\#}P < 0.05$ and $^{\#\#}P < 0.01$ vs model. Scale bar = 100 μm.

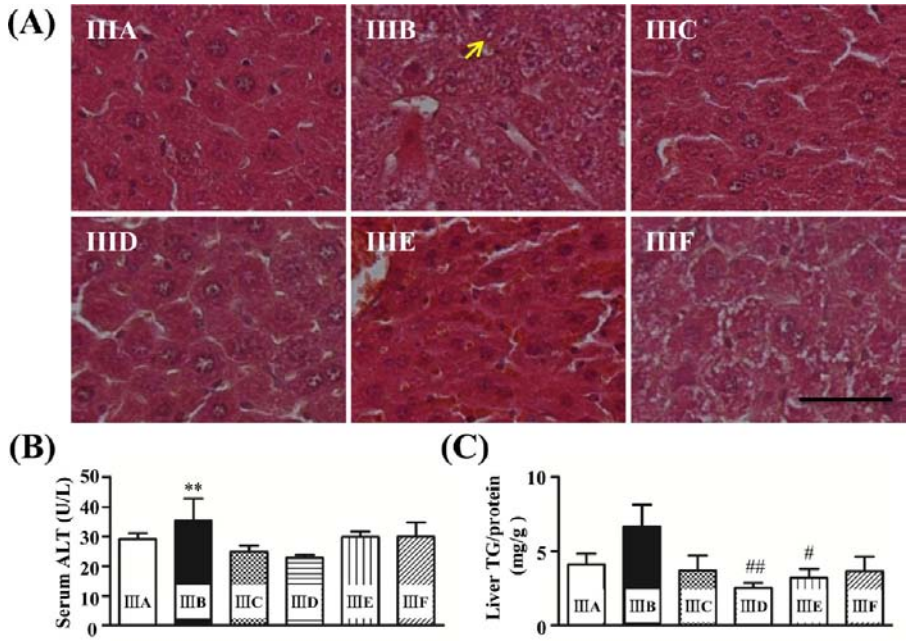

Figure 5. Fraction 2 was the active fraction of the *n*-butyl alcohol extract. Animals were randomly divided into six groups with 6−9 mice per group: Group IIIA, control (normal saline treated); Group IIIB, treated with 5 g/kg ethanol only; Groups IIIC, IIID, IIIE, and IIIF were orally treated with 5 g/kg ethanol plus the *n*-butanol fraction (3.33 mg/kg), fraction 1 (3.10 mg/kg), fraction 2 (0.22 mg/kg), or fraction 3 (0.03 mg/kg), respectively, every 12 h for a total of three doses. (A) Representative photomicrographs of H&E staining of liver sections. The arrow indicates vacuolated hepatocytes. (B) Serum alanine aminotransferase (ALT) activity. (C) Quantitation of hepatic triglyceride (TG) content. Data are expressed as the mean ± SD, $n = 6–9$; $^{**}P < 0.01$ vs control; $^{\#}P < 0.05$ and $^{\#\#}P < 0.01$ vs model. Scale bar = 100 μm.

diminished by treatment with fraction 2. EEGS, chlorogenic acid, and silymarin also prevented the increase in ALT activity to a certain extent, but were not significantly different from Group IVB. Chronic ethanol-induced vacuolation in H&E staining and red staining in the oil red O staining of liver sections were far more serious than that of the acute sections (Figure 6A−C). All of the treatments, including EEGS, fraction 2, chlorogenic acid, and silymarin, attenuated chronic ethanol-induced liver lipid accumulation. EEGS and fraction 2 were more potent than chlorogenic acid and silymarin. Fraction 2 had similar effects as EEGS but was purer and more powerful (10 mg/kg/day vs 75 mg/kg/day).

EEGS Alleviated the Ethanol-Induced Expression of Genes Involved in Lipid Metabolism and Inflammation

DOI: 10.1021/acs.jafc.5b03504
J. Agric. Food Chem. 2015, 63, 8460−8471

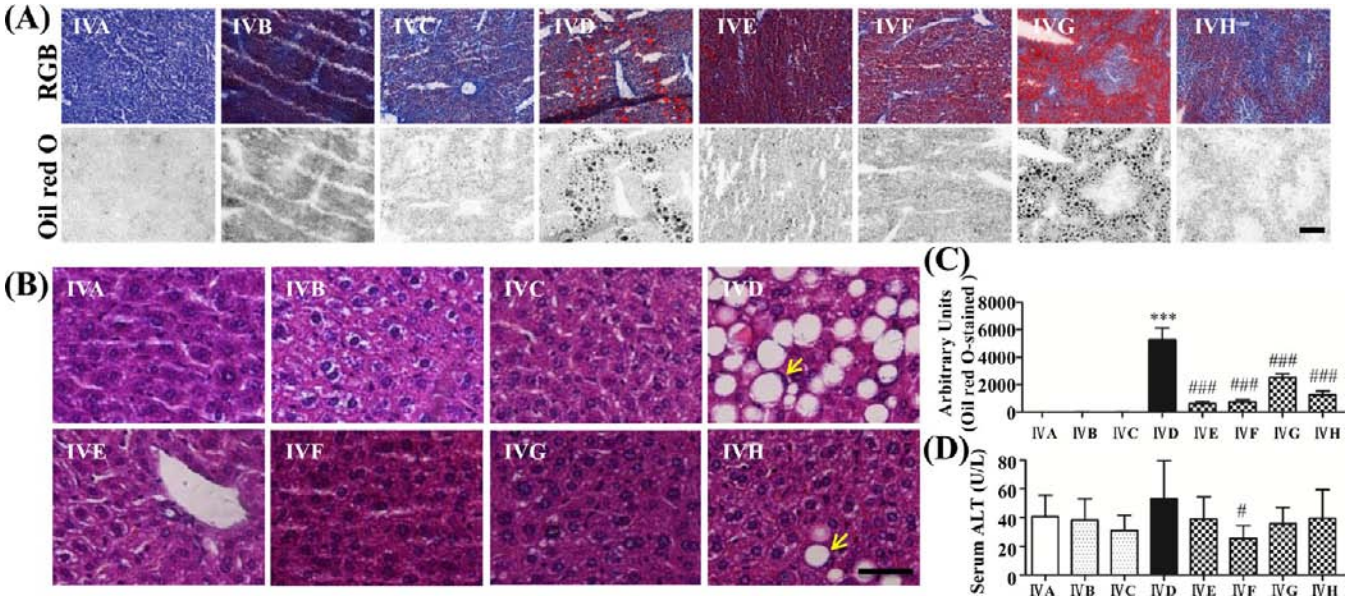

Figure 6. EEGS, fraction 2, and chlorogenic acid attenuated chronic ethanol-induced lipid accumulation in liver. Mice were divided into eight groups with 6−10 mice per group: Group IVA received a standard solid diet and water ad libitum; Group IVB, control (received an isocaloric maltodextrin-containing diet in a pair-fed fashion); Group IVC received an isocaloric maltodextrin-containing diet and was orally treated with EEGS (75 mg/kg/day) for the last 2 weeks; Groups IVD−IVH were treated with an ethanol-containing diet; Groups IVE, IVF, IVG, and IVH were orally treated with EEGS (75 mg/kg/day), fraction 2 (10 mg/kg/day), chlorogenic acid (10 mg/kg/day), or silymarin (100 mg/kg/day), respectively, for the last 2 weeks. Either the ethanol-containing diet or the isocaloric maltodextrin (control) diet was fed to the animals for 8 weeks. (A) Representative photomicrographs of oil red O staining of liver sections and (C) densitometric analysis of staining. Red is positive oil red O staining, and blue is hematoxylin counterstain. Top panels in (A): RGB images. Bottom panels: unmixed oil red O images of the up panel. (B) Representative photomicrographs of H&E staining of liver sections. Arrow indicates vacuolated hepatocytes. (D) Serum alanine aminotransferase (ALT) activity. Data are expressed as the mean ± SD, $n = 6-10$; $^{***}P < 0.001$ vs pair-fed control; $^{\#}P < 0.05$ and $^{\#\#\#}P < 0.001$ vs model. Scale bar for (A) = 100 μm. Scale bar for (B) = 50 μm.

in an Acute Model. Ethanol significantly induced the expression of fatty acid-uptake genes, including *Fabp1* and *Fabp4*, and fatty acid-synthesis genes, including *Fasn* and *SREBP-1*, in the liver (Figure 7A). Intriguingly, EEGS treatment reduced the expression levels of *Fabp1*, *Fabp4*, *Fasn*, and *SREBP-1*. The genes involved in fatty acid *β*-oxidation (*CPT1A*) and TG-secretion (*MTTP*) were also enhanced by ethanol exposure. However, EEGS significantly reduced the mRNA expression of *CPT1A* and *MTTP*. Moreover, ethanol did not show any significant effects on *PPAR-α*, *PPAR-γ*, or *ApoB* mRNA expression when compared to normal controls. *PPAR-γ* and *ApoB* mRNA expressions were upregulated by EEGS in the presence or absence of ethanol.

We also analyzed inflammation markers including *CD68*, *IL-1β*, *IL-6*, *CD163*, *Arginase*, *TGF-β*, *F4/80*, *MCP-1*, and *TNF-α* (Figure 7B). We found that ethanol exposure elevated the expression of almost all of the above genes except for *F4/80* and *TNF-α*. However, EEGS treatment reversed these ethanol-induced mRNA changes. Even *F4/80* and *TNF-α* mRNA expressions were reduced by EEGS treatment. These data indicated that EEGS might relieve ethanol-induced liver damage by regulating of lipid metabolism and reducing inflammatory responses in the liver.

Administration of EEGS, Fraction 2, or Chlorogenic Acid Alleviated Hepatic Steatosis through MAPK/SREBP-1c-Dependent and -Independent Pathways. Premature SREBP-1c (pSREBP-1c) is cleaved and activated in response to ethanol feeding, which is closely associated with an increased expression of hepatic lipogenic genes and the accumulation of TG in the liver.[28] To investigate the possible underlying mechanisms of EEGS-mediated hepatic improvements, we measured the changes of SREBP-1c and its upstream regulators (MAPK and AMPK) and downstream effector (ACC) in the chronic model. There are two obvious bands of SREBP-1c in Figure 8A, the top one is so-called pSREBP-1c, and the bottom one is mSREBP-1c. The pSREBP-1c band in the present study represented both normal and phosphorylated form of premature SREBP-1c. Both the premature and mature forms of SREBP-1c were significantly elevated by chronic ethanol administration. After treatment with EEGS or fraction 2, the influence of ethanol on mSREBP-1c was abolished.

Consequently, we measured the changes of key MAPK members, which suppress SREBP-1c activity by phosphorylation.[15,29] The administration of ethanol significantly decreased the phosphorylation of both p38 MAPK and p44/42 MAPK (Figure 8B). After treatment with EEGS or fraction 2, the influence of ethanol on the phosphorylation of both p38 MAPK and p44/42 MAPK proteins was abolished. In addition, ethanol treatments decreased the total expression of p38 MAPK but not p44/42 MAPK.

Moreover, the effect of ethanol on SREBP-regulated promoter activation was mediated, at least in part, through inhibition of AMPK.[30] However, neither the ethanol nor the EEGS treatments demonstrated any effects on the expression of the total or phosphorylated form of AMPK (Figure 8C). These data indicated that AMPK was not involved in the SREBP-1c pathway in the present study.

The first committed step in fatty acid biosynthesis is carried out by ACC.[10] The regulation of ACC occurs at multiple levels. The first level is regulated by phosphorylation/dephosphorylation, and AMPK phosphorylates and inhibits ACC enzymatic activity.[10,31] The second level is regulated by

J. Agric. Food Chem. 2015, 63, 8460−8471

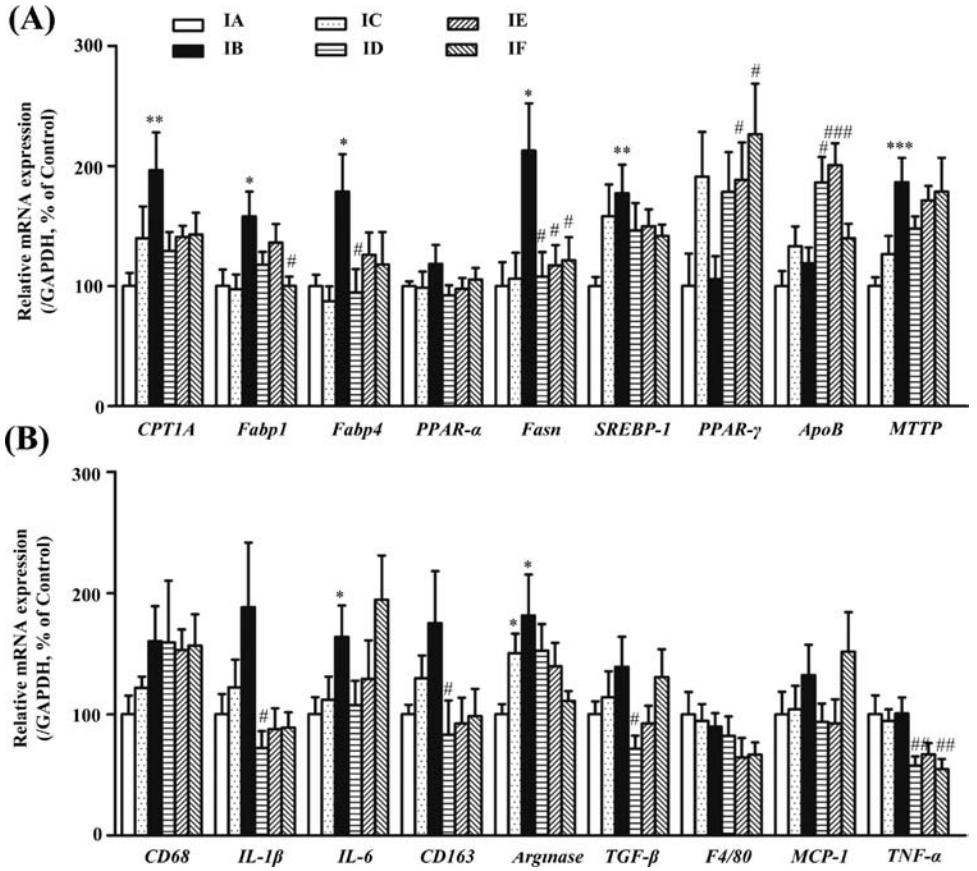

Figure 7. Hepatic expression levels of lipid metabolism-related and inflammation marker genes in mice. Group IA, control (normal saline treated); Group IB received EEGS at a dose of 50 mg/kg only; Groups IC–IF were treated with ethanol orally every 12 h for a total of three doses; Groups ID, IE, and IF were treated with EEGS at a dose of 12.5, 25, and 50 mg/kg, respectively. The mice were sacrificed 4 h after the last ethanol treatment. The mRNA expression of lipid metabolism-related genes (A) and the mRNA expression of inflammation markers (B) were evaluated by quantitative real-time PCR analysis and normalized to the housekeeping gene GAPDH. Data are expressed as the mean ± SD of 15 mice; $^{*}P < 0.05$ and $^{**}P < 0.01$ vs control; $^{\#}P < 0.05$, $^{\#\#}P < 0.01$, and $^{\#\#\#}P < 0.001$ vs model.

transcription, and SREBP-1c increases *ACC* expression.[11,12] In the present study, total ACC and its phosphorylated form were evaluated during chronic ethanol administration (Figure 8C). However, the ratio between the phosphorylated and total ACC forms was progressively decreased by chronic ethanol administration, and after treatment with EEGS or fraction 2, the influence of ethanol on the ratio was abolished.

The administration of EEGS and fraction 2 abolished the influence of ethanol on SREBP-1c activation, its upstream regulators (phosphorylation of both p38 MAPK and p44/42 MAPK) and downstream effectors, such as ACC. Thus, the MAPK/SREBP-1c-dependent pathway participated in the protective effect of EEGS and fraction 2 against hepatic steatosis.

As one of the major active ingredients of fraction 2, chlorogenic acid canceled the negative effect of ethanol on ACC expression and activation. However, unlike fraction 2, chlorogenic acid did not change the MAPK or SREBP-1c activity in the current study. This result indicated that chlorogenic acid inhibited ACC in a MAPK/SREBP-1c-independent manner and that there are other ingredient(s) in fraction 2 that impact the MAPK/SREBP-1c pathway.

DISCUSSION

Over the past decade, dozens of herbs and individual compounds isolated from herbs have been shown to possess protective effects against ethanol-induced liver injury. A previous review has collected 34 herbal medicines and/or active compounds specifically used for that purpose.[27] As summarized by Ding et al. in that review, the underlying mechanisms and active ingredients have not been sufficiently elucidated. In the present study, the capability of EEGS and its fractions to protect against ethanol-induced liver injury were investigated. Emphasis was placed upon the underlying molecular mechanisms and the active ingredient and its contributions to the protective effect.

The ability to prevent increased serum ALT activity and hepatic lipid accumulation in acute ethanol-induced liver steatosis was used as an assessment criterion to screen the active fraction(s) from EEGS. The *n*-butyl alcohol extract was the active fraction of EEGS and was selected for further fractionation by the polyamide glass column. The 60% ethanol-eluted fraction that contained 13.6% chlorogenic acid was the most active fraction, and its effects were further evaluated in the chronic model.

Data in the chronic model demonstrated that treatment with the *n*-butyl alcohol extract, 60% ethanol-eluted fraction, or chlorogenic acid protected against ethanol-induced liver steatosis, indicating that chlorogenic acid, at least in part, contributed to the beneficial effect of *G. procumbens* on alcoholic fatty liver. Compared with the doses of well-known commercial products, such as *Panax notoginseng* saponins

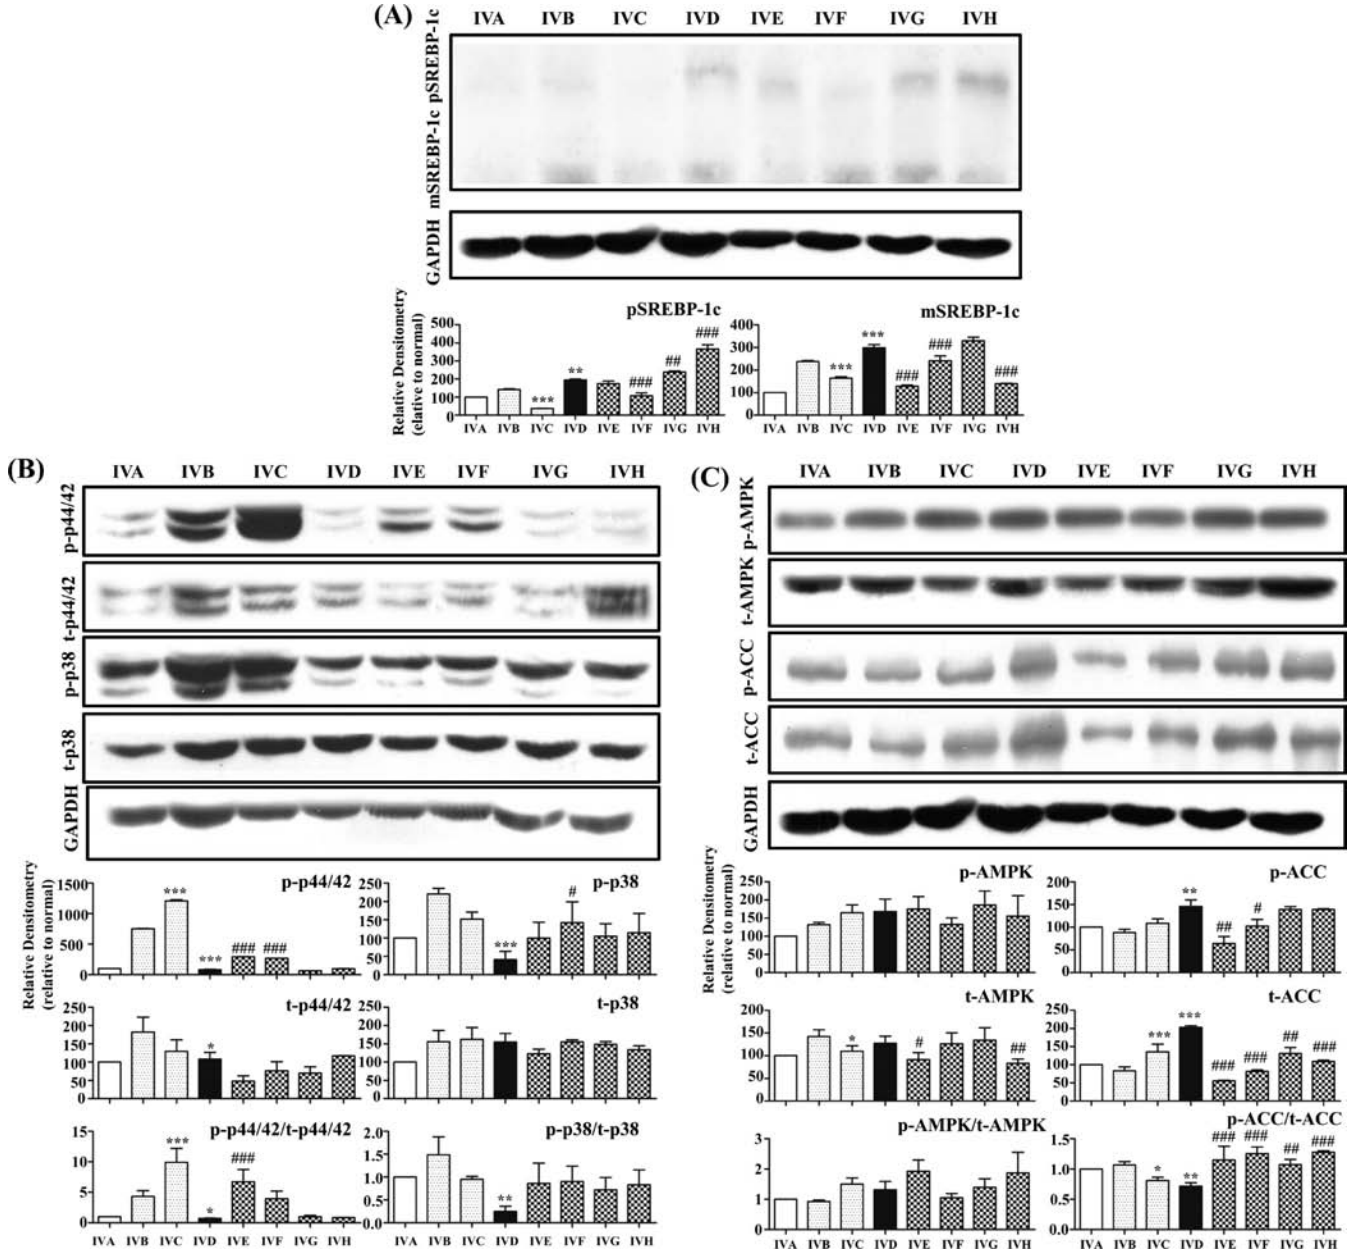

Figure 8. Effect of EEGS, fraction 2, or chlorogenic acid on the protein expression of the MAPK/SREBP-1c/ACC pathway. Mice were divided into eight groups with 6−10 mice per group: Group IVA received a standard solid diet and water ad libitum; Group IVB, control (received an isocaloric maltodextrin-containing diet in a pair-fed fashion); Group IVC received an isocaloric maltodextrin-containing diet and was orally treated with EEGS (75 mg/kg/day) for the last 2 weeks; Groups IVD−IVH were treated with an ethanol-containing diet; Groups IVE, IVF, IVG, and IVH were orally treated with EEGS (75 mg/kg/day), fraction 2 (10 mg/kg/day), chlorogenic acid (10 mg/kg/day), or silymarin (100 mg/kg/day), respectively, for the last 2 weeks. Either the ethanol-containing diet or the isocaloric maltose-dextrin (control) diet was fed to the animals for 8 weeks. Western blot analysis using a specific antibody was used to examine the expression of the proteins in the mouse liver homogenates. Bands densities were determined using ImageJ, normalized to GAPDH, and expressed as a percentage of the standard solid diet control. Representative photographs of Western blots of SREBP-1c (A), p44/42 MAPK and p38 MAPK (B), and ACC and AMPK (C), with quantitative analysis of blots given below each set of photographs, where each bar represents the mean ± SD of the results obtained from three mice. $^{*}P < 0.05$, $^{**}P < 0.01$, and $^{***}P < 0.001$ vs pair-fed control; $^{\#}P < 0.05$, $^{\#\#}P < 0.01$, and $^{\#\#\#}P < 0.001$ vs model.

(100−300 mg/kg/day),[5] silymarin (100−200 mg/kg/day),[21] or most of the above-mentioned herbal medicines, the dose of fraction 2 and chlorogenic acid used in the present study was much lower, just 10 mg/kg/day. In addition, in the present study, fraction 2 showed better potential than chlorogenic acid and silymarin to prevent ethanol-induced liver steatosis.

The mechanism by which ethanol causes fatty liver and liver injury is complicated. Anti-oxidative stress, anti-inflammation, and lipid metabolism regulation are three major mechanisms that are involved in the protective effect of herbal medicines against ALD.[1,27] Alcoholic fatty liver is the earliest and most common response of the liver to alcohol and may be a precursor of more severe forms of liver injury. SREBP-1c is a master regulator of lipid homeostasis, and SREBP-1 knockout mice are completely protected from ALD, indicating a causal involvement of SREBP-1 in ALD.[16] SREBP-1c positively

regulates the expression of genes encoding lipogenic enzymes, including ACC and FAS.[11,12] The most important function of ACC is to provide the malonyl-CoA substrate for the synthesis of fatty acids, and the main function of FAS is to catalyze the synthesis of palmitate. The present study indicated that ethanol induced expression levels of ACC and FAS, which is in accordance with a previous report.[28]

The effect of ethanol on SREBP-regulated promoter activation was mediated, at least in part, through inhibition of AMPK and MAPK.[30] In several studies, AMPK phosphorylation is increased,[32,33] whereas in other studies, AMPK phosphorylation is decreased.[34,35] Ethanol (amount and feeding duration) and fat (type and dose) used in these studies might contribute to the discrepancies.[36] Unlike AMPK, the changes of MAPK were in accordance with SREBP-1c, indicating a possible link between MAPK and SREBP-1c and its downstream genes in the present study. The administration of EEGS and fraction 2 abolished the influence of ethanol on SREBP-1c activation and its upstream regulators and downstream effectors. Thus, the MAPK/SREBP-1c-dependent pathway contributes to the mechanism of the beneficial effect of EEGS and fraction 2 on alcoholic fatty liver.

As one of the major active ingredients of fraction 2, chlorogenic acid was chosen to further investigate the underlying mechanism. Chlorogenic acid has many biological properties, including anti-bacterial, anti-oxidant, and anti-carcinogenic activities. Recently, the roles and applications of chlorogenic acid in relation to hepatic steatosis have been highlighted.[37,38] Chlorogenic acid inhibits the MAPK pathway[39,40] to protect drug-induced liver injury while activating AMPK to improve lipid metabolism in non-alcoholic fatty liver disease.[37] However, unlike fraction 2, chlorogenic acid did not change MAPK or SREBP-1c activity in the current study, which indicated that chlorogenic acid inhibited ACC in a MAPK/SREBP-1c-independent pathway and that there was an addtional ingredient(s) in fraction 2 that impacted the MAPK/SREBP-1c pathway. In addition to AMPK, protein kinase A also has the ability to phosphorylate ACC. Other kinases are also suspected to be important in this regulation, because many other possible phosphorylation sites exist on ACC.[41] Both MAPK/SREBP-1c-dependent and -independent pathways contributed to the regulation of *G. procumbens* on lipid metabolism-related genes, which exerted subsequent protective effects against ethanol-induced hepatic lipid accumulation.

ALD is a complex process. In addition to lipid accumulation, ethanol-induced liver injury is highly linked to inflammatory and oxidative stress.[1] Inflammation and oxidative stress are two etiological factors that have been suggested to play important roles in the development of ethanol-induced liver injury. Silymarin, the positive control in the present study, is a good example of an agent that protects against alcohol-induced liver disease via anti-inflammatory and anti-oxidative features.[21] Increased pro-inflammatory cytokine levels have been well documented in ALD.[42] EEGS treatment alleviated the ethanol-induced upregulation of cytokine levels, which should have resulted in a corresponding attenuation of ethanol-induced liver injury. In addition, because chlorogenic acid is an anti-oxidant and ethanol treatment enhances oxidative stress in the liver,[43] we could assume that the reduction of oxidative stress may also partially contribute to the prevention of liver injury in the present study, but more precise experiments are needed to further confirm that hypothesis.

In summary, our data show that *G. procumbens* protected against ethanol-induced liver steatosis, possibly through ameliorating hepatic lipid accumulation by modulating lipid metabolism-related genes through MAPK/SREBP-1c-dependent and -independent pathways. Our findings also suggest that *G. procumbens* and one of its active ingredients, chlorogenic acid, could potentially be developed as effective agents for acute or chronic ethanol-induced liver injury.

resveratrol and its derivatives, *E*-piceatannol, *E*-ε-viniferin, ampelopsin A, *E*-miyabenol C, *Z*/*E*-vitisin B, hopeaphenol, and isohopeaphenol (Figure 1), between conducting tissues, cortex, and pith has been studied in grape canes from healthy and downy mildew-infected vineyards.

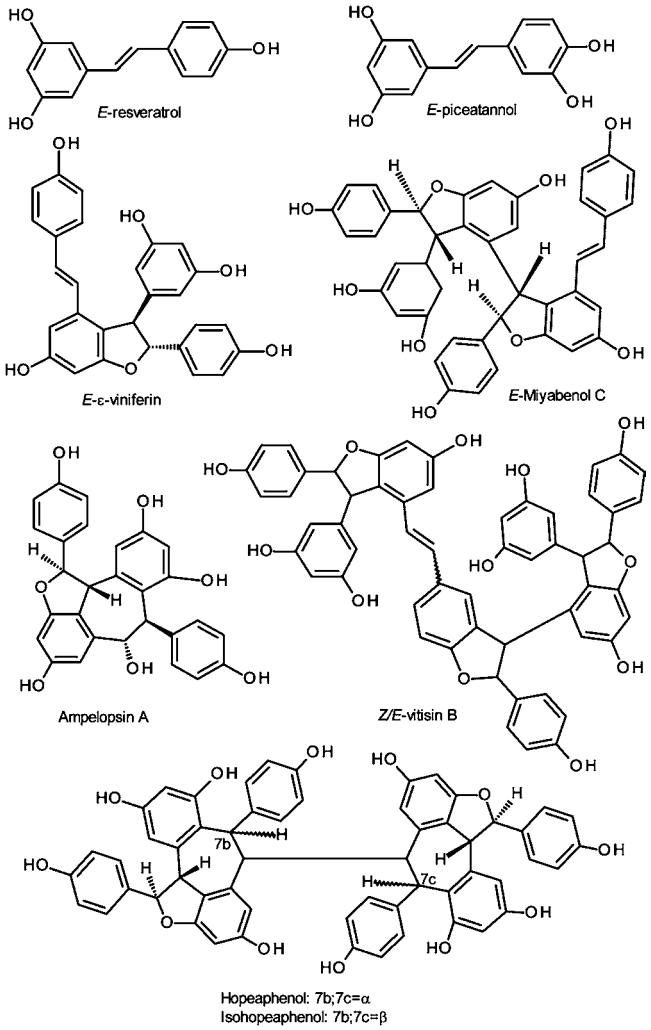

Figure 1. Selected structures of typical stilbenoids present in grape canes.

MATERIALS AND METHODS

Plant Material. The study was conducted on 35-year-old vineyards of the Bourgueil district in the Loire Valley region (France) in vintage 2011. Vineyards were planted with *V. vinifera* cv. Cabernet franc (clone 327 grafted onto 3309 rootstock) on a clay−silica−limestone soil at a spacing of 1 m (within row) × 2 m (between rows) corresponding to 5000 vines ha^{-1}. Two adjacent vineyard parcels (plot A, 47°17′28.82″ N, 0°13′28.51″ E; plot B, 47°17′49.07″ N, 0°14′34.46″ E) were selected for the study, covering areas of 0.18 and 0.233 ha, respectively. Both plots were subjected to organic management with similar practices except for the copper-based fungicide treatments. In plot A, solutions of copper were applied corresponding to 1 kg ha^{-1}. In plot B, the copper treatments were prohibited during the entire growing season to allow fungal infection. Consequently, downy mildew disease intensities at grape harvest were 5 and 95% in plots A (healthy) and B (infected), respectively. Grape canes from both parcels were harvested in December 2011. Grape canes (60 stalks per plot) were randomly pruned across the total area of plots A and B to overcome intraplot variation. Then, grape canes were stored for 10 weeks at 20 °C in the dark as 10 cm long sections.[29] After storage, five lots were constituted within grape canes originating from plots A and B to compare the stilbenoid compositions from healthy and infected vineyards. Wood sections were manually dissected to separate cortex, pith, and conducting tissues.

Stilbenoid Analysis. Whole and dissected tissues of grape canes were ground for 2 min with a cooled analytical grinder (Ika-Werke, Staufen, Germany). A second grinding step was performed using a cutting mill (Polymix PX-MFC 90 D, Kinematica AG, Switzerland) to obtain a powder with an average particle size of 1 mm. Freeze-drying was performed at 0.01 mbar and −20 °C for 48 h with a Christ Alpha I-5 freeze-dryer. For stilbenoid extraction, 50 mg of lyophilized powder was extracted in 1 mL of an ethanol/water solution (60:40; v/v), shaken for 30 min at 1400 rpm and 83 °C, and centrifuged at 18000*g* for 5 min. HPLC analyses were performed on a Waters system (Waters 600 controller, Milford, MA, USA) equipped with a UV−visible photodiode array detector (Waters 996) and a column packed with 3 μm particles (250 × 4 mm, Multospher 120 RP18HP; CS-Service, Langerwehe, Germany) at 24 °C. The mobile phase was aqueous phosphoric acid (0.1% w/v; eluent A) and acetonitrile (eluent B) pumped at 0.5 mL min^{-1}. The gradient started at 5% B and increased linearly to 72.5% after 60 min, followed by washing and reconditioning of the column. Compounds in extracts were identified according to their UV spectra and retention time by comparison with external standards. Quantification was performed using reference standards of *E*-resveratrol, *E*-piceatannol, *E*-ε-viniferin, *Z*/*E*-vitisin B, ampelopsin A, *E*-miyabenol C, and hopeaphenol and five-point calibration curves (0−100 ppm) using the Maxplot detection mode.

Chemicals. *E*-Resveratrol and *E*-piceatannol were purchased from Sigma-Aldrich (St. Louis, MO, USA). *E*-ε-Viniferin, *Z*/*E*-vitisin B, ampelopsin A, *E*-miyabenol C, and hopeaphenol were extracted from grape canes as previously described.[6] Acetonitrile and ethanol were purchased from Thermo Fisher Scientific (Courtaboeuf, France). Ultrapure water was obtained from a Millipore Milli-Q water purification system (Bedford, MA, USA).

Microscopic Analysis. Free-hand cross sections of freshly pruned grape canes from Cabernet franc variety were observed with an epifluorescence microscope (Olympus BX51; Olympus Optical, Tokyo, Japan) equipped with a digital camera (Olympus DP71) and the corresponding software (SIS Cell). The autofluorescence was observed with a UV excitation filter set (Olympus WU2, 330−385 nm excitation filter, 420 nm long pass emission filter).

Fluorescence Spectroscopy. Pure standards of *E*-resveratrol and *E*-ε-viniferin in methanol solution (2 μg mL^{-1}) and 1:100 dilution of grape cane extracts prepared as described above (whole tissues, pith, cortex, or conducting tissues) were used. Excitation and emission spectra were acquired with a spectrofluorometer (Hitachi F-4500; Hitachi, Ltd., Tokyo, Japan). The excitation spectra were acquired with an emission at 390 nm, and the emission spectra were acquired with an excitation at 320 nm.[34]

Statistical Analysis. Data were analyzed with Statistica, version 6.0 (StatSoft Inc., Tulsa, OK, USA). Statistical significance from different treatments was revealed after one-way analysis of variance (ANOVA) followed by post hoc Tukey's honestly significant difference (HSD) test.

RESULTS AND DISCUSSION

Two adjacent vineyard plots planted with the Cabernet franc grape variety both on a clay−silica−limestone soil were selected for this study to avoid stilbenoid changes due to genetic or pedo-climatic variations. The two parcels were subjected to similar agricultural practices with the exception of the copper-based fungicide treatments that were applied to plot A (1 kg ha^{-1}) and absent in plot B. As a result, mildew disease intensities at midveraison were drastically contrasted at 5 and 95% in plots A (healthy) and B (infected), respectively. Specifically in plot B, 95% of the leaves were infected by downy mildew with at least 50% of leaf area being necrotic as well as

DOI: 10.1021/acs.jafc.5b02997
J. Agric. Food Chem. 2015, 63, 8472−8477

the occurrence of clusters turning brown. During winter, grape canes from both parcels were randomly pruned across the total area of plot A and B to overcome intraplot variation and stored for 10 weeks at 20 °C in the dark as 10 cm long sections to allow postpruned stilbenoid accumulation.[29] HPLC chromatograms of grape canes from healthy (plot A) and infected (plot B) vineyards showed differences in stilbenoid composition (Figure 2). *E*-Resveratrol and *E*-ε-viniferin, the two prominent

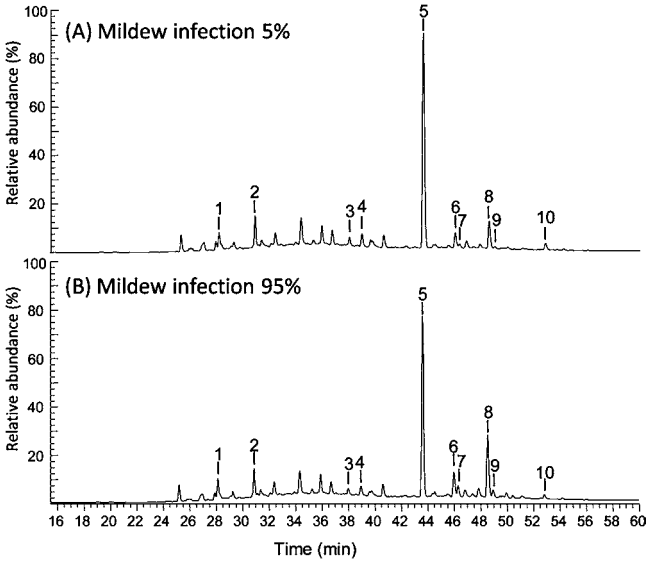

Figure 2. HPLC chromatograms measured in maxplot detection of hydroalcoholic cane extracts of *Vitis vinifera* cv. Cabernet franc from 5% (A) and 95% (B) downy mildew-infected vineyards. Peaks: (1) catechin, (2) epicatechin, (3) ampelopsin A, (4) *E*-piceatannol, (5) *E*-resveratrol, (6) hopeaphenol, (7) isohopeaphenol, (8) *E*-ε-viniferin, (9) *E*-miyabenol C, (10) *Z*/*E*-vitisin B.

compounds, were strongly influenced by downy mildew infection. Surprisingly, the concentration of *E*-resveratrol, a well-characterized grape phytoalexin in leaf and berries, decreased in infected grape canes, whereas *E*-ε-viniferin, the dimer of resveratrol, increased (Figure 3). Interestingly, hopeaphenol, the third most accumulated compound, remained

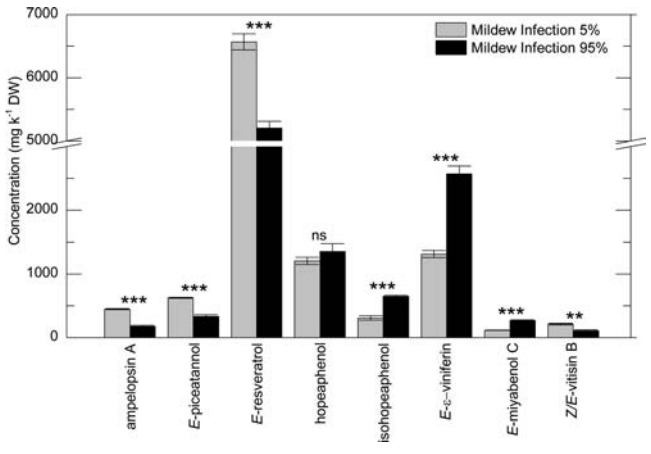

Figure 3. Stilbenoid composition in total tissues of grape canes from 5 and 95% downy mildew-infected vineyards. Asterisks indicate significant differences between the two infection levels (∗, $P < 0.05$; ∗∗, $P < 0.01$; ∗∗∗, $P < 0.001$). NS, no significant differences.

unchanged, whereas other minority stilbenoids either significantly decreased (ampelopsin A, *E*-piceatannol, *E*/*Z* vitisin B) or increased (isohopeaphenol, *E*-miyabenol C) in grape canes from downy mildew-infected vineyards.

Under favorable conditions, *Plasmopara viticola*, the etiological agent of downy mildew, infects leaves via stomata, spreads within the leaf tissue through the intercellular space of the spongy mesophyll, and later forms haustoria that penetrate host cells. Previous studies showed an induction of stilbenoids in necrotic areas after downy mildew infection,[35] but the effect on grape cane stilbenoids was not investigated. The change in stilbenoid composition observed in grape canes might affect the antifungal activity of grape cane extracts. Indeed, the toxicity of ε-viniferin against downy mildew is 2-fold higher than that of resveratrol,[30,36] and the level of resveratrol dimerization is considered as a marker of grapevine resistance to downy mildew.[37,38] The resistance level of grapevine cultivars depends on their ability to rapidly induce high concentrations of stilbenoids at the infection site.[39] Among the *V. vinifera* Cabernet franc clone collection, the resistance level to downy mildew was linked to higher production of stilbenoid phytoalexins in leaves including ε-viniferin and δ-viniferin.[40] δ-Viniferin was not detected in the grape cane extracts of either the present or previous studies.

The stilbenoid composition of stored grape canes results from a sequential accumulation of oligomers and monomers.[29] Oligomers accumulated before pruning and their levels remain unchanged during storage, but monomers (*E*-resveratrol and *E*-piceatannol) are mainly biosynthesized during storage along with an induction of stilbene synthase. In the present study, the stilbenoid composition was affected, but the total concentration was not significantly different between plot A (10792 ± 180 mg kg^{-1} DW) and plot B (10666 ± 331 mg kg^{-1} DW). The high level of *E*-ε-viniferin in grape canes from infected vineyards was offset by a limited accumulation of monomers during postpruning storage, suggesting a tight regulation of stilbenoid metabolism in grape canes. Resveratrol dimerization involves peroxidase isoenzymes located both in the vacuoles and in cell walls.[41] The accumulation of *E*-ε-viniferin in grape canes from downy mildew infected vineyards might result from a local conversion in stems or biosynthesis in leaves at the local infection site followed by phloem-mediated relocation.

To further assess the impact of downy mildew infection during the growing season on winter-harvested grape canes, the change in spatial distribution of stilbenoids was investigated. Stilbenoids emit a blue fluorescence under UV light with an excitation peak around 320 nm and an emission peak at 390 nm.[42] Therefore, fluorescence analyses were used to investigate the spatial distribution of stilbenoids in healthy grapevine tissues. A free-hand cross section of freshly pruned grape canes from Cabernet franc variety was prepared and observed by fluorescence microscopy. Figure 4 reveals the microscopical structure of a healthy grape cane including pith, conducting tissues, and cortex. The blue fluorescence observed in conducting tissues may rely on lignin fluorescence but also suggests a major accumulation of stilbenoids in vascular tissues of grape canes. No changes were observed between healthy and infected grape canes either in the blue fluorescence intensity or in the tissue structure (data not shown). To evaluate the contribution of stilbenoid fluorescence in the observed blue fluorescence, in vitro fluorescence spectra of pure solutions (*E*-resveratrol and *E*-ε-viniferin) and grape cane extracts were compared. Panels A and E of Figure 5 present respectively the

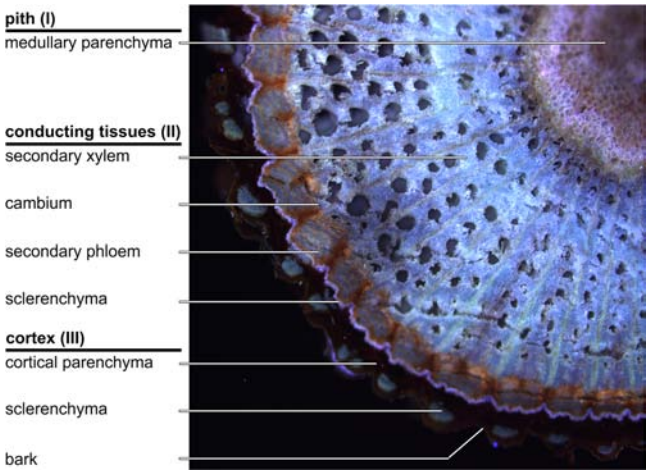

Figure 4. Fluorescence microscopy under UV excitation of a freshly pruned cross section of healthy grape cane from *Vitis vinifera* cv. Cabernet franc.

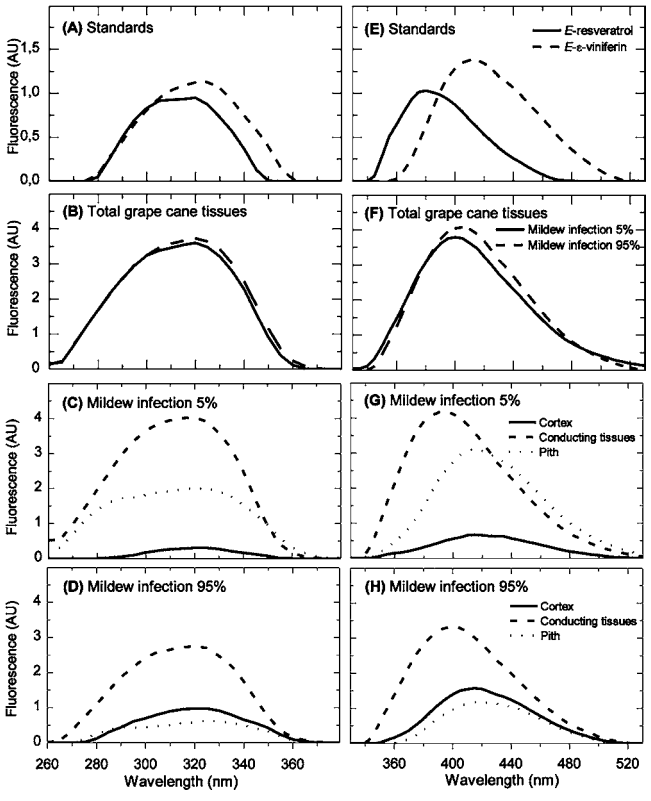

Figure 5. Fluorescence spectra of stilbenoid compounds and grape cane extracts: excitation (A–D) (emission wavelength, 390 nm) and emission (E–H) (excitation wavelength, 320 nm) fluorescence spectra of *E*-resveratrol and *E*-ε-viniferin (A, E) in solution; total tissue extract of grape canes from 5 and 95% downy mildew-infected vineyards (B, F); and dissected tissues of grape canes from 5% (C, G) and 95% (D, H) downy mildew-infected vineyards.

excitation and emission fluorescence spectra of pure *E*-resveratrol and *E*-ε-viniferin with similar broad excitation spectra (290–330 nm) and an emission maximum around 380 nm for *E*-resveratrol and 420 nm for *E*-ε-viniferin. The excitation fluorescence spectrum of the grape cane extract was similar to those of pure stilbenoids, and the emission maximum was around 400 nm, corresponding to an intermediate emission peak between 380 and 420 nm (Figure 5B,F). These results are in agreement with HPLC stilbenoid analyses, where *E*-resveratrol and *E*-ε-viniferin were the major accumulated compounds (Figure 3). Fluorescence analyses have been reported as a rapid technique to localize the stilbenoid distribution in grape leaves.[34,43] Here this technique points out that conducting tissues represent the main site of accumulation for stilbenoids in grape canes. After manual dissections of cortex, pith, and conducting tissues of grape canes, the spatial distribution of stilbenoids from healthy and downy mildew-infected vineyards was evaluated. The emission and excitation spectra indicate that conducting tissues represent the main site of stilbenoid accumulation in grape canes (Figure 5C,G). The emission maximum around 400 nm for conducting tissues and that around 420 nm for cortex and pith suggest a predominance of monomers in conducting tissues and oligomers in cortex and pith. Moreover, fluorescence spectra suggest that downy mildew affects the spatial repartition of stilbenoids with an increase in the cortex and a decrease in the pith (Figure 5C,D,G,H). To ascertain these global trends, HPLC analyses were performed on the corresponding dissected tissues (Figure 6). Striking differences of stilbenoid composition were revealed in the different grape cane tissues. Although the pith represented only 2% of the whole tissues, it contained high levels of oligomers, particularly hopeaphenol, isohopeaphenol, and *E*-ε-viniferin, compared to other tissues and was poor in monomers. Conducting tissues represented 88% of the overall tissues, and as a consequence the specific stilbenoid composition of conducting tissues mainly reflected the composition of the whole grape canes (Figure 3). The cortex representing 10% of the whole tissues was poor in stilbenoids, with hopeaphenol and *E*-ε-viniferin as major compounds. The HPLC tissue-specific analyses allowed a fine description of downy mildew impact on spatial distribution of stilbenoids. Indeed, the levels of all stilbenoid compounds were massively decreased in the pith of canes from infected plants whereas some oligomers were increased in conducting tissues and cortex. It should be noted that there was a drastic increase of *E*-ε-viniferin in conducting tissues (× 2) and cortex (× 3.4) following downy mildew infection.

The spatial characterization of stilbenoids in grape canes as well as the impact of downy mildew on stilbenoid distribution was unprecedented in the literature. Several studies are in agreement with the presence of stilbenoids in conducting tissues of grape canes. In young grape plants, resveratrol was shown to accumulate mainly in the stem.[27] HPLC analyses of xylem sap collected during the bleeding period revealed the presence of resveratrol.[44] Interestingly, in the xylem sap of vines infected by esca-associated fungi, a decrease of resveratrol was observed as in downy mildew-infected grape canes. In Norway spruce bark, the stilbenoids accumulate mainly in phloem parenchyma cells,[45] and after infection with the bark-beetle-associated fungi *Ceratocystis polonica*, an increase in stilbenoid dimers was observed accompanied by the loss of monomers. In grape canes from downy mildew-infected vineyards, resveratrol dimerization might be induced in conducting tissues for transport purpose, whereas in pith, a tissue with storage functions, the oligomer accumulation might be limited. The strong increase of *E*-ε-viniferin in the cortex, a tissue notably involved in protection against mechanical damage and microbial attack, might result from a systemic defense response to protect the plant against upcoming infections. It should be mentioned that a potential effect of copper treatments in plot A

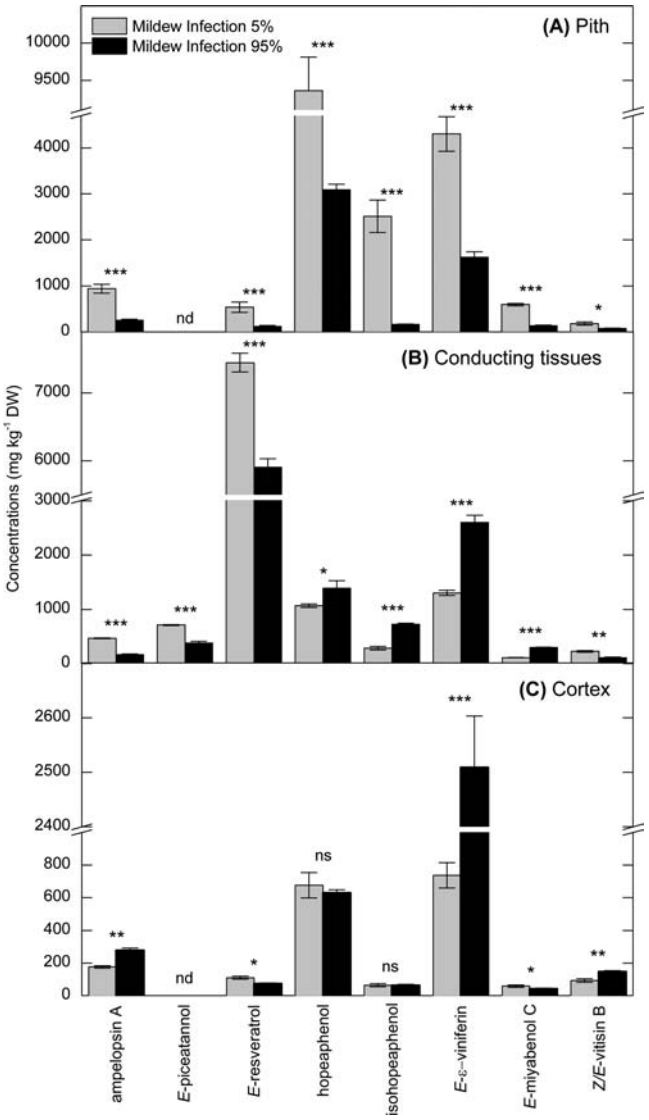

Figure 6. Stilbenoid composition in pith (A), conducting tissues (B), and cortex (C) of grape canes from 5 and 95% downy mildew-infected vineyards. Asterisks indicate significant differences between the two infection levels (*, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$). NS, no significant differences; ND, not detected.

on the stilbenoid contents in grape canes cannot be excluded because an elicitation has been reported on excised grape leaves of in vitro grown plants.[46]

In conclusion, this study indicates that stilbenoid composition in winter-pruned grape canes was greatly affected by downy mildew infection over the growing season. A change in spatial distribution of stilbenoids was observed, particularly in conducting tissues, where an increase in *E*-ε-viniferin and a decrease in *E*-resveratrol were seen. These findings suggest that the health status in vineyards could modify the composition of stilbenoids in winter-harvested grape canes. As vineyard management contributes to wine quality, it might also influence the composition of bioactive compounds of grape canes and the resulting potential biological properties of these valuable extracts. Further studies are still required to evaluate the influence of pedo-climatic factors on the variations of stilbenoid contents.

ment under a water deficit, which provide new insights into the biochemical mechanism of wheat grain development in response to drought stress.

MATERIALS AND METHODS

Wheat Materials, Water Deficit Treatment, and Sampling. The elite Chinese winter wheat cultivar Jing 411 (*Triticum aestivum* L; $2n = 6x = 42$; AABBDD) was used as material in this study, which has been widely cultivated in Beijing and the north wheat production area of China since the 1990s. It has many desirable features such as high yield and good yield stability, strong cold hardiness, wide adaptability, and commendable resistance.[17] The cultivar was grown at the Wuqiao experimental station of the Agricultural University of China during the 2013−2014 growing season. The station is located in Hebei province (latitude 37°41′02″N, longitude 116°37′23″E) with an average amount of annual sunlight of 2690 h, a high temperature of 32 °C, and ∼125 mm of rainfall during the wheat growing season. Plants were grown at three biological replicates, and each plot was 50 m^2. Water stress treatment was conducted as follows. In the control group as local field cultivation management, wheat was watered approximately 750 m^3/ha at sowing, jointing, and flowering stages, while in the stress group, no watering was used after sowing. The soil water content ranged from 13.3 to 9.18% in water deficit conditions and from 18.1 to 13.3% in control conditions at the jointing stage, flowering stage, and mature stage. This soil water content was approximately 20−30% lower in stressed than in control groups. The treatment belonged to medium-to-severe drought stress according to Guttieri.[18] Wheat spikes were immediately marked once they had flowered and collected 15, 21, 26, 30, and 45 days after flowering (DAF). The middle four to six grains of each ear were used as experimental materials. Husks were first removed from seeds, and then the embryo and aleurone layer were separated from the remainder of the seed at low temperatures.[13] Embryo and endosperm samples were stored at −80 °C prior to being used.

Measurement of Physiological Indicators, Agronomic Traits, and Quality Parameters. Flag leaves of five stages (12, 15, 18, 21, and 26 DAF) were sampled. Five biology replications of each period were measured. Physiological indicator testing consisted of the contents of leaf relative water (RWC), malondialdehyde (MDA), soluble sugar, free proline, and chlorophyll. The measurement of RWC was followed by the method of Smart.[19] MDA and soluble sugar contents were based on the procedure of Zhao et al.[20] The free proline content was referenced to the work of Bates et al.[21] The chlorophyll content was according to Arnon[22] with minor modifications.

After the grain matured, the main agronomic traits were measured and the plant samples were collected. The grain yield was measured according to three plot replications, and theoretical and practical yields were obtained. Different grain quality parameters were tested, including the total protein content (14% moisture basis), falling number, gluten content, Farinograph, Extensograph, Mixograph, loaf volume, appearance score, and C-cell properties. The flour protein content was determined according to American Association of Cereal Chemists Approved Methods (AACC) 39-10A with a near-infrared (NIR) analyzer (Instalab610, Dickey-john Co. Ltd.). Falling numbers (Perten) were determined with method AACC 56-81B. The Mixograph index (National Manufacturing), including water absorption rate, peak time, and time × width, was determined according to method AACC 54-40A. The gluten content was measured according to the method of Czuchajowska.[23] Farinograph and Extensograph (Brabender) were followed by methods AACC 54-21 and 54-10, and breadmaking was followed with method AACC 10-10B. The internal structure of bread was tested and evaluated by the means of C-CELL (UK CCFRA Co.). Data analysis was performed using an independent Student's *t* test with SPSS statistical software (version 17.0).

Protein Extraction and Nonlinear Two-Dimensional Electrophoresis (2-DE). Protein was extracted from the embryo and endosperm according to the process of Guo et al.[24] with minor modifications. A total of 500 mg samples were quickly ground into a fine power in liquid nitrogen. Protein extractions were dissolved with lysis buffer (7 M urea, 2 M thiourea, and 4% CHAPS) for ∼5 h. Protein concentrations were evaluated with a 2-D Quant Kit (Amersham Bioscience) using bovine serum albumin (BSA, 2 mg/mL) as the standard.

Nonlinear 2-DE isolation was performed according to the steps of Jiang et al., which can significantly improve the resolution of protein separation compared to that with traditional linear 2-DE.[8] In total, 500 μg protein samples were mixed with 1 mg of DTT, 0.5% IPG buffer (GE Healthcare/Amersham Biosciences), 1 μL of a 1% bromophenol blue solution, and moderate rehydration buffer [7 M urea, 2 M thiourea, and 2% (w/v) CHAPS], and 350 μL of a mixed solution was loaded onto an ImmobilineDryStrip (pH 3−10, 18 cm, nonlinear strip, GE Healthcare) for isoelectric focusing (IEF). After IEF, the strips were treated with equilibration buffer for the second sodium dodecyl sulfate−polyacrylamide gel electrophoresis. At least two technical replicates for each sample were performed to obtain statistically reliable results. Protein spot images were visualized by Coomassie Brilliant Blue staining (R-250/G-250 = 4:1; Sigma) and scanned at 600 dpi with a UMAX Power Look 2100XL scanner (Maxium Tech Inc., Taiwan, China). Image analysis was conducted with ImageMaster 2D Platinum Software version 7.0 (Amersham Bioscience). The abundance of protein spots from biological and technical replicates was estimated by percentage volumes (vol %). Data analysis was conducted using an independent Student's *t* test with SPSS statistical software (version 17.0). Only those with significant and reproducible changes (at least 2-fold increase and/or decrease and p value of <0.05) were considered as differentially expressed protein (DEP) spots.

MALDI-TOF/TOF-MS. DEP spots were manually excised from the gels, digested with trypsin, and identified by matrix-assisted laser desorption ionization time-of-flight/time-of-flight mass spectrometry (MALDI-TOF/TOF-MS). After being bleached, exposed to enzymes, and dried, the peptides were analyzed by using an ABI 4800 Proteomic Analyzer MALDI-TOF/TOF-MS instrument (Applied Biosystems/MDS Sciex). The parameters were set as follows: laser intensity of 4500 and mass range of 900−3500 Da. The MS/MS spectra was searched against Viridiplantae (green plant) sequences in the nonredundant National Center for Biotechnology Information (NCBI) database (November 28, 2012; including 1154529 protein sequences) by using software MASCOT (version 2.1.0) with the following parameter settings: trypsin cleavage, one missed cleavage allowed, peptide mass tolerance set to ±0.3 Da, and fragment tolerance set to ±0.4 Da. Only the proteins with both Protein Score C.I. % and Total Ion Score C.I. % above 95% were identified as credible results.

Multivariate and Cluster Analysis. The multivariate method was conducted by principal component analysis (PCA) in the R language with the average relative abundance of all the identified DEP spots.[25,26] PCA is a way of identifying patterns in data and expressing the data in such a way as to emphasize their similarities and differences. In our study, identified DEP spots of control and stressed embryo and endosperm during the five development stages were analyzed by PCA. Cluster analysis of the differentially abundant protein data was performed by using cluster software (version 3.0). Euclidean distances and Ward's criteria were used for the analysis. Cluster results were displayed by Java Tree view software.

Bioinformatics and Statistical Analysis. The possible functions of identified proteins were classified according to the information from the Uniprot database (www.uniprot.org) and Gene Ontology (GO) database (www.geneontology.org). The sequences of all identified proteins were used for BLAST analysis with the NCBI cluster of eukaryotic Orthologous Groups (KOG) database to obtain the KOG numbers of those proteins. Information about the protein−protein interaction was used with these KOG numbers with the Search Tool for Retrieval of Interacting Genes/Proteins (STRING) database (version 9.1, www.string-db.org) to construct an interaction network graph[27] with a confidence score of potential substrates of at least 0.9. The network was displayed using the cytoscape software (version 3.0).[28] When an unknown named protein was identified, a homologous protein of known function with the highest query cover (>90%) and lowest E value was a blast in the NCBI database.

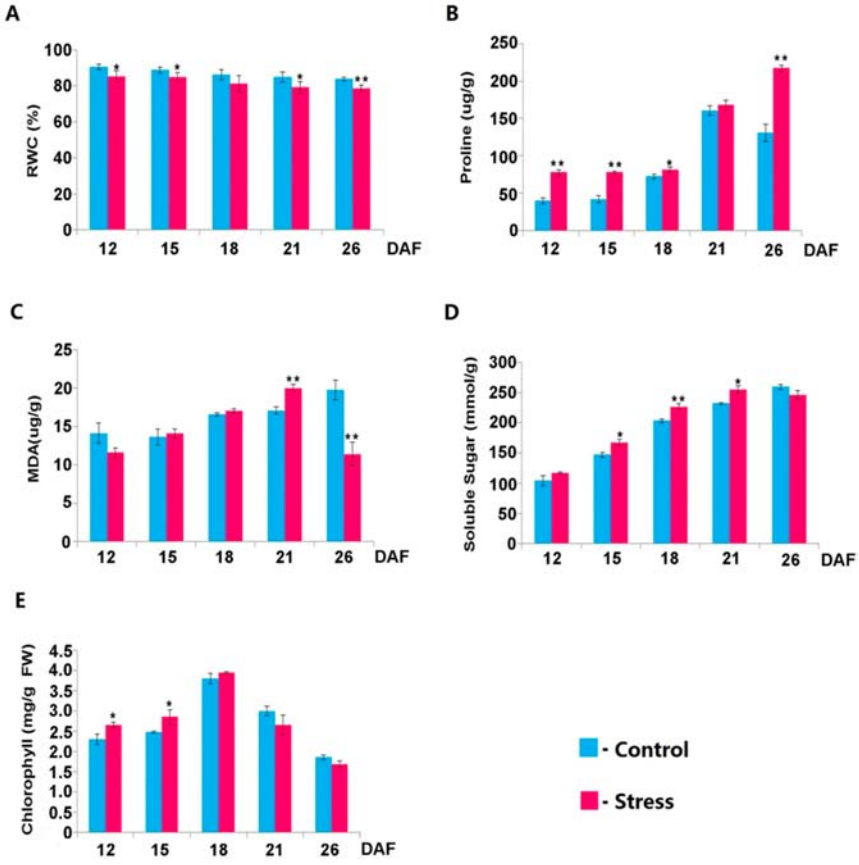

Figure 1. Physiological index changes of wheat flag leaves in the control and water stress samples during the development progress. (A) RWC, relative water content. (B) Proline content. (C) MDA, malondialdehyde content. (D) Soluble sugar content. (E) Chlorophyll content. DAF, day after flower. Control, the control samples. Stress, the water-stressed samples. Two asterisks and one asterisk denote significant differences between the stress and the control samples at 1 and 5% levels, respectively.

Subcellular localizations of identified proteins were forecasted by the UniprotKB (http://www.uniprot.org/) database, WoLF PSORT (http://wolfpsort.org/), and Predotar (http://urgi.versailles.inra.fr/predotar/predotar.html).[29,30] The most likely location of a given protein was determined by similar results from at least two programs.

RESULTS

Changes in Leaf Physiological Indexes, Agronomic Traits, and Breadmaking Quality Properties in Response to a Water Deficit. Results for leaf physiological indexes are shown in Figure 1. RWC displayed a decreasing trend during the five development periods and a significantly lower content in water stress samples. In contrast, the contents of free proline, MDA, and soluble sugar were all significantly higher in the water stress samples. MDA, which can react with proteins and nucleic acids and inhibit protein synthesis, is the final decomposition product of lipid peroxidation and reflects the degree of cell damage, while free proline and soluble sugars help to protect the structure of proteins, adjust the osmotic balance, and protect the proteins from stress damage.[31] The chlorophyll content increased in the first three stages and then decreased during the subsequent stages and displayed significant changes under water stress. These physiological index changes might reflect the general wheat response to a water deficit during grain development.

The results for agronomic traits, yield, and quality performance showed a significant difference between control and water stress samples (Table 1 and Figure S1). Under water stress, the seeds had significant lower spikelet numbers, spike grain numbers, and grain weights and exhibited an approximate 12% reduction in yield compared to that of the control (Table S1). Water stress shortened the time of wheat grain filling, which explains the lower weight and yield under a water deficit. Grain quality analysis showed that total protein and gluten contents were higher in control samples. However, some breadmaking-related parameters of Mixograph, Extensograph, loaf volume, loaf appearance score, and C-cell testing showed significant increases under water-stressed treatment compared with the control values (Table 1).

Proteome Characterization of the Embryo and Endosperm in Response to a Water Deficit during Grain Development. Protein spots for the embryo and endosperm were detected by nonlinear 2-DE during grain development under a water deficit (Figure 2A,B). In total, 876 ± 8 and 752 ± 5 spots on all gels of the embryo and endosperm, respectively, were detected. Of these, 155 DEP spots in the embryo that corresponded to 112 unique proteins and 130 DEP spots in the endosperm that corresponded to 96 unique proteins were successfully identified by MALDI-TOF/TOF-MS (Figures 2A,B and 3 and Tables S2 and S3). Among these DEP spots, 60 representing 47 unique DEPs were found in both embryo and endosperm samples, while 95 representing 76 unique DEPs and 70 representing 60 unique DEPs were identified in the embryo and endosperm, respectively (Figure 3). Detailed peptide information for all of the identified proteins is shown in Table S4. To obtain more information about the unknown/

endosperm 15 days after flowering; ENC21, control endosperm 21 days after flowering; ENC26, control endosperm 26 days after flowering; ENC30, control endosperm 30 days after flowering; ENC45, control endosperm 45 days after flowering; ENS15, stressed endosperm 15 days after flowering; ENS21, stressed endosperm 21 days after flowering; ENS26, stressed endosperm 26 days after flowering; ENS30, stressed endosperm 30 days after flowering; ENS45, stressed endosperm 45 days after flowering. The protein spot was numbered by the order of the first letter of the protein names. The same differential protein spot in the embryo and endosperm has the same number, whereas different protein spots had different numbers.

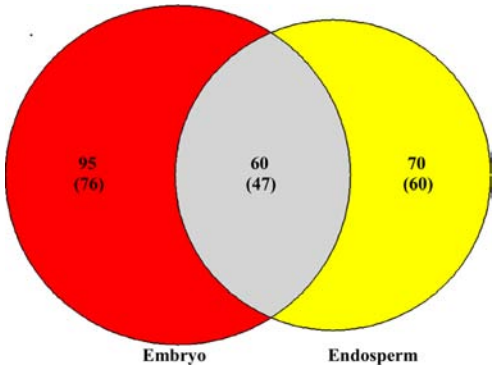

Figure 3. Numbers of identified DEP spots in the embryo and endosperm. Numbers in parentheses are the corresponding numbers of unique proteins.

predicted proteins, their sequences were used to search for homologues by BLASTP. Predicted proteins with a level of sequence similarity of >90% were considered homologues.[14] BLASTP revealed homologues for 20 spots (Table S5).

PCA showed major differences between the two organs during the grain development stages under drought stress. DEP spots of different stages in the endosperm were located in the same plot and were in a different plot of those in the embryo (Figure 4A,B). These results indicate that the difference between organs was dominant over differences during grain development under water stress. Samples from five different development stages were grouped into different plots in these two organs, but differences between control and water deficit samples were modest (Figure 4C,D). Our moderate treatment might explain this phenomenon. Cluster results showed differential protein expression trends in the embryo and endosperm during grain development under a water deficit (Figure S1). Protein expression profiles 15−21 DAF and 30−45 DAF generally showed similar patterns of accumulation in control embryo and protein expression profiles 26 DAF close to those 30−45 DAF (Figure S1A), whereas under a water deficit, protein accumulation 21 DAF was similar to that 26 DAF and different from that 15 DAF (Figure S1B), which might indicate proteins in embryo in response to water deficit mainly from 21 DAF. By comparison of panels C and D of Figure S1, proteins in the endosperm responded to a water deficit mainly from 26 DAF.

According to the protein function, these DEPs could be classified into nine categories in embryo development: stress/defense response, energy metabolism, storage proteins, nitrogen metabolism, protein metabolism/folding, starch metabolism, transport, lipid metabolism, and other important functions (Table S2). The DEP spots identified in endosperm development under a water deficit showed similarly functional classifications (Table S3), except for the absence of lipid metabolism-related proteins. Prediction of protein−protein interactions is shown in Figure 5. Proteins identified in both embryo and endosperm samples were located in the middle. Proteins identified specifically in the embryo and endosperm were located to the left and right, respectively. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH, KOG0657), 70 kDa heat shock-related protein (HSP70, KOG0101), and ubiquitin (KOG0001) had the most connections with other proteins and were located in the center, suggesting their important roles in embryo and/or endosperm development in response to a water deficit. Proteins with different functions were closely connected with each other and formed a large network to play central roles in response to a water deficit. Subcellular localizations of the identified proteins were predicted. They were mainly located in the cytoplasm, mitochondria, vacuole, and nucleus (Tables S2 and S3).

Comparative Proteome Analysis of the Embryo and Endosperm in Grain Development under a Water Deficit. The embryo was identified to have more stress/defense response-related DEP spots and fewer starch metabolism and storage-related proteins than endosperm in this study. Approximately 40 and 34 DEP spots involved in stress/defense response were identified in the embryo and endosperm, respectively (Tables S2 and S3), whereas 10 and 19 DEP spots taking part in starch metabolism were identified, respectively. Aldose reductase-related protein (spot 30), cold-regulated protein (spot 54), peroxidase 1 (spot 151), and stromal 70 kDa heat shock-related protein (spot 164) involved in stress/defense response were identified in only the embryo, while β-amylase (spot 45) with important roles in starch metabolism, storage proteins such as putative avenin-like α precursor (spot 169), and HMW gultenin subunit Dy 12 (spot 115) were identified in only the endosperm (Table 2).

DISCUSSION

Stress/Defense-Related Proteins. Cells suffer harmful damage during grain development because of various biotic and abiotic stresses, especially under a water deficit. Large amounts of ROS accumulate in cells under stress, leading to lipid peroxidation, protein (enzyme) instability, and a loss of osmotic balance.[4] Defense signals are activated in cells in response to stress. Many proteins largely accumulated in cells under stress, such as peroxidase, HSP, and LEA. 1-Cys peroxiredoxin PER1 (spot 3) is involved in ROS scavenging and has been reported to be a dormancy-related protein expressed in the embryo and aleurone layer of barley.[32] This enzyme may help maintain dormancy and prevent germination under unfavorable conditions.[33] It displayed a higher level of expression from 21 DAF in both the embryo and the endosperm under a water deficit and reached a 4.56-fold accumulation level in the embryo 26 DAF compared with 15 DAF, much more than that increased in the endosperm (Tables S2 and S3). The higher level of accumulation improved the ability to survive a harsh environment during grain development. Four peroxidase proteins (spots 150−153) that also take part in ROS scavenging were specifically up-accumulated in the embryo during grain development in response to defense stress (Table 2 and Table S2).[34] Stromal 70 kDa heat shock-related protein (HSP 70), a chaperone, binds extended peptide segments of polypeptides with a net hydrophobic character

Red color indicates a relatively higher level of accumulation.

during translation and membrane translocation and may interact with newly imported proteins to assist in their maturation by protein folding and reassembly.[35] A related study has reported the overexpression of HSP genes in wheat in response to environmental stress.[36] Three HSP DEP spots (spots 164, 191, and 211) were specifically identified in the embryo (Table S2). Spots 191 and 211 (corresponding to KOG 0101) and spot 164 (corresponding to KOG0102) were predicted to interact with many other proteins and played a key role in embryo development[14] (Figure 5). Two other proteins were obtained, 16.8 kDa heat shock protein (spot 133) and predicted 17.9 kDa class I heat shock protein-like (spot 216), the homologous protein of hypothetical protein TRIUR3_03549 and an unnamed protein product, respectively (Table S5). The abundance of small Hsps in plants played a part in binding and stabilizing non-native proteins and might play a role in plant-acquired tolerance to drought and salt.[37] These phenomena enhanced the embryo's ability to tolerate drought and might show the main function in stress/defense response in the embryo under a water deficit. α-Amylase inhibitors (spots 1, 32, 33, 52, 66, 67, 118, 147, and 181) inhibit the degradation of starch and increase the level of accumulation of starch in cells, which are related to the adjustment of the osmotic balance and protecting the cells from damage by insects.[38] It has been reported that the wheat endosperm proteome contained abundant levels (~11% of total proteins) of α-amylase inhibitors and α-amylase/trypsin inhibitors to protect the starch reserves from degradation.[39] Their expressions were upregulated in drought tolerance genotypes but were downregulated in sensitive genotypes.[16] Consistent with our results, nine related DEP spots were identified in the endosperm; seven of them showed higher levels of expression under a water deficit (Table S3). In particular, spot 147 had reached 5.15-, 8.15-, and 7.77-fold levels of accumulation 21, 26, and 45 DAF (compared with 15 DAF), respectively. These results reveal the main function of adjusting starch accumulation in the endosperm under drought.

Energy Metabolism-Related Proteins. Proteins participating in ATP synthesis, glycolysis, and the tricarboxylic acid (TCA) cycle provide plenty of energy and molecular materials for grain development under a water deficit. In this study, many DEPs related to energy metabolism were identified under

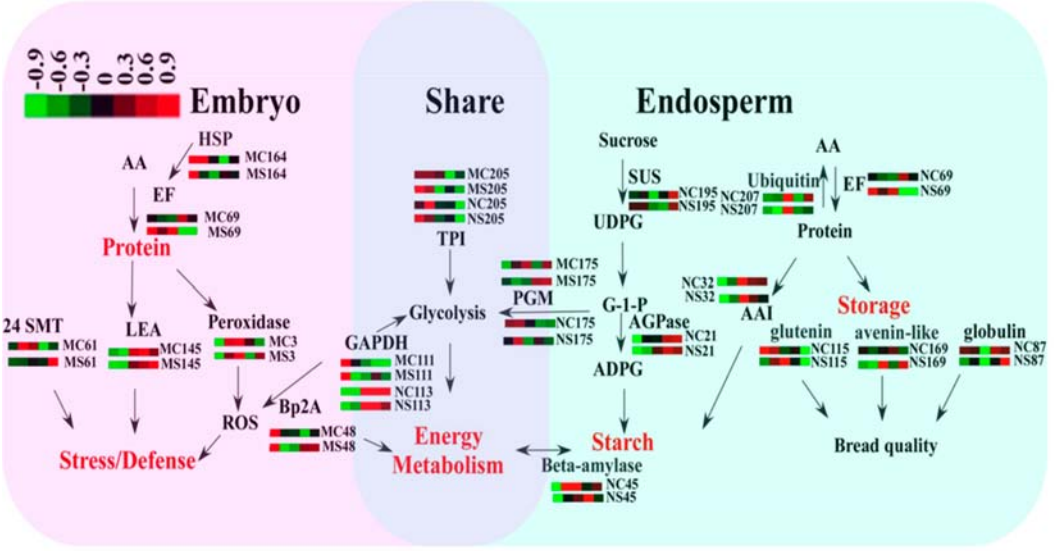

Figure 6. Overview of possible metabolic pathways of embryo and endosperm development in response to a water deficit. Abbreviations: AA, amino acid; AAI, α-amylase inhibitor; ADPG, ADP-glucose; AGPase, ADP-glucose pyrophosphorylase large subunit; Bp2A, Bp2A protein; DHAR, dehydroascorbate reductase; EF, elongation factor; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; G-1-P, glucose 1-phosphate; HSP, heat shock-related protein; LEA, late embryogenesis abundant protein Lea14-A; MC, control embryo; MS, stressed embryo; NC, control endosperm; NS, stressed endosperm; PGM, phosphoglucomutase; ROS, reactive oxygen species; 24SMT, Δ-24-sterol methyltransferase; SUS, sucrose synthase, UDPG, uridinediphosphate glucose.

drought. GAPDH (spots 57 and 110−114), a key enzyme of glycolysis, catalyzes the conversion of D-glyceraldehyde 3-phosphate (G3P) to 3-phospho-D-glyceroyl phosphate. In the study presented here, this enzyme showed a higher level of accumulation in early embryo and late endosperm development and was upregulated 30 DAF in embryo under a water deficit [spot 111 (Table 2)]. This favored embryo cells regulating a stress defense mechanism. Protein−protein interaction analysis showed that many other proteins related to energy metabolism and stress/defense responses were closely connected with GAPDH (Figure 5) and indicated its central role in metabolism. Other energy metabolism-related proteins such as ATP synthase-related proteins, dihydrolipoyl dehydrogenase 1, Bp2A protein, triosephosphate isomerase, etc., were identified in response to a water deficit in the embryo and/or endosperm during grain development. All of these proteins closely interacted with each other and provided enough carbohydrates and energy for embryo and endosperm development under a water deficit.

Starch Metabolism-Related Proteins. The embryo has been reported to be a powerful sink for nutrients and also acquires a moderate level of starch for germination, but many starches were degraded into carbohydrates to improve the desiccation tolerance during development.[40,41] Storage starch mainly accumulates in the endosperm (approximately 70−80% dry weight) and largely determines wheat yield during development. Seven and 10 related proteins were identified in the embryo and endosperm in this study, respectively, and most of them displayed a lower level of accumulation under drought compared with the control, leading to a reduction in yield (Table S1). Sucrose synthase (SUS, spots 192−197) catalyzes the first step in the conversion of sucrose to starch, which provides UDP-glucose and fructose for various metabolic pathways. ADP-glucose pyrophosphorylase large subunit (AGPase, spot 21) is a major rate-limiting enzyme in grain starch biosynthesis. It initiates starch biosynthesis in plants and catalyzes the formation of ADP-glucose from Glc-1-P and ATP. SUS and AGPase are considered to be crucial for development, carbon partitioning, and synthesis of storage starch during grain development and are active when starch accumulates in storage tissues.[42,43] In the study presented here, these two proteins mainly displayed down-accumulation in late embryo and endosperm development under a water deficit. Fructokinase-1-like, a homologue of the hypothetical protein F775_30384 (spot 130), which may help to maintain the flux of carbon toward starch formation,[44] showed a similar decreasing level of expression under drought. β-Amylase (spot 45), which hydrolyzes (1→4)-α-D-glucosidic linkages in polysaccharides and removes successive maltose units from the nonreducing ends of the chains, was specifically identified in the endosperm and downregulated during late development under water stress (Table 2), so the endosperm expressed α-amylase inhibitors to ease the reduced starch under a water deficit.

Storage Proteins. Wheat storage proteins mainly present in the endosperm, especially glutenins and gliadins, have important effects on nutritional quality for humans and livestock and on functional properties in food processing.[45] Under a water deficit, many of them displayed a similar expression pattern and had fewer changes than the control (Table S3). Some globulins displayed downregulation during grain development, which is similar to the previous results of Laino.[15] However, some storage proteins showed a higher level of expression under a water deficit than the control, such as HMW glutenin subunit Dy12 (spot 115), putative avenin-like α precursor (spot 169) (Table 2), and the hypothetical protein F775_27291 (spot 124), a homologue of avenin-3 (Table S5). One gliadin protein spot (spot 84) and four protein spots, globulin-1 S allele (spots 87−90), also displayed >3-fold upregulation during grain development under a water deficit (Table S3). Glutenins and gliadins are two prolamine groups of gluten constituents, contain many cysteine residues that are involved in intramolecular and intermolecular linkages, and

DOI: 10.1021/acs.jafc.5b00575
J. Agric. Food Chem. 2015, 63, 8478−8487

contribute to the viscoelastic properties of gluten that determine dough strength.[46] Avenin-like proteins are also rich in cysteine and may contribute to wheat dough viscoelastic properties via interchain disulfide bonds.[47] Globulins are cross-linked by both disulfide and non-disulfide cross-links, which affects dough and crumb properties.[48] As we all know, there is a great relationship between dough strength and breadmaking quality. Therefore, it is suggested that these proteins have positive significance for the improvement of breadmaking quality. As shown in Table 1, although the amount of gluten decreased, bread quality improved under a water deficit.

Overview of Central Metabolic Changes during Wheat Embryo and Endosperm Development in Response to a Water Deficit. Here, we propose a putative proteomic metabolic pathway during wheat embryo and endosperm development in response to a water deficit, which provides an overview of the main DEP differences between the embryo and endosperm (Figure 6). The embryo mainly synthesized proteins related to stress/defense responses during grain development, such as peroxidase and HSP, while storage starch and storage proteins mainly accumulated in the endosperm. Many energy metabolism-related enzymes were both identified in these two organs. Under a water deficit, most proteins related to energy metabolism and stress/defense responses were upregulated in the embryo. Proteins related to starch were downregulated in the endosperm, which might explain the lower grain weights and reduced yields, but some storage proteins, such as HMW glutenin, globulins, and avenin-like proteins, showed upregulated expression under a water deficit, which might benefit breadmaking quality.

J. Agric. Food Chem. 2015, 63, 8478−8487

phosphate, disodium hydrogen phosphate, and anhydrous sodium sulfate were purchased from Grüssing (Filsum, Germany). MGO (40%, w/w), DHA, *ortho*-phenylenediamine (*o*PD), and 2,4,6-trimethylpyridine (TMP) were obtained from Sigma-Aldrich (Steinheim, Germany). 5-Hydroxymethylfurfural (HMF) was provided by Alfa Aesar (Karlsruhe, Germany). D(−)-Fructose, D(+)-glucose, D(+)-saccharose, and acetic acid were purchased from Carl Roth (Karlsruhe, Germany). Sodium hydroxide pellets were purchased from Fisher Scientific (Schwerte, Germany). For all experiments, ultrapure water was used, prepared by an ELGA LabWater PURELAB Plus water system (Celle, Germany).

Reversed-Phase High-Performance Liquid Chromatography with Ultraviolet Detection (RP-HPLC−UV) Analysis of MGO and DHA after Derivatization to Quinoxalines. The determination of MGO and DHA was performed according to the literature,[11] with some modifications. Briefly, for quantitation of MGO, 1 mL aliquots of 10% (w/v) honey solutions in 0.5 M phosphate buffer (pH 6.5) were mixed with 300 μL of phosphate buffer (pH 6.5) and 300 μL of *o*PD solution (1% in phosphate buffer at pH 6.5). Samples were incubated in the dark at room temperature overnight and membrane-filtered (0.45 μm). For quantitation of DHA, 1 mL aliquots of 10% honey solutions in 0.5 M acetate buffer (pH 4.0) were mixed with 300 μL of acetate buffer (pH 4.0) and 300 μL of *o*PD solution (1% in acetate buffer at pH 4.0), followed by incubation for 16 h at 37 °C and membrane filtration (0.45 μm).

HPLC analyses were performed using an Äkta basic system from Amersham Pharmacia Biotech (Uppsala, Sweden) with a pump P-900 and an online degasser K-5004 (Knauer, Berlin, Germany) as well as an UV detector UV-900 and an auto sampler A-900. Peak evaluation was managed using the software UNICORN 4.11. The separation of quinoxalines was realized on a stainless-steel column filled with Eurospher 100 RP18 material (250 × 4.6 mm, 5 μm particle size, with integrated pre-column, Knauer, Berlin, Germany). The mobile phase were 0.075% acetic acid in water (solvent A) and a mixture of 80% methanol and 20% solvent A (solvent B). The gradient started with 40% solvent B for 1 min, was elevated linearly to 100% B over a period of 20 min, was changed back to 40% B in 4 min, and was held there for 7 min. The flow rate was 0.9 mL/min; the separation was performed at 30 °C; 20 μL sample solution was injected; and peaks were detected by measurement of UV absorbance at 312 nm. Quantitation was achieved by external calibration with MGO standard solution or the standard addition method for DHA.

RP-HPLC−UV Analysis of HMF. The determination of HMF was performed according to the literature,[15] with some modifications. Briefly, 1 mL aliquots of 10% honey solutions in ultrapure water were membrane-filtered (0.45 μm) and subsequently analyzed via HPLC−UV.

The HPLC system and column was used as mentioned above. The mobile phase consisted of 0.05 M phosphate buffer at pH 5.5 (solvent A) and HPLC-grade methanol (solvent B). The elution was carried out isocratically with 15% solvent B over 30 min. The flow rate was 1.0 mL/min at ambient temperature; 50 μL sample solution was injected; and peaks were detected by measurement of UV absorbance at 283 nm. Quantitation was achieved by external calibration with freshly prepared HMF standard solution.

Analysis of Proline in Honey. A total of 1 g of honey was dissolved in 10 mL of phosphate buffer (0.1 M, pH 2) and subjected to a column (25 × 110 mm) filled with ion-exchange resin Dowex 50WX8, 100−200 mesh. The ion-exchange resin was previously activated with 50 mL of HCl (2 mol/L). The amino acids were eluted with 100 mL of a solution of ammoniac (7 mol/L). The eluate was evaporated to dryness, and the dry residue was dissolved in ultrapure water. After lyophilization, the sample was dissolved in 1 mL of lithium citrate buffer (0.12 M, pH 2.2), diluted (1:10), and subjected to amino acid analysis. The analyses were performed using a SYKAM S4300 amino acid analyzer (Fuerstenfeldbruck, Germany) with conditions according to the instructions of the manufacturer. The ninhydrin derivate of proline was detected at 440 nm.

Gas Chromatography−Mass Spectrometry (GC−MS) Analysis of 2-AP. A total of 10 g of honey was dissolved in 10 mL of ultrapure water. A total of 50 μL of TMP solution (195 mg/L) was added, and the pH was adjusted to 8 with 1 M sodium hydroxide solution. The alkaline honey solution was mixed with 5 mL of dichloromethane, agitated vigorously for 60 s, and centrifuged afterward. The organic layer was collected, and extraction with dichloromethane was repeated once. The collected organic layer was washed with 5 mL of water and dried with anhydrous sodium sulfate. An aliquot of 1 mL was transferred to a GC vial and subjected to GC−MS analysis. Matrix calibration was achieved by adding known amounts of 2-AP to an artificial honey, which was then extracted as described above. The artificial honey was prepared following ref 16. Briefly, 46.5 g of fructose, 35 g of glucose, 1.5 g of saccharose, and 17 g of water were mixed and stirred until a fine crystalline suspension was formed. The artificial honey/2-AP mixture was diluted with pure artificial honey, and 10 g of each mixture was analyzed according to the extraction procedure above. The actual 2-AP concentration of the commercial standard was determined by RP-HPLC with a chemiluminescent nitrogen detector (CLND) according to ref 17.

GC−MS analysis of 2-AP was performed using an Agilent 7890A system, consisting of a 7683 Series injector with a sample tray and a 5975C MS detector working in electron ionization (EI) mode, all from Agilent (Boblingen, Germany). The GC system was equipped with a TR-FFAP capillary column (30.0 m × 0.25 mm inner diameter, with a 0.25 μm film thickness) from Thermo Scientific (Runcorn, U.K.). Helium was used as the carrier gas with a constant flow of 1 mL/min. The injector temperature was set to 250 °C, and a 1 μL sample was injected using the pulsed splitless mode. The auxiliary temperature was set to 235 °C, and the ion source and quadrupole temperatures were set to 230 and 150 °C, respectively. The initial oven temperature was set to 40 °C and held for 2 min, then raised at 2.25 °C/min to 80 °C, finally raised at 30 °C/min to 235 °C, and held for 5 min. The mass spectrometer was working in EI mode at 70 eV in the scan (mass range of m/z 40.0−300.0) and selected ion monitoring (SIM) mode. For quantitation, the SIM mode was used with the monitoring of the following ions: m/z 111 and 83 (2-AP) and m/z 121 and 79 (TMP). The ions underlined were used for quantitation. The retention time of the analytes was 15.0 min for 2-AP and 17.9 min for TMP, respectively. Data acquisition and evaluation were performed with MSD ChemStation software (Agilent, Germany).

Model Studies on 2-AP Formation in Honey. Commercial non-manuka multifloral honey from Germany was mixed with MGO alone (100 mg/kg, labeled as "low", or 500 mg/kg, labeled as "high", respectively) or MGO and DHA in a 1:2 ratio (100 and 200 mg/kg, labeled as "low", or 500 and 1000 mg/kg, labeled as "high", respectively). The samples were stirred vigorously and stored in the dark at room temperature and 37 °C. The storage temperature of 37 °C was chosen to simulate accelerated ripening and to study chemical reactions that occur during longer storage. Samples were taken after 0, 2, 4, 8, and 12 weeks of storage. A control (multifloral honey without added MGO) was stored under the same conditions, and samples were taken after 0, 4, and 12 weeks of storage. The samples were analyzed according to the extraction procedure mentioned above.

Statistics. Results are expressed as mean values of two separate measurements, except otherwise indicated. Hypothesis testing was performed via a two sample t test with a significance level of 0.01. Intraday variation of 2-AP analysis was investigated using five replicate injections of a 2-AP standard solution. Interday precision was determined using four calibration standards, which were analyzed during 8 months.

RESULTS AND DISCUSSION

The aim of this study was to investigate whether 2-AP, a specific flavor compound formed from MGO and proline, is present in manuka honeys from New Zealand. Identification and quantitation of 2-AP in manuka honey was achieved using GC−MS based on a method recently described in the literature for 2-AP analysis.[18] For sample preparation, a crucial step for reliable quantitation of 2-AP, solid-phase microextraction (SPME), or solvent extraction methods are reported.[7,9,18]

J. Agric. Food Chem. 2015, 63, 8488−8492

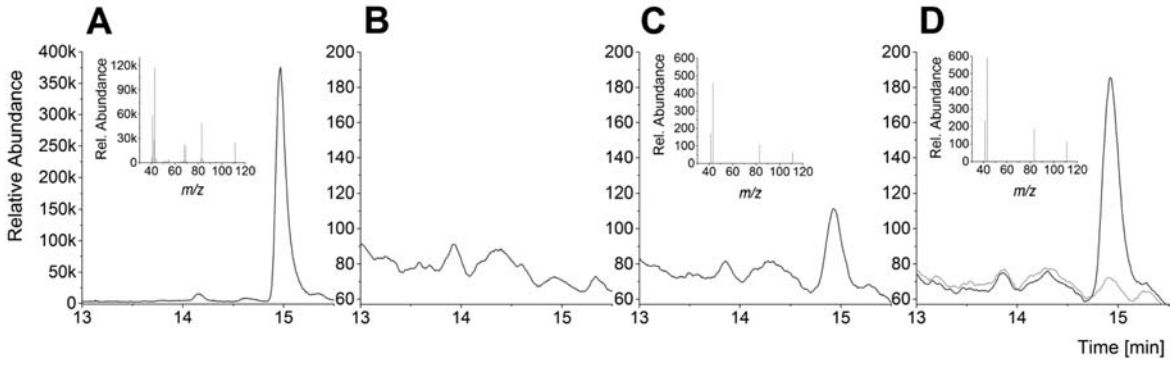

Figure 1. GC−MS data for identification and quantitation of 2-AP: (A) synthetic standard solution, (B) lime honey; (C) manuka honey, and (D) artificial honey spiked with proline and MGO (black line) and DHA (gray line) incubated for 20 weeks at 37 °C.

Because 2-AP formation in manuka honey is probably enhanced by a high temperature, an extraction procedure using dichloromethane without heating was chosen. Furthermore, concentration steps like drying with nitrogen were avoided to prevent a loss of 2-AP during sample preparation. TMP was used as an internal standard to check the recovery during the extraction procedure. Comparing peak areas for 2-AP standard samples extracted from aqueous solutions or from honey matrix calibration resulted in an estimated 60% recovery of 2-AP. Therefore, quantitation was carried out via external matrix calibration, using a synthetic 2-AP standard and artificial honey. The actual 2-AP concentration of the commercial standard was checked with RP-HPLC and chemiluminescent nitrogen detection (CLND) to be 83.3% of the specification given by the supplier. A regression coefficient R^2 of 0.998 was calculated for the linear calibration range from 0.1 to 2.0 mg/kg. The limit of detection (LOD) was 0.04 mg/kg, and the limit of quantitation (LOQ) was 0.09 mg/kg. LOD and LOQ were calculated on the basis of the signal-to-noise-ratio. Inter- and intraday precisions were 3.1 and 6.1%, respectively. 2-AP was unequivocally identified in commercial samples of manuka honey by comparing retention time and corresponding mass spectra of honey samples and standard solutions (panels A and C of Figure 1). The comparison of the fragmentation pattern and the characteristic ratio of the quantifier ion to the qualifier ion (m/z 83 and 111, respectively) of the 2-AP standard and the 2-AP peak in honey yields identical relative intensity ratios. The hypothesis that 2-AP in manuka honey results from the reaction of MGO and proline was confirmed by significantly smaller signals of 2-AP in non-manuka honeys without MGO (Figure 1B) and the detection of 2-AP in an artificial honey containing MGO and proline after 20 weeks of incubation (Figure 1D).

For 11 commercially available manuka honeys, amounts of 2-AP ranging from 0.08 to 0.45 mg/kg were measured (Figure 2). In contrast to this, the majority of non-manuka honeys analyzed in this study contained 2-AP only in very small amounts between 0.08 and 0.11 mg/kg. However, some aromatic non-manuka honeys, namely, buckwheat, lime, and thyme honey, contained 2-AP in concentrations ranging between 0.20 and 0.31 mg/kg. According to the literature, 2-AP has been found in different sorts of food as an aroma active compound. The concentrations vary between 78 μg/kg for white-bread crust and 0.8 mg/kg for cooked rice.[8,9] Concerning honey, 2-AP has already been detected in lime honey from the linden tree.[19] The authors pointed out that 2-AP is an

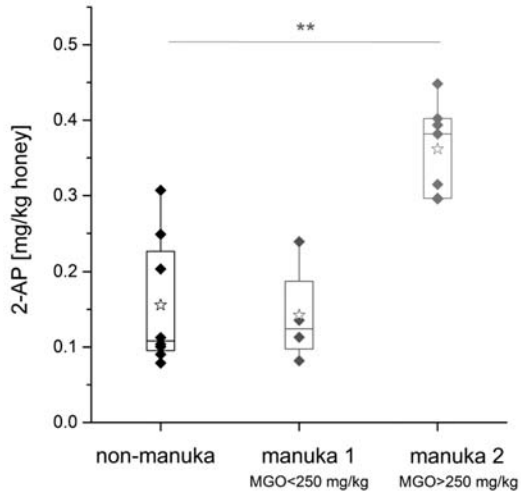

Figure 2. 2-AP concentration of commercial samples of non-manuka honey (n = 8) and manuka honey with MGO below 250 mg/kg (manuka 1) (n = 4) and above 250 mg/kg (manuka 2) (n = 7). Stars indicate the average value for each group.

important odorant of linden honey but did not report on quantitative amounts of 2-AP. Interestingly, no 2-AP was detected in the blossoms of the linden tree, what supports the hypothesis that 2-AP originates from reactions in the honey matrix. The 2-AP concentration of manuka honey with a MGO concentration below 250 mg/kg is comparable to the non-manuka honeys. However, the concentration of 2-AP in manuka honeys with a MGO concentration above 250 mg/kg was significantly increased in comparison to the non-manuka group (Figure 2). The average amount of 2-AP in manuka honeys with MGO contents above 250 mg/kg was 0.36 mg/kg, and the average amount of 2-AP in non-manuka honeys was 0.16 mg/kg. For this samples, the 2-AP content of the analyzed manuka honeys increased with increasing MGO concentrations up to a MGO value of approximately 500 mg/kg honey (see Figure S1). For concentrations of 600−1000 mg of MGO/kg of honey, no further increase of 2-AP was found. Proline is the most abundant amino acid in honey, accounting for 260−890 mg/kg, which represents 70% of the total free amino acids.[14] The analysis of the proline concentration of the studied honeys showed no significant difference between the non-manuka and manuka honeys with varying MGO contents. The proline concentration ranged between 200 and 540 mg/kg and did not correlate with the MGO content (for data on MGO and

DOI: 10.1021/acs.jafc.5b03042
J. Agric. Food Chem. 2015, 63, 8488−8492

proline, see Table S1). In fact, MGO appears to be the crucial factor for 2-AP formation. The observation that MGO contents between 600 and 1000 mg/kg do not lead to a further increase of 2-AP in manuka honeys could be explained by competitive reactions. MGO can react with other honey substances or with another MGO molecule to form adducts or aroma-active compounds, such as furaneol, respectively. To assess whether storage of non-manuka honey containing artificially added MGO or DHA results in the formation of 2-AP, a commercial multifloral honey was spiked with MGO or a 1:2 mixture of MGO and DHA, respectively, and stored at room temperature and 37 °C for 12 weeks. Figure 3A shows the 2-AP concentration depending upon the incubation time. When high amounts of MGO (500 mg/kg) were added to the honey, 2-AP significantly increased after 4 weeks of storage at 37 °C. After 12 weeks, the 2-AP concentration reached the amount that was quantitated in the commercial manuka honey samples

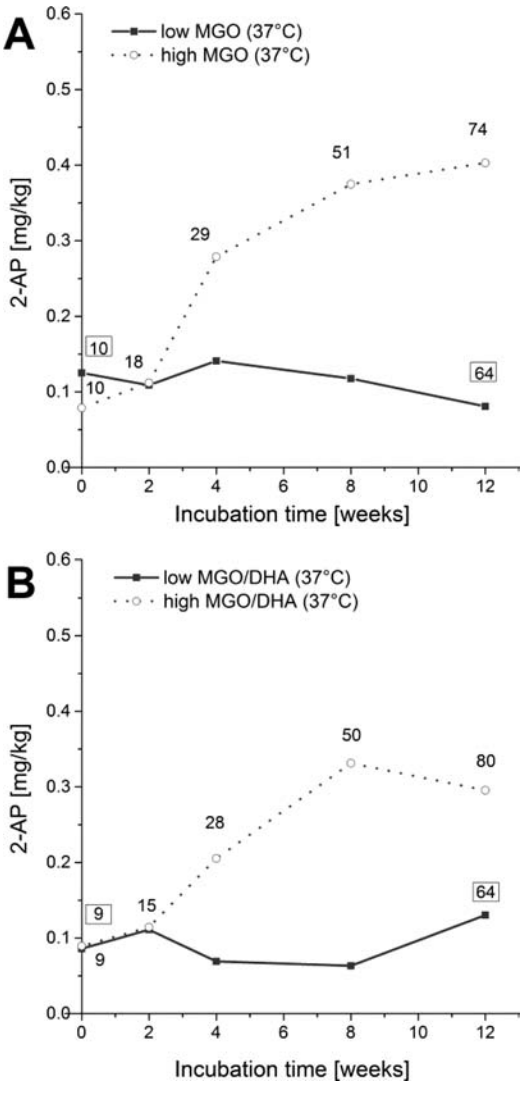

Figure 3. 2-AP formation in a non-manuka multifloral honey with (A) added MGO and (B) added MGO and DHA, stored at 37 °C (n = 2 for each time point and sample). Values above symbols are HMF concentrations (mg/kg) at the given time points (values without boxes belong to samples with a high addition of MGO or MGO/DHA, and values in boxes belong to samples with a low addition of MGO or MGO/DHA).

with high MGO contents, followed by no further increase. No increase of 2-AP was found during storage of non-manuka honey with artificially added MGO at ambient temperature and non-manuka honey without MGO (ambient temperature and 37 °C; data not shown). There was also no increase in 2-AP when low MGO concentrations (100 mg/kg) were added to non-manuka honey and stored at an elevated temperature for 12 weeks (see Figure 3). This is in accordance with the 2-AP amounts of commercial manuka honeys containing MGO below 250 mg/kg. The average 2-AP content of these samples was 0.14 mg/kg. The non-manuka honey with artificially added MGO (low MGO) had approximately the same amount of 2-AP, which did not increase after storage. This indicates that a "threshold level" of MGO of approximately 250 mg/kg is necessary to initiate a reaction of proline and MGO and significantly increase the 2-AP content in manuka honey. Competitive reactions as a possible reason for the disproportionate conversion of MGO and proline to 2-AP were discussed above. The 2-AP concentration in non-manuka honey was not influenced by the addition of DHA and subsequent storage (Figure 3B). For the spiked honey samples, which were stored for 8 weeks or longer at 37 °C, a significant increase in the concentration of HMF in addition to the formation of 2-AP was observed. HMF is used as a quality parameter of honey and should not exceed 40 mg/kg.[20] All commercial manuka honeys in this study were below this threshold level. This result points to the fact that, following "artificial" spiking of a non-manuka honey with MGO, 2-AP concentrations do only increase during storage at elevated temperatures, which also leads to increasing amounts of HMF. 2-AP, therefore, might be an interesting indicator to control the storage conditions and the quality of manuka honey. High amounts of 2-AP, as a result of high MGO levels, together with an increased concentration of HMF may point to a fraudulent addition of MGO and increased temperatures for "artificially" producing high-price manuka honey products. A manuka honey with a high MGO content together with a high 2-AP concentration and a low HMF level has likely been stored at low temperatures over a longer time period. This "natural" ripening process cannot be simulated by MGO addition followed by a high temperature storage. According to the literature, the storage of manuka honey initially leads to a MGO increase as a result of continuous formation from DHA, followed by a MGO decrease, probably as a result of reactions of MGO with other honey components.[21] Further studies are needed to clarify the reaction pathways of MGO and its role in the unique chemistry of manuka honey. In addition to MGO and DHA, 2-AP as a direct reaction product of MGO and proline could be a suitable parameter to characterize the quality of manuka honey.

molecular basis. From this information, molecular models composed of fatty acids and bitter substances can be constructed to elucidate the mode of interaction.

MATERIALS AND METHODS

Chemicals. These were obtained from commercial sources. Hexanoic, octanoic, decanoic, linoleic, and linolenic fatty acids as well as sodium thiocyanate, taurine, acesulfame K, saccharin sodium dehydrate, caffeine, thiamine hydrochloride, and amygdalin were obtained from Wako Pure Chemical Industries Ltd. (Osaka, Japan); lauric acid, *N*-phenylthiocarbamide, salicin, berberine hydrochloride monohydrate, and quinine hydrochloride dihydrate were obtained from Nacalai Tesque, Inc. (Kyoto, Japan). The myristoleic, palmitoleic, oleic, and arachidonic fatty acids as well as glycerol monooleate, (±)-propranolol hydrochloride, promethazine hydrochloride, chloramphenicol, yohimbine hydrochloride, colchicine, cromolyn disodium salt, limonin, and ouabain octahydrate were obtained from Sigma-Aldrich Co. (Tokyo, Japan). Methyltryptophan and naringin were obtained from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan). Acetic acid and antipyrine were obtained from Kanto Chemical Co. Inc. (Tokyo, Japan), and glycerol monolaurate was obtained from Chem-Implex International, Inc. (Wood Dale, IL, USA).

Screening of Bitter Substances. ITC was carried out using a MicroCal iTC200 instrument (Malvern Instruments Japan Corp., Kobe, Japan). The fatty acids were neutralized and solubilized by adding an equimolar amount of sodium hydroxide. The interactions between 22 bitter substances, whose structures are shown in Figure S1-1, and sodium oleate were measured. The concentrations of the bitter substances and sodium oleate were 1.5 and 0.5 mM, respectively. The compounds were dissolved in 5 mM phosphate buffer (pH 7.0). The reference cell was filled with Milli-Q water (Millipore Corp., Billerica, MA, USA). The bitter substances in buffer solutions were titrated into sodium oleate dissolved in 5 mM phosphate buffer (pH 7.0) at a stirring rate of 1000 rpm and at 25 °C. Each titration was carried out with an initial injection volume of 0.4 μL, followed by 18 main injections of 2 μL each at 120 s intervals. The first titration (0.4 μL) was excluded from the analysis. The data corresponding to the dilution of the ligand in the buffer was subtracted from the titration data.

Measurement of Interactions between Fatty Acids and Bitter Substances. The interactions between five bitter substances, QHCl, promethazine hydrochloride (PHCl), propranolol hydrochloride (PrHCl), berberine hydrochloride (BHCl), and yohimbine hydrochloride (YHCl), and sodium salts of eight fatty acids (sodium hexanoate, sodium octanoate, sodium decanoate, sodium laurate, sodium myristoleate, sodium oleate, sodium linoleate, and sodium linolenate) and two monoacylglycerides (glycerol monolaurate and glycerol monooleate) were measured. The concentrations of the fatty acids were 0.5 mM, and those of the bitter substances are given in Table S1. The samples were dissolved in 5 mM phosphate buffer (pH 7.0). Titrations were conducted as described above.

The data were analyzed according to the "one set of sites" model provided in Origin 7.0 software for MicroCal iTC_{200}. The binding constant (K) and enthalpy change (ΔH) of binding were obtained from the fitted curve. The entropy change (ΔS) and free energy change (ΔG) of binding were obtained using the following equation:

$$\Delta G = \Delta H - T\Delta S = -RT \ln K$$

where R is the gas constant and T is the thermodynamic temperature.

Preparation of Crystals. QHCl (3 mmol, 1.08 g) was dissolved in 3 L of Milli-Q water. A solution of sodium laurate (3 mmol, 0.67 g) in Milli-Q water (50 mL) was added to the QHCl solution, and the mixture was thoroughly stirred. The mixture was allowed to stand overnight at room temperature. The precipitated crystals were filtered (No. 5A, Toyo Rishi Kaisha, Ltd., Tokyo, Japan), rinsed with water, and air-dried. Differential scanning calorimetry (DSC) measurements were carried out using a Shimazu DSC-60 (Kyoto, Japan) in the temperature range of 5−60 °C at a heating rate of 5 °C/min under a nitrogen atmosphere.

NMR Spectroscopy. All NMR experiments except for solid-state NMR were conducted on a Varian Inova 500 NMR spectrometer (500 MHz) at 25 °C (Varian Inc., Palo Alto, CA, USA). The bitter substances (32 μmol; QHCl, PHCl, and PrHCl) were measured in the absence and presence of sodium laurate. The samples were dissolved in 600 μL of DMSO-d_6. The ^{1}H NMR measurement conditions were as follows: number of data points: 16 384; acquisition time: 1.75 s; delay time: 5 s; and number of scans: 16. The NOESY (nuclear Overhauser enhancement spectroscopy) measurement conditions were as follows: number of data points: 512 and 1024 for F1 and F2, respectively; digital resolutions of F1 and F2: 5.50 and 8.79 Hz, respectively; delay time: 1.5 s; mixing time: 1.0 s; and number of scans: 16. Solid-state NMR was conducted using an ECA 500 (500 MHz) (JEOL, Tokyo, Japan) at 0 °C to stop the crystals from melting, using 4 mm of CP/MAS (cross-polarization/magic angle spinning) probe at 10 000 rpm. The measurement was as follows: number of data points: 1024; digital resolution: 49.2 Hz; delay time: 5.0 s; and number of scans: 2048.

Molecular Modeling. Initial models of conformations that were consistent with the NOESY data of the three bitter substances in the absence and presence of sodium laurate were manually constructed using GaussView 5.0 (Gaussian, Inc., Wallingford, CT, USA). The geometries were optimized in vacuo at the B3LYP/6-31G (d) level of theory; then, the geometries were optimized in DMSO at the same level of theory. The polarizable continuum model (PCM) was used to calculate solvent effects in DMSO. All calculations were carried out using the Gaussian 09 software package.[27]

RESULTS

ITC Measurements. The interactions between 22 bitter substances and sodium oleate were studied using ITC (Figure S1-2). Five bitter substances, QHCl, PHCl, PrHCl, BHCl, and YHCl were found to interact with sodium oleate. Notably, each of these substances bears a nitrogen atom (Figure 1). The

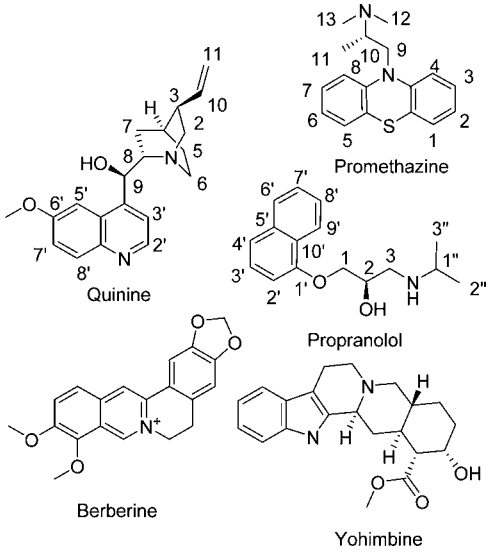

Figure 1. Chemical structures of five bitter substances showing exothermic interactions with sodium oleate.

interactions between these five substances and six fatty acids were then studied (Table 1). The change in Gibbs free energy (ΔG) was negative for all the interactions detected, meaning that these interactions occurred spontaneously. The change in enthalpy (ΔH) contributed to ΔG in all cases, and the change in entropy (ΔS) contributed in some cases (Table 1). In these

cases, the titrated solutions became turbid upon injecting the bitter substances, indicating that insoluble complexes had been formed between the fatty acids and the bitter substances. Of the five bitter substances examined, BHCl and YHCl exhibited relatively weak interactions with the fatty acids (Table 2). Therefore, only the three that had strong interactions with the fatty acids were examined: QHCl, PHCl, and PrHCl.

No interactions were detected between fatty acids with 10 or fewer carbon atoms and the three bitter substances. All three substances showed the greatest binding constants upon binding with sodium oleate, which increased as the number of carbon atoms in the alkyl chain of the fatty acids increased. The binding constant also decreased as the number of double bonds in the fatty acids increased (Table 2). These results suggested that the carbon chain length and the number of double bonds in the fatty acids affected these interactions.

To examine the effect of the carboxyl group in the fatty acids, the interactions between the bitter substances and glycerol monolaurate and glycerol monooleate were also measured. However, no interactions between the bitter substances and these glycerol esters were detected (Table 2).

Overall, carbon chains of a certain length and the presence of carboxyl groups in the fatty acids were necessary to induce interactions with the bitter substances.

NMR Measurements. ITC measurements proved that fatty acids interacted directly with some bitter substances. To examine the mechanism of these interactions, the ^{1}H NMR spectra of three bitter substances (QHCl, PHCl, and PrHCl) were measured in the absence and presence of an equimolar amount of sodium laurate. Because these bitter substances are insoluble in water when sodium laurate is added, DMSO-d_6 was used as the solvent instead.

The three bitter substances contained a nitrogen atom (Figure 1). The signals of the protons on the hydrogen atoms located near the nitrogen atoms was shifted upfield in the presence of sodium laurate (H2, H6, and H8 of QHCl; H9–H13 of PHCl; and H1″ and H3 of PrHCl; Figure 2). The changes in the chemical shift ($\Delta\delta$) of these protons were more than 0.3 ppm for QHCl and PHCl and more than 0.2 ppm for

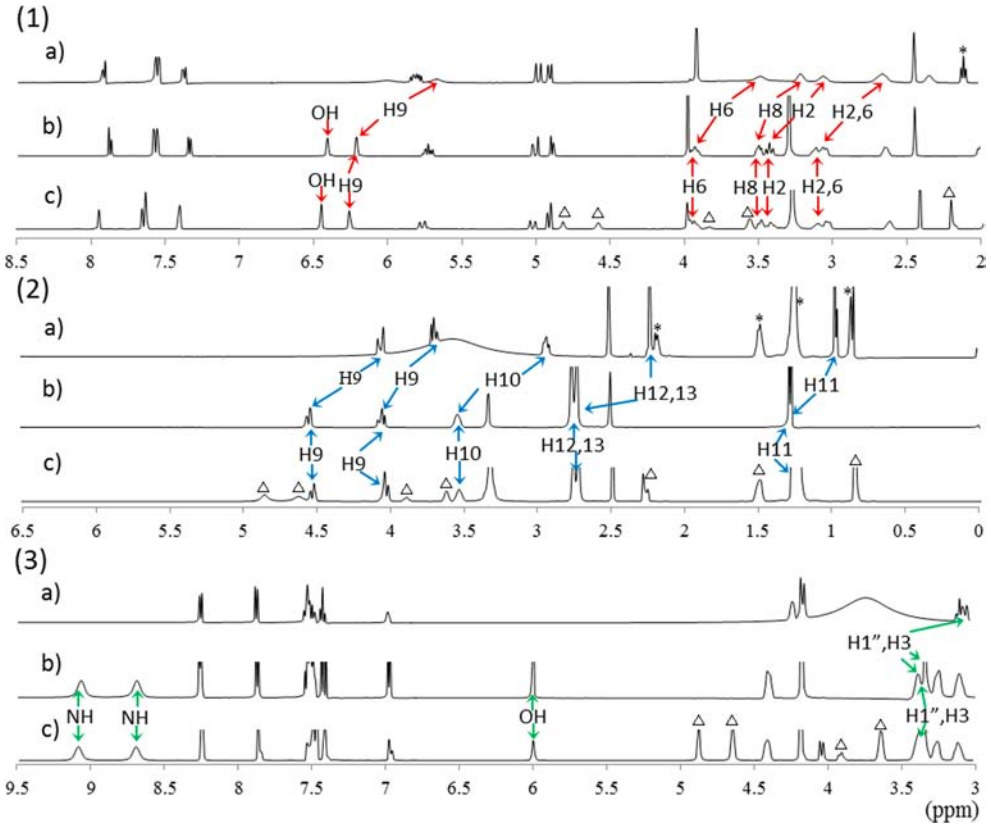

Figure 2. ^{1}H NMR spectra of (1) QHCl, (2) PHCl, and (3) PrHCl. Spectra of (a) bitter substances in the presence of sodium laurate, (b) bitter substances alone, and (c) bitter substances in the presence of glycerol monolaurate. Characteristic protons are indicated by arrows. The broadening of the OH and perturbation of H9 in QHCl and the broadening of OH and NH in PrHCl resulted from the exchange of OH or NH protons with those in the carboxyl moiety in sodium laurate. *, signals of sodium laurate; △, signals of glycerol monolaurate.

PrHCl (Table S2). In the presence of glycerol monolaurate, no significant changes were observed ($\Delta\delta$ < 0.02 ppm) (Table S3).

The ^{1}H NMR spectra of QHCl were also measured in the presence of sodium decanoate (10:0), sodium octanoate (8:0) and sodium hexanoate (6:0) which caused the signals corresponding to H2, H6, and H8 of QHCl (Table S4) to be shifted upfield ($\Delta\delta$ > 0.3 ppm). These results suggested that the hydrogen bond between the nitrogen atom of the bitter substances and the carboxyl group of the fatty acid was formed in DMSO.

In addition, the ^{1}H NMR spectra were measured after changing the molar ratio of sodium laurate to QHCl (0, 0.2, 0.5 and 0.8). The changes in the chemical shifts of H2, H6, and H8 ($\Delta\delta$) were plotted as a function of the molar ratio of sodium laurate (Figure 3). As the chemical shifts depended on the molar ratio of sodium laurate, the exchange between the free and complexed states was faster than the chemical shift difference between the two states.

ITC measurements revealed that the length of the carbon chain and the number of double bonds in the fatty acids affected the binding constants, which suggested that the alkyl chains contributed to the interactions. To examine where the hydrophobic interactions occurred, the NOESY spectra of the bitter substances were measured in the absence and presence of sodium laurate (Figure 4).

In the present study, there were three possible locations for hydrophobic interactions: the first was between the fatty acids and bitter substances, the second was between different molecules of the bitter substances, and the third was between

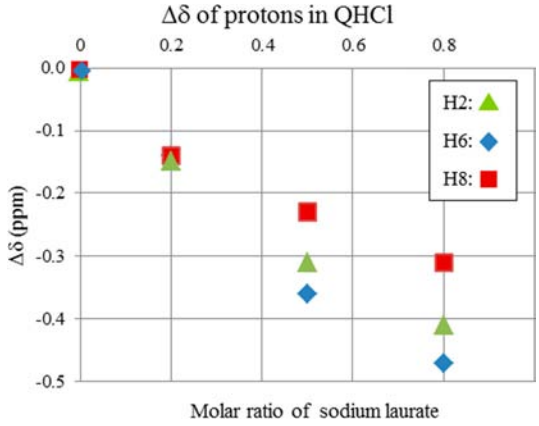

Figure 3. Titration curve corresponding to QHCl (H6, H8, and H2) upon addition of sodium laurate. The change in the chemical shift ($\Delta\delta$) in 32 μmol of QHCl is plotted as a function of the molar ratio of sodium laurate (0, 0.2, 0.5, and 0.8).

different molecules of the fatty acids. Although no cross-peaks were observed between sodium laurate and QHCl, some were observed between H2′ and H8′ of QHCl in the presence of sodium laurate (Figure 4). Because these protons cannot interact with each other within a single molecule of QHCl, intermolecular hydrophobic interactions between two molecules of QHCl occurred in the presence of sodium laurate. However, in the case of PHCl and PrHCl, no interactions between bitter substances and fatty acids and between different molecules of bitter substances were observed (Figure S3 and

DOI: 10.1021/acs.jafc.5b03193
J. Agric. Food Chem. 2015, 63, 8493−8500

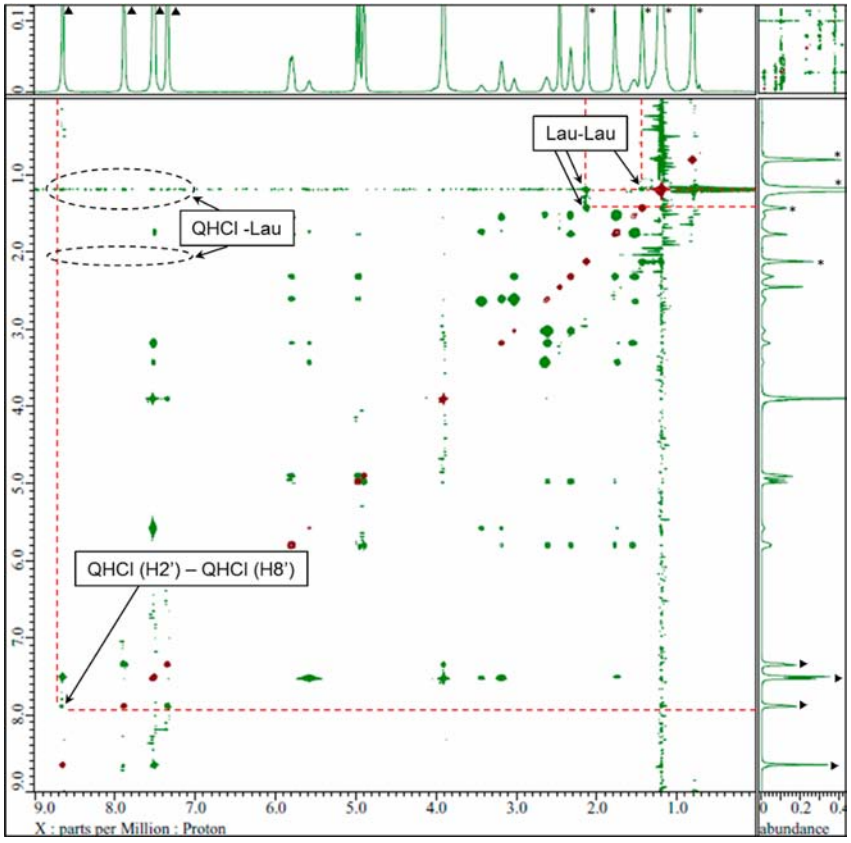

Figure 4. NOESY spectra of QHCl in the presence of sodium laurate. ^{1}H NMR spectra of QHCl/sodium laurate is displayed on X−Y axis. Characteristic cross-peaks are indicated by red circles. *, signals of sodium laurate; ▲, signals of aromatic protons in QHCl.

Table S5). Detailed analysis of the cross-peaks between carbon chains was impossible because many signals overlapped. However, because the length of the carbon chain affected the strength of the interactions in the ITC experiment, we concluded that hydrophobic interactions existed primarily between the carbon chains in an aqueous environment. On the basis of the NOESY results, we constructed molecular models of the binary complexes formed between the bitter substances and sodium laurate in DMSO (Figure 5).

Crystal Analysis of Sodium Laurate and QHCl. Needlelike crystals were observed upon mixing an aqueous solution of sodium laurate and QHCl (Figure 6a). These crystals were composed of an equimolar amount of laurate and quinine, as indicated by ^{1}H NMR. The DSC curve of the crystal revealed a wide exothermic peak (Figure 6b). From CP/MAS NMR spectra, it appeared that C2, C6, and C8 in QHCl resonated at chemical shifts of 62.3, 56.9, and 66.3 ppm, respectively, and each of the signals split into three peaks with a broadened peak width when the crystal was formed with lauric acid (Figure S2). This indicates that at least three states were involved in the crystal. In addition, peak broadening of the methyl and methylene carbon atoms in lauric acid upon formation of crystal demonstrated an incoherent microcrystalline structure. X-ray diffraction analysis was applied to the ground crystal samples using the radial distribution function $4\pi r^2\rho$ (r) to obtain structural information. The sum of the data for QHCl and lauric acid, measured independently, was different from that of the data for the ground crystal sample, implying that specific interactions had been formed in the complex. The crystal seems to be in an intermediate state regarding its amorphosity and crystal style (data not shown).

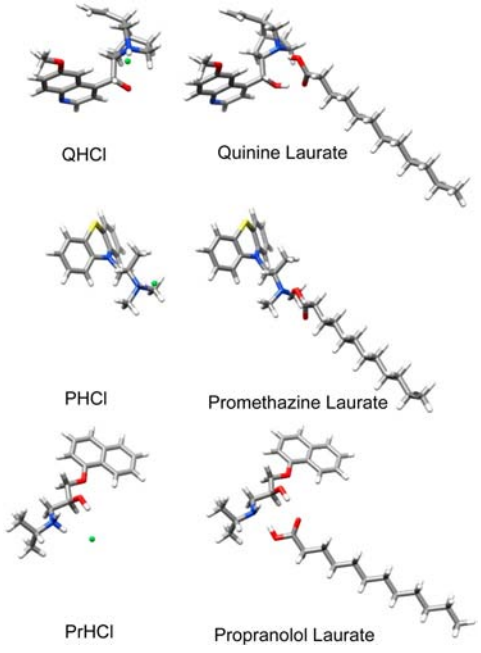

Figure 5. Structures of three bitter substances and their laurates. Atoms are presented as carbon in gray, oxygen in red, sulfur in yellow, nitrogen in blue, and chloride in light green.

These results suggested that the crystal was composed of various conformations. The bitterness of the crystal was significantly less than that of QHCl alone using sensory testing (data not shown).

DISCUSSION

In a previous report,[26] it was shown that sodium oleate suppressed the bitterness of QHCl. Exothermic interactions were observed when QHCl was added to the fatty acid, associated with masking the bitterness of QHCl by direct interaction with the fatty acids. However, the detailed mechanism of the bitterness-masking reaction has not been elucidated. In the present study, we found that two types of interaction, hydrogen bonds and hydrophobic interactions, were necessary to mask the bitterness of some compounds. Specifically, NMR revealed that hydrogen bonding occurred between the nitrogen atom of the bitter substances (N1 of QHCl, N11 of PHCl, and N4 of PrHCl) and the carboxyl group of the fatty acids in DMSO (Figure 2). In addition, the ITC experiments in water indicated that the strength of the interaction between the bitter substance and the fatty acid depended on the length of the carbon chain of the fatty acid, demonstrating the involvement of hydrophobic interactions.

In aqueous solutions, the bitter substances and fatty acids dissociated as weak bases and acids, respectively.[28] In neutral pH solutions, the dissociation equilibrium of the long-chain fatty acids (RCOOH) shifted to the left of the equilibrium reaction (eq 1), given that the pK_a values of oleic acid, linoleic acid, and linolenic acid are 9.85, 9.24, and 8.28, respectively.[28]

$$RCOOH \leftrightarrows RCOO^- + H^+ \quad (1)$$

However, the dissociation equilibrium of bitter nitrogenous substances (BN) such as quinine, promethazine, and propranolol shifted to the left side of the equilibrium reaction (eq 2), given that the pK_a values of quinine,[29] promethazine,[30] and propranolol[31] are 8.3, 8.6, and 9.2, respectively.

$$BNH^+ \leftrightarrows BN + H^+ \quad (2)$$

The ΔH values for the interactions between the fatty acids and bitter substances were in the range of 10−40 kJ/mol in all cases (Table 1). These results suggested that hydrogen bonds existed between the fatty acids and bitter substances. Two possible mechanisms of hydrogen bond formation are proposed: One involves interaction between RCOOH and BN that comprises a unit of the binary complex, and the other interaction occurs between BH^+ and $RCOO^-$. The former hypothesis can explain the observation that long-chain fatty acids interact with the bitter substances whereas short-chain fatty acids do not. The latter hypothesis can account for the ionic attraction between oppositely charged species.

Of the 22 bitter substances examined, those that exhibited strong interactions with the fatty acids contained secondary or tertiary amino groups. Although some bitter substances that did not interact with the fatty acid also had nitrogen atoms, most of these nitrogen atoms were present in amide groups or in conjugated systems. The rest were present in primary amino groups that might be unsuitable for forming hydrophobic interactions with the carbon chain of the fatty acids.

Regarding hydrophobic interactions, the contribution of the carbon chains was obvious because the length of the carbon chain and the number of double bonds affected the binding constants (Table 2). The NOESY data indicated the possibility of a stacking effect between the aromatic rings of QHCl. However, the $T\Delta S$ values varied widely and were not correlated with ΔG, especially with sodium linoleate (Table 1). This phenomenon was perhaps due to either the conformational variation of the fatty acids or the decreased solubility of the mixture of hydrochloride salts of the bitter substances and the sodium salts of the fatty acids.

On the basis of these results, we propose that the bitterness of substances can be masked with fatty acids by the formation of a binary complex between these species through a hydrogen bond and a hydrophobic interaction (Figure 7). Specifically, the aggregation of a unit of binary complex of fatty acids and bitter substances generated large insoluble complexes. The formation of these complexes made it more difficult for the bitter substances to interact with the bitter taste receptors, thereby masking the bitterness. Particularly in the case of QHCl and sodium laurate, both substances aggregated because of hydrophobic interactions between the carbon chains, forming needlelike crystals (Figure 7). As suggested by DSC, the crystal was probably composed of quinine laurate in various conformations with stacking interactions between the aromatic rings of QHCl.

In the present study, fatty acids have been found to interact directly with bitter substances through hydrogen bonds and hydrophobic interactions. Moreover, both types of interaction played important roles in masking bitterness. This study has been described how direct interactions between bitterness-masking substances and bitter substances can suppress bitterness. The results of this study should lead to the development of new method for masking bitterness, which may be directly applicable to food processing. More research would be needed to investigate the taste and acceptability of

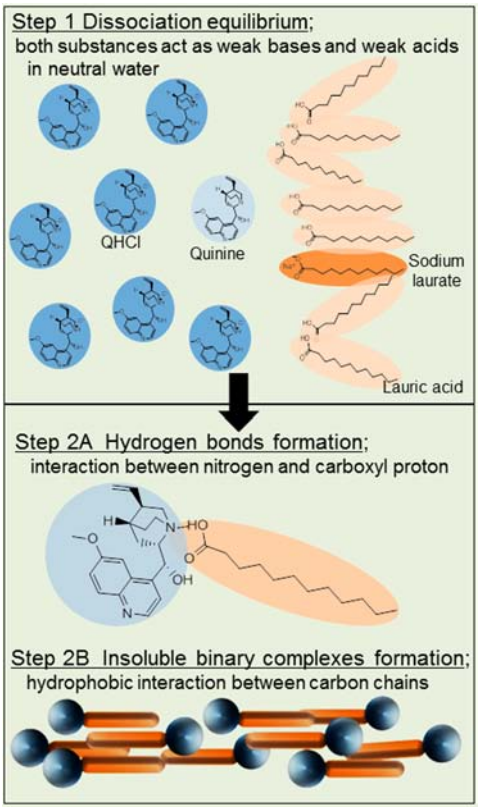

Figure 7. Possible mechanism of interaction between sodium laurate and QHCl. Sodium laurate and QHCl interact weakly via step 1, comprising dissociation equilibrium of QHCl as weak bases and sodium laurate as weak acids. Hydrogen bonding and insoluble binary complexes occur via step 2; for fatty acids with a chain length of 12 or more carbon atoms, hydrogen bonds form between quinine and laurate. The complex model is presented in the lower image. QHCl molecules are colored blue, and sodium laurate is shown in orange. The binary complexes are connected to each other by hydrophobic interactions and grow in a single direction, forming needlelike crystals.

food containing fatty acids and nitrogen-containing bitter compounds.

From this study, we can propose a possible mechanism for how fatty acids mask the bitterness of bitter substances. Both hydrogen bonds and hydrophobic interactions are essential for forming the insoluble binary complexes composed of bitter substances and fatty acids. Nitrogen atoms in the bitter substances and fatty acids with chain lengths of 12 or more carbon atoms are necessary for forming the binary complexes.

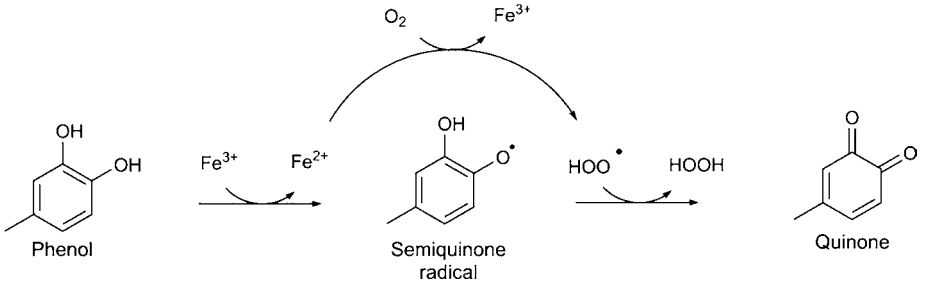
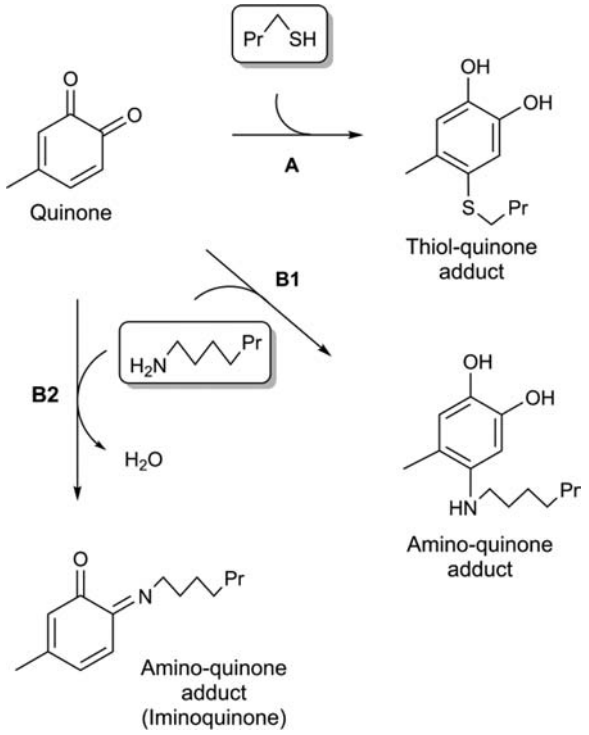
Scheme 1. Two-Step Metal-Catalyzed Oxidation of a Phenol To Yield the Intermediate Semiquinone Radical and Subsequently the Quinone and Hydrogen Peroxide



Scheme 2. Nucleophilic Addition between a Quinone and a Protein Thiol Group (A) To Yield a Thiol−Quinone (TQ) Adduct or between a Quinone and a Protein Amino Group To Yield Amino−Quinone (AQ) Adducts by Either Michael Addition (B1) or Formation of Schiff Base-Like Structures (B2)



present study was to determine how protein−phenol adduct formation between the quinones of 4-methylcatechol (4MC) or catechin (Cat) affects the metal-catalyzed oxidation of β-lactoglobulin (β-LG). The two phenolic compounds were added in either their reduced phenolic form or in their oxidized quinoic form to identify possible changes in the oxidation pattern of β-LG depending upon the redox status of the phenolic compounds. The oxidation was followed for prolonged incubation times to investigate both early and later stages of oxidation.

2. MATERIALS AND METHODS

2.1. Reagents. β-LG ($M_w \sim 18\,300$) consisting of a mixture of the variants A and B was isolated from bovine milk as described by Kristiansen et al.[13] Malic acid was obtained from Scharlau SL, Sentmenat, Spain. Cat, 4MC, Trizma base, 5,5-dithiobis(2-nitrobenzoic acid) (DTNB), *N*-ethylmaleimide (NEM), Trolox, neocuproine, Amberlyst A26, and fluorescamine was obtained from Sigma-Aldrich, St. Louis, MO. Reagent-grade chemicals and double-deionized (Milli-Q) water were used throughout.

2.2. Peroxidation of Phenols by Periodate Resin. Periodate resin was prepared according to Harrison and Hodge,[14] with slight modifications as recently described by Jongberg et al.[15] 4MC and Cat was oxidized by mixing 158 mg of periodate resin with 12.4 mg of 4MC or 14.5 mg of Cat dissolved in acetonitrile for 3 min during stirring. The amount of 4MC converted to 4-methylbenzoquinone (4MBQ) was estimated to be ∼95% by high-performance liquid chromatography−ultraviolet/visible spectroscopy (HPLC−UV/vis),[16] giving an estimated concentration of ∼95 mM 4MBQ or 47.5 mM catechin−quinone (CatQ). The quinone solutions were used immediately for the preparation of samples.

2.3. Preparation of Samples. Samples were prepared in 0.1 malic acid buffer (pH 5.8) to contain 5.0 mg/mL (273 μM) β-LG alone or with addition of 273 μM 4MC or Cat or their corresponding quinones, 4MBQ or CatQ, and left to react for 10 min at room temperature (20 °C). In parallel, blank phenol and quinone samples were prepared in the same concentrations without the addition of β-LG. NEM-derivatized β-LG was prepared by letting 273 μM β-LG react with 7.2 mM NEM for 90 min at room temperature (20 °C). A corresponding blank NEM sample was prepared in parallel without the addition of protein. In total, 11 samples were prepared in triplicate: 6 samples with protein, β-LG, β-LG−4MC, β-LG−4MBQ, β-LG−Cat, β-LG−CatQ, and β-LG−NEM, and 5 samples without protein, 4MC, 4MBQ, Cat, CatQ, and NEM.

2.4. Metal-Catalyzed Oxidation. Oxidation of all 11 samples was initiated by the addition of 50 μM $FeSO_4$ and 5 mM H_2O_2 both dissolved in Milli-Q water. The samples were oxidized in the dark at 37 °C for up to 20 days with constant stirring. Prior to initiation, day 0 samples were collected for thiol and Schiff base analyses, which were carried out on the same day. Samples for α-aminoadipic semialdehyde (AAS) and γ-glutamic semialdehyde (GGS) quantification were frozen at −80 °C until analysis. Onward, samples were collected at days 1, 3, 5, 8, 12, and 20, and the same procedure as for the day 0 samples was followed.

2.5. Antioxidative Activity by the Cupric Reducing Antioxidant Capacity (CUPRAC) Assay. Samples were prepared as described above (section 2.3), although including additional concentrations of 4MC, 4MBQ, Cat, and CatQ. For each, three concentration levels were added to 273 μM β-LG in 0.1 M malic acid buffer (pH 5.8), namely, 137, 273, or 546 μM, corresponding to the molar ratio between β-LG and the phenol or quinone of 1:0.5, 1:1, or 1:2, respectively. In parallel, blank samples without the addition of β-LG were prepared, containing only 137, 273, or 546 μM 4MC, Cat, 4MBQ, or CatQ, respectively. Samples containing β-LG−NEM and its corresponding blank NEM was prepared as described above. An aliquot of 0.1 mL sample was added to a test tube containing 1.0 mL of 10 mM $CuCl_2$ dissolved in water, 1.0 mL of 1 M ammonium acetate buffer (pH 7.0), 1.0 mL of 7.5 mM neucoproine in ethanol, and 1.0 mL of water. The mixture was mixed and left to react at room temperature (20 °C) for 30 min before the absorbance at 450 nm was read on a HITACHI U-2000 spectrophotometer. Trolox dissolved in 80% ethanol was used as the standard, and data are given as Trolox equivalent antioxidant capacity (TEAC) and presented as millimolar

DOI: 10.1021/acs.jafc.5b02551
J. Agric. Food Chem. 2015, 63, 8501−8509

Trolox equivalents (mean ± standard deviation) of three independent replicates (n = 3). Three different TEAC values are presented: one of the model system containing β-LG, one with of the blank model system without β-LG, and finally, a summarized TEAC, which represents the sum of the TEAC of the blank model system plus the TEAC of β-LG alone.

2.6. Quantification of Thiol Groups. Protein thiol groups in samples prior to oxidation by $FeSO_4/H_2O_2$ were determined by derivatization with DTNB[17] and recently described by Jongberg et al.[15] The thiol concentrations given as nanomoles of thiol per milligram of protein are presented as means ± standard deviation of three independent replicates (n = 3). All protein-containing samples were subtracted from the contribution measured in the corresponding blank sample without protein.

2.7. Quantification of Free Amino Groups. Free amino groups in samples prior to oxidation by $FeSO_4/H_2O_2$ were determined as described by Weigele et al.[18] and Strauss and Gibson.[19] An aliquot of 850 μL of sample containing ~0.01 mg/mL β-LG was added to 2.0 mL of 0.05 M sodium tetraborate (pH 8.5) in a 4 mL quartz spectrofluorometer cell, and 150 μL of 0.7 mM fluorescamine solution in acetone was added. The cell was inverted 4 times, and the resulting fluorescence was measured using 390/485 nm for excitation and emission, respectively, on a PerkinElmer LS45 fluorescence spectrometer (Llantrisant, U.K.). The contribution from malic acid buffer (pH 5.8) was recorded under the same conditions and subtracted all samples. The free amino group concentration was calculated on the basis of a standard curve prepared from lysine diluted in malic acid buffer (pH 5.8). The concentration is given as micromoles of amino groups per milligram of protein and are presented as means ± standard deviation of three independent replicates (n = 3). All protein-containing samples were subtracted from the contribution measured in the corresponding blank sample without protein.

2.8. Quantification of the Semialdehydes AAS and GGS. The protein oxidation products AAS and GGS were quantified in samples from the samples containing protein according to the method described by Utrera et al.[20] An aliquot of 250 μL of sample was precipitated with 1.3 mL of ice-cold 10% trichloroacetic acid (TCA) and centrifuged at 5000 rpm for 30 min and the supernatant was discarded. The pellet was precipitated again with 1.5 mL of ice-cold 5% TCA and centrifuged for 5 min and the supernatant was discarded. The pellet was derivatized by the addition of 0.5 mL of 1% sodium dodecyl sulfate and 1 mM diethylenetriaminepentaacetic acid in 0.25 M MES buffer at pH 6.0 (SDS/DTPA), 0.5 mL of 50 mM aminobenzoic acid in MES buffer (ABA), and 0.25 mL of 100 mM $NaBH_3CN$ in MES buffer. The mixture was incubated at 37 °C for 90 min with stirring every 30 min. Subsequently, the proteins were precipitated twice, first with 0.25 mL of ice-cold 50% TCA and then with 1.5 mL of 5% ice-cold TCA. The precipitates were hydrolyzed in 6 N HCl at 110 °C for 18 h and subsequently dried *in vacuo* at 40 °C using a Savant speed-vac concentrator. Hydrolysates were reconstituted with 0.2 mL of Milli-Q water and filtered through hydrophilic polypropylene GH Polypro (GHP) syringe filters (0.45 μm pore size, Pall Corporation, Port Washington, NY). Samples were analyzed using ultrahigh-pressure liquid chromatography (UHPLC, Shimadzu USA Manufacturing, Inc., Canby, OR) equipped with a COSMOSIL 5 μm C18-AR-II RP-HPLC column (15 cm × 4.6 mm × 5 μm) coupled to a RF-10A XL Shimadzu fluorescence detector (FLD) (excitation and emission wavelengths of 283 and 350 nm, respectively). The mobile phase was a mixture of 50 mM sodium acetate buffer (pH 5.4) and acetonitrile, increasing gradually with a flow rate of 1.0 mL/min of the acetonitrile concentration from 0 to 8% between 0 and 20 min, then from 8 to 90% between 20 and 30 min, and finally, ending up at 100% buffer after 40 min. Identification of both ABA-derivatized semialdehydes in the FLD chromatograms was carried out by comparing their retention times to those from standard AAS and GGS (synthesized *in vitro* according to Akagawa et al.[21]). Data are expressed as nanomoles of carbonyls per milligram of protein as quantified using an ABA standard curve.

2.9. Quantification of Schiff Base Structures. The emission of fluorescence by protein oxidation products (Schiff base structures) was assessed by use of fluorescence spectroscopy.[22] Samples were diluted 50-fold in malic acid buffer and then dispensed in a 4 mL quartz spectrofluorometer cell. The excitation wavelength was set at 350 nm, and emission spectra were recorded from 400 to 500 nm (LS45 PerkinElmer fluorescence spectrometer, Llantrisant, U.K.). Emission spectra of the malic acid buffer (pH 5.8) were recorded under the same conditions and subtracted all sample spectra. Excitation and emission slit widths were set at 10 nm, and data were collected at 500 nm/min in both measurements. The content of Schiff base structures (AU) was expressed as fluorescence intensity units emitted at 440 nm and presented as the mean ± standard deviation of three independent replicates (n = 3). All protein-containing samples were subtracted from the contribution measured in the corresponding blank sample without protein.

2.10. Statistical Data Analysis. Statistical analysis were performed by analysis of variance (ANOVA) using R, version 2.12.1, The R Foundation for Statistical Computing (ISBN 3-900051-07-0).

3. RESULTS

3.1. Phenol- or Quinone-Derived Modifications of β-LG. To evaluate the extent of protein−phenol adduct formation, the concentration of amino and thiol groups of β-LG were evaluated before initiation of oxidation by Fe/H_2O_2. The samples without β-LG were used as blank samples in the analyses to compensate for any interference from the phenols or quinones in the assays. The results showed a significant decrease of 22% amino groups by the addition of 4MBQ to β-LG (upper panel of Figure 1). Higher reactivity of the phenols and quinones was observed for the reaction with thiol groups, where the addition of 4MBQ and 4MC significantly reduced the thiol group concentration by 60 and 12%, respectively

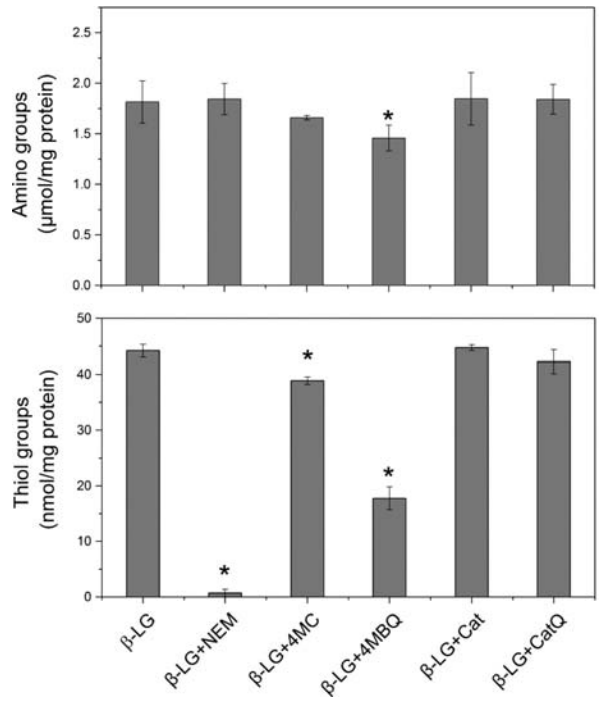


Figure 1. Free amino and thiol groups (mean ± standard deviation; n = 3) in samples (pH 5.8, no oxidants added) containing 273 μM β-LG alone or after reaction with 273 μM 4MC, 4MBQ, Cat, or CatQ for 10 min or after treatment with excess NEM for 90 min at room temperature. The asterisks (∗) indicate that the sample is significantly different (p < 0.05) from the model system containing only β-LG.

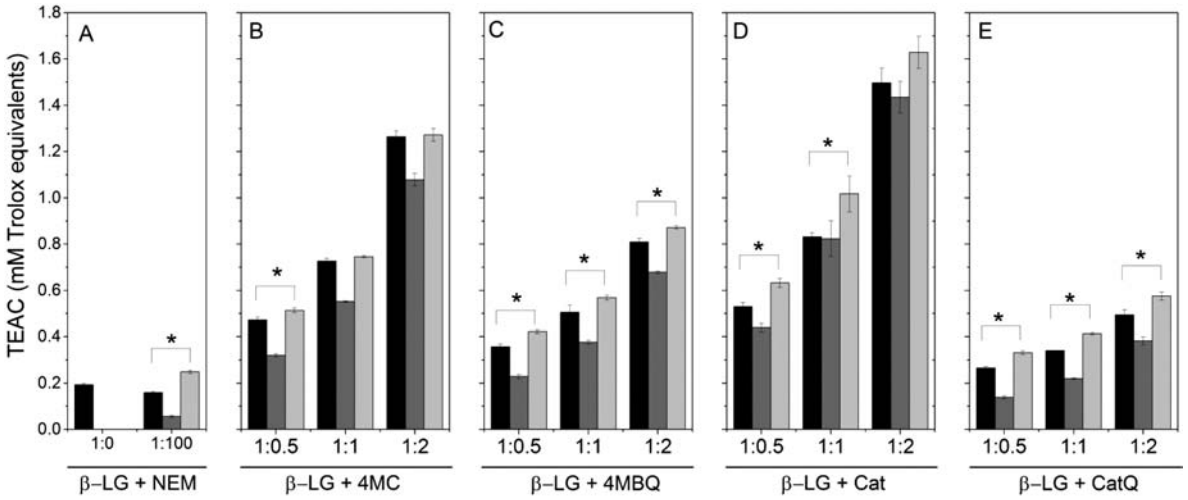

Figure 2. Antioxidative capacity as determined by TEAC (millimolar Trolox equivalents; mean ± standard deviation; $n = 3$) in samples (pH 5.8, no oxidants added) containing 273 μM β-LG (A) alone (1:0) or after treatment with 27.3 mM NEM or after 10 min of reaction at room temperature with 137 μM (1:0.5), 273 μM (1:1), or 546 μM (1:2) (B) 4MC, (C) 4MBQ, (D) Cat, or (E) CatQ. Black bars represent TEAC of the model systems containing β-LG. Dark gray bars represent TEAC of the blank model systems without β-LG. Light gray bars represent the summarized TEAC of the model systems without β-LG added to the TEAC of 273 μM β-LG alone (A, 1:0). The asterisks (∗) denote a statistical significant difference ($p < 0.05$) between the measured TEAC and the summarized TEAC.

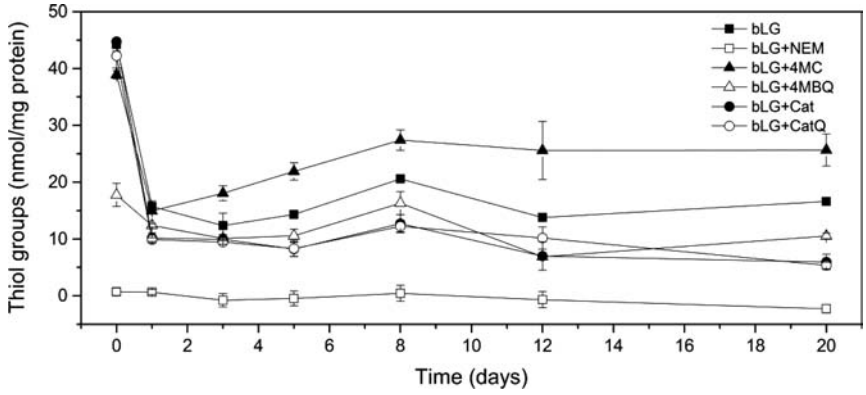

Figure 3. Thiol group concentration (mean ± standard deviation; $n = 3$) during *in vitro* oxidation by Fe(II)/H_2O_2 of samples (pH 5.8, 37 °C) containing 273 μM β-LG alone or after treatment with 27.3 mM NEM (β-LG−NEM) or in the presence of equal molar concentrations of 4MC (β-LG−4MC), 4MBQ (β-LG−4MBQ), Cat (β-LG−Cat), or CatQ (β-LG−CatQ). Data from Figure 1 are included as $t = 0$ day.

(lower panel of Figure 1). As a control, the thiol concentration was also determined in NEM-treated β-LG, and NEM was found to block 98% of the thiol groups.

3.2. Antioxidative Capacity of the β-LG Samples. The antioxidative capacity of the samples prior to oxidation by Fe(II)/H_2O_2 was evaluated by the CUPRAC assay (Figure 2). The overall antioxidative capacity was determined for all samples with or without β-LG, including not only the 1:1 molar ratio between the protein and phenol or quinone, but also the ratios 1:0.5 and 1:2. The TEAC obtained for all samples increased proportionally with the concentration of phenol or quinone (panels B−E of Figure 2). Comparing the measured TEAC of the sample with the summarized TEAC indicates whether the combination of protein and phenol or quinone interact to provide an additive, synergistic, or antagonistic antioxidative capacity. A statistically significant difference (marked by ∗ in Figure 2) between the measured TEAC and the summarized TEAC indicates a synergistic or antagonistic effect, whereas the effect is additive for the samples with no significant difference between the measured and summarized TEAC. In this way, additive effects were observed in the β-LG samples containing 4MC in the ratios 1:1 and 1:2 and in the β-LG sample containing Cat in the ratio 1:2 (panels B and D of Figure 2). All β-LG samples containing quinones (panels C and E of Figure 2) as well as the low ratios of 4MC (1:0.5) and Cat (1:0.5 and 1:1) resulted in antagonistic antioxidative capacities, which means that the combination of β-LG and phenols or quinones in most cases reduces the overall antioxidative capacity. Also, derivatization of β-LG with NEM (Figure 2A) led to a significant decrease of TEAC, as compared to β-LG alone.

3.3. Thiol Loss during *in Vitro* Oxidation. The samples were oxidized by Fe/H_2O_2 at 37 °C for up to 20 days. The results showed that thiols were rapidly lost and reached steady state already at day 1 after initiation for most samples (Figure 3). The samples containing only β-LG reached ∼15 nmol of thiols/mg protein at day 1, and this level was not significantly different from the level at day 20 (Figure 3). The same pattern was observed in the β-LG samples containing 4MBQ, Cat, and CatQ (Figure 3), although with a lower starting point for the 4MBQ as a result of the modifications induced to the protein thiols, as shown in Figure 1. In contrast, a significant increase in

J. Agric. Food Chem. 2015, 63, 8501−8509

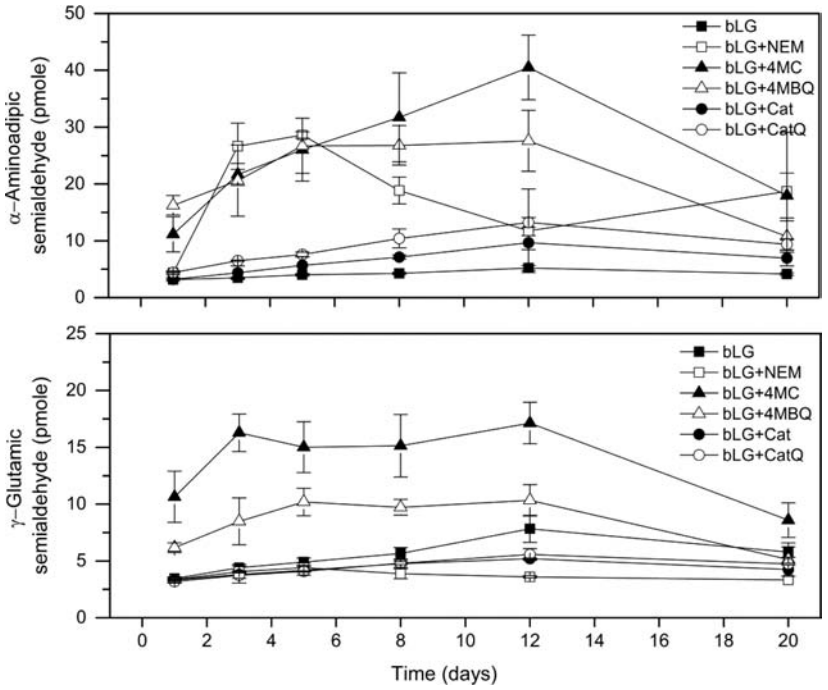

Figure 4. AAS (upper panel) and GGS (lower panel) (mean ± standard deviation; $n = 3$) during *in vitro* oxidation by Fe(II)/H_2O_2 of samples (pH 5.8 and 37 °C) containing 273 μM β-LG alone or after treatment with 27.3 mM NEM (β-LG−NEM) or in the presence of equal molar concentrations of 4MC (β-LG−4MC), 4MBQ (β-LG−4MBQ), Cat (β-LG−Cat), or CatQ (β-LG−CatQ).

the thiol level from days 1 to 8 was found in the β-LG sample containing 4MC, which unfortunately cannot be definitely explained on the basis of the experimental design of the present study.

3.4. AAS and GGS Formation during *in Vitro* Oxidation. Both AAS and GGS were quantified in the β-LG samples, and results showed that limited but significant formation took place up to day 12 in the samples containing only β-LG (Figure 4). In β-LG treated with NEM, where all thiol groups were blocked, a rapid and significant increase in AAS was observed until day 5, where the concentration of carbonyl peaked to decrease afterward. For β-LG containing 4MC, 4MB, Cat, or CatQ, the concentration of AAS increased significantly until day 12 and then subsequently decreased (upper panel of Figure 4). The presence of 4MC or 4MBQ significantly increased the concentration of GGS already at day 1, which continued to be significantly higher until day 12, as compared to β-LG alone, whereas Cat and CatQ had no significant effect on GGS formation in β-LG (lower panel of Figure 4). For β-LG treated with NEM, no GGS was found.

3.5. Formation of Schiff Base Structures during *in Vitro* Oxidation. The reaction between various carbonyl and amino groups leads to the formation of unspecific Schiff base tructures that can be quantified by fluorescence spectroscopy. In the sample containing only β-LG, the Schiff base structures increased significantly after 12 days of storage, whereas in β-LG treated with NEM, the structures increased significantly already from day 1 (Figure 5). In the present study, the emission spectra for the sample containing only β-LG or β-LG and NEM showed a maximum at 420 nm. However, the maximum shifted toward a higher wavelength (440 nm) by the addition of phenols or quinones. Both emission wavelengths were monitored, but because no differences in the overall results were observed, only the data from 440 nm are presented. In the β-LG samples containing 4MC or 4MBQ, significantly elevated

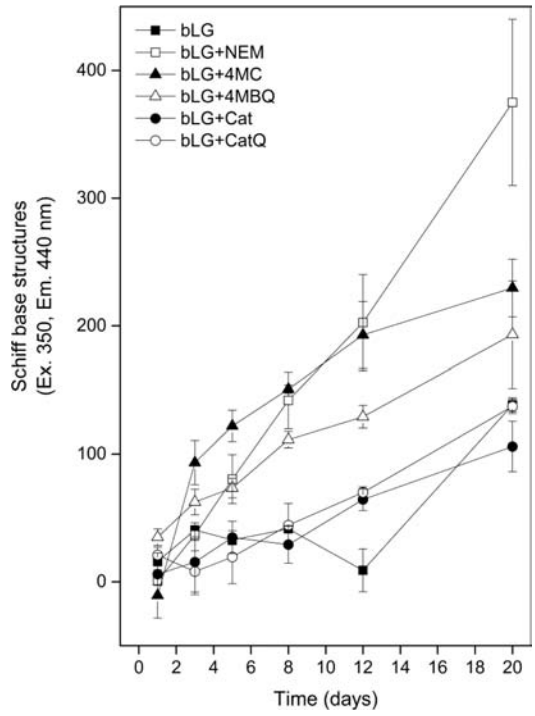

Figure 5. Schiff base structures (mean ± standard deviation; $n = 3$) during *in vitro* oxidation by Fe(II)/H_2O_2 of samples (pH 5.8 and 37 °C) containing 273 μM β-LG alone or after treatment with 27.3 mM NEM (β-LG−NEM) or in the presence of equal molar concentrations of 4MC (β-LG−4MC), 4MBQ (β-LG−4MBQ), Cat (β-LG−Cat), or CatQ (β-LG−CatQ).

fluorescence was observed at day 3, as compared to β-LG alone. In contrast, in β-LG samples containing Cat or CatQ, the Schiff base structures increased significantly after day 8 (Figure 5). No

apparent differences were observed between Cat and CatQ with regard to Schiff base structures.

4. DISCUSSION

4.1. β-LG Oxidation and Effect of NEM-Blocking of Thiol Groups. The overall antioxidative capacity of β-LG as determined by CUPRAC was significantly reduced after treatment with NEM, indicating that β-LG was less resistant toward oxidation when the thiols were blocked. The CUPRAC assay was selected as a marker of overall antioxidative activity because it also includes the reducing effect of protein thiols,[23] and the result is in accordance with a recent report showing that thiol groups in a myofibrillar protein isolate (MPI) are important for the scavenging of perferrylmyoglobin radicals.[24] In the present study, the thiols were rapidly lost during the first day of storage in the presence of Fe(II) and hydrogen peroxide generating hydroxyl radicals (Figure 3). NEM effectively blocked the thiol groups of β-LG, and consequently, no thiols were available for oxidation in β-LG treated with NEM, which changed the target of the oxidants. This is evident from the rapid formation of AAS during the first days of storage in β-LG treated with NEM as opposed to a slower formation of AAS in untreated β-LG. Similarly, the formation of Schiff base structures also increased more rapidly in NEM-treated β-LG compared to untreated β-LG. These data show that thiols are oxidized more rapidly in our system than alkaline amino acids and are, therefore, better markers of early oxidation events in systems without polyphenols, which is consistent with the higher rate constants reported for the reaction of hydroxyl radicals with thiols than with alkaline amino acids. Sulfur-containing amino acid residues, such as Cys and Met, may act as intramolecular antioxidants in proteins by scavenging radical species.[25] Elias et al.[26] found no loss of Met during oxidation of β-LG but a rather rapid initial loss of thiols, followed by a plateau during continuing oxidation. This sacrificial protection by the protein thiols was not possible in β-LG treated with NEM, and therefore, other susceptible amino acid residues, such as alkaline amino acids, were subsequently attacked by the oxidants.

Concomitantly, in β-LG treated with NEM, AAS increased rapidly during the first days of storage, whereas GGS increased slowly until day 12 together with the formation of Schiff base structures, which continued to increase throughout the reaction period. This finding emphasizes the role of metal-catalyzed oxidation in the carbonylation of β-LG when thiols are not available for oxidation. AAS, GGS, and other protein oxidation products may engage in reactions involving a carbonyl group and an amino group, leading to advanced protein modifications similar to Maillard reactions with the generation of Schiff base structures.[27,28] The overall higher concentration of AAS compared to that of GGS in the β-LG systems is in agreement with previous reports and may be derived from the higher concentration and susceptibility of lysine in β-LG toward metal-catalyzed oxidation compared to other alkaline amino acids.[29]

4.2. Effect of Protein−Phenol Adducts on β-LG Oxidation. In the present study, quantification of amino and thiol groups prior to initiation of oxidation showed that the addition of 4MBQ decreased the concentration of protein amino and thiol groups, suggesting the formation of covalent TQ and AQ adducts for β-LG in the presence of 4MBQ (Scheme 2). In a previous study, it was shown by liquid chromatography−mass spectrometry (LC−MS) analysis that >20% of β-LG was found as protein−phenol adducts when 4MBQ was added in a equimolar ratio at pH 8.0, while 40% of the thiols were lost.[15] In the present study, 60% of the thiols were lost by the addition of an equimolar concentration of 4MBQ at pH 5.8. However, the concentration in the present study was 5 times higher, and pH was lower than in the aforementioned study, which may have led to an increased reaction rate and changes in the protein structure that may have altered the reactivity of specific amino acid side chains as a result of changed exposure to the environment.[30] The smaller loss of amino groups (ca. 20%) suggests that the reaction with quinones was slower than that with thiols. This may be explained by the difference in pK_a of the nucleophilic sites (e.g., pK_a for ε-amino group of Lys is 10.79, and pK_a for thiol group of Cys is 8.37) because a larger proportion of the thiols will be deprotonated and, thereby, more reactive at pH 5.8 compared

DOI: 10.1021/acs.jafc.5b02551
J. Agric. Food Chem. 2015, 63, 8501−8509

to the amines. On the basis of these data, it is not possible to clarify whether the thiol loss is caused by pro-oxidative behavior oxidation or adduct formation. During the *in vitro* oxidation, the thiol level at day 1 was found to be similar in β-LG independent of the presence of 4MC or 4MBQ.

The addition of both 4MC and 4MBQ also caused an increase in the formation of AAS, GGS, and Schiff bases. This apparent pro-oxidative effect was similar to the observation of the NEM-blocked β-LG and may be explained by three different mechanisms. First, it may likely be caused by the elimination of the thiols as oxidation targets or radical scavengers in β-LG, exposing other amino acids to oxidation. Second, phenols may also act as pro-oxidants, forming hydrogen peroxide in the presence of transition metals (Scheme 1). Zhou and Elias[31] showed that 400 μM (−)-epigallocatechin-3-gallate (EGCG) produced 350 μM hydrogen peroxide during 4 days of storage of emulsions in the presence of 25 μM Fe^{3+} (pH 7.0). In the present study, the phenols or quinones (273 μM) and Fe(II) (50 μM) may in a similar manner generate hydrogen peroxide during oxidation as part of a pro-oxidant mechanism. However, 5 mM hydrogen peroxide was added initially as the oxidation initiator, and this concentration indeed exceeds any possible hydrogen peroxide formation by oxidation of the phenols. Previous studies have shown that a similar concentration of whey protein was able to quench 0.45 mM hydrogen peroxide during 3 days of storage.[32] This indicates that any hydrogen peroxide generated by phenol oxidation may be considered insignificant compared to the excess hydrogen peroxide added as an initiator. Finally, besides additions to Cys, quinones may also react, as already mentioned with other nucleophiles, and both Lys and Trp have previously been found as targets.[10] The reaction with amino groups from Lys to yield AQ adducts can occur by two mechanisms: (i) substitution of an aromatic carbon by the 1,4-Michael addition or (ii) formation of a Schiff base, where the oxo group of the quinone reacts with the amino group to yield iminoquinones and the release of water (Scheme 2). As depicted in Scheme 3, the iminoquinone may transform to the iminophenol, which through an oxidative deamination mechanism releases an aminophenol and the corresponding semialdehyde, AAS.[33,34] This carbonyl, in turn, may engage further in advanced reaction pathways to yield Schiff base structures with other amino groups. Extracts from green tea, black tea, and coffee were found to deaminate oxidatively lysine residues of bovine serum albumin in the presence of metal ions, indicating a lysyl oxidase-like activity of the phenolic compounds in the extracts.[34] This pro-oxidant mechanism of certain phenolics has also been described for myofibrillar proteins oxidized *in vitro* by a hydroxyl-radical-generating system[2,35] and also in complex muscle foods.[36] Scheme 3 shows how AAS may be generated through either metal-catalyzed oxidation of Lys (reaction A) or as described above by the oxidative deamination pathway (reaction B). In the present study, the latter pathway seem to be most pronounced, because the presence of phenols and quinones significantly increased AAS and the Schiff base structures in β-LG. Taking these three mechanisms into consideration, the ability of 4MC and 4MBQ to eliminate thiols as an oxidation target and to promote the oxidative deamination pathway may be the major mechanisms behind the apparent pro-oxidative effect of these species toward carbonylation of β-LG.

The chemical structure of 4MC is similar to the B ring of Cat, indicating that the reactivity of the two compounds may be similar. However, the effects of Cat or CatQ were not as clear as that of 4MC or 4MBQ. Neither Cat nor CatQ were found to decrease the concentration of amino groups or thiol groups prior to oxidation. However, significantly lower levels of thiols were detected from day 1 and throughout the *in vitro* oxidation, suggesting other pro-oxidative activities than the TQ adduct formation. The formation of AAS in the presence of Cat or CatQ was found to be higher than that for β-LG alone, indicating again a pro-oxidative activity; however, no significant effect was observed for the formation of GGS, and Schiff bases were only significantly higher at day 12. Utrera and Estévez[35] also found diverse effects of the same phenolic compounds on the different expressions of the oxidative damage caused in proteins by a hydroxyl-radical-generating system. These findings reflect the different chemistry (factors, catalysts, and pathways) behind each of the chemical changes induced in food proteins by oxidants (reviewed by Lund et al.[37]). On the other hand, these results emphasize the specificity of certain phenol−protein interaction mechanisms. For instance, the lysyl oxidase activity of certain phenols is only applicable to alkaline amino acids and promote carbonylation (pro-oxidant effect), while the effect of the same phenolic compound on thiol residues may lead to a different outcome (i.e., antioxidant, pro-oxidant, or no effect at all).

4.3. Redox Chemistry of Phenols and Quinones. No difference was observed between the addition of Cat or CatQ for all protein oxidation products evaluated throughout 20 days of *in vitro* oxidation, indicating that the redox state of Cat did not affect the oxidation of β-LG. This is interesting, because the overall antioxidative activity as determined by the CUPRAC assay showed a large variation between Cat and CatQ (dark gray bars in panels B−E of Figure 2). Indeed, the reducing capacity of Cat was found to be 4-fold higher than the reducing capacity of CatQ, because 1 mol of Cat or CatQ corresponded to 2.4 or 0.6 mol of Trolox, respectively. In contrast, the reducing capacity for 4MC was 1.7-fold higher than that for 4MBQ. The reducing capacity observed for Cat is close to previously published data, showing that 1 mol of Cat corresponded to 3.1 mol of Trolox.[38] The presence of β-LG in the present study was not found to influence these ratios, but the results indicate that the oxidation to the quinoic structures had a larger impact on Cat than on 4MC.

The lack of coherence between the results of the CUPRAC assay and the determination of oxidation products *in vitro* demonstrates the drawback of antioxidant assays and demonstrates how they rarely provide exact information on the antioxidant capacity of a given system and that the reducing capacity or antioxidant activity is highly dependent upon the oxidation substrate and the actual conditions. However, in the present study, the antioxidant assay may provide information on the reaction between the protein and quinones and the effect that their interactions may have on the given system. For the equimolar concentrations applied during the oxidation of β-LG, the presence of 4MBQ, Cat, and CatQ resulted in antagonistic antioxidative effects in β-LG, whereas 4MC showed an additive affect. Antagonistic effects has previously been observed for quercetin-derivatized bovine serum albumin (BSA), where covalent attachment between the phenol to the protein reduced TEAC, as compared to free quercetin.[12]

The formation of covalent TQ or AQ adducts may explain the antagonistic effects because the reaction between the quinone and a nucleophile results in the substitution at a carbon in the aromatic ring of the quinone. The substitution

DOI: 10.1021/acs.jafc.5b02551
J. Agric. Food Chem. 2015, 63, 8501−8509

reduces the quinone to the hydroquinone, and this substitution is commonly considered as the mechanism by which quinones regenerate in cycles of polymerization reactions with other phenols to yield polymeric compounds. In aqueous media, if no nucleophiles or other phenols are available, quinones are reduced spontaneously in a single-step two-electron two-proton process to yield the phenol,[39] and this may explain why a reducing activity was observed for the quinoic compounds, 4MBQ and CatQ, in the CUPRAC assay in the present study. For each polymerization cycle or nucleophile addition reaction, the ability of the quinone to regenerate is reduced, which leads, in turn, to a less antioxidative activity of the compound. The larger difference in reducing capacity observed between Cat and CatQ (4-fold) than that between 4MC and 4MBQ (1.7-fold) may result from different reduction or polymerization mechanisms. It may be hypothesized that Cat preferably is reduced through polymerization and 4MBQ is reduced through spontaneous reduction in the aqueous media. Spontaneous reduction will not compromise the antioxidative capacity in contrast to polymerization, and hence, less difference between the antioxidant capacity of the phenol and quinone may be observed for 4MBQ.

In the present study, the nucleophile reaction between β-LG and the quinones were simulated by the NEM reaction with the thiol groups, which indeed resulted in a change in oxidation targets in β-LG by promoting AAS and Schiff base formation. The CUPRAC assay also showed that the reducing capacity of β-LG was reduced by blocking the thiol groups with NEM. The decrease in the overall reducing capacity of NEM-blocked β-LG may also explain the antagonistic effect observed for the combination of β-LG and 4MBQ, because TQ adducts were generated in this sample. However, this does not explain the antagonistic effects of β-LG combined with Cat or CatQ because neither amino groups nor thiols were lost in those samples prior to oxidation.

In conclusion, after reaction with 4MC and 4MBQ, β-LG had a decrease of thiol groups by 12 and 60%, respectively, and a 22% decrease in amino groups was found by the addition of 4MBQ. The addition of Cat or CatQ did not lead to any instant decrease in either thiol or amino groups. The oxidative stability of β-LG after reaction with 4MC, 4MBQ, Cat, or CatQ was impaired during 20 days of storage in the presence of Fe(II) and hydrogen peroxide. Especially, the presence of 4MC and 4MBQ served as apparent pro-oxidants, and the changes observed were ascribed to the redirection of oxidation as a result of the blocking of thiol groups but also to the oxidative deamination pathway accelerating the production of semialdehydes and subsequently Schiff base structures. The complex chemistry of the interaction mechanisms between phenols and different protein residues urges the necessity of more mechanistic studies in this field. The pro-oxidant effect and, hence, potential harmful effect of certain phenolic compounds on proteins provide advice toward a more detailed toxicological evaluation prior to use of phenolic compounds for food protection and in dietary supplements.

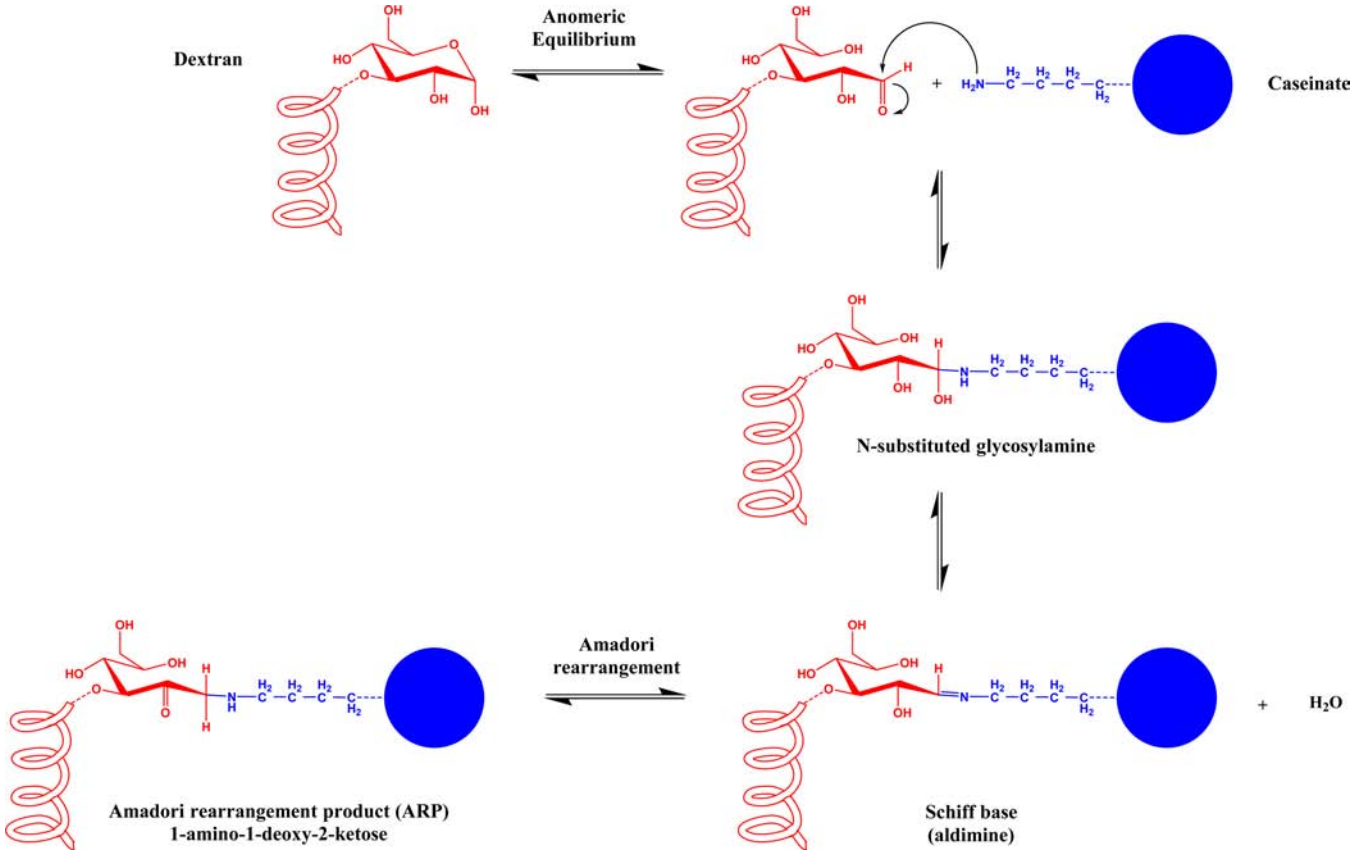

Figure 1. Schematic representation of the Maillard conjugation reaction between the reducing end of a sugar molecule and a free amine group of a protein. This figure only shows the initial phase of the Maillard reaction until the formation of the Amadori products; the further stages of the reaction are not shown.

addition than were emulsions prepared using only β-lactoglobulin.[19,20] Maillard conjugates (MC) between caseinate and maltodextrin have previously been used to stabilize caseinate against precipitation at the isoelectric point.[21] Biopolymer particles fabricated using conjugates of whey protein isolate and maltodextrin displayed better thermal stability than particles produced using nonconjugated biopolymers.[22]

Resveratrol (trans-resveratrol; trans-3,5,4′-trihydroxy-stilbene), a polyphenolic compound that can be isolated from wine byproducts,[23] has been shown to have several potential beneficial effects on human health.[24−26] Nevertheless, its utilization as a nutraceutical ingredient within the food industry is currently limited because of its poor water solubility, low oral bioavailability, and chemical instability.[27−29] There is therefore a need to encapsulate this bioactive component so that it can be used as a functional ingredient in the food and other industries.

On the basis of this background, we hypothesize that the use of MC of caseinate and high-molecular-mass polysaccharides will generate enough steric repulsion to stabilize the zein nanoparticles created by LAS even in the presence of low or zero electrostatic repulsion. Therefore, the aim of the current work was to evaluate the physical stability of zein nanoparticles produced by LAS and coprecipitation with MC of sodium caseinate and polysaccharides with different molecular masses. The physical stability of these particles was assessed under conditions commonly encountered within the food industry, i.e., thermal processing, salt addition, and pH changes. The capacity of this system to encapsulate a grape skin extract (GSE) rich in resveratrol was also assessed by analyzing the encapsulation efficiency. The results of our study will be useful to evaluate the viability of creating stable delivery systems to encapsulate hydrophobic nutraceuticals to enrich a wide variety of food products without compromising their physical quality.

MATERIALS AND METHODS

Materials. Resveratrol standard (purity ≥ 99%), potassium bromide (≥99%), calcium chloride (≥97%), *o*-phthalaldehyde (OPA, ≥ 99%), 2-mercaptoethanol, and dextran (with molecular masses of 37 and 150 kDa) were purchased from Sigma-Aldrich Co. (St. Louis MO, USA). All other chemicals, reagents, and solvents were purchased from Fisher Scientific (Waltham, MA, USA) and were of analytical grade unless stated otherwise. GSE containing 99% resveratrol was purchased from Changsha Organic Herb, Inc. (Changsha, China). Food-grade zein (F4000) was purchased from Flo Chemicals (Ashburnham, MA, USA). Sodium caseinate was purchased from American Caseinate Company (Burlington, NJ, USA). Maltodextrin samples (with a degree of esterification of 6.4 and 17.2 and calculated molecular masses of 1 and 2.8 kDa) were kindly provided by Grain Processing Corporation (Muscatine, IO, USA).

Maillard Conjugate Formation. Sodium caseinate (2.00 w/v %) and the polysaccharides (3.5 w/v %) were individually solubilized overnight at 5 °C in water. The completely solubilized and hydrated samples were subsequently mixed in a 1:1 ratio, which led to a final sodium caseinate concentration of 1.00 w/v %. The mixture was spray-dried (Buchi, Switzerland) using an inlet temperature of 150 °C, a feed rate of 7.5 mL/min, a compressed air pressure of 600 kPa, and an air flow rate of 35 m^3/h.[22] Maillard conjugation reactions were performed by incubating the spray-dried mixture at 60 °C and 76% relative humidity for 48 h.[21,30] After conjugation, the samples were allowed to cool down to room temperature and ground using a mortar and pestle.

DOI: 10.1021/acs.jafc.5b02699
J. Agric. Food Chem. 2015, 63, 8510−8518

The samples were subsequently stored in a desiccator prior to their use.

Maillard Conjugate Characterization. *Conjugation Efficiency.* The conjugation efficiency was determined by measuring the reduction in free amino groups using the OPA assay.[30] The OPA reagent was prepared according to Pan and colleagues.[30] In short, 40 mg of OPA (dissolved in 1.0 mL of 95% ethanol), 25 mL of 0.100 M sodium tetraborate buffer (pH 9.5), 2.5 mL of 20% SDS solution, and 0.10 mL of 2-mercaptoethanol were mixed together and brought to a final volume of 50 mL. The OPA reagent was prepared freshly before use. After dispersing the conjugates, 0.10 mL of the dispersion was mixed with 2.70 mL of OPA reagent and incubated for 1 min at room temperature; the absorbance at 340 nm was measured immediately. The calibration curves were constructed using L-leucine (0.2−5 mM) as a standard amino-group-containing compound.[21,30] The conjugation efficiency was defined as follows:

$$\text{conjugation efficiency (\%)} = \left(1 - \frac{\text{amine groups after conjugation (M)}}{\text{amine groups before conjugation (M)}}\right) \times 100$$

Quantification of Unreacted Protein Using the Lowry Assay. The quantification of the unreacted protein remaining in the system was assessed on the basis of the methodology described by Markman and Livney.[21] The samples were dissolved in double-distilled water at concentrations of 10 mg/mL and subsequently acidified to pH 4.6 with HCl. The sample suspensions were centrifuged at 1000 g for 10 min and then filtered (P5 filter paper, Fisher Scientific, Pittsburgh, PA). The pH of the supernatant was readjusted to 7.0 with NaOH. The protein contents of the suspension (after pH adjustment and before centrifugation) and supernatant were measured by the Lowry method.[31] The amount of protein was subsequently calculated using a calibration curve prepared using sodium caseinate concentrations ranging from 0.2 to 1.0 mg/mL. The conjugation yield was defined as follows:

$$\text{conjugation yield (\%)} = \left(\frac{\text{protein in supernatant (mg/L)}}{\text{protein in the suspension (mg/L)}}\right) \times 100$$

Size Exclusion Chromatography. The conjugation products were analyzed by high-performance size-exclusion chromatography (1260 Infinity, Agilent Technologies, Santa Clara, CA). A 100 μL aliquot of the sample (containing 1.0 w/v % solids) was injected and separated over a OHpak SB-806 M HQ column (Shodex, Showa Denko America Inc., Torrance, CA, USA) at a flow rate of 1.0 mL/min and 20 °C. The mobile phase consisted of 0.200 M NaCl solution. Two detectors were used: a light-scattering detector (Dawn Heleos-II, Wyatt Technology) and a refractive index detector (Optilab, T-rex, Wyatt Technology). The light-scattering data were collected at a cell temperature of 30 °C and with a detector angle of 90°. The cell temperature of the refractive index detector was set to 40 °C.

Fabrication of Nanoparticles. Protein nanoparticles were fabricated by LAS as described in a previous manuscript.[1] Zein (3.0 w/v %) was suspended in 85 v/v % ethanol by stirring for 2 h followed by centrifugation at 9900 g for 12 min. The supernatant was collected, and after overnight storage at 4 °C, it was centrifuged again (9900 g for 12 min) and filtered using filter paper (P5, Fisher Scientific) to remove any precipitated material. The filtered zein solution was subsequently added to the antisolvent at a 1:5 ratio under continuous stirring (440 rpm) at room temperature. Bare zein particles were produced using water (at pH 7.0) as antisolvent, whereas coated particles were produced by coprecipitation in aqueous sodium caseinate and maltodextrin or dextran or conjugate solutions (pH 7.0, final protein concentration of 1.00 w/v %). After addition, the particle suspensions were stirred for an additional 2 min. Ethanol was removed from the mixtures using a rotary evaporator at 30 °C (Buchi RE 111, Flawil, Switzerland). For the nanoparticles loaded with resveratrol, 0.15 w/v % of GSE was added to the solvent phase, i.e., the initial zein solution, stirred for 30 min, and then filtered using Whatman paper (No. 42) prior to particle production. The particle suspensions after the LAS procedure hence contained 0.5 w/v % zein and 0.025 w/v % resveratrol.

Resveratrol Quantification. The resveratrol level contained in the nanoparticles was measured using a UV−vis spectrophotometer (Ultrospec 3000 pro, Biochrom Ltd., Cambridge, UK) at a wavelength of 307 nm. The nanoparticles were dissolved in dimethyl sulfoxide prior the analysis. Nanoparticles without resveratrol were used as blank. Pure resveratrol was dissolved in dimethyl sulfoxide at 100 μg/mL and then diluted to create a calibration curve with concentrations ranging from 0.2 to 6.0 μg/mL.

Characterization of Nanoparticles. *Particle Size and ζ Potential.* Mean particle diameter, polydispersity index, and particle size distribution were obtained using a dynamic light-scattering instrument (Zetasizer Nano ZS, Malvern Instruments, Malvern, UK). The ζ potential was determined by particle electrophoresis using the same instrument. Samples were diluted 40-fold to avoid multiple scattering effects and equilibrated at 25 °C prior to analysis.

Encapsulation Efficiency. The encapsulation efficiency (EE,%) of the nanoparticles prepared by coprecipitation with the physical mixture of caseinate and maltodextrin of 2.8 kDa or dextrans of 37 and 150 kDa as well as those prepared with the Maillard conjugates was determined using the following equation:

$$\text{EE (\%)} = \left(1 - \frac{\text{Res}_\text{F}}{\text{Res}_\text{T}}\right) \times 100$$

in which Res_T is the resveratrol contained in the suspension (M) and Res_F is the amount of free resveratrol (M). The free resveratrol was determined as the amount of resveratrol that was collected by the filtrate receiver after being centrifuged at 1840 g for 60 min using a centrifugal filter (Amicon Ultracel-10 kDa, 2 mL Millipore, Cork Ireland).[6] The recovery yield of resveratrol after passing through the filter (92%) was taken into account to correct the actual amount of resveratrol in the filtrate. The resveratrol contained in the nanoparticles and the filtrate was assessed by diluting the suspension in dimethyl sulfoxide[32] prior to quantification. The suspensions without resveratrol were used as blank samples.

Morphology. The morphology of the conjugated and nonconjugated particles with dextran 37 kDa was analyzed using transmission electron microscopy (2000FX TEM, JEOL, Tokyo, Japan) at a voltage of 200 kV. The sample was diluted 40-fold following the same procedure as that used for the particle size and ζ potential measurements. An aliquot (5 μL) of the diluted sample was drop-cast onto a carbon-coated copper grid (400 mesh). The grid was then air-dried at room temperature before loading it into the microscope. Images of the biopolymer particles were recorded in randomly selected fields.[33]

Particle Stability to Environmental Stresses. *$CaCl_2$ Stability.* After production, the particle dispersions were diluted twofold using $CaCl_2$ solutions (0.0−200 mM) to obtain systems with final $CaCl_2$ concentrations ranging from 0.0 to 100 mM. The samples were then stored for 24 h at room temperature, after which the particle size distribution was analyzed by dynamic light scattering.

Temperature Stability. Freshly prepared particle dispersions were diluted twofold using NaCl solutions (600 and 1200 mM) to obtain systems with final NaCl concentrations ranging of 300 and 600 mM and then incubated in a water bath set at different temperatures (30−90 °C) for 30 min. The samples were then allowed to cool down to 23 °C and were stored for 24 h, after which the particle size distribution was analyzed by dynamic light scattering.

pH Stability. The pH stability of freshly prepared 40-fold-diluted particle dispersions was assessed using an automatic titrator (MPT-2, Malvern Instruments) with NaOH (0.25 M) and HCl (0.10 M) as the titrating base and acid. The particle size distribution and ζ potential were measured from pH 9.0 to pH 3.0 (titrating intervals of 0.5) by dynamic light scattering and particle electrophoresis.

Data Analysis. All experiments were performed at least in duplicate, and the results are given as mean values ± standard deviation.

RESULTS AND DISCUSSION

Conjugation Efficiency and Yield. The conjugation efficiency of the reaction of caseinate with carbohydrates with molecular masses of 1.0, 2.8, 37, or 150 kDa was analyzed by quantifying the unreacted amino groups of the caseinate after the conjugation reaction using the OPA test (Figure 2). The conjugation yield was tested by studying the behavior of the nonconjugated and conjugated protein−carbohydrate samples at the isoelectric point of the protein (pH 4.6). The protein that does not precipitate at this pH is considered to be stabilized by conjugation to the carbohydrate. It is, however, possible that this technique underestimates the real conjugation yield because protein aggregates, although conjugated to dextran molecules, will likely also precipitate under these conditions and hence be considered unconjugated. This technique is also a simple way to purify the conjugated from the nonconjugated proteins (Figure 2).[21] The molecular mass of the polysaccharide had an influence on both the conjugation efficiency and conjugation yield. With an increase in molecular mass of the polysaccharide the conjugation efficiency diminished. The lowest efficiency was reached at 37 kDa, and it did not significantly change upon further increases in molecular mass (Figure 2). Simultaneously, the increase in molecular mass of the polysaccharide substantially increased the conjugation yield. The conjugation of carbohydrates with a higher molecular mass to the proteins clearly stabilized the caseinate proteins against aggregation near the isoelectric point. The conjugation yield, hence, reflects two processes: (i) the conjugation of the carbohydrate and the protein (conjugation efficiency) and (ii) the ability of the carbohydrate to stabilize the protein near its isoelectric point. On the basis of previous studies,[21,30] the average number of amino groups per caseinate molecule available to react with the reducing sugars of the polysaccharides is 13.6. We therefore estimated the average number of carbohydrates conjugated per caseinate molecule in

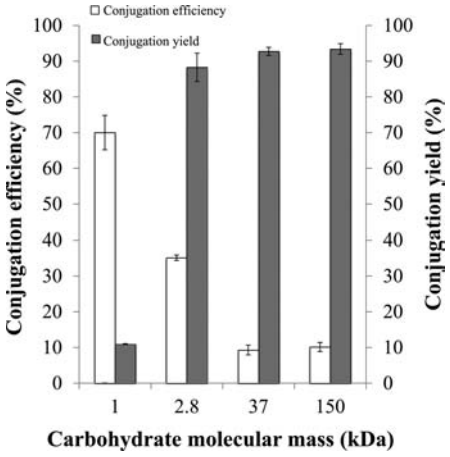

Figure 2. Conjugation yield and efficiency of the conjugation of caseinate to maltodextrin/dextran.

Table 1. Molecular Mass of the Dextran, Nonconjugated Dextran−Caseinate, and Conjugated Dextran−Caseinate Samples as Determined by High-Performance Size-Exclusion Chromatography

	dextran (37 kDa)	dextran (150 kDa)
pure dextran	32 kDa	229 kDa
nonconjugated casein−dextran	34 kDa	231 kDa
conjugated casein−dextran	1402 kDa and 628 kDa	1242 kDa and 682 kDa

Figure 3. Figure 5. Encapsulation efficiency of zein particles loaded with grape skin extract (GSE) prepared with conjugated (Maillard conjugates of sodium caseinate and dextran) and nonconjugated (physical mixture of unreacted sodium caseinate and dextran) biopolymers in the antisolvent [1.0% (w/v)]. The ratio of polysaccharides to sodium caseinate was 1.75 to 1.0. Zein and GSE concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively.

our study to be about 9, 5, 0.7, and 0.7 for the 1.0 and 2.8 maltodextrins and 37 and 150 kDa dextrans, respectively. The reduction in the conjugation efficiency could be explained by an increase in the steric hindrance when longer polysaccharides are conjugated with a protein, reducing the accessibility of the surrounding unconjugated amino groups. The steric hindrance effect using dextrans of 37 and 150 kDa appears to be similar because the number of carbohydrates conjugated per caseinate molecule was equal for both treatments. Furthermore, the molar ratio between the caseinate and the polysaccharides was also reduced by increasing the molecular mass of the carbohydrates, resulting in less reducing sugar ends to conjugate to the protein. The protein−carbohydrate mass ratio used was not changed between the carbohydrate samples because increasing the concentration of the high-molecular-mass dextran to keep the same molar ratio resulted in hazy solutions with incomplete solubilization.

Size-exclusion chromatography confirmed the molecular mass reported by the supplier of the dextrans and showed that the molecular mass of the dextran molecules was not altered by spray-drying the dextran−caseinate mixture (Table 1). The subsequent incubation of the spray-dried caseinate−dextran mixture resulted in the formation of large complexes (Table 1). It was, however, impossible to estimate the ratio of

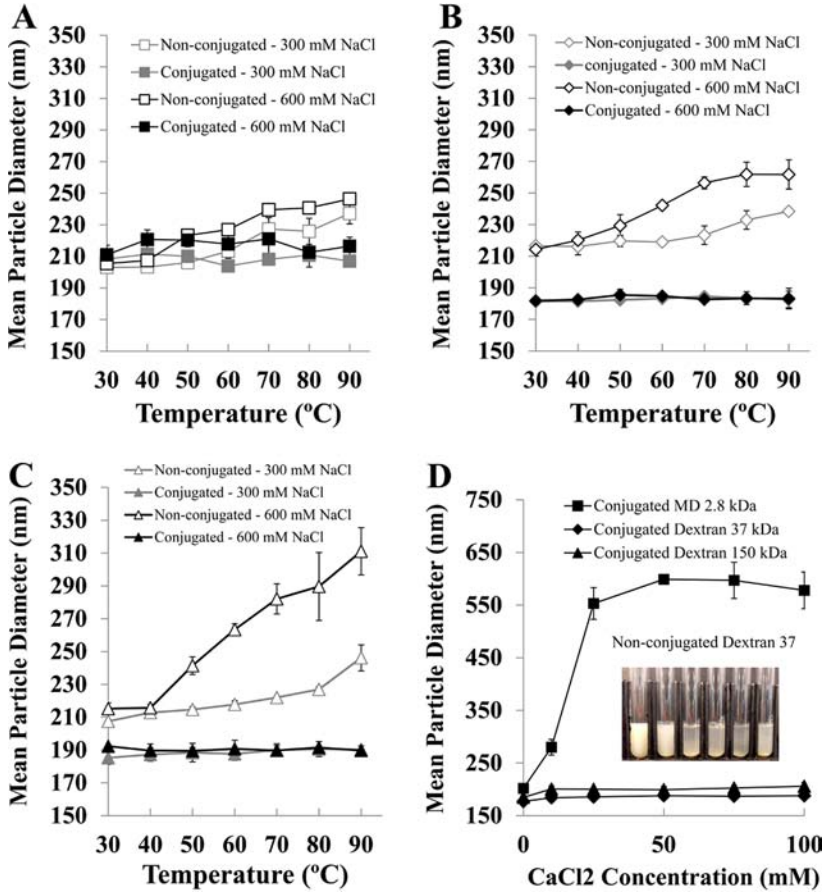

Figure 6. Effect of ions on the particle diameter of zein particles coated with nonconjugated or conjugated caseinate. The particles were incubated in short high-temperature treatments (30 min) and/or elevated salt conditions (300 and 600 mM NaCl and 0−100 mM $CaCl_2$). The effect of the molecular mass of the conjugated carbohydrate was studied for NaCl/temperature treatments (A) maltodextrin (MD) 2.8 kDa, (B) dextran 37 kDa, and (C) dextran 150 kDa and for (D) $CaCl_2$ incubation. Insert in panel D: Appearance of precipitated particles made with the physical mixture of sodium caseinate and dextran 37 kDa in the presence of $CaCl_2$. Zein and GSE concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively.

J. Agric. Food Chem. 2015, 63, 8510−8518

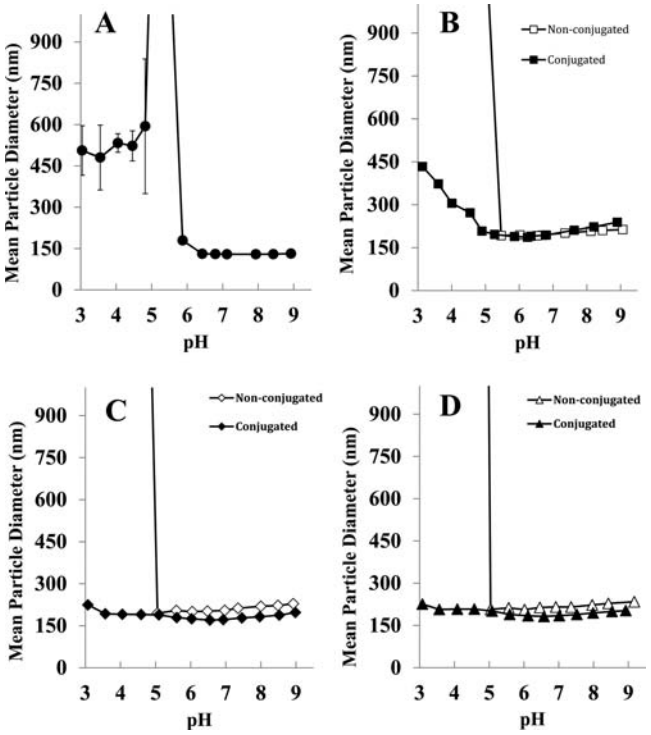

Figure 7. Effect of pH on the mean diameter of (A) plain zein nanoparticles and (B–D) zein nanoparticles prepared with conjugated (Maillard conjugates of sodium caseinate and dextran) and non-conjugated (physical mixture of unreacted sodium caseinate and dextran) biopolymers in the antisolvent (1.0% (w/v)). The effect of the molecular mass of the conjugated carbohydrate was studied as a function of pH: (B) maltodextrin (MD) 2.8 kDa, (C) dextran 37 kDa, and (D) dextran 150 kDa. Zein and GSE concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively.

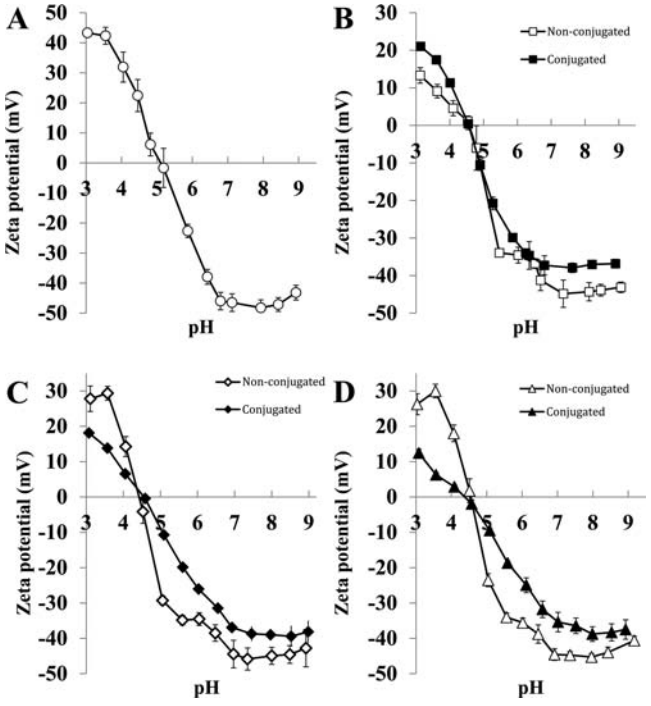

Figure 8. Effect of pH on the zeta potential of (A) plain zein nanoparticles and (B–D) zein nanoparticles prepared with conjugated (sodium caseinate and dextran) and nonconjugated (physical mixture of unreacted sodium caseinate and dextran) in the antisolvent (1.0% (w/v)). The effect of the molecular mass of the conjugated carbohydrate was studied as a function of pH: (B) maltodextrin (MD) 2.8 kDa, (C) dextran 37 kDa, and (D) dextran 150 kDa. Zein and GSE concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively.

caseinate to dextran molecules on the basis of these data because caseinate probably does not occur as single molecules but rather as caseinate aggregates.[34] The broad molecular weight distribution of the signals picked up for the conjugated samples could be ascribed to the presence of a variety of conjugation degrees between the caseinate and the dextran molecules or, more likely, to the aggregation or micellization of unreacted protein in the column.[34,35] Around pH 4.6, nonconjugated caseinate has no or a very low net charge, leading to aggregation and precipitation because of the loss of electrostatic repulsion between the protein chains. After conjugation, the stability of the caseinate–carbohydrate conjugates is believed to be driven by steric repulsion. As clearly shown by the conjugation yield data, the steric repulsion caused by the conjugation with the maltodextrin of 1.0 kDa is not enough to stabilize the protein solution near the isoelectric point of the protein. Increasing the molecular mass of the polysaccharide by approximately threefold already had a sharp effect on the stability of the protein by increasing the recovery yield from 10% to almost 90% at pH 4.6. Further increases in the molecular mass of the polysaccharide resulted in even higher yields of up to 93%.

Particles Characterization. MC of caseinate and carbohydrates with molecular masses of 2.8, 37, and 150 kDa were included in the antisolvent phase to study the effect of the glycation of caseinate on the characteristics and the stability of caseinate-coated zein nanoparticles encapsulating resveratrol produced by LAS. The conjugates formed with maltodextrin of 1.0 kDa were not used for further studies because these polysaccharide chains were not long enough to create the steric repulsion needed to stabilize the caseinate at pH 4.6. The mean particle diameter of the resveratrol-loaded particles created with the conjugates and the nonconjugated physical mixture of caseinate and carbohydrates was subsequently analyzed (Figure 3A). All the samples presented a monomodal particle size distribution (Figure 3C). The mean particle diameter remained relatively stable for particles produced with the nonconjugated mixture of caseinate and carbohydrates. Furthermore, the diameter did not change significantly for the particles coprecipitated with the caseinate–maltodextrin (2.8 kDa) conjugates versus those produced in the presence of the nonconjugated mixture of caseinate and maltodextrin (2.8 kDa).

For the zein particles produced with the antisolvent mixtures containing conjugates of caseinate and the higher molecular mass dextrans (37 and 150 kDa), the mean particle diameter decreased relative to that of those particles coprecipitated with nonconjugated protein–carbohydrate mixtures. The reason for this decrease could be a reduction in the packing parameter and an associated increase in the curvature of the coated nanoparticles. The reduction is a consequence of the increase in the bulkiness of the hydrophilic domains of the caseinate protruding into the environment caused by the attachment of the polysaccharide chains.[21] Another possibility to explain the reduction in size is steric repulsion caused by the carbohydrate structures protruding from the particle surface that restrict particle growth because no other zein or caseinate molecules

DOI: 10.1021/acs.jafc.5b02699
J. Agric. Food Chem. 2015, 63, 8510–8518

can approach the inner core of the particles. The increase in the bulkiness of the conjugates with maltodextrin with a molecular mass of 2.8 kDa is not enough to decrease the packing parameter or ensure enough steric repulsion. Conversely, the zein particles coprecipitated with the nonconjugated mixture of caseinate and dextran (37 and 150 kDa) had an increased particle diameter compared to the ones made with 2.8 kDa maltodextrin. A slight aggregation of the particles caused by depletion flocculation could be responsible for the observed increase in mean particle diameter. The long-chain polysaccharides generated a thermodynamic incompatibility with the nanoparticles, pushing the particles together.[36] Electrophoresis measurements of the particles that coprecipitated with the conjugates and the nonconjugated mixtures of caseinate and carbohydrates indicated that the magnitude of the zeta potential decreased upon conjugation (Figure 3B). The decrease, however, was greater for the conjugates made with the dextrans of 37 and 150 kDa. Lesmes and McClements[19] observed similar results with lipid droplets coated by β-lactoglobulin−dextran MC and hypothesized that the reduction in the zeta potential could be explained by two phenomena. First, the number of ionizable groups at the particle surface is reduced because of the formation of the Amadori compounds that consume free amino groups (Figure 1). Second, the decrease in the apparent zeta potential of the nanoparticles can be due to a screening effect in which the distance between the protein charges and the aqueous continuous phase is increased. The presence of resveratrol did not change the size and zeta potential of the nanoparticles (data not shown), which can be attributed to the fact that it is incorporated into the internal hydrophobic core or embedded in the biopolymer network of the particles. Figure 4 shows the microscopic morphology of zein nanoparticles loaded with resveratrol prepared with nonconjugated and conjugated caseinate with dextran 37 kDa. The particles have a spheroid shape and proved to be stable against aggregation. The size of the conjugated particles is smaller, supporting the results obtained with the dynamic light-scattering instrument. The surface of the nonconjugated particles appears to be rougher and less even than the surface of the conjugated particles. The difference in the surface of the particles can be related to the hypothesized differences in molecular arrangements in the particle structure.

Encapsulation Efficiency. The EE was measured for the particles coprecipitated with the nonconjugated mixture of caseinate and the polysaccharides with molecular masses of 2.8, 37, and 150 kDa and for their conjugates. The EE of the particles produced with the nonconjugated and the conjugated caseinate−carbohydrate samples in the antisolvent all varied around 80 and 85% without a clear tendency of increasing or decreasing EE depending on the evaluated treatments (Figure 5). Therefore, it was concluded that the conjugation of caseinate did not negatively affect the EE. Moreover, the percentages are similar to the ones obtained previously, in which resveratrol was encapsulated in zein particles stabilized by sodium caseinate without the addition of carbohydrates.[1] In that research, it was found that resveratrol could form complexes with sodium caseinate in the system that could be part of the particle coating or be dispersed within the continuous phase as a complementary method of resveratrol encapsulation. It is also know that polysaccharides can stabilize resveratrol in aqueous medium mainly through the formation of hydrogen bonds.[37] This can certainly also contribute to a higher EE of resveratrol in these systems.

Particle Stability. The ultimate goal of the use of protein−polysaccharide conjugates to coat the zein particles was to increase the stability of the final nanoparticles without compromising particle functionality, e.g., EE. We therefore tested the influence of a variety of environmental stresses on the stability of the particles.

Sodium ions were included in the aqueous phase of the nanoparticle suspensions that were then subjected to thermal treatments. The ions shield the surface charges on the particles, hence reducing the electrostatic repulsion between them. This approach also more closely matches the conditions encountered in real-world food systems. In accordance with previous research on caseinate-coated zein particles,[38] the mean diameter of zein nanoparticles made with caseinate and maltodextrin (both nonconjugated and conjugated) did not change appreciably with increasing temperature or high salt concentrations (Figure 6A). For both dextran samples, however, the mean diameter increased with increasing temperature for the nonconjugated samples (Figure 6B,C) and presented a multimodal particle size distribution indicating the presence of aggregates (data not shown). This was more pronounced with increasing salt concentration and increasing molecular mass of the carbohydrate moiety. In nonconjugated samples, free dextran molecules will be found in the suspension that promote depletion flocculation and destabilization of the particle suspensions, resulting in increased particle sizes. In this case, the free biopolymers therefore act as an additional destabilization factor. Depletion flocculation occurs because of steric exclusion of polymers from the particle surfaces, which leads to osmotic pressure gradients that increase the attractive forces between the particles.[39] Previous research already indicated that the critical concentration at which depletion flocculation occurs decreases with the molecular mass of the nonadsorbed polymer.[40] Larger molecules will be more easily excluded from the particle surfaces, and their effect will therefore be more pronounced at lower concentrations (assuming similar properties of the polymers). Particle and biopolymer mobility will be increased by higher temperatures, which will speed up the flocculation process. The conjugation of dextran to caseinate molecules coating the zein particles inhibited destabilization due to depletion flocculation, probably because of steric repulsion and the fact that the free dextran concentration in the conjugated samples was also significantly lower than that in the nonconjugated samples. The mean diameter of the conjugated dextran−caseinate zein nanoparticles did not grow significantly with increasing temperature, even in the presence of elevated salt concentrations (Figure 6B,C), and the particle size distribution remained monomodal.

Calcium chloride, as a divalent salt, has a strong cross-linking and destabilizing effect on biopolymer-based nanoparticles,[41] especially when they are only stabilized by electrostatic repulsion. As outlined above, in general protein particles are mainly stabilized by electrostatic repulsion between the particles. Calcium ions can form salt bridges between anionic protein particles. The increase of the steric repulsion by conjugating carbohydrates to the caseinate molecules coating the zein particles is expected to increase the stability of the nanoparticles. The hairy carbohydrate protrusions hamper the formation of calcium bridges between particles. The particles coated with nonconjugated caseinate destabilized in the presence of calcium ions (Figure 6D insert). Conjugation of the carbohydrate with the lowest molecular mass, i.e., maltodextrin, to the coating caseinate only marginally stabilized

J. Agric. Food Chem. 2015, 63, 8510−8518

the particles against bridging by calcium ions (Figure 6D). Conversely, dextran stabilized the particles against aggregation at elevated calcium concentrations, which can be attributed to the greater steric repulsion generated by the longer carbohydrate molecules (Figure 6D).

Protein particles are especially sensitive to pH changes. Near the isoelectric point of the protein particles, the charge on the particle surface is reduced, which minimizes the electrostatic repulsion between particles and promotes aggregation. Plain zein particles destabilized around pH 5.0 (Figure 7A), where they showed the lowest absolute zeta potential (Figure 8A). This would seriously hamper the use of these protein particles in many food products. Coating of zein particles with caseinate slightly reduced the pH at which the particles aggregated, i.e., to around pH 4.5 (Figure 7B–D),[38] but extensive aggregation still occurred. Conjugation of a carbohydrate to the caseinate coating the zein particles does not significantly affect the isoelectric point of the particles relative to the values found for the nonconjugated samples (Figure 8B–D). However, it did reduce the magnitude of the electrical charge on the particles below and above the isoelectric point. As discussed earlier, this can be attributed to the association of carbohydrates to amino groups on the proteins and to shielding of the particle surface charge by carbohydrate layer. Nonconjugated particles were still destabilized near and below the isoelectric point. However, when the zein particles were coated with caseinate–carbohydrate conjugates, the mean particle diameter did not increase appreciably when the pH was reduced to around and below the isoelectric point. Maltodextrin did not perform as efficiently as the higher molecular mass dextrans. Indeed, the dextran molecules with a molecular mass of 37 kDa were able to completely stabilize the particles against size increments caused by pH effects.

We have shown that the stability of resveratrol-fortified zein nanoparticles can be improved by coating them with MC made from sodium caseinate and neutral carbohydrates. The molecular mass of the carbohydrates used to form the MC had a significant impact on particle stabilization, with the stability of the delivery systems increasing with increasing carbohydrate molecular mass. This is an important result in view of the potential application of zein particles in real-world food applications. The nanoparticles produced in this work were highly stable against environmental stresses that might be encountered by delivery systems in real-life food processing applications, e.g., temperature, pH, and ionic strength changes.

hydroperoxyoctadecatrienoic acid ($C_{18}H_{30}O_4$)	31.3	309.2066	1	291.1972 ($C_{18}H_{27}O_3$; $-H_2O$; hydroxyoctadecadienynoic acid), 171.1029 ($C_9H_{15}O_3$; hydroxynonenoic acid)

Germany. Both samples were stored under vacuum prior to analysis. All other chemicals were purchased from Sigma-Aldrich, Vienna, Austria, and Carl Roth, Karlsruhe, Germany.

Sample Preparation. Green and King's oolong tea infusions were prepared by first adding 50 mL of double-distilled, boiling water to 1 g of dried leaves.[14] After 10 min, the infusion was refilled with water to consider evaporated water and was passed through a Whatman cellulose filter with a pore size of 11 μm and a polyvinylidene fluoride syringe filter with a pore size of 0.45 μm. Additionally, samples were prepared to which 50 μL of $CuSO_4$ (300 mM) was added to freshly prepared tea infusions (50 mL) to yield a 300 μM surplus in copper concentration. After filtration, the samples were stored at −20 °C prior to analysis.

LC-MS Analyses. Analyses of the fatty acid profiles of the tea samples were performed on a Nano-LC system (Dionex Ultimate 3000 RSLC, Thermo Fisher Scientific, Vienna, Austria) coupled to a Nano-ESI-LTQ-Orbitrap mass spectrometer (Thermo Fisher Scientific). The trap column (Acclaim PepMap 100, 100 μm × 2 cm nanoViper, C18, 5 μm, Thermo Fisher Scientific) was loaded with 5 μL of sample, which was separated on a nano LC column (Acclaim PepMap 100, 75 μm × 15 cm nanoViper, C18, 3 μm, Thermo Fisher Scientific). The columns were maintained at 35 °C. The gradient program started with 3% acetonitrile in water acidified with 0.1% formic acid (pH 2.69) and increased to 100% acidified acetonitrile (pH 1.66) after 40 min at a flow rate of 300 nL/min. The ESI-MS was operated in the negative mode, scanning a mass range of m/z 100−1000. Ionization of fatty acids as carboxylate anions might be facilitated in the ESI(−) mode.[15] The capillary temperature and the capillary voltage were set at 300 °C and 3.0 kV, respectively. For structural identification, MS/MS experiments were performed by applying higher energy collisional dissociation with a normalized collision energy of 30%. To avoid cross-contamination, water was run as blank after each sample. Quantitation of 13-hydroperoxy-9*Z*,11*E*-octadecadienoic acid in tea samples was performed by external calibration using standard concentrations in the range of 0.01−1 μM. The ion peak with a m/z of 457.0768 was identified as epigallocatechin-3-gallate, which eluted after 22.8 min, and showed characteristic fragments at m/z 305.067 (gallocatechin) and m/z 169.0143 (gallic acid). The ion peak at m/z 457 was used to quantitate epigallocatechin-3-gallate in tea by applying the external calibration method.

Synthesis of 13-Hydroperoxy-9*Z*,11*E*-octadecadienoic Acid. The synthesis of 13-hydroperoxy-9*Z*,11*E*-octadecadienoic acid was performed with slight modifications according to the method of Schieberle et al.[16] Briefly, 0.64 mmol of linoleic acid was emulsified with 8 mL of 0.1% Tween-80 and approximately 2 mL of 1 M NaOH. The pH was adjusted to 9.0 after the addition of 190 mL of 0.02 M sodium borate buffer (pH 9.0). After cooling on ice, the solution was saturated with oxygen and vigorously stirred for 5 min. To start the enzymatic reaction, 4.2 mg of soy lipoxygenase type I dissolved in 1 mL of borate buffer was added to the substrate. The solution was then vigorously stirred and bubbled with oxygen for 2 h. The reaction was stopped by adding 2 M HCl to adjust the pH to 3.0. The reaction mixture was extracted three times with 200 mL of diethyl ether, and the pooled extracts were washed with 200 mL of double-distilled water and dried with Na_2SO_4. The solvent was removed by rotating evaporation. A purity of 98% was determined by mass spectrometry. The synthesized product, 13-hydroperoxy-9*Z*,11*E*-octadecadienoic acid, was identified by means of ESI(−)MS (m/z 311 and 293) and NMR. ^{1}H NMR (500 MHz, $(CD_3)_2SO$): δ (ppm) 4.40 [q, 1 H, CH, C(13)], 5.42 [m, 1 H, J = 11.1 Hz; CH, C(9)], 5.59 [dd, 1 H, J = 15.0 Hz; CH, C(12)], 5.98 [t, 1 H, J = 11.1 Hz; CH, C(10)], 6.46 [dd, 1 H, J = 15.0 Hz; CH, C(11)]. ^{13}C NMR (500 MHz; $(CD_3)_2SO$, HMBC): δ (ppm) 14.3 [CH, C(18)], 85.1 [CH, C(13)], 128 [CH, C(11)], 129 [CH, C(10)], 133 [CH, C(9)], 134 [CH, C(12)], 175 [COOH, C(1)].[17]

Quantitation of Copper in Tea Samples. Total copper concentrations in tea samples were determined using a PinAAcle 900Z graphite furnace atomic absorption spectrometer (PerkinElmer, Vienna, Austria) as described previously.[18] A volume of 8 mL of 34% HNO_3 (TraceSELECT Fluka) was added to 1 mL of each tea sample and heated to 180 °C in a microwave MARS XPRESS system (CEM Corp., Kamp-Lintfort, Germany). After treatment in the microwave oven, double-distilled water was added, leading to a final volume of 20 mL, which was passed through a 0.2 μm polytetrafluoroethylene filter prior to measurement. The limit of detection for copper was determined to be 0.2 μg/L.

EPR Measurement of Copper Complex. Tea extracts (1 g/50 mL H_2O, 100 °C, 10 min) were incubated with Cu(II) (300 μM) at pH 7.5 and recorded by a Bruker ESP300e EPR spectrometer at room temperature, using a TM_{110} resonator ER 4103 equipped with a quartz flat cell using the following parameters: center field, 3203.5 G; field range, 1507 G; microwave frequency, 9.796 GHz; microwave power, 20 mW; modulation frequency, 100 kHz; modulation amplitude, 10.8 G; receiver gain, 1 × 10^4; time constant, 81.9 ms; conversion time, 81.9 ms; 1024 data points; 5 scans accumulated.

Data Processing. The statistical analysis program XCMS online[19] was applied to identify (i) the fatty acid profile in the tea samples by comparing tea infusions with the water blank, (ii) the difference with regard to fatty acids between green and oolong teas, and (iii) the differences of fatty acid patterns between untreated and copper-treated tea samples. Prior to data processing, the raw data files were converted to the mzXML format using MSConvert.[20] The centWave algorithm was applied for highly sensitive feature detection.[21] A maximally tolerated m/z deviation in consecutive runs of 2.5 ppm and a peak width range of 10−90 s were chosen for feature detection. Retention time correction was performed with the OBI-Warp method.[22] Chromatographic alignment of the mass spectrometry data was defined by (i) a minimum fraction of samples of 0.5 in at least one of the sample groups, (ii) a 5 s bandwidth of the Kernel smoother, and (iii) a m/z 0.015 width of overlapping m/z slices. To minimize the false discovery rate for peak annotations of isotopes and adducts, the parts per million error and the m/z absolute error were set to 5 and 0.015, respectively. The METLIN metabolomics database[23,24] was consulted for structural identification of $[M - H]^-$ adducts. The tolerance for this database search was set to 5 ppm.

Statistical Analysis. All experiments were performed three to four times independently with two technical replicates each. Principal component analysis (PCA) was performed to assess any effects of copper on the fatty acid profile. For identifying the fatty acid profiles, the copper-induced changes in the tea samples, and the differences between tea samples in fatty acid profiles, the unpaired Welch t test was applied. A difference was considered significant when the p value was ≤ 0.01. The signal intensity was $\geq 10^5$ or $\geq 10^6$, as indicated in the table titles and figure captions, and at least 2-fold changes were detected. Differences in copper concentrations between the oolong and green teas were determined by Kruskal−Wallis one-way ANOVA on Ranks, where a p value of <0.05 was considered significant. Differences between non- and copper-treated tea samples with regard to 13-hydroperoxy-9*Z*,11*E*-octadecadienoic acid were calculated by one-way ANOVA, where also a p value of <0.05 was considered significant.

RESULTS AND DISCUSSION

Fatty Acid Profile in Green and Oolong Teas. Tables 1 and 2 show the most abundant fatty acids in the green and oolong tea samples, as identified by high-resolution MS, and MS/MS fragmentation. A total of 13 fatty acids were identified in the green tea, but only 6 fatty acids with a peak intensity of at least 10^6 au were detected in the oolong tea sample. In both the green and oolong tea samples, the vast majority of the fatty acids was already oxidized and appeared as hydroxy or hydroperoxy derivatives of medium- and long-chain saturated and unsaturated fatty acids. By comparing the fatty acid profiles of the green and oolong tea samples, five oxidized fatty acids were identified as having a >2-fold higher abundance in green tea than in oolong tea, although more oxidized fatty acids were expected in the semifermented oolong tea. The most pronounced difference between the green and oolong teas with regard to the oxidized fatty acids was obtained for hydroperoxyoctadecatrienoic acid and hydroxyoctadecatrienoic acid. An at least 2-fold higher abundance of hydroxyundecenoic acid (2.3-fold), hydroxynonenoic acid (4.4-fold), hydroperoxyoctadecadienoic acid (2.3-fold), trihydroxyoctadecadienoic acid (3.4-fold), hydroperoxyoctadecatrienoic acid (16-fold), and hydroxyoctadecatrienoic acid (38-fold) could be shown in the green tea compared to the oolong tea sample.

Copper Content in Green and Oolong Teas. To explain the higher abundance of oxidized fatty acids in nonfermented green tea, which was not subjected to oxidation after harvest, the amount of copper was quantitated. The total copper concentration represents the maximum concentration of copper, which might, however, be partially bound to traces of tea proteins or amino acids, thereby restricting its participation in redox reactions. It could be shown that copper bound to proteins or amino acids led to a reduced formation of reactive oxygen species compared to free copper.[25] In the current study, the total copper concentrations in the green tea and oolong tea infusions were determined by atomic absorption spectroscopy to be 1.52 ± 0.38 and 0.25 ± 0.05 μM, respectively (Figure 1).

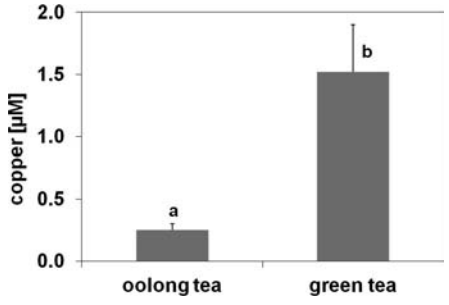

Figure 1. Concentration (μM) of copper in green and oolong tea infusions. Data are expressed as the mean ± SD (n = 4). Different letters indicate statistically significant differences between the tea samples ($p < 0.05$).

Thus, the approximately 6-fold higher copper concentration in the green tea compared to the oolong tea ($p < 0.05$) may be an explanation for the higher abundance of oxidized fatty acids in this sample. Gallaher et al.[26] reported a relatively narrow concentration range of 0.79 ± 0.05 μM copper in various teas, whereas other researchers quantified larger differences among different tea varieties. For example, Wong et al.[11] quantitated a concentration of 0.96 ± 0.17 μM copper in a 1% aqueous

concentration of iron.[27] Other factors may also influence the copper contents of tea infusions. Soil pH influences the uptake of trace metals by tea plants,[28] and elements including copper are more readily taken up from acidic soils.[10,28]

Effect of Copper Addition on the Fatty Acid Profiles in Green and Oolong Tea Samples. In addition to copper in tea infusions, copper in foods consumed together with tea might also affect the profiles of fatty acids and oxidized fatty acids in tea infusions. For example, 28.3 g of beef liver contains 4.13 mg of copper.[29] If this amount is consumed together with 250 mL of tea, a total amount of approximately 16 mg (about 260 μM) of copper would result in the stomach. Thus, to model the effect of copper from other food or nonfood sources on the fatty acid profiles of green and oolong teas, 300 μM $CuSO_4$ was added to freshly prepared tea infusions. It was also aimed to simulate a copper enrichment occurring, for example, as a result of the use of copper-containing pesticides, fertilizers, or equipment during tea production.[10,13] PCA was performed to determine any effects of copper on the fatty acid profile. Figure 2 demonstrates a distinct difference between copper-enriched tea and tea without copper addition. By applying nontargeted profiling, at least 2-fold changes in the abundance of five fatty acids with a peak intensity of a minimum of 10^5 au were caused by the addition of copper to the green tea sample (Table 3). Compared to the untreated sample, copper supplementation of the green tea resulted in significant decreases of methyl tetradecadioic acid (5.8-fold decrease), octadecatetraenoic acid (22-fold decrease), and hydroxyoctadecatrienoic acid (3.3-fold decrease), whereas methyl hydroperoxy bis-epidioxy eicosadienoate (3.0-fold increase) and isopropylhexanoic acid (2.2-fold increase) were increased. In the oolong tea sample, 12 fatty acids with a peak intensity of $\geq 10^5$ au showed at least a 2-fold change as a result of copper addition (Table 4). Most of these were oxidized fatty acids such as hydroxy- and hydroperoxy derivatives. Ten of these were significantly reduced, and only hydroxynonanoic acid and hydroxydecenoic acid were increased. The types of fatty acids affected by the addition of copper to oolong tea were comparable to those in copper-supplemented green tea. The long-chain unsaturated fatty acids were decreased after the addition of copper to oolong tea, the most pronounced effect being observed with hydroxyoctadecadienoic acid (49-fold decrease). Overall, the addition of copper resulted in more pronounced changes in the fatty acid profile in the oolong tea than in green tea. The different susceptibility to oxidation of the fatty acids in green and oolong tea as a result of the copper addition was also observed by quantitative analysis of 13-hydroperoxy-9Z,11E-octadecadienoic acid (Figure 3). Whereas

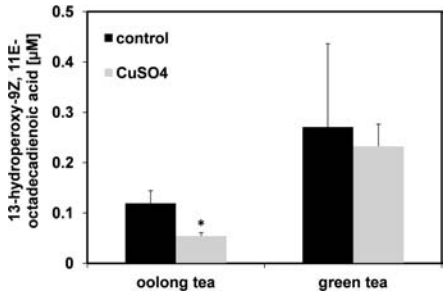

Figure 3. Concentration of 13-hydroperoxy-9Z,11E-octadecadienoic acid in green and oolong tea infusions with or without addition of 300 μM $CuSO_4$. Data are expressed as the mean ± SD (n = 4). The asterisk indicates statistically significant difference versus control (p < 0.05).

copper addition did not induce significant changes in the concentration of 13-hydroperoxy-9Z,11E-octadecadienoic acid in green tea, it resulted in a clear reduction from 0.12 ± 0.02 to 0.05 ± 0.01 μM in the oolong tea. This result suggests that green tea, but not oolong tea, contains substances that might interact with copper to inhibit the copper-induced degradation of the oxidized fatty acids.

Effect of Addition of Copper on the Concentration of Epigallocatechin-3-gallate in Green and Oolong Tea Samples. To investigate a possible cause for the different susceptibilities of the green and oolong tea samples to copper-

DOI: 10.1021/acs.jafc.5b02792
J. Agric. Food Chem. 2015, 63, 8519−8526

induced fatty acid oxidation, changes in the abundance of epigallocatechin-3-gallate, the major polyphenol in untreated tea leaves, were also investigated for the green and oolong tea samples in the presence and absence of 300 μM $CuSO_4$. The green tea polyphenols, such as epicatechin, epicatechin-3-gallate, epigallocatechin, and epigallocatechin-3-gallate, constitute 25−35% of the dry weight of green tea leaves[30−33] and represent approximately 50 mg/g tea infusion,[34] whereas in black tea, the more highly condensed thearubigin and theaflavin represent the main polyphenolic compounds.[35] In the current study, extracted ion chromatograms for m/z 457.0765−457.0780, representing epigallocatechin-3-gallate, are illustrated in Figure 4. Epigallocatechin-3-gallate was approximately 2-fold

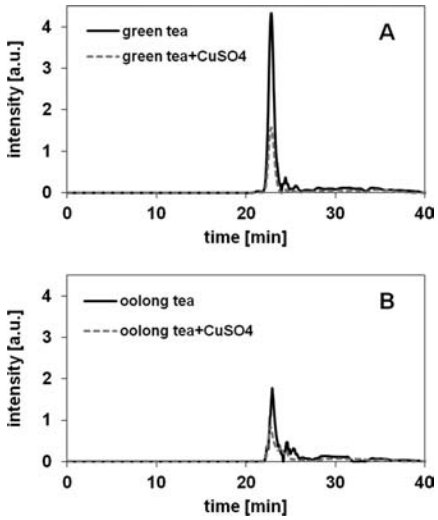

Figure 4. Extracted ion chromatogram of epigallocatechin-3-gallate in green (A) and oolong tea (B) samples in the presence or absence of 300 μM $CuSO_4$ at a mass range of m/z 457.0765−457.0780. Representative chromatogram of four experimental and two technical replicates.

higher in the green tea sample than in the oolong tea sample and is, thus, a candidate for mitigating the copper-induced degradation of oxidized fatty acids in green tea.

The antioxidative activity of tea flavanols has been demonstrated in several in vitro and in vivo studies.[36−38] Higdon and Frei[39] reported a 2−15% increase in plasma antioxidant activity after consumption of tea. In vitro experiments revealed that epigallocatechin-3-gallate is a more effective radical scavenger than other major green tea polyphenols.[38] It has been proposed that catechin polyphenols exert their antioxidant activities by chelating redox-active transition metals, such as copper, thereby preventing the formation of free radical and nonradical oxidation products.[40,41] Mira et al.[41] showed that catechins chelate Cu(II) ions at the *o*-catechol group at pH 7.4. Similar results were obtained by Yoshioka et al.,[42] who confirmed the copper-coordinating activity of catechins by showing that 125 μM epigallocatechin-3-gallate formed a complex with 63 μM Cu(II) ions in phosphate buffer. Furthermore, the green tea polyphenols gallic acid and epigallocatechin-3-gallate tend to form polymeric complexes with Cu(II) at acidic and neutral pH values and precipitate from pure solutions.[43] However, in the present study, the concentration of epigallocatechin-3-gallate was not only substantially decreased by a factor of 2 in the green tea sample (from 252 ± 7.97 to 128 ± 4.00 μM) but also decreased in oolong tea sample (from 129 ± 4.07 to 59.3 ± 1.87 μM) after the addition of 300 μM $CuSO_4$, suggesting that epigallocatechin-3-gallate was not the predominant "antioxidant" source in the green tea sample.

EPR Measurements of Green and Oolong Teas with Cu(II) at Neutral pH. In the present study, the LC-MS experiments did not reveal any copper-derived compounds in the copper-treated teas, possibly because of instability of the complexes during the ionization process in the mass spectrometer. However, EPR measurements by Goodman et al.[44] indicated the formation of a number of Cu(II) complexes in copper-supplemented teas at neutral and weakly acidic pH values. Goodman et al.[44] proposed involvement of tea-containing amino acids, such as theanine, because the EPR results were inconsistent with the formation of soluble Cu(II) chelates of epigallocatechin-3-gallate. Goodman et al.[44] also observed a substantial reduction in the EPR-detectable Cu(II) in tea solutions at these pH values, a result that is consistent with the formation of polymeric species or precipitates as observed in reactions of Cu(II) with solutions of the green tea polyphenols gallic acid and epigallocatechin-3-gallate.[43,45] In the current study, the EPR spectra of all tea extracts were dominated by a six-line signal from solvated Mn(II) (not shown), which has been discussed previously,[44,46] and was subtracted from all spectra to record the Cu(II) signals resulting from the addition of 300 μM $CuSO_4$ (Figure 5). Both

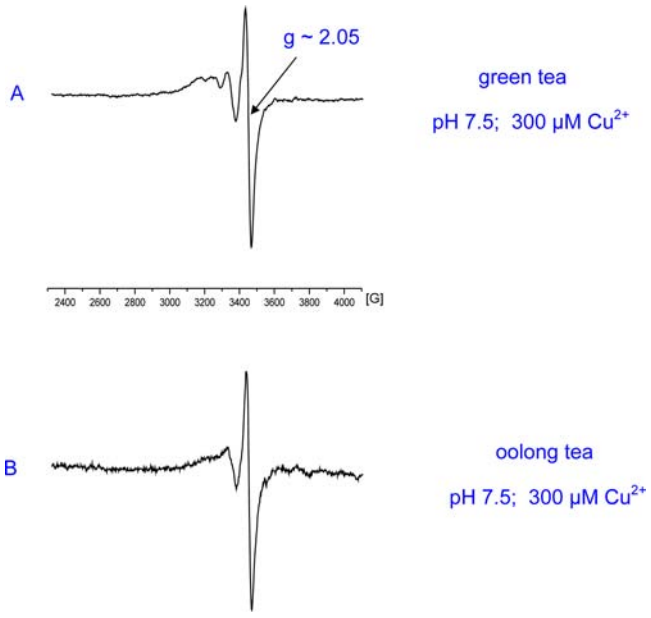

Figure 5. EPR measurements of copper complexes formed at pH 7.5 by adding 300 μM $CuSO_4$ to green (A) or oolong (B) tea infusions.

tea samples showed EPR signals at pH 7.5 that are similar to those reported previously for green and black teas (a_{Cu} = 70 G; g = 2.138).[44] The line width variation in these spectra is the result of incomplete averaging of the anisotropy through molecular motion and is a normal phenomenon in the EPR solution spectra of Cu(II) complexes. In addition, the better resolution of the spectrum from the green tea sample compared to that from the oolong tea is indicative of more rapid molecular motion and, hence, a lower molecular mass complex. Because the EPR signals of the individual Cu complexes could be obtained only after a series of spectral subtractions, the

DOI: 10.1021/acs.jafc.5b02792
J. Agric. Food Chem. 2015, 63, 8519−8526

reported values for the spectral parameters must be considered to be approximate, because unequivocal assignment to a specific complex was not possible. However, the parameters obtained from the green tea spectrum are consistent with Cu(II) bis(amino acid) complexes[47] and the bis complex of Cu(II) with theanine showing solution spectral parameters of a_{Cu} = 70 G and g = 2.135.[44] Polyphenols, on the other hand, tend to form EPR-silent complexes and precipitate in solutions around neutral pH, and although a spectrum was observed with Cu(II)/epigallocatechin-3-gallate solutions,[43] it has greater line width anisotropy than that observed with the green tea solution. Therefore, the spectrum in Figure 5A does not correspond to a bis complex of Cu(II) with epigallocatechin-3-gallate, although the involvement of catechins in mixed complexes with amino acids cannot be discounted. This tentative assignment to mixed complexes is consistent with the differences between the Cu(II) spectra from the green and oolong teas (Figure 5), because of the overall higher molecular mass of the polyphenolic components in fermented teas.

Thus, green tea polyphenols and other low-molecular-weight compounds, such as amino acids, might help to protect the oxidized fatty acids from copper-induced degradation (Figure 6). A redox reaction of oxidized fatty acids or polyphenols with

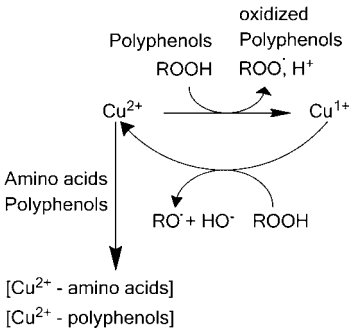

Figure 6. Proposed reaction explaining the fate of oxidized fatty acids in the presence of cupric sulfate in non- and semifermented teas.

Cu(II) resulting in the formation of Cu(I) and peroxy radicals[17,48,49] is illustrated in Figure 6. Reoxidation of Cu(I) by hydroperoxides produces alkoxy radicals, which might further decompose into aldehydes.[50] Formation of polymeric Cu(II) species by reaction with green tea polyphenols[43,45] or amino acids[47] could remove Cu(II) from the reaction cycle and, therefore, inhibit the degradation of oxidized fatty acids. However, the higher copper concentration of the green tea sample and the higher abundance of fatty acid oxidation products prior to copper addition might have contributed to the less pronounced effect of copper administration compared to oolong tea.

Overall, the present study suggests that low concentrations of copper, which occur naturally in teas, might contribute to the oxidation of tea fatty acids, whereas higher concentrations of copper may lead to degradation of these oxidized fatty acids. Future mechanistic studies should verify whether copper-induced decomposition of oxidized fatty acids might be hampered by green tea polyphenols and amino acids. Because fatty acids are among the precursors of aroma molecules, such reactions may contribute to the aroma characteristics of tea infusions.

DOI: 10.1021/acs.jafc.5b02792
J. Agric. Food Chem. 2015, 63, 8519−8526

If NPs are not emitting any signal when mixed within food samples, it is difficult to find them. However, some NPs present in food samples, such as carbon dots, could emit fluorescent signals; hence, they can be extracted easily by using size exclusion chromatography. Carbon dots belong to a new class of quantum dot-like NPs that have wavelength-tunable emission properties, good photostability, and biocompatibility.[7−13] They are considered promising candidates for potential biomedical applications because they are safer and nontoxic both in vitro and in vivo.[7,8,14−17] The preparation, physicochemical properties, and applications of carbon dots in metal ion sensing, cell imaging, and photochemical catalysis have been intensively documented worldwide since the original report in 2004.[15,18−20] We have discovered that the fluorescence of Nescafé Original instant coffee originated from the presence of carbon dots,[6] which has motivated us to analyze the presence of carbon dots in other common beverages.

Carbon dots in beverages are being consumed constantly with no known toxicity. Thus, it is reasonable to believe that they may be safely utilized in many biological applications. In this study, the presence of carbon dots in common beverages including fermented beverages (kvass, pony malta, pilsner beer) and sport beverages (Vivant and Profit) were investigated. The extraction methods of carbon dots were established and their fluorescence properties were characterized. The representative carbon dots from kvass were systematically studied, including their surface chemistry, fluorescence lifetime, stability, and cytotoxicity. Their application as bioimaging agents in tumor cells and onion epidermal cells was also explored.

MATERIALS AND METHODS

Materials. Kvass was purchased from Harbin Tyurin in Dawes Food Co., Ltd. (Harbin, China). Pony malta was purchased from Cervecería Nacional Cn S.A. Co. (Guayaquil, Ecuador). Pilsner beer was also purchased from Cervecería Nacional Cn S.A. Co. Vivant Storm was purchased from Corporation Azende S.A. Co. (Guayaquil, Ecuador). Profit was purchased from Industrias Lácteas Toni S.A. (Guayaquil, Ecuador). Quinine sulfate was purchased from Aladdin Reagent Co. (Shanghai, China). Sephadex gel G-25 was purchased from Sigma-Aldrich Co. LLC (St. Louis, MO, USA). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) was purchased from Aladdin Reagents Co., Ltd. (Shanghai, China). Chinese hamster ovary (CHO) cell line was a gift kindly provided by the Institute of Biochemistry and Cell Biology, Shanghai Institute for Biological Sciences, Chinese Academy of Sciences. RPMI-1640 medium was purchased from HyClone Laboratories (Logan, UT, USA). Onion was purchased from the local market. Human tongue squamous carcinoma cell line Tca-8113 was purchased from the Cell Bank of Type Culture Collection of the Chinese Academy of Sciences (Shanghai, China).

Instrumentation. Absorption spectra were recorded at room temperature on a UV-2550 UV−vis spectrophotometer (Shimadzu, Japan). The fluorescence spectra were measured by an LS55 fluorescence spectrometer (PerkinElmer, USA). The steady-state fluorescence and time-resolved fluorescence decays were recorded using a FluoroMax-4 spectrofluorometer (Horiba Scientific Co., Albany, NY, USA) with a 376 nm laser as the excitation source. Transmission electron microscopy (TEM) measurements were performed on a model JEM-2000EX transmission electron microscope (JEOL, Akishima, Japan) for characterization of the shape and size of the carbon dots by deposition on 400-mesh C-coated Cu grids. X-ray photoelectron spectroscopy (XPS) spectra were used to characterize the chemical composition using an Escalab 250 Xi X-ray photoelectron spectrometer (Thermo Scientific, USA). The Fourier transform infrared spectroscopy (FTIR) spectra were measured by VECTOR 22 (Bruker, Germany) with the KBr pellet technique ranging from 500 to 4000 cm^{-1}. Fluorescent microscope imaging was conducted with a laser-based point scanning FV1000 confocal fluorescent microscope (Olympus, Japan), equipped with a 40× objective lens in *xy* mode with 600 × 600 pixel resolution; 405 and 488 nm lasers were used for excitation of carbon dots with emitted light collected between 425 and 475 nm and between 500 and 600 nm, respectively.

Carbon Dots Extraction. Beverages were concentrated and purified. For kvass, 150 mL of sample was added to a beaker and stirred at room temperature for 4 h to remove the gas. The kvass was then lyophilized. To further purify the kvass, 1 mL of the concentrated aqueous solution was added to a Sephadex G-25 column and the fluorescent fractions were collected. Other soluble fractions were retained on the column and eluted after the C-dots were collected. The resulting fluorescent carbon dot fractions (∼20 mL) were further lyophilized and stored in the dark at 4 °C for further characterization and use.

Fluorescence Quantum Yield and Lifetime Measurement. To calculate fluorescence quantum yield (Φ), eq 1 was used

$$\Phi_1 = \Phi_2 I_1 A_2 \eta_1^{\,2} / I_2 A_1 \eta_2^{\,2} \quad (1)$$

where I_1 and I_2 are fluorescence intensities of carbon dots and the quinine sulfate standard, respectively; A_1 and A_2 are optical densities of carbon dots and the standard, respectively; η_1 and η_2 are refractive indices of carbon dots and the standard, respectively. The standard quantum yield of Φ_2 was 0.54 for quinine sulfate at 360 nm in 0.1 M H_2SO_4 (refractive index: $\eta_2 = 1.2$), and carbon dots were dissolved in water (refractive index: $\eta_1 = 1.2$). Absorbance values of each solution in cuvette were maintained under 0.1 at the excitation wavelength to minimize reabsorption effects. Excitation and emission slit widths were both 4.5 nm for the fluorescence spectra measurement. The fluorescence lifetime (τ) of the C-dots was calculated using eq 2[7]

$$\tau = (A_1\tau_1 + A_2\tau_2 + A_3\tau_3)/(A_1 + A_2 + A_3) \quad (2)$$

where A_i is the fractional contributions of time-resolved decay lifetime of τ_i. The average fluorescence lifetime of carbon dots from kvass was calculated to be 10.59 ns.

pH Effect on Fluorescence Intensity. Various pH (pH 2−11) solutions were prepared by adding different amounts of 0.2 mmol/L NaOH solution to the Britton−Robinson buffer consisting of 0.04 M H_3BO_3, 0.04 M H_3PO_4, and 0.04 M CH_3COOH. To 2 mL of Britton−Robinson buffer solution was added 200 μL of carbon dots solution (1 mg/mL), and the fluorescence intensity was recorded with a fluorescence spectrometer using a 330 nm excitation wavelength and a 1200 nm/min scan rate. Measurements were done in triplicate.

Cytotoxicity Assay. CHO cells were seeded in 96-well plates at a density of 5 × 10^3 cells/well and cultured for 24 h in 10% serum containing DMEM (Sigma-Aldrich Co. LLC) supplemented with penicillin (100 units/mL) and streptomycin (100 μg/mL) in a humidified atmosphere with 5% CO_2 at 37 °C. After incubation with different concentrations (0, 0.31, 0.63, 1.25, 2.5, 5.0, 10.0, 20.0, and 40.0 mg/mL, $n = 3$) of carbon dots from kvass for 24 h, 20 μL of MTT (5 mg/mL) reagent was added to each cell well. After further incubation for 3 h, the cells were washed with PBS three times, and 100 μL of dimethyl sulfoxide (DMSO) was added. The optical density (OD) of the mixture was measured at 570 nm using a microplate reader. The cell viability was estimated according to eq 3

$$\text{cell viability (\%)} = (\text{OD}_{\text{treated}}/\text{OD}_{\text{control}}) \times 100\% \quad (3)$$

where $\text{OD}_{\text{control}}$ is measured in the absence of agent and $\text{OD}_{\text{treated}}$ is the intensity of carbon dots from kvass. The viability was expressed as the percentages of viable cells compared to the survival of a control group (untreated cells as controls of 100% viability).

In Vitro Tumor Cell Imaging. Human tongue squamous carcinoma (Tca)-8113 cells were cultured and maintained in DMEM containing 10% FBS, antibiotic−antimycotic solution L-glutamine (2 mmol/L), and nonessential amino acids (1%) in 5% CO_2 at 37 °C. After the cells were trypsinized and seeded in tissue culture plates at an initial cell density of 1 × 10^5 cells/well, they were

DOI: 10.1021/acs.jafc.5b04216

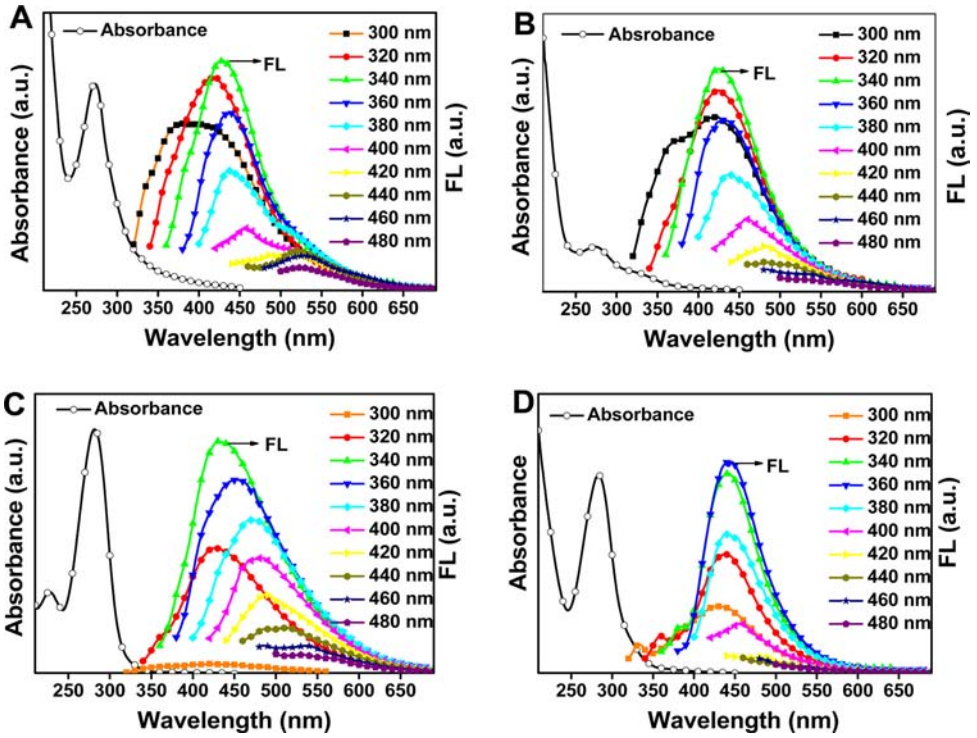

Figure 1. UV−vis absorption and fluorescence (FL) spectra of (A) pony malta, (B) pilsner beer, (C) Vivant, and (D) Profit.

treated with the carbon dots from kvass at a concentration of 10 mg/mL. After incubation at 37 °C for 24 h, the Tca-8113 cells were washed three times with fresh media and imaged with a laser confocal fluorescent microscope with excitation of 405 and 488 nm laser and emission of 425−475 and 500−600 nm for blue and green region imaging, respectively.

Onion Epidermal Cells Imaging. A small piece of the epidermal membrane of a fresh onion was laid flat on the surface of a slide, and 0.9% saline containing 40 mg/mL kvass carbon dots was added. The sample was then covered with a thin glass coverslip ensuring that there were no air bubbles. After 6 h, onion epidermal cells were imaged with a laser confocal fluorescent microscope with excitation of a 405 nm laser, and the collecting wavelengths were 425−475 nm for blue emission.

RESULTS AND DISCUSSION

Extraction of Carbon Dots and Their Fluorescent Properties. The beverages, such as fermented beverages (kvass, pony malta, pilsner beer) and sport beverages (Vivant Storm and Profit), are all common drinks. Carbon dots were extracted from all five beverages by using a size exclusion Sephadex G-25 column. The extraction of carbon dots from the five commercial beverages can be simply done by column chromatographic separation. Sephadex G-25 was used here because it was a well-established gel filtration medium prepared by cross-linking dextran with epichlorohydrin for desalting. The overall production yield of the carbon dots is about 2−5% w/w calculated from the beverages. Similar results were also reported as 2−3% w/w of carbon dots present in bread, jaggery, corn flakes, and biscuit.[2] The aqueous solution of carbon dots from the five beverages exhibited strong fluorescence under excitation of ultraviolet light at 365 nm. The UV−vis absorption and fluorescence spectra of the aqueous solution of carbon dots are shown in Figure 1. A strong absorption feature centered at 275 nm in the UV−vis absorption spectra was observed for all of the carbon dots derived from the four beverages, indicating the presence of aromatic π orbitals. When excited in the range of 300−480 nm, these carbon dots emit fluorescence around 430−450 nm. The emission peaks shift to longer wavelengths accompanied by a remarkable fluorescence intensity decrease. The bathochromic emission phenomenon is consistent with previous reports on carbon dots.[16] Their fluorescent properties are summarized in Table 1. The fluorescent quantum yields of C-dots from the five beverages are in the range of 1.48−11.9%. The morphology of carbon dots from pony malta, pilsner beer, Vivant Storm, and Profit was characterized using TEM by dropping a dilute aqueous solution of the carbon dots on a carbon-coated copper grid. The carbon dots are nearly spherical in shape and well dispersed, with average sizes of 23.5, 39.1, 2.8, and 17.5 nm for pony malta, pilsner beer, Vivant Storm, and Profit, respectively (Figure 2; Table 1). This indicates the presence of nanoparticles in the four beverages. An organic macromolecule that has absorbed a small fluorescence molecule might not be visible in the classic TEM without counterstaining, due to the low contrast of the light elements such as carbon and hydrogen.

Table 1. Fluorescent Properties of the Carbon Dots from Beverages

C-dots	av size (nm)	max ex (nm)	max em (nm)	fwhm (nm)	quantum yield (%)
pony malta	23.5	352	447	100	6.10
pilsner	39.1	329	414	101	1.48
Vivant Storm	2.8	326	399	107	1.90
Profit	17.5	352	447	80	11.90
kvass	5.0	328	411	106	2.22

Pony malta is a nonalcoholic malt beverage. Currently the drink is produced and marketed in several countries in South and Central America, including Colombia, Peru, Ecuador,

DOI: 10.1021/acs.jafc.5b04216
J. Agric. Food Chem. 2015, 63, 8527−8533

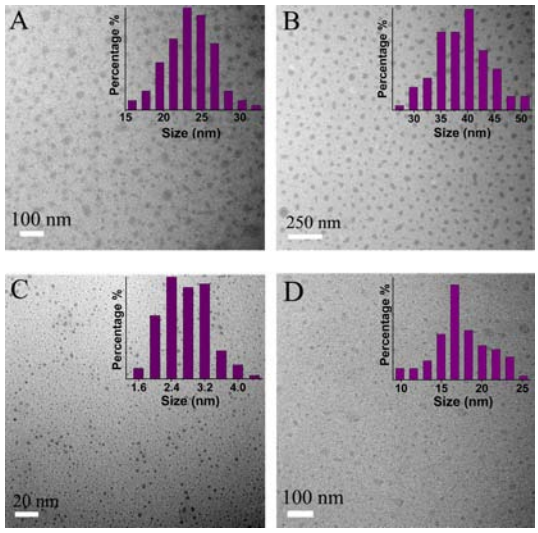

Figure 2. TEM images of (A) pony malta, (B) pilsner beer, (C) Vivant, and (D) Profit carbon dots. (Insets) Corresponding particle size histograms.

Panama, and Venezuela. The beverage is made from barley malt, sugar, fiber, protein, niacin, thiamin, riboflavin, and calcium. The origin of carbon dots from pony malta possibly is due to the heating of the starting materials, such as sugar, which has been reported to form carbon dots in food products.[2] Pilsner beer is an alcoholic beverage produced by the saccharification of starch and the subsequent fermentation of the resulting sugar. The basic ingredients of pilsner beer are water, malt, hops, and yeast. The preparation of beer is called brewing. Any starting materials involved in the heating process could produce the carbon dots. Sugar is a common ingredient in the other two beverages, Vivant Storm and Profit, as well. We believe the origin of carbon dots in all four beverages is due to the heating of sugar during the manufacturing process.

Characterization of Carbon Dots from Kvass. The carbon dots derived from kvass were selected as representative nanoparticles, and their properties were investigated thoroughly. Kvass is a fermented beverage made from black or regular rye bread and is classified as a nonalcoholic drink by Russian and Ukrainian standards, as the alcohol content from fermentation is typically <1.2%. Carbon dots have been found in bread, where the baking process involves heating of the starting materials.[2] Because carbon dots are highly water-soluble, they might be dissolved in the beverage kvass during the fermentation process. Therefore, the origin of carbon dots from kvass could be attributed to the bread. The kvass carbon dots were analyzed by UV−vis and fluorescence spectroscopy, respectively. Figure 3A shows the typical absorption and fluorescence emission spectra measured from the kvass carbon dots in aqueous solution. The absorption spectrum exhibits only one peak around 265 nm, which extends to 500 nm without noticeable fine structures. Similar to previous studies, the peak at 265 nm denotes $\pi-\pi^*$ transition of aromatic C═C bonds.[21] The fluorescence emission spectrum displays an emission maximum at 425 nm for excitation at 360 nm, and the emission wavelength and intensity show clear excitation wavelength dependency, similar to that of previously reported carbon dots.[22] This complex behavior might be associated with a variety of emitting centers present in the carbon dots suspension.[23] It clearly indicates the presence of carbon dots in kvass. The inset in Figure 3A shows the optical image of kvass carbon dots in aqueous solution irradiated by a 365 nm UV lamp, and the fluorescence was strong enough to be seen with the naked eye. A typical luminescence lifetime (τ) was also measured (Figure 3B), where a value of 10.59 ns was obtained. The decay of fluorescence emission was non-monoexponential for the kvass carbon dots suspension. The possible mechanism of fluorescence might be attributed to the radiative recombination of the energy-trapping sites on the carbon dots.[6,18] Using quinine bisulfate (QY = 0.54 in 0.1 M H_2SO_4) as reference, the QY of the kvass carbon dots in aqueous solution was determined to be 2.22%, comparable to previous results.[2]

The TEM image (Figure 4A) illustrates that the kvass carbon dots are spherical in shape and well dispersed, with an average size of 5.0 ± 0.7 nm, in good agreement with sizes of carbon dots observed previously.[6] The TEM result further confirmed

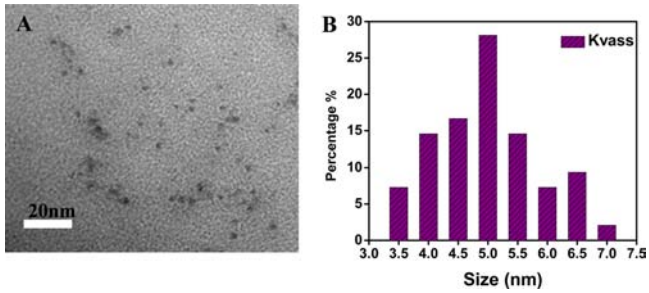

Figure 4. (A) Representative TEM image of kvass carbon dots and (B) particle size histogram.

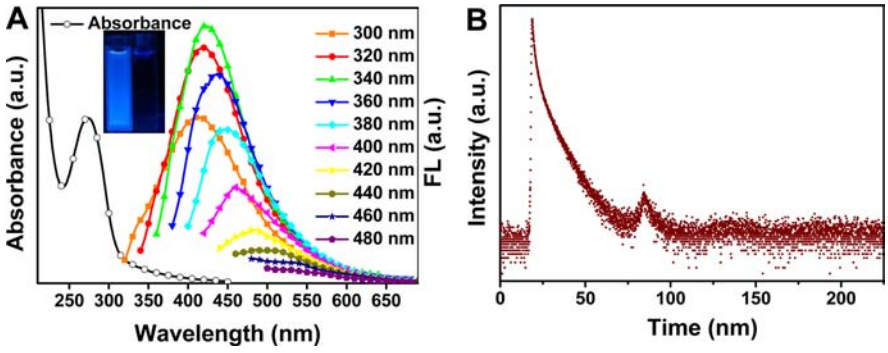

Figure 3. (A) UV−vis absorption and fluorescence (FL) spectra and (B) fluorescence decay curve of kvass carbon dots. (Inset) Photograph of the kvass carbon dot aqueous solution and water under the excitation of UV light.

J. Agric. Food Chem. 2015, 63, 8527−8533

the presence of carbon dots in the kvass beverage. The size distribution of the carbon dots was relatively narrow, with the majority falling within 3.5−7.0 nm based on the statistical analysis of 100 particles (Figure 4B). The ultrasmall size of the kvass carbon dots may facilitate their entry into live cells for bioimaging applications.

XPS elemental analysis revealed the composition of the kvass carbon dots to be C 83.17%, O 13.83%, and N 3.00%, thus indicating these dots are carbon-rich nanodots. Figure 5A

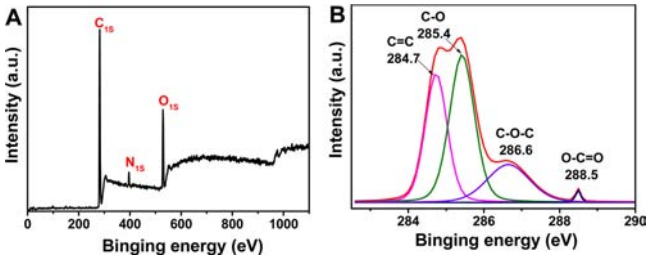

Figure 5. (A) XPS spectrum and (B) high-resolution XPS spectra of C 1s of kvass carbon dots.

shows the XPS spectrum of kvass carbon dots, in which three peaks were observed at 285, 532, and 399.4 eV, corresponding to carbon, oxygen, and nitrogen, respectively. Figure 5B shows the high-resolution C 1s peak of the carbon dots, which could be fitted into four peaks at 284.7, 285.4, 286.6, and 288.5 eV. They were attributed to C═C, C—O, C—O—C, and O—C═O bonds, respectively.[21] These data show that the kvass carbon dots are mainly composed of graphitic carbon (sp2) and carbon defects (sp3), and abundant hydroxy and carbonyl/carboxylate groups are found at their surfaces.[24]

FTIR spectroscopy was used to gain further structural insights about the kvass carbon dots. As shown in Figure 6, a

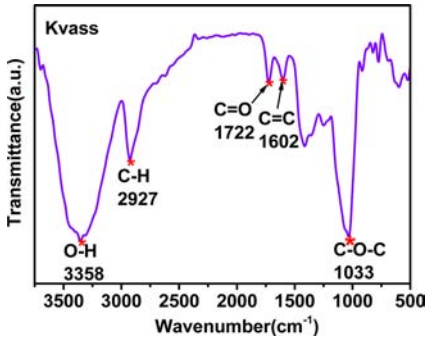

Figure 6. FTIR spectra of kvass carbon dots.

broad and intense peak around 3358 cm^{-1} was attributed to the O—H stretching vibration, indicating the existence of large numbers of hydroxyl groups. The peak at 2927 cm^{-1} corresponds to the C—H vibrations of methylene. The predominant peak of a C═O group at 1722 cm^{-1} and C═C double bonds at 1602 cm^{-1} can also be observed, consistent with the XPS results. Another strong peak with high intensity at 1033 cm^{-1} indicates the existence of aromatic alkoxy bonds in the kvass carbon dots. These results revealed that there are many carboxyl/hydroxyl groups on the surface of the kvass carbon dots. These hydrophilic groups greatly improve the aqueous dispersibility and stability of the carbon dots in aqueous solution and may facilitate their applications in biomedical fields.[21]

Interestingly, the fluorescence intensity of the kvass carbon dots appeared to be pH independent with the pH ranging from 2 to 11. This is quite similar to the carbon dots extracted from Nescafe Original instant coffee,[6] whereas the carbon dots from candle soot displayed a pH-dependent fluorescence intensity.[25] These results indicated that the radiative recombination of the energy-trapping sites on the kvass carbon dots was not affected by changing pH from alkaline to acidic. Moreover, the effect of sodium chloride concentration on fluorescence intensity of the kvass carbon dots was also investigated. When the sodium chloride concentration increased from 0 to 2.5 mol/L, the fluorescence intensity decreased only 20%. The good stability of the kvass carbon dots in a wide range of pH and NaCl concentration suggested that these carbon dots might find good biological applications.

Cytotoxicity Study of the Kvass Carbon Dots. The cytotoxicity of the kvass carbon dots was assessed by MTT assay with CHO cells. Figure 7 shows the cell viability profile

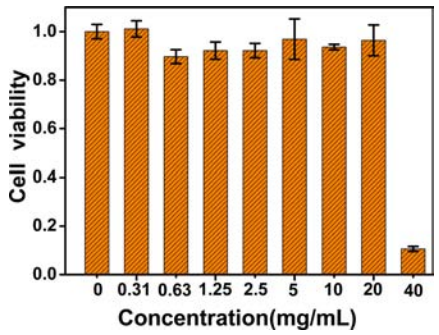

Figure 7. Cytotoxicity of kvass carbon dots with increasing concentrations from 0 to 40 mg/mL in CHO cells. All values are the average of triplicate measurements.

after incubation with the kvass carbon dots at concentrations of 0.31−40 mg/mL for 24 h. The results suggested that the cytotoxicity of the kvass carbon dots was negligible up to a concentration of 20 mg/mL, whereas most of synthesized carbon dots are toxic at 2 mg/mL.[15,17,26] However, the cell viability fell significantly when the concentration of the kvass carbon dots became >20 mg/mL. Overall, the cytotoxicity of the kvass carbon dots was only marginal even at relatively high concentration (20 mg/mL), which makes them suitable for bioimaging applications. Moreover, further experiments are required to study their safety issue for the new carbon nanomaterials in future biomedical applications, although carbon is not considered an intrinsically toxic element.

In Vitro Tumor Cell Imaging. To illustrate the bioimaging potential of the kvass carbon dots, we studied their in vitro uptake by human tongue squamous carcinoma (Tca-8113) cells. Cells were cultured and maintained in DMEM containing the kvass carbon dots for 24 h. Figure 8 shows confocal images of Tca-8113 cells treated with the kvass carbon dots at bright field; excitation wavelengths were 488 and 405 nm, respectively. The human tongue squamous carcinoma cells incubated with the kvass carbon dots became bright at λ_{ex} 405 and 488 nm, as compared to the control cells without the addition of the carbon dots. The fluorescent images of Tca-8113 cells clearly show the agglomeration of blue and green fluorescent carbon dots distributed inside the cytoplasm area of the tumor cells.

DOI: 10.1021/acs.jafc.5b04216
J. Agric. Food Chem. 2015, 63, 8527−8533

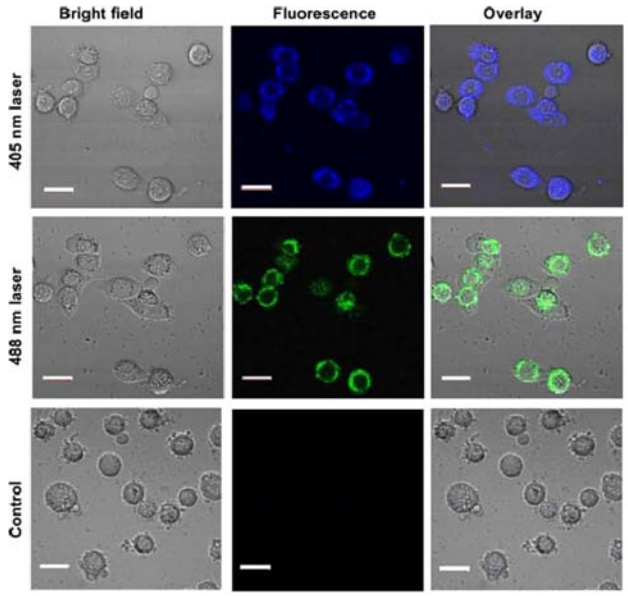

Figure 8. Laser scanning confocal microscopy images of Tca-8113 cells under bright field, by excitation at 488 and 405 nm. Cells without carbon dots were used as a control. Scale bar = 30 μm.

Notably, the excitation-dependent fluorescence of the kvass carbon dots made it possible for multicolor (blue and green) cell imaging.

Onion Epidermal Cell Imaging. The kvass carbon dots were also used for imaging onion epidermal cells inside the onion skin. The kvass carbon dots were directly applied to the onion skin. After 6 h, the onion epidermal cells were imaged at bright field, with an excitation wavelength of 405 nm. As shown in Figure 9, strong fluorescence of the kvass carbon dots was

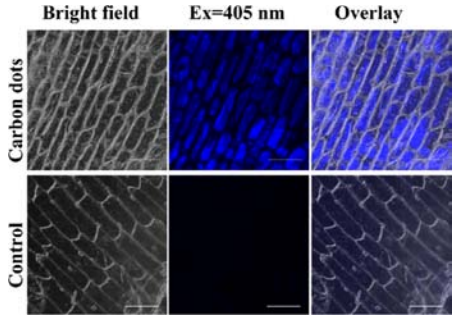

Figure 9. Laser scanning confocal microscopy images of onion epidermal cells under bright field, by excitation at 405 nm. Cells without carbon dots were used as a control. Scale bar = 200 μm.

observed as compared to the control, indicating that the fluorescence was from the carbon dots. It can be clearly seen that the kvass carbon dots were uniformly disturbed in the cytoplasm area, emitting strong blue fluorescence. The carbon dots obtained from kvass can serve as a potential substitute for organic dyes or semiconductor quantum dots in bioimaging.

In the present study, the fluorescent carbon dots were extracted from five beverages, kvass, pony malta, pilsner beer, Vivant, and Profit. TEM analysis demonstrated that the extracted carbon dots are in the nanosize range. Carbon dots from the five beverages exhibited an excitation-dependent emission behavior. XPS elemental analysis revealed the kvass carbon dots are carbon-rich nanodots with excellent pH and ion strength stability and excellent biocompatibility. The kvass carbon dots can be directly applied in the imaging of human tongue squamous carcinoma and onion epidermal cells. The discovery of the NPs in human beverages may provide valuable insights into their safety, distribution, and potential biological imaging applications.

It has recently been proposed that *excipient foods* can be designed to boost the bioavailability of nutraceuticals in fruits and vegetables.[31,32] The type, concentration, and structural organization of the ingredients in an excipient food are specifically selected to enhance nutraceutical bioavailability by altering their bioaccessibility, absorption, and/or transformation in the GIT.[22] The first step in the design of an excipient food involves identifying the major factors that normally limit the bioavailability of the desired nutraceuticals[22] An excipient food is then designed to overcome these factors by incorporating specific ingredients or structures within it.[31]

The objective of the present study was to investigate the utilization of excipient emulsions to increase the bioaccessibility of carotenoids from yellow peppers. Peppers are known to be a good source of carotenoids,[33−35] and so their consumption may be beneficial to human health. The overall bioavailability of carotenoids is often limited due to their relatively low bioaccessibility, which may be due to poor release from the plant cell tissues and/or due to poor solubilization within the GIT fluids.[22] In this study, we examined the effectiveness of oil-in-water excipient emulsions containing either digestible or indigestible lipids on the bioaccessibility of carotenoids from yellow peppers.[36] Our hypothesis was that digestible lipids would be rapidly digested within the small intestine phase of the GIT and form mixed micelles capable of solubilizing any carotenoids released from the yellow peppers. In addition, we examined the influence of lipid phase type, long chain triglycerides (LCT), medium chain triglycerides (MCT), and indigestible oil (orange oil), since this factor has previously been shown to impact the bioaccessibility of carotenoids encapsulated in colloidal delivery systems.[37,38] The information obtained from this study would facilitate the rational design of excipient foods that can boost the bioavailability of health promoting nutrients and nutraceuticals from natural sources.

MATERIALS AND METHODS

Chemicals. Fresh yellow peppers and corn oil (a source of LCTs) were obtained from a local supermarket. Miglyol 812 (a source of MCTs) was obtained from SASOL (Houston, TX). Orange oil (OO, 10× decolorized) was obtained from the Chemistry Store (Cayce, SC). β-Carotene (≥93%), gallic acid (≥99%), lipase (porcine pancreas, type II), bile extract, and calcium chloride were purchased from Sigma-Aldrich (St. Louis, MO). All other chemicals were of analytical grade. All aqueous solutions were prepared using double-distilled water from a water purification system.

Preparation of Excipient Emulsion and Yellow Pepper. An aqueous phase was prepared by dispersing 1.5% nonionic surfactant (Tween 20) in buffer solution (10 mM phosphate, pH7.0). An organic phase was prepared that contained LCT, MCT, or orange oil. A coarse emulsion was then prepared by blending the organic phase (8%, w/w) with the aqueous phase (92%, w/w) using a high-shear mixer (10 000 rpm, 2 min). Excipient emulsions were then formed by passing the coarse emulsion through a microfluidizer (Model 101, Microfluidics, Newton, MA) three times at a homogenization pressure of 9000 psi.

Yellow peppers were cut into small pieces that were used directly ("raw") or were subjected to a thermal treatment ("boiled") by heating them in a pan of boiling water for 5 min. These two treatments were used to take into account that peppers may be consumed raw (e.g., in salads) or they may be cooked (e.g., in sauces).

Simulated Gastrointestinal Tract. The yellow peppers were converted into a puree by grinding with a mortar and pestle to simulate tissue breakdown in the mouth due to mastication. The pureed yellow pepper (6 g) was then mixed with excipient food (6 g of buffer or emulsion), and the resulting mixture was passed through a static simulated GIT:[37,38]

Mouth Phase. Simulated saliva fluid (SSF) was prepared by dispersing mucin and various salts in water and then stirring overnight, as described previously.[39] The pepper/excipient sample (12 g) was then mixed with SSF (12 g), and the system was adjusted to pH 6.8 with sodium hydroxide solution. The resulting mixture was incubated at 37 °C for 10 min with continuous agitation (100 rpm).

Stomach Phase. Simulated gastric fluid (SGF) was prepared by dissolving 2 g of sodium chloride and 7 mL of hydrogen chloride (37%) in 1 L of water and then dispersing 0.064 g of pepsin into 20 mL of this solution followed by stirring for 45 min. The sample resulting from the mouth phase (20 g) was then mixed with SGF (20 g), and adjusted to pH 2.5 with sodium hydroxide solution. The stomach sample was placed in an incubator at 37 °C for 2 h with continuous swirling at 100 rpm to simulate gastric digestion.

Small Intestine. A sample from the stomach phase (30 g) was placed in a temperature-controlled (37 °C) water bath, and the pH value was adjusted to pH 7.0. Then, 4 mL of bile salt solution (187.5 mg/4 mL) and 1.5 mL of simulated small intestine solution (10 mM of calcium chloride and 150 mM of sodium chloride) were added into the mixture, and the mixture was adjusted to pH 7.0. Afterward, 4 mL of freshly prepared lipase suspension (187.5 mg/4 mL) dissolved in phosphate buffer was added to the mixture. The pH of the mixture was monitored, and the volume of 0.25 M NaOH (mL) necessary to neutralize the free fatty acids (FFA) released from the lipid digestion was recorded over 2 h using an automatic titration (pH stat) method (Metrohm USA Inc., Riverview, FL). The percentage of FFA released was calculated using the following equation:

$$\mathrm{FFA}(t) = 100 \times \left(\frac{V_{\mathrm{NaOH}}(t) \cdot C_{\mathrm{NaOH}} \cdot M_{\mathrm{Oil}}}{2 \cdot m_{\mathrm{Oil}}} \right) \quad (1)$$

Here, $V_{\mathrm{NaOH}}(t)$ is the volume of NaOH solution required to neutralize the FFAs produced at digestion time t (L), C_{NaOH} is the molarity of the NaOH solution used to titrate the sample (mol/L), M_{oil} is the molecular weight of the oil (g/mol), and m_{oil} is the total mass of lipid initially present in the incubation cell (g).The molecular weights of the LCT and MCT were taken to be 872 and 492 g/mol, respectively.

Particle Characterization in Excipient Emulsions and Digesta. The mean particle diameter, particle size distribution, and electrical charge of the samples were monitored after exposure to each stage of the simulated GIT. The mean particle diameter and particle size distribution were measured using static light scattering (Mastersizer 2000, Malvern Instruments Ltd., Worcestershire, UK). The samples were diluted in 10 mM phosphate buffer (pH 7.0) prior to measurement to avoid multiple scattering effects. The particle size was reported as the surface-weighted mean diameter (d_{32}). The electrical charge (ζ-potential) on the particles in the samples was measured using a particle electrophoresis method (Nano ZS, Malvern Instruments, Malvern, UK).

Bioaccessibility. The bioaccessibility of β-carotene was determined after each sample had been subjected to the full *in vitro* digestion process using a method described previously.[37,38] After the small intestine stage, raw digesta samples were collected and centrifuged (4400 rpm for 1 h), which resulted in samples that contained a sediment at the bottom with a supernatant above. The supernatant was collected and assumed to be the "micelle" fraction, in which the carotenoids were solubilized. The bioaccessibility was calculated from the concentrations of total carotenoids determined in the micelle fraction and supernatant using a procedure described previously.[37,38] The bioaccessibility of total carotenoids was calculated using the following equation:

$$\mathrm{Bioaccessibility} = 100 \times \left(\frac{C_{\mathrm{Micelle}}}{C_{\mathrm{Raw\ Digesta}}} \right)$$

where C_{micelle} and $C_{\mathrm{Raw\ Digesta}}$ are the concentrations of total carotenoids in the micelle fraction and in the overall sample (raw digesta) after the simulated intestinal digestion experiment, respectively. The carotenoid content of each sample was determined according to the method described previously.[40]

Microstructure Analysis. The microstructure of the samples initially and after exposure to various GIT phases was characterized using optical and confocal scanning fluorescence microscopy (Nikon D-Eclipse C1 80i, Nikon, Melville, NY). The samples analyzed by confocal microscopy were stained with a lipophilic fluorescent dye (Nile Red) to highlight the location of the lipid phase. The Nile red was dissolved in absolute ethyl alcohol at a concentration of 1 mg/mL. Then, before analysis 2 mL samples were mixed with 20 μL of Nile Red solution (1 mg/mL ethanol) to dye the oil phase. All images were captured with a 10× eyepiece and a 60× objective lens (oil immersion).

Statistical Analysis. All experiments were conducted in at least duplicate, and analyses of each sample were also carried out in duplicate. Results are expressed as the mean and the standard deviation of these measurements. Variance analyses were performed by statistical analysis software (SPSS19.0, IBM). Multiple comparisons were conducted to determine the significant differences at the 5% level ($p < 0.05$).

RESULTS AND DISCUSSION

The potential impact of excipient emulsions on the gastrointestinal fate of the nutraceuticals in the yellow peppers was assessed using a static *in vitro* digestion model: mouth, stomach, and small intestine.

Properties of Initial Excipient Emulsions. Initially, the size and charge of the lipid droplets in the excipient emulsions was characterized before mixing them with the raw or boiled pureed yellow pepper samples. The mean particle diameter (d_{32}) of the excipient emulsions containing digestible lipids was relatively small: 0.14 and 0.18 μm for the MCT and LCT emulsions, respectively (Figure 1). In addition, these two emulsions had monomodal particle size distributions (Figure 2c and d) and exhibited no visible phase separation throughout storage for 1 week (data not shown). Optical and confocal microscopy images indicated that the droplets in these emulsions were relatively small and evenly distributed throughout the samples (Figure 3). Thus, microfluidization was an effective means of preparing stable excipient emulsions from these types of triglyceride oils. Conversely, the initial excipient emulsions containing the indigestible lipids (orange oil) had relatively large mean particle diameters (0.64 μm) as measured by light scattering (Figure 1a), and there were some large droplets observed in the particle size distributions (Figure 2b) and microscopy images (Figure 3). After a few hours of storage, the orange oil emulsions separated into a cream layer at the top and a serum layer at the bottom (data not shown). The reason for the relatively large droplet size in these emulsions can be attributed to Ostwald ripening: orange oil is a relatively polar lipid, and so a substantial amount may diffuse from the small droplets to the large droplets due to a thermodynamic driving force associated with differences in interfacial curvature.[41] The resulting increase in droplet size due to this process leads to enhanced creaming and coalescence of the droplets, which accounts for the visual appearance of phase separation.

The lipid droplets in all the excipient emulsions were moderately anionic, with ζ-potentials of −11, −14, and −19 mV for the MCT, LCT, and orange oil emulsions, respectively (Figure 4a). The negative charge on the droplets can be attributed to the presence of anionic impurities (such as free fatty acids) in the nonionic surfactant or lipid ingredients used to fabricate the emulsions.[42]

Influence of Mouth Phase. The pureed yellow peppers (raw or boiled) were mixed with either excipient emulsion (MCT, LCT, or orange oil) or buffer solution (control) and then exposed to simulated mouth conditions. Samples were collected at the end of the incubation period, and then their particle sizes, microstructures, and electrical characteristics were measured (Figures 1−4).

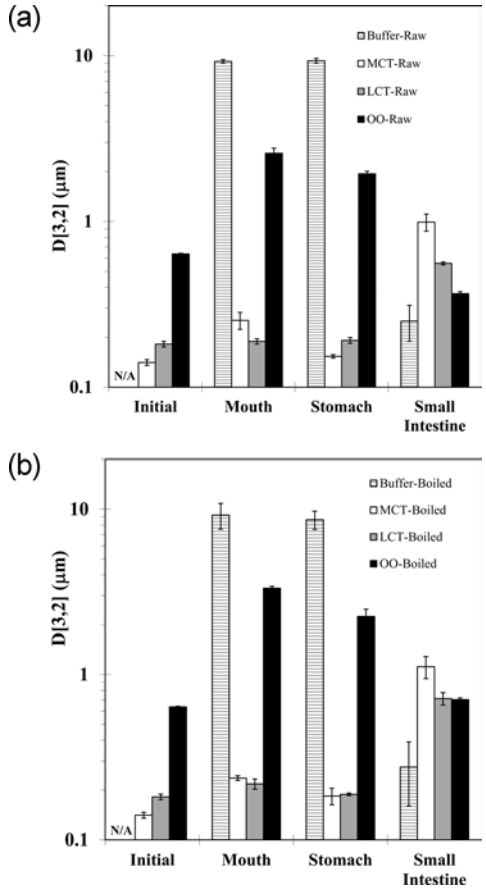

Figure 1. (a) Influence of passage through a simulated GIT on the mean particle diameter (d_{32}) of samples containing raw yellow pepper and either buffer solution (control) or excipient emulsions with different oil types: long chain triglycerides (LCT), medium chain triglycerides (MCT), or orange oil (OO). (b) Influence of passage through a simulated GIT on the mean particle diameter (d_{32}) of samples containing boiled yellow pepper and either buffer solution (control) or excipient emulsions with different oil types: long chain triglycerides (LCT), medium chain triglycerides (MCT), or orange oil (OO).

In the absence of lipid droplets (control), the light scattering measurements indicated that both the raw and boiled yellow pepper samples contained relatively large particles ($d_{32} \approx 10$ μm) after exposure to the mouth phase (Figure 1). These large particles were presumably fragments of yellow pepper generated during the simulated mastication process. Indeed, the optical microscopy images clearly showed the presence of a number of relatively large particles within these samples (Figure 3b and d). There was evidence of bright regions within the confocal microscopy images for the yellow pepper in buffer samples, which suggests that the Nile red dye may have been localized within some hydrophobic regions in the plant tissue (Figure 3a and c). The fragments in both the raw and boiled yellow pepper control samples had fairly high negative charges ($\zeta \approx -18$ mV), which may have been due to the presence of anionic biopolymers (e.g., pectin) at the surfaces of the yellow pepper pieces. Interestingly, the raw and boiled samples

behaved very similarly throughout the GIT (see later). These results suggest that boiling did not have a major impact on the initial size or electrical properties of the yellow pepper fragments. Nevertheless, there are likely to have been other changes that would not be detected by light scattering or microscopy methods, such as tissue softening.

In the presence of the excipient emulsions, the mean particle diameter measured by light scattering was much smaller than that for the yellow pepper alone, particularly for the MCT and LCT samples (Figure 1a and b). Conversely, the optical and confocal microscopy images clearly suggested that there were large particles in these samples (Figure 3). These large particles appeared to be tissue fragments from the yellow pepper, as well as some clumps of droplets. These apparent contradictory results may be attributed to the ability of the mucin molecules from the simulated saliva fluids to promote depletion flocculation of the lipid droplets.[43] The lipid droplets were coated by a nonionic surfactant with a polymeric headgroup (Tween 20), and so one would not expect the mucin molecules to strongly adhere to the droplet surfaces. However, the presence of nonadsorbed biopolymers in the aqueous phase surrounding the droplets generates an osmotic attraction between them that causes them to become flocculated.[44] The forces holding the droplets together in aggregates formed by depletion flocculation are usually relatively weak, and reduced when the sample is diluted and stirred for light scattering measurements. Hence, the droplets may have been highly aggregated in the original samples, but appear to be relatively small in the light scattering measurements. The mixtures containing orange oil emulsions and yellow pepper had much larger mean particle diameters than the ones containing digestible lipids. In addition, the particle size distribution data showed that most of these samples had a bimodal distribution with a population of small particles around 0.1−0.3 μm and a population of large particles around 10 μm (Figure 2b). The small particles were likely to be the lipid droplets, and the large particles, the yellow pepper fragments. The large mean particle size in these samples can be attributed to the contribution of large orange oil droplets formed due to Ostwald ripening.[41] Nevertheless, the microscopy images also indicated that extensive droplet flocculation still occurred under oral conditions, which can be attributed to the depletion flocculation mechanism discussed earlier.

The electrical charges on the particles in the mixed systems were more highly negative than those in the control systems (Figure 4), but they followed a similar trend to those observed in the initial emulsions, with the charge becoming increasingly negative in the following order: control < MCT < LCT <

orange oil. The negative charge on the particles in the mixed systems is due to the fact that they contained a mixture of anionic lipid droplets and anionic yellow pepper fragments.

Influence of Stomach Phase. The samples resulting from the oral phase were incubated in simulated gastric fluids, and then their size, microstructure, and charge were measured (Figures 1–4). In the yellow pepper controls (no lipids), the particle size remained relatively large after exposure to gastric conditions, $d_{32} \approx 10$ μm (Figure 1). Hence, the highly acidic environment of the gastric fluids did not appear to breakdown the yellow pepper tissue fragments. On the other hand, the mean particle diameter remained relatively small in the presence of the digestible lipid droplets (MCT and LCT), which suggests that these droplets were resistant to droplet coalescence under gastric conditions. In addition, the mean particle diameter of the mixtures containing the orange oil emulsions remained relatively high, which can be attributed to droplet growth by Ostwald ripening. The optical and confocal micrographs indicated that the large clumps of droplets observed in the excipient emulsions in the mouth stage were not present after exposure to the gastric phase (Figure 3). The breakdown of these clumps may have been because the emulsions were diluted (1:1) with simulated gastric fluids, which weakened the attractive osmotic forces acting between the droplets, thereby reducing the tendency for depletion flocculation to occur.[44] In addition, the change in solution pH and ionic strength may have altered the relative magnitude of the other attractive and repulsive colloidal interactions operating between the lipid droplets, leading to changes in the tendency for droplets to come together. The particle size distribution data also showed that there was a reduction in the population of large particles after exposure to gastric conditions

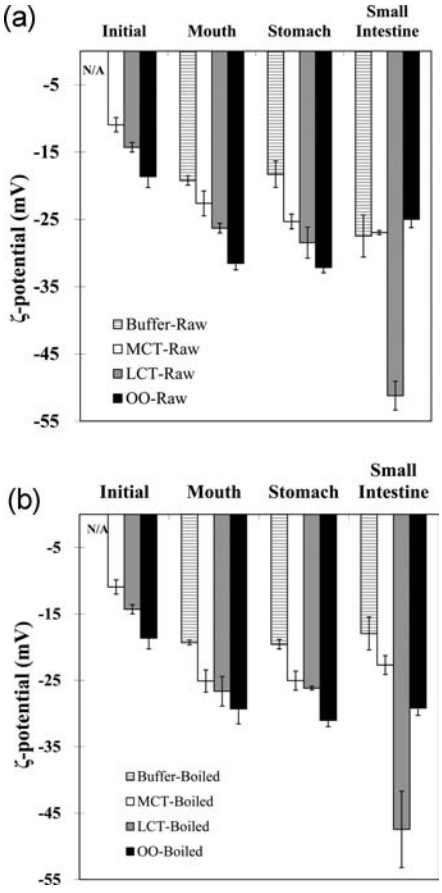

Figure 4. (a) Influence of passage through a simulated GIT on the electrical characteristics of the particles (ζ-potential) of samples containing raw yellow pepper and either buffer solution (control) or excipient emulsions with different oil types: long chain triglycerides (LCT), medium chain triglycerides (MCT), or orange oil (OO). (b) Influence of passage through a simulated GIT on the electrical characteristics of the particles (ζ-potential) of samples containing boiled yellow pepper and either buffer solution (control) or excipient emulsions with different oil types: long chain triglycerides (LCT), medium chain triglycerides (MCT), or orange oil (OO).

(Figure 2). This observation suggests that the presence of the lipid droplets somehow promoted the disruption of the yellow pepper fragments under simulated gastric conditions, although the origin of this effect is currently unknown.

The ζ-potential of the gastric samples was measured under the same solution conditions (pH 7) as those used for the other stages of the simulated GIT, so that alterations in interfacial properties could be directly compared between different samples. The ζ-potential on the particles in all the samples became slightly more negative after they were exposed to stomach conditions (Figure 3), which suggests that there was some alteration in the interfacial composition of the lipid droplets and/or the yellow pepper fragments. This alteration may have occurred due to adsorption of anionic species to their surfaces, such as mucin or pepsin.

Influence of Small Intestine Phase. The gastric samples were then exposed to simulated small intestine conditions and their particle size, microstructure, and charge were measured at the end of the incubation period (Figures 1−4). In the control yellow pepper samples (no lipid), there was an appreciable decrease in the mean particle size measured by light scattering (Figure 1), which may have been due to some breakdown of the yellow pepper fragments, or due to the contribution of particles originating from the small intestine fluids to the light scattering signal (such as mixed micelles formed by bile salts or insoluble aggregates from the lipase extract). The optical microscopy images of both the raw and boiled yellow pepper samples indicate that there were still some large fragments present (Figure 3b and d), which suggests that the small sizes measured by light scattering were probably due to particles arising from the simulated small intestinal fluids. These results highlight the importance of confirming light scattering results using microscopy analysis.

In the presence of lipid droplets, there was an appreciable change in the mean particle diameter after exposure to small intestine conditions: the particle size increased in the mixtures containing digestible lipid droplets, but decreased in the mixtures containing indigestible lipid droplets (Figure 1). This change in particle dimensions can be attributed to the formation of a complex mixture of different colloidal particles that can scatter light, such as undigested lipid droplets, micelles, vesicles, insoluble calcium soaps, and liquid crystals. The number, type, and dimensions of these particles formed is likely to depend strongly on lipid composition. Consequently, it is difficult to interpret the results from light scattering measurements in such complex colloidal mixtures. The optical and confocal microscopy images indicated that various kinds of structures were formed in the small intestinal fluids depending on lipid type (Figure 3). In the orange oil emulsions, there appeared to be a fairly even distribution of relatively small particles spread through the system.

Interestingly, both the raw and boiled yellow peppers, containing MCT emulsions, contained an interwoven network of hair-like structures after digestion. These long thin structures may have been liquid crystals formed from the medium chain fatty acids and other substances in the digesta. To the authors' knowledge this is the first time this kind of structure has been observed, and their origin and nature are currently unknown. The samples that initially contained LCT excipient emulsions contained a number of large lipophilic spheroids after digestion, which may have been undigested fat droplets or large vesicle-like structures. These structures were particularly apparent in the boiled yellow pepper sample. Overall, our microscopy results show that there is a large change in the microstructures formed within the digesta produced in the small intestine phase. Other studies have also indicated that various kinds of structures may be formed in simulated small intestine fluids depending on the nature of the lipid phase used.[45,46]

In the presence of lipid droplets, there was evidence that the population of large particles observed in the particle size distribution was reduced, which also suggested that there was some breakdown of the yellow pepper fragments under simulated small intestine conditions. Cellular disruption may have occurred because the surface-active bile salts, free fatty acids, and monoacylglycerols present in the intestinal fluids penetrated into the plant tissues and disrupted the bonds between them. After exposure to the small intestine phase the system containing MCT emulsions exhibited two major peaks around 0.27 and 46 μm for raw yellow pepper and 0.21 and 35 μm for boiled, respectively. LCT emulsions exhibited two major peaks around 0.16 and 2.2 μm for raw but three major peaks around 0.18, 2.2, and 180 μm for boiled, respectively, which suggests that different kinds of colloidal structures were formed after digestion. These larger particles may have been undigested lipid droplets or liposomes formed from the long

J. Agric. Food Chem. 2015, 63, 8534−8543

chain fatty acids released by lipid digestion or yellow pepper fragments.

The electrical charge on the particles in the small intestine phase was negative for all of the samples studied (Figure 3), which can be attributed to the presence of anionic species in the small intestinal fluids, such as bile salts, free fatty acids, peptides, and mucin. Nevertheless, the negative charge was much higher for the samples containing LCT, which may have been because lipid digestion generated long chain fatty acids that accumulated at the surfaces of the lipid droplets or were incorporated into micelle micelles. Again, the results were very similar for the samples containing raw and boiled yellow pepper.

Lipid Digestion. The digestion of the lipid phase in the mixtures containing excipient emulsions was followed using an automatic titration (pH-stat) method. The volume of alkaline solution that had to be titrated into the reaction vessel to neutralize the free fatty acids (and any other acids) released during digestion of the raw and cooked yellow pepper was measured (Figure 5a and b). These data were then used to calculate the percentage of free fatty acids released from the lipid phase for the two digestible oils, i.e., LCT and MCT (Figure 6a and b). The volume of alkaline determined for the control sample (no lipid) was subtracted from the volume measured for the samples containing digestible lipids prior to making these calculations so as to account for any changes of pH due to the reactants employed.

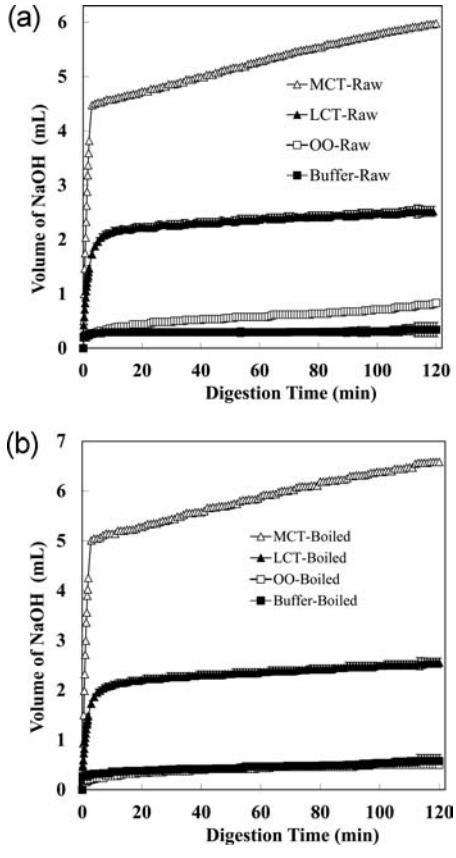

Figure 5. (a) Volume of alkaline solution (0.25 M NaOH) required to maintain the pH at neutral under simulated small intestine conditions: The samples analyzed originally contained raw yellow pepper and either buffer solution (control) or excipient emulsions with different oil types: LCT, MCT, or orange oil. (b) Volume of alkaline solution (0.25 M NaOH) required to maintain the pH at neutral under simulated small intestine conditions: The samples analyzed originally contained boiled yellow pepper and either buffer solution (control) or excipient emulsions with different oil types: LCT, MCT, or orange oil.

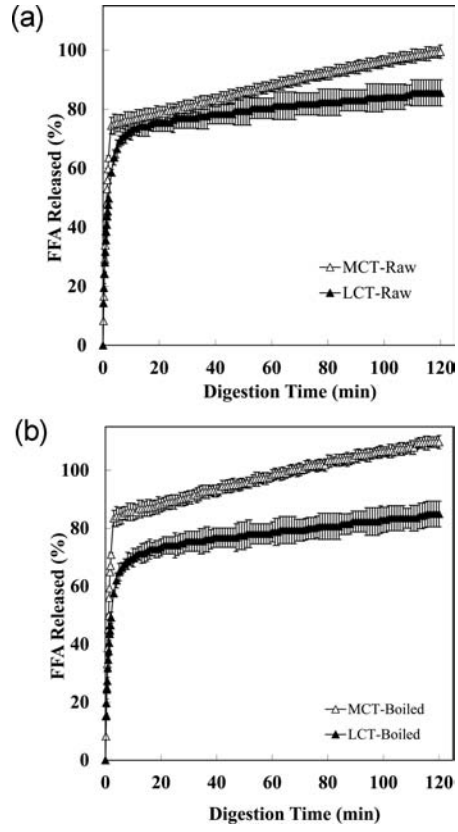

Figure 6. (a) Percentage of free fatty acids released under simulated small intestine conditions for samples initially containing raw yellow pepper and excipient emulsions with different digestible oil types: LCT or MCT. (b) Percentage of free fatty acids released under simulated small intestine conditions for samples initially containing boiled yellow pepper and excipient emulsions with different digestible oil types: LCT or MCT.

In the absence of digestible lipids (control and orange oil sample), there was only a slight increase in the volume of alkaline solution added to the reaction chamber during the course of the experiment (Figure 5), which may be due to the digestion of some components in the reagents (such as bile salts or lipase). The volume of alkaline solution titrated into the mixture containing LCT was appreciably lower than that titrated into the one containing MCT, which is at least partly due to the higher molecular weight of LCT.[47]

For both digestible lipids, and for both raw and boiled samples, there was a rapid increase in free fatty acids released during the first few minutes, followed by a much slower increase at later times (Figure 6a and b). The rate of increase in FFAs released at later times appeared to be higher for the MCT system than for the LCT system. Consequently, by the end of the 2 h digestion period only about 80% of the LCT had been digested, but over 100% of the MCT had been digested. These calculations are based on the assumption that every triglyceride molecule produces two free fatty acids, so that the high value determined for MCT may be because more than two FFAs were released per triglyceride molecule.[48] In addition, previous studies have shown that lipid digestion may be inhibited in LCT emulsions because of accumulation of long chain fatty

DOI: 10.1021/acs.jafc.5b04217
J. Agric. Food Chem. 2015, 63, 8534−8543

acids at the lipid droplet surfaces.[49] These long chain FFAs form a liquid crystalline shell around the lipid droplets that restricts the access of lipase to the remaining triglycerides, thereby inhibiting further digestion. The lipase can continue to function properly once the long chain free fatty acids are removed from the droplet surfaces by solubilization within mixed micelles or by precipitation by calcium ions. It is therefore possible that there was insufficient bile salts or calcium present in the simulated small intestinal fluids used in our study to completely remove all of the long chain FFAs from the LCT droplet surfaces. Finally, at neutral pH not all of the carboxylic acid groups on the fatty acids may be ionized, therefore inhibiting proton release.[48]

Bioaccessibility. Finally, we measured the bioaccessibility of the carotenoids released from the yellow pepper tissue after their passage through the simulated GIT (Figure 7). The

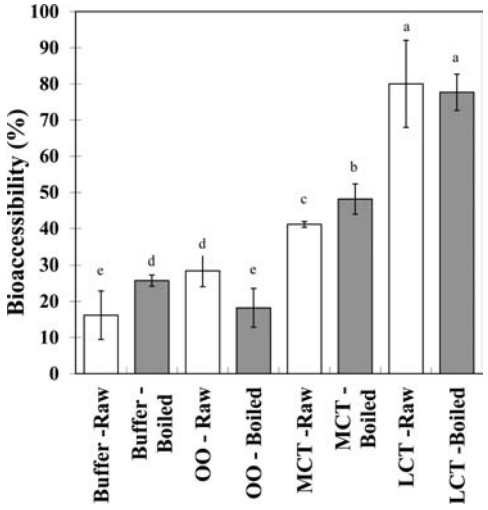

Figure 7. Bioavailability of carotenoids released under simulated GIT conditions from samples initially containing boiled yellow pepper and either buffer solutions or excipient emulsions with different oil types: LCT, MCT, and orange oil.

bioaccessibility was calculated by measuring the carotenoid concentrations in the mixed micelle phase and the total digesta. The bioaccessibility of the carotenoids in the control samples (no lipids) and in the samples containing indigestible oil (orange oil) were relatively low (<30%). This phenomenon can be attributed to the fact that there were no free fatty acids produced that could form mixed micelles with the bile salts and increase the solubilization capacity of the small intestinal fluids. In this case, the carotenoids released from the yellow pepper tissue were probably solubilized in simple micelles that only consisted of bile salts. There was a significant increase in the bioaccessibility of the carotenoids for the yellow peppers (raw and boiled) that had been mixed with the excipient emulsions containing digestible lipids (MCT and LCT). This effect can be attributed to the fact that the free fatty acids produced by lipid digestion were incorporated into mixed micelles with bile salts, which increases the solubilization capacity of the small intestinal fluids.[50] Moreover, the bioaccessibility of the carotenoids was significantly higher for the samples containing LCT droplets than for those containing MCT droplets, which agrees with earlier studies that have reported that the bioaccessibility of carotenoids encapsulated in emulsion-based delivery systems is higher for LCT than MCT.[37,38] This effect can be attributed to the ability of the long chain free fatty acids arising from LCT digestion to form mixed micelles that have hydrophobic regions big enough to accommodate long nonpolar molecules.[45,46] Conversely, the hydrophobic regions in the mixed micelles formed by MCT are insufficiently large to incorporate the carotenoid molecules. This result has important implications for the design of excipient emulsions to boost the bioavailability of large hydrophobic nutraceuticals, such as carotenoids. Boiling the yellow peppers appeared to have little impact on their overall bioaccessibility. In previous studies, it has been reported that certain types of domestic cooking (such as stir-frying) lead to a major improvement in carotenoid bioaccessibility, whereas others (such as boiling) only cause a modest increase.[30] Presumably, the oil used in stir-frying helps to solubilize the carotenoids and to form mixed micelles in the gastrointestinal tract.

In conclusion, this study has shown that excipient emulsions can boost the bioaccessibility of carotenoids in yellow pepper, with the magnitude of the effect depending strongly on lipid phase type. Excipient emulsions fabricated from LCT gave a significantly higher bioaccessibility than those fabricated from MCT, which can be attributed to the greater solubilizing power of mixed micelles formed from long chain fatty acids. Boiling the yellow peppers had little influence on their gastrointestinal fate or on carotenoid bioaccessibility. Overall, these results highlight the potential of designing excipient emulsions to boost the fraction of beneficial nutraceuticals present in natural fruits and vegetables. For example, it may be possible to design an excipient dressing to pour on raw peppers in salads, or an excipient creamy sauce to pour on cooked peppers.

produce more aromatic alcohols per cell than yeast cells at low population density.[4,12]

In the present study, we aimed to correlate our previously implemented quantitative kinetics model to monitor the aromatic alcohols 2-phenylethanol, tryptophol, and tyrosol in *S. cerevisiae*[15] and the expression of the *ARO8*, *ARO9*, and *ARO10* genes. Additionally, we were interested in whether, and to what extent, the parameters to which yeast are exposed during wine fermentation affect the production of these quorum-sensing molecules. Of the multiple stresses that can affect yeast vitality during fermentation, here ethanol stress was selected, with examination of the possible effects on 2-phenylethanol, tyrosol, and tryptophol production. Thus, after ethanol addition to the medium to create stress, the relative expression levels of the *ARO8*, *ARO9*, and *ARO10* genes were compared to the kinetics of the production of these quorum-sensing aromatic alcohols.

MATERIALS AND METHODS

Strains and Inoculum Preparation. This study was performed with the wine-yeast strain *S. cerevisiae* ZIM 1927, which was originally isolated from the must of 'Malvasia' wine grapes. The strain was obtained from the Collection of Industrial Microorganisms (ZIM) at the Biotechnical Faculty, University of Ljubljana, Ljubljana, Slovenia. The preparation of the inoculum and the fermentation were carried out using MS300 synthetic must, as described previously,[16] with some modifications. The medium contained 100 g/L glucose and 100 g/L fructose, and no anaerobic factors were used. It contained also 460 mg/L ammonium chloride, a mixture of 19 amino acids (612.6 mg/L L-proline, 505.3 mg/L L-glutamine, 374.4 mg/L L-arginine, 179.3 mg/L L-tryptophan, 145.3 mg/L L-alanine, 120.4 mg/L L-glutamic acid, 78.5 mg/L L-serine, 759.2 mg/L L-threonine, 48.4 mg/L L-leucine, 44.5 mg/L L-aspartic acid, 44.5 mg/L L-valine, 37.9 mg/L L-phenylalanine, 32.7 mg/L isoleucine, 32.7 mg/L L-histidine, 31.4 mg/L L-methionine, 18.3 mg/L L-tyrosine, 18.3 mg/L L-glycine, 17.0 mg/L lysine, 13.1 mg/L L-cysteine), mineral salts (750 mg/L KH_2PO_4, 500 mg/L K_2SO_4, 250 mg/L $MgSO_4{\cdot}7H_2O$, 155 mg/L $CaCl_2{\cdot}2H_2O$, 200 mg/L NaCl, 4 mg/L $MnSO_4{\cdot}H_2O$, 4 mg/L $ZnSO_4$, 1 mg/L $CuSO_4{\cdot}5H_2O$, 1 mg/L KI, 0.4 mg/L $CoCl_2{\cdot}6H_2O$, 1 mg/L H_3BO_3, 1 mg/L $NaMoO_4{\cdot}2H_2O$), and vitamins (20 mg/L *myo*-inositol, 2 mg/L nicotinic acid, 1.5 mg/L calcium panthothenate, 0.25 mg/L thiamin HCl, 0.25 mg/L pyridoxine HCl, 0.003 mg/L biotin). The medium supports 300 mg of assimilable nitrogen, as provided by 460 mg/L ammonium chloride (corresponding to 120 mg of nitrogen) as well as by the mixture of 19 amino acids (corresponding to 180 mg of nitrogen). The inoculum was prepared aerobically in 100 mL Erlenmeyer flasks on a rotary shaker at 220 rpm constant shaking, at 22 °C. After 48 h of cultivation, the inoculum was centrifuged at 1500*g* and resuspended in 5 mL of fresh MS300 medium. The concentration of the yeast cells was determined by automatic counting of viable cells using ImageJ software, as described previously.[15] The yeast suspensions were diluted with MS300 to obtain two different initial concentrations, 1.2×10^7 cells/mL and a 20-fold dilution for 6×10^5 cells/mL, with 1.5 mL of the inoculated medium distributed in four repetitions into perforated 2 mL microcentrifuge tubes.

Fermentation Conditions. The mini-fermentations were carried out at 22 °C, as described previously.[15] Throughout the 42 h of the mini-fermentations, four of the microcentrifuge tubes were sampled every 2 h, to determine the concentrations of viable cells and quorum-sensing molecules (i.e., 2-phenylethanol, tryptophol, tyrosol), and to collect cell biomass for RNA analysis.

Determination of Viable Cell Concentrations. The viable cell concentrations were determined as described previously.[15] Briefly, 20 μL of the cell suspensions was collected from each fermenter and diluted 1:1 (v/v) with methylene blue. The stained suspension was transferred to a Bürker–Türk hemocytometer, and bright-field microscope images were recorded using an attached camera. The viable cells were then counted using ImageJ software.

Determination of the 2-Phenylethanol, Tryptophol, and Tyrosol Concentrations. The monitoring and kinetics analyses for 2-phenylethanol, tryptophol, and tyrosol were performed as described previously.[15] Briefly, high-performance liquid chromatography (HPLC) analysis was performed using a reverse phase column (XBridge Phenyl, 5 μm, 4.6 mm × 150 mm; Waters) and H_2O/acetonitrile (80:20, v/v) as the mobile phase. Prior to the HPLC analysis, 1 mL of the samples was centrifuged (initially 1500*g* for 5 min, then 6500*g* for 5 min) and filtered through 0.2 μm filters (Phenex, Phenomenex, Italy). 2-Phenylethanol, tryptophol, and tyrosol were detected using a fluorescence detector (Shimadzu RF551, Japan), at their optimal wavelengths of 255/285, 280/368, and 275/315 nm, respectively.

Quorum-Sensing Kinetics. We described the quorum-sensing kinetics with the recently implemented parameter of "production rate", which was calculated on the basis of the data from the measurements of the cell concentrations and the quorum-sensing molecule concentrations. The production rate of the quorum-sensing molecules (R_{QSM}) on the interval (t_1, t_2) was calculated as

$$R_{\mathrm{QSM}\left(\frac{t_1+t_2}{2}\right)} = \frac{\left(c_{\mathrm{QSM}(t_2)} - c_{\mathrm{QSM}(t_1)}\right)}{\left(\frac{c_{t_1}+c_{t_2}}{2}\right) \times (t_2 - t_1)} [\mathrm{fmol/cells/h}] \quad (1)$$

where t is time, c_{QSM} is the concentration of the quorum-sensing molecule, c is the concentration of the cells, and $dc_{QSM}/dt \approx (c\mathrm{QSM}(t_2) - c\mathrm{QSM}(t_1))/(t_2 - t_1)$. To plot R_{QSM}, curve fitting for the concentration of cells and the quorum-sensing molecules was performed, from which 100 data points were generated. These data points from the fitted curves were then used in eq 1.

RNA Isolation. From samples with an initial cell concentration of 1.2×10^7 cells/mL, the total RNA was isolated after 0, 4, 12, 16, 24, and 32 h of cultivation; in samples with an initial cell concentration of 6×10^5 cells/mL, total RNA was isolated after 0, 18, 26, 30, 34, and 38 h of cultivation. RNA was isolated using the commercial Qiagen RNeasy mini kits, as described by the manufacturer. Briefly, cell lysates were prepared using 350 μL of lysis buffer (RLT; Qiagen GmbH) containing β-mercaptoethanol (10 μL/L RLT buffer), acid-washed glass beads (diameter = 420–600 μm; Sigma), and a homogenizer (Bullet Blender Storm, Next Advance). After this, the samples were centrifuged (12000*g*, 10 min) and 900 μL of supernatant was transferred to new centrifuge tubes. To remove the residual DNA, on-column DNase digestion with the RNase-free DNase set (Qiagen) was performed. Total RNA was eluted in 50 μL of RNase-free water (Qiagen) and stored at −80 °C until use.

The quantity and purity of the total RNA were measured with a spectrophotometer (Lambda Bio, PerkinElmer), and visualized by agarose gel electrophoresis.

Reverse Transcription and cDNA Synthesis. The reverse transcription reaction was performed using commercial Superscript VILO cDNA synthesis kits (Invitrogen), according to the manufacturer's instructions, with some modifications. For each single reaction, we combined 2 μL of 5-fold concentrated VILO reaction mix, 1 μL of 10-fold concentrated Superscript enzymatic mix, the RNA, and diethylpyrocarbonate-treated water, to a final reaction volume of 10 μL. The RNA concentrations in the samples were determined spectrophotometrically, and the starting RNA concentration was normalized to 650 ng. The reaction mixtures were successively incubated for 10 min at 25 °C, for 60 min at 42 °C, and for 5 min at 85 °C.

Primer and Probe Design. The primers and probes for the *ARO8*, *ARO9*, and *ARO10* target genes and the *ACT1*, *18S rRNA*, *TEF1* reference genes were designed with the Primer 3 software package.[17] The oligonucleotides and probes used were designed in silico, using the NCBI database. The probes were labeled at their 5′-end using 6-carboxyfluorescein (FAM) and at their 3′-end using 5′-tetramethylrhodamine-5(6)-carboxamide (TAMRA).

Controls. Each sample was analyzed as three biological repetitions and two technical repetitions. To check for residual DNA, each RNA sample was also subjected to a cDNA synthesis reaction without addition of the reverse transcriptase enzyme (NoRT control). When a

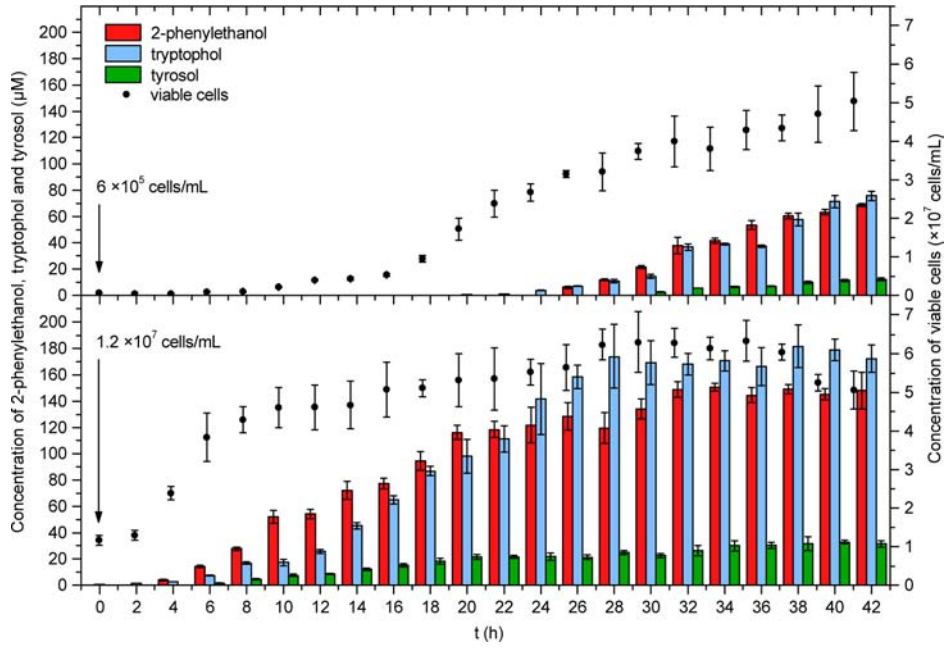

Figure 1. Concentrations of viable cells (circles) and production of 2-phenylethanol, tryptophol, and tyrosol (histograms, as indicated) over 42 h of mini-fermentations with *S. cerevisiae* at the initial cell concentrations of 6×10^5 cells/mL (top) and 1.2×10^7 cells/mL (bottom).

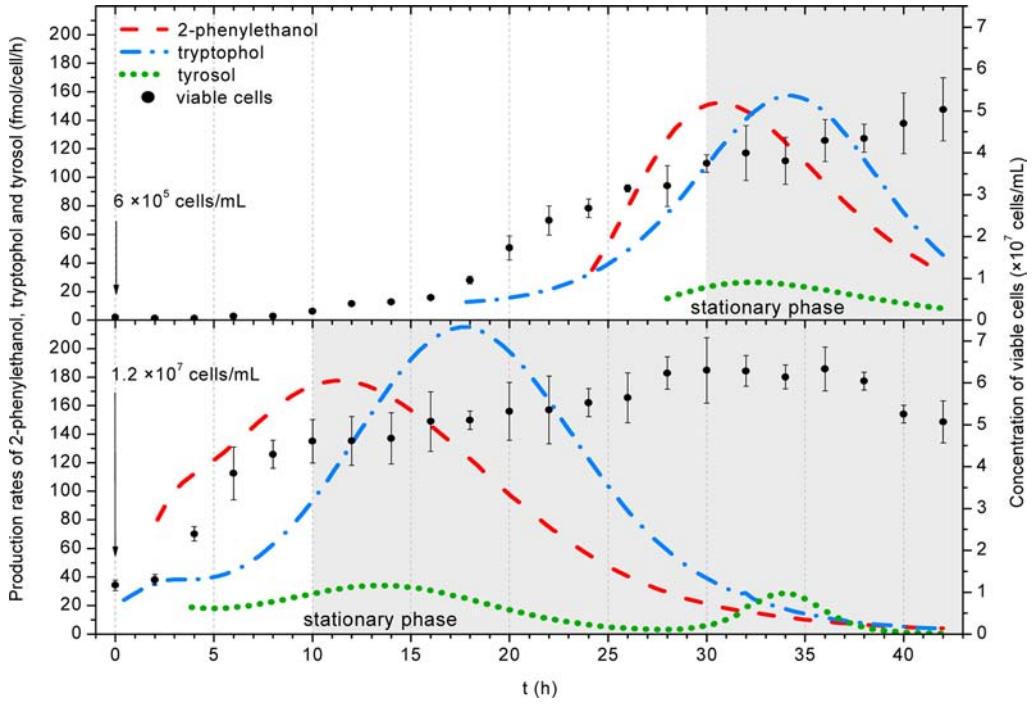

Figure 2. Production rates of 2-phenylethanol (dashed line), tryptophol (dash-dotted line), and tyrosol (dotted line) over 42 h of mini-fermentations with *S. cerevisiae* at the initial cell concentrations of 6×10^5 cells/mL (top) and 1.2×10^7 cells/mL (bottom). The production rates were calculated from concentrations of aromatic alcohols and cells presented in Figure 1.

ΔC_t of >4 between the sample and its respective NoRT control was obtained, the DNA contamination level was considered negligible. Negative control templates consisted of the master mixture with sterile water as the template.

Real-Time Quantitative PCR. Real-time quantitative PCR was carried out with the ABI PRISM 7900 HT Sequence Detection System, using the SDS 3.2 application software (Applied Biosystems). For each reaction, 5 μL of EXPRESS qPCR SuperMix Universal was mixed with 0.02 μL of passive reference dye (ROX), 2.25 μL of 125 nM probe, the optimal oligonucleotide concentration (300 or 600 nM), and nuclease-free water, to give a final volume of 8 μL. The 8 μL reaction mixture and 2 μL of diluted cDNA (final concentration = 1 ng/μL) were transferred to each well of 384-well optical reaction plates (MicroAmp, Applied Biosystems). The following cycle profile was used: one cycle at 50 °C for 15 min, one cycle at 95 °C for 2 min, 40 cycles at 95 °C for 15 s, and 60 °C for 1 min. The C_t values obtained by real-time PCR were quantified using a relative standard curve. For this purpose, a stock solution of cDNA was prepared, from which 2-fold serial dilutions were made.

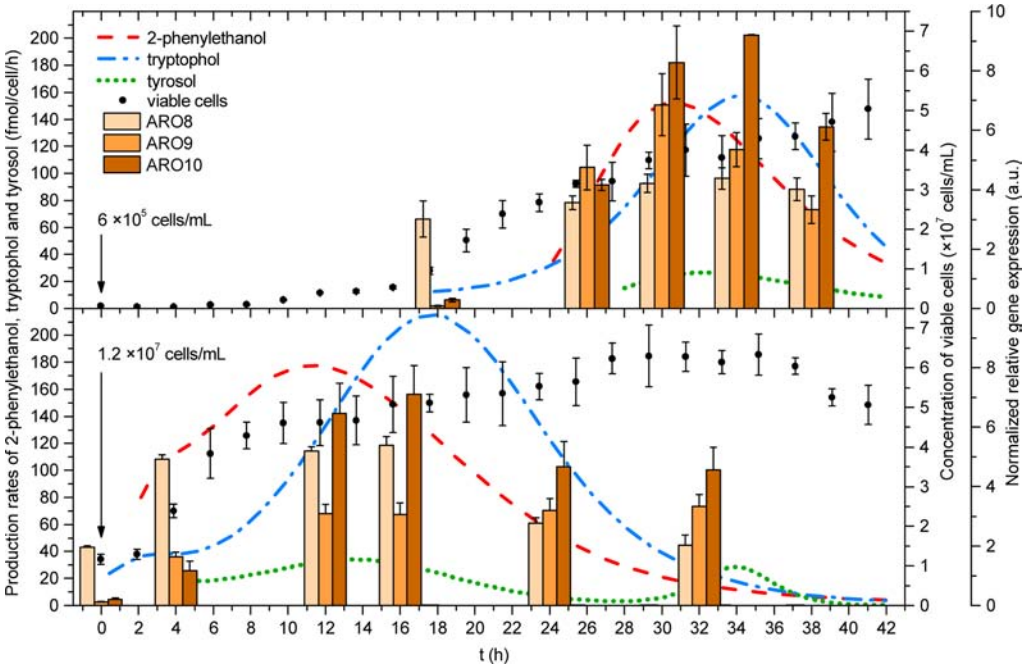

Figure 3. Relative expression of the *ARO8*, *ARO9*, and *ARO10* genes (as indicated) and correlation with the production rates of 2-phenylethanol (dashed line), tryptophol (dash-dotted line), and tyrosol (dotted line) over 42 h of mini-fermentations with *S. cerevisiae* at the initial cell concentrations of 6×10^5 cells/mL (top) and 1.2×10^7 cells/mL (bottom).

Analysis of the Relative Expression Levels of *ARO8*, *ARO9*, and *ARO10*. To analyze the variability of the housekeeping genes used, the software program geNorm^{PLUS} was used.[18] This program calculates first the gene stability measure M (which must be <1.5) for each housekeeping gene used and, second, the normalization factor for the housekeeping genes used, which is applied in the data processing. The relative *ARO8*, *ARO9*, and *ARO10* gene expression levels were normalized to the relative quantities of the three different housekeeping genes using geNorm^{PLUS}.

Effects of Ethanol on *ARO* Gene Expression and Production of Quorum-Sensing Molecules in *S. cerevisiae*. At the start of the mini-fermentations in MS300 medium, where the initial cell count was 2×10^7 cells/mL, 2, 6, 8, and 12% ethanol were added to the medium (as final concentrations). Cell viability and quorum-sensing molecule production was monitored after 0, 4, 8, 12, 24, and 28 h of cultivation and compared to the control sample with no ethanol added. The total RNA was isolated from the control sample and from the sample with initial 2% ethanol, after 0, 4, 8, 12, and 24 h, whereas the RNA was isolated from the sample with initial 6% ethanol after 0, 8, 12, 24, and 28 h, as described above. *ARO8*, *ARO9*, and *ARO10* gene expression levels were compared to the kinetics of the 2-phenylethanol, tryptophol, and tyrosol production.

RESULTS AND DISCUSSION

In our previous study,[15] we claimed that in *S. cerevisiae*, the kinetics of the production of 2-phenylethanol, tryptophol, and tyrosol indicate their involvement in the mechanism of quorum sensing. We showed that the kinetics can be calculated from the concentrations of these quorum-sensing molecules and the viable cells, as we took into consideration that only live cells with active permeases,[19] transaminases, decarboxylases, and reductases[20,21] can produce 2-phenylethanol, tryptophol, and tyrosol. As the mechanism of quorum sensing starts with the activation of the *ARO* genes,[13,14] in the present study, we aimed to correlate the kinetics model that we had previously developed with the expression of the *ARO* genes that are responsible for 2-phenylethanol, tryptophol, and tyrosol biosynthesis (i.e., *ARO8*, *ARO9*, *ARO10*). In addition, to show the correlation of the quorum-sensing kinetics and cell concentration, we conducted two parallel fermentations with low (6×10^5 cells/mL) and high (1.2×10^7 cells/mL) initial concentrations of the yeast cells.

Quorum-Sensing Kinetics in *S. cerevisiae* Correlate with Expression of the *ARO8*, *ARO9*, and *ARO10* Genes. The monitored parameters of the two fermentations with low and high initial cell concentrations are presented in Figure 1. Here, it can be seen that the first quorum-sensing molecules in the medium were detected in both cases when the concentrations of viable cells were between 1×10^7 and 2×10^7 cells/mL (i.e., the quorum was reached), despite the differences in the slopes of the growth curves. To examine the kinetics of these quorum-sensing molecules, eq 1 was used, and the production rates obtained for each quorum-sensing molecule are plotted in Figure 2.

From the peaks of these production rates, the kinetics of the quorum sensing can be determined; namely, at both low and high cell concentrations, cells in the exponential phase started with an intense production of tryptophol, which was then closely followed by 2-phenylethanol. At both cell concentrations, when the peak production of 2-phenylethanol was first achieved (at 30 and 12 h, respectively), the cell growth curves showed that the cells were in the declining growth phase. The peak of the tryptophol production rate appeared around 4 and 6 h later in the case of the low and high cell concentrations, respectively, which corresponded also to the declining growth phase, whereas the tyrosol production rate reached its peak between the peaks of 2-phenylethanol and tryptophol. The production of all three aromatic alcohols reached its peak in the declining growth phase, which is earlier than reported by others, who connected quorum-sensing molecule release with stationary growth phase.[12]

An interesting phenomenon appeared after 30 h of fermentation with the initial high cell concentration. At this point, a slight decrease in cell growth was observed together

DOI: 10.1021/acs.jafc.5b03400
J. Agric. Food Chem. 2015, 63, 8544−8550

with the increased tyrosol production rate, similar to the growth decline after 10 h of fermentation, when the first tyrosol peak was determined. This cell response might have implications on a quorum-sensing mechanism where the regulation differs from that of 2-phenylethanol and tryptophol. With regard to its stimulative effect on germ-tube formation in the yeast *C. albicans*,[5] the increase of tyrosol in the declining growth phase could be similarly explained as an antagonistic mechanism against the effect of 2-phenylethanol and tryptophol. However, the second peak at 34 h did not result in increased cell growth as observed after the first peak, but this could be explained by the high concentration of already accumulated 2-phenylethanol and tryptophol in the medium. On the other hand, this increased tyrosol concentration in the medium might represent the consequence of intracellular tyrosol release from lysed cells, especially after 30 h of fermentation.

Through the prism of quorum-sensing theory, these observations indicate that the accumulation of aromatic alcohols in the medium is growth-phase dependent and is regulated by the cell concentration. This is in agreement with previous findings,[12] despite some major differences in experimental approach. Indeed, Chen and Fink[12] estimated the cell concentrations by OD_{600} measurements, which did not take differences between live and dead cells into consideration, and they used silica gel thin layer chromatography for the detection of quorum-sensing molecules. They also analyzed only one time point, which did not make it possible to study the production kinetics of the putative quorum-sensing molecules. The development of better experimental techniques has now provided us with a more detailed view into this biological phenomenon. Thus, from the data in the present study, it can be hypothesized that cells start to regulate their concentration first with the intense release of tryptophol, which is then followed by the release of 2-phenylethanol and tyrosol. When the cells reach the stationary phase, the intensity of the production of these quorum-sensing molecules decreases, most likely because their production is repressed either by autoregulation or by some other event that occurs during this phase (e.g., nutrient limitation). As well as these more detailed kinetics of the quorum-sensing molecules 2-phenylethanol and tryptophol in the present study, the correlation of tyrosol production with cell concentration in *S. cerevisiae* has also not been reported previously, to the best of our knowledge.

If the established model is valid, the peak production rates of 2-phenylethanol, tryptophol, and tyrosol should match the peak expression of the genes that are responsible for their synthesis. In this regard, these quorum-sensing kinetics were correlated with *ARO8*, *ARO9*, and *ARO10* expression (Figure 3).

The expression of the *ARO* genes was normalized to the mean *M* (i.e., the gene stability measure; see Materials and Methods) of the selected housekeeping genes *ACT1*, *18S rRNA*, and *TEF1*. The small differences between these *M* values (0.690, 0.707, 0.742, respectively) indicated that each of these housekeeping genes was constitutively expressed under the experimental conditions and that they were therefore suitable as internal controls.

The expression of the selected *ARO* genes was monitored after 0, 4, 12, 16, 24, and 32 h of cultivation for the low initial cell concentration and after 0, 18, 26, 30, 34, and 38 h of cultivation for the high initial cell concentration. In both cases, the *ARO8* gene, which encodes the aminotransferase enzyme that is responsible for early synthesis of aromatic alcohols, was the first of these three genes to be activated, which occurred early in the exponential growth phase. This was followed by *ARO9* and *ARO10* gene expression in the declining growth phase, which thus paralleled later peak activities (Figure 3). These kinetics are in agreement with the kinetics of the quorum-sensing molecules in the medium determined as described above. Moreover, the peak expression of these *ARO* genes corresponded relatively closely to the peak production rates of the quorum-sensing molecules (Figure 3).

Positive feedback regulation by 2-phenylethanol and tryptophol,[4,12] and maybe by tyrosol, would explain the continued relatively high expression of these *ARO* genes into the late stationary phase. It should be stressed that despite the apparent decrease in the production rates of these quorum-sensing molecules after entry into the stationary phase (Figure 2), they were still present in the medium at high concentrations, also at the last measurement time (see Figure 1).

Ethanol Addition Affects the Production of Quorum-Sensing Molecules at the Metabolic and Transcriptomic Levels. To date, there have not been any studies on the kinetics of the quorum-sensing molecules 2-phenylethanol, tryptophol, and tyrosol during alcoholic fermentation. In the present study, ethanol was selected from among several potential stress factors, as its toxicity is one of the major stress factors that undermine the fermentative abilities of yeast.[22] Although *S. cerevisiae* is ethanol tolerant, relatively high ethanol concentrations inhibit cell growth and viability, which limits fermentation productivity and ethanol yield.[23,24] The effects of ethanol on the production of the quorum-sensing molecules 2-phenylethanol, tryptophol, and tyrosol in the medium were thus examined under addition of different ethanol concentrations at an initial cell count of 2×10^7 cells/mL. At the same time, the cell growth and the expression of the *ARO* genes were measured.

Here, the addition of 2% ethanol to the medium did not alter the cell growth of *S. cerevisiae*, whereas the kinetics of tryptophol and tyrosol production were weakly repressed when compared to the control with no ethanol addition (Figure 4). For 6% ethanol addition, a significant delay in the peak production of all three of these aromatic alcohols was detected, most probably due to weak suppression of cell growth. At 8% ethanol addition, the suppression of cell growth escalated, which resulted in a complete suppression of tryptophol production, whereas the other two measured aromatic alcohols were delayed and only weakly expressed. With the highest ethanol addition to the medium (12% initial concentration), no additional cell growth was seen, which is in agreement with previously reported findings;[25] moreover, cell viability dropped to 47% from the point of inoculation to 28 h, when none of these three aromatic alcohols were detected (data not shown).

An interesting observation in this part of the study can be noted. The times when the aromatic alcohols were first detected in the medium highly correlated with the specific cell concentrations; that is, in all cases of ethanol addition, the production of 2-phenylethanol, tryptophol, and tyrosol still started when the cells reached a concentration between 2×10^7 and 3×10^7 cells/mL, between 3×10^7 and 4×10^7 cells/mL, and between 2×10^7 and 4×10^7 cells/mL, respectively, despite the differences in the cell growth curves. These concentrations appear to represent the quorums that are specific for each of these three aromatic alcohols when they are synthesized under defined conditions of wine fermentation. On the other hand, the shapes of the production rate curves show

DOI: 10.1021/acs.jafc.5b03400
J. Agric. Food Chem. 2015, 63, 8544−8550

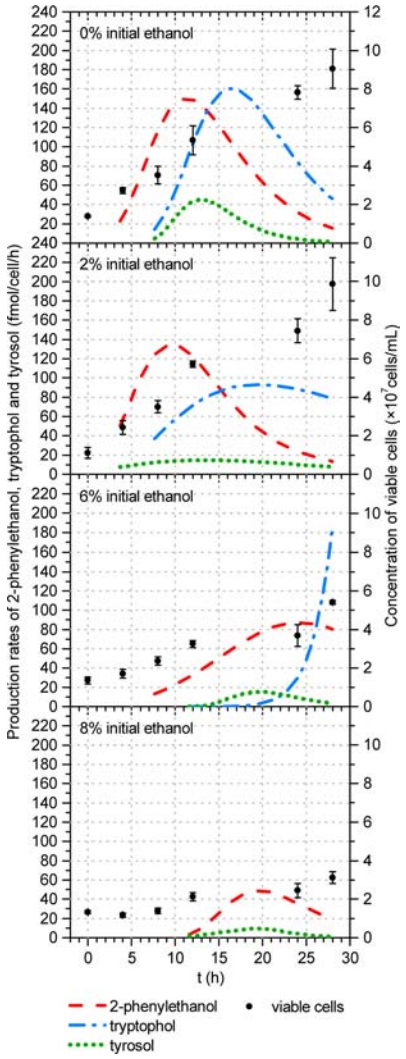

Figure 4. Production rates of 2-phenylethanol (dashed line), tryptophol (dash-dotted line), and tyrosol (dotted line) over 28 h of mini-fermentations with *S. cerevisiae* at the initial cell concentration of 1.2×10^7 cells/mL, without and with the addition of ethanol at 2, 6, and 8% (as indicated).

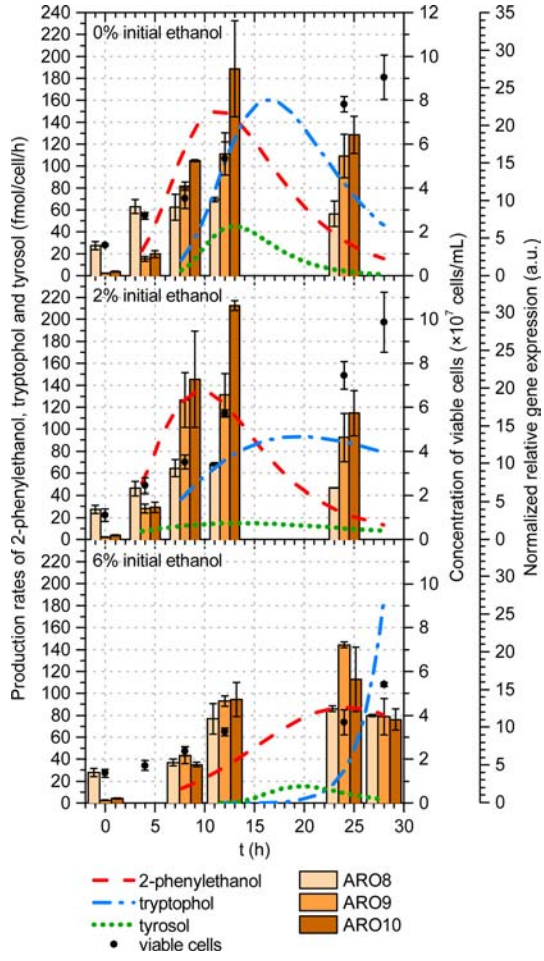

Figure 5. Relative expression of the *ARO8*, *ARO9*, and *ARO10* genes (as indicated) and correlation with the production rates of 2-phenylethanol (dashed line), tryptophol (dash-dotted line), and tyrosol (dotted line) over 28 h of mini-fermentations with *S. cerevisiae* at the initial cell concentration of 1.2×10^7 cells/mL, without and with the addition of ethanol at 2 and 6% (as indicated).

that ethanol addition had either a direct or an indirect effect on the production of all three monitored quorum-sensing molecules. It seems that cell concentration and ethanol addition influenced the start and the intensity of the production of quorum-sensing molecules, respectively.

To enrich these findings, we also measured the relative expression of the *ARO8*, *ARO9*, and *ARO10* genes during these mini-fermentations with the addition of ethanol. As seen in Figure 3, only *ARO8* expression was detected at the start of the fermentation, probably due to its involvement in the early stages of aromatic alcohol synthesis. As before, with the addition of 2 and 6% ethanol to the medium, the relative expression levels of these *ARO* genes that are responsible for the production of 2-phenylethanol, tryptophol, and tyrosol showed the same trends as the production rates of these three aromatic alcohols (Figure 5). This also again confirms the usability of the HPLC/microscopy methods developed here.

The experiments with added ethanol clearly showed that ethanol has a direct or an indirect effect on aromatic alcohol production rates. With the increased concentration of added ethanol, the production rates of 2-phenylethanol, tryptophol, and tyrosol seem to decrease, which is most probably correlated with the general disruption of numerous cell processes caused by ethanol stress including decreased cell growth and viability, amino acid and glucose transport systems, membrane structure and function, etc.[26] However, the addition of 6% of ethanol resulted in a significant increase of tryptophol production rate, which could be connected to the increased biosynthesis of tryptophan during ethanol stress as reported by Hirasawa et al. On the other hand, *ARO10* gene (coding for phenylpyruvate decarboxylase) was down-regulated, which might be the consequence of some specific ethanol involvement in decarboxylases and dehydrogenases regulation reported also by other authors.[27] In the case of the initial 8% ethanol addition, no tryptophol was detected and the cell concentration did not exceed the threshold that we showed here to be specific for the onset of tryptophol production, that is, around 3.5×10^7 cells/mL (Figure 4).

In the present study, we have demonstrated that the expression of the *ARO8*, *ARO9*, and *ARO10* genes correlates with the kinetics of the release of the aromatic alcohols 2-phenylethanol, tryptophol, and tyrosol. This thus demonstrates the connection between these activated quorum-sensing-related genes and their corresponding products that are released into

DOI: 10.1021/acs.jafc.5b03400
J. Agric. Food Chem. 2015, 63, 8544−8550

the medium. Furthermore, this study confirms the adequacy of our previously implemented model[15] for the study of these quorum-sensing kinetics. It also recognizes the quorums (i.e., the cell concentrations) at which *S. cerevisiae* start to produce 2-phenylethanol, tryptophol, and tyrosol, apparently as a response to their abundant growth. These findings thus open a new field of research that is aimed at the control of yeast quorum-sensing during wine fermentation or, even more specifically, at the control of yeast fermentation through the use of such quorum-sensing molecules themselves.

chemicals responsible for flavors and fragrances, bitterness, acidity, viscosity, mouth feel, etc., is reached.

Fructose is a reducing sugar that exists as a mixture of five isomers, when dissolved in water. The different isomers in the form of β-pyranose, α-pyranose, β-furanose, α-furanose, and ketohexose (Figure 1) are distinct compounds, differing from

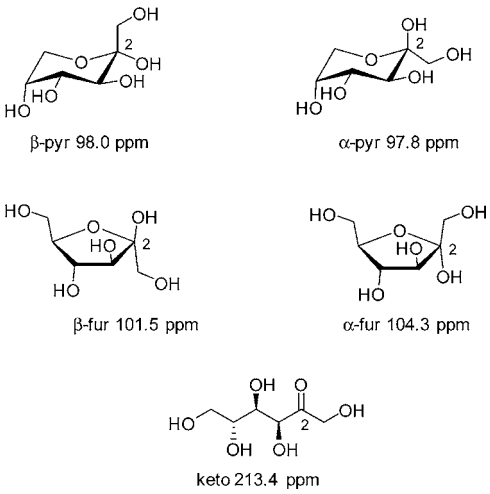

Figure 1. Structures of fructose isomers, with the chemical shift of carbon 2 in wines indicated.

each other in their chemical, physical, and biological properties.[14] These forms can be observed by nuclear magnetic resonance (NMR) spectroscopy, and their proportion in the equilibrium mixture can be measured. However, because of the low sensitivity of ^{13}C NMR, the majority of the studies have been performed with ^{1}H NMR and mainly in pure water solutions. The sweetness arising from fructose is the most variable among the naturally occurring sugars (this variation is directly related to the mutarotational behavior), and it is well-known that the sweetness of aqueous solutions containing fructose markedly decreases as the temperature increases.[15] The β-pyranose isomer is reported as the major form in aqueous solution and as the isomer responsible for sweetness, while β-furanose and α-furanose are nearly void of taste; the decrease in sweetness with increasing temperature is attributed to the lesser proportion of the β-pyranose isomer.[15] Analytical techniques, including gas chromatography (GC), high-performance liquid chromatography (HPLC),[16−20] and solid-phase microextraction (SPME),[21,22] and spectroscopic techniques, such as infrared (IR),[23] have been applied to the detection and measurement of fructose and other carbohydrates in wines. However, some of these analytical procedures are somewhat restricted and usually require time-consuming sample preparation procedures. ^{1}H NMR spectroscopy has been used extensively for identifying carbohydrates and other compounds in wines, but its application is limited in that the spectral region where the carbohydrate signals are observed is highly congested as a result of the presence of overlapping resonances, requiring multidimensional NMR approaches for deconvolution. Consistent analyses of ^{1}H NMR spectra of wine are further complicated by the large number of compounds present and also by the variations in ^{1}H chemical shifts that can occur as a result of changes in the pH, concentration, and presence of other compounds. For this reason, proper analysis typically requires sophisticated data treatment techniques, or alternatively, samples need to be pH-buffered and ideally have accurate pH adjustments made to minimize chemical shift variations, so that reliable assignment of specific resonances to individual compounds is possible.[24] Even with these sample manipulations prior to spectral acquisition, peak alignment and fine adjustments are often still required before spectral analyses can be reliably undertaken.[25] Although the qualitative and quantitative measurements of sugars in wine based on ^{1}H NMR spectra are challenging, advances have been made possible by the availability of innovative statistical analysis methods[25,26] and modern chemometric tools.[27] There have been multi-site demonstrations for the methodology of the Wine-Screener,[28] which showed the use of identical (400 MHz) NMR instrumentation, in conjunction with standardized, optimized sample preparation, data acquisition, data processing, and data analysis protocols for chemical analysis of wines and fruit juices based on ^{1}H NMR spectra.[24,29]

Although ^{13}C NMR has been used for the identification of individual components within complex mixtures, relatively few papers have described its use for quantitative analysis of carbohydrates in natural mixtures.[30,31] Analytical evaluation of honey by ^{13}C quantitative nuclear magnetic resonance (qNMR), aimed at revealing its origin and possible adulteration, which used a cryogenically cooled NMR probe to achieve higher sensitivity, has been reported.[32,33] Duquesnoy et al. developed a procedure using ^{13}C qNMR spectroscopy, which allowed for the direct identification and quantification of the carbohydrates in ethanolic extracts of two conifers, using an internal standard method.[34] Concerning wine analysis, a first quantitative analysis of contaminants (diethylene glycol and natural compounds, such as sugars, sugar alcohols, glycerol, and sugar acids) by ^{13}C NMR was reported in the mid-1980s.[35] Most recently, with the introduction of advanced technologies for direct sample analysis, full-bottle ^{13}C NMR was applied for the measurement of acetic acid content in wine.[36] Although the method was not practical for the quantification of wine components, such as tannins, flavonoids, phenols, and aldehydes, it was perfectly suitable for the study of the specific enological problem of acetic acid spoilage and the quality of fine wines.

We describe herein the use of ^{13}C qNMR for the quantitative determination of the relative fructose isomer composition and the total fructose content in wines. The method is also applicable to the detection and quantification of other compounds, including ethanol, other sugars, such as glucose and sucrose, or additional chemicals, as long as they have at least one ^{13}C signal that does not overlap with resonances from other compounds present.

MATERIALS AND METHODS

NMR Sample Preparation. Fructose, sucrose, and ethanol−OD (CH_3CH_2OD, 99.95% pure) were purchased from Sigma-Aldrich. D-[UL-$^{13}C_6$] fructose was purchased from Omicron Biochemicals. White wines produced from different grape varieties, including Baccus Weiss (2012 vintage), Pinot Gris (2013), Chardonnay Blanc (2013), and a late-harvest Riesling (2012), were purchased from wine stores in British Columbia, Canada. A sweet Moscato wine (2013) was purchased from an Italian winery. The 600 MHz grade, 5 mm NMR tubes (from Bruker) were filled with 550 μL of the wine or solution to be analyzed.

^{13}C NMR Spectra. Spectra were acquired on a Bruker AVANCE II digital spectrometer operating at 600.33 MHz for ^{1}H and 150.90 MHz for ^{13}C equipped with a Bruker 5 mm quadruple nucleus probe (QNP) cryoprobe. This direct-detect probe for ^{13}C has cold (~20 K) ^{13}C, ^{1}H, and ^{2}H coils, and the ^{13}C and ^{1}H preamplifier channels are both cooled to 77 K. The sample temperature was maintained at the desired temperature (283, 293, and 310 K) using a Bruker BVT-3000 and a Bruker BCU-05 air controller to regulate the sample temperature by

actively controlling the temperature of flow of heated air over the NMR tubes. The air flows ranged from 670 L/h for 293 K to 800 L/h for 310 K. These higher than normal flows compared to those used on conventional NMR probes are necessary to compensate for the cooling effect of the cold but vacuum-insulated NMR radio frequency (rf) coils surrounding the sample. The sample temperature was calibrated using 99.9% methanol[37] and was found to show a variation of less than 0.1 K from the displayed value. An inversion recovery pulse sequence was used to measure ^{13}C T^1 values for the carbons of interest with a recycle delay of 120 s and an array of 12 different recovery delays covering the range from 100 ms to 120 s. Relaxation data were fit using the T_1/T_2 analysis routines in the Topspin software. T_1 relaxation times for the C-2 carbons of fructose in 15 vol % ethanol at 298 K were 11.3 s for ketohexose, 8.9 s for α-furanose, 8.2 s for β-furanose, 8.5 s for β-pyranose, and 10.2 s for α-pyranose. Quantitative proton-decoupled ^{13}C NMR spectra were acquired using an inverse-gated pulse sequence to eliminate nuclear Overhauser effect (NOE) enhancements.[38] The ^{13}C transmitter frequency was set to 100 ppm, a spectral width of 250 ppm was used, and 32 scans, each consisting of 131 072 complex points, were accumulated with a recycle delay of 120 s between scans (65 min per spectrum). Proton decoupling was performed using the WALTZ-64 decoupling sequence (^{1}H pulses of 100 μs, with the ^{1}H transmitter set to 4.00 ppm).[39] A total of 5−12 spectra were recorded for each sample.

Dependence of the Equilibrium Composition of Fructose in Wine upon the Temperature. Fructose was dissolved in 15% ethanol−OD and 85% H_2O (fructose concentration of 1.11 M). Upon complete dissolution, the samples were transferred to 5 mm NMR tubes and equilibrated at three different temperatures (283, 293, and 310 K). ^{13}C qNMR experiments of 32 scans (65 min for each spectrum) were recorded, and six experiments were performed for each temperature. The effect of pH on the isomeric composition was evaluated by dissolving fructose (fructose concentration of 1.11 M) in 15% ethanol−OD and 85% H_2O solution, with the addition of diluted HCl or NaOH to the desired pH (pH 2.0 and 6.2, respectively). ^{13}C qNMR spectra of 32 scans were recorded for each sample, and six experiments were performed for each temperature (283, 293, and 310 K). For direct wine analysis, NMR tubes containing 550 μL of pure Riesling and Moscato were were prepared and five ^{13}C qNMR spectra (32 scans each) were acquired for each wine at each temperature.

Equilibrium Composition of Fructose at 293 K. Samples at different pH were prepared by dissolving fructose (1.11 M) in 15% ethanol−OD and 85% H_2O, previously acidified with diluted HCl and NaOH to the desired pH (pH 2.0, 3.0, 5.0, and 6.2, respectively). Samples containing different volume percentages of ethanol were prepared by dissolving fructose (1.11 M) in 5, 10, 20, and 30% ethanol−OD, respectively. Six ^{13}C qNMR spectra (32 scans) were recorded for each sample at 293 K.

Quantitative Determination Using the PULCON Method. An aqueous solution of sucrose of accurately known concentration (0.293 M) was prepared in 15 vol % ethanol−OD for the external reference sample, and ^{13}C qNMR spectra were recorded at 283, 293, and 310 K, respectively. For ethanol quantification, a solution of ethanol−OD (99.95% pure) was used as an external reference and ^{13}C qNMR spectra were recorded at 293 K. Samples of 550 μL of unaltered Baccus Weiss, Pinot Gris, and Chardonnay Blanc wines were added to separate NMR tubes, and five successive ^{13}C qNMR spectra (32 scans) were recorded of each wine at 293 K.

Analysis of ^{13}C NMR Spectra. Fourier transformation of the free induction decays (FIDs) was performed with 2-fold zero-filling and application of an exponential apodization (line broadening of 2 Hz). Spectra were manually phased and baseline-corrected using Bruker TopSpin software. The resulting series of ^{13}C qNMR spectra were deconvoluted using procedures coded in a Mathematica 5.1 notebook written by Dr. Darren Brouwer.[36] Because ^{13}C satellite peaks may be comparable to resonances of low-concentration components, deconvolution was applied and the contribution of satellites was taken into account (see the Supporting Information). An initial, automated deconvolution over the chemical shift range of interest for the carbon signals of fructose isomers was performed by reading in the phased, baseline-corrected spectrum. Experimental spectra were fit using the

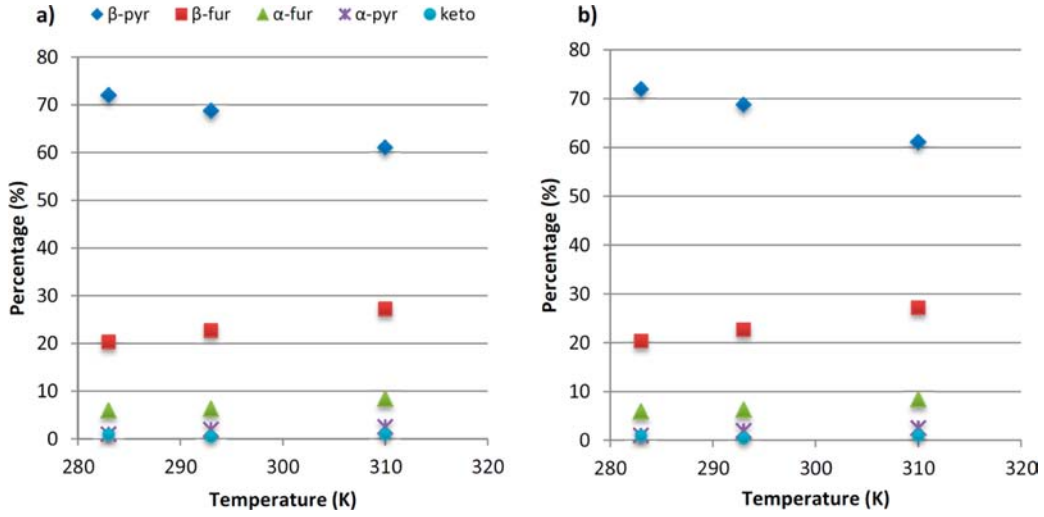

Figure 3. Equilibrium composition of fructose isomers (β-pyranose, β-furanose, α-furanose, α-pyranose, and ketohexose in order of abundance) and dependence of the individual components with increasing temperatures in wines: (a) Moscato and (b) late-harvest Riesling.

least-squares "nonlinearRegress" function in Mathematica. Starting from the initial parameters, the peak positions, peak widths at half height, and optimal combination of Lorentzian and Gaussian peaks were allowed to vary, to reach the best match for the resonances of the specific sample.

RESULTS AND DISCUSSION

^{13}C qNMR experiments were initially carried out on wine-like mixtures made by dissolving fructose in water containing up to 15% ethanol by volume to determine accurately the relative isomer ratios. High-resolution spectra and accurate quantification using peak area integration and peak deconvolution analyses of these data permitted accurate measurements of relative ratios of the fructose isomers. ^{13}C qNMR analysis of wines at 293 K was then carried out (Figure 2). Late-harvest and dessert wines are made with naturally dehydrated grapes and are very concentrated in sugars. A few hours of data acquisition using a cryoprobe provided ^{13}C NMR spectra with signal-to-noise ratios suitable for reliable quantification, and less than 1 mL aliquot of wine was required to perform the analysis. Here, we describe the application of the PULCON method[38] to ^{13}C qNMR spectra of wines for measuring fructose concentrations in wines sampled directly from the bottle and added to a NMR tube by using a sucrose solution as the external quantification standard. PULCON is a method that correlates the absolute intensities of two spectra measured in different solution conditions.[40] It overcomes the need to add an additional reference compound (internal standard) of known concentration to the sample being analyzed. PULCON therefore permits direct comparisons of integrals from different spectra and, thus, also different samples.[41] The use of ^{13}C NMR is inherently selective for the fructose isomers in wine because these sugars are present in the highest concentrations after water (which has no ^{13}C signal and is therefore not detected) and ethanol (whose ^{13}C signals are well-resolved from those of the sugars). Other organic compounds are present at much lower concentrations and do not interfere with the identification of the sugar resonances or peak area determinations of these signals. The protocol used in the present study only requires that an accurately measured volume of wine be transferred directly to the NMR tube. No solvents, standards, or buffer solutions are added, and no pH adjustments, chemical separations, derivatizations, or other pretreatments are carried out. The high spectral dispersion and narrow peak widths in ^{13}C NMR spectra, when coupled with the field stability and slow drift rates of the main magnet field available on most modern, shielded superconducting magnets, also make it possible to turn off the usual ^{2}H-based field locking if desired. This approach eliminates the need to add a deuterated solvent, which means that the wine can be tested and analyzed in its native condition.

The limit of detection (LOD) for ^{13}C qNMR, assuming a signal-to-noise of 3:1 for a 1 h acquisition on the 600 MHz QNP cryoprobe, is 0.6 g/L. The LOD was measured with samples of fructose of known concentration in wine-like solution. By comparison using ^{1}H NMR, the reported limits of quantification (LOQs) for the WineScreener are 0.2 g/L for sucrose and 0.5 g/L for glucose and fructose. Assuming that the LOQ is based on a 10:1 signal-to-noise ratio, we can estimate that WineScreener LODs are approximately one-third of the LOQ values. The ^{13}C-NMR-based methodology presented in the current work provides a useful, straightforward, and alternative analytical technique for analyzing sugars in wine (and other beverages). ^{13}C NMR removes the need to suppress the strong water and ethanol signals (which ^{1}H-NMR-based WineScreener requires), eliminates the need for pH adjustments (because ^{13}C chemical shifts do not vary much for the range of pH that most wines have), does not require a specific brand of NMR spectrometer or type of NMR probe, and can be carried out at any magnetic field strength, making it possible to implement it on virtually all NMR spectrometers designed for analyzing liquid samples. Furthermore, in the current ^{13}C NMR method, 550 μL of intact, unmodified wine is simply added directly to a NMR tube; there is no extra time, special equipment, or chemical addition required. The WineScreener protocol requires several pretreatment steps, including adding buffer and adjusting the pH.

Equilibrium Composition of Fructose in Wine: Variation with the Temperature. Previous investigations aimed at determining fructose isomeric composition resulted sometimes in inconsistent data, essentially as a result of the complexity of the mutarotation phenomenon and the limitations of the different methods employed.[42,43] Isomeric composition studies have been performed in different solvents, suggesting different relative compositions but also giving rise to confusing and incorrect interpretations.[44,45] ^{13}C qNMR spectroscopy has been considered unsuitable for determination of the isomeric ratios of fructose because of its low sensitivity and the difficulties in

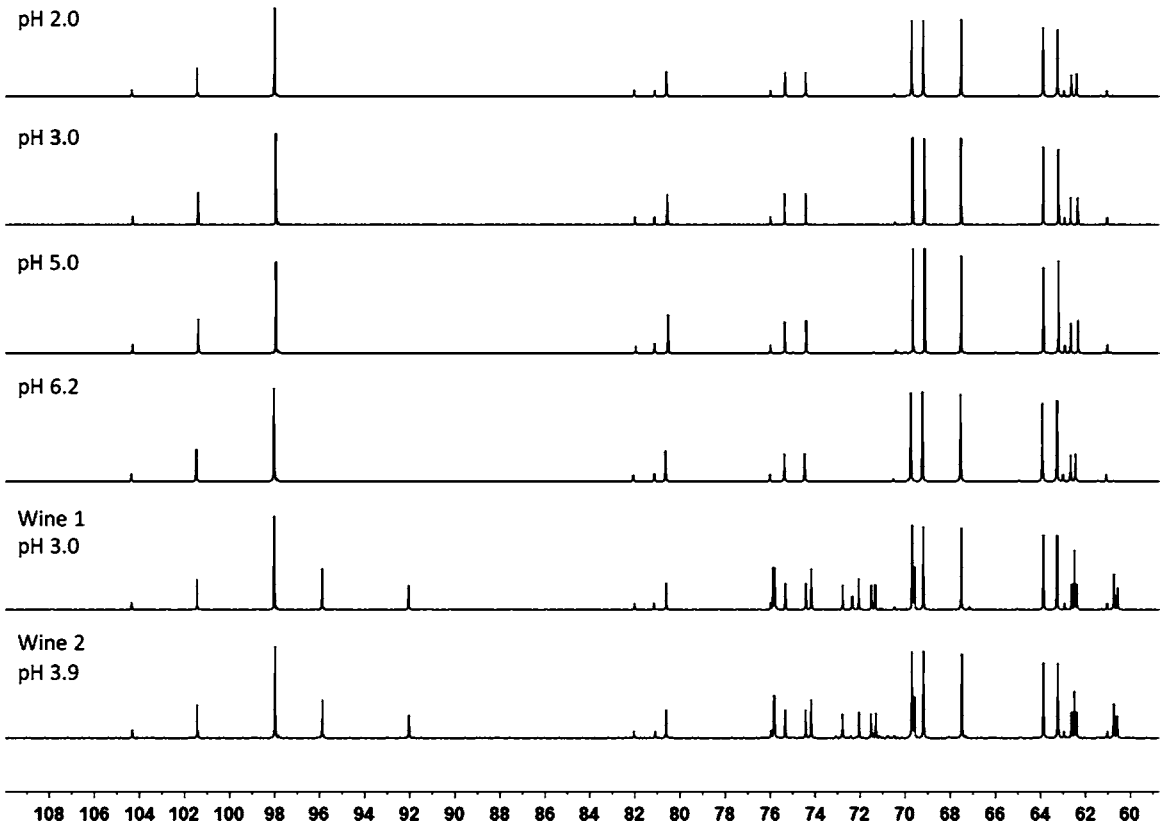

Figure 4. Representative ^{13}C NMR spectra of wine-like solutions at 293 K at different pH (pH 2.0, 3.0, 5.0, and 6.2 from the top) and for wines: wine 1, late-harvest Riesling at pH 3.0; wine 2, Moscato at pH 3.9.

detecting minor isomers, such as α-pyranose and keto forms.[46] However, in our cryprobe-enhanced experiments, ^{13}C signals for all five isomers of fructose (Figure 1) at a reasonable concentration (about 1 M) were observed. The analyses were performed on the resonances corresponding to the C-2 carbon of each isomer: β-pyranose (98.0 ppm), α-pyranose (97.8 ppm), β-furanose (101.5 ppm), α-furanose (104.3 ppm), and ketohexose (213.4 ppm). These signals were chosen because they generally do not overlap with other signals in wine samples. To guarantee the quantitative reliability of ^{13}C spectroscopy, it is necessary to set an interscan delay at least 5 times as long as the longest T_1 value, before applying another pulse, combined with a 90° pulse, to allow for complete relaxation of each carbon of the wine compounds to be analyzed. Quantitative spectra can also be obtained using a fast train of short pulses, which leads to a minor change in the steady-state magnetization as T_1 is varied. The integration of these two approaches usually provides excellent results.[32] We measured the T_1 values of all of the carbons for pure fructose in 15% ethanol solution, finding T_1 values ranging from 0.2 to 11.3 s. The highest T_1 values were observed for carbon 2 (11.3 s for the keto form). On the basis of the largest T_1 value, the interscan delay was fixed at 120 s (10 times the highest T_1) to ensure accurate signal intensities. WALTZ-16 composite pulse decoupling was used to minimize any rf-induced heating of the samples. The main objective of this set of experiments was to confirm the general trend observed for changes in the relative ratios of the fructose isomers in wines as the temperature of the samples was altered. The dependence of the individual components with increasing temperatures in Moscato and late-harvest Riesling is shown in Figure 3 and is very similar to wine-like solutions at different pH (see the Supporting Information).

The relative amounts of the various isomers of fructose, including the contribution of the keto form, were recently reported by Barclay et al. based on ^{1}H NMR spectroscopic

DOI: 10.1021/acs.jafc.5b03641
J. Agric. Food Chem. 2015, 63, 8551−8559

measurements of pure fructose in D_2O.[47] An accurate quantitative analysis of isomeric forms by ^{13}C qNMR spectroscopy was reported by Mega et al., who used ^{13}C-enriched fructose in water solution (30% D_2O and 70% H_2O).[48]

To the best of our knowledge, the current analysis of the relative ratios of the various fructose isomers is the first using real wine samples. These results provide useful information about the actual isomeric composition in aqueous ethanolic solutions and wines at different temperatures and help to resolve the previous inconsistencies in the literature regarding the equilibrium fructose concentrations in ethanolic solutions.[43] Our results correlate with those reported by Barclay et al.[45] and Mega et al.,[46] suggesting no significant variation in the equilibrium isomeric ratios with either the pH, solvent composition (pure water, aqueous solution containing 15% ethanol by volume, or wines) or a combination of these parameters.[45,46] No significant differences in the relative amounts of the various isomers were apparent in our measurements when comparing the ratios obtained at different pH or fructose concentrations in the presence of ethanol or in wines. The absolutely critical parameter to fix *a priori* for a quantitative evaluation of fructose is the temperature; therefore, for all other evaluations of the fructose content, the temperature was held constant at 293 K. The dependence of the fructose isomeric composition in wines upon temperature variation gives rise to fascinating speculations about the suggested serving temperatures for white wines. Although there are a number of factors responsible for the complexity of wine taste, the temperature should be taken into consideration for its contribution to sweetness, which is determined primarily by fructose isomer proportions.

Equilibrium Composition of Fructose at a Constant Temperature. Equilibrium compositions of fructose at 293 K of wine and wine-like samples at different pH are reported in Table 1. The negligible variability of peak chemical shifts and invariability of fructose isomer peak intensities from spectra recorded on different samples is shown in Figure 4. Table wines generally have a pH between 2.5 and 4.5. However, considering that late-harvest Riesling and Moscato wine have pH 3.0 and 3.9, respectively, a range between 2.0 and 6.2 was examined in this study. Table 1 shows the variations among the set of ethanolic solutions at different pH, revealing a slight percentage variation in the wide range considered. The values reported by Barclay et al.[45] and Mega et al.[46] are included for comparison. Although the pH has been reported to have an influence on the rate of the mutarotation of fructose[46] (which is often approximated using a simple first-order process representing just the conversion of β-pyranose to the furanose forms), it was previously also reported that the isomeric composition at equilibrium was not significantly affected by variations in pH,[46] as corroborated by our data. To find a mean percentage value reflecting the distribution of the isomeric forms at a constant temperature, we combined data generated from samples at different pH and selected ethanol contents ranging from 5 to 30 vol % ethanol (without pH buffering). As a consequence, the small variations observed are considered to derive from random effects and, thus, mimic the case of directly analyzing wines without pretreatment and without knowledge of the actual pH or ethanol concentration.

Artificial mixtures of fructose were investigated, and mean values of the molar percent ratios were obtained and compared to the values measured using different methods of analyzing the ^{13}C qNMR spectra (see the Supporting Information). Three different techniques were used: (1) mean values determined using integration of the peaks for all of the carbons, including the contributions from the associated ^{13}C satellite peaks, (2) mean values from peak areas obtained by peak deconvolutions of signals from all carbons, including the ^{13}C satellite peaks, and (3) values calculated using peak areas from peak fitting (deconvolution) using the main resonance and the associated satellite peaks for the signals related to only carbon 2 for each isomer (Figure 6). These satellite peaks arise from the coupling of the

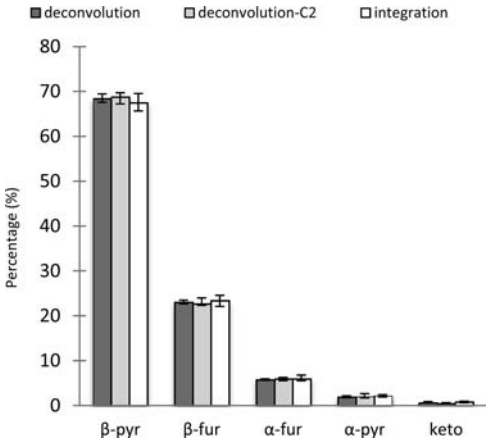

Figure 5. Variation in the equilibrium composition of fructose isomers (β-pyranose, β-furanose, α-furanose, α-pyranose, and ketohexose in order of abundance) in wine-like solutions at 293 K. Averages values are reported in the graph. The error bars reflect the range of the standard deviation. For each isomer, the three bars reflect different methods of data analysis (in order from left to right, deconvolution of all carbon peaks, deconvolution applied to C-2 peaks, and integration of all carbon peaks).

observed ^{13}C nuclei to an adjacent (directly bonded) ^{13}C at natural abundance, have separations of 30−70 Hz as expected for $^1J_{C-C}$ couplings, and are not due to incomplete proton decoupling. In the latter case, C-2 was selected because it exhibited a well-resolved, reasonably strong peak for all five fructose isomers. Histograms describing the isomeric composition depending upon the different analysis methods employed are reported in Figure 5. The largest standard deviations were found when the integration method was used. The smallest spread about the average was achieved using deconvolution analysis for all signals, even though deconvolution applied to just carbon 2 of each isomer also yielded a smaller standard deviation than integration. However, the data obtained from deconvolutions just at carbon 2 of each isomer (Table 2) represent a good compromise between speed and accuracy and were thus considered more appropriate for further evaluation of the fructose content in wine. The mean values also match perfectly with the isomeric ratios obtained from a fully ^{13}C-enriched fructose sample in 15% ethanolic solution (Table 2).

Fructose Quantification in Wine. Concentration measurements with the PULCON method use the principle of reciprocity, which indicates that the lengths of a 90° or 360° pulse are inversely proportional to the NMR signal intensity.[49,50] When the concentration of the external reference sample is known precisely, the unknown concentrations of different samples can be obtained using eq 1, where U and R indices stand for unknown and reference, respectively (fructose and sucrose, respectively)

$$c_U = kc_R \frac{A_U T_U \theta_{90}^U n_R}{A_R T_R \theta_{90}^R n_U} \quad (1)$$

where C is the concentration, T is the temperature, θ^{90} is the 90° pulse length, n is the number of transients used for the experiments, and k is a correction factor taking into account the use of different receiver gains for measurement of the reference and unknown samples or incomplete relaxation. In our experiments T and n have the same values for both the reference and unknown samples; therefore, the formula could be further simplified. The reference sucrose spectra were measured 5 times, and areas were calculated for all of the carbon signals, averaged, and used in the PULCON equation (A_R; eq 1). We investigated the reliability of the PULCON method for the determination of the fructose content with wines already analyzed, comparing our results to those from a WineScreener analysis carried out on different bottles of the (supposedly) identical wines. ^{13}C qNMR spectra of the Baccus Weiss, Pinot Gris, and Chardonnay Blanc wines were measured. The most important cause of different signal strength (peak areas) between spectra derives from differences in conductivities of the samples, which results in a variation of the 90° rf pulse length. However, as long as the probe is properly tuned and matched for each sample, this effect can be compensated for by applying the principle of reciprocity.[47] For each sample, the magnetic field was shimmed to provide symmetrical peak shapes and the actual duration required for a true 90° rf pulse was determined, keeping the power of the rf pulse fixed. All other acquisition and processing parameters remained unaltered. The quantitative reliability of the NMR peak area measurements can suffer if the delay between successive rf pulse scans is too short to allow for full recovery of the magnetization. An interscan delay of 120 s was employed, which afforded >99.9% recovery of magnetization for the fructose carbons having the largest longitudinal relaxation times (C-2 in the keto form; T_1 = 11.3 s). For fructose quantification, the information obtained from relative isomer composition (Table 2) was used and eq 1 was modified, leading to a simpler formula for calculating the fructose concentrations in wine samples. Just considering the area of the region between 97.0 and 99.9 ppm (related to the β-pyranose and α-pyranose isomers) which from reported evaluations (Table 2) accounts for 70% of the total concentration of fructose, the fructose content in wine samples could be expressed as reported in eq 2, where c_R is the molar concentration of a sucrose reference sample and A_* is the area of the 97.0−99.9 ppm region.

$$\text{fructose}\left(\frac{g}{L}\right) = M\frac{100}{P^U}c_R\frac{A_*\theta_{90}^U}{A_R\theta_{90}^R} \quad (2)$$

Fructose concentrations (in g/L) can be directly calculated using eq 2 by measuring the peak areas related to the two isomers (^{13}C satellite peaks included) and applying a multiplication factor determined from the product of the molecular weight of fructose M (180 g/mol) and the fractional amount of total fructose (on the basis of a percentage estimation of the isomers being used; $100/P^U$, where P^U is 70).

The values obtained compare remarkably well to those measured using the ^1H-NMR-based WineScreener analysis (Table 3). These ^{13}C-NMR-based concentration measurements were repeated 5 times for each wine sample, and the precision of the measurements was estimated using the standard deviations calculated from these separate measurements. Equation 2 can be extended to measure other carbohydrates, such as glucose and sucrose, present in wine, by measuring the peak areas related to one of the two isomers for glucose (β-pyranose and α-pyranose isomers) or measuring the peak area of one isolated signal for

[a]Standard deviation related to the concentrations obtained from five experiments. Each experiments used a $^{13}C\{^1H\}$ inverse-gated WALTZ-64 CPD, SFU Bruker AV II 600 with a QNP cryoprobe (unlocked; T = 293 K; $D1$ = 120 s; NS = 32; 65 min).

sucrose (which exists as a single isomer, *O*-α-D-glucopyranosyl-(1−2)-β-D-fructofuranoside). The multiplication factor M and percentage estimation of the isomers should be adapted to the carbohydrate to be measured. Baccus Weiss wine contained 1.6 g/L sucrose (WineScreener), which we could detect readily by ^{13}C qNMR peaks at 81.3 and 103.6 ppm (see the Supporting Information). From the same spectra, ethanol concentrations could also be determined. An external reference, a sample of 99.95% ethanol−OD, was used, and eq 3 was employed.

$$\text{ethanol (vol\%)} = 99.95 c_R \frac{A_U \theta_{90}^U}{A_R \theta_{90}^R} \quad (3)$$

These results are also in close agreement with those obtained using the official WineScreener analyses and printed on the bottle labels (Table 4), especially for the volume percent ethanol

Table 4. Ethanol Content Determination in Wine

	label	WineScreener (%)	eq 3 (%)	σ (%)[a]
Baccus Weiss	12.9	13.5	13.3	0.07
Pinot Gris	13.4	13.5	13.3	0.09
Chardonnay Blanc	13.8	14.0	13.5	0.05

[a]Standard deviation related to the ethanol percentage measured from five experiments.

contents. The one outlier was the Baccus Weiss wine, which yielded a significantly (more than 1% by volume) higher alcohol content based on the two independent NMR-based analyses than reported on the label.

In conclusion, a straightforward method is described for the direct determination of fructose isomers and total contents in wines without chemically altering the samples. ^{13}C qNMR analysis works essentially as a sensitivity "filter", removing the problem of water and ethanol suppression (which are the highest abundance components of wines) on the one hand and avoiding the detection of minor components and low abundance substances on the other hand. This type of analysis can also be readily performed on 400 MHz NMR spectrometers, extending the acquisition to a simple overnight experiment (see the Supporting Information). This method can detect and quantify ethanol and multiple sugars (and other compounds) at all stages of wine production, including grape must, during fermentation, and before and after bottling, providing a way to monitor possible back-blending practices. The method is also applicable to the analysis of fruit juices (up to 100 g/L sugar), carbonated soft drinks (100−120 g/L sugar), and certain energy drinks (up to 160 g/L sugar).

J. Agric. Food Chem. 2015, 63, 8551−8559

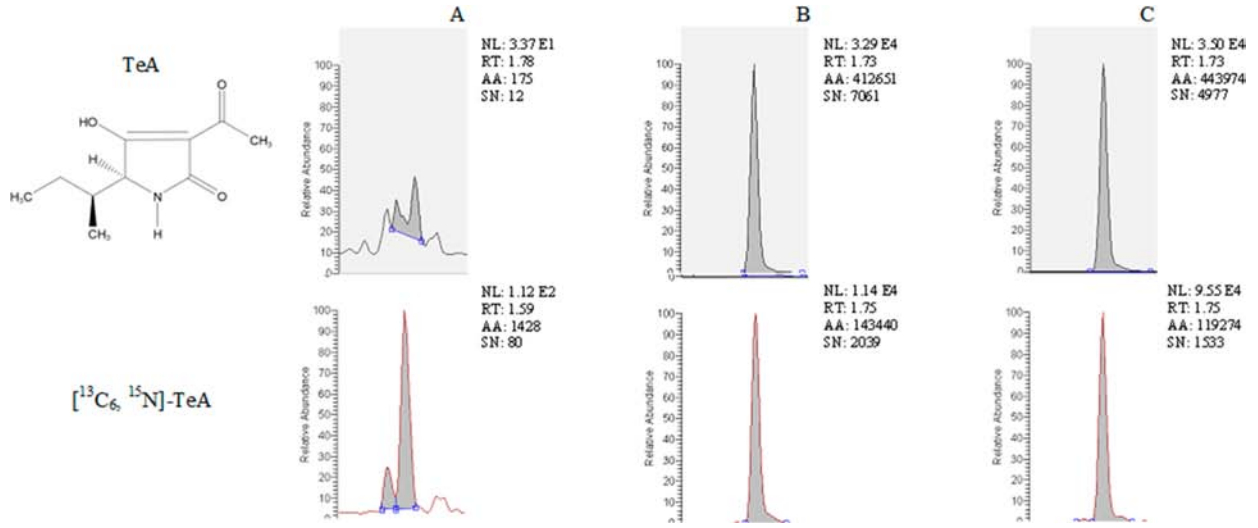

Figure 1. Chemical structure of tenuazonic acid (TeA, left) and LC-MS/MS chromatograms of (A) a blank pig plasma sample, (B) a spiked pig plasma sample (TeA concentration = 100 ng/mL), and (C) an incurred pig plasma sample that was taken at 0.5 h pa of a single oral dose of 0.05 mg TeA/kg body weight (TeA concentration = 129 ng/mL). The upper trace presents TeA, and the lower trace presents the internal standard ([$^{13}C_6$, ^{15}N]-TeA).

of TeA in food without the need for derivatization have been described.[5,13,14] Therefore, the present study aimed to develop a LC-MS/MS method without a derivatization step.

Next, toxicokinetic and plasma protein binding studies in both animal species were performed. The absolute oral bioavailability (F) and the main toxicokinetic parameters were calculated: area under the plasma concentration−time curve (AUC), maximum concentration after oral administration (C_{max}), plasma concentration at time of intravenous injection (C_0), time to maximal plasma concentration (t_{max}), elimination rate constant (k_{el}), elimination half-life ($t_{1/2el}$), total body clearance (Cl), volume of distribution (V_d), and mean residence time (MRT).

MATERIALS AND METHODS

Chemicals, Products, and Reagents. The analytical standard of TeA (purity ≥ 99%) was purchased from Fermentek (Jerusalem, Israel). The chemical structure of this compound is presented in Figure 1. The internal standard (IS) [$^{13}C_6$, ^{15}N]-TeA was synthesized according to the method of Asam et al.[15] TeA and the IS were stored at ≤ −15 °C. Water, methanol (MeOH), and acetonitrile (ACN) were of LC-MS grade and obtained from Biosolve (Valkenswaard, The Netherlands). Ammonium bicarbonate (purity ≥ 99.5%) and ammonium formate (purity > 99.0%) were of analytical grade and purchased from Sigma-Aldrich (Diegem, Belgium). Absolute ethanol was of analytical grade and obtained from VWR (Leuven, Belgium). Millex-GV PVDF filters (0.22 μm) and Amicon Ultra-0.5 mL centrifugal filter devices (molecular weight cutoff = 30 kDa) were purchased from Merck-Millipore (Overijse, Belgium).

Preparation of Stock and Working Solutions. Stock solutions of TeA (1 mg/mL) and IS (100 μg/mL) were prepared in MeOH. Working solutions (WS) of 1, 0.1, and 0.01 μg TeA/mL were prepared daily by appropriate dilution of the stock solution and WS with water. A WS (1 μg/mL) of IS was made by further dilution of the stock solution in MeOH. Stock solutions of TeA and stock and WS of IS were stored at ≤ −15 °C.

Animal Experiments. Toxicokinetic studies with TeA were performed in eight 10-week-old male piglets (Seghers hybrids, Ratterlow Seghers Holding, Lokeren, Belgium) and five 4-week-old broiler chickens (Ross 308, Geluveld, Belgium) of mixed gender. The mean BW was 33.44 ± 1.71 and 1.56 ± 0.20 kg for pigs and broilers, respectively. Both animal trials were designed as a two-way crossover. After an acclimatization period of at least 3 days, each pig or broiler chicken received either an oral (po) or intravenous (iv) dose of 0.05 mg TeA/kg BW. The analytical standard of TeA was dissolved in ethanol at a concentration of 1.75 or 1.00 mg TeA/mL for pigs or chickens, respectively. The stock solution was further diluted with water (po) or saline (iv) up to a final concentration that corresponded with a dose of 0.05 mg/kg BW.

Animals were deprived of feed from 12 h before until 4 h after administration of TeA. Pigs and broiler chickens had ad libitum access to drinking water at all times. Oral bolus administrations were given in the crop (chickens) or by gastric gavage (pigs), whereas iv injections were performed in the wing vein (*vena basilica*, chickens) or through a double-lumen catheter (*vena jugularis externa*, pigs).[16] About 1 mL of blood was sampled via the catheter (pigs) or the leg vein (*vena metatarsalis plantaris superficialis*, broilers) and collected in EDTA-coated tubes just before (0 h) and at different time points postadministration (pa), that is, at 0.08, 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, 8, and 10 h pa for pigs and at 0.08, 0.16, 0.32, 0.50, 1, 2, 4, 6, 8, and 10 h pa for broiler chickens. The blood samples were centrifuged (2095*g*, 10 min, 4 °C), and plasma samples (aliquots of 250 μL) were stored at ≤ −15 °C until analysis.

The animal experiments were approved by the Ethical Committee of the Faculty of Veterinary Medicine and Bioscience Engineering of Ghent University (EC 2013/145).

Plasma Sample Preparation. To 250 μL of plasma was added 12.5 μL of the IS WS (1 μg/mL). After a vortex-mixing step, 750 μL of ACN was added followed by vortex-mixing and centrifugation (8517*g*, 10 min, 4 °C). The supernatant was evaporated under a gentle nitrogen (N_2) stream (45 ± 5 °C). The dry residue was dissolved in 262.5 μL of water/MeOH (80:20, v/v) for pig plasma and in 5 mM ammonium formate in water (pH 9)/MeOH (95:5, v/v) for chicken plasma. After a vortex-mixing step, the sample was filtered through a Millex-GV PVDF filter (0.22 μm) and transferred to an autosampler vial. A 10 μL aliquot was injected onto the LC-MS/MS instrument.

Plasma Protein Binding. Plasma protein binding of TeA was assessed by spiking fresh blank pig and broiler chicken plasma at 10, 50, and 100 ng/mL. At each concentration level, one aliquot (aliquot 1) followed the plasma sample treatment (vide supra), but without filtering through a Millex-GV filter. A second aliquot and a third aliquot (aliquots 2 and 3) were incubated in a hot water bath, set at 37 and 41 °C for pig and broiler chicken plasma, respectively. After 1 h, aliquots 2 and 3 were transferred onto Amicon Ultra-0.5 centrifugal filter devices. Following centrifugation (8517*g*, 15 min, 37 or 41 °C), aliquots 2 and 3 were treated in a similar way as aliquot 1.

DOI: 10.1021/acs.jafc.5b02828
J. Agric. Food Chem. 2015, 63, 8560−8567

Corresponding calibration curves were used to quantify TeA in each aliquot. Plasma protein binding was calculated at each level (10, 50, and 100 ng/mL) using the following equation:[17]

$$\text{plasma protein binding} = \frac{(C_{\text{aliquot 1}} - C_{\text{av in aliquots 2 and 3}}) \times 100}{C_{\text{aliquot 1}}} \quad (1)$$

Liquid Chromatography. The LC system consisted of a quaternary, low-pressure mixing pump with vacuum degassing (type Surveyor MSpump Plus, ThermoFisher Scientific, Breda, The Netherlands) connected to an autosampler with a temperature-controlled tray and column oven (type Autosampler Plus, ThermoFisher Scientific). Chromatographic separation was achieved on a Zorbax Eclipse Plus column (C18; i.d., 3.0 × 100 mm; d.p., 3.5 μm) in combination with a guard column of the same type (i.d., 2.1 × 12.5 mm; d.p., 5 μm), both from Agilent Technologies (Sint-Katelijne-Waver, Belgium).

Mobile phase A consisted of 0.1 mM ammonium bicarbonate in water/MeOH (95:5, v/v) or 5 mM ammonium formate in water (pH 9) for pig and chicken plasma analysis, respectively. Mobile phase B consisted of MeOH. For the analysis of pig plasma samples, the following gradient elution program was run: 0.0−0.5 min (70% A, 30% B), 0.5−2.0 min (linear gradient to 20% A, 80% B), 2.0−7.0 min (20% A, 80% B), 7.0−7.5 min (linear gradient to 70% A, 30% B), 7.5−12.5 min (70% A, 30% B). For the analysis of broiler plasma samples, the gradient elution program was as follows: 0.0−2.0 min (90% A, 10% B), 2.0−2.5 min (linear gradient to 2% A, 98% B), 2.5−8.5 min (2% A, 98% B), 8.5−9.0 min (linear gradient to 90% A, 10% B), 9.0−12.5 min (90% A, 10% B). The flow rate was set at 300 μL/min. The column oven and tray temperature were set at 50 and 5 °C, respectively.

Mass Spectrometry. The LC column effluent was interfaced to a TSQ Quantum Ultra triple-quadrupole mass spectrometer, equipped with a heated electrospray ionization (h-ESI) probe operating in the negative ionization mode (all from ThermoFisher Scientific). Instrument parameters were optimized by syringe infusion of a WS (1 μg/mL) of TeA and the IS. The following MS/MS parameters were used: spray voltage, 4000 V; vaporizer temperature, 250 °C; sheath gas pressure, 40 arbitrary units (au); ion sweep gas pressure, 2.0 au; auxiliary gas pressure, 23 au; capillary temperature, 300 °C; source CID collision energy, 5 eV; and collision pressure, 1.5 mTorr. The resolution for Q1 and Q3 was set at 0.7 full width at half-maximum (fwhm).

Acquisition was performed in the selected reaction monitoring (SRM) mode. The following transitions (m/z) were monitored for qualification and quantification, respectively, for TeA, 196 → 112 and 196 → 139, and for IS, 203 → 142 and 203 → 113. Tube lens offset was set at 98 and 84 V for TeA and IS, respectively.

Method Validation. The method was validated according to a validation protocol previously described by De Baere et al., using spiked blank plasma samples obtained from healthy, untreated animals.[18] A set of parameters that were in compliance with the recommendations and guidelines defined by the European Community and with criteria described in the literature were evaluated.[18−22] These include evaluation of linearity, within- and between-run accuracy and precision, limit of quantitation (LOQ), limit of detection (LOD), specificity, carry-over, extraction recovery (R_E), and matrix effects (signal suppression or enhancement, SSE).

Linearity. Linearity was evaluated by preparing three matrix-matched calibration curves on three different days. Additionally, freshly prepared calibration curves were included during the analysis of the samples obtained from the toxicokinetic study. Calibration curve samples (range of 5−200 ng/mL) were prepared by applying standard working solutions directly onto the blank plasma samples, followed by a vortex mixing step. After 5 min of equilibration, the calibration curve samples were treated in a similar way as the unknown samples. The correlation coefficients (r) and goodness-of-fit coefficients (g) were calculated and had to be ≥0.99 and ≤20%, respectively.[18,21,22] The following equation was used to calculate g:

$$g = \sqrt{\frac{\sum (\%\text{difference})^2}{n-1}} \quad (2)$$

$$\text{with \% difference} = \frac{x_{\text{back-calculated}} - x_{\text{nominal}}}{x_{\text{nominal}}} \times 100$$

Accuracy and Precision. Within-run accuracy and precision (repeatability) were determined by analyzing six blank samples that were spiked at 5, 10, and 100 ng/mL in the same run. The between-run accuracy and precision (reproducibility) were determined by analyzing two blank samples per concentration level (5, 10, and 100 ng/mL) on three different days (n = 6). The acceptance criteria for accuracy were −30% to +10% and −20% to +10% for concentration levels between 1 and 10 ng/mL and ≥10 ng/mL, respectively. The precision was evaluated by the determination of the relative standard deviation (RSD), which had to be below the RSD_{max} value. For the within-day precision, RSD_{max} is fixed at 25, 15, and 10% for concentrations of 5, 10, and 100 ng/mL respectively,[20] whereas for between-run precision, the RSD had to be below the RSD_{max} calculated by the Horwitz equation:

$$RSD_{max} = 2^{(1-0.5\log(\text{concn}))} \quad (3)$$

Limit of Quantitation. The LOQ was the lowest concentration of the analyte for which the method was validated with an accuracy and precision that fell within the recommended ranges (see Accuracy and Precision). The LOQ was also established as the lowest point of the calibration curve. The LOQ was determined by analyzing six samples spiked at a TeA concentration level of 5 ng/mL, on the same day.

Limit of Detection. The LOD was defined as the lowest concentration that could be recognized by the detector with a signal-to-noise (S/N) ratio of ≥3. The LOD values were calculated using the samples spiked at the LOQ level.

Specificity. The specificity of the method was verified by analyzing 20 different blank plasma samples from both pigs and broiler chickens. The eventual analyte concentration of a peak in the elution zone of TeA or the IS had to be below the LOD.

Carry-over. The absence of carry-over was verified by analyzing the reconstitution solvent injected after the highest calibration sample (200 ng/mL). If a peak was observed in the elution zone of TeA or the IS, it had to be below the LOD.

Extraction Recovery and Matrix Effects. The slopes of three calibration curves were used to determine the extraction recovery (R_E) and the matrix effects (SSE) as described by Matuszewski et al.[23] The first calibration curve was made by spiking blank plasma samples before extraction at concentration levels of 1, 2, 5, 10, 20, 50, 100, and 200 ng/mL (= spiked samples). The second calibration curve was made by spiking blank plasma samples after extraction (= spiked extracts), whereas the third curve was prepared using standard solutions in the reconstitution solvent (= standard solutions). No IS was added, and absolute areas were used to calculate the R_E and SSE through the following equations:

$$R_E = \frac{\text{slope curve spiked samples}}{\text{slope curve spiked extracts}} \quad (4)$$

$$\text{SSE} = \frac{\text{slope curve spiked extracts}}{\text{slope curve standard solutions}} \quad (5)$$

Toxicokinetic Analysis. Noncompartmental toxicokinetic analysis was performed with WinNonlin 6.3 (Pharsight, St. Louis, MO, USA). The following main toxicokinetic parameters were calculated for iv and po administration in both animal species: area under the plasma concentration−time curve from time 0 to last concentration (AUC_{0-t}, ng·h/mL), area under the plasma concentration−time curve from time 0 to infinity (AUC_{0-inf}, ng·h/mL), maximum concentration after oral administration (C_{max}, ng/mL), plasma concentration at time of iv injection (C_0, ng/mL), time to maximal plasma concentration (t_{max}, h), elimination rate constant (k_{el}, h^{-1}), elimination half-life ($t_{1/2el}$, h), total body clearance (Cl, mL/h/kg), volume of distribution (V_d, mL/kg),

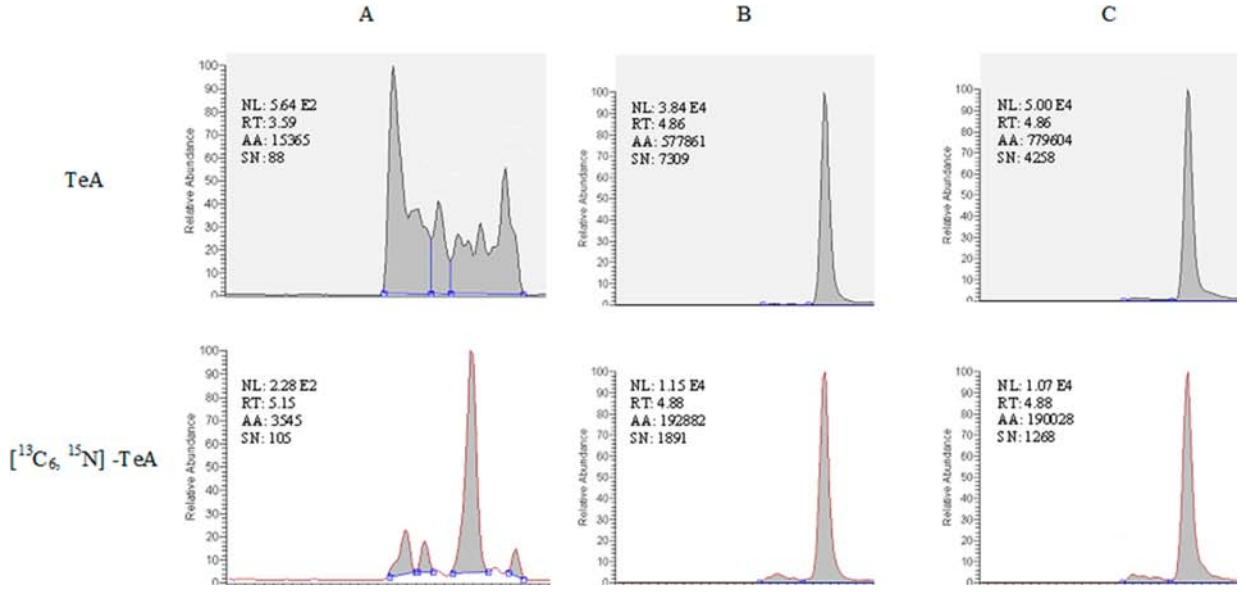

Figure 2. LC-MS/MS chromatograms of (A) a blank broiler plasma sample, (B) a spiked broiler plasma sample (tenuazonic acid (TeA) concentration = 100 ng/mL), and (C) an incurred broiler plasma sample that was taken at 2 h pa of a single oral dose of 0.05 mg TeA/kg BW (TeA concentration = 139 ng/mL). The upper trace presents TeA, and the lower trace presents the internal standard ([$^{13}C_6$, ^{15}N]-TeA).

Table 1. Results of the Evaluation of Linearity (Goodness-of-fit Coefficient (g), Correlation Coefficient (r)), Extraction Recovery (R_E), Matrix Effects (Signal Suppression or Enhancement, SSE), Limit of Quantitation (LOQ), and Limit of Detection (LOD) for the Analysis of Tenuazonic Acid in Plasma from Pigs and Broiler Chickens[a]

matrix	calibration range (ng/mL)	g (%)	r	R_E (%)	SSE (%)	LOQ (ng/mL)	LOD (ng/mL)
pig plasma	5−200	3.17	0.9996	91.8	37.8	5.0	0.01
broiler chicken plasma	5−200	5.96	0.9992	86.2	102.5	5.0	0.22

[a]Acceptance criteria: $g \leq 20\%$, $r \geq 0.99$.

and mean residence time (MRT, h). The absolute oral bioavailability (F) was calculated using the following equation:

$$F = \frac{AUC_{0-inf\,po}}{AUC_{0-inf\,iv}} \quad (6)$$

Cl and V_d after po administration were corrected for F. The mean absorption time (MAT, h) was calculated using the following equation:

$$MAT_{po} = MRT_{po} - MRT_{iv} \quad (7)$$

Statistical Analysis. To assess the repeatability and reproducibility, a one-way analysis of variance (ANOVA, SPSS 21, IBM, Armonk, NY, USA) was performed at each calibrator concentration level (5, 10, and 100 ng/mL) for both broiler chicken and pig plasma. Furthermore, ANOVA was performed on all toxicokinetic parameters in both animal species and between both routes of administration. $AUC_{0-inf\,iv}$, $AUC_{0-t\,iv}$, $t_{1/2el\,iv}$, MRT_{iv}, $t_{max\,po}$, $t_{1/2el\,po}$, and MRT_{po} were compared between broilers and pigs using a Kruskal−Wallis test. The level of significance was set at 0.05.

RESULTS

LC-MS/MS Method. In the present study, the use of a double end-capped Zorbax Eclipse Plus column resulted in good chromatographic properties because TeA and the IS eluted as a sharp peak in both pig and broiler plasma (Figures 1 and 2). The use of ammonium bicarbonate and MeOH as mobile phases in a gradient elution program gave reproducible results in pig plasma. For the analysis of chicken plasma, the mobile phase ammonium bicarbonate in water/MeOH was replaced by ammonium formate in water and the gradient was adjusted. This resulted in a better chromatographic performance and a more robust method for TeA in broiler plasma (Figure 2).

Table 1 summarizes the validation results obtained for TeA in pig and chicken plasma. Linear matrix-matched calibration curves were reached (range of 5−200 ng/mL) with g and r values falling well within the acceptance criteria. The LOQ was 5.0 ng/mL in both pig and broiler plasma, whereas the LODs were 0.01 and 0.22 ng/mL in pig and chicken plasma, respectively. Furthermore, the protein precipitation sample treatment yielded high extraction recoveries, that is, 91.8% in pig plasma and 86.2% in broiler chicken plasma. There was a strong suppression of the signal of TeA in pig plasma (SSE = 37.8%), but not in broiler chicken plasma (SSE = 102.5%).

The within-day and between-day precision and accuracy fell within the acceptance ranges and are presented in Table 2. There was no statistically significant difference in within-day and between-day precision for both pig and broiler chicken plasma at the concentration levels tested (5, 10, and 100 ng/mL). The method was specific in both pig and broiler plasma because no interfering peaks could be detected in any of the blank samples at the retention time of TeA. Moreover, no significant carry-over was present, because no TeA was detected with a concentration higher than the LOD in the reconstitution solvent injected after the highest calibration sample (data not shown).

Toxicokinetic Studies. No general side effects were observed after the po or iv administration of 0.05 mg TeA/kg BW as a single dose. The plasma concentration−time profile of TeA in pigs and broiler chickens is shown in panels A and B of Figure 3, respectively. Table 3 summarizes the main

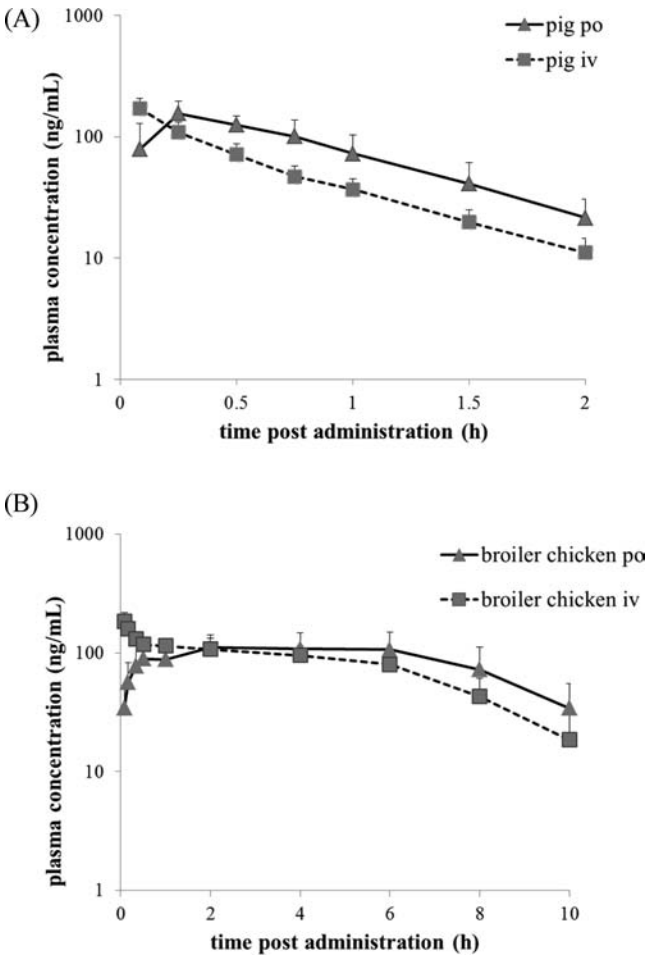

Figure 3. Plasma concentration−time profile of tenuazonic acid in (A) pigs (n = 8) and (B) broiler chickens (n = 5) after oral (po) and intravenous (iv) administration. Values are presented as mean ± SD.

toxicokinetic parameters. Mean AUC_{0-t} values were 108.9 and 151.7 ng·h/mL in pigs and 805.6 and 893.2 ng·h/mL in broiler chickens after iv and po administration, respectively. Consequently, TeA was completely absorbed after oral administration in pigs (mean F = 1.47) and broiler chickens (mean F = 1.24). Mean maximum concentration after oral administration was reached at 0.32 h pa in pigs and at 2.60 h in broiler chickens. Furthermore, TeA was rapidly eliminated after po administration in pigs, but not in broiler chickens. In pigs, $t_{1/2el}$ was 0.51 and 0.55 h after iv and po administration, respectively. In contrast, $t_{1/2el}$ was much longer in broiler chickens, that is, 2.03 and 2.45 h after iv and po administration, respectively. The mean Cl values were 448.4 and 446.1 mL/h/kg in pigs and 59.3 and 59.2 mL/h/kg in broiler chickens after iv and po administration, respectively. The mean V_d values were 325.8 and 358.4 mL/kg in pigs and 164.6 and 207.2 mL/kg in broiler chickens after iv and po administration, respectively. The mean MRT values were 0.70 and 0.94 h in pigs and 4.46 and 5.52 h in broiler chickens after iv and po administration, respectively. In both animal species, the k_{el}, $t_{1/2el}$, Cl, and V_d did not statistically differ after iv or po administration. Plasma protein binding did not significantly differ between both animal species and was 72.8 ± 3.4 and 58.1 ± 9.2% in broiler chickens and pigs, respectively (p = 0.06).

DISCUSSION

LC-MS/MS Method. First, a sensitive and specific LC-MS/MS method was developed and validated to quantify TeA in pig plasma. Next, minor modifications were made for quantification of TeA in chicken plasma.

The sample pretreatment consisted of a plasma protein precipitation method using ACN. Initially, a rather extensive sample preparation procedure for chicken plasma was evaluated. Three solid-phase extraction (SPE) columns were tested, that is, HybridSPE-Phospholipid cartridges (Sigma-Aldrich), C18 Bond elut (Agilent Technologies), and Oasis HLB columns (Waters, Zellik, Belgium). Compared to the protein precipitation method, the signal was reduced by factors of approximately 100 and 10 when using the Bond elut and HLB columns, respectively. The signal was completely lost when using the HybridSPE-Phospholipid cartridges. Therefore, the protein precipitation method was preferred as the final sample preparation method in both chicken and pig plasma. Protein precipitation is a frequently used sample preparation method for the LC-MS/MS analysis of several mycotoxins in pig and broiler chicken plasma.[24−27] Despite several benefits of this extraction procedure, such as high throughput and cost effectiveness, a main drawback is the sustainability of the LC-MS equipment due to remaining matrix compounds such as phospholipids in chicken plasma. Clotting was prevented by adjusting the mobile phase and gradient elution program for the analysis of TeA in chicken plasma, which resulted in a delayed retention time. Also, the divert valve was set to send as much effluent as possible to the waste.

With regard to chromatographic performance, TeA has been described as a troublesome compound because of its acidic and metal-chelating properties. To obtain better chromatographic properties, modifiers such as $Zn(II)SO_4$ were added to the mobile phase. However, these modifiers were not suited for MS.[5,12,13] Shephard et al. improved the chromatographic performance of TeA by using an end-capped C18 column, which prevented interactions between the amine moiety of TeA and active silanol groups on the column.[14] In the present study,

[a]Values are presented as the mean ± SD. AUC_{0-t}, area under the plasma concentration−time curve from time 0 to last concentration > LOQ; AUC_{0-inf}, area under the plasma concentration−time curve from time 0 to infinity; F, oral bioavailability; C_{max}, maximal plasma concentration; C_0, plasma concentration at time 0; t_{max}, time to maximal plasma concentration; k_{el}, elimination rate constant; $t_{1/2el}$, elimination half-life; Cl, total body clearance corrected for F; V_d, volume of distribution corrected for F; MRT, mean residence time; MAT, mean absorption time. Values sharing a lower case online letter for the same parameter do not differ from one another at the 5% global significance level.

the use of a double end-capped Zorbax Eclipse Plus column resulted in good chromatographic properties because TeA and the IS eluted as a sharp peak in both pig and broiler chicken plasma. Furthermore, the addition of ammonium bicarbonate to the mobile phase has been described to give reliable chromatographic properties of TeA in tomato and pepper product extracts, and ammonium formate has been used in LC-MS/MS analysis of TeA in different food commodities.[5,13] However, it must be mentioned that the use of ammonium formate resulted in a more robust method in the long term, because it produces no precipitation of the transfer tube, in contrast to ammonium bicarbonate.

The validation results (Tables 1 and 2) demonstrate the applicability of the developed LC-MS/MS method for a proper quantification of TeA in plasma samples taken during the toxicokinetic studies. Notwithstanding the strong suppression of the signal of TeA in pig plasma, a correct quantification was attained by using a stable isotopically labeled IS. Moreover, the IS was added before the start of the sample pretreatment and thus compensates for analyte losses during the extraction and cleanup procedure.[28,29]

Toxicokinetic Studies. The single dose of 0.05 mg/kg BW administered in the study presented corresponds with a daily intake of feed (approximately 1.5 kg for pigs and 150 g for broiler chickens) contaminated with realistic levels and covers the range between the median and maximum levels detected by Streit et al., namely, 68 and 1983 μg/kg feed, respectively.[3] Comparison of the toxicokinetic parameters after po and iv administration of TeA in both pigs and broiler chickens reveals no statistically significant difference in k_{el}, $t_{1/2el}$, Cl, and V_d between both routes of administration. However, both AUC_{0-t} and AUC_{0-inf} are higher after po administration compared to iv administration (Table 3). The higher AUC after po administration results in an F > 1, for both animal species. Toutain and Bousquet-Mélou list various reasons why a bioavailability >100% is regularly reported.[30] In the study presented, the dose and Cl, two factors influencing AUC, did not differ between both routes of administration. Furthermore, the plasma samples obtained after iv and po administration of one animal were analyzed on the same day, using the same procedure, to exclude analytical variation. The percentage extrapolated AUC_{t-inf} was <20% in both animals, indicating appropriate and sufficient selection of blood collection time points pa.[30] On the other hand, some earlier blood sample collection immediately after iv administration (<5 min pa) could possibly more accurately estimate the AUC and initial phase after iv bolus administration.[30] This could result in a higher AUC after iv administration, especially in pigs, which showed a rapid Cl. Consequently, a higher AUC after iv administration could result in a bioavailability approximating 100%.

The toxicokinetic behavior of TeA is noticeably different between pigs and broiler chickens. Although TeA was completely absorbed after oral administration in both animal species, the absorption rate was deemed to be slower in broilers.

Furthermore, the shorter $t_{1/2el}$ demonstrates the significantly more rapid elimination of TeA in pigs. V_d is rather small in both pigs and broiler chickens. Although statistically significant, the difference in V_d between pigs and broiler chickens is negligible in comparison to the striking difference in Cl between both animal species. Thus, the longer $t_{1/2el}$ is most likely due to the significantly lower Cl of TeA in broilers.

The total body Cl of a compound equals the sum of all clearances, with the most important organs being the liver and kidney. Remarkably, our results indicate a distinctly lower Cl in broilers, suggesting clear differences in elimination processes between both animal species. Because only non-plasma protein bound compounds are eliminated by glomerular filtration,[31] TeA plasma protein binding was determined in the present study. Mean plasma protein binding did not significantly differ between broiler chickens (72.8%) and pigs (58.1%). However, differences in Cl between pigs and broilers could also be attributed to species differences in active tubular secretion and/or reabsorption.[31] Another hypothesis for the slower elimination of TeA in broiler chickens could be zero-order biotransformation kinetics, in which a saturation of biotransformation enzymes or a clear inhibition of these enzymes occurs.[32] However, in humans, metabolization of TeA seems limited, because 90% of the ingested dose was excreted

DOI: 10.1021/acs.jafc.5b02828
J. Agric. Food Chem. 2015, 63, 8560−8567

unchanged in the urine.[6] Additionally, considering complete oral bioavailability, no first-pass effect by the liver was seen in pigs or broiler chickens. Because, to our knowledge, no in vitro nor in vivo information about the biotransformation of TeA is available, further research is needed to elucidate phase I and II metabolites in pigs and broiler chickens.

Few toxicity studies have been performed in chickens. After chronic exposure, Giambrone et al. noted a decreased weight gain and lowered feed efficiency when TeA was given at 10 mg/kg feed or by daily esophageal intubation (1.25 or 2.5 mg/kg BW) for 3 weeks. Other symptoms in the chickens receiving TeA via intubation were an enlarged and mottled spleen, erosions of the gizzard, and hemorrhages.[9] Because the maximum feed contamination level detected by Streit et al. was <2 mg TeA/kg feed, the 10 mg TeA/kg feed administered daily by Giambrone et al. is rather high.[3,9] Nevertheless, more subtle toxic effects could possibly occur when broiler chickens are fed daily highly contaminated feed, especially because the elimination rate is low and accumulation could occur. Accumulation of TeA in tissues and edible offal of broiler chickens could implicate health risks for human consumers. Therefore, future tissue residue studies are recommended. To our knowledge, no studies concerning the toxicity of TeA in pigs have been performed. Further research is imperative for a better understanding of the possible harmful effects of TeA in both animal species and humans. Moreover, the toxicokinetic parameters and toxic effects in pigs could be an indication for those in humans, because pigs possess multiple anatomical, physiological, and biochemical characteristics that closely resemble humans.[33−35]

In conclusion, a LC-MS/MS method to quantitate TeA in pig and broiler chicken plasma was successfully developed and validated. Using this method, TeA plasma concentrations were determined after single po and iv administration of 0.05 mg TeA/kg BW in pigs and broiler chickens, in a two-way crossover design. This study demonstrated the complete absolute oral bioavailability and significant differences in the toxicokinetic profile of TeA between pigs and broiler chickens. The elimination of TeA was slower in broiler chickens ($t_{1/2el,\ iv}$, 2.03 h; Cl_{iv}, 59.3 mL/h/kg) compared to pigs ($t_{1/2el,\ iv}$, 0.51 h; Cl_{iv}, 448.4 mL/h/kg). Tissue residue studies are recommended to assess the carry-over of TeA from feed to edible tissues and offal. Further research is needed to elucidate the biotransformation and excretion processes of TeA and other *Alternaria* mycotoxins in animal species and humans for a better understanding of the possible toxicity of these mycotoxins.

roasting until it turns to dark brown. After roasting, sometimes the roasted coffee beans are brought to the family members or visitors to allow them to experience the aroma. Afterwards, it will be ground to a fine powder using a traditional wooden mortar and pestle. The powder is poured into boiled water in a special local coffee clay pot called a "jebena". Coffee will be ready to serve when the steam with an attractive flavor starts to come out from the nozzle. After that, the jebena is placed on ground for about 3 min to let the coffee sludge settle to the bottom. The brewed coffee is then poured into small cups and served (personal observation). In general, coffee is an important crop for domestic consumption as well as a source of hard currency for the nation.

However, studies have indicated that coffee beans have different pesticide residues. Even though coffee is the most important agricultural product for human consumption as well as for the economic growth of the producing countries, the beans might have different pesticide residues that can expose consumers to hazardous agrochemicals.[7] Because of the high consumption of coffee and its economic importance, people from the producer, exporter, and consumer countries give more attention to its safety.[8] Even though pesticide contamination in green coffee beans is limited during agricultural treatments, there may be contamination during transportation and storage.[9] Different studies have stated that coffee is contaminated by different classes of pesticides applied in the field. According to the U.S. Food and Drug Administration, from a survey of 60 imported green coffee bean samples, some of them contained different pesticide residues, such as chlorpyrifos at a concentration ranging from 0.01 to 0.04 mg/kg and pirimiphos methyl at 0.01 mg/kg.[10] From a study done in Brazil, the residues of different pesticides, such as endosulfan, chlorpyrifos, cypermethrin, and captafol, have been detected in coffee beans from either registered or illegal use.[11] Additionally, from the previous study done in Ethiopia, DDT, cypermethrin, permethrin, deltamethrin, chlorpyrifos ethyl, and endosulfan (α and β) were detected in coffee beans at concentrations ranging from 0.011 to 1.115 mg/kg[7].

The pesticide residues, to a variable extent, left in the food materials after harvesting, are beyond the control of consumers and may have deleterious effects on human health. Because Ethiopia is the largest producer, exporter, and consumer of coffee in Africa, a pragmatic solution should be developed to tackle the problem of coffee safety. Different studies have revealed that food processing can be one important solution that has a significant role for the reduction of pesticide residues in different food items.[2−4,12] Nowadays, there is an increasing need for information on the effect of various food processes on pesticide residues. Few studies have indicated the effect of coffee roasting on the reduction of pesticide residues.[13,14] However, no studies are available on the effect of household coffee processing (washing, roasting, and brewing) methods on pesticide residues. Therefore, the main aim of the present study is to evaluate the effect of household processing on pesticide residues in coffee and to determine the processing factor (PF) for each of the processing steps.

2. MATERIALS AND METHODS

2.1. Chemicals and Reagents. Analytical grade acetonitrile (99.9% purity) was supplied by VWZ-prolabo. High performance liquid chromatography grade *n*-hexane (98% purity) and acetone (98.9% purity) that were obtained from ALLthec were used to extract the pesticide residues from the raw coffee beans and after different processing steps. Thermo Fisher Scientific supplied $MgSO_4$ (98% purity), NaAc (99% purity), the 50 mL centrifuge tube, the 15 mL dispersive solid phase extraction cleanup tube packed with primary secondary amine (PSA: 99% purity), magnesium sulfate ($MgSO_4$, 98% purity), and octadecyl (C18, 99% purity). The pesticides under study ($p'p$-DDE (99.9%), $p'p$-DDD (99.3%), $o'p$-DDT (100%), $p'p$-DDT (99%), endosulfan α (98.5%), endosulfan β (98%), Permethrin (98%), cypermethrin (98%), deltamethrin (99%), Chlorpyrifos ethyl (99.5%), Heptachlor epoxide (99.5%) and hexachlorobenzene (98%)) with their highest analytical purity, were obtained from Supelco and delivered by Sigma-Aldrich Logistic Analytical. The physicochemical properties of the pesticides studied in the present study are presented in Table 1.

Table 1. Physicochemical Properties of the Pesticides under Study[a]

pesticides	water solubility (mg/L)	log k_{ow}	vapor pressure (mmHg)	mode of action
$p'p$-DDE	0.025	6.91	1.6×10^{-7}	contact
$p'p$-DDD	0.120	6.51	1.4×10^{-6}	contact
$o'p$-DDT	0.090	6.02	6.0×10^{-6}	contact
$p'p$-DDT	0.085	6.79	1.1×10^{-7}	contact
endosulfan α	0.530	3.83	1×10^{-5}	contact
endosulfan β	0.280	3.62	1×10^{-5}	contact
permethrin	0.006	6.10	2.15×10^{-8}	contact
cypermethrin	0.009	5.40	2.3×10^{-7}	contact
deltamethrin	0.002	6.10	1.5×10^{-8}	contact
heptachlor epoxide	0.350	5.40	3.0×10^{-4}	contact
hexachlorobenzene	0.006	5.73	1.09×10^{-5}	systemic
chlorpyrifos ethyl	1.400	4.70	1.9×10^{-5}	contact

[a]log k_{ow} = logarithm of octanol-water partion coefficient.

2.2. Sampling. A 3 kg portion of green coffee beans was bought from a local market in Jimma zone, southwestern Ethiopia in August, 2014 and served as a blank and spiked sample. Samples were packed in polyethylene plastic bags, after which they were sealed and labeled properly. The samples were transported to the laboratory and stored at −20 °C until extraction was done.

2.3. Quality Control. *2.3.1. Linearity.* The quantitative determination of the pesticide residues in processed and unprocessed coffee beans was done on the basis of an external standard method. The calibration curves were obtained by injecting five different concentrations of the pesticide standards in the range of 0.005−1 mg/L. The regression coefficient (r^2) was >0.995 for all the pesticides under study. Identification and quantification of the pesticides were done on the basis of the retention time and peak area, respectively.

2.3.2. Recovery Study. To evaluate the performance of the analytical procedures recovery (% recovery), studies were undertaken for each pesticide. A 10 g sample of pesticide-free coffee beans was weighed on the analytical balance and spiked with 40 μL of 100 mg/L of each pesticide in three replicates. The extraction was performed in a similar way with the samples. The percent recovery was derived from the equation: (amount of pesticide observed)/(amount of pesticides spiked) × 100. The percent relative standard deviation (% RSD) was obtained by dividing the standard deviations by the average concentration and multiplying the result by 100.

DOI: 10.1021/acs.jafc.5b03327
J. Agric. Food Chem. 2015, 63, 8568−8573

2.4. Treatment of Raw Coffee Bean. A 10 g portion of raw coffee beans was weighed on an analytical balance and spiked with 40 μL of a 100 mg/L solution of each pesticides under study (DDT metabolites, cypermethrin, deltamethrin, permethrin, endosulfan [α, β] and chlorpyrifos ethyl, heptachlor epoxide, and hexachlorobenzene) in three replicates to increase the reliability of the results. Spiking was done for each household coffee processing method (washing, roasting, and brewing). The pesticides selected for this study were detected in the previous study done on Ethiopian coffee beans,[7] except for heptachlorepoxide and hexachlorobenzene, in which the investigators expected them from previous application in the environment. The spraying of the coffee beans was done in a Petri dish to get equal distribution of the pesticides for each bean. After spraying, the Petri dishes were covered with aluminum foil and placed in refrigerator at 4 °C for 24 h to increase the contact time between the pesticides and the matrix. After 1 day, the processing methods (washing, roasting, brewing) and the extraction, clean up, and analysis were followed as stated below.

2.5. Extraction and Cleanup of the Samples. To assess the effect of washing, roasting, and brewing of coffee on pesticide residues, the extraction and cleanup of the raw and processed coffee beans were done using the modified Quick, Easy, Cheap, Effective, Rugged and Safe (QuEChERS) method combined with a dispersive solid phase extraction cleanup (d-SPE) method. The analytical procedure was based on the method AOAC 2007.01.[15] The subsequent processing steps of the coffee beans were done to correspond, as closely as possible, to the actual traditional household coffee processing in Ethiopia. Blank coffee bean (nonspiked) was also analyzed together with the raw and processed coffee beans. The extraction and cleanup procedures for raw coffee beans and processed coffee beans were as follows:

2.5.1. Raw coffee beans. After holding the spiked samples for 1 day, the treated raw coffee bean was ground and homogenized using a coffee grinder with a knife in it. A 15 mL portion of acetonitrile was added, and the sample was shaken by hand for 30 s. Then 6 g of $MgSO_4$/1.5 g of NaCl/1.5 g of Na_3citrate·$2H_2O$/0.750 g of Na_2Hcitrate was added, and the mixture was again shaken for 5 min to prevent formation of agglomerates between the water and $MgSO_4$. Then the samples were centrifuged at 5000 rpm for 5 min. The upper organic layer was taken for cleanup using a 15 mL dispersive solid phase extraction tube (d-SPE) containing 300 mg of PSA, 900 mg of $MgSO_4$, and 150 mg of C18 and then shaken for 30 s. The cleaned extracts were centrifuged to get a clear solution. After centrifugation, 5 mL of the upper layer was taken into a 100 mL flat bottom flask and evaporated to dryness using a rotary evaporator (N18673 Rotavapor; Buchi) at a temperature of 40 °C. A 2 mL portion of *n*-hexane/acetone (9:1 V/V) was added for solvent exchange to make the sample amenable for GC/ECD analysis. The blank coffee bean was also extracted in a similar way, as were with the spiked samples. Then the extract was placed into a vial for GC/ECD analysis.

2.5.2. Washed Coffee Beans. The spiked coffee beans were washed thoroughly for 5 min under normal tap water (25−30 °C), which resembles coffee bean washing at the household level. Then all other procedures for the unprocessed coffee beans were applied for the extraction, cleanup, and analysis for the presence of pesticides.

2.5.3. Roasted Coffee Beans. The spiked coffee beans were roasted on a stove at a temperature range of 230−240 °C (light to medium) roasting and an average time of 12−14 min until the characteristics aroma or flavor of coffee appears. The roasting temperature and duration of roasting was based on a study done by Moon and Shibamoto.[16] The roasting processes were done in a way similar to the traditional Ethiopian household coffee roasting procedures. Then the other procedures for extraction and cleanup used for raw coffee beans were applied.

2.5.4. Brewed Coffee Beans. Some heat-resistant pesticides may be detected in a cup of coffee after the coffee beans were roasted. To determine the effect of brewing on the pesticides under study, the brewing process was also undertaken. The roasted coffee beans were ground to a fine powder using a coffee grinder (type 4041, 220-230 V/150w). The fine coffee powder was added to a coffee pot traditionally called a "Jebena" containing 100 mL boiled water and brewed for 10−12 min in a way similar to that of the tradition Ethiopian coffee brewing processes (personal observation). After brewing, the coffee pot was picked up from the stove and put on the ground until the infusion of the coffee was cooled and the coffee powder or sludge had settled to the bottom of the coffee pot. Then the upper liquid layer was removed carefully to the cups, and then extraction, cleanup and analysis of the brewed coffee solution was done in a way similar to that of the raw coffee beans.

2.6. Determination of Processing Factor (PF). The effect of household processing on the level of pesticides often correlates with the physicochemical properties of the pesticides under study, so it is important to adequately monitor the processing factor. The processing factor (PF) for all transformation steps was calculated as the ratio between the pesticide concentrations in the processed commodity (mg/kg) to the pesticide concentration in unprocessed (raw) commodity (mg/kg). According to Bonnechere and his colleagues,[17] a PF of <1 indicated that there is reduction of pesticides by the processing method (PF < 1 = reduction factor), whereas >1 indicated no reduction in weight or volume, (PF > 1 = a concentration factor). The processing factor is the proportional amount by which residues change when food is processed. For this study, it is calculated by the formula below:

$$\text{processing factor (PF)} = \frac{\text{concentration of pesticides in processed coffee beans (mg/kg)}}{\text{concentration of pesticides in raw coffee beans (mg/kg)}}$$

After obtaining the processing factor, the percent reduction (% reduction) for each processing method was calculated as follows: % reduction = (1 − PF) × 100.

2.7. Wash Water and Coffee Sludge Remaining at the Bottom of Pot after Coffee Brewing. Before the coffee was roasted, it was washed with water (which may remove some residues on the surface of the coffee beans). Additionally, after the coffee was brewed, there is sludge (powder or coffee residue) remaining in the bottom of the coffee pot, which may contain some pesticide residue that can evade the roasting process. Traditionally, this wash water and coffee sludge is often disposed of in the environment, which may contaminate food grown there. To check whether the wash water from the samples and the sludge of the coffee contain pesticide residues, these two samples were analyzed. The procedure was as follows: A 10 mL portion of the wash water (assuming 10 g of water) and 6−8 g of coffee sludge were weighed on an analytical balance and placed into a 50 mL centrifuge tube.

DOI: 10.1021/acs.jafc.5b03327
J. Agric. Food Chem. 2015, 63, 8568−8573

Then the extraction, cleanup, and analysis were done in a way similar to that of the raw coffee bean.

2.8. Analytical equipment. Quantitative estimations and chromatographic separation of each pesticide were done by gas chromatography with an electron capture detector (GC−ECD, Agilent Technologies 6890N) with an auto sampler. The coffee bean processing was undertaken to see their effect on the pesticides previously detected in Ethiopian green coffee beans,[7] so the chromatographic conditions for this study were the same as the previous paper, as explained below. A HP-5 capillary column of 30 m × 0.25 mm i.d. × 0.25 μm film thickness coated with 5% phenyl methyl siloxane (model no. Agilent 19091J-433) was used in combination with the following oven temperature program: initial temperature, 80 °C; ramp at 30 °C min^{-1} to 180 °C; ramp at 3 °C min^{-1} to 205 °C; held for 4 min; ramp at 20 °C min^{-1} to 290 °C; held for 8 min; ramp at 50 °C min^{-1} to 325 °C. For deltamethrin, the oven temperature was maintained initially at 130 °C, held for 1 min, ramped at 30 °C min^{-1} to 280 °C, held for 16 min, ramped at 50 °C min^{-1} to 325 °C, and held for 3 min. The total GC run time was 27.92 min. Helium (99.9999% purity) was used as a carrier gas at a flow rate of 20 mL min^{-1}, and nitrogen was the makeup gas at a flow rate of 60 mL min^{-1}. An aliquot of 1 μL was injected in split mode at a split ratio of 50:1 and injection temperature of 280 °C. The pesticide residues were detected with an electron capture detector (μ-ECD) operated at a temperature of 300 °C. For the reliability of the results, each sample was analyzed in triplicate, and the mean concentration was computed accordingly.

2.9. Statistical Analysis. All the treatments for the three processing methods were done in three replicates, and values are shown as mean ± SD. Statistical significance was checked using the Kruskal−Wallis test to see if the processing methods (washing, roasting, and brewing) are different in the percent reduction of the pesticides under study. Differences at $P < 0.05$ were considered as significant.

3. RESULTS AND DISCUSSION

3.1. Quality Control Studies. The mean percent recovery for most of the pesticides was 80−120% and the percent relative standard deviation (% RSD) was below 10% for all the pesticides under study, except for cypermethrin and deltamethrin. All pesticides were in the acceptable analytical range (70−120% recovery and RSD < 20%). The regression coefficients (r^2) were >0.995 for all the pesticides. This method is accurate and precise for the analysis of the pesticides under study and fulfilled the requirement of European Document no. SANCO/12495/2011.[18] The results are indicated in Table 2.

3.2. Effect of Household Processing of Coffee Beans on Pesticide Residues. This study investigated the effect of household processing of coffee (washing, roasting, and brewing) on the stability of 12 pesticides, including metabolites and isomers. The concentration of the pesticides under study in raw and processed coffee beans are presented in Figure 1. Among the household processes, washing decreased the pesticide residues by 14.63−57.69%. This effect may be due to the fact that most of the pesticides have contact action and are found on the surface of the coffee beans. This washing process may help for the removal of the pesticides with the silverskin of the coffee (very thin layer of a coffee bean located just above the main part of the coffee beans), dust, or soil. Reports indicated that surface residues are easily amenable to removal by simple washing processes with water.[4] The majority

Table 2. Results of Regression Coefficient, Percent Recovery and Percent RSD[a]

pesticides	r^2	% recovery	% RSD
endosulfan α	0.998	80	6.3
endosulfan β	0.997	130	3.8
chlorpyrfos ethyl	0.995	122.5	2.0
permethrin	0.998	112.5	8.9
cypermethrin	0.999	127.5	19.6
deltamethrin	0.999	100	15.0
$p'p$-DDE	0.999	102.5	2.4
$p'p$-DDD	0.999	102.5	4.9
$o'p$-DDT	0.998	125	4.0
$p'p$-DDT	0.988	125	2.0
heptachlorepoxide	0.999	117.5	10.6
hexachlorobenzene	0.999	120	0.20

[a]RSD = relative standard deviation.

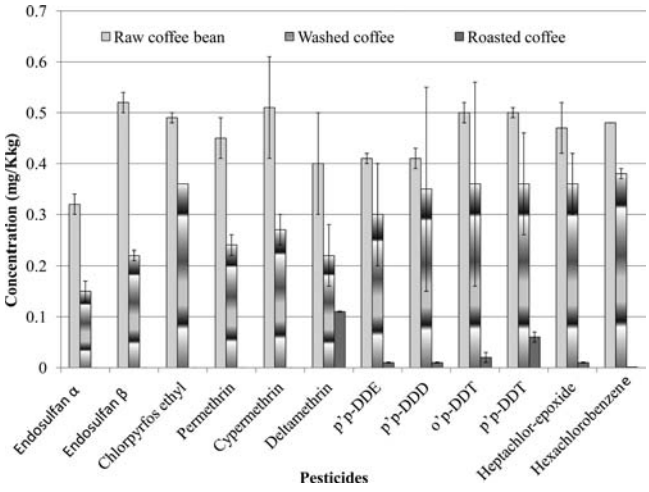

Figure 1. Mean pesticide residues (mg/kg) at different coffee processing steps. The error bars indicate standard deviation. Pesticides from brewed coffee were not detected and are not shown in this graph.

of the pesticides applied to agricultural crops are confined to the surface and a much smaller amount undergoes penetration to the plant system.[19] As a result, they can easily be acquiescent to being washed, trimmed, or peeled from the surface of the crop. The maximum reduction was observed for endosulfan α and β, for which the residue decreased by 53.13−57.69%, respectively. A similar result was observed from a study done in India: washing of the vegetable brinjal with tap water decreased endosulfan residue up to 55%; however, a lesser removal of heptachlor epoxide in cucumber was observed.[20]

The rinsability of some pesticides by washing with water may not always correlate with its water solubility.[21] As indicated in Table 1, most of the pesticides under study have low water solubility and high octanol-water partition coefficient (log k_{ow} > 3). Washing was found comparatively less effective in reducing the residues of $p'p$-DDD (14.63%), hexachlorobenzene (20.83%), heptachlor epoxide (23.40%), chlorpyrifos ethyl (26.53%), $o'p$-DDT ((28%), and $p'p$-DDT (28%).

In this study, roasting was found to be effective in affecting the stability of pesticide residues in coffee beans. By this process, reductions of the residues of the pesticides were in the range of 72.5−99.8%. The maximum reductions were observed in hexachlorobenzene (99.8%), heptachlor epoxide (97.9%), $p'p$-DDE, $p'p$-DDD (97.6%), and $o'p$-DDT (96%). Five of the

DOI: 10.1021/acs.jafc.5b03327
J. Agric. Food Chem. 2015, 63, 8568−8573

spiked pesticides (chlorpyrifos ethyl, permethrin, cypermethrin, and endosulfan α and β) were not detected after the roasting process. This may be due to the instability of these pesticides to the heat applied during the roasting process. Thermal processing treatments such as cooking, backing, blanching, steaming, and boiling have been found effective for the breakdown of various pesticides, depending on the type of pesticide.[22] Additionally, there may be a loss of the pesticides during the application of heat depending on their physicochemical properties, such as evaporation or thermal degradations.[23] From a study done in Japan on the behavior of pesticides in coffee beans, the pesticide residues decreased a significant amount after the coffee beans were roasted.[14]

After the coffee brewing process, none of the pesticides under study were detected. This process is found to be the most effective for the breakdown of the pesticides under study. As it has been explained by Abou-Arab and Abou Donia,[24] the elimination of the pesticide residue from the boiled extract (brewed coffee) may be due to the decomposition of the pesticide residue by the application of heat during brewing. The pesticide residues were significantly influenced by the roasting and brewing processes. In general, the three household coffee bean processing methods have a cumulative effect in the reduction of pesticides and help in solving health problems that can occur from exposure to pesticides in coffee.

3.3. Determination of the Processing Factor. The processing factor for each pesticide from each processing step was determined. The PFs for coffee samples after each processing step was <1, which indicated that the processing methods have an effect on pesticide residues. A study done by Bonnechere et al[17] has also indicated that a PF of less than a unit is an indication of pesticide residue reduction due to a specific food processing step. The PFs for the detected pesticides in the roasting process were the lowest, particularly for hexachlorobenzene. Heptachlorepoxide, $p'p$-DDE, $p'p$-DDD, and $o'p$-DDT ranged from 0.001 to 0.04. This indicated that the roasting process played the most important role in removing the pesticides from coffee beans compared with the washing process. The processing factor was not calculated for the pesticides not detected after the processing (Table 3).

The Kruskal–Wallis test showed that there is a strong variation in the stability of pesticide residues in coffee beans among the processing methods (P = 0.00001). The reduction of pesticide residues due to washing is significantly lower than roasting (p = 0.0001) and brewing processes (P = 0.00001); however, there is no significant difference between coffee roasting and coffee brewing (P > 0.05). According to Hasmukh et al.,[25] the washing process may depend on different factors, such as location, age of residue, water solubility, and temperature; this may be the reason for the variation. From the household processing methods, roasting and brewing are the most effective in decreasing the pesticides in coffee beans.

Table 3. Processing Factor for the Effect of Washing, Roasting and Brewing Processes[a]

Pesticide	PF Washing	PF Roasting	PF Brewing
endosulfan α	0.47	*a*	*a*
endosulfan β	0.42	*a*	*a*
chlorpyrefos ethyl	0.73	*a*	*a*
permethrin	0.53	*a*	*a*
cypermethrin	0.53	*a*	*a*
deltamethrin	0.55	0.28	*a*
$p'p$-DDE	0.73	0.02	*a*
$p'p$-DDD	0.85	0.02	*a*
$o'p$-DDT	0.72	0.04	*a*
$p'p$-DDT	0.72	0.12	*a*
heptachlor epoxide	0.77	0.02	*a*
hexachlorobenzene	0.79	0.001	*a*

[a]Not detected and the processing factor is not calculated.

3.4. Pesticide Residue in Wash Water and Coffee Sludge. To determine the level of pesticide liquid waste (wash water) and the coffee sludge that settled to the bottom of the coffee pot after the coffee was brewed, these two samples were analyzed. The result of the analyses revealed that all DDT metabolites ($p'p$-DDE, $p'p$-DDD, $o'p$-DDT, and $p'p$-DDT) and deltamethrin were detected in the wash water (Figure 2). This

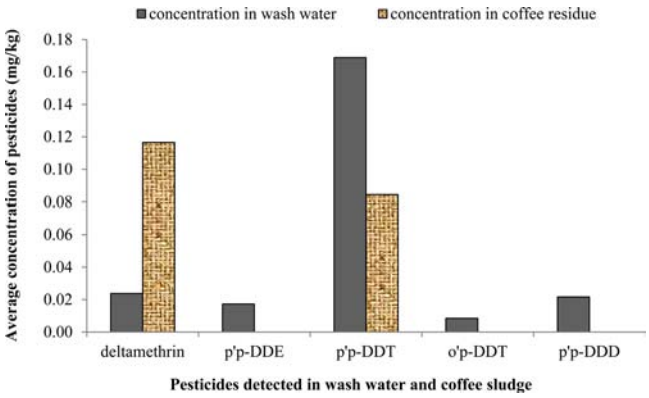

Figure 2. Average concentrations of pesticides detected in wash water and coffee sludge (mg/kg).

may be due to the fact that these pesticides have contact action (acting on surface) and may be removed with the coffee silverskin and found in the wash water. Most of the pesticides disappeared from the coffee beans during the roasting process. In the meantime, pesticides were not detected in the coffee sludge after brewing, except for deltamethrin and $p'p$-DDT. This may be because the percent reductions of deltamethrin (72.5%) and $p'p$-DDT (88%) after roasting of the coffee beans were low compared with other pesticides under study (Figure 2). The results indicated that the coffee sludge should not be scored when pouring the brewed coffee into a cup before human consumption. After brewing, it is necessary to wait some time until the sludge of the coffee completely settles to the bottom of the coffee pot.

In Ethiopia, the wash water from coffee beans and the residue from the brewed coffee are discarded to the open environment, which may pose contamination, so care should be taken during the disposal of both the liquid (wash water) and semi-solid coffee sludge) waste. In addition, during pouring of the coffee solution to drink or serve coffee, only the upper layer (not mixed with the sludge at the bottom of the pot) should be used for the safety of the consumers.

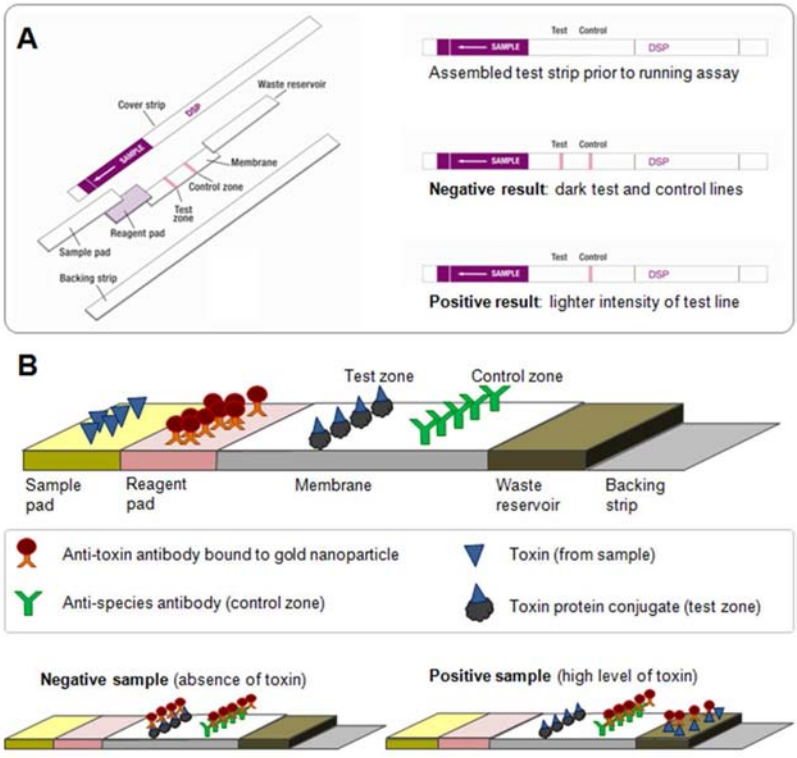

Figure 2. Diagrammatic views of the lateral flow immunoassay. Representations of the architecture and assembled test strips (A) and schematics of key interactions (B) are illustrated.

(TEFs) have been assigned equally for OA and DTX1 (1.0) and lower for DTX2 (0.6).[20] Acyl-derivatives (DTX3) have the TEF corresponding to the parent unesterified toxin. DTX3 esters cannot usually be detected directly via analytical methods, functional assays, or immunoassays because of their high molecular weight, lipophilicity, variability in structure, and/or lack of standards. Alkaline hydrolysis is a widely employed procedure to revert the esters back to the parent toxins by removal of the fatty acids, allowing an estimation of total toxicity.[21,22]

In Europe, the two main reference methods employed by national reference laboratories are the mouse bioassay (MBA) and liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). Alternative or complementary methods can be used if they are appropriately validated and are shown to provide an equivalent level of public health protection. In the United States, regulatory monitoring of OA toxins has been established in recent years, and LC-MS/MS is the preferred method.[13,23] The MBA has been regarded as a simple and generally effective method, keeping consumers safe.[24] However, limitations include low sensitivity (close to the MPL), the risk of false results, possible interference from hydrophilic toxins such as domoic acid and saxitoxin, in addition to moral and ethical concerns.[4,25] LC-MS/MS methods provide a more sensitive and specific option, but require high-cost equipment and skilled personnel, and fully replaced the MBA in the EU at the end of last year.[26]

As a result of the characteristics of the current method, there is an accepted need for rapid and low-cost screening tools which are sufficiently sensitive and specific.[25,27] Two main approaches which have been developed to help meet this need are functional assays based on protein phosphatase 2A (PP2A) receptor inhibition activity or immunoassays based on competitive antibody ligand reactions. PP2A is one of the enzymes inhibited by OA group toxins[28] and this enzymatic response has been employed to produce functional assays. Immunoassays, such as enzyme linked immunosorbent assays (ELISAs), provide another option. Both aforementioned methods are sensitive and specific while being faster than conventional confirmatory methods. However, these functional assays can be cumbersome, requiring multiple steps, laborious sample preparation, and often have longer time to results. Therefore, these assays do not fully meet the desired criteria for a rapid test. The lateral flow immunoassay (LFIA) format has higher potential to meet the criteria for a rapid and simple test. However, previous attempts at developing a suitable LFIA have not possessed the desired speed, cross-reactivity, sensitivity, or accuracy in addition to notable matrix effects.[27,29,30]

Furthermore, current extraction methods typically require relatively high solvent volumes, centrifugation, and in some cases expensive 0.2 or 0.45 μM membrane filtration, none of which were desired for a rapid and low-cost test.

As there are currently no means for rapid and effective screening for OA toxins in shellfish, the goals were to develop a simple to use and accurate LFIA which would have the potential for laboratory or field use.[31] In the LFIA system reported here, simple extraction and test procedures were developed in conjunction with an antibody possessing a favorable cross-reactivity profile.[32] A sample could be qualitatively screened for the presence of free toxins (OA, DTX1, DTX2) in less than 20 min, including sample extraction. Total toxins, including DTX3, could be detected with an additional hydrolysis step. There were no requirements for extensive equipment, calibration standards, or analyses of results.

DOI: 10.1021/acs.jafc.5b01254
J. Agric. Food Chem. 2015, 63, 8574−8583

Once developed, the LFIA was validated to determine accuracy, sensitivity, cross reactivity, matrix effects, reproducibility, robustness, ruggedness, and stability.

In the present study, the development and validation of a rapid and simple LFIA for the screening of the OA group of toxins, at concentrations relevant to regulations, is reported.

MATERIALS AND METHODS

Safety. OA group toxins are responsible for incidents of DSP. Therefore, special care should be taken when using OA toxin standard solutions or contaminated shellfish. Gloves and eye protection should be worn at all times. Appropriate disposal methods should also be utilized.

Toxins. Certified reference standards (CRM-OA-c, CRM-DTX1, CRM-DTX2) were obtained from the National Research Council of Canada (NRCC, Halifax NS, Canada).

Equipment and Apparatus. *Extraction Materials.* Methanol (Fisher, U.K.) was used as the extraction solvent. Microperforated filter bags (280 μM) (BagPage +100, Interscience, France) and metal seam rollers (Trade1st, U.K.) were used for the manual extraction. Extracted samples were filtered using a glass fiber filter syringe (Product 9420, Neogen, U.S.).

Materials Required for Hydrolysis Procedure (to Include Detection of DTX3 Toxins). Sodium hydroxide (Sigma, U.K.), hydrochloric acid (Fisher, U.K.), a block heater (Stuart SBH130D), and screw cap glass vials (600000751CV, Waters, U.K.) were employed for the hydrolysis procedure.

LFIA Readers. Portable electronic LFIA readers (Reveal AccuScan PRO) were supplied by Neogen Corporation (MI, U.S.).

Sources and Treatment of Samples. Certified negative mussel samples (CRM-Zero-Mus) and contaminated mussel tissues (CRM-DSP-Mus-B) were obtained from the NRCC. LC-MS/MS and/or MBA verified toxin-free and OA group contaminated samples (mussels, oysters, scallops, clams) were obtained from the Agri-Food and Biosciences Institute (U.K.); CFSAN, FDA (MD, U.S.); or RIKILT (Netherlands, EU) or were locally sourced. Fresh samples were cleaned and opened by cutting the adductor muscles. Tissue was removed from the shell, transferred to strainers, and drained prior to homogenization using a blender or Ultra Turrax. Homogenates were distributed into aliquots and stored at −20 °C for up to three years until analysis.

Principle of LFIA Test Strips. The LFIA is a single-step test based on a competitive immunoassay format (Figure 2). Antibody production for the detection of okadaic acid and DTXs was previously described elsewhere.[32] The sample was wicked through a reagent zone containing antibodies specific for OA-group toxins that were conjugated to colloidal gold particles. If OA toxins were present, they would be captured by the particle−antibody complexes. The complexes wicked onto a nitrocellulose membrane, which contained a stationary capture zone of a toxin−protein conjugate (test zone). The test zone would capture any particle−antibody complexes which had not bound to toxin. Therefore, as the concentration of toxins in the sample increased, the test zone intensity decreased. The membrane also contained a stationary control zone, consisting of antispecies antibodies, which would always form regardless of the level of toxins.

Sample Preparation. Two grams of homogenized shellfish tissue were weighed into each filter bag. Compliant samples, containing less than the limit of detection of 25 μg OA eq/kg via LC-MS/MS, were spiked with fixed volumes of the relevant standard concentration of OA toxins for the preparation of spiked matrix samples.

Procedure for the Extraction of Free Toxins (OA, DTX1, DTX2). Methanol (8 mL) was added to 2 g of shellfish tissue and a roller applied for 30 s. The filtrate was passed through a filter syringe.

Procedure for the Detection of Total OA Toxins (OA, DTX1, DTX2, DTX3). Filtered methanolic extract (800 μL), obtained using the free toxin procedure described above, was mixed with 100 μL of 2.5 M sodium hydroxide for 30 s in a glass vial. The vial was placed in a heat block set at 76 °C for 40 min. The vial was cooled to room temperature (18−25 °C), and 100 μL of 2.5 M hydrochloric acid was mixed with the extract for 30 s.

One variation of the standard LFIA extraction protocol was also evaluated, whereby the filter bag and roller method was replaced with centrifugation for 10 min (2000 *g*).

Analysis by the LFIA. For the detection of free toxins (OA, DTX1, DTX2), 100 μL of the unhydrolysed extract was added to 1.4 mL of buffer and mixed for 30 s. For the detection of total OA toxins (i.e., including DTX3), 100 μL of the hydrolyzed extract was added to 1.1 mL of buffer and mixed for 30 s. The buffers contained salts and surfactants optimized for the assay. A 100 μL portion of buffered sample extract was added to a microwell. A test strip was placed within the microwell for 15 min prior to immediate placement into an LFIA reader to obtain the result. The qualitative result generated using the electronic reader was derived from numerical test and control line readings obtained from the test strip. Because of the competitive nature of the assay, the optical density reading of the test line was greatest in the absence of toxin and the derived values were therefore assigned response values of 100% in dose−response graphs.

Comparative Analysis of LFIA with LC-MS/MS Analysis. Two different LC-MS/MS reference methods, based on McNabb[33] and Gerssen,[34] were employed to quantify toxin concentrations in spiked or naturally contaminated samples. Except where stated, the Gerssen protocol was employed for analyses, with the uncertainty of the in-house method stated as 26.1% and a limit of detection of 25 μg/kg.

LFIA Method Validation. *Extraction Efficiency.* Two studies were conducted to determine extraction efficiencies from naturally contaminated samples in terms of toxin recoveries from LFIA extracts in comparison to LC-MS/MS extracts. Oyster samples (n = 4) known to contain acyl-OA (DTX3) at high levels (90−98%) were employed for the initial study. Samples consisting of mussels (n = 4) and clams (n = 1) known to contain primarily DTX1 and acyl-DTX1 (DTX3) were employed for the second study. Extracts prepared using LC-MS/MS methodologies were compared to those prepared via the standard LFIA extraction method (n = 2 extractions per each condition). All extractions were carried out in parallel, and analyses were carried out at a single site. LFIA extracts were analyzed using LC-MS/MS to determine toxin recoveries. The LFIA extraction protocol had two key differences from the standard LC-MS/MS procedures: the absence of sample centrifugation and a lower solvent to sample ratio. LFIA extracts were diluted to match extracts from LC-MS/MS methods with respect to matrix dilution factors and amount of solvent. Hydrolysed LFIA extracts were diluted to contain equivalent levels of acid and base. All LFIA extracts analyzed via LC-MS/MS were subsequently filtered through a 0.2 μM PVDF syringe filter.

Toxin Response Calibration Curves for Sensitivity and Specificity. Toxin standard concentrations ranging from 0−200 ng/mL were prepared using CRM-OA-c, CRM-DTX1, and CRM-DTX2 to generate dose−response graphs to determine sensitivity and specificity. The optimal matrix dilution factor to effectively screen samples containing suspect levels of OA toxins was determined based on the dose−response data. The dilution factors were selected based on three criteria: the region on the curve which would (1) provide sufficient resolution at the target cutoff for noncompliant results, (2) allow for a simple and practical dilution scheme, and (3) be large enough to reduce or eliminate nonspecific interference on assay performance from various shellfish matrices. OA spiked mussel samples and naturally contaminated oyster samples, containing acyl-derivatives of OA (DTX3), were also evaluated at a range of concentrations.

Accuracy Study for the LFIA Device. A study to determine the accuracy of the LFIA method relative to LC-MS/MS verification was conducted using four species (mussels, oysters, scallops, and clams) spiked at various concentrations of OA toxins ranging from 0 to 320 μg OA eq/kg.

LC-MS/MS verified naturally contaminated samples (mussels, oysters, clams, and scallops) were also used as part of the validation to determine the accuracy and toxin recovery with real samples.

Matrix Effects. A two-operator study was conducted to determine the extent of matrix effects with respect to sensitivity and cross reactivity across various species (mussels, scallops, oysters, and clams)

DOI: 10.1021/acs.jafc.5b01254

*McNabb protocol (LC-MS/MS extracts analyzed 2008, U.S.; LFIA extracts analyzed 2011, U.K.). **Mean ± SD (n = 2 extractions per sample). LC-MS/MS standard working range of 25−1600 μg/kg.

spiked at 0, 40, and 160 μg OA eq/kg of each of the toxins (n = 3 tests per condition). Samples were extracted and assayed according to both free toxin (unhydrolysed) and total toxin (hydrolysis) LFIA procedures.

Interspecies CVs across the range of concentrations and for both extraction procedures were calculated based on quantitative readings.

All studies were conducted randomized blind and, except where stated, all samples were evaluated using five LFIA tests per each condition.

Naturally Contaminated Samples and Comparisons with Reference Methods. A comparative study of various naturally contaminated shellfish samples was performed in two different laboratories (lab 1, n = 72; lab 2, n = 40) using the LFIA method and standard reference method. For laboratory 1, samples consisted of mussels, oysters, clams, and scallops sourced from the EU and United States, and samples from laboratory 2 consisted of mussels, oysters, and scallops.

Robustness. Robustness studies were performed to determine the uncertainty, associated with the method, to various intrinsic and extrinsic factors (including operators, days, LFIA lots, extractions, and readers). A multiday (n = 3) study consisting of multiple LFIA lots (n = 3), readers (n = 3), and operators (n = 3) was conducted. Each operator carried out two extractions of 10 spiked shellfish tissues each day. A total of 190 mussel samples were prepared and consisted of OA (40, 120, 160 μg OA eq/kg), DTX1 (40, 120, 160 μg OA eq/kg), DTX2 (80, 160, 320 μg OA eq/kg), and a toxin-free sample (methanol only). Higher concentrations of DTX2 were employed to take account of the cross reactivity profile of the assay to this analyte, in addition to its lower toxic potency. Each different sample was extracted and analyzed according to LC-MS/MS protocols to determine spiking accuracy.

Interlaboratory Evaluations (Free Toxins). A study involving six mussel samples, two samples each at concentrations less than 40, 120, and 170 μg OA eq/kg, was conducted by three external participants. Samples were extracted and assayed according to the unhydrolysed LFIA procedure (n = 2 tests per condition).

RESULTS AND DISCUSSION

Extraction Efficiencies. The results for the comparison of the LFIA and LC-MS/MS extract for extraction efficiencies are presented in Table 1 and demonstrate equivalence of results for the oyster samples with a mean recovery of 102.2% ± 48.4% (n = 4). The large standard deviation was possibly due to several reasons, including (1) poor sample homogeneity and/or (2) that LC-MS/MS and LFD extractions were carried out in two different laboratories in 2008 and 2012, respectively.

For mussel and clam samples, the results shown in Table 1 demonstrate equivalence with a mean recovery of 113.8% ± 13.4% (n = 5) and 105% ± 1.7% (n = 3 samples with results within the standard working range).

Toxin Response Calibration Curves for Sensitivity and Specificity. The linear portion of the dynamic range of the assay was approximately 0.5−10 ng/mL for each of the toxins, as shown in Figure 3. To ensure samples were effectively screened at the desired 160 μg OA eq/kg cutoff, a matrix dilution factor of approximately 60 fold was selected. As the intention of the assay was to provide a qualitative screening result for suspect samples, the cutoff for noncompliant results was selected at 60% response, which equated to the equivalent of approximately 120 μg OA/kg (75% MPL), 140 μg DTX1/kg (88% MPL), and 240 μg DTX2/kg (90% MPL) in shellfish, based on the dilution factor. OA spiked mussel samples and naturally contaminated oyster samples, containing acyl-derivatives of OA (DTX3), were also evaluated at a range of concentrations, as shown in Figure 3. No matrix effects were observed, with comparable sensitivity and specificity for these toxins.

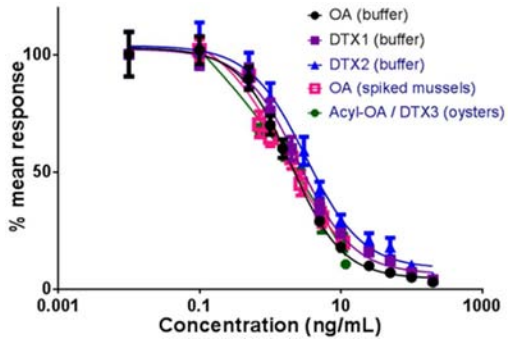

Figure 3. Spiked buffer dose−response graph. Plots are of mean response ± SD (n = 3) for various concentrations of OA and DTXs in buffer and shellfish, using data derived from the electronic reader. The qualitative cutoff for noncompliant results was generated based on a predetermined mean response value of 60%. Note: Acyl-OA/DTX3 (oysters) indicates that DTX3, specifically acyl-OA, was present in the analyzed oyster sample. The detected toxins were derived using alkaline hydrolysis.

Accuracy Study. The accuracy study showed that for OA all samples spiked at 0 or 40 μg/kg were correctly identified as compliant to the action level. A 95% accuracy level at correctly identifying 60 μg/kg samples as compliant was observed. Samples containing 120 μg/kg generated 85% noncompliant results, and all samples spiked at or above 140 μg/kg generated noncompliant results.

[a]NA = no data. ND = not detected. C = compliant. NC = noncompliant.

J. Agric. Food Chem. 2015, 63, 8574−8583 DOI: 10.1021/acs.jafc.5b01254

For DTX1, all samples spiked at 0 or 40 μg/kg were correctly identified as compliant. A 95% accuracy level at correctly identifying 100 μg/kg samples as compliant was observed. A 50% accuracy level was observed at 120 μg/kg, with 95% accuracy to generate noncompliant results at 140 μg/kg. All samples containing at or above 160 μg/kg correctly generated noncompliant results.

For DTX2, all samples spiked at 0 or 66 μg/kg were correctly identified as compliant. A 95% accuracy level at correctly identifying 133 μg/kg samples as compliant was observed. Samples containing 267 μg/kg (160 μg OA eq/kg) generated 50% noncompliant results, and all samples spiked at or above 400 μg/kg (240 μg OA eq/kg) correctly generated noncompliant results.

Matrix Effects. Results indicated matrix effects on performance were negligible with CVs calculated as 1.9% and 2.6% for operators one and two, respectively.

The equivalency of data generated by both unhydrolysed and hydrolyzed extracts when containing equivalent levels of toxin indicated a low level of variation between extraction methods with CVs of 4.0% and 5.6% for operators one and two, respectively.

Naturally Contaminated Samples and Comparisons with Reference Methods. For laboratory 1, there were no false compliant results with the LFIA method in comparison to the LC-MS/MS results (Table 2). All samples generating a noncompliant result by the unhydrolysed LFIA procedure were also noncompliant to the action level by LC-MS/MS. Samples 4, 54, and 70 generated false noncompliant results by the hydrolyzed LFIA procedure and contained 125, 127, and 125 μg OA eq/kg via LC-MS/MS, respectively. It should be noted, however, that sample 54 was also noncompliant by MBA.

The comparison of results for laboratory 2 are shown in Table 3. There were no false compliant results with the hydrolysis procedure, and all samples producing a noncompliant result with the unhydrolysed extracts also produced a noncompliant result with the hydrolyzed extracts. The hydrolyzed LFIA method generated false noncompliant results with samples 9 and 28, which were quantified via LC-MS/MS to contain 130 and 149 μg OA eq/kg, respectively. Sample 13 was compliant by the unhydrolysed LFIA procedure and MBA, but noncompliant with the hydrolyzed LFIA procedure and LC-MS/MS (177 μg OA eq/kg).

Method Robustness. For the robustness studies all compliant (toxin-free) samples generated compliant results by LFIA. Samples containing OA at 40 μg/kg (LC-MS/MS, 35 ± 9 μg/kg), 120 μg/kg (LC-MS/MS, 95 ± 25 μg/kg), and 160 μg/kg (LC-MS/MS, 123 ± 32 μg/kg) generated 14%, 67%, and 98% noncompliant results, respectively. Samples containing DTX1 at 40 μg/kg (LC-MS/MS, 36 ± 9 μg/kg), 120 μg/kg (LC-MS/MS, 117 ± 30 μg/kg), and 160 μg/kg (LC-MS/MS, 139 ± 36 μg/kg) generated 9%, 51%, and 94% noncompliant results, respectively. Samples containing DTX2 at 80 μg OA eq/kg (LC-MS/MS, 57 ± 15 μg OA eq/kg), 160 μg OA eq/kg (LC-MS/MS, 178 ± 46 μg OA eq/kg), and 320 μg OA eq/kg (LC-MS/MS, 343 ± 89 μg OA eq/kg) generated 31%, 90%, and 100% noncompliant results, respectively. The overall mean CV of the method, based on test and control line readings, was 5.9% ± 2.9% (n = 10 samples), which indicated the sum of inter- and intra- variability (operators, readers, extractions, LFIA lots, days). Because of errors in extraction (mainly operator 3, day 1), data from 12 samples were not analyzed.

Interlaboratory Evaluations (Free Toxins). The overall accuracy for the interlaboratory study, to indicate compliant results to the action level below 40 μg/kg and noncompliant results at 170 μg/kg, was 100%. Samples containing 120 μg/kg generated 75% noncompliant tests (n = 12).

Summary of Results and Discussion. The use of LFIAs has been previously exploited for the detection of marine biotoxins from extracts of shellfish tissues. However, two major weaknesses identified with past attempts have been the cross reactivity profile and the subjective nature of the interpretation of results. The reported LFIA was designed as a reader-based assay to eliminate any subjective element, with a qualitative cutoff for noncompliant results at concentrations relevant to the regulatory limits. It also allowed the option of both free toxins and/or total toxins to be rapidly screened from the same initial sample extract. Sample homogenates could be screened in 20 min for free toxins (including extraction and assay time) while waiting for hydrolysis. If a sample was deemed noncompliant, then the hydrolyzed extract would not need to be screened. If the sample was deemed compliant, the hydrolyzed extract would be screened to determine total toxicity (including any esters). Because of the nature of antibody-based assays (immunoassays), which are based on structure as opposed to function, cross reactivity to structural analogues will often vary from the parent compound to which the antibody was raised. In some cases, the cross reactivity profile may mirror the defined toxicity of the compounds.[32] In the reported assay, the cross reactivity profile to DTX1 and DTX2 resembles the toxicity closer than any previously reported, portable immunoassays for this toxin group. Furthermore, although the possibility of false compliant results was observed with samples spiked with DTX2, validation data demonstrated the occurrence of no false compliant results with naturally contaminated samples (various toxin profiles and matrices) containing 160 μg OA eq/kg or greater. Furthermore, results indicated no false noncompliant results with samples containing up to approximately 80 μg OA eq/kg.

Therefore, we report on the development and validation of an LFIA which is a practical, simple, and accurate screening method for shellfish contaminated with OA group toxins. The assay can be utilized as a rapid screening tool for use within the shellfish industry including shipboard or remote locations, providing added protection of shellfish consumers. There is also a significant potential for this method to be used in regulatory laboratories to complement the costly LC-MS/MS- or MBA-based tests that are routinely employed as part of national monitoring programmes because the assay utilizes the simplest OA group extraction and detection systems reported to date, allowing reliable results to be obtained significantly faster and at lower costs. Such simple to use and low-cost methods are ideal for laboratories in developing countries where the ability to purchase, run, and maintain expensive LC-MS/MS equipment is very difficult or the MBA method is not feasible or desirable to conduct routinely.

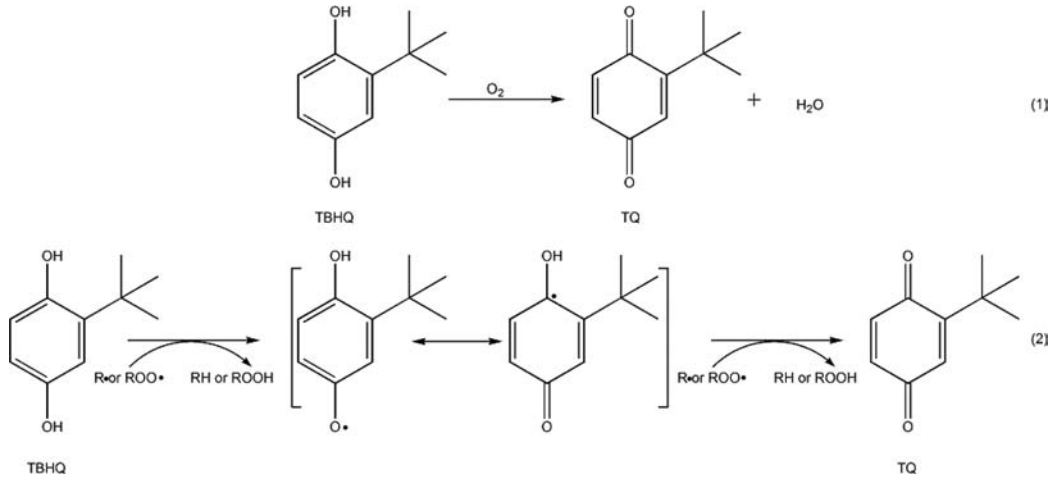

Figure 1. Two pathways of TBHQ converting to TQ.

MATERIALS AND METHODS

Chemicals. Standards of TBHQ (purity > 99.0%) and TQ (purity > 98.0%) were purchased from Sigma-Aldrich (St. Louis, MO). Fresh refined SBO (acid value of 0.13 mg of KOH/g and peroxide value of 1.22 mmol/kg) with no synthetic antioxidants was obtained from Henan Sunshine Oils and Fats Co., Ltd. (Zhengzhou, China). Fresh refined lard (acid value of 0.10 mg of KOH/g and peroxide value of 1.03 mmol/kg) with no antioxidants was purchased from Tianjin Tianyuan Oils & Fats Co., Ltd. (Tianjin, China). Liquid chromatography (LC) solvents (methanol, *n*-hexane, isopropanol, ethyl acetate, and acetonitrile) were of HPLC grade, obtained from VBS Biologic, Inc. (New York), and used after filtration by a 0.45 μm organic membrane. Glacial acetic acid (purity > 99.8%, HPLC grade) was purchased from Kerch Chemical Reagent Co., Ltd. (Tianjin, China). All other solvents were analytical-grade and used without further purification.

Apparatus. The RP-HPLC spectra were measured with a 2695 separation module and an ultraviolet (UV)/visible-2489 detector (Waters, Milford, MA). The NP-HPLC spectra were measured with a 2695 separation module and an UV/visible-2487 detector (Waters, Milford, MA). The vortex mixer (Staufen, German), SCQ-250B ultrasonic apparatus (Shanghai, China), and 800 low-speed centrifuge (Jintan, China) were also used in the experiments.

Preparation and Storage of TBHQ or TQ Standard Solutions. To prepare a standard stock solution, 0.10 g (accurately weighted to 0.1 mg, similarly hereinafter) of TBHQ or TQ was individually weighted into a 100 mL amber volumetric flask and dissolved with methanol. The stock solutions were stored in a refrigerator (4 °C) and away from light for a maximum of 1 month. Before use, standard working solutions of variable concentrations (0.10, 1.00, 2.00, 5.00, 10.00, 20.00, 50.00, 100.00, 200.00, and 500.00 μg/mL) were prepared daily by diluting appropriate volumes of the stock solution in methanol.

Preparation of SBO or Lard Containing 2000 mg/kg of TBHQ or TQ. Lard was preheated at 40 °C until completely melted. A total of 0.12 g of TBHQ or TQ was added to 59.88 g of refined SBO or lard and then shaken until homogeneous.

Preparation of SBO or Lard Containing 50, 100, and 200 mg/kg of TBHQ or TQ. Lard was preheated at 40 °C until completely melted. A total of 1.50, 3.00, and 6.00 g of SBO or lard containing 2000 mg/kg of TBHQ or TQ were diluted to 60.00 g with control SBO or lard and then shaken until homogeneous.

Preparation of SBO or Lard Containing 150 mg/kg of TBHQ Plus 50 mg/kg of TQ, 100 mg/kg of TBHQ Plus 100 mg/kg of TQ, and 50 mg/kg of TBHQ Plus 150 mg/kg of TQ. Lard was preheated at 40 °C until completely melted. A total of 4.50, 3.00, or 1.50 g of SBO or lard containing 2000 mg/kg of TBHQ and 1.50, 3.00, or 4.50 g of SBO or lard containing 2000 mg/kg of TQ were diluted to 60.00 g with SBO or lard without TBHQ and TQ and then shaken until homogeneous.

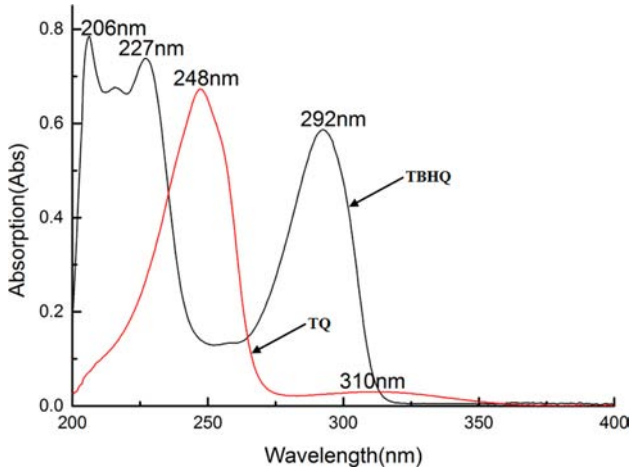

Figure 2. UV absorption spectra of TBHQ and TQ.

Extraction Procedure. The extraction procedure was in accordance with previous methods.[16,21,23] A total of 0.50 g of each of the oil samples was weighed into a 10 mL test tube, and 4 mL of methanol was added. The mixture was agitated for 3 min using a vortex mixer and then centrifuged at 3000 rpm for 2 min at room temperature. The supernatant was quantitatively transferred to a 10 mL flask. The extraction procedure was repeated twice, adding 3 mL of methanol each time. Finally, sufficient methanol was added to achieve a 10 mL solution. The solution was filtered through a 0.45 μm membrane before HPLC analysis.

Analysis of TBHQ and TQ. The conditions of RP-HPLC analysis were as follows:[16,24,25] the injection volume for TBHQ or TQ samples was 20 μL; the column was Symmetry C18 (4.6 × 250 mm, 5 μm, Waters); the solvent system was methanol−H_2O containing 0.5% AcOH (65:35, v/v); the flow rate was 0.8 mL/min; the dual detection wavelengths were 280 nm for TBHQ and 310 nm for TQ; and the column temperature was 35 °C. Methanol and H_2O containing 0.5% AcOH were both degassed for 15 min by an ultrasonic apparatus.

The conditions of NP-HPLC analysis were as follows: the injection volume for TBHQ or TQ samples was 20 μL; the column was Sunfire Prep Silica (4.6 × 250 mm, 5 μm, Waters); the solvent system was *n*-hexane containing 5% ethyl acetate (solvent A) and *n*-hexane containing 5% isopropanol (solvent B); the gradient elution was isocratic mode of 8% solvent B for 10 min, linear gradient from 8 to 100% solvent B for 5 min, and then isocratic mode of 100% solvent B for 12 min; the flow rate was 0.8 mL/min; the dual detection wavelengths were 280 nm for TBHQ and 310 nm for TQ; and the column temperature was 30 °C. Solvents A and B were both degassed for 40 min by an ultrasonic apparatus. Identification of compounds was

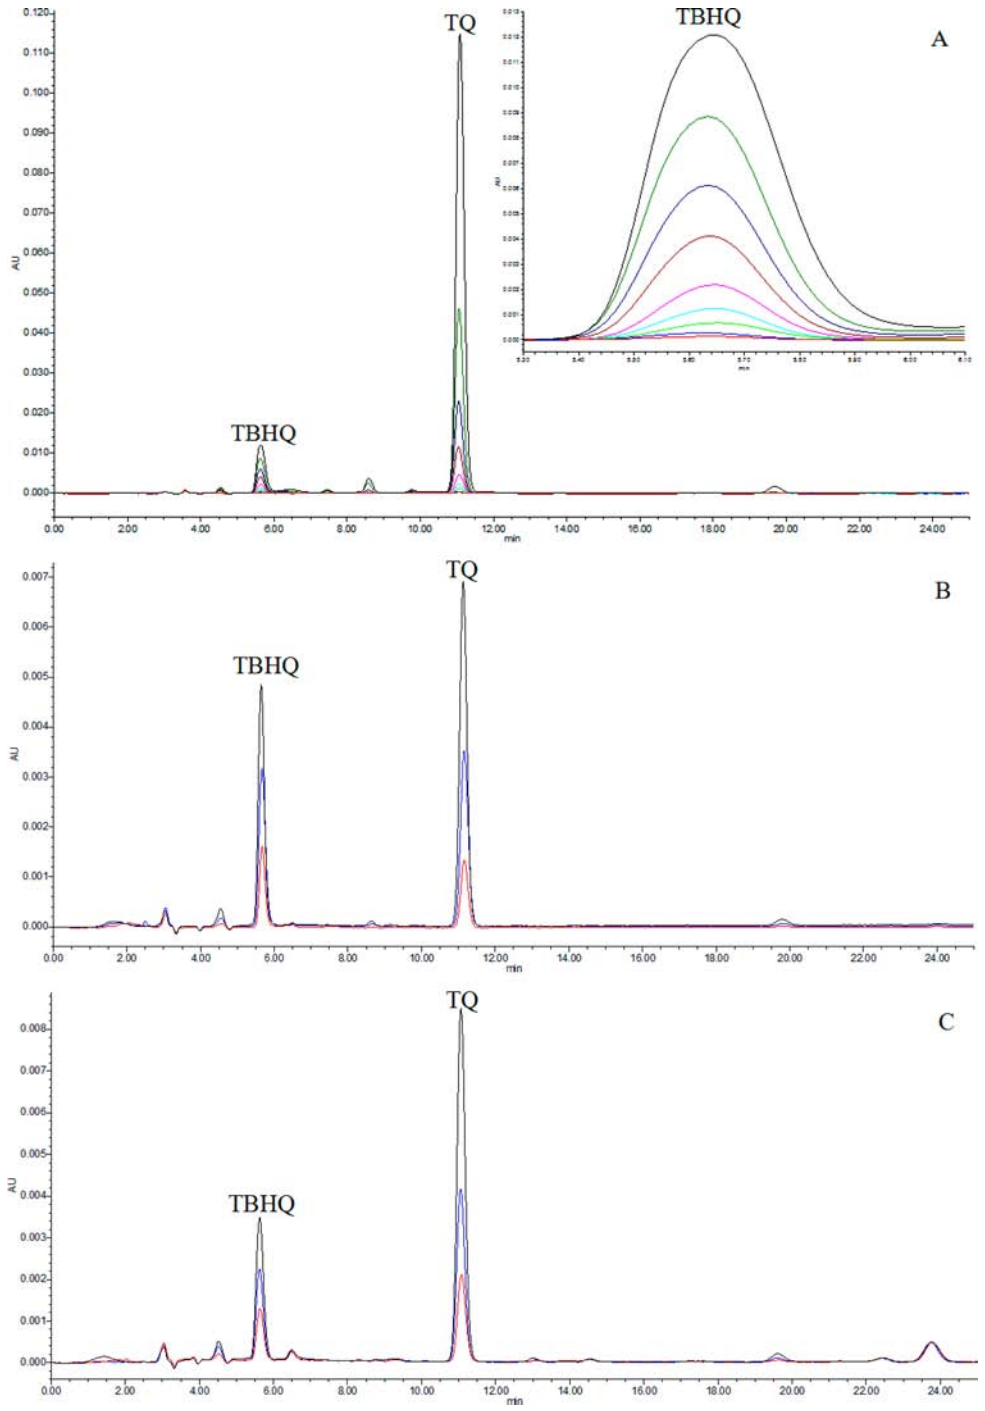

Figure 3. Superimposed RP-HPLC chromatograms of variable concentrations of (A) TQ standard solutions, (B) methanol extracting solutions of SBO adding 50, 100, and 200 mg/kg of TQ, and (C) methanol extracting solutions of lard adding 50, 100, and 200 mg/kg of TQ. Analysis conditions: the injection volume for TQ samples was 20 μL; the column was Symmetry C18 (4.6 × 250 mm, 5 μm, Waters); the solvent system was methanol−H_2O containing 0.5% AcOH (65:35, v/v); the flow rate was 0.8 mL/min; the dual detection wavelengths were 280 nm for TBHQ and 310 nm for TQ; and the column temperature was 35 °C. Methanol and H_2O containing 0.5% AcOH were both degassed for 15 min by an ultrasonic apparatus.

achieved by comparing their retention times to those of standards. Data were collected and processed using Empower 2.0 software (Waters Corporation).

Statistical Analyses. All experiments were performed at least in duplicate. All data were presented as the mean ± standard deviation (SD).

RESULTS AND DISCUSSION

Wavelength Screening. The UV absorption spectra of TBHQ and TQ were shown in Figure 2. The characteristic absorption wavelengths of TBHQ were 206, 227, and 292 nm. The characteristic absorption wavelengths of TQ were 248 and 310 nm. According to the American Oil Chemists' Society (AOCS) method,[24] 280 nm was selected as the appropriate detection wavelength for TBHQ. As a result of 248 nm less than the UV cutoff wavelength of ethyl acetate (254 nm)[26] and weak absorption of TQ at 280 nm (Figure 2), 310 nm was selected as an appropriate detection wavelength for TQ. Finally,

DOI: 10.1021/acs.jafc.5b03002
J. Agric. Food Chem. 2015, 63, 8584−8591

dual wavelengths (280 and 310 nm) were selected to detect TBHQ and TQ.

Determination of TBHQ by RP-HPLC. *Specificity, Linearity, Limit of Detection (LOD), and Limit of Quantification (LOQ) of TBHQ.* Specificity of the RP method for TBHQ detection was verified by comparing the chromatograms of TBHQ standard solution, oil samples, and lard samples before and after spiking with TBHQ. In oil and lard blank samples, no signal of TBHQ was detected.

The calibration curve was constructed by plotting the measured peak area versus the concentration of TBHQ. Excellent linearity was obtained within the concentration range of 0.10−500.00 μg/mL for TBHQ (R^2 > 0.9999).

The instrumental LOD was estimated and defined as the average response (n = 3) of the lower concentration level of the calibration curve for TBHQ plus 3 times the standard deviation.[27] The instrumental LOQ was taken as 10/3.3 times LOD.[28] The results showed that LOD and LOQ of TBHQ were below 0.06 and 0.18 μg/mL, respectively, which were both lower than that reported by Saad et al.[20]

Intra- and Interday Precision and Accuracy of TBHQ. The precision of the RP-HPLC system was demonstrated by intra- and interday variation studies.[29] In the intraday studies, six repeated injections of TBHQ standard solutions (5.00, 10.00, and 20.00 μg/mL) were made in 1 day and its relative standard deviation (RSD) and bias were calculated. In the interday variation studies, three repeated injections of TBHQ standard solutions (5.00, 10.00, and 20.00 μg/mL) were performed on 3 consecutive days and its RSD and bias were also calculated. Results showed that intra- and interday precisions of TBHQ with the RP-HPLC system were acceptable, with its RSD lower than 0.58% and bias lower than 1.52% (Table S1 of the Supporting Information).

Recoveries and Precision of TBHQ in SBO or Lard. Recoveries of TBHQ were determined using SBO or lard spiking with TBHQ. The recovery experiments were carried out at three levels of 50, 100, and 200 mg/kg (n = 6), and the percentage recoveries were calculated and presented in Table S2 of the Supporting Information. Recoveries of TBHQ in SBO and lard were in the ranges of 96.45−99.02 and 94.23−99.56%, respectively, with the RSD less than 0.64 and 0.45%.

Determination of TQ by RP-HPLC. *Specificity of TQ.* Verification of specificity of the RP-HPLC method for TQ detection was similar to that of TBHQ. In oil or lard blank samples, no signal of TQ was detected. However, in TQ standard solution (Figure 3A) and oil samples (Figure 3B) and lard samples (Figure 3C) spiking with TQ, there were all signals of TBHQ and the peaks were symmetric, which indicated that, during the injection, TQ was reduced to TBHQ by reduced hydrogen ([H]). Reduction ratios of TQ were calculated (Figure S1 of the Supporting Information), and specific results were presented in Tables 1 and 2. The [H] was from the mobile phase (water and acid solution) of the RP-HPLC system (Figure S2 of the Supporting Information).

Determination of TBHQ and TQ by NP-HPLC. *Specificity, Linearity, LOD, and LOQ of TBHQ and TQ.* Verification of specificity of the NP-HPLC method for TBHQ and TQ detections was also similar to that of the RP-HPLC method for TBHQ. In oil or lard blank samples, no signal of TBHQ and TQ was detected. In TBHQ standard solution, no signal of TQ was detected (Figure 4A). In TQ standard solution, no signal of TBHQ was also detected (Figure 4B).

Table 1. Reduction Ratios and Precision of Variable Concentrations of TQ Standard Solutions with the RP-HPLC System[a]

concentration of TQ (μg/mL)	reduction yield of TQ (%)[b]	RSD (%)
1.00	9.55 ± 0.36	3.77
2.00	9.70 ± 0.14	1.44
5.00	8.70 ± 0.38	4.37
10.00	8.03 ± 0.42	5.23
20.00	7.24 ± 0.56	7.73
50.00	5.55 ± 0.61	10.99
100.00	4.30 ± 0.42	9.77
200.00	3.17 ± 0.14	4.41
500.00	1.89 ± 0.22	11.64

[a]Analysis conditions: the injection volume for TQ samples was 20 μL; the column was Symmetry C18 (4.6 × 250 mm, 5 μm, Waters); the solvent system was methanol−H_2O containing 0.5% AcOH (65:35, v/v); the flow rate was 0.8 mL/min; the dual detection wavelengths were 280 nm for TBHQ and 310 nm for TQ; and the column temperature was 35 °C. Methanol and H_2O containing 0.5% AcOH were both degassed for 15 min by an ultrasonic apparatus. [b]Mean ± SD.

Table 2. Reduction Ratios and Precision of the Spiked TQ from SBO and Lard with the RP-HPLC System[a]

sample	concentration of TQ (mg/kg)	reduction yield of TQ (%)[b]	RSD (%)
SBO	50	7.98 ± 0.47	5.89
	100	8.26 ± 0.59	7.15
	200	5.94 ± 0.60	10.13
lard	50	5.71 ± 0.04	0.62
	100	6.14 ± 0.14	2.30
	200	5.15 ± 0.14	2.74

[a]Analysis conditions: the injection volume for TQ samples was 20 μL; the column was Symmetry C18 (4.6 × 250 mm, 5 μm, Waters); the solvent system was methanol−H_2O containing 0.5% AcOH (65:35, v/v); the flow rate was 0.8 mL/min; the dual detection wavelengths were 280 nm for TBHQ and 310 nm for TQ; and the column temperature was 35 °C. Methanol and H_2O containing 0.5% AcOH were both degassed for 15 min by an ultrasonic apparatus. [b]Mean ± SD.

These results indicated that the redox reaction of TBHQ and TQ did not happen during the NP-HPLC analysis.

Constructions of calibration curves of TBHQ and TQ with the NP-HPLC system were similar to that of TBHQ with the RP-HPLC system. Excellent linearity was obtained within the concentration range of 0.10−500.00 μg/mL for TBHQ and TQ (R^2 > 0.9999).

The estimations and definitions of instrumental LOD and LOQ with the NP-HPLC system were similar to that of the RP-HPLC system. Results showed that LOD and LOQ of TBHQ were below 0.30 and 0.91 μg/mL, respectively, which were both lower than those of Saad et al.[20] The LOD and LOQ of TQ were below 0.10 and 0.30 μg/mL, respectively.

Intra- and Interday Precision and Accuracy of TBHQ and TQ. The demonstration of the precision of the NP-HPLC system was similar to that of the RP-HPLC system. Corresponding RSD and bias were calculated and presented in Table S3 of the Supporting Information. Results showed that intra- and interday precisions of TBHQ and TQ with the NP-HPLC system were acceptable, with the RSD lower than 1.76% and the bias lower than 5.55%.

Selection of the Extraction Solvent. In general, phenolic antioxidants in edible oils can often be extracted using some polar solvents, such as methanol, acetonitrile, etc.[30] Nonpolar

sunflower seed oil	57.85 ± 2.47	–	57.85 ± 2.47	46.34 ± 0.85	10.09 ± 0.42	56.43 ± 0.43	17.44

[a]Analysis conditions: the injection volume for TBHQ and TQ samples was 20 μL; the column was Sunfire Prep Silica (4.6 × 250 mm, 5 μm, Waters); the solvent system was *n*-hexane containing 5% ethyl acetate (solvent A) and *n*-hexane containing 5% isopropanol (solvent B); the gradient elution was isocratic mode of 8% solvent B for 10 min, linear gradient from 8 to 100% solvent B for 5 min, and then isocratic mode of 100% solvent B for 12 min; the flow rate was 0.8 mL/min; the dual detection wavelengths were 280 nm for TBHQ and 310 nm for TQ; and the column temperature was 30 °C. Solvents A and B were both degassed for 40 min by an ultrasonic apparatus. [b]Mean ± SD. [c]"–" represents no TBHQ or TQ found.

ratio of TQ in *n*-hexane and methanol (or acetonitrile), 5 mL of *n*-hexane was added to 5 mL of 500.00 μg/mL TQ methanol solution (or acetonitrile solution). The mixtures were mixed for 2 min using a vortex mixer and then centrifuged at 3000 rpm for 2 min at room temperature. After filteration using 0.45 μm organic membrane, the *n*-hexane fraction and methanol fraction (or acetonitrile fraction) were analyzed. Results showed that the distribution ratios of TQ in *n*-hexane and methanol were 44.91 and 54.62%, respectively; the distribution ratios of TQ in *n*-hexane and acetonitrile were 33.84 and 66.16%, respectively. Therefore, in the work, if nonpolar solvents were used to remove the oil matrix coextracted, approximately half or one-third of TQ was removed from methanol or acetonitrile extracting solution and dissolved in nonpolar solvents. In addition, mobile phases of NP-HPLC were low polarity or nonpolar solvents,[31,32] which can easily dissolve the oil matrix coextracted. The oil matrix coextracted could be eluted from stationary phase by mobile phases, which has little effect on the lifetime of the silica gel column and the baseline (Figure S3 of the Supporting Information). Therefore, the process of removing the oil matrix coextracted could be left out. In addition, considering the higher toxicity and cost of acetonitrile than that of methanol,[33] methanol was used to extract TBHQ and TQ from the edible oils.

Recoveries and Precision of TBHQ or TQ in Edible Oil Samples. The determination of recoveries of TBHQ or TQ with the NP-HPLC system was similar to that of TBHQ with the RP-HPLC system. The recoveries were calculated and presented in Table 3. Recoveries of TBHQ in SBO and lard were in the ranges of 98.92–102.34 and 96.11–99.42%, with the RSD less than 0.38 and 2.06%, respectively. Recoveries of TQ in SBO and lard were in the ranges of 96.28–100.58 and 98.83–99.24%, with the RSD less than 1.71 and 3.58%, respectively.

Recoveries and Precision of TBHQ and TQ in Edible Oil Samples. Recoveries of TBHQ and TQ were determined using SBO and lard spiking with TBHQ and TQ. The recovery experiments were carried out at three levels of 150/50, 100/100, and 50/150 (mg/kg)/(mg/kg) (n = 6), and the recoveries of TBHQ and TQ were calculated and presented in Table 4. Recoveries of TBHQ and TQ in SBO and lard were in the ranges of 97.83–98.72 and 96.93–99.30%, with the RSD less than 0.96 and 2.25%, respectively, which indicated that the NP-HPLC method can be used to evaluate the original added load of TBHQ in edible oils (Figure S4 of the Supporting Information).

Analysis of Contents of TBHQ and TQ in SBO and Lard during Storage at Room Temperature. On the basis of the NP-HPLC method, the contents of TBHQ and TQ in SBO and lard containing 200 mg/kg of TBHQ during storage at room temperature were determined. Results showed that, with the increase of the storage time, the contents of TBHQ in SBO and lard decreased gradually, while the contents of TQ in SBO and lard increased (Table 5). For example, the original added

DOI: 10.1021/acs.jafc.5b03002
J. Agric. Food Chem. 2015, 63, 8584–8591

load of TBHQ in SBO was 197.35% without TQ. After SBO samples were stored for 1 and 2 months, the contents of TBHQ were 182.98 and 178.59 mg/kg, respectively, and the contents of TQ were 14.17 and 16.15 mg/kg, respectively. The original added load of TBHQ in lard was 198.50% without TQ as well. After lard samples were stored for 1 and 2 months, the contents of TBHQ were 146.99 and 87.25 mg/kg, respectively, and the contents of TQ were 51.07 and 95.32 mg/kg, respectively. Meanwhile, contents of TBHQ converting to TQ in SBO were less than those in lard, which might be attributed to the presence of tocopherols (approximately 1000 mg/kg[34]) in SBO. Partial oxidation of tocopherols can consume partial oxygen dissolved in SBO, which can slow the conversion of TBHQ to TQ.

Analysis of TBHQ and TQ in Some Commercial Vegetable Oils. Some commercial oil samples were analyzed using the NP-HPLC method. Results showed that TBHQ existed in all original oil samples but TQ was not detected, which might be no oxygen presented in the commercial bottled oils before opening. However, when the package of the original samples was unclosed and stored at 25 °C for 2 months, TQ can be detected (Table 6). Conversion ratios of TBHQ to TQ were in the ranges of 10−20% in all commercial vegetable oils tested. These results indicated that, after the continuous exposure of oils in air, TBHQ can be converted to TQ in the presence of oxygen and free radicals of oils. In addition, none of the positive samples violated the legal limit (200 mg/kg[3]).

In conclusion, in comparison to the RP-HPLC system, the NP-HPLC method overcame the reduction of TQ, can simultaneously and accurately analyze the contents of TBHQ and TQ in edible oils, and was also successfully applied to evaluate the original added load of TBHQ in edible oils.

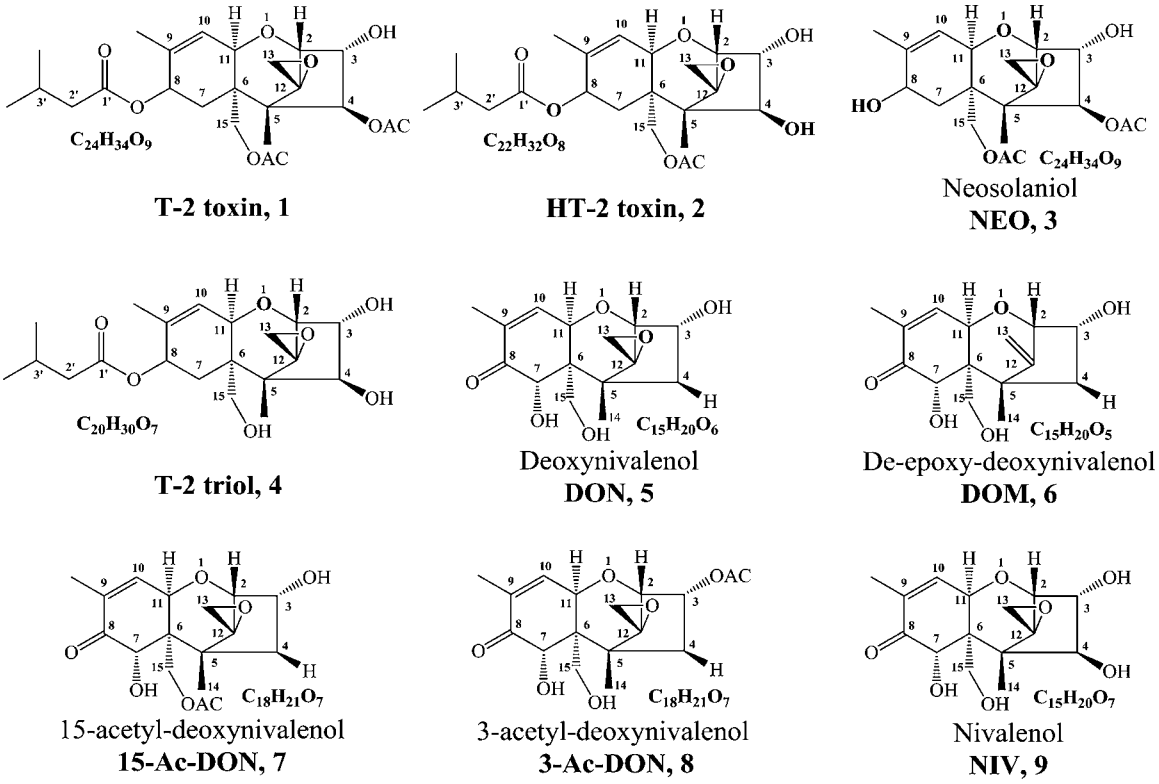

Figure 1. Chemical structures of T-2 toxin, HT-2 toxin, NEO, T-2-triol, DON, DOM, 15-Ac-DON, 3-Ac-DON, and NIV.

be rapidly deacetylated, such as 3-acetyldeoxynivalenol (3-Ac-DON) (**7**), where deacetylation was the predominant biotransformation reaction and minimal deepoxidation occurred.[2,7] On the other hand, 15-acetyldeoxynivalenol (15-Ac-DON) (**8**) showed only small amounts of the deacetylation products, but produced large amounts of products having both the acetyl and epoxy functionalities removed.[2] However, in the metabolism of nivalenol (NIV) (**9**), only one deepoxy metabolite was found.[2]

Accurate and reliable methods for the detection and quantitation of these compounds, and their metabolites, are required for studying the toxicodynamics or concentration levels in naturally contaminated samples. A variety of methods have been published for the determination of trichothecenes, including thin-layer chromatography (TLC), enzyme-linked immunosorbent assays (ELISAs), gas chromatography−electron capture detection (GC−ECD), gas chromatography−mass spectrometry (GC−MS), and liquid chromatography coupled with ultraviolet detection (HPLC−UV).[10−14] However, since liquid chromatography coupled with tandem mass spectrometry (LC−MS/MS) offers more accurate quantitation, better selection, and higher sensitivity compared to other analytical methods, it plays an increasingly important role in the analysis of mycotoxins.[4] Numerous LC−MS/MS methods have been developed for determination of trichothecenes.[15−19] However, these methods are primarily focused on cereals and their derivative foods,[15−19] because there is a high likelihood that trichothecenes or their metabolites can enter the human food chain via meat products or secondary animal products, such as eggs and milk, as the result of livestock eating contaminated feed.[2] Currently, many publications have reported mycotoxins in urine, milk, and eggs.[17,20−24] For animal meat, such as chicken and pork, only one available publication reported a method to detect DON and T-2 toxin in meat.[25] In fact, when T-2 toxin and DON are ingested by food animals, they are rapidly metabolized to HT-2 toxin, DOM, and other metabolites.[2] In comparison with T-2 toxin and DON, their metabolites were more likely to be present at high levels in meat products, especially HT-2 toxin.[1,2] Therefore, it is necessary to develop a method for also detecting the main metabolites of these mycotoxins in animal tissues.

The aim of this study was to develop and validate an accurate and sensitive LC−MS/MS method for simultaneous determination of type A and type B trichothecenes, and their main metabolites, in animal tissues. Such a method would be valuable for studies of metabolism, residue elimination, and safety evaluation.

MATERIALS AND METHODS

Standards. The standards of T-2 toxin, HT-2 toxin, T-2-triol, NEO, DON, 3-Ac-DON, 5-Ac-DON, DOM, and NIV were purchased from Fermentek Biotechnology (Jerusalem, Israel). Stock standard solutions (100 mg/L) of individual compounds were prepared in acetonitrile and stored at −20 °C in darkness. Working solutions (5 mg/L) of the standards were prepared by diluting stock solutions with a mixture of acetonitrile/water (10:90, v/v) and stored at 4 °C in the dark.

Chemicals and Reagents. Acetonitrile and methanol were HPLC and MS grade, purchased from Fisher Chemical Co. (Fair Lawn, NJ). Ammonium hydroxide (28% NH_3) was purchased from Alfa-Aesar (Ward Hill, MA). Analytical grade ethyl acetate and *n*-hexane were purchased from Sinopharm Chemical Reagent Co., Ltd. (Beijing, China). Water was purified using a Milli-Q system (resistivity 18.2 MΩ, Millipore, Bedford, MA). Oasis HLB cartridges (3 cm^3, 60 mg) were purchased from Waters Co. (Milford, MA). Other reagents were of analytical grade and were obtained from the Beijing Reagent Co. (Beijing, China).

Samples. A total of 15 blank samples, including 3 of chicken meat, 3 of pork, 6 chicken livers, and 3 whole pig livers, were purchased from randomly chosen local supermarkets in Beijing, China. All samples

DOI: 10.1021/acs.jafc.5b03281
J. Agric. Food Chem. 2015, 63, 8592−8600

were homogenized before use in a high-speed food blender. Then the samples were stored at −20 °C until analysis.

Animal Study. Twelve chickens (1.1 ± 0.1 kg) were purchased from Beijing Huadu Co. Ltd. (Beijing, China). The experimental protocol was approved by the University Ethics Committee and conformed to the China Agricultural University regulations concerning protection of animals used for scientific purposes (2010-SYXK-0037). Chickens were given a single oral dose of T-2 (3 mg/kg of body weight (bw), dissolved in ethanol/water (30:70, v/v)). Muscle and liver tissues were collected 6, 12, 24, and 48 h after oral administration. All samples were frozen at −20 °C until analysis.

Sample Preparation. One gram of sample was extracted with 8 mL of acetonitrile/ethyl acetate (1:3, v/v) during 5 min on a vortex shaker. The sample extract was then centrifuged at 10141*g* for 10 min, and the supernatant was transferred into a new tube. The residue was extracted a second time with 5 mL of the extraction solution according to the above procedure. The supernatants were combined and placed in a −80 °C freezer to remove the fat. After 20 min, the tubes were taken out and centrifuged at 10141*g* for 10 min at 4 °C. The supernatant was removed and dried with N_2 gas at 40 °C. Then the residue was reconstituted in 600 μL of acetonitrile/water (10:90, v/v) and diluted by 10 mL of water. Afterward, the obtained solution was further cleaned up using Oasis HLB cartridges. First, the cartridges were preconditioned with 3 mL of methanol, followed by 3 mL of water. The sample extract was loaded onto an HLB cartridge, which was washed by 3 mL of water and then 3 mL *n*-hexane, and finally eluted with 5 mL of dichloromethane. The elution was dried under N_2 gas at 40 °C, and the residue was redissolved with 1 mL of acetonitrile/water (10:90, v/v) and filtered with a 0.22 μm syringe filter into a UPLC−MS/MS autosampler vial for analysis.

UPLC−MS/MS Analysis. Chromatographic analysis was performed on an Acquity ultraperformance liquid chromatography system equipped with a degasser and an autosampler (Waters, Milford, MA). The MS/MS detection was performed using a Quattro LC triple-quadrupole mass spectrometer equipped with an electrospray ionization (ESI) source (Micromass, Manchester, U.K.). The separation was performed on a 50 mm × 2.1 mm i.d., 1.7 μm Acquity BEH RP18 column (Waters) using a gradient elution program consisting of mobile phase A (0.005 mmol/L ammonia) and mobile phase B (acetonitrile). The gradient elution program was as follows: 0 min, 100% A; 0−1 min, A linearly decreased to 90%; 1−6 min, A linearly decreased to 20%; 6−6.5 min, A increased to 100%. The column temperature was maintained at 30 °C, and the injection volume was 10 μL with a flow rate of 0.3 mL/min.

The UPLC system was connected to the mass spectrometer via an ESI interface. The analysis was performed in ESI positive mode with the capillary voltage set at 3.0 kV. The extractor and radio frequency (rf) lens voltages were at 3.0 and 0.5 V, respectively. The source temperature was held constant at 100 °C and the desolvation temperature at 350 °C. Nitrogen was used as the desolvation gas at a flow rate of 600 L/h, while the cone gas flow rate was 30 L/h. Collision-induced dissociation was performed using argon as the collision gas at a pressure of 2.5×10^{-3} mbar in the collision cell. The monitoring mode was set to multiple-reaction monitoring (MRM), with the detailed parameters for each analyte shown in Table S1.

Method Validation. To validate the method, spiked blank samples were used, in accordance with a validation protocol provided by the European Community and the FDA.[26] These validation experiments included linearity, accuracy, precision, LODs, and LOQs.

Because a matrix effect was observed on the ESI source, matrix-matched calibration curves were used for quantitation. Linearity was tested using matrix-matched calibration curves by spiking blank extracted animal tissues at seven concentration levels.

Recovery and intraday precision were studied with spiked samples at three concentration levels. The interday precision was obtained using three spiked levels of standards, and the recoveries were determined on three separate days. LODs and LOQs were determined on the basis of signal-to-noise ratios (S/N) of ≥3 and ≥10, respectively.

RESULTS AND DISCUSSION

Optimization of the UPLC Conditions. The choice of mobile phase is important for ionization efficiency and also for protection of the chromatography column and MS. To obtain a high response intensity, trace levels of ammonium acetate and/or acetic acid are usually added to the mobile phase.[10] According to our previous study, ammonia could improve the ionization of T-2 toxin and HT-2 toxin under ESI positive mode.[15] In the present study, different concentrations of ammonia (0.001, 0.003, 0.005, 0.010, and 0.020 mmol/L) were tested in mobile phase A (water). Satisfactory results were obtained for all analytes when 0.005 mmol/L ammonia was added to water. Therefore, water containing 0.005 mmol/L ammonia (mobile phase A) and acetonitrile (mobile phase B) were selected as the mobile phases. All analytes were eluted with high selectivity and good sensitivity in less than 6.5 min using the gradient elution program described above.

In general, type B trichothecenes are highly polar compounds. This is especially true for NIV, which is hardly retained by the column. However, type A compounds, such as T-2 toxin and HT-2 toxin, have relatively weak polarity. Therefore, a reversed-phase C_{18} (RP18) column may be the best choice considering the wide differences in polarity between the trichothecenes. The ACQUITY UPLC BEH C_{18} and ACQUITY UPLC BEH Shield RP18 chromatography columns were compared in this work. The RP18 column exhibited reasonable retention effects and separation efficiency for all analytes.

Optimization of the MS/MS Determination. Both positive and negative ion modes of the electrospray ion source were tested to evaluate the ionization of every analyte. Most of the compounds exhibited precursor ions and product ions with reasonably high signal intensities in ESI positive mode. For optimization of MS and MS/MS parameters, individual standard solutions at 100 μg/L prepared in acetonitrile/water (10:90, v/v) were injected at different values of the cone voltage (5−50 V) and collision energy (5−60 eV). According to European Union (EU) convention, at least two product ions should be selected for each analyte.[26] The most abundant product ion is used for quantitation, and another product ion is monitored for confirmation of the identity. The parameters of the optimized MRM transitions for all compounds are detailed in Table S1.

All type A trichothecenes tend to generate the precursor ions $[M + NH_4]^+$, $[M + Na]^+$, and $[M + K]^+$ in ESI positive mode. Although $[M + Na]^+$ adducts exhibited the highest intensities, this precursor ion was not suitable due to a lack of fragmentation in further MS/MS experiments. The addition of 0.005 mmol/L ammonia in mobile phase A suppressed the formation of $[M + Na]^+$, as reported by Sulyok et al.[19] Therefore, the ammonium $[M + NH_4]^+$ adducts were chosen as precursor ions for T-2 toxin, HT-2 toxin, NEO, and T-2-triol. Other studies have reported that type B trichothecenes give a higher response in ESI negative mode, and $[M - H]^-$ and $[M + CH_3COO]^-$ were selected as their precursor ions.[21,22,27] Under experimental conditions, the protonated molecules of $[M + H]^+$ were observed for all type B trichothecenes in ESI positive mode, giving higher signal intensities than the related $[M - H]^-$ species. In ESI positive mode, the mass value of DON at *m/z* 297 ($[M + H]^+$) showed an almost 7-fold intensity in comparison with that at *m/z* 295 ($[M - H]^-$), which was obtained in ESI negative mode. Therefore, $[M + H]^+$

DOI: 10.1021/acs.jafc.5b03281
J. Agric. Food Chem. 2015, 63, 8592−8600

ions were selected as the precursor ions for DON, NIV, 15-Ac-DON, 3-Ac-DON, and DOM due to their relatively higher responses.

The chemical structure of 3-Ac-DON is similar to that of 15-Ac-DON; the difference is the position of the acetyl group (Figure 1). Due to the similar polarities of these two mycotoxins, it is difficult to achieve chromatographic separation, as reported by Monbaliu et al.[28] However, the selective detection power of MS/MS can facilitate their identification. Although the protonated molecules of $[M + H]^+$ have the same m/z 339.3, separate identification can be achieved due to the difference in characteristic daughter ions in MRM mode, identified as m/z 339.5 > 137.2 and 339.5 > 321.1 and m/z 339.5 > 213.0 and 339.5 > 230.9 for 15-Ac-DON and 3-Ac-DON, respectively.

Sample Pretreatment Optimization: Selection of the Extraction Solvent. In the present study, a total of nine mycotoxins served as target analytes. It was difficult to recover all mycotoxins equally during sample preparation, because their chemical structures are diverse. Thus, a compromise method had to be made. Many extraction methods have been reported in previous works. Methanol/water (84:16, v/v), acetonitrile/water (84:16, v/v), and methanol/water/acetic acid (79:20:1, v/v/v) were frequently used to extract mycotoxins.[16,18,19] However, these methods were mainly used to extract multiple mycotoxins in cereals and derived products. For meat and liver samples, limited information was available. In comparison with cereal samples, the sample matrix of meat and liver is very complex, containing lipids, proteins, inorganic salts, etc.[25] To reduce matrix effects, choosing a suitable extraction solvent is of critical importance. Acetonitrile and acetonitrile/water/acetic acid (79:20:1, v/v/v) have been reported to give good results for extracting multiple mycotoxins from meat and fish samples.[25,27] However, in the present study, we found that when acetonitrile was used during the extraction process, the meat tissue precipitated to a "cake" consistency, which would lead to poorer recoveries of the analytes. To select a suitable extraction solvent, acetonitrile, ethyl acetate, and acetonitrile/ethyl acetate solutions of different ratios were successively tested. As a result, better recoveries were obtained for all analytes when acetonitrile/ethyl acetate (1:3, v/v) was employed as the extraction solvent.

Optimization of Cleanup. To minimize matrix interferences, a cleanup procedure after extraction is necessary. A Waters Oasis HLB cartridge, which is suitable for the extraction of both polar and nonpolar compounds, was investigated first. According to reports, HLB cartridges have been used for the successful analysis of T-2 toxin and DON in meat and fish samples.[25,27] However, our results indicate that it failed to retain the more polar compounds of DON and NIV when standard protocols were used. To get a high recovery of DON and NIV, a modified protocol was applied, wherein water/methanol (95:5, v/v) was replaced by pure water at the washing step. Due to a significant proportion of fatty matrix compounds present in animal tissues, an *n*-hexane defatting step was also added. In this way, polar compounds could be recovered and the fatty matrix compounds removed. To further reduce background noise and the matrix effect, several eluents were tested, such as methanol, ethyl acetate, and dichloromethane. As shown in Figure 2, a higher relative response intensity was found for all analytes when dichloromethane was the elution solvent. Additionally, higher recovery values ranging from

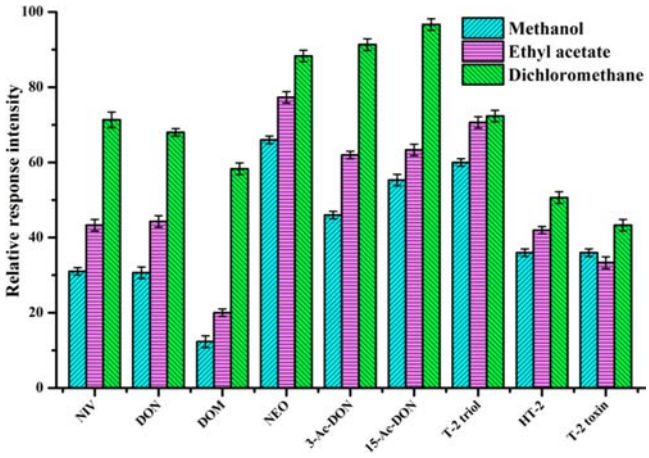

Figure 2. Effects of three eluents (methanol, ethyl acetate, and dichloromethane) on the response of analytes after cleanup using an Oasis HLB cartridge in pork.

74.1% to 96.9% were obtained for all analytes, as shown in Table 1.

Evaluation of Matrix Effects. Coelution of the matrix can affect the ionization efficiency of the analytes, leading to either suppression or artificial enhancement of the signal. The matrix effect is an important consideration since the ESI source can be easily influenced. Although the use of isotopic internal standards can overcome matrix effects, these compounds are usually expensive and suitable candidates cannot easily be obtained for all applications. Therefore, matrix-matched calibration curves are generally adopted. To evaluate the matrix effect, the slope of the matrix-matched calibration standards was compared to that of standard calibration in pure solvent. Referred to as the signal suppression/enhancement (SSE) value, this was calculated for each analyte. The results indicated that signal suppression can be observed for both strongly and weakly polar compounds, such as DON and T-2 toxin, no matter which matrix was chosen.

Method Validation. *Selectivity.* Twenty blank samples of chicken muscle, pork, chicken liver, and swine liver were analyzed to evaluate the selectivity of this method. The samples were prepared according to the developed method. Blank samples were spiked with standard solutions and analyzed; the resultant MRM chromatograms are depicted in Figure 3. As shown, there were no interferences in the analyte peaks, compared with the standards made in solvent, demonstrating the high selectivity of the method.

Linearity. Four matrix-matched calibration curves for all analytes were made at concentrations ranging from 3 to 1000 μg/kg to evaluate the linearity of the method. a linear relationship was observed with correlation coefficients (r) higher than 0.9900 for all analytes. These results are summarized in Table 1, demonstrating that this method could be used to monitor these analyte residues in animal tissues.

Accuracy and Precision. Accuracy and precision were evaluated by comparing the recoveries of each analyte at three spiked levels, with six replicates, on three separate days. The mean recoveries and coefficients of variation of target compounds are shown in Table 1. According to the criteria of SANCO Protocol No. 12495/2011, the acceptable recoveries for analytes should be in the range of 70−120%.[29] In the present study, all compounds were recovered satisfactorily, with

mean values in the range of 80.1−91.4% for chicken muscle, 79.2−96.6% for pork, 80.8−96.9% for chicken liver, and 74.1−93.1% for swine liver. Additionally, the intraday and interday RSD values were in the range of 1.4−9.9% and 4.3−9.1%, respectively. These results indicate that the developed method is suitable for the detection of type A and B trichothecenes, and their main metabolites, in food animal tissues.

Limit of Detection and Limit of Quantitation. The LOD is defined as the lowest analyte concentration reliably detected in the samples, and the LOQ is defined as the lowest concentration that can be reliably measured. For each analyte in each investigated matrix, the LODs and LOQs were determined by diluting the stock standard solutions with the blank matrixes. According to the IUPAC (International Union of Pure and Applied Chemistry) settings, the S/N ratios of LODs and LOQs should be more than 3 and 10, respectively.[18,28] Table 1 outlines LOD and LOQ values for every analyte in each investigated matrix, which ranged from 3.0 to 15.0 μg/kg and from 10.0 to 50.0 μg/kg, respectively. The European Commission has set maximum levels for *Fusarium*

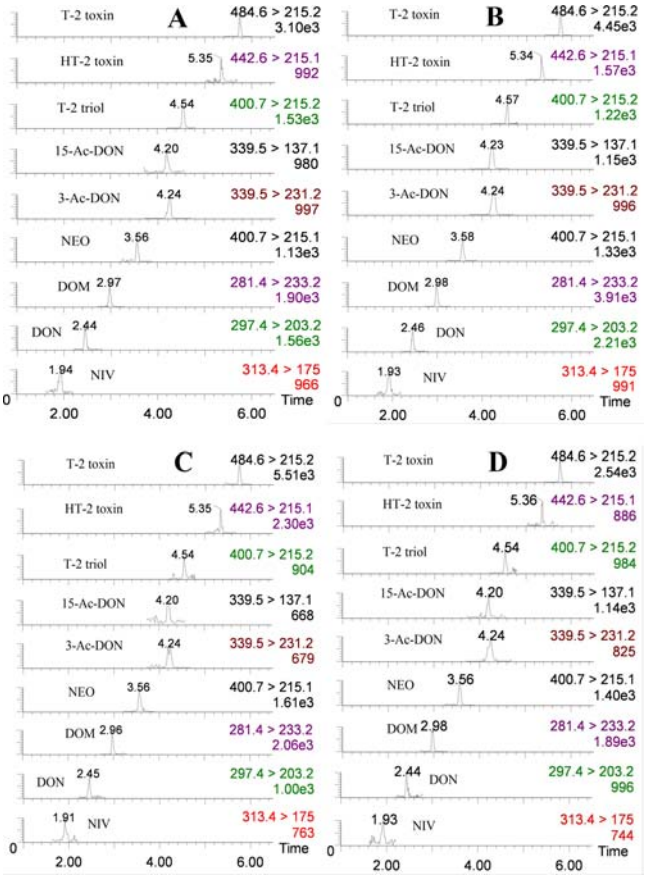

Figure 3. UPLC−MS/MS chromatograms of quantitative ions of (A) chicken muscle, (B) pork, (C) chicken liver, and (D) swine liver with concentrations of 15 μg/kg for NIV, 15-Ac-DON, and T-2-triol, 6 μg/kg for DON, DOM, 15-Ac-DON, and HT-2 toxin, and 3 μg/kg for NEO and T-2 toxin.

toxins in maize and maize products.[30] Regarding animal tissues for food, no regulatory limits have been set for these mycotoxins. According to the reports published by the European Food Safety Authority (EFSA), the tolerable daily intake (TDI) for DON together with its acetyl derivatives, 3-Ac-DON and 15-Ac-DON, was set at 1 μg/kg of bw per day.[31] For NIV, a TDI of 1.2 μg/kg of bw per day was established.[32] Considering that T-2 toxin is rapidly metabolized to a large number of products, HT-2 toxin being a major metabolite, a group TDI of 100 ng/kg of bw for the sum of T-2 and HT-2 toxins was recommended by EFSA.[33] In the present study, the UPLC−MS/MS method developed could detect all target analytes at parts per billion (μg/kg) levels, meaning it could effectively be applied to analyze mycotoxins in meat and liver samples. Only one publication reported the LOQs of T-2 toxin and DON in chicken meat and pork, 0.007 and 0.02 μg/kg, respectively.[25] In addition, another paper reported the LOQs of T-2 toxin, HT-2 toxin, and DON in fish samples, ranging from 0.5 to 3.0 μg/kg.[27]

Application of the Proposed Method to Real Samples.

Twelve chickens were given T-2 toxin at levels of 3 mg/kg of bw by oral administration. Muscle and liver tissues were collected 6, 12, 24, and 48 h after dose. The tissue samples were then analyzed using the methods developed here. The detailed results are shown in Table 2. Within 6 h after oral administration, only trace amounts of T-2 toxin could be detected, indicating that T-2 toxin was rapidly metabolized in the chicken. A large amount of HT-2 toxin was found in chicken muscle and liver. Even 48 h later, it was also detected in the liver, which suggested that HT-2 toxin was a main metabolite of T-2 toxin. In addition, the other two metabolites of T-2 toxin, NEO and T-2-triol, were also detected in both tissues at trace levels. These results suggest that, compared with T-2 toxin, it is more important to develop the method to detect its metabolites, especially HT-2 toxin.

In summary, a UPLC−MS/MS method for simultaneous analysis of DON, T-2 toxin, NIV, 3-Ac-DON, and 15-Ac-DON and their main metabolites DOM, HT-2 toxin, NEO, and T-2-triol, in chicken meat, pork, chicken liver, and swine liver was developed in the present work. The analytical method was developed and validated, and the resulting data demonstrated good accuracy and precision, indicating that this method was reliable, sensitive, and convenient. In addition, this method was successfully applied to the analysis of chicken muscle and liver taken from chickens that received an oral dose of T-2 toxin. The proposed analytical procedure can therefore be used for the determination of DON, T-2 toxin, NIV, 3-Ac-DON, and 15-Ac-DON and four of their major metabolites in animal tissues.

For example, Pinalate, a yellowish mutant of Navelate orange (*Citrus sinensis* L. Osbeck), accumulates linear carotenes;[31] and both Hong Anliu, a red-flesh mutant of sweet orange (*C. sinensis* L. Osbeck),[30] and Cara Cara, a red-flesh mutant of Navel orange (*C. sinensis* L. Osbeck),[32] accumulate lycopene. However, very few studies have been focused on other biological processes that may be affected by the altered carotenoid profile in these mutants.

Similar to other perishable agricultural products, citrus fruits are susceptible to the damage caused by physical disorder and pathogenic diseases during shipping, storing, and marketing.[33] Citrus green mold rot, which is caused by *Penicillium digitatum*, leads to huge postharvest losses in the citrus industry.[34] Although the application of artificial fungicide proved inexpensive and effective to control this disease, it is greatly limited by the emergence of new resistant fungal strains as well as by its low potency, poisonousness, poor solubility, and nonbiodegradability.[34,35] Enhancing the natural defense of the fruit by reprogramming its physiological status would be a promising alternative strategy in the prevention of this pathogen.[33−35] Flavonoids are a group of polyphenolic compounds that include flavanone, flavanone- and flavone-*O*-glycosides, flavone-*C*-glycosides, flavone, and polymethoxyflavone aglycones.[35] The PMFs in citrus are a class of flavones found in glycosylated and aglycone states, showing a great variety of compounds with their structure frequently multisubstituted by hydroxyl and/or methoxyl groups.[36] Flavonoids, especially polymethoxylated flavones (PMFs) which are rich in citrus peel, have proved essential barriers against pathogen attack and can be induced to accumulate in citrus fruits.[34,36−38]

A nontargeted metabolomic analysis revealed significantly different primary and secondary metabolites in fruits between the bud mutant Hong Anliu and its parent.[39] Enhanced carotenoid accumulation in citrus calli by overexpressing *CrtB* affected redox status and starch metabolism and was linked with flavonoid/anthocyanin accumulation.[2] These results indicate that the altered carotenoid accumulation might affect other metabolisms potentially associated with carotenoids. However, no studies have tested the influences of the carotenoid-associated changes of metabolism on the abiotic and biotic stress resistance in fruits of these citrus mutants. A yellowish bud mutant has been identified from Ponkan (*C. reticulata* Blanco), which has reduced xanthophyll accumulation in fruits. Here, we used this bud mutant to explore the possible alterations in primary and secondary metabolisms, especially flavonoid accumulation, which is strongly related to the resistance against abiotic and biotic stresses. The feasibility of applying this bud mutant to improve postharvest performance of fruits was further tested by storage experiment and inoculation with *P. digitatum*.

MATERIALS AND METHODS

Plant Materials. The yellowish bud mutant of Ponkan (*C. reticulata* Blanco) (PK) was found in year 2008 by Quzhou Bureau of Agriculture Economic Specialty Station from the grafted seedlings of PK in orchard. The yellowish coloring in fruits of YP was confirmed to be stable by an investigation of six years. The materials of YP and PK used for the present study were grown following commercial cultivation practices in the same orchard in Quzhou, Zhejiang Province, China. Ripening fruits were harvested on November 10 (coloring stage 1, CS1), November 20 (coloring stage 2, CS2), and November 30 (coloring stage 3, CS3) in 2013 and 2014.

Thirty fruits grouped as one sample were peeled and immediately frozen in liquid nitrogen. One half of the pulp was immediately frozen in liquid nitrogen, whereas the other half was used for quality analysis. All samplings were performed in three biological repeats. Frozen samples were kept at −80 °C until use. The transverse and longitudinal diameters of leaves were determined by a vernier caliper.

Chemicals. Acetonitrile, methanol, formic acid, and authentic standards of flavonoids were of HPLC grade and were provided as follows: acetonitrile and methanol by Fisher (Fisher Scientific, USA), formic acid by Guangfu (Tianjin Guangfu Fine Chemical Research Institute, China), eriocitrin (ERI), narirutin (NART), hesperidin (HES), didymin (DID), nobiletin (NOB), and tangeretin (TAN) (purity ≥98%) by YiFang S&T (Tianjin, China), sinensetin (SIN) from Chromadex (Santa Ana, CA, USA), and 5-demethyl-nobiletin (DEM) from MeiLian (Shanghai, China). Deionized water was prepared by distilled water through a Milli-Q A10 system (Millipore, Milford, MA, USA).

Color Measurement. Fruit color was measured by a color analyzer (KONICA MINOLTA CR-400, Japan). The red to green was expressed as $+a$ to $-a$, yellow to blue was expressed as $+b$ to $-b$, and brightness was expressed as L. The color index (CI) was calculated by the eq 1:

$$\mathrm{CI} = \frac{1000a}{Lb} \tag{1}$$

Analysis of Titratable Acid and Total Soluble Solids. Hand-squeezed juice from sliced pulp was filtered and subjected to titratable acid (TA) and total soluble solids (TSS) analysis. TA was determined by a Fruit Acidity Meter (GMK-835F, G-WON HITECH CO.,LTD, Korea), and TSS was determined by a Brix Refractometer (Pocket PAL-1, ATAGO, Japan).

Carotenoid Extraction and HPLC Analysis. Carotenoid extraction and analysis by reverse-phase high-performance liquid chromatography (RP-HPLC) were performed according to a previous work.[31] Retention time and UV spectrum of isolated carotenoids are listed in Table 1 of the Supporting Information.

Analysis of Abscisic Acid. Abscisic acid (ABA) was extracted from 1.0 g of fresh sample with 4 mL of extraction solution (MeOH/water = 4:1, 1 mM BHT, 2, 6-di*tert*-butyl-4-methyl-phenol) at 4 °C as previously described.[40] Samples and standard solutions were analyzed by the indirect enzyme-linked immunosorbent assay (ELISA). The ELISA kit was kindly supplied by Professor Baomin Wang (China Agricultural University).

Analysis of Primary Metabolites by GC-MS. Primary metabolites were extracted and analyzed by GC-MS as previously described.[33]

Flavonoid Analysis by UPLC. A 1.0 g aliquot of flavedo or 4.0 g of pulp was ground by liquid nitrogen and extracted using 80% MeOH more than three times. After centrifugation, the supernatants were collected and metered to volume (25 mL for flavedo and 10 mL for pulp). After the filtering through a 0.22 um filtration membrane (Millipore, USA), a 2 uL sample was injected and analyzed in a Waters H-Class UPLC system (eλ PDA detector, HSS T3 column: 150 mm × 3.0 mm i.d., 1.8 um particle, Waters, USA). Optimum mobile phase was composed of phase A (water/acetonitrile/formic acid = 100:2:0.1) and phase B (acetonitrile containing 0.1% formic acid). The elution program was performed as follows (min, % A): (0, 100), (2, 95), (8, 75), (12, 55), (20, 25), and (23, 0). The equilibration time after gradient analysis was 5 min. The flow rate was 0.5 mL/min, and the column temperature was kept at 35 °C. Detection was at 283 nm for flavanones and at 330 nm for PMFs. The concentration range, LOD, LOQ, and linearity of standards were listed in Table 2 of the Supporting Information. The structure and UV spectrum of the identified flavonoids were listed in Table 3 of the Supporting Information.

Fruit Storage and Sampling. The fruits from CS3 were stored at 16−20 °C with relative humidity (RH) at 80−90%. The flavedo of fruits from 0, 15, 25, 35, and 45 days after storage (DAS) was sampled, immediately frozen in liquid nitrogen, and kept at −80 °C until analysis.

***P. digitatum* Inoculation and Sampling.** Fruits from 35 DAS were used for *P. digitatum* inoculation according to the previous work.[33] Each group of nine fruits was incubated in a storage chamber

(c) Total content of carotenoids and xanthophylls in flavedo and pulp at three coloring stages. Top, year 2013, and bottom, year 2014. Error bars represent SDs of the means ($n \geq 3$, biological triplicates). Results were averaged values plus SDs of the means and statistically analyzed using a paired-samples *t*-test. *, $p < 0.05$, and **, $p < 0.01$; CS1/2/3: coloring stage 1/2/3.

(25 °C, 95% RH). Disease incidence rate and lesion diameter were calculated on the basis of the following equations (eq 2−4):

$$\text{Infection rate of inoculated fruits (IRIF, \%)} = \frac{\sum \text{number of infected fruits}}{9 \times 100} \quad (2)$$

$$\text{Infection rate of inoculated fruits (IRIF, \%)} = \frac{\sum \text{number of infected spots}}{18 \times 100} \quad (3)$$

$$\text{Lesion diameter (LD, cm)} = \frac{\sum \text{lesion diameter of decaying spots}}{\text{total number of decaying spots}} \quad (4)$$

Two groups were sampled each time at 0, 2, 6, 12, 24, 48, and 72 hours after inoculation (HAI). Samples with a radius of 1.5 cm were cut off from the inoculated YP flavedo (IYPF) and inoculated PK flavedo (IPKF) spots, respectively. Samples peeled from the uninoculated YP flavedo (UYPF) and uninoculated PK flavedo (UPKF) spots at 6, 12, 24, 48, and 72 HAI were used as the control of IYPF and IPKF, respectively. The inoculated and the uninoculated flavedo were cut off from the same fruit. Groups for investigation of pathogenesis process were kept until 240 HAI and also sampled finally. All the samples were immediately frozen in liquid nitrogen and kept at −80 °C until flavonoid analysis.

Transmission Electron Microscopy. Fruits from CS3 without damage were used for transmission electron microscope (TEM) analysis according to a previous method.[41] More than one hundred individual cells from 30 fields of vision were used to obtain statistics of plastids by ImageJ.

RNA Isolation and Quantitative Real Time PCR Analysis. Total RNA was extracted according to the method of a previous work.[31] Integrity of RNA was electrophoretically verified; then, its concentration as well as A_{260}/A_{280}, and A_{230}/A_{260} absorption ratios were detected by Nanodrop (Agilent 2100, USA). Potential contamination with DNA was eliminated by treatment with DNase I (RNase-free, Fermentas MBI). A 1 μg aliquot of total RNA from each sample was used to synthesize the first-strand cDNA using the RevertAid First Strand cDNA Synthesis Kit (Fermentas, Thermo Fisher Scientific, Waltham, MA), following the manufacturer's recommendations. Quantitative reverse transcription PCR (qRT-PCR) was carried out in an ABI PRISM 9600 Sequence Detection System (Applied Biosystems) using SYBR Green Supermix according to the manufacturer's instructions, under the thermal cycle conditions of an initial denaturation step (94 °C for 10 min), followed by 40 cycles of 94 °C for 15 s and 60 °C for 31 s for annealing, and a final step of extension at 72 °C for 7 min. The expression levels of the selected genes were calculated by the $\delta-\delta$-Ct method.[42] The expression level of β-actin is more stable than that of GPADH; thus, the β-actin gene was used as reference gene for data normalizations. Each biological sample was examined in duplicate with three technical replicates. Genes and primers for qRT-PCR analysis are listed in Table 4 of the Supporting Information.

Western Blot Analysis. Total proteins were extracted as described previously[43] and quantified using a RC DC protein assay kit (Bio-Rad, Hercules, CA, USA). Then, 30 ug of total flavedo protein or 50 ug of total pulp protein was separated by SDS-PAGE (12.5%) and blotted onto PVDF membranes (Millipore, USA). The subsequent Western blot analyses were conducted as previously described.[41] The primary antibodies (1:3000, v/v) were rabbit anti-plastoglobulin 35 (PGL35) antibody (Agrisera, Sweden) and mouse anti-plant actin (as an internal reference, Abbkine, USA); the secondary antibodies (1:15 000, v/v) were peroxidase-conjugated immunopure goat anti-rabbit or goat anti-mouse IgG [H+L] (Pierce, USA). The signal was detected using a Clarity Western ECL Substrate (Bio-Rad, Hercules, CA, USA) according to the manufacturer's instructions. The chemiluminescence signal was imaged using a ChemiDoc XRS (Bio-Rad) and quantified using Quantity One software (Bio-Rad, USA). The calculated intensity volumes were fitted with a variable-slope dose−response relationship using ImageJ.

[a]TSS: total soluble solids; TA: titratable acid; and CS1/2/3: coloring stage 1/2/3. Results were averaged values plus SDs of the means ($n \geq 3$, biological triplicates). Different letters at each parameter indicate significant differences according to Duncan's multiple tests ($p < 0.05$).

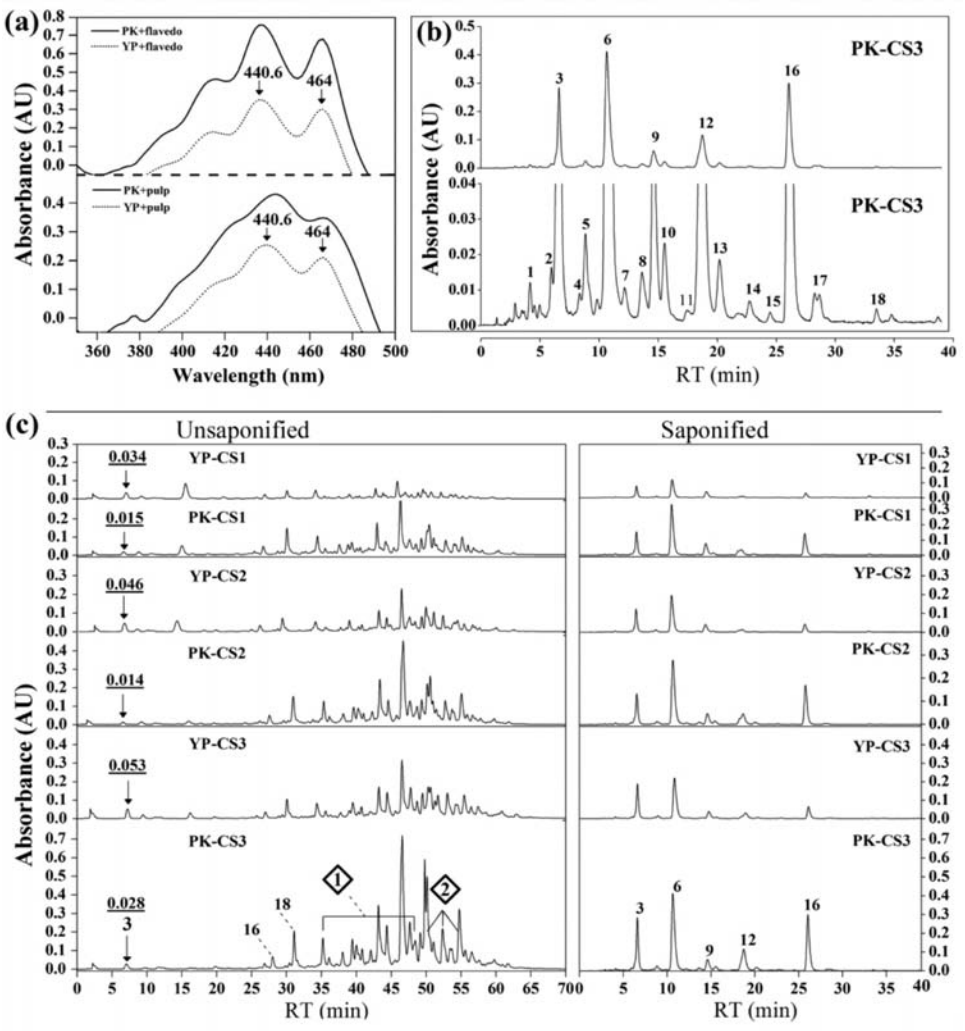

Figure 2. Carotenoid profile analysis. (a) Representative absorbance spectra of *n*-hexane solutions of unsaponified carotenoid extracts from fruits of CS3. Black line: PK; dotted line: YP. Numbers above the arrows represent the maximum wavelengths of absorbance. (b) Representative HPLC chromatogram of saponified carotenoid extract in PK flavedo of CS3. The bottom half is a magnified image of the top part. Peaks were extracted at 450 nm and labeled as 1, violaxanthin; 2, unknown; 3, 9-*cis*-violaxanthin 1; 4, unknown; 5, luteoxanthin; 6, 9-*cis*-violaxanthin 2; 7, neoxanthin 1; 8, neoxanthin 2; 9, lutein; 10, zeaxanthin; 11, lutein isomer 1; 12, lutein isomer; 13, lutein isomer 2; 14, α-cryptoxanthin; 15, all-trans-phytoene; 16, β-cryptoxanthin; 17, α-carotene; and 18, β-carotene. (c) Representative HPLC chromatogram of unsaponified (left) and saponified (right) carotenoid extracts in flavedo from both genotypes. Left: Peak 3 violaxanthin (free type) was marked by arrows, and their absorbances were shown by underlining. 16, β-cryptoxanthin (free type), and 18, β-carotene (free type). Arabic numerals in Rhombic blocks: 1, violaxanthin esters; 2, β-cryptoxanthin esters. Right: The main peaks were shown and labeled according to b. All the samples used above were from year 2013. CS1/2/3: coloring stage 1/2/3.

The relative value of plastoglobulin 35 was calculated by normalization using actin value.

Measurement of H_2O_2. A 0.5 g aliquot of flavedo powder was homogenized by liquid nitrogen and extracted in 5 mL of physiological saline. Measurement of H_2O_2 was conducted as previously described.[33]

Statistical Analysis. The variance of data was analyzed using SPSS software package release 16.0 (SPSS Inc. Chicago, IL). Multiple comparisons were performed by one-way ANOVA based on Duncan's multiple range tests, whereas paired-samples *t* tests were performed to test the statistical significance between two genotypes.

RESULTS AND DISCUSSION

YP Is Characterized by Yellowish Coloring with Reduced Carotenoid and Xanthophyll Accumulation and Better Postharvest Performance. Yellowish coloring in both the flavedo and pulp was observed in YP at not only ripening stage but also the postharvest stage. No difference in leaf morphology was found between YP and PK (Figure 1a). The lower CI in YP indicates a slower coloring (Figure 1b). Compared with that of PK, the total content of carotenoids and xanthophylls in YP was decreased by half in flavedo and by one-quarter in pulp (Figure 1c, top: year 2013, bottom: year 2014). Along with the ripening, TSS showed an increased accumulation, whereas TA showed an obvious decrease in both YP and PK. However, the slower decrease of TA in YP resulted in a less remarkable increase of TSS/TA in YP (Table 1). These results indicate a slight difference of internal quality between YP and PK. We also observed a better postharvest performance of YP, as indicated by a lower decay rate (Figure S2a) and better quality in YP during storage (Figure S2b,c). These phenotypes were confirmed to be stable by consecutive investigations for several years.

Xanthophyll Esters Are Reduced in YP. Information concerning the natural binding form of carotenoids is usually lost because of the saponification procedure, a commonly used step in carotenoid analysis.[20] To obtain a comprehensive understanding of the carotenoid and xanthophyll accumulation process, flavedo samples with and without alkaline saponification were analyzed (Figure 2). In unsaponified samples, YP shared the maximum wavelengths (440.6 and 464 nm) of absorbance with PK (Figure 2a). In detail, in YP samples, violaxanthin esters and cryptoxanthin esters showed a significantly lower absorbance, but unesterificated carotenoids showed a higher absorbance at each coloring stage (Figure 2c, left).

In the flavedo, the contents of α-carotene, β-carotene, zeaxanthin, and lutein isomers were onefold or more lower in YP than in PK, whereas the content of lutein was onefold lower in the year 2013 but showed no decrease in the year 2014 in YP (Figures 2c, right, and 3a, respectively). Violaxanthin and 9-*cis*-violaxanthins in YP showed about onefold decrease in the year 2013 but only a slight decrease in the year 2014 (Figure S3a). This inconsistency was speculated to be caused by the varying coloring behaviors in different years (Figure 1b). It is noteworthy that YP flavedo showed a fivefold lower accumulation of β-cryptoxanthin in both years. Compared with contents in the pulp of PK, in the pulp of YP, a consistent onefold decrease in the contents of β-cryptoxanthin, lutein, and lutein isomers was observed in both years, whereas the contents of violaxanthin, neoxanthin, and zeaxanthin showed no consistent decrease. In addition, it was noted that the content of β-carotene was stably decreased by fourfold or more (Figures 3b and S3b).

As compared with violaxanthin-abundant citrus, the main contributor to the orange-reddish appearance in Ponkan pulp is β-cryptoxanthin (violaxanthins and β-cryptoxanthin in flavedo).[29] However, unlike the fruits of both violaxanthin-abundant type and β-cryptoxanthin-abundant type, YP showed steadily reduced contents of total carotenoids and xanthophylls (mainly β-cryptoxanthin) in both the pulp and flavedo. These results indicate different behaviors of carotenoid accumulation and esterification between YP and PK. It is noteworthy that the carotenoid profile of YP was also different from that of Pinalate, a yellowish mutant of Navelate orange (*C. sinensis* L. Osbeck) which accumulates linear carotenes.[31]

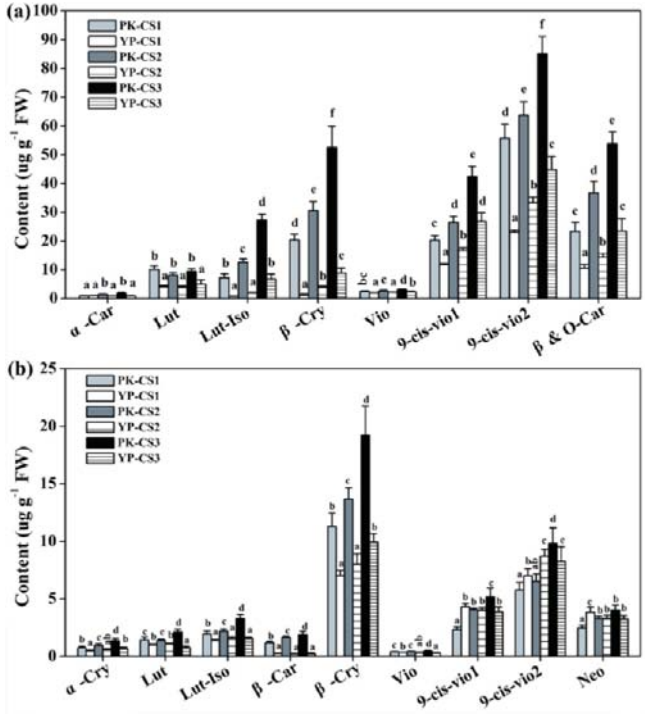

Figure 3. Changes in contents of carotenoids and xanthophylls in fruits of three coloring stages: (a) flavedo and (b) pulp. All the samples used were from year 2013. Abbreviations: α-Car: α-carotene; α-Cry: α-cryptoxanthin; Lut: lutein; Lut-Iso: lutein isomer; β-Car: β-carotene; β- and O-Car: β-carotene and other carotenoids; β-Cry: β-cryptoxanthin; Vio: violaxanthin; 9-*cis*-vio1: 9-*cis*-violaxanthin1; 9-*cis*-vio2: 9-*cis*-violaxanthin 2; Neo: neoxanthin. Error bars represent SDs of the means ($n \geq 3$, biological triplicates). Columns with different letters at each sample indicate significant differences according to Duncan's multiple tests ($p < 0.05$). CS1/2/3: coloring stage 1/2/3.

Abscisic Acid Accumulation Is Higher in YP at Earlier Coloring Stages. To investigate whether ABA accumulation is influenced by altered carotenoid composition in YP, quantification of ABA was performed in flavedo and pulp (Table 2). In the flavedo, ABA content started to decrease at CS2 in PK but was maintained at higher levels at CS1 and CS2 in YP. In the pulp of both genotypes, ABA content increased from CS1 to CS3. However, YP pulp showed a higher accumulation of ABA at CS1 (about a twofold increase) and CS3 (38% increase) when compared with PK pulp. In total, YP has a higher accumulation of ABA at the earlier period. Results indicated that the reduced accumulation of xanthophylls showed strong correlation with the ABA accumulation in YP. This conclusion was supported by the expression of *NCED5* in the later mentioned results (Figure 6).

Organic Acids and Flavonoid Are the Main Differentially Accumulated Metabolites during Coloring. A total of 52 and 57 identified primary metabolites were detected in the pulp and flavedo, respectively, mainly including sugars, organic acids, amino acids, alcohols, fatty acids, and several other metabolites (Table 3). All together there were 41 metabolites in the pulp and 48 metabolites in the flavedo that had significantly different accumulations between YP and PK. It is noteworthy that the accumulations of four metabolites (xylose, ribofuranose, succinic acid, and 10,12-tricosadiynoic acid) in the pulp and isocitric acid in the flavedo were significantly different at all three CSs between YP and PK ($p < 0.01$). Briefly, the dominant sugars were lower in YP pulp, whereas the dominant organic acids were

Table 2. Abscisic Acid Contents in the Flavedo and Pulp of PK and YP[a]

	ABA content (ng g^{-1} FW)			
coloring stage	PK+flavedo	YP+flavedo	PK+pulp	YP+pulp
CS1	88.29 ± 3.43	100.98 ± 21.40 ns.	37.39 ± 13.18	108.62 ± 27.07 **
CS2	50.50 ± 3.21	106.40 ± 3.96 **	80.59 ± 8.67	108.69 ± 16.48 ns.
CS3	46.77 ± 12.96	41.34 ± 14.36 ns.	98.91 ± 12.96	135.74 ± 14.66 **

[a]Results were averaged value plus SDs of the means and statistically analyzed using a paired-samples *t*-test. *: significant difference, $p < 0.05$;**: significant difference, $p < 0.01$; ns.: no significant difference. CS1/2/3: coloring stage 1/2/3.

higher in both the flavedo and pulp of YP when compared with in the flavedo and pulp of PK.

Analyses of secondary metabolites were performed on coloring fruits by LC-MS/MS. Except for flavonoid, other phenolic acids (protocatechuic acid, *p*-hydroxybenzoic acid, caffeic acid, vanillic acid, coumaric acid, ferulic acid, and sinapic acid) showed no significant difference between YP and PK (data not shown). Five flavanones (eriocitrin, ERI; hesperidin, HES; poncitrin, PON; narirutin, NART; and didymin, DID) and four PMFs (sinensetin, SIN; nobiletin, NOB; sinensetin, SIN; and 5-demethylnobiletin, DEM) were indentified (Figure 4a and Tables S2 and S3) and quantified for the two consecutive years (Figures 4b and S4). In flavedo, higher accumulations of ERI, HES, and PON were found in YP compared with those in PK in the year 2013. Similar accumulations of HES and PON were observed in YP in the year 2014. NART and DID showed no significant difference between YP and PK in the year 2013, whereas NART showed lower accumulation at CS2 and CS3 in YP in the year 2014. Furthermore, in YP flavedo, all the PMFs at CS2 and CS3 were significantly higher in the year 2013, whereas NOB at CS2 and SIN and DEM at CS3 showed a significantly higher level of accumulation in year 2014, as compared with those in PK flavedo (Figures 4b and S4a). In YP pulp, a significantly higher level of HES was found at CS1 in the year 2013 and at CS2 and CS3 in the year 2014. Interestingly, in YP pulp, higher accumulations of PMFs were found at CS1 and CS2 in the year 2013 but at CS1 and CS3 in the year 2014 (Figure S4b,c).

The results showed that in addition to some sugars and the dominant organic acids (citric acid, malic acid, succinic acid, and isocitric acid), PMFs were the main different metabolites between YP and PK. Because of the anticancer and antivirus activities as well as the other benefits of PMFs to humans, the YP fruits might be more attractive as fresh fruit for their higher level of PMFs. Furthermore, higher levels of PMFs mean higher antimicrobial activity in YP flavedo.[36]

YP Has Enhanced Resistance Against *P. digitatum*. *P. digitatum* was used as an elicitor to test the resistance of fruits from 45 DAS to pathogen infection (Figure 5). After inoculation, infection lesions appeared on PK fruits at 60 HAI, whereas no infection lesion was found on YP fruits (Figure 5a). Inhibited development of *P. digitatum* and a lower rotting rate were found during the infection process of *P. digitatum* in all YP groups when compared with in PK groups (Figure 5a,b). Statistical results of IRIS, IRIF, and LD from 60 to 144 HAI indicated a higher infection rate in PK than in YP, though the infection rate varied among three groups of the same genotype (Figure 5c−e). We previously found that YP showed a lower rotting rate and better internal quality in storage experiments for three consecutive years (Figure S2). We speculated that the antimicrobial activity might be improved in YP flavedo. Here, our results indicated that the development of *P. digitatum* was more effectively inhibited in YP compared with in PK.

Increase in Expression of Carotenoid Catabolism Genes Exceeds That of Biosynthesis Genes in YP versus PK. To understand the regulation of carotenoid accumulation at the transcription level, the relative expression of carotenoid-related genes was investigated (Figure 6). The dominantly expressed deoxy-D-xylulose 5-phosphate synthase (DXS) gene *DXS1* showed significantly lower expression at CS1 and CS2 in YP as compared with expression in PK. Interestingly, deoxy-D-xylulose 5-phosphate reducto-isomerase (*DXR*) and 1-hydroxy-2-methyl-2-(E)-butenyl 4-diphosphate synthase (*HDS*) showed significantly higher expression at all CSs, whereas isopentenyl diphosphate isomerase (*IPI*) and GGPP synthase (*GGPS*) showed several-fold higher expression at CS3 in YP relative to PK. In YP pulp, *DXS1* and *DXS2* showed relatively higher expression at all CSs, whereas *IPI* and *GGPS* showed higher expression at CS3 (Figure 6).

In the flavedo, most of the carotenoid biosynthesis genes except for ζ-carotene desaturase (*ZDS*) showed higher expression during coloring, especially at CS3 in YP than in PK (Figure 6a). In the pulp, most of these genes showed decreased expression at CS1 but no different expression or only slightly increased expression at the last two CSs in YP relative to PK (Figure 6). It is noteworthy that the dominantly expressed phytoene synthase (*PSY*) gene, *PSY1*, showed 12-fold higher expression in YP flavedo and 3-fold higher expression in YP pulp at CS3 compared with that in PK flavedo and pulp (Figure 6).

The upregulation of the expression of most of the genes for ABA synthesis and carotenoid cleavage was stronger than that of the genes of MEP pathway and carotenoid biosynthesis at the later CSs in YP (Figure 6). The expression of 9-*cis*-epoxycarotenoid dioxygenase 3 (*NCED3*) was stable and showed no significant difference between YP and PK, whereas *NCED5* showed more than 20-fold higher expression in YP flavedo at all three CSs and 3-fold higher expression in YP pulp at CS3 when compared with its expression in PK. In addition, the expression of *CCD1* and *CCD4b1* was two or three folds higher at all CSs in YP flavedo, whereas *CCD1* showed no difference in expression between YP and PK in the pulp. Surprisingly, *CCD4b1* was only detected in YP pulp. However, compared with expression in PK pulp, more than fivefold higher expression of *CCD4b2* was found in YP pulp at CS2 and in YP flavedo at CS3, and more than sevenfold higher expression of *CCD4c* was observed in YP pulp at CS3 in the present study (Figure 6).

NCED5 and NCED3 cleave 9-*cis*-violaxanthin at the 11−12 position to form xanthoxin, a precursor of ABA, whereas CitCCD1 protein cleaves β-cryptoxanthin, zeaxanthin, and all-trans-violaxanthin at the 9−10 and 9′−10′ positions and 9-*cis*-violaxanthin at the 9′−10′ position.[26] The 20-fold higher expression of *NCED5* might result in the higher accumulation of ABA in YP flavedo (Table 2). It is noteworthy that CCD4b1 in citrus (CitCCD4) was shown to produce a fruit-specific C_{30} apocarotenoid (β-citraurin) from cryptoxanthin and zeaxanthin.[27,28] However, β-citraurin was not detected in either YP or PK. Thus, except for the production of

[a]Results are shown as the YP/PK ratio of each compound. *: $p < 0.05$; **: $p < 0.01$; up: detected the YP but not in PK; down: detected in the PK but not in YP; BN: undetected in both genotypes; and CS1/2/3: coloring stage 1/2/3. Metabolites in each category were arranged in an order of absolute contents.

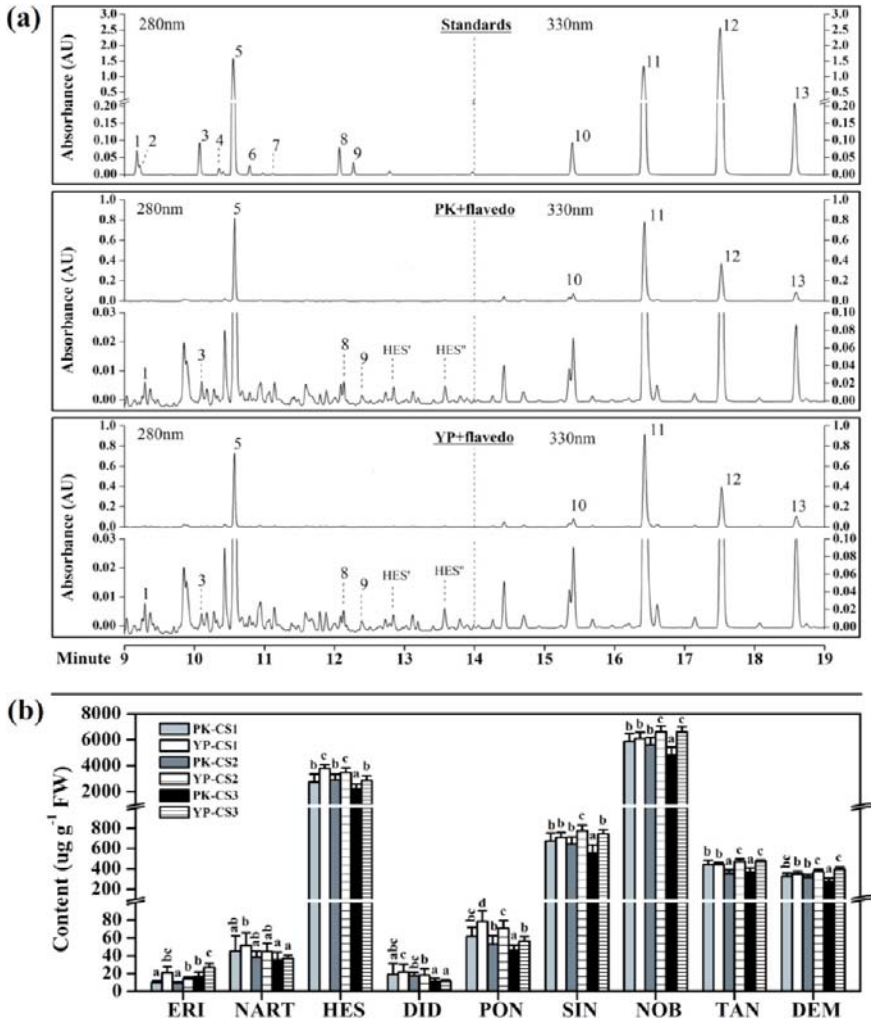

Figure 4. Separation and quantity of flavonoid in flavedo by UPLC analysis. (a) UPLC profiles of flavonoid standards (top) and flavonoid extracts in flavedo from PK (middle) and YP (bottom) of CS3. Peaks: 1, eriocitrin; 2, rutin; 3, narirutin; 4, naringin; 5, hesperidin; 6, neohesperidin; 7, scutellarein; 8, didymin; 9, poncirin; 10, sinensetin; 11, nobiletin; 12, tangeretin; and 13, 5-demethylnobiletin. HES′ and HES″ were deduced to be analogues of hesperidin by their UV absorption characteristics (HES′: 224, 282.3, 328.9; HES″: 224, 282.3, 328.9). (b) Compositions and contents of flavonoid in flavedo from both genotypes at three coloring stages. Error bars represent SDs of the means ($n \geq 3$, biological triplicates). Columns with different letters at each substance indicate significant differences according to Duncan's multiple tests ($p < 0.05$). CS1/2/3: coloring stage 1/2/3.

β-citraurin, CCD4b1 might be involved in other catalytic reactions. *CCD4c* is restricted to petals and may be related to the cleavage of carotenoids to colorless volatile apocarotenoids (C_9–C_{13}). *CCD4a* transcripts were detected in all pulp, peel, leaf, stem, root, and petal samples but were relatively higher in leaf.[28] For their unclarified functions and low absolute expression levels, the relationship between *CCD4a*, *CCD4b2*, or *CCD4c* and carotenoid catabolism in citrus fruits has to be further investigated.

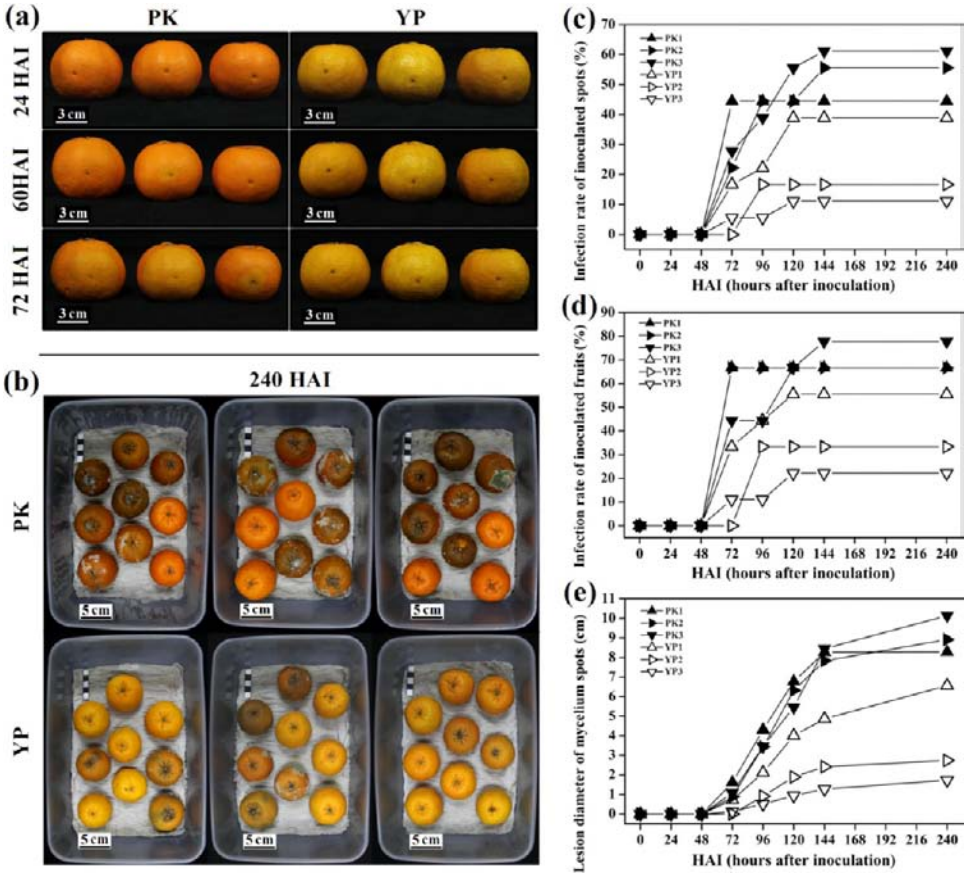

Figure 5. Inoculation experiment of *P. digitatum* in PK and YP fruits. (a) Invasion process of *P. digitatum* in PK and YP. (b) Infection of *P. digitatum* on fruits of PK and YP up to 240 HAI. (c) IRIS, (d) IRIF, and (e) LD of *P. digitatum* were investigated during 240 HAI. PK1, PK2, and PK3 represent three biological repeats of inoculations of PK fruits, and YP1, YP2, and YP3 represent independent biological repeats of inoculations of YP fruits.

Although the expression of upstream genes (*DXR, HDS, IPI, GGPS*, and *PSY*) was unexpectedly upregulated in YP, the reduced carotenoid accumulation of YP might be due to the fact that the increase in expression of carotenoid catabolism genes exceeds that of biosynthesis genes in YP versus PK. The unexpected upregulation of upstream genes for carotenoid biosynthesis in YP at CS3 might be due to the feedback regulation by the higher accumulation of ABA at the earlier coloring stages and a potential higher oxidative stress, as indicated by the higher H_2O_2 level (Figure S8). Furthermore, it was recently reported that OR controls carotenoid biosynthesis via posttranscriptional regulation of PSY in plants.[18] Thus, the transcripts of these upregulated genes may not always be translated to active proteins because of the potential regulation at posttranscriptional level.

Carotenoid Sequestration Capacity and Compartment of Chromoplastid Are Reduced in YP. Western blot analysis was performed to detect fibrillin/PGL35 protein, a lipoprotein in plastoglobulus related to lipid storage and carotenoid and tocopherol synthesis.[17] Compared with expression in PK flavedo and pulp, a significant lower abundance of PGL35 at CS1 and CS2 was found in YP flavedo (Figure 7a), whereas a lower abundance of PGL35 at CS1 was found in YP pulp (Figure 7b).

As shown in Figure S5a, to investigate the compartment of chromoplastid in flavedo, more than 100 cells from 30 TEM sections were used to obtain statistics for chromoplastids. The average number and density of plastids were lower in YP flavedo than in PK flavedo: 38.78% of the investigated YP cells held one plastid, which is obviously higher than that of PK (20.69%), whereas only 3.06% of YP cells held four chromoplastids, which is far less than that of PK (15.86%) (Figure S5b). In addition, more plastids with areas of 0.00−7.00 um^2 were found, whereas fewere plastids with areas of 7.01−16.00 um^2 were found in YP compared with those in PK (Figure S5c). Similarly, more cells with 0.00−10.00% total plastid compartment area (TPCA) were present in YP relative to in PK, whereas fewer cells with 12.00 to over 30.00% TPCA were present in YP relative to in PK (Figure S5d). In summary, compared with those from PK, plastids from YP were characterized by lower density, smaller size, and smaller TPCA. These results indicate reduced storage capacity for carotenoids and xanthophylls in YP.

The relatively lower abundance of PGL35 in YP fruits at earlier stages indicates reduced capacity of carotenoid sequestration during coloring. Recently, the QTL with the largest effect on β-cryptoxanthin content was detected. This QTL includes the Gn0005 locus, a marker derived from the *CitPAP* cDNA sequence (GenBank: AB011797).[44] Although the relation between *CitPAP* and carotenoid accumulation has not been clarified in citrus, the reduced abundance of PGL35 in YP at the earlier stages of coloring showed a strongly positive correlation with the reduced carotenoid accumulation. Thus, our results suggest that the carotenoid accumulation in YP is the integrated result of the disequilibrium between carotenoid catabolism and biosynthesis and the weakened storage capacity of carotenoids.

PMFs Levels Are Stabilized and H_2O_2 Accumulation Is Increased in YP during *P. digitatum* Expansion. As shown in Figure S6, compared with in PK, *PAL1* expression was upregulated in YP flavedo but was not upregulated in YP pulp during coloring. However, the accumulation of PMFs was increased

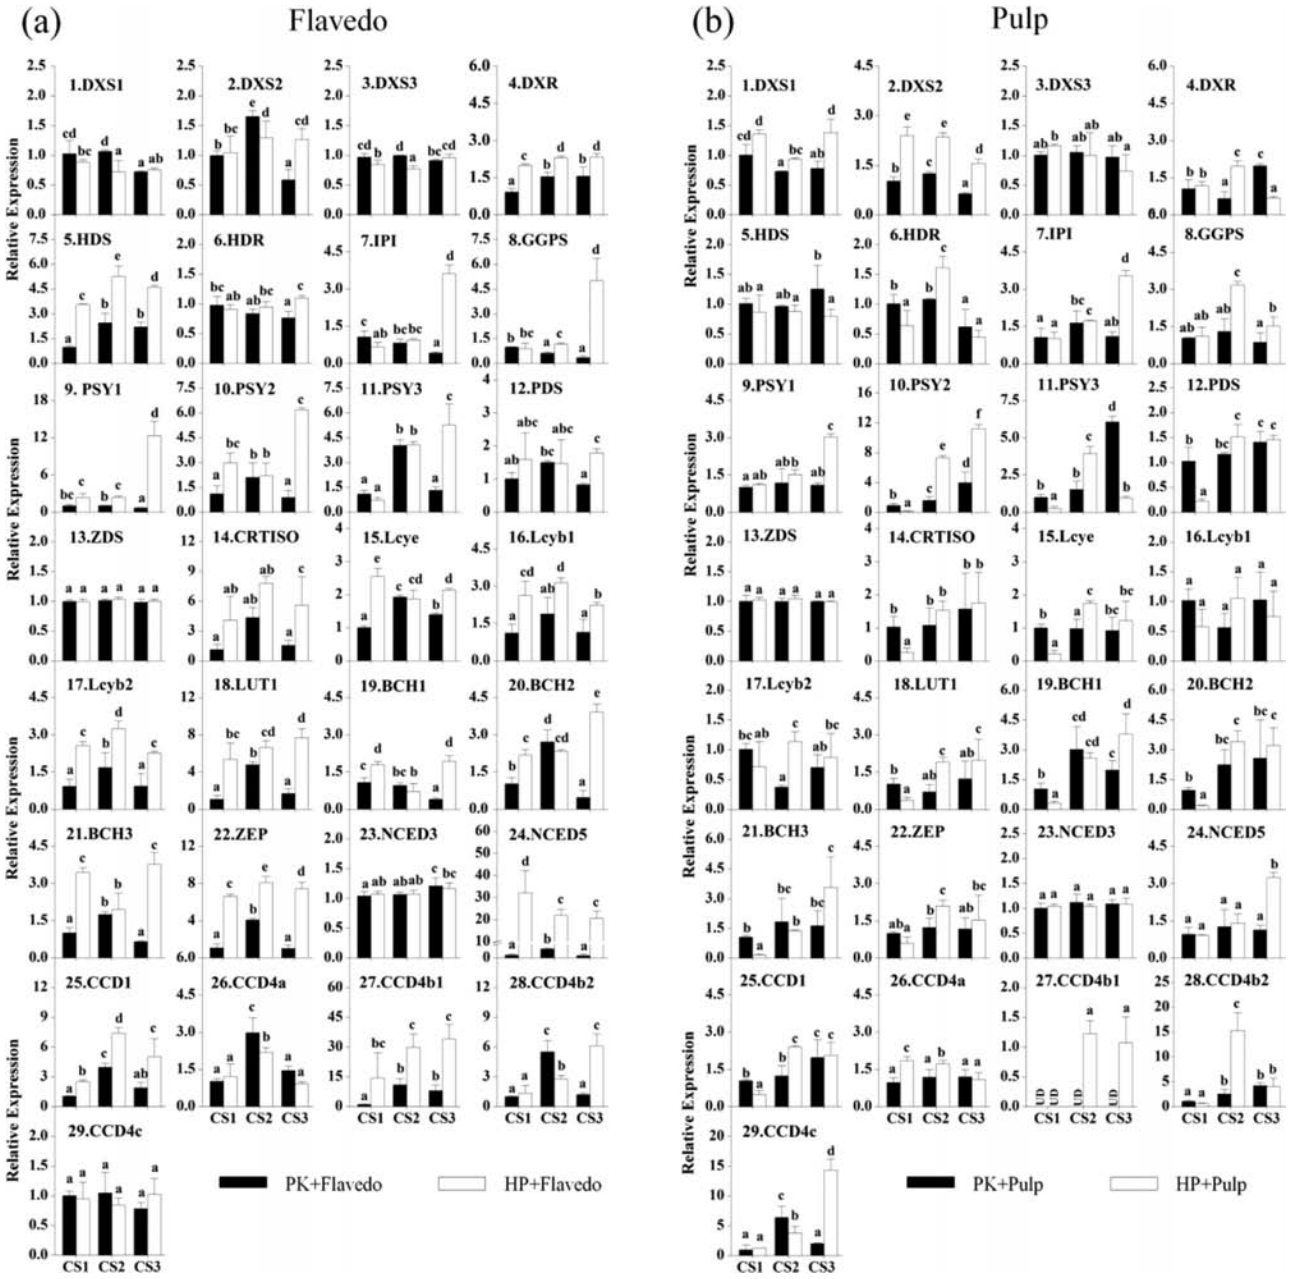

Figure 6. Expression of genes involved in carotenoid biosynthesis and catabolism: (a) flavedo and (b) pulp. DXS1/2/3: DXP (deoxy-D-xylulose 5-phosphate) synthase 1/2/3; DXR: DXP reducto-isomerase; HDS: 1-hydroxy-2-methyl-2-(*E*)-butenyl 4-diphosphate synthase; HDR: 1- hydroxy-2-methyl-2-(*E*)-butenyl 4-diphosphate reductase; IPI: isopentenyl diphosphate isomerase; GGPS: GGPP synthase; PSY1/2/3: phytoene synthase 1/2/3; PDS: phytoene desaturase; ZDS: ζ-carotene desaturase; CRTISO: carotenoid isomerase; Lcye: lycopene ε-cyclase; Lcyb1/b2: lycopene β-cyclase b1/b2; LUT1: an ε-carotene hydroxylase; BCH1/2/3: β-carotene hydroxylase 1/2/3; ZEP: zeaxanthin epoxidase; NCED3/5:9-*cis*-epoxy-carotenoid dioxygenase 3/5; CCD1/4*a*/4b1/4b2/4c: carotenoid cleavage dioxygenase 1/4*a*/4b1/4b2/4c. Error bars represent the SDs of the means ($n \geq 3$). Columns with different letters indicate significant differences according to Duncan's multiple range tests ($p < 0.05$). CS1/2/3: coloring stage 1/2/3.

in both of the flavedo and pulp of YP when compared with that in PK (Figures 4b and S4). Thus, the correlation between the expression of *PAL1* and PMFs accumulation might be tissue-specific because flavedo is the interface to environment and is subjected to various stresses. In addition, the expression of *PAL*1 showed positive correlation with the abscisic acid content in flavedo. An ABRE cis element was found in the promoter of *PAL*1. Thus, we speculated that the increased accumulation of ABA might increase the flavonoid accumulation by upregulating the expression of *PAL*1.

During 45 days of postharvest storage, the levels of PMFs fluctuated and reached the highest value at 15 DAS, but overall they were significantly higher in YP flavedo compared with levels in PK flavedo, except for NOB, DEM, and TAN (tangeretin) at 35 DAS (Figure S7). Thus, higher levels of PMFs in YP at both coloring and storage stages might be a biochemical basis for the enhanced resistance. Consistent with this deduction, the YP fruits from 45 DAS showed enhanced resistance against *P. digitatum* (Figure 5).

To understand the biochemical basis for the enhanced resistance against *P. digitatum*, a sequential monitoring of secondary metabolites was conducted in inoculated or uninoculated flavedo by UPLC (Figure 8) and LC-MS/MS. In previously reported

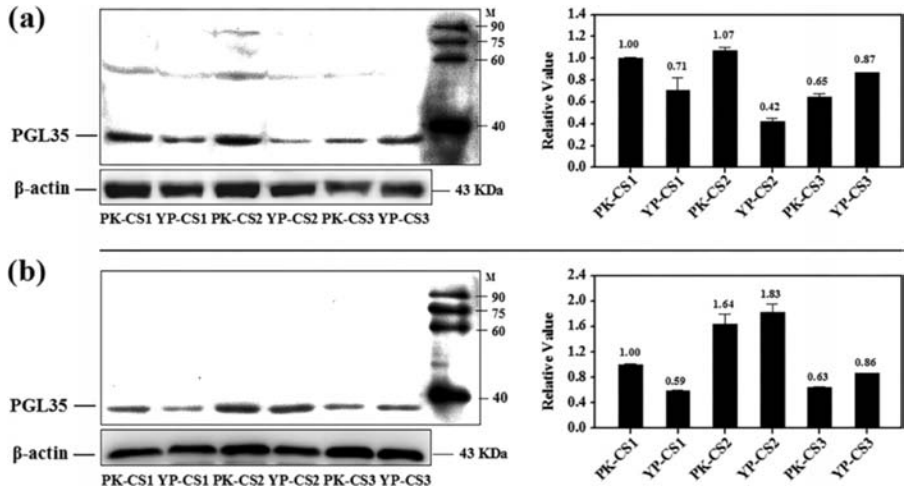

Figure 7. Western blot analysis of PGL35 protein: (a) flavedo and (b) pulp. Exposure time was 2 and 3 min for flavedo and pulp samples, respectively. CS1/2/3: coloring stage 1/2/3.

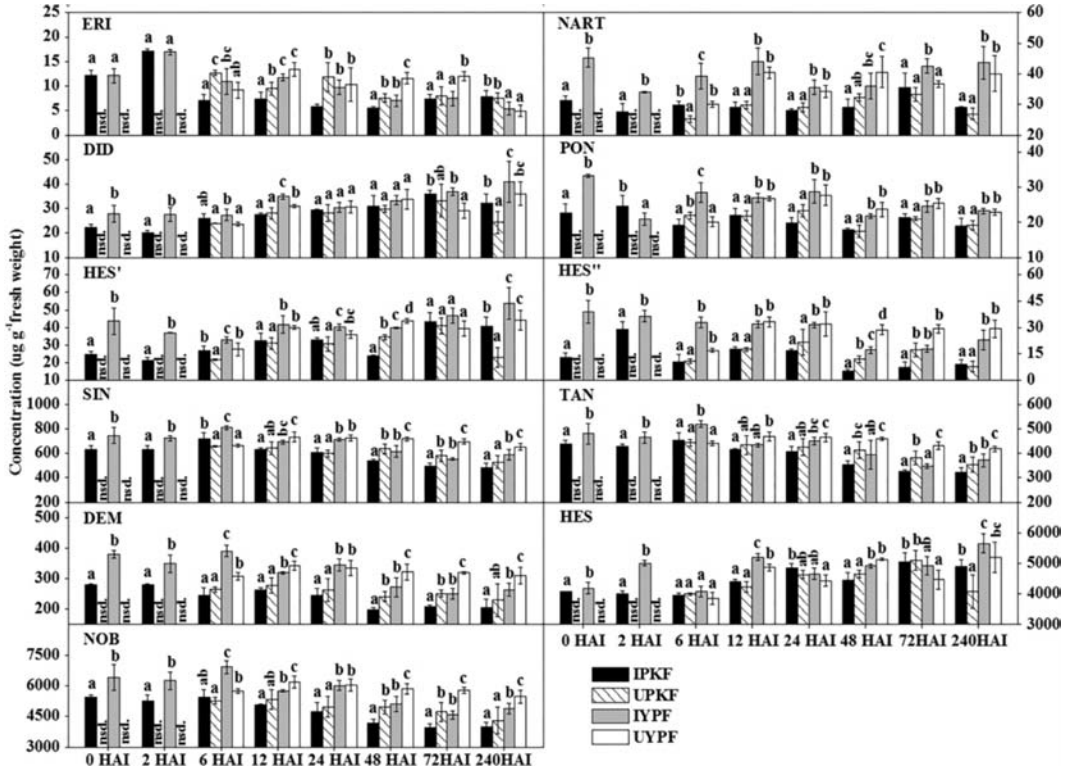

Figure 8. Flavonoid contents in flavedo inoculated with *P. digitatum* or uninoculated flavedo during 240 h. Error bars represent SDs of the means ($n \geq 3$, biological triplicates). Columns with different letters at each substance indicate significant differences according to Duncan's multiple tests ($p < 0.05$). IPKF: inoculated PK flavedo; UPKF: uninoculated PK flavedo; IYPF: inoculated YP flavedo; UYPF: uninoculated YP flavedo; nsd: not sampled for detection; and HAI: hours after inoculation.

studies, the inoculated and uninoculated materials for monitoring flavonoids were sampled from different fruits.[34,37,38,45] In contrast to these methods, we sampled the inoculated and uninoculated flavedo materials for flavonoid detection from the same fruit. Because the same fruit represents the same physiological background, our sampling method should be more reliable. No novel metabolite derived from the inoculation was found (data not shown). The contents of all the flavonones fluctuated but in general showed higher levels in YP (IYPF/UYPF) relative to those in PK (IPKF/UPKF) during 240 HAI. HES′ was deduced to be hesperetin 7-*o*-glucoside in previous document, which is the probable product of HES hydrolysis by enzymes from fungi.[45] It is noteworthy that the levels of HES′ and HES″ (another unknown flavonone) were increased by folds in YP relative to those in PK at 240 HAI. The contents of PMFs in IPKF and UPKF did not increase and started to decrease from 12 to 24 HAI, respectively, whereas their contents in IYPF and UYPF were increased and reached peak values at 6 and 12 HAI, respectively. It is noteworthy that the PMFs in UYPF stayed unchanged from 12 to 72 HAI and started to decrease slowly afterward. Our results indicate that the stabilized level of PMFs in the uninoculated flavedo in YP help to construct an effective barrier against the attack of *P. digitatum*.

J. Agric. Food Chem. 2015, 63, 8601−8614

H_2O_2 was shown to be an important secondary messenger for the induction of the expression of defense genes.[46] It is noteworthy that H_2O_2 level was higher in both inoculated and uninoculated spots in YP flavedo than that in PK flavedo during *P. digitatum* expansion (Figure S8). The integration of reactive oxygen species/redox status and sugars/carbon status can account for most of the effects of the major environmental factors that influence carotenoid biosynthesis, and carotenoids or their derivatives can in turn act as stress signaling molecules.[47] Reasonably, H_2O_2 might participate in the regulation of carotenoid biosynthesis and the induction of the expression of defense-related genes. A more efficient transduction of the H_2O_2 signal from the inoculated spots to healthy tissues may facilitate the establishment of barriers against pathogens, such as the accumulation of PMFs in YP.

The volatile oil in flavedo is another group of important metabolites that might be related to the resistance against *P. digitatum*.[35,48] We conducted a comparative analysis of chemical composition of the volatile oil in flavedo between YP and PK. The previously proven antifungal components against *P. digitatum*, D-limonene, γ-terpinene, and β-linalool showed lower accumulation, whereas α-terpineol and octanal showed higher accumulation in YP flavedo when compared with levels in PK flavedo. (Table S5 and Figure S9). However, the antifungal activity of α-terpineol and octanal against *P. digitatum* might be weak because of their low accumulation in flavedo (Table S5). In total, the content of antifungal components was lower in YP than in PK. Thus, volatile oil might not contribute to the enhanced resistance in YP.

Our results demonstrate that the disequilibrium between catabolism and biosynthesis and the reduced sink capacity of carotenoids are responsible for the reduced xanthophylls and the yellowish coloring in YP fruits. Through a comprehensive investigation of YP by analysis of its primary and secondary metabolites and resistance against abiotic and biotic stresses, this study reveals that reprogramming of metabolisms may help to enhance the resistance against abiotic and biotic stresses in YP. However, the improvement of postharvest performance was at the expense of a part of nutritional quality such as carotenoids, but higher PMFs might compensate for this loss of nutrition in the pulp. Taken together, our work is the first report that confirms the practicability of using the reprogramming of metabolisms in mutants to improve the postharvest performance of citrus fruit.

compounds in urine or plasma. To monitor intake frequency in individuals, it is extremely helpful to have a noninvasive biomarker in hand that is specific to coffee and sensitive enough for detection with straightforward analytical chemistry tools.[36] Several biomarkers for coffee have been proposed, including caffeine, polyphenols, and trigonelline.[37−41] Ingestion of caffeine results in excretion of caffeine and other xanthine derivatives;[37] chlorogenic acid leads to excretion of different quinic acids and hippuric acids;[38−40] and trigonelline and its roasting product *N*-methylpyridinium are also directly excreted in urine.[41] However, most detected markers to date are not specific to coffee consumption. For example, caffeine can be found in other stimulatory beverages, and the excretion of polyphenol-derived markers is not specific to coffee because fruits, vegetables, and tea are also rich in polyphenols.[38,42] Furthermore, metabolism of polyphenols is dependent on the gut microbiota and therefore subject to high interindividual variation in humans.[43−45]

Nontargeted metabolic profiling has in the past been shown to deliver novel food biomarkers, without prior knowledge of ingredients or processing and metabolism steps.[46−48] Here, we conducted a multistep approach for sequentially elucidating novel biomarkers for coffee consumption and established their temporal excretion profiles using ^{1}H NMR based metabolic profiling of a coffee intervention study.

MATERIALS AND METHODS

Dietary Intervention Study. A nutritional intervention study was designed to detect urinary biomarkers of different food consumption by using a nontargeted metabolic profiling approach. The study involved eight volunteers (seven women and one man; age range, 28−45 years) who met the following inclusion criteria: healthy, aged 18−45 years, nonsmokers, body mass index (BMI; in kg/m^2) 18−25, absence of regular drug intake and regular food supplement intake, and no antibiotic use within the previous 3 months. Participants consumed a standardized breakfast, lunch, and dinner that comprised whole-grain bread and cheese (breakfast), a ham sandwich (lunch), and different dinners on each day (dinner) from the run-in day (day 0) until lunch on day 7. Participants were allowed to drink coffee between 8 am and 12 (i.e., for breakfast and as desired, until 12 am). Urine was collected 4 times/day (first morning urine, before lunch, before dinner, and at bedtime), from the morning of day 1 until the evening of day 6. Urine specimens were collected into sterile tubes (Sterilin, Aberbargoed, UK) and kept in the refrigerator for a maximum of 12 h before storage at −40 °C until analysis. The study was approved by Imperial College London Research Ethics Committee and is registered at clinicaltrials.gov as NCT01102049.

Coffee Study. A food study was undertaken to characterize the excretion profile of 2-furoylglycine after coffee consumption. Five volunteers (three women and two men; age range: 24−34 years) who met the inclusion criteria of being self-assessed as healthy, aged 18−45 years, nonsmokers, a BMI of 18−30 kg/m^2, and an absence of regular drug intake and regular food supplement intake were recruited. The number of volunteers was based on power calculations with values from the previous dietary intervention study with $\alpha = 0.05$ and power of the test 0.80. Other than coffee consumption, participants were not restricted in their choice of foods for the duration of the study. Day 0 served as a run-in day, where no coffee consumption was allowed; a coffee challenge (1 espresso with or without milk) was administered on day 1 at 10 am and spot urine specimens were collected on day 1 (i.e., baseline samples, 6 times/d, collected at 8 am, 10 am, 12 am, 4 pm, and 8 pm and at bedtime); and at 8 am and 10 am on day 2 (study finish). Urine specimens were collected in sterile tubes (Sterilin) and kept in the refrigerator before they were stored at −80 °C until analysis.

Standard Spiking Experiment. The chemical standard of 2-furoylglycine was purchased from Sigma-Aldrich, was dissolved in NMR buffer, and was analyzed with ^{1}H NMR spectroscopy. Furthermore, a representative urine sample from time point "12 am" was analyzed with the same spectroscopic settings as the standard. Lastly, a ^{1}H NMR spectrum of the same urine, spiked with 2-furoylglycine in appropriate physiological amounts, was acquired, and the resulting spectrum was compared with the original spectrum.

Coffee Analysis. Three different kinds of coffee were analyzed: espresso, instant espresso, and chicory coffee. Coffees were prepared as per normal consumption, i.e., 12.5 g of bean powder per 50 mL of extraction water, 15 g of instant espresso powder per 50 mL of water, and 8 g of chicory coffee powder per 200 mL of water, and an aliquot of 50 μL was mixed with 200 μL of NMR buffer (90% D_2O 500 mM PO_4 buffer with 0.1% TSP, pH 7.4), centrifuged, and transferred to 3 mm outer diameter NMR Bruker Match tubes (Hilgenberg GmbH, Malsfeld, Germany).

NMR Spectroscopic Analysis. *Urine Analysis.* An aliquot of each urine sample was analyzed by ^{1}H NMR analysis. Urine and NMR buffer were mixed 2:1 and centrifuged, and 550 uL of the supernatant was transferred to 5 mm (dietary intervention study) or 120 uL to 3 mm (coffee study) outer diameter NMR Bruker Match tubes. Urine specimens of the dietary intervention study were acquired on a Bruker 600 MHz spectrometer (Bruker Biospin, Rheinstetten, Germany) that operated at 600.13 MHz. The spectrometer used a standard one-dimensional (1D) pulse-sequence [recycle delay (RD)-90°-t1-90°-mixing time (tm)-90°-acquire] free-induction decay (FID) with water-suppression irradiation during a RD of 2 s with tm set to 100 ms and a 90° pulse set to 10 μs. Spectra were acquired with 128 scans into 32 K data points with a spectral width of 12000 Hz. Urine specimens from the coffee study were analyzed on a Bruker 800 MHz spectrometer operating at 800.35 MHz with a quadrupole inverse cryogenic probe. A standard 1-dimensional pulse sequence [recycle delay (RD)-90°-t1-90°-tm-90°-acquire FID] was acquired, with water suppression irradiation during RD of 2 s, mixing time (tm) set on 200 ms, and a 90° pulse set to 10.13 μs, collecting 512 scans into 64 K data points with a spectral width of 12 ppm. All spectra were manually phased, baseline corrected, and calibrated to TSP (δ 0.00) with TopSpin 3.2 (Bruker BioSpin, Rheinstetten, Germany). Data were imported to Matlab (Mathworks, Massachusetts, US) and further processed, i.e., water region removed (δ 4.70−5.21). The spectra were normalized by using a probabilistic quotient normalization algorithm[49] to account for urinary dilution effects and aligned by using a recursive segment-wise peak-alignment algorithm.[50] Relative quantification of metabolites of interest was done by integration of the area under the curve (AUC), as outlined in Heinzmann et al.[46] and expressed as relative measure to creatinine concentration.

Coffee Analysis. Coffee samples were analyzed with a Bruker 800 MHz spectrometer equipped with a quadrupole inverse cryogenic probe, wherewith ^{1}H NMR spectra and 2D spectra (total correlation spectroscopy (TOCSY) and heteronuclear single quantum coherence (HSQC)) were acquired. For 2D NMR spectra, phase-sensitive sensitivity-improved 2D TOCSY with water suppression by gradient tailored excitation (WATERGATE) (3-9-19) and using decoupling in the presence of scalar interactions (DIPSI-2), were acquired. For each spectrum, 19228 × 1024 data points were collected using 32 scans per increment, an acquisition time of 1 s, and 16 dummy scans. The spectral widths were set to 12 and 12 ppm in the F2 and F1 dimensions, respectively. For the 2D ^{1}H−^{13}C HSQC spectra, phase-sensitive ge-2D-HSQC using preservation of equivalent pathways (PEP) and adiabatic pulses for inversion and refocusing with gradients were used. For each 2D spectrum, 4096 × 1024 data points were collected using 32 scans per increment, an acquisition time of 0.25 s, and 16 dummy scans. The spectral widths were set to 12 and 230 ppm in the proton and carbon dimensions, respectively. Processing of the spectra was carried out in TopSpin 3.2. FIDs were multiplied by an exponential decaying function corresponding to a line broadening of 0.3 Hz before Fourier transformation. All spectra were manually phased, baseline corrected, and calibrated to TSP (δ 0.00).

Multivariate Analysis. All timed urine specimens of the dietary intervention study that were collected at lunchtime were defined as "coffee samples", all others (first morning urine, before dinner, and

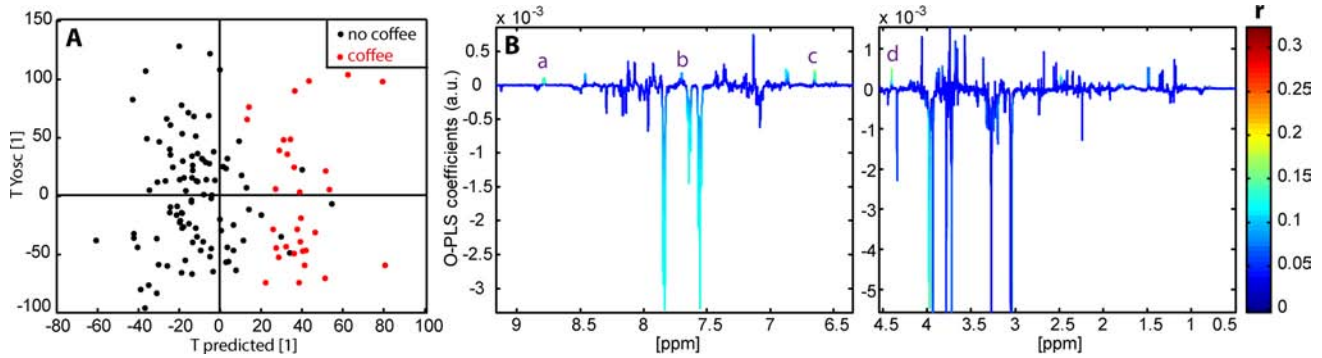

Figure 1. OPLS-DA scores and loadings plots of urine specimen after coffee challenge (12 am) vs all other urine collection (8 am, 8 pm, bedtime). (A) The scores plot shows a clear separation of coffee vs no coffee groups with a goodness of fit (R^2Y) of 0.58 and predictive value (Q^2Y) of 0.22. (B) Loadings plot of the coffee challenge indicates putative biomarkers with chemical shifts at a δ 8.79 (d), b δ 7.20, c δ 6.65 (dd), d δ 4.40 (s), with highest correlation coefficient for δ 6.65 (dd).

Figure 2

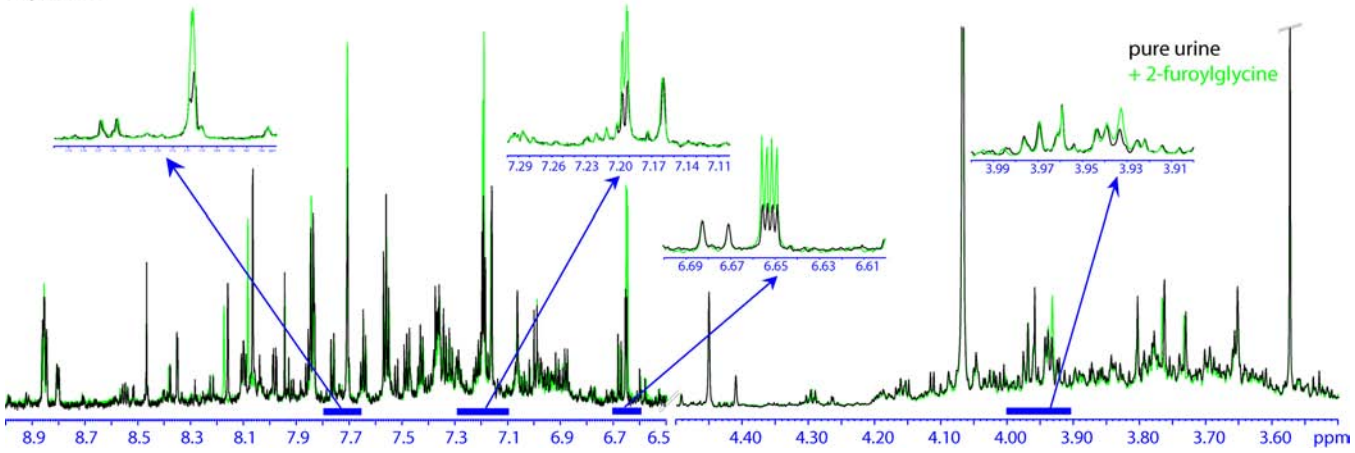

Figure 2. Standard addition experiment of 2-furoylglycine to a urine sample. Black, urine sample collected after coffee consumption; green, spiking of 2-furoylglycine to the same urine sample for confirmation of the assumed chemical structure of the biomarker. Chemical shifts are δ 7.71 (d), δ 7.20 (dd), δ 6.65 (dd), and δ 3.93 (s).

before bed) as "no coffee samples". Volunteers participated in the dietary intervention trial for 6 days; therefore, 24 urine samples per participant were collected. Pairwise orthogonal partial least-squares discriminant analysis (OPLS-DA)[51] was carried out with Matlab software. The OPLS-DA loading plots were created with an in-house Matlab script according to the method of Cloarec et al.[52]

RESULTS AND DISCUSSION

Discovery Phase: Nontargeted ^{1}H NMR Metabolic Profiling of Urine from a 6-Day Dietary Intervention Study. To discover novel biomarkers of food consumption, we performed a human dietary intervention trial (n = 8), where participants consumed a standardized breakfast and lunch and varying dinner each day (for more details, see also Heinzmann et al.[46]). As part of the dietary protocol, participants were allowed coffee for breakfast and until 12 am each day (SI Figure 1). Six participants chose coffee, one participant consumed chicory coffee, and one deviated from the protocol and drank Earl Grey tea every day. Urinary metabolite profiles were acquired to enable comparison of metabolites excreted after coffee consumption. OPLS-DA analysis of the urines from coffee-drinking volunteers revealed putative biomarker(s) with chemical shifts at δ 8.79 (d), δ 7.20, δ 6.65 (dd), δ 4.40 (s) (Figure 1B). 2D HSQC NMR suggested these shifts derived from two different metabolites (see SI Figure 2), namely 2-furoylglycine (2-FG) and *N*-methylpyridinium (NMP). Confirmation of the chemical structures was carried out by standard spiking experiments of the chemical standards 2-FG and NMP into urine samples (Figure 2 and SI Figure 3). ^{1}H NMR shifts of 2-FG standard were δ 6.65 (dd, H-C4 of furoyl), δ 7.20 (dd, H-C3 of furoyl), δ 7.71 (d, H-C5 of furoyl), δ 3.93 (s, CH_2 of glycine). The standard matched the prediction from the OPLS-DA analysis, with the exception of the two latter signals, which were overlapped with other metabolites and did not resolve in the OPLS-DA loadings plot. NMP has previously been linked to coffee consumption by Lang et al.[41] Urinary excretion of the glycine conjugate of derivatized furan, 2-FG, has not, to our knowledge, been reported to be associated with coffee consumption. In serum, however, it has been previously detected.[53] Integration of the H-C3 of furoyl signal confirmed high excretion of 2-FG in coffee consumers especially in the urine samples at lunch time. Neither chicory coffee nor Earl Grey tea consumption resulted in excretion of 2-FG with urine (Figure 3), and inspection of urine spectra after consumption of these coffee alternatives did not show ^{1}H NMR-detectable quantities of 2-FG (SI Figure 4). Interestingly, hippurate, which is discussed as a potential biomarker for coffee consumption,[37] correlated negatively with coffee consumption. The coffee consumption period was closely aligned with breakfast, which

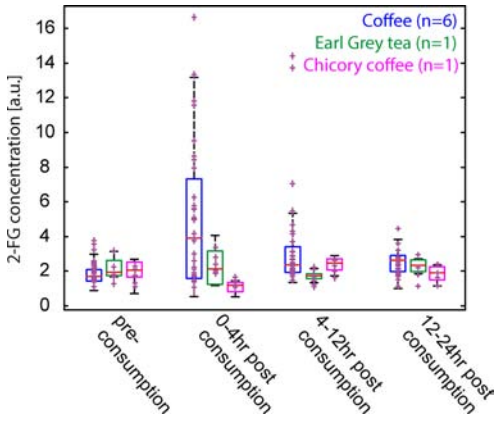

Figure 3. Boxplot and individual measurement points (purple) of urinary 2-furoylglycine excretion in volunteers at the four different time points. Boxplots are divided into blue, "coffee consumption"; green, "alternative consumption of Earl Grey tea"; and magenta, "alternative consumption of Chicory coffee".

was not rich in polyphenols, while dinner (i.e., part of the "noncoffee sample" group) was always rich in fruit and vegetables,[46] and polyphenols can be metabolized to hippurate.[45,54]

Dietary Sourcing Phase: Possible Sources of 2-Furoylglycine in Coffee. To investigate the origin of 2-FG in participant's urine samples after coffee consumption, we interrogated existing literature on furan derivates in different coffees, their concentration, and possible degradation pathways in humans after consumption (Figure 4). Indeed, furan metabolites arise through roasting of coffee beans via the Maillard reaction,[55] and the highest concentrations can be found in roasted ground coffee (6900 μg/kg) and considerably lower amounts in instant coffee (569 μg/kg).[56−59] The amount of furan varies, depending on coffee bean species and roast degree.[33] Other sources of furan exist but provide much lower quantities, e.g., baby foods with up to 29 μg/kg, soups and sauces (<24 μg/kg), and 0−4 μg/kg in tea,[55,60,61] and are therefore not expected to interfere with 2-FG excretion. Dependent on the chosen coffee brewing procedure, about 2−50% of the bean-derived furans get extracted into coffee.[59] Moon et al. have identified furans in coffee and found seven different furan derivatives such as furfuryl alcohol and furfural.[34] After consumption, furans undergo conversion to furfural and 2-furoic acid, then conjugation with glycine to 2-FG, which can then be excreted via the kidney,[62−64] see Figure 4. Remarkably, while the roasting process can potentially produce furan and various 2-furan metabolites, the human metabolism reduces such diversity to a single metabolite being excreted, namely 2-FG.

From our ^{1}H NMR spectral analysis, we detected furan derivatives such as 2-furoic acid and furfuryl alcohol in relatively high quantities in espresso (Figure 5 and SI Figure 6). Instant espresso also contained 2-furoic acid, and much lower quantities were found in chicory coffee. This overview of furan derivates is in consensus with suggested furan concentrations in existing literature.[33,34,57−59] Furfuryl alcohol was not found in instant espresso or chicory coffee. Trigonelline and its roasting product NMP could be found in espresso and instant espresso but not in chicory coffee. An additional furan derivate, 5-hydroxymethylfurfural, appeared in instant espresso and in high amounts in chicory coffee, and only little amounts in espresso. This metabolite is proposed to get metabolized to 5-hydroxymethylfuroic acid and 2,5-furandicarboxylfuroic acid and their glycine adducts[65] and is therefore not expected to influence 2-FG excretion in the chicory coffee or instant espresso consumer.

Confirmation Phase: Excretion Kinetics of 2-Furoylglycine after Coffee Consumption. To confirm the putative biomarker and investigate the mode of excretion, we carried out an additional coffee intervention study where participants avoided coffee for 24 h and then collected several timed spot urine samples over 24 h after a single dose of espresso.

Excretion of 2-FG was quantified by the ratio of area under the curve integration of 2-FG (δ 6.640−6.653) and creatinine (δ 4.0405−4.0475). All participants showed a maximal

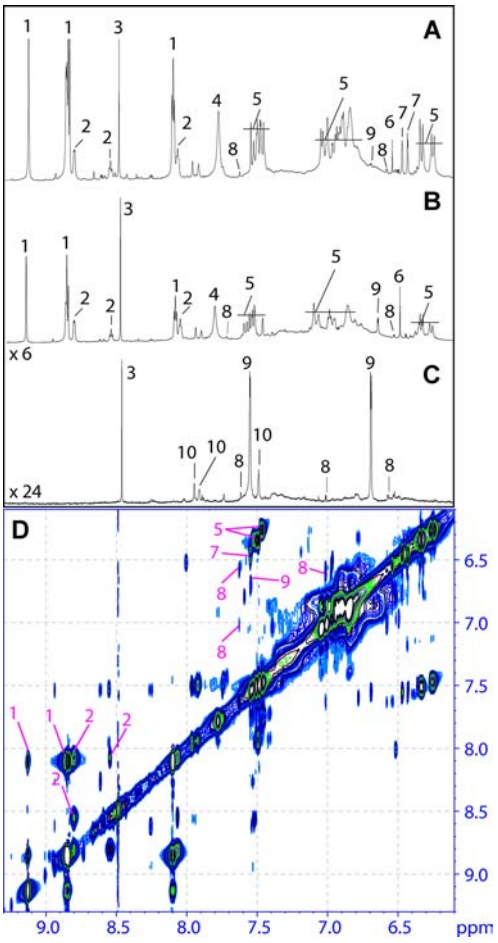

Figure 5. ^{1}H NMR spectrum of (A) espresso coffee, (B) instant espresso, and (C) chicory coffee with main peaks labeled. Spectra of B and C are enlarged by ×6 and ×24, respectively. (D) Two-dimensional NMR spectroscopy (^{1}H−^{1}H-TOCSY) of the aromatic area (δ 9.3−6.0) of espresso coffee: 1, trigonelline; 2, *N*-methylpyridinium; 3, formate; 4, caffeine; 5, chlorogenic acids; 6, fumarate; 7, furfurylalcohol; 8, 2-furoic acid; 9, 5-hydroxymethylfurfural (5-HMF); and 10, unknown compound (signals linked in TOCSY).

excretion of 2-FG after 2 h (p = 0.0002) and a rapid decline to near baseline after 24 h (p = 0.74), as shown in Figure 6. In more detail, the mean value of 2-FG/creatinine ratio was 0.0038 and 0.0041 2 and 0 h before coffee consumption, where this value is a result of baseline and other peak background integration. At 2 h after consumption, the value increased to 0.031, dropped rapidly to 0.011 4 h after consumption, and further declined to 0.0044 after 24 h. The interindividual variation was minimal, and all participants showed a similar trajectory (Figure 6). Deviation of the excretion curve, e.g. volunteer A did not decline to baseline after 24 h, was largely attributed to peak overlap in the spectral region of 2-FG. Overall, the excretion can be described as first-order excretion kinetics, as evidenced by a fast accumulation of the metabolite in urine and decline to baseline within 24 h. It can be discussed, however, that more sensitive analytical chemistry measurements such as UPLC-MS might allow detection of 2-FG for a longer period.[66] This has been shown by Lang et al.,[41] where NMP could be detected up to 5 days after coffee consumption. For comparison, NMP showed excretion kinetics similar to that of 2-FG (SI Figure 5).

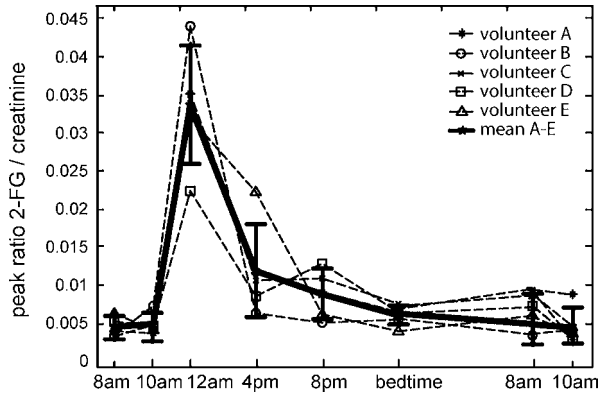

Figure 6. Excretion kinetics of 2-furoylglycine after coffee consumption (n = 5) over 26 h. Coffee was consumed at 10 am. 2-FG was relatively quantified by integration of the spectral region δ 6.640−6.654, including the doublet of doublets at δ 6.647 in relation to creatinine (δ 4.056−4.072). The five individuals showed similar trajectory in 2-FG excretion with maximal excretion of the biomarker at 2 h post coffee consumption and little interindividual variation.

In summary, we introduced a novel biomarker for coffee consumption by combining nontargeted ^{1}H NMR metabolic profiling in a nutritional intervention study, investigation of possible dietary sources of the biomarker, and finally validation of the putative marker in a second food intervention study. In contrast to previously identified biomarkers such as caffeine and chlorogenic acid degradation products, we identified a biomarker that is dependent on the roasting procedure of the coffee bean and therefore not influenced by consumption of tea, fruit and vegetables, or caffeine-containing energy drinks, which makes it highly specific to coffee. As a next step, the biomarker could now be further validated in a larger cohort, where coffee drinking behavior, different coffee types, and varying amounts of ingested coffee are recorded and matching urine samples are available for quantification of 2-FG to assess its quantitative rather than qualitative value. A combination of data from a well-monitored coffee drinking cohort as assessed by urinary 2-FG quantification with, e.g., CVD risk factors such as blood pressure, blood lipid parameters, and BMI, should deliver valuable information on potential health benefit of coffee consumption on disease risk and disease progression. For example, urinary metabolic profiling data from the INTERMAP study highlighted the here-assigned coffee biomarker to be inversely associated with BMI.[67] Taking advantage of the fact that different coffee biomarkers derive from different ingredients of coffee, a simultaneous analysis of several coffee biomarkers should pave the way for designing a biomarker pattern for sensitive and highly specific detection of coffee consumption in individuals and allow researchers to reach meaningful conclusions on the influence of coffee consumption on health and disease.

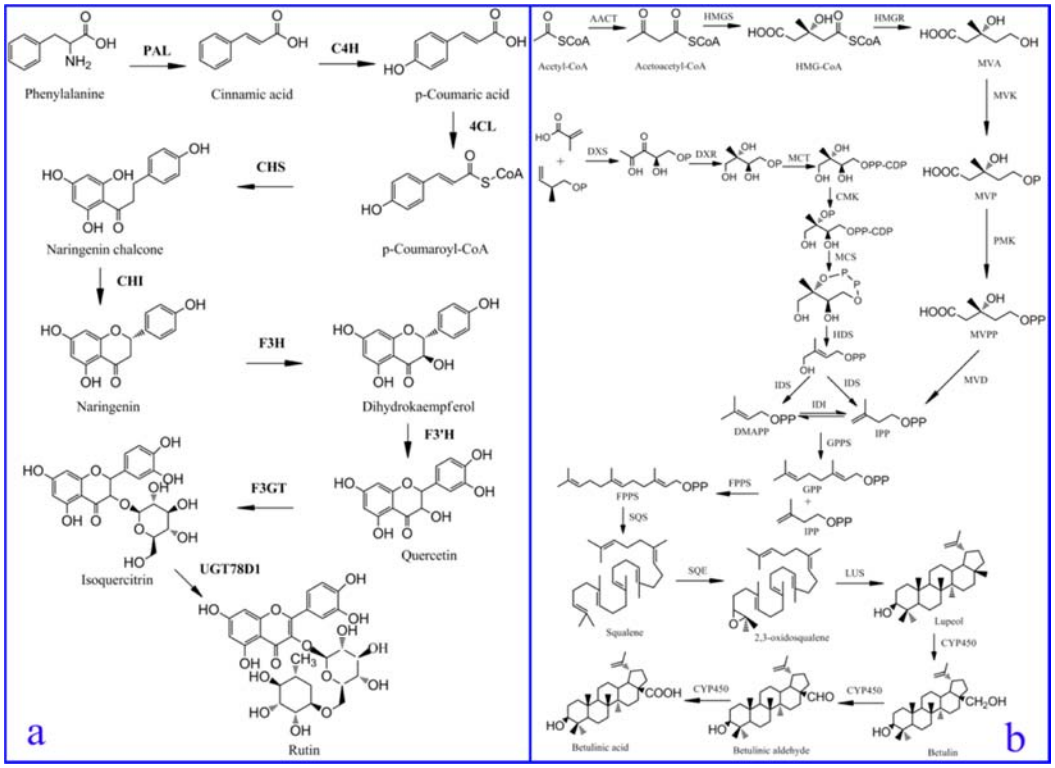

Figure 1. Schematics of (a) rutin biosynthesis and (b) betulin and betulinic acid biosynthesis. PAL, phenylalanine ammonia lyase; C4H, cinnamic acid 4-hydroxylase; 4CL, 4-coumarate-CoA ligase; CHS, chalcone synthase; CHI, chalcone isomerase; F3H, flavone 3-hydroxylase; F3′H, flavonoid 3′-hydroxylase; F3GT, flavonol 3-*O*-glucosyltransferase; UGT78D1, flavonol-3-*O*-glucoside L-rhamnosyltransferase; AACT, acetyl-CoA acetyltransferase; HMGS, hydroxymethylglutaryl-CoA synthase; HMGR, 3-hydroxy-3-methylglutaryl-coenzyme A reductase; MVK, mevalonate kinase; PMK, phosphomevalonate kinase; MVD, diphosphomevalonate decarboxylase; DXS, 1-deoxyxylulose-5-phosphate synthase; DXR, 1-deoxy-D-xylulose-5-phosphate reductoisomerase; MCT, 2-C-methyl-D-erythritol 4-phosphate cytidylyltransferase; CMK, 4-diphosphocytidyl-2-C-methyl-D-erythritol kinase; MCS, 2-C-methyl-D-erythritol 2,4- cyclodiphosphate synthase; HDS, 4-hydroxy-3-methylbut-2-enyl diphosphate synthase; IDS, 4-hydroxy-3-methylbut-2-enyl diphosphate reductase; IDI, Isopentenyl-diphosphate delta-isomerase; GPPS, geranyl diphosphate synthase; FPPS, farnesyl diphosphate synthase; SQS, squalene synthetase; SQE, squalene epoxidase; and LUS, lupeol synthase.

(MEP) pathway at the initial period (Figure 1b). These pathways generate the same products: isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP). Then, geranyl diphosphate synthase (GPPS) catalyzes the condensation of IPP and DMAPP to form geranyl pyrophosphate (GPP). GPP then unites with another molecule of IPP to form farnesyl pyrophosphate (FPP), catalyzed by farnesyl pyrophosphate synthetase. Next, squalene synthase (SQS) and squalene epoxide (SQE) catalyze two NADPH-requiring reactions to form squalene and 2,3-oxidosqualene, respectively; 2,3-oxidosqualene is the common precursor of triterpenes through different pathways. In betulinic acid biosynthesis, 2,3-oxidosqualene is converted to lupeol by lupeol synthase (LUP), and betulinic acid is derived from lupeol followed by successive oxidation at the C-28 position by the cytochrome P450 family.

Mulberry (*Morus alba* L., Moraceae) is used in traditional Chinese medicine and is the sole food source of the silkworm. The medicinal value of mulberry is derived from the many important secondary metabolites compounds it produces and includes protection against liver damage as well as antidiabetic, antioxidant, anticancer, and antifever effects.[11−17] Secondary metabolites produced by *M. alba* include flavonoid compounds[18−20] such as anthocyanin and rutin,[16,21] which have strong antioxidant and anti-inflammatory effects.[22,23]

Mulberry contains many more phenolic and flavonoid compounds than do other fruits and vegetables.[24] Some studies have assessed the rutin content in mulberry leaves,[25,26] but the contents of betulin and betulinic acid have not been evaluated for this plant. Although the draft genome sequence has been reported for another mulberry species, *Morus notabilis*,[27] and although most phenylpropanoid and triterpene biosynthetic genes have been identified, currently the genetic background is not clear for *M. alba*. In a previous study, our group sequenced the transcriptome of *M. alba* L. by using an NGS sequencing platform (unpublished), which is the first report of transcriptome analysis for *M. alba*. Here, we investigated the expression levels of genes related to phenylpropanoid and triterpene biosynthesis with reference to this transcriptome data and analyzed the rutin and betulinic acid contents in different organs by using quantitative real-time PCR (qRT-PCR) and high-performance liquid chromatography (HPLC), respectively. Our results are expected to provide baseline information toward elucidating the mechanism of astragaloside biosynthesis in *M. alba*.

MATERIALS AND METHODS

Plant Materials. *M. alba* plants were grown at the experimental farm of National Academy of Agricultural Science, Rural Development Administration (Wanju, Korea). The fruits, flowers, leaves, stems ,and roots were excised from mature plants. The samples were immediately frozen in liquid nitrogen and stored at −80 °C and/or freeze-dried for RNA isolation and/or HPLC analysis.

RNA Isolation and cDNA Synthesis. Samples (200 mg) of different organs of *M. alba* L. were ground with a mortar and pestle in liquid nitrogen. RNA was isolated separately using a Plant Total RNA Mini Kit (Geneaid, Taiwan) according to the manufacturer's instructions. The quality and concentration of total extracted RNA were determined by 1.2% formaldehyde RNA agarose-gel electrophoresis and NanoVue Plus spectrophotometer analysis (code no. 28956058, GE Healthcare, UK), respectively. For cDNA synthesis, 1 μg of total RNA was reverse transcribed (RT) using a ReverTra Ace-R kit (Toyobo, Osaka, Japan) and oligo (dT) 20 primer according to the

GenBank database. Identified gene sequences were submitted to GenBank.

Quantitative Real-Time Polymerase Chain Reaction. On the basis of the published gene sequences of *MaPAL1, MaPAL2, MaPAL3, MaC4H1, MaC4H2, Ma4CL2, Ma4CL7-1, Ma4CL7-2, Ma4CL9, MaCHS1, MaCHS2, MaCHS3, MaCHS9, MaCHI1, MaCHI2, MaCHI3, MaF3H, MaF3′H1, MaF3′H2, MaF3GT, and MaUGT78D1* (DNA Data Bank of Japan (DDBJ) accession nos. KJ616395−KJ616404 and KT630878−KT630889) for phenylpropanoid biosynthesis and those of *MaAACT1, MaAACT2, MaHMGS, MaHMGR1, MaHMGR2, MaMVK, MaPMK, MaMVD, MaIDI, MaDXS, MaDXR, MaMCT, MaCMK, MaMCS, MaHDS, MaIDS, MaGPPS, MaFPPS, MaSQS, MaSQE, and MaLUP* (DDBJ accession nos. KR080458−KR080471 and KR132245−KR132251), real-time PCR primers were designed using the Primer 3 web site (http://frodo.wi.mit.edu/primer3/) (Table S1). The expression of these genes was calculated by relative quantification with the *actin* housekeeping gene (DDBJ accession no. KJ616403) of *M. alba* as a reference. For quantification of the standard, PCR products amplified from cDNA were purified, and the concentration of the products was measured to calculate the number of cDNA copies. qRT-PCR was performed in a 20 μL reaction mixture including 5 μL of template cDNA, 10 μL of 1× SYBR Green Real-time PCR Master Mix (Toyobo, Osaka, Japan), 0.5 μL of each primer (10 μL), and DEPC-treated water. Thermal cycling conditions were as follows: 95 °C for 15 min and 41 cycles of 95 °C for 20 s, 55 °C for 40 s, and 72 °C for 30 s. The PCR reactions were performed on a CFX96 Real-Time system (Bio-Rad Laboratories, Hercules, CA). PCR products were analyzed with the Bio-Rad CFX Manager 2.0 software. Three replications per sample were used for the real-time PCR analysis, and values were expressed as means ± SD.

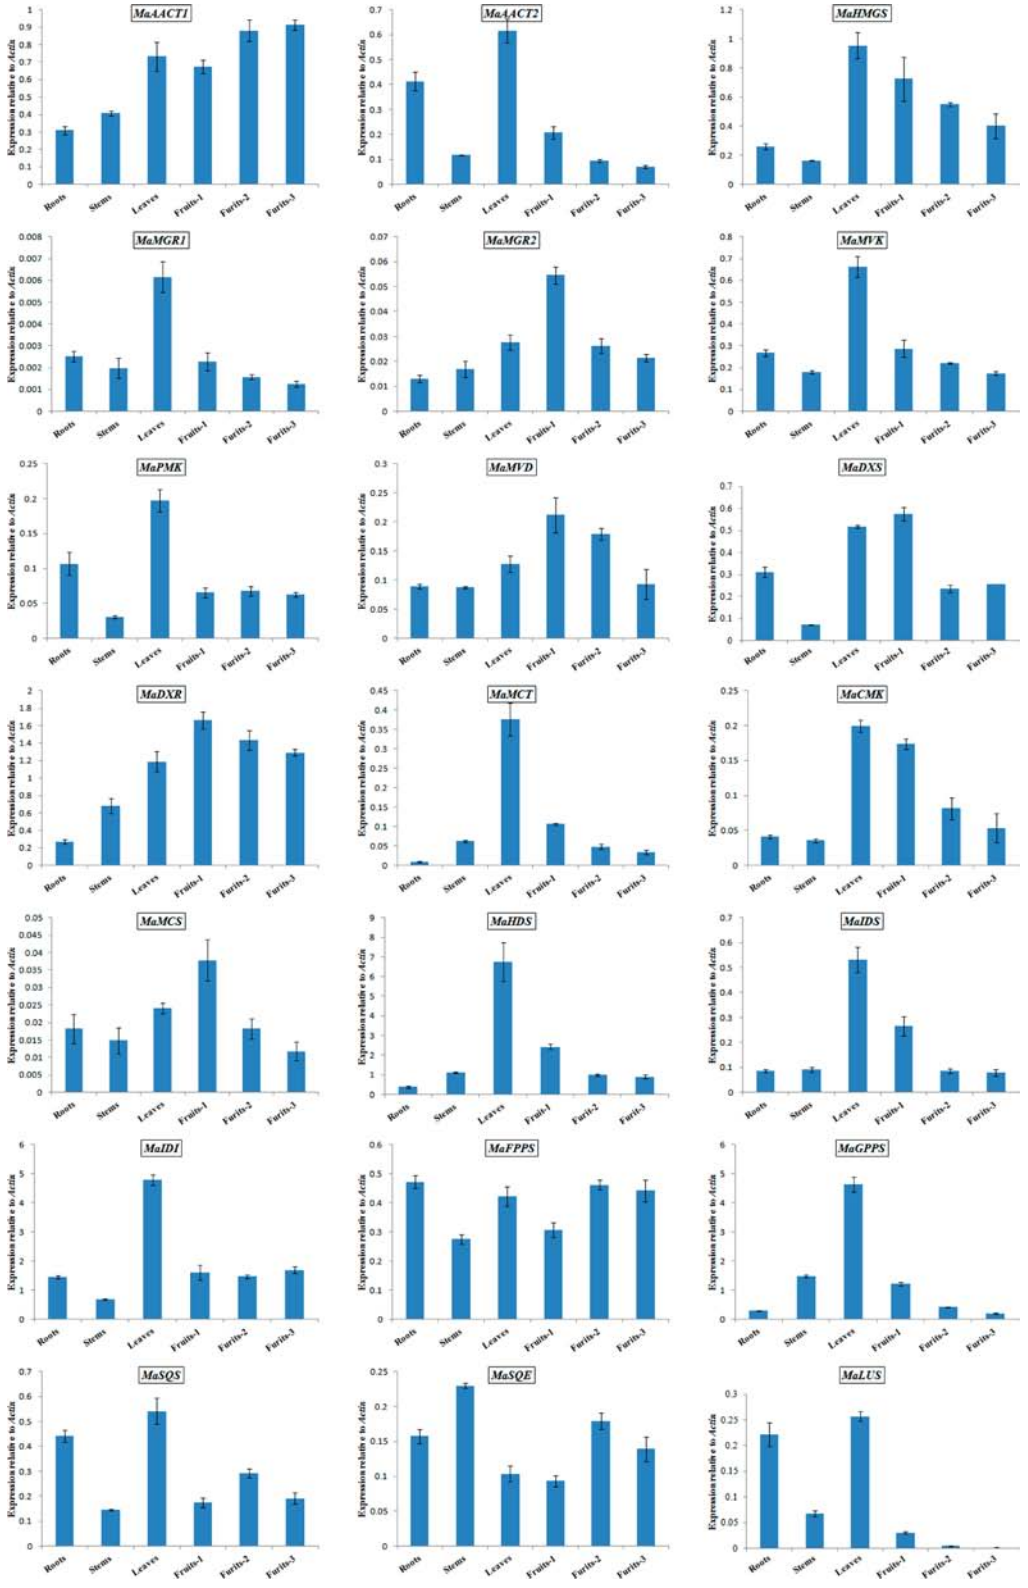

Figure 3. Expression levels of triterpene biosynthetic genes in different organs of mulberry (*Morus alba* L.) calculated by relative quantification with the mulberry *actin* housekeeping gene. Each value is the mean of three replicates, and error bars indicate standard deviations.

High-Performance Liquid Chromatography Analysis. Different organs of *M. alba* L. were freeze-dried at −80 °C for 48 h and then ground into a fine powder using a mortar and pestle. Rutin was released from the samples (50 mg) by adding 3 mL of 80% methanol containing 0.1% ascorbic acid (w/v) at 60 °C for 1 h. After centrifuging the extract (3000 g), the supernatant was filtered with a 0.22 μm Acrodisc syringe filter (Pall Corp.; Port Washington, NY) and analyzed by HPLC. The phenylpropanoids were separated on a C18 column (250 × 4.6 mm^2, 5 μm; RStech, Daejeon, Korea) using an Agilent 1100 HPLC system (Agilent Technologies, Massy, France) equipped with a photodiode array detector. The mobile phase consisted of methanol, water, and 0.2% acetic acid, and the column

DOI: 10.1021/acs.jafc.5b03221
J. Agric. Food Chem. 2015, 63, 8622−8630

was maintained at 30 °C. The parameters were as follows: the flow rate was maintained at 1.0 mL/min, the injection volume was 20 μL, and the detection wavelength was 280 nm. Pentacyclic triterpenes were released from the *M. alba* samples (500 mg) by adding 5 mL of 95% methanol containing 250 μL of 1% hydrogen chloride, sonicating for 15 min, and then allowing to stand for 30 min. After centrifugation and filtration, pentacyclic triterpenes were separated on a ProntoSIL 120–5 C18 ace-EPS (150 × 4.6 mm^2, 5 μm; ProntoSIL, Bollinger, Germany) using a Futex NS-4000 HPLC system (Futex Chromatography, Daejeon, Korea). The parameters were as follows: the mobile phase consisted of acetonitrile and water (9:1), the column was maintained at 25 °C, the flow rate was 1.0 mL/min, the injection volume was 20 μL, and the detection wavelength was 210 nm. The concentrations of compounds were determined by using a standard curve. All samples were analyzed in triplicate. Values were expressed as means ± SD.

RESULTS AND DISCUSSION

Sequence Analyses of Phenylpropanoid and Triterpene Biosynthetic Genes from Mulberry. Full-length cDNAs encoding PAL1, PAL2, C4H1, C4H2, 4CL7-1, 4CL7-2, CHS3, CHI1, CHI3 AACT1, AACT2, HMGS, PMK, MVD, IDI, DXS, MCS, HDS, IDS, GPPS, SQE, and LUS, and partial-length cDNA clones encoding PAL3, 4CL2, 4CL9, CHS1, CHS2, CHS9, CHI2, F3H, F3′H1, F3′H2 F3GT, UGT78D1, HMGR1, HMGR2, MVK, DXR, MCT, CMK, FPPS, and SQS were identified. They were confirmed for homology with the BLAST program and designated as MaPAL1 (722 amino acids [aa]), MaPAL2 (749 aa), MaPAL3 (344 aa), MaC4H1 (525 aa), MaC4H2 (507 aa), Ma4CL2 (365 aa), Ma4CL7-1 (547 aa), Ma4CL7-2 (539 aa), Ma4CL9 (471 aa), MaCHS1 (257 aa), MaCHS2 (259 aa), MaCHS3 (399 aa), MaCHS9 (218 aa), MaCHI1 (228 aa). MaCHI2 (308 aa), MaCHI3 (208 aa), MaF3H (228 aa), MaF3′H1 (354 aa), MaF3′H2 (177 aa), MaF3GT (339 aa), MaUGT78D1 (447 aa), MaAACT1 (403 aa), MaAACT2 (416 aa), MaHMGS (464 aa), MaHMGR1 (548 aa), MaHMGR2 (586 aa), MaMVK (356 aa), MaPMK (507 aa), MaMVD (421 aa), MaIDI (295 aa), MaDXS (714 aa), MaDXR (363 aa), MaMCT (243 aa), MaCMK (254 aa), MaMCS (248 aa), MaHDS (740 aa), MaIDS (461 aa), MaGPPS (380 aa), MaFPPS (182 aa), MaSQS (408 aa), MaSQE (524 aa), and LcLUS (754 aa). The data provided in Tables 1 and 2 showed that the mulberry phenylpropanoid and triterpene biosynthetic genes exhibited high identity with other orthologous genes.

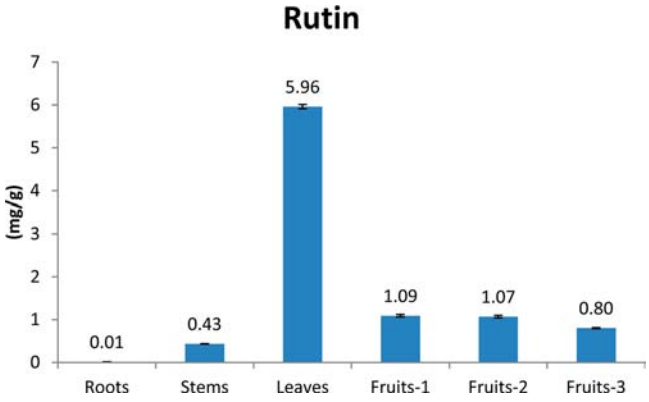

Figure 4. Accumulation of rutin in different organs of mulberry (*Morus alba* L.). Each value is the mean of three replicates, and error bars indicate standard deviation.

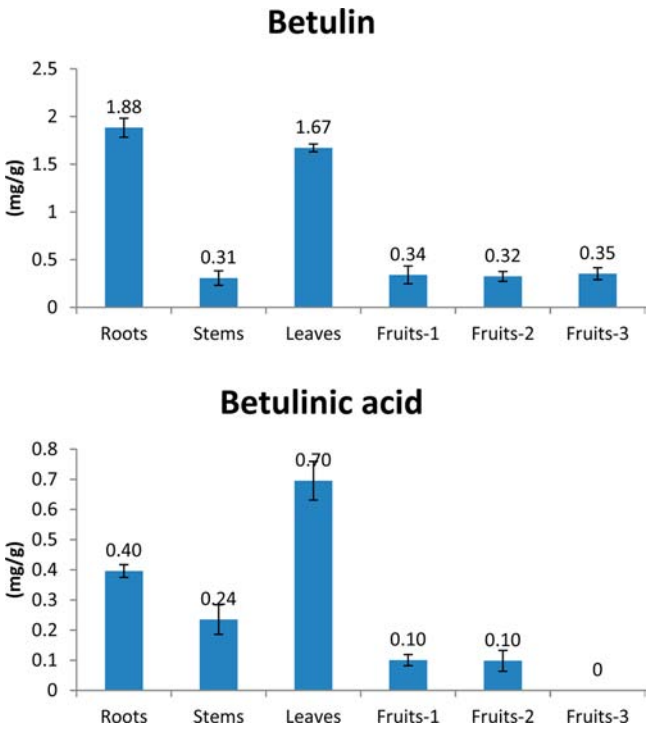

Figure 5. Accumulation of betulin and betulinic acid in different organs of mulberry (*Morus alba* L.). Each value is the mean of three replicates, and error bars indicate standard deviation.

Expression of Phenylpropanoid and Triterpene Biosynthetic Genes in Mulberry. The expression of phenylpropanoid and triterpene biosynthetic genes was analyzed in roots, stems, and leaves as well as in three fruit stages (unripe: fruits-1, semiripe: fruits-2, and fully ripe: fruits-3) by qRT-PCR (Figure 2). The expression patterns of phenylpropanoid biosynthetic genes differ among species.[28−32] In *M. alba*, the expression level of three isoform *PAL* genes were different: *MaPAL1* was expressed at the highest levels in stems and fully ripe fruits; however, *MaPAL2* and *MaPAL3* were highly expressed in leaves. The expression level of *MaC4H1* was the highest in the stems relative to expression in the other organs, whereas the expression level of MaC4H2 was similar in all mulberry organs. The expression levels of *Ma4CL2* and *Ma4CL9* were high in unripe fruits. *Ma4CL7-1* was highly expressed in the leaves, and *Ma4CL7-2* was highly expressed in the roots. *MaCHS1* showed high expression levels in fruits; *MaCHS2* was highly expressed in the leaves and unripe fruits, intermediately expressed in semi- and fully ripe fruits, and showed low expression in the roots and stems. However, *MaCHS9* was highly expressed in the root. *MaCHI1* was highly expressed in the leaves, whereas *MaCHI2* and *MaCHI3* was mainly expressed in the fruits. The expression patterns of *MaF3H*, *MaF3′H1*, and *MaF3GT* were similar, with relatively higher expression in fruits than in roots, stems, and leaves. However, *MaF3′H2* was different from *MaF3′H1*, with the highest expression level in roots. *MaUGT78D1* showed significantly higher expression in leaves than in other organs. During fruit ripening, the expression of *MaPAL2*, *MaPAL3*, *MaC4H2*, *Ma4CL*, *MaCHS2*, *MaCHS3*, *MaCHS9*, and *MaCHI3* declined gradually. In contrast, the expression of *MaPAL1*, *MaCHS1*, *MaCHI*, *MaF3H*, *MaF3′H*, and *MaF3GT* increased gradually as fruit ripened. In the triterpene biosynthetic pathway, most genes were highly expressed in

DOI: 10.1021/acs.jafc.5b03221
J. Agric. Food Chem. 2015, 63, 8622−8630

leaves (Figure 3). During fruit development, the expression of most triterpene biosynthetic genes decreased, including that of *MaAACT2*, *MaHMGS*, *MaHMGR1*, *MaHMGR2*, *MaMVK*, *MaMVD*, *MaDXS*, *MaDXR*, *MaMCT*, *MaCMK*, *MaMCS*, *MaHDS*, *MaIDS*, *MaGPPS*, and *MaLUS*. *MaIDI* and *MaPMK* were expressed at the same level in the three fruit-ripening stages. In contrast, *MaAACT1*, *MaFPPS*, *MaSQS*, and *MaSQE* showed increased expression during ripening. Possibly, these genes were relative with fruit maturation.

There are various explanations for the diverse expression levels of phenylpropanoid biosynthetic genes among plant species, including the existence of different gene isoforms in different organs. Xu et al.[33] cloned three isoforms of *PAL* in *Scutellaria baicalensis* and found different transcript levels in different organs. Expression of isoform *SbPAL1* was highest in stems, *SbPAL2* was highest in leaves, and *SbPAL3* expression was highest in roots. Li et al.[28] compared two isoforms of *4CL* in buckwheat and found that *Fe4CL1* was most strongly expressed in roots, whereas *Fe4CL2* had the highest expression in stems. Biotic and abiotic environmental factors can also influence phenylpropanoid gene expression because of the protective function of phenylpropanoid compounds. Ozone can modify phenylpropanoid and lignin expression pathways in leaves and stems of poplar.[34] Gene expression in leaves was stimulated by ozone exposure, but in stems, gene expression was decreased by ozone. Xu et al.[33] also found that different concentrations of methyl jasmonate (a plant hormone) and wounding treatments affected the transcript levels of phenylpropanoid genes.

A few reports have examined differences in transcription levels of triterpene biosynthetic genes in different plant organs. Huang et al.[35] investigated the expression of amyrin synthase (AS) and amyrin oxidase (AO) in *Catharanthus roseus* and found that both genes were more highly expressed in leaves. Here, we isolated 21 triterpene biosynthesis-related genes and examined their expression levels in different organs. Similarly, we found that most genes were highly expressed in leaves. The transcription level of *MaLUS* was very high in leaves and roots, which was related to higher levels of betulin and betulinic acid in these organs. We propose that *MaLUS* is the key regulator of betulin and betulinic acid accumulation in mulberry; however, further studies are needed to confirm this.

Rutin, Betulin, and Betulinic Acid Content. Mulberry fruits have been used for centuries as food, tea, and traditional medicine in southwestern Asia. The same plant materials used for qRT-PCR were used for the HPLC analysis of rutin, botulin, and betulinic acid accumulation (Figure 4). Rutin contents in various species have been shown to differ depending on environmental factors and growth stages.[28,36] Our results indicated that larger amounts of rutin (6−7-fold higher) were detected in leaves than in fruits and that rutin content decreased during fruit maturation (Figure 4). Small quantities of rutin were detected in the stems. As mentioned above, *MaUGT78D1* was highly expressed in leaves (Figure 2); we speculate that *MaUGT78D1* may play an important regulatory role in the rutin biosynthetic pathways, which would require further confirmation by transformation experiments. UGT78D1, a flavonol-specific glycosyltransferase, has been shown to be responsible for transferring rhamnose or glucose to the 3-OH position in vitro.[37]

The natural compound, betulinic acid, has been shown to have potent anticancer activity in cancer cells and thus is a new and promising experimental anticancer agent for the treatment of human cancers.[38] Large amounts of betulin were found in the roots and leaves (Figure 5), whereas only a little was detected in the stems and fruits (average of approximately 0.3 μg/mg DW). Leaves contained the highest levels of betulinic acid, followed by the roots and stems; little or no betulinic acid was detected in the fruit (Figure 5).

We conducted detailed investigations of the phenylpropanoid and triterpenoid biosynthetic pathways in the mulberry plant. To our knowledge, this is the first study on expression of triterpenoid biosynthetic pathway genes in mulberry. We identified 18 phenylpropanoid and 21 triterpenoid biosynthetic genes with different isoforms showing varied levels of expression. In addition, we found abundant rutin in mulberry leaves and abundant betulin and betulinic acid in the roots and leaves. Because of the significant medicinal functions of these compounds, we believe that our results will provide the basic data for research on the significant health benefits and medicinal potential of mulberry roots and leaves. Furthermore, the molecular characterization of genes involved in the phenylpropanoid and triterpene biosynthesis broadens our understanding of the molecular mechanisms in these biosynthesis pathways in *Morus alba*.

methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA), methoxyamine hydrochloride, pyridine, kojic acid, mushroom tyrosinase (1000 units/mL), L-tyrosine, and commercial standard compounds were obtained from Sigma Chemical Co. (St. Louis, MO). Disodium hydrogen phosphate 12-water and sodium dihydrogen phosphate dehydrate were obtained from Junsei chemical (Tokyo, Japan).

Plant Materials. The samples were prepared as follows; germination was initially triggered in a climate-controlled greenhouse with day and night temperatures of 26 and 20 °C, respectively. After 5 weeks, they were transplanted into an experimental field shelter, located at Geumsan-gun, Chungcheongnam-do, in the Republic of Korea (36°13′N, 127°23′E; elevation of 170 m). The leaves and stems of *L. maximowiczii* were collected 3, 4, 6, 8, 15, and 18 months after germination from the shelter. All sampling was conducted between June 2013 and September 2014. The samples were identified by J. Lee at the Department of Environment and Forest Resources of Chungnam National University (Daejeon, Republic of Korea), and voucher specimens were deposited at the herbarium (KRIB). The harvested plant samples were dried under shade conditions and ground into fine homogeneous powders using a grinder (sieve size mesh no. 8, Jworldtech, Seoul, Korea). The samples were stored at −20 °C prior to extraction. The information regarding the *L. maximowiczii* samples used in this study is listed in Table 1.

Table 1. List of *L. maximowiczii* Harvested during Different Growth Periods after Germination[a]

growth period (after germination) (months)	length (cm) (size)[b]	harvest date	growing conditions (temperature[c]/ precipitation[d]/ duration of sunshine[e])	collected part
3	10−15 (Δ 4)	June 2013	23 °C/118 mm/ 169 h	leaves, stems
4	20−30 (Δ 12.5)	July 2013	26 °C/217 mm/ 113 h	leaves, stems
6	70 (Δ 22.5)	September 2013	20 °C/81 mm/ 147 h	leaves, stems
8	80 (Δ 5)	November 2013	5 °C/55 mm/ 136 h	leaves, stems
15	110−120	June 2014	22 °C/46 mm/ 146 h	leaves, stems
18	>120	September 2014	20 °C/91 mm/ 157 h	leaves, stems

[a]All samples were cultivated in Chungcheongnam-do, Republic of Korea. Growing conditions were those in the harvest month. [b]The Δ value means the average value of the elongated length per month. [c]Monthly average temperature. [d]Monthly average precipitation. [e]Monthly average duration of sunshine.

Sample Extraction and Derivatization for GC-MS. Approximately 1 g of dried leaves and 2 g of dried stems were extracted at room temperature with 40 mL of methanol for 24 h at 200 rpm using a Twist Shaker (Biofree, Seoul, Korea). The resulting mixture was centrifuged at 5000 rpm and 4 °C for 15 min (Hettich Zentrifugen, Universal 320). The supernatant was then concentrated using a speed-vacuum machine (Modulspin 31, Biotron). The samples were then dissolved in methanol and filtered through a 0.2 μm PTFE filter for the UPLC-Q-TOF-MS and ultra-high-performance liquid chromatography-electrospray ionization-mass spectrometry/mass spectrometry (UHPLC-ESI-MS/MS) analyses. For the GC-MS analysis, the dried extract was oximated with 50 μL of methoxyamine hydrochloride in pyridine (20 mg/mL) for 90 min at 30 °C using a thermomixer (Eppendorf, Hamburg, Germany). Then, the oximated samples were silylated with 50 μL of MSTFA for 30 min at 37 °C, using a thermomixer. The final concentration of the samples was 5 mg/mL for UPLC-Q-TOF-MS, UHPLC-ESI-MS/MS, and GC-TOF-MS analyses. All MS analyses were conducted with five analytical replications.

GC-TOF-MS Analysis. GC-MS analysis was performed on an Agilent 7890A GC system (Agilent, Atlanta, GA) equipped with an Agilent 7693 autosampler coupled to a Pegasus HT TOF-MS (Leco Corp., St. Joseph, MI) system. An Agilent HP-5MS capillary column with an internal diameter of 0.25 mm, a film thickness of 0.25 μm, and a length of 30 m was employed for the separation. Chromatographic-grade helium with a constant flow of 1.0 mL/min served as the carrier gas. The injector and transfer line temperatures were both set at 240 °C. The oven temperature was held at 75 °C for 2 min, then increased to 300 °C at a rate of 15 °C/min, and maintained at 300 °C for 3 min. The mass data collected in electron ionization mode with an ionization energy of 70 eV were used to conduct a full scan at m/z 50−1000. One microliter of each derivatized sample was injected into the GC-TOF-MS instrument without split.

UPLC-Q-TOF-MS and UHPLC-ESI-MS/MS Analyses. UPLC was performed using a Waters Micromass Q-TOF Premier with a UPLC Acquity system (Waters Corp., Milford, MA) equipped with a binary solvent delivery system, an autosampler, and an ultraviolet (UV) detector. The UPLC system was set up with an Acquity UPLC BEH C18 column [100 mm × 2.1 mm, 1.7 μm particle size (Waters Corp.)]. The mobile phase consisted of 0.1% (v/v) formic acid in water (A) and 0.1% (v/v) formic acid in acetonitrile (B). The solvent gradient system was as follows: 5% B for 1 min, increased to 100% B for 9 min, held at 100% for 1 min, decreased to 5% B over 2 min, and finally held at 5% B for 1 min. Five microliters of a sample extract solution was injected, and the flow rate was maintained at 0.3 mL/min. The waters Q-TOF Primer (Micromass MS Technologies, Manchester, U.K.) was operated in quadrupole mode for the MS data, and the TOF data were collected in the range of m/z 100−1000 in both negative (−) and positive (+) ion modes. The operating parameters were as follows: ion source temperature, 100 °C; desolvation gas flow, 650 L/h at 200 °C; capillary voltage, 2.3 kV; and cone voltage, ≤35 V. The V mode of the mass spectrometer was used, and data were collected in the centroid mode with a scan accumulation time of 0.2 s. Leucine enkephalin was used as a reference lock mass ([−] m/z 554.2615, [+] m/z 556.2771, 10 μL/min) to ensure accuracy and reproducibility, by independent LockSpray interference.

LC-MS data were analyzed using an LTQ XL linear ion trap mass spectrometer/mass spectrometer from Thermo Fischer Scientific (San Jose, CA) coupled with an RS autosampler, RS column compartment, RS diode array detector, and DIONEX UltiMate 3000 RS pump (Dionex Corp., Sunnyvale, CA). The separation was performed on a Thermo Scientific Syncronis C18 UHPLC column with a particle size of 1.7 μm. The mobile phases were 0.1% (v/v) formic acid in water (A) and acetonitrile (B). The gradient system was as follows: from 10 to 100% solvent B over 18 min and then re-equilibrated to initial conditions over 4 min. The flow rate was 0.3 mL/min, and the injection volume was 10 μL. Mass spectra were obtained using ion traps in both negative (−) and positive (+) modes within a range of m/z 100−1000. A photodiode array was set for detection at 200−600 nm and managed using 3DField. The operating parameters were as follows: source voltage, ±5 kV; capillary temperature, 350 °C; and capillary voltage, 39 V. Tandem MS analysis was conducted via scan-type turbo data-dependent scanning (DDS) under the same conditions used for MS scanning.

Tyrosinase Inhibitory Activity. The analysis of tyrosinase inhibitory activity was performed as previously described with slight modifications.[20] The reaction mixture, consisting of 125 μL of 0.1 M sodium phosphate buffer (pH 6.5), 5 μL of the methanol extract of *L. maximowiczii* dissolved in 100% methanol, 40 μL of 1.5 mM L-tyrosine, and 30 μL of mushroom tyrosinase (1000 units/mL), was added to a 96-well plate. After incubation at 37 °C for 20 min, the absorbance was measured at 490 nm every 0 and 20 min with a spectrophotometer (Spectronic Genesys 6, Thermo Electron, Madison, WI). Kojic acid was used as a positive control. The percentage inhibition of tyrosinase activity was expressed using the following formula:

DOI: 10.1021/acs.jafc.5b03566
J. Agric. Food Chem. 2015, 63, 8631−8639

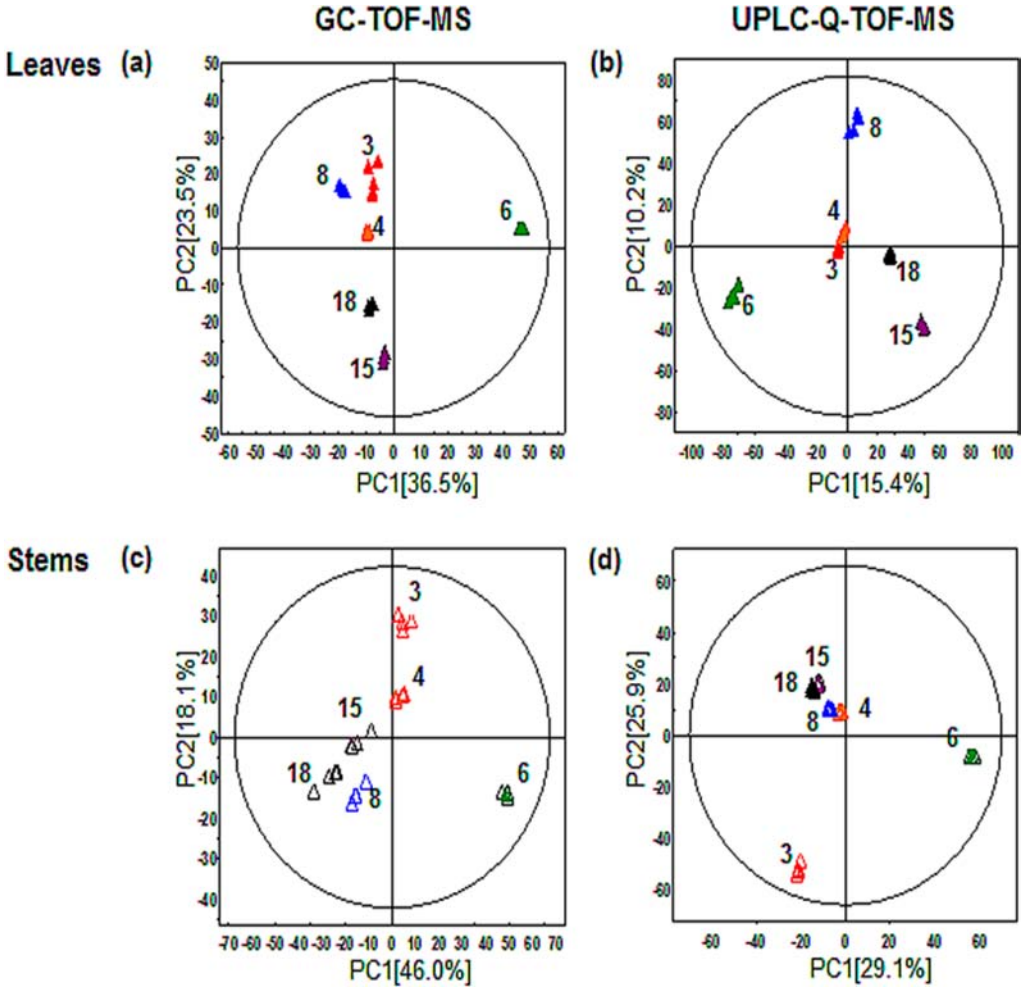

Figure 1. Principal component analysis (PCA) score plots of leaves (a and b) and stems (c and d) collected during different growth periods of *L. maximowiczii* and analyzed by GC-TOF-MS (a and c) and UPLC-Q-TOF-MS (b and d). Each symbol represents a growth period after germination, in either the leaves or stems of *L. maximowiczii* (filled triangles, leaves; empty triangles, stems): red for 3 months (harvest date, June 2013), orange for 4 months (July 2013), green for 6 months (September 2013), blue for 8 months (November 2013), purple for 15 months (June 2014), and black for 18 months (September 2014). PLS-DA models were fitted using the following quality parameters. (a) $R^2X_{(cum)} = 0.941$; $R^2Y_{(cum)} = 0.992$; $Q^2_{(cum)} = 0.989$. (b) $R^2X_{(cum)} = 0.425$; $R^2Y_{(cum)} = 0.992$; $Q^2_{(cum)} = 0.843$. (c) $R^2X_{(cum)} = 0.935$; $R^2Y_{(cum)} = 0.997$; $Q^2_{(cum)} = 0.991$. (d) $R^2X_{(cum)} = 0.835$; $R^2Y_{(cum)} = 0.994$; $Q^2_{(cum)} = 0.999$. The p values were below 0.05 in all analyses.

$$\%\ \text{inhibition rate} = [(C_{20\ \text{min}} - C_{0\ \text{min}}) - (S_{20\ \text{min}} - S_{0\ \text{min}}) / (C_{20\text{min}} - C_{0\ \text{min}})] \times 100$$

where $C_{20\ \text{min}}$ and $C_{0\ \text{min}}$ are the absorbance of the control after 20 and 0 min, respectively, whereas $S_{20\ \text{min}}$ and $S_{0\ \text{min}}$ are the absorbance of the sample after 20 and 0 min, respectively.

Data Processing and Multivariate Analysis. GC-TOF-MS data files were converted to CDF format (*.cdf) using the Leco ChromaTOF software program (version 4.44, Leco Corp.). Data processing for the UPLC-Q-TOF-MS analysis was conducted using MassLynx software, and raw data files were converted into netCDF (*.cdf) format using Waters DataBridge version 4.1. After conversion, the MS data were processed using the metAlign software package (http://www.metalign.nl) to obtain a data matrix containing retention times, accurate masses, and normalized peak intensities. The resulting data were exported to Excel (Microsoft, Redmond, WA), and multivariate statistical analysis was performed using SIMCA-P+ (version 12.0, Umetrics, Umea, Sweden). Unsupervised PCA and supervised PLS-DA models were used to compare the production of different metabolites among growth periods in the leaves and stems of *L. maximowiczii*, respectively. The OPLS-DA was also performed to compare metabolite differences at 6 months of the growth period between leaves and stems of *L. maximowiczii*. Metabolites with variable importance as determined by a projection (VIP) value of >0.7 and a p value of <0.05 were selected. To visualize differences in metabolites among samples, heat map analyses were performed using Mev software program version 4.8 (http://www.tm4.org). Significant differences were tested by one-way analysis of variance (ANOVA) using the STATISCA program (version 7.0, StaSoft Inc., Tulsa, OK). Differences in tyrosinase inhibitory activity were analyzed by one-way ANOVA and Duncan's multiple-range test using PASW Statistics 18 (SPSS Inc., Chicago, IL). Pairwise correlations between secondary metabolites and tyrosinase inhibitory activity were calculated by Pearson's correlation coefficient test using PASW Statistics 18, and correlation maps were generated by the MEV software program.

RESULTS

The Differentiated Metabolites in the Leaves and Stems of *L. maximowiczii* during Different Growth Periods Using GC-TOF-MS Analysis. Differences between the growth periods of the leaves and stems of *L. maximowiczii* were clearly visible in the principal component analysis (PCA) and partial least-squares discriminant analysis (PLS-DA) score plots, respectively (panels a and c of Figure 1, respectively). In particular, both leaves and stems harvested 6 months after

DOI: 10.1021/acs.jafc.5b03566
J. Agric. Food Chem. 2015, 63, 8631−8639

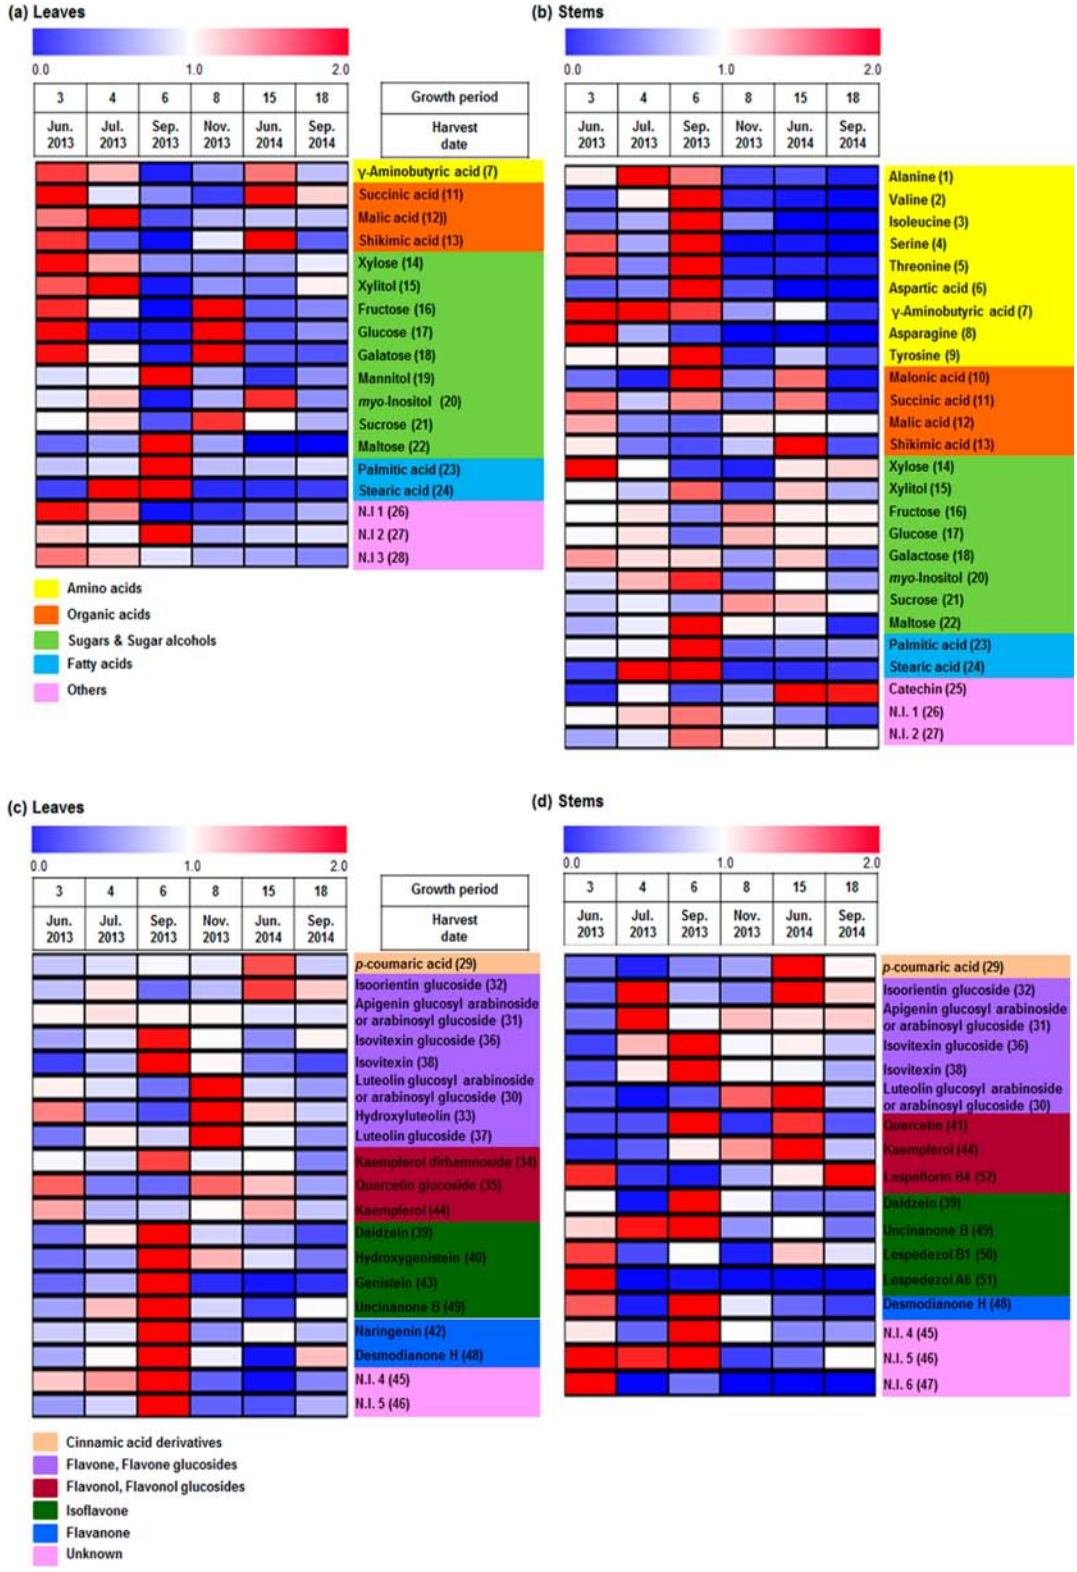

Figure 2. Heat maps of different metabolites from the leaves (a and c) and stems (b and d) of *L. maximowiczii* during different growth periods, from GC-TOF-MS (a and b) and UPLC-Q-TOF-MS (c and d) analysis. Growth periods after germination are shown in each column, with colors representing relative abundance, and relative intensities indicated by the heat scale. The numbering of metabolites is identical to that in Tables S1 and S2.

germination were significantly distinguished from those harvested during other months. Significantly different metabolites were selected as variables by PLS1 and PLS2 in the PLS-DA score plot, based on variable importance in the projection (VIP) value (>0.7) and p value (<0.05). As shown in the Supporting Information (Table S1), 18 and 26 metabolites in the leaves and stems, respectively, were selected as variables, which changed with growth period. Metabolites in leaves and

DOI: 10.1021/acs.jafc.5b03566
J. Agric. Food Chem. 2015, 63, 8631−8639

stems, including amino acids, organic acids, sugars and sugar alcohols, fatty acids, and catechin, were identified on the basis of their retention times and mass fragmentation, using the NIST library, and compared to the commercial standards.

Among discriminated variables according to the growth period in leaves, most primary metabolites, except for mannitol (**19**), maltose (**22**), palmitic acid (**23**), stearic acid (**24**), and nonidentified metabolite (**27**), were produced in relatively smaller quantities 6 months after germination than during other months (Figure 2a). Four metabolites, including fructose (**16**), glucose (**17**), galactose (**18**), and sucrose (**21**), were detected in the largest quantities in *L. maximowiczii* leaves harvested in November (at 8 months).

However, the following metabolites were detected in the largest quantities in stems 6 months after germination (Figure 2b): amino acids such as valine (**2**), isoleucine (**3**), serine (**4**), threonine (**5**), aspartic acid (**6**), and tyrosine (**9**); sugars such as xylitol (**15**), *myo*-inositol (**20**), and maltose (**22**); malonic acid (**10**); palmitic acid (**23**); and two nonidentified metabolites (**26** and **27**). The levels of sugars such as fructose (**16**), glucose (**17**), and sucrose (**21**) were higher in stems harvested in November (at 8 months) than in stems harvested during other months.

The Discriminated Metabolites in Leaves and Stems of *L. maximowiczii* during Different Growth Periods Using UPLC-Q-TOF-MS Analysis. In the UPLC-Q-TOF-MS analysis, the leaves and stems of *L. maximowiczii* samples were observed to produce different patterns in the PCA and PLS-DA score plots, according to growth period (3, 4, 6, 8, 15, and 18 months). In terms of overall secondary metabolites, leaves harvested 6 months after germination were significantly different from those harvested during other months (Figure 1b). As seen in Figure 1d, the stem samples collected 6 months after germination are clearly separated by PC1 (29.1%) from those collected at other times. To reveal the differences in secondary metabolites produced in the leaves and stems during different growth periods, both a VIP value of >0.7 and a p value of <0.05 of variables obtained from PLS1 and PLS2 were applied. As shown in the Supporting Information (Table S2), these metabolites were tentatively identified according to retention time, molecular weight, elemental composition, error and i-Fit, from the UPLC-Q-TOF-MS and UV spectral data, MS^n fragmentation patterns obtained via UHPLC-ESI-MS/MS, and comparisons with reference compounds.

A total of 19 metabolites, including *p*-coumaric acid (**29**), luteolin glucosyl arabinoside or arabinosyl glucoside (**30**), apigenin glucosyl arabinoside or arabinosyl glucoside (**31**), isoorientin glucoside (**32**), hydroxyluteolin (**33**), kaempferol dirhamnoside (**34**), quercetin glucoside (**35**), isovitexin glucoside (**36**), luteolin glucoside (**37**), isovitexin (**38**), daidzein (**39**), hydroygenistein (**40**), naringenin (**42**), genistein (**43**), kaempferol (**44**), desmodianone H (**48**), uncinanone B (**49**), and two nonidentified metabolites (**45** and **46**), were found to be significant metabolites for distinguishing each growth period of the leaves of *L. maximowiczii* (Table S2).

In stems, 10 metabolites (**29**−**32**, **36**, **38**, **39**, **44**, **48**, and **49**) selected from the leaf data, as well as quercetin (**41**), lespedezol B1 (**50**), lespedezol A6 (**51**), lespeflorin B4 (**52**), and three nonidentified metabolites (**45**−**47**), were selected as variables suitable for the study of the stem metabolites of *L. maximowiczii* during different growth periods (Supporting Information, Table S2).

To explain the changes in the secondary metabolite contents of leaves and stems of *L. maximowiczii* over the growth period, heat maps were generated (Figure 2). In both leaves and stems, most metabolites were present in relatively larger quantities 6 months after germination than in other months. Eleven secondary metabolites, including kaempferol dirhamnoside (**34**), isovitexin glucoside (**36**), isovitexin (**38**), daidzein (**39**), hydroygenistein (**40**), naringenin (**42**), genistein (**43**), desmodianone H (**48**), uncinanone B (**49**), and two non-identified metabolites (**45** and **46**), were found to be present at higher levels in leaves harvested at 6 months than other samples from different harvest periods (Figure 2c). In particular, luteolin glucosyl arabinoside or arabinosyl glucoside (**30**), hydroxyluteolin (**33**), and luteolin glucoside (**37**) were present in the largest quantities during November (at 8 months) in *L. maximowiczii* leaves.

As shown in Figure 2d, eight metabolites were present in large quantities in stems collected 6 months after germination: isovitexin glucoside (**36**), isovitexin (**38**), daidzein (**39**), quercetin (**41**), desmodianone H (**48**), uncinanone B (**49**), and two nonidentified metabolites (**45** and **46**).

Correlation between Tyrosinase Inhibitory Activity and Secondary Metabolites in the Leaves and Stems of *L. maximowiczii*. Both the leaves and stems of *L. maximowiczii* collected 6 months after germination showed the highest levels of tyrosinase inhibitory activity, while those harvested 8 months after germination showed the lowest activity (Figure 3a,b). The tyrosinase inhibitory activity in leaves (54.6%) at 6 months was significantly higher than that in stems at the same harvest time (20.3%).

To visualize the correlations between tyrosinase inhibitory activity and secondary metabolites in the leaves and stems of *L. maximowiczii*, correlation maps are presented (Figure 3c,d). The Pearson's correlation coefficients (r) of all secondary metabolites were calculated and represented as positive correlations when $0 < r < 1$ and negative correlations when $-1 < r < 0$. The results indicate that nine secondary metabolites were positively correlated with tyrosinase inhibitory activity in the leaves: kaempferol dirhamnoside (**34**), isovitexin glucoside (**36**), isovitexin (**38**), daidzein (**39**), hydroxygenistein (**40**), naringenin (**42**), genistein (**43**), desmodianone H (**48**), and uncinanone B (**49**). Meanwhile, seven secondary metabolites were strongly positively correlated with tyrosinase inhibitory activity in the stems: isovitexin (**38**), daidzein (**39**), quercetin (**41**), desmodianone H (**48**), uncinanone B (**49**), and two nonidentified metabolites (**45** and **46**). Of the secondary metabolites that were positively correlated with tyrosinase inhibition activity, four metabolites were present in the largest quantities in both leaves and stems 6 months after germination: isovitexin (**38**), daidzein (**39**), desmodianone H (**48**), and uncinanone B (**49**).

Differences in the Tyrosinase Inhibitory Activity and Metabolite Composition According to Plant Parts. The result that tyrosinase inhibitory activity in leaves of *L. maximowiczii* was higher than that in stems irrespective of the growth period was considered on the basis of difference in metabolite composition between them. Therefore, we applied PCA and PLS-DA from LC-MS data sets to identify metabolite differences between the plant parts, leaves and stems. The PLS-DA models demonstrated the differences between samples: $R^2X_{(cum)} = 0.647$, $R^2Y_{(cum)} = 0.992$, $Q^2_{(cum)} = 0.877$, and $p < 0.05$. Leaves and stems were clearly separated by PLS1 (Supporting Information, Figure 1Sa). Eight metabolites were

J. Agric. Food Chem. 2015, 63, 8631−8639

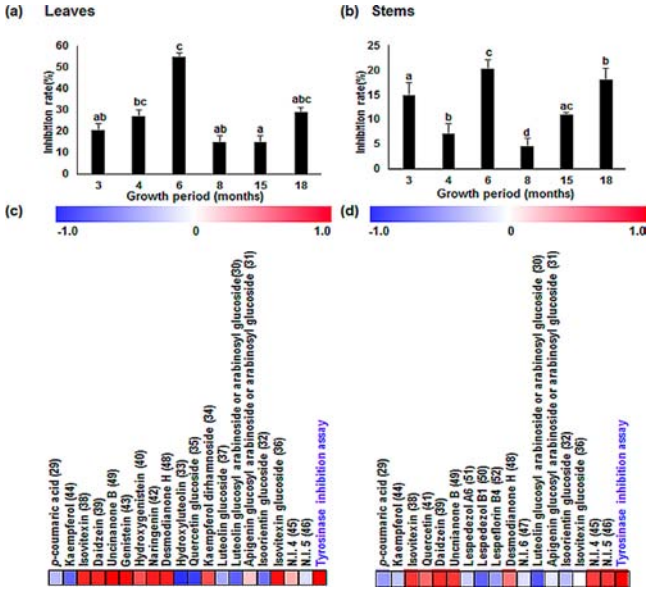

Figure 3. Tyrosinase inhibitory activity in (a) leaves and (b) stems of *L. maximowiczii* during different growth periods, and a correlation map of metabolites and tyrosinase inhibitory activity in the (c) leaves and (d) stems of *L. maximowiczii*. Data were evaluated using a one-way ANOVA followed by Duncan's multiple-range test. Means with different letters, e.g., "a" or "b", are statistically different. Differences were considered significant at p values of <0.05. All assays were conducted in triplicate. Each square (c and d) indicates the r (Pearson's correlation coefficient values) for a pair of averaged values from either metabolites or tyrosinase inhibitory activity. Red represents positive ($0 < r < 1$) correlations, and blue represents negative ($-1 < r < 0$) correlations.

determined to be significantly different in the PLS-DA score plot: *p*-coumaric acid (**29**), luteolin glucosyl arabinoside or arabinosyl glucoside (**30**), isoorientin glucoside (**32**), isovitexin (**38**), daidzein (**39**), kaempferol (**44**), nonidentified metabolites (**46**), and uncinanone B (**49**). Among these metabolites, the contents of five metabolites (**29**, **30**, **38**, **39**, and **49**) were higher in leaves than in stems. On the other hand, the contents of three metabolites (**32**, **44**, and **46**) were lower in leaves than in stems (Supporting Information, Figure 1Sb).

Furthermore, leaves and stems showed a big difference up to 40% in tyrosinase inhibitory activity 6 months after germination. To compare the differences in secondary metabolites closely associated with bioactivity between leaves and stems at 6 months, we applied an orthogonal projection to latent structures discriminate analysis (OPLS-DA) model from the LC-MS data sets. In Figure 2Sa of the Supporting Information, the OPLS-DA model showed a clear separation between the leaves and stems of *L. maximowiczii* harvested at 6 months of the growth period along with discriminating the goodness of fit parameter, R^2 (0.52), and the predictive ability parameter, Q^2 (0.97). A clear difference between the leaves and stems at 6 months was seen in the first OPLS component ($t[1]$ = 45%). The OPLS score plot and loading S plot were conducted using *par* scaling to identify the metabolites contributing to the difference. Eleven metabolites were determined to be significantly different using the VIP values (VIP > 0.7) and p value ($p < 0.05$) of the S plot (Supporting Information, Figure 2Sb): *p*-coumaric acid (**29**), isoorientin glucoside (**32**), kaempferol dirhamnoside (**34**), daidzein (**39**), hydroxygenistein (**40**), quercetin (**41**), genistein (**43**), kaempferol (**44**), N.I. 5 (**46**), desmodianone H (**48**), and uncinanone B (**49**). Of these variables, eight leaf secondary metabolites (**29**, **34**, **39**, **40**, **43**, **46**, **48**, and **49**) placed in the positive section were present in larger quantities in leaves, whereas three metabolites (**32**, **41**, and **44**) in the negative section were present in smaller quantities in leaves.

DISCUSSION

In this study, we determined that *L. maximowiczii* underwent the most significant changes in metabolites in both the leaves and the stems 6 months after germination. This was determined by comprehensive MS-based metabolite profiling. Tyrosinase inhibitory activity was also significantly affected by secondary metabolite changes. Six months after germination, many primary metabolites were present in smaller quantities in the leaves, while most metabolites were present in larger quantities in the stems than in other months (Figure 2a,b). In particular, amino acids were more abundant in stems than in leaves and were present in high concentrations 6 months after germination. Amino acids are the major metabolic carbon and nitrogen sources for plant metabolic engineering during growth and development.[21] Our data also showed that primary metabolites such as sugars, organic acids, and fatty acids were present in larger quantities in stems than in leaves. Among them, the level of sucrose, an important product from photosynthesis, was elevated in both leaves and stems harvested at 3 and 4 months, which are the summer quarter, from June to July. In general, the rate of photosynthesis during the summer season is higher than in other seasons because more sunlight and higher temperatures elevate the rate of photosynthesis. In plants, primary metabolites are essential for growth, development, respiration, and photosynthesis.[22] As is shown in Table 1, the *L. maximowiczii* plants grew to 70 cm within 6 months of germination. The rate of vertical growth was also the highest 6 months after germination. These data indicate that the morphological changes observed are largely related to changes in metabolite production during growth.

We also detected variations with growth period in the production of many flavonoids, such as isoflavone, flavanone, flavonol, flavone, flavone glucosides, and flavonol glucosides. Our results show a remarkable difference between the chemical contents and constituents of *L. maximowiczii* leaves and stems 6 months after germination and other months during the growth period (Figure 2c,d). Moreover, our data showed significant tyrosinase inhibitory activity in both leaves and stems during the same period. The activity in the leaves was significantly higher than in the stems 6 months after germination. In the correlation map (Figure 3c,d), four metabolites, isovitexin (**38**), daidzein (**39**), desmodianone H (**48**), and uncinanone B (**49**), which were strongly positively correlated with each other, were reported to be regulatory agents of melanogenesis.[9,23,24] As these metabolites were present with the largest quantities in samples harvested 6 months after germination, they may be the most active 6 months after germination. The samples at this time were harvested in September, which is the start of the fall season in Korea. Among the secondary metabolites, the accumulation of isoflavones and flavanones contributed to high tyrosinase inhibitory activity in the fall (September 2013). On the other hand, a correlated decline in isoflavones and flavanone resulted in relatively low tyrosinase inhibitory activity in winter (November). For a year after germination, the tyrosinase inhibitory activity at 15 months (June 2014) was lower than after 3 months (June 2013). This was identically

DOI: 10.1021/acs.jafc.5b03566
J. Agric. Food Chem. 2015, 63, 8631−8639

shown between 6 months (September 2013) and 18 months (September 2014). Moreover, the phenotypes of *L. maximowiczii* showed differences in the same period of the two different years. The leaves and stems within 1 year of germination were smaller and thinner than others. On the other hand, the shapes of leaves and stems harvested in the same period of the second year were larger and thicker than those of leaves and stems harvested within one year. These differences were closely associated with metabolite changes. These results indicated that differences in phytochemicals for the one year interval were attributed to the contents of secondary metabolites, such as flavonoids, affecting tyrosinase inhibitory activity in each growth period. Also, the tyrosinase inhibitory activity in both leaves and stems harvested in September was higher than those in June. Therefore, our study suggests that harvesting *L. maximowiczii* in the fall will be useful in bioactivities because the inhibition properties of melanogenesis were the highest during this season.

In the winter season, the changes in metabolites for surviving with cold tolerance were greater than those related to tyrosinase inhibitory activity. We found the changes in the production of some sugars 8 months after germination to be particularly significant. One of the environmental factors potentially affecting plant growth is temperature.[25] Low temperature, in particular, subjects growing plants to cold stress and induces carbohydrate changes in many plant species.[26] Sugar metabolism plays an important role in the survival of cold stress. Sucrose is well-known as one of the soluble sugars, which accumulate in plants as a reserve carbon source in preparation for cold conditions.[27,28] Our results showed that the levels of fructose (**16**), glucose (**17**), and sucrose (**21**) were significantly increased in both leaves and stems harvested in November (Figure 2), which is the beginning of the winter season to start at a low temperature (average temperature of 5 °C) in Korea. These results suggest that changes in sugars are associated with seasonal variations depending on the growth period. Various derivatives of luteolin dominated the metabolite profiles of leaves harvested in November (8 months after germination), including luteolin glucosyl arabinoside or arabinosyl glucoside (**30**), hydroxyluteolin (**33**), and luteolin glucoside (**37**). Phenolic compounds play an important role by replacing other compounds in cellular metabolism during the winter.[29] Phenolic compound contents are affected by environmental factors such as temperature, UV light, rainfall, and soil conditions.[30] Our data suggest that the accumulation of phenolic compounds in the leaves might be an adaptation to low-temperature stress during the winter. From the overall results, the relationship between metabolite changes and tyrosinase inhibitory activity in *L. maximowiczii* during the growth period is briefly summarized in Figure 4.

In addition, the variation of metabolites from *L. maximowiczii* was largely influenced by the monthly average precipitation within a year of germination. In the summer rainy season, the levels of organic acids such as succinic acid and shikimic acid were significantly decreased. In the fall dry season, amino acid contents were generally increased (Figure 2).

Moreover, we determined a significant difference in the contents of metabolites and tyrosinase inhibition activity between the plant parts, leaves and stems. Many researchers reported that gene expression varied between plant parts, in spite of being subjected to the same environmental factors. For this reason, they predicted that there are differences also in the metabolite composition of plant parts.[31] Also, our team

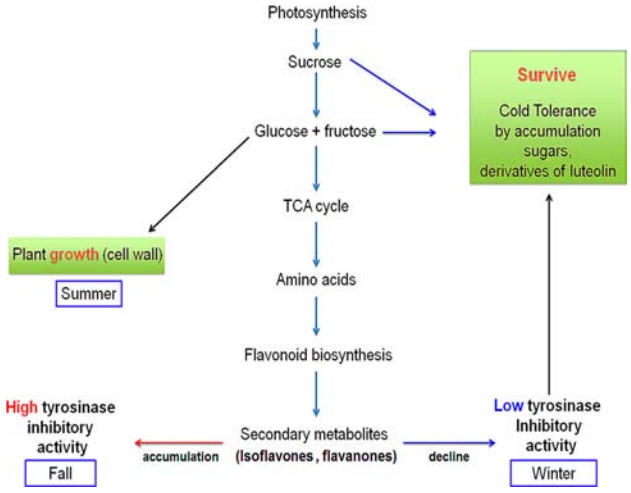

Figure 4. Suggested mechanism of seasonal metabolite changes resulting in tyrosinase inhibitory activity.

previously studied the fact that phytochemical production was dependent on the particular parts of the plant in *Lespedeza*.[32]

Leaves are exposed to much higher levels of UV radiation than stems, and therefore, photosynthesis in the leaves is heavily influenced by leaf structure characteristics such as thickness and density.[33,34] Thus, we assume that metabolite production in the leaves is more strongly affected by these conditions than that in the stems. In particular, these tendencies were remarkably shown 6 months after germination (Supporting Information, Figure 2S). Isoflavonoids such as daidzein (**39**), hydroxygenistein (**40**), genistein (**43**), and uncinanone B (**49**) were closely associated with tyrosinase inhibitory activity,[24] and their contents in leaves were superior to those in stems 6 months after germination in our data. This phenomenon was also observed in the different distributions of isoflavones in different parts of red clover and in red clover harvested at different growing stages.[35] This study demonstrated the two different parts of *L. maximowiczii* plants exhibited different levels of tyrosinase inhibitory activity due to differences in bioactive metabolites. These results suggest these metabolites are the variables discriminated from the plant parts in *L. maximowiczii* and affect its activity.

In conclusion, we confirmed that the production of primary and secondary metabolites in the leaves and stems of *L. maximowiczii* changed in response to seasonal variations. Furthermore, *L. maximowiczii* was found to undergo remarkable changes in morphology and activity after germination along with seasonal variations. The tyrosinase inhibitory activity was high in the fall because secondary metabolites involved in the activity accumulated. Both leaves and stems possessed the capacity to produce melanogenesis-regulatory substances, but the leaves had tyrosinase inhibitory activity higher than that of stems. This study revealed the relationship between metabolite changes and activity in *L. maximowiczii* during the growth period. This MS-based metabolomics approach can be applied to understand correlation between bioactivities and the changes in metabolites according to seasonal variations of any other plants.

[a] *n* = number of individuals collected on the site. For bilberry, also pH of soil is reported.

majority of ACs found in blueberries, constituting about 70% of total ACs.[18] Acylated ACs are also found in blueberries and bilberries, but they account for only a small portion of the total amount.[18,19]

Latitude appears to influence the accumulation of ACs in bilberries, as a clear increasing trend in AC production toward the north has been reported in high latitudes. Higher AC content was reported in northern (63−70° N) latitudes of northern Europe, compared to southern latitudes (54−62° N).[10,11] The berries of the northernmost clones have been shown to contain higher total content of ACs and higher proportions of the more hydroxylated anthocyanidins, Dps and Mvs, whereas Cys accumulated more in the more southern populations of northern Europe (latitudes 54−62° N). Studies have also been performed in relation to different altitudes, although they have given contradictory results. Spinardi et al.[20] reported higher levels of ACs and ascorbic acid in blueberries grown at 600 m asl compared with the same cultivar grown at 450 m asl in Valtellina (northern Italy). In a two-year study in Austria,[7] decreasing AC contents were found in bilberry fruits along with increasing altitude (between 800 and 1500 m asl). In studies performed in the areas of northern Europe, where altitudinal differences are less pronounced, no clear relationship with elevation and AC concentration has been found.[11,21]

In the present study, we investigated the effect of the altitude on the accumulation of ACs in the berries of two *Vaccinium* species (*V. myrtillus* L., bilberry, and *V. corymbosum* L. cv. Brigitta Blue) growing in northern Italy over two growing seasons. The aim was to investigate the effect of temperature and light conditions on the accumulation of ACs. The AC profiles of six wild bilberry populations growing in the Alps of northern Italy along an altitudinal gradient of about 650 m were analyzed and compared with the AC profile of one of the most popular varieties of highbush blueberry (cv. Brigitta Blue), which is cultivated in a range of about 550 m. Furthermore, temperature and light conditions monitored along the altitudinal gradient were compared with AC profiles of berries. The study provides detailed information about the AC composition of *Vaccinium* berries, which is valuable for food quality control in the berry industry. With specific regard to the wild species, the metabolic profile of individuals within each bilberry population may also allow selection of specific genotypes for cultivation and breeding purposes.

MATERIALS AND METHODS

Plant Material and Altitudinal Gradients. The field trials were established along altitudinal gradients in the region of Trentino (Italy). Permissions for field work were granted by the municipalities of Grumes, Valda, and Zambana and the Province of Trento (Italy). Six sites were identified for bilberry (*V. myrtillus* L., Vm) experimental fields. The gradient was established between Val di Cembra (46.22° N, 11.26° E) and Monte Paganella (46.16° N, 11.04° E) at 1166, 1261, 1406, 1520, 1620, and 1829 m asl (Table 1). In each site 10−25 individual bilberry plants within an area of about 20 m^2 were considered for AC analysis of the berries.

Blueberries (*V. corymbosum* L., Vc) of cv. Brigitta Blue were collected from plants cultivated by farmers of Valsugana valley (46.08° N, 11.50° E). Three sites, located in Telve (495 m asl.), Spera (749 m asl), and Pinè (1034 m asl) were considered for the altitudinal gradient (Table 1). Plants were cultivated according to conventional farming methods. Fruits were collected from five plants chosen randomly on five different rows of plants in the field in an area of 100 m^2.

Fruit Harvesting. The study was conducted in two consecutive growing seasons (years 2013 and 2014). Bilberries were harvested when fruits reached the full development in size and color, and total soluble solid content (TSSC) was >6.0 °Brix. In 2013, bilberry fruits from Val di Cembra were collected between July 17 (in lowest location, site Vm1) and July 24 (in middle-high locations, sites Vm2 and Vm3), whereas on Monte Paganella, on sites Vm4 and Vm5, bilberries were collected on August 21 and bilberries from the highest location (site Vm6) on September 3. In 2014, the growing season was anticipated in Val di Cembra, as the berry harvesting started on June 20 in the lowest site (Vm1). The harvest continued on July 3 on sites Vm2 and Vm3, on August 1 for Vm4, and on August 28 on sites Vm5 and Vm6 (Table 1).

Blueberry fruits were manually picked at the commercial ripening stage, when berries were fully developed in size and color, with TSSC content >10 °Brix, and at least 80% of berries on the plant reached ripeness. Fruit collection started on July 22, 2013, in sites of Telve (Vc1) and Spera (Vc2) and ended on August 12, 2013, in the highest location, Pinè (Vc3). In the following year, 2014, fruits were harvested on the same plants, starting from Telve on July 7 and finishing on August 12 in Spera and Pinè (Table 1).

Berries were placed in plastic tubes and stored on ice to prevent sample degradation during transport from the field to the laboratories, where they were stored at −80 °C. Metabolic analyses were performed within 3 months from the collection.

Total Soluble Solid Content Analysis. TSSC analyses were conducted on mature fruits, as homogeneous as possible for size and color. TSSC was measured with a DBR35 refractometer.

AC Extraction. Frozen ripe berries were ground into a fine powder with a cryomill (Retsch, Haan, Germany). The homogenized samples (1 g fresh weight, FW, of at least 10 g of fresh berries) were extracted twice in 1.5 mL of 80% methanol under shaking for 1 h. Samples were centrifuged at 12000*g* for 2 min. Supernatants were pooled and brought to a volume of 5 mL. Samples were filtered (0.22 μm PVDF filters), transferred to glass vials, and randomized before analysis by UPLC-MS/MS.[22]

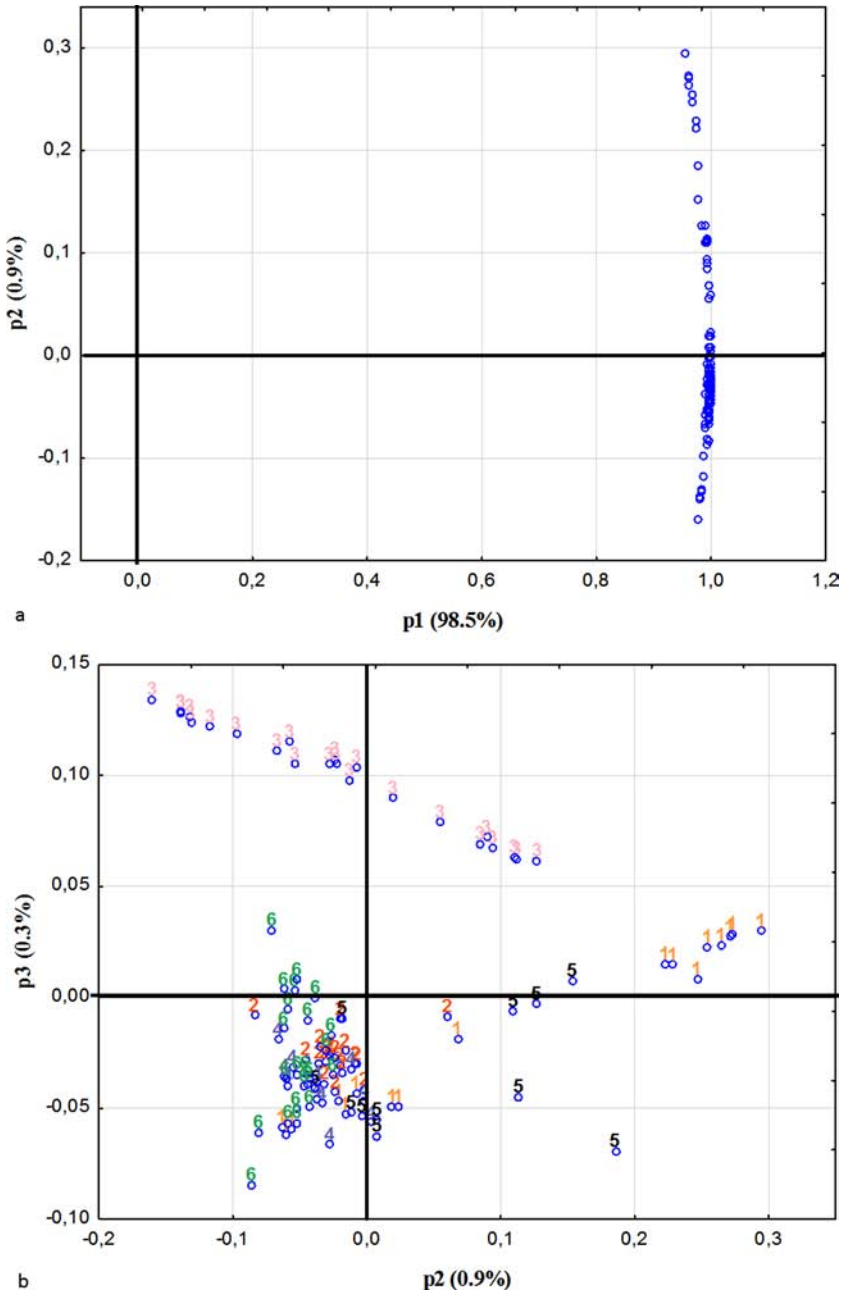

Figure 1. AC variability estimated by PCA among bilberry individuals from six bilberry populations in northern Alps of Italy: variability explained by first and second PCA components (a) and by second and third PCA components (b).

UPLC Analysis. Analytical separation of ACs was performed in an Acquity ultraperformance liquid chromatographic (UPLC) system (Waters, UK) operating under MassLynx XS software. The system was coupled to a mass spectrometer detector Waters Xevo TQ MS (Milford, MA, USA) equipped with an electrospray (ESI) source. All samples were analyzed on a reverse phase Acquity UPLC BEH C18, 1.7 μm, 2.1 × 150 mm column (Waters), protected with an Acquity UPLC BEH C18, 1.7 μm, 2.1 × 5 mm precolumn (Waters) at 40 °C and under mobile phase flow rate of 0.4 mL/min. Water was used as weak eluting solvent (A) and methanol as strong eluting solvent (B); formic acid 5% v/v was used as additive in both eluents. The multistep linear gradient used was as follows: from 95 to 60% for the first 4 min, from 60 to 45% A from 4 to 9 min, from 45 to 5% A from 9 to 11 min, and an isocratic hold for 3 min to clean the column. The equilibration time was 4 min, and the injection volume was 2 μL. 4-Hydroxystilbene was used as internal standard (2.5 ppm) to check that the sensitivity of the machine was kept constant during the analysis. A quality control standard mixture was injected periodically to check that the sensitivity of the machine was kept constant during the analysis.

Identification and Quantification (MS/MS). ACs were detected by multiple reaction monitoring (MRM), by screening the MS/MS transitions and using the parameters earlier optimized for grape wine.[22] The method was slightly modified to allow the detection of gal and ara anthocyanidins that have earlier been described for bilberry. For some of the compounds, there were no standards available, but they could be tentatively identified on the basis of their MRM transitions and the relative retention time with respect to known compounds and considering previous results (Supplementary Table 1).[19]

For quantification, external calibration curves were prepared by injecting authentic standards of each compound at different concentrations. When the authentic standard was not available, the ACs were quantified relative to Mv-3-*O*-glu, using the Mv-3-*O*-glu calibration curve (Supplementary Table 1). Data processing was done

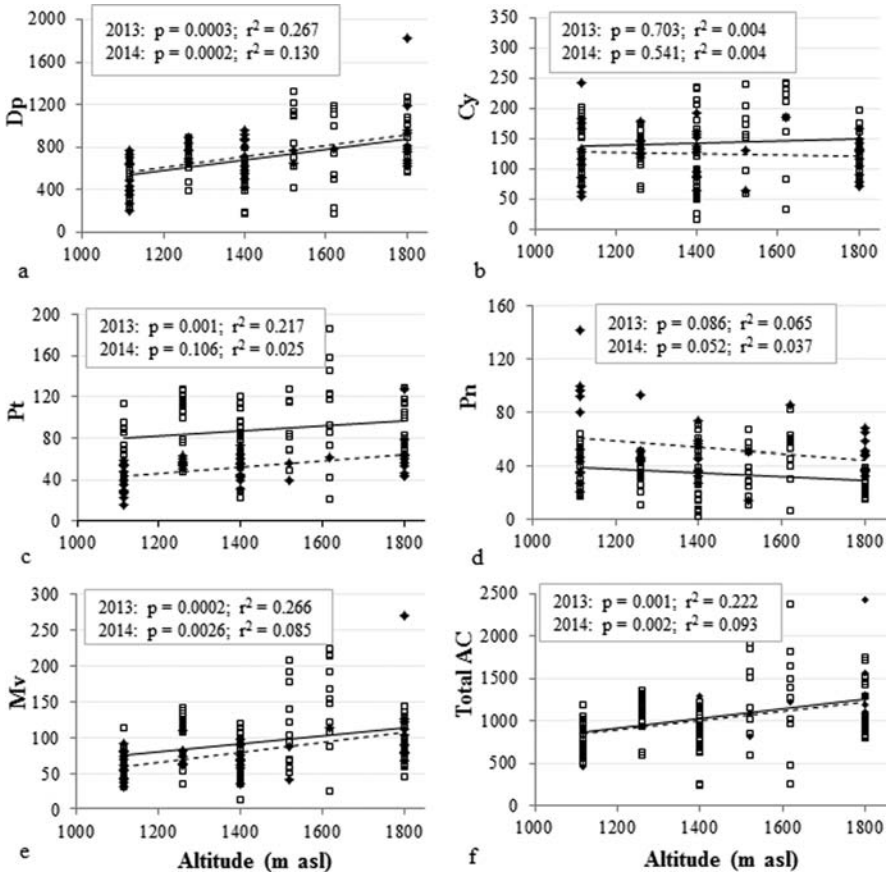

Figure 2. AC accumulation (mg/100 g FW) in bilberries along altitudinal gradient in two consecutive seasons (2013−2014). Regression analysis was performed, and coefficient of determination r^2 and p value were calculated for each class of anthocyanidin (a, Dp; b, Cy; c, Pn; d, Pt; e, Mv) and the total AC content (f). (■) 2013 samples; (□) 2014 samples; (broken line) regression line of 2013 samples; (solid line) regression line of 2014 samples.

using Waters MassLynx 4.1 and TargetLynx software. The amount of anthocyanidin classes (Dp, Cy, Mv, Pn, and Pt) and total ACs was calculated by summing the amounts of single AC compounds identified.

Air Temperature Measurement. The air temperature was measured along the altitudinal gradient, between 410 and 2125 m asl, at the meteorological stations of the Protezione Civile of Trento (Italy). Among all of the stations present in the province of Trento, the ones chosen were the nearest to the experimental fields. In detail, stations were located in Telve (T0392, 46.06° N, 11.47° E, 410 m asl), Bieno (T0015, 46.08° N, 11.56° E, 843 m asl), Lavarone (T0032, 45.94° N, 11.25° E, 1155 m asl), Monte Bondone (T0368, 46.01° N, 11.05° E, 1490 m asl), and Monte Paganella (T0099, 46.14° N, 11.04° E, 2125 m asl). Maximum daily temperatures were recorded in 2013 and 2014 during berry growing season (June 1−August 31). Data are available online at www.meteotrentino.it.

Solar Radiation and Light Quality Measurements. Light at the tops of canopies was measured with a USB 2000 spectrometer (Ocean Optics, Dunedin, FL, USA). Measurements were recorded during fruit development and ripening at noon on sunny days under a clear sky, within a range of altitude between 495 and 1404 m asl (at locations Vc1, Vc2, Vc3, Vm1, Vm2, and Vm3). The quality of light reaching the plants was measured as photosynthetic active radiation (PAR) by integrating the area between 200 and 850 nm for full sunlight spectra, 200−380 nm for UV light, 380−750 nm for visible light, 380−495 nm for blue components, 590−710 nm for red components, and 710−750 nm for far-red components.[23] Spectra and integration of light were measured from five consecutive scans of the sunlight, after calibration of the instrument according to the manufacturer's instructions.

Soil pH. For bilberry, in every location, five points were spotted out of the edges of the bilberry matrix frame for soil sampling. In these spots, about 1 kg of soil between 20 and 50 cm underground was collected. The samples were first cleaned of plant roots, leaves, and small stones and then pooled together. A pooled sample of 80 g was dissolved in 200 mL of distilled water[24] and stirred overnight, and the next day the pH was measured with Crison PH 25+ (Hach Lange Srl, Derio, Spain).

Statistics. All data were analyzed using Statistica 9 software (StatSoft Inc., Tulsa, OK, USA). Two-way ANOVA followed by pairwise comparison using Fisher's least significant difference (LSD) test was made between the variables: metabolites versus altitude and year of collection, light conditions versus altitude, and temperature versus altitude. Differences were considered significant when $p < 0.05$.

Principal component analysis (PCA) was performed on bilberries' AC composition to investigate the variation within bilberry populations and to discriminate geographic areas of collection. Regression analyses were made on the full set of bilberry samples to measure the coefficient of determination r^2 and p value between the anthocyanidin classes (Dp, Cy, Pn, Pt, Mv), total ACs, and altitude.

■ RESULTS AND DISCUSSION

AC Profile of Bilberry Populations. AC profiles of bilberry fruits as well as AC variation among native bilberry populations in the Alps of northern Italy were systematically analyzed. The ACs identified were Dp, Cy, Pn, Pt, and Mv, conjugated with glu, gal, and ara, and their acylated forms, including acetylated and para-coumaroylated ACs. In small amounts, also Cy 3 sambubioside and Pg were identified (Supplementary Table 2). The amounts of Dp glycosides were higher than of Cy glycosides on average, similarly to the profiles

DOI: 10.1021/acs.jafc.5b02833
J. Agric. Food Chem. 2015, 63, 8641−8650

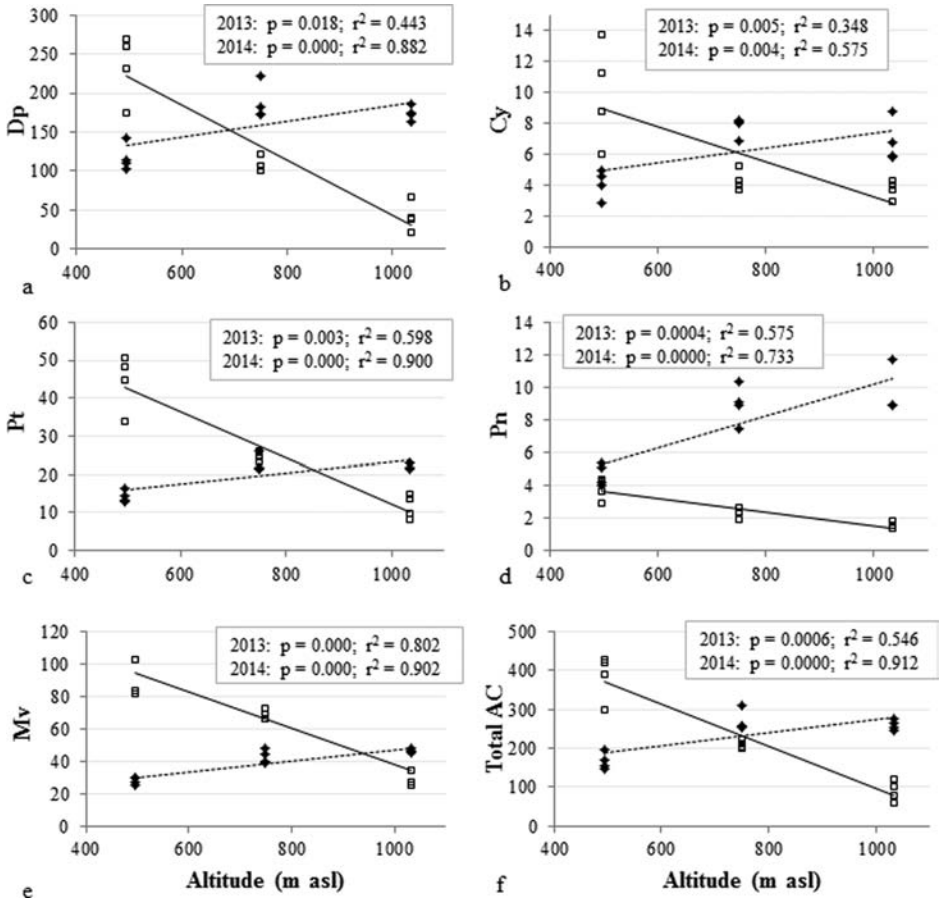

Figure 3. AC accumulation (mg/100 g FW) in blueberries (cv. Brigitta Blue) along altitudinal gradient in two consecutive seasons (2013−2014). Regression analysis was performed, and coefficients of determination r^2 and p value were calculated for each class of anthocyanidin (a, Dp; b, Cy; c, Pn; d, Pt; e, Mv) and the total AC content (f). (■) 2013 samples; (□) 2014 samples; (broken line) regression line of 2013 samples; (solid line) regression line of 2014 samples.

detected in other southern European bilberries, for example, from Austria,[7] Slovenia,[8] and Montenegro,[25] but also in northern European bilberries, for example, from Finland.[10,19] However, the comparison between bilberries from Finland[19] and Italy (presented in this study) which were analyzed with the same analytical method[22] revealed differences in the sugar moiety. In bilberries growing in northern Europe >60% of the ACs was conjugated with glu, whereas the remaining 40% was shared equally between gal and ara.[19] In the present study, ACs were equally conjugated with the three sugars (about 30% each), which is in line with the results of the study on Slovenian bilberries.[8] In the present study, also climate differences affected accumulation of acetylated compounds, which were more abundant in 2013 than in 2014 (Supplementary Table 2).

The AC variability among bilberry populations, estimated through PCA, was minimal as the first axis explained the 98.5% of the diversity, but grouped all samples in a single cluster (Figure 1a). However, the second and third axes, which respectively explained 0.9 and 0.3% of the diversity, separated the populations from sites Vm1, Vm3, and Vm5 (Figure 1b), indicating that the AC profile may be used as a discriminative factor of bilberry populations from close geographical sites.

AC Profile of Blueberries (cv. Brigitta Blue). The AC profile was typical for the cv. Brigitta Blue,[26] with Dp and Mv as predominant anthocyanidins, followed by Pt and in lowest proportion Cy and Pn (Supplementary Table 3). AC compounds were conjugated with glu, gal, and ara sugars, but were not uniformly distributed among the anthocyanidins. Dp was equally conjugated with glu and ara, whereas very little Dp 3 gal was detected. On the contrary, Mv and Pt (which are methylated forms of Dps[27]) and the monohydroxylated Cy and Pn were equally conjugated with gal and ara and to a small extent with glu. No acylated forms were identified in blueberries (Supplementary Table 3).

AC Accumulation in Wild and Cultivated *Vaccinium* spp. along Altitudinal Gradients. The two *Vaccinium* species, bilberry and blueberry, showed important differences in the accumulation of ACs along the altitudinal gradient. Our results indicated an increase in the accumulation of ACs in bilberries along a gradient of about 650 m, which was consistent over the two growing seasons (Figure 2). Indeed, regression analysis of total AC concentration gave a significant positive correlation between altitude and total AC accumulation in berries ($p = 0.001$ in 2013 and $p = 0.002$ in 2014) in both years (Figure 2). The trend was due to a significant increase in the trihydroxylated anthocyanidins such as Dp ($p = 0.0003$ in 2013, $p = 0.0002$ in 2014) and Mv ($p = 0.0002$ in 2013, $p = 0.0026$ in 2014). To a small extent also Pt increased with increasing altitude ($p = 0.001$ in 2013). The accumulation of the monohydroxylated Cy and Pn glycosides, instead, was not affected by the altitude (Figure 2).

The results of the present study are in line with those of Jovancevic et al.,[25] who showed that bilberries collected in sunny locations contained higher amounts of ACs with

J. Agric. Food Chem. 2015, 63, 8641−8650

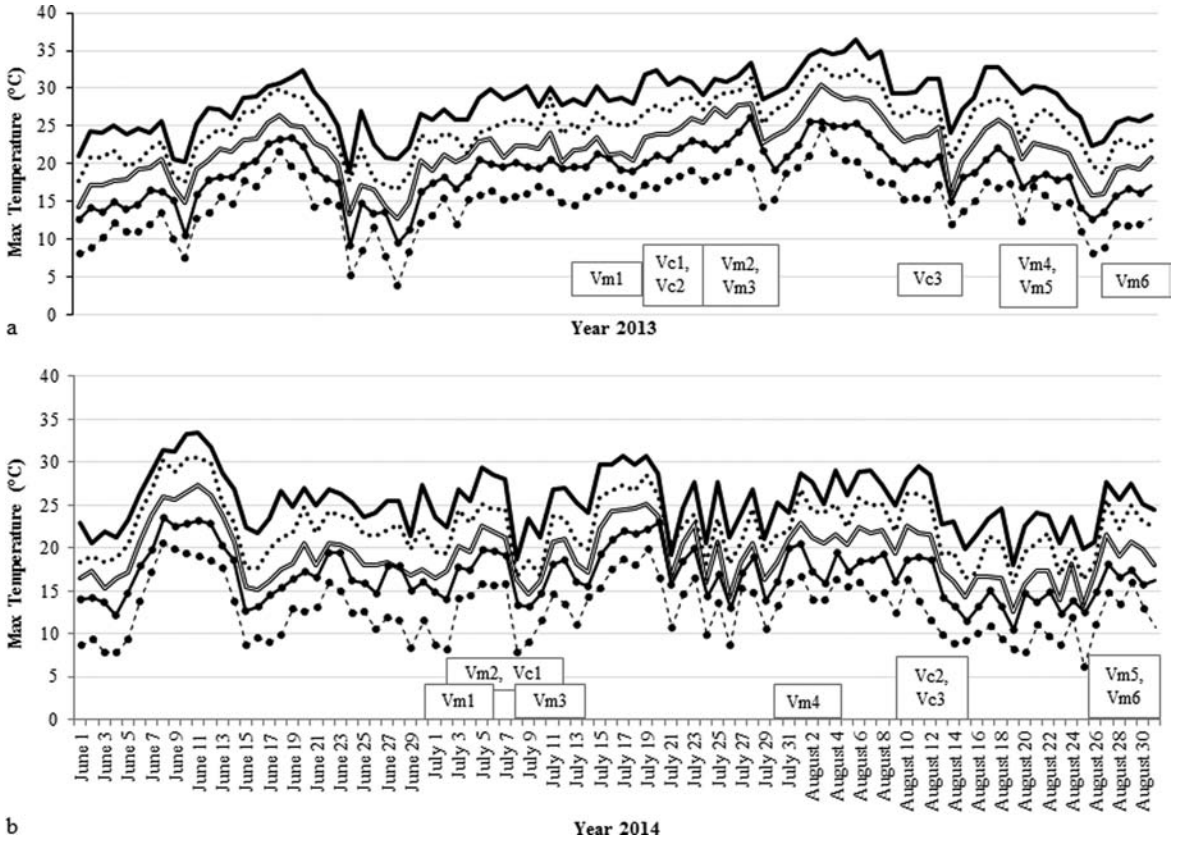

Figure 4. Maximum daily temperatures recorded along the altitudinal gradient during berry ripening (June 1−September 4) in 2013 (a) and 2014 (b). The temperatures were recorded at the meteorological stations in Telve (410 m asl, solid line), Bieno (843 m asl, broken line), Lavarone (1155 m asl, double line), Monte Bondone (1490 m asl, solid line with dots), and Monte Paganella (2125 m asl, broken line with dots) in the region of Trentino (northern Italy). The harvest date for each location is provided.

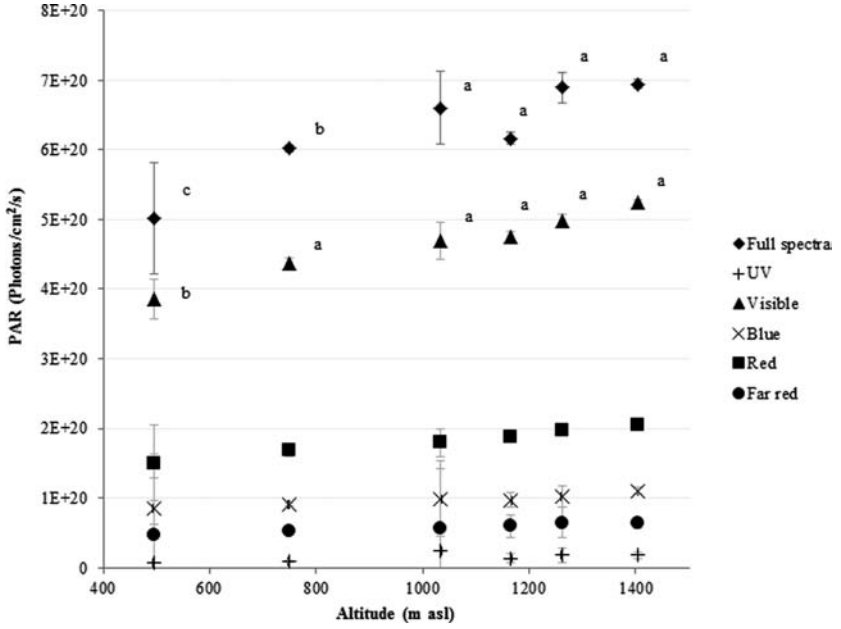

Figure 5. Solar radiation PAR measured along the altitudinal gradient. PAR was measured in six locations between 495 and 1404 m asl by integrating the spectra between 200 and 850 nm for full sunlight spectra, 200−380 nm for UV light, 380−750 nm for visible light, 380−495 nm for blue components, 590−710 nm for red components, and 710−750 nm for far-red components.

increasing altitude. In particular, an increase in Dp-type ACs was observed in locations above 1500 m asl.[25] Contrasting results were reported by Rieger et al.[7] in bilberries collected at different altitudes in Austria, where decreasing amounts of ACs were observed with increasing altitude. However, results by Rieger et al.[7] are also in contrast with the same analysis

DOI: 10.1021/acs.jafc.5b02833
J. Agric. Food Chem. 2015, 63, 8641−8650

performed within the same study on other plant species (*Calluna vulgaris* L. and *Sambucus nigra* L.). Moreover, no information about the exposure and climatic conditions of the bilberry collection sites was presented. The content and composition of ACs in bilberries are highly affected by environmental factors such as light intensity, light quality, and temperature,[19,28−30] which need to be taken into consideration to explain the accumulation of metabolites in fruits growing in natural environments.

In blueberry, an opposite trend was observed during the two years in the present study; in 2013 the accumulation of total AC was positively increasing toward higher altitudes (p = 0.0006), whereas in 2014 accumulation was negatively correlated with altitude (p = 0.0000; Figure 3). In the case of blueberry, only the cultivar (Brigitta Blue) was used in the study and, therefore, the seasonal differences in the AC content were considered to be connected to environmental effects.

Environmental Effect on AC Accumulation. In all types of fruits, environmental factors affect the quantitative and qualitative composition of ACs in the ripening fruit.[31] In general, the genetic background of the species/variety determines the AC content in fruit, yet the environmental factors can affect the concentration of diverse ACs in different ways. Temperature, solar radiation, and soil are considered the major environmental factors affecting the accumulation of ACs in fruits.[32] All of these factors may vary markedly along latitudinal gradients, where changes in phenolic content of bilberries were recorded with changing environments from southern to northern latitudes.[10,11,21]

In the present study we observed that the same factors vary markedly also along an altitudinal gradient. Maximum daily temperatures decreased progressively with increasing altitude (Figure 4). Moreover, differences in temperatures were recorded throughout the two growing seasons, which significantly affected the accumulation of ACs in berries (p < 0.05; Supplementary Table 2). Higher temperatures were recorded during the year 2013, when also higher accumulation of AC was found in bilberries, with higher proportion of acylated forms of ACs (Supplementary Table 2) in line with findings in grape berries (cv. Merlot)[33] and in our previous study on bilberry.[30]

Light conditions were also measured in six locations along the gradient, within 495 and 1404 m asl; Figure 5). Sunlight PAR (full spectra) increased constantly toward increasing altitudes, and significant changes (p < 0.001) were recorded between locations at 495 and 756 m asl and locations higher than 1034 m asl. The increase was due to a progressive increase of visible light along with altitude, although the blue and red components were not significantly affected with increasing altitude. The UV radiation accounted for only 1.3−3.8% of the total radiation and was not significantly affected by altitude. The soil pH ranged between 4.3 and 5.1 (Table 1), which is optimal for the growth of bilberry,[35] but did not show any particular trend connected with altitude.

Our results suggest that lower temperatures have a major effect on the accumulation of ACs in bilberry. Decreasing temperatures observed with increasing altitude, positively influenced the accumulation of ACs in bilberries being in line with the results of Uleberg et al.,[28] who showed that higher amounts of Dp derivatives are produced at low temperatures (12 °C) compared to higher temperatures (18 °C). Recently, we also observed that when plants from the same bilberry populations were moved from higher to lower altitude (485 m asl), in open-field conditions with higher temperature, berries accumulated lower amounts of ACs, confirming the role of temperature in the determination of the final AC profile of berries.[30] Thus, the difference in the average daily temperature in the original locations (Vm1−Vm6) was at least 5 °C lower than in the test field at 485 m asl and the AC accumulation was almost 2-fold higher in the original site. Excessive light stress appeared to inhibit AC accumulation,[30] but considering the present results, where light intensity is higher at altitudes above 1034 m asl compared to fields at altitude 495 m asl (Figure 5), light intensity appears to have less influence than temperature on AC accumulation in bilberry fruits growing in natural environments. Supporting this assumption, in the locations above 1034 m asl, where bilberry populations were growing, no significant difference in the intensity of the light reaching the plants was detected (Figure 5). Therefore, we hypothesized that bilberry plants grown at higher altitudes may have developed genetic adaptation mechanisms which respond to low temperatures with an increased production in ACs, in particular of the Dp type.

The biosynthesis of Dp-type ACs is driven by the flavanone 3′5′-hydroxylase (*F3′5′H*) gene, which is responsible for the hydroxylation at the 3′,5′-positions of the B-ring of the precursor dihydrokaempferol into Dp and the methylated derivatives Mv and Pt and which also shifts the biosynthesis from the Cy and Pn branch toward the branch of the flavonoid pathway producing Dp, Mv, and Pt as final core structures of ACs.[27] Studies conducted on blueberry,[27] bog bilberry (*Vaccinium uliginosum* L.),[36] and grape berries (*Vitis vinifera* L.)[37] showed that the *F3′5′H* gene is weakly expressed during the earliest ripening stages and is abundant only during the late ripening stages, closely paralleling the appearance of ACs. In blueberry, as the fruit ripens and the exocarp color changes from mostly green to partially pink, blue-purple Dp-type ACs begin to accumulate. The appearance of the trihydroxylated anthocyanidin Dp and its derivatives Mv and Pt is coordinated with the abundance of *VcF3′5′H* transcripts at developmental stage S5 (at the initiation of ripening).[27] On the basis of the conservation of the flavonoid pathway in diverse species, *VmF3′5′H* gene expression is expected to increase at the late ripening stages of bilberry as well as when exposed to low temperatures, as found in the present study and as suggested for grapevine.[38]

In blueberry, marked differences in AC content were recorded in the same locations during the two seasons. The accumulation of ACs in blueberries is developmentally regulated and occurs during the pink and purple-blue (full ripe) stages of berry development.[27] At the lowest location, Vc1, the berries started in 2013 to visibly turn color and to accumulate ACs on June 30, and they reached full ripeness on July 22, whereas in 2014 the berries started to turn color on June 10 and reached ripeness by July 7. In the central location Vc2, blueberries started to turn color on June 30 in 2013 and reached ripeness on July 22 (as in location Vc1), whereas in 2014 the ripening was delayed by almost 3 weeks as berries started AC accumulation on August 1 and ripened on August 12. In the highest location, Vc3, the ripening of berries was more uniform during the two seasons and the berries started to turn color around August 1 in both years and were ready for picking on August 12.

The accumulation of AC in blueberries is regulated also by environmental factors.[30] To our knowledge, very little information is known about the effect of temperature on AC

biosynthesis in blueberries. Therefore, in the present study, the cultivation of blueberries at different altitudes allowed us to investigate the effect of natural differences in temperature on the AC composition of the berries at harvest. The meteorological station present in location Vc1 (Telve, Figure 4) recorded maximum daily temperatures ranging from 26 °C at the beginning of the pink stage that progressively increased to 32.5 °C at full ripeness in 2013. In 2014, during the pink stage, the temperature peaked at 33.5 °C and later decreased, fluctuating around an average of 26 °C until ripening (Figure 4). In correspondence with the temperature flow recorded in 2014 (i.e., high temperatures during the pink stage followed by lower temperatures during the last ripening phase), blueberries ripened more quickly and accumulated the highest content of AC (385 ± 59 mg/100 g FW), which was doubled compared to the amount recorded in 2013 (168 ± 22 mg/100 g FW; Figure 3f; Supplementary Table 3). Meteorological stations were not present on the site for the other two localities (Vc2 and Vc3), and therefore information from the closest meteorological stations (Bieno, 6 km from Vc2, and Lavarone, 43 km from Vc3, respectively) was used. In location Vc2, temperatures recorded were almost constant throughout the pink and purple stages of berry development in both years (Figure 4). Consistently, the difference in the content of ACs in berries between the two seasons was not as marked as in the other two localities (270 ± 28 mg/100 g FW in 2013 and 210 ± 11 mg/100 g FW in 2014; Figure 3f; Supplementary Table 3). In location Vc3, a difference of 5−10 °C between the two seasons markedly affected the accumulation of AC in blueberries. In 2013, temperatures ranged between 20 and 28 °C during berry ripening (Figure 4) and the AC content of blueberries was 260 ± 13 mg/100 g FW. In 2014, accumulation of total ACs was only 91 ± 27 mg/100 g FW due to the lower temperatures (between 14 and 25 °C) during the berry-ripening stage. The optimum temperatures for blueberry fruit set, size, and ripening are 20−26 °C during the day and 16 °C during the night.[39] However, the temperature conditions registered in location Vc1 during 2014 appeared to be optimal for AC accumulation in blueberries (Figure 3f; Supplementary Table 3). The present results are comparable with studies conducted on grape berries, in which the highest concentration of ACs was recorded in berries grown in temperature regimens with maximum daily temperatures of 25 °C.[40] The AC content instead dramatically dropped when the maximum daily temperatures reached 35 °C.[40]

The present study suggests that temperature is the major environmental factor affecting AC concentration and composition in berries of the *Vaccinium* species under examination. This information will be helpful when the effects of climate change on the species under examination are considered. If the scenarios of global warming to be continued in the future become true, the distribution of bilberry populations may change both in Nordic countries and Alpine environments, and the nutritional value of berries may change consequently. Furthermore, the proportions of specific ACs such as Dp- and Mv-glycosides in bilberry along increasing altitude followed the same trend along increasing latitude, indicating that temperature conditions are related to adaptation of bilberry to the environment.[10,11] The present study indicates that for production of high-quality berries with regard to AC production, bilberry plants located at high latitudes or altitude should be preferred for propagation. However, it is important to take environmental conditions and suitable bilberry genotypes into consideration during the establishment of field propagation. For this purpose, the metabolic profile of individuals within each bilberry population may allow selection of potential genotypes for cultivation and breeding purposes. This aspect is also important to blueberry growers, who may have to compromise agro-economical needs to offer berries with high nutritional value to consumers.

Table 1. Chemical Names, HPLC Retention Times, and TLC R_f Values for (*Z*)-(1*R*,3*R*)-Profluthrin and Its Metabolites

compound	chem name	HPLC t_R [min]	TLC R_f value syst A	syst B
(*Z*)-(1*R*,3*R*)-profluthrin	2,3,5,6-tetrafluoro-4-methylbenzyl (*Z*)-(1*R*,3*R*)-2,2-dimethyl-3-(prop-1-enyl) cyclopropanecarboxylate	50.8	ND[a]	ND
M1	2,3,5,6-tetrafluoro-4-(hydroxymethyl)benzoic acid	11.0	ND	ND
M2	1,4-bis(hydroxymethyl)-2,3,5,6-tetrafluorobenzene	16.0	0.82	0.43
M3	*N*-acetyl-*S*-[2,3,5,6-tetrafluoro-4-(hydroxymethyl)benzyl]cysteine	21.0	ND	ND
M4	2,3,5,6-tetrafluoro-4-methylbenzoic acid	34.1	0.76	0.41
M5	2,3,5,6-tetrafluoro-4-methylbenzyl alcohol	36.6	0.89	0.63
M6	2,3,5,6-tetrafluoro-4-(hydroxymethyl)benzyl (1*R*,3*R*)-2-(1,2-dihydroxypropyl)-3,3-dimethylcyclopropanecarboxylate	30.7, 31.9, 33.9, 35.3[b]	0.71	0.15
M7	2,3,5,6-tetrafluoro-4-(hydroxymethyl)benzyl (*Z*)-(1*R*,3*R*)-2-carboxy-2-methyl-3-(prop-1-enyl) cyclopropanecarboxylate	41.1	0.86	0.45
M8	2,3,5,6-tetrafluoro-4-methylbenzyl (*Z*)-(1*R*,3*R*)-2-(2-carboxyvinyl)-3,3-dimethylcyclopropanecarboxylate	45.2	0.91	0.66

[a]ND: Not determined. [b]This metabolite contains 4 isomers and can be separated under the HPLC conditions.

R_f values for authentic metabolite standards are shown in Table 1, and their structures are shown in Figure 5. Unlabeled (*Z*)-(1*R*,3*R*)-profluthrin (purity: 99.3%) and 6 authentic standards of M1, M2, M4, M5, M6, and M8 were synthesized, and their structures were confirmed using nuclear magnetic resonance (NMR) and mass spectrometry (MS). The spectroscopic information on these 6 metabolites is as follows. M1: ^{1}H NMR (DMSO-d_6, δ in ppm) 4.597 (t, 2H, J = 2 Hz, PhCH_2OH); APCI-MS (negative), m/z = 223 ([M − H]$^-$). M2: ^{1}H NMR (CD_3OD, δ in ppm) 4.716 (t, 4H, J = 1 Hz, PhCH_2OH); ESI-MS (positive), m/z = 218 ([M + Na + H]$^+$). M4: ^{1}H NMR (CD_3OD, δ in ppm) 2.346 (t, 3H, J = 3 Hz, PhCH_3); ESI-MS (negative), m/z = 207 ([M − 1]$^-$). M5: ^{1}H NMR (CD_3OD, δ in ppm) 2.274 (t, 3H, J = 2 Hz, PhCH_3), 4.687 (t, 2H, J = 2 Hz, PhCH_2OH); ESI-MS (positive), m/z = 234 ([M + Na + H]$^+$). M6: ^{1}H NMR (CD_3OD, δ in ppm) 1.111 (d, 3H, J = 6 Hz, CH(OH)CH_3), 1.175 (m, 6H, C(CH_3)$_2$), 1.505 (m, 1H, C*H*CH(OH)), 1.602 (d, 1H, J = 6 Hz, C*H*COO), 3.054 (m, 1H, CHC*H*(OH)CH(OH)), 3.630 (m, 1H, CH(OH)C*H*(OH)CH_3), 4.718 (t, 2H, J = 1 Hz, PhCH_2OH), 5.251 (q, 2H, J = 2, 5 Hz, PhCH_2OCO); ESI-MS (negative), m/z = 379 ([M − H]$^-$). M8: ^{1}H NMR ($CDCl_3$, δ in ppm) 1.219 (s 3H, CCH_3), 1.342 (s, 3H, CCH_3), 1.727 (d, 1H, J = 7 Hz, C*H*COO), 3.313 (m, 1H, CH═CHC*H*), 5.227 (s, 2H, PhCH_2OCO), 5.918 (m, 1H, CHC*H*═CH), 5.918 (m, 1H, CH═C*H*COOH); ESI-MS (negative), m/z = 359 ([M − H]$^-$).

The two other authentic standards, those of M3 and M7, were isolated and purified in our laboratory. Their spectroscopic information is described in Identification of Isolated Metabolites in Results. Other chemicals were reagent grade and were purchased from Nacalai Tesque (Japan) or Wako Pure Chemicals (Japan).

Chromatographic Procedures. HPLC was conducted with a system consisting of an HPLC pump (L-2130, Hitachi, Tokyo, Japan), a UV detector (L-2400, Hitachi), and an online radioactivity monitor (Radiomatic 610TR, PerkinElmer, Waltham, MA, USA) fitted with an ODS column (Atlantis dC18, 5 μm, 4.6 mm i.d. × 150 mm, Waters, MA, USA). The mobile phases were A, 0.05% trifluoroacetic acid, and B, acetonitrile, and gradient conditions were % B = 5% (0 min), 5% (5 min), 25% (15 min), 25% (30 min), 100% (50 min), 100% (55 min) for metabolite analyses and % B = 10% (0 min), 60% (30 min) for purification and for purity analysis of metabolites, at a flow rate of 1 mL/min.

Precoated silica gel 60 F254 chromatoplate (20 × 20 cm, 0.25 or 0.5 mm layer thickness, Merck, Darmstadt, Germany) was used for TLC. The solvent systems were A, ethyl acetate/water/formic acid (35:2:2, v/v/v), and B, toluene/ethyl acetate/formic acid (50:50:1, v/v/v). Unlabeled standards on TLC plates were detected by viewing under UV light (around 254 nm). Radioactivity on TLC plates was detected by scraping−LSC (liquid scintillation counter) method or autoradiography using an imaging plate processed with a fluoro-image analyzer (FLA-5000, Fujifilm, Tokyo, Japan).

Spectroscopic and Spectrometric Analysis. Chemical structures of purified metabolites were determined using NMR spectrometry and mass spectrometry together with high performance liquid chromatography (LC/MS). ^{1}H NMR spectra were obtained with a Unity 400 plus spectrometer (Varian, Palo Alto, CA, USA) operating at 400 MHz with methanol-d_4, DMSO-d_6, or chloroform-d as the solvent. LC/MS spectra were obtained with an LTQ XL (Thermo Fisher Scientific, Waltham, MA, USA).

Treatment of Animals. Male and female Crl:CD(SD) untreated rats at the age of 6 weeks and bile duct cannulated rats at the age of 8 weeks were purchased from Charles River Japan Inc. (Kanagawa, Japan) and maintained under constant environmental conditions: room temperature of 21−25 °C; relative humidity of 55 ± 15%; ventilation of 10 air exchanges per hour; and artificial lighting from 8:00 am to 8:00 pm. Animals had free access to pelleted diet and water throughout the study. All animal experiments were conducted in accordance with the Guidance for the Care and Use of Laboratory Animals in our laboratory, which corresponds to the Guidelines for Proper Conduct of Animal Experiments (Science Council of Japan). All tested animals except bile duct cannulated rats showed normal weight gain and no abnormal clinical symptoms during 7 days of quarantine and acclimation, and their body weights were 250−306 g for males and 177−215 g for females when dosed. Bile duct cannulated rats were dosed on the day of arrival. All animals were euthanized by bleeding from the abdominal artery under anesthesia.

Preparation of Dosing Solutions. [Benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin was radiochemically diluted with unlabeled (*Z*)-(1*R*,3*R*)-profluthrin with a specific activity of 6.51 MBq/mg for low dose and 108 kBq/mg for high dose. The test compound was dissolved in corn oil to give 1 and 60 mg/5 mL in the dosing solutions. The radiochemical purities of the ^{14}C-labeled compound in the dosing formulations were analyzed by HPLC, and were confirmed to be 100% for all the dose groups.

^{14}C-Excretion Study. Male and female rats at 7 weeks old were given a single oral dose of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at 1 and 60 mg/kg/5 mL of corn oil at 4 animals per group, and the animals were housed separately in glass metabolism cages (Metabolica CO_2, Sugiyamagen Iriki, Tokyo, Japan) to collect urine, feces, and expired air. Urine and feces from each rat were collected at 6 and 12 h (urine only), and 1, 2, 3, 5, and 7 days after administration. Expired air was passed through an alkaline trap containing 10% NaOH solution for 1 day after administration to collect expired CO_2 gas. Following the collection of feces and urine, each metabolism cage was washed with water to recover the remaining ^{14}C (cage-wash). Radioactivity in the cage-wash was included in the urinary excretion.

Biliary Excretion Study. Bile duct cannulated rats at 8 weeks old were given a single oral dose of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at 1 mg/kg/5 mL of corn oil at 4 animals per group, and the animals were housed separately in glass metabolism cages. In addition to collecting urine and feces, bile was collected with a free

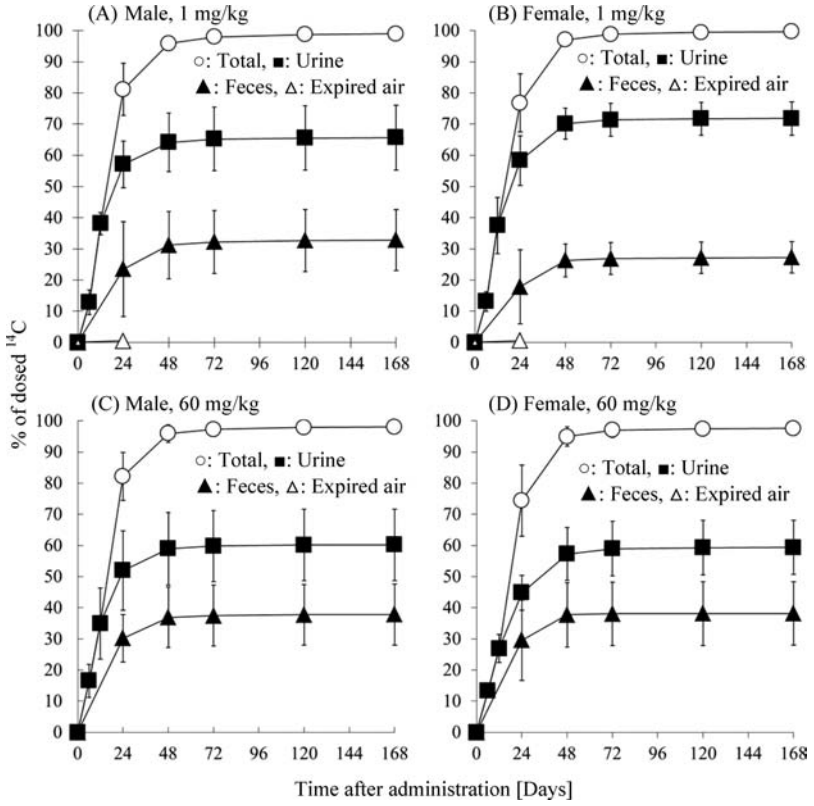

Figure 2. Cumulative ^{14}C-excretion after single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin to rats. Points and bars are mean values and standard deviations for data from four rats.

moving system adapted to the cages at 6 and 12 h (urine and bile), and 1, 2, and 3 days after administration.

Plasma ^{14}C Concentration Study. Male and female rats at 7 weeks old were given a single oral dose of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at 1 and 60 mg/kg/5 mL of corn oil at 3 animals per group. Blood samples were collected from tail vein at 15 and 30 min, and 1, 2, 4, 6, 8, 12, 24, 48, 72, 120, and 168 h after the administration, and aliquoted into vials. The rest of the blood was centrifuged at 3000*g* for 10 min, and separated blood cells and plasma were transferred to vials. Maximum plasma concentration (C_{max}, μg equiv of (*Z*)-(1*R*,3*R*)-profluthrin/g) and time to peak concentration (T_{max}, h) were obtained from the actual measured values. Area under the concentration−time curve to 168 h (AUC_{0-168h}, μg equiv of (*Z*)-(1*R*,3*R*)-profluthrin·h/g) was determined by trapezoid method for the time interval of actual measurement of concentration, assuming the value of "0 μg/mL" as the concentration at time 0. Half-life of radioactivity was obtained by calculating ln 2/α of the slope (α) of a regression line fitted to the β phase of plasma concentration curve (48 to 168 h without including values less than the quantification limit), with the least-squares method.

^{14}C-Tissue Distribution Study. Male and female rats at 7 weeks old were given a single oral dose of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at 1 and 60 mg/kg/5 mL of corn oil at 4 time points per dose and sex, and 3 or 4 animals each per group. The animals were euthanized after the defined time points, and the tissues were dissected for the radioanalysis. Duplicate aliquots of blood were collected, and the remaining blood was separated into blood cells and plasma by centrifugation at 2000*g* for 10 min. The residual carcasses were solubilized with 3 M KOH alkaline solution. The percentage of the ^{14}C-distribution to tissue was calculated on the basis of the weight of each tissue dissected, except blood, bone, fat, muscle, and skin, for which the actual weight cannot be measured.

Measurement of Radioactivity. Radioactivity in urine, cage wash, bile, $^{14}CO_2$-trapped alkaline solution, solubilized carcass (decolorized by hydrogen peroxide), and organosoluble fraction was directly quantified with a Tri-Carb 2700TR liquid scintillation (LS) analyzer (PerkinElmer) after mixing with scintillation cocktail, Emulsifier Scintillator Plus or Hionic Fluor (PerkinElmer). Feces (homogenized with 2 times weight of water), blood, plasma, blood cell, tissues, and unextractable fecal residues were combusted with a 308 sample oxidizer (PerkinElmer) prior to LS analysis. As the $^{14}CO_2$ absorbent and the scintillator, 8 mL of Carbo Sorb and 8 mL of Permafluor E$^+$ (PerkinElmer) were used, respectively.

Isolation and Purification of Metabolites. Two metabolites (M3 and M7 in Table 1) were isolated from rat excreta by HPLC and TLC. Three female rats were given a single oral dose of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at 50 mg/kg/5 mL of corn oil and housed in metabolism cages. Urine sample was collected 1 day after administration, and a small part of the sample was applied to HPLC analysis. Fractions eluted at 22 and 42 min were collected, and these fractions were used as crude standards for the further purification procedures of M3 and M7, respectively. The rest of the urine sample was applied to preparative TLC analysis (solvent system A) after extraction with ethyl acetate or HCl-acidified ethyl acetate. Separated organosoluble fractions were collected, concentrated, and then applied to preparative HPLC for purification. The purified metabolites were identified by spectroanalyses, and then used as metabolite standards of M3 and M7.

Metabolite Analysis. Urine, bile, and homogenate of feces in the excretion study and plasma and homogenate of liver and kidney in the tissue distribution study were analyzed with HPLC. Homogenates of feces, liver, and kidney and plasma samples were applied to HPLC after extraction with 3-fold volume of methanol and concentrated. Major unknown metabolites were isolated by HPLC and applied to enzyme hydrolysis under the following conditions: metabolites were incubated with β-glucuronidase/aryl sulfatase (from *Helix pomatia*, Merck) in 0.2 M acetic acid buffer (pH 5.0) with or without β-glucuronidase inhibitor, D-saccharic acid 1,4-lactone, at 37 °C for 4 h. Assay was terminated by adding 2 times of acetonitrile, and the supernatant was applied to 2D TLC analysis (first D, solvent system A; second D, solvent system B). Consistency of metabolites was confirmed against authentic standards by 2 of the following 3

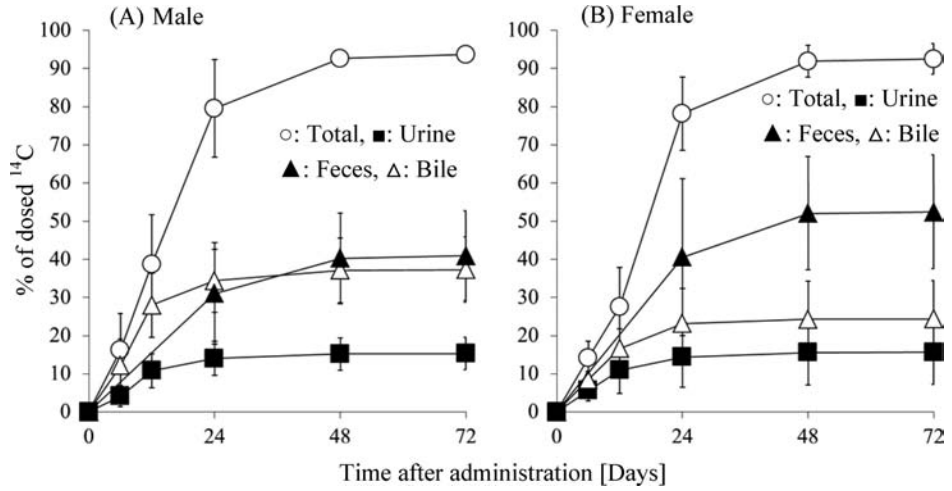

Figure 3. Cumulative ^{14}C-excretion after single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at the dose of 1 mg/kg to bile duct cannulated rats. Points and bars are mean values and standard deviations for data from four rats.

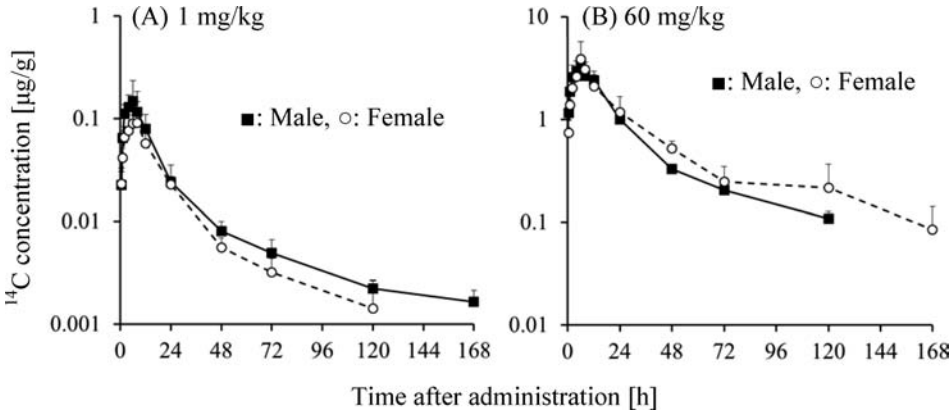

Figure 4. Plasma concentration after single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin to rats.

methods: (1) comparing their retention time in radio-HPLC analysis against coeluted authentic standards, (2) cochromatography of TLC analysis, and (3) comparing MS and MS/MS spectra in LC/MS analysis against those of authentic standards.

RESULTS

^{14}C-Elimination into Urine, Feces, and Bile. ^{14}C-Excretion profiles into urine, feces, and expired air during 7 days after a single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin to normal rats are shown in Figure 2. ^{14}C was rapidly and almost completely excreted into urine and feces when dosed at 1 and 60 mg/kg. ^{14}C-Excretion into expired air was not more than 1% at 1 day after the administration at low dose, thus it was not examined further nor at high dose since it could be regarded as negligible. ^{14}C-Excretion within 7 days after administration was 99.0% (feces, 32.8%; urine, 65.6%; and expired air, 0.5%) in male rats and 99.7% (feces, 27.3%; urine, 71.8%; and expired air, 0.6%) in female rats at 1 mg/kg groups. At high dose, ^{14}C-excretion was 98.1% (feces, 37.8%; and urine, 60.2%) in male rats and 97.6% (feces, 38.2%; and urine, 59.4%) in female rats, which revealed that the ratio excreted through urine was approximately 10% lower at high dose. No marked sex-related differences were observed in the rate of ^{14}C-elimination.

The ^{14}C-excretion rates within 2 days after a single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at a dose of 1 mg/kg (low dose) to bile duct cannulated rats are shown in Figure 3. ^{14}C-Excretion was rapid in both males and females with average rates for 3 animals of 93.6% in males (41.0% in feces, 15.3% in urine, and 37.3% in bile), and 92.5% in females (52.4% in feces, 15.7% in urine, and 24.4% in bile) within 3 days after administration.

Plasma ^{14}C Concentration Study. The plasma−concentration curves after a single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at low and high doses are shown in Figure 4, and the kinetic parameters are shown in Table 2. At both low and high dose, plasma ^{14}C concentration was rapidly increased and reached C_{max} at 6 to 8 h after the

Table 2. Pharmacokinetic Parameters of ^{14}C in Plasma after Single Oral Administration of [Benzyl-α-^{14}C]-Labeled (*Z*)-(1*R*,3*R*)-Profluthrin to Male and Female Rats at 1 and 60 mg/kg

administration. The elimination of ^{14}C was comparatively slow, and the half-lives were around 2 days. C_{max} and AUC of the high dose group were 24−43 times and 32−53 times higher at high dose when compared to low dose, respectively. There were no marked sex-related differences in kinetics of (*Z*)-(1*R*,3*R*)-profluthrin.

^{14}C Concentrations in Tissues. The ^{14}C concentration−time profiles in tissues after a single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at low and high doses are shown in Tables 3 and 4, respectively. The ^{14}C concentrations in most of the tissues other than gastrointestinal tract were highest at first sampling time, 6 to 8 h after administration, and thereafter decreased rapidly. For almost all groups and all time points, liver showed the highest radioactivity, followed by fat, thyroid gland, uterus, ovary, kidney, skin with hair, blood cells, and adrenal gland. At the last time point, 7 days after the administration, total residual radioactivity was no more than 0.3% of administered dose, which indicates that the dosed (*Z*)-(1*R*,3*R*)-profluthrin was rapidly excreted from the body, and showed no accumulation to specific organs or tissues.

Identification of Isolated Metabolites. The unknown metabolites detected in urine were purified and identified by both NMR spectroscopic technique and MS spectrometric analysis. ^{1}H NMR data of identified metabolites are shown in Table 5.

M3. In the ^{1}H NMR spectrum, the signal from the benzyl proton at 5.23 ppm (2H, t) detected in (*Z*)-(1*R*,3*R*)-profluthrin was observed as the methylene signal at 3.89 ppm (2H, dd), and the signal from the 4-methyl group at 2.29 ppm (3H, t) was observed as the hydroxymethyl group at 4.70 ppm (2H, s). In addition, signals from one methyl group and one methine group were observed at 1.99 ppm (3H, s) and 4.51 ppm (1H, m), and one methylene group was observed at 2.89 ppm (1H, dd) and 3.09 ppm (1H, dd), respectively. In APCI-MS measurement in the positive ion mode, protonated ion peak m/z = 356 $[M + H]^+$ was observed, and from the MS/MS analysis of the protonated ion, dehydrated ion, m/z = 338 $[M + H - H_2O]^+$, and the ion supposed to be derived from *N*-acetyl-L-cysteine, m/z = 162 $[C_5H_8NO_3S]^+$, were also detected. Based on these results, M3 was considered to be an *N*-acetyl-L-cysteine (mercapturic acid) conjugate of M2.

M7. In the ^{1}H NMR spectrum, the signal from proton of 4-methyl group at 2.29 ppm (3H, t) detected in (*Z*)-(1*R*,3*R*)-profluthrin was observed as the methylene signal at 4.71 ppm (2H, s), and the signal from the methyl group at 1.14 ppm (3H, s) was not observed. In APCI-MS measurement in the positive ion mode, molecular ion peak m/z = 377 $[M + H]^+$ was obtained, and as its product ions in the MS/MS analysis, dehydrated ion, m/z = 359, and the ion supposed to be derived

from acid side (i.e., 2,2-dimethyl-3-(prop-1-enyl)-cyclopropanecarboxylate), m/z = $[C_9H_{11}O_3]^+$, were detected. M7 was considered to be formed from (*Z*)-(1*R*,3*R*)-profluthrin via hydroxylation of 4-methyl group and oxidation of one of the methyl groups bound to the 2-cyclopropane ring to give a carboxylic acid.

Amounts of Metabolites in Urine, Feces, and Bile. Amounts of metabolites (% of the dose ^{14}C) in urine and feces within 2 days after single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin to normal rats are presented in Table 6. In feces, (*Z*)-(1*R*,3*R*)-profluthrin was the most abundant, especially at high dose. Only M7 was identified as a metabolite in the feces, but the amount was not so large (not more than 2.11%). In urine, 8 metabolites, including 3 glucuronides, were identified. A glucuronide of M5 (M5-glu) was the most abundant in urine, followed by a glucuronide of M2 (M2-glu). The sum of these two metabolites was 44 to 51% of dosed ^{14}C in all groups. M1 and M4, which are oxidized metabolites of M2 and M5, and M3, which is a mercapturic acid conjugate of M2, were also detected in urine, but the amounts were each around 2 to 5% of the dosed ^{14}C. As the ester-retaining metabolites, only M7 and its glucuronide were detected. The sums of these metabolites in urine and feces were 1 to 12%, which indicates that (*Z*)-(1*R*,3*R*)-profluthrin is easily cleaved at its ester bond.

Amounts of metabolites (% of the dosed ^{14}C) in urine, feces, and bile within 2 days after single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin to bile duct cannulated rats are shown in Table 7. Ten metabolites, including 4 glucuronides, were identified in bile and urine. Composition of metabolites identified in urine of bile-cannulated rats was similar to that of normal rats. In bile, M5-glu was most abundant followed by M2-glu, M6-glu, M8, M7, and M7-glu. As the nonhydrolytic metabolites that were not observed in urine, M6-glu and M8 were detected in bile and the amounts were small (0 to 3%). No unchanged (*Z*)-(1*R*,3*R*)-profluthrin was detected in bile or urine, and the major components in bile were almost similar to those in urine. Also, the metabolites identified in bile were rarely detected in feces of normal rats, which suggests that the metabolites excreted via bile were mostly reabsorbed in the intestinal tract, and finally excreted via urine.

Metabolites in Blood, Kidney, and Liver. Concentrations of metabolites in liver, kidney, and plasma of rats after a single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin at low dose and high dose are presented in Table 8. In kidney, the components of metabolites in the methanol-extractable fraction were almost similar to those in urine, and M5-glu was the most abundant metabolite, followed by M7, M7-glu, M2, M2-glu, and M3. In liver, the ratios of the ester metabolites were higher than those in urine or kidney, and M7 and its glucuronide were the most abundant. As another ester metabolite that was not observed in urine, M8 was also detected in liver. This metabolite was also detected in plasma of the low dose group. M5-glu, M7, M2, and its glucuronide were also observed in plasma.

DISCUSSION

There were no significant sex- or dose-related differences on the ADME profile of (*Z*)-(1*R*,3*R*)-profluthrin. After single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-proflu-

[a]ND: Not detected.

thrin to male and female rats, the ^{14}C concentration in plasma rapidly reached C_{max} (0.148 and 0.091 μg equiv/g at low dose and 3.54 and 3.87 μg equiv/g at high dose, respectively) at 6 to 8 h after the administration. Radioactivity in plasma was time-dependently decreased with a half-life of 37.3 to 52.2 h, and the tendency of elimination of ^{14}C in tissues and organs was almost the same as that in plasma. ^{14}C concentrations in major tissues reached a peak within 6 to 8 h for both low and high dose, and thereafter decreased rapidly to low levels on the seventh day. Remaining ^{14}C in whole body was less than 0.3% of the dosed ^{14}C at 168 h after the administration, and no organ-specific accumulation was observed.

Dosed ^{14}C was rapidly and almost completely excreted within 2 days after administration with the major route of urine. The amounts of excreted ^{14}C into the urine and feces were 59.3 to 71.7% and 27.2 to 38.2%, respectively, with total recoveries of 98.1 to 99.7%. The amount of ^{14}C excreted into urine (59.3% to 71.7% of the dose) was considered to be absorbed from the gastrointestinal (GI) tract and excreted. In the biliary excretion study, the amounts of excreted ^{14}C into urine, bile, and feces were 15.3 to 15.7%, 24.4 to 37.3%, and 41.0 to 52.4%, respectively. GI absorption rates were evaluated to be 53.2% and 40.3% for males and females, respectively, as the sum of ^{14}C detected in urine, bile, and residual carcass, and they were lower than the amount excreted into urine from normal rats. It has been reported[12−14] that the decreased intestinal absorption due to the lack of bile components (i.e., taurocholate) in the intestinal fluid was observed by bile duct cannulation, and the situation was supposed to occur also for (Z)-(1R,3R)-profluthrin. Since no parent compound was detected in bile and almost all of the ^{14}C components in feces were derived from the unchanged (Z)-(1R,3R)-profluthrin, it was suggested that the amount of ^{14}C excreted into feces can be regarded as unabsorbed, and it was considered that the amount of ^{14}C excreted into urine under normal conditions can alter the intestinal absorption rate. On these bases, intestinal absorption rates were determined to be approximately 65.6 to 71.8% at low dose and 59.4 to 60.2% at high dose, which suggests a 6 to 12% decrease in intestinal absorption at high dose. The obtained parameters of AUC in the kinetic study were 32−53 times higher at high dose, and were lower than the actual dose ratio,

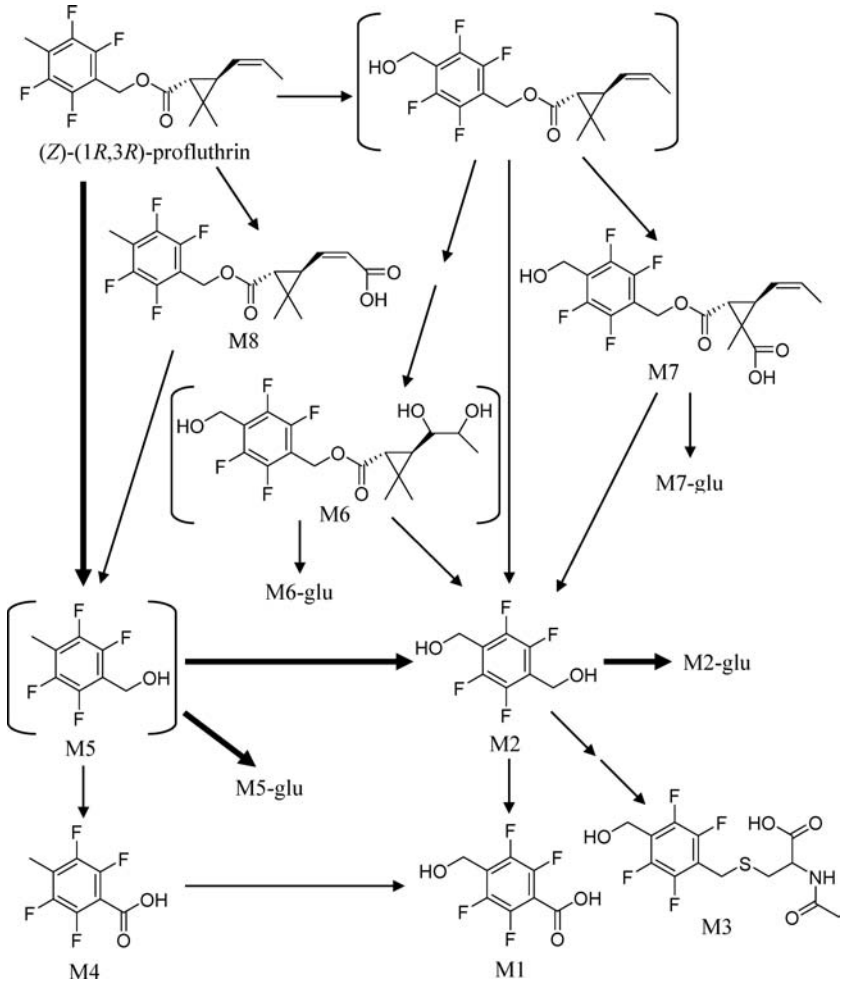

Figure 5. Proposed metabolic pathways of (*Z*)-(1*R*,3*R*)-profluthrin in rats.

60 vs 1 mg/kg. These results were also considered to support the saturation of absorption at the high dose.

As shown in Tables 6 and 7, 10 metabolites, including 4 glucuronides, were identified in bile, feces, and urine within 2 days after single oral administration of [benzyl-α-^{14}C]-labeled (*Z*)-(1*R*,3*R*)-profluthrin. In both urine and bile, glucuronic acid conjugate of the ester-hydrolyzed metabolite, M5-glu, was most abundant, followed by M2, M7, and their glucuronides. Only in urine, M4, M1, and M3 (a mercapturic acid conjugate of M2) were detected. M6-glu and M8 were both ester metabolites, and were only detected in bile and in small amounts. The composition of metabolites identified in urine of bile-cannulated rats was similar to that of normal rats.

The proposed metabolic pathways of (*Z*)-(1*R*,3*R*)-profluthrin are shown in Figure 5. The main metabolic reactions are the cleavage of the ester bond, hydroxylation of the methyl group on the C4 of the phenyl ring, and monoglucuronidation of these metabolites. Also, oxidation of the methyl group on the C2 of the cyclopropane ring, hydration of the double bond of propenyl group following the epoxidation, ω-hydroxylation of propenyl group, and oxidation and conjugation with mercapturic acid of benzyl alcohol were observed as minor reactions.

As described previously, it is commonly observed for synthetic pyrethroids that they are mostly metabolized via cleavage of ester bond followed by oxidation and glucuronidation,[1,4,5] and these reactions were also observed with (*Z*)-(1*R*,3*R*)-profluthrin. The extent of metabolic transformation of (*Z*)-(1*R*,3*R*)-profluthrin is summarized in Table 9. In urine and feces, 55% to 58% of dosed ^{14}C was excreted as ester-cleaved metabolites, while 1% to 12% (not including unchanged (*Z*)-(1*R*,3*R*)-profluthrin in feces) was confirmed to be ester-retaining. As we indicated above, the existence or nonexistence of cyano moiety on its α-position of the alcohol side and the stereochemical conformations of the 1- and 3-positions of cyclopropane can affect the ratio of ester linkage-retained metabolites.[1,4,6−8] Since (*Z*)-(1*R*,3*R*)-profluthrin does not have cyano moiety on its α-position of the alcohol side and its steric conformation about the substituent of 1- and 3-cyclopropane is *trans*, it was supposed to be easily hydrolyzed. Actually, the amount of ester metabolites in excreta was between 1 and 16%,

Table 9. Extents of Metabolic Transformations (%)

mercapturic acid conjugate	3	3	1	2

[a]Not including unchanged (*Z*)-(1*R*,3*R*)-profluthrin.

DOI: 10.1021/acs.jafc.5b03321
J. Agric. Food Chem. 2015, 63, 8651−8661

relatively low, and thus in agreement with the known rules for pyrethroid metabolism.

As also shown in Table 9, the amounts of ester metabolites in excreta, which consisted of M7 and its glucuronide, were significantly higher at low dose than at high dose, and in contrast, the amount of C4-hydroxylated metabolites, which consisted of M1, M2-glu, M2, M3, M4, M5-glu, M7, and M7-glu, decreased at high dose, probably due to the saturation of C4 hydroxylation at high dose. The reason for the decrease in ester-retaining metabolites remains unclear, but it is considered a possibility that the polarization step of Ph−C4 hydroxylation was saturated at high dose, and the rate of ester cleavage relatively increased.

As an S-containing metabolite, M3 (a mercapturic acid conjugate of M2) was detected in urine, bile, and tissues in small amount. The metabolic pathway of mercapturic acid conjugate has been well characterized for many pesticides and chemicals previously.[15−20] van Doorn et al. reported mercapturic acid conjugation of benzyl group in the metabolism of toluene and xylene.[17] M3 was also supposed to be produced via conjugation of glutathione, amide cleavage of glutamate and glycine, and addition of acetyl group to the amino group of the cysteine moiety.

In this study, only alcohol side labeled compound was used to determine the metabolic fate of (*Z*)-(1*R*,3*R*)-profluthrin, and thus the further metabolism of the acid side following the ester cleavage has not been investigated. The acid side, 2,2-dimethyl-3-(prop-1-enyl)cyclopropanecarboxylic acid, is almost similar to chrysanthemic acid, with the only difference being the presence of methyl moiety of the 2-propenyl moiety. There are many pyrethroids with chrysanthemic acid as an acid moiety, i.e., tetramethrin, phenothrin, cyphenothrin, empenthrin, and allethrin. The metabolic fate of chrysanthemic acid is well characterized.[6−8] In short, the ω-position of chrysanthemic acid is oxidized to alcohol and carboxylic acid, and/or conjugated to glucuronide, and rapidly excreted mainly in urine. These previous reports, including the metabolism of chrysanthemic acid, provide sufficient basis on which to estimate the metabolic pathways of the acid side of (*Z*)-(1*R*,3*R*)-profluthrin; however, further experimentation with acid side labeled (*Z*)-(1*R*,3*R*)-profluthrin or other compound that has the same substructure is considered to be prudent to elucidate the whole metabolic fate of (*Z*)-(1*R*,3*R*)-profluthrin.

In conclusion, the metabolic fate of (*Z*)-(1*R*,3*R*)-profluthrin in rat is almost completely revealed. Dosed (*Z*)-(1*R*,3*R*)-profluthrin was absorbed approximately 70% in intestine, and excreted rapidly, mainly via urine. Absorbed ^{14}C was once excreted into bile as metabolites, but most of this was reabsorbed, underwent enterohepatic circulation, and finally was excreted into urine. The plasma concentration reached the peak at 6 to 8 h, and decreased with a half-life of 37 to 52 h. ^{14}C concentration in tissues also decreased at basically the same rate as in plasma. When dosed at 60 mg/kg, saturation of the absorption occurred, and the rate decreased to approximately 60%. There were no marked differences in the kinetics or ^{14}C distribution to tissues and organs. The most abundant metabolite in urine was M5-glu, followed by M2-glu. As minor metabolites, M3 (a mercapturic acid conjugate of M2), M1, and M4 (oxidized metabolites of M2 and M5) and M7 and its glucuronide were also detected. In the feces, most of the detected radioactivity was derived from unabsorbed (*Z*)-(1*R*,3*R*)-profluthrin, especially in the high dose group. The main routes of the metabolism are the cleavage of the ester bond, hydroxylation of the methyl group on the C4 of the phenyl ring, and its glucuronidation. Also, oxidation of the methyl group on the C2 of the cyclopropane ring, hydration of the double bond of propenyl group following the epoxidation, ω-hydroxylation of propenyl group, and oxidation and conjugation with mercapturic acid of benzyl alcohol were observed as minor reactions. Decreased ester metabolites were observed at high dose, and it was probably due to the saturation of Ph−C4 hydroxylation; however, there were no qualitative differences between high dose and low dose. No marked sex-related differences were observed in ^{14}C-elimination, ^{14}C-distribution, or metabolite profiles.

indicated that ~50% and ~70% of them, respectively, were bioaccessible upon in vitro gastrointestinal digestion conditions. The authors did not detect free crocetin in the saffron extract digestate, a finding verified a few years later by Lautenscläger et al. (2015).[8] In vivo studies, however, point out that crocetin is the form detected in biological fluids,[9−11] suggesting that this is the most biologically relevant form. In addition, Lautenscläger et al. (2015)[8] detected free crocetin in the digestate only when they added a freshly prepared tissue homogenate from purged small mouse intestine to their in vitro model. However, no information is available in the literature for the intestinal absorption and metabolism of picrocrocin.

The present study aimed at investigating the cellular transport of the second major saffron apocarotenoid picrocrocin as this glucoside is coextracted with crocetin sugar esters using water or alcoholic mixtures. A Caco-2 cell model coupled with an in vitro digestion procedure was employed. Caco-2 cells are human colon adenocarcinoma cells, which can be differentiated to resemble small intestinal epithelial cells.[12] This cell line is a well-established tool for the in vitro assessment of cellular transport and prediction of the bioavailability of nutrients and non-nutrient bioactive compounds (e.g., carotenoids and phenols). Using the same model, the cellular transport of pure picrocrocin was also investigated in comparison to that of the other two major saffron apocarotenoids, i.e., *trans*-crocetin (di-β-D-gentiobiosyl) ester (*trans*-4-GG crocetin ester) and crocetin. Moreover, the potential biological activity of picrocrocin in terms of protection against oxidant-induced DNA damage in U937 cells and antiproliferative effects in Caco-2 and HepG2 cells were also investigated using the Comet and MTT assays, respectively. The data of the present study will add to existing knowledge on the degree of cellular transport of polar apocarotenoids and also to the limited information regarding the bioactivity of picrocrocin. Our findings may also be useful to the requirements of food legislation regarding saffron preparations.

MATERIALS AND METHODS

Chemicals. Authentic Greek saffron (harvest year 2013, Category I according to ISO 3632-1 specifications[13]) was donated by the Saffron Cooperative of Kozani (Greece).

All of the chemicals were of the highest purity needed for each assay. In particular, the enzymes (pepsin, pancreatin) and bile salts used were from Sigma Chemical Co. (Dublin, Ireland). Fetal bovine serum (FBS) was purchased from Invitrogen (Paisley, Scotland, UK). Dulbecco's Modified Eagle's Medium (DMEM), Hank's Balanced Salt Solution (HBSS), and RPMI-1640 medium were from Sigma Chemical Co. (Dublin, Ireland). Cell culture plastics were supplied by Cruinn Diagnostics (Dublin, Ireland). Corning 24 mm transwell plates with collagen coated PTFE membrane and 0.4 μm pore size (product code: CLS3491) were supplied by Sigma Chemical Co. (Dublin, Ireland). All solvents used were of HPLC grade. Ultrahigh purity water was produced in the laboratory using a SG Ultra Clear Basic UV system (SG Wasseraufbereitung and Regenerierstation GmbH, Barsbüttel, Germany).

Apocarotenoid Isolation. Individual apocarotenoids were isolated and characterized as follows:

Picrocrocin Isolation. Picrocrocin was isolated according to Sánchez et al. (2009).[14] Purity (91%) of the isolated compound was checked chromatographically by RP-HPLC-DAD (HPLC system I) and calculated as the percentage of the total peak area at 250 nm. The HPLC system I consisted of a pump, model P4000 (Thermo Separation Products, San Jose, CA, USA), a Midas autosampler (Spark, Emmen, The Netherlands), and a UV 6000 LP diode array detector (DAD) (Thermo Separation Products, San Jose, CA, USA). Separation was carried out on a LiChroCART Superspher 100 C18 (125 mm × 4 mm i.d.; 4 μm) column (Merck, Darmstadt, Germany). The elution system used consisted of a mixture of water:acetic acid (1%, v/v) (A) and acetonitrile (B). The linear gradient was 20−100% B in 20 min. The flow rate was 0.5 mL/min. Chromatographic data were processed using the ChromQuest Version 3.0 software (Thermo Separation Products, San Jose, CA, USA). Monitoring was in the range of 200−550 nm. Its identity was confirmed by LC-ESI-MS analysis (model 2010 EV, Shimadzu, Kyoto, Japan) and by nuclear magnetic resonance (NMR) spectroscopy recording the ^{1}H 1D spectra at 300 MHz on a Bruker 300AM spectrometer (Rheinstetten, Germany) (see Supporting Information I).

trans-4-GG Crocetin Ester Isolation. The procedure described below was according to Kyriakoudi et al. (2012).[3] In particular, saffron stigmas were carefully ground with an agate pestle and mortar and passed through a 0.4 mm sieve just prior to further analysis. Finely ground saffron (0.36 g) was extracted with ultrahigh purity water (20 mL) with the aid of ultrasounds for 30 min. Sample temperature was kept at 15 ± 0.5 °C in a thermostated water bath. The extract was centrifuged (4100 rpm, 15 min, 4 °C), and the supernatant was lyophilized and stored at −22 °C until further use. *trans*-4-GG crocetin ester was then isolated by semipreparative RP-HPLC (HPLC system II). The system consisted of two Marathon IV series HPLC pumps (Rigas Laboratories, Thessaloniki, Greece), a Rheodyne injection valve (model 7125) with a 250 μL fixed loop (Rheodyne, Cotati, CA), and a diode array linear UVIS-206 multiple wavelength detector (Linear Instruments, Fermont, CA). Separation was carried out on a Nucleosil 100 C18 (250 mm × 10 mm i.d.; 7 μm) chromatographic column (Macherey-Nagel, Düren, Germany). The gradient elution system used consisted of water (A) and methanol (B). The gradient was: 0 min, 30% (B), 0−10 min, 45% (B), 10−20 min, 70% (B), 20−30 min, 100% (B), 30−40 min, 100% (B), 40−50 min, 30% (B) with a flow rate of 3.0 mL/min. Monitoring was at 440 nm. Purity (97%) of isolated *trans*-4-GG crocetin ester was checked chromatographically by RP-HPLC-DAD (HPLC system I) in the range 200−550 nm and calculated as the percentage of the total peak area at 440 nm. The identity of the isolated *trans*-4-GG crocetin ester was confirmed by LC-ESI-MS analysis and by NMR spectroscopy, recording the ^{1}H 1D spectra at 300 MHz on a Bruker 300AM spectrometer (Rheinstetten, Germany) (see Supporting Information II).

Crocetin Preparation. Crocetin was prepared from an aqueous saffron extract by acid hydrolysis according to a protocol described by Ordoudi et al. (2009).[15] Purity (99%) of isolated crocetin was checked chromatographically by RP-HPLC-DAD (HPLC system I) in the range of 200−550 nm and calculated as the percentage of the total peak area at 440 nm. Its identity was confirmed by LC-ESI-MS analysis and by NMR spectroscopy recording the ^{1}H 1D spectra at 500 MHz on a Agilent spectrometer (California, United States) (see Supporting Information III).

Preparation and Characterization of Saffron Aqueous Extract. Saffron was carefully ground with a pestle and mortar just prior to analysis. The finely ground plant material (0.05 g) was extracted with ultrahigh purity water (100 mL) by rigorous agitation (~500 rpm) at ambient temperature for 1 h. All manipulations were performed under subdued (yellow) light to minimize photodecomposition of crocetin esters. The characterization was achieved using RP-HPLC. The HPLC system (HPLC system III) (Finnigan Spectra system; Thermo Scientific, Philadelphia, PA) consisted of a P2000 pump, a AS300 autosampler, and a diode array detector (DAD; Finnigan Spectra system; Thermo Scientific, Philadelphia, PA). Separation was carried out on the same chromatographic column [LiChroCART Superspher 100 C18 (125 mm × 4 mm i.d.; 4 μm) column (Merck, Darmstadt, Germany)]. The elution system consisted of a mixture of water:acetic acid (1%, v/v) (A) and acetonitrile (B). The linear gradient was 20−100% B in 20 min. The flow rate was 0.5 mL/min, and the injection volume was 20 μL. Chromatographic data were processed using ChromQuest software (version 4.2, Thermo Fisher Scientific). Monitoring was in the range of 200−550 nm. Quantification of picrocrocin was accomplished with the aid of a

DOI: 10.1021/acs.jafc.5b03363
J. Agric. Food Chem. 2015, 63, 8662−8668

proper calibration curve ($y = 12830x - 2950$; $R^2 = 1.00$; 9.8−570 ng/20 μL injected volume; $n = 6$). The total and major individual crocetin esters content of saffron was also determined by constructing a calibration curve of pure *trans*-4-GG crocetin ester ($y = 35561x - 381548$; $R^2 = 0.99$; 12−600 ng/20 μL injected volume; $n = 6$).

In Vitro Gastrointestinal Digestion Procedure. The in vitro digestion procedure was carried out as previously described by Kyriakoudi et al. (2013).[7] Briefly, aliquots (2 mL) of the saffron aqueous extract were transferred into amber bottles and HBSS was added to a final volume of 20 mL. To each bottle, 1 mL of freshly prepared pepsin (0.04 g pepsin/0.1 mol/L HCl) was added and the pH was acidified to 2.0 using 1 mol/L HCl. The samples were overlaid with nitrogen gas and incubated at 37 °C for 1 h in a shaking water bath (Grant, OLS200; Keison Products, Chelmsford, Essex, UK) at 95 rpm to mimic the gastric phase of human digestion. The intestinal phase involved increasing the pH to 5.3 with 0.9 mol/L sodium bicarbonate, followed by the addition of 200 μL of bile salts glycodeoxycholate (0.8 mmol/L), taurodeoxycholate (0.45 mmol/L), and taurocholate (0.75 mmol/L) and 100 μL of porcine pancreatin (0.08 g/mL HBSS). The final pH was adjusted to 7.4 using 1 mol/L NaOH. Samples were overlaid with a layer of nitrogen gas and incubated at 37 °C for 2.5 h to mimic the duodenal phase of human digestion. After the intestinal phase, the digestate was centrifuged at 14000*g* using a Sigma 4K15 centrifuge (SIGMA Laborzentrifugen GmbH, Osterode am Harz, Germany) for 60 min at 4 °C. After centrifugation, the supernatants were collected and filtered through a 0.45 μm membrane filter. The resulting filtrates were stored at −80 °C until further analysis.

Cellular Transport of Picrocrocin. Human colon adenocarcinoma Caco-2 cells were purchased from the European Collection of Animal Cell Cultures (Salisbury, Wilts, UK). Cells were maintained in the DMEM supplemented with 10% (v/v) fetal bovine serum and 1% (v/v) nonessential amino acids. Cells were grown at 37 °C in a humidified incubator with 5% CO_2 in the absence of antiobiotics. Culture medium was replaced three times a week. Caco-2 cells were seeded at a density of 1.0×10^5 cells/mL on transwell inserts in 6-well transwell plates. Cells were maintained in DMEM (10% FBS) for 21−25 days to obtain a differentiated cell monolayer; media was changed every 2−3 days. Transepithelial electrical resistance (TEER) measurements were taken before each transport experiment by a transepithelial electrical resistance voltohmmeter (Millicel-ERS, Merck Millipore, Merck KgaA, Darmstadt, Germany) to ensure that the monolayer was intact. Only inserts with TEER values >250 $\Omega \cdot cm^2$ in culture medium were selected for transport experiments. At the beginning of each experiment, the insets were washed twice with 2 mL of HBSS.

Saffron Extract Digestate. The apical (mucosal) compartment received increasing volumes of the saffron extract digestate diluted with HBSS up to a final volume of 2 mL. The basolateral (serosal) compartment received 1.5 mL of HBSS.

Pure Compounds. The cellular transport of pure picrocrocin was determined after its dissolution in HBSS at a concentration range between 8 and 24 μM. Pure *trans*-4-GG crocetin ester and crocetin were also examined at equimolar concentrations for comparison.

The incubation time of the cells with the tested samples was 3 h for all experiments. Following incubation, the TEER values were determined again, and wells with TEER values <250 $\Omega \cdot cm^2$ were discounted. Media from both the apical and basolateral chambers was isolated and stored at −80 °C until further analysis. Samples were analyzed by RP-HPLC (HPLC system III) as detailed above. The injection volume was 90 μL. Quantification of picrocrocin, *trans*-4-GG crocetin ester, and crocetin was accomplished with the aid of proper calibration curves. Cellular transport was the quantity measured in the basolateral chamber expressed as a percentage of the concentration of the compound that was initially added to the Caco-2 cells.

In Vitro Bioactivity Studies of Picrocrocin and Other Major Saffron Apocarotenoids. *Cell Cultures.* Caco-2 cells were maintained in the DMEM supplemented with 10% (v/v) fetal bovine serum (FBS) and 1% (v/v) nonessential amino acids. HepG2 cells were maintained in DMEM supplemented with 10% (v/v) FBS. U937 cells were maintained in RPMI-1640 supplemented with 10% (v/v) FBS. The cells were grown at 37 °C and 5% (v/v) CO_2 in a humidified incubator. Cells were cultured in the absence of antibiotics and were subcultured every two to 3 days.

Sample Preparation for Bioactivity Assays. A 5000 μM stock solution of picrocrocin and *trans*-4-GG crocetin ester in water as well as crocetin in DMSO:PBS (10:90, v/v) were prepared. Samples were filtered through a 0.45 μm membrane filter. The resulting filtrates were stored at −20 °C until further analysis.

Determination of DNA Damage (Comet Assay). U937 cells (1×10^5 cells/mL) were supplemented with increasing nontoxic concentrations of individual apocarotenoids, i.e., picrocrocin, *trans*-4-GG crocetin ester, and crocetin (25 μM) in 6-well plates with a final volume of 2 mL and incubated for 24 h at 37 °C. The cytotoxicity of the tested compounds against this cell line was determined by the fluorescein diacetate/ethidium bromide (FDA/EtBr) assay as previously detailed.[7] Following incubation, cells were treated with 75 μM H_2O_2 for 30 min. Cells were harvested, suspended in a low melting point (LMP) agarose, placed on microscope slides, and allowed to solidify. Slides were placed in cold lysis solution [2.5 M NaCl, 100 mM EDTA, 10 mM Tris, pH = 10, 1% (w/v) sodium sarcosinate], with 1% (v/v) Triton X-100 and 10% (v/v) DMSO, added freshly before each use, for 1.5 h. Slides were then placed in a horizontal gel electrophoresis tank containing fresh electrophoresis solution (1 mM EDTA, 300 mM NaOH) for 30 min. Subsequently, electrophoresis was carried out for 25 min at 4 °C with a current of 25 V (300 mA) using a compact power supply. After electrophoresis, the slides were washed three times with neutralizing buffer (0.4 M Tris, pH = 7.5) at 4 °C for 5 min each. Slides were stained with ethidium bromide (20 μg/mL) and covered with coverslips. Komet 5.5 image analysis software (Kinetic Imaging Ltd., Bromborough, UK) was utilized to measure the level of DNA damage, which was expressed as percentage tail DNA.

Cell Proliferation. The antiproliferative effects of individual apocarotenoids (picrocrocin, *trans*-4-GG crocetin ester, crocetin) were examined in the Caco-2 and HepG2 cell lines using the (4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay (MTT I proliferation kit, Roche Diagnostics, West Sussex, United Kingdom). Caco-2 and HepG2 cells were seeded at a density of 1×10^5 cells/mL in 96-well plates and allowed to adhere overnight. Cells were then exposed to increasing concentrations of individual apocarotenoids. After 24 h incubation at 37 °C, 5 μL of MTT solution was added to each of the samples and incubated for 4 h at 37 °C. Following incubation, 100 μL of the solubilization solution (10% SDS in 0.01 M HCl) was added. A further incubation period of 24 h at 37 °C followed. Absorbance was read using a Tecan Spectrafluor Plus microplate reader at a wavelength of 570 nm with a reference wavelength of 690 nm. Cell proliferation was expressed as a percentage of the control, untreated cells. GraphPad Prism version 4.00 software (San Diego, USA) was used to determine IC_{50} values for each of the samples in Caco-2 and HepG2 cells.

Statistical Analysis. Statistical comparisons of the mean values were performed by one-way ANOVA, followed by the multiple comparison Duncan test ($p < 0.05$ confidence level) using the SPSS 14.0 software (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Chemical Characterization of Saffron Aqueous Extract. The RP-HPLC-DAD profile of the saffron aqueous extract at 250 and 440 nm indicated the presence of picrocrocin and crocetin sugar esters, respectively, as expected. The picrocrocin content (14.4 ± 0.7 g/100 g dry stigmas) and that of total crocetin sugar esters (29.3 ± 0.5 g/100 g dry stigmas) and major individual ones, i.e., *trans*-4-GG crocetin ester (15.6 ± 0.3 g/100 g dry stigmas) and *trans*-crocetin (β-D-glucosyl)-(β-D-gentiobiosyl) ester (*trans*-3-Gg crocetin ester) (7.4 ± 0.2 g/100 g dry stigmas) were representative of those of high quality saffron and of similar size to reported data.[3,14,16]

DOI: 10.1021/acs.jafc.5b03363
J. Agric. Food Chem. 2015, 63, 8662−8668

Bioaccessibility of Picrocrocin in Saffron Aqueous Extract. Treatment of the saffron aqueous extract under the simulated digestion conditions showed that ~75% of the initial amount of picrocrocin survived the harsh gastrointestinal conditions, in agreement with the results of our previous study.[7] Picrocrocin was found to be more stable under these conditions than the total crocetin sugar esters of the saffron extract (~40% loss), in agreement with previous results.[7,8] Picrocrocin is reported to be resistant to thermal treatment,[17] however, there is no information available about the effect of pH and/or digestive enzymes to its degradation rate.

Cellular Transport of Picrocrocin and Other Major Saffron Apocarotenoids. *Saffron Extract Digestate.* The cellular transport of picrocrocin was then examined by applying the saffron digestate to the Caco-2 cell monolayer. As the digestate itself can be toxic to the Caco-2 cells due to the presence of proteolytic and lipolytic enzymes, it was first diluted with medium (HBSS), at least 1:2 (v/v), and then added to the cell monolayer. Blank digestates that contained all the digestive enzymes except for the saffron extract were also examined. Dilutions that resulted in TEER values <250 $\Omega \cdot cm^2$ were not examined further. After a 3 h incubation period in the Caco-2 cells with three increasing concentrations of the saffron digestate corresponding to 2.3, 2.6, and 2.8 mg picrocrocin/L digestate, no picrocrocin was detected in the basolateral compartment even though a high fraction of its initial amount was bioaccessible. This observation could be attributed to the presence of the sugar moiety that results in lack of affinity toward the cellular membranes and does not allow passive diffusion.[18] Numerous studies have demonstrated that hydrolysis by digestive enzymes or intestinal microflora may be necessary for the absorption of glucosides of phenolic compounds due to their structural complexicity. Two metabolic pathways have been reported for the absorption of glucosides.[19] Glucosides may be hydrolyzed by lactase phloridizin hydrolase (LPH), which is located on the brush border of small intestinal epithelial cells into the aglycone, or alternatively, they may be absorbed by means of the active sodium-dependent glucose transporter (SGLT-1) and then they can be hydrolyzed within the intestinal cells by cytosolic β-glucosidase. In the present study, however, no sign of picrocrocin hydrolysis and release of the aglycone 4-hydroxy-2,6,6-trimethyl-1-cyclohexene-1-carboxaldehyde (HTCC)[1] was evidenced on the chromatogram at 250 nm [relative retention time (RRT) toward picrocrocin = 1.53]. It has also been observed in the literature that other glucosides, such as quercetin-4′-glucoside,[20] *trans*-piceid,[21] genistin, and daidzein,[22] are not transported across the Caco-2 cell monolayer, possibly due to an absence of β-glucosidase activity in this in vitro model. The crocetin sugar esters of the saffron extract digestate were found to be barely transported across the Caco-2 cell monolayer (data not shown). In particular, only 0.4% of the bioaccessible fraction of total crocetin sugar esters was found to be transported to the basolateral compartment, i.e., was bioavailable. Similarly, the major crocetin ester, *trans*-4-GG, which accounts for ~60% of the total crocetin esters content of saffron, was transported by ~0.4−0.5%. *trans*-3-Gg crocetin ester was detected in the basolateral chamber but at concentrations below the limit of quantification (LOQ) of the specific analytical method employed. No evidence of the hydrolysis of crocetin sugar esters to release the aglycone crocetin was evidenced during cellular transport experiments, probably due to the reasons detailed above. Lautenschläger et al. (2015)[8] also found that only 0.34% of pure *trans*-4-GG crocetin ester was transported across the Caco-2 cells monolayer with no concomitant generation of free crocetin during absorption. However, the presence of free crocetin has been observed in rodent plasma after the oral administration of either a mixture of crocetin esters or pure *trans*-4-GG crocetin ester, derived from the dried fruits of *Gardenia jasminoides* Ellis.[9,10] Moreover, when human volunteers consumed a cup of saffron tea, no crocetin esters but only crocetin was detected in their bloodstream.[11] Compounds that are not absorbed in the small intestine are expected to reach the colon, where they may exert their biological effects.

Pure Compounds. The cellular transport of pure picrocrocin versus that of the other two major saffron apocarotenoids, i.e., *trans*-4-GG crocetin ester and crocetin, was then examined at equimolar concentrations (8−24 μM) using the same in vitro model. The pure compounds were applied directly onto the Caco-2 cell monolayer. In this case, the cellular transport of picrocrocin was found to be ~0.2% (Figure 2). The observed

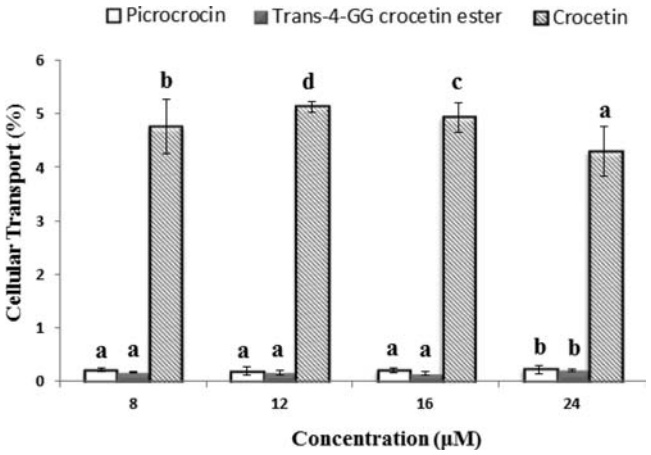

Figure 2. Cellular transport (%) of pure picrocrocin, *trans*-4-GG crocetin ester, and crocetin across the Caco-2 cell monolayer. Cells were incubated with increasing concentrations (8−24 μM) of the compounds for 3 h. Data are mean values ± SD of three independent experiments (n = 3) and were analyzed by one-way ANOVA. Different lowercase letters for each compound indicate significant difference according to Duncan's test at $p < 0.05$.

cellular transport in comparison to that found for picrocrocin in the saffron extract digestate could be attributed to antagonistic interactions with other copresent constituents (e.g., crocetin sugar esters) that may have similar mechanisms of absorption.[23] Data in Figure 2 showed a 10-fold higher cellular transport of the aglycone crocetin (~5% in the range 8−24 μM) compared to that of picrocrocin and also its natural sugar ester forms. Lautenschläger et al. (2015)[8] measured the absorption of *trans*-crocetin in Caco-2 cells and found an average permeation rate of 32%; they also found that the absorption was similar for each concentration in the range of 10−114 μM and was not dose dependent. In addition, there was no specific transporter associated with the transport of *trans*-crocetin and the authors concluded that transport was via the paracellular route. Several experimental factors such as the pH of the transport buffer, the solvent used to deliver the test compound,[24] and the TEER values of the Caco-2 monolayers can affect transport across Caco-2 cells.[25] Theoretically, crocetin is expected to be efficiently absorbed after oral administration as it meets the Lipinski's requirements for optimal oral bioavailability.[26]

DOI: 10.1021/acs.jafc.5b03363
J. Agric. Food Chem. 2015, 63, 8662−8668

According to Lipinski's rule,[27] a compound is expected to display optimum gastrointestinal absorption if "it has a molecular mass of equal or less than 500 g/mol, less than five hydrogen bond donors, and less than ten hydrogen bond acceptors and a calculated partition coefficient (log *P*) less than five". Therefore, crocetin, with a molecular mass of 328.40 g/mol, four hydrogen bond acceptors, two hydrogen bond donors, and a value of log *P* equal to 4.72,[28] may fulfill better these requirements in comparison to the more polar apocarotenoids.

Once carotenoids are absorbed by the intestinal cells, metabolism becomes the major barrier to their bioavailability.[29] The metabolism of apocarotenoids derived from saffron has not been fully eludidated, however, β-carotene 9′,10′-oxygenase (BOC2), which is expressed in mammalian tissues, has a broad substrate specificity and has been shown to metabolize xanthophylls.[30] In the present study, however, peaks at retention times earlier than those of picrocrocin and *trans*-4-GG crocetin ester were not detected on the chromatograms of the basolateral medium. Similar observations have been also made in the case of quercetin from red onions[31] and apples[32] using the same cell line. It is well documented that conjugation via glucuronidation occurs to a greater extent in the liver where the expression of glucuronosyltranferases (UGTs) is much higher compared to that in the small intestine.[33]

DNA Protective Effects of Picrocrocin and Other Major Saffron Apocarotenoids. To determine the protective effects of the individual major saffron apocarotenoids against oxidant-induced DNA damage, the Comet assay was employed. The Comet assay is a sensitive tool for measuring DNA single-strand breaks in individual cells.[34] In the present study, the addition of 75 μM H_2O_2 to U937 cells caused an increase in DNA damage to 52.6% tail DNA compared to the unchallenged control (4% tail DNA) (Figure 3). Cell supplementation with a nontoxic concentration (data not shown) of pure picrocrocin and *trans*-4-GG crocetin ester (25 μM) did not exhibit a significant ($p < 0.05$) DNA protective effect under these experimental conditions. When the aglycone crocetin was examined at an equimolar concentration (25 μM), it caused a significant ($p < 0.05$) decrease in DNA damage (~43% tail DNA). It has been shown that saffron compounds including crocetin may form a complex with DNA and scavenge free radicals which can protect DNA from oxidant induced damage.[35] Literature data focus on the protective effects of saffron extracts and pure *trans*-4-GG crocetin ester against oxidant-induced DNA damage. In particular, Kyriakoudi et al. (2013)[7] reported a significant decrease (13.2% tail DNA) in DNA damage induced by hydrogen peroxide after supplementation of U937 cells with a saffron aqueous extract. *trans*-4-GG crocetin ester has previously demonstrated a dose dependent decrease in H_2O_2-induced DNA damage, as determined by the Comet assay, in a mouse lymphoma (L5178Y) cell line, however, it did not protect against methylmethanesulfonate (MMS)-induced DNA damage in the same study.[36] The protective effect of a saffron extract and pure *trans*-4-GG crocetin ester has been also reported in vivo against methylmethanesulfonate-induced DNA damage in mice organs using the Comet assay.[37]

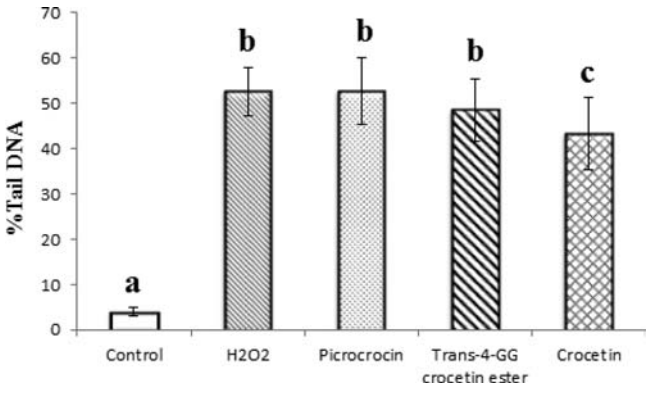

Figure 3. DNA damage in U937 cells following pretreatment with or without pure picrocrocin, *trans*-4-GG crocetin ester, and crocetin (25 μM) for 24 h followed by exposure to 75 μM H_2O_2 for 30 min at 37 °C. DNA damage was assessed by the comet assay. Data are the mean values of six independent experiments, with standard errors represented by vertical bars. Statistical comparisons of the mean values were performed by one-way ANOVA followed by Duncan's test. (a,b,c) Mean value was significantly different from that for H_2O_2-challenged cells ($p < 0.05$).

Antiproliferative Effects of Picrocrocin and Other Major Saffron Apocarotenoids in Human Cancer Cell Lines. Several constituents of saffron have shown antitumor effects through an inhibition of cancer cell growth. The antiproliferative effects of saffron extracts have been demonstrated in breast cancer cells (MCF-7), hepatocarcinoma cells (HepG2), colorectal cancer cells (HCT-116, SW-480, HT-29), and lung cancer cells (NSCLC), among others.[38] Additionally, ethanolic extracts of saffron have demonstrated selective toxicity to cancer cells and did not induce toxicity in normal, noncancerous cells.[39] The effect of picrocrocin, *trans*-4-GG crocetin ester, and crocetin on the in vitro proliferation of human tumoral cells was studied using the human adenocarcinoma, Caco-2, and the human hepatocellular carcinoma, HepG2, cell lines. As illustrated in Figure 4A, picrocrocin and *trans*-4-GG crocetin ester reduced Caco-2 cell proliferation in a dose-dependent manner. Crocetin was found to stimulate cell growth at the lower concentrations (125 and 250 μM) but reduced cell proliferation at higher ones. The IC_{50} value for each compound is presented in Table 1. These values were found to range from 840 to 1700 μM, with crocetin exhibiting the highest antiproliferative effect followed by picrocrocin and *trans*-4-GG crocetin ester. Picrocrocin had an IC_{50} value of 3000 μM in TC-1, malignant murine, cells following a 48 h incubation and *trans*-4-GG crocetin ester had an IC_{50} value of 1500 μM.[40] The differences in IC_{50} values for the various saffron constituents could result from differences in the uptake, transport, and retention of these compounds. In the HepG2 cell line, it was found that picrocrocin triggered a dose-dependent decrease in cell proliferation (Figure 4B), similar to the trend observed in the Caco-2 cell line. In this cell line, *trans*-4-GG crocetin ester and crocetin were found to increase cell viability at the lower concentrations examined, 125 and 250 μM, but decreased cell proliferation at higher concentrations. The IC_{50} values for the tested apocarotenoids were found to be similar in both the HepG2 and the Caco-2 cell lines (Table 1). These data indicate that picrocrocin, *trans*-4-GG crocetin ester, and crocetin may have chemopreventative effects. The ability of crocetin to impede cancer cell growth has been related to an enhancement of the cellular antioxidant systems, the inhibition of nucleic acid synthesis, and the induction of apoptosis.[41]

In conclusion, even though picrocrocin is the most bioaccesible among the major saffron apocarotenoids, it was found to be transported across the Caco-2 cell monolayer at

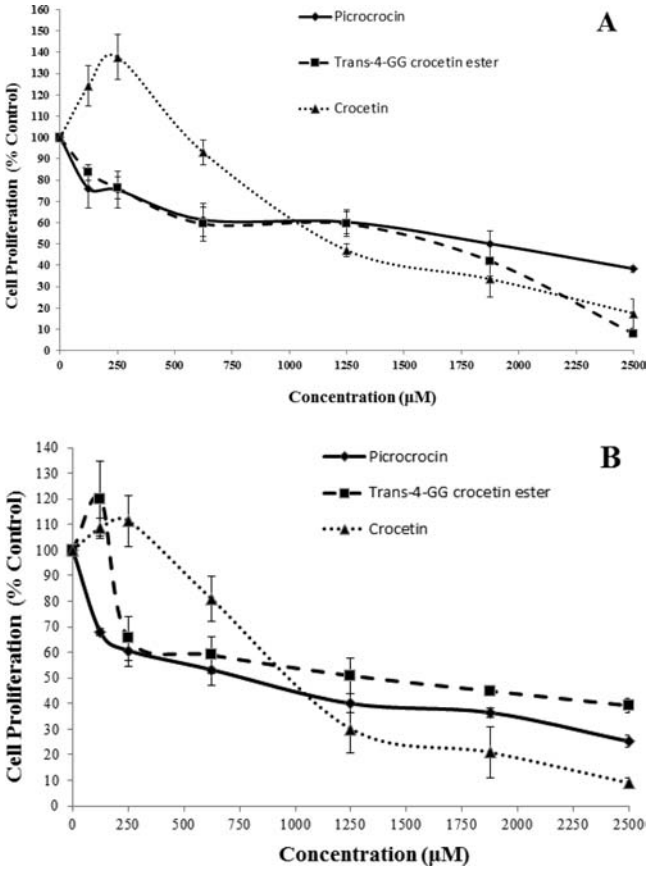

Figure 4. Cell proliferation in Caco-2 (A) and HepG2 (B) cell lines following 24 h exposure to picrocrocin, *trans*-4-GG crocetin ester, and crocetin. Cell proliferation was assessed using the MTT assay. Data are the mean values ± SD of six independent experiments (n = 6).

Table 1. IC_{50} Values for Picrocrocin, *Trans*-4-GG Crocetin Ester, and Crocetin in Human Colon Adenocarcinoma Caco-2 Cells and Human Hepatocarcinoma HepG2 Cells

	IC_{50} values (μM)[a]	
	Caco-2 cells	HepG2 cells
picrocrocin	1160 ± 0.88	1100 ± 0.13
trans-4-GG crocetin ester	1700 ± 0.11	1250 ± 0.03
crocetin	840 ± 0.21	750 ± 0.25

[a]Each value is the mean of triplicate determinations ± SD.

very low levels. When pure picrocrocin was examined at equimolar concentrations with other major saffron apocarotenoids, i.e., *trans*-4-GG crocetin ester and crocetin using the same in vitro model, its cellular transport was found to be approximately similar to that of *trans*-4-GG crocetin ester and ∼10-fold lower than that of the aglycone crocetin. To the best of our knowledge, this is the first time that the data on the cellular transport of picrocrocin itself or in the presence of other saffron apocarotenoids are presented. Picrocrocin also demonstrated antiproliferative activity in human cancer cell lines. This study highlights the relevance of picrocrocin to investigations of the bioavailability and bioactivity of saffron extracts.

J. Agric. Food Chem. 2015, 63, 8662−8668

Therefore, we need to develop a new system for a more efficient delivery of β-carotene with an enhanced stability.

It is well-known that the carboxyl groups can coordinate with divalent and trivalent ions, such as Ca^{2+} or Fe^{3+}. In this way, the carboxyl-containing polymers are physically cross-linked by those ions, leading to a gel formation. For example, calcium alginate microspheres for prolonged drug release were prepared by ionic gelation of alginate with calcium chloride ($CaCl_2$).[20] A gelation of poly(acrylic acid) (PAA) polymers can be induced by coordination with Fe^{3+} ions.[21] Polysaccharide microspheres can be obtained by cross-linking carboxylmethyl konjac glucomannan via Fe^{3+} ions.[22] We have reported a polysaccharide microsphere prepared of oxidized konjac glucomannan where the carboxyl (COO^-) groups are physically cross-linked by Fe^{3+} ions.[23] On the basis of the literature, we propose to prepare a new microsphere by cross-linking COO^- groups on oxidized starch with Fe^{3+} ions by an emulsion-cross-linking method. Oil-in-water-in-oil (O/W/O) double emulsions have a high potential for application in the food processing industry to encapsulate or protect sensitive and hydrophobic components.[24] β-carotene can be dissolved in the inner oil phase, and the oxidized starch can be solidified by Fe^{3+} in the middle water phase. In this way, β-carotene can be encapsulated inside oxidized starch microspheres via the double-emulsion method.

The objective of this study is to develop an oral delivery system that specifically delivers β-carotene to the intestine, aiming to improve its water solubility and stability. First, β-carotene-loaded oxidized starch microspheres were made of 90% degree of oxidation (DO) oxidized starch polymer, where the COO^- groups are physically cross-linked via ferric ions (Fe^{3+}) through O/W/O double-emulsion methods. Second, the surface morphology and distribution of the oil phase inside microspheres were observed by scanning electron microscopy (SEM) and confocal laser scanning microscopy (CLSM). The properties of microspheres, such as size distribution and ζ-potential, as a function of pH and ionic strength were characterized. Then, the *in vitro* release of β-carotene from the oxidized starch microspheres in simulated gastric and intestinal fluids was measured. Finally, the scavenging activity of encapsulated β-carotene after heat treatment was measured by 1,1-diphenyl-2-picrylhydrazyl radical, 2,2-diphenyl-1-(2,4,6-trinitriphenyl) (DPPH), methods. The storage stability of encapsulated β-carotene at room temperature was tested as well. The results indicated that oxidized starch microspheres can be potentially used to deliver β-carotene into intestine with an enhanced stability.

MATERIALS AND METHODS

Materials. Native potato starch polymer was kindly provided by AVEBE, Netherlands. The oxidation catalyst TEMPO was purchased from Merck, Germany. Whey protein isolate (WPI) was kindly provided by Davisco Foods International, Inc. (Le Sueur, MN). β-carotene (purity > 97%) was purchased from TCI, Japan. DPPH was purchased from Sigma. Sodium hypochlorite, ferrous sulfate ($FeSO_4 \cdot 7H_2O$), paraffin liquid, Tween 80, and Span 80 were purchased from Beijing Chemical Reagent Factory, China. Pepsin was obtained from Biosharp, China. Pancreatin powder was purchased from AOBOX Biotechnology Company, China. All other chemicals used were of analytical grade. Deionized water was used throughout.

Preparation of the β-carotene-Loaded Oxidized Starch Microsphere. By TEMPO-mediated oxidation, the primary alcohol groups at the C-6 position on potato starch polymer were selectively oxidized into carboxyl groups. In this way, starch polymers of 90% DO were prepared, following the procedure described by de Nooy et al.[14] The DO was controlled by the amount of sodium hypochlorite added during oxidation. The oxidation was performed at a constant pH (pH 10) using 2 M NaOH at 10 °C.

An emulsion cross-linking method was used to prepare the oxidized starch microsphere. O/W/O double emulsion was used to prepare the β-carotene-loaded oxidized starch microsphere. First, 10% (w/w) crystalline β-carotene was dissolved in corn oil to obtain the inner oil phase (O_I). Then, 1% (w/v) WPI was dissolved in aqueous buffer solution (0.02 M citric acid−phosphate buffer at pH 3) to obtain aqueous phase I (W_I). The volume ratio of O_I to aqueous phase I (W_I) was 1:4 (O_I/W_I). The O_I/W_I emulsion was prepared by ultrasonic emulsification (32 W for 5 min). Then, 20 mg of 90% DO oxidized starch polymer and 5 mg of $FeSO_4 \cdot 7H_2O$ were dissolved in 100 μL to prepare aqueous phase II (W_{II}). The 100 μL (O_I/W_I) emulsion and 100 μL water phase II (W_{II}) were mixed to obtain primary emulsion [$O_I/(W_I + W_{II})$]. A total of 0.67 g of Span 80 was dissolved in 20 g of paraffin oil to obtain continuous oil phase II (O_{II}). The volume ratio of primary emulsion [$O_I/(W_I + W_{II})$] to O_{II} was 1:100. The primary emulsion was gradually added to O_{II} under stirring at 1000 rpm to make the double emulsion. Later, oxygen gas was pumped into the double emulsion during stirring at 35 °C for 20 min to oxidize Fe^{2+} to Fe^{3+}, leading to the gel formation caused by the coordination between Fe^{3+} and carboxyl groups on oxidized starch. Finally, the micropheres were washed 2 times with hexane and 2 times with methanol. After each washing step, the system was centrifuged (3000 rpm for 2 min), then the liquid was decanted, and the particles were redispersed in pH 3 HCl solution. In the end, the β-carotene-loaded oxidized starch microspheres were obtained.

Morphology of the β-carotene-Loaded Oxidized Starch Microsphere. The surface morphology of the β-carotene-loaded oxidized starch microsphere was examined by SEM using a scanning electron microscope (S-4700, Hitachi Company, Tokyo, Japan) with an accelerating voltage of 15 kV. The microspheres were sputter-coated with gold prior to observation.

CLSM. Because β-carotene is a natural fluorescent pigment, the distribution of β-carotene in oxidized starch microspheres can be directly observed by CLSM (TCS SP2, Leica, Wetzlar, Germany). The excitation wavelength for β-carotene is 488 nm, and the emission wavelength is 560 nm.

Determination of β-carotene Encapsulated Inside the Oxidized Starch Microspheres by High-Performance Liquid Chromatography (HPLC). The β-carotene content was determined using a standard curve created from a series of β-carotene solutions at different concentrations. β-carotene encapsulated inside the oxidized starch microspheres was extracted by hexane under sonication. HPLC was used to determine its concentration with 450 nm as a detection wavelength. The HPLC parameters of the experiment were as follows: A Diamonsil C_{18} chromatographic column (250 × 4.6 mm, 5 μm, Dikma) was employed at 28 °C. The mixture of acetonitrile and dichloromethane with a volume ratio of 3:1 was used as the mobile phase. The flow rate was 1.5 mL/min, and 20 μL of each sample was injected.

The loading capacity (L) was calculated according to the following formula:

$$\text{loading capacity}\left(\frac{\text{mg}}{\text{g}}\right) = \frac{\text{mg of β-carotene encapsulated}}{\text{g of oxidized starch polymers in microspheres}} \quad (1)$$

The loading capacity was 2.3 mg of β-carotene/g of oxidized starch microspheres.

Chemical Structure Analysis by Fourier Transform Infrared (FTIR) Spectra. The FTIR spectroscopy technique was used to analyze the chemical structures of non-oxidized starch polymers, oxidized starch polymers, and the microspheres. A total of 200 mg of KBr and 8 mg of sample were pressed under 10 MPa for 10 min to obtain a tablet that was investigated using a FTIR spectrophotometer (Araffinity-1, Shimadzu, Kyoto, Japan).

Size Distribution and ζ-Potential Measurements of the β-carotene-Loaded Oxidized Starch Microsphere. The size distribution of oxidized starch microspheres in suspension was determined by dynamic light scattering (DLS, MasterSizer 2000, Malvern, London, U.K.). The microspheres in suspension were measured at 25 °C. The weight concentration of particles used in measurement was 0.05 mg/mL. Before the measurements, suspensions were sonicated for 2 min, to obtain finely dispersed microphores.

The ζ-potential of oxidized starch microspheres in suspension was determined using a DLS system (Zetasizer Nano ZS series, Malvern, London, U.K.). The temperature of all samples was controlled at 25 °C. The weight concentration of oxidized starch microspheres used in measurement was 0.3 mg/mL in citric acid−phosphate buffer (0.02 M, pH 3−7) with different ionic strengths. Before the measurements, the suspensions were sonicated for 2 min, to obtain finely dispersed particles.

***In Vitro* Release of β-carotene from Oxidized Starch Microspheres in Simulated Gastrointestinal Fluids.** The simulated gastrointestinal fluids were prepared according to previously described methods.[19] The percentage of released β-carotene was defined as the ratio of the weight of released β-carotene to the weight of absorbed gross. The percentage of β-carotene released $A_{released}$ was calculated from the measured released β-carotene concentration ($C'_{\beta\text{-C}}$) as

$$A_{released} = (C'_{\beta\text{-C}} V_{extracted})/(Lm_{microspheres}) \times 100\% \quad (2)$$

where $V_{extracted}$ is the volume of released β-carotene, L is the loading capacity, and $m_{microspheres}$ is the weight of β-carotene encapsulated inside oxidized starch microspheres.

Following standard pharmacopoeia methods, the β-carotene-loaded oxidized starch microspheres were first incubated for 120 min in simulated gastric fluid at 37 °C and the percentage of released β-carotene were measured at times 0, 15, 30,45, 60, 75, 90, and 120 min. Thereafter, the microspheres were transferred into simulated intestinal fluid for continuous release for another 3 h. The percentage of released β-carotene was measured at times 0, 15, 30, 45, 60, 90, 120, 150, and 180 min in stimulated intestinal fluid. All of the samples were centrifuged under 3000 rpm for 2 min. Released β-carotene in the supernatant was extracted with solvent [*n*-hexane/ethanol (v/v) = 2:1]. The absorbance of β-carotene under 450 nm was measured by HPLC. The concentration of β-carotene released was calculated from a standard calibration curve.

DPPH Radical-Scavenging Activity of Oxidized Starch Microspheres That Encapsulated β-carotene. The oxidized starch microsphere loaded with β-carotene and free β-carotene were heated at 80 °C for 40 h and sampling at different time intervals (0, 4, 8, 22, 26, 32, and 40 h). DPPH was dissolved in ethanol (0.4 mmol). β-carotene loaded by 10 mg of microspheres was extracted by hexane. Free β-carotene in hexane solution was adjusted to the same concentration as the extract. A total of 200 μL of β-carotene extracted from microspheres and free β-carotene hexane solution were added to 3.8 mL of DPPH solution. The mixtures were stirred 30 min to scavenge free radicals. The absorbance of solution was determined at 517 nm to measure the scavenging rate. A_0 is the absorbance of initial DPPH solution before scavenging, and A_t is the absorbance of DPPH solution after scavenging at 30 min.

The scavenging rate A_{scan} (%) could be calculated as

$$A_{scan}\ (\%) = (A_0 - A_t)/A_0 \times 100\% \quad (3)$$

Storage Stability of Oxidized Starch Microspheres That Encapsulated β-carotene. The β-carotene-loaded oxidized starch microsphere and free β-carotene were placed in a storage chamber with a constant temperature of 25 °C. The β-carotene concentration was determined daily, and the sampling lasted for 10 days. The collected samples were detected by HPLC, described in a previous section. The storage stability of β-carotene was expressed as a residual rate in percent: C_t/C_0, where C_t is the β-carotene concentration after storage for a period of time t and C_0 is the β-carotene content at the time of preparation.

Statistical Analysis. Each experiment was performed in triplicate. A spreadsheet statistical package was used to analyze the mean of the three measurements and standard deviations.

RESULTS AND DISCUSSION

Distribution of β-carotene Inside Oxidized Starch Microspheres. By means of an O/W/O double-emulsion method, in the water phase, TEMPO oxidized starch polymers, of which the carboxyl groups are cross-linked via Fe^{3+} ions and in which β-carotene can be simultaneously incorporated in the inner oil phase. The left image of Figure 1a showed that β-carotene did not dissolve in water. In the contrast, after loading it in the oxidized starch microspheres, the dispersibility of β-carotene in water was improved. It was demonstrated by the homogeneous yellow suspension of β-carotene-loaded starch microsphere solution (right image of Figure 1a). The surface morphology of the β-carotene-loaded starch microspheres was shown in panels b and c of Figure 1. Their diameter ranged from 10 to 40 μm. They possessed a rough surface, which was related to the heterogeneous cross-link reaction. The optical microscopic image of β-carotene-loaded microspheres was shown in Figure 1d. It can be clearly seen that the oil droplets were encapsulated inside the oxidized starch microspheres. Because of the fluorescent nature of β-carotene, the distribution of β-carotene inside the microspheres was further observed by CLSM. Red-colored β-carotene molecules were present in the inner oil phase (Figure 1e). The above results suggested that β-carotene was successfully incorporated inside oxidized starch microspheres and its dispersibility in aqueous solution was improved.

Characterization of the Physical and Chemical Properties of Oxidized Starch Microspheres. The chemical structure of the Fe^{3+} cross-linked oxidized starch microspheres was mesured by FTIR spectrometry. As shown in Figure 2, the asymmetric vibration ν_{as} and symmetric vibration

DOI: 10.1021/acs.jafc.5b03575
J. Agric. Food Chem. 2015, 63, 8669−8675

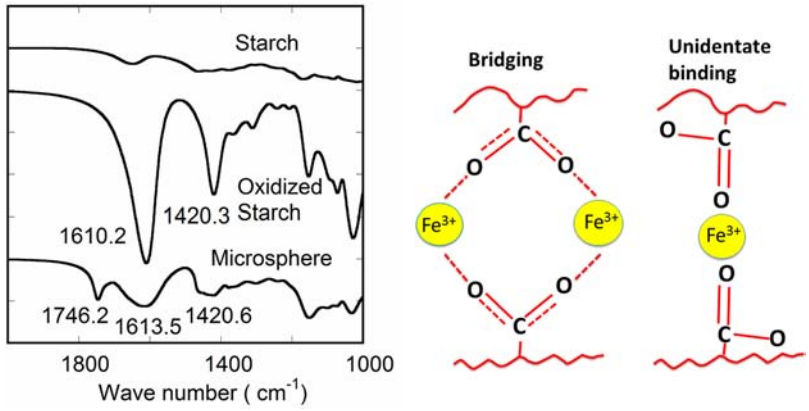

Figure 2. (Left) FTIR spectra of starch, TEMPO-oxidized starch, and oxidized starch microspheres. (Right) Schematic illustration of unidentate binding and bridging between COO^- and Fe^{3+} in the oxidized starch microspheres.

ν_s of COO^- in the oxidized starch polymer appear at 1610.2 and 1420.3 cm^{-1}, suggesting the successful oxidation of primary alcohol groups on starch polymers to carboxyl groups. For Fe^{3+} cross-linked starch, we found that the asymmetric vibration peak of COO^- (1610.2 cm^{-1}) for the oxidized starch polymer was split into two peaks at 1746.2 and 1613.5 cm^{-1}. It is well-known in the literature that the wavenumber separation between the asymmetric and symmetric stretching vibrations, $\Delta\nu_{as-s} = \nu_{as}(COO^-) - \nu_s(COO^-)$, of COO^- groups reflects their coordination state.[25] $\Delta\nu_{as-s} \gg 200$ cm^{-1} points to unidentate binding, and $\Delta\nu_{as-s} \approx 200$ cm^{-1} indicates binding by bridging. The symmetric vibration ν_s for the gel is at 1421.3 cm^{-1}. Thus, two wavenumber separations $\Delta\nu_{as-s}$, 1746.2−1420.6 and 1613.5−1420.6 cm^{-1}, suggested the coexistence of unidentate binding ($\Delta\nu_{as-s} \gg 200$ cm^{-1}) and bridging ($\Delta\nu_{as-s} \approx 200$ cm^{-1}) between COO^- and Fe^{3+} in the oxidized starch microspheres (illustrated in the left image of Figure 2). This explained the mechanism of the gel formation between the oxidized starch polymer and Fe^{3+}. It is consistent with the FTIR results of Fe^{3+} cross-linked oxidized konjac glucomannan microspheres.[23]

Figure 3A showed the particle size distribution for oxidized starch microspheres in pH 3 HCl solution, revealing a diameter

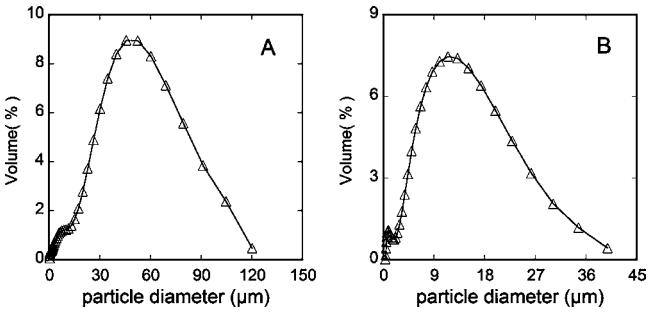

Figure 3. Size distribution of oxidized starch microspheres in (A) pH 3 HCl solution and (B) ethanol.

distribution between 10 and 90 μm, with an average of 39 μm. The size of microspheres in pH 3 HCl solution was slightly bigger than that at the dry state (SEM in Figure 1b) probably as a result of the swelling of microspheres in water. Figure 3B presented the size distribution of oxidized starch microspheres in ethanol, and it has an average size of 10.5 μm. The shrinkage of oxidized starch microspheres in ethanol was caused by the dehydration of oxidized starch polymers as a result of competitive binding of water by ethanol. It suggested that microspheres contained a large amount of water, and this swelling capacity may provide a large space for accommodating more bioactive ingredients.

The pH dependence of the ζ-potential of oxidized starch microspheres is shown in Figure 4A. The negative value of the ζ-potential increases with increasing pH. It approached a maximum near pH 5, where the dissociation of the carboxyl groups reached completion. An increasing salt concentration lowered the ζ potential of oxidized starch microspheres (Figure 4B), reaching a plateau value at 0.1 M NaCl. This is due to screening of the negative charges in the oxidized starch microspheres by counterions, i.e., Na^+. Apparently, charge screening reached a maximum at 0.1 M salt. This result is consistent with the salt dependence of oxidized starch microgel made of trimetaphosphate cross-linked oxidized starch polymers.[15]

***In Vitro* Release Kinetics of Encapsulated Ingredients from Oxidized Starch Microspheres in Simulated Gastrointestinal Fluids.** The *in vitro* release experiment under simulated gastrointestinal conditions is an important indication for their behavior in a physiological environment. The *in vitro* release of β-carotene from oxidized starch microspheres was studied under simulated gastric and intestinal fluids. Inset microscopic images of Figure 5A showed that the structure of microspheres remained intact when incubated in simulated gastric fluid for 120 min. Around 10% of β-carotene was released from oxidized starch microspheres after 120 min. According to the literature, the degradation of β-carotene in nanoemulsion is faster at an acidic pH value, such as gastric pH (pH < 2).[26,27] Therefore, a carrier system is needed to prevent the early release of β-carotene under gastric pH. Obviously, the oxidized starch microspheres were largely protected from acid degradation, so that β-carotene remained stable in microspheres. Then, β-carotene-containing microspheres were transferred to simulated intestinal fluid (pH 7.0) to continue their release. At intestinal conditions, oxidized starch microspheres will be dissociated gradually because the cross-linker Fe^{3+} may react with OH^- at pH 7. The degradation of microspheres led to a release of the encapsulated drugs from the spheres into the intestine. As shown in Figure 5B, about 83% of β-carotene was released after 180 min in simulated intestinal fluid. It has been reported that the absorption and metabolism of β-carotene mainly occur in the small intestine.[1,28,29] It is desirable to have a

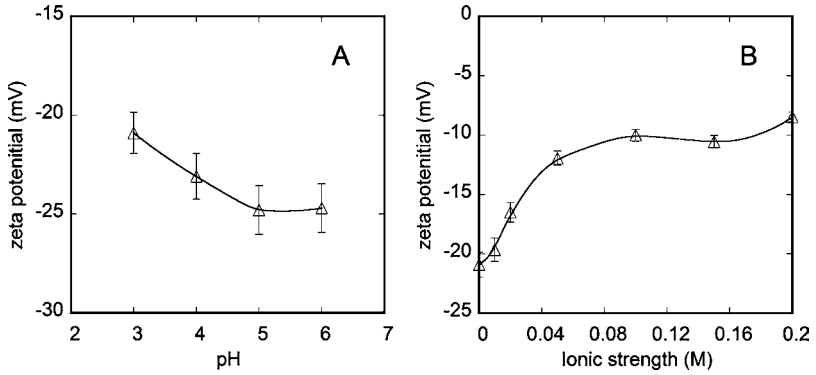

Figure 4. (A) ζ-Potential of oxidized starch microspheres as a function of pH, with no salt added, and (B) as a function of the ionic strength at pH 3.

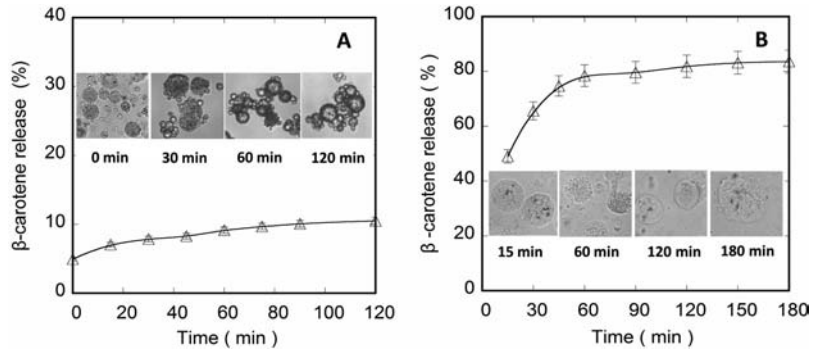

Figure 5. (A) *In vitro* release kinetics of *β*-carotene from oxidized starch microspheres during incubation in simulated gastric fluid. The inset microscopic images represented loaded microspheres incubated at times 0, 30, 60, and 120 min. (B) *In vitro* release kinetics of *β*-carotene from oxidized starch microspheres during incubation in simulated intestinal fluid. The inset microscopic images represented loaded microspheres incubated at times 15, 60, 120, and 180 min.

slow release at gastric conditions for the oral delivery system, because the gastric degradation of encapsulated carotenoids can be reduced, so that the active molecules available for absorption in the intestine can be increased. These results indicated that oxidized starch microspheres can potentially be used in targeted simultaneous delivery of hydrophobic drugs to the intestine. Yi et al. have reported a *β*-carotene nanocarrier made of *β*-lactoglobulin−dextran Maillard conjugates.[30] Their *in vitro* release experiments showed that *β*-carotene was protected at acidic gastric conditions and released at intestinal conditions. They explained that their particles were more accessible to trypsin at intestinal conditions rather than pepsin at stomach conditions. Later, they found that encapsulated *β*-carotene had a high transport rate through a Caco-2 cell monolayer. They concluded that the bioavailability of *β*-carotene was improved by nanoparticle encapsulation. Tan et al. also found that the release of *β*-carotene from liposomes was inhibited in a simulated gastric fluid, while a slow and sustained release was achieved in a simulated intestinal fluid. They explained that the liposomes were disrupted under intestinal conditions by penetration of bile salts and pancreatin, leading to the release of encapsulated *β*-carotene.[9] However, the heat stability of above-mentioned *β*-lactoglobulin−dextran nanoparticles may be low as a result of the protein presented. The high tendency of oxidation of liposome may cause uncontrolled leakage of the encapsulated ingredients. Therefore, the carrier system made of polysaccharides may have advantages over proteins and lipids on this point.

Enhancement of Antioxidant Activity against Heat and Storage Stability of *β*-carotene in Oxidized Starch Microspheres.

It is well-known that *β*-carotene is sensitive to heat.[26,27] Encapsulation in oxidized starch microspheres may protect them from degradation by heat. To study the stabilizing effect of *β*-carotene in oxidized starch microspheres, antioxidant activity (eq 1), i.e., scavenging DPPH radicals, of *β*-carotene-loaded oxidized microspheres and individual components were measured during continuous heating at 80 °C. Figure 6 showed

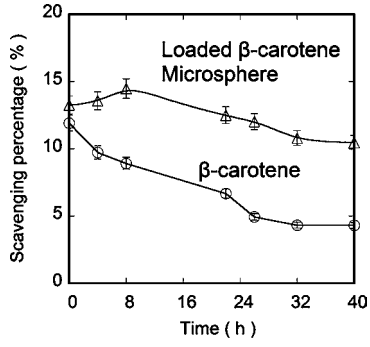

Figure 6. DPPH scavenging percentage (%) for oxidized starch microspheres that encapsulated *β*-carotene and free *β*-carotene after a continuous heating at 80 °C.

that the loaded microspheres exhibited a stronger antioxidant activity than those of individual *β*-carotene upon prolonged heating at 80 °C. It suggested that the stability of *β*-carotene against heat was improved by encapsulation inside oxidized starch microspheres. Recent studies suggested that antioxidant activity of *β*-carotene was improved when loaded it in chitosan-

J. Agric. Food Chem. 2015, 63, 8669−8675

graft-poly(lactide) nanomicelles.[31] Besides, β-carotene can be self-assembled into the core of casein micelles, which improved their heat stability during processing.[10,11] It can be seen that microencapsulation is an effective way to protect heat-sensitive bioactives during processing and storage. It already proved that the structure of oxidized starch microspheres was stable against heat and acid. It can be a good candidate for β-carotene stabilization against hazard conditions, such as acid and heat.

In addition to the damage of β-carotene under heat, it may also suffer from light and oxygen oxidation during storage. Therefore, the storage stability of β-carotene-loaded oxidized starch microspheres was investigated. The residual rate C_t/C_0 (β-carotene concentration after storage for a period time C_t/the initial concentration C_0) was measured daily for 10 days at room temperature (Figure 7). Both encapsulated and non-

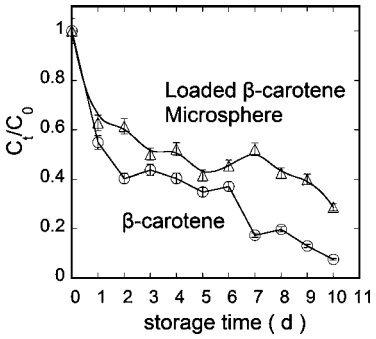

Figure 7. Residual rate C_t/C_0 of β-carotene for oxidized starch microspheres that encapsulated β-carotene and free β-carotene stored at ambient temperature for a prolonged 10 days.

encapsulated β-carotene have a decreasing trend. However, the residual rate for encapsulated β-carotene was around 30%, and that for non-encapsulated β-carotene approached 0%. It seems that, without any protection, β-carotene was totally destroyed after 10 days of storage. It showed that encapsulation by oxidized starch microspheres had delayed the β-carotene degradation. It indicates that the oxidized starch microspheres are able to protect β-carotene during storage to some extent. However, cross-linker Fe^{3+} of the microspheres may undergo light reduction, which may cause the disruption of the microsphere network, leading to a weakened stabilizing effect. Chen et al. had reported that the storage stability of β-carotene at 37 °C was improved by inclusion inside ferritin nanocages.[8] However, the heat stability of ferritin protein still needs to be a concern. Spada et al. have reported that the storage stability of encapsulated β-carotene by hydrolyzed pinhão starches after freeze-drying was improved under ultraviolet light at 25 °C and under dark at 25 and 4 °C. They postulated that the high content of amylose in pinhão starches may form a network by hydrogen bonds, which can entrap and protect β-carotene from degradation.[32] The starch network in our case may function in a similar way. It was also reported that the degradation of β-carotene in microemulsions formulated with peppermint oil was inhibited undergoing ultraviolet radiation and thermal treatments at 60 and 80 °C.[33] They explained that antioxidants in peppermint oil may play an important role against oxidative and thermal degradation. Similarly, the stabilizing effect of our oxidized starch microspheres may be improved by replacing the inner oil phase soybean oil with the oil rich in antioxidants.

In this study, oxidized starch microspheres for releasing β-carotene to intestine and improving their thermal and storage stabilities were developed. It is based on TEMPO-oxidized starch, a carboxyl polysaccharide, which can be cross-linked by Fe^{3+} ions, leading to an oil-in-water (O/W) polymer network formation that is able to simultaneously incorporate hydrophobic components. The oxidized starch microspheres were found to be stable at acidic stomach conditions (pH < 2), whereas at neutral intestinal conditions (pH 7.0), they disrupt to release loaded β-carotene. The results showed that β-carotene-loaded starch microspheres possessed an improved antioxidant activity against heat and enhanced storage stability. Thus, oxidized starch microspheres showed a potential in delivering the hydrophobic bioactives to the specific sites with an enhanced stability.

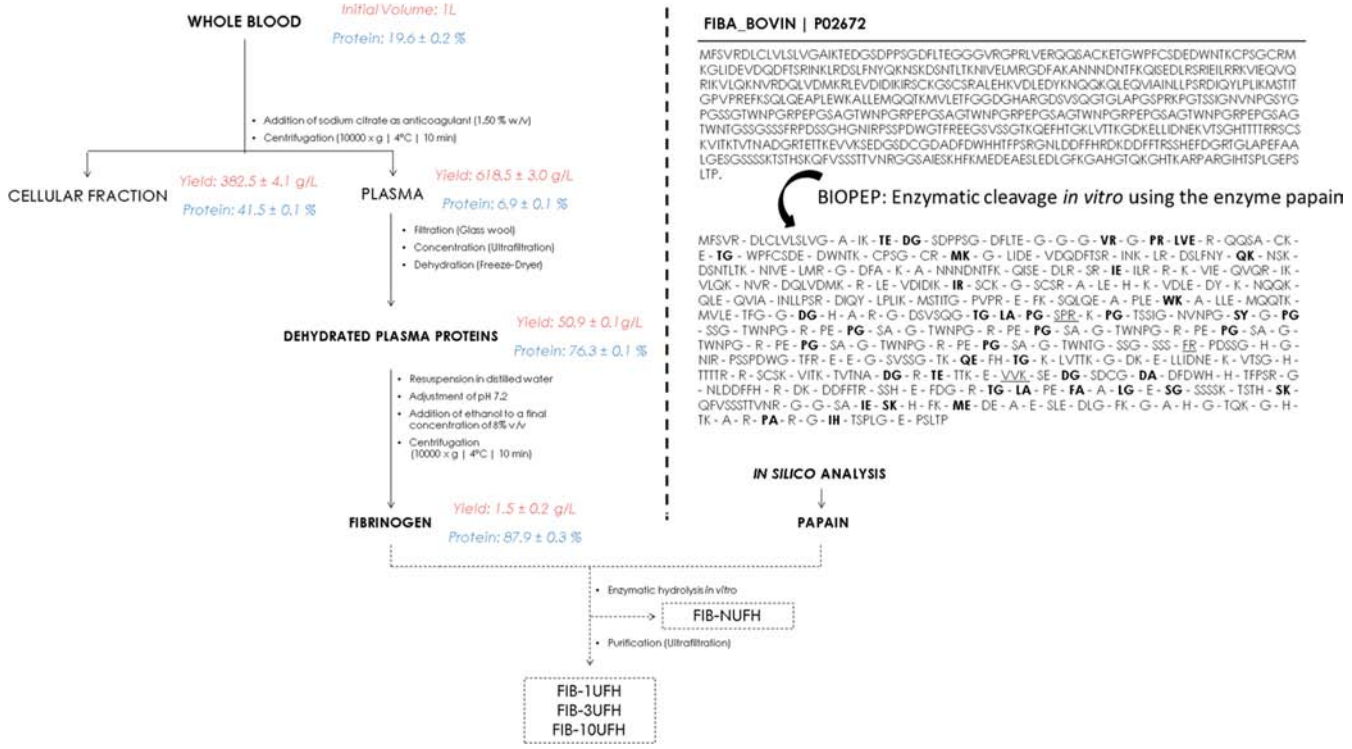

Figure 1. Schematic representation of the procedure followed for the generation of bioactive peptides from bovine fibrinogen. Blood plasma was separated from the cellular fraction by centrifugation at 10000*g* for 10 min. Plasma was frozen and freeze-dried. A protein fraction rich in fibrinogen was obtained by cold ethanol precipitation, frozen, and freeze-dried. In silico analysis was used for enzyme selection. Papain was chosen as the most efficient enzyme for the generation of a hydrolysate with ACE-I-, renin-, and DPP-I-inhibiting properties. Di- and tripeptides in bold are known ACE-I, renin, or DPP-IV inhibitors available in BIOPEP. Bovine fibrinogen was hydrolyzed using papain, and four fractions were generated by ultrafiltration: FIB-NUFH, FIB-1UFH, FIB-3UFH, and FIB-10UFH.

following this process. Selected peptides were chemically synthesized for in vitro confirmation of their renin and ACE-I inhibitory activities. Moreover, the concentration of peptide required to inhibit the activity of ACE-I and renin by half (IC_{50}) was calculated for identified active renin and ACE-I inhibitory peptides, and their resistance to gastrointestinal digestion and bitter taste were predicted using in silico analysis.

MATERIALS AND METHODS

Materials and Reagents. Formic acid (FA), glycerol, tricine, dithiothreitol, ethanol, dimethyl sulfoxide (DMSO), acetonitrile (ACN), sodium citrate, papain from *Carica papaya*, the specific renin inhibitor Z-Arg-Arg-Pro-Phe-His-Sta-Ile-His-Lys-(Boc)-OMe, and the ACE-I inhibitor captopril were supplied by Sigma-Aldrich (Dublin, Ireland). The DPP-IV inhibitor screening assay kit, containing the DPP-IV inhibitor and positive control sitagliptin, and the renin inhibitor screening assay kit were supplied by Cambridge BioSciences (Cambridge, UK). The ACE-I inhibition assay kit was supplied by NBS Biologicals Ltd. (Cambridgeshire, UK). Tris-Tricine 10−20% SDS gels, sodium dodecyl sulfate (SDS), Coomassie Blue G-250, Coomassie Brilliant Blue R-250 destaining solution, and the Bio-Safe Coomassie Blue G-250 stain were purchased from Fischer Scientific (Dublin, Ireland). All other chemicals used were of analytical grade.

Blood Collection and Fractionation Procedure. Whole bovine blood was collected at time of slaughter under hygienic conditions in the abattoir at the Teagasc Food Research Centre, Ashtown, Dublin 15, Ireland. All animals slaughtered were female, Charolais cross heifer breed and were aged between 23 and 24 months. Sodium citrate solution was used as an anticoagulant and was added immediately to blood following collection at a final concentration of 1.5% (w/v). Blood was chilled to 4 °C and handled carefully to minimize hemolysis.

Whole blood cells were separated from plasma by centrifugation at 4 °C and 10000*g* for 10 min using a Sigma 6K10 centrifuge (Sigma Laborzentrifugen GmbH, Osterode am Harz, Germany). Plasma was kept at 4 °C, filtered through glass wool, and freeze-dried using an industrial scale freeze-drier, FD 80 model (Cuddon Engineering, Marlborough, New Zealand). The temperature was maintained at <35 °C during the freeze-drying process. A fibrinogen-rich protein fraction was obtained from the freeze-dried extract by precipitation following a previously described method.[13] Briefly, dehydrated plasma proteins were resuspended in Milli-Q water to a final concentration of 35 g/L, the pH was adjusted using 0.1 M HCl, and ethanol was added as the fractionation agent. A protein fraction rich in fibrinogen was obtained by precipitation after the addition of ethanol to plasma at a final concentration of 8% (v/v) and adjustment of the pH to 7.2. Ethanol was added drop by drop, and the process was carried out at temperatures close to 0 °C to minimize protein denaturation. Fibrinogen was separated by centrifugation at 4 °C and 10000*g* for 5 min, resuspended in water, frozen, and freeze-dried.

The total protein content was determined using a LECO FP628 Protein analyzer (LECO Corp., St. Joseph, MI, USA) based on the Dumas method and according to AOAC method 992.15, 1990. The conversion factor of 6.25 was used to convert total nitrogen to protein. The total protein content was calculated as shown in Figure 1.

In Silico Analysis. The amino acid sequence of bovine fibrinogen (UniProt ID: FIBA_BOVIN | UniProt AC: P02672; UniProt ID: FIBB_BOVIN | UniProt AC: P02676 and UniProt ID: FIBG_BOVIN | UniProt AC: P12799) was accessed from the UniProt database, available at http://www.uniprot.org/. The predicted cleavage sites of fibrinogen using the enzymes papain, pepsin (EC 3.4.23.1), trypsin (EC 3.4.21.4), bromelain (EC 3.4.22.4), ficain (EC 3.4.22.3), and thermolysin (EC 3.4.24.27) were calculated using BIOPEP, available at http://www.uwm.edu.pl/biochemia/index.php/pl/biopep.[14] These

DOI: 10.1021/acs.jafc.5b03167
J. Agric. Food Chem. 2015, 63, 8676−8684

enzymes were selected on the basis of the availability of cleavage information and their documented ease of use in the meat industry and in previous hydrolysis studies. The database BIOPEP was also used to compare the peptides generated in silico and the peptides identified by de novo peptide sequencing with previously reported ACE-I-, DPP-IV-, and renin-inhibiting bioactive peptides. PeptideRanker, available at http://bioware.ucd.ie, was used to predict peptides with bioactivities.[15]

Computer simulations of proteolysis were used to study the bioavailability of selected peptides after simulated gastrointestinal digestion using ExPASy PeptideCutter, available at http://web.expasy.org/peptide_cutter/, and gastrointestinal enzymes including pepsin (pH 1.3 and pH >2), trypsin (EC 3.4.21.4) and chymotrypsin (EC 3.4.21.1). The bitterness of the synthesized peptides was predicted using the "Q rule" in accordance with a previously published method.

Enzymatic Hydrolysis. Papain hydrolysates of the bovine fibrinogen enriched fraction were prepared in triplicate using a BioFlo 110 Modular Benchtop Fermentor (New Brunswick Scientific Co., Cambridge, UK) with agitation, temperature, and pH control. A substrate solution was prepared by resuspending the dried bovine fibrinogen in Milli-Q purified water at a concentration of 10 g/L at a total volume of 500 mL. Agitation, temperature, and pH conditions were adjusted to 350 rpm, 65 °C, and 6.5, respectively. The pH was kept constant using 0.1 M NaOH. Once the optimum pH and temperature conditions were achieved, the enzyme papain (activity ≥ 3 U/mg) was added in a substrate to enzyme ratio of 100:1 (w/w). After 24 h, papain was heat-deactivated at 95 °C for 10 min in a Grant JB Aqua 12 water bath (Grant Instruments, Cambridge, UK).

The non-ultrafiltered hydrolysate and the 1, 3, and 10 kDa permeate fractions obtained using MWCO membranes (Millipore, Tullagreen, Carrigtwohill, Co. Cork, Ireland) were labeled FIB-NUFH, FIB-1UFH, FIB-3UFH, and FIB-10UFH, respectively. All fractions were frozen, freeze-dried, and stored at −20 °C until further use.

Electrophoretic Separation Using Tris-Tricine Peptide Gels. Electrophoresis was carried out using a Bio-Rad Mini-PROTEAN 3 cell System (Bio-Rad Laboratories Ltd., Hertfordshire, UK) and a 10-well Mini-PROTEAN Tris-Tricine gel according to the manufacturer's instructions. Commercial low (1.7−42 kDa in size) and high (2−250 kDa in size) molecular weight (MW) markers were used.

Renin Inhibition Assay. This assay was carried out following a previously described method using a renin inhibitor screening assay kit in accordance with the manufacturer's instructions.[5] All fractions were assayed at a concentration of 1 mg sample/mL DMSO in triplicate and standard deviations (SD) calculated. Fluorescence intensity was recorded with a FLUOstar Omega microplate reader (BMG LABTECH GmbH, Offenburg, Germany) using an excitation wavelength of 340 nm and an emission wavelength of 500 nm. The known renin inhibitor Z-Arg-Arg-Pro-Phe-His-Sta-Ile-His-Lys-(Boc)-OMe was used as a positive control, and renin IC_{50} values were determined in triplicate for active peptides and hydrolysates by plotting the percentage of renin inhibition as a function of the concentration of test compound.

ACE-I Inhibition Assay. This assay was carried out following a previously described method using an ACE-I inhibitor assay kit and in accordance with the manufacturer's instructions.[5] All fractions were assayed at a concentration of 1 mg/mL HPLC grade water in triplicate, and means and SD were calculated. The known ACE-I inhibitor captopril was used as a positive control at a concentration of 1 mg/mL. Absorbance was measured with a FLUOstar Omega microplate reader (BMG LABTECH GmbH) at 450 nm. ACE-I IC_{50} values were determined for active hydrolysates and peptides by plotting the percentage of inhibition as a function of the concentration of test compound.

DPP-IV Inhibition Assay. This assay was carried out following a previously described method using a DPP-IV inhibitor screening assay kit and in accordance with the manufacturer's instructions.[5] All hydrolysates were assayed in triplicate, and means and SD were calculated. The known DPP-IV inhibitor sitagliptin was used as a positive control. Fluorescence intensity was recorded with a FLUOstar Omega microplate reader (BMG LABTECH GmbH) using an excitation wavelength of 355 nm and an emission wavelength of 460 nm. DPP-IV IC_{50} values were determined for active hydrolysates by plotting the percentage of inhibition as a function of the concentration of test compound.

De Novo Peptide Sequencing. The FIB-1UFH fraction of the papain hydrolysate of bovine fibrinogen was resuspended in HPLC grade water at a concentration of 1 mg/mL and filtered through a 0.45 μm CHROMAFIL Xtra PVDF-45/25 syringe filter (Macherey-Nagel GmbH & Co., Düren, Germany). The filtered hydrolysate was analyzed using a Q-TOF Premier mass spectrometer (Waters Corp., Milford, MA, USA), coupled to an Alliance 2695 HPLC system (Waters Corp.). The chromatographic separation was carried out at a flow rate of 0.2 mL/min with an injection volume of 10 μL on an Atlantis dC18 column, 100 mm × 2.1 mm, 3 μm particle size (Waters Corp.). Peptides were separated using 0.1% FA in HPLC grade water (solvent A) and 0.1% FA in ACN (solvent B). Column temperature was maintained at 40 °C. The gradient program was as follows: (i) 0 min, 98% A; (ii) 0−0.1 min, 98% A; (iii) 0.1−18 min, 90% A; (iv) 18−20 min, 85% A; (v) 20−21 min, 40% A; (vi) 21−22 min, 20% A; (vii) 22−25 min, 98% A; and (viii) 25−30 min, 98% A. HPLC-MS/MS was performed using a data-dependent acquisition (DDA) on electrospray ionization (ESI) in positive ion mode at 1 s scan. Argon was used as collision gas with the collision energy ramp from 15 eV for low MW peptides to 60 eV for high MW peptides. The tandem mass spectrometry (MS/MS) spectral data were deconvoluted using the MaxEnt 3 algorithm, and their amino acid sequences were determined using the peptide sequencing software available in the Waters Biolynx software package.

Chemical Synthesis. Peptides were synthesized by microwave-assisted solid phase peptide synthesis (MW-SPPS) performed on a Liberty CEM microwave peptide synthesizer (Mathews, NC, USA). Peptides were synthesized on H-Ala-HMPB-ChemMatrix and H-Ile-HMPB-ChemMatrix resins (PCAS Biomatrix Inc., Quebec, Canada) and purified using RP-HPLC on a Semi Preparative Jupiter Proteo (4u, 90A) column (Phenomenex, Cheshire, UK). Fractions containing the desired molecular mass were identified using matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) and were pooled and freeze-dried on a Genevac HT 4X lyophilizer (Genevac Ltd., Ipswich, UK).

Statistical Analysis. All tests were replicated three times, and mean values and SD were calculated. ANOVA one-way analysis was carried out using Minitab v17 (Minitab Ltd., UK). When significant differences were present, a Tukey pairwise comparison of the means was conducted to identify where the sample differences occurred.

RESULTS AND DISCUSSION

In Silico Analysis. In silico analysis was previously shown to be an efficient method to predict the release of bioactive peptides with prolyl endopeptidase- (PEP; EC 3.4.21.26), ACE-I-, and DPP-IV-inhibiting properties.[5−7,16] In this work, a bovine fibrinogen enriched protein fraction was generated and hydrolyzed using papain to generate bioactive peptides with ACE-I, renin, and DPP-IV inhibitory activities. Bovine fibrinogen is composed of two sets of disulfide-bridged α-, β-, and γ-chains.[17] The amino acid sequences of bovine fibrinogen α-, β-, and γ-chains were accessed from the UniProt database. In silico analysis was carried out using BIOPEP to select a suitable enzyme to generate a hydrolysate rich in bioactive peptides with potential to inhibit ACE-I, renin, and DPP-IV (Figure 1). A number of enzymes including papain, pepsin, trypsin, ficain, bromelain, and thermolysin were trialled using in silico analysis to generate peptides from bovine fibrinogen. Table 1 describes the number of known ACE-I-, renin-, and DPP-IV-inhibiting peptides, available in BIOPEP, which were generated in this study from bovine fibrinogen using selected enzymes in silico. Few renin inhibitory peptides were predicted to be released from bovine fibrinogen by in silico cleavage

compared to ACE-I and DPP-IV inhibitory peptides. This may be due to the limited reports that exist regarding the generation of renin inhibitors from natural sources. Renin and DPP-IV inhibitory peptides generated in silico include the peptides IR and FA, corresponding to $f(180-181)$ and $f(533-534)$ of the α-chain of bovine fibrinogen. The peptide FA was previously reported to inhibit DPP-IV,[18] and the peptide IR was previously generated from pea protein and was reported to have a renin IC_{50} value of 9.2 ± 0.2 mM.[19] Papain was the enzyme selected for use in vitro in this study. Papain was used previously to generate ACE-I and renin inhibitors as well as antioxidant peptides from seaweed as well as bovine proteins.[20,21] Moreover, papain was found to generate the largest number of known ACE-I- and renin-inhibiting peptides from fibrinogen. In addition, application of papain to bovine fibrinogen generated 48 DPP-IV-inhibiting peptides. This compared favorably to the enzymes pepsin, trypsin, bromelain,

and thermolysin, which generated 8, 4, 22, and 22 DPP-IV inhibitory peptides, respectively, following in silico analysis (Table 1).

Generation of a Bovine Fibrinogen-Enriched Protein Fraction. Plasma constitutes approximately 65−70% of the total weight of blood and can be separated from the cellular fraction by centrifugation.[22] Yields for cellular and plasma fractions were calculated as 61.65 ± 0.31 and 38.35 ± 0.32% for the plasma and the cellular fraction, respectively. Moreover, the yield of the fibrinogen-rich fraction was found to be 1.5 ± 0.2 g/L. This fraction was analyzed by electrophoresis using a Tris-Tricine 10−20% peptide gel. Results, shown in Figure 2, suggest that although some impurities were present in the isolated fraction, fibrinogen was the main constituent with bands shown at 63.5 kDa (α-chain), 56 kDa (β-chain), and 47 kDa (γ-chain). In addition, the total protein content of the fibrinogen-rich fraction generated following the procedure described in Figure 1 was determined as 87.9 ± 0.3% using the LECO method. This value is comparable to the protein contents obtained in previous hydrolysis studies where high protein yields were obtained following hydrolysis of peanut.[23] In addition, the use of fibrinogen in combination with the enzyme thrombin was determined as safe for human consumption by the European Food Safety Authority (EFSA) in 2005.[24] Bovine blood proteins including hemoglobin and serum albumin have previously been used for the generation of bioactive proteins,[1,4] but to the best of our knowledge, no ACE-I, renin, or DPP-IV inhibitors have been generated from bovine fibrinogen to date. The identification of bioactive peptides within the sequence of bovine fibrinogen adds further value to this protein product. Electrophoresis results, shown in Figure 2, demonstrate that the generated fibrinogen protein fraction was hydrolyzed by papain and that the fractions generated by MWCO filtration consist mainly of peptides with MW <10 kDa. This is clear from the gel as the bands present at positions 63.5, 56, and 47 kDa no longer appear in the 10, 3, and 1 kDa fractions. Bands are shown in the low molecular weight range (1.7−10 kDa range).

ACE-I and Renin Inhibitory Activities in Vitro. The in vitro ACE-I and renin inhibitory activities of the generated hydrolysates were calculated and are shown in Figure 3. At a concentration of 1 mg/mL, fraction FIB-1UFH inhibited ACE-I by >50% compared to the positive control captopril, which had an ACE-I inhibitory activity of 88.10 ± 4.75%. The ACE-I IC_{50} values of FIB-NUFH, FIB-1UFH, FIB-3UFH, and FIB-10UFH were calculated and determined as 1.86 ± 0.12, 0.92 ± 0.08, 1.41 ± 0.09, and 1.55 ± 0.09 mg/mL, respectively. Ultrafiltration of FIB-NUFH led to increased ACE-I inhibitory activity, and the FIB-1UFH fraction had the lowest ACE-I IC_{50} value compared to the FIB-NUFH, FIB-10UFH, and FIB-3UFH fractions ($p < 0.05$). These results are consistent with the fact that peptidic ACE-I inhibitors usually consist of short amino acid sequences.[25] Results are comparable to inhibition values obtained for other protein hydrolysates, where sequential ultrafiltration of blood protein hydrolysates with 10, 3, and 1 kDa membranes resulted in increased ACE-I-inhibiting activity.[26]

Furthermore, the renin inhibitory activity of the generated hydrolysates was measured at a concentration of 1 mg/mL. Again, MWCO led to a significant increase in the renin-inhibiting activity of the FIB-1UFH fraction compared to the FIB-NUFH, FIB-10UFH, and FIB-3UFH fractions ($p < 0.05$). These results are consistent with the fact that dipeptides were

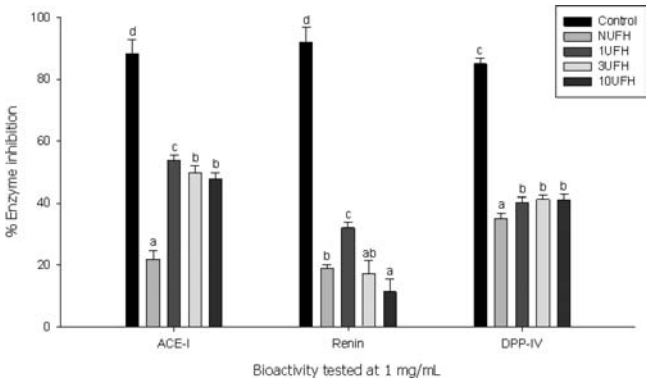

Figure 3. ACE-I-, renin-, and DPP-IV-inhibiting properties in vitro of studied papain hydrolysates and ACE-I, renin, and DPP-IV inhibitory bioactivities of papain hydrolysates of bovine fibrinogen when tested in vitro at a sample concentration of 1 mg/mL. Z-Arg-Arg-Pro-Phe-His-Sta-Ile-His-Lys-(Boc)-OMe, sitagliptin, and captopril were used as positive controls for renin, DPP-IV, and ACE-I, respectively. Enzyme inhibition is expressed as percent inhibition, and the values represent the means of three independent experiments ± SD. For each bioactivity tested, bars with different letters have mean values that are significantly different ($p < 0.05$).

previously suggested as the most effective for renin inhibition.[19] Furthermore, long peptides present within a hydrolysate can mask the activity of small active peptides. The activity of the FIB-10UFH fraction was lower than that of FIB-NUFH ($p < 0.05$). This may be due to the presence of one or more polypeptides with renin inhibitory properties within the FIB-NUFH fraction, as longer peptides such as IRLIIVLMPILMA have been reported to inhibit renin.[21] The fraction FIB-1UFH was the most active and inhibited renin by 32.09 ± 1.93%. This result concurs with previously reported research on flaxseed protein hydrolysates and renin inhibitory activities.[27] In this work, flaxseed was hydrolyzed with Thermoase and only a marginal improvement in renin inhibitory activity was observed for virtually all samples after membrane ultrafiltration.[27] No studies regarding the use of blood proteins for the generation of renin-inhibiting hydrolysates and peptides have been carried out to date.

In Vitro DPP-IV Inhibitory Activity. The in vitro DPP-IV inhibitory activity of the studied fractions was calculated, and results are shown in Figure 3. All studied fractions showed a moderate inhibition of DPP-IV. The most active fraction, FIB-3UFH, inhibited DPP-IV by 41.29 ± 1.17% when tested at a concentration of 1 mg/mL. The DPP-IV IC_{50} value of this fraction was calculated and was 1.03 ± 0.01 mg/mL. A slight increase in the DPP-IV-inhibiting activity of the ultrafiltered fractions compared to the nonultrafiltered fraction was observed ($p < 0.005$). The removal of higher MW fractions previously led to an increase in the DPP-IV inhibitory activity in vitro.[28] Moreover, most of the peptides with DPP-IV inhibitory activity described in the literature to date are between two and eight amino acid residues in length.[7] The DPP-IV-inhibiting activities of the papain hydrolysates generated in this study were comparable to those of other hydrolysates from natural sources. These include the trypsin hydrolysates of *Amaranthus hypochondriacus* L. proteins, with IC_{50} values ranging from 1.2 to 2.0 mg/mL, depending on the enzyme to substrate ratio,[28] and a Flavourzyme hydrolysate of Atlantic salmon gelatin with an IC_{50} value of 1.35 mg/mL.[29] The IC_{50} values obtained herein were also similar to those

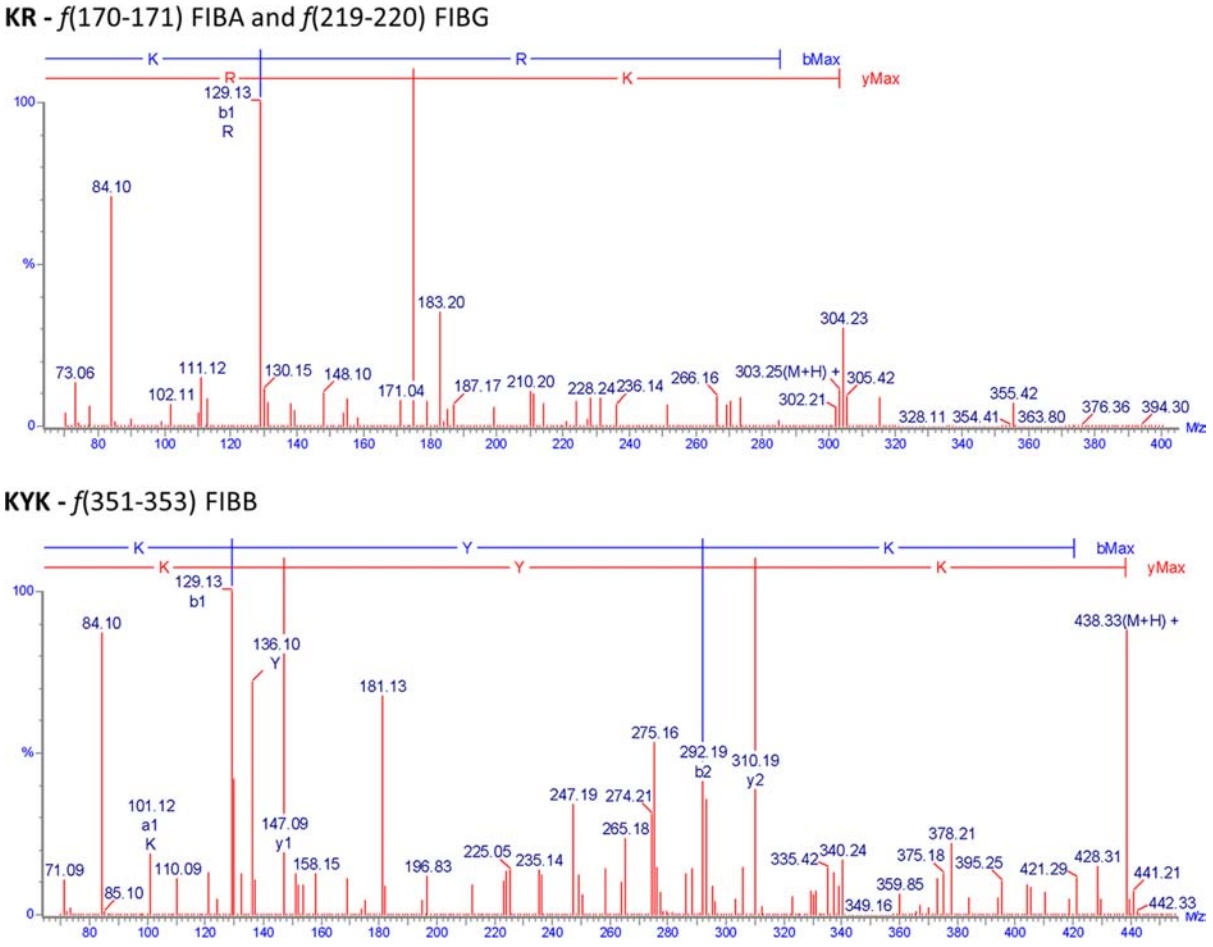

Figure 4. ESI-MS/MS spectra for de novo sequence determination of peptides KR and KYK. Peptides KR, FR, YF, RR, YR, SLK, SPR, and KYK were identified by de novo peptide sequencing software within the BioLynx software package (Waters Corp., Milford, MA, USA).

obtained from a trypsin hydrolysate of whey protein, which had an IC_{50} value of 1.51 mg/mL. The pentapeptide IPAVF, corresponding to β-lactoglobulin $f(78-82)$, had an IC_{50} value of 44.7 μM and was responsible for the observed DPP-IV inhibitory activity.[30]

Peptide Identification by de Novo Peptide Sequencing. The characterization of bioactive peptides within an active protein hydrolysate is of key importance. To identify bioactive peptides, it is often necessary to fractionate and purify the whole hydrolysate using filtration and chromatography methods. Today, widely used methods for peptide fractionation and enrichment include ultrafiltration and liquid chromatography.[31] In this study, the identification of peptides contained in FIB-1UFH was carried out using HPLC-MS/MS. A total of 20 di-, tri-, and tetrapeptides were identified by de novo peptide sequencing as represented in Figure 4. These peptides are listed in Table 2 together with their position in the parent protein and their observed masses as well as their calculated masses. Identified bioactive peptides were compared to previously reported ACE-I, DPP-IV, and renin inhibitors available in the database BIOPEP.[14] A number of the identified peptides were bioactive and were previously generated from various natural sources. For example, the peptide RR was generated by the action of dipeptidyl peptidases purified from porcine skeletal muscle and was reported to inhibit ACE-I.[32] There were sequence similarities between the peptides identified in this study and previously reported ACE-I and DPP-IV inhibitors available in BIOPEP, as shown in Table 2. For example, the peptide RR, corresponding to $f(145-147)$ and $f(452-453)$ of the α-chain of bovine fibrinogen, was found to share the same peptides at the C-terminus of the peptide with the previously reported DPP-IV inhibitor WRR, which had a reported DPP-IV IC_{50} value of 570 $\pm$ 62 μM.[33]

Chemical Synthesis and Confirmation of Bioactivity. A number of the identified peptides were selected for chemical synthesis and bioassay assessment. PeptideRanker scores were calculated for each peptide and are shown in Table 2. Peptide selection for chemical synthesis was based on the current knowledge of bioactive peptides, the known attributes of ACE-I and renin inhibitors, and the score assigned by PeptideRanker to each peptide (Table 2). The amino acids tryptophan, tyrosine, proline, and phenylalanine were reported previously as the most effective amino acids in an ACE-I-inhibiting peptide when they are present at the C-terminal side of a dipeptide.[34] A quantitative structure−activity relationships study (QSAR), which modeled biological activity of ACE-I-inhibiting peptides as a function of molecular structure, suggested that amino acid residues with large bulky chains as well as hydrophobic side chains such as found in the amino acids phenylalanine, tryptophan, and tyrosine are the most effective residues in a dipeptide.[25] Amino acid residues with small as well as hydrophobic side chains, which include valine, leucine, and isoleucine, were suggested for the N-terminal side of ACE-I inhibitory peptides. Hydrophobic amino acid residues with high

[a]Data accessed from PeptideRanker, available at http://bioware.ucd.ie/ in April 2015. [b]Data accessed from BIOPEP, available at http://www.uwm.edu.pl/biochemia/index.php/pl/biopep in April 2015.

electronic properties such as proline, phenylalanine, and tryptophan are usually found at the C-terminal end of active ACE-I inhibitory tripeptides.[25] Furthermore, dipeptides with hydrophobic residues at the N-terminus and a bulky or aromatic group at the C-terminus were observed to be the most effective peptides for renin inhibition.[19]

The dipeptides KR, FR, YF, RR, and YR and the tripeptides SLR and KYK were chemically synthesized by MW-SPPS and tested for ACE-I- and renin-inhibiting properties in vitro. The IC_{50} values were determined for active peptides by plotting the percentage of enzyme inhibition as a function of the concentration of test compound. At a concentration of 1 mg/mL, the peptides KR, FR, YF, YR, SLR, and KYK inhibited ACE-I by >60%. ACE-I IC_{50} values were calculated for active peptides and were found to be 383.76 ± 1.64, 425.12 ± 21.49, 94.62 ± 5.83, 124.12 ± 8.40, 171.95 ± 25.44, and 280.12 ± 33.14 μM for KR, FR, YF, YR, SLR, and KYK, respectively. The peptide RR is a known ACE-I inhibitor with an IC_{50} value of 267.1 ± 11.3 μM.[32] No ACE-I peptide inhibitors have been generated from bovine fibrinogen to date. However, the ACE-I-inhibiting activity of the peptides identified in this study compared favorably to ACE-I-inhibiting peptides generated from bovine blood proteins such as hemoglobin.[35] These include the peptides corresponding to *f*(67−106), *f*(73−105), and *f*(100−105) of the α-chain of bovine hemoglobin, which inhibited the activity of ACE-I by half at a concentration of 366, 518, and 1095 μM, respectively.[35] Selected peptides were also screened for their ability to inhibit renin. Only the dipeptide YR and the tripeptide SLR were found to inhibit renin with IC_{50} values of 8.78 ± 0.37 and 7.29 ± 0.16 mM, respectively. These results compare favorably to previously describe renin inhibitors including the peptides IR and IRLIIVLMPILMA, generated by enzymatic hydrolysis of pea and seaweed proteins and with calculated IC_{50} values of 9.2 and 3.3 mM, respectively.[19,21]

Prediction of Resistance to Gastrointestinal Degradation and Bitterness. The use of bioactive peptides as functional ingredients is usually limited by a number of issues including low stability of the peptides against gastrointestinal degradation. Although bioavailability should be assessed in vivo, resistance of a peptide to degradation can be predicted by computer simulations of proteolysis. In this study, the in silico tool ExPASy PeptideCutter was used to predict the stability of the identified bioactive peptides after a simulated gastrointestinal digestion. Results suggest that the peptide RR may be resistant to degradation by pepsin, trypsin, and chymotrypsin. The peptides FR, YR, and YF were predicted to be cleaved by both pepsin and chymotrypsin into the amino acids phenylalanine and arginine, tyrosine and arginine, and tyrosine and phenylalanine, respectively. Moreover, the peptide KR was

DOI: 10.1021/acs.jafc.5b03167
J. Agric. Food Chem. 2015, 63, 8676−8684

predicted to be degraded by trypsin, and the tripeptides SLR and KYK were predicted to be broken down into the dipeptides SL and LR and KY and YK, respectively. The peptides SL and KY are known DPP-IV inhibitors, and the peptides KY and YK were both previously reported to inhibit ACE-I and are available in BIOPEP.

Bioactive hydrolysates and peptides are usually bitter in taste, and Western consumers do not seem to be willing to compromise taste for health benefits.[36] A number of methods have been used to predict the bitterness of a peptide. The "Q rule" formulated by Ney[37] quantifies the bitterness of a peptide on the basis of its amino acid composition, whereby a Q value is calculated from the solubility data of the individual amino acids. According to this method, when the Q value of a peptide, with a MW under 6 kDa, exceeds 1400 cal/mol, this peptide will be almost certainly bitter. The Q values for the peptides KR, FR, YF, RR, YR, SLR, and KYK were 1125.0, 1337.0, 2400.0, 750.0, 1525.0, 950.0, and 1766.6 cal/mol, respectively. Obtained Q values suggest that the peptides YF, YR, and KYK may be bitter in taste. Moreover, the Q value of peptides generated by the action of digestive enzymes in silico was also calculated. The peptides SL, LR, KY, and YK, which were predicted to be generated by the cleavage of the tripeptides SLR and KYK, had Q values of 1050.0, 1275.0, 1900.0, and 1900.0 cal/mol, respectively. The peptide KYK was predicted to be degraded by gastrointestinal enzymes and to be cleaved into the peptides KY and YK, which had higher predicted Q values and therefore could have enhanced bitterness following digestion. Ney's rule can be applied to the majority of known peptides, but there are exceptions. For example, a recent study characterized the flavor, chemical properties, and hydrophobicity of a number of peptides derived from two commercial enzymatic hydrolysates of soy protein. The obtained hydrophobicity data based on Q values did not support Ney's rule as a predictor of bitterness.[38]

In this work a sequential fractionation and enrichment methodology was used to generate fibrinogen-enriched fractions with inhibitory activities against the enzymes ACE-I, DPP-IV, and renin. This is the first report that evaluates the ACE-I, renin, and DPP-IV inhibitory activity from papain hydrolysates of bovine fibrinogen. Results presented in this study show the presence of biologically active peptides with renin- and ACE-I-inhibiting properties. These peptides were encrypted in bovine fibrinogen and released by enzymatic cleavage with the food-grade enzyme papain. The generated papain hydrolysates and peptides were found to inhibit renin, ACE-I, and DPP-IV, and the percentage inhibition values obtained compared favorably with those found previously for hydrolysates and peptides isolated from animal and plant sources. A number of known as well as novel bioactive peptides were generated and identified. The peptides identified herein were predicted to be bitter and to be degraded by digestive enzymes in silico. However, in silico analysis is not enough to predict the resistance of a peptide to degradation and its taste, and in vivo studies in animal models are required to assess the bioavailability of a peptide after ingestion. These results demonstrate the potential of bovine fibrinogen as a resource for bioactive peptide generation and opens new commercial opportunities for its use beyond its current applications in the food industry.

offering an array of tools to valorize bran matrix without altering its nutritional benefits.[2,9] Bioprocessing of rye and wheat bran with microbes and hydrolytic enzymes improved the bioaccessibility of phenolic compounds, significantly impacted the dietary fiber and protein fraction, and enhanced the overall nutritional quality.[10−12] Fermentation with *Lactobacillus brevis* E95612 and *Kazachstania exigua* C81116 in the presence of an enzyme mixture having carbohydrase activity improved the nutritional properties of wheat bran fractions, including proteins.[10] In a recent study, bran treatment with proteolytic enzymes was shown to significantly increase the solubilization of the protein mostly in the subaleurone layer, whereas they were less effective on the proteins in the aleurone cells.[13] Innovative and simple transformation processes are the key to exploit the nutritional quality of bran matrix and are also applicable to industrial production. However, more knowledge on the mechanisms underlying protein bioaccessibility should still be acquired to enhance the potential of the protein component of bran.

This article will focus on the release and modification of the protein fraction of wheat bran after enzymatic and microbial bioprocessing. A coarse bran fraction, characterized by a more-intact cell wall structure[11] was used in order to assess the role of the endogenous enzymatic activity, alone or in combination with cell-wall-degrading enzymes and microbial fermentation, on protein changes during bioprocessing. The effects on in vitro protein digestibility, phytase activity, and release of total phenols were also evaluated.

MATERIALS AND METHODS

Raw Material, Enzymes, And Microorganisms. The commercial wheat bran used in this study (Fazer Mills, Lahti, Finland) had a particle size of 750 μm and the following chemical composition: total dietary fiber, 44.3 ± 0.60%; starch, 16.8 ± 0.16%; fermentable sugars, 3.57 ± 0.24%; protein, 15.98 ± 0.12%; and fat, 4.1 ± 0.10%.

Two commercial enzymes, Depol 761P (Biocatalysts Ltd., Cardiff, UK) and Viscoferm, were used for bran treatments. The xylanase, β-glucanase, polygalacturonase, acidic protease, cellulase, endoglucanse, and ferulic acid esterase activity were measured according to the methods reported by Santala et al.[14] The resulting activity profile of the two enzymes is described in Table 1.

L. brevis E-95612 and *Candida humilis* E-96250, belonging to VTT Culture Collection (VTT, Technical Research Centre of Finland), were used as starters for fermentation. *L. brevis* E95612 was cultivated for 24 h at 30 °C in MRS (Oxoid LTD, Basingstoke, Hampshire, UK) under anaerobic conditions, whereas *C. humilis* E-96250 was cultivated for 24 h at 25 °C in YM (3 g/L malt extract, 3 g/L peptone, and 10 g/L dextrose). After the late exponential phase of growth was reached, cells were recovered by centrifugation (10 000 g for 10 min), successively washed twice in 0.05 M phosphate buffer (pH 7.0), and resuspended in tap water (ca. 15% of the initial volume of the culture).

Bioprocessing of Bran. A mixture of wheat bran and water (20:80 w/v) was treated with the addition of enzymes, antibiotics, and/or lactic acid bacteria and yeast according to Table 2, obtaining six different bioprocessing combinations. In three samples, aiming at the evaluation of the enzymatic activity of endogenous (End), exogenous (E), and endogenous + exogenous enzymes (End/E) respectively, the antibiotics cycloheximide (0.01% w/w) and chloramphenicol (0.01% w/w) were added into the mixture to prevent microbial growth. The pH of samples End and End/E was adjusted to 4.5 by an organic acid buffer (lactic acid/acetic acid at a 4:1 molar ratio) in order to activate the endogenous enzymes of wheat bran.[15] The enzyme preparations were dosed at 100 nkat/g bran according to their xylanase activity, and the enzymes were added at the beginning of fermentation to the samples E, End/E, St/E, and Sp/E. In controlled fermentations (St and St/E), the starter microorganisms *L. brevis* E-95612 and *C. humilis* E-96250 were both inoculated at a cell density of ca. 6.0 log cfu/g of sample. Sample Sp/E was incubated only with the addition of enzymes to evaluate the effect of the spontaneous fermentation. All the samples were incubated for 24 h at 30 °C. A control (ct) sample, corresponding to a mixture of bran and water prepared as described above, was frozen at −20 °C after preparation (time 0).

Table 2. Bioprocessing Combinations of the Bran/Water Mixtures*

sample	bioprocessing (bran/water mixture 20:80 w/v)	Depol 761P and Viscoferm	starter	antibiotics	chemical acidification
ct	no bioprocessing (time 0)				
End	endogenous enzymes activity			+	4.5
E	enzymatic processing (exogenous enzymes)	+		+	
End/E	enzymatic processing (endogenous + exogenous enzymes)	+		+	4.5
St	controlled fermentation		+		
St/E	controlled fermentation + exogenous enzymes	+	+		
Sp/E	spontaneous fermentation + exogenous enzymes	+			

*All the mixtures were incubated at 30°C for 24 h except for control bran (ct). The initial pH of samples End and End/E was adjusted with a solution lactic acid/acetic acid in 4:1 molar ratio.

Water/salt-soluble extracts (WSE) were prepared from each sample according to the method originally described by Osborne and modified by Weiss et al.[16] An aliquot of sample (37.5 g) was diluted with 30 mL of Tris-HCl 50 mM (pH 8.8), held for 1 h at room temperature under stirring conditions, and centrifuged at 20 000 g for 20 min. The supernatants, containing the water/salt-soluble nitrogen fraction were freeze-dried and used for further analyses.

Microbiological Analyses and pH Determination. Bran samples (10 g) were homogenized with 90 mL of sterile saline in a Stomacher 400 lab blender (Seward Medical, London). Serial dilutions were made, and enumeration of the main microbial groups was carried out. Lactic acid bacteria count was obtained by plating on MRS agar (Oxoid) at 30 °C for 48 h; yeasts were counted on YM agar after incubation at 25 °C for 48 h. Total *Enterobacteriaceae* were counted on VRGBA agar (Oxoid) after incubation at 37 °C for 24 h, and total aerobic bacteria count was carried out on PCA agar (Oxoid) at 30 for 48 h. The pH value was measured on-line by a Foodcare pH meter HI99161 (Hanna Instruments, Woonoscket, USA).

Chemical Analyses. The moisture contents of the samples were determined by drying in oven at 130 °C for 1 h. Aiming at the determination of the protein and protein derivatives, the organic

*Samples with same letter among the group and column have no statistical difference ($p > 0.05$). Values in the same column with different letter differ significantly ($p < 0.05$). RP-FPLC chromatograms are available in the Supporting Information.

nitrogen concentration of samples and corresponding WSE was analyzed with the Kjeldahl method (AACC) 46-11A.[17] The organic nitrogen solubilized after bioprocessing was calculated as follows:

$$\text{Solubilized organic nitrogen ratio (\%)} = \frac{\text{organic nitrogen in WSE}}{\text{total organic nitrogen}} \times 100$$

To evaluate the degree of proteolysis during bioprocessing, the concentration of proteins, peptides and free amino acids was determined in WSE. In details, the concentration of proteins was determined by Bradford method.[18] The concentration of peptides in the WSE was determined by the *o*-phtaldialdehyde (OPA) method as described by Church et al.[19] Peptide profiles were obtained by reversed-phase fast protein liquid chromatography (RP-FPLC), using a Resource RPC column and ÄKTA FPLC equipment, with a UV detector operating at 214 nm (GE Healthcare Bio-Sciences AB, Uppsala, Sweden) as described in Coda et al.[11] Free amino acids were analyzed by a Biochrom30 series Amino Acid Analyzer (Biochrom Ltd., Cambridge Science Park, UK) with a Na-cation-exchange column (20 cm × 0.46 cm internal diameter) as reported in Coda et al.[11]

The water-extractable pentosan (WE-pentosan) content was analyzed as described by Santala et al.,[21] and the reducing sugars content was estimated with the dinitrosalicylic acid method.[22] Phytase activity was measured as described by Shimuzu[23] and expressed as the amount of inorganic orthophosphate released from the phytic acid by phytase.

Analysis of total phenols was carried out in agreement with the method of Slinkard and Singleton[24]on methanolic extracts. The concentration of total phenols was expressed as gallic acid equivalent (mmol/100 g).

In Vitro Protein Digestibility. The in vitro digestibility of the samples was determined by the method of Akeson and Stahmann.[20] A known amount of sample was incubated with 1.5 mg of pepsin in 15 mL of 0.1 M HCl at 37 °C for 3 h. After neutralization with 2 M NaOH and addition of 4 mg of pancreatin in 7.5 mL of phosphate buffer (pH 8.0), 1 mL of toluene was added to prevent microbial growth, and the solution was incubated for 24 h at 37 °C. After 24 h, the enzyme was inactivated by addition of 10 mL of trichloroacetic acid (20%, wt/vol), and the undigested protein was precipitated. The volume was increased to 100 mL with distilled water, and the mixture was centrifuged at 5000 rpm for 20 min. The precipitate was subjected to protein extraction, according to Weiss et al.,[16] and the concentration of protein was determined. The in vitro protein digestibility of the bran samples was expressed as the percentage of the total protein that was solubilized after the in vitro enzyme hydrolysis mimicking the in vivo digestion in the gastrointestinal tract.[20]

Electrophoresis. The water/salt-soluble protein fraction was extracted from the freeze-dried sample as described by Weiss et al.[16] using 50 mM tris-HCl (pH 8.8). The extracts were analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE)[25] The samples were mixed at a ratio of 1:1 with SDS sample buffer, boiled for 10 min, and 10 μL of sample was pipetted to NuPage Bis-tris 12% minigels (Invitrogen, Waltham, MA). As a protein standard, Novex Sharp Prestained was used (10−250 mol/g, LC5800, Invitrogen, Waltham, MA). After the run (2 h, 200 V, 100 mA), the gels were stained overnight by Coomassie blue and destained with water until clear gels were achieved.

Statistical Analyses. The results were calculated as means of at least four analysis results. The data was analyzed by one-way ANOVA with using a Bonferroni adjustment to test for significance ($p > 0.05$) among the replicates. The statistics were carried out with IBM SPSS Statistics, version 22. When the response differed significantly ($p < 0.05$), it was indicated with a different letter. Biochemical properties of the bran samples were analyzed through principal component analysis[26] (PCA), using the software Statistica 8.0 (StatSoft Inc., Tulsa, USA).

RESULTS AND DISCUSSION

Effect of Bioprocessing on Microbiological Quality, Acidity, and Cell-Wall Degradation of Bran. Microbiological analysis was carried out before and after bioprocessing to monitor the impact of the microbial population on the different treatments. Before bioprocessing, the bran/water mixture (time 0) was characterized by total mesophilic bacteria cell density varying from 5.0 ± 0.3 to 6.6 ± 0.1 log cfu/g, total *Enterobacteriaceae* cell density of 4.0 ± 0.1 log cfu/g, and lactic acid bacteria and yeast cell densities below 3.0 and 2.0 log cfu/g, respectively. After bioprocessing, no microbial growth was detected in the samples that were chemically acidified and/or that had enzymes added (End, E, and End/E), confirming the efficiency of the antibiotic. In the treatments in which *L. brevis* E-95612 and *C. humilis* E-96250 were used as starters for fermentation (St and St/E), the cell density of lactic acid bacteria showed an increase of ca. 3 log cycles after fermentation, reaching values of 9.9 ± 0.1 log cfu/g in the case of enzyme-added sample (St/E). The yeast cell density increased of ca. 2 log cycles, reaching a final value of 8.6 ± 0.1 log cfu/g (St/E). No *Enterobacteriaceae* were detected in 10 g of sample in conditions of controlled fermentation. In comparison with controlled fermentation, the sample subjected to spontaneous fermentation (Sp/E) was characterized by similar lactic acid bacteria cell density (9.4 ± 0.0 log/cfu g), higher total enterobacteria cell density (7.8 ± 0.1 log cfu/g), and lower yeast density (4.0 ± 0.2 log/cfu g). The total mesophilic bacteria count was comparable among all the fermented samples, varying from 9.4 ± 0.7 to 9.9 ± 0.0 log cfu/g. No significant difference between the controlled fermentations was observed in terms of microbial growth because similar cell counts were obtained for both the starters, with or without

DOI: 10.1021/acs.jafc.5b03495
J. Agric. Food Chem. 2015, 63, 8685−8693

the addition of enzymes. On the contrary, spontaneous fermentation was characterized by a different microflora, even though a high cell density of lactic acid bacteria was still present. The initial values of pH for enzyme-added bran (E) and for chemically acidified bran (End and End/E) were 6.7 or 4.5, respectively, and did not show any significant variation throughout bioprocessing. From an initial pH value of 6.7, after 24 h of fermentation, samples St, St/E, and Sp/E reached pH values in the range 4.3−3.7, showing the lowest value when starter and enzymes were added (St/E).

Spontaneous fermentations are the result of competitive activities of a variety of autochthonous and contaminating microorganisms, and compared to controlled fermentation, they are characterized by a more complex microbiota. This also reflects on the acidification properties of the fermented matrix, which typically occurs faster when starter cultures are used independent of the final cell density of lactic acid bacteria.[27] The interaction between exogenous enzymes and starter microorganisms is evident in the final pH value of the controlled fermentation. It was already shown that in the presence of xylose, ribose, or arabinose not only a higher acidification rate but also higher growth rate and cell yield can be expected.[28]

WE-pentosan and reducing sugar content were determined to monitor the effect of the treatments on cell wall degradation (Table 3). In the chemically acidified and/or enzyme-added treatments, (End, E, and End/E), the addition of hydrolytic enzymes increased WE-pentosan and reducing sugar content by 2.7−3.5- and 24−37-fold, respectively, in comparison with those of ct. The highest amount of soluble carbohydrates were shown by treatment End/E (4.9% and 364.7 mg/L of WE-pentosan and reducing sugar, respectively), where the action of endogenous hydrolytic activity was supported by enzyme addition. Also, the high cellulase activity of Viscoferm (Table 1) could have impacted on the final carbohydrate content of the chemically acidified sample End/E. The consumption of carbohydrates during fermentation was visible as the lower content of WE-pentosans and reducing sugar of the fermented samples in comparison with those of the previous samples. The higher content of reducing sugar observed in the spontaneous fermentation Sp/E (189.2 g/L) confirms a slower growth/acidification process if compared to that of the controlled fermentation (Table 3). Because controlled fermentation was characterized by higher cell density of the starters relative to the beginning of bioprocessing, microbial metabolism occurred at a faster rate, therefore affecting the final carbohydrate concentration.

Impact of Bioprocessing on Protein Solubility and Proteolysis. The solubility of wheat bran proteins and protein derivatives (peptides and free amino acids) after different treatments was evaluated in the water/salt-soluble extract by different methods. The Kjeldahl method, determining the organic nitrogen, was used to estimate the overall solubilization of all the proteinaceous compounds, whereas the degree of proteolysis was investigated by the determination of the concentration of proteins, peptides, and free amino acids (Table 3). In untreated bran (ct), the total solubilized organic nitrogen ratio was 14%. The most significant increase of solubilized organic nitrogen (corresponding to 74.7%) was achieved by treatment End, representing the sole activity of bran endogenous enzymes. In this treatment, the pH of the sample was adjusted to ca. 4.5 to achieve rapid activation of the endogenous proteinases.[15] A significantly lower solubilization value (39.1%) was observed for the treatment in which only the added enzymes were active (treatment E), as a consequence of the high pH (ca. 6.7) maintained throughout the processing. An intermediate value of organic nitrogen solubilization (62.6%), was obtained through the combined activity of endogenous and exogenous enzymes (End/E), which was also subjected to pH adjustment. In the fermented samples, the use of starters alone or with the addition of enzymes (St and St/E, respectively) did not show significantly different values of solubilized organic nitrogen (52%), whereas the lowest increase (34.2%) was observed for the bran spontaneously fermented in the presence of enzymes (Sp/E). This difference might be due to the acidification conditions during fermentation because optimal pH values for bran proteases were reached in a longer time when spontaneous fermentation occurred, in comparison with the faster acidification due to the starter metabolism. This could also explain the lowest value of nitrogen solubilization observed in Sp/E, in which the acidification process was the slowest among the fermented samples. Overall, pH values during bioprocessing seemed to have the strongest impact on protein solubilization and were enhanced in the treatment in which pH 4.5 was kept throughout the bioprocessing (End and End/E) or when optimal pH was achieved by a more effective acidification (St and St/E). The protein concentration in the water/salt-soluble extract as measured by Bradford assay was highest (1.2−1.1 mg/mL) in the samples in which only the activity of endogenous and/or added enzymes was involved (End, E, and End/E) with no significant difference among the samples. In the fermented samples, the use of the starters alone (St) showed the highest protein concentration (0.8 mg/mL), whereas no significant difference was shown by the treatments St/E and Sp/E, showing the lowest amount of protein (Table 3). The water/salt-soluble extracts, containing low-molecular-mass peptides naturally present in samples or deriving from protein degradation during bioprocessing, were analyzed with OPA method and liquid chromatography. The peptide content of the water/salt-soluble extract of the bioprocessed brans ranged from 15.0 to 17.7 mg/mL. Overall, the highest peptide concentration was found for E and Sp/E, in which low protease activity or a slow fermentation occurred. The lowest peptide content was observed for the controlled fermentation samples (St and St/E) with no significant variation between them. The peptide area, intended here as the total peak area in the chromatogram, confirmed the tendency observed about peptide amount in the different treatments. This data was used together with OPA analysis to avoid the interference of high concentration of FAA with the OPA reagent. The highest areas, indicating a moderate proteolysis, were found for the samples treated with enzymes E, End/E, and Sp/E, with the only exception of St/E, in which the lowest peptide content/area was found, indicating that a more intense proteolysis occurred in this sample. In the fermented samples, the addition of enzymes to the microbial inoculum enhanced peptide degradation to amino acids as consequence of improved microbial activity. Generally, the free amino acids content after bioprocessing ranged from 2148 to 4391 mg/kg of bran and was in agreement with the data previously analyzed, showing a smaller increase in the treatments chemically acidified and/or with added enzymes and a larger increase in the fermented samples. The effect of enzyme addition during starter fermentation (St/E) led to the highest amount of free amino acids, increasing the total amino acids content up to 55% in comparison with that of untreated bran (ct). Overall, the

J. Agric. Food Chem. 2015, 63, 8685−8693

differences among the proteolytic end-products of the treatments were mostly due to the activity of the microorganisms involved in the fermentation, and a marked effect of the starter microorganisms in comparison with the spontaneous microflora was also evident. In cereal fermentation, during primary proteolysis, oligopeptides are released mainly by the activity of cereal endoproteases, whereas secondary proteolysis releases free amino acids and small-sized peptides and occurs through microbial peptidase activity, especially that of lactic acid bacteria.[29] In particular, the proteolytic activity of the lactic acid bacteria was enhanced under the condition of fermentation controlled by the addition of enzymes.

Polypeptide, Amino Acid Profiles, and In Vitro Digestibility of Wheat Bran Proteins after Bioprocessing. The profile of the water/salt-soluble proteins of bioprocessed bran was analyzed by SDS-PAGE (Figure 1).

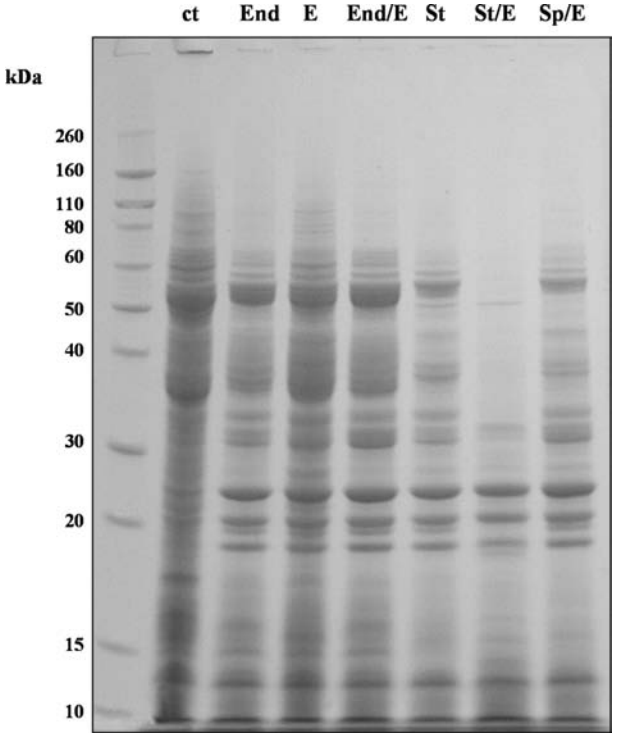

Figure 1. SDS-PAGE of water/salt-soluble extracts polypeptides from control and bioprocessed wheat bran. ct: untreated bran (time 0); End, endogenous enzymes; E: exogenous enzymes; End/E: endogenous and exogenous enzymes; St: controlled fermentation; St/E, controlled fermentation and exogenous enzymes; and Sp/E, spontaneous fermentation and exogenous enzymes.

Analysis of the untreated bran soluble fraction (ct) showed a distribution of polypeptides throughout the length of the gel, with most of the bands ranging from 70 to 20 kDa. Compared to that of the ct, the profile of the bioprocessed bran appeared modified in all the cases but with different intensities. Overall, more intense bands were observed in the lower range of the gel (32−18 kDa). Only minor differences could be detected between the chemically acidified and/or enzyme-added treatments (samples End, E, and End/E) in comparison with untreated bran, showing very similar polypeptide profiles. Nevertheless, weaker signals for many bands ranging from 35 to 45 kDa were found compared to ct, indicating hydrolysis to some extent. As expected, an intense proteolysis was found in these samples for polypeptides having high molecular weight as the consequence of the activity of the endogenous proteinases. Similar to wheat flour, in which proteolytic activity is mainly due to aspartic proteinases and serine carboxypeptidases located in the endosperm that are active under acidic conditions, wheat bran has serine carboxypeptidases with an optimum peptidase pH of 4−4.5.[30] Compared to the untreated bran and to the chemically acidified and/or enzyme-added samples, microbial fermentation intensely modified the polypeptides profile, especially in the range 55−35 kDa (St, St/E, and Sp/E). A clear difference in the overall quality of the proteolysis was also visible among the fermented samples. In particular, all the high-molecular-weight polypeptides were almost completely hydrolyzed in St/E.

This difference is also highlighted in the free amino acids profiles as reported in Figure 2. In the water/salt-soluble extract of untreated bran (ct), Arg, Ser, Lys, Leu, Phe, and Asp were the most abundant amino acids, ranging from 135 to 208 mg/kg for Asp and Arg, respectively. Compared to ct, almost all the amino acids increased after bioprocessing, with very few exceptions, such as Tyr and Arg, which decreased in the fermented samples. Generally, the observed increase ranged from 8% of Cys in the chemically acidified sample (End) up to 90% of Glu in the starter fermented sample (St). The highest increase was observed for Glu, Pro, and Orn, which were, respectively, found at a concentration of 650, 544, and 325 mg/kg of bran in the controlled fermentation with added enzymes (St/E). Very few differences were shown among the chemically acidified and/or enzyme-added treatments End, E, and End/E, except for Thr, Glu, Gly, and Pro, which were significantly more abundant in E. On the contrary, more differences were detected among the fermented samples, particularly Glu, Phe, Orn, and Pro, which had higher concentrations when starters were used together with enzymes (St/E), followed by the use of starters alone and spontaneous fermentation (St and Sp/E, respectively). Lactic acid bacteria and yeast activity are known to be responsible for amino acid level increase when compared to chemically acidified doughs.[31] Also, the composition of the fermentation microbiota has an effect on the overall proteolytic events and can strongly influence the composition and the concentration of amino acids in fermented flour. In our case, for instance, the high amount of Orn in the controlled fermentation could derive from the yeast biomass or arginine metabolism of lactic acid bacteria.[32] Bioprocessing with starter and enzymes allowed doubling of the amount of Phe, His, Leu, and Val, some of the essential amino acids, whereas it increased the concentration of Pro and Glu of 5−9-fold, respectively. The high amount of Pro and Glu could also partly originate from prolamin degradation. This is in agreement with the data previously observed by Coda et al.[11] for wheat bran bioprocessing in the presence of hydrolytic enzymes. Thus, these results showed that in the fermented samples the primary proteolysis was followed by degradation to peptides and amino acids as a consequence of microbial metabolism. Particularly in the case of controlled fermentation (St/E), the addition of enzymes, favoring a faster growth and acidification of the starters, led to a higher accumulation of amino acids and improved free amino acid composition.

A multistep protocol, which mimics the in vivo gastrointestinal digestion, was used to estimate the in vitro protein digestibility of bran (Table 4). The in vitro digestibility gives information on both the stability of protein hydrolyzates and how they withstand digestive processes. Overall, all the bioprocessing methods significantly increased the protein

Table 4. In Vitro Protein Digestibility, Phytase Activity, And Total Phenols Of Control And Bioprocessed Wheat Bran*

sample	in vitro protein digestibility (%)	phytase activity (U)**	total phenols (mM gallic acid)
ct	14.6[a]	7.1a	1.2[a]
End	20.0[b]	10.8[b,c]	4.1[b]
E	25.3[c]	8.9[a,b]	5.6[c]
End/E	18.4[b]	11.0[b,c]	3.8[b]
St	32.7[e]	12.1[c]	6.7[c,d]
St/E	39.1[f]	12.1[c]	6.8[d]
Sp/E	28.7[d]	10.0[b,c]	4.4[b]

*Values in the same column with different superscript letter differ significantly ($p < 0.05$). Samples with same letter among the group and column have no statistical difference ($p > 0.05$). **One unit (U) of phytase activity represents the amount of enzyme required to release 1 μmol of phosphate/min under the assay conditions.

digestibility. Among the chemically acidified and/or enzyme-added samples, the use of the exogenous enzymes (E) corresponded to significantly higher values of the protein digestibility compared to the effect of the sole endogenous enzymes activation (End). The digestibility of the End/E sample was similar to that found for the End sample, probably as a consequence of the lower activity of exogenous enzymes in acidic conditions. The highest values of in vitro protein digestibility were observed for the fermented samples, varying from 32.7 to 39.1%. The microbial activity clearly affected the overall digestibility, also due to a more intense proteolysis, and showed the highest value when the starters were used in combination with enzymes (St/E), in agreement with the data previously reported. Compared to an analogous study on wheat bran,[11] the in vitro digestibility found under these conditions, including control bran, was lower; nonetheless, the increase observed after bioprocessing was higher (up to 2.7-fold the initial value) than that previously reported.

Effect of Bran Bioprocessing on Phytase Activity and Total Phenols. After bioprocessing, the phytase activity increased in all the samples (Table 4). In the chemically acidified treatments with or without the addition of enzymes (End and End/E), the phytase activity was significantly higher in comparison with the sole addition of exogenous enzymes (E). This is probably due to the activation of endogenous enzymes, including phytases, as a consequence of pH lowering during bioprocessing because endogenous wheat phytases have optimal activity at around pH 5.[6,33] A further increase of phytase activity (12.1 U) was found in the controlled fermentations (St and St/E) and was most probably due to the activity of lactic acid bacteria and yeast phytases. This seems a possible explanation also for the lowest phytase activity during spontaneous fermentation in the presence of enzymes (Sp/E), characterized by a more diverse microflora and slower acidification rate. The increase of phytase activity during bioprocessing of bran was previously reported.[11,34] Under the conditions here applied, fermentation with lactic acid bacteria and yeast showed the best performance in terms of an increase of phytase activity, independent of the addition of enzymes, indicating an important role of the microbial activity compared to the endogenous phytases alone.

Phenolic acids of wheat bran are mostly hydroxycinnamic acids, of which ferulic acid represents a structural component of the cell walls of aleurone and pericarp, mainly esterified with arabinoxylans.[12] The concentration of total phenols significantly increased in all of the treatments in comparison with ct bran (Table 4). Among the chemically acidified and/or enzyme-added samples, the highest content of total phenols (5.6 mmol/100 g) was obtained for sample E, in which the higher pH of the treatment allowed a predominant activity of the exogenous enzymes, especially xylanase, thus leading to a more intense release of phenols. The highest increase of total phenols was obtained with controlled fermentation (St and St/E), but no significant difference was found with the addition of enzymes. Phenolic acids can be released during bioprocessing by ferulic acid esterase activity of bran, whereas xylanase activity further releases hydroxycinnamic acids from its bound form.[35] The enhanced degradation of wheat bran during bioprocessing is also reflected in the increase of phenols release, which is probably also a consequence of an increased amount of WE-pentosans. This is in agreement with previous findings where bioprocessing with enzymes and lactic acid bacteria fermentation have been shown to increase the content of free phenols.[10−12,35] However, in contrast with previous results, in our study, no further release of phenols was observed during controlled fermentation with added enzymes (St/E), probably because the enzyme preparation here used did not possess ferulic acid esterase activity.

Total Variance and Correlation between the Biochemical Components after Bioprocessing. Data collected

from chemical characterization and related to bioprocessing conditions were subjected to principal component analysis (PCA) and shown in Figure 3. Factor 1, representing 44.26% of the total variance, displayed a continuous variance between the samples, whereas factor 2, representing 39.39% of the total variance, clearly separated the untreated bran from the other samples. The fermented samples St and St/E were grouped in the same area of the plot because they shared several features (highest free amino acids, total phenols concentration, phytase activity, and in vitro protein digestibility; lowest reducing sugars, WE-pentosans, and peptide concentrations). Similarly, the chemically acidified and/or enzyme-added samples End, E, and End/E were grouped together, opposite to the fermented samples because of their different chemical characteristics. Spontaneously fermented bran (Sp/E) was not grouped with any of the other samples because of its intermediate characteristics. The correlation matrix among the biochemical properties of the samples clearly showed a strong positive relationship among in vitro protein digestibility, free amino acids, and total phenols and, to a lesser extent, phytase activity (Table 5). On the contrary, a large negative correlation was observed between not only pH and phytase activity but also free amino acids and total solubilized nitrogen ratio. The correlations among all the parameters were considered, and protein solubilization were less strong in comparison with the in vitro protein digestibility, suggesting the role of several concurrent factors in the release and solubilization of proteins from wheat bran. The effect of pH was crucial for the activation of endogenous enzymes and the primary solubilization of protein derivatives from wheat bran. However, even if the activity of the sole endogenous enzymes was more effective in solubilizing the proteins, the in vitro digestibility was lower after treatment with microbes. The use of exogenous cell-wall-degrading enzymes showed a lower impact on the overall protein solubility but positively affected the digestibility especially when microbes were involved. The use of starter

J. Agric. Food Chem. 2015, 63, 8685−8693

cultures affected the release and composition of free amino acids and the release of phenols as well as showing a stronger impact on the in vitro digestibility of protein, in particular when in combination with cell-wall-degrading enzymes, thus conferring the best nutritional characteristics to wheat bran.

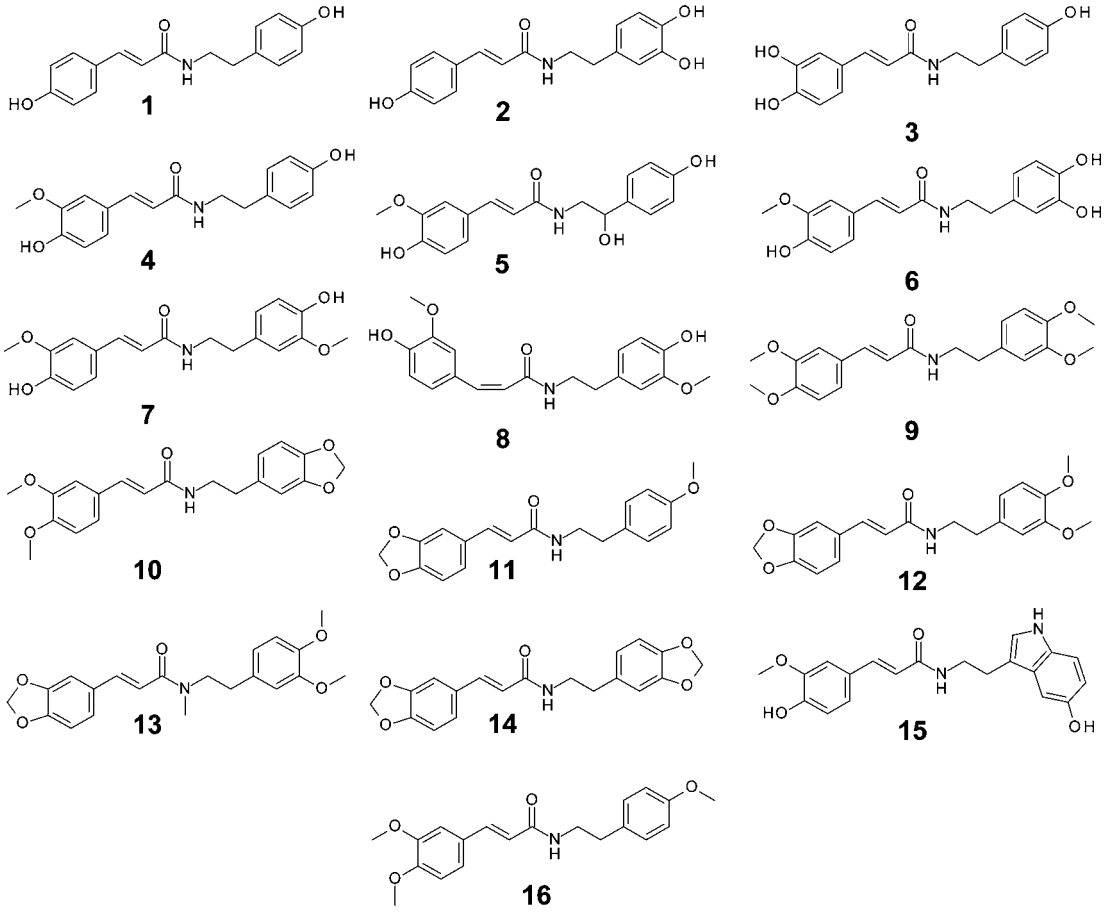

Figure 1. Structures of naturally occurring *N*-cinnamoyl amines **1**–**16**; for natural occurrence, see Table 1.

have been described as weakly pungent substances[18] and some avenanthramides show cooling properties.[19] Until recently, no data about the umami effect of these secondary metabolites where reported, but during the reviewing process for this paper, a study was published showing the umami effects of rubemamine (**9**) and its homologue *N*-3,4-dimethoxycinnamoyl-4-methoxyphenethylamine (**16**).[20]

To identify potential umami-modulating compounds, a series of naturally occurring *N*-cinnamoyl derivatives of substituted phenethylamines and serotonin was prepared (Figure 1; natural occurrence, Table 1) and tested by a sensory panel. In addition, advanced sensory studies investigated the potential of these compounds to function as general taste modifiers and synergistic umami taste modulators. Furthermore, in order to identify a biological basis for the observed sensory effects, the compounds were tested by means of an in vitro TAS1R1-TAS1R3 receptor assay for their intrinsic and synergistic activity together with MSG.

MATERIALS AND METHODS

General. Reagents, solvents, and consumables were purchased from commercial suppliers (Acros Organics, Geel, Belgium; Sigma-Aldrich, Steinheim, Germany; Alfa Aesar GmbH & Co KG, Karlsruhe, Germany) or produced by Symrise and used without further purification or drying. Monosodium glutamate (MSG) was obtained from Oskar Berg GmbH, Germany. Monitoring of the reaction was accomplished by thin-layer chromatography on silica-gel GF254 plates with either UV detection or by use of a staining reagent consisting of ammonium molybdate, cerium sulfate, and sulfuric acid. Purity was determined via GC chromatography using either an Agilent 6890N or Agilent 7890N (Agilent Technologies, Santa Clara, USA) system equipped with DB-WAX and DB-1 columns (length, 20 m; inside diameter, 0.18 mm; film, 0.18 μm; flow rate, 0.5–3.0 mL min^{-1}; injector, split ratio 1/70, 12 °C/s, 80–250 °C; carrier gas, H_2; and detector, FID, 275 °C (Agilent Technologies, Santa Clara, USA)) or a high-temperature MXT column (length, 15 m; inside diameter, 0.25 mm; film, 0.10 μm; flow rate, 1.0–5.0 mL min^{-1}; injector, split ratio 1/100, 10 °C/s, 60–380 °C; carrier gas, H_2; and detector, FID, 420 °C (Restek, Bad Homburg, Germany)). If the purity could not be determined via GC because of decomposition, then the below-mentioned NMR and UPLC instruments were used to determine the purity. The purity of all reported compounds was ≥95%. ^{1}H and ^{13}C nuclear magnetic resonance spectra were recorded on a Varian Gemini, Varian Mercury Plus or Varian Unity Innova spectrometer (Varian, Darmstadt, Germany) using tetramethylsilane as an internal reference. GC-MS spectra (EI, 70 eV, detector: quadrupole) were obtained by using either a Shimadzu GC2010/QP2010 (Shimadzu Corporation, Kyoto, Japan) or an Agilent 6890N (Agilent Technologies, Santa Clara, USA) system. HR-MS spectra (EI, 70 eV, detector: TOF) were recorded on a coupled system consisting of a Bruker micrOTOF Q-II (Bruker Daltonik GmbH, Bremen, Germany) and a Waters Acquity UPLC (Waters, Eschborn, Germany).

General Procedure A for the Synthesis of Amides 1–7, 11, 12, and 15. A 1.0 equiv amount of the corresponding cinnamic acid derivative and a 1.0 equiv amount of the *N*-hydroxysuccinimide were dissolved in 2.5–5.0 mL/mmol dioxane at 35 °C. Subsequently, 1.0 equiv of DCC in 1.5–2.5 mL/mmol dioxane was added, and the resulting mixture was stirred overnight at room temperature. The formed solid was removed by filtration and washed with dioxane. This mixture was added slowly to a suspension of 1.1–1.5 equiv of the corresponding amine in 2.0–3.0 mL/mmol water containing 1.0–2.5 equiv of $NaHCO_3$, keeping the temperature below 40 °C; after completion of the addition, the mixture is stirred at room temperature

Table 1. Structural Analogs Investigated as Potential Umami Compounds[a]

name, occurrence	sensory screening in water
N-coumaroyltyramine (**1**), *Aristolochia manshuriensis*[39]	10 ppm: no taste 50 ppm: coffee, card board, burned, anis 100 ppm: anis, bitter
N-coumaroyldopamine (**2**), *Atraphaxis spinosa* L., var. *sinaica* Boiss.[40]	10 ppm: dry, coffee 50 ppm: dry, coffee, bitter 100 ppm: bitter, coffee
N-caffeoyltyramine (**3**), *Capsicum annuum*[41]	10 ppm: roasty, coffee 50 ppm: bitter, flowery, coffee 100 ppm: bitter, plastic
N-feruloyltyramine (**4**), e.g., *Beta vulgaris*[42]	10 ppm: neutral 50 ppm: neutral 100 ppm: bitter, dry, chalky
N-feruloyloctopamine (**5**), *Salsolia tetranda*[43]	10 ppm: neutral, weakly bitter 50 ppm: glue, coffee
N-feruloyldopamine (**6**), *Amaranthus* spp.[44]	10 ppm: vanille 50 ppm: vanille, dry 100 ppm: bitter, plastic
N-feruloyl-3-methoxytyramine (**7**), e.g., *Beta vulgaris*[42]	10 ppm: neutral, weakly pungent 50 ppm: bitter, scratchy dry 100 ppm: bitter
N-*cis*-feruloyl-3-methoxytyramine (**8**), *Cinnamomum reticulatum*[45]	10 ppm: dry 50 ppm: dull, dry 100 ppm: strongly dry
rubemamine (**9**), *Chenopodium album*, *Zanthoxylum rubescens*[32,46]	10 ppm: **weakly umami** 50 ppm: **umami**, weakly sweet 100 ppm: **strongly umami**
rubescenamine (**10**), *Z. rubescens*[21]	10 ppm: **umami**, quick onset 50 ppm: **strongly umami**, soapy
armatamide (**11**), *Zanthoxylum armatum*[47]	10 ppm: neutral, dry 50 ppm: weakly pungent 100 ppm: weakly sour, weakly sweet, tingling
zanthosine (**12**), *Z. rubescens*[48]	10 ppm: bitter 50 ppm: bitter 100 ppm: bitter
zanthosinamide (**13**), *Z. rubescens*[48]	10 ppm: alcoholic 50 ppm: bitter, **weakly umami** 100 ppm: strongly bitter, **umami aftertaste**
dioxamine (**14**), *Z. rubescens*[46]	10 ppm: neutral 50 ppm: neutral, weakly bitter 100 ppm: bitter, acidic, weakly sweet
moschamine (**15**), *Carthamus tinctorius* L.[49]	10 ppm: neutral 50 ppm: neutral 100 ppm: bitter

[a]All compounds were tested by a trained consensus panel (n = 8) in water. For structures of **1**–**15**, see Figure 1.

and monitored by TLC. After the reaction is finished, 10% aqueous HCl is added to adjust the pH to 1.5, and the reaction mixture is extracted two times with ethyl acetate. The combined organic layers are consecutively washed with saturated aqueous $NaHCO_3$ solution and brine before being dried over $NaSO_4$. (If necessary, activated charcoal can be added during the drying process.) After removal of the solvent, the products were subjected to crystallization, flash chromatography, or preparative HPLC for final purification.

General Procedure B for the Synthesis of Amides 9, 10, 13, and 14. A 1.05–1.2 equiv amount of oxalyl chloride was slowly added to a mixture of 1.0 equiv of the corresponding cinnamic acid derivative in 2.0–4.0 mL/mmol of dichloromethane. The mixture was allowed to stir overnight before refluxing for an additional 30 min. After evaporation of the solvent, the crude acid chloride was dissolved in 1.0–2.0 mL/mmol of acetone and added to a mixture of the amine (or the corresponding hydrochloride) in 1.0–2.0 mL/mmol acetone and 1.0–2.0 mL/mmol water containing 1.0 equiv (or 2.0 equiv if the hydrochlorides are used) of sodium hydroxide. The mixture is allowed to stir for an additional 2 h before the product is filtered out and washed several times with water. Further purification is possible where needed by recrystallization.

Spectral data of all compounds were in accordance with those reported in the literature as listed in Table S.1.

N-*E*-Coumaroyltyramine (**1**) was prepared following procedure A starting from *p*-coumaric acid and tyramine hydrochloride. Final purification was possible via crystallization from ethyl acetate.

^{1}H NMR (200 MHz, CD_3OD): 2.74 (dd, J = 8.1, 6.6 Hz, 2H), 3.44 (dd, J = 8.2, 6.5 Hz, 2H), 3.64 (s, 1H), 6.40 (d, J = 15.7 Hz, 1H), 6.73 (m, 2H), 6.80 (m, 2H), 7.07 (m, 2H), 7.41 (m, 2H), 7.49 (d, J = 15.8, 1H) ppm. HR-MS (ESI$^+$): 284.1281 ([$M^{+\cdot}$ + H], $C_{17}H_{19}NO_3^+$; calcd 284.1281).

N-(*E*)-Coumaryldopamine (**2**) was prepared following procedure A starting from *p*-coumaric acid and dopamine hydrochloride. Final purification was possible via two consecutive flash chromatography steps (first chromatography employing ethyl acetate as eluent; second chromatography employing chloroform/methanol 10:1 as eluent).

^{1}H NMR (200 MHz, CD_3OD): 2.69 (dd, J = 8.1, 6.5 Hz, 2H), 3.44 (m, 2H), 6.38 (d, J = 15.7 Hz, 1H), 6.54 (dd, J = 7.9, 2.2 Hz, 1H), 6.67 (d, J = 2.1 Hz, 1H), 6.71 (d, J = 8.0, 1H), 6.78 (m, 2H), 7.39 (m, 2H), 7.48 (d, J = 15.7, 1H) ppm. HR-MS (ESI$^+$): 300.1235 ([$M^{+\cdot}$ + H], $C_{17}H_{18}NO_4^+$; calcd 300.1230).

N-(*E*)-Caffeoyltyramine (**3**) was prepared following procedure A starting from caffeic acid and tyramine. Final purification was possible via crystallization from chloroform/methanol 10:1.

^{1}H NMR (400 MHz, CD_3OD): 2.74 (dd, J = 8.0, 6.9 Hz, 2H), 3.45 (m, 2H), 6.32 (d, J = 15.7 Hz, 1H), 6.71 (m, 2H), 6.74 (d, J = 8.2 Hz, 1H), 6.88 (ddd, J = 8.2, 2.1, ~0.5 Hz, 1H), 6.98(d, J = 2.1 Hz, 1H), 7.05 (m, 2H), 7.37 (d, J = 15.6 Hz, 1H) ppm. HR-MS (ESI$^+$): 300.1235 ([$M^{+\cdot}$ + H], $C_{17}H_{18}NO_4^+$; calcd 300.1230).

N-(*E*)-Feruloyltyramine (**4**) was prepared following procedure A starting from ferulic acid and tyramine. Final purification was possible via flash chromatography employing ethyl acetate as eluent.

^{1}H NMR (400 MHz, CD_3OD): 2.75 (t, J = 7.4 Hz, 2H), 3.35 (s, 1H), 3.46 (m, 2H), 3.88 (s, 3H), 6.38 (dd, J = 15.5, 1.1 Hz, 1H), 6.72 (m, 2H), 6.77 (dd, J = 8.3, 1.1 Hz, 1H), 7.01 (dd, J = 8.3, 1.9 Hz, 1H), 7.05 (m, 2H), 7.10 (d, J = 1.9 Hz, 1H), 7.43 (d, J = 15.7 Hz, 1H) ppm. GC/EI-MS: 343 (6, [$M^{+\cdot}$]), 329 (20), 194(12), 193(10), 192(10), 177(40), 151(10), 150(100), 149(9), 145(14), 137(11), 89(8).

N-(*E*)-Feruloyloctopamine (**5**) was prepared following procedure A starting from ferulic acid and octopamine hydrochloride. Final purification was possible via flash chromatography employing ethyl acetate as eluent.

^{1}H NMR (400 MHz, CD_3OD): 3.43 (dd, J = 13.6, 7.9 Hz, 1H), 3.53 (dd, J = 13.6, 5.0 Hz, 1H), 3.88 (s, 3H), 4.72 (m, 1H), 6.45 (d, J = 15.7, 1H), 6.76 (m, 2H), 6.79 (d, J = 8.2, 1H), 7.02 (dd, J = 8.1, 2.0 Hz, 1H), 7.12 (d, J = 2.0 Hz, 1H), 7.22 (m, 2H), 7.44 (d, J = 15.6 Hz, 1H) ppm. HR-MS (ESI$^+$): 330.1335 ([$M^{+\cdot}$ + H], $C_{18}H_{20}NO_5^+$; calcd 330.1336).

N-(*E*)-Feruloyldopamine (**6**) was prepared following procedure A starting from ferulic acid and dopamine hydrochloride. Final purification was possible via two consecutive flash chromatography steps (first chromatography employing ethyl acetate as eluent; second chromatography employing chloroform/methanol 10:1 as eluent).

^{1}H NMR (400 MHz, CD_3OD): 2.70 (t, J = 7.4 Hz, 2H), 3.45 (dd, J = 8.0, 6.7 Hz, 2H), 3.87 (s, 3H), 6.40 (dd, J = 15.7, 0.4 Hz, 1H), 6.55 (dd, J = 8.0, 2.1 Hz, 1H), 6.67 (d, J = 2.1 Hz, 1H), 6.69 (d, J = 8.0 Hz, 1H), 6.79 (d, J = 8.2 Hz, 1H), 7.02 (dd, J = 8.2, 2.0, 1H), 7.11 (d, J = 2.0 Hz, 1H), 7.43 (d, J = 15.7 Hz, 1H) ppm. GC/EI-MS: 329 (20,

DOI: 10.1021/acs.jafc.5b04402
J. Agric. Food Chem. 2015, 63, 8694–8704

[$M^{+\cdot}$]), 194 (64), 193 (13), 192 (29), 177 (100), 145 (30), 136 (38), 123 (13), 117 (14), 89 (15).

N-(*E*)-Feruloyl-3-methoxytyramine (**7**) was prepared following procedure A starting from ferulic acid and 3-methoxytyramine hydrochloride. Final purification was possible via two consecutive flash chromatography steps (first chromatography employing ethyl acetate as eluent; second chromatography employing chloroform/methanol 10:1 as eluent).

^{1}H NMR (200 MHz, CD_3OD): 2.74 (t, *J* = 7.2 Hz, 2H), 3.44 (dd, *J* = 7.9, 6.5 Hz, 2H), 3.76 (s, 3H), 3.81 (s, 3H), 6.48 (d, *J* = 15.5 Hz, 1H), 6.73 (dd, *J* = 8.0, 1.8 Hz, 1H), 6.79 (d, *J* = 8.1 Hz, 1H), 6.83 (d, *J* = 8.2 Hz, 1H), 6.88 (d, *J* = 1.9 Hz, 1H), 7.09 (m,1H), 7.17 (d, *J* = 1.9 Hz, 1H), 7.49 (d, J = 15.6 Hz, 1H) ppm. GC/EI-MS: 343 (6, [$M^{+\cdot}$]), 194 (12), 193 (10), 192 (10), 177 (40), 151 (10), 150 (100), 149 (9), 145 (14), 137 (11), 89 (8).

N-(*Z*)-Feruloyl-3-methoxytyramine (**8**) was prepared by dissolving *N*-*E*-feruloyl-3-methoxytyramine (**7**) in 100 mL/g ethanol and subsequently treating it with UV irradiation (LW 366) for 100 h. The resulting *E*/*Z* mixture of isomers was purified by HPLC chromatography.

^{1}H NMR (400 MHz, CD_3OD): 2.70 (t, *J* = 7.3 Hz, 2H), 3.42 (dd, *J* = 7.9, 6.7 Hz, 2H), 3.78 (s, 3H), 3.82 (s, 3H), 5.81 (d, *J* = 12.7, 1H), 6.60 (dd, *J* = 8.0, 2.0, 1H), 6.62 (d, *J* = 12.6 Hz, 1H), 6.69 (d, *J* = 8.0 Hz, 1H), 6.73 (d, *J* = 8.2 Hz, 1H), 6.77 (d, *J* = 2.0 Hz, 1H), 6.92 (dd, *J* = 8.2, 2.0 Hz, 1H), 7.36 (d, *J* = 2.0 Hz, 1H) ppm. GC/EI-MS: 343 (5, [$M^{+\cdot}$]), 194 (12), 193 (8), 177 (39), 151 (11), 150 (100), 145 (19), 137 (10), 135 (8), 117 (9), 89 (10).

Rubemamine (**9**) was prepared following procedure B starting from (*E*)-3,4-dimethoxy cinnamic acid and 3,4-dimethoxyphenylethylamine. If necessary, further purification is possible via crystallization from n-propanol/*n*-hexane 2:3. Spectral data were in accordance with those reported in the literature.[21]

^{1}H NMR (400 MHz, $CDCl_3$): 2.84 (t, *J* = 6.9 Hz, 2H), 3.64 (td, *J* = 6.9, 5.9 Hz, 2H), 3.87 (s, 3H), 3.87 (s, 3H), 3.90 (s, 3H), 3.90 (s, 3H), 5.58 (t, *J* = 5.9 Hz, 1H), 6.20 (d, *J* = 15.5 Hz, 1H), 6.75 (d, *J* = 2.0 Hz, 1H), 6.77 (dd, *J* = 8.0, 1.9 Hz, 1H), 6.83 (d, J = 8.0 Hz, 1H), 6.85 (d, *J* = 8.3 Hz, 1H), 7.00 (d, *J* = 2.0 Hz, 1H), 7.07 (ddd, *J* = 8.2, 2.0, ∼0.5 Hz, 1H), 7.56 (d, *J* = 15.5 Hz, 1H) ppm. GC/EI-MS: 371 (6, [$M^{+\cdot}$]), 207 (3), 206 (10), 192 (5), 191 (29), 165 (11), 164 (100), 163 (5), 151 (7), 149 (6).

Rubescenamine (**10**) was prepared following procedure B starting from (*E*)-3,4-dimethoxy cinnamic acid and 2-(1,3-benzodioxol-5-yl)ethanamine hydrochloride. If necessary, further purification is possible via crystallization from n-propanol/*n*-hexane 2:3. Spectral data were in accordance with those reported in the literature.[21]

^{1}H NMR (400 MHz, $CDCl_3$): 2.80 (t, *J* = 6.8 Hz, 2H), 3.61 (td, *J* = 6.8, 5.9 Hz, 2H), 3.90 (s, 6H), 5.56 (t, *J* = 6.1 Hz, 1H), 5.94 (s, 2H), 6.20 (d, *J* = 15.5 Hz, 1H), 6.67 (dd, *J* = 7.8, 1.7 Hz, 1H), 6.72 (d, *J* = 1.7 Hz, 1H), 6.77 (d, *J* = 7.9 Hz, 1H), 6.85 (d, *J* = 8.3 Hz, 1H), 7.01 (d, *J* = 2.0 Hz, 1H), 7.07 (dd, *J* = 8.3, 2.0 Hz, 1H), 7.56 (d, *J* = 15.5 Hz, 1H) ppm. GC/EI-MS: 355 (17, [$M^{+\cdot}$]), 207 (58), 206 (79), 192 (12), 191 (69), 163 (11), 149 (11), 148 (100), 147 (13), 77 (11).

Armatamide (**11**) was prepared following procedure A starting from (*E*)-3,4-methylendioxy cinnamic acid and 2-(4-methoxyphenyl)-ethanamine. Final purification was possible via crystallization from ethyl acetate.

^{1}H NMR (200 MHz, CD_3OD): 2.77 (dd, *J* = 8.0, 6.6 Hz, 2H), 3.46 (m, 2H), 3.73 (s, 3H), 6.02 (s, 2H), 6.42 (d, *J* = 15.6 Hz, 1H), 6.83 (d, *J* = 8.1, 1H), 6.86 (d, *J* = 8.7 Hz, 2H), 7.04 (ddd, *J* = 8.0, 1.7, ∼0.5 Hz, 1H), 7.11 (m, 1H), 7.16 (m, 2H), 7.44 (d, *J* = 15.6, 1H) ppm. HR-MS (ESI$^+$): 326.1387 ([$M^{+\cdot}$ + H], $C_{19}H_{20}NO_4^+$; calcd 326.1387).

Zanthosine (**12**) was prepared following procedure A staring from (*E*)-3,4-methylendioxy cinnamic acid and 3,4-dimethoxyphenylethylamine. For final purification, the product was dissolved in ethyl acetate under reflux. After cooling down to room temperature, the product was precipitated by the addition of diethyl ether.

^{1}H NMR (200 MHz, $CDCl_3$): 2.83 (t, *J* = 6.9 Hz, 2H), 3.63 (td, *J* = 6.9, 5.9 Hz, 2H), 3.87 (s, 3H), 3.87 (s, 3H), 5.66 (m, 1H), 5.99 (s, 2H), 6.15 (d, *J* = 15.5 Hz, 1H), 6.70−6.88 (m, 4H), 6.92−7.02 (m, 2H), 7.53 (d, *J* = 15.5 Hz, 1H) ppm. HR-MS (ESI$^+$): 356.1490 ([$M^{+\cdot}$ + H], $C_{20}H_{22}NO_5^+$; calcd 356.1492).

Zanthosinamide (**13**) was prepared following procedure B staring from (*E*)-3,4-methylendioxy cinnamic acid and 2-(3,4-dimethoxyphenyl)-*N*-methyl-ethanamine. As the expected, product did not precipitate from the reaction mixture; the product is extracted with ethyl acetate. After evaporation of the solvent, no further purification was necessary.

^{1}H NMR (100 °C, 400 MHz, $CDCl_3$): 2.81 (m, 2H), 2.99 (s, 3H), 3.62 (m, 2H), 3.77 (s, 3H), 3.80 (s, 3H), 5.94 (s, 2H), 6.50 (d, *J* = 15.3 Hz, 1H), 6.70 (s, 2H), 6.72 (d, *J* = 2.0 Hz, 1H), 6.78 (d, *J* = 8.3 Hz, 1H), 6.80 (d, *J* = 8.1 Hz, 1H), 6.92 (d, *J* = 6.5 Hz, 2H), 7.46 (d, *J* = 15.3 Hz, 1H) ppm. GC/EI-MS: 369 (7, [$M^{+\cdot}$]), 176 (9), 175 (78), 165 (11), 164 (100), 151 (7), 149 (4), 145 (25), 117 (12), 89 (15). HR-MS (ESI$^+$): 353.1369 ([$M^{+\cdot}$ + H], $C_{20}H_{21}N_2O_4^+$; calcd 353.1496).

Dioxamine (**14**) was prepared following procedure B starting from (*E*)-3,4-methylendioxy cinnamic acid and 2-(1,3-benzodioxol-5-yl)-ethanamine hydrochloride.

^{1}H NMR (200 MHz, CD_3OD): 2.80 (t, *J* = 6.8 Hz, 2H), 3.60 (td, *J* = 6.8, 5.9 Hz, 2H), 5.54 (s, 1H), 5.94 (s, 2H), 5.99 (s, 2H), 6.14 (d, *J* = 15.5 Hz, 1H), 6.66 (dd, *J* = 7.8, 1.6 Hz, 1H), 6.71 (d, *J* = 1.5 Hz, 1H), 6.76 (d, *J* = 7.8, 1H), 6.79 (dd, *J* = 7.6, ∼0.8 Hz, 1H), 6.96 (dd, *J* = 7.6, 1.7, 1H), 6.98 (s, 1H), 7.53 (d, *J* = 15.5 Hz, 1H) ppm. HR-MS: 340.1172 ([$M^{+\cdot}$ + H], $C_{19}H_{18}NO_5$; calcd 340.1179).

Moschamine (**15**) was prepared following procedure A starting from ferulic acid and serotonine hydrochloride. Final purification was possible via flash chromatography employing ethyl acetate as eluent with subsequent recrystallization from ethyl acetate.

^{1}H NMR (400 MHz, $CD_3S{=}OCD_3$): 2.78 (t, *J* = 7.4 Hz, 2H), 3.43 (m, 2H), 3.80 (s, 3H), 6.45 (d, *J* = 15.7 Hz, 1H), 6.59 (dd, *J* = 8.6, 2.3 Hz, 1H), 6.79 (d, *J* = 8.1 Hz, 1H), 6.85 (d, *J* = 2.4 Hz, 1H), 6.98 (dd, *J* = 8.1, 1.9 Hz, 1H), 7.05 (d, *J* = 2.5 Hz, 1H), 7.12 (d, *J* = 2.0 Hz, 1H), 7.13 (dd, *J* = 8.8, ∼0.6 Hz, 1H), 7.33 (d, *J* = 15.7 Hz, 1H), 8.03 (t, *J* = 5.7 Hz, 1H), 8.59 (s, 1H), 10.48 (d, *J* = 2.4 Hz, 1H) ppm. HR-MS: 353.1374 ([$M^{+\cdot}$ + H], $C_{20}H_{21}N_2O_4$; calcd 353.1496).

Sensory Tests. Sensory tests were carried out with healthy and trained panelists without known taste disorders. Panelists were fully informed about procedure and intention of the project and had given written consent. Because of the FEMA/GRAS status of rubemamine (**9**)[22] and rubescenamine (**10**)[23] and the positive evaluation EFSA for rubemamine (**9**),[24] the other compounds were considered to be a low risk for the screening phase. In addition, the panelists were advised not to swallow the samples (maximum 10 mL of solution) but rather to use the sip and spit method. The tests were conducted in sensory panel rooms under standardized conditions, and they were blind and randomized. For the preparation of the test solutions, Vittel water was used. The panelists had participated earlier at regular intervals in sensory work and were, therefore, familiar with the techniques applied.

Pre-Evaluation. A number of 5−8 trained panelists received each compound in a dosage of 10, 50, and 100 ppm in a 0.5% salt and a 5.0% sugar solution, and were asked to describe the sample and give a qualitative statement for the umami intensity. No additional reference (e.g., MSG) was presented during this session.

Using as the base an American beef extract (Beef Meat Extract Stock Type, Symrise), a corresponding base mixed with MSG, or a corresponding base mixed with MSG, the test compound was in each case administered blindly and individually to 15−25 trained panelists at slightly elevated temperatures (30−35 °C) for profiling. Using the descriptors previously decided upon by discussion (mouth feel, salty, metallic, meaty, bitter, mouth-watering, barbecued−roasted, sweet, sour, and lingering), the strength of each of these was assessed on a scale from 0 (imperceptible) to 9 (very strong). The individual results of the panelists were averaged.

The taste detection threshold for rubemamine (**9**) in water (Vittel) was determined by a forced-choice ascending concentration series method of limits according to the established ASTM protocol.[25] Threshold for rubescenamine (**10**) was determined at elevated temperature (∼30 °C) according to the same method.

Quantification of Taste Modulation Effects of Rubemamine (9) and Rubescenamine (10) on Umami Taste of MSG

DOI: 10.1021/acs.jafc.5b04402
J. Agric. Food Chem. 2015, 63, 8694−8704

(Yamaguchi Protocol). For the quantification of the synergistic effects, the intrinsic and positive umami-modulating activity of the test compound in comparison to MSG was determined by means of a paired choice comparison test as proposed by Yamaguchi.[2] For the determination of the intrinsic activity, a binary solution (pH 6.0) containing the test compound in water (fixed sample) was compared to a series of aqueous solutions containing logarithmically increasing concentrations of MSG (reference samples; 30% intervals: 0.17, 0.22, 0.28, 0.37, 0.49, 0.63, 0.82, 1.07, 1.4, and 1.82% w/w). For the determination of the modulating activity, a binary solution (pH 6.0) containing the umami compound and MSG (0.17% or 0.22%) in water (fixed sample) was compared to a series of aqueous solutions containing logarithmically increasing concentrations (30% intervals) of MSG (reference samples). In each sensory session, the assessors were asked to evaluate four sample pairs presented in randomly coded cups and to identify the sample exhibiting the stronger umami taste using a forced choice methodology (2-AFC). The panelists wore nose clips during tasting. Each test was repeated three times for each panelist. To control for significance, Student's t test was conducted, and the level of significance was set to $p < 0.1$ because of the relatively low panelist number ($n = 14–18$).

Activation of TAS1R1-TAS1R3 Umami Receptor in Transfected HEK 293 Cells. To elucidate umami receptor activation by the test compounds, a cell-based assay was used as described elsewhere.[26] In brief, functional experiments were carried out using HEK293-PEAKrapid cells (American Type Culture Collection) modified for stable expression of human TAS1R1 (hTAS1R1) subunit and the promiscuous G protein subunit Gα15. For umami receptor expression, cells were transiently transfected with vector encoding for the rat Tas1r3 (rTas1r3) subunit using Lipofectamine2000 (Invitrogen). Transfection was carried out 24 h prior to calcium imaging experiments.

To enable functional calcium imaging, transfected cells were loaded with 2 μM Fluo4-AM (Molecular Probes) in serum-free DMEM low-glucose Glutamax (Gibco) medium containing 2.5 mM probenecide. After 1 h of incubation at 37 °C, cells were washed three times with bath solution (130 mM NaCl, 5 mM KCl, 10 mM Hepes, 2 mM $CaCl_2$, pH 7.4) and incubated for 20 min at room temperature in the dark between washing steps to allow complete de-esterification of the dye. Calcium imaging experiments were carried out using a fluorimetric imaging plate reader (FLIPR^{tetra}, Molecular Devices). This allows automated substance application and simultaneous fluorescence measurements. Compounds were solved and applied in bath solution or low concentrations of DMSO (0.03–0.3%) for better solubility. Subsequent to application of test compounds, isoproterenol was applied onto the cells to control for cell number and vitality. Cells transfected with empty vector were used to control for unspecific responses of the cellular background. To control for responses of the diluent, cells were treated with bath solution or the respective concentration of DMSO.

Raw fluorescence changes were corrected for unspecific fluorescence changes of empty vector expressing cells using ScreenWorks 2.0. Relative fluorescence change was then calculated ($\Delta F = F_{max} - F_{min}$) and normalized to baseline fluorescence ($\Delta F/F$). To calculate concentration–response curves, $\Delta F/F$ values were plotted half-logarithmically against concentration of the test compound. Half-maximal effective agonist concentrations (EC_{50}) were calculated using nonlinear regression to the sigmoidal function $f(x) = \min + (\max - \min/(1 + [x/EC_{50}]^{Hillslope}))$ (SigmaPlot 9.01, Systat Software). To control for significance, one-way analysis of variance was carried out using SPSS.

RESULTS AND DISCUSSIONS
