QDs@MIP for the FL Detection of Carbaryl. In this system, the FL quenching followed the Stern−Volmer equation. Under optimum conditions, the QDs@MIP exhibited linear fluorescent quenching for carbaryl in the concentration range from 4.97×10^{-7} to 3.98×10^{-4} mol L^{-1}, with a correlation $R^2 = 0.9954$, as shown in Figure 10b. The LOD for carbaryl was 1.47×10^{-7} mol L^{-1}. The precision for five replicate detections of carbaryl (10 mg L^{-1}) was 2.4% (relative standard deviation). The reproducibility of QDs@MIP was also investigated. Three replicate measurements were carried out under the same conditions. The relative standard deviation was 3.8%.This indicates that the FL sensing method with QDs@ MIP could be used for simple, rapid determination of carbaryl with efficiency and sensitivity.

Application of the QDs@MIP to the Detection of Carbaryl in Real Samples. The ability of the developed FL method to quantify concentration of carbaryl in a real sample was examined. Samples of rice and Chinese cabbage were purchased from a supermarket. No response corresponding to carbaryl was observed by HPLC. Furthermore, three levels of carbaryl at 5, 10, and 20 mg L^{-1} were spiked. The sample pretreatment procedures were performed as follows: 2 g of spiked sample was treated by mixing 6 mL of methanol and shaking at 200 rpm on the rotary shaker for 30 min. The extracts were purified by filter paper. The filtrate was concentrated to near dryness and redissolved with acetonitrile

DOI: 10.1021/acs.jafc.5b01072

before analysis. A summary of the spiked concentration for samples and the corresponding analysis results is shown in Table 1. The concentrations of carbaryl in the spiked samples

Table 1. Spiked Recovery Results for the Determination of Carbaryl in Rice and Chinese Cabbage Samples by QDs@MIP, HPLC, and ELISA

sample	spiked level (mg kg^{-1})	QDs@MIP (mean ± SD; n = 3, mg kg^{-1})	ELISA (mg kg^{-1})	HPLC (mg kg^{-1})
rice	5	4.22 ± 0.30	4.36 ± 0.15	4.27 ± 0.10
	10	8.14 ± 0.65	8.47 ± 0.24	8.70 ± 0.13
	20	15.72 ± 1.04	16.10 ± 0.50	16.29 ± 0.28
Chinese cabbage	5	4.01 ± 0.35	4.14 ± 0.17	4.08 ± 0.14
	10	8.56 ± 0.79	8.87 ± 0.27	8.65 ± 0.20
	20	14.19 ± 1.09	14.94 ± 0.35	14.78 ± 0.27

determined by the developed FL method based on QDs@MIP were in good agreement with those of carbaryl spiked. The recoveries of carbryl were between 74% and 88%. The detected results were also validated by HPLC and ELISA, respectively. And the correlation between these methods was good (Figure 11, R^2 = 0.98).

In summary, we here reported an optosensing material which is a simple and effective method to detect carbaryl. The material had attractive advantages, such as being easily prepared and highly selective and photostable. The high selectivity of the analytical method based on QDs@MIP as the sensing material was successfully applied to analyze carbaryl in rice and Chinese cabbage samples. The study could also provide the technical support for the rapid detection in food safety fields.

ABSTRACT: A bioactive compound is a food component that may have an impact on health. Its bioaccessibility, defined as the fraction released from the food matrix into the gastrointestinal tract during digestion, depends on compound stability, interactions with other food components, and supramolecular organization of food. In this study, the effect of pH on the bioaccessibility of the bioactive dipeptide carnosine was evaluated in two commercial samples of the Italian cured beef meat bresaola at two key points of digestion: before the gastric and after the duodenal phases. The digestion process was simulated using an in vitro static system, whereas capillary zone electrophoresis (CZE) and ^{1}H nuclear magnetic resonance (NMR) were used for quantitative analysis. The gap between the total carnosine content, measured by CZE, and its free diffusible fraction observable by NMR spectroscopy, was 11 and 19% for two independent bresaola products, where such percentages represent the fraction of carnosine not accessible for intestinal absorption because it was adsorbed to the food matrix dispersed in the digestion fluid.

INTRODUCTION

Bioactive compounds are extra nutritional constituents of food that typically occur in small quantities but can have a positive impact on body functions or conditions and may ultimately influence health.[1] For their potential positive effects, they have been extensively studied in the past decade, isolated from different food sources and chemically and functionally characterized. Most of the research has focused on secondary plant materials such as phytosterols or polyphenols; meat and meat products, despite being recognized as good suppliers of high-grade proteins, vitamins, and minerals, are generally not considered as sources of bioactive substances. Yet, research has made progress in the meat segment, too, and today many compounds found in meat, such as, small peptides, carnosine, anserine, taurine, creatinine, and coenzyme Q10, have been recognized as bioactives with a wide spectrum of physiological actions.[2−4]

Carnosine is a β-alanine and L-histidine dipeptide, which is distributed widely and abundantly in the excitable tissues (particularly muscle and nervous tissues) of several animal species. Although its physiological role is not been completely understood yet, many beneficial actions have been attributed to carnosine, such as being an antioxidant and a free radical scavenger, an antiglycating and an ion-chelating agent, and a wound-healing promoter.[5] These biological activities may explain the ability of carnosine to exert an antiaging activity at cellular and whole animal levels[6] and to restrain some oxidative-based diseases such as diabetes,[7−9] atherosclerosis,[10] metabolic distress syndrome,[11] and also ischemia−reperfusion damage in different organs.[12−14]

After meat digestion, the amount of dietary carnosine becoming available for intestinal absorption depends not only on its original concentration in food (related to animal species and tissue type) but also on its bioaccessibility, that is, the fraction of the compound that is released from the food matrix in the gastrointestinal tract during digestion and is available for intestinal absorption.[15] Nutrient bioaccessibility is affected by digestion conditions (pH, enzyme concentration, and activity), compound stability, and interactions with other food components, as well as the supramolecular organization of the food.[16] Particularly, the pH of the environment is a critical parameter, being able to modify the net charge of a molecule, its structure, and consequently the degree of interaction with the solvent and other food molecules.

In this work, the effect of pH on the solubility and in turn bioaccessibility of carnosine was assessed in bresaola, a typical beef-based product of northern Italy (Valtellina), which is produced by curing the intact beef muscle through different processing steps including a careful selection and skillful trimming of cuts of meat, followed by a dry salting step, during which wine, spices, and sugar (with the aim of encouraging

microbial phenomena responsible for much of the aging of the product) are added, and then the meat is stuffed into natural or artificial casings and sent to the next stage of drying in special cells for a slow maturation. As this substrate is consumed crude, the evaluation of carnosine content is not expected to be affected by alterations due to the cooking process, which can cause a reduction of carnosine of up to 50% in other beef products, depending on the cooking procedure.[17,18] The digestion of bresaola occurring in vivo in the human gastrointestinal tract was simulated using an in vitro static system,[19] and the soluble free compound in the digestion fluid was evaluated by coupling ^{1}H nuclear magnetic resonance spectroscopy (^{1}H NMR) and capillary zone electrophoresis (CZE). These techniques were operated at different pH values to obtain a global description of the free fraction of the molecule at three key points of digestion, those being the end of the oral phase and after 180 and 300 min of duodenal digestion.

To the best of our knowledge this research work represents the first study estimating the effect of pH on the interactions of carnosine with the digested meat matrix and, therefore, on its bioaccessibility. The presence of emulsifiers, metal ions, fats, biopolymers, and other chemical species able to bind the bioactive compounds could sequester them, thus limiting their free diffusion through the extracting digestion fluid, from the food matrix, where bioactive molecules are embedded, to the gut mucosa where their absorption occurs. The modification of bioaccessibility due to interactions with the food matrix is a key factor that should be considered while evaluating the potential significance of bioactives in human health. Each compound, indeed, is susceptible to chemical exchange between environments, being either freely diffusible in the digestion fluids or being adsorbed on the surfaces of the macromolecular food matrix; this could affect the bioactive bioaccessibility and, therefore, effectiveness, when it is delivered in the human diet as part of a complex food matrix and not as a discrete molecule.

MATERIALS AND METHODS

All chemicals and solvents were of the highest analytical grade and were purchased from Sigma-Aldrich (St. Louis, MO, USA), except where indicated. The two types of commercial bresaola, named B1 and B2, were bought in a local market.

Cured Meat Sample Preparation for Carnosine Quantification in Raw Material. Bresaola meat samples were prepared for carnosine quantification by grinding them with a common mincer. Five grams of minced meat was then homogenized with 10 mL of distilled water for 4 min at 25000 rpm using a homogenizer. Thereafter, the pH was adjusted to 2.5 with 37% HCl and, after centrifugation for 30 min at 11500 rpm at 4 °C, the supernatant was filtered through a 0.45 μm filter, boiled for 10 min, centrifuged for 20 min at 11500 rpm and 4 °C, and filtered again using a 0.22 μm filter. For CZE analysis the filtered sample was diluted 1:20 with 100 mM phosphate buffer, pH 2.5 (BioRad Laboratories, Hercules, CA, USA). For ^{1}H NMR spectroscopy 160 μL of deuterium oxide (D_2O), containing 10 mM 3-trimethylsilyl-propanoic-2,2,3,3-d_4 acid sodium salt (TSP), as chemical shift calibration standard, was added to 1 mL of filtered sample, and the pH was adjusted to the investigated value by adding 10% NaOH or 1 M HCl.

Cured Meat Sample Preparation for Carnosine pH Dependence Evaluation. The pH dependence of carnosine in bresaola meat was analyzed by ^{1}H NMR in samples prepared as described in the previous section. In these experiments, before the first centrifugation, the pH was adjusted, by adding 10% NaOH or 1 M HCl, to the following values: 2, 2.5, 3.5, 5, 6, 7, and 8. Afterward, the samples were centrifuged at 14000 rpm for 5 min to remove precipitates.

Cured Meat in Vitro Digestion. The bresaola samples were digested in triplicate according to the method of Bordoni,[19] following the scheme reported in Figure 1.

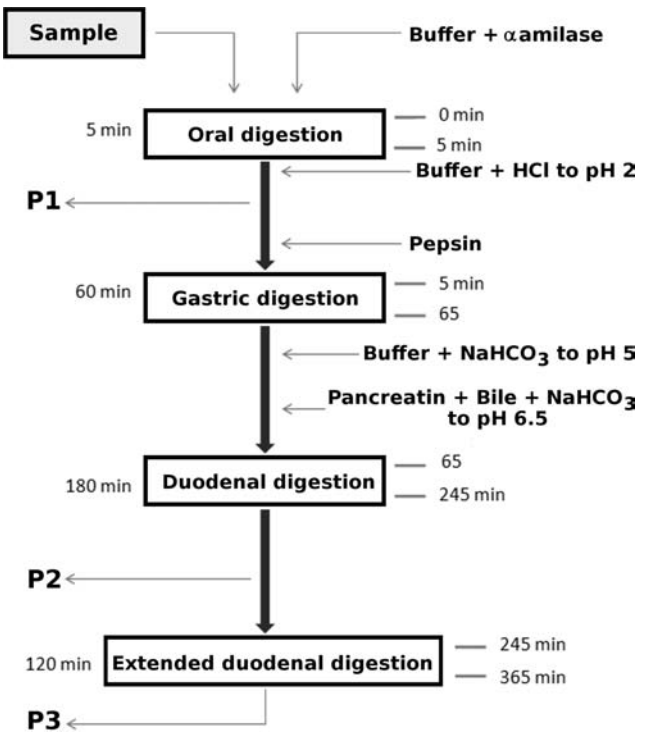

Figure 1. Flowchart of human in vitro digestion. P1, P2, and P3 are the labels of samples collected at the beginning of the gastric phase (P1) and after 180 min (P2) and 300 min (P3) from the beginning of the duodenal phase.

In detail, human digestion was simulated in vitro inside a 100 mL flask, kept at 37 °C in a water bath on a magnetic stirrer equipped with a heating plate.[20] The chemical composition of the digestive fluid, pH, and residence periods were adjusted to mimic physiological conditions. Three samples were collected during digestion: P1, before the gastric phase, when the food enters the stomach and the pH decreases to 2; P2 and P3, at 180 and 300 min from the beginning of the duodenal phase, respectively.

Samples P2 and P3 were acidified to pH 2 with 37% HCl to stop hydrolysis by the pancreatic enzymes. P1, P2, and P3 samples were stored at −80 °C before CZE and ^{1}H NMR experiments, before any further treatment.

For CZE, 500 μL of samples P1−P3 was boiled for 10 min, immediately cooled, and then centrifuged for 30 min at 9500g and 4 °C; the supernatant was filtered through a 0.22 μm before analysis.

Samples P1−P3 were prepared for ^{1}H NMR by adding 160 μL of D_2O, containing 10 mM TSP, as chemical shift calibration standard, to 1 mL of each sample. After adjustment of the pH to 7, the samples were centrifuged at 14000 rpm for 5 min to remove precipitates.

Carnosine Quantification by CZE. CZE analysis and data processing were performed on a Biofocus 2000 from Bio-Rad Laboratories. Uncoated fused-silica capillaries with a diameter of 50 μm and an effective length of 51 cm were used for the analysis. The temperature during the analysis was maintained constant at 38 °C, and samples were analyzed in a 110 mM phosphate buffer at pH 2.5 (Bio-Rad Laboratories). The voltage was kept at 15 kV, and the separated components were detected at 200 nm (UV), without derivatization. The quantification was performed in duplicate by area integration.

^{1}H NMR Evaluation of Carnosine Concentration and Carnosine pH Dependence. All ^{1}H NMR spectra were recorded at 25 °C on a Bruker US+ Avance III spectrometer operating at 600 MHz, equipped with a BBI-z probe and a B-ACS 60 sampler for

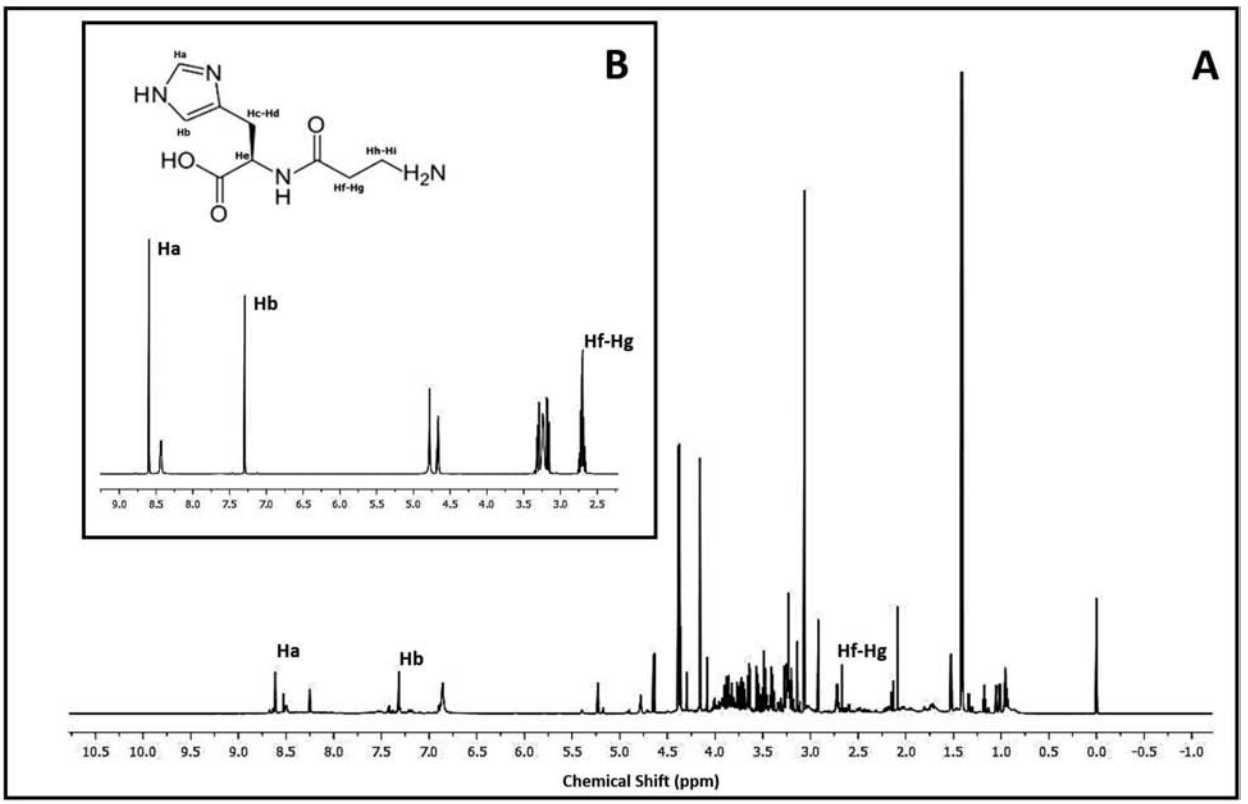

Figure 2. ^{1}H NMR spectrum of (A) bresaola B1 sample at P1 digestion point (pH 7.0) and (B) carnosine standard, showing the signals from L-histidine (Ha, Hb, Hc, Hd, and He) and β-alanine (Hh, Hi, Hf, and Hg) residues.

automation (Bruker BioSpin, Karlsruhe, Germany). Spectra were collected with a 90° pulse of 14 μs with a power of 10 W, a relaxation delay of 5 s, and an acquisition time of 2.28 s.

Spectra were registered by means of the first increment of a NOESY sequence, designed to suppress the HOD residual signal while giving, for each proton, signals proportional to the concentration of the substance they belong.

Statistical Analysis. Data normality and homogeneity of the variances were assessed by means of Shapiro−Wilks and Barlett tests, respectively. Sample and pH effects on carnosine concentration were investigated through an ANOVA test, followed by a post hoc LSD test. Every calculation was performed by means of the correspondent packages implemented in R computational language. A trim value of 0.05 was considered, unless differently stated.

RESULTS AND DISCUSSION

Carnosine Quantification in Raw Bresaola Meat by CZE and ^{1}H NMR Spectroscopy. In undigested raw samples, carnosine content was measured by both CZE and ^{1}H NMR, using the purified compound as reference standard. Measurements were performed at pH 2.5, which optimizes carnosine resolution through CZE.[21]

By CZE the content of carnosine was estimated at 628 and 671 mg/100 g in raw B1 and B2, respectively.

A typical ^{1}H NMR spectrum of bresaola extract, with carnosine highlighted, is reported in Figure 2. For the quantification of this molecule the signals at 7.30 and 8.60 ppm, corresponding to imidazole hydrogens Ha and Hb of the histidine residue, were considered, because they are singlets (thus granting the highest signal-to-noise ratio) and well resolved from signals ascribable to other molecules. In all of the registered spectra it was possible to observe a 1:2 ratio between the area of these signals and those from β-alanine appearing in the range of 2.65−2.80 ppm, corresponding to the two protons Hf and Hg, indicating that the amount of free histidine in all samples was negligible.

By ^{1}H NMR the amount of measured carnosine was estimated as 623.3 and 664.1 mg/100 g of raw products, in B1 and B2 samples, respectively. The very low difference in carnosine concentration detected by ^{1}H NMR and CZE values (Δ = 0.7 and 1.0% for B1 and B2 samples, respectively) clearly indicates a good agreement between the two techniques when working at the same acidic pH.

These values are higher than those reported in the literature for beef meat, for which carnosine content ranged from 32.6 mg/100 g in heart to 452 mg/100 g in semitendinosus muscle,[22,23] being generally higher in anaerobic, glycolitic, white muscle than in red, aerobic muscle.[6] It is conceivable that the higher carnosine content is related to the dehydration process that raw meat undergoes during bresaola production, which increases the protein content from 20.5 to 32 g/100 g.[24]

Effect of pH on Carnosine Quantification in Bresaola Meat. Previous investigations have shown that the solubility of low molecular weight molecules during food digestion depends on the physiological pH of the different digestion environments, which can be modulated by the interaction with the food matrix undergoing digestion.[25] This especially holds for carnosine, the net charge of which strongly depends on pH for the presence of three ionizable groups, namely, the histidine α carboxylic group (pK_a = 2.64), the histidine imidazolic group (pK_a = 6.83), and the alanine β aminic group (pK_a = 9.51).

To better elucidate the relationship between carnosine bioaccessibility and pH, the dipeptide concentration in raw B1 and B2 samples was quantified by ^{1}H NMR in the pH 2−8 range. As reported in Figure 3, in both samples the amount of

[a]The values of three replicates of digestion and their average ± standard deviation are presented, expressed in mg/100 g of meat.

free carnosine was maximum at pH <2.5 or >8 and was characterized by a curvilinear relationship with pH, with a minimum around pH 5.3, corresponding to the isoelectric point of meat proteins. In detail, carnosine concentration in solution appeared significantly different between pH 2 and 7 ($P < 0.05$).

The quantification of carnosine alone in water solution did not show any change of concentration depending on pH (data not reported), pointing out that such behavior was peculiarly ascribable to the interaction between carnosine and the food matrix. The lowest recovery around meat proteins' isoelectric point suggested in particular the interaction of carnosine with the hydrophobic patches over the surface of meat proteins.

Meat is characterized by its own pH, depending on the quality and manufacturing processes in the case of curing, aging, or other technological transformations. The purpose of this study was to describe the effect of the digested meat matrix on the solubility of carnosine, which modulates its accessibility, for example, the diffusion of the dipeptide toward the gut mucosa where the absorption will occur. The possible implication of this phenomenon on the kinetics of absorption should be taken into account in the development of new meat products, by considering that matrix could be modified, thus reacting to digestion in different ways.

Carnosine Bioaccessibility during in Vitro Bresaola Digestion. To study carnosine bioaccessibility during

DOI: 10.1021/acs.jafc.5b01157
J. Agric. Food Chem. 2015, 63, 4973−4978

digestion, its concentration was measured in the soluble fraction of samples collected at different phases of an in vitro static digestion process. CZE and ^{1}H NMR were used in parallel at pH 2.5 and 7, respectively. pH values were adjusted before sample injection (CZE) or transfer to the NMR tube, respectively. As mentioned above, measurement at pH 2.5 optimizes carnosine resolution through CZE;[21] furthermore, it allowed a direct comparison between data obtained on raw samples and digestates. Measurement by ^{1}H NMR were performed at pH 7 to focus on the carnosine concentration at pH values similar to those found in the intestine, where absorption takes place.

Carnosine concentrations in the soluble fractions of digestate obtained at three different time points (P1, P2, and P3), as the result of three repetitions of in vitro digestion processes of B1 and B2 products, are reported in Table 1.

Carnosine concentration at P1 corresponds to the amount of compound brought into solution after the oral step, during which the meat is chewed in the presence of saliva. CZE analysis allowed the comparison of carnosine content at P1 and in raw, undigested samples, evidencing that in both samples the simple action of chewing and subsequent acidification actually released most of the dipeptide (96 and 90% in B1 and B2, respectively).

In both samples carnosine concentration measured by ^{1}H NMR at pH 7 was lower than by CZE, in agreement with the above-reported data on the effect of pH on carnosine quantification. Comparison was made between the gastric samples analyzed by CZE at pH 2.5 and the same samples analyzed by NMR after bringing the pH to 7. This change of pH may parallel the jump occurring when the bolus exits the stomach and enters the duodenum.

As well, carnosine concentration at P2 and P3 (at 180 and 300 min from the beginning of the duodenal digestion, respectively) was higher by CZE than by ^{1}H NMR. It is important to consider that the pH of the intestinal environment is close to 7, so ^{1}H NMR analysis actually mirrors the amount of carnosine available for absorption (i.e., the bioaccessible carnosine), values obtained with CZE being an artifact due to the condition of analysis. ^{1}H NMR showed that, after 180 min of duodenal digestion, the amount of compound found as the bioaccessible soluble fraction was 89 and 81% of the total extracted from the raw samples B1 and B2, respectively. Prolongation of the in vitro duodenal digestion for a further 120 min (P3) did not lead to any significant increase in carnosine concentration, indicating that carnosine release from the food matrix is almost completed after 3 h of duodenal digestion.

In summary, in the present work two different techniques, CZE and NMR spectroscopy, were used in parallel to evaluate the carnosine concentration in two samples of a typical Italian cured meat based product, bresaola. Evaluation was performed on both the raw material and after in vitro digestion of samples. Both analyses were performed on raw bresaola at pH 2.5, and results evidenced a good agreement between the two techniques. In digested samples, CZE analysis was still performed at pH 2.5, which represents the optimum pH value for the analysis, whereas NMR spectroscopy was performed at a pH value resembling the one in the intestine (pH 7). In this way, it was possible to evidence the influence exerted by the matrix on carnosine transfer from the food to the soluble fraction, avoiding interference due to the herein evidenced effect of pH on carnosine quantification.

The nutritional evaluation of a food as a source of specific nutrients is usually based on the chemical composition of the food itself. This approach does not take into account the digestion process, which regulates the amount of nutrients that can be absorbed, leading to a handy approximation often exceeding the real role of the food in the satisfaction of human metabolic needs. The availability of nutrients depends on the food matrix in which they are embedded and on food processing, which can interfere with the digestion process. An exhaustive evaluation of the nutritional meaning of a food should take into account, among others, the modifications occurring during the digestion process, becaise only nutrients that are absorbed have the possibility to modulate the physiological processes occurring in the human body.

Although the present study aimed to investigate the concentration of free carnosine in the gastric and duodenal digestion fluids, the same phenomenon may occur in meat samples before digestion. It is interesting to note that pH 5.3 is typical of meat, and at this pH carnosine has the lowest fraction as free diffusible molecule, which could prevent depletion of such dipeptide during drip loss.

The potential of NMR spectroscopy to describe the interactions between a bioactive compound and the food matrix, directly in the digestion fluid and at the physiological pH, provides a tool that may help to differentiate meat products on the basis of their matrix effect. Matrix is difficult to study during digestion, but its definition may be inferred through the study of its chemical interactions with soluble molecules. The simple quantification of the total amount of each compound extracted from the meat prevents the differentiation of meat products on the supramolecular scale, that is, on the basis of its matrix. NMR spectroscopy offers the opportunity to leave the molecules in their physiological environments, including those characterizing the digestion process and for which the food matrix may play an important role for the diffusibility of the bioactive molecules from food to the gut mucosa.

An omic approach is needed to describe the food system and its relationship with the human system. This approach, known as foodomics, has gained momentum in recent years because it allows reaching a deeper level of knowledge about the nutritional value of a food and of the relationship between food and health.

Supporting Information

ABSTRACT: 3,7,3′,4′-Tetrahydroxyflavone (fisetin) is a flavonoid found in vegetables and fruits having broad biological activities. Here the effects of fisetin on adipogenesis and its regulatory mechanism in mouse adipocytic 3T3-L1 cells are studied. Fisetin inhibited the accumulation of intracellular lipids and lowered the expression of adipogenic genes such as peroxisome proliferator-activated receptor γ and CCAAT/enhancer-binding protein (C/EBP) α and fatty acid-binding protein 4 (aP2) during adipogenesis. Moreover, the mRNA levels of genes such as acetyl-CoA carboxylase, fatty acid synthase, and stearoyl-CoA desaturase involved in the fatty acid biosynthesis (lipogenesis) were reduced by the treatment with fisetin. The expression level of the glucose transporter 4 (GLUT4) gene was also decreased by fisetin, resulting in down-regulation of glucose uptake. Furthermore, fisetin inhibited the phosphorylation of the mammalian target of rapamycin (mTOR) and that of p70 ribosomal S6 kinase, a target of the mTOR complex, the inhibition of which was followed by a decreased mRNA level of the C/EBPα gene. The results obtained from a chromatin immunoprecipitation assay demonstrated that the ability of C/EBPα to bind to the GLUT4 gene promoter was reduced by the treatment with fisetin, which agreed well with those obtained when 3T3-L1 cells were allowed to differentiate into adipocytes in medium in the presence of rapamycin, an inhibitor for mTOR. These results indicate that fisetin suppressed the accumulation of intracellular lipids by inhibiting GLUT4-mediated glucose uptake through inhibition of the mTOR-C/EBPα signaling in 3T3-L1 cells.

KEYWORDS: *fisetin, glucose uptake, mTOR, C/EBPα, adipocytes*

INTRODUCTION

Obesity is now an important public health problem[1] and is closely linked to the trigger of various metabolic diseases such as cardiovascular disease, hypertension, and type II diabetes.[2,3] Obesity occurs by an energy imbalance of intake and expenditure that leads to growth and enlargement of adipose cells. Excess body fat is accumulated in adipose cells as lipids (mostly triglycerides), resulting in an elevated triglyceride level in plasma as well as liver and muscle. Accumulation of body fat and differentiation of adipocytes are closely associated with obesity. In contrast, recent studies have demonstrated that adipocytes are important cells for the regulation of energy homeostasis, as well as for that of endocrine cells that secrete a number of adipocytokines.[4−6]

Adipogenesis is controlled by various factors through complex processes. The molecular mechanisms regulating adipogenesis have been well-studied, and many transcription factors are involved in the control of adipocyte differentiation.[7] Peroxisome proliferator-activated receptor (PPAR) γ, CCAAT/enhancer-binding proteins (C/EBPs), and sterol regulatory element-binding protein (SREBP) play central roles in adipogenesis.[8−10] C/EBPβ and C/EBPδ are expressed in preadipocytes and in the early phase of adipogenesis. They sequentially enhance the expression of C/EBPα and PPARγ genes, which are involved in the differentiation of adipose cells.[8,11] SREBP-1 regulates the expression of various genes involved in fatty acid metabolism in adipocytes.[12]

Various antiobesity drugs have been utilized clinically.[13,14] However, aside from their antiobesity effects, in some cases such drugs show unexpected side effects.[13,14] Defining the mechanisms underlying the suppressive regulation of adipogenesis is critical for the development of antiobesity drugs without side effects or with minimal ones. Natural compounds from plants display various biological and pharmacological activities such as anti-inflammatory, anticancer, and antioxidant ones.[15] Moreover, these activities are often useful for weight management when such compounds are used as nutritional supplements.[16,17] 3,7,3′,4′-Tetrahydroxyflavone (fisetin; Figure 1A) is a flavonoid that is found in fruits and vegetables, especially apples, strawberries, kiwis, cucumbers, and onions,[18] and it has various biological effects resulting from its antimicrobial and antioxidant activities, as well as other cellular regulatory properties.[19] Fisetin has been found as a novel regulator of the mammalian target of rapamycin (mTOR) signaling in prostate cancer cells.[19,20] Moreover, fisetin prevents adipocyte differentiation and obesity through inhibition of mTOR signaling in high fat diet fed mice.[21]

The mTOR protein is a serine/threonine kinase and is a member of the phosphoinositide 3-kinase (PI3K)-related kinase

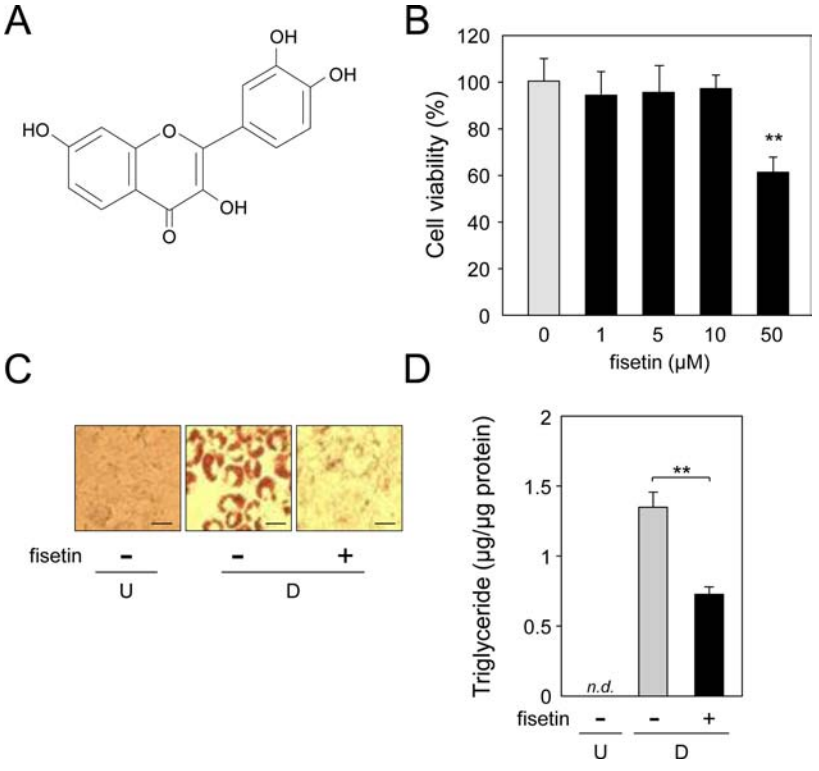

Figure 1. Repression of accumulation of intracellular lipids by fisetin. (A) Structure of fisetin. (B) Cell toxicity of fisetin toward 3T3-L1 cells. Cells were incubated with various concentrations of fisetin (0−50 μM) for 6 days, and cell toxicity was then measured in terms of cell viability. DMSO [final concentration is 0.01% (v/v)] was added as the vehicle. Data are the means ± SD (n = 3). (**) $p < 0.01$, as compared with that of the vehicle (0 μM). (C) Staining for intracellular lipids in 3T3-L1 cells with Oil Red O. The cells (undifferentiated cells, U) were caused to differentiate into adipocytes (D) for 6 days in DMEM with or without fisetin (10 μM). Intracellular lipid droplets were stained with Oil Red O. (D) Fisetin-mediated suppression of the intracellular triglyceride level in 3T3-L1 cells. The cells (undifferentiated cells, U) were caused to differentiate (D) into adipocytes for 6 days in the absence (gray bar) or presence of fisetin (10 μM; black bar). Data are the means ± SD (n = 3). (**) $p < 0.01$, as indicated by the bracket. n.d., not detected.

family, which is involved in the regulation of cell growth and cell proliferation.[22] mTOR consists of two functionally different protein complexes: mTOR complex 1 (mTORC1) and mTORC2.[22] mTORC1 responds to nutrient signals such as glucose and amino acids[23] and is composed of mTOR, raptor, mammalian lethal with sec-13 (mLST8), and proline-rich Akt substrate of 40 kDa (PRAS40); this complex is involved in cellular processes triggered by external signals such as growth factors, oxygen, and amino acids. Recently, the involvement of mTOR signaling in adipogenesis and lipid metabolism has been well recognized.[22] Rapamycin, an mTOR inhibitor, suppresses the progression of adipogenesis.[24,25] Moreover, rapamycin-sensitive mTOR signaling regulates adipocyte differentiation via regulation of PPARγ activity in response to nutritional signals such as insulin and amino acids.[25−28] Constitutive activation of mTORC1 via deletion of tuberous sclerosis 2 enhances adipocyte differentiation.[29]

In this study, we showed a molecular mechanism of fisetin-repressed accumulation of intracellular lipids in adipose cells. We found that fisetin repressed the accumulation of intracellular lipids by down-regulating glucose transporter 4 (GLUT4)-mediated glucose uptake through repression of mTOR-C/EBPα signaling in 3T3-L1 cells.

MATERIALS AND METHODS

Materials. Fisetin, Oil Red O, insulin, 3-isobutyl-1-methylxanthine, and dexamethasone were purchased from Sigma (St. Louis, MO, USA). Rapamycin and deoxy-2-[(7-nitro-2,1,3-benzoxadiazol-4-yl)-amino]-D-glucose (2-NBDG) were obtained from Cayman Chemical (Ann Arbor, MI, USA). Anti-C/EBPα (C-18) and p70 S6 kinase (S6K: C-18) polyclonal antibodies and normal rabbit IgG were obtained from Santa Cruz Biotech (Santa Cruz, CA, USA). Monoclonal antibodies against mTOR (2983), phospho-mTOR (5536), and phospho-S6K (9234) were from Cell Signaling (Danvers, MA, USA). Anti-fatty acid-binding protein 4 (aP2) was purchased from Epitomics (Burlingame, CA, USA). Anti-GLUT4 polyclonal and anti-β-actin (AC-15) monoclonal antibodies were from Sigma. Secondary antibodies such as anti-mouse or anti-rabbit IgG antibody conjugated with horseradish peroxidase were purchased from Santa Cruz Biotech. Other reagents were obtained from Wako Pure Chemicals (Osaka, Japan), Nacalai Tesque (Kyoto, Japan), and Sigma.

Cell Culture. Mouse adipocytic 3T3-L1 cells were obtained from Human Science Research Resources Bank, (Osaka, Japan) and were cultured in Dulbecco's modified Eagle's medium (DMEM; Sigma) supplemented with 10% (v/v) fetal calf serum and antibiotics and in a humidified atmosphere of 5% CO_2 at 37 °C.

Adipocyte differentiation of 3T3-L1 cells was started by incubation of the cells for 2 days in DMEM containing adipocyte differentiation cocktail: insulin (10 μg/mL), 0.5 mM IBMX, and 1 μM dexamethasone. On day 2, the medium was changed to DMEM containing insulin (10 μg/mL) alone and replaced every 2 days.

Fisetin was added to the culture medium at the start of incubation, and when the medium was replaced, fisetin was also added every 2 days.

Cell Toxicity Test. 3T3-L1 cells were cultured in 96-well plates overnight at 37 °C. Then, cells were cultured in DMEM with various concentrations of fisetin (0−50 μM) for 6 days. Cell toxicity was measured by the use of Cell Count Reagent SF (Nacalai Tesque).

Measurement of Intracellular Triglyceride Level. 3T3-L1 cells were allowed to differentiate into adipocytes for 6 days in DMEM in the presence or absence of fisetin. Cells were disrupted in 5% (v/v) Triton-X100 for 3 min at 90 °C after sonication. The extracts were centrifuged for 15 min at 12000*g* at 20 °C. The supernatant was utilized for measurement of the intracellular triglyceride levels (WAKO LabAssay Triglyceride Kit; Wako Pure Chemical) and protein concentration (Pierce BCA Protein Assay Reagent; Thermo Scientific, Rockford, IL, USA).

Measurement of mRNA Levels. Total RNA was extracted from the cells by the use of TriPure Isolation Reagent (Roche Diagnostics, Mannheim, Germany). cDNAs were synthesized from total RNA (1 μg) with ReverTra Ace Reverse Transcriptase (Toyobo, Osaka, Japan) and random hexamer (Takara-Bio, Kyoto, Japan) at 42 °C for 1 h after denaturation at 72 °C for 3 min. After the reverse transcription, the enzyme was denatured at 99 °C for 5 min.

Transcription levels of the desired genes were measured by using a LightCycler system (Roche Diagnostics) with THUNDERBIRD SYBR qPCR Mix (Toyobo) and gene-specific primer sets (Table 1). PCR was conducted under the following condition: 95 °C for 30 s, followed by 40 cycles of 95 °C for 5 s and 60 °C for 30 s. After PCR, the products were heated at 95 °C for 15 s and then cooled to 40 °C, followed by melting at 0.2 °C/s to 95 °C with fluorescence data acquisition.

The expression levels of the genes were normalized to that of the TATA-binding protein (TBP).

Chromatin Immunoprecipitation (ChIP) Assay. ChIP assays were carried out as described previously.[30] The precipitated DNA fragments were further utilized for PCR amplification with a specific primer set: 5′-GCAGGCGGGAACCTTAGGGGCG-3′ (from −184 to −163; transcription initiation site as +1) and 5′-CCAAGGCTC-TCCGGGATCTAGTG-3′ (from −4 to +18). PCR was performed with KOD FX DNA Polymerase (Toyobo) under the following conditions: initial denaturation at 94 °C for 2 min, followed by 32 cycles of 98 °C for 10 s, 55 °C for 20 s, and 68 °C for 20 s. The input control DNA that was prepared from samples prior to immunoprecipitation was diluted 10-fold before PCR amplification. The PCR products (expected size of amplicons was 202 bp) were analyzed by 1% (w/v) agarose gel electrophoresis.

Western Blot Analysis. Crude cell extracts were prepared as described previously[31] with slight modification. Phosphatase inhibitors 1 mM NaF, 50 μM Na_2MoO_4, and 1 mM Na_3VO_4 were added to the extraction buffer. Protein concentration was measured as described above.

The proteins were separated on SDS-PAGE gels (10%) and then transferred onto nylon PVDF membranes (Immobilon; Millipore, Bedford, MA, USA). Blots were first incubated with each primary antibody. After the membranes had been washed, they were incubated with the appropriate secondary antibody, that is, anti-rabbit or anti-mouse IgG antibody conjugated with horseradish peroxidase. The signals were detected by using Pierce Western Blotting Substrate (Thermo Scientific) and an LAS-3000 Image Analyzer (Fujifilm, Tokyo, Japan) and analyzed with Multi Gauge software (Fujifilm).

2-Deoxyglucose Uptake Assay. 3T3-L1 cells were allowed to differentiate into adipocytes in a 96-well plate in DMEM with or without fisetin for 6 days. After removal of the medium, the cells were washed three times with PBS(−) and then cultured for 30 min at 37 °C in PBS(−) containing 150 μg/mL of a fluorescent glucose analogue, 2-NBDG. After the buffer had been discarded, the cells were washed three times with PBS(−), and the fluorescence was observed in PBS(−) under a fluorescence microscope (CKX-41FL, Olympus, Tokyo, Japan). The fluorescence was measured by use of an Enspire Multimode Plate Reader (excitation and emission wavelengths of 485 and 535 nm; PerkinElmer, Waltham, MA, USA). Then, the cells were disrupted, and the protein concentration was determined as described above. The uptake level of 2-NBDG was normalized to the protein concentration.

Statistical Analysis. Comparison of two groups was analyzed by using Student's *t* test. For comparison of more than two groups with comparable variances, one-way ANOVA and Tukey's post hoc test were performed. $p < 0.05$ was considered significant.

RESULTS

Effects of Fisetin on Lipid Accumulation of 3T3-L1 Cells. First, we examined the effect of fisetin (Figure 1A), a plant flavonoid, on the growth of 3T3-L1 cells. Cells were incubated for 6 days in DMEM containing various concentrations of fisetin (0−50 μM), and then cell toxicity was measured. No significant cell toxicity was detected up to 10 μM fisetin (Figure 1B). However, when the cells were cultured in medium with 50 μM fisetin, the cell viability was decreased about 38% as compared with that of the untreated cells (0 μM; Figure 1B).

Next, we investigated the effects of fisetin on lipid accumulation in adipose cells. 3T3-L1 cells were allowed to differentiate into adipocytes for 6 days in DMEM in the presence or absence of fisetin, and thereafter the intracellular lipids were stained with Oil Red O. The number of lipid droplets in the differentiated cells was elevated as compared with that in the undifferentiated cells (Figure 1C). In contrast, when we differentiated the cells into adipocytes in DMEM containing fisetin, the number of intracellular lipid droplets was clearly and drastically decreased (Figure 1C).

Then, the level of intracellular triglycerides was measured. When 3T3-L1 cells were differentiated into adipocytes for 6 days in DMEM in the presence or absence of fisetin, the intracellular triglyceride level in the differentiated cells was increased as compared with that in the undifferentiated cells (Figure 1D). However, when fisetin was present during the adipocyte differentiation of 3T3-L1 cells, the intracellular triglyceride level was decreased to approximately 48% of that in the differentiated cells (Figure 1D). These results, taken

DOI: 10.1021/acs.jafc.5b00821
J. Agric. Food Chem. 2015, 63, 4979−4987

together, reveal that fisetin repressed the accumulation of intracellular lipids in adipocytes.

Suppression of Expression of Adipogenic Genes by Fisetin. Next we studied the effects of fisetin on the transcription of adipogenic genes such as PPARγ, C/EBPα, aP2, and SREBP-1c by quantitative PCR. We differentiated 3T3-L1 cells into adipocytes for 6 days in DMEM containing fisetin, and RNA was then prepared. The expression level of the PPARγ, C/EBPα, aP2, and SREBP-1c genes in the control cells was enhanced approximately 22-, 1.8-, 134-, and 5.0-fold, respectively, during adipogenesis (Figure 2). In contrast,

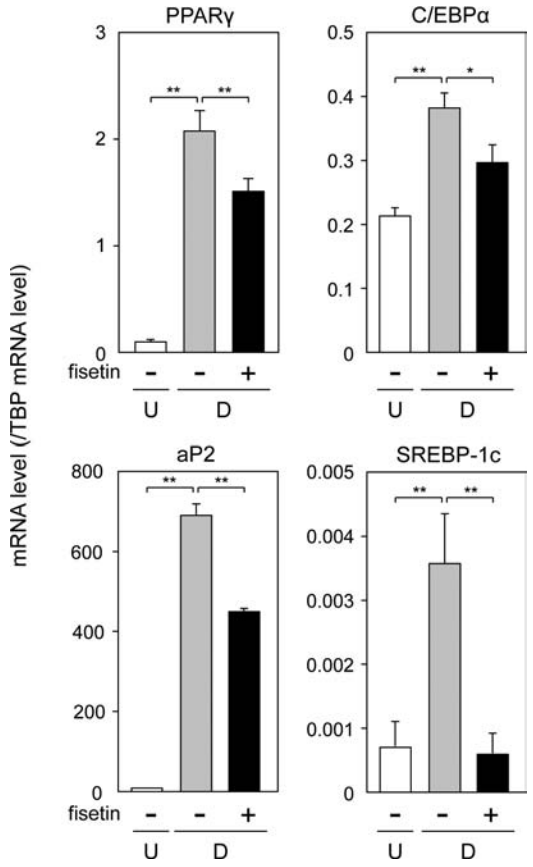

Figure 2. Suppressed expression of adipogenic genes in fisetin-treated 3T3-L1 cells: expression levels of adipogenic genes of PPARγ, C/EBPα, aP2, and SREBP-1c in fisetin-treated cells. 3T3-L1 cells (undifferentiated cells, U; bars) were caused to differentiate (D) into adipocytes for 6 days in DMEM in the absence (gray bars) or presence of fisetin (10 μM; black bars). The mRNA levels were measured by quantitative PCR analysis. Data are the means ± SD (n = 3). (**) p < 0.01, as indicated by the brackets.

mRNA levels of the PPARγ, C/EBPα, aP2, and SREBP-1c genes in the fisetin-treated cells were decreased about 27, 22, 35, and 82%, respectively, as compared with those in the vehicle-treated differentiated cells (Figure 2). These results indicate that fisetin repressed the mRNA levels of adipogenic genes in 3T3-L1 cells.

Repression of Expression of Lipogenic Genes by Fisetin. To assess the effect of fisetin on fatty acid metabolism, we examined the alteration in the mRNA level of lipogenic genes in the fisetin-treated 3T3-L1 cells. When we differentiated 3T3-L1 cells into adipocytes for 6 days in DMEM without fisetin, the mRNA levels of lipogenic genes such as acetyl-CoA carboxylase (ACC), fatty acid synthase (FAS), and stearoyl-CoA desaturase (SCD) were elevated about 1.2-, 1.2-, and 1.8-fold, respectively, as compared with each of those of the undifferentiated cells (Figure 3). In contrast, when fisetin was

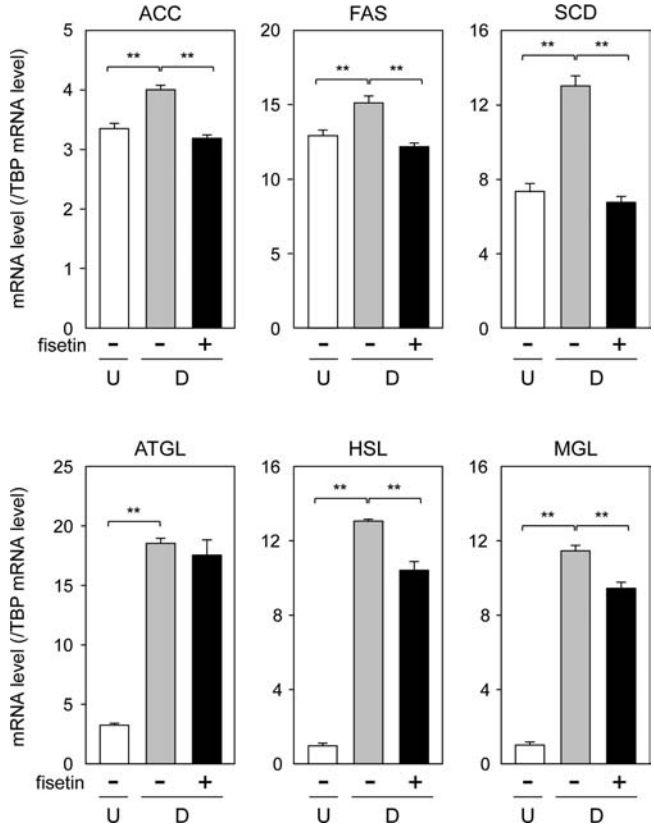

Figure 3. Expression of lipogenic and lipolytic genes in fisetin-treated 3T3-L1 cells: expression in fisetin-treated 3T3-L1 cells of ACC, FAS, and SCD of lipogenic genes and ATGL, HSL, and MGL genes involved in lipolysis. The cells (undifferentiated cells, U; white bars) were caused to differentiate (D) into adipocytes for 6 days in DMEM without (gray bars) or with (black bars) fisetin (10 μM). Transcription levels were measured by quantitative PCR analysis. Data are the means ± SD from three independent experiments. (**) p < 0.01, as indicated by the brackets.

present during the differentiation, the transcription levels of the ACC, FAS, and SCD genes were reduced about 20, 19, and 47%, respectively, as compared with those of the vehicle-treated differentiated cells (Figure 3). These results suggest that lipogenesis was suppressed by fisetin in adipocytes.

Next, we studied the mRNA level of genes involved in lipolysis, that is, adipocyte triglyceride lipase (ATGL), hormone-sensitive lipase (HSL), and monoacyl glyceride lipase (MGL). In the absence of fisetin, the transcription levels of the ATGL, HSL, and MGL genes were up-regulated during adipogenesis, about 5.7-, 13-, and 11-fold, respectively, as compared with those of the undifferentiated cells (Figure 3). Moreover, when we differentiated the cells into adipocytes in DMEM containing fisetin, the transcription levels of the HSL and MGL genes were decreased to about 80 and 83%, respectively, of those of the differentiated cells (Figure 3). However, the expression level of the ATGL gene in these cells was not altered (Figure 3). These results indicate that lipolysis in 3T3-L1 cells may have been slightly repressed by fisetin.

Fisetin Inhibits GLUT4-Mediated Glucose Uptake in Adipocytes. Next we examined the glucose uptake in fisetin-

J. Agric. Food Chem. 2015, 63, 4979−4987

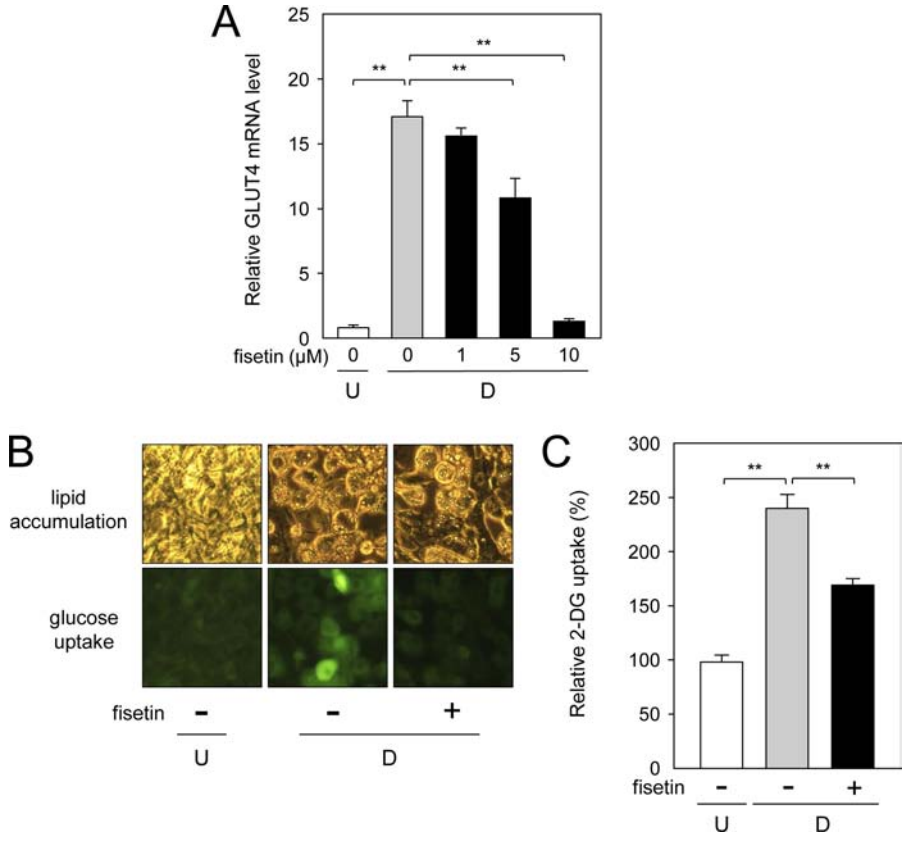

Figure 4. Fisetin-mediated decrease in glucose uptake in 3T3-L1 cells. (A) Repression of GLUT4 expression in fisetin-treated cells. 3T3-L1 cells (undifferentiated cells, U; white bars) were caused to differentiate (D) into adipocytes for 6 days in DMEM without (gray bars) or with various concentrations of fisetin (1−10 μM; black bars). The mRNA level of the GLUT4 gene was measured by quantitative PCR analysis. Data are the means ± SD (n = 3). (**) $p < 0.01$, as indicated by the brackets. (B) Suppression of glucose uptake by fisetin. 3T3-L1 cells (undifferentiated cells, U) were caused to differentiate into adipocytes for 6 days in DMEM without (differentiated cells, D) or with fisetin (10 μM; fisetin-treated differentiated cells, D/fisetin), and glucose uptake was then observed under fluorescence microscope by the use of the fluorescent 2-NDBG (upper, phase contrast; lower, fluorescent). (C) Quantification of glucose uptake in fisetin-treated 3T3-L1 cells. Cells were prepared as described for panel B. The data are presented as the value relative to that of the undifferentiated cells and are shown as the means ± SD (n = 3). (**) $p < 0.01$, as indicated by the brackets.

treated 3T3-L1 cells. First, we investigated the change in the expression level of the GLUT4 gene in fisetin-treated 3T3-L1 cells. Without fisetin, the mRNA level of the GLUT4 gene was elevated about 21-fold, as compared with that of the undifferentiated cells (Figure 4A). However, when fisetin was present during the adipocyte differentiation of 3T3-L1 cells, the mRNA level of the GLUT4 gene was reduced in a concentration-dependent manner of fisetin and decreased to about 18% (at 10 μM fisetin) of that for the vehicle-treated differentiated cells (Figure 4A).

Then, we examined glucose uptake in the fisetin-treated 3T3-L1 cells by the use of the fluorescent 2-NBDG. 3T3-L1 cells were differentiated into adipocytes in DMEM with or without fisetin, and then the cells were incubated with 2-NBDG, followed by observation with the fluorescence microscope. The fluorescence of 2-NBDG was clearly enhanced in the vehicle-treated differentiated cells, as compared with that of the undifferentiated cells (Figure 4B). On the contrary, the fisetin-treated cells showed a decrease in fluorescence, as compared with the fluorescence of the vehicle-treated differentiated cells (Figure 4B). Moreover, we measured the fluorescence in the cells to quantify the uptake of glucose. Glucose uptake in the absence of the fisetin was activated about 2.3-fold during adipogenesis (Figure 4C). In contrast, in its presence, the uptake was suppressed approximately 37%, as compared with that by the vehicle-treated differentiated cells (Figure 4C). These results reveal that glucose uptake was suppressed by fisetin through down-regulation of the GLUT4 expression in 3T3-L1 cells.

Fisetin-Reduced Ability of C/EBPα To Bind to the GLUT4 Promoter. To elucidate the molecular mechanism of the repression of accumulation of intracellular lipids by fisetin in 3T3-L1 cells, we investigated the effect of fisetin on the regulatory mechanism of GLUT4 gene expression. The GLUT4 gene expression is enhanced by C/EBP in 3T3-L1 cells.[32,33] As the C/EBPα gene was expressed in 3T3-L1 cells and its expression level was repressed by fisetin (Figure 2A), we carried out a ChIP assay to study the involvement of the C/EBPα in the fisetin-mediated transcriptional suppression of GLUT4 gene expression. The expected size (202 bp; Figure 5A) of PCR products containing the C/EBP-binding element at −92 to −88 from the mouse GLUT 4 promoter was detected when anti-C/EBPα antibody was added (Figure 5B). The efficiency of binding of C/EBPα to this C/EBP-binding element in the differentiated cells was clearly enhanced, as compared with that for the undifferentiated cells (Figure 5B). In contrast, when the cells were allowed to differentiate into adipocytes in DMEM with fisetin, the band intensity was decreased as compared with that for the vehicle-treated differentiated cells (Figure 5B). No detectable signal was

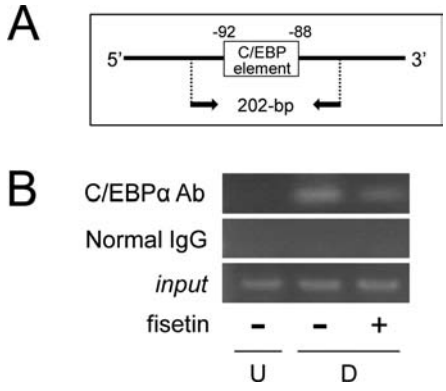

Figure 5. Decrease in the ability of C/EBPα to bind to the GLUT4 promoter in fisetin-treated 3T3-L1 cells. (A) Scheme for the ChIP assay of the GLUT4 promoter. (B) ChIP assay. The cells (undifferentiated cells, U) were caused to differentiate (D) into adipocytes in DMEM with or without fisetin (10 μM) for 6 days, and the ChIP assay was then carried out. The profile of the amplicon is shown, and the input control (*input*) means that a small diluted aliquot before immunoprecipitation was used for PCR amplification.

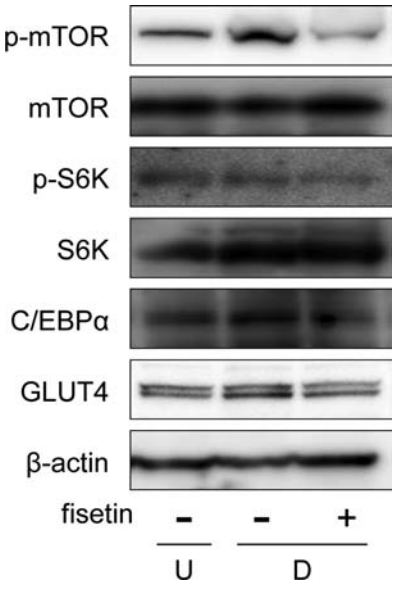

Figure 6. Suppression of GLUT4 expression by fisetin through mTOR-C/EBPα signaling. Expression of mTOR, S6K, C/EBPα, and GLUT4 and phosphorylation of mTOR and S6K in fisetin-treated 3T3-L1 cells. The cells were caused to differentiate (D) into adipocytes in DMEM with or without fisetin (10 μM) for 6 days. Western blot analysis was performed (10 or 15 μg/lane).

observed when normal IgG was used in the immunoprecipitation (Figure 5B). In addition, when the input control was used as the template for PCR analysis, the signals were detected in all samples. These results suggest that C/EBPα bound to the C/EBP-binding element of the GLUT4 gene promoter. Moreover, its binding ability was suppressed by the treatment with fisetin. Therefore, fisetin repressed the C/EBPα-activated GLUT4-mediated glucose uptake in 3T3-L1 cells.

Suppression of mTOR-C/EBPα Signaling by Fisetin. As fisetin is involved in the regulation of obesity through mTORC1 signaling,[34] we further examined the involvement of mTOR signaling in the regulation of the C/EBPα-activated GLUT4-mediated glucose uptake in 3T3-L1 cells. We differentiated 3T3-L1cells into adipocytes in DMEM with or without fisetin for 6 days, after which the expressions of mTOR, S6K, C/EBPα, and GLUT4 and the phosphorylation of mTOR and S6K proteins were examined by Western blot analysis (Figure 6 and Figure S1). The phosphorylation level of mTOR was enhanced in the control differentiated cells as compared with that of the undifferentiated cells. Moreover, its phosphorylation level was clearly decreased when the cells were allowed to differentiate into adipocytes in DMEM with fisetin. The total mTOR protein level was almost the same in all samples. On the contrary, the phosphorylation of S6K was slightly decreased in the cells treated with fisetin, although the pan-S6K level was not changed in any of the samples. Moreover, when we allowed the cells to differentiate into adipocytes for 6 days without fisetin, the protein levels of C/EBPα and GLUT4 were enhanced, whereas a decrease in both was observed when fisetin was present. All of these results agree well with those obtained from the quantitative PCR analysis (Figures 2 and 4A), indicating that fisetin repressed the phosphorylation of mTOR and S6K, thus causing a decrease in the expression of C/EBPα and GLUT4 in adipocytes.

In addition, to confirm the involvement of mTOR signaling in the regulation of C/EBPα-activated GLUT4 gene expression, we utilized rapamycin, an mTOR inhibitor. 3T3-L1 cells were allowed to differentiate into adipocytes in DMEM with rapamycin for 6 days, after which the intracellular lipids were stained with Oil Red O. Rapamycin suppressed the accumulation of intracellular lipid in 3T3-L1 cells, revealing that mTOR signaling is involved in the accumulation of intracellular lipids in these cells (Figure 7A). Moreover, when we added rapamycin during the adipocyte differentiation process at play in the cells, the mRNA level of C/EBPα and GLUT4 genes was reduced approximately 33 and 96%, respectively, in the fisetin-treated cells as compared with those in the vehicle-treated differentiated cells (Figure 7B). In addition, glucose uptake was decreased to about 68% of that in the vehicle-treated differentiated cells by the treatment with rapamycin (Figure 7C,D). Furthermore, the ability of C/EBPα to bind to the promoter region of GLUT4 gene was decreased by rapamycin, as revealed by the results of a ChIP assay (Figure 7E). Thus, rapamycin, an mTOR inhibitor, deceased the accumulation of intracellular lipids via inhibition of the binding of C/EBPα to the GLUT4 promoter, which is in agreement with the results obtained when fisetin was added to the medium during adipogenesis.

■ DISCUSSION

Obesity is a trigger factor for the development of various metabolic diseases[2,3] and is defined as an overaccumulation of body fat; adipose cells in obese individuals contain a large amount of lipids. Excess adipose tissue is the result of an increased number (hyperplasia) and enlarged size (hypertrophy) of adipocytes. Therefore, treatments that inhibit either hyperplasia or hypertrophy, or both, may be a new therapeutic approach for obesity. Recently, it was reported that some flavonoids have antiadipogenic activities.[16,17] Apigenin[35] and quercetin[36] repress adipogenesis through activation of AMP-activated protein kinase (AMPK) and the mitogen-activated protein kinase pathway. Curcumin[37] and genistein, a soy-derived isoflavone,[38,39] suppress adipocyte differentiation. Fisetin represses adipocyte differentiation by inhibiting mTOR signaling in high fat diet fed mice.[19,34] However, the regulatory mechanism of fisetin-mediated suppression of adipogenesis has never been identified. Our present study

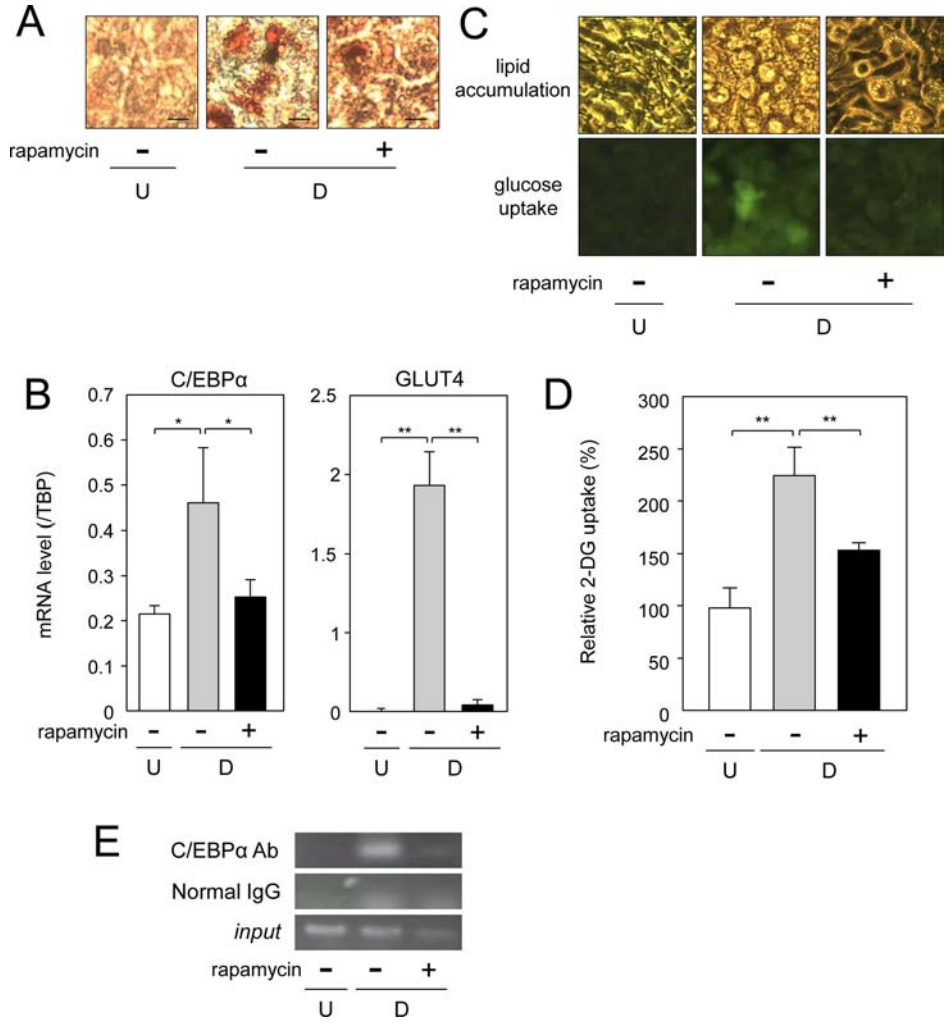

Figure 7. Inhibition of adipogenesis by rapamycin. (A) Staining of intracellular lipids in 3T3-L1 cells with Oil Red O. The cells (undifferentiated cells, U) were caused to differentiate into adipocytes (D) for 6 days in DMEM with or without rapamycin (20 nM). Intracellular lipid droplets were stained with Oil Red O. (B) Transcription levels of the C/EBPα and GLUT4 genes in rapamycin-treated cells. 3T3-L1 cells (undifferentiated cells, U; white bars) were caused to differentiate (D) into adipocytes for 6 days in DMEM without (gray bars) or with (black bars) rapamycin (20 nM). The mRNA level was then measured by quantitative PCR analysis. Data are the means ± SD ($n = 3$). (**) $p < 0.01$ and (*) $p < 0.05$, as indicated by the brackets. (C) Reduction in glucose uptake by rapamycin. Cells (undifferentiated cells, U) were caused to differentiate into adipocytes for 6 days in DMEM without (differentiated cells, D) or with rapamycin (20 nM; rapamycin-treated differentiated cells, D/rapamycin), and glucose uptake was then observed under fluorescence microscope by the use of the fluorescent 2-NDBG (upper, phase contrast; lower, fluorescent). (D) Quantification of glucose uptake in rapamycin-treated 3T3-L1 cells. Cells were prepared as described for panel C. The data are represented as the value relative to that of the undifferentiated cells and are shown as the means ± SD ($n = 3$). (**) $p < 0.01$, as indicated by the brackets. (E) ChIP assay. 3T3-L1 cells (undifferentiated cells, U) were caused to differentiate (D) into adipocytes in DMEM with or without rapamycin (20 nM) for 6 days, and the ChIP assay was then carried out. The profile of the amplicon is shown, and the input control (*input*) means that a small diluted aliquot before immunoprecipitation was used for PCR amplification.

showed a regulatory mechanism by which fisetin suppressed adipogenesis by inhibiting C/EBPα-activated GLUT4-mediated glucose uptake through suppression of mTOR signaling.

Glucose is incorporated into the cells by glucose transporter proteins, the GLUT family in mammals.[40] Glucose transport is the rate-limiting step in glucose uptake, which is responsible for glucose metabolism.[41] GLUT4, a member of the glucose transporter family, plays a dominant role in adipocytes, and the increased intrinsic activity of GLUT4 induces elevated glucose incorporation into 3T3-L1 cells.[42] As incorporation of an excess amount of glucose into the cells causes an increase in the intracellular lipids, the control of glucose transport is critical for its regulation and therefore is closely related to obesity. In this study, we demonstrated that fisetin repressed the glucose uptake with the marked decrease of GLUT4 mRNA level (Figure 4A) and slight reduction of GLUT4 protein (Figure 6) in 3T3-L1 cells, resulting in decreased accumulation of intracellular lipids. The difference of GLUT4 mRNA and protein level (Figures 4A and 6) may be derived from their distinct stabilities.[43,44] Thus, fisetin is a useful flavonoid for the regulation of the accumulation of intracellular lipids via suppression of glucose uptake. Some other flavonoids also have the potential to regulate glucose uptake in adipocytes, for example, apigenin, avicularin, quercetin, genistein, and epigallocatechin gallate.[27,33]

mTOR is a key regulator that integrates hormonal and nutritional inputs,[22] and it is involved in the regulation of various cellular functions. The hormonal and nutritional activation of the mTORC1 complex and its downstream signaling molecule, S6K, a member of the ribosomal S6K family

DOI: 10.1021/acs.jafc.5b00821
J. Agric. Food Chem. 2015, 63, 4979−4987

of serine/threonine kinases, is inhibited by rapamycin.[22] mTOR plays critical roles in the regulation of both lipid metabolism and adipogenesis. The inhibition of this pathway represses the PI3K/Akt pathway through insulin-activated insulin receptor substrate 1 (IRS-1) signaling, resulting in the suppression of glucose uptake in adipocytes.[26,45−48] The mTOR-S6K1 signaling is activated in obesity, overnutrition, and insulin resistance.[21,49] In vivo analysis of mTOR signaling has been performed by the use of gene-knockout mice. Ablation of S6K1 decreases body weight gain in mice on a high-fat diet[50,51] and represses insulin resistance through decreased phosphorylation of IRS-1;[50] in the absence of Raptor, a component of mTORC1, the mice became lean.[52] Akt-mediated phosphorylation of TSC2 activates mTORC1 signaling, followed by elevation of adipogenesis.[29] Therefore, the inhibition of mTOR-S6K1 signaling is useful for the improvement of insulin resistance and antiobesity.

mTOR and PI3K/Akt signalings are involved in the activation of PPARγ in adipogenesis.[28] C/EBPα and PPARγ regulate each other to enhance adipogenesis.[7] Moreover, activation of mTORC1 increases the expression of PPARγ.[29] In this study, we revealed that fisetin reduced the expression of C/EBPα through mTOR signaling. Therefore, this fisetin-mediated decrease in C/EBPα expression may have been regulated through PPARγ. Moreover, although fisetin suppressed the phosphorylation of mTOR and S6K, ae well as the expression of C/EBPα and GLUT4, when the cells were cultured for 6 days in its presence, these levels were not altered when the cells were cultured for just 1 day in DMEM containing fisetin (data not shown). Thus, fisetin-mediated suppression of mTOR signaling may be dependent on the differentiation stage of adipogenesis. Furthermore, the intracellular energy homeostasis is regulated by mTORC1 through AMPK, a master sensor of intracellular energy homeostasis. In addition, when energy was depleted, AMPK reduces mTORC1 activity via phosphorylation of Raptor.[53] Thus, fisetin-mediated suppression of the accumulation of intracellular lipid may be associated with the AMPK signaling. In further study, the signal network such as AMPK and PI3K/Akt pathways involved in fisetin-mediated inhibition of the accumulation of intracellular lipid will be elucidated.

In summary, fisetin, a plant flavonoid, represses the accumulation of intracellular lipids by suppressing direct regulation of the expression of GLUT4 gene by C/EBPα, followed by decreasing GLUT4-mediated glucose uptake through inhibition of mTOR signaling in 3T3-L1 cells. In a future study, we plan to evaluate the action of fisetin as an antiobesity agent in vivo. Additionally, the molecular mechanism underlying the suppression of activation of mTOR by fisetin will be investigated to elucidate the molecular mechanism of fisetin-mediated suppression of glucose uptake in adipocytes.

Supporting Information

ABSTRACT: Ellagic acid (EA), a phenolic lactone, inhibited tautomerase activity of human macrophage migration inhibitory factor (MIF) noncompetitively (K_i = 1.97 ± 0.7 μM). The binding of EA to MIF was determined by following the quenching of tryptophan fluorescence. We synthesized several EA derivatives, and their structure−activity relationship studies indicated that the planar conjugated lactone moiety of EA was essential for MIF inhibition. MIF induces nuclear translocation of NF-κB and chemotaxis of peripheral blood mononuclear cells (PBMCs) to promote inflammation. We were interested in evaluating the effect of EA on nuclear translocation of NF-κB and chemotactic activity in human PBMCs in the presence of MIF. The results showed that EA inhibited MIF-induced NF-κB nuclear translocation in PBMCs, as evident from confocal immunofluorescence microscopic data. EA also inhibited MIF-mediated chemotaxis of PBMCs. Thus, we report MIF-inhibitory activity of EA and inhibition of MIF-mediated proinflammatory responses in PBMCs by EA.

INTRODUCTION

Phenolic compounds or polyphenols comprise one of the most plentiful and widely distributed groups of phytochemicals. More than 8000 different chemical structures have been identified and reported.[1] Plants produce phenolic compounds as secondary metabolites (i.e., they are not essential for growth or reproduction), which exist mostly in their storage tissues. Phenolic compounds may play roles as antioxidants as well as modulators of several biological macromolecules. As a chemical family, polyphenols can be classified into several groups on the basis of their basic structures.[1] These groups can be distinguished according to the number of aromatic rings and the structural moieties that connect them. The phenolics contain at least one aromatic ring bearing one hydroxyl (phenol) or more hydroxyl (polyphenol) groups. Thus, polyphenolic compounds include a large array of molecules, including phenols, phenolic acids, tannins, lignans, flavonoids, stilbenes, and lignins. A wide range of biological actions have been reported for different polyphenols, including antimicrobial, analgesic, antibiotic, anticancer, and anti-inflammatory properties.[2−5] Their biological actions are mostly attributes of the antioxidant effects of their phenolic groups. Blocking of the phenolic group results in decreased activity, whereas extended unsaturated bond conjugation, proper ester linkage, and an extended fused ring system increased the activity of these polyphenolics.[6−8]

Ellagic acid (EA), a polyphenolic tannin-based dilactone (4,4′,5,5′,6,6′-hexahydroxydiphenic acid 2,6,2′,6′-dilactone) is reportedly known to possess a broad range of beneficial human health (antiviral,[9] antibacterial,[10] gastro-protective,[11] cardio-protective,[12] antimutagenic,[13] antimicrobial,[14] antimalarial,[15] anti-inflammatory,[16] and anticancer[17]) properties. Previous studies revealed that aromatic conjugated −OH groups of EA are the main scaffold responsible for its antioxidant nature.[18,19] Apart from its −OH mediated antioxidant activity, recent literature suggests several other modes of action of EA, which may not be directly linked to its antioxidant property.[20,21] EA interacts with receptors, cytokines, and enzymes.[22−24] Macrophage migration inhibitory factor (MIF) is one of the pivotal cytokines that plays an important role in both innate and acquired immunity. In certain cancers, proinflammatory cytokines serve as the major mediators of intercellular communication in the tumor microenvironment,[25] thus paving the way for developing malignancy; in others, oncogenic changes drive a tumor-promoting inflammatory microenvironment. With intricate and various activities, MIF has been considered to be a missing link between inflammation and

tumorigenesis.[26] Moreover, MIF has been proposed to regulate proliferation, DNA-damage response, apoptosis, senescence, and invasion during carcinogenesis.[27−30] Studies revealed that MIF, via regulating nuclear translocation of NF-κB, plays an important role in inflammatory diseases.[31] NF-κB signaling has long been known as a significant event regulating inflammation, mainly due to the role of NF-κB in regulating the expression of several proinflammatory mediators, including cytokines, chemokines, and adhesion molecules.[32] Inhibition of MIF has been shown to reduce activation of NF-κB and consequent activation of other cytokines.[33] During inflammatory disorders PBMCs enhance the proinflammatory cytokines and suppress the anti-inflammatory cytokines.[34] Secreted proinflammatory cytokines such as MIF further recruit PBMCs to the site of inflammation through chemotactic migration.[35] Therefore, the involvement of PBMCs via chemotactic migration in response to a concentration gradient of MIF is an essential event involved in the inflammatory response. Several natural product polyphenolics such as curcumin, eugenol, resveratrol, and caffeic acid have been found to inhibit MIF, mainly via blocking the tautomerase activity of the cytozyme.[36]

Here we report that EA, a naturally occurring polyphenolic compound, binds to MIF and inhibits its tautomerase activity. Spatiotemporal inhibition of EA on MIF tautomerase activity is solely dependent on the dimensionally conformed lactone moiety. We further report that EA significantly inhibits MIF-induced nuclear translocation of NF-κB and MIF-mediated chemotactic migration in human PBMCs, two signature events associated with tissue inflammation.

MATERIALS AND METHODS

Chemicals. Ellagic acid, pyrene, DMSO, paraformaldehyde, kanamycin, chloramphenicol, and protease inhibitor cocktail were procured from Sigma (St. Louis, MO, USA). PBS (Hyclone), isopropyl-β-D-thiogalactopyranoside (IPTG), prestained marker and unstained protein ladders, rapid DNA ligation kit, NcoI, and *Hin*dIII were purchased from Fermentas (Thermo Scientific, USA). Luria−Berteni medium was obtained from Hi-Media (Mumbai, India). A gel extraction kit and MiniElute PCR purification kit was procured from Qiagen USA. pET28a was purchased from Novagen (Merck KGaA, Darmstadt, Germany). Gallic acid and benzyl bromide were procured from SRL (New Delhi, India). NF-κB antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). AlexaFluor 647 conjugated secondary antibody was purchased from Invitrogen (Carlsbad, CA, USA). All other chemicals were of analytical grade.

Overexpression and Purification of Human MIF. Human MIF was cloned by following the protocol as described earlier with slight modification.[37] In brief, full length MIF cDNA was cloned using pCMV6-XL5 cloning vector obtained from ORIGENE USA. Complete ORF from the clone pCMV6-XL5 was PCR amplified with the forward primer 5′-CTAACCATGGCCCCGATGTTCATTGTAAATACCAACGTGCCCC-3′ (NcoI restriction site underlined) and reverse primer 5′-TTAAAGCTTCTGCGGTTCTTAGGCGAAGGTAGAGTTGTTCCAGCCC-3′ (*Hin*dIII restriction site underlined). PCR was performed with initial denaturation at 95 °C for 3 min and then 35 cycles of denaturation (95 °C for 30 s), annealing (52 °C for 30 s), and extension (72 °C for 1 min) with a final extension of 72 °C for 10 min. PCR product was then cloned in *Escherichia coli* expression vector pET28a (Novagen). Ligation mix was transformed in competent DH5α cells, and clones were screened by colony PCR and double-digestion release of insert from positive colonies.

Host strain *E. coli* Rosetta (Novagen) was used for recombinant MIF overexpression and purification. Lysogency Broth (LB; 1 L) was inoculated with 1% (v/v) of overnight (16 h) grown culture on the following morning and incubated at 37 °C with shaking at a rate of 200 rpm. Culture was induced with IPTG (1 mM final concentration) in the OD_{600} range 0.6−0.8 and was further allowed to grow for 4 h. Cells were harvested (11000*g*, 5 min, 4 °C) and reconstituted in 10 mL of lysis buffer (PBS with 10% (v/v) glycerol) containing protease inhibitor cocktail. Cells were incubated on ice for 60 min and subsequently lysed by sonication (30 cycles of pulse rest at 60% amplitude; pulse duration 10 s and rest duration 1 min), after which supernatant was collected by centrifuging the lysate at 40000*g*. Overexpression of MIF in the soluble fraction was confirmed by 15% SDS-PAGE of the supernatant. All further steps were performed at 4 °C. The obtained supernatant was concentrated to 4 mL by an Amicon Ultra Centrifugal Filter Ultracel-3K (Millipore Ireland Ltd.) and then passed through a 0.2 μm filter. Finally, MIF was purified by performing gel filtration chromatography through a Sephadex G50 (GE Life Sciences, Uppsala, Sweden) column using PBS as the solvent with a flow rate of 6 mL/h.

MALDI-TOF and Peptide Fingerprinting. Purified protein was processed by μ-C18 ZipTip tips (Millipore) for removal of salts as per the manufacturer's instructions and subjected to MALDI-TOF mass analysis. In short, trifluoroacetic acid (TFA) was added to the purified protein solution to 0.1% (the pH should be less than 4) and then aspirated in pre-equilibrated (with 0.1% TFA) tips in a 10 μL pipet to the maximum volume. The solution was dispensed and aspirated again in the tip. This cycle was repeated 10 times for maximum binding. Washing was performed twice with 0.1% TFA with 5% methanol, and elution was done in 4 μL of 0.1% TFA with 50% acetonitrile. This protein was directly used for MALDI-TOF analysis using an Applied Biosystems 4700 Proteomics Analyzer170 instrument. For confirmation of the identity of the protein, peptide mass fingerprinting was performed. The protein band was excised from the gel and destained followed by reduction, alkylation, and digestion into peptides using an In-Gel Tryptic Digestion Kit (Thermo Scientific) as instructed by the manufacturer. Briefly, a gel piece was treated with reducing buffer (50 mM TCEP and 25 mM ammonium bicarbonate) and then with alkylation buffer (100 mM iodoacetamide and 25 mM ammonium bicarbonate) and then shrunk using acetonitrile, air-dried, and swelled by activated trypsin with digestion buffer added after 15 min (kept overnight at 30 °C with shaking). Buffer was collected back the next day without gel. This contained peptides released and could be directly used for MALDI MS/MS. 1% trifluoroacetic acid was used to extract the remaining peptides and deactivate trypsin. This final product was used for MALDI MS/MS. The spectrum obtained was searched in the NCBI database by GPS explorer using a MASCOT browser.

L-Dopachrome Methyl Ester (L-DOPA) Preparation To Follow MIF Tautomerase Activity Assay. The tautomerase activity of MIF was followed as described earlier.[38] Activity was determined at 25 °C by adding L-DOPA (0.25−1.5 mM) to a cuvette containing 60 nM MIF in 10 mM potassium phosphate buffer, pH 6.2, containing 0.5 mM EDTA. The activity of MIF was monitored by measuring the conversion of L-DOPA (colored) to indolecarboxylic acid methyl ester (colorless) at 475 nm. Inhibitory activities of the synthesized EA derivatives were measured by dissolving in dry DMSO, subsequently adding to the cuvette containing MIF at different concentrations, and finally incubating the mixture for 30 min before addition of L-DOPA. The IC_{50} values were obtained with different concentrations of compounds, and finally K_i (inhibition constant) values were determined using nonlinear regression analysis with Prism4 (GraphPad Prism).

Fluorescence Spectroscopy. The concentration-dependent response of EA on MIF tryptophan fluorescence was monitored as mentioned earlier[39] by serial addition of EA to MIF (7.5 μM). The resulting solution was excited at 295 nm for the tryptophan residue, and the intrinsic fluorescence emission was scanned at 300−400 nm. Fluorescence quenching was determined by analyzing the data by the classical Stern−Volmer equation

$$F_0/F = 1 + k_q\tau_0[Q] = 1 + K_{SV}[Q] \quad (1)$$

where F_0 and F are the fluorescence intensities in the absence and the presence of the quencher respectively, K_q and K_{SV} are the quenching rate constant and dynamic quenching constant, respectively, the

J. Agric. Food Chem. 2015, 63, 4988−4998

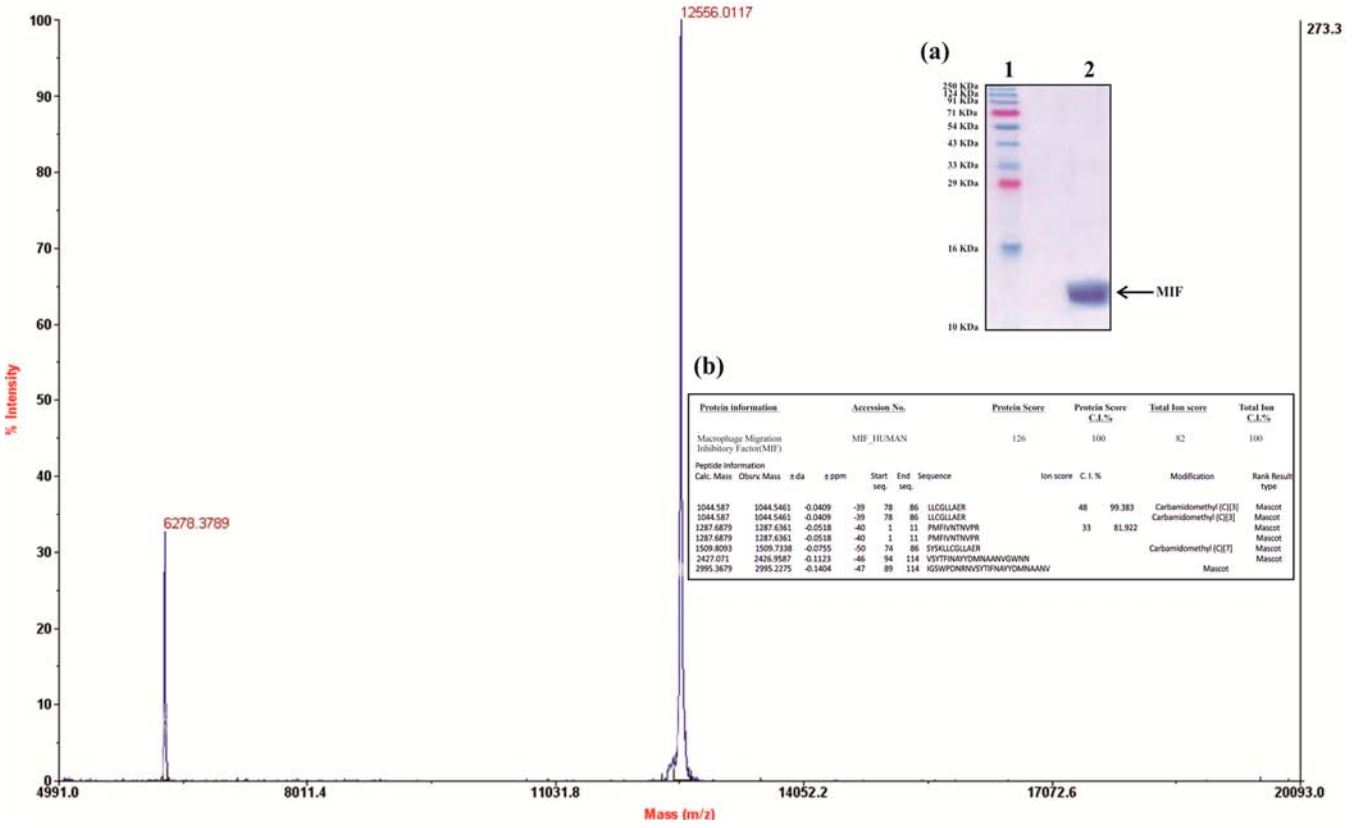

Figure 1. Purification of recombinant MIF: MALDI spectrum showing the molecular mass of MIF. Inset a: 15% SDS-PAGE, (lane 1) prestained molecular weight marker and (lane 2) MIF. Inset b: MALDI MS/MS for confirmation of protein identity by peptide fingerprinting and matching fragmented sequences with the database.

average lifetime of the protein in the absence of the quencher is expressed in terms of τ_0, and [Q] is the concentration of the free quencher, as mentioned earlier.[40] When small molecules interact with several comparable sites in a protein, the equilibrium between liberated and bound molecules is expressed by the equation

$$\log((F_0 - F)/F) = \log K_b + n \log[Q] \quad (2)$$

where K_b represents the binding constant for a quencher−protein interaction and n is the number of binding sites per molecule of MIF. Utilizing K_b, the free energy change (ΔG°) value can be estimated from the equation

$$\Delta G^\circ = -RT \ln K_b \quad (3)$$

The negative sign of the ΔG° value validates the spontaneity of the quencher−protein interaction.

Circular Dichroism (CD) Spectroscopy. CD spectroscopy was used to evaluate the structural changes in MIF as mentioned before.[41] The secondary structure of MIF was evaluated in the presence of different concentrations of EA (10, 25, and 50 μM) in the far-UV range by a J-810 CD spectrometer. CD spectra were recorded at a range of 190−270 nm from 10 μM of MIF in optically clear buffer. Spectra represented an average of five scans (a step size of 0.2 nm, an averaging time of 3 s) with buffer baseline subtracted, smoothed over four data points to generate the data reported in units of mean residue ellipticity. Secondary structure analysis of the CD spectra was performed by the Dichroweb online server (http://dichroweb.cryst.bbk.ac.uk/html/home.shtml).

Molecular Docking. Ideal coordinates for EA (PubChem CID 5281855) and MIF (PDB code 3L5S; 1.86 Å resolution) were obtained from the PDB. Molecular docking calculations were performed using SwissDock, based on the docking software EADock DSS.[42] A grid (box size 40 × 40 × 40 Å) was designed in which many binding modes were generated and their CHARMM energies were estimated on the grid.[43] The docking type was accurate, and MIF was treated as rigid during docking calculations. Each docking experiment was a composite of 250 different consecutive runs. Fast analytical continuum treatment of solvation (FACTS) was used to evaluate the modes of binding with the most favorable energies and finally clustered. Clusters were then ranked according to the average full fitness of their elements.[44] The results of SwissDock were visualized and rendered by a PyMOL molecular viewer.

General Procedure for Formation of Esters by EDC Coupling. Reactions of 1-ethyl-3-(3-(dimethylamino)propyl)carbodiimide (EDC) coupling were carried out as described earlier with slight modification.[45] To a solution of benzoic acid (1 equiv), amine (hydrochloride)/alcohol (1.5 equiv), 1-hydroxybenzotriazole (HOBt) (1 equiv, for amine), and Et_3N (5 equiv, for amine)/DMAP (1 equiv, for alcohol) in *N*,*N*-dimethylformamide was added EDC hydrochloride (1.5 equiv) at 0 °C. Then the reaction mixture was stirred at room temperature until completion of the reaction (12 h) as monitored by TLC. The reaction was terminated by the addition of ice and the mixture extracted with ethyl acetate. The ethyl acetate layer was washed with brine and dried over Na_2SO_4. The solvent was then removed in a rotavap under vacuum, and the crude mass was chromatographed over a silica gel column.

General Procedure of Debenzylation (Hydrogenolysis). A combination of benzylated compound and 10% palladium on carbon (catalytic) in a methanol/chloroform mixture (4/1) (10 mL) was stirred under a hydrogen atmosphere (using a hydrogen balloon) until completion of the reaction (2 h) as monitored by TLC. The reaction mixture was passed through a small pad of Celite. The filtrate was evaporated in vacuo to dryness to obtain the product.

Peripheral Blood Mononuclear Cell (PBMC) Isolation. Human PBMCs were isolated using Histopaque density gradient centrifugation following the instruction of the manufacturer. Briefly, 10 mL of blood was collected from the median cubital vein of a healthy volunteer by sterile disposable syringe and dispensed in tubes containing heparin.

DOI: 10.1021/acs.jafc.5b00921
J. Agric. Food Chem. 2015, 63, 4988−4998

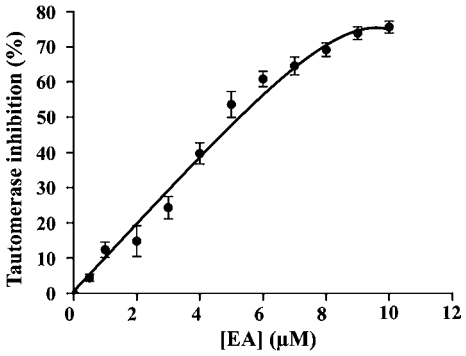

Figure 2. Inhibition of MIF tautomerase activity by EA. MIF (60 nM) is treated with different concentrations of EA for 30 min to measure the tautomerase activity at 474 nm. Data are presented as mean ± SD.

Next 6 mL of blood was carefully layered on a preformed Histopaque gradient (6 mL) prepared by layering Histopaque 1077 over Histopaque 11191 in a 1/1 ratio. The tubes were next centrifuged at 700*g* for 30 min at room temperature. The mononuclear cell fraction was carefully aspirated out and collected in a fresh tube. The cells were washed three times in phosphate buffered saline (PBS) and checked for cell viability by Trypan blue. A total of 90−95% of the isolated cells were alive. Finally an aliquot of the isolated cells was stained by crystal violet and observed under a microscope to check the purity of the isolated PBMCs. Isolated PBMCs were resuspended in RPMI-1640 containing 5% FBS (Gibco) and maintained at 37 °C in a 5% CO_2 environment for all subsequent experiments.

Confocal Microscopy. Isolated PBMCs were used for immunofluorescence microscopy as mentioned earlier[46,47] with minor modifications. Briefly, about 1 × 10^6 cells/mL were plated in RPMI-1640 containing 10% FBS and treated in four sets: control, MIF (1 μg/mL), EA (50 μM), and EA+MIF for 4 h at 37 °C and 5% CO_2. Cells after treatment were washed with prewarmed PBS (HyClone) and fixed with 4% paraformaldehyde at room temperature for 10 min. Cells were next washed with PBS by a swirling motion and permeabilized with 0.1% Triton X-100 at room temperature for 10 min. After washing, the cells were blocked in a solution containing 2% BSA in PBS for 2 h at room temperature. Immunostaining of the fixed cells was performed by incubating the cells in the blocking solution containing rabbit anti-NF-κB (p65) antibody overnight. The next day the cells were stained with antirabbit Alexa Fluor 647-conjugated secondary antibody (1/2000; Invitrogen). The nucleus was stained with DAPI. Cells were imaged at 512 × 512 resolution with a Leica TCS-SP8 confocal microscope. Samples were viewed under a 63× oil immersion lens, and digital zooming was performed according to the requirements. The overlap of red (NF-κB) and blue (nucleus) signals was quantified using the software provided with the microscope. Pearson's correlation coefficient was considered to present the intranuclear NF-κB. The data presented are a representation of one of four experiments showing similar values.

Chemotaxis Assay. A chemotactic assay was performed with human PBMCs as mentioned before[47,48] with minor modifications. Briefly, isolated PBMCs (2.5 × 10^5 cells/well) were loaded into the inserts (having a polycarbonate membrane with 5 μm pore size) of a Transwell cell migration chamber (Corning) in a 24-well plate format. The chemoattractant MIF (1 μg mL^{-1}) was added into the lower chambers in the presence and/or absence of increasing concentrations of EA (10−50 μM). Cells without any treatment were used as a control, and macrophage inflammatory protein-1 alpha (MIP-1α), a chemoattractant cytokine, was used as a positive control. Heat-inactivated MIF (MIF heated to 65 °C for 30 min) was also used as a negative control. Transwell plates were incubated for 4 h at 37 °C in 5% CO_2. PBMCs that had migrated through the membrane were dislodged using 2 mM EDTA and fixed with methanol. The number of cells that migrated from the upper chamber into the filter and reached its lower side was determined by staining with crystal violet and counting under a microscope (Leica). To compare the results from different experiments, a chemotaxis index (CI = number of PBMCs migrating toward MIF or MIF plus EA-loaded wells divided by the number of PBMCs migrating toward control medium) was calculated. The counts provided were the results observed in five randomly selected fields under a microscope. The results were reported as the mean CI ± SD change with respect to control of at least three independent experiments.

Statistical Analysis. For IC_{50} determination, respective experiments were repeated in triplicate. Data were presented as mean ± SD. Student's *t* test was used to analyze the data in GraphPadPrism 4. Values of $p < 0.05$ were considered significant.

RESULTS

Purification of MIF. MIF was cloned in pET28a vector, overexpressed in *E. coli*, and purified using gel permeation chromatography. The purity of the protein was checked by 15% SDS-PAGE, and the molecular weight (12.556 kDa) was confirmed by MALDI-TOF mass spectrometry (Figure 1, inset a). Peptide fingerprinting (Figure 1, inset b) finally confirmed the identity of MIF by MALDI MS/MS with a perfect match from the NCBI database.

Inhibition of MIF Tautomerase by Ellagic Acid (EA): Kinetics and Mode of Inhibition. The tautomerase activity of recombinant MIF was measured by following the tautomerization of L-DOPA in the absence or presence of increasing concentrations of EA. Data indicated that EA

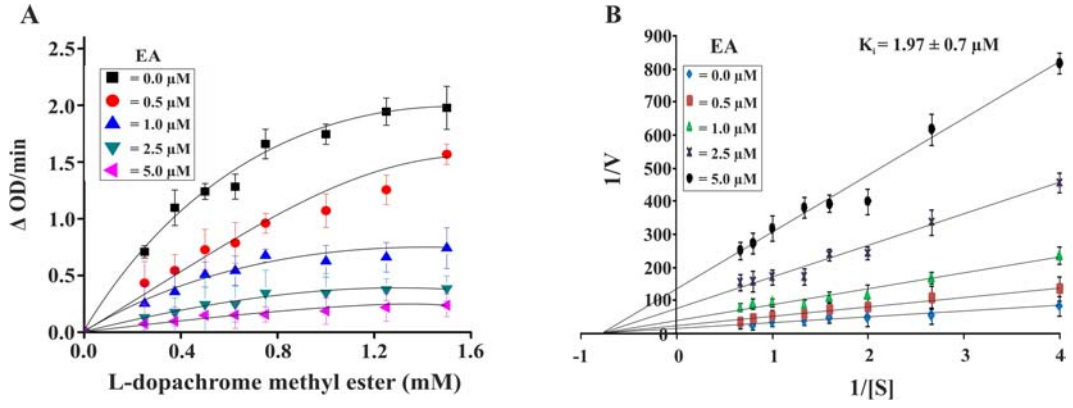

Figure 3. Kinetics of inhibition of MIF by EA: (A) concentration−response curve of EA versus substrate L-DOPA; (B) inhibition constant (K_i) of EA against L-DOPA. The noncompetitive inhibition pattern of EA with MIF is revealed by a Lineweaver−Burk plot. The details of the methodologies are described in Materials and Methods. Data are presented as means ± SD of three independent experiments.

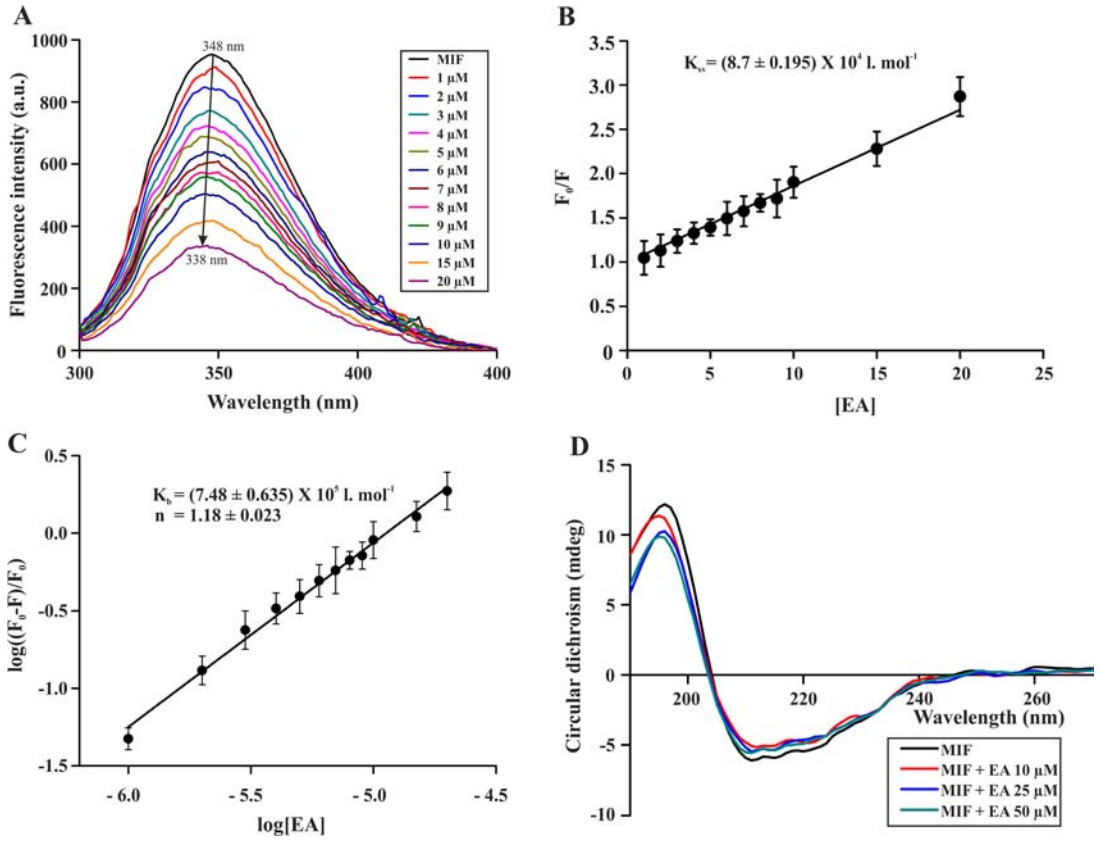

Figure 4. Binding of EA to MIF. (A) Fluorescence quenching spectra of MIF. The protein solution is excited and quenching of fluorescence is recorded in the presence of varying concentrations of EA (1−20 μM). (B) Stern−Volmer plot of decrease in fluorescence of MIF in the presence of varying concentrations of EA. The dynamic quenching rate constant K_{sv} is evaluated from the slope of the line. (C) Logarithmic plots of relative fluorescence quenching of MIF against logarithmic concentrations of EA to calculate K_b. K_b is calculated from the intersection of the line with the y axis and the number of binding sites (n) from the slope of the line. (D) CD spectra of MIF in the presence or absence of EA.

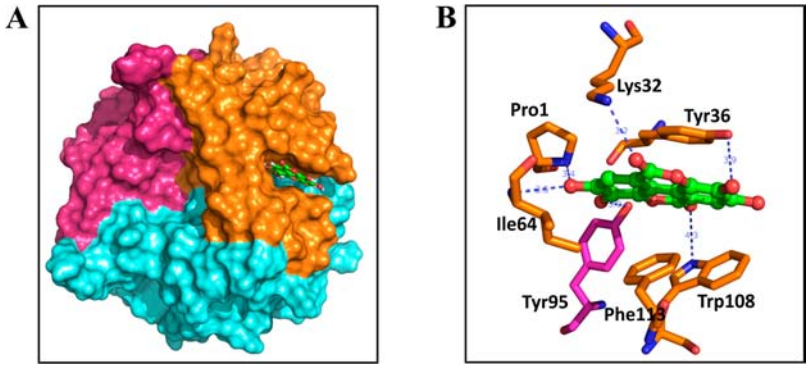

Figure 5. Molecular docking of EA with MIF. (A) Surface diagram of MIF homotrimers docked with EA. Each monomer is indicated by a different color: chain A, orange; chain B, cyan; chain C, magenta. EA is shown in green. The docked conformation produced by SwissDock indicates that EA interacts with MIF in a pocket formed at the interface of chains A and B. (B) Interacting side chains of amino acid residues shown by sticks and the ligand by a ball and stick model. Hydrogen bonds are depicted as blue dashed lines. The binding pocket is formed by the side chains of Pro-1, Lys-32, Tyr-36, Ile-64, Trp-108, Phe-113, and Tyr-95 from two neighboring subunits. The figures were generated using PyMOL.

significantly inhibited the tautomerase activity of MIF (IC_{50} = 4.77 ± 0.52 μM) (Figure 2). Next, we were interested in analyzing the type of inhibition offered by EA. A concentration−response curve and Lineweaver−Burk plot were plotted (Figure 3). A Lineweaver−Burk plot of concentration−response curves revealed a noncompetitive mode of inhibition of MIF by EA. The inhibition constant (K_i) was determined from the concentration−response curve and found to be 1.97 ± 0.7 μM. Binding of EA to MIF was assessed by following the quenching of tryptophan (Trp-108) fluorescence in the presence of increasing concentrations of EA. The only tryptophan in human MIF is distantly located from the catalytic Pro-1 and is exposed to the solvent. MIF in optically clear assay buffer was excited at 295 nm for recording the fluorescence spectra, which were mainly attributed to the only tryptophan residue. MIF showed an emission maximum at 348 nm. The protein solution was titrated by consecutive additions of EA (1−20 μM), and its fluorescence intensity was gradually found to decrease with

increasing concentrations of EA (Figure 4A). A small blue shift of the λ_{max} value was also observed with increasing concentrations of EA. The nature of fluorescence quenching of the MIF−EA (0−20 μM) interaction was analyzed using the Stern−Volmer equation (Figure 4B). Subsequently K_{SV} was calculated from the linear regression curve of F_0/F versus [Q]. The binding constant (K_b), number of binding sites (n), and free energy change (ΔG°) of the EA−MIF interaction were determined from eqs 2 and 3, respectively (Figure 4C). The binding affinity of EA was found to be quite strong, and its value was found to be $\Delta G^\circ = -33.53 \pm 0.729$ kJ mol^{-1}. We analyzed the conformation of MIF in the presence of 10, 25, and 50 μM EA by CD spectroscopy to confirm any effect of EA on the MIF secondary structure (manifested as a gradual decrease in MIF fluorescence). Secondary structural elements such as α-helices, β-sheets, and random coils absorb specific components of the circularly polarized light of a CD spectrum, thereby providing information about specific structural elements within a protein. The addition of EA did not alter much of the basic secondary structure of MIF (Figure 4D). For further confirmation of minimum changes in structure we analyzed the spectral data in a DICHROWEB web server by four widely used algorithms. The outcome of these algorithms established (data not shown) that EA did not significantly alter the secondary structure of MIF.

To get the exact binding location of EA with MIF, we tried to cocrystallize EA with MIF but failed to get the cocrystallized product. Hence, molecular docking was performed to get a preliminary idea about the possible interaction between MIF and EA. Structural details for human MIF (Protein Data Bank

DOI: 10.1021/acs.jafc.5b00921
J. Agric. Food Chem. 2015, 63, 4988−4998

code 3L5S; 1.86 Å resolution) and EA (PubChem CID 5281855) were obtained from the respective databases. For molecular docking studies, the homotrimer of MIF was docked with EA. Each docking experiment was a composite of 250 independent runs. Molecular docking outputs showed that EA interacted at or close to the active site of the N terminal of MIF. EA binds in a pocket formed by the N terminal (Pro-1, Lys-32, Tyr-36) and C terminal (Ile-64, Trp-108, Phe-113) residues of chain A and Tyr-95 of chain B (Figure 5A). In this orientation EA formed hydrogen-bond interactions with MIF through the amino acids Pro-1, Lys-32, Tyr-36, Ile-64, Tyr-95, Trp-108, and Tyr-95 (Figure 5B). The ligand was also stabilized by hydrophobic interactions with the aromatic side chains of Tyr-36, Ile-64, Tyr-95, Trp-108, and Phe-113. In addition, the aromatic side chain of Tyr-36 makes a $\pi-\pi$ stacking interaction with EA. These hydrogen bonds and hydrophobic interactions were thought to play a role in the binding of EA with MIF.

Functional Group Pattern Recognition Study: Orientation and Role of Lactone Moiety. Following the identification of EA as a new MIF inhibitor, we were now interested in identifying the active pharmacophore. We therefore synthesized several molecules as structural dissects/parts of EA and screened them for MIF tautomerase activity. Gallic acid, a unit structural scaffold of EA, did not show any activity. Synthesized EA metabolites urolithin B and urolithin A (Figure 6A) contained only three fused rings with one lactone group and showed inhibitory activity with higher IC_{50} values (Table 1). To check the specific involvement of the lactone moiety on tautomerase inhibition, we synthesized a distant dimeric gallic acid derivative (compound **2d**). Compound **2d**, a dimer of GA comprising two labile ester groups and six free hydroxyl groups (like EA), was synthesized using the distant linker ethylene glycol (Figure 6B). Compound **2d** showed very low activity against MIF (IC_{50} = 35.9 ± 0.72 μM) (Table 1). To explore the role of planar conjugated fused systems, we took pyrene, a planar polycyclic, fused aromatic hydrocarbon without any functional group. Pyrene did not show any tautomerase inhibitory activity. Thus, compounds having lactone or ester groups were found to be active and hydroxyl groups had no effect on MIF tautomerase inhibition.

Prevention of MIF-Mediated Nuclear Translocation of NF-κB by EA: Molecular Event Essential for Proinflammatory Signaling. MIF promotes inflammation by activating signaling cascades involving NF-κB. MIF is known to cause translocation of NF-κB into the nucleus. Therefore, nuclear translocation of NF-κB was followed by confocal microscopy in PBMCs. Blue fluorescence represented the nucleus (Figure 7, first column), while red fluorescence represented cells immunostained with NF-κB primary antibody and Alexa Fluor 647 conjugated secondary antibody (Figure 7, second column). The third column represent the merged images of the red and blue fluorescence, while the area of intranuclear NF-κB is depicted as white dots in the fourth column. In the fifth column, intranuclear versus non-intranuclear NF-κB is presented as a bar diagram. In the control set (Figure 7, first row), there was a basal level of NF-κB (red fluorescence) in the nucleus; however, the red signal was confined mostly in the cytosol. PBMCs with exogenously treated MIF (Figure 7, second row) showed a significantly higher level of NF-κB in the nucleus depicting the role of MIF on nuclear translocation of NF-κB. In contrast, PBMCs treated with MIF preincubated with EA (50 μM) showed a much lower intranuclear NF-κB, as evident from reduced overlap of the red and blue signals and the white dots. Because PBMCs normally secrete a basal level of MIF,[34] treatment of PBMCs with EA alone also resulted in lowering of nuclear NF-κB in comparison to the control. Thus, the data showed that the stimulatory effect of MIF on the nuclear translocation of NF-κB was significantly compromised upon treatment with EA.

Table 1. Chemical Structure and Activities of EA Derivatives against MIF Tautomerase

Compounds	Inhibition of tautomerase activity of MIF (IC_{50}) (μM) Mean ± S.D
 EA	4.77 ± 0.52
 GA	Not active
 Compound 2d	35.9 ± 0.72
 Urolithin A	50.03 ± 4.37
 Urolithin B	57.42 ± 3.93
 Pyrene	Not active

Prevention of MIF-Mediated Chemotaxis of Human Peripheral Blood Mononuclear Cells (PBMCs) by EA: Cellular Event Necessary for Inflammation. MIF promotes macrophage chemotactic migration and also plays an important role in neutrophil infiltration during inflammatory diseases. To check any probable effect of EA on MIF-mediated chemotactic activity, we performed a chemotactic migration assay using PBMCs in the presence or absence of increasing concentrations of EA. EA showed a potent concentration-dependent inhibitory effect on MIF-induced chemotactic migration of PBMCs (CI = 2.31, 1.93, and 1.14 for EA 10, 25, and 50 μM, respectively, in comparison with CI = 3.38 for MIF-treated cells where the control set CI was fixed at 0.0) (Figure 8). We validated the chemotactic migration assay using heat-inactivated MIF, which further showed negligible chemotactic migration of PBMCs in comparison to the control (Figure 8). MIP-1α, a classical chemoattractant, used in this assay also resulted in significant chemotactic migration (CI = 2.96) of the PBMCs. However, it is interesting to note that EA even at a high concentration (50 μM) failed to inhibit the MIP-1α-induced

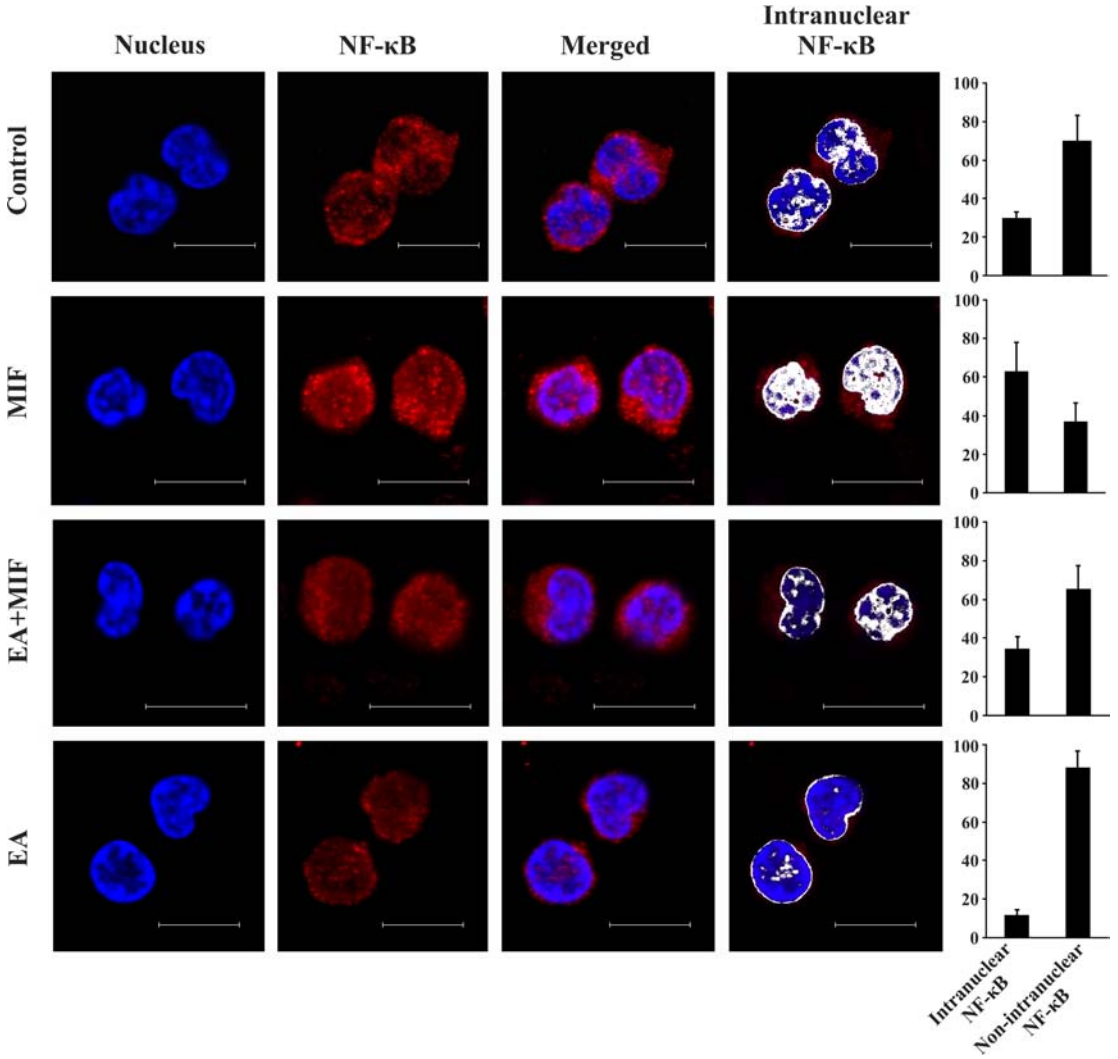

Figure 7. Inhibition of MIF-mediated nuclear translocation of NF-κB in PBMCs by EA. Localization of NF-κB (red) into the nucleus (blue) is calculated from Pearson's correlation coefficient (fifth column). The white spots in the fourth column indicate the area of maximum intranuclear NF-κB. Scale bars indicate 10 μm. Data are presented as means ± SD of three independent experiments.

chemotactic migration of PBMCs (Figure 8), suggesting the specificity of EA for MIF-mediated chemotaxis.

DISCUSSION

EA is long since known for its antioxidant and anti-inflammatory activity. However, here we report that EA inhibits tautomerase activity of human MIF, a proinflammatory protein. Further, we identified that the planar conjugated lactone moiety is responsible for tautomerase inhibition after performing extensive structure−function analysis. EA also inhibited MIF-mediated proinflammatory responses in PBMCs.

The inhibitory action of EA against MIF followed a concentration gradient. Moreover, EA noncompetitively inhibited MIF, as there was no structural similarity between the EA and MIF assay substrate L-DOPA. This suggested that EA might bind to the allosteric site (away from the active site) or close to the active site with slack binding of MIF, which did not block it from binding to the substrate but inhibited the tautomerase activity of MIF. Binding of EA to MIF was evaluated by fluorescence spectroscopy. Structural conformations of a globular protein may change upon binding of a small molecule due to alterations in the intramolecular forces responsible for maintaining the secondary and tertiary structures. A decrease in Trp-108 fluorescence λ_{max} value therefore suggested that the EA−MIF interaction might alter the microenvironment of Trp. Emission spectra of MIF were measured using an excitation wavelength at 295 nm to ensure that light caused excitation of Trp residues only. A blue shift of the λ_{max} of Trp emission spectra indicated a decrease in hydrophilicity in its surrounding region within the globular protein, indicating that Trp residue might have shifted to a more hydrophobic environment due to a presumptive change in the secondary structure of the protein. Moreover, the free energy change having a negative sign indicated the spontaneity and stability of the EA−MIF interaction. Since human MIF has only one Trp, which is distant from the catalytic Pro-1 and exposed to the solvent, therefore the results of the fluorimetric quenching of Trp λ_{max} may result in either a change in microenvironment around Trp or a gross alteration in the secondary structure of MIF upon addition of EA.[49] This change in protein structure is expected to be reflected in circular dichroism (CD) spectra. Our CD data, however, indicated almost no changes in the secondary structure of MIF even in the presence of high concentrations of EA (50 μM), therefore showing that quenching of MIF fluorescence was

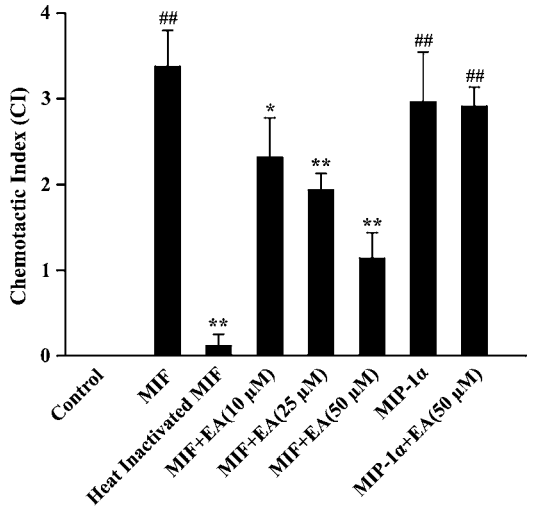

Figure 8. Inhibition of MIF-mediated chemotactic migration of PBMCs by EA. The chemotactic index is plotted with the number of cells migrated toward the lower chamber and expressed as change over control, keeping the control value at 0. Data are presented as mean ± SD ((##) $p < 0.001$ versus control; (*) $p < 0.01$; (**) $p < 0.001$ versus MIF).

probably due to alteration in the microenvironment around Trp-108 and was not due to the alteration in the secondary structure of the whole protein. Molecular docking of EA to MIF revealed that the NH backbone of Pro-1, Lys-32, and Tyr-36, the CO terminal of Ile-64, Trp-108, Phe-113, and Tyr-95 and $\pi-\pi$ interactions with Tyr-36, Ile-64, Tyr-95, Trp-108, and Phe-113 allowed a favorable interaction of EA with MIF. These interactions shown in the docking study were consistent with our previous kinetics of tautomerase inhibition and fluorimetric binding.

Next, we were interested in identifying the active functional scaffold of EA responsible for MIF tautomerase inhibition. Gallic acid (GA), a unit structural motif of EA previously shown to exhibit anti-inflammatory and antioxidant activity,[50,51] may also inhibit MIF tautomerase activity. To test this hypothesis, we performed a dopachrome tautomerization assay to screen the inhibitory activity of GA and all synthetic GA-related polyphenolic compounds. We found EA to be the most potent inhibitor among all of the compounds, followed by compound **2d**, urolithin A, and urolithin B. GA, however, exhibited no inhibitory activity at all. Therefore, it appears that the difference in activity between EA and GA probably arises from the two lactone groups present in EA, although both have free hydroxyl groups. Compound **2d**, having an ester group, was also found to be active. The conjugated aromatic system was also not responsible for the inhibition of tautomerase activity, because pyrene did not exhibit any inhibitory activity. Therefore, ester groups play an important role, whereas hydroxyl groups do not have any impact on inhibition of MIF tautomerase activity. Although free ester groups are capable of inhibiting MIF, their activity is much less than that of a cyclic ester group, i.e. lactone, as is evident from the IC_{50} values. The presence of a higher inhibitory activity of EA (having two lactone groups) in comparison to urolithin A and urolithin B (both having a single lactone group) indicates the importance of conformationally restricted lactones as well as the role of lactones in MIF inhibition. Thus, the structurally restricted lactone group of EA is probably the most essential scaffold responsible for MIF inhibition.

MIF is an inflammatory cytokine.[52] Therefore, we investigated the effect of EA on MIF-mediated inflammatory response such as nuclear translocation of NF-κB in PBMCs. It has been reported that binding of MIF to a CD74 complex involving CD44 leads to the release of the intracellular domain of CD74 (CD74 ICD), which triggers the downstream signaling pathway leading to the activation of NF-κB.[53] Activation of the NF-κB in turn plays a central role in inflammation by switching on the transcription of a plethora of proinflammatory target genes. As NF-κB is a transcription factor, which enters the nucleus and binds to the DNA of its targets to mediate its actions,[54] we therefore investigated the inhibitory effect of EA on MIF-induced translocation of NF-κB into the nucleus. The data clearly indicated that MIF greatly induced NF-κB translocation to the nucleus in PBMCs, whereas the control (without MIF) and EA (50 μM) treated cells did not show such NF-κB translocation, as is evident from confocal images. Interestingly ISO-1, which is a well-established MIF inhibitor reported to bind the tautomerase active site of MIF, inhibits its proinflammatory activity and also significantly reduces the nuclear translocation of NF-κB.[55] Inhibition of MIF tautomerase activity or interference in the tautomerase active site might therefore be a restraining factor behind the inhibition of MIF-induced nuclear translocation of NF-κB. However, we cannot exclude other possibilities of anti-inflammatory properties of EA that can mediate the inhibition of nuclear translocation of NF-κB.

Chemotactic migration plays a major role during inflammation by leucocyte recruitment to the site of inflammation. MIF promotes macrophage chemotactic migration and also plays an important role in leukocyte recruitment during inflammation.[56] EA inhibited MIF-induced chemotaxis of PBMCs, and this inhibition was specific, as no inhibition was found when MIP-1α was used as the chemoattractant. However, knowledge about the exact mechanism of inhibition of MIF-mediated chemotaxis by EA needs further detailed investigation. Blocking of tautomerase activity or the tautomerase active site of MIF by EA might be a reason behind this inhibition. This study therefore reports that the naturally occurring antioxidant EA inhibits the tautomerase activity of MIF and MIF-mediated proinflammatory responses in PBMCs.

ABSTRACT: Essential oils were obtained by hydrodistillation of the flowers+leaves and stems of *Artemisia kotuchovii* Kupr. ($AKEO_{f+l}$ and $AKEO_{stm}$, respectively) and analyzed by gas chromatography (GC) and gas chromatography−mass spectrometry (GC-MS). The primary components of the oils were estragole, (*E*)- and (*Z*)-*β*-ocimenes, methyleugenol, limonene, spathulenol, *β*-pinene, myrcene, and (*E*)-methyl cinnamate. Seventy-four constituents were present at concentrations from 0.1 to 1.0%, and 34 compounds were identified in trace (<0.1%) amounts in one or both plant components. Screening of the essential oils for biological activity showed that $AKEO_{stm}$, but not $AKEO_{f+l}$, inhibited *N*-formyl-Met-Leu-Phe (*f*MLF)-stimulated Ca^{2+} flux and chemotaxis and phorbol-12-myristate-13-acetate (PMA)-induced reactive oxygen species (ROS) production in human neutrophils. Selected pure constituents, representing >96% of the $AKEO_{stm}$ composition, were also tested in human neutrophils and HL-60 cells transfected with *N*-formyl peptide receptor 1 (FPR1). One component, 6-methyl-3,5-heptadien-2-one (MHDO), inhibited *f*MLF- and interleukin 8 (IL-8)-stimulated Ca^{2+} flux, *f*MLF-induced chemotaxis, and PMA-induced ROS production in human neutrophils. MHDO also inhibited *f*MLF-induced Ca^{2+} flux in FPR1-HL60 cells. These results suggest that MHDO may be effective in modulating some innate immune responses, possibly by inhibition of neutrophil migration and ROS production.

KEYWORDS: *Artemisia kotuchovii, calcium flux, chemotaxis, essential oil, neutrophil, N-formyl peptide receptor 1 (FPR1), reactive oxygen species*

INTRODUCTION

Artemisia is one of largest genera in the Asteraceae family, with approximately 500 species. Many of these species produce essential oils used in folk and modern medicine and in the cosmetics and pharmaceutical industries.[1,2] Extracts or compounds isolated from *Artemisia* have been shown to exhibit a wide range of biological properties, including anti-inflammatory activities that help to reduce inflammation.[3,4] Essential oils from several species of this genus have also been reported to decrease the production of pro-inflammatory mediators.[5,6] Extensive studies of the chemical components of these oils have demonstrated that they contain diverse bioactive secondary metabolites, including volatile monoterpenes and sesquiterpenes, with artemisinin as one of the best studied.[1,2,7,8] However, the chemical composition and biological properties of many endemic *Artemisia* spp. have not been evaluated.

Artemisia kotuchovii Kupr. is endemic in the Kazakhstan Altai. This perennial herb was described in 1999 and is closely related to *Artemisia dracunculus* L. (tarragon).[9] To date, the chemical composition and biological properties of *A. kotuchovii* have not been analyzed. Although ethnobotanical and ethnopharmacological data on medicinal usage of this herb are unknown, the related herb tarragon has been reported to have a wide range of applications in traditional medicine because of its therapeutic properties for a variety of ailments.[1] For example, pharmacological evaluation of tarragon extracts demonstrated anti-inflammatory activity.[1,10] Although tarragon essential oil was inactive in modulating human neutrophil phagocytosis,[11] essential oils from other *Artemisia* spp. exhibited some immunomodulatory properties, such as inhibition of nuclear factor (NF)-*κ*B transcriptional activity and stimulation of nitric oxide and prostaglandin E_2 production by macrophages.[5,6]

Neutrophils are a key cellular component of the immune response to infection or tissue injury.[12] These phagocytes are recruited to sites of injury or infection by a variety of factors, including formyl-Met-Leu-Phe (*f*MLF), a bacterial or mitochondria-derived peptide, and chemokines such as

interleukin 8 (IL-8).[13] IL-8 and *f*MLF activate G-protein coupled receptors (GPCR) to induce neutrophil chemotaxis and the release of various mediators, such as reactive oxygen species (ROS), proteases, and cytokines.[13] Growing evidence supporting the anti-inflammatory and tissue-protective effects of chemokine antagonists led to the design and screening of synthetic compounds and plant-derived constituents for novel small-molecule *N*-formyl peptide receptor (FPR) and α-chemokine receptor (CXCR) antagonists.[14,15] Human neutrophil elastase (HNE) also plays an important role in regulation of inflammation, and some plant-derived compounds have been identified as elastase inhibitors.[16]

In the present work, we defined the composition of essential oils from *A. kotuchovii* and evaluated their biological activity.

MATERIALS AND METHODS

Chemicals. The major and several minor constituents of essential oils were obtained from commercial sources. Sabinene, (−)-linalool, hexanal, *p*-cymen-8-ol, 3,7-dimethyl-1,3,6-octatriene (β-ocimene), and MHDO were purchased from Sigma-Aldrich Chemical Co. (St. Loius, MO, USA). Citronellol, (+)-limonene, *trans*-anethole, (−)-caryophyllene oxide, 4-allylanisole (estragole), 1,2-dimethoxy-4-(2-propenyl) (methyleugenol), myrcene, isopropyl myristate, *p*-cymene, α-terpinene, and (−)-limonene were purchased from Acros Organics (Geel, Belgium). Myristic acid, α-pinene, and terpinolene were from Santa Cruz Biotechnology (Dallas, TX, USA). Methyl cinnamate, 4-methoxystyrene (4-vinylanisole), palmitic (hexadecanoic) acid, and (1*S*)-(−)-β-pinene were from Alfa Aesar (Ward Hill, MA, USA). For biological evaluation, compounds were dissolved in dimethyl sulfoxide (DMSO; 20 mM stock solutions) and stored at −20 °C.

Materials. 8-Amino-5-chloro-7-phenylpyridol[3,4-*d*]pyridazine-1,4-(2*H*,3*H*)-dione (L-012) was obtained from Wako Chemicals (Richmond, VA, USA). DMSO, *f*MLF, HEPES, bacterial lipopolysaccharide (LPS) from *Escherichia coli* K-235, phorbol-12-myristate-13-acetate (PMA), and Histopaque 1077 were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Roswell Park Memorial Institute (RPMI) 1640 medium and penicillin−streptomycin solution were purchased from Mediatech (Herdon, VA, USA). Human neutrophil elastase, *N*-methylsuccinyl-Ala-Ala-Pro-Val-7-amino-4-methylcoumarin, ionomycin, and bovine serum albumin were purchased from EMD Biosciences (San Diego, CA, USA). Fetal bovine serum (FBS) was purchased from Atlas Biologicals (Fort Collins, CO, USA). Human IL-8 was purchased from Peprotech Inc. (Rocky Hill, NJ, USA). Tween-20 was from VWR (Radnor, PA, USA). Tris was from J. T. Baker (Phillipsburg, NJ, USA). Blasticidin S and zeocin were obtained from Invivogen (San Diego, CA, USA). Hanks' balanced salt solution (HBSS; 0.137 M NaCl, 5.4 mM KCl, 0.25 mM Na_2HPO_4, 0.44 mM KH_2PO_4, 4.2 mM $NaHCO_3$, 5.56 mM glucose, and 10 mM HEPES, pH 7.4) and G418 were from Life Technologies (Grand Island, NY, USA). HBSS containing 1.3 mM $CaCl_2$ and 1.0 mM $MgSO_4$ is designated $HBSS^+$; HBSS without ions Ca^{2+} and Mg^{2+} is designated $HBSS^-$.

Plant Material. Aerial parts of *A. kotuchovii* were collected at the end of the blossoming stage in August 2013 in the southern Altai on the Tarbagatai range at altitude 1709 m above sea level (latitude, N 49°03′52″; longitude, W 85°59′35″). The plant was identified by Dr. Yuriy Kotukhov, and voucher specimens were deposited at the Institute of Plant Biology and Biotechnology (Almaty, Kazakhstan). Plant components were air-dried for 7−10 days at room temperature away from direct sunlight. Weighed samples were cut under laboratory conditions before hydrodistillation.

Essential Oil Extraction. Two types of air-dried material (inflorescence+leaves or stems) were separately subjected to hydrodistillation for 3 h using a Clevenger type apparatus to yield essential oils. Conventional hydrodistillation is considered the primary method for essential oil extraction.[17] Although hydrodistillation could lead to artifacts when performed at higher temperatures over long hydrodistillation times at low pH,[18] we applied only conditions accepted by the European Pharmacopoeia (European Directorate for the Quality of Medicines, Council of Europe, Strasbourg, France, 2014) and thus avoided these artifacts. Solutions of the essential oils were made in DMSO (10 mg/mL stock solutions) for biological evaluation, and in *n*-hexane (10 % w/v) for gas-chromatographic analysis.

Gas Chromatography−Mass Spectrometry (GC-MS) Analysis. GC-MS analysis of the oils was carried out with an Agilent 5975 GC-MSD system, as reported previously.[19,20] An Innowax FSC column (60 m × 0.25 mm, 0.25 μm film thickness) was used with He as carrier gas (0.8 mL/min). GC oven temperature was kept at 60 °C for 10 min, increased to 220 °C at a rate of 4 °C/min, kept constant at 220 °C for 10 min, and then increased to 240 °C at a rate of 1 °C/min. The split ratio was adjusted to 40:1, and the injector temperature was at 250 °C. MS were taken at 70 eV. Mass range was from m/z 35 to 450.

GC analysis was carried out using an Agilent 6890N GC system. To obtain the same elution order as with GC-MS, simultaneous injection was performed using the same column and appropriate operational conditions. Flame ionization detector (FID) temperature was 300 °C. The components of essential oils were identified by co-injection with standards (whenever possible), which were purchased from commercial sources or isolated from natural sources. In addition, compound identities were confirmed by comparison of their mass spectra with those in the Wiley GC/MS Library (Wiley, New York), MassFinder software 4.0 (Dr. Hochmuth Scientific Consulting, Hamburg, Germany), Adams Library, and NIST Library. A C_8−C_{40} *n*-alkane standard solution (Fluka, Buchs, Switzerland) was used to spike the samples for the determination of relative retention indices (RRI). Relative percentage amounts of the separated compounds were calculated from FID chromatograms.

Cell Culture. Human MonoMac-6 monocytic cells (DSMZ, Germany) were grown in RPMI 1640 supplemented with 10% (v/v) endotoxin-free FBS, 10 μg/mL bovine insulin, 100 μg/mL streptomycin, and 100 U/mL penicillin. Human monocytic THP-1Blue cells obtained from InvivoGgen were cultured in RPMI 1640 medium supplemented with 10% (v/v) endotoxin-free FBS, 100 μg/mL streptomycin, 100 U/mL penicillin, 100 μg/mL zeocin, and 10 μg/mL blasticidin S. These cells are stably transfected with a secreted embryonic alkaline phosphatase gene that is under the control of a promoter inducible by NF-κB and AP-1. Human promyelocytic leukemia HL-60 cells stably transfected with human FPR1 (FPR1-HL60 cells) were cultured in RPMI-1640 medium supplemented with 10% heat-inactivated fetal calf serum, 10 mM HEPES, 100 μg/mL streptomycin, 100 U/mL penicillin, and G418 (1 mg/mL).[15]

Measurement of TNF Production. MonoMac-6 cells were plated in culture medium supplemented with 3% (v/v) endotoxin-free FBS in 96-well plates at a density of 2×10^5 cells in 100 μL per well. The cells were pretreated with or without essential oil or DMSO (vehicle control) for 30 min, followed by treatment with LPS (200 ng/mL) and incubation for 24 h at 37 °C and 5% CO_2. An enzyme-linked immunosorbent assay kit for human tumor necrosis factor (TNF) (Biolegend; San Diego, CA, USA) was used to measure cytokine levels in the cell supernatants.

Analysis of NF-κB/AP-1 Activation. Activation of NF-κB/AP-1 transcriptional activity was measured using an alkaline phosphatase reporter gene assay in THP1-Blue cells (2×10^5 cells in 100 μL per well). The cells were pretreated with or without essential oil or DMSO (vehicle control) for 30 min, followed by treatment with LPS (200 ng/mL) and incubation for 24 h at 37 °C and 5% CO_2. Alkaline phosphatase activity was measured in cell supernatants using QUANTI-Blue mix (Invivogen). Activation of NF-κB is reported as absorbance at 655 nm and compared with positive control samples (LPS).

Human Neutrophil Elastase (HNE) Inhibition Assay. Essential oils and individual compounds were dissolved in 100% DMSO at 5 mM stock concentrations. The final concentration of DMSO in the reactions was 1%, and this level of DMSO had no effect on enzyme activity. One of our previously described HNE inhibitors (compound **5b**) was used as a positive control.[21] The inhibition assay was performed, as described previously.[22] Briefly, a buffer solution

[a]The data are presented as relative % for components of essential oil from flowers+leaves (A) and essential oil from stems (B). RRI, relative retention indices calculated against *n*-alkanes; % calculated from flame ionization detector data. Trace amounts (tr) are present at <0.1%. [b]Identification based on comparison with co-injected with standards. [c]Tentatively identified using Wiley and MassFinder mass spectra libraries and published RRI. Compounds that were selected for further biological screening are indicated in bold.

containing 200 mM Tris-HCl, pH 7.5, 0.01% bovine serum albumin, and 0.05% Tween-20 and 20 mU/mL of human neutrophil elastase was added to black, flat-bottom 96-well microtiter plates containing different concentrations of test compounds. Reactions were initiated by the addition of 25 μM elastase substrate *N*-methylsuccinyl-Ala-Ala-Pro-Val-7-amino-4-methylcoumarin in a final reaction volume of 100 μL/well. Kinetic measurements were obtained every 30 s for 10 min at 25 °C using a Fluoroskan Ascent FL fluorescence microplate reader (Thermo Electron) with excitation and emission wavelengths at 355 and 460 nm, respectively. The concentration of inhibitor that caused 50% inhibition of the enzymatic reaction (IC_{50}) was calculated by plotting percent inhibition versus logarithm of inhibitor concentration.

Neutrophil Isolation. For isolation of human neutrophils, blood was collected from healthy donors in accordance with a protocol approved by the Institutional Review Board at Montana State University. Neutrophils were purified from the blood using dextran sedimentation, followed by Histopaque 1077 gradient separation and hypotonic lysis of red blood cells, as described previously.[15] Isolated neutrophils were washed twice and resuspended in HBSS. Neutrophil preparations were routinely >95% pure, as determined by light microscopy, and >98% viable, as determined by trypan blue exclusion.

Ca^{2+} Mobilization Assay. Changes in intracellular Ca^{2+} were measured with a FlexStation II scanning fluorometer using fluorescent dye Fluo-4AM (Invitrogen). Neutrophils or FPR1-HL60 cells, suspended in HBSS, were loaded with Fluo-4AM dye (final concentration, 1.25 μg/mL) and incubated for 30 min in the dark at 37 °C. After dye loading, the cells were washed with HBSS, resuspended in $HBSS^+$, separated into aliquots, and deposited into the wells of flat-bottom, half-area well black microtiter plates (2×10^5 cells/well). The compound source plate contained dilutions of test essential oil or pure compound in $HBSS^+$, and changes in fluorescence were monitored (λ_{ex} = 485 nm, λ_{em} = 538 nm) every 5 s for 240 s at room temperature after automated addition of compounds. Maximum change in fluorescence, expressed in arbitrary units over baseline, was used to determine agonist response. Responses were normalized to the response induced by 5 nM *f*MLF, which was assigned a value of 100%. Curve fitting (at least five or six points) and calculation of median effective concentration values (EC_{50} or IC_{50}) were performed by nonlinear regression analysis of the dose−response curves generated using Prism 5 (GraphPad Software, Inc., San Diego, CA, USA).

Chemotaxis Assay. Human neutrophils were suspended in $HBSS^+$ containing 2% (v/v) heat-inactivated fetal bovine serum (2×10^6 cells/mL), and chemotaxis was analyzed in 96-well ChemoTx chemotaxis chambers (Neuroprobe, Gaithersburg, MD, USA), as described previously.[23] In brief, neutrophils were preincubated with the indicated concentrations of the test sample (oil or pure compound) or DMSO for 30 min at room temperature and added to the upper wells of the ChemoTx chemotaxis chambers. The lower wells were loaded with 30 μL of $HBSS^+$ containing 2% (v/v) FBS and the indicated concentrations of test sample, DMSO (negative control), or 1 nM *f*MLF as a positive control. Neutrophils were added to the upper wells and allowed to migrate through the 5.0 μm pore polycarbonate membrane filter for 60 min at 37 °C and 5% CO_2. The number of migrated cells was determined by measuring ATP in lysates of transmigrated cells using a luminescence-based assay (CellTiter-Glo; Promega, Madison, WI, USA), and luminescence measurements were converted to absolute cell numbers by comparison of the values with standard curves obtained with known numbers of neutrophils. Curve fitting (at least eight or nine points) and calculation of median effective concentration values (IC_{50}) were performed by nonlinear regression analysis of the dose−response curves generated using Prism 5.

ROS Production. ROS production was determined by monitoring L-012-enhanced chemiluminescence, which represents a sensitive and reliable method for detecting superoxide anion ($O_2^{\bullet-}$) production.[23] Human neutrophils were resuspended at 2×10^5 cells/mL in $HBSS^+$ supplemented with 40 μM L-012. Cells (100 μL) were aliquoted into wells of 96-well flat-bottom microtiter plates containing essential oil or compounds at different concentrations (final DMSO concentration, 1%). Cells were preincubated for 30 min, and 200 nM PMA was added to each well to stimulate ROS production. Luminescence was monitored for 60 min (2 min intervals) at 37 °C using a Fluoroscan Ascent FL microtiter plate reader (Thermo Electron, Waltham, MA, USA). The curve of light intensity (in relative luminescence units) was plotted against time, and the area under the curve was calculated as total luminescence. The compound concentration that inhibited ROS production by 50% of the PMA-induced response (positive control) was determined by graphing the percentage inhibition of ROS production versus the logarithm of concentration of test sample (IC_{50}). Each curve was determined using five to seven concentrations.

Compound Cytotoxicity. Cytotoxicity was analyzed with a CellTiter-Glo Luminescent Cell Viability Assay Kit (Promega), according to the manufacturer's protocol. Briefly, MonoMac-6 cells were cultured at a density of 1×10^5 cells/well with different concentrations of essential oil or compound for 4 or 24 h at 37 °C and 5% CO_2. Following treatment, the cells were allowed to equilibrate to room temperature for 30 min, substrate was added, and the samples were analyzed with a Fluoroscan Ascent FL microplate reader.

RESULTS

Composition of the Essential Oils from *A. kotuchovii*. Essential oils were obtained by conventional hydrodistillation of the dried stems or flowers+leaves of *A. kotuchovii* (designated $AKEO_{stm}$ and $AKEO_{f/l}$, respectively) and analyzed by GC and GC-MS techniques simultaneously to determine their chemical compositions. Hydrodistillation of the stems and flowers+leaves produced 0.096 and 1.010% (v/w on the basis of the weight of dried material) essential oils, respectively. The main constituents of $AKEO_{f/l}$ and $AKEO_{stm}$ were estragole (75.1 and 76.6%), (*E*)- and (*Z*)-β-ocimene (9.2 and 8.2%), methyleugenol (4.3 and 4.6%), limonene (1.0 and 1.0%), spathulenol (0.8 and 1.0%), β-pinene (0.9 and 1.0%), myrcene (1.5 and 0.7%), and (*E*)-methyl cinnamate (1.9 and 0.5%, respectively). Seventy-four constituents were present at concentrations from 0.1 to <1.0% in one or both plant sources. The remaining 34 volatile compounds were identified in trace amounts, and their relative percentage amounts are indicated in Table 1. Thus, the major components of the $AKEO_{f/l}$ and $AKEO_{stm}$ are phenylpropanoids (81.5 and 79.6%, respectively) and monoterpene hydrocarbons (13.0 and 14.4%, respectively). Sesquiterpenes compose around 2−2.2% in both plant components. It should be noted that $AKEO_{stm}$ had more oxygenated monoterpenes and fatty acids compared to $AKEO_{f/l}$ (0.5 vs 0.1% and 0.5 vs 0.2%, respectively).

Evaluation of Essential Oil Effect on Phagocyte Function. The essential oils from *A. kotuchovii* were screened

DOI: 10.1021/acs.jafc.5b01307
J. Agric. Food Chem. 2015, 63, 4999−5007

for modulatory activity in various cell and enzymatic systems related to mechanisms of innate immunity (Table 2). Essential oils and their components have been reported previously to modulate intracellular Ca^{2+} levels[24] and inhibit leukocyte migration.[25,26] We found that $AKEO_{stm}$, but not $AKEO_{f/l}$, inhibited *f*MLF-stimulated Ca^{2+} flux and *f*MLF-induced chemotaxis in human neutrophils, with IC_{50} values of 12.5 and 10.1 μg/mL, respectively (Figure 1 and Table 2). Recently, several essential oils were reported to modulate ROS production in neutrophils.[27,28] Thus, we evaluated the effect of $AKEO_{stm}$ and $AKEO_{f/l}$ on PMA-induced ROS production by human neutrophils and found that $AKEO_{stm}$ inhibited ROS production with an IC_{50} of 49.2 μg/mL, whereas $AKEO_{f/l}$ had no activity (Table 2). Although some essential oils and their components were previously identified as HNE inhibitors,[29] evaluation of $AKEO_{stm}$ and $AKEO_{f/l}$ showed that they did not inhibit HNE, even at concentrations up to 50 μg/mL.

Table 2. Biological Screening of the Essential Oils from *A. kotuchovii*

biological activity	IC_{50} (μg/mL)	
	$AKEO_{f/l}$	$AKEO_{stm}$
LPS-induced NF-κB/AP-1 activity in THP-1Blue cells	NA[a]	NA
LPS-induced TNF production in MonoMac-6 cells	NA	NA
neutrophil elastase enzymatic activity	NA	NA
*f*MLF-induced Ca^{2+} flux in human neutrophils[b]	NA	12.5 ± 2.7
*f*MLF-induced chemotaxis in human neutrophils[c]	NA	10.1 ± 3.1
PMA-induced ROS production in human neutrophils[d]	NA	49.2 ± 5.4

[a]NA, no activity was observed, even at the highest concentration tested (50 μM). [b]Activity was evaluated as inhibition of Ca^{2+} flux induced by 5 nM *f*MLF in neutrophils. [c]Inhibition of chemotactic activity in neutrophils was evaluated in the presence of 0.5 nM *f*MLF. [d]Inhibition of ROS production in neutrophils was evaluated in the presence of 200 nM PMA and 40 μM L-012.

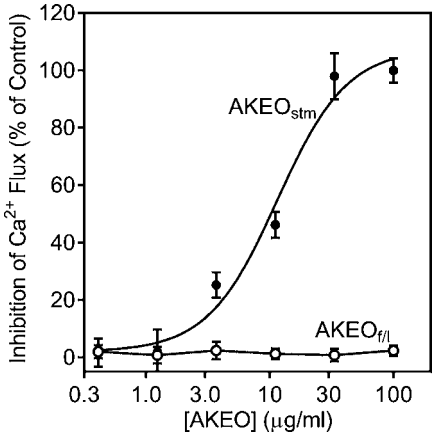

Figure 1. Effect of essential oils from *A. kotuchovii* on Ca^{2+} mobilization in human neutrophils. Neutrophils were preincubated with the indicated concentrations of essential oils isolated from stems ($AKEO_{stm}$) (solid circles) and flowers+leaves ($AKEO_{f/l}$) (open circles) of *A. kotuchovii* for 30 min at 25 °C and then stimulated with 5 nM *f*MLF. The response induced by the peptide agonist alone was assigned a value of 100%. Values are the mean ± SD of triplicate samples from one experiment that is representative of three independent experiments.

Because various essential oils have been reported to inhibit NF-κB/AP-1 transcriptional activity and production of pro-inflammatory cytokines,[30,31] we also evaluated the effects of $AKEO_{stm}$ and $AKEO_{f/l}$ on these responses using cultures of monocytic cells. However, we found that $AKEO_{stm}$ and $AKEO_{f/l}$ did not alter NF-κB/AP-1 activity or TNF production in monocytic cells (Table 2).

Although our functional cell-based assays suggested that the essential oils were relatively nontoxic, we evaluated their potential cytotoxic effects to determine if the results might be influenced by background cytotoxicity. Using a cytotoxicity assay, we determined that neither of the essential oils significantly affected the viability of MonoMac-6 cells over a concentration range up to 50 μg/mL, further demonstrating that $AKEO_{stm}$ and $AKEO_{f/l}$ were not cytotoxic (data not shown).

Effect of $AKEO_{stm}$ Components on Neutrophil Function. Because $AKEO_{stm}$ inhibited neutrophil functional responses, we focused on analysis of the effects of $AKEO_{stm}$ constituents to possibly identify the active compound(s). Twenty-five commercially available components of $AKEO_{stm}$, including 8 major (≥1%) and 17 minor compounds, were tested. Note that among the minor constituents tested, hexanal, α-terpinene, *p*-cymene, MHDO, (*E*)-anethole, isopropyl myristate, and palmitic acid were all present at higher levels in $AKEO_{stm}$ compared to $AKEO_{f/l}$ (Table 1).

All selected compounds were evaluated for agonist and antagonist effects on Ca^{2+} flux in human neutrophils. We found that four compounds from different chemical classes, including β-pinene, sabinene, palmitic acid, and myristic fatty acid, had direct but weak agonist activity, as determined by monitoring Ca^{2+} flux (Table 3). Of all of the component compounds tested, only MHDO inhibited *f*MLF-stimulated Ca^{2+} mobilization in neutrophils (IC_{50} = 8.2 μM), which is far below our common hit threshold of 50 μM,[15] and this inhibition was concentration-dependent (Table 2 and Figure 2A). MHDO did not directly activate Ca^{2+} flux, suggesting it was not down-regulating the subsequent response to *f*MLF but was directly inhibiting *f*MLF-stimulated Ca^{2+} mobilization via a different mechanism. Furthermore, MHDO inhibited Ca^{2+} flux in *f*MLF-stimulated FPR1-HL60 cells (Table 2) and IL-8-induced Ca^{2+} mobilization in human neutrophils (IC_{50} = 3.2 μM) (Figure 2B). On the other hand, MHDO did not inhibit nonspecific Ca^{2+} flux induced by 10 μM ionomycin (data not shown). Thus, these data indicate that MHDO can modulate intracellular signaling pathways that are common to both FPR1 and CXCR1/2 chemokine receptors, but it is not an ion channel inhibitor or a calcium chelator.

Consistent with its effect on Ca^{2+} mobilization, MHDO also inhibited neutrophil chemotaxis with an IC_{50} in the low micromolar range (Table 3). Among the other compounds tested, β-pinene, sabinene, β-citronellol, and elemicin were weak inhibitors of neutrophil chemotaxis (Table 3).

All 25 compounds were also evaluated for their effect on neutrophil ROS production. As with the other responses, only MHDO inhibited PMA-induced ROS production in human neutrophils (IC_{50} = 2.8 μM) (Table 3).

To ensure that the results on inhibition of Ca^{2+} flux and neutrophil chemotaxis were not influenced by possible compound toxicity, cytotoxicity of MHDO was evaluated at various concentrations (up to 100 μM) in MonoMac-6 cells during a 4 h incubation, which is relevant for relatively short times used to measure Ca^{2+} mobilization (up to 35 min) and

[a]Inhibition of Ca^{2+} flux induced by 5 nM *f*MLF. [b]Inhibition of chemotactic activity in neutrophils was evaluated in the presence of 0.5 nM *f*MLF. [c]Inhibition of ROS production in neutrophils was evaluated in the presence of 200 nM PMA and 40 μM L-012. [d]NA, no activity was observed, even at the highest concentration tested (50 μM).

chemotaxis (up to 90 min). As shown in Figure 3, MHDO did not affect cell viability, even at the highest tested concentration, thereby verifying that this compound, like the parent essential oil, was also not cytotoxic, at least during the 4 h incubation period.

DISCUSSION

Essential oils are natural mixtures of terpenes, mainly monoterpenes and sesquiterpenes, which have a wide range of pharmacological activities.[11,32−34] Furthermore, essential oils from various plants, including *Artemisia* spp., have been reported to exhibit various biological effects in vitro and in vivo.[2,35] In the present study, we defined the chemical profile of essential oils isolated from *A. kotuchovii* and evaluated their effects on phagocyte function.

Similar to the composition of essential oils from *A. dracunculus*,[1] we found that estragole, (*E*)- and (*Z*)-β-ocimenes, and methyleugenol were the primary constituents of *A. kotuchovii* essential oils. Other primary constituents present at lower concentrations (1−1.9% total weight) were limonene, spathulenol, β-pinene, myrcene, and methyl cinnamate. These compounds, with the exception of methyl cinnamate, are also present in tarragon essential oils.[1,36]

Although various essential oils have previously been found to inhibit NF-κB/AP-1 transcription and production of pro-inflammatory cytokines[5,30] and HNE activity,[29,37] we did not find these activities in *A. kotuchovii* essential oils. Indeed, none of the major components of *A. kotuchovii* essential oils (>1% by total weight) have been reported previously to inhibit HNE, NF-κB/AP-1 activity, or TNF production. Among the minor compounds (~1%), only limonene has been reported to inhibit NF-κB activation in vivo during acute lung injury.[38]

Evaluation of biological activities of *A. kotuchovii* essential oils revealed that only $AKEO_{stm}$ inhibited Ca^{2+} flux and chemotaxis in human neutrophils. To date, there are no publications on the modulation of Ca^{2+} mobilization in neutrophils by essential oils. Because intercellular Ca^{2+} flux is involved in chemotaxis, the inhibitory effect of $AKEO_{stm}$ on neutrophil chemotaxis is likely

J. Agric. Food Chem. 2015, 63, 4999−5007

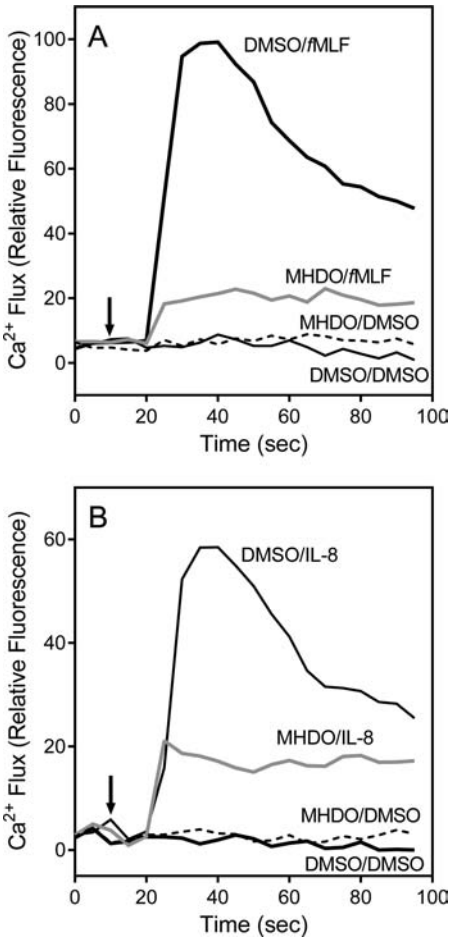

Figure 2. Effect of MHDO on *f*MLF-induced Ca^{2+} mobilization in human neutrophils. (A) Human neutrophils were preincubated for 30 min (at 25 °C) with 15 μM MHDO or DMSO (vehicle control), followed by treatment with 5 nM *f*MLF or DMSO (vehicle control). (B) Effect of MHDO on IL-8-induced Ca^{2+} mobilization in human neutrophils. Human neutrophils were preincubated for 30 min (at 25 °C) with 15 μM MHDO or DMSO (vehicle control), followed by treatment with 25 nM IL-8 or DMSO (vehicle control). Arrows indicate time of treatment additions. The data shown in both panels are representative of three independent experiments.

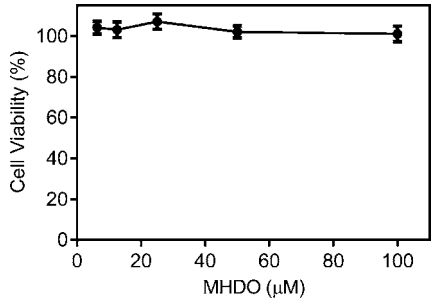

Figure 3. Effect of MHDO on cell viability. MonoMac-6 cells were incubated for 4 h with the indicated concentrations of MHDO, and cell viability was determined using a luminescent cell viability assay kit, as described. Values are the mean ± SD of triplicate samples from one experiment that is representative of two independent experiments. No statistically significant differences between untreated cells (DMSO alone) and cells treated with the compound were found.

due to a primary effect on Ca^{2+} flux. Previously, other essential oils or their constituents have been reported to inhibit cell migration. For example, rosemary and geranium essential oils inhibited leukocyte recruitment and chemotaxis.[39,40] In addition, *Thymus vulgaris* L. and *Citrus latifolia* (Yu. Tanaka) Tanaka essential oils also inhibited leukocyte migration.[25,41] Although we found that $AKEO_{stm}$ also inhibited PMA-induced ROS production in human neutrophils, the potency of this effect was relatively low compared to that of essential oils from *Sideritis italica* (Miller) Greuter et Burdet.[27]

To further define the active component(s) in $AKEO_{stm}$, we evaluated 25 of its constituents and found that β-citronellol, elemicin, β-pinene, and sabinene had low activity, whereas MHDO was a relatively potent inhibitor of neutrophil chemotaxis (Table 3), suggesting that it could be one of the primary essential oil components responsible for the inhibitory effects of $AKEO_{stm}$ on human neutrophils in vitro (Table 2). Indeed, only MHDO inhibited the other neutrophil responses tested (i.e., PMA-induced ROS production and *f*MLF- and IL-8-induced Ca^{2+} flux). Furthermore, MHDO was not present in $AKEO_{f/l}$ (Table 1). Thus, these data provide a molecular basis to explain at least part of the inhibitory activity of $AKEO_{stm}$ on neutrophil chemotaxis. However, on the basis of the molecular weight of MHDO (124.18 Da), its relative percentage (~0.1%) in $AKEO_{stm}$, and the IC_{50} values for biological activities of $AKEO_{stm}$ (~10−50 μg/mL) (see Tables 1 and 2), effective concentrations of this component would be in the range of 0.08−0.4 μM, which is several-fold lower than the IC_{50} values for the biological activity profiles of MHDO (2.8−8.2 μM, see Table 3). Thus, we could not exclude possible synergetic effects of other minor compounds, which are higher in $AKEO_{stm}$ (dehydro-1,8-cineole, *trans*-α-bergamotol, etc.) versus $AKEO_{f/l}$. Because β-pinene and sabinene directly activated Ca^{2+} mobilization in neutrophils, albeit with low efficacy, it is possible that they could contribute to receptor desensitization and/or intracellular Ca^{2+} store depletion. Recently, Siani et al.[42] reported that effective inhibition of eosinophil migration by essential oils from *Syzygium cumini* Skells and *Psidium guajava* L. correlated with the presence of β-pinene. Because α-pinene was completely inactive in all of our test systems (Table 3), we suggest that human neutrophils can discriminate between α- and β-isomers of this bicyclic monoterpene. In support of this isomer preference, α-pinene inhibited inflammatory pathways in human chondrocytes, whereas β-pinene was inactive.[43] Thus, various cell and/or molecular targets may determine the potency of the biological activities of these isomers.

Although previous papers indicate estragole and limonene can inhibit neutrophil and eosinophil migration,[25,26,44] we did not observe inhibition of neutrophil function by *R*- and *S*-enantiomers of limonene. Likewise, we did not observe any effects of anethole on neutrophil function, although it was reported to inhibit paw edema in mice in acute and persistent inflammation models.[45] These discrepancies may be explained by differences in methodologies and species specificity. For example, Kummer et al.[26] used murine neutrophils, which respond differently from human neutrophils to *f*MLF and other agonists.

Neutrophils express a large number of receptors for the recognition of pathogen invasion and communication, including chemosensory, chemoattractant, and chemokine GPCR, Fc-receptors, various cytokine receptors, and adhesion receptors as well as innate immune receptors, such as Toll-like receptors.[46,47] Here, we found that MHDO inhibited both *f*MLF- and IL-8-induced Ca^{2+} fluxes in neutrophils and the *f*MLF-induced response in FPR1-HL60 cells. Thus, MHDO may

DOI: 10.1021/acs.jafc.5b01307
J. Agric. Food Chem. 2015, 63, 4999−5007

interfere with intracellular signaling pathways common for both FPR1 and CXCR1/2. Nevertheless, further studies will be necessary to determine the precise molecular targets for MHDO in human neutrophils. It should be noted that MHDO is found in paprika and tomato oleoresins[48] and can be formed by thermal degradation of lycopene (ψ,ψ-carotene),[49] a red pigment of some fruits and vegetables. Although there are many publications describing the anti-inflammatory and antioxidant effects of lycopene,[50] our studies suggest that inhibition of leukocyte activation and/or migration could also contribute to the biological effects of paprika and tomato oleoresins, including lycopene metabolites and products of its thermal degradation.

In summary, we have defined the essential oil composition of *A. kotuchovii* and shown that these essential oils and a primary component compound are able to inhibit human neutrophil responses, including Ca^{2+} mobilization, chemotaxis, and ROS production. Further studies are now needed to determine the molecular targets for MHDO, as well as the biological activity of other minor constituents of the oil and evaluation of therapeutic efficacy of $AKEO_{stm}$ and MHDO in animal models of acute or chronic inflammatory diseases.

ABSTRACT: Selenomethionine (SeMet) and Se-methyl-L-selenocysteine (MSeC) are natural organoselenium compounds found in garlic, onion, and broccoli. In addition, these compounds have lower toxicity and better anticancer activities than inorganic Se. This study investigated the effects of MSeC treatment on the growth of COLO 205 human colorectal adenocarcinoma cells and evaluated the mechanisms related to the MSeC-induced effects. When COLO 205 cells were treated with 200 μM MSeC for 24 h, MSeC caused 80% apoptosis in cells. MSeC increased the expression of Fas and FasL, followed by the cleavage of caspase-3, caspase-8, DNA fragmentation factor (DFF45), and poly(ADP-ribose) polymerase (PARP). MSeC also increased the levels of Bax protein and decreased the levels of Bid and Bcl-2 proteins. However, MSeC did not cause apoptosis through reactive oxygen species (ROS) stress but instead through endoplasmic reticulum (ER) stress. The cleavage of caspase-12 and caspase-9 was shown to increase the growth arrest and protein levels of DNA-damage inducible genes (GADD) 153 and 45. MSeC also downregulated the ERK1/2 and PI3K/AKT protein levels and upregulated the p38 and JNK protein levels in COLO 205 cells. These results showed that the mechanism by which MSeC induced apoptosis in COLO 205 cells involved caspase activation, the extrinsic apoptotic pathway, and the regulation of ER-stress-induced apoptosis.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer worldwide and the second most frequent cause of cancer death in men and women.[1] Most cases of CRC are thought to arise from adenomatous polyps, and a routine colonoscopy may be a good tool for detecting adenomatous polyps early, thereby decreasing the incidence and mortality of CRC.[2] However, CRC may arise between two colonoscopy examinations.[3] The occurrence of CRC is highly related to diet. Red meat and alcohol consumption are recognized dietary risk factors for the development of CRC.[4]

Selenium (Se) is an essential micronutrient required by the human body and is an important element of glutathione peroxidase, which protects the body.[5,6] Se can be obtained from inorganic compounds, such as selenites and selenates, or in organic forms, such as selenoamino acids, selenopeptides, and selenoproteins.[5,7,8] Although the inorganic forms of Se are common sources of Se and have been shown to effectively induce apoptosis in different cancer cells, they may also cause toxicity in normal cells.[9] An increasing number of studies have shown that organic Se, such as selenomethionine (SeM) and Se-methyl-L-selenocysteine (MSeC), have better anticancer activities and lower toxicities than inorganic Se.[10] In 1971, Shamberger and Willis indicated that people living in areas with high dietary Se consumption have lower mortality rates because of gastrointestinal tract, lung, and breast cancers.[11,12] Moreover, epidemiological surveys have also demonstrated that selenium deficiency in the body can increase the risk of colonic, gastric, lung, and prostate carcinomas.[7] Se can be obtained from food and is abundant in natural foods, such as nuts, eggs, fish, liver, chicken, and garlic.[5] It seems that Se may be a supplement for CRC prevention. Thus, in the present study, we investigated the organoselenium compounds SeM, MSeC, *N*-γ-(L-glutamyl)-L-selenomethioine (GSeM), and *N*-γ-(L-glutamyl)-Se-methyl-L-selenocysteine (GMSeC) for their inhibitory activities on the cell growth of human COLO 205 colorectal adenocarcinoma cells. We identified the most potential anticancer compound and explored the mechanism underlying the promotion of apoptosis in cancer cells. MSeC was shown to inhibit COLO 205 cancer cell growth through multiple underlying mechanisms to promote apoptosis. Altogether, these results indicate a potential application for MSeC in the prevention of colon cancer.

MATERIALS AND METHODS

Cell Culture. The cell line COLO 205 [CCL-222, American Type Culture Collection (ATCC), Rockville, MD] was cultured in the RPMI-1640 medium with 10% fetal bovine serum (Gibco, Grand Island, NY) and penicillin–streptomycin (Biowest, Nuaille, France) and maintained in a humidified 5% CO_2 atmosphere at 37 °C.

Chemicals and Reagents. SeM, GSeM, MSeC, and GMSeC are kindly provided by American Medical Holdings, Inc. (New York, NY) (Figure 1). The purity of those compounds is over 99.2% according to

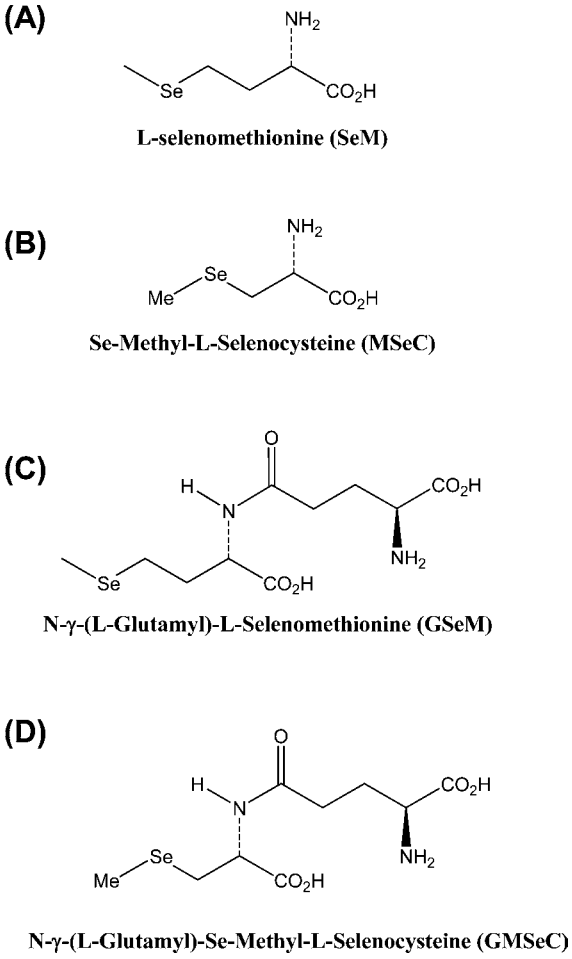

Figure 1. Chemical structures of (A) SeM, (B) MSeC, (C) GSeM, and (D) GMSeC.

high-performance liquid chromatography analysis. Trypan blue, acridine orange (AO), and propidium iodide (PI) were purchased from Sigma-Aldrich (St. Louis, MO). Anti-Akt and anti-PARP antibodies were purchased from Merck (Whitehouse Station, NJ); anti-Bcl-2 and anti-Bax were purchased from Santa Cruz Biotechnology (Dallas, TX); anti-Bid, anti-Fas, and anti-FasL were purchased from Becton-Dickinson (San Jose, CA); anti-DFF-45/ICAD and anti-caspase 8 were purchased from MBL (Woburn, MA); anti-p44/42 (ERK1/2) was purchased from Cell Signaling Technology (Danvers, MA); anti-p53 was purchased from Oncogen (La Jolla, CA); and anti-phospho-Akt and anti-caspase 3 were purchased from Novus (Littleton, CO).

Cytotoxicity Assay. COLO 205 cells were seeded in the 24 well plate with the density of 2×10^4 cells/mL overnight. Cells were treated with 0, 50, 100, 200, and 250 μM SeM, GSeM, MSeC, and GMSeC for 24 h. Cell viability was assayed by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) and determined by scanning with an enzyme-linked immunosorbent assay (ELISA) reader at 570 nm.

Trypan Blue Exclusion Assay. COLO 205 cells were cultured in the 24 well plate with the 2×10^5 cells/mL density. After overnight growth, cells were treated with 0, 50, 100, 200, and 250 μM MSeC for 24 h. After a 24 h co-culture with different concentrations of MSeC, the cell suspension was collected and dyed with trypan blue by a 1:1 ratio. Cells were then counted in a hemacytometer by a microscope (Olympus America, Inc., Lake Success, NY).

Flow Cytometry. Incubated COLO 205 cells were seeded with the 2×10^5 cells/mL density in the 24 well plate overnight and treated with different concentrations of MSeC for 24 h. After 24 h, cells were harvested with phosphate-buffer saline (PBS), fixed with iced 100% ethanol, and then stored in −20 °C. Cells were resuspended with hypotonic buffer (0.5% Triton X-100 in PBS and 0.5 μg/mL RNase) and then stained with PI at 37 °C for 15 min, individually. Fluorescence intensity was quantified by flow cytometry (Becton-Dickinson, San Jose, CA).

AO Staining Assay. COLO 205 cells were cultured in the 24 well plate with 2×10^5 cells/mL density overnight and treated with 200 μM MSeC for another 24 h. After 24 h, cells were harvested and suspended in the PBS. Equal volumes of cell suspension and AO were mixed, and the fluorescence intensity was observed by a microscope (Olympus America, Inc., Lake Success, NY).

DNA Fragmentation. COLO 205 cells were seeded with the 2×10^5 cells/mL density in a 100 mm Petri dish overnight and then treated with different concentrations of MSeC for 24 h. Cells were also treated with 200 μM MSeC for 0, 3, 6, 9, 12, 18, and 24 h. Cells were harvested, centrifuged, and suspended in PBS. The cell solution was centrifuged, and then the cell lysate was collected and mixed with DNA lysis-PK buffer at 56 °C overnight. RNase A (0.5 μg/mL) was added to the cell lysate solution at 50 °C for 3 h, and an equal volume of phenol/chloroform/isoamyl (25:24:1) was added in the cell lysate solution to obtain DNA. DNA was loaded in the 2% agarose gel electrophoresis and run at 50 V for 120 min in Tris–borate/ethylenediaminetetraacetic acid (EDTA) electrophoresis buffer (TBE). The gel was stained by ethidium bromide, visualized under ultraviolet (UV) light, and photographed.

Caspase Activity. COLO 205 cells were seeded in 100 mm with the 2×10^5 cells/mL density Petri dish overnight and then treated with 200 μM MSeC for 0, 3, 6, 9, 12, 18, and 24 h. Harvest cells were washed by PBS and centrifuged, and then the supernatant was removed. Protein was extracted by mixing cell pellet with gold lysis buffer [50 mM tris(hydroxymethyl)aminomethane (Tris)–HCl at pH 7.4, 1 mM NaF, 150 mM NaCl, 1 mM ethylene glycol bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA), 1 mM phenylmethanesulfonyl fluoride, 1% NP-40, and 10 g/mL leupeptin] and then centrifuged at 12 000 rpm for 30 min at 4 °C. A total of 50 μg of each sample was mixed with the caspase substrate (acetyl-Asp-Glu-Val-Asp-7-amino-4-methylcoumarin) at 30 °C for 1 h, and the fluorescence intensity was quantified by the ELISA reader at 360 nm excitation wavelength and 460 nm emission wavelength.

Determination of Superoxide, Hydroperoxide, Glutathione, and Mitochondrial Transmembrane Potential. COLO 205 cells were incubated with the 2×10^5 cells/mL density in the 24 well plate overnight and treated with 200 μM MSC for 0, 15, 30, 60, and 120 min. Cells were harvested and washed by PBS twice and mixed separately with dihydroethidium (DHE), 5-cholomethylfluoroescein diacetate (CMFDA), 2′,7′-dicholofluoroescein diacetate (DCFHDA), and 3,3′-dihexyloxacarbocyanine iodide (DiOC6) for 30 min, and the reactions were stopped by trypsin–EDTA at 37 °C and then analyzed by flow cytometry.

Analysis of Antioxidant and Apoptosis. COLO 205 cells (2×10^5 cells/mL) were seeded in the 24 well plate overnight and 50 and 100 μM allopurinol (ALL), 200 and 400 units/mL catalase (CAT), 10 and 20 μM diphenylene iodonium (DPI), 2.5 and 5 μM *N*-acetylcysteine (NAC), and 100 and 200 μg/mL superoxide dismutase (SOD) were added for 1 h, individually. After the treatment with different antioxidants, the cells were treated with 200 μM MSeC for 24 h and the reaction was stopped by trypsin–EDTA and analyzed by flow cytometry.

Western Blotting. COLO 205 cells were seeded in 100 mm with the 2×10^5 cells/mL density Petri dish overnight and then treated with 0, 50, 100, 200, and 250 μM for 24 h and 200 μM MSeC for 0, 3, 6, 9, 12, 18, 24 h, individually. Protein was extracted with gold lysis buffer (50 mM Tris−HCl at pH 7.4, 1 mM NaF, 150 mM NaCl, 1 mM EGTA, 1 mM phenylmethanesulfonyl fluoride, 1% NP-40, and 10 μg/mL leupeptin) by mixing the cells and gold lysis buffer on ice for 30 min, followed by centrifugation at 10000*g* for 30 min at 4 °C. The total protein (50 μg) was used in the 12% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) at a constant current of 20 mA. Proteins were electrotransferred from gel to immobile membrane [polyvinylidene fluoride (PVDF), Millipore Corp., Bedford, MA] with transfer buffer (25 mM Tris−HCl at pH 8.9, 192 mM glycine, and 20% methanol). The membranes were blocked with blocking solution [20 mM Tris−base, 125 mM NaCl, 0.2% Tween 20, 1% bovine serum albumin (BSA), and 0.1% sodium azide] and then immunoblotted with primary antibodies [including Anti-Akt and anti-PARP antibodies purchased from Merck (Whitehouse Station, NJ), anti-Bcl-2 and anti-Bax purchased from Santa Cruz Biotechnology (Dallas, TX), anti-Bid, anti-Fas, and anti-FasL purchased from Becton-Dickinson (San Jose, CA), anti-DFF-45/ICAD and anti-caspase 8 purchased from MBL (Woburn, MA), anti-p44/42 (ERK1/2) purchased from Cell Signaling Technology (Danvers, MA), anti-p53 purchased Oncogen (La Jolla, CA), and anti-phospho-Akt and anti-caspase 3 purchased from Novus (Littleton, CO)] at 4 °C overnight. Detection was achieved by measuring the chemiluminescence of the blotting agent [electrochemiluminescence (ECL), Amersham Corp., Arlington Heights, IL], after exposure of the filters to Kodak X-Omat films.

Statistical Analysis. All results were presented as means ± standard error of the mean (SE) in the independently performed experiments. The differences between the control group and different concentrations of Se compounds were analysis by Student's *t* test. Data were considered statistically significant at a p value of <0.05.

RESULTS

Cytotoxic Effects of SeM, MSeC, GSeM, and GMSeC in Human COLO 205 Cells. The cytotoxic effects of SeM, MSeC, GSeM, and GMSeC in human colorectal adenocarcinoma (COLO 205) cells were evaluated using the MTT assay. As shown in Figure 2A, the viability of COLO 205 cells was reduced by MSeC treatment but not by treatment with the other three organoselenium compounds. The cell viabilities were 60.6 ± 12.9, 31.3 ± 9.4, and 24.8 ± 5.4% after treatment with 150, 200, and 250 μM MSeC, respectively. The cytotoxic effects of MSeC in COLO 205 cells were further confirmed by trypan blue analysis. Figure 2B shows that MSeC induced significant cell death in COLO 205 cells in a dose-dependent manner. These results clearly revealed the cytotoxic effect of MSeC in COLO 205 cells.

MSeC Induced Apoptosis in Human COLO 205 Cells. Because MSeC-induced cytotoxic effects in COLO 205 cells were found in our study, the mechanism of these cytotoxic effects was evaluated by treating COLO 205 cells with MSeC and examining the cellular morphology. After the cells were treated with 200 μM MSeC for 24 h, membrane blebbing and apoptotic bodies were clearly observed (top panels of Figure 3A). MSeC also caused chromatin condensation that was detected through the use of the fluorescent dye AO (bottom panels of Figure 3A). DNA fragmentation is considered to be a hallmark of apoptosis. Thus, DNA fragmentation analysis was also performed in the present study. As shown in Figure 3B, significant DNA ladders were observed in COLO 205 cells treated with 150 μM MSeC for 24 h (left). In addition, DNA ladders were observed after treatment with 200 μM MSeC after 18 or 24 h (right). The MSeC-induced apoptotic effect in

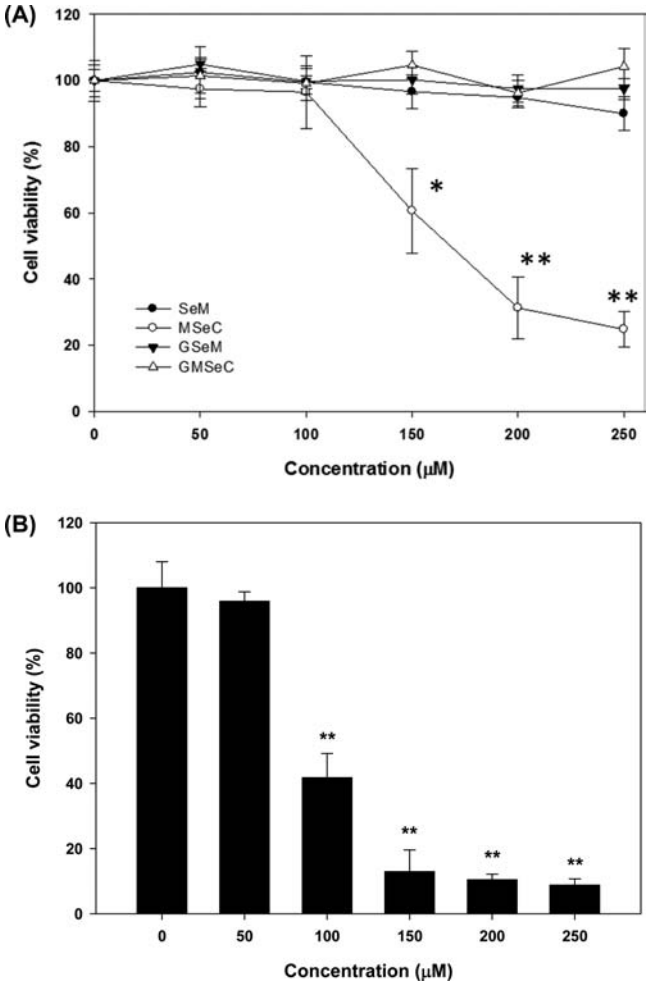

Figure 2. Cytotoxic effects of SeM, MSeC, GSeM, and GMSeC in COLO 205 cells. COLO 205 cells were treated with various concentrations (0, 50, 100, 150, 200, and 250 μM) of SeM, MSeC, GSeM, and GMSeC for 24 h. The cells were harvested, and the cell viability was determined by (A) MTT assay and (B) trypan blue exclusion assay. (*) $p < 0.01$ and (**) $p < 0.001$ indicate statistically significant differences relative to the control group.

COLO 205 cells was confirmed using flow cytometry. As seen in Figure 3C, the number of apoptotic cells was markedly increased by MSeC treatment. The quantitative results for the percentage of apoptotic cells showed that MSeC significantly induced apoptosis (Figure 3D). These results suggested that the cytotoxic effect caused by MSeC in human COLO 205 cells occurred mainly through the induction of apoptosis.

MSeC Induced Cleavage of PARP, DFF45, and Caspase Activation. To explore the mechanism of MSeC-induced apoptosis, the enzymatic activity of caspase was measured using fluorescent substrates. After treatment with 200 μM MSeC, the activities of caspase-8 and caspase-9 significantly increased by 6 h and continued to increase until 24 h (Figure 4A). After treatment with 200 μM MSeC, caspase-3 was activated by 12 h and markedly increased in activation by 18 and 24 h. Figure 4B shows the COLO 205 cells that were treated with MSeC for 24 h, which resulted in the proteolytic cleavage of PARP and DFF45 in a dose-dependent manner. A decreased level of procaspase-3 protein also occurred when cells were treated with MSeC (lower). Moreover, the COLO 205 cells treated with 200 μM MSeC showed marked PARP and DFF45 cleavage by

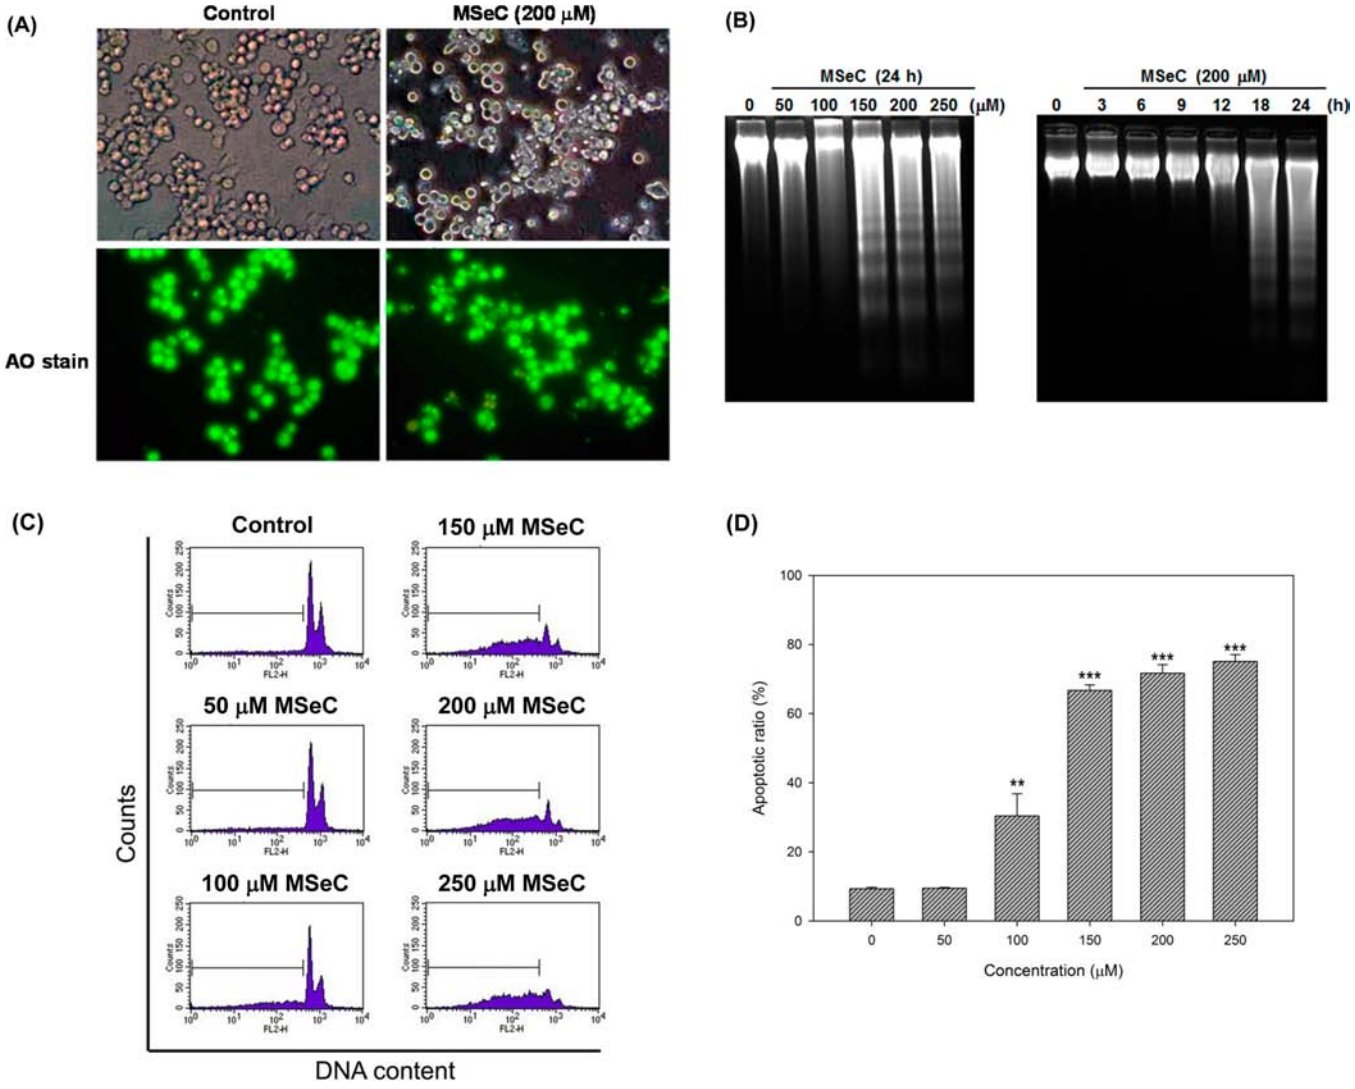

Figure 3. MSeC-induced apoptosis in COLO 205 cells. COLO 205 cells were treated with different concentrations of MSeC for 24 h or with 200 μM MSeC for the indicated time. (A) Cells were stained with AO, and the morphological changes and chromatin condensation were examined using fluorescence microscopy. (B) DNA was extracted, and the DNA fragmentation was analyzed using agarose gel electrophoresis. (C and D) Cells were harvested and fixed with ethanol overnight and stained with PI. Apoptotic cells were detected by flow cytometry and presented as the apoptotic ratio (%). (*) $p < 0.01$ and (**) $p < 0.001$ indicate statistically significant differences compared to the control group.

12 h, which continued until 24 h (Figure 4C). This result was consistent with the DNA fragmentation results (Figure 3B). These findings suggested that the activation of caspases participated in the MSeC-induced apoptosis of human COLO 205 cells.

MSeC Induced Apoptosis via the Death Receptor and Mitochondrial Signaling Pathways. To further investigate the mechanism underlying MSeC-induced apoptosis, the total protein was extracted and analyzed by western blot analysis. The activation of Fas results in FasL signaling, which promotes the autocatalytic activation of procaspase-8 and initiates death signaling.[13] Figure 5A shows that the treatment of COLO 205 cells with 200 μM MSeC caused the increased expression of Fas and FasL proteins by 9 h, which continued until 24 h. Meanwhile, the cleavage of procaspase-8 also occurred from 9 to 24 h (top panel of Figure 5B). MSeC also caused the time-dependent cleavage of procaspase-9 by the early time point of 3 h, whereas cleaved procaspase-3 was detected by 18 h (middle and bottom panels of Figure 5B). The protein expression of the Bcl-2 family members, which plays an important role in regulating mitochondria-dependent apoptosis, was also measured in the MSeC-treated cells.[14] As illustrated in Figure 5C, the MSeC treatment caused an increase in the protein level of Bax. However, MSeC treatment reduced the protein expression levels of Bcl-2 and Bid. These data suggested that MSeC-induced apoptosis in human COLO 205 cells may have occurred through both the intrinsic and extrinsic pathways.

Effects of MSeC on the Mitochondrial Membrane Potential ($\Delta\Psi_m$) and the Levels of Hydrogen Peroxide, Superoxide, and Glutathione (GSH). Mitochondria are the main source of reactive oxygen species (ROS), such as hydrogen peroxide and superoxide, which are known to cause cell death under conditions in which excess ROS are generated.[15] The imbalance of redox systems, such as reduced GSH, results in oxidative stress that also participates in the regulation of apoptosis.[16,17] To understand whether MSeC-induced cell apoptosis occurred through the upregulation of ROS, the intracellular hydrogen peroxide and superoxide levels were detected using flow cytometry with the fluorescent dyes DCFHDA and DHE. As illustrated in Figure 6A, MSeC did not

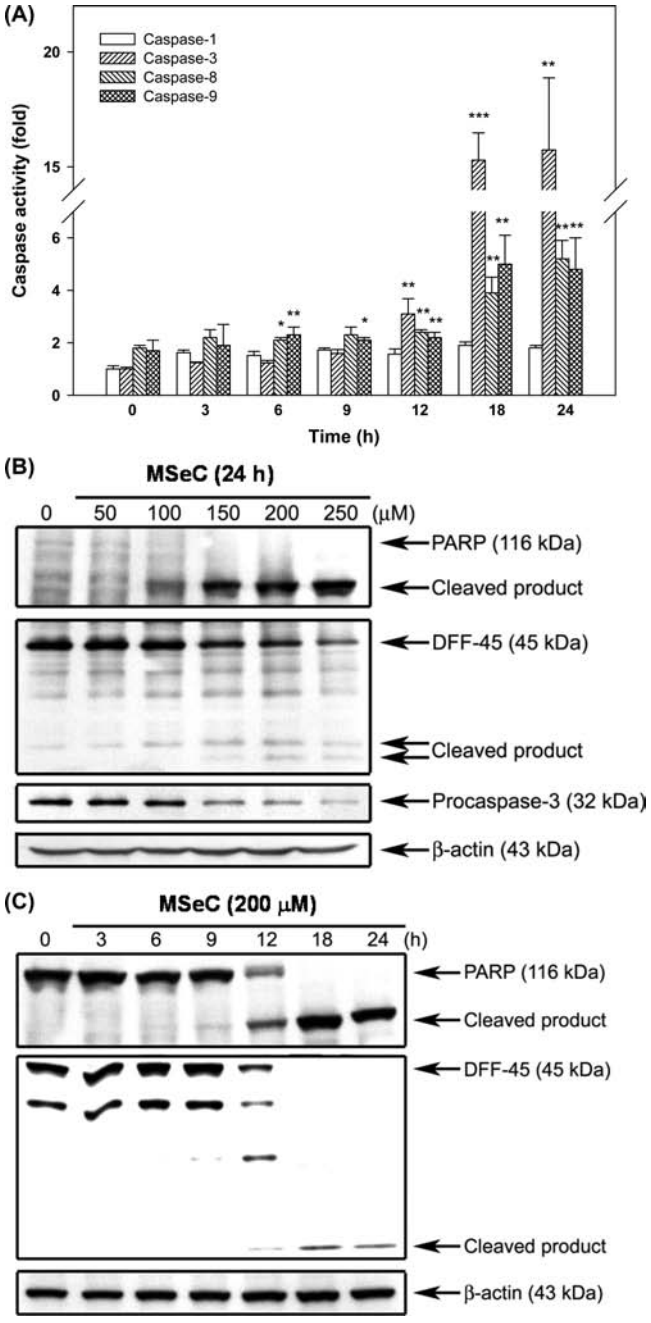

Figure 4. MSeC-induced PARP cleavage, DFF-45 degradation, and activation of caspases in COLO 205 cells. COLO 205 cells were treated with various concentrations of MSeC for 24 h or 200 μM MSeC for the indicated time. The total protein was extracted, and the enzymatic activities of caspase-1, caspase-3, caspase-8, and caspase-9 were determined using fluorogenic substrates, as described in the Materials and Methods. (B and C) Cleavage of PARP and DFF-45 was analyzed by western blot analysis. The values are expressed as the means ± standard deviation (SD) of triplicate tests. (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ indicate statistically significant differences compared to the control group.

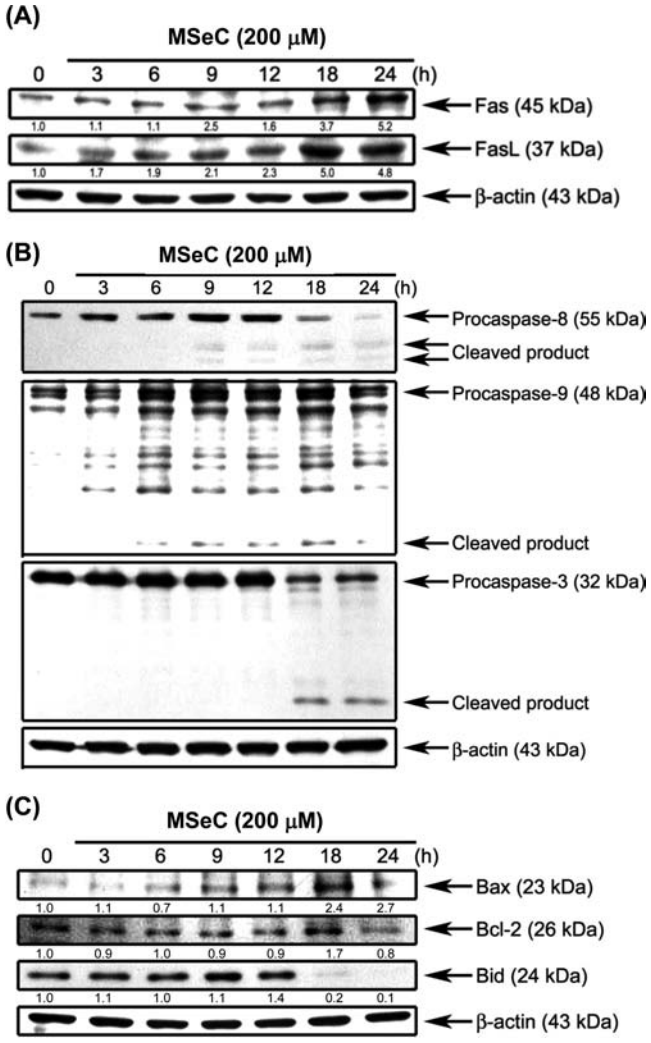

Figure 5. MSeC-induced apoptosis in COLO 205 cells through the death receptor and mitochondrial pathways. Cells were treated with 200 μM MSeC for the indicated time. The total protein was extracted, and the protein levels of (A) Fas and FasL, (B) caspase-8 and caspase-3, and (C) Bcl-2 family proteins were analyzed by western blot analysis. This experiment was repeated 3 times with similar results.

increase the levels of either hydrogen peroxide or superoxide by 6 and 12 h. However, after treatment with MSeC, a slight reduction in the level of GSH was observed through the use of the fluorescent probe CMFDA (right panel of Figure 6A). Although increased levels of ROS were not detected, a slight disruption of the mitochondrial membrane potential ($\Delta\Psi_m$) occurred after MSeC treatment, which was evidenced by the reduced levels of DiOC6 fluorescence intensity (left panel of Figure 6A). To further examine the role of ROS in MSeC-induced apoptosis, COLO 205 cells were preincubated with various antioxidants and treated with MSeC and then the apoptotic ratio was measured. As shown in Figure 6B, none of the antioxidant treatments reduced the MSeC-induced apoptosis, suggesting that ROS may not play a major role in MSeC-induced apoptosis. The treatment with MSeC dramatically induced the expression of both DNA-damage inducible genes (GADD) 153 and 45 proteins in a time-dependent manner (Figure 6C). This result indicated that the induction of DNA damage or endoplasmic reticulum (ER) stress may be one of mechanisms involved in MSeC-induced apoptosis.

Effects of MSeC on the Phosphorylation of MAPK Kinases and PI3K/Akt. The mitogen-activated protein kinases (MAPKs), including extracellular signal-regulated kinase (ERK), c-Jun NH2-terminal kinase (JNK), and p38 MAPK, play critical roles in the regulation of gene expression, mitosis, proliferation, motility, metabolism, and apoptosis in the cells.

Previous studies have reported the anti-apoptotic role of ERK1/2,[18−20] whereas p38 MAPK and JNK have been shown to be stress-responsive proteins that tend to induce apoptosis.[21] Here, we found that MSeC treatment downregulated the protein level of phospho-ERK1/2 while markedly increasing the protein levels of phospho-p38 MAPK and phospho-JNK (Figure 7A). PI3K and its downstream kinase Akt, which are

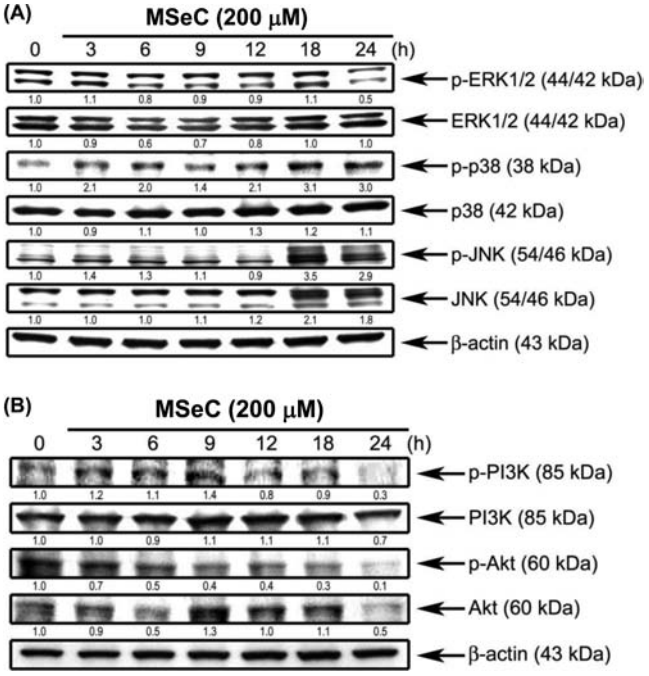

Figure 7. Effects of MSeC on MAPKs and PI3K/Akt signaling in COLO 205 cells. The cells were treated with 200 μM MSeC for an indicated time, and the total protein was extracted. The protein levels of (A) ERK, phospho-ERK, p38, phospho-p38, JNK, and phospho-JNK and (B) PI3K, phospho-PI3K, Akt, and phosph-Akt were analyzed by western blot analysis. This experiment was repeated 3 times with similar results.

pivotal to cell survival and cell growth, are highly upregulated in various human cancers.[22] When the cells were treated with MSeC, the phosphorylation of both PI3K and Akt were decreased (Figure 7B). These results indicated that the modulation of stress and survival signaling was one of the possible mechanisms contributing to MSeC-induced apoptosis.

DISCUSSION

MSeC, a naturally occurring monomethylated selenoamino acid, is the most valuable form of Se found in vegetables, such as garlic. Studies have shown that MSeC has a high oral bioavailability and metabolizes to methylselenol, which is known to be an excellent anticarcinogen.[23] The chemopreventive effects of MSeC have been suggested to occur through mechanisms, such as anti-inflammation,[24] anti-tumorigenesis,[25] and anti-angiogenesis.[26] Several studies have reported that MSeC inhibits cell growth in various cancer cells through the induction of cell cycle arrest and apoptosis.[27,28] In the present study, MSeC displayed more potent cytotoxic effects than three other Se compounds that were tested in COLO 205 cells. The cytotoxic effects caused by MSeC contributed to the induction of apoptosis, which was evidenced by morphological changes, nuclear condensation, and DNA fragmentation (Figure 2). At the molecular level, the upregulation of Fas and FasL and the activation of caspase-8 occurred in MSeC-treated cells, suggesting a role for the death receptor pathway in MSeC-induced apoptosis. Although alterations in the expression of Bcl-2 family proteins were also observed after MSeC treatment, this may not be an early signaling event because altered protein levels were observed at a later time point (Figure 5). Moreover, MSeC induced a slight decrease in the mitochondrial membrane potential but did not increase the production of ROS. This finding was also confirmed by pretreatment with various antioxidants (Figure 6), implying that the ROS-triggered intrinsic signaling was not a major mechanism contributing to the MSeC-mediated apoptosis.

Accumulating evidence has suggested that ER stress signaling involves the modulation of the intrinsic (mitochondrial) and/or the extrinsic (death receptor) apoptotic pathways. The ER stress-induced expression of GADD genes, including GADD34, GADD45, and GADD153, are known to promote apoptosis. GADD153, which is also known as CEBP homology protein (CHOP), is rapidly induced by UV irradiation, oxidative stress, genotoxic agents, and ER stress. Studies using the overexpression of a plasmid have demonstrated that GADD153 functions in the initiation of apoptosis,[29] although one study has suggested that GADD153 expression alone does not trigger cell death and, instead, sensitizes cells to ER-stress-induced death.[30] The mechanism by which GADD153 promotes apoptosis is complicated and indistinct, whereas the overexpression of GADD153 has been shown to downregulate the transcription of Bcl-2.[30] Although no evidence has confirmed the existence of a GADD153 binding site in the Bcl-2 promoter, GADD153 may regulate the transcription of Bcl-2 through interactions with other transcription factors.[31,32] In the present study, MSeC induced the early expression of GADD153, which may have initiated apoptotic signaling and further repressed the Bcl-2 protein levels (Figure 6C). Another GADD protein, GADD45, which also has a role in controlling the cell cycle, apoptosis, and DNA repair, has been shown to respond to stress signaling.[33] In the present study, the expression of GADD45 was upregulated by treatment with MSeC. A previous study has demonstrated that the activation of JNK and ERK is involved in the induction of the GADD45 promoter activity, while other studies have suggested that GADD45 is required for the activation of JNK and apoptosis via modulation of the upstream JNK kinase.[34] Here, after the cells were treated with MSeC, the phosphorylation of JNK1/2 occurred far later than the upregulation of GADD45, indicating that MSeC increased GADD45 prior to the activation of JNK1/2 and the JNK-dependent apoptosis signaling pathway. Another study has implicated p38 MAPK in the induction of GADD45 transcription.[35] GADD45 was found to be upregulated early by MSeC treatment in the present study, which suggested the possibility that MSeC mediates the activation of p38 MAPK to regulate GADD45. However, we cannot exclude the possible role of p38 MAPK in modulating other molecules and signaling cascades involved in MSeC-induced apoptosis. The anti-apoptotic role of PI3K/Akt signaling, which is pivotal in regulating cell survival in response to ER stress, has been previously documented.[36] Studies have also suggested that the inactivation of PI3K/Akt induces GADD153 expression and cell death under conditions of ER stress.[37] In the present study, we found that MSeC treatment caused the early downregulation of Akt, implying that the MSeC-induced expression of GADD153 was associated with the inactivation of PI3K/Akt.

DOI: 10.1021/acs.jafc.5b01779
J. Agric. Food Chem. 2015, 63, 5008−5016

However, more experiments are needed to investigate this mechanism in detail.

In conclusion, MSeC-induced apoptosis in human colorectal adenocarcinoma COLO 205 cells may occur through the death receptor and ER stress signaling pathways via the modulation of multiple kinase signaling events. These findings suggest that MSeC could be a potential compound for the prevention and treatment of colon cancer.

ABSTRACT: The electrochemical genosensor is one of the most promising methods for the rapid and reliable detection of pathogenic bacteria. In a previous work, we performed an efficient electrochemical genosensor detection of *Staphylococcus aureus* by using lead sulfide nanoparticles (PbSNPs). As a continuation of this study, in the present work, the electrochemical genosensor was used to detect *Escherichia coli* O157:H7. The primer and probes were designed using NCBI database and Sigma-Aldrich primer and probe software. The capture and signalizing probes were modified by thiol (SH) and amine (NH_2), respectively. Then, the signalizing probe was connected using cadmium sulfide nanoparticles (CdSNPs), which showed well-defined peaks after electrochemical detection. The genosensor was prepared by immobilization of complementary DNA on the gold electrode surface, which hybridizes with a specific fragment gene from pathogenic to make a sandwich structure. The conductivity and sensitivity of the sensor were increased by using multiwalled carbon nanotubes (MWCNT) that had been modified using chitosan deposited as a thin layer on the glass carbon electrode (GCE) surface, followed by a deposit of bismuth. The peak currents of *E. coli* O157:H7 correlated in a linear fashion with the concentration of tDNA. The detection limit was 1.97×10^{-14} M, and the correlation coefficient was 0.989. A poorly defined current response was observed as the negative control and baseline. Our results showed high sensitivity and selectivity of the electrochemical DNA biosensor to the pathogenic bacteria *E. coli* O157:H7. The biosensor was also used to evaluate the detection of pathogen in real beef samples contaminated artificially. Compared with other electrochemical DNA biosensors, we conclude that this genosensor provides for very efficient detection of pathogenic bacteria. Therefore, this method may have potential application in food safety and related fields.

KEYWORDS: *electrochemical genosensor, sandwich structure, cadmium sulfide nanoparticle, E. coli O157:H7, beef sample*

INTRODUCTION

Foodborne bacterial infections and diseases are a major cause of illness and death worldwide[1] *Escherichia coli* is a common bacterium in both food and humans and a predominant species of facultative anaerobes in the gut of animals. *E. coli* O157:H7 (designated by its somatic, O, and flagellar, H, antigens) was first recognized as a human pathogen following two hemorrhagic colitis outbreaks in 1982.[2,3] There is an enterohemorrhagic strain of the bacterium and Gram-negative pathogen that has been responsible for several diseases, such as hemorrhagic colitis (HC) and hemolytic uremic syndrome (HUS), caused by the presence and expression of Shiga toxins that can occur with very low exposure (<10 cells) to the bacterium.[3−5] Some of the *E. coli* strains found in human feces also are themselves pathogenic.

E. coli is associated with infection in both food and humans; it has been associated with food-related outbreaks in many countries and often involves contaminated beef or fresh produce. It exists in soils, fruits, and raw vegetables, and it is a significant foodborne pathogen carried in the intestinal tract of cattle and other animals. The bacteria may be transmitted to humans through fecal contamination of food.[5] The common source of infection is the consumption of contaminated food, especially meats, untreated water, unpasteurized milk, and foods that have been in direct contact with animals. *E. coli* O157:H7 is commonly found in the intestinal tract of warm-blooded animals, and the contamination depends on interaction with gut tissues where the pathogens adhere to the host cells. Consumption of foods contaminated with this pathogen can cause gastroenteritis as well as life-threatening diseases. Therefore, food safety becomes an issue of worldwide interest when we have repeated outbreaks of bacterial pathogens. Food safety in many countries requires monitoring, and more consumers and organizations now pay attention to food safety issues, which may prevent complication.

Testing of food and food raw materials for the presence of pathogenic microorganisms and toxin producers is classically done using traditional methods such as plate samples. This is widely used and relies on a series of selective or nonselective media, each of which allows for growth of a certain group of pathogens. The detection of microorganisms using this traditional method (conventional plate count) is time-consuming, taking at least 2−5 days for results and up to 7−10 days for the final confirmation. Therefore, polymerase chain reaction (PCR) has been used to amplify the target DNA.

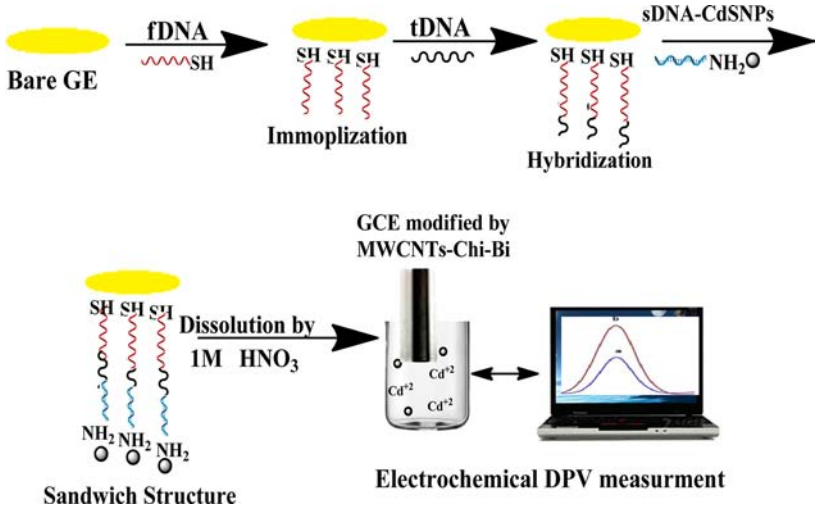

Figure 1. Schematic performance of the electrochemical detection of target DNA based on CdSNPs-labeled oligonucleotides DNA probes.

However, this method is time consuming and requires expensive instrument.[6] In recent years, research has developed new methods.[7] However, these methods often fail to differentiate pathogenic species from nonpathogenic ones. Presently, the electrochemical method for DNA detection of pathogenic microorganisms in food safety has been receiving more attention because of its advantages of speed, sensitivity, selectivity, and lower cost. In a method based on nanoparticles, the specific gene can be detected.[8] Another method developed is the biosensor. Much literature has focused on the biosensor, especially the genosensor due to its high specificity, which avoids false results as happen in traditional methods and biochemical methods. This approach is crucial in connection with research efforts directed at gene analysis as well as in detection of genetic disorders and tissue matching. Electrochemical sensors have received considerable attention due to their quick response, remarkably higher sensitivity, good selectivity, and strong operability for the detection of pathogenic microorganisms.[9,10] The target DNA must be hybridized with a fixing probe (which is conjugated with nanoparticles). Another signalizing probe must be used that is fixed on a gold electrode surface that has been modified by a thiol group. To be clear, the most critical step in the preparation of DNA electrochemical biosensors is the immobilization of DNA strands on the surface of the gold electrode.[11] If the hybridization step is successful and creates a sandwich structure, the signal can be measured electronically. The development of nanotechnology and nanoscience has produced different nonmaterials that can be used for sensor design to develop sensitivity and selectivity. The use of a heavy metal to develop electrochemical biosensors is done to differentiate signals from the sandwich hybridization using a stripping method.[12] The nanoparticle was used as a marker to label a sequence known as the oligonucleotide.[13] For example, one study used the Cd nanocrystal based electrochemiluminescence biosensor cadmium sulfide (CdS), one of the most important binary semiconductors that we have, which has been extensively studied in the field of sensors.[14] Another study[15] used multiwalled carbon nanotubes (MWCNT) to increase the sensitivity of the electrode. The carbon nanotube (CNT) is one of the most widely studied nonmaterials. Numerous researchers have investigated the biocompatibility of functional CNTs, both in vitro and in vivo. However, the toxicological effects of MWCNT have not been thoroughly investigated, and some of the findings remain controversial.[16] MWCNT provide a large surface area, significant mechanical strength, efficient electrocatalytic activity, and high electrical conductivity that enhance electron transfer with the electrode surface. In addition, they may serve as catalysts.[17] Specific nucleic acid sequences were detected by single-stranded DNA probes complementary to the target DNA.[15] The key step in setting up such systems is the employment of high-efficiency testing methods, which must be accurate and sensitive enough to detect even low levels of contamination in a given commodity to prevent pathogens from being transmitted through the food chain to the consumer. In the present study, we measure a highly sensitive electrochemical genosensor for the rapid detection of *E. coli* O157:H7. We used complementary probes to construct a sandwich structure, CdNPs, and glass carbon electrode (GCE) decorated with MWCNT-Chi. Figure 1 shows the preparation of the sandwich structure on a GE surface and depicts electrochemical DNA detection using cadmium sulfide nanoparticles (CdSNPs) labels.

MATERIALS AND METHODS

Materials and Reagents. Cadmium chloride ($CdCl_2$), sodium sulfide (Na_2S), sodium hydroxide (NaOH), and 3-mercaptoacetic acid were used for the synthesis of CdSNPs. Tri(2-carboxyethyl)-phosphinehydrochloride (TCEP) and [1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC)] purchased from Sigma-Aldrich were used as carboxyl activating agents for the coupling of primary amines to create amide bonds with carboxylic group on the surface of NPs. Salmon sperm DNA was used as blocking agent during the hybridization. Sodium dodecyl sulfate (SDS) was used to remove the unhybridized DNA after immobilization and hybridization. Multiwalled carbon (purity > 95%, diameter = 50 nm, length = 10−20 μm) was obtained from Nanjing Xianfeng Nanomaterials Technology, China. Bismuth nitrate obtained from Scharlau Chewwice S.A. (Spain) was applied to the surface of the electrode to increase the sensitivity. All of the oligonucleotides used in the sensor were purchased from Takara Co. (Dalian, China) and Sangon Biotechnology Co., Ltd. (Shanghai, China), with HPLC purification. All of the solutions were prepared using ultrapure water from a Millipore Milli-Q system.

Apparatus. A centrifuge was used to concentrate and wash the NPs. A vortex mixer was used to combine the amine group with the CdSNPs. An incubator was used for the hybridization reaction and a refrigerator for the preservation of the CdSNPs. A Nanodrop 1000

spectrophotometer (Thermo Scientific, Ashville, NC, USA) was used to measure the concentration and purity DNA. Electrochemical experiments were performed on potentiostat/galvanostat (Shanghai CH Instruments Co.) The three-electrode electrochemical detection system consisted of a GCE as a working electrode, an Ag/AgCl (saturated KCl) as a reference electrode, and platinum wire as a counter electrode. Scanning and transmission electron microscopes (SEM and TEM, respectively) were used to obtain images and morphologies of the CdSNPs and GCE surfaces, respectively.

Bacteria Culture and Genomic DNA Extraction. *E. coli* O157:H7 (accession no. JX206444.1) was obtained from the Zhangjiagang Entry-Exit Inspection and Quarantine Bureau (Suzhou, Jiangsu province, China). *Aeromonas hydrophila* (accession no. M84709) was obtained from the Freshwater Fisheries Research Center (Wuxi, China) and used as a negative control in this biosensor. The other strains were obtained from Jiangnan University laboratory. *A. hydrophila* was grown in ampicillin starch agar phenol red, whereas *E. coli* O157:H7 was grown in MacConkey agar (CM908) obtained from Beijing Land Bridge Technology Co., Ltd. Inoculum media strains were grown aerobically and incubated at 37 °C for 24 h in tryptic soy broth media (TSB). Genomic DNA was extracted after incubation for 18 h. Then, the DNA was extracted using a modified boiling method.[18] Briefly, the culture was boiled for 10 min to kill all pathogenic bacteria, and 1 mL of the culture was transferred into an Eppendorf tube and centrifuged at 13000 rpm for 5 min at 4 °C to pellet the cells. The supernatant was discarded, and the pellet obtained was suspended in 500 μL of sterile deionized water with a vigorous vortex. The cell suspension was boiled in a water bath for 15 min and immediately cooled at −20 °C for 10 min to cause a shock to the cells. Then, the sample was centrifuged a second time at 12000 rpm for 3 min. Finally the supernatant containing genomic DNA was harvested into another sterile Eppendorf and used as the DNA template for the PCR amplification.

Oligonucleotides, PCR Condition, and DNA Purification. All oligonucleotides used in this study were synthesized using the integrated DNA technology of Takara Co. and were purified by HPLC. The DNA probes for the *E. coli* were established by designing the primers used for the insertion element gene of *E. coli* to be complementary with the probes. For the amplification of the DNA samples, two primers (forward and reverse) were used. The pairs of primers were designed according to the target bacterial gene using the databases of the National Center for Biotechnology Information (NCBI) and the Basic Local Alignment Tool (BLAST) software (http://www.ncbi.nlm.nih.gov/)[19] DNA calculator from Sigma-Aldrich. The specificity of the primer sequences was further verified using software (http://www.sigmagenosys.com/calc/DNACalc.asp). All primer and probe sequences used in this study are listed in Table 1.

The reaction solution for PCR was performed in a total reaction volume of 25 μL, containing 2.5 μL of 10× PCR buffer, 2 μL of 10 mM of each dNTP (10 mM of each dNTP), 1 μL of each of the forward and reverse primers (0.4 μM concentration), 0.25 μL of Qiagen Taq, 17.25 μL DNase-free deionized water, and 1 μL of tDNA. *A. hydrophila* (ATCC 7966) was used as a negative control. The amplifications were carried out in a thermal cycler (TAkaRa, GRADIENT PCR, Japan) using the following conditions: an initial denaturation at 94 °C for 2 min, followed by 30 cycles of denaturation at 94 °C for 30 s, annealing at 45−53 °C for 30 s for *E. coli* O157:H7 and *A. hydrophila*, respectively, and, finally, extension at 72 °C for 5 min and holding at 4 °C. PCR amplifications were run on 2% agarose gel electrophoresis. Then, the bands were stained with Andy Safe, and the images were obtained using ultraviolet light using the Bio-Rad Gel doc 1000. A DNA fragment of 100 bp was used as the molecular size. A fragment (752 pb) of the *E. coli* O157:H7 (accession no. JX206444.1) was used, along with one (161 pb) of *A. hydrophila*. A PCR-purified kit purchased from Sangon Biotech Co. (Shanghai, China) was set up to purify the DNA products after PCR amplification and used according to the manufacturer's guidelines.

Synthesis of Nanoparticles. Glassware used in the procedure was cleaned in a bath of freshly prepared 3:1 HCl/HNO_3, rinsed thoroughly in twice-distilled water, and dried in an oven. CdSNPs were prepared according to the literature[20,21] with a slight modification. Specifically, 0.023 g of cadmium chloride ($CdCl_2$) was dissolved into 100 mL of deionized water to yield an aqueous solution at a concentration of 0.1 mM. Then 2 μL of mercaptoacetic acid ($C_2H_4O_2S$) was added as a stabilizer using vigorous stirring. The pH was adjusted to a final level of pH 11 using additional concentrated 0.5 mol L^{-1} NaOH. The solution was bubbled with nitrogen for 30 min, and then 50 mL of 1.34 mmol L^{-1} freshly prepared sodium sulfide (Na_2S) was added dropwise. Solutions were filtered prior to use with a 0.22 μm microporous membrane filter. The mixture turned yellow immediately due to the formation of CdS, and after additional stirring, the reaction was carried out for 24 h under bubbled nitrogen. The prepared colloid CdSNPs were stored in brown glass bottles at 4 °C until being used.

TEM, SEM. TEM has been found to be an excellent tool for characterizing the morphology of nanoparticles. A drop of the mixed solution was put on a TEM specimen and lit until it dried; then, TEM and SEM images were performed. This equipment was chosen to characterize the morphology of the electrode surface.

Conjugation between CdSNPs and NH_2-Modified Oligonucleotides. CdS was conjugated to the NH_2-modified oligonucleotides by using imidazole and EDC according to ref 22 with slight modifications. Briefly, 2 OD of NH_2-modified oligonucleotides was mixed with 200 μL of 0.1 M imidazole buffer and stirring for 30 min. Then 100 μL of freshly prepared EDC (0.1 M) was added. Washed CdSNPs were added and incubated at room temperature for 24 h with gentle stirring. Afterward, the solution was centrifuged at 10000 rpm for 30 min to purify the CdNP-NH_2-modified oligonucleotide. The precipitate was washed and centrifuged at 13000 rpm, and the pellet was resuspended and stored at −20 °C.

DNA Immobilization. Prior to the immobilization step, the gold electrode was heated in a piranha solution (3:7 H_2O_2/concentrated H_2SO_4), rinsed with DD water, and dried under nitrogen flow. Then, the gold electrodes were polished to a mirror-like finish using a microcloth with alumina powder of grain sizes 0.03 μm and 0.05 nm. Then, the electrodes were washed with water and 95% ethanol, respectively, for 5 min to remove the residual alumina powder and adsorbed impurities. To achieve the maximum cleaning process, the bare gold electrode was cleaned electrochemically in 0.5 mol/L H_2SO_4 until a repeatable cyclic voltammogram was obtained. The clean electrodes were washed with ultrapure water and dried under a pure nitrogen stream. The dried electrodes were initially immersed in a

DOI: 10.1021/acs.jafc.5b00675
J. Agric. Food Chem. 2015, 63, 5017−5025

fixing probe modified with a thiol group at 4 °C overnight to allow adsorption onto the gold surface. Finally, the electrodes modified with fixing probes were thoroughly rinsed with 10 mM PBS solution (1 M NaCl, pH 7.4) to remove unbound fDNA.[8,11,23]

DNA Hybridization. Prior to hybridization, the purified tDNA was denatured in a water bath (95 °C) and immediately chilled in ice for 5 min. The product was diluted with a PBS buffer solution (pH 7.0) and serial dilution. The first hybridization was performed by immersing the gold electrodes in tDNA and incubating at 45 °C for 1 h to allow the hybridization between the fixing probe and the tDNA. Then the electrodes were immersed in 0.1% sodium dodecyl sulfate (SDS) for 10 min to remove the unhybridized tDNA. In the second hybridization, the electrodes were incubated again for 1 h with a signalizing probe containing sDNA-CdSNPs. Then, the sandwich structure (fDNA-tDNA-sDNA-CdSNPs) was constructed. The electrochemical response was performed using an electrochemical analyzer at room temperature.[8,23,24]

Dissolution of CdS and Electrochemical Measurements. After immobilization and hybridization, the gold electrode with a sandwich structure was immersed in 150 μL of 1.0 mol L^{-1} HNO_3 solution for 5 min to dissolve the CdSNPs fixed on the surface of the electrode. The released CdSNPs ions were then ready for electrochemical measurement. For the decoration step, MWCNT-Chi was dropped onto the GCE surface and dried at room temperature. Then bismuth layer was deposited electrochemically by immersing the modified electrode into a solution containing 0.1 M acetate buffer solution and 100 μL of bismuth ions, and a negative potential for 100 s was applied.[25] Electrochemical measurements including DPV, clean electrode, cyclic votammetry (CV), and electrochemical impedance spectroscopy (EIS) were performed using an electrochemical analyzer (CHI Inc., Shanghai, China) and a three-electrode system at room temperature. All experiments were carried out at room temperature, and all measurements were replicated three times. All curves were the average of at least three test results. Different bacteria concentrations were used, and each bacterial concentration was plotted against the current peak. The deposition potential used in this study was −1.2 Vvs for 100 s, whereas the DPV potential was −1.2 Vvs.

Real Application of Sensor in Food Matrix. Fresh beef meat was purchased from a local market in Wuxi, China. The sample was prepared and examined according to the literature.[26] Briefly, the sample was divided into different parts and sterilized with radiation. Then, 10 g of beef sample was inoculated with 100 μL of different bacterial concentrations (*E. coli* O157:H7) ranging from 10 to 10^5 CFU/mL onto the surface of the beef sample and stored at 4 °C for 4 h. In the same manner, controls consisting of uninoculated samples were used. Afterward, each beef sample was transferred to a sterile 250 mL Erlenmeyer flask, and 90 mL of TSB was added to obtain the proportion 1:10 (sample weight/total weight). Then, a 1.5 mL portion of rinse fluid was removed from each bottle and placed in a sterile 2 mL microcentrifuge tube for DNA extraction. The DNA of the pellet was extracted using a boiling method, and the PCR products were checked as above.

RESULTS AND DISCUSSION

Characterization of Nanoparticles and Electrode. The morphologies and size of the CdSNPs were estimated using TEM (Figure 2). The image of the CdSNPs shows the average length ranged from 8 to 11 nm with good dispersion. Furthermore, the image shows that the particles did not aggregate after synthesis and storage. The size of the NPs affected the quality and connection with the signalizing probe.[27] We found that the size of the CdS was approximately 7−53 nm, which agrees with research[28] documenting use of CdSNPs with size >10 nm. After electrode polish, the GE was cleaned electrochemically by scan in 0.5 mol/L H_2SO_4; Figure 3 shows the scan of electrode. The modified GCE was characterized by SEM in different steps. Figure 4A shows the image of the bare GCE (blank control) and shows only a blurred background of

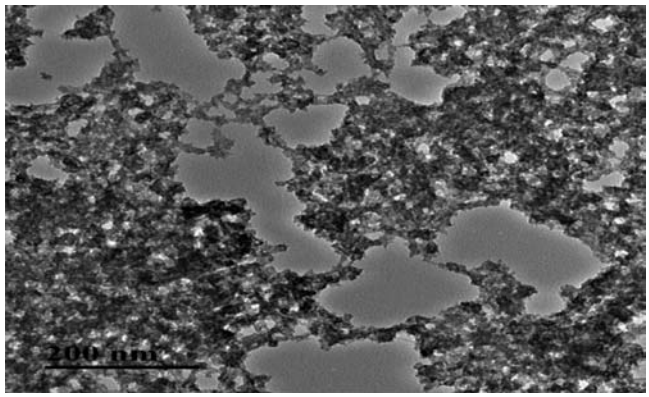

Figure 2. TEM micrographs of the synthesized CdSNPs.

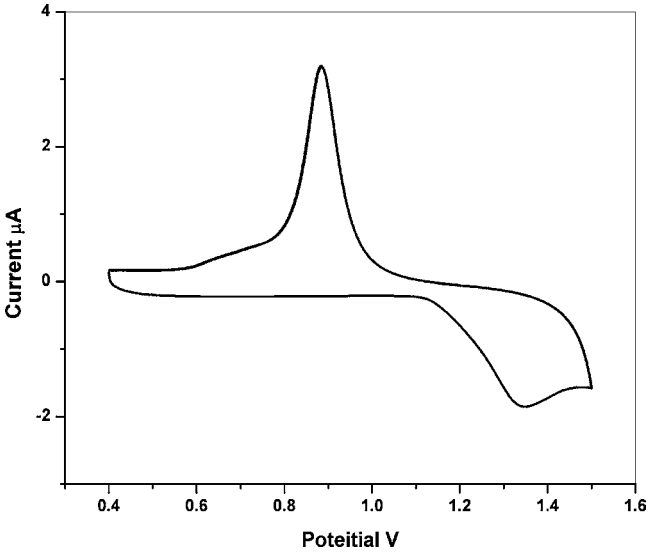

Figure 3. Cleaning gold electrode by using 0.5 mol/L H_2SO_4.

the electrode surface. Figure 4B shows the GCE covered with MWCNT-Chi after being dried. There was an electrochemical deposition of bismuth to the GCE modified by the MWCNT, as Figure 4C confirms.

PCR Amplification. A pair of primers was designed to be specific to *E. coli* O157:H7. The specificity of the PCR products of the pure culture using positive and negative bacteria is shown in Figure 5. The results indicate that the primer pair was specific for the corresponding target organisms. It used the amplification reactions for the PCR detection of the target genes of *E. coli* O157:H7 at approximately 752 bp and at 161 bp for *A. hydrophila*. It produced a high yield of specific DNA target sequences. This yield was verified by gel electrophoresis, which revealed a band that did not appear in any PCR reaction with another DNA template (negative control). The band's intensity was different when the genome was extracted from pure culture and real sample. The PCR product had double-stranded DNA oligonucleotides with a complementary sequence of both fDNA and sDNA.

Eectrochemical Impedance Spectroscopy (EIS) and Cyclic Voltammetry (CV). EIS experiments were performed to characterize a modified electrode surface in different steps. It was extensively used for the study of electron transfer on the modified surface. It also measured the sensitive electrode surface phenomena and changes in bulk properties.[10] EIS data

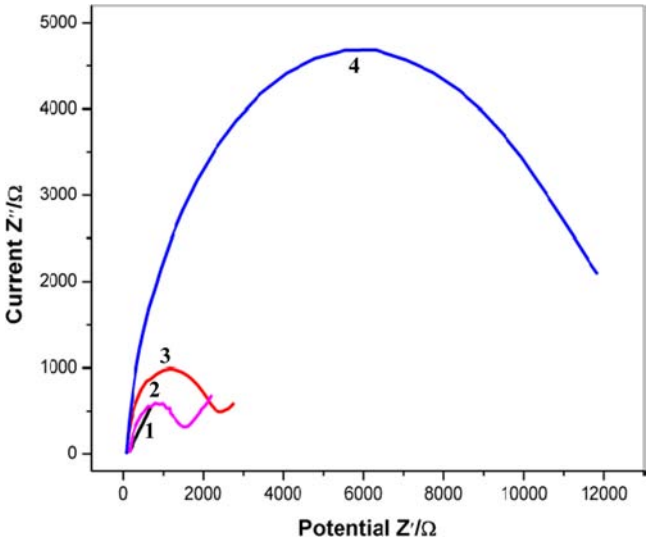

Figure 6. EIS of the electrode at different stages (different film modified electrodes) in potassium ferricyanide $[K_3OFe(CN)_6]$: (1) on the bare gold electrode surface; (2) gold electrode and fixing probe; (3) gold electrode, fixing probe, and tDNA; (4) gold electrode, fixing probe, tDNA, and capture probe.

were measured from 100 kHz to 1 Hz at a wave amplitude of 5 mV and an electrode potential of 0.20 V in $Fe(CN)_6^{3-/4-}$. Figure 6 shows the EIS in various modified GE steps. In this study, we selected thiol-terminated fDNA because of the strong affinity of thiol−metal (SH−Au) linkages, which provides connection with the gold surface.[11] The bare electrode showed a straight line. The R_{et} increased after being modified and hybridized, which indicated that electron transfer became more difficult. This phenomenon resulted from the negative charge on the sDNA that made the electron transfer of ferricyanide probes difficult due to electrostatic repulsion[8] and interaction between the material and ferricyanide anion.

Figure 7 characterizes modified GCE measured by EIS. The bare GCE showed a clear well-defined reversible redox peaks corresponding to the $[Fe(CN)_6]^{3-/4-}$ electron transfer process. When GCE was modified with MWCNT-Chi, the semicircular curve was observed. The bismuth layer formed during electrodeposition showed a slight decrease in peak currents and a negligible semicircle was observed. The bismuth slightly inhibits the electron transfer process in solution. The combination of MWCNT-Chi-Bi enhanced the sensitivity, adherence, and electrodeposition of released Cd^{2+}. GCE decorated by MWCNT-Chi can allow several uses. Prior to another detection, a potential of +0.3 V for 30 s can be applied to remove the Bi-CdSNPs from the electrode surface, and then a new bismuth layer could be generated by electrodeposition.

The effect of the scan rate on the electrochemical performance (redox reaction) of modified GCE (MWCNT-Chi-Bi) was investigated, using CV at different scan rates from 10 to 150 mV, to measure the current response of a ferricyanide solution exposed to different potentials. It was found that the sharp increase in peak currents was observed with an increase of scan rate, and the relationship was linearly related to the scan

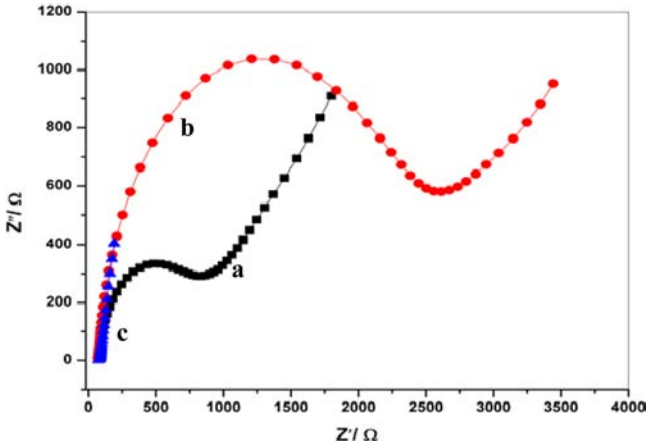

Figure 7. Impedance spectroscopy EIS for GCE in different modification steps obtained in 1 mM $K_3Fe(CN)_6$ solution: (a) bare GCE; (b) GCE modified by MWCNT-Chi; (c) GCE modified by MWCNT-Chi-Bi.

rate, indicating that the sensor has a good electrochemical conductivity. After the deposition of bismuth, the charge transfer decreased, which indicates that the electron transfer of $[Fe(CN)_6]^{3-/4-}$ was blocked. Bismuth has poor electrical conductivity, so the electrical characteristics were improved by using MWCNT in the GCE surface to enhance the efficiency. Figure 8 shows the scan rate in a different current.

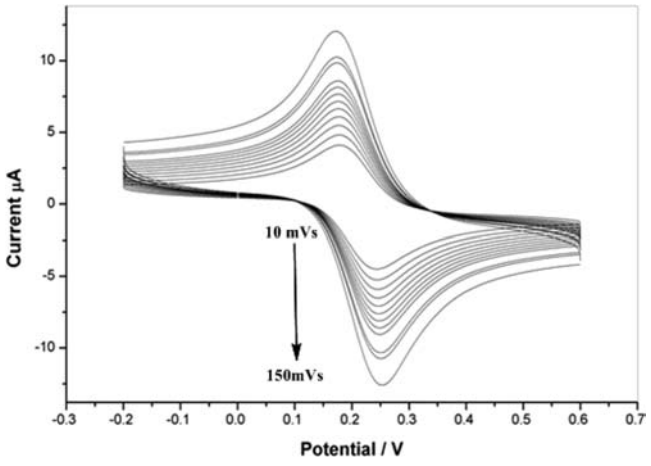

Figure 8. Cyclic voltammetry acquired on modified GCE in a solution containing $Fe(CN)_6^{3-/4-}$, at different scan rates from 10 to 150 mV s^{-1}. Scan range was between −0.2 and 0.6 V.

Electrochemical. The DNA detection process was performed in two main steps. The first was immobilization to allow the modified fixing probe on the GE surface to connect the thiol group with the GE.[15] Prior to immobilization, fDNA was mixed with tri(2-carboxyethyl)phosphine hydrochloride at a proportion of 1:2 and incubated at room temperature for 1 h to allow the thiol group bond to be free. This procedure facilitated the attachment to the GE surface. Bovine serum albumin (BSA) blocking was carried out after the probe immobilization and washed with PBS. Then, hybridization was accomplished by first adding serial concentrations of tDNA to connect with fDNA and then adding signalizing DNA containing CdSNPs. To conjugate and complete the sandwich structure, sDNA modified by CdSNPs with EDC was used to cross-link the CdSNPs and the amine group[22] and washed with GE to remove any unhybridized DNA. In the next step, the GE was submerged in 1 M HNO_3 solution[20] to release the sandwich structure content CdNPs to be measured by DPV. GCE was decorated with MWCNT-Chi-Bi, which improves the deposition release of cadmium ions on the electrode surface. CNT accelerates electron transfer due to the high conductivity. Therefore, it increases the sensitivity of MWCNT and characterizes the different steps, as shown in Figure 4. The electrochemical behavior of the CdSNPs ion was measured to investigate the sandwich using differential pulse voltammetry at the GCE surface and taking measurements of peak current. The DPV responses of the sensor to various concentrations of *E. coli* O157:H7 are shown in Figure 8. The negative control *A. hydrophila* was measured, and both steps (immobilization and hybridization) were included in tests.

Electrochemical DPV Measurements. DPV is a useful method for the sensitive detection of micro amounts of metal ion. Therefore, it is used in the measurement of Cd^{2+}.[20] The electrochemical behavior of the sandwich structure of the genosensor was detected as shown in Figure 9. The peak

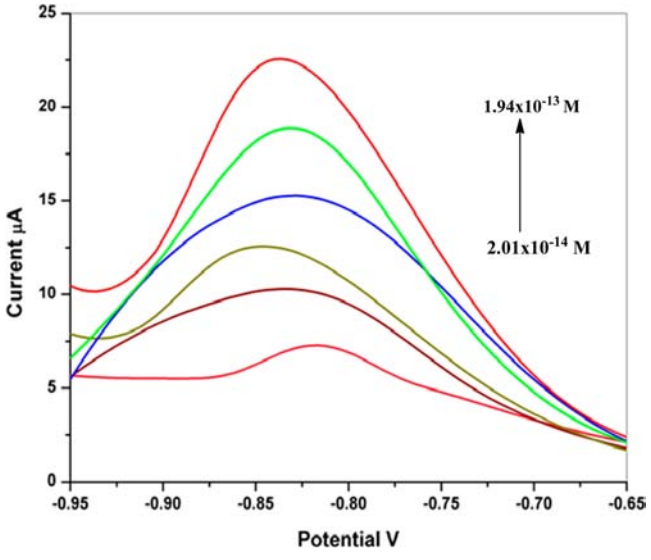

Figure 9. DPV analysis of electrochemical DNA sensors to detect tDNA with different concentration using CdSNPs for *E. coli* O157:H7 genomic DNA labeling, with sandwich structure fDNA−tDNA−cDNA−CdSNPs. The tDNA concentration ranged between 1.94×10^{-13} and 2.01×10^{-14} M.

current of various tDNA concentrations was observed, and we observed that the signal intensities increased dynamically with the increase of the concentration of tDNA. The calibration plot in Figure 10 shows that the signals of released Cd^{2+} had a good linear relationship with the peak currents and serial dilution of tDNA, with a correlation coefficient of 0.981 and the linear equation of $y = 113.9x + 5.86$), where y is the concentration of *E. coli* O157:H7 and x is the current. However, the peak appears at approximately −0.85 V. The detection limit of this study was 1.97×10^{-14} M with the ratio of signal-to-noise (s/n) equal to 3. The hybridization selectivity of the genosensor was investigated by the negative control sample (noncomplementary sequence), and the results did not show response at 0.8−0.9 V (CdSNPs). The results indicate that the MWCNT had a remarkable enhancement effect on the electrochemical response. The synergistic effect of the electronic conductivity

and electrocatalytic activity of the MWCNT enhanced ionic conductivity and ion-exchange capacity.[17] Overall, these results showed that this genosensor has good specificity and that only the complementary DNA sequence could form a sandwich structure. Therefore, the DNA genosensor sensitivity for the detection of *E. coli* O157:H7 has a limit of 1.97×10^{-14} M, whereas in the previous study,[29] the limit of detection was 3.17×10^{-14} M using *S. aureus* and PbNPs. The sensor is highly sensitive and has high specificity compared to other studies. Table 3 shows the detection limits of other studies and shows that this method performs better in sensitivity and specificity with regard to tDNA. Positive correlation was observed when the signal generated by CdSNPs was compared to the positive sample. The peaks showed a slight shift when using different tDNA concentrations. This phenomenon occurred in the interaction between the deposited materials and the metals formed during electrodeposition.

Application of Genosensor in a Food Matrix. The application of the present system is tested for enumeration of bacteria in six samples. The time between sampling and analysis has to be controlled to prevent changes in the concentration of the target microorganism that occur naturally over time.[4] The counts ranged from $(6.00 \pm 0.24) \times 10^2$ to $(2.47 \pm 0.75) \times 10^4$ cfu/mL for *E. coli* O157:H7. Although the infectious dose varies among pathogen types, it is generally believed that most bacterial pathogens are able to cause infection when $>10^3$ cfu/mL is ingested.[26] There were significant growth increases for different dilutions. Table 2 shows the enrichment for bacteria inoculated onto a beef sample. The DNA was extracted and amplified as described above. The gel electrophoresis detection of PCR products for serial dilution inoculums in beef samples is shown in Figure 11. The PDV obtained for the beef samples is shown in Figure 12. Measurement of the electrochemical response of the positive samples was indicated at −0.85 V, and the peak increased with the increase in concentration. On the

other hand, the negative control *A. hydrophila* produced a negligible current. The electrochemical genosensor detection method has many advantages: it is quick, specific, and sensitive for pathogenic bacteria detection. In the present study, the electrochemical genosensor detection method was used to detect *E. coli* O157:H7 and showed high precision in *E. coli* O157:H7 detection. It could detect a very small amount of *E. coli* O157:H7. The genosensor was also applied in real samples (beef samples contaminated artificially) and showed good sensitivity and selectivity to pathogenic bacteria. The fDNA modified by a thiol group was enhanced and immobilized on GE. CdSNPs were synthesized using chemical methods and characterized by TEM; they were then conjugated with an amine group on the modified probe. Modification of MWCNT-chitosan with bismuth on the GCE surface increased electrochemical detection capacity. The signal of the released cadmium ions increased with increasing tDNA concentration. Therefore, this method will be very useful in food safety and quality control as an efficient and quick method for monitoring pathogenic bacteria in samples.

From Producer to Consumer: Greenhouse Tomato Quality As Affected by Variety, Maturity Stage at Harvest, Transport Conditions, and Supermarket Storage

Michèl J. Verheul,* Rune Slimestad, and Irene Holta Tjøstheim

Norwegian Institute for Agricultural and Environmental Research—Bioforsk Vest Særheim, Postvegen 213, N-4353 Klepp Station, Norway

ABSTRACT: Possible causes for differences in quality traits at the time of buying were studied in two widely different red tomato types. Three maturity stages were harvested from commercial greenhouses and transferred immediately to controlled environments simulating different storage, transport, and supermarket conditions. Results show significant differences in development of color, fruit firmness, contents of soluble solids (SSC), titratable acids (TTA), phenolics, and carotenoids from harvest to sale, as related to postharvest conditions. Fruit firmness, SSC, and TTA of vine-ripened red cherry tomatoes was 30, 55 and 11% higher than for those harvested at breakers and ripened to red. Temperature, light, UVC radiation, or ethylene during 4 days transport affected tomato quality traits, and differences persisted during 3 weeks of supermarket storage. Ethylene exposure gave a 3.7-fold increase in lycopene content in cherry tomatoes, whereas UVC hormesis revealed a 6-fold increase compared with the control. Results can be used to update recommendations concerning optimal handling.

KEYWORDS: *Lycopersicon esculentum Mill., quality, on-vine ripening, postharvest treatment, color, firmness, taste, soluble solid content, total acid content, carotenoids, flavonoids*

INTRODUCTION

Tomato fruit quality is usually understood as a combination of some or all of the following parameters: visual appearance, firmness and texture, dry matter content, organoleptic compounds, and health influencing compounds.[1] Research on tomato fruit storage has mostly focused on shelf life in terms of appearance and firmness.[2] However, taste and health-influencing compounds of fresh tomatoes are of high relevance from a consumer perspective.[3] The initial decision to buy fruit and vegetables is usually made on the basis of appearance and firmness, while the frequency and magnitude of subsequent purchases depend largely on consumer assessment of eating quality. In the case of tomatoes, taste is mainly defined by the content of reducing sugars and organic acids.[4−6] Both sugars and acids contribute to the sweetness and to the overall aroma intensity.[7] Firmness is appreciated by Norwegian consumers who consider firmness and texture to be strongly related.[3]

Tomatoes together with processed products thereof are important parts of the traditional Mediterranean diet associated with low mortality of cardiovascular diseases.[8] Lycopene, the main carotenoid in red tomato, has received special attention because of results from epidemiological studies as well as from cell culture and animal studies that suggest that lycopene may lower the risk of cancer and cardiovascular diseases.[9] In addition, tomato is a valuable source of β-carotene, a pro-vitamin A compound, which, like lycopene, is a strong lipophilic antioxidant. Because of the high consumption of tomato-based products worldwide, attention has also been given to other phytochemicals from this species. The flavonol rutin (quercetin 3-(6″-rhamnosyl)-glucoside), together with chalconaringenin (a chalcone), was found at higher concentrations than lycopene in fresh cherry tomatoes.[10] Both compounds exhibit antiradical and antioxidant properties. Because rutin and apiorutin (quercetin 3-(2″apiosyl-6″-rhamnosyl)-glucoside)[11] are hydrophilic compounds, they are supposed to work differently from the carotenoids. Chlorogenic acid (5′-caffeoyl quinic acid) is an aromatic acid in fresh tomatoes that occurs together with isomeric compounds and other minor phenylpropanoids. Together, these compounds may account for concentrations similar to rutin in fresh tomatoes. As a result of the orto-catechol structure of chlorogenic acid, it is supposed to have some of the same antioxidant functions as rutin.

Early harvesting is a common practice employed to obtain firmer fruit suitable for transport. In Norway, wholesalers demand fruits to be harvested at maturity stage "breakers". A storage temperature of 10−13 °C in the dark is often chosen to guarantee a long shelf life.[12] Wholesalers obtain firmer fruits suitable for long distance transport and a longer marketable period. This commercial practice was justified by Lin and Block.[13] Because newer varieties often have a longer shelf life, this practice also leads to long-time storage, up to 3 weeks, in the supermarket before red ripe tomatoes reach the consumer.[14] Little is known about the effects of storage conditions on organoleptic and health-influencing compounds of fresh tomatoes. Consumers complain about the lack of taste of tomatoes in numerous newspaper and magazine articles.[15] The number of tomato varieties and types grown in Norwegian greenhouses for fresh consumption has increased dramatically the last 5 years. All types and varieties are stored the same way, and it is not known whether different tomato varieties and types react differently to storage conditions.

Variables such as maturity stage at harvest and environmental conditions during transport and supermarket storage might be crucial for tomato quality. Earlier studies have shown that maturity stage at harvest may influence postharvest quality.[1] The effects of growing conditions on the quality of different tomato cultivars were reviewed earlier.[16]

Postharvest treatment with UVC radiation might increase tomato quality, and sunlight might decrease tomato quality.[17] Long-distance transport in Norway often includes suboptimal storage conditions because of joint transport with other products that require low temperature (2−8 °C) or give off ethylene. Little is known about the effects and possible aftereffects of transportation on the quality of the tomato that reaches the consumer.

We carried out an experiment to quantify the effects of (1) maturity stage at harvest and (2) environmental conditions during transport on tomato quality during simulated supermarket storage at 22 °C. Two widely different tomato varieties were used. Storage at 22 °C was compared to standard storage conditions at 12 °C in the dark. The effects of postharvest treatment with UVC radiation or ethylene were elucidated.

MATERIALS AND METHODS

Plant material. Fully developed cherry tomatoes (*Lycopersicon esculentum* Mill. 'Susanne') and round tomatoes (*Lycopersicon esculentum* Mill. 'Dometica') at maturity stage "breakers", "pink", or "red"[18] were harvested from two commercial greenhouses in southwestern Norway (58°47′ N, 5°41′ E) on August 30 and September 8, 2010 and stored at 12 °C (±0.2 °C) in the dark at a relative humidity (RH) of 85% (±3%). Only undamaged fruits were harvested and handled carefully to decrease possible effects on flavor perception.[15] Fruit age at harvest was respectively 40, 47, and 54 days after flowering for 'Susanne', and 50, 57, and 64 days after flowering for 'Dometica' for maturity stages breakers, pink and red. Fruit size was 17 ± 3 g for 'Susanne' and 80 ± 5 g for 'Dometica'. Samples for analyses were taken on August 31 and September 3, 6, 14, and 20 for first harvest and on September 9, 13, 16, 23, and 30 for second harvest. All treatments included three maturity stages and three replications. Each sample consisted of six fruits, giving a total number of 9720 fruits.

Storage Conditions. Fruits from both cultivars and all three maturity stages were transferred randomly to 20 m^3 storage rooms with forced ventilation and different temperature and light conditions. In the time period from day 1 until day 4 after harvesting, different transport conditions were simulated. Conditions, selected after communication with Norwegian wholesalers, included different temperatures: 2, 8, 12, and 15 °C, all in the dark, exposure to light provided by fluorescent tubes (Osram L58W/21) with a light intensity of 150 μmol m^{-2} s^{-1} at fruit height while kept at a temperature of 12 °C, or exposure to ethylene (150 ppm) at a temperature of 2 °C in the dark. To elucidate the effects of UVC radiation, fruits were exposed to UVC radiation provided by UV lamps (Osram HNS 15W OFR) with a light intensity of 350 μmol m^{-2} s^{-1} at fruit height for 15 or 90 s at 12 °C and thereafter kept at 12 °C in the dark. All treatments were kept at a relative humidity of 85% (±3%). Temperature fluctuations in all storage rooms were kept within ±0.2 °C.

After simulated transportation for 96 h (day 4), the fruits were transferred to a storage room with a temperature of 22 °C, a light intensity of 40 μmol m^{-2} s^{-1} at fruit height provided by fluorescent tubes (Osram L58W/21), and a relative humidity of 85% (±3%) for 17 days, thus simulating storage conditions measured in Norwegian supermarkets in August 2010. As a control, fruits were kept in a storage room at 12 °C and 85% relative humidity in the dark. Fruits showing microbiological decay were excluded from the quality analysis.

Chemicals. Chalconaringenin (CN) and rutin were isolated from cherry tomatoes as described previously.[10] All other chemicals were obtained from Sigma-Aldrich, Norway.

Quality Traits. Color, firmness, soluble solid content (SSC), and total titratable acid (TTA) were measured following the methods of Mitcham and co-workers,[19] and the mean value from the measurements of four to six individual tomatoes was used to describe the quality of a sample. Tomato color was determined in accordance with a color sheet scaling from 1, which is equivalent to full green, to 12 which is fully red fruit. Colors 4, 8, as 12 represent maturity stages "breakers", "pink", and "red".[18] Firmness was measured on two opposite sides at a maximum distance from the columella for each of four tomatoes by use of a durometer (Durofel, Agro-Technologies, France). Complete lack of firmness is given number 1, whereas 100 means full firmness. Fruit firmness below 40 is considered to be nonsaleable in a Norwegian supermarket. SSC was determined by the use of a digital PR-100α refractometer (Atago Co., Japan) of tomato juice at ambient temperature. Juice was pressed by hand and measured; the data were expressed as the equivalent °Brix (or percent SSC). For the assessment of TTA, four to six tomatoes for each sample were chopped in a food processor until maximum homogenization was achieved. The sample was transferred to a 0.5 L plastic bag, sealed, and stored at −20 °C until further analyses. Within 2 weeks, ∼5 g of each sample was thawed, mixed with ∼20 mL of deionized water, and titrated (Basic Titrini 794, Metrohm, Switzerland) against 0.1 M NaOH until end equivalence point at pH 8.5−8.9. Total acid was expressed as citric acid equivalents (milligrams of CAE per 100 g FW).

HPLC Analyses. HPLC analyses were made on samples from the second harvest. A liquid chromatograph (Agilent 1100 system, Agilent Technologies) supplied with an autosampler and a photodiode array detector was used for the analysis of individual phenolics and carotenoids. Separation of the phenolics was achieved by an Eclipse XDB-C8 (4.6 × 150 mm, 5 μm) column (Agilent Technologies) and the use of a binary solvent system consisting of (A) 0.05% TFA in water and (B) 0.05% TFA in acetonitrile. The gradient (B in A) was linear from 5% to 10% in 5 min; from 10% to 25% for the next 5 min; from 25% to 85% in 6 min; from 85% to 5% in 2 min; and finally, reconditioning of the column by 5% for 2 min. The flow rate was 0.8 mL min^{-1}; 10 μL samples were injected onto the column, and separation took place at 30 °C. Flavonoids were detected at 370 nm, whereas aromatic acids were detected at 320 nm. Carotenoids were separated over the same column by use of the binary solvent system (A) methanol−acetonitrile−water−0.2 M Tris−HCl (pH 7.4) (15:65:18:2 v/v) and (B) methanol-*n*-hexane (7:1) with the gradient (B in A) linear from 0% to 100% in 15 min; 100% isocratic for 10 min; linear from 100% to 0% in 3 min; and finally, reconditioning of the column for 2 min.[20] The flow rate was 1.0 mL min^{-1}, 20 μL samples were injected onto the column, and separation took place at 30 °C. Lycopene and β-carotene were detected at 450 nm. All HPLC samples were filtered through a 13 mm syringe filter (Whatman Nylon filter 0.45 μm, Sigma-Aldrich) prior to injection. Individual standard curves were used to quantify chalconaringenin, rutin, chlorogenic acid, lycopene, and β-carotene. Quercetin 3-(2″-apiosyl-6″-rhamnosyl)-glucoside (apiorutin) was quantified as an equivalent of rutin, whereas the phenolic compounds **1**−**3** (Figure 7) exhibiting chromatographic and spectral properties similar to that of chlorogenic acid were quantified as equivalents of chlorogenic acid.

Statistics. Statistical analysis included two sampling dates at harvesting, three replications, two cultivars, three maturity stages, nine treatments (nine storage conditions during simulated transport and two storage conditions after transport) and five sampling dates after harvesting. For statistical analysis, mean values for six fruits were used. To evaluate the effects of supermarket conditions, fruits kept from day 1 to day 4 at 12 °C in the dark before transfer to 22 °C in the light were compared with fruits kept at 12 °C in the dark for 21 days. The effects of simulated transport conditions were evaluated after transfer to 22 °C in the light. Results were subjected to analysis of variance using the GLM procedure from the SAS statistical computer program (version 9.2). The SNK test was used to determinate significant differences between cultivars, maturity stages, storage conditions, transport conditions and days after harvesting at a level of significance of $P < 0.05$.

RESULTS AND DISCUSSION

Tomato Quality at Harvest. Tomato quality traits at the start of the experiment are given in Table 1. Maturity stage at harvest had a significant effect on color; taste; and taste-related factors, such as firmness, soluble solid content (SSC), and total titratable acid concentration (TTA). The effects were different for the two tomato types. In 'Susanne', SSC was considerably higher when harvested more mature, whereas this effect was absent in 'Dometica'. TTA was lower in more mature fruits of both cultivars. As expected, fruits were less firm when harvested more mature, but this effect was more pronounced in 'Susanne'. In addition, the content of flavonoids and carotenoids increased with increasing maturity stage. The highest contents of lycopene and β-carotene were found in red cherry tomatoes ('Susanne'), as expected from earlier observations.[21,22] Earlier studies with respect to taste-related components for tomato at harvesting time show contrasting results. Watada and Aulenbach could not find significant differences in SSC between fruits of round tomatoes harvested at different maturity stages.[23] Lopez et al. found the highest concentrations of sugars and acids in tomatoes at the breakers stage.[6] According to Davies and Hobson, a decrease in sugar content as the fruit approaches full ripeness was most frequently found, whereas Roberts et al., Raffo et al., and Cantwell found higher SSC in fruits of specialty tomatoes that were harvested more mature.[24−27] It is well established that tomato varieties can vary markedly in acidity. Titratable acidity has earlier been reported both to increase and to decrease with ripening stage.[6,24] Contrasting results might be explained by the use of different tomato types or cultivars in the experiments. Specialty tomato types and newer varieties might be more sensitive to changes in taste-related components at harvesting time than common round tomatoes or older varieties.[25]

Development of Tomato Quality during Storage. The main effects of the development of tomato quality during storage at simulated supermarket conditions when compared with storage at a temperature of 12 °C in the dark (control) are shown in Table 2. The color value increased at 22 °C when compared with 12 °C. The color development of 'Susanne' was severely reduced for all three maturity stages when kept in the dark, whereas 'Dometica' fruits harvested at breakers stage were not able to reach a fully red color in the "supermarket" (Figure 1). Color development in tomatos is reported to depend on the temperature. The optimal temperature for lycopene synthesis is between 16 and 26 °C.[28,29] Firmness decreased more when the tomatoes were stored at 22 °C compared with 12 °C, and the firmness decreased more in 'Susanne' when compared with 'Dometica', resulting in considerable losses of saleable fruits for "Susanne" harvested red after 14−21 days at 22 °C (Figure 2). The SSC content in both tomato cultivars decreased during storage, and even more at 22 °C compared with 12 °C (Figure 3). This might correspond to a higher respiration rate at the higher temperature.[25] The initial differences in SSC in tomatoes harvested at different maturity stages persisted during storage. Particularly, tomatoes harvested at the breakers stage retained a higher SSC when stored at 12 °C as compared with those

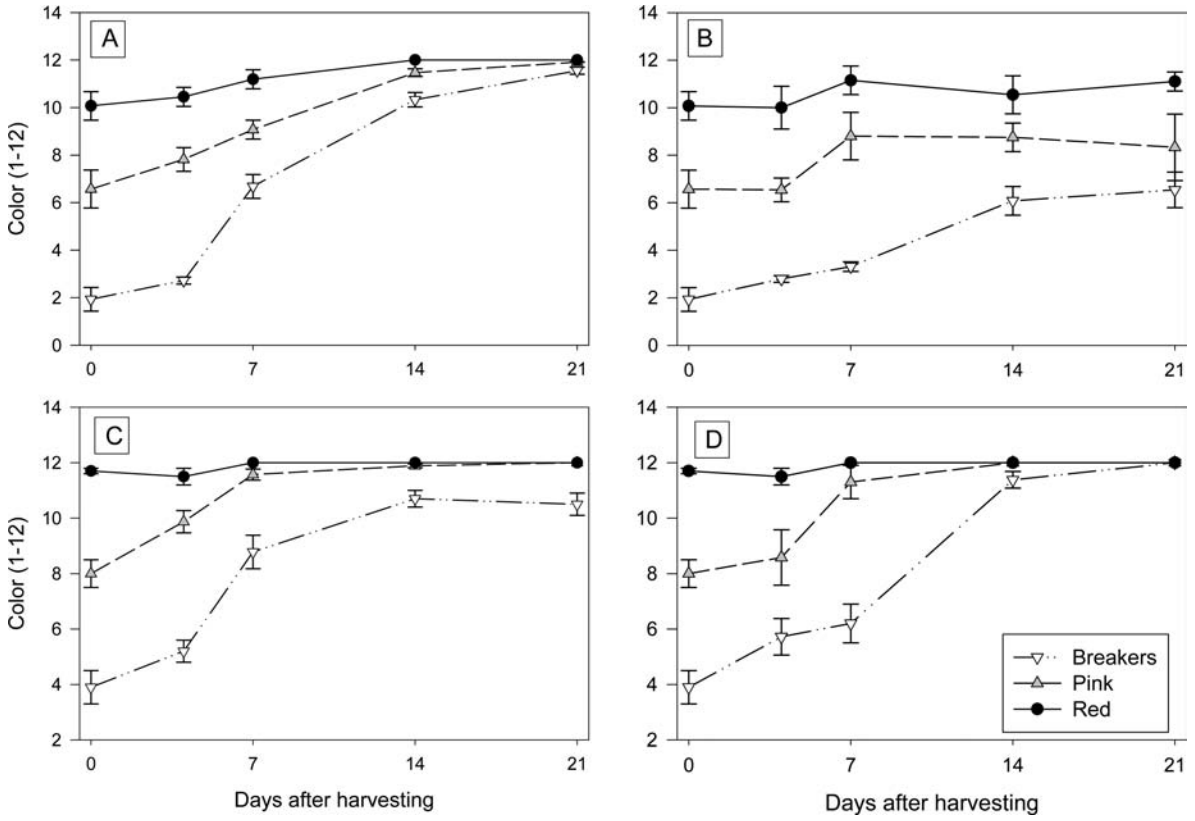

Figure 1. Color value of tomato 'Susanne' (A,B) and "Dometica" (C,D) harvested at different ripening stages (—··· breakers, - - - pink, — red) and stored under simulated supermarket conditions (A,C) or in the dark at 12 °C (B,D) for 21 days (mean values ± s.e., n = 6).

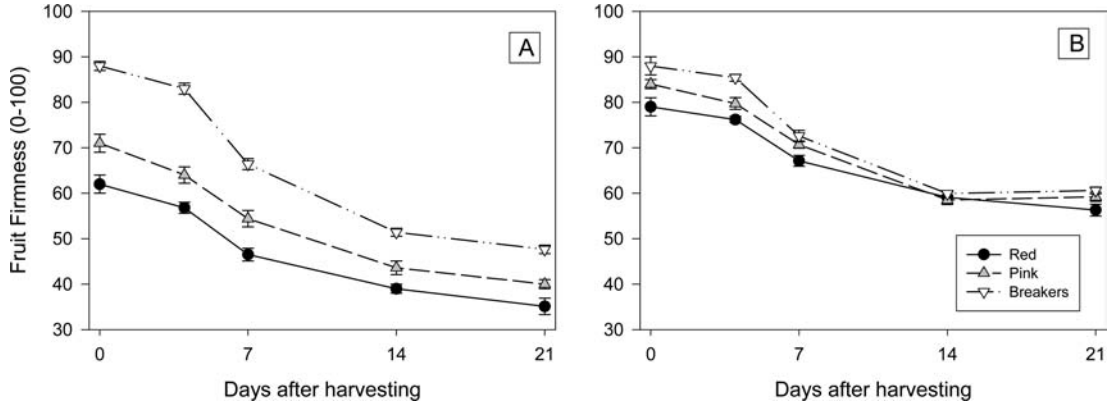

Figure 2. Fruit firmness of tomato 'Susanne' (A) and 'Dometica' (B) harvested at different ripening stages (—··· breakers, - - - pink, — red) and stored under simulated supermarket conditions for 21 days (mean values ± s.e., n = 6).

stored at 22 °C (Table 3). The TTA also decreased during storage (Table 1). Fruit firmness, SSC, and TTA of vine-ripened red 'Susanne' were 30, 55, and 11% higher than for those harvested at breakers and ripened to red. For 'Dometica', this was 32, 15, and 12%, respectively.

Mention of a decrease in firmness after harvesting tomatoes is commonly found in literature. Earlier experiments show contrasting results for taste-related components. Lin and Block concluded that vine-ripe red round tomatoes have quality attributes similar to that of tomatoes room-ripened at 20−22 °C.[13] Bui et al. pointed out that SSC and TTA did not change during postharvest.[30] The present experiment shows that the taste attributes of vine-ripened red tomatoes are considerably better than those of tomatoes harvested at breakers or pink and ripened to red, particularly for 'Susanne' (Figure 4). A better taste of vine-ripened tomatoes is confirmed by earlier observations by Betancourt et al.[31] and Roberts et al.[25]

Color, firmness, and taste are important quality parameters for consumers' willingness to pay.[3] Results in the present experiment show that fruits of a tomato variety with the same color and firmness may have different taste-related components. The uncertainty about taste may reduce consumers' willingness to pay. More knowledge on the effects of storage conditions on taste of high-quality tomato types is required to compete in lucrative markets. Reaching this market will also bring more challenges. The vine-ripened red cherry tomato type 'Susanne' in the present experiment had the best taste-

related properties but shorter shelf life and will therefore require quicker handling to reach consumers.

Breaker tomatoes with no initial extractable lycopene exhibited a slow production of lycopene upon storage in darkness at 12 °C (Figure 4). After 2 weeks, a slight increase in this content was recognized in 'Susanne', whereas 'Dometica' during the first week seemed to initiate a certain production, but this faded during the rest of the storage period. Tomatoes harvested as pink had a higher initial lycopene concentration but followed the same pattern with respect to lycopene content. Red controls gave an abrupt decrease in lycopene content for both tomato types. From the 4th to the 15th day of storage, the content of extractable lycopene was low, but content increased rapidly at the end of the storage period, especially in 'Susanne'. The metabolism of β-carotene closely followed that of lycopene for the two tomato types; however, at a concentration level about one-tenth that of lycopene. The content of extractable lycopene did not correlate well with tomato color under some circumstances, especially not for breakers and red tomatoes (Figures 1b,d and 5). Correlation coefficients (R) were found to be −0.30 and −0.87 for breaker and red tomatoes of 'Dometica', and 0.32 and 0.09 for breaker and red tomatoes of 'Susanne'. In most of the analyzed samples, the content of lycopene is in agreement with their visible maturity stage or it is lower. In some cases. the content of extractable lycopene is higher than what would be expected on the basis of fruit color. For example, in 'Susanne', 21 days after harvesting, the content of extractable lycopene is 8 times higher than those analyzed at day 15, but this difference was not measurable as a color change. The results show that color by itself is not necessarily a good marker for extractable lycopene. Among the tomatoes that were stored in the darkness, those that were harvested fully ripened and had been stored for 3 weeks revealed the highest content of extractable lycopene. During fruit ripening, lycopene accumulates in the outer skin layer. One reason for low extractivity of the compound is the compactness of the tomato peel tissue, which hinders solvent penetration and transport to the chromoplasts. Furthermore, lycopene is tightly bound to membranous structures inside the organelle. These structures seem to be broken by action of cellulases, hemicellulases, and pectinases, which thus enhances the extractability of lycopene.[32] It seems that tomato carotenoids in ripened and mature fruit are not so strongly connected to membranous structures compared with the content found in less-ripened tomatoes. This might be an important issue with respect to impact of lycopene on human health because extractability of lycopene has been shown to correlate with the bioavailability of lycopene.[33]

Effects of Transport Conditions on Tomato Quality in the Supermarket. The main effects of transport conditions on tomato quality in the supermarket are shown in Table 4. No significant interactions were found between transport conditions and storage duration. Thus, differences in tomato quality traits directly after transport (sampling date 4) were also evident afterward at 22 °C (sampling dates 7, 14, and 21). Color development was highest after a transport temperature of 15 °C and lowest when tomatoes were submitted to ethylene

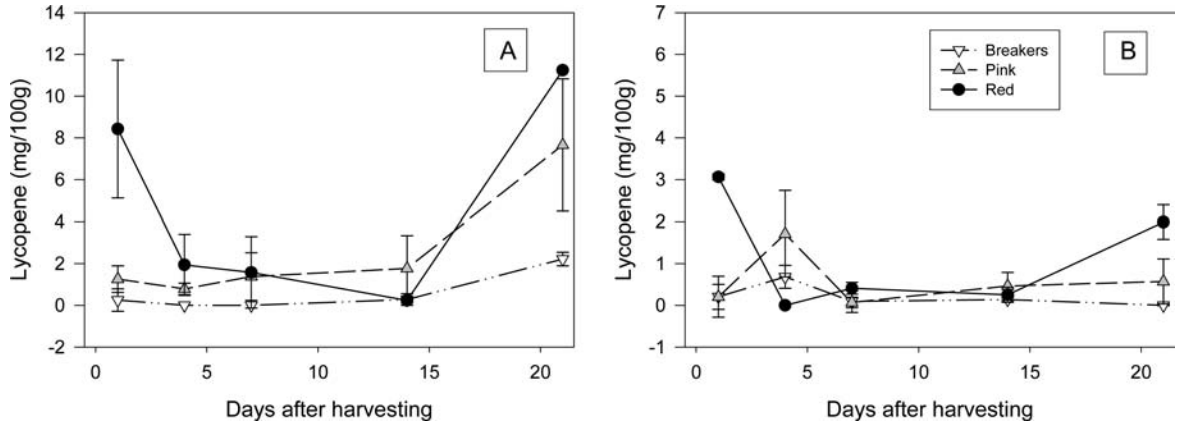

Figure 4. Content of lycopene in 'Susanne' (A) and 'Dometica' (B) of tomatoes harvested at different ripening stages (—··· breakers, - - - pink, — red) and stored in the dark at 12 °C during 21 days (mean values ± SD, n = 3).

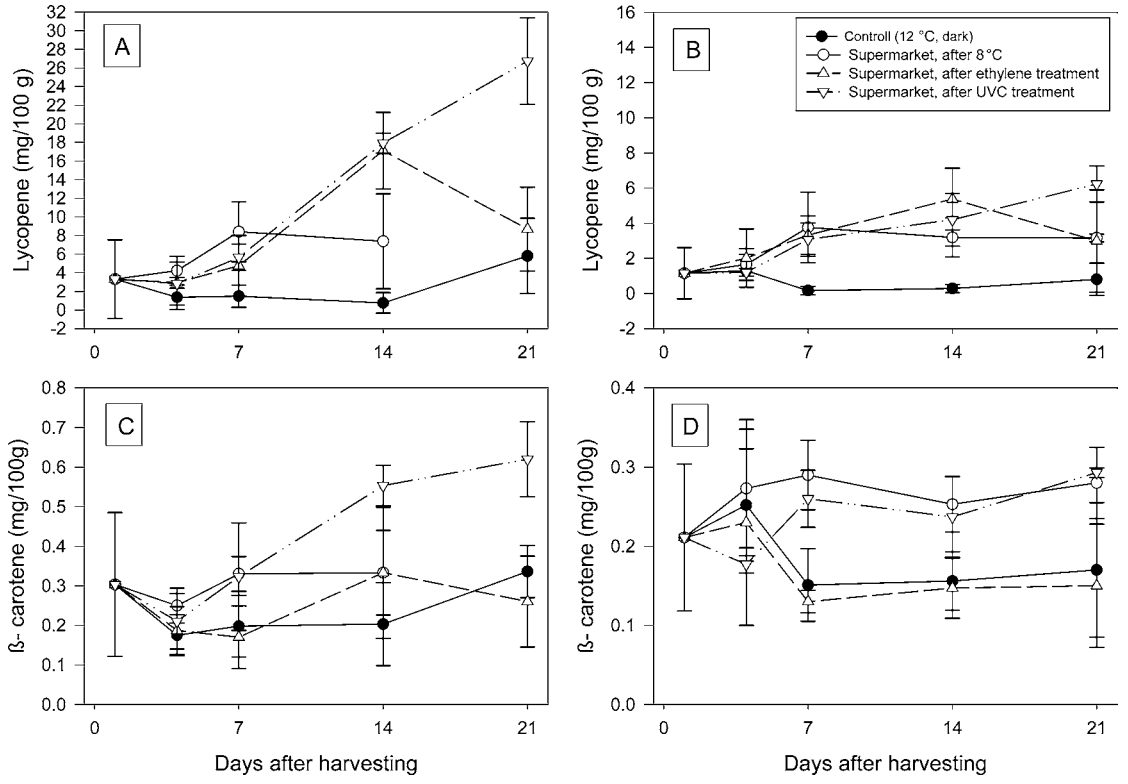

Figure 5. Content of lycopene (A,B) and β-carotene (C,D) in samples of 'Susanne' (A,C) and 'Dometica' (B,D) as a function of transport and storage conditions: supermarket, after transport at 8 °C in the dark (−o−), ethylene treatment (−Δ−), or 90 s UVC treatment (−V−) or control at 12 °C in the dark (−●−). All tomatoes were harvested at ripening stage pink. Mean values ± SD (n = 3).

Table 4. Main Effects of Transport Conditions on Color, Firmness, SSC, and TTA of Tomatoes in the Supermarket[a]

transport conditions	color (1−12)	firmness (1−100)	SSC (°Brix)	TTA (milligrams per 100 g)
2 °C	9.6 (cd)[b]	62 (ab)	5.9 (ab)	480 (b)
8 °C	9.5 (cd)	64 (a)	5.8 (ab)	520 (a)
12 °C	9.5 (cd)	64 (a)	5.8 (ab)	520 (a)
15 °C	10.5 (a)	58 (b)	5.9 (a)	472 (b)
light exposure	9.6 (cd)	61 (ab)	5.7 (bc)	475 (b)
ethylene exposure	9.0 (d)	62 (ab)	5.6 (c)	498 (ab)
UVC; 15 s	10.3 (ab)	59 (b)	5.9 (a)	466 (c)
UVC; 90 s	9.9 (bc)	62 (ab)	5.9 (ab)	493 (b)

[a]Two tomato cultivars with three maturity stages; 4,7,14, and 21 days after harvest; n = 144. [b]Values followed by different letters are significantly different according to SNK-test at $P < 0.05$ level.

during 4 days of transport. Transport at 15 °C and submission to UVC radiation for 15 s reduced tomato firmness compared with other transport conditions. Soluble solid content at 22 °C was higher for fruits transported at 15 °C or submitted to UVC radiation for 15 s and significantly lower for fruits transported when submitted to ethylene or fluorescent light. The TTA content at 22 °C was highest for fruits kept at 8 or 12 °C during transport and lowest for fruits submitted to 15 s of UVC radiation.

The results of the present experiment show that transport conditions during 4 days after harvest can have measurable effects on tomato quality in the supermarket. However, the effects are small compared with the effects of the cultivar and maturity stage at harvest on tomato quality (Table 2).

Earlier research has indicated that tomatoes should be stored at 10 °C or higher to avoid chilling injury.[25,34] Kader et al. provided evidence of adverse effects of low temperature (5 °C) on tomato flavor.[35] Even storage temperatures of 12.5 °C or lower may be detrimental to tomato flavor quality.[15] The present experiments shows that a temperature of 2−12 °C during transport had only a limited effect on tomato quality parameters such as color, firmness, SSC, and TTA. Kader reported a positive effect of ethylene on tomato quality, but the opposite was the case in the present experiment.[36] Charles et al. found that UV-treated fruits stored at 13 °C for 21 days had better texture and taste than nontreated fruits, although their appearance and color were rated poorer.[37]

Optimal storage conditions might be dependent on cultivar and maturity stage.[12] This could be confirmed in the present experiment. Significant interaction was found between conditions during transport and cultivar for color ($p < 0.05$), SSC ($p < 0.001$), and TTA ($p < 0.001$) and between transport conditions and maturity stage for SSC ($p < 0.01$) (data not shown). Recommended transport and storage conditions for tomatoes might therefore have to be reconsidered, depending on cultivars and maturity stage at harvest, to provide better-tasting tomatoes for the consumer.

Postharvest effects on carotenoids and flavonoids. Tomatoes harvested at maturity stage "pink" and kept at 8 °C in the dark for the first 4 days before being transferred to supermarket conditions (22 °C, light), exhibited a linear increase in lycopene and β-carotene production compared with control samples, kept at 12 °C in the dark, during the first 3 days after transfer to supermarket conditions (Figure 5).

DOI: 10.1021/jf505450j
J. Agric. Food Chem. 2015, 63, 5026−5034

Thereafter, the increase in the amount of both metabolites in both cultivars stagnated. In tomatoes initially exposed to ethylene, the amount of lycopene exceeded that found in nontreated fruits, and the concentrations increased continuously until 2 weeks after harvest. The effect of ethylene exposure on the development of β-carotene was different, however, and followed the low-concentration path found in control samples. The effects of initial UVC radiation for 90 s were even more pronounced than those of ethylene. The rise in concentration of lycopene and β-carotene prolonged during the whole storage period and was most pronounced for 'Susanne'.

Carotenoids are present in the thylakoid membranes of plants.[38] One part of their function is to serve as accessory pigments for light-harvesting in photosynthesis. Because they are part of light-harvesting complexes, the level of carotenoids will, in general, increase as a function of light irradiation. The dependence on light and temperature was demonstrated upon transfer of nontreated fruits to supermarket conditions (Figure 5). Alba et al. demonstrated the role of light quality on tomato phytochromes in the production of lycopene in tomato cultivars.[39] It was found that red light induced lycopene 2.3-fold, whereas far-red light reversed this production. The proportion of far-red light in the lamps used in the present experiment was lower than the proportion of red light. This might in part explain the rise in carotenoid content during the "supermarket" storage period.

The increase in content of tomato lycopene follows the general fruit ripening process. In addition, specific environmental factors make an impact on this metabolism. The most common stimulators of lycopene synthesis in harvested fruits are storage temperature and ethylene.[40] In general, storage temperatures of 20−30 °C stimulate lycopene production, whereas temperatures of 5 °C or less reduce lycopene.[2,41] Storage at 22 °C may thus have stimulated the carotenoid production in the tomatoes. Together with the light effect, this may explain the rise in lycopene during the simulated supermarket storage period; however, the temperature effect is reported to be specific for the different carotenoids, and an increase in temperature from 21 to 26 °C has been found to reduce the content of β-carotene without affecting lycopene.[42]

Ethylene acts as a plant hormone that stimulates ripening, cell wall softening, and subsequent lycopene formation in tomatoes and bitter melon.[40] In watermelon, subsequent use of ethylene caused cellular breakdown of placental tissue in immature and mature fruit and increased lycopene content by 10%. Here, ethylene treatment of 'Susanne' displayed a 3.7-fold enhancement in lycopene toward the control. Because the exposure took place at 2 °C (for 2 days), followed by 2 days without ethylene but at same low temperature and in darkness, the effect of temperature alone could give a decrease in lycopene.[2,41] It is therefore reasonable to conclude that the increase in lycopene is an effect of ethylene alone. The initial effect of ethylene might explain the prolonged increase in lycopene level of the "supermarket" storage of both tomato types versus the control.

The effectiveness of UVC hormesis for manipulation of tomato lycopene and β-carotene content has been found to depend on dosage(s) and combined treatments.[43] Liu and coworkers reported a strong increase in lycopene content after daily irradiation of mature green (breaker) tomatoes, whereas the concentration of β-carotene was unaffected.[17] Others reported a negative effect on lycopene and color development.[44,45] In addition to these results, the present data reveal a hormesis effect on both carotenoids in both tomato types.

Breaker cherry tomatoes were found to contain higher levels of flavonoids than fruits harvested at pink and red stages (Table 1). Chalconaringenin (CN) is the major compound among the flavonoids in breakers and pink tomatoes, and its content increased in pink tomatoes under simulated transportation conditions, especially at 8 °C in darkness. During storage at 22 °C, the concentration of CN declined, irrespective of simulated transport conditions (Figure 6). This is consistent with

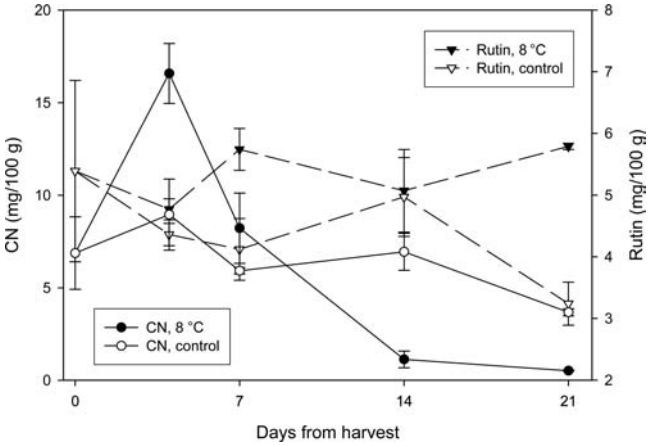

Figure 6. Content of chalconaringenin (CN) (−●−) and rutin (−▼−) in 'Susanne' harvested at breaker stage, pretreated at 8 °C, and stored under simulated supermarket conditions for 21 days. Controls (−o−, −V−) were stored at 12 °C in the darkness. Mean values ± SD (n = 3).

previous observations of the cherry cultivar Jennita.[21] However, controls (12 °C, darkness) of 'Susanne' gave no significant reduction in either CN or total flavonoid contents. This may imply that the CN metabolic turnover relies on genetic differences for otherwise close cultivars. Rutin is the major flavonoid in red cherry tomatoes, and its content, together with those of quercetin 3-apiosylrutinoside and kaempferol 3-rutinoside, were found to be stable during simulated transportation and supermarket conditions. This is in agreement with earlier observations.[21] Chlorogenic acid is the major aromatic acid in tomatoes.[16] Its concentration declined as a function of maturity stage upon harvest and during "supermarket" storage irrespective of "transport" conditions (Figure 7). This seems to follow a recognized pattern of caffeic acid derivatives in tomatoes.[21,26] Three more compounds were tentatively identified as more hydrophilic caffeic acid derivatives than chlorogenic acid, according to their HPLC retention factors, online UV-spectra, and previous detection of such compounds in tomatoes.[46] In contrast to chlorogenic acid, a weak rise in concentration was observed both as a function of ripening degree at harvest and during postharvest ripening, that is, under simulated supermarket conditions.

The results might explain discrepancies found in earlier research in postharvest tomato quality, and this justifies a need to update earlier recommendations concerning optimal handling conditions for high-quality tomatoes in the consumers' market.

Inhibition of the Aggregation of Lactoferrin and (−)-Epigallocatechin Gallate in the Presence of Polyphenols, Oligosaccharides, and Collagen Peptide

Wei Yang, Fuguo Liu, Chenqi Xu, Cuixia Sun, Fang Yuan, and Yanxiang Gao*

Beijing Key Laboratory of Functional Food from Plant Resources, College of Food Science & Nutritional Engineering, China Agricultural University, Beijing 100083, People's Republic of China

ABSTRACT: The aggregation of lactoferrin and (−)-epigallocatechin gallate (EGCG) was inhibited by polyphenols, oligosaccharides, and collagen peptide in this study. Polyphenols, oligosaccharides, or collagen peptide can effectively prevent the formation of lactoferrin−EGCG aggregates, respectively. The addition sequence of lactoferrin, polyphenols (oligosaccharides or collagen peptide) and EGCG can affect the turbidity and particle size of the ternary complexes in the buffer solution; however, it hardly affected the ζ-potential and fluorescence characteristics. With either positive or negative charge, polyphenols and collagen peptide disrupted the formation of lactoferrin−EGCG aggregate mainly through the mechanism of its competition with EGCG molecules which surrounded the lactoferrin molecule surface with weaker binding affinities, forming polyphenols or a collagen peptide−lactoferrin−EGCG ternary complex; for neutral oligosaccharides, the ternary complex was generated mainly through steric effects, accompanied by a change in the lactoferrin secondary structure induced by gallic acid, chlorogenic acid, and xylo-oligosaccharide. Polyphenols, oligosaccharides, or collagen peptide restraining the formation of lactoferrin−EGCG aggregate could be applied in the design of clear products in the food, pharmaceutical, and cosmetic industries.

KEYWORDS: *aggregation inhibitors, lactoferrin, (−)-epigallocatechin gallate, polyphenols, oligosaccharides, collagen peptide*

INTRODUCTION

Polyphenol may interact with protein reversibly by usually noncovalent forces such as hydrogen bonding, hydrophobic bonding, and van der Waals forces.[1−3] Turbidity is generally due to the binding of polyphenol present in beverage and food products from plant origin with proteins to form aggregates. At the same time, the protein−polyphenol complexes are considered to be responsible for the sensation of astringency on the human palate. Astringency is often perceived as an undesirable quality factor in some beverages such as fruit juices and red wine if they are too intense.[4] The interaction between polyphenol and proteins has been proven to generate negative effects, reducing the palate lubrication, causing an unpleasant sensation of roughness, dryness, and constriction and reducing absorption of nutrients.[5−7]

There exist a number of factors, such as pH, ionic strength, alcohol, nature of the solvent, and presence of carbohydrates, affecting the protein−polyphenol haze formation in food systems.[8] Several studies have demonstrated that some polysaccharides, such as pectin, xanthan gum, and arabic gum, can be applied as food colloids, to disrupt polyphenol and protein interaction in food systems.[7,9−13] There are three mechanisms responsible for the inhibition of protein−polyphenol aggregation by some polysaccharides: (1) molecular association between polysaccharides, such as arabic gum, β-cyclodextrin, and polyphenols, competing with protein aggregation;[7,13] (2) the formation of a protein−polyphenol−polysaccharide ternary complex, enhancing its solubility in aqueous medium, such as pectin;[13] (3) steric effects, limiting the number of available binding sites of proteins to readily fit polyphenols, such as dextran.[9]

It is well-known that EGCG can act as a multidentate ligand and bridge protein,[2,14] forming a lactoferrin−EGCG aggregate. Yang et al. reported that EGCG was spontaneously bound to lactoferrin by a two-stage mechanism: first EGCG molecules were bound within the hydrophobic pockets of lactoferrin with strong binding affinities, and then EGCG molecules surrounded the lactoferrin molecule surface with weaker binding affinities. A further increase in EGCG concentration led to phase separation (haze formation).[15]

Some functional food ingredients, such as polyphenols, oligosaccharides, and collagen peptide, are widely used in beverage, food, and pharmaceutical formulations. Proteins are thought to have a number of sites bound by polyphenols, oligosaccharides, or peptides.[16−18] Oligosaccharides and collagen peptide, on the other hand, have a number of ends that could bind polyphenols. Therefore, polyphenols, oligosaccharides, or peptides might affect the interaction between the protein and polyphenol when these components are intergrated together. So far, the effect of polyphenols, polysaccharides, and collagen peptide on the interaction of the polyphenol with protein has been largely overlooked. Phenolic compounds are chemically structured as a hydroxyl group bonded to an aromatic ring. Dietary polyphenols, natural compounds largely in fruits, vegetables, and cereals, are consumed as part of the human diet in significant amounts[19,20] and have become an intense focus of research interest due to their health-beneficial effects, especially in the treatment and prevention of several chronic diseases. Oligosaccharides,

especially xylo-oligosaccharide (XOS) and fructo-oligosaccharide (FOS), with a mouthfeel similar to that of sugar but being only 20−70% as sweet as table sugar, have received much attention recently as functional food ingredients.[21] They are often applied to enhance the survivability and colonization of probiotic bacteria when they are enriched in foods.[22] Because of its nutritional and medical benefits, collagen peptide is easily absorbed by the human body due to its low molecule weight and is often used as an ingredient and additive of functional foods and nutraceuticals.[23]

The objective of this work was to elucidate the effect of polyphenols, oligosaccharides, and collagen peptide on the aggregation of EGCG with lactoferrin. A clear dispersion containing lactoferrin, EGCG, and polyphenols (oligosaccharides or collagen peptide) can be applied in many fields, such as the food, pharmaceutical, and cosmetic industries.

MATERIALS AND METHODS

Materials and Chemicals. Lactoferrin (purity ≥92.0%) from bovine whey was purchased from New Image International Limited (New Zealand). EGCG (purity ≥95.0%), gallic acid (purity ≥98.0%), and chlorogenic acid (purity ≥99.0%) was purchased from BSZH Science (Beijing, People's Republic of China). Glucose (purity ≥99.0%) was purchased from Beijing Chemical Reagent (Beijing, People's Republic of China). XOS (purity ≥95.0%) was supplied by Longlive Biotechnology Co., Ltd. (Shandong, People's Republic of China). FOS (purity ≥95.0%) was supplied by Baolingbao Biotechnology Co., Ltd. (Shandong, People's Republic of China). Collagen peptide (purity ≥99.0%; 2000 Da) from tilapia skin was supplied by Beijing Semnl Biotechnologies Co., Ltd. (Beijing, People's Republic of China).

Sample Preparation. Lactoferrin (1.6% w/v, 0.2 mM) and EGCG (0.1832 w/v, 4.0 mM) were dissolved in 10 mM potassium phosphate buffer solution (pH 6.0), and the solutions were each stirred constantly at 25 °C for at least 2 h.

Preparation of Ternary Complexes Containing Lactoferrin, EGCG, and a Polyphenol, Oligosaccharide, or Collagen Peptide. Three addition sequences were applied to prepare the ternary complexes in the buffer solution. Different volumes of polyphenols, oligosaccharides, or collagen peptide stock solutions were mixed with designed volumes of potassium phosphate buffer solution. For the experiments, stock solutions of polyphenols (0.3% gallic acid, 1.0% chlorogenic acid), glucose and oligosaccharides (21.0%), and collagen peptide (9.0%) were prepared with potassium phosphate buffer solution.

Method I (M1). Briefly, 2.0 mL of lactoferrin (1.6% w/v, 0.2 mM) and 1.0 mL of EGCG (0.1832% w/v, 4.0 mM) solutions were mixed on a vortex shaker (QL-866, Haimen QILINBEIER Instruments Co., Ltd., Haimen, People's Republic of China) at 3000 rpm for 1 min. The mixture was allowed to stand for 2 h. After that, 1.0 mL of polyphenol, oligosaccharide, or collagen peptide solution in different concentrations was added and mixed for 1 min, and the mixture was allowed to stand for 2 h before the measurement.

The abbreviation X-1 (X = gallic acid, chlorogenic acid, glucose, XOS, FOS, collagen peptide) is used to represent the ternary complexes containing lactoferrin, EGCG, and a polyphenol, oligosaccharide, or collagen peptide prepared by M1.

Method II (M2). Briefly, 2.0 mL of lactoferrin (1.6% w/v, 0.2 mM) and 1.0 mL of a polyphenol, oligosaccharide, or collagen peptide solution in different concentrations were mixed on a vortex shaker (QL-866, Haimen QILINBEIER Instruments Co., Ltd., Haimen, People's Republic of China) at 3000 rpm for 1 min. These mixtures were allowed to stand for 2 h. Then, 1.0 mL of EGCG (0.1832% w/v, 4.0 mM) solution was added to the different mixtures. After that, these mixtures were blended for 1 min and allowed to stand for 2 h before the measurement.

The abbreviation X-2 (X = gallic acid, chlorogenic acid, glucose, XOS, FOS, collagen peptide) is used to represent the ternary complexes containing lactoferrin, EGCG, and a polyphenol, oligosaccharide, or collagen peptide prepared by M2.

Method III (M3). In brief, 1.0 mL of EGCG (0.1832% w/v, 4.0 mM) and 1.0 mL of a polyphenol, oligosaccharide, or collagen peptide solution in different concentrations were mixed on a vortex shaker (QL-866, Haimen QILINBEIER Instruments Co., Ltd., Haimen, People's Republic of China) at 3000 rpm for 1 min. The mixtures were allowed to stand for 2 h. After that, 2.0 mL of lactoferrin (1.6% w/v, 0.2 mM) solution was added to these mixtures. Then these mixtures were blended for 1 min and allowed to stand for 2 h before the measurement.

The abbreviation X-3 (X = gallic acid, chlorogenic acid, glucose, XOS, FOS, collagen peptide) is used to represent the ternary complexes containing lactoferrin, EGCG, and a polyphenol, oligosaccharide, or collagen peptide prepared by M3.

Turbidity Measurements. Nephelometry experiments were performed with a HACH 2100N Laboratory Turbidimeter (Loveland, USA), and the aggregation behavior of lactoferrin and EGCG in the absence and presence of polyphenol, oligosaccharide, or collagen peptide solution in buffer solution was evaluated. The optical apparatus was equipped with a tungsten-filament lamp with three detectors: a 90° scattered-light detector, a forward-scatter light detector, and a transmitted light detector. The calibration was performed using a Gelex Secondary Turbidity Standard Kit (HACH, Loveland, USA), which consists of stable suspensions of a metal oxide in a gel. All experiments were performed in triplicate.

Particle Size Measurements. Particle size and size distribution of the ternary complexes in the buffer solution were determined by dynamic light scattering (DLS) using a Zetasizer Nano-ZS90 (Malvern Instruments, Worcestershire, U.K.). The intensity of light scattered was monitored at a 90° angle. Results are described as cumulant mean diameter (size, nm) for particle size and polydispersity index (PdI) for size distribution. All experiments were performed in triplicate.

ζ-Potential Measurements. The ζ potential of ternary complexes in the buffer solution was determined by a Zetasizer Nano-ZS90 particle electrophoresis instrument (Malvern Instruments, Worcestershire, U.K.). Samples were loaded in the cell, and the temperature was set at 25 °C without further dilution. The ζ-potential values are reported as the average of measurements for three freshly prepared samples, with three readings recorded for each sample.

Fluorescence Spectroscopy Measurements. Fluorescence measurements were carried out using a fluorescence spectrophotometer (F-7000, Hitachi, Japan). Spectra were collected when the mixtures were kept at 25 °C for 2 h.

Fluorescence emission spectra of the ternary complexes were recorded with an excitation wavelength at 292 nm. The synchronous fluorescence spectra were determined in the continuous range of 300−600 nm with $\Delta\lambda$ at 60 nm. Both excitation and emission band widths were set at 10 nm.

Circular Dichroism Measurements. The CD spectra were recorded using a CD spectropolarimeter (Pistar π-180, Applied Photophysics Ltd. U.K.) in rhw far-UV (190−250 nm) region under constant nitrogen flush. The path length was 0.1 cm for the far-UV region. Ellipticity was recorded at a speed of 100 nm/min, 0.2 nm resolution, 20 accumulations, and 2.0 nm bandwidth. The collected data were analyzed using Dichroweb, the online Circular Dichroism Web site (http://dichroweb.cryst.bbk.ac.uk).[24,25] Each spectrum presented was obtained as the average of three consecutive scans with automatic subtraction of the buffer and/or polyphenol, oligosaccharide, or collagen peptide spectra. The concentrations of polyphenols, oligosaccharides, or collagen peptide in ternary complexes were 0.75% for gallic acid, 0.25% for chlorogenic acid, 10.25% for glucose, FOS, and XOS, and 2.25% for collagen peptide.

Statistical Analysis. The experiments were conducted in duplicate, and all analyses were done in triplicate. The results are presented as the means ± standard deviation. Data were analyzed by one-way analysis of variance using the SPSS 16.0 package (SPSS Inc., Chicago, IL, USA), and significant differences of means ($p < 0.05$) were determined using the Duncan multiple-range test. The correlation analysis was carried out using the Pearson mode. The

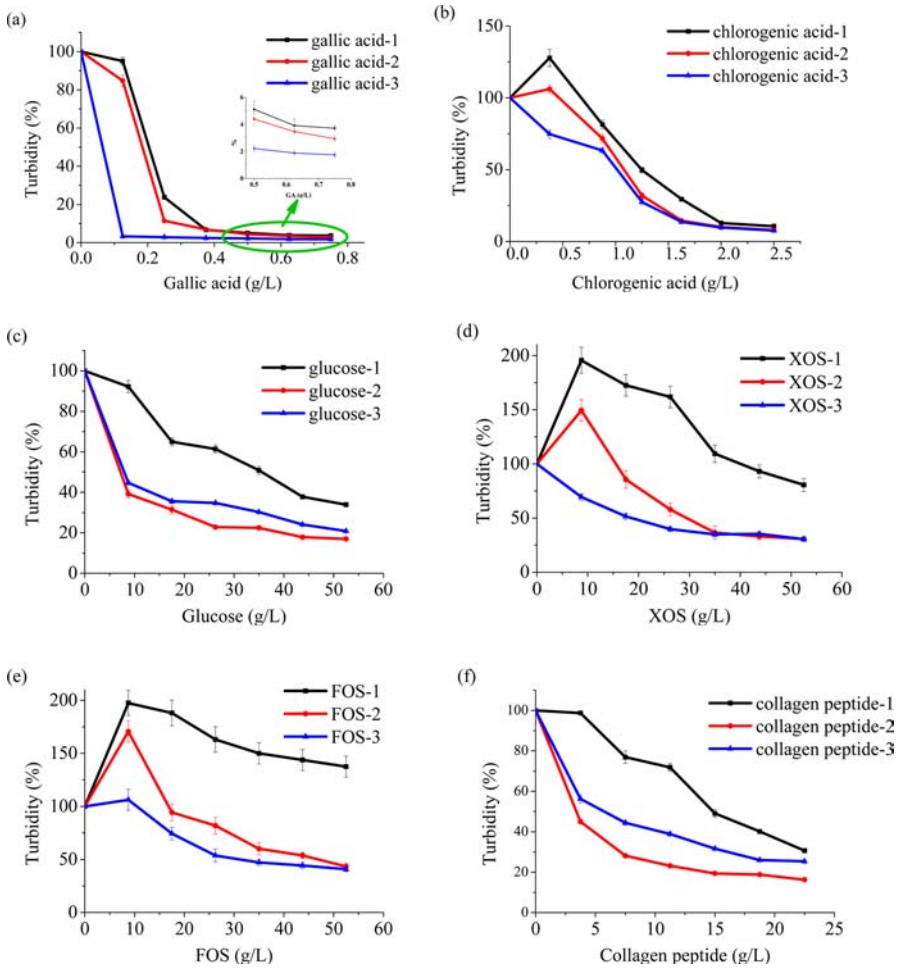

Figure 1. Variation (%) in turbidity of lactoferrin−EGCG aggregate (containing 1.0 mM EGCG) with increasing concentrations of polyphenols, oligosaccharides, or collagen peptide.

concordance between experimental data and calculated values was established by the root-mean-squared deviation.

RESULTS AND DISCUSSION

The turbidity of the lactoferrin−EGCG aggregate in the buffer solution was around 160 NTU when the EGCG concentration was 1.0 mM. It should be noted that the ζ potential of the lactoferrin and lactoferrin−EGCG aggregate was around 0 mV, despite the pH of the buffer being below the reported isoelectric point of lactoferrin (pI ≈ 8). The most likely explanation for this effect is that the cationic groups on the adsorbed lactoferrin bound some anionic phosphate ions present in the buffer.[26]

Several assays were performed with progressively increasing concentrations of polyphenols, oligosaccharides, or collagen peptide, until practically no changes in the amount of insoluble lactoferrin−EGCG aggregate were observed. The effect of the component addition sequence on the turbidity, particle size, and structure of the ternary complexes was also investigated.

Nephelometry Measurements. Nephelometry measures the formation of the structures of high-molecular-weight substances at a macromolecular level, taking into account all physicochemical driving forces involved in the formation of aggregates. It is very interesting to find that, except for a few cases, the presence of the polyphenols, oligosaccharides, or collagen peptide in the solution restrained the formation of lactoferrin−EGCG insoluble aggregates (Figure 1).

The turbidity of the aggregates in the buffer solution prepared by three addition sequences progressively decreased with an increase in gallic acid, chlorogenic acid, and collagen peptide concentrations, respectively, which indicated that smaller particles were formed to scatter light for the ternary complexes. M3 was the most effective method to inhibit the formation of lactoferrin−EGCG aggregate for gallic acid and chlorogenic acid, while M2 was the most effective method for collagen peptide. These results revealed that gallic acid was the most effective (the gallic acid amount required was about 10-fold lower than that of chlorogenic acid and about 100-fold lower than that of collagen peptide) in restraining the interaction between lactoferrin and EGCG.

The presence of glucose, XOS, and FOS, respectively, in the solution retarded the formation of insoluble lactoferrin−EGCG aggregate with use of M2 and M3. M2 was the most effective method for glucose, while M3 was the most effective method for XOS and FOS.

It should be noted that some exception was observed for chlorogenic acid, XOS, and FOS by M1 and M2. Significant ($p < 0.05$) increases of the insoluble aggregates were found at low concentrations, 0−0.5 g/L for chlorogenic acid and 0−10 g/L for XOS and FOS, which could be explained by their size increase, resulting from the adsorption of chlorogenic acid,

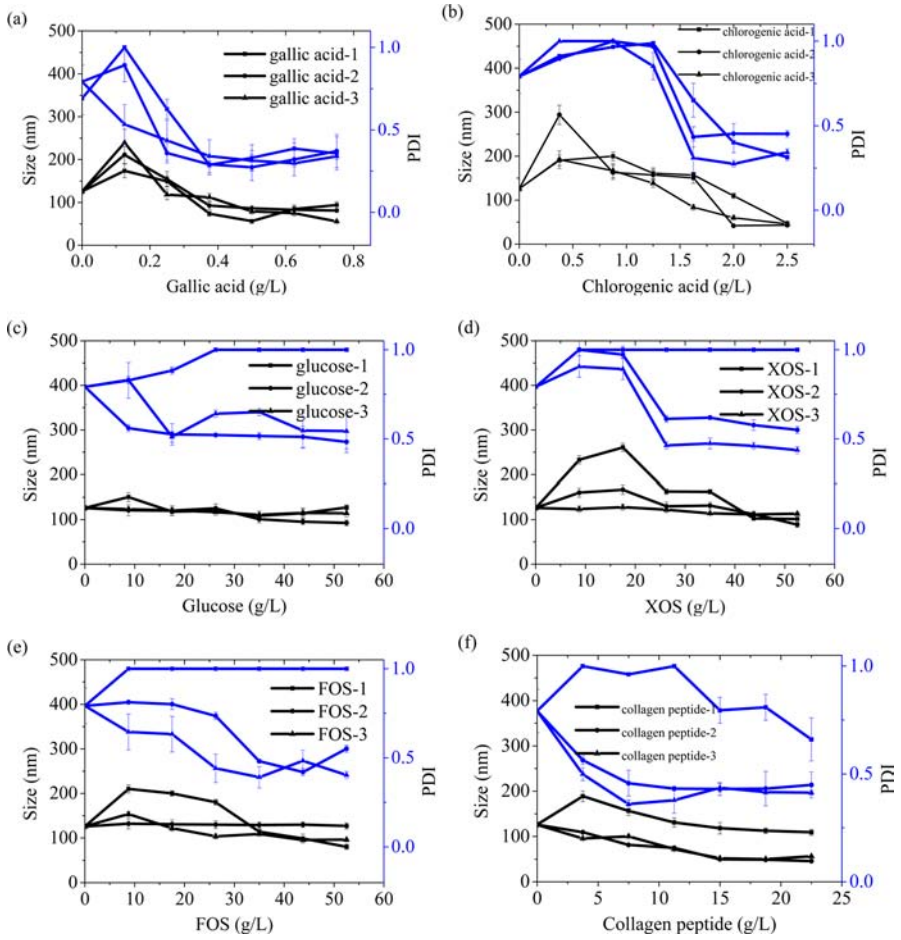

Figure 2. Influence of polyphenol, oligosaccharide, or collagen peptide concentration on the particle size of lactoferrin−EGCG aggregate (containing 1.0 mM EGCG).

XOS, or FOS molecules on the surface of lactoferrin−EGCG aggregate. This result was similar to that in the report of de Freitas et al., which showed that the presence of dextran in the insoluble aggregates formed by procyanidins and bovine serum albumin tended to remain constant or to slightly increase.[9] In particular, for XOS and FOS by M1, but not by M2, a further increase in the concentration of XOS and FOS did not show an effective inhibition of the aggregation between lactoferrin and EGCG. These results obviously revealed that the turbidity of the ternary complexes in the buffer solution was mostly related to the addition sequence of lactoferrin, polyphenol (oligosaccharide or collagen peptide), and EGCG, especially for XOS and FOS.

On the basis of the aforementioned results, it was possible to classify the capacity of polyphenols, oligosaccharides, and collagen peptide in retarding the aggregation: gallic acid > chlorogenic acid > collagen peptide > glucose > XOS > FOS.

Size Measurements of Ternary Complexes. The measurement of ternary complex size in the buffer solution resulting from the interaction between lactoferrin and EGCG in the absence and presence of polyphenols, oligosaccharides, or collagen peptide was performed by DLS. Figure 2 shows the mean particle size and polydispersity of aggregates. As expected, with an increase in polyphenol, oligosaccharide, or collagen peptide concentration, the mean particle size showed changes synchronous with the turbidity.

It is interesting to find that, as the aggregation decreased, a narrow range of particle size distribution was observed for gallic acid, chlorogenic acid, and collagen peptide, respectively, by M1, M2, and M3 (a decreased PDI value, from 0.792 to 0.34 for gallic acid, to 0.314 for chlorogenic acid, and to 0.413 for collagen peptide), indicating a homogeneous population of these aggregates.

As glucose, XOS, and FOS concentrations increased, the aggregation of the ternary complexes decreased and a narrow range of the particle size distribution was also observed (a decreased PDI value, from 0.792 to 0.483 for glucose, to 0.437 for XOS, and to 0.403 for FOS) by M2 and M3, also implying a heterogeneous population of these aggregates. An opposite phenomenon was observed by using M1; that is, the PDI value was increased to around 1.0 as the concentrations of glucose, XOS, and FOS, respectively, were increased, indicating the formation of more heterogeneous aggregates.

Yang et al. reported that EGCG molecules might be first bound within the hydrophobic pockets of lactoferrin with strong binding affinities. As the concentration of EGCG increased, it surrounded the lactoferrin molecule surface with weaker binding affinities, acting as multidentate ligands and bridge proteins or as a protein−polyphenol complex, leading to the formation of metastable dispersions of particles; further, an increase of polyphenols led to phase separation (haze formation).[15] Therefore, it is hypothesized that when lactoferrin and EGCG were mixed together in the absence of

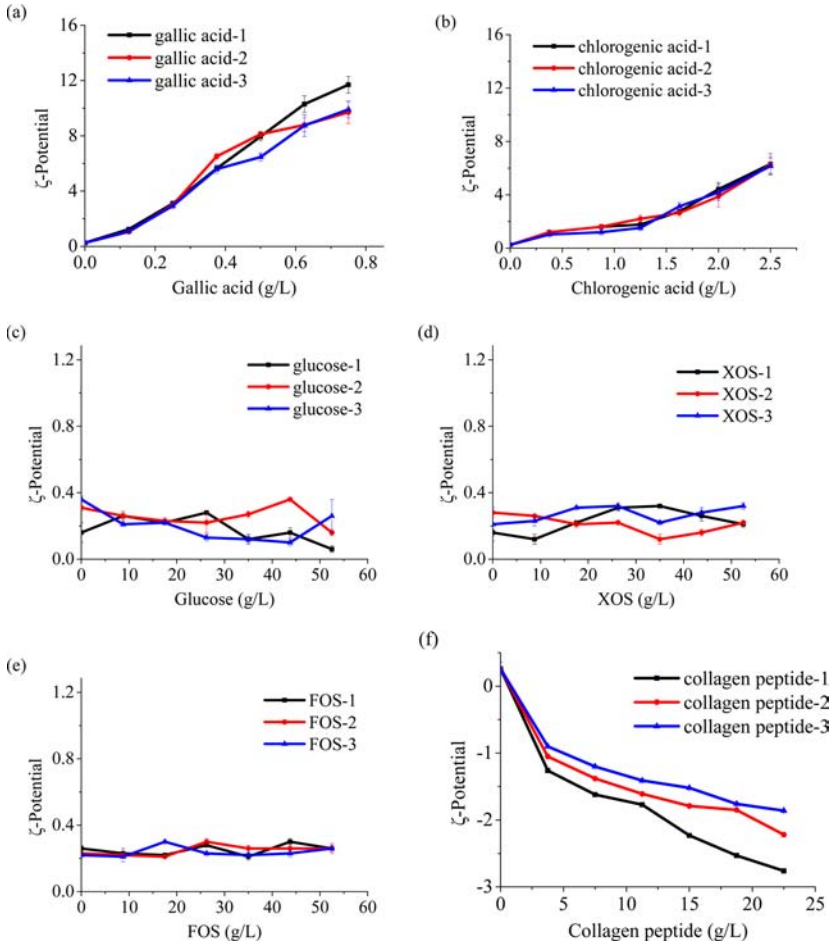

Figure 3. Influence of polyphenol, oligosaccharide, or collagen peptide concentration on the ζ potential of lactoferrin−EGCG aggregate (containing 1.0 mM EGCG).

polyphenols, oligosaccharides, or collagen peptide (M1), a large network structure with high PDI value was first formed, leading to phase separation. After the addition of a certain amount of polyphenols, oligosaccharides, or collagen peptide, the network was gradually disrupted by EGCG molecules which covered the lactoferrin molecule surface with weaker binding affinities, forming new smaller networks or complexes with low PDI value (for example, gallic acid and chlorogenic acid) or larger networks with a PDI value of around 1.0 (for example, XOS and FOS). When lactoferrin or EGCG and a polyphenol, oligosaccharide, or collagen peptide were first mixed together (M2 and M3, respectively), the interaction between lactoferrin and EGCG was disrupted by the polyphenol, oligosaccharide, or collagen peptide through a competition mechanism or steric effects, forming new smaller networks accompanied by a decreased PDI value.

ζ-Potential Measurements. The ζ potential plays an important role in the stability of protein−polysaccharide or protein−polyphenol complexes in aqueous solution. Figure 3 shows the ζ potential of complexes presented in the solution resulting from the interaction between lactoferrin and EGCG in the absence and presence of polyphenols, oligosaccharides, or collagen peptide.

In this study, the ζ-potential values of the ternary complexes increased with an increase of gallic acid and chlorogenic acid and decreased with an increase of collagen peptide, leading to particle deaggregation at higher concentration. Unlike the case for gallic acid, chlorogenic acid, and collagen peptide, it was interestingly found that the ζ potential of the ternary complexes was around 0 mV, also leading to particle deaggregation at higher concentrations of glucose, XOS, and FOS, respectively. However, the concentrations of a neutral carbohydrate, such as glucose, XOS, or FOS, were much higher in comparison to those of gallic acid, chlorogenic acid, and collagen peptide, which are thought to have an ionic character. This result interpreted the low affinity of neutral carbohydrates for polyphenols, as reported by other authors.[27,28]

There might be a simple relationship between the ability to inhibit the formation of lactoferrin−EGCG aggregate and ζ potential; that is, charged polyphenols and collagen peptide (whether positively or negatively charged) were more effective in the decrease of aggregation than noncharged oligosaccharides.

Fluorescence Spectroscopy Measurements. There are 13 tryptophan residues in the lactoferrin structure.[29] The emission of tryptophan may be blue-shifted if the group is buried within a native protein, and its emission may be red-shifted when the protein is unfolded.[30] By monitoring of the emission peak change, some information could be obtained concerning the structural change and the microenvironment surrounding the fluorophore in the protein. Synchronous fluorescence spectra supplied some information about the molecular environment in the vicinity of the chromophore molecules. When $\Delta\lambda$ = 60 nm, spectral characteristics of

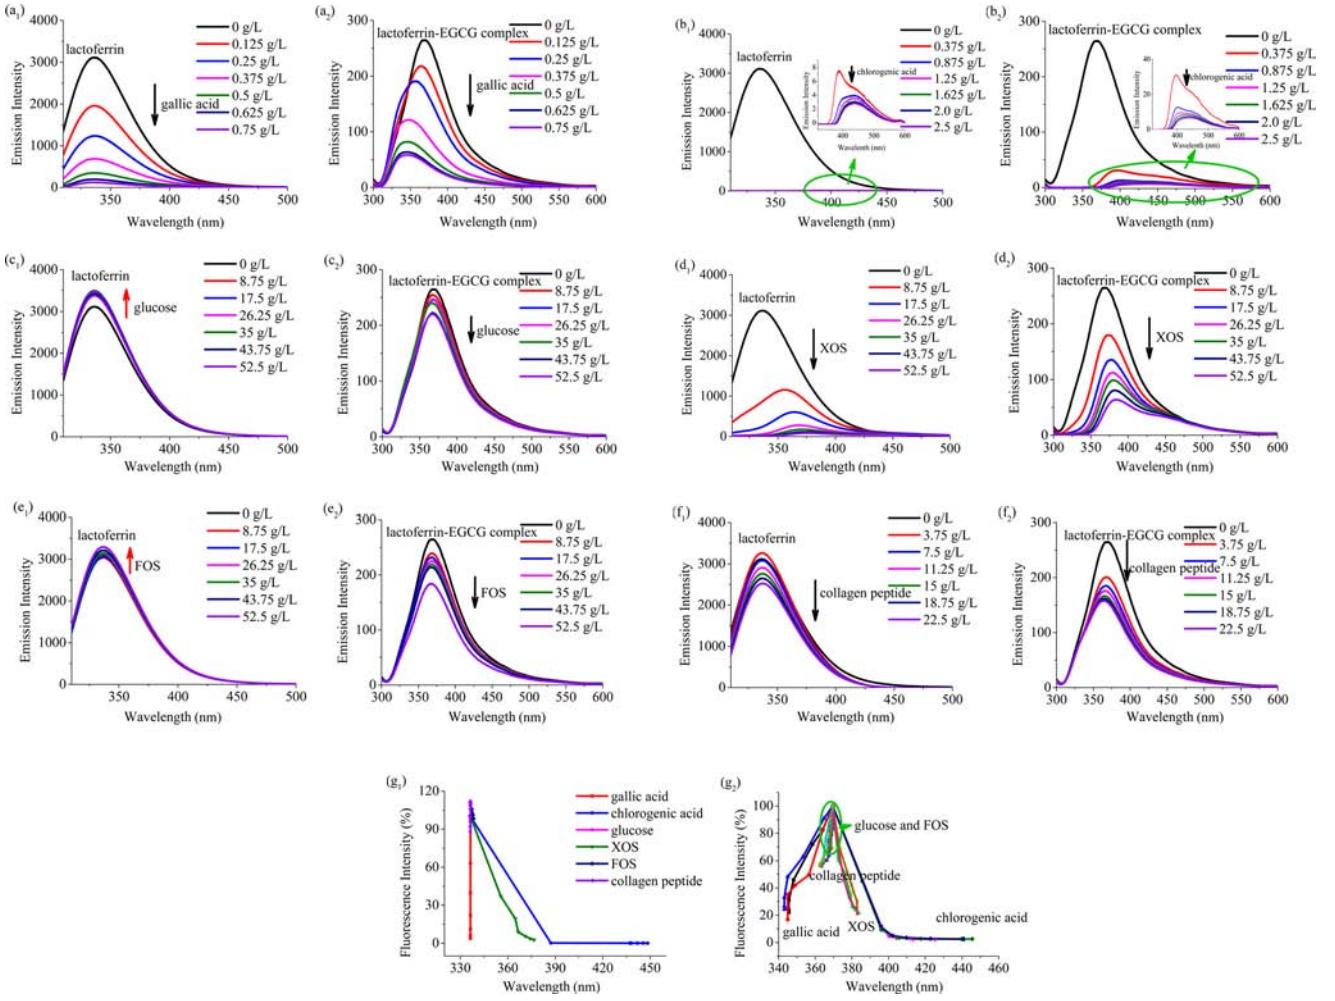

Figure 4. Fluorescence emission spectra of lactoferrin, in the absence and presence of polyphenols, oligosaccharides, or collagen peptide (a_1–f_1), influence of increasing concentrations of polyphenols, oligosaccharides, or collagen peptide on the variation of the fluorescence of lactoferrin solution (g_1), fluorescence emission spectra of lactoferrin–EGCG aggregate (containing 1.0 mM EGCG), in the absence and presence of polyphenols, oligosaccharides, or collagen peptide (a_2–f_2), and the influence of increasing concentrations of polyphenols, oligosaccharides, or collagen peptide on variation of the fluorescence of lactoferrin–EGCG aggregate (containing 1.0 mM EGCG) (g_2).

tryptophan residues in the protein were observed.[31] The shift in the position of the emission maximum (λ_{max}) corresponded to the change in polarity around the chromophore molecule. Thus, the conformation change of lactoferrin could be estimated by this measurement.[32,33]

The fluorescence emission spectrum (at λ_{ex} 292 nm) obtained for lactoferrin in the absence and presence of polyphenols, oligosaccharides, or collagen peptide is shown in Figure 4a_1–f_1. A high degree of fluorescence quenching was observed for gallic acid (from 100% to 3.9%), chlorogenic acid (from 100% to 0.09%), and XOS (from 100% to 2.7%). However, as the concentrations of glucose, FOS, and collagen peptide were respectively increased, the intensity of the fluorescence only slightly increased (for glucose and FOS) or decreased (for collagen peptide). Similar trends were also observed with synchronous fluorescence (Figure 5a_1–f_1). This implied that binding behavior existed between lactoferrin and gallic acid, chlorogenic acid, or XOS, respectively but that there was hardly any interaction between lactoferrin and glucose, FOS, or collagen peptide, respectively. Since M2 and M3 showed fluorescent properties closely similar to those of M1 (the fluorescence spectra data of M2 and M3 are not shown), only M1 is used for analysis in the following sections.

The fluorescence emission spectrum obtained for lactoferrin–EGCG aggregate in the absence and presence of polyphenols, oligosaccharides, or collagen peptide is shown in Figure 4a_2–f_2. Similar to the effect of polyphenols, oligosaccharides, or collagen peptide on lactoferrin, a high degree of fluorescence quenching of lactoferrin–EGCG aggregate was observed for gallic acid (from 100% to 2.4–2.6%), chlorogenic acid (from 100% to 16.8–24.3%), and XOS (from 100% to 20.8–24%) (Figure 4g_1,g_2). At the same time, there were obvious blue shifts of the maximum λ_{em} of fluorescence for gallic acid (from 369.6 to 343.2–351.4 nm), obvious red shifts with chlorogenic acid (from 369.6 to 440.6–445.6 nm), and red shifts with XOS (from 369.6 to 382.4–383.8 nm), accompanied by significant quenching of the fluorescence, which implied that binding behaviors existed between lactoferrin–EGCG aggregate and gallic acid, chlorogenic acid, or XOS, respectively. Therefore, it was inferred that the interactions of lactoferrin–EGCG aggregate with gallic acid, chlorogenic acid, or XOS, respectively, led to the compact structure of lactoferrin and increase of the hydrophobicity in the microenvironment of tryptophan residues with gallic acid, while the protein structure was unfolded and the hydrophilicity of the microenvironment of tryptophan residues for chloro-

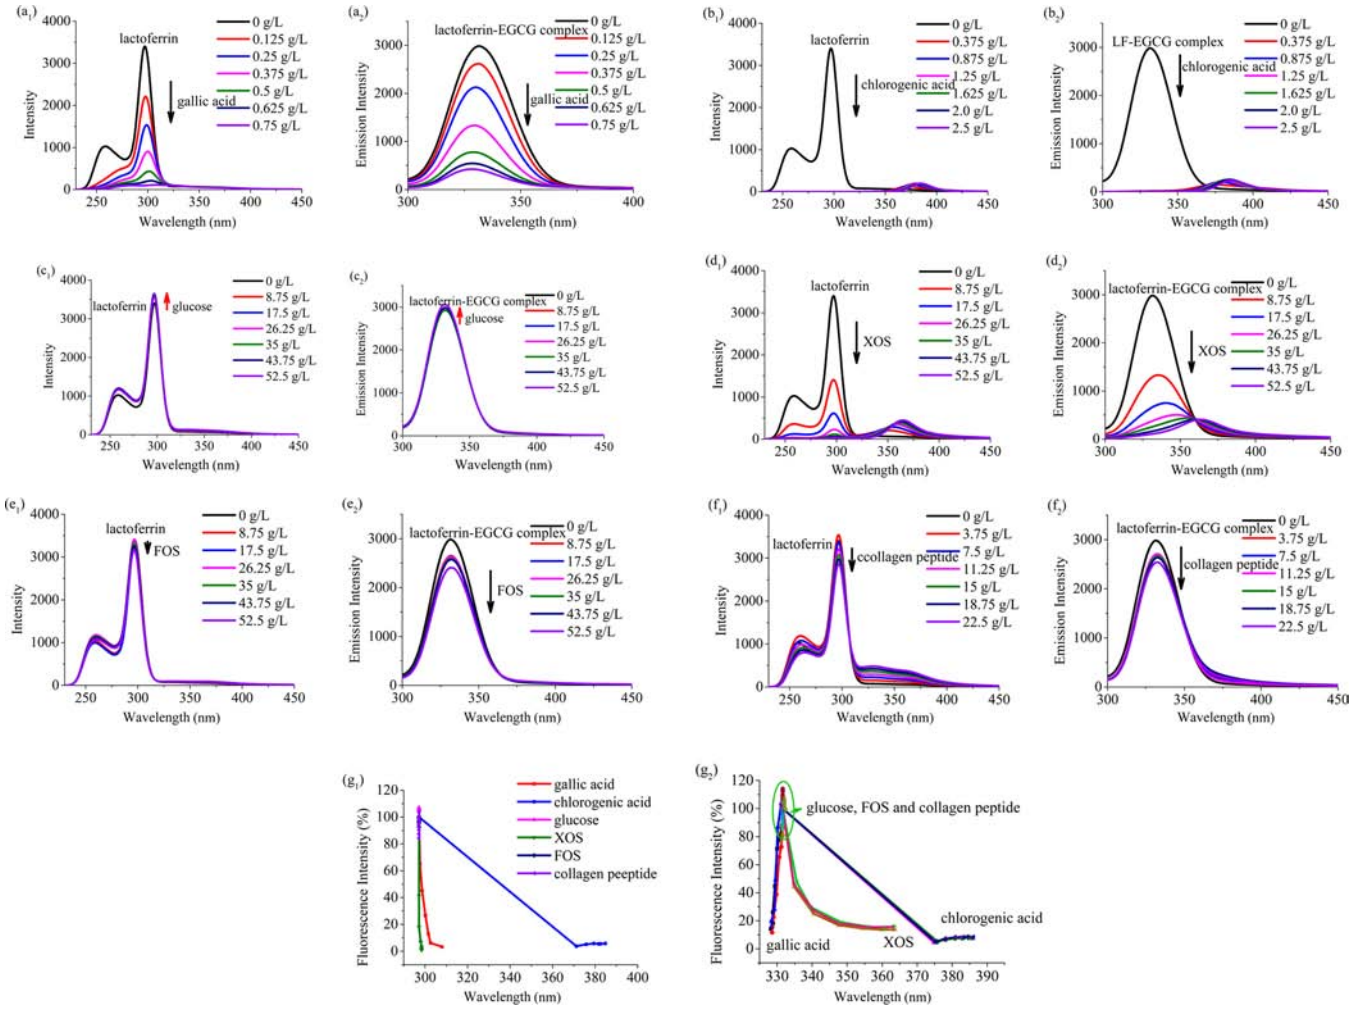

Figure 5. Synchronous fluorescence spectra of lactoferrin, in the absence and presence of polyphenols, oligosaccharides, or collagen peptide (a_1–f_1), influence of polyphenols, oligosaccharides, or collagen peptide concentration on the variation of the synchronous fluorescence of lactoferrin (g_1), synchronous fluorescence spectra of lactoferrin–EGCG aggregate (containing 1.0 mM EGCG), in the absence and presence of polyphenols, oligosaccharides, or collagen peptide (a_2–f_2), and the influence of polyphenols, oligosaccharides, or collagen peptide concentration on the variation of the synchronous fluorescence of lactoferrin–EGCG aggregate (containing 1.0 mM EGCG) (g_2).

genic acid and XOS increased. Additionally, this also suggested that gallic acid, chlorogenic acid, or XOS was situated in close proximity to the tryptophan residues for quenching to occur, and the microenvironment of tryptophan residues was changed.

The fluorescence intensity of lactoferrin–EGCG aggregate also regularly decreased with an increase in glucose, FOS, or collagen peptide concentration. Unlike the case for gallic acid, chlorogenic acid, and XOS, a low degree of fluorescence quenching was observed for glucose (from 100% to 66.9–89.9%), FOS (from 100% to 64.5–69.3%), and collagen peptide (from 100% to 46.8–59.6%). Meanwhile, there were only slight blue shifts for glucose (from 369.6 to 366.2–367 nm), FOS (from 369.6 to 366–367 nm), and collagen peptide (from 369.6 to 363.4 nm). These results revealed that glucose, FOS, and collagen peptide might enhance the interaction of lactoferrin and EGCG but there was hardly any binding behavior between lactoferrin and glucose, FOS, and collagen peptide, respectively, and the structure of lactoferrin interacting with 1.0 mM EGCG was not altered significantly in the presence of glucose, FOS, and collagen peptide, respectively. Additionally, this also implied that the microenvironment of tryptophan residues did not change after the addition of glucose, FOS, or collagen peptide, respectively.

The synchronous fluorescence spectra of lactoferrin–EGCG aggregate in the absence and presence of polyphenols, oligosaccharides, or collagen peptide are shown in Figure 5a_2–f_2, which show synchronous fluorescence trends similar to those obtained for lactoferrin in the absence and presence of polyphenols, oligosaccharides, or collagen peptide (Figure 5g_1,g_2). It was apparent that the emission maximum of tryptophan residues had a slight blue shift for gallic acid (from 331.6 to 328.2–328.8 nm) but a stronger red shift for chlorogenic acid (from 331.6 to 385.4–385.8 nm) and XOS (from 331.6 to 363.6 nm). These shifts revealed that the conformation of lactoferrin changed, the polarity around the tryptophan residues decreased, and the hydrophobicity increased with gallic acid, while the presence of chlorogenic acid or XOS modified the microenvironment from a nonpolar into a polar state; in other words, tryptophan residues were located in a less hydrophobic environment and were more exposed to the solution.[34] These shifts in the spectra expressed some changes in conformation of lactoferrin upon binding with gallic acid, chlorogenic acid, and XOS, respectively.

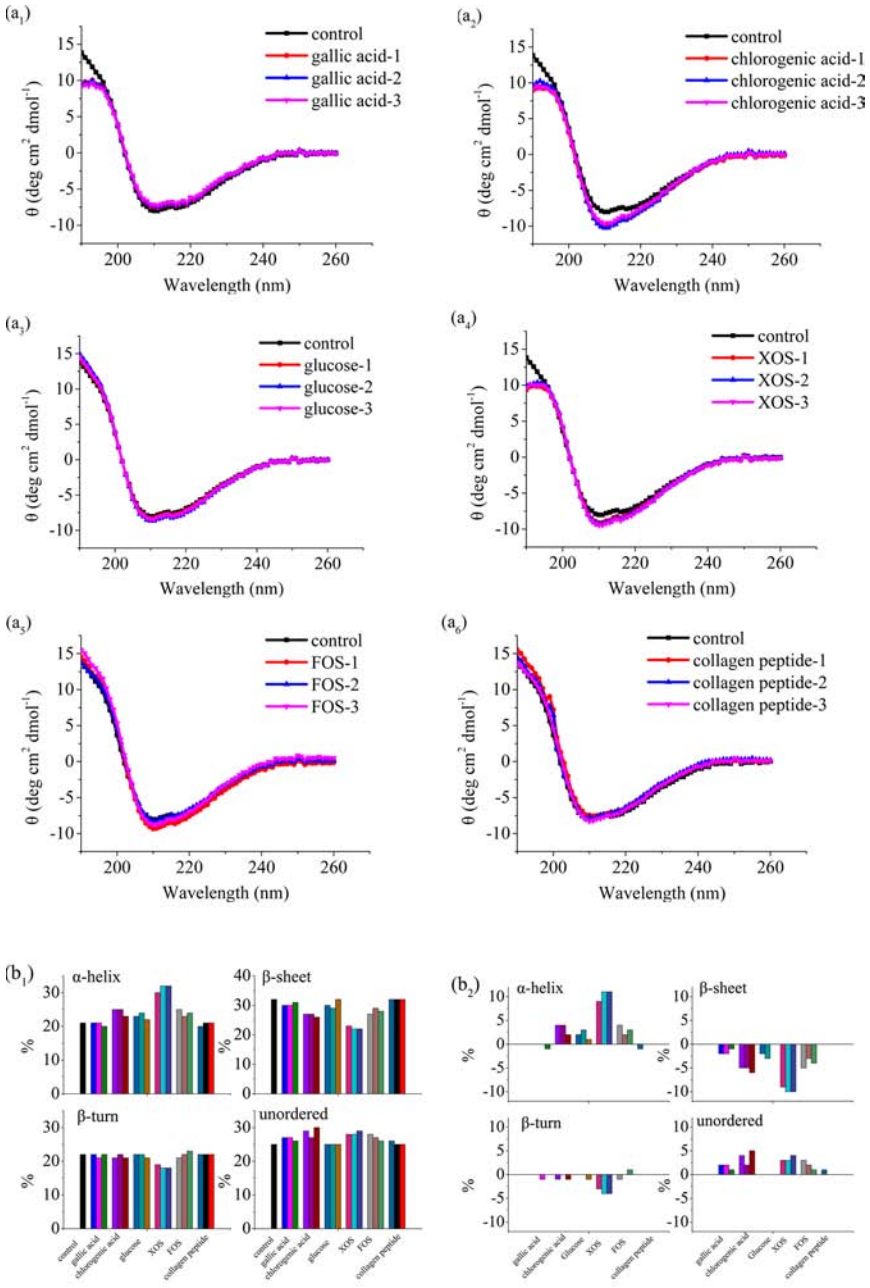

Figure 6. Far-UV CD spectra of lactoferrin in the absence and presence of polyphenols, oligosaccharides, or collagen peptide with 1.0 mM EGCG (a_1−a_6), secondary structure of lactoferrin in the absence and presence of polyphenols, oligosaccharides, or collagen peptide with 1.0 mM EGCG (b_1), changes in the secondary structure of lactoferrin in the presence of polyphenols, oligosaccharides, or collagen peptide with 1.0 mM EGCG (b_2), and near-UV CD spectra of lactoferrin in the absence and presence of polyphenols, oligosaccharides, or collagen peptide with 1.0 mM EGCG (c_1−c_6). "Control" represents the lactoferrin−EGCG complex (containing 1.0 mM EGCG) in the absence of polyphenols, oligosaccharides or collagen peptide.

The conformation of lactoferrin in lactoferrin−EGCG aggregate was not monitored when glucose, FOS, or collagen peptide was added, respectively, since no shifts in fluorescence quenching spectra and synchronous fluorescence spectra were found.

On the basis of the fluorescence results, we hypothesize that gallic acid, chlorogenic acid, and XOS not only interacted with lactoferrin and/or EGCG molecules which surrounded the lactoferrin molecule surface with weaker binding affinities via being substituted and/or adsorbed by them but also affected the internal structure of lactoferrin and/or EGCG which were bound within the hydrophobic pockets of lactoferrin with strong binding affinities, leading to a decrease in turbidity and blue or red shifts of the maximum λ_{em} value of lactoferrin fluorescence as their concentrations were increased (except for XOS by M1, which showed increases in the turbidity with increasing concentrations of XOS). However, glucose, FOS, or collagen peptide only interacted with the surface of lactoferrin and EGCG molecules which surrounded the lactoferrin molecule surface, leading to a decrease in turbidity but no shift of the maximum λ_{em} value of lactoferrin fluorescence (except for FOS by M1, which showed an increase of the turbidity as the concentration of FOS was increased).

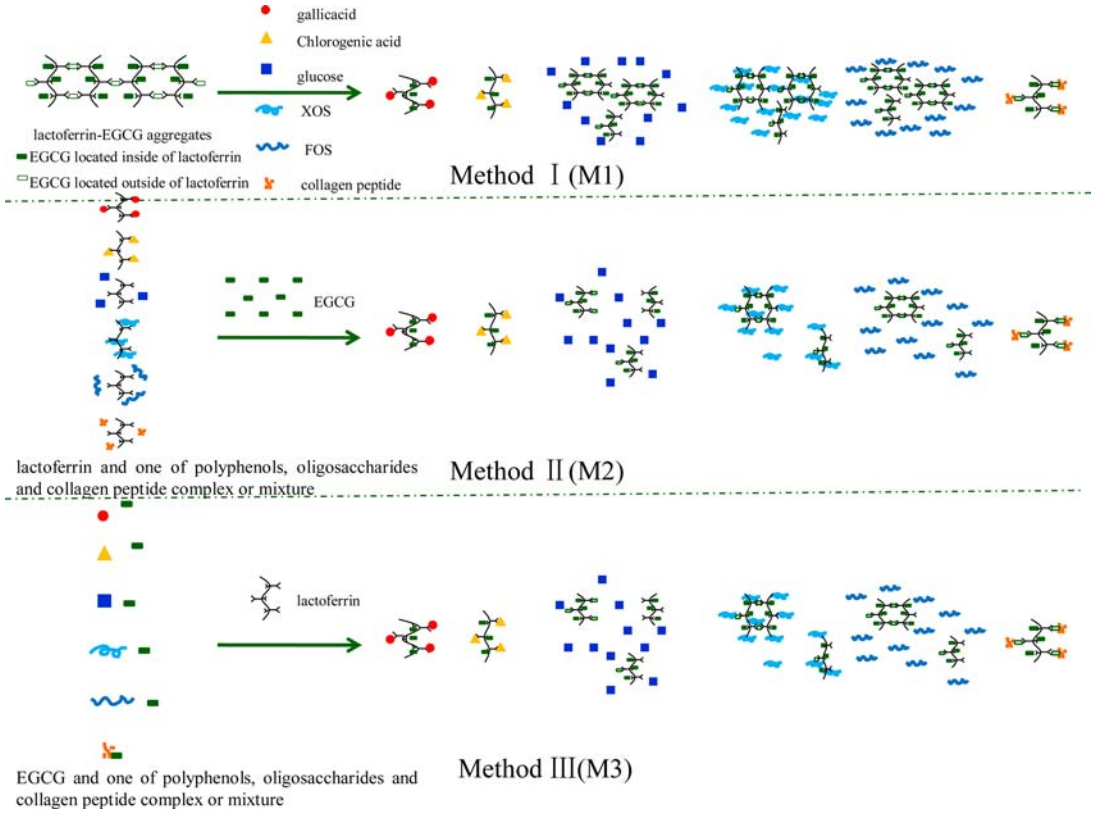

Figure 7. Possible mechanisms and structures involved in the inhibition of the aggregation of lactoferrin and EGCG in the presence of polyphenols, oligosaccharides, or collagen peptide.

Analysis of the Secondary Structure of Lactoferrin Using Circular Dichroism (CD). To obtain more information about the secondary structural changes of lactoferrin induced by EGCG and a polyphenol, oligosaccharide, or collagen peptide, the ternary complexes were analyzed by far-UV CD.

As shown in Figure 6a_1−a_6, in the region of 190−260 nm, the spectrum of lactoferrin in the presence of 1.0 mM EGCG was composed of a broad negative band centered at 208−210 nm and a shoulder at 218−220 nm. In the presence of chlorogenic acid, gallic acid, and XOS, the peak showed a significant ($p < 0.05$) decrease for chlorogenic acid and XOS and a slight increase for gallic acid in negative ellipticities, which is characteristic of a lactoferrin secondary structure conformation change, and the peak showed little change for glucose, FOS, and collagen peptide in negative ellipticities, which indicated no change in lactoferrin secondary structure.

The secondary structure contents were estimated using the DICHROWEB procedure, which is an online server for protein secondary structure analyses, from circular dichroism spectroscopic data.[35] The fractions of α-helix, β-sheet, turn, and unordered coil were estimated by CDSSTR and are shown in Figure 6b_1. In the presence of 1.0 mM EGCG, lactoferrin had 21% α-helix, 32% β-sheet, 22% β-turn, and 25% unordered. In the ternary complexes, lactoferrin had a relatively higher content of α-helix for chlorogenic acid, XOS, and FOS, a lower content of β-sheet for chlorogenic acid, XOS, and FOS, a lower content of β-turn for XOS, and a higher content of unordered for gallic acid, chlorogenic acid, XOS, and FOS, while the contents remained relatively unchanged for glucose and collagen peptide (Figure 6b_2). The protein conformational analysis based on CD data indicated that the presence of polyphenols or oligosaccharides in the ternary complexes led to a change in lactoferrin secondary structure; that is, polyphenols or oligosaccharides induced a progressive increase in the proportion of α-helix structure at the cost of the β-sheet structure of lactoferrin and the conformation became slightly looser due to an increase in the unordered coil fraction. These results showed that lactoferrin secondary conformational changes were consistent with the findings from fluorescence spectra.

Figure 7 shows the possible mechanisms and structures involved in the inhibition of the aggregation of lactoferrin and EGCG by polyphenols, oligosaccharides, or collagen peptide. Polyphenols, such as gallic acid and chlorogenic acid, could form a protein−polyphenol complex with lactoferrin by cooperative hydrogen bonding and hydrophobic interactions. Gallic acid and chlorogenic acid molecules are too small to form insoluble aggregates with lactoferrin through effective cross-linking (data not shown). Therefore, the results obtained for gallic acid and chlorogenic acid strongly suggested that the main mechanism by which these two compounds inhibited the aggregation of lactoferrin and EGCG was to compete with EGCG molecules, which were bound on the surface of lactoferrin. The ternary complex structures EGCG−lactoferrin−gallic acid and EGCG−lactoferrin−chlorogenic acid were formed and exhibited a smaller particle size accompanied by the change of lactoferrin structure (compacting structure of lactoferrin for EGCG−lactoferrin−gallic acid aggregate and unfolding structure of lactoferrin for EGCG−lactoferrin−chlorogenic acid aggregate).

Carbohydrates should have a suitable structure and composition (ionic character) and sufficient size and flexibility to be able to complex with polyphenols. The association of the neutral carbohydrates with polyphenols was thought to be

DOI: 10.1021/acs.jafc.5b01881
J. Agric. Food Chem. 2015, 63, 5035−5045

primarily a surface effect, resulting from a cooperative hydrogen-bonding interaction between the hydroxyl groups of these carbohydrates and the phenolic hydroxyl groups of polyphenols.[13] According to M1, with increasing glucose concentration, there was a gradual disruption of the binding between lactoferrin and EGCG molecules which surrounded the lactoferrin molecule surface with weaker binding affinities; new smaller networks were formed. By M2 and M3, glucose limited the number of available binding sites of lactoferrin to readily fit EGCG through steric effects, leading to a decrease in the turbidity. The disruption or reconstitution of the lactoferrin−EGCG aggregate by glucose might be the main mechanism to form smaller aggregates with higher PDI values in comparison to those for gallic acid and chlorogenic acid.

As mentioned above, the amount of aggregates precipitated tended to increase significantly ($p < 0.05$) with increasing concentration of XOS by M1, while this amount decreased by M2 and M3, which indicated that XOS, unlike gallic acid, chlorogenic acid, and glucose, did not have the ability to compete with EGCG molecules which were bound on the surface of lactoferrin. Fluorescence spectra of lactoferrin with XOS were generally similar to those of lactoferrin with chlorogenic acid, since it could form a lactoferrin−XOS complex. The results obtained strongly suggested that the main mechanism for XOS influence on the lactoferrin−EGCG aggregation was to form a complex or simple ternary complex by an interaction between lactoferrin and XOS. For example, $(\text{lactoferrin−EGCG})_n$-XOS, a more complex structure, exhibiting a larger particle size accompanied by a change in lactoferrin structure, was formed by M1; lactoferrin−EGCG−XOS with a ternary structure, exhibiting a smaller particle size accompanied by a change in lactoferrin structure, was formed by M2 and M3.

Unlike XOS, FOS did not have the ability to influence the fluorescence characteristics of lactoferrin, only interacting with the surface of lactoferrin and EGCG molecules which surrounded the lactoferrin molecule surface. The fluorescence spectra of FOS were generally similar to those of glucose. FOS, whose molecular weight was greater than that of glucose, could adsorb onto the lactoferrin−EGCG aggregate surface (associative interaction) and the larger complex $(\text{lactoferrin−EGCG})_n$−FOS was formed by M1, leading to the insolubilization of the ternary complex. By M2 and M3, in addition to the formation of soluble ternary complex, another explanation could be attributed to the steric effects in solution, limiting the number of available binding sites of lactoferrin to readily fit EGCG, which was able to prevent the interaction between proteins and polyphenols, as suggested for glucose.

XOS species are oligomers containing 2−10 xylose molecules linked by β 1−4-bonds;[36] FOS species are composed of 2,1-linked or 2,6-linked β-D-fructofuranosyl units.[37] Therefore, the chemical composition of these oligosaccharides may affect their interactions with proteins or polyphenols. A more in-depth investigation should be performed to support these findings.

Collagen peptide had changes of fluorescence similar to those of glucose and FOS. However, two significant differences were observed between collagen peptide and glucose or FOS: first, unlike glucose and FOS, collagen peptide could interact with EGCG, forming a new collagen peptide−EGCG complex;[38] second, the PDI values of the ternary complex fabricated by collagen peptide, lactoferrin, and EGCG (0.41−0.66), similar to those of gallic acid and chlorogenic acid (0.34−0.372 for gallic acid, 0.314−0.452 for chlorogenic acid), were lower than those fabricated by glucose or FOS, lactoferrin, and EGCG (0.483−1.0 for glucose, 0.403−1.0 for FOS) as their concentrations were increased. A competition mechanism was postulated between collagen peptide and lactoferrin with EGCG molecules, which surrounded the lactoferrin molecule surface, leading to a decrease in turbidity. A ternary complex structure, lactoferrin−EGCG−collagen peptide, was formed and exhibited a smaller particle size without a change in lactoferrin structure.

The aforementioned findings imply that polyphenols, oligosaccharides, or collagen peptide, like some anionic polysaccharides, were able to resolubilize the protein−polyphenol aggregates. Charged oligosaccharides or collagen peptide, with either positive or negative charge, disrupted the lactoferrin−EGCG aggregate mainly through the mechanism of competition of EGCG molecules which surrounded the lactoferrin molecule surface with weaker binding affinities, forming a ternary complex, accompanied by changes in lactoferrin structure (for gallic acid and chlorogenic acid) or no change (for collagen peptide), while neutral molecules disrupted the aggregate mainly through steric effects and formation of ternary complexes, also accompanied by changes in lactoferrin structure (for XOS) or no change (for glucose and FOS).

Polyphenols, oligosaccharides, or collagen peptide effectively inhibit the formation of lactoferrin−EGCG aggregate by M2 or M3 instead of M1: that is, adding polyphenols, oligosaccharides, or collagen peptide to lactoferrin or EGCG buffer solution before the formation of lactoferrin−EGCG aggregate. Therefore, the pros and cons of polyphenols, oligosaccharides, or collagen peptide on the turbidity and particle size of the ternary complexes mostly depended on the addition sequence of lactoferrin, polyphenols (oligosaccharide or collagen peptide), and EGCG.

Overall, the exceptional properties of polyphenols, oligosaccharides, and collagen peptide, present at high levels in food and beverage products, exhibit a possible additional contribution for reducing the astringent response or turbidity of polyphenols. The inhibition of polyphenols, oligosaccharides, and collagen peptide for the formation of lactoferrin−EGCG aggregate could be applied to the design of clear products in specific food, pharmaceutical, and cosmetic industries.

Fabrication Mechanism and Structural Characteristics of the Ternary Aggregates by Lactoferrin, Pectin, and (−)-Epigallocatechin Gallate Using Multispectroscopic Methods

Wei Yang, Chenqi Xu, Fuguo Liu, Cuixia Sun, Fang Yuan, and Yanxiang Gao*

Beijing Key Laboratory of Functional Food from Plant Resources, College of Food Science & Nutritional Engineering, China Agricultural University, P.O. Box 112, No. 17 Qinghua East Road, Beijing 100083, People's Republic of China

ABSTRACT: The ternary aggregates were fabricated by lactoferrin (LF), pectin (high methylated pectin (HMP)/low methylated pectin (LMP)), and (−)-epigallocatechin gallate (EGCG) through three different fabrication methods at pH 5.0. The turbidity, particle size, and ζ-potential of ternary aggregates were influenced by the types of pectin, the concentration of EGCG, and fabrication methods. The fluorescence intensity of LF decreased with an increase in EGCG concentration for all ternary aggregates. Far-UV circular dichroism results indicated that EGCG could alter the secondary structure of LF with an increase in the proportion of β-sheet structure at the cost of unordered coil structure. According to near-UV circular dichroism results, EGCG could also modulate the tertiary structure of LF at the presence of pectin. In addition, EGCG could increase the viscoelasticity of the ternary aggregates with HMP, leading to better stability of the ternary aggregates. An opposite result was observed for the ternary aggregates with LMP. These findings should provide an insight into the fabrication mechanism and applications of ternary aggregates formed by protein, polysaccharide, and polyphenol in the food, pharmaceutical, and cosmetic industries.

INTRODUCTION

Polyphenols can bind noncovalently to proteins.[1−3] Some researchers have focused on the disadvantage of the use of polyphenols, since they can precipitate proteins to form an insoluble state, resulting in undesirable turbidity and colloidal haze products.[4] From a nutritional point of view, the interaction between polyphenols and proteins, such as α-amylase and trypsin, has been shown to have negative effects, reducing the palate lubrication, causing an unpleasant sensation of roughness, dryness, and constriction, and reducing absorption of nutrients.[5,6] Polyphenols also affect the conformational changes of proteins. It was pointed out that the conformation of proteins (such as β-lactoglobulin, casein, collagen, bovine serum albumin, and lysozyme) was modified by polyphenols (such as tea polyphenols, resveratrol, genistein, curcumin, and procyanidin).[7−11] The conformational changes of proteins, signs of a partial protein unfolding upon protein−polyphenol complexes, might affect the formation and properties of the electrostatic complexes between protein and polysaccharide.

Polysaccharides are widely used as stabilizers, thickening, or gelling agents in the food industry.[12] The interaction between polysaccharides and polyphenols might result from cooperative hydrogen bonding between the hydroxyl groups of polysaccharide and polyphenols and from hydrophobic interactions.[13−16] Sun-Waterhouse et al. reported the effect of fruit polyphenols and pectin on the properties of bread and suggested possible polyphenol complexes, via nonbinding interactions such as hydrogen bonding, with pectin.[17] Hayashi et al. showed that the presence of pectin mitigated the astringency of tea infusions and attributed the observed behavior to pectin−catechin complex formation.[18] Mercedes Lataza Rovaletti et al. indicated that polysaccharides could react with tannic acid in beer, and this reaction actually caused a considerable increase in turbidity.[19]

Several studies have demonstrated the ability of some polysaccharides to disrupt polyphenol−protein interactions in dilute solution.[6,15,16,20−22] Two hypotheses were proposed for this disrupting effect of polysaccharides toward protein and polyphenol interactions: (i) the ability of polysaccharides to form a protein−polyphenol−polysaccharide ternary complex with enhanced solubility in aqueous medium and (ii) the ability of polysaccharides to encapsulate polyphenols, competing with the binding to proteins.[23] Recent studies have shown that the complexation of preheated whey protein isolate−pectin complexes inhibited the protein precipitation with polyphenols.[24]

As main components of foods, proteins and polysaccharides play a key role in the formation of the building blocks of structure and texture. The interactions occurring between polysaccharides and proteins are influenced by their surface charge, hydrophobicity, and the rheological characteristics. The formation of aggregates between proteins and polysaccharides might be the starting point for the development of delivery systems in the food, cosmetics, and pharmaceutical industries. These aggregates could be used to encapsulate, protect, and deliver functional or bioactive components, such as minerals, polyphenols, vitamins, enzymes, drugs, and peptides,[25−31] to specific sites, controlling the rate or extent of their digestibility in different regions of the human digestive system within the

consumer's body: e.g., mouth, stomach, small intestine, or colon.[25,32−34]

Pectins are normally extracted from several raw materials (such as apple pomace, sugar beet chips, and citrus peels) and are used in the food industry as thickening, gelling, and stabilizing agents. Chemically, they are mainly composed of D-galacturonic acid linked by α-(1,4)-glycosidic bonds, forming polygalacturonic acid. Pectins have different degrees of esterification (DE), with those higher or lower than 50% methylation corresponding to high or low methoxyl pectins, respectively.[35] Lactoferrin (LF) has attracted strong interest as a functional bioactive ingredient for applications in food, personal care, and pharmaceutical products. It has a relatively high p*I* (8−9) and therefore tends to be cationic at a pH value below 8.0. Thus, the electrostatic interaction between LF and pectin has been harnessed to form various particulate systems and modulate emulsion functionality over a wide pH range.[36,37]

Recently, there has been increasing interest in the incorporation of polyphenols into protein−polysaccharide aggregates and the functionality of the ternary electrostatic aggregates between polysaccharides and proteins might be affected by the presence of polyphenols. An understanding of the fabrication mechanism and structural characteristics of the ternary aggregates is a key step for optimizing the formation of aggregates with applications in coatings, emulsions, etc. In the present work, ternary aggregates fabricated from lactoferrin (LF), pectin, and (−)-epigallocatechin gallate (EGCG) were designed to form a novel delivery systems for foods and other products. The effect of binding sequence for LF, pectin, and EGCG on the physical characteristics of the aggregates was also investigated.

MATERIALS AND METHODS

Materials and Chemicals. Lactoferrin (purity ≥92%) from bovine whey was purchased from New Image International Limited (Auckland, New Zealand). EGCG (purity ≥95%) from green tea was purchased from BSZH Science (Beijing, People's Republic of China). High methoxylated pectin (HMP) with a DE value of 72% (GENU pectin type YM-150-H) and low methoxylated pectin (LMP) with a DE value of 36% (GENU pectin type LM-101-AS) were obtained from CP Kelco (Copenhagen, Denmark). All other chemicals used were of analytical grade, unless otherwise stated.

Solution Preparation. LF (3.2% w/v), EGCG (8.0 mM), and pectin (1.8% w/v) were dissolved in 10 mM acetate buffer (pH 5.0), and the mixture was stirred constantly at room temperature for 2 h and then stored overnight at 4 °C to achieve complete dissolution.

Formation of the Ternary Aggregate Solutions (Fabricated from LF, Pectin, and EGCG). The ternary aggregate solutions were formed with three addition sequences of LF, pectin, and EGCG. All solutions were mixed on a vortex shaker (QL-866, Haimen QILINBEIER Instruments Co., Ltd., Haimen, People's Republic of China) at 3000 rpm for 2 min.

Method I (M1). First, 1.0 mL of LF (3.2% w/v) and 2.0 mL of pectin (1.8% w/v) solutions were mixed and allowed to stand for 2 h. After that, 1.0 mL of EGCG solutions with different concentrations (0−2.0 mM) were mixed with LF−pectin complexes and the mixtures allowed to stand for 2 h before the measurement.

Method II (M2). First, 1.0 mL of LF (3.2% w/v) solution and 1.0 mL of EGCG solutions with different concentrations (0−2.0 mM) were mixed and allowed to stand for 2 h. After that, 2.0 mL of pectin solution (1.8% w/v) was mixed with different LF−EGCG complexes, and the mixtures were allowed to stand for 2 h before the measurement.

Method III (M3). First, 2.0 mL of pectin (1.8% w/v) solution and 1.0 mL of EGCG solutions with different concentrations (0−2.0 mM) were mixed and allowed to stand for 2 h. After that, 1.0 mL of LF (3.2% w/v) solution was mixed with the pectin−EGCG complexes, and the mixtures were allowed to stand for 2 h before the measurement.

The abbreviations TA_{Pectin}, TA_{HMP}, and TA_{LMP} represent the ternary aggregates prepared using LF, EGCG, and pectin (both HMP and LMP), HMP, and LMP, respectively. TA_{Pectin}-*x*, TA_{HMP}-*x*, and TA_{LMP}-*x* (*x* = 1−3) were used to represent the ternary aggregates prepared by M1, M2, and M3, respectively.

Turbidity Measurements. Nephelometry experiments were performed in a HACH 2100N Laboratory Turbidimeter (Loveland, TX, USA). All samples were diluted 1/10 (v/v) with acetate buffer solution (pH 5.0). The optical apparatus was equipped with a tungsten-filament lamp with three detectors: a 90° scattered-light detector, a forward-scattering light detector, and a transmitted light detector. The calibration was performed using a Gelex Secondary Turbidity Standard Kit (HACH, Loveland, TX, USA), which consists of stable suspensions of a metal oxide in a gel. All experiments were performed in triplicate.

Particle Size and ζ-Potential Measurements. Particle size and ζ-potential were determined using a combined dynamic light scattering (DLS) and particle electrophoresis instrument (Nano-ZS90, Malvern Instruments, Worcestershire, U.K.). Basically, all samples were diluted 1/10 (v/v) with acetate buffer solution (pH 5.0) and then equilibrated for 1 min inside the instrument before dynamic light backscattering, and then data were collected over at least 10 sequential readings. The *Z*-average particle diameter was calculated by the instrument using the Stokes−Einstein equation. The ζ-potential of the particles was calculated using the Smoluchowski model through electrophoretic mobility measurements performed in a capillary electrophoresis device inserted into the DLS instrument.

Fluorescence Spectroscopy. Fluorescence measurements were carried out using a fluorescence spectrophotometer (F-7000, Hitachi, Japan). All samples were diluted 1/3 (v/v) with acetate buffer solution. Spectra were collected when the diluted solutions were kept at 25 °C for 2 h. Fluorescence emission spectra of LF were recorded with the excitation wavelength at 292 nm. Both excitation and emission slit widths were set at 10 nm.

Circular Dichroism Measurements. The CD spectra were recorded using a CD spectropolarimeter (Pistar π-180, Applied Photophysics Ltd., Surrey, U.K.) at both far-UV (190−250 nm) and near-UV (250−320 nm) regions under a constant nitrogen flush. Path lengths were 0.1 cm for the far-UV region and 1 cm for the near-UV region. Ellipticity was recorded at a speed of 100 nm/min, 0.2 nm resolution, 20 accumulations, and 2.0 nm bandwidth. The collected data were analyzed using Dichroweb: the online circular dichroism web site (http://dichroweb.cryst.bbk.ac.uk.) The fractions of α-helix, β-sheet, turn, and unordered coil were estimated by SELCON3. Each spectrum presented is the average of three consecutive measurements.

Viscoelastic Properties. The viscoelastic properties of the samples were evaluated by optical microrheology (Rheolaser LAb from Formulaction, Union, France). In the experiment, 20 mL of samples was injected by a syringe into a flat-bottomed cylindrical glass tube (height 70 mm, external diameter 27.5 mm). The tube was immediately placed in the sample chamber of the Rheolaser LAb instrument. During the measurement, the speckle pattern of the sample, which was generated by the interfering backscattering wave of the incident laser at 650 nm caused by the Brownian motion of the particles, was collected by a multipixel detector for 3 min. The generated speckle image was treated to plot the decorrelation curve, which could quantify the particle mobility and displacement and in turn be used to characterize the viscoelastic properties of the samples.

Physical Stability Measurements. The stabilities of the solutions were measured by the LUMi-Sizer (L.U.M. GmbH, Berlin, Germany), an instrument employing centrifugal sedimentation to accelerate the occurrence of instability phenomena such as sedimentation, flocculation, and creaming. The samples were subjected to centrifugal force, while near-infrared light illuminated the entire sample cell to measure the intensity of transmitted light as a function of time and position over the entire sample length simultaneously. The sample stability was shown as a space- and time-related transmission profile

DOI: 10.1021/acs.jafc.5b01592
J. Agric. Food Chem. 2015, 63, 5046−5054

over the sample length. At the start of the measurement, the solutions were intact. As the sample was centrifuged, however, the heavier and less transparent aqueous phase moved to the bottom, which gave higher transmission; the lighter and more transparent phase moved to the top. The instrumental parameters used for the measurement were as follows: volume, 1.8 mL of dispersion; 3000 rpm; $time_{Exp}$, 3600 s; time interval, 30 s; temperature, 25 °C.

Statistical Analysis. The experiments were conducted in duplicate, and all of the analyses were done in triplicate. The results are presented as the means ± standard deviation. Data were analyzed by one-way analysis of variance using the SPSS 16.0 package (SPSS Inc., Chicago, IL, USA), and significant differences of means ($p < 0.05$) were determined using the Duncan multiple-range test. The correlation analysis was carried out using the Pearson mode. The concordance between experimental data and calculated values was established by the root-mean-squared deviation (RMSD).

RESULTS AND DISCUSSION

A fixed concentration of pectin (0.9% w/v) was used in the experiments to saturate the LF (0.8% w/v) molecules, as no further change in ζ-potential was observed above this concentration (data not shown).

Effect of Addition Sequence of LF, Pectin, and EGCG on Turbidity, Particle Size, and ζ-Potential of the Ternary Aggregates. It is well-known that EGCG can bind to LF with strong affinity and form nanosized particles at pH 5.0.[38] At the same time, pectin and EGCG can form a pectin−EGCG complex by cooperative hydrogen bonding between the hydroxyl groups of polysaccharide and groups of polyphenols. Therefore, the addition sequence of LF, pectin, and EGCG may directly affect the interactions of these compounds, thereby affecting the structural characteristics of the ternary aggregates. The turbidity, particle size, and ζ-potential of the ternary aggregates are shown in Figure 1. The magnitude of the

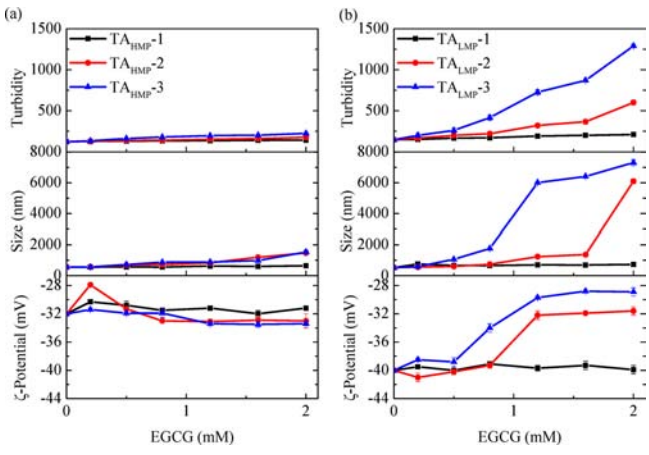

Figure 1. Turbidity, particle size, and ζ-potential of TA_{HMP} (a) and TA_{LMP} (b) as a function of EGCG concentration (0−2.0 mM) at pH 5.0.

negative charge on the LF−pectin complexes was greater for LMP than for HMP, which could be attributed to the fact that LMP has a higher linear charge density: i.e., more carboxylic acid groups per unit chain length. The turbidity and particle size exhibited a synchronous trend with the rise of EGCG concentration.

For TA_{Pectin}-1, the turbidity, particle size, and ζ-potential were not apparently changed with different concentrations of EGCG; in other words, the aggregates large enough to scatter light strongly were not formed, and EGCG hardly affected the structural properties of TA_{HMP}-1 and TA_{LMP}-1. Our results were similar to those of Thongkaew et al., who showed that the presence of catechin, grape seed extract, and hibiscus extract to whey protein isolate−pectin complex at pH 3.5 did not show a obvious difference of mean particle diameter and the addition of catechin, grape seed extract, and tannic acid did not affect the ζ-potential of preheated whey protein isolate−pectin complex at pH 5.2.[23] The increasing concentration of EGCG exhibited some effects on the turbidity and particle size of TA_{Pectin}-2 and TA_{Pectin}-3, which suggested that the ternary aggregates were formed to be large to scatter light. The larger turbidity and particle size of TA_{Pectin}-3 in comparison to those of TA_{Pectin}-2 indicated that more complex structures were formed by M3 than by M2.

The effect of EGCG on the formation of large aggregates was more prominent for TA_{LMP} than for TA_{HMP}, which was consistent with the greater change in ζ-potential of TA_{LMP} than of TA_{HMP} (discussed below). The particle sizes of TA_{HMP}-1, TA_{HMP}-2, and TA_{HMP}-3 were smaller than those of TA_{LMP}-1, TA_{LMP}-2, and TA_{LMP}-3, respectively, which suggested that the aggregates formed with HMP were more numerous than those formed with LMP. A possible explanation of this phenomenon is that LMP, containing a higher charge density than HMP, may have a greater propensity to form large complexes or sediments through neutralization of LF−EGCG complexes. On the other hand, more localized interactions between protein and polysaccharide molecules led to the formation of complexes of more limited size, because there are free segments of biopolymers that promote complex repulsion through electrostatic or steric hindrance effects.[39] Thus, the particles formed with HMP were likely less compact and possessed more biopolymer segments extending into solutions in comparison to LMP particles.

For TA_{Pectin}-2 and TA_{Pectin}-3, the presence of EGCG significantly ($p < 0.05$) affected the ζ-potential of the ternary aggregates. Interestingly, the addition of EGCG resulted in a decrease in negatively charged ζ-potential for TA_{HMP}-2 and TA_{HMP}-3 but an increase for TA_{LMP}-2 and TA_{LMP}-3. The charges of HMP, LMP, and EGCG at pH 5.0 were −32 ± 0.1, −40 ± 0.6, and −16 ± 1.0 mV, respectively. Therefore, it was estimated that the types of pectin and electrostatic repulsion between pectin and EGCG might have some effect on the charge distribution of those ternary aggregates. However, an EGCG concentration of more than 1.2 mM had almost no effect on the ζ-potential of the ternary aggregates, indicating that the aggregates formed may retain their charged functional groups.

Fluorescence Spectroscopy Measurements. There are 13 tryptophan residues in the LF molecule.[40] By monitoring of the emission peak change, some useful information could be obtained concerning the structural changes of LF.

It was obvious that, for all ternary aggregates, the fluorescence intensity of LF regularly decreased with an increase in EGCG concentration, and this implied that there existed binding behavior between LF and EGCG (Figure 2a,b). The maximum λ_{em} was slightly red-shifted (from 334.4 to 335.8 nm for TA_{HMP} and from 334.4 to 337.2−338 nm for TA_{LMP}, more red-shifted emission in comparison to TA_{HMP}) in the presence of EGCG (Figure 2c). These results revealed that there were some changes in the immediate environment of the tryptophan residues of LF in TA_{HMP} and TA_{LMP} and that EGCG was situated in closer proximity to the tryptophan residues in TA_{LMP} than in TA_{HMP} for quenching to occur.

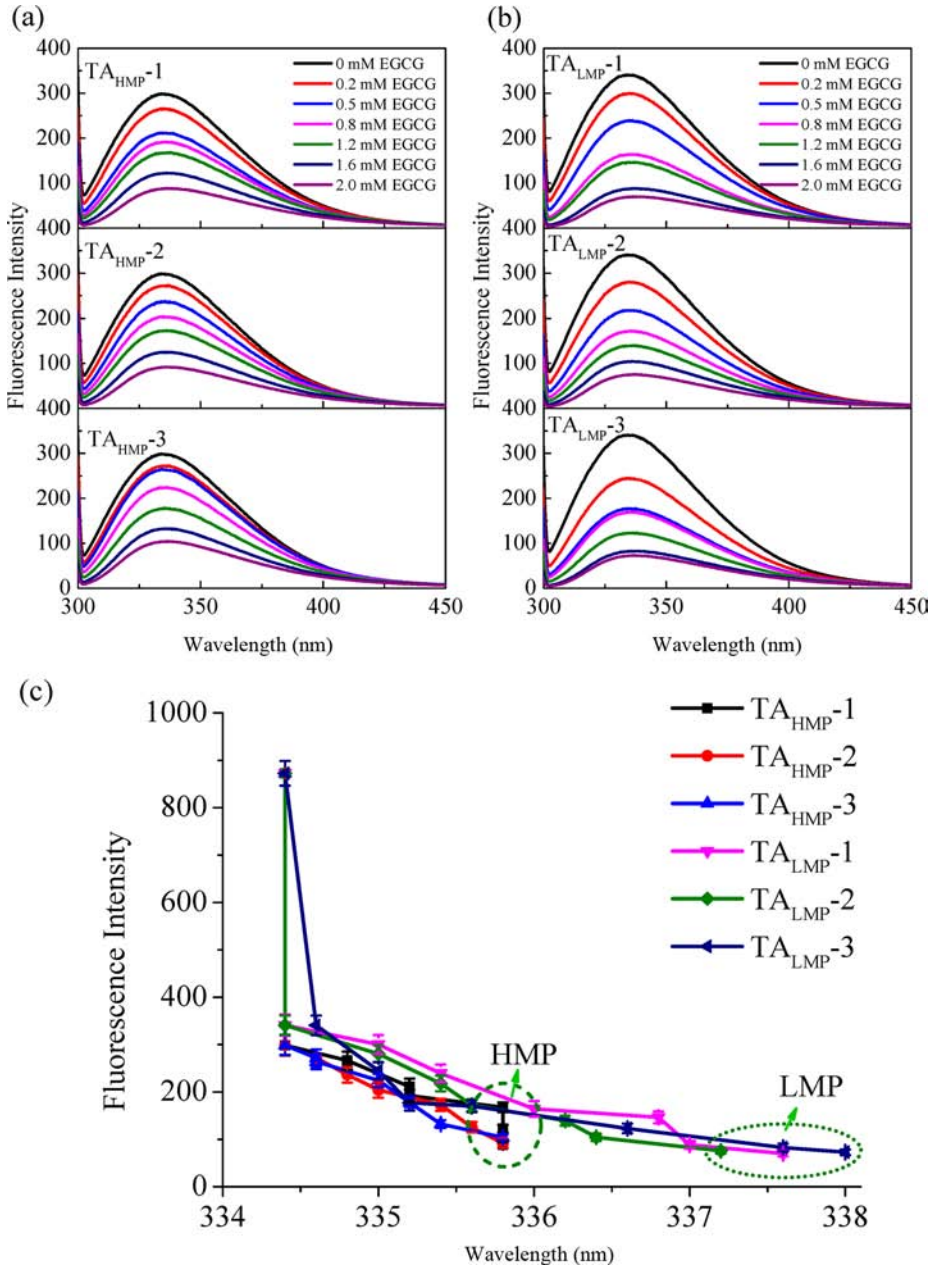

Figure 2. Fluorescence spectra of LF in TA_{HMP} (a) and TA_{LMP} (b) at different EGCG concentrations (0−2.0 mM) at pH 5.0. Influence of increasing concentration of EGCG on the fluorescence variation of LF in TA_{HMP} and TA_{LMP} (c).

In the solution prepared by M1, LF−pectin aggregates were formed first; then, EGCG was added to the aggregates, and it might be embedded in the gaps of LF−pectin aggregates and interact with LF, leading to almost complete loss of fluorescence intensity in TA_{Pectin}-1, as in TA_{Pectin}-2 and TA_{Pectin}-3. Meanwhile, with increasing concentrations of EGCG, the outer layer of pectin prevented the formation of a larger "$-(LF-EGCG)_n-$" network structure, leading to little change in turbidity, particle size, and ζ-potential of TA_{Pectin}-1 (see Figure 1). Therefore, the structure of TA_{Pectin}-1 was LF in the inner layer, pectin in the outer layer, and EGCG in the middle layer (Figure 3a).

In the solution prepared by M2, "$-(LF-EGCG)_n-$" complex showed a small or large particle size formed at relatively low or high concentration of EGCG first; after pectin was added to the solution, the pectin had a sufficient capacity to coat the "$-(LF-EGCG)_n-$" complex. Therefore, the structure of TA_{Pectin}-2 was "$-(LF-EGCG)_n-$" complex in the inner layer

and pectin in the outer layer (Figure 3b). Pectin, which forms the outer layer of TA_{Pectin}-2, also could prevent further aggregation of these compounds; thus, TA_{Pectin}-2 exhibited a particle size relatively larger than that of TA_{Pectin}-1 but a smaller particle size than TA_{Pectin}-3 (see Figure 1).

In the solution prepared by M3, "−pectin−EGCG−" complex was formed first; after LF was added to the solution, "$-[LF-EGCG-pectin-EGCG-LF]_n-$" aggregates, more complicated than those of TA_{Pectin}-2, were formed and showed the greatest turbidity and largest particle size at corresponding concentrations of EGCG (see Figure 1). The structure of TA_{Pectin}-3 was a complex network structure fabricated by LF, EGCG, and pectin (Figure 3c).

Circular Dichroism (CD) Measurements. Far-UV CD is used to obtain the information about the changes occurring at a secondary folding level of proteins. In this section, the influence of pectin type on the secondary structure of LF- and EGCG-induced conformational transitions of LF in TA_{HMP} and TA_{LMP} (containing 1.0 mM EGCG) was monitored by far-UV CD spectroscopy (Figure 4a,b). The fractions of α-helix, β-sheet, turn, and unordered coil are shown in Figure 4c,d.

It was found that LF in the LF−HMP aggregate contained 20% α-helix, 30% β-sheet, 21% β-turn, and 29% unordered, and 21% α-helix, 29% β-sheet, 22% β-turn, and 29% unordered fractions occurred in LF−LMP aggregate. The slight difference in the secondary structure of LF in LF−HMP and LF−LMP aggregates might be attributed to the different physiochemical characteristics of HMP and LMP.

It is well-known that the noncovalent interactions of EGCG and proteins affect the structure of proteins.[7,8,41,42] Hence, in the presence of EGCG, the secondary structural composition of LF in TA_{HMP} and TA_{LMP} possibly changed when LF−EGCG complex was formed. As is shown in Figure 4a,b, in the presence of 1.0 mM EGCG, the broad negative band centered at 208−210 nm showed a slight decrease in negative ellipticities for TA_{HMP} and TA_{LMP}, while the shoulder at 218−220 nm showed a decrease or an increase in negative ellipticities, which is a characteristic of LF secondary structure conformation change.

The protein conformational analysis based on CD data indicated that the addition of EGCG led to changes in the secondary structure of LF in TA_{HMP} and TA_{LMP}. In the presence of 1.0 mM EGCG, the β-sheet and β-turn contents

DOI: 10.1021/acs.jafc.5b01592
J. Agric. Food Chem. 2015, 63, 5046−5054

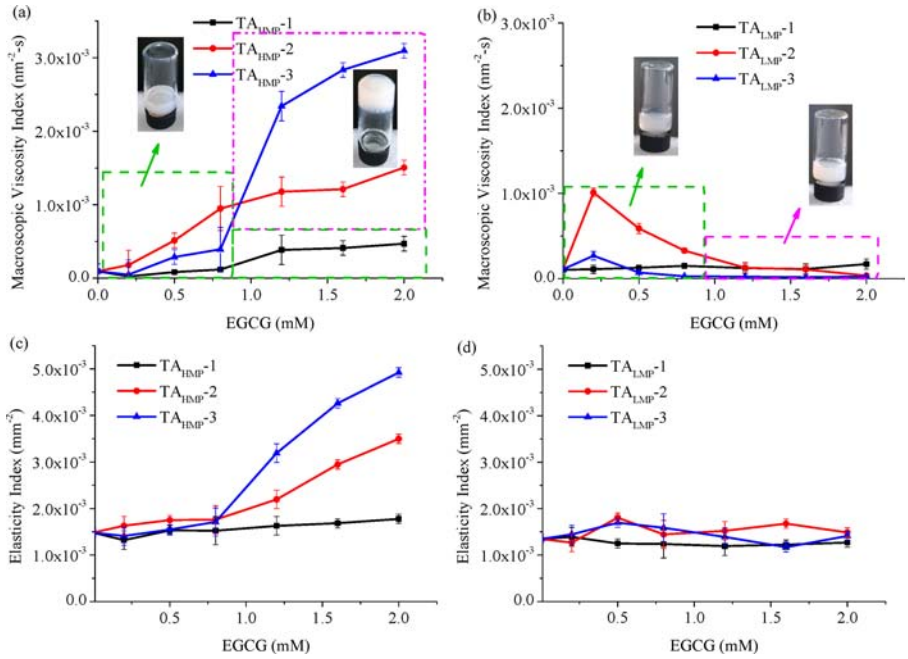

Figure 5. MVI and EI of TA_{HMP} (a, c) and TA_{LMP} (b, d) as a function of EGCG concentration (0−2.0 mM) at pH 5.0.

increased with a concomitant reduction of α-helical and unordered coil fractions in TA_{HMP}-1, TA_{HMP}-2, TA_{HMP}-3, TA_{LMP}-1, and TA_{LMP}-2. Therefore, it could be concluded that, for these ternary aggregates, EGCG contributed largely to the stability of LF β-sheet conformation and LF assumed a slightly compact conformation due to the decrease of unordered coil fraction.

It is interesting to find that an inverse result, an increase of α-helix (about 2%) and decrease of β-turn (about −1%), was observed in TA_{LMP}-3, which might be one reason for the lower viscoelasticity and less stability of TA_{LMP}-3 in comparison to TA_{HMP}-3.

Near-UV CD is a powerful tool for probing the tertiary structure of proteins. CD spectra in the region of 250−320 nm were attributed to aromatic amino acids, and the real shape and magnitude of the near-UV CD spectrum of a protein were determined by the number of each type of aromatic amino acids present, their mobility, the nature of the environment (hydrogen bonds, polar groups, and polarizability), and spatial disposition in the protein.[43] From Figure 4e,f, the near-UV CD spectra of LF in TA_{HMP} and TA_{LMP} showed a broad distribution range from 250 to 300 nm, comprising four maxima at 254, 277, 285, and 292 nm, which were attributed to phenylalanine (Phe), tyrosine (Tyr), and tryptophan (Trp), respectively.[43] The presence of EGCG led to a remarkable decrease in the ellipticities, which suggested that the LF tertiary conformation had changed. It should be noted that LF in TA_{LMP} showed a greater decrease in the magnitudes of the near-UV CD bands in comparison to that in TA_{HMP}, which indicated that the LMP−EGCG complex had a greater impact than HMP−EGCG complex on the structure of LF.

As EGCG caused different changes of LF secondary and tertiary structures in TA_{HMP} and TA_{LMP}, respectively, it may alter the stoichiometry of the LF−pectin complexes, which might increase the tendency for charge neutralization and lead to stronger bridging forces between LMP and LF and therefore the nature of ternary aggregates with larger particle size formed by LMP in comparison to HMP (see Figure 1).

Thus, EGCG could interact with LF in TA_{HMP} and TA_{LMP}, leading to changes of LF secondary and tertiary structures, and the effects of EGCG on LF secondary structure mainly depended on the types of pectin and fabrication methods.

Viscoelastic Properties. Passive particle tracking is a direct method consisting of monitoring the Brownian motion of tracer particles within a system and interpreting such movements in terms of the local viscoelasticity, or microrheology.[44] Particle tracking microrheology is a powerful technique that enables researchers to measure the viscoelastic properties of complex fluids with relatively low viscoelastic moduli (typically <1 Pa) in small sample volumes which are inaccessible to macrorheology and to spatially map structural heterogeneities at a microlevel.[45] Therefore, particle tracking microrheology has considerable potential in food gels, since the system is commonly inhomogeneous.[46]

Biopolymer particles increased the overall system viscosity when they were incorporated into the aqueous solution. The LF−HMP and LF−LMP aggregates had very similar viscoelastic properties. The initial macroscopic viscosity indexes (MVIs) of LF−HMP and LF−LMP aggregates were $0.96 \times 10^{-4} \pm 1 \times 10^{-5}$ and $1.09 \times 10^{-4} \pm 1 \times 10^{-5}$ nm^{-2} s, respectively. The initial elasticity indexes (EIs) of LF−HMP and LF−LMP aggregates were $1.48 \times 10^{-3} \pm 1 \times 10^{-4}$ and $1.34 \times 10^{-3} \pm 1 \times 10^{-4}$ mm^{-2}, respectively. Since EGCG could noncovalently bind to protein and polysaccharide, respectively, therefore, it might be incorporated into LF−pectin biopolymer particles to modify their viscoelastic characteristics.

As shown in Figure 5, EGCG exhibited a slight effect on MVI and EI for TA_{HMP}-1 and TA_{LMP}-1. For TA_{HMP}-2 and TA_{HMP}-3, the values of MVI and EI were relatively small at low EGCG concentrations but steeply increased when the EGCG concentration was more than 0.8 mM. However, TA_{LMP}-2 and TA_{LMP}-3 showed a somewhat sinuous behavior: at low EGCG concentration (less than 0.2 mM), the values of MVI and EI increased. When the EGCG concentration was 0.5 mM for TA_{LMP}-2 and 1.6 mM for TA_{LMP}-3, MVI values decreased to the initial levels and then decreased significantly ($p < 0.05$) to

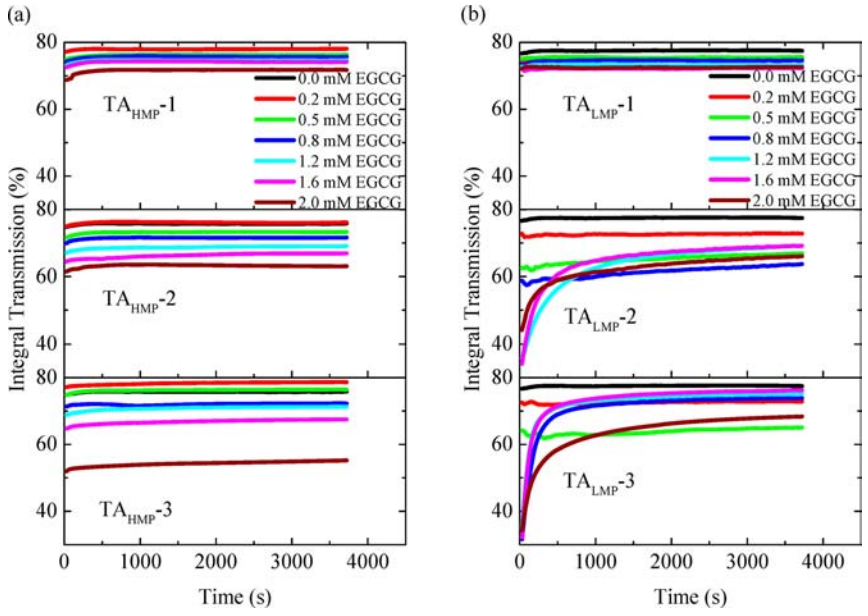

Figure 6. Evolution of transmission profiles of TA_{HMP} (a) and TA_{LMP} (b) as a function of EGCG concentration (0–2.0 mM) at pH 5.0.

31.9% and 22.4% of the initial levels when the EGCG concentration was 2.0 mM for TA_{LMP}-2 and TA_{LMP}-3, respectively. EI showed the similar trend as MVI with a rise of EGCG concentration.

Aberkane et al. reported that the presence of quercetin increased β-lactoglobulin–acacia gum binding and improved the stability of the β-lactoglobulin–acacia gum complex and coacervates.[47] However, in our study, we interestingly found that the viscoelastic properties of the ternary aggregates fabricated by LF, pectin, and EGCG were mainly affected by the types of pectin and fabrication methods. The increase in MVI and EI for TA_{HMP}-2 and TA_{HMP}-3 could be attributed to the fact that the presence of EGCG increased the binding of LF to HMP and improved the stability of the LF–HMP aggregates. An inverse result was observed for TA_{LMP}.

Influence of EGCG on the Physical Stability of LF–Pectin Aggregates. According to Stokes' law ($V_0 = a\Delta\rho d^2/18\eta$, where V_0 is the floating rate of solution droplets, d is the particle diameter, $\Delta\rho$ is the density contrast between the two phases, a is the acceleration of centrifugation, and η is the viscosity of the continuous phase),[48] a smaller particle size and a greater viscosity resulted in a slower floating rate of droplets and , thus enhanced physical stability of the aggregates. The stabilities of aggregates were expressed as space- and time-related transmission profiles over the sample length (Figure 6). The greater the change of the transmission with centrifugation, the less stable the ternary aggregates. The stability of aggregates could be reflected quantitatively by plotting the integrated transmission profiles against the measuring time, and the slope of the resultant curve was inversely related to the stability.[49]

There were appreciable differences in the influence of types of pectin on the stability of ternary aggregates. From Figure 6, it could be found that TA_{HMP} exhibited less change in the transmission profiles and low slope values over space and time, resulting in better stability of the aggregates. TA_{LMP}-2 and TA_{LMP}-3, with high slope values, showed less stability than TA_{HMP}-2 and TA_{HMP}-3, respectively, when the EGCG concentration was more than a critical value (1.2 mM for TA_{LMP}-2 and 0.8 mM for TA_{LMP}-3), despite having a greater negative charge.

Three possible reasons could be used to explain why TA_{LMP}-2 and TA_{LMP}-3 were more prone to aggregation and sedimentation than TA_{HMP}, with the rise of EGCG concentration. First, the ternary aggregates had different changes in ζ-potential: a decrease for TA_{HMP} and an increase for TA_{LMP}. Second, both TA_{LMP}-2 and TA_{LMP}-3 had larger particle sizes and lower viscosity in comparison to those of TA_{HMP}. Finally, the LF structures in TA_{HMP} and TA_{LMP} were different, including the secondary structure, especially for α-helix and β-turn, and the tertiary structure.

CONCLUSION

In the present study, the turbidity and viscoelastic properties of ternary aggregates could be manipulated by controlling the concentration of EGCG, types of pectin, and especially fabrication methods. EGCG always interacted with LF and affected the secondary and tertiary structures of LF in LF–pectin aggregates. TA_{HMP}-2 and TA_{HMP}-3 had better transparency and higher viscoelasticity and could be applied in clear beverages or gel-like solutions. In contrast, TA_{LMP}-2 and TA_{LMP}-3 had higher turbidity and lower viscoelasticity and could be applied in cloudy beverages or liquid foods. Overall, the ternary aggregates containing EGCG could have prospective potential in the food, pharmaceutical, and cosmetic industries, as delivery systems to encapsulate, protect, and release bioactive components or as functional ingredients to modify optical, rheological, and sensorial properties of food products.

ABSTRACT: Foods such as bulk oils, salad dressings, and nutritionally fortified beverages that are susceptible to oxidative degradation are often packaged in poly(ethylene terephthalate) (PET) bottles with metal chelators added to the food to maintain product quality. In the present work, a metal-chelating active packaging material is designed and characterized, in which poly(hydroxamic acid) (PHA) metal-chelating moieties were grafted from the surface of PET. Biomimetic PHA groups were grafted in a two-step UV-initiated process without the use of a photoinitiator. Surface characterization of the films by attenuated total reflective Fourier transform infrared spectroscopy (ATR-FTIR) and scanning electron microscopy (SEM) suggested successful grafting and conversion of poly(hydroxyethyl acrylate) (PHEA) to PHA chelating moieties from the surface of PET. Colorimetric (ferrozine) and inductively coupled plasma mass spectroscopy (ICP-MS) assays demonstrated the ability of PET-*g*-PHA to chelate iron in a low-pH (3.0) environment containing a competitive metal chelator (citric acid). Lipid oxidation studies demonstrated the antioxidant activity of PET-*g*-PHA films in inhibiting iron-promoted oxidation in an acidified oil-in-water (O/W) emulsion model system (pH 3.0). Particle size and ζ-potential analysis indicated that the addition of PET-*g*-PHA films did not affect the physical stability of the emulsion system. This work suggests that biomimetic chelating moieties can be grafted from PET and effectively inhibit iron-promoted degradation reactions, enabling removal of metal-chelating additives from product formulations.

KEYWORDS: *active packaging, metal chelation, lipid oxidation, poly(ethylene terephthalate), poly(hydroxamic acid)*

INTRODUCTION

The presence of transition metals (e.g., iron) enhances lipid oxidation in foods containing lipids, leading to nutrient loss and the generation of off-flavors. This is due to the ability of iron to promote the breakdown of lipid hydroperoxides to generate reactive radicals that degrade bioactive molecules such as fatty acids, antioxidants, and carotenoids.[1] Synthetic metal chelators (e.g., ethylenediaminetetraacetic acid, EDTA) are commonly used in food and beverage products and have been shown to be potent inhibitors of lipid oxidation in emulsion-based systems.[2] However, growing consumer concern over the use of synthetic additives has led researchers to seek alternative solutions to prevent lipid oxidation, such as natural additives and active packaging.[3−5] Unfortunately, natural additives are often not as effective as their synthetic counterparts, and their safety limits are largely unknown.[6,7] Active packaging represents an attractive strategy for protecting labile food ingredients, but in some cases may involve migration of active compounds or alteration of the bulk properties (mechanical strength, appearance) of the packaging material.[8−10] Therefore, nonmigratory covalent modifications to packaging materials capable of chelating prooxidative transition metals have been investigated.[11]

Our group previously reported grafting of nonmigratory biomimetic hydroxamic acid (PHA) chelating groups from a polypropylene (PP) surface.[12] The resulting materials chelated iron across a pH range relevant to foods and performed better than EDTA in inhibiting volatile lipid oxidation product formation in oil-in-water (O/W) emulsions.[11] However, PP-*g*-PHA synthesis requires the use of an added chemical photoinitiator (e.g., benzophenone) to enable grafting from the PP surface. To expand the industrial potential of nonmigratory chelating packaging, the overall goal of this work was to graft PHA from an alternative food packaging material and determine its efficacy in an acidified (pH 3.0) model food emulsion system. Poly(ethylene terephthalate) (PET) was chosen because of its lower oxygen transmission rate, clarity, moisture barrier, temperature tolerance, lightweight nature, and widespread use in the food and beverage industry.[13,14] In addition, an advantage of PET is that its chemical structure can be leveraged to graft polymerize a monomer without the need for a photoinitiator. The challenge in hydroxamic acid grafted PET (PET-*g*-PHA) is that it requires an alternative chemical synthesis to polymerize a monomer PHA precursor from the PET surface.

Herein, we describe a two-step grafting procedure in which hydroxyethyl acrylate (HEA) was grafted from the surface of PET films via UV-induced graft polymerization. Poly(hydroxyethyl acrylate) (PHEA) groups were then converted to PHA groups by exposure to hydroxylamine. The resulting PET-*g*-PHA was capable of chelating iron at pH 3.0 in the

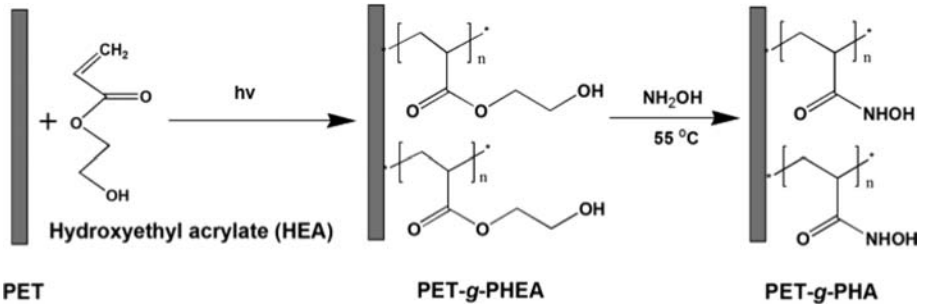

Figure 1. Schematic of two-step UV-initiated graft polymerization and conversion of (poly)hydroxamic acid from the surface of poly(ethylene terephthalate) PET-*g*-PHA.

presence of a competitive chelator (citric acid). Materials were characterized for changes in surface chemistry, and the ability to inhibit lipid oxidation was demonstrated in an acidified (pH 3.0) O/W emulsion. This work demonstrates that biomimetic chelating moieties can be grafted from PET and effectively inhibit iron-promoted degradation reactions.

MATERIALS AND METHODS

Materials. Commercial soybean oil (Wesson 100% natural vegetable oil) was purchased from a local grocer. A PET (oriented) sheet with a thickness of 178 ± 18 μm was purchased from McMaster-Carr (Elmhurst, IL, USA). Acetone, ferric chloride anhydrous, hydrochloric acid, trichloroacetic acid (TCA), 4-(2-hydroxyethyl)-1-piperazineethane sulfonic acid (HEPES), water (HPLC), 2-propanol, isooctance, 1-butanol, methanol, sodium citrate dihydrate, sodium acetate trihydrate, sodium hydroxide, disodium EDTA, and Brij 35 (a nonionic surfactant) were purchased from Fisher Scientific (Fair Lawn, NJ, USA). Citric acid monohydrate and hydroxyethyl acrylate (HEA, 97%, stabilized) were purchased from Acros Organics (Morris Plains, NJ, USA). 3-(2-Pyridyl)-5,6-diphenyl-1,2,4-triazine-*p*,*p*′-disulfonic acid monosodium salt hydrate (ferrozine, 97%), imidazole, hydroxylamine solution (50 wt % in water), barium chloride dihydrate, ammonium thiocyanate, cumene hydroperoxide (80%), and hexanal (98%) were purchased from Sigma-Aldrich (St. Louis, MO, USA). All chemicals and solvents were used without further purification.

Grafting of PHA from the PET Film Surface. PET film was cut into 1 cm × 2 cm coupons, which were cleaned sequentially in isopropanol, acetone, and deionized water (2 × 10 min cleanse per solvent) by sonication. Cleaned PET films were dried in a desiccator overnight (25 °C, 15% relative humidity) for future use. PHA was grafted from the surface of PET films using a two-step process (Figure 1). In the first step, PHEA was grafted from the PET film surface using UV-induced graft polymerization. Briefly, PET coupons were submerged in 6 mL of 30 wt % HEA in water using individual septum screw cap vials. The monomer solution was purged with nitrogen for 15 min to remove oxygen, followed by sonication to disrupt air bubble formation on the films. Films were then subjected to ultraviolet (UV) irradiation for 2.5 min in a Dymax light-curing system (model 5000 flood, 320−395 nm, 200 mW/cm^2, Dymax Corp., Torrington, CT, USA) to graft PHEA from the surface of PET. The resulting PET-*g*-PHEA films were then washed in deionized water for 30 min at room temperature followed by washing for 1 h at 60 °C followed by the same washing overnight at room temperature to remove adsorbed HEA monomers and PHEA homopolymers.

PHEA grafts were then converted to PHA grafts by a modification of the method reported by Polomoscanik et al.[15] PET-*g*-PHEA films were submerged in an aqueous solution of hydroxylamine (16.67 wt %) at a surface area to volume ratio of 1 cm^2 to 2.5 mL and stirred at 55 °C for 1 h (Figure 1). The resulting PET-*g*-PHA films were then rinsed three times in deionized water followed by 30 min of exposure to acidic water (adjusted by HCl, pH 3.0) to protonate hydroxamic acid groups and finally rinsed again in copious deionized water. The obtained PET-*g*-PHA films were dried and stored over anhydrous calcium sulfate (25 °C, 15% RH) until further use.

Surface Characterization. The surface chemistry of films, before and after PHA grafting, was characterized using attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) by an IRPrestige-21 FTIR spectrometer (Shimadzu Scientific Instruments, Inc., Kyoto, Japan) equipped with a diamond ATR crystal. Using clean, native PET as background spectrum, each spectrum was generated from 32 scans at a 4 cm^{-1} resolution and collected from three independent films. Representative spectra were replotted with SigmaPlot 12.2 (Systat Software, Inc., Chicago, IL, USA). The surface morphology of films was analyzed by field emission scanning electron microscopy (SEM) (JCM-6000 NeoScope, JEOL, Japan) at 10 kV. Prior to imaging, samples were sputter-coated with gold to prevent charging.

Iron Chelating by the Ferrozine Assay. The ferric iron (Fe^{3+}) chelating activity of PET-*g*-PHA films was determined at pH 3.0 in citric acid/citrate buffer (10 mM) as described previously.[16,17] Citrate was used to both mimic the acid used in many foods and also to help maintain iron solubility. Films (native PET, PET-*g*-PHEA, and PET-*g*-PHA) were submerged in 0.06 mM Fe^{3+} (from ferric chloride anhydrous) in citric acid/citrate buffer, with Fe^{3+} solution without films serving as a control. Films were allowed to chelate in the dark for 24 h at room temperature while on an orbital shaker (200 rpm). The Fe^{3+}-chelating activity of films was calculated by the difference of the Fe^{3+} concentration (determined by ferrozine assay, described below) in Fe^{3+} solution with films against the control group (Fe^{3+} solution with no films).[11]

A modification of the ferrozine assay was performed to quantify the Fe^{3+} concentration of chelating solutions, in which a colorimetric complex is formed between Fe^{2+} and ferrozine reagent.[16,17] First, Fe^{3+} was reduced to Fe^{2+} by exposure to 5 wt % hydroxylamine hydrochloride in 10 wt % trichloroacetic acid followed by the addition of ferrozine reagent (18 mM in 0.05 M HEPES buffer, pH 7.0) and mixing for 1 h at room temperature to enable color formation. Absorbance was measured at 562 nm. Fe^{3+} concentration was quantified by comparison to a standard curve made from ferric chloride anhydrous. Results are representative of two experiments performed on independent days.

Inductively Coupled Plasma−Mass Spectroscopy (ICP-MS). As a direct quantification of iron chelation to support results from ferrozine assay, native and modified PET films (performed in duplicates) were subjected to ICP-MS analysis after films were exposed to iron in the ferrozine assay (see above). Films were prepared for ICP-MS using a standard method.[18] Approximately 100 mg of the PET film was weighed directly into microwave digestion vessels, followed by the addition of nitric acid (5.0 mL). Microwave digestion by a Mars Xpress (CEM, Matthews, NC, USA) was carried out at 210 °C for 10 min. Digested samples were then diluted with deionized water and held at 4 °C until analysis. ICP-MS analysis was conducted on a PerkinElmer Elan 9000 equipped with an autosampler (Waltham, MA, USA). Iron concentration was determined by a standard curve prepared using an iron ICP-MS standard (Ricca Chemical Co., Arlington, TX, USA).

Effect of PET-*g*-PHA films of the Oxidative Stability of O/W Emulsions. To demonstrate the effectiveness of chelating PET-*g*-PHA films in preventing iron-promoted degradation reactions, an accelerated lipid oxidation study was performed using an acidified O/W emulsion as a model food system. Emulsions were prepared by dissolving Brij 35 (0.10% w/w) and commercial soybean oil (1.0% w/w) in a 0.05 M sodium acetate/imidazole buffer (pH 3.0), followed by homogenization with a hand-held homogenizer (Biospec Products, Inc., Bartlesville, OK, USA) at 7000 rpm for 2 min. The coarse emulsion then underwent three passes through a microfluidizer (Microfluidics, Newton, MA, USA) at 9 kbar. Films (1 cm^2) were submerged in 1 mL of emulsion and stored in the dark at 55 °C for 29 days. Emulsions without films served as a negative control; emulsions containing the synthetic chelator EDTA at two concentrations (0.01 mM, equivalent to the chelating capacity of the PET-*g*-PHA films, and 0.08 mM, the maximum legal limit) served as positive controls (FDA Food Additive Regulation 21 CFR 172.120).

The formation of primary and secondary lipid oxidation products (lipid hydroperoxides and hexanal, respectively) were quantified throughout the study to determine the oxidative stability of the O/W emulsions. Lipid hydroperoxides were quantified according to the method reported by Waraho et al.[19] Briefly, 0.30 mL of emulsion was mixed with 1.5 mL of iso-octane/isopropanol (3:1 v/v) by vortex for 3 × 10 s and then centrifuged at 3000*g* for 2 min. The upper layer, containing the lipid hydroperoxides, was collected and added to 2.8 mL of methanol/1-butanol (2:1 v/v), followed by the addition of 30 μL of thiocyanate/Fe^{2+} solution (obtained from mixing an equal volume of 3.94 M thiocyanate solution with 0.072 M Fe^{2+}). The reaction samples were held for 20 min at room temperature to enable color formation. Absorbances were read at 510 nm, and lipid hydroperoxide concentrations were determined by comparison to a standard curve prepared using six concentrations of cumene hydroperoxide between 0 and 600 mmol/kg oil (r^2 = 0.99, linear regression). Samples were diluted with methanol/1-butanol to maintain their absorbance within the prepared concentration range.

The secondary lipid oxidation product hexanal was quantified by gas chromatography (GC, model GC-2014, Shimadzu, Tokyo, Japan) equipped with an autosampler and flame ionization detector (FID) as in Tian et al.[11] Samples (1 mL) were incubated at 55 °C for 10 min to allow volatile compounds from the emulsion to enter the headspace of the 10 mL headspace gas chromatography vial. A divinylbenzene/carboxen/polydimethylsiloxane (DVB/carboxen/PDMS) solid-phase microextraction (SPME) fiber (50/30 μm, Supelco, Bellefonte, PA, USA) was exposed to the headspace above the sample for 2 min to adsorb volatile components, followed by desorption for 3 min at 250 °C in the injector at a split ratio of 1:7. Volatile compounds were separated on a fused-silica capillary column (30 m × 0.32 mm inner diameter × 1 μm) coated with 100% poly(dimethylsiloxane) (Equity-1, Supelco). The run time was 10 min per sample with temperatures of 250, 65, and 250 °C for the injector, oven, and detector, respectively. Hexanal concentration was calculated from the peak areas using a standard curve prepared using authentic hexanal (concentrations ranging from 0 to 43.6 mmol/kg oil, r^2 = 0.91, linear regression)

Time to lipid oxidation was quantified by determining the lag phase, defined as the day before a statistically significant increase in concentration of primary or secondary oxidation products as compared to initial concentrations.

To demonstrate that the PET-*g*-PHA films did not affect emulsion stability, emulsion particle size distribution and electrical charge were characterized using a Zetasizer Nano ZS (Malvern Instruments, Worcestershire, UK). Particle size was determined by dynamic light scattering (DLS) after 10-fold dilution of the emulsion with sodium acetate/imidazole buffer (0.05 M, pH 3.0). The diluted emulsion was equilibrated for 60 s before particle size measurements were recorded with an average of 11 readings, reported as the *Z*-average in mean diameter (nm). Size measurements were followed immediately by electrical charge measurements (10 readings for each measurement) with an equilibration time of 60 s, and the zeta (ζ) potential (mV) of the emulsion droplets was collected. Stability tests were both performed for two measurements per sample and performed in duplicates.

Statistical Analysis. Results are presented as means and standard deviations of analysis conducted in triplicate, unless otherwise stated. Oxidation lag phases were defined as the first data point statistically greater than the 0 time within each treatment tested using one-way analysis of variance (ANOVA) with comparison of the means performed using Tukey's HSD post hoc test ($p < 0.05$). Calculations were performed using IBM SPSS Statistics version 22 (IBM SPSS, Chicago, IL, USA).

RESULTS AND DISCUSSION

Characterization of Biomimetic PET-*g*-PHA Active Packaging Films. Metal-chelating active packaging films were produced in a two-step process in which PHEA was grafted from the surface of PET by UV-initiated graft polymerization followed by conversion to PHA by exposure to hydroxylamine (Figure 1). The surface chemistry at each step in the modification was analyzed by ATR-FTIR (Figure 2).

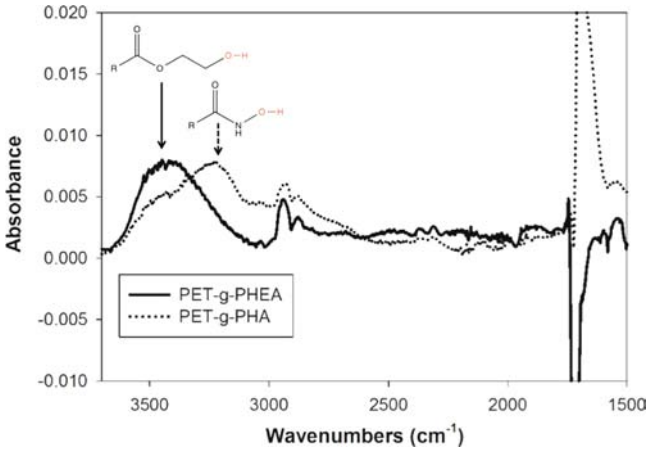

Figure 2. ATR-FTIR spectra of PET-*g*-PHEA and PET-*g*-PHA films using native PET as the background. Each spectrum is representative of measurements collected from three independent films.

Using clean, native PET as the background, the spectrum of PET-*g*-PHEA showed a strong absorption band at 3500−3300 cm^{-1} characteristic of an −OH stretch and two smaller peaks at 2900−2800 cm^{-1} corresponding to −CH stretch, suggesting successful covalent grafting of PHEA from PET. Conversion of PHEA to chelating hydroxamate groups (PHA) was confirmed by the introduction of an −OH stretch at 3300−3100 cm^{-1} typical of a hydroxyl group adjacent to an amide as present in the hydroxamic acid chelating moiety (Figure 2). The absorption in the 3000−2900 cm^{-1} range, attributed to the −CH stretching for the long alkyl backbone of PHEA, did not change, suggesting specific conversion of the ester to a hydroxamic acid moiety. ATR-FTIR spectroscopy on both sides of the film confirmed that grafting did not occur on the backside of PET films.

The effect of PHA grafting on the film surface morphology was determined by electron microscopy (Figure 3). Native PET (Figure 3A) exhibited small irregularities, similar to those observed by others in commercial PET films.[20] PET-*g*-PHEA films had uniform surface morphology across and between samples (Figure 3B), exhibiting ridge-like structures typical of hydrophilic polymer/hydrogels that shrink upon dehydration.[11,21] As expected, the films lost the ridge-like structure after conversion to PET-*g*-PHA (Figure 3C) due to the change

in surface hydrophilicity by conversion to the relatively hydrophobic hydroxamate groups. Qualitatively, the effect of grafting from the surface of PET had no influence on film visual character (images not shown).

Iron Chelation by Biomimetic PET-*g*-PHA Active Packaging Films. The ability of the hydroxamic acid grafted PET (PET-*g*-PHA) films to chelate iron was quantified by the colorimetric ferrozine iron-binding assay (Figure 4). Iron

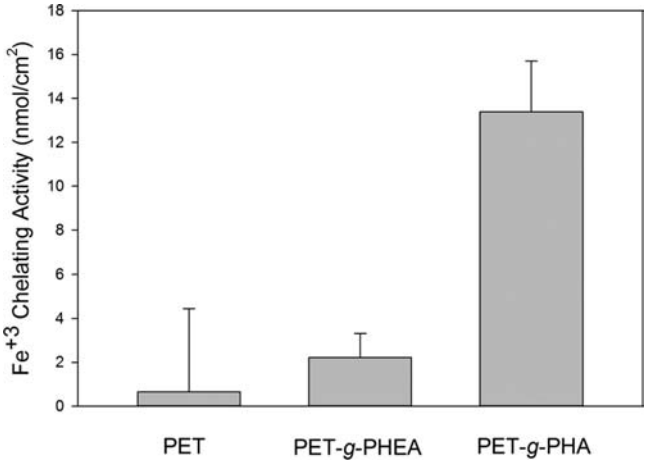

Figure 4. Ferric iron chelation by PET, PET-*g*-PHEA, and PET-*g*-PHA films (24 h of incubation, pH 3.0 citric acid/citrate buffer). Values represent means ± standard deviation (n = 4). Results are representative of two experiments performed on independent days.

chelating of native PET was not detectable (PET, 0.60 ± 3.80 nmol Fe^{3+}/cm^2), and grafted PHEA exhibited statistically negligible activity (PET-*g*-PHEA, 2.22 ± 1.10 nmol Fe^{3+}/cm^2). PET-*g*-PHA films demonstrated significant iron-chelating activity (13.39 ± 2.30 nmol Fe^{3+}/cm^2) in competitively chelated citrate−Fe^{3+} solutions. Given these data, the density of the chelating groups on the PET-*g*-PHA film can be estimated between 13 and 39 nmol HA groups, assuming a HA/Fe^{3+} ratio of between 1:1 and 3:1. The lack of chelating by native PET and PET-*g*-PHEA suggests that chelating shown by PET-*g*-PHA groups is due to specific iron−HA interactions. The minimal chelation of PET-*g*-PHEA films was likely the result of nonspecific absorption or swelling into the grafted layer. Previously, our group demonstrated the effectiveness of grafted PHA from polypropylene (PP-*g*-PHA).[12] The chelating activity of the PET-*g*-PHA materials reported herein is lower than found in our previous studies on PP-*g*-PHA materials; however, it is important to note that those studies were performed at a higher pH value (pH 5.0), at which the film chelated 21.39 ± 1.28 nmol Fe^{3+}/cm^2. In this work, we have demonstrated the ability of the synthesized PET-*g*-PHA films to maintain chelating abilities in an environment representative of an acidified liquid food system (pH 3.0), in which citric acid was used as an acidulant (10 mM) and competitive chelator.

Direct quantification of iron chelation by ICP-MS was performed to complement ferrozine assay results. After exposure to ferric iron solution, native PET films presented insignificant iron (−1.00 ± 1.70 nmol Fe^{3+} cm^{-2}), whereas PET-*g*-PHA films presented 7.20 ± 1.10 nmol Fe^{3+} cm^{-2}. These values are on the order of, but lower than, those obtained using the ferrozine assay. This discrepancy may be a result of differences in assay sensitivities or incomplete microwave digestion of the PET-*g*-PHA films during the preparation step for ICP-MS analysis.

Controlling Lipid Oxidation by Iron Chelating PET-*g*-PHA Films. The ability of PET-*g*-PHA films to delay lipid oxidation in acidified (pH 3.0) soybean O/W emulsions was determined by quantifying the formation of lipid hydroperoxides and hexanal during storage at 55 °C in the dark (Figures 5 and 6). Effective inhibition of lipid oxidation was determined by extension of lag phase, defined as the day before a statistically significant increase in concentration of primary or secondary oxidation products as compared to initial concentrations. Once lipid oxidation had occurred, samples were therefore removed from the study and not further characterized for oxidation products. As expected, emulsions in the absence of metal chelators (control and native PET samples) oxidized rapidly with a lag phase of 3 days for both lipid hydroperoxide and hexanal production. The addition of PET-*g*-PHA films to the emulsions extended the lag phase to 5 days for lipid hydroperoxide production and to 7 days for hexanal production. The PET-*g*-PHA films were less effective than emulsions containing the positive controls (EDTA and no film), which at both concentrations extended lag phase to 20 days and 26 days for lipid hydroperoxides and hexanal, respectively.

The effective inhibition of lipid oxidation by EDTA suggests that transition metal-promoted degradation was a major oxidative instability mechanism in the O/W emulsions. The iron content of the commercial soybean oil was determined to be 330 ppb by ICP-MS analysis, which is in agreement with prior reports on iron content of refined soybean oil (200 ppb).[22] The results indicated that both EDTA concentrations were in excess of the transition metals (e.g., iron or copper) present in the emulsion system because an increase in EDTA concentration did not extend the lag phase of lipid hydroperoxide or hexanal production. It is interesting to note that although the PET-*g*-PHA film had theoretical equivalent

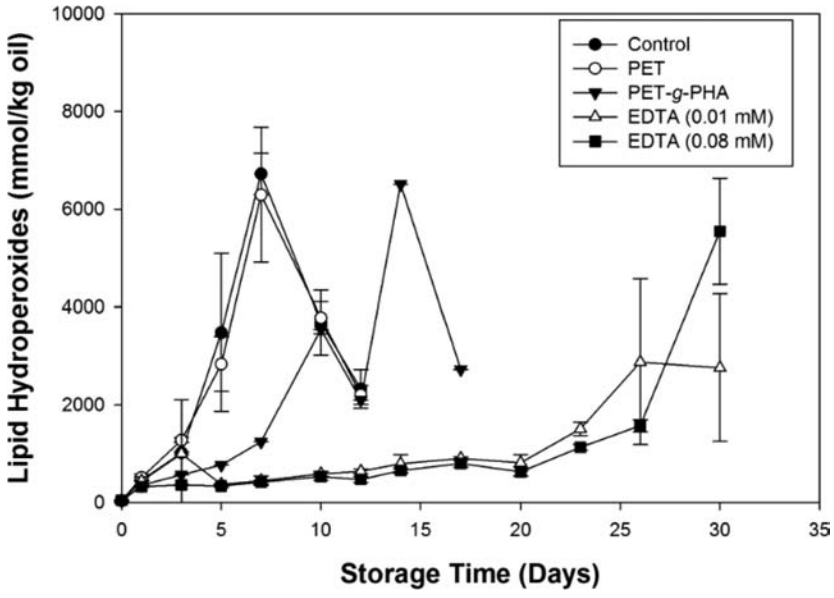

Figure 5. Formation of lipid hydroperoxides in 0.05 M sodium acetate−imidazole-buffered (pH 3.0) soybean O/W emulsions stored at 55 °C: in the absence of a metal chelator (control and native PET), a metal chelator (EDTA 0.01 and 0.08 mM), or PET-*g*-PHA film. Values represent means ± standard deviation (n = 3).

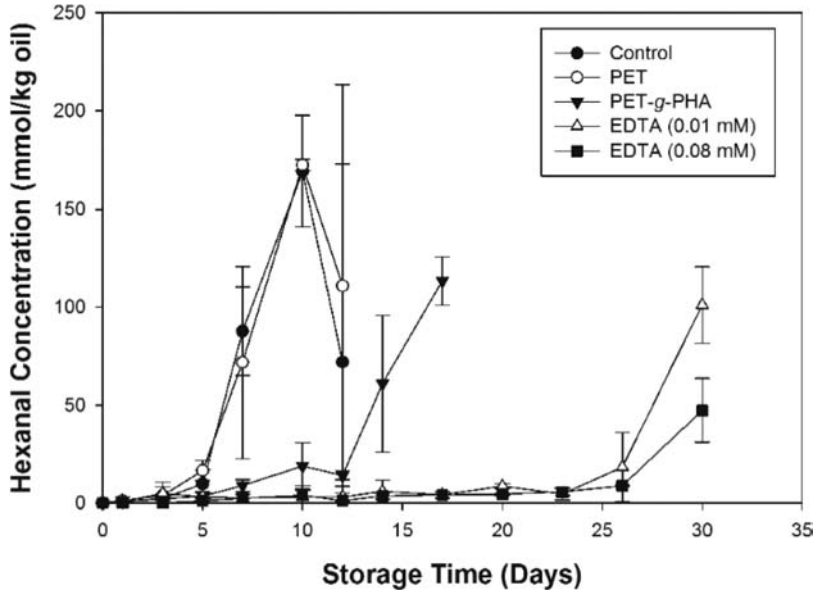

Figure 6. Formation of hexanal in 0.05 M sodium acetate−imidazole-buffered (pH 3.0) soybean O/W emulsions stored at 55 °C: in the absence of a metal chelator (control and native PET), a metal chelator (EDTA 0.01 and 0.08 mM), or PET-*g*-PHA film. Values represent means ± standard deviation (n = 3).

chelating capacity to the emulsion containing 0.01 mM EDTA, it was significantly less effective at inhibiting lipid oxidation. A possible explanation for the higher efficacy of EDTA, as compared to PET-*g*-PHA, may be related to the physical structure and chelation geometry.[23] PET-*g*-PHA chelating groups are tethered to the PET polymer, and chelating may be dependent upon iron diffusion to the HA groups, whereas EDTA molecules are uniformly dispersed in the solution. In addition, the enhanced oxidative stability of emulsions containing EDTA could be due to EDTA's low $pK_{1,2}$ (1.99, 2.67) that allows greater chelating capacity under acidic conditions (pH 3.0).

Previously, our group demonstrated the effectiveness of grafted PHA from polypropylene (PP-*g*-PHA) in controlling lipid oxidation in an O/W emulsion system (pH 3.0) composed of stripped soybean oil.[11] Although PP-*g*-PHA films were unable to effectively inhibit lipid hydroperoxide development, they demonstrated better performance than EDTA (0.01 mM) in preventing the formation of hexanal. Herein, the developed PET-*g*-PHA film demonstrated ability to delay development of both lipid hydroperoxide and hexanal, albeit to a lesser extent than EDTA. In this study, an acidified food or beverage system using commercial oil was studied to demonstrate the potential application of PET-*g*-PHA modified packaging in extending the shelf life of an O/W emulsion system.

The physical stability of the emulsions at days 0 and 19 was evaluated to confirm that the physicochemical properties of the emulsion did not change during the course of lipid oxidation.

DOI: 10.1021/acs.jafc.5b00796
J. Agric. Food Chem. 2015, 63, 5055−5060

Throughout the study, there was no significant change in the size and charge of the Brij 35-stabilized emulsion, suggesting that the reported PET-*g*-PHA films do not influence the physical stability of emulsions (Table 1).

Table 1. Physical Stability of 0.05 M Sodium Acetate−Imidazole-Buffered (pH 3.0) Soybean O/W Emulsions Stored at 55 °C at Days 0 and 19 for Particle Size Diameter and ζ Potential[a]

sample emulsion	particle size diameter (nm)	ζ potential (mV)
original emulsion (day 0)	290 ± 61a	−1.13 ± 0.62
no film	221 ± 18b	0.24 ± 0.10
PET	224 ± 17b	0.08 ± 0.04
PET-*g*-PHA	198 ± 14bc	0.57 ± 0.45
EDTA (0.01 mM)	182 ± 3c	−0.99 ± 0.30
EDTA (0.08 mM)	180 ± 2c	−0.58 ± 0.12

[a]Values are means ± standard deviation of two measurements per sample, performed in duplicate (n = 4).

In conclusion, the potential applicability of a biomimetic iron-chelating moiety (PHA), grafted from a commercially applicable food-packaging polymer (PET), was demonstrated in controlling lipid oxidation of a commercial soybean oil-in water emulsion system. Herein, we developed a synthesis method to graft iron-chelating group precursors and convert them into active iron-chelating HA groups. PET-*g*-PHA films demonstrated strong iron-chelating activity in buffered systems relevant for chelating iron levels found in acidified food and beverages (pH 3.0) with competitive chelators. Results from this study demonstrate the applicability of biomimetic active packaging technology that can be utilized to protect foods and beverages from iron-promoted degradation.

Supporting Information

ABSTRACT: Concentrations of lutein and lutein esters were determined in an ample collection of 75 wheat genotypes comprising bread wheat (*Triticum aestivum* L.), durum (*Triticum durum* Desf.), spelt (*Triticum spelta* L.), emmer (*Triticum dicoccum* Schrank), and einkorn (*Triticum monococcum* L.) grown in five different environments. Einkorn genotypes showed the highest total amounts of lutein (4.5−7.8 μg/g dry matter), followed by durum (2.0−4.6 μg/g), spelt (0.9−2.0 μg/g), emmer (0.8−1.9 μg/g), and bread wheat (0.7−2.0 μg/g). Due to the observed highly significant genetic variance and high heritability, lutein contents of wheat genotypes may be increased by future plant breeding. Detailed HPLC-DAD-APCI(±)-MS^n data allowing the identification of six lutein monoesters and nine diesters are presented. Linoleic, palmitic, and oleic acids were the most abundant fatty acids in both the lutein esters and total free lipid fractions. Lutein esters were virtually absent in the tetraploid durum and emmer species, whereas their concentrations considerably differed among the genotypes belonging to the other species.

KEYWORDS: *carotenoid ester, heritability, xanthophylls, mass spectrometry, fatty acids*

INTRODUCTION

Wheat (*Triticum* spp.) is one of the most important cereal crops in Europe and worldwide.[1] Although this staple food is mainly consumed as an energy supplier due to its high starch and protein contents, it also contains nutritionally relevant compounds, such as vitamin E and carotenoids.[2] Among the present carotenoids, lutein is predominant in wheat (Figure 1A), accounting for 90−100% of the total carotenoids.[3] Lutein also occurs at high concentrations in the human macula, and its increased dietary intake has been associated with a reduced incidence of eye diseases, such as age-related macular degeneration (AMD), cataract, and retinitis pigmentosa.[4,5] The prevention of mild cognitive impairment and Alzheimer's disease in elderly people by lutein has also been discussed.[6−8] A yet unknown function of lutein in the infant brain has recently been hypothesized, as approximately 60% of the total carotenoids in their brain have been assigned to lutein, and its levels were found to be depleted in preterm infants.[9]

Although lutein concentrations in most wheat products are rather low (0.1−0.5 mg/100 g fresh weight (FW))[10] compared to common lutein-rich foods, such as green leafy vegetables (>2 mg/100 g FW)[11] and egg yolk (approximately 1 mg/100 g FW),[12] their high per capita consumption makes them an important dietary source. In 2007, annual per capita consumption of wheat products in Germany has been estimated to be 87 kg (women) and 114 kg (men), respectively.[13] In addition to its nutritional relevance, the carotenoid content in wheat is an important prerequisite for the product's color, substantially differing when processing flours from different species and genotypes.[3,14] In particular, durum wheat (*Triticum durum* Desf.) was bred for a high carotenoid content, due to its use for the production of semolina and pasta, where the resulting yellowish color hue is highly desirable.[15] Nevertheless, the carotenoid content in einkorn (*Triticum monococcum* L.), an ancient diploid wheat species, was previously reported to be up to 4-fold higher than in other wheat species.[3,14] However, investigations into carotenoid levels of flours from different wheat species are so far limited to a low number of included species and genotypes, additionally lacking multiyear and multisite studies.

According to the semisystematic carotenoid nomenclature,[16] lutein is characterized by hydroxylated β- and ε-rings (Figure 1A). Due to their asymmetric esterification with fatty acids, regioisomers of lutein esters are frequently observed. Recent studies of different nonwheat sources provided detailed information about lutein esters, including their regioisomers.[17−19] Although an earlier study demonstrated that lutein in wheat may occur in both the nonesterified and esterified forms,[20] comprehensive reports about the occurrence and identification of lutein acyl esters in wheat and cereals in general are scarce.[19,20] Particularly, a comprehensive study on carotenoid esters in old wheat species, such as spelt, emmer, and einkorn, has not been carried out to date.

In the present study, the determination of lutein and its esters in an ample set of 75 genotypes from 5 wheat species

grown in 5 different environments should illustrate the genetic variation and modificatory variability, that is, diversity of xanthophyll contents among different and identical species as affected by both genotype and environment. Considering the applied HPLC-DAD-MS^n method, the advantages of combining positive and negative ionization techniques for the identification of lutein ester regioisomers are additionally discussed.

MATERIALS AND METHODS

Plant Material and Sample Preparation. Fifteen genotypes each of bread wheat (*Triticum aestivum* L.), durum (*Triticum durum* Desf.), spelt (*Triticum spelta* L.), einkorn (*Triticum monococcum* L.), and emmer (*Triticum dicoccum* Schrank) were grown at four sites in Germany (Hohenheim, Eckartsweier, Oberer Lindenhof, Seligenstadt). All samples originated from harvest 2013, except for those from Hohenheim, which were from 2012 and 2013. A detailed sample list and further information about the different sites are provided in Supplemental Tables 1−6. Cereal samples used in this study were produced by the State Plant Breeding Institute (University of Hohenheim, Stuttgart, Germany) in separate but adjacent trials with two replicates for each species. After harvest, all spelt, einkorn, and emmer samples were dehulled and cleaned with a laboratory seed cleaner (Samatec-Roeber, Bad Oeynhausen, Germany) to remove hulls, straw, and damaged kernels. For chemical analyses, the kernels of the two replicates of one site were combined. The samples were stored under identical conditions (≤18 °C, ≤40% relative humidity) prior to milling to a particle size ≤0.5 mm by a laboratory mill ZM1 (Retsch, Haan, Germany). Subsequently, whole grain flour was stored at −20 °C until further analysis. Dry matter content was determined using an infrared moisture analyzer MA 40 (Sartorius, Göttingen, Germany).

Chemicals. Methanol, methyl *tert*-butyl ether (MTBE), potassium hydroxide (KOH), sodium chloride (NaCl), and ammonium acetate were purchased from VWR International (Darmstadt, Germany). Acetone, diethyl ether, and *n*-hexane were from Merck (Darmstadt, Germany). Lutein (purity ≥ 95%) originated from CaroteNature (Lupsingen, Switzerland). Fatty acids (FAs), their respective methyl esters (FAMEs) of GC purity, and a methanolic boron trifluoride solution (10% BF_3 in methanol) were obtained from Sigma-Aldrich (Steinheim, Germany). A marigold (*Tagetes erecta* L.) extract (10% lutein esters) was kindly provided by BioActives Europe (Frankfurt, Germany). Purified water was prepared using a Sartorius arium 611 Ultrapure Water System.

Extraction of Carotenoids. Carotenoids were extracted for their quantification according to a previously described method.[21] Briefly, an

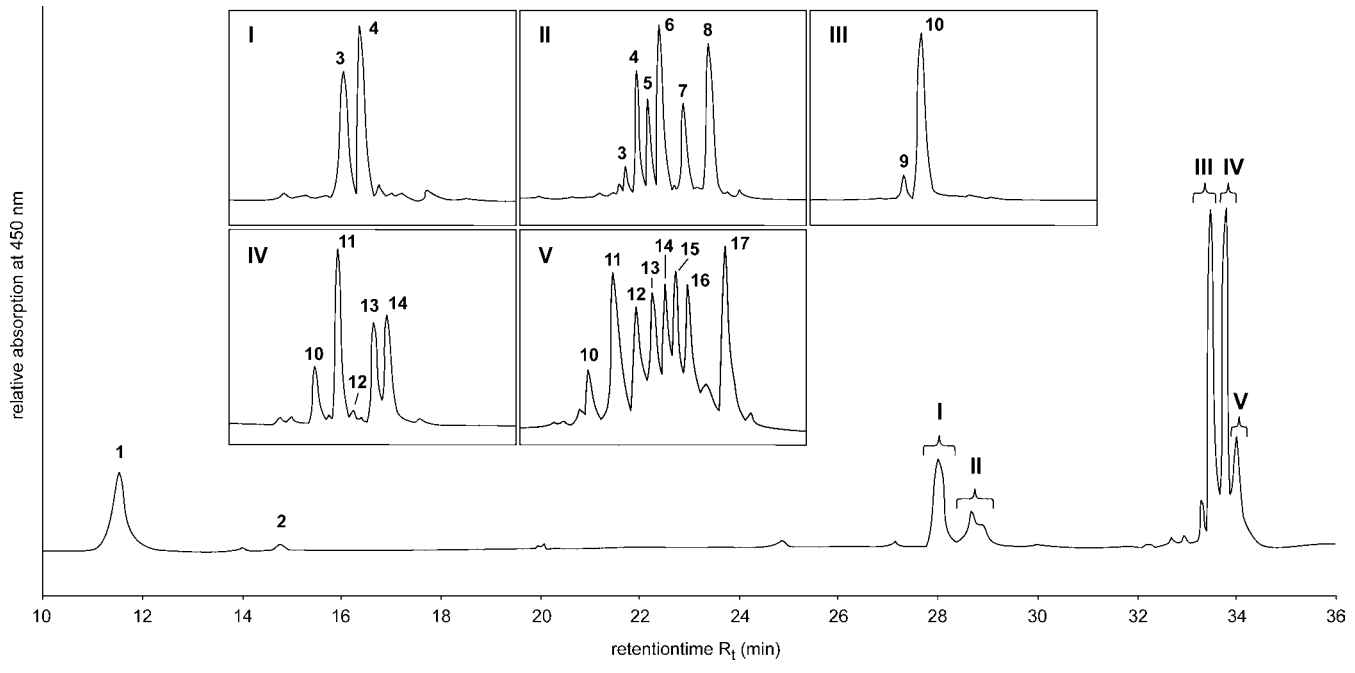

Figure 2. C_{18} HPLC chromatogram of a carotenoid extract from einkorn and C_{30} HPLC chromatograms of the isolated lutein ester fractions (I−V).

DOI: 10.1021/acs.jafc.5b01477
J. Agric. Food Chem. 2015, 63, 5061−5071

aliquot of 0.70 ± 0.05 g of whole grain flour was extracted three times with acetone (2, 1.5, and 1.5 mL, respectively) using an Ultra Turrax T-25 homogenizer (IKA-Werke, Staufen, Germany). Separation of the acetone extracts from the solid extraction residue was enhanced by centrifugation at 1750*g* for 2 min (Heraeus Labofuge 400R, Thermo Fisher Scientific, Osterode, Germany). The combined acetone extracts were dried under a gentle nitrogen stream and stored at −80 °C until HPLC analyses. As described by Burkhard and Böhm,[22] a soaking step was applied prior to the exhaustive extraction of carotenoids from the tetraploid wheat species durum and emmer. For this purpose, 0.7 mL of water was added to the wheat flour and soaked for 5 min prior to extraction. After the application of this soaking step, average carotenoid yields were increased by 44.5 and 39.1% for durum and emmer when all samples from genotypes of these species were compared, respectively (data not shown). In contrast, total carotenoid contents were decreased by 2.4−17.9% in the case of bread wheat, spelt, and einkorn. Therefore, the data reported for the latter species refer to an extraction omitting the soaking step.

For semipreparative isolation and subsequent identification of lutein esters, the extraction procedure described was scaled up to 40 g of extracted flour. The dried extract was redissolved in 5 mL of MeOH/MTBE (1:1, v/v) and, subsequently, lutein esters were fractionated by semipreparative HPLC using a 250 × 21.2 mm i.d. Phenomenex Aqua 5 μm C_{18} 125 Å column (Phenomenex, Torrance, CA, USA). For this purpose, a linear gradient from MeOH/water (90:10, v/v) to MTBE/MEOH/water (60:36:4, v/v/v) within 40 min was applied. As shown in Figure 2, the lipophilic wheat extracts were separated into five fractions (I−V), evaporated in vacuo (T = 25 °C), and analyzed by HPLC-DAD-MS^n as described below.

Saponification of Carotenoid Extracts. Confirming the occurrence of lutein esters, saponification of carotenoid extracts was conducted as follows. After carotenoid extraction as described above, the dried extracts were saponified following a method described by Mellado-Ortega and Hornero-Méndez.[19] Briefly, the dried extracts were redissolved in 2 mL of diethyl ether. Subsequently, 0.5 mL of methanolic KOH (10%, w/v) was added, and the mixture was stirred (ca. 500 rpm) for 1 h under a nitrogen atmosphere. After the addition of 1 mL of $NaCl_{aq}$ (30%, w/v), carotenoids were extracted with diethyl ether. The combined ether phases were evaporated in vacuo (T = 25 °C), and the dried extracts were stored at −80 °C until HPLC analyses.

HPLC-DAD-MS^n Analyses of Lutein and Lutein Esters. Prior to HPLC-DAD-MS^n analyses, the dried carotenoid extracts were redissolved in MeOH/MTBE (1:1, v/v) and membrane-filtered (0.45 μm, PTFE) into amber glass vials. Separation of carotenoids was performed on a series 1100 HPLC (Agilent, Waldbronn, Germany) equipped with a G1315B diode array detector. The carotenoid C_{30} column (150 × 3.0 mm i.d., 3 μm particle size, YMC, Dinslaken, Germany) with a YMC C_{30} guard column (10 × 3.0 mm i.d.) of the same material was operated at 25 °C. The mobile phase consisted of two different mixtures of MeOH/MTBE/10 g/L ammonium $acetate_{aq}$ (80:18:2 (v/v/v), solvent A; 6:92:2 (v/v/v), solvent B). The gradient program was as follows: 0−60% B (45 min), 60−100% B (5 min), 100% B isocratic (2 min), 100−0% B (3 min). Re-equilibration of the column was achieved at 0% B within 5 min. Total run time was 60 min at a flow rate of 0.42 mL/min. Injection volume was 20 μL. All carotenoids and carotenoid esters were monitored at 450 nm. Additionally, UV−vis spectra were recorded in the range of 220−700 nm. The HPLC system was coupled online to a Bruker (Bremen, Germany) model Esquire 3000+ ion trap mass spectrometer. MS^n analyses of carotenoids were performed using an atmospheric pressure chemical ionization (APCI) source in positive and negative mode in the range of m/z 200−1200 at a scan speed of 13000 Th/s. Nitrogen was used both as drying gas at a flow rate of 5 L/min and as nebulizer gas at a pressure of 55 psi. Vaporizer and dry temperature were set at 350 °C with a capillary voltage of ±2800 V, and the corona was set at 3000 nA in both positive and negative modes. Helium was used as the collision gas for collision-induced dissociation (CID) experiments at a pressure of 4.9×10^{-6} mbar. The fragmentation amplitude was set at 1.0 V.

Identification of carotenoids was carried out by comparing their retention times, UV−vis absorption, and mass spectra with those of authentic standards. Because commercial standards of lutein esters were unavailable, they were identified by their UV−vis absorption matching free lutein and by their characteristic mass spectral behavior as discussed below.[17−19,23] The identification of lutein esters was confirmed by cochromatographic analyses of a marigold (*Tagetes erecta* L.) extract containing known lutein esters (lutein dimyristate, lutein palmitate-myristate, lutein dipalmitate, lutein stearate-palmitate, and lutein distearate).[17] The respective chromatogram and corresponding identification parameters are provided in the Supporting Information.

The quantification of free, mono-, and diesterifed lutein was conducted by RP-C_{18}-HPLC-DAD using an authentic lutein standard recently described.[21] Due to their coelution on RP-C_{18} columns, zeaxanthin was quantitated together with free lutein. However, zeaxanthin contributes only 0−10% to the total carotenoids in *Triticum* according to previous studies[3] and our observations using a C_{30} column. Therefore, peak 1 was assigned to free lutein. Because the chromophore of xanthophylls remains identical after esterification,[24] the concentrations of lutein esters were determined by using the linear calibration for free lutein and molecular weight correction factors when data were converted from micromoles to micrograms. Limits of detection (LOD) and quantitation (LOQ) were determined[25] to be 0.01 and 0.03 μmol lutein/g DM, respectively.

Fatty Acid Extraction, Derivatization, and Analyses by GC-FID. Fatty acids (FAs) were determined according to a previously published protocol[26] with some modifications. Briefly, total free lipids of wheat flours were extracted in a Soxhlet apparatus for 2 h with boiling *n*-hexane. The organic solvent was evaporated in vacuo at 30 °C, and the total free lipid content was gravimetrically determined. Subsequently, an aliquot of 20−30 mg of the obtained total free lipids was combined with 1 mL of methanolic KOH (0.5 M) and heated at 80 °C for 10 min. After the mixture had cooled to room temperature, 1 mL of methanolic BF_3 reagent was added and heated for another 5 min at 80 °C. The samples were subsequently cooled to room temperature, and then 2 mL of $NaCl_{aq}$ (30%, w/v) was added. The fatty acid methyl esters (FAMEs) obtained were then extracted with *n*-hexane prior to GC-FID analyses. Heptadecanoic acid was added as internal standard prior to saponification.

For determination of FAMEs, a Chrompack CP 9001 gas chromatograph (Chromopack, Middleburg, The Netherlands) equipped with a CP 9010 autosampler and a FID detector was used. Separation was performed on a Supelcowax-10 fused silica capillary column (30 m × 0.25 mm i.d., 0.25 μm; Supelco, Bellafonte, PA, USA). Helium (purity 5.0) was used as carrier gas with a constant flow of 0.92 mL/min, and the injection volume was 1 μL at a split ratio of approximately 1:55. The oven temperature was ramped from 180 to 240 °C at a heating rate of 3 K/min. The final temperature was held for 3 min. The temperature of both the injector and detector was set at 250 °C. FAMEs were identified by comparison of their retention times with those of authentic standards. Quantitation was performed using linear calibrations of authentic reference compounds, additionally corrected by the internal standard signal (heptadecanoic acid).

Statistical Analysis. Variance components were determined by the restricted maximum likelihood (REML) method, assuming a random model using classical one-stage analyses.[27] Significance of variance component estimates was tested by model comparison with likelihood ratio tests in which halved P values were used as approximation.[28] Heritability h^2 was calculated according to eq 1

$$h^2 = 1 - \frac{\vartheta}{2\sigma_G^2} \quad (1)$$

where ϑ is the mean variance of a difference of two best linear unbiased predictors (BLUP) and σ_G^2 the genetic variance.[29,30] All analyses were performed with the statistical software R (R Development Core Team 2011) and the software ASReml 3.0.[31]

RESULTS AND DISCUSSION

Identification of Lutein and Its Fatty Acid Esters. *General Considerations.* All compounds monitored at 450 nm revealed identical UV−vis absorption spectra with maxima at 445 and 473 nm, also being identical to that of an authentic lutein standard (Table 1). In contrast to compounds **1** and **2**, compounds **3**−**17** were absent in the saponified carotenoid extracts (Supplemental Figure 1B,C). The highest concentrations of these compounds (**3**−**17**), presumably lutein mono- and diesters as described below (Table 2), were found in the einkorn breeding line '8.103/04', the bread wheat genotype 'Tabasco', and the spelt genotype 'Oberkulmer Rotkorn'. Thus, these genotypes were used for the identification of lutein esters.

For identification by RP-C_{30}-HPLC-DAD-MS^n as described above, the lutein ester-rich extracts were first divided into five fractions (I−V) by RP-C_{18} semipreparative HPLC (Figure 2). For the identification of lutein esters, mass spectral data obtained from an authentic lutein standard were helpful. Because the hydroxyl group of the ε-ring is in an allylic position (Figure 1A), the *in source*-formation of the dehydrated fragment at m/z 551 $[M + H - H_2O]^+$ is highly favored in the positive APCI experiments due to mesomeric effects (Figure 1B). The abundance of this ion at m/z 551 was drastically higher than that of the protonated pseudomolecular ion at m/z 569 $[M + H]^+$ (Table 1), being in agreement with previous studies.[32−34] CID experiments of the *in source*-fragment $[M + H - H_2O]^+$ at m/z 551 revealed several characteristic fragments (Figure 1C),[33,34] such as the predominant daughter ion $[M + H - 2H_2O]^+$ at m/z 533 (base peak), resulting from an additional loss of water from the hydroxyl group of the β-ring. The carotenoid-specific elimination of toluene from the central polyene chain of the carotenoid skeleton resulted in a characteristic loss of 92 amu,[32] leading to product ions at m/z 459 $[M + H - H_2O - 92]^+$ and 441 $[M + H - 2H_2O - 92]^+$. As shown in Figure 1C, the neutral loss of 56 amu may be due to an ε-ring-specific fragmentation following a retro-Diels−Alder reaction as described previously.[32,33] Consequently, the product ions detected at m/z 495 and 477 may correspond to $[M + H - H_2O - 56]^+$ and $[M + H - 2H_2O - 56]^+$, respectively (Table 1). The elimination of the cyclic β- or ε-end groups from the carotenoid skeleton resulted in the fragment ions $[M + H - H_2O - 122]^+$ at m/z 429 and $[M + H - 2H_2O - 122]^+$ at m/z 411 (Figure 1C),[33] whereas the ion at m/z 345 was previously described to be a fragment of $[M + H - H_2O]^+$ at m/z 551.[35]

The described fragmentation pattern of lutein was instrumental for the identification of lutein esters, particularly their regioisomers. By analogy to the *in source* water loss from C3′ of the ε-ring, acyl residues were separated from the ε-ring of lutein esters during APCI(+) experiments. As a result, the protonated molecular ion $[M + H]^+$ of 3′-*O*-monoesters and diesters is commonly observed at poor intensity. However, the differing fragmentation patterns of the β- and ε-ring hydroxyl and acyl moieties allow the differentiation of lutein ester

[a]Up to 10% of the total lutein content may be zeaxanthin. [b]Mean. [c]Number of environments where the respective genotype was grown. [d]Mean ± standard deviation.

regioisomers, as the predominant *in source*-fragment ion indicates the position of the fatty acid moiety.[17−19] Briefly, lutein 3′-*O*-monoesters showed *in source*-fragments $[M + H - \text{fatty acid}]^+$ at m/z 551 as the most abundant ion, whereas $[M + H - H_2O]^+$ at higher m/z represented the predominant positive fragment ion of 3-*O*-monoesters, for example, at m/z 789 for lutein 3-*O*-palmitate. Similarly, the most abundant *in source*-fragment ion of lutein diesters indicated the loss of the fatty acid located at position 3′ (ε-ring). Consequently, the identity of the fatty acid attached to position 3 (β-ring) can be deduced by exclusion principle. However, this identification strategy requires the unambiguous assignment of the m/z of the (pseudo)molecular ion, which may be intricate when only APCI(+) is used. Therefore, APCI(−) experiments were conducted as described previously.[36,37] Under the chosen MS conditions, the authentic lutein standard showed a predominant ion in the negative mode at m/z 568, corresponding to its molecular ion $[M]^-$. Among others, Breithaupt[36] reported that APCI(−) produced a higher abundance of the negatively charged molecular ions $[M]^-$ of astaxanthin esters than the corresponding $[M - H]^-$ ions.

Identification of Lutein Monoesters. Following the identification strategy described above, six compounds (**3**−**8**) contained in fractions I and II were assigned to lutein monoesters by RP-C_{30}-HPLC-MS^n (Figure 2). Lutein being the core carotenoid of diverse esters was identified on the basis of its characteristic UV−vis absorption spectrum identical to that of free lutein (Table 1) as well as the disappearance of lutein esters after saponification and the concomitant increase of the signal of free lutein. Both 3′-*O*- and 3-*O*-regioisomers of lutein linoleate (**3**, **4**), oleate (**5**, **6**), and palmitate (**7**, **8**) were identified, because characteristic molecular ions $[M]^-$ at m/z 830, 832, and 806 were observed during APCI(−)-MS experiments, respectively. With regard to the 3′-*O*-regioisomers, the *in source*-fragment $[M + H - \text{acyl}]^+$ at m/z 551 was the prevailing ion, whereas the 3-*O*-regioisomers showed predominant dehydrated *in source*-fragment ions corresponding to $[M + H - H_2O]^+$ of lutein linoleate (m/z 813), lutein oleate (m/z 815), and lutein palmitate (m/z 789), respectively. In contrast to APCI(−)-MS, molecular ions $[M + H]^+$ were detected only at very low intensity, if they were detectable at all. However, CID experiments of the above-mentioned predominant *in source*-fragment ions of 3′-*O*-regioisomers provided characteristic daughter ions at m/z 495, 459, and 429, thus indicating the occurrence of a free hydroxyl group at the β-ring as described above. After fragmentation of 3-*O*-regioisomers, the lutein backbone $[M + H - H_2O - \text{fatty acid}]^+$ at m/z 533 was the most abundant ion, followed by product ions at m/z 411 and 477, corresponding to a further lutein-specific fragmentation. In addition, identification of 3′-*O*-regioisomers of lutein monoesters was confirmed by their elution before the respective 3-*O*-isomers as has been previously reported for the RP-C_{30} conditions applied.[17−19]

Identification of Lutein Diesters. Eight compounds (**9**−**17**) present in the isolated fractions III−V (Figure 2) were identified to be lutein diesters due to their characteristic UV−vis absorption spectra identical to that of free lutein (Table 1), their disappearance after saponification, and their characteristic mass spectral behavior.

DOI: 10.1021/acs.jafc.5b01477
J. Agric. Food Chem. 2015, 63, 5061−5071

The first eluting diester (compound **9**) showed a negative ion $[M]^-$ at m/z 1090. The occurrence of the positive *in source*-fragment ions $[M + H - 278 \text{ (linolenic acid)}]^+$ at m/z 813 and $[M + H - 280 \text{ (linoleic acid)}]^+$ at m/z 811 indicated a lutein linolenate-linoleate. Unexpectedly, elucidation of its regioconfiguration was impossible, due to the almost identical intensities of the above-mentioned *in source*-fragments $[M + H - \text{acyl}]^+$. Possibly, this finding may be explained by the coelution of both regioisomers.

Compound **10** exhibited a predominant molecular ion $[M]^-$ at m/z 1092 in APCI(−), whereas APCI(+) produced corresponding *in source*-fragments $[M + H - 280]^+$ at m/z 813 (100%) and $[M + H - 280 - 280]^+$ at m/z 533 (17%). After CID of the ion at m/z 813, a prevailing fragment at m/z 533 confirmed the relationship of both ions. Due to the absence of a second *in source*-fragment $[M + H - \text{fatty acid}]^+$ indicating the loss of a fatty acid other than linoleic acid, compound **10** was identified as a homogeneous diester, namely, lutein dilinoleate.

Due to its $[M]^-$ at m/z 1094 and characteristic *in source*-fragments $[M + H - 282 \text{ (oleic acid)}]^+$ at m/z 815, $[M + H - 280]^+$ at m/z 813, and $[M + H - 282 - 280]^+$ at m/z 533 (Table 1), compound **11** was assigned to lutein 3′-*O*-linoleate-3-*O*-oleate.

Compound **12** revealed a molecular ion $[M]^-$ at m/z 1096. The *in source*-fragments $[M + H - 282]^+$ at m/z 815 allowed its identification as lutein dioleate (**12**), particularly because additional losses of fatty acids other than oleic acid were missing.

A negative molecular ion $[M]^-$ at m/z 1068 was observed for both compounds **13** and **14**, indicating related regioisomers. As described above, the relative ion abundances of the two $[M + H - \text{acyl}]^+$ *in source*-fragments were used for the identification of the regioconfiguration. The occurrence of product ions $[M + H - 256 \text{ (palmitic acid)}]$ at m/z 813 (100%) and $[M + H - 280]^+$ at m/z 789 (4%) identified compound **13** as lutein 3′-*O*-palmitate-3-*O*-linoleate, whereas compound **14** producing ions at m/z 789 (100%) and m/z 813 (8%) occurring at reversed intensity was assigned to lutein 3′-*O*-linoleate-3-*O*-palmitate. By analogy, peaks **15** and **16** were identified as lutein 3′-*O*-palmitate-3-*O*-oleate (**15**) and lutein 3′-*O*-oleate-3-*O*-palmitate (**16**). Compound **17** revealed a molecular ion $[M]^-$ at m/z 1044 as well as a characteristic *in source*-fragment $[M + H - 256]^+$ at m/z 789. Because neutral losses of other fatty acids were not observed, compound **17** was identified as lutein dipalmitate.

In addition to these observations, the CID spectra presented in Table 1 confirmed our proposed structures of compounds **9**−**17**. The identity of the carotenoid core molecule lutein was supported by CID spectra of the respective *in source*-fragments, consisting of a characteristic product ion at m/z 411, which corresponds to the lutein backbone after elimination of one cyclic end group (β- or ε-ring).[33] Furthermore, compounds **10**, **11**, and **14**−**17** revealed a product ion at m/z 477 corresponding to a retro-Diels−Alder fragment of the ε-ring of the lutein backbone. Notably, further fragment ions less important for structure elucidation were observed (data not shown).

Lutein Content and Degree of Esterification in *Triticum* spp. Lutein contents of whole grain flours from 15 genotypes of wheat species comprising bread wheat, durum, spelt, einkorn, and emmer were determined after their cultivation in five different environments, that is, different sites and harvest years. Concentrations of free lutein (compound **1**), total lutein monoesters (fractions I and II, Figure 2), total lutein diesters (fractions III−V), and total lutein (free + esterified) were determined using the whole sample set, whereas concentrations of single lutein esters were determined only in a representative subset of samples (see below).

Table 2 shows the lutein contents and their degree of esterification of the investigated 75 genotypes belonging to 5 species of bread wheat, durum, spelt, einkorn, and emmer. The einkorn genotypes clearly showed the highest total lutein content (total median = 5.65 μg/g DM), followed by the 1.7-fold lower content of durum (3.26 μg/g DM). Spelt (1.53 μg/g DM) and emmer (1.52 μg/g DM) contained comparable amounts, being slightly higher than in bread wheat (1.35 μg/g DM). The highest total lutein contents were found for the einkorn breeding line M-04033/03, consistently over all environments investigated (6.95−8.95 μg/g DM), although not being significantly different from the also lutein-rich einkorn genotypes M-04033/01 (6.75−8.83 μg/g DM) and 8.116/04 (6.92−8.33 μg/g DM). The lutein contents determined in *Triticum* spp. are comparable to previously reported values.[3,14] Similarly, einkorn was previously reported to be the most lutein-rich *Triticum* species.[3,38] Due to its high carotenoid content, the production of pasta may be a promising application of einkorn, because the resulting yellow color is highly desirable. Hence, lutein concentrations up to 0.6 mg/100 g could be reached in vegan pasta, being even higher than in egg pasta (0.5 mg/100 g).[39,40]

The degree of lutein esterification varied strongly among and within species. Interestingly, lutein esters were completely absent in all durum and emmer genotypes. Because durum and emmer are both tetraploid wheat species, the inability to form carotenoid esters may be congenital. However, further investigations may be intricate, because, to the best of our knowledge, the genes and enzymes responsible for carotenoid esterification have not yet been reported. Although the absence of lutein esters in emmer has been reported for the first time, sporadic reports about a few durum genotypes lacking lutein esters are available.[15,23]

With regard to bread wheat, lutein esters were absent in seven genotypes, whereas 22.7−38.3% of total lutein was esterified in the remaining eight genotypes (Table 2). In contrast, all spelt and einkorn genotypes consistently contained lutein esters. However, the degree of esterified lutein in spelt (median = 29.7%) was significantly higher than in einkorn (7.6%). Furthermore, the ratio of mono- to diesters was about 2:1 in spelt. In einkorn, this ratio was even higher, ranging from 7:1 to 20:1, with the einkorn breeding line 8.103/04 being the only exception. The latter contained 48.7−72.6% lutein esters, mainly diesters. A correlation between the amount of esterified lutein and the total lutein content could not be revealed (data not shown).

Notably, the simultaneous occurrence of lutein and its esters in significant amounts, as shown for *Triticum* in the present work, is very unusual. In photosynthetically active tissues, lutein commonly occurs only in its free form, whereas it is predominantly esterified in chromoplasts of diverse fruits or petals.[41]

In previous studies, the occurrence of lutein esters in cereals has been hypothesized to be related to storage conditions such as temperature, humidity, and time.[23,42−44] Because all samples investigated in the presented study were stored under the same conditions and originated from five different environments, we

DOI: 10.1021/acs.jafc.5b01477
J. Agric. Food Chem. 2015, 63, 5061−5071

hypothesize a significant genetic factor to be responsible for the observed differences among genotypes and species.

Genetic Variance and Heritability of Total Lutein Contents. In all five wheat species, a highly significant genetic variance (σ^2_G) was determined for the total lutein content (Table 3). Furthermore, a very high heritability (h^2) exceeding 0.93 was calculated for all wheat species, thus confirming previous studies of tetraploid wheats.[45,46] Accordingly, total lutein contents in einkorn, emmer, spelt, durum, and bread wheat appear to be mainly affected by genetic factors, whereas environmental effects play a minor role. The variability of the total lutein content of individual genotypes is illustrated in Supplemental Tables 2−6, showing comparatively small differences among the different cultivation sites or harvest years. However, over all environments, the same einkorn genotypes revealed the highest total lutein contents (M-04033/03, M-04033/01, and 8.116/04), whereas the bread wheat genotypes Julius and Event consistently showed the lowest lutein contents. The wheat species durum and einkorn both exhibiting the highest average lutein contents also showed the largest genetic variance. Thus, especially in the latter species, a future increase of total lutein content by plant selection efforts seems to be promising.

Quantification of Individual Lutein Esters in Selected Genotypes. Concentrations of individual lutein esters were determined in bread wheat (var. Tabasco), spelt (var. Oberkulmer Rotkorn), and einkorn (var. 8.103/04). As shown in Table 4, all esters so far identified were found in einkorn, which exhibited the highest total ester content of the investigated genotypes (7.7 μg/g DM). The monoesters lutein 3-*O*-oleate (**6**) and lutein 3-*O*-palmitate (**8**), as well as the diesters lutein dioleate (**12**) and lutein 3′-*O*-oleate-3-*O*-palmitate (**16**), could not be detected in bread wheat and spelt. In the latter species, lutein linoleate-linolenate (**9**) and lutein 3′-*O*-palmitate-3-*O*-oleate (**15**) were found only in traces (<LOQ). Lutein dilinoleate was the prevailing ester in all three species, with particularly high concentrations in einkorn (2.637 μg/g DM). This lutein diester seems to be characteristic of cereals, because it has previously been described in bread wheat and tritordeum (×*Tritordeum* Ascherson et Graebener).[19,42] To the best of our knowledge, its occurrence in other plants has not been reported so far.

In agreement with a previous study on lutein regioisomers from tritordeum grains,[19] 3-*O*-regioisomers of lutein monoesters occurred at higher concentrations than their related 3′-*O*-regioisomers, displaying a ratio of about 2:1 in einkorn (Table 4). However, because bread wheat and spelt showed the opposite with lower or even undetectable amounts of 3-*O*-regioisomers, conclusions about preferred regiospecific esterification cannot be drawn. By analogy, this specific einkorn genotype contained 3.8-fold higher diester levels than monoesters, whereas bread wheat and spelt contained almost equal amounts of both forms.

Fatty Acid Composition in Lutein Esters and Total Free Lipids. To reveal putative similarities, the fatty acid pattern of the carotenoid esters was compared to that of total free lipids in wheat after saponification of a limited subset of samples (Table 5). Linoleic acid was the predominant fatty acid

[a]Mean ± standard deviation (n = 2).

(50.7−61.6%) of the total free lipids in all five genotypes investigated. As previously reported,[47,48] palmitic acid was the second most common fatty acid in bread wheat (17.7%), followed by oleic acid (14.4%), whereas it was vice versa in the other four species investigated (13.4−15.8% palmitic and 18.7−29.2% oleic acid). Linolenic acid accounted for 3.5−5.9% of the total fatty acids. Stearic acid, eicosenoic acid, and arachidic acid occurred only in minor amounts. Major fatty acids of the total free lipids were found to be identical with those being esterified with lutein. Figure 3 illustrates the strong correlation (Pearson

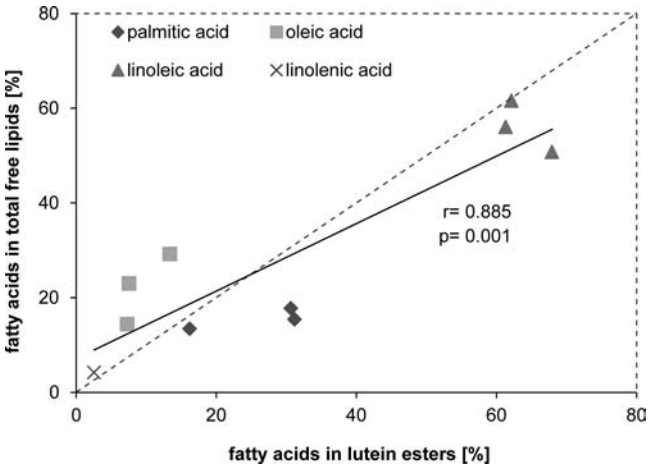

Figure 3. Correlation between the abundance of fatty acids in the total free lipids and of lutein esters.

correlation coefficient r = 0.885, p = 0.001) between the fatty acids present in carotenoid esters and those of total free lipids. As demonstrated by the dashed reference line (slope = 1), the abundance of linoleic and palmitic acid in the lutein esters was significantly higher (61−68 and 16−31%, respectively), that of oleic and linolenic acid being relatively underrepresented (7−13 and 2%, respectively). However, these findings do not yet allow the hypothesis of a highly fatty acid-specific xanthophyll acyltransferase in wheat, as has previously been suggested for tritordeum.[19,23] Briefly, Mellado-Ortega and Hornero-Méndez[19] found palmitic acid to be the most common fatty acid in lutein esters, whereas its relative abundance among the fatty acids of the total free lipids was lower. In addition, oleic acid was found to be present at high concentrations in the total lipids of tritordeum, being absent in its lutein esters. Therefore, they suggested a highly specified enzyme involved in the esterification of lutein.

In our study, the relative amounts of fatty acids being esterified with carotenoids were determined, showing that only up to 0.06% w/w of the total fatty acids in all wheat species was esterified with lutein.

In conclusion, einkorn genotypes showed the highest lutein contents among all genotypes belonging to five *Triticum* species investigated in the present study. The presence of lutein esters was demonstrated to be a characteristic trait of specific genotypes and species, being independent of their total carotenoid content. The absence of lutein esters in tetraploid wheat species (i.e., durum, emmer) was found to be a general trait, which merits further investigation. Genotypes devoid of and being rich in lutein esters may be useful tools for the identification of the yet unknown genes and enzymes responsible for carotenoid esterification. Whether the bioavailabilities of lutein and its esters from wheat differ is yet unknown, although their esterification should impart a highly distinct solubility in dietary lipids and, thus, also different liberation and absorption behaviors from wheat products. In addition, lutein and lutein esters may be deposited in different plastidal substructures, which may further affect their bioavailability.[49,50] Therefore, a nutritional preference of lutein ester-containing sources to those mainly containing free lutein should be based on in vitro and in vivo experiments. Although the lutein contents in vegetables and fruits are by far higher than in wheat (i.e., up to 20-fold higher in spinach or kale than in einkorn),[51] wheat products are generally consumed more frequently and in higher quantities in many countries worldwide. Therefore, wheat and, in particular, the yet underutilized species einkorn and durum should be considered as valuable sources of lutein in the human diet. In addition, manufacture of yellow-tinted vegan wheat products may become feasible without the addition of egg yolk or other colorants by the sole use of einkorn flours.

ABSTRACT: The aim of the present study was to characterize the structure of two different types of pasta, namely *Triticum turgidum* ssp. *durum* (cv. Saragolla) and *Triticum monococcum* ssp. *monococcum* (cv. Monlis), under different processing conditions. MRI analysis and NMR spectroscopy (i.e., T_1 and T_2 NMR relaxation times and diffusion parameters) were conducted on pasta, and ^{1}H NMR spectroscopic analysis of the chemical compounds released by pasta samples during the cooking process was performed. In addition, starch digestibility (enzimatically determined) was also investigated. The NMR results indicated that Saragolla pasta has a more compact structure, ascribed to pasta network and in particular to different technological gluten properties, that mainly determine the lower ability of Monlis pasta in binding water. These results correlate well with the lower rate of starch hydrolysis measured for Monlis pasta compared to Saragolla when both are dried at high temperature.

KEYWORDS: *pasta microstructure, MRI, ^{1}H NMR spectroscopy, T_1/T_2 relaxation times, diffusion, in vitro starch digestibility*

INTRODUCTION

Wheat provides a significant amount of carbohydrates and proteins and constitutes a good source of lipids, antioxidants and minerals that, although present in a limited concentration, cover most of the human requirements.[1] Einkorn (*Triticum monococcum* L. ssp. *monococcum*), a diploid hulled wheat with high protein,[2] carotenoids, tocols,[3] and microelements, is a promising candidate for the development of bakery products, baby food and enriched foods.[5,3] In addition, the French-led Protected Geographical Indication[6] in Italy led to the development of a new einkorn variety called Monlis. Monlis is characterized by excellent bread-making aptitude, high tocol and carotenoid content and good yielding ability.

The digestibility of starch products is widely studied due to its positive correlation with the glycemic response in humans. Recently, the European Food Safety Authority, via the Panel on Dietetic Products, Nutrition and Allergies, concluded that high postprandial glycemic responses may be detrimental to human physiology. The panel concluded that slowly digestible starch (SDS) in cereal products, compared to rapidly digestible starch (RDS), has a reduced post-prandial glycemic response.[7] The digestibility of pasta, a very common starchy food, was reported to depend on both intrinsic properties of the wheat ingredients and the processing conditions during extrusion, drying and cooking.[8,9] For example, extrusion leads to the formation of starch−protein and starch−lipid complexes,[10] which decreases digestibility. Similarly, the high-temperature drying process leads to highly aggregated proteins that are cross-linked via covalent bonds and disulfide bridges, thereby also decreasing starch digestibility.[9] Starch gelatinization occurs during cooking, causing swelling of starch granules that in turn leads to an increased enzymatic activity during starch digestion. The efficiency of enzymes also depends on starch hydration[11,12] and limited amylase affinity and catalytic efficiency have been observed in conditions with low water content.[13] Finally, inherent characteristics of the wheat, linked to geographical and botanical origins, play important roles, as these characteristics have been shown to be correlated with starch architecture[11] and metabolic profile.[14]

All of these processes further influence the pasta structure. Nuclear magnetic resonance (NMR) is a widely recognized innovative methodology used in the molecular characterization of food. It is a noninvasive and nondestructive technique capable of probing molecular processes occurring over a wide range of time scales.

High-resolution NMR spectroscopy can be combined with magnetic resonance imaging (MRI) approaches to characterize the molecular structure as well as the state of water in heterogeneous systems as a food matrix. Specific for the MRI technique, image contrast is governed by spatial variation of the NMR parameters. Depending on the imaging protocol, spin−lattice (T_1) and spin−spin (T_2) relaxation times or self-diffusion coefficient (D) maps can be obtained for a defined sample region. For example, the ^{1}H relaxation properties of starch samples exhibit a complex multiexponential behavior and show an increase in the more mobile fractions upon gelatinization.[15,16] The application of NMR was extended to the study of starch in complex systems that contain fat and sucrose in large amount such as cakes,[17] while water diffusion analysis has been applied to pasta,[18] cooked rice,[19] and spaghetti.[20] However, while some information is available on the behavior of durum wheat pasta during digestion,[8] very few data are reported in the literature on einkorn pasta.

The present study aims at investigating the physical, microstructural, and digestibility properties of different types of pasta prepared from *Triticum turgidum* ssp. *durum* (cv. Saragolla) and *Triticum monococcum* ssp. *monococcum* (cv. Monlis) processed at two drying temperatures, 92 and 40 °C. Microstructural characterization was performed by MRI, via analysis of T_1 and T_2 relaxation and diffusion parameters, in combination with NMR T_2 relaxation and free induction decay (FID) analysis. In addition, ^{1}H NMR analysis of the chemical compounds released by cooking pasta was performed. NMR results correlated well with starch digestibility data, enzymatically determined. Finally, the MRI results were confirmed with Environmental Scanning Electron Microscopy (ESEM) images.

MATERIALS AND METHODS

Samples. The kernels of *T. turgidum* L. ssp. *durum* Desf (cv. Saragolla) and *T. monococcum* L. ssp. *monococcum* (cv. Monlis) were harvested from 100 m^2 plots that were cropped in 2008−2009 at Sant'Angelo Lodigiano (Po Plain, Italy) following standard agronomic practices. Before milling, the seeds of Monlis (M) were de-hulled with an Otake FC4S thresher (Satake, Japan); de-hulling was not necessary for the free-threshing durum wheat Saragolla (S). Overnight tempering was performed at 14% moisture for M and at 16% for S. The kernels were milled with a Bona 4RB (Bona, Italy) experimental mill, which separates the flour fraction from bran and germ.

Pasta Preparation. Approximately 4 kg samples of M and S flours were processed into short-cut pasta (macaroni) with a P630VR lab pasta maker (Parmasel, Parma, Italy). Dough mixing, performed under vacuum (−60 kPa), lasted 7 min. The pre-extrusion moisture of the dough was 30% for M and 32% for S; the extrusion was performed under 8000 kPa pressure. Pasta drying was carried out at two different temperatures, specifically low (peak temperature 40 °C, 24 h) and high (peak temperature 92 °C, 4 h), in a dark drying cabinet (Braibanti, Padova, Italy) at a constant 75% relative humidity. Samples of S and M pasta at both drying conditions of 92 and 40 °C were obtained. Hereafter, the different S and M pasta species, dried at 40 and 92 °C will be referred to as S40, S92, M40, and M92, respectively.

Cooking Parameters. Pasta samples were cooked in deionized boiling water at a ratio of 1:10. The "al dente" cooking time was determined by observing the disappearance of the white core of the pasta squeezed between two glass plates, according to the AACC 16−50 method (AOAC, 2000).

Chemical Composition of Cooked Pasta. Protein, starch and ash quantifications were performed in duplicate for all types of pasta cooked at 11 and 15 min. Protein quantification was carried out using the Kjeldahl method, as reported in the official method of analysis 976.05.[21] The total starch content was measured according to method 996.11. Ash content was determined as described in method 923.03.[21]

ESEM Analysis. The microscopic structure of cooked pasta samples was assessed using a TM-1000 Tabletop environmental electronic scanning microscope (Hitachi High-Technology, Tokyo, Japan) at 15 kV accelerating voltage and 28.6 mA emission current. Samples were placed in a metallic support without coating under low vacuum. Images were captured at different magnifications and in triplicate.

^{1}H NMR Relaxation and MRI. Proton NMR T_1 and T_2 relaxation, free induction decay (FID), and MRI experiments were carried out on a Bruker AM 200 WB spectrometer (Bruker, Karlsruhe, Germany) operating at 4.7 T, equipped with a standard microimaging accessory consisting of a ^{1}H tunable probe-head and a gradient drive unit. Orthogonal field gradient coils were capable of achieving gradients up to 150 G·cm^{-1} with a trigger pulse of 5 μs. Each pasta sample (1 g) was boiled in 100 mL of distilled water for 11, 15, or 20 min. For each time point, the sample was drained in a steel colander and, after removing surface water, inserted into a 10 mm NMR tube. The same protocol was applied to pasta samples with an identical mass boiled in 100% D_2O. Three repetitions were performed for each boiling time. T_1, T_2 and diffusion MRI experiments were performed in a single experimental session. T_1 and T_2 weighted images were recorded by employing the standard phase/frequency encoding 2D spin−echo sequence. A spectral width of 33 kHz was employed together with an 11 mm field of view (FOV) and a voxel resolution of 86 × 86 × 1000 μm^3. Selective radiofrequency pulses (1000 Hz bandwidth, Gaussian shaped, truncated at 5% level) were used for slice selection. Other acquisition parameters are reported in the figure captions. T_1-weighted images were recorded by adopting an echo time of 6.07 ms to minimize the T_2 effect. For each experiment, 15 images (number of averages (NE) = 4) were collected, by varying the repetition time (TR) between 0.05 and 60 s. The two equally spaced echo times were systematically varied in the range of 6−80 ms to collect T_2-weighted images with a TR = 20 s to eliminate T_1 artifacts. A total of 15 images (NE = 4) were sequentially collected. Diffusion-weighted images were acquired by adopting a modified STEAM sequence specifically tailored for imaging of biological samples characterized by long T_1 and short T_2 relaxations. Seven images (NE = 4) were recorded: a reference image with Z gradient = 0 T·m^{-1} and six images with the Z-diffusion encoding gradients with little delta (δ) of 3 ms in the 0−340 mT·m^{-1} range separated by a big delta (Δ) of 50 ms. All the images were processed on the O2 Workstation (Silicon Graphics, California) with the Paravision software package (Version 2.6, Bruker).

Proton relaxation times and FID analyses were carried out on identical weighed S92 and M92 samples, boiled for 15 min in H_2O or 100% D_2O. The longitudinal magnetization decay (T_1) was measured by the inversion recovery sequence by adopting the following acquisition parameters: inversion recovery time (2τ) from 50 ms to 10 s, NE = 15, NS = 8, TR = 20s. The transversal magnetization decay (T_2) was measured by the common Hahn spin−echo sequence: echo times from 5 μs to 5 s, NE = 45, NS = 4. The CPMG sequence was also employed: 90° = 9 μs, 180° = 19 μs, 180° interpulse delay = 1.1 ms. The CPMG train was varied between 2 and 80 ms. FIDs were determined with one transient in single channel detection mode, 4096 data points, acquisition time = 0.4096 s, dwell time = 100 μs, TR = 30 s. All experiments were carried out in triplicate at 297 K.

Relaxometric and Diffusion Data Analysis. Two or more circular regions of interest (ROIs) of approximately 2 × 10^6 μm^2 and a ROI on the entire surface were tracked over each T_1, T_2 and diffusion weighed recorded image. The software returned the maps containing the signal intensity values to be used for the calculation of the T_1, T_2 and diffusion parameters. Normalized peak intensities of the Fourier-transformed ^{1}H spectra recorded by using the spin−echo and/or the CPMG pulse sequences were used versus the corresponding time, 2τ, to calculate the T_1 and T_2 relaxation values. All relaxometric data were fitted to a multiexponential function, whose rate constant represented, respectively, the parameters T_1, T_2, and D. The experimental data were fitted using the Maquardt−Levenberg algorithm, implemented by the Sigma Plot (Version 1.02) software (Jandel).

^{1}H NMR Spectroscopy of Boiling Water. Each pasta sample (1 g) was boiled in 100 mL of distilled water for 11 and 15 min. The

DOI: 10.1021/acs.jafc.5b01993
J. Agric. Food Chem. 2015, 63, 5072−5082

boiling water was carefully withdrawn, centrifuged and lyophilized; 15 mg of each sample was then dissolved in phosphate-buffered (pH 7.0) D_2O and inserted into a 5 mm NMR tube (550 μL) for ^{1}H NMR experiments. ^{1}H NMR spectra were recorded on a Bruker DMX 500 spectrometer (Bruker Biospin GmbH Rheinstetten, Karlsruhe, Germany) operating at 11.7 T and equipped with a 5 mm inverse probe and *z*-gradient. All spectra were acquired in triplicate at 300 K. The spectral width was 6500 Hz, and 32K data points were collected using the standard one-dimensional NOESY pulse sequence.[22] We employed a water presaturation scheme with low radiofrequency power during the mixing time (100 ms) and the relaxation delay (1.2 s). An exponential function with a line broadening of 0.3 Hz was applied before Fourier transformation. Processing (phase and spectra baseline correction) was performed with TOPSPIN software (Bruker Biospin). Integrals were normalized to sodium 3-trimethylsilyl propionate (TSP) as a reference.

***In Vitro* Starch Digestion.** Starch digestion of each pasta type was performed *in vitro* following 11 and 15 min of cooking time, modifying the method of Kim et al.[23] Briefly, cooked pasta was minced to mimic the oral food breakdown. Approximately 1 g of minced sample was put into glass vials, each representing a single point of starch digestion. The extent of digestion was assessed at five time points (0, 20, 60, 120, and 150 min). All samples were subjected to a 30 min incubation with pepsin (pepsin from hog stomach, 3348 U·mL^{-1}, Fluka; enzyme:protein ratio 1:30, pH 2.5) to simulate the gastric phase. Afterward, the pH was adjusted to 7.2 and 4 mL of (10 mg·mL^{-1}) pancreatic amylase (Megazyme, Ireland) was added to perform starch digestion. Samples were incubated at 37 °C while being shaken at 170 rpm for 20, 120, and 150 min. The digestion reaction was stopped by ethanol addition. The samples were then centrifuged at 5000 rpm for 10 min at 8 °C and supernatants diluted to 100 mL with 100 mM sodium acetate buffer (pH 4.5). A 100 μL aliquot was treated with 10 μL of amyloglucosidase (300 U·mL^{-1}) and incubated at 50 °C for 20 min. Subsequently, 3 mL of glucose oxidase/peroxidase (Megazyme, Ireland) was added, and the samples were incubated for an additional 20 min at 50 °C prior to absorbance detection. The glucose released during digestion was quantified as hydrolyzed starch during the amount of time elapsed, multiplying the absorbance by 0.9. From this value, the rapidly digestible starch (RDS) content was estimated.[24] The experiments were performed in triplicate.

Statistical Analysis. Statistical analysis for relaxation and diffusion data was performed by the Prism program Version 4 (GraphPad Software Inc., La Jolla, CA, USA) and the Sigma Plot software (Jandel). The results were compared by one-way analysis of variance (ANOVA). Tukey-Kramer multiple comparison test was used to determine significant differences between samples. $P < 0.05$ was accepted as the level for statistical significance.

RESULTS AND DISCUSSION

Chemical Composition of Cooked Pasta. Chemical and nutritional compositions of M and S pasta samples dried at 40 and 92 °C after 11 and 15 min cooking times were determined, and the results are reported in Table 1. In all tested conditions, S and M samples exhibited significantly different ($p < 0.001$) protein contents, which was not affected by the cooking time. The total starch in cooked pasta was quantified and the results suggest that for S pasta starch content increased significantly ($P < 0.001$) with cooking time. Although a significantly higher ($p < 0.001$) ash content was found in S (mean value of all S samples = 0.60%) compared to M (mean = 0.29%), both these figures fall into the typical range for plain flour.

ESEM Analysis. ESEM experiments were carried out for all pasta samples. Representative results from M92 and S92 are displayed in Figure 1. A different structural matrix for the two pasta types: S (Figure 1A) and M (Figure 1B) at each processing phase can be observed. Dried S (a) and M (b) both showed the presence of partially gelatinized starch. It is well known that the gelatinization process during pasta preparation (in particular, during kneading−extrusion and drying) can cause a transition of the starch structure from crystalline to amorphous.[25] This phenomenon was more evident at the high drying temperature (92 °C) and in S (a) compared to M (b). The different matrix characteristics were preserved after cooking. At 11 min, in S pasta, some defects were apparent, as observed by the big inhomogeneity in the matrix (see arrow, (c)). These defects were probably introduced during the mixing and/or forming steps and can be ascribed to not completely hydrated and mixed dough and/or to the extrusion process. The relevance of structuring of pasta components at each processing step has been widely reported in the literature.[26] Release of starch degradation products was found to be slower in pasta than in other cereal products mainly due to pasta compact structure resulting from the extrusion process.[27] The relationship between mixing time and structural homogeneity, in relation to fine gluten structure formation was investigated as well.[28] In the present study in-homogeneities partially disappeared with overcooking, giving rise to holes endowed with a regular roundish shape of lower dimension (not shown). Moreover, at 11 min the compact structure of the kneading matrix displayed a cluster-like structure of durum wheat as well as swollen but not disrupted starch granules embedded on a protein matrix. These features show up in the cross section ESEM image displayed in e). In contrast, several cracks were easily detectable on the external surface of the M92 pasta sample (d) as well as in the cross section image (f) most likely due to the lower technological gluten properties. At 15 min, integral starch granules were localized in the internal matrix and were clearly observable in S (g). Zones of gelatinized starch filaments and fibrils close to the cracks were detectable in M (h), suggesting microstructural changes of the inner layer.

Table 1. Chemical and Nutritional Compositions of Monlis (M) and Saragolla (S) Pasta Types, Dried at 40 and 92 °C, at Cooking Times of 11 and 15 min[a]

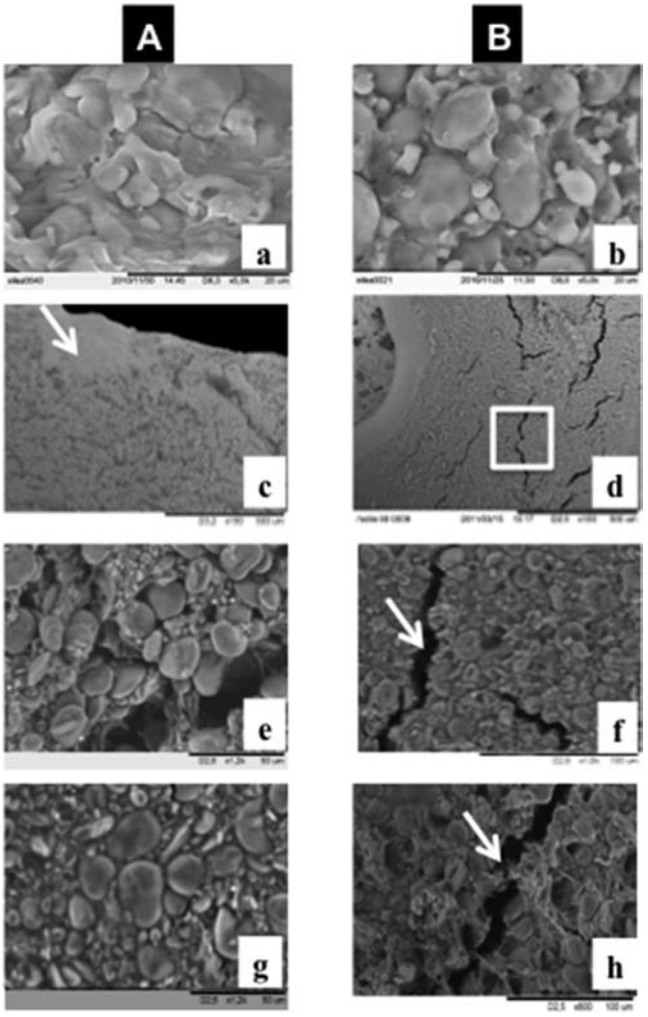

Figure 1. Coupled ESEM images of (A) S92 and (B) M92 pasta samples. S92 (a) and M92 (b) dried pasta sections, scale bar 20 μm. For 11 min cooking: surface sections of S92 (c) and M92 (d), scale bar 500 μm. A big inhomogeneity is shown in (c) (see arrow); gelatinized cracks are visible in (d) (see square). Cross sections of S92 (e), scale bar 50 μm, and M92 (f), scale bar 100 μm. For 15 min cooking: cross sections of S92 (g), scale bar 50 μm, and M92 (h), scale bar 100 μm. Internal cracks are shown (see arrows).

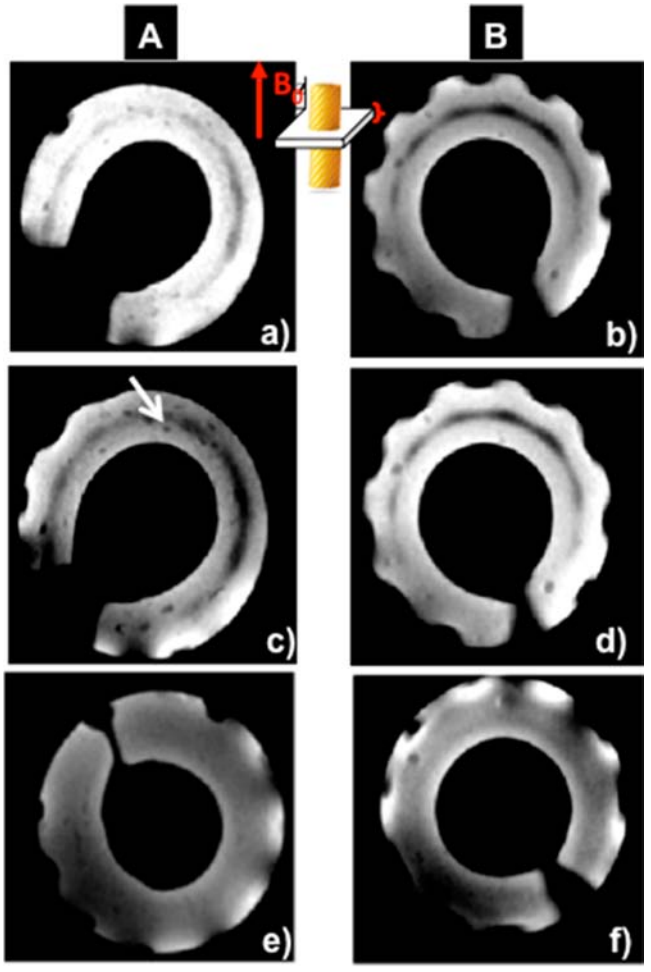

Figure 2. Coupled MRI transversal *xy* spin echo images of (A) S92 and (B) M92 pasta samples. The sketch shows the *xy* imaging plane cutting the pasta sample that is orthogonally placed in the NMR tube. All images were recorded with 128 × 128 matrix, FOV = 11 mm × 11 mm, voxel resolution = 86 × 86 × 1000 μm^3, NE = 4, RG = 4, and are displayed at the same gray levels for comparison. For 11 min cooking: S92 (a) and M92 (b) T_1 (TR = 1s) weighed images. A central dark region, ascribable to the "al dente" texture, is visible in both the images. S92 (c) and M92 (d) T_2 (TR = 10 ms) weighed images. A magnification of the defects attributed to the processing phases is shown (indicated by the arrow in (c)). For 15 min cooking: S92 (e) and M92 (f) T_1 weighed image (TR = 1s). The central dark region due to the pasta matrix not being uniformly cooked disappeared with overcooking.

MRI Analysis. Figure 2 shows T_1- and T_2-weighted *xy* transversal spin−echo MRI images collected from S92 (A) and M92 (B) pasta samples after 11 and 15 min of cooking. At 11 min, a central dark region throughout the whole sample was observable in the T_1-weighted images of both S92 (a) and M92 (b) pasta samples, ascribable to the so-called "al dente" pasta texture, namely to regions that were not completely cooked. In addition, in-homogeneities were present in the T_2-weighted image displayed in (c) (see arrow) and (d) and were ascribed to processing dough defects that were also observed by ESEM (Figure 1). A dimension of about 400 μm was estimated from Figure 1c, which should also be detectable by the MRI technique. A more homogeneous pasta reticulate, with an increased signal-to-noise ratio (SNR) could be observed by lengthening the cooking time to 15 min in S92 (e) and M92 (f). It is clear from both the images that there was disappearance of the central dark region observed at 11 min. As observed in ESEM images, inhomogeneities changed their shape and reduced with overcooking at dimensions below MRI resolution.

T_1 MRI Relaxation. The T_1 mean data values (±SD) and signal percentages for the different pasta types (11, 15, and 20 min) are reported in Table 2. T_1 magnetization decay resulted in a single exponential for all pasta types at 11 min, with significantly shorter values for S pasta compared to M pasta ($P < 0.05$), suggesting, even after short cooking time, S pasta network endowed with a greater rigidity than M. All pasta types resulted in significantly different T_1 values ($P < 0.05$) on the basis of Tukey's multiple comparison test. In particular, M92 exhibited the longest T_1 value and the greatest variability (SD). This latter could be ascribed to the presence of not uniformly cooked pasta regions as highlighted also by the T_1- and T_2-weighted images (see Figure 2). At 15 min, two relaxation

[a]Standard deviations are given in parentheses. Different lowercase letters (a, b, c, d) indicate significant differences of the types of pasta within each boiling time. Different capital letters (A, B, C, D) indicate significant differences of the same type of pasta at the different boiling times. Symbols: $^{*}P < 0.05$, $^{\#}P < 0.001$.

components could be identified for all pasta types: a short component (significantly shorter than at 11 min, $p < 0.001$) and a long component with different signal percentages (approximately 70−80% in M and 15% in S92). Both short and long components of T_1 values lengthened after 20 min of cooking, with the short component of S92 being significantly shorter ($P < 0.05$) than M92. Upon lengthening the cooking time, the S92 pasta type maintained its compact network.

In heterogeneous systems, relaxation is affected by the interior structure as a result of water-macromolecules interaction. Therefore, not only translation and rotation of water molecules affect relaxation, but also a diffusive and chemical exchange process between water molecules and biopolymers strongly contributes to relaxation values. Starch, the most abundant biopolymer in pasta systems, together with proteins, plays an important role in these processes.[29] As a consequence relative populations of the components cannot necessarily be taken as accurately reflecting the number of spin in a particular environment.[30] Only under the slow diffusion limit ($a^2\Delta R_2/D \ll 1$, where a is the size of the environment and $R_2 = 1/T_2$) NMR signals will be characterized by several components signature of different local environments, each with its own relaxation time.[31] Multiexponential relaxation behavior for water has been consistently reported in starch−water systems because of slow diffusive exchange and this regimen is also suggested by combining ESEM (30 μm for granule size) and diffusion (in the order of 10^{-10}) results in the current study. The distribution and dynamic state of water, following swelling and gelatinization, was previously studied in rice starch granules.[32] By the analysis of the longitudinal magnetization decay curve during the swelling process the authors identified two components, and the short T_1 value was ascribed to water−starch interaction. After gelatinization, only one T_1 value associated with water in the gel state was observed. A similar trend could be identified in the present study by the T_1 analysis (Table 2). Two components were identified even when the cooking time was extended to 20 min, with the exception of M40 whose relaxation was fitted to a single exponential. Indeed, we hypothesize that, upon lengthening the cooking time, the pasta matrix mobility can be enhanced by an increase in the gelatinization processes, thereby causing a progressive passage from a inhomogeneous network toward a more uniform carbohydrate gel phase. However, gelatinization appeared to take place to a greater extent in M pasta type, generally showing a longer T_1 relaxation value and particularly in M40 after 20 min of cooking. The different behavior of M, compared to S, might be ascribed to the different protein reticulate and, at the same time, this feature might be at the basis of a greater accessibility of starch granules to the enzymatic attack in M compared to S (see below).

MRI Diffusion. At 11 min, for all types of pasta, water diffusion resulted in a single exponential. A significantly higher ($p < 0.05$) diffusion value for M40 with respect to S pasta type was calculated (Table 3). In contrast, two components could be identified at 15 min, with the short component of M92 reaching a D value close to free water (2.22×10^{-9} m·s^{-2}, $r^2 = 0.98$). Both M92 short and long components attained significantly higher values with respect to S92 ($P < 0.05$), suggesting greater translational mobility. The diffusion data at 20 min resulted in a single exponential with D values far from those found for pure water and significantly lower ($P < 0.05$) than the short components calculated at 15 min.

T_1 relaxation and diffusion parameters indicated that the S pasta endowed a more compact structure than M pasta at all cooking times. The different components identified might be related to the starch gelatinization process occurring during cooking.

As pointed out, gelatinization, by far the most common and impactful transformation in starch (pasting, baking), results from the input of heat in the presence of water. Water enters the granule and plasticizes the amorphous component of the starch. The lengthening of the cooking time is known to cause an increase in the degree of gelatinization through swelling of starch granules and rupture and ultimately produces the gel

state. To observe the starch through the complete process of gelatinization, the cooking time for the pasta was extended up to 20 min, well beyond the usually adopted cooking time. Indeed, the gelatinization process is strongly affected by many parameters, including botanical species, source, presence and amount of solutes (such as sugars) that lead to changes in many functional properties such as viscosity, solubility and digestibility. At the same time, functional changes are expected to be determined by structural modifications of the pasta network that can be monitored by MRI, throughout an estimation of rotational (T_1) and translational (D) mobility, mainly of water. The enhanced rotational and translational mobility of water, probed by T_1 relaxation and diffusion data, indicated a greater network mobility of M compared to S, taking into account exchange effects. In other words, the constituents of M (protein bodies, filaments, and fibrils) are less effective at restricting water movement. Water mobility significantly increased at 15 min, while further differences were not observed at 20 min. This result suggests similar interactions between water and macromolecules at 15 and 20 min but not unrestricted diffusion, which would be observed if there was complete disruption of the starch granule. In fact, self-diffusion constants (D) were in the order of 10^{-10} $m^2 \cdot s^{-1}$, significantly slower than that of free water. At the same time, the root-mean-square distance in one-dimensional diffusion, $(2D\Delta)^{1/2}$ was approximately 6−7 μm. This distance is considerably below the mean granule size of approximately 30 μm calculated by ESEM analysis (Figure 1e,g), thus confining diffusion pathway within the granule. On the other hand, if the internal granule structure was ruptured by gelatinization, water would display diffusion parameters similar to those in a normal three-dimensional pathway. We can therefore conclude that hindered diffusion within the starch gels takes place as a consequence of incomplete gelatinization.

T_2 Relaxation Analysis. Different from longitudinal relaxation, transverse relaxation is sensitive to dipole−dipole interactions. Thus, T_2-weighted images are effective at highlighting sample inhomogeneities (Figure 2c,d). However, even if image contrast clearly pointed to the presence of regions endowed with different mobility, all T_2 decays calculated from MRI data were fitted to a single exponential. The calculated T_2 values (13−20 ms range, data not shown) lengthened when the cooking time increased but were shorter than bulk water, therefore reflecting the interactions between water and macromolecules. It is well known that water molecules with a near isotropic motion are characterized by a T_1/T_2 ratio value near unity and T_2 values that are low compared to those of bulk

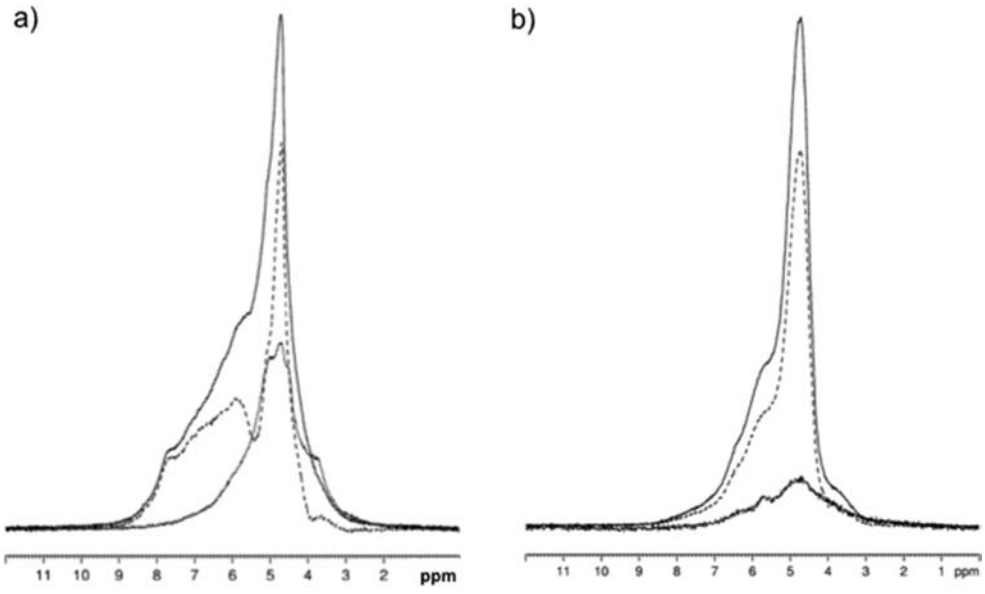

Figure 3. 200 MHz ^{1}H NMR 1D spectra recorded from identically weighing S92 (a) and M92 (b) pasta samples cooked for 15 min in H_2O (continuous line) and D_2O (dotted line). The calculated difference spectra are also displayed (dashed line).

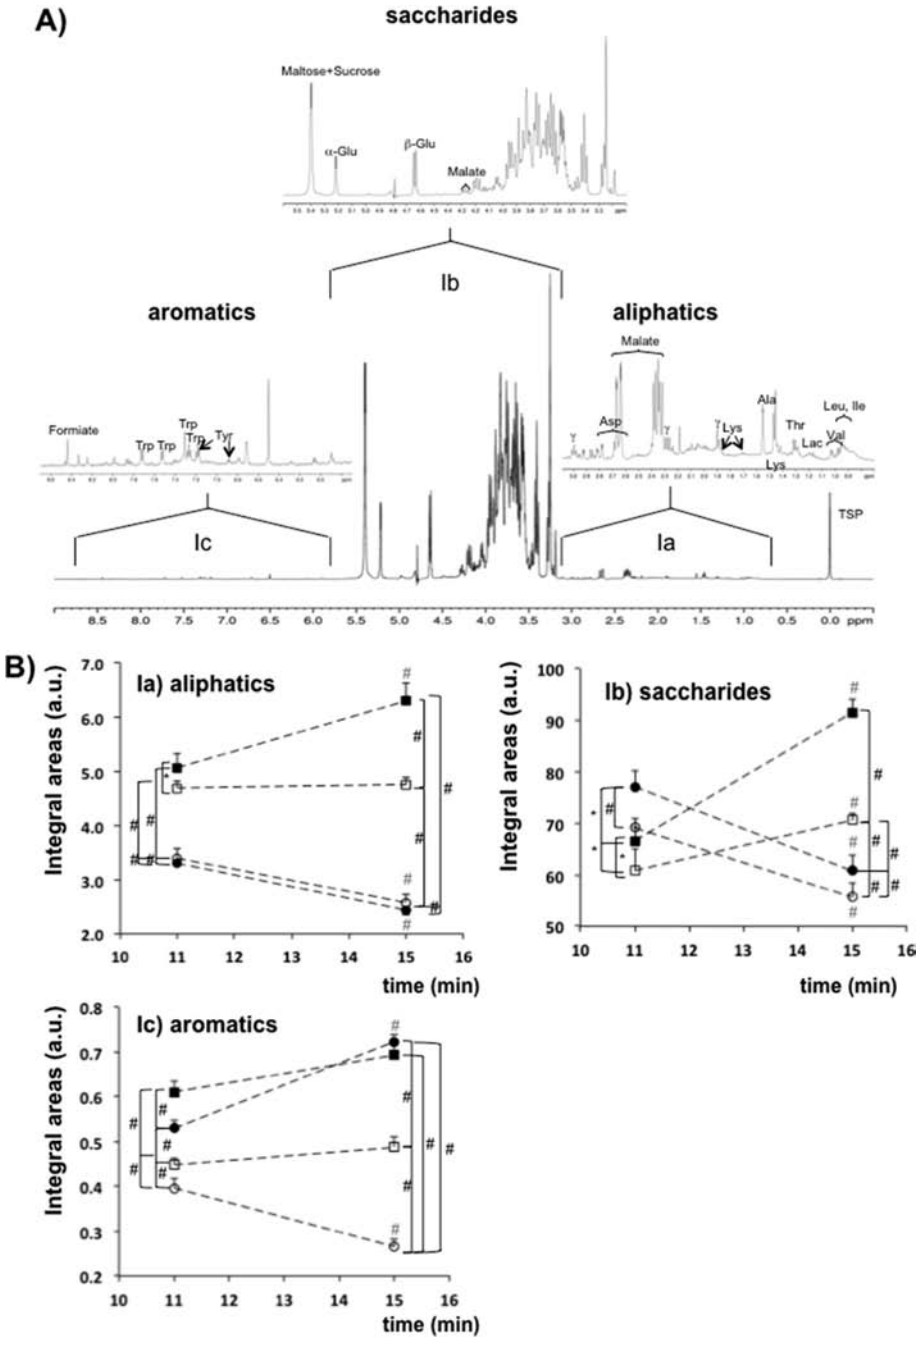

Figure 4. (A) 500 MHz 1D ^{1}H NMR spectrum recorded from the cooking water of a S92 sample at 15 min of cooking time. The integrated spectral regions are shown into brackets: Ia, aliphatics (1−3 ppm); Ib, saccharides (3−5.6 ppm); and Ic, aromatics (5.8−8 ppm). The regions are zoomed-in in the insets with labeling of the main assigned compounds. (B) Plots of the integral areas (arbitrary units) versus the cooking time (11−15 min) of the three integrated spectral regions (Ia−Ic): M92 (■), M40 (□), S92 (●), and S40 (○). Results are expressed as mean ± SD. Significant differences of types of pasta at the same cooking time are indicated by brackets; significant differences at different cooking times are displayed in gray. Symbols: $^*P < 0.05$, $^\#P < 0.001$. Dotted straight lines are drawn to guide the eye.

water were ascribed to an interaction of water molecules with starch.[32] In the present study, the T_2 values calculated from T_2-weighted images reflected the presence of a water-biopolymer interactions, mainly by starch. Unfortunately, the echo time adopted by the spin−echo MRI method (TE = 6.07 ms) prevented the determination of fast T_2 relaxation mechanisms. Therefore, the relaxation mechanism was further investigated by spectroscopic analysis. The dynamics were monitored on a short time scale (10−1000 μs) using the spin−echo sequence and on a longer time scale (2−80 ms) using the CPMG pulse sequence. The study focused on S92 and M92 samples at 15 min of cooking time. Two main relaxation time components resulted from the spin−echo analysis; the long component (M92, 26.35 ± 6.15 ms; S92, 20.19 ± 3.95 ms) with a greater percentage signal (approximately 80%) in both pasta types. By contrast, the short component (M92, 6.00 ± 0.7 ms; S92, 1.99 ± 0.99 ms) was significantly shorter for S92 ($P < 0.01$), thereby suggesting a more rigid structure for this latter. Intriguingly, although one might expect the solid part of the FID of the spin−echo decay to have a significant Gaussian component, all

data were well represented as a biexponential decay with no evidence of a solid-like dipolar component, independently of the cooking time, in agreement with the results obtained by Tang et al. on fully swollen native potato starch granules at 295 K.[33]

Pasta is an extremely complex matrix. It includes carbohydrates, proteins and fiber elements that cannot be analyzed individually. Therefore, the structural network as a whole was further investigated by the comparison of the FIDs recorded from M92 and S92 pasta samples of identical weight cooked for 15 min in either H_2O or D_2O (100%). After D_2O exchange, the NMR signal of pasta samples mainly originates from the nonexchanging protons, i.e., those of CH groups involved in the H-bonded network that will contribute to the rigid component of the decay.

Figure 3 shows the 1D ^{1}H NMR spectra from S92 (a) and M92 (b) samples in H_2O (continuous line) and D_2O (dotted line) and the difference spectra (dashed line) The spectral signals of these latter originate from water and exchangeable protons mainly starch, and in a lower amount from proteins (see Table 1), while a contribution of fats could be almost excluded, due to the absence of the wheat germ in both pasta types. A dry matter percentage of 92.33 ± 0.001 and 93.25 ± 0.001% was calculated for raw M92 and S92, respectively, while measuring the sample weight at both the end of cooking and raw a ratio of 2.69 ± 0.08 and 2.28 ± 0.09 on dry basis for S92 and M92 was calculated. Based on these data, from the normalized spectral areas, the amount of water and mobile protons was calculated as 58 ± 0.5 and 41 ± 0.7% of the cooked weight on dry basis for M92 and S92 respectively. The results enabled us to conclude that, during the cooking process, water is absorbed by starch of both pasta types in the same way. However, this water is then distributed in the pasta matrix differently, essentially owing to the lower ability of M92 matrix in binding water and this was ascribed to the lower technological gluten properties of M92 pasta, with respect to S92 type.

^{1}H NMR Spectroscopy of Cooking Water. The pasta–water interaction was also elucidated by high-resolution ^{1}H NMR spectroscopy. Data were acquired from samples of the water in which the pasta was boiled (11 and 15 min) to identify and quantify the chemical compounds released by the different types of pasta that were calculated from the spectra via integral areas.

Figure 4A shows the ^{1}H NMR spectrum recorded from a S92 cooked water sample at 15 min. The resonance assignments of the main signals were made with an internal database of standard compounds and by the aid of two-dimensional experiments (TOCSY and HSQC). All samples were found to contain the same chemical compounds: amino and organic acids (malate and formate) and saccharides (α- and β-glucose, sucrose, and maltose). However, these components were in different amounts depending on the duration of the cooking time. The plots of the calculated integrals are displayed in Figure 4B. A clear separation of M with respect to S species could be observed in both aliphatic (organic and amino acids)

region (a): M showed a greater amount of released compounds than S, independent of the drying temperature and cooking time. An opposite trend was observed for M and S pasta as concerns saccharides, whose release, between 11 and 15 min, was found to significantly ($P < 0.001$) increase and decrease, respectively. The behavior of the compounds investigated by NMR spectroscopy (i.e., amino acids, saccharides, and low-molecular-weight molecules released in water during the cooking process) can be viewed as complementary to that involved in the digestibility analysis, where the chemical components retained in the pasta matrix (i.e., those not released into the water during the cooking process) contribute to the measurement. Demonstrating this phenomenon, when increasing the duration of the cooking time, M92 was found to release the most compounds into the cooking water, in agreement with the more mobile matrix that was suggested with relaxation and diffusion data (Tables 2 and 3).

In conclusion, our results enabled us to establish a correlation between matrix structures and low-molecular-weight compounds released into water while boiling (i.e., water-soluble compounds). Our data suggest a greater release of compounds from matrices with higher mobility, as observed for M. Accordingly, a lower tendency to release compounds with a longer cooking time was found for S, which is inherently poorer in proteins and exhibited significantly shorter values for T_1 (Tables 1 and 2).

Starch Digestibility Analysis. The effect of cooking time on S and M pasta both low and high temperature dried on starch digestibility was assessed. Starch digestibility was measured by detecting saccharides released during *in vitro* starch digestion. Figure 5a shows the kinetics of starch hydrolysis (digestion curves) for the four pasta types cooked for 11 min. The trend of starch hydrolysis appeared to be similar for each sample. However, M92 pasta seemed to be less digested than the analogous durum (S92), as shown by the lower hydrolyzed starch value at each time point (Figure 5c). Specifically, a significant difference between the two curves was observed at 20 min of starch digestion ($P < 0.05$), corresponding to the rapidly digestible starch (RDS) fraction. This fraction is nutritionally important because it correlates with high postprandial blood glucose levels. The presence of higher amounts of readily digestible sugars and starches contributes to a high glycemic index.[7]

The degree of starch hydrolysis of pasta cooked for 15 min (Figure 5b) increased for M92, M40, and S40 compared to pasta cooked for 11 min. However, no significant differences ($P > 0.05$) were detected during the first 20 min of digestion, suggesting that RDS did not increase as a consequence of increasing the duration of the cooking time. Nevertheless, a significant difference between M92 and S92 pasta (Figure 5d) at 120 and 150 min was detected. In particular, the digestibility did not change for S92 between 120 and 150 min of digestion, as shown by the hydrolyzed starch values at these time points. These results suggest that starch hydrolysis was likely not enhanced from overcooking, but more likely that there was a synergic effect of the high temperature drying process and the presence of the strong protein network.[9] As a result, there was a delay in the accessibility of amylolitic enzymes to the starch. On the other hand, the starch hydrolysis drastically increased between 120 and 150 min of digestion in M92 pasta. NMR data in general suggested a less compact structure of M with respect to S. In particular, as already pointed out, M and S saccharide release showed an opposite trend at 11 versus 15 min.

These results are in agreement with the NMR, MRI and ESEM analyses where an increase in the cooking time corresponded to a rise in starch gelatinization of the inner part of M pasta (Figure 1h). By contrast, ESEM analysis did not show relevant differences of the internal microstructure in S pasta (Figure 1e), suggesting that starch gelatinization was limited. Additionally, NMR data suggested a reduced water mobility of S92 with respect to M92 pasta, mainly ascribable to the different ability of the gluten proteins to bind water (see Figure 3). At the same time, diffusion data suggested that water movement was restricted to the inner part of the starch granule.

Currently, durum wheat semolina is the preferred ingredient for the production of high quality pasta due to its color, flavor and cooking quality. Its structure is complex, with starch granules incorporated in a protein matrix. In particular, it is believed that gluten protein aids in the formation of network surrounding the starch granules, thereby acting as a barrier to starch digestion.[34] This can explain why S92 pasta was not more susceptible to amylolitic digestion at a prolonged cooking time. ESEM analysis also confirmed this result, showing that at 15 min of cooking, starch granules were partially gelatinized and entrapped in the protein network (Figure 1g). MRI analysis also indicated that S pasta is endowed with a more packed structure ascribable to the protein reticulate; M pasta was characterized by water with greater rotational and translational mobility. In addition, this is the reason that for M92, starch hydrolysis increased with increasing incubation time with digestive enzymes, while this was not observed for S92. Water availability in the food matrix is important for amylase activity: the more the water diffuses into the system, the higher is the catalytic efficiency.[13]

Analysis of the cooking water by NMR spectroscopy showed that a higher release of compounds into the water was found from the network with higher mobility. With respect to S, at 11 min, M pasta demonstrated a high leakage of aliphatic compounds from the pasta matrix, while the leakage of polysaccharides required at least 15 min, in agreement with the starch digestibility data. The present study highlighted significant differences in starch digestion of pasta made with *T. monococcum* (cv. Monlis), compared to the commonly used durum wheat (cv. Saragolla) dried at 92 °C cooked to "al dente" texture. These results suggest a synergic effect between wheat genotype and processing. As reported in the literature, drying is essential for maintaining the pasta structure, especially during overcooking. The protein network of LT (55 °C) dried and then cooked pasta was found partially disrupted. On the contrary, the protein network was found preserved after VHT (100 °C) together with a lower extent of starch swelling.[35] High drying levels could play an effect on microstructure by enhancing protein cross-link thereby highlighting the protective role played by proteins, limiting water absorption by granules.[36] In agreement with literature data, in this study, NMR relaxation and diffusion results suggested a considerable effect of drying temperature mainly with overcooking as well. Moreover the release of compounds in the aliphatic region (Figure 4B) differed significantly ($p < 0.001$) for M and S pasta species at both 11 and 15 min cooking times.

NMR analysis suggested that S pasta has a more compact structure, ascribable to different network properties. More generally, this study demonstrates that investigating the food structure aids to understand its behavior during gastro-intestinal digestion. For this purpose, we propose NMR, in conjunction with enzymatic digestibility methods as valid methodologies for

estimating how starch may behave during cooking and subsequently during its degradation in the human body.

Supporting Information

ABSTRACT: Azaspiracids (AZAs) are marine biotoxins produced by dinoflagellates that can accumulate in shellfish, which if consumed can lead to poisoning events. AZA7−10, **7**−**10**, were isolated from shellfish and their structures, previously proposed on the basis of only LC−MS/MS data, were confirmed by NMR spectroscopy. Purified AZA4−6, **4**−**6**, and **7**−**10** were accurately quantitated by qNMR and used to assay cytotoxicity with Jurkat T lymphocyte cells for the first time. LC−MS(MS) molar response studies performed using isocratic and gradient elution in both selected ion monitoring and selected reaction monitoring modes showed that responses for the analogues ranged from 0.3 to 1.2 relative to AZA1, **1**. All AZA analogues tested were cytotoxic to Jurkat T lymphocyte cells in a time- and concentration-dependent manner; however, there were distinct differences in their EC_{50} values, with the potencies for each analogue being: AZA6 > AZA8 > AZA1 > AZA4 ≈ AZA9 > AZA5 ≈ AZA10. This data contributes to the understanding of the structure−activity relationships of AZAs.

KEYWORDS: *azaspiracid, structure confirmation, LC−MS molar response, NMR, mass spectrometry, purification, Jurkat T, toxicity*

INTRODUCTION

The consumption of shellfish contaminated with azaspiracids (AZAs) leads to the syndrome azaspiracid poisoning (AZP).[1] Poisoning incidents associated with this toxin group have been reported in Europe and in the United States.[2,3] In these cases, the source of the implicated shellfish was Ireland, where the levels and number of AZA occurrences have been most problematic.[4] AZAs have been reported to produce "neurotoxin-like" symptoms via intraperitoneal injection in mice, with death in 20−90 min.[5] Oral administration was found to produce clinical disease that was dose- and time-dependent, in addition to damaging the intestinal organs.[6−9] AZA1, **1**, (Figure 1) is a K^+ channel blocker[10] and is highly cytotoxic to multiple cell types, which undergo atypical apoptosis after exposure.[11]

AZAs were first identified in the late 1990s, and since then, more than 30 analogues have been observed in shellfish,[12] phytoplankton,[13−15] crabs,[16] and a marine sponge.[17] Only **1**; AZA2, **2**; and AZA3, **3** (Figure 1), are currently regulated in raw shellfish.[18] Compounds **1** and **2** are produced by the dinoflagellate *Azadinium spinosum*,[13] whereas many of the other analogues are shellfish metabolites.[19,20] Compounds **1**;[21] **2**; **3**;[22] AZA4, **4**; AZA5, **5**;[23] and AZA6, **6**,[24] have been isolated and their structures elucidated through a combination of NMR spectroscopy and chemical reactions. More recently, 37-*epi*-**1** was isolated from shellfish extracts and found to differ structurally from **1** with respect to the orientation of the methyl group at C-37 and to be 5-fold more toxic than **1** using the Jurkat T lymphocyte cell assay.[25]

LC−MS analysis revealed the presence of hitherto unknown AZAs in the dinoflagellates *Amphidoma languida*,[13] *Azadinium poporum*[14] and *Azadinium spinosum*.[15] The AZAs identified in *A. spinosum*, subsequently named AZA33 and -34, were found to be the same structurally at the amine end of the molecule (C-21−40) compared with **1**, producing the characteristic *m*/*z* 362 fragment during LC−MS/MS analysis.[15] AZAs from *A. poporum* (AZA36 and −37), on the other hand, differ by the lack of a methyl or methylene group in the I-ring, resulting in an equivalent fragment with *m*/*z* 348.[9] The AZAs (with molecular masses of 815 and 829 Da) detected in the *A. languida* also displayed fragment ions with *m*/*z* 348, suggesting that these compounds also may lack a methyl or methylene group in the I-ring.[14]

To protect shellfish consumers while at the same time avoiding unnecessary closures of shellfish farms, more information is required about the type and toxity of AZAs found in shellfish and how to quantitate them. Here, we describe the isolation of **4**, **5** and for the first time AZA7, **7**; AZA8, **8**; AZA9, **9**; and AZA10, **10** (Figure 1), from shellfish, with confirmation by NMR of the structures previously postulated on the basis of LC−MS/MS. Relative molar response studies using mass spectrometry were performed following the preparation of reference standards, which had concentrations assigned using quantitative NMR (qNMR). The toxicity of **4**−**10** was assessed using the Jurkat T lymphocyte cell assay and the results used to discern structure−activity relationships (SARs).

MATERIALS AND METHODS

Chemicals. All solvents (pesticide analysis grade) were from Labscan (Dublin, Ireland) and Caledon (Georgetown, Ontario, Canada). Distilled H_2O was further purified using a Barnstead nanopure diamond UV purification system (Thermo Scientific, Waltham, MA). Sodium chloride (99+%), triethylamine (99%), ammonium acetate (97+%), ammonium formate (reagent grade), formic acid (>98%), silica gel (10−40 μm, type H), sodium chloride (99+%), sodium periodate, Trace CERT caffeine, and CD_3OD (100.0 atom % D) were from Sigma−Aldrich (Steinheim, Germany). Sephadex LH-20 was from GE Healthcare (Uppsala, Sweden), LiChroprep RP C8 (25−40 μm) was from Merck (Darmstadt, Germany), Luna Phenyl-Hexyl (15 μm) was from Phenomenex (Cheshire, UK), CD_3OH (99.5 atom % D) for qNMR was from Cambridge Isotope Laboratories (Tewksbury, MA). AZA certified reference materials (CRMs) were obtained from the National Research Council (Halifax, NS, Canada).

Isolation and Purification of 4−10. The isolation procedure was described previously.[24] Final purification of AZAs was achieved by semi-preparative chromatography on a model 1200 instrument (Agilent Technologies, Santa Clara, CA) with photodiode array detection (210 nm) using a 250 mm × 4.6 mm i.d., 5 μm, Cosmosil C18 column (Nacalai tesque, Kyoto, Japan) eluted with CH_3CN/H_2O (1:1, plus 2 mM ammonium acetate) at 1 mL/min. The column temperature was 30 °C. Because of the presence of co-eluting compounds, two additional semipreparative steps using CH_3CN/H_2O (0.8:1, plus 2 mM ammonium acetate) were required to attain sufficient purity for NMR. Purified AZAs were recovered by diluting the fractions with H_2O (to 20% CH_3CN), loading onto solid-phase extraction cartridges (Oasis HLB, 200 mg), washing with $MeOH/H_2O$ (1:9, 10 mL) to remove the buffer, and eluting with $MeOH/H_2O$ (9:1, 20 mL). Removal of solvent by evaporation in vacuo afforded purified AZAs as white solids.

Accurate reference standards of the purified AZAs were prepared by diluting the qNMR stock solutions in high-purity degassed MeOH. The concentrations of the working solutions were ∼1 μM for all analogues.

Periodate Cleavage. Dilutions (∼100 ng/mL) of purified **1**−**10** in MeOH were used. To 100 μL of each sample was added 50 μL of 0.2 M sodium periodate solution, and the reactions were analyzed immediately by LC−MS (method B), including traces at *m*/*z* 448.4 (for the **7** oxidation product), *m*/*z* 464.4 (for the **8** oxidation product), *m*/*z* 434.4 (for the **9** oxidation product), and at *m*/*z* 450.4 (for the **10** oxidation product).

Mass Spectrometry. *Method A.* Recoveries were determined by quantitative analysis of fractions on a model 2695 LC instrument (Waters, Manchester, UK) coupled to a triple-stage quadrupole (TSQ) Ultima instrument (Micromass, Manchester, UK) operated in selected reaction monitoring (SRM) mode for the following transitions: *m*/*z* 842.5 → 824.5/362.3 (**1** and **6**); *m*/*z* 856.5 → 838.5/362.3 (**2**); *m*/*z* 828.5 → 810.5/362.3 (**3**); *m*/*z* 844.5 → 826.5/362.3 (**4** and **5**), and *m*/*z* 858.5→ 840.5/362.3 (**7**−**10**). The cone voltage was 60 V; collision energy was 50 V; the cone and desolvation gas flows were set at 100 and 800 L/h, respectively; and the source temperature was 150 °C.

Binary gradient elution was used, with phase A consisting of H_2O and phase B of CH_3CN (95%) in H_2O (both containing 2 mM ammonium formate and 50 mM formic acid). The column used was a 50 mm × 2.1 mm i.d., 3 μm, Hypersil BDS C8 column with a 10 mm × 2.1 mm i.d. guard column of the same stationary phase (Thermo Scientific, Waltham, MA). The gradient was from 30% to 90% B over 8 min at 0.25 mL/min, held for 5 min, then held at 100% B at 0.4 mL/min for 5 min, before returning to the initial for equilibration. The

[a]Not detected because of limited signal-to-noise.

injection volume was 5 μL, and the column and sample temperatures were 25 and 6 °C, respectively.

Method B. Structures and purities were assessed on a model 2795 LC instrument (Waters, Manchester, UK) coupled to a quadrapole time-of-flight (QToF) Ultima instrument (Micromass, Manchester, UK) by running MS scans (m/z 100−1000) using the same chromatographic conditions as method A. The possible presence of other AZA contaminants was determined by performing product ion scans, in which the precursor ions were selected and then fragmented, for all the known AZA analogues.

Method C. For a relative molar response study, analysis was performed on a model 1200 LC instrument (Agilent Technologies, Santa Clara, CA) connected to a model API4000 QTRAP mass spectrometer (AB Sciex, Framingham, MA) equipped with a Turbospray ionization source. The MS was operated in positive ion mode, and SRM transitions were as follows: m/z 842.5 → 824.5/672.5/462.3/362.3 (**1**); m/z 844.5 → 826.5/658.5/362.3 (**4**); m/z 844.5 → 826.5/674.5/362.3 (**5**); m/z 842.5 → 824.5/658.5/362.3 (**6**); m/z 858.5 → 840.5/672.5/362.3 (**7**); m/z 858.5 → 840.5/688.5/362.3 (**8**); m/z 858.5 → 840.5/658.5/362.3 (**9**), and m/z 858.5 →

J. Agric. Food Chem. 2015, 63, 5083−5091

840.5/674.5/362.3 (**10**). For selected ion monitoring (SIM) experiments, *m/z* 842.5 (**1** and **6**), 844.5 (**4** and **5**), and 858.5 (**7**−**10**) were analyzed. Typical parameters were 5500 V electrospray voltage, 400 °C source temperature, 70 V declustering potential, and collision energies of 45−70 V (where applicable). Method C (i) used gradient elution with the same acidic mobile phase as method A. The column used was a 2.1 mm × 50 mm i.d., 2.5 μm Luna C18(2) HST column (Phenomenex, Cheshire, UK). The gradient was from 25 to 100% B over 5 min at 300 μL/min and held at 100% B for 2 min, before re-equilibration for the next run. The injection volume was 1−5 μL, and the column and sample temperatures were 25 and 6 °C, respectively. Method C (ii) used isocratic elution with the acidic mobile phase on the same Luna column, with 60% B at 300 μL/min.

Method D. For separation of the 37-epimers,[25] a neutral gradient elution was used.[27] The column used was a 2.1 mm × 50 mm i.d., 2.5 μm, Luna C18(2) HST column (Phenomenx, Cheshire, UK), operated at 15 °C, injecting 1−5 μL samples. A binary mobile phase of H_2O (A) and CH_3CN (95%) in H_2O (B), each containing 5 mM ammonium acetate (pH 6.8), was used with a linear gradient from 25 to 100% B over 5 min at 350 μL/min and held at 100% B for 2 min before re-equilibration for the next run.

Method E. Accurate mass measurements were performed on an Acquity UPLC instrument coupled to a Xevo G2-S QToF (Waters, Manchester, UK) operated in MS^e mode, scanning from *m/z* 100−1200 and using leucine enkephalin as the reference compound. The cone voltage was 40 V; collision energy was 50 V; the cone and desolvation gas flows were set at 100 and 1000 L/h, respectively; and the source temperature was 120 °C.

The column used was a 50 mm × 2.1 mm i.d., 1.7 μm, Acquity UPLC BEH C18 (Waters, Wexford, Ireland), using the same mobile phase as that described in method A. The gradient was from 30 to 90% B over 5 min at 0.3 mL/min, held for 0.5 min, and returned to the initial conditions and held for 1 min to equilibrate the system. The injection volume was 2 μL and the column and sample temperatures were 25 and 6 °C, respectively.

NMR Spectroscopy. NMR experiments for structure elucidation were run using Avance I and Avance II 600 MHz spectrometers (Bruker, Fällanden, Switzerland) equipped with TCI cryoprobes and Z-gradient coils, at 30 °C, and a Bruker DRX-500 spectrometer (Milton, Ontario, Canada) with a TXI probe and Z-gradient coils at 20 °C was used for qNMR. Structures were determined by analysis of ^1H, COSY, TOCSY, NOESY, ROESY, HSQC, HMBC, ^{13}C, and DEPT135 NMR spectra. Samples of **4**−**10** (∼0.1 mg) were dissolved in ∼0.5 mL CD_3OD at 30 °C, and chemical shifts were referenced to internal CHD_2OD (3.31 ppm) or CD_3OD (49.0 ppm). Single- or double-frequency pre-saturation of solvent resonances was performed using continuous wave or excitation sculpting, as required.

Quantitation of **1** and **4**−**10** was performed on aliquots of the purified compounds by dissolving in CD_3OH. The samples were run against external standards of caffeine dissolved in H_2O (4.1 mM) as described previously for AZA CRMs.[28]

Toxicology. *Cell Culturing.* Human Jurkat E6−1 T lymphocyte cells (American Type Culture Collection TIB-152, Manassas, VA) were grown as described by Twiner et al.[29] Briefly, cells were grown in RPMI medium (Invitrogen, Carlsbad, CA) supplemented with 10% (v/v) fetal bovine serum (Invitrogen, Carlsbad, CA) and maintained in a humidified incubator with 5% CO_2 in air at 37 °C. Cells were subcultured with fresh medium at an inoculum ratio of 1:4 every 3−4 days by transferring 2.5 mL of the cells to 7.5 mL of fresh supplemented medium in 75 cm^2 screw-cap culture flasks.

Cytotoxicity Assay. To determine the effect of **1**, **4**−**6**, and **8**−**10** on cellular toxicity, Jurkat T lymphocyte cells were continuously exposed to toxins, and the viability was determined. The non-adherent human cell line Jurkat T lymphocyte was grown in RPMI medium supplemented with 10% (v/v) fetal bovine serum. Cells were maintained in humidified 5% CO_2 in air at 37 °C and subcultured with fresh medium at an inoculum ratio of 1:10 every 5−7 days by transferring 1 mL of the cells to 9 mL of fresh supplemented medium in 75 cm^2 screw-cap culture flasks. Cells were seeded in a volume of 100 μL of the supplemented medium at a density of 35 000 cells per well in black, sterile, 96-well culture plates for 24 h to allow for recovery and settling. Each AZA was added at a single concentration (10 nM) for 24, 48, or 72 h of continuous exposure prior to assessment of cytotoxicity. Parallel controls of equivalent amounts of MeOH/phosphate buffered saline were used to normalize the viability data for each treatment. Cellular viability/cytotoxicity was assessed using the 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium (MTS) assay (Promega Biosciences, Sunnyvale, CA). Like other tetrazolium-based assays, MTS in the presence of an electron coupling reagent (phenazine methosulfate; PMS) measures cellular viability by determining the activity of mitochondrial dehydrogenase.[30] As a substrate for dehydrogenases, MTS becomes reduced into a soluble, purple dye that can be quantitated colorimetrically to determine the relative level of cellular viability/cytotoxicity per well. Following exposure of the cells to the AZA analogues for the specified period of time, each well received 10 μL of a PMS/MTS (1:20) solution. Cells were incubated for 4 h, after which absorbance readings at 485 nm were obtained using a FluoStar microplate reader (BMG Lab Technologies, Cary, NC). Data are presented as means ± SE (n = 3−5). In addition, each cytotoxicity experiment was performed using duplicate wells. Cytotoxicity data were blank-corrected and normalized to the control (% viability) and plotted using GraphPad Prism (version 5.0c).

RESULTS AND DISCUSSION

The isolation of **6** has previously been described.[24] Hydroxylated analogs **4**, **5**, and **7**−**10** are less lipophilic than **1**−**3** and **6**

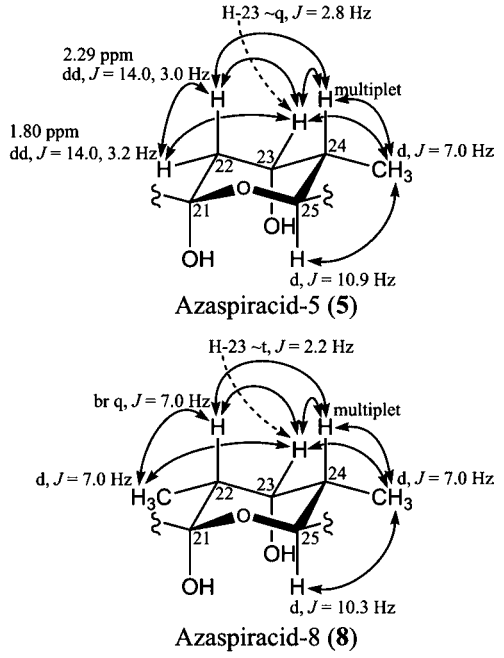

Figure 2. Structures for the E-rings of **5** and **8** showing dispositions of substituents. Observed $^1H-^1H$ coupling constants and correlations (arrows) in the ROESY NMR spectra are also shown.

and, therefore, eluted earlier[12] and were more difficult to separate from the other contaminants in the sample. In the initial semipreparative HPLC step, **4** and **5** and **7**−**10** were collected as two separate fractions. Individual analogues were separated in a second chromatographic step, and a third was required to achieve sufficient purity for NMR spectroscopy. The amounts purified ranged from ∼100 to 200 μg. Each analogue also contained its corresponding 37-epimer (∼2−15%) as recently reported.[25] Sufficient purity for the cytotoxicity assay was achieved for all AZAs except for **7**

(purity ∼63%), which was contaminated with **5** and another hitherto unreported AZA (∼20%) with a molecular mass of 825 Da, which was also detected in the initial hepatopancreas extract. Compounds **4**, **5**, **6**, **8** and **10** had purities (including the 37-epimers) of >95%; **9** had a purity of 89%.

Structure Determination. The AZAs isolated in this study showed typical AZA mass spectral fragmentation patterns, namely, a protonated molecular ion, retro Diels−Alder (RDA), and m/z 362 fragments (Figure 1), all of which appeared in clusters, indicative of several H_2O losses. NMR structure elucidation was done using 1D and 2D-homonuclear ^{1}H, ^{13}C, and heteronuclear ^{1}H{^{13}C} spectroscopy to assign the ^{1}H and ^{13}C resonances, the chemical shifts of which were then compared with the published ^{1}H (for **1**−**6**) and ^{13}C NMR (for **1**−**3** and **6**) data for **1**−**6**.[21−24] The majority of chemical shifts in Table 1 are from 1D-NMR spectra, but some chemical shifts were from 2D-spectra where necessary because of weak or overlapping signals. All samples inevitably contained low percentages of the corresponding 37-epimer,[25] but this did not interfere with NMR analyses and is not discussed further. Other minor AZAs were sometimes present as contaminants in the samples but not at levels sufficient to prevent spectrometric analysis.

*AZA4 (**4**) and AZA5 (**5**).* Structure assignments for **4** have been published on the basis of ^{1}H NMR and fast atom bombardment MS,[23] which was considered to show C-3 hydroxylation. This study confirmed those findings. In addition to the expected fragments, the MS spectra showed a molecular ion cluster (m/z 782.5), suggesting a loss of CO_2, followed by several H_2O losses, that is indicative of C-3 hydroxylation. NMR spectroscopic analysis also demonstrated that **4** is 3-hydroxylated. We also determined ^{13}C NMR assignments for **4** (Table 1). Although it is not possible to determine the configuration at C-3 from ROESY correlations or coupling constants, **4** has been shown to be 3*R*-hydroxyazaspiracid-3 by degradation reactions and synthesis of the degradation products.[21] ^{1}H NMR assignments for **4** closely paralleled those of Ofuji et al.,[23] apart from variations[25] attributable to the degree of protonation on the amino group and to the reversal of the resonances for H-7 and H-9 due to the revised position of the double bond in the A-ring.[24,31,32] The ^{13}C and ^{1}H chemical shifts for the 22-positions of **4** were markedly different from those reported recently for **6** (39.0, and 2.13 (2H) ppm).[24] However, examination of the original NMR data[24] for **6** indicates that these signals resonate at 31.5 ppm and at 1.50 and 2.10 ppm, in accord with the published NMR data for **3**,[22] as well as that presented here for **4**.

The MS/MS spectrum of **5** showed a fragment peak at m/z 408 that is indicative of C-23 hydroxylation.[33] As with **4**, the ^{1}H NMR assignments (Table 1) for **5** closely paralleled those of Ofuji et al.[23] Analyses of the ^{1}H NMR data that we recorded for **5** confirmed the presence of a hydroxyl group at C-23 and showed that H-23 (3.93 ppm, ∼q, J = 2.7 Hz) was equatorially oriented toward the upper (β) face of the C-21—C-25 ring (Figure 2) and that the 23-hydroxyl group was therefore axially inclined toward the lower (α) face of this ring.

*AZA7 (**7**) and AZA9 (**9**).* Analogously to **4**, the MS, MS/MS, periodate cleavage and NMR data showed C-3 hydroxylation (Table 1, Figure 3).

*AZA8 (**8**) and AZA10 (**10**).* Analogously to **5**, the MS, MS/MS, periodate cleavage, and NMR data showed C-23 hydroxylation (Table 1, Figures 2 and 3).

Examination of the assignments within Table 1 and comparison with NMR assignments for **1**−**3**[21,22] and **6**[24] obtained under the same conditions and calibrated identically reveals diagnostic effects on chemical shifts arising from the hydroxylations and methylations of the AZA skeleton. Hydroxylation at C-3 leads not only to marked changes in the C-3 and H-3 resonances but also to significant changes (≥∼1 ppm for ^{13}C, ≥∼0.05 ppm for ^{1}H) to the nearby C-2, C-4, H-2, H-5, and H-6 resonances. Similarly, hydroxylation at C-23 leads to consistent alterations in the chemical shifts of C-22−C-25 and H-22−H-25 as well as the appended 22- (if present) and 24-methyl groups in the E-ring. Addition of a methyl group at C-8 also results in characteristic changes to the C-7−C-9 and H-6−H-9 resonances. Similarly, the presence or absence of a 22-methyl has a pronounced effect on the chemical shifts of C-22−C-24 and H-22 and H-23.

The previously reported effect attributed to the state of ionization of the amino group[23] is evident in Table 1, leading to

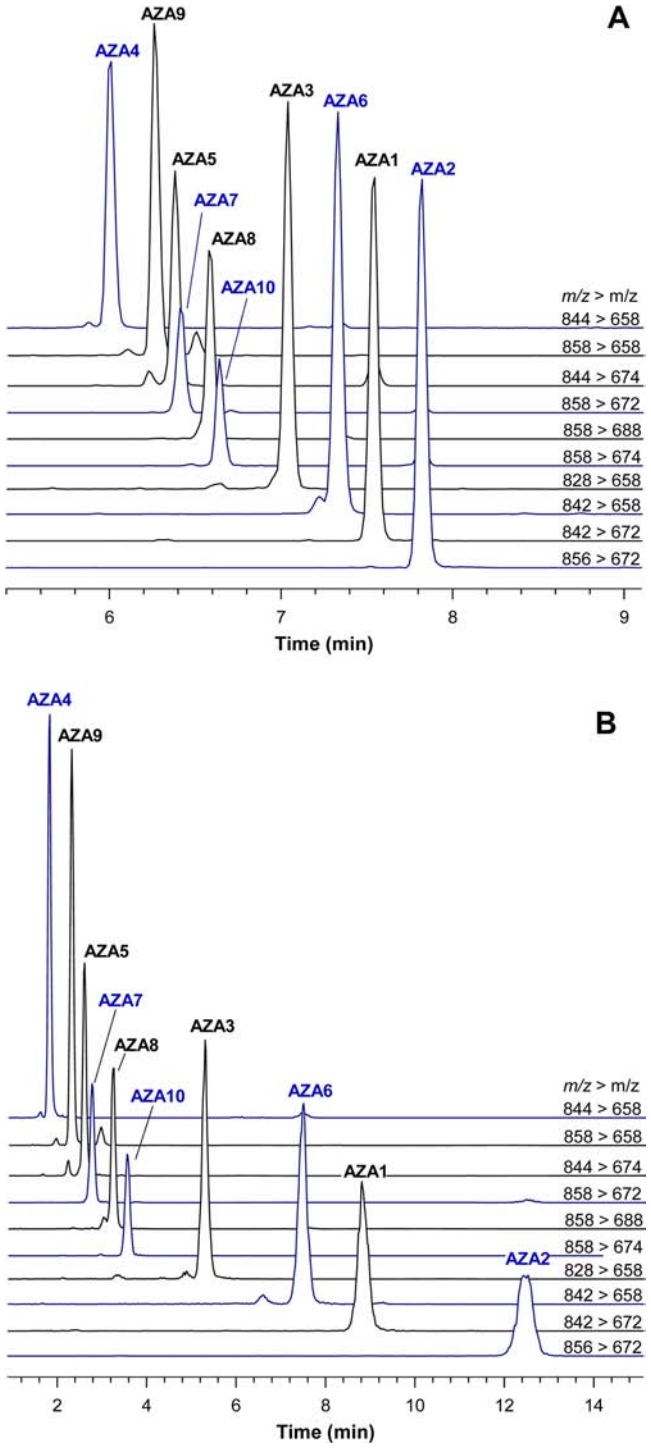

Figure 4. LC–MS/MS analysis (method C) of reference standards prepared for **1**–**10** under (A) gradient and (B) isocratic conditions. Note: two combined reference standards were prepared, as indicated by the colors (blue, black).

systematic changes to most of the resonances of rings F–I (C-35, C-37–C-40, H-29, H-31–H-40, and the 37- and 39-methyl groups). This effect is also observable on a number of remote resonances (H-18, H-19, and the olefinic methylene at C-26), consistent with molecular modeling and ROESY correlations indicating the ring systems F–I to be folded over in such a way that the amino group is near H-19 so that **1**, **2**,[23] **4**, **5**, and **7**–**10** showed ROESY correlations between H-19 and H-40$_{eq}$. Knowledge of these consistent substituent effects on the AZA skeleton will be helpful during NMR structure analysis of other AZA congeners and metabolites.

Further structural evidence was obtained by treatment with periodate that cleaves whenever a diol moiety is present. LC–MS analysis showed that treatment of **7**–**10** with periodate yielded C-20–C-21-cleavage products at m/z 448.4 for **7** (with the same retention time as the cleavage products from **1** and **2**), m/z 464.4 for **8**, m/z 434.4 for **9** (same retention time as products from **3** and **6**), and m/z 450.4 for **10** (same retention time as the product from **5**) (Figure 3). Because the structures of **1**–**6** are well established,[21−24] these results confirm the C-20–C-40 substructures of **7**, **9**, and **10** that were determined by NMR spectroscopy shown (Figure 1).

Because **4**, **5**, **7**, **8**, **9**, and **10** are produced in mussels by enzymatic oxidations and decarboxylations of **1** and **2** biosynthesized by dinoflagellates, it follows that their absolute configurations are as shown in Figure 1. Analogs **4**, **5**, **7**, and **8** are proposed to be bioconversion products of **1**, whereas **9** and **10** appear to be bioconversion products of **2**.[20,34]

Relative Molar Response Study. For the AZAs studied, differences in response factors were less significant in SIM mode under isocratic conditions (Table 2). In LC–MS/MS, the mobile phase composition can influence the ionization efficiency; therefore, analysis under isocratic conditions produces more accurate results. The response factor for **6** was very similar to that of **1**. All the hydroxylated AZAs gave lower response factors, with **7**, **9**, and **10** being the lowest at ~0.5 (Figure 4).

The data shows that the SRM transition selected for analysis of all the AZAs, including **6**, can significantly impact quantitation when using **1** as a calibration standard (Table 2). The H_2O loss transition for **6** was similar to that of **1**; however, the RDA cleavage of the A-ring resulted in significantly higher response factors under both isocratic and gradient conditions. For all the other AZAs, the differences in SRM mode were even greater. The results suggest that, in the absence of standards for the hydroxylated analogues, quantitation will be more accurate in SIM mode under isocratic conditions and that the concentration of hydroxylated AZAs may be significantly underestimated when AZA1 alone is used for calibration (Table 2).

Toxicology. All available AZA analogues tested were cytotoxic to Jurkat T lymphocyte cells in a time- and concentration-dependent manner (Figure 5). However, there were distinct differences in the relative potencies of each analogue, as revealed by their EC_{50} values (Table 3). The range of EC_{50} values for the eight analogues tested in this study were 0.1–3.1 nM, a 31-fold range. On the basis of the EC_{50} values, the relative potencies were **2**[35] > **6** > **8** ≈ **3**[35] > **1** > **4** ≈ **5** ≈ **9** > **10**. Impurities in **7** prevented it from being subjected to the Jurkat cell assay.

In the present study, the AZAs tested represented differing sites of methylation and hydroxylation. Collectively, SAR analysis using these data and published data for **2** and **3**[35] suggest that AZA potency was somewhat increased by methylation at C-8 or C-22 (i.e., **2**, **6**), whereas potency was reduced somewhat by hydroxylation at C3 or C23 (i.e., **4**, **5**) (Table 3, Figure 5). These findings allow us to speculate on the relative potencies of other analogues, such as AZA12 (predicted to have relatively higher potency) and AZA13 (predicted to have relatively lower potency), on the basis of their structures. Interestingly, reduced potencies of **4** and **5** relative to **1** in the

10	2.9	1.2−6.8	3.2	2.1−4.8	3.1	1.8−5.5	3.1	0.2

[a]Confidence interval. [b]Comparisons between analogues should be done cautiously as data were collected from different experiments during which minor changes in in vitro AZA1 potency were observed. Relative potency values for AZA4, -5, -6, and -8 were compared to AZA1 EC_{50} values of 0.96, 1.1, and 1.3 for 24, 48, and 72 h. Relative potency values for AZA9 and -10 were compared to AZA1 EC_{50} values of 0.51, 0.89, and 0.88 for 24, 48, and 72 h.

Jurkat cell assay are the same as those determined by intraperitoneal injection in mice.[23] The utility of this in vitro cytotoxicity assay for relative analogue potencies (i.e., TEFs) are further corroborated by previous in vitro and in vivo studies whereby both techniques also clearly demonstrated increased potencies of **2** and **3** relative to **1**.[21,22,35] However, recent in vivo studies (mouse intraperitoneal and mouse oral) showed that **1** is more toxic than **2** (mouse intraperitoneal ≈ oral; TEF = 0.6−0.7) and **3** (mouse intraperitoneal = oral; TEF = 0.5).[9] Furthermore, the toxicity of **6** was determined by mouse intraperitoneal for the first time and was found to be less toxic (TEF = 0.7) than **1**.[9] Although the reason for this discrepancy is unknown at this time, the oral in vivo studies probably have more relevance for protecting shellfish consumers. However, oral dosing experiments are difficult to perform because of the high mass of toxins needed. Hence, further studies should be

DOI: 10.1021/acs.jafc.5b01320
J. Agric. Food Chem. 2015, 63, 5083−5091

conducted to isolate more of the minor analogues to conclusively clarify their toxicological importance.

In summary, compounds **4**−**10** were purified from shellfish, with the structures of **7**−**10** being elucidated for the first time by NMR, which confirmed the previously postulated structures based on LC−MS/MS studies. qNMR was performed on all purified samples and subsequent LC−MS(MS) relative molar response factors and cytotoxicity were determined. Differences in the molar responses relative to **1** were observed, particularly for the hydroxylated analogues (up to 3-fold). The differences were least significant when analyzing in SIM mode under isocratic conditions. Combining all the cytotoxicity data published to date for AZAs using the Jurkat T lymphocyte cell assay, the order of potencies is **2** > **6** ≈ AZA34[15] ≈ 37-*epi*-**1**[25] > **8** ≈ **3** > **1** > **4** ≈ **9** > **5** ≈ **10** > AZA33.[15]

Supporting Information

ABSTRACT: After oral (PO) and intravenous (IV) administration of zearalenone (ZEN) to broiler chickens, laying hens, and turkey poults, the mycotoxin was rapidly absorbed (T_{max} = 0.32−0.97 h) in all three species; however, the absolute oral bioavailability was low (F% = 6.87−10.28%). Next, also a rapid elimination of the mycotoxin in all poultry species was observed ($T_{1/2el}$ = 0.29−0.46 h). Both α- and β-zearalenone (ZEL) were formed equally after IV administration in all species studied, whereas an increased biotransformation to β-ZEL was demonstrated after PO administration, indicating presystemic biotransformation mainly in broiler chickens and laying hens. In comparison to the latter, turkey poults demonstrated a more extensive biotransformation of ZEN to α-ZEL after PO administration which could, in combination with the observed higher volume of distribution of ZEN, indicate a higher sensitivity of this species to the effects of ZEN in comparison to other poultry species.

KEYWORDS: *poultry, laying hen, turkey, broiler chicken, zearalenone, toxicokinetics, biotransformation*

INTRODUCTION

Mycotoxins are secondary metabolites produced by different fungal species contaminating several food and feed commodities. Over 400 mycotoxins have been identified, although only a few of them are known to have distinct toxic effects. The most prevalent mycotoxin producing fungi in moderate climates are *Fusarium* species. Zearalenone (ZEN) is one of the most frequently occurring *Fusarium* mycotoxins. In a recent study by Streit,[1] 87% of the 83 investigated feed and feed raw material samples were contaminated with ZEN, with a median contamination level of 14 μg/kg and a maximum of 5.3 mg/kg. ZEN can be listed as a nonsteroidal estrogen or myco-estrogen.[2] It resembles 17β-estradiol, the principal hormone produced by the ovary, which allows ZEN to bind to estrogen receptors in target cells.[3] Once the estrogen receptor is bound, it undergoes a conformational change allowing the receptor to interact with chromatin and to modulate transcription of target genes.[4] Not all compounds have the same affinity for estrogen receptors. It has been shown that some phase I metabolites of ZEN can express lower or even higher affinities to estrogen receptors than the parent compound. In general, ZEN is metabolized by 3α- and 3β-hydroxysteroid dehydrogenase (HSD) into α- and β-zearalenol (ZEL), respectively. β-ZEL has a 2.5 times lower affinity for the estrogen receptor, whereas α-ZEL has a 92 times higher binding affinity in comparison to ZEN. The biotransformation to β-ZEL can therefore be regarded as an inactivation pathway, whereas the biotransformation to α-ZEL can be seen as a bioactivation.[5] The rate and extent of α- or β-ZEL production, and consequently the susceptibility, is species dependent. Pigs are regarded as the most sensitive species, as suggested by in vitro data demonstrating that pig liver microsomes dominantly convert ZEN into α-ZEL.[5] This has been confirmed in vivo, where α-ZEL was the only phase I metabolite detected in plasma, urine, and faeces of pigs intravenously (IV) dosed with ZEN.[6] Next, in a study by Zöllner[7] the α-ZEL/β-ZEL ratios were 2.5/1 and 3/1 in pig liver and urine, respectively, after oral intake of ZEN. In vitro results suggest that laying hens and cattle metabolize ZEN to a large extent into β-ZEL, which confirms that they are less prone to the effects of ZEN.[5,8] Next, also phase II biotransformation (conjugation) is regarded as a detoxification pathway. The extent of conjugation has also been found to have major interspecies variation. Migdalof[9] reported that glucuronidated metabolites account for 99% of the total ZEN recovered in humans, whereas in dogs glucuronidation only accounts for 1% of the excreted ZEN metabolites.

To date, no in vivo data are available in poultry regarding the phase I and phase II biotransformation of ZEN after oral exposure, which is mandatory to confirm the in vitro findings and the species-dependent sensitivity. Also, limited information on in vivo toxicokinetics and absolute oral bioavailability is available. Osselaere[10] reported a rapid elimination of ZEN after IV administration of 0.3 mg of ZEN/kg body weight (BW) to broiler chickens ($T_{1/2el}$ = 0.53 h), whereas after oral (PO) administration of the same dose, no ZEN or phase I metabolites could be detected in plasma (limit of quantification: 1−5 ng/mL). The rapid elimination and the assumed low oral bioavailability of the mycotoxin supports the limited toxicity of ZEN in this animal species. Furthermore, Dailey[11] administered 10 mg of [^{14}C]ZEN/kg BW to laying hens and demonstrated

J. Agric. Food Chem. 2015, 63, 5092−5098

that 94% of the administered dose was eliminated via the excreta within 72 h, with one-third as unchanged [^{14}C]ZEN and the other part as unidentified metabolites. Feeding mature laying hens a diet contaminated with ZEN up to 800 mg/kg did not affect their reproductive performance.[12,13] In contrast, feeding 100 mg of ZEN/kg of feed to mature female turkeys reduced the egg production by 20%.[14] Next, feeding 800 mg of ZEN/kg of feed to male turkeys for 2 weeks induced strutting behavior and an increased size and coloration of caruncles and dewlaps, which was not present in birds fed the uncontaminated diet.[15] This difference in sensitivity between broiler chickens and turkey poults is most probably attributed to differences in toxicokinetics and/or biotransformation processes.

Therefore, the aim of the present study was to unravel the toxicokinetic behavior, absolute oral bioavailability, and biotransformation of ZEN after PO as well as IV administration in the economically most important poultry species, namely broiler chickens, laying hens, and turkey poults.

MATERIALS AND METHODS

Chemicals, Products, and Reagents. The analytical standard of ZEN, used for both plasma analysis and the animal experiment, was obtained from Fermentek (Jerusalem, Israel). The analytical standards of α-ZEL, β-ZEL, α-zearalanol (α-ZAL), β-zearalanol (β-ZAL), and zearalanone (ZAN) used for the analytical experiments were obtained from Sigma-Aldrich (Bornem, Belgium). The internal standard (IS), $^{13}C_{18}$-ZEN, used for the analytical experiments was obtained from Romer Laboratories (Tulln, Austria). All analytical standards were stored at ≤−15 °C. Working solutions of ZEN, the described metabolites, and the IS were prepared by appropriate dilution of the stock solutions with acetonitrile (ACN) and stored at 2−8 °C. Water, methanol (MeOH), ACN, and glacial acetic acid used for the plasma analysis were of LC-MS grade and were obtained from Biosolve (Valkenswaard, The Netherlands). Water and dimethyl sulfoxide (DMSO) used for the animal experiment were of analytical grade and were obtained from Filterservice (Eupen, Belgium). Millex-GV PVDF filter units (0.22 μm) were obtained from Merck-Millipore (Overijse, Belgium).

Animals and Experimental Procedure. Six turkey Hybrid Converter poults (3 ♂/3 ♀, 0.95 ± 0.06 kg BW), broiler chickens (Ross 308, 3 ♂/3 ♀, 1.05 ± 0.05 kg BW) and laying hens (Brown Leghorn, 6 ♀, 1.04 ± 0.05 kg BW) were obtained from a commercial breeder. During the experiment, animals were housed in group and a 16 h light/8 h dark light cycle was applied. Feed and water were given ad libitum throughout the 1 week acclimatization period. Subsequently, 12 h before the start of the experiment, the animals were deprived of feed. After this period, three birds per species were administered ZEN (3 mg/kg BW) by oral gavage (PO), whereas the other three birds/species were injected the same dose of ZEN in the wing vein (IV). The PO and IV bolus solution was prepared by dissolving the ZEN standard in DMSO (10 mg/mL) and further diluted with water (PO) or physiological saline (IV) up to a volume of 1 mL. Following administration of the mycotoxin, 0.5 mL of blood was drawn from the leg vein at various time points: 0 (just before administration) and 2, 5, 10, 20, 30, 40, 50, 60, 120, 180, and 240 min postadministration. Samples were centrifuged (2851*g*, 10 min, 4 °C), and aliquots of plasma (150 μL) were stored at ≤−15 °C until analysis. After a 2 day wash-out period, the protocol was repeated in a two-way crossover design. The birds that received an IV injection of the mycotoxin then received a PO bolus and vice versa. The dosing, blood collection, and sample storage was performed in the same way as the first administration. The animal experiment was approved by the Ethical Committee of the Faculty of Veterinary Medicine and Bioscience Engineering of Ghent University (EC 2014/118).

LC-MS/MS Analysis. Sample treatment and quantification of ZEN, and its phase I metabolites (α-ZEL, β-ZEL, α-ZAL, β-ZAL and ZAN; see Figure 1 in the Supporting Information), in poultry plasma were performed as previously described by De Baere et al. with minor modifications. Briefly, 50 μL of IS working solution (50 ng/mL) was added to 150 μL of plasma, followed by the addition of ACN up to 1 mL. Next, the sample was vortex mixed (15 s) and centrifuged (8517*g*, 10 min, 4 °C). The supernatant was evaporated to dryness using nitrogen (N_2, 45 ± 5 °C). The dry residue was reconstituted in 200 μL of water/MeOH (85/15, v/v), vortex mixed (15 s), filtered through a Millex GV-PVDF syringe filter, and transferred into a conical autosampler vial. An aliquot (5 μL) was injected onto the LC-MS/MS instrument.

Chromatographic separation was achieved on a Hypersil Gold column (50 mm × 2.1 mm i.d., dp 1.9 μm) in combination with a guard column of the same type (10 mm × 2.1 mm i.d., dp 3 μm), both from ThermoFisher Scientific (Breda, The Netherlands). Mobile phase A consisted of 0.1% acetic acid in water, whereas mobile phase B was ACN. The following gradient elution program was run: 0−0.5 min (70% A, 30% B), 0.5−5.0 min (linear gradient to 70% B), 5.0−6.4 min (30% A, 70% B), 6.4−6.5 min (linear gradient to 30% B), 6.5−8.5 min (70% A, 30% B). The flow rate was set at 300 μL/min, and the temperatures of the column oven and autosampler tray were set at 45 and 5 °C, respectively.

Detection was performed on a Waters Xevo TQ-S triple-quadrupole mass spectrometer by means of electrospray ionization (ESI) in the negative ionization mode. The instrument was tuned by direct infusion of a 10 ng/mL working solution of ZEN, the metabolites, and the IS. The following parameters were retained for optimal detection: capillary voltage, 2.5 kV; cone voltage, 15 V; source temperature, 150 °C; desolvation temperature, 600 °C; cone gas flow, 150 L/h; desolvation gas flow, 1000 L/h. Acquisition was performed in the selected reaction monitoring (SRM) mode. The following transitions (m/z) were used as quantifier and qualifier ion, respectively: for ZEN, 317.1 > 175.0 and 317.1 > 131.0; for α-ZEL, 319.0 > 275.0 and 319.0 > 159.9; for β-ZEL, 319.0 > 159.9 and 319.0 > 275.0; for ZAN, 319.0 > 205.0 and 319.0 > 275.0; for α-ZAL, 321.1 > 277.1 and 321.1 > 303.0; for β-ZAL, 321.1 > 277.1 and 321.1 > 303.0; for IS, 335.2 > 168.9 and 335.2 > 185.0. The method was validated for the compounds listed above according to a validation protocol described by De Baere[16] based on European[17] and international[18] guidelines. The validation protocol encompassed the following parameters: linearity (correlation coefficient and goodness-of-fit), within- and between-run accuracy and precision, carryover, limit of quantification (LOQ), and limit of detection (LOD). The LOQ was set at 0.5 ng/mL for ZEN, 0.2 ng/mL for α-ZEL and α-ZAL, and 0.1 ng/mL for β-ZEL, β-ZAL, and ZAN.

UHPLC-HRMS Analysis. The extracted samples were also analyzed by UHPLC coupled to HRMS analysis for identification and semiquantification of the glucuronide conjugates of ZEN and of its phase I metabolites as previously described by De Baere.[19] This was performed on the basis of the peak area ratios of the metabolites, versus the IS. The UHPLC system consisted of an Accela type 1250 high-speed LC and autosampler, both from ThermoFisher Scientific. The same HPLC column and mobile phases were used as described above. The UHPLC was interfaced to an Exactive Orbitrap HR mass spectrometer, equipped with a heated ESI probe operating in the negative ionization mode (ThermoFisher Scientific). Accurate masses were based on the predicted masses (m/z; $[M - H]^-$) described by De Baere[19] and Stevenson:[20] ZEN-glucuronide (ZEN-GlcA, $C_{24}H_{30}O_{11}$), 493.17153; ZAN-GlcA, α-ZEL-GlcA and β-ZEL-GlcA ($C_{24}H_{32}O_{11}$, no chromatographic separation or distinction between these compounds based on accurate masses possible), 495.18718; α-ZAL-GlcA and β-ZAL-GlcA ($C_{24}H_{34}O_{11}$, no chromatographic separation or distinction between these compounds based on accurate masses possible), 497.20283. Confirmation of the GlcA peaks observed in the extracted ion chromatogram (EIC) was performed by comparing the theoretically calculated $^{13}C/^{12}C$ isotope ratios for the $[M - H]^-$ ion with the corresponding isotope ratios detected in the analyzed samples, as described by De Baere.[19]

Toxicokinetic Analysis. Noncompartmental toxicokinetic analysis of ZEN and α- and β-ZEL was performed with WinNonlin 6.3 (Pharsight, St. Louis, MO, USA). For ZEN, the following toxicokinetic parameters were calculated for IV and PO administration: maximum plasma concentration for PO (C_{max}), plasma concentration at time 0 for IV (C_0), time to maximum plasma concentration (T_{max}), area under the

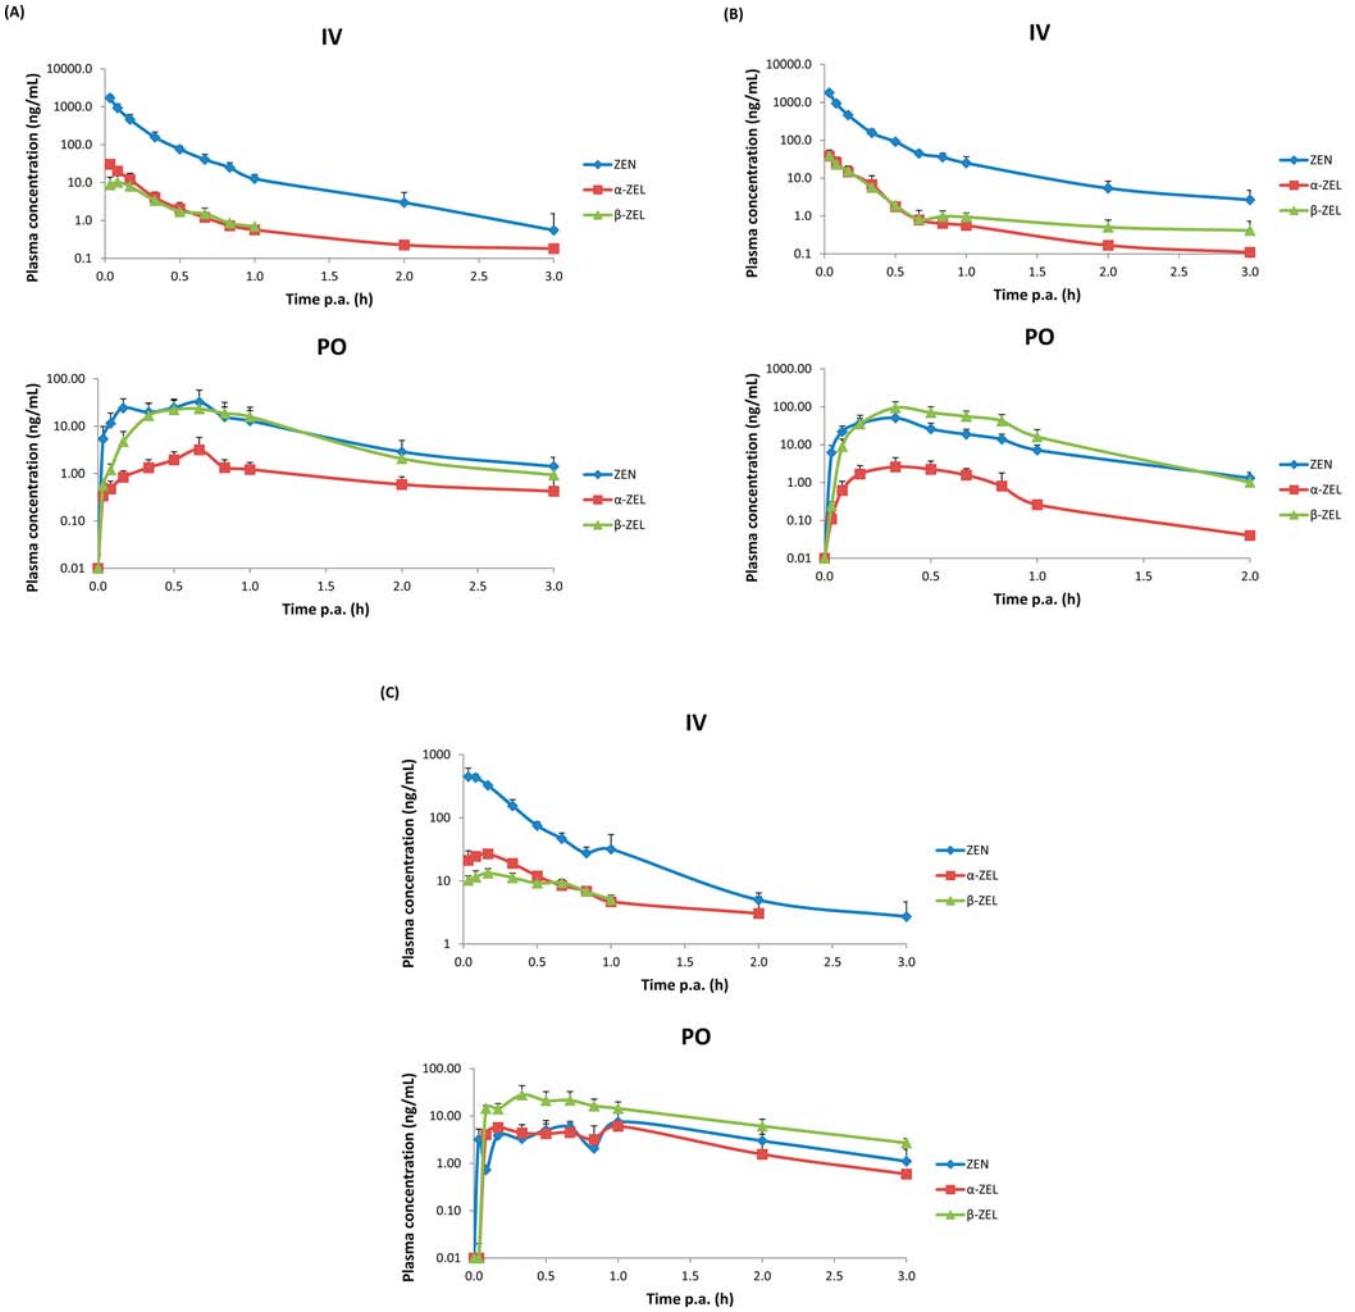

Figure 1. Plasma concentration−time profile of zearalenone (ZEN), α-zearalenol (α-ZEL), and β-zearalenol (β-ZEL) after intravenous (IV) and oral (PO) administration of 3 mg of ZEN/kg of body weight to broiler chickens (A), laying hens (B), and turkey poults (C) ($n = 6$). Values are presented as means + SD.

plasma concentration−time curve from time 0 to 3 h (AUC_{0-t}), area under the plasma concentration−time curve from time 0 to infinite (AUC_{0-inf}), elimination rate constant (k_{el}), elimination half-life ($T_{1/2el}$), total body clearance (Cl), volume of distribution (V_d), and mean residence time (MRT).

The absolute oral bioavailability (F, expressed as %, F%) for each individual bird was calculated according to the formula

$$F\% = AUC_{0-inf\,PO}/AUC_{0-inf\,IV} \times 100$$

The Cl and V_d values after PO administration were calculated by multiplying the data generated by the toxicokinetic software (i.e., V_d/F and Cl/F) by the F value from each individual bird.

The mean absorption time (MAT) was calculated according to the formula

$$MAT = MRT_{PO} - MRT_{IV}$$

The absorption rate constant (k_a) and absorption half-life ($T_{1/2a}$) were derived from the MAT:

$$k_a = MAT^{-1}$$

$$T_{1/2a} = 0.693/k_a$$

For α- and β-ZEL, the C_{max}, T_{max}, AUC_{0-t} (from time 0 to the last time point above the LOQ, i.e. 2 or 3 h) and AUC_{0-inf} values were determined after both IV and PO administration of ZEN. Next, ZEL/ZEN ratios were calculated according to the formulas

$$\alpha\text{-ZEL/ZEN} = AUC_{0-inf\,\alpha\text{-ZEL}}/AUC_{0-inf\,ZEN}$$

$$\beta\text{-ZEL/ZEN} = AUC_{0-inf\,\beta\text{-ZEL}}/AUC_{0-inf\,ZEN}$$

[a]Values are presented as means ± SD. A different superscript (a or b) denotes a significant difference between animal species for each administration route at $p < 0.05$. [b]C_{max} = maximum plasma concentration. [c]C_0 = plasma concentration at time 0. [d]T_{max} = time to maximum plasma concentration. [e]AUC_{0-t} = area under the plasma concentration−time curve from time 0 to 3 h. [f]AUC_{0-inf} = area under the plasma concentration−time curve from time 0 to infinite. [g]k_a = absorption rate constant. [h]$T_{1/2a}$: = absorption half-life. [i]MRT = mean residence time. [j]MAT = mean absorption time. [k]Cl = total body clearance. [l]k_{el} = elimination rate constant. [m]$T_{1/2el}$ = elimination half-life. [n]V_d = volume of distribution. [o]F = absolute oral bioavailability.

$$\text{ZEL/ZEN} = (\text{AUC}_{0-\text{inf}\,\alpha\text{-ZEL}} + \text{AUC}_{0-\text{inf}\,\beta\text{-ZEL}})/\text{AUC}_{0-\text{inf ZEN}}$$

Finally, the α-ZEL/β-ZEL ratio was calculated according to the formula

$$\alpha\text{-ZEL}/\beta\text{-ZEL} = \text{AUC}_{0-\text{inf}\,\alpha\text{-ZEL}}/\text{AUC}_{0-\text{inf}\,\beta\text{-ZEL}}$$

Statistical Analysis. All toxicokinetic parameters from each compound (ZEN, α- and β-ZEL) and each administration route were compared between animal species using one-way analysis of variance (ANOVA) (SPSS 21, IBM, USA). The level of significance was set at 0.05.

RESULTS AND DISCUSSION

The goal of this study was to unravel the toxicokinetic behavior, absolute oral bioavailability, and biotransformation of ZEN in different poultry species in order to assess potential species-dependent sensitivity to this mycotoxin. During the animal experiment, no clinical symptoms were observed after PO or IV administration of ZEN to the birds. Furthermore, no sex differences in toxicokinetic parameters were observed for broiler chickens and turkey poults. In Figure 1, the plasma concentration−time profiles of ZEN and α- and β-ZEL after IV and PO administration of ZEN to broiler chickens, laying hens, and turkey poults are presented. Only trace amounts of α- and β-ZAL and ZAN were detected, but none were above the LOQ of 0.2, 0.1, and 0.1 ng/mL, respectively. As can be seen in Figure 1 and Table 1, ZEN is rapidly absorbed in all studied poultry species, namely broiler chickens (T_{max} = 0.35 h, MAT = 0.37 h), laying hens (T_{max} = 0.32 h, MAT = 0.35 h), and turkey poults (T_{max} = 0.97 h, MAT = 0.44 h). However, the F% is low in all studied poultry species: 8.34%, 10.28%, and 6.87%, in broiler chickens, laying hens, and turkey poults, respectively. This might indicate either a low extent of absorption and/or extensive presystemic biotransformation, and is attributed to the generally accepted high tolerance of poultry to ZEN, since F is a measurement for systemic exposure. Next to rapid absorption, the mycotoxin is rapidly eliminated in all species as well with $T_{1/2el}$ values between 0.34 and 0.36 h and between 0.29 and 0.46 h after PO and IV administration, respectively. Osselaere[10] reported a similar $T_{1/2el}$ value of 0.53 h after IV administration of 0.3 mg of ZEN/kg of BW to broiler chickens. Furthermore, a high V_d value is observed after PO and IV administration in all animal species (V_d = 3.21−10.65 L/kg). For broiler chickens, an even higher V_d value has been reported previously by Osselaere,[10] namely 22.26 L/kg; however, this value was reported with a high uncertainty (15.15 L/kg). Of interest here is that turkey poults have a significant higher V_d value (9.03−10.65 L/kg) in comparison to broiler chickens (3.21−4.16 L/kg) and laying hens (6.18−6.24 L/kg), which supports the hypothesis of a higher sensitivity to ZEN of this species. Furthermore, the higher V_d value explains why the C_0 value is significantly lower in turkey poults (C_0 = 700.5 ng/mL) in comparison to broiler chickens (C_0 = 2607.0 ng/mL) and laying hens (C_0 = 2789.2 ng/mL), although they were administered the same dose of ZEN (3 mg/kg BW). In addition, pigs display a high V_d value of ZEN, comparable to that of turkey poults, after IV administration, namely 10.84 L/kg, leading to a high tissue distribution of the mycotoxin.[6] In addition to a higher V_d value in turkey poults, also a significantly higher Cl value in turkeys (Cl = 16.57−19.66 L/h/kg) in comparison to those in broiler chickens (Cl = 9.06−11.1 L/(h kg)) and laying hens (Cl = 9.39−11.38 L/(h kg)) was noticed. Since both V_d and Cl values are higher in turkey poults, this leads to comparable $T_{1/2el}$ values between the latter ($T_{1/2el}$ = 0.35−0.38 h) and broiler chickens ($T_{1/2el}$ = 0.29−0.34 h) and laying hens ($T_{1/2el}$ = 0.36−0.46 h). Next, due to the higher Cl values in turkey poults and comparable F values, the AUC_{0-inf} value is significantly lower in this species after both administration routes ($AUC_{0-inf\,PO}$ = 10.21 (h ng)/mL, $AUC_{0-inf\,IV}$ = 183.12 (h ng)/mL) in comparison to broiler chickens ($AUC_{0-inf\,PO}$ = 23.59 (h ng)/mL, $AUC_{0-inf\,IV}$ = 292.10 (h ng)/mL) and laying hens ($AUC_{0-inf\,PO}$ = 30.04 (h ng)/mL, $AUC_{0-inf\,IV}$ = 324.93 (h ng)/mL). Similarly, also the AUC_{0-t} value was significantly lower.

As described above, species-dependent biotransformation of ZEN has a distinct impact on sensitivity to this mycotoxin, and the in vitro estrogenic potency of its phase I metabolites is as follows: α-ZAL > α-ZEL > β-ZAL > ZEN > β-ZEL.[21] Phase I biotransformation of ZEN consists of reduction of the ketone group of ZEN to its corresponding alcohol by 3α-/3β-HSD,

thereby forming α-/β-ZEL, and aromatic hydrogenation of α-/β-ZEL to α-/β-ZAL by cytochrome P450 (CYP450) enzymes. Finally, α-/β-ZAL can be oxidized by 3α-/3β-HSD to ZAN. The biotransformation of ZEL to ZAL and ZAN has been reported for pigs and humans; however, the extent is negligible.[21] In addition, in the present study only trace amounts of α-/β-ZAL and ZAN were detected, demonstrating that formation of α- and β-ZEL is also the predominant phase I biotransformation in poultry. In all three poultry species both α- and β-ZEL could be detected, although the extent differed between species and routes of administration (Figure 1 and Table 2). Turkey poults have a more efficient biotransformation of ZEN to α- and β-ZEL in comparison to broiler chickens and laying hens, with higher α-ZEL/ZEN and β-ZEL/ZEN ratios after both PO and IV administration (although not significant for β-ZEL/ZEN after PO), whereas these ratios are comparable between broiler chickens and laying hens (Table 2). Consequently, also the ZEL/ZEN ratio in turkey poults is significantly higher after PO (ZEL/ZEN_{PO} = 5.226) as well as IV administration (ZEL/ZEN_{IV} = 0.152) in comparison to broiler chickens (ZEL/ZEN_{PO} = 1.149, ZEL/ZEN_{IV} = 0.032) and laying hens (ZEL/ZEN_{PO} = 2.086, ZEL/ZEN_{IV} = 0.042). Furthermore, the biotransformation of ZEN to α- and β-ZEL occurs to a greater extent after PO than after IV administration in all animal species. This difference in ZEL formation between both administration routes indicates presystemic biotransformation of ZEN in the gut and/or the liver. After IV administration, the α-ZEL/β-ZEL ratio is not statistically different between bird species and is around 1 (α-ZEL/$\beta\text{-ZEL}_{IV}$ = 1.073 to 1.629). In contrast, after PO administration the β-ZEL isomer is predominantly formed in broiler chickens (α-ZEL/$\beta\text{-ZEL}_{PO}$ = 0.153) and laying hens (α-ZEL/$\beta\text{-ZEL}_{PO}$ = 0.027), but this is significantly different in turkey poults (α-ZEL/$\beta\text{-ZEL}_{PO}$ = 0.749). Again, this indicates presystemic formation of mainly β-ZEL, especially in broiler chickens and laying hens. These data confirm the in vitro findings in laying hen: namely, a predominant β-ZEL formation.[5] Since the α-ZEL/ZEN ratio after PO and IV ZEN administration is significantly higher in turkey poults in comparison to both other bird species, this supports the hypothesis of increased sensitivity of turkey poults to the estrogenic effects of the mycotoxin.

Phase II biotransformation of ZEN and its phase I metabolites comprises glucuronidation which is catalyzed by uridine 5′-diphosphate glucuronosyltransferase (UGT).[22] Since no analytical standards of glucuronidated ZEN (ZEN-GlcA) or glucuronidated α- or β-ZEL (ZEL-GlcA) are commercially available, no accurate quantitative analysis could be performed. However, a semiquantitative using HR-MS was done (Figure 2). After IV administration of ZEN, ZEN-GlcA is the predominant phase II metabolite in all three bird species. Although the ZEL/ZEN ratio is higher in turkey poults, namely 0.152, in comparison to broiler chickens and laying hens, 0.032 and 0.042, respectively, no ZEL-GlcA could be detected in this species after IV administration, which is in contrast to the other species. After oral ZEN administration, comparable amounts of ZEN-GlcA and ZEL-GlcA were detected in broiler chickens and laying hens, whereas in turkey poults only ZEL-GlcA was detected, attributed to the high ZEL/ZEN ratio in this species after PO administration (ZEL/ZEN = 5.226). This confirms the phase I biotransformation data: namely, a presystemic ZEL formation and consequent predominant ZEL glucuronidation. Differences in phase II biotransformation might also account for differences in sensitivity. For the mycotoxin DON, for instance, limited sulfation was described for turkeys in contrast to broiler chickens, which might explain the increased sensitivity of turkeys to deoxynivalenol.[23] In addition, for the mycotoxin aflatoxin B1 (AFB1), turkeys are more sensitive in comparison to other poultry and animal species on the basis of differences in biotransformation of AFB1. In turkeys, the phase I bioactivation of AFB1 to AFB1-8,9-epoxide is highly efficient and the epoxide metabolite is held responsible for the hepatotoxic and carcinogenic effects of AFB1.[24] Furthermore, turkeys have a glutathione-*S*-transferase deficiency (phase II biotransformation) which adds to the sensitivity of this species.[25]

In conclusion, this paper describes—for the first time—the toxicokinetic behavior, absolute oral bioavailability, and comparative phase I and II biotransformation of ZEN in broiler

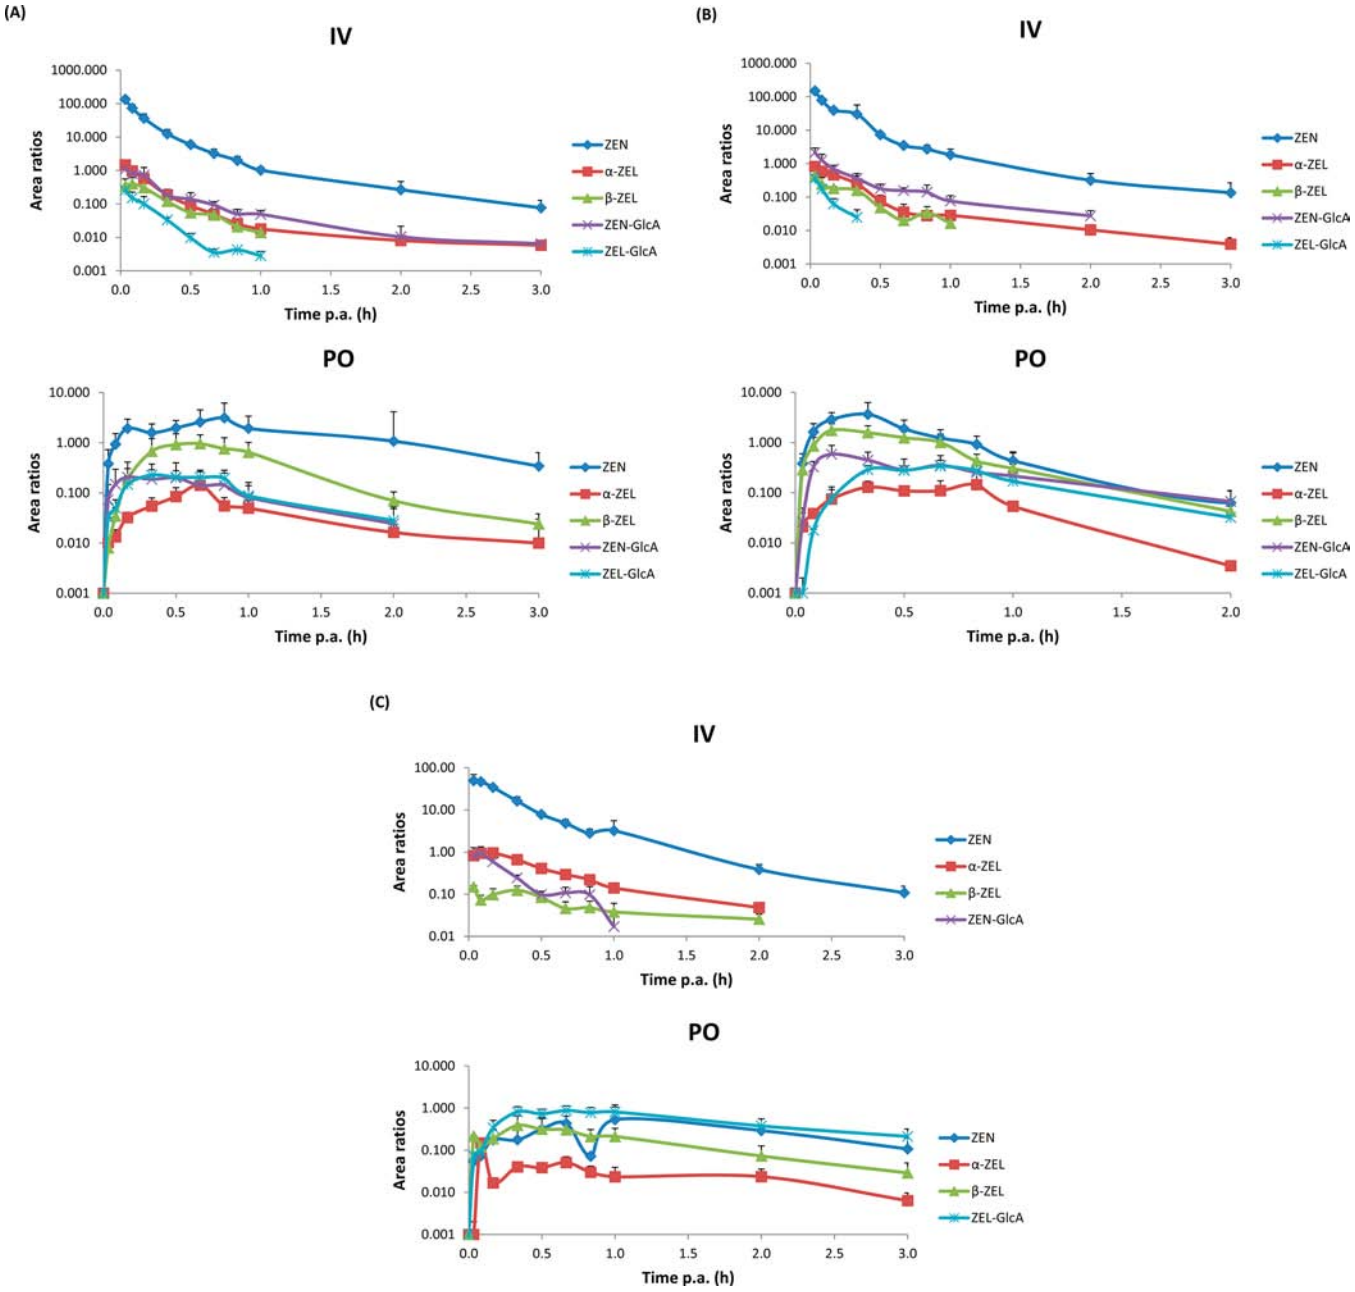

Figure 2. Ratio of the peak area detected by ultrahigh-performance liquid chromatography coupled to high-resolution mass spectrometry of zearalenone (ZEN) or its metabolites, namely α-zearalenol (α-ZEL), β-zearalenol (β-ZEL), ZEN-glucuronide (ZEN-GlcA), and ZEL-glucuronide (ZEL-GlcA), and the internal standard ($^{13}C_{18}$-ZEN) plotted against the time after intravenous (IV) or oral (PO) administration (p.a.) of 3 mg of ZEN/kg of body weight to broiler chickens (A), laying hens (B), or turkey poults (C) (n = 6). Values are presented as means + SD.

chickens, laying hens, and turkey poults. ZEN is rapidly absorbed in all studied poultry species, but the absolute oral bioavailability of the mycotoxin is low. Furthermore, it is rapidly eliminated as well after both PO and IV administration. Both α- and β-ZEL were formed equally after IV administration in all bird species, whereas an increased biotransformation to β-ZEL was demonstrated after oral administration, indicating presystemic biotransformation processes, primarily in broiler chickens and laying hens. Finally, the presented data suggest that turkey poults might be more sensitive to the effects of ZEN on the basis of the higher V_d value of ZEN and the more extensive presystemic biotransformation of ZEN to α-ZEL in comparison to the two other poultry species.

Symposium Introduction

pubs.acs.org/JAFC

51st North American Chemical Residue Workshop

ABSTRACT: Manuscripts collected in this 51st North American Chemical Residue Workshop (NACRW) Symposium issue of the *Journal of Agricultural and Food Chemistry* (*JAFC*) were originally presented at the 51st NACRW meeting. The 2014 NACRW *JAFC* symposium collects 14 publications representing the broad range of topics in chemical analyses presented at the 2014 meeting. These include the analysis of chemical residues and contaminants in food, environment, feed, botanical, and bee samples as well as the application of quality control/quality assurance protocols in routine and method development.

The 51st North American Chemical Residue Workshop (NACRW, www.nacrw.org) was held July 20−23, 2014, in its traditional location at the TradeWinds Island Grand Resort in St. Pete Beach, FL, USA. The NACRW has been sponsored by the FLAG Works Inc. (www.flagworks.org) since 1963, as well as manufacturers of laboratory consumables, analytical standards and reference materials, sample preparation kits, and analytical equipment. Formerly known as the Florida Pesticide Residue Workshop (FPRW), the new name NACRW was established in 2013 to reflect the increasing scope of the workshop. This year, the NACRW attracted 310 registered attendees representing academics, government and industrial sectors from 17 countries worldwide. Together, the Program Committee put together a four day program encompassing 5 keynotes, 29 oral presentations, 106 posters, 41 exhibitors, and a short course.

Under the general theme "Science without Borders", scientists from 17 countries delivered 140 oral and poster presentations. The workshop started with a short course, "Fundamentals of Gas and Liquid Chromatography for Residue Analysis", on Sunday; followed by 10 scientific sessions including veterinary drug residue analysis, new approaches to ensure quality, pesticide and bees, state laboratory forum, tools and toxicological effects, high-throughput sample preparation and analysis methods, perfluorinated compounds, and two sessions dedicated to general topics; it ended Wednesday evening with a special mass spectrometry forum focusing on issues associated with targeted and nontargeted screening methods. Papers published in this 51st NACRW Group of *JAFC* were originally presented and/or derived from intensive discussions at the 4 day workshop.

The papers included in this NACRW symposium of *JAFC* are a good representation of topics presented and discussed at the 51st NACRW and should provide an open invitation to all for the future meetings, especially for the 2015 NACRW to be held July 19−22, 2015, also at the TradeWinds in St. Pete Beach. Please come to learn, discuss, network, enjoy the science with your colleagues, and take advantage of the many opportunities the NACRW has to offer.

Single-Laboratory Ruggedness Testing and Validation of a Modified QuEChERS Approach To Quantify 185 Pesticide Residues in Salmon by Liquid Chromatography– and Gas Chromatography–Tandem Mass Spectrometry

Brittany Holmes,* Arlene Dunkin, Royal Schoen, and Chris Wiseman

Chemical and Hop Laboratory, Washington State Department of Agriculture, Suite 106, 21 North First Avenue, Yakima, Washington 98902, United States

Supporting Information

ABSTRACT: In this study, we successfully applied a previously modified version of the QuEChERS approach to quantify pesticide residues in samples of fresh salmon. Analysis was performed using a combination of liquid and gas chromatography–tandem mass spectrometry (LC-MS/MS and GC-MS/MS). The validated QuEChERS method used ethyl acetate for the extraction solvent and involved two freezing steps and a C18 dispersive solid phase extraction for removal of lipids. Of the 228 pesticides initially screened, only 185 passed the method validation criteria (103 on LC-MS/MS and 82 on GC-MS/MS). In a quantitative validation, acceptable performances were achieved with overall recoveries of 70–120% and <20% RSD for 179 analytes (n = 7) over the course of five different extractions at 2 times the limit of quantification. Over 12 months, this method was used in the analysis of 708 salmon samples collected as part of the U.S. Department of Agriculture's Pesticide Data Program. Ruggedness testing conducted throughout the entire study showed this method to be robust and suitable for long-term use.

INTRODUCTION

Accurate pesticide dietary risk assessments by the U.S. Environmental Protection Agency (EPA) require incidence and level pesticide residue data. The Pesticide Data Program (PDP) is a voluntary, federal–state pesticide residue monitoring program administered by the U.S. Department of Agriculture (USDA) Agricultural Marketing Service since 1991. The purpose of PDP is to collect and report pesticide residue data on commodities selected from the U.S. food supply. Commodities included in PDP surveys are selected on the basis of consumption rates compiled from the Continuing Survey of Food Intakes by Individuals, with an emphasis on foods most consumed by children and infants. PDP food sampling is based on a rigorous statistical design that ensures the data are reliable for use in dietary exposure assessments.[1] Pesticides included in the PDP survey are prioritized on the basis of input from data users, stakeholders EPA, FDA private grower groups, industry, consumer/environmental groups), and current U.S. tolerances and action levels, but data are collected for any additional pesticides tested by the participating laboratory. Analytical methods used for PDP sample analyses must fulfill PDP's stringent method validation and ongoing quality control requirements.[2]

Analytical methods have been developed for assessing various chemical residues in fish tissue, with the distinguishing factor being the sample preparation technique. Common preparations include solid–liquid extraction, Soxhlet extraction, sonication-assisted extraction, or accelerated solvent extraction coupled to a cleanup step involving solid phase extraction or gel permeation chromatography.[3−5] With these methods come high costs and low sample throughput; the labor-, time-, and solvent-intensive procedures also require advanced analytical expertise and laboratory equipment. To overcome these challenges the "quick, easy, cheap, effective, rugged, and safe" (QuEChERS) approach, originally developed for the determination of pesticide residues in fruits and vegetables,[6] has been modified over the years for different compounds and matrices.[7−9] There are hundreds of publications in the scientific literature that have utilized QuEChERS for sample preparation and analysis. The original approach is characterized by an extraction step using the polar solvent acetonitrile followed by subsequent liquid–liquid partitioning of residues through the addition of salts and buffering agents. Samples are then subjected to various cleanup steps to remove coextractives and further isolate pesticide residues for analysis by either liquid or gas chromatography coupled to a tandem mass spectrometer. As part of PDP, the National Science Laboratory in Gastonia, NC, USA, modified the QuEChERS approach to analyze pesticide residues in catfish.[10] Major modifications included changing the extraction solvent from acetonitrile to ethyl acetate and incorporating two freezing steps for removal of lipids. Figure 1 provides a complete comparison of these two approaches. Changing to a less polar solvent improves partitioning of analytes from the fatty lipid layer in fish tissue.[11] However, this will also increase the amount of coextractives

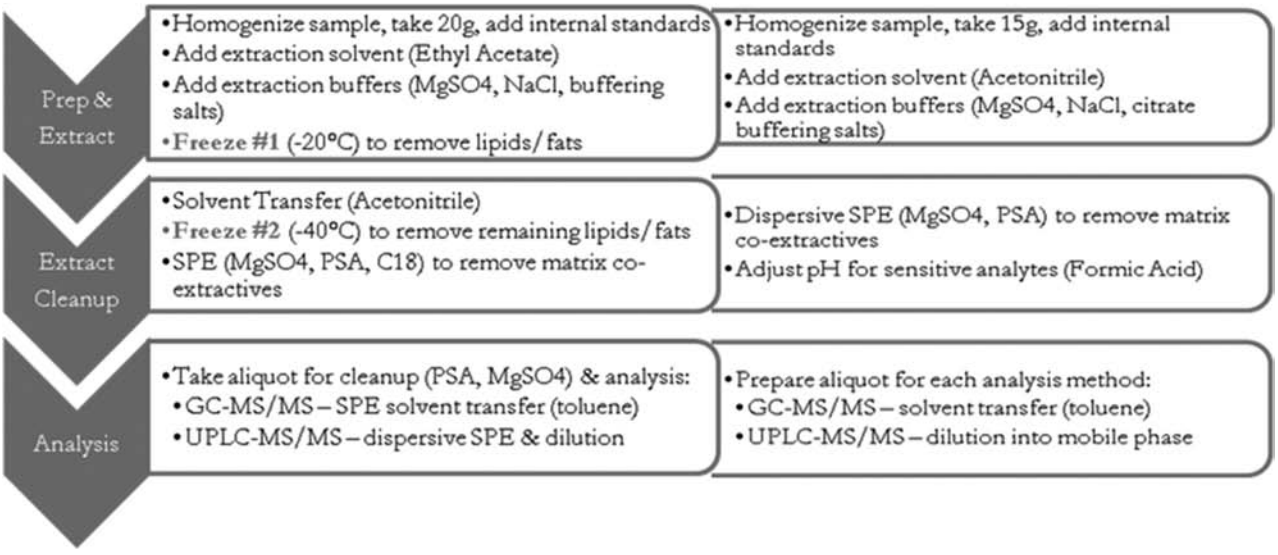

Figure 1. Modified QuEChERS for salmon (left) compared to original QuEChERS approach (right).

(especially lipids),[12] which can be removed by freezing the extract to below −20 °C.[11] To ensure complete lipid removal, two separate freezing steps were added. The objective of this study was to apply this method originally developed for catfish to the salmon matrix and evaluate its efficiency and robustness. One major concern was the lipid content of salmon, as it can be 2−3 times higher than that of catfish.[13] The two freezing steps in the original method should be enough to reduce matrix interferences from the additional lipid content in salmon, but to ensure that matrix effects are reduced as much as possible, C18 sorbent was added to the LC-MS/MS dispersive solid phase extraction (dSPE) cleanup step. The pigments that give salmon its trademark pink color could cause interference with analytes of interest if included in the final extract. Most commercial dSPE kits use a combination of primary−secondary amine and/or graphitized carbon black (GCB) to remove pigments. GCB is known to remove planar pesticides,[6] and because the goal of PDP is to provide as much data as possible, this sorbent was not investigated for any of the dSPE cleanup steps.

Method validation was accomplished by assessing selectivity and conducting single-laboratory intra- and interday precision and accuracy studies. The performance of the method validation was evaluated using criteria outlined in Table 1, set by the USDA-PDP quality assurance program and based on EPA Good Laboratory Practices. Once validated, this modified approach extends the scope of previously validated multiresidue methods for fish[5,7,8] and salmon[3,4,11] tissue in terms of instrumentation (both LC- and GC-MS/MS), number of samples (60 samples per month), length of study (1 year), and size of pesticide screen. The initial screen includes all of the major chemical classes: carbamates (n = 21), ureas (n = 12), organophosphorus (n = 44), organochlorines (n = 35), pyrethroids (n = 22), conazoles (n = 66), pyrethroids (n = 22), triazines (n = 5), and dinitroanilines (n = 6).

Table 1. Method Validation Criteria Set for PDP by USDA Agricultural Marketing Service

	criteria	range[a]
analysis selectivity	LC retention time	±0.5 min
	GC retention time	±0.05 min
	minimum no. of MS/MS transitions	quantitative, 2; qualitative, 1
	MS/MS ion response ratio	%CV < 20%
analysis accuracy	calibration STD linearity	R^2 > 0.990
	calibration STD range	1×, 5×, and 10× LOQ
	linearity range	80−120% of the test concentrations
	calibration STD accuracy	80−120% of actual concentration
	fortification recovery	50−150% at 2 × LOQ
analysis precision	calibration STD precision	%CV < 30%
	interday: fortification recovery	%CV < value predicted by Horwitz
	interday: matrix-matched STD recovery	
method LOQ	quantitative MS/MS transition	>10:1 S:N ratio
	qualitative MS/MS transition	>3:1 S:N ratio

[a]%CV = coefficient of variation, defined as a ratio of the standard deviation (s) of a set of numbers (n), to their average (x), expressed as a percentatge: $s/x \times 100\%$; LOQ = limit of quantitation, at least 10:1 signal: noise; Horwitz %CV = $2^{(1-0.5\log C)}$, where C is concentration.

MATERIALS AND METHODS

Reagents and Chemicals. Acetonitrile, ethyl acetate, toluene, acetone, and acetic acid (HPLC grade or better) and methanol and formic acid (LCMS grade Optima) were purchased from Fischer Scientific. Magnesium sulfate, anhydrous reagent grade ($MgSO_4$), sodium chloride, reagent grade (NaCl), primary−secondary amine (PSA), 1 mL mini-centrifuge tubes, polypropylene (PPE) 15 and 50 mL centrifuge tubes, and solid phase extraction (SPE) columns were purchased from UCT.

Standards with valid certificates of analysis were obtained from the National Pesticide Standard Repository, EPA, and ChemService. All neat standards were stored in a freezer at −20 °C or lower, unless degradation occurred, in which case standard was stored at the recommended temperature. Individual stock solutions at 1.0 mg/mL were prepared in methanol or acetone depending on solubility and instrumentation. Mixed standard solutions containing about 140 pesticides for LC and 90 pesticides for GC were prepared from the stock standards in methanol and acetone, respectively. All standard solutions were stored in a freezer at 0 °C; all cold-storage devices were secured and monitored according to ANSI/ISO/IEC 17025. Anytime a neat standard or solution was removed from cold storage, it was first

DOI: 10.1021/jf5055276
J. Agric. Food Chem. 2015, 63, 5100−5106

brought to room temperature before being used. Individual standard solutions were good for 1 year, whereas mixed solutions were used for only 6 months and then remade accordingly.

Sample Collection and Processing. Using a rigorous statistical design, PDP has developed extensive procedures that ensure samples are randomly selected from the national food distribution system and reflect what is typically available to the consumer. PDP State sample collectors and State testing facilities are trained to adhere to detailed program Standard Operating Procedures that provide criteria for site selection and specific instructions for sample selection, collection, shipping, and handling. Samples are collected year-round from markets, terminal markets, distribution centers, and retail sites selected by the National Agricultural Statistics Service (NASS) using probability proportional to size methodology so that the data reported are a statistically defensible representation of the U.S. food supply. State population figures are used to assign the number of samples scheduled for collection each month.[1] These population and distribution network-based numbers result in the following monthly collection assignments for each state: California, 13; Colorado, 2; Florida, 7; Maryland, 4; Michigan, 6; New York, 9; Ohio, 6; Texas, 8; and Washington, 4. This schedule results in a monthly target of 59 salmon samples, for a target of 708 total samples to be collected beginning July 2013 and ending June 2014.

Acceptable samples included farm-raised, wild, organic, conventional, domestic, and imported Atlantic or Pacific salmon for the following species: Chinook (King), Chum (Dog, Keta, Silverbite), Coho (Silver), Pink (Humpback), and Sockeye (Red). Each sample consisted of 1 pound fresh or frozen (raw, uncooked) fillets, nuggets, steaks, or strips. Salmon with guts and/or heads, breading, seasonings, or flavoring (i.e., smoked) were excluded, but both bone-in/out and skin/skinless were included in sampling. Sample collectors rely solely upon the label for identification of collected samples. To ensure samples arrived at the laboratory in a frozen or cold-to-the-touch condition, they were collected in pesticide-free polyethylene bags, frozen overnight, and then shipped the following day by next-day air with ample frozen cold packs and insulating materials surrounding all sample units. Any samples that were no longer frozen or cold-to-the-touch once they arrived at Yakima Laboratory were discarded, and a resample was requested.

Frozen salmon samples were held in a freezer at 0 °C or lower until the sample could be homogenized. Samples could also be refrigerated overnight before cutting approximately 1 pound portions into approximately 1 in. squares and frozen in labeled ziplock bags in a −20 °C freezer until homogenization. Each sample was then homogenized in a Retsch food processor for approximately 45 s in reverse and forward mode at 2200−4500 rpm until homogeneous. Portions of the homogenized sample were transferred into two labeled 8 oz polypropylene (PPE) sample cups, and 20 ± 0.2 g (±1%) was weighed out into two labeled 50 mL PPE centrifuge tubes containing a ceramic homogenizer; exact weight was recorded. Homogenized samples were stored at −20 °C for up to 72 h and moved to a −40 °C freezer for long-term storage (>72 h).

GC-MS/MS Instrumentation. The GC system (Agilent 7890A, Palo Alto, CA, USA) was equipped with an autosampler (Agilent 7693) and coupled to a quadrapole mass spectrometer (Agilent MSD 7000B). MassHunter software was used for instrument control and data acquisition. Analytes were separated using two HP-1 ms columns (15 m long × 0.25 mm i.d. × 0.25 μm df) (J&W Scientific, Folsom, CA, USA), connected through a backflush union for a total column length of 30 m. The column head pressure was set at 16.727 psi at a total flow rate of 34.6 mL/min, using helium as carrier gas. The injection volume was 1 μL in splitless mode at 220 °C with a 3.5 min solvent delay. The oven temperature was programmed as follows: oven held at 90 °C for 1 min, then raised at 50 °C/min to 150 °C, then 6 °C/min to 200 °C, then 16 °C/min to 280 °C, and held at 280 °C for 9 min. Total run time was 21.533 min. The ion source and transfer line and source temperatures were set at 300 °C. Electron multiplier voltage was set by automatic tuning. Nitrogen and helium were used as the collision gases for all MS/MS experiments, and the flow in the collision cell was set at 1.5 and 2.25 mL/min, respectively. For each analyte a scheduled multiple reaction monitoring (MRM) was optimized for two ion transitions in a 60 s detection window with a 10 ms dwell time. Complete method details can be found in the Supporting Information.

LC-MS/MS Instrumentation. The LC system (Acquity UPLC, Waters Corp., Milford, MA, USA) was coupled to a tandem quadrapole mass spectrometer (Xevo TQ-S, Waters Corp.). MassLynx software (version 4.1) was used for instrument control and data acquisition. Analytes were separated on a universal, silica-based bonded phase Acquity HSS T3 column (2.1 mm × 50 mm, 1.8 μm particle size, Waters Corp.) at 40 °C with a sample injection of 4 μL. A binary mobile phase was composed of 0.1% v/v formic acid and 10 mM ammonium formate in water (A) and in methanol (B). A mobile phase gradient at 0.45 mL/min started at 5% B and went to 100% B in 9.5 min, was held for 1.5 min, and concluded by column equilibration at initial conditions for 4 min for a total run time of 15 min. The MS source operated using positive electrospray mode with the following conditions: capillary voltage of 1000 V, source offset of 25 V, desolvation gas flow of 850 L/h, desolvation and cone temperatures of 550 and 150 °C (respectively), cone gas flow of 150 L/h, collision gas flow of 0.15 mL/min, and nebulizer gas of 5 bar. For each analyte, at least one scheduled MRM with a 60 s detection window was optimized for qualitative analysis, and two were optimized for quantitative analysis. Complete method details can be found in the Supporting Information.

Sample Extraction. For reagent blank, 20 mL of deionized water was used. The previously weighed out 20 g samples were thawed at 4 °C overnight or in cold water on the day of extraction. Thirty milliliters of ethyl acetate was added using an automated liquid dispensing unit verified before use by gravimetric check. Samples were then shaken for 5 min on a SPEX 2000 Geno grinder (SPEX Sample Prep, LLC, Metuchen, NJ, USA) at 1200 rpm and then centrifuged (1000 rcf, 5 min, ambient temperature) to compact the contents, allowing for addition of extraction buffers (8 g of $MgSO_4$ and 2 g of NaCl). Samples were shaken for another 5 min at the same speed and inspected for air or liquid pockets; for tubes with visible air or liquid pockets, a disposable PPE transfer pipet was used to disperse the pocket and ensure complete mixing of buffer salts with sample. Sealed tubes were placed into a −20 °C freezer for 30 min and then centrifuged (3000 rcf, 5 min, ambient temperature); the upper ethyl acetate layer was decanted through a funnel and filter paper into a calibrated 50 mL glass graduated centrifuge tube. Target recovery for this layer is 18 mL (A1); excess liquid was aspirated to waste, or if <18 mL was recovered, the exact volume collected was recorded. A1 was concentrated to 3 mL under a stream of nitrogen set at no more than 10 L/min with a water bath at 60−70 °C. Samples were diluted to 15 mL with acetonitrile, capped and vortexed for 30 s, and then frozen for a second time at −40 °C for 30 min. To facilitate layer separation after freezing, samples were centrifuged (1000 rcf, 3 min, ambient temperature) immediately before they were thawed out.

SPE columns were prepared by adding 1 g of $MgSO_4$ to the top of SPE cartridges containing 1000 mg of C18. Conditioning involved 1% acetic acid in acetonitrile using a positive pressure or vacuum SPE manifold and eluting to waste. Ten milliliters (A2) of the extract was loaded onto the SPE column and eluted in a dropwise manner into a calibrated 15 mL glass centrifuge tube. Each SPE column was washed with two 2.5 mL volumes of 1% acetic acid in acetonitrile; after the second washing, the column was kept under pressure for about 1 min to completely elute the extract from the column. Eluted extract was concentrated to 2 mL under a stream of nitrogen set at no more than 10 L/min with a water bath set at 50 °C. Final extract volume adjustments were made with acetonitrile. Target sample concentration was 4 g/mL if all target volumes were met for aliquots A1 and A2, as shown by eqs 1 and 2.

$$\text{sample concn}\left(\frac{\text{g}}{\text{mL}}\right) = \frac{\text{sample size (g)}}{\text{extraction solvent (mL)}} \times \frac{\text{A1}}{15\ \text{mL}} \times \frac{\text{A2}}{2\ \text{mL}} \quad (1)$$

DOI: 10.1021/jf5055276
J. Agric. Food Chem. 2015, 63, 5100−5106

$$\text{target sample concn} = \frac{20\text{ g}}{30\text{ mL}} \times \frac{18\text{ mL}}{15\text{ mL}} \times \frac{10\text{ mL}}{2\text{ mL}} = 4\text{ g/mL} \quad (2)$$

Sample Cleanup. Due to the sensitivity of the instrumentation, samples were subjected to additional cleanup and dilution steps prior to analysis. For LC-MS/MS 1 mL of final extract was quantitatively transferred into a mini-centrifuge tube containing 150 mg of $MgSO_4$, 50 mg of PSA, and 50 mg of C18, vortexed for 1 min, and centrifuged (1000 rcf, 2 min, ambient temperature). Samples were diluted 1:8 in the following fashion: 125 μL of clean sample extract, 20 μL of 1.55 ppm TPP (internal standard), 355 μL of acetonitrile, 500 μL of methanol, and 1000 μL of 0.67 mM formic acid. Samples were filtered through a nylon 0.2 mm syringe filter into a maximum recovery LC vial. Remaining extract in mini-centrifuge tubes was held in reserve at 0 °C or lower. Final LC-MS/MS sample concentration was 0.25 g/mL.

For GC-MS/MS, 1 mL of final extract was quantitatively transferred to a conditioned (4 mL, 3:1 acetone/toluene) SPE column containing 500 mg of PSA. Each SPE column was washed three times with 4 mL of 3:1 acetone/toluene. After the last washing, the column was kept under pressure for about 1 min to completely elute extract from the column. Samples were then concentrated to 0.5 mL under a stream of nitrogen set at no more than 10 L/min with a water bath set at 50 °C. To completely displace the other solvents from the final extract, 3 mL of toluene was added, and samples were concentrated again to 0.5 mL. Final volume was adjusted to 1 mL with toluene, and the sample was vortexed for 30 s. About half of the extracts were transferred to GC autosampler vials with 0.5 mL glass inserts; remaining extract was held in reserve at 0 °C or lower. Final GC-MS/MS sample concentration was 4 g/mL.

Standard matrix blank homogenate followed the same extraction procedure for LC-MS/MS samples, but for GC-MS/MS it was doubly concentrated during the cleanup step by transferring 2 mL instead of 1 to create an 8 g/mL matrix blank for use in preparing GC-MS/MS calibration standards.

Pesticide Residue Quantitation. Following extraction and cleanup, samples were analyzed for pesticide residues using both LC- and GC-MS/MS instrumentation. For quantification, a matrix-matched standard of blank salmon extract was prepared at 1, 5, and 10 times the limit of quantification (LOQ) for each pesticide by adding appropriate volumes of mixed fortification standard to the blank sample extract (after each instrument's specific cleanup). The peak area of the primary transition was used to generate an external, three-point calibration curve using least-squares linear regression analysis. A matrix-matched standard at 2 × LOQ was used to assess the validity of the generated calibration curve; method recoveries were not background subtracted.

Quality Assurance/Control. Confirmation of pesticides found in fortified and incurred samples was determined by comparing expected retention time and the ratio of the two transition results to matrix-matched standards, per PDP criteria for identification and acceptable recovery as shown in Table 1. The stability of chromatography was assessed by analyzing continuing calibration verification standards every 7−11 samples. The accuracy and precision of continuing calibration standards were typically within ±20% of expected values. The presence of artifact pesticide residues arising from laboratory-associated procedures, reagents, and/or matrix was assessed through the analysis of laboratory reagent and matrix blanks. Additionally, interday accuracy and precision were monitored throughout the entire study by means of statistical process control charting and review.

RESULTS AND DISCUSSION

Method Validation. First, different samples of salmon were extracted and analyzed to find the lowest contaminated matrix for use in blanks and fortified samples. The interday precision and accuracy of recoveries for 88 GC and 142 LC analytes were determined by spiking a matrix blank in triplicate with a mixture of these pesticides at concentrations of 1, 5, and 10 times the LOQ for each analyte. Spiked samples were then extracted and cleaned up using the modified QuEChERS approach for salmon. At the lowest level validated, 85% of GC and 91% of LC analytes had acceptable recoveries (70−120%). At the highest level validated, these values improved to 95% of GC and 97% of LC analytes. Of the 228 analytes initially screened by this method, 7 were not detected at any spike level, 5 were not detected at the lowest spiking level, 5 were detected but had recoveries outside the 50−150% range, 2 had irreproducible results (%CV > 30%), and 25 had poor peak shape or resolution between matrix coextractive peaks. These analytes were subsequently dropped from analysis, resulting in a final screen of 103 analytes by LC-MS/MS and 82 analytes by GC-MS/MS. Of the compounds that were not detected or had poor recovery at the lowest spike level, a pesticide group that stood out included the highly lipophilic pesticides (i.e., acephate, chlorthalonil, imazalil, oxidemeton methyl, methamidophos, thiabendazole). This group of pesticides is liable to partition into the fat layer[9] that formed during extraction procedure and settled out of the final extract, as shown in Figure 2. Extract pH was not controlled in this method, thus compromising the stability of base-sensitive and/or acid-labile pesticides (i.e., thiodicarb, chlorthalonil, 1-naphthol). Complete details on the results of the interday experiment can be found in the Supporting Information (Table S3).

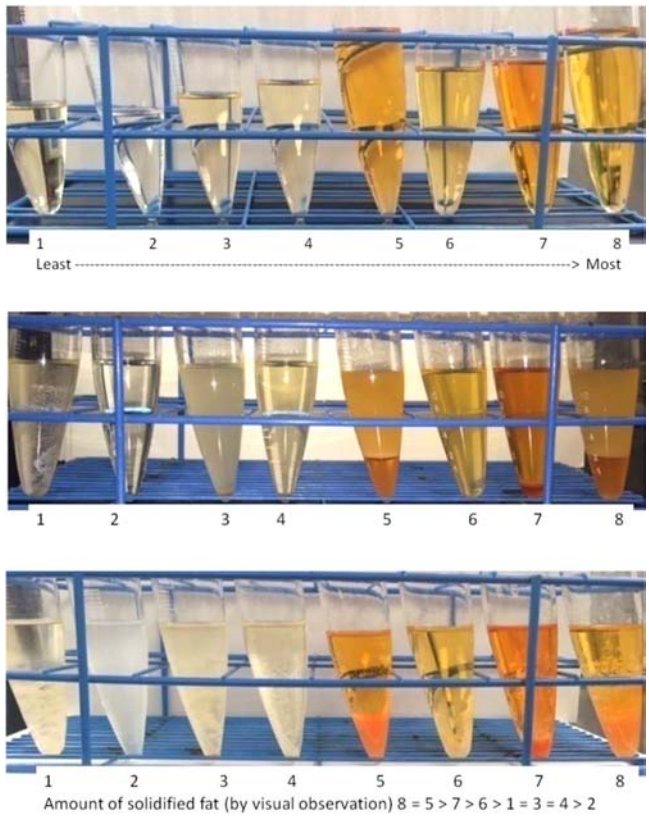

Figure 2. Sample diversity is apparent throughout the extraction: not only did the color vary between salmon samples but varying amounts were recovered for A1 (top) and different amounts of fat were separated and removed from extract after solvent exchange from ethyl acetate to acetonitrile (middle) and at the conclusion of the second freezing step (bottom).

The accuracy of this method was confirmed by a blind, internal proficiency sample using the same matrix material as the blank. Ideally, a standard reference material would be used,

but none that met the scope of method (different fish species, incomplete analyte list) were available at the time of study. Internal proficiency testing consisted of two blind samples; each contained a mixture of seven analytes at concentrations ranging from 0.020 to 0.080 μg/mL. These samples were included with a regularly scheduled analysis set and subjected to the same extraction procedure as a regular sample, including the addition of quality controls and analysis by LC- and GC-MS/MS. Amounts found were reported to a quality control officer for evaluation; overall, the recoveries were 70−100% with a minimum recovery of 71% for parathion ethyl by GC-MS/MS. Complete proficiency testing results are included in the Supporting Information (Table S4).

Intraday precision and accuracy for the final screen of 185 analytes were determined by monitoring a sample fortified at 2 × LOQ throughout the entire study duration for a total of about 18 data points for each analyte. Analysis by LC-MS/MS, summarized in Figure 3, had higher variability (expressed as % CV) than GC-MS/MS, summarized in Figure 4. Despite this, some compounds had irreproducible peak shapes as a result of interfering matrix coextractives that resulted in a subjective analysis. Of these compounds, five were eventually dropped from the GC-MS/MS screen; they were bioallethrin, folpet, hydroprene, oxychlordane, and prothiofos. Even with the addition of a C18 cleanup step, the amount of coextractives in the final sample was enough to negatively impact the precision of recovery for cymoxanil, dichlorvos (DDVP), diuron, endosulfan sulfate, fluridone, flusilazole, indaziflam, methomyl, napropamide, Prebane, and pirimiphos methyl, as shown in Figures 3 and 4.

Method Ruggedness. The goal of this study was to survey salmon for pesticide residues over the course of a year; the diversity of samples collected over such a long period was going to be large. To account for varying matrix effects from different salmon species (Atlantic, Pacific, King, Chinook, etc.) and origin (import, domestic, farmed, wild), two internal standards were spiked into every sample at 5 × LOQ: methyl chlorpyrifos (MC) and propoxur (P) for GC and LC analysis, respectively. The observed sample diversity was apparent throughout the entire study as shown in Figure 2, with extract color, volume extracted, and visible fat content being the most discernible features. The samples shown in Figure 2 are from a single analysis set of 30 samples; observed extract color varied from clear and colorless, clear and colored, and opaque and colorless to opaque and clear and remained throughout the extraction process. However, all of the data sets analyzed with this method successfully met PDP's criteria listed in Table 1 for interlaboratory precision with average set recoveries of 101 and 77% for P and MC, respectively. During the course of this study several lots of reagents, materials, consumables, and standards were used, and a total of six operators were included to test the overall robustness of the written procedure. The statistical process control chart in Figure 5 shows that as the study progressed, the process variation decreased from around 20%CV to 10%CV, and the moving mean stabilized for both analyses. Initially the moving mean changed significantly between sample sets and %CV was high; after investigation, it was found that the standard operating procedure contained steps that were either confusing or had engineering controls that were not clearly defined (i.e., nitrogen flow rate and temperature for N-Evap). The procedure was revised in January 2014 and implemented starting with the second October data set (10FS13B). Sets analyzed with the new written procedure had improved precision, thereby stabilizing the moving mean. This demonstrates the significance a clear, concise, and

DOI: 10.1021/jf5055276
J. Agric. Food Chem. 2015, 63, 5100−5106

thoroughly documented procedure has on ensuring a method's ruggedness.

During the course of this study, the analytical instruments had decreased sensitivity and poor intra- and interbatch precision as a result of source (LC) and inlet (GC) contamination by the salmon matrix. To reduce contamination and improve stability of instrument between runs, the frequency of routine maintenance tasks such as changing the GC liner, trimming the GC column, and cleaning the LC-MS/MS source components was increased from one to two times per month to daily at around the October data sets. Nonroutine maintenance tasks for the LC-MS/MS were also increased from one to two times per year to after every 200−300 injections of salmon matrix; this included cleaning the ion block heater and ion optics. This increased maintenance suggests that the final salmon extract should have been subjected to an additional cleanup or dilution step to minimize instrument downtime.

The observed process variation throughout the study cannot be attributed to just unclear written directions or contamination of analytical instrumentation by matrix coextractives; additional testing to isolate each source of error is needed before a statement can be made. However, the ruggedness testing results presented here support the claim that these extraction and analysis methods are suitable for long-term use by different operators and analysts using different lots of reagents and materials. Before this method can be considered official, it is recommended that it should be compared with reference methods in side-by-side analysis of the same sample and an interlaboratory study should also be performed.

Development of an Automated Column Solid-Phase Extraction Cleanup of QuEChERS Extracts, Using a Zirconia-Based Sorbent, for Pesticide Residue Analyses by LC-MS/MS

Bruce D. Morris* and Richard B. Schriner

Food and Bioanalytical Division, R. J. Hill Laboratories, Private Bag 3205, Hamilton East, New Zealand

Supporting Information

ABSTRACT: A new, automated, high-throughput, mini-column solid-phase extraction (c-SPE) cleanup method for QuEChERS extracts was developed, using a robotic X-Y-Z instrument autosampler, for analysis of pesticide residues in fruits and vegetables by LC-MS/MS. Removal of avocado matrix and recoveries of 263 pesticides and metabolites were studied, using various stationary phase mixtures, including zirconia-based sorbents, and elution with acetonitrile. These experiments allowed selection of a sorbent mixture consisting of zirconia, C_{18}, and carbon-coated silica, that effectively retained avocado matrix but also retained 53 pesticides with <70% recoveries. Addition of MeOH to the elution solvent improved pesticide recoveries from zirconia, as did citrate ions in CEN QuEChERS extracts. Finally, formate buffer in acetonitrile/MeOH (1:1) was required to give >70% recoveries of all 263 pesticides. Analysis of avocado extracts by LC-Q-Orbitrap-MS showed that the method developed was removing >90% of di- and triacylglycerols. The method was validated for 269 pesticides (including homologues and metabolites) in avocado and citrus. Spike recoveries were within 70−120% and 20% RSD for 243 of these analytes in avocado and 254 in citrus, when calibrated against solvent-only standards, indicating effective matrix removal and minimal electrospray ionization suppression.

INTRODUCTION

The "quick, easy, cheap, effective, rugged, and safe" (QuEChERS) method for the analysis of multiclass pesticide residues in fruits and vegetables introduced the use of dispersive solid-phase extraction (d-SPE) cleanup, to reduce the amounts of coextracted matrix in extracts, before instrumental analysis, using a mixture of $MgSO_4$ and PSA sorbents, with C_{18} and graphitized carbon black (GCB) added if required to improve removal of nonpolar matrix and chlorophyll.[1−4] In the original QuEChERS method, d-SPE was used instead of column SPE (c-SPE) to provide a quicker and cheaper cleanup.[1] Recently the zirconia-based sorbent HybridSPE, in well-plates or columns, has been utilized for the removal of phopholipids from plasma[5−7] and eggs.[8] The zirconia materials Z-Sep and Z-Sep+ have been evaluated for d-SPE cleanup of QuEChERS extracts for analysis of environmental pollutants and pesticides in fish and shrimp[9−11] and pesticides from oily fruits or vegetable oils,[12−16] due to their abilities to remove the lipophilic matrix. However, in our experience, used routinely, Z-Sep d-SPE can result in the transfer of solid phase into analysis vials and subsequently into the HPLC, building up over time to cause retention of some analytes and poor peak shapes or carry-over. Consequently, we investigated the development of an automated c-SPE cleanup, based on zirconia-coated silica, using Instrument Top Sample Preparation (ITSP) mini-cartridges, on a robotic X-Y-Z instrument autosampler. This could be as quick and cheap as d-SPE, as many instruments are already equipped with robotic autosamplers; however, it could also give the improved matrix removal that is possible with c-SPE[17] and avoid zirconia transfer to the LC-MS/MS.

Avocado extracts were selected as a matrix with high oil content,[18,19] and experiments were carried out to evaluate the weight of matrix removed after acetonitrile (MeCN) elution through ITSP c-SPE cartridges with six different stationary phases. Recoveries of 263 pesticides and metabolites spiked on avocado were determined through five of these sorbents and, along with matrix weight-removal results, allowed selection of a Z-Sep/C_{18}/CarbonX mixture for further method development. Investigation of the effect of different elution solvents (MeCN, MeCN/MeOH (1:1), MeOH, coextracted citrate in a CEN (European Committee for Standardization method,[20]), QuEChERS extract, and formate buffer at three concentrations in MeCN/MeOH (1:1), on pesticide recoveries through Z-Sep/C_{18}/CarbonX, resulted in a method using elution of CEN QuEChERS extracts with 100 mM formate buffer in MeCN/MeOH (1:1). To the best of our knowledge, this study is the first to use ITSP mini-cartridges for cleanup of QuEChERS extracts and zirconia solid phase in an SPE column, rather than used dispersively, for pesticide residue analysis. Removal of avocado di- and triacylglycerols by Z-Sep, monitored by LC-Q-Orbitrap-MS, is also presented. The method was validated for the analysis of 269 pesticides, including homologues and metabolites, in avocado and citrus, to give spike recovery and reproducibility data.

MATERIALS AND METHODS

Reagents and Consumables. MeCN and MeOH (Lichrosolv grade), formic acid (98−100%), NaCl (99.5%), trisodium citrate dihydrate, disodium hydrogen citrate sesquihydrate, and ammonium formate were purchased from Merck (Darmstadt, Germany). $MgSO_4$ (anhydrous) used for QuEChERS extractions was from Scharlau (Sentmenat, Spain). Water was purified using a Sartorius (Goettingen, Germany) Arium 611UV unit. Formate buffer (100 mM) for c-SPE was prepared in MeOH/MeCN (1:1) by dissolving ammonium formate (70 mM) and adding 30 mM formic acid. Lower concentrations of formate buffer (50 and 10 mM) were prepared by dilution of the 100 mM solution with MeOH/MeCN (1:1). Two zirconia-coated silica sorbents, Supel Que Z-Sep and Z-Sep+, were obtained from Supelco (Bellefonte, PA, USA), as was Supel-Select HLB SPE. Z-Sep+ is a zirconia-coated silica, with octadecyl derivatization of silanol groups. Silanols are underivatized in Z-Sep material. PSA and C_{18}-functionalized silicas, and anhydrous $MgSO_4$ used for SPE experiments were from UCT (Bristol, PA, USA). The carbon-coated silica, CarbonX was supplied by United Science Corp (Center City, MN, USA). Ceramic grinding rods ($^3/_8$ in. × $^7/_8$ in.) to aid QuEChERS extractions were sourced from SPEX (Metuchen, NJ, USA).

Analytical Standards. High-purity analytical standards were obtained from Dr. Ehrenstorfer (LGC Standards, Middlesex, UK), Sigma-Aldrich (St. Louis, MO, USA), Wako (Osaka, Japan), Accustandard (New Haven, CT, USA), and Chemservice (West Chester, PA, USA). Penthiopyrad was purchased from Kanto Chemical Co. (Tokyo, Japan). Atrazine-d_5, used as an internal standard, and triphenylphosphate, added as a system monitoring compound (SMC), were from Sigma-Aldrich. A 20 mg/L solution of triphenylphosphate was prepared in MeOH and a 2 mg/L solution of atrazine-d_5 in MeCN. Pesticides were separated into 10 mixes, prepared in MeCN with 0.05% formic acid (10 mg/L). These were used for spiking experiments and diluted in 10 mM formate buffer (aqueous, pH 4)/MeOH/MeCN (13:2:1) to give calibration standards (0.02, 0.05, 0.1, 0.2, 0.4, 1, 2, 5, 10, 20, 40 μg/L).

Samples and Extraction. Samples, for analyte recovery experiments and method validation, of avocado (cv. Hass), citrus (orange, mandarin, and lemon) and buttercup squash were obtained from New Zealand growers. Avocados were mature, but unripe, and citrus fruits were without wax coating. Real samples of avocado, navel orange, and mandarin were purchased from local markets in Hamilton, New Zealand, and used to demonstrate the application of the validated method for recovery of incurred residues. Extraction was based on the citrate-buffered CEN QuEChERS method.[4,20] Frozen samples were homogenized using a Blixer 6 blender (Robot Coupe, Vincennes, France). Subsamples (5 g for avocado and citrus, 20 g for squash) were weighed into 50 mL polypropylene tubes containing two ceramic rods. SMC (100 μL of 20 mg/L) was added to each. Spikes (50 μL of each 10 mg/L mix) were split between two samples, with approximately 50% (five mixes) of the pesticides in each, which separated parents from breakdown products (e.g., acephate from methamidophos, naled from dichlorvos, furathiocarb from carbofuran). Water (10 mL) and MeCN (9.65 mL, to give 10 mL total volume including spikes, or 10 mL for unspiked blanks), were added, and tubes were shaken by hand for 1 min. After the addition of salt mixture (13 g of $MgSO_4$/NaCl/trisodium citrate dihydrate/disodium hydrogen citrate sesquihydrate (8:2:2:1)), tubes were shaken on a horizontal shaker for 15 min. For citrus an additional 4 g of trisodium citrate was added along with the salt mixture, to compensate for the citric acid in samples and bring the pH back into the buffer region. Tubes were centrifuged at 2000 rpm, for 5 min, and then 1 mL of the MeCN layer was transferred into autosampler vials, to which 100 μL of atrazine-d_5 (2 mg/L) was added. For validation, three samples of avocado, and samples of lemon, orange, or mandarin, were extracted without spiking, plus in triplicate or quadruplicate with spikes, using different technicians, in three batches, over a more than 2 week period, to give a total of 10 replicates. Lemons, oranges, and mandarins were extracted in separate batches.

Automated Mini-Column SPE and Dispersive SPE. Miniaturized c-SPE cartridges, for use on X-Y-Z autosamplers, were supplied by ITSP Solutions (Hartwell, GA, USA), with 30 mg of Z-Sep/C_{18}/CarbonX (2:5:0.24), 45 mg of PSA/C_{18}/CarbonX/$MgSO_4$ (3:3:0.25:5), and 10 mg of Z-Sep or 30 mg of Z-Sep+ sorbents, the first two as homogeneous mixtures. Cartridges with 20 mg of HLB/Z-Sep/CarbonX (1:1:0.22) were handmade in the laboratory. ITSP c-SPE cartridges were 3.5 cm long, including a 0.6 cm tip, with a sorbent bed 6 mm in diameter × 2.5 mm in height (0.5 mm bed height for 10 mg of Z-Sep). Sorbent weights for each mixture were amounts that could fit into the fixed cartridge volume. The upper section of the cartridge comprised a syringe needle guide with a sealing septum on top (Figure 1). Robotic c-SPE used a PAL HTS-xt, X-Y-Z

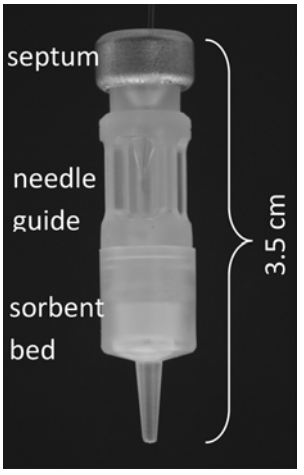

Figure 1. Automated ITSP c-SPE cartridge.

autosampler (CTC Analytics, Zwingen, Switzerland), with HW-54P and HW-96P aluminum trays (ITSP Solutions) and a 250 μL syringe (CTC Analytics). c-SPE cartridges were conditioned (with 150 μL of elution solvent) in the HW-96P tray, then transferred, on the end of the syringe needle, to the HW-54P tray, where they were inserted into 2 mL amber glass vials with split-septa clip caps. Extract (150 μL) was then loaded onto the cartridge followed by elution solvent (150 μL), with the combined eluent collected. For cartridges with 30 mg of sorbent (Z-Sep/C_{18}/CarbonX and Z-Sep+) or 45 mg of PSA/C_{18}/CarbonX/$MgSO_4$, approximately 75 μL of solvent was retained; therefore, 150 μL was 2 column void volumes. Elution rate was 2 μL/s. Cleaned up extracts were diluted 5-fold for analysis, with 10 mM formate buffer (aqueous, pH 4)/MeOH/MeCN (13:2:1).

D-SPE used 30 mg of Z-Sep/C_{18}/CarbonX (2:5:0.24) in a 2 mL glass vial. Two-fold diluted avocado extract (150 μL) was added, plus 150 μL of MeCN, to match the dilution on c-SPE. The vial was vortexed for 1 min, the solid-phase was allowed to settle for 5 min, and then 200 μL of extract was transferred to a second vial for 5-fold dilution with 10 mM formate buffer (aqueous, pH 4)/MeOH/MeCN (13:2:1) for analysis.

Gravimetric Recovery Experiments. Glass 2 mL vial inserts (350 μL flat-bottomed) were weighed on a five-figure analytical balance (Sartorius CPA225D), then either 150 μL of 2-fold-diluted crude avocado extract or the eluent from 150 μL of the same extract passed through automated ITSP c-SPE was collected in the preweighed inserts. Solvent was evaporated at 40 °C under a gentle flow of nitrogen, and the inserts were allowed to re-equilibrate to room temperature (15 min) before reweighing to determine the dry weight of avocado matrix recovered.

LC-MS/MS Parameters. LC-MS/MS was carried out on Triple Quad 5500 and 6500 triple-quadrupole instruments (AB Sciex, Toronto, ON, Canada), coupled to 1200 HPLC systems (Agilent, Palo Alto, CA, USA) with PAL HTS-xt autosamplers and DLW syringes (CTC Analytics). The MS/MSs were operated in positive electrospray ionization (ESI) mode, with source temperatures of 350 °C (Triple Quad 5500)

DOI: 10.1021/jf505539e
J. Agric. Food Chem. 2015, 63, 5107−5119

and 285 °C (Triple Quad 6500), and an ionspray voltage of 5500 V. Multiple reaction monitoring (MRM) transitions are given in Supporting Information Table SI-B and were optimized by undertaking multiple injections with differing declustering potential (DP) and collision energy (CE) parameters. HPLC used Ascentis Express C18 columns (10 cm × 2.1 mm, 2.7 μm particle size) from Supelco at a flow rate of 0.4 mL/min and a column oven temperature of 50 °C. Mobile phase A was 10 mM ammonium formate/formic acid buffer (pH 4) in H_2O/MeOH (9:1), and mobile phase B was MeOH. Gradient elution started at 12.5% B (held for 0.5 min) and ramped to 40% B over 1.5 min, then to 62.7% B over 6 min, followed by a final ramp to 95% B over 6 min (held at 95% for 2 min), to give an even spread of peaks across the chromatogram. Injection volume was 10 μL.

Validated Method. The final method validated used QuEChERS extraction of 5 g subsamples of homogenized fruit, with citrate buffering, as outlined under Samples and Extraction. Automated c-SPE was carried out with ITSP cartridges containing 30 mg of Z-Sep/C_{18}/CarbonX (2:5:0.24). Extracts (150 μL) were loaded onto cartridges and eluted with 150 μL of 100 mM formate buffer in MeOH/MeCN (1:1), with loading and elution volumes collected. After 5-fold dilution with 10 mM formate buffer (aqueous, pH 4)/MeOH/MeCN (13:2:1), extracts were analyzed by LC-MS/MS. Details are provided in the relevant c-SPE and LC-MS/MS sections.

LC-Q-Orbitrap-MS Analysis. The LC consisted of an Ultimate 3000 UHPLC pump, autosampler, degasser, and column compartment and was coupled to a Q-Exactive quadrupole-orbitrap mass spectrometer (Thermo Fisher Scientific, San Jose, CA, USA) operated in positive ESI mode. A Kinetex C18, 10 cm × 2.1 mm, 2.6 μm particle size, HPLC column (Phenomenex, Torrance, CA, USA) was used. Mobile phase A was 10 mM ammonium formate/formic acid buffer (pH 4) in water/MeOH (9:1), and mobile phase B was 10 mM ammonium formate/0.015% formic acid in MeOH/isopropanol (1:1). The flow rate was 0.4 mL/min, and the column oven held at 50 °C. The injection volume was 5 μL. The elution gradient started at 30% B (held for 0.5 min) with a ramp to 60% B at 2 min, followed by a second ramp to 98% B at 10 min (held for 8 min before returning to 30% B for re-equilibration). The Q-Exactive was tuned using LTQ ESI Positive Ion Calibration Solution <24 h before use, and data were acquired by full-scan MS (range set at m/z 75−1000), with mass resolution set to 17500 fwhm (m/z 200). This resolution was adequate to separate and identify (to <5 ppm accuracy) the triacylglycerols (TAGs) and diacylglycerols (DAGs) being targeted while giving a high enough scan rate to give the number of points per peak desired. The source sheath gas flow was set to 60, auxiliary gas flow to 20, sweep gas flow to 5, spray voltage to 3 kV, capillary temperature to 380 °C, S-lens RF level to 50, and heater temperature to 350 °C. Crude QuEChERS avocado extract was diluted 40-fold with MeCN for analysis or was diluted 2-fold before automated ITSP c-SPE, or d-SPE, with both using 30 mg of Z-Sep/C_{18}/CarbonX (2:5:0.24). C-SPE and d-SPE extracts were finally diluted 10-fold with MeCN, to match the dilution of crude extract, before injection. Data analysis used Thermo Xcalibur Qual Browser. Extracted ion chromatograms were constructed by entering the accurate masses of each TAG or DAG peak, with a 10 ppm range. To identify TAGs and DAGs, accurate masses were entered into ChemSpider Advanced Search.[21]

RESULTS AND DISCUSSION

Automated C-SPE Method Development. Initial gravimetric recovery experiments were aimed at assessing the retention of nonpolar coextracted matrix by various c-SPE stationary phase mixtures, using avocado as a sample with high oil content, comprising mono-, di-, and triacylglycerides, free fatty acids, sterols, and tocopherols.[18,19] Five different stationary phase packings were compared in the first weight-recovery experiment (extract 1, Table 1): PSA/C_{18}/CarbonX/$MgSO_4$ (45 mg), Z-Sep (10 mg), HLB/Z-Sep/CarbonX (20 mg), Z-Sep+ (30 mg), and Z-Sep/C_{18}/CarbonX (30 mg), with each sorbent weight being the maximum amount that could be packed into the bed volume of the cartridges. Z-Sep (10 mg) was included to show the effect it alone was having in the Z-Sep/C_{18}/CarbonX (30 mg) mixture. Comparison of dry weights recovered after MeCN elution of 2-fold diluted avocado, extract 1, indicated Z-Sep+ retained the greatest amount of matrix (79%), followed by Z-Sep/C_{18}/CarbonX (56%, Table 1). Matrix retention by 10 mg of Z-Sep alone (47%) indicated it was responsible for the greatest proportion (84%) of this retention in the Z-Sep/C_{18}/CarbonX mixture, meaning the increased removal by Z-Sep+ may have been partly due to the greater weight of zirconia material in these cartridges (30 mg compared with 10 mg). To investigate this, a second extract, extract 2, was passed through 30 mg of Z-Sep, which resulted in 70% matrix removal (Table 1), slightly poorer than for 30 mg of Z-Sep+, but greater than the 47% removed by 10 mg of Z-Sep. These results indicated that the C_{18} functional group of Z-Sep+ was improving avocado matrix removal over Z-Sep, as was addition of C_{18}-silica to Z-Sep in the mixed Z-Sep/C_{18}/CarbonX cartridge. The cartridge with PSA/C_{18}/CarbonX/$MgSO_4$, a mixture similar to that used in many studies for d-SPE cleanup of oily extracts,[2,22,23] showed poorer retention of avocado matrix (32%) than those containing Z-Sep, in agreement with previous d-SPE results for avocado extracts comparing Z-Sep with PSA/C_{18}.[12,13] Two-fold dilution of avocado extract was used as it gave measurable breakthrough of matrix, even for the most retentive Z-Sep+ stationary phase.

Table 1. Dry Weight Recoveries for 150 μL of 2-Fold-Diluted Avocado Extract, before and after Automated C-SPE, Using Various Stationary Phase Mixtures, Eluted with MeCN or MeCN/MeOH (1:1)

		Avocado Extract 1[a]				
		elution solvent: MeCN (150 μL)				
	crude extract	PSA/C_{18}/CarbonX (45 mg)	Z-Sep/C_{18}/CarbonX (30 mg)	Z-Sep+ (30 mg)	Z-Sep (10 mg)	Z-Sep/HLB/CarbonX (20 mg)
dry wt recovered (mg)	0.34	0.23	0.15	0.07	0.18	0.20
% dry wt recovered		68	44	21	53	59

		Avocado Extract 2			
		elution solvent: MeCN (150 μL)		elution solvent: MeCN/MeOH (1:1) (150 μL)	
	crude extract	Z-Sep (30 mg)	C_{18} (30 mg)	Z-Sep/C_{18}/CarbonX (30 mg)	
dry wt recovered (mg)	0.40	0.12	0.32	0.11	
% dry wt recovered		30	80	28	

[a]50 of the 300 μL eluted volume was taken for LC-MS/MS analysis (Table 2), prior to evaporation of solvent. The weight of crude extract was also corrected for this and was 0.41 mg for 150 μL of 2-fold-diluted extract.

[a]Recoveries <70% are highlighted in bold type. [b]Mean of isomers A and B.

Although Z-Sep+ removed the highest percentage of avocado matrix, it also gave the poorest pesticide recoveries (Table 2). Recoveries were low for the 18 triazoles, with cyproconazole (1%), flutriafol (4%), hexaconazole (0%), metconazole (3%), and tebuconazole (4%) most strongly retained (Figure 2). These 5 fungicides have an acidic −OH group on the carbon α to the aromatic ring, missing from the other 13 triazoles, suggesting retention via lone-pair electron interactions with zirconia vacant d-orbitals or electrostatic interactions with zirconia. Zirconia has vacant 3d orbitals, which have Lewis acid character, and can form coordination bonds with Lewis bases (electron donors), one of the main retention mechanisms for zirconia,[5,12,24,25] along with electrostatic interactions with a positively charged zirconium surface, present at pH <5.9.[24,25] Previous studies[9,12,14] obtained >70% recoveries for triazole pesticides, using Z-Sep d-SPE cleanup. D-SPE, using the same Z-Sep/C_{18}/CarbonX mixture as packed into cartridges and the same extract to sorbent ratio as c-SPE, also gave greater recoveries of these analytes than c-SPE (Table 2, final column), reflecting the relatively poor retention of d-SPE, although recoveries were still <70% for cyproconazole, fenbuconazole, flutriafol, hexaconazole, and tebuconazole from d-SPE. These lower d-SPE recoveries, compared with those of other authors, possibly reflect the lower weight ratio of avocado to zirconia used (9:1), compared with the 28.6:1 ratio of Lozano et al.[12] and Rajski et al.,[14] our inclusion of C_{18} sorbent, or differing sample matrices.

Several organophosphate insecticides (acephate, dicrotophos, methamidophos, omethoate, and trichlorfon) were strongly retained on Z-Sep and Z-Sep+ (Table 2). Comparison of the structures of omethoate and dimethoate (4 and 90% recoveries, respectively, from Z-Sep+) indicates that lone pairs on the phosphate P═O of omethoate may have been interacting with the zirconia, with a weaker interaction for the equivalent thiophosphate P═S of dimethoate. Similar relative recoveries of omethoate and dimethoate were previously found for shrimp

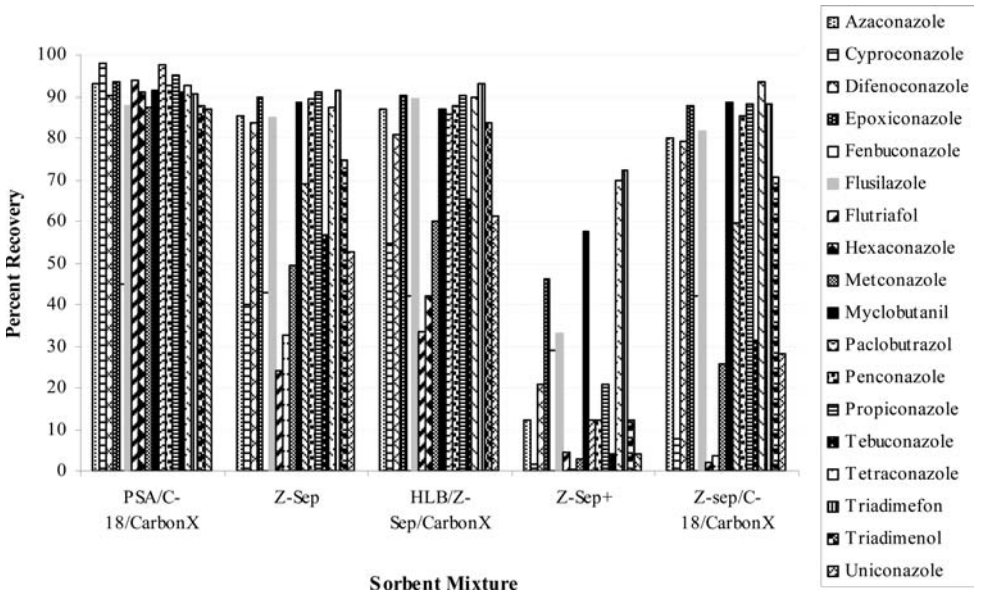

Figure 2. Triazole pesticide recoveries from avocado spiked at 100 μg/kg, extracted by QuEChERS and passed through automated c-SPE with different sorbent mixtures, eluted with MeCN, and analyzed by LC-MS/MS.

extracts cleaned up using PSA/Z-Sep/C_{18} d-SPE in filter vials,[10] whereas low recoveries of dicrotophos were observed after Z-Sep d-SPE of catfish extracts.[9]

Macrocyclic lactones (avermectin B1a, emamectin B1a, milbemycins A3 and A4, spinetoram, spinosyns A and D), all showed low recoveries from Z-Sep and Z-Sep+. This is in agreement with the poor recoveries of spinosyns A and D of Han et al.,[10] although >70% recoveries were obtained from Z-Sep d-SPE by Rajski et al.,[14] possibly reflecting the relatively poor retention of d-SPE compared with c-SPE, as recoveries from Z-Sep/C_{18}/CarbonX were 37 and 41% for d-SPE and 1 and 0% for automated c-SPE, for spinosyns A and D, respectively (Table 2).

The quaternary ammonium analyte DDAC was retained on stationary phase mixtures containing C_{18} in combination with zirconia or PSA material, with greater recoveries from Z-Sep alone, and HLB/Z-Sep/CarbonX, suggesting primarily hydrophobic interaction with C_{18} (Table 2).

Of the 280 analytes (including isomers and homologues, comprising 263 pesticides and metabolites) tested with the five different stationary phase packings (results for selected pesticides shown in Table 2), 71 showed <70% recovery from Z-Sep+, whereas 53 were below 70% recovery from Z-Sep/C_{18}/CarbonX. Therefore, the Z-Sep/C_{18}/CarbonX mixture was chosen for further method development, as a compromise between matrix removal and analyte recoveries. This is similar to the conclusions reached by other authors using d-SPE, to use Z-Sep rather than Z-Sep+ for final method development, due to higher analyte recoveries.[11,12,14] A lower weight of zirconia-based sorbent in the Z-Sep/C_{18}/CarbonX cartridges than in the Z-Sep+ cartridges could also improve recoveries of analytes being retained on zirconia, whereas inclusion of 70% by weight of C_{18} may improve removal of citrus matrix[2,15] and sterols.[26]

Methods developed using zirconia-based SPE for phospholipid removal from plasma, serum, or tissue samples have used formic or citric acids in MeCN to recover analytes with acidic functional groups, as formate and citrate are stronger Lewis bases than most analytes and cause their displacement from zirconia.[5,6] Ammonium formate in MeOH has been used for elution of basic compounds from HybridSPE, by blocking interaction with negatively charged silanols, or Zr-bound formate;[6] however, ammonium formate has poor solubility in MeCN, used for QuEChERS extractions, requiring MeOH in the elution solution. To investigate the effects of adding MeOH to the elution solvent, spikes were prepared in MeCN only and eluted with MeCN, MeCN/MeOH (1:1), or MeOH. Results of these experiments (Table 3) showed 57 compounds were retained (having <70% recovery) on Z-Sep/C_{18}/CarbonX cartridges, with MeCN elution, and only 8 showed <70% recovery with MeCN/MeOH (1:1) or MeOH elution (Table 3). This suggests that MeOH is disrupting the interactions of analytes with Z-Sep, either Lewis acid−Lewis base or electrostatic interactions. The percent dry weight of avocado matrix recovered with MeCN/MeOH (1:1) elution was 28%, compared with 44% for MeCN elution (Table 1), likely due to decreased solubility of avocado oils in MeOH, resulting in an improvement in cleanup. Elution with MeOH only showed lower recoveries of many nonpolar analytes (those with long retention times), such as cyfluthrin, cypermethrin, fenvalerate, fluvalinate, halfenprox, and permethrin (Table 3), due to lower solubility in MeOH compared with MeCN, favoring partitioning onto the sorbents.

The effect of citrate ions, present in CEN QuEChERS extracts, and ammonium formate/formic acid buffer on compound recoveries was investigated by spiking a pesticide-free squash extract (100 μg/L) and then passing it through Z-Sep/C_{18}/CarbonX automated c-SPE cartridges, eluted with MeCN, MeCN/MeOH (1:1), or 10, 50, or 100 mM buffer solutions in MeCN/MeOH (1:1). Squash was selected as giving a QuEChERS extract with low levels of matrix acids, sugars, or nonpolar compounds and lack of significant LC-MS/MS suppression. Elution of the squash extract with MeCN resulted in increased recoveries of all of the analytes that were lost from MeCN-only spikes, when eluted with MeCN (Table 3). Recoveries of the macrocyclic lactones avermectin B1a, emamectin B1a, milbemycins A3 and A4, spinetoram, and spinosyns A and D increased from between 0 and 1% to between 62 and 76% with the presence of citrate. Similarly, triazole

[a]Spikes were into MeCN-only or squash extract. Recoveries <70% are highlighted in bold type. [c]Mean of isomers A and B. [d]Mean of two peaks observed.

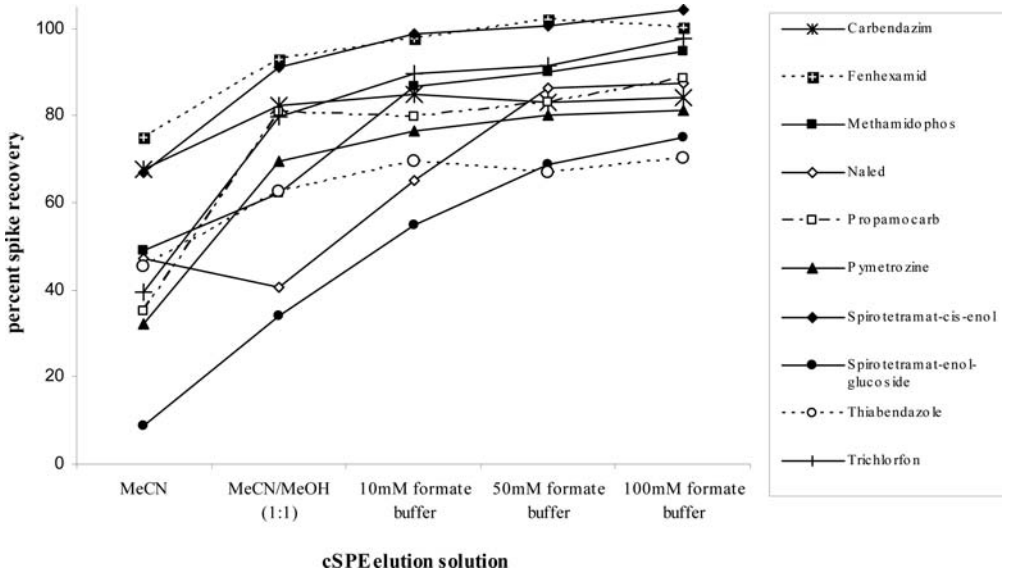

Figure 3. Recoveries from QuEChERS squash extract spiked at 100 μg/L before automated c-SPE using different elution solutions. Buffer solutions were prepared in MeCN/MeOH (1:1). Analyzed by LC-MS/MS.

recoveries were all >70%, as were organophosphates, except for methamidophos (49%), naled (47%), and trichlorfon (40%). Citrate is a stronger Lewis base than formate or acetate and can interact with Zr vacant orbitals through chelation.[5,6] The increased recoveries of macrocyclic lactones, triazoles, and organophosphates with the presence of citrate ions in MeCN indicate that they may be retained by interaction with Z-Sep Zr vacant orbitals and were being displaced by citrate. Consequently, trichlorfon, with a hydroxyl group α- to the phosphate P═O, may bind through chelation more than other organophosphates, giving lower recovery. The basic analytes with amine groups, carbendazim, propamocarb, pymetrozine, and thiabendazole, showed <70% recoveries with MeCN elution of squash extract (Table 3). Recoveries of these compounds improved using MeCN/MeOH (1:1) elution and then improved further with addition of ammonium formate/formic acid buffers (Figure 3). Elution with 10 mM buffer increased the recoveries of pymetrozine from 70 to 76% and of thiabendazole from 62 to 70%, over elution with MeCN/MeOH (1:1). Pymetrozine and thiabendazole, along with carbendazim, also appeared to be retained on CarbonX, limiting their maximum recoveries, as observed in previous studies using graphitized carbon black.[23,27] With increasing buffer strength (10, 50, 100 mM) methamidophos, naled, and trichlorfon recoveries increased (Figure 3). Naled showed the greatest increase, from 41% (MeCN/MeOH (1:1)) to 65% (10 mM buffer), 86% (50 mM buffer), and 87% (100 mM buffer). The spirotetramat metabolite spirotetramat-enol-glucoside had the lowest recovery of the analytes tested, with MeCN/MeOH (1:1) elution (34%); this increased to 55, 69, and 75% as the buffer strength was raised from 10 to 50 and 100 mM, respectively (Figure 3). Consequently, the final method validated used 100 mM buffer (in MeCN/MeOH (1:1)), for elution from Z-Sep/C_{18}/CarbonX cartridges, as this gave >70% recoveries for all 263 analytes in these experiments.

Removal of Di- and Triacylglycerols by Zirconia-Based SPE. LC-HRMS, using a Q-Orbitrap instrument, of crude avocado extract identified six triacylglycerols (TAGs), as their NH_4^+ adducts, with retention times between 13 and 14 min (PLL (*m*/*z* 872.7683; 13.08 min), LLO (*m*/*z* 898.7840; 13.18 min), PLO (*m*/*z* 874.7825; 13.34 min), OOL (*m*/*z* 900.7998;

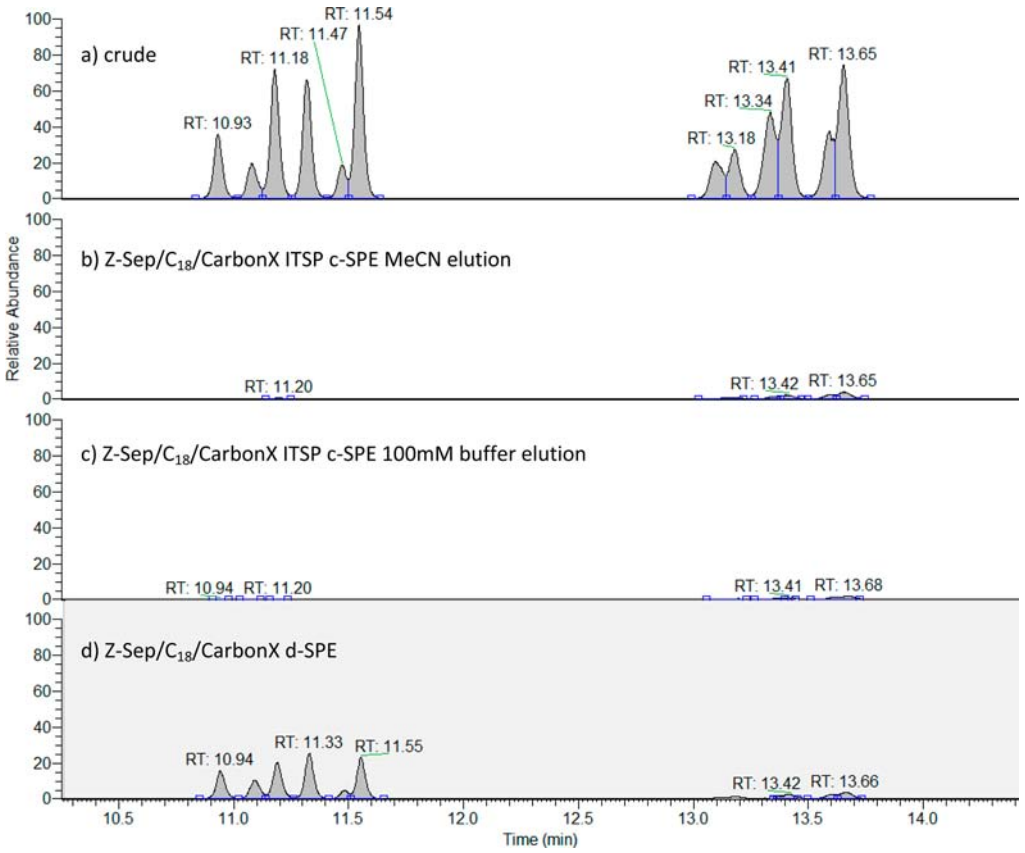

Figure 4. Di- and triacylglycerol recoveries from QuEChERS avocado extract: (a) crude extract; (b) 2-fold dilution and Z-Sep/C_{18}/CarbonX automated c-SPE ITSP eluted with MeCN; (c) 2-fold dilution and Z-Sep/C_{18}/CarbonX automated c-SPE ITSP eluted with 100 mM ammonium formate/formic acid buffer in MeCN/MeOH (1:1); (d) 2-fold dilution and Z-Sep/C_{18}/CarbonX d-SPE. LC-Q-Orbitrap-MS extracted ion chromatograms, with the *y*-axis scale normalized to chromatogram a and the same final dilution for chromatograms a–d.

13.41 min), POO (*m/z* 876.7987; 13.59 min), OOO (*m/z* 902.8160; 13.65 min)), where P = palmitic acid, L = linoleic acid and O = oleic acid (Figure 4). Identities of TAGs were confirmed by reference to the LC-APCI-MS data of Jakab et al.[28] A second group of diacylglycerols (DAGs) and what appeared to be DAG-acetates (based on their accurate masses) was present between 10.9 and 11.6 min, also identified as their NH_4^+ adducts (OL (*m/z* 636.5552; 10.93 min), LL-acetate (*m/z* 676.5508; 11.10 min), OO (*m/z* 638.5704; 11.18 min), OL-acetate (*m/z* 678.5663; 11.32 min), OP-acetate (*m/z* 654.5659; 11.47 min), OO-acetate (*m/z* 680.5819; 11.54 min)).

Comparison of peak areas in chromatograms for avocado crude extract and 2-fold diluted crude extract cleaned up by automated c-SPE on Z-Sep/C_{18}/CarbonX cartridges, eluted with MeCN or 100 mM buffer in MeCN/MeOH (1:1), showed c-SPE removal of >90% of the TAGs and DAGs (Figure 4). Addition of 100 mM buffer and MeOH to the elution solvent showed no observable increase in TAG and DAG recovery, indicating they were not displacing oil from Z-Sep. D-SPE, using the same sorbent mixture (Z-Sep/C_{18}/CarbonX) and ratio of extract to sorbent as c-SPE, with MeCN solvent, resulted in similar removal of TAGs, but poorer retention of DAGs and putative DAG-acetates (24–54% recovery), possibly due to their greater solubility in MeCN. Ismaiel et al.[7] also found that zirconia SPE (using Supelco HybridSPE-PPT well-plates) effectively removed TAGs from blood plasma; however, DAGs were poorly removed.

Method Validation. The method was validated for avocado and citrus, following the Eurachem Method Validation Guide,[29] to provide data on pesticide recoveries and reproducibility through the automated ITSP c-SPE method developed (Table 4). The finalized method used c-SPE cartridges containing 30 mg of Z-Sep/C_{18}/CarbonX, with 150 μL of QuEChERS extract loaded and 150 μL of 100 mM ammonium formate/formic acid buffer in MeCN/MeOH (1:1) used for elution.

Because there appeared to be some matrix suppression of flumethrin, permethrin A, and halfenprox when 2-fold diluted avocado extract was cleaned up using Z-Sep/C_{18}/CarbonX (Table 2), 5-fold dilution before d-SPE was used for avocado validation, with the aim of improving cleanup and reducing ionization suppression while still meeting method detection limits needed to meet the maximum residue limits (MRLs) required, using the Triple Quad 6500 LC-MS/MS.

Avocado was chosen due to its high oil content, up to 30% by weight,[19] which can precipitate on the addition of aqueous buffer for LC-MS/MS analysis, interfere with chromatographic separations by accumulating on C_{18} analytical columns, or elute several injections later and therefore should be removed from extracts before injection.[14,30] During LC-Q-Orbitrap-MS experiments avocado TAGs failed to elute from the C_{18} HPLC column with 95% MeOH, requiring 98% MeOH/isopropanol (1:1), and therefore may accumulate on the column with multiple injections during routine multiresidue analyses. Avocado extracts produce significant matrix suppression for late-eluting compounds, without cleanup.[31] Citrus was selected as "citrus fruits are notoriously difficult matrices for pesticide residue analysis"[2] and can result in high levels of LC-MS/MS matrix ionization suppression,[2,31−33] whereas the high acidity may affect extraction

[a]Recoveries <70% or >120% are highlighted in bold type. [b]Normalized to triphenylphosphate (SMC). [c]Mean of isomers. [d]Mean of two peaks observed.

recoveries of acid labile or basic pesticides, such as acephate and pymetrozine.[2,34] There was also the possibility that the relatively high concentrations of citric acid in citrus fruit, plus the extra trisodium citrate that we added during extraction to bring the pH back into the citrate buffer region (centered on pK_a = 4.76), may have affected cleanup on Z-Sep by displacing matrix.

Validation results for avocado showed recoveries below 70% for 16 of the 269 pesticides tested (including homologues and metabolites, with the 6 pyrethrins considered as one pesticide). Five of the16 analytes at <70% recovery in avocado also fell below 70% recoveries in citrus (Table 4). Recoveries were quantitated against solvent-only calibration standards and therefore include any ESI matrix suppression. Of the compounds falling below 70% recovery, anilazine, carbendazim, forchlorfenuron, methamidophos, pymetrozine, and thiabendazole commonly have poor QuEChERS extraction recoveries,[2,14,15,34,35] due to their basicity or being highly polar. This is in addition to <100% recovery through the c-SPE cleanup (84% for carbendazim, 81% for pymetrozine, 70% for thiabendazole with 100 mM buffer elution, Figure 3). Spirotetramat-enol-glucoside recovery was 52% for avocado, compared with 75% when spiked directly into squash extract before cleanup (Figure 3), and 76% for citrus, indicating some loss, or MS suppression, in the presence of avocado matrix. Naled, clofentezine, and thiophanate-methyl are base sensitive[35] and appeared to be decomposing in aqueous solution, giving low recoveries in avocado (33, 62, and 65%, respectively) and improved recoveries in acidic citrus (60, 100, and 99%, respectively). Matrix suppression was apparent in avocado for the late-eluting analytes bifenthrin (14.21 min), flumethrin (13.97 min), halfenprox (14.51 min), and permethrins A (13.63 min) and B (13.94 min); however, recoveries were >50%, with relative standard deviations (RSDs) <26%, acceptable for screening purposes. Some analytes exhibited >120% recoveries from citrus, with signal enhancement apparent at around 2.30 min affecting clothianidin (2.30 min) and imidacloprid (2.29 min). For the quaternary ammonium compound DDAC, and sulfentrazone, it appeared fewer losses occurred in the instrument injector with high levels of citrate in citrus extracts, giving >120% recoveries (Table 4). RSDs were >20% for 20 compounds but were >30% for only 6 compounds, with mean RSDs of 10% for both matrices, indicating that the automated ITSP c-SPE cleanup was highly reproducible and giving very similar reproducibility to previous studies using d-SPE,[2,33] or no cleanup,[36] and matrix-matched calibration standards. Overall, mean spike recovery for avocado was 87%, and that for citrus was 102%.

The validated method was used to analyze nine avocado and nine orange samples, New Zealand grown, and obtained from local shops in Hamilton, New Zealand. Incurred residues >0.01 mg/kg were detected in eight avocado and eight orange samples. DDAC was present in four avocado samples between 0.23 and 0.42 mg/kg, prochloraz in three samples (0.080–0.15 mg/kg), chlorpyrifos in one sample (0.19 mg/kg), piperonyl butoxide in one sample (0.035 mg/kg), and uniconazole in one sample at 0.010 mg/kg. In the orange samples, diazinon was detected in four samples from 0.014 to 0.24 mg/kg, malathion in three samples, ranging from 0.018 to 0.061 mg/kg, piperonyl butoxide in one sample (1.2 mg/kg), terbuthylazine in one sample (0.010 mg/kg), and the spirotetramat metabolite spirotetramat-*cis*-enol in one sample at 0.019 mg/kg. The oranges with terbuthylazine also showed a trace level of terbuthylazine-desethyl (0.00096 mg/kg), confirming the presence of this herbicide, whereas the sample with spirotetramat-*cis*-enol also contained low levels of spirotetramat-*cis*-ketohydroxy and spirotetramat-enol-glucoside (0.0069 mg/kg for both). The levels of pesticides found were below the New Zealand MRLs,[37] except for chlorpyrifos (MRL = 0.2 mg/kg), taking into account a 7% RSD found for chlorpyrifos recovery in avocado during method validation (Table 4). These results indicate the effectiveness of the method in the detection of incurred pesticide residues in fruits available for purchase by New Zealand consumers.

This is the first investigation into the use of ITSP mini-cartridges for cleanup of QuEChERS extracts for multiresidue pesticide analysis. The zirconia stationary phases Z-Sep and Z-Sep+ have recently been used as d-SPE sorbents to clean up QuEChERS extracts;[9−16] however, this study uses these sorbents in SPE columns, which appear to be more retentive than d-SPE (Table 2). A mixture of Z-Sep, C_{18}, and CarbonX, in mini-column ITSP cartridges, effectively removed oils from QuEChERS extracts of avocado (Figure 4), and elution with formate buffer in MeCN/MeOH gave acceptable recoveries for 269 pesticide analytes (Table 4; Table SI-A). Validation data showed minimal matrix-induced LC-MS/MS ionization suppression for avocado and orange extracts. Automation and miniaturization of c-SPE on an instrument autosampler make this method quick and easy, as well as robust and reproducible.

Characterization of Trisiloxane Surfactants from Agrochemical Adjuvants and Pollinator-Related Matrices Using Liquid Chromatography Coupled to Mass Spectrometry

Jing Chen and Christopher A. Mullin*

Department of Entomology, Center for Pollinator Research, The Pennsylvania State University, University Park, Pennsylvania 16802, United States

Supporting Information

ABSTRACT: Trisiloxane surfactants (TSSs) have been associated with honeybee learning impairment and the ongoing global bee decline. A liquid chromatography−mass spectrometry strategy for the identification of TSSs from agrochemical adjuvants and pollinator-related matrices is introduced here. The strategy incorporates chromatographic retention behavior, isotope ratio, reference to a compiled database of accurate masses, and TSS hydrolysis when necessary. Using this analytical strategy, three TSSs (x = 0, R = H, m = 1, 2, or 3) were identified for the first time from almond flowers of a commercial orchard. The three major purified TSS components in popularly used spray tank adjuvants were identified as TSS (x = 0, m = 0, R = H, CH_3, or $C(O)CH_3$) and their structures confirmed by nuclear magnetic resonance spectroscopy. These monitoring tools allow the assessment of the agricultural residues and potential risks of major TSS contaminants to important nontarget species such as honeybee and other essential pollinators.

KEYWORDS: *trisiloxane surfactant, organosilicone, honeybee decline, LC-MS, adjuvants*

INTRODUCTION

Poor honeybee and other pollinator health continues to be a major threat worldwide since 2006,[1,2] and factors such as parasites, pesticides, pathogens, or their combinations have been implicated in bee decline.[3,4] More recently, the focus has been on the role of pesticide residues in foraging areas or beehives as a primary trigger of bee death.[5] However, no direct correlation has been found between any single pesticide and colony collapse.[3,6,7] Compared to technical grade pesticides, formulated pesticides are usually more toxic to honeybees and other nontarget species.[8] Some formulation additives and solvents are known to be acutely or sublethally toxic to bees, although they are considered and classed as "inerts".[9,10]

Organosilicone surfactants used in agriculture are new-generation adjuvants containing a fully methylated siloxane backbone as the hydrophobic part and mostly one or occasionally more poly(ethylene oxide) (EO)/poly(propylene oxide) (PO) chains as the hydrophilic part. Most often, a propyl group is used to connect the siloxane backbone and EO/PO side chain (Figure 1), but occasionally an alternative alkyl from 1 to 4 carbons or an aryl group can serve as a spacer. According to specific application or the commercial product, the surfactant structure can differ in end group R and the values of x, m, and n,[8,11−13] which are generally not revealed by manufacturers. In agro-ecosystem use, the trisiloxane surfactants (TSSs; x = 0 in Figure 1) dominate and are increasingly applied as spray adjuvants due to their superior spreading and penetrating abilities.[12,13] Recently, high nanograms per gram levels of TSS residues were detected in North American bee hives,[14] and adult bees fed 20 μg of tested TSS adjuvant were strongly impaired in their learning ability to associate a floral odor with an imminent sugar nectar reward.[10] Thus, more attention should be paid to monitoring environmental TSS residues to assess their potential role in the ongoing bee decline.

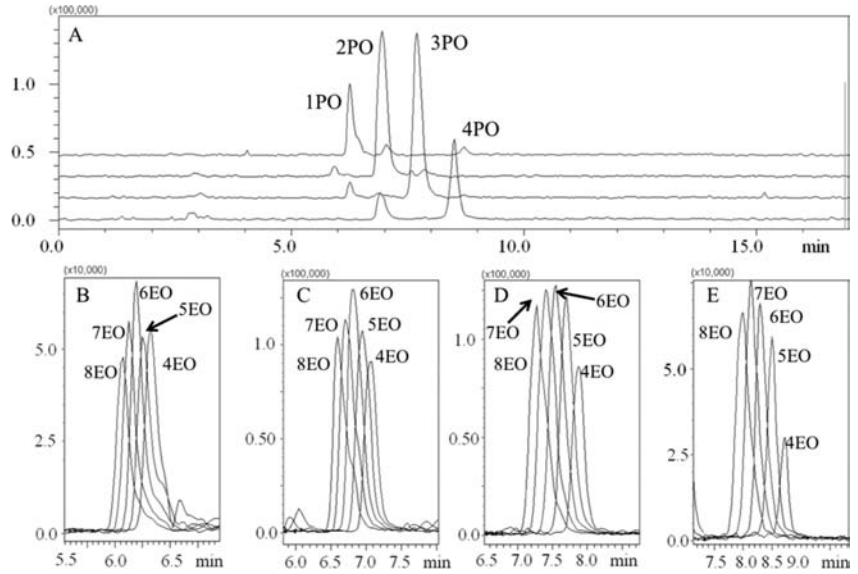

Figure 2. Extracted ion chromatograms of trisiloxane surfactant (R = H) oligomers: (A) oligomers containing 1−4 poly(propylene oxide) (PO) units with 8 poly(ethylene oxide) (EO) units; (B) oligomers of 4−8 EO and 1 PO units; (C−E) oligomers of 4−8 EO and 2−4 PO units, respectively.

Major components of the first commercial TSS, Silwet L-77, were previously identified as primarily methoxy- and some hydroxy-capped TSS (Figure 1; $x = 0$, $m = 0$, R = CH_3 or H; CAS Registry No. 27306-78-1 and 67674-67-3).[15] Subsequently, analytical methods were developed to monitor residues of these TSSs in water,[16] and in addition the acetyl-capped TSS ($x = 0$, $m = 0$, R = $C(O)CH_3$; CAS Registry No. 125997-17-3) in honey, pollen, and beewax.[14] New kinds of TSSs are continually being synthesized and reported,[17−23] and their possible future use in bee environments can be anticipated. It is important to develop an identification strategy for analyzing TSSs and primary degradates in bee-related samples.

Here, a strategy for identifying TSSs and their environmental degradates, based on liquid chromatography coupled to mass spectrometry (LC-MS), is described. Techniques used include low- and high-resolution mass spectrometry (MS), isotope ratio, nuclear magnetic resonance (NMR) spectroscopy, TSS hydrolysis, chromatographic retention behavior, and reference to a compiled database of diagnostic masses. Particular attention was made to distinguishing TSSs from competing polyethoxylate ions in samples. With this strategy, TSSs were identified from almond flower and from commercial high-volume agrochemical adjuvants.

MATERIALS AND METHODS

Chemicals. Acetonitrile (HPLC grade) and formic acid (98%) were purchased from EMD Chemical Inc. (Gibbstown, NJ, USA). Ammonium formate was purchased from Alfa Aesar (Wayne, PA, USA). Magnesium sulfate ($MgSO_4$, anhydrous) and ENVIRO Clean 2 mL dispersed solid phase extraction (SPE) tube (containing 150 mg of $MgSO_4$, 150 mg of CUPSA, and 50 mg of CEC18) were from UCT (Bristol, PA, USA). Sodium acetate (99%, anhydrous) was from Sigma-Aldrich (St. Louis, MO, USA). Chloroform-*d* was from Isotec Inc. (OH, USA). Water used in all experiments was purified using a MilliDI system (Millipore, MA, USA).

LC-MS Conditions. Liquid chromatography coupled to mass spectrometry was performed on an LC-MS 2020 system (Shimadzu, Kyoto, Japan) equipped with an electrospray ionization (ESI) source. A Shim-pack XR-ODS column (100 mm × 2.0 mm) (Shimadzu) was used for LC separation at 50 °C and a flow rate of 0.35 mL/min. Mobile phases A and B were water and acetonitrile, respectively, both containing 2 mM ammonium formate and 0.01% formic acid.

For almond flower analysis, the gradient was started with 15% B and changed to 70% B at 1 min, then changed to 100% B at 9 min and kept at 100% B until 12 min. The gradient was set back to 15% B at 12.1 min and kept for 5 min. In adjuvant analysis, the gradient was set at 5% B and kept for 3 min. It was changed to 50% B at 25 min, changed to 60% B at 40 min, and kept for 20 min. Then, the gradient was changed to 100% B at 62 min and kept for 3 min. Finally, it was set back to 5% B and kept for 5 min.

MS was performed in the positive ion mode. The nebulization gas flow was set to 1.5 L min^{-1}, drying gas flow was set to 10 L min^{-1}, heat block temperature was 300 °C, and DL temperature was set to 250 °C. The interface bias voltage was set to 4500 V.

Accurate mass was determined in the Pennsylvania State University Proteomics and Mass Spectrometry Core Facility on a Waters LCT Premier time-of-flight (TOF) MS (Waters Corp. (Micromass Ltd.), Manchester, UK). The nitrogen drying gas temperature was set to 300 °C, and capillary voltage was 2400 V. The MS was set to scan from m/z 100 to 1000 in positive ion mode, using ESI.

Sample Collection and Preparation. Commercial organosilicone adjuvants analyzed included Dyne-Amic, Kinetic HV, and Silwet L-77 from Helena (Collierville, TX, USA), Sylgard 309 from Dow-Corning (Midland, MI, USA), Syl-Tac from Willbur-Ellis (San Francisco, CA, USA), and Silkin from Agriliance LLC (Inver Grove Heights, MN, USA). All adjuvants were dissolved in acetonitrile at 100 ppm. Almond flowers from Stanislaus county, California, USA, were collected in March 2010 on the same day of a pesticide spray treatment and stored at −20 °C. Floral extracts were prepared as before using a QuEChERS method.[14] One gram of almond flowers was ground in liquid nitrogen before extraction.

TSS Purification. Three TSSs (R = H, CH_3, and $C(O)CH_3$) were purified respectively from the corresponding adjuvants using C18 SPE cartridges (500 mg/6 mL, Supelco, Sigma-Aldrich). Fractions were collected and dried under nitrogen. The purified fractions were analyzed by LC-MS and shown to be >95% pure.

TSS Hydrolysis. Hydrolysis experiments were performed on 100 ppm of purified TSS fractions and sample extracts in 2 mM ammonium formate buffer (pH 2.75) for at least 30 min at room temperature. Hydrolyzed products were analyzed by LC-MS.

NMR Spectroscopy. NMR spectroscopy of the three purified TSS compounds was conducted on a 600 MHz, 14.1 T Bruker AV-III-600 (Bruker-Biospin Corp., Billerica, MA, USA) in the Pennsylvania State

DOI: 10.1021/jf505634x
J. Agric. Food Chem. 2015, 63, 5120−5125

University NMR Facility. Proton nuclear magnetic resonance (^{1}H NMR) and heteronuclear multiple-quantum coherence (HMQC) spectra were collected. Samples were dissolved in chloroform-*d*.

Reference Database. A database was built of accurate masses for TSS oligomers including $[M + H]^+$, $[M + Na]^+$, $[M + K]^+$, and $[M + NH_4]^+$ adducts. TSS oligomers contained 0−20 EO units, 0−10 PO units, end group R = C_aH_{2a+1} (a = 0−18), R = $C(O)C_aH_{2a+1}$ (a = 0−18), or other functional groups. The database is being updated as new TSS structures are published and is available upon request from the authors.

RESULTS AND DISCUSSION

Chromatography and Mass Spectrometry. TSSs can be separated on the basis of the R end group and respective oligomeric array using gradient elution on a C18 reversed phase column.[14] TSS (R = H) oligomers with 8 EO units and 1−4 PO units were eluted in order of increasing number of PO units (Figure 2A). Conversely, oligomers with 4−8 EO and the same PO units increasing from 1 to 4 were eluted in order of decreasing length of EO chain (Figure 2B−E), due to the greater hydrophilic nature of the EO chain.

Protonated ($[M + H]^+$) or deprotonated ($[M - H]^-$) molecular ions are usually produced in the ESI source, but these ions cannot be easily observed for TSSs.[15,24] Instead, $[M + NH_4]^+$, $[M + Na]^+$, or $[M + K]^+$ adducts are usually observed due to a cation trapped in the polyalkylene oxide side chain. The mechanism of forming cation adducts can be explained by the respective chelating effect of the alkali metal.[25]

Peak areas of respective cation adducts for TSSs are displayed in supplementary Figure S1 in the Supporting Information. In the absence of the ammonium buffer in the mobile phase, all $[M + NH_4]^+$, $[M + Na]^+$, and $[M + K]^+$ adduct ions are observed because of trace levels of each cation in glassware and the LC system. Oligomers with longer EO chains show an increased abundance of $[M + K]^+$ adducts (data not shown), which is consistent with results from Bonnington et al.[15] By adding 2 mM ammonium formate to the mobile phase, the incidence of $[M + Na]^+$ and $[M + K]^+$ ions is substantially reduced, and $[M + NH_4]^+$ ions dominate the mass spectrum (supplementary Figure S1). Therefore, inclusion of 2 mM ammonium formate buffer in the mobile phase simplifies spectral identification and provides better sensitivity. However, a higher buffer concentration can result in ion suppression,[26] which reduces LC-MS signal intensity.

TSS Identification Using High-Resolution MS. High-resolution MS enables assignment of elemental compositions based on the measured accurate mass. TSS (m = 0, R = CH_3) at 250 μg/L was prepared in acetonitrile and injected into the TOF-MS. Three silicon ions were found in each oligomer, and a CH_2CH_2O difference was found in all neighboring oligomers (data not shown). The $[M + NH_4]^+$ structure is hard to elucidate due to lack of MS/MS information because the high stability of the adduct does not allow sufficient fragmentation. Because data from TOF-MS only suggest the elemental composition with three silicon atoms and EO/PO duplicates, other structural analysis tools must be included.

Our identification strategy for TSSs is displayed in Figure 3. It can be adapted easily to a low-resolution MS, for example, a single-quadrupole MS, and includes the following steps:

Identifying the EO/PO in the Side Chain. TSS with only EO or an EO/PO combination dominated by EO is mainly used in commercial products. The mass differences of neighboring oligomers are 44.03 and 58.04 amu, respectively, for an EO and PO unit. A TSS oligomer with a longer EO chain has a reduced

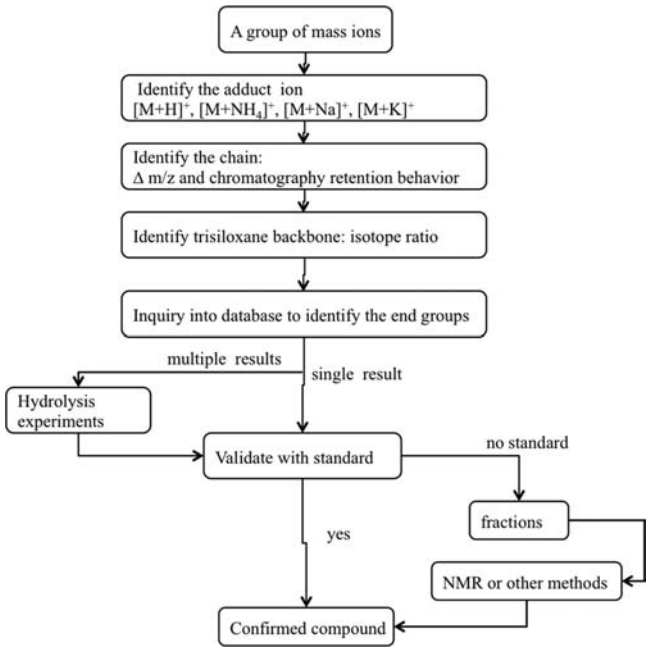

Figure 3. Trisiloxane surfactant identification strategy.

retention time on a reversed phase column (Figure 2B−E), which is similar to other nonionic surfactants.[27] A PO unit further enhances hydrophobicity, and oligomers with increasing PO units have increased retention time (Figure 2A). Combining mass spectral and retention behavior, a prediction for the ratio of EO/PO units in the side chain can be obtained.

Distinguishing TSS from Other Nonionic Surfactants. With a low-resolution MS, accuracy of the determined mass does not support calculating the elemental composition. However, the number of silicon atoms can be determined by isotope ratios. A linear relationship is found with increasing EO chain for TSS between the isotope ratio ($I_{[M+1]}/I_{[M]}$) and m/z (Figure 4A). Surfactants with 0−4 silicon atoms have the same slope values, =0.05, and the intercept value is increased according to the number of silicon atoms. For example, intercept values of nonylphenol ethoxylates (NPEO) and TSSs (m = 0, R = CH_3) are around −1.2 and 12 with 0 or 3 silicon atoms in the structure, so by determining the m/z and $I_{[M+1]}/I_{[M]}$ of an unknown surfactant, its intercept value, B, can be calculated using eq 1.

$$B = 100 \times I_{[M+1]}/I_{[M]} - 0.05 \times m/z \quad (1)$$

By referring to the intercept values in Figure 4 or by comparing those calculated for other similar alkyphenol ethoxylates and alkyl ethoxylates, a putative TSS can be identified and distinguished from other co-occurring nonionic surfactants. Moreover, the relationship of $I_{[M+2]}/I_{[M]}$ ratio and m/z is displayed in Figure 4B. For m/z < 1000, the $I_{[M+2]}/I_{[M]}$ ratios of TSS or higher siloxane surfactant are >13%, whereas they are below 10% in other nonionic surfactants without silicon atoms,[14] the latter attribute confirming that the surfactant is a TSS. A similar strategy can be used to distinguish the TSS (m = 0, R = CH_3) from octylphenol ethoxylates, in which same mass ions were observed.[14,28]

Identifying the End Group. New structural types of TSSs with improved spreading ability and stability have been published recently.[17−23] We have built a reference database that encompasses the mass ions of various TSSs that are used

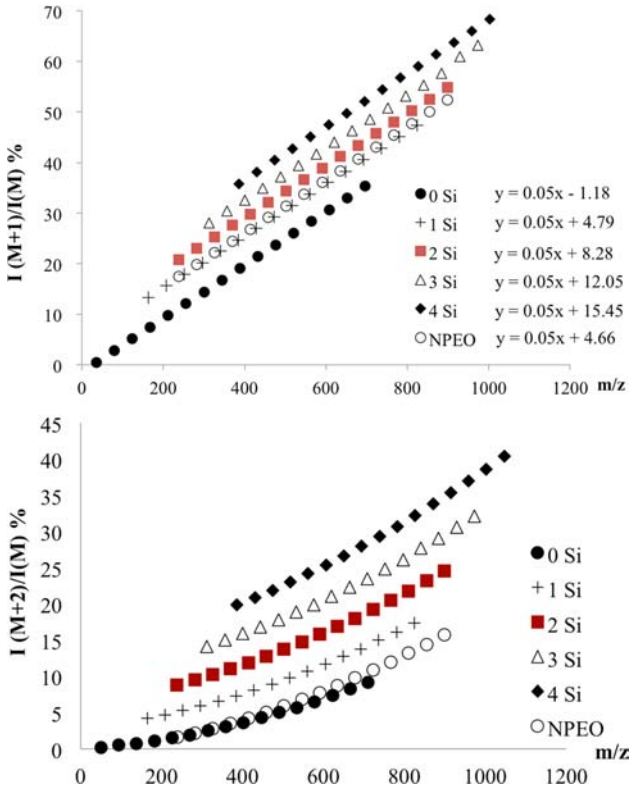

Figure 4. Correlations between (A) m/z and $I_{[M+1]}/I_{[M]}$% and (B) m/z and $I_{[M+2]}/I_{[M]}$% for nonylphenol ethoxylates (NPEO) and siloxane surfactants of various EO chain lengths and siloxanes of increasing methylated silicon atoms (0–4 Si).

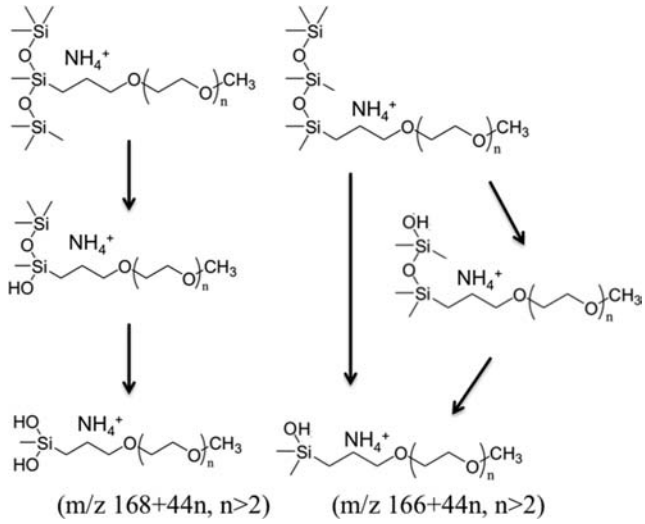

Figure 5. Proposed major hydrolysis pathways of trisiloxane surfactant (m = 0, R = CH_3) in 2 mM ammonium formate buffer, pH 2.75.

or potentially used in bee environments. TSSs with 2–20 EO units, 1–10 PO units, and various end groups (hydroxyl, methyl, acetate, etc.) are included in the database. Entry of the m/z value of an unknown TSS reveals candidate oligomers and their identity.

Identifying Single or Double Side Chains on the TSS Backbone. Most TSSs used in agrichemical formulations have a single hydrophilic side chain to maintain adequate water solubility, but for some product applications requiring increased polarity, a double alkoxylate side chain may be incorporated. Hydrolysis experiments can be used to identify the number of side chains and to which silicon atoms they are attached.

Silicon–oxygen bonds can be hydrolyzed to silanol in acidic or alkaline aqueous solutions.[29,30] In 2 mM ammomiun formate (pH 2.75) buffer, TSS mainly hydrolyzes to silanols with various EO chain lengths (Figure 5). For example, TSS (x = 0, m = 0, R = CH_3) with a single side chain attached to the middle silicon atom hydrolyzes to oligomers of m/z 168 + 44n (n > 2), whereas those with a side chain attached to the terminal silicon atom hydrolyze to oligomers of m/z 166 + 44n (n > 2). If a TSS has two side chains attached to both the middle and end silicons, two oligomer families representing degradation from the either side chain can be detected during LC-MS analysis. If the two side chains are on both terminal silicons, only one degradate of m/z 168 + 44n (n > 2) is produced, but the ratio of "hydrolyzed product/TSS" is double that of the single-chain TSS.

Identifying TSS from Almond Flower Samples. Almond production provides the largest honeybee pollination event in the United States, and agrochemical sprays containing organosilicone adjuvants are applied intensively at bloom, resulting in honeybee exposures to TSS residues.[10] Thus, almond flowers were extracted and analyzed by LC-MS as above, and the total ion chromatogram is displayed in supplementary Figure S2 in the Supporting Information. In the mass range m/z 500–1000, four clusters of oligomers with 44 amu mass differences were found: surfactant 1, m/z 502 + 44n (t_R = 3.5–3.7 min); surfactant 2, m/z 532 + 44n (t_R = 5.8–6.3 min); surfactant 3, m/z 502 + 44n (t_R = 6.3–7.2 min); and surfactant 4, m/z 516 + 44n (t_R = 6.7–8.0 min).

For each cluster, larger m/z mass ions have lower retention times successively separated by 44 amu, indicating these surfactants have EO units. Equivalent mass ions were found in surfactants 1 and 3. By calculating the $I_{[M+1]}/I_{[M]}$ isotope ratios and using eq 1, the calculated intercept value (~5) indicated that surfactant 1 had no silicon atom, and it was further confirmed as NPEO using a standard.

By parallel analysis, surfactants 2, 3, and 4 all had three silicon atoms. Upon hydrolysis in 0.1% formic acid solution at pH 2.6, all three clusters were lost in the LC-MS analysis, indicating the existence of silicon–oxygen bonds. Concomitant LC-MS analysis of respective peaks from the hydrolysis of surfactants 2, 3, and 4 indicated a TSS with a single side chain of EO and possibly PO units. Mass ion m/z 532 from surfactant 2, based on our reference database, indicated a TSS (n = 5, m = 0, R = CH_3) or TSS (n = 4, m = 1, R = H). TSS (n = 5, m = 0, R = CH_3) was previously identified as Silwet L-77.[14,15] Because the longer retention time for m/z 532 from surfactant 2 is not consistent with our standards for Silwet L-77, we assign this m/z 532 to the respective EO side chain with a single PO unit, TSS (n = 4, m = 1, R = H), and surfactant 2 was identified as TSS (m = 1, R = H). Similarly, surfactants 3 and 4 were identified as TSS (m = 2, R = H) and TSS (m = 3, R = H), respectively.

Identifying TSS and Other Nonionic Surfactants from Agrochemical Adjuvants. TSSs in commercial spray adjuvants are often undisclosed and labeled as a "nonionic surfactant", "silicone surfactant", "polyethoxylate", "methylated silicone polyethoxylate", etc. Detailed information about TSS structures and their percentages is rarely revealed. On the basis of pounds of usage on California almonds (primary global site for honeybee pollination) reported from the California Pesticide Information Portal,[10,31] the top-used organosilicone

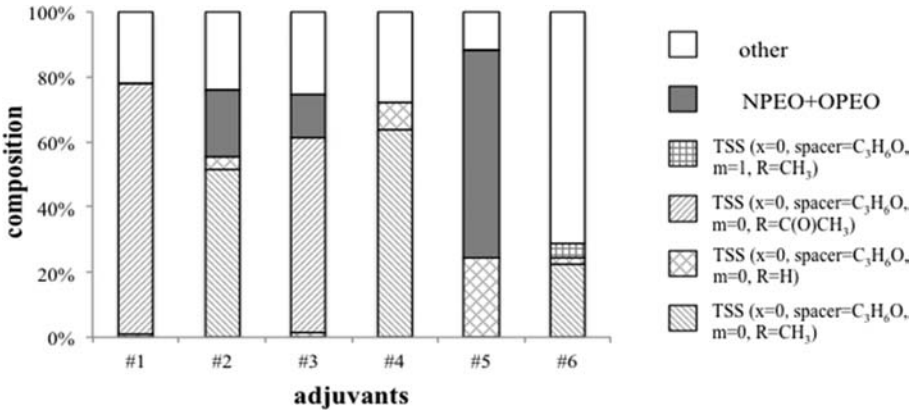

Figure 6. Identification results from top-used spray adjuvants (see text for product details). NPEO and OPEO are nonylphenol ethoxylates and octylphenol ethoxylates, respectively.

surfactant adjuvants were selected and analyzed by LC-MS. On the basis of the identification strategy herein, major TSS and other nonionic surfactants were identified from Dyne-Amic, Kinetic HV, Silkin, Silwet L-77, Sylgard 309, and Syl-Tac (Figure 6). TSS (m = 0, R = H), TSS (m = 0, R = CH_3), and TSS (m = 0, R = $C(O)CH_3$) dominated these popularly used adjuvants. Chemical structures of these TSS were confirmed by ^{1}H NMR and HMQC spectroscopy (Supporting Information, supplementary Figure S3) using purified fractions.

Trisiloxane surfactants were recently detected in every beeswax sample up to 390 ng/g and in 60% of pollen samples up to 39 ng/g.[14] Interest in applications for higher homologues, particularly the tetrasiloxanes (Figure 1, x = 1), is increasing.[32] The prevalence of organosilicone surfactants in agrochemicals including tank adjuvants[13] and other industrial products, along with uncertainty of their environmental fate, advocates more robust efforts for their biomonitoring.

A structural identification strategy for TSSs is described here based on mostly low- and some high-resolution LC-MS. TSSs were identified from a range of commercial spray adjuvants using accurate mass and isotope ratios, a reference database, and hydrolytic experiments. To verify the utility of our protocol, TSS (m = 1, R = H), TSS (m = 2, R = H), and TSS (m = 3, R = H) were identified for the first time from a California almond flower sample. Major TSS components in popularly used spray adjuvants were identified as TSS (m = 0, R = H), TSS (m = 0, R = CH_3), and TSS (m = 0, R = $C(O)CH_3$), and structures were confirmed by NMR. Exploring TSS exposures in bee environments helps us better evaluate this risk factor for honeybees.

Development of a Liquid Chromatography–Tandem Mass Spectrometry Method for the Determination of Sulfite in Food

Katherine S. Robbins,* Romina Shah, Shaun MacMahon, and Lowri S. de Jager

Center for Food Safety and Applied Nutrition, U.S. Food and Drug Administration, 5100 Paint Branch Parkway, HFS 706, College Park, Maryland 20740, United States

ABSTRACT: Sulfites are widely used food preservatives that can cause severe reactions in sensitive individuals. As a result, the U.S. FDA requires that sulfites be listed on the label of any food product containing >10 mg/kg (ppm) sulfite (measured as sulfur dioxide). Currently, the optimized Monier–Williams (MW) method (AOAC Official Method 990.28) is the most common approach for determining sulfite concentrations in food samples. However, this method is time-consuming and lacks specificity in certain matrices. An improved rapid, sensitive, and selective method has been developed using electrospray ionization (ESI) high-performance liquid chromatography–tandem mass spectrometry (LC-MS/MS) for the determination of sulfite in various food matrices. A total of 12 different types of foods were evaluated. These included dried fruits and vegetables, frozen seafood, sweeteners, and juices. The matrix is extracted with a buffered formaldehyde solution, converting free and reversibly bound sulfite to the stable formaldehyde adduct, hydroxymethylsulfonate (HMS). Extracts are prepared for injection using a C_{18} SPE cartridge to remove any lipophilic compounds. HMS is then separated from other matrix components using hydrophilic interaction chromatography (HILIC) and detected using multiple reaction monitoring (MRM). The method was validated at 5 concentrations in 12 food matrices. Accuracy data showed spiked recoveries ranging from 84 to 115% in representative foods. Six commercially available sulfited products were analyzed using the LC-MS/MS method, as well as the MW method, to determine if differences exist.

KEYWORDS: *LC-MS/MS, sulfites, food additives*

INTRODUCTION

Sulfites are a family of food preservatives that commonly include sulfur dioxide, sodium sulfite, sodium metabisulfite, potassium metabisulfite, sodium bisulfite, and potassium bisulfite. They are used worldwide in a broad range of food and beverage products including dried fruits, dried vegetables, jams, flours, juices, and seafood due to their antioxidant, antimicrobial, and antibrowning properties.[1] Sulfite is present in three forms in food systems: free, reversibly bound, and irreversibly bound. Free sulfite, as its name suggests, is not bound to any other food component and is easily quantified by most existing methods. Reversibly and irreversibly bound sulfites exist when adducts form between sulfite and various food components such as acetaldehyde, sugar monomers, or sugar acids.[2] Through sample preparation steps, such as pH adjustment and heating, sulfite can be released from reversibly bound sulfite and quantified. Irreversibly bound sulfite is very stable, making it difficult to quantify.[1]

Although sulfites contribute beneficial properties to a food system, a small subset of the population has an adverse allergy-like reaction upon consumption. In sensitive individuals, sulfites can produce health effects including skin rashes, nausea, and respiratory distress.[1] In 1986, the U.S. Food and Drug Administration (FDA) began requiring that all sulfite be declared on the label of any product in which the concentration exceeded 10 mg/kg (ppm) (measured as sulfur dioxide (SO_2)) and that no sulfites be added to any food product intended to be served raw or presented fresh to the public such as those items found on a salad bar.[3,4] Similar guidance was adopted by other regulatory agencies including those in Europe, Canada, and Korea.[5−7] The FDA identified AOAC Official Method 990.28,[8] the optimized Monier–Williams (MW) method, as the required method for all regulatory analyses. This method allows for accurate determination of sulfites in most food products and requires readily available glassware and reagents.[9] However, this method includes an extended distillation, displays reduced sensitivity at levels below 10 ppm of SO_2, and lacks specificity in some matrices such as *Allium* and *Brassica* vegetables.[10] Various alternatives to this method have been reported in the literature. These include electrochemical methods,[9,11,12] ion exchange chromatography,[13,14] liquid chromatography,[15] flow injection analysis,[16−18] spectrophotometry,[19] and iodometry.[20] Although these methods have shown promise for sulfite determination, there are still several limitations including lack of sensitivity, specificity, and applicability across multiple food types, making them unsuitable for routine regulatory use.

Sulfite is challenging to analyze in its highly unstable free form, leading to the use of chemical derivatization prior to analysis.[21] Warner et al.[21] found that the addition product of sulfite and formaldehyde, hydroxymethylsulfonate (HMS), is easily formed and more stable than the free form. HMS has been previously determined using ion-pairing high-performance liquid chromatography (HPLC).[22,23] Although this HPLC

method is sensitive and selective for sulfite, the postcolumn reaction step requires specialized instrumentation and expertise. Liquid chromatography−tandem mass spectrometry (LC-MS/MS) is a technique that affords high specificity and sensitivity and has become widely used for food analysis. The present study describes the development and validation of an improved LC-MS/MS method for sulfite determination in a variety of food matrices. Sulfite is converted to HMS and then separated using hydrophilic interaction liquid chromatography (HILIC) and quantified by LC-MS/MS. Following method development and optimization for a wide range of food categories, validation was performed at five different concentrations ranging from 0.5 to 100 ppm of SO_2. The LC-MS/MS method was then compared to the MW method using commercially available sulfited products. LC-MS/MS proved to be a more sensitive, selective, and rapid method that will enable improved enforcement of the sulfite labeling requirements protecting sensitive individuals from inadvertently ingesting sulfite.

MATERIALS AND METHODS

Reagents and Materials. Both the internal standard, sodium sulfite-^{34}S ($Na_2{}^{34}SO_3$, 95%), and the surrogate, chloroacetic acid ($ClCH_2CO_2H$, ≥99%), in addition to formaldehyde (37%), ammonium acetate (Sigma Ultra, minimum 98%), and sodium sulfite (Na_2SO_3, ≥ 98%) were acquired from Sigma-Aldrich (St. Louis, MO, USA). LC-MS grade acetonitrile, water, and methanol, in addition to glacial acetic acid, methylene chloride, hydrogen peroxide (30%), sodium hydroxide (certified 0.1 and 0.01 N), and concentrated hydrochloric acid, were purchased from Thermo Fisher Scientific (Pittsburgh, PA, USA). Methyl red from Mallinckrodt Baker (Phillipsburg, NJ, USA) was used in the MW titration. Samples were diluted and extracted using 18 MΩ water obtained from an Aqua Solutions water purification system (Jasper, GA, USA). Unsulfited food samples were purchased online and from grocery stores located in Greenbelt, MD, USA. For comparison of the LC-MS/MS and MW methods, products with sulfite declared on the label were obtained from local grocery stores. All food samples were stored according to the manufacturer's suggested storage conditions.

Standard Preparation. A 2% formaldehyde solution in 0.05 M ammonium acetate was prepared by dissolving 1.925 g of ammonium acetate in 50 mL of 18 MΩ water, adding 27 mL of 37% formaldehyde solution and diluting to 500 mL with 18 MΩ water. The pH of this solution was adjusted to 4.5 by dropwise addition of acetic acid. Working 0.2% formaldehyde extraction solutions were prepared by diluting 2.0% solution 1:10 with 18 MΩ water. The 0.2 and 2% formaldehyde solutions were stable at room temperature for at least 1 week and 3 months, respectively.

Both the chloroacetic acid and $Na_2{}^{34}SO_3$ (IS) solutions were prepared using the formaldehyde extraction solvent. Briefly, a 25 ppm IS stock solution was prepared by dissolving 2.5 mg of $Na_2{}^{34}SO_3$ in 100 mL of 2% formaldehyde solution. This stock was further diluted to form a 5 ppm working solution. The chloroacetic acid stock solution (10 mg/mL) was prepared by weighing 100 mg into a tared 10 mL volumetric flask and diluting to volume with 0.2% formaldehyde solution. Working standards of 2.5 mg/mL, 1 mg/mL, and 5 μg/mL chloroacetic acid were prepared by diluting the stock solution with the appropriate volume of 0.2% formaldehyde. Stock solutions were stored for up to 1 year at 4 °C, and working standards were stored for up to 1 month.

Stock solutions of HMS were prepared by weighing 100 mg of Na_2SO_3 into a tared 10 mL volumetric flask and diluting with 2% formaldehyde solution. On the day of analysis, a 1 mg/mL solution was prepared by diluting the stock solution with 18 MΩ water. Further dilutions with 0.2% formaldehyde solutions were made to give final concentrations of 1, 10, and 100 ppm of Na_2SO_3 working standards. Ten standards (0.01, 0.02, 0.05, 0.1, 0.2, 0.4, 0.8, 1.5, 3.0, and 4.5 μg Na_2SO_3/mL) were prepared in 2 mL glass autosampler vials with a PTFE/red silicone septum cap (Agilent Technologies, Palo Alto, CA, USA) by diluting the 1, 10, or 100 ppm working standards with 0.2% formaldehyde to 100 μL and then adding 100 μL of IS working solution, 100 μL of 5 μg/mL chloroacetic acid, and 700 μL of acetonitrile.

Sample Preparation. Due to the wide variety of food commodities analyzed, both liquid and solid preparation methods were developed. Refrigerated samples were allowed to come to room temperature prior to analysis. For solid samples, the sample (50 ± 1 g) was cut into small $^1/_4$ in. pieces and homogenized with 100 g of 0.2% formaldehyde solution in a variable-speed laboratory blender (Waring Laboratory Science, Torrington, CT, USA) with a 500 mL glass jar. A portion of the homogenate (15.0 ± 0.5 g) was transferred into 50 mL centrifuge tubes, and 20 mL of 0.2% formaldehyde was added along with 50 μL of 2.5 mg/mL chloroacetic acid. The centrifuge tubes were mixed end-over-end on a tube rotator (Glass-Col, Terra Haute, IN, USA) at 70 rpm for 10 min prior to 8 min of sonication (Branson 3510 ultrasonic cleaner, Sigma-Aldrich). The tubes were then centrifuged at 4000 relative centrifugal force (rcf) for 5 min (Marathon 2100R centrifuge, model 120, Thermo Fisher Scientific), and the supernatant was decanted into a 50 mL stoppered graduated cylinder. The extraction steps were repeated on the same sample portion, the supernatant was pooled, and the final volume was brought to 50 mL with the extracting solvent. A 6 mL Bakerbond C_{18} SPE cartridge with a sorbent bed of 500 mg (MG Scientific, Pleasant Prairie, WI, USA) was used to clean up the extract. The cartridges were conditioned by rinsing sequentially with 3 mL portions of methylene chloride, methanol, and 0.2% formaldehyde solution. The extract (2 mL) was passed through the cartridge and the eluent discarded. An additional 2 mL of extract was passed through and collected into a 4 mL clear glass screw cap vial with a solid cap and PTFE liner (Sigma-Aldrich). The vials were heated at 80 °C for 30 min using a DB3 Dri-Block Sample Concentrator from Techne (Staffordshire, UK) and then allowed to cool to room temperature. Samples were prepared for injection by diluting 200 μL of cooled extract with 100 μL of IS working solution (5 ppm) and 700 μL of acetonitrile in a 2 mL glass autosampler vial with a PTFE/red silicone septum cap (Agilent Technologies). After mixing, the vial contents were filtered with a 0.20 μm PTFE filter (17 mm, Thermo Fisher Scientific) into a new vial. Liquid samples were prepared for analysis by weighing 1.00 ± 0.05 g of sample into a 10 mL volumetric flask and diluting to volume with 0.2% formaldehyde solution. The samples were then analyzed in the same manner as the solid samples beginning with the SPE cleanup step and continuing through the heating and filtering steps. For the validation spiking, samples were fortified after grinding but prior to extraction.

LC-MS/MS. An Acquity Ultraperformance LC System (Waters, Milford, MA, USA) equipped with a SeQuant ZIC HILIC analytical

DOI: 10.1021/jf505525z
J. Agric. Food Chem. 2015, 63, 5126−5132

column (150 × 2.1 mm × 5 μm; The Nest Group, Inc., Southborough, MA, USA) was used for separation. The column was thermostated at 30 °C, and a flow rate of 0.30 mL/min was employed. The following 24 min gradient program was used: 6 min hold at 90% mobile phase A (10 mM ammonium acetate in 90:10 ACN/H_2O) and 10% mobile phase B (10 mM ammonium acetate in 50:50 ACN/H_2O), gradient to 50% A in 4 min, 5.75 min hold at 50% A, gradient back to 90% A in 0.25 min, and equilibration at 90% A for 8 min before the next injection. All samples and standards utilized a 5 μL injection volume. An external valve (Valco Instruments Co., Houston, TX, USA) was directed to waste at 0.0, 4.5, and 9.0 min and to the mass spectrometer at 2.0 and 6.5 min.

An AB Sciex 4000 QTRAP mass spectrometer equipped with an electrospray ionization (ESI) source in the negative ion mode was used for analysis. Analyst 1.5.2 (AB Sciex, Foster City, CA, USA) controlled both systems and data analysis. The source parameters were optimized for the HMS transitions. The curtain gas was set to 35 arbitrary units (au), the collisionally activated dissociation (CAD) gas was run at medium, an ion spray voltage of −1200 V was used, the source temperature was 550 °C, gas 1 pressure was 70 au, and gas 2 pressure was 40 au. The MS/MS data were acquired using the MRM mode (unscheduled) with unit resolution of both Q1 and Q3. Table 1 highlights the MS/MS conditions for each monitored transition including the compound ID, dwell time, declustering potential (DP), entrance potential (EP), collision energy (CE), and collision cell exit potential (CXP). There was a 5 ms pause between each transition, and the total scan time was 0.99 s.

Quantitation. A 10-point calibration curve ranging from 0.01 to 4.5 ppm of Na_2SO_3 was generated for the quantitation of sulfite. The curve was created from the MRM ratios of the peak areas of the analyte to the internal standard ($Na_2{}^{34}SO_3$). A quadratic fit with $1/x^2$ weighting was used for the calibration curve due to the 3 orders of magnitude range of standard concentrations. The R^2 values of all curves were >0.990. Concentrations obtained using the calibration curve were adjusted by the appropriate dilution factor (250 for solid samples and 50 for liquid samples) and converted from Na_2SO_3 to SO_2. All values were reported as micrograms of SO_2 per gram of food sample.

Optimized Monier–Williams Method. Six different commercially available sulfited products were analyzed using the optimized MW method (AOAC Method 990.28). Briefly, a volume of 400 mL of 18 MΩ water was added to a 1 L round-bottom flask. A 30% hydrogen peroxide stock solution was diluted 1:10 to give 30 mL of 3% hydrogen peroxide. Three drops of a methyl red indicator were added to the solution, and then 0.01 N NaOH was added dropwise until a yellow end point was reached. This solution was added to a 50 mL graduated cylinder and placed under the bubbler. Nitrogen was bubbled through the entire closed apparatus for 15 min. Fifty grams of sample (both solid and liquid) was added to the round-bottom flask, and the transferring container was rinsed with 100 mL of 5% ethanol. Using the dropping funnel, 90 mL of 4 N HCl was added to the flask. The nitrogen flow was restarted, and the heating mantle (Glas-col, Terre Haute, IN, USA) was turned on to a heating level that produced 80–90 drops/min of condensate from the condenser. The contents of the flask were boiled under these conditions for 105 min. Upon completion of the distillation, the cylinder containing the hydrogen peroxide was removed, and its contents were quantitatively transferred to a 125 mL Erlenmeyer flask. The contents were titrated with either 0.1 or 0.01 N NaOH until the yellow end point was again reached. The volume of titrant needed to reach the end point was recorded. The sulfite content (as μg SO_2/ g food sample) was determined by

$$\text{ppm of } SO_2 = \frac{32.03 \times V_B \times N \times 1000}{w}$$

where 32.03 = milliequivalent weight of SO_2, V_B = volume (mL) of NaOH of normality N required to reach end point, 1000 = factor to convert milliequivalents to microequivalents, and w = weight (g) of sample added to the round-bottom flask.

RESULTS AND DISCUSSION

Method Development. During the early stages of method development, there was no commercially available stable isotopically labeled sulfite, which led to the use of chloroacetic acid as an internal standard. However, chloroacetic acid was not ideal because of its much earlier elution time compared to HMS. During method development, a stable isotope sodium sulfite ($Na_2{}^{34}SO_3$) became commercially available and was added into the method as the internal standard. Although this particular isotopic labeling was not ideal given that approximately 4% of naturally occurring sulfur occurs as the ^{34}S isotope, the calibration curve accounts for this effect, and the use of a true labeled internal standard greatly improved sample quantitation. However, due to the isotope's cost-prohibitive nature, chloroacetic acid remained in the method as a surrogate to identify any significant losses from the extraction process. The chloroacetic acid transitions are not used for quantitation and serve only as a visual check. The chloroacetic acid elutes first at 3.5 min, and HMS elutes at 7.5 min. A sample chromatogram of a 0.4 ppm of Na_2SO_3 (10 ppm of SO_2 in sample) standard is shown in Figure 1.

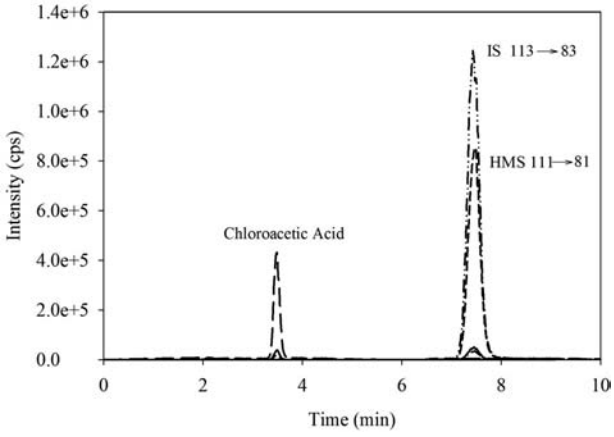

Figure 1. Sample LC-MS/MS chromatogram for a 0.4 ppm of Na_2SO_3 standard with both the chloroacetic acid surrogate and stable isotope internal standard.

Filtration of the extract prior to LC-MS/MS analysis was necessary because a precipitate formed in the autosampler vial for most solid samples after the combination of the cooled extract, IS, and ACN. Initially, an investigation of several types of SPE cartridges was conducted to determine if the precipitation could be prevented. Polystyrene-divinylbenzene, weak anion exchange, strong anion exchange, and primary/secondary amine cartridges from several different manufacturers were examined. Although most resulted in a cleaner extract, none of these cartridges produced consistent sulfite recoveries of >75%. Both the weak anion exchange and strong anion exchange cartridges bound the sulfite too strongly, and no combination of elution solvents could recover the analyte. A mixed-mode cartridge, Isolute HAX (Biotage), yielded high sulfite recovery (>80%) for some matrices, but these results were neither repeatable nor achievable for all required samples. A systematic review of the conditioning and elution solvents did not improve the results. The Bakerbond C_{18} cartridge produced the most consistent and repeatable results and, once coupled with the additional filtering step, produced a clean extract for injection. To determine the best filtering material,

dried potato	88 (5)	87 (12)	89 (17)	94 (5)	93 (16)
dried vegetable mix	92 (11)	89 (5)	89 (7)	91 (7)	87 (13)
bamboo shoots	89 (10)	106 (9)	106 (7)	108 (5)	109 (16)
white grape juice	104 (6)	100 (8)	98 (7)	109 (16)	97 (7)
red wine vinegar	93 (9)	105 (11)	111 (6)	102 (4)	94 (3)
molasses	93 (15)	105 (1)	104 (15)	105 (4)	115 (8)
apricot jam	84 (15)	102 (4)	100 (4)	101 (3)	91 (6)
shrimp	99 (10)	103 (9)	105 (6)	104 (5)	99 (2)

[a] $n = 3$; % RSD is shown in parentheses.

both PTFE and nylon filters (0.20 and 0.45 μm) were evaluated with blank matrix samples, as well as 5 and 10 ppm of Na_2SO_3 spikes. At all three concentrations tested, the PTFE filters resulted in lower sample losses. For this reason, only PTFE filters are used in this method.

Complete conversion of reversibly bound sulfite to free sulfite is necessary for accurate quantitation. Previous studies in wine and apricot have shown that sulfites bind easily with reducing sugars and carbonyls, such as acetaldehyde, galacturonic acid, and glucose.[2,24,25] All of these could potentially be present in the skin and flesh of dried fruits and vegetables. An 8 min sonication step was added in the extraction process to reduce or reverse this binding. The inclusion of this step increased the overall recovery yield in apricot samples. Because there was no indication that its addition would be detrimental to other food matrices, it was permanently added into the method. A heating step was included in the method to ensure that all sulfite−carbonyl adducts remaining after the SPE cleanup were converted to their free form.

On the basis of the large range of samples investigated, slight modifications to the sample preparation method described previously were necessary for a small number of matrices. Solid vegetable samples with low moisture content (i.e., dried potatoes or vegetable mix) formed a thick paste upon the initial addition of extracting solvent making analysis difficult. To avoid paste formation, samples were ground without extracting solvent into a homogeneous powder using the laboratory blender. After grinding, 5 g of the sample was accurately transferred into the 50 mL centrifuge tube, and 30 mL of 0.2% formaldehyde solution was added. The extraction, SPE cleanup, and heating steps were performed in the same manner as described for solid samples. For these matrices, a large amount of precipitate formed with the acetonitrile addition. It was determined that a better cleanup was achieved using a 0.45 μm PTFE filter.

All jam and preserve samples were best analyzed as solid samples. These samples have higher moisture content than the dried fruits and vegetables, so the extracting solvent volume was reduced to 15 mL for both extraction steps. Due to the high lipid content of coconut, after centrifugation three visible layers were present: solid coconut shavings in the bottom of the centrifuge tube, formaldehyde extracting solvent in the middle, and a lipid layer on top. The lipid top layer made pouring off the supernatant difficult. To improve this step, an empty 20 mL reservoir and frit (Agilent) were used to filter the extracting solvent. Additionally, the higher lipid content of the coconut samples necessitated a reduction in SPE extract volume to 1.5 mL. The heating and filtering steps remained the same as detailed previously for the other solid samples.

Two MS/MS transitions were identified for the HMS molecule, but there was some concern as to their validity because the transitions differed by only 1 mass unit. However, previous studies have reported that these two structurally significant product ions are commonly observed during mass spectrometric analysis of sulfonic acids.[26] The MS/MS product ion ratios ranged from 1 to 8% for all of the standards and samples analyzed. For regulatory analyses, all ratios must be within 10% absolute of the value, with a signal-to-noise ratio of >3:1. After several months of analysis with the same column, the peak shape started to degrade and the peaks became extremely broad (>1 min). The column was cleaned using the manufacturer's recommendations: 30 column volumes each of water, 0.5 M NaCl, and water followed by column equilibration. After washing, the peak shape and size returned to their original values.

Initially, a linear regression was used for the calibration curve, but linearity was maintained only over the range from 0.01 to 0.8 μg/mL Na_2SO_3, which equates to a range of 0.25−20 ppm of SO_2 in the food sample. Whereas the 10 ppm of SO_2 regulatory action concentration fits into this range well, there are several foods that commonly contain much more than the 20 ppm of SO_2, which could not be measured with the linear curve. It was found that a quadratic regression maintained a good fit ($r > 0.990$) over the range of 0.25−114 ppm of SO_2, so three additional curve points were added on the upper end. A $1/x^2$ weighting was included to ensure that the lower points on the curve received proper weighting because the curve spanned 3 orders of magnitude.

During analyses of liquid samples, a white powder was observed in the source and on the electrode. The sensitivity also decreased markedly, and the peak shape quickly deteriorated. An external valve was installed to divert the flow to waste when data collection was not necessary. The switching valve was used for all samples, and the white powder was not observed again. Throughout the analysis, the source and the curtain plate were cleaned approximately twice per month during times of heavy analysis.

METHOD VALIDATION

Twelve different matrices representing four commodity categories were selected to determine method accuracy. The four categories investigated included dried fruit (apricot,

DOI: 10.1021/jf505525z
J. Agric. Food Chem. 2015, 63, 5126−5132

coconut, crystallized ginger, and pineapple), dried vegetables (dried potato, dried vegetable mix, and canned bamboo shoots), liquids/sweeteners (white grape juice, red wine vinegar, and molasses), and seafood (shrimp). Each unsulfited matrix was spiked prior to extraction in triplicate at five different SO_2 concentrations (0.5, 5, 10, 20, and 100 ppm of SO_2). Recoveries were determined and are reported in Table 2 along with the relative standard deviation (RSD) for the triplicate measurements. The target values for the percent recovery and the RSD were 80−115 and <16%, respectively. All recoveries in all matrices at all concentrations fell within the desired specifications. The only matrix that did not fall within the target RSD value was the 10 ppm of SO_2 spike with the dried potato. The dried potato and dried vegetable mix samples had among the lowest overall recoveries with 87−94 and 87−92%, respectively. It is believed that these lower values are a result of sample binding, which could produce some irreversibly bound sulfite. The lowest and highest concentration spikes (0.5 and 100 ppm of SO_2) had the largest RSD values on average. At the lowest concentration, the spikes were close to the limit of quantitation for the method, affecting the repeatability. For the 100 ppm of SO_2 spikes, the points lay near the flat portion of the quadratic calibration curve, where small differences in instrument response cause a relatively large variation in the SO_2 value.

One matrix from each category was selected for a stability study. Both the SPE extract and the LC vials were reanalyzed at days 1, 3, and 7. The SPE extract and LC vials were stored at 4 °C and room temperature, respectively. No observable trends or significant differences ($p > 0.05$) were observed for the potatoes or the shrimp. The apricot samples stored in the refrigerator had no significant differences ($p > 0.05$) appear until day 7 of storage, but the samples stored in the autosampler (25 °C) had significant differences for days 1 and 7 ($p < 0.05$). For this reason if any reanalysis needs to be completed, it should be conducted from the cooled SPE extract stored in the refrigerator. The red wine vinegar had no significant differences ($p > 0.05$) except for day 1 with refrigerator storage. Due to these differences in stability, further investigation into other matrices is necessary prior to any attempt to store samples for reanalysis.

Limit of detection (LOD) and limit of quantitation (LOQ) determinations were difficult due to the presence of a blank response in both the matrix and method blanks. The background concentration in the method blanks is due to the presence of sulfite in both the formaldehyde and labeled stable isotope (purity = 95%). Because this background concentration should be consistent for all samples, the standard curve corrects for the increased area. However, all of the samples investigated had an additional concentration of background sulfite. White grape juice had the smallest background with a mean area response of 80 ppb of SO_2. Figure 2 compares the response of a method blank and an apricot blank. An LOD could not be determined for any of the matrices analyzed because sulfite could be detected even in the blank analyses. Because the signal-to-noise ratio is >10 for any injected sample, the LOQ was calculated by analyzing seven blank samples for each matrix studied. The mean (μ_b) and standard deviation (σ_b) of these analyses were calculated, and the LOQ was determined using the following formula: $LOQ = \mu_b + 3.3\sigma_b$. The LOQ was determined for six different matrices to determine the expected range for common sulfite matrices. The matrices selected were white grape juice, molasses, dried potatoes, crystallized ginger, dried apricots, and frozen raw shrimp; results are shown in Table 3. Due to the variation in the mean response (0.08−0.59 ppm), the LOQ varied from 0.12 ppm in white grape juice to 0.75 ppm in dried apricots (Table 3), all of which are >2 orders of magnitude below the Monier−Williams method.

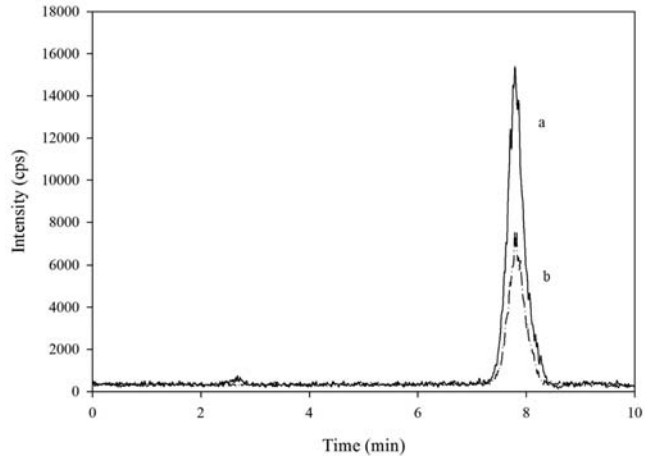

Figure 2. LC-MS/MS HMS transition for (a) a blank apricot sample and (b) a solvent blank sample.

Table 3. Limit of Quantitation (LOQ) in Six Food Matrices

food matrix	blank concentration[a] (ppm of SO_2)	LOQ[b] (ppm of SO_2)
white grape juice	0.08	0.12
molasses	0.36	0.67
dried potatoes	0.17	0.27
crystallized ginger	0.12	0.30
dried apricots	0.40	0.75
frozen raw shrimp	0.59	0.72

[a]Calculated concentration of seven method blanks in food matrix. [b]LOQ was calculated using the following formula: $LOQ = \mu_b + 3.3\sigma_b$, where μ_b is the mean blank concentration for seven method blank replicates and σ_b is the standard deviation for these blanks.

METHOD COMPARISON

Six of the validated matrices (dried pineapple, dried apricot, crystallized ginger, dried potatoes, white grape juice, and raw shrimp) were analyzed in triplicate by both the LC-MS/MS method and the MW distillation to determine differences between the two methods (see Table 4). Dried potato was the only matrix for which there were no significant differences ($p > 0.05$) between the methods. The dried fruit samples (pineapple, apricot, and ginger) tested produced higher values for the MW titration than the LC-MS/MS, whereas the other three matrices investigated produced lower values for the MW titration than the LC-MS/MS. The product labels listed sulfur dioxide as the sulfiting agent for the dried fruit samples, whereas bisulfites and metabisulfites were used in the other products. It is possible that the type of sulfiting agent, along with the physical properties of the food system, may have an effect on the quantitation via the two methods. Further investigation is necessary to determine the cause of this discrepancy.

The relative standard deviations of the analyses for both methods ranged from 1 to 8% for all matrices with the exception of shrimp. The shrimp RSD values were 11 and 28% for the MW and LC-MS/MS methods, respectively. The large

Table 4. Comparison of the Monier−Williams Distillation Method and the LC-MS/MS Method for Sulfite Determination in Six Matrices

food matrix	Monier−Williams titration[a] (ppm of SO_2)	LC-MS/MS (ppm of SO_2)
dried pineapple	266 (4)	207 (8)
dried apricot	2596 (3)	2051 (4)
crystallized ginger	227 (8)	168 (4)
dried potatoes	58 (3)[b]	54 (6)
white grape juice	74 (1)	84 (4)
raw shrimp	50 (28)	94 (11)

[a]n = 3; % RSD is shown in parentheses. [b]Dried potato is the only matrix with no significant differences between methods by a two-sample t test ($p > 0.05$).

variation in sulfite concentration in lots of shrimp may account for the differences observed between the methods. Hardisson et al.[27] investigated the sulfite concentration of frozen prawns from Spain and Venezuela and reported large ranges, values ranging from 12.8 to 546 ppm sulfite. Similar concentration variation was reported by Iammarino et al.[14] for shrimp samples collected over a four year timespan of 2009−2012, and the authors reported that due to the sulfite application process used for shrimp, the residual amount of sulfite present can vary greatly. Therefore, the range found in shrimp in this comparison could be expected.

The LC-MS/MS method presented here can be used in determining sulfite concentrations in a wide range of food and beverage matrices, and the sensitivity limitations of other published sulfite methods have been eliminated. Sulfite concentrations between 0.5 and 1.0 ppm of SO_2 can be detected in most matrices. The sample preparation involves basic extraction techniques and allows for as many as 30 samples to be completed by a single analyst in a single day. This method will be a useful tool for food safety laboratories to monitor sulfite concentrations in foods to ensure compliance with U.S. regulations. Further investigation is needed with this method to determine the rate of false positives in those matrices that contain a high quantity of endogenous sulfur compounds such as *Allium* and *Brassica* vegetables.

ABSTRACT: This study involved the development of a multiresidue method for the rapid analysis of 43 antibiotics in meats using ultrahigh-performance liquid chromatography–tandem mass spectrometry. This method was performed using dispersive-solid phase extraction, which is able to analyze 20 samples within 2 h. All compounds were determined simultaneously on a C18 separation column with gradient elution. Validation of the analytical method was performed by carrying out linearity, limit of quantification (LOQ), accuracy, precision, and recovery tests in different meat products. The validation criteria were set according to AOAC International and Japanese validation guidelines. The linearity of each compound was almost the coefficient of determination (r^2) > 0.98. The LOQs of all tested antibiotics were <10 μg/kg. The results verify that this method is capable of quantitative analysis of 36, 33, and 37 compounds in beef, pork, and chicken, respectively. This method can be used for rapid and easy multiresidue screening of antibiotics for three meats (pork, beef, and chicken).

INTRODUCTION

Antibiotics have been widely used globally for the treatment and prevention of infectious diseases in fishery products to maintain and improve productivity and quality. Some antibiotics are also used as growth-promoting agents in animal feed.[1,2] However, the use of these compounds as feed additives for growth promotion has been banned in the European Union (EU).[3] National agencies and international organizations, such as the Joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives, establish limits on the residue levels of veterinary drugs that are allowed to be present in food of animal origin so that consumers are not exposed to unacceptable levels. Levels are set using risk-based assessments from pharmacokinetic, metabolic, toxicity, and carcinogenicity data.[4,5] It is suggested that if incorrect usage and inadequate withdrawal periods are used, then antibiotic residues in food products may become a health hazard in humans.[6,7]

To monitor chemical residues, food products are checked at various steps of the distribution chain, such as farmers, exporters, importers, supermarkets, and governmental intervention. Thus, many analytical laboratories analyze residual antibiotics using various analytical methods: a simple and rapid analysis method is required to not only reduce time, cost, and labor but also to produce a standard analysis procedure enabling direct comparisons between the results of different laboratories. Numerous methods have been published to analyze antibiotics in foodstuff, and these methods usually involve several steps, such as extraction, concentration, separation, and purification.[8−17] We have developed an easy and rapid multiresidue method that can determine a wide range of residual antibiotics in meat samples using ultrahigh-performance liquid chromatography–tandem mass spectrometry (UHPLC-MS/MS).

The objective of our study was to develop a fast, reliable, easy, and robust analytical method to determine residual antibiotics in hundreds of meat samples for use in developing countries, which often do not have adequate fundamental logistical support: basic equipment, such as a vacuum system or glassware with precise graduation, may not be available even though outstanding and expensive instruments have been provided by developed countries. The proposed method was based on our previous study[18] and involved extraction and dispersive solid phase extraction (SPE) using the C18 particle, without liquid–liquid partition and evaporation after clean-up.[19−24]

MATERIALS AND METHODS

Samples. Chicken, pork, and beef muscles were purchased from retail stores in Osaka, Japan. Fat was removed from the samples as much as possible before they were minced using a food processor (MK-K61, Panasonic, Japan) at room temperature and stored in polypropylene bags at −20 °C until analysis. We confirmed the meat samples did not contain any of the antibiotics being analyzed in our study before their use in the validation tests.

[a]Retention time. [b]β-Lactam group. [c]Quinolone group. [d]Macrolide group. [e]Sulfonamide group.

Chemicals. Kitasamycin (leucomycin hydrate), mecillinam, and oleandomycin phosphate dehydrate were purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany). Nafcillin sodium salt monohydrate, neospiramycin, and spiramycin were purchased from Hayashi Pure Chemical Industries (Osaka, Japan). Danofloxacin mesylate, penicillin G sodium, sulfamethoxazole, sulfamerazine, sulfamethazine (sulfadimidine), sulfamonomethoxine, sulfamethoxypyridazine, sulfachlorpyridazine, sulfaquinoxaline, sulfadoxine, sulfadimethoxine, and josamycin were purchased from Kanto Chemical (Tokyo, Japan). Ampicillin trihydrate, cloxacillin sodium salt hydrate, dicloxacillin sodium salt hydrate, oxacillin sodium, penicillin V potassium salt, suflapyridine, diaveridine, erythromycin A dehydrate, and lincomycin hydrochloride hydrate were purchased from Riedel-de Haën (St. Louis, MO, USA). Aspoxicillin and orbifloxacin were purchased from Fluka (St. Louis, MO, USA). Norfloxacin and sulfaclozine were purchased from Sigma-Aldrich (St. Louis, MO, USA). Ciprofloxacin, enrofloxacin, ofloxacin, marbofloxacin, sarafloxacin, difloxacin, trimethoprim, and thiamulin fumarate were purchased from Wako Pure Chemicals Industries (Osaka, Japan). Pirlimycin, mirosamicin, tilmicosin, and tylosin were provided by the Japan Scientific Feeds Association (Tokyo, Japan). Acetonitrile and methanol, used in the preparation of test solutions and stock solutions, were of pesticide analytical grade; acetonitrile and formic acid were of LC-MS and LC grade, respectively (Wako Pure Chemicals Industries). Purified water was obtained using a Millipore system (Elix advantage 3 and Milli-Q advantage, Merck Millipore, Billerica, MA, USA). Dispersive SPE BONDESIL-C18 (C18) was purchased from Agilent Technologies (Santa Clara, CA, USA).

Sample Extraction. A 2 g aliquot of each sample was weighed in a 50 mL polypropylene tube. A 10 mL aliquot of acetonitrile/water

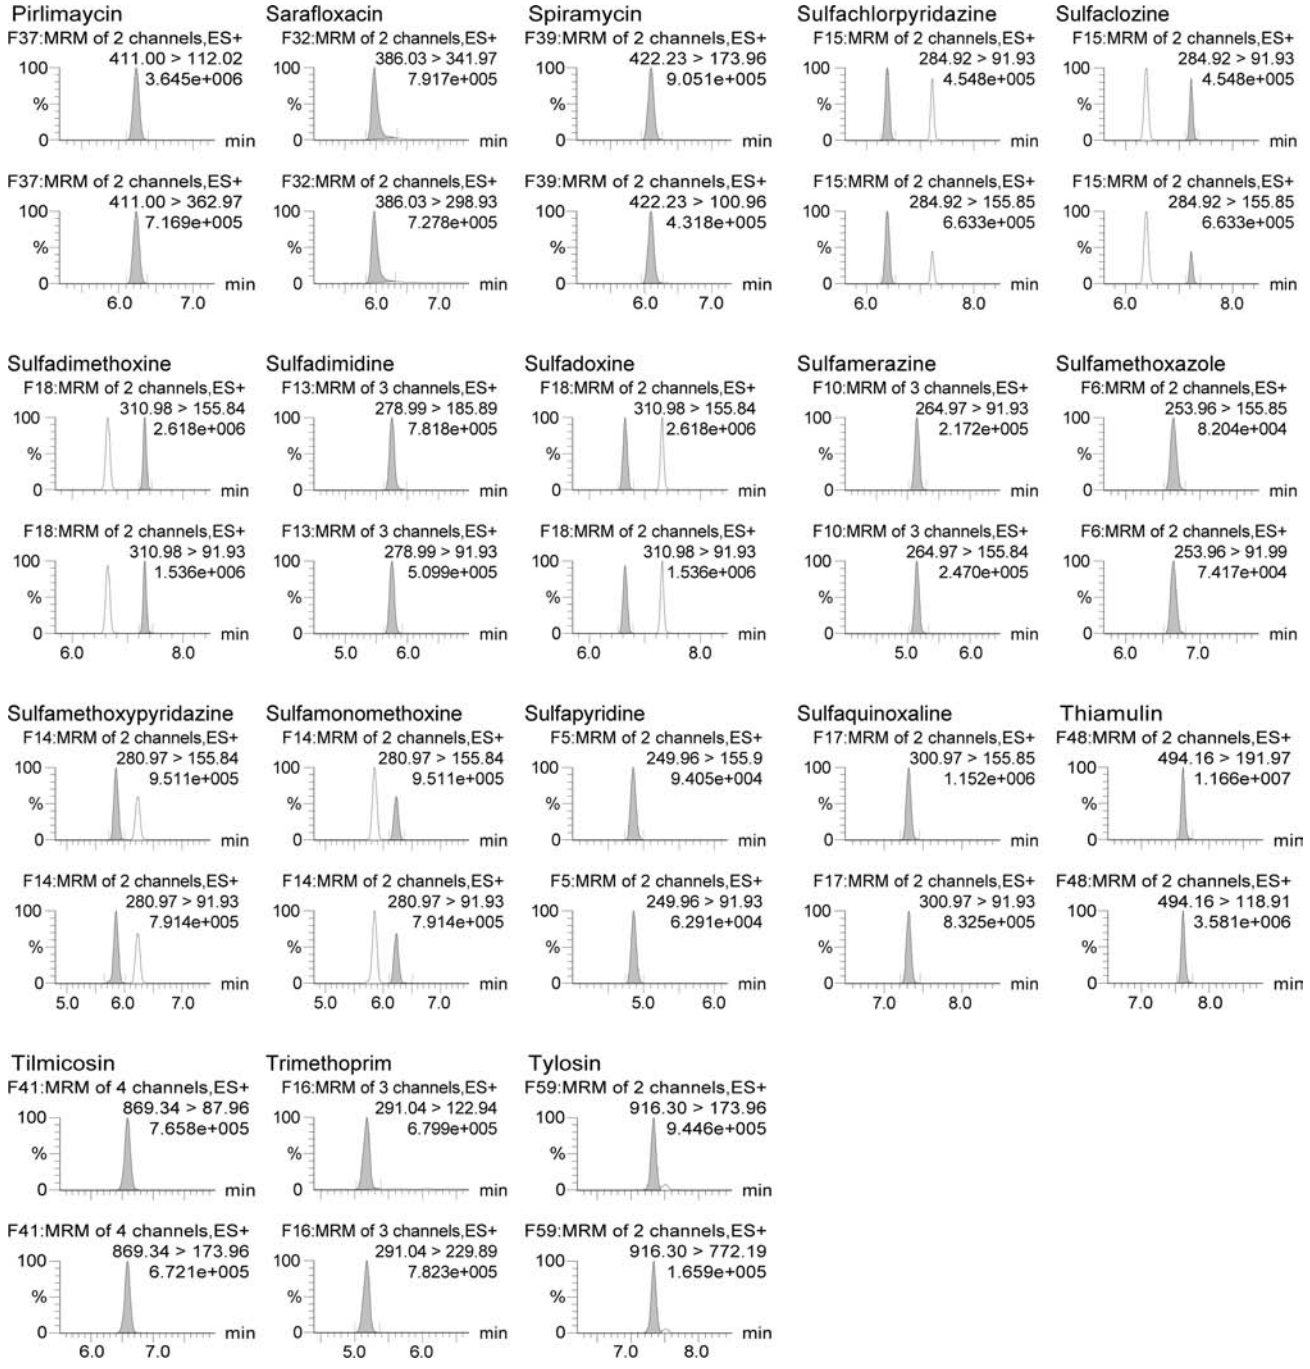

Figure 1. Chromatograms of standard solutions (10 ng/mL).

(4:1) solution was then added and homogenized using a blender (20,000 rpm, 1 min) (PT3100, Kinematica AG, Luzern, Switzerland). The sample was centrifuged using a himac CF7D2 centrifuge (Hitachi Koki, Ibaragi, Japan) at 1500*g* for 5 min, and the supernatant was poured into a 15 mL polypropylene tube containing 0.3 g of dispersive C18. The supernatant was then shaken for 1 min and centrifuged at 1500*g* for 5 min. An aliquot of 1 mL was taken and diluted with 1 mL of distilled water. The extract was filtered through a PTFE membrane filter (Advantec, Tokyo, Japan). This final extract corresponded to 0.1 g/mL sample equivalent.

Determining the Required Amounts of Dispersive SPE. The required amount of C18 particles was examined as follows: 40 g of pork was homogenized with 200 mL of acetonitrile/water (4:1) solution. Ten mililiters of extract solution was then mixed with 0, 0.1, 0.2, 0.3, 0.4, and 0.5 g of C18 particles or 10 mL of hexane, shaken for 1 min, and centrifuged at 1500*g* for 5 min. Each 7 mL of supernatant was placed on an aluminum weighing dish and heated at about 100 °C for 2 h in an incubator; dried residues were weighed after cooling to measure the amount of coextractives.

Instruments and Analytical Methods. UHPLC-MS/MS analysis was performed using a Waters ACQUITY UPLC i-class interfaced with a TQ-S (Milford, MA, USA). Waters Cortecs C18 columns (100 × 2.1 mm i.d., 1.6 μm) with ACQUITY UPLC BEH C18 precolumns (5 × 2.1 mm, 1.7 μm, Waters) were used for chromatography. The column temperature was maintained at 40 °C. Sample injection volume was 2 μL, mobile phases A and B were water with 0.1% formic acid and acetonitrile, respectively. Selected operating parameters were as follows: capillary voltage, 3 kV; desolvation temperature, 400 °C; desolvation gas, 1000 L/h; cone gas, 150/h; and collision gas, 0.15 L/min. Antibiotic analytes were resolved using a gradient program as

DOI: 10.1021/acs.jafc.5b00170
J. Agric. Food Chem. 2015, 63, 5133−5140

follows: 5−10% B (3 min), 10−95% B (9 min), 95% B (3 min), 95−5% B (0.5 min), 5% (3.5 min). The mass spectrometer was operated in the positive electrospray ionization (ESI+) mode. MS/MS detection was selected for multiple reaction monitoring (MRM). Information on the monitored ions and chromatograms is presented in Table 1 and Figure 1.

Stock Standard Solutions. Four milligrams of each standard was weighed in a glass bottle and then transferred to a 20 mL glass volumetric flask and dissolved in methanol. Purified water was used if the standard was insoluble in methanol. Standards, except β-lactam antibiotics, were stored in 15 mL polypropylene tubes at −20 °C until required. β-Lactam antibiotic standards were stored at −80 °C and prepared every 3 months.[25]

Intermediate and Working Standard Solutions. Intermediate standards were prepared from stock standard solutions (200 μg/mL) for each category. Individual intermediate standard solutions (10 μg/mL) for sulfonamides, quinolone, and macrolide antibiotics diaveridine and trimethoprim were prepared using methanol in polypropylene tubes and stored at −20 °C. The same concentration of β-lactam mixture was prepared using distilled water. Working standard solutions were prepared by mixing the intermediate standards to produce concentrations of 0.5, 1, 5, 10, 20, and 50 ng/mL using acetonitrile/water (4:6) and stored at 4 °C before use.

Method Validation. Validation was established according to the guidelines of AOAC International and the Japanese Ministry of Health, Labor and Welfare.[26,27] Method validation was carried out by performing linearity, limit of quantification (LOQ), accuracy, precision, and recovery tests. Repeatability (RSD_r) and within-laboratory reproducibility (RSD_R) precision values for two spiking levels were calculated by one-way analysis of variance (ANOVA).

RESULTS AND DISCUSSION

Method Development. This method intended to provide an easy and rapid multiresidue screening method with the ability to determine a wide range of residual antibiotics in meat samples. Conventional instruments have decreased sensitivity, and sample solutions need to be purified to eliminate interferences before injection and purification steps, such as liquid−liquid partition and column cleanup followed by concentration, which are time-consuming. Novel instruments have very high sensitivity and require very small amounts of sample for analysis,[28] due to less interference and reduced sample purification procedures. Dispersive SPE is a very simple cleanup approach.[29−32] In this study, we used C18 sorbent to remove coextractives. An acetonitrile/water (4:1) solution was chosen for extraction because it efficiently extracts polar components and deproteinizes.[19,33] This solution was convenient for dispersive SPE with C18 and suitable for UHPLC-MS/MS analysis after dilution with water. The entire procedure can be performed without evaporation. In comparison with hexane partitioning, 0.1−0.2 g of C18 produced similar amounts of residue, whereas 0.3−0.5 g of C18 showed a gradual decrease in residue recovery (Figure 2). We also examined recovery of antibiotics in the cleanup steps described above: 10 mL of extract solution was mixed with 0, 0.1, 0.2, 0.3, 0.4, and 0.5 g of C18 particles or 10 mL of hexane, shaken for 1 min, and centrifuged at 1500*g* for 5 min. An aliquot of 1 mL was then diluted with 1 mL of distilled water before UHPLC-MS/MS analysis. Recovery tests for the antibiotics produced similar results: about 40 compounds showed from 70 to 120% recovery at each cleanup step. Considering the cost and interference removal efficiency, 0.3 g of C18 was adopted for the cleanup step.

Validation of Target Compounds. Validation was performed by determining the parameters of a calibration curve, LOQs, precision, and accuracy.

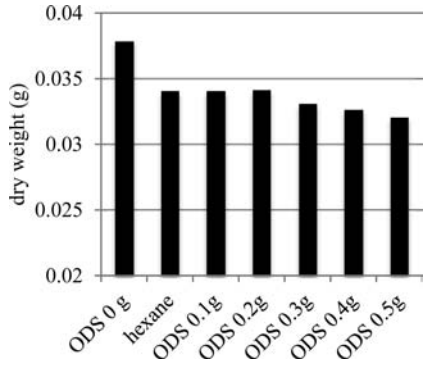

Figure 2. Comparison of the dried weight of extracts after defatting, hexane partitioning, and dispersion with various amounts of C18 particles.

The concentration of the spiked samples was calculated from matrix-matched standards. The resulting coefficient of determination (r^2) values were >0.99 for almost all target compounds, except sulfapyridine and sulfadoxine, which were >0.98. The LOQs were estimated from the signal-to-noise ratio (S/N) (Table 2). S/N was determined at the peak height of beef, pork, and chicken samples spiked with 1 ng/mL target compounds. The background noise was estimated near each analyte peak. Precision and accuracy were performed according to the guidelines of AOAC International and the Japanese Ministry of Health, Labor and Welfare.[26,27] Recovery tests of 43 antibiotic residues from beef, pork, and chicken were performed at two different concentration levels, 10 and 100 μg/kg, in duplicate by three persons on two separate days. No interfering peaks were detected near the retention time of the analytes. The validation data were evaluated on the basis of recoveries of 70−125%, RSD_r of <15%, and RSD_R of <15% for two spiking levels upon recommendation of AOAC International and the Japanese government.[26,27] The results of recovery, RSD_r, and RSD_R precision values are shown in Table 2. All compounds were evaluated at the level of 10 μg/kg LOQs.

The number of compounds that met the criteria were 36, 33, and 37 for beef, pork, and chicken, respectively. Sulfamethoxazole failed to comply with the criteria in all samples. Diaveridine and sulfapyridine complied with the criteria in pork only. Aspoxicillin met with criteria in chicken only. Sarafloxacin and sulfamerazine met with criteria in beef only. Aspoxicillin and sulfaclozine failed to comply with the uniform limit only in beef. Spiramycin failed to comply with the uniform limit only in chicken.

Ciprofloxacin, danofloxacin, difloxacin, enrofloxacin, and sarafloxacin failed to comply with the criteria in pork because the results of the recovery test at a level of 10 μg/kg were <70%; in addition, penicillins G and V failed to comply with the RSD_r criteria standard.

Quinolone was speculated to affect the pork matrix due to the low spiked concentration on recovery.

Our results suggest this method is capable of quantitative analysis of 36, 33, and 37 antibiotic residues in beef, pork, and chicken, respectively. This method is considered to be capable of performing more efficient monitoring of antibiotic residues in meat, and it is possible to simultaneously process a large number of samples without evaporation. This analysis method is specialized for convenient screening, particularly in laboratories with reduced equipment, if they have UHPLC-MS/MS. This method is considered to facilitate contamination

ABSTRACT: A monitoring plan of residual antibiotics in food of animal origin was conducted in Vietnam from 2012 to 2013. Meat samples were collected from slaughterhouses and retail stores in Ho Chi Minh City and Nha Trang. A total of 28 antibiotics were analyzed using a LC-MS/MS screening method. Sulfonamides, fluoroquinolones, and tilmicosin were detected in some of the samples. Sulfaclozine and fluoroquinolones were mainly detected in chicken samples, and sulfamethazine was mainly detected in pork samples. High levels of sulfonamide residues, ranging between 2500 and 2700 μg/kg sulfaclozine and between 1300 and 3600 μg/kg sulfamethazine, were present in two chicken and three pork samples, respectively. Tilmicosin was detected at ranges of 150−450 μg/kg in 10 chicken samples. Positive percentages were 17.3, 8.8, and 7.4% for chicken, pork, and beef, respectively, for an average of 11.9%. The results suggest an appropriate withdrawal period after drug administration had not been observed in some livestock.

KEYWORDS: *residual antibiotics, Vietnam, food, liquid chromatography−tandem mass spectrometry*

INTRODUCTION

Antibiotics have been widely used in the treatment and prevention of infectious diseases to maintain and improve quality in livestock and fisheries.[1,2] Advanced nations and national organizations set limits, using risk-based assessments,[3,4] for residual levels of veterinary drugs so that consumers are not exposed to unacceptable levels of residues in foods of animal origin. The European Union (EU) establishes maximum residue limits (MRLs) for antibiotics in food, and the use of these compounds as feed additives for growth promotion is banned.[5] Production of livestock and fisheries is increasing with rapid population growth in developing countries. It is suggested that the management of antibiotics is insufficient in advancing countries.

Vietnam's economic influence in Asia is emerging as its GDP growth has exceeded 5% over the past 25 years.[6] There are nearly 90 million inhabitants, and it is the world's 13th most populated country.[6] The production quantity of indigenous meats (pork, beef, and chicken) increased by 90% from 2002 to 2012.[7] Pork is the main meat food in Vietnam: in 2012, it accounted for about 80% of the production quantity. There is a complex farming style in Vietnam, the so-called "VAC (Vuon, Ao, Chuong = field, pond, stockyard) system" that consists of agriculture, aqua farming, and stockbreeding.[8] In this system, each byproduct of one farming method is used for the other farming methods, such as for feed or fertilizer. This style has promoted many small stockbreeding farms, and it is difficult to regulate the use of antibiotics on the many small farms.

Resistant bacteria carriers are rapidly increasing in Asia,[9,10] particularly in Vietnam, where there are higher carriage ratios compared with other countries. Currently, 42% of the population carry drug-resistant bacteria, which leads to growing concerns over further diffusion.[11] The threat of resistant bacteria has been caused by the abuse of antibiotics in medicines and in stockbreeding and aqua farming.[12−14] Residual antibiotics in food and the spread of resistant bacteria are a cause for concern in human health and the environment.[15,16] Therefore, we investigated residual antibiotics in meats at Ho Chi Minh City (HCM) and Nha Trang (NT). All samples were transferred to the Institute of Public Health, Ho Chi Minh City, for analysis using a liquid chromatography−tandem mass spectrometry (LC-MS/MS) method. We discuss the risk to human health from residual antibiotics in meat from Vietnam.

MATERIALS AND METHODS

Chemicals. Sulfachlorpyridazine, sulfaclozine (sulfachlorpyrazine), sulfadimethoxine, sulfamerazine, sulfamethazine (sulfadimidine), sulfa-

oxacillin, penicillin G, penicillin V, spiramycin, tilmicosin, trimethoprim, and tylosin were purchased from Fluka (St. Louis, MO, USA). A dispersive solid-phase extraction (SPE) BONDESIL-C18 (C18) was purchased from Agilent Technologies. (Santa Clara, CA, USA). High-performance liquid chromatography (HPLC) grade acetonitrile was purchased from Scharlau (Barcelona, Spain), and formic acid was from J. T. Baker (Avantor Performance Materials, Center Valley, PA, USA). Membrane filter (PTFE, 3 mm ⌀, 0.2 μm) was obtained from Agilent.

Ultrapure water was made using an EASY pure II system (Thermo Fisher Scientific Inc., Waltham, MA, USA).

Samples. About 50 g–1 kg of samples was obtained from slaughterhouses and retail stores in HCM from October 2012 to December 2013 and a central market of NT, which contained about 400 small shops including over 50 butchers in July 2013. A total of 68 beef samples consisting of 65 meat and 3 internal organs (heart, nerve, stomach), 171 pork samples consisting of 160 meat and 11 liver, and 156 chicken samples consisting of 148 meat and 8 liver were analyzed. Samples were minced, mixed, and stored in polypropylene bags at −20 °C until analysis.

Stock Standard Solutions. Individual stock standard solutions (200 μg/mL) of sulfonamides, fluoroquinolones, and macrolide antibiotics and trimethoprim were prepared in methanol using polypropylene volumetric flasks and stored in the freezer at −20 °C until use. The same concentration of β-lactam antibiotics was prepared using distilled water and stored in the refrigerator at 4 °C for no more than 2 weeks.

Sample Preparation. Samples were prepared according to our method for LC-MS/MS[33] and previous analytical reports.[17,18] A 2 g aliquot of each sample was weighed in a 50 mL polypropylene tube before 10 mL of an acetonitrile/water (4:1) solution was added and homogenized for 30 s at high- speed (20000 rpm) using a blender (PT1300 D, Kinematica AG, Luzern, Switzerland) at room temperature. The sample was centrifuged (Universal 320R, Hettich GmbH & Co. KG, Tuttlingen, Germany) at 1500*g* for 5 min, and the supernatant was poured into a 15 mL polypropylene tube containing 0.3 g of dispersive C18. The supernatant was shaken for 1 min and centrifuged at 1500*g* for 5 min. A 1 mL aliquot was taken and diluted with 1 mL of distilled water. The extract was then filtered through a PTFE membrane filter. This final extract corresponded to a 0.1 g/mL sample equivalent.

Instruments and Analytical Methods. LC-MS/MS analysis was performed using a Prominence UFLC (Shimadzu, Kyoto, Japan) interfaced with an API-5500QTRAP (AB SCIEX, Framingham, CA, USA). The antibiotics were separated in Luna C18 columns (100 × 3 mm i.d., 2.5 μm) (Phenomenex, Torrance, CA, USA) with Alltima HP C18 precolumns (5 × 4.6 mm i.d., 5 μm, Thermo Fisher Scientific Inc.), using a binary gradient system (solvent A, 0.1% formic acid in water; solvent B, acetonitrile), at a flow rate of 0.4 mL/min. Analytes were quantified by multiple reaction monitoring (MRM) using positive electrospray ionization mode. Column temperature was maintained at 40 °C, and the sample injection volume was 5 μL. The antibiotic analytes were resolved using a gradient program, as follows: 5% solvent B at 0.2 mL/min increased to 95% over 10 min and maintained at 95% solvent B for 8 min. Details of the ions monitored are presented in Table 1. LOQs were confirmed to be >10 times the signal-to-noise ratio for the peak intensity of each compound at 10 μg/kg except tilmicosin, which was confirmed to be 10 times more signal-to-noise at 100 μg/kg. The instrument was calibrated every 3 months, and a blank meat sample and six fortified samples were analyzed with every batch of analysis.

RESULTS AND DISCUSSION

Residual antibiotics were detected with an average of 11.9% in the samples analyzed, particularly 17.3, 8.8, and 7.4% in chicken, pork, and beef, respectively (Table 2). Sulfaclozine was detected in chicken samples from HCM but not NT and was not detected in beef or pork samples from either city. Sulfamethazine, enrofloxacin, and tilmicosin were detected in samples from both cities, but difloxacin and norfloxacin were found only in one particular region, suggesting an isolated use of these antibiotics.

In the case of chicken, detected percentages (number of detects/total number of samples analyzed) ranged from 11.9 to 25.0% from each site. The detected percentage of sulfaclozine was comparable between retail stores and slaughterhouses in HCM, and nearly a fourth of chicken samples contained antibiotics. Tilmicosin was detected in 10 samples, 5 each from HCM and NT. Three types of fluoroquinolones were detected in chicken, and its detected percentages were <5%. Only sulfamethazine was detected in pork, and its detected percentages ranged from 3.5 to 17.9% for each site. Samples from HCM stores showed approximately 3 times higher residual

DOI: 10.1021/jf505254y
J. Agric. Food Chem. 2015, 63, 5141–5145

antibiotic percentages compared with samples from slaughterhouses. NT samples had lower residual antibiotic percentages compared with HCM samples. In the case of beef, detected percentages were 0% (slaughterhouse) and 13.2% (stores). In Vietnam, consumption of beef is lower than chicken and pork, and it is not a major import. Beef samples from slaughterhouses contained no antibiotics because they were imported from Australia as live cattle. Some of the samples from stores contained low levels of residual antibiotics, and it was thought that they were domestic.

The concentration of detected antibiotics and their MRLs for the EU and Japan are summarized in Figure 1. Sulfaclozine,

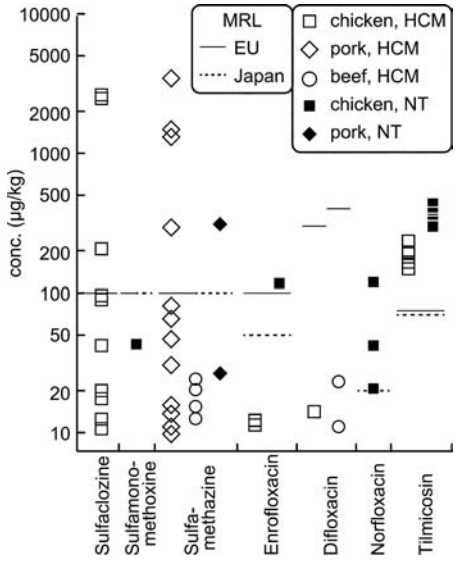

Figure 1. Concentrations of detected antibiotics and their maximum residue limits (MRL) in EU and Japan. Solid and broken lines represent MRLs established by EU and Japan, respectively, and their vertical levels correspond to legislated concentrations.

sulfamonomethoxine, enrofloxacin, norfloxacin, and tilmicosin were detected in chicken, sulfamethazine was detected in pork and beef, and difloxacin was detected in chicken and beef. Although there are no MRLs for these detected antibiotics in each food in Vietnam, 17 chicken samples and 5 pork samples would be illegal if they were found in the EU or Japan.

Chicken samples from HCM were collected on five separate occasions. In March 2013, high amounts of sulfaclozine were detected in 5 of 10 samples, ranging from 93 to 2710 μg/kg. On other occasions, lesser amounts of sulfaclozine were detected in samples collected, ranging from 11 to 44 μg/kg. Sulfamethazine was frequently found in pork samples, especially from HCM. Pork samples were collected seven times from HCM. In August 2013, samples from slaughterhouses and retail stores showed very high amounts of sulfamethazine, ranging from 1350 to 3560 μg/kg. Two samples from HCM and NT also showed high amounts of sulfamethazine, around 300 μg/kg.

We revealed that residues of two sulfonamides were present in meat at high concentrations and high frequency. Sulfaclozine was developed as an antibiotic for poultry coccidiosis and specific bacterial diseases in 1967.[19] Since the first report of sulfamethazine's synthesis in 1941, it has been used in the treatment of bacterial pneumonia, cervical abscesses, and bacterial swine enteritis.[20,21] In addition, sulfamethazine has been detected in water in the Mekong Delta area,[22] suggesting sulfamethazine is a popular antibiotic for Vietnamese farmers. According to reports studying residue depletion, residual levels of sulfaclozine in chicken and turkey were <100 μg/kg after 14 and 21 days, respectively, when a dose of 50 mg/kg body weight/day had been administered orally for 3 days.[23,24] Residual levels of sulfamethazine in pork were <100 μg/kg after 8 days, when a dose of 110 mg/kg feed had been administered orally for 3 days.[25] It is suspected that some farmers do not pay attention to residual antibiotic levels or that there is a lack of understanding about the required withdrawal period after antibiotics have been administered. Sulfaclozine, enrofloxacin, and tilmicosin were also found in a report of chicken jerky dog treats that were imported to the United States from China.[26] It is suggested that these antibiotics are commonly used in Vietnam and China.

The detected percentages of antibiotics in this study were higher than the results presented in the 2008−2012 Osaka, Japan, report, which revealed an 0.8% (1/1183) level,[27] and the 2012 EU monitoring program showing positive sample percentages of 0.13% (60/46905), 0.20% (61/25240), and 0.12% (23/18412) in pork, beef, and poultry, respectively.[28]

Antibiotics are available for use in livestock without prescription, and imported products sometimes lack instructions in local languages. The publicity for careful use of antibiotics is also insufficient in most developing countries.[29] In Vietnam, widespread resistant bacteria may have arisen from abuse of antibiotics during animal husbandry.[30] Coexistence of enteric bacteria in the intestinal tracts of animals and humans facilitates the transfer of antibiotic-resistant genes between commensal and pathogenic bacterial species.[31,32] In this study, residual antibiotics were frequently detected in chicken and pork, and some samples showed high amounts. Pork and chicken are often eaten in Vietnam, suggesting inhabitants will consume low levels of antibiotics, which may increase the occurrence of resistant bacteria. This presents a challenge to reduce exposure and control the use of antibiotics because most agriculture in Vietnam is contributed by small, family farms. We recommend better education and greater regulation of the farmers in Vietnam.

Method for the Detection of Desmethylbromethalin in Animal Tissue Samples for the Determination of Bromethalin Exposure

Michael S. Filigenzi,* Adrienne C. Bautista, Linda S. Aston, and Robert H. Poppenga

California Animal Health and Food Safety Laboratory System, Toxicology Laboratory, University of California, Davis, California 95616, United States

ABSTRACT: Bromethalin, a potent neurotoxin, is widely available for use as a rodenticide. As access to other rodenticides is reduced due to regulatory pressure, the use of bromethalin is likely to increase with a concomitant increase in poisonings in nontarget animals. Analytical methods for the detection of bromethalin residues in animals suspected to have been exposed to this rodenticide are needed to support post-mortem diagnosis of toxicosis. This paper describes a novel method for the analysis of desmethylbromethalin (DMB), bromethalin's toxic metabolite, in tissue samples such as liver, brain, and adipose. Samples were extracted with 5% ethanol in ethyl acetate, and an aliquot of the extract was evaporated dry, reconstituted, and analyzed by reverse phase ultrahigh-performance liquid chromatography–mass spectrometry. The mass spectrometer utilized electrospray ionization in negative ion mode with multiple reaction monitoring. This method was qualitatively validated at a level of 1.0 ng/g in liver tissue. The quantitative potential of the method was also evaluated, and a method detection limit of 0.35 ng/g wet weight was determined in fat tissue. DMB was detected in tissue samples from animals suspected to have been poisoned by this compound. To the authors' knowledge, there have been no other methods reported for analysis of DMB in tissue samples using LC-MS/MS.

KEYWORDS: *bromethalin, desmethylbromethalin, electrospray, LC-MS/MS, poisoning*

INTRODUCTION

Bromethalin (Figure 1a) is a substituted diphenylamine used for rodent control. It is widely available to the general public in a variety of formulations. Bromethalin was developed from an analogue that was originally considered for use as a fungicide, but which was determined to be overly toxic for that purpose. Desmethylbromethalin (DMB; Figure 1b) was determined to be an effective rodenticide; however, low palatability in wild rats required the addition of a methyl group to eliminate an acidic proton.[1] This resulted in the commercial product that is used currently.[2]

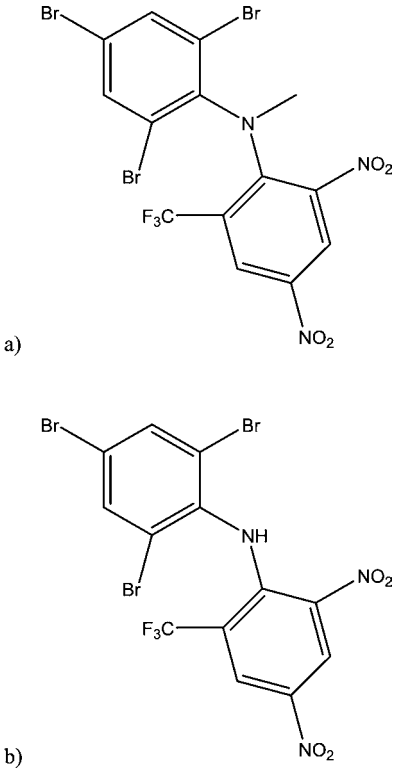

Figure 1. Structures of (a) bromethalin and (b) DMB.

Commercially available as 0.01% bait pellets, bars, and place packs, the rodenticide bromethalin selectively targets the nervous system. Following ingestion, bromethalin is metabolized by the liver to DMB, the active metabolite. Desmethylbromethalin uncouples mitochondrial oxidative phosphorylation leading to decreased cellular adenosine triphosphate production and disruption of sodium–potassium ATPase pumps.[3] With decreased activity of the ATPase pumps, the central nervous system (CNS) no longer maintains a normal sodium–potassium gradient, leading to fluid buildup inside the CNS and subsequently the development of cerebral edema and increased cerebrospinal fluid pressures.

Clinical signs of intoxication, including muscle tremors, hyperthermia, hyperexcitability, and focal or generalized seizures, which have been observed in rodents, cats, dogs, monkeys, and other wildlife such as raccoons, usually develop within 24 h after ingestion of bromethalin at or above the median lethal dose.[2,3] At concentrations below the median

lethal dose, lethargy, hind limb weakness, and/or paralysis can develop several days after exposure.[4]

Documented oral median lethal doses range from as low as 1.8 mg/kg in the cat to as high as 13 mg/kg in the rabbit with dogs and monkeys falling in between at around 5 mg/kg.[2] Bromethalin poisonings have been documented in nontarget animals[5−7] and in one fatality in a human.[8]

Recently, the U.S. EPA has canceled the registrations of a number of second-generation anticoagulant rodenticide formulations.[9] There are relatively few alternative commercially available rodenticides, and it is highly likely that bromethalin use will increase along with the attendant nontarget poisonings. Therefore, a reliable method of determination of bromethalin and/or its metabolites in tissue samples is critical for confirmation of bromethalin exposure and toxicosis postmortem. The distribution and accumulation of bromethalin and DMB in adipose tissue are expected on the basis of their octanol−water partition coefficients (log P values) of 6.70 and 4.26, respectively. Consequently, adipose tissue may serve as the best diagnostic sample[7] and could easily be harvested ante- or post-mortem.

Bromethalin rapidly metabolizes to DMB.[2] Thus, the ability to detect DMB would serve as confirmation of exposure to the neurotoxic rodenticide bromethalin. This is particularly important in cases in which there is no history of exposure to the rodenticide.

MATERIALS AND METHODS

HPLC grade methanol, water, acetonitrile, ethyl acetate, and formic acid were obtained from Fisher Scientific (Pittsburgh, PA, USA). Anhydrous USP grade ethanol (Koptec brand) was obtained from VWR (Radnor, PA, USA).

Analytical Standards. Bromethalin (99.3%) was obtained from the U.S. Environmental Protection Agency National Pesticide Standard Repository (Fort Meade, MD, USA). DMB (98%) was obtained from Toronto Research Chemicals (Toronto, ON, Canada).

Control Matrices. Fresh control bovine adipose tissue was obtained from animals submitted to the California Animal Health and Food Safety Laboratory for necropsy. Fresh control liver tissue was purchased from a local market. Control samples were tested to ensure that no detectable DMB was present and were stored at −20 °C.

Extraction of DMB from Tissue. One gram of tissue (adipose or liver) was weighed into a 250 mL French square homogenization jar. Fifty milliliters of 5% ethanol in ethyl acetate was added, and the sample was homogenized using an Ultra-Turrax homogenizer (IKA Works, Inc., Wilmington, NC, USA). The homogenate was centrifuged for 5 min at 52g, and a 5 mL aliquot of the extract was transferred to a clean 15 mL glass tube. The solution was dried under nitrogen using an N-Evap nitrogen evaporator (Organomation, Berlin, MA, USA). The dried extract was reconstituted in 200 μL of methanol and filtered through a 0.45 μm Millex-HV PVDF syringe filter (Millipore, Billerica, MA, USA) into a 2 mL autosampler vial.

Instrument Calibration Standards. Five-point calibration curves for quantification of DMB in adipose tissue samples were prepared by fortifying control bovine adipose tissue and extracting per the method listed above. Calibrators were prepared at levels of 1.0, 5.0, 10, 25, and 50 ng/g.

Quality Control Samples. Each batch of 3−12 diagnostic samples included an appropriate negative control tissue sample and a positive control sample consisting of negative control tissue fortified at a level of 1 ng/g DMB. Fortified samples were prepared by adding an appropriate level of standard solution in methanol to the negative control matrix and allowing it to equilibrate for at least 15 min prior to extraction. Each batch of validation samples included an appropriate negative control tissue sample.

LC-MS/MS Analysis. A model 1290 high-performance liquid chromatograph coupled to a model 6460 triple-stage quadrupole mass spectrometer equipped with a Jetstream electrospray interface (Agilent Corp., Santa Clara, CA, USA) was used for all reported analyses. The chromatograph was fitted with a 100 mm × 2.1 mm i.d., 1.7 μm, Zorbax Eclipse Plus C 18 column fitted with an Eclipse Plus guard column (Agilent Corp.). The mobile phases consisted of 0.1% aqueous formic acid (channel A) and 0.1% formic acid in acetonitrile (channel B). The flow rate was 0.350 mL/min throughout. Gradient elution was used beginning at 20% B, which was held for 1 min and then ramped to 95% B over 8 min. It was held at 95% B for 4 min and then returned to the initial conditions and held for 4 min for re-equilibration. The column was maintained at 35 °C. DMB eluted at approximately 8.5 min under these conditions. Chromatographic flow was diverted to waste for the first 2 min and after 15 min. The injection volume was 10 μL. For diode array detection, an Agilent model 1290 diode array detector was placed in line between the HPLC column and the mass spectrometer. The detector was set to acquire the UV spectrum in the range of 190−400 nm. Agilent's Masshunter software was used for all data acquisition and processing.

The mass spectrometer was tuned and calibrated in negative ion mode using its automated tuning procedure and the provided tuning solution (Agilent Corp.), a proprietary mixture of substituted phosphazines and triazines. DMB was monitored by multiple reaction monitoring (MRM) using a precursor ion of m/z 562 and product ions of m/z 278 and 254. Fragmentation voltage was 135 V, and cell accelerating voltage was 7 V. Collision energies were 25 eV for the m/z 562 → 278 transition and 35 eV for the m/z 562 → 254 transition. Other ion source parameters were as follows: drying gas temperature, 350 °C; drying gas flow, 10 L/min; nebulizer pressure, 45 psi; sheath gas temperature, 300 °C; sheath gas flow, 11 L/min; capillary, 4500 V.

Infusions of bromethalin and DMB were performed by connecting a syringe pump inline with the HPLC, directly ahead of the MS ion source. Separate standards for the two compounds at 1 μg/mL were infused into the MS at 20 μL/min.

Each analytical sequence for qualitative screening began and ended with a 1 ng/mL standard of DMB in methanol. Each sequence for quantitative analysis for method validation began and ended with a five-point calibration curve extracted from fortified negative control matrix.

A sample was considered positive when a peak was detected at a signal-to-noise ratio >3 within 5% of the retention time established for DMB with the ratio of response between the two product ions being within ±15% of that determined by analysis of the standard. These identification criteria are consistent with those defined in the European Commission Health and Consumer Protection Directorate-General guidance document for analytical quality control and validation procedures for pesticides in food and feed (SANCO/12571/2013).[10]

Full Scan LC-MS Analysis. A model 1200 Rapid Resolution HPLC system coupled with an Exactive high-resolution accurate mass spectrometer (Thermo Corp.) was used for full scan LC-MS analysis. The column and HPLC conditions were similar to those used for LC-MS/MS analysis. The mass spectrometer was run in negative ion mode with electrospray ionization. Mass calibration and instrument tuning for negative ion mode were performed <24 h prior to sample analysis. The instrument was tuned and calibrated using the solution provided by the manufacturer, which included sodium dodecyl sulfate, sodium taurocholate, and Ultramark 1621. Spray voltage was 3000 V, capillary temperature was 250 °C, and sheath gas and auxiliary gas were set at 50 and 10, respectively (arbitrary units). Mass resolution was set at 100,000, and the AGC target was 1×10^6.

Method Validation. The method was validated using criteria for qualitative screening methods established in the SANCO/12571/2013 document. Twenty samples each of homogenized liver and homogenized brain tissue were fortified with 1 ng/g of DMB (the screening detection limit) and analyzed. The method was also evaluated by analyzing six replicate control adipose tissue samples fortified at each level of 1.0, 5.0, and 50 ng/g and quantifying the detected DMB against the calibration curve determined by analysis of the extracted calibrators.

RESULTS AND DISCUSSION

Few methods for the analysis of bromethalin and/or DMB in tissue samples have been reported. These methods have included thin layer chromatography,[11] gas chromatography with electron capture detection,[8] and gas chromatography with negative ion chemical ionization.[8] High-pressure liquid chromatography with diode array and atmospheric pressure chemical ionization mass spectrometry (HPLC-negative ion-APCI-MS)[12] was used for the identification of bromethalin in rodenticide bait formulations. The authors reported that bromethalin gave a broad and intense UV absorbance band between 300 and 415 nm. They also reported that negative ion-APCI-MS did not yield pseudomolecular ions but instead showed extensive fragmentation with a variety of isotopic clusters related to molecular species such as $[M - Br]^-$, $[M - HBr]^-$, and $[M - HBr - NO_2]^-$.

Infusion of a DMB standard solution gave a predominant ion cluster consisting of nominal m/z 560, 562, 564, and 566 in ratios consistent with those expected from its $[M - H]^-$ ions (Figure 2) in negative ion mode. No identifiable signal was detected using positive ion mode. Product ions at m/z 278 and 254 from fragmentation of the precursor at m/z 562 were chosen for MRM acquisition. Analysis by HPLC-MS/MS showed high sensitivity and adequate retention on the reverse phase column.

For qualitative screening method validation, 20 replicate samples of homogenized liver tissue were fortified with DMB at a level of 1 ng/g (the screening detection limit). DMB met detection criteria in all 20 samples, demonstrating that it may be detected reliably at that level. The primary goal of this work was to develop a method suitable for support of post-mortem diagnosis of bromethalin intoxication. Accordingly, it is usually performed on a qualitative, "presence/absence" basis. To provide further support for the screening detection limit and evaluation of the method's quantitative potential, we performed a quantitative method evaluation in fat tissue. Figures of merit for the fat validation data are shown in Table 1. A quadratic model best fit the calibration curve giving a correlation coefficient (r^2) of 0.996. The method detection limit, calculated using Student's t value for five degrees of freedom and the 99% confidence level was determined to be 0.35 ng/g, supporting the 1 ng/g screening detection limit used for qualitative validation. These data indicate that this method is likely to be useful for researchers interested in quantitative analysis for DMB. Figure 3 shows extracted ion chromatograms for a single injection of an extract from an adipose tissue sample fortified with 1 ng/g of DMB. The validation results for fat and liver indicate that this method will provide relevant detection limits for analysis of a variety of tissue types.

Table 1. Figures of Merit for the Quantitative Method Validation

spike level (ppb; n = 6)	mean % recovery	% relative standard deviation
1.0	110	11
5.0	110	15
50	105	24

This method has been used successfully to establish bromethalin exposure in several animals suspected of suffering fatal bromethalin poisoning.[7] Figure 4 shows chromatograms from a single analysis of fat tissue taken from a fox. This animal had displayed signs of severe neurological impairment and was initially suspected of having suffered head trauma. No history of bromethalin exposure or use of the rodenticide in the area inhabited by the animal was noted on the submission form. Upon necropsy, there was no indication of head trauma and the samples taken from the animal were negative for canine distemper and rabies. Results of DMB analysis, along with other case information including clinical signs consistent with bromethalin toxicosis, were considered sufficient to diagnose bromethalin poisoning in this animal. The response of detectable DMB in samples from affected animals has ranged from slightly below that of the associated 1 ng/g spiked negative control sample to approximately 200 times that of the associated spike.

It should be noted that the original goal of this project was the development of an analytical procedure to detect bromethalin rather than the demethylated form, DMB. When a standard of bromethalin was infused into the mass spectrometer, the ions detected were inconsistent with those expected from the $[M - H]^-$ ions for bromethalin (m/z 574, 576, 578, and 580). Instead, the dominant signals were consistent with the cluster of brominated ions at m/z 560, 562, 564, etc., expected for DMB, albeit with poor sensitivity. Initially, it was difficult to determine whether the dominant ion cluster was due to DMB in the standard (as a contaminant or a breakdown product of bromethalin) or to demethylation of bromethalin in the ion source as there was no DMB standard available at the time. LC-MS/MS conditions were developed on the basis of MS/MS of the ions at m/z 562 and 564 from the bromethalin standard, and analysis of liver and fat from some animals suspected of exposure to bromethalin gave positive results. When a DMB standard became available and

was analyzed using LC-MS/MS, it was determined that the retention time and ions measured for DMB were identical to those from the bromethalin standard. This raised questions as to the reliability of the bromethalin standard material or the ability to detect bromethalin itself by electrospray LC-MS. To resolve these issues, a highly concentrated bromethalin standard (1000 μg/mL) was analyzed on a system in which a diode array detector was placed ahead of the mass spectrometer

set to full scan Q1MS mode, with no MS/MS fragmentation. Chromatograms from this analysis are shown in Figure 5. The dominant signal on the MS system was that of DMB at m/z 564 (Figure 5a), corresponding to <0.1% of the bromethalin concentration in the standard based on comparison to a 10 μg/mL DMB standard. This indicated that the detected DMB was likely a low-level impurity present in the bromethalin standard. The diode array detector showed a very intense, saturated peak eluting shortly after DMB (Figure 5c). The UV spectrum of this peak (Figure 6) matched the UV spectrum of bromethalin, which was previously described as "a strong broad absorption band extending from 300 to 415 nm in the mobile phase"[12] and also was nearly identical to the UV spectrum obtained via analysis of DMB under the same conditions (data not shown). No other significant peaks were noted in the UV analysis. This analysis provides compelling evidence that the standard material provided was intact bromethalin. The fact that no other significant peaks were detected by LC-UV despite the saturation in the bromethalin peak indicates that the purity of the bromethalin standard was ≥99%, as reported in the associated certificate of analysis. There were detectable signals in the MS chromatograms for both m/z 564 (DMB, Figure 5a) and m/z 574 (intact bromethalin, Figure 5b) coeluting with bromethalin on the UV detector. These signals may be representative of bromethalin detection by LC-MS/MS, but, if so, they are extremely weak given the concentration of bromethalin injected and indicate that sensitivity using these MS/MS transitions would be well below that necessary for detection in tissue samples. The 1000 μg/mL standard was also analyzed using full scan mode on an Exactive high-resolution LC-MS system in an attempt to determine whether ionization of bromethalin produced ions with m/z ratios other than those from the $[M - H]^-$ ions from bromethalin or those produced by DMB. These systems provide highly sensitive analysis using full scan high-resolution accurate mass analysis of a wide mass range. A 1000 μg/mL concentration would be expected to produce a strong signal for any compound that responds well by this method, but no significant peaks were detected in the range of m/z 100−600 as determined by plotting the total ion chromatogram (TIC) for that range. Analysis of a 100 ng/mL standard of DMB gave a peak that was clearly detectable (S:N > 3) when plotting the TIC from the m/z 100−600 mass range. This finding is in agreement with the detection of bromethalin by APCI because the retention times for diode array and APCI-MS detected coincided. On the basis of the differences between infusion data from our work and that of Mesmer and Flurer, it appears that bromethalin responds differently to the APCI and electrospray ionization processes.

In summary, injection of a 1000 μg/mL bromethalin standard gave a strong response by LC-UV but a barely detectable corresponding response by LC-MS/MS for its $[M - H]^-$ and $[M - CH_3 - H]^-$ ions. Injection of a 1.0 ng/mL standard of DMB consistently gave a peak with >3:1 S:N under the same conditions. A 1000 μg/mL bromethalin standard gave no detectable peak in the TIC of a full scan LC-MS analysis, whereas a 100 ng/mL DMB standard was clearly detectable under those conditions. Together, these results indicate that bromethalin responds very poorly by electrospray LC-MS and that this technique is not suitable for its low-level detection in tissue samples and that diagnostic analysis of tissue samples using electrospray LC-MS should rely on DMB analysis.

To our knowledge, this is the first detailed report of an LC-MS/MS method for the analysis of DMB. The method is fast, efficient, and sufficiently sensitive to detect low, clinically relevant levels of DMB in complex tissue samples and allows for accurate post-mortem diagnosis of bromethalin exposure and intoxication.

Determination of Neonicotinoid Insecticides and Strobilurin Fungicides in Particle Phase Atmospheric Samples by Liquid Chromatography−Tandem Mass Spectrometry

Renata Raina-Fulton*

Department of Chemistry and Biochemistry, University of Regina, 3737 Wascana Parkway, Regina, Saskatchewan S4S 0A2, Canada

Supporting Information

ABSTRACT: A liquid chromatography−tandem mass spectrometry method has been developed for the determination of neonicotinoids and strobilurin fungicides in the particle phase fraction of atmosphere samples. Filter samples were extracted with pressurized solvent extraction, followed by a cleanup step with solid phase extraction. Method detection limits for the seven neonicotinoid insecticides and six strobilurin fungicides were in the range of 1.0−4.0 pg/m^3. Samples were collected from June to September 2013 at two locations (Osoyoos and Oliver) in the southern Okanagan Valley Agricultural Region of British Columbia, where these insecticides and fungicides are recommended for use on tree fruit crops (apples, pears, cherries, peaches, apricots) and vineyards. This work represents the first detection of acetamiprid, imidacloprid, clothianidin, kresoxim-methyl, pyraclostrobin, and trifloxystrobin in particle phase atmospheric samples collected in the Okanagan Valley in Canada. The highest particle phase atmospheric concentrations were observed for imidacloprid, pyraclostrobin, and trifloxystrobin at 360.0, 655.6, and 1908.2 pg/m^3, respectively.

KEYWORDS: *neonicotinoid insecticides, strobilurin fungicides, atmospheric particle concentrations of pesticides*

INTRODUCTION

In this paper a new method for the simultaneous analysis of neonicotinoid insecticides and strobilurin fungicides in particles in the atmosphere was developed. Table 1 shows that these pesticides have low volatility such that particle transport in the atmosphere may play a role in their movement in the environment. Neither of these classes of pesticides has been previously detected in atmospheric samples (gas or particle phase) in North America, and a suitable method was required to be developed for their analysis in atmospheric samples capable of detection in the low picograms per cubic meter range. The range of volatility of these pesticides and similar solubility in organic solvents that are required to extract pesticides from solid matrices such as particles make development of a simultaneous method for both of these classes of pesticides feasible. Pressurized solvent extraction was used for their extraction as this approach is commonly used in our laboratory and others for the analysis of pesticides and other related contaminants in atmospheric samples.[1−4]

Neonicotinoids are a class of neuroactive insecticides that have high binding affinity to insect acetylcholine receptor.[5] Neonicotinoids registered for use in Canada include acetamiprid, clothianidin, imidacloprid, thiacloprid, and thiamethoxam (see Table 1).[6] They are commonly used on crops within Canada including corn, soybean, canola, sunflower, and a wide variety of fruit tree crops; some as well are used in commercial products such as flea collars for dogs and cats.[6,7] Strobilurin fungicides are a newer class of fungicides of the quinine outside inhibitors (Qol) group or act in a similar way to the natural strobilurin A, produced by the strobilurus tenacellus fungus.[8] This class includes azoxystrobin, fluoxastrobin, kresoxim-methyl, pyraclostrobin, and trifloxystrobin, which are also registered for use in Canada (see Table 1).[6]

In recent years, liquid chromatography−tandem mass spectrometry (LC-MS/MS) methods have been developed for the analysis of selected neonicotinoid insecticides with the number of applications of these methods increasing due to concerns of their harmful effects on honey bees and potential transport in the environment in surface waters due to their higher water solubilities.[7−12] Little attention has been given to studying the presence of neonicotinoids or strobilurin fungicides in the atmosphere. Due to the low volatility and high polarity of neonicotinoids, liquid chromatography is preferred over more complex GC methods. LC with the use of photodiode array or electrochemical detectors has also been used as well as capillary electrophoresis with mass spectrometry.[13−15] However, most recent methods of analysis of selected neonicotinoid insecticides have LC-MS/MS with electrospray ionization in positive ion mode (ESI+) and included their analysis in honey liqueur, bee pollen, fruits, and vegetation.[9,14,16−23] These sample matrices differ significantly from atmospheric samples.

LC-MS/MS methods for neonicotinoids have not included the simultaneous analysis of strobilurin fungicides, nor do the majority of the methods contain as complete a list of individual neonicotinoid insecticides as this study. Strobilurin fungicides can be analyzed by GC or LC methods. GC-MS for analysis of strobilurin fungicides has utilized selected ion monitoring (SIM) mode with electron impact ionization (EI), whereas only selected strobilurin fungicides have been included in multiresidue

[a]Boldfaced pesticides were detected in air samples collected from Okanagan Valley. Water solubility and vapor pressures were obtained from manufacturers' MSDS sheets.

LC-MS/MS methods or specific LC-MS/MS methods for individual fungicides.[24−28] Although many of the strobilurin fungicides can be analyzed by GC-MS with EI, confirmation of fungicide identity is limited[29] and atmospheric sample extracts are more prone to MS interference issues with EI as compared to negative chemical ionization GC-MS at low atmospheric concentrations.[30,31] LC-MS/MS methods also provide added confirmation ability with a four-point identification approach (two selected reaction monitoring (SRM) transitions) rather than monitoring of a single ion for each strobilurin fungicide in GC-MS. In addition, the use of LC-MS/MS allows for an opportunity to simultaneously analyze both strobilurin fungicides and neonicotinoids for atmospheric particles where sample extract volume available for chemical analysis is limited.

The sample preparation methods developed for use in LC-MS/MS methods for analysis of neonicotinoids are largely designed for water analysis rather than the solid matrices that are required for collection of atmospheric samples. Extraction of pesticides from these solid matrices used in air sampling has generally utilized pressurized solvent extraction with organic solvents rather than water prior to any cleanup steps such as solid-phase extraction (SPE).[1−4] Selected neonicotinoid insecticides or strobilurin fungicides in solid food product samples have also been extracted with pressurized solvent extraction, and particle phase atmospheric samples have been extracted with microwave-assisted extraction.[17,18,32,33] A variety of other chemical classes of pesticides (organochlorines, organophosphorus pesticides, and azole fungicides) have been extracted from solid matrices used in atmospheric sampling using pressurized solvent extraction.[1−4] Due to the high solubility of these insecticides and fungicides in organic solvents generally ethyl acetate, acetonitrile, or acetone are selected as the extraction solvent or for sample preparation.[14,17−20,24−28,32,33] It should be noted that it is extremely difficult to selectively extract specific chemical classes of pesticides in a specific organic solvent without loss of other target compounds, and thus multiple pressurized solvent extraction steps are generally not preferred. SPE methods are generally used to provide the cleanup of sample extracts (in organic solvents from pressurized solvent extraction) and often designed for specific chemical classes of pesticides due to the large range in polarities of pesticides and solubilities in different organic solvents. Atmospheric sample extract volume is limited with often only 1 mL of final extract available for SPE stages for all chemical classes of pesticides of interest.

Table 1 shows that the vapor pressures of neonicotinoid insecticides and strobilurin fungicides are generally $<10^{-5}$ Pa, and on the basis of the author's experience, if sufficient usage is present, there will be a greater potential for partition into the particle phase. The vapor pressures of these pesticides are also less than those of previously studied organophosphorus pesticides or some azole fungicides, and consequently the focus of the method development was on chemical analysis of the particle phase fraction of atmospheric samples. Sampling locations within the southern Okanagan Valley were selected as there was known current usage of these pesticides on tree fruits or grapes in the region (see Pesticide Usage Information in the Supporting Information). Strobilurin fungicides and neonicotinoid insecticides were targeted for the new method for their simultaneous analysis with pressurized solvent extraction of filters followed by an SPE cleanup stage prior to LC-ESI+/MS/MS. This new analytical method must be capable of detecting low picogram per cubic meter concentrations of pesticides in the atmosphere for future seasonal and annual trend analysis. These pesticide classes have not been previously detected in atmospheric samples in Canada, and this new method allows for the investigation of their occurrence in atmospheric particles at sampling locations in an agricultural region where these pesticides are recommended for use on fruit tree crops and in vineyards.

MATERIALS AND METHODS

Chemicals and Materials. Ethyl acetate, acetonitrile, and methanol were of pesticide grade and supplied by Fisher Scientific. Deionized water (<18 MΩcm resistivity) was from a Nanopure Diamond system (Barnstead International, Dubuque, IA, USA). Aqueous solvents were passed through a 0.45 μm membrane filter

[a]SRM transition used for determination of response ratio (area standard/area internal standard).

from Nucleopore (Whatman, Florham Park, NJ, USA). Formic acid (>88.0%) and ammonium acetate (>97.0% purity) were obtained from VWR Scientific (West Chester, PA, USA). Solids or stock solutions at 100 μg/mL in acetonitrile or methanol of strobilurin fungicides (azoxystrobin, dimoxystrobin, fluoxastrobin, kresoxim-methyl, pyraclostrobin, and trifloxystrobin) and neonicotinoid insecticides (acetamiprid, clothianidin, dinotefuran, imidacloprid, nitenpyram, thiamethoxam, and thiacloprid) were supplied by Chem Service Inc. (West Chester, PA, USA). Solid imidacloprid-d_4, diazinon-d_{10}, and malathion-d_{10} were purchased from C/D/N Isotopes Inc. (Pointe-Claire, QC, Canada).

Pesticide Standards. Deuterated internal standard (diazinon-d_{10}) had previously been used as a surrogate standard for other chemical classes in our laboratory[1] and was found to behave with similar retention characteristics as the pesticides under study on C18 SPE sorbent tubes and was used to evaluate recoveries. Diazinon-d_{10} also provides excellent sensitivity with both LC-MS/MS and GC-MS methods and thus can be used as a multiclass surrogate compound. No deuterated strobilurin fungicides were commercially available. The only commercially available deuterated neonicitinoid insecticide at the time of this study was imidacloprid-d_4, which was used as the internal standard for LC-MS/MS analysis. Malathion-d_{10} can also be used as an internal standard and was used to determine the final volume of the dried fraction F1 from the SPE cleanup after the addition of internal standard from the SPE stage, which was ∼1.0 mL.

Solids of individual pesticides (∼1 mg) were dissolved in 1 mL of methanol with further dilution to prepare individual stock solutions at 1.00×10^5 ng/mL in methanol and stored at −4 °C. Suitable calibration standards were prepared by dilution of a standard mixture at 1000 ng/mL and internal standard (IS) with pesticide grade methanol with a final concentration of the internal standard, imidacloprid-d_4, at 20 ng/mL in all standards and samples. All final diluted standards and samples were prepared on the day of analysis. The calibration range

DOI: 10.1021/acs.jafc.5b01347
J. Agric. Food Chem. 2015, 63, 5152−5162

typically examined was MDL−100 ng/mL with lowest standard prepared at 0.5 ng/mL.

Sample Collection and Preparation of Air Extracts. Air samples were collected in the southern Okanagan Valley agricultural region at two field sites (BC Ministry of Environment/Canada Customs Border station in Osoyoos, British Columbia (BC), Canada; and Environment Canada Water Quality Site near Oliver, BC, Canada). The distance between the Osoyoos and Oliver field sites is ∼20 km. Air samples were collected using a polyurethane foam (PUF) high-volume air sampler (Tisch Environmental, Cleves, OH, USA) operated continuously at a flow rate of 225 L/min. The start dates for the samples collected for this study at Osoyoos were June 28, 2013; July 29, 2013; August 6, 2013; August 9, 2013, and August 20, 2013. The last sampling period end date was September 3, 2013. At the Oliver site sampling start dates were the same except no sample was available for the August 6 or 9, 2013, sampling period due to instrument issues. Average duration of samples collected at the Osoyoos sampling location was 13.2 days. Due to restrictions on the use of the sampler at night due to noise concerns from the motor of the air sampler to nearby public homes adjacent to the customs station, the air sampler at Osoyoos was operated continuously from the hours of 7 a.m. to 9 p.m. local time (no operation overnight) with counter time reported for the duration the sample motor was operated. At the Oliver site the air sampler was operated continuously (24 h daily throughout the sampling period).

The sampling module contained the PUF/sorbent cartridge (for gas phase) and a glass fiber filter (for particle fraction) as previously described.[1] The sampling head is equipped with a PM10 cyclone with levels of PM10 (particles <10 μm in diameter) determined from gravimetric analysis of the filters ranging from 13.1×10^6 to 22.8×10^6 pg/m^3 and from 15.3×10^6 to 22.4×10^6 pg/m^3 at Osoyoos and Oliver, respectively. There was a weak relationship of PM10 levels and temperature over the agricultural season; however, for this period under investigation the average temperature during the sampling period ranged from 21.3 to 26.0 °C. Precipitation amounts were low at both sites with rainfall amounts <3 mm.

Particle phase air concentrations of neonicotinoid insecticides and strobilurin fungicides were determined for samples collected between June 28, 2013, and September 3, 2013, at Osoyoos and Oliver and are presented under Results and Discussion.

Extraction and Cleanup. The glass fiber filters were transferred after sampling into 30 mL extraction cells and extracted with ethyl acetate using an ASE100 pressurized solvent extraction system (Dionex, Sunnyvale, CA, USA). Used were the following extraction procedures: temperature, 100 °C; static mode time, 30 min at 1500 psi; two static cycles; 60% flush volume; purge time with nitrogen (UHP) at the end of 600 s. The total extraction volume was approximately 1.5 times the cell volume. A second extraction step with acetonitrile using the same pressurized solvent extraction procedure was performed on the filter samples.

After extraction, samples were dried to ∼5−10 mL, transferred to 15 mL vials, and dried to near dryness. This extract was stored at −4 °C until sample cleanup. The dried extract was redissolved to 1 mL with the addition of 100 μL of 1000 ng/mL diazinon-d_{10} and 900 μL of methanol prior to SPE cleanup. C18 SPE tubes (6 mL, 1000 mg, Canadian Life Science, Peterborough, ON, Canada) were conditioned with 6 mL of methanol and 6 mL of water. Sample extract (250 μL) was loaded onto the preconditioned tubes with 750 μL of water. This was eluted into an F0 fraction. Further rinses of 20:80 v/v% methanol/water were also eluted into the F0 fraction for a total volume of 2 mL. The eluted solvent collected into fraction F0 was observed to contain no insecticides or fungicides of interest. The neonicotinoid insecticides and strobilurin fungicides were eluted with 5 mL of 100% methanol in the next fraction (F1), and the Versiprep drying attachment (Supelco) was used to evaporate and concentrate eluted extracts from SPE (and from ASE) to ∼0.95−1.00 at 0.5 mL/h. To determine the volume of this F1 fraction 10 μL of 1000 ng/mL malathion-d_{10} was added. Internal standard imidacloprid-d_4 (1000 ng/mL) was also added at 20 μL to the these fractions prior to LC-MS/MS analysis such that total volume was ∼1 mL. Surrogate recoveries evaluated with diazinon-d_{10} were 82−105% within batch recoveries of ±10%. A second fraction (F2) was eluted from the SPE tubes with an additional 5 mL of 100% methanol after fraction F1 and showed no presence of pesticides. Particle phase concentrations were determined from the amount of pesticides determined to be in the particle phase extract divided by the total air volume sampled during each collection period. Detection limits could be improved by a factor of 4 by increasing the volume of extract loaded onto the SPE tubes; however, the extract is preserved for future analysis of other chemical classes of pesticides.

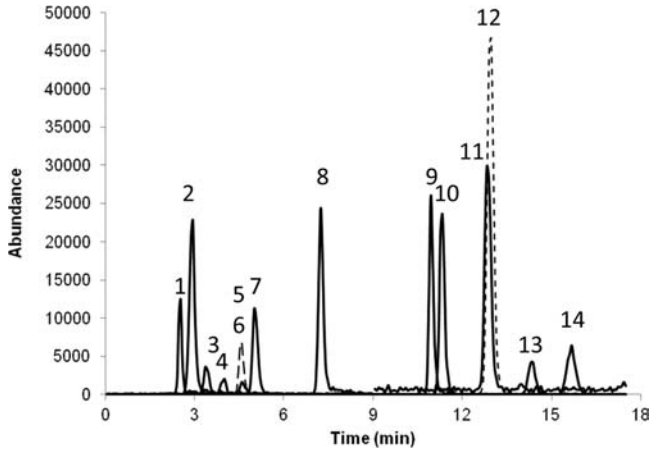

Figure 1. Selected reaction monitoring chromatogram of neonicotinoid insecticides and strobilurin fungicides standard mixture. Analytes (quantitative SRM transition): 1, dinotefuran (203.1 → 157.2); 2, nitenpyram (271.2 → 56); 3, thiamethoxam (292.4 → 211.4); 4, clothiadindin (250.1 → 169.3); 5, internal standard, imidacloprid-d_4 (260.1 → 213.1); 6, imidacloprid (256.1 → 175); 7, acetamiprid (223.1 → 126.1); 8, thiacloprid (253.1 → 126); 9, azoxystrobin (404.1 → 372.4); 10, dimoxystrobin (372.6 → 205.3); 11, fluoxastrobin (459.2 → 427.4); 12, kresoxim-methyl (314.1 → 206.3); 13, pyraclostrobin (388.1 → 163.5); 14, trifloxystrobin (409.1 → 186.4). Standard mixture of neonicotinoid and strobilurin fungicides at 60 ng/mL with internal standard imidacloprid-d_4 at 20 ng/mL (10 μL sample injection).

LC-MS-MS Analysis. LC analysis was performed with a Waters LC system consisting of a 1525 μ binary pump and column heater. A LEAP Technologies autosampler (Carrboro, NC, USA) was used for 10 μL injections at 100 μL/s and two pre- and postcleans with ethyl acetate followed by acetonitrile to minimize sample carry-over. A guard column (4 mm × 2.0 mm, C18 Gemini) was connected to the analytical column, Synergi Polar-RP column, 50 mm × 2.00 mm i.d., 2.5 μm (Phenomenex, Torrance, CA, USA), which was placed in a column heater at 30 °C. Initially the column was equilibrated with 40% acetonitrile containing 0.1% formic acid and 60% aqueous phase containing 0.1% formic acid and 5.0 mM ammonium acetate at a flow rate of 0.10 mL min^{-1}. Mobile phase gradient of acetonitrile with 0.1% formic acid was changed linearly as follows: 0−1.0 min, 40%; 3.0 min, 62.0%, held for 9.0 min; 13.0 min, 85%, then held at 85% for 5 min. All analytes are eluted prior to 18.0 min. The column was then reconditioned with gradient conditions adjusted back to initial mobile phase conditions by 20.0 min and held at initial mobile phase conditions for an additional 10.0 min prior to the next injection (total re-equilibration time of 12.0 min). This gradient program provided reproducibility in retention times within ±0.1 min; carry-over was not observed and was tested with blank injections containing the internal standard approximately every fifth injection. Blank injections were also completed prior to any sample injections.

The Waters LC system was connected to a Quattro Premier (Milford, MA, USA) triple quadrupole, which had electrospray ionization. The temperature of the source was set to 120 °C, desolvation temperature of 300 °C, desolvation gas at 750 L/h, and cone gas at 150 L/h. The optimized settings for ESI were as follows: capillary voltage, 3.50 kV; extractor voltage, 4 V; RF lens, 0.1 V. The collision gas used for SRM was argon (UHP) at 0.15 mL min^{-1} or 9.3×10^{-4}

[a]Based on calibration standards—lowest calibration standard within ≤25% deviation from best-fit regression line. [b]Based on average air volume obtained from samples collected at Osoyoos of 4073 m^3 (average duration of sampling, 13.2 days, continuous air sampling); sample extract volume 1.0 mL with 0.25 mL taken for SPE cleanup stage.

mbar. Cone voltage and collision energy were set up in the MS method and are shown in Table 1. Infusion experiments were conducted for each insecticide or fungicide to determine the SRM conditions in ESI+ with a syringe pump flow rate of 50 μL min^{-1}.

RESULTS AND DISCUSSION

Selection of LC-MS/MS Parameters. Table 2 shows that most neonicotinoid insecticides and strobilurin fungicides have a minimum of two viable SRM transitions that are available for quantitative and confirmation analysis. The most sensitive SRM transition was used for quantitative analysis, and the second most sensitive SRM transition was used for confirmation. Several pesticides including dinotefuran, nitenpyram, thiamethoxam, acetamiprid, and kresoxim-methyl had a third available SRM transition that could be used for additional confirmation analysis when sufficient concentration was available. In general, more background matrix signal was observed for early-eluting compounds such as dinotefuran, nitenpyram, and thiamethoxam. These neonicotinoids were not detected in particle phase atmospheric samples. Dinotefuran has previously been observed to exhibit matrix suppression.[34] The % RSD for the response ratio of SRM2/SRM1 was <25% for all pesticides with the exception of thiacloprid (SRM2/SRM1 ratio of 0.0350 ± 32.6), which was also not detected in any particle phase atmospheric samples.

The column and mobile phase were also selected to achieve the required chromatographic resolution and selectivity and sensitivity in MS detection. All compounds have unique SRMs, and there were no issues of coelution with other target anaytes. Fluoxastrobin, kresoxim-methyl, and diazinon-d_{10} have similar retention times with the optimized gradient program (organic modifier acetonitrile) but can be distinguished by their unique SRMs (see Table 2). When methanol was used as the organic modifier, there was significantly less chromatographic selectivity and much lower resolution obtained for all strobilurin fungicides as compared to when a gradient with acetonitrile as the organic modifier was used. In addition, when the organic modifier in the mobile phase was switched from acetonitrile to methanol, the total analysis time increased by >5 min even under lower chromatographic resolution of the strobilurin fungicides. For example, azoxystrobin, dimoxystrobin, and diazinon-d_{10} had complete coelution with retention times between 20.32 and 20.44 min. Trifloxystrobin and pyraclostrobin also observed significant coelution (retention times 21.63 and

DOI: 10.1021/acs.jafc.5b01347
J. Agric. Food Chem. 2015, 63, 5152−5162

21.87 min) when methanol was used. Prior studies have also shown that better separations of only neonicotinoid insecticides (no strobilurin fungicides) with gradient elution were obtained when acetonitrile rather than methanol was used as the organic modifier in mobile phase.[23,28]

The mobile phase gradient of acetonitrile was required for the separation of all target analytes and provided the best balance between MS sensitivity, selectivity for the separation, and reproducibility of analysis. Previously, higher MS sensitivity has been shown for neonicotinoid insecticides with acetonitrile rather than methanol mobile phases.[22,28] In terms of MS sensitivity under these separation conditions only imidacloprid, imidacloprid-d_4, clothianidin, and thiamethoxam showed significantly higher response (peak area) when a methanol rather than an acetonitrile gradient was used and can be partially attributed to the larger retention times for each analyte when a gradient with methanol is used (corresponding higher percentage of organic modifier in mobile phase at retention times under the same gradient program); however, clothianidin and thiamethoxam also showed poorer reproducibility when methanol was used. Nitenpyram and acetamiprid showed ~3 and 1.5 improvement in sensitivity, respectively, and reductions in % RSD of peak areas from 14 to 8% when acetonitrile rather than methanol was used as the organic modifier in the mobile phase. In general, better consistency in retention times (within ±0.1 min) and smaller % RSD in peak areas were observed when a gradient with acetonitrile containing mobile phase was used. No carry-over effects were observed in the analysis when a gradient with acetonitrile was used and was tested with blank injections.

Synergi Polar-RP stationary phase is an end-capped ether-linked phenyl phase that provides different selectivity from C18 stationary phases. C18 stationary phases can be used for the separation of neonicotinoid insecticides, but require a high percentage of acetonitrile (90−100 v%) at the end of the gradient program.[23,28] The Synergi Polar-RP column provided better selectivity and shorter total analysis times, particularly for the strobilurin fungicides, which elute after the neonicotinoid insecticides, and thus was selected. It is recommended that if a C18 stationary phase is selected, a short column length (e.g., 50 mm) and small particle size (<2 μm) be used to avoid large total analysis times, and the selectivity of the strobilurin fungicides should be further evaluated. With a Synergi Polar-RP column along with the gradient of acetonitrile, the simultaneous analysis of strobilurin fungicides was feasible in the same LC-MS/MS method as required for optimal sensitivity and reproducibility for neonicotinoid insecticides with a total run time <18 min as shown in Figure 1. Under the separation conditions presented herein the strobilurin fungicides eluted later in the separation than the neonicotinoid insecticides, and with the use of acetonitrile in the mobile phase better chromatographic resolution was obtained for the strobilurin fungicides and shorter overall analysis times as compared to when a gradient with methanol was used. Only a few strobilurin fungicides (pyraclostrobin, azoxystrobin, and trifloxystrobin) have been included in LC-MS/MS methods of fungicides, and acetonitrile was the preferred organic modifier in the mobile phase for these methods.[24−26] MS sensitivity for strobilurin fungicides is not significantly different for methanol or acetonitrile containing mobile phases under similar mobile phase gradient conditions.

Calibration, Matrix Effects, and Method Detection Limits (MDLs). Calibration curves showed good linearity with

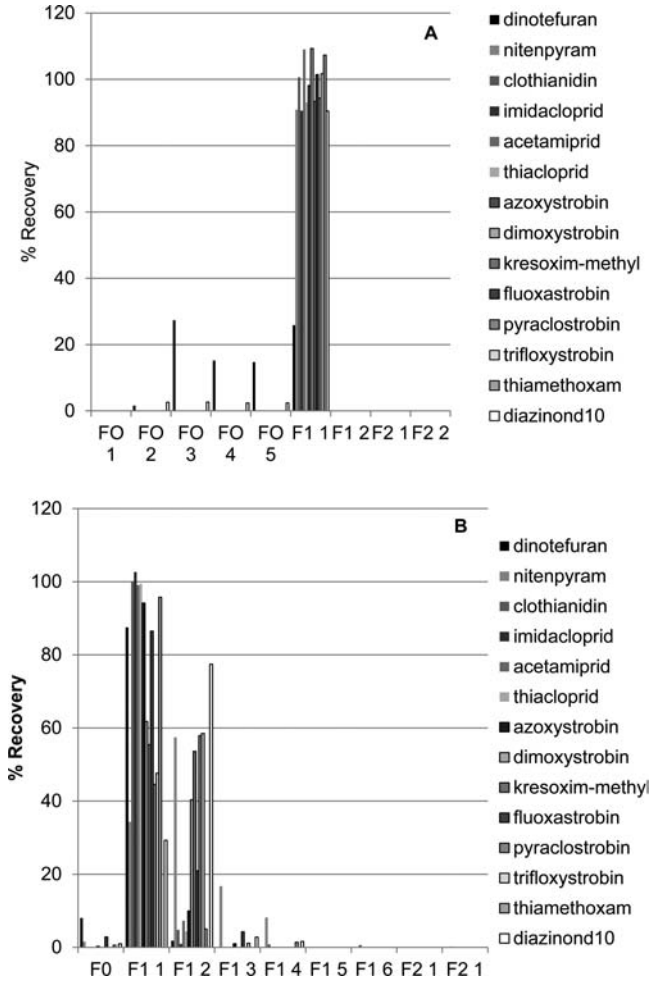

Figure 2. Percent recoveries of neonicotinoid insecticides and strobilurin fungicides from SPE C18 clean-up procedure: (A) F0 solvent 80:20 v/v% water/methanol in 1 mL portions (includes F0 1, F0 2, F0 3, F0 4, and F0 5, where 1−5 represent the 1 mL portions from 1 to 5 mL); F1 fraction is 5 mL of methanol (includes F1 1 as first 5 mL fraction and F1 2 as second 5 mL fraction); F2 fraction is 5 mL of methanol (includes F2 1 as first 5 mL fraction and F2 2 as second 5 mL fraction). (B) F0 fraction 2 mL of 80:20 v/v% water/methanol, F1 1−6 are each 1 mL portions of 100% methanol (for total volume of 6 mL methanol); F2 1 and 2 are each 5 mL portions of methanol. Sample was loaded at 50 ng/mL neonicotinoid insecticides and strobilurin fungicides.

r^2 generally >0.99 as shown in Table 3. MDLs were determined by the lowest standard concentration within 25% deviation of the best-fit line. MDLs generally ranged from 0.98 to 2.0 pg/m^3 except for imidacloprid, thiacloprid, dimoxystrobin, and azoxystrobin, with one SRM showing MDL ≥ 4 pg/m^3. A test for matrix effects was made by comparison of slopes of calibration curves from standards prepared with and without addition of 40 μL of filter extract of a sample collected at Osoyoos. Most pesticides showed a slight reduction in slope of the calibration curve when sample extract was added to standards with difference from −0.7 to −8.3%. Only thiamethoxam, fluoxastrobin, kresoxim-methyl, and pyraclostroin showed a small increase in slope for standards with sample matrix added (1.9−5.7%), which is well within an acceptable range. Reproducibility of samples with matrix added was from 0.8 to 11% and within the range observed for standards with no matrix added.

Table 4. Percent Recoveries of Neonicotinoid Insecticides and Strobilurin Fungicides from Extraction (and Drying)[a]

compound	% recoveries ± relative standard deviation (N = 3)
dinotefuran	97.3 ± 5.8
nitenpyram	<MDL−16.6[b]
thiamethoxam	97.5 ± 12.9
clothianidin	94.9 ± 5.2
imidacloprid	97.0 ± 8.9
acetamiprid	99.5 ± 1.1
thiacloprid	98.2 ± 6.3
azoxystrobin	91.6 ± 12.2
dimoxystrobin	99.9 ± 5.6
fluoxastrobin	100.8 ± 10.4
kresoxim-methyl	101.2 ± 0.2
pyraclostrobin	99.9 ± 0.7
trifloxystrobin	97.7 ± 6.3

[a]Accelerated solvent extraction recoveries from first extraction with solvent selected as ethyl acetate. Drying step is included as it is required for concentration of extracts prior to LC-MS/MS analysis. Particles on filter spiked at pesticide level of 50 ng/mL in final 1 mL extract. [b]Reported as range as 2 replicated <MDL.

SPE Method. SPE was used to clean up the organic extracts obtained from pressurized solvent extraction of filters containing particles from air sampling. Matrix-matched standards are not feasible in atmospheric sampling as the sample matrix changes as a function of time and is often unknown. The matrix is expected to contain hydrocarbons and ammonium sulfate or nitrates on the basis of the fact that both sampling sites are within the vicinity of agricultural and residential activities. For some sampling periods the matrix may also contain other compounds such as polycyclic aromatic hydrocarbons produced from forest fires or residential wood burning. The SPE cleanup method utilizes C18 sorbent, which is commonly used in cleanup of air extracts.[1−4,30] The SPE method is modified from those used for water samples to accommodate the organic solvent used in extraction of the pesticides from the solid particles on filter media and for the small volume of sample extract loaded onto the SPE tubes. Following pressurized solvent extraction a drying step is commonly used in methods for the analysis of air extracts to concentrate the pesticides of interest and also to exchange the solvent from ethyl acetate to methanol (or solvent suitable for subsequent instrumental analysis).[2,3] In this method the dried sample extract is dissolved in methanol to allow for better retention of analytes on SPE C18 sorbent and is suitable for future analysis of other chemical classes of pesticides. In this method an F0 fraction is used to remove potential matrix components that would be more soluble in a higher percentage of water (~80:20 v/v % water/methanol in F0 fraction). The method required the SPE sorbent tubes to be preconditioned in methanol followed by conditioning of the sorbent with water to allow for adequate retention of dinotefuran on the C18 SPE sorbent. Figure 2A shows that most pesticides other than dinotefuran remained retained on the C18 sorbent with up to an elution volume of 5 mL of 80:20 v/v % water/methanol, which was collected in the F0 fractions (F0 1 to F0 5). A final elution volume of 2 mL of 80:20v/v % water/methanol was chosen for the F0 fraction to minimize the loss of dinotefuran. After collection of the F0 fraction, all of the neonicotinoid and strobilurin fungicides were adequately recovered when 5 mL of 100% methanol was used for elution of pesticides in the first F1 fraction as shown in Figure 2A. Methanol was chosen as the elution solvent for pesticides of interest in the F1 fraction to ensure elution of more strongly retained strobilurin fungicides on reversed-phase sorbent. Further investigation (see Figure 2B) of retention of these pesticides with methanol shows that most pesticides were eluted within the first 3 mL of methanol collected in the F1 fraction (F1 1 to F1 3). However, a final volume of 5 mL of methanol for elution of the F1 fraction was chosen as small amounts of clothianidin, thiamethoxam, and diazinon-d_{10} still eluted in the fourth 1 mL portion of methanol (F1 4), and trace levels (but below MDL) were still observed in the fifth 1 mL portion of methanol (F1 5). Figure 2A also showed that overall recoveries of pesticides were excellent when 5 mL of methanol was used for the collection of the F1 fraction. Figure 2B shows that further elution with methanol (in F2 fractions) did not recover any pesticides of interest.

Pressurized Solvent Extraction. The recoveries of neonicotinoid insecticides and strobilurin fungicides were also tested through the pressurized solvent extraction step and subsequent drying step required to concentrate the pesticides of interest. The volume of extract obtained from pressurized solvent extraction is ~45 mL, and after drying the extraction is dissolved with methanol prior to cleanup for LC-MS/MS analysis. Table 4 shows for spiked filter samples all pesticides with the exception of nitenpyram were efficiently extracted with ethyl acetate in the first extraction step (this procedure utilizes two static steps to ensure a more complete extract and contact time with particles). Further evaluation of the low recoveries of nitenpyram showed that nitenpyram was lost during the drying step and that it has a relatively high vapor pressure (vapor pressure = 1×10^{-4} Pa). In earlier experiments it was

also noted that thiacloprid and azoxystrobin were more susceptible to loss during the drying step but that a drying at a rate of ~0.95−1.00 at 0.5 mL/h provided acceptable recoveries of >85%. A second or third accelerated solvent extraction step of spiked filters (following a first extraction with ethyl acetate) showed no recoveries of pesticides when the solvent was ethyl acetate, acetonitrile, or acetone. For filter samples collected at the two sites in the Okanagan Valley a precautionary second extraction step was included to test if pesticides could be bound more strongly to particles under various field conditions. Although in our spike filter tests we found no difference with choice of organic solvent for the second pressurized extraction step, acetonitrile was selected as the second extraction solvent as nitenpyram and dinotefuran have been shown to have better recoveries with acetonitrile than with acetone or methanol.[22] Particle phase samples with the highest concentrations of pyraclostrobin and trifloxystrobin had <16% of their total concentration detected in the extract obtained from a second pressurized extraction with acetonitrile. Reproducibility of repeat injections (N = 5) of neonicotinoid insecticides and strobilurin fungicides was from 2 to 7%. Most samples had pesticide concentrations <5 pg/m^3 in the second extraction with acetonitrile. Field blank filter samples also showed no presence of pesticides in either the the first or second extraction with ethyl acetate or acetonitrile.

Particle Phase Atmospheric Concentrations of Neonicotinoid and Strobilurin Fungicides. Azoxystrobin, which has a sensitive SRM1 signal, could be detected at trace levels (~2−4 pg/m^3) in two filter samples collected at the Osoyoos sampling site, but could not be confirmed due to the higher MDL for SRM2. Acetamiprid, clothianidin, imidacloprid, kresoxim-methyl, pyraclostrobin, and trifloxystrobin were detected in particle phase samples as shown in Table 5 and represent the first detections of neonicotinoid insecticides and strobilurin fungicides in atmospheric particles in Canada. No prior studies have reported the detection of kresoxim-methyl, clothianidin, pyraclostrobin, or trifloxystrobin in the atmosphere worldwide.

Although there was no detection of thiamethoxam in particle phase atmospheric samples, thiamethoxam may be converted to clothianidin in insects and plants.[35] At this stage of the sampling it is not possible to identify the source of clothianidin in atmospheric particle phase samples collected. The particle phase atmospheric samples collected from the southern Okanagan Valley of British Columbia show the highest reported literature concentrations of neonicotinoid insecticides with particle phase atmospheric concentrations of acetamiprid, clothianidin, and imidacloprid reaching 35.7, 92.1, and 360.0 pg/m^3, respectively (Table 5). Acetamiprid and imidacloprid are the only neonicotinoids that have been detected in the particle phase (particulate matter < 2.5 or 10 μm in diameter (PM2.5 or PM10)) in Spain.[17,32] Particulate (PM10) concentrations of acetamiprid and imidacloprid in the atmosphere at these sites in Spain were 11.9−31.3 and 14.9 pg/m^3, respectively, with a low detection frequency.[32]

The strobilurin fungicides, pyraclostrobin and trifloxystrobin, were observed at the highest concentrations of the pesticides studied with particle phase atmospheric concentrations reaching 655.6 and 1908.2 pg/m^3, respectively. Detection of these strobilurin fungicides in the atmosphere has not been previously reported in the literature, and the concentrations of these pesticides indicate the importance of further studies on their movement in the environment by atmospheric transport. Studies on redistribution of radiolabeled strobilurins on wheat indicate that trifloxystrobin has potential for molecular redistribution by air.[35] These neonicotinoid insecticides and strobilurin fungicides are known to have usage in the southern Okanagan Valley. Further analysis is underway on the gas phase concentrations of these pesticides as gas/particle phase partitioning is expected.

Figure 3 shows the quantitative and confirmation SRM chromatograms for pyraclostrobin and trifloxystrobin in a particle phase air extract obtained from a sample collected at Osoyoos and a 10 ng/mL stanadard mixture. Confirmation of the identity of pesticides in samples included retention time match and a response ratio of SRM2/SRM1 in % RSD range determined on the day of analysis from standards (see Table 2). The particle phase air extract did show some peaks in the chromatogram at different retention times than any of the tested neonicotinoids or strobilurin fungicides such as observed in Figure 3D. The identity of these peaks at retention times of 13.9 and 16.8 min observed in the 409.1 → 206.4 SRM chromatogram is currently unknown. The unknown components in the sample did not have a measurable response at 409.1 → 186.4 and also did not coelute with trifloxystrobin.

In conclusion, a liquid chromatography−tandem mass spectrometry method has been developed for the determination of neonicotinoids and strobilurin fungicides in the particle phase fraction of atmosphere samples. Pyraclostrobin and trifloxystrobin were observed at the highest concentrations of the pesticides studied at the two sites in the Canadian Okanagan Valley agricultural region with this study representing the first reported occurrence of strobilurin fungicides in the atmosphere within Canada. In addition, neonicotinoid insecticides were also detected in the particle phase with maximum concentrations for acetamiprid, clothianidin, and imidacloprid of 35.7, 92.1, and 360.0 pg/m^3, respectively. This study provides support for the occurrence of these compounds in the atmosphere in the particle phase. Further research is required to assess seasonal trends and potential for regional and long-range transport of these neonicotinoids and strobilurin fungicides in the atmosphere.

Evaluation of Different Parameters in the Extraction of Incurred Pesticides and Environmental Contaminants in Fish

Yelena Sapozhnikova and Steven J. Lehotay*

Eastern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture, 600 East Mermaid Lane, Wyndmoor, Pennsylvania 19038, United States

Supporting Information

ABSTRACT: Sample processing is often ignored during analytical method development and validation, but accurate results for real samples depend on all aspects of the analytical process. Also, validation is often conducted using only spiked samples, but extraction yields may be lower in incurred samples. In this study, different variables in extraction for incurred pesticides and environmental contaminants in fish were investigated. Among 207 analytes screened using low-pressure gas chromatography−tandem mass spectrometry, consisting of 150 pesticides, 15 polycyclic aromatic hydrocarbons (PAHs), 14 polychlorinated biphenyls (PCBs), 6 polybrominated diphenyl ethers (PBDEs), and 22 other flame retardants (FRs), 35 (16 pesticides, 9 PCBs, 5 PBDEs, and 5 PAHs) were identified for quantification in samples of salmon, croaker, and NIST Standard Reference Material 1947 (Lake Michigan Fish Tissue). Extraction efficiencies using different extraction devices (blending, vortexing, and vibrating) versus time, sample size, and sample/solvent ratio were determined. In comparison to blending results, use of a pulsed-vortexer for 1 min with 1/1 (g/mL) sample/acetonitrile ratio was generally sufficient to extract the incurred contaminants in the homogenized fish tissues. Conversely, extraction with a prototype vibration shaker often took 60 min to achieve 100% extraction efficiency. A main conclusion from this study is that accurate results for real samples can be obtained using batch extraction with a pulsed-vortexer in a simple and efficient method that achieves high sample throughput.

KEYWORDS: *extractability, sample preparation, pesticides, environmental contaminants, fish, residue analysis*

INTRODUCTION

Prior to obtaining regulatory approval of a new pesticide application on crops, the registrant must usually demonstrate that the proposed regulatory method of analysis achieves total extractability of the defined pesticide residues from the crop and soil.[1] Liquid scintillation counting of sample extracts containing radioactive isotopes of the pesticide applied in the field is typically conducted to show if the method meets this total extractability requirement.[2] However, the approved regulatory method is rarely used in practice for monitoring of pesticide residues because it is typically designed only for a single pesticide (including defined metabolites), and it is often unwieldy to perform. Instead, multiclass multiresidue monitoring methods, such as QuEChERS (quick, easy, cheap, effective, rugged, and safe),[3] are employed to provide wide analytical scope with high sample throughput at an affordable cost. In addition, official methods tested for total extractability exist only for registered pesticide/crop combinations, not for unapproved pesticides or environmental contaminants that must also be routinely monitored for food safety, risk assessment, and a range of other purposes.

However, radiotracing to determine total extractability of residues from a diverse range of samples is not feasible for many chemicals of interest. Method development and validation studies involving multiresidue analysis of contaminants in foods and environmental matrices often only involve laboratory-fortified (spiked) samples to assess suitable method performance. Yet, it is common knowledge that analytes are more easily extracted from laboratory-spiked tissues than from real-world incurred samples, which may have stronger analyte−matrix interactions to be overcome. Furthermore, normalization of incurred analytes to a spiked internal standard does not compensate for lower extraction efficiency if incurred recoveries are different from those for spiked samples.

In a search of "extractability" in Scopus, hundreds of papers in the scientific literature were found on the topic, but nearly all of them concerned metals, soils, and food composition studies. Only one paper addressed extractability of chemical contaminants from fish, describing the effect of freeze-drying and how rehydration of samples improves extraction of incurred residues.[4] It is a well-known phenomenon and standard practice to add water to dry samples in pesticide residue analysis.[5] For example, Cajka et al. demonstrated that underestimation of various pesticide concentrations in incurred tea samples was 25−74% when comparing two methods with different degrees of extractability.[6] Also, Anastassiades et al. extensively studied extractability of multiple pesticides from fruits and vegetables by assessing extraction time, temperature, and shaking intensity in QuEChERS.[7]

After method implementation, quality control samples to check ongoing method performance are also typically spiked with the analytes, not incurred.[8] Even in the case of proficiency testing, spiked samples are usually sent to the laboratories for

evaluation, and even if incurred samples are used, the true analyte concentration is seldom known for comparison with the experimental results. Thus, it is conceivable that reported concentrations in real samples are lower than actual because total extractabilities of analyte−matrix combinations are rarely tested for common multiresidue monitoring methods.

Ideally, standard reference materials (SRMs)[9,10] would be used to determine total extractability, but none are available for many common contaminants and food sample types. Despite the known concerns related to spiked-only samples, few chemists validate their methods using incurred samples[6,11,12] because it is often difficult to obtain appropriate samples, and the true concentrations remain unknown. When possible, a bridging study should be conducted in which results from new methods of extraction should be compared with reference methods in side-by-side analysis of the same sample.[13] However, this is not common practice due to the extra time, effort, and cost involved. Thus, many chemists risk inaccurate results in their analyses, even if they follow standard practices for method validation, quality control, and laboratory accreditation (including proficiency testing).

The goal of this study was to investigate variables affecting QuEChERS-based extraction yields of incurred pesticides and environmental contaminants in fish samples (white croaker, salmon, and NIST SRM 1947 − Lake Michigan fish tissue). A diverse range of pesticides, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and flame retardants (FRs) were chosen for analysis using low-pressure gas chromatography−tandem mass spectrometry (LPGC-MS/MS). We sought to compare extraction efficiencies of different sample sizes, sample/solvent ratio, and extraction time using different shakers and a probe blender as extraction devices.

MATERIALS AND METHODS

Samples, Reagents, and Extraction Devices. Fish samples of salmon and Pacific white croaker (*Genyonemus lineatus*) were from the National Institute of Standards and Technology (NIST) Marine Environmental Specimen Bank in Charleston, SC, USA. The croaker was collected in 2002 from Palos Verdes Shelf Los Angeles Sanitation District Zone 1 EPA Superfund site in Palos Verdes, CA, USA. Croaker samples were received as a frozen, homogenized powder. The salmon of undetermined type collected from an unknown location was contributed to the Specimen Bank by Axys Analytical, Sidney, BC, Canada. The salmon was received frozen as a whole body 81 cm fish weighing 5096 g. It was thawed, filleted into skinless and boneless chunks, refrozen, and then homogenized with dry ice using a Robot Coupe (Ridgeland, MS, USA) RSI 2Y1 chopper and stored in glass containers in a −18 °C freezer until portions were thawed for analysis. Measured moisture contents were 63 and 79% for the salmon and croaker, respectively. Reported average lipid contents are 3−4 and 5−10% for croaker and salmon, respectively.[14] SRM 1947 (Lake Michigan Fish Tissue) was purchased from NIST (Gaithersburg, MD, USA) and contained 73% moisture and 10% fat content.

Pesticide standards were from the Environmental Protection Agency's National Pesticide Repository (Fort Meade, MD, USA), Dr. Ehrenstorfer GmbH (Augsburg, Germany), Chemservice (West Chester, PA, USA), and AccuStandard, Inc. (New Haven, CT, USA). PCB and PBDE congeners and PAHs were purchased from AccuStandard, and standards of FRs were from AccuStandard and Sigma-Aldrich (St. Louis, MO, USA). For use as internal standards (ISTDs), $^{13}C_{12}$-2,2′,4,4′,5,5′-hexachlorobenzene ($^{13}C_{12}$-PCB 153) and $^{13}C_{12}$-*p*,*p*′-DDE, PAH surrogate cocktail containing acenaphthylene-d_8, benzo(*a*)pyrene-d_{12}, benzo(*g*,*h*,*i*)perylene-d_{12}, fluoranthene-d_{10}, naphthalene-d_8, phenanthrene-d_{10}, and pyrene-d_{10}, were purchased from Cambridge Isotope Laboratories (Tewksbury, MA, USA). 5′-Fluoro-2,3′,4,4′,5-pentabromodiphenyl ether (FBDE 126) was purchased from AccuStandard, and atrazine-d_5 (ethyl-d_5) and fenthion-d_6 (*o*,*o*-dimethyl-d_6), were from C/D/N Isotopes (Pointe-Claire, Quebec, Canada). All standards were of ≥98% purity.

All solvents were of HPLC grade. Acetonitrile (MeCN) was from Fisher Scientific (Pittsburgh, PA, USA), and methanol (MeOH) was from VWR International (Radnor, PA, USA). Anhydrous magnesium sulfate (anhydrous $MgSO_4$) and sodium chloride (NaCl) reagent-grade salts and primary−secondary amine (PSA) and C18 sorbents were purchased from UCT (Bristol, PA, USA). Deionized water of 18.2 Ω-cm was prepared with an E-Pure model D4641 from Barnstead/Thermolyne (Dubuque, IA, USA). Zirconium dioxide based sorbent (Z-Sep) was from Supelco (Bellefonte, PA, USA). Ammonium formate was from Sigma-Aldrich. PVDF 0.2 μm filter vials were from Thomson Instrument Co. (Oceanside, CA, USA).

As shown in Figure 1, the extraction devices used in the study consisted of an Ultra-Turrax T25 probe-blending homogenizer (Janke & Kunkel GmbH & Co., IKA Labortechnik, Wilmington, NC, USA), a pulsed-vortexer (Glas-Col, Terre Haute, IN, USA), and a prototype vibration shaker (GL Sciences, Eindhoven, The Netherlands).

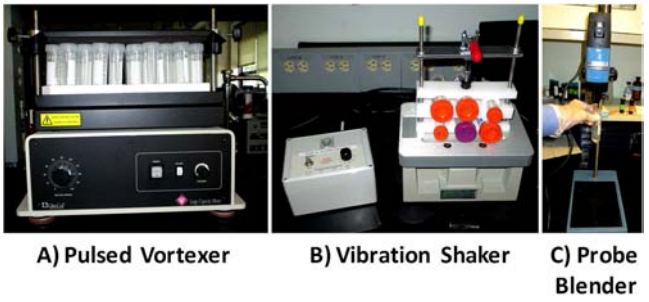

Figure 1. Three types of extraction devices compared in the study.

Sample Preparation. The initial experiments to determine incurred contaminants in fish samples were performed using a QuEChERS sample preparation method described earlier.[9] After addition of internal standards, 10 g of homogenized fish subsamples were extracted by shaking for 1 min with 10 mL of MeCN in triplicate each of salmon and croaker and one replicate for SRM 1947. Anhydrous $MgSO_4$ (4 g) and NaCl (1 g) were added to the initial extracts to induce phase separation, and after centrifugation, a 1 mL portion of the extract was transferred to 2 mL mini-centrifuge tubes containing 150 mg of $MgSO_4$ and 50 mg of Z-Sep for dispersive solid-phase extraction (d-SPE) cleanup. The tubes were centrifuged, and extracts were subjected to LPGC-MS/MS analysis. The final sample preparation method used in experiments described below was updated in accordance with subsequent streamlining improvements already reported.[15]

To determine the optimum extraction time and compare extraction devices, croaker and salmon homogenized tissues (10 g) were weighed into 50 mL polypropylene tubes (5 g was used for SRM 1947) and spiked with the internal standards mixture to achieve 100 ng/g for isotopically labeled pesticides, 50 ng/g for FBDE 126, 20 ng/g for isotopically labeled PAHs, and 2 ng/g for $^{13}C_{12}$ PCB 153. After the addition of 10 mL of MeCN, the tubes were placed into the pulsed-vortexer and shaken at 80% setting with maximum pulsing for 1, 10, 30, and 60 min. Another set of samples was extracted for the same time intervals using the vibration shaker. Four replicates of salmon and croaker and one replicate of SRM 1947 were conducted for each extraction/time parameter. Another four replicates each of croaker, salmon, and SRM 1947 subsamples were extracted using the probe blender for 1 min. After extraction, 5 g of ammonium formate was added to induce phase separation,[16] and the samples were shaken for 1 min on the pulsed-vortexer and centrifuged for 2 min at 3700 rcf. Extracts (0.5 mL) were transferred into the shells (bottom half) of 0.2 μm PVDF filter-vials containing 75 mg of anhydrous $MgSO_4$, 25 mg of PSA, 25 mg of C18, and 25 mg of Z-Sep sorbents. The filter-vial

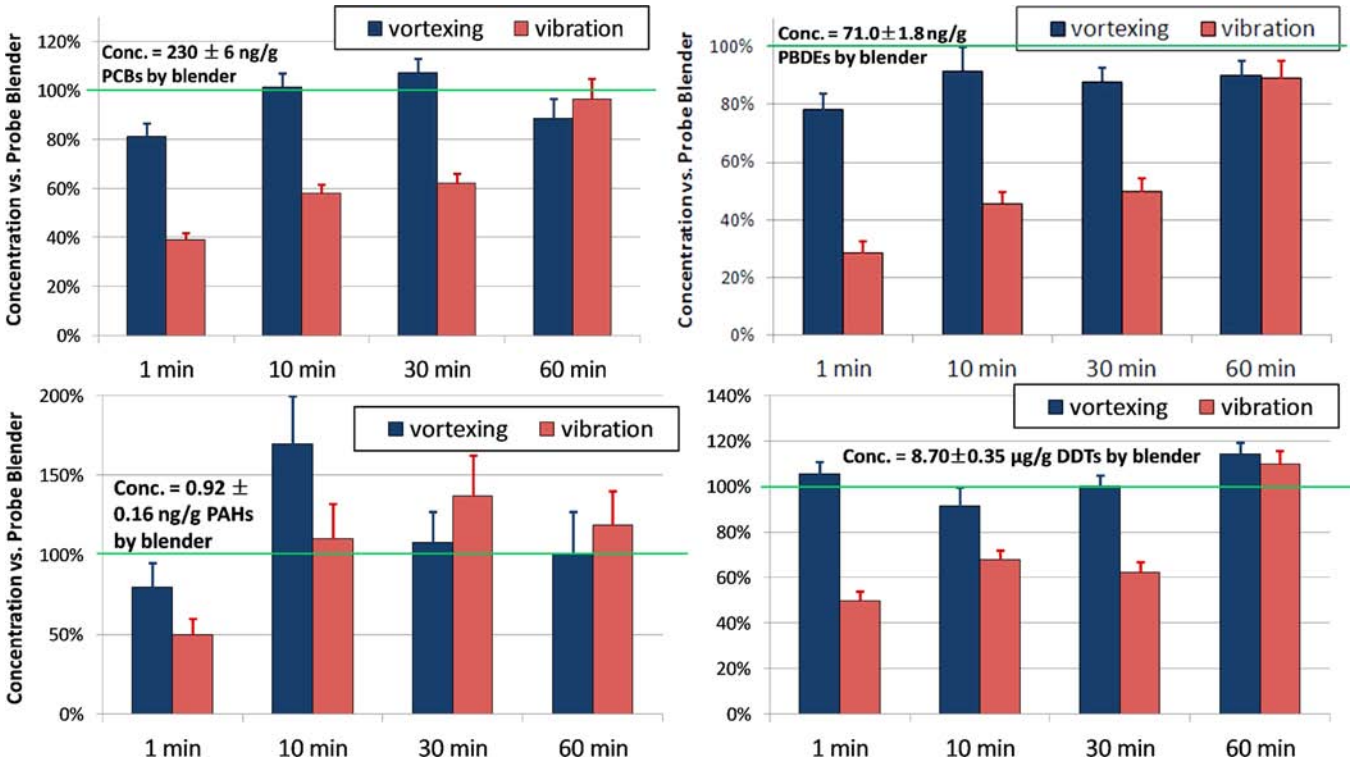

Figure 2. Extraction yields of contaminants in croaker: sum of 9 PCB congeners, sum of 5 PBDE congeners, sum of 5 DDT pesticides, and sum of PAHs (fluorene and anthracene). The pulsed-vortexer and vibrating shaker results are normalized to the probe blender results. Error bars represent standard deviation (n = 4).

plungers (top half) were partially depressed, the extracts were shaken by hand for 30 s in an autosampler vial tray, and then the plungers were fully depressed into the filter-vial shells. A commercial product of this filter-vial d-SPE approach was not yet available; thus, we had to transfer 200 μL of the filtered extracts to glass autosampler vials containing inserts prior to LPGC-MS/MS analysis.

Sample size and solvent ratio were studied in additional experiments using the pulsed-vortexer at 80% setting with maximum pulsing for 10 min and the streamlined filter-vial d-SPE cleanup method. Sample sizes of 2, 4, and 10 g of each fish were extracted with 2, 4, and 10 mL of MeCN for a 1 g/mL sample/solvent ratio, as well as 4 g of each fish was extracted with 8 mL of MeCN to evaluate the 0.5 g/mL sample/solvent ratio. These experiments were also conducted using four replicates at each set of conditions for salmon and croaker and one replicate for the limited amount of SRM 1947.

Rapid LPGC-MS/MS Analysis. An Agilent 7890 GC system with multimode inlet (MMI) interfaced to a 7000B triple-quadrupole MS/MS was used for analysis. The GC instrument was upgraded with a 220 V rapid heating oven device. A restriction capillary of 5 m × 0.18 mm i.d., HydroGuard (Restek, Bellefonte, PA, USA) coupled to 15 m × 0.53 mm i.d. × 1 μm film thickness Rti-5 ms column (Restek) was used for low-pressure (vacuum outlet) GC. High-purity He was the carrier gas at a constant flow rate of 2 mL/min. Injection volume was 5 μL using the MMI initially set at 80 °C for 0.31 min with vent at 50 mL/min, then ramped at 420 °C/min to 320 °C, and held until 9.5 min. The initial oven temperature was at 70 °C for 1.5 min, which was ramped at 80 °C/min to 180 °C and then at 40 °C/min to 250 °C, followed by 70 °C/min to 290 °C, at which it was held until 9.5 min. The transfer line and ion source were set at 280 and 320 °C, respectively, and the quadrupole was at 150 °C. Two MRMs per each analyte were used with a dwell time of 2.5 ms, similar to settings used in previous studies.[9,15,17]

The initial MRM method was divided into 28 time segments totaling 207 analytes and 12 ISTDs (see Supporting Information, Table S1, for the full list, retention times, and MRM transitions). This screen included 150 pesticides, 14 PCB congeners, 15 PAHs, 6 PBDE congeners, and 22 FRs. After nondetected analytes were dropped, the modified method included 35 analytes (16 pesticides, 5 PBDE and 9 PCB congeners, and 5 PAHs) and 9 isotopically labeled ISTDs (atrazine-d_5, fenthion-d_6, $^{13}C_{12}$-p,p'-DDE, pyrene-d_{10}, acenaphthylene-d_8, fluoranthene-d_{10}, phenanthrene-d_{10}, $^{13}C_{12}$-PCB 153, and FBDE 126) divided into 8 time segments. The ISTDs were not used to normalize the results for the analytes, but only as quality control spikes to demonstrate ISTD recoveries.

Due to matrix effects in GC-MS analyses of certain pesticides,[17] we intended to use matrix-matched calibration standards, but we could not find analyte-free salmon or white fish tissues. However, previous studies[9,15,17−19] demonstrated that matrix effects in the GC-MS method were insignificant for the nonpolar analytes determined in the samples, which enabled our use of solvent-based calibration standards to obtain accurate quantification of the final list of monitored contaminants. Calibration points were typically set at 0.1, 1, 5, 10, 50, 100, 250, and 500 ng/g for the analytes and 10 times lower levels for PCB congeners. In the case of croaker, additional points were added for PCB congeners at 100 and 150 ng/g. To quantify the high concentrations of DDE in the croaker, a 1000 ng/g calibration standard of o,p'-DDE was added along with 500, 1000, 2500, 5000, 7500, 10000 and 15000 ng/g of p,p'-DDE. To avoid detector saturation and still achieve linear calibration in the same injected extract as the ultratrace level contaminants, the least intense MRM transitions were selected for DDE, which avoided re-injection of diluted extracts just for this high concentration analyte.

RESULTS AND DISCUSSION

Extraction Devices. Figure 1 displays the three shaking devices employed in the study. A probe blender, or tissue homogenizer, works by inserting the metal probe mixer into a container containing the extraction solvent surrounding the fish tissue, which is ripped to tiny pieces, thus providing effective access of the solvent to the chemicals within the tissue. The pulsed-vortexer, capable of holding two standard trays with 25

DOI: 10.1021/jf506256q
J. Agric. Food Chem. 2015, 63, 5163−5168

tubes of 50 mL each, operates by intensive whirling action in pulsating fashion to thoroughly mix the prehomogenized samples with the extraction solvent. The tubes were placed vertically into the vortexer, although horizontal placement is also possible. The prototype vibration shaker permitted only horizontal placement of the tubes and entailed rapid vibrational motion to conduct extraction. This device was provided by the manufacturer to be evaluated for possible commercialization.

In terms of sample throughput, the pulsed-vortexer was able to process 50 samples at a time, whereas the prototype vibration shaker fits 6 tubes at a time. The probe blender, however, is not well-suited for use to extract a batch of samples because it requires cleaning of the probe between each sample to avoid cross-contamination. Thorough cleaning involved disassembling the probe, scrubbing with soap and water, rinsing with solvent, drying, and reassembly. The probe blender procedure has higher potential for introducing chemical interferences or excess liquid (if drying was not complete) into the sample, and always causes partial loss of extract onto the probe surfaces. The probe is also a safety risk, is very loud, and requires an open vessel that lets possible laboratory contaminants into the tube and sprays extract out of the tube. The sequential operation of the probe blender to extract samples is inconvenient, slow, laborious, and potentially hazardous.

We previously showed that the use of MeCN as an extraction solvent allows for simultaneous extraction of liphophilic nonpolar and relatively polar analytes (such as PAHs and some FRs) in one extraction step, with the added benefit of decreased amount coextracted fat compared to use of nonpolar solvents such as hexane or ethyl acetate.[9] However, even the extensively validated QuEChERS sample preparation method is not exhaustive, and therefore it is not known if total extractability of incurred contaminants is achieved, particularly for lipophilic analytes in fat-containing matrices.

The probe blender extraction method serves as a traditional standard procedure, which entails thorough homogenization of tissues with the solvent to yield total extraction. Table S2 (Supporting Information) lists average determined concentrations of incurred contaminants in croaker and salmon using 1 min extraction with the probe blender, and concentrations measured in SRM 1947 also using the probe blender versus the NIST-certified/reference concentrations. Percent accuracy of results for SRM 1947 was 69−144% with probe-blending extraction, thus demonstrating the degree of total extractability of the analytes in fish tissue with 10% lipid content. The determinations were 100% within typical expected experimental error for ultratrace level analyses. This supports the assertion that the probe blender provided 100% yield of incurred contaminants in the incurred fish samples. Extraction efficiency of contaminants in croaker (Figure 2) and salmon (Table 1) was expressed as relative recovery (%) for concentrations determined in samples extracted using the pulsed-vortexing and vibration-based shakers normalized to the probe blender results.

In terms of extraction efficiency, probe blender extraction for 1 min yielded the same concentrations of nearly all contaminants as maximum concentrations obtained for both types of shakers, which further supports the assertion that total extraction was achieved and true analyte concentrations were determined. As Figure 2 demonstrates, 1 min of shaking with the pulsed-vortexer was enough to yield 80−100% relative recovery of incurred contaminants from all classes in croaker tissues. Meanwhile, the vibration shaker yielded 30−50% extraction efficiency in 1 min and, in most cases, required 60 min of extraction time to achieve ≈100% relative recoveries. This trend also held true for pesticides, PCBs, and PBDEs. With respect to the detected PAHs (anthracene and fluorene), Figure 2 shows that 10 min of extraction with the vibration shaker was enough to yield 100% relative recovery, although <1 ng/g concentrations led to greater uncertainty in the results. This example illustrates how properties of the analytes affect the ease or difficulty of their extractability depending on the sample matrix. The log K_{ow} values of 4.1 and 4.9 for anthracene and fluorene, respectively, are lower compared to the other analyte classes (6.8−7.4 for PCBs, 5.9−7.9 for PBDEs, and 5.4−5.9 for DDT pesticides), and this may explain their faster partitioning into the MeCN extractant.

[a]See Table S2 in the Supporting Information for the specific analytes determined.

High concentrations of PCBs and DDE in croaker are explained by the fish's origin near the EPA Superfund site in Palos Verdes Peninsula, which was a discharge site for production of PCBs and DDTs until ≈1974. Because these contaminants are highly lipophilic and persistent, they accumulate in fish tissues. The Pacific white croaker was collected in 2002 and stored in the Marine Specimen Bank, so it does not reflect the current situation at the collection site. However, a recent study by Venkatesan et al.[20] reported relatively high concentrations of PCBs and DDTs in Santa Monica Bay sediments and suggested that the contaminants could have been transported from the Palos Verdes Shelf area.

Extraction Time. Extraction time for the probe blender was always 1 min, but 1, 10, 30, and 60 min extractions were investigated using the vibration shaker and pulsed-vortexer. Table 1 and Figure 2 show the results for incurred contaminants from salmon and croaker, respectively (individual analyte results are shown in Table S2 in the Supporting Information). The results for individual analytes in NIST SRM 1947 versus extraction time and method are also presented in Figures S1−S4. In salmon tissue, 1 min extraction yielded 62−75 and 74−100% for the vibrating and pulsed-vortexing shakers, respectively, relative to the probe blender results. These yields were greater than those in croaker, suggesting fish composition can play a role in extractability of the

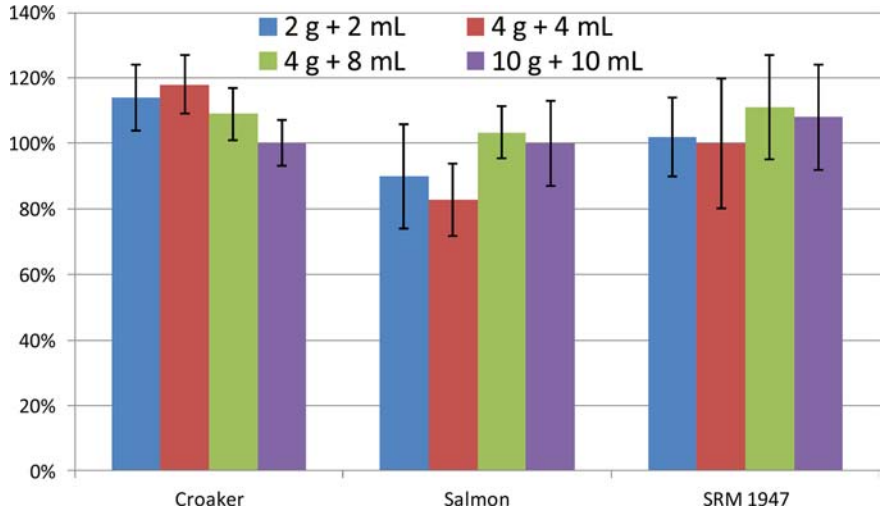

Figure 3. Average recoveries of incurred contaminants from croaker (23 analytes) and salmon (13 analytes), normalized to concentrations measured in samples using 10 g/10 mL (100%) and accuracy of measurements for SRM 1947 versus certified concentrations (27 analytes) for different sample/solvent ratios. See Table S2 in the Supporting Information for the specific analytes determined. Error bars represent standard deviation (n = 4).

contaminants. Lipid content in croaker is reported to be 3−4%, whereas salmon contains 5−10% fat, which often complicates the analysis due to the negative effects of lipids in both sample preparation and analysis. The concentrations of the contaminants in salmon were much lower compared to croaker, and the >100% relative recoveries (high bias) and worse precision in the results were probably due to greater measurement uncertainty at low analyte concentrations, especially in fatty samples.

In our previous study,[18] we observed negative correlations between recoveries of PBDE congeners and their log K_{ow} values. Pearson correlation coefficients were from −0.95 to −0.99, indicating that increased log K_{ow} caused decreased recoveries from lipid-containing samples. PBDE 153 has the highest log K_{ow} value of 7.9 compared to the other congeners determined in SRM 1947. PBDE 153 required 60 min of extraction time with the vibration shaker to reach the same yield as 1 min extraction with the pulsed-vortexer or probe blender (see Supporting Information Figure S5). Clearly, the pulsed-vortexer performed well to fully extract even the most lipophilic analytes in the fish samples containing up to 10% fat, and the prototype vibrational shaker did not adequately meet the need for rapid total extraction.

Sample Size and Solvent Ratio. Another aspect of the study was to determine the effect of sample size and sample/solvent ratio on the results for the incurred fish tissues. Smaller subsample size often translates into faster, easier, and less wasteful methods, provided that the subsample adequately represents the original sample. We used the pulsed-vortexer with 10 min of extraction time in the experiments to assess subsample sizes of 2, 4, and 10 g extracted with 2, 4, and 10 mL of MeCN, respectively (1 g/mL sample/MeCN ratio), and subsamples of 4 g were extracted with 8 mL of MeCN to evaluate 0.5 g/mL ratios. Due to the limited supply and high cost of SRM 1947, only 5/5 g/mL (n = 4) was tested in that case.

For salmon and croaker, the determined concentrations from extractions of 2/2, 4/4, and 4/8 g/mL were compared to concentrations measured using 10/10 g/mL, which was already shown to yield total extractability. As Figure 3 demonstrates, there was no difference in yields for any combination of sample/solvent ratio. This finding suggests that homogeneous subsample size can be minimized as long as it remains representative,[21] thereby requiring less organic solvent and leading to less waste. The same conclusions were drawn for SRM 1947 in the experiment, in which percent accuracy of determined versus certified concentrations did not depend on the subsample amount or sample/solvent ratio. This finding exposes another disadvantage of extraction using the probe blender, which needs at least 5 mL of solvent to work properly.

Fussell et al. evaluated homogeneity of analytical samples homogenized cryogenically versus room temperature, and they concluded that smaller portions of analytical sample can be representative when using cryogenic homogenization for certain matrices.[2] In the case of sample/solvent ratios in QuEChERS, Chamkasem et al. investigated sample/solvent ratios of 3/10, 3/15, 3/20, 3/25, and 3/30 g/mL MeCN for the analysis of lipophilic pesticides in avocado (≈15% fat),[22] and they concluded that 3/25 g/mL was sufficient to yield 100% recoveries from fortified samples. In our study, we did not observe a difference in extraction efficiencies for the same nonpolar pesticides using 1/1 or 1/2 g/mL sample/MeCN ratios in incurred fish. Perhaps the higher fat content in avocado and fat composition differences (salmon contains ≈3.5% of monounsaturated fat vs ≈9.5% in avocado) affected these findings.

In conclusion, we compared extractabilities of 35 incurred contaminants in 3 different types of fish tissues using 3 extraction devices (vibration shaker, pulsed-vortexer, and probe blender) for different lengths of time, subsample size, and solvent ratio. Our results showed that 1 min of extraction with the pulsed-vortexing shaker was sufficient for extraction of many incurred contaminants in the prehomogenized fish tissues, but we chose to use 10 min extractions as a precaution, which still attains 0.2 min/sample equivalent for a batch of 50 samples. The probe blender yielded similar results in 1 min, but cannot come close to approaching the high sample throughput, ease, convenience, safety, versatility, and other practical benefits of the pulsed-vortexer. Extraction with the prototype vibration shaker often took 60 min to achieve total extractability, and the

DOI: 10.1021/jf506256q
J. Agric. Food Chem. 2015, 63, 5163−5168

device is not likely to be commercialized. In other respects, 1 g/mL sample/MeCN was sufficient to achieve full extraction, and 2 g of homogenized subsample gave results equivalent to those with 4 and 10 g subsamples of the cryogenically homogenized fish tissues. This study demonstrated for real-world fish samples up to 10% fat content that a simple QuEChERS method using the pulsed-vortexer for batch extraction of 2 g subsamples with 2 mL of MeCN, followed by a convenient filter-vial d-SPE cleanup, provides complete extraction and high sample throughput. The use of LPGC-MS/MS permitted 10 min quantitative and qualitative analysis of 207 targeted contaminants (pesticides, PCBs, PAHs, PBDEs, and other FRs) at ultratrace concentrations in fish and similar sample types.

Supporting Information

ABSTRACT: This study used two LC columns of different adsorbents and liquid chromatography−electrospray ionization−high-resolution mass spectrometry to study the relationship between matrix effects (ME), the LC separations, and elution patterns of pesticides and those of matrix components. Using calibration standards of 381 pesticides at three dilution levels of 1×, 1/10×, and 1/100×, 108 samples were prepared in solvent and five different sample matrices for the study. Results obtained from principal component analysis and slope ratios of calibration curves provided measurements of the ME and showed the 1/100× sample dilution could minimize suppression ME for most pesticides analyzed. Should a pesticide coeluting with matrix components have a peak intensity of 25 times or higher, the suppression for that pesticide would persist even at 1/100× dilution. The number of pesticides had enhancement ME increased with increasing dilution from 1× to 1/100×, with those early eluting, hydrophilic pesticides affected the most.

INTRODUCTION

The development and use of liquid chromatography−electrospray ionization−mass spectrometry (LC-ESI-MS) instrumentation have gained tremendous momentum since the turn of the century. Using different LC-MS platforms, analytical methods have been developed for the analysis of organic contaminants such as pesticides,[1−3] antibiotics, pharmaceuticals, personal care products,[4−6] cyanotoxins,[7] and mycotoxins[8−10] in complex environmental and food matrices. These methods are characterized by their superior performance in sensitivity, selectivity, and ability to use rugged sample preparation procedures without requiring the extensive cleanup or derivatization that are commonly required by gas chromatography methods and allow for the development of multiresidue methods capable of analyzing >200 pesticides[11−15] in a single analysis.

LC-MS-based analytical methods suffer from matrix effects (ME)[16−22] that are common in environmental and food analyses and affect the data quality and accuracy of quantitative analyses. Matrix effects are commonly observed as suppression or enhancement of analyte signal in the ESI source and have been studied by many researchers since the mid-1990s. Most of the studies have been focused on the ESI suppression rather than the enhancement. The phenomenon of ESI suppression was first recognized by Kebarle and Tang[23,24] in 1993 with detailed mechanisms explained by Bruins.[25] The upper limit of the effective concentrations (total concentration of the analyte and matrix components) of those ion-emitting droplets in the ESI source was estimated[24] at 1×10^{-5} M (or 6.02×10^{18} charged ions/L). As long as the effective concentration is $<1 \times 10^{-5}$ M, the ESI source should be able to effectively ionize all analytes eluted from the column and no suppression of analyte(s) will be observed. Should the effective concentration become $>1 \times 10^{-5}$ M, the analyte(s) are forced to share the surface of the ion-emitting droplets with matrix components on a competitive basis, resulting in the suppression. Studies to date have been carried out by LC−tandem MS (LC-MS/MS) instrumentation with the sole goal of investigating the ESI suppression of target analytes.

Matrix components are "unknowns" in targeted LC-MS/MS analyses and have not been studied concurrently with the

analytes to gain an in-depth understanding of the ME. Consequently, operating strategies have been focused on the analytes without examining the possibility of resolving ME in the context of the matrix components. For example, exhaustive sample cleanup may help remove interfering components, but this is time-consuming and has the risk of losing analytes of interest and of variability of sample results. The use of matrix-matched calibration standards (MMCS) can be an effective approach, but this requires the availability of uncontaminated sample matrix to be used to prepare calibration standards, and this can be a difficult task. The blank matrix may not be identical to the sample matrix and still can cause biases in quantitative analysis. The use of standard addition[18] with which a fixed amount of analytical standards is added to the samples to generate a calibration curve for each sample may be effective but is tedious and impractical for real world sample analysis, where one must deal with a large number of samples and analytes. An effective approach to compensating for ME is the application of isotope dilution MS quantitation using isotopically labeled compound.[10] However, this is an impractical practice for multiresidue analysis with a large number of analytes. At the present time, sample dilution has been demonstrated to be the most effective approach to minimize ME.[20,26] This is performed by serially diluting the final extract such that lesser amounts of matrix components and analytes will be injected into the analytical system. Using post-column infusion and ME versus retention time (RT) plots, Stahnke et al.[26] demonstrated that a dilution factor of 25−40 of extracts would reduce the suppression of total ME to <20% of the initial suppression. This approach, and a similar split of the LC eluent flow before it enters the mass spectrometer, will be limited by the available sensitivity of a specific LC-MS system to reach the desired and required detection limits of the diluted extracts.

The availability of LC-ESI−high-resolution mass spectrometry (LC-ESI-HRMS)[27] systems offers the opportunity to investigate ME with new perspectives. These systems have the ability to acquire high-resolution, full mass spectral data with sensitivity comparable to that of LC-MS/MS systems. Full scan mass spectra not only provide information for the analyte(s) that are affected by sample matrix but also provide an opportunity to investigate other components in the sample that may be responsible for the suppression. These mass spectral data have high mass accuracy and peaks with full width at half-maximum (fwhm) in the 1.5×10^{-3} Da range, allowing for the use of a very narrow mass extraction window (MEW),[28] that is, 5 ppm, to construct extracted ion chromatogram (XIC) for target analyte(s) and matrix components. XICs obtained from these experiments separate pesticides and matrix components in both chromatographic and mass spectrometric domains, provide retention time and area count for the identification and quantization of target pesticides and area counts for the semiquantitative analysis of "unknown", that is, matrix components, and become vital for the concurrent study of ME from the perspective of both target analyte(s) and matrix components. We report in this paper results obtained from LC-ESI-HRMS experiments with an emphasis on the relationship

J. Agric. Food Chem. 2015, 63, 5169−5177

between ME and pesticides in terms of the LC separations and elution patterns.

EXPERIMENTAL PROCEDURES

Chemicals. The majority of the 381 pesticide standards were obtained from the United States Environmental Protection Agency (U.S. EPA) Pesticide Repository (Ft. Meade, MD, USA), whereas others were obtained through Fluka/Sigma-Aldrich (St. Louis, MO, USA), EQ Laboratories (Dr. Ehrenstofer, Atlanta, GA, USA), and Wako Chemicals USA (Richmond, VA, USA) and are listed in the Supporting Information (SI) (Table S1). HPLC grade water, acetonitrile (CH_3CN), methanol (MeOH), formic acid (HCOOH), ammonium formate (CH_3COONH_4), anhydrous $MgSO_4$, and NaCl were purchased from Fisher Scientific (Pittsburgh, PA, USA). Deuterium-labeled diazinon ($^2H_{10}$-diazinon) was purchased from CDN-Isotopes (Montreal, QC, Canada) and used as internal standard. The QuEChERS product, that is, 4 g of anhydrous magnesium sulfate and 1 g of sodium chloride in 50 mL centrifuge tubes, was purchased from United Chemical Technologies (UCT; Bristol, PA, USA). Five sample matrices consisting of avocado, spinach, honey, orange, and hazelnut were purchased as organic products from commercially available sources. Laboratory nanopure water generated by passing reverse osmosis water through a Thermo Scientific Barnstead Nanopure water purification system was used in the sample preparation and HPLC analysis.

Sample and Standard Preparation. All sample matrices (avocado, orange, spinach, honey, and hazelnut) were prepared using a modified AOAC QuEChERS (quick, easy, cheap, effective, rugged, and safe) method.[1,2] Avocado, orange, and spinach were prepared by weighing 10 ± 0.2 g of cryo-ground sample in 50 mL disposable screw-capped polypropylene centrifuge tubes (Fisher Scientific). Ten milliliters of water was first added to honey (10 ± 0.2 g) and ground hazelnut (5.0 ± 0.02 g) and mixed thoroughly to lessen the viscosity of the honey and to form a homogeneous mixture in the same 50 mL centrifuge tubes. These sample tubes were extracted by the addition of 10 mL of CH_3CN, 4 g of anhydrous $MgSO_4$, and 1 g of anhydrous sodium chloride (UCT). After hand-shaking the sample to prevent clumping of the salts, the sample tubes were placed on a GenoGrinder mechanical shaker (SPEX Sample Prep, LLC, Metuchen, NJ, USA) for 1 min at 1000 strokes/min. Samples were then centrifuged (Labnet Z383, Atlanta, GA, USA) at 4500 rpm for 5 min to separate the sample and extracts. The extracts (~9 mL), which had about 1.0 g/mL of matrix components, were transferred into 12 mL screw-capped polypropylene centrifuge tubes through 0.2 μm PTFE membrane filters (Sun SRi, Rockwood, TN, USA) and used later in the preparation of matrix-matched calibration standard (MMCS).

Six intermediate, solvent-only calibration standards (SOCS) of 381 pesticides were prepared in CH_3CN at six concentration levels of 400, 200, 100, 50, 10, and 5 ng/g (ppb). Using 100 μL of these SOCS with 900 μL of CH_3CN in six separate 1.5 mL autosampler vials resulted in six SOCS at concentration levels of 40, 20, 10, 5, 1, and 0.5 ng/g, which are labeled as 1× SOCS samples (Figure 1). Those 1× MMCS samples were prepared in the same manner by mixing 100 μL of the SOCS and 900 μL of matrix materials in 36 autosampler vials, achieving five MMCS sample sets at six concentrations of 40, 20, 10, 5, 1, and 0.5 ng/g. The 1/10× samples were prepared by diluting 100 μL of the 1× samples using 900 μL of CH_3CN, resulting in 36 samples at pesticide concentrations of 0.05−4 ng/g. Those 1/100× samples were prepared using 100 μL of 1/10× samples and 900 μL of CH_3CN, resulting in concentrations from 0.005 to 0.4 ng/g. After removal of 100 μL of solution from each of the 1/100× sample sets, 20 μL of 2000 ng/g internal standard $^2H_{10}$-diazinon was added to all sample vials to compensate for possible sample volume variation, homogenized on a vortex at 100 rpm, and stored in a freezer at −5 °C until ready for analysis. Matrix components in the 1×, 1/10×, and 1/100× MMCS solutions were about 900, 80, and 7 mg/mL, respectively. Quality control samples prepared with each sample set include matrix blank and system blank (CH_3CN).

LC-Orbitrap MS Analysis. A Thermo Scientific Dionex UltiMateTM 3000 HPLC system consisting of an HRG-3400RS binary pump, a WPS-3000 autosampler, and a TCC-3400 column compartment was used in the HPLC analysis. LC separations were achieved on a Restek Ultra Aqueous non-end-capped C-18 (uAqueous, 3 μm, 100 Å pore size, 15% carbon loading, Bellefonte, PA, USA) and a Thermo Scientific Accucore aQ end-capped C-18 (Accucore, 2.6 μm, 80 Å pore size, 9% carbon loading, San Jose, CA, USA) columns. Both columns had dimensions of 100 × 2.1 mm and had 10 × 2.1 mm guard cartridges. The injection volume used was 15 μL. Mobile phases used were (A) 5 mM $HCOONH_4$ and 0.1% HCOOH in CH_3OH/H_2O = 5:95 v/v and (B) 5 mM $HCOONH_4$ and 0.1% HCOOH in CH_3OH/H_2O = 95:5 v/v. The HPLC separation used an initial equilibration time of 3 min at 5% B. Gradient separation was achieved from 5% B at 0 min, increased to 20% B at 4 min, increased to 40% B at 5.5 min, and increased to 98% B at 10.5 min and maintained at 98% B until the end of the analysis at 15 min. The column temperature used was 35 °C. The flow rates used were 350 μL/min (uAqueous) and 420 μL/min (Accucore).

The HPLC was interfaced to a Thermo Scientific Exactive Plus (Orbitrap MS) using heated ESI (HESI) interfaces. The Orbitrap MS system were tuned and calibrated in positive ion mode by infusion of standard mixtures of MSCAL5 (Sigma-Aldrich). High-purity nitrogen (>99%) was used in the ESI source (35 L/min). The capillary and the HESI temperatures were set at 300 °C. Mass spectrometric data were collected using a spray voltage of 3000 V and a resolving power of 140,000 (full width half-maximum peak width at m/z 200, R_{fwhm}), resulting in a data acquisition rate of 1.5 scans/s when using automatic gain control of 1×10^6 and a C-trap inject time of 50 ms. The R_{fwhm} used meets the minimally required R_{fwhm} of 60,000[29] to carry out multiresidue chemical analysis. The flow rates and analytical columns used in the separation result a chromatographic fwhm of 3−9 s. Therefore, at least nine data points were available to accurately define XIC chromatograms for quantitative analysis. Retention times (RT) from the two LC columns and instrument detection limit (IDL) of the system are listed in Table S1 (SI).

Data Analysis. Analytical data collected were processed offline using Xcalibur 3, TraceFinder 3.2, and SIEVE 2.1 (Thermo Scientific, San Jose, CA, USA) data processing packages. Xcalibur was used to process mass spectral data for graphic presentation. TraceFinder was used to derive area counts, to do quantitative analysis, and to evaluate the ME. A MEW of 5 parts per million (ppm) was used to create XIC chromatograms for quantitative analysis of target analytes and semiquantitative analysis of matrix components. Results were exported to Excel for data compilation, statistical evaluation, and the determination of R_{slope}. Principal component analysis (PCA) and differential expression analysis (DEA) were achieved by SIEVE using Orbitrap mass spectral data sets without further modifications.

RESULTS AND DISCUSSION

Effects of LC Separation and Sample Dilution on ME. Effects of matrix components on the 381 pesticides studied were first examined. Values of slope ratio (R_{slope}) have been used to gauge the extent of ME exerted by different matrices on target pesticides.[2] Different from the post-column infusion approach, which used ME versus RT plots[30] to estimate combined ME at a specific RT, the R_{slope} approach calculated the ratio of slopes of MMCS and SOSC calibration curves for each pesticide to provide ME information for a specific pesticide. In the absence of experimental error, a value of 1.00 for the R_{slope} shows no ME, whereas values deviating from 1.00 indicate the existence of ME as ESI suppression or enhancement. Values of the R_{slope} are listed in Si Tables S2 and S3, respectively, for the uAqueous and Accucore columns. The lowest calibration levels for 1×, 1/10×, and 1/100× samples were 0.5, 0.05, and 0.005 ng/g, equivalent to LC column loadings of 7.5×10^{-12}, 0.75×10^{-12}, and 0.075×10^{-12} g.

From Table S1, pesticides in low-level calibration solutions may become less than their corresponding IDL and were not detected, labeled as "not detected", and not used for calibration. That pesticide will be marked as "NA" in SI Tables S2 and S3 with more than three calibration levels in a specific sample set failing to meet this criterion. Plots of R_{slope} versus RT for the five sample matrices, three dilutions levels, and two LC columns are shown in SI Figures 1−5. The effect of sample dilutions on suppression is demonstrated in Figure 2 using results obtained from uAqueous column for anilofos, tribufos (DEF), and vernolate, with results obtained from Accucore column shown in SI Figure 6.

From Figure 2 and SI Figure 6, one could observe that suppression is dependent on the LC columns but may not be

DOI: 10.1021/jf505168v
J. Agric. Food Chem. 2015, 63, 5169−5177

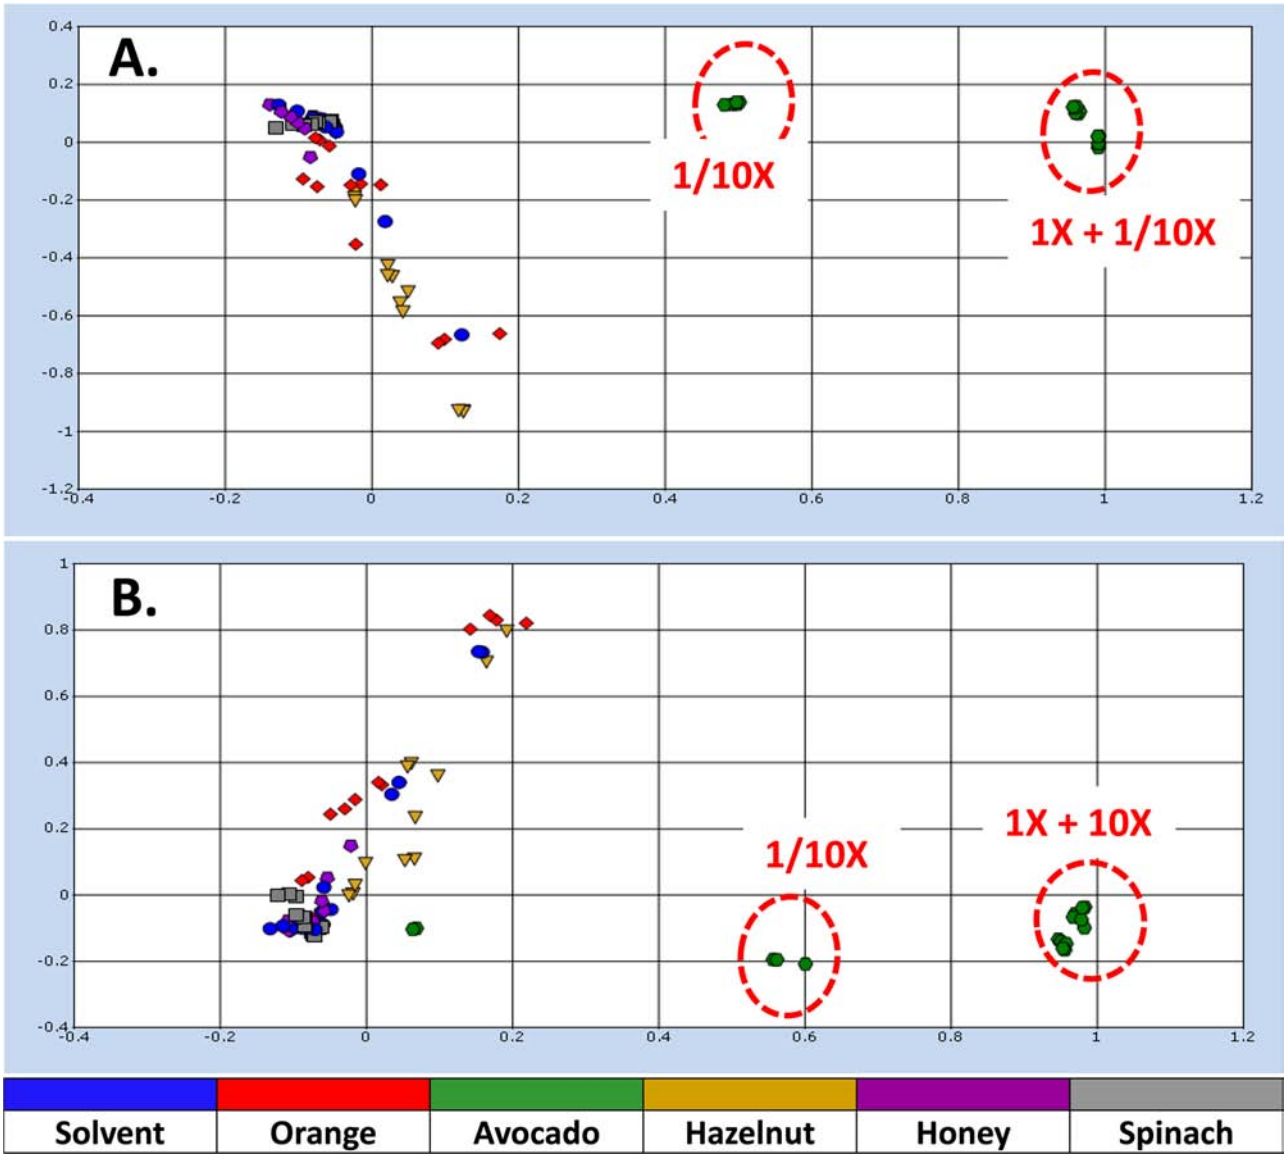

Figure 3. Results of PCA loadings (scores) of SOCS and MMCS samples (denoted by the color chart at the bottom) using uAqueous and Accucore for 1×, 1/10×, and 1/100× diluted samples.

proportional to dilution. Tribufos is the most suppression-affected pesticide and has R_{slope} values of 0.286 and 0.290 from uAqueous and Accucore columns in 1× samples (Figure 2F and SI Figure 6F). Figures 2E and SI Figure 6E show R_{slope} values of tribufos improved by about 100% to 0.599 and 0.574 for the 1× to 1/10× dilution and reached 0.956 and 0.850, respectively, at 1/100× dilution using uAqueous and Accucore columns (Figure 2D and SI Figure 6D). The effect of 1/10× dilution is less for anilofos and is estimated at 27 and 6%, respectively, for uAqueous and Accucore columns (Figure 2B and SI Figure 3B). Minimal suppression can be observed with a 1/100× dilution (Figure 2A,D and SI Figure 6A,D) for anilofos and tribufos using either LC column. In the case of vernolate, minimal suppression is observed using either uAqueous or Accucore columns.

Table 1 summarizes the number of pesticides with values of R_{slope} > 1.2 (enhancement), 1.2 > R_{slope} > 0.8 (minimal ME), and R_{slope} < 0.8 (suppression) for the two columns. Using Table 1 and SI Figures 1−5, one could conclude that suppression decreased with increasing dilutions for all but the honey matrix, which had suppression increased from dilutions 1/10× to 1/100× in both columns. A behavior may be associated with the high sugar contents of honey. One can also observe from SI Figures 1−5 the number of pesticides with R_{slope} > 1.2 increased with dilutions from 1× to 1/10× to 1/100×. In addition, enhancement affected those hydrophilic pesticides more than those less polar ones. The enhancement is more obvious in the uAqueous column than in the Accucore column. There is a minimal understanding of the enhancement ME at the present time, and we cannot explain this phenomenon. As expected, suppression decreases with increasing sample dilution, and the number of pesticides found in the 1.2 > R_{slope} > 0.8 range reached the maximum at 1/100× dilution. The avocado matrix exerted the highest level of suppression on the 381 pesticides compared to the other matrices as only 23% pesticides were ME free at 1× dilution. At 1/100× dilution, >77% of the pesticides became suppression-free in avocado. Honey as an outlier had >96% pesticides ME free at 1/10× dilution. These demonstrate that dilution is an effective approach to alleviate suppression ME in LC-MS analysis.

DOI: 10.1021/jf505168v
J. Agric. Food Chem. 2015, 63, 5169−5177

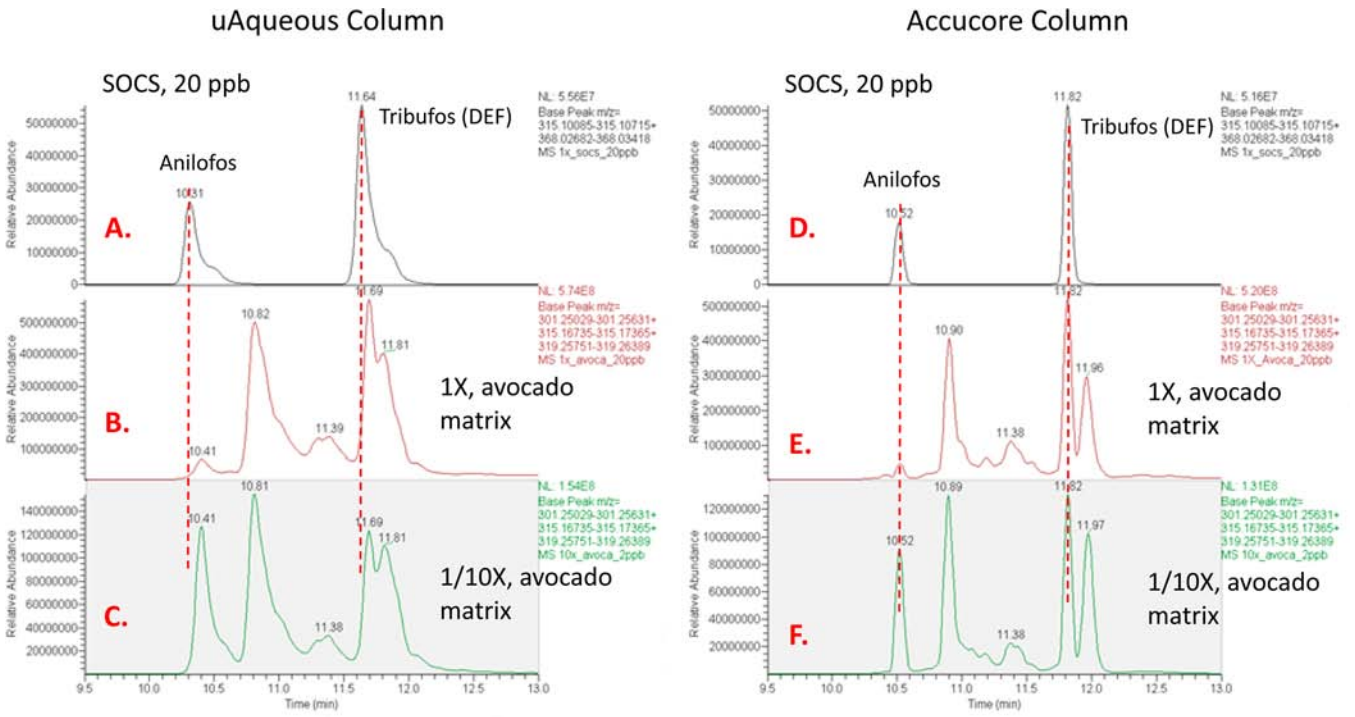

Figure 4. Extracted ion chromatograms (XICs) of pesticides anilofos and tribufos obtained from SOCS (20 ppb) and avocado MMCS samples using uAqueous and Accucore LC columns at 1× and 1/10× dilutions.

At 1/100× dilution, and with the increasing number of pesticides not having a valid R_{slope}, the number of pesticides in the $1.2 > R_{slope} > 0.8$ range was less than expected. For example, 340 and 359 of the 381 pesticides in spinach matrix using uAqueous or Accucore columns at 1/10× dilution were considered as ME free. The number of suppression-free pesticides decreased to 325 and 315 in spinach, whereas the number of those "NA" pesticides increased >20 times to 6.0 and 6.3%, respectively, for uAqueous and Accucore columns. It is clear that higher levels of dilution reduce the overall analytical sensitivity of LC-MS analysis and should be optimized according to the ionization efficiency of each pesticide during the method development and validation stages to ensure a consistent data quality.

Principal Component and Differential Expression Analysis of LC-Orbitrap MS Data. Shown in Figure 3 are results obtained from PCA of the uAqueous and Accucore LC-Orbitrap MS data sets by plotting the sample loadings (scores) of SOCS and MMCS samples collected at the three dilution levels. The PCA used mass spectral data of the 108 samples to form a data set of m/z versus intensities of pesticides and matrix components. Using the first three orthogonal factors (eigenvalues) calculated from the data set, the contribution of each sample to the data set was calculated as a linear combination of weighted values (scores) and plotted along the eigenvectors. Samples with similar contributions to the data set will have similar scores along the eigenvectors and form clusters in the plot. From Figure 3A (uAqueous) and Figure 3B (Accucore), MMCS samples of avocado (green) at 1× and 1/10× dilutions are separated from the other samples in two distinct clusters of 1/10× and ($1x$ + 1/10×) and would have different contributions on the data sets. Other MMCS samples (including those 1/100× avocado samples) have similar contributions to those of SOCS samples, clustered together around the origin, and are considered to have been minimally affected by ME. This observation is supported by the differential expression analysis (DEA) results in which XICs obtained from targeted pesticides (known) and matrix components (unknown) were aligned and shown in SI Figure 7A,B to allow a visual examination of all XICs in one plot. From SI Figure 7, matrix components of avocado (green) and hazelnut (brown) eluted between 10 and 12 min, whereas orange matrix components (red) eluted around 10 min. The avocado matrix components have peak intensities reaching 4×10^9, whereas hazelnut (brown, underneath avocado) and orange (red, around 9−11 min) matrices have peak intensities $<1 \times 10^9$. The XIC base peak intensities of pesticides and other matrix components (i.e., honey and spinach) were much lower than 1×10^9 and were around the baseline area. It is also observed that base peak XICs obtained from the Accucore column (using adsorbent of a 1.75 μM effective core, SI Figure 7B) have, in general, a narrower fwhm chromatographic peak than those from the uAqueous column, which uses 2.6 μm sized particles.

Relationship between Matrix Component Base Peaks and Matrix Effects. Base peak XICs obtained from DEA also provided m/z information on matrix components with significant intensities. Avocado matrix has three major base peaks at m/z 301.2546, 315.1705, and 319.2637, whereas orange matrix has only one base peak at m/z 373.1285. Base peak XICs obtained from m/z 301.2546, 315.1705, and 319.2637 using 1× (1 ng/g) and 1/10× (0.1 ng/g) avocado MMCS samples are shown in Figure 4B,C (uAqueous) and 4E,F (Accucore). Base peak XICs of anilofos and tribufos obtained from corresponding SOCS samples are shown in Figure 4A,D for comparison. Expanded plots of Figure 4A−F are shown in SI Figures 8 and 9. From Figure 4, the avocado XIC peaks had intensities $\approx 5.1 \times 10^8$ in the 1× samples from uAqueous (B) and Accucore (E), decreased by 80% to $(1.2-1.5) \times 10^8$ in the 1/10× samples (C and F), and still have

Table 2. Peak Concentrations Calculated for Seven Pesticides of Different Molecular Weights Eluted at Different Retention Times and Two Different Injection Concentrations

compound	LC column	RT (min)	N_{HETP}	V_{peak} (μL)	peak concentration (M)	
					20 ppb inj	100 ppb inj
acetaprimid (222.0672)	uAqueous C18	7.58	1.02×10^4	28	3.20×10^{-8}	1.60×10^{-7}
	Accucore C18	6.72	5.97×10^4	10	8.74×10^{-8}	4.37×10^{-7}
ametryn (227.1205)	uAqueous C18	9.31	2.87×10^4	21	4.27×10^{-8}	2.14×10^{-7}
	Accucore C18	9.18	1.15×10^5	10	8.68×10^{-8}	4.34×10^{-7}
warfarin (308.1048)	uAqueous C18	9.58	4.37×10^4	17	3.78×10^{-8}	1.89×10^{-7}
	Accucore C18	9.64	1.23×10^5	10	6.30×10^{-8}	3.15×10^{-7}
azinphos-ethyl (345.0371)	uAqueous C18	9.76	3.81×10^4	19	3.09×10^{-8}	1.55×10^{-7}
	Accucore C18	10.12	1.64×10^5	9	6.18×10^{-8}	3.09×10^{-7}
anilofos (367.0232)	uAqueous C18	10.31	4.25×10^4	19	2.91×10^{-8}	1.45×10^{-7}
	Accucore C18	10.50	2.76×10^5	8	7.27×10^{-8}	3.63×10^{-7}
diazinon (304.1010)	uAqueous C18	10.43	5.18×10^4	17	3.83×10^{-8}	1.91×10^{-7}
	Accucore C18	10.55	1.31×10^5	11	6.02×10^{-8}	3.01×10^{-7}
tribufos (315.0961)	uAqueous C18	11.63	8.45×10^4	15	4.25×10^{-8}	2.12×10^{-7}
	Accucore C18	11.82	2.09×10^5	10	6.57×10^{-8}	3.29×10^{-7}

significant ME on the two pesticides. This observation matches well with a prior study[26] that ME correlate linearly with the logarithm of the matrix concentration. The second avocado peak at RT 10.4 and 10.5 min (uAqueous and Accucore, respectively) behaves in an opposite manner with the peak intensity increased by >100% from $\approx 0.5 \times 10^8$ in the 1× (B and E) to $\approx 1.0-1.2 \times 10^8$ (C and F) in the 1/10× MMCS samples.We attribute this to the redistribution of the ESI resource from the 11.7 min to the 10.4 min avocado peaks. It is possible that the 11.7 min peak consumes a majority of the ESI resource and suppresses the ionization of coeluting analyte and other matrix components. With the 11.7 min avocado component diluted 1/10×, both the analyte and other matrix components can be ionized better and, thus, increase peak intensity.

Anilofos and tribufos coeluted separately with the 10.4 and 11.7 min avocado peaks and have peak intensities of $(1.8-2.2) \times 10^6$ and $(2.9-33) \times 10^6$ (Figure 4A,D). The 10.4 min avocado peak has a 20 times higher peak intensity than anilofos, whereas the 11.7 min avocado peak is about 170 times higher than tribufos. As a result, suppression of anilofos (R_{slope} values of 0.648 or 0.745 in uAqueous and Accucore columns) was less than that of tribufos (R_{slope} values of 0.286 or 0.290 in uAqueous and Accucore columns). This supports the suppression ME occurring for a specific pesticide that coelutes with a matrix component with a peak intensity of 25 times or higher. The level of suppression of the pesticide will vary with the close proximity of the RT and relative intensity of the coeluting matrix component. Sample dilution can alleviate or eliminate the level of ME for pesticides with RT different from the coeluting matrix component; however, it will be difficult to reduce ME for pesticides analyzed with matrix component coeluted at the exact RT and a peak intensity of 25 times or higher.

Examination of Matrix Effects in Multiresidue Pesticide Analysis. The discussions above lead to the root cause of ME in LC-MS multiresidue analysis. Kebarle et al.[23,24] determined that suppression of analyte intensity would occur when the total concentration of analytes eluting from a HPLC column is $>10^{-5}$ M. The concentration (C, in units of molar concentration) of an analyte eluted from the HPLC column can be calculated stoichiometrically using the estimated peak volume (V_{peak}) of that specific peak and the column loading (W) such that[31]

$$C = (W/\mathrm{MW})/V_{peak} \quad (1)$$

where MW is the molecular weight of an analyte, W is the weight of a specific pesticide and can be calculated using the injection volume (i.e., 10 μL) and the analyte concentration (i.e., ppb or ng/g), and

$$V_{peak} = 4 \times (V_0 \times (1 + k')/(N_{HETP})^{1/2}) \quad (2)$$

where V_0 is the column void volume used in the analysis, k' is the peak capacity of the peak, and N_{HETP} is the number of height equivalent theoretical plates.

Using eqs 1 and 2, estimated peak concentrations of seven selected pesticides with MW from 222 to 367 and RT from 6.57 to 11.82 min were calculated for the three different LC columns used in this study and are listed in Table 2.

In the case of LC analysis with effective peak concentrations ranging from 2×10^{-7} to 9×10^{-8} M, a matrix component (assuming the same ionization efficiency) with a 100× higher concentration than the coeluting pesticide would bring the total effective peak concentration to approximately 2×10^{-5} M, higher than the 1×10^{-5} M threshold, resulting in ME. Coeluting matrix component(s) have similar chemical properties to target compounds and cannot be removed using nonspecific cleanup procedures. The use of different LC gradients and/or columns, along with the collection of mass spectral data of all eluents, would allow the optimization of LC parameters during the method development and validation stages. This will minimize ME and allow dilute-and-shoot LC-MS analysis without prior cleanup to improve data quality and

DOI: 10.1021/jf505168v
J. Agric. Food Chem. 2015, 63, 5169−5177

operation efficiency in targeted pesticide analysis. It is worth noting from Table 2 that LC peak concentration of pesticides from 20 ppb SOCS ranged from 2×10^{-7} to 9×10^{-8} M, indicating that any ESI source can effectively ionize at least 40 coeluting pesticides (assuming similar ionization efficiency) without causing any concern for ME. This provides a viable solution during the method validation to develop an optimized LC gradient to separate analytes from matrix components and resolve ME in routine LC-MS analysis.

Supporting Information

ABSTRACT: Biolignin, a wheat straw lignin produced by acetic acid/formic acid/water hydrolysis, was characterized by ^{31}P and ^{13}C−^{1}H 2D NMR spectroscopy and by size-exclusion chromatography. Biolignin is a mixture of low molar mass compounds (M_n = 1660 g/mol) made up of S, G, and H units and of coumaric and ferulic acid units. β-5 and β-O-4 interunit linkages are partially acylated in the γ-position by acetate and *p*-coumarate groups. Deacylated samples with a low content of contaminants were obtained by combining alkaline hydrolysis and solvent extraction. The high phenolic OH content found by ^{31}P NMR reflects the presence of condensed aromatic units, such as 5−5 units. Reaction of purified lignin with ethanol and ethane-1,2-diol yielded esterified lignins much more soluble than Biolignin in common organic solvents. During this reaction, the secondary OH of β-O-4 linkages was simultaneously etherified. Phenol hydroxyethylation by 2-chloroethanol yielded samples containing only aliphatic hydroxyl groups.

KEYWORDS: *wheat straw lignin, NMR, esterification, etherification*

INTRODUCTION

Conversion of lignin to value-added products is one of the challenges for the expanding biobased products industry. In this context, the utilization of lignin from grasses, and especially from crop residues, has attracted increasing research attention.[1,2] Wheat straw lignin is a major industrial crop residue and its separation, purification, and structure have been extensively studied.[3−12] Like lignins from other grasses, wheat straw lignin is a complex polymer formed of three types of aromatic units, syringyl (S), guaiacyl (G), and 4-hydroxyphenyl (H) units, linked to each other by short aliphatic "side chains" of various types through C−C or C−O−C bonds. It presents a relatively high content of acetate and *p*-hydroxycinnamate groups, predominantly bound at the γ-position of side chains.[13] In plants, lignin is linked to polysaccharides, mainly hemicellulose, by ether or ester groups, thus ensuring structural cohesion and rigidity to cell walls. The delignification process, designed to cleave lignin−saccharide bonds, leads to more or less extensive modification of native lignin structure. Therefore, the composition of the resulting technical lignins, for example, the relative abundance of S/G/H units, the nature of side chains, the presence of cinnamate and acetate groups and the content in functional groups (alcohols, phenols, and carboxylic acids), is highly dependent on the delignification process conditions.[14]

Technical lignins are highly functionalized aromatic compounds and, as such, particularly attractive for use as comonomers in polymeric materials.[15] Lignins have thus been used as rigid polyols in polyester,[15−18] polyurethane,[19−21] and epoxy[22−24] thermosetting resins and, after modification, for the synthesis of starlike polystyrene and poly(methyl methacrylate).[25] However, several issues have to be addressed before lignins can find extensive applications in polymeric materials:

(1) Technical lignins are rarely recovered in pure form. While the major portion of hemicelluloses is removed during the fractionation step, the presence of residual carbohydrates in crude lignin fractions (i.e., obtained directly after the delignification process) cannot be excluded. Wax and sugar content in a lignin sample are closely related to the process and to the pre- or posttreatment steps used for lignin isolation. Their presence has to be carefully considered as it may influence lignin reactivity and, therefore, the properties of final materials. Treatment of straw by apolar/polar solvents mixtures prior to the fractionation process is used in some cases to produce dewaxed straw.[3−5] On the other hand, basic hydrolysis is an efficient way to remove residual polysaccharides by cleavage of ester linkages between hemicellulose and lignin, yielding almost polysaccharide-free technical lignins.[4,6,26,27]

(2) As mentioned above, the structure of technical lignins depends heavily on the conditions used in the delignification and purification processes. In order to elaborate materials with controlled properties and to ensure synthesis repeatability, an in-depth knowledge of lignin structure and reactivity is required.

(3) With regard to polymer synthesis, the major drawbacks of technical lignins are their low solubility in organic medium, their functional group heterogeneity, and their relatively poor hydroxyl group accessibility.

DOI: 10.1021/acs.jafc.5b02071
J. Agric. Food Chem. 2015, 63, 5178−5188

To overcome these issues, preliminary purification and chemical modification of technical lignins have been described: for example, esterification of hydroxyl groups by anhydrides,[28] reaction with epichlorhydrin,[22] or reaction with propylene oxide.[29−31] While the characterization of oxypropylated lignin with modern methods has been reported,[31,32] most modified technical lignins, however, have subsequently been used without detailed characterization.

The aim of this study was to evaluate the influence of purification steps and of esterification and etherification chemical modifications of wheat straw lignin on its chemical and structural characteristics. This study was undertaken on wheat straw lignin produced by the CIMV (Compagnie Industrielle de la Matière Végétale) acetic acid/formic acid/water fractionation process,[11,33] available under the trade name Biolignin. Lignin was first purified by hydrolysis and solvent extraction and then modified by esterification with ethanol or ethane-1,2-diol to mask acid groups or by etherification with 2-chloroethanol in alkaline conditions to convert phenol groups into more reactive primary alcohols. The modification reactions were expected to provide samples with enhanced solubility, homogenized functionality in terms of function types, and improved reactivity for future applications as comonomer in polymeric materials. These samples were thoroughly characterized by means of ^{31}P and $^{13}C-^{1}H$ 2D NMR spectroscopy and size-exclusion chromatography (SEC).

MATERIALS AND METHODS

Materials. Absolute ethanol, ethane-1,2-diol (99.8%), 2-chloroethanol (99%), *p*-coumaric acid (98%), ferulic acid (99%), sinapic acid (98%), *p*-toluenesulfonic acid monohydrate (98.5%), sulfuric acid (99%), 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane (95%), anhydrous pyridine (99.8%), chromium(III) acetylacetonate (97%), and acetic anhydride (≥99%) were obtained from Sigma−Aldrich (Saint-Quentin-Fallavier, France). *N*-Hydroxy-6-norbornene-2,3-dicarboximide (>96%) was obtained from Fluka (Saint-Quentin-Fallavier, France). All reagents were used without further purification.

Biolignin (Klason lignin content 89.8%)[34] was obtained from CIMV (Compagnie Industrielle de la Matière Végétale, Neuilly, France). Wheat straw from *Triticum aestivum* L. subsp. *aestivum*, seeded in November 2011, was harvested in Champagne region (France) in July 2012. Biolignin was extracted by the CIMV process with acetic acid/formic acid/water 30:55:15 v/v/v) at 105 °C under atmospheric pressure.[12,33]

Lignin Purification. Biolignin (20.19 g) was hydrolyzed by 1 M aqueous NaOH (300 mL) at 80 °C for 4 h. The reaction mixture was then acidified to pH 2 with 3 M aqueous HCl. The precipitate was filtered and washed thoroughly with deionized water until neutral pH, then dried at 50 °C under reduced pressure for 24 h to give 18.13 g of hydrolyzed Biolignin (Lh; yield 90 wt %). The acidic filtrate was concentrated under reduced pressure to afford a dried hydrolysis residue, Rh.

Lh was further purified by repeated washing steps with CH_2Cl_2 (2×) and ethyl acetate (3×) as follows: Lh (17 g) was poured into 100 mL of solvent, heated to reflux for 1 h, and filtered. After drying under reduced pressure, 13.33 g of purified Biolignin (Lp) was obtained (overall yield from Biolignin 70.5 wt %). Organic phases were evaporated to yield the purification residue, Rp.

Modification of Lignin with Ethanol. Lp (2 g), ethanol (30 mL), and *p*-toluenesulfonic acid monohydrate as a catalyst (200 mg, 0.8 wt %) were heated at 80 °C for 20 h. The insoluble fraction was filtered on sintered glass filter (porosity 5), washed with deionized water until neutral pH, and dried overnight at 50 °C under vacuum to give 1.25 g of ethanol-insoluble modified lignin (i-Lp-Et). The alcohol phase was concentrated under reduced pressure. The residue was precipitated in 200 mL of water, filtered on sintered glass filter (porosity 5), and dried overnight at 50 °C under vacuum to yield 0.75 g of ethanol-soluble modified lignin (s-Lp-Et).

Modification of Lignin with Ethane-1,2-diol. Lp (5 g), ethane-1,2-diol (75 mL) and *p*-toluenesulfonic acid monohydrate as a catalyst (530 mg, 0.6 wt %) were heated at 90 °C for 20 h. The homogeneous mixture was poured into 500 mL of deionized water. The precipitate was filtered on sintered glass filter (porosity 5), washed with deionized water until neutral pH, and dried at 50 °C under vacuum for 24 h to give 4.95 g of ethane-1,2-diol-modified lignin (Lp-EG).

Modification of Lignin with 2-Chloroethanol. Lp (3.1 g) was dissolved in 30 mL of 1 M aqueous NaOH at 90 °C. 2-Chloroethanol (6 mL, 84 mmol) was added dropwise and the mixture was heated at 90 °C for 20 h. The mixture was poured into 300 mL of water and neutralized with 2 M aqueous HCl. The precipitate was filtered on sintered glass filter (porosity 5) and dried at 50 °C under vacuum for 24 h to give 2.80 g of 2-chloroethanol-modified lignin (Lp-CE).

Synthesis of 4-(2-Hydroxyethoxy)cinnamic Acids. 4-(2-Hydroxyethoxy)cinnamic acids were synthesized by reacting the corresponding 4-hydroxycinnamic acids with 2-chloroethanol in alkaline medium according to a procedure described for hydroxyethoxylation of 4-hydroxybenzoic acid.[35]

(2E)-3-[4-(2-Hydroxyethoxy)phenyl]prop-2-enoic Acid, ***20****.* A solution of *p*-coumaric acid (8.2 g, 50 mmol) in 40 mL of 3 M aqueous NaOH was heated to 50 °C. 2-Chloroethanol (5 mL, 75 mmol) was added slowly, and the mixture was heated at 90 °C for 6 h. After cooling, the mixture was poured into 50 mL of deionized water and acidified with 1 M aqueous HCl. The residue was filtered and washed with acetone to remove residual *p*-coumaric acid and ester byproducts. Product **20** was recrystallized from ethanol: yield 6.2 g (60%). ^{1}H NMR (DMSO-d_6) δ, ppm 7.61 (d, J = 8 Hz, H-2, H-6), 7.54 (d, J = 16 Hz, H-α), 6.96 (d, J = 8 Hz, H-3, H-5), 6.36 (d, J = 16 Hz, H-β), 4.02 (t, J = 6 Hz, $-CH_2-$OAr), 3.72 (t, J = 6 Hz, $-CH_2-$OH). ^{13}C NMR (DMSO-d_6) δ, ppm 167.7 (C-γ), 160.3 (C-4), 143.6 (C-α), 129.8 (C-2, C-6), 126.6 (C-1), 116.4 (C-β), 114.8 (C-3, C-5), 69.6 ($-CH_2-$OAr), 59.4 ($-CH_2-$OH).

(2E)-3-[4-(2-Hydroxyethoxy)-3-methoxyphenyl]prop-2-enoic Acid, ***21****.* Compound **21** was synthesized from ferulic acid following the same procedure: yield 5.6 g (47%). ^{1}H NMR (DMSO-d_6) δ, ppm 7.51 (d, J = 16 Hz, H-α), 7.31 (d, J^4 = 2 Hz, H-2), 7.17 (dd, J^4 = 2 Hz, J^3 = 8 Hz, H-6), 6.97 (d, J^3 = 8 Hz, H-5), 6.44 (d, J = 16 Hz, H-β), 4.00 (t, J = 6 Hz, $-CH_2-$OAr), 3.81 (s, $-CH_3$-O−), 3.72 (t, J = 6 Hz, $-CH_2-$OH). ^{13}C NMR (DMSO-d_6) δ, ppm 167.9 (C-γ), 150.1 (C-4), 149.0 (C-3), 144.1 (C-α), 127.0 (C-1), 122.5 (C-6), 116.6 (C-β), 112.5 (C-5), 110.4 (C-2), 70.1 ($-CH_2-$OAr), 59.4 ($-CH_2-$OH), 55.5 (CH_3O−).

(2E)-3-[4-(2-Hydroxyethoxy)-3,5-dimethoxyphenyl]prop-2-enoic Acid, ***22****.* A solution of sinapic acid (0.9 g, 4 mmol) in 5 mL of 3 M aqueous NaOH was heated to 50 °C. 2-Chloroethanol (0.65 mL, 9.5 mmol) was added slowly, and the mixture was heated at 90 °C for 6 h. After cooling, the mixture was poured into 20 mL of deionized water, acidified with 1 M aqueous HCl, and extracted with ethyl acetate (3 × 20 mL). Organic phases were washed with brine and concentrated under reduced pressure. Product **22** was recrystallized from ethyl acetate: yield 0.11 g (10%). ^{1}H NMR (DMSO-d_6) δ, ppm 7.52 (d, J = 16 Hz, H-α), 7.03 (d, J = 2 Hz, H-2, H-6), 6.53 (d, J = 16 Hz, H-β), 3.90 (t, J = 6 Hz, $-CH_2-$OAr), 3.81 (s, CH_3-O−), 3.61 (t, J = 6 Hz, $-CH_2-$OH). ^{13}C NMR (DMSO-d_6) δ, ppm 167.6 (C-γ), 153.0 (C-3, C-5), 144.0 (C-α), 138.4 (C-4), 129.6 (C-1), 118.4 (C-β), 105.8 (C-2, C-6), 74.1 ($-CH_2-$OAr), 60.1 ($-CH_2-$OH), 56.0 (CH_3O−).

Ethyl (2E)-3-[4-(2-Hydroxyethoxy)-3-methoxyphenyl]prop-2-enoate, ***23****.* A mixture of **22** (4.02 g, 16.9 mmol), ethanol (60 mL), and 18 M sulfuric acid as a catalyst (310 mg, 0.6 wt %) was refluxed for 20 h. After cooling, the solution was concentrated under vacuum to yield an orange-colored viscous product. This product was dissolved in 100 mL of diethyl ether, and this solution was washed twice with 30 mL of 0.5 M aqueous solution of $NaHCO_3$, twice with 30 mL of saturated NaCl solution, then twice with 30 mL of deionized water. The organic phase was dried on $MgSO_4$, filtered, and evaporated to dryness under vacuum. The resulting white powder was dried at 60 °C under vacuum for 12 h: yield 3.25 g (72%). ^{1}H NMR (DMSO-d_6) δ, ppm 7.57 (d, J = 16 Hz, H-α), 7.35 (d, J^4 = 2 Hz, H-2), 7.21 (dd, J^4 = 2 Hz, J^3 = 8 Hz, H-6), 6.98 (d, J^3 = 8 Hz, H-5), 6.54 (d, J = 16 Hz, H-β), 4.86 (t, J = 5 Hz,

−O*H*), 4.17 (q, *J* = 7 Hz, −C*H*$_2$−OOC−), 4.01 (t, *J* = 5 Hz, −C*H*$_2$−OAr), 3.81 (s, C*H*$_3$−O−), 3.72 (q, *J* = 5 Hz, −C*H*$_2$−OH), 1.25 (t, *J* = 7 Hz, −C*H*$_3$). ^{13}C NMR (DMSO-d_6) δ, ppm 166.4 (C-γ), 150.3 (C-4), 149.0 (C-3), 144.5 (C-α), 126.8 (C-1), 122.8 (C-6), 115.5 (C-β), 112.4 (C-5), 110.5 (C-2), 70.05 (−CH_2−OAr), 59.7 (−CH_2−OOC−), 59.35 (−CH_2−OH), 55.5 (CH_3O−), 14.1 (−CH_3).

Spectroscopic Methods. One-dimensional (1D) ^{1}H and ^{31}P NMR spectra and two dimensional (2D) ^{13}C−^{1}H NMR correlation spectra were recorded on a Avance 500 spectrometer (Bruker, Karlsruhe, Germany), at 500 MHz (^{1}H NMR), 125 MHz (^{13}C NMR), or 202 MHz (^{31}P NMR) with a 5 mm double-resonance broadband inverse probe (BBI). The 1D ^{13}C NMR spectra were recorded on the same spectrometer at 125 MHz with a 10 mm double-resonance broadband observe probe (BBO). Lignin samples were dissolved in deuterated dimethyl sulfoxide, DMSO-d_6 (^{1}H, ^{13}C, and 2D ^{13}C−^{1}H NMR), or CDCl$_3$/pyridine mixture (^{31}P NMR).

The 2D ^{13}C−^{1}H correlation spectra were recorded through a phase-sensitive gradient-enhanced 2D heteronuclear single quantum coherence (HSQC) with echo−antiecho experiment (HSQCETGP sequence). The 2D ^{13}C−^{1}H long-range correlation heteronuclear multiple bond correlation (HMBC) spectra were recorded via heteronuclear zero and double quantum coherence experiment (HMBCGPLPNDQF sequence). Chemical shifts were referenced to residual DMSO-d_5 (δ = 2.50 ppm) for ^{1}H NMR and to DMSO-d_6 (δ = 39.43 ppm) for ^{13}C NMR.

^{31}P NMR experiments were carried out following a slightly modified previously reported method:[36] Lignin (30 mg) was dissolved in a CDCl$_3$/pyridine mixture (1:1.6 v/v, 0.5 mL). The phosphitylation reagent, 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane (150 μL), and the internal standard, *N*-hydroxy-6-norbornene-2,3-dicarboximide (100 μL of 0.1 M solution in 1:1.6 v/v CDCl$_3$/pyridine mixture)[37] were added successively. Chromium(III) acetylacetonate (100 μL of 0.014 M solution) in the same CDCl$_3$/pyridine mixture was added to the solution in order to homogenize and accelerate phosphorus relaxation. Spectra were recorded with a 25 s relaxation time and an average number of 10 000 scans. The quantitative results shown are the average of duplicate NMR experiments. Chemical shifts are relative to the signal of the phospholane hydrolysis product at 132.2 ppm. The integral value of the internal standard was used for calculations of the absolute amount of each functional group.

Size-Exclusion Chromatography. SEC analyses were performed on a 300 × 7.5 mm i.d., 5 μm Mixed-C (200−(2 × 10^6) Å) PLgel three-column set (Agilent Technologies, Les Ulis, France), connected to a VE5200 automatic injector (Malvern Instruments Ltd., Guyancourt, France) and a model 515 pump and a model 410 differential refractometer (Waters Corp., Guyancourt, France). Tetrahydrofuran (THF) was used as eluent (1 mL/min). Acetylated lignin solution in THF (100 μL, 5 g/L) was injected. Chromatograms were processed by use of OmniSEC software. Polystyrene standards (Polymer Laboratories) were used for the calibration.

Lignin Acetylation. Lignin (220 mg) was reacted with acetic anhydride (5 mL) and pyridine (5 mL) at room temperature for 72 h.[38] The resulting mixture was poured in water (100 mL). The precipitated acetylated lignin was filtered and dissolved in CH_2Cl_2. The solution was dried over $MgSO_4$ and evaporated under reduced pressure to afford acetylated lignin (210 mg, 95% yield).

RESULTS AND DISCUSSION

Purification and Characterization of Biolignin. Biolignin was first hydrolyzed in 1 M aqueous NaOH solution for 4 h at 80 °C, leading to hydrolyzed Biolignin (Lh). This alkaline hydrolysis leads to the cleavage of ester bonds, including those involved in carbohydrate−lignin complexes, and allows the elimination of residual polysaccharides and esters together with some aromatic compounds.[27] Moreover, traces of acetic and formic acids present in the starting material and resulting from the delignification process are also removed. In order to remove water-insoluble impurities, such as low molar mass aromatic compounds and waxes, Lh was then extracted with dichloromethane and ethyl acetate, yielding a final, purified Biolignin (Lp) with highly reduced contaminant content. The purification steps were followed by ^{1}H NMR. Analysis of the hydrolysis and purification residues confirmed the elimination of polysaccharides and of fatty acids, *p*-coumaric acid, and ferulic acid,

respectively, together with various low molar mass aromatic compounds.

2D $^{13}C-^{1}H$ HSQC NMR Analyses of Biolignin, Lh, and Lp. 2D $^{13}C-^{1}H$ HSQC NMR analyses were performed in DMSO-d_6 (Figures 1 and 2). Correlations were assigned according to literature (Figures 3 and 4).[7,27,38−40] The β-O-4 linkages (alkyl−aryl ether), **1**, of H, G, and S units are easily detected by their α, β, and γ resonances. γ-Esterified β-O-4 linkages, **2**, are also present in Biolignin, as shown by the correlations corresponding to their β- and γ- positions, the latter being more intense (Figure 1A). These two correlations are no longer present after hydrolysis in Lh and Lp spectra (Figure 1B,C). α-Oxidized alkyl−aryl ether structures, **3**, are also detected by a correlation corresponding to the β-position. Correlations corresponding to the α-, β-, and γ-positions of β-5 (phenylcoumaran), **4**, and $\beta-\beta$ (resinol) linkages, **5**, are of much lower intensity as compared to those

of *β*-O-**4**, which, therefore, seem to be predominant. However, it is difficult to conclude on their relative abundance, since the NMR sequence used for these analyses does not allow cross-peak quantitation.

In the aromatic domain (Figure 2A), the resonances of H, G, and S units are observed together with moieties derived from *p*-coumaric and ferulic acids. As previously reported in studies on wheat straw lignin,[41] sinapic acid derivatives are not present, since their characteristic signal at 106.1/6.98 ppm (2,6-positions) is not detected. In Biolignin, the presence of free *p*-coumaric and ferulic acids **7** and **9**, and of their esters **8** and **10**, is reflected by their 2,6-, *α*- and *β*-correlations. A cross-peak close to

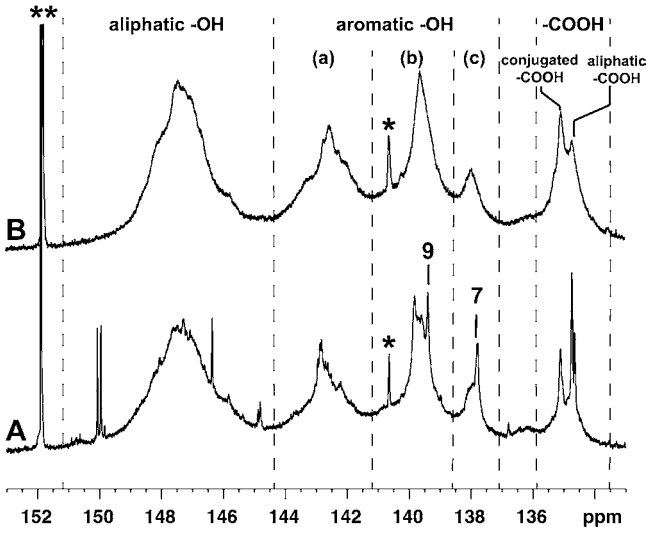

Figure 6. ^{31}P NMR spectra of (A) phosphitylated Biolignin and (B) phosphitylated purified Biolignin Lp. (*) Impurity; (**) internal standard; (a) disubstituted *p*-hydroxyphenyl structure as syringyl and condensed phenolic units; (b) monosubstituted *p*-hydroxyphenyl structure as guaiacyl units; (c) unsubstituted *p*-hydroxyphenyl structure.

the 6-correlation of **9** and **10** was assigned to *p*-etherified ferulic acid **11**, with the help of a model of these moieties, namely, (2*E*)-3-[4-(2-hydroxyethoxy)-3-methoxyphenyl]prop-2-enoic acid **21** (Figure 5). Low molar mass aromatic derivatives are also detected: syringic acid **14**, vanillin **15**, and syringaldehyde **16**. Correlations at 122.9/7.54, 112.8/6.78, and 149.1/8.10 ppm were assigned to the CH groups of furaldehyde **18**, a product of polysaccharide degradation, by comparison with the spectrum of an authentic sample. The CH═O correlation of **18** was also observed at 178.3/9.61 ppm (region not shown).

After hydrolysis (Figure 2B), *p*-coumarates and ferulates **8** and **10** are no longer detected, but free acids **7**, **9**, and **14** and aldehydes **15** and **16** are still present, and a correlation corresponding to acetosyringone **17** appears. These low molar mass compounds are removed during the solvent extraction steps, and the spectrum of Lp (Figure 2C) exhibits a very simplified pattern consisting mainly of signals relative to H, G, and S units and to *p*-etherified ferulic acid (**11**). As found for other lignin types,[13] *p*-etherified ferulates are an integral part of the lignin backbone. These findings were confirmed by the 2D NMR study of hydrolysis and solvent extraction residues.

Milled wood (MW) wheat straw lignin is also reported to contain flavonoids, such as tricin [5,7-dihydroxy-2-(4-hydroxy-3,5-dimethoxyphenyl)-4*H*-chromen-4-one], which presents strong and well-resolved HSQC signals.[7] However, these signals are not detected in Biolignin spectra. The acidic conditions of the CIMV process probably lead to the elimination of this type of compound.

Table 2. Number- and Mass-Average Molar Masses and Molar-Mass Dispersities of Acetylated Lignin Samples[a]

sample	Biolignin	Lp	i-Lp-Et	s-Lp-Et	Lp-EG	Lp-CE
M_w (g/mol)	31890	18400	24270	4160	23520	4633

$Đ_M$	19.2	11.8	11.6	3.1	13.3	4.0

[a]Determined by size-exclusion chromatography.

^{31}P NMR Spectroscopy. ^{31}P NMR spectroscopy was used to differentiate and quantitate the different types of free hydroxyl groups (aliphatic, phenolic, and carboxylic) in Biolignin and Lp, after phosphitylation by 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane, as described by Argyropoulos and co-workers.[8,36] *N*-Hydroxy-5-norbornene-2,3-dicarboximide was used as internal standard instead of cyclohexanol,[37] as its signal at 151.9 ppm is well separated from those of lignin. It should be noted that the un-, mono-, and disubstituted 4-hydroxyphenyl groups quantitated by this method correspond only to a fraction of the H, G, and S units present in lignin, that is, those bearing free phenol groups. Moreover, the disubstituted 4-hydroxyphenyl structures detected by this method comprise syringyl units with free phenol groups, as well as condensed phenolic units.[36]

There are two main differences between the spectra of Biolignin and Lp (Figure 6): (1) lower relative intensity of unconjugated carboxylic acid resonances with respect to conjugated ones (134.70 and 135.05 ppm,[27] respectively) in the spectrum of Lp, due to the elimination of fatty acids and residual acetic and formic acids during the hydrolysis and purification steps; and (2) disappearance of the sharp peaks emerging from broad signals in the phenolic OH region of Biolignin spectrum (un-, mono-, and disubstituted 4-hydroxyphenyl groups at 137−144 ppm). The well-resolved peaks at 137.80 and 139.40 ppm are assigned to *p*-coumaric and ferulic acids, respectively.[27]

Aliphatic, phenolic, and acidic hydroxyl contents were determined by integration of the corresponding peaks with respect to the internal standard (Table 1). In Biolignin, phenolic OH groups are preponderant, with the aliphatic/phenolic OH ratio r_{OH} being close to 0.8, and acidic OH groups represent about 10% of total OH content. Monosubstituted 4-hydroxyphenyl OH unit content is slightly higher than that of disubstituted units (mono/disubstituted = 1.2), while unsubstituted 4-hydroxyphenyl units represent ca. 15% of total phenolic groups. Hydrolysis and purification lead to a slight increase in total OH content (6.90 vs 5.61 mmol/g) without

Table 1. Hydroxyl Content of Biolignin, Lp, Lp-Et, Lp-EG, and Lp-CE Lignins[a]

	OH content (mmol/g)			OH content (% of total OH + COOH)				
sample	phenolic	aliphatic	COOH	(a)[b]	(b)[b]	(c)[b]	aliphatic	COOH
Biolignin	2.84	2.24	0.53	19.40	23.35	7.85	39.95	9.45

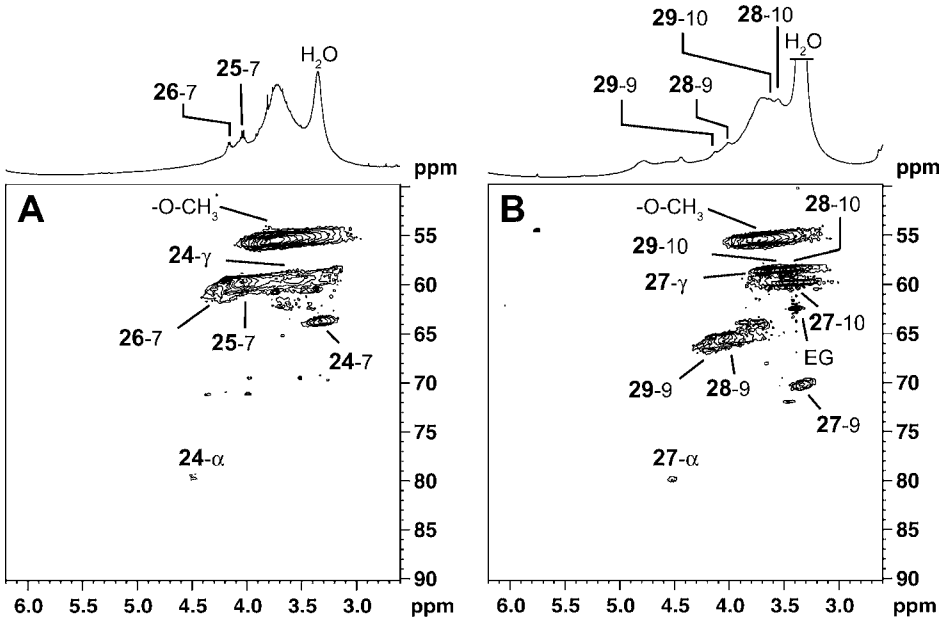

Figure 7. 2D $^{13}C-^{1}H$ HSQC NMR spectra of (A) s-Lp-Et and (B) Lp-EG: expansion of the lignin side-chain domain. Structure notations are given in Figure 8. EG, residual ethane-1,2-diol.

much affecting the aliphatic/phenolic ratio and, therefore, lignin main structure. Although free aliphatic and cinnamic acids were removed by the hydrolysis and purification steps, COOH concentration increases, due to hydrolysis of the ester functions of 4-O-etherified ferulates.

The high total phenolic group content indirectly reflects the presence of condensed phenolic units, such as 5−5 units, **6** (Figure 3). Shoulders at ca. 143 and 142 ppm in the ^{31}P NMR spectra of phosphitylated lignins have been assigned to condensed phenolic structures.[36] However, it is difficult to make any accurate quantitation in this region, even by deconvolution, due to the unknown number and width of signals that overlap in this region. Condensed phenolic units might also be detected in the aromatic region of HSQC spectra. On the basis of NMR literature data on model compounds,[42,43] the 5−5 structure arising from coniferyl alcohol should give two signals (2- and 6-positions), close to the 2- and 6-correlations of G units. Unassigned correlations at 109.5/7.10 and 119.4/6.95 ppm are observed in the HSQC spectrum of Lp (Figure 2C). They could reflect the presence of 5−5 units, but this has yet to be confirmed.

Comparison of ^{31}P NMR literature data on technical wheat straw lignins highlights the importance of the fractionation method on the chemical composition of resulting lignin samples. When either bases, for example, soda wheat straw lignin (GreenValue SA),[32] or organic acids[44] are used, lignins samples exhibit aliphatic/phenolic OH ratio $r_{OH} \leq 1$, close to that found for Biolignin in the present work. On the other hand, r_{OH} is close to 2.4−3 for MW wheat straw lignin[8] and dioxane/HCl lignin[45] samples. The un/mono/disubstituted 4-hydroxyphenyl unit distribution is also process-dependent, with MW samples exhibiting higher unsubstituted unit content as compared to samples obtained by alkaline or acidic processes. Crestini and Argyropoulos[8] studied the effect of 2 M alkaline hydrolysis on MW wheat straw lignin. They observed a strong decrease in unsubstituted 4-hydroxyphenyl unit content, reaching values close to that found above for Biolignin and Lp. They showed that this was mainly due to release of *p*-coumaric acid by the basic hydrolysis of *p*-coumarates present in lignin structure. A similar *p*-coumarate hydrolysis during the acidic CIMV delignification process could also be involved to explain the low unsubstituted 4-hydroxyphenyl unit content of Biolignin.

Size-Exclusion Chromatography. The impact of the hydrolysis and purification steps on average molar masses and molar mass distributions was evaluated by SEC (Table 2). The samples were acetylated, in order to improve their solubility in THF and to avoid the formation of aggregates.[46] Biolignin is a mixture of oligomeric compounds (M_n = 1660 g/mol) exhibiting a very large molar-mass dispersity, close to $Đ_M$ = 19. The hydrolysis and purification steps do not affect molar mass since the M_n of Lp lies in the same range. The molar-mass dispersity of Lp is lower, but still quite high ($Đ_M$ = 11.8). The M_n values previously reported for various technical wheat straw lignins (1000−3780 g/mol)[7,9,12,44] are close to those found for Biolignin in this work, while literature $Đ_M$ values vary between 1.7[9] and 10.6.[44] However, it is difficult to compare these SEC values, since delignification and/or analysis conditions are different from each other. In this work, molar mass values are compared before and after chemical modification, in order to detect potential lignin backbone changes.

Modification of Purified Biolignin. Modification of lignin prior to its use as macromonomer presents many advantages. Besides improving sample solubility in common organic solvents, this could allow selective masking of some functions and homogenizing of reactive group types. Lp was modified by three methods: esterification by (i) ethanol or (ii) ethane-1,2-diol to mask acid groups and (iii) etherification with 2-chloroethanol under alkaline conditions to replace phenol groups by more reactive aliphatic OH groups.

Lignin Modification by Esterification. Both esterification reactions were catalyzed by *p*-toluenesulfonic acid. When esterifications were carried out in ethanol, the reaction mixture remained heterogeneous. After reaction, the insoluble fraction, i-Lp-Et, was isolated from the soluble fraction, s-Lp-Et, by filtration. Both samples were soluble in DMSO-d_6 and were analyzed by ^{1}H and 2D NMR spectroscopy. Spectra with very

J. Agric. Food Chem. 2015, 63, 5178−5188

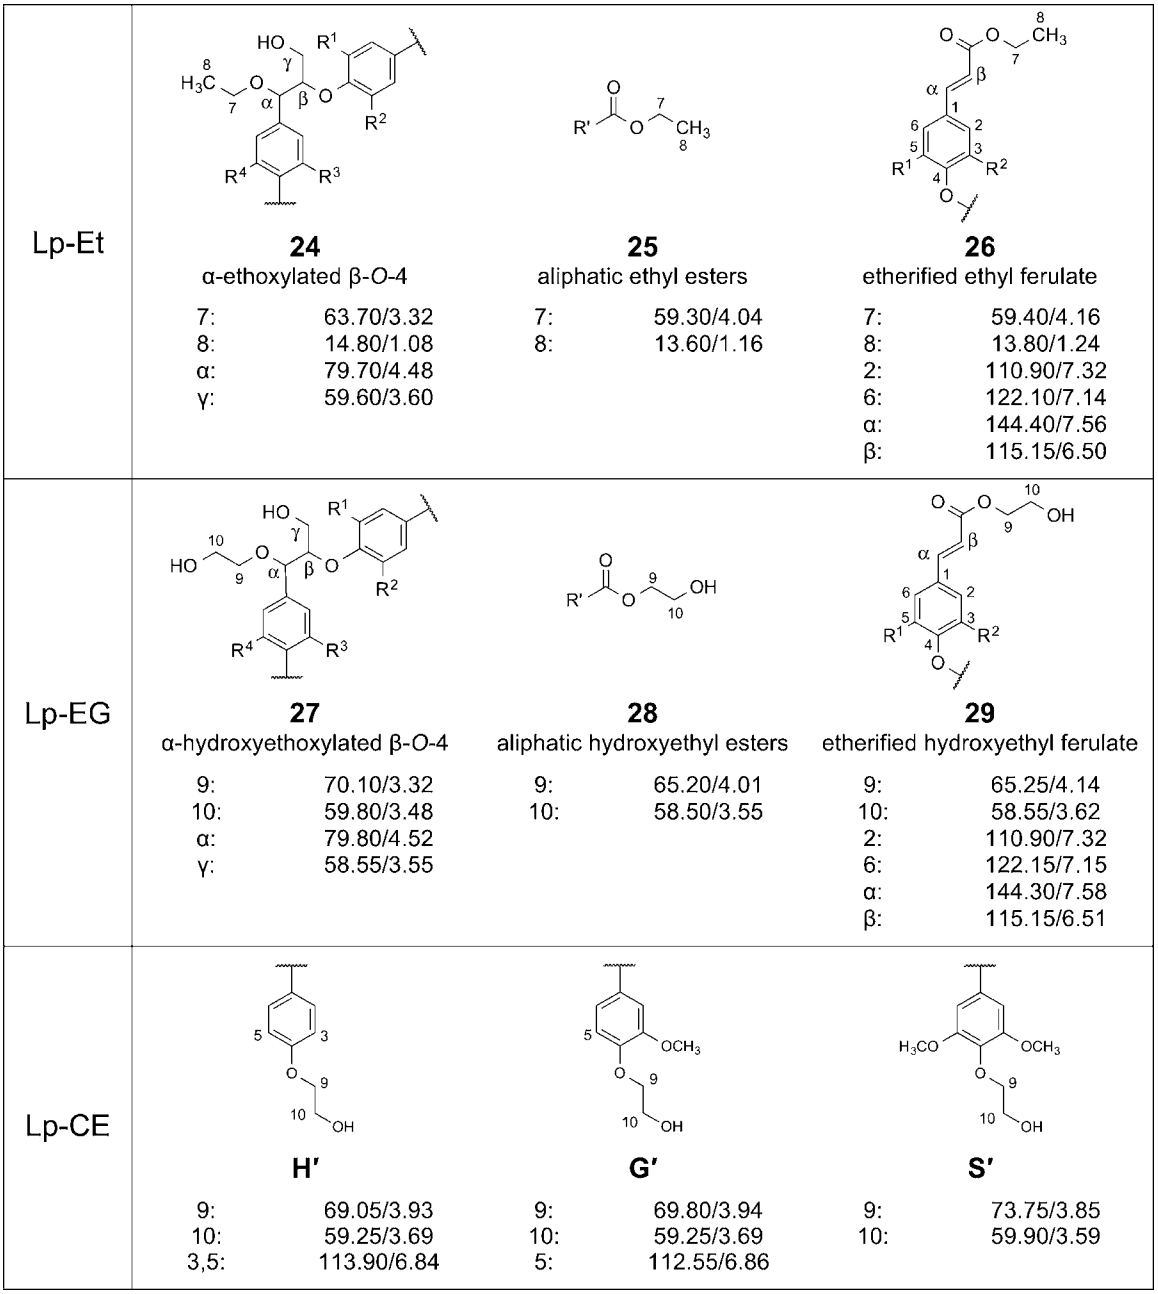

Figure 8. Structures, atom numbering and HSQC correlations (δ^C/δ^H, ppm) of modified lignin units found in Lp-Et, Lp-EG, and Lp-CE (R^{1-4} = H, CH_3O; R′ = aliphatic chain).

similar profiles were obtained, so that only the spectra of s-Lp-Et will be further discussed. On the other hand, esterification with ethane-1,2-diol led very rapidly to a homogeneous reaction mixture and afforded a sample, Lp-EG, that was soluble in common organic solvents such as CH_2Cl_2, THF, and DMSO.

The aliphatic domains of s-Lp-Et and Lp-EG HSQC NMR spectra are presented in Figure 7 with assignments in Figure 8. The spectrum of s-Lp-Et exhibits two distinct signals at 59.3/4.04 and 59.4/4.16 ppm (Figure 7A), assigned to the methylenes of ethyl ester groups of nonlignin aliphatic esters **25**, and of *p*-etherified ethyl ferulate moieties **26**, respectively. This was confirmed by long-range correlations between the corresponding carbonyl carbons and the methylene protons of ethyl esters at 172.45/4.04 and 166.25/4.16 ppm, respectively, observed in the HMBC $^{13}C-^{1}H$ NMR spectrum of s-Lp-Et. These assignments were also confirmed by comparisons with the spectra of ethyl (2*E*)-3-[4-(2-hydroxyethoxy)-3-methoxyphenyl]prop-2-enoate **23**, a model of *p*-etherified ethyl ferulate groups (Figure 5). The HSQC NMR spectrum also reveals that the secondary alcohols of *β*-O-4 structures were simultaneously etherified: The *α*-CH signal of *β*-O-4 linkages (**1**-*α*) is shifted to 79.70/4.48 ppm after reaction (**24**-*α*), that is, in the secondary ether resonance region. Moreover, new correlations are detected at 63.7/3.32 ppm (Figure 7A) and 14.80/1.08 ppm (not shown), which correspond, respectively, to methylene and methyl of the ethyl ether group of **24**. Etherification of the secondary alcohol of *β*-O-4 linkages has already been reported for *Miscanthus giganteus* lignin obtained by the ethanol−water−HCl process.[47]

Similar results were obtained when the reaction was carried out with ethane-1,2-diol. The −COO−CH_2−CH_2−OH meth-

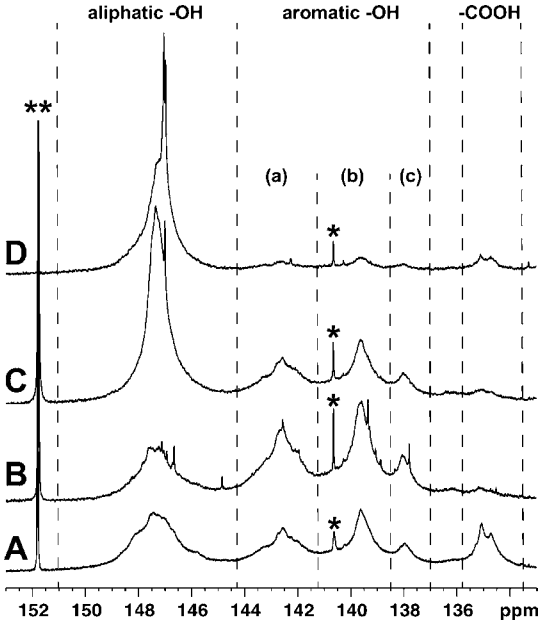

Figure 9. ^{31}P NMR spectra of phosphitylated lignin samples: (A) Lp, (B) s-Lp-Et, (C) Lp-EG, and (D) Lp-CE. (*) Impurity; (**) internal standard; (a) disubstituted *p*-hydroxyphenyl structures as syringyl and condensed phenolic units; (b) monosubstituted *p*-hydroxyphenyl structures as guaiacyl units; (c) unsubstituted *p*-hydroxyphenyl structures.

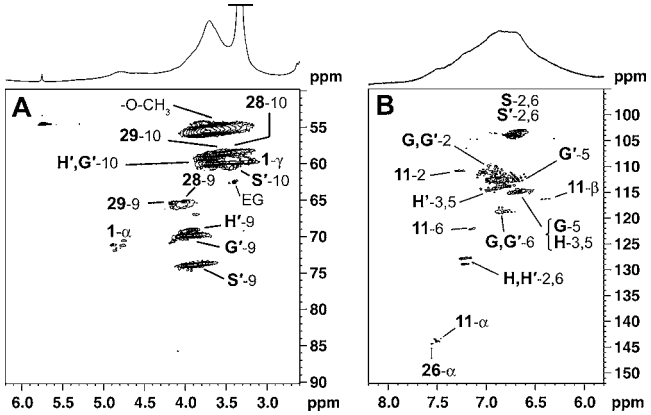

Figure 10. 2D ^{13}C−^{1}H HSQC NMR spectra of Lp-CE: expansion of lignin (A) aliphatic and (B) aromatic domains. Structure notations are given in Figure 8. EG, residual ethane-1,2-diol.

ylenes of non-lignin aliphatic esters **28** and ferulates **29** are clearly identified at 65.20/4.01 and 65.25/4.14 ppm (Figure 7B). As discussed above in the case of modification by ethanol, *α*-etherified *β*-O-4 structures **27** are also observed. No noticeable differences were observed in the aromatic domain, except a slight shift of the *α*- and *β*-resonances of feruloyl moieties after reaction, **29**.

Comparison of Lp, s-Lp-Et, and Lp-EG ^{13}C NMR spectra confirmed the preceding conclusions, in particular with the 2 ppm upfield shift of −COO− resonances (esterification of acids) and the detection of new peaks assigned to $-CH_2-O-$ ether resonances of **24** and **27** at 63.7 and 70.1 ppm, respectively.

The ^{31}P NMR spectra (Figure 9) show that, as expected, carboxylic acid content strongly decreases, from 0.84 mmol/g in Lp to 0.04 mmol/g in s-Lp-Et and in Lp-EG (Table 1). The ratio of un-, mono-, and disubstituted 4-hydroxyphenyl units remains unaffected by the chemical modification. A decrease in the aliphatic/phenolic OH ratio is observed for s-Lp-Et (r_{OH} = 0.36), due to formation of ethyl ethers **24**. In the case of Lp-EG, the aliphatic/aromatic OH ratio increases (r_{OH} = 1.28). In this case, the formation of hydroxyethyl ethers **27** does not change total aliphatic hydroxyl group content, while the hydroxyethylation of **11** leads to etherified hydroxyethyl ferulates **29** and to hydroxyl group concentration increase.

SEC analysis shows that s-Lp-Et exhibits lower M_n (1340 g/mol) and dispersity ($Đ_M$ = 3.1) than Lp, while the M_n of the ethanol-insoluble fraction is slightly higher (2100 g/mol) and dispersity is similar ($Đ_M$ = 11.6). Lp and Lp-EG present very close M_n and molar-mass dispersity (Table 2). Cleavage of lignin *β*-O-4 linkages and their rearrangement into lignin-based polymeric materials was reported for beech MW lignin liquefaction with ethane-1,2-diol.[48] The experimental hydroxyethylation conditions used in the present work (0.6% *p*-toluenesulfonic acid, 90 °C) are significantly milder than those used for wood liquefaction (3% p-toluenesulfonic acid, 150 °C) and appears to leave *β*-O-4 linkages unchanged, with the exception of the *α*-hydroxyethoxylation reaction discussed above.

Lignin Modification by Etherification with 2-Chloroethanol. Etherification of Lp phenol groups with 2-chloroethanol under alkaline conditions yields a modified lignin, Lp-CE, that is insoluble in CH_2Cl_2 and only partially soluble in DMSO. Lp-CE characterization was, therefore, carried out on the soluble fraction. Analysis of the HSQC aliphatic domain (Figure 10A) shows that phenol groups have reacted, since three different signals are observed at 69−74/3.8−4.0 ppm, assigned to the Ar−O−CH_2−CH_2−OH methylene of 2-hydroxyethoxy groups in the 4-position of H, G, and S aromatic rings (Figure 8). Assignments of the resulting etherified units H′, G′, and S′ were made with the help of model compounds **20**, **21**, and **22** (Figure 5) obtained by reaction of coumaric, ferulic, and sinapic acids with 2-chloroethanol in similar conditions. The $-CH_2-$OH methylenes of these groups and of *β*-O-4 linkages (**1**-*γ*) give overlapping cross-peaks. During the reaction, carboxylic acids are partly esterified into hydroxyethyl esters since signals corresponding to ferulate (**29**-9 and **29**-10) and aliphatic esters (**28**-9 and **28**-10) are also detected. On the other hand, *β*-O-4 aliphatic secondary hydroxyl groups remain unchanged, since no signal corresponding to aliphatic ethers (**24**-*α*) is detected at 79.7/4.48 ppm. Etherification of phenol groups by 2-chloroethanol is reflected by new correlations at 112.55/6.86 (G′-5) and 113.90/6.84 ppm (H′-3,5) (Figure 10B).

Lp-CE was also analyzed by ^{31}P NMR (Figure 9). Since the sample was not fully soluble in phosphitylation medium, quantitative determination of OH groups was not possible. The relative aliphatic/aromatic OH content was nevertheless determined on the soluble fraction, showing an almost 7-fold decrease in phenol content, with unchanged ratio of un-, mono-, and disubstituted 4-hydroxyphenyl units. Hydroxyethylation by 2-chloroethanol in basic medium, therefore, appears to be a very efficient modification method of lignin phenol groups.

Since Lp-CE was only partially soluble in THF, even after acetylation, the SEC analyses were performed on the soluble fraction after filtration, leading to lower molar mass (M_n = 1155 g/mol) and dispersity ($Đ_M$ = 4.0) than Lp, as expected for a fractionated polymer sample.

Finally, we can conclude that alkaline hydrolysis (1 M NaOH at 80 °C) and solvent extraction of Biolignin yields a purified, deacylated lignin sample (Lp) with very low content of

DOI: 10.1021/acs.jafc.5b02071
J. Agric. Food Chem. 2015, 63, 5178−5188

contaminants and that the purification does not significantly affect starting lignin main structure and molar masses. Lp contains primary and secondary alcohol groups, carboxylic acid groups, and phenolic OH groups. The large phenolic OH content reflects the existence of condensed aromatic structures, such as units of 5−5 type, which bring two additional phenolic OH groups per lignin molecule.

Modification of Lp by esterification with ethanol or ethane-1,2-diol in the presence of *p*-toluenesulfonic acid catalyst was efficient and, as expected, led to esterified lignin samples (Lp-Et and Lp-EG, respectively) with a very low carboxylic acid content. In these conditions, the secondary alcohols were also totally etherified, but no β-O-4 linkage cleavage was observed, leading to modified lignin containing only primary alcohols and phenols. With ethane-1,2-diol, simultaneous hydroxyethoxylation of secondary OH groups during COOH esterification resulted in an increased aliphatic OH/phenolic OH ratio with respect to Lp-Et. Etherification of phenolic OH groups with 2-chloroethanol yielded lignins containing only aliphatic alcohol groups.

These modification reactions (ethylation, hydroxyethylation, ethoxylation) allow control of the nature and content of OH groups and, therefore, of the chemical functionality of lignins. This is a prerequisite for their use as comonomers in polycondensation reactions, where stoichiometry is a key parameter (e.g., polyesterifications), or as initiators in ring-opening polymerizations and, after further tailored modification, in controlled radical polymerizations. The purified and modified lignins described in this work are, therefore, interesting macromonomers for the preparation of well-defined polymers or polymer blends.

Uptake, Translocation, and Metabolism of Phenols by Submerged Rooted Macrophyte, Water Milfoil (*Myriophyllum elatinoides*)

Daisuke Ando,* Takuo Fujisawa, and Toshiyuki Katagi

Environmental Health Science Laboratory, Sumitomo Chemical Company, Limited, 4-2-1 Takatsukasa, Takarazuka, Hyōgo 665-8555, Japan

ABSTRACT: Shoot and root uptakes of ^{14}C-labeled phenol (**1**), 4-nitrophenol (**2**), 4-cyanophenol (**3**), 4-hydroxybenzamide (**4**), and 4-hydroxybenzoic acid (**5**) by *Myriophyllum elatinoides* were individually examined with water or sediment treatments using the sequestered chamber. Shoot uptake of each ^{14}C-phenol dissolved in water amounted to 21.0% (**1**), 14.3% (**2**), 12.8% (**3**), 4.2% (**4**) and 41.7% (**5**) of the applied radioactivity (AR) after 96 h without significant ^{14}C translocation from shoot to root (≤0.9% AR), and the major metabolite produced was the glucose conjugate. On the other hand, root uptake of ^{14}C-phenols from sediment was much slower/smaller (≤6.6% AR), and ^{14}C transportation from root to shoot was scarcely observed, except for compound **5** (≤1.5% AR). For the water treatment, a kinetic analysis on uptake/metabolism was conducted using the assumed compartment. Good correlation was observed between lipophilicity and shoot uptake rate constants, and the electronic state of the hydroxyl group (σ, σ^-, or $E_{HOMO(OH)}$) and the transformation rate constant of glucosidation.

KEYWORDS: *rooted macrophyte, shoot uptake, root uptake, metabolism, translocation, phenol, kinetics*

INTRODUCTION

Submerged macrophytes are very important aquatic plants for production/circulation of oxygen and nutrient in the water layer and stabilization of the bottom sediment in water bodies, which securely provide precious food and shelter for many aquatic biota.[1−3] Therefore, an adverse effect on the macrophyte community will have serious impact on the overall aquatic ecosystem. Incidentally, herbicides and plant-growth regulators are considered to reach water bodies by spray drift, runoff, drainage, or accidental spills, which may cause substantial damage toward non-target aquatic plant species. In the previous European Union (EU) Directive 91/414/EEC, the acute toxicity data [50% effect concentration (EC_{50})] for two algae and one macrophyte, such as *Lemna* spp., had been required to determine the adverse effect to aquatic plants.[4] However, the assessment with these limited species could underestimate the risk to the sediment-rooted macrophytes because the chemicals may have been taken up not only from the water via shoot but also from the bottom sediment via root.[3,5−7] Hence, in the latest aquatic guidance issued by the European Food Safety Authority (EFSA) on 2013, the risk assessment for submerged-rooted macrophytes, such as *Myriophyllum elatinoides*, a water milfoil, was newly included as additional test species to be evaluated if both algae and *Lemna* are highly susceptible to the chemical or if chronic sediment exposure is to cause concerns.[8]

Despite their importance in the aquatic ecosystem, there are few basic knowledge on the uptake, translocation, and metabolism of pesticides and their degradates by submerged-rooted macrophytes. Therefore, we have studied the behavior of simple phenols, as model compounds, in *M. elatinoides* using a special glass aquarium equipped with a partition board, which enabled separate exposure of the plant by two routes, i.e., water treatment (shoot exposure) and sediment treatment (root exposure).[9] In addition, investigation on the relationship between the uptake/metabolism behavior and various chemical indexes was performed to explain the observed results.

MATERIALS AND METHODS

Chemicals. The ^{14}C compounds uniformly radiolabeled at the phenyl ring were used in the study (Figure 1): phenol (**1**) and 4-nitrophenol (**2**) were purchased from American Radiolabeled Chemicals. Inc., and 4-cyanophenol (**3**), 4-hydroxybenzamide (**4**), and 4-hydroxybenzoic acid (**5**) were prepared in our laboratory according to the reported methods.[10−12] The specific activities were 2.96 GBq/mmol (**1**), 2.85 GBq/mmol (**2**), and 4.37 GBq/mmol (**3**−**5**). Each ^{14}C compound had the radiochemical purity exceeding 98%, as purified by reversed-phase high-performance liquid chromatography (HPLC) prior to use. Non-radiolabeled compounds **1**−**5** with the chemical purity of >95% were purchased from Sigma-Aldrich Co. All

of the reagents and solvents used in this experiment were of analytical grade.

Chromatography. A reversed-phase HPLC system to analyze the test phenols and their metabolites consisted of a Hitachi LC module (model L-7000) equipped with a SUMIPAX ODS A-212 column (5 μm, 6 mm inner diameter × 15 cm, Sumika Chemical Analysis Service, Ltd.). The following gradient system was employed to analyze each phenol and its metabolites at a flow rate of 1 mL/min, with 0.1% formic acid (solvent A) and acetonitrile (solvent B): 0 min, 100:0 (% A/% B, v/v); 40 min, 10:90; 40.1 min, 100:0; and 45 min, 100:0. The typical retention times of the corresponding phenols were 18.6 min (**1**), 22.1 min (**2**), 19.8 min (**3**), 6.7 min (**4**), and 12.9 min (**5**). The radioactivity in the column effluent was counted with a flow scintillation analyzer radiomatic 150TR (PerkinElemer Co.) radiodetector equipped with a 500 μL liquid cell using Ultima-Flo AP (PerkinElemer Co.) as a liquid scintillator. The limit of detection (LOD) for the radioactivity in HPLC analysis was 30 dpm. A thin-layer chromatography (TLC) was carried out using precoated silica gel 60F254 thin-layer chromatoplates (20 × 20 cm, 0.25 mm thickness, E. Merck) for the purification of the glucose conjugates of each tested phenol. The TLC solvent used for development was 4:1:1 (v/v/v) butanol/acetic acid/water. The autoradiogram was prepared by exposing the TLC plates to BAS-IIIs Fuji imaging plates (Fuji Photo Film Co., Ltd.) for several hours, and the corresponding radioactive spot transcribed onto the imaging plate was detected by a bioimaging analyzer Typhoon (GE Healthcare).

Spectroscopy. One-dimensional (^{1}H) and two-dimensional [^{1}H−^{1}H, correlation spectroscopy (COSY)] nuclear magnetic resonance (NMR) spectra of the sugar conjugates of compounds **2**, **4**, and **5** were measured in methanol-d_4 with 0.03% tetramethylsilane using a Varian Mercury 400 spectrometer (Varian Technologies, Ltd.) at 400 MHz. Liquid chromatography−electrospray ionization−tandem mass spectrometry (LC−ESI−MS/MS) analysis was conducted for the phenols and their metabolites using a Waters Tandem Quadruple TQD spectrometer equipped with a Waters Separation Module Acquity ultra performance liquid chromatograph (UPLC) and a Waters Acquity photodiode array detector. The following parameters were used for the typical analysis: source temperature, 150 °C; desolvation temperature, 450 °C; capillary voltage, 3.2 kV; cone voltage, 10−40 V; and collision energy, 5−20 V.

Radioanalysis. Radioactivity in water medium and sediment and plant extract was determined by liquid scintillation counting (LSC) with a Packard model 2900TR spectrometer after mixing each aliquot with 10 mL of PerkinElmer Emulsifier Scintillator Plus. The LOD for LSC analysis was 30 dpm. The post-extracted bound residues in plant and sediment were combusted using a PerkinElmer model 307 sample oxidizer. $^{14}CO_2$ produced by the procedure was trapped into 9 mL of a PerkinElmer Carb-CO_2 absorber and mixed with 15 mL of a PerkinElmer Permafluor scintillator. The radioactivity therein was quantified by LSC. The efficiency of the combustion was determined to be greater than 94.4%.

Plant Material and Treatment. *M. elatinoides* purchased from Shimizu Laboratory Suppliers. Co., Ltd. was used in the experiments as previously described.[9] After 10 days of root development in an aquarium filled with an American Academy of Pediatrics (AAP) water medium[13] and Organisation for Economic Co-operation and Development (OECD) synthetic bottom sediment,[14] the plant was sterilized using 0.5% sodium hypochlorite with sonication under reduced pressure for 1 min, washed using sterilized water, and subjected to the exposure experiment. The glass test vessel used for this study had the glass partition board, which completely separates shoot and root chambers, as shown in Figure 1.[9] The growth stage of the plants was as follows: shoot length, 17.1−18.8 cm; root length, 4.2−5.2 cm; root number, 7−11; and fresh body weight, 0.41−0.49 g. The shoot and root chambers were individually filled with 120 mL of the water medium and medium-moistened sediment (20 mL and 35 g), respectively. The medium and sediment were adjusted to pH 7.0 ± 0.1 and autoclaved (1.5 kg cm^{-2} at 120 °C for 20 min) before use. A total of 20−55 μL of the methanol solution containing each ^{14}C-phenol isotopically diluted with the corresponding non-radiolabeled compound was either spiked into the medium in the shoot chamber (water treatment) or the bottom sediment in the root chamber (sediment treatment) and homogeneously mixed to prepare an exposure concentration of 0.1 ppm (0.083 MBq). Approximately 2 cm of the root node was buried into the sediment in the root chamber, and the shoot was gently placed to be immersed under the water in the shoot chamber (Figure 1). To prevent ^{14}C cross-contamination via vaporization/deposition between the chambers, an AAP-moistened cotton was settled on the partition board and each chamber was covered with a polyethylene wrap. Then, the glass vessel was incubated in a climate chamber LH-220S (NK Systems, Ltd.) at 20 ± 2 °C under fluorescence light (8000 lx, 16 h per day) up to 96 h. Each exposure was conducted in triplicate.

Analytical Procedures. The sampling was conducted sequentially after 1, 3, 6, 12, 24, 48, and 96 h of each exposure. The plant sampled from the exposure chamber was surface-washed using 50 mL of a fresh water medium, and the rinsate was combined with the water medium recovered from the corresponding chamber. After measuring its length and wet weight, the plant was further rinsed with 50 mL of acetonitrile (surface rinse). Then, the plant was divided into shoot and root portions, and the total radioactivity in each portion was measured by the combustion analysis, except for the shoots of the water treatment. The corresponding shoot portion was extracted with 20 mL of methanol using a homogenizer AM-8 (Nissei, Ltd.) at 10 000 rpm and 0 °C for 10 min. The homogenate was vacuum-filtered, and the plant residue was further extracted twice in the same manner. The sediment and water medium in the root chamber were separated by vacuum filtration. The sediment was washed once with 100 mL of a fresh water medium, and the combined water was radioassayed. The ^{14}C-treated sediment was further extracted with 30 mL of methanol by 10 min of mechanical shaking with a Taiyo SR-IIw recipro-shaker (Taiyo Chemical Industry Co., Ltd.). The soil residue after vacuum filtration was successively extracted twice in the same manner. Each aliquot of the surface rinses, extracts, and water media was analyzed with LSC and HPLC co-chromatography with authentic standards. The plant/sediment-extracted residues and ^{14}C-unexposed sediment were subjected to the combustion analysis.

Identification of Major Metabolites. The major metabolites were isolated/purified by TLC from the plant samples and subjected to LC−MS and NMR analyses.

Kinetic Analysis. To understand the behavior of the phenols in *M. elatinoides*, kinetic analysis was employed for the samples of the water treatment system using the Model-Maker program (version 4, ModelKinetix). The simulation was conveniently carried out by a compartment model shown in Figure 2. On the basis of the kinetic parameters of compound **1**, the relative rate constants on the uptake and metabolism of each phenol derivative were calculated and their logarithm values were subjected to regression analysis with various physicochemical parameters of the phenols using Microsoft Excel 2010. Physicochemical parameters applied for the analysis are listed in

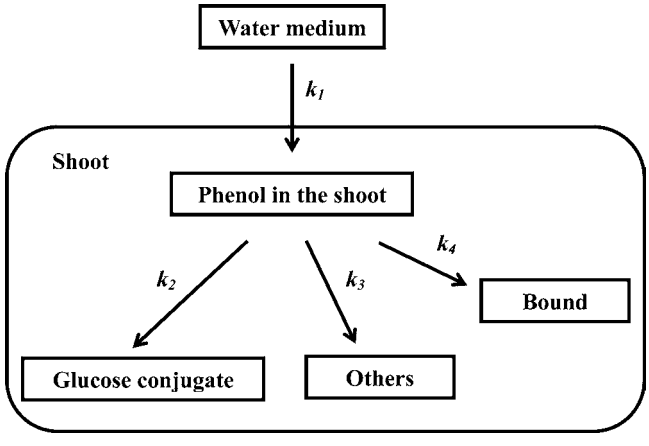

Figure 2. Compartment model employed for the kinetic analysis.

Table 1.[15−19] Because the phase II conjugation reactions of chemicals are considered to be affected by nucleophilicity of the substrates,[20] the energy level of the highest occupied molecular orbital (E_{HOMO}, eV) with its distribution was calculated by SCIGRESS MO Compact program (version 1, standard, Fujitsu, Ltd.) as a potential index to examine the correlation with the transformation rate constant to produce glucoside conjugate of phenols. The molecular geometry of each phenol was optimized by MNDO-PM 3 Hamiltonian with the dielectric constant of $\varepsilon = 78.4$, assuming the water environment, and calculated with a criterion introduced by inputting the PRECISE command. The calculation of each phenol was conducted for the neutral and ionized form at phenoxy oxygen abbreviated as $E_{HOMO(OH)}$ and $E_{HOMO(O^-)}$, respectively. Classical Hammett's constants (σ and σ^-) at the reaction center, i.e., phenolic oxygen, were also examined for the reactivity of phenols.[19] The fraction of the undissociated form of each phenol in the medium at pH 7 was calculated from its acid dissociation constant (K_a) by applying the Henderson−Hasselbalch equation as follows: $f_{neutral} = [K_a/10^{-7} + 1]^{-1}$. Logarithm of the distribution constant (log D), which indicates the hydrophobicity of chemicals adjusted with the dissociation effect was obtained from log K_{ow} and pK_a values according to the method of van der Waterbeemd et al.[18]

RESULTS

Validity Confirmation of the Test System. During the 96 h uptake period, no growth inhibition was observed for the plants exposed to any phenols compared to those acclimated in the control aquarium: increase in length, 0.4−1.1 cm; fresh body weight, 0.04−0.09 g. Cross-contamination of the applied ^{14}C between the shoot and root chambers was considered negligible because extremely little radioactivity [≤0.1% applied radioactivity (AR)] was detected from the ^{14}C-untreated chambers throughout the study. The inner wall of the test vessel was thoroughly washed with methanol after each sampling, and the recovered ^{14}C in the rinsate was below the LOD (<30 dpm), which clarified negligible loss of ^{14}C by adhesion onto the vessel.

^{14}C Distribution in the Water Treatment System. The ^{14}C distribution in the water treatment system after 96 h is summarized in Table 2. The total ^{14}C recovery for compounds **2**−**5** ranged from 93.7 to 97.2% AR with less recovery for compound **1** (81.3% AR). A large amount of the applied radioactivity remained in the water layer for compounds **2**−**4** (>80.9% AR), while a lower amount was observed for compounds **1** (55.8% AR) and **5** (54.5% AR). From the HPLC analysis, the radioactive component in exposure water was clarified to be the unaltered parent only for all of the test materials. The amount of ^{14}C taken up from water via shoot with the incubation period is shown in Figure 3. The ^{14}C uptake by the shoot after 96 h reached 4.2−25.5% AR for compounds **1**−**4**, and 41.7% AR for compound **5**. No detectable radioactivity was recovered from the plant surface wash. For most of the tested phenols, shoot uptake was rapid at the beginning and gradually approached its steady state at the end of exposure. The majority of ^{14}C taken up remained in the shoot, and very minor radioactivity was detected from the root, which amounted to 0.4% AR (**1**), ≤0.1% AR (**2**−**4**), and 0.9% AR (**5**). These results suggest that the basipetal ^{14}C translocation from shoot to root is a minor process.

^{14}C Distribution in the Sediment Treatment System. The ^{14}C distribution in the test system at 96 h exposure is summarized in Table 3. The total ^{14}C recovery ranged from 91.7 to 98.2% AR. The radioactivity in the sediment is shown as the sum of ^{14}C in the methanol extract and unextractable bound residue, in which the latter amounted to be less than 3.5% AR. For all of the phenols, most of the applied ^{14}C remained in the root chamber (≥89.1% AR) and the radioactivity detected from the untreated water in the shoot chamber was insignificant (≤0.1% AR). In the root chamber, the amount of ^{14}C in water/sediment after 96 h was 47.0% AR/42.1% AR (**1**), 34.4% AR/61.0% AR (**2**), 42.2% AR/51.8% AR (**3**), 85.9% AR/11.5% AR (**4**), and 84.3% AR/6.5% AR (**5**). For both water and sediment fractions in the root chamber, the unchanged phenols were the only radioactive constituent confirmed by HPLC analysis. Root uptake behavior of ^{14}C from the sediment is shown in Figure 4. The ^{14}C taken up after

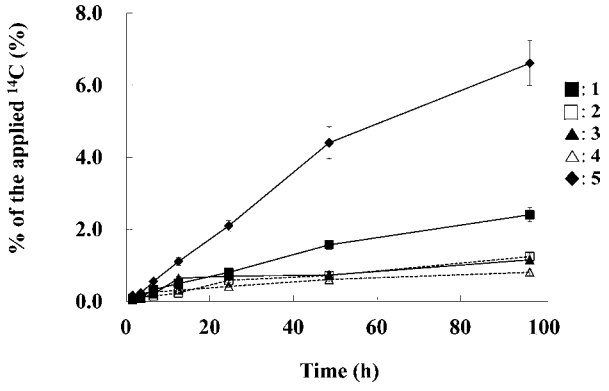

Figure 4. Accumulated ^{14}C by *M. elatinoides* in the sediment treatment system. The error bars represent mean standard deviation ($n = 3$; $p < 0.05$).

96 h reached 0.8−2.4% AR for compounds **1**−**4** and 6.6% AR for compound **5**. No radioactivity was recovered by the plant surface rinse. In comparison to the water treatment, the ^{14}C uptake from sediment via root was much lower and slower than the ^{14}C uptake from water via shoot for all of the test materials. The radioactivity translocated from root to shoot after 96 h was extremely low for compounds **1**−**4** (≤0.1% AR), which suggested that the acropetal ^{14}C translocation from root to shoot was unlikely to occur, whereas compound **5** showed the relatively higher potential of translocation because the radioactivity detected in the shoot was 1.5% AR. For the sediment treatment, the metabolic profiles in root and shoot were not clarified because of their insufficient ^{14}C to be characterized.

Distribution of Metabolites in the Exposed Shoot. The metabolite distribution in the shoot portion of milfoil at 96 h exposure is summarized in Table 4, as representative. In the shoot, 84.4−97.5% of the total radioactive residue (TRR) was extractable and 2.5−6.3% TRR remained as the unextractable bound fraction. In the extracts, the unchanged phenols were quantified to be 14.0−20.5% TRR for compounds **1**−**4**, while the one was only 6.0% TRR for compound **1**, respectively. The glycoside conjugate of each phenol was the main metabolite, which amounted to 72.9% TRR (**6**), 78.8% TRR (**7**), 83.4% TRR (**8**), 63.5% TRR (**9**), and 88.0% TRR (**10**), respectively, after 96 h. For identification, metabolites **6**−**10** were analyzed by LC−MS and LC−MS/MS. The MS analysis of each metabolite gave molecular-related ions, which were identical to the mass number of the monoglucose conjugate of the corresponding phenol. Furthermore, the MS/MS analysis of $[M + H]^+$ or $[M - H]^-$ gave mass fragments suggesting the structure as follows: **6**, m/z 279 $[M + Na]^+$, 257 $[M + H]^+$, and 95 [**1** + H; M − sugar + H]$^+$; **7**, m/z 324 $[M + Na]^+$, 302 $[M + H]^+$, and 140 [**2** + H; M − sugar + H]$^+$; **8**, m/z 322 $[M + Na]^+$, 300 $[M + H]^+$, and 138 [**3** + H; M − sugar + H]$^+$; **9**, m/z 304 $[M + Na]^+$, 282 $[M + H]^+$, and 120 [**4** + H; M − sugar + H]$^+$; and **10**, m/z 299 $[M - H]^-$, 255 $[M - CO_2 - H]^-$, and 137 [**5** − H; M − sugar − H]$^-$. Incidentally, the fragment ion m/z 255 was detected in a negative-ion mode for compound **10**. Because this ion is considered to be produced by decarboxylation during the mass fragmentation similar to compound **5**, compound **10** was concluded to have a free carboxylic acid group and to form an O-glycosidic bond at the phenoxy oxygen. After the tentative identification by LC−MS, the conjugates **7**, **8**, and **10** were subjected to NMR analyses. The chemical shifts of protons were assigned as follows: **7**, δ = 8.36 ppm (2H, d, J = 9.21 Hz, aromatics), 7.34, (2H, d, J = 9.21 Hz, aromatics), 5.16 ppm (1H, d, J = 8.01 Hz, anomeric), and 3.60−4.01 ppm (5H, m, glucose); **8**, δ = 7.80 ppm (2H, d, J = 8.81 Hz, aromatics), 7.27 (2H, d, J = 8.81 Hz, aromatics), 5.14 ppm (1H, d, J = 7.61 Hz, anomeric), and 3.52−3.98 ppm (5H, m, glucose); and **10**, δ = 7.87 ppm (2H, d, J = 8.61 Hz, aromatics), 7.16 (2H, d, J = 8.61 Hz, aromatics), 5.02 ppm (1H, d, J = 6.81 Hz, anomeric), and 3.52−3.98 ppm (5H, m, glucose). The correlation between the anomeric and vicinal protons was distinguishable by the ^{1}H−^{1}H COSY NMR technique for each conjugate, which also indicated the glucoside structure.

Kinetic Analysis. The kinetic analysis was conducted for each phenol in the water treatment. The graph showing the

simulated ^{14}C dissipation curves to estimate shoot uptake and metabolic rate constants for compound **5** is given in Figure 5, as

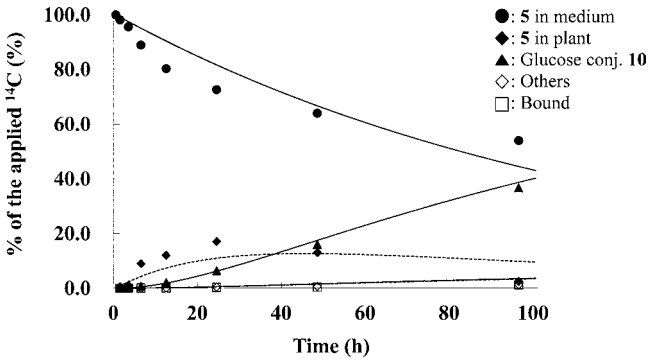

Figure 5. Uptake and metabolism curve of compound **5** by *M. elatinoides* simulated by the Model-Maker program.

representative. The optimization of the rate constants was performed with a good correlation ($r^2 > 0.97$; $p < 0.05$) for all phenols. The relative rate constants of compounds **2**−**5** with respect to compound **1** are summarized in Table 5. The relative rate constants for the production of "others" and "bound" were not obtained because these metabolic processes were insignificant to be compared to those of the most predominant process "glucose conjugation". Successively, the correlation between the physicochemical parameters and the logarithm of the relative rate constants is examined by the regression analysis, as listed in Table 6. The highest correlation for shoot uptake, $\log[k_{1(i)}/k_{1(1)}]$, was observed for log K_{ow} as 0.656 (standard deviation of 0.325), while the other indexes showed a lower correlation (<|0.264|). With respect to the transformation rate to produce a glucose conjugate, $\log[k_{2(i)}/k_{2(1)}]$, better correlations were obtained for the electrochemical parameters σ, σ^-, and $E_{HOMO(OH)}$ because their absolute values exceeded 0.871 with the standard deviation of less than 0.036. The kinetic simulation for the sediment treatment resulted in poor fitting ($r^2 < 0.50$), so that no comparison to the parameters was attempted.

DISCUSSION

In some test systems, the total ^{14}C recovery gradually decreased over the period of incubation. The loss of radioactivity was prominent for compound **1** probably because of the vaporization from the test vessel considering its high vapor pressure at ambient temperature (0.35 mmHg at 25 °C).[21]

In the water treatment, the ^{14}C uptake/accumulation to the plant decreased in the order of compounds **5**, **1**, **2**, **3**, and **4**. With regard to the regression analysis between the relative rate constants and physicochemical parameters, the log K_{ow} index showed the strongest correlation with the shoot uptake rate constants (k_1). Similar to many living organisms, this tendency complies with the observation that uptake of water-dissolved chemicals through the macrophyte surface closely correlates with their lipophilicity. For example, Gobas et al. investigated the uptake of non-ionizable pesticides from water by *M. spicatum* under submergence, and they observed the linear positive correlation between the accumulation factors and log K_{ow} values.[22] The same relationship was also reported on macrophytes by Carvalho et al. but without the linearity at the lower range of log K_{ow}, approximately below 1, which exhibits the minimum uptake potential.[23] Meanwhile, we also compared shoot uptake rate constant and log D, reflecting the actual lipophilicity of an ionizable chemical under dissociation. For example, better positive correlation for log D than log K_{ow} was

reported for the accumulation of ionized chemicals by fish.[24] Incidentally, we have obtained a poor correlation, especially because highly dissociated carboxylic acid derivative **5** ($f_{neutral}$ = 0.004 at pH 7) exhibited outstanding accumulation despite its lowest log D value. In general, the ionized chemicals are considered unlikely to bioaccumulate in the leaf/shoot portion of plants because lipophilic materials, such as epicuticular wax, on the plant surface prevent the penetration of ionized compounds. However, Zhang et al. have clarified that many carboxylic compounds, which intensively dissociate in natural water bodies, are largely taken up by macrophytes, irrespective of their extremely low lipophilicity expressed by log D (less than zero).[25] In addition, 3-phenoxybenzoic acid (PBacid), which intensively dissociates in water at pH 7, as indicated by $f_{neutral}$ = 0.001, was largely taken up by *M. elatinoides*.[9] This trend may be explained from the reasons that ions could receive electric attraction/repulsion from electrically charged cell membranes, formation of molecular complex with cations, and as the most crucial process for weak acids, retention of anions at inner cells (ion trap theory), followed by metabolism, which generally increase the solubility of xenobiotics to enhance the trapping.[26]

For the metabolic reaction, glucose conjugation was observed in this study. The conjugation followed by storage into vacuoles is the generally accepted detoxification process in terrestrial plants. This is probably the case for macrophytes, because glucosidation is observed for many aquatic plants. For example, Day and Sounders reported glucose conjugation of halogenated phenols by duckweed, which is one of the major macrophytes.[27] In our kinetic analysis of the transformation rate constants to a glucose conjugate (k_2), high correlations were found for the Hammett constant (σ and σ^-) and $E_{HOMO(OH)}$. These results imply that the electronic distribution at the phenoxy group and/or phenol structure as a whole is important for glucose conjugation at the enzyme active site. Moreover, because the index σ^- also correlated with glucosidation, the inductive effect of the electron-withdrawing substituent on the phenyl ring, such as deprotonation and polarization enhancements, was considered to associate with the conjugation. The key mechanism for glucosidation by glucosyl transferases is generally expressed by the following steps:[28] (1) interaction of histidine at the binding acceptor domain of the enzyme with the hydroxyl group of the sugar-accepting substance to induce deprotonation and (2) nucleophilic attack by the deprotonated acceptor to the C1 anomeric carbon of the donor sugar. Hence, the nucleophilicity expressed by the index, such as σ, σ^-, or $E_{HOMO(OH)}$, likely showed good correlation to k_2. However, with regard to the reaction analysis using the molecular orbital calculation approach, the energy gap between HOMO and lowest unoccupied molecular orbital (LUMO) of the nucleophile and electron acceptor and their transition states are assumed to be important for the bond formation. Furthermore, the conformation rearrangement during interaction with the binding domain followed by HOMO redistribution of the nucleophile at the active site should be taken into account within the specific enzyme to precisely simulate the reaction.[29]

Incidentally, compound **5** possesses both phenoxy and carboxyl groups as the reaction site for glucosidation, but the phenoxy group was the predominant reaction site in *M. elatinoides*. The HOMO coefficients at the carboxylic and phenoxy oxygen were calculated as −0.372 and 0.047, respectively, while the LUMO constant at the anomeric carbon of glucose was −0.241. From deduction of the estimated electronic distribution, the carboxyl group is more likely to be involved in conjugation, but only this may not exclusively explain the selectivity of enzymatic glucosidation. The glucosidation of hydroxybenzoic acids including compound **5** by glucosyl transferases is known to proceed at the hydroxyl or carboxyl group to give glucose ether or ester conjugate, respectively, depending upon the substrate and the gene pattern of the enzymes.[30] Additionally, there are bifunctional glucosyl transferases, which are possible to catalyze either etherification and esterification, and the selectivity is known to be controlled by the reaction pH. For example, the glucosyl transferase in grape can selectively produce the ether glucoside of resveratrol at basic conditions (pH > 7) and the ester glucoside of resveratrol at acidic pH.[31] Because etherifying glucosidation of 3-phenoxybenzoic acid is previously confirmed,[9] *M. elatinoides* is considered to have both types or bifunctional type of glucosyl transferases.

In the sediment treatment, the ^{14}C uptake/accumulation to plant decreased in the order of compounds **5**, **1**, **2**, **3**, and **4**, which was the same trend observed with the water treatment. However, the total amount of radioactivity detected in the plant was much less than that in the water treatment. To estimate the uptake/transport of organic compounds from root to shoot, the transpiration stream concentration factor (TSCF), the concentration ratio of the compound in xylem (transpiration stream), and the solution adjacent to the roots are commonly applied for terrestrial plants. Briggs et al. have reported bell-shaped Gaussian curves for plotting TSCF versus log K_{ow} with the non-ionizable compounds, which imply that significant root uptake and translocation occur for the compound having an intermediate lipophilicity, log K_{ow} of around 1−3, and the maximum uptake is expected at the vertex of 1.8.[32] The similar uptake trend was observed for water milfoils with emergent leaves incubated hydroponically.[33] On the other hand, Dettenmaier et al. have proposed the sigmoidal relationship and suggested that the highly soluble/non-ionizable compound with a very low log K_+ has the highest uptake potential, while that with a high log K_{ow} has the lowest uptake potential.[34] On the basis of Briggs's theory, the amount of radioactivity in the shoot was considered to decrease in the order of compounds **2**, **3**, **5**, **1**, and **4**, but the obtained results were not as expected. One of the reasons for this discrepancy may be explained by the low applicability of the TSCF concept to submerged macrophytes, because their transpiration stream diminishes under submergence. Incidentally, Dettenmaier's theory seems to better elucidate our results, but further accumulation of basic data/knowledge would be necessary to understand precise root uptake profiles of organic chemicals for submerged-rooted macrophytes.

J. Agric. Food Chem. 2015, 63, 5189−5195

In conclusion, the shoot uptake of phenols by *M. elatinoides* was faster and larger than the root uptake. The carboxylic acid derivative **5** showed the highest accumulation for both shoot and root treatment, which indicated some specific potential for the dissociated ions to be taken up by aquatic plants. Similar to terrestrial plants, the major metabolic pathway was the formation of a glucose conjugate, which was considered as a detoxification strategy. Furthermore, the kinetic analysis had shown high correlations between the shoot uptake rate constant and log K_{ow} and transformation rate constant (glucose conjugation) and Hammett constants or $E_{HOMO(OH)}$ parameter, respectively.

Physicochemical Characteristics and Slow Release Performances of Chlorpyrifos Encapsulated by Poly(butyl acrylate-*co*-styrene) with the Cross-Linker Ethylene Glycol Dimethacrylate

Yu Wang, Zideng Gao, Feng Shen, Yang Li, Sainan Zhang, Xueqin Ren,* and Shuwen Hu*

College of Resources and Environmental Sciences, China Agricultural University, Beijing 100193, China

ABSTRACT: Chlorpyrifos' application and delivery to the target substrate needs to be controlled to improve its use. Herein, poly(butyl acrylate-*co*-styrene) (poly(BA/St)) and poly(BA/St/ethylene glycol dimethacrylate (EGDMA)) microcapsules loaded with chlorpyrifos as a slow release formulation were prepared by emulsion polymerization. The effects of structural characteristics on the chlorpyrifos microcapsule particle size, entrapment rate (ER), pesticide loading (PL), and release behaviors in ethyl alcohol were investigated. Fourier transform infrared and thermogravimetric analysis confirmed the successful entrapment of chlorpyrifos. The ER and PL varied with the BA/St monomer ratio, chlorpyrifos/monomer core-to-shell ratio, and EGDMA cross-linker content with consequence that suitable PL was estimated to be smaller than 3.09% and the highest ER was observed as 96.74%. The microcapsule particle size (88.36−101.8 nm) remained mostly constant. The extent of sustainable release decreased with increasing content of BA, St, or chlorpyrifos in the oil phase. Specifically, an adequate degree of cross-linking with EGMDA (0.5−2.5%) increased the extent of sustainable release considerably. However, higher levels of cross-linking with EGDMA (5−10%) reduced the extent of sustainable release. Chlorpyrifos release from specific microcapsules (monomer ratio 1:2 with 0.5% EGDMA or 5 g chlopyrifos) tended to be a diffusion-controlled process, while for others, the kinetics probably indicated the initial rupture release.

KEYWORDS: *microcapsule, slow release, chlorpyrifos, poly(butyl acrylate-co-styrene), ethylene glycol dimethacrylate, emulsion polymerization*

INTRODUCTION

Chlorpyrifos (*O*,*O*-diethyl *O*-(3,5,6,-trichloro-2-pyridyl phosphorothioate)) is a broad-spectrum, chlorinated organophosphate insecticide, acaricide, and nematicide.[1] It is used worldwide as a moderately toxic organophosphate pesticide against diverse chewing and sucking mouthparts pests on rice, wheat, cotton, fruit, vegetables, and tea trees through the triple effects of stomach action, contact poison, and fumigation. Because of its high volatilization and widespread use, chlorpyrifos represents one of the most significant sources of organophosphate exposure during application, resulting in adverse effects such as pollution of surface/underground water and biological systems. Additionally, its high toxicity to humans can result in severe illnesses, such as prostate cancer[2] and respiratory problems.[3] In China, the high volatilization and easy spreading of chlorpyrifos in the soil and water lead to low utilization efficiencies. As a result, chlorpyrifos needs to be repeatedly applied for effective performance, and that consequently increases the level of adverse health risks to both the environment and humans. Thus, control over the application of chlorpyrifos in the agricultural sector is necessary.

Microcapsule-controlled release technology has been widely used for the delivery of target molecules over the past decades. Microencapsulation offers advantages such as target molecule protection, controlled and triggered release, and the development of new product features.[4] It has been recognized as a new technology and promising solution in the fields of pharmaceuticals, biotechnology, pesticides, environmental engineering, cosmetics, coatings, and food chemistry.[5] Additionally, microcapsule technology has bright prospects in the agriculture sector to prepare controlled release formulation systems for pesticides. It is an effective approach to efficiently increase the performance level of pesticides and reduce human labor and hazard risks to the environment and humans.

In recent years, many papers have reported the preparation of pesticide-based microcapsules. Numerous methods were investigated toward the encapsulation of pesticides namely, interfacial polymerization,[6−9] in situ polymerization[10] and condensation,[11] and solvent evaporation[12−15] methods. Some of these methods successfully achieved the preparation of wall-type material membranes and chlorpyrifos-encapsulating matrices. The materials included synthetic polymers (e.g., polyamide and polyurethane) prepared by interfacial polymerization and natural polymeric membranes (e.g., alginate, chitosan, starch, and cellulose) prepared by condensation methods. However, studies typically focused on the properties of the encapsulating units only rather than on the release profiles of the encapsulated target pesticide.[16−18]

It has been reported that some wall-type materials such as urea formaldehyde, prepared by in situ polymerization,[19] afford short sustainable release profiles, whereas other materials, such as polylactic acid[20,21] and mesoporous silica,[22] afford longer sustainable release profiles. In contrast, emulsion polymerization affords the synthesis of microcapsules with a relatively wide range of sustainable release profiles for the delivery of

active ingredients by varying the contents and ratios of typical monomers including butadiene, styrene, acrylonitrile, acrylate ester, and methacrylate ester.[23−26] Furthermore, the preparation process of emulsion polymerization for chlorpyrifos will not involve any organic solvent, such as toluene, xylene, and cyclohexanone, etc., which might be considered more environmentally friendly. And the chlorpyrifos-loaded microcapsules emulsion can be directly sprayed onto plants following synthesis, thereby not requiring the dispersion of the pesticide microparticles in water before application. The chlorpyrifos-loaded microcapsules prepared by emulsion polymerization have been discussed in several patents and in several research papers.[27−30] However, reports on the effects of the structural characteristics of wall materials on the sustainable release of chlorpyrifos encapsulated in microcapsules are rare.

In the present study, butyl acrylate (BA), styrene (St), and cross-linker ethylene glycol dimethacrylate (EGDMA) were used to synthesize microcapsules by emulsion polymerization. Two series of chlorpyrifos-loaded polyacrylate microencapsulating systems were prepared i.e., microcapsules of chlorpyrifos-loaded poly(BA/St) and chlorpyrifos-loaded poly(BA/St/EGDMA) (poly(BA/St) cross-linked with EGDMA). The glass transition temperature (T_g) of poly(butyl acrylate) is low, and hence, it features an elastomeric state (soft and sticky) at room temperature; whereas, polystyrene features a glassy state (hard and brittle) because of its higher T_g. Hence, it is expected that copolymerization of BA and St whose T_g can be easily designed by the Fox equation may generate microcapsules with the required hardness and viscosity. Furthermore, the addition of cross-linker EGDMA is expected to afford the synthesis of a denser microcapsule wall material or better connections among the microcapsule particles. Thus, copolymerization between BA and St or between BA/St and EGDMA would afford microcapsules with fine characteristics (hardness, viscosity, and dense) to achieve long sustainable release properties as desired. More particularly, the preparation conditions of the chlorpyrifos microcapsules, i.e., the effects of monomer ratio (BA/St), core-to-shell ratio, and content of cross-linker EGDMA in oil phase on the characteristics of the microcapsules (particle size, entrapment rate, and pesticide loading), especially the sustained release performance, were investigated.

MATERIALS AND METHODS

Materials. BA (chemical pure, National Medicine Group Chemical Reagent Co., Ltd.), St (chemical pure, National Medicine Group Chemical Reagent Co., Ltd.), nonylphenol polyoxyethylene (OP-10), sodium dodecyl sulfate (SDS), ammonium persulfate (APS; analytical pure, National Medicine Group Chemical Reagent Co., Ltd.), sodium bisulfite (SBS; analytical pure, Beijing Chemical Reagent Co.), chlorpyrifos (Jiangsu YiJin Agrochemical Co., Ltd.), and EGDMA (99%, J&K Beijing Science and Technology Co., Ltd.) were used in this study.

Preparation of Chlorpyrifos Microcapsules. The chlorpyrifos-loaded poly(BA/St) and chlorpyrifos-loaded poly(BA/St/EGDMA) microcapsules were synthesized by emulsion polymerization in a 250 mL four-neck flask equipped with a mechanical stirrer, a heating mantle with a digital thermometer and a condenser. In a typical synthesis, exact amounts of chlorpyrifos were dissolved in a mixture of BA, St, and EGDMA to form the oil phase. Then, the oil phase was poured into distilled water (30 g) containing OP-10 (0.15 g) and SDS (0.4 g) and emulsified using a homomixer at 1500 rpm for 10 min to form the pre-emulsion. Another solution that was prepared by dissolving OP-10 (0.1 g) and SDS (0.2 g) into distilled water (25 g) was added to the four-neck flask with mechanical stirring at 300 rpm. The initiator solution was prepared by dissolving APS (0.25 g) and SBS (0.25 g) in distilled water (15 g). One-third of the prepared pre-emulsion was added to a four-neck flask under nitrogen gas and maintained at 80 °C. Then, one-third of the initiator was introduced to initiate polymerization. The remainder of the pre-emulsion and initiator solutions was slowly dropped into the reaction mixture over a period of 1 h. The reaction was continued further for 3 h under nitrogen gas. The resulting emulsion was collected after cooling to room temperature for further characterization. The formulations employed for the synthesis of the chlorpyrifos microcapsules are listed in Table 1.

Table 1. Particle Size of the Chlorpyrifos Microcapsules Prepared under Different Conditions

	oil phase			
sample	monomer (BA/St wt/wt)	chlorpyrifos (g)	EGDMA/monomer (mol/mol)	mean diameter (nm)
M1	1:5	1.0	0	88.80 ± 1.47 ef
M2	1:2	1.0	0	95.45 ± 1.96 c
M3	1:1	1.0	0	90.21 ± 1.93 e

P3	1:2	15.0	0	97.17 ± 1.71 bc

Effect of Different Formulations on the Characteristics of Microcapsules. The individual effects of different factors on particle size, entrapment rate, pesticide loading, and slow release behaviors were examined. More specifically, the effects of the monomer ratio, core-to-shell ratio, and EGDMA cross-linker content in the oil phase on the characteristics of the microcapsules were studied. The BA/St monomer ratios (w/w) in the oil phase were 1:5, 1:2, 1:1, 2:1, and 5:1 in the oil phase. The chlorpyrifos/monomer core-to-shell ratios (w/w) in the oil phase were 1:30, 5:26, 10:21, and 15:16. The contents of cross-linker EGDMA in the oil phase (relative to EGDMA/monomer ratio (mol %/mol %)) were 0, 0.5, 1.0, 2.5, 5, and 10%.

Characterization. *Entrapment Rate and Pesticide Loading.* The two parameters entrapment rate (ER, %) and pesticide loading (PL, %) were used to characterize the efficiency of the encapsulation process. ER is defined as the ratio between the weight of encapsulated chlorpyrifos and the theoretical weight of chlorpyrifos during the preparation process

$$\text{ER}\ (\%) = \frac{\text{weight of encapsulated chlorpyrifos}}{\text{theoretical weight of chlorpyrifos}} \times 100\%$$

PL is defined as the weight of encapsulated chlorpyrifos divided by the weight of the corresponding chlorpyrifos-containing microcapsules

$$\text{PL}\ (\%) = \frac{\text{weight of encapsulated chlorpyrifos}}{\text{weight of microcapusles}} \times 100\%$$

Prior to measuring ER and PL of the pesticide microcapsules, the emulsion was demulsified. Typically, the emulsion (2 mL) was added to a 1:1 (w/w) mixture of ethanol and 2% $CaCl_2$ aqueous solution. The demulsified pesticide microcapsule solution was filtered using a mutche filter to obtain aggregates of chlorpyrifos-containing microcapsules. Then, the microcapsules were washed with 50 wt % ethanol/water solution once and distilled water twice to remove any nonencapsulated chlorpyrifos, followed by drying at 45 °C for 24 h.

The microcapsule aggregates (~0.3 g) were introduced into 50 mL centrifuge tubes containing *n*-hexane (20 mL). The encapsulated

DOI: 10.1021/acs.jafc.5b01378
J. Agric. Food Chem. 2015, 63, 5196−5204

chlorpyrifos was extracted into *n*-hexane upon stirring at 150 rpm for 4 h at 25 °C. The concentration of chlorpyrifos in *n*-hexane was analyzed on a WTF UV-2102PC ultraviolet−visible spectrophotometer (UNICO Shanghai Instrument Co., Ltd., China) at 292 nm and the weight of encapsulated chlorpyrifos was calculated.

Particle Size Measurement. The mean diameter of the microcapsule particles was calculated using a HORIBA LA-950 laser particle analyzer (HORIBA Co., Ltd., Japan) at the Beijing Centre for Physical & Chemical Analysis (Beijing, China)

Fourier Transform Infrared (FTIR) Spectroscopy. For sample analysis, the microcapsules obtained from the demulsified solution described above were dried at 40 °C overnight. All the FTIR measurements were conducted on a Nicolet NEXUS-470 spectrometer (Madison, WI, USA).

Thermogravimetric Analysis (TGA). Thermogravimetric analysis for the chlorpyrifos microcapsules was conducted by using a TGA/DSC simultaneous thermal analyzer (Mettler Toledo, Switzerland) at a heating rate of 10 °C/min under a nitrogen atmosphere from 25 to 500 °C.

Transmission Electron Microscopy (TEM). Prior to TEM analysis, the emulsion was diluted 600-fold, followed by negative staining. TEM photographs were taken on a JEM-1230 transmission electron microscope (JEOL Japan Electronics Co., Ltd., Japan) operating at an accelerating voltage of 80 kV at the required magnification (80 000−200 000×) at room temperature.

Slow Release Behaviors of Chlorpyrifos Microcapsules. For the chlorpyrifos release experiments, a chlorpyrifos microcapsule emulsion (5.0 g) was injected into a dialysis bag with molecular weights of 8000−12 000. The dialysis bag was placed in a conical flask (250 mL) containing absolute ethyl alcohol (100 mL) as the release medium under static conditions at 25 °C. The amounts of chlorpyrifos released at different time intervals were measured by recording the absorbance of the release medium at 291 nm on an ultraviolet−visible spectrophotometer (UNICO Shanghai Instrument Co., Ltd., China).

RESULTS AND DISCUSSION

FTIR Spectroscopy Analysis of Chlorpyrifos Microcapsules. To assess the successful encapsulation of chlorpyrifos, the FTIR spectra of the chlorpyrifos, poly(BA/St) microcapsules, and chlorpyrifos-loaded poly(BA/St) microcapsules were recorded (Figure 1). The spectrum of chlorpyrifos (Figure 1a) featured stretching vibration peaks corresponding to pyridine ring C═N, aromatic P−O−C, aliphatic P−O−C, and P═S at 1549.64, 1169.59, 852.84, and 1016.97 cm^{-1}, respectively. These characteristic peaks are typical of chlorpyrifos. The poly(BA/St) microcapsules (Figure 1b) were characterized by the absorption peak at 1727.69 cm^{-1} (corresponding to C═O), which proved the existence of BA/St copolymer. Moreover, the characteristic absorption peak of C═C belonging to monomer BA and St at 1637 cm^{-1} was absent, which proved the successful preparation of the poly(BA/St) wall material. The characteristic peaks observed in both Figure 1a and b were present in the spectrum of the chlorpyrifos-loaded poly(BA/St) microcapsules (Figure 1c), thereby confirming the successful entrapment of chlorpyrifos by poly(BA/St) wall material.

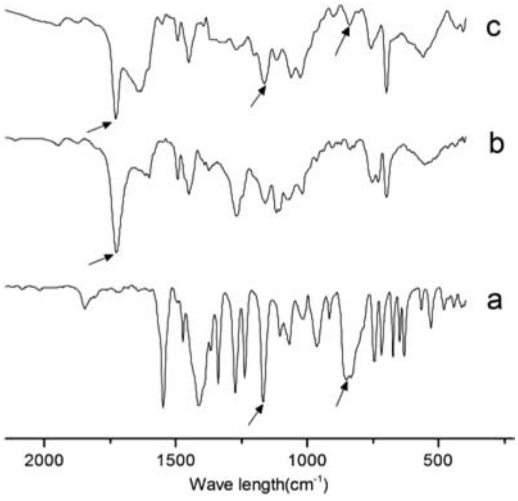

Figure 1. FTIR spectra of (a) chlorpyrifos, (b) poly(BA/St) (1:1, wt/wt) microcapsules, and (c) chlorpyrifos-loaded poly(BA/St) (1:1, wt/wt) microcapsules.

TG Analysis of Chlorpyrifos Microcapsules. Figure 2 demonstrated TGA thermogram of prepared poly(BA/St) chlorpyrifos microcapsules (Figure 2c) comparing with pure chlorpyrifos (Figure 2a), blank poly(BA/St) microcapsules (Figure 2b), and a physical mixture of chlorpyrifos and blank poly(BA/St) microcapsules (Figure 2d). TG curves presented the weight loss of pure chlorpyrifos occurred at 143 °C while that of blank poly(BA/St) microcapsule occurred at 360 °C. TG curves of poly(BA/St) chlorpyrifos microcapsules showed two stage degradation with an initial weight loss from 234 to 301 °C and a second from 360 to 425 °C. Comparing with TG curves of pure chlorpyrifos and blank poly(BA/St) microcapsule, the first stage might result from the gasification of chlorpyrifos and the second one was attributed to the decomposition of poly(BA/St). It also proved that the chlorpyrifos was encapsulated by poly(BA/St) microcapsule successfully. Additionally, TG curves of poly(BA/St) chlorpyrifos microcapsules had the same degradation feature as the TG curves of physical mixture of chlorpyrifos and blank poly(BA/St) microcapsule, which might imply the physical combination between chlorpyrifos and poly(BA/St) wall materials.

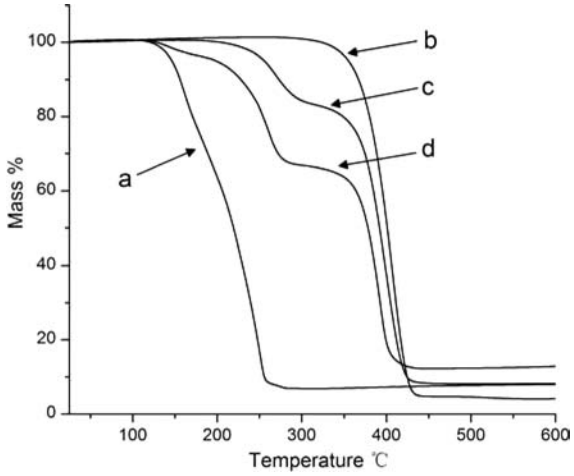

Figure 2. TGA thermogram: (a) chlorpyrifos; (b) blank poly(BA/St) microcapsule; (c) poly(BA/St) microcapsule of chlorpyrifos; (d) physical mixture of chlorpyrifos and blank poly(BA/St) microspheres.

Particle Size of Chlorpyrifos Microcapsules. In order to investigate the diameter feature of microcapsule pesticide sample prepared in this study, particle size distribution analysis was conducted. The particle size distribution of M3 was demonstrated in Figure 3. The diameter presented an approximately normally distribution and the particle size mostly distributed at about 90 nm with the mean diameter of 90.21 nm. For other samples, a similar distribution was

DOI: 10.1021/acs.jafc.5b01378
J. Agric. Food Chem. 2015, 63, 5196−5204

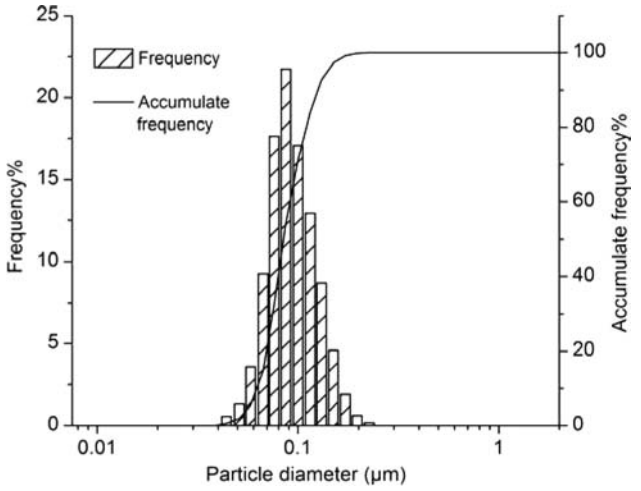

Figure 3. Particle size distribution of chlorpyrifos poly(BA/St) microcapsule with the monomer ratio 1:1 (BA/St wt/wt).

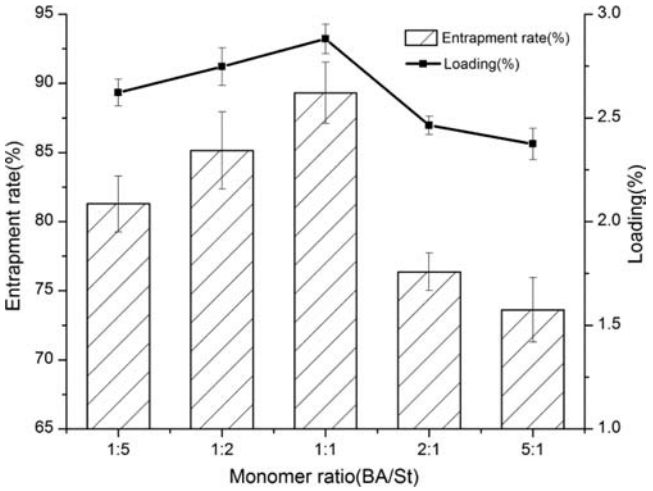

Figure 4. Effect of BA/St monomer ratio in the oil phase on the ER and PL of the microcapsules.

observed. It revealed a narrow and concentrated distribution of the particle size of each sample. As to the mean diameter, presented in Table 1, mean diameters of sample P1−P3 were slightly bigger than others, which probably indicated the influence of chlorpyrifos content on particle mean diameter. When only considering the monomer ratio (M1−M5), M2 is slightly bigger than other formulations (M1, M3, M4, and M5) where no significant difference was observed. Similarly, the mean diameters of E1−E5 were almost the same (about 90 nm), which indicated that the change of EGDMA content had little effect on particle size. These results demonstrated that the content of the monomer, pesticide, and EGDMA minimally influenced the particle size. Consequently, it could be inferred that the release performance of the microcapsules would not be influenced by the diameter of the microcapsules that remained mostly unchanged across the different synthesis conditions studied herein.

Effect of Monomer Ratio on Characteristics of Chlorpyrifos Microcapsules. As observed in Table 2 and Figure 4, when the BA/St monomer ratio changed from 1:5 to 1:1, ER and PL increased from 81.28 to 89.31% and 2.62 to 2.88%, respectively. In contrast, when the BA/St monomer ratio changed from 1:1 to 5:1, ER and PL decreased from 89.31 to 73.62% and 2.88 to 2.37%, respectively. As deduced, excess amounts of BA and St were detrimental to the encapsulation of chlorpyrifos as indicated by the corresponding lower measured ER and PL values when compared with those of other formulations comprising lower amounts of BA and St. At excessive amounts of St (M1), the resulting poly(BA/St) became hard and brittle because of its higher T_g over 55 °C. Hence, the polymer was prone to rupture during the encapsulation of chlorpyrifos. Similarly, when the content of BA in the formulation was high (M4, M5), poly(BA/St) featured soft and sticky characteristics with the lower T_g of about −21 and −39 °C and, hence, was not adequately mechanically stable for the effective entrapment of the pesticide. Therefore, the ER and PL values of the microcapsules were satisfactory at moderate monomer ratios of 1:2 and 1:1 owing to the desirable soft and hard characteristics of poly(BA/St). The monomer ratio of 1:2 was studied further in the subsequent experiments.

Table 2. Characteristics of the Pesticide Microcapsules Prepared under Different BA/St Monomer Ratio Conditions

			characteristic parameter	
sample	monomer (BA/St wt/wt)	designed T_g[a] (°C)	entrapment rate (%)	pesticide loading (%)
M1	1:5	55.13	81.28 ± 2.02 b	2.622 ± 0.07 b
M2	1:2	25.02	85.14 ± 2.80 b	2.747 ± 0.09 b
M3	1:1	−0.023	89.31 ± 2.21 a	2.881 ± 0.07 a
M4	2:1	−21.18	76.37 ± 1.37 c	2.464 ± 0.04 c
M5	5:1	−39.31	73.62 ± 2.34 c	2.375 ± 0.08 c

[a]Calculated by the Fox equation.

Effect of Core-to-Shell Ratio on Characteristics of Chlorpyrifos Microcapsules. The influence of different chlorpyrifos/monomer BA and St core-to-shell ratios on ER and PL was investigated (Table 3, Figure 5). The weight of the oil phase was kept constant and the total weight of chlorpyrifos and monomer BA and St was 31 g. Only the weight of chlorpyrifos was varied from 1 to 15 g to achieve chlorpyrifos/monomer BA and St weight ratios of 1:30, 5:26, 10:21, and 15:16. As observed in Figure 5, PL increased from 2.74 to 29.11% when the loading content of pesticide increased owing to the increased content of pesticides in the oil phase. In contrast, ER decreased from 85.14 to 60.15% when the loading content of chlorpyrifos increased from 1 to 15 g. These results showed that moderate dosages of monomer in the chlorpyrifos emulsion preparation process afforded desirable ER and PL values, whereas similar weight levels of chlorpyrifos and monomer did not result in desirable ER values. However, higher PL values were obtained. This phenomenon was

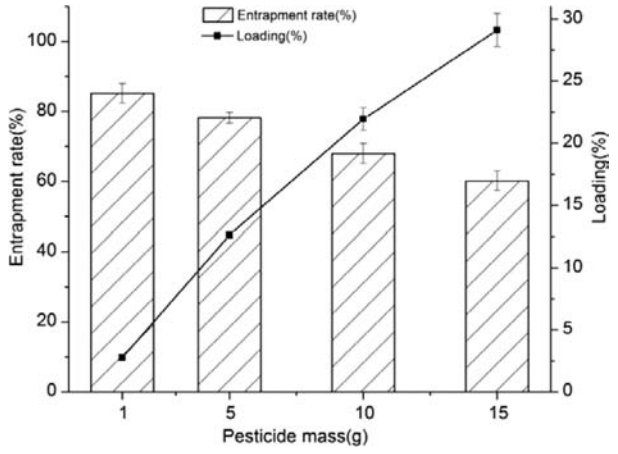

Figure 5. Effect of additive amount of pesticide in the oil phase on the ER and PL of the microcapsules.

attributed to ineffective chlorpyrifos entrapment owing to the inadequately dense polymer obtained in the presence of relatively low monomer dosages. Optimum weight ratios of the pesticide and monomer were determined at 1:30−5:26 for the effective encapsulation of chlorpyrifos into poly(BA/St) microcapsules by emulsion polymerization.

Effect of Content of Cross-Linker EGDMA on Characteristics of Chlorpyrifos Microcapsules. EGDMA, a widely employed cross-linker for emulsion polymerization, will form a dense network within the microcapsule wall material or generate links among the microcapsule particles upon copolymerization with BA and St. In the present study, the effect of EGDMA on the characteristics of the microcapsules was investigated by varying its contents at 0, 0.5, 1.0, 2.5, 5, and 10% (relative to the EGDMA/monomer ratio, mol/mol). The results are shown in Table 4. As observed in Figure 6, ER and

Table 4. Characteristics of the Pesticide Microcapsules Prepared under Different Content of Cross-Linker EGDMA

		characteristic parameter	
sample	EGDMA/monomer (mol/mol)	entrapment rate (%)	pesticide loading (%)
M2	0	85.14 ± 2.02 c	2.747 ± 0.09 c
E1	0.5%	96.74 ± 0.47 a	3.094 ± 0.01 a
E2	1.0%	93.05 ± 1.69 ab	2.951 ± 0.05 b
E3	2.5%	90.02 ± 1.89 b	2.783 ± 0.06 c
E4	5.0%	86.11 ± 3.24 c	2.557 ± 0.10 d
E5	10%	85.78 ± 1.45 c	2.359 ± 0.04 e

PL both reached a maximum when an EGDMA concentration of 0.5% was used, and then decreased with increasing concentrations of cross-linker EGDMA. The observed increase in ER and PL may be attributed to the denser structure of poly(BA/St/EGDMA) relative to that of poly(BA/St) owing to the higher degree of cross-linking. In contrast, the considerable decrease in ER and PL with further increases in the amount of EGDMA may be attributed to the excessively high degrees of cross-linking owing to the higher content of cross-linker. Higher degrees of cross-linking would result in tighter connections among the polymer chains, thereby inhibiting effective encapsulation of the pesticide.

Pesticide Release Study. An important aim of the present study was to study the release performance of chlorpyrifos from

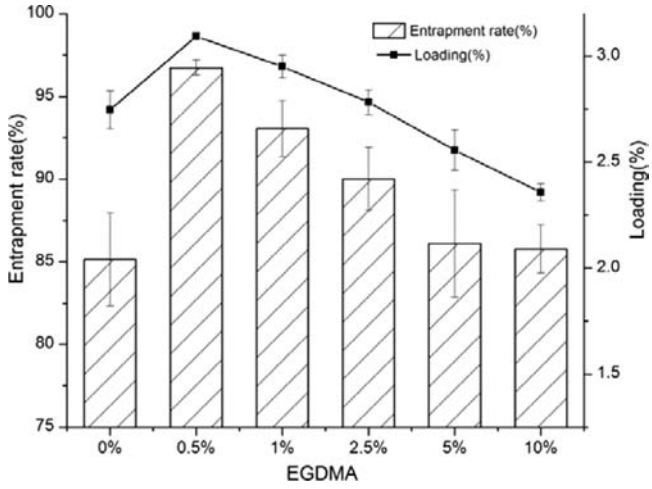

Figure 6. Effect of additive amount of EGDMA in the oil phase on the ER and PL of the microcapsules.

the poly(BA/St) and poly(BA/St/EGDMA) microcapsules. First, the effect of the monomer ratio (BA/St) used in emulsion polymerization on the release profile is discussed. The pesticide microcapsule emulsion was introduced into a dialysis bag and the release of the pesticide from the dialysis bag was monitored over ∼170 h. The results are shown in Figure 7. As observed,

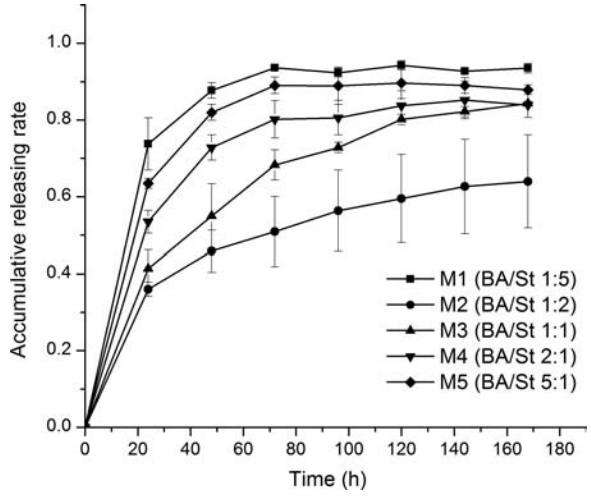

Figure 7. Profiles of chlorpyrifos release from formulations prepared using different ratios of BA/St monomer.

the release of chlorpyrifos from the poly(BA/St) microcapsules M1 and M5 prepared with monomer ratios of 1:5 and 5:1 was fast. A sustainable pesticide release over ∼72 h was observed. A slower release profile was obtained for the chlorpyrifos-loaded poly(BA/St) microcapsules M4 prepared with a monomer ratio of 2:1. The release profile of the microcapsules M2 prepared with a monomer ratio of 1:2 was satisfactory: a lower chlorpyrifos release was observed at the early stages of the release studies that lasted for 168 h. The maximum sustainable release content of the pesticide was 63.9%. These results may be explained by the different chlorpyrifos microcapsule characteristics as a result of the different monomer ratios used in the formulations as observed in Table 2. The ER and PL values of the chlorpyrifos-loaded microcapsules M1 and M5 were relatively lower, which not only led to poor chlorpyrifos encapsulation, but also to a high content of chlorpyrifos

DOI: 10.1021/acs.jafc.5b01378
J. Agric. Food Chem. 2015, 63, 5196−5204

retained on the microcapsule surface or in the water phase. Thus, the fast release profile was caused by the fast dissolution of chlorpyrifos in the external phase at the early stages of the release process and prompt release of the pesticide from the mechanically weak chlorpyrifos-loaded poly(BA/St) microcapsules. Furthermore, the T_g of M1 was much higher than the release temperature of 25 °C while the T_g of M5 was much lower than 25 °C. A relatively large difference between T_g and environmental temperature might lead to a relatively complete polymer state transitions to elastomeric state for M5 and glassy state for M1, which seemed to be conducive to the chlorpyrifos release in the present study. The rapid early release observed for the microcapsules M4 was due to the same phenomena occurring in microcapsules M1 and M5 as discussed previously. However, the slower release profile was due to the stronger mechanical property of the microcapsules. Poly(BA/St) microcapsules M2 and M3 had mechanical properties suited for entrapping the pesticide as well as obtaining high ER and PL values. T_g of M2 and M3 were close to the release temperature, which might let the microcapsule had characteristics of both elastomeric state and glassy state. It seemed to be very suitable for slow release of chlorpyrifos.Therefore, both the early release and sustainable release (>168 h) profiles of these particular pesticide microcapsules were satisfactory. More importantly, our results indicated that the poly(BA/St) microcapsules prepared at a monomer ratio of 1:2 (M2) were the best candidate for achieving sustainable release of chlorpyrifos.

Second, the effect of varying the EGDMA cross-linker content in the microcapsule formulation on the release profile of chlorpyrifos was investigated. The content was varied from 0 to 10%, while the BA/St monomer ratio was fixed at 1:2. The results are depicted in Figure 8. As observed, the sustainable

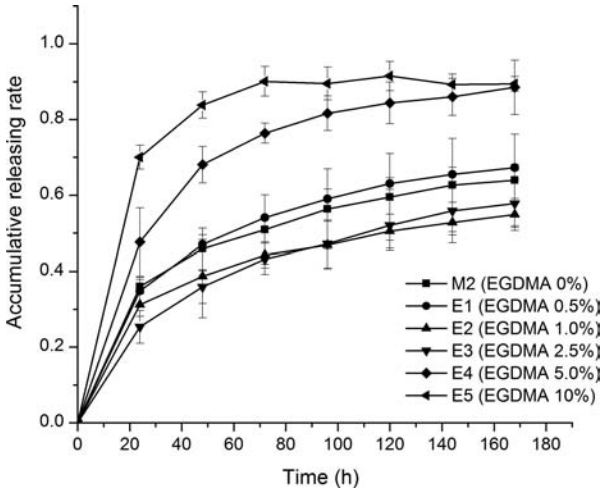

Figure 8. Profiles of chlorpyrifos release from formulations prepared using different contents of EGDMA (The BA/St monomer ratio was 1:2).

release of chlorpyrifos loaded in the microcapsules M2−E3 prepared with increasing EGDMA contents from 0 to 2.5% increased. Further increases in the EGDMA content above 2.5% led to shorter sustainable releases (E4−E5). The reduction in the sustainable release behavior may be due to the dense poly(BA/St/EGDMA) network that prevents effective release of chlorpyrifos from the microcapsule. Moreover, more EGDMA reacted with BA and St, resulting in tighter and denser polymer chains, consequently leading to the decrease in sustainable release. In contrast, increasing the content of EGDMA from 2.5 to 10% resulted in considerably fast release profiles of chlorpyrifos. The fast release profiles may be due to the low mechanical stability of the microcapsules in ethyl alcohol release medium owing to the greater extent of cross-linking by EGDMA. Besides, the relatively lower ER and PL values resulted in a higher level of pesticide retainment on the microcapsule surface or in the water phase that may account for the rapid initial release rate.

To further understand the release profiles of the pesticide-loaded EGDMA-cross-linked microcapsules, TEM analysis was conducted on the pesticide-loaded microcapsules prepared with different cross-linker EGDMA contents. The morphology and dispersion of the microcapsules can be observed in Figure 9. The dark circles of microcapsule from TEM might also represent the relative thin shell polymer forming by the slowly dropped process of monomer, which indicated a core−shell structure of these microcapsules. Figure 9a shows the homogeneous dispersion of the chlorpyrifos-loaded poly(BA/St) microcapsules prepared in the absence of cross-linker EGDMA. In contrast, connections among the pesticide-loaded microcapsules prepared in the presence of 5% EGDMA were obvious (Figure 9b). The external connections among the microcapsules that resulted in denser structures led to slower release of chlorpyrifos when compared with that observed for microcapsules prepared without EGDMA. Unfortunately, excessive connections led to the aggregation of the microcapsules that were prepared in the presence of 10% EGDMA (Figure 9c). Furthermore, the inhomogeneous microcapsule structure may be prone to rupture during the microcapsule synthesis and pesticide release processes. Therefore, poly(BA/St/EGDMA) microcapsules prepared in the presence of 5−10% EGDMA featured fast release profiles, whereas those prepared in the presence of 0.5−2.5% featured slower release characteristics.

Figure 10 shows that the length of sustainable release of chlorpyrifos decreased significantly with increasing loading contents of chlorpyrifos (1−10 g). Accordingly, changes in the loading content of chlorpyrifos altered the chlorpyrifos/monomer BA and St core-to-shell ratio. More specifically, increasing the dosage of pesticide led to decreasing dosages of the monomer at a given combined pesticide and monomer content. The polymer matrix prepared with a lower amount of monomer was not dense enough for chlorpyrifos entrapment. On the basis of the results discussed previously, the lower ER of the microcapsules P1 and P2 loaded with 5 and 10 g pesticide is another reason for the rapid release profile observed. These results indicated that a core-to-shell ratio of 1:30 was optimum to achieving good release profiles, whereas microcapsules loaded with higher contents of chlorpyrifos (5−10 g) featured faster release profiles.

Chlorpyrifos Release Kinetics. All of the slow release profile curves were composed of the gradual release curve followed by constant release curve that implied the fully release of chlorpyrifos. In order to investigated the release mechanism of chlorpyrifos-loaded microcapsule in the present study, data of the gradual release curve from chlorpyrifos release experiments were fitted to the following equation:[31]

$$\frac{M_t}{M_\infty} = kt^n$$

DOI: 10.1021/acs.jafc.5b01378
J. Agric. Food Chem. 2015, 63, 5196−5204

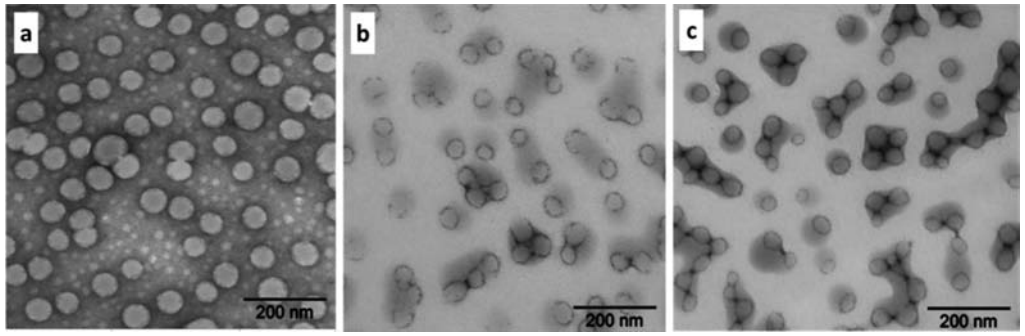

Figure 9. TEM images of the different pesticide microcapsules prepared with (a) 0, (b) 2.5, and (c) 10% EGDMA.

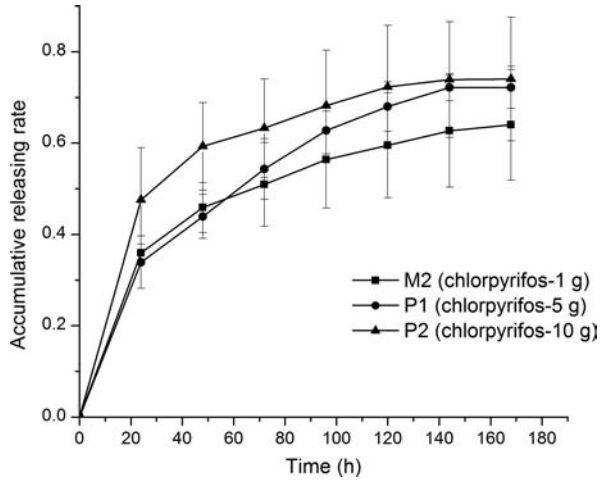

Figure 10. Profiles of chlorpyrifos release from microcapsules prepared with different loading contents of chlorpyrifos (1−10 g).

M_t is the amount of chlorpyrifos released at time t, M_∞ is the total amount of chlorprifos in microcapsules, k is a release constant, and n is a diffusional exponent.

As described in previous study,[20,32,33] the diffusion exponent n was equal to 0.43 for a Fickian diffusion system, when the diffusion of chlorpyrifos was controlled by its concentration difference, and diffusional exponent n was close to 0.85 for a degradation release system, when the release of chlorpyrifos was controlled by the degradation of microcapsules.

Slow release data were fitted with nonlinear regression. The release constant, diffusional exponent and the correlation coefficient R were presented in Table 5.

The release exponent n close to 0.43 of samples M2, M3, E3, and P1 with a high R values that indicated good fitting of exponential equations revealed the release mechanism of these microcapsules to be controlled by diffusion. When the release exponent n values were much lower than 0.43, there might be some other factors that influenced the chlorpyrifos release system, and the rapid initial release profile of these sample probably implied the rupture of microcapsules in the early release stage. All n values were below 0.43, proving that degradation of microcapusle was not the dominant factor of the release.

As to the effects of monomer ratio on the microcapsule, release profiles of M2 and M3 with BA/St ratios of 1:2 and 1:1 fitted well with the equation while profiles of microcapsules of other BA/St monomer ratio did not, which indicated the same conclusion that suitable monomer ratios for chlorpyrifos slow release were 1:2 and 1:1. The n value of E3 with 2.5% EGMDA was 0.428, which represented a good diffusion system of chlorpyrifos. As a result, E3 with 2.5% EGMDA was the finest slow release formulation for controlled chlorpyrifos. For the effects of different core-to-shell ratios, results of slow release kinetics showed that M2 and P1 with core-to-shell ratios of 1:30 and 5:26 basically matched the diffusion system while a ratio of 10:21 might lead to an initial rupture of microcapsule. It might be related to lower ER as a consequence of higher PL.

Table 5. Parameters Characterizing Fitting of the Model Equation on Chlorpyrifos Gradual Release Data

sample	k	n	R
M1	0.433	0.180	0.980
M2	0.132	0.317	0.998
M3	0.120	0.398	0.993
M4	0.161	0.383	0.976
M5	0.234	0.316	0.985
E1	0.167	0.274	0.992
E2	0.126	0.288	0.998
E3	0.067	0.428	0.996
E4	0.187	0.327	0.964
E5	0.337	0.232	0.991
P1	0.086	0.431	0.997
P2	0.230	0.237	0.990

A series of poly(BA/St) and poly(BA/St/EGDMA) microcapsules loaded with various amounts of chlorpyrifos were prepared by emulsion polymerization. All prepared microcapsules featured particles sizes of ∼90 nm with a little difference among each samples. The microcapsules show promise as a carrier for the slow release of pesticide chlorpyrifos. FTIR and TG analysis of the microcapsules confirmed the successful entrapment of chlorpyrifos in the poly(BA/St) wall material. The microcapsule ER varied from 60.15 to 96.74%. The highest ER (96.74%) was observed for microcapsules prepared with a BA/St monomer ratio of 1:2 in the presence of moderate EGDMA cross-linker content of 0.5%. In contrast, lower ERs of 60.15−67.97% were observed for microcapsules prepared with higher contents of chlorpyrifos (5−10 g). Variations in ER were consistent with variations in PL except for the series of microcapsules prepared with different core-to-shell ratios. In this series, maximum PL (29.11%) resulted in the lowest ER (60.15%).

The release performance of chlorpyrifos from the microcapsules was characterized by the medium dialysis method. Microcapsules prepared with a monomer ratio of 1:2 whose T_g was close to the release temperature displayed optimum sustainable release of chlorpyrifos. In contrast, microcapsules prepared with monomer ratios of 1:5 and 5:1 displayed

DOI: 10.1021/acs.jafc.5b01378
J. Agric. Food Chem. 2015, 63, 5196−5204

significantly high pesticide release at the early stages of the release process. Microcapsules featuring adequate degrees of cross-linking by EGDMA (0.5−2.5% EGDMA) displayed prolonged sustainable release profiles, whereas those prepared with higher EGDMA contents of 5−10% displayed enhanced chlorpyrifos release. Additionally, microcapsules prepared with a chlorpyrifos/monomer BA and St core-to-shell ratio of 1:30 displayed optimum release profiles, whereas those prepared at other ratios displayed faster release profiles. Chlorpyrifos release was characterized by nonlinear regression analysis. The diffusion release from microcapsules was found due to having a diffusional exponent n close to 0.43, while for samples that had n values much lower than 0.43, their faster release might be caused by the initial rupture of microcapsule.

The current study investigated the influences of monomer ratio, core-to-shell ratio, and degree of cross-linking on the characteristics and sustainable release behaviors of chlorpyrifos entrapped in poly(BA/St) and poly(BA/St/EGDMA) microcapsules via emulsion polymerization. Moreover, the findings provide a reference for the release profile studies of polyacrylate chlorpyrifos microcapsules.

Supporting Information

ABSTRACT: The environmental behavior and stereoselectivity of the chiral fungicide benalaxyl and its chiral metabolite benalaxyl acid in water, sediment, and water−sediment microcosms were studied. The microcosms were incubated at 25 °C with light or under darkness. The influencing factors such as light and microorganism were investigated. The results showed that benalaxyl had half-lives of >21 days in the microcosm system and that the metabolite benalaxyl acid could exist in the microcosm for >70 days. Benalaxyl was mainly transformed through microbial degradation, and thus sediment microorganisms played a major role in the dissipation of benalaxyl in the aquatic microcosm. The stereoselective behavior of benalaxyl and benalaxyl acid was also investigated. (−)-Benalaxyl was preferentially degraded in the microcosm, resulting in an enrichment of the more toxic enantiomer (+)-benalaxyl, which may cause higher risk to the aquatic system. Moreover, (−)-benalaxyl acid was preferentially formed in the microcosm. The enantioselectivity of the enantiomers in the microcosm should be taken into consideration for an accurate risk assessment.

KEYWORDS: *benalaxyl, water−sediment microcosm, stereoselectivity, contamination*

INTRODUCTION

The enantiomers of a chiral compound have identical physical and chemical properties but possibly have different bioactivities, toxicities, metabolisms, and environmental behaviors.[1] Chiral pesticides are widely used in agriculture, and the number is increasing with the development of complex pesticide molecules. It is a common situation that only one of the enantiomers performs the desired effect, whereas the other ineffective enantiomers may be even more toxic to other nontarget organisms or ecosystem and cause environmental problems. For example, of the eight enantiomers of the chiral insecticide deltamethrin, only the (αS,1R,3R)-enantiomer has the desired insecticidal activity, whereas the others are noneffective or less active.[2] The toxicity of the racemate of the herbicide metolachlor to *Daphnia magna* is 100 times higher than that of *S*-metolachlor, and *rac*-metolachlor degraded more slowly than *S*-metolachlor in soil.[3] Therefore, it is necessary to study the environmental behavior of chiral pesticides on an enantiomeric level to evaluate the risks more accurately.

The chiral fungicide benalaxyl (BX) [(±)-methyl *N*-(phenylacetyl)-*N*-(2,6-methylphenyl) alaninate] (Figure 1) has been widely used on cucumber, tomato, tobacco, and many other vegetables and fruit crops to control downy mildew, early blight, late blight, and *Peronospora tabacina* for many years. As a kind of chiral pesticide, BX has two enantiomers, with *R*-(−)-BX more active than *S*-(+)-BX. It has a series of advantages such as high efficiency, low toxicity, and long effective period. Because of its wide usage and relatively long half-life period,[4] BX could be detected in the environment.[5] A number of studies have been conducted to evaluate the enantioselective environmental behaviors on an enantiomeric level in soil,[6,7] animals such as lizards, earthworms, rainbow trout, and rabbits,[8−10] and plants such as cucumber and tomato.[6,11] BX can enter the water system through rainfall, surface runoff, and leaching[12−14] and then cause water pollution and affect aquatic organisms.[15] Unfortunately, few studies have focused on the fate of BX in the aquatic system.

Benalaxyl acid (BX acid) [(±)-*N*-(2,6-xylyl)-*N*-(phenylacetyl)alanine] (Figure 1) is the primary metabolite, which is more water-soluble and persistent than BX in the environment and may be more harmful for aquatic organisms. It also possesses a chiral center to make a couple of enantiomers. There are no published reports for the degradation and stereoselective behavior of the metabolite BX acid.

The impacts of pesticide and metabolite contamination for aquatic ecosystems are tremendous. As a research method for the environmental fate of pesticides, microcosms have been widely used with a series of advantages such as authenticity, flexibility, high performance−price ratio, and security.[16−19] In an artificial microcosm, the incubation conditions can be controlled and the fate of the target compound can be understood clearly.

In this study, the chiral analysis method for the enantiomers of BX and BX acid in water and sediment was set up. The fate and stereoselective behavior of BX and BX acid in water, sediment, and a water−sediment microcosm were studied to evaluate the environmental behavior of BX in the aquatic system. The effect of light and microorganism was also studied following the discussion of the degradation mechanism.

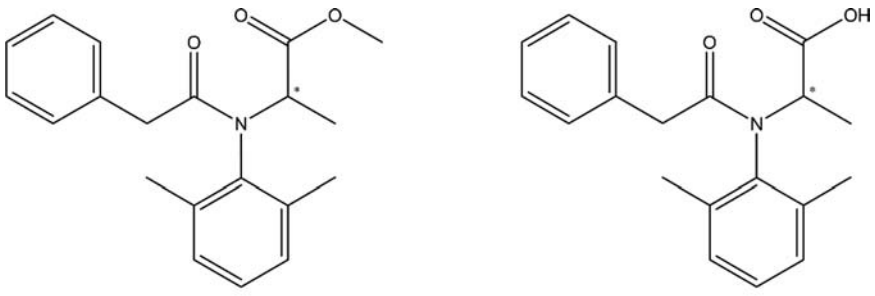

Figure 1. Chemical structures of BX and BX acid.

MATERIALS AND METHODS

Chemicals. BX (>99.0% purity) was obtained from the Institute for the Control of Agrochemicals, Ministry of Agriculture (Beijing, China). Metabolite BX acid (>99.0% purity) was synthesized by the Department of Applied Chemistry, China Agricultural University (Beijing, China). All of the reagents were of analytical grade and obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Mobile phase reagents were distilled and filtered through a 0.22 μm filter membrane before use.

Instrumental Analysis. HPLC analysis in this study was performed by using an Agilent 1200 series HPLC (Agilent Technology) equipped with a G1322A degasser, a G1311A pump, a G1328A injector, a G1314B VWD, and an AT-930 column attemperator (Tianjin Automatic Science Instrument Co. Ltd., China). The signal was received and processed by Agilent Chemstation software.

A Chiralcel OD chiral column (250 mm × 4.6 mm i.d., Daicel Chiral Technology Co., Ltd.) was used to separate the enantiomers of BX and BX acid. Mobile phase was *n*-hexane and 2-propanol (91:9, v/v) with trifluoroacetic acid (1‰, v/v) at the flow rate of 0.8 mL/min. The injection volume was 20 μL, and the UV detection wavelength was 225 nm. The separation was conducted at 20 °C.

The elution order of BX and BX acid enantiomers was determined by a polarimeter detector. The polarimeter detector wavelength was 426 nm. The elution order was as follows: (−)-BX (15.4 min), (+)-BX (18.8 min), (−)-BX acid (21.6 min), and (+)-BX acid (32.0 min).

Assay Validation. The linearity of the instrument for BX (5−1500 mg/L) and BX acid (5−600 mg/L) was investigated by standard solution in 2-propanol (n = 3). The linearity of the method, recovery, limit of detection (LOD), and limit of quantification (LOQ) of the method were investigated. Linearity and recoveries were determined in blank samples (uncontaminated environmental matrix) that were fortified with BX and BX acid at different levels. The linearity of BX (0.2−20 mg/kg) and BX acid (0.2−5 mg/kg) in water samples and of BX (0.2−50 mg/kg) and BX acid (0.2−20 mg/kg) in sediment samples was checked (n = 3). The recoveries of BX enantiomers in water and in sediment (1, 5, and 10 mg/kg) and of BX acid enantiomers in water (0.5, 1, and 2 mg/kg) and in sediment (1, 5, and 10 mg/kg) were investigated (n = 3). The external calibration curves were generated by regression analysis of the peak area against concentrations. Blank sediment and water samples were also analyzed to check the interference from the matrix. LOD and LOQ were defined as concentrations that produced signal-to-noise (S/N) ratios of 3 and 10, respectively.

Degradation in Sediment. The test sediment and water were sampled from Shangzhuang reservoir (Beijing, China) that had not been treated with BX. The sediment was air-dried at room temperature and sieved (2 mm). It took 7 days to activate microorganisms before incubation. Sediment (400 g, moisture content = 25%, m/m) was added in a 500 mL beaker, and BX was fortified at 20 mg/kg. Four variations of incubation were designed: (1) unsterilized, with light (12 h per day); (2) unsterilized, under darkness; (3) sterilized, with light (12 h per day); (4) sterilized, under darkness (experiments S1, S2, S3, and S4, respectively; Table 1). The sediment was sterilized by two periods of autoclaving (2 h per period). The light was provided by fluorescent bulbs in an incubator, and the intensity of light was 2640 lx.

Table 1. Summary of Experiment Designs

		√	√	W3
		√	×	W4
water−sediment	water	×	√	WS1
		×	×	WS2
	sediment	×	√	SW1
		×	×	SW2

[a]"√" means "yes" and "×" means "no".

Degradation in Water. Water (400 g) was added in a 500 mL beaker, and BX was fortified at 20 mg/kg. Four variations of incubation were designed: (1) unsterilized, with light (12 h per day); (2) unsterilized, under darkness; (3) sterilized, with light; (4) sterilized, under darkness (experiments W1, W2, W3, and W4, respectively; Table 1). The water was sterilized by two periods of autoclaving (1 h per period).

Degradation in Water−Sediment Microcosm. The water−sediment microcosm was made up of 35 g of sediment (moisture content = 25%, m/m) and 150 g of water in a 500 mL beaker. There were two methods of contamination: water contamination and sediment contamination. For water contamination, BX was fortified in water at 20 mg/kg under light (12 h per day) or darkness (experiments WS1 and WS2, respectively; Table 1). For sediment contamination, BX was fortified in sediment at 20 mg/kg under light or darkness (experiments SW1 and SW2, respectively; Table 1).

All experiments were conducted in an incubator at 25 °C, and water was added every 3 days for supplement of evaporation. Sediment and water samples were collected for analysis at 0, 1, 5, 12, 21, 35, 50, 70, and 90 days. Each incubation was carried out in triplicate. The summary of experiment designs is shown in Table 1.

Dissipation curves were defined as $C = C_0\, e^{-kt}$ or $C = at^2 + bt + C_0$, in which C means concentration, C_0 means the highest concentration, k means elimination rate coefficient, and a and b are empirical constants. Half-life ($t_{1/2}$, days) was obtained from the equation $t_{1/2} = \ln 2/k$ or $0 = at^2 + bt + {}^1/_2C_0$ ($t_{1/2} = t$). The enantiomer fraction (EF) was used to evaluate the enantioselective behavior of enantiomers, which was defined by the equation EF = peak areas of the (−)/[(−) +

(+)], in which (−) and (+) indicate the peak areas of the (−)-enantiomer and (+)-enantiomer, respectively. EF values vary from 0 to 1, with EF = 0.5 indicating no enantioselectivity.

Sample Preparation. A solvent extraction method was used for extraction in the experiment. Ethyl acetate (15 mL) and saturated salt water (3 mL) were added to a 50 mL polypropylene centrifuge tube containing 15 g of sediment sample/10 g of water sample (pH was adjusted to 2 by HCl). The centrifuge tube was vortex-mixed for 5 min (sediment) or 3 min (water), exposed to ultrasonic vibration for 15 min, and then centrifuged at 4000 rpm for 7 min (sediment) or 3 min (water). After removing 15 mL of ethyl acetate (extraction solvent), the procedure described above was repeated by adding another 15 mL of ethyl acetate. The combined extraction solvent (30 mL of ethyl acetate) was evaporated to near dryness on a vacuum rotary evaporator at 37 °C and blown to dryness by a gentle stream of

nitrogen. Finally, the extract was reconstituted with 0.5 mL of 2-propanol and filtered through a 0.22 μm filter membrane.

RESULTS AND DISCUSSION

Assay Validation. The enantiomers of BX and BX acid were baseline separated, and there were no interference peaks from the matrix around the peaks of the four enantiomers (Figure 2). Linearities of the instrument for BX and BX acid in 2-propanol were satisfactory ((−)-BX, $Y = 71.3 + 55.68X$, $R = 0.9993$; (+)-BX, $Y = 62.7 + 90.25X$, $R = 0.9996$; (−)-BX acid, $Y = -66.1 + 35.9X$, $R = 0.9991$; (+)-BX acid, $Y = -79.3 + 61.25X$, $R = 0.9994$). Good linearities of method and recoveries were obtained in water and sediment for BX and BX acid enantiomers (see the Supporting Information, Table S1). Correlation coefficients (R) of linear regression equations were 0.9993−0.9999. In water, the recoveries of BX and BX acid enantiomers were 92.33−118.86 and 91.29−115.96%, respectively; in sediment, the recoveries of BX and BX acid enantiomers were 91.49−113.10 and 79.36−92.48%, respectively. The RSDs were all below 10%. The limits of detection (LODs) for BX and BX acid were 0.013−0.015 mg/kg in water and 0.014−0.016 mg/kg in sediment; the limits of quantitation (LOQs) for BX and BX acid were 0.06−0.08 mg/kg in water and 0.08−0.10 mg/kg in sediment.

Degradation of BX in Sediment. Dissipation equations and half-lives are in the Supporting Information (Table S2). As shown in Figure 3a, the degradation of BX in unsterilized sediment in experiments S1 (unsterilized, with light) and S2 (unsterilized, under darkness) was rapid with half-lives of 26.8 and 28.0 days, but very slow in sterilized sediment in experiments S3 (sterilized, with light) and S4 (sterilized, under darkness) with half-lives of 112.7 and 132.0 days, indicating that microbial degradation played an important role in the degradation of BX and that photolysis affected the degradation slightly.

The trend of metabolite BX acid in sediment is shown in Figure 3c. BX acid in experiments S1 (unsterilized, with light) and S2 (unsterilized, under dark) reached the highest values of 11.3 and 12.9 mg/kg at the 35th day, but in S3 (sterilized, with light) and S4 (sterilized, under dark), very low levels of BX acid were detected, showing microbial degradation was the main factor affecting the formation of BX acid.

Degradation of BX in Water. As shown in Figure 3b, in experiments W1 (unsterilized) and W3 (sterilized) under light, the half-lives of BX were 95.6 and 98.3 days and in experiments W2 (unsterilized) and W4 (sterilized) under darkness, the half-lives were 132.0 and 137.2 days. Obviously, microbial degradation was not a major pathway because water contained fewer microorganisms. Light could accelerate the degradation of BX in water, with a similar result as in sediment, indicating that photolysis was also a pathway for the dissipation of BX. In experiment W4 (sterilized, under darkness), the fact that BX also degraded obviously in unsterilized water under darkness indicated that hydrolysis was the main pathway for the degradation of BX in water.

As shown in Figure 3d, in experiments W1−4, low levels of BX acid (about 0.8 mg/kg) were found from 12 to 90 days in water due to the slow degradation of BX, and further degradation of BX was very slow.

Fate of BX in Water−Sediment Microcosm. Figure 4 shows the concentration−time curves of BX and BX acid in the water and sediment of the microcosm. In experiment WS1 (with light, water contamination), when the water of the microcosm was contaminated (BX was fortified in water), the concentration of BX decreased in water with $t_{1/2}$ = 39.6 days and increased first and then decreased in the sediment because of adsorption and degradation. In WS2 (under darkness, water

contamination) BX was more easily transferred from water into the sediment with the highest concentration of 34.9 mg/kg at the 12th day (Figure 4b) compared with the result in WS1 (with light). Correspondingly, the decline of BX in water in WS2 (under darkness) was faster ($t_{1/2}$ = 18.4 days) than that in WS1 (with light) ($t_{1/2}$ = 39.6 days). BX acid appeared since the

J. Agric. Food Chem. 2015, 63, 5205−5211

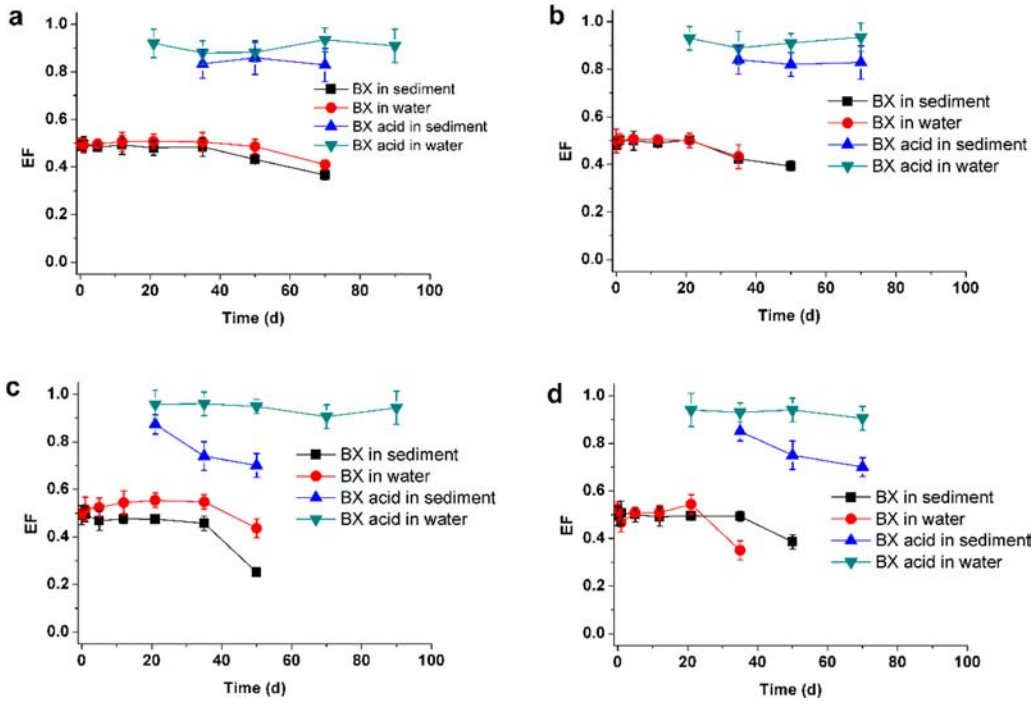

Figure 7. EF−time curves of (a) WS1 (with light, water contamination), (b) WS2 (under darkness, water contamination), (c) SW1 (with light, sediment contamination), and (d) SW2 (under darkness, sediment contamination). (Values represent the mean ± SD.) EF = peak areas of the (−)/[(−) + (+)].

21st day and remained at a relatively low level in both water and sediment. There was no significant difference for BX acid between WS1 (with light) and WS2 (under dark), and the concentrations of BX acid in both experiments WS1 and WS2 were about 0.8 mg/kg.

The result of SW1 (with light, sediment contamination) is shown in Figure 4c. When the sediment of the microcosm was contaminated (BX was fortified in sediment), the concentration of BX in sediment decreased with time, increased to 3.27 mg/kg in water at the 12th day and could not be detected at the 90th day. Compared with SW1 (with light), less BX transferred from sediment into water in SW2 (under darkness, sediment contamination). The concentration of BX in water in SW2 (under darkness) was lower than that in SW1 (with light) at the corresponding time points (Figure 4d). It was found that light could help the distribution of BX in water. There was no significant difference for the formation of BX acid between SW1 (with light) and SW2 (under darkness), and the highest concentrations of BX acid in both experiments SW1 and SW2 were about 2.0 mg/kg. The concentrations of BX acid were always higher in water than in sediment, perhaps because of the high water solubility; for example, in SW2 (under darkness) BX acid could be detected at the 21st day and reached the highest values of 2.16 and 0.85 mg/kg in water and sediment, respectively (Figure 4d).

The material balance in the microcosm during the experiments was also roughly investigated on the basis of the amount of BX/BX acid distributed in water and sediment in the microcosm. The original doses of BX fortified in microcosms were 9.22 μmol (3 mg WS1, WS2, water contamination) and 2.15 μmol (0.7 mg, SW1, SW2, sediment contamination). Considering the nonextractable amount (about 10% of BX and 15% of BX acid) according to the average recoveries, the material balance is shown in Figure 5, from which there was no obvious decline of BX in the first 12 days, showing BX was relatively persistent in the aquatic environment.

Stereoselectivity. *Stereoselectivity of BX Enantiomers.* EF−time curves were plotted (Figure 6 and 7) to characterize enantioselectivity of the enantiomers of BX and BX acid. As shown in experiments S3 (sterilized, with light), S4 (sterilized, under darkness) (Figure 6a) and experiments W1−4 (Figure 6b), the EF values of BX were all approximately 0.5, indicating that both photolysis and hydrolysis did not cause stereoselective degradation. Compared with experiments S3 (sterilized, with light) and S4 (sterilized, under darkness), stereoselectivity of BX enantiomers was found in experiments S1 (unsterilized, with light) and S2 (unsterilized, under darkness) with EF < 0.5. In conclusion, (−)-BX was preferentially degraded in the sediment and microbial degradation played the key role for the stereoselectivity. No stereoselectivity was found in water that contained fewer microorganisms. (−)-BX was also found to be preferentially degraded in the water−sediment microcosm, especially in experiments SW1 (with light, sediment contamination) and SW2 (under darkness, sediment contamination) (Figure 7c,d), which was caused by the microorganisms in the sediment.

Stereoselectivity of BX Acid Enantiomers. (−)-BX acid was preferentially formed in the sterilized sediment in experiments S3 (sterilized, with light) and S4 (sterilized, under darkness) (Figure 6c), and no stereoselectivity was found in the unsterilized sediment (experiments S1 and S2). In water, almost only (−)-BX acid was formed (experiments W1−4, Figure 6d). Figure 7 shows the EF values of BX acid in the water−sediment microcosm. (−)-BX was found to be preferentially degraded in the water−sediment microcosm, and (−)-BX acid was the main form of the primary metabolite. Therefore, it could be inferred that (−)-BX was preferentially transformed to (−)-BX acid.

J. Agric. Food Chem. 2015, 63, 5205−5211

In this study, the fate and stereoselective behavior of BX and BX acid in a water−sediment microcosm were studied. BX and the metabolite BX acid had long half-lives in the water−sediment microcosm, and it was found that sediment in the microcosm played the most important role in the remediation of BX pollution in the aquatic environment and that microorganism biodegradation and hydrolysis were the major pathways. Significant enantioselective environmental behavior of BX (EF = 0.2−0.4 in microcosm) and the formation of BX acid (EF = 0.7−0.95 in microcosm) were found. It was reported that the toxicity of (+)-benalaxyl for some aquatic organisms was higher than that of *rac*-benalaxyl,[4] so the evaluation of the enantioselective environmental behavior of BX is of significance. Furthermore, there were no published reports on the toxicology information on BX acid, which might be a potential concern to the aquatic environment. The evaluation of the metabolite BX acid should be taken into consideration for an accurate risk assessment, especially on an enantiomeric level.

ABSTRACT: Conjugated linoleic acid (CLA) has been reported to prevent body weight gain and fat accumulation in part by improving physical activity in mice. However, the effects of postweaning administration of CLA on the development of obesity later in life have not yet been demonstrated. The current study investigated the role of postweaning CLA treatment on skeletal muscle energy metabolism in genetically induced inactive adult-onset obese model, nescient basic helix−loop−helix 2 knockout (N2KO) mice. Four-week-old male N2KO and wild type mice were fed either control or a CLA-containing diet (0.5%) for 4 weeks, and then CLA was withdrawn and control diet provided to all mice for the following 8 weeks. Postweaning CLA supplementation in wild type animals, but not N2KO mice, may activate AMP-activated protein kinase (AMPK) and peroxisome proliferator-activated receptor-δ (PPARδ) as well as promote desensitization of phosphatase and tensin homologue (PTEN) and sensitization of protein kinase B (AKT) at threonine 308 in gastrocnemius skeletal muscle, improving voluntary activity and glucose homeostasis. We suggest that postweaning administration of CLA may in part stimulate the underlying molecular targets involved in muscle energy metabolism to reduce weight gain in normal animals, but not in the genetically induced inactive adult-onset animal model.

KEYWORDS: *conjugated linoleic acid, childhood obesity, voluntary activity, glucose homeostasis, AMP-activated protein kinase*

INTRODUCTION

Since 1980, the prevalence of childhood obesity has almost tripled.[1,2] Along with overnutrition, lack of physical activity during the childhood period is one of the significant contributing factors to the development of childhood obesity. Similar to adult obesity, childhood obesity is known to be associated with the increased risk of chronic metabolism diseases.[3,4] Even though early childhood has been considered to be critical for health later in life, most studies in humans and animals have mainly addressed the effects of dietary and exercise regimens rather than focusing on early-onset interventions during critical developmental periods.[5]

Conjugated linoleic acid (CLA) is a term describing a mixture of 18-carbon unsaturated fatty acid isomers with conjugated double bonds. The name, CLA, was first used when its anticancer activities were reported in 1987.[6] Since then, other biological activities of CLA have been reported, including its effects on prevention of atherosclerosis development, modulation of immune responses, promotion of young animal growth, and modulation of body composition, particularly reduction of body fat and improvement of lean and bone masses.[7] It has been suggested that CLA reduces body fat by multiple biochemical mechanisms, including increased energy expenditure, modulated adipogenesis, and/or enhanced fatty acid β-oxidation.[7,8]

The beneficial effects of CLA supplementation during the obesity onset period in nescient basic helix−loop−helix 2 (Nhlh2) knockout mice (N2KO) have been previously reported.[9] Targeted deletion of the Nhlh2 transcription factor expressed in the hypothalamus precedes adult-onset obesity in mice, resulting from a disruption of the hypothalamic−pituitary axis. While N2KO mice have normal levels of food intake, their spontaneous voluntary movement is decreased by more than 50% in both genders.[10] It was suggested that CLA supplementation in young N2KO animals prevented excessive weight gain by improving voluntary activity.[9] However, it is not clear if supplementation of CLA during the preobesity stage would benefit later in life, as was reported in nonobese animals.[11] Thus, the purpose of this study was to determine the effects of CLA supplementation during the early growth period in N2KO animals on the development of obesity and symptoms of type 2 diabetes later in life.

MATERIALS AND METHODS

Materials. CLA was provided by Natural Lipids Ltd. AS (Hovdebygda, Norway). The CLA used consisted of 80.7% CLA (37.8% *cis*-9,*trans*-11, 37.6% *trans*-10,*cis*-12, and 5.3% other CLA isomers) and 13.7% oleic acid, 3.2% stearic acid, 0.4% palmitic acid, 0.2% linoleic acid, and 1.8% unknown. Semipurified powdered diet (TD07518) was obtained from Harlan Laboratories (Madison, WI). Serum triacylglyceride (TG), glucose, and total cholesterol assay kits were purchased from Genzyme Diagnostics (Charlottetown, PE, Canada). A DC protein assay kit (Bio-Rad, Hercules, CA) was used for protein quantitation. Rabbit antibodies for phosphorylated AMP-activated protein kinase α (p-AMPKα), AMPKα, phosphorylated

phosphatase and tensin homologue (p-PTEN), phosphorylated phosphoinositide-dependent kinase (p-PDK), phosphorylated protein kinase B at threonine 308 (p-Akt Thr308) and serine 473 (p-Akt Ser473), Akt, and superoxide dismutase 2 (SOD2) were obtained from Cell Signaling (Berberly, MA). Rabbit antibodies for peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α), sirtuin 1 (SIRT1), peroxisome proliferator-activated receptor-δ (PPARδ), nuclear respiratory factor 1 (NRF-1), mitochondrial transcription factor A (Tfam), cytochrome *c* (Cyt C), cytochrome c oxidase (COX IV), insulin receptor substrate 1 (IRS-1), glucose transporter type 4 (GLUT4), and β-actin were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). Horseradish peroxidase-conjugated goat antirabbit IgG antibody was obtained from Boston Bioproducts Inc. (Ashland, MA). Other chemicals used were purchased from either Sigma Chemical Co. (St. Louis, MO) or Fisher Scientific (Pittsburgh, PA).

Animals and Diet. All animal work was conducted in compliance with the Institutional Animal Care and Use Committee at the University of Massachusetts. As described in a previous report,[10] 129 Sv/J male offspring mice were obtained through inbreeding between heterozygous male and female breeders. Litters were housed together with dams until weaning. At 3 weeks old, all male mice were biopsied (0.5 cm tail) for genotyping. Ten wild type and eight N2KO mice were selected for this study and then placed in individual wire-bottomed cages on a 12 h:12 h light:dark cycle in a temperature- and humidity-controlled room. During a 1 week acclimatization period, all mice were fed a semipurified powdered control diet (20 w/w % fat) to induce obesity in rodents[9,12,13] and were subjected to a baseline test for voluntary movement and glucose tolerance in serum. On the basis of body weight, all animals in different genotype groups (wild type and N2KO) were divided into two diet groups and fed either control or 0.5% CLA containing diet for 4 weeks. Then, all animals received the control diet for 8 weeks. Previously it was determined that feeding CLA for 4 weeks in mice was enough to result in changes in body composition as well as changes in activity levels.[14,15] Moreover, it was reported that most CLA remaining in the tissues (liver, adipose tissue, and muscle) returned to levels comparable to that of control animals at 8 weeks postwithdrawal.[14] Thus, we selected 8 weeks post CLA supplementation in the current study. The dose of CLA was determined on the basis of previous reports that supplementing 0.5% CLA for 2−4 weeks in rats led to a serum level range of 23−120 μM and serum levels of CLA after supplementation of 0.8−3.2 g per day for 2 months in humans ranged from 23 to 200 μM.[16,17]

The compositions of diets are shown in Table 1. Diet and water were available ad libitum throughout the experiment and were provided freshly twice per week. Body weight and food intake were monitored weekly. At the end of the study, mice were fasted for 6 h and sacrificed by CO_2 asphyxiation. Blood was immediately collected by cardiac puncture, and the internal organs (liver, heart, kidney, spleen, and white adipose tissues including epididymal, retroperitoneal, and mesenteric fat pads) were weighed at sacrifice.

Figure 1. Effect of postweaning administration of conjugated linoleic acid (CLA) on body weight (A) and food intake (B) in wild type and nescient helix−loop−helix knockout (N2KO) mice. Mice were treated with either control or 0.5% CLA diets until 4 weeks and then switched diets from CLA supplementation to control for the following 8 weeks. Values represent means ± SE (n = 3−5). n.s.: not significant. Means with different letters at the same time points are significantly different (P < 0.05). P values in the table are from two-way repeated measures ANOVA with the slice option in the Least Square Means statement to compare the group differences at each week.

Voluntary Movement Measurement (Nonexercise Physical Activity Test). Nonexercise physical activity (voluntary movement) was recorded using LoliTrack Quatro Video Tracking Software Version 1.0 (Loligo Systems, Tjele, Denmark) with a high-resolution infrared camera under dark conditions. This tracking system simultaneously monitored four mice placed in individual cages (30 × 46 × 40 cm) during the dark phase (5:00 pm−5:00 am) once a month with free access to diet and water (provided as HydroGel, Clear H_2O, Portland, ME). Movement data for 8 h (7:00 pm−3:00 am) excluding the first 2 h (5:00 pm−7:00 pm) during the early phase for adapting to environmental change and 2 h (3:00 am−5:00 am) during the late phase due to lack of movement were analyzed.

Serum Parameters. The levels of glucose, total cholesterol, and TG in serum separated by centrifugation at 3000*g* for 20 min at 4 °C were

determined using commercial kits as specified by the manufacturer's instructions.

Glucose Tolerance. As described previously,[18] intraperitoneal glucose tolerance tests (IGTT) were conducted every 4 weeks. All mice underwent 6 h fasting and then were subjected to baseline measurement of blood glucose levels at 0 min. Blood was collected from the tail vein using a blood glucose meter, Advocate Redi-Code^{+} (Advocate Meters Inc., Dorado, Puerto Rico). Subsequently, 30% glucose solution (2.0 g of glucose/kg of body weight) was administered through intraperitoneal injection and then blood glucose levels were monitored at 15, 30, 60, 90, and 120 min. Collected data were calculated as the areas under the curve (AUC) with SigmaPlot 11.0 (Systat Software, Inc., San Jose, CA).

Western Blot Analysis. The frozen gastrocnemius skeletal muscle tissue was ground, and 50 mg aliquots were prepared and stored at −80 °C until analysis. Each sample was homogenized in premixed lysis radioimmune precipitation assay (RIPA; 50 mM Tris-HCl, 10 mM NaCl, 5 mM $MgCl_2$, and 0.5% NP-40, pH 8.0) buffer (Boston Bioproducts Inc., Ashland, MA), protease inhibitor cocktail (Sigma-Aldrich, St. Louis, MO), and phosphatase inhibitor cocktail (Thermo Scientific, Rockford, IL) and then lysed on ice for 2 h and centrifuged at 12000g for 20 min at 4 °C. The concentration of protein from tissue lysate was determined using the DC protein assay kit. The normalized lysates (37.5 μg/mL of protein) were separated by an 8–15% (w/v) sodium dodecyl sulfate–polyacrylamide gel and transferred to a polyvinylidene fluoride membrane (Millipore, Bedford, MA). After incubation with the appropriate primary rabbit antibodies, membranes were treated with horseradish peroxidase-conjugated goat antirabbit IgG antibody for 1 h at room temperature. Detection was performed using Enhanced Chemiluminescence solution (Bio-Rad, Hercules, CA) with an Image Station 4000MM instrument (Carestream Health, New Heaven, CT). The band density was normalized by β-actin intensity as an internal control. The results were quantified using ImageJ software (U.S. National Institutes of Health).

Statistical Analyses. All data analyses were performed by two-way analysis of variance (ANOVA) followed by the PROC MIXED procedure with Least Squares (LS) Means statement of the SAS software (Version 9.3, SAS Institute Inc., Cary, NC). For data on body weight, food intake, voluntary movement, and glucose tolerance test, two-way repeated measures ANOVA and the slice option in the LS means statement to examine the group differences at each time point with PROC MIXED were used. For internal organ, adipose tissue weight, and serum parameter data, two-way ANOVA with PROC MIXED was conducted. The experimental groups were compared by the multiple comparison basic Tukey–Kramer method in SAS. The Dunnett test in SAS was used for the relative protein expression level. Data are shown as the means ± SE; P values less than 0.05 are reported as statistically significant.

RESULTS

Body Weights and Food Intake. There was significant genotype effect on weight gain; N2KO mice had significantly greater body weight gain over wild type mice (P = 0.0001, Figure 1A). CLA supplementation during the first 4 weeks resulted in no significant different effects on weight gain overall, although the wild type CLA-fed group had the least body weight gain among all treatment groups during the whole experimental period (Figure 1A).

Overall N2KO mice consumed more food than wild type animals during the experimental period (P = 0.0252). No significant differences in food intake were observed between controls and CLA treatment during the preobese period, although the N2KO CLA group temporarily consumed more food right after withdrawal of CLA supplementation for 2 weeks (N2KO control; 50.5 ± 5.6 g vs N2KO CLA; 63.0 ± 2.3 g, the mean ± SE). Although three-way interaction among genotype, CLA, and time was observed, there was no significant two-way interaction in overall food intake (Figure 1B).

Tissue and Organ Weights. Total adipose tissue weights, including epididymal, mesenteric, and retroperitoneal adipose tissue, and internal organ weights (liver, heart, kidney, and spleen) are shown in Table 2. Epididymal, mesenteric, and total adipose tissue weights were significantly increased in N2KO animals in comparison to wild types (all P values were less than 0.05), but no significant effects of genotypes was observed for retroperitoneal fat weights. No significant effects of CLA supplementation for the first 4 weeks were observed for adipose tissue weights.

No differences of genotype effects were observed in the liver, heart, and spleen weights, while significant genotype effects were observed for the kidney weights (P = 0.0261). CLA-fed animals had significantly increased liver, heart, and kidney weights in comparison to control animals. No significant interaction between genotype and CLA was observed in any tissue or organ weight.

Voluntary Movement (Nonexercise Physical Activity). To evaluate the effects of postweaning administration of CLA on physical activity, voluntary movement (nonexercise physical activity) was measured every 4 weeks. Travel distance as total (19:00–03:00) and two time periods, early (19:00–23:00) and late (23:00–03:00), are shown in Figure 2A–C. The changes in total travel distance over time are shown in Figure 2D.

	Genotype (G)	CLA (D)	Time (T)
19:00-03:00	0.0492	0.0444	0.0458
19:00-23:00	n.s.	n.s.	0.0256
23:00-03:00	n.s.	0.0234	n.s.

Figure 2. Effect of postweaning conjugated linoleic acid (CLA) treatment on voluntary movement (nonexercise physical activity) in wild type and nescient helix−loop−helix knockout (N2KO) mice. Mice were fed control or 0.5% CLA diets for 4 weeks (from 4 to 8 weeks old) and then changed diets from CLA-containing to control for the next 8 weeks (from 9 to 17 weeks old). Voluntary movement was recorded during 17:00−05:00 every 4 weeks for 12 weeks (A−C). The data show different time points (total, 19:00−23:00 and 23:00−03:00). Total stands for movement measure during 19:00−03:00, divided into 4 h segments (19:00−23:00 and 23:00−03:00) representing the early or late phase of the dark cycle, respectively. (D) Trend for total travel distances (19:00−03:00). Values represent means ± SE (n = 3−5). n.s.: not significant. Means with different letters at the same time points are significantly different ($P < 0.05$).P values in the tables are from two-way repeated measures ANOVA with the Least Square Means statement to compare the group differences at each time point.

Consistent with the previous reports,[9,19] N2KO mice showed a significantly decreasing tendency of activity in comparison to wild type animals (P = 0.0492). It was evident that all experimental groups except the wild type CLA group showed declining activity over time (Figure 2D), with overall CLA effects being significant (P = 0.0444), particularly during the late period (P = 0.0234). No difference in activity between N2KO groups was observed, while CLA-fed wild types, but not N2KO animals, maintained activity levels throughout the experiment. This suggests that supplementation of CLA during the preobese state prevented reduction of voluntary movement over time in wild types but not in N2KO animals.

Glucose Tolerance Test. To determine the effects of postweaning CLA treatment on glucose homeostasis, glucose tolerance tests were conducted every 4 weeks (Figure 3A−D). N2KO mice showed glucose intolerance in comparison to wild type animals (P = 0.0061). In addition, there was a significant overall time effect (P = 0.0148), suggesting these animals develop glucose intolerance with aging along with the high-fat diet as used in this study. No significant CLA effect was observed; however, the CLA-treated wild type animals showed improved glucose tolerance at week 12 in comparison to wild-type controls, even after CLA withdrawal for 8 weeks (Figure 3E, $P < 0.0001$ for the interaction effect between CLA and time). This suggests that postweaning CLA administration may improve glucose tolerance in wild types but not in N2KOs.

Serum Parameters. The serum levels of TG, glucose, and total cholesterol were analyzed and are shown in Table 3. There were no genotype or CLA effects on these markers in this study, except glucose levels for CLA (P = 0.036). No interactions between genotype and CLA were observed in any of these parameters.

Effects on Muscle Energy Metabolism. To assess whether postweaning administration of CLA contributes to improved

Figure 3. Effect of time-specific postweaning conjugated linoleic acid (CLA) treatment on glucose levels (A–D), the area under the curve (AUC) change (E), and the overall trend of AUC change (F) in wild type and nescient helix–loop–helix knockout (N2KO) mice. Glucose tolerance was measured every 4 weeks during the whole experimental period. Blood was collected from the tail vein, and glucose levels were determined at 0 min for a baseline. Then glucose solution was administrated by intraperitoneal injection and measured at five different time points (15, 30, 60, 90, and 120 min). The data (E) are changed values of AUC and main effect analysis of AUC change dependent on different time points in the table. Values represent means ± SE (n = 3–5). n.s.: not significant. Means with different letters at the same time points are significantly different ($P < 0.05$). P values in the table are from two-way repeated measures ANOVA with the slice option in the Least Square Means statement to compare the group differences at each time point.

skeletal muscle energy metabolism, we investigated the AMPK signaling pathway, a master sensor to maintain energy homeostasis (Figure 4). Total AMPKα was measured, as it is known that two subunits (α1 and α2) are regulated differentially and overall AMPKα activity is more important.[20] There were no overall effects of any genotype or CLA effects on AMPKα expression, but interaction between them was observed (P = 0.0471) (Figure 4B). For phosphorylated AMPKα (the active form of AMPKα), N2KO animals had significantly lower levels of p-AMPKα in comparison to wild type animals (P = 0.0399). The mice supplemented CLA for the first 4 weeks showed significantly higher expression of phosphorylation of AMPKα in comparison

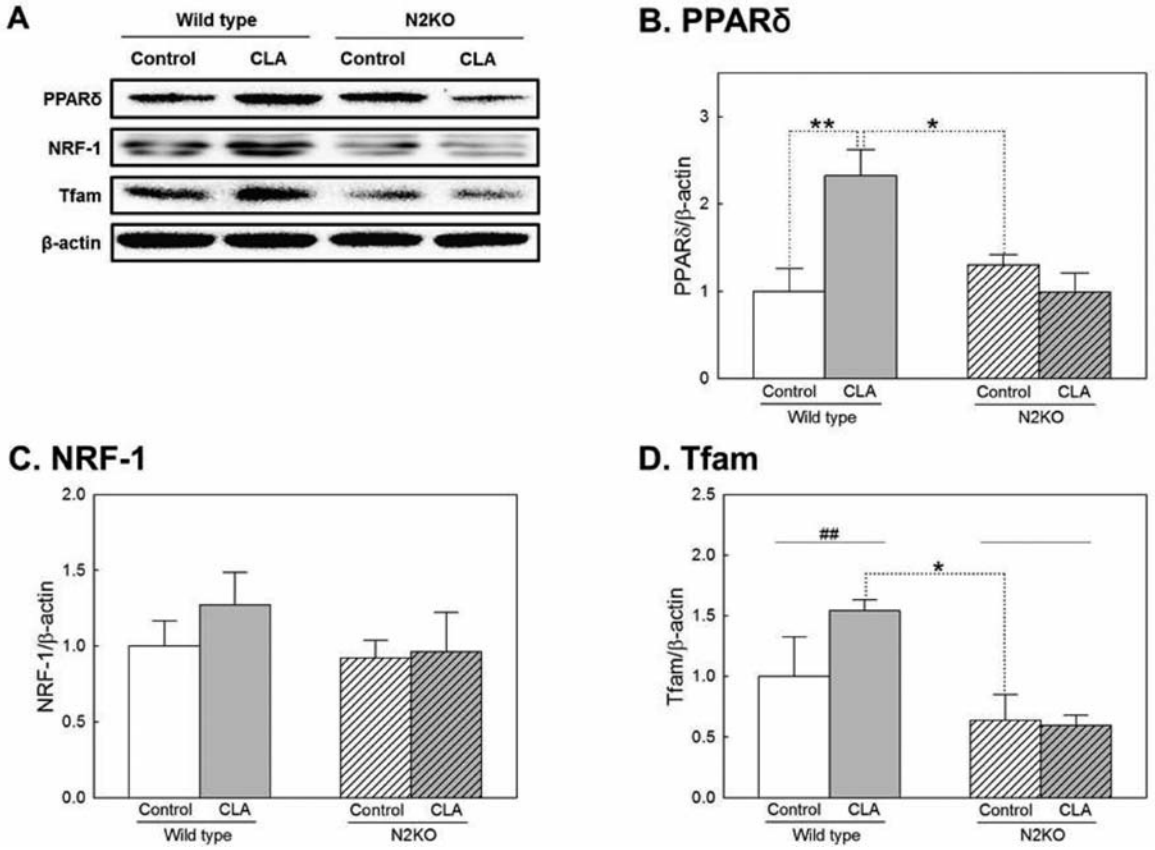

Figure 5. Effect of postweaning treatment of conjugated linoleic acid (CLA) on mitochondrial biogenesis-related factors from the gastrocnemius muscle. Pictures represent results of immunoblotting (A). The relative expression levels of peroxisome proliferator-activated receptor δ (PPARδ; B), nuclear respiratory factor 1 (NRF-1; C), and mitochondrial transcription factor A (Tfam; D) were determined and normalized using β-actin as the internal control. Values represent means ± SE (n = 3−5). ## denotes a significant overall genotype effect ($P < 0.01$). * denotes a significant difference in comparison to the wild type or N2KO control group (*, $P < 0.05$; **, $P < 0.01$). N2KO: nescient helix−loop−helix knockout.

to the control groups (Figure 4C, $P = 0.0264$); in particular, the wild type CLA group in comparison to the respective control (Figure 4C). In addition, an increased ratio of phosphorylated AMPKα to AMPKα by CLA was observed (Figure 4D, P = 0.0471).

Along with AMPKα, SIRT1 (a NAD-dependent deacetylase) is a key activator of PGC-1α (one major downstream marker for AMPKα). There were no significant effects of genotype and CLA on SIRT1 observed, whereas the wild type CLA group showed increased SIRT1 expression level in comparison to the N2KO control (Figure 4E). The expression of PGC-1α, a master regulator of mitochondrial biogenesis, was also not influenced by genotype or CLA (Figure 4F). However, it was evident that CLA treatment had a greater effect on PGC-1α in comparison to the control diet group in wild type animals.

Effects on Mitochondrial Biogenesis-Related Factors. We further determined the effect of postweaning CLA supplementation on mitochondrial biogenesis in the gastrocnemius muscle. Mitochondria are important organelles in determining oxidative capacity and fatigue resistance, resulting in prolonged endurance capacity.[21−23] For mitochondrial biogenesis several nuclear encoded precursor proteins are involved in this metabolic process;[24−26] among them, we selected PPARδ, NRF-1, and Tfam.

PPARδ is a marker involved in mitochondrial biogenesis as well as muscle type transformation from glycolytic to oxidative fiber.[27] No significant overall effects of genotypes or CLA were observed on PPARδ; however, wild type CLA-fed animals showed significantly greater expression levels of PPARδ in comparison to both control diet groups (Figure 5B). No significant difference in NRF-1, a regulator to mediate nuclear-encoding mitochondrial proteins, was observed in any experimental group (Figure 5C). The expression of Tfam, which is the key regulator for mitochondrial DNA replication and transcription, was significantly downregulated in N2KO mice in comparison to wild type mice (P = 0.0062). The CLA supplemented group in wild type animals showed significantly greater Tfam expression over the control group in N2KO mice (Figure 5D).

To estimate overall mitochondrial relative content, we used an indirect method to measure mitochondrial proteins, including cytochrome c and COX IV, located in the inner membrane of mitochondria.[28,29] Additionally, we tested another mitochondrial protein, superoxide dismutase 2 (SOD2) in the inner mitochondrial matrix, to assess mitochondrial function.[30] The expression levels of cytochrome c were significantly decreased in N2KO mice in comparison to wild type animals (P = 0.0496), but no CLA effects were observed (Figure 6B). No genotype or CLA effects were observed in COX IV (Figure 6C). Overall SOD2 protein levels were significantly reduced in N2KO mice (P = 0.0224), while no effects of CLA were observed (Figure 6D).

Effects on Markers of Glucose Metabolism. Along with assessment of postweaning administration of CLA on

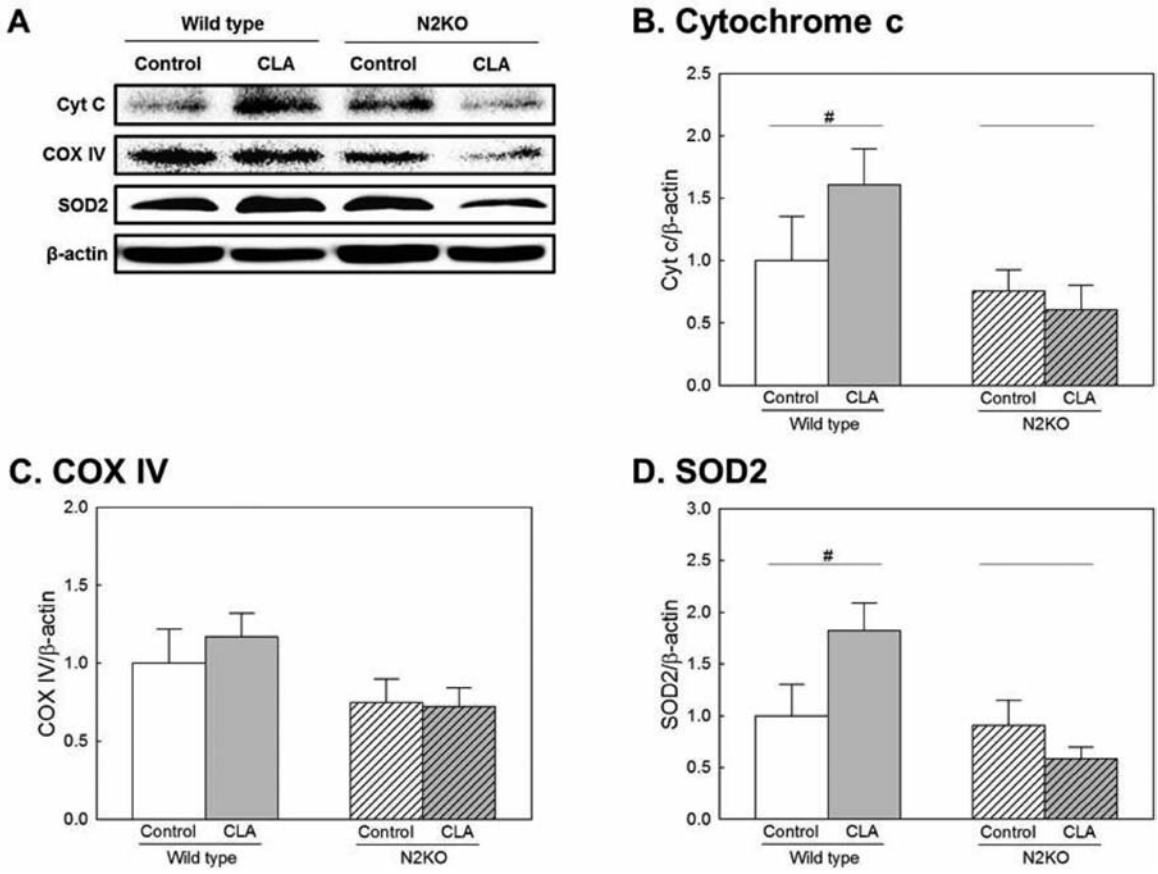

Figure 6. Effect of postweaning treatment of conjugated linoleic acid (CLA) on mitochondrial content and function from the gastrocnemius muscle. Pictures are representative results (A). The relative expression levels of cytochrome *c* (Cyt C, B), cytochrome *c* oxidase (COX IV, C), and superoxide dismutase 2 (SOD2, D) were detected. *β*-Actin was used as the loading control. Data are means ± SE ($n = 3–5$). # denotes a significant overall genotype effect ($P < 0.05$). N2KO: nescient helix–loop–helix knockout. Means with different letters are significantly different ($P < 0.05$).

mitochondrial biogenesis-related factors, we determined the effects of CLA supplementation during the first 4 weeks on markers of glucose metabolism in the gastrocnemius muscle. The expression levels of IRS-1, a member of the IRS family regulating insulin signaling, were significantly decreased in N2KO animals over wild types, while no CLA effects were observed (Figure 7B, overall genotype effect, $P = 0.0335$).

A downstream biomarker of IRS (PTEN, attributed to negatively regulate the AKT signaling pathway) significantly reduced phosphorylation (inactive form of PTEN) in N2KO mice in comparison to wild type animals ($P = 0.0094$). No significant effect of postweaning administration of CLA was observed on PTEN expression in N2KO mice. However, CLA-treated wild type animals significantly upregulated phosphorylated PTEN in comparison to the respective control, while no differences were observed in N2KO animals (Figure 7C).

No difference in protein expression of phosphorylated PDK, a downstream marker of PTEN, was observed for either genotype or CLA (Figure 7D). There were no significant effects of genotypes and CLA on total AKT expressions and phosphorylated AKT (Serine 473) and GLUT4, one of the insulin-regulated glucose transporters (Figure 7E–H). However, we observed marginally increased responses from wild type animals fed CLA on phosphorylated AKT (threonine 308) in comparison to the respective controls ($P = 0.0547$ vs wild-type control and $P = 0.0528$ vs N2KO control, respectively).

DISCUSSION

It was previously reported that supplementation of CLA prevents weight gain and body fat accumulation both during the growth period and in aged N2KO mice.[9,31,32] In particular, CLA increased voluntary activity when supplemented during the growth period.[9,31] Results from the current study suggest that supplementation of CLA in the preobese state may reduce weight gain in normal animals but not in the genetically induced inactive adult-onset animal model, although the stimulation of voluntary activity and improved glucose tolerance remain even after CLA withdrawal in this model.

Previously CLA was reported to be linked with reduced food intake in a number of animal models, although it was not consistent.[14,33,34] Moreover, it was determined that the reduction of food intake by CLA was independent of its effects on body fat reduction.[14,35] Others suggested that CLA reduces food intake by decreasing neuropeptides Y (NPY) and agouti-related protein (AgRP), both of which are known to be related to increased appetite[36] and inducing the storage of glycogen in muscle and liver, which may subsequently serve as satiety signals.[37,38] In the current study, we did not observe any significant differences in food intake during CLA supplementation periods in both genotypes. However, when CLA was withdrawn, apparent compensation of food intake occurred in N2KO animals fed CLA but not in wild type animals, coinciding with greater weight gain during this period (weeks 4–6 in Figure 1A). It is not clear how CLA influenced food intake in these animals; however, these

results suggest that CLA may influence food intake differently in obese animals, which has been previously reported in other animal models.[14,33,34,39]

We observed that N2KO mice had significantly reduced physical activity, consistent with previous reports for N2KO animals.[9,10,40] Overall, postweaning CLA supplementation significantly prevented reduction of voluntary activity levels in comparison to controls, particularly in wild type animals. Intriguingly, our results showed that the effects of CLA on activity during the late phase (23:00−03:00) might remain even after termination of CLA treatment up to 8 weeks, whereas during the early phase (19:00−23:00) there was no significant CLA effect in all experimental groups.

Among various molecular mechanisms to affect increased or maintained physical activity levels, the AMPK signaling pathway has drawn significant attention since the 1990s.[41] An upregulated AMPK signaling pathway is involved in skeletal muscle energy metabolism as well as mitochondrial biogenesis, resulting in enhanced endurance capacity and attenuated exercise intolerance.[42−45] Previously, our group demonstrated the effect of CLA on stimulation of mitochondrial biogenesis through an AMPK signaling pathway.[46] In the same context, our data supported that postweaning administration of CLA might stimulate activation of AMPKα and related factors in wild type but not in N2KO animals.

Wild type animals fed CLA for the first 4 weeks showed improved glucose tolerance over time even after no benefits on weight were observed in comparison to the respective control, suggesting that CLA may have lasting effects on glucose metabolism later in life. On the basis of this observation, we assessed the effects of CLA treatment during the growth period on glucose metabolism through the insulin signaling pathway. Among several measured markers involved in insulin signaling cascades, phosphorylated PTEN and phosphorylated AKT at threonine 308 partially provided evidence regarding how to moderate glucose tolerance in the current study. PTEN and AKT are important effectors of insulin responses mediating glucose uptake and glycogen synthesis in skeletal muscle.[47−50] Our data are consistent with early studies that CLA-specific isomers mediate AKT sensitization.[51,52]

The current results suggest potential benefits of postweaning CLA administration to reduce health risk, as suggested previously.[19,31] This is important, since one potential health concern associated with CLA supplementation is glucose intolerance. We observed a nonsignificant increase in glucose intolerance following CLA supplementation in wild type mice (Figure 3B, week 4); however, when CLA was withdrawn, glucose tolerance improved in the treated groups (week 12 in Figure 3D). As suggested before, this may be due in part to a significant shift of energy metabolism by CLA, such as increased fatty acid β-oxidation associated with reduced glucose utilization.[53,54] However, further studies such as HOMA-IR to better understand glucose and insulin metabolism are needed to determine how postweaning administration of CLA changes energy sources.

As seen in previous studies,[15,55,56] we observed a significant increase in liver weight, as fatty liver, after CLA supplementation. It is unlikely that CLA is directly accumulated in the liver, as levels of CLA in the liver and muscle reached a maximum 1 week for the liver and 2 weeks for muscle after supplementation in mice.[57] Previously it was reported that CLA-fed animals accumulate TG in the liver.[58,59] This is believed to be associated with CLA's dramatic effects on lipid metabolism, particularly in the liver and adipose tissues, increased hepatic lipogenesis, and decreased fat accumulation in adipose tissues.[8,60−62] It is unlikely that an enlarged liver caused by CLA is due to increased glycogen content, as it was previously shown that CLA had no effects on enzyme activities involved in gluconeogenesis.[57] In addition, previous studies reported no pathologically significant observations after 18 months of CLA supplementation or no changes in hepatic gene expressions in lipogenesis from N2KO animals.[9,32,63] Although we provided CLA only during the preobese state and then withdrew CLA, the significant effect of CLA on liver weight still remains. This is consistent with the previous study that withdrawal of CLA did not completely reverse liver enlargement at the end of a 4 week recovery period.[64] Our study might not have enough adaptive time to complete this reversal of CLA's effect. Thus, additional investigation of the relationship between short-term CLA supplementation and changes in hepatic genes should be considered to determine if the liver enlargement caused by CLA is completely reversible or not. Clinical trials with CLA reported no changes or increased markers for liver function, and all were within the normal ranges. In addition, it was reported that a high dose of CLA (14.6 g of *cis*-9,*trans*-11 and 4.7 g of *trans*-10,*cis*-12 CLA per day) for 3 weeks had no changes on markers of liver function in healthy subjects. Thus, it is possible that rodents are more sensitive to CLA's effect in comparison to humans.

In conclusion, CLA supplementation during the preobese state may attenuate reduction of voluntary activity and glucose intolerance after CLA withdrawal in this mouse model. However, it is not sufficient per se to maintain health benefits such as prevention of weight gain and fat accumulation until later life in genetically obese mice. Wild type animals fed CLA may activate AMPKα and PPARδ as well as promote desensitization of PTEN and sensitization of AKT at threonine 308 in gastrocnemius skeletal muscle, improving voluntary activity and glucose homeostasis. We suggest that postweaning administration of CLA may partially stimulate the underlying molecular targets involved in muscle energy metabolism in normal animals but not in the genetically induced inactive adult-onset animal model. The present study should provide a scientific foundation for future trials of targeted application of postweaning CLA intervention in modulating long-term obesity. If further research on genetically predisposed obese mice discovered an appropriate intervention or combination with an additional regime such as exercise, it may be possible to more effectively use it to prevent childhood obesity.

ABSTRACT: The plant growth regulatory activity of furofuran lignan (7,9′:7′,9-diepoxylignan) was evaluated by employing optically pure synthesized (+)- and (−)-enantiomers. (+)-Sesamin possessing a 3,4-methylenedioxy group on the aromatic rings and 7-aryl structure showed growth promotion activity against lettuce roots (EC_{50} = 0.50 mM); on the other hand, growth inhibitory activity was observed against lettuce shoots (EC_{50} = 0.38 mM). Against ryegrass shoots, (−)-sesamolin, which has 3,4-methylenedioxy groups on the aromatic rings and a 7-acetal structure, was effective in showing growth inhibitory activity (EC_{50} = 0.23 mM). Different activity levels were observed between (+)- and (−)-enantiomers. It was assumed that the 3,4-methylenedioxy group on the aromatic ring was more potent for the plant growth regulatory activity.

INTRODUCTION

Furofuran lignans (Figure 1) are a representative group of lignans in food plants,[1,2] possessing a 7,9′:7′,9-diepoxy[3] structure and a wide range of biological activities.[2] Although lignans are biosynthesized by plants, the effect of the main structure and stereochemistry on the plant growth regulatory activity had not been clarified. Recently, we demonstrated the plant growth inhibitory activity of 7,9′-epoxylignan[4,5] and 7,7′-epoxylignan,[6,7] giving information on the favored stereochemistry and substituent for the activity. As for dietary furofuran lignan, we can find some reports on the plant growth regulatory activity using isolated compounds.[8−10] The activity of isolated oxo-type furofuran lignan was also reported.[11] On the other hand, the enantiomeric excess of natural furofuran lignan was estimated as 20−30%,[12,13] suggesting that the effect of stereochemistry on the activity should be examined by employing optically pure synthesized compounds.

In this research, both enantiomers of common dietary furofuran lignans, (+)- and (−)-pinoresinol, **1** and **2**, (+)- and (−)-medioresinol, **3** and **4**, (+)- and (−)-syringaresinol, **5** and **6**, (+)- and (−)-sesamin, **7** and **8**, (+)- and (−)-sesamolin, **9** and **10**, (+)- and (−)-sesamolinol, **11** and **12**, and (+)- and (−)-samin, **13** and **14**, were selected to clarify the plant growth regulatory activity of components of the food plants. With the results of this research, effects of enantiomeric, acetal, and hemiacetal structure on the activity could be compared for the first time. The previously described synthetic methods[14−16] were employed with modification to provide the optically pure furofuran lignans.

MATERIALS AND METHODS

Chemicals. Optical rotation values were measured with a P-2100 instrument (JASCO, Tokyo, Japan). HPLC analysis for compounds was performed with LC-6AD and SPD-6AV instruments (Shimadzu, Kyoto, Japan). The column used for HPLC analyses was a 250 mm × 4.6 mm i.d., 5 μm, CHIRALCEL AD-H and OD-H (DAICEL Chemical Industries, Ltd., Tokyo, Japan).

Furofuran lignans, **1**−**14**, were synthesized by employing a previously described method[14−16] with modification.

(+)-Pinoresinol, **1**: NMR data agreed with those in the literature;[17] $[\alpha]_D^{25}$ +67 (*c* 0.2, $CHCl_3$), $[\alpha]_D^{22}$ +63 (*c* 1.2, $CHCl_3$) in the literature;[18] t_R 51.3 min (OD-H, hexane/isopropyl alcohol = 1:1, v/v, 1 mL/min, detected at 276 nm); >99% ee.

(−)-Pinoresinol, **2**: NMR data agreed with those in the literature;[17] $[\alpha]_D^{25}$ −68 (*c* 0.1, $CHCl_3$), $[\alpha]_D^{25}$ −34.7 ($CHCl_3$) in the litearure;[19] t_R 17.7 min (OD-H, hexane/isopropyl alcohol = 1:1, v/v, 1 mL/min, detected at 276 nm); >99% ee.

(+)-Medioresinol, **3**: NMR data agreed with those in the literature;[20] $[\alpha]_D^{25}$ +68 (*c* 0.2, $CHCl_3$), $[\alpha]_D^{22}$ +54 (*c* 1.0, $CHCl_3$) in the literature;[18] t_R 23.1 min (AD-H, hexane/isopropyl alcohol = 1:4, v/v, 1 mL/min, detected at 280 nm); >99% ee.

(−)-Medioresinol, **4**: NMR data agreed with those in the literature;[20] $[\alpha]_D^{25}$ −69 (*c* 0.3, $CHCl_3$), $[\alpha]_D^{25}$ −17.0 (*c* 0.14, $CHCl_3$) in the literature;[21] t_R 19.8 min (AD-H, hexane/isopropyl alcohol = 1:4, v/v, 1 mL/min, detected at 280 nm); >99% ee.

(+)-Syringaresinol, **5**: NMR data agreed with those in the literature;[20] $[\alpha]_D^{25}$ +38 (*c* 0.4, $CHCl_3$), $[\alpha]_D^{22}$ +23 (*c* 0.7, $CHCl_3$) in the literature;[18] t_R 27.4 min (OD-H, hexane/isopropyl alcohol = 1:4, v/v, 1 mL/min, detected at 273 nm); >99% ee.

(−)-Sesamolinol, **12**: NMR data agreed with those of (+)-form in the literature;[29] $[\alpha]_D^{25}$ −178 (*c* 1.4, $CHCl_3$); t_R 12.8 min (AD-H, hexane/isopropyl alcohol = 1:1, v/v, 1 mL/min, detected at 287 nm); >99% ee.

(+)-Samin, **13**: diastereomeric mixture of 7*R* and 7*S*; NMR data agreed with those in the literature;[30] $[\alpha]_D^{25}$ +92 (*c* 1.2, $CHCl_3$), $[\alpha]_D$ +81.4 (*c* 0.5, $CHCl_3$) in the literature.[31]

(−)-Samin, **14**: diastereomeric mixture of 7*R* and 7*S*; NMR data agreed with those in the literature;[30] $[\alpha]_D^{25}$ −90 (*c* 2.5, $CHCl_3$), $[\alpha]_D^{24}$ −88.18 (*c* 1.1, $CHCl_3$) in the literature of synthetic research.[28]

Evaluation of Plant Growth Regulatory Activity. The plant growth regulatory activity of all stereoisomers of lariciresinol was evaluated using lettuce (*Lactuca sativa* L. Green-wave (Takii Seed Co. Ltd., Kyoto, Japan)) and Italian ryegrass (*Lolium multiflorum* Lam. Wase-fudo (Takii Seed Co. Ltd.)). A sheet of filter paper (90 mm diameter) was placed in a 90 mm Petri dish and wetted with 500 μL of test sample solution dissolved in acetone at concentrations from 6.0×10^{-3} to 6.0×10^{-8} M. After the filter paper had dried, 3 mL of water was poured into the dish to adjust the final concentration from 1.0×10^{-3} to 1.0×10^{-8} M. Thirty seeds of each plant were placed on the filter paper, and the Petri dishes were sealed with Parafilm. The Petri dishes were then incubated in the dark at 20 °C. The lengths of roots and shoots were measured after 3 days for lettuce and after 5 days for ryegrass by using an ordinary ruler. The roots and shoots lengths of the control were ca. 3 and 1 cm for lettuce and 4 and 3 cm for ryegrass, respectively. Data are presented as percentage differences from the control; positive and negative values represent stimulation and inhibition of plant growth, respectively. Experiments were performed in triplicate or more for each sample (n = 3−7). Statistical analyses were conducted by one-way ANOVA followed by Tukey's multiple-comparison test using PRISM software (Graphpad Software, San Diego, CA, USA), and the values of $p < 0.01$ and 0.05 were considered to be statistically significant.

RESULTS AND DISCUSSION

Optically pure natural furofuran lignans, **1**−**14**, were synthesized by employing a previously described method with modification.[14−16] Although some isolated furofuran lignans, (−)-pinoresinol,[19] (−)-medioresinol,[21] and (−)-syringaresinol,[22] from plants showed lower specific optical rotation in the previous studies, we obtained optically pure samples by organic syntheses for this research. These synthetic results enabled us to evaluate the biological activity of the (−)-form for the first time. In the case of hemiacetal type lignans, (+)- and (−)-samin (**13** and **14**), diastereomeric mixtures of the (7*R*/*S*)-form were employed.

All synthesized furofuran lignans, **1**−**14**, were applied to plant growth regulatory activity test at 1 mM (Figure 2) as a first stage. Against lettuce roots, (+)- and (−)-syringaresinol (**5** and **6**) and (+)- and (−)-sesamin (**7** and **8**) promoted the growth (from 40 to 60% from control) with significant difference, whereas (+)- and (−)-medioresinols (**3** and **4**) had lower activity, suggesting that the 3,5-dimethoxy-4-hydroxyphenyl group or 3,4-methylendioxyphenyl group at both the 7 and 7′ positions is favorable for the growth promotion of lettuce roots. A comparable activity level was shown between the corresponding enantiomers. Even if two 3,4-methylenedioxyphenyl groups are present in the structure, the acetal type compound, (+)- and (−)-sesamolin (**9** and **10**) was inactive, indicating that the 7-aryl structure is more important than the 7-aryloxy group for the growth promotion activity against lettuce roots. No or very weak activities of both enantiomers of pinoresinol (**1** and **2**) medioresinol (**3** and **4**), sesamolinol (**11** and **12**), and samin (**13** and **14**) would be due to the presence of 3-methoxy-4-hydroxy groups and the acetal/hemiacetal structure. On the other hand, growth promotion was not observed, but growth inhibitory activity was exhibited against lettuce shoots for (+)- and (−)-sesamin (**7** and **8**), (+)- and (−)-sesamolin (**9** and **10**), and (+)- and (−)-samin (**13**

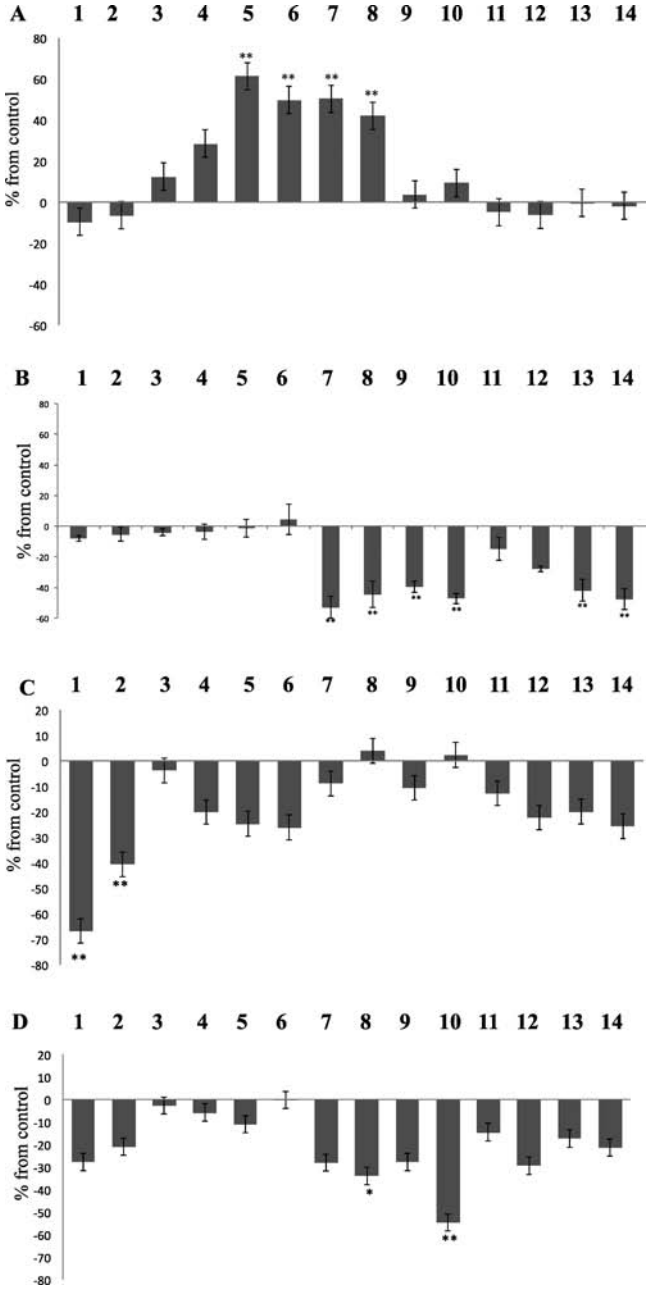

Figure 2. Plant growth regulatory activity of (+)- and (−)-furofuran lignans, **1**−**14**, at 1 mM against (A) lettuce roots, (B) lettuce shoots, (C) ryegrass roots, and (D) ryegrass shoots. (**) $p < 0.01$; (*) $p < 0.05$. (−)-Verrucosin showed −95 and −60% growth inhibition activity against lettuce roots and shoots, respectively. (+)-Verrucosin showed −98 and −63% growth inhibition activity against ryegrass roots and shoots, respectively.[6]

and **14**), showing growth inhibitory activity with significant difference (from −40 to −50% from control). Because the activity level of the 7-aryl structure, **7** and **8**, was similar to that of the 7-acetal structure, **9** and **10**, it could be assumed that the 3,4-methylenedioxy groups on both 7 and 7′ aromatic rings are important for growth inhibitory activity against lettuce shoots. The activity of the 7-hemiacetal structure is also similar to those of the 7-aryl and 7-acetal structures. The enantiomeric structures did not affect the activity. The activities of both enantiomers of pinoresinol (**1** and **2**), medioresinol (**3** and **4**), syringaresinol (**5** and **6**), and sesamolinol (**11** and **12**) were less potent against lettuce shoots. These facts suggest that the substituent on the aromatic ring is a more important factor than the structure of the 7 position and the enantiomeric structure against growth inhibition of lettuce shoots at 1 mM. In our previous study on lignans bearing a 7,9′-epoxy structure[4,5] and a 7,7′-epoxy structure,[6,7] only growth inhibitory activity against lettuce was observed. We found growth promotion activity of furofuran lignan bearing a 7,9′:7′,9-diepoxy structure against lettuce roots in this study. (+)- and (−)-Sesamin showed both growth promotion activity against lettuce roots and growth inhibitory activity against lettuce shoots at 1 mM.

Against ryegrass at 1 mM (Figure 2C,D), we observed only growth inhibitory activity on both roots and shoots elongation. (+)-Pinoresinol (**1**) (−65%) was 1.5-fold more potent than (−)-pinoresinol (**2**) (−40%) against ryegrass roots with significant difference. The activities of other compounds against ryegrass roots were lower (< −25%). (−)-Sesamolin (**10**) exhibited the highest activity of the growth inhibitory activity against ryegrass shoots (−55%) with significant difference at 1 mM; on the other hand, its enantiomer, (+)-sesamolin (**9**), was 2-fold less potent. The activities of other compounds containing pinoresinol, which had the highest activity against ryegrass roots, were < −35%. The higher growth inhibitory activities of shoots against both lettuce and ryegrass at 1 mM were observed in only (−)-sesamolin (**10**), bearing a 3,4-methylenedioxyphenyl group and acetal structure. However, the activity of **10** against roots of lettuce and ryegrass was not observed. In the ryegrass growth experiment, different activity levels between corresponding enantiomers were observed.

As a next step, dilution experiments (from 10^{-4} to 10^{-8} M) of the active compounds at 1 mM were performed (Figure 3). Although significant difference was not observed, (+)-sesamin (**7**) was effective to some extent, exhibiting promotion activity (+40%) against lettuce roots at 10^{-4} M (Figure 3A,B). In the experiment on growth of lettuce shoots, (+)- and (−)-sesamin (**7** and **8**) and (+)- and (−)-sesamolin (**9** and **10**) were proved to show from −40 to −30% inhibitory activity with significant difference at 10^{-4} M. The growth promotion activity of (+)- and (−)-syringaresinol (**5** and **6**) and (−)-sesamin (**8**) against lettuce roots and the growth inhibitory activity of (+)- and (−)-samin (**13** and **14**) against lettuce shoots at 1 mM dramatically disappeared by 10-fold dilution as in our previous experiment employing 7,9′- and 7,7′-epoxylignan possessing a 3-methoxy-4-hydroxyphenyl group.[4,6] Considering these results, 7-(3,4-methylenedioxyphenyl)/(3,4-methylenedioxyphenoxy) and 7′-(3,4-methylenedioxyphenyl) compounds are more advantageous for lettuce growth regulation at diluted concentration. The enantiospecific activity of sesamin was clarified by this dilution experiment; only (+)-sesamin (**7**) showed growth promotion activity (+40%) against lettuce roots at 10^{-4} M. In the dilution experiment on ryegrass (Figure 3C,D), (−)-sesamolin (**10**) showed growth inhibitory activity (−45%) against shoots at 10^{-4} M with significant difference; on the other hand, the higher activities of (+)- and (−)-pinoresinol (**1** and **2**) against roots at 1 mM dramatically disappeared at 10^{-4} M. It could be assumed that the (−)-form, 7-(3,4-methylenedioxyphenoxy) acetal structure, and 7′-(3,4-methylenedioxyphenyl) structure are favorable for the highest ryegrass shoot inhibitory activity at diluted condition. The lower activity of hemiacetal type (−)-samin (**14**), which is converted from **10** by hydrolysis, means that the acetal type (−)-sesamolin (**10**) is an active compound in the plant body.

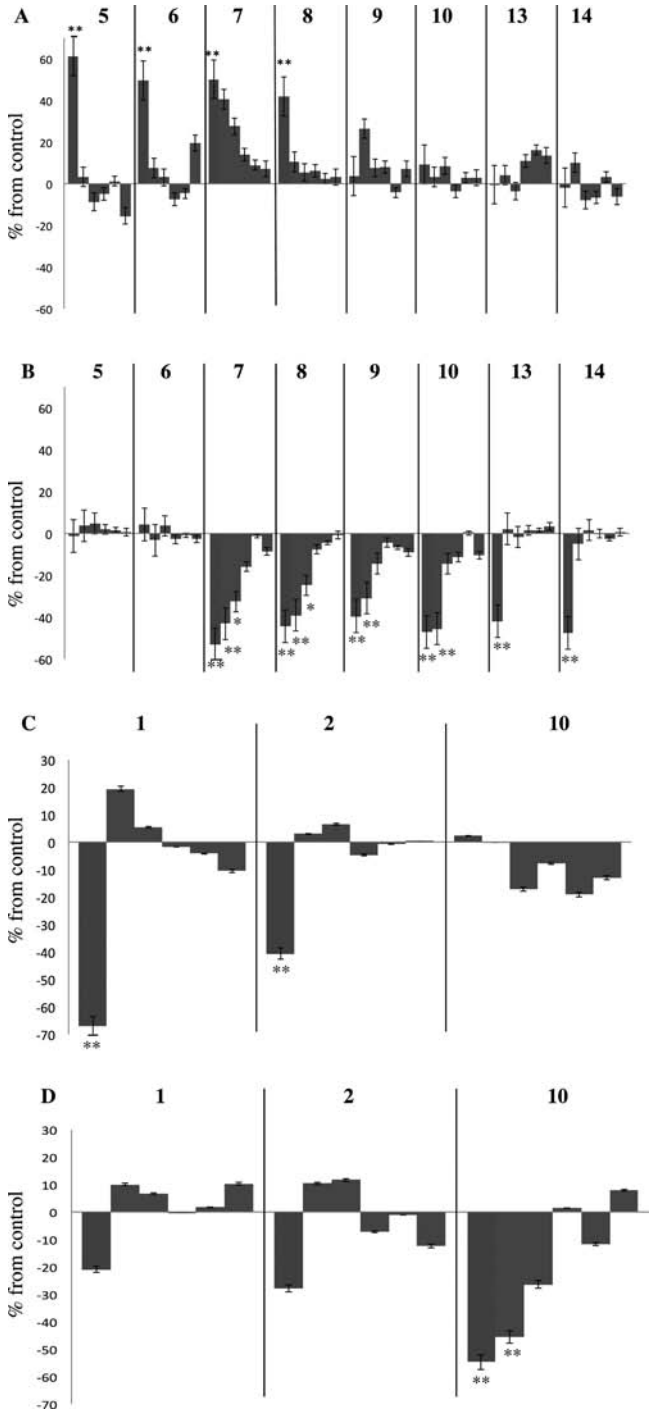

Figure 3. Plant growth regulatory activity of (+)- and (−)-furofuran lignans under diluted conditions against (A) lettuce roots, (B) lettuce shoots, (C) ryegrass roots, and (D) ryegrass shoots. (**) $p < 0.01$; (*) $p < 0.05$.

We evaluated EC_{50} values of furofuran lignans of higher activity (7,9′:7′,9-diepoxylignan) in this experiment (Table 1). The highest active compounds were (+)-sesamin (**7**) against lettuce shoots (growth inhibition, EC_{50} = 0.38 mM) and (−)-sesamolin (**10**) against ryegrass shoots (growth inhibition, EC_{50} = 0.23 mM). The activity of compounds bearing a 3-methoxy-4-hydroxyphenyl group, which is a common phenyl group in the natural lignans, was weak. The highest activity of 7,9′:7′,9-diepoxylignan bearing a 3-methoxy-4-hydroxyphenyl group was shown against ryegrass roots by (+)-pinoresinol (**1**) (growth inhibition, EC_{50} = 0.95 mM). In this experiment, growth promotion activity of lignan was also discovered. The growth promotion activity of (+)-sesamin (**7**) against lettuce roots (EC_{50} = 0.50 mM) was 2-fold higher than that of (+)-syringaresinol (EC_{50} = 1.00 mM). To confirm the growth promotion/inhibitory activities of these compounds, the effects of these compounds on germination were examined, showing 83−101% germination from control. These compounds did not affect much the germination.

This research clarified the plant growth regulatory activity of popular furofuran lignan bearing a 7,9′:7′,9-diepoxy structure using enantiomerically pure synthesized (+)- and (−)-enantiomers for the first time. Compared the activity, the potency of a methylenedioxy group on the aromatic rings and some difference of activity level between enantiomers were more shown. It is evaluated that (+)-sesamin and (−)-sesamolin were more potent in this research. It is noteworthy that (+)-sesamin promotes the growth of lettuce roots and inhibits lettuce shoots. It could be assumed that a 7,9′:7′,9-diepoxy structure is less potent than the 7,9′- and 7,7′-epoxy structures at 1 mM. However, a 7,9′:7′,9-diepoxy structure bearing a 3,4-methylenedioxy group is more potent at lower concentration. Because both enantiomers showed activity, enantiomers seem to have no specific target. Lignans have been focused on their antioxidant activities and medicinal effect.[32] This research showed the plant growth regulatory activity of (+)- and (−)-furofuran lignans. The biosynthetic research of furofuran lignan is now continuing.[33,34] By the combination of structure−activity relationships with the biosynthetic research, new food plants producing higher amounts of growth regulatory lignans could be developed.

Identification and Quantification of Flavonoids from Two Southern Italian Cultivars of *Allium cepa* L., Tropea (Red Onion) and Montoro (Copper Onion), and Their Capacity to Protect Human Erythrocytes from Oxidative Stress

Idolo Tedesco,[†] Virginia Carbone,[†] Carmela Spagnuolo,[†] Paola Minasi, and Gian Luigi Russo*

Institute of Food Sciences, National Research Council, 83100 Avellino, Italy

ABSTRACT: Onions (*Allium cepa*) are consumed worldwide and represent an important source of dietary phytochemicals with proven antioxidant properties, such as phenolic acids, flavonoids, thiosulfinates, and anthocyanins. Epidemiological and experimental data suggest that regular consumption of onions is associated with a reduced risk of degenerative disorders. Therefore, it is of interest to investigate the biological properties of different varieties of onions. Here, we characterized for the first time a variety of onion, called Ramata di Montoro (coppery onion from Montoro), grown in a niche area in southern Italy, and compared its phenolic profile and antioxidant properties to a commercial ecotype of red onion, Tropea, also present in southern Italy. An analytical method based on high-performance liquid chromatography coupled with UV detection and mass spectrometry was used to separate and characterize the phenolic fraction (anthocyanins and flavonols) extracted from both coppery and red types. The main compounds detected in the two ecotypes were quercetin and quercetin glucosides, isorhamnetin glucosides, kaempferol glucoside, and, among anthocyanins, cyanidin glucosides. Tropea ecotype onion showed a higher content of flavonols (632.82 mg/kg fresh weight) than Montoro type onion (252.91 mg/kg fresh weight). Accordingly, the antioxidant activity of the former was 2.8-fold higher compared to the latter. More pronounced were the differences existing between the four anthocyanins detected in the two ecotypes, with those in the Tropea ecotype onion present at concentrations 20−230-fold higher than in the Montoro type onion. Both extracts reduced LDL oxidation about 6-fold and protected human erythrocytes from oxidative damage induced by HClO by about 40%. In addition, as a consequence of HClO treatment, glutathione concentration in erythrocytes was reduced about 50% and pretreatment with onion extracts induced a recovery of glutathione level by about 15−22%. Qualitative differences highlighted in the chemical composition of the two phenolic extracts, especially the total content of anthocyanins, which was 30-fold higher in Montoro type onion compared to Tropea ecotype, can be associated with the protective effects measured against oxidative damage induced in human erythrocytes.

KEYWORDS: *Allium cepa, Tropea red onion, Montoro copper onion, polyphenols, antioxidants, oxidative stress, HPLC-MS*

INTRODUCTION

Onions are the second most produced vegetable crop after tomatoes, with about 3 642 000 ha grown annually worldwide and a production of 53.6 Mt.[1,2] Their large distribution is probably due to the versatile culinary uses as raw food or in different modes of cooking (baked, boiled, braised, grilled, fried, roasted, etc.). In addition, onions are considered among the healthier vegetables due to the high levels of nonnutrient compounds, such as phenolic acids, flavonoids, thiosulfinates, and anthocyanins. For these reasons, it is of interest to study and characterize the chemical and biological properties of new varieties, including those grown in niche geographical areas, which are produced in limited amounts but may represent a potential source of new biological compounds. Onions are among the richest sources of dietary flavonoids. In bulbs, only compounds belonging to flavonols, anthocyanins, and dihydroflavonols have been detected. As reviewed,[3] yellow onions contain 270−1187 mg/kg fresh weight (FW) flavonols, whereas red onions contain 415−1917 mg/kg FW flavonols. Quercetin derivatives (quercetin 4′-glucoside and quercetin 3,4′-diglucoside) are the predominant flavonols in all onion cultivars. The anthocyanins of red onions (approximately 10% of the total flavonoid content) are mainly cyanidin glucosides acylated with malonic acid or nonacylated.[3] Storage of onions for 6 weeks in different conditions resulted in a decrease of 64−73% of total anthocyanins,which paralleled a reduction in total antioxidant activity of 29−36%.[4] In this regard, it is worthwhile to mention that onions are considered among the major sources of antioxidant compounds,[5] whose level of activity is related to the different cultivars and colors.[6−10]

The scientific literature of the last 20 years or so has been influenced by the syllogism that since free radicals damage cellular structures, their scavenging by antioxidants is health-protective. As a consequence, an increased uptake of antioxidants, such as those deriving from a fruits- and vegetables-rich diet, may increase resistance to reactive-species-induced pathologies. Although this concept probably overestimates the antioxidant capacity of phytochemicals and, possibly, generated misinterpretations in the field,[11,12] biochemical and genetic studies on cellular and animal models on the mechanism(s) of action of phytochemicals provide a

functional explanation of how and why a diet rich in fruits and vegetables can protect against degenerative diseases.[13,14]

Therefore, scientists in this field are constantly in search of novel agronomic species and/or local varieties possessing enhanced protective effects against oxidative damage in cellular and animal models. In the present work, we focused our attention on a local variety of onion, known as Ramata di Montoro (coppery onion from Montoro area; COM), whose cultivation was born and passed down through generations in the area of Montoro Inferiore, a village located in the province of Avellino (southern Italy). We compared the antioxidant properties of polyphenols isolated from COM to a better-characterized commercial ecotype, red Tropea onion (RTO), a variety of red onion grown in a specific area of Calabria, a region in southern Italy.[15]

In the present study, an analytical method based on high-performance liquid chromatography (HPLC) coupled with UV detection and mass spectrometry was used to separate and characterize the phenolic fraction (anthocyanins and flavonols) extracted from cultivated bulbs of COM compared to RTO ecotype. Polyphenolic extracts from the two onions were evaluated for their antioxidant activity. Subsequently, we investigated the protective role of phenolic extracts from RTO and COM against low-density lipoprotein (LDL) oxidation and hypochlorous acid-induced oxidative damage in normal red blood cells (RBCs, erythrocytes) and their interference with the antioxidant defense systems active in erythrocytes. Oxidized LDL contain a diverse set of toxic species, such as aldehydes, oxysterols, and lipid peroxides.[16] They are considered as an important initial step in the development of atherosclerosis; therefore, lowering LDL levels by independent mechanisms is considered protective against the likelihood of atherosclerotic events.[17−19] Previous studies indicated that phytochemicals, such as phenolic acids, flavonoids, and anthocyanins, inhibited LDL oxidation.[20−23] RBCs have been selected as the study model since, for their physiological role, they are exposed to continuous oxidative stress deriving from endogenous[24] or exogenous sources.[25] For these reasons, RBCs have developed efficient enzymatic and nonenzymatic antioxidant defenses to preserve themselves from oxidative damage. In addition, due to their mobility, erythrocytes can be considered as ideal antioxidant scavengers acting throughout the circulation and reducing the damaging mass effect of elevated levels of reactive oxygen species (ROS) on different tissues.[24−26] Therefore, we established a novel in vitro model using RBCs isolated from whole blood, treated with HClO (hypochlorous acid). Millimolar concentrations of HClO generate osmotic fragility and formation of transient membrane pores with the consequent hemolysis of erythrocytes.[27] Treatment with HClO cannot be seen as an experimental adaptation to allow the functionality of our assay on RBCs, but it is very close to physiological processes; in fact, following inflammatory tissue injury and microbial killing, neutrophils and monocytes generate hyperproduction of HClO in the millimolar range.[28]

On the basis of these observations, we first chemically characterized the polyphenolic contents of RTO and COM ecotypes, the latter representing a new variety while the former was used as a reference, being already described and characterized. Subsequently, we compared their protective effect against oxidative damage by taking advantage of two different assays: (i) capacity to reduce LDL oxidation and (ii) protection of human RBCs from healthy subjects from oxidative insult caused by HClO treatment.

MATERIALS AND METHODS

Chemicals. Methanol and formic acid were obtained from Merck (Darmstadt, Germany). Quercetin, Folin−Ciocalteu's reagent, 2,4,6-tris(2-pyridyl)-*s*-triazine (TPTZ), glutathione (GSH), phthaldialdehyde, trichloroacetic acid (TCA), hydrogen peroxide (H_2O_2), low-density lipoprotein (LDL) from human plasma, cupric sulfate anhydrous, xylenol orange, ferrous ammonium sulfate, and butylated hydroxytoluene (BHT) were purchased from Sigma−Aldrich (Milan, Italy). Isoquercitrin (quercetin 3-*O*-glucoside) was obtained from Fluka (Buchs SG, Switzerlandand). Cyanidin 3-*O*-glucoside chloride (kuromanin chloride), delphinidin 3-*O*-glucoside chloride (myrtillin chloride), quercetin 3,4′-di-*O*-glucoside, quercetin 4′-*O*-glucoside (spiraeoside), and kaempferol 3-*O*-glucoside were purchased from Extrasynthese (Genay, France). Ferric chloride, sodium carbonate, and sodium hypochlorite were from Carlo Erba (Milan, Italy). Phosphate-buffered saline (PBS) tablets were purchased from Invitrogen (S. Giuliano Milanese, Milan, Italy). HPLC-grade water (18.2 mΩ) was prepared by use of a Millipore Milli-Q purification system (Millipore Corp., Bedford, MA). All other chemicals used were of research highest purity grade.

Onion Collection and Sample Treatment. Cultivated bulbs of onion, *Allium cepa* L. Tropea ecotype, were collected in Tropea (Calabria, Italy), while cultivated bulbs of brown onion, *Allium cepa* L. Montoro type, were kindly provided by local committee promoters of Cipolla Ramata di Montoro (www.cipollaramatadimontoro.it) located in Montoro (Campania, Italy). The name Cipolla Ramata (coppery onion) derives from the color of the external skin of the bulb. This variety is cultivated in a niche geographical area in southern Italy (17 areas within Avellino and Salerno districts).

For each variety, two bulbs were finely chopped and 10 g was extracted with 20 mL of 80% aqueous methanol, at room temperature, on a horizontal shaker. After 10 min, samples were placed in an ultrasonic bath and sonicated for 15 min and then filtered through filter paper. Extracts were then dried in a rotary evaporator (LaboRota 4000/HB Efficient, Heidolph) and stored at −20 °C until being used.

Analysis of Total Phenolic Content and Antioxidant Capacity. Dry extracts were suspended in PBS to obtain a stock solution of 50 mg/mL (w/v) and kept at 4 °C in the dark. This stock solution was used in all biological assays performed in the present study and for the analysis of total phenolic content and antioxidant capacity. The amount of total phenols was determined according to the Folin−Ciocalteu procedure[29−31] with quercetin as a reference standard. Briefly, 50 μL of Folin−Ciocalteu's reagent and 500 μL of distilled water were added to 10 μL of suitable aqueous dilution of the stock solution (50 mg/mL, w/v). The reaction mixture was mixed and allowed to stand for 2 min. Finally, 0.1 mL of sodium carbonate and 0.34 mL of distilled water were added, and the solution was incubated in the dark for 120 min. The sample's absorbance was measured at 760 nm. The results were expressed as micromolar equivalent of quercetin (QE) in 1 mg/mL onion extracts. All measurements were carried out in triplicate.

The antioxidant capacity of different onion extracts was determined by a ferric reducing antioxidant power (FRAP) assay, as reported,[32] and results were calculated as micromolar QE in 1 mg/mL of the two onion extracts.

Ascorbic acid (AA) content in onion extracts was determined by the ferric reducing ascorbate (FRASC) method.[33] Samples were treated with 10 international units of ascorbate oxidase/mL, diluted in FRAP solution (20 mM $FeCl_3$ and 10 mM TPTZ in acetate buffer, pH 3.5), and finally incubated for 5 min at 37 °C. The absorbance was measured at 595 nm, and micromolar concentrations of AA were calculated by use of a standard curve.

HPLC-UV Analyses. Extracts from cultivated bulbs of the two different onion types were reconstituted in 1% formic acid and analyzed by HPLC-UV/vis on a HP 1110 series HPLC (Agilent, Palo Alto, CA) equipped with a binary pump (G-1312A) and an UV

DOI: 10.1021/acs.jafc.5b01206
J. Agric. Food Chem. 2015, 63, 5229−5238

detector (G-1314A). Individual phenols were separated on a Hypersil BDS C18 column (250 mm × 4.6 mm, 5 μm) (Thermo, Bellefonte, PA) at a flow rate of 1 mL/min; solvent A was 1% formic acid and solvent B was 1% formic acid in methanol and water (50:50, v/v). After a 5 min hold at 20% solvent B, elution was performed according to the following conditions: from 20% B to 80% B in 22 min, isocratic elution (80% B) for the next 13 min, from 80% B to 95% B in 10 min, followed by 15 min of maintenance. Flavonols were monitored at 340 nm and anthocyanins at 520 nm. Standard curves for each flavonol standard were prepared over a concentration range of 1−180 μg/mL with six different concentration levels and triplicate injections at each level. Quantification of anthocyanins was performed with external calibration curves generated by repeated injections of a fixed volume of standard solutions of cyanidin 3-*O*-glucoside over a concentration range of 0.5−20 μg/mL with five different concentration levels and duplicate injections at each level. All samples were prepared and analyzed in duplicate. Results were expressed as millgrams per kilogram fresh weight (FW).

HPLC-ESI-ITMS^n Analysis. Identification of phenolic compounds in the extracts from cultivated bulbs of the two different onion ecotypes was effected by HPLC coupled to electrospray ionization multistage ion trap mass spectrometry (HPLC/ESI-ITMS^n) on a Surveyor MS micro HPLC coupled with a Finnigan LCQ DECA XP Max ion trap mass spectrometer, equipped with Xcalibur system manager data acquisition software (Thermo Finnigan, San Jose, CA). Individual phenols were separated on a Hypersil BDS C18 column (250 mm × 2.1 mm, 5 μm) (Thermo, Bellefonte, PA) at a flow rate of 200 μL/min. The HPLC conditions were as described for the HPLC-UV system. Mass spectra were recorded from mass-to-charge ratio (m/z) 50 to 1200 both in negative and in positive ionization mode. The capillary voltage was set at −13 V, the spray voltage was 4.5 kV, and the tube lens offset was −15 V in negative-ion mode, while in positive-ion mode the capillary voltage was set at 38 V, the spray voltage was 3 kV, and the tube lens offset was 50 V. The capillary temperature was 275 °C. Data were acquired in MS, MS/MS, and MS^n scanning modes.

Low-Density Lipoprotein Oxidation. The assay was performed by incubating 0.1 mL of LDL (200 μg of protein) with or without onion extracts (0.25 mg/mL, w/v) for 15 min, and then oxidation was induced by adding 50 μM $CuSO_4$ at 37 °C for 15 h. Subsequently, 0.9 mL of FOX reagent (1 mM xylenol orange, 2.5 mM ferrous ammonium sulfate, and 4.4 mM BHT in methanol) was added to each sample. After 30 min, samples were centrifuged in a microfuge at maximal speed for 5 min, and absorbance of the supernatants was detected spectrophotometrically at 560 nm. Values were expressed as hydrogen peroxide equivalents.[30,34]

Blood Samples. Whole blood samples were obtained from 16 healthy donors, collected in ethylenediaminetetraacetate (EDTA) -treated tubes and immediately used. All blood samples were obtained after informed consent. Erythrocytes were isolated by centrifugation, 2000*g* for 15 min, to remove plasma, platelets and buffy coat and washed twice in PBS. Erythrocyte pellets were suspended in PBS, and aliquots of 1.2×10^5 cells/μL were used in all experiments presented.

Reaction of Human Erythrocytes with HOCl and Hemolysis Assay. NaOCl was diluted with PBS, and the pH of the solution was adjusted to 7.4 immediately before use. At this pH, the solution contains approximately equimolar amounts of HClO and NaOCl and is referred to hereafter as HClO.[35]

Diluted erythrocytes in PBS (1.2×10^5 cells/μL) were pretreated with onion extracts at the indicated concentrations for 45 min and then 0.3 mM HClO was added for 15 min at 37 °C. After incubation with HClO, samples were centrifuged at 2000*g* for 2 min, and percent hemolysis was determined spectrophotometrically at 540 nm.[24]

Glutathione Measurement and Catalase Assay. In parallel with the hemolysis assay, glutathione (GSH) concentration and catalase enzymatic activity were measured. GSH determination was evaluated by a spectrofluorometric method. Following treatments, erythrocyte pellets were washed with PBS and then proteins were precipitated with TCA (5.0% v/v final concentration in 0.1 M HCl and 10 mM EDTA). Fluorescence of the supernatants was measured at 340 nm (excitation wavelength) and 460 nm (emission wavelength). GSH concentration was calculated from a standard curve and reported as a percentage compared to controls (untreated samples).[24]

To determine catalase activity, after treatment, erythrocytes were diluted with cold distilled water, ethanol, and chloroform (1.5:1:1 v/v/v) to precipitate the hemoglobin. Samples were shaken vigorously and centrifuged at 13000*g* for 3 min, and the water−ethanol layer was used. Catalase activity was evaluated as the first-order kinetic constant of the rate of disappearance of H_2O_2, measured by absorbance at 240 nm, as reported previously.[36] Values were expressed as specific activity of the samples and reported as a percentage of control (untreated sample).

Statistical Analysis. Data are presented as mean values ± standard deviation (SD). For LDL oxidation, hemolysis assay, GSH measurement, catalase assay, and concentration of individual and total polyphenolics determined by HPLC, significance was measured by use of Student's t test. Number of determinations is reported in the figure legends.

RESULTS AND DISCUSSION

Total Polyphenol Content and Antioxidant Activity. Total phenolic content of onion extracts indicate that the highest content of total polyphenols was found in Tropea onion ecotype (29.35 μM QE). They were 2.3-fold higher than those present in Montoro onion (12.68 μM QE) (Table 1). As expected, considering the result of the Folin−Ciocalteu assay, the antioxidant capacity was proportional to the polyphenol content, with RTO showing the highest values, which were about 3-fold higher than COM extract (Table 1).

Table 1. Concentration of Total Polyphenols and Antioxidant Activity of Tropea and Montoro Onion Bulb Extracts[a]

	Tropea red onion (μM QE)	Montoro copper onion (μM QE)	P
total polyphenols[b]	29.35 ± 0.03	12.68 ± 0.02	8.91×10^{-5}
antioxidant activity[c]	4.79 ± 0.02	1.67 ± 0.01	8.67×10^{-5}

[a]With reference to 1 mg/mL (w/v) extract. Results are expressed as average (mean) concentration ± SD of triplicates. [b]By Folin−Ciocalteu method. [c]By ferric reducing antioxidant power (FRAP) assay.

While for COM no previous data were reported in the literature on its total polyphenol content and antioxidant activity to allow a comparison with our results, the information on red onion ecotypes is widely available. Although the use of different extraction protocols complicates the comparison among data from different articles, our determinations are comparable to those reported by others. As an example, Marotti and Piccaglia[37] measured a total amount of flavonoids in the ecotype Tropea rossa tonda of 762.9 mg/kg, not far from 632.82 mg/kg of total flavonols reported in Table 3. In three red ecotypes from Spain, total flavonols ranged between 211.7 and 304.3 mg/kg, lower than Tropea onion but of the same order of magnitude.[2] Comparative evaluation of antioxidant capacity appears more complicated because of the different methods and units used to measure it. However, in general, red onion ecotypes present higher values of antioxidant capacity independently from the scale of color. A good example in this sense is reported by a Turkish group who demonstrated that, in 14 different cultivars differing in color, the red onions had higher antioxidant activities than yellow and white onions although the former had the richest phenolic contents.[15]

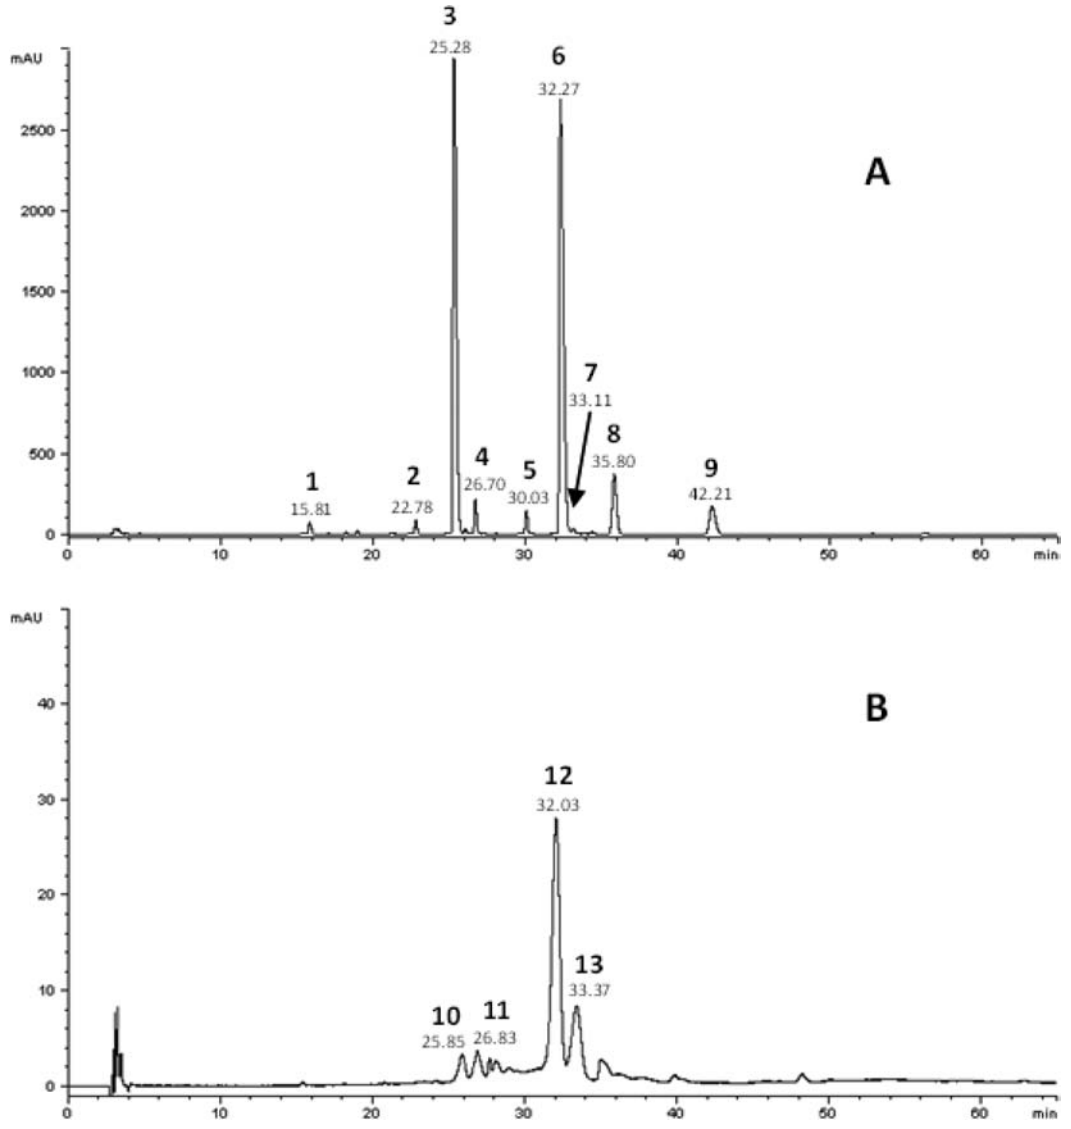

Figure 1. HPLC chromatograms of extract from cultivated bulbs of *Allium cepa* L. Montoro type, recorded at (A) 340 nm and (B) 520 nm. Peaks are labeled according to Table 2.

Identification and Quantification of Polyphenols in the Two Different Onion Extracts. HPLC-UV/vis chromatograms of extract from cultivated bulbs of *Allium cepa* L. Montoro type are shown in Figure 1. Nine flavonols and four anthocyanins were identified and quantified (Tables 2 and 3). The main flavonols found in this onion type were quercetin 3,4′-di-*O*-glucoside and quercetin 4′-*O*-glucoside (spiraeoside), which accounted for ∼85% of the total flavonol content. Results obtained from HPLC-UV/vis and ESI−ITMS^n analyses of Tropea ecotype onion and the total phenolic content measured by HPLC-UV/vis (expressed as mg/kg FW) are also reported in Table 3. RTO showed a higher content of flavonols (632.82 mg/kg FW) than COM (252.91 mg/kg FW). Only kaempferol 3-*O*-glucoside was present in COM and absent in RTO. More pronounced were the differences existing between the four anthocyanins detected in the two ecotypes, with those in RTO present at concentrations between 20-fold (peak 12 in Table 3) and 230-fold (peak 10 in Table 3) higher than in COM. All these differences, including the significant difference in anthocyanin content, may justify the high level of antioxidant capacity measured in RTO (Table 1).

As to anthocyanins, both RTO and COM contained cyanidin glucosides, acylated or not with malonic acid (Tables 2 and 3), which are known to be present in various cultivars of red onions.[3,38,39] The presence of delphinidin and petunidin derivatives has been reported in RTO.[3,4] However, our analyses did not confirm these results. In fact, the HPLC analysis at 340 nm of RTO, specifically used for monitoring flavonols, showed the presence of two very intense peaks at t_R 25.35 and 32.51 min and minor peaks at t_R 26.72 and 36.01 min (data not shown). Compounds present in these fractions produced molecular ions at m/z 627, 465, 641, and 479 respectively, in ESI−ITMS^n analysis carried out in positive-ion mode and were identified as flavonols quercetin 3,4′-diglucoside, quercetin 4-*O*-glucoside, isorhamnetin 3,4′-diglucoside, and isorhamnetin 4′-glucoside. In addition, ESI−ITMS^n analysis of these fractions carried out in negative-ion mode further confirmed the presence of these flavonols (Table 3). In contrast, compounds originating at the same m/z values (m/z 627, 465, 641 and 479) were previously identified as delphinidin and petunidin derivatives.[3,4] It is important to note that quercetin and delphinidin, as well as isorhamnetin and petunidin, displayed

peak	t_R (min)	$[M - H]^-$ (m/z)	MS/MS ions (m/z)	identification
1	15.81	787	625, 463, 301	quercetin 3,7,4′-triglucoside
2	22.78	625	463, 301	quercetin 7,4′-diglucoside
3	25.28	625	463, 301	quercetin 3,4′-diglucoside
4	26.70	639	477, 315	isorhamnetin 3,4′-diglucoside
5	30.03	463	300	quercetin 3-*O*-glucoside[a]
6	32.27	463	301	quercetin 4′-*O*-glucoside
7	33.11	447	285	kaempferol 3-*O*-glucoside
8	35.80	477	315	isorhamnetin 4′-glucoside
9	42.21	301	179, 151	quercetin
peak	t_R (min)	$[M]^+$ (m/z)	MS/MS ions (m/z)	identification
10	25.85	449	287	cyanidin 3-glucoside
11	26.83	611	449, 287	cyanidin 3-laminaribioside[b]
12	32.03	535	449, 287	cyanidin 3-(6″-malonylglucoside)
13	33.37	697	535, 449, 287	cyanidin 3-malonyllaminaribioside[c]

[a]Also known as isoquercitrin. [b]Also known as cyanidin 3-glucosylglucoside. [c]Also known as cyanidin 3-malonylglucosylglucoside.

the same m/z value in the mass spectrum in positive ESI mode (m/z 303 pseudomolecular ion $[M + H]^+$ for quercetin and protonated molecular ion M^+ for delphinidin; m/z 317 pseudomolecular ion $[M + H]^+$ for isorhamnetin and protonated molecular ion M^+ for petunidin). Moreover, quercetin 3,4′-diglucoside, quercetin 4-*O*-glucoside, isorhamnetin 3,4′-diglucoside, and isorhamnetin 4′-glucoside originated MS/MS spectra in positive-ion mode very similar to those of delphinidin (glucosyl glucoside), delphinidin-3-glucoside, petunidin (glucosyl glucoside), and petunidin glucoside, respectively, so that, in this case, tandem mass spectrometry does not lead to a definite discrimination of these compounds and accurate HPLC data are crucial to achieve a conclusive result. In order to rule out the presence of at least delphinidin 3-glucoside, the corresponding standard was analyzed by HPLC-UV/vis under the reported experimental condition. In agreement with the elution order reported by Wu and Prior,[40] the retention time of this compound (t_R 22.64 min) was lower than that of cyanidin 3-glucoside (t_R 25.88) and of any peak in our HPLC chromatogram (Figure 2), thus definitively ruling out the presence of delphinidin-3-glucoside in RTO.

Effect of Onion Extracts on Oxidized Low-Density Lipoprotein. To confirm the antioxidant role of onion extracts and to highlight potential differences between them, we evaluated their ability to reduce the oxidative state of LDL (Figure 3). We incubated commercial LDL with 50 μM Cu^{2+} for 15 h to obtain oxidized LDL. Pretreating isolated LDL for 30 min with 0.25 mg/mL (w/v) onion extracts resulted in a strong and significant reduction in oxidized LDL (Figure 3). The extracts derived from COM and RTO were tested at the same final concentration of 0.25 mg/mL, corresponding to 3.1 and 7.2 μM QE, respectively. Therefore, although the relative polyphenolic amounts of COM was 2.3-fold lower than RTO, they exerted a similar and significant protective effect when compared to oxidized LDL (Cu^{2+} bar in Figure 3), while the difference between RTO + Cu^{2+} and COM + Cu^{2+} time points was not significant. These data suggest that the higher antioxidant capacity of RTO, emerging from Table 1, does not reflect an increased protective activity against LDL oxidation compared to COM.

Protective Effect of Onion Extract against Erythrocyte Oxidative Damage. From the previous results, we hypothesized that the antioxidant activity of the two onion extracts

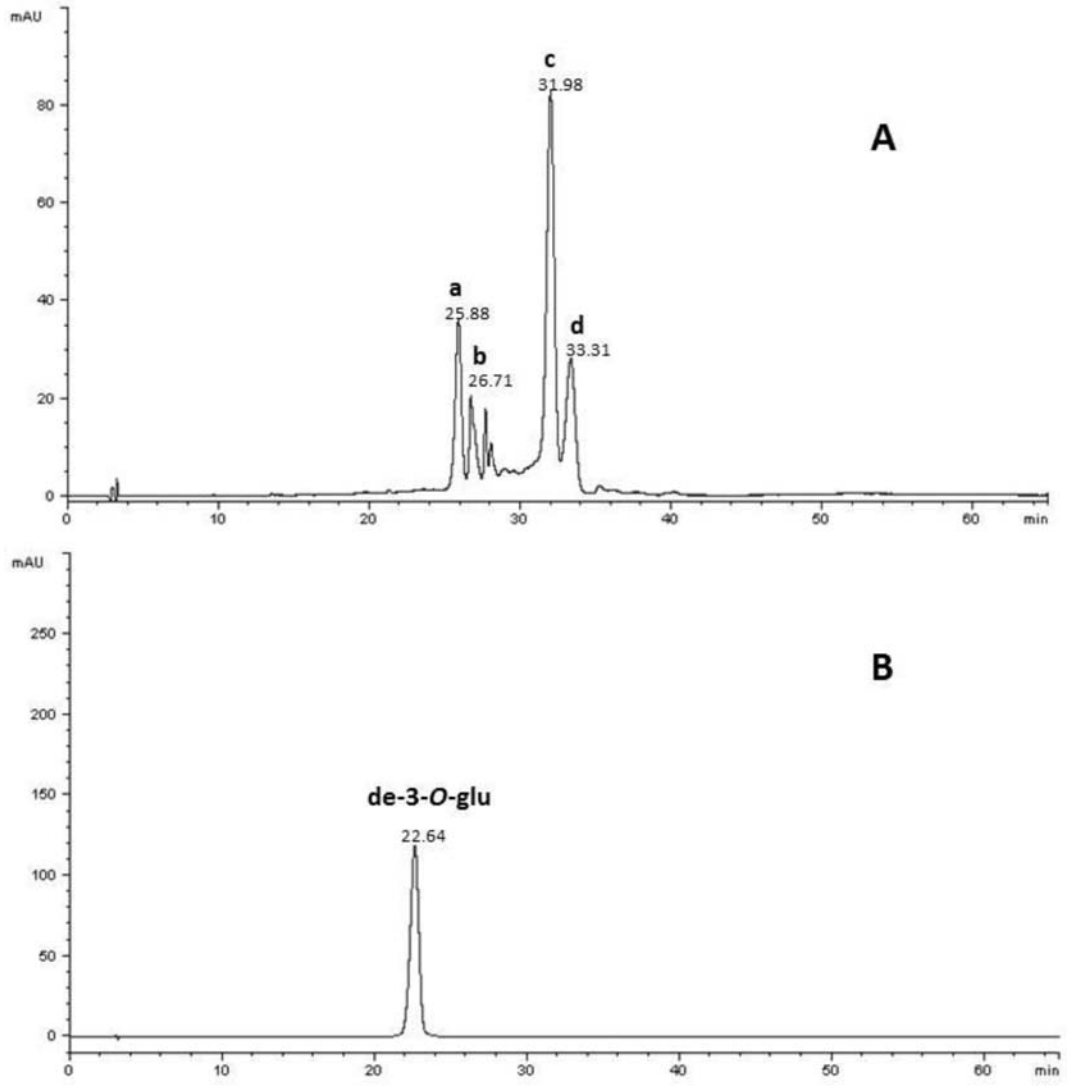

Figure 2. HPLC chromatograms of (A) extract from cultivated bulbs of *Allium cepa* L. Tropea ecotype recorded at 520 nm, with peaks (a) cyanidin 3-glucoside, (b) cyanidin 3-laminaribioside [cyanidin 3-glucosylglucoside], (c) cyanidin 3-(6″-malonylglucoside), and (d) cyanidin 3-malonyllaminaribioside [cyanidin 3-malonylglucosylglucoside]; and of (B) delphinidin 3-*O*-glucoside standard (de-3-*O*-glu).

(Table 1 and Figure 3) could be protective in maintaining redox homeostasis in human erythrocytes. On the basis of this model, we stimulated RBCs isolated from 16 healthy donors, with 0.3 mM HClO to obtain hemolysis of about 25% (Figure 4). Pretreating with 0.25 mg/mL (w/v; corresponding to 3.1 μM QE COM and 7.2 μM QE RTO) of the two onion extracts for 45 min resulted in a significant protective effect against HClO-induced hemolysis of 15% and 17% for RTO and COM, respectively (Figure 4a). The selected concentration applied (e.g., 0.25 mg/mL) was not hemolytic per se; moreover, from previous data we deduce that the total concentration of polyphenols applied in our assay was of the same order of magnitude as that reachable in vivo following ingestion of an amount of onion enough to bring the blood concentration of quercetin near 1 μM.[41−43]

It is worthwhile to note that also in this case, as above for LDL oxidation, the two onion types induced a similar protective effect, despite the 2.31- and 2.86-fold higher amount of polyphenolic content and antioxidant capacity in RTO compared to COM, respectively (Table 1). To better clarify this point, we treated RBCs with equal concentrations of polyphenols (final concentration 2.7 μM QE). In this case, the total amount of polyphenols expressed as QE in our assays was 0.963 μg for RTO and 0.978 μg for COM. As reported in Figure 4b, we observed that COM significantly protected RBCs against HClO-induced hemolysis, while the limited reduction observed for RTO was not significant compared to the control (HClO bar). Mathematical elaboration of data presented in Figure 4 (data not shown) indicates that, to increase by 1% the protective effect of RTO against HClO, 0.208 μg QE of extract is necessary. In the case of COM, only 0.081 μg QE (2.5-fold less) is sufficient. This calculation further demonstrates the higher efficacy of COM extract compared to RTO.

In addition, we can exclude that the presence of AA could contribute to the protection from HClO damage shown in Figure 4. In fact, upon measuring by FRASC assay the AA amount present in 0.25 mg/mL COM and RTO extracts, we observed that AA was null in RTO and present at a concentration of 0.277 μM in COM. When we repeated the assay in the presence of AA in a wide range (0.11−0.55 μM), no reduction of HClO-dependent hemolysis was observed (data not shown).

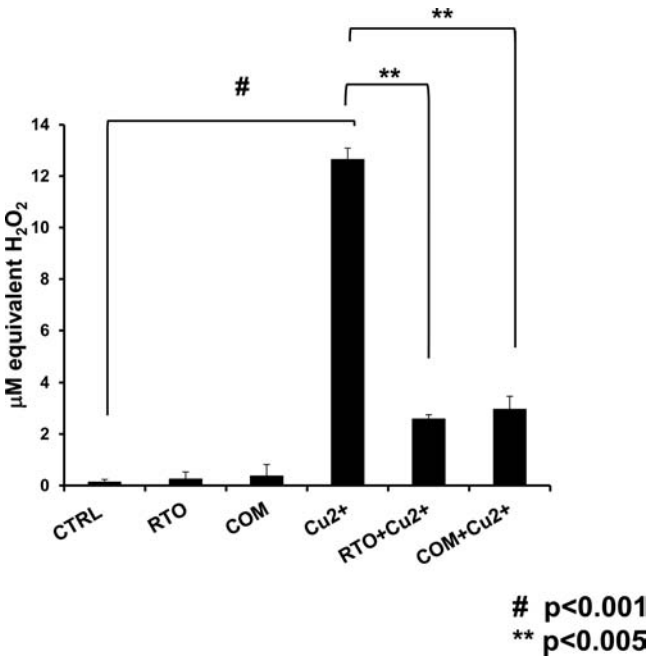

Figure 3. Effect of onion extracts on LDL oxidation. LDL were incubated for 30 min in the presence of 0.25 mg/mL (w/v) of the two different onion extracts before addition of 50 μM Cu^{2+} for 15 h. At the end of treatment, FOX assay was performed to determinate the level of H_2O_2 generated following LDL oxidation. Bar graphs represent the mean ± SD. Experiments were carried out in duplicate. Symbols indicate significance: (#) $p < 0.001$ with respect to untreated LDL (CTRL), (**) $p < 0.005$ with respect to Cu^{2+}-treated samples.

Effects of Onion Extracts on Antioxidant Defenses in Human Erythrocytes. RBCs excellently regulate intracellular oxidative stress; in fact, through the combined activities of GSH peroxidase, catalase, superoxide dismutase (SOD), and shunting of hexose monophosphate, they are able to protect themselves against ROS.[44] We measured GSH level in RBCs isolated from 16 healthy donors, pretreated with 0.25 mg/mL COM and RTO extracts (corresponding to 3.1 and 7.2 μM QE, respectively) for 45 min before HClO addition. As a consequence of HClO treatment, we observed about 50% reduction in GSH concentration present in RBCs. Pretreatment with onion extracts induced a recovery of GSH level of about 22% and 15% for RTO and COM, respectively (Figure 5a). Data were significant for the former, and the trend of increased production of GSH was confirmed in COM. Similarly to diseases associated with increased production of ROS, the presence of a strong electrophile, such as HClO, causes rapid consumption of GSH in RBCs,[24,45] and restoration of the normal erythrocyte GSH concentration has been shown to have a positive therapeutic effects.[45,46] The protective role of onion extracts against oxidative stress was also confirmed by their effect on catalase activity, which increases 2.3-fold compared to basal level after HClO treatment and decreases after pretreatment with the two onion extracts (Figure 5b).

We hypothesized that treatment of whole human blood with a HClO concentration not far from that reachable in vivo following an inflammatory process induces large hemolysis in RBCs, caused by a burst of intracellular ROS. Pretreatment of whole blood with onion extracts generates a protective effect against HClO-induced hemolysis. We postulated that the bioactive compounds in RTO and COM extracts trigger downstream events leading to increased GSH concentration,

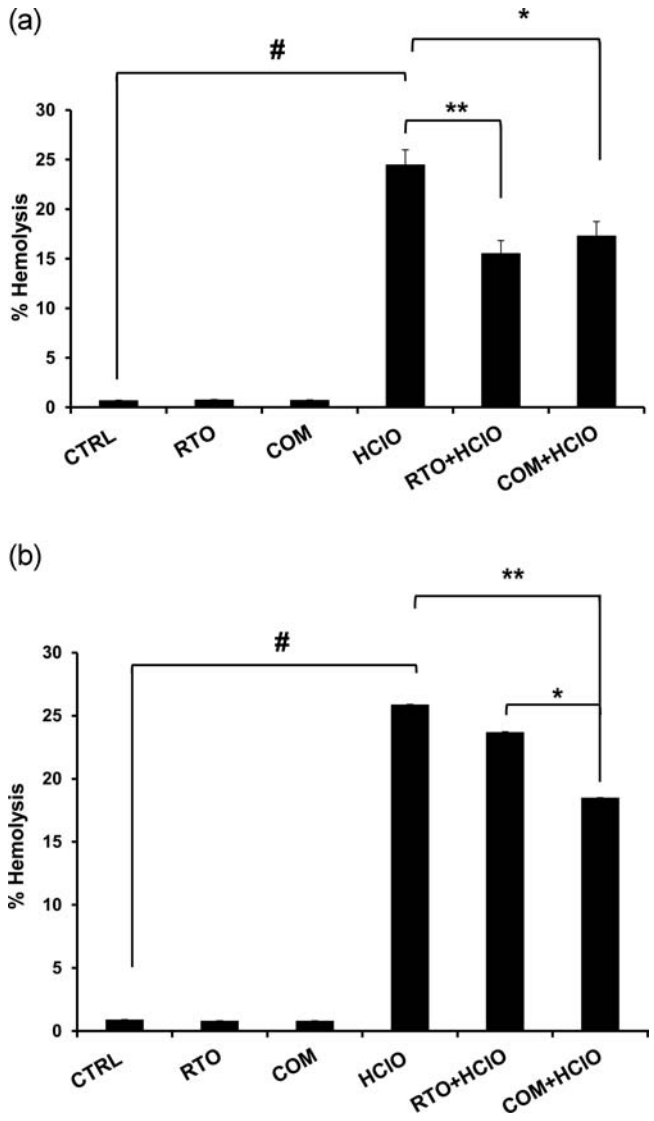

Figure 4. Effect of onion extracts on hemolysis of human erythrocytes. (a) RBCs from 16 healthy donors (in duplicate) were stimulated with 0.25 mg/mL extracts prepared from the two different onion cultivars and incubated for 45 min at 37 °C. (b) RBCs were stimulated with 50 μM QE (final concentration in the assay 2.7 μM QE). Following incubation with the onion extracts, samples were treated with 0.3 mM HClO for 15 min at 37 °C and percentage of hemolysis was measured. Bar graphs represent the mean ± SD. Symbols indicate significance: in panel a, (#) $p < 0.0001$ with respect to untreated RBCs (CTRL) and (*) $p < 0.005$ and (**) $p < 0.0005$ with respect to HClO; in panel B, (#) $p < 0.0001$ with respect to untreated RBCs (CTRL), (*) $p < 0.05$ for RTO + HClO vs COM+HClO, and (**) $p < 0.005$ for COM +HClO vs HClO.

which in turn protects erythrocytes from subsequent oxidative damage caused by HClO (Figure 5). How molecules present in the extracts are responsible for de novo GSH synthesis is actually under investigation in our laboratory. A model for GSH synthesis and turnover in the human erythrocyte has been recently published and represents the starting point for future studies.[47]

We described for the first time to our knowledge the flavonoid composition of a new ecotype of red onion, the coppery onion, cultivated in a well-limited area of about 40 ha within the districts of Avellino and Salerno in southern Italy.

DOI: 10.1021/acs.jafc.5b01206
J. Agric. Food Chem. 2015, 63, 5229−5238

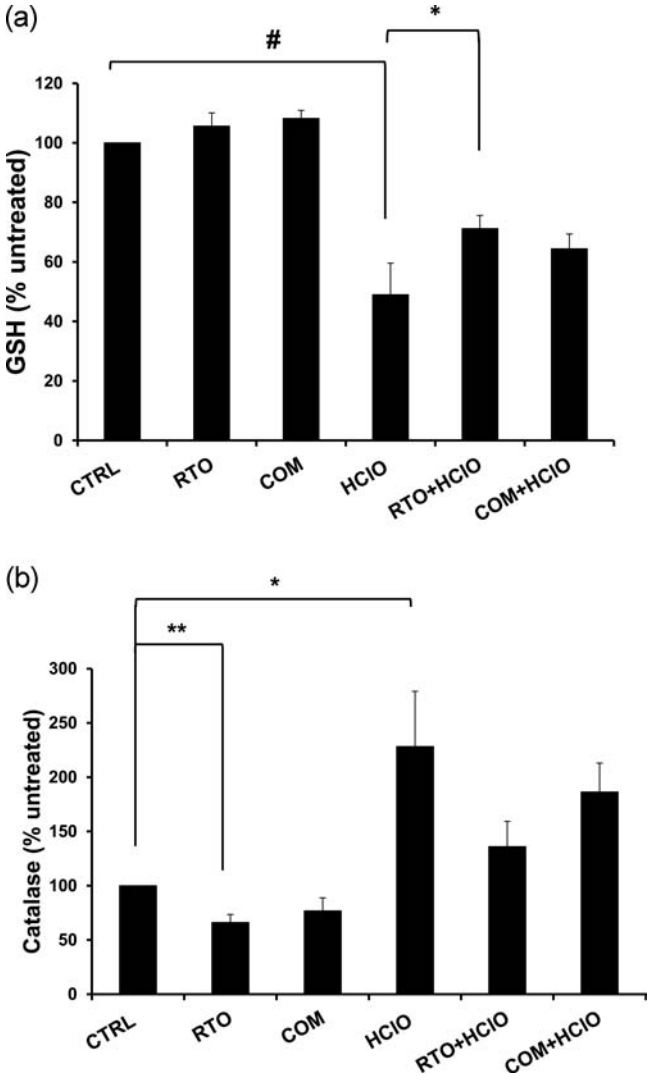

Figure 5. Effects of onion extracts on human erythrocyte antioxidant defense: (a) glutathione (GSH) and (b) catalase levels. (a) GSH content was determined after treatment of RBCs with 0.25 mg/mL extracts prepared from the two different onion cultivars. After 45 min of incubation, samples were treated with 0.3 mM HClO for 15 min at 37 °C. At the end of treatment, RBCs were lysed and phthaldialdehyde was used as a substrate, and GSH levels were measured spectrofluorometrically. (b) Catalase activity was measured in hemolysates prepared from RBCs treated as reported above and compared to untreated samples. Bar graphs represent the mean (expressed as percentage of untreated) ± SD of determinations performed on samples (in duplicate) derived from (a) 16 or (b) 11 healthy donors. Symbols indicate significance: in panel a, (#) $p < 0.0001$ with respect to untreated samples (CTRL) and (*) $p < 0.05$ with respect to HClO treatment; in panel b, (**) $p < 0.005$ and (*) $p < 0.05$ with respect to untreated samples (CTRL).

We also characterize the protective effects of COM against oxidative stress experimentally induced on LDL and RBCs. COM was compared to a red onion variety, RTO, selected for its close geographic origin (southern Italy), high concentration of polyphenols[15,37] and larger commercial distribution. From our study an important observation emerged: although total polyphenol concentration and single flavonoid compounds were both significantly higher in RTO compared to COM, the biological activity was comparable or even more pronounced in COM. This result led us to formulate the following hypotheses: (1) Qualitative compositions differ in the flavonol and anthocyanin families in the two ecotypes. (2) Synergistic associations within the pool of flavonoids in COM result in enhanced antioxidant capacity compared to RTO. (3) Polyphenols in red and coppery onions are not directly responsible for the protective antioxidant effect, which in turn can be attributed to compounds of unknown chemical structure present in relatively comparable amounts in the two extracts. (4) It may be possible that, at least for RBCs, the protective effect of onion extracts, resulting in the reconstitution of depleted intracellular GSH pools, occurs by mechanisms independent from the antioxidant activity of the extracts and involving specific binding to intracellular targets. Hypotheses 3 and 4 require intense experimental efforts, currently in progress, to be verified.

We focused our attention on the different polyphenolic composition between the two ecotypes. Data reported in Tables 2 and 3 indicate that in COM anthocyanins are almost absent (about 0.46% of the total) compared to those present in RTO (4.54%), a difference of about 1 order of magnitude. This may suggest that in Figure 4b, when we assayed comparable amount of QE, the relative abundance of anthocyanins in RTO could counteract the antioxidant effect of the flavonols present. However, initial attempts to identify a cause−effect relationship between the flavonol/anthocyanin ratio and protection from oxidative damage in erythrocytes did not provide conclusive answers.

Perhaps we are facing a situation not totally novel regarding the mechanisms of action of phenolic compounds. In fact, several cases exist in the literature demonstrating that flavonoids may exert their biological activities independently from the capacity to scavenge ROS. Quercetin represents a perfect example in this context, as we largely demonstrated in leukemic cell lines resistant to apoptotic stimuli.[48−50]

In summary, the present work reports for the first time the chemical characterization of polyphenols present in a new variety of onion from southern Italy and suggests that the phenolic-enriched extract prepared from this ecotype exerts a protective effect against oxidative damage in LDL and human erythrocytes. We also highlighted the possibility that synergistic combination of specific phenolic compounds and/or the contribution of uncharacterized molecules may explain the quantitative differences in biological activities measured when extracts derived from different onion varieties are compared.

ABSTRACT: Ozonation of uncooked corn mash from the POET BPX process was investigated as a potential disinfection method for reducing bacterial contamination prior to ethanol fermentation. Corn mash (200 g) was prepared from POET ground corn and POET corn slurry and was ozonated in 250 mL polypropylene bottles. Lactic and acetic acid levels were monitored daily during the fermentation of ozonated, aerated, and nontreated corn mash samples to evaluate bacterial activity. Glycerol and ethanol contents of fermentation samples were checked daily to assess yeast activity. No yeast supplementation, no addition of other antimicrobial agents (such as antibiotics), and spiking with a common lactic acid bacterium found in corn ethanol plants, *Lactobacillus plantarum*, amplified the treatment effects. The laboratory-scale ozone dosages ranged from 26−188 mg/L, with very low estimated costs of $0.0008−0.006/gal ($0.21−1.6/m^3) of ethanol. Ozonation was found to decrease the initial pH of ground corn mash samples, which could reduce the sulfuric acid required to adjust the pH prior to ethanol fermentation. Lactic and acetic acid levels tended to be lower for samples subjected to increasing ozone dosages, indicating less bacterial activity. The lower ozone dosages in the range applied achieved higher ethanol yields. Preliminary experiments on ozonating POET corn slurry at low ozone dosages were not as effective as using POET ground corn, possibly because corn slurry samples contained recycled antimicrobials from the backset. The data suggest additional dissolved and suspended organic materials from the backset consumed the ozone or shielded the bacteria.

KEYWORDS: *ozonation, no-cook, BPX process, corn mash, fuel ethanol, bacteria, dry-grind ethanol, lactic acid*

INTRODUCTION

POET leads the fuel ethanol industry in streamlining corn dry milling to improve ethanol production efficiency, as well as with their feed coproduct, Dakota Gold BPX distiller grains. The efficient BPX, or no-cook, process involves raw starch hydrolysis that, like the conventional process, adds enzymes to convert starch to sugars and adds yeast to ferment sugars to ethanol but without the cooking step.[1] The BPX process is now used by 24 of the 27 POET biorefineries. POET produces over 1.5×10^9 gal (5.7×10^6 m^3) of ethanol annually in a network spanning seven Midwestern states.

The POET BPX process for dry-grind corn ethanol production has important advantages over the conventional process. The energy-intensive liquefaction and cooking steps are omitted, thus reducing plant energy requirements by 8−15%.[1] The BPX process achieves higher ethanol yields by improving starch accessibility, lowers volatile organic carbon (VOC) emissions, cuts cooling water needs, and enhances the nutrient quality, flowability, and anticaking properties of the distillers dried grains with solubles (DDGS) coproduct. Amino acid digestibility in DDGS samples varies considerably among conventional ethanol facilities, attributable to heat damage from corn mash cooking and DDGS drying.[2−5] Heat damage is responsible for lower amino acid digestibility in DDGS than in corn grain.[4,6] Removing the cooking step, therefore, improves the feed quality of Dakota Gold BPX DDGS over conventional DDGS by reducing heat damage of the protein.[7]

Unlike most beverage alcohols, fuel ethanol fermentations are not conducted under pure culture conditions.[8] High-temperature jet cooking (90−165 °C) in the conventional process not only gelatinizes the corn starch but also helps reduce contamination and yield losses caused by unwanted lactic acid bacteria (LAB).[9] Contamination in fuel ethanol fermentations originates from bacteria present on the corn from the fields.[10] Bacteria compete with yeast for nutrients—glucose, trace minerals, vitamins, and free amino nitrogen—and lower ethanol yields by diverting glucose to lactic and acetic acids, which are inhibitory compounds to yeast.[11−13] In addition to yield losses by chronic LAB contamination, acute infections arise unpredictably and can result in plant shutdowns for cleaning, resulting in expensive losses in productivity.[8,13,14]

Gram-positive and Gram-negative bacterial isolates from fuel ethanol production include species of *Pediococcus*, *Enterococcus*, *Acetobacter*, *Gluconobacter*, *Clostridium*, and *Lactobacillus*.[8,15] *Lactobacillus* sp. are the most prevalent in the industry and are ubiquitous in nature. In a study of two commercial dry-grind ethanol plants by Skinner and Leathers,[8] the genus *Lactobacillus* was isolated most frequently, representing 38% and 77% of total bacterial isolates from the first and second plants,

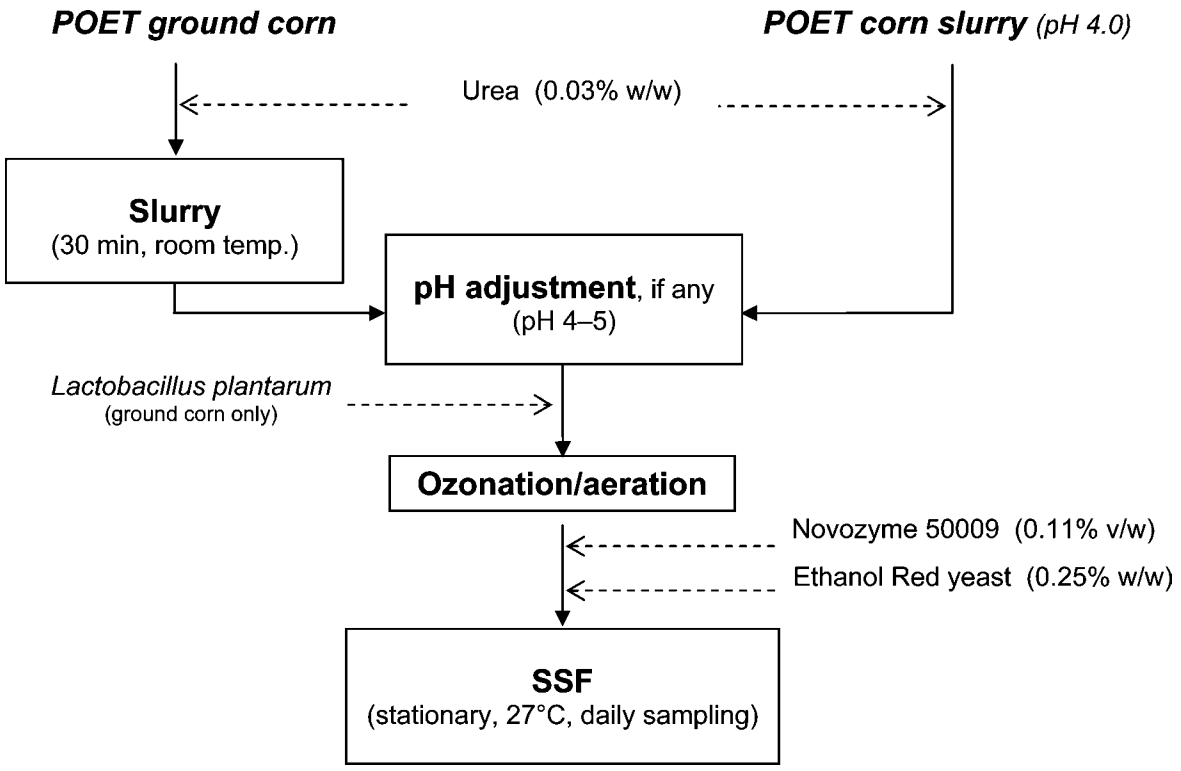

Figure 1. Corn mash preparation, ozonation/aeration, and fermentation with POET ground corn and POET corn slurry.

respectively. Gram-positive LAB are ethanol-tolerant, grow faster than yeast, and produce organic acids that inhibit yeast.

During this research, bacterial growth was controlled at POET biorefineries potentially by dosing with antibiotic and antimicrobial agents and by operation at lower pH levels (pH~ 4.2). Conventional ethanol plants, despite jet cooking, also add antibiotics to fight chronic or acute bacterial infections.[8,16−18] If no antibiotics are used, it is common for a facility to lose 1−5% of its potential ethanol yield.[10] Rising concerns about the use of antibiotics and the emergence of antibiotic-resistant bacteria are creating a demand for alternative methods of controlling bacteria.

Cleaning and sanitation are important microbial control measures in the corn ethanol industry. Infections in process tanks and continuous yeast propagators, as well as resistant biofilms within the process train, can continually reintroduce bacterial contaminants into the fermentors.[8,19] Large yeast inocula (≥2% v/v) help control contamination during fermentations; however, yeast growth and fermentation rates are still reduced by high lactobacilli concentrations.[20]

Penicillin and virginiamycin are the antibiotics available commercially for fuel ethanol production.[15,21] Virginiamycin, produced by *Streptomyces virginiae*, has had limited use in human medicine but extensive use as a growth-promoting additive in animal feed.[22] The recommended dose of virginiamycin in fuel ethanol fermentations is 0.25−2.0 ppm.[23] The use of antibiotics has limitations. Commercial antibiotic applications are essentially selection experiments for resistant microorganisms. Hynes et al.[23] observed reductions in the effectiveness of virginiamycin after extended fermentations, possibly resulting from its breakdown by lactobacilli.[24] *Lactobacillus* sp. with higher tolerance to virginiamycin have been isolated from fuel ethanol plants that dose with virginiamycin. Moreover, bacterial isolates have emerged with resistance to both virginiamycin and penicillin.[15,25]

Hop acids offer a natural alternative to antibiotics for fuel ethanol production.[10] Many of the organic acids found in hops exhibit antimicrobial activities. Hop compounds inhibit growth by disrupting the transmembrane pH gradient of microbes.[26,27] Hops have long been used in the brewing industry to contribute to the flavor of beer, by adding bitterness and aroma, and to improve product shelf life. IsoStab, a liquid hop extract, is a commercially available product for fuel ethanol applications. U.S. producers using IsoStab have obtained higher ethanol yields with less fluctuation.

A variety of disinfectants have been investigated on a laboratory scale for fuel ethanol fermentations, including hydrogen peroxide, chlorine dioxide, potassium metabisulfite, 3,4,4′-trichlorocarbanilide, and lactate with a lactate-tolerant yeast strain.[8,28−33] Bacteria were inhibited over yeast by these agents, but the effectiveness depended on the bacterial strain.[8] Chlorine dioxide and ozonation are common alternatives to chlorination for disinfection of drinking water. Meneghin et al.[30] evaluated the effect of chlorine dioxide against bacteria prevalent in ethanol fermentations (e.g., *Lactobacillus plantarum* and *Lactobacillus fermentum*). The minimum inhibitory concentrations (MIC) for chlorine dioxide on the bacteria and on the yeast inoculum were determined in nutrient media; the effectiveness in nutrient media is likely different from that in the high suspended solids corn mash at fuel ethanol plants. The MICs ranged from 10 to 125 ppm for the bacterial strains tested; *L. plantarum* had the highest MIC of 125 ppm. Yeast growth was also affected at chlorine dioxide concentrations over 50 ppm.

Ozone is a microbial inhibitor that is considered an alternative to chlorine and hydrogen peroxide in food applications.[34] The rate of microbial inactivation is affected

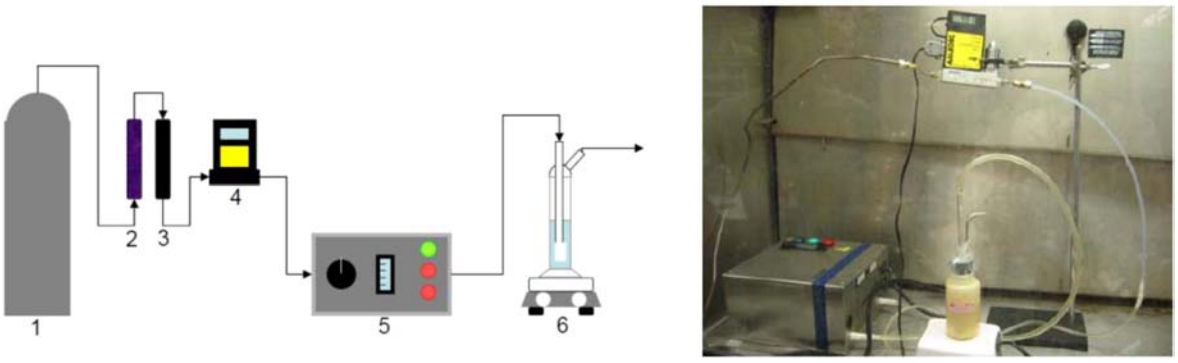

Figure 2. Setup and photo of ozonation of corn mash: (1) compressed air tank, (2) moisture trap, (3) hydrocarbon trap, (4) mass flow controller, (5) corona-discharge ozone generator, and (6) corn mash sample (200 g) in 250 mL PP bottle.

by several environmental factors (concentration of organic compounds, physiological state of the microorganism, pH of the medium, temperature).[35] Thus, ozone has had mixed success in the food industry. García-Cubero et al.[36] illustrated the benefit of pretreatment of straw with ozone, resulting in a reduction in acid-insoluble lignin (Klason lignin) and improved enzymatic hydrolysis of cellulose and hemicelluloses for biofuel production. Freitas-Silva and Venâncio[37] demonstrated mycotoxin degradation by ozone use in corn on the cob, corn kernels, and corn and rice powder. Miller et al.[38] reviewed the advantages and disadvantages of ozonation use for fruits and vegetables preservation, while Gerrity and Snyder[39] review its use in water reuse applications. Thus, the application of ozone in dry-grind corn ethanol production is needed.

Research Objectives. In this research, ozone was used in place of antibiotics (e.g., Lactrol and IsoStab) for control of bacterial contamination in ethanol (yeast) fermentations. Preliminary experiments were subsequently performed on corn slurry to evaluate the effectiveness of ozonation for reducing bacterial contamination under conditions more similar to plant operation, including the contributions of recycled water sources.

MATERIALS AND METHODS

Corn Mash Preparation. Ground corn and corn slurry were obtained from POET Biorefining in Jewell, IA, in the fall and spring of 2007 and 2008. The corn slurry obtained from POET contains the ground corn in a slurry with recycled water streams, such as backset. Figure1 illustrates corn mash preparation, ozone treatment, and simultaneous saccharification and fermentation (SSF) procedures. Corn mash was prepared in 250 mL polypropylene (PP) bottles with 35% (w/w) ground corn (200 g of mash/bottle) and deionized water or with 200 g of corn slurry/bottle. Urea was added (0.03% w/w) as a N source. The final corn mash volume was 186 mL/bottle. Bottles were shaken for 30 min at 250 rpm and room temperature to slurry contents. The pH was adjusted to 5.0 in select experiments. In preliminary work (pH 4.2), all controls with and without Lactrol and/or IsoStab added had similar values for lactic and acetic acids, glycerol, and ethanol, which indicated minimal bacterial contamination even without ozonation (results not shown). Therefore, no antibiotics or other antimicrobials (i.e., Lactrol or IsoStab) were added in these experiments to exemplify treatment effects of ozone. The POET corn slurry experiments, however, potentially contained recycled antimicrobials contributed in the backset from previous fermentations at the plant. Select samples were also LAB-spiked and/or not yeast-supplemented to amplify the differences in treatment effects.

Microorganisms. Select corn mash samples were spiked with *Lactobacillus plantarum*, a lactic acid bacterium, obtained from the American Type Culture Collection (ATCC 14917, Rockville, MD) prior to ozone treatment. Stock cultures of *L. plantarum* were freeze-dried and stored previously in sterile skim milk at 4 °C. Fermentis Ethanol Red (Lesaffre Yeast Corp., Milwaukee, WI), containing the yeast *Saccharomyces cerevisiae*, was added (0.5 g) after ozone treatment for ethanol fermentation.

Ozonation. The laboratory-scale installation used to apply the ozone treatment is shown in Figure 2. Ozone gas was generated from oxygen supplied by a compressed-air gas cylinder by use of a corona-discharge ozone generator (TOG C2B, Trigon, Glasgow, Scotland). Moisture and hydrocarbon traps (Restek, State College, PA) were placed between the ozone generator and compressed-air cylinder to remove impurities in the feed gas. A mass flow controller (GLC17, Aalborg, Orangeburg, NY) was used to control the gas flow rate.

Ozone gas was bubbled into the corn mash samples (200 g) in 250 mL PP bottles at a flow rate of 500 mL/min. The ozone concentration in the gas phase was measured by the potassium iodide titration method.[40] The ozone dose, or consumption, was calculated on the basis of ozone concentrations in the influent and effluent gas from the bottle over time. Corn mash samples were ozonated and residual ozone in off-gas was measured by titration after varying ozonation times. This setup was used to determine the effects of different ozone dosages on ethanol fermentation of corn mash samples prepared from ground corn or corn slurry. Aeration treatment, as a control, was also performed with this equipment. The aeration and ozonation procedures were the same (e.g., similar gas flow rate), but with the ozone generator turned off.

Ethanol Fermentation. Following ozonation, raw starch hydrolyzing enzyme (Novozyme 50009, 0.11% v/w) and Ethanol Red (0.25% w/w) were added to ozonated, aerated, and nontreated corn mash (Figure 1). Bottles were shaken for 2 min at 250 rpm to mix contents and incubated without shaking at 27 °C (POET incubation temperature) until ethanol levels reached a plateau, up to 168 h. SSF samples were HPLC-analyzed on a daily basis.

Sample Analyses. The ethanol, glycerol, lactic acid, and acetic acid contents of corn mash and SSF samples were quantified on a Waters high-pressure liquid chromatograph (HPLC) (Millipore Corp., Milford, MA). The HPLC system was equipped with a Waters model 401 refractive index detector, column heater, automatic sampler, and computer controller. The Aminex HPX-8711 column (300 × 7.8 mm, Bio-Rad Chemical Division, Richmond, CA) separated sample constituents with a mobile phase of 0.012 N sulfuric acid, flow rate of 0.8 mL/min, injection volume of 20 μL, and column temperature of 65 °C.[41]

Experiment Sets. A pH experiment was conducted prior to fermentation. Aeration treatment was included to confirm that ozonation, rather than aeration and mixing, lowered the initial corn mash pH prior to fermentation (0 h).

The ethanol fermentation experiments reported in this publication are divided into three sets, two with POET ground corn and one with POET corn slurry, as outlined in Table 1.

POET Ground Corn (Experiment Sets 1 and 2). Two sets of fermentation experiments with ozone-treated corn mash prepared

Table 1. Experiments Performed with Corn Mash Prepared from POET Ground Corn and POET Corn Slurry[a]

corn mash	treatment	initial pH[b]	LAB spiked	yeast added
	Experiment Set 1			
ground corn	ozone (0−188 mg/L)	5.0	yes	no
ground corn	ozone (0−152 mg/L)	5.0	yes	yes
	Experiment Set 2			
ground corn	none	4.7	no	yes
ground corn	air (60 min)	4.7	no	yes
ground corn	ozone (60 min)	4.7	no	yes
ground corn	none	4.7	yes	yes
ground corn	air (60 min)	4.7	yes	yes
ground corn	ozone (60 min)	4.7	yes	yes
	Experiment Set 3			
corn slurry	none	4.0	no	yes
corn slurry	none	4.0	no	no
corn slurry	none	5.0	no	yes
corn slurry	ozone (60 min)	5.0	no	yes

[a]No antimicrobials were added in these experiments; however, corn slurry obtained from POET contained backset, which potentially has antimicrobials from previous fermentations. [b]Initial pH refers to the pH after adjustment and before treatment. Without adjustment, the pH of corn mash prepared from ground corn was 4.7 and from corn slurry was 4.0.

from ground corn were performed. The first set included spiking with *L. plantarum* before ozone treatment (0−188 mg/L) of corn mash; no yeast and no other antimicrobial agents were added to select bottles to further amplify the treatment effects. The second set included ozonation and aeration treatments of corn mash prior to ethanol fermentation. Select bottles were spiked with *L. plantarum*. Fermentation experiments were conducted with aeration treatment as a control to determine whether lower lactic acid contents in daily samples resulted from ozonation as a disinfect/oxidant or from possible stimulatory effects of aeration on the yeast.

POET Corn Slurry (Experiment Set 3). A preliminary set of fermentation experiments was conducted with POET corn slurry to assess the effectiveness of ozonation for reducing bacterial contamination under conditions more similar to plant operation, including contributions of recycled water streams. The recycled backset potentially contributed other antimicrobials in these experiments. Corn mash samples were prepared with/without addition of yeast, with the slurry initial pH of 4.0 and adjusted to pH 5.0, and with/without ozone treatment, as shown in Table 1.

Statistical Analysis. All treatments were performed in replicates of three. Statistical analysis was carried out with the Statistical Analysis System package (SAS computer program version 9.1.2, SAS Institute Inc., Cary, NC). Student's *t*-test analyses were performed on HPLC data sets to determine statistical significance with a p value of 0.05.

RESULTS AND DISCUSSION

Ozone Dosages. The results of ozonating corn mash samples for various treatment times in order to determine ozone consumption (i.e., ozone dosage) are illustrated in Figure 3. Ozone consumption is the difference between ozone applied to the corn mash, $f(x)$, and unused ozone exiting the headspace of the treated corn mash over time (off-gas), $g(x)$; it equals the green area in Figure 3. The following fitted equations were used to calculate ozone consumption/dosage:

$$\text{applied ozone (mg/min)} = f(x) = 0.996 \quad (1)$$

$$\text{off-gas ozone (mg/min)} = g(x) = 0.00319x + 0.000538x^2 \quad \text{for } 0 \le t \le 37.5 \text{ min} \quad (2)$$

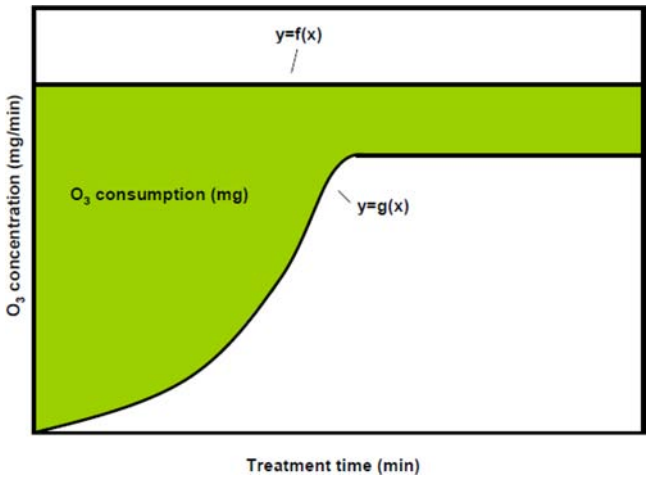

Figure 3. Ozone consumption/dose (green area) as a function of ozonation treatment time for corn mash samples. The curve was fit on the basis of effluent ozone discharge rates, $g(x)$, observed in corn mash over time. The influent ozone application rate was constant, $f(x)$, and $n = 4$.

$$\text{off-gas ozone (mg/min)} = g(x) = 0.884 \quad \text{for } 37.5 \text{ min} \le t \quad (3)$$

$$\int_0^t f(x)\,dx - \int_0^t g(x)\,dx = 0.996t - 0.00159t^2 - 0.000179t^3 \quad \text{for } 0 \le t \le 37.5 \text{ min} \quad (4)$$

$$\int_0^t f(x)\,dx - \int_0^t g(x)\,dx = 0.112(t - 37.5) + 25.7 \quad \text{for } 37.5 \text{ min} \le t \quad (5)$$

The ozone dosages computed for each treatment time are provided in Table 2. In our preliminary work, additional dosages of 26 and 75 mg O_3/L were tested. The higher dosages (127, 152, and 188 mg/L) were chosen for replicate experiments, as reported in this publication.

Table 2. Ozone Dosages Applied to Corn Mash and Estimated Costs in Our Study for Different Ozonation Times

ozonation time (min)	ozone dose[a] (mg of O_3)	ozone dose[b] (mg of O_3/L of corn mash)	est cost[c] ($/1000 gal of ethanol)
5	5	26	0.84
15	14	75	2.39
30	24	127	4.04
60	28	152	4.82
120	35	188	5.97

[a]Ozone dose/consumption was determined by ozonating corn mash samples. The resulting equations used for ozone calculations (milligrams) are $0.996t - 0.00159t^2 - 0.000179t^3$ for $0 \le t \le 37.5$ min and $0.112(t - 37.5) + 25.7$ for $t \ge 37.5$ min. [b]The volume of ozonated corn mash was 0.186 L; ozone dose (milligrams) was divided by this volume. [c]Estimated cost was calculated from ozone dose (milligrams per liter) based on the conversion factor of 3.79 L/gal, an ozone cost of $\$1.68 \times 10^{-6}$/mg, and the assumption of 20% (v/v) final ethanol content (or 1 gal of ethanol to 5 gal of corn mash).

Ozone Cost Estimates. The ozone cost estimates include operating costs to purchase electricity for the ozone generator and to prepare air for the ozonation. The costs of electricity and air are calculated as follows:

DOI: 10.1021/acs.jafc.5b00563
J. Agric. Food Chem. 2015, 63, 5239−5248

electricity consumption of typical ozone generators

$$= 10\ \text{kW·h/kg of ozone} \quad (6)$$

$$\text{electricity} = \$0.07/\text{kW·h} \quad (7)$$

Equation 7represents the 2009 average for industrial consumers.[40]

electricity consumption for air feed drying

$$= \sim 2\ \text{kW·h/kg of ozone} \quad (8)$$

$$\text{total electricity consumption} = 12\ \text{kW·h/kg} \quad (9a)$$

$$\text{total electricity cost} = \$0.84/\text{kg} \quad (9b)$$

Capital costs: since the ozone dosage has not yet been optimized in relation to corn mash formulations in industry, including recycled water sources, the required ozone generator size for a typical plant cannot be determined. As a rough guide, the amortization costs will equal the energy costs. The cost of ozone, therefore, can be expected to amount to roughly $1.68/kg. This cost still needs to be determined to a greater degree of accuracy. Table 2 presents the estimated ozonation costs based on the ozone dosages applied in experiments to date.

Initial pH Experiment. The initial pH of corn mash prepared from ground corn, prior to fermentation (0 h), was adjusted to 4.2 or 5.0. The pH of corn mash samples tended to decrease with increasing ozone treatment times/dosages (Figure 4). The pH of ozonated samples (initial pH 5.0) started to decrease after 15 min of ozonation (75 mg of O_3/L), reaching an average pH of 4.8 in 60 min (152 mg of O_3/L). With an initial pH of 4.2, the corn mash pH was also reduced by 0.2 pH unit to 4.0 after 60 min of ozonation. Aeration with the same procedure, but no ozone generated, did not affect the corn mash pH. This finding shows that the ozone or ozone byproducts, rather than aeration and additional mixing, were responsible for the corn mash pH reductions observed in all experiments with ground corn.

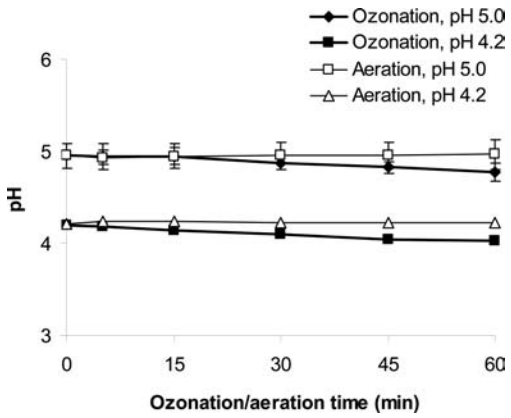

Figure 4. Initial pH experiment: changes in pH observed during ozonation and aeration of corn mash samples prepared from ground corn and adjusted to different initial pH values, 5.0 (n = 3) and 4.2 (n = 1).

Corn mash samples were analyzed by HPLC before and after treatment to detect any changes in concentrations, in particular for organic acids. No consistent changes were observed for ozonated and aerated samples. A slight increase in acetic acid of 0.35 g/L occurred in one ozonated sample but not in replicate samples. There were no changes in acetic acid in aerated samples. No lactic acid was detected in any samples before or after ozonation/aeration.

Ground Corn (Experiment Sets 1 and 2). *Effects of Ozonation on pH and Lactic Acid Contents.* In experiment set 1 (Figure 5), daily pH values of ozonated and nonozonated corn mash samples decreased for the first 24−48 h of fermentation only. The exceptions were samples with higher ozone dosages (152 and 188 mg/L) and no yeast added; the pH of these samples started decreasing after 24−48 h of fermentation and stabilized by 96−120 h. All pH trends corresponded with increases in lactic acid contents. Higher daily pH values, and less lactic acid, were observed in samples subjected to higher ozone dosages.

Statistical analysis was conducted to compare the significance ($p < 0.05$) of 96-h fermentation samples. As expected, lactic acid production in samples without yeast added was higher than in samples with yeast added. Yeast inoculum size affects the ability to compete with bacteria for the same substrate, fermentable sugars.[20] Increasing the ozone dosages from 0 to 127 mg/L and from 127 to 152 mg/L, without yeast added, resulted in significantly lower (p = 0.0004 and p = 0.007, respectively) lactic acid contents; no significant difference (p = 0.4) was observed between 152 and 188 mg ozone/L. These differences were amplified by not supplementing with yeast. With yeast added, the 152 mg/L ozone dosage resulted in significantly lower (p = 0.04) lactic acid contents than the 127 mg/L dosage, indicating less bacterial activity; there was no significant difference (p = 0.9), however, between 0 and 127 mg/L dosages.

In experiment set 2 (Figure 6), daily pH values of ozonated, aerated, and nontreated corn mash samples decreased for the first 24−48 h of fermentation only, without exception. These results agree with experiment set 1 since yeast was added to all samples in this set. Likewise, the daily pH values for all samples corresponded with increases in lactic acid contents.

Nontreated samples tended to have lower daily pH values and higher lactic acid concentrations. Ozonated samples had the highest pH values and least lactic acid throughout the fermentation period, indicating less bacterial and more yeast activity. LAB-spiked, aerated samples had trends similar to those of nontreated samples. Non-LAB-spiked, aerated samples had lower lactic acid values than nontreated samples, which suggest the indigenous LAB populations prefer a reduced oxygen environment. Thus, aeration was effective for reducing lactic acid production only in samples without LAB spiking, but ozonation was still more effective. Statistical comparisons of 96-h fermentation samples showed that all differences in lactic acid contents among ozonated, aerated, and nontreated samples were significant (p values <0.05).

Effects of Ozone on Glycerol Contents. In experiment set 1, glycerol production was lowest in corn mash treated with 127 mg/L of ozone prior to fermentation, compared to nontreated and 152 mg/L ozone-treated samples (Table 3). The 127 mg of O_3/L samples had the highest acetic acid and ethanol contents, which create osmotic stress on the yeast, triggering glycerol production;[42] lactic acid contents, however, were comparable to those of nontreated samples (Figure 5, yeast added). Reduced glycerol contents were also observed in preliminary experiments with increasing ozone dosages, indicating the yeast were less stressed compared to nonozonated samples.

Daily ethanol contents of ozonated and nonozonated corn mash samples began to plateau by 96 h of fermentation (Figure

no	ozone (60 min)	0.4	8.6	0.3	143
yes	none	0.2	10.4	0.9	145
yes	aerated (60 min)	0.3	10.5	1.0	145
yes	ozone (60 min)	0.4	8.8	0.3	143

[a]Prepared from ground corn with yeast addition after ozone treatment (n = 3). No other antimicrobial agents (Lactrol or IsoStab) were added. [b]Initial pH values, prior to ozonation, of experiment sets 1 and 2 were 5.0 and 4.7, respectively. The initial fermentation pH values were 4.8 and 4.5, respectively.

(Table 3). Samples subjected to 152 mg/L ozone dosage had more ethanol than nonozonated samples, but the difference was not significant (p = 0.06). Ethanol production was observed in corn mash samples even without yeast added (up to 61 g/L in 96-h, nonozonated samples); the ground corn used to prepare the corn mash was obtained from POET and presumably contained yeast from exposure during storage at the ethanol biorefinery. Without supplemental yeast, ozone dosage had no significant effect (p values >0.05) on ethanol contents in 96-h samples (Figure 7).

In experiment set 2 (Table 3), daily glycerol trends in corn mash samples were not affected by spiking with *L. plantarum*. Aerated and nontreated samples had similar glycerol production throughout the fermentation period, with slightly more glycerol in the aerated samples. Ozonated samples had the least glycerol after 24 h of fermentation, which coincided with lower daily ethanol production.

The ethanol concentrations in all samples, LAB-spiked and nonspiked, began to plateau by 96 h of fermentation, as observed in experiment set 1. The 96-h ethanol concentration ranged from 143 to 147 g/L. Spiking with *L. plantarum* resulted in somewhat less ethanol than in nonspiked samples (Table 3). The ozonated samples had less ethanol and less lactic acid (Figure 6), than aerated and nontreated samples in this set of experiments, which accounts for less glycerol production. The ethanol findings suggest that higher ozone dosages (152 mg/L) may negatively impact ethanol yields, despite lowering lactic acid contents, depending on the initial pH. The starting pH (posttreatment) for fermentations in the first and second experiment sets was 4.8 and 4.5, respectively.

Corn Slurry (Experiment Set 3). *Yeast Addition.* Corn mash samples were prepared from POET corn slurry (pH 4) by adding urea, enzymes, and yeast. No yeast was added to select samples. As expected, samples without yeast added had higher levels of lactic acid within 24 h and acetic acid within 48 h of fermentation (Figure 8B,C). Higher yeast inoculum size enables the yeast to be more competitive with bacteria. Addition of yeast resulted in significantly (p = 0.002) higher ethanol contents within 24 h of fermentation (Figure 8E); 96-h samples had an average ethanol yield of 146 g/L, with yeast added, as compared to 130 g/L without yeast added.

Initial pH. The initial pH of corn mash prepared with corn slurry from POET was 4.0. This experiment was performed to investigate the effect of increasing the initial corn mash pH to 5.0 on ethanol fermentation with yeast added. Corn mash samples were prepared at slurry pH 4.0 and with pH adjusted to 5.0. The pH of corn mash samples dropped the first 24 h of fermentation (Figure 8A); corn mash with initial pH 4.0 and 5.0 decreased to pH 3.6 and 4.0 in 24 h, respectively. The pH increased gradually to pH 3.8 and 4.2 by the end of the experiment (168 h). The lactic and acetic acid contents increased for the first 24−48 h of fermentation, coinciding with decreasing pH values (Figure 8B,C). Production of lactic/acetic acids and glycerol (Figure 8D) was higher in samples at adjusted pH 5.0 than at slurry pH 4.0, which illustrates an active LAB population. Growth of lactic acid bacteria is reduced at pH less than 4.0. Ethanol production was affected by the increased levels of organic acids; this was demonstrated by higher ethanol concentrations at the slurry pH 4, indicating higher yeast activity.

Ozonation. Corn mash (adjusted pH 5) prepared with POET corn slurry was ozonated to investigate potential reductions in bacterial activity. Lactic acid production in ozonated samples was somewhat lower than in nonozonated

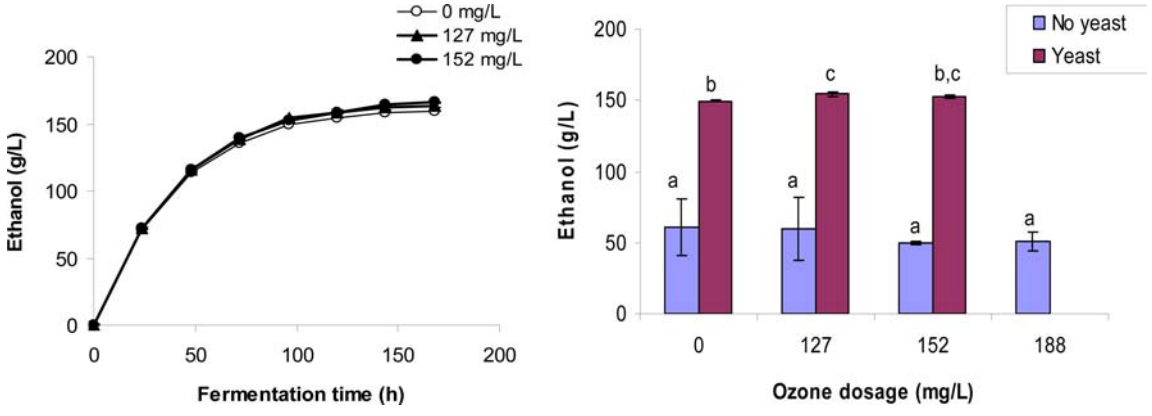

Figure 7. Experiment set 1: (Left) ethanol contents of daily fermentation samples for corn mash prepared from ground corn, spiked with *L. plantarum* and ozonated, with yeast added. No other antimicrobial agents (Lactrol or IsoStab) were added. (Right) Comparison of ethanol contents of 96-h samples (n = 3).

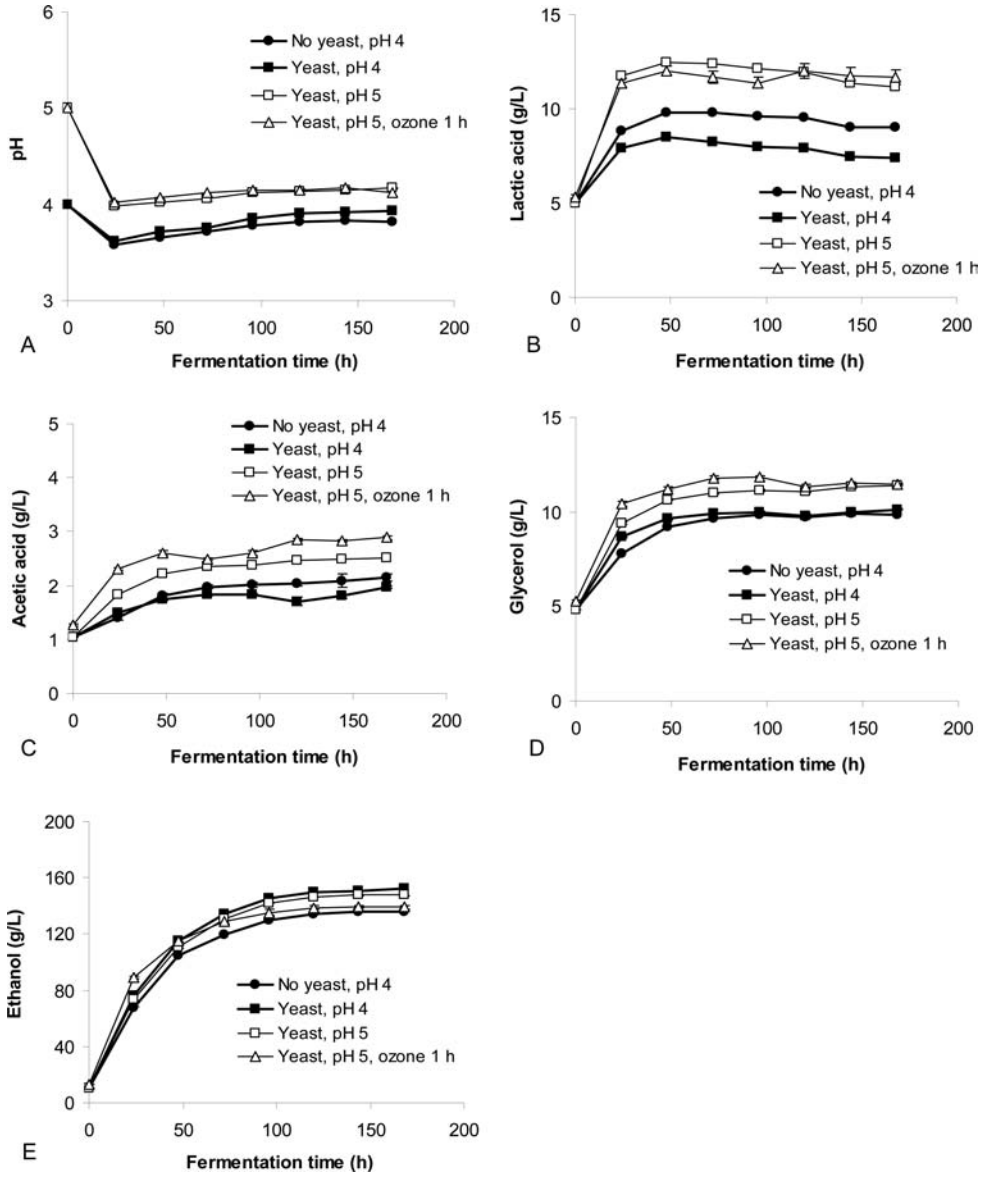

Figure 8. Corn mash prepared from POET corn slurry, which potentially contains recycled antimicrobials in the backset from previous fermentations: (A) pH, (B) lactic acid, (C) acetic acid, (D) glycerol, and (E) ethanol contents of daily fermentation samples from nonozonated/ozonated corn mash samples, with or without yeast added, and initial pH of 4 or 5 (n = 3).

samples (e.g., 12.0 versus 12.5 g/L in 48 h, respectively) up to 120 h (Figure 8B). Acetic acid contents of ozonated samples, however, were higher throughout the fermentation (e.g., 2.6 versus 2.2 g/L in 48 h) (Figure 8C). The initial acetic acid contents, after ozonation, were 0.3 g/L higher in the ozonated samples, which helps explain this finding. These results suggest that ozonation is not as effective in samples prepared from corn slurry in place of ground corn. Additional dissolved and suspended organic materials contributed from the backset may have consumed most of the ozone or shielded the bacteria. Recycled antimicrobial agents, Lactrol and IsoStab, in the corn slurry from the backset may also have reduced the effects of ozonation compared to the nonozonated controls.

Conclusions. Fermentation experiments were conducted with ozone treatment and without the addition of other antimicrobial agents, such as antibiotics. The experiments were performed with POET ground corn and corn slurry.

For POET ground corn we observed the following: (1) Ozonation could be used to lower corn mash pH and, therefore, reduce sulfuric acid requirements to adjust the pH prior to fermentation. (2) Lower lactic acid levels were observed in experiments with ground corn; on this basis, ozonation may reduce bacterial contamination, and thus antibiotic dosages, during fuel ethanol fermentations. (3) The impact of ozonation on ethanol yields, regardless of lowering lactic acid contents, depends on the ozone dosage and initial fermentation pH.

For POET corn slurry, which potentially contained some antimicrobials, we observed the following: (1) Yeast inoculum size affects the ethanol yields and enables the yeast to be more competitive than bacteria, as expected. (2) Ethanol production was higher at initial pH 4.0 than pH 5.0, indicating more yeast activity. (3) Ozone treatment, as applied to ground corn mash, is not as effective in samples prepared from corn slurry.

DOI: 10.1021/acs.jafc.5b00563
J. Agric. Food Chem. 2015, 63, 5239−5248

Additional experiments with POET corn slurry, and the various recycled water streams at a POET ethanol biorefinery, may help clarify the effectiveness of ozonation under fermentation conditions closer to those in plant operation. Higher ozone dosages and use of only recycled water sources that do not contain antimicrobials could be investigated.

Lysine-Based Site-Directed Mutagenesis Increased Rigid β-Sheet Structure and Thermostability of Mesophilic 1,3−1,4-β-Glucanase

Chengtuo Niu,[†,‡,§] Linjiang Zhu,[†,‡,§] Pei Zhu,[†,‡] and Qi Li*[,†,‡]

Supporting Information

ABSTRACT: 1,3−1,4-β-Glucanase is widely applied in the food industry, while its low thermostability often reduces its performance. In a previous study, chemical modification of surface lysine residues was proved to increase the thermostability of β-glucanase. To improve the thermostability, the mesophilic β-glucanase from *Bacillus terquilensis* was rationally engineered through site-directed mutagenesis of the 12 lysines into serines. The results showed that the K20S, K117S, and K165S mutants could both enhance the specific activities and thermostability of β-glucanase. The triple mutant (K20S/K117S/K165S) could increase the optimal temperature and T_{50} value by 15 and 14 °C, respectively. Five percent more structured residues were observed in the mutant, which formed new β-sheet structures in the concave side. Molecular dynamics simulation analysis showed that the flexibility in the mutation regions was decreased, which resulted in the overall rigidity of the β-glucanase. Therefore, the lysine-based site-directed mutagenesis is a simple and effective method for improving the thermostability of β-glucanase.

KEYWORDS: *1,3−1,4-β-glucanase, lysine residues, molecular dynamics simulation, site-directed mutagenesis, thermostability*

INTRODUCTION

1,3−1,4-β-Glucanase (EC 3.2.1.73) is an endo-β-D-glucanase that can hydrolyze 1,3−1,4-β-glucan containing mixed β-1,3 and β-1,4 glycosidic bonds into oligosaccharides.[1] It is widely used in the brewing and animal-feed industries.[2] In the brewing industry, β-glucanase is used to increase the yields of malt extract and the filtration rate of wort and beer, thus enhancing the nonbiological stability of the finished beer.[3] In the animal-feed industry, β-glucanase will increase the digestibility of barley-based diets for animals, especially broiler chickens and piglets.[4] However, these applications often encounter some industrial stresses such as high temperature and low thermostability of β-glucanase, which will reduce its performance. For example, the mashing temperature is elevated from 48 °C to 78 °C[5] and the temperature in animal-feed pelleting is usually between 60 and 90 °C before cooling,[6] whereas the optimal temperatures of 1,3−1,4-β-glucanases from *Bacillus* spp., which are the main sources of β-glucanases, just vary from 45 to 65 °C.[7] The β-glucanases from non-*Bacillus* bacteria and fungi also have similar thermostability.[2] As for thermostable β-glucanases from thermophiles, the optimal temperature can reach 80 °C,[8] but it cannot have a high enzymatic activity under the relatively low-temperature industrial condition of 60−70 °C. Therefore, the thermostability of mesophilic 1,3−1,4-β-glucanase derived from *Bacillus* spp. needs to be improved to meet industrial applications.[2,9]

Enzyme thermostability theoretically involves the maintenance of the balance between overall rigidity of a protein and local flexibility of a catalytic center at a certain temperature.[10] Some amino acid residues located at the protein surface often cause flexible regions at a maladapted high temperature, then reduce the activity, and even lose total activity.[11] Therefore, it is a common strategy for enhancing enzyme thermostability to modify the flexible amino acids on the protein surface.[11,12] As for the mesophilic 1,3−1,4-β-glucanase from *Bacillus* spp., some lysine residues on the protein surface was proved to negatively affect the thermostability, since the chemical modification of five (out of 12) ε-amino groups of lysine residues could significantly enhance its thermostability.[13] Several other researchers also reported that lysine residues on the protein surface influenced the protein thermostability.[14,15] Therefore, some surface lysine residues might induce flexible regions of a protein at a high temperature and reduce protein thermostability. However, there is still a lack of direct evidence about the negative effect of lysine residues on protein thermostability. Considering that chemically modifying some of the 12 ε-amino groups of lysine into hydroxyl groups could simultaneously enhance the catalytic activity and thermal tolerance,[13] the lysine-based site-directed mutagenesis was supposed to improve the overall rigidity and thermostability of 1,3−1,4-β-glucanases from *Bacillus* spp.

In recent years, molecular dynamics (MD) simulation is a common computer-based tool to characterize the detailed dynamical behaviors of protein in different situations, such as high temperature, high pressure, and the presence of detergents,[16] or to identify the flexible regions when temperature is elevated.[17] MD simulation has been applied to compare the unfolding pathways of 12 mesophilic and thermophilic xylanases and predicted the unstable regions at a high temperature.[18] Through MD simulation, the flexibility of 1,4-β-endoglucanase from the GH5 family was found to be highly correlated with their optimal temperatures, and the 1,4-β-endoglucanase was then stabilized by introducing a new

disulfide bond in this flexible region.[19] MD simulation has also been used to study the effect of structural changes on protein properties.[20]

In this study, a new β-glucanase with high enzymatic activity (*bglT*) from *B. terquilensis* CGX 5-1[1] was used. All its 12 lysine residues were mutated into serine residues, which could result in similar structures to those in the previous chemically modified enzyme.[13] The catalytic properties and thermostability properties of the wild-type BglT and the mutant enzymes were determined. Differences in the enzyme dynamical behaviors at high temperatures and the protein structures were also compared.

MATERIALS AND METHODS

Strains, Vectors, and Materials. The recombinant plasmid pET28a(+)-*bglT* was constructed in our previous study.[1] The vector pET28a(+) (Invitrogen, Shanghai, China) was used for construction of the recombinant vector harboring mutant genes. *Escherich coli* JM109 and BL21(DE3) cells were used for plasmid amplification and expression. The *E. coli* cells were incubated at 37 °C in Luria−Bertani media containing ampicillin (50 μg/mL) or kanamycin (100 μg/mL) when necessary. Other reagents of analytical grade were purchased from Sangon (Shanghai, China) or Sinopharm (Shanghai, China).

MD Simulation. The three-dimensional (3D) structures of wild-type BglT and the mutants were homologically modeled in the SWISS-MODEL online server[21] with the reference structure (PDB code: 1GBG).[22] The amino acid sequence identity between BglT and the reference is 92.49% (Online Resource 1, SI). These 3D structures were then submitted to the 2 ns MD simulation processes at 300 K to calculate their total energy values. To further evaluate the thermostability of β-glucanases, the wild-type BglT and triple mutant were subjected to MD simulation processes at 450 K for 20 ns. In the MD, the Gromacs 4.6 package[23] and GROMOS53a6 field force[24] were applied and the structures were put in a cubic box and solvated. Before the final run, the systems were minimized in energy and equilibrated in temperature and pressure using the Berendsen coupling algorithm[25] and the Rahman−Parrinello algorithm,[26] respectively. All bonds were constrained using the LINCS algorithm, and periodic boundary conditions were applied. The long-range electrostatic interactions were calculated by the Particle Mesh Ewald method,[25] while the nonbonded van der Waals interactions were calculated by the L−J model with a cutoff distance of 14 Å. All the MD simulation processes were repeated in triplicate. The root-mean-square deviation (RMSD) and root-mean-square fluctuation (RMSF) analyses were performed using the available Gromacs analysis tools.

Generation of Recombinant 1,3−1,4-β-Glucanase and Its Mutants. The recombinant plasmid pET28a(+)-*bglT*, which was constructed in the previous experiment,[1] was used as a template for site-directed mutagenesis (the gene sequence of *bglT* is shown in Online Resource 2, SI). Mutant β-glucanase gene fragments were obtained by the overlapping extension PCR technique. The primer sequences and the corresponding mutation sites are listed in Online Resource 3, SI. The obtained PCR products were ligated into pET28a(+) and then transformed into *E. coli* BL21(DE3) cells. Positive clones were selected, and the sequences were verified by DNA sequencing (BGI, Shanghai, China).

The expression and purification of recombinant proteins in *E. coli* BL21(DE3) (pET28a-bglT) were as follows. Cells were incubated in optimized TB medium (20 g yeast extract/L; 12.5 g trypton/L; 14.1 mL glycerol/L; 2.17 g KH_2PO_4/L; and 2.74 g K_2HPO_4/L). After incubation at 24 °C for 6 h, 0.06 mM isopropyl β-D-thiogalactoside and 8 mM α-lactose were added. The supernatant was harvested by centrifugation at 9000*g* for 20 min and then loaded into a 5 cm × 1 cm^2 Ni-NTA affinity column (Qiagen, Shanghai, China), which was pre-equilibrated with binding buffer (50 mM NaH_2PO_4, 0.5 M NaCl, and 10 mM imidazole). The column was washed following a step gradient of 50, 100, and 250 mM imidazole solutions as described previously.[13] The obtained liquid was then desalted using a PD-10 desalting column (GE Healthcare, Tianjin, China) and eluted with 20 mM phosphate buffer (pH 6.5). Subsequently, the eluent was concentrated using a Pellicon Cassette concentrator (Millipore, Darmstadt, Germany) with a 10 kDa cutoff membrane. The protein purity was analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) using 12% (w/v) polyacrylamide gel. The total concentrations of protein samples were estimated according to the Bradford method[27] with bovine serum albumin as the standard protein.

Activity Assay of 1,3−1,4-β-Glucanase. 1,3−1,4-β-Glucanase activity was measured using the improved AZO method[1] with 1% AZO blue barley β-glucan (Megazyme, Wicklow, Ireland) as substrate. The reducing sugar content was measured using the 3,5-dinitrosalicylic acid method.[28] The assay was carried out in a 500 μL volume containing an appropriate amount of diluted enzyme solution and 1% (w/v) substrate at 40 °C for 10 min. Precipitation solution (32.5 g sodium acetate/L, 4 g zinc sulfate/L, and 800 mL methoxy ethanol/L) was added to terminate the reaction, and the OD_{590} was recorded. One unit of enzymatic activity was defined as the amount of enzyme that released 1 μmol of reducing sugar from the substrate per minute at pH 6.5. Each measurement was repeated in triplicate. As for catalytic kinetic properties of wild-type BglT and its mutants, the Lineweaver−Burk double reciprocal method was adopted.[29] The enzyme concentration was set at 100 μg/mL, while the substrate concentration varied from 0 to 10 mg/mL.

Determination of Thermostability Parameters. The optimal temperature of 1,3−1,4-β-glucanase was determined by measuring the enzymatic activity from 35 to 70 °C at 5 °C intervals. For each enzyme, the highest activity measured was designated as 100%. Enzyme thermostability was analyzed by measuring the residual activity as a function of temperature and heating time at elevated temperatures. The enzyme half-inactivation temperature (T_{50}) was evaluated by measuring the enzymatic activity at different temperatures. The enzymes were incubated from 40 to 80 °C for 10 min, followed by 10 min of cooling on ice. The T_{50} value is defined as the temperature that can reduce the enzymatic activity to half after incubation for 10 min. Furthermore, the decay of enzymatic activity over time at 50 and 60 °C was monitored by incubating the enzyme solution at high temperature and measuring the remaining activity at a series of time points. The $t_{(1/2,X°C)}$ value was obtained from the inactivation curve when the β-glucanase lost half of its activity.

Circular Dichroism (CD) Analysis. The far-UV CD spectra of wild-type BglT and the mutant enzymes were measured from 190 to 250 nm by a MOS-450 AF circular dichroism spectrometer (Biologic, Claix, France) with a resolution of 1 nm. The concentration of all enzymes in 20 mM phosphate buffer (pH6.5) was set at 50 μg/mL. The CD spectra of the phosphate buffer were recorded and subtracted from sample spectra. The percentages of secondary structure elements (helix, β-sheet, β-turn, and loop) were predicted using Dichroweb online software.[30]

RESULTS AND DISCUSSION

Enzymatic Properties of 12 Single-Site Mutant β-Glucanases. The 1,3−1,4-β-glucanase from *B. terquilensis* CGX 5-1 is composed of 214 amino acid residues and contains 12 surface lysine residues. All 12 single-site mutants were constructed through the overlapping PCR method, and the recombinant enzymes were expressed in *E. coli* BL21(DE3) through pET28a. The main enzymatic activities of recombinant β-glucanases were detected in the supernatant of the culture media, which were purified by a Ni-NTA column (Online Resource 4, SI). Their specific activities were measured as shown in Table 1. The K20S, K117S, and K165S mutants displayed higher specific activities than the wild-type BglT (2490.1 U/mg), which were increased by 47.6%, 19.4%, and 43.9%, respectively. The other nine mutants showed lower specific activities, which were decreased by 30% to 73.6%.

The effect of lysine-based mutation on the enzyme kinetic parameters was also characterized (Table 2). The K_m value of wild-type BglT was 0.297 mM, while the K_m values of K20S, K117S, and K165S mutants were 0.293, 0.283, and 0.284 mM. This indicated that all three single mutants increased the binding affinity with the substrate of barley β-glucan. Furthermore, the K_{cat} values and K_{cat}/K_m values of K20S, K117S, and K165S mutants were significantly increased. The K20S mutant had the highest K_{cat} value (175.40 s^{-1}) and K_{cat}/K_m value (598.63 $s^{-1}\cdot mM^{-1}$), which were 27.7% and 29.4% higher than those of wild-type BglT, respectively. These results indicated that three out of 12 single-site mutations of lysine residues into serine residues could increase the enzymatic efficiency and the binding affinity of the substrate.

K20S/K117S/K165S	0.278 ± 0.004	184.93	665.22

Thermostability Prediction by MD. To predict the enzyme thermostability, changes in the enzyme total energy values induced by mutation of lysine residues were calculated by MD simulation. The total energy values were closely correlated with the entropy values of protein unfolding.[31] Compared with the value of wild-type BglT (−733.200 kJ/mM), nine out of 12 single-site mutants displayed lower total energy values, which means that the nine single-site mutants might have a better thermostability. Furthermore, the number of hydrogen bonds formed in these protein structures was calculated. Compared with the wild-type BglT (153), 10 out of 12 mutants showed an increased number of hydrogen bonds formed in the whole protein structure (Table 1). As for each mutant region, more hydrogen bonds were also observed in seven mutant regions (K20S, K113S, K117S, K132S, K165S, K178S, and K213S), while two mutant regions (K83S and K214S) showed fewer hydrogen bonds (Table 2). Hydrogen bonds can increase protein thermostability in many proteins.[32] Therefore, mutant enzymes with more hydrogen bonds and lower total energy values were predicted to be more thermostable.

Thermostability Parameter Analysis of Three Activity-Improved Mutants. To compare the thermostability of the

mutants, three single-site mutants (K20S, K117S, and K165S) with higher activity and more hydrogen bond formation were subjected to further analysis. One mutant (K58S) with slightly lower enzymatic activity and predicted lower thermostability was also characterized. As shown in Figure 1, the optimal temperatures of K20S, K117S, and K165S mutants were 60, 60, and 55 °C, which were 15, 15, and 10 °C higher than that of wild-type BglT, respectively (Figure 1a). The T_{50} values of wild-type BglT and K20S, K117S, and K165S mutants were determined to be 62, 76, 76, and 75 °C (Figure 1b), respectively, which indicated that the single-site mutations could increase the T_{50} values by 13−14 °C. The comparisons of $t_{(1/2,\ 50°C)}$ and $t_{(1/2,\ 60°C)}$ at 50 and 60 °C are shown in Figure 1c and d, respectively. The $t_{(1/2,\ 50°C)}$ values of K20S, K117S, and K165S mutants reached 149, 210, and 102 min, which were 88.6%, 165.8%, and 29.1% longer than that of wild-type BglT. Especially, the K20S mutant could even maintain 100% of activity after incubation for 125 min. The $t_{(1/2,\ 60°C)}$ values of K20S, K117S, and K165S mutants were 46, 58, and 37 min, which were much higher than that of wide-type BglT (32.5 min). As for the K58S mutant, with a higher predicted total energy value, it showed slightly lower thermostability compared to wild-type BglT. Its optimal temperature and T_{50} value were 45 and 61 °C, while its half-life values at 50 and 60 °C were 77 and 31 min. These results indicated that K20S, K117S, and K165S mutants could significantly enhance the thermostability of β-glucanase, which is in accordance with the above predicated results based on calculations of total energy values.

Analysis of Thermostability in the K20S/K117S/K165S Mutant Enzyme. To further improve the thermostability of 1,3−1,4-β-glucanase, the triple mutant enzyme harboring the K20S, K117S, and K165S mutant sites was constructed and expressed since beneficial substitutions might have an additive effect on protein thermostability.[33] The triple mutant (K20S/K117S/K165S) displayed both higher catalytic activity and better thermostability. Its specific activity reached 3936.4 U/mL, which was almost 2 times higher than that of wild-type BglT. Furthermore, its total energy value was −733.535 kJ/mM (Table 1), which was the lowest among wild-type BglT and all the mutants. The number of hydrogen bonds formed in the triple mutant is 165, more than the wild-type BglT. The optimal temperature and T_{50} value of the triple mutant were 60 and 76 °C, which were 15 and 14 °C higher than those of wild-type BglT, respectively (Figure 1). The half-life values of the triple mutant at 50 and 60 °C were 214 and 59 min, which were 170.9% and 81.5% longer than those of wild-type BglT, respectively. These results indicated that the thermostability of β-glucanase was further improved by combinational mutation of the three lysine sites.

Comparative Analysis of Flexibility between Wild-Type BglT and Triple Mutant Enzyme. To evaluate the effect of lysine mutation on the rigidity of the enzyme structure, the overall and local flexibility of the wild-type BglT and K20S/K117S/K165S mutant was compared using MD simulation. As shown in Table 4, the Cα RMSD value of wild-type BglT stabilized around 0.67 nm at 450 K, while the triple mutant showed an average Cα RMSD value of 0.59 nm. The RMSD values of the backbone, main chain, and side chain also showed a similar trend (Online Resource 5, SI). The flexibility of the three mutant regions was also calculated. Table 4 shows that the average RMSD values of the residues within 5 Å of the three mutant residues in the K20S/K117S/K165S mutant were 0.47, 0.27, and 0.43 nm, which were all slightly lower compared

to the wild-type BglT. The RMSD value is a thermodynamic parameter that reflects the maintenance capability of protein at high temperatures.[34] The lower the RMSD value, the more rigid the protein backbone and the better its thermostability.[35] Therefore, the results indicated that the triple mutant showed more conformational rigidity than the wild-type BglT at high temperature. A more detailed description about residue mobility was described using RMSF values as shown in Figure 2. The triple mutant displayed lower overall RMSF values. The main different regions in the RMSF curves between wild-type BglT and the K20S/K117S/K165S mutant were the lysine-mutation regions. Furthermore, several other regions, such as residues no. 30−40, no. 55−75, no. 80−100, no. 105−115, and

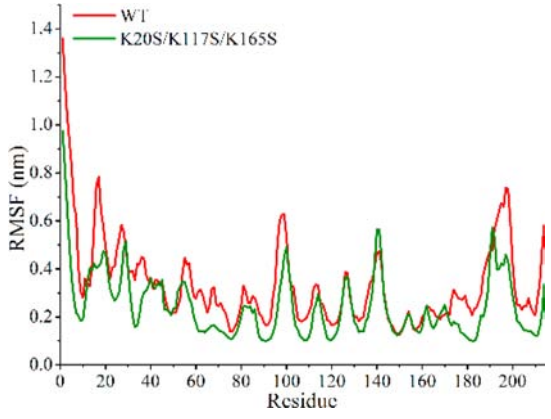

Figure 2. Comparison of Cα RMSF values of wild-type BglT (red line) and K20S/K117S/K165S triple mutant (green line) according to residue numbers after calculation at 450 K for 20 ns.

J. Agric. Food Chem. 2015, 63, 5249−5256

no. 171−195, also displayed a large decrease in RMSF values in the triple mutant compared to the wild-type BglT. The RMSF value could indicate the flexibility of an atom or a residue. A high RMSF value on the protein surface often means highly flexible regions and large fluctuations of local configuration at a high temperature, which might start the protein unfolding.[11] These results provided the direct evidence that mutation of lysine residues into serine residues could significantly reduce the local RMSF values around lysine-mutation sites, resulting in a higher rigid structure and better thermostability of β-glucanase.

Changes in the Molecular Structure Induced by Mutation of Lysine Residues. Previous reports[34] showed that the increase of RMSF values was always accompanied by the loss of secondary structure. Therefore, to understand the mechanism of the enhanced thermostability, CD analysis was applied to detect the changes in the protein secondary structure. As shown in Figure 3, wild-type BglT and the K20S/K117S/K165S mutant displayed similar CD spectra. Both enzymes were predicted to be composed of mainly β-sheets and β-turns. However, both the positive and negative bands in the CD spectrum were shifted to larger wavelength in the triple mutant compared to the wild-type BglT. The positive band was moved from 193 nm to 196 nm, while the negative band was moved from 210 nm to 217 nm, which means that the proportion of β-sheets in the K20S/K117S/K165S mutant was increased. As shown in Table 5, the percentage of β-sheets was increased from 38% to 46%, while the proportion of helixes, β-turns, and loops decreased. Besides, the percentage of structured residues in the triple mutant was increased from 61% to 66%.

protein sample	helix (%)	β-sheet (%)	β-turn (%)	loop (%)
WT	11	37	13	39
K20S/K117S/K165S	9	46	11	34

More structured residues usually could result in more rigid secondary structure of the protein,[20] which might be responsible for the increased predicted rigidity of β-glucanase.

To further analyze the structure change induced by lysine mutation, the predicted 3D structures of wild-type BglT and the K20S/K117S/K165S mutant were also compared (Figure 4). The three mutation sites (K20S, K117S, and K165S) were all located on the protein surface. Lys20 was located in the middle of a long loop (loop 2). When the Lys20 was mutated to Ser20, a hydrogen bond between Lys20 and Ala36 was removed, while a new hydrogen bond was formed between Ser20 and Tyr13 (Figure 4a). These two residues were located in the same loop, and the mutation of Tyr13 was reported to have a positive effect on thermostability.[7,36] Therefore, the rigidification of Tyr13 by this hydrogen bond led to a lower RMSF value and more rigidity of the local region. In the wild-type BglT, the mutant sites Lys117 and Lys165 were located within two β-sheets (β7 and β11), respectively. In contrast, although there were no significant changes in conformation around Ser165 in the triple mutant, Ser117 was no longer located in the β7. In the wild-type BglT, there was one hydrogen bond formed between Lys117 and Asp114, while two hydrogen bonds were formed between Ser117 and Asp114 in the mutant enzyme (Figure 4b). This change led to the formation of the β-turn in the Ser117 site instead of the original β-sheet. These two residues were close to the catalytic site, and this change might be the reason for the enhancement of the catalytic properties. In mutant site no. 165, one more hydrogen bond between Ser165 and Trp158 was observed, which linked β10 and β11 (Figure 4c). Besides these, changes in several other regions in the protein structure were also observed. A short helix structure (α2) composed of the residue no. 96−100 in wild-type BglT was lost. As shown in Figure 4d, four hydrogen bonds existed within the helix in the wild-type BglT, while in the triple mutant only one hydrogen bond remained (Figure 4f). Furthermore, several loop regions in the concave side of the wild-type BglT structure turned into β-sheets. The residues no. 88−93 and no. 108−110, which were located in the middle of loop 6 and loop 7, formed two new β-sheets (β14 and β15). The β12 was lengthened by residues no. 179−182. The transformations of loops into β-sheets should be responsible for the lower RMSF values in these regions of the triple mutant. Figure 4e and g showed the hydrogen bond networks within the concave sides of the wild-type BglT and the triple mutant. Three new hydrogen bonds were formed in the mutant. Two hydrogen bonds (Phe110−Ser89 and Thr93−Ile106) were formed between the newly formed β14 and β15, while the third one (Phe92−Met180) was formed between β14 and β12. These three newly formed hydrogen bonds may draw the neighboring residues closer and result in the formation of new β-sheets. Overall, these changes in the predicted enzyme structure induced by the mutation were in accordance with the above results of secondary structure analysis through the CD spectrum.

For the mesophilic β-glucanase BglT, mutations of three out of 12 lysines to serines can increase the thermostability. Interestingly, a recent report showed that a higher percentage of lysine residues was found in some thermophilic enzymes, while mesophilic enzymes tended to contain more serine residues.[37] Moreover, the mutation of lysines to serines was also found in some psychrophilic proteins.[38] In contrast, the positive effects of lysine mutation on BglT thermostability in this study might result from the large-scale changes in the secondary structure of neighboring regions induced by the mutation of the lysine residues. Compared with the wild-type BglT, mutation of lysine residues caused more hydrogen bonds

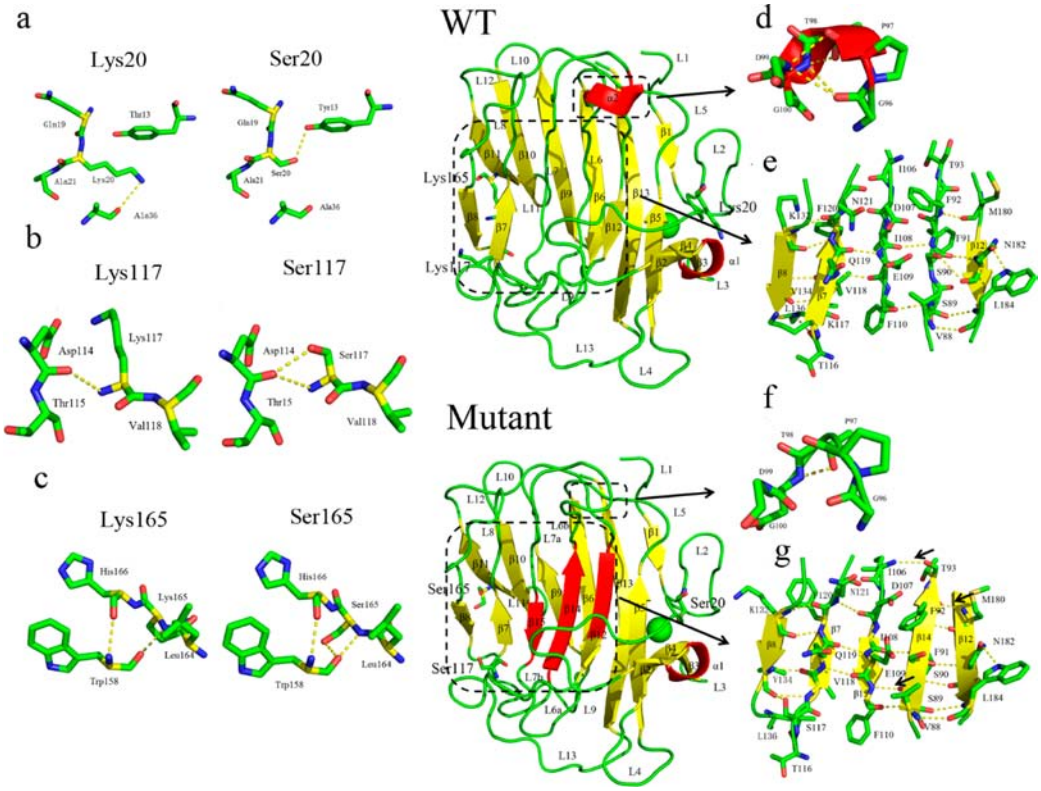

Figure 4. Comparison of the 3D structures of wild-type BglT and the K20S/K117S/K165S mutant (the three mutant sites are shown as sticks): (a) comparison of hydrogen bonds in the K20S mutant region; (b) comparison of hydrogen bonds in the K117S mutant region; (c) comparison of hydrogen bonds in the K165S mutant region; (d) 3D structure of the loop region of no. 96−100 in wild-type BglT; (e) 3D structure of the loop region of no. 96−100 in the triple mutant; (f) hydrogen bond network in the concave side of the structure of wild-type BglT; (g) hydrogen bond network in the concave side of the structure of the triple mutant (the arrows indicate the newly formed hydrogen bonds). The left side shows the interactions between the three mutant sites. The helix, β-sheet, and loop are shown in red, yellow, and green, respectively. The hydrogen bonds are depicted as dashed yellow lines. Structure visualization was performed using the software Pymol 1.7.1.

in both the three local mutant sites and the concave side of the enzyme structure. These changes resulted in more structured amino acids in the triple mutant, especially the formation of new β-sheets in the concave side. This could enhance the rigidity of the local structure, which was confirmed by the lower RMSF values. Rigidifying the local flexible regions in a protein could enhance the protein thermostability.[39] Growing evidence has shown that the loss of the protein thermostability is likely to be directed by some local fluctuation and partial unfolding.[11,40] Therefore, these transformations are thought to rigidify both the global and local structure, thus leading to a better overall thermostability of β-glucanase. Furthermore, the catalytic activity and binding affinity of the substrate in the triple mutant were proved to be increased. As shown by the changes in structure, the concave side of β-glucanase was the region for substrate binding. Several residues related to substrate binding, including Ser90, Glu109, Glu131, and Asn182, were located at these transformed regions. The reason for the enhancement of the catalytic efficiency might be the conformational changes in this region, especially the formation of the hydrogen bond between Phe110 and Ser89, which could influence the catalysis of the substrate.

In conclusion, the site-directed mutagenesis of lysine sites no. 20, no. 117, and no. 165 enhanced both the catalytic properties and the thermostability of β-glucanase BglT. The optimal temperature and T_{50} of the triple mutant were increased by 15 and 14 °C. The half-life values at 50 and 60 °C were also largely extended. New hydrogen bonds were observed in the mutant sites and the concave side of the protein structure, which led to the formation of more β-sheet elements and reduced local flexibility. The large-scale changes in the secondary structure of neighboring regions should be responsible for the increased thermostability and catalytic activity. This study provides a new strategy for improving thermostability by engineering surface lysine residues.

Supporting Information

ABSTRACT: Typically, heat-induced aggregation of proteins is studied using a single protein under various conditions (e.g., temperature). Because different studies use different conditions and methods, a mechanistic relationship between molecular properties and the aggregation behavior of proteins has not been identified. Therefore, this study investigates the kinetics of heat-induced aggregation and the size/density of formed aggregates for three different proteins (ovalbumin, β-lactoglobulin, and patatin) under various conditions (pH, ionic strength, concentration, and temperature). The aggregation rate of β-lactoglobulin was slower (>10 times) than that of ovalbumin and patatin. Moreover, the conditions (pH, ionic strength, and concentration) affected the aggregation kinetics of β-lactoglobulin more strongly than for ovalbumin and patatin. In contrast to the kinetics, for all proteins the aggregate size/density increased with decreasing electrostatic repulsion. By comparing these proteins under these conditions, it became clear that the aggregation behavior cannot easily be correlated to the molecular properties (e.g., charge and exposed hydrophobicity).

KEYWORDS: *β-lactoglobulin, ovalbumin, patatin, pH, ionic strength, concentration*

INTRODUCTION

Heat-induced aggregation of globular proteins is generally described as being caused by the exposure of the internal hydrophobic amino acids due to unfolding.[1,2] After unfolding and exposure of the hydrophobic amino acid residues, the (partially) unfolded protein either refolds or irreversibly aggregates with other (partially) unfolded proteins.[3,4] The likelihood of refolding or aggregation depends on the balance between the increased hydrophobic attraction due to unfolding and the mainly electrostatic barrier for aggregation. Qualitatively, aggregation has been investigated extensively, mainly in terms of (1) aggregation kinetics,[5−7] (2) aggregate size,[8,9] and (3) aggregate structure.[10,11] These studies typically investigate the effect of conditions (e.g., ionic strength) on the aggregation of a single protein (e.g., β-lactoglobulin). A detailed mechanistic comparison of the aggregation of different proteins, on the other hand, is still missing. Exactly such information may advance the understanding of the aggregation process of globular proteins, especially with respect to an overall description of the effect of parameters influencing the aggregation process. Hence, the aim of the present paper is to obtain a mechanistic understanding of the aggregation process and determine the effect of the properties of three proteins on the aggregation behavior under various conditions.

The aggregation kinetics (i.e., order (n) and rate (k)) are generally derived from the decrease of the concentration of nonaggregated protein in time. Therefore, they provide information on the kinetics of protein unfolding and integration of nonaggregated proteins in aggregates, whereas they do not provide information on the size and structure of the formed aggregates.

Aggregation Order. To determine the order of aggregation, two approaches have been described: (A) determination of the concentration dependence of the initial aggregation rate[5−7] and (B) fitting the decrease of the concentration of nonaggregated protein in time with the specific reaction equations. These are eqs 1 and 2 for first- and nth-order kinetics, respectively:[12]

$$C_t = C_0 \times e^{-kt} \text{ for } n = 1 \quad (1)$$

$$C_t = (C_0^{1-n} + (n-1) \times k \times t)^{1/1-n} \text{ for } n \neq 1 \quad (2)$$

C_t and C_0 are the concentrations of nonaggregated protein at time t and at time 0 (g/L), respectively, n is the aggregation order (unitless), and k is the aggregation rate ($(g/L)^{(1-n)}/s$).

The discrepancies between the two approaches are assumed to originate from the fact that the aggregation process becomes more complex at longer heating times. This is due to simultaneous aggregation of nonaggregated protein with other nonaggregated protein, nonaggregated with aggregated proteins, and aggregated proteins with other aggregated proteins.

For ovalbumin, the initial aggregation rate was shown to be concentration independent. Hence, the aggregation process has been described as a first-order reaction.[6] The aggregation rate of β-lactoglobulin, on the other hand, increases with increasing concentration, indicating concentration dependence. This resulted in an aggregation order of 1.5.[5,7,13] In addition, the aggregation orders of ovalbumin and β-lactoglobulin were shown to be independent of temperature,[6,14,15] pH,[8,14] and ionic strength.[6,16]

Aggregation Rate. For proteins, the fraction of unfolded protein and the diffusion rate of the protein molecules typically increase with increasing temperature.[17,18] The fraction unfolded

Pat	P07745	40.0	5.25	43/32	0/1	−17.9	0.73

[a]#COOH and #NH_2 are the maximum numbers of negatively charged (aspartic and glutamic acid) and positively charged (arginine and lysine) groups in the primary sequence, respectively. [b]σ_w is the theoretical net surface charge density at pH 7. [c]Rel Q_H is the relative exposed hydrophobicity of the proteins as determined previously.[50] [d]Molecular weight of a β-lactoglobulin dimer (native state under the selected conditions).

proteins depends on the heating temperature relative to the denaturation temperature (T_d). For a more fundamental comparison of the aggregation properties of different proteins, the proteins are studied at a fixed temperature relative to T_d, rather than an absolute temperature. This results in a constant fraction of unfolded protein. An increase of the diffusion rate results in an increased likelihood of the proteins to meet, collide, and aggregate.[19,20] The aggregation rate is also affected by electrostatic repulsion. However, a clear link is difficult to make, because the main factors (i.e., ionic strength and pH) can have several effects. Increasing the electrostatic repulsion increases both the intra- and intermolecular repulsions. The increased intramolecular repulsion decreases the denaturation temperature.[21,22] The increase of intermolecular repulsion, on the other hand, increases the electrostatic barrier for aggregation.[23] Whereas the first effect would (when heating at given temperature) result in an increase of the aggregation rate, the second would decrease the aggregation rate. In addition, a pH change not only affects the electrostatic interactions but also changes the reactivity of the disulfide bonds. Whereas changes in the electrostatic repulsion (i.e., ionic strength and pH) do not affect the aggregation rate of ovalbumin,[6,24] the aggregation rate of β-lactoglobulin increases with increasing ionic strength (<0.1 M)[16] and pH.[8,14] This difference indicates that the electrostatic repulsion affects both proteins differently. The enhancing effect of ionic strength on the aggregation rate of β-lactoglobulin showed that the increase of the denaturation temperature was less important than the decrease of the electrostatic barrier for aggregation.[16] At the same time, a higher denaturation temperature and a decrease of the reactivity of the disulfide bonds were described to reduce the aggregation rate of β-lactoglobulin with decreasing pH.[14]

Aggregate Formation. To describe the aggregate formation, the size and structure of the aggregates are typically determined by scattering techniques (i.e., neutron, X-ray, and light scattering). The structure of the aggregates is described by the fractal dimension. The fractal dimension was found to be independent of the heating temperature.[15,25] As temperature affects only the aggregation kinetics and not the formation of aggregates, the effect of temperature has been described as a purely kinetic effect.[15] Electrostatic repulsion, however, strongly affects the aggregate formation (size as well as structure). A decrease of the electrostatic repulsion, due to an increase of the ionic strength and/or a shift of the pH toward the iso-electric point (pI), resulted in the formation of larger aggregates of ovalbumin,[26,27] β-lactoglobulin,[8,28] BSA,[9] and patatin,[29] as observed via light scattering. At conditions with high electrostatic repulsion (i.e., low ionic strength and pH far from the pI), linear aggregates with a fractal dimension of 1.7 were formed by ovalbumin[30] and β-lactoglobulin.[31,32] When the electrostatic repulsion was decreased (i.e., by increasing the ionic strength from 10 to 100 mM), the β-lactoglobulin and ovalbumin aggregates became more branched. This was indicated by a fractal dimension of 2.0[15,30,33−35] and confirmed by cryo-TEM.[30] When the electrostatic repulsion is minimal (i.e., close to the pI), β-lactoglobulin forms even more compact aggregates with a fractal dimension of 3.0.[36] The effect of electrostatic repulsion on the aggregate size and structure is explained by the electrostatic barrier for aggregation.[30,32,35] Furthermore, the size of β-lactoglobulin and BSA aggregates increased with increasing concentration.[9,15,33,37] This concentration dependence has been postulated to be a result of an increase of the ionic strength due to the counterions of the protein.

Because β-lactoglobulin has most often been used to study the aggregation process, its aggregation behavior is quite well understood. However, little is known of how this knowledge can be extrapolated to describe the aggregation of other proteins. To obtain a more mechanistic understanding of the effect of protein molecular properties on the aggregation of globular proteins, this study compares the aggregation process of different proteins. Hence, the differences in the kinetics and factors influencing the aggregation of three proteins (β-lactoglobulin, ovalbumin, and patatin) under various conditions (pH, ionic strength, temperature, and protein concentration) are studied. The three proteins are selected as their similarities (globular structure, pI, and molecular weight) and differences (surface charge, exposed hydrophobicity, and number of disulfide bridges) (Table 1) enable a comparison of the effects of charge, hydrophobicity, and disulfide bridges on the aggregation behavior.

MATERIALS AND METHODS

Materials. Ovalbumin [A-5503, lot 031M7008 V; pI = 5.19; protein content 92% (N × 6.22)[38] of which ≥98% was ovalbumin (based on agarose gel electrophorese)] and β-lactoglobulin [L-0130, lot SLBC2933 V; pI = 4.83; protein content of 94% (N × 6.38)[38] of which 99% was β-lactoglobulin (based on PAGE)] were purchased from Sigma-Aldrich (St. Louis, MO, USA). Potatoes were provided by AVEBE BA (Veendam, The Netherlands). Patatin was isolated from potato juice as described previously,[39] except that gel filtration was performed on a Superdex 200 column (52 × 10 cm). The obtained patatin fraction [pI = 5.25; purity ≥ 90% based on analytical size exclusion chromatography (SEC)] was dialyzed against demineralized water, freeze-dried, and stored at −20 °C. All other chemicals were of analytical grade and purchased from either Sigma-Aldrich or Merck.

Differential Scanning Calorimetry (DSC). The denaturation temperature of the proteins was determined using a VP-DSC MicroCalorimeter (MicroCal Inc., Northampton, MA, USA). The proteins were dissolved in 10 mM sodium phosphate buffer, pH 7.0, at a concentration of 2 g/L. Subsequently, thermograms were recorded from 20 to 100 °C at a heating rate of 1 °C/min. The denaturation temperatures (T_d) of ovalbumin, β-lactoglobulin, and patatin were found to be 77.5, 75.0, and 60.0 °C, respectively (Supporting Information). This is in close agreement with the denaturation temperatures reported in the literature.[6,21,39]

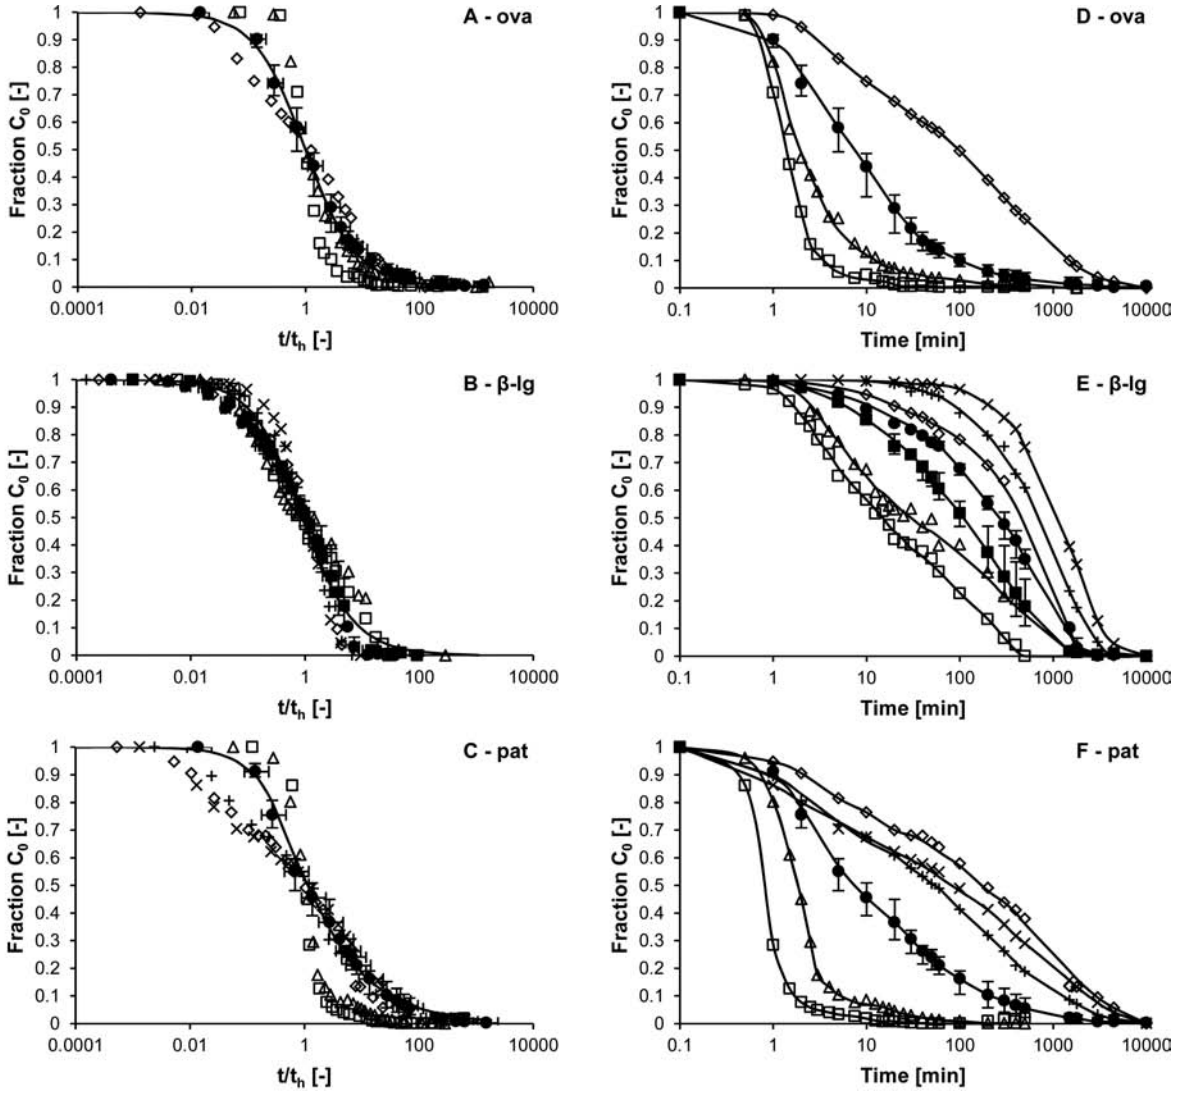

Figure 1. Fraction of nonaggregated protein (C_0) as a function of the time normalized by t_h (A–C) and as a function of the time (D–F) for ovalbumin (A, D), β-lactoglobulin (B, E), and patatin (C, F). The markers represent the different conditions: T_d − 10 °C (◇), T_d (△), T_d + 5 °C (□), pH 5.0 (×), pH 6.0 (+), 5 g/L, 10 g/L, 40 mM NaCl, and 90 mM NaCl (■), and the average of all remaining conditions (T_d − 5 °C, 2 g/L, 10 mM NaCl, and all not indicated by the other markers), with error bars indicating the standard deviation (●). Solid lines in panels D–F are guides to the eye. The solid lines in panels A–C represent the best fits (n = 2.1 for ovalbumin, n = 2.5 for β-lactoglobulin, and n = 2.9 for patatin).

Heat-Induced Aggregation. Heat-induced aggregation was performed in a water bath. Aliquots of 1 mL were heated for different time intervals (0, 1, 2, 5, 10, 20, 30, 40, 50, 60, 100, 200, 300, 400, 500, 1500, 1800, 3000, 4500, and 10080 min) in Kimax tubes. After heating, the samples were cooled on ice–water. Four different sets of experiments were performed.

Effect of Temperature. Proteins were dissolved in 10 mM sodium phosphate buffer, pH 7.0, at a concentration of 2 g/L. Subsequently, these solutions were heated at temperatures at the same distance from the denaturation temperature (T_d): T_d − 10 °C, T_d − 5 °C, T_d, and T_d + 5 °C. This was chosen to ensure as well as possible a similar rate of unfolding for all proteins. The reason is that at T_d, for all proteins, the native and unfolded proteins are present in equal amounts.[12,17] This equilibrium between native and unfolded protein shifts toward the native protein with decreasing and toward unfolded protein with increasing temperature. This equilibrium is, at a certain temperature from T_d (e.g., T_d − 5 °C), assumed to be equal for all proteins. For the incubations at the two highest temperatures, additional time intervals (i.e., 0.5, 1.5, 2.5, 3, 4, 7.5, 12.5, 15, 17.5, and 25 min) were included.

The aggregation rate was determined on the basis of the decrease of the concentration of nonaggregated protein in time using eq 1 or 2. From the temperature dependence of the aggregation rate (k), the activation energy (E_a) was calculated by the Arrhenius equation.

Effect of pH. Proteins were dissolved in 10 mM sodium phosphate buffer, pH 7.0, 6.0, and 5.0, at a concentration of 2 g/L. Subsequently, the solutions were heated at T_d − 5 °C.

Effect of Ionic Strength. Proteins were dissolved in 10 mM sodium phosphate buffer, pH 7.0, in the presence or absence of 10, 40, and 90 mM NaCl at a concentration of 2 g/L. Subsequently, the solutions were heated at T_d − 5 °C.

Effect of Protein Concentration. Proteins were dissolved in 10 mM sodium phosphate buffer, pH 7.0, at concentrations of 1, 2, 5, and 10 g/L. Subsequently, the solutions were heated at T_d − 5 °C.

Size Exclusion Chromatography. The concentration of nonaggregated protein (i.e., monomer concentration for ovalbumin and dimer concentration for β-lactoglobulin and patatin) was determined using SEC on an Äkta Micro equipped with a Superdex 200 PC 3.2/30 column (GE Healthcare, Uppsala, Sweden). Prior to analysis, the samples were centrifuged (16100g, 10 min, 20 °C) to remove insoluble aggregates. Subsequently, samples (20 μL) were injected and eluted with 10 mM sodium phosphate buffer, pH 7.0, at a flow rate of 0.06 mL/min. The elution was monitored at 214 nm. The calibration was performed with globular proteins with a mass range of

DOI: 10.1021/acs.jafc.5b00927
J. Agric. Food Chem. 2015, 63, 5257–5265

13.7−67 kDa (GE Healthcare). The typical experimental error for the determination of the amount of nonaggregated protein was <10% as determined from duplicate time incubations of ovalbumin and patatin, 2 g/L, T_d − 5 °C, 10 mM sodium phosphate buffer, pH 7.0.

Determination of the Aggregation Kinetics. The aggregation kinetics are determined in several ways: (1) concentration dependence of the time required to aggregate half of the protein (i.e., t_h as an indication of the aggregation rate), (2) fitting the decrease of the concentration of nonaggregated protein in time using eqs 1 and 2, and (3) fitting the natural logarithm of concentration (n = 1.0), reciprocal of the square root of concentration (n = 1.5), and the reciprocal of the concentration (n = 2.0) against time with a linear function, fixing the intercept with the y-axis corresponding to the initial concentration (C_0). The first approach includes only the data points $C_t \geq 0.5C_0$, whereas the other two approaches are applied to the regime $C_t \geq 0.05C_0$. For the second approach the data are fitted by minimizing the sum of squares error using the Microsoft Excel solver.

Static Light Scattering (SLS). The scattered light intensity was determined in time using a Malvern Zetasizer Nano ZS (Malvern Instruments, Worcestershire, UK). The protein solutions (as described under Heat-Induced Aggregation) were filtered over a 0.1 μm PTFE filter (Puradisc 13; Whatman, Kent, UK). Subsequently, the filtered solutions were heated at the temperatures described under Heat-Induced Aggregation. The scattered light intensity was measured every 30 s for 7200 s. The intensity of the scattered light is generally described by eq 3[13,40]

$$I(q) \propto K \times C \times M_w \times P(q) \times S(q) \quad (3)$$

in which $I(q)$ is the intensity of the scattered light at angle q (i.e., 173°), K is an optical constant, c is the concentration (g/L), M_w is the molar mass of the particles (g/mol), $P(q)$ is the particle form factor, which describes the shape and size of the particles, and $S(q)$ is the structure factor that describes the spatial arrangement of the particles.

As the concentration (C) and the optical constant (K) are constant during and between the measurements, eq 3 can be simplified to

$$I(q) \propto M_w \times P(q) \times S(q) \quad (4)$$

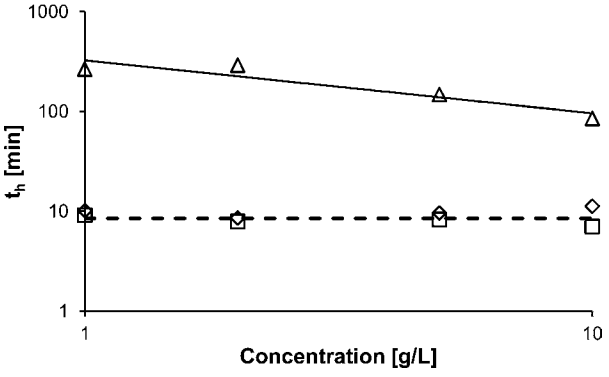

Figure 2. Concentration dependence of the time required to aggregate half of the proteins (t_h) for ovalbumin (□), β-lactoglobulin (△), and patatin (◇) heated at T_d − 5 °C. The solid line has a slope of −0.5. The dashed line is a guide to the eye.

This shows that an increase of the scattered light intensity relates to an increase of the aggregate size and/or a more dense aggregate structure.

RESULTS AND DISCUSSION

Aggregation Order. Generally, the aggregation kinetics are described by the aggregation order and aggregation rate. The first parameter used to compare the aggregation behavior of different proteins is the aggregation order (n). To exclude the effect of aggregation rate and thereby obtain information only on the influence of conditions on the aggregation order, the decrease of the concentration of nonaggregated protein is plotted against the time divided by the time required to aggregate half of the proteins (t_h) (Figure 1A−C). All curves of one protein superimpose onto one master curve, indicating that the aggregation order is not affected by temperature, concentration, pH, or ionic strength. In other words, the general aggregation process of each protein can be described by a single aggregation order under the different conditions studied. The small variations for ovalbumin and patatin at T_d and T_d + 5 °C were ascribed to small inaccuracies as a result of the fast aggregation rate (i.e., indicated by a $t_h \leq 2$ min; Table 3). The observed discrepancies for patatin under conditions with slower aggregation rates (i.e., indicated by a $t_h \geq 50$ min; Table 3) are not completely understood, but could be caused by a stronger tendency to form larger aggregates in the initial stage of the aggregation process.

The aggregation order for each of the three proteins was determined using three approaches. The first approach derives the aggregation order from the concentration dependence of t_h (Figure 2 and Table 2). The t_h is concentration independent for ovalbumin and patatin, indicating a first-order reaction. For ovalbumin, this is in line with previous data,[6] whereas for patatin no previous data are present. For β-lactoglobulin, on the other hand, t_h depends on the concentration. The slope of the concentration dependence of t_h is −0.5. This shows that, within the experimental error, t_h scales with $\sqrt{C}$, implying an order of 1.5.[7] This is in line with the literature.[5,7] The second approach is based on fitting the decrease of the concentration of nonaggregated protein in time using eqs 1 and 2. For all proteins, the order of the aggregation process is higher than second-order kinetics (i.e., n = 2.5, 2.1, and 2.9 for β-lactoglobulin, ovalbumin, and patatin, respectively) (Table 2). This indicates a complex aggregation process, in which nonaggregated proteins, for example, aggregate with other nonaggregated proteins as well as aggregated proteins. The third approach is based on fitting the decrease of ln C_t, $1/\sqrt{C_t}$, or $1/C_t$ in time to a linear function. This resulted in the best fit (i.e., R^2) of an aggregation order of 2.0 for ovalbumin and patatin (R^2 = 0.95 ± 0.04 and 0.97 ± 0.01 for ovalbumin and patatin, respectively) (Table 2). Moreover, it showed that the first-order kinetics for ovalbumin and patatin, as determined by the first approach,

Table 2. Aggregation Order of Ovalbumin (Ova), β-Lactoglobulin (β-Lg), and Patatin (Pat) Determined by Different Methods[a]

determination of the aggregation order	Ova	β-Lg	Pat
(1) concentration dependence of t_h ($C_t \geq 0.5C_0$)	1.0	1.5	1.0
(2) fit concentration in time using eqs 1 and 2 ($C_t \geq 0.05C_0$)	2.1	2.5	2.9
(3.1) linear fit of ln(C_t) in time (n = 1.0) ($C_t \geq 0.05C_0$)	R^2 = 0.28 ± 0.32	R^2 = 0.85 ± 0.13	R^2 = 0.28 ± 0.30
(3.2) linear fit of $1/\sqrt{C}$ in time (n = 1.5) ($C_t \geq 0.05C_0$)	R^2 = 0.80 ± 0.13	R^2 = 0.96 ± 0.04	R^2 = 0.83 ± 0.09
(3.3) linear fit of $1/C$ in time (n = 2.0) ($C_t \geq 0.05C_0$)	R^2 = 0.95 ± 0.04	R^2 = 0.93 ± 0.07	R^2 = 0.97 ± 0.01

[a]The variation reported for methods 3.1−3.3 represents the standard deviation between R^2 values obtained from fitting the individual conditions separately.

[a]Aggregation rate determined on the basis of n = 2.

with low R^2 (i.e., R^2 = 0.28), disqualifies the first-order kinetics. This discrepancy between the concentration and time fit has been described previously.[41] Because the time fit approaches include all of the data for fitting, it is concluded that the overall aggregation can be well described on the basis of second-order kinetics. The best for β-lactoglobulin was an aggregation order of 1.5 (R^2 = 0.96 ± 0.04). The fit of the data of β-lactoglobulin for a second-order reaction is, however, not significantly different from that of an order of 1.5. Although the aggregation process of β-lactoglobulin can overall be described by an aggregation order of 1.5 or 2.0, the aggregation process at pH 5.0 shows a better fit with first-order kinetics (i.e., R^2 = 0.99 and 0.84 for n = 1.0 and 1.5, respectively).

Summarizing, the aggregation process of all tested proteins, β-lactoglobulin, ovalbumin, and patatin, is described by an order of 2.0 (R^2 > 0.90 for all proteins). The aggregation process of β-lactoglobulin at pH 5.0 is a first-order process.

Aggregation Rate. In the previous section, the reaction order was determined from rescaled data (i.e., t/t_h). The aggregation rate (k) is determined by fitting the decrease of the concentration of nonaggregated protein versus real time (t) with eq 2. To allow quantitative comparison of the aggregation rates, the data of all proteins are fitted with an aggregation order of 2.0 (R^2 > 0.90 for all proteins) (Table 2).

Effect of Temperature (2 g/L in 10 mM Buffer, pH 7.0). Quantitatively, the effect of temperature on the aggregation rate varies significantly between the proteins (Figures 1D-F and Table 3). Whereas the decrease of the concentration of nonaggregated protein for ovalbumin and patatin at T_d − 5 °C (pH 7.0, I = 10 mM, and C = 2 g/L) is in the same order of magnitude (i.e., t_h ∼ 10 min), the decrease of nonaggregated β-lactoglobulin is significantly slower (i.e., t_h ∼ 220 min) (Table 3). In addition, the temperature dependence of the aggregation rate varies significantly between the proteins. This temperature dependence is reflected in the activation energy (E_a), calculated using the Arrhenius equation, which was found to be 343, 293, and 220 kJ/mol for patatin, ovalbumin, and β-lactoglobulin, respectively (Supporting Information). These activation energies are lower than those reported in the literature (i.e., ∼ 260−300 kJ/mol for β-lactoglobulin[42,43] and 338 kJ/mol for ovalbumin[24]) under similar conditions (i.e., pH 6.5−7.0).

Summarizing, the aggregation rate decreases in the order ovalbumin ≥ patatin ≫ β-lactoglobulin. On the basis of the relative exposed hydrophobicity, the order was expected to be β-lactoglobulin > patatin > ovalbumin. On the basis of the net surface charge density, no large differences were expected. Considering the possibility that the free sulfhydryl groups can interchange with disulfide bonds,[44] the expected order is ovalbumin > β-lactoglobulin > patatin. From the preceding, it is concluded that there is no clear unambiguous relationship between one of these protein properties and the determined rate of aggregation. One parameter that has not often been considered is the extent of protein unfolding. The extent of unfolding may be limited by the presence of disulfide bonds. Therefore, patatin and ovalbumin are expected to unfold more completely than β-lactoglobulin, due to the presence of two disulfide bonds in β-lactoglobulin. Consequently, fewer hydrophobic amino acids become exposed for β-lactoglobulin than for the other two proteins, leading to fewer noncovalent interactions.

Effect of pH (2 g/L in 10 mM Buffer Heated at T_d − 5 °C). The aggregation rate of ovalbumin is not affected by the pH in the range from pH 5 to 7 (Figure 1D and Table 3). The aggregation rates of β-lactoglobulin and patatin, on the other hand, are slower at a pH closer to the isoelectric point (pI), with t_h of 223 and 10.8 min at pH 7.0, compared to t_h of 1052 and 73 min at pH 5.0 for β-lactoglobulin and patatin, respectively (Figure 1E,F and Table 3).

For patatin, the effect of pH seems to be due to a difference in the denaturation temperature. When the aggregation rates of patatin at pH 5 and 6 are compared to those at pH 7 at different temperatures, they are similar to those at pH 7 at a temperature between T_d − 5 °C and T_d − 10 °C (Table 3). This corresponds with a theoretical increase of T_d of ∼4 °C, which is in close agreement with the literature, that is, a 3 °C increase of T_d from pH 7 to 6.[45] For β-lactoglobulin, the aggregation rate at pH 5 and 6 is slower than that at pH 7 and T_d − 10 °C (Table 3). The observed decrease of the aggregation rate by shifting the pH toward the pI is in line

DOI: 10.1021/acs.jafc.5b00927
J. Agric. Food Chem. 2015, 63, 5257−5265

with the literature.[5,7,8,14] However, on the basis of the temperature dependence of the aggregation rate (Table 3), the T_d should increase by 7−10 °C to explain the decrease in aggregation rate. Experimentally, the T_d of β-lactoglobulin was reported to increase by only 2 °C when the pH was decreased from pH 7 to 5.[16] Consequently, another factor also has to be influenced by the pH change. The association state of β-lactoglobulin, as measured by SEC, was not affected by the pH changes (data not shown). The thiol groups, on the other hand, become less reactive with decreasing pH.[8] Therefore, the decreased reactivity of the thiol groups can explain the observed differences.

Effect of Ionic Strength (2 g/L in Buffer, pH 7.0, Heated at T_d − 5 °C) and Concentration (10 mM Buffer, pH 7.0, Heated at T_d − 5 °C). For β-lactoglobulin, the aggregation rate increases with increasing ionic strength (i.e., t_h decreases from 223 min at 10 mM to 87 min at 100 mM) and protein concentration (i.e., t_h decreases from 255 min at 1 g/L to 84 min at 10 g/L) (Figure 1E and Table 3). The effect of ionic strength is explained by a decrease of the electrostatic repulsion within and between the protein molecules. This was described to result in an increase of the denaturation temperature (i.e., 2 and 5 °C from 0 to 100 mM for β-lactoglobulin and BSA, respectively).[21,22] In addition, it also results in a decrease of the electrostatic barrier for aggregation.[23] As in this case the aggregation rate increases rather than decreases, the enhancing effect of electrostatics was more important than the observed increase of the denaturation temperature. The effect of concentration on the aggregation rate is in line with previous data.[7] The effect is postulated to be caused by the fact that at higher protein concentrations the absolute number of unfolded protein increases, resulting in an increased likelihood of proteins to meet, collide, and aggregate. In contrast to the observation for β-lactoglobulin, the aggregation rates of ovalbumin and patatin are affected neither by the ionic strength nor by the protein concentration (Figure 1D,F). These results show that it is important to use different proteins, as the behavior of proteins cannot be extrapolated from one protein to another.

Formation of Aggregates. Whereas some protein solutions remained transparent after heating, others became translucent or opaque. These clear visual differences between the heated protein solutions are also reflected in the ionic strength dependence of the aggregated protein in time determined by SEC (Figure 3).

At all ionic strengths, the UV peak area corresponding to the aggregates initially increases and subsequently decreases. This decrease shifted to shorter heating times with increasing ionic strength. This decrease at increased ionic strength and longer times is due to the formation of larger aggregates, which are removed during the centrifugation step prior to SEC analysis.

To obtain insights into the effect of the conditions (e.g., pH) on the formation of aggregates, the scattered light intensity is monitored in time (Figure 4A−C). According to eq 4, an increase in the scattered light intensity is caused by an increase of the aggregate size and/or alterations of the aggregate shape (at a given concentration). On the basis of the aggregation kinetics (Table 3), the time is recalculated into the fraction aggregated protein (Figure 4D−F). This provides insights into the aggregation mechanism (e.g., preference toward the formation of small or large aggregates).

For ovalbumin and β-lactoglobulin, the scattered light intensity does not significantly increase when the proteins are heated at T_d − 5 °C in a concentration of 2 g/L. For patatin, on the other hand, the intensity of the scattered light increases significantly (i.e., I/I_0 = 8 after 7200 s). This indicates that the patatin aggregates are larger and/or denser than the ovalbumin and β-lactoglobulin aggregates. These differences cannot be explained on the basis of the aggregation kinetics (i.e., t_h values of ovalbumin and patatin are similar). This shows that for patatin the formation of fewer, but larger, aggregates is favored over more, smaller aggregates, as is the case for ovalbumin and β-lactoglobulin under these conditions.

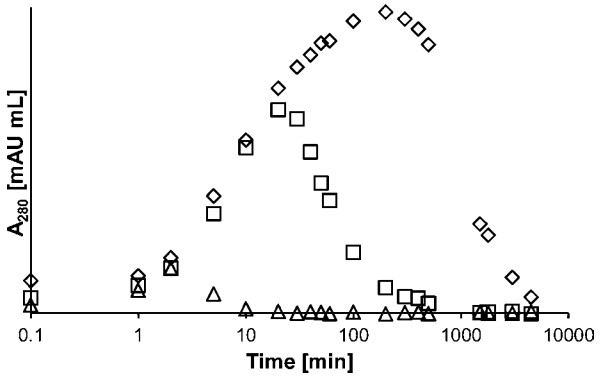

Figure 3. UV peak area of aggregated patatin (10 mM sodium phosphate buffer pH 7.0, 2 g/L, T_d − 5 °C) in time determined by size exclusion chromatography. The markers represent samples heated at different NaCl concentrations: 0 mM NaCl (◇), 10 mM NaCl (□), and 90 mM NaCl (△).

Effect of pH and Ionic Strength. For β-lactoglobulin, a lag phase precedes the intensity increase (Figure 4B). Moreover, the intensity of the scattered light in time increases for all three proteins (i.e., ovalbumin, β-lactoglobulin, and patatin) with increasing ionic strength or a shift of the pH toward the p*I* (Figure 4A−C). The intensity, however, increases more strongly for patatin (i.e., I/I_0 = 47 and 12 after 200 s for pH 5 and 100 mM, respectively) compared to β-lactoglobulin (i.e., I/I_0 = 10 and 22 after 7200 s for pH 5 and 100 mM, respectively) and ovalbumin (i.e., I/I_0 = 12 after 900 s and 8 after 7200 s for pH 5 and 100 mM, respectively). The observed lag phase for β-lactoglobulin has also been reported in the literature, where it is ascribed to the monomer−dimer equilibrium[46] or the formation of small aggregates.[16] Furthermore, it was concluded that a decrease of the electrostatic repulsion results in the formation of larger and/or denser aggregates. This is explained by a lower electrostatic repulsion between the aggregates. Consequently, aggregates can continue to grow to larger sizes and/or the formed aggregates are denser. In the literature, the molecular mass and size of β-lactoglobulin aggregates were also described to increase when the pH shifts toward the p*I* or the ionic strength increases.[8,47,48] However, as shown, this effect is not the same for all proteins. The difference among the proteins indicates that the magnitude by which the aggregate size/structure in time is affected by electrostatics depends on the protein.

Recalculating time into the fraction aggregated protein provides information on the mechanism of aggregation (Figure 4D−F). Close to the p*I* (i.e., pH 5), for patatin and β-lactoglobulin, the intensity increases with the incorporation of even a minor fraction of the protein into the aggregates (i.e., ∼5%) (Figure 4E,F). For ovalbumin, the intensity increased after ∼25% of the protein aggregated (Figure 4D). At a pH away from the p*I* or at lower ionic strength, a larger fraction of aggregated protein is required

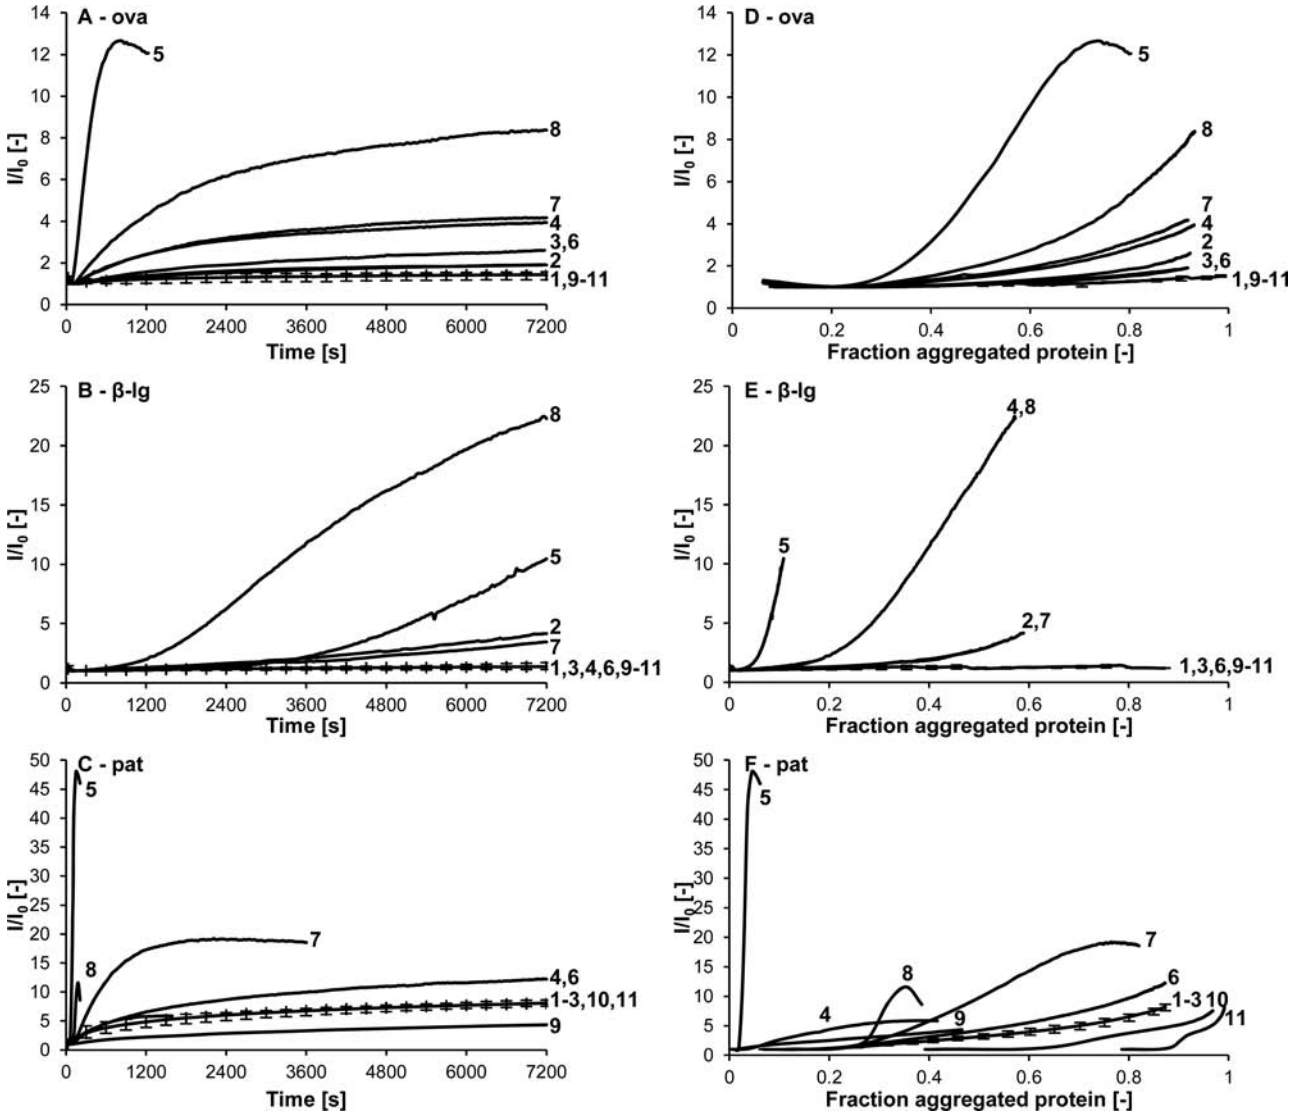

Figure 4. Normalized intensity (I/I_0) of heated ovalbumin (A, D), β-lactoglobulin (B, E), and patatin (C, F) in time (A−C) and as a function of the fraction of aggregated protein (D−F). The numbers represent the different conditions: (1) T_d − 5 °C and 2 g/L; (2) 10 g/L; (3) 5 g/L; (4) pH 6.0; (5) pH 5.0; (6) 10 mM NaCl; (7) 40 mM NaCl; (8) 90 mM NaCl; (9) T_d − 10 °C; (10) T_d; (11) T_d + 5 °C. The error bars indicate the standard deviation between the different conditions with similar behaviors.

for the intensity to increase. These results show that for patatin and β-lactoglobulin at low electrostatic repulsion (i.e., pH 5) even in the initial stages (i.e., <10% aggregated protein) large and/or dense aggregates are formed. For ovalbumin, on the other hand, the lag phase indicates that initially (i.e., <25% aggregated protein) smaller and/or more open aggregates are formed. Subsequently, at a higher fraction of aggregated protein, large and/or denser aggregates are formed. Similarly, also at higher electrostatic repulsion initially smaller and/or more open aggregates are formed, followed by the formation of larger and/or denser aggregates. The differences between the proteins show that patatin has the highest tendency to form larger and/or denser aggregates.

Effect of Concentration and Temperature. In general, changes in temperature or concentration resulted in only minor changes of the light scattering intensity as a function of heating time (Figure 4A−C). This shows that these two parameters do not affect the aggregate formation (i.e., size and structure) as strongly as the ionic strength or pH. For patatin, the intensity increase upon heating is concentration independent, whereas it decreases with decreasing temperature (i.e., $I/I_0 = 4$ after 7200 s) (Figure 4C). For β-lactoglobulin and ovalbumin, the intensity in time increases slightly with increasing concentration (i.e., $I/I_0 =$ 4 and 3 at 10 g/L after 7200 s for β-lactoglobulin and ovalbumin, respectively) (Figure 4A,B). This increase is in line with the literature, as the mass and size of β-lactoglobulin aggregates have been described to increase with concentration (at higher concentrations until 110 g/L).[7,28,49] The effect of temperature on the aggregation of patatin is expected to be purely determined by kinetics, as a consequence the aggregate formation in time is reduced.

From the intensity as a function of the fraction aggregated protein it can be observed that, even at large fractions of aggregated protein, the intensity is not affected by concentration and temperature. This confirms that, also after correcting for the aggregation kinetics, the aggregate size and structure are, within the tested temperature and concentration range, independent of temperature and concentration. Hence, at high electrostatic repulsion (i.e., pH 7.0 and 10 mM), relatively small and/or open aggregates are formed.

DOI: 10.1021/acs.jafc.5b00927
J. Agric. Food Chem. 2015, 63, 5257−5265

In summary, aggregate formation is limited by the electrostatic repulsion between proteins or protein aggregates due to their charge. In the case of charge screening (i.e., increased ionic strength) or a decreased surface charge (i.e., pH closer to p*I*), this electrostatic barrier decreases and larger and/or denser aggregates are formed. Concentration and temperature, on the other hand, did not strongly affect the aggregate size or structure. Although for all proteins aggregate formation was qualitatively similar, quantitatively the behavior was significantly different. This shows that the information on one protein cannot directly be related to another protein. In general, ovalbumin showed to have the least tendency to form larger and/or denser aggregates, followed by β-lactoglobulin. Patatin, on the other hand, directly forms large and/or dense aggregates.

In conclusion, the comparison of different proteins shows that the sensitivity toward system conditions (i.e., pH, ionic strength, and concentration) varies significantly between the proteins. Whereas it was expected that the aggregation behavior relates to the molecular properties of a protein, there is no clear link between the observed aggregation behavior and known protein molecular properties such as surface charge and exposed hydrophobicity. This was, for instance, illustrated by the lower tendency of ovalbumin to form larger, denser aggregates than patatin and β-lactoglobulin, although the surface charges of these proteins are similar. Therefore, the generic relationships commonly assumed in the literature need to be considered with care.

In addition, although the classical reaction rate kinetics are often used to describe the aggregation process of proteins, it was shown to contain little information about the actual size/density of the formed aggregates. Consequently, for a more complete description of the aggregation process, not only the loss of monomers but also a detailed analysis of the aggregates is required.

For a fundamental understanding of the influence of molecular properties on the aggregation process and to exclude factors relating to differences in unfolding behavior, it is important to compare the aggregation behavior at a constant distance from T_d. This is in contrast to the fact that for practical situations a comparison at a constant temperature is more valuable (i.e., realistic).

Supporting Information

ABSTRACT: To enhance the oral bioaccessibility of flavonoids, including quercetin, naringenin, and hesperetin, we prepared an edible oil-based lipid nanoparticle (LNP) system. Flavonoid-loaded LNPs were similar to the blank LNP in physicochemical characteristics (z average <154.8 nm, polydispersity index <0.17, and ζ potential < −40.8 mV), and their entrapment efficiency was >81% at 0.3 wt % flavonoid concentration of the lipid phase. In the simulated digestion assay (mouth, stomach, and small intestine), LNPs were hydrolyzed under small intestine conditions and protected successfully incorporated flavonoids (≥94%). Moreover, the relative bioaccessibility of flavonoids was >71%, which was otherwise <15%, although flavonoids were released rapidly from LNPs into the medium. In conclusion, since the flavonoids incorporated in LNPs were preserved well during oral digestion and had improved bioaccessibility, the designed LNP system may serve as an encapsulation strategy to enhance the bioavailability of nonbioaccessible nutraceuticals in foods.

INTRODUCTION

Quercetin is the representative flavonol in various vegetables and fruits such as onion and apple[1] and has antioxidative,[2] anticarcinogenic,[3] anti-inflammatory,[4] antiaggregatory,[5] and vasodilatory[6] effects. Naringenin and hesperetin are the representative flavanones in various fruits, such as orange, lemon, and grape;[7] they have antioxidant[8] and anti-inflammatory[9] activities and influence lipid[10] and sex hormone metabolism.[11] This could imply that quercetin, narigenin, and hesperetin, as the major flavonoids, are easy to take in from foods in the common diet and have crucial roles in human health. Despite their health benefits, the parent forms have low bioavailability because of their low water solubility. Although these compounds can be ingested as their glycosides, such as rutin, naringin, and hesperidin, directly from vegetables and orange/grape juices to increase bioavailability, plasma flavonoid levels are low in comparison to the amount ingested.[12,13] Moreover, as flavonoid glycosides are cleaved by enzymes and microflora before absorption in the small and large intestines, respectively, bioavailability could vary among individuals.[1] Therefore, the bioavailability of the flavonoid parent forms must be improved.

Lipid nanoparticle (LNP) systems have drawn attention for using physiological lipids, protection of core materials, and improvement of the oral bioaccessibility of lipophilic materials; due to their submicron size, they have an increased residence time by adhering to the gastrointestinal wall or entering the intervillar spaces.[14] Some researchers have recently reported that the bioaccessibility of polyphenols such as resveratrol,[15] curcumin, and genistein[16] was enhanced by LNP encapsulation. Despite the benefits of oral administration of bioactive lipophilic molecules such as flavonoids, colloidal stability problems such as aggregation impede food applications. The LNP matrix crystallizes into a β polymorphic form during cooling and can cause morphological changes in individual particles and increase surfactant-depleted areas (hydrophobic patches) of the LNP, resulting in aggregation due to interactions between hydrophobic patches that minimize the uncovered surface area facing the water phase.[17] Additionally, partial coalescence of oil droplets containing crystals during cooling can cause aggregation.[18,19] Thus, methods to enhance stability have been reported, including using a lipid source that prevents or retards β-form crystallization[20] and using an emulsifier that prevents particle aggregation by increasing steric hindrance and electrostatic repulsive forces.[21]

The behavior of flavonoid-loaded LNPs in the oral and gastrointestinal tracts has been described to demonstrate their benefits when the system is adopted to enhance bioaccessibility and protect against physical and biochemical stressors, such as salts, pH, and digestive enzymes.[22] For the same reason, the digestion of LNPs encapsulating bioactive lipophilic components (nutraceuticals) has been evaluated extensively. LNPs mix with saliva in the mouth (neutral pH) after ingestion and

J. Agric. Food Chem. 2015, 63, 5266−5272

then travel to the stomach (pH 1−3), which provides complex flow and changes the pH, ionic strength, and digestive enzyme levels[23,24] that could promote oxidation of nutraceuticals and particle aggregation due to flocculation and/or coalescence. After it enters the small intestine, the mixture of LNPs, saliva, and gastric juice is blended with duodenal and bile juices containing pancreatic lipase, colipase, bile salts, phospholipids, and bicarbonate, and digestive enzymes convert LNP triglycerides into monoglycerides and free fatty acids. The products of lipid digestion are taken up into bile salt/phospholipid micelles, and the mixed micelles incorporate the nutraceuticals, resulting in transportation of the micelles to the surfaces of enterocytes, where they are absorbed.[21]

Therefore, LNPs encapsulating flavonoids must be resistant to the harsh conditions in the mouth and stomach to improve their bioaccessibility and protect them until they are absorbed into enterocytes. Unfortunately, many studies have investigated the individual digestion process of LNPs under in vivo and in vitro conditions of the mouth, stomach, or small intestine, making it difficult to describe the serial events occurring in an actual digestive system. In this study, the composition of LNPs prepared using food grade materials—including fully hydrogenated canola oil as the solid lipid, liquid oils (liquid soybean oil, squalene, or canola oil) to prevent or retard crystallization, Tween 20 as a nonionic emulsifier to produce a steric effect, and soybean lecithin as an ionic emulsifier providing electrostatic repulsive force—was optimized in terms of colloidal stability. Furthermore, the fates of quercetin-, naringenin-, and hesperetin-loaded LNPs during the serial events of digestion in the mouth, stomach, and small intestine were mimicked in simulated digestive media.

MATERIALS AND METHODS

Chemicals. Lotte Samkang Co. Ltd. (Seoul, Korea) provided fully hydrogenated canola oil (FHCO), which was composed of 79.5 wt % stearic acid, 8.8 wt % palmitic acid, 4.2 wt % oleic acid, 1.8 wt % lauric acid, 1.6 wt % arachidic acid, 1.4 wt % linoleic acid, 0.9 wt % myristic acid, and 1.8 wt % other ingredients. Liquid soybean oil (LSO; 49.3 wt % linoleic acid, 23.2 wt % oleic acid, 10.2 wt % palmitic acid, 4.9 wt % linolenic acid, 3.8 wt % stearic acid, 0.3 wt % arachidic acid, 0.2 wt % lauric acid, 0.2 wt % erucic acid, 0.1 wt % myristic acid, and 7.7 wt % other ingredients) and liquid canola oil (LCO; 58.3 wt % oleic acid, 20.0 wt % linoleic acid, 8.3 wt % linolenic acid, 4.4 wt % palmitic acid, 1.8 wt % stearic acid, 1.3 erucic acid, 0.6 wt % arachidic acid, and 5.3 wt % other ingredients) were obtained from CJ Cheiljedang Co. (Seoul, Korea). Squalene (>98%; SQ) was obtained from Alfa Aesar (Heysham, England). Tween 20 (T20; polyoxyethylene sorbitan monolaurate) and soybean lecithin (SL) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA) and Fisher Scientific (Pittsburgh, PA, USA), respectively. Quercetin and naringenin were obtained from MP Biomedicals LLC (Solon, OH, USA), and hesperetin was obtained from Sigma-Aldrich Co. All other chemicals were of analytical reagent grade.

Lipid Nanoparticle Production. The LNPs were prepared using an oil-in-water emulsion technique with a high-speed blender and sonication probe as reported previously by us,[17] with a slight modification. First, the lipid (5 wt %) and aqueous (95 wt %) phases were heated to 85 °C, mixed using a high-speed blender (Ultra-Turrax T25D, Ika Werke GmbH & Co., Staufen, Germany) at 8000 rpm for 1 min and then at 11000 rpm for 1 min, and maintained at 85 °C; the lipid phase of the blank LNPs was a mixture of 5−3.5 wt % FHCO (100−70 wt % of the lipid phase) and 0−1.5 wt % of each liquid oil (0−30 wt % of the lipid phase) among LSO, LCO, and SQ;, and the aqueous phase was prepared by adding an emulsifier mixture (one-third of the lipid phase weight) composed of T20 (100−0 wt % of the emulsifier mixture) and SL (0−100 wt % of the mixture) in doubly distilled water (DDW) containing 0.02 wt % sodium azide. After the coarse oil-in-water emulsion was produced, the droplet size was further reduced by sonication (VCX 750, Sonics & Materials Inc., Newtown, CT, USA) for 4 min at 60% amplitude, a duty cycle of 1 s, and 95 °C. After the droplet size was reduced, postsonication for 6 min was applied to the emulsions during cooling to 25 °C in a jacketed beaker, and the samples were maintained at room temperature (25 °C).

The lipid phase was composed of FHCO blended with 30 wt % SQ of the phase to prepare the LNP-loaded flavonoid molecules (quecetin, naringenin, and hesperetin) and the additional flavonoids of 0.1−0.5 wt % concentration in the lipid; a mixture of T20 (32.28 wt % of the mixture) and SL (67.72 wt % of the mixture) was used as an emulsifier in the aqueous phase to optimize system stability. The lipid phase incorporating the flavonoids was stirred gently at 85 °C for 30 min, and the remaining production process was conducted as for the blank LNP.

Quantification of Nonaggregated Lipid Nanoparticles (Yield). LNPs diluted 10-fold with DDW were passed through a 1 μm pore size glass microfiber filter (GF/B, Whatman Ltd., Loughborough, U.K.). The aggregated LNPs remaining on the filter (micrometer scale) were weighed after drying in an oven at 50 °C. The difference in filter weights before and after the procedure, which was the weight of the creamed or aggregated LNPs, was recorded.

Measurements of Lipid Nanoparticle Size and ζ Potential. The prepared LNPs (4.5 mL) were diluted with 40.5 mL of DDW in a vial to separate the layers containing the creamed (creaming layer) and noncreamed LNPs (aqueous layer). The vial containing the diluted samples was sealed tightly with a screw cap and incubated overnight at room temperature. The LNPs in the aqueous layer were collected by filtering with a 1 μm pore size glass microfiber filter (GF/B, Whatman Ltd.) to determine the size of the noncreamed LNP, and their mean particle size (z average) and polydispersity index (PDI) were measured using a Zetasizer instrument (Nano ZS, Malvern Instruments Ltd., Worcestershire, U.K.) operated at a 173° angle with a helium−neon laser (λ 633 nm). In addition, the ζ potential (ZP) was measured using the Zetasizer. The ZP measurement was based on the Smoluchowski equation at 25 °C with an electric field strength of 20 V cm^{-1}.

Entrapment Efficiency of the Flavonoid-Loaded Lipid Nanoparticles. A 1 mL portion of n-butanol was added to 1 mL of each LNP sample encapsulating the flavonoids (quercetin, naringenin, and hesperetin). The sample was vortexed for 10 s and then centrifuged at 10000 RCF for 10 min (Centrifuge Smart 15, Hanil Science Industrial Co., Ltd., Incheon, Korea). After centrifugation, the n-butanol layer was transferred to a microquartz cell, and the absorbance at 377.5 nm (quercetin), 291.5 nm (naringenin), and 289.5 nm (hesperetin) was determined using a spectrophotometer (Pharmaspec UV-170, Shimadzu Corp., Kyoto, Japan). The concentrations of quercetin, naringenin, and hesperetin in the n-butanol layer were calculated using standard curves ranging from 3.125 to 100 μg mL^{-1} for quercetin (R^2 = 0.9975), naringenin (R^2 = 0.9990), and hesperetin (R^2 = 0.9974). Flavonoid entrapment efficiencies (EE) of the LNP samples were determined using the equation

$$\text{EE}\ (\%) = \frac{W_t - W_n}{W_t} \times 100$$

where W_t is the total flavonoid molecule weight in the entire LNP sample system and W_n is the flavonoid molecule weight in the n-butanol layer after centrifugation.

Determining the in Vitro Digestion Patterns of the Lipid Nanoparticles. The simulated in vitro digestion test model was modified from the version described by Hur et al:[25]

(I) preingestion: LNPs were filtered with a 1 μm pore sized filter
(II) mouth (pH 7; 5 min): 5 mL of filtered LNPs was blended with 6 mL simulated salivary medium
(III) stomach (pH 3; 2 h): 12 mL of simulated gastric juice was added
(IV) small intestine (pH 6.5−7; 2 h): simulated duodenal juice (12 mL), bile juice (6 mL), and $NaHCO_3$ solution (2 mL) were added

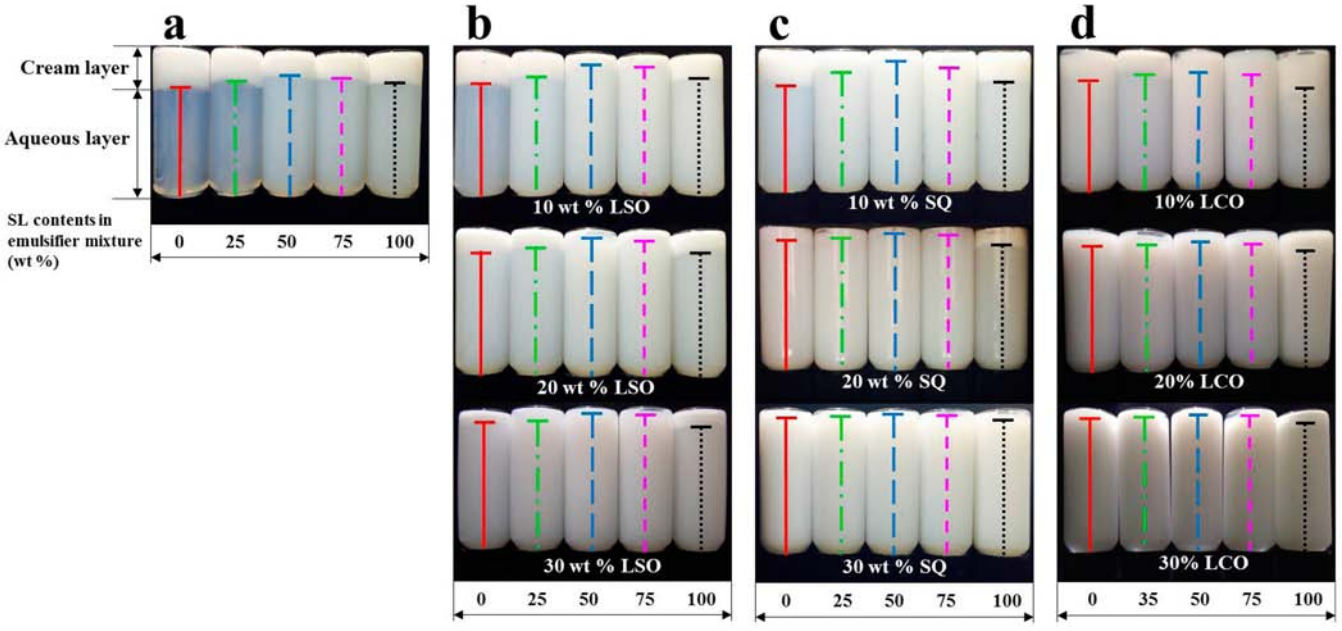

Figure 1. Creaming pattern of the blank lipid nanoparticle dispersion diluted 10-fold: (a) blank lipid nanoparticle dispersions prepared using 100 wt % fully hydrogenated canola oil (FHCO) as the lipid phase; blank lipid nanoparticle dispersions prepared using a mixture of 90–70 wt % FHCO and 10–30 wt % liquid oil, including (b) liquid soybean oil (LSO), (c) squalene (SQ), or (d) liquid canola oil (LCO) as the lipid phase.

The formulations of the simulated saliva medium and gastric, duodenal, and bile juices are shown in Table 1. All samples were stirred (60 rpm) in a shaking water bath (BS-31, JEIO Tech., Seoul, Korea) during the in vitro digestion test and maintained at 37 °C to mimic gastrointestinal tract motility. After each digestion step (I–IV), the size distribution of samples was measured using the Zetasizer.

After 4 h 5 min of digestion, the relative bioaccessibility of the flavonoid (quecetin, naringenin, and hesperetin) was determined as described earlier,[16] with modifications. Briefly, 2 mL of digesta was centrifuged at 1500 RCF for 30 min, and 1 mL of the supernatant was recentrifuged at 16000 RCF for 20 min. A 0.2 mL aliquot of the supernatant was collected and diluted 10-fold with 1.8 mL of methanol, and the solution was centrifuged at 16000 RCF for 20 min. The concentration of flavonoids in the supernatant was quantified using a spectrophotometer and calculated using standard curves ranging from 0.625 to 10 μg mL^{-1} for quercetin (λ 384 nm, R^2 = 0.9971), naringenin (λ 325 nm, R^2 = 0.9990), and hesperetin (λ 324.5 nm, R^2 = 0.9999). The relative bioaccessibility of the flavonoids in the digested micellar fraction was determined using the equation

$$\text{bioaccessibility (\%)} = \frac{W_t - W_s}{W_t} \times 100$$

where W_s is the weight of the flavonoid molecules in the supernatant after digestion and centrifugation. In addition to the flavonoid-encapsulated LNPs, equivalent quantities (150 μg mL^{-1}) of quercetin, naringenin, and hesperetin in their native forms were also investigated.

The protectibility (%) of LNPs for flavonoids against harsh conditions (pH and salt) was determined after each digestion step

(II−IV) without enzymes. After each step, 0.2 mL of digesta was collected and diluted 10-fold with 1.8 mL of methanol and centrifuged at 16000 RCF for 20 min. The concentration of flavonoids in the supernatant was quantified using a spectrophotometer and calculated using standard curves ranging from 0.625 to 10 μg mL^{-1}: step II, quercetin (λ 389 nm, R^2 = 0.9999), naringenin (λ 325.5 nm, R^2 = 1.0000), and hesperetin (λ 325.5 nm, R^2 = 0.9999); step III, quercetin (λ 379 nm, R^2 = 1.0000), naringenin (λ 290 nm, R^2 = 0.9998), and hesperetin (λ 287.5 nm, R^2 = 0.9998); step IV, quercetin (λ 389 nm, R^2 = 0.9999), naringenin (λ 325 nm, R^2 = 1.0000), and hesperetin (λ 325 nm, R^2 = 1.0000)). The protectibility of the LNPs incorporating the flavonoids against the enzyme-free digestion medium was determined by the equation

$$\text{protectibilty (\%)} = \frac{W_t - W_s}{W_e} \times 100$$

where W_e is the weight of the flavonoids encapsulated in the LNPs immediately after preparation.

The release patterns of the flavonoids from the LNPs were studied using dialysis bags with a 12 kDa molecular weight cutoff. The bags were immersed in DDW for 12 h before use. They were filled with 1 mL of the flavonoid-loaded LNP sample, tightly sealed, and suspended in 49 mL of 50% (v/v) ethanol to produce a sink condition. The enzyme-free simulated in vitro digestion medium mixture was added, and the bags were rotated at 100 rpm in a 37 °C water bath. At predetermined time intervals, a 1 mL aliquot was withdrawn from the medium mixture, and 1 mL of fresh medium was replaced immediately. Next, the absorbance of the aliquot at the wavelengths for quercetin (377.5 nm), naringenin (291.5 nm), and hesperetin (289.5 nm) was measured with a spectrophotometer. The concentrations of quercetin, naringenin, and hesperetin in the aliquots were calculated using standard curves ranging from 3.125 to 250 μg mL^{-1} for quercetin (R^2 = 0.9996), naringenin (R^2 = 0.9999), and hesperetin (R^2 = 0.9999).

Statistical Analysis. All results were analyzed using Tukey's significant difference test using the IBM SPSS Statistics version 21.0 software (IBM Co., Armonk, NY, USA). Data represent means of at least three independent experiments or measurements. A p value <0.05 was considered to indicate a significant difference.

RESULTS AND DISCUSSION

Stability of the Blank Lipid Nanoparticles. The partially coalesced LNPs and the LNPs with surfactant-depleted patches on the surfaces formed micrometer-sized aggregates.[17] According to Stokes' law, the particle size effect on the creaming rate predominates over the density difference at the same composition. Therefore, the aggregated micrometer-sized particles creamed readily, whereas the stable nanosized LNPs were well-dispersed in aqueous solution.[17]

The creaming phenomenon of the LNP aggregates was observed when blank LNPs prepared with 100 wt % FHCO as the lipid phase were diluted 10-fold with DDW (Figure 1a). The micrometer-sized LNP aggregates and the nanosized LNPs formed creaming and aqueous layers, respectively. The particle size of all blank LNPs prepared with 100 wt % FHCO was 123.2−165.1 nm, indicating that submicron-sized particles comprised the aqueous layer. Thus, the thickness of the aqueous layer reflected the number of LNPs stably produced on a nanosize scale, which was related to the colloidal stability of the LNP system.

The aqueous layers of samples stabilized with a single emulsifier (SL contents: 0 and 100 wt %) were thinner than those emulsified with T20 and SL (SL contents: 25, 50, and 75 wt %). Additionally, the yields of the 25, 50, and 75 wt % SL content samples were larger than those of the 0 and 100 wt % SL content samples (Table S1 in the Supporting Information), suggesting that combined use of T20 and SL enhanced the colloidal stability of the LNP system, which agrees with other studies.[26] This tendency was also applied to the LNP samples fabricated using a lipid mixture with FHCO and liquid oil (LSO, SQ, or LCO) as the lipid phase (Figure 1b−d).

We observed in our previous study that increasing the liquid oil content in the LNP lipid phase improves the colloidal stability of the system,[17] which was confirmed here (Figure 1b−d). Furthermore, the thickness of the aqueous layer differed when the liquid oil type was changed. Therefore, LNP samples with SQ as the liquid oil in the lipid matrix had the thickest aqueous layer at the same liquid oil and SL contents. This result is in agreement with the yield data (Table S1 in the Supporting Information). These results suggest that using SQ as the liquid oil could produce optimum colloidal stability among LSO, SQ, and LCO. Thus, the preparation formula of blank LNP was optimized by using SQ as the liquid oil.

(a) Particle size (*z* average) changes in blank and lipid nanoparticles (LNPs) loaded with 0.3 wt % quercetin (0.3Q), 0.3 wt % naringenin (0.3N), and 0.3 wt % hesperetin (0.3H) after simulated in vitro digestion tests (preingestion, mouth, stomach, and small intestine). (b) Bioaccessibility (%) of Q, N, and H contents in the digested micellar fraction after simulated digestion was completed. (c) Protectibility (%) of flavonoid-loaded LNPs for flavonoids after incubation in an enzyme-free simulated digestion medium. (d) In vitro cumulative release profiles of flavonoid molecules from the lipid matrix in the enzyme-free simulated digestion medium using a dialysis membrane under sink conditions (50% v/v ethanol).

Characteristics of Lipid Nanoparticles. As shown in the previous section, SQ in the lipid phase produced the most stable LNPs, and utilizing the combination of T20 and SL increased the stability. Thus, SQ and SL contents in blank LNPs may be the main factors determining colloidal stability. Consequently, the optimum SQ and SL contents (SQ content, 30 wt %; SL content, 67.72 wt %) for preparing blank LNPs were determined in terms of the stability using RSM (Supporting Information), and the formula was applied also to preparation of the flavonoid-loaded LNPs. Their physicochemical characteristics are shown in Table 2.

All LNP systems had similar yields and PDI values. Moreover, no changes in the particle size (144.9−156.2 nm) or the ZP (−45.1 to −40.5 mV) values were observed, regardless of the concentration and type of flavonoid. In other words, the flavonoid molecules in the LNP did not affect the physicochemical characteristics (yield, particle size, PDI, and ZP). Therefore, an LNP system encapsulating flavonoids at 0.1−0.5 wt % of the lipid phase would have colloidal stability similar to that of the blank system optimized.

Flavonoids are generally water insoluble, and the octanol/water distribution coefficients of quercetin, naringenin, and hesperetin at pH 7.0 (log *P*) were 2.74, 2.30, and 2.59, respectively.[27] Therefore, quercetin, naringenin, and hesperetin in a hydrophobic solvent including oil are more soluble than the flavonoids in water. Even though low oil content (5 wt %) could induce partitioning flavonoids from the oil to the water phase during LNP preparation, flavonoid molecules may have a low concentration in the water phase due to a low concentration of flavonoids in the oil phase (0.1−0.5 wt %).[28] Furthermore, after the preparation, the solid lipid matrix in LNPs could block the migration of flavonoids to the water.[29] Thus, a high flavonoid EE was expected for all LNPs, but it was not detected (Table 2). The EE value was the highest at the 0.3 wt % flavonoid concentration, regardless of the flavonoid type. Hence, the LNPs with a 0.3 wt % flavonoid concentration were chosen for the in vitro digestion assay in terms of their high EE values.

In Vitro Digestion of Lipid Nanoparticles. The purpose of encapsulating flavonoids in nanosized LNPs is to increase their bioaccessibility.[21] Thus, the LNPs incorporating flavonoids must not degrade or aggregate until arrival in the small intestine. The loss of emulsifiers on the particle surface could induce aggregation,[30] or the colloidal particles could aggregate due to the high salt or low pH conditions due to the electrostatic attraction.[22] Fortunately, the initial particle size values of our optimized blank LNPs and all flavonoid-loaded LNPs were maintained under the high-salt conditions of the in

J. Agric. Food Chem. 2015, 63, 5266−5272

vitro mouth (Figure 2a), indicating nonaggregation of the LNPs due to salts and nondegradation due to α-amylase. Phospholipids consisting of the SL covering the LNPs have a positive charge under basic conditions, whereas the molecules have a negative charge under acidic conditions.[31] Thus, the SL molecules on the LNP surface aggregated the LNPs due to interactions between the phospholipids and the divalent cations in gastric juice. However, despite the low-pH conditions of in vitro gastric juice; i.e., pH 3, the particle size of all LNPs after the 2 h incubation was similar to the initial size (Figure 2a). This result may have been due to the action of T20 as a costabilizer. This nonionic surfactant can sterically stabilize the particles under low-pH conditions,[32] and the emulsion system stabilized with T20 showed good stability under simulated gastric conditions.[16] After 2 h of digestion in the small intestine juice, all particle size values increased ~5-fold over those preingestion due to degradation and aggregation of the particles (Figure 2a). The emulsifiers (T20 and SL) coating the surface were hydrolyzed by lipase, resulting in aggregation of the particles or displacement of the emulsifiers by bile salts, which exposed the LNPs to lipolysis by digestive enzymes.[16] After enzymatic hydrolysis, lipid degradation products such as monoglycerides and fatty acids form mixed micelles with the bile salts, phospholipids in SL, and the degraded T20 fragments. As a result, the particle size of the mixed micelles increased ~5-fold over that preingestion. Thus, these optimum LNP-loaded flavonoids were not degraded in the mouth or stomach and were digested in the small intestine.

Flavonoids have many health benefits but have limited bioavailability due to low permeability across the apical surface of intestinal epithelial cells.[33] We adopted a lipid-based delivery system (LNPs) to overcome this problem. As mentioned previously, the LNP system is degraded in the intestine by bile salts and digestive enzymes, which results in formation of mixed micelles. Flavonoids incorporated into LNPs would solubilize well in these micelles, whereas a native flavonoid would not be easily taken up by intestinal epithelial cells. The micelles amassed at the epithelial surface are absorbed by enterocytes,[16] which would increase the quantity of bioaccessible and bioavailable flavonoids. In this regard, the experimental data could endorse the previous discussion (Figure 2b). The flavonoid bioaccessibilities (%) of the fabricated LNP samples were greater than that of the native flavonoid, regardless of the type (quercetin, ~12-fold; naringenin, ~5-fold; hesperetin, ~5-fold). The high bioaccessibility of the quercetin-loaded LNPs may be due to the considerable hydrophobicity (log P = 2.74).[27] In any case, all LNP systems prepared successfully increased flavonoid bioaccessibility. These results were in agreement with previously reported research in cases of curcumin and genistein.[16]

The antioxidant activity of flavonoids is sensitive to pH[34] and salt,[35] which could decrease the therapeutic benefit due to the dramatic changes in pH and ion concentrations encountered during oral digestion. The LNPs were incubated with in vitro media without enzymes during digestion tests (mouth, stomach, and small intestine) to evaluate the protectibility of flavonoid-loaded LNPs. During the serial digestion test, the protectibility values of quercetin-, naringenin-, and hesperetin-loaded LNPs decreased to 97, 96, and 95%, respectively (Figure 2c), which meant successful protection of the flavonoids by the LNP system against harsh conditions such as low pH and high concentration of salts. In vitro degradation of other bioactive materials (curcumin and genistein) has also been reported at similar levels.[16] Therefore, our LNP system protected the flavonoids from pH and salt changes during digestion, and the protected flavonoids could maintain their antioxidant activity.

The in vitro flavonoid release test from LNPs was conducted in a medium comprising saliva and gastric, duodenal, and bile juices to mimic the small intestine. The reason for using a medium without digestive enzymes was to separate LNP degradation from the flavonoid release effect. Because of the low water solubility of flavonoids, 50% (v/v) ethanol was added to provide a sink condition in the enzyme-free mixture medium. Almost 100% of the flavonoids within the LNPs were released from the matrix into the medium during the 8 h release test, regardless of type (Figure 2d). The quercetin-, naringenin-, and hesperetin-loaded LNPs released ~74% of the quercetin, 81% of the naringenin, and 86% of the hesperetin into the medium, respectively, 2 h (small intestine residence time) after beginning the test. Although the condition was accelerated by 50% ethanol, these values were larger in comparison with those reported in other studies.[16,36] Lipid crystallization was initiated from the LNP core during cooling while the LNPs were prepared, and the core lipid crystals may have pushed flavonoids to the outer shell of the LNP, resulting in a flavonoid-enriched shell and rapid release of the flavonoids.[37] Nevertheless, this burst release did not affect flavonoid solubility in the mixed micelle, bioaccessibility (%), that formed after degradation by digestive enzymes (Figure 2b). Consequently, our LNP system optimized for colloidal stability successfully enhanced the bioaccessibility of quercetin, naringenin, and hesperetin.

The flavonoid-loaded LNP system, which was optimized by controlling the SQ and SL contents, protected the encapsulated flavonoid molecules against the harsh conditions of the in vitro digestion test until arrival in the small intestine. Moreover, flavonoids incorporated in LNPs were solubilized well into micelles mixed with the LNP digesta (fatty acids, monoglycerides, etc.), bile salts, and phospholipids at the end of the simulated digestion. Consequently, our LNP system using edible materials successfully protected flavonoids and improved bioaccessibility of flavonoids. In conclusion, this work may serve as a basis for further studies to develop an oral delivery system for nonbioaccessible molecules, such as flavonoids, for functional foods.

4-Hydroxy-2-nonenal (4-HNE) and Its Lipation Product 2-Pentylpyrrole Lysine (2-PPL) in Peanuts

Martin Globisch, Diana Kaden, and Thomas Henle*

Institute of Food Chemistry, Technische Universität Dresden, D-01062 Dresden, Germany

Supporting Information

ABSTRACT: After synthesis of a deuterated 4-hydroxy-2-nonenal (4-HNE) standard, the formation of 4-HNE during heating of peanut oil and whole peanuts, respectively, was measured by GC-MS. Whereas a significant increase in 4-HNE levels was observed for peanut oil, the amount of 4-HNE decreased when whole peanuts were roasted due to lipation reactions with amino acid side chains of the proteins. The ε-amino group of lysine was identified as the favored reaction partner of 4-HNE. After heating N^{α}-acetyl-L-lysine and 4-HNE, a Schiff base, a novel pyridinium derivative, a 2-pentylpyrrol derivative and, following reduction and hydrolysis, a reduced, cyclized Michael adduct were identified. 2-Amino-6-(2-pentyl-1*H*-pyrrol-1-yl)hexanoic acid (2-PPL) was synthesized and quantitated in peanut proteins, which had been incubated with various amounts of 4-HNE by HPLC-ESI-MS/MS after enzymatic hydrolysis. At low 4-HNE concentrations the modification of lysine could be entirely explained by the formation of 2-PPL. Additionally, 2-PPL was quantified for the first time in peanut samples, and an increase depending on the roasting time was observed. 2-PPL represents a suitable marker to evaluate the extent of food protein lipation by 4-HNE.

KEYWORDS: *peanut, peanut oil, lipid peroxidation, lipation, carbonyl protein reaction, 4-hydroxynonenal, 4-hydroxynon-2-enal, 4-hydroxy-2-nonenal, 4-HNE, HNE, 2-pentylpyrrole lysine, 2-PPL, 2-pentylpyrrole*

INTRODUCTION

4-Hydroxynon-2-enal (4-HNE) is a well-known secondary product of lipid peroxidation, which is mainly formed from ω-6 polyunsaturated fatty acids.[1] The formation of secondary lipid peroxidation products during roasting of peanuts, which contain 14% linoleic acid,[2] was shown,[3] and the presence of 4-HNE in commercially available peanuts was recently published, ranging from 0.8 to 3.8 μmol/kg peanut.[4] As a result of roasting peanuts, 30−40% of peptide-bound lysine was modified, but only 10% of this lysine modification could be explained by the formation of Maillard reaction products such as N^{ε}-fructosyllysine, pyrraline, and N^{ε}-carboxymethyllysine.[5] The possibility for a reaction between secondary lipid peroxidation products and amino acid side chains in peanut proteins was recently shown for 2-heptenal, resulting in *cis*- and *trans*-BPP-lysine derivatives. For these protein−carbonyl reactions, the term "lipation" was suggested.[6] Because of its ability to react easily with nucleophilic compounds, the formation of lipation products between 4-HNE and amino acid side chains of peanut proteins during roasting of peanuts is highly likely. Due to the three functional groups of 4-HNE, various reactions are possible. They include the formation of Michael addition products, which are able to undergo secondary reactions involving the carbonyl and the hydroxyl groups,[7] resulting, for example, in stable, cyclic hemiacetals.[8] After the formation of Schiff bases with primary amines, further reactions can lead to the formation of 2-pentylpyrrole residues,[9] which was shown for bovine serum albumin incubated with 4-HNE under physiological conditions.[10] Using ^{13}C NMR spectroscopy, 20% of the protein-bound 4-HNE was found as 2-pentylpyrrole,[10] which was classified as an advanced lipoxidation endproduct (ALE).[8,11] The incubation of RNase A with 4-HNE in sodium phosphate buffer (pH 7.2) at room temperature for 5 h resulted in the formation of a 2-hydroxy-2-pentyl-1,2-dihydropyrrol-3-one iminium fluorophore, accounting for protein cross-linking.[12] The yield of the fluorophore was estimated to account for 1.8% of the lysine residues on the protein. Another possible cross-linking mechanism would be the simultaneous formation of a Michael adduct and a Schiff base at one molecule of 4-HNE.[12,13] Using immunochemical methods, 4-HNE-pyrrole adducts were found to be significantly elevated in the plasma of patients with end-stage renal disease as well as in the plasma of atherosclerotic patients compared to that of healthy volunteers.[14] Furthermore, 4-HNE−pyrrole adducts were detected in collagen fibers of an advanced atherosclerotic lesion. In another study, 4-HNE−lysine adducts in intact apo B and apo B fragments of atherosclerotic lesions were observed by Western blot analysis.[15] Due to the fact that 4-HNE-pyrroles are stable advanced lipoxidation endproducts,[8,11] their quantitative levels in human blood may be an indelible marker of 4-HNE generation in vivo.[14] With regard to 4-HNE−protein adducts in food, only a few studies are available. Using an indirect ELISA, 4-HNE−protein adducts were detected in protein fractions of stored beef.[16] However, the specific proteins and 4-HNE adducts that were detected by the antibodies were not known. In protein extracts prepared from defatted meals of raw and roasted peanuts, 4-HNE−protein adducts were detected by direct ELISA.[17,18] In these studies, no significant differences in 4-HNE adduct levels

between raw and roasted peanuts were detected by observing the UV absorbance. Additionally, the levels of N^{ε}-carboxymethyllysine (CML) did not change either. This is in contrast to a study in which CML was directly quantified in raw and roasted peanuts by GC-MS,[5] clearly showing that CML was not detectable in native peanuts, whereas CML levels increased depending on the roasting conditions.

Up to now, direct and unambiguous quantification of individual, chemically characterized 4-HNE-derived lipation products has not been performed. The aim of this study, therefore, was to develop an HPLC-ESI-MS/MS method for the direct quantification of 4-HNE–lysine adducts in food proteins. For quantification of free 4-HNE in native and heated peanut oil and native and roasted peanuts, a GC-MS (EI) method was developed using synthesized deuterated 4-HNE as internal standard. To identify possible lipation products between 4-HNE and the ε-amino group of lysine, N^{α}-acetyl-L-lysine was incubated with 4-HNE and reaction products were identified by HPLC-ESI-MS/MS. After synthesis of 2-pentylpyrrole lysine, this lipation product was directly quantified in peanuts by HPLC-ESI-MS/MS for the first time.

MATERIALS AND METHODS

Materials. Pepsin (EC 3.4.23.1), Pronase E (EC 3.4.24.4), methanol, γ-nonalactone, ammonium chloride, sodium borohydride, and hydrochloric acid (37%) were obtained from Merck (Darmstadt, Germany). Leucine aminopeptidase (EC 3.4.11.1), prolidase (EC 3.4.13.9), dialysis tubing cellulose membrane (MWCO 14 kDa), tetradeuteromethanol, deuterochloroform, aluminum hydride, 1-octen-3-ol, Hoveyda–Grubbs catalyst second generation, acrolein dimethylacetal, amberlyst 15 (hydrogen form), fumaraldehyde bis(dimethyl acetal), petroleum ether (boiling point 40–60 °C), diethyl ether, *o*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride, bis-(trimethylsilyl)trifluoroacetamide, triethylamine, pyridinium chlorochromate, and magnesium chips were obtained from Sigma-Aldrich (Taufkirchen, Germany). N^{α}-Acetyl-L-lysine and *N*-benzoylglycyl-L-phenylalanine were obtained from Bachem (Bubendorf, Switzerland). Dichloromethane, hexane, ethyl acetate (pure), and heptafluorobutyric acid were obtained from VWR (Darmstadt, Germany). Acetonitrile, chloroform, tetrahydrofuran, and sulfuric acid were obtained from Fisher Scientific (Schwerte, Germany). Monosodium phosphate, disodium phosphate, sodium sulfate, sodium carbonate, sodium hydroxide, ascorbic acid, sodium tetraborate, and magnesium sulfate were obtained from Grüssing (Filsum, Germany). Tris-(hydroxymethyl)aminomethane was obtained from Serva (Heidelberg, Germany). Thymol and acetone were obtained from Carl Roth (Karlsruhe, Germany). Pentane was from Th. Geyer (Renningen, Germany). Molybdatophosphoric acid was obtained from ChemPUR (Karlsruhe, Germany). 1,1-Dideuterio-1-bromopentane was from Campro Scientific (Berlin, Germany). All chemicals were of the highest purity, except otherwise indicated. For all experiments, ultrapure water was used, prepared by an ELGA LabWater Purelab Plus water system (Celle, Germany). For HPLC-ESI-MS/MS measurements, double-distilled water, prepared in the presence of potassium permanganate, was used. Refined peanut oil and roasted commercial peanuts were obtained from a local market. Raw peanuts were obtained from Veggie's Delight (Düsseldorf, Germany).

Preparation of Samples. Raw peanuts with shell were roasted in a ULM 500 laboratory oven (Memmert, Schwabach, Germany) for 20 and 40 min at 170 °C, respectively. Afterward, the samples were shelled, skinned, and crushed, using a kitchen machine. Commercially available, roasted peanuts were crushed analogously. Protein contents were analyzed by the Kjeldahl method using the factor 5.3 for oilseeds.[19] Fifty grams of refined peanut oil was heated in 250 mL round-bottom flasks for 20 and 40 min at 170 °C, respectively.

Nuclear Magnetic Resonance Spectroscopy (NMR). For nonane-1,4-diol (1,4-ND), 4-oxononanal (4-ON), and 2-pentylpyrrole lysine (2-PPL), ^{1}H NMR spectra were recorded on a Bruker Avance 600 instrument (Rheinstetten, Germany) at 600.16 MHz. 4-Hydroxynonenal dimethyl acetal (4-HNE-DMA) was measured on a Bruker DRX 500 instrument at 500.13 MHz. ^{13}C NMR spectra were recorded on a Bruker DRX 500 instrument at 150.9 MHz, respectively. For fumaraldehyde dimethyl acetal and (*E*)-5,5-dideuterio-1,1-dimethoxynon-2-en-4-ol dimethyl acetal (4-HNE-DMA-d_2), ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker Avance 400 instrument (Rheinstetten, Germany) at 400.13 MHz and at 100.61 MHz, respectively. For 4-HNE-DMA, 1,4-ND, 4-ON, fumaraldehyde dimethyl acetal, and 4-HNE-DMA-d_2, deuterochloroform ($CDCl_3$) and for 2-PPL tetradeuteromethanol (MeOH-d_4) were used as solvent. All chemical shifts are given in parts per million (ppm) relative to the solvent signal serving as internal standard. The following 2D-NMR experiments were performed additionally for 4-HNE-DMA, 4-HNE-DMA-d_2 4-ON, 1,4-ND, and 2-PPL: correlation spectroscopy (COSY), nuclear Overhauser enhancement spectroscopy (NOESY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC).

Elemental Analysis. Elemental analysis was performed using an EuroEA3000 (Eurovector, Milan, Italy) to quantitate the product content in the 2-PPL standard. Therefore, the analyzed percentage of nitrogen was compared to the calculated nitrogen percentage. The purity of 2-PPL is expressed in percent by weight.

Acid and Enzymatic Hydrolysis. For acid hydrolysis, a ratio of 8 mg of protein per 1.0 mL of 6 M hydrochloric acid was used. Samples were hydrolyzed under nitrogen for 23 h at 110 °C. For enzymatic hydrolysis the method published elsewhere was used.[6,20]

Amino Acid Analysis. For measuring of the lysine modification rate and comparison of the release of amino acids after acid and enzymatic hydrolysis, amino acid analyses were performed using a SYKAM S4300 amino acid analyzer (Fürstenfeldbruck, Germany). Amino acids were separated by cationic ion exchange chromatography, derivatized by ninhydrin, and detected using a wavelength of 570 nm.[21] Valine was taken as internal standard, and amino acids were expressed as valine equivalents.

Synthesis of (*E*)-1,1-Dimethoxynon-2-en-4-ol (4-HNE-DMA). For 4-HNE-DMA synthesis, a method published elsewhere was adopted.[22] Therefore, 25 mL of nitrogen-purged dichloromethane, 496 μL of 1-octen-3-ol, 1164 μL of acrolein dimethyl acetal, and 25.9 mg of a Hoveyda–Grubbs catalyst second generation were given in a 50 mL three-neck flask and stirred for 5 h at room temperature under nitrogen. After the addition of another 25.9 mg of catalyst, stirring was continued for 20 h at room temperature under nitrogen. After evaporation of dichloromethane, 4-HNE-DMA was purified by silica gel chromatography using diethyl ether/pentane (50:50, v/v) and 0.1% triethylamine as eluent. Fractions containing 4-HNE-DMA were identified by silica gel thin layer chromatography using the same mobile phase. Detection was realized by spraying a solution of 5% molybdatophosphoric acid in ethanol with 10% sulfuric acid and heating for 5 min in a Memmert laboratory-type drying cabinet (Schwabach, Germany) at 105 °C. Relevant fractions were combined, the solvent was evaporated in vacuo at 40 °C, and the product was lyophilized. ^{1}H NMR (500 MHz, $CDCl_3$) δ 0.86 (t, 3H, J = 7.9 Hz, H-9), 1.23–1.33 (m, 6H, H-6, H-7, H-8), 1.50 (m, 2H, H-5), 3.30 (s, 6H, H-11, H-12), 3.45 (s, 1H, H-10), 4.13 (q, 1H, J = 6.3 Hz, H-4), 4.77 (d, 1H, J = 4.7 Hz, H-1), 5.63 (ddd, 1H, J = 1.3 Hz, J = 4.7 Hz, J = 15.8 Hz, H-2), 5.86 (ddd, 1H, J = 1.3 Hz, J = 6.0 Hz, J = 15.8 Hz, H-3). The compound was found to be pure by observance of a single spot on TLC. Yield = 346 mg (molar yield = 53.7%).

Synthesis of (*E*)-5,5-Dideuterio-1,1-dimethoxynon-2-en-4-ol Dimethyl Acetal (4-HNE-DMA-d_2). The precursors fumaraldehyde dimethyl acetal and deuterated pentylmagnesium bromide were synthesized according to a method published elsewhere.[23] Therefore, 45.9 mL of acetone was given in a 100 mL three-neck flask, and 0.4605 g of amberlyst-15 catalyst and 0.339 mL of water were added. After the addition of 2.084 mL of fumaraldehyde bis(dimethyl acetal), the reaction was continued for 6 min at room temperature with stirring. After filtration through a bed of anhydrous sodium carbonate, the solvent was evaporated in vacuo at 40 °C to yield fumaraldehyde

DOI: 10.1021/acs.jafc.5b01502
J. Agric. Food Chem. 2015, 63, 5273–5281

dimethyl acetal. ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.38 (s, 6H, H-5, H-6), 5.07 (dd, 1H, J = 1.2 Hz, J = 3.9 Hz, H-4), 6.38 (ddd, 1H, J = 1.2 Hz, J = 7.8 Hz, J = 15.9 Hz, H-3), 6.64 (dd, 1H, J = 3.9 Hz, J = 15.9 Hz, H-2), 9.64 (d, 1H, J = 7.8 Hz, H-1). Purity = 93.1% (GC-MS). Yield = 1.2105 g (molar yield = 76.3%). Diethyl ether (0.8 mL) and 0.103 g of magnesium chips were given in a 25 mL three-neck flask. After the addition of 50 μL of 1,1-dideuterio-1-bromopentane, the reaction mixture was heated at 45 °C under reflux with stirring. The emerging white coloration indicated the starting reaction of the formation of the Grignard reagent deuterated pentylmagnesium bromide. Another 5.52 mL of diethyl ether were added followed by 350 μL of 1,1-dideuterio-1-bromopentane in 1.11 mL of diethyl ether, and the reaction mixture was heated under mild reflux at 45 °C for 30 min while the reaction mixture turned dark. After the reaction mixture had been cooled to 0 °C in an ice bath, 280 μL of fumaraldehyde dimethyl acetal in 1.84 mL of diethyl ether were added, and the reaction mixture was stirred for 30 min at 0 °C. By adding 2.76 mL of a solution of saturated ammonium chloride, the reaction was quenched and then extracted four times with 15 mL of diethyl ether, respectively. After drying over anhydrous sodium sulfate, the solvent was removed in vacuo at 40 °C. Purification of 4-HNE-DMA-d_2 was realized as described for the undeuterated 4-HNE-DMA. ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.87 (t, 3H, J = 6.4 Hz, H-9), 1.29 (m, 6 H, H-6, H-7, H-8), 3.31 (s, 6H, H-11, H-12), 3.46 (s, 1H, H-10), 4.13 (d, 1H, J = 6.3 Hz, H-4), 4.78 (d, 1H, J = 4.8 Hz, H-1), 5.64 (ddd, 1H, J = 0.9 Hz, J = 4.8 Hz, J = 15.7 Hz, H-2), 5.87 (ddd, 1H, J = 0.9 Hz, J = 6.0 Hz, J = 15.7 Hz, H-3). The compound was found to be pure by observance of a single spot on TLC. Yield = 154 mg (molar yield = 44.6%).

GC-MS (EI) Quantification of Free 4-HNE in Peanut Oil and Peanut Samples. The developed method is partially comparable to a recently published method.[4] The internal standard 4-HNE-d_2 was obtained by acid hydrolysis of 2 mg of 4-HNE-DMA-d_2 with 0.5 mL of 0.1 mol/L hydrochloric acid with stirring for 1 h in a 5 mL flask at room temperature. Following a 3-fold extraction with hexane (0.5 + 0.3 + 0.3 mL) to prohibit further release of free 4-HNE-d_2 if the reaction was not complete, the concentration was calculated on the basis of the molar extinction coefficient for 4-HNE in hexane,[1] ε = 14400 L mol^{-1} cm^{-1}. To 1.0 g of crushed, shelled, and skinned peanuts or peanut oil were added 20 μL of an internal standard solution containing 95 nmol of 4-HNE-d_2 and 10 mL of a solution of 0.1% ascorbic acid in water. The samples were homogenized using an ultraturrax at 11.200 rpm for 2 min, and the supernatant was collected after centrifugation at 10000g for 10 min at 4 °C. The extraction was repeated analogously, and the combined supernatants were extracted 3-fold with 10 mL of dichloromethane for 1 min, respectively. The organic phases were separated by centrifugation at 10000g for 2 min at 4 °C. After filtration (Whatman, 595 $^1/_2$) the dichloromethane was evaporated at 30 °C with nitrogen. The first derivatization step was realized by adding 200 μL of a o-(2,3,4,5,6-pentafluorobenzyl)-hydroxylamine hydrochloride (PFBHA-HCl) solution (20 mg/mL water) and heating in a water bath for 1 h at 40 °C. Hexane (1.3 mL) was added, and the samples were vortexed, followed by an addition of 100 μL of concentrated sulfuric acid[24] and vortexing again. After centrifugation at 2100g for 3 min at room temperature, the hexane phase was removed, dried over anhydrous sodium sulfate, filtered (0.45 μm), and evaporated at 30 °C under nitrogen. The second derivatization step was performed at room temperature for 3 h by adding 200 μL of N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA). An aliquot was used for GC-MS (EI) analysis using an Agilent 7890A system, consisting of a 7683 series injector with a sample tray and a 5975C MS detector working in EI mode, all from Agilent (Böblingen, Germany), and a ZB-5 Guardian capillary column (30.0 m plus 5.0 m guard column, inner diameter = 0.25 mm, 0.25 μm film thickness) from Phenomenex (Torrance, CA, USA). Helium was used as carrier gas with a constant flow of 1.0 mL/min. With the injector temperature set to 250 °C, 1 μL of sample was injected by using the pulsed splitless mode. The auxiliary temperature was set to 250 °C, and the ion source and quadrupole were set to 230 and 150 °C, respectively. The initial oven temperature was set to 100 °C and held for 4 min and then raised at 15 °C/min to 300 °C. The post run time was set to 3 min at 300 °C. The mass spectrometer was working in electron impact mode at 70 eV. The solvent delay time was set to 10 min. SIM parameters were as follows: for 4-HNE (syn and anti), quantifier ion m/z 242 and qualifier ion m/z 352; and for 4-HNE-d_2 (syn and anti), quantifier ion m/z 244 and qualifier ion m/z 352. The dwell time was set to 80 ms. Quantification was realized using authentic 4-HNE, being obtained from 4-HNE-DMA as previously described for 4-HNE-DMA-d_2, the addition of 95 nmol of internal standard 4-HNE-d_2, and an analogous derivatization procedure.

Incubation of N^α-Acetyl-L-lysine with 4-HNE. For identification of major amino acid side chain reaction products formed between 4-HNE and N^α-acetyl-L-lysine, 10 mM 4-HNE and 10 mM N^α-acetyl-L-lysine were heated for 4 h at 75 °C in 5 mL of methanol in a 10 mL round-bottom flask under reflux. 4-HNE was obtained by acid hydrolyses as described above, and its concentration in aqueous solution was determined using the molar extinction coefficient[1] ε = 13750 L mol^{-1} cm^{-1}. One milliliter of the reaction mixture was taken for direct HPLC-ESI-MS/MS analysis. For reduction, 1.0 mL of the reaction mixture was evaporated under nitrogen, and 3.0 mL of a 0.2 M sodium tetraborate solution (pH 9.5) and 2.0 mL of a 1.0 M sodium borohydride solution in 0.1 M sodium hydroxide were added. After reduction for 17 h at room temperature, 1.0 mL of 6 M hydrochloric acid and 5 mL of 12 M hydrochloric acid were added, and the samples were hydrolyzed for 23 h at 110 °C. Afterward, the hydrochloric acid was removed by using a waterjet pump at 40 °C. The residue was dissolved in 1.0 mL of methanol and analyzed by HPLC-ESI-MS/MS.

Incubation of Peanut Proteins with 4-HNE. Peanut proteins of raw peanuts were extracted as described elsewhere,[6,25] except for using non-defatted peanuts instead of defatted peanuts. Approximately 50 mg of peanut protein extract was dissolved in 25 mL of 0.1 M phosphate buffer (pH 7.4), and 4-HNE, obtained from 4-HNE-DMA, was added in the following molar ratios related to the sum of relevant reactive amino acids cysteine, histidine, lysine, and arginine:[6] 0.1:1, 0.2:1, 1:1, and 5:1. Additionally, a blank sample consisting of peanut proteins without 4-HNE was prepared. The incubation was carried out under nitrogen for 24 h at 37 °C with stirring, followed by a dialysis (14 kDa MWCO) against deionized water for 24 h at 6 °C. Afterward, the samples were lyophilized and protein contents were analyzed by the Kjeldahl method using the factor 5.3 for oilseeds.[19] For analysis of amino acid modification rates of cysteine, lysine, histidine, and arginine, the samples were hydrolyzed enzymatically. For analysis of 2-PPL, the samples were hydrolyzed enzymatically, freeze-dried, and redissolved in 400 μL of water and 100 μL of methanol. The 0.1:1 sample was diluted 100-fold using water/methanol (80:20, v/v), whereas the other samples were diluted 500-fold including 40 μL of internal standard N-benzoylglycyl-L-phenylalanine in methanol/water (50:50, v/v) with a final concentration of 3.06 pmol/mL sample. The blank sample was used without dilution. After filtration (0.45 μmol), samples were subjected to HPLC-ESI-MS/MS analysis. Quantification was realized using authentic 2-PPL and internal standard N-benzoylglycyl-L-phenylalanine with a final concentration of 3.06 pmol/mL in an enzymatic hydrolysate matrix calibration of the native peanut protein extract, prepared analogously to the samples.

Synthesis of 2-Amino-6-(2-pentyl-1*H*-pyrrol-1-yl)hexanoic Acid (2-PPL). Lithium aluminum hydride (2.6 g) was added to 150 mL of tetrahydrofuran in a 500 mL three-neck flask, and the solution was cooled by an ice bath. γ-Nonalactone (12.5 mL) in 50 mL of tetrahydrofuran was added while cooling continued. After the three-neck flask was allowed to warm to room temperature, the reaction mixture was heated for 3 h under reflux with stirring. After cooling in an ice bath, ice-cold water was added until the formation of hydrogen stopped. After filtration over magnesium sulfate and drying over magnesium sulfate overnight, the tetrahydrofuran was evaporated at 40 °C. ^{1}H NMR of nonane-1,4-diol (600 MHz, $CDCl_3$) δ 0.82 (t, 3H, J = 7.2 Hz, H-9), 1.23 (m, 4 H, H-7, H-8), 1.37 (m, 4H, H-3, H-6), 1.57 (m, 4H, H-2, H-5), 3.52 (m, 2H, H-1), 3.57 (m, 1H, H-4). Purity = 98.2% (GC-MS). Yield = 8.4473 g (molar yield = 67.5%). In a 500 mL three-neck flask 17.0 g of pyridinium chlorochromate was suspended in 100 mL of dichloromethane.[26] Nonane-1,4-diol (8.4473 g) in 50

DOI: 10.1021/acs.jafc.5b01502
J. Agric. Food Chem. 2015, 63, 5273−5281

mL of dichloromethane was added with stirring. The reaction mixture was kept for 2 h at room temperature, resulting in a dark coloration of the reaction mixture. Afterward, 150 mL of diethyl ether were added, and the reaction mixture was filtered over magnesium sulfate. The addition of diethyl ether followed by a filtration step was repeated until no precipitation occurred. After evaporation of the diethyl ether at 40 °C, 4-oxononanal was purified by silica gel chromatography using ethyl acetate/hexane (15:85, v/v) as eluent.[9] Fractions containing 4-oxononanal were detected by GC-MS (EI) and combined, and the solvent was evaporated at 40 °C. ^{1}H NMR of 4-oxononanal (600 MHz, $CDCl_3$) δ 0.85 (m, 6H, H-9), 1.26 (m, 9H, H-7, H-8), 1.55 (m, 3H, H-6), 2.43 (t, 2H, J = 7.5 Hz, H-5), 2.71 (m, 4H, H-2, H-3), 9.77 (s, 1H, H-1). Purity = 49.3% (GC-MS). Yield = 2.3225 g (molar yield = 13.9%). One gram of 4-oxononanal and 2.0 g of N^{α}-acetyl-L-lysine were dissolved in 25 mL of acetonitrile/water (1:1, v/v) in a 50 mL flask under nitrogen and reacted in a Paal–Knorr synthesis at room temperature for 72 h. Afterward, the solvent was evaporated at 40 °C. Hydrolysis of the acetyl group was realized by adding 250 mL of a 2 M sodium hydroxide solution and heating for 23 h under reflux. The solvent was evaporated at 60 °C, and the residue was extracted three times with 10 mL of chloroform, respectively, filtered over magnesium sulfate, and dried over magnesium sulfate overnight. The solvent was evaporated at 40 °C, and 2-PPL was purified using a semipreparative HPLC system. The system consisted of a Smartline solvent manager 5000, a Smartline pump 1000, and a Smartline UV detector 2500 (all from Knauer, Berlin, Germany). Twenty-five milligrams of the unpurified reaction mixture were dissolved in 1.0 mL of methanol and separated after filtration (0.45 μm) using an Eurospher 100-10 C18 column (250 × 16 mm; Knauer, Berlin, Germany) at 23 °C (room temperature), a flow rate of 4.0 mL/min, and a detection wavelength of 227 nm. A gradient was used with solvent A (water) and B (acetonitrile). The gradient program started with 10% solvent B for 2 min, increased to 95% B within 28 min, isocratic elution with 95% B for 10 min, decrease to 10% B within 2 min, followed by an isocratic elution at 10% B for 10 min. 2-PPL eluted between 21 and 23 min. Multiple separations were performed, relevant fractions were combined, and finally the solvent was evaporated at 40 °C prior to HPLC-ESI-MS/MS and one- and two-dimensional NMR analysis. ESI-MS (positive mode), $[M + H]^+$ m/z 267.3; ^{1}H NMR (600 MHz, MeOD) δ 0.99 (m, 6H, H-15), 1.44 (m, 6H, H-14, H-13), 1.51 (m, 5H, H-7), 1.68 (m, 2H, H-12), 1.80 (m, 2H, H-6), 1.98 (m, 2H, H-8a,b), 2.6 (t, 2H, J = 7.5 Hz, H-11), 3.56 (t, 1H, J = 6.0 Hz, H-9), 3.91 (t, 1H, J = 7.5 Hz, H-5), 5.8 (m, 1H, J = 3.0 Hz, H-2), 6.00 (t, 1H, J = 3.0 Hz, H-3), 6.64 (d, 1H, J = 3.0 Hz, H-4). 2-PPL eluted chromatographically pure by HPLC-ESI-MS analysis. Purity based on elemental analysis = 75.1%. Yield = 13.7 mg (molar yield = 4.4%).

Quantitation of 2-PPL in Roasted Peanuts. For quantification of 2-PPL in peanuts, 35 mg of crushed raw, roasted or commercially available peanuts were hydrolyzed enzymatically using the 3-fold amounts of enzymes and solutions as described above. For evaluating amino acid release after enzymatic hydrolysis, the amounts of valine and leucine were compared to those obtained after acid hydrolysis before and after defatting of the samples. Afterward, the samples were freeze-dried and redissolved in 250 μL of water, 80 μL of methanol, and 20 μL of internal standard N-benzoylglycyl-L-phenylalanine in methanol/water (50:50, v/v) with a final concentration of 0.57 pmol/mL. After filtration (0.45 μm), samples were subjected to HPLC-ESI-MS/MS analysis. Quantification was realized using authentic 2-PPL and internal standard N-benzoylglycyl-L-phenylalanine with a final concentration of 0.57 pmol/mL in an enzymatic hydrolyzate matrix calibration of raw peanuts, prepared analogously to the samples.

HPLC-ESI-MS/MS Analysis. The HPLC system consisted of a degasser, a pump, an autosampler, and a diode array detector, all from Agilent Technologies 1200 series (Böblingen, Germany). A triple quad LC-MS 6410 from Agilent Technologies was used for MS/MS measurements. For identification of major reaction products between 4-HNE and N^{α}-acetyl-L-lysine, 10 μL of samples were injected and separated using a Eurospher 100-5 C18 column (250 × 3.0 mm; Knauer) at 30 °C, a flow rate of 0.38 mL/min, and a detection wavelength of 227 nm. A gradient was used with solvent A (water) and B (acetonitrile), each containing 2 mM heptafluorobutyric acid and 11 mM acetic acid. The gradient increased from 2 to 70% B within 50 min and to 90% B within 15 min, isocratic elution at 90% B for 10 min, decreased to 2% B within 3 min, and isocratic elution at 2% for 10 min. First, full scan analyses and then product ion scans were performed. Full scan analyses were performed from 5.1 to 78.0 min in positive mode, scan ranges were from m/z 80 to 1000, scan time was 500 ms, fragmentor voltage was 135 V, gas temperature was 300 °C, gas flow was 11 L/min, and nebulizer pressure was 15 psi. Product ion scans were performed for the unhydrolyzed samples from 15 to 45 min with precursor ions m/z 365.3 for the pyridinium derivative, m/z 327.3 for the Schiff base, m/z 309.2 for the 2-pentylpyrrol-acetyllysine, and m/z 287.2 for the reduced and cyclized Michael adduct after reduction and acid hydrolyses using the same conditions as described above. Product ion scan ranges were from m/z 60 to 400 with a scan time of 200 ms, a fragmentor voltage of 135 V, and collision voltages of 25, 20, 25, and 15 V for the pyridinium derivative, Schiff base, 2-pentylpyrrol-acetyllysine, and the reduced and cyclized Michael adduct, respectively. For quantification of 2-PPL in modified peanut proteins and in peanut samples, 40 and 60 μL of samples, respectively, were separated using a Zorbax SB-C18 column (50 × 2.1 mm) from Agilent Technologies at 30 °C and a flow rate of 0.25 mL/min. A gradient was used with solvent A (water) and B (acetonitrile), each containing 2 mM heptafluorobutyric acid and 11 mM acetic acid. The gradient was as follows: 2% B was held for 5 min, increased to 51% within 17 min, increased to 90% B within 2 min, isocratic elution at 90% B for 6 min, decreased to 2% B within 1 min, and isocratic elution at 2% B for 9 min. Measurements were performed using the multiple reaction monitoring (MRM) mode in positive mode, gas temperature was set to 300 °C, gas flow was set to 11 L/min, and nebulizer pressure was set to 15 psi. Internal standard N-benzoylglycyl-L-phenylalanine was analyzed from 15.5 to 20.6 min with a mass transition from m/z 327.1 to 166.1 for quantification using fragmentor and collision voltages of 90 and 4 V, respectively, and a dwell time of 300 ms. Mass transition from m/z 327.1 to 105.1 was used for qualification using fragmentor and collision voltages of 90 and 34 V, respectively, and a dwell time of 300 ms. 2-PPL was analyzed from 20.6 to 28 min with a mass transition from m/z 267.1 to 204.2 for quantification using fragmentor and collision voltages of 148 and 18 V, respectively, and a dwell time of 100 ms. Mass transition from m/z 267.1 to 84.1 was used for qualification using fragmentor and collision voltages of 148 and 29 V, respectively, and a dwell time of 100 ms.

Statistical Treatment. Results are expressed as mean values ± standard deviations of two separate measurements,[27] except otherwise indicated.

RESULTS AND DISCUSSION

Quantitation of Free 4-HNE in Heated Peanut Oil and Peanut Samples. As reference material for the quantification of free 4-HNE in heated peanut oil and peanut samples, a deuterated 4-HNE-DMA-d_2 standard was synthesized (see Supporting Information Figure I). Figure 1 shows the observed relevant HMBCs of 4 HNE-DMA-d_2. After development of a GC-MS (EI) method, the amounts of 4-HNE were quantified in peanut oil and peanut samples. Figure 2 (left) shows the amounts of free 4-HNE in a native and refined peanut oil as well as in a peanut oil after heating under roasting conditions (20 and 40 min at 170 °C). The amounts were between 0.1 and

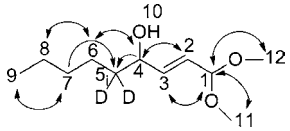

Figure 1. Structure of synthesized 4-HNE-DMA-d_2, showing the observed relevant heteronuclear multiple bond correlations (HMBCs).

DOI: 10.1021/acs.jafc.5b01502
J. Agric. Food Chem. 2015, 63, 5273–5281

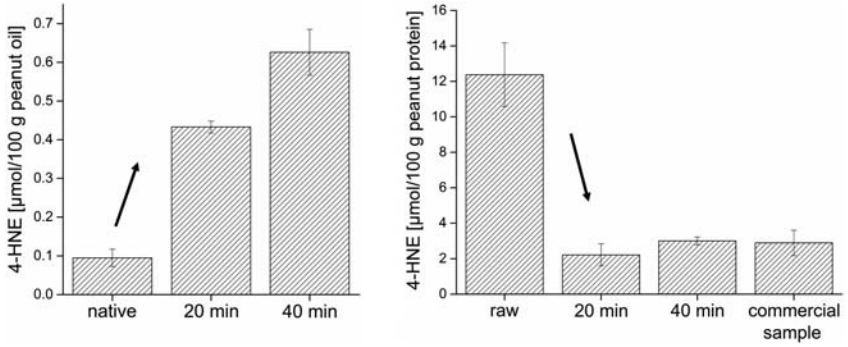

Figure 2. Quantitation of free 4-HNE by GC-MS (EI): (left) amounts of 4-HNE in peanut oil heated at 170 °C; (right) amounts of 4-HNE in peanuts roasted at 170 °C.

0.6 μmol/100 g oil or between 0.2 and 1.0 μg/g oil, clearly indicating an increase in free 4-HNE depending on the heating time. These data are in agreement with published values for 4-HNE in heated soybean oil, butter oil, and corn oil, resulting from HPLC analysis.[28,29] For olive oil (extra virgin), amounts ranging from 0.06 to 0.12 μg 4-HNE/g oil were found using GC-MS.[4] After methyl linoleate had been heated at 185 °C for up to 6 h, it was observed by HPLC analysis that within the first hour of heating, most of the 4-HNE had been formed.[30] The amounts of the precursor linoleic acid in peanut oil and in peanuts are 21.6 and 14%, respectively,[2] indicating that most of the 4-HNE may be formed in the initial stage of heating. This corresponds with the results in Figure 2 (left) and the more pronounced increase in 4-HNE formation during the first 20 min of roasting. Raw peanuts were roasted analogously (20 and 40 min at 170 °C), and the amounts of free 4-HNE are shown in Figure 2 (right). A decrease in free 4-HNE from 12.37 μmol/100 g protein (4.47 mg/kg peanut) in the native to 2.22 μmol/100 g protein (0.82 mg/kg peanut) in the roasted samples was found. The formation of 4-HNE in native peanuts could be a result of drying processes and storage of peanuts after harvesting. Commercially available, roasted peanuts contained 4-HNE in amounts of 2.88 μmol/100 g protein (1.29 mg/kg peanut). No difference between the samples roasted for 20 and 40 min was detectable, indicating that at this stage the formation and degradation of 4-HNE is in equilibrium. This fits with the amount of 4-HNE found in the commercial peanut sample, for which the starting amount is not known. Recently published results for 4-HNE in two commercially available peanut samples were between 0.12 and 0.60 mg/kg peanut sample, analyzed by GC-MS,[4] which is comparable to the amounts of 4-HNE found in this study. Also, 0.14−0.41 mg 4-HNE/kg of sample was found in walnuts and 0.21 mg/kg in an infant formula.[4] In beef and pork, amounts ranging from 2.19 to 21.87 mg/kg and from 0.16 to 23.75 mg/kg, respectively, were found by HPLC analysis,[31] whereupon a correlation between the amounts of 4-HNE and ω-6 fatty acids contents in pork was observed. In fresh blue mackerel, yellowtail, and chicken, amounts of 1.16, 0.50, and 0.04 mg/kg were found, respectively, analyzed by HPLC.[32] A general statement about the toxicology of these levels of 4-HNE is not possible, because data about 4-HNE amounts reaching the small intestine after a gastrointestinal digestion are not available. Due to the fact that in the absence of further peanut constituents heated peanut oil shows an increase of 4-HNE, further reactions with nucleophilic amino acid side chain groups are supposed to be responsible for the loss of 4-HNE when whole peanuts are roasted. These lipation reactions[6] may contribute to the loss of lysine, which cannot be explained by the formation of Maillard reaction products.[5]

Amino Acid Modifications in Modified Peanut Proteins. To investigate the reactions of 4-HNE with nucleophilic amino acid side chains, extracted peanut proteins of raw peanuts were incubated with 4-HNE at 37 °C for 24 h in phosphate buffer (pH 7.4) as previously described for the incubation of other secondary products.[6,33−35] Incubations were performed in different molar ratios between 4-HNE and the sum of the reactive amino acids cysteine, histidine, lysine, and arginine. Samples were hydrolyzed enzymatically because of the instability of certain possible reaction products toward acid hydrolysis. Figure 3 shows the decreases of the amino acids

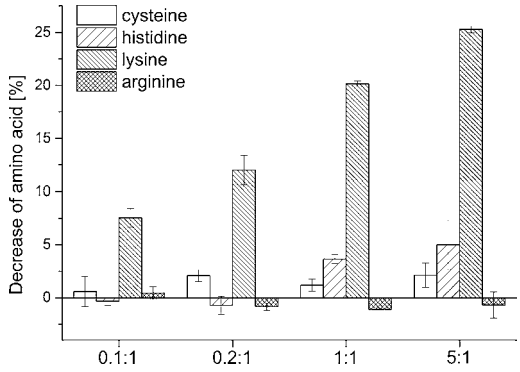

Figure 3. Decreases of amino acids cysteine, histidine, lysine, and arginine in extracted peanut proteins modified by 4-HNE for 24 h at 37 °C in 0.1 M phosphate buffer, analyzed by amino acid analysis. Decreases are presented relative to the amounts of the blank sample.

cysteine, histidine, lysine, and arginine relative to the amounts in the blank sample. Lysine modifications increased from 7.5 to 25.3%, whereas histidine, cysteine, and arginine remained unchanged. Due to the fact that cysteine is able to form disulfide bonds, its accessibility for 4-HNE may be limited, although its reactivity toward 4-HNE is higher than that of lysine.[9]

Identification of Major Reaction Products of 4-HNE and N^{α}-Acetyl-L-lysine. For identification of major reaction products of 4-HNE and the ε-amino group of lysine, 4-HNE and N^{α}-acetyl-L-lysine were incubated in equimolar amounts in methanol for 4 h at 75 °C. Lipation products were identified by HPLC-ESI-MS/MS analysis before hydrolysis (Figure 4). The Michael adduct was identified due to its instability[36] in its reduced, cyclized form after reduction and acid hydrolysis

DOI: 10.1021/acs.jafc.5b01502
J. Agric. Food Chem. 2015, 63, 5273−5281

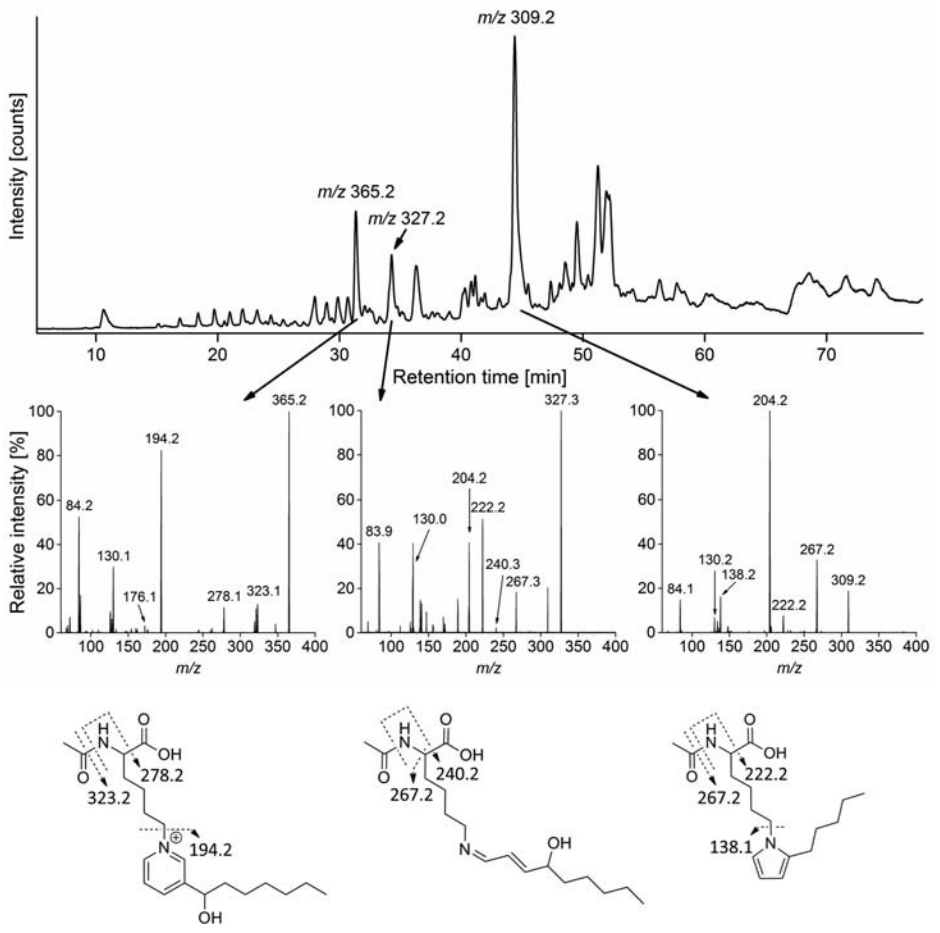

Figure 4. Identification of lipation products by HPLC-ESI-MS/MS after incubation of N^{α}-acetyl-L-lysine and 4-HNE in equimolar amounts in methanol for 4 h at 75 °C. The HPLC-ESI-MS-scan chromatogram (top) shows peaks of N^{α}-acetyl-L-lysine (m/z 189.2), a pyridinium derivative (m/z 365.2), a Schiff base (m/z 327.2), and a 2-pentylpyrrol adduct (m/z 309.2). (Middle) Product ion patterns after fragmentation of the derivatives and selected ions (bottom) resulting from the derivatives, respectively. Detailed explanations of the ions are given in the text.

(Figure II in the Supporting Information). The monoisotopic mass of m/z 365.2 $[M]^+$ and characteristic fragments of the pyridinium moiety (m/z 194.2) after additional loss of water (m/z 176.1) are indicative for a 4-HNE-lysine pyridinium derivative. Furthermore, the fragmentation pattern shows typical lysine fragments (m/z 84.2 and 130.1). Ions with m/z 323.1 and 278.1 are indicative for secessions of the acetyl group and the carboxyl and acetyl groups, respectively. After incubation of 4-hydroxypentenal and glycine, an analogous pyridinium derivative was detected, and a possible reaction pathway was proposed[37] requiring two molecules of 4-hydroxypentenal and one molecule of glycine. To the best of our knowledge, this is the first report of a pyridinium derivative resulting from 4-HNE and the ε-amino group of lysine. Therefore, its formation is also possible in proteins. Further strong hints indicating the presence of a Schiff base were found: a monoisotopic mass of m/z 327.2 $[MH]^+$ and characteristic fragments m/z 240.3 indicating losses of the acetyl and carboxyl groups, m/z 267.3, indicating a secession of the α-amino group with its acetyl moiety, and m/z 222.2, which results after cyclization as analogously postulated for free lysine.[38] The fragment with m/z 204.2 is indicative for loss of water from the cyclized ion. With fragments m/z 267.2 and 222.2, the monoisotopic mass m/z 309.2 $[MH]^+$ shows typical ions of the 2-pentylpyrrole-acetyl lysine (2-PPAcL) indicating losses of the acetyl and carboxyl groups, respectively. The ion m/z 138.2 is indicative for the pyrrol moiety. The characteristic fragment m/z 204.2 might result from a cyclization step analogous to the Schiff base. A possible formation pathway of the characteristic ion with m/z 204.2 is given in Figure III in the Supporting Information, based on the proposed fragmentation of adducts between the ε-amino group of lysine and hexanal.[38]

Formation of the 2-pentylpyrrol derivative occurs initially by the formation of a Schiff base, being in an equilibrium with its enamine, which undergoes keto−enol tautomerism to the 4-oxo-enamine derivative that finally cyclizes to the 2-pentylpyrrol derivative.[9] After reduction and acid hydrolysis, a monoisotopic mass of m/z 287.2 $[MH]^+$ and fragments m/z 242.2 (loss of carboxyl group), m/z 224.2 (losses of carboxyl and amino groups), m/z 158.2 (cleavage between δ carbon and ε nitrogen), and, as typical lysine fragments, m/z 84.1 and 130.1 (Figure II in the Supporting Information) were observed. This points to the presence of the reduced, cyclized Michael adduct.

Due to the fact that 2-PPL is an advanced lipation end product,[8,11] further studies were performed. For synthesis of 2-PPL (for the reaction scheme see Figure IV in the Supporting Information), γ-nonalactone was reduced to nonane-1,4-diol by $LiAlH_4$, which was oxidized to 4-oxononanal by pyridinium chlorochromate. Following a Paal−Knorr synthesis including N^{α}-acetyl-L-lysine, the acetyl group was removed by basic hydrolysis using a 2 M sodium hydroxide solution. Purification

DOI: 10.1021/acs.jafc.5b01502
J. Agric. Food Chem. 2015, 63, 5273−5281

was realized by semipreparative HPLC with UV detection, using an RP-18 column. Identification of 2-PPL was performed by HPLC-ESI-MS/MS measurements and one- and two-dimensional NMR spectroscopy. Figure 5 shows the structure of 2-amino-6-(2-pentyl-1*H*-pyrrol-1-yl)hexanoic acid (2-PPL) and the relevant HMBCs.

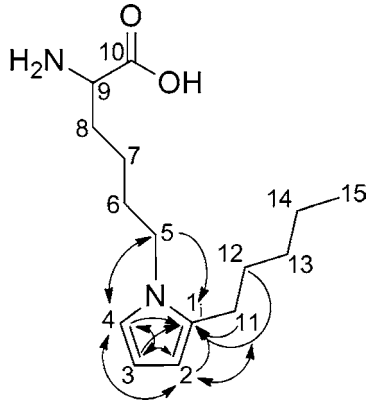

Figure 5. Structure of 2-PPL showing the observed relevant heteronuclear multiple bond correlations (HBMC).

Quantitation of 2-PPL in Modified Peanut Proteins. 2-PPL was quantified after enzymatic hydrolysis by HPLC-ESI-MS/MS. Figure 6 shows the decreases of lysine compared to

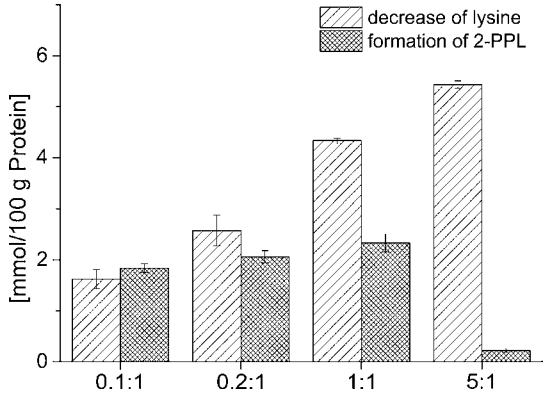

Figure 6. Decrease of lysine due to modification of extracted peanut proteins by 4-HNE after incubation at 37 °C for 24 h in 0.1 M phosphate buffer, analyzed by amino acid analysis compared to the lysine level in the blank sample and amounts of 2-PPL quantitated after enzymatic hydrolysis by HPLC-ESI-MS/MS.

the blank sample analyzed by amino acid analysis and the formation of 2-PPL analyzed by HPLC-ESI-MS/MS, each after enzymatic hydrolysis. In the blank sample, 2-PPL was not detectable. The results indicate that 2-PPL is readily formed when 4-HNE is present and only a slight increase can be observed when the ratio of 4-HNE is increased. In the 5:1 sample, only 12% of the 2-PPL amount compared to the 0.1:1 sample was quantified. These results show that the amounts of 2-PPL as well as the loss of lysine do not increase depending on the amount of 4-HNE. Furthermore, it can be seen that at low concentrations of 4-HNE (0.1:1 and 0.2:1 samples), 2-PPL is the major reaction product, explaining the total loss of lysine, whereas at higher 4-HNE concentrations (1:1 and 5:1 samples), other reaction products must be formed. At higher concentrations of 4-HNE, a polymerization or oxidation of 4-HNE may occur, so that less 4-HNE would be available for the reaction with lysine. In further studies the amounts of free 4-HNE could be measured to check whether the amounts of free 4-HNE are really lowered in the 1:1 and 5:1 samples. Supposing that 2-PPL would be the kinetically preferred reaction product, the reaction pathway could shift at higher concentrations so that, for example, the reaction can remain on the level of the Schiff base, the precursor of 2-PPL.

Quantitation of 2-PPL in Peanuts. Due to its instability during acid hydrolysis, 2-PPL was released from the peanut protein samples enzymatically. To ensure complete enzymatic degradation, results for the amounts of valine and leucine obtained after enzymatic hydrolysis for the native, the two roasted, and the commercial samples were compared to the corresponding values after acid hydrolysis. For valine the enzymatic release ranged from 87.5 to 103.6% and for leucine from 83.4 to 97.0%, indicating complete enzymatic hydrolysis. Quantitation of 2-PPL was realized by HPLC-ESI-MS/MS (MRM mode). Figure 7 shows a representative HPLC-ESI-

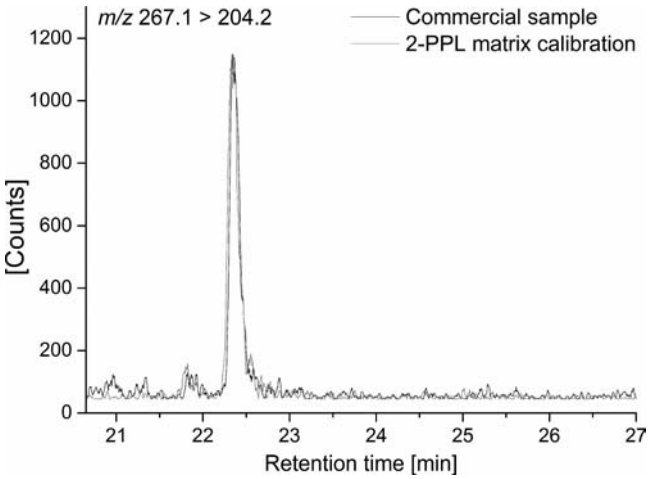

Figure 7. Representative HPLC-ESI-MS/MS chromatogram (MRM mode, transition m/z 267.1 → 204.2) of the enzymatic hydrolysate of the commercial peanut sample (black) and the 2-PPL standard in a raw peanut hydrolyzate matrix (gray).

MS/MS chromatogram (m/z 267.1 → 204.2) of the hydrolyzed commercial peanut sample and the 2-PPL standard in a raw peanut hydrolyzate matrix. The quantitated amounts of 2-PPL in raw, roasted, and commercial peanut samples are given in Figure 8. In raw peanuts, 2-PPL was not detectable, whereas in roasted peanuts, the amounts ranged from 112.1 to 175.1 nmol/100 g protein or from 29.9 to 46.7 μg/100 g protein. In the commercial sample, 144.5 nmol/100 g protein or 38.5 μg/100 g protein was found. These results point to an increase of 2-PPL depending on the roasting conditions. Data obtained for the commercial sample and the samples roasted in laboratory scale were comparable. It should be noted that the formation of 2-PPL would also be possible by a Paal–Knorr reaction if 4-oxononanal was present. Compared to the loss of free 4-HNE as a result of peanut roasting, approximately 1 and 2% of 4-HNE could be recovered, bound to the ε-amino group of lysine as 2-PPL in the peanut samples roasted for 20 and 40 min, respectively. In this estimation, the formation of 4-HNE during the roasting process could not be taken into account. Due to the fact that at low 4-HNE concentrations the total loss of lysine can be explained by the formation of the lipation product

DOI: 10.1021/acs.jafc.5b01502
J. Agric. Food Chem. 2015, 63, 5273–5281

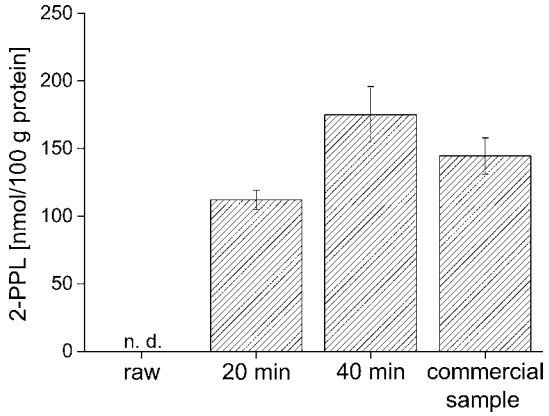

Figure 8. Quantitated amounts of 2-PPL in raw and roasted (170 °C) peanut samples as well as in a commercial peanut sample by HPLC-ESI-MS/MS after enzymatic hydrolysis. n.d., not detectable, (n = 3).

2-PPL (Figure 6), other 4-HNE–lysine adducts should not be of importance. With regard to the loss of amino acids as a result of a modification of raw peanut proteins by 4-HNE (Figure 3), reactions of 4-HNE with other amino acid side chains besides the ε-amino group of lysine seem not to be relevant. A slight decrease in histidine was observed, which might be explained by the formation of Michael adducts or its resulting hemiacetal.[39] Besides the one-to-one 4-HNE–amino acid adducts, cross-linking products may also contribute to the loss of lysine, caused by fluorophores or a Schiff base and Michael adduct at the same molecule of 4-HNE.[12,13] Heating of 4-HNE and primary amines results in only trace amounts of pyrrole and mainly in the condensation product of 4-HNE, 2-pentylfuran.[9] This might, in contrast to peanut oil, contribute to a loss of 4-HNE when proteins are present.

In conclusion, our results show that 4-HNE, a well-known secondary product of the autoxidation of ω-6 polyunsaturated fatty acids,[1] is formed as a result of heating peanut oil depending on the roasting time. Roasting whole peanuts, however, led to a significant decrease in 4-HNE, due to reactions with the amino acid side chains of the peanut proteins as well as a possible degradation of 4-HNE to 2-pentylfuran. As shown, especially lysine derivatives are formed, among which a novel identified pyridinium derivative, Schiff bases, Michael adducts, and 2-pentylpyrrol adducts represent potential lipation products. For a model system, consisting of extracted peanut proteins incubated with 4-HNE at 37 °C for 24 h, the complete decrease of lysine could be explained by the formation of 2-PPL at low concentrations of 4-HNE, indicating that 4-PPL is a good marker for a protein modification by 4-HNE. Furthermore, to the best of our knowledge, a direct quantification of 2-PPL was performed for the first time, showing an increase in 2-PPL depending on the roasting time. This post-translationally formed lipation product contributes to a small percentage of the total loss of lysine observed when peanuts are roasted,[5] showing that lipation products are formed in the course of peanut roasting. Considering the broad spectrum of possible precursors formed when lipid-rich peanuts are roasted, a complex spectrum of lipation products can be formed, accounting for the large modification rate of lysine.[6] Further studies are needed to quantify the amounts of other 4-HNE–lysine adducts and to investigate the influence of these adducts on the allergenic potential of roasted peanuts.

Supporting Information

ABSTRACT: The present study provides an assessment of the compositional diversity in maize B73 hybrids derived both from the Nested Association Mapping (NAM) founder lines and from a diverse collection of landrace accessions from North and South America. The NAM founders represent a key population of publicly available lines that are used extensively in the maize community to investigate the genetic basis of complex traits. Landraces are also of interest to the maize community as they offer the potential to discover new alleles that could be incorporated into modern maize lines. The compositional analysis of B73 hybrids from the 25 NAM founders and 24 inbred lines derived from landraces included measurements of proximates (protein, fat, ash, and starch), fibers, minerals, amino acids, fatty acids, tocopherols (α-, γ-, and δ-), β-carotene, phytic acid, and raffinose. Grain was harvested from a replicated trial in New York, USA. For each data set (NAM and landrace) canonical discriminant analysis allowed separation of distinct breeding groups (tropical, temperate, flint, mixed/intermediate) within each data set. Overall, results highlighted extensive variation in all composition components assessed for both sets of hybrids. The variation observed for some components within the landraces may therefore be of value for increasing their levels in modern maize lines. The study described here provided significant information on contributions of conventional breeding to crop compositional variation, as well as valuable information on key genetic resources for the maize community in the development of new improved lines.

INTRODUCTION

Maize (*Zea mays* L.) is a key agricultural commodity and a major source of animal food and feed as well as raw material for industrial processes worldwide.[1] Breeding programs committed to improving agronomic, compositional, and nutritional qualities extend globally and include renowned organizations such as the International Maize and Wheat Improvement Center (CIMMYT) headquartered in Mexico. In addition to its commercial significance, maize is also well-established in the scientific community as a model plant for the study of fundamental biological phenomena such as genome evolution and hybrid vigor.[2]

Maize was domesticated from teosinte (*Zea mays* ssp. *parviglumis*) approximately 9000 years in southern Mexico. This domestication and subsequent spread of maize across the Americas resulted in open-pollinated, heterogeneous populations adapted to specific environments called landraces. Although defined by distinct genetic and morphological characteristics, there is often more diversity within a landrace than between landraces.[3] Modern inbred lines developed from landraces through breeding and selection are nearly homozygous; that is, they breed true as additional seed is made by crossing the line with itself (i.e., self-pollinating). Maize hybrids are developed by crossing two distinct inbred lines. Hybridization was initiated in the late 1800s with commercialization of hybrids in the early 1900s.[4]

Today, *Zea* germplasm is defined in terms of teosinte, landraces, and inbred lines. The availability of these distinct germplasm pools has intriguing implications for breeding and the development of new maize hybrids. Although maize inbred lines contain an extraordinary amount of genetic diversity when assessed across all lines, subsets of genes are invariant or have reduced variation due to directional selection and bottlenecks associated with domestication and/or plant breeding.[5] Variation for these genes could be reintroduced into modern maize from landraces and teosinte to support further crop improvement.[6]

Diverse collections of genetically distinct maize inbred lines are now preserved in carefully maintained germplasm banks.[7] The USDA-ARS North Central Regional Plant Introduction Station (NCRPIS), for example, has conserved lines representing almost a century of breeding. The landrace accessions for this study were selected from such a collection representing the geographical diversity of maize adaptation in North and South America and were self-pollinated to generate landrace inbred lines,[8,9] In addition to naturally occurring collections, novel populations are being generated to understand the genetic

complexity of maize. One extensively used population is the Nested Association Mapping (NAM) population. The NAM population[10] was generated by crossing 25 NAM founder lines to B73, an inbred line that has contributed extensively to the pedigree of many important commercial lines[11] and which serves as the source of the high-quality reference genome for maize.[12] The 25 NAM founder lines were chosen solely based on genetic diversity from a collection of 301 maize inbred lines adapted to various climatic regions including tropical, subtropical and temperate regions.[13]

Maize landraces are an extremely heterogeneous germplasm group, in terms of genetic and phenotypic diversity both within a landrace and between landraces.[3] Because any given landrace plant is unique, being heterozygous at a large percentage of loci across the genome, it is very difficult to assess the merit of specific landraces or landraces collections. In addition, landraces often display undesirable traits such as photoperiod sensitivity and unadaptedness to target environments. Thus, genetically stable genetic resources are needed to systematically explore diversity within landraces, just as the NAM population was used to initiate exploration of diversity within maize inbreds. The Seeds of Discovery (SeeD) Project (http://seedsofdiscovery.org) is a large-scale project to explore landrace diversity by sampling a single plant per landrace. Unfortunately, the single plant used for the SeeD project does not allow for follow-up genetic studies. However, a small set of inbred lines was derived by self-pollinating directly out of a set of landraces;[8] thus, these landrace inbred lines are true breeding and can be used for innumerable follow-up studies.

The purpose of the current study was to provide a compositional survey of maize hybrids derived from landraces adapted to diverse geographies and the genetically diverse NAM founder lines. An earlier comparative assessment of teosinte, landrace, and inbred lines revealed key differences in kernel proximates (protein, fat, ash, and starch),[14] but to our knowledge compositional surveys have not extended to diverse hybrids or to a diverse range of kernel components. The NAM population has been utilized to reveal key genetic loci associated with kernel compositional features such as starch, protein, and oil[15] and carotenoids.[16] There has been, however, no systematic compositional evaluation of the NAM founders. Such information could prove beneficial as there are genetic loci known to affect kernel composition such as crtRB1 that influences β-carotene concentration[16] or DGAT 1-2 (acyl-CoA:diacylglycerol acyltransferase) that affects oil content and fatty acid profiles.[17] Similarly, there have been no systematic studies on compositional variation in landrace populations of maize. Understanding the compositional diversity of these lines adapted to local environments could prove significant in improving the nutrient profile of new maize hybrids. Information on compositional diversity of these genetically diverse population is also of interest to researchers involved in compositional evaluation of new crops including genetically modified (GM) crops.[18]

MATERIALS AND METHODS

Biological Materials. The germplasm used in this study was selected to represent a broad diversity within maize landraces and inbred lines. Hybrids were used to decrease the range of maturity and thus decrease environmental effects on the composition data. For example, the inbreds flower over a period of 40−50 days in Missouri, but the B73 hybrids all flower within 22 days (S.F.-G., unpublished data).

The landrace inbred lines were derived from open-pollinated landrace accessions as described in Chia et al.[8] and Hufford et al.[9] The following landrace inbred lines were used in the study: MR01 (Araguito), MR02 (Assiniboine), MR03 (Bolita), MR04 (Canilla), MR05 (Cateto), MR06 (Chapalote), MR07 (Comiteco), MR08 (Costeno), MR09 (Cravo Riogranense), MR10 (Crystalino Norteno), MR11 (Cuban Flint), MR12 (Havasupai), MR13 (Hickory King), MR14 (Longfellow Flint), MR15 (Palomero de Jalisco), MR16 (Pepetilla), MR18 (Reventador), MR19 (Santo Domingo), MR20 (Shoe Peg), MR21 (Tabloncillo), MR22 (Tuxpeno), MR23 (Zapalote Chico), MR25 (Poropo), and MR26 (Pollo). The geographical origins of landrace inbreds are described in Hufford et al.[9] and are indicated in Supplementary Figure 7. On the basis of geographical origin and historical data[19] these inbreds have been classified as tropical/subtropical (Pepetilla, Cateto, Tuxpeno, Araguito, Tabloncillo, Comiteco, Canilla, Poropo, Zapalote Chico, Reventador, Pollo, Cravo Riogranense, Crystalino Norteno, Costeno, Bolita, and Cuban Flint), temperate (Shoe Peg and Hickory King), northern flint (Santo Domingo, Longfellow Flint, Assiniboine, and Havasupai), and intermediate (Palomero de Jalisco and Chapalote). The intermediate group refers to a geographical origin that is less clear, with membership in multiple groups (e.g., Palomero de Jalisco is a flint from a subtropical region).

Modern inbred lines used in the study are the parental lines of the NAM population:[10] B97, CML103, CML228, CML247, CML277, CML322, CML333, CML52, CML69, Hp301, IL14H, Ki11, Ki3, Ky21, M162W, M37W, Mo18W, MS71, NC350, NC358, Oh43, Oh7B, P39, Tx303, and Tzi8. The geographical origin of these inbreds is indicated in Supplementary Figure 7. The inbreds were classified by population structure using genetic marker data as described in Flint-Garcia et al.[13] as tropical/subtropical (NC350, CML103, CML333, Tzi8, Ki11, Ki3, CML69, NC358, CML228, CML247, CML52, CML322, and CML277), nonstiff stalk temperate (MS71, Oh43, B97, Ky21, M162W, and Oh7B), northern flint (P39, Il14H, and HP301), and mixed (Mo18W, M37W, and Tx303). Inbreds classified as mixed group have membership probabilities of <80% in any one of the groups, indicating admixture (shared breeding history) among the tropical and temperate groups. The common parent, B73, is a temperate stiff-stalk inbred and is therefore suitable as a tester for making hybrid seed. In addition, B73 is the reference genome line allowing for downstream genomic and bioinformatic analyses in these materials. Inbred seed material used in the study can be procured from the North Central Regional Plant Introduction Station (NCRPIS).

Production of Hybrid Seed. Hybrid seed of B73 crossed with the landrace inbred lines and the NAM founders was produced over four different seasons: 24 and two entries were produced, respectively, in Columbia, MO and Puerto Rico, USA, in 2008; 18 entries were produced in Puerto Rico in 2009; and six entries were produced in 2010 in Columbia, MO, USA. All hybrids were produced by controlled hand pollination, using B73 as the female for each hybrid.

Field Design. Materials for composition analyses were generated in 2012 near Aurora, NY, USA. The 25 B73 × NAM founder hybrids and 24 B73 × landrace hybrids were planted in a randomized complete block design in 3 m × 0.9 m rows in three replications. Three to five plants were self-pollinated for each row, and selfed ears were hand harvested and dried to 12−13% moisture. Dried ears from each row were bulk-shelled, and grain was stored at room temperature before shipping to Monsanto Co. in St. Louis, MO, USA. Grain samples were homogenized by grinding on dry ice to a fine powder and stored frozen at approximately −20 °C until compositional analysis.

Phenotypic Data. Plant, ear, and kernel traits were evaluated as follows. Anthesis dates were collected on a row basis, when half the plants in the row were shedding pollen, and subsequently converted to days to anthesis by subtracting the planting date from the anthesis date. Plant and ear heights were measured for three plants per plot after flowering from the ground to the collar of the flag leaf and the node of the top ear, respectively. Three self-pollinated ears were harvested per row and used to study the following ear and kernel traits: the number of kernel rows around the ear; the weight of the ear,

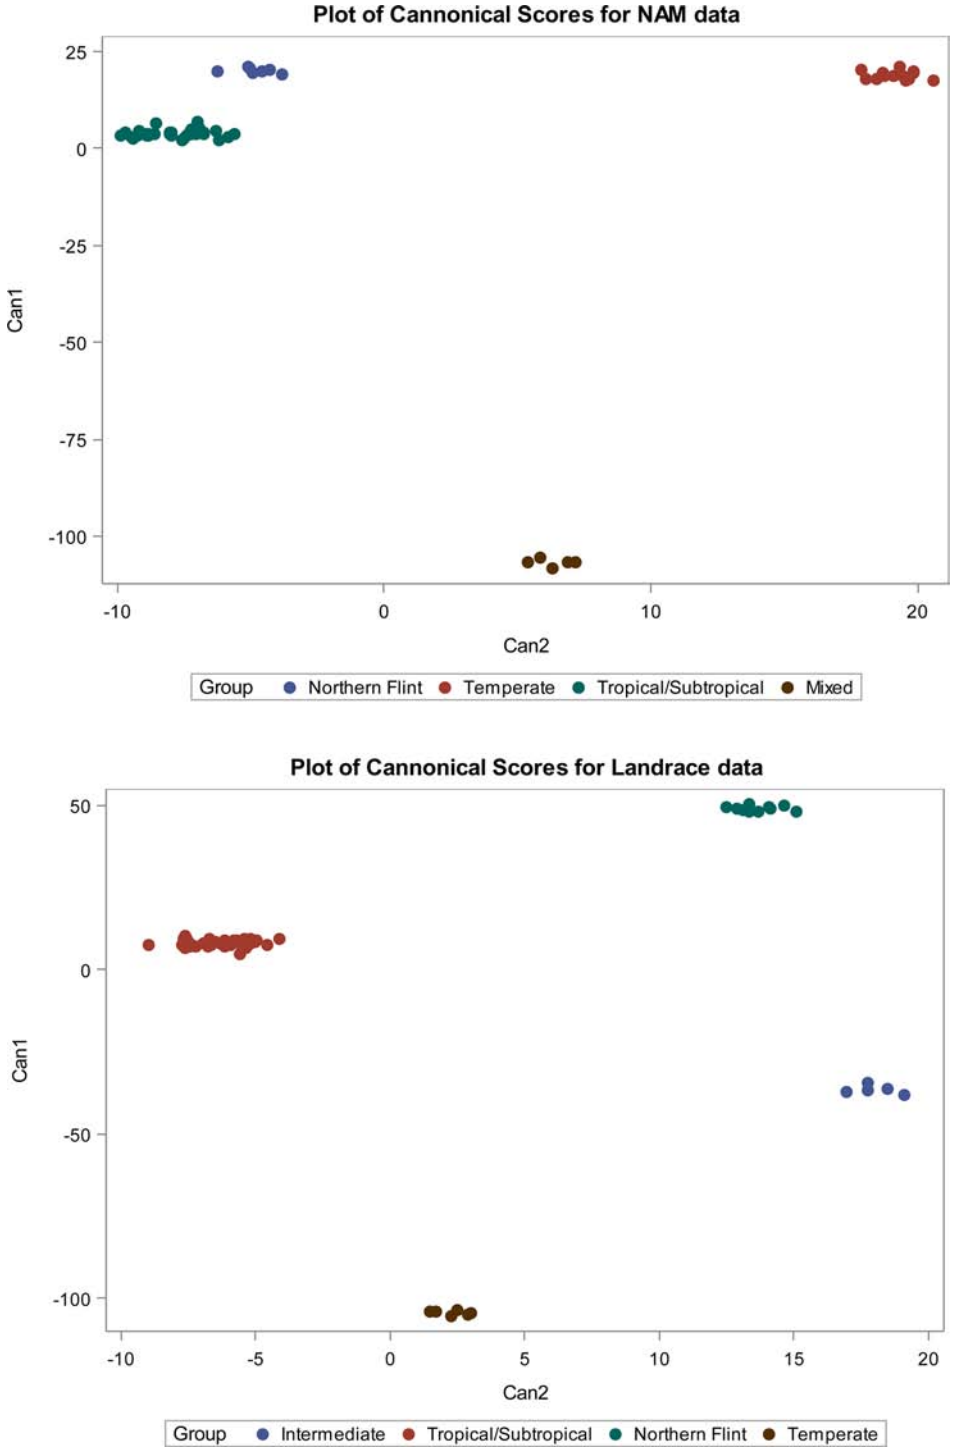

Figure 1. CDA of composiotional data from the NAM hybrids (top) and landrace hybrids (bottom).

the cob, and 50 kernels; the width of the ear and cob; and the length of the ear.

Composition Analysis. Assays for proximates (protein, fat, ash, and starch) except starch have been described before.[20] Starch was based on AOAC[21] protocols. Assays for fatty acids and amino acids,[22] minerals, raffinose, phytic acid, and β-carotene[20] have also been previously reported. Tocopherol analysis was based on a reversed-phase HPLC method using fluorescence detection with excitation at 290 nm and emission at 336 nm.[23] Tocopherols were extracted from ground lyophilized seed with 0.1% pyrogallol in ethanol. The reversed-phase HPLC system comprised a Keystone Aquasil C_{18} column at 40 °C and methanol as the mobile phase. The flow rate was 1 mL/min, and moisture was measured to allow for dry weight conversions. All compositional data are reported as percent dry weight (dwt) and are available in Supporting Information Files S1 and S2.

Three biological replicates were available for all samples except hybrids CML277, M37W, Oh43, and Oh7B, Bolita, Chapalote, Costeno, Cuban Flint, and Tabloncillo (two replicates each), and Canilla and Havasupai (one replicate each). Some assays were not repeated due to sample limitations. Thus, there is only one replicate of the Comiteco hybrid for protein, fat, starch, carbohydrates by calculation, β-carotene, raffinose, ADF, and NDF; one Araguito hybrid replicate for starch and phytic acid; one Tuxpeno hybrid replicate for raffinose; one CML103 hybrid replicate for NDF; and one

Ky21 replicate for NDF. Samples with missing data due to sample limitations are noted in Supporting Information Files S1 and S2.

Statistical Analysis. Simple descriptive statistics were employed. Means, minimum replicate values, and maximum values were calculated in JMP 10 (SAS Institute, Cary, NC, USA). Analytes for which 50% of values were below the assay limit of quantitation (LOQ) were not included in the statistical summaries. These analytes included nine fatty acids (C11:0, C12:0, C14:0, C18:4n3, C20:2, C22:0, C22:5, C22:6, and C24:1), as well as sodium. No fatty acid data for one replicate of the M162W hybrid were assessed as one of the major fatty acids (oleic acid, C18:1) was assigned an LOQ during data acquisition. As in typical chemical analysis,[20a,24] analyte values below the LOQ were assigned a value of half of the assay LOQ. This included 54 values of C13:0, 20 values of C17:0, 25 values of C18:3n6, 22 values of C20:1n9, 4 values of C20:5, 24 values of C22:1n9, and 15 values of C24:0 with a value of 0.025% total fatty acid. The five values of β-carotene were assigned a value of 0.02 mg/100 g. All imputed values and associated samples are documented in Supporting Information Files S1 and S2.

We employed canonical discriminant analysis (CDA)[25] to determine if patterns existed in the data that could separate the hybrid groups, using the canonical discriminant CANDISC procedure in SAS. CDA is a dimension reduction technique related to principal component analysis and canonical correlation.[25] CDA analysis finds linear combinations of the quantitative variables that provide maximal separation between classes or groups. Given a classification variable and several quantitative variables, the CANDISC procedure in SAS derives canonical variables, linear combinations of the quantitative variables that summarize between-class variation in much the same way that principal components summarize total variation. The classification variable was hybrid groupings for NAM and landrace inbreds, and the quantitative variables were compositional components/phenotypic observations. Correlations between each of the analyte values and canonical scores 1 and 2 were derived using the multivariate CORR procedure in SAS.

RESULTS AND DISCUSSION

Maize is a highly diverse species, despite the narrow genetic base within U.S. commercial breeding programs.[26] Recently, genetic diversity within inbred lines has been explored to greater depth[7,10b] than ever before. However, systematic exploration of the landraces is lagging behind. In this study, we focus on the phenotypic evaluation of kernel composition traits in B73 hybrids derived from the NAM founders and a set of American landraces. The compositional analysis included quantitative measurement of proximates (protein, fat, ash, and starch), fatty acids, amino acids, minerals, raffinose, phytic acid, tocopherols, and β-carotene levels in mature grain of the two hybrid data sets.

CDA. CDA of the NAM hybrid data set established effective separation of the breeding groups assigned for the NAM hybrids (northern flint, temperate, tropical/subtropical, and mixed). CDA additionally provided effective separation of groups within the landrace hybrid set (northern flint, temperate, tropical/subtropical, and intermediate). Group assignments for each hybrid are provided in all tabulated data sets. The results clearly imply unique compositional characteristics that can distinguish between different sets of maize hybrids (Figure 1). The data also contrast the variation

associated with conventional breeding to the relative lack of impact of GM on composition.[18] Overall, however, correlations between the canonical scores (Can1 and Can2; Supplementary Table 1) and individual analytes that provided the separation were generally low (Supporting Information), and no one component was uniquely different in one breeding group versus another. In general, all components were characterized by extensive variation in grain levels, although values were typical for maize hybrids (ILSI, 2014).[27] Variation for individual components and their association with canonical scores is discussed in more detail below.

NAM Founder Hybrid Proximates and Fibers. Results for proximates and fibers are presented in Table 1, where the NAM founder hybrids are tabulated in order of highest to lowest mean protein values. The CML69 × B73 hybrid had the highest mean protein value (14.01% dwt) and M37W × B73 the lowest (10.25% dwt); the corresponding amino acid data are presented in Supplementary Table 2. Overall, all proximates values were variable, and no clear distinctions between the different NAM hybrid subsets were observed. We found that the hybrids with flint ancestry (derived from the sweetcorn lines P39 and Il14H and the popcorn HP301) were characterized by a relatively high-fat, low-carbohydrate profile (see Figure 2). For example, P39 × B73 and Il14H × B73 had the highest mean fat values (7.13 and 5.72% dwt), respectively; P39 × B73 had the lowest mean carbohydrate values (77.89% dwt). These observations are consistent with the abnormal starch content of sweetcorn lines due to the *sugary1* locus.[28] The extensive variation in protein values observed is presented in Supplementary Figure 1. Interestingly, the correlation between the inbred values for the same NAM parents reported by Cook et al.[15] for protein, oil, and starch were $r = -0.02$, 0.58, and 0.38, respectively. It appears that the B73 parent of the hybrids used in this study is contributing strongly to differences in protein content, but not for starch or oil. Correlations between protein, starch, and carbohydrates with canonical score 1 were $r = 0.358$, −0.363, and −0.333, respectively (Supporting Information). These were among the highest correlations observed, and these components are clearly some of the larger contributing factors to the separation of the different breeding groups.

NAM Founder Hybrid Fatty Acids. Results for fatty acids are presented in Table 2. The NAM founder hybrids are tabulated in order of highest to lowest mean linoleic acid (C18:2) values, the major fatty acid in maize. B97 × B73 had the highest mean value (58.92% total FA) and M162W × B73 the lowest mean value (41.68% total FA). The sweetcorn hybrids (derived from P39 and Il14H) and the popcorn HP301 were characterized by a relatively low oleic acid (C18:1) and high linolenic acid (C18:3) profile (see Figure 3), consistent with prior observations that high oil materials have high linolenic acid (C18:3) levels.[15] Correlations of the major individual fatty acids with the canonical scores were generally low; palmitic acid (C16:0) had a value of $r = -0.384$ with canonical score 2, representing the highest correlation for these components.

NAM Founder Hybrid Vitamins and Metabolites. Results for vitamin and metabolites are presented in Table 3. The NAM founder hybrids are tabulated in order of highest to lowest mean α-tocopherol values. Overall, vitamin and metabolite values were highly diverse; values for γ-tocopherol and β-carotene are presented in Figure 4 and for raffinose presented in Supplementary Figure 2. Despite this variation, some of these metabolites represented some of the highest correlations with the canonical scores; for example, raffinose and canonical score 1 ($r = -0.381$), phytic acid and canonical score 2 ($r = -0.418$), and γ-tocopherol and canonical score 2 ($r = 0.353$). Again, none of these components, by themselves, uniquely distinguished any breeding group. The β-carotene values (Table 3) in the hybrids were well correlated with the

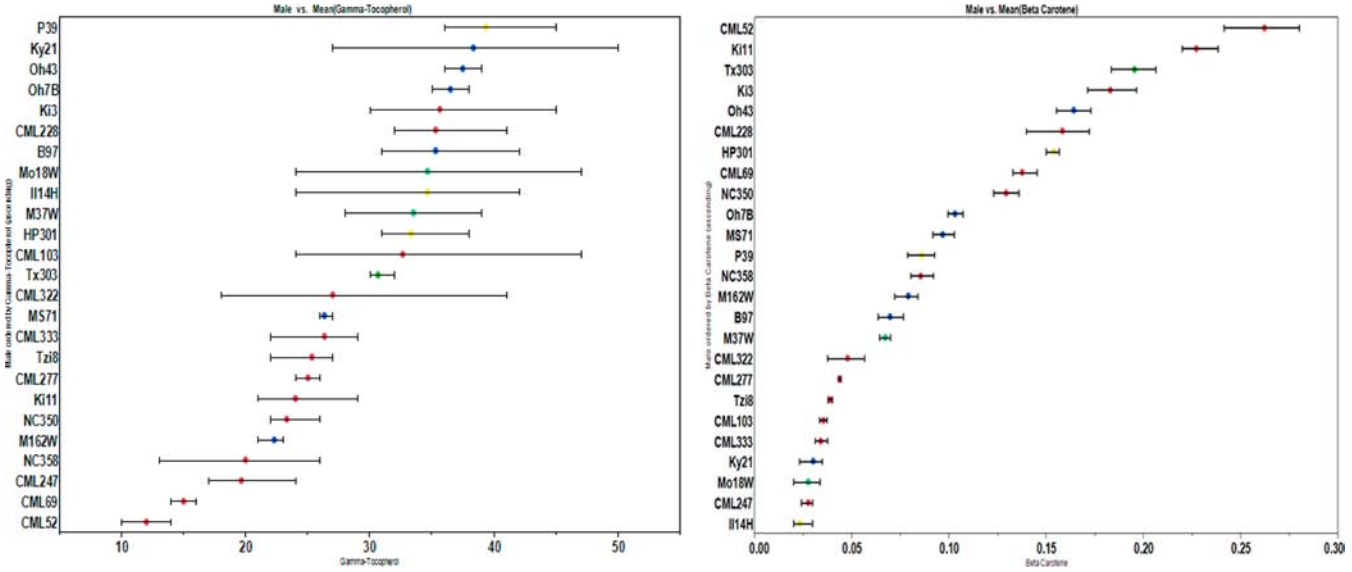

Figure 4. Means and ranges for γ-tocopherol (left) and β-carotene (right) of the NAM founder hybrids.

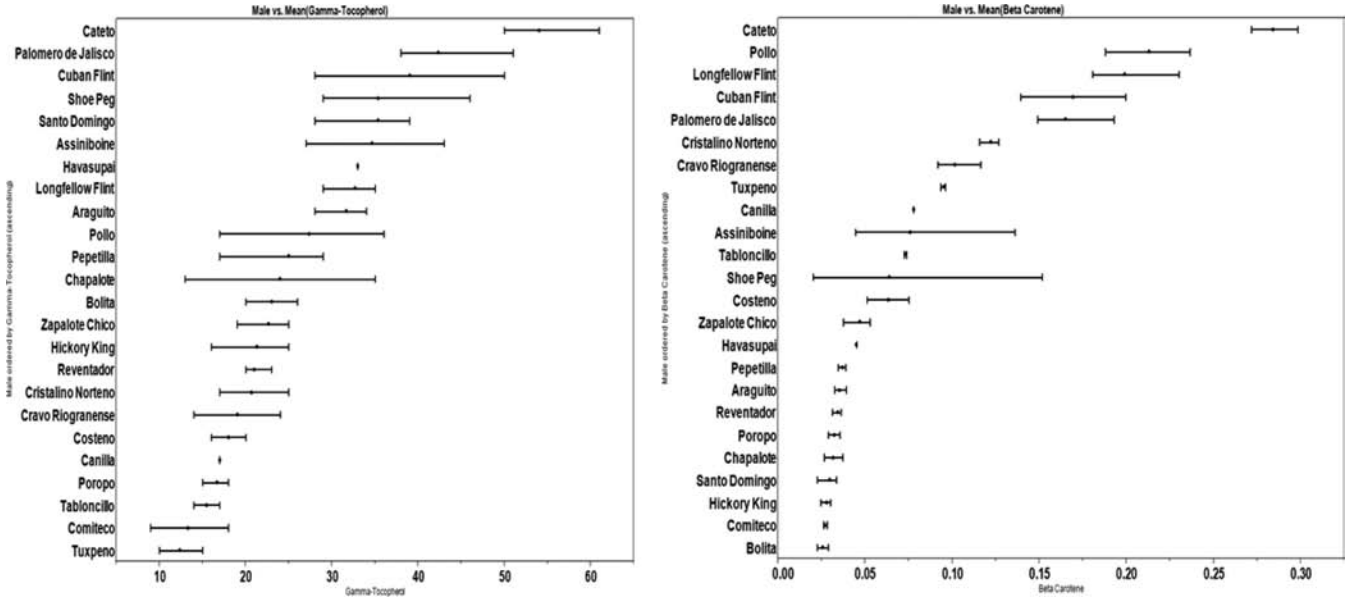

Figure 5. Means and ranges for γ-tocopherol (left) and β-carotene (right) of the landrace hybrids.

parents (P39, NC358, NC350, CML69, HP301, CML228, Ki3, Tx303, Ki11, and CML52) having the highest β-carotene values, and the yellow parents having intermediate values. However, the relationship between kernel color and carotenoid content is not perfect, which is consistent with previous results.[16a] The red kernel color observed for the CML52 hybrid (Figure 6; Supplementary Table 7) originates in the pericarp, the outer layer of the seed, which is derived from maternal tissue. The pericarp does not contain carotenoids, but rather contains other phenolic compounds such as anthocyanins, flavonoids, and phlobaphenes.[29] It is interesting that both the B73 and CML52 inbreds have clear pericarps, but the F1 ear produces red pericarp. This was observed during the development of the NAM population (S.F.-G., unpublished data) and is likely due to independent mutations in the *P1* locus in the two inbred lines that were complemented in the hybrid.

NAM Founder Hybrid Minerals. Mineral values among the NAM founder samples varied within the different subgroups (Supplementary Table 3). Two minerals showed some correlation with the canonical scores (in contrast with the landrace hybrid results shown below). These were manganese and canonical score 1 (r = 0.372) and phosphorus and canonical score 2 (r = −0.535). The phosphorus results are consistent with those of phytic acid (a phosphorus storage compound in maize grain).

Landrace Hybrid Composition Traits. Results for proximates and fibers, minerals, fatty acids, and vitamins and metabolites are presented in Table 4, Supplementary Table 5, Table 5, and Table 6, respectively. Overall, proximates and mineral values were typical for maize hybrids.[27] It is interesting that the hybrid derived from the popcorn Palomero de Jalisco had the highest mean protein value (14.69% dwt) just as was observed for the NAM popcorn parent HP301. Shoe Peg × B73, a landrace that is commonly eaten fresh in the United States, had the lowest protein value (10.12% dwt) (Supplementary Figure 3); the corresponding amino acid data are

presented in Supplementary Table 4. Similar variations in mineral levels were reported by Aliu et al.[30] in local populations of maize grown in Kosovo.

Fatty acids were highly variable for the landrace hybrids (Table 5; tabulated in order of highest to lowest mean linoleic acid (C18:2) values. Tuxpeno × B73 had the highest mean value (55.18% total FA) and Zapalote Chico × B73 the lowest (42.11% total FA). The oleic (C18:1) and linolenic (C18:3) fatty acid values are represented in Supplementary Figure 4. Likewise, there were high levels of variability for vitamins and metabolites in the landrace data set, including carotenoids, tocopherols, phytic acid, and raffinose. Values for γ-tocopherol and β-carotene are presented in Figure 5, and those for raffinose are presented in Supplementary Figure 5. Just as in the NAM founders, the carotenoid content of the landrace hybrids closely followed the kernel color. The striking exceptions were the Comiteco and Revenatdor hybrids, where the pink and red

Figure 7. Photographs of the B73 × landrace ears: (top row) MR01 (Araguito), MR02 (Assiniboine), MR03 (Bolita), MR04 (Canilla), MR05 (Cateto), MR06 (Chapalote), MR07 (Comiteco), MR08 (Costeno), MR09 (Cravo Riogranense), MR10 (Crystalino Norteno), MR11 (Cuban Flint), MR12 (Havasupai); (bottom row) MR13 (Hickory King), MR14 (Longfellow Flint), MR15 (Palomero de Jalisco), MR16 (Pepetilla), MR18 (Reventador), MR19 (Santo Domingo), MR20 (Shoe Peg), MR21 (Tabloncillo), MR22 (Tuxpeno), MR23 (Zapalote Chico), MR25 (Poropo), MR26 (Pollo).

pericarp colors masked white endosperm (Supplementary Table 8; Figure 7).

Correlations with Canonical Scores within Landraces. Correlations between proximates values and the canonical scores showed a pattern different from that for the NAM hybrid data set with, in general, much lower correlations (Supplementary Table 1; Figure 1). The minerals represented some of the highest correlations with canonical score 1; for example, iron, magnesium, manganese, and phosphorus were all >0.4 (Supporting Information). It is therefore probable that these components contribute more so than other components to separation of the breeding groups in the landrace set. This

DOI: 10.1021/acs.jafc.5b00208
J. Agric. Food Chem. 2015, 63, 5282−5295

contrasts slightly with results from the NAM set where minerals (with the possible exceptions of manganese and phosphorus) were less affected. Correlations between fatty acid values and canonical scores were low, suggesting that these components are unlikely to contribute to any separation of the different breeding groups. Of the metabolites, phytic acid showed the highest correlation with canonical score 1 (r = 0.394), whereas γ-tocopherol showed the highest correlation with canonical score 2 (r = 0.384).

Comparison of NAM to Landraces for Composition Traits. Box plots comparing compositional variation of NAM and landrace hybrids for selected analytes discussed above are presented in Supplementary Figure 6 (a−e). Sevaral composition components such as iron, manganese, phosphorus, ash, γ-tocopherol, raffinose, and phytic acid had the highest correlations for both hybrid sets. For most composition traits, the landrace hybrids had either the same or wider ranges of phenotypic variation than the inbred lines. The exceptions were the proximates fat, starch, and carbohydrates (Tables 1 and 4), several of the fatty acids such as palmitic acid (C16:0), stearic acid (C18:0), oleic acid (C18:1), and linoleic acid (C18:2) (Tables 2 and 5), the vitamins and minerals α- and γ-tocopherol and raffinose (Tables 3 and 6), the amino acids methionine and proline (Supplementary Tables 2 and 4), and the minerals copper, manganese, and zinc (Supplementary Tables 3 and 5). Interestingly, for most of these exceptions the lower range for the landrace hybrids did not exceed the lower range of the inbreds, whereas the upper range of the landrace hybrids still exceeded the inbred range, indicating that the landraces may be more valuable for increasing these trait values rather than decreasing them. The wide diversity of phenotypes for all of the kernel composition traits in the landrace hybrids warrants further studies of the genetic architecture underlying composition traits, as well as the exploration of this diversity for maize improvement.

Plant, Ear, and Kernel Phenotypic Data. Results of the CDA on the phenotypic data for both the NAM and landrace hybrid sets are provided in Supplementary Table 6. Positive correlations with canonical scores 1 or 2 were observed for days to anthesis, ear weight, ear width, kernel weight, cob weight, and ear height in the NAM hybrid set. In the landrace hybrid set positive correlations with canonical scores 1 or 2 were observed for days to anthesis, plant height, ear height, ear length, and ear fill length. The majority of the ear/kernel phenotypes showed negative correlations in the landrace hybrid data set. There was wide variability for all plant, ear, and kernel traits in both the NAM and landrace hybrid sets (Supplementary Tables 7 and 8). As with the composition data, the landrace hybrids had wider ranges of plant, ear, and kernel phenotypes. The exceptions were ear and cob weight, which are likely a function of the unadaptedness of the landraces to the temperate environment in which they were evaluated, where the landrace hybrids were not able to produce full-sized ears. These phenotypes have been studied extensively at the genetic level in the NAM population,[31] but as for the composition traits discussed above, they have not been explored in landraces.

The development of modern plant breeding techniques has greatly facilitated wider use of a wealth of genetic diversity from many sources including landraces. Exploitation of genetic diversity in breeding programs has allowed food production to keep up with population growth.[32] The development of improved maize hybrids will require optimization of current resources to guide breeding strategies. The genetic diversity preserved in germplasm banks represents a key current resource. In this study we have provided the maize research community a first survey of kernel composition of hybrids from two important genetic resources: the NAM founder lines and landraces selected from wide geographic areas in the Americas. Multivariate analysis (CDA) showed that subsets within each of the NAM and landrace hybrid data sets could be distinguished by breeding group. Overall, results highlighted extensive variation in all compositional components assessed for both sets of hybrids reflecting the underlying genetic diversity of these lines. Data generated here will be of value to plant breeders and plant biotechnologists involved in the nutritional and agronomic improvement of corn and will be a resource for the wider research community utilizing the NAM founder lines to understand the genetic basis of compositional and other complex traits. The data also contrast the variation associated with conventional breeding to the relative lack of impact of GM on composition.[18b] The natural variability associated with composition observed in these conventional natural populations may therefore also be of interest to regulatory scientists and policy makers involved in safety evaluation of transgenic crops from a food and feed perspective.[33]

ABSTRACT: The present study describes chlorpyrifos residues in duck commodities through the duck food chain, transfer factors, and dietary risks to Chinese consumers. After duck feeding experiments with pellet feed that lasted for 42 days, chlorpyrifos residues found in all samples collected from the ducks on maximum estimated dose group (3.20 mg/kg level) were from <0.0005 to 0.019 mg/kg. The residue levels of the fat, intestine, and tongue were obviously higher than those of the meat and other edible tissues. The transfer factors of all duck commodities were from 0.0001 to 0.0049 among different contamination levels, which indicated that chlorpyrifos had a low persistency in duck meat and metabolism organs. The chronic exposure assessment revealed that only 0.034−0.150% of the acceptable daily intake (ADI; 0−0.01 mg/kg/bw/day) of chlorpyrifos was consumed via the duck commodities for different age and gender groups in China. The acute exposure assessments of different age and gender groups were only 0.019−0.082% of the acute reference dose (ARfD; 0−0.1 mg/kg/bw). The results show that the single dietary exposure risk of chlorpyrifos raised by the intake of duck commodities was quite low in China.

KEYWORDS: *chlorpyrifos, duck commodities, transfer, dietary exposure*

INTRODUCTION

The potential effects of pesticide accumulation along the food chain on human health are of increasing concern to consumers and food safety authorities worldwide.[1−3] Currently, maximum residue limits (MRLs) for various pesticides in products of animal origin were mainly set by international organizations and developed countries, but only a few MRLs (e.g., endosulfan, quintozene) in animal commodities have been set by the Chinese government due to limited research for pesticide transfer along the food chain.[4,5] Evaluations of pesticide transfer from contaminated feed to animal commodities and their potential dietary exposure to consumers are increasingly needed in China.

Chlorpyrifos (*O*,*O*-diethyl *O*-3,5,6-trichloro-2-pyridyl phosphorothioate) is one of the most widely used organophosphorus pesticides in China.[6] Chlorpyrifos kills insects by inhibiting pest acetyl cholinesterase, but the pesticide has potential toxicity to mammals and humans including birth defects, nervous system disorders, and increased rates of leukemia and immune system abnormalities.[7] Therefore, the use of chlorpyrifos in agricultural production has been constantly monitored in many agro-products, mainly including foods of plant origin (e.g., vegetables, fruits, and grain crops).[6,8] However, scant information has been obtained on chlorpyrifos residues in animal commodities. For example, Sun et al. detected the highest concentration of chlorpyrifos residue as 0.46 mg/kg in farmed fish.[9] Kammerbauer et al. found the presence of chlorpyrifos residues (0.011 mg/kg) in the tissues of fish that had been raised near an agricultural field.[10] High chlorpyrifos residues were detected as the one of the main pollutants in raw buffalo's milk in Egypt and cow's milk in Italy.[11,12] Unfortunately, monitoring and controlling chlorpyrifos residues in livestock commodities are still in the early stages, and published data related to pesticide residues and risk assessment of livestock commodities are scattered. Meanwhile, this situation also poses serious problems for the Chinese government and livestock producers to manage chlorpyrifos residues in livestock commodities.

The risk assessment of feed contaminants to humans has often been hampered by a lack of knowledge concerning their behavior after feeding on domestic animals. Several livestock metabolism and feeding studies indicated that organophosphorus pesticide residues (including chlorpyrifos) were rapidly absorbed and excreted mainly through the urine at the test dose of pesticides. Hsu et al. recovered a maximum of 0.14% of chlorpyrifos intake via eggs at a single dose (90 mg) for 8 days, similar to a report by Schenck and Donoghue.[13,14] The levels of chlorpyrifos in milk ranged from <0.01 mg/kg at dietary levels of ≤10 mg/kg to 0.02 mg/kg at 30 mg/kg, and chlorpyrifos residues in cream were approximately 10 times higher than in milk.[15] Chlorpyrifos residues were detected in eggs of laying hens at dietary levels of 0.3−10 mg/kg for 30 days.[15] Currently, little attention has been paid to pesticide residues in farm-raised ducks under realistic dietary burden intake, although duck meat,

eggs, and other derived products are among the most popular food items in the Chinese diet.[16]

According to the result of an earlier study in our laboratory, the chlorpyrifos residue determined in the processed duck pellet feed was 3.20 mg/kg.[17] Animal feed is one potential pesticide exposure pathway to transfer pesticides to human foods. We further wondered if chlorpyrifos could contaminate duck commodities through the livestock food chain and influence consumers' health. At present, an obstacle to the evaluation of the risk posed by chlorpyrifos residues in feed is the lack of relevant data related to the transfer of residues from feed to livestock commodities. In the food chain transfer, transfer factors (TFs) are defined as the ratio of the pesticide residue in the tissue or commodity of interest to the pesticide residue in the animal feed. Generally, feeding studies are used to determine transfer factors, which are usually adopted to assist dietary assessment of pesticide intake from animal commodities. Therefore, the objectives of the current study were to investigate the chlorpyrifos residues and transfer in duck commodities (i.e., meat, eggs, and other edible tissues) through feeding trials based on maximum levels in feed contaminated by chlorpyrifos and also to obtain TFs from feed to animal commodities. Finally, the potential dietary exposure risk of chlorpyrifos from consumed duck commodities were further evaluated by using the deterministic approach.

MATERIALS AND METHODS

Materials. Stock solution of chlorpyrifos (100 μg/mL in acetonitrile) was purchased from the Agro-Environmental Protection Institute, Ministry of Agriculture (Tianjin, China). *N*-Propylethylenediamine (PSA) and graphitized carbon black (GCB) were obtained from Bonna-Agela Technologies Inc. (Tianjin, China). Analytical grade acetonitrile, ethyl acetate, $MgSO_4$, and NaCl were obtained from East China Pharmaceutical Group Co., Ltd. (Hangzhou, China). Unless otherwise noted, all reagents used in the study were of HPLC grade. Pure water was generated by a Milli-Q water-purification system (Millipore, Bedford, MA, USA).

Experimental Design and Duck Husbandry. The present study was approved by the Animal Welfare Committee of Zhejiang Academy of Agricultural Sciences. All of the animal studies were conducted in accordance with the guidelines of the Ministry of Public Health of the People's Republic of China. Ducks were raised in cages with plastic-wire floors (60 × 170 × 70 cm^3). The cages were maintained with 24 h of constant light, a relative humidity of 60 ± 10%, and a room temperature of 20 ± 5 °C. The ducks were daily provided commercial pellet feed containing 18.0% protein and water ad libitum throughout the experimental period. All efforts were made to minimize the number of animals used in the study and their suffering.

Randomized Controlled Feeding Trial with Broiler Ducks (Pekin Duck). Pekin duck is the predominant breed used for meat production in China. A total of 30 white Pekin ducks (7 days of age, each weighed 0.09−0.11 kg) were randomly divided into three different groups and were fed duck pellet feed containing chlorpyrifos at levels of 3.20 mg/kg (1×), 9.60 mg/kg (3×), and 32.0 mg/kg (10×) for 42 days, respectively. Three ducks randomly selected from the groups were placed on a pesticide-free diet as a control. After 42 days, all ducks were slaughtered to collect the muscle, fat, heart, stomach, tongue, intestine, liver, and kidney tissues, respectively. All samples were cleaned with deionized water and sealed in plastic bags to minimize the possibility of contamination. All samples were then stored at −20 °C in darkness until analysis.

Randomized Controlled Feeding Trial with Egg-Laying Ducks (Shaoxing Brown Duck). Shaoxing brown duck is a major egg layer breed in southern China. A total of 30 Shaoxing brown ducks (150 days of age, each weighed 1.4−1.6 kg) were randomly divided into three different groups and were fed duck pellet duck containing chlorpyrifos at levels of 3.20 mg/kg (1×), 9.60 mg/kg (3×), and 32.0 mg/kg (10×) in the diet for 42 days. Three ducks randomly selected from the groups were placed on a pesticide-free diet as a control. The eggs from all ducks were collected on days 1, 3, 7, 14, 21, 28, 35, and 42 during the experimental periods. All samples were sealed in plastic tubes and stored at −20 °C in darkness until analysis.

Sample Preparation and Analytical Conditions. Extraction and cleaning procedures of chlorpyrifos from duck samples (meat, eggs, and other edible tissues) were performed according to the method of Li et al. with minor modifications.[18] Briefly, 2.0 g of homogenized sample was transferred to a 50 mL Teflon centrifuge tube with 10 mL of acetonitrile acidified with 1 M HCl (99:1, v/v), along with 2.0 g of $MgSO_4$ and 1.0 g of NaCl. The tube was shaken vigorously for 1 min

DOI: 10.1021/acs.jafc.5b01839
J. Agric. Food Chem. 2015, 63, 5296−5304

followed by centrifugation for 5 min at 966*g*, and the supernatant was transferred to a clean conical tube. The extraction step was repeated again, and all of the supernatant was pooled into a conical tube and frozen at −20 °C (>1 h); the fat layers formed on the sample surface were removed before the next analysis. The remaining liquid extract (10 mL) was concentrated using a rotary vacuum evaporator at 40 °C and dried with a gentle stream of nitrogen. The residue was then redissolved with 1.0 mL of ethyl acetate in a 2.5 mL microcentrifuge tube with a mixture of 150 mg of $MgSO_4$, 25 mg of GCB, and 50 mg of PSA. The tube was shaken vigorously for 1 min and centrifuged for 5 min at 9030*g*. The extract was filtered through a 0.22 μm PVDF filter before analysis by GC-MS/MS.

TSQ Quantum gas chromatography with a GC system TRACE GC Ultra and a triple-quadrupole mass spectrometer Quantum (Thermo Fisher Scientific, USA) were used for the analysis. The Zebron ZB-MultiResidue-2 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness; Phenomenex, Torrance, CA, USA) was applied for analyte separation. The injection inlet temperature was 250 °C. The oven temperature was initially at 60 °C for 1 min and then increased in several steps: to 180 °C at a rate of 30 °C/min, to 220 °C at a rate of 10 °C/min, and to 280 °C at a rate of 60 °C/min. The transfer line and ionization source temperatures were set at 260 and 250 °C, respectively. The injection mode was splitless. The mass spectrometer was under the selected reaction monitoring (SRM) mode. The highest intensity ion (m/z 314) was used for parent ions to produce product ions m/z 286 and 258 (quantitative ion) in the GC-MS system.

Pesticide recovery analysis was evaluated by fortified blank samples at four chlorpyrifos concentrations with six replicates. Matrix effects were evaluated by comparing the slopes of solvent and matrix calibration sets. Series 1 was prepared by diluting the stock standard solution in solvent at four concentrations and series 2 by diluting the stock standard solution in matrix extract that was obtained from a pesticide-free sample.

Chinese Food Consumption Data. Chinese food consumption data were derived from the 2002 China National Nutrition and Health Survey (CNNHS) covering residents from 31 areas including provinces, autonomous regions, and metropolises in China (excluding Hong Kong, Taiwan, and Macau).[19] The survey employed a 24 h recall method using a multistage, random cluster process over three consecutive days (two weekdays and 1 weekend day, holidays excluded). In this survey, 23470 families were obtained from a stratified random sample of 68962 individuals including 33551 males and 35411 females. The food types were categorized into 10 groupings, such as rice, flour, coarse cereal, pulses, vegetables, fruits, meat, milk, eggs, and aquatic products. Demographic information on the participants, including age, gender, and body weight, was also gathered in the survey and used for later calculation. Various duck commodities, consumption data in the survey for different age groups (2−3, 4−6, 7−10, 11−13, 14−17, 18−29, 30−34, 45−59, 60−69, and ≥70 years old), and gender (male and female) are presented in Table 1.

Calculation of Pesticide Residue Intakes. Due to the prominent advantages (i.e., simplicity, worldwide use, and acceptance), the deterministic approach is usually selected as the first screening tool to identify the potential risks of pesticides in food.[20] This approach was selected to calculate chlorpyrifos exposure of duck commodities in our study. Here, on the basis of the residue results of the 1× dose in a feeding trial, chlorpyrifos intakes were estimated using STMR and HR to evaluate long- and short-term health risks to consumers on the basis of methods recommended by the WHO.[21]

The data of food consumption and chemical residues are two obligatory factors in the quantification of dietary risk (exposure assessment).[22] The dietary exposure to pesticides was calculated on the basis of consumption data, individual body weights, and residue data from animal feeding studies, usually presented as acute (short-term) and chronic (long-term) exposures. Estimated intakes on a daily basis were expressed as percentages of the ADI (0−0.01 mg/kg/bw/day) and ARfD (0−0.1 mg/kg/bw) values of chlorpyrifos, which were derived from a Joint FAO/WHO Meeting on Pesticide Residues.[23] Chronic intake assessment was calculated by multiplying median residue concentration and the average daily per capita consumption for livestock commodities obtained from the 2002 CNNHS. The estimated daily intake (EDI) and the hazard quotient (HQ) of pesticide residue were calculated by the following the equations: EDI = Σ((Fi × STMR)/(mean body weight)) and HQ = (EDI/ADI) × 100%; Fi is the average food consumption from the 2002 CNNHS, STMR is the median residue level from animal feeding trials, and the mean body weight was obtained from the 2002 CNNHS. For the calculation of acute intake assessment, estimations of short-term intake (ESTI) and acute hazard index (aHI) were calculated by the following equations: ESTI = Σ((F × HR)/(mean body weight)) and aHI = (ESTI/ARfD) × 100%; F is a single-day high-consumption data (at the 97.5th percentile level) from the 2002 CNNHS, and HR was the highest residue obtained from duck commodities. The mean body weight was obtained from the 2002 CNNHS.

Statistical Analysis. Unless otherwise indicated, all tests were performed in three replicates, and of the values are presented as means ± standard deviation (SD). Data were statistically evaluated by one-way ANOVA analysis with SPSS base 11.0 software. Once a significant difference was observed, the least significant difference (LSD) test was applied to validate the differences among means.

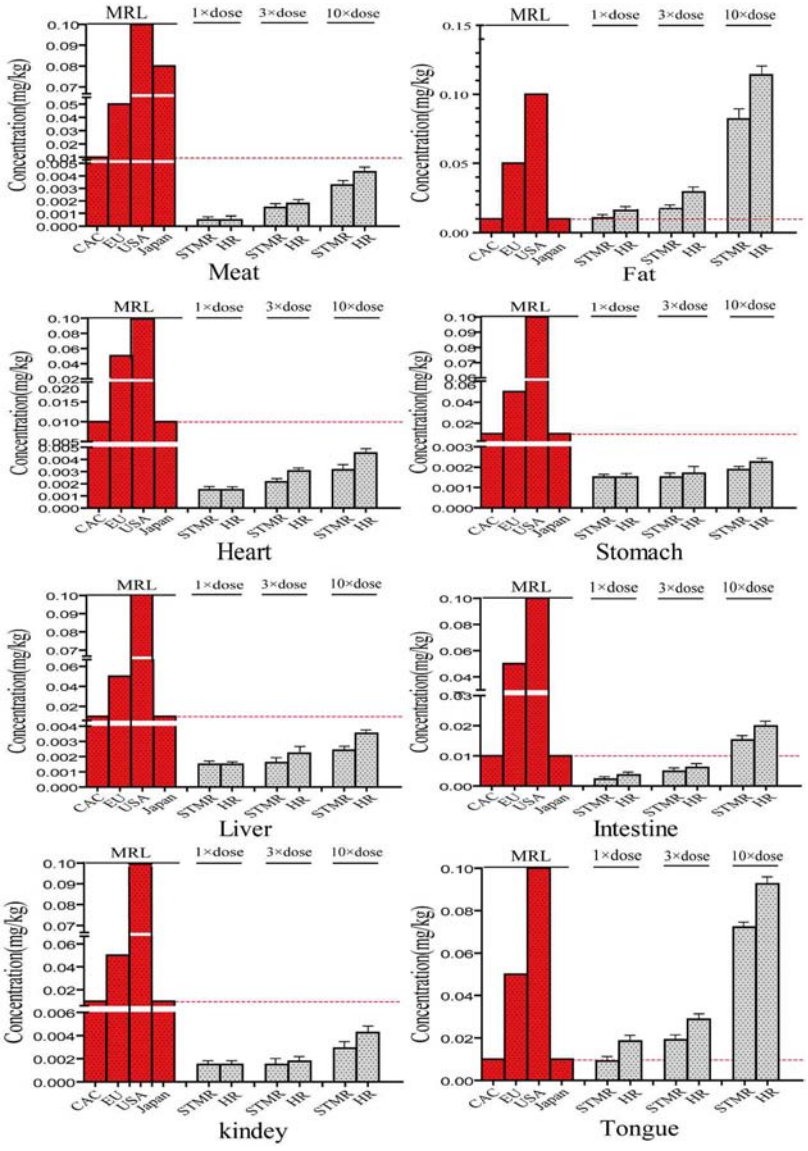

Figure 1. Chlorpyrifos median residue level (STMR) and highest residue level (HR) in meat and edible tissues of Pekin duck at the 1×, 3×, and 10× dose levels in the feed for 42 days.

RESULTS AND DISCUSSION

Analytical Method Validation. The GC-MS analytical results of chlorpyrifos extracted from four fortified concentrations showed that chlorpyrifos recoveries ranged from 72.1 to 106.8% in different matrices (Table 2). All of the relative standard deviations (RSDs) (from 3.0 to 13.6%) were <15%, which indicated good precision and specificity. The LOD (3 × signal-to-noise ratios) and LOQ (10 × signal-to-noise ratios) were 0.0003 and 0.001 mg/kg, respectively, for the duck meat, which were estimated on the basis of signal-to-noise ratio (S/N) of 3 (3:1) and 10 times (10:1) the background chromatographic noise in the present study. As for the substrates of eggs, the LOD and LOQ were 0.0006 and 0.002 mg/kg, respectively. As for the substrates of duck fat and other edible tissues (heart, stomach, liver, intestine, and tongue), the LOD and LOQ were 0.0009 and 0.003 mg/kg, respectively. Matrix effects of chlorpyrifos ranged from 92.4 to 117%, which indicated that the matrix effect was acceptable for quantitative analysis. The validation results based on GC-MS/MS indicated that the analytical method was reliable and efficient for chlorpyrifos determination in different substrates of duck in this study.

Levels and Distribution of Chlorpyrifos Residues in Different Edible Duck Tissues. Animal feeding studies are usually applied by regulators to set MRLs for animal commodities and to assess the dietary risk to consumers.[4] According to the Joint Meeting on Pesticide Residues (JMPR), livestock are typically fed at 1×, 3× (or 5×), and 10× dose level, where 1× is a level based on the maximum estimated dose (highest residue in processed pellet feed) from an earlier study in our laboratory.[17,24] The 10× dose will allow an estimate of what will happen if the normal level is exceeded, which indicates whether residues are proportionate to the intake, and provide additional data when new ways to use the product are introduced.

For the residue values of duck commodities below the LOQs of the analytical method, data were treated with LOQ/2.[25] In the present study, a decrease in body weight was observed in a dose-dependent manner. As compared to the control, the two higher groups of ducks (3× and 10× doses) showed a

DOI: 10.1021/acs.jafc.5b01839
J. Agric. Food Chem. 2015, 63, 5296−5304

significantly decreased body weight at the end of the experiment ($P < 0.05$) and the 1× dose group ducks showed a slightly decreased body weight (data not shown). The loss of body weight could be attributed to oxidative stress induced by chlorpyrifos and the interaction of chlorpyrifos with the enzymes and hormones that are essential for normal metabolic processes.[26]

The market age for meat production ducks is usually 6−8 weeks. Chlorpyrifos residues in various broiler duck tissues are presented in Figure 1. On the basis of this study, China's duck commodities appeared to meet international market standards in good agricultural practice (GAP) conditions. The results showed that chlorpyrifos levels in duck commodities increased with the pesticide levels of daily intake feed, and the chlorpyrifos residues were highest in the 10× dose group.

However, no obvious linear dose−response was observed between chlorpyrifos residues in duck commodities and the dose levels spiked in feed. The above findings could be due to the saturation between absorption and metabolism pathways with increasing dose levels added in the feed. Chlorpyrifos residues (0.0005−0.0045 mg/kg) found in all duck meat, heart, stomach, liver, and kidney samples were below the MRL (0.01 mg/kg) set by the Codex Alimentarius Commission (CAC). These results indicated that chlorpyrifos had a low persistency in the livestock meat and the metabolism organs and that depletion of parent compound residues from the body occurred rapidly, which was different from bioaccumulation of persistent pollutant (e.g., polybrominated diphenyl ether) in ducks.[27] The HR (0.016 mg/kg) in fat of the 1× dose group was slightly higher than the MRL (0.01 mg/kg) set by CAC and Japan and lower than the MRL (0.05 and 0.1 mg/kg) set by the European Union (EU) and the United States, respectively. The HR (0.11 mg/kg) in fat of the 10× dose group was higher than the MRL (0.1 mg/kg) set by the United States. The residues of samples containing fat from all dose groups were obviously higher than those of meat and other edible tissues. This might be attributed to the high fat-soluble characteristic of chlorpyrifos (logarithm of partition coefficient P is 5.1).[28] Chlorpyrifos residues in tongue of each dose group were higher than the MRL (0.01 mg/kg) set by the CAC and Japan. The HRs in tongue in each group were 0.019, 0.029, and 0.093 mg/kg, respectively, which were obviously higher than that of the meat, liver, and stomach. The above findings were probably due to the high level of chlorpyrifos in feed debris and the adhesion property of the tongue structure. The STMR (0.015 mg/kg) and HR (0.020 mg/kg) in the intestine of the 10× dose group were higher than the MRL (0.01 mg/kg) set by the CAC and Japan. Our results showed nondetectable levels or levels close to the quantification limits were observed in the majority of animal foods (e.g., meat and offal) under GAP production conditions. In addition, the findings in our present study were consistent with the results obtained in a market-basket survey of determining residues of organophosphorus pesticides in animal foods in China.[29]

The initial residues in eggs of Shaoxing brown ducks fed diets containing different chlorpyrifos concentrations on day 1 were not detected (Figure 2). However, the chlorpyrifos residues determined in eggs of all treatment groups increased slowly as the feeding time lasted to day 28, which indicated that chlorpyrifos was passed from the feed to the eggs. The STMR (0.012 mg/kg) and HR (0.016 mg/kg) in samples collected at days 28 for the 10× dose group treatment exceeded the MRL (0.01 mg/kg) set by the CAC, EU, United States, and Japan.

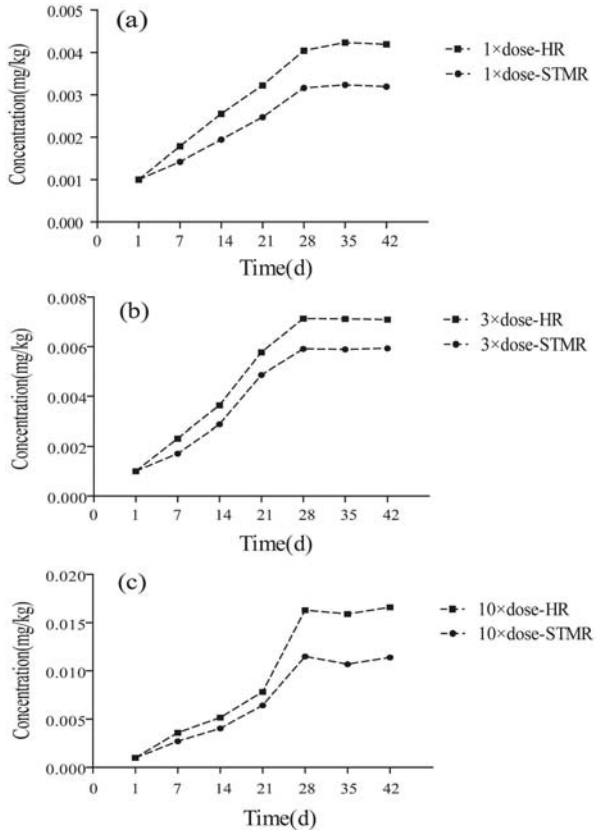

Figure 2. Chlorpyrifos median concentrations (STMR) and highest concentrations (HR) in eggs of Shaoxing brown duck at the 1× dose (a), 3× dose (b), and 10× dose (c) levels in the feed for 42 days.

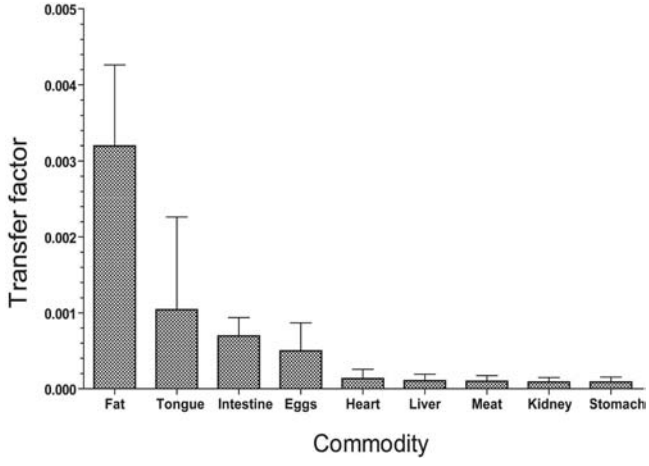

Figure 3. Transfer factors (TFs) of chlorpyrifos feeding trials for ducks.

The chlorpyrifos residues in all samples collected from the 1× and 3× dose groups during 42 days of treatment were not higher than the MRL (0.01 mg/kg), which was similar to the results of eggs from laying hens fed diets containing chlorpyrifos (10 mg/kg in feed) over 28 days.[30] The STMR and HR in all samples collected at days 35 and 42 of treatments were close to the value of day 28, which indicated a 28 day feeding trial was long enough for pesticide residues to reach plateau levels in duck eggs.

Several similar metabolism studies were available for chlorpyrifos in livestock. McKellar et al. fed cattle dairy feed

containing chlorpyrifos (0.3−30 mg/kg) for 2 weeks, and low levels (<0.01 mg/kg) of chlorpyrifos were found in milk and cream.[31] Dishburger et al. reported that the average 0.02 mg/kg residue was found predominately in fat tissue of cattle fed 3.0 mg/kg chlorpyrifos in the diet.[32] The above metabolism studies were conducted at experimental dosing levels instead of the realistic dietary burden of livestock. Another limitation was that these livestock feeding studies used Western representative livestock species such as lactating cows and chicken, not traditional Chinese domestic animals. Therefore, it was difficult to obtain correct information about chlorpyrifos residues for a general situation, especially considering possible differences in metabolism, feed concentrations, and exposure periods for each livestock animal by extrapolation. In this study, pesticide residues in livestock commodities were appropriately estimated under simulated duck production in real life.

Chlorpyrifos Transfers from Feed to Commodities. In the present study, the results showed that the differentiation of TFs depended on the potential accumulation of chlorpyrifos in different matrices of duck, feeding levels, and feeding periods (Figure 3). All duck commodity TFs in each group were generally <0.005, and these results were consistent with previous metabolism studies.[4,33] TFs (<0.0001−0.0003) for the meat, heart, stomach, liver, and kidney were generally lower compared with those of fat, tongue, intestine, and eggs (<0.0001−0.0049) among the different feeding levels ranging from 3.20 to 32.0 mg/kg. This result was consistent with chlorpyrifos being rapidly metabolized and excreted through metabolic organs.[33] TFs determined in the duck commodities were in the following order: fat > tongue > intestine > eggs > heart > liver > meat > kidney > stomach. The highest TF found in duck fat was 0.0049, which was similar to the TF (0.005) in chicken fat at a feeding level of 10 mg/kg for 30 days.[30] TFs in animal fat were indeed found to be related to lipophilic compounds, which tended to accumulate in the body fat. It was noted that the fatty tissues (intestine and eggs) had a higher potential accumulation for pesticides when compared to meat and other tissues. This finding was similar to the study of MacLachlan in which the lipophilic pesticides accumulated early in the fat tissue.[34] However, the high TF (0.0028) found in tongue may be attributed to the special structure of duck tongue with numerous lateral brush-like horny lingual papillae. Our results showed that the transfer of chlorpyrifos from the animal feed to the tissues was fairly lower when compared to that of other pesticides (e.g., abamection, emamection, edosulfan, and fipronil).[35−38]

Exposure Assessment and Risk Characterization. Chronic intake assessment revealed that only 0.034−0.150% ADI (HQ) of chlorpyrifos was consumed via the meat, fat, edible tissues, and eggs for different age and gender groups in China (Table 3). Generally, children from 2 to 6 years of age are considered as the most vulnerable group because they tend to eat greater quantities of food commodities on a body weight basis. Our results indicated that the exposure of youths (2−17 years old), especially children, was higher than that of adults (18−59 years old) and seniors (>60 years old). No significant differences were observed in the long-term exposure of gender groups (male and female).The highest EDI (8.2×10^{-6} mg/kg/bw/day) for duck fat tissue was <100 times of ADI, indicating that the dietary risk of chlorpyrifos from duck commodities was fairly low for Chinese consumers. A similar result was obtained from Sun et al., who concluded that only a negligible risk (0.4% of ADI) was observed for chlorpyrifos exposure through consumption of fishery products from Taiwan.[39] Another similar survey from cumulative exposure amount of organophosphorus pesticides to Chinese population accounted for 7.3% of the ADI.[23] The dietary exposure risk of chlorpyrifos raised by the intake of animal foods showed that the products of animal origin contaminated by chlorpyrifos appeared to be safer than products of plant origin in China.[25,40]

The aHIs (0.019−0.082%) for different age and gender groups were far lower than 100% through duck commodity consumption (Table 4). The aHIs of youths (2−17 years old) were significantly higher than those of adults (18−59 years old) and seniors (>60 years old). No significant difference was observed in the short-term exposure of gender groups (male and female). In general, acute dietary risks from the highest residue levels of these duck commodities were still within the safe level in China. Furthermore, the critical intake events identified in the acute risk assessment calculations were considered very unlikely to occur, taking into account the frequency of critical residues and the frequency of extreme consumption events.

It is noteworthy that the intake calculations were conservative because processing factors were not considered here. When processing factors (e.g., boiling and frying) are included, the estimated exposure would be even lower. On the other hand, residual data for dietary risk assessment should be obtained not only from the animal feeding trials but also from other different sources (e.g., market surveys, farms). Furthermore, consumers are usually exposed to various pesticides or toxic chemicals with multiple exposure pathways. Different pesticides or chemicals sometime pose synergized toxicity to organisms; thus, it should be also stated that our results here did not evaluate the total diet exposure but only determined the intake of chlorpyrifos from duck commodities. To the best of our knowledge, this is the first study to evaluate the transfer of chlorpyrifos from contaminated feed to duck commodities and the dietary risk for Chinese consumers through consumption. Results of the study could be considered as a useful reference for the establishment of pesticide MRLs for livestock in China.

Comment on Authenticity and Traceability of *Vanilla* Flavors by Analysis of Stable Isotopes of Carbon and Hydrogen

Vanilla species are a source of one of the most popular flavors in the world with *Vanilla planifolia* of exceptional importance to the flavor and food industry. In Europe, extract from *Vanilla tahitensis* is much valued in the production of ice cream. Due to an ever-increasing demand and limited sources, the price of *vanilla* has greatly increased over the years, and this has led to adulteration of genuine *vanilla*, in particular by the fraudulent addition of non-natural vanillin to *Vanilla* extracts.

In a recent paper published in this *Journal*, Hansen et al.[1] reported their findings on the assessment of authenticity and traceability of *vanilla* flavor using compound-specific isotope ratio mass spectrometry measuring the carbon and hydrogen stable isotope signatures of vanillin. The analytical procedures employed in the study appear sound, and extracts from 79 natural *vanilla* pods from 12 different regions throughout the world were analyzed. However, the authors have greatly over interpreted their data set and thus the subsequent conclusions drawn now require critical comment and discussion.

Characteristic differences in the $\delta^{13}C$ values of vanillin in extracts from *V. planifolia* ($n = 54$) and *V. tahitensis* ($n = 15$) are reported for samples collected from several regions throughout the world. This finding is in accordance with the literature.[2] *Vanilla* species differentiation is important not only for the quality assessment of the *vanilla* flavor but also for consumer confidence and protection. Hansen et al. attempted to use both the $\delta^{13}C$ and $\delta^{2}H$ values of the vanillin from the *vanilla* extracts not only for species verification but also to determine the geographical origin (traceability) of *vanilla* pods. However, despite what the authors claim, from Figure 4 it is clearly obvious that the values measured for *V. planifolia* from almost all geographical regions overlap one another and thus no inference about geographical origin can be drawn for this species. All that can be deduced from this data set is that it is possible to differentiate the two species investigated and to distinguish between the two geographical origins of *V. tahitensis*.

At this point it is worth emphasizing that from the viewpoint of European Union food law the authenticity of flavors is of considerably more importance than their traceability. Thus, authentic *vanilla* flavor solely comprises vanillin originating from pods of the tropical orchid *Vanilla* species. In terms of European Union food law definitions, natural flavoring substances are flavor active substances formed by biosynthesis.[3] It is irrelevant if these substances are produced in plant or animal tissues or by microorganisms supplemented with natural substrates, for instance, by microbial enzymatic oxidation of naturally occurring 4-hydroxy-3-methoxycinnamic acid (ferulic acid). Because ferulic acid is a natural readily accessible substance in rice bran, the cost of production of natural vanillin microbially from this source is considerably lower when compared with that extracted from *vanilla* pods. This microbially derived flavor compound may be obtained only by authorized preparation processes whereby the biogenic generated structure of the substance remains unaltered during the preparation process. European legislation (EC 178/2002, article 8)[4] requires that vanillin produced by such processes must not be labeled as the popular "Bourbon Vanilla" as this would be fraudulent and also mislead the consumer.

To ensure that the legislation is adhered to and properly policed, new methodologies have recently been developed. For vanillin this has led to position-specific isotope measurements employing site-specific natural isotope fractionation—nuclear magnetic resonance (SNIF-NMR) and gas chromatography isotope ratio mass spectrometry (GC-IRMS).[5−8] Our group developed a procedure for the selective analysis of $\delta^{13}C$ and $\delta^{2}H$ of plant methoxyl groups ($O-CH_3$).[9,10] The procedure is based on the "Zeisel method",[11] whereby methoxyl groups are transformed to methyl iodide using hydriodic acid and isotope measurements are made on the halomethane. In 2010 we adapted and applied the method for selective analysis of the 3-methoxyl group of vanillin.[5]

In the 2010 study we reported the $\delta^{13}C$ and $\delta^{2}H$ values of both vanillin bulk and vanillin methoxyl groups and demonstrated that correlations between these values can be used to fully differentiate between natural vanillin extracted from pods of the tropical orchid *vanilla* and biotechnological vanillin produced from, for example, ferulic acid (from rice bran) by microorganisms or synthetic vanillin of any kind of chemical synthesis.[5] Furthermore, the information gained from two-dimensional plots of the $\delta^{13}C$ and $\delta^{2}H$ values makes it virtually impossible for adulterated vanillin to remain undetected, even when sophisticated adulteration techniques are employed to change the isotopic content of the vanillin. Moreover, we would point out that because the two *vanilla* species, *V. planifolia* and *V. tahitensis*, used in our 2010 study showed much larger isotopic differences in the $\delta^{13}C$ and $\delta^{2}H$ values of their methoxyl values when compared to those observed for their bulk values, we consider the carbon and hydrogen signatures of methoxyl groups to be better suited for studying the geographical origin of *vanilla* species.

It is most unfortunate that even though in their paper Hansen et al. cited several studies, including ours, on vanillin authenticity (references 16−18), they did not use the information contained therein to fully discuss and evaluate their data set. Had they done so, we are certain that despite the evident interesting trends in the carbon and hydrogen δ values of vanillin, the authors would have realized that these values are not sufficient for verification of the authenticity of *vanilla* flavors.

In conclusion, we consider position-specific analysis of vanillin to be the best approach for the authenticity assessment of vanillin because it clearly distinguishes between vanillin from *vanilla*, from biotechnology or chemical synthesis. Moreover, we highly recommend that Hansen et al. consider analyzing the

relatively large number of *vanilla* pod samples from different geographical locations using position-specific analysis. From a scientific point of view, these additional data would add significantly to the current database of known stable isotope ratios of natural vanillin and thus be of immense benefit to future authenticity studies and may also assist with the determination of the geographical origin of *vanilla* pods.

Rebuttal to Comment on Authenticity and Traceability of Vanilla Flavors by Analysis of Stable Isotopes of Carbon and Hydrogen

In Hansen et al.[1], we have published data on $\delta^{13}C$ values and $\delta^{2}H$ values of vanillin extracted from 79 vanilla pods collected from many countries around the world and concluded that "The combined use of results of $\delta^{13}C$ and $\delta^{2}H$ analyses for vanillin, extracted from vanilla pods, shows a relatively close clustering pending upon species as well as geographical location of growth. Analysis of δ values of carbon and hydrogen by compound-specific IRMS is a useful tool in the verification of the authenticity and traceability of vanilla pods".

The goal of previous work by Greule et al.[2] was development of an analytical method to identify vanilla extracted from pods versus vanilla produced synthetically or from a biotechnological process and reported the $\delta^{13}C$ and $\delta^{2}H$ values of both bulk and methoxyl group of vanillin extracted from five vanilla pods. Their $\delta^{13}C$ values for bulk vanillin are very similar to our values for the two different species. The reported values for $\delta^{2}H$ in bulk vanillin show very little variation and are in the range from −47 to −58‰, indicating close geographical origin. We acknowledge that analysis of $\delta^{13}C$ and $\delta^{2}H$ values of both bulk and methoxyl group of vanillin may provide additional information useful in authenticity and traceability studies.

We were interested in the use of δ values of carbon and hydrogen measured on bulk vanilla for authenticity and traceability studies.

The δ values for hydrogen differ around the world primarily as a result of logitudinal and continental effects, and the δ values for hydrogen can therefore differ between countries and even within a single country. Plants take up water from the surroundings, and the ratio of stable hydrogen isotopes in the plant constituents will resemble the ratio of their specific geographical location. Having only information regarding from which country a plant constituent originates, the δ values for hydrogen are expected to show some variation, and also overlap between countries can be expected. We have reported δ values for hydrogen in vanillin together with information on from which country the vanilla pods originate. Information on the specific origin of the vanilla pods was not available. However, information on the δ values for hydrogen is useful in traceability studies as, for example, vanillin with δ values outside the range of −68 to −60‰ is unlikely to originate from Indonesia. Screening of samples against reference datasest enables the possibility to exclude origin possibilities in the verification of label claims. Therefore, we are convinced that our data and results support our discussion and conclusions.

Ethanol in Olive Fruit. Changes during Ripening

ABSTRACT: Ethanol is one of the precursors of ethyl esters, the virgin olive oil quality parameter for the "extra" category recently adopted by the European Union and International Olive Oil Council. Although ethyl ester content has great importance for virgin olive oil classification, the origin of ethanol is not clear. A possible source of ethanol may be the olive fruit itself while it remains on the tree. Variation of fruit ethanol content during ripening was studied for three different olive cultivars: 'Picual', 'Hojiblanca', and 'Arbequina'. Ethanol was measured in fruit homogenates by HS-SPME-GC-FID. The ethanol content varied between 0.56 and 58 mg/kg. 'Hojiblanca' fruits showed the highest ethanol concentration. For all of the cultivars, ethanol content of fruit increased during the ripening process, although a clear cultivar-dependent effect was observed because 'Hojiblanca' fruits showed the most significant raise. Therefore, results indicated that ethanol can be accumulated during fruit maturation on the olive tree.

KEYWORDS: *Olea europaea L., olive fruit, ethanol, ripening, cultivar*

INTRODUCTION

Olive (*Olea europaea* L.) growing has great importance in the Mediterranean basin because is the base of two important food industries, table olives and virgin olive oil production. Although it has great importance, information about the raw material characteristics is scarce, mainly in olives for oil mill use.

In this way, ethanol in olive fruit is a metabolite that has achieved great importance for the past two years because it is one of the precursors of ethyl esters. The level of ethyl esters is a virgin olive oil quality parameter adopted recently by both the European Commission and the International Olive Oil Council[1,2] to discriminate "extra virgin olive oil" produced from healthy and high-quality olive fruits. In fact, for oil classification into "extra virgin" category ethyl ester content must be <40 mg/kg. This limit will be reduced in sequence for the next crop years: 35 mg/kg in 2014/2015 and, finally, 30 mg/kg for the crop year 2015/2016.

Although a close relationship between virgin olive oil quality and ethyl esters was described,[3−5] their biosynthesis and the source of ethanol as ethyl ester precursor are not clear and have to be analyzed.

Conte et al.[6] proposed that ethanol can be solely produced by fermentation during virgin olive oil extraction and storage process. However, a possible source of ethanol may be the synthesis in the olive fruit itself. The production of ethanol in olives may originat on the tree, during fruit collection or transport, and/or in the postharvest treatments until processing. However, to our best of knowledge there are no data for ethanol content in olive fruit and its possible biosynthesis from the olive tree to the oil mill.

Ethanol in fruits is formed by the enzyme alcohol dehydrogenase (ADH; EC 1.1.1.1); it has been described for oranges and pears to increase during maturation.[7,8] Fruits have been described as the source of ethanol, as during ripening on the tree it activates reactions to produce aroma and other components requiring the synthesis of anaerobic metabolites, among them ethanol.[9]

Furthermore, ethanol is accumulated in different fruits that remain for long periods on the tree such as oranges and grapefruits. In these cases the concentration of ethanol showed a fast increase while the fruits were on the tree.[10] Litchi fruits increased ethanol production during maturation on tree.[11] Peaches and nectarines showed increases in aroma volatiles and ethanol during maturation.[12]

Ethanol can be accumulated in over-ripe and senescent fruits than remain on the tree for a long period. In apple cultivars, although a small amount of ethanol can be detected, it can be synthesized at higher concentrations in over-ripe and senescent fruits.[13]

Olive is a nonclimateric fruit that usually remains for long periods on the tree until harvest. This period can oscillate between 5 and 9 months, depending of olive cultivar, including fruit development, ripening, and overmaturation. The mean ripening period described for World Olive Germplasm Bank cultivars varied between 53 and 69 days for the earliest and latest olive cultivars, respectively.[14] However, a considerable part of the olive production can remain on the tree until overmaturation (2−3 months) because of adverse climatic conditions during the harvesting period or high crop yields. Thus, it is of great importance to determine how ethanol content varies in fruit during the ripening process in order to evaluate if ethanol is synthesized on the tree; if so, harvest date may have effect the levels in fruit, olive paste, and finally virgin olive oil of ethanol and ethyl esters.

The objective of this work was to study the ethanol content in olive fruit and its variation during ripeness. To achieve this aim three olive cultivars were selected according to their importance in world olive oil production: 'Picual', 'Hojiblanca', and 'Arbequina'. Acetaldehyde content, as ethanol precursor, was analyzed, too.

MATERIALS AND METHODS

Plant Material. The study was carried out for the crop year 2012/2013. Olive trees of three olive cultivars, 'Picual', 'Hojiblanca', and 'Arbequina', were selected by their crop load homogeneity (3−4). Two trees were selected for each cultivar. The 25-year-old trees were grown in the Wold Olive Germplasm Collection of IFAPA Center Venta del Llano in Mengibar, Jaen, Spain. The trees were spaced 7 × 7 m and grown under irrigation and traditional techniques.

'Arbequina'	0	0.3	1.0	2.0	2.4

[a]WAF, weeks after flowering. [b]Harvest dates common for the three olive cultivars.

Olive Samples. Two kilograms of olives was collected from each tree and cultivar at three harvest dates for 'Picual', 'Hojiblanca', and 'Arbequina'. In addition, for 'Arbequina' more harvest dates were included because of the stepped maturation of its fruits. Fruit ripening index was measured according to the method proposed by the Estacion de Olivicultura y Elaiotecnia.[15] The fruit sampling dates and ripening index are shown in Table 1. After harvesting, the fruits were washed using Milli-Q water, dried with filter paper, and processed immediately (15 min) to avoid any alteration.

Fruit Homogenates. To measure the ethanol content, a fruit homogenate approach was followed.[16] For this purpose, 4 g of olive fruit mesocarp, from at least 20 olive fruits, was homogenized with 8 mL of distilled water by means of a homogenizer Ultra-Turrax T-25 at the highest speed (24000 rpm) for 2 min. After an equilibrium period of 5 min at 25 °C, homogenate aliquots of 2 mL were taken into 10 mL vials containing 2 mL of a saturated $CaCl_2$ solution to deactivate the enzyme systems, which were sealed and stored at −18 °C until analysis. Two homogenates were prepared in duplicate for each olive sample.

Analysis of Ethanol and Acetaldehyde. Solid-phase microextraction (SPME) followed by GC-FID was used to analyze the ethanol and acetaldehyde in the samples studied according to the method described by Sanchez-Ortiz et al.[16] Briefly, homogenate samples were conditioned to room temperature and then placed in a 10 mL vial fitted with a silicone septum heater at 40 °C. After 10 min of equilibrium time, ethanol from headspace was adsorbed by exposing the SPME fiber DVB/Carboxen/PDMS 50/30 μm 1 cm (Supelco Co., Bellefonte, PA, USA) for 50 min at 40 °C in the headspace of the sample and then retracting it into the needle, followed by immediate transfer and desorption for 5 min into the injection port of a gas chromatograph equipped with an FID.

Ethanol and acetaldehyde were analyzed using a Varian CP 3800 GC equipped with a Supelcowax 10 capillary column (30 m × 0.25 mm, 0,25 μm, Sigma-Aldrich Co. LLC). Operating conditions were as follows: He was the carrier gas; injector and detector at 250 °C; and column held for 5 min at 40 °C and then programmed at 4 °C min^{-1} to 200 °C. Compound identification was carried out on an ISQ single-quadrupole MS (Thermo Fisher Scientific, Austin, TX, USA) operating in EI mode (70 eV) under identical conditions for GC-FID, matching against the Wiley/NBS Library, and by GC retention time against standard. Quantification was performed using individual calibration curves in the matrix (olive mesocarp homogenate). Results were expressed as milligrams per kilogram of fruit.

Data Analysis. Data for harvest dates are shown as mean value and standard deviation, whereas for cultivar content as mean value and standard error. ANOVA was performed to establish the effect of cultivar and ripening stage considering the three common harvest dates for the three olive cultivars. Tukey's test was applied to establish differences between means, $p = 0.05$. Statistical analyses were performed with Statistix 8.0 software.

RESULTS AND DISCUSSION

ADH activity catalyzes the reversible reduction of aldehydes to alcohols using reduced pyridine nucleotides as cofactors. In previous works ADH activity was measured only in crude extracts prepared from acetone powders of olive mesocarp and seed tissues,[17] whereas it was not detected in crude extracts from fresh tissues.[16] To determine the effect of homogenization process in ethanol synthesis, a previous experiment was carried out. Fruit frozen tissue was ground in a cold blender containing $CaCl_2$ at 0.33 g g^{-1} tissue to inhibit enzyme activities during homogenization compared with the method used in this work. Both methods showed similar contents of ethanol (data not shown).

Ethanol content in fruit varied depending on olive cultivar. For 'Hojiblanca' fruits ethanol concentration varied between 6 and 58 mg/kg, whereas 'Picual' cultivar oscillated from 0.56 to 2.90 mg/kg. 'Arbequina' olives showed an ethanol content that ranged between 1.5 and 11.5 mg/kg.

When ANOVA was performed, the olive cultivar was observed to be mainly responsible for the variability of ethanol concentration, although the harvest date showed similar values (Table 2). Among the olive cultivars analyzed, 'Hojiblanca' showed the highest ethanol content in fruit and 'Picual' achieved the lowest concentration (Table 3). Significant differences between olive cultivars were obtained ($p = 0.05$). These differences in ethanol content between cultivars were described for apples and nectarines previously.[16] There are no previous works describing differences in olive ethanol content between cultivars. The differences observed in this work may be explained by the ADH content/activity in different olive cultivars as described for 'Coratina' and 'Carolea' olive cultivars for C6 volatile alcohols.[18] In our case, the levels of ethanol in fruits of different cultivars corresponded to similar differences for its precursor, acetaldehyde (data not shown).

Harvest date showed a highly significant effect on ethanol content in olive fruits (Table 2). During olive fruit ripening,

ethanol concentration increased slightly at the beginning of maturation, and then a fast increase was detected (Figure 1).

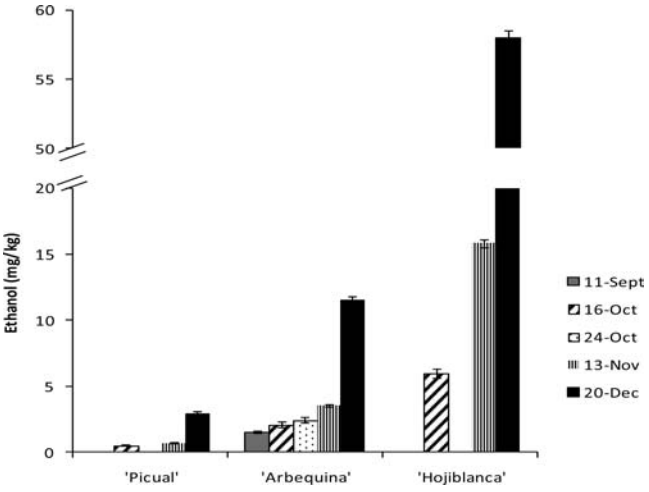

Figure 1. Changes during the ripening process in ethanol concentration of fruits from the olive cultivars 'Picual', 'Hojiblanca', and 'Arbequina'.

Although 'Arbequina' has a fruit stepped maturation and was studied for more harvest dates, the behavior was similar to that of the other cultivars. In the first raise, ethanol showed an increase between 23% for 'Picual' cultivar and 62% for 'Hojiblanca'. For the last harvest date the fastest increases were detected; the increases obtained varied around 70% for the three olive cultivars. Between the first sample collection and the final one, ethanol content rose around 80% for 'Picual' and 'Arbequina', whereas 'Hojiblanca' fruits achieved an increase of 89%. Therefore, 'Hojiblanca' fruits achieved the highest ethanol content during fruit maturation. These differences between cultivars in the biosynthesis of ethanol may be explained by the high significance obtained for the interaction between olive cultivar and harvest date in the ANOVA (Table 2). Ethanol is formed from acetaldehyde by the enzyme ADH. Salas et al.[17] described an increase of ADH activity from 13 weeks after flowering up to 25 weeks after flowering when fruits are still green. After this point ADH activity decreased during the ripening process. Therefore, the increase of fruit ethanol content observed for the three cultivars may not be explained by a higher ADH activity because the period analyzed corresponded to a reduction of ADH activity.

Both acetaldehyde and ethanol have been shown to accumulate in various fruit (both climacteric and non-climacteric) that remain on the tree for long periods.[9] The increase in anaerobic respiration in over-ripen fruit may be explained by a reduction of mithocondrial activity in its tissues. In our case both of them are accumulated in the fruit during maturation, although ethanol showed a faster increase, giving a reduction of the ratio acetaldehyde/ethanol (Figure 2). This ratio can be used as an indicator of fruit anaerobic respiration.

The increase of ethanol content observed for the three cultivars was similar to those described for both climacteric and nonclimateric fruits during the ripening and their residence on the tree for long periods,[10,19] although in our case over-ripening was not achieved.

The results confirm that ethanol is produced naturally in olive fruits while they remain on the tree because for this work their processing was immediate. Ethanol content in olives had a very important genetic component because significant differences were observed between cultivars. 'Hojiblanca' fruits showed the highest ethanol concentration. During fruit ripening ethanol concentration rose, showing a slight increase at the beginning and a fast rise for the last harvest date. Ethanol production during fruit ripening was affected by the cultivar, too. Therefore, ethanol was accumulated in the olive fruit during its residence on the tree as a result of anaerobic respiration. Further works should be focused on the formation of ethanol from olive tree to virgin olive oil and how ethyl esters are synthesized.

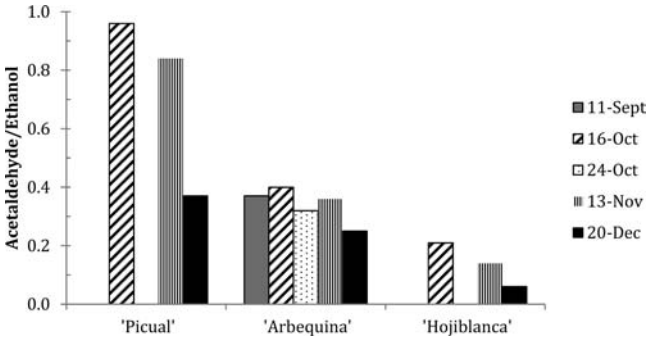

Figure 2. Changes during the ripening process in the ratio of acetaldehyde to ethanol of fruits from the olive cultivars 'Picual', 'Hojiblanca', and 'Arbequina'.

Postharvest Exogenous Application of Abscisic Acid Reduces Internal Browning in Pineapple

Qin Zhang,[†] Yulong Liu,[†] Congcong He, and Shijiang Zhu*

Guangdong Province Key Laboratory of Postharvest Physiology and Technology of Fruits and Vegetables, College of Horticulture, South China Agricultural University, Guangzhou, Guangdong 510642, China

ABSTRACT: Internal browning (IB) is a postharvest physiological disorder causing economic losses in pineapple, but there is no effective control measure. In this study, postharvest application of 380 μM abscisic acid (ABA) reduced IB incidence by 23.4−86.3% and maintained quality in pineapple fruit. ABA reduced phenolic contents and polyphenol oxidase and phenylalanine ammonia lyase activities; increased catalase and peroxidase activities; and decreased $O_2^{\cdot-}$, H_2O_2, and malondialdehyde levels. This suggests ABA could control IB through inhibiting phenolics biosynthesis and oxidation and enhancing antioxidant capability. Furthermore, the efficacy of IB control by ABA was not obviously affected by tungstate, ABA biosynthesis inhibitor, nor by diphenylene iodonium, NADPH oxidase inhibitor, nor by lanthanum chloride, calcium channel blocker, suggesting that ABA is sufficient for controlling IB. This process might not involve H_2O_2 generation, but could involve the Ca^{2+} channels activation. These results provide potential for developing effective measures for controlling IB in pineapple.

KEYWORDS: *abscisic acid, antioxidant systems, internal browning, pineapple, phenolic compounds, quality*

INTRODUCTION

Internal browning (IB), also referred to as blackheart, is a physiological disorder of pineapple (*Ananas comosus* L.) that often occurs during postharvest processes. The affected fruit develop browning spots or areas mainly in the flesh surrounding the core with no obvious external damage, hence the name. Most cultivars of pineapple are susceptible to internal browning;[1] therefore, the losses due to this disorder are often heavy in production countries.[2,3] For example, it brings about US$1.3 million in annual losses to the Australian pineapple industry,[4] and it could cause even heavier losses to the Chinese pineapple industry, as over 90% of total production in China is from the susceptible cultivar "Comte de Paris". Over the years, various methods have been tried to control IB, including preharvest application of potassium[5] or calcium[6] and postharvest use of calcium,[1,7] strontium chloride,[1] modified atmosphere,[7,8] 1-methylcyclopropene,[9] waxing,[2] and heat treatment.[7,10] However, to date, not a single effective way has been found to be commercially useful, mainly because of their relatively low efficacies. Take the most extensively studied calcium application, for example. Although some contributions reported that calcium was effective in reducing IB incidence, whether applied preharvest[6,11] or postharvst,[1,12] others did not show any effects[7,13] or could not confirm the effects.[14] This implies a complex nature of IB, as harvested pineapple could either develop IB symptoms under low temperature (LT; 10 °C or lower)[1,2,4−6,15] or at ambient temperature (AT; 20 °C or higher).[15,16] The LT-caused IB could be related to chilling injury,[4] while the IB occurred in AT could be the manifestation of senescence. However, the fact plant hormone gibberellins (GAs) are involved in this disorder could make things simpler because exogenous GAs treatment induced IB,[15,17] and this is true for pineapple stored either at LT or AT (20 °C −25 °C).[15] In addition, endogenous GAs levels were found to be positively correlated to IB incidence.[15] It is not known whether abscisic acid (ABA), the antagonist of GAs, can inhibit IB. It is likely that ABA could inhibit IB developed as a result of chilling under LT, as ABA has been widely confirmed to induce chilling tolerance in plants.[18,19] In addition, ABA applied in combination with calcium hydroxide and wax sprays significantly reduced pineapple IB severity under LT.[20] Because LT storage alone can effectively inhibit development of IB for sufficiently long,[16] from the industry point of view, it is not necessary to use ABA to control IB of pineapple stored in LT. On the other hand, pineapple is mostly transported and sold under AT in China and other developing countries that produce it; therefore, it is of great value to develop IB control measures for pineapple stored and shipped under AT. This study investigated effects of application of ABA on IB development in AT, aiming to develop an effective alternative to control IB. In addition, this research investigated the mechanism of ABA in controlling IB to help understand the role of exogenous ABA.

MATERIALS AND METHODS

Plant Materials and Treatment. Pineapple (*Ananas comosus* L. cv "Comte de Paris") fruit of "Queen" group at 70% maturity (commercial maturity in China, with fruit being green with a trace of yellow) were collected from a commercial plantation in Xuwen County, Guangdong Province and transported 300 km to Guangdong Province Key Laboratory of Postharvest Physiology and Technology of Fruits and Vegetables, College of Horticulture, South China Agricultural University, Guangzhou, Guangdong Province. Fruit uniform in size (average weight about 500 g) and free of physical injury or

disease symptoms were selected, with the crown being half-cut and sprayed with a fine mist of solution of diphenylene iodonium (DPI) (5 μM), ABA (95 or 380 μM), tungstate (TS) (50 μM), or lanthanum chloride ($LaCl_3$) (50 μM), each containing 0.01% Tween 80, until runoff and air-dried. For the combination of DPI with ABA, $LaCl_3$ with ABA, and TS with ABA, pineapples were permitted to dry at AT for 6 h before being treated further. The control fruit were sprayed in the same way with distilled water containing 0.01% Tween 80. Each treatment was applied to three replications, each containing 20 fruit. Following treatment, pineapples were wrapped with perforated polyethylene film and kept at 20 °C in the dark at 95% RH. Samples of pulp tissues were collected at 6 h, 12 h, 24 h, 3 days, 6 days, 9 days, and 12 days; frozen in liquid nitrogen; and stored at −80 °C.

Internal Browning Incidence Assessment. Three fruit from each treatment, one from each replicate, were cut every 3 days for monitoring the development of IB. Upon obvious onset of browning in flesh or core of pineapples from any treatment, all the other fruit, 45−60 fruit per treatment, were then cut for observation of IB. IB incidence was calculated as percentage of fruit with symptoms of IB, irrespective of the size of the browning on cut surface. The strict standard is used because fruit with slight or severe browning are all affected fruit in the eyes of consumers. Therefore, the commercial value is lost upon the appearance of the first trace of internal browning.

Determination of Soluble Solids, Titratable Acids, and Ascorbic Acid. Pineapple flesh (100 g) was cut into small pieces, homogenized, and filtered. The filtrate was used for measuring soluble solids concentrations (SSC), titratable acid (TA), and ascorbic acid (AsA) contents according to methods described by Lu et al.[21]

Assay of Enzyme Activity. Polyphenol oxidase (PPO), peroxidase (POD), and catalase (CAT) were extracted and activity was assayed according to the methods we described previously with modification.[22,23] Frozen pineapple flesh (1 g) were ground in liquid nitrogen to fine powder and then homogenized in 4 mL of precooled 0.05 mM potassium phosphate buffer, pH 7.8, containing 5% (w/v) polyvinylpyrrolidone. The homogenate was centrifuged at 15 000*g* for 20 min at 4 °C. The supernatant, referred to as the crude enzyme extract, was used to assay the activity of enzymes. For PPO assay, a 3 mL reaction mixture contained 2 mL of 50 mM phosphate buffer, pH 7.8, 0.9 mL of 10 mM pyrocatechol, and 0.1 mL of crude enzyme extract. PPO activity was expressed as units of grams per fresh weight (FW). One unit was defined as an increase in A_{398} of 0.01 min^{-1}. For POD assay, a 3 mL reaction solution consisted of 0.1 mL of 1% (v/v) guaiacol (1%), 0.1 mL of 0.46% H_2O_2, 2.7 mL of 0.1 M potassium phosphate buffer, pH 7.8, and 0.1 mL of enzyme extract. The enzyme activity was detected by following the change in optical density at 470 nm due to the oxidation of guaiacol. One unit of POD activity was defined as an increase in A_{470} of 0.01 min^{-1}. For CAT assay, a 3 mL reaction mixture contained 2.9 mL of 15 mM H_2O_2 in 0.05 M potassium phosphate buffer, pH 7.8, and 0.1 mL of enzyme extract. Catalase activity was expressed in units of grams per FW, where one unit of CAT activity was defined as causing an increase in A_{240} of 0.01 min^{-1}.

Phenylalanine ammonia lyase (PAL) was extracted and the activity determined according to the method described previously.[23] Frozen pineapple flesh (1 g) was homogenized in 4 mL of precooled 0.05 M sodium borate buffer, pH 7.0, in an ice−water bath. The homogenate was centrifuged at 15 000*g* for 15 min at 4 °C, and the supernatant (enzyme extract) was used for PAL assays. A 3 mL reaction mixture contained 0.4 mL of enzyme extract, 1.6 mL of 0.1 mM sodium borate, pH 8.8, supplemented with 5 mM dithiothreitol and 1 mL of 0.02 M L-phenylalanine as substrate. The mixture was incubated at 38 °C for 3 h. PAL activity was expressed as the difference in optical density at 290 nm before and after incubation. One unit was defined as an increase in A_{290} of 0.01 h^{-1}.

Assay of Total Phenolic Compounds (TPC). The contents of TPC were detected using Folin−Ciocalteu reagent according to the method described previously.[23] The absorbance at 765 nm was measured and used to calculate the phenolic contents using gallic acid (GA) as a standard. Results were calculated and expressed as milligrams of GA equivalent (GAE) per gram of fresh samples.

Determination of $O_2^{\cdot-}$, H_2O_2, and MDA. The contents of superoxide radicals ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), and MDA were determined according the method described by Li et al.[24] with modification. First, 0.5 mL of the same supernatant as for measuring PPO, POD, and CAT was reacted with 1 mL of hydroxylamine hydrochloride for 1h, then 1 mL of *p*-aminobenzenesulfonic acid and 1 mL of α-naphthylamine were added, and the solution was kept at 25 °C for 20 min. The absorbance at 530 nm was measured, and the result was expressed as nmol/min·gFW. The H_2O_2 content was determined as a H_2O_2−titanium complex resulting from the reaction of tissue−H_2O_2 with titanium tetrachloride. Absorbance values at 415 nm were calibrated to a standard curve generated using known concentrations of H_2O_2. The MDA content was determined following the method described by Li et al.[24]

Statistical Analyses. The experiments were repeated two or three times with similar results. There were three replications for analysis of each parameter. Data were analyzed by one-way analysis of variance (ANOVA). Mean separations were performed using the least significant difference method (LSD test). Statistically significant differences were assumed when their *P* values were $\leq$0.01.

RESULTS

Effect of ABA on Pineapple IB Incidence. The first experiment conducted in November 2012 showed that ABA at 95 and 380 μM reduced IB incidence by 2.8% and 25%, respectively, with 380 μM ABA treatment being statistically significantly different from the control ($P \leq 0.01$) (Figure 1). Therefore, 380 μM was used in a series of experiments that followed over a period of two years to check whether ABA works for fruit harvested from different seasons. As is shown in Figure 2, exogenous application of ABA at 380 μM obviously inhibited IB development for pineapple harvested in different seasons and different years, with the IB incidence being reduced by 70.83% for the trial in June 2013, 58.00% for September 2013, 23.40% for November 2013, 86.30% for June 2014, and 36.60% for September 2014 (Figure 2). Although there were big variances for fruit from different batches or seasons, the difference between the ABA-treated fruit and the water-treated control reached statistically significant levels for all batches ($P < 0.01$).

Effects of ABA on Quality of Pineapple. The time-course changes of the SSC, TA, and AsA were similar, with the values rising to a peak on day 3 and then declining during the remaining time (Figure 3A). Compared with the control, ABA-treated fruit were almost the same as the control in SSC

J. Agric. Food Chem. 2015, 63, 5313−5320

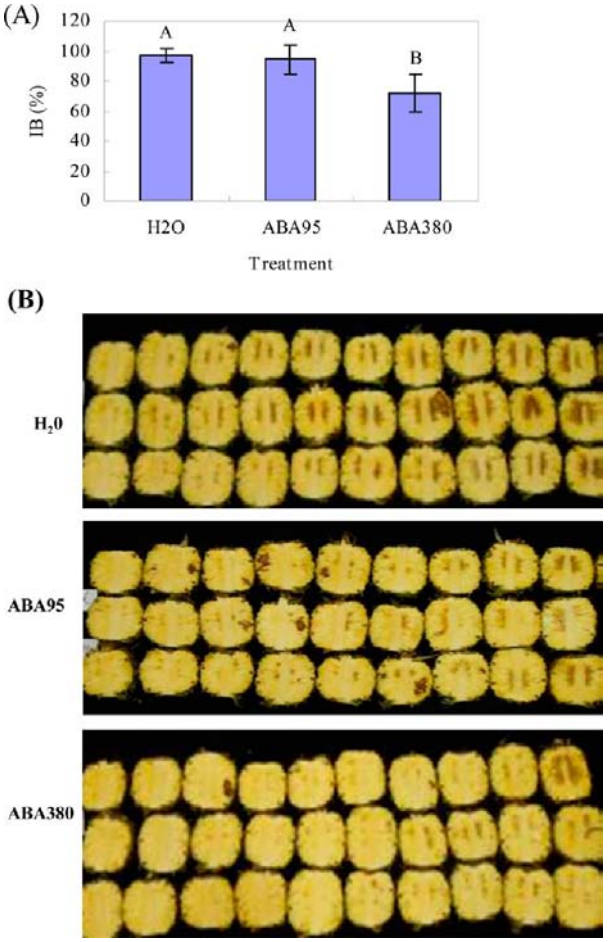

Figure 1. Effect of exogenous ABA at different concentrations on internal browning incidence of harvested pineapple fruit stored at ambient temperature (20 °C). Pineapples were harvested in November 2012 and sprayed with distilled water or ABA solution at 95 μM (ABA95) or 380 μM (ABA380). IB incidence (A) was evaluated and pictures (B) were taken 12 days after treatment. Significance of differences between the control and the treatment is indicated by letters above the bars ($P \leq 0.01$). Standard errors are shown.

contents, while they had 4.5% and 25.7% more contents of TA and AsA, respectively, than the control at the end of storage (Figure 3B,C).

Effect of ABA on TPC Contents and Related Enzymes Activities. The control increased dramatically in contents of TPC and activities of PAL and PPO during the first 9 days, whereas those of the ABA-treated fruit increased much less (Figure 4). As a result, the ABA-treated fruit had much lower TPC contents and enzyme activities during the last 6 days of storage, especially on day 9, when those with ABA treatment were 12.2%, 29.0%, and 32.6% lower than the control in TPC, PAL, and PPO, respectively.

Effects of ABA on Activities of CAT and POD and Levels of ROS and MDA. During storage, CAT activity in pineapple decreases with time, while POD activity first rose to a peak, and then decreased. ABA-treated fruit showed CAT and POD activities higher than that of the control, and they had lower levels of $O_2^{\cdot-}$, H_2O_2, and MDA during the whole storage period (Figure 5).

Role of ROS in ABA-Induced Resistance to IB. To investigate whether ROS plays a role in ABA-induced resistance to IB, DPI, an important ROS generation inhibitor, was applied to pineapple before treatment with ABA. The DPI plus ABA treatment increased IB incidence by only 3.3% compared with treatment with ABA alone, while it significant reduced IB occurrence, by 23.3%, compared with the control ($P \leq 0.01$) (Figure 6).

Effect of $LaCl_3$ on ABA-Induced Resistance to IB. To investigate the effect of blocking of the calcium channel, harvested pineapple fruit were treated with $LaCl_3$ alone or $LaCl_3$ plus ABA. Compared with the control, $LaCl_3$ treatment increased IB incidence by 13.4%, although the difference did not reach a statistically significant level ($P < 0.01$). The combination treatment significantly reduced IB incidence by 20% and 36.4%, compared with the control and $LaCl_3$ treatment, respectively ($P < 0.01$) (Figure 7).

Effects of TS on Efficacy of ABA. To show what role endogenous ABA plays, especially whether it adds to the effects of exogenous ABA, the TS, inhibitor of ABA biosynthesis, was applied before the pineapple was exposed to ABA. When pineapple was treated with TS alone, the IB incidence was only slightly higher than the control (Figure 8). However, the combination of TS and ABA treatment reduced IB incidence by 23% compared with the control ($P < 0.01$), suggesting that exogenous ABA can work alone in controlling IB.

DISCUSSION

Internal browning has been regarded as one of the major problems of the pineapple industry. Over the past 30 years, many researchers have been trying to develop techniques to control it, but they have not found a commercially effective measure. In this study, it was shown that exogenous ABA treatment is effective in inhibiting IB development for storage at 20 °C and that it works well for pineapple harvested in different seasons (Figures 1 and 2). This result is inspiring for two reasons. First, it allows the industry to extend this technique to packing houses because of the decreased ABA production cost as a result of improvement of ABA production methods.[25] Second, it provides a good perspective for studying and unraveling the nature of IB.

In this study, over a period of two years, experiments were conducted with "spring pineapple", pineapple harvested in period from March to June, and "autumn/winter pineapple", the fruit harvested in period from September to February. However, no experiment was conducted in the summer because farmers do not produce pineapple during that period because pineapple is not profitable in the presence of many other fancy fruits produced in the summer. The industry has long noticed that the spring pineapple is less susceptible to IB than autumn/winter pineapple. This study also showed that the efficacy of ABA in controlling IB is obviously higher for spring pineapple than for autumn/winter pineapple (Figure 2). The difference in IB incidence between spring and autumn/winter pineapples could be related to the weather, as the autumn/winter pineapple is exposed to the high temperature and rainfall during development in summer, while the spring pineapple develops in mild temperature and dry season in Xuwen County, Guangdong Province, the major pineapple production area in China. The fact that the fruit develops faster in summer and slower in winter might contribute to the different IB incidences. This could also account for the difference in effects of ABA. How temperature and rainfall during fruit development influence IB incidence and ABA effects remains to be elucidated.

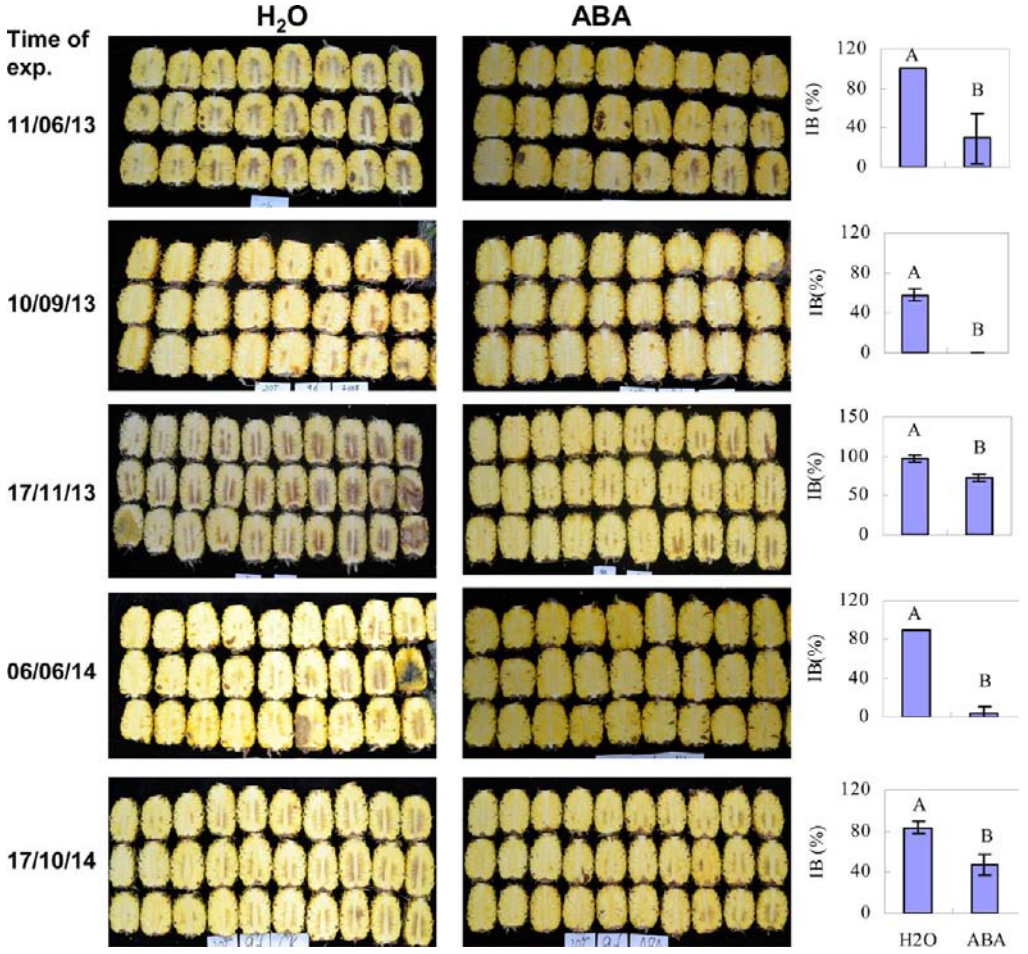

Figure 2. Effects of exogenous ABA treatment on IB incidence of pineapple fruit harvested in different seasons. Fruit were sprayed with distilled water or 380 μM ABA solution before storage at 20 °C. IB incidence was evaluated at 12, 9, 9, 12, and 9 days for trials conducted in June 2013, September 2013, November 2013, June 2014, and October 2014, respectively. Significance of differences between the control and the treatment is indicated by letters above the bars ($P \leq 0.01$). Standard errors are shown.

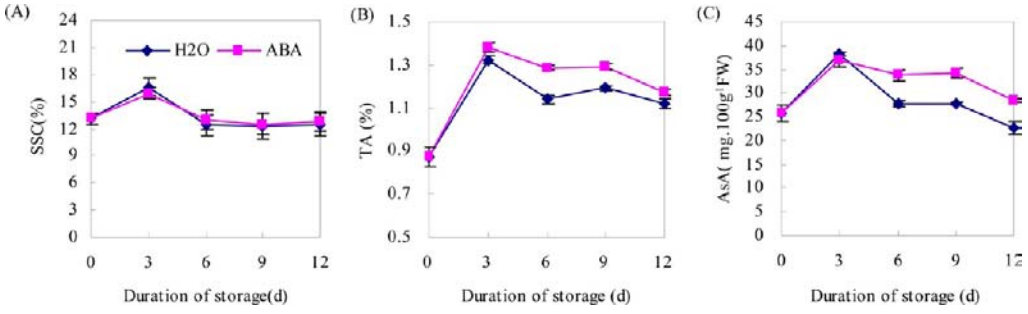

Figure 3. Effects of exogenous ABA treatment on soluble solid concentrations (SSC) (A), TA (B), and AsA (C) contents of harvested pineapple fruit. Fruit were sprayed with distilled water or 380 μM ABA solution before storage at 20 °C. The samples were from experiments conducted in June 2013.

Different studies varied or even conflicted regarding the effects of exogenous ABA on fruit quality such as SSC and TA. Preharvest application of ABA improved color of grapes and increased acidity but reduced SSC contents.[25] ABA application to plants increased tomato fruit soluble sugar, while decreasing organic acid concentrations.[26] ABA treatment at the color-break stage did not affect postharvest quality attributes such as soluble solids and acidity in litchi fruit.[27] In this study, postharvest ABA treatment slowed the decease of TA and AsA levels, while it did not affect SSC contents (Figure 3). These results indicate that ABA maintained the quality of harvested pineapple.

Development of internal browning involves oxidation of phenolic compounds by PPO.[28] In this study, ABA-treatment reduced PPO activity (Figure 4) and inhibited internal browning (Figures 1 and 2), consistent with previous studies that show activities of PPO were positively correlated with severity of IB in pineapple.[15,29] This result suggests that ABA could control IB by inhibiting enzymatic oxidation of phenolic compounds. How ABA inhibited PPO activities remains to be

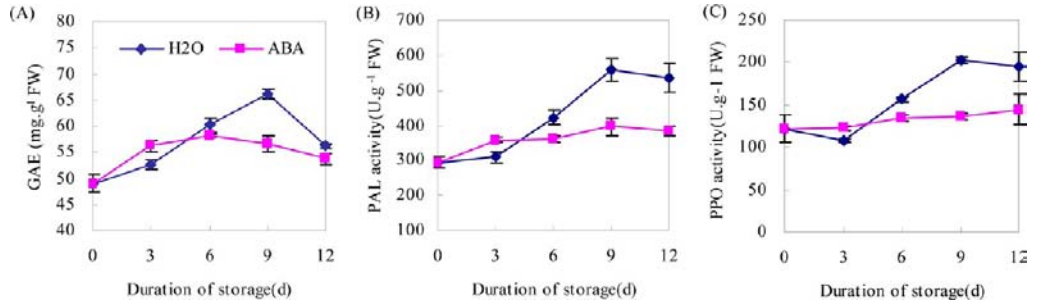

Figure 4. Effects of exogenous ABA treatment on contents of total phenolic compounds (A) and activities of PAL (B) and PPO (C) of harvested pineapple fruit. Fruit were sprayed with distilled water or 380 μM ABA solution before storage at 20 °C. The samples were from experiments conducted in June 2013.

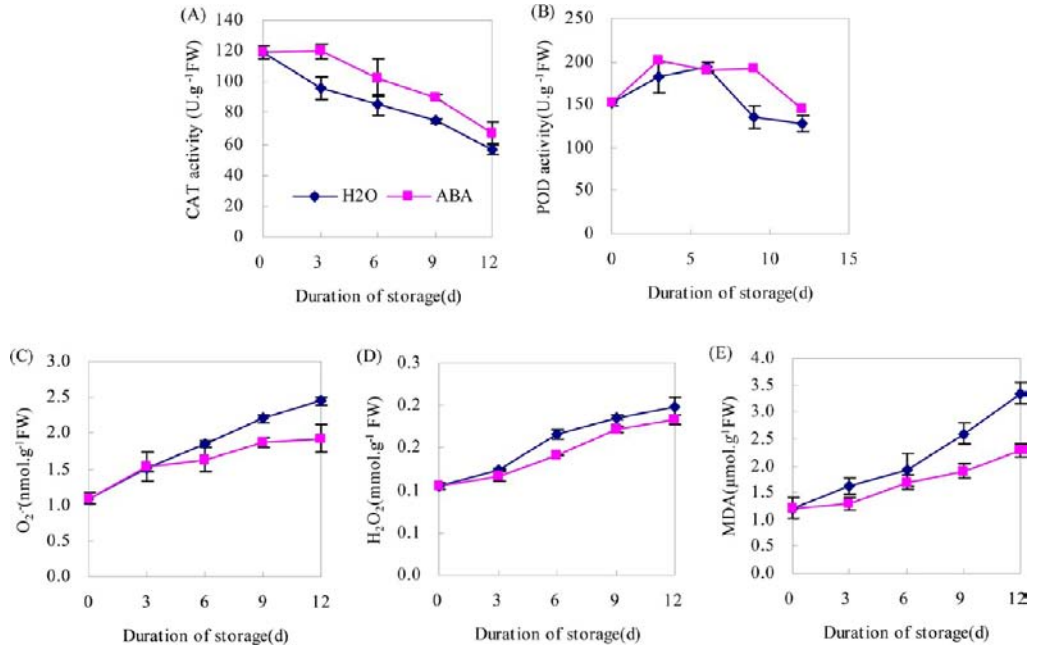

Figure 5. Effects of exogenous ABA treatment on activities of CAT (A) and POD (B) and contents of $O_2^{\cdot-}$ (C), H_2O_2 (D), and MDA (E) of harvested pineapple fruit. Fruit were sprayed with distilled water or 380 μM ABA solution before storage at 20 °C. The samples were from experiments conducted in June 2013.

elucidated. Phenolics are the prerequisite for the PPO enzymatic browning. In eggplant, although both the phenolic content and PPO activity play important roles in browning of stored fruit, the phenolic compounds play a major role, as the cultivar with higher TPC showed higher browning, although the PPO activity was lower.[30] In this study, ABA-treated pineapples had significantly lower TPC, which might be closely related to the lower IB in those fruits. PAL plays an important role in the browning process of fruits and vegetables,[31] as it plays a pivotal role in the biosynthesis of phenolics.[32] In pistachio (*Pistacia vera* L.), there was a high positive correlation between PAL activity and total phenolics contents.[33] In this study, ABA-treated pineapple showed obviously lower PAL activities (Figure 4), suggesting that ABA could reduce biosynthesis of TPC by decreasing PAL activity. How ABA reduces activities of PAL remains to be studied.

The ROS, which include superoxide radicals ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2$), and perhydroxy radical ($HO_2^{\cdot-}$), affect many cellular functions by damaging nucleic acids, oxidizing proteins, and causing lipid peroxidation.[34] A strong oxidative burst will cause cellular damage and death.[35] Under normal and healthy conditions, the ROS molecules are scavenged by various antioxidative defense mechanisms.[34] These include enzymatic antioxidant systems, such as SOD, POD, glutathionereductase (GR), and CAT, and nonenzymatic low molecular metabolites, such as AsA and reduced glutathione (GSH).[36] Studies with different plants showed ABA increased contents of AsA and activities of CAT and POD.[36,37] In this study, ABA elevated levels of AsA (Figure 3) and enhanced activities of CAT and POD (Figure 5A,B), suggesting that it enhanced antioxidant defense system of pineapples. That ABA-treated pineapple had levels of $O_2^{\cdot-}$ and H_2O_2 lower than those of the control (Figure 5C,D) implies the strengthened defense system efficiently scavenged ROS molecules and thus protected the integrity of cells. This is further confirmed by the reduced MDA contents in ABA-treated fruit (Figure 5E), as MDA is used as an indicator of the severity of cell membrane injury.[36] These results suggest that ABA protected cell membrane systems through activating the antioxidative defense system to reduce ROSs, which greatly contributed to reduced IB.

However, the role of H_2O_2 seems to be complicated. On the one hand, it acts as a cytotoxic molecule. On the other hand, it can function as a signaling molecule.[38] What actual role it plays

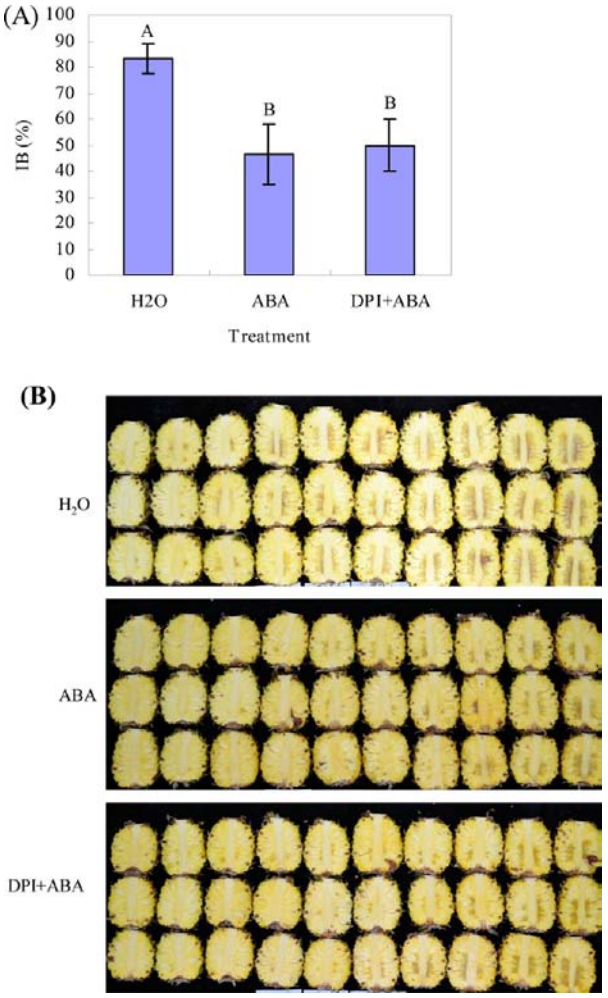

Figure 6. Effect of DPI on ABA induced resistance to internal browning in pineapple fruit stored at 20 °C. Fruit were sprayed with distilled water, 380 μM ABA, or 5 μM DPI before treatment with 380 μM ABA. Incidence (A) was evaluated and pictures (B) were taken 9 days after treatment. Significance of differences between the control and the treatment is indicated by letters above the bars ($P \leq 0.01$). Standard errors are shown. The experiment was conducted in October 2014.

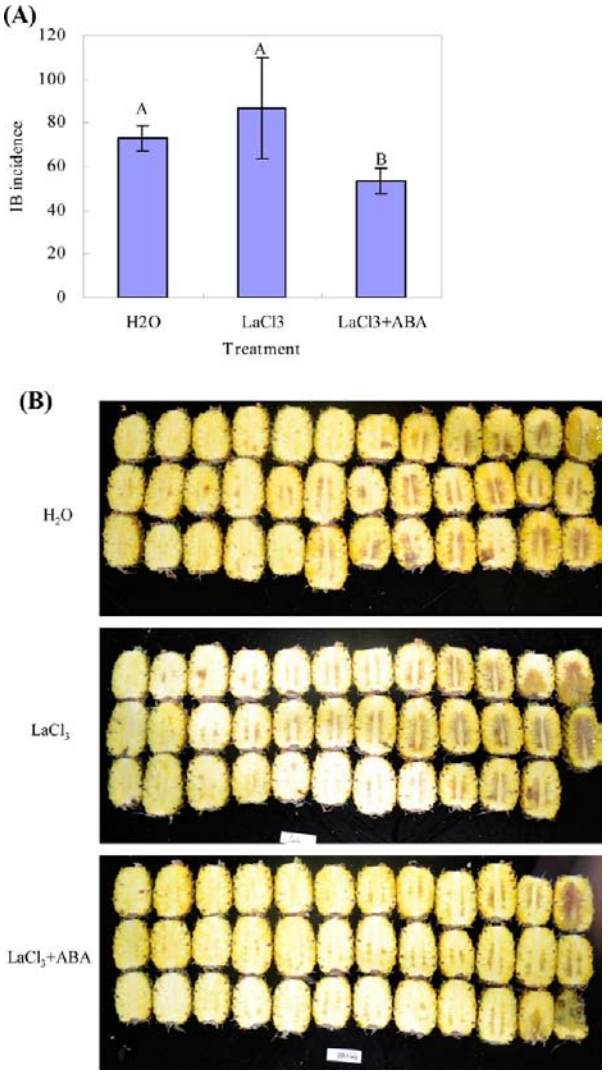

Figure 7. Effects of $LaCl_3$, calcium channel blocker, on IB development in harvested pineapple fruit stored at 20 °C. Fruit were sprayed with distilled water, 50 μM $LaCl_3$, or 380 μM ABA following $LaCl_3$ treatment. Incidence (A) was evaluated and pictures (B) were taken 9 days after treatment. Significance of differences between the control and the treatment is indicated by letters above the bars ($P \leq 0.01$). Standard errors are shown. The experiment was conducted in September 2013.

depends on the delicate equilibrium between ROS production and scavenging at the proper site and time.[39] ABA is a key inducer of H_2O_2 production in maize leaves under water stress.[40] Synthesis of H_2O_2 is essential for ABA-induced stomatal closure in various species.[41] In *Arabidopsis*, ABA-induced stomatal closure was inhibited by DPI, an inhibitor of NADPH oxidase.[42] These suggest that certain functions of ABA depend on H_2O_2 as a signaling molecule. It is worth investigating whether H_2O_2 as a signaling molecule is needed by ABA for activating of the antioxidant system that leads to alleviated internal browning. The result showed that the combination of DPI and ABA treatment did not obviously increase IB severity compared with ABA treatment alone (Figure 6), suggesting that H_2O_2 is not needed by ABA as a signaling molecule to activate the ROS scavenging system and inhibit IB. How ABA activates ROS scavengers, such as POD and CAT, remains to be elucidated.

As a second messenger, cytosolic calcium ($[Ca^{2+}]_{cyt}$) mediates ABA-induced plant's responses to abiotic stresses, such as chilling[43] and heat.[44] ABA functions by activating Ca^{2+}-permeable channels.[45] ABA-induced $[Ca^{2+}]_{cyt}$ increases are mediated by Ca^{2+} influx through plasma membrane Ca^{2+}-permeable (I_{Ca}) channels and Ca^{2+} release from internal stores.[46] If it is the case in harvested pineapple that ABA controls IB by activating Ca^{2+}-permeable channels, what happens when the channels are blocked would be an interesting question. To address this question, $LaCl_3$, a Ca^{2+}-permeable channels blocker, was applied alone or in combination with ABA to harvested pineapple fruit. The results showed the $LaCl_3$ alone increased the IB incidence by 13.7% compared with the control, indicating that blocking calcium channels was unfavorable for control of IB. However, the combination treatment reduced IB by 33.4% compared with $LaCl_3$ treatment alone (Figure 7), indicating that ABA could reactivate the Ca^{2+} channels blocked by $LaCl_3$. These results suggest that control of IB by ABA involves activation of Ca^{2+}-permeable channels.

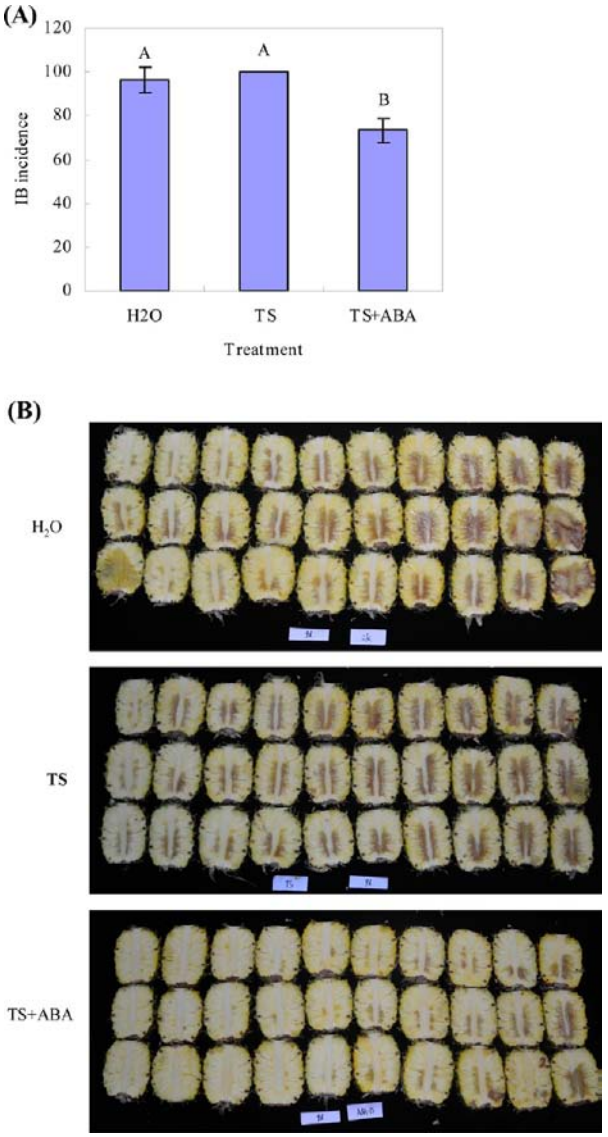

Figure 8. Effects of sodium tungstate dehydrate (TS), inhibitor of ABA biosynthesis, on IB development in harvested pineapple fruit stored at 20 °C. Fruit were sprayed with distilled water, 50 μM TS, or 380 μM ABA following TS treatment. Incidence (A) was evaluated and pictures (B) were taken 9 days after treatment. Significance of differences between the control and the treatment is indicated by letters above the bars ($P \leq 0.01$). Standard errors are shown. The experiment was conducted in November 2013.

To check how important ABA is for pineapple to keep healthy during storage, TS, the inhibitor of ABA biosynthesis, was applied to harvested pineapples. The results showed that TS alone slightly aggravated IB symptoms compared with the control, while the combination of TS and ABA treatment effectively inhibited IB development (Figure 8). This result is consistent with that of Pusittigul et al.[15] which showed that aggravated IB in pineapple coincided with decreased ABA contents. This implies that sufficient ABA content is necessary for controlling IB and that the deficiency or degradation of endogenous ABA during storage process could result in development of IB.

In conclusion, ABA induced resistance to IB and maintained quality of harvested pineapples. ABA reduced IB development by reducing biosynthesis of phenolic substrates, inhibiting enzymatic oxidation of phenolics, and enhancing ROS-scavenging capability to protect cell membranes. ABA-induced resistance to IB is not dependent on synthesis of H_2O_2, but could be through activating the Ca^{2+} channels. ABA is sufficient for controlling IB, and deficiency of ABA in pineapple tissue could induce IB.

Supporting Information

ABSTRACT: This study was designed to assess natural variation in composition and metabolites in 50 genetically diverse non genetically modified maize hybrids grown at six locations in North America. Results showed that levels of compositional components in maize forage were affected by environment more than genotype. Crude protein, all amino acids except lysine, manganese, and β-carotene in maize grain were affected by environment more than genotype; however, most proximates and fibers, all fatty acids, lysine, most minerals, vitamins, and secondary metabolites in maize grain were affected by genotype more than environment. A strong interaction between genotype and environment was seen for some analytes. The results could be used as reference values for future nutrient composition studies of genetically modified crops and to expand conventional compositional data sets. These results may be further used as a genetic basis for improvement of the nutritional value of maize grain by molecular breeding and biotechnology approaches.

KEYWORDS: *maize, hybrid, natural variation, nutrient composition, substantial equivalence, compositional analysis*

INTRODUCTION

Maize is a major crop providing not only animal and human nutrition but also raw materials for manufacturing industrial products. World production and consumption of maize were about 989,608 and 953,133 thousand metric tons in 2013/2014, respectively.[1] Maize yield has improved substantially in the past two decades through conventional breeding combined with molecular marker-assisted selection and biotechnology.[2] To feed an expanding world population, projected to reach 9.6 billion in 2050,[3] and to supply feedstock for industrial products, biotechnology is needed to improve crop productivity and sustainability.

Genetically modified (GM) crop varieties were grown on >175.2 million hectares worldwide in 2013.[4] GM crops have been stringently scrutinized by global regulatory agencies in many aspects including agronomic, environmental, toxicological, and nutritional compositional data since the initial application of biotechnology to crops in the 1990s. One of the risk assessments, substantial equivalence evaluation for nutrient composition of GM crops, was first outlined by the Food and Agriculture Organization of the United Nations (FAO)/World Health Organization (WHO) consultation[5,6] and further developed by the Organization for Economic Co-operation and Development (OECD)[7,8] and additional FAO/WHO consultation.[9] Currently, many international organizations including FAO, WHO, and the International Life Sciences Institute (ILSI) have adopted substantial equivalence as an accepted principle in the safety assessment of GM plants.

In substantial equivalence analysis, measurements of analytes representing key nutrients, antinutrients, toxicants, and secondary metabolites from GM crops are compared to data collected from non-GM near-isogenic plants and non-GM conventional hybrids grown under identical conditions and are also compared to historic values from the literature and the ILSI crop composition database.[10,11] This comparative safety assessment approach provides assurance that foods and feeds derived from GM crops are as safe as their conventional counterparts.

Compositional studies of grain as well as forage have been conducted in both non-GM conventional crops and GM crops including maize,[12] soybean,[13] cotton,[14] rice,[15] wheat,[16] potato,[17] and others.[18,19] Many studies have shown that transgenes have less of an effect on nutrient composition than genotypes and environments.[20,21]

Maize was domesticated about 8000 years ago and has undergone extensive human selection for agronomic performance for more than a century. Whereas genetic improvement contributes about 70% of the yield gained in the development of modern hybrids, grain quality and composition also have been changed.[22] This study was designed to assess the degree of genotypic and environmental impact on forage and grain composition in 50 non-GM commercial maize hybrids that

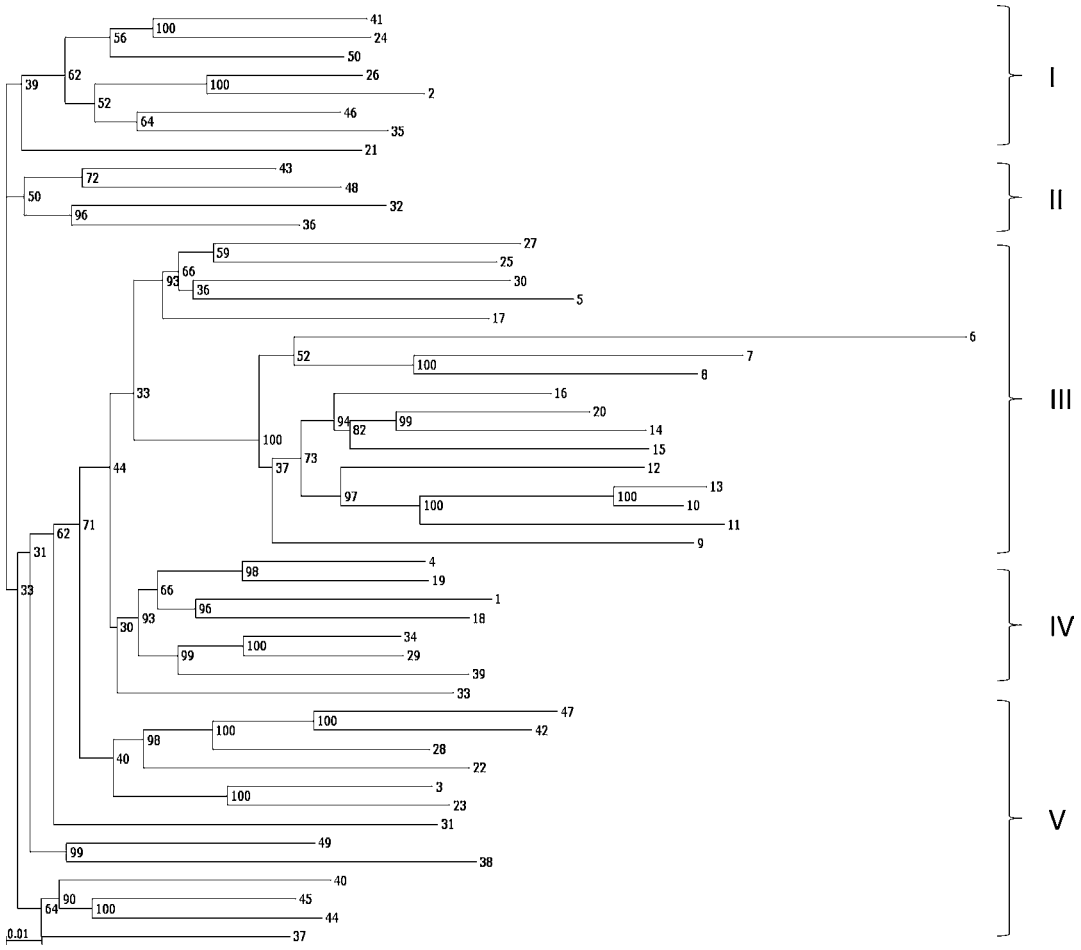

Figure 1. Phylogenetic analysis of 50 hybrids based on SNP genotype data. Fifty hybrids (entry codes 1−50) are clustered in five major distinct groups labeled I, II, III, IV, and V. Five hybrids (entry codes 1−5) were selected to grow at all six sites.

represent different genetic backgrounds and maturity groups. These hybrids were grown in six different geographical regions in North America during the 2010 growing season with each site having 20 unique genotypes. Forage and grain samples collected from the commercial maize hybrids were analyzed for key nutritional components. The genotype data for approximately 3000 single-nucleotide polymorphisms (SNPs) were used in genome-wide association studies (GWAS) for several nutrients. The results for oleic acid are reported here to demonstrate that the genetic variation in the selected hybrids is sufficient in providing an independent confirmation of previous GWAS results for oleic acid. Furthermore, the Pearson correlation matrix was applied to calculate the distance matrix for the analytes. This study provides insights into natural variation in maize nutrient composition by identifying effects of genotype, environment, and their interaction at the analyte level. In addition, the results may offer opportunities for further genetic improvement of maize forage and grain composition.

MATERIALS AND METHODS

Materials. Fifty DuPont Pioneer non-GM commercial maize hybrids (entry codes 1−50) with diverse genetic backgrounds and different maturity groups were grown at six sites in North America (Illinois (IL), Kansas (KS), Minnesota (MN), Nebraska (NE), Texas (TX), and Ontario (ON)). Twenty genotypes were grown at each location as shown in Table 1 of the Supporting Information reported by Asiago et al.[23] At each location, the selected genotypes were planted in three blocks and two replicates per block.

Forage and Grain Sample Collection. One forage sample and one grain sample were collected from each hybrid in each block for compositional analysis. Each forage sample was obtained by cutting the aerial portion of three plants from the root system, approximately 2.5 cm above the soil surface line. The plants were then cut into sections approximately ≤7.5 cm, the cut material was mixed, and one-third of the cut material was collected into a prelabeled, plastic-lined cloth bag and placed on dry ice until transfer to frozen storage (≤ −10 °C).

Each grain sample was obtained by harvesting the grain from five hand-pollinated ears. Grain samples were collected at typical harvest maturity and placed in prelabeled, plastic-lined cloth bags. Samples were kept on dry ice until transfer to frozen storage (≤ −10 °C).

Processing. Grain and forage samples were shipped frozen to EPL Bio Analytical Services (EPL BAS, Niantic, IL, USA) and maintained at approximately −20 °C until processing. Forage samples were dried at 60 °C in a forced-air oven and then ground with a Wiley laboratory mill (model 4, Thomas Scientific, Swedsboro, NJ, USA) to pass a 1 mm screen. Grain samples were not dried prior to grinding in an ultra centrifugal mill fitted with a 0.75 mm distance ring/sieve (ZM 200, Retsch, Newton, PA, USA). Ground samples were stored at −20 °C.

Nutrient Composition Analysis. Compositional analyses were conducted by EPL BAS using GLP validated methods. Both forage and grain were analyzed for crude protein, crude fat, ash, carbohydrates, crude fiber, acid detergent fiber (ADF), neutral detergent fiber (NDF), and minerals (calcium and phosphorus). Grain was further analyzed for fatty acids, amino acids, additional minerals (manganese, iron, magnesium, copper, potassium, sodium, and zinc), vitamins (β-carotene, thiamin, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid, and α-, β-, γ-, and δ-tocopherol), secondary metabolites, and antinutrients (inositol, raffinose, furfural, ferulic acid, *p*-coumaric acid, phytic acid, and

DOI: 10.1021/acs.jafc.5b01764
J. Agric. Food Chem. 2015, 63, 5321−5334

trypsin inhibitor). Most compositional analyses were performed as described by Herman et al.[24] Modified procedures used for measuring fatty acids, minerals, inositol, and raffinose and procedures used for measuring crude fat, niacin, pantothenic acid, and pyridoxine are briefly described below.

Crude Fat. Crude fat content was quantified by an automated hydrolysis method using an ANKOM^{HCl} hydrolysis system (Ankom Technology, Macedon, NY, USA) and an automated extraction method using an ANKOM^{XT15} extraction system.[25−27] Samples were hydrolyzed at 90 °C for 80 and 60 min for forage and grain, respectively, and then extracted using a mixed solvent of petroleum ether/ethyl ether/ethanol (45:45:10). Extracts were evaporated, and the fat residue remaining was determined gravimetrically.

Fatty Acids. Lipid material was extracted from the grain with petroleum ether using a Soxhlet apparatus.[28] Lipids were saponified with 2% methanolic NaOH followed by methylation with 14% BF_3/methanol reagent. The fatty acid methyl esters were extracted with hexane and analyzed by gas chromatography with flame ionization detection (GC-FID).

Minerals. The concentrations of calcium and phosphorus in forage and grain as well as those of copper, iron, magnesium, manganese, potassium, sodium, and zinc in grain were measured by inductively coupled plasma−optical emission spectrometry (ICP-OES) after digestion in 28% aqueous nitric acid with a MarsXpress (CEM Corp., Matthews, NC, USA) microwave.[29,30] Emission intensity at the appropriate wavelength was determined for each element and compared to that of external standards for quantification.

Niacin (Vitamin B3). Grain sample analysis was based on a method from the AACC.[31] Aqueous extracts were prepared of samples and then an aliquot of the extract was mixed with a niacin-free bacterial growth medium. The mixture was inoculated with *Lactobacillus plantarum*. The niacin concentration was determined by measuring the turbidity of the *L. plantarum* growth response in the sample and comparing it with the growth response in standard concentrations of niacin.

Pantothenic Acid (Vitamin B5). Grain sample analysis was based on a method from the AOAC.[32] Panthothenic acid was extracted with a pH 5.65 acetate buffer and autoclaving. The extract was mixed with a pantothenic acid-free bacterial growth medium and then the mixture inoculated with *L. plantarum*. The pantothenic acid concentration was determined by measuring the turbidity of the *L. plantarum* growth response in the sample and comparing it with the growth response in standard concentrations of pantothenic acid.

Pyridoxine, Pyridoxal, and Pyridoxamine (Vitamin B6). Grain sample analysis was based on a method from the AACC.[33] Vitamin B6 was extracted with 0.44 N sulfuric acid and autoclaving. The extract was mixed with a vitamin B6-free microbiological growth medium and then the mixture inoculated with *Saccharomyces cerevisiae*. The vitamin B6 concentration was determined by measuring the turbidity of the *S. cerevisiae* growth response in the sample and comparing it with the growth response in standard concentrations of pyridoxine.

Inositol and Raffinose. Measurement of inositol and raffinose was based on three methods.[34,35] Grain samples were extracted with 50% aqueous ethanol. The ethanol extract was partitioned against chloroform and then split into aliquots and dried. One aliquot was resuspended in 50% aqueous acetonitrile and then analyzed by reverse phase HPLC with refractive index (RI) detection to quantify raffinose. External standards were used to calibrate the HPLC-RI. The other aliquot was treated with butylboronic acid, and butylboronic acid-derivatized inositol was quantified by GC-FID. External standards were used to calibrate the GC-FID.

Statistical Analyses. Statistical analyses were conducted using R[36] and SciPy.[37] For each nutrient composition analyte, the arithmetic means and ranges at each site and across sites were calculated across hybrid maize lines. In each location, measurements were taken for each hybrid with replication in three different blocks. Additive corrections were applied to the data for the replicates to remove the variation between blocks. A two-way ANOVA procedure was used to calculate the explained variance for genotype, location, and genotype by location interaction.

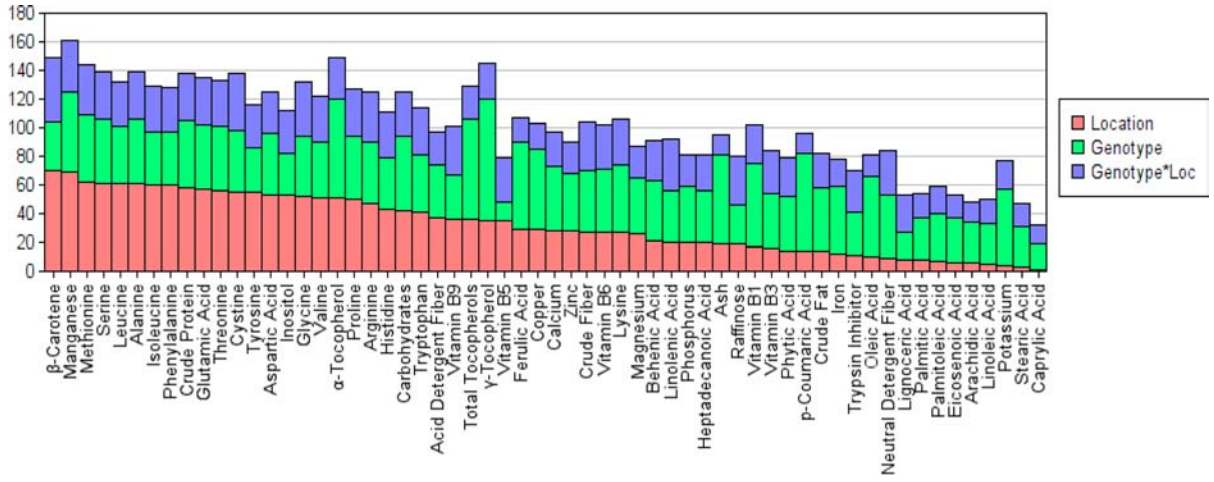

Figure 2. Environmental and genetic impacts on natural variation of analytes. Bar plot of the explained variance from a two-way ANOVA analysis of genotype by environment effects. Variability (from the highest to the lowest) of each analyte explained by location effects was used to order analytes on the *x*-axis.

The inbred parents for the 50 non-GM commercial hybrids were genotyped using Illumina custom bead arrays for 3072 SNPs. Genotypes for the hybrids were inferred from the homozygous base calls for each of the parents, with lexicographic ordering of the base calls. The median for the missing genotype calls was 8%, and the maximum was 32%. Additional genotype data for 2000 SNPs were also included with missing genotype calls up to 78%. The neighbor-joining phylogenetic analysis with 1000 bootstrap iterations was carried out using QuickTree.[38] The phylogeny analysis result file was imported into Archaeopteryx to produce the tree graph.[39]

The genotype data for approximately 3000 SNPs were used in a GWAS for oleic acid. Genotype data for an individual SNP were used as the predictors in a linear statistical model for the phenotype. In the GWAS graph, explained variation, r^2, is plotted versus genetic coordinate for the SNPs. SNPs with minor allele counts of <8 were ignored.

Compositional data for the hybrids in six locations were used to calculate the Pearson correlation matrix for the analytes. A distance matrix was obtained by converting each correlation coefficient to a distance, $1 - r^2$. The distance matrix was used in QuickTree with the neighbor-joining algorithm to calculate the dendrogram.[38] The phylogeny analysis result file was imported into Archaeopteryx to produce the tree graph.[39]

RESULTS AND DISCUSSION

In substantial equivalence analysis, comparative composition analyses have been conducted by measuring and comparing analyte values from GM crops and their non-GM comparators including near-isogenic lines or commercial conventional hybrids. Compositional data generated from comparators have been used as references for biological relevance evaluation because these crops have a long history of safe consumption as food or feed. To shed light on natural variation of compositional components attributable to genetic background, growing location, or the interactions of genetics by environment, evaluation of the composition of commercial hybrids with diverse genetic backgrounds grown at multiple maize production regions is needed. In this study, 50 DuPont Pioneer non-GM commercial hybrids differing in genetic background and maturity group were selected and grown at six sites in commercial maize-growing regions in North America. Associations of the 50 hybrids are shown in a dendrogram based upon marker analysis by using approximately 3000 SNPs across maize genome (Figure 1), suggesting that these 50 hybrids comprise 5 major distinct genetic groups and represent broad genetic diversity of commercial maize hybrids.[40] Mean and range values for each analyte from 20 hybrids grown at each site are reported (Tables 1−7). The composition data collected from this study could expand conventional compositional data sets and be used as reference values for substantial equivalence assessment for GM crops.

In maize breeding programs the standard procedure is to test only the best adopted hybrids in a given location, which are classified into maturity zones. Hybrids with flowering time outside the range for a zone would present a problem for crop management of the field testing and commercial production. This maturity zone constraint resulted in an unbalanced experiment design for this study, but every effort was made to include hybrids across locations that could be adopted to the zones.[21] In the study, five hybrids, representing clades I, III, IV, and V, were grown in all six locations (Figure 1). Data analysis was performed with these 5 hybrids, and the results showed similar trends with the results analyzed from the 50 hybrids (Supplemental Figure 1). Furthermore, two previously published forage and grain metabolomics studies have shown similar results.[23,41] These two studies used samples collected from the same set of non-GM DuPont Pioneer commercial hybrids as reported in this study, with one study focusing on data analysis of metabolites measured from the 50 hybrids and the other one on metabolomics data measured only from the 5 hybrids grown at all locations.[23,41] We regard the hybrids as constituting a representative population for a given location and the data as providing estimates for the population mean and variance for nutrient. Our use of the two-way ANOVA method for the analysis of genotype by environment effects relies on the validity of this approximation. Therefore, our conclusions about genotype by environment interactions are best interpreted as corresponding to elite maize germplasm subject to the maturity zone restriction. The effects of genotype, environment, and their interactions are also reported (Tables 1−7).

Proximate, Fiber, Calcium, and Phosphorus Contents in Forage. Crude protein, fat, carbohydrates, fiber including ADF and NDF, calcium, phosphorus, ash, and moisture were measured and/or calculated for forage from the 50 hybrids across six locations. Statistical analysis demonstrated that natural variation for all components measured in forage was attributed largely to environmental effects rather than genotypic effects (Table 1). The similar results have been previously reported.[23,41]

Proximate and Fiber Composition in Maize Grain. Grain quality is determined by its carbohydrate, oil, and protein contents.[42] Some hybrids selected for this study were bred to produce grains with enhanced values of oil, protein, or carbohydrate. Table 2 shows proximate and fiber means and ranges obtained from maize grain at each location. Carbohydrates were the major components (~85%) in corn grain composition; crude protein and NDF were present in similar levels (~10%); crude fat and ADF were present in similar levels (~4%); and ash and crude fiber were present in the lowest amounts (1.4−2.6%).

Values of crude fat varied. Statistical analysis from the 50 hybrids grown in the six locations indicated that variation of crude fat content is mainly contributed by genetic background of the hybrids (Table 2 and Figure 2). Twenty-two oil QTLs were identified including *DGAT1-2* for oil content improvement explaining about 70% of the total variation. The finding in this study agrees with the notion that genetics primarily controls oil content.[43,44]

Protein and carbohydrate are the two components closely associated with maize grain yield. The average content of crude protein is negatively correlated with the average content of carbohydrates ($R^2 = 0.83$, $p = 2.98 \times 10^{-139}$). Crude protein and carbohydrates were genetic traits (46 and 52.2% explained by genotype, respectively), supported by a previous study in which 26 protein and 21 starch QTLs were identified.[44] The quantity of protein and carbohydrates, however, was significantly affected by location, the effects of which account for 58.5 and 42.1% of the total variation with the interaction effects of genotype by location also accounting for 33.4 and 30.2% of the total variation (Table 2 and Figure 2). This is in agreement with the previous findings that protein and carbohydrates in maize grain are mainly influenced by both genotype and environment.[22]

Fatty Acid Composition in Maize Grain. Table 3 shows means and ranges of 12 fatty acids obtained from hybrids at each location. Of the total 29 fatty acids measured, 17 fatty acids were below the low level of quantification (LLOQ) and were excluded from data analysis. Eicosadienoic acid (C20:2) was quantified in three sites in this study, and arachidic acid (C20:0), eicosenoic acid (C20:1), and behenic acid (C22:0) were successfully quantified. The results also showed that palmitic acid (C16:0), oleic acid (C18:1), and linoleic acid (C18:2) constituted the majority of the fatty acid contents. The measurements obtained in the study could be used as reference values in substantial equivalence analysis. Further statistical analysis suggested that genotype and the interaction effects of genotype by environment are primary determinants for levels of all fatty acids measured (Table 3), which was also evident in crude fat content as discussed earlier (Table 2).

Oleic acid is one of the major oil components, and oils with higher oleic acid content are more stable.[45] To meet market demands, some varieties have been developed to increase oleic acid content through long-standing breeding programs. Studies showed that a fatty acid desaturase (*FAD2*) on maize chromosome 4 is responsible for oleic acid content change.[45] To test whether the quantitative trait locus (QTL) *FAD2* is present in the hybrids based on the experimental design reported in this study, the measurements of oleic acid were used in GWAS, and the results show that an association was detected on chromosome 4, at 132 cM, which coincides with the known QTL *FAD2* (Figure 3).[45] This finding not only confirms that oleic acid in maize grain is significantly correlated with genetic effects but also suggests that QTLs underlying other valuable analytes could be mapped or identified in a similar manner. The identified QTLs could be used further for crop improvement by molecular breeding and biotech approaches.

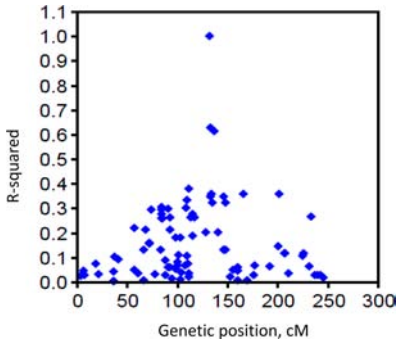

Figure 3. Genome-wide association study for oleic acid for 50 hybrids. For one of the locations (TX), an association is observed on chromosome 4, at 132 cM, which coincides with the known QTL *FAD2*.

Linoleic acid, another major component representing about 50% of the total fatty acid, is a metabolic product downstream of oleic acid. Its content was significantly inversely correlated with oleic acid ($R^2 = 0.70$, $p = 9.85 \times 10^{-95}$). No strong environmental effects were observed for this trait, which is consistent with the findings reported in the literature.[22] In summary, the results from this study confirmed the molecular basis underlying natural variation of oil and oleic acid contents in plants.

Total Amino Acid Composition in Maize Grain. Eighteen amino acids were measured and are summarized in Table 4. Most interestingly, the levels of 17 of 18 total amino acids were strongly correlated with location, which suggests that the variability of these amino acids was mainly due to environmental effects with the exception of lysine, which appears to be more dependent on genotype (Figure 2 and Table 4). The results are similar to a finding in a previous paper that the levels of the 13 amino acids were found to be significantly affected by location.[46]

Mineral Composition in Maize Grain. Minerals including calcium, manganese, phosphorus, iron, magnesium, copper, potassium, sodium, and zinc were analyzed in maize grain samples (Table 5). The range of natural variation in manganese accumulation was significantly associated with sites (68.7%) and genotypes (56.5%). Copper, potassium, iron, calcium, zinc, phosphorus, and magnesium were mainly affected by genotypic effects (Table 5).

Vitamins in Maize Grain. Vitamins were measured from maize grain and are presented in Table 6. There were no previous records for the ranges of vitamins B3 and B5 in the ILSI crop composition database. γ-Tocopherol is the major compound (combined value) followed by B3 and then β-carotene (Table 6). The values could be used as reference values for future substantial equivalence analysis.

β-Carotene, a major dietary source of provitamin A, showed considerable variation across the six sites. Location effects accounted for 69.7% of natural variability (Table 6 and Figure 2). These results indicate strong geographical effects on the level of β-carotene or pro-vitamin A.

Among the four types of tocopherols known as vitamin E, α-tocopherol is a major source of vitamin E in humans and animals and is the most important for human health, whereas γ-tocopherol is the predominant form in the total tocopherols as reported in Table 6 and a previously published paper.[47] Maize grain oil containing a higher concentration of tocopherols has been found to be beneficial in maintaining oil quality in high-oil

maize. Substantial natural variation (about 3-fold differences) of α- and γ-tocopherols among the sites was evident in this study, and similar substantial natural variation of α- and γ-tocopherols was observed in previous studies.[48,49] Analysis of variance revealed strong genetic and environmental effects for α-tocopherol (68.9 and 50.7%, respectively), which is in accordance with other reports for maize.[49] Statistical analysis also showed that considerably higher heritabilities were found for γ- and δ-tocopherols explaining 85.1 and 81.1% of total variability, respectively, despite the strong genotype by environment interactions and environmental effects that were detected. These results demonstrated that genetic variation was the main contributor to tocopherol variability, implying that breeding efforts may be suitable for improving maize kernel tocopherol composition. Indeed, QTLs for α-, γ-, and δ-tocopherols were identified in previous linkage studies.[50,51] Thus, diverse maize germplasms with broad heritability and wide natural variation for α-, γ-, and δ-tocopherols can be used for breeding to biofortify crops with enhanced levels of tocopherols, with particular emphasis on modulating levels of α-tocopherol by mapping QTLs for tocopherols. This, in turn, can be used to increase the tocopherol concentration by genetic engineering.

Secondary Metabolite and Antinutrient Composition in Maize Grain. Seven analytes of secondary metabolites and antinutrients were measured except furfural, which was below the limit of quantification (Table 7). Levels of the secondary metabolites *p*-coumaric acid and ferulic acid varied from hybrid to hybrid, which demonstrated that their levels were affected mainly by genotype by 68.7 and 60.7%, respectively. Differences for inositol observed among locations implied that location played an important role in the biogenesis of inositol with 53.1% of variability explained by location. Levels of phytic acid were mainly controlled by genotype and the interactions of genotype by location (Table 7). Levels of the antinutrient phytic acid can be decreased by breeding and biotechnology approaches because high levels of phytic acid in grains reduce absorption of minerals. A reduced phytic acid level in maize kernel has been developed by silencing the *lpa1* gene.[52]

Correlations of Analytes Measured from 50 Hybrids. To understand biosynthetic interactions of compositional components from maize grain, the Pearson correlation matrix for the analytes was calculated. Significantly related analytes with the same or related biosynthetic pathways are clustered in groups. Nonsignificantly correlated analytes are in distantly related groups. Such correlations among composition analytes are depicted phylogenetically in Figure 4. For example, all amino acids, correlated to crude protein, appeared in the same clade based on the values of r^2. Significant correlations were observed between carbohydrates and crude protein and between oleic acid and linoleic acid, as described previously in the text, and between fatty acids, etc. Tocopherols were previously known to be synthesized in one pathway and, indeed, the tocopherols were closely clustered (Figure 4). These correlation data suggested that concentrations of the compounds with nonsignificant correlations are influenced by different pathways or regulated by independent genes. Levels of the compounds can be improved simultaneously by molecular breeding. However, the compounds with significant correlations indicate that they are on the same pathway or regulated by a similar set of genes with closely biosynthetic relationships, which need to be bred individually. These results may offer opportunities for further genetic improvement of maize forage and grain composition.

Natural variation of plant metabolites is contributed not only by genetic variation but also by environmental factors.

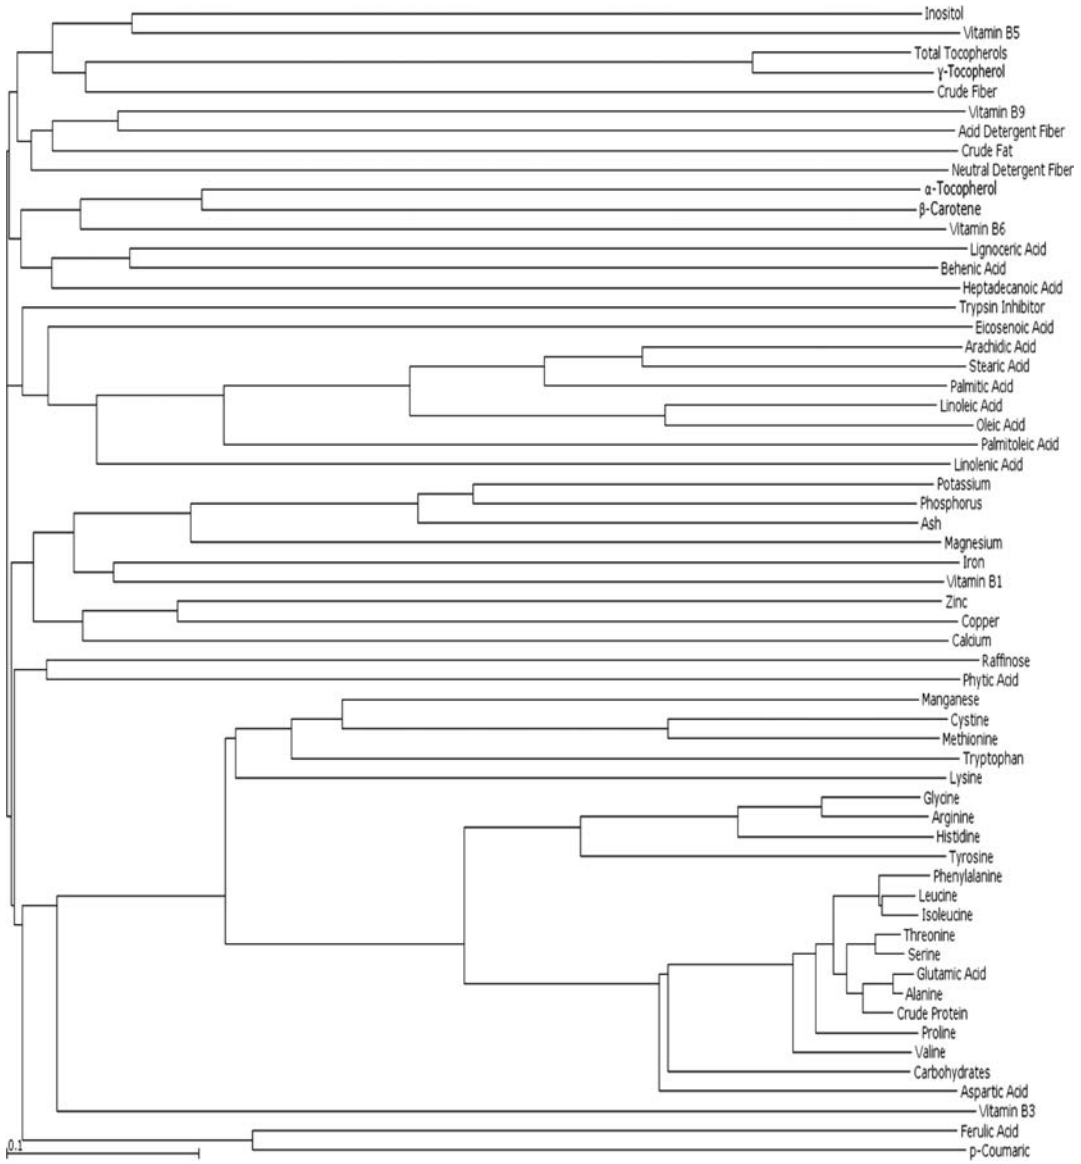

Figure 4. Phylogenetic analysis of analytes for 50 hybrids.

This variability in nutrient composition is important within the context of comparative safety assessments for GM crops. When analytes in GM crops are statistically significant different from those in the isogenic comparators, the Codex guideline states "The statistical significance of any observed differences should be assessed in the context of the range of natural variations" to determine the biological relevance.[53] Understanding the natural variation of conventional crop composition with a history of safe consumption is critical in establishing a baseline for comparison to GM crops. This study documented natural variability of nutrient composition from 50 diverse conventional maize hybrids grown at six commercial maize production locations in North America. All of the composition data were deposited to expand the ILSI crop composition database (version 5) and are ready to be used for GM crop assessment.

ABSTRACT: Several studies have described the effects of seed exudates against microorganisms, but only few of them have investigated the proteins that have defensive activity particularly against nematode parasites. This study focused on the proteins released in the exudates of soybean seeds and evaluated their nematicidal properties against *Meloidogyne incognita*. A proteomic approach indicated the existence of 63 exuded proteins, including β-1,3-glucanase, chitinase, lectin, trypsin inhibitor, and lipoxygenase, all of which are related to plant defense. The presence of some of these proteins was confirmed by their *in vitro* activity. The soybean exudates were able to reduce the hatching of nematode eggs and to cause 100% mortality of second-stage juveniles (J2). The pretreatment of J2 with these exudates resulted in a 90% reduction of the gall number in tobacco plants. These findings suggest that the exuded proteins are directly involved in plant defense against soil pathogens, including nematodes, during seed germination.

KEYWORDS: *Glycine max, exudation, seed proteins, defense proteins, soil pathogen, Meloidogyne*

INTRODUCTION

Root-knot nematodes (*Meloidogyne* spp.) are obligate endoparasites comprising a major group of plant-parasitic nematodes that affect crop production, causing annual losses of more than one hundred billion U.S. dollars worldwide.[1] Among all *Meloidogyne* species, *Meloidogyne incognita* is the most damaging phytonematode, and it is disseminated throughout the world, particularly in regions with previous plantings of coffee or cotton.[2] Root-knot nematodes have developed a highly specialized and unique way to infect their hosts. The infection takes place when the motile second-stage juvenile (J2), the infective form, is attracted to the root system by the root exudates and enters the elongation zone just behind the root tip.[3] The parasite then moves intra- and intercellularly to reach the primary phloem or the undifferentiated cells of the adjacent parenchyma, where it becomes sedentary and establishes a feeding site.[4]

Currently, the most commonly used procedure in nematode control is the application of synthetic nematicides. However, their high cost and toxicity to the environment and live organisms has encouraged the development of new methods of nematode control.[5] Although transgenic technology, which has offered potential new avenues for crop improvement programs, is useful for designing nematode-resistant crops, this alternative approach has not sufficiently demanded an urgent need for the design of novel management strategies.[6] In this sense, a number of studies have been performed to develop non-chemical and environmentally friendly nematode management practices, including the use of botanicals.[7]

Seed exudates represent a useful source of defense molecules, which are mainly peptides/proteins and secondary metabolites with the capacity to inhibit soil-borne pathogens and, thereby, prevent infection.[8] Although several studies have described the inhibitory effects of seed exudates against microorganisms, only a few of these studies have investigated the proteins that may contribute to the defense activity of the exudates; thus, our knowledge remains essentially incomplete.[9] The present study focused exclusively on the exuded proteins from soybeans [*Glycine max* (L.) Merril]. Soybean seeds stand as an ideal system for the study of the exudates−pathogen interaction because of their great economic value and high protein content.[10] Many seed proteins are usually stored in specialized cellular compartments, preventing their hydrolysis.[11] In addition, it was shown that soybean seeds are capable of exuding large amounts of protease inhibitors along with other proteins in hot water, suggesting their potential role in the defense against pathogens.[12] In this work, the identification and

characterization of some proteins were performed by studying the soybean seed exudates using capillary liquid chromatography/nanoelectrospray ionization tandem mass spectrometry (ESI−LC−MS/MS) in association with data searching for protein identification and by measuring the activity of some classical defense proteins. Moreover, the efficiency of the exuded seed proteins in inhibiting the development of *M. incognita* was investigated. This study was performed to contribute to the understanding of the physiological role of exuded proteins in the defense against soil pathogens, particularly during the germination process as well as to demonstrate the potential of seed exudates as a source of nematicidal compounds.

MATERIALS AND METHODS

Biological Materials and Reagents. Mature soybean seeds cv. BRS Pala, a commercial and conventional soybean cultivar with high protein content (38.8%) and good resistance/tolerance to both biotic and abiotic stresses, were supplied by the Brazilian Agricultural Research Corporation [Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA)] in partnership with the Foundation for ProSeed Research Support, Passo Fundo, Brazil.[13] Rabbit blood was obtained from the animals of colonies maintained at the Federal University of Ceará (Fortaleza, Brazil). *M. incognita* (race 1) eggs were isolated from tomato roots growing in a greenhouse at the Plant−Pest Molecular Interaction Laboratory, Embrapa, Brasília, Brazil. All chemicals used were of analytical grade.

Preparation of the Soybean Seed Exudates. Seed exudates were obtained from 20 whole soybean seeds with no cracks or other injuries. Seeds were surface-sterilized with 30% (v/v) ethanol for 5 min, rinsed exhaustively with distilled water, and soaked in 6 mL of 0.1 M sodium acetate buffer at pH 5.0, 28 °C, and 70% relative humidity. After different time periods of soaking (1, 6, 12, 18, and 24 h), the seeds were removed, the exudates were collected, and the volumes were recorded. The soybean seed exudates were subject to exhaustive dialysis against distilled water to remove organic compounds with a molecular mass below 3500 Da and centrifuged at 8000*g* for 10 min at 4 °C; the supernatant was collected; and its protein content was determined by the Bradford[14] method using bovine serum albumin (BSA) as the standard protein.

Phytochemical Compound Analysis. The presence of phytochemical compounds was assessed[15] in the ethanolic (70%) extract obtained from the lyophilized soybean exudates. To detect phenols and tannins, the extract was mixed with a few drops of alcoholic ferric chloride solution. Color varying between blue and red shows the presence of phenols, and a dark blue or green precipitate denotes tannins. Leucoanthocyanidins were detected by the appearance of red color after acidification of the extract with HCl (pH 1−3), followed by heat treatment for 2−3 min. To identify flavonoids and xanthones, the extract was mixed with magnesium granules in concentrated HCl. The appearance of red color indicates the presence of these compounds. In the test for steroids and triterpenoids, the extract was mixed with chloroform, a few drops of acetic anhydride, and concentrated sulfuric acid. The appearance of blue or green color indicates the presence of steroids, and brown to red color indicates the occurrence of triterpenoids. The test for saponins was performed in the precipitate formed after treatment of the extract with chloroform, followed by the addition of distilled water and vigorous shaking. The appearance of stable froth indicates the presence of saponins. Alkaloids were detected after extraction of the organic bases with diluted HCl, followed by the addition of drops of the Hagger, Mayer, and Dragendorff reagents. The appearance of cream white precipitate indicates the presence of alkaloids.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS−PAGE) Analysis. SDS−PAGE was performed in a 12.5% discontinuous polyacrylamide gel prepared in 0.025 M Tris−HCl buffer at pH 8.9 containing 1% sodium dodecyl sulfate (SDS).[16] Samples (25 μg) were prepared in 0.5 M Tris-HCl buffer at pH 6.8 containing 1% SDS and heated at 100 °C for 10 min before electrophoresis. Electrophoresis was performed at 20 mA, and the protein bands were visualized after staining with Coomassie Brilliant Blue G-250.[17]

ESI−LC−MS/MS Analysis and Database Searching. The 50 μg aliquots of the dialyzed soybean seed exudates were dissolved in 0.05 M ammonium bicarbonate, denatured in the presence of 0.2% (v/v) RapiGEST SF (Waters, Manchester, U.K.) at 80 °C for 15 min in a dry bath, reduced with 0.1 M dithiothreitol (DTT) at 60 °C for 60 min, and alkylated with 0.3 M iodoacetamide (IAA) for 30 min in the dark at room temperature (23 ± 2 °C). Next, the samples were enzymatically digested overnight, at 37 °C, with the addition of a modified trypsin (Promega, catalog number V5111, Madison, WI) at a 1:100 (w/w) enzyme/protein ratio. To hydrolyze RapiGEST SF and stop digestion, 10 μL of 5% trifluoroacetic acid (TFA) was added, the sample was mixed, incubated for 90 min at 37 °C, and centrifuged (14000*g* for 30 min at 6 °C), and the supernatant was transferred to a Waters Total Recovery vial (Waters, Manchester, U.K.). The nano-ultra-performance liquid chromatography (UPLC) separation of tryptic peptides was performed using a nanoACQUITY UPLC system (Waters, Manchester, U.K.) equipped with a HSS T3 C_{18} reverse-phase column (1.8 μm, 75 μm × 20 mm) equilibrated with the mobile phase A [0.1% (v/v) formic acid in water]. Elution was carried out at 0.35 μL/min flow rate using the mobile phase B [0.1% (v/v) formic acid in acetonitrile] in a gradient mode of 0−40% for 90 min and 40−85% for 5 min. All samples were measured using a data-independent analysis (MS^E, where E represents dynamically variable collision energy), and the tryptic peptides were analyzed using a nano-ESI−LC−MS/MS mass spectrometer (Synapt G1 HDMS, Waters, Manchester, U.K.). The instrument was operated in the electrospray positive-ion mode nano-ESI (+) and in "V" mode, with a precursor double-charge resolution of at least 10 000 full width at half-maximum (fwhm). The mass spectrometer was calibrated by infusion of the standard [Glu1]−fibrinopeptide B human (Glu−Fib) ($[M + 2H]^{2+}$ = 785.2486) into the NanoLockSpray source. Analyses were performed using a Glu−Fib mass channel for every 30 s. The exact mass retention times (EMRTs) of nano-LC−MS^E data were collected in scans alternating between lower (3 eV) and elevated (15−50 eV) collision ramp energy applied to the argon collision cell. The scan time was 1.5 s with a 0.2 s interscan delay for each MS scan at m/z 50−2000. The radio frequency (RF) offset (MS profiles) was adjusted such that LC−MS data were effectively acquired from m/z 300 to 2000, which ensured that any masses observed in the LC−MSE data less than m/z 300 were known to arise from dissociations in the collision cell. The LC−MSE data were processed, and the proteins were identified using Protein Lynx Global Server, version 2.4, software (PLGS) against a reverse *G. max* annotated database, which is accessible on the Universal Protein Knowledgebase (UniProtKB) database. For spectra and database searching, the following default parameters on PLGS were used: a maximum of 1 missed cleavage by trypsin, a fixed modification specified as carbamidomethylation (C), and oxidation (M) as variable modification. The identified proteins were analyzed using AgBase tools.[18] The Plant GOSlimViewer was used to summarize the molecular function and biological process categories using UniProtKB as the reference. The identified proteins were further analyzed by TargetP,[19] iPSORT,[20] and SignalP 3.0,[21] three independent software programs that predict the secreted proteins into the medium via a classical pathway based on their N-terminal signal peptide sequences. In addition, the predictive characterization of proteins secreted via non-conventional pathways was performed using the neural network-based software SecretomeP, version 2.0.[22]

Activity Assay of Plant Defense-Related Proteins. β-1,3-Glucanase (EC 3.2.1.39) was measured by determining the amount of glucose liberated by the action of the enzyme on laminarin (Sigma, St. Louis, MO) used as a substrate. After the addition of the appropriate reagents to the reaction mixture, according to Boller,[23] absorbance readings were taken at 520 nm and the amount of reducing sugars liberated was calculated on the basis of a standard curve created with known amounts (7.5−240.0 mg/L) of commercial glucose (Sigma Chemical Company) dissolved in 0.05 M sodium acetate buffer (pH

DOI: 10.1021/acs.jafc.5b01109
J. Agric. Food Chem. 2015, 63, 5335−5343

5.2) containing 0.5 M NaCl. The activity was expressed as nanokatals per milligram of protein (nkat/mg of protein), with 1 nkat defined as 1.0 nmol of D-glucose released from laminarin per second at 37 °C. Chitinase (EC 3.2.1.14) was assayed using a colorimetric procedure that detects *N*-acetyl-D-glucosamine (NAG) produced by the combined hydrolytic action of chitinases and β-glucuronidase upon the non-radioactive substrate colloidal chitin.[23,24] Colloidal chitin was prepared using non-radioactive acetic anhydride.[25] Absorbance was read at 585 nm, and the amount of NAG produced was calculated on the basis of a standard curve obtained with known concentrations (0.1−0.7 mg/L) of commercial NAG dissolved in 0.05 M sodium acetate buffer (pH 5.2). Chitinase was calculated as nanokatal per milligram of protein (nkat/mg of protein), with 1 nkat defined as 1.0 nmol of NAG produced per second at 37 °C. Peroxidase (EC 1.11.1.7) activity was determined using guaiacol as the proton donor substrate and hydrogen peroxide as the electron donor.[26] Aliquots of 0.02 mL of the dialyzed seed exudates appropriately diluted were mixed with 0.98 mL of 0.05 M sodium acetate buffer at pH 5.2, 0.5 mL of 0.06 M H_2O_2, and 0.5 mL of 0.02 M guaiacol in a total volume of 2.0 mL. The reaction mixture was incubated at 30 °C for 10 min, and the absorbance was measured at 480 nm. The variation of 1 unit of absorbance per minute was defined as 1 unit of peroxidase activity (1 AU) and expressed as activity per milligram of protein (AU/mg of protein). Total proteolytic activity was measured using azocasein as a non-specific substrate.[27] The soybean exudates (500 μL), at different concentrations, dissolved in 0.025 M Na−phosphate buffer at pH 6.0 containing 0.003 M DTT were incubated with 200 μL of 1% (m/v) azocasein for 1 h at 37 °C. The reaction was stopped by the addition of 300 μL of 20% (v/v) trichloroacetic acid (TCA). The tubes were centrifuged (5000*g* for 10 min at 25 °C), and the supernatants obtained were alkalinized with 400 μL of 0.2 N NaOH. The proteolytic activity was expressed as activity unit per milligram of protein per minute (AU mg^{-1} of protein min^{-1}), with 1 AU defined as the change of 0.01 absorbance unit per minute at 420 nm. The trypsin inhibitor assay was carried out by the method originally described by Kakade et al., using N_α-benzoyl-D,L-arginine 4-nitroanilide hydrochloride (L-BAPNA) as the substrate.[28,29] Seed exudates (0.1 mL) at different protein concentrations were mixed with 1.6 mL of 0.05 M Tris−HCl at pH 8.2 containing 0.02 M $CaCl_2$, with 0.1 mL of trypsin (Sigma, type I), from a stock solution of 0.4 mg in 10 mL of 0.001 M HCl, plus 0.1 mL of BAPNA [10 mg/mL in 1% (v/v) dimethyl sulfoxide (DMSO) plus H_2O]. The mixture was incubated for 45 min at 37 °C, and 0.2 mL of 30% (v/v) acetic acid solution was added. The enzymatic hydrolysis of BAPNA was evaluated by recording the absorbance at 410 nm. The amount of trypsin inhibited was calculated from a calibration curve using soybean trypsin inhibitor (Sigma, type I-S). The trypsin inhibitory activity was expressed as the amount of trypsin inhibited per milligram of protein (mg of TI/mg of protein). Papain inhibitory activity was performed as described by Abe et al.[30] using N_α-benzoyl-D,L-arginine-*p*-naphthylamide (BANA) as the substrate. To 20 μL of papain solution (0.1 g/L in 0.025 M sodium phosphate buffer at pH 6.0), 40 μL of an activation solution [containing 0.002 M ethylenediaminetetraacetic acid (EDTA) and 0.003 M DTT at pH 6.0], 100 μL of the dialyzed seed exudates at different concentrations, and 340 μL of 0.025 M sodium phosphate buffer at pH 6.0 were added. The mixture was incubated for 10 min at 37 °C. The reaction was initiated by the addition of 200 μL of 0.001 M BANA solution, prepared in 1% (v/v) DMSO and 0.025 M sodium phosphate buffer at pH 6.0. After 20 min at 37 °C, the reaction was stopped by the addition of 500 μL of 2% HCl in 95% ethanol. The color product was developed by adding 500 μL of 0.06% *p*-dimethylaminocinnamaldehyde in ethanol. Papain inhibitory activity was expressed as inhibition unit per milligram of protein (IU/mg of protein), with 1 IU defined as the amount of inhibitor capable of decreasing the absorbance in 0.01 at 540 nm. Lectin activity was assessed by serial 2-fold dilution of samples, employing native and trypsin-treated rabbit red blood cells.[31,32] The seed exudates were diluted with 0.15 M NaCl in glass tubes and mixed with rabbit erythrocytes (2% suspension prepared in 0.15 M NaCl). The red cell suspensions were enzyme-treated with trypsin (10 mg/L solution prepared in 0.15 M NaCl) for 1 h at room temperature (22 ± 3 °C). Cells were washed 4 times with 0.15 M NaCl, and the suspension final volume was adjusted to attain the original concentration (2%). The degree of agglutination was monitored visually after the tubes had been left to stand at 37 °C for 30 min and at room temperature for a further 30 min. Lectin activity was expressed as hemagglutinating unit per milligram of protein (HU/mg of protein), with 1 HU defined as the reciprocal of the highest dilution giving a visible agglutination to the naked eye.

Nematode Egg Extraction and Production of Juveniles. *M. incognita* (race 1) eggs were extracted from infected tomato roots.[33] These roots were washed with distilled water, cut into 5 cm pieces, and ground in a blender with 0.5% sodium hypochlorite, and the eggs were collected on a 500 mesh sieve (26 μm). Second-stage juveniles (J2s) were hatched from the eggs in distilled water at approximately 28 °C for 48 h. The J2 population was counted and used as the inoculum within 1−2 days of collection.

Attraction Assay. The attraction of *M. incognita* to dialyzed soybean seed exudates was performed following a protocol based on Wang et al.[34] A total of 3 mL of 23% pluronic gel containing 800 freshly hatched J2s was pipetted onto 35 × 10 mm Falcon Easy-Grip Petri dishes (BD Biosciences, San Jose, CA) and kept at room temperature for 24 h. Thereafter, filter paper discs (6 mm diameter) soaked with seed exudates (500 and 1000 mg of protein/L) were added to the center of each dish and then kept at room temperature. The number of nematodes touching the terminal 2 mm of the disc tip was counted at 1, 3, 5, and 24 h time intervals. Distilled water was used as the negative control. The experiment was repeated twice and carried out in triplicate.

***In Vitro* Egg Hatching Test.** Egg suspensions (approximately 500 eggs in distilled water) were incubated at 28 °C in a 12 well culture plate (BD Biosciences, San Jose, CA) with dialyzed seed exudates at a final concentration of 250 and 500 mg of protein/L. The experiment was repeated twice and carried out in triplicate using distilled water as the control. After the incubation time, the number of unhatched eggs was counted under a microscope and the hatch rates were assessed 24 and 48 h after treatment.[35]

***In Vitro* Mortality/Mobility Test of J2s.** A suspension of 50 freshly hatched J2s in distilled water was incubated at 28 °C in a 12-well culture plate with dialyzed seed exudates at final concentrations ranging from 60 to 500 mg of protein/L in a final volume of 0.0005 L. Distilled water was used as the control. After 24 and 48 h of treatment, the mobile and non-mobile J2s were counted under a stereomicroscope. Nematodes were considered dead if they did not move even after the dilution of the exudates to an innocuous concentration.[36] The data were transformed into the percentage mortality [mortality (%) = dead number of J2s/total number of J2s × 100] before the statistical calculations. The experiment was repeated twice and carried out in triplicate.

Root Infection Assay. J2s were kept in contact with the dialyzed seed exudates (125 mg of protein/L) at 28 °C in the dark for 24 h. Thereafter, treated J2s were used in the root inoculation of 1-month-old tobacco seedlings growing in sand/sandy loam (2:1, v/v) in plastic pots. Each seedling received 150 J2s. Tobacco seedlings with J2s exposed to distilled water served as a control. Seedlings inoculated with J2s were maintained in the greenhouse at 28 °C and under a 12/12 h light/dark cycle. At 6 weeks after inoculation, the whole plant was collected and the root system was washed with tap water to remove the soil. The root gall numbers and egg masses were assessed.[35] Seedlings were arranged in a completely randomized block design with 10 individuals per block and three biological replicates.

Statistical Analysis. The experimental design used in all biological assays was completely randomized. The mean of each treatment was compared to its respective control. The data analysis was performed by two ways: (i) when the data were in normal distribution, the analysis was performed using analysis of variation (ANOVA) and Tukey's test to compare means ($p < 0.05$), and (ii) when the data were not in normal distribution, analysis was performed in the JMP 5.1 software using the Wilcoxon/Kruskal−Wallis non-parametric test with a

DOI: 10.1021/acs.jafc.5b01109
J. Agric. Food Chem. 2015, 63, 5335−5343

significance level of 5%. The measurement of dispersion was calculated using standard error.

RESULTS

Protein Content and Molecular Mass of the Exuded Proteins. The type of proteins accumulated in the medium during the imbibition of soybean seeds did not change over time, because the exudates showed similar electrophoretic patterns for the different time periods analyzed. However, the highest amount of protein in the medium was observed 18 h after soaking, which amounted to approximately 3190.00 ± 100.00 mg/L, corresponding to 0.39 ± 0.01 mg/seed. Thus, the exudates obtained under this condition were selected for use in further analyses. Phytochemical compounds were not observed in the dialyzed exudates. SDS−PAGE showed that these exudates contained several proteins ranging in size from 4202 to 97 000 Da, with predominant bands of apparent molecular masses of approximately 28 000 and 45 000 Da (Figure 1).

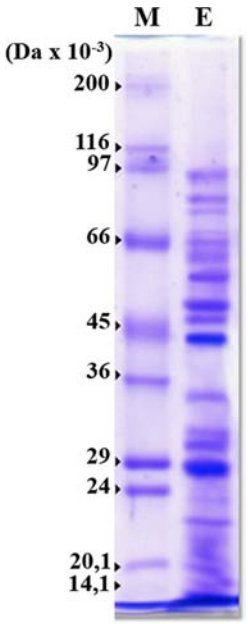

Figure 1. SDS−PAGE of soybean seed exudates: (M) mass markers and (E) soybean seed exudates collected 18 h after soaking in 0.1 M sodium acetate buffer at pH 5.0 and 28 °C. Proteins (25 μg) from seed exudates were loaded in lane E. Protein bands were stained with Coomassie Brilliant Blue G-250.

Identification and Functional Classification of the Exuded Proteins. A gel-free proteomic approach identified 63 protein accessions based on the sequences in the UniProtKB database (Table 1). The distribution of the identified proteins according to their theoretical molecular weights by ESI−LC−MS/MS was corroborated by the results of SDS−PAGE. Among the identified proteins, glycinins, lipoxygenases, proteinase inhibitors, and seed maturation proteins were the most common. Gene ontology annotation allowed for classification of the identified proteins into nine categories: nutrient reservoir activity (14 proteins), DNA binding (1 protein), binding (1 protein), catalytic activity (7 proteins), structural molecule activity (1 protein), hydrolase activity (3 proteins), response to stress (3 proteins), enzyme regulator activity (10 proteins), and carbohydrate binding (1 protein). The 22 remaining proteins were not classified. Interestingly, several proteins identified by ESI−LC−MS/MS are related to plant defense, including β-1,3-glucanase, chitinase class I, lectin, Kunitz and Bowman−Birk trypsin inhibitors, lipoxygenases, late embryogenesis abundant protein, and 7S globulin. In addition, it was observed that most proteins were secreted into the medium via a classical mechanism. However, some of them seem to be secreted via a non-classical, novel fashion pathway (Table 2), because they have scores higher than the threshold value of neural network (NN) > 0.5. One example was the Bowman−Birk protease inhibitor, which was the most highly represented protein.

Activity of Plant Defense-Related Proteins in the Exudates. Specific assays revealed the presence of activities related to some classical defense proteins in the exudates (Table 3). The presence of lectin was evaluated on the basis of the hemagglutinating activity, which was the most pronounced in the seed exudates, particularly when the trypsin-treated rabbit erythrocytes (609.52 HU/mg of protein) were used, reaching up to 4.8 times the value observed for untreated red cells (126.98 HU/mg of protein). To a lesser extent, both β-1,3-glucanase (58.26 nkat/mg of protein) and papain inhibitor (30.48 IU/mg of protein) showed high activities. On the other hand, chitinase activity was not detected, probably because of the low concentration of this protein in the soybean seed exudates.

Biological Effects of Exuded Proteins on Nematodes. A chemotaxis assay showed that the exudates have a repellent effect on the nematode (Figure 2). Indeed, the percentages of J2s of *M. incognita* touching the disc tips immersed in the exudates at 1000 mg of protein/L concentration but not 500 mg of protein/L were significantly ($p < 0.05$) lower compared to the control. This result was particularly true for 1, 3, and 5 h of exposure time. However, at 24 h of exposure, there was no difference between the control and the exudate-treated nematodes.

As demonstrated by the *in vitro* assays, the dialyzed soybean exudates also showed adverse effects on several developmental parameters of *M. incognita*. Indeed, the exudates (500 mg of protein/L) reduced the hatching of the *M. incognita* eggs at 48 h of incubation compared to the control by allowing less than 22% of the eggs to hatch (Figure 3). In addition, the motility of J2s was inhibited by the soybean exudates (60−500 mg of protein/L) compared to the control (Figure 4). The percentage of inactive J2s was approximately 90%, even at the lowest protein concentration (60 mg of protein/L) used. In general, this percentage did not change with the protein concentration of the exudates or the incubation period. Further tests revealed that the exudates were lethal to *M. incognita* J2s (Figure 5). In this case, the percentage of mortality of J2s increased with the incubation period from 24 to 48 h, reaching 100% even in one of the lowest tested protein concentrations (125 mg of protein/L).

The greenhouse experiment using tobacco plants also demonstrated the efficacy of the soybean seed exudates in the *M. incognita* controls. At 6 weeks after inoculation, the pretreatment of J2s with the soybean exudates resulted in around 90 and 94% reduction of the *M. incognita* gall and egg mass number, respectively, in tobacco plants (Figure 6) compared to the control.

DISCUSSION

Plant defense mechanisms have been studied very intensively in vegetative tissues. However, little is known about the strategies

[a]All proteins were identified in *G. max*. [b]Neural network (NN) scores of >0.5 are considered to predict extracellular localization.

Table 3. Activities of the Plant Defense-Related Proteins Present in the Soybean Seed Exudates[a]

protein activity	seed exudates
lectin (HU/mg of protein)	
untreated erythrocytes	126.98 ± 4.39
trypsin-treated erythrocytes	609.52 ± 0.01
trypsin inhibitor (mg of TI/mg of protein)	4.81 ± 0.23
papain inhibitor (IU/mg of protein)	30.48 ± 1.83
protease (AU mg^{-1} of protein min^{-1})	1.52 ± 0.05
peroxidase (AU mg^{-1} of protein min^{-1})	0.01 ± 0.00
β-1,3-glucanase (nkat/mg of protein)	58.26 ± 3.02
chitinase (nkat/mg of protein)	ND[b]

[a]Values are the means ± standard deviation (SD) of biological triplicates. [b]ND = not detected.

used by seeds to survive and germinate in substrates densely populated with microorganisms.[37] It is known that the initial infections of seeds and roots by pathogens may be driven by attractive nutritive exudates, which may be hampered by exuded defense-related compounds.[9] Thus, in an attempt to gain better insight into the role of seed exudates in plant defense, the present study focused on the characterization of exuded soybean seed proteins and their effects against the root-knot nematode *M. incognita*.

Proteins with potential roles in plant defense were identified by ESI−LC−MS/MS in soybean seed exudates. Among them, glycinin, lipoxygenase, and protease inhibitors were the predominant exuded proteins (Table 1). Indeed, several storage proteins, of which a majority are globulins, have been identified in soybeans. The plant globulin family can be subdivided into two main classes according to their sedimentation coefficients: glycinin (11S) and β-conglycinin (7S). In addition to their high nutritional value, it has been shown that these proteins exhibit antimicrobial activities against pathogenic bacteria in equivalent or even higher levels than penicillin, suggesting the involvement of these molecules in the innate defense system of soybeans.[38] Along with the traditionally classified storage proteins, plant lipoxygenases are commonly associated with plant defense

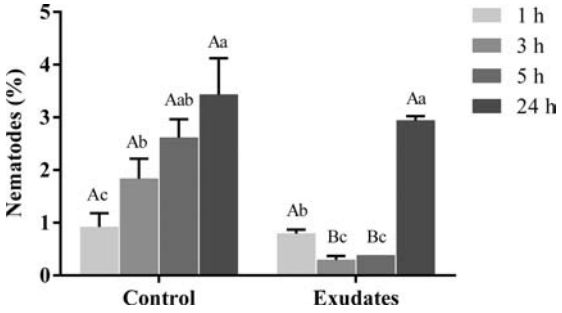

Figure 2. Chemotactic response of the *M. incognita* J2s at 1, 3, 5, and 24 h of exposure to the soybean seed exudates (1000 mg/L). Values represent the means ± SD of triplicates. Significant differences ($p < 0.05$) of the means within the control or within the exudate-treated J2s at different time points are denoted by different lowercase letters. Significant differences ($p < 0.05$) of the means comparing the controls and the exudate-treated J2s at a given time point are denoted by different capital letters ($p < 0.05$).

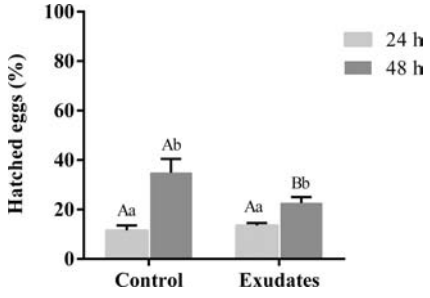

Figure 3. Effect of soybean seed exudates on *M. incognita* eggs at 24 and 48 h of exposure time. Values represent the means ± SD of triplicates. Significant differences ($p < 0.05$) of the means within the control or within the exudate-treated eggs at different time points are denoted by different lowercase letters. Significant differences ($p < 0.05$) of the means comparing the controls and the exudate-treated eggs at a given time point are denoted by different capital letters ($p < 0.05$).

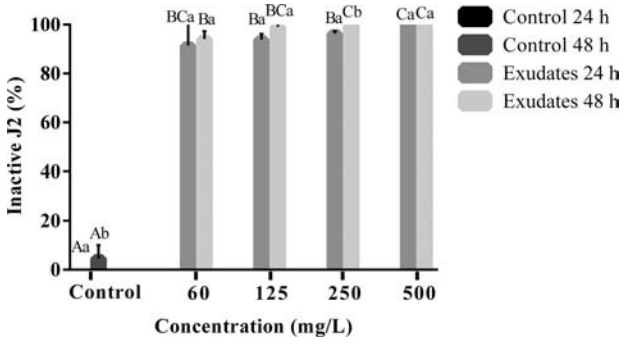

Figure 4. Inactivation of *M. incognita* J2s at 24 and 48 h of exposure to soybean seed exudates. The values represent the means ± SD of triplicates. Significant differences ($p < 0.05$) of the means within the control or within the exudate-treated J2s at different time points are denoted by different lowercase letters. Significant differences ($p < 0.05$) in the means comparing the controls and the exudate-treated J2s at a given time point are denoted by different capital letters ($p < 0.05$).

mechanisms because they are related to the synthesis of a number of different compounds with signaling functions and antimicrobial activity or the development of the hypersensitive response.[39]

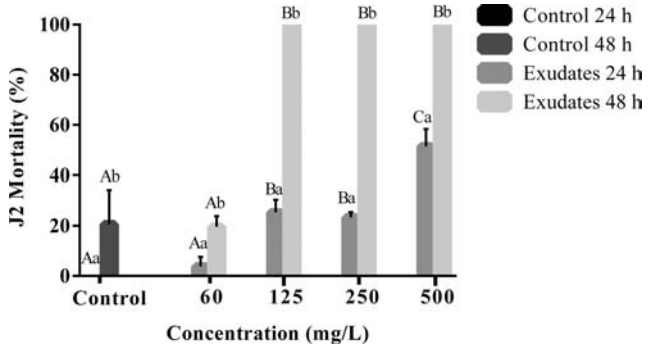

Figure 5. Mortality of *M. incognita* J2s at 24 and 48 h exposure time to soybean seed exudates. The values represent the means ± SD of triplicates. Significant differences ($p < 0.05$) of the means within the control or within the exudate-treated J2s at different time points are denoted by different lowercase letters. Significant differences ($p < 0.05$) of the means comparing the controls and the exudate-treated J2s at a given time point are denoted by different capital letters ($p < 0.05$).

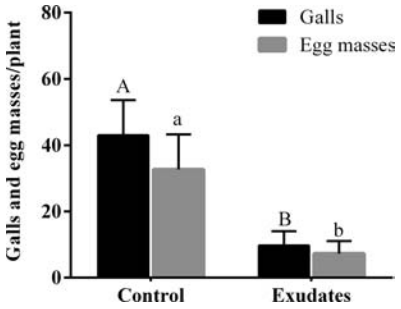

Figure 6. Effect of soybean seed exudates on *M. incognita* virulence. Gall number and egg masses were assessed 6 weeks after inoculation of tobacco roots under greenhouse conditions. Significant differences ($p < 0.05$) of means are denoted by different letters (one-way ANOVA and Tukey test).

Additionally, protease inhibitors can act as storage proteins involved in plant defense. In soybeans, trypsin inhibitors have been reported, which comprise approximately 6% of the total seed proteins. Members of the trypsin inhibitor family inhibit various proteases from plant pathogenic microorganisms and phytophagous insects, suggesting the importance of exudates in the successful seed germination.[40] Other classes of proteins, such as chitinase, β-1,3-glucanase, and lectin, were also released by imbibed soybean seeds. These results agree with those described for legume seed exudates, confirming the complexity of legume proteomes.[9,12]

Most of the exuded soybean proteins appeared to have been released into the germinating medium via a classical mechanism. In contrast, the Bowman−Birk protease inhibitor has been predicted by SecretomeP software to be potentially secreted via a non-conventional pathway. As previously noted, many proteins in soybean exudates undergo secretion via classical mechanisms, with signal peptides targeting the molecules to storage vacuoles.[41] Nevertheless, there is evidence for the existence of plant proteins that are secreted via rough endoplasmic reticulum (RER)−Golgi apparatus-independent routes. The existence of an alternative secretory route can be explained by the need for a rapid and effective defense response to external stress.[42] Accordingly, the Bowman−Birk protease inhibitor might participate in this plant defense process.

To validate the presence of some proteins identified using the gel-free quantitative proteomic approach, the enzymatic and hemagglutinating activities were detected in the soybean exudates. Using these approaches, the presence of proteins, such as lectin, trypsin inhibitor, and β-1,3-glucanase, was confirmed. However, the use of proteomics to identify a certain protein in a sample does not always mean that the *in vitro* assay method is robust enough to detect the activity of that protein, particularly when it is present in low amounts. This can be exemplified by the absence of chitinase activity in the seed exudates, despite the detection of a class I chitinase by ESI−LC−MS/MS. Moreover, the reverse situation was also observed, in which the *in vitro* activity was detected but the corresponding protein was not identified by MS/MS. For instance, our study showed the inhibitory activity of papain in the soybean exudates *in vitro* (Table 3), although the MS/MS analysis did not identify any phytocystatins. Nevertheless, some Kunitz trypsin inhibitors have been reported as bifunctional inhibitors with the ability to inhibit two different enzyme classes (serine and cysteine proteinases).[43] Thus, it is possible that the *in vitro* papain inhibitory activity found in the soybean exudates (Table 3) might be associated with the Kunitz trypsin inhibitors identified through ESI−LC−MS/MS (Table 1).

The *in vitro* inhibitory effect of seed-exuded proteins on the fungal growth has previously been shown.[8] Nonetheless, there have been very few similar studies to date that have addressed plant parasite nematodes. Therefore, after validation of the identities of the exuded proteins involved in plant defense and their corresponding *in vitro* enzymatic activities, our next step was to assess the potential activity of the soybean exudates against *M. incognita*. Indeed, a significant reduction in the mobility and an increase in the mortality of *M. incognita* J2s were observed after treatment with the soybean exudates even at low protein concentrations (60 and 125 mg of protein/L, respectively) (Figures 4 and 5). The nematostatic and nematicidal effects of the exudates on *M. incognita* J2s were also verified using a proteinaceous papain inhibitor purified from *Crotalaria pallida* roots.[7] These effects were found to be lethal, with 95% mortality, when the parasite was exposed to a 50 μg dose of this inhibitor for 48 h.[7] Although the repellent effect of the soybean exudates toward the nematodes was transient (Figure 2), this delay affected their infectivity. This assumption is supported by our experimental findings in which tobacco plants that were inoculated with soybean seed exudate-treated J2s showed around 90 and 94% reductions in the number of galls and egg masses, respectively. The nematicidal activity of the soybean seed exudates is promising because it apparently exerted this effect during more than one stage of the life cycle of the parasite. After 48 h of treatment, the exuded proteins (at 500 mg of protein/L) inhibited the hatching of the nematode eggs by 40% (Figure 3) relative to the controls. This observation is very important because the nematode egg shell has three protective layers, which might complicate the use of chemical agents to control the further development of the nematodes.

Among the various proteins and activities detected in soybean exudates, some can be associated with the nematicidal activity against *M. incognita*, such as the papain inhibitor, which could have impaired the growth rate and fecundity of the nematode. For example, transgenic tomato overexpressing a gene that encodes for the *Colocasia esculenta* cysteine proteinase inhibitor exhibited enhanced resistance to *M. incognita* infection by means of a diminished gall number, decreased proportion of female nematodes, and reduced egg masses.[44] These effects appear to be related, at least in part, to the inhibition of the cysteine proteinase activity present in the nematode intestine.[7] In addition, the hydrolytic enzymes chitinase and protease could have also contributed to the nematicidal activity of the exudates because the *M. incognita* egg shell contains chitin and proteins.[1] This supposition in reinforced by the observation that only 30% of the eggs from transgenic tomato expressing a novel chitinase gene (PjCHI-1) were able to develop to the multi-cell/J1 stage compared to more than 96% from control plants.[45]

Lectin could also be involved in the deleterious activity of the seed exudates against root-knot nematodes. The hemagglutinating properties of lectins have been associated with the protection of plants against roundworms, because these molecules have been shown to impede the penetration of the roots by nematodes, resulting in a reduction in gall development.[46] For example, it has been reported that soybean agglutinin (SBA) interacts with amphids (sensory structures located in the nematode head region) and secretions from J2s, lowering the motility of this parasite and affecting its ability to locate the plant.[47]

In addition, because peroxidase and lipoxygenase are associated with plant responses to pathogens, these proteins may have collaborated with the nematicidal activity of soybean exudates.[26,48] For instance, lipoxygenase activity has been shown to increase in soybean roots upon infection with cyst nematodes.[49]

Taken together, our data indicate that the selective secretion of proteins by soybean seeds may contribute to the defense mechanisms against *M. incognita*. In this context, the present data bring new contributions to the understanding of the physiological role of exuded proteins in the plant defense against soil pathogens and, particularly, against parasite nematodes.

Supporting Information

ABSTRACT: We previously reported that *Bacillus amyloliquefaciens* biocontrol strain SD-32 produces powerful antifungal lipopeptides, C_{17} bacillomycin D homologues. In the course of the investigation we found that the antifungal activity of the culture supernatant of this bacterium was not ascribed exclusively to bacillomycin D. We attempted to identify metabolites other than bacillomycin D to gain insight into the mechanism for the biocontrol by this bacterium. After purifying the fractions of the culture supernatant exhibiting synergistic activity with bacillomycin D, we isolated two new cyclic lipodepsipeptides, *anteiso*-C_{13} and *iso*-C_{13} [Ile^7]surfactins, together with three known [Ile^7]surfactins. Interestingly, [Ile^7]surfactins showed synergistic activities with bacillomycin D to gray mold disease on cucumber leaves but not to *Botrytis cinerea* itself in vitro, suggesting that the synergistic effects might be on infection processes of the fungus. Actually, we observed that they did not show synergistic actions on conidial germination or mycelial growth of *B. cinerea* on the leaves.

KEYWORDS: *Bacillus amyloliquefaciens, Botrytis cinerea, biological control, lipodepsipeptide, surfactin, [Ile^7]surfactin, lipopeptide, bacillomycin D*

INTRODUCTION

Plant pathogenic fungi exhibit a remarkable ability to change and adapt: fungicide-resistant pathogenic strains continually arise and can no longer be controlled by chemicals that were once effective.[1,2] For example, *Botrytis cinerea* Pers., a plant pathogenic fungus, frequently exhibits resistance to, at least, one fungicide or, in the case of many isolates, multiple fungicides.[3] As a result, it is necessary to continue developing novel and effective fungicidal chemicals for control of plant diseases.

Because of the rapid emergence of fungicide resistance and the high cost of discovering, developing, and registering new chemical fungicides, biological control agents (BCAs) have been attracting considerable attention.[4] In fact, many BCA formulations are already available for practical use.[5] Among them, *Bacillus* species-based BCAs are considered to have promising potential due to their safety, ubiquity in nature, and exhibition of high thermal tolerance through the formation of resistant spores. Biological control by *Bacillus* sp. involves a number of mechanisms, such as competitions for space and nutrition, antagonism, and systemic resistance induction. Many strains of *Bacillus* species have been reported to secrete several antimicrobial metabolites.[6] Among these antimicrobial compounds, cyclic lipopeptides (iturins) and cyclic lipodepsipeptides (surfactins and fengycins or plipastatins) have received much attention as key compounds in BCAs because they play an important role in colonization on the plant, show potent activities against a wide variety of microorganisms, and induce plant systemic resistance.[7] Their roles in each biological control system, however, remain to be fully elucidated.

In our previous paper,[8] we reported that *Bacillus amyloliquefaciens* SD-32 was isolated from a soil sample obtained in Japan as a promising and effective agent against gray mold disease, and two new compounds, *anteiso*- and *iso*-C_{17} bacillomycin D, were found in its fermentation broth. Strain SD-32 is quite different from other strains previously reported because it produces C_{17} bacillomycin D homologues as major metabolites. We also showed that the activities of C_{17} bacillomycin D homologues against *B. cinerea* were stronger than those of the known C_{15} and C_{16} homologues both in vitro and in vivo. These data indicate that the strain is a potentially promising resource for the biological control of gray mold disease, and indeed, the culture supernatant of this strain possesses a strong suppressive effect on gray mold disease in vivo. However, we also found that bacillomycin D homologues did not account for all of the activity in the culture supernatant of this strain, suggesting that other factors effective against gray mold disease were also present. The identification of all factors in SD-32 that are effective in controlling gray mold disease could contribute to an understanding of the molecular basis of this biological control system.

To gain insight into the mechanisms responsible for the biological control by *B. amyloliquefaciens* strain SD-32, we attempted in this study to identify the factors that contribute to control gray mold disease, other than bacillomycin D produced by the bacterium, and to clarify the role of these factors in the

biological control system. In the course of purifying the fractions exhibiting synergistic activity with bacillomycin D, two new cyclic lipodepsipeptides (**1** and **2**) were found in the culture supernatant of this strain, together with three known metabolites, *iso*-C_{14}, *anteiso*-C_{15}, and *iso*-C_{15} [Ile^7]surfactins (**3**, **4**, and **5**). Spectroscopic and chemical analyses identified the structures of new compounds **1** and **2** as *anteiso*-C_{13} [Ile^7]surfactin, cyclo[(3*R*)-3-(L-Glu-L-Leu-D-Leu-L-Val-L-Asp-D-Leu-L-Ile-*O*)-10-methyldodecanoyl], and *iso*-C_{13} [Ile^7]surfactin, cyclo[(*R*)-3-(L-Glu-L-Leu-D-Leu-L-Val-L-Asp-D-Leu-L-Ile-*O*)-11-methyldodecanoyl], respectively (Figure 1). Finally, the synergistic effects of compounds **1**−**5** with bacillomycin D in the suppression of gray mold disease were evaluated using an in vivo cucumber leaf-disk assay.

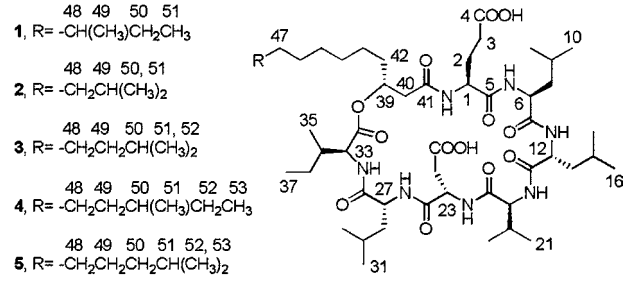

Figure 1. Structures of compounds **1**−**5**.

MATERIALS AND METHODS

General Experimental Procedures. The solvents and reagents used in this study were purchased from Sigma-Aldrich (St. Louis, MO, USA) unless otherwise noted. NMR spectra were measured with Bruker Avance II 600 and Bruker Ascend 400 systems (Bruker Daltonics, Billerica, MA, USA). The spectra for compounds **1**−**5** were acquired in DMSO-d_6 (δ_H 2.49; δ_C 39.5) at room temperature. HR-FAB-MS was obtained with a JEOL JMS-700 spectrometer (JEOL, Tokyo, Japan). Preparative HPLC and HPLC analyses were performed with a Waters Alliance system (Waters, Milford, MA, USA).

Microorganisms. Isolation and identification of the *Bacillus amyloliquefaciens* strain SD-32 were described in our previous paper.[8]

Partial Purification of Factors Effective against Gray Mold Disease. Strain SD-32 was grown at 30 °C with shaking at 150 rpm for 64 h in a 500 mL flask containing 50 mL of liquid medium, composed of maltose (80 g/L), soybean powder (80 g/L; J-OIL MILLS, Tokyo, Japan), yeast extract (10 g/L; Becton, Dickinson and Co., Franklin Lakes, NJ, USA), $MgSO_4{\cdot}7H_2O$ (2 g/L), $CaCl_2$ (2 g/L), K_2HPO_4 (1 g/L), $FeSO_4{\cdot}7H_2O$ (0.1 g/L), $MnSO_4{\cdot}5H_2O$ (0.1 g/L), and H_2O adjusted to pH 7.0 by Na_2CO_3. The culture supernatant (44 mL) was extracted with 50 mL of EtOAc three times after adjustment of the pH (pH 4.0) with HCl. The EtOAc solution was dried over anhydrous Na_2SO_4 and concentrated in vacuo. The dry extract was dissolved in H_2O, and the pH of the solution was adjusted to 7.0. The solution was purified with solid-phase extraction (C18-SPE, Oasis HLB 6g/35 cc LP Extraction Cartridge; Waters) eluted stepwise with 50 mL each of 0, 20, 40, 60, 80, and 100% (v/v) CH_3CN/H_2O containing 0.1% TFA. Each fraction was evaporated in vacuo. The residues of each fraction were dissolved in 40 mL of phosphate buffer (40 mM, pH 7.2), and each solution was evaluated in an in vivo cucumber leaf-disk assay.

HPLC Analyses of Culture Supernatant and C18-SPE Fractions. The amount of bacillomycin D in culture supernatant was determined by HPLC (XBridge C18, 250 × 4.6 mm; Waters), eluted with a linear gradient from 20 to 100% (v/v) CH_3CN/H_2O containing 0.1% TFA for 20 min at a flow rate of 1.0 mL/min at 40 °C, and detected by absorbance at 205 nm. The purified *anteiso*-C_{17} bacillomycin D was used as standard bacillomycin D.[8] The C18-SPE fractions were analyzed under the same condition.

Isolation of Compounds 1−5. Strain SD-32 was grown at 30 °C with shaking at 150 rpm for 64 h in 500 mL flasks containing medium, which was the same as the case of partial purification (50 mL/flask, 1.6 L in total). The metabolites were extracted from the culture supernatant (1.5 L) with 2 L of EtOAc three times after adjustment of the pH (pH 4.0) with HCl. The EtOAc solution was dried over anhydrous Na_2SO_4 and concentrated to dryness to afford a crude extract (4.6 g). This extract was dissolved in H_2O, and the pH of the solution was adjusted to 7.0. The solution was purified by SPE (C18-SPE, Oasis HLB 6g/35 cc LP extraction cartridge) eluted stepwise with 50 mL each of 0, 20, 40, 60, 70, 80, 90, and 100% (v/v) CH_3CN/H_2O containing 0.1% TFA. The fractions eluted with 70−80% CH_3CN/H_2O were combined and concentrated to dryness to afford a residue (0.35 g). The residue was further purified by preparative HPLC (XBridge C18, 250 × 10 mm), eluted with 70% (v/v) CH_3CN/H_2O containing 0.1% TFA at a flow rate of 4.7 mL/min at 40 °C, and detected by absorbance at 205 nm to afford the active compounds **1** (17 mg), **2** (16 mg), **3** (79 mg), **4** (15 mg), and **5** (10 mg). The purified compounds **1**−**5** were analyzed by HPLC (XBridge C18, 250 × 4.6 mm), eluted with 70% (v/v) CH_3CN/H_2O containing 0.1% TFA at a flow rate of 1.0 mL/min at 40 °C, and detected by absorbance at 205 nm.

Amino Acid Analysis. Amino acid analysis of compound **3** was conducted according to the method described in our previous paper.[8]

Matrix-Associated Laser Desorption Ionization Time of Flight (MALDI-TOF) MS/MS Analysis. MALDI-TOF MS/MS analysis of compound **3** was performed according to the method described in our previous paper.[8]

Determination of Lactone Linkage. Determination of the lactone linkage position in compound **3** was conducted according to the method reported by Naruse et al.[9] Compound **3** (10 mg) was treated with $LiBH_4$ (50 mg) in dry THF (5 mL) under reflux for 6 h. The reaction mixture was diluted with H_2O and extracted with EtOAc at pH 2.0. The extract was dried with N_2 and hydrolyzed with 6 N HCl at 110 °C for 20 h. Amino acids in the hydrolysate were analyzed according to the method described in our previous paper.[8]

Absolute Configuration of α-Amino Acids. Absolute configurations of the α-amino acids, except for the three Leu residues, of compound **3** were determined according to Marfey's method.[10] The experimental details were described in our previous paper.[8]

To determine the absolute configurations of Leu^2 and Leu^3, four tripeptides, NH_2-L-Leu-L-Leu-L-Val, NH_2-D-Leu-D-Leu-L-Val, NH_2-D-Leu-L-Leu-L-Val, and NH_2-L-Leu-D-Leu-L-Val, were used as standard peptides (Sigma-Aldrich). Compound **3** (3 mg) was hydrolyzed in 0.5 mL of 12 N HCl/AcOH (2:1, v/v) at 60 °C for 6 h and then dried with N_2. To the hydrolysate was added 150 μL of 25% (v/v) CH_3CN/H_2O, and then the solution was analyzed by LC-MS system (Prominence HPLC system, Shimadzu Corp., Tokyo, Japan; and 3200 QTRAP, AB SCIEX, Framingham, MA, USA) equipped with a reverse-phase column (Zorbax Extend C18, 150 × 2.1 mm; Agilent Technologies, Santa Clara, CA, USA), eluted with a linear gradient of 10−30% (v/v) CH_3CN/H_2O containing 0.1% formic acid in 30 min at a flow rate of 0.2 mL/min and 30 °C. Four standard tripeptides, NH_2-L-Leu-L-Leu-L-Val, NH_2-D-Leu-D-Leu-L-Val, NH_2-D-Leu-L-Leu-L-Val, and NH_2-L-Leu-D-Leu-L-Val, were eluted at 11.4, 15.5, 16.9, and 23.0 min, respectively.

To determine the absolute configuration of Leu^6, two tripeptides, NH_2-L-Asp-L-Leu-L-Ile and NH_2-L-Asp-D-Leu-L-Ile, were used as standard peptides (Sigma-Aldrich). The hydrolysate solution of compound **3** described above was analyzed by LC-MS system (Prominence HPLC system and 3200 QTRAP) equipped with a reverse-phase column (Zorbax Extend C18, 150 × 2.1 mm) and eluted with a linear gradient of 5−95% (v/v) CH_3CN/H_2O containing 0.1% formic acid in 30 min at a flow rate of 0.2 mL/min and 30 °C. Two standard tripeptides, NH_2-L-Asp-L-Leu-L-Ile and NH_2-L-Asp-D-Leu-L-Ile, were eluted at 10.4 and 11.9 min, respectively.

Absolute Configuration of the 3-Hydroxy Fatty Acid. Mosher's method was used to determine the absolute stereochemistry

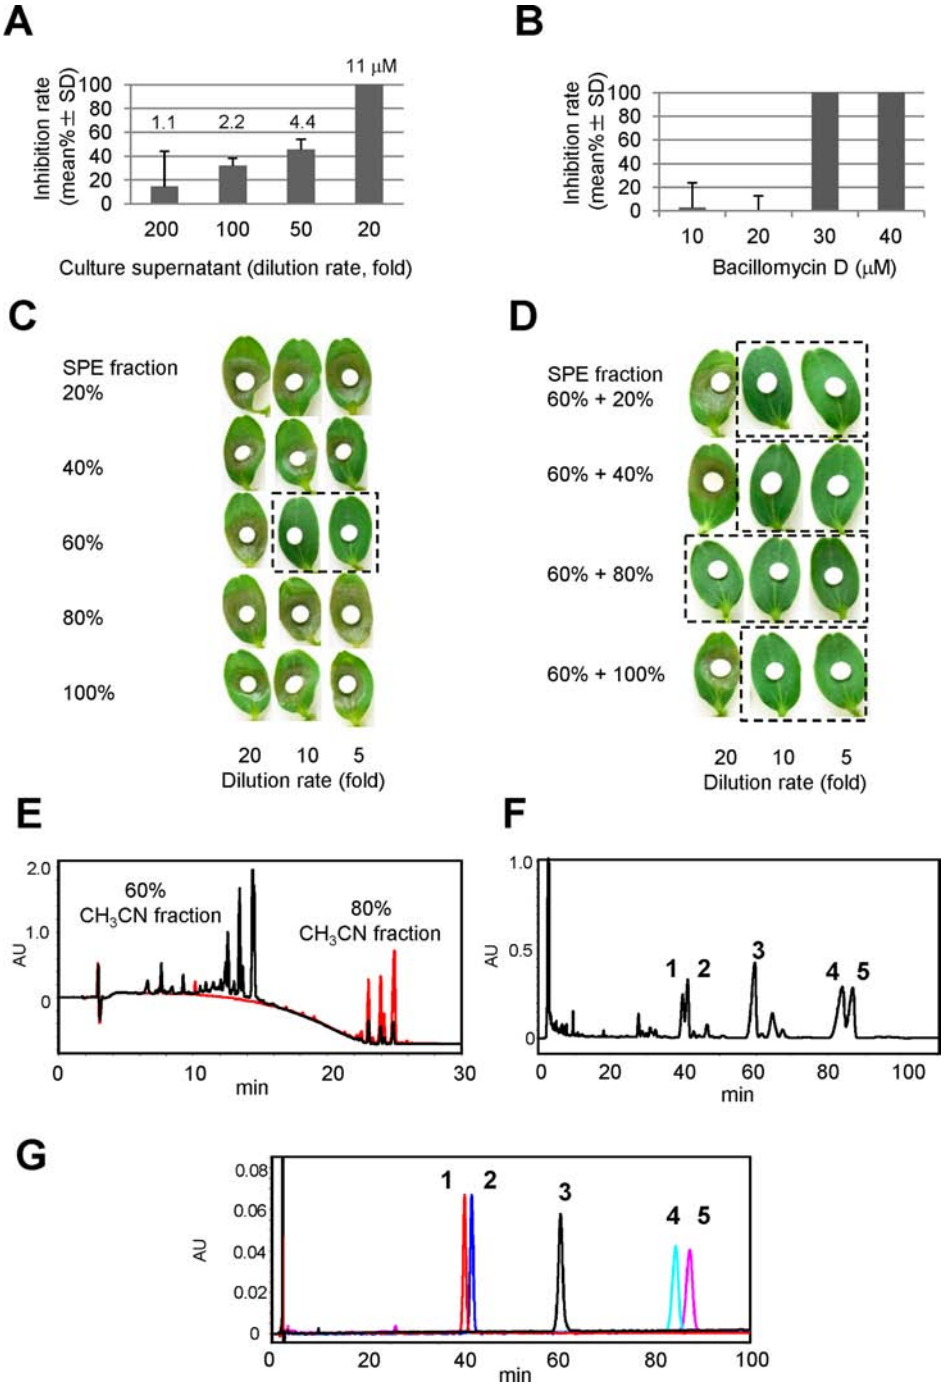

Figure 2. In vivo cucumber leaf-disk assay of the culture supernatant and C18-SPE (Oasis HLB) fractions and HPLC of the metabolites. (A) In vivo cucumber leaf-disk assay of the culture supernatant (n = 4). The values above each bar indicate the bacillomycin D concentrations. (B) In vivo cucumber leaf-disk assay of the purified *anteiso*-C_{17} bacillomycin D (n = 4). (C) In vivo cucumber leaf-disk assay of the SPE fractions. Gray mold disease was completely inhibited on the leaves in the dashed box. (D) In vivo cucumber leaf-disk assay of the SPE fractions combined with a 60% CH_3CN fraction. (E) HPLC analyses of the fractions obtained from partial purification. Chromatograms of the 60 and 80% CH_3CN fractions were overlaid: black line, 60% CH_3CN fraction containing bacillomycin D; red line, 80% CH_3CN fraction containing unknown metabolites. (F) Elution profile at the final HPLC purification step of compounds **1**−**5**. Each peak was fractionated, pooled, and then freeze-dried. (G) HPLC analyses of purified compounds. Each chromatogram was overlaid: red line, compound **1** (0.4 mg/mL); blue line, **2** (0.4 mg/mL); black line, **3** (0.5 mg/mL); sky blue line, **4** (0.5 mg/mL); purple line, **5** (0.5 mg/mL).

of the 3-hydroxy fatty acid residue.[11,12] Compound **3** (10 mg) was hydrolyzed in 1.0 mL of 6 N HCl at 110 °C for 15 h. The hydrolysate was diluted with 5 mL of H_2O, extracted with 5 mL of $CHCl_3$ three times, and dried by N_2. The residue was dissolved with 1 mL of CH_2Cl_2/MeOH (3:1, v/v) and then 0.1 mL of TMS−diazomethane (Tokyo Chemical Industry Co., Ltd., Tokyo, Japan) was added to the solution. The solution was allowed to stand at room temperature for 30 min, and the reaction was terminated by the addition of 10% acetic acid in MeOH. The solution was dried by N_2, and the residue was dissolved in 0.5 mL of dry CH_2Cl_2 and mixed with 5.0 mg of (dimethylamino)pyridine, 2.8 μL of triethylamine, and 3.8 μL of (+)-MTPA chloride (Tokyo Chemical Industry). The solution was

[a]Compound **3**, 150 MHz; **1**, **2**, **4**, and **5**, 100 MHz. [b]Overlapped with DMSO. [c]Assignments may be interchanged in each column. [d]Overlapped in each column. [e]Assignments may be interchanged in each column. [f]Overlapped in each column.

allowed to stand at room temperature for 4 h. 3-[(Dimethylamino)-propyl]amine (1.9 μL) was added, and after standing for 10 min, the solution was poured into 10 mL of 0.6 N HCl and extracted with 10 mL of EtOAc three times. The EtOAc extract was washed twice with 10 mL of 0.1 M $NaHCO_3$ and evaporated, affording (*R*)-MTPA ester of 3-hydroxy fatty acid methyl ester. The (*S*)-MTPA ester of 3-hydroxy fatty acid methyl ester was prepared according to the same procedure using (−)-MTPA chloride in place of (+)-MTPA chloride.

In Vivo Cucumber Leaf-Disk Assay against *B. cinerea*. Cucumber seeds (*Cucumis stativus* L. Sagami-Hanjiro) were planted in 12 cm pots containing artificial soil and grown in the greenhouse at 16−23 °C without supplemental lighting. The cotyledons were collected from 3-week-old plants. The test compound (or supernatant) was dissolved in an appropriate amount of phosphate buffer (40 mM, pH 7.2), and 50 μL of the solution was applied to a paper disk (8 mm in diameter, thick type, Advantec Toyo Kaisha, Ltd., Tokyo, Japan) on the cucumber cotyledon. For the control, only phosphate buffer was applied. Then the paper disks on the leaves were inoculated with 50 μL of *B. cinerea* spore suspension (2×10^4/mL) containing 0.2% (w/v) yeast extract and 2% (w/v) sucrose. The leaves were kept in a humidity chamber (RH > 95%) at 20 °C for 4 days in darkness. The experiment was repeated four times. The inhibition rate of *B. cinerea* infection was calculated as

$$\text{inhibition rate of infection (\%)} = (1 - D_a/D_b) \times 100$$

where D_a is the diameter of the infection zone in the leaf with a test compound and D_b is the diameter of the infection zone in the control leaf. The results were expressed as inhibition rate (mean % ± SD). The assay was observed under a stereomicroscope SZX7 (Olympus Co., Tokyo, Japan).

In Vitro Mycelial Growth Inhibition Assay. The assay procedure and calculation methods were described in our previous paper.[8] The combined action of two compounds was evaluated using Abbott's formula.[13] The expected efficacy of a mixture of two compounds, expressed as E_{exp}, can be predicted by Abbott's formula:

$$E_{exp} = c + d - (cd/100)$$

c and d are the control levels given by the single compounds. Synergistic interaction was determined to be present in the mixture when the ratio of the experimentally observed efficacy of the mixture (E_{obs}) to the expected one (E_{exp}) was >1.

In Vitro Conidial Germination Inhibition Assay. The compound was dissolved in an appropriate amount of phosphate buffer (40 mM, pH 7.2), and 100 μL of the solution was applied to a tissue culture plate (a 96-well flat-bottom plate with a low evaporation lid; Becton, Dickinson and Co.). For the control, only phosphate buffer was applied. The solution in each well of the tissue culture plate was supplied with 100 μL of *B. cinerea* conidia (2×10^4/mL) containing 0.2% (w/v) yeast extract and 2% (w/v) sucrose. Compound **3** and *anteiso*-C_{14} bacillomycin D were tested at final concentrations of 20 and 4 μM, respectively. The tissue culture plate was kept at 20 °C for 20 h in darkness. The germination of conidia was observed under a light microscope CK2 (Olympus Co.). The assay was done in triplicate.

RESULTS AND DISCUSSION

Contribution of Bacillomycin D to the Suppressive Activity of the Culture Supernatant against Gray Mold Disease. Strain SD-32 produces C_{15-17} bacillomycin D homologues, which are powerful antifungal lipopeptides.[8] To clarify the actual contribution of bacillomycin D to the suppressive activity of the culture supernatant against gray mold disease, we subjected the culture supernatant to an in vivo cucumber leaf-disk assay and also measured the bacillomycin D concentration in the culture supernatant. A 20-fold dilution of the culture supernatant was sufficient to inhibit the infection of *B. cinerea* completely, and the total concentration of bacillomycin D homologues in this solution was 11 μM (Figure 2A). In this assay, 30 μM bacillomycin D was needed to completely control *B. cinerea* (Figure 2B),[8] suggesting that factors other than bacillomycin D contributed to the effect of the culture supernatant on gray mold disease. These data prompted us to perform the following experiments.

Contribution of Synergistic Factors to the Control of Gray Mold Disease. We partially purified the culture supernatant from SD-32 culture with EtOAc extraction followed by solid-phase extraction (C18-SPE) and evaluated the activities of each fraction. The 60% CH_3CN fraction of C18-SPE showed a suppressive effect against gray mold disease in the in vivo assay (Figure 2C), and this fraction contained bacillomycin D homologues (Figure 2E). Fractions other than the 60% CH_3CN fraction showed no suppressive effects (Figure 2C); interestingly, however, the activity of the 60% fraction was enhanced 2-fold in the presence of the 80% CH_3CN fraction (Figure 2D), suggesting a synergistic effect of the 80% CH_3CN fraction with bacillomycin D homologues. The 80% CH_3CN fraction did not contain bacillomycin D, but did contain several unidentified metabolites (Figure 2E). These data led us to isolate and identify the synergistic factors in the 80% fraction.

Isolation of Compounds 1−5 from *Bacillus amyloliquefaciens* SD-32. SD-32 was cultured in a medium (1.6 L) composed of maltose, soybean powder, yeast extract, and some minerals at 30 °C for 64 h. Synergistic activity-guided purification of the EtOAc extract of the culture supernatant with SPE and preparative HPLC afforded compounds **1** (17 mg), **2** (16 mg), **3** (79 mg), **4** (15 mg), and **5** (10 mg) as white amorphous powders (each purity >90%). The elution profile at the final HPLC purification step is shown in Figure 2F. The chromatograms of each purified compound are shown in Figure 2G.

Structures of Compounds 1−5. Compound **3** was the most abundant in the culture broth, and therefore its structure was elucidated first. Compound **3** gave an $[M + Na]^+$ peak at m/z 1044.6602 (calcd for $C_{52}H_{91}N_7O_{13}Na$, 1044.6573) in HR-FAB-MS. Five α-amino acids, Leu, Glu, Val, Asp, and Ile, were found in a 3:0.9:0.9:0.9:0.7 ratio in an amino acid analysis of the hydrolysate. The ^1H NMR data for compound **3** (Table 1) indicated the presence of seven amide protons (δ_H 8.34−7.68) and seven α-protons (δ_H 4.53−4.08, partially overlapped) of amino acid residues of the peptide. The ^{13}C NMR (Table 2)

DOI: 10.1021/acs.jafc.5b01198
J. Agric. Food Chem. 2015, 63, 5344−5353

and HSQC data for compound **3** exhibited 50 signals (δ_C 172.1 and 22.5; 2C each), including 9 carbonyl (δ_C 174.1−169.4; δ_C 172.1, 2C), 1 methylene (δ_C 41.6−24.5), and 11 methyl carbon signals (δ_C 23.1−11.1; δ_C 22.5, 2C). On the basis of the ^{1}H−^{1}H COSY, HSQC, HMBC, and NOESY data (Figure 3A) and the molecular formula, compound **3** was deduced to be *iso*-C_{14} [Ile^7]surfactin, a cyclic depsipeptide consisting of three Leu residues, one Glu, one Val, one Asp, and one Ile residue and a 3-hydroxy fatty acid with a $-(CH_2)_8CH(CH_3)_2$ group as a side chain. To obtain the sequence information, compound **3** was analyzed by MALDI-TOF MS/MS to afford the sequence shown in Figure 3B, which corresponded with that of *iso*-C_{14} [Ile^7]surfactin. Then, to determine the location of the lactone linkage, compound **3** was reduced with $LiBH_4$ in THF and the amino acid composition of the product was analyzed. The reaction product lacked the Ile residue (Figure 3C; the intact and reduced compound **3** afforded Leu, Val, Glu, Asp, and Ile in the ratios 3:0.9:0.9:0.9:0.7 and 3:1:0.8:0.9:0.03, respectively), indicating that the lactone linkage was between the carboxyl group of Ile and the 3-hydroxy group of the fatty acid. From these results compound **3** was determined to be *iso*-C_{14} [Ile^7]surfactin (Figure 1).

The absolute configurations of α-amino acids in compound **3** were determined by treatment of the hydrolysate with Marfey's reagent[10] and HPLC analyses of the derivatives. The hydrolysate was shown to contain L-Glu, L-Val, L-Asp, L-Ile, L-Leu, and D-Leu. There is no ambiguity in the absolute configuration of the four amino acids other than Leu. The absolute configurations of Leu^2 and Leu^3 were determined by LC-MS comparison of the tripeptide in the products from the partial hydrolysis of compound **3** with four synthesized tripeptides, NH_2-L-Leu-L-Leu-L-Val, NH_2-D-Leu-D-Leu-L-Val, NH_2-D-Leu-L-Leu-L-Val, and NH_2-L-Leu-D-Leu-L-Val. The existence of NH_2-L-Leu-D-Leu-L-Val in the hydrolysate allowed us to determine the absolute configuration of Leu^2 and Leu^3 to be L and D, respectively. The absolute configuration of Leu^6 was also determined by LC-MS comparison of the tripeptide in the products from the partial hydrolysis of compound **3** with two synthesized tripeptides, NH_2-L-Asp-L-Leu-L-Ile and NH_2-L-Asp-D-Leu-L-Ile. The existence of L-Asp-D-Leu-L-Ile in the hydrolysate finally established the amino acid sequence, NH_2-L-Glu-L-Leu^2-D-Leu^3-L-Val-L-Asp-D-Leu^6-L-Ile. The absolute configuration at C-3 of the fatty acid part of compound **3** was determined according to the modified Mosher's method[11,12] as shown in Figure 3D. ^{1}H NMR spectra of the (*R*)-MTPA and (*S*)-MTPA esters of 3-hydroxy fatty acid methyl ester were measured, respectively, and from the $\Delta\delta_{(S-R)}$ values the absolute configuration of C-3 was determined to be *R*.

The HR-FAB-MS of compounds **1** and **2** showed their $[M + H]^+$ ion peaks at *m/z* 1008.6581 (calcd for $C_{51}H_{90}N_7O_{13}$, 1008.6596) and 1008.6575 (calcd for $C_{51}H_{90}N_7O_{13}$, 1008.6596), respectively. The HR-FAB-MS of compounds **4** and **5** showed their $[M + Na]^+$ ion peaks at *m/z* 1058.6741 (calcd for $C_{53}H_{93}N_7O_{13}Na$, 1058.6729) and 1058.6727 (calcd for $C_{53}H_{93}N_7O_{13}Na$, 1058.6729), respectively. A series of NMR spectral analyses revealed that compounds **1**, **2**, **4**, and **5** had the same amino acid sequence as compound **3** but differed from compound **3** with respect to the structure of their 3-hydroxy fatty acids. The ^{1}H NMR and ^{13}C NMR spectra of compounds **1**, **2**, **4**, and **5** showed the presence of the $-(CH_2)_6CH(CH_3)CH_2CH_3$, $-(CH_2)_7CH(CH_3)_2$, $-(CH_2)_8CH(CH_3)CH_2CH_3$, and $-(CH_2)_9CH(CH_3)_2$ groups, respectively. Thus, we concluded that compounds **1**, **2**, **4**, and **5** were *anteiso*-C_{13}, *iso*-C_{13}, *anteiso*-C_{15}, and *iso*-C_{15} [Ile^7]surfactin, respectively (Figure 1).

Compounds **3**, **4**, and **5** are known,[14−18] and **1** and **2** are new. Compounds **1** and **2** have *anteiso*- and *iso*-C_{13} 3-hydroxy fatty acids and seven α-amino acids with the same chiral sequence, LLDLLDL, as the surfactin family. Surfactins are cyclic lipodepsipeptides produced by several strains of *Bacillus* species and contain seven α-amino acids and a 3-hydroxy fatty acid. Standard surfactin possesses a heptapeptide moiety, L-Glu^1-L-Leu^2-D-Leu^3-L-Val^4-L-Asp^5-D-Leu^6-L-Leu^7, linked by an ester bond to an (*R*)-3-hydroxy fatty acid.[19−21] In addition to standard surfactin, [Ala^4]surfactin,[22,23] [Leu^4]surfactin,[24] [Ile^4]-surfactin,[24] [Val^7]surfactin,[14−16,25−27] [Ile^7]surfactin,[14−18] and halobacillin[28,29] (or lichenysins)[30,31] have been reported as main variants. [Ile^7]surfactin homologues have been reported to be produced by *Bacillus subtilis*[14,16−18] and *Bacillus licheniformis*.[15] The present study shows that *B. amyloliquefaciens* strain SD-32 is a producer of [Ile^7]surfactin homologues. Recently, the ^{13}C NMR data (in DMSO) of *anteiso*-C_{15} [Ile^7]surfactin were reported by Tang et al.,[18] and our ^{13}C NMR data for compound **4** were identical to the data in their report, except for the chemical shift of αCH of Ile^7 (δ_C 56.5, present study; δ_C 50.7, reported). The metabolite in the HPLC fraction from *Bacillus subtilis* OKB 105 was characterized from NMR and MS data as C_{13} [Ile^7]surfactin by Kowall et al.,[17] although its chemical structure was not unambiguously determined.

Synergistic Actions of Compounds 1−5 with Bacillomycin D in an in Vivo Cucumber Leaf-Disk Assay against Gray Mold Disease. The effects of compounds **1−5** on the suppressive activity of bacillomycin D were evaluated. The results are shown in Table 3 and Figure 4A. When administered singly, bacillomycin D (10, 15, and 20 μM) did not inhibit the development of gray mold disease on cucumber leaves. Compounds **1−5** (20 and 100 μM) also exhibited no inhibition of gray mold disease in cucumber leaves when administered alone, suggesting that compounds **1−5** (20 and 100 μM) could neither inhibit the growth of *B. cinerea* directly nor induce the resistance of cucumber leaves to gray mold disease. However, the addition of compounds **1−5** (20 and 100 μM) to bacillomycin D (10, 15, and 20 μM) significantly enhanced the effect of bacillomycin D activity in the in vivo assay, indicating that compounds **1−5** have synergistic activities with bacillomycin D under this condition. The inhibition rates of compounds **1−5** (100 μM) with bacillomycin D (10 μM) were 26.8, 51.2, 78.7, 81.7, and 66.5%, indicating that the C_{14} and C_{15} [Ile^7]surfactins were more active than the C_{13} [Ile^7]surfactins. Although these data could not fully explain the suppressive activity gap between the culture supernatant and bacillomycin D in it, they clearly demonstrated that the [Ile^7]surfactin homologues enhance the suppressive activity of bacillomycin D against gray mold disease and can partially close the gap.

To examine the mechanism underlying the synergism of the [Ile^7]surfactin homologues with bacillomycin D, a mycelial growth inhibition assay and a conidial germination inhibition assay using *B. cinerea* were performed in vitro (Figure 4B,C). In the mycelial growth inhibition assay, no significant difference between E_{obs} and E_{exp} was observed, and thus the effect of compound **3** on the activity of bacillomycin D was additive (Figure 4B). In the conidial germination inhibition assay, the addition of 20 μM of compound **3** to 4 μM of bacillomycin D did not enhance the activity of bacillomycin D (Figure 4C).

[a]Data are expressed as inhibition rate (mean % ± SD, $n = 4$). Groups significantly different (by ANOVA followed by Dunnett's test) from the control group (bac D only) in each row are shown by * ($P < 0.05$) or ** ($P < 0.01$). [b]*ai*-C_{17} Bacillomycin D was used.

Finally, we conducted stereomicroscope observation in the cucumber leaf-disk assay (Figure 4D). The synergistic activity to the disease was observed in the condition 20 μM of compound **3** with 20 μM of bacillomycin D, although mycelial growth of *B. cinerea* was apparently normal in the same condition. These data suggested that the synergistic action of [Ile[7]]surfactin and bacillomycin D does not interfere with the mycelial growth and conidial germination of the gray mold, but rather might inhibit infection processes such as appressorium formation and penetration into the host.

Surfactin family lipodepsipeptides are well-known to act as potent surface-active compounds and antibiotics against a number of bacteria and phytopathogenic fungi.[32] In addition, recent investigations have illustrated a number of other diverse activities for these compounds, including roles in the induction of plant resistance or the mechanism of biofilm formation as part of the biological control system of *Bacillus* species.[7] The present study has shed light on a novel role of [Ile[7]]surfactin homologues in the biological control system of strain SD-32, namely, the compounds were shown to work synergistically with bacillomycin D in controlling gray mold disease under natural conditions, and this synergism may be particularly important for inhibiting the infection process of gray mold in cucumber leaves.

It has been reported that *B. amyloliquefaciens* produces a wide variety of bioactive metabolites such as nonribosomally synthesized polyketides (bacillaenes, difficidin, oxidifficidin, and macrolactins),[33,34] siderophore (bacillibactin),[35] lipopeptide (bacillomycin D),[36] and lipodepsipeptides (surfactins and fengysins or plipastatins)[36] and ribosomally synthesized peptides (plantazolicins).[37] However, to our best knowledge, interactions of each metabolite have not been investigated.

Many *Bacillus* strains have been reported to produce surfactin and bacillomycin D simultaneously,[36,38−41] but the interaction of bacillomycin D and surfactin has not been studied. In contrast, several researchers have focused on the interactions of standard surfactin and iturin A.[42−44] Bacillomycin D belongs to the iturin class lipopeptides, and bacillomycin D (Asn-Tyr-Asn-Pro-Glu-Ser-Thr-β-AA) and iturin A (Asn-Tyr-Asn-Gln-Pro-Asn-Ser-β-AA) have closely related structures.[7] Hiraoka et al.[42] showed that *B. subtilis* RB14 produced both standard surfactin and iturin A and that the standard surfactin could enhance the in vitro activity of iturin A against *Fusarium oxysporum*. They discussed the importance of the structural similarities between surfactin and iturin A in their synergism. Thimon et al.[43] reported that the antifungal activity of iturin A against *Saccharomyces cerevisiae* in vitro was enhanced in the presence of standard surfactin and that this effect was clear at a subinhibitory concentration of iturin A. Their results are in agreement with ours from the point of view of the necessary concentration, although we found their synergism not in vivo but in vitro. A mechanism for the antibiotic action of bacillomycin D and the other lipopeptides has been proposed.[44−46] Lipopeptide molecules penetrate the cytoplasmic membrane of the target cell and form oligomeric structures (lipopeptide aggregates) that are ion-conducting. Maget-Dana et al.[47] stated that the marked surfactant properties of surfactin helped iturin A to reach and disrupt the membrane of the target cells. In our experiment, however, the synergistic action of [Ile[7]]surfactin and bacillomycin D was not observed with respect to in vitro mycelial growth or the conidial germination inhibition assays. These data clearly suggest that the synergistic

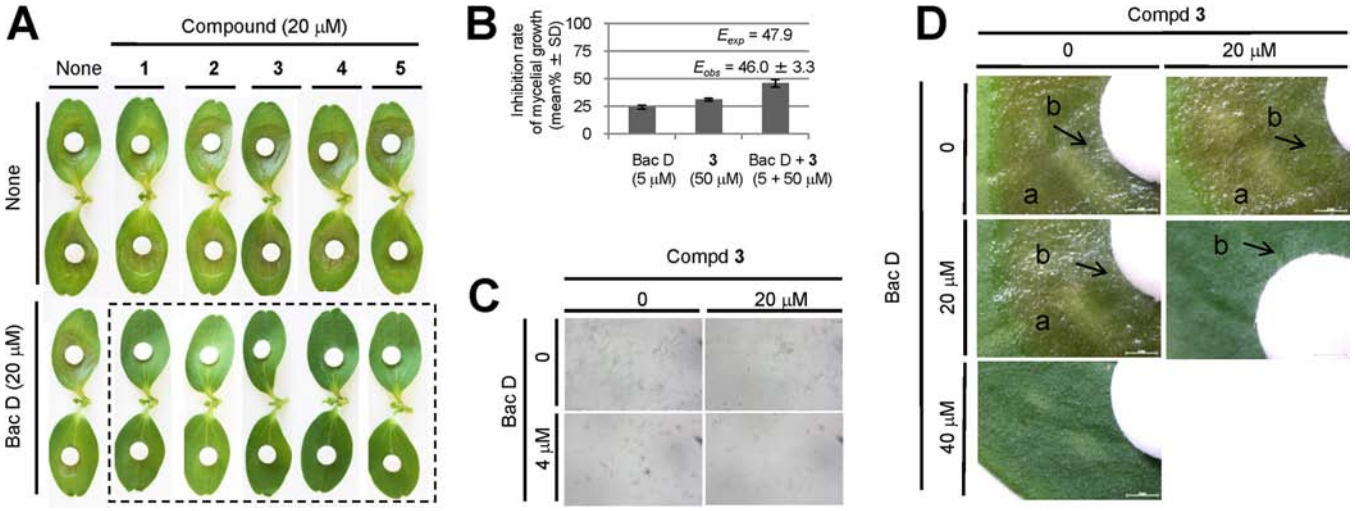

Figure 4. In vivo and in vitro assays of compounds **1**−**5** with bacillomycin D against *B. cinerea*. (A) In vivo assay of compounds **1**−**5** with bacillomycin D using cucumber cotyledon and *B. cinerea* (n = 4). Bac D indicates *anteiso*-C_{17} bacillomycin D. Gray mold disease was completely inhibited on the leaves in the dashed box. (B) Mycelial growth inhibition assay of compound **3** with bacillomycin D in vitro (n = 3). (C) Conidial germination inhibition assay of compound **3** with bacillomycin D in vitro (n = 3). (D) Stereomicroscope observation of in vivo assay of compound **3** with *anteiso*-C_{17} bacillomycin D. Scale bar indicates 2 mm. (a) Infection zone of *B. cinerea*; (b) mycelial growth of *B. cinerea*.

actions of [Ile^7]surfactin and bacillomycin D were different from those of surfactin and iturin A.

The detailed mechanism by which [Ile^7]surfactin homologues enhanced the suppressive effect of bacillomycin D in the cucumber leaf-disk assay is still unknown and remains to be studied. In addition, the data shown in this study could not fully explain the suppressive activity gap between the culture supernatant and bacillomycin D in it. Therefore, to close the gap in the suppression realized by the culture supernatant and bacillomycin D, research to identify relevant factors other than [Ile^7]surfactin and bacillomycin D should be continued.
