ABSTRACT: Myrcene, a monoterpene (C_{10}), has gathered attention as a starting material for high-value compounds, such as geraniol/linalool and (−)-menthol. Metabolic engineering has been successfully applied to produce monoterpenes, such as pinene and limonene, at high levels in microbial hosts. However, microbial synthesis of myrcene has not yet been reported. Thus, we metabolically engineered *Escherichia coli* for production of myrcene by introducing a heterologous mevalonate pathway and overexpressing tailoring enzymes, such as geranyl diphosphate synthase (GPPS) and myrcene synthase (MS). Although MSs have broad ranges of functionality for producing various monoterpenes, our engineered *E. coli* strains harboring MS from *Quercus ilex* L. produced only myrcene (1.67 ± 0.029 mg/L). Subsequent engineering resulted in higher production of myrcene by optimizing the levels of GPPS in amino-acid-enriched (EZ-rich) defined medium, where glycerol as a carbon source was used. The production level of myrcene (58.19 ± 12.13 mg/L) was enhanced by 34-fold using *in situ* two-phase extraction to eliminate cellular toxicity and the evaporation of myrcene.

KEYWORDS: *mevalonate pathway, metabolic engineering, monoterpene, myrcene*

INTRODUCTION

Monoterpenes [C_{10} terpenes, consisting of two isoprene (C_5) units] are an important and large class of natural products that are widely used in the cosmetic and pharmaceutical industries.[1,2] Either the mevalonate (MVA) pathway[3] in eukaryotes and some bacteria or the methylerythritol phosphate (MEP) pathway[4] in plastids, bacteria, protozoa, and algae can produce isopentenyl diphosphate (IPP) and dimethylallyl disphosphate (DMAPP). These are catalyzed by prenyltransferase to form geranyl diphosphate (GPP, a precursor to monoterpene), which is further converted to monoterpene by various monoterpene synthases. Over 1000 naturally occurring monoterpenes (C_{10}; acylic-, mono-, and bicyclic monoterpene isomers) have been identified among the volatile organic compounds found in the resins of many woody plants, notably in citrus plants.[5]

Among the monoterpenes, myrcene (β-myrcene, the only naturally occurring isomer) has been considered as a starting material for complex compounds, including heteroatom-linked chemicals (nerol/geraniol/linalool) and carbon-rearranged chemicals [(−)-menthol], which can be used as commercial olefinic scents.[1] Myrcene synthase (MS) encoded by cDNA from flowers,[6] grand fir,[7] holm oak,[8] and labiatae leaves[9] was isolated and functionally characterized. Although myrcene can be extracted from essential oils or derived from β-pinene by pyrolysis, economic large-scale production has not yet been commercialized because of the high volatility of the substance and the inefficiency of the harvesting technology. Thus, development of engineered microbial platforms for large-scale industrial production is needed to provide myrcene from sugars.[10,11]

Metabolic engineering of microorganisms has enabled production of monoterpenes, such as α/β-pinene,[12−14] limonene,[15,16] and sabinene.[17] The monoterpenes were biosynthesized in *Escherichia coli* by introducing a heterologous MVA pathway for re-directing carbon flux from acetyl-coA to IPP/DMAPP and in a yeast by engineering the native MVA pathway. However, the levels of monoterpenes are lower than the levels of sesquiterpene[18,19] (C_{15}) or diterpene[20] (C_{20}) from the same microbial hosts, suggesting that geranyl pyrophosphate synthase (GPPS) and monoterpene synthase are still bottlenecks to high-level productions. It is also important that monoterpenes, including myrcene, are toxic to microbial hosts (minimum inhibitory concentrations: myrcene, 2.12 mM; β-pinene, 1.45 mM; and limonene, 0.44 mM, for yeast).[12,15,21,22]

Here, we report metabolic engineering of *E. coli* for the production of myrcene using heterologous expression of the MVA pathway and engineering at prenyl phosphate nodes with overexpression of GPPS and MS. In addition, the toxicity of myrcene was investigated and relieved in *E. coli* using *in situ* two-phase extraction. Further biological engineering to optimize high-cell-density fermentation will be the next challenge for achieving high-level myrcene production for industrial applications.

MATERIALS AND METHODS

Construction of Plasmids and Strains. *E. coli* DH5α (RBC Bioscience, Songnam, South Korea) was used as a host for cloning.

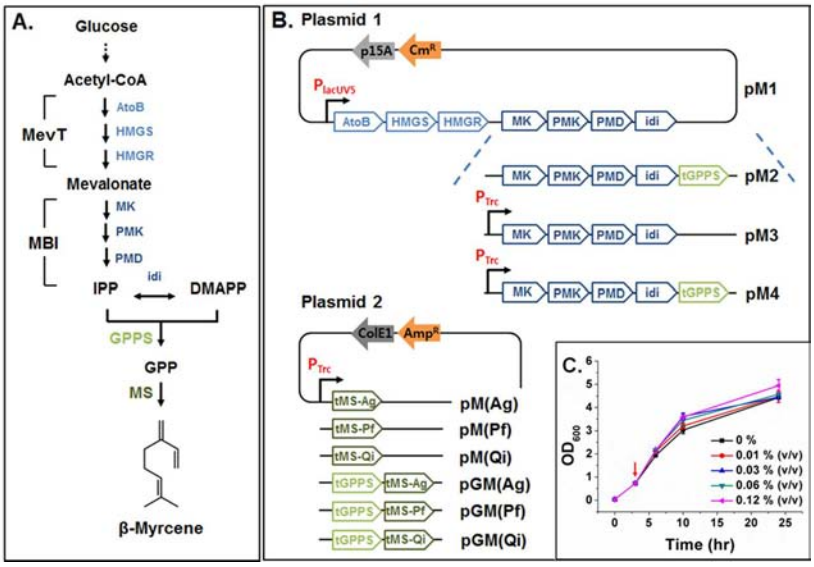

Figure 1. Scheme of myrcene production in engineered *E. coli* and the cellular toxicity of myrcene. (A) Construction of the myrcene biosynthetic pathway in *E. coli*. The heterologous MVA pathway in *E. coli* consists of six enzymes for conversion from acetyl-CoA to IPP. To convert IPP to myrcene, GPPS and MS were expressed. Abbreviations of the corresponding genes to the MVA pathway were described in the Materials and Methods. (B) Plasmid construction for metabolic engineering of *E. coli* for myrcene production. A two-plasmid system was used. Plasmid 1 contains genes corresponding to the MVA pathway or MVA pathway with truncated AgGPPS2 on a medium copy number vector and medium strength promoter. Plasmid 2 harbors genes encoding for tMS or tGPPS2-MS on a high copy number vector and strong promoter. Three different kinds of MSs were introduced. (C) Cellular toxicity test of myrcene to *E. coli*. Growth of *E. coli* under various concentrations of myrcene [0, 0.01, 0.03, 0.06, and 0.12% (v/v)] was tested. The arrow indicates the myrcene addition to the culture medium at OD_{600} of 1.

All plasmids and strains used in this study are listed in Table 1. All plasmids were prepared from the BglBrick expression plasmid library using the BglBrick standard cloning method.[23,24]

For construction of the heterologous MVA pathway in *E. coli*, the top portion (MevT) of the MVA pathway (Figure 1A) contains three genes needed for the conversion of acetyl-CoA to MVA.[18] These are the genes encoding for acetyl-CoA thiolase (AtoB from *E. coli*), 3-hydroxyl-3-methyl-glutaryl-coA synthase, and reductase (HMGS and HMGR from *Saccharomyces cerevisiae*). The bottom portion (MBI) of the MVA pathway contains four genes for the conversion of MVA to IPP and DMAPP.[25] These are the genes encoding mevalonate kinase (MK from *S. cerevisiae*), phosphomevalonate kinase (PMK from *S. cerevisiae*), mevalonate diphosphate decarboxylase (PMD from *S. cerevisiae*), and isopentenyl diphosphate isomerase (Idi from *E. coli*). For construction of the MVA pathway plasmids (plasmid 1 in Figure 1B), the gene encoding for farnesyl disphodphate synthase from *E. coli* (*ispA*) was removed from pBbA5c-MevT(co)-MBIS(co, ispA)[25] using polymerase chain reaction (PCR) amplification of MevT(co)-MBI(co) (forward primer, 5′-ATT GAA TTC AAA AGA TCT AAA GGA GGC C-3′; reverse primer, 5′-TAT CTC GAG TTT GGA TCC TTA TTT AAG CTG GGT AAA TGC AG-3′, where underlines describe restriction enzyme sites), which was inserted into the pBbA5c plasmid. This resulted in a pM1 plasmid (Table 1). An additional pTrc promoter was inserted into a pM1, to construct a single operon of MevT and MBI, resulting in a pM3 plasmid. The DNA sequences were confirmed by DNA sequencing.

To convert IPP/DMAPP to myrcene, a myrcene production plasmid containing genes encoding for MS and GPPS was constructed. The

J. Agric. Food Chem. 2015, 63, 4606−4612

N-terminal plastid-targeting sequence of MSs and GPPS2 was truncated, and four codon-optimized genes (three MSs and one GPPS2) were synthesized (GenScript, Inc., Piscataway, NJ). Using the SignalP 4.1 server, amino acid sequences for signal peptide cleavage were predicted as followings: MS(Ag), 1−62; MS(Pf), 1−57; MS(Qi), 1−56; and GPPS2(Ag), 1−84, in the amino acid sequence. The genes encoding for MS were cloned in a pBbE1a, resulting in pM(Ag), pM(Pf), and pM(Qi). Subsequently, the gene encoding for GPPS2 was cloned into MevT-MBI plasmids (pM1 and pM3), resulting in pM2 and pM4. In addition, the *GPPS2* gene was cloned into the myrcene production plasmids, yielding the series pGM(Ag), pGM(Pf), and pGM(Qi). The gene accession numbers of MSs and GPPS2 are MS(Ag) from *Abies grandis* (AAB71084), MS(Pf) from *Perilla frutescens* (AAF76186), MS(Qi) from *Quercus ilex* L. (CAC41012), and GPPS2 from *A. grandis* (AF513112).

For myrcene production, the MevT-MBI plasmids and the myrcene production plasmids were combinatorially co-transformed into a *E. coli* DH1 strain, yielding different myrcene production strains.

Growth Conditions for Myrcene Toxicity Test. *E. coli* DH1 was used as a host for the myrcene toxicity test and was cultured in an amino-acid-enriched (EZ-rich) defined medium (Teknova, Hollister, CA) in an Erlenmeyer flask (250 mL) at 37 °C and 200 rpm. When cell densities reached an OD_{600} of 0.8−1.0, different concentrations of myrcene [0, 0.01, 0.03, 0.06, 0.12% (v/v)] were added for the myrcene toxicity test in the absence of dodecane overlay. Then, cells were cultivated at 30 °C and 200 rpm for optical density (OD) measurements.

Growth Conditions for Myrcene Production. *E. coli* DH1 was used as a host for myrcene production and was pre-cultured in Luria−Bertani (LB) medium. Myrcene production strains were grown in the three different media: LB medium, EZ-rich defined medium (Teknova, Hollister, CA), or M9-MOPS medium [M9 salt, 75 mM 3-(*N*-morpholino)propanesulfonic acid (MOPS), 2 mM $MgSO_4$, 0.01 mM $CaCl_2$, 1 mg/L thiamine·HCl, and 2.78 mg/L $FeSO_4$ at pH 7]. The micronutrients provided were 3 nM ammonium molybdate, 0.4 μM boric acid, 30 nM cobalt chloride, 23 nM cupric sulfate, 80 nM manganese chloride, and 10 nM zinc sulfate. These were supplemented with either 1% glucose or 1% glycerol. Chloramphenicol (Cm) and ampicillin (Amp) were provided for plasmid maintenance at final concentrations of 30 and 100 μg/mL, respectively.

Pre-cultured production strains were added to inoculate the media (1:100 dilution). For the cultivation in M9-MOPS medium, cells were adapted to M9-MOPS medium. The cultures (50 mL) were grown in an Erlenmeyer flask (250 mL) at 37 °C and 200 rpm. When cell densities reached at OD_{600} of 0.8−1.0, 100 μM isopropyl-β-D-1-thiogalactopyranoside (IPTG) was added for induction and 20% (v/v) dodecane overlay was added for *in situ* extraction. Cells were cultivated at 30 °C and 200 rpm for production of myrcene. Samples were collected from the dodecane layer at 24, 48, and 72 h for quantification of myrcene.

Myrcene Analysis and Quantification. After the centrifugation (4400*g* for 10 min), the dodecane layers were collected. The collected samples (20 μL) were diluted with ethyl acetate (980 μL) containing 5 μg/mL (−)-*trans*-caryophyllene as an internal standard. To quantify myrcene, the diluted samples were analyzed using gas chromatography−mass spectrometry [GC−MS, Aglilent 6890N series GC/TOF-MS (LECO), under these conditions: injector temperature, 250 °C; flow rate, 1.2 mL/min; split ratio, 2:1; oven initially at 60 °C for 5 min, followed by 4 °C/min, and increase to 240 °C; carrier gas, He; and HP-Ultra2 column (25 m long, 0.2 mm diameter, and 0.11 μm film thick)]. Myrcene (CAS Registry Number 123-35-3) was used as an authentic standard for quantitative analysis, and the concentrations were normalized using an internal standard. All chemicals used in this study were purchased from Sigma-Aldrich.

RESULTS AND DISCUSSION

Development of the *E. coli* Strain for Myrcene Production. For microbial production of myrcene, a two-plasmid system was employed to modulate the MVA pathway and terpene biosynthesis as previously studied.[18,26] The first plasmid, MevT-MBI (plasmid 1 in Figure 1B), consisted of seven genes of the heterologous MVA pathway (see the Materials and Methods). As shown by the authors of the previous studies,[15,18,26] balanced gene expression was crucial for high-level production of terpenes. Because a pBbA5c vector containing a medium copy origin and a medium strength promoter has worked for production of various terpenes, including mono- and sesquiterpenes,[12,18,27] we also chose the pBbA5c vector for the expression of MVA pathway genes. In combination with the MevT-MBI plasmid, we chose the pBbE1a vector (the second plasmid), which has a high copy origin and a strong pTrc promoter. Thus, MS was overexpressed in the pBbE1a vector (plasmid 2 in Figure 1B) to achieve myrcene production based on the "push and pull strategy" of metabolic engineering. Also, this two-plasmid system allowed screening for more efficient MS versions, from diverse candidates.

Another important strategy for myrcene production is providing sufficient intermediates. Biosynthesis of monoterpene in an engineered *E. coli* was previously limited because of insufficient GPP and the low activity of monoterpene synthase.[12,14] Combinational expression of tGPPS2 from *A. grandis* and pinene synthase Pt30 from *Pinus taeda* increased α-pinene production significantly up to 5.44 mg/L in a shaking flask and 0.95 g/L in fed-batch fermentation.[14] Thus, we used tGPPS2 from *A. grandis*, specific geranyl diphosphate synthase, which has been shown to achieve high production results in monoterpene synthesis.[12,15] Truncated AgGPPS2 was expressed in different plasmids to optimize gene expressions in (1) MevT-MBI plasmids (pM2/pM4), (2) myrcene production plasmids (pGM), and (3) both plasmids. AgGPPS2 expressions from different gene expression platforms could produce different levels of GPP, which are used as a substrate for MS. Also, higher levels of GPP might inhibit the activity of monoterpene synthase.[28] Therefore, optimal gene expression of GPP is to be examined for higher production of myrcene, and we constructed the Ec-pM1/pGM, Ec-pM2/pM, and Ec-pM2/pGM strains.

The last strategy for the development of the production strain was balancing gene expression in the MVA pathway. As shown previously using targeted proteomics, low expression of MK and PMK was identified as potential bottlenecks to sesquiterpene production.[26] To overcome low expression, a strong pTrc promoter was inserted to increase gene expressions in the bottom portion of MVA, resulting in high production of bisabolene[25] and limonene.[15] Thus, we employed this strategy, yielding Ec-pM3/pGM, Ec-pM4/pM, and Ec-pM4/pGM strains.

Monoterpene, including pinene and limonene, has been shown to exhibit microbial toxicity because of phase toxicity caused by extraction during cell−solvent contact and molecular level of toxicity.[13,21,22,29] To alleviate monoterpene toxicity, two-phase extraction fermentation was widely applied to restore the growth to the level of the control. Interestingly, myrcene showed relatively low toxicity to microbial cells. The minimum inhibitory concentration (MIC, the amount of terpene for 50% reduction in growth) of myrcene for *S. cerevisiae* is 2.12 mM (288 mg/L), higher compared to other monoterpenes (limonene, MIC of 0.4 mM; β-pinene, MIC of 1.45 mM).[21] Thus, we determined the myrcene toxicity in *E. coli* by adding different amounts of myrcene up to 0.12% (v/v) in the absence of dodecane when the cells reached an OD_{600} of 1 (Figure 1C). As a result, *E. coli* spiked with myrcene showed almost no growth inhibition. However, because myrcene has very low solubility (0.043 mM) and high volatility, we applied *in situ* extraction of myrcene from cell cultures using dodecane overlay.

Selection of Myrcene Synthases for Myrcene-Specific Production. Monoterpene synthases are capable of producing a

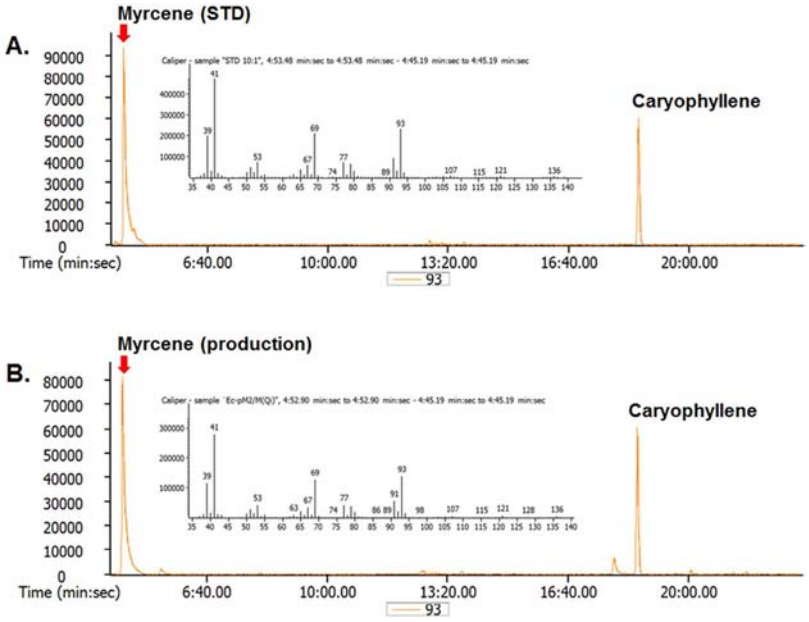

Figure 2. GC−MS analysis of dodecane fractions from the engineered *E. coli* strains: (A) standard myrcene and (B) myrcene produced by a production strain [Ec-pM2/pM(Qi)]. Caryophyllene was used as the internal standard.

variety of monoterpenes from GPP. Monoterpene synthase catalyzes divalent metal ion-dependent ionization and isomerization of GPP to enzyme-bound linalyl diphosphate, which further converts to various monoterpenes.[7] After isomerization and cyclic steps of the α-terpinyl cation, monocylic [(−)-limonene] and bicyclic [(−)-α/β-pinene and β-phellandrene] products were synthesized, whereas deprotonation of the carbocatation leads to an acyclic product (myrcene). Thus, it is important to express a myrcene-specific synthase in *E. coli* to achieve microbial synthesis of myrcene.

From the literature of identified and characterized MSs, we selected three promising MSs (from *A. grandis*,[7] *P. frutescens*,[9] and *Q. ilex* L.[8]). Using a two-plasmid system, we cloned each MS encoding gene, yielding pM(Ag), pM(Pf), and pM(Qi), respectively. Subsequently, each plasmid was co-transformed with the MevT-MBI plasmid in *E. coli* DH1. Thus, we constructed three production strains: Ec-pM1/pM(Ag), Ec-pM1/pM(Pf), and Ec-pM1/pM(Qi). None of these strains produced myrcene (data not shown). To express heterologous GPPS in *E. coli*, truncated AgGPPS2 was cloned into three MS-containing plasmids. As a result, Ec-pM2/pM(Ag), Ec-pM2/pM(Pf), and Ec-pM2/pM(Qi) were constructed. LB medium with 1% glucose was used for the production test. Only strains harboring MS(Qi) produced amounts of myrcene detectable by GC−MS (Figure 2A, 1.67 ± 0.029 mg/L myrcene was produced; limit of detection of 0.030 mg/L). As reported previously,[8] we also confirmed that MS(Qi)-expressing *E. coli* produced only myrcene and other side products were not detected. Therefore, we further engineered the *E. coli* strain harboring the MS(Qi)-encoding gene [Ec-pM2/pM(Qi)] to enhance myrcene production.

Microbial Synthesis of Myrcene. Metabolic engineering of the *E. coli* strain harboring the MS(Qi)-encoding gene was applied to increase myrcene production. On the basis of the "push and pull" strategy, we decided to overexpress AgGPPS2 in addition to MS. The Ec-pM2/pM(Qi), Ec-pM1/pGM(Qi), and Ec-pM2/pGM(Qi) strains were cultivated in LB medium with 1% glucose (Figure 3A). Over the production times (24, 48, and 72 h), the three strains produced low levels of myrcene (less than 2 mg/L). Thus, we changed the medium to the EZ-rich defined and M9-MOPS media with 1% glucose. The growth profiles were similar, regardless of the media and strains, resulting in the fact that the pattern of the myrcene concentration (mg/L) is almost identical to that of specific production of myrcene (mg/L/OD_{600}). Higher levels of myrcene (over 15 mg/L) were produced using the M9-MOPS medium compared to production when using the LB or EZ-rich media (Figure 3). Although each expression of AgGPPS2 in the three production strains was not quantitatively analyzed, different gene expressions of AgGPPS2 could be tested for the optimization based on the combination of the number of plasmid copies and the promoter strength of the BglBrick vectors.[24] Thus, we expected that the relative levels of AgGPPS2 expression would differ in Ec-pM2/pM(Qi), Ec-pM1/pGM(Qi), and Ec-pM2/pGM(Qi) and that the levels of expression would be low, intermediate, and high, respectively. Interestingly, Ec-pM1/pGM(Qi) showed the highest level of myrcene (15.08 ± 0.63 mg/L) with 1% glucose, which is a 3-fold increase from the lowest level of production. This result suggests that the Ec-pM1/pGM(Qi) strain, with the intermediate level of AgGPPS2, is optimal for myrcene production.

As a third approach, balancing the gene expression of the top and bottom portions by dividing two-different operons [Ec-pM3/pGM(Qi), pM4/pM(Qi), and Ec-pM4/pGM(Qi)] did not enhance myrcene production (5−8 mg/L). This could be due to poor GPPS and MS activity in converting IPP/DMAPP to myrcene; however, molecular analysis of MS has not yet been extensively studied.

Besides glucose, glycerol was used as a renewable carbon source, a byproduct of the biodiesel synthesis.[30,31] Because glycerol is a more reduced carbon source than glucose, it could enhance the production of myrcene in the NADPH-consuming MVA pathway. Thus, the Ec-pM2/pM(Qi), Ec-pM1/pGM(Qi), and Ec-pM2/pGM(Qi) strains were cultivated with 1% glycerol in either EZ-rich or M9-MOPS medium (panels A and B of Figure 4). As a result, the Ec-pM2/pM(Qi) strain in EZ-rich medium showed the highest level of myrcene production (58.19 ± 12.13 mg/L) from 1% glycerol, which is a 34-fold increase,

compared to production by the same strain in LB medium with 1% glucose.

Unlike for myrcene production from glucose, a relatively low expression of AgGPPS2 was preferred in *E. coli* for production of myrcene from glycerol. Therefore, the combinatorial expressions of GPPS and MS must be regarded as a critical task for myrcene production in *E. coli*. Targeted proteomic analysis[18,26] could be informative to understand the quantitatively correlation with GPPS/MS expressions and myrcene production depending upon the carbon sources (glucose and glycerol). Nonetheless, the level of myrcene production (58.19 ± 12.13 mg/L) from our engineered strain showed the highest production level published thus far. Further protein engineering of AgGPPS2 and MS based on directed evolution through random mutagenesis or protein structures could be necessary for enhancing activities of GPPS and MS and improving myrcene production.

***In Situ* Extraction of Volatile Myrcene from *E. coli*.** Because of high volatility of myrcene, *in situ* extraction of myrcene from cell cultures was conducted using dodecane overlay.[12,15,18] The dodecane layer can be used as an efficient product sink. Without the dodecane overlay, we observed the complete loss of the myrcene product from the Ec-pM2/pM(Qi) strain using 1% glycerol (Figure 5A). From this result, we

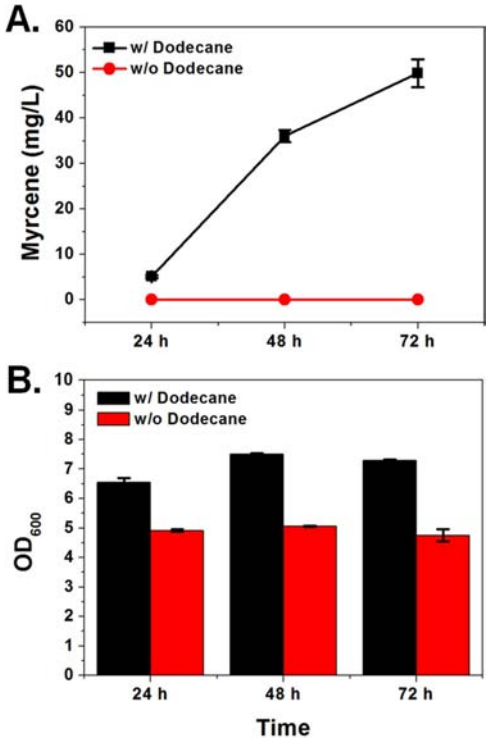

Figure 5. *In situ* extraction of myrcene using a dodecane overlay. (A) Concentration of myrcene produced by the Ec-pM2/M(Qi) strain from 1% glycerol in the EZ-rich medium either with (black square) or without (red circle) dodecane over the culture medium. (B) Cell growth of the Ec-pM2/M(Qi) strain either with (black bar) or without (red bar) dodecane over the culture. OD_{600} was measured at 24, 48, and 72 h. Error bars present the SD from triplicate cultures.

confirmed that myrcene rapidly evaporates after microbial synthesis. The cellular growth was also inhibited (Figure 5B), although the level of microbial synthesis of myrcene in *E. coli* was far less than exogenous myrcene tested for cellular toxicity in this study. This could be due to molecular level toxicity of intracellular myrcene. Therefore, a two-phase culture system with *in situ* extraction using dodecane is needed to eliminate cellular toxicity and the evaporation of myrcene.

For the first time, we have demonstrated metabolic engineering of *E. coli* for the production of myrcene. Combinatorial gene expression of tGPPS2(Ag) and tMS(Qi) was a key success for myrcene production in *E. coli* harboring the heterologous MVA pathway. For enhanced production, system biology could be applied to understand the cellular metabolism of the myrcene-producing *E. coli* to identify bottlenecks. Furthermore, bioprocess engineering is needed to achieve commercially relevant product concentrations and space-time yields of myrcene from engineered *E. coli*.

Supporting Information

ABSTRACT: To elucidate the influence of wood polysaccharide components on lignin formation in vitro, models for polysaccharide matrix in wood secondary cell wall were fabricated from two types of bacterial cellulosic films, flat film (FBC) and honeycomb-patterned film (HPBC), as basic frameworks by depositing xylan onto the films. An endwise type of dehydrogenative polymerization, "Zutropfverfahren", of coniferyl alcohol was attempted in the films with/without xylan. The resultant dehydrogenation polymer (DHP) was generated inside and outside xylan-deposited films, whereas DHP was deposited only outside the films without xylan. The amount of the generated DHP in the xylan-deposited films was larger than that in the films without xylan. The frequency of 8-*O*-4′ interunitary linkage in DHP was also increased by the xylan deposition. These results suggest that xylan acts as a scaffold for DHP deposition in polysaccharides matrix and as a structure regulator for the formation of the 8-*O*-4′ linkage. In addition, mechanical properties, i.e., tensile strength and modulus of elasticity (MOE), of both cellulosic films were found to be augmented by the deposition of xylan and DHP. Especially, DHP deposition remarkably enhanced MOE. Such effects of xylan on DHP formation and augmentation of mechanical strength were clearly observed for HPBC, revealing that HPBC is a promising framework model to investigate wood cell wall formation in vitro.

KEYWORDS: *honeycomb-patterned bacterial cellulose film, xylan, dehydrogenation polymer, 8-O-4′ linkage, mechanical property*

INTRODUCTION

Lignin is one of the three major components in wood secondary cell wall and has a complex structure due to a variety of interunitary linkages resulting from radical coupling of monolignols initiated by hydrogen abstraction with oxidase and/or peroxidase.[1] A main interunitary linkage is 8-*O*-4′ bonding. Its frequency in native lignin is much greater than that of dehydrogenation polymer (DHP) as an artificial lignin, even though DHP is prepared by the endwise polymerization method "Zutropfverfahren," which yields DHP richer in 8-*O*-4′ bonding than the bulk polymerization does.[2−5] The radical coupling of monolignols in a living tree, namely lignification, always occurs in the polysaccharides matrix composed of cellulose and hemicelluloses,[6,7] whereas DHP is normally prepared in an aqueous medium. Thus, it is plausible to suppose that the polysaccharides play a significant role in the lignin formation.[8−10] In fact, the frequency of 8-*O*-4′ linkages in DHP was increased by adding polysaccharides, such as pectin,[11−14] extracted hemicellulose,[13] and cyclodextrin,[15] to the reaction media. However, such effects of polysaccharides addition on lignification in solid media are still unclear.

Xylan, as a major hemicellulose, accounts for 15−30% of wood components in hardwood and for 5−10% in softwood,[16] and its influence on lignification is in debate. When xylan is fully deposited in S1 and S2 layers of phloem fibers in *Mallotus japonicus*, lignin deposition is spatially associated with xylan location.[17] In addition, Reis and Vian[18] reported that xylan acted as a "host structure" for the regulation of lignin structure. Salmén and Burgert[8] reported that highly substituted xylan was closely associated with lignin with less condensed structure in hardwood. The 8-*O*-4′ frequency of DHP was increased by the presence of xylan.[19] Thus, xylan is assumed to contribute to lignin deposition in cell wall and steric regulation of lignin polymerization.

On the other hand, Donaldson and Knox[20] reported that xylan was not closely related to the degree of lignification in radiata pine. In *Eucalyptus globulus*, a xylan-bonded lignin fraction had fewer 8-*O*-4′ linkages than other hemicellulose-bonded lignin.[21,22] In spruce, the lignin−xylan fraction was also rich in condensed structure (fewer 8-*O*-4′ linkages) in comparison with the lignin−glucomannan fraction.[23,24] There were, thus, opposite findings and hypotheses in the previous reports. The first objective in this investigation was to elucidate the effects of xylan on lignin formation in vitro, using solid models for wood polysaccharide matrix.

Wood has excellent mechanical strength. Of course, this characteristic is mainly attributed to a crystalline material, cellulose.[25−27] However, the contribution of other components, hemicellulose and lignin, to the mechanical strength of wood cell wall is also unclear. Our second objective was to clarify the

influence of such components on the mechanical properties of cellulose.

To achieve the objectives, we prepared models for polysaccharide matrices from bacterial cellulose (BC) secreted by *Gluconacetobacter xylinus* as a basic framework. The bacterium produces pellicles in Hestrin−Schramm (HS) liquid media.[28] The pellicle produced for a short time can be used as a thin film. However, most cellulose fibrils of the film are not exposed outside, indicating low response of cellulose filaments to guest molecules or external stimuli. To overcome the problem, we fabricated honeycomb-patterned bacterial cellulose film (HPBC), in addition to flat bacterial cellulose film (FBC), as a BC pellicle. Most fibrils of HPBC are assumed to be exposed to the outer circumstance, and thus, they would have high accessibility to external guests. Its hexagonal alignment mimicked the cross-section of native wood cell wall arrangement. Therefore, we consider HPBC as a better model framework than FBC to investigate the effect of xylan on lignification and the contribution of xylan and DHP to the mechanical property of cellulose.

MATERIALS AND METHODS

Fabrication of HPBC and FBC. HPBC was prepared by our method reported previously.[29,30] Briefly, a precultured *G. xylinus* (ATCC53582) was cultured on a template of concave honeycomb-patterned agarose film containing the nutrients of HS medium. After 48 h incubation, HPBC was obtained by dissolving the agarose film with hot, distilled water at 70 °C.

FBC as a normal BC pellicle was prepared by culture of the bacterium in HS medium for 12 h. Both HPBC and FBC were soaked in 1 M aqueous sodium hydroxide at 65 °C for 1 h and then washed by distilled water repeatedly until the pH of the washings became 7. Afterward, the films were air-dried and kept in a refrigerator until use.

Xylan Adsorption Analysis. Beech xylan was purchased from Sigma-Aldrich (Steinheim, Germany), and used as received. Xylan was subjected to acid hydrolysis bythe Klason method for measuring its lignin content, and neutral sugar compositions in the filtrate by this method were analyzed.[31] Uronic acid content of xylan was determined according to the method reported by Blumenkranz and Asboe-Hansen,[32] using a calibration line.[33]

A sheet of cellulosic film (2.5 mg of FBC and 0.8 mg of HPBC with 90 mm in diameter) was immersed in 10 mL of aqueous xylan solution at different concentrations of 0.1−1.0 mg/mL for 1 d at room temperature and then washed with 1 mL of distilled water. After the adsorption, the residual xylan solutions were subjected to HPLC to measure the xylan concentration. The column used was a 300 × 7.5 mm i.d., Shodex Asahipak GF 7 M HQ, with a 50 mm × 7.5 mm i.d. guard column of the same material (Showa Denko K.K., Tokyo, Japan). Column oven temperature was set at 40 °C, and Milli-Q water as an eluent and a Corona detector (ESA Bioscience Inc., Chelmsford, MA) were used. The xylan concentration was calculated from the total area of the xylan peak using a calibration line. The adsorption of xylan was expressed as the following equation

$$W = \frac{10(C_0 - C_1)}{M}$$

where W (g/g of cellulose) is the adsorption of xylan on a BC film, 10 (mL) is the volume of xylan solution, C_0 (mg/mL) is xylan concentration before adsorption, C_1 (mg/mL) is xylan concentration after adsorption, and M (mg) is the weight of a BC film.

The cellulosic films, which were soaked in xylan solution at 1 mg/mL, washed once with 1 mL of distilled water, and air-dried, were subjected to the following experiment.

Dehydrogenative Polymerization of Coniferyl Alcohol with Enzyme in the Presence of Cellulosic Films. Coniferyl alcohol was synthesized according to the procedure reported previously.[34] For its polymerization with enzyme (horseradish peroxidase), the following three solutions were prepared.[4] Solution I: 100 mg of coniferyl alcohol was dissolved in 2 mL of acetone and then mixed with 48 mL of phosphate buffer saline (PBS) solution (pH 6.1, 0.01 M phosphate containing 0.8 w/v% of NaCl and 0.02 w/v% of KCl). Solution II: 5 mg of horseradish peroxidase (100 units/mg) (Wako Pure Chemicals, Osaka, Japan) was dissolved in 50 mL of PBS solution. Solution III: 0.25 mL of hydrogen peroxide (30 wt % in aqueous solution, 14.6 mmol) was mixed with 50 mL of PBS solution. Both HPBC and FBC with/without adsorption of xylan were immersed in solution II, and solutions I and III were injected dropwise into solution II separately from two syringes each using a YSP-101 syringe pump (YMC Keyboard Chemistry, Kyoto, Japan) at a flow rate of 5 mL/h for 10 h, and then the mixture was kept for a further 16 h. The resultant films were picked up and immersed in distilled water two times for 5 min each and then air-dried.

The remaining DHP not deposited on the film but suspended in the buffer solution was collected by centrifugation (2000*g*, 10 min) and washed two times with distilled water and then lyophilized. The collected DHP was used as a lignin standard for the acetyl bromide method.

The morphologies of the obtained films were observed under a VK-9500 violet-laser color 3D profile microscope (Keyence, Osaka, Japan) or a JSM-6301F field emission scanning electron microscope (FE-SEM) (JEOL Ltd., Tokyo, Japan) operated at an accelerating voltage of 5 kV. The samples for SEM observation were coated with gold−palladium by cathodic spreading with an E101 ion sputter (Hitachi, Tokyo, Japan).

Lignin Bromination and SEM−EDXA Analysis. DHP on the cellulosic films was brominated with bromine vapor in a sealed desiccator. The cellulosic films and bromine (5 mL, 99% purity) in a Petri dish were separately placed in the desiccator and kept for 1 d at room temperature after being tightly sealed in the desiccator with a glass cap. The brominated films were placed in air for half a day and then embedded in epoxy resin. After polymerizing in an oven (35 °C for 1 d, followed by 45 °C for 1 d, and then 65 °C for 3 d), the resins were trimmed with a RM2255 microtome (Leica Biosystems, Nussloch, Germany) to obtain the cross sections of films. The location of bromine on the cross sections of films was analyzed on a S-800 FE-SEM (Hitachi, Tokyo, Japan) equipped with an EMAX-2000 energy dispersive X-ray analyzer (EDXA) (Horiba, Tokyo, Japan) after specimens were coated with carbon under a VC-100 carbon coater (Vacuum-Device Ltd., Ibaraki, Japan). SEM analysis was completed at an accelerating voltage of 10 kV. The EDXA images were represented as an inversion mode of black and white using Microsoft Powerpoint 2007 software.

Immunofluorescence Labeling. Immunofluorescence labeling of xylan was preformed according to the method of Kim et al.[35] Two kinds of primary antibodies, LM 10 and LM 11 (PlantProbes, Leeds, UK), were used to label xylan. A secondary antibody, goat anti-rat IgG Alexa Fluor 568 (Invitrogen, Carlsbad, CA), was used to recognize the primary antibodies. As control experiments, the specimens were incubated with the secondary antibody only. Micrographs of immunolabeling specimens were taken with a BX50 fluorescence microscope (Olympus, Tokyo, Japan) equipped with a Semrock TxRed-4040C filter set (Opto-Line Inc., Tokyo, Japan).

Characterization of DHP. All specimens were washed with 5 mL of 90% 1,4-dioxane aqueous solution (aq dioxane) once, and dried in vacuo at 50 °C. DHP contents in DHP-deposited cellulosic films before and after washing were determined by the acetyl bromide method.[36] The absorptivity of acetylated DHP at 280 nm was found to be 19.9 L/g cm, which was obtained by using the DHP not deposited on the film but recovered from the suspension by centrifugation, as mentioned above.

Alkaline nitrobenzene oxidation for the specimens washed with aq dioxane was conducted according to the method reported by Chen.[37] Reaction products (vanillin and vanillic acid) were determined by a GC-2010 gas chromatograph (Shimadzu, Kyoto, Japan) under the following conditions: detector, FID; column, InertCap 1701 (30 m, 0.25 mm i.d., 0.25 μm film thickness) (GL Science, Tokyo, Japan); split ratio, 5.0; carrier gas, He (110 mL/min); injector temperature,

DOI: 10.1021/acs.jafc.5b01070
J. Agric. Food Chem. 2015, 63, 4613−4620

250 °C; detector temperature, 280 °C; column temperature program, 150 °C (5 min), 5 °C/min to 230 °C (1 min), 10 °C/min to 250 °C (10 min). All experiments described above were performed in duplicate, and the average value was shown as a result.

Mechanical Test. Films were gently pressed under a 300 g load for 10 min, and then cut into 1−2 mm in width and 5 mm in length. The cut specimens were allowed to stand at 50% relative humidity and 22 °C for 1 d and subjected to tensile testing under ambient conditions. Tensile strength, modulus of elasticity (MOE), and elongation were measured on a specially designed testing apparatus reported previously.[38] Film thickness was measured for at least five different positions under the aforementioned 3D profile microscope. The mechanical test was carried out for at least 20 specimens cut from four different films.

RESULTS AND DISCUSSION

Deposition of Xylan onto HPBC and FBC. Beech xylan used in this study contained 1.3% of lignin as Klason lignin. The lignin-free part of this xylan was found to give 86.0% xylose, 1.2% galactose, 0.5% mannose, 0.5% glucose, and 11.8% glucuronic acid.

Adsorption isotherms of the xylan on HPBC and FBC are shown in Figure 1. The adsorption of xylan on HPBC was much higher than that on FBC at any concentration. This result indicated that HPBC had a larger accessible area to xylan than FBC did. The reason may be attributed to the difference in cellulose fibrils: most cellulose fibrils in HPBC are exposed outward (facing air and solvent), whereas most of the fibrils in FBC face inside the pellicle and only the fibrils at the surface are exposed outward. Thereby, xylan could easily interact with most of the cellulose microfibrils in HPBC as compared with those in FBC. We thus considered that HPBC was a suitable platform for the evaluation of the interaction between cellulose microfibrils and guest molecules.

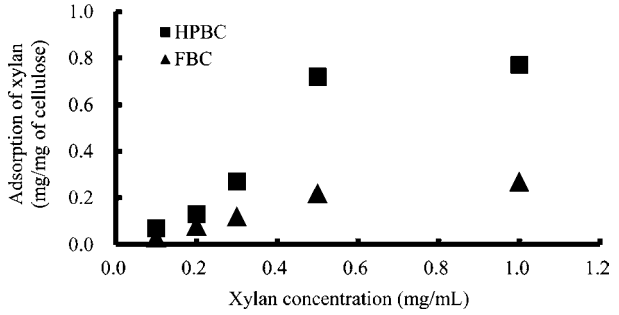

Figure 1. Adsorption isotherms of xylan on HPBC and FBC films.

Dehydrogenative Polymerization of Coniferyl Alcohol in the Presence of Cellulosic Films with/without Xylan. The endwise polymerization of coniferyl alcohol[4] was attempted in the presence of cellulosic films to obtain DHP-deposited cellulosic films. Surface images of the resultant films are shown in Figure 2. Before DHP deposition, no white region was observed for HPBC and FBC, respectively (Figure 2A,B). After DHP deposition, white regions were observed on the surfaces of all HPBC and FBC, respectively (Figure 2C−F). The number of white regions in xylan-deposited FBC (Xyl−FBC) (Figure 2F) was much larger than that in FBC without xylan (Figure 2D). It was presumed that white regions of HPBC and FBC were deposited DHP. To prove this assumption, bromination of the specimens was conducted in order to stain and visualize DHP with bromine. The bromine distribution on the surface of the films was observed under a

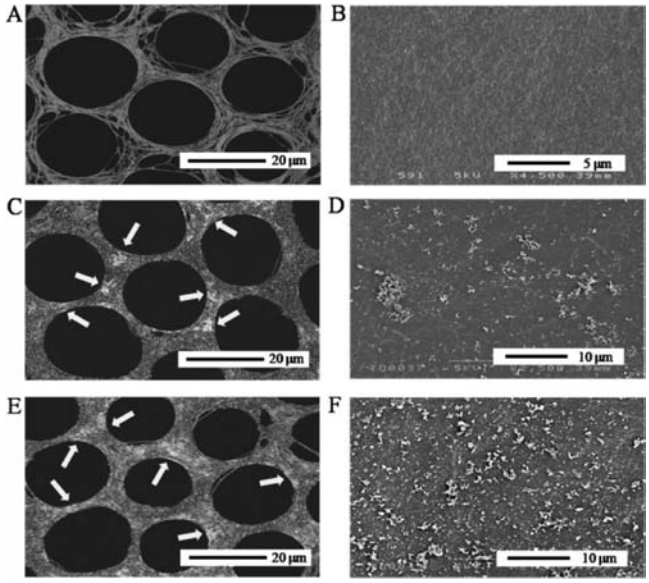

Figure 2. 3D microscopic images of the HPBC series (A, C, and E) and SEM images of the FBC series (B, D, and F). A and B are intact cellulosic films. C and D are images of both cellulosic films after DHP preparation. E and F are images of xylan-deposited films after DHP preparation. White arrows show the "white region" in HPBC.

SEM-EDXA.[39] Figure 3 shows the SEM-EDXA images of Figure 2 at high magnification. The location of bromine dots in parts a3, b3, c3, and d3 of Figure 3 was consistent with the location of white regions in parts A3, B3, C3, and D3 of Figure 3, respectively. Consequently, DHP deposition on the surface of cellulosic films was confirmed by a combined analysis of bromination and SEM-EDXA. Afterward, films were identified as follows: DHP-deposited HPBC and FBC (DHP−HPBC and DHP−FBC, respectively) and DHP-deposited Xyl−HPBC and Xyl−FBC (DHP−Xyl−HPBC and DHP−Xyl−FBC, respectively).

Effects of Xylan on DHP Formation. To further investigate the DHP location inside the films, the Br-stained films were embedded into epoxy resins, and then the specimens were trimmed and microtomed after polymerizing the resins. Figure 4 shows the microtomed positions for HPBC and FBC series. Two cross sections from the first and the second micotome cutlines were analyzed under SEM-EDXA. Figure 5 shows the SEM-EDXA images of the cross sections of DHP-deposited cellulosic films at the first cutline (line 1) (Figure 4). In Figure 5a3 of DHP−FBC without xylan, Br dots (or DHP) were observed only at the outside of the film, but not in the inside. However, when xylan was adsorbed on FBC (DHP−Xyl−FBC), DHP was located on both sides of the film (Figure 5b3). Identical results (Figure S1, Supporting Information) were obtained from the cross sections at the second cutline (line 2) (Figure 4). From these images, we anticipated that xylan induced DHP formation into the inside of the FBC films.

To confirm this assumption, xylan distribution in the films was observed by a combination of immunolabeling and fluorescent microscopy. LM 10 can recognize low-substituted and/or unsubstituted xylan, while LM 11 can recognize not only low-substituted and/or unsubstituted xylan but also arabinoxylan.[40] Both antibodies have been widely used for immunolabeling xylan in both hardwood and softwood, for instance, birch,[40] poplar,[41] pine,[20] and cedar.[35] The control specimens (with the secondary antibody only) omitting

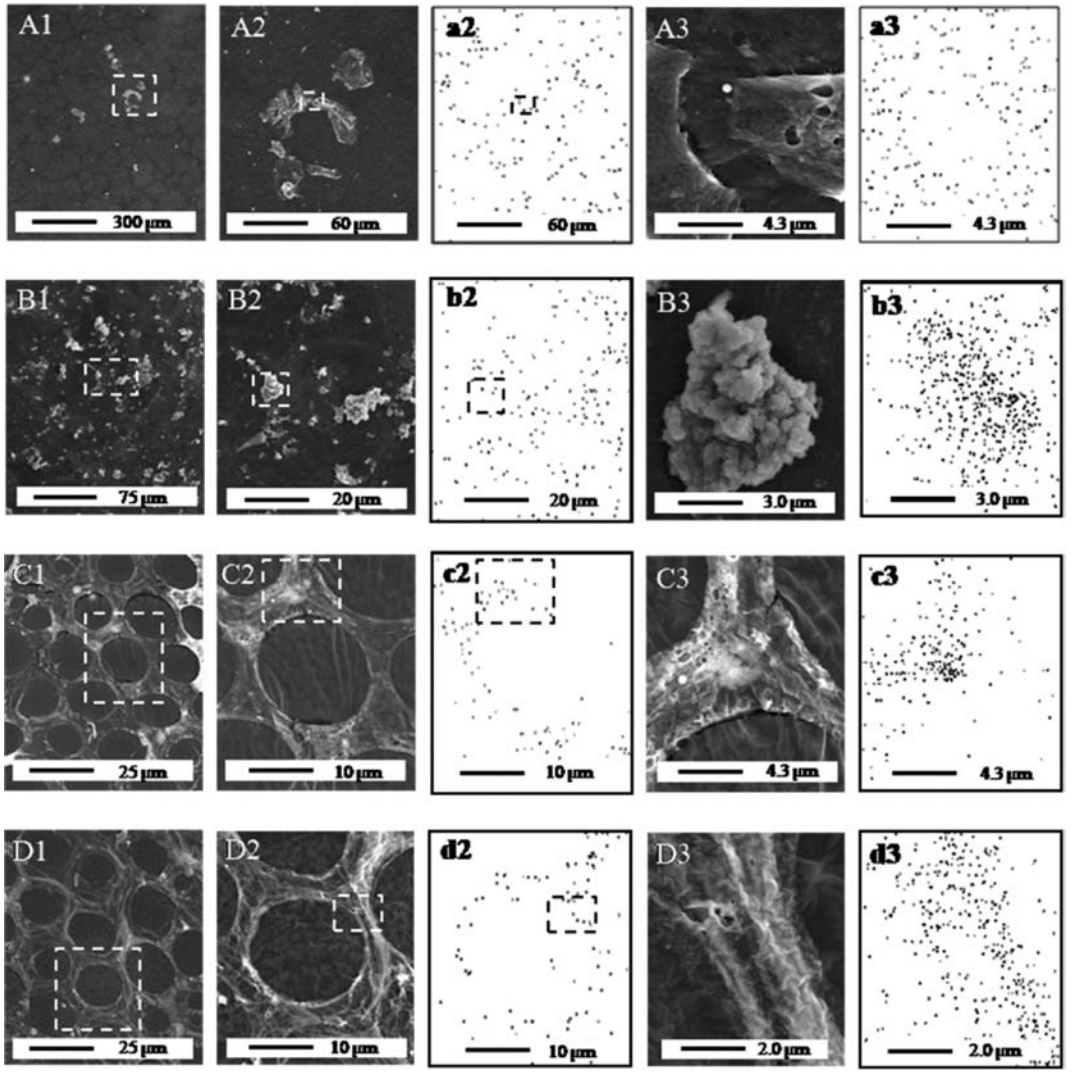

Figure 3. SEM-EDXA images of the surface of DHP-deposited FBC and HPBC films. A series, FBC after DHP preparation without xylan; B series, xylan-deposited FBC after DHP preparation; C series, HPBC after DHP preparation without xylan; and D series, xylan-deposited HPBC after DHP preparation. The magnification is shown by the bar below each panel. The area in the dotted square was magnified under SEM and is shown in the photo for which the numerical label is increased by one (e.g., A1 to A2). The lower case letters, a, b, c, and d, are Br-mapping images by EDXA for the corresponding images labeled with upper case letters.

incubation of primary antibodies (LM 10 and LM 11) did not show obvious fluorescence, including self-fluorescence of lignin (Figure 6A1−D1), whereas the other test specimens clearly indicated red fluorescence, which revealed the existence of xylan. In Figure 6A2, and A3, xylan distributes in the whole inside of Xyl−FBC. In addition, the xylan distribution was also confirmed in the whole inside of DHP−Xyl−FBC (Figure 6B2,B3). From Figures 5b3 and 6B2,B3, DHP existed with xylan. These phenomena suggest the following DHP formation in the matrix; xylan first penetrates into the cellulosic film. Coniferyl alcohol attaches to the xylan-deposited film, and then it migrates inside the film because of its high affinity for xylan.[33] Finally, the coniferyl alcohol is polymerized with peroxidase to form DHP in the polysaccharide matrix.

In the case of HPBC, Br dots or DHP were observed (Figure 5c3,d3). The density of dots was increased by the xylan adsorption. In addition, xylan deposition inside the film was confirmed in Figure 6D2,D3. These observations suggest that coniferyl alcohol can easily penetrate inside HPBC because most bundles or fibrils composed of several microfibrils in HPBC are exposed outward. By xylan deposition, migration of coniferyl alcohol was accelerated. Consequently, more DHP was observed in Figure 5d3 than in Figure 5c3.

Effects of Xylan on Lignin Content and Frequency of 8-*O*-4′ Linkage. To further examine the effects of xylan on DHP formation quantitatively, DHP content in the films and the frequency of interunitary linkage in DHP were estimated by the acetyl bromide method and alkaline nitrobenzene oxidation, respectively.

Parts A and B of Figure 7 show DHP contents in the cellulosic films based on the total weight of DHP-deposited films and the initial weight of cellulose before and after washing with aq dioxane, respectively. The DHP contents of FBC and HPBC, based on the initial weight of cellulose, were increased by the xylan adsorption on cellulosic films in both parts A and B of Figure 7. This result also suggests that xylan enhances the amount of DHP deposition in the films and contradicts the previous findings,[13,14] where hemicelluloses (pectin, pectic acid, and dilute alkali-extracted hemicellulose) did not affect the

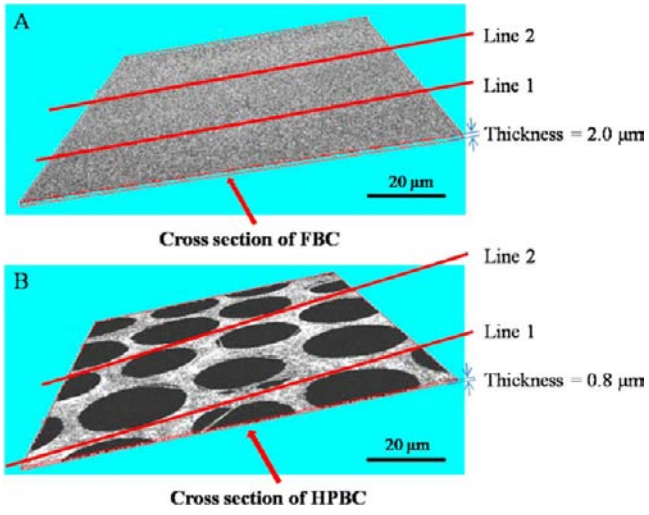

Figure 4. Cutting positions for SEM-EDXA observation at the cross section of (A) FBC and (B) HPBC. Images were taken under the violet-laser color 3D profile microscope.

DHP formation in both solid and liquid media. Consequently, xylan affected DHP formation as a scaffold.

DHP content was remarkably decreased by washing with aq dioxane. However, a significant amount of DHP remained in the films, for HPBC in particular (Figure 7B). The remained DHP fraction was tightly associated with the polysaccharide matrix, suggesting that this aq-dioxane-unwashable DHP fraction might be a lignin−carbohydrate complex.

The DHP-deposited films, after washing with aq dioxane, were then subjected to nitrobenzene oxidation. The oxidation products, vanillin and vanillic acid, are generated from the noncondensed structure of lignin, and therefore, the yield of the oxidation products is one of the measures to estimate the frequency of aryl ether interunitary linkages in lignin, mainly the 8-*O*-4′ linkage.[37]

The yield of the oxidation products from DHP prepared in liquid media (without cellulosic films) was increased by the addition of xylan into the buffered media, as shown in Figure 8. Similarly, the yield from DHP formed in the HPBC and FBC films was increased by the xylan adsorption. These results

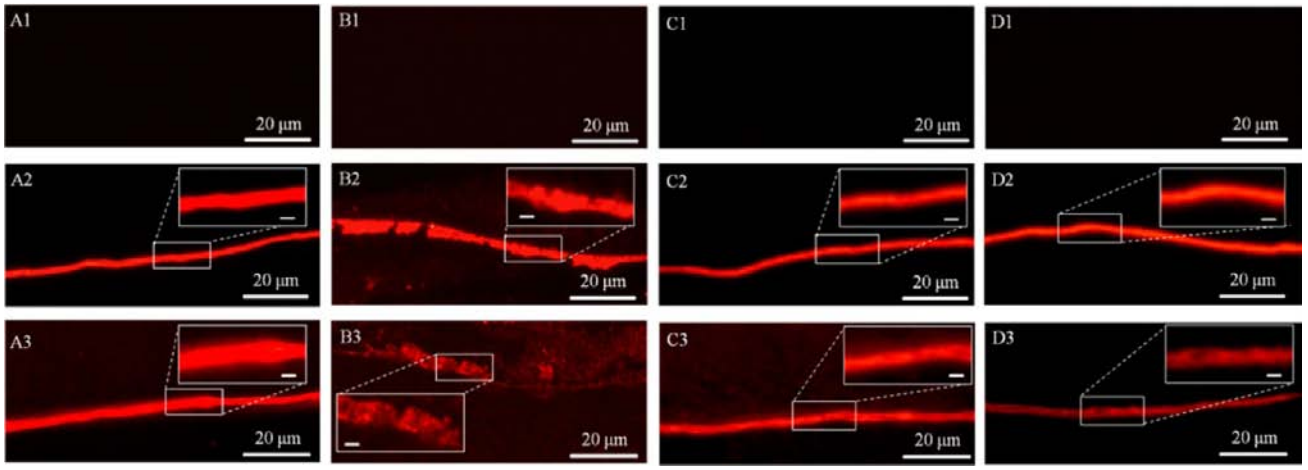

Figure 6. Immunofluoresence labeling of xylan in the cross sections of the xylan−FBC series (A1−A3), DHP−xylan−FBC series (B1−B3), xylan−HPBC series (C1−C3), and DHP−xylan−HPBC series (D1−D3). A1−D1, controls without primary antibodies labeling; A2−D2, immunolabeling with LM 10; A3−D3, immunolabeling with LM 11. Bars in magnified images are 2 μm.

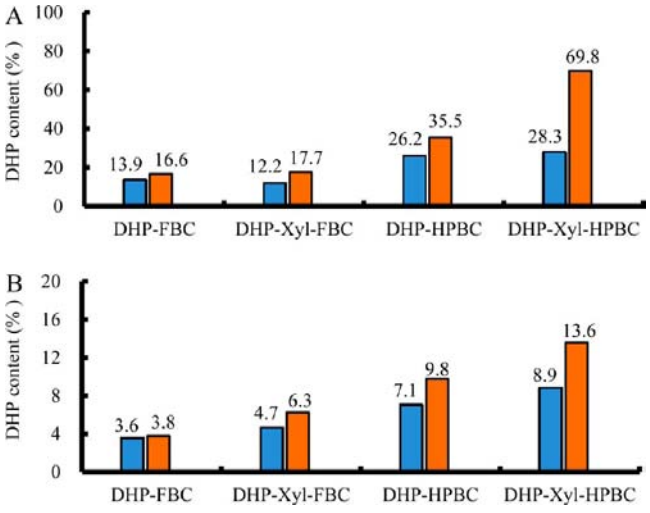

Figure 7. DHP content in the cellulosic films (A) before and (B) after washing with 90% 1,4-dioxane solution: blue, based on the total weight of DHP-deposited films; orange, based on the initial weight of cellulose.

suggested that xylan enhanced the frequency of the aryl ether linkage in DHP, probably resulting in the predominant formation of the 8-*O*-4′ linkage. This observation is consistent with the findings by Barakat et al.,[19] where the higher the concentration of arabinoxylan added to the DHP reactant, the higher the yield of thioacidolysis products obtained. Therefore, we conclude that xylan can act not only as a scaffold for lignin deposition but also as a structure regulator of lignin, especially formation of the aryl ether linkage.

Figures 7 and 8 also demonstrated the difference of the two cellulosic models in the deposition of DHP. A larger amount of DHP was deposited on/in the HPBC film, but a lower frequency of the 8-*O*-4′ linkage was formed than on the FBC film. It is supposed that HPBC is a promising model for the adsorption of wood components on cellulose, while FBC gives a good framework to increase the frequency of the 8-*O*-4′ linkage in DHP in artificial polysaccharide matrix. Our next target is to elucidate the effect of glucomannan on the cell wall formation using the similar models of polysaccharides matrices.

Effects of Xylan and DHP on the Mechanical Properties of Cellulosic Films. In general, hemicellulose and lignin influence the mechanical properties of wood cell wall or cellulosic framework.[8,25,42] To confirm these hypotheses, the

[a]Modulus of elasticity.

mechanical properties, tensile strength, and modulus of elasticity (MOE) were measured for the specimens prepared in this study. Table 1 summarizes the mechanical properties of cellulosic films after deposition of xylan and/or DHP. The tensile strength and MOE of HPBC were smaller than those of FBC, which was attributed to the lower density of HPBC (0.17 mg/mm^3) than that of FBC (0.36 mg/mm^3). The amount of cellulose in HPBC is much smaller than that in FBC with same thickness. The smaller amount of cellulose in HPBC caused the weaker mechanical strength.[38]

The tensile strength of FBC and HPBC was increased 1.6 and 1.9 times, respectively, by xylan deposition followed by DHP deposition. MOE of FBC and HPBC was augmented 2.4 and 3.0 times, respectively, by the deposition of xylan and DHP. Thus, both materials strengthen the cellulosic films. If the increment between tensile strength and MOE was compared, the MOE increment was larger than that of tensile strength upon the deposition of both xylan and DHP on FBC and HPBC, especially DHP deposition on HPBC. It seems that DHP gives cellulose more rigidity.

In addition, the increments of tensile strength and MOE were clearly observed for HPBC. Therefore, we suppose that HPBC is a better model for the investigation of the mechanical effect of wood components than FBC.

Significant Enrichment of Polyunsaturated Fatty Acids (PUFAs) in the Lipids Extracted by Supercritical CO_2 from the Livers of Australian Rock Lobsters (*Jasus edwardsii*)

ABSTRACT: Australian rock lobster (*Jasus edwardsii*) liver contains approximately 24.3% (w/w) lipids, which can contain a high amount of polyunsaturated fatty acids (PUFAs). However, this material has been found to be contaminated with arsenic (240 mg/kg) and cadmium (8 mg/kg). The high level of contaminants in the raw material and the large amount of PUFAs in the lipids prove a significant challenge in the extraction of high-quality lipids from this byproduct by conventional methods. Supercritical carbon dioxide (SC-CO_2) extraction is a highly promising technology for lipid extraction with advantages including low contamination and low oxidation. The technique was optimized to achieve nearly 94% extraction of lipids relative to conventional Soxhlet extraction in Australian rock lobster liver at conditions of 35 MPa and 50 °C for 4 h. The extracted lipids are significantly enriched in PUFAs at 31.3% of total lipids, 4 times higher than those in the lipids recovered by Soxhlet extraction (7.8%). Specifically, the concentrations of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) in SC-CO_2 extraction are 7 times higher than those obtained by Soxhlet extraction. Moreover, very small amounts of toxic heavy metals such as lead (Pb), arsenic (As), mercury (Hg), and cadmium (Cd) were detected in the SC-CO_2-extracted lipids, 0.5−27 times lower than those in the Soxhlet-extracted lipids, which are 40−200 times lower than the regulatory limit maximum values. The low levels of contaminants and the high proportion of PUFAs (dominated by DHA and EPA) found in the SC-CO_2-extracted lipids from Australian rock lobster liver suggest that the material could potentially be used as a valuable source of essential fatty acids for human consumption.

KEYWORDS: *Australian rock lobster (Jasus ewardsii), rock lobster liver, supercritical CO_2 extraction, ω-3 fatty acids, heavy metal*

INTRODUCTION

Polyunsaturated fatty acids (PUFAs) have been extensively reported in the literature as being beneficial to human health.[1−3] In particular, omega-3 (ω-3) or highly unsaturated fatty acids (HUFAs) are believed to play an important role in the prevention of certain health problems such as diabetes, allergies, and some types of cancers, as well as having antithrombotic, antiarrhythmic, and anti-inflammatory effects.[4] Fishery processing byproducts have been recognized as an important potential source of ω-3 fatty acids, which could be used in the production of ω-3-rich lipids. According to a previous investigation by Tsvetnenko et al.,[5] one major source of PUFAs in the Australian rock lobster (*Panulirus cygnus*) is the hepatopancreas (liver), but this inedible part is usually removed during processing and discarded. Australia is the largest producer and exporter of rock lobster in the world.[5] More than 10000 tons of rock lobster processing wastes including heads, shells, and livers are produced each year, in which the lobster liver accounts for 2−5%. However, only about 25% of these materials are utilized for manufactured products and almost entirely for low commercial value items, such as animal feed, aquafeed, and biofertilizer; the other 75% of the materials are often disposed of as waste with a cost to the processor of up to $150/ton.[6] As a result of the cost and environmental burdens, the Australian lobster processing industry is examining how to utilize these processing coproducts, especially the rock lobster liver, as a valuable potential resource for the production of ω-3-rich lipids.

In recent years, processing coproducts from different types of fish including tuna,[7] herring,[8] salmon,[9] walleye pollock,[10] and shrimp[11] have been extensively studied for lipid extraction; however, very little work has been done on rock lobster liver. It is also important to improve the current extraction procedure of marine coproducts to produce lipids with a high concentration of PUFAs and low contaminants of heavy metals.

Currently, there are several available technologies for the extraction of lipids and pigments from crustacean processing coproducts. The most common technology is solvent extraction.[3,11,12] The solvent selection, a decisive factor in the quality of the extracted lipids, is crucial. Lipids are generally soluble in nonpolar solvents that have been traditionally used for lipid extraction.[13] Several organic solvents including acetone, ethyl acetate, hexane, isopropanol, methanol, methyl ethyl ketone, and ethanol are used in the food industry, whereas others such as dicloromethane, dimethyl sulfoxide, and chloroform cannot be used due to their toxicity.[14] There is, however, increasing public awareness of the health, environ-

mental, and safety hazards related to the use of organic solvents for lipid extraction and the possible solvent contamination of the final lipid products. These issues have stimulated the interest in developing alternative extraction methods.[15] As such, supercritical fluid extraction (SFE) has become an important technology for extracting high-quality lipids[16−19] from fishery processing coproducts[20−22] and is also performed as an effective separation technique in the production of nutraceutical supplements and functional foods.[23,24] SFE can be employed at moderate temperature and provides an oxygen-free medium in reducing lipid oxidation during the extraction process. In addition, it allows for the selective extraction of low-polar lipid compounds, avoiding the coextraction polar impurities such as some organic derivatives with heavy metals.[25] Supercritical carbon dioxide (SC-CO_2) extraction is the common SFE technology because this technique is able to extract the heat-sensitive, easily oxidized compounds such as PUFAs and omega-3[17−19,21,22,26] without any contaminated residues in the products. Moreover, CO_2 is a generally recognized as safe (GRAS) solvent type, which is relatively cheap and easy to separate from the solid matrix and extracts.[3,13,23] The excellent extraction performance of the SC-CO_2 extraction is a result of the low viscosity of SC-CO_2, high diffusivity, and high solubility. In contrast, conventional extraction processes such as Soxhlet extraction produce dilute extracts and contain materials that are easily oxidized. Furthermore, the subsequent steps of solvent separations can lead to the degradation of the target products. Several authors have used SC-CO_2 successfully to extract lipids and carotenoids from vegetable[27−30] and animal matrices.[20,30−32] Recent studies have used the SC-CO_2 extraction of lipids and astaxanthin from crustacean processing waste such as shrimp byproducts.[33−36] To our knowledge, no work has been done on the SC-CO_2 extraction of lipids from rock lobster liver. Therefore, the PUFAs proportion and heavy metal contamination, which are major concerns for potential consumers of rock lobster lipids extracted by SC-CO_2 and Soxhlet, have not yet been investigated. The objectives of this study were to optimize the SC-CO_2 extraction of lipids from Australian rock lobster liver, with the aims of obtaining the lipids with enriched PUFAs, comparing them with the lipids extracted from conventional processing methods, and evaluating the PUFA profiles and heavy metal content of the extracted lipids for potential health benefits and to confirm that they meet food safety standards.

MATERIALS AND METHODS

Materials. Fresh livers of Australian rock lobsters were provided by Ferguson Lobster Co. in South Australia. Food grade carbon dioxide (CO_2) gas used for SFE was supplied by CoreGas, South Australia.

Methods. *Proximate Analysis of Lobster Liver.* According to the AOAC (2006) methods, moisture was determined by oven-drying at 105 °C (AOAC 950.46) until a constant weight was obtained, whereas ash content was quantified by incineration in a muffle furnace at 600 °C (AOAC 920.153). Lipid content was determined by using the Soxhlet extraction method (AOAC 991.36), and protein content was determined according to the micro-Kjeldahl method (AOAC 928.08).

Preparation of Rock Lobster Liver for Extraction. One kilogram of fresh lobster liver was held frozen (Thermo Scientific, TSE series -86C Ultra Low Temperature freezer) at −80 °C for 8 h. The frozen lobster liver was transferred to a plastic box with a large surface before it was freeze-dried at −85 °C and 15 mTorr for 48 h by a benchtop freeze-dryer (Virtis model BT6KEL 301804). The freeze-dried lobster liver was collected and stored in the freezer at −80 °C for 1 week before it was used for the lipid extraction.

Supercritical CO_2 Extraction of Lipids from Rock Lobster Liver. Extractions were carried out by using the laboratory supercritical CO_2 extraction system (Applied Separation model Spe-ed SFE-2 7071) equipped with 100 and 1000 mL extraction vessels. The 100 mL extraction vessel was packed with around 10 g of freeze-dried lobster liver for each batch of extraction, and the void volumes at two ends of the extraction vessel were completed with washed sand and glass wool layers. A 20 min static time was used for making a good contact between the sample and the supercritical solvent before the needle valve was opened to release the extracted lipid. For extraction, CO_2 at supercritical state was continuously drained through the extraction vessel, and the extracted lipid was collected in a preweighed dark glass bottle. The CO_2 mass flow rate was maintained at around 0.434 kg/h, and the time for extraction was 240 min. The extraction temperatures of the oven, valve, and vessel were set at 50, 60, and 50 °C, respectively, whereas the extraction pressures were adjusted to 25, 30, and 35 MPa as experimental design. The lipid-collecting bottle was weighed every hour to calculate lipid recovery. Extractions at every condition were carried out in three replicates.

Soxhlet Extraction of Lipids from Rock Lobster Liver. Soxhlet extraction of lipids from rock lobster liver was carried out at the National Measurement Institute (NMI) of Australia. Ten grams of freeze-dried rock lobster liver was homogenized thoroughly before it was placed in a Soxhlet thimble. The thimble containing the sample was then placed in a hot extraction beaker while 90 mL of diethyl ether was added and locked into the hot extraction unit. Extraction was carried out using a preprogramed period of approximately 4 h with a temperature of 40 °C. The amount of crude lipids obtained by this method was 2.43 g/10 g of the freeze-dried lobster liver.

Fatty Acid Analysis. The fatty acid composition of the lipids extracted by SFE and Soxhlet was analyzed at NMI.

Extracted fats were converted into fatty acids methyl esters (FAME), separated, and then measured on a Hewlett-Packard 6890 gas chromatograph equipped with a 50 cm capillary column (0.32 mm i.d.; SGE, Victoria, Australia) coated with 70% (w/w) cyanopropyl polysilphenylene-siloxane (BPX-70) (0.25 μm film thickness), which was fitted with a flame ionization detector. Helium was the carrier gas (flow rate = 60 mL/min). and the split ratio was 20:1. The injector temperature was set at 250 °C and the detector temperature at 300 °C. The initial oven temperature was 140 °C and programmed to rise to 220 °C at 5 °C/min and then held for up to 3 min. FAMEs were identified on the basis of the retention time of standards obtained from Nucheck Prep Inc. (Elysian, MN, USA) using Chemstation software. An external standard of 463 from NuCheck Prep Inc. was analyzed and used for calibration.

Heavy Metals and Inorganic Arsenic Analysis. The content of heavy metals and inorganic arsenic was determined using the standard methods VL247 ver. 9.1[37] and NT 2.56[38] described by NMI of Australia.

RESULTS AND DISCUSSION

Australian rock lobster liver was analyzed. As shown in Figure 1, the two major components of the Australian rock lobster livers obtained in this study are protein (41.1% by dry weight) and lipids (24.3% by dry weight). The lipid content obtained in this study is higher than the 19.4% lipid content reported in the study by Tsvetnenko et al.[5] This could be caused by different species of lobster being used in the experiments or by

environmental or other factors. Compared with the lipid content of menhaden, which is an Atlantic fish caught primarily for production of fish oil and meal (9.13%), the lipid content in rock lobster liver was nearly 3 times higher. Moreover, Tsvetnenko et al.[5] also reported that the lipids recovered from rock lobster cephalothorax were rich in PUFAs, of which HUFAs accounted for 50.8%. The results indicated that Australian rock lobster liver, a relatively readily available lobster

processing byproduct, could be a valuable but inexpensive resource for the extraction of ω-3-rich lipids.

Heavy Metal Composition. The concentration of heavy metals found in Australian rock lobster liver is shown in Table 1. Copper was detected in very high amounts of approximately 1000 mg/kg. This value for copper is several times higher than 151 mg/kg in veal liver, which in turn is regarded as a very high copper content food.[39] Consuming just 10−15 g of rock lobster liver could meet the daily requirement for copper suggested by the WHO/FAO. Copper is an essential mineral required for bone and connective tissue production and for coding specific enzymes that possess the function of eliminating free radicals. A deficiency in copper can lead to osteoporosis, joint pain, and lowered immunity because copper is essential for the absorption of iron.[40] Apart from having a rich copper content, Australian rock lobster liver also has high contents of zinc (170 mg/kg) and selenium (16 mg/kg), which are beneficial for human health.[39] Whereas zinc is good for skin care, healing of wounds, prostate disorders, colds, weight loss, appetite loss, pregnancy, diarrhea, respiratory infections, and malaria,[41] selenium is one of the most effective mineral antioxidants because it actually prevents the formation of new free radicals by participating in various cellular reactions that lower the peroxide concentration in the cellular body.[42] Therefore, Australian rock lobster liver could be an excellent dietary source of zinc and selenium for human demands.

However, four other elements including lead (Pb), cadmium (Cd), arsenic (As), and mercury (Hg) that are generally considered to be hazardous to human health at low to medium concentrations[43] have also been found in Australian rock lobster liver. The amounts of Pb and Hg were just half of the regulatory limit (0.5 mg/kg) of seafood products, but the total As and Cd were quite high, at contents of 240 and 8.7 mg/kg,

respectively (Table 1). The high contamination of these toxic heavy metals could be caused by a large amount of As and its derivatives present in seawater due to natural processes[44] and pollution as many species of fish and shellfish can bioaccumulate As and toxic heavy metals.[45] Despite contamination with high levels of As, the vast majority of As and its derivatives in Australian rock lobster liver are in organic forms, which are harmless,[45] and its limit is not specified in the food code. By contrast, soluble inorganic arsenic compounds, which

DOI: 10.1021/jf5059396
J. Agric. Food Chem. 2015, 63, 4621−4628

are highly toxic,[46] are present in very small amounts of about 0.67 mg/kg compared with the regulatory limit of 2 mg/kg. However, the content of Cd in rock lobster liver is 4 times higher than the maximum value recommended for seafood according to our study. This high Cd content should be brought into account when rock lobster liver is directly consumed or utilized as a raw material for food. As a result of this, rock lobster liver is usually removed during lobster processing to avoid cross-contamination of toxic heavy metals. An advanced technology is required to ensure the extracted lipids have significantly reduced contaminants.

Optimization of SC-CO_2 Extraction of Lipids from Rock Lobster Liver. SC-CO_2 extraction has been applied to several materials to investigate extraction yield. A number of processing parameters including pressure, temperature, CO_2 rate, and extraction time have been reported to have significant influence on lipid recovery, with extraction pressure and temperature being the most important factors. Several optimum conditions have been suggested for SC-CO_2 extraction of lipids from different materials, but these conditions could be changed depending upon the nature of the materials being treated. In the literature, the suggested pressure usually ranges from 20 to 40 MPa and the temperature varies from 40 to 60 °C. In the present work, extractions of lipids from Australian rock lobster liver were carried out with pressures from 25 to 35 MPa for 1−4 h at 50 °C and the CO_2 flow rate of 0.434 kg/h in order to find the efficient condition for lipid extraction from this material. Although the SC-CO_2 extraction can be carried out at the mild temperature for better prevention of lipid oxidation, the results from initial studies carried out at the same temperature as the Soxhlet extraction (40 °C) indicated that lipid recovery was very low (only 32.17% after 2 h of extraction). Therefore, a slightly higher extraction temperature of 50 °C was chosen to minimize negative effects on the PUFA profile but to achieve a high enough lipid recovery (>90%).

As shown in Figure 2, the extraction curves obtained in this study fit well with the empirical model suggested by Kandiah and Spiro,[47] with an assumption that two diffusion stages, which are based on the amount of lipids accessible to the supercritical CO_2, could control the process. At the early stage, the content of most accessible lipids is high and, thus, the extraction rate is high. As can be seen in Figure 2, the initial extraction rate, or the lipid recovery, increases significantly with applied pressure. When the extraction pressure rose from 25 to 35 MPa, the lipid recovery increased significantly by about 30% (from 47.30 to 75.86%) during the first 2 h of extraction. Up to 90% of the lipids in rock lobster liver relative to the Soxhlet extraction could be recovered in this stage once the pressure of 35 MPa was applied, but for the extraction pressure of 30 and 25 MPa these values were just 75 and 67%, respectively. This result indicates that the internal mass transfer is negligible and the process is controlled by the lipid solubility in SC-CO_2. Because both solvent density and capacity increase with pressure, a rise in pressure leads to an increase in the lipid solubility of the solvent. However, at the second stage, the remaining lipids, which are less accessible to the solvent, were extracted much more slowly because of the considerably higher internal mass transfer resistance.[21] This can be clearly observed in Figure 2 when only around 4, 13, and 19% of the lipids were recovered during the last 2 h of extraction with pressures of 35, 30, and 25 MPa, respectively. The results indicate that using high pressure for SC-CO_2 extraction of lipids from rock lobster liver can shorten the extraction time because the extraction rate increases with pressure.

Although the amount of recovered lipids can be increased with an extended extraction time at all observed pressures, the maximum value of lipid recovery was found at 4 h of extraction. The lipid recovery for 4 h of extraction at 35 and 30 MPa was approximately 94.0%, whereas this value for 25 MPa was reduced to 80.76%. The result, that lipid recovery increased with higher extraction pressure, is in agreement with the previous investigation by Sahena et al.[48] Therefore, SC-CO_2 extraction of lipids from rock lobster liver using high pressure not only shortened the extraction time but also improved the extraction yield.

It is also observed in Figure 2 that the appropriate time for extraction is significantly different among the extraction pressures. Although 4 h of extraction seems to be an appropriate time for the pressure of 30 MPa, this time is clearly not suitable for 35 MPa. This is because the lipid recovery for the pressure of 35 MPa at 2 and 4 h was not significantly different (nearly 90.0 and 94.0%). The prolonged extraction time could lead to a considerable increase in processing costs, and in the case of extraction at 35 MPa, 2 h of extraction is clearly more economical than others. In the overall consideration of extraction yield, extraction time, and PUFA content, the SC-CO_2 extraction at 35 MPa and 50 °C for 2 h of extraction was chosen as the efficient condition for lipid extraction from freeze-dried rock lobster liver.

Significant Improvement in Nutritional Profile of the SC-CO_2-Extracted Lipid. *PUFA-Rich Lipid Extracted by SC-CO_2 Extraction.* Lipid extraction with SC-CO_2 has been suggested as a promising alternative for producing lipids with a high amount of PUFAs. CO_2 at supercritical condition possesses superior mass transfer characteristics, and this technique involves the use of a nonoxidant atmosphere and mild temperature, which could prevent the oxidation of PUFAs. In current research, the lipids extracted from Australian lobster liver by SC-CO_2 extraction and Soxhlet were analyzed, and their fatty acid profiles were compared. It can be observed in Figure 3 that there are significant differences in the fatty acid composition of the two extracted lipid mixtures. Whereas the majority of total fatty acids in the Soxhlet-extracted lipids are saturated fatty acids (SFAs) and monounsaturated fatty acids (MUFAs), its PUFAs are very low, at only around 7.8%. In contrast, the SC-CO_2-extracted lipids have a very high proportion of PUFAs (31.3%), which is greater than the level of MUFAs (29.4%) and equivalent to SFAs. Notably, the level of PUFAs in the SC-CO_2-extracted lipids is 4 times higher than that in the Soxhlet-extracted lipids and considerably higher compared to 22.6% of PUFAs in the previous work of Tsvetnenko et al.,[5] who extracted lipids from rock lobster (*Panulirus cygnus*) cephalothorax using a mixture of methanol/chloroform solvent that was then evaporated under vacuum. This result is also supported by the study of Cheung et al.,[49] who compared the fatty acid composition of lipids extracted from brown seaweed by SC-CO_2 and Soxhlet. Their work also showed that the lipid oxidation of PUFAs had been minimized under low oxidizing conditions used in SC-CO_2 extraction and, therefore, the obtained lipids contained higher PUFAs.

Apart from significantly enriching PUFAs, the SC-CO_2-extracted lipids also have a significantly higher proportion of ω-3 fatty acids, which account for 18% of total fatty acids, 6 times higher compared with the 3.1% of ω-3 fatty acids found in the lipids recovered by the Soxhlet method (Figure 4). This result

DOI: 10.1021/jf5059396
J. Agric. Food Chem. 2015, 63, 4621−4628

is similar to the study of Cheung et al.,[49] who discovered that ω-3 fatty acid levels in the SC-CO_2-extracted lipids from brown seaweed were significantly higher than those in the Soxhlet-extracted lipids and concluded that ω-3 fatty acids were extracted more effectively with SC-CO_2 extraction than with the Soxhlet. More specifically, ω-3 HUFAs such as DHA, EPA, and DPA, which have biochemical activities that may be useful in the prevention and treatment of several disorders and diseases including coronary heart disease, rheumatoid arthritis, asthma, cancers, diabetes, and others,[50] were the most dominant PUFAs of the lipids extracted by SC-CO_2 extraction. These ω-3 HUFA concentrations were 7 times higher than those in the Soxhlet-extracted lipids, and they comprised >95% of the total ω-3 fatty acids in the SC-CO_2-extracted lipids. The maintenance of a high amount of PUFAs in the composition of the extracted lipids with the vast majority of these being ω-3 HUFAs provides a significant advantage for the SC-CO_2 extraction technique for extracting ω-3 rich lipids from the liver of Australian rock lobster.

The investigation on the evolution of PUFAs and ω-3 fatty acids of the SC-CO_2-extracted lipids over the extraction time (Figure 5) indicated that these fatty acid contents are relatively constant in the first 3 h and slightly increase in the fourth hour. The extraction time does not have a significant impact on the fatty acid profile.

Significantly Lower Toxic Heavy Metals in the SC-CO_2 Extracted Lipids. More than 50 different arsenic species have been found in marine environments, and arsenic derivatives, such as arsenobetaine, being the main species and water-soluble form, have been detected in fish.[51] Therefore, seafood is considered as a major dietary source for arsenic exposure.[46] In our current work, the heavy metal content of the extracted lipids have been especially taken into account because some toxic heavy metals were detected over the regulatory limit in the raw materials used for extracting the lipids. This becomes more necessary because a considerable amount (4.3−10.5 ppm) of arsenolipids, which are nonpolar lipids bound with As, have been found in 10 different fish lipids.[52] Table 2 shows the concentration of heavy metals detected in the lipids extracted by the SC-CO_2 extraction and by the Soxhlet. The lipids extracted by both methods contain very small amounts of heavy metals compared with the raw materials and the regulatory limits, whereas their beneficial elements such as Zn and Se are still quite high. The content of these heavy metals in the extracted lipids changed significantly from 0.5 to 870 times depending on the method used for the lipid extraction and the types of trace elements. The low contamination of heavy metals in the extracted lipids is a result of these methods utilizing nonpolar solvents for extraction, which usually solubilize mainly the nonpolar compounds and leave behind the polar compounds.

However, this work has been specifically focused on an investigation of toxic heavy metals because contamination with these compounds can render the material unusable due to potential risks of excessive ingestion, which may lead to a decline in mental, cognitive, and physical health. As shown in Figures 6 and 7, there are significant differences in the amounts of toxic heavy metals in the lipids extracted by SC-CO_2 and Soxhlet techniques. The contents of all toxic heavy metals in the SC-CO_2-extracted lipids were considerably lower than those in the Soxhlet-extracted lipid. Whereas the concentration of Pb in the SC-CO_2-extracted lipids was just half of that in the Soxhlet-extracted lipids (0.022 mg/kg), the content of inorganic arsenic in the former was 4 times lower compared with the amount of 0.22 mg/kg in the latter. Notably, the content of Cd in the SC-CO_2-extracted lipids (<0.01 mg/kg) was 27 times lower than that in the Soxhlet-extracted lipids, whereas the concentration of total arsenic was nearly 15 times lower (2.2 mg/kg compared with 31 mg/kg). This trend is strongly supported by the recent investigations by Rubio-Rodríguez et al.[25] Their results indicate that SC-CO_2 extraction is an effective technology for extracting fish lipids with greatly reduced contamination with toxic heavy metals.

Lipid Profiles. Table 3 illustrates the fatty acid composition of the lipids extracted by SC-CO_2 (50 °C, 35 MPa, 0.434 kg/h) and by Soxhlet from Australian rock lobster liver. It needs to be highlighted that there are significant differences in the fatty acid compositions of the lipids extracted by these two methods. Whereas the highest proportion in the Soxhlet-extracted lipids was SFAs (47.3%) followed by MUFAs (41.2%) and PUFAs (7.8%), these contents in the SC-CO_2-extracted lipids were 35.4% of SFAs, 29.4% of MUFAs, and 31.1% of PUFAs, respectively. The former was rich in SFAs and MUFAs but very poor in PUFAs, whereas the latter has very high amounts of PUFAs dominated by ω-3 (18%) and ω-6 (13.3%). The differences in fatty acid profiles of these two lipids could be explained by differences in conditions used for extracting the lipids. Whereas the Soxhlet method employed organic solvents such as diethyl ether for extraction in this study, the SC-CO_2 extraction used CO_2 at supercritical condition that has high diffusion and very low surface tension compared to liquid solvents.[53] These novel properties could be a favorable condition for PUFA extraction. This point, that the yield of omega-3 fatty acids extracted by SC-CO_2 extraction at higher pressure (31.0 and 37.9 MPa) was significantly higher than that in the Soxhlet, was confirmed by Cheung et al.[49]However, both lipids have diversified fatty acids in which oleic is the most dominant in their composition (20.5% for SC-CO_2-extracted lipids and 28.4% for Soxhlet-extracted lipids). Palmitic is abundant in SFAs (16.7% for SC-CO_2-extracted lipids and 22.5% for Soxhlet-extracted lipids), whereas DHA, EPA, and arachidonic are three main fatty acids in PUFAs, accounting for up to 75%.

Isomerization of Cholecalciferol through Energy Transfer as a Protective Mechanism Against Flavin-Sensitized Photooxidation

Regina S. Scurachio,[†] Willy G. Santos,[†] Eduardo S. P. do Nascimento,[†] Leif H. Skibsted,*[,‡] and Daniel R. Cardoso*[,†]

[†]Instituto de Química de São Carlos, Universidade de São Paulo, Avenida Trabalhador São Carlense 400, CP 780, 13560-470 São Carlos, Brazil

[‡]Food Chemistry, Department of Food Science, University of Copenhagen, Rolighedsvej 30, DK-1958 Frederiksberg C, Denmark

ABSTRACT: Cholecalciferol, vitamin D_3, was found to isomerize to 5,6-*trans*-vitamin-D_3 with a quantum yield of 0.15 ± 0.01 in air-saturated 7/3 *tert*-butyl alcohol/water (v/v) at 25 °C, increasing to 0.32 ± 0.02 in the absence of oxygen, through quenching of triplet excited state flavin mononucleotide, FMN, rather than becoming oxidized. The quenching was found by laser flash photolysis to have a rate constant of 1.4×10^8 L mol^{-1} s^{-1} in 7/3 *tert*-butyl alcohol/water (v/v) at 25 °C, assigned to energy transfer from ^{3}FMN* to form a reactive vit.D_3 diradical. vit.D_3 forms a 1/1 precomplex with FMN by hydrophobic stacking with $\Delta H° = -36 \pm 7$ kJ mol^{-1} and $\Delta S° = -4 \pm 3$ J mol^{-1} K^{-1}, as shown by single photon counting fluorescence spectroscopy and steady-state fluorescence spectroscopy. Both ground-state precomplex formation and excited-state energy transfer seem important for vit.D_3 protection against flavin-sensitized photooxidation of nutrients in food and biological systems.

KEYWORDS: *vitamin D, riboflavin, photochemistry, 5,6-trans-vitamin D*

INTRODUCTION

Vitamins have varying reactivity depending on their biological functions. For some vitamins, the reactivity is modulated in provitamins with better stability, and the vitamin function depends on an activation step. The lipophilic vitamin D provides examples such as 7-dehydrocholesterol, which is found as a pro-vitamin D in food of animal origin, and ergosterol, which is found as pro-vitamin D in food from the plant kingdom.[1,2] The activation step involves for both provitamins a photochemical reaction to form cholecalciferol, vit.D_3, or ergocalciferol, vit.D_2, respectively, as occurring in human skin upon exposure to UV-B sunlight.[1−3] Among the water-soluble vitamins, vitamin B_2 is also photoactive, since riboflavin, the form of vitamin B_2 normally in foods, and the biological forms of vitamin B_2, flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), are potent photosensitizers, inducing oxidative damage in food and skin, including degradation of the isoalloxazine ring common for these flavins.[4,5]

Vitamin B_2 and vitamin D_2 or D_3 (Figure 1) or their pro-vitamin forms will interact upon light exposure when the two types of vitamins are present together. Milk and dairy products provides such examples where the lipophilic vitamin D forms are found in the lipid phase of the emulsions, while vitamin B_2 is water-soluble.[2] Human skin provides another example, since both of the different vitamin B_2 forms, including flavoproteins located at the plasma membrane, and pro-vitamin D_2 or D_3 are present in the skin and become exposed to light.[6,7] Riboflavin is known to initiate photodegradation of important nutrients in dairy products upon light exposure in reactions normally assigned to oxidation.[5] A more detailed understanding of the interaction between light-activated forms of the flavins and the vitamin D homologues is, however, not available at present. Such knowledge at the mechanistic level would be important both in relation to improvement of the stability of food exposure to light and also in relation to skin health.[5−7]

Vitamin B_2 and vitamin D apparently have opposite effects on skin health upon light exposure, since riboflavin induces oxidative damage and radical formation with increased cancer risk, while the different forms of vitamin D apparently protect against light damage to the skin.[8−10] Most importantly, exposure of biological systems containing both vitamin B_2 and vitamin D to visible light and UV-A light will activate only the flavin vitamin forms due to the spectral characteristic of the two types of vitamins, and the activated flavin may react with vitamin D. We have accordingly undertaken photophysical studies using visible and UV-A light for activation of flavins and studied the interaction with vitamin D; the results of these investigations should be valuable for both protection of the nutritive value of foods and for nutritional advice for better skin health.

MATERIALS AND METHODS

Chemicals. Cholecalciferol (vitamin D_3), flavin mononucleotide (FMN), $LiClO_4$ salt, and deuterated methanol (CD_3OD) were purchased from Sigma-Aldrich (Steinheim, Germany). Acetonitrile HPLC grade was purchased from Mallinckrodt (Phillipsburg, NJ). *tert*-Butanl alcohol (99.5%) and Tween-20 (pure) were purchased from Acros Organics (Geel, Belgium). Water was purified (18 MΩ cm) by means of a Milli-Q purification system from Millipore (Billerica, MA).

Steady-State Fluorescence Spectroscopy. Fluorescence measurements were carried out using a Hitachi F-7000 fluorescence spectrometer (Hitachi High-Tech, Tokyo, Japan). The samples were excited in 1.0 cm × 1.0 cm fluorescence cuvettes from Hellma (Mulheim, Germany) at 440 nm. Emission spectra were recorded using

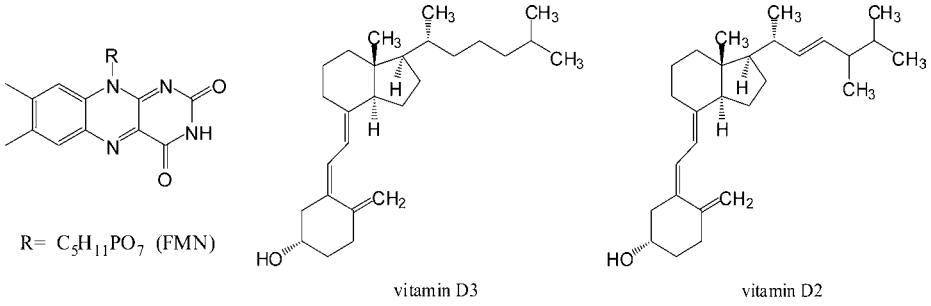

Figure 1. Chemical structures for FMN, vitamin D_3, and vitamin D_2.

a 2.0 nm band pass for the excitation monochromator and a 4.0 nm band pass for the emission monochromator. The recorded spectra were corrected for instrument response. The fluorescence was measured at 25.0 ± 0.2 °C in 7/3 *tert*-butyl alcohol/water solution (v/v).

Time-Resolved Fluorescence Spectroscopy. Time-resolved fluorescence were measured by time-correlated single-photon counting using a picosecond spectrometer equipped with Glan-Laser polarizers (Newport, Irvine, CA), a Peltier-cooled PMTMCP from Hamamatsu, Model R3809U-50 (Hamamatsu, Japan), as the photon detector, and Tennelec-Oxford (Oxford, Abingdon, U.K.) counting electronics. The light pulse was provided by frequency-doubling the 200 fs laser pulse of a Mira 900 Ti-sapphire laser pumped by a Verdi 5 W coherent laser (Santa Clara, CA), and the pulse frequency was reduced to 800 kHz using a Conoptics pulse picker. The fluorescence decays were taken at the magic angle (λ_{exc} 400 nm) and analyzed by a reconvolution procedure with instrument response function (irf) with exponential decay models, and the goodness of the fit was evaluated by the statistical parameter χ^2. The fluorescence was measured at 25.0 ± 0.2 °C in 7/3 *tert*-butyl alcohol/water solution (v/v).

Laser Flash Photolysis. Laser flash photolysis experiments were carried out with an LFP-112 nanosecond laser flash photolysis spectrometer from Luzchem (Ottawa, Canada) using the third harmonic (355 nm) of a pulsed Q-switched Nd:YAG laser (BrilliantB, LesUlis, France) attenuated to 10 mJ cm^{-2} as the excitation source with pulse duration 8 ns. Appropriate UV cutoff filters were used to minimize the sample degradation by the monitoring light. The signal from the monochromator/photomultiplier detection system was captured by a Tektronix TDS 2012 digitizer (Beaverton, OR). The laser system and the digitizer were connected to a personal computer via a general purpose instrumentation bus (GPIB) and serial interfaces controlling all the experimental parameters and providing suitable processing and data storage capabilities. Each kinetic trace was averaged 16 times, and observed rate constants were determined by parameter fitting with MatLab R2013 to exponential decay functions (Mathworks Inc., Natick, MA). All measurements were made with fresh 7/3 *tert*-butyl alcohol/water (v/v) solutions or Tween-20 micelle (0.1 mol l^{-1}) thermostated at 25.0 ± 0.5 °C and purged with high-purity N_2 for at least 30 min before the experiment.

Steady-State Photolysis. A 7/3 *tert*-butyl alcohol/water (v/v) solution containing 1.0×10^{-4} mol L^{-1} of FMN and 1.0×10^{-3} mol L^{-1} of vitamin D_3 was exposed to 440 nm monochromatic light generated by a mercury lamp (HBO 200 w/4 short arc, Osram, Augsburg, Germany) accommodated with a focusing quartz lens, a water-filled heat filter, and an Oriel narrow-band interference filter (center wavelength, 440 nm; Oriel Corp., Irvine, CA). The intensity of light, $q^0_{n,p}$, was measured by ferrioxalate actinometry[11] and had an average value of 2.53×10^{-8} einstein min^{-1}. The absorbance measurements were carried out employing a Hitachi U-3501 (Hitachi-Hitech, Japan) spectrophotometer.

Cyclic Voltammetry. Cyclic voltammetry of vit.D_3 (1.0×10^{-3} mol L^{-1}) dissolved in nitrogen-purged acetonitrile containing $LiClO_4$ (0.5 M) was carried out using a PAR 264A potentiostat (Princeton Applied Research, Princeton, NJ) equipped with glassy carbon as the working electrode, a platinum wire as the auxiliary electrode, and an Ag/AgCl reference electrode. The scan rate was 100 mV s^{-1}, and the electrochemical cell was thermostated at 25.0 ± 0.2 °C.

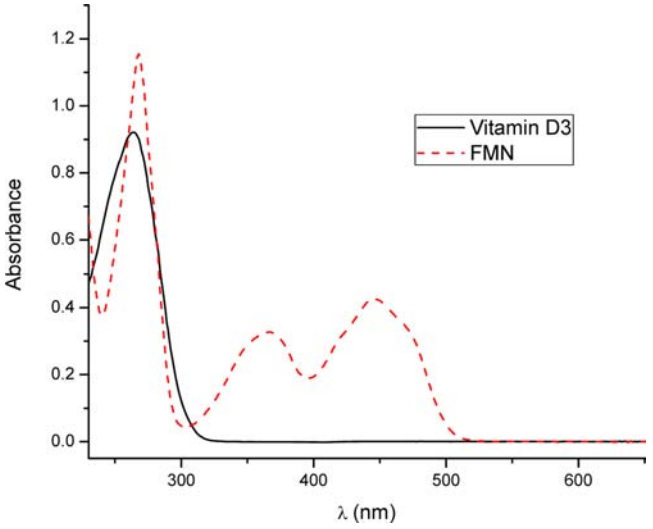

Figure 2. UV−vis absorption spectra for solutions of flavin mononucleotide and vitamin D_3 (both 1.0×10^{-4} mol L^{-1}) in 7/3 *tert*-butyl alcohol/water (v/v) at 25 °C.

LC-DAD-SPE. The irradiated sample of FMN (1×10^{-4} mol L^{-1}) and vit.D (1×10^{-4} mol L^{-1}) was analyzed by LC-DAD (Shimadzu Prominence 20A system, Shimadzu Co., Kyoto, Japan). Chromatographic separation was carried out on an Agilent Extend C18 reverse phase column (2.1 mm × 150 mm × 50 μm). The injection volume was 100 μL. The chromatographic separation was performed at a flow rate of 0.25 mL min^{-1} in isocratic mode consisting of 15% of solvent B in solvent A (A, 80/20 ACN/H_2O (v/v); B, MeOH). The peaks of interest were detected using the UV response at 265 nm. After the chromatographic separation, peaks of interest were trapped on Hysphere C18 cartridges from Spark-Holland using a Prospek-II automatized SPE system (Spark-Holland, Emmen, Holland) attached to the LC-DAD instrument; the target peaks from 10 chromatographic runs were sequentially trapped on the SPE cartridge to ensure enough quantity for the NMR analysis. Solvents used were nondeuterated. A makeup flow of eluent A was added to the postcolumn eluate in a ratio of 10/1 in order to improve the retention. After the trapping process, the cartridges were dried with high-purity nitrogen to remove residual solvents. Pure deuterated methanol was used to flush the peak from the SPE cartridge directly into the sample vial for posterior NMR analysis.

Nuclear Magnetic Resonance Spectroscopy. ^1H NMR experiments were performed using a Bruker Avance-III 600 MHz NMR spectrometer equipped with a ^1H {^{13}C, ^{15}N} triple-resonance inverse cryoprobe (TCI).

The one-dimensional ^1H NMR experiment was based on the 1D version of the NOESY sequence, using double presaturation suppression (methanol and water) during the relaxation delay (4 s). The spectrum was acquired using 16k data points in a 9578.54 Hz spectral width, giving an acquisition time of 3.42 s. Processing was performed using exponential multiplication, applying a line broadening factor of 0.5 Hz.

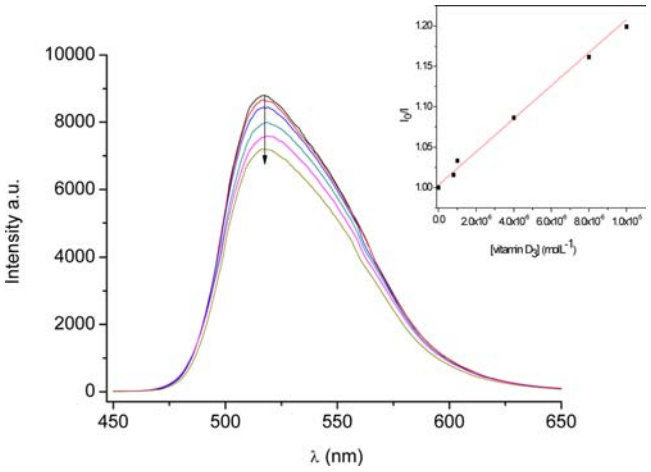

Figure 3. Fluorescence emission spectra at 25 °C of 1.0×10^{-4} mol L^{-1} flavin mononucleotide (in 7/3 *tert*-butyl alcohol/water (v/v)) for increasing concentrations of vit.D_3, from 8.0×10^{-7} to 8.0×10^{-6} mol L^{-1}. Inset: Stern–Volmer plot (see eq 1). λ_{exc} 440 nm and λ_{emis} 520 nm.

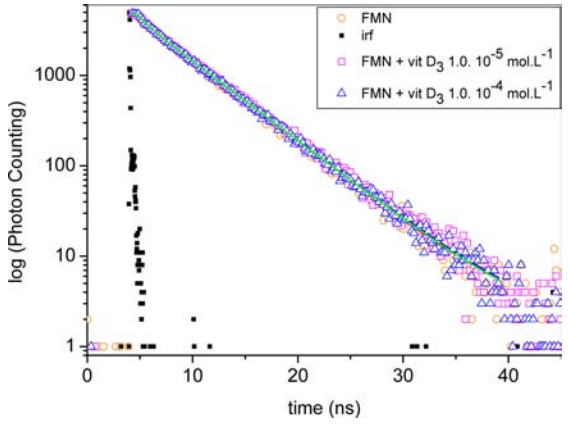

Figure 4. Fluorescence lifetime measurements at 25 °C by time-resolved single-photon counting for 1.0×10^{-5} mol L^{-1} flavin mononucleotide, in the absence or presence of 1.0×10^{-5} or 1.0×10^{-4} mol L^{-1} vitamin D_3 in 7/3 *tert*-butyl alcohol/water (v/v). irf denotes the instrument response function.

High-Resolution Accurate Mass Spectrometry. Direct infusion high-resolution accurate ESI-MS spectra of reaction products were obtained on an LTQ-Orbitrap Thermo Fisher Scientific mass spectrometry system (Bremen, Germany) operating in the positive ion detection mode. General conditions: heater temperature, 50 °C' sheath gas flow rate, 5 au; spray voltage, 3.7 kV; capillary temperature, 275 °C; flow rate, 5 μL/min.

RESULTS AND DISCUSSION

The biologically active forms of vitamin B_2, i.e. flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), may be present in human skin together with a form of vitamin D, cholecalciferol (vit.D_3) or ergocalciferol (vit.D_2), and certain vitamin D precursors.[3,5] FMN and FAD absorb visible light, in contrast to vit.D, as is seen from Figure 1 for FMN and vit.D_3. Vitamin D precursors as well as vit.D absorb only UV-B light, which, however, initiates their conversion. Exposure to sunlight with its UV-B component is important for the vit.D status of humans, due to these photoconversions and to other sterol photoreactions.[6] In contrast, FAD and FMN form excited states

by absorption of visible light, with the risk of inducing oxidative damage to the skin.[12] The clear spectral separation between FMN/FAD and vit.D_3, as seen from Figure 2, gave inspiration to a novel approach for a photophysical investigation of a possible protective effect of vit.D_3 against vit.B_2 induced pathological conditions in human skin upon exposure to sunlight. No complications from spectral interference from vit.D_3 was to be expected, as seen from Figure 2, upon excitation of FMN with 355 nm or with 440 nm monochromatic light, the wavelengths

DOI: 10.1021/jf505958c
J. Agric. Food Chem. 2015, 63, 4629–4637

used for the time-resolved photophysical investigation of the triplet states of riboflavin and of the excited singlet state of riboflavin, respectively, and their interaction with vit.D_3.

Exposure of FMN to 440 nm monochromatic light resulted in intense fluorescence, which for 7/3 *tert*-butyl alcohol/water (v/v) as solventwas centered at 540 nm with a lifetime of 4.8 ns for 25 °C[13] (see Figures 3 and 4). The fluorescence intensity decreased in the presence of increasing concentrations of vit.D_3 without affecting the fluorescence lifetime, as probed by time-resolved single photon counting fluorescence spectroscopy with 355 nm light excitation for experiments with a FMN concentration of 1.0×10^{-5} mol L^{-1} and a vit.D_3 concentration of 1.0×10^{-5} or 1.0×10^{-4} mol L^{-1}. The quenching of FMN fluorescence intensity by vit.D_3 was analyzed in accord with the Stern−Volmer equation for vit.D_3, ranging from 8.0×10^{-7} to 1.0×10^{-6} mol L^{-1}:

$$\frac{I_0}{I} = 1 + k_q \times \tau \times [\text{vit.D}_3] \quad (1)$$

where I_0 is the fluorescence intensity at 525 nm in the absence of vit.D_3, I is the fluorescence emission intensity for increasing concentrations of vit.D_3, τ is the natural lifetime of the FMN singlet excited state, determined to have a value of 4.8 ns (see Figure 4, confirming previous findings),[13] and k_q is the specific rate constant for singlet excited state quenching (see insert in Figure 3). The experimentally obtained Stern−Volmer constants for different temperatures (15, 25, 35, and 45 °C) are collected in Table 1. The high values observed for the second-order rate constant, which were above the diffusion limit, indicate static quenching involving formation of a FMN−vit.D_3 ground-state precursor complex. An increase in temperature from 15 to 45 °C

Figure 6. J. Agric. Food Chem. 2015, 63, 4629−4637

reduces the observed quenching rate constant, indicating formation of the ground-state precursor complex to be an exothermic process. Formation of a ground-state complex was further investigated by analyzing FMN fluorescence emission decay curves in the presence of increasing concentrations of vit.D_3 (Figure 4). The normalized time decay curves for the FMN singlet excited emission did not change for increasing concentrations of vit.D_3, confirming the formation of the ground-state precursor complex and static quenching.

The formation of this precursor complex may be represented by the reaction

$$n \text{ vit.D}_3 + \text{FMN} \overset{K_a}{\rightleftharpoons} [\text{vit.D}_3]_n - \text{FMN} \quad (2)$$

The number of quenchers binding (n) to the fluorophore FMN was calculated according to

$$\log[(I_0 - I)I] = \log K_a + (n \log[\text{vit.D}_3]) \quad (3)$$

where K_a is the equilibrium constant for the reaction of eq 2. The experimental values determined for K_a and n for four different temperatures were obtained by fitting eq 3 to the data plotted in Figure 5A and are collected in Table 2. The thermodynamic parameters for the ground-state complex formation were found to have values of $\Delta H° = -36 \pm 7$ kJ mol^{-1} and $\Delta S° = -3.9 \pm 3.0$ J mol^{-1} K^{-1} according to the van't Hoff equation for a 1/1 stoichiometry (see Figure 5). The binding of FMN to vit.D_3 is suggested to be due to a hydrophobic interaction, which often is an exothermic process, as is the present case. The small change in entropy for binding of FMN to vit.D_3 seems to indicate little solvent involvement. The isoalloxazine ring of FMN is hydrophobic and has the possibility of binding to hydrophobic parts of vitamin D_3 through $\pi-\pi$ stacking.[14] The observed FMN fluorescence quenching by vit.D_3 indicates interaction between these two vitamins when they are in their ground states, due to hydrophobic interaction.

As a consequence of an efficient intersystem crossing in singlet excited FMN (and riboflavin and FAD) to their lowest-energy triplet states, these vit.B_2 forms become strongly reactive upon light exposure, as in skin or in dairy products.[15] vit.D_3 is a possible reactant for ^{3}FMN in the skin, and the reaction between ^{3}FMN and vit.D_3 was studied using transient absorption spectroscopy following laser flash photolysis. The triplet−triplet absorption of ^{3}FMN around 720 nm[13,16] was used to monitor the decay of the reactive ^{3}FMN in the presence of increasing concentrations of vit.D_3 (see Figure 6). ^{3}FMN was found to decay mono-exponentially for 7/3 *tert*-butyl alcohol/water (v/v) as solvent according to

$$\Delta A_t = \Delta A_{t=0} \exp^{-k_{obs}t} \quad (4)$$

and k_{obs} was determined for increasing vit.D_3 concentration. As may be seen from the inset in Figure 6, k_{obs} showed a linear dependence on vit.D_3 concentration:

$$k_{obs} = k_0 + k_2[\text{vit.D}_3] \quad (5)$$

where k_0 is the rate constant for the triplet-state self-decay and k_2 is the second-order rate constant for the triplet-state deactivation by vit.D_3. The value of $k_2 = 1.4 \times 10^8$ L mol^{-1} s^{-1} at 25 °C (7/3 *tert*-butyl alcohol/water (v/v)) was calculated by linear regression (Figure 6) together with $k_0 = 5.0 \times 10^4$ s^{-1} corresponding to a natural triplet-FMN lifetime of 13 μs at 25 °C, in agreement with previous findings.[16] However, in aqueous Tween-20 micelles, as a probe for specific microdomain reactivity of ^{3}FMN toward vit.D_3 that is preferentially located

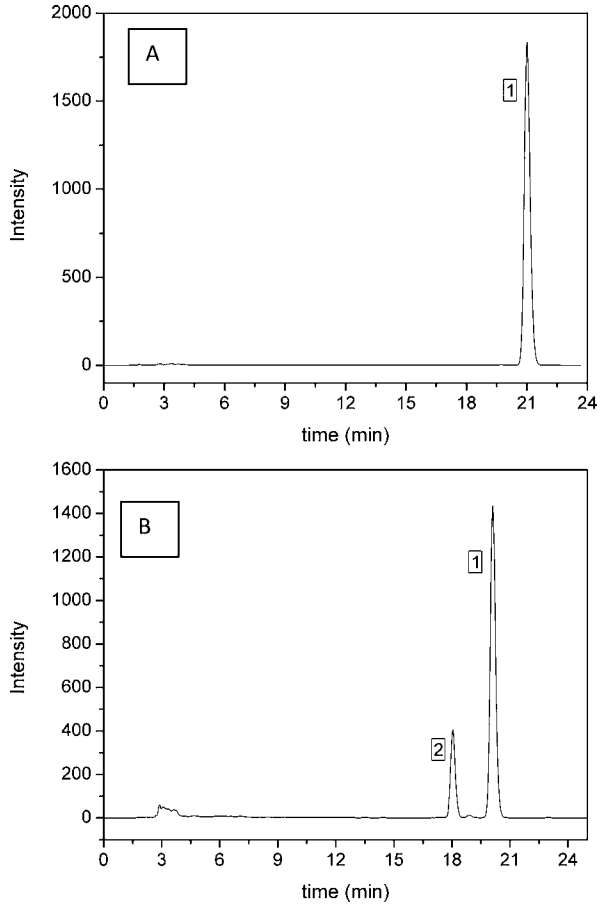

Figure 8. LC-DAD-SPE chromatograms monitored at 265 nm of flavin mononulceotide/vit.D_3 solution in 7/3 *tert*-butyl alcohol/water (v/v) prior to light exposure (A) and following 120 min of exposure to 440 nm monochromatic light (B).

inside the hydrophobic core of the micellar aggregates, ^{3}FMN was found to shown a triple-exponential decay curve (experimental goodness of fit $\chi^2 = 1.05$) according to

$$\Delta A_t = \Delta A_{1,t=0} \exp^{-k_{1,obs}t} + \Delta A_{2,t=0} \exp^{-k_{2,obs}t} + \Delta A_{3,t=0} \exp^{-k_{3,obs}t} \quad (6)$$

From fitting of eq 6 to the experimental data in Figure 7A, the k_{obs} values for each microdomain were determined for increasing concentrations of vit.D_3 together with the estimated percentage distributions of ^{3}FMN in the three observed microdomains (average of 89.4% in the continuous phase, 9.6% at the interface, and 1% at the disperse phase in the presence of 0.83 mM vit.D_3), as extracted from the pre-exponential term of eq 6. Figure 7B shows the linear dependence of k_{obs} for each microdomain with increasing concentrations of vit.D_3, yielding the second-order rate constant for the triplet-state deactivation by vit.D_3 in the three different environments: $k_2 = 6.9 \times 10^9$ L mol^{-1} s^{-1} for the reaction at the continuous phase, $k_2 = 7.1 \times 10^8$ L mol^{-1} s^{-1} for the reaction at the micelle interface, and $k_2 = 7.2 \times 10^7$ L mol^{-1} s^{-1} for the reaction inside the hydrophobic core of the micellar aggregates. The right panel of Figure 7A illustrates the three different microdomains for deactivating ^{3}FMN by vit.D_3 in aqueous Tween-20 micelles. The kinetic results in aqueous Tween-20 micelles provide strong evidence that ^{3}FMN may be deactivated by vit.D_3 at the interface of the cell membrane or inside the plasma membrane when ^{3}FMN is present as a

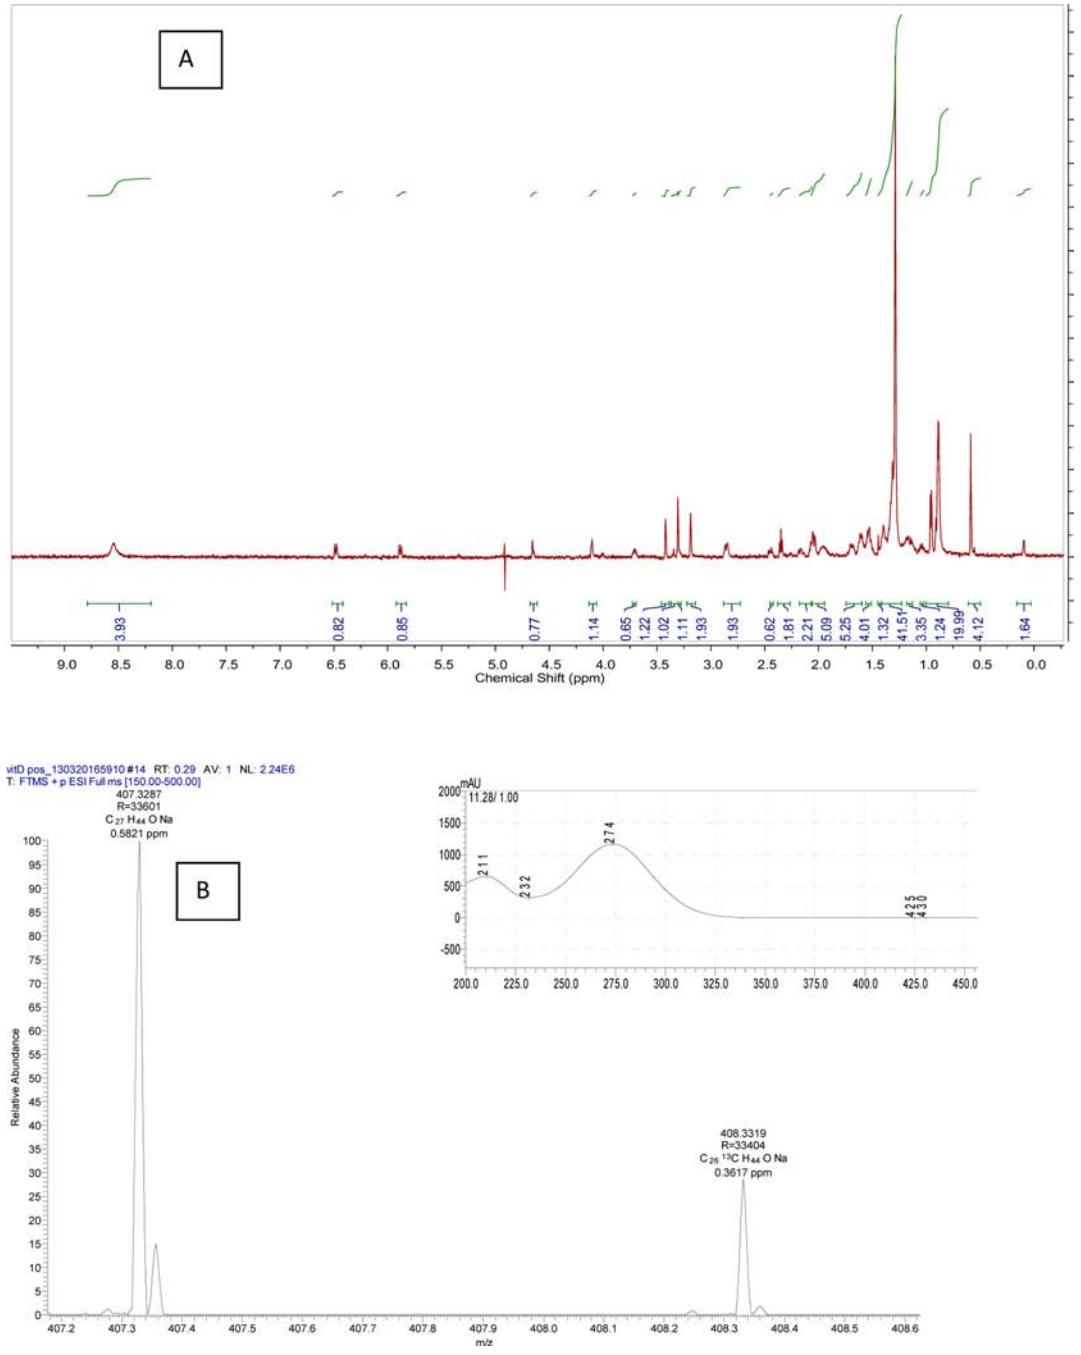

Figure 9. Spectroscopic characterization of photoproduct from exposure of flavin mononucleotide/vit.D3 solution in 7/3 *tert*-butyl alcohol/water (v/v) for 120 min with 440 nm monochromatic light: (A) ^{1}H NMR spectrum of photoproduct from isolated peak 2 of chromatogram B of Figure 6; (B) ESI-MS high-resolution accurate mass spectrum of photoproduct from peak 2 of chromatogram B in Figure 6. Inset in (B): UV−vis absorption spectrum of photoproduct.

flavoprotein, as in NAD(P)H oxidase and NAD(P)H quinone oxidoreductase.

The photochemical reaction quantum yield (Φ) for vit.D_3 disappearance provides a more practical measurement of the efficiency with which the reaction between the two vitamins occurs upon visible UV-A light exposure occurs and may be determined from eq 7 for 440 nm light exposure:

$$\Phi = \frac{\text{molecules}_{\text{reacted}}}{\text{photons}_{\text{absorbed}}} = \frac{V([\text{vit.D3}]_{\text{dark}} - [\text{vit.D3}]_{\text{irradiated}})}{q^0_{\text{n,p}}(I - 10^{-A_\lambda})} \quad (7)$$

in which the ratio between the number of molecules of vit.D_3 reacted and the number of photons absorbed by vit.B_2 was calculated from the results of HPLC analysis of vit.D_3 exposed to and protected against light in a solution together with FMN and from chemical actinometry. $q^0_{\text{n,p}}$ is the light intensity for the 440 nm monochromatic light used for exposure, and A_λ is the absorbance at 440 nm of the 7/3 *tert*-butyl alcohol/water (v/v) solution with vit.D_3 and FMN. Φ for disappearance of vit.D_3 in the photoreaction sensitized by FMN was found to have a value of 0.15 ± 0.01 in air-saturated 7/3 *tert*-butyl alcohol/water (v/v) for a concentration of 1.0×10^{-3} mol L^{-1} for vit.D_3 and 1.0×10^{-4} mol L^{-1} for FMN. For anaerobic conditions, a value of

DOI: 10.1021/jf505958c
J. Agric. Food Chem. 2015, 63, 4629−4637

0.32 ± 0.01 was found; both values are means of three independent determinations at 25 °C.

The photoprocess of vit.D_3 considered relates to the triplet state of FMN as a photosensitizer, ^{3}FMN*, and not to the singlet state, ^{1}FMN*, since the lifetime of ^{3}FMN* decreases in the presence of vit.D_3 in contrast to the lifetime of ^{1}FMN*, as is seen from Figures 6 and 7 and Figure 5, respectively. The photochemical reaction occurs accordingly as a sequence:

$$\text{FMN} + h\nu \rightarrow {}^1\text{FMN}^* \quad (8)$$

$$^1\text{FMN}^* \rightarrow {}^3\text{FMN}^* \quad (9)$$

$$^3\text{FMN}^* + \text{vit.D}_3 \rightarrow \text{FMN} + \text{photoproduct} \quad (10)$$

in which initial excitation of FMN to form the excited singlet state is followed by an efficient intersystem crossing (ISC) conversion to the reactive triplet state. ^{3}FMN* is reacting with vit.D_3 to form a photoproduct, which was identified by high-resolution accurate ESI-MS and LC-SPE-NMR to be 5,6-*trans*-vit.D_3. The FMN/vit.D_3 solution was exposed to 440 nm monochromatic light for 2 h. Prior to and following irradiation, the solution was analyzed by LC-SPE; the chromatograms obtained are shown in Figure 8. In chromatogram A shown in Figure 8, the peak 1 eluting at 20 min refers to standard vit.D_3. In chromatogram B shown in Figure 8, peak 2 eluting at 18 min refers to the photoproduct formed. Peak 2 was isolated by LC-SPE and further analyzed by ^{1}H NMR and ESI-MS. The electrospray high-resolution accurate mass spectrum, recorded in the positive ion mode, showed a peak related to the photoproduct with a pseudomolecular ion at m/z 407.3287 with a error of 0.6 ppm and the expected isotopic pattern calculated for $C_{27}H_{44}ONa$ and assigned to a sodium adduct of an isomer of vit.D_3 (see Figure 9).

With the purpose of obtaining more information about the identity of the photoproduct, the isolated photoproduct was analyzed by ^{1}H NMR. The ^{1}H NMR spectrum obtained is shown in Figure 9A. The spectrum displays signals in the region 0−7 ppm. On the basis of the chemical shifts reported in Table 3, in comparison with literature values for vit.D_3 isomers, it was concluded that the photoproduct was the isomer 5,6-*trans*-vit.D_3.[17] The UV−vis absorption spectrum of the isolated photoproduct (Figure 9B) with a maximum absorption at 274 nm matches that of the 5,6-*trans*-vit.D_3 isomer.[17,18]

Riboflavin and its biologically active forms, FMN and FAD, are known to be strong oxidants in their triplet excited state with $E^{\ominus}$ = +1.7 V[5]. This very reactive triplet state is formed by an efficient intersystem crossing from the initially populated singlet excited state as the result of light absorption. For vit.D_3, FMN was found to form a 1/1 precursor complex in the ground state, resulting in static quenching, as was previously observed for cholesterol and ergosterol and assigned to hydrophobic $\pi-\pi$ stacking.[13] The singlet excited state of FMN was found to be too short-lived for any bimolecular reactions to occur, with a lifetime of 4.8 ns. The reaction of light-activated FMN was accordingly assigned to the triplet state and found to have a second-order rate constant of 1.4×10^8 L mol^{-1} s^{-1} for 7/3 *tert*-butyl alcohol/water (v/v) as solvent or of 6.9×10^9 L mol^{-1} s^{-1} at the continuous phase, 7.1×10^8 L mol^{-1} s^{-1} at the micelle interface, and 7.2×10^7 L mol^{-1} s^{-1} at the hydrophobic core of the micellar aggregates.[13] This is faster than the ^{3}FMN* reaction with most lipids, including cholesterol, but comparable with the ^{3}FMN* reaction with ergosterol with a rate constant of 6.2×10^8 L mol^{-1} s^{-1}.[13] The most important observation for the ^{3}FMN* reaction with vit.D_3 is, however, that ^{3}FMN* does not oxidize vit.D_3. Other lipophilic substrates and uric acid have been found to be oxidized by flavin triplet states.[13,19] An estimate of the redox potential for vit.D_3 was obtained by cyclic voltammetry (see Figure 10), and with a value of +1.5 V, oxidation of vit.D_3 by ^{3}FMN* was shown to be possible with +1.7 V for triplet FMN. However, isomerization dominates completely and no oxidation products of vit.D_3 were detected. Isomerization of vit.D_3, to yield 5,6-*trans*-vit.D_3 requires rotation around the conjugated double bonds in vit.D_3 and would be facilitated in a diradical triplet state of vit.D_3. The formation of the diradical form of vit.D_3 followed by rotation and recombination to a vit.D_3/5,6-*trans*-vit.D_3 mixture apparently competes efficiently with electron transfer from vit.D_3 to ^{3}FMN*:

$$^3\text{FMN}^* + \text{vit.D}_3 \rightarrow \text{FMN} + {}^3\text{vit.D}_3\text{-diradical} \quad (11)$$

$$^3\text{FMN}^* + \text{vit.D}_3 \rightarrow {}^2\text{FMN}^{\bullet-} + {}^2\text{vit.D}_3{}^{\bullet+} \quad (12)$$

An energy transfer mechanism involving the ^{3}vit.D_3 diradical is outlined in Scheme 1A for photosensitized isomerization of vit.D_3. The triplet energy of vit.D_3 has been estimated to be around 200 kJ mol^{-1}, while the energy of the triplet 5,6-*trans*-vit.D_3 is

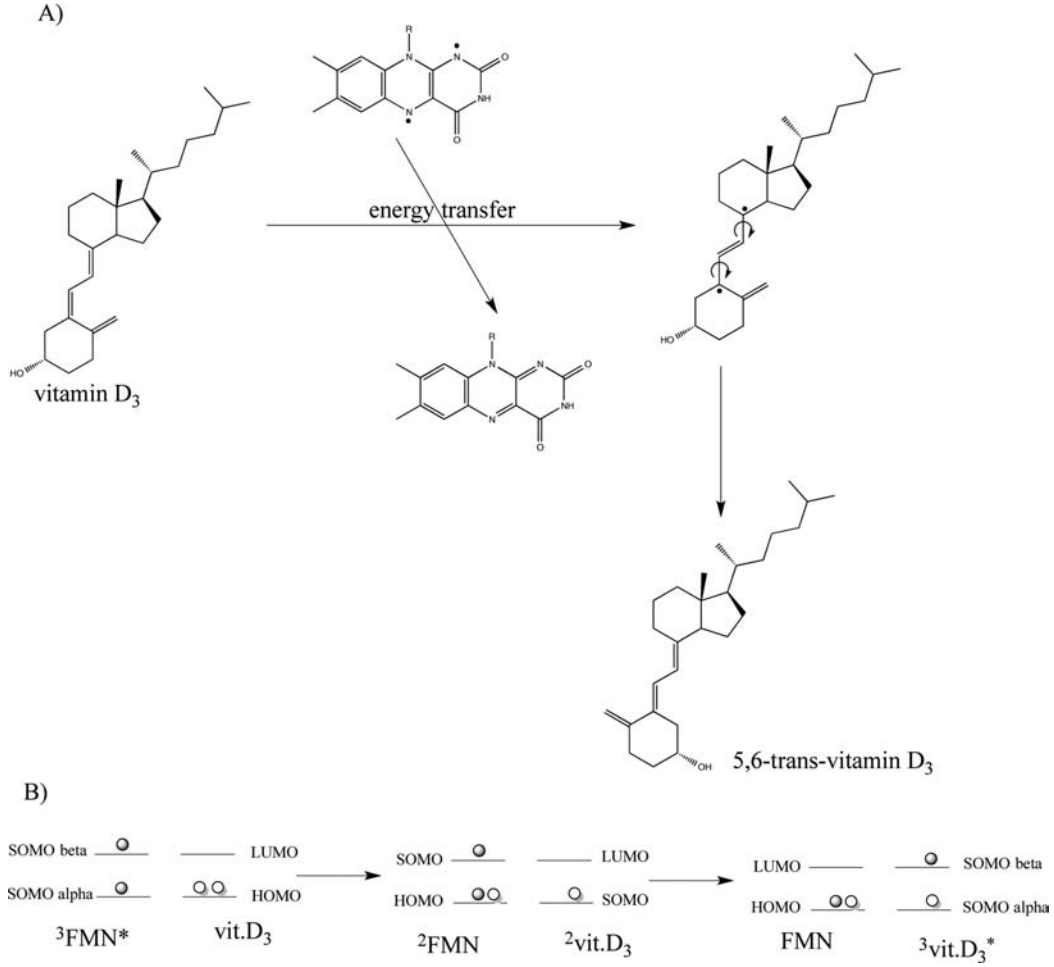
Scheme 1. Proposed Reaction Mechanism for Vitamin D_3 Isomerization through Charge Transfer Exchange of Electrons (Energy Transfer) From Triplet-State Flavin Mononucleotide Yielding 5,6-*trans*-Vitamin D_3



lower with a value of around 170 kJ mol^{-1}, both comparable to that of ^{3}FMN*.[20] The observed quenching constant of $k_2 = 1.4 \times 10^8$ L mol^{-1} s^{-1} may thus be assigned to the reaction of eq 11, with the electron transfer reaction of eq 12 being significantly slower.

An energy transfer mechanism rather than electron transfer could be explained by a stepwise charge transfer exchange of electrons where vit.D_3 donates an electron to the lowest energy SOMO orbital of ^{3}FMN* with formation of a radical ion pair [$^2FMN^{\bullet -}\cdots{}^2vit.D_3^{\bullet +}$] followed by electron transfer from the SOMO orbital of the $^2FMN^{\bullet -}$ to the LUMO orbital of $^2vit.D_3^{\bullet +}$ of the radical ion pair (see Scheme 1B). For FMN this exchange will deactivate ^{3}FMN* to form ground-state FMN, while for vit.D_3 a triplet diradical is formed in order to conserve spin. The ^{3}vit.D_3 may rotate as shown in Scheme 1A around the 5,6- and 7,8-bonds to form an equilibrium mixture prior to deactivation. Notably, this mechanism entails that the trans product formed may re-form the vit.D_3 also in a photochemical process. 5,6-*trans*-vit.D_3 still has biological effects in relation to calcium biomineralization.[7]

The competition between deactivation of ^{3}FMN* by $^3O_2$ and vit.D_3 depends on the second-order rate constants 9.8×10^8 L mol^{-1} s^{-1} for oxygen and 1.4×10^8 L mol^{-1} s^{-1} for vit.D_3 in the reaction of eq 11 and the actual concentrations of quenchers to yield the relative deactivation by vit.D_3 to yield 5,6-*trans*-vit.D_3:

$$\text{relative } {}^3\text{FM}^* \text{ deactivation by vit.D}_3 = \frac{k_{\text{vit.D3}}[\text{vit.D}_3]}{k_{\text{vit.D3}}[\text{vit.D}_3] + k_{\text{O2}}[\text{O}_2]} \quad (13)$$

The relative deactivation by vit.D_3 corresponds accordingly, using $[O_2] = 3 \times 10^{-4}$ mol L^{-1}, the value for water, also for the mixed solvent and $[\text{vit.D}_3] = 1 \times 10^{-3}$ mol L^{-1}, to a fraction of 0.32, which should be compared to the ratio between the quantum yields in the presence and in the absence of oxygen, which is seen to have an approximate value of 0.5. This is an acceptable agreement, and in the absence of electron transfer, this explains the surprising protective effect of oxygen against isomerization. Ground-state oxygen will form singlet oxygen, $^1O_2$, but the reaction of $^1O_2$ with vit.D_3 apparently is too slow to result in oxidation under the present conditions, and $^1O_2$ may deactivate thermally or react with FMN.[21]

Vitamin D_3 was found to be an efficient quencher of the triplet excited state of FMN, one of the biologically active forms of riboflavin, vitamin B_2. Triplet flavins such as FMN are strong oxidants, which ae known to be harmful for skin and eyes under light exposure and deplete nutrients in milk during retail display.[4,21] A number of otherwise biologically important nutrients are known to deactivate these photosensitizers derived from vitamin B_2 in food and tissue exposed to light.[5] Our findings are important in the respect that we have shown that vit.D_3 isomerizes rather than being oxidized as the result of this

DOI: 10.1021/jf505958c
J. Agric. Food Chem. 2015, 63, 4629−4637

quenching reaction. The isomerization leads to a photostationary state, and vit.D_3 is still active as a vitamin in this mixture and may re-form vit.D_3 from the isomerized 5,6-*trans*-vit.D_3 photochemically. These observations may add a new perspective to the role of vit.D_3 accumulated in the skin as a protector against light-induced oxidative damage and radical formation from flavins acting as photosensitizers.

Supporting Information

ABSTRACT: The objective of this research was to investigate the development of a reliable fingerprint from elemental and isotopic signatures of Argentinean honey to assess its geographical provenance. Honey, soil, and water from three regions (Córdoba, Buenos Aires, and Entre Ríos) were collected. The multielemental composition was determined by ICP-MS. $\delta^{13}C$ was measured by isotopic ratio mass spectrometry, whereas the $^{87}Sr/^{86}Sr$ ratio was determined using thermal ionization mass spectrometry. The data were analyzed by chemometrics looking for the association between the elements, stable isotopes, and honey samples from the three studied areas. Honey samples were differentiated by classification trees and discriminant analysis using a combination of eight key variables (Rb, K/Rb, B, U, $^{87}Sr/^{86}Sr$, Na, La, and Zn) presenting differences among the studied regions. The application of canonical correlation analysis and generalized procrustes analysis showed 91.5% consensus between soil, water, and honey samples, in addition to clear differences between studied areas. To the authors' knowledge, this is the first report demonstrating the correspondence between soil, water, and honey samples using different statistical methods, showing that elemental and isotopic honey compositions are related to soil and water characteristics of the site of origin.

KEYWORDS: *honey, trace elements, isotopic composition, geographical origin, authenticity, traceability, fingerprint*

INTRODUCTION

In these past years, authenticity and traceability of foodstuffs became a major requirement for consumers and producers worldwide. Food products have been linked to a specific geographical origin; however, such links have disappeared over time mostly because of the globalization of the food industry[1] Food is becoming more regulated, with the increase in global trade and free markets. That is why there is an increased need for developing new methods and techniques to discriminate different food origins, sources, or farming systems.[2]

Honey is a high value-added product, which is of high interest for assessing its authenticity (both geographical origin and floral sources). Additionally, the detection of disallowed substances, such as syrups or sugars, contributes to honey authenticity and safety.[3,4] According to the European legislation (Council Directive 2001/110), the country where the honey was collected has to be declared. Honey with geographical and botanical origins declared are differently valued and, for that reason, subjected to frauds, leading to doubtful labeling.[3]

Honey chemical composition is generally associated with its botanical origin and, to a lesser degree, with the geographical area where it was collected, because environment (soil and climate) determine the melliferous flora.[5,6] For botanical origin classification, conventional methods (physical characteristics, chemical composition, pollen analysis, and sensory parameters) are mainly used.[3,7−10]

The multielemental content of food reflects the type of soil and environment conditions.[11−13] Honey contains between 0.04 and 0.2% (w/w) of trace elements. The soil composition of the origin, determined by geochemical and geological features (i.e., regional geology and climatic changes), affects the composition and concentration of metals in honey.[14,15] The botanical origin (nectar, pollen, and floral type of honey plants) are also responsible for the metal content of honey.[14,16] Furthermore, trace element contents in honey could also serve as indicators of environmental pollution.

On the other hand, the analysis of stable isotopes has gained importance in the determination of the geographic origin of food. Stable isotope measurements were first introduced within the European wine industry to ensure authenticity and to detect adulteration using carbon, oxygen, and hydrogen, mostly, but also strontium.[17] These measurements have been extended to many other foods (e.g., milk, meat, honey, juices, spirits, and flavors).[9,11−13,18,19] Small but significantly different ratios of stable isotopes can be correlated with the botanical−metabolic and/or geographical−geological origin of a product. Isotope ratios may add to the element fingerprint information on the plant type and the geographical−geological origin.[20]

Even though there are many studies focusing on the elemental profile of honey,[6,21−23] or on stable isotopes,[9,19,24] there are few that combine both parameters.[9] In addition, there are also few studies that consider the association with soil and water from places where honey is made.[19] Furthermore, there has been little research on the determination of both the content of elements and stable isotopes in Argentinean honey.[14,21,25] In this paper, for the first time, we present the results of the determination of 33 elements and carbon and strontium isotopes in Argentinean honey from three different regions (Buenos Aires, Córdoba, and Entre Ríos). Additionally, we were interested in demonstrating the link between honey, soil, and water by applying different chemometric tools. To our knowledge, this is the first approach in Argentina on the combined use of Sr and C isotope ratios and multielement analysis of soil, water, and honey to assess the geographical origin.

MATERIALS AND METHODS

Reagents and Materials. Ultrapure water (<5 μg L^{-1} total organic content) was obtained from an Arium 61316-RO purification system combined with an Arium 611 UV (Sartorius, Germany). The certified ICP-MS multielement Merck VI CertiPUR standard solution was obtained from Merck Química Argentina (Buenos Aires, Argentina). Nitric acid (63.7%), sub-boiling grade, was prepared from analytical grade acid (Merck Química Argentina) using a distiller (Figmay sub-boiling distiller, Córdoba, Argentina).

The purity of nitric acid was verified by ICP-MS. Filters (0.45 μm, HAWG04756) were obtained from Millipore (São Paulo, Brazil). Trace element certified reference material (CRM) wheat flour 1567a was obtained from the National Institute of Standards and Technology (Gaithersburg, MD, USA). The best estimate values for constituent elements in CRM 1567a are detailed in the accompanying certificate of analysis provided by the manufacturer. Ion exchange chromatography Sr Spec resin was obtained from Eichrom Technologies (USA). Strontium isotopic standard (NBS SRM 987) was employed to determine mass discrimination during the isotopic analyses by thermal ionization mass spectrometry (TIMS). All other analytical grade reagents were used.

Sampling. Soil, water, and honey samples were collected from selected producing areas from three provinces of Argentina: Buenos Aires, Córdoba, and Entre Ríos. These provinces are the most important honey-producing areas in Argentina (Figure 1). The sampling area in Buenos Aires is located between 37°25′ and 37°38′ S and between 59°10′ and 59°14′ W; the Córdoba sampling area is located between 30°30′ and 31°08′ S and between 63°34′ and 64°08′ W; and the Entre Ríos sampling area is located between 32°49′ and 32°53′ S and between 58°32′and 58°34′ W. The altitude varies from 460 m above sea level in Córdoba to 240 m above sea level in Buenos Aires to 30 m above sea level in Entre Ríos. Soil, water, and honey samples were collected from different beekeepers during three harvests (2007, 2008, and 2009): seven in Córdoba, five in Buenos Aires, and six in Entre Ríos. Soil and water samples were collected and processed according to the method of Baroni et al.[11] A total of 79 honey samples were collected: 27 samples were collected in Buenos Aires, 25 in Córdoba, and 27 in Entre Ríos. Five hundred grams of honey was collected in plastic recipients, transported to the laboratory within 48 h, and stored at 4−8 °C until analysis.

Figure 1. Map of the three regions where honey samples were collected.

Elemental Analyses. Five hundred milligrams of honey sample was mineralized with 8 mL of concentrated nitric acid using a microwave oven (Anton Paar Multiwave 3000, Vienna, Austria) following methods described by Podio et al.[13] CRM 1567a was processed and measured in the same way used for honey. Values obtained for the latter were between 85 and 105% of certified values.

Thirty-one elements were quantified in honey samples: Al, B, Ba, Ca, Cd, Ce, Co, Cs, Cu, Eu, Ga, K, La, Li, Lu, Mg, Mn, Mo, Na, Nd, Ni, Pb, Rb, Se, Sm, Sr, Tl, U, V, Yb, and Zn. The analysis was carried out by quadrupole inductively coupled plasma mass spectrometry (QICP-MS) for all elements except sodium as stated in Baroni et al.[11]

Stable Isotope Analysis. *Carbon Isotope Analysis.* Carbon isotope ratios were determined on whole honey and protein fraction. Protein isolation and purification were done according to AOAC Official Method 998.12 (repetitive washing procedure), using tungstic acid, sodium salt, and sulfuric acid. Both honey and protein samples were placed in quartz tubes, with added copper oxide. Tubes were prepared for combustion by evacuation on a vacuum line and sealed with a torch. Combustion was performed at 550 °C over 8 h, after which the tubes were allowed to cool at room temperature inside the oven. Following combustion the tubes were cracked open to extract pure CO_2 on the vacuum line using a cryogenic trap to retain water and non-CO_2 gases. The purified CO_2 was collected with a liquid nitrogen trap in a glass collection tube. The purified CO_2 was measured in a Multiport Dual Inlet IRMS (Finnigan MAT Delta S), using CO_2 gas as reference.

The isotope ratios were normalized using laboratory working standards, calibrated with international standards supplied by the International Atomic Energy Agency (NBS 22, NBS18). The $^{13}C/^{12}C$ ratios are expressed in the delta notation, $\delta^{13}C$ as the deviation per mil (‰) from the Vienna Pee Dee Belemnite (V-PDB) standard. The uncertainty of carbon isotope determinations was ±0.2‰.

Strontium Isotope Analysis. Bulk samples were processed by dry ashing technique in a muffle furnace. More than 100 g of sample was placed in porcelain crucibles and heated at 550−600 °C. The furnace was programmed to ramp up to the ashing temperature over a period of 8 h. Complete ashing was ensured by maintaining this temperature for 10 h. Residues were treated with concentrated HNO_3 on a hot plate and then transferred again to the muffle until white ashes appeared. The residues were dissolved in HNO_3, and subsequently Sr was separated by ion chromatography on a Sr-specific resin (Sr-spec). Sample manipulation was carried out in a clean environment (Class 100 laboratory). To prevent contamination, all laboratory-ware was soaked in 50% (v/v) nitric acid for at least 24 h, rinsed several times with ultrapure water, and dried in a Class 100 laminar flow exhaust hood.

Strontium isotope ratios were measured following the method described by Baroni et al.[11]

Soil and Water Analysis. The methodology and the results of soil and water samples in the regions under study were published by Baroni et al.[11]

Statistical Analysis. Data were analyzed using the statistical package Statistica 8.0 from StatSoft Inc. (2007) and the Infostat software package.[26]

Analysis of Variance. Results were analyzed by ANOVA, and significant differences between mean values were determined by DGC test ($p < 0.05$).

Classification Tree Analysis (C&RT). Classification trees are used to predict membership of cases or objects in the classes of a categorical dependent variable from their measurements on one or more predictor variables. These methods consist of algorithms based on rule induction, which is a way of partitioning the data space into different class subspaces. Basically, the data set is recursively split into smaller subsets, where each subset contains objects belonging to as few categories as possible. A test set, containing objects not used in the training and also with known class memberships, serves to test the performance of the classifier.[27] The training set contains 75% of total honey samples. The subsets were selected randomly for each class separately. A leave-one-object out cross-validation procedure was adopted to optimize models constructed. The efficiency of the model was used to characterize quality of model prediction, which is the total percentage of a correctly classified test sample.

Discriminant Analysis (DA). DA was performed in stepwise mode to discriminate honey samples according to their geographical origin. Most significant variables were selected according to the F value. A cross-validation test was used to evaluate the robustness of the classification model.

Generalized Procrustes Analysis (GPA). GPA is a useful statistical method to evaluate the correspondence between different data from the same object. In this case, we evaluate correspondence of elemental and isotopic data from soil, water, and honey from each geographical origin.[11]

Canonical Correlation Analysis (CCA). CCA was used to find relationships between concentrations of elements and isotopes in soil, water, and honey. This analysis allows us to investigate the relationship of two sets of variables, honey versus soil and honey versus water.

RESULTS AND DISCUSSION

Multielement Contents. Table 1 shows mean values and standard deviations of element data for honey samples from the

J. Agric. Food Chem. 2015, 63, 4638−4645

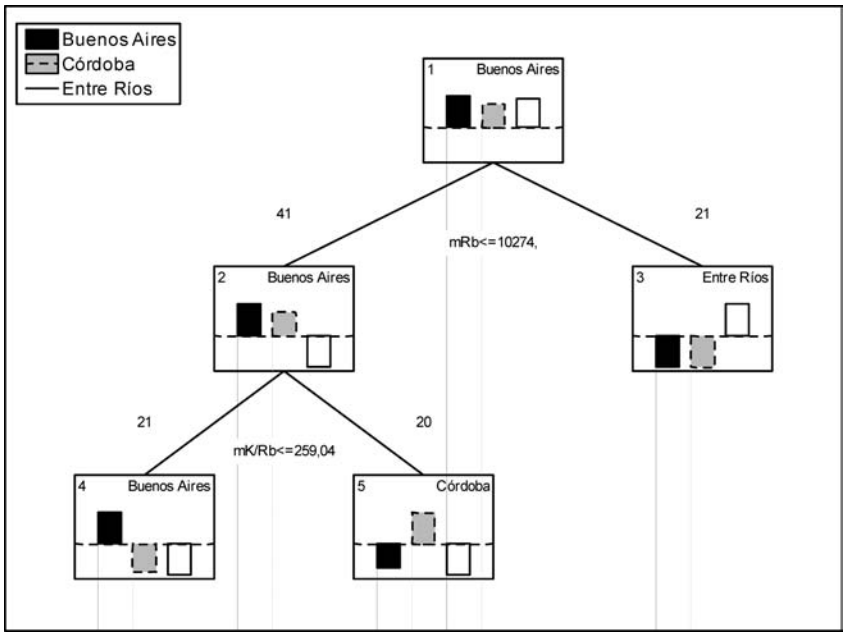

Figure 2. Classification tree of honey samples according to their type using the classification tree method.

three studied regions. Furthermore, K/Rb and Ca/Sr ratios were included. The K/Rb ratio can greatly differ among various types of rocks and soils.[28] On the other hand, the Ca/Sr ratio has been used as a chemical tracer in geochemistry, hydrogeochemistry, and bioavailability studies.[29]

Tl was the only element analyzed that fell below the detection level in honey. In line with most previous studies,[21−23,27] potassium (K) was the most abundant element in studied honey, followed by Ca, Mg, and Na. B, Al, Mn, Zn, Rb, and Ba were present in intermediate concentrations (Table 1). The other analyzed elements were below 1 ppm.

We observed some differences between the geographical origins despite honey samples being multifloral in majority causing certain variability in the elemental composition. Twenty-five elements were significantly different at least in one region ($p < 0.05$), demonstrating that honeys from different regions have a characteristic elemental profile. Five variables (B, Mg, K, Mn, and Sr) were significantly different among the three studied regions. Conversely, V, Ni, Yb, and Pb did not show significant differences between the three studied areas. Ba presented lowest values in Buenos Aires, whereas Córdoba and Entre Ríos had similar higher values. Additionally, Li, Na, Al, Ca, Co, Cu, Zn, Rb, Mo, Ce, Nd, Eu, Yb, and Lu presented highest values in honey from Entre Ríos, whereas Buenos Aires and Córdoba presented similar lower values. Conversely, Sm presented lower values in Entre Ríos and similar higher values in Córdoba and Buenos Aires.

The ratios Ca/Sr and K/Rb also showed variations. Ca/Sr was higher in Buenos Aires and had similar lower values in Córdoba and Entre Ríos, whereas K/Rb was higher in Córdoba and presented lower values in Buenos Aires and Entre Ríos.

The contents of nutritionally important elements were calculated in a daily intake of 42.8g of honey (two spoons) and compared to their daily dose allowance (DDA) in the human body, taken from Seiler et al.[30] The ingestion of two spoons of honey represents between 0.1 and 12% of the DDA (Table 1).[31]

Apart from mineral nutrients, the analysis of the elemental composition of honey may also give information about environmental pollution. The contents of trace elements in the Argentinean honey were comparable with the contents in honey from uncontaminated areas.[22,23,27] This emphasizes the good quality of Argentinean honey, especially with regard to the contents of toxic trace elements, such as Cd, Pb, and U. All of the honey samples presented a concentration of heavy metals below maximum levels for food set by Commission Regulation (EC) No. 1881/2006 (EC, 2006) amended by EC 629/2008 (EC, 2008).[32] With respect to cadmiun content, samples from Córdoba showed the highest values (600 ppb), even though these values are below the maximum levels set. From previous studies, it can be noted that industry, mining, automobile exhaust gases, etc., may be responsible for cadmium contamination in honey.[33]

Carbon Isotopes. The carbon isotopes in plants and resulting products are mainly influenced by metabolism (carbon fixation), which is why the $\delta^{13}C$ values can be used to detect honey adulterated with C4 plant sugars, such as high fructose corn syrup (HFCS).[6,30,31] On the other hand, carbon isotopes are related to humidity and temperature (climate) and can be useful for food geographical origin assignment.[34]

On the basis of $\delta^{13}C$ values obtained, samples of this study were derived from C3 plants and have not been adulterated, at least with respect to C4 plant addition (corn or cane) (Table 11).[35,36] In previous studies[11,13] we found differences in meat and wheat $\delta^{13}C$ values from the same geographical origin, so we expected to find similar differences in honey samples. Córdoba showed the highest $\delta^{13}C$ value, whereas Buenos Aires and Entre Ríos had similar lower values. The difference between the highest (Córdoba) and lowest (Buenos Aires and Entre Ríos) $\delta^{13}C$ mean values is 1.6‰. $\delta^{13}C$ values of honey increase with increasing temperatures, increasing amount of sun exposure, and decreasing humidity.[19] As noted for wheat,[13] the highest $\delta^{13}C$ values from Córdoba honey samples could be related to an evaporation effect due to its warm and dry growing conditions with respect to Buenos Aires and Entre Ríos. This is so because the cultivation area of Córdoba is located close to a semiarid region. The difference between the climate in Córdoba and Buenos Aires−Entre Ríos is sufficient to influence the $\delta^{13}C$

DOI: 10.1021/jf5060112
J. Agric. Food Chem. 2015, 63, 4638−4645

values of the honey and make this parameter useful to discriminate the geographic origin of food.[19] However, one has to bear in mind that there is variability also within each sampling area. Observed variations could be explained by different temperature ranges at harvest times of each honey, leading to different $\delta^{13}C$ values.

Strontium Isotopes. The strontium isotope composition of plants, and the animals that eat them, is related to the $^{87}Sr/^{86}Sr$ signature of the bioavailable strontium derived from water and soil (bedrock). Once a $^{87}Sr/^{86}Sr$ database of one crop has been constructed, it can be applicable to new crops from the same geographical origin. For example, it has been reported that $^{87}Sr/^{86}Sr$ values of water could be used to estimate the geographic origin of honey and wheat.[37] Therefore, the Sr isotope ratio inherits the geological character of a production area.[38]

We found statistically significant differences for $^{87}Sr/^{86}Sr$ between honeys from Córdoba, Entre Ríos, and Buenos Aires. Cordoba had the highest values, followed by Entre Ríos and Buenos Aires. Similar results were found in our previous studies for meat and wheat from the same geographical origin.[11,13] This shows the importance of including strontium isotopes in the determination of the geographical origin of foods.

Honey Geographical Classification. Analyzing only one isotopic element gives us an incomplete view regarding the interpretation of the origin of food in general and honey in particular. A multielement evaluation is essential to enhance the reliability of origin classification of food. To get greater origin resolution, the first choice will be to use multivariate statistical methods. In this case, classification trees and lineal discriminant analysis were applied.

Classification and regression tree (C&RT) analysis is a nonparametric methodology that segments populations into subgroups of increasing group homogeneity. The results are formed into a tree structure (decision tree), according logical rules "if–then". C&RT selects those variables that are most important for predicting classification without concern for the possible relationships between variables.[27]

Variables selected by C&RT as most important were Rb and K/Rb, which have 100 and 95% prediction power, respectively. The content of Rb allows discriminating Entre Ríos honey from the others, whereas K/Rb content separated Buenos Aires honey from Córdoba honey samples (Figure 2). The results are shown in Table 2. In the training set none of the samples were misclassified, whereas in the test set two samples of Buenos Aires were misclassified (13.4%).

Linear Discriminant Analysis. Eight of 35 original variables were pointed out by stepwise discriminant analysis as the most important for geographical discrimination, Rb being the most significant variable, followed by K/Rb, B, U, $^{87}Sr/^{86}Sr$, Na, La, and Zn. With these eight elements and isotopes, 98.7% of samples were classified correctly according to its origin. Two different independent discriminant functions were obtained by linear combination of these variables. The combination of the two canonical variables explained 100% of variability (Figure 3A). As shown in Figure 3, Rb was the most important variable in root 1, separating Entre Ríos samples from Buenos Aires and Córdoba; meanwhile, B and K/Rb improved the discrimination between Córdoba and Buenos Aires in root 2.

Rb, Na, Zn, and La presented higher values in Entre Ríos and lower values in Buenos Aires and Córdoba (Figure 3D). Additionally, $^{87}Sr/^{86}Sr$ shows higher values in Córdoba, intermediate values in Entre Ríos, and lowest values in Buenos Aires (Figure 3C). The K/Rb ratio shows the highest values in Córdoba and lower values in Entre Ríos and Buenos Aires (Table 1). Finally, B is capable of differentiating the three honey origins (Figure 3B).

Table 2. Classification Tree Analysis: Recognition and Prediction Ability[a]

		Córdoba	Entre Ríos	Buenos Aires	total correct classification (%)
training set $N = 62$	Córdoba ($N = 19$)		0	0	
	Entre Ríos (N=21)	0		0	
	Buenos Aires ($N = 22$)	0	0		
% correctly classified		100	100	100	**100**
test set $N = 17$	Córdoba ($N = 6$)		0	0

	Buenos Aires ($N = 5$)	2	0		
% correctly classified		60	100	100	**86.6**

[a]Number of samples in the training and test set and efficiency (in percentage) of the model.

Elements and isotopes selected by discriminant and classification tree analysis were also pointed out in previous studies as capable of differentiating diverse food matrices from the same Argentinean regions. For example, wheat samples from Córdoba, Buenos Aires, and Entre Ríos were classified by K/Rb, Na, $^{87}Sr/^{86}Sr$, and Zn;[13] meat samples from the same provinces were characterized by $\delta^{13}C$, Rb, $\delta^{15}N$, Ca/Sr, and $^{87}Sr/^{86}Sr$.[11] Furthermore, wine samples from different Argentinean regions were classified by B, Na, Zn, and $^{87}Sr/^{86}Sr$.[12] It is worth noting that $^{87}Sr/^{86}Sr$ is not capable of discriminating wine variety, but it is always associated with geographical origin. Voerkelius et al.[37] noted that $^{87}Sr/^{86}Sr$ serves as an indicator of geographical origin; in fact, they found a good correlation between honey strontium isotopes values and surface water values.

Furthermore, in various papers honey was also discriminated by the same elements. Chua et al.[23] found that Na, between other elements, was capable of discriminating the geographical origin of honey. Pisani et al.[39] showed that some geological and geochemical features appeared to affect honey chemistry composition, Na being one of the most important. Pellerano et al.[14] also classified Argentinean honey but from other locations using La and Zn as the most important elements.

Correlation between Soil, Water, and Honey Chemical Composition. Taking into account the previous background where it is known that metals in honey derived from soil and to some extent also from nectar and pollen, we were interested in evaluating the correlation between geographical origin (soil and water) and honey.[38−41] Characterization (elemental profile and isotopes ratios) of soil and water from the three regions of origin has been previously published (see the Supporting Information).[11]

GPA was applied to evaluate the correspondence between the elemental profile and isotopes ratios of honey, soil, and water. One hundred percent of the variability between samples could be explained by first and second principal axes (Figure 4). Furthermore, multielement and isotope concentrations from

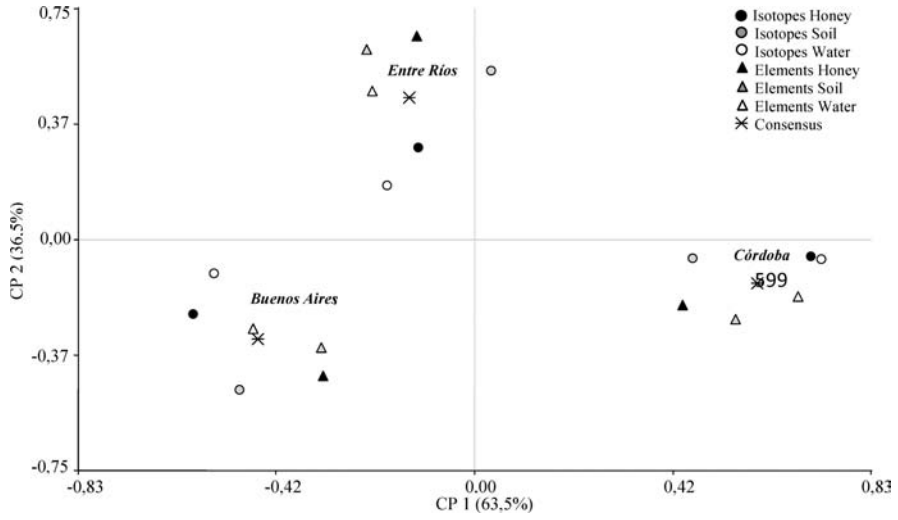

Figure 4. Consensus space from Generalized Procrustes analysis: plot in the plane defined by the first two dimensions.

soil, water, and honey samples allow discrimination of the three geographical origins. Honey chemical data have a significant consensus (91.5%) with those obtained from soil and water, as three data sets project the different geographical origins in the same way onto the plane defined by its first and second principal axes. GPA results show evidence on the correspondence between the three studied matrices.

Finally, we applied CCA to assess the correspondence between soil, water, and honey composition. The first CCA showed significant correlation (r^2 = 0.99732; p < 0.001) between soil and honey data sets. Contents of Co, Ni, Sr, and K/Rb in soil as well as Mn and Rb in honey were pointed out as the variables that mainly contribute to the correlation between soil and honey. The CCA between water and honey data sets also showed a significant correlation (r^2 = 0.9899; p < 0.001). Ca, B, and Ca/Sr contents in water as well as Rb and Mg contents in honey were the variables that mainly contribute to the correlation between water and honey. Therefore, both GPA and CCA coincide, showing the influence of environment (soil and water) on honey composition.

In this work, geographical discrimination of honey through a suitable multivariate statistical analysis was accomplished because differences between elemental concentrations and isotope ratios were found. Linear discriminant analysis enabled

correct classification of honey samples from different Argentinean regions when the isotopic ratio $^{87}Sr/^{86}Sr$ as well as elements such as Rb, La, U, B, Na, Zn, and the K/Rb ratio were considered. Moreover, we were able to demonstrate correspondence between soil, water, and honey samples by appropriate statistical methods, such as Generalized Procrustes analysis and canonical correlations.

ABSTRACT: Sweet potato starch was modified by cross-linking, hydroxypropylation, and combined cross-linking and hydroxypropylation, and the starches were subsequently sieved to obtain differently sized granule fractions. The effects of granule size of native and modified sweet potato starch fractions and all fractions were investigated with respect to their physicochemical properties. The large-size granule fraction (27−30 μm) showed a 16−20% higher chemical phosphorylation and a 4−7% higher hydroxypropylation than the small-size granule fraction (14−16 μm). The large-size granule fractions of native and modified sweet potato starches showed lower transition temperatures (0.7−3.1 °C for peak temperature of gelatinization) and lower enthalpy changes (0.6−1.9 J/g) during gelatinization than the small-size granule fractions, making the sweet potato starch different from cereal starches. The large-size granule fraction of native starch showed a higher paste viscosity (78−244 cP) than the corresponding small-size granule fraction. In addition, cross-linking and hydroxypropylation affected the paste viscosity of the large-size granule fraction significantly more than that of the small-size granule fraction when compared to the corresponding parental starch fractions. The large-size granule fraction of native and dual-modified starches showed a lower syneresis after freeze−thaw treatments than the small-size granule fractions. The difference in swelling power between large- and small-size granule fractions was not significant. In general, the large-size granule fraction of sweet potato starch was more susceptible for cross-linking and hydroxypropylation and the physicochemical properties were changed to a higher extent compared to the corresponding small-size granule fraction.

KEYWORDS: *cross-linking, hydroxypropylation, physicochemical property, paste viscosity, syneresis*

INTRODUCTION

Starch is one of the main ingredients used in the food industry. Starch is often modified to overcome shortcomings of native starches, such as cooking loss and syneresis of frozen food. Cross-linking and hydroxypropylation are two important types of modification. Cross-linking reinforces the molecule structure of granular starch by covalent bonds between starch chains, thereby improving the stability of starch under acid, heat, and shear force conditions.[1] Hydroxypropylation allows starch to have good clarity, higher viscosity, reduced syneresis, and improved freeze−thaw stability.[2] Cross-linking of starch is often combined with other modifications, such as hydroxypropylation, to obtain even better functional properties.[3]

Sweet potato (*Ipomoea batatas* Lam.) is one of the most important economic species of tropical root and tuber crops, which can grow in great abundance on marginal soils.[4] Isolated sweet potato starch is widely used as a food ingredient for noodles, bakery foods, snack foods, and confectionery products.[5] To overcome limitations of native sweet potato starch, chemical modifications have been performed to extend the range of food applications. Cross-linking reduced the swelling power and apparent viscosity and increased the gelatinization temperature, enthalpy, storage modulus, loss modulus, and complex viscosity of sweet potato starch.[6] Hydroxypropylation increased the swelling power, freeze−thaw stability, and flow behavior index and decreased the transition temperature and enthalpy of gelatinization, consistency index, apparent viscosity, and complex viscosity of sweet potato starch.[7] It has also been reported that the processability and quality of dried and cooked sweet potato starch noodles made from the small-size granule fraction were significantly better than those made from the parental starch preparation and much better than those made from the large-size granule fraction.[8,9] In addition, it was reported that the small-size granule fractions of acetylated yellow pea, cow pea, and chick pea starch exhibited larger swelling volumes and higher peak viscosities compared to the corresponding large-size fractions.[10] Until now, the improved functional properties of small-sized sweet potato granules have not been explained. In addition, the effect of granule size on the functional properties of hydroxypropylated sweet potato starch and the effect of granule size of dual-modified sweet potato starch have not been investigated thus far.

In this study, sweet potato starch was modified with cross-linking and/or hydroxypropylation, and the granules were sieved to obtain the large- and small-size granule fractions. All fractions were investigated for their physicochemical properties. The effects of starch granule size on the starch properties of the various modified starches are discussed.

MATERIALS AND METHODS

Starch Samples. Native sweet potato starch (NT-SPS, SuShu2) having a amylose content of 19.3% (w/w, dry basis), was isolated as described previously.[5] The modified starches were prepared at the AVEBE Research and Development facilities (Veendam, Netherlands). All of the modifications were conducted in aqueous suspensions of the granular starches. The cross-linked sweet potato starch (CL-SPS) was obtained by adding 0.002 mol of trimetaphosphate/mol of glucose to the starch suspension. A 39% (w/w) suspension of starch (1 kg) was prepared with tap water, and 0.70 mol of Na_2SO_4 was dissolved in this suspension at room temperature. The pH of the suspension was adjusted to 10.5 with dropwise 4.4% (w/w) NaOH. Subsequently, 0.002 mol of sodium trimetaphosphate (STMP) was added for reaction of 6 h at 35 °C, and then the suspension was neutralized to pH 5.5 with H_2SO_4 (10 N) and dewatered over a Büchner funnel. The product was washed with tap water (1:5) and dried at 40 °C in an oven.

The hydroxypropylated sweet potato starch (HP-SPS) was obtained by adding 0.2 mol of propylene oxide/mol of glucose residues. A 39% (w/w) suspension of starch (1 kg) was prepared with tap water, and 0.70 mol of Na_2SO_4 was dissolved in this suspension at room temperature. The pH of the suspension was adjusted to 10.5 with dropwise 4.4% (w/w) NaOH. A total of 0.2 mol of propylene oxide was added with a dropping funnel to the closed vessel. After 24 h of reaction at 35 °C, the suspension was neutralized to pH 5.5 with 10 N H_2SO_4 and dewatered over a Büchner funnel. The filter cake was washed with tap water (1:5). The starch was dried in an oven at 40 °C.

The cross-linked and hydroxypropylated sweet potato starches (CLHP-SPS) were first cross-linked and subsequently hydroxypropylated.

Starches were fractionated by sieving on an analytical sieve shaker (20 μm sieve, model AS200 digit, Retsch, Haan, Germany) at a vibrational amplitude of 1 mm and rinsing with tap water. When the rinsing water was clear and no starch granules could be detected visually, the sieving was stopped. The large-size granule fraction (>20 μm) and the small-size granule fraction (<20 μm) of the starches were collected, allowed to precipitate overnight, and collected after decanting. The starch was dried at 40 °C overnight before analysis.

Particle Size Distribution of Starches. Particle size distribution of starch granules was measured with a laser diffraction system (Mastersizer 2000, Malvern Instruments, Worcestershire, U.K.) equipped with a small volume sample dispersion unit (Hydro 2000SM). Starch granules were dispersed in Millipore water in a sampler by stirring at 1500 rpm. The particle size was evaluated as volume-weighted mean diameter (μm). Results given are the average values of three measurements.

Level of Starch Modification. The phosphorus and hydroxypropyl group contents of native and modified sweet potato starches were determined using spectrophotometric methods, and these values were used to calculate the degree substitution (DS) of chemical phosphorylation and molar substitution (MS) of hydroxypropylation.[11]

Thermal Properties of Starch Samples. Thermal properties were measured using a differential scanning calorimeter (DSC 7, PerkinElmer, Walthan, MA) equipped with a thermal analysis data station and a cooling system following the method by Gunaratne and Corke,[12] with some modifications. Starch (3 mg, dry weight basis) was directly weighed into an aluminum differential scanning calorimeter (DSC) pan. Distilled water (7 μL) was added to the starch with a micropipette. After mixing, the pan was hermetically sealed and allowed to stand for at least 1 h at room temperature to obtain an even distribution of water with the sample. The scanning temperature included a gradient from 20 to 100 °C at the rate of 10 °C/min. An empty pan was used as a reference for all measurements. The parameters onset temperature (T_o), peak temperature (T_p), conclusion temperature (T_c), and enthalpy change during gelatinization (ΔH) were calculated using the Pyris software provided by the manufacturer. The reported results are an average of three measurements.

Paste Properties of Starch Samples. The pasting properties of starches were measured using a rapid visco analyzer (RVA-4, Newport Scientific, Warriewood, New South Wales, Australia). The starch slurry (7%, w/v, in distilled water, dry weight basis, 27 g of total slurry) was prepared in a RVA canister. A paddle was placed into the canister, and the blade was vigorously stirred through the sample up and down to avoid lump formation. Next, the canister was inserted into the instrument for measurement. The sample was equilibrated at 50 °C for 1 min, heated to 95 °C in 7.5 min, held at 95 °C for 5 min, cooled to 50 °C in 7.5 min, and held at 50 °C for 2 min.

Swelling Power of Starch Samples. The swelling power of starches was measured as described before,[5,13] with some modifications. Starch was weighed (0.1−0.2 g, dry weight basis) into a 15 mL polypropylene tube, and 12 mL of distilled water was added, followed by mixing. The tubes were equilibrated at 25 °C for 5 min and subsequently heated for 30 min in a water bath at a given temperature (55−95 °C range) with shaking to avoid lump formation. The sample was cooled to 25 °C and centrifuged (1000*g* at 25 °C for 15 min). The supernatant was removed by pipetting, and the swollen starch sediment was weighed. The swelling power was the ratio in weight of the swelled starch sediment to the initial weight of dry starch.[14] Results used for calculation were means of triplicate measurements.

Freeze−Thaw Stability of Starch Samples. Freeze−thaw stability was determined as syneresis as described before.[15] In short, starch was suspended (6%, w/w, dry weight basis, 5 g of slurry) in distilled water in a 10 mL screw-capped tube. The tubes were tightly capped and heated in a 95 °C water bath for 30 min with agitation by inverting the tubes 5 times at 3 min intervals during the first 15 min of heating. These tubes were cooled and stored at 4 °C for 24 h before being subjected to 7 freeze−thaw cycles. The tubes were centrifuged (1500*g* at 25 °C for 15 min) to remove the excluded water. During each cycle, the tubes were put into a freezer at −20 °C for 22 h and thawed at 30 °C in a water bath for 1.5 h. After centrifugation (1500*g* at 25 °C for 15 min), the water eliminated from the gel was weighed. The syneresis was expressed as the proportion of the weight of the separated water to the total weight of the initial paste. Duplicated tests were used for each cycle.

Refrigerated Storage Stability of Starch Samples. Syneresis of starch gel without freeze−thaw treatment was measured by storing the gel at 4 °C. Starch pastes were prepared as described above. The tubes were stored in a refrigerator at 4 °C for several days. With a 1 day interval, the excluded water was measured after centrifugation (1000*g* at 25 °C for 20 min). The weight difference of the gel before and after 4 °C storage was measured as water loss. The syneresis was calculated as the weight percentage of water loss based on the parental starch paste weight.

Statistical Analysis. The statistical analysis was performed using SAS 9.2 for Windows (SAS Institute, Cary, NC). The analysis of variance was conducted using Tukey's range test using honestly significant difference (HSD) values at a 0.05 significance.

RESULTS AND DISCUSSION

Particle Size Distribution of Starch Granules. The native, cross-linked, hydroxypropylated, and dual-modified sweet potato starches were sieved with a 20 μm sieve to obtain two fractions consisting of the large-size (>20 μm) and small-size (<20 μm) granules. The particle size distributions of native and cross-linked sweet potato starch and the corresponding sieved fractions (<20 and >20 μm) are shown in Figure 1. Before sieving, the particle diameter of native sweet potato starch granules is in the range of 5−70 μm, with an average diameter of 19.7 μm. This result is in agreement with previous research.[16,17] After sieving, the particle diameters of the large- and small-size granule fractions are in the range of 11−70 μm (67.5%, w/w) and 5−40 μm (32.5%, w/w) with average diameters of 27.6 and 14.5 μm, respectively.

After the modifications (cross-linking, hydroxypropylation, and cross-linking combined with hydroxypropylation), the

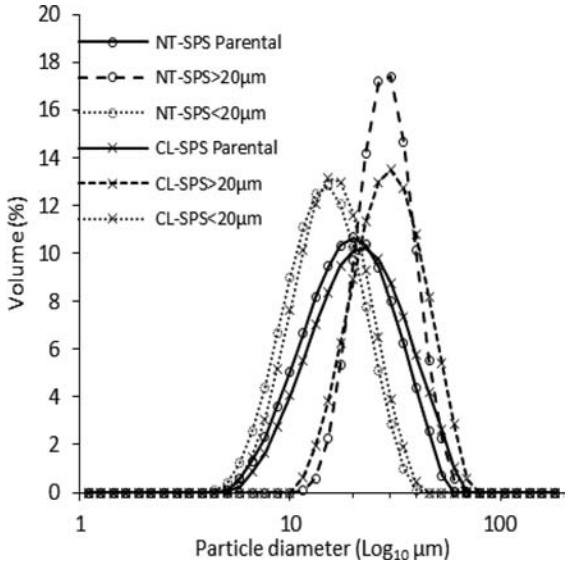

Figure 1. Granule diameter distribution of native (NT-SPS) and cross-linked sweet potato starch (CL-SPS) before and after sieving over a 20 μm sieve using a laser diffraction system in water. Parental, unfractionated starch; >20 μm, large-size granule fraction; and <20 μm, small-size granule fraction.

average diameters of starch granules increased slightly compared to the corresponding native starch granules, as visualized by the granule diameter distribution of cross-linked starch compared to the native starch (Figure 1). The probable reason is that the cross-linking and/or the hydroxypropylation reaction slightly enhance the water absorptivity. Hence, the granule diameter was slightly enlarged.

Level of Starch Modification. The contents of phosphorus and hydroxypropyl groups in the starches are shown in Table 1. The natural phosphorus in sweet potato starch is almost exclusively present as phosphorus monoester.[18] The phosphorus content of the large-size granule fraction of the native sweet potato starch was lower than that of the small-size granule fraction. These findings are in agreement with those found for native potato starch.[19] This can be explained by the lower amylopectin content in large-size granules[20] and the fact that phosphorus is primarily present in the amylopectin part of native starch.[21] It should be noted that the phosphorus content of the parental starch was always slightly higher than those found for both size fractions, for which a possible reason is that traces of residual inorganic phosphorus as present in the parental starch are removed in the additional washing procedure of wet sieving.

When comparing the phosphorus contents of modified starches and native starch (Table 1), it is seen that cross-linking increased the phosphorus content of the non-sieved starches at around 50%. Subsequent hydroxypropylation decreased the phosphorus content at around 20%, because of the alkaline condition of hydroxypropylation and the consequent saponification of phosphate esters. When combining the two treatments of cross-linking and hydroxypropylation, the integral effect resulted in a phosphorus increase of 35% compared to the native starch.

To estimate the effect of chemical phosphorylation, the change in the phosphorus content (ΔP, %, w/w) of the modified starch was compared to the phosphorus level of the native starch (Table 1). The degree of substitution (DS) was calculated on the basis of this value. After modification, the large-size granule fraction still had a lower phosphorus content than the small-size granule fraction. Nevertheless, it was seen that the increment in the phosphorus content (ΔP, %) of the large-size granule fraction (>20 μm) was around 20% higher than that found for the small-size granule fraction (<20 μm). The results indicate that the large-size granule fraction is more susceptible to the cross-linking agent than the small-size granule fraction. Because it has been reported that the reaction of starch with trimetaphosphate is rather slow[22] and surface effects on the reaction are not significant, our findings suggests that the level of cross-linking is not determined by a surface reaction only and that, e.g., the more loosen packing of larger granules might play a role.[23]

For the hydroxypropylated starch, the hydroxypropyl content of the large-size granular fraction was about 5% higher than that of the small-size granule fraction (Table 1), indicating that there was a slight difference of hydroxypropylation reactivity for the different size granules. Next to the mentioned effect of a loose packing of large starch granules, the higher amylose

[d]T_o, T_p, and T_c are the onset, peak, and conclusion temperatures of gelatinization, respectively. [e]ΔH is the enthalpy of gelatinization.

content of the large-size fraction,[8] which might be more susceptible to hydroxypropylation than amylopectin,[23] could explain these increased levels. In contrast, for potato, maize, and wheat starch, it has been reported that there were no evident differences in hydroxypropylation between the large- and small-size granule fractions.[24] This may be due to the difference of starch biosynthesis, the granule architecture, and possibly the amylose content. Overall, the large-size granule fraction of sweet potato starch is more efficiently cross-linked and hydroxypropylated than the small-size granule fraction, indicating that the reactions are influenced by the packing density of the starch granules.

Effect of Modification on Thermal Properties. The thermal transition properties of starch are commonly measured using a DSC and expressed as the onset temperature (T_o), peak temperature (T_p), conclusion temperature (T_c), and enthalpy change (ΔH) of gelatinization.[3] The transition temperatures and their range ($T_c - T_o$) give a measure of crystallite quality (double helix length), and the enthalpy change (ΔH) gives an overall measure of crystallinity (quantity and quality) and is an indicator of the loss of molecular order within the granule on gelatinization. The results of thermal properties for the native starch and modified large- and small-size granule fractions are presented in Table 2. It is found that the cross-linking reaction slightly increased in most cases the transition temperatures (~1 °C) and enthalpy (~0.7 J/g) of starch gelatinization, which can be explained by the formation of additional covalent bonds during cross-linking, tightening the starch granule structure.[2,25]

Hydroxypropylation significantly decreased the transition temperature by 13−16 °C and enthalpy of starch gelatinization by 4−7 J/g compared to native starch, probably as a result of disruption of part of the double helices present within the amorphous regions of the starch granules by the hydroxypropylation.[7] The results of DSC suggest that both cross-linking and hydroxypropylation affect the thermal behavior of starch, but the hydroxypropylation has the strongest effect in dually modified starch.

Effect of Starch Granule Size on Thermal Properties. The parental starch showed higher enthalpy change (relatively higher 1.8−59.0%) of gelatinization compared to its sieved size fractions (Table 2). The significant difference of enthalpy may indicate that sieving with washing has an effect on the starch granules, where minor quantities of phosphorus and other minerals may have been lost during sieving. Furthermore, the large-size granules showed a lower enthalpy change than small-size granules, indicating that large-size granules have less crystallinity than small-size granules, which also explains the higher levels of modification found for large-size granules compared to small-size granule fractions (Table 1). This tendency is different for native wheat and potato starch, of which the large-size granule fraction showed a lower temperature and higher enthalpy of gelatinization than the small-size granule fractions.[26,27] The probable reason is the differences in the amylose content (amylose in sweet potato starch, 19.3%;[5] potato starch, 19.4−27.0%;[26] and wheat starch, 27.8%[28]) and contents of amylose−lipid complexes in starches (lipids in sweet potato starch, 0.4%;[5] potato starch, 0.19%[24]).

The large-size granule fraction of cross-linked starch showed only a slightly lower peak temperature and enthalpy when compared to the small-size granule fraction. In general, cross-linking increased the transition temperatures and enthalpy of the large-size granule fraction more than the small-size granule fraction, and the transition temperature and enthalpy of the large-granule fraction remained close to the values found for the small-size granule fraction.

For hydroxypropylated starch, the modification significantly decreased the peak temperature and enthalpy of gelatinization. The large-size granule fraction showed a significantly lower transition peak temperature than the small-size granule fraction. In fact, all of the large-size granule fractions showed a lower transition peak temperature than the small-size fractions, indicating a less crystalline structure in the large-size granules. The significantly lower transition peak temperatures of the hydroxypropylated starches indicate that hydroxypropylation further decreased the crystallite quality to come to the same level of crystallinity for both large- and small-size granule fractions maintained equally for both the large- and small-size granule fractions. All of the large-size granule fractions showed a lower transition peak temperature than the small-size fractions, suggesting the less crystallite structure in the large-size granules. The significantly lower transition peak temperatures of the hydroxypropylated starches indicate that hydroxypropylation decreased the crystallite quality similarly for both the large- and small-size granule fractions.

Dual-modified granules showed a similar tendency of the transition temperature and enthalpy of gelatinization to the

hydroxypropyl-modified granules. This indicated that the change of the transition temperature and enthalpy of gelatinization after dual modification predominantly resulted mainly from the hydroxypropylation.

Pasting Properties of Starches. The pasting curves of native sweet potato starch showed a high peak viscosity and rapid shear thinning at high temperatures (Figure 2A). The peak viscosity of the large-size granule fraction is slightly lower than that of the small-size granule fraction, probably because of the lower phosphorus and lower amylopectin content of the large-size granule fraction (Table 1). The viscosity of the parental starch was lower than that of the large- and small-size granule fractions, which was also found for potato starch.[29] This may be due to an optimal packing of small and large granules in the parental starch paste, resulting in a lower viscosity.

The pasting curve of cross-linked starches expressed a low but stable viscosity (20−80 cP) and no obvious pasting peak (Figure 2B). The large-size granule fraction had the higher degree of cross-linking than the small-size granule fraction, resulting in even a lower pasting viscosity. This indicates that the viscosity of starch paste is sensitive to the degree of cross-linking.

As expected, it was found that the hydroxypropylation increased the peak viscosity and decreased the trough and final viscosity of starch pasting (Figure 2C). The introduction of hydroxypropyl groups increased the hydrophilicity of starch molecules, resulting in swelling to a greater extent, creating a high peak viscosity.[3,12] The large-size granule fraction showed a higher viscosity than the small-size granule fraction, probably because of the slightly higher level of hydroxypropylation. The parental hydroxypropylated starch showed a viscosity profile just between the profiles of the large- and small-size granule fractions.

The dual-modified starches showed similar profiles to the cross-linked starch with very low viscosities (Figure 2D). This indicated that the effect of cross-linking on the viscosity was more predominant than that of hydroxypropylation. Furthermore, no difference in viscosity was found between the large- and small-size granule fractions. This may be due to the combination of counteracting effects of cross-linking and hydroxypropylation on viscosity.

Swelling Power of Starches. The swelling power of the large- and small-size granule fractions of starches was measured in water at various temperatures. The results showed that the swelling power of native and modified sweet potato starches decreased in the order: hydroxypropylated > native > dual-modified > cross-linked starches (Figure 3).

The small-size granule fractions of hydroxypropylated sweet potato starch showed a slightly higher swelling power than the large-size granule fraction and parental starch fraction, indicating that the higher amylopectin content in the small-size granule fraction increases the swelling power more than the hydroxypropylation. The swelling power of the parental hydroxypropylated starch was lower than that of sieved starch fractions. Swelling power indicates the extent of water absorption and volume expansion of the starch granules. The volume includes the starch granule itself and the interspace between swollen granules. It is probable that the volume of

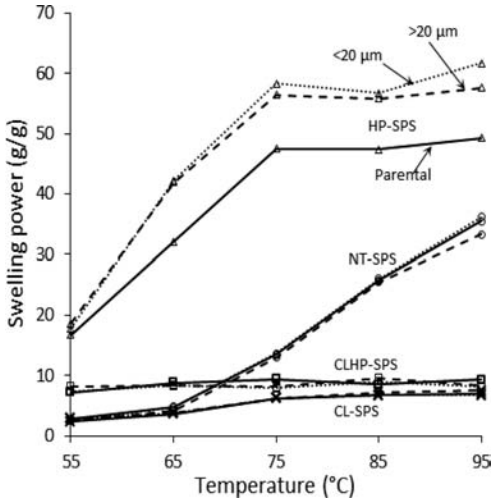

Figure 3. Swelling power of native (NT-SPS), cross-linked (CL-SPS), hydroxypropylated (HP-SPS), and dual-modified (cross-linked and hydroxypropylated, CLHP-SPS) sweet potato starches at various temperatures. Parental, unfractionated starch; >20 μm, large-size granule fraction; and <20 μm, small-size granule fraction.

interspace between granules affects the swelling power. Parental starch has a heterogeneous size of starch granules, where small granules may fill in the interspace between large granules, leading to a relatively small total volume and small total weight increase compared to the same dry weight of more uniform starch granules.

The cross-linked as well as the dual-modified starch showed a lower swelling power than the native starch. There was not a significant difference in swelling power between the large- and small-size granule fractions of cross-linked starch.

The swelling tendency of sweet potato starch in different granule size fractions is different from that reported for wheat starch, in which the small-size fraction had the lowest swelling power. Most likely, this can be explained by the high level of amylose−lipid complexes present in the small-size fraction of wheat starch.[30]

Effects of Starch Modification on the Refrigeration and Freeze−Thaw Properties. Low-temperature storage stability involves the sensitivity of starch to retrogradate when cooling and stored, in which the process may result in syneresis of the starch gel, resulting in excluded water from the gel. In our experiment, we used 6% starch pastes heated at 95 °C, before subjecting the gel to the storage conditions. As a consequence of the swelling power of the parental and modified

starches (Figure 3), the gelatinized parental starch granules will fill the available volume of water rather completely, while the cross-linked starch will be far from a close packing because of the lower swelling power. Hydroxypropylation of the starch will not influence the packing enormously, although the hydroxypropyl groups will prevent a rapid interaction between the molecules, preventing the retrogradation process.[31] Storage under refrigerator conditions at 4 °C lead to some syneresis for the parental starch (Figure 4A), while there is significantly more water expulsed from the cross-linked starch (Figure 4B). Because the retrogradation is a concentration-dependent process, the close packing of the parental starch molecules will not change dramatically, leading to a minor release of water only. In contrast, the cross-linked starch, having a considerably higher starch concentration within swollen granules, will retrogradate rather easily, and syneresis is significant (Figure 4B; up to 26%). Hydroxypropylation leads to less syneresis of the singly modified starch (Figure 4C) compared to the parental starch and corrects the enormous water exclusion of the cross-linked starch to a great extent for the dual-modified starch (Figure 4D). This effect has been described before for corn and amaranth starches.[31]

When considering the freeze−thaw effect, the syneresis observed for the various starches is quite different (panels A−D of Figure 5). Under these conditions, the parental starch shows the highest syneresis of all starches, followed by the cross-linked starch, while hydroxypropylation stabilized the starch gel during the freeze−thawing process significantly. During the freezing step, ice crystals will be formed progressively and the remaining starch phase will gradually enrich in starch. A higher starch concentration persists throughout the freeze−thaw process until the melting is complete. The retrogradation will be enhanced during freezing and thawing stages. Because of the high effective starch concentration, considerable retrogradation happened during the thawing process, resulting in the syneresis behavior, as seen in Figure 5A. Cross-linked starch is affected less by the freezing process. Although the enrichment of starch in the starch phase is expected to be roughly similar to the native starch, the cross-links clearly offer some protection against syneresis (compare panels A and B of Figure 5). The effect of hydroxypropyl substitution is clear, in both native and cross-linked starches. Obviously, the hydroxypropyl groups are quite effective in suppressing retrogradation during the freezing and thawing stages (panel A versus panel C of Figure 5 and panel B versus panel D of Figure 5).

Effects of Granule Size on the Refrigeration and Freeze−Thaw Properties. Obviously, the same considerations on the effective concentration of the starch gels are valid

relative difference (%)	27	64	28	69
granules showing better cold storage stability	>20 μm	>20 μm	<20 μm	>20 μm
difference at 4 days (%)	0.2	0.4	1.4	2.7
relative difference (%)	25	50	8	36

[a]Relative difference is the relative percentage of difference of property between large- and small-granule fractions to the average of property between large- and small-granule fractions. NT, native; CL, cross-linked; HP, hydroxypropylated; CLHP, cross-linked and hydroxypropylated; and SPS, sweet potato starch.

when looking at the effect of the granule size toward the cold storage and freeze−thaw stability in the gels. Other parameters influencing gel properties of starches and which may be different for the different size fractions are the phosphorus content of the parental size fraction and the levels of cross-linking and hydroxypropylation (Table 1). As reported before, the amylose content of small-sized (19.2%) and large-sized (19.7%) fractions are slightly different.[20] The cold storage and freeze−thaw stability of the starch gels from the size fraction can be seen in Figures 4 and 5, respectively. Both the large-size and small-size starch fractions showed a better stability compared to the parental starch. The lower syneresis for the large-size granules during the freeze−thawing process when compared to the small-size fractions has also been seen before[8] but cannot easily be explained because a higher amylose content and a lower phosphorus content are found for these larger granules (Table 1). As expected from these same starch parameters, the stability during cold storage of the large granules is lower than that found for the small-size granule at the end of 7 cycles. However, this is not the case for earlier cycles (Figure 4A), and this observation cannot be explained. The better stability for the dual-modified large-size fraction (Figures 4D and 5D) seemed to be a consequence of the higher hydroxypropylated content, which counteracts the lower degree of cross-linking. For cross-linked starches, the better stability of the small granules (Figures 4B and 5B) can be governed by the lower level of cross-linking compared to large granules. The higher hydroxypropyl content of large-size granules of hydroxypropylated (Table 1) starch does only explain the better refrigeration stability (Figure 4C) but not its poorer freeze−thaw stability (Figure 5C).

A summary of starch granule size, type of starch modification, and physicochemical characteristics is given in Table 3. As discussed above and as seen from this table, the functional differences between different size populations are quite diverse, making it rather difficult to assign them to specific structural characteristics. In general, it can be stated that large-sized granules are more sensitive to modification reactions than small granules, but no generic prediction can be made for specific benefits for a given application.

Supporting Information

ABSTRACT: The efficiency of zeolite X nanocrystals (FAU-type framework structure) containing different extra-framework cations (Li^+, Na^+, K^+, and Ca^{2+}) in slowing the thermal oxidation of palm oil is reported. The oxidation study of palm oil is conducted in the presence of zeolite nanocrystals (0.5 wt %) at 150 °C. Several characterization techniques such as visual analysis, colorimetry, rheometry, total acid number (TAN), FT-IR spectroscopy, ^{1}H NMR spectroscopy, and Karl Fischer analyses are applied to follow the oxidative evolution of the oil. It was found that zeolite nanocrystals decelerate the oxidation of palm oil through stabilization of hydroperoxides, which are the primary oxidation product, and concurrently via adsorption of the secondary oxidation products (alcohols, aldehydes, ketones, carboxylic acids, and esters). In addition to the experimental results, periodic density functional theory (DFT) calculations are performed to elucidate further the oxidation process of the palm oil in the presence of zeolite nanocrystals. The DFT calculations show that the metal complexes formed with peroxides are more stable than the complexes with alkenes with the same ions. The peroxides captured in the zeolite X nanocrystals consequently decelerate further oxidation toward formation of acids. Unlike the monovalent alkali metal cations in the zeolite X nanocrystals (K^+, Na^+, and Li^+), Ca^{2+} reduced the acidity of the oil by neutralizing the acidic carboxylate compounds to $COO^-(Ca^{2+})_{1/2}$ species.

KEYWORDS: *palm oil, oxidation, inhibition, zeolite nanocrystals, extra-framework cations*

INTRODUCTION

The overwhelming palm oil global production (30% of global vegetable oil output) and trade volume (60% of global exports) are due to its cheaper production cost and nontoxic nature. Palm oil has been utilized as a base oil in formulating lubricants due to its favorable viscosity−temperature characteristics, high flash point, and compatibility with mineral oil and additive molecules.[1,2] However, the low thermal and oxidative stabilities, poor low-temperature fluidity, and hydrolytic instability limit the use of palm oil as a long-life cooking oil for deep-frying culinary purposes. Previous studies have reported that heated cooking oils may pose health risks to consumers due to the generation of oil oxidation products.[3−5] Although natural antioxidants can improve the oxidation stability of vegetable oil, their performances are usually heavily rely on the oil composition, heating temperature, and presence of other additives.[6] Thus, thermally stable, low-cost, and environmentally safe antioxidant additives are desired to replace the traditional antioxidants in inhibiting oil oxidation, particularly in the food industry.

Zeolites are aluminosilicate microporous solids with well-defined pores and cages, which are commonly used as heterogeneous catalysts, ion exchangers, and adsorbents. In our previous investigation, zeolite nanocrystals (NCs) were used as selective adsorbents for oil purification.[7−9] This was based on the fact that zeolite molecular sieves with electrostatic charged frameworks tend to adsorb and trap polar compounds (e.g., moisture contaminant and carbonyl oxidized products) in the pores of zeolites without interacting with the nonpolar oil molecules. As a result, the oxidized mineral oil after purification can be recycled and reused with longer service lifetimes. Recently, the use of zeolite NCs as an ecofriendly antioxidant additive was also reported.[10,11] Zeolite NCs with different framework type structures (LTL, EMT, and FAU) were found to possess distinctive antioxidation behavior in palm oil during oxidation at high temperature (180 °C) for a long period of time (40 days).[10,11] It was shown that the delay of oxidation progress is the result of free radical inactivation, C═C bond stabilization, and also adsorption of polar primary (hydroperoxides) and secondary (carboxylic acids) oxidation products, which are greatly dependent on the hydrophilicity, pore openings, and framework type of the zeolites.

Contrary to the well-understood mechanism of chemical reactions contributed by protonated forms of zeolites (Brönsted acids), the chemical properties in cation-exchanged zeolites remain the subject of intense study. The extra-framework cations are compensating the negatively charged framework of zeolites, and they are reactive and readily interact with a variety of guest molecules.[12,13] This is due to the van der Waals and Coulombic interactions between the extra-framework cations and guest molecules. The charge, polarizability, deformation ability, and influence of non-framework cations on the homogeneity of the framework electric field will eventually affect the sorption and stabilization of diffused species because these cations are capable of generating strong local electrical fields. Thus, attracting the negative centers of polar molecules and polarizing or deforming the polarizable molecules through static electric induction was observed.[14,15]

Synthetic high alumina-containing zeolites (FAU, LTA) having alkali and alkaline earth metals as extra-framework cations have been extensively studied and mainly used as selective adsorbents and for separation of oxygen from air. However, the effect of these cation-exchanged zeolites in oil oxidation has not been investigated. On the other hand, it has been shown that nanosized zeolites prepared via a template-free synthesis method do not cause toxicity under cell viability and cell life cycle studies (evaluation of living or dead cells due to toxins was reported).[16] Hence, these zeolites prepared from template-free precursor suspensions can be considered as additives in palm oil. Furthermore, nanosized zeolites can be incorporated in membranes or deposited as thin films on culinary tools for deep-frying, apart from being added directly into the cooking oil.

Herein, we report the influence of extra-framework cations in nanosized FAU type zeolite (X type) on the oxidation process of palm oil. Nanosized zeolite X samples with four different types of extra-framework cations (Li^+, Na^+, K^+, and Ca^{2+}) are prepared and added as additives during the thermal oxidation of palm oil. The oil oxidative evolution is then characterized and followed by various analytical methods. In addition, periodic DFT calculations are performed to clarify the effect of extra-framework cations on the chemical interactions and binding energy during host−guest interactions.

EXPERIMENTAL PROCEDURES

Synthesis and Ion Exchange of Zeolite Nanocrystals. The sodium form of zeolite X (Na-X) nanocrystals (ca. 20 nm) was synthesized without organic template.[17] The Li-, K-, and Ca-X NCs were prepared through ion exchange method. Typically, 1.50 g of zeolite powder was stirred in 100 mL of nitrate solution of the targeted metal cations (0.50 mol/L) at 60 °C for 6 h. The process was repeated five times by separating supernatant from the mother liquid, redispersing in metal nitrate solution, and carrying on with aforementioned ion exchange process to ensure that the highest possible ion exchange was achieved. The samples after ion exchange were washed thoroughly (pH 7.5) prior to freeze-drying.

Oxidation of Palm Oil. Zeolite nanocrystals (0.250 g, equivalent to 0.5 wt %) were activated at 180 °C overnight prior to addition into 50.00 g of palm oil. The oxidation process was carried out at 150 °C under continuous stirring (300 rpm) and reflux; the oil samples were periodically collected after 100, 200, 300, and 400 h. The zeolite NCs were recovered from the oils via centrifugation (25000 rpm, 2 h). For comparison, a similar amount of palm oil (50.00 g) without zeolite NCs was also oxidized at the same oxidation conditions and denoted as a reference sample (reference).

Characterization. The X-ray diffraction (XRD) patterns of zeolite samples were recorded using a PANalytical X'Pert PRO XRD diffractometer. The morphology of the as-synthesized and ion-exchanged zeolite NCs was evaluated by field emission scanning electron microscope (FE-SEM) using a Leo Supra 50VP with an accelerating voltage of 30 kV. The porosity of the samples was determined by nitrogen sorption with a Micromeritics ASAP 2010 instrument. The chemical composition of all zeolite samples was measured by induced couple plasma using an Agilent 720 series ICP-OES spectrometer. The IR spectra of zeolites were recorded using a PerkinElmer 3000 FTIR spectrophotometer. The thermal stability of the zeolites was measured using a Mettler TGA SDTA851 instrument with a heating rate of 10 °C/min under nitrogen flow.

Evaluation of the Oxidation Degree of Palm Oil. Visual analysis of oil samples was carried out by following their color change after 100, 200, 300, and 400 h of oxidation at 150 °C. Colorimetric measurements of oil samples were performed using a Shimadzu UV 3000 spectrophotometer at 530 nm; fresh palm oil was used as a reference. Two measurements were made for each oil sample, and no difference was observed. Qualitative information for the formation of carbonyl compounds, hydroperoxides, and moisture in the oil samples was obtained by recording the IR spectra. The IR measurements (50 scans, 4 cm^{-1}) were performed on 0.5 mL of oil introduced in a ZnSe liquid cell (1 mm spacer).

The rheological behavior of the oils was investigated by a Malvern Kinexus rheometer. The analysis was performed twice for each sample, and the average values were used for plotting the results. The amount of moisture and organic compounds adsorbed by the zeolite nanocrystals was measured by a Mettler TGA SDTA851 instrument with a heating rate of 10 °C/min under air flow.

The water content in oil was measured using a volumetric Karl Fischer titrator. The Karl Fischer titration system (Metrohm) was charged with Hydranal Composite-2 reactant (Riedel-de Häan) and Hydranal Solvent CM (Riedel-de Häan). All samples were analyzed twice to obtain average values by direct injection without preliminary treatment.

The potassium hydroxide (KOH) titrimetric method was applied to determine the total acid number (TAN) of the oil samples. Typically, 0.200 g of oil was mixed with 2.000 g of a mixture containing water/isopropanol/toluene with a molar ratio equal to 1:30:20, followed by the addition of 3 drops of phenolphthalein indicator. The resulting solution was titrated with 0.01 mol/L ethanolic KOH solution until a color change was observed. The results were recorded, and the TAN was calculated as milligrams of KOH per gram of oil using the equation

$$\text{TAN (mg KOH/g oil)} = \frac{V \times M \times M_r}{m} \quad (1)$$

where V is the volume (mL) and M is the molarity (mol/L) of the ethanolic KOH solution, M_r is the molar mass of KOH (g/mol), and m is the mass (g) of the oil sample. Two titrations of each oil sample were performed.

^{1}H NMR analyses were performed using a Bruker AVIII spectrometer operating at a frequency of 500 MHz with the following acquisition parameters: pulse sequence, zg30; acquisition time, 3.17 s; relaxation delay, 5 s; pulse width, 30° for 512 scans. Prior to analysis, the oil samples were dissolved in deuterated chloroform ($CDCl_3$) (mass ratio of zeolite/ $CDCl_3$ = 1:3); tetramethylsilane (TMS) was used as an internal standard.

DFT Modeling of the Interaction of Absorbates with Metal Ions in Zeolite Nanocrystals. Periodic density functional theory (DFT) calculations were performed with the PW91 exchange-correlation functional[18] using a Vienna ab initio simulation package (VASP).[19,20] Ultrasoft pseudopotentials were used as implemented in the VASP package.[21,22] Due to the large unit cell of the zeolites, the Brillouin zone was sampled using only the Γ point.[23] The valence wave functions were expanded in a plane-wave basis with a cutoff energy of 400 eV.

The unit cell of the cubic FAU type zeolite was optimized using a pure silica structure with dimensions $a = b = c = 24.345$ Å.[24] During the geometry optimization, all of the zeolite atoms and the adsorbate species were allowed to relax until the force on each atom was <2 ×

DOI: 10.1021/acs.jafc.5b00380
J. Agric. Food Chem. 2015, 63, 4655−4663

10^{-4} eV/pm. The binding energy (BE) of the adsorbates hydroperoxides (C_2H_5OOH and HOOH) and alkenes including ethene (C_2H_4) and *cis*-butene (C_4H_8) per ligand was determined as

$$\mathrm{BE\ [adsorbate/Zeo]} = (E[\mathrm{adsorbate/Zeo}] - E[\mathrm{Zeo}] - E[\mathrm{adsorbate}])$$

where E[adsorbate/Zeo] is the energy of the zeolite together with the adsorbed molecule in the optimized geometry; E[Zeo] and E[adsorbate] are the energies of the pure zeolite and pure adsorbate molecule in the gas phase, respectively. With the above definition, the negative values of BE imply favorable interactions.

RESULTS AND DISCUSSION

Ion-Exchanged Zeolite Nanocrystals. The degree of crystallinity and phase purity of FAU zeolite NCs are characterized by XRD. The XRD patterns of all zeolite samples show that the peaks' intensity remains intact and no phase transformation occurs, revealing that the degree of crystallinity and phase purity do not change after ion exchange (see the Supporting Information, Figure S1). Besides, the FE-SEM analyses reveal that the size and morphology of zeolite NCs remain stable after ion exchange. All of the crystals have a narrow particle size distribution and diameter of 20−40 nm (Figure 1).

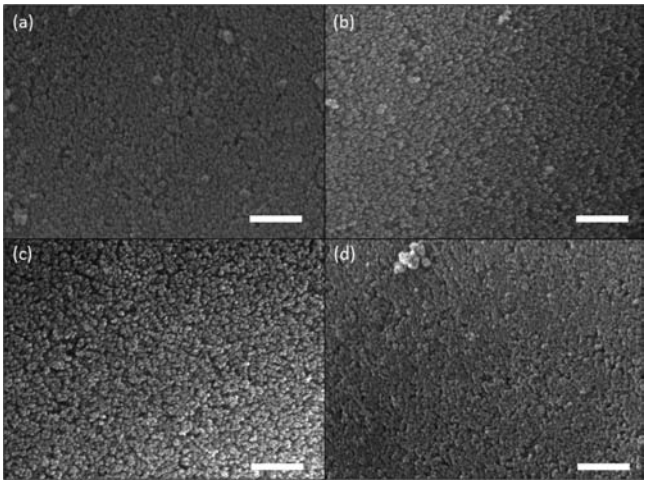

Figure 1. SEM images of (a) Li-X, (b) Na-X, (c) K-X, and (d) Ca-X zeolite nanocrystals. Scale bar = 500 nm.

The schematic structure of zeolite X and the potential positions (I, I′, II, II′, III, and III′) to be occupied by its charge compensating cations are shown in Figure S2, and the results from the chemical analysis of zeolite NCs exchanged with alkali metal and alkali earth metal cations are also listed (Table S1). As can be seen, zeolite X with the FAU framework topology contains pores with a size of 0.74 nm and supercages made up of sodalite cage connected via double 6-rings. The zeolite X nanocrystals have a Si/Al ratio of ca. 1.3. After five cycles of ion exchange at 60 °C, the Li-X, K-X, and Ca-X zeolites are successfully prepared while keeping the same Si/Al ratio. In all cases, not 100% exchange of Na^+ is attained (Table S1). The highest degree of exchange of Na-X is achieved for Ca^{2+} (88%), followed by K^+ (86%) and Li^+ (74%). Their different ionic radiuses of univalent and divalent cations explain the various degrees of ion exchange of Na^+ in zeolite X.[25] On the other hand, Li-X has the lowest degree of ion exchange, which can be due to its high hydration energy, high mobility, and low occupancy of certain sites.[26−28]

The porosity of zeolite nanocrystals after ion exchange was probed by N_2 sorption analysis. All samples exhibit type I isotherm at low P/P_0, which is characteristic for microporous materials (Figure 2). A high adsorption uptake at $P/P_0 > 0.8$ is

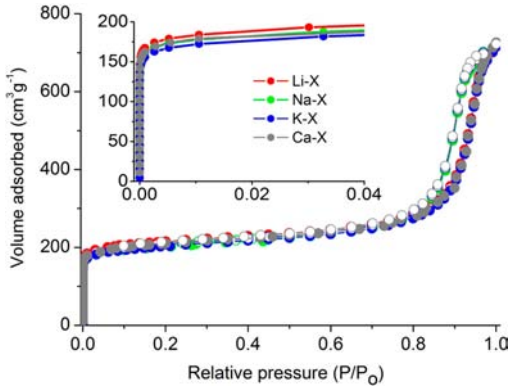

Figure 2. Nitrogen adsorption (solid symbols) and desorption (open symbols) isotherms of zeolites Li-X, Na-X, K-X, and Ca-X.

due to the textural mesoporosity resulting from the close packing of zeolite NCs. From the N_2 sorption isotherms, it can be seen that the N_2 uptake at low P/P_0 is inversely proportional to the size of cations (Table S1; inset of Figure 2). As a result, Li-X zeolite exhibits the highest BET surface area and pore volumes (both V_{micro} and V_{meso}), whereas the K-X zeolite containing the larger cation K^+ (1.33 Å) gives the lowest porosity (Tables S1 and S2). Ca^{2+} (0.99 Å) is almost similar to Na^+ (0.97 Å) in size, but Ca^{2+} is a divalent ion and the amount of Ca^{2+} in the Ca-X zeolite is lower. As a result, a slightly increased surface area and pore volume are measured for the Ca-X zeolite. Thus, the results from nitrogen sorption are in agreement with the chemical analysis data, demonstrating that the porosity is slightly affected by the size and number of cations introduced into zeolite X via ion exchange.

Characterization of Palm Oil Oxidation. *Color Change and Colorimetry Analysis of Palm Oil.* Color change is a simple indication of oil degradation. Basically, the reference oil containing no zeolites shows faster color change where the oil color progressively turns from yellow to amber, dark brown, and finally black color as the severity of the oxidation conditions was increased with time (photograph not shown here). The reference oil sample also has a strong smell resulting from volatile organic acids or carbonyl compounds, showing that the oil is degraded. The appearance of oil samples containing zeolite NCs (Na-, Li-, K-, and Ca-X) as a function of oxidation time is shown in Figure 3. As can be seen, the oils oxidized with zeolites have brighter color, highly basic K-X displaying the brightest color even after 400 h of oxidation. The color change was also found to follow the polarizability/basicity of the cations present in zeolite X: $Li^+ < Na^+ < Ca^{2+} < K^+$.

The oxidative deterioration of palm oil is always associated with a darkening effect. Some organic substances are responsible for the development of color in oil during autoxidation. For example, the oxidation of carotene, which naturally exists in palm oil, can cause increasing red and yellow colors in vegetable oils.[29] Apart from carotene, high molecular weight compounds are also accountable for the color change of palm cooking oil.[6]

The color change was also characterized quantitatively using colorimetry at wavelength λ = 530 nm, where the signal at this

DOI: 10.1021/acs.jafc.5b00380
J. Agric. Food Chem. 2015, 63, 4655−4663

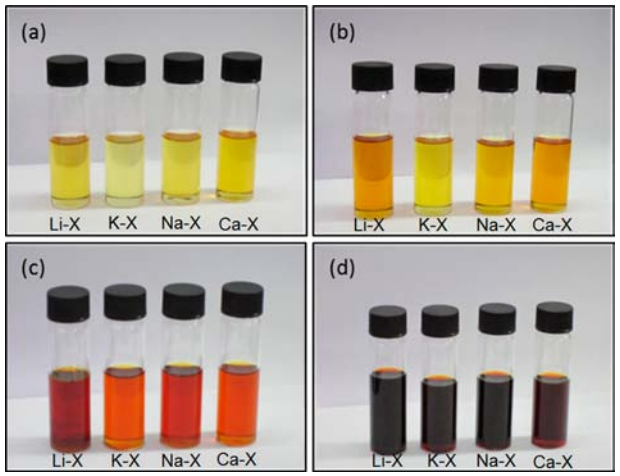

Figure 3. Color change of palm oil with increasing oxidation time: (a) 100 h; (b) 200 h; (c) 300 h; (d) 400 h.

wavelength is strongly influenced by the degree of oil deterioration.[30]

As observed by visual analysis, the reference oil evidenced a fast increment in light absorption, and the absorbance value increased tremendously from 3.49 (at 200 h) to 47.11 (at 400 h) (Figure 4). The addition of zeolite NCs to the palm oil

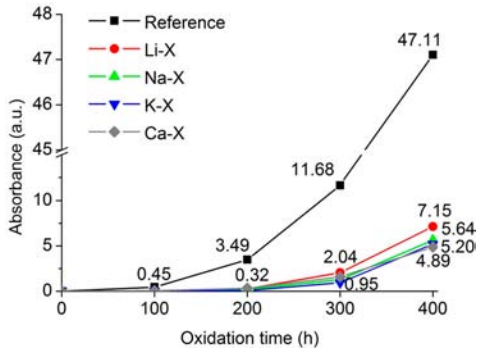

Figure 4. Colorimetric evaluation of palm oil samples oxidized with and without zeolites Li-X, K-X, Na-X, and Ca-X.

lowered significantly the level of oil darkness. As shown, the control of absorbance values is highly dependent on the polarizability/basicity of the non-framework cations. Particularly, the oil samples oxidized with highly basic Ca-X and K-X zeolite NCs exhibit much slower increment in absorbance intensity before 300 h, where only about 0.95 of light absorbance was recorded. After 400 h of oxidation, the palm oil with Ca-X zeolite has the lowest absorbance value of 4.89, whereas the palm oil containing K-X has an absorbance value of 5.20. On the other hand, less basic Li-X and Na-X were less effective in controlling oil darkening; absorbance values of 7.15 and 5.64 were measured, respectively, after 400 h of oxidation.

Viscosity and Acidity Changes of Palm Oil. Rheometry was used to determine the fluidity of the palm oil samples as a function of oxidation time (Figure 5). At the beginning, the fresh oil had a viscosity value as low as 72 cSt. With increasing oxidation time, each oil sample experienced different extents of viscosity elevation. The rate of oil thickening was significantly reduced when zeolite X NCs were added. For instance, the viscosity of palm oil with K-X NCs increased slowly to 912 cSt after 400 h of oxidation, which was 5 times lower than that of

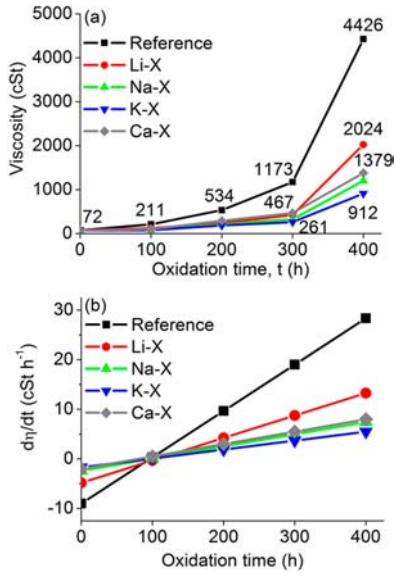

Figure 5. (a) Viscosity of palm oil samples with or without zeolites Li-X, K-X, Na-X, and Ca-X with oxidation time and (b) plot of $d\eta/dt$ versus time showing the increasing rate of viscosity of the oil samples.

the oxidized reference oil (4426 cSt). The rate of viscosity change with time was also calculated on the basis of the slope of the original function ($d\eta/dt$), where this derivative enables the correlation of cation properties with oil viscosity at any instant (Figure 5b). The results show that the control of oil viscosity in the presence of zeolite NCs is dependent on the cations' charge density and polarizability. For example, larger extra-framework cations with low charge density such as K^+ (0.101 e/Å^3) and Na^+ (0.268 e/Å^3) have better performance in resisting the change in viscosity of palm oil than Li^+ (0.779 e/Å^3) and Ca^{2+} (0.505 e/Å^3).[31] Thus, the results show that the oil oxidized with zeolite K-X has the lowest viscosity due to the presence of a low concentration of polymeric oxidized compounds.

Furthermore, oil viscosity and oil darkening are also related to oil acidity because the presence of polar acidic groups (oxidized products) tends to enhance the polarity of oil molecules, thus attracting the organic compounds and resulting in bulkier molecules. Typically, the acidic compounds are mainly alcohols, aldehydes, lactones, and carboxylic acids. These oxidation products, which contain acidic protons, are formed as a result of scission reactions of unsaturated fatty acid chains during oxidative chain reaction.[32] The acidity of oil was evaluated on the basis of total acid number (TAN) measurements of the oil samples. As expected, the trend of oil acidity is somewhat similar to the trend of viscosity of oil, where the reference oil shows fast increment in the TAN value, that is, a TAN of 46.83 mg KOH/g oil was recorded after 400 h (Figure 6a). In contrast, the oils with zeolite NCs exhibit a slow rise in acidity. The acidity of the oils containing zeolite NCs is approximately 4 times lower than that of reference oil. The derivative measurement of the instantaneous changes in the TAN value of oil samples was also performed, and the plot is shown in Figure 6b. It can be clearly seen that the oils oxidized with highly basic zeolite K-X have the lowest rate of TAN value change, indicating that K-X is the most effective in controlling oil deterioration, whereas the basic divalent cation in sample Ca-X has comparable performance to sample Na-X in halting oil oxidation, followed by Li-X. Thus, the similarity of trend in the TAN plot to those of colorimetry and rheometry provides

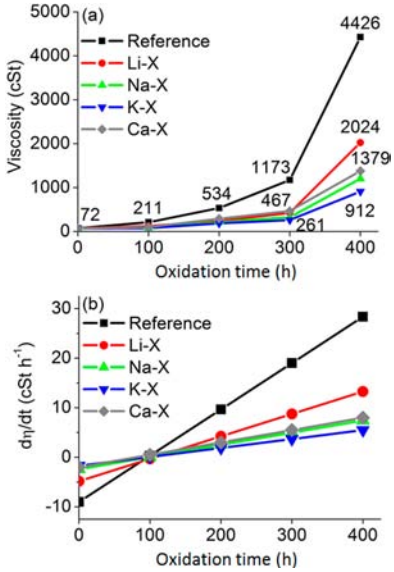

Figure 6. (a) Development of TAN and (b) differential function of TAN of palm oil samples with or without zeolites Li-X, K-X, Na-X, and Ca-X with oxidation time. (b, inset) magnification of the plot is shown.

strong proof of the existence of a relationship between oil composition, the rate of oil darkening, and the total acidic compounds produced, which is consistent with our previous finding.[10]

Oil Oxidation Followed by FTIR and ^{1}H NMR Spectroscopy. FTIR spectroscopy was further applied to study the development of carbonyl-oxidized products in the oil (vibrations in the range 1900−1400 cm^{-1}). Mainly, four signals are slowly developed at 1784, 1743, 1703, and 1655 cm^{-1} during the oxidation process of oil, which correspond to lactones, esters, carboxylic acids, and water, respectively (inset of Figure 7). The reference sample (oil without zeolite)

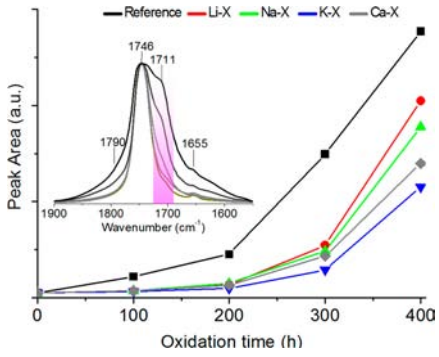

Figure 7. Development of integrated IR peak area (1690−1725 cm^{-1}) corresponding to the carboxylic acids formed during the oxidation of palm oil with and without zeolites Li-X, K-X, Na-X, and Ca-X. (Inset) FTIR spectra of reference oil in the range of 1550−1900 cm^{-1}. The pink area indicates the region used for integration of peak area.

experiences fast peak broadening and significant baseline offset at 1680−1740 cm^{-1} during the oxidation process (inset of Figure 7). Integration of the peak area (1690−1725 cm^{-1}) is used to provide a comprehensive view of the quantitative evolution of carboxylic acids along the oxidation for 400 h (Figure 7). The result reveals a sharp increase in peak area in the reference oil, especially after 200 h of oxidation, indicating the fast development of carbonyl-oxidized compounds in the palm oil. The addition of zeolite NCs slows oxidation, and the broadening of the IR peak at 1700−1800 cm^{-1} indicates deceleration of carboxylic acids in the oil. The effect of extra-framework cations in halting oil oxidation is followed; the changes in the integrated peak area at 1700−1720 cm^{-1} show the dependency of carboxylic acid generation on the types of extra-framework cations in the zeolite nanocrystals. As can be seen, the production rate of carboxylic acid is directly proportional to the polarizability of the alkali metal cations (Figure 7). This is evidenced by the steeper slope of the curves obtained from the integrated peak area for oil samples treated with Li-X than those with K-X and Ca-X. Among all oil samples, the one containing K-X has the least steep slope, suggesting that the oxidative inhibition of the zeolite improves with increasing basicity.

Additionally, the formation of hydroxyl compounds in the oil under oxidation is estimated using the FTIR data. The absorption bands of alcohols (ca. 3615 cm^{-1}), water (ca. 3534 cm^{-1}), and hydroperoxides (ca. 3468 cm^{-1}) are overlapping; thus, only an indication for the overall development of these compounds in the oil samples is observed (Figure S3). The IR results reveal that the zeolite NCs are controlling the rate of formation of hydroxyl compounds in comparison to the oil free of zeolite (reference) during the oxidation process. The formation rate of hydroxyl compounds in the palm oil with Li-X is higher than those of Na-X, K-X, and Ca-X oil samples, indicating that Ca-X and K-X are able to hinder the formation of hydroxyl compounds.

Water is an undesirable oxidized byproduct because it catalyzes oil oxidation and promotes acid formation. Hence, the water content in the oil samples is evaluated using the area of the IR peaks in the region 3500−3350 cm^{-1}. As can be seen, the peaks areas in this region increase with oxidation time, which is a clear indication for the increase of water content during the oxidation process (Figure S3). Nevertheless, this region is not sensitive and accurate to determine the water content in oil media due to the disrupted O−H (alcohols, carboxylic acids, and hydroperoxides) stretching vibration modes.[33] Therefore, the moisture content was quantitatively measured with the Karl Fischer titration method.

The initial water content in the fresh palm oil is 826 ppm, which is <0.1% of the mass of cooking oil—a desired level of water content according to the Palm Oil Refiners Association of Malaysia (PORAM) specification (Figure 8).[34] As can be seen, in the reference oil the water content during the oxidation process is increasing quickly. This can be explained by the high oxidation rate of the oil, where water is produced as a

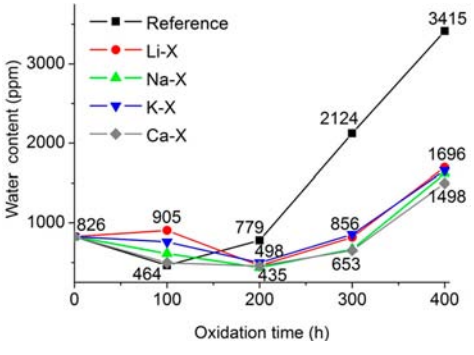

Figure 8. Change in water content of oxidized palm oil samples with and without zeolites Li-X, K-X, Na-X, and Ca-X with oxidation time.

DOI: 10.1021/acs.jafc.5b00380
J. Agric. Food Chem. 2015, 63, 4655−4663

degradation byproduct via condensation. On the contrary, the oil samples containing zeolite NCs overall have a lower water content than the reference oil during the oxidation period. The moisture content in palm cooking oil is dropped during the first 200 h, which might be due to the adsorption of water in the zeolites. Since then, the quantity of water slowly increases, depending on the type of counterions of zeolite X. The lowest water content after 400 h is detected in the oil with Ca-X (1498 ppm), whereas the oil with Li-X has the highest level of moisture (1696 ppm). These changes in water content can be explained by the effect of controlled thermal oxidation process. The better the zeolite in reducing the rate of oxidation, the slower the generation of water, and hence the lower amount of water is present in the oil.

Furthermore, a detailed study on the formation of carbonyl compounds including carboxylic acid (>9.6 ppm) and aldehydes (9.3−9.6 ppm) using ^{1}H NMR spectroscopy is performed. It is demonstrated that the cations with lower polarizability/lower basicity are acting less effectively in slowing the formation of the acidic components in the palm oil (Figure 9). For instance, the formation of aldehydes and carboxylic

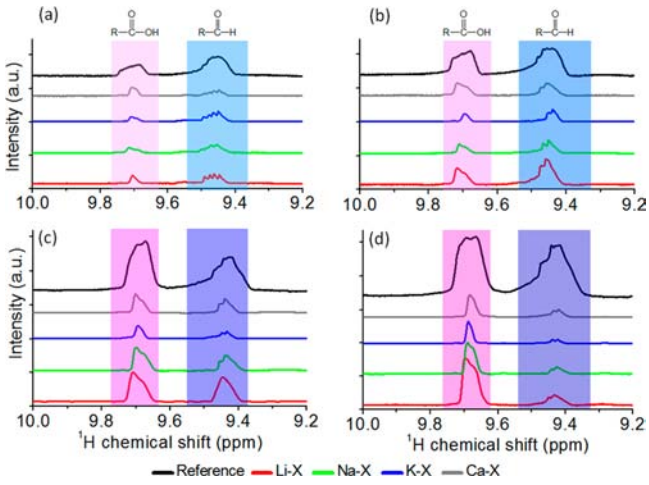

Figure 9. ^{1}H NMR spectra of palm oil samples oxidized with and without zeolites Li-X, K-X, Na-X, and Ca-X for (a) 100 h, (b) 200 h, (c) 300 h, and (d) 400 h.

acids in the palm oil oxidized in the presence of Li-X is faster than the oil containing more basic cations. Among all samples, the palm oil containing K^+ with high cation polarizability has the least increment in both aldehyde and carboxylic contents, followed by the divalent Ca-X in halting oil oxidation possess.

The different colors in oil samples can be due to the presence of high-molecular-weight polymeric oxidized compounds via intensive light absorption and scattering effect. In addition, different contents of β-carotene will also lead to different colors in oxidized oil samples as well. Hence, ^{1}H NMR spectroscopy was used to detect the presence of β-carotene in oil samples after 300 h of oxidation (Figure S4). These oil samples were selected because they exhibited colors significantly different from their counterparts. The ^{1}H NMR spectra show the characteristics peaks of β-carotene at 6.77 ppm arising from protons 11/11′ (6.76 ppm) and protons 15/15′ (6.74 ppm). In addition, protons 7/7′ (6.24 ppm) together with protons 10/10′ (6.23 ppm) show an overlapping signal at 6.24 ppm. The protons 8/8′ are found at 6.19 ppm.[35] It can be seen that the peak intensity of carotene in the oils oxidized with zeolite NCs is almost identical to that of reference oil, indicating that the oxidation rate of carotene is not affected by the presence of zeolite NCs. Thus, taking this fact into consideration, the change of oil color is mainly due to the oxidation products.

Besides, the content of hydroperoxides in the palm oils is also followed by ^{1}H NMR spectroscopy; the signal at ca. 8.80 ppm corresponds to hydroperoxide group (RO−OH).[36] It can be seen that no peak is observed in the reference oil throughout the oxidation process, showing that the hydroperoxides (primary oxidized products) are very unstable and they are directly converted into carboxylic acids, aldehydes, etc. (secondary oxidized products) (Figure S5). As a result, the oxidation rate and acidity of the palm oil increases. In contrast, a broad peak at 8.8 ppm is observed in all oils samples containing zeolite NCs during the first 200 h, indicating their stabilization in the zeolite NCs (Figure S6). Thus, fewer secondary oxidized products (e.g., carboxylic acids and aldehydes) and lower TAN values are observed in these samples. Among four basic exchanged cations, the Ca^{2+} with the highest polarizability contributes most significantly to the stabilizing of hydroperoxides, followed by K^+, Na^+, and Li^+. The broad peak at 8.8 ppm, however, completely disappears after 300 h, and the oxidation rate increases as shown by colorimetry, TAN, rheometry, and IR spectroscopic studies. This can be explained by competitive adsorption of primary and secondary oxidation products. The mechanism of oxidative inhibition of palm oil by zeolite NCs will be discussed further under Characterization of Zeolite Nanocrystals after Oil Oxidation.

Characterization of Zeolite Nanocrystals after Oil Oxidation. The zeolite nanocrystals used during oil oxidation were separated from the oil and washed before being subjected to characterization. Figure S7 shows the IR spectra of zeolite samples before and after use in oil oxidation. It can be seen that fresh Na-X has several peaks at 1006, 752, 670, 566, and 459 cm^{-1} characteristic for the framework structure of zeolite X, and the peaks at 3410 and 1647 cm^{-1} are due to adsorbed water. After oil oxidation, the IR bands of zeolite NCs remain unchanged, indicating that the framework structure of all zeolite samples does not change after 400 h of oxidation. In addition, several peaks are observed at 2921, 2857, 1462, and 1363 cm^{-1}, which are attributed to the adsorption of organic molecules by the zeolite NCs. Furthermore, the hydroxyl band at 3410 cm^{-1} is broadened and slightly shifted to 3405 cm^{-1}, revealing that the zeolites adsorb also hydrocarbons containing hydroxyl groups such as alcohols and hydroperoxides. For zeolite NCs with monovalent cations, a signal at 1745 cm^{-1} that corresponds to esters is overlapping with the signal of 1650 cm^{-1} (OH bending). Thus, the IR results conclude that the oxidative inhibition in oil by monovalent cation exchanged zeolite is not due to oxidation products removal action because no carboxylic acids are adsorbed (no peak is found at 1715 cm^{-1}). On the other hand, the zeolite Ca-X containing divalent cations exhibits a strong peak at 1599 cm^{-1}, which corresponds to the COO^- species.

All zeolites used during the oxidation of palm oil are studied by TG/dTG analysis. Basically, all samples display two steps of weight losses. The zeolites adsorb almost similar amounts of water (5.0%), which is desorbed at 160 °C (Figure S8a). However, the amount of organic compounds adsorbed and their desorption temperature vary depending on the type of zeolite nanocrystals. Li-X with the largest surface area and pore volume adsorbs the highest amount of organic compounds (35.0%) followed by Na-X (28.0%) and K-X (23.0%). The

DOI: 10.1021/acs.jafc.5b00380
J. Agric. Food Chem. 2015, 63, 4655−4663

temperature of desorption identifies the species adsorbed and also provides information on the strength of interaction between that compound and the countercations of zeolite. The dTG curve of Li-X exhibits two signals at 275 and 338 °C (Figure S8b), whereas only one signal around 301−310 °C for samples Na-X and K-X is observed (Figure S8b). As seen, the desorption temperature for K-X is slightly lower than that of Na-X, indicating that K-X has weaker interaction with the organic compounds due to its lower charge density. On the other hand, divalent cations in sample Ca-X adsorb about 30% of organic compounds, which is almost similar to Na-X. Three signals at 275, 387, and 433 °C for sample Ca-X are observed, showing that the Ca^{2+} has higher affinity to organic species than monovalent cations.

Modeling of the Interaction of Peroxide and Alkene Complexes with Metal Ions in Zeolite Nanocrystals. Countercations in the zeolites can interact with C═C bonds and hydroperoxides during the oil oxidation process. Therefore, we consider adsorption of simplified hydroperoxides (e.g., HOOH and C_2H_5OOH) and alkenes (e.g., ethene and *cis*-butene) on the M-X zeolites (M = Li, Na, K, Ca). The calculations show that the countercations introduced in zeolite X more preferably interact with the hydroperoxides than with the alkenes. As shown in Table S3, the binding energy of peroxides (from −50 to −109 kJ/mol) with the metal cations is much higher than that of the binding energy of alkenes (from −17 to −69 kJ/mol), which clearly indicates that the extra-framework cations of zeolite X tend to stabilize peroxides. This result is in good agreement with the ^{1}H NMR spectroscopy data, where a large concentration of hydroperoxides is detected in the oil containing zeolite NCs during the first 200 h of oxidation and, thus, the decomposition rate of hydroperoxide is decelerated due to the stabilization of hydroperoxides by the extra-framework cations (Figure S6). On the other hand, basic countercations have a lower tendency to interact with the alkenes as indicated by their lower binding energy (from −17 to −69 kJ/mol). An attempt to investigate the effect of the addition of methyl and ethyl groups in the alkene molecules on the binding energy is made. The DFT calculations reveal that the insertion of alkyl groups in the alkene chain has an insignificant effect (<5 kJ/mol) on their binding energy toward monovalent cations (Li^+, Na^+, and K^+). This effect, nevertheless, is larger for the divalent Ca^{2+}, where the binding energy of *cis*-butene (−69 kJ/mol) is larger than the binding energy of ethane (−54 kJ/mol). The same trend is also valid for the interaction of the peroxides with Ca-X zeolite, and a strong binding with HOOH (−94 kJ/mol) and C_2H_5OOH (−109 kJ/mol) is calculated.

The periodic DFT calculations show that the interaction of the peroxide with the metal ions is stronger than the interaction of the alkenes with the same ions. This rationalizes the experimental results that M-X zeolites slow the thermal oxidation of palm oil, because the formed peroxides are mostly captured from the metal cations in the zeolites and consequently decelerate further oxidation toward acidic organic compounds such as aldehydes and carboxylic acids. On the basis of the DFT calculations one can conclude that the Ca-X zeolite is the best candidate for hindering the oxidation of palm oil, whereas Li-X, Na-X, and K-X are equally plausible (binding energies for these three cations toward peroxides are somewhat similar). The latter finding is not completely in accordance with the conclusion drawn from the experimental part where K-X shows the best results followed by Ca-X, Na-X, and Li-X. On the other hand, some of the experiments conducted in this work (e.g., colorimetric evaluation, water content analysis, and TAN) show minor differences between the Li^+, Na^+, K^+, and Ca^{2+} cations, which may be difficult to be distinguished by the DFT calculations because oil oxidation is a complex process.

Proposed Mechanisms of Oxidative Inhibition of Palm Oil in the Presence of Zeolite Nanocrystals. The influence of extra-framework alkali metal and alkali earth metal cations on hindering oil oxidation is demonstrated. On the basis of the experimental results and DFT calculations shown in the previous sections, a mechanism of inhibiting oil oxidation by zeolite nanoparticles is proposed. At high temperature, the initiation step starts where unsaturated hydrocarbons are oxidized by air, and hydroperoxides are formed as primary oxidation products (eq 2). The hydroperoxides are very unstable according to ^{1}H NMR spectroscopy (no peak at 8.8 ppm corresponding to hydroperoxides is detected, Figure S6). The hydroperoxides tend to decompose into radicals (water is produced as a byproduct) and react to form more stable compounds (propagation step) (eqs 3a−5). In addition, the reactive radicals also have a high tendency to attack unsaturated C═C bonds of triglycerides. This affects the breaking of C═C bonds, yielding secondary acidic oxidized products (e.g., aldehydes, lactones, and carboxylic acids) as presented in eq 6. The oxidation and propagation continue until the polymerization processes occur (eqs 7 and 8).

$$\text{initiation step: } RH + O_2 \rightarrow ROOH \tag{2}$$

$$\text{propagation: } ROOH \rightarrow RO^{\bullet} + HO^{\bullet} \tag{3a}$$

$$ROOH \xrightarrow{\text{slow}} RO^{\bullet} + HO^{\bullet} \tag{3b}$$

$$2ROOH \rightarrow ROO^{\bullet} + RO^{\bullet} + H_2O \tag{4a}$$

$$2ROOH \xrightarrow{\text{slow}} ROO^{\bullet} + RO^{\bullet} + H_2O \tag{4b}$$

$$ROO^{\bullet} + R'H \rightarrow R'OO^{\bullet} + RH \tag{5}$$

$$\text{cleavage and oxidation: } >C{=}C< + ROO^{\bullet} \rightarrow >C{=}O + >C{=}O + R^{\bullet} \tag{6}$$

$$\text{polymerization: } R^{\bullet} + R'^{\bullet} \rightarrow R - R' \text{(high molecular weight compounds)} \tag{7}$$

$$\text{and termination: } ROO^{\bullet} + R^{\bullet} \rightarrow ROOR \tag{8}$$

When the zeolite NCs containing different alkali metal cations are added during oil oxidation, the oxidation process pathway is altered, and the oxidation rate is slowed. Initially, the hydrocarbons are oxidized to hydroperoxides. In the presence of zeolites, the hydroperoxides are stabilized by the extra-framework cations and, thus, the decomposition rate of the hydroperoxides is decelerated (eqs 3a and 4a). This process is confirmed by the ^{1}H NMR spectroscopy results and supported by the periodic DFT calculations. The palm oild with zeolite NCs have large amountd of hydroperoxides as proven by the presence of a broad signal at 8.8 ppm in the ^{1}H NMR spectra. As a result, this reaction becomes a limitation step to inhibit the oxidation reaction. Thus, a slow oxidation process of the palm oil is observed during the first 200 h by colorimetry, rheometry, TAN, and IR spectroscopy analyses (Figures 4−7). Among the exchanged cations, the divalent Ca^{2+} with the highest ion

DOI: 10.1021/acs.jafc.5b00380
J. Agric. Food Chem. 2015, 63, 4655−4663

polarizability stabilizes the peroxides better than the monovalent K^+, Na^+, and Li^+ cations.

The stabilizing effect by extra-framework cations, however, becomes weaker and the ^1H NMR signal at 8.8 ppm completely disappears after 300 h (Figure S6). Hence, oil oxidation and polymerization increase after 300 h. At this stage, the zeolites are also behaving as oxidative inhibitors by adsorbing oxidation products such as alcohols, hydroperoxides, esters, and water. Unlike monovalent alkali metal cation exchanged zeolites, the alkaline earth Ca-X also reduced the acidity of the oil by neutralizing the acidic carboxylate compounds to $COO^-(Ca^{2+})_{1/2}$ species as proven by IR spectroscopy (Figure S7) and DFT simulations (Figure 10; Table S3).

Conclusions. This work reveals the effect of extra-framework cations in zeolite X nanocrystals on the oxidation of palm oil. The results show that the antioxidation behavior of zeolite nanocrystals depends on basicity, charge density, and polarizability of the countercations of the zeolites. Li-X zeolite nanocrystals with the lowest cation polarizability are found to have the lowest oxidative inhibition activity, whereas the highly basic and highly polarized K-X zeolite nanocrystals are the best candidates to hinder oil oxidation. The effect of zeolite nanocrystals on oil oxidation is found to be different for mono- and divalent cations containing materials. According to ^1H NMR spectroscopy and periodic DFT calculation, all counterions, especially Ca^{2+} with bidentate property, are able to stabilize the hydroperoxides, which are the primary oxidation products and, hence, the decomposition rate of hydroperoxides and the propagation step are decelerated. Furthermore, the adsorption is also another mechanism in halting oil degradation by removing harmful compounds such as esters, alcohols, water, and hydroperoxides as revealed by IR spectroscopy. For Ca-X zeolite nanocrystals, the bidentate capability of Ca^{2+} leads to neutralization of the acidic carboxylate compounds that reduces the acidity of the oil and further decelerates the oil oxidation process.

Influence of Grape Composition on Red Wine Ester Profile: Comparison between Cabernet Sauvignon and Shiraz Cultivars from Australian Warm Climate

Guillaume Antalick,*[,†] Katja Šuklje,[†] John W. Blackman,[†,‡] Campbell Meeks,[†] Alain Deloire,[†] and Leigh M. Schmidtke[†,‡]

[†]National Wine and Grape Industry Centre and [‡]School of Agricultural and Wine Sciences, Charles Sturt University, Locked Bag 588, Wagga Wagga, NSW 2678, Australia

ABSTRACT: The relationship between grape composition and subsequent red wine ester profile was examined. Cabernet Sauvignon and Shiraz, from the same Australian very warm climate vineyard, were harvested at two different stages of maturity and triplicate wines were vinified. Grape analyses focused on nitrogen and lipid composition by measuring 18 amino acids by HPLC-FLD, 3 polyunsaturated fatty acids, and 6 C6-compounds derived from lipid degradation by GC-MS. Twenty esters and four higher alcohols were analyzed in wines by HS-SPME-GC-MS. Concentrations of the ethyl esters of branched acids were significantly affected by grape maturity, but the variations were inconsistent between cultivars. Small relative variations were observed between wines for ethyl esters of fatty acids, whereas higher alcohol acetates displayed the most obvious differences with concentrations ranging from 1.5- to 26-fold higher in Shiraz than in Cabernet Sauvignon wines regardless of the grape maturity. Grape analyses revealed the variations of wine ester composition might be related to specific grape juice nitrogen composition and lipid metabolism. To the authors' knowledge the present study is the first to investigate varietal differences in the ester profiles of Shiraz and Cabernet Sauvignon wines made with grapes harvested at different maturity stages.

KEYWORDS: *yeast metabolism, nitrogen, lipids, grape berry maturity*

INTRODUCTION

Wine aromatic composition is one of the primary attributes assessed by the wine consumer and is an integral component of the overall wine tasting experience. Wine aromatic compounds are classified within three different groups according to their origin: varietal (primary), fermentative (secondary), and derived from aging (tertiary). Although the tertiary component is primarily important in aged wines, the varietal and fermentative components are crucial for wine aroma quality regardless of wine age.[1] Fermentative aromas are mainly derived from yeast activity and are considered as the wine-like aromatic base common to all wines.[1] The varietal component, which is derived from grape aroma and aromatic precursors, imparts specific aromas depending on the cultivars and vineyard characteristics. Within wine categories produced by a similar winemaking process, varietal aromas are considered to contribute to the unique characters.[2] Therefore, the varietal component regulated by the environment and cultural practices appears to be more related to the concept of wine aromatic typicality[2] than the fermentative component.

Several key markers of varietal aroma have been identified in white cultivars such as Muscat, Sauvignon blanc, and Gewürstraminer.[1] In contrast, the understanding of red wine aroma is less advanced, possibly because of the higher level of complexity of such a medium. A limited number of key varietal markers associated with herbaceous[3] and peppery aromas[4] have been identified in red wines. Conversely, the origin of fruity aroma in red wines is still poorly understood despite the evidence of the existence of fruity attributes (red and black berry) typical of red wines.[5] Several studies have emphasized the potential role of some grape-derived compounds such as C13-norisoprenoids and furanones in the perception of fruity aromas specific to red wines.[6−8] However, the contribution of these markers in red wine aroma seems to be indirect through complex perceptive interactions.[7,8]

Other authors have recently highlighted the potential role of esters in the fruity attributes typical of red wines via similar complex interactions.[7−9] Most wine esters are enzymatically synthesized by yeast during alcoholic fermentation[10] and can also be modulated by the lactic acid bacteria (LAB) during malolactic fermentation (MLF).[11,12] However, the possibility of fermentation-derived volatiles, such as esters, playing an important role in varietal differentiation of wines has not been studied extensively. The subsequent opportunity to utilize these esters as "varietal markers" is therefore novel and contradicts paradigms that have been previously assigned to varietal and fermentative aroma and the understanding of wine aroma perception. A lack of knowledge of "key" aromatic compounds responsible for typical fruity aromas of red wines does not necessarily mean that they do not exist.[9] Conversely, esters are known to significantly contribute to aromas of red and black berry fruits generally used as attributes to describe the specific aromas of red wines.[13] Furthermore, it has been shown that esters such as isoamyl acetate contribute

significantly to the varietal aromas of Pinotage[14] and Tempranillo.[15]

Although it is accepted that grape berry parameters such as nitrogen status[16] influence the final wine ester profile, the association between grape and wine ester compositions is poorly understood and requires investigation. This study examined the relationship between grape composition and red wine ester profiles by comparing Cabernet Sauvignon and Shiraz at two different stages of maturity, from a warm to very warm and irrigated region of Australia (Riverina, New South Wales). Distinct cultivars were utilized to contrast the ester profiles between varieties.

MATERIALS AND METHODS

Experimental Vineyard and Harvesting. Grapes were sourced from two adjacent commercial vineyard plots, Shiraz and Cabernet Sauvignon, located within the same larger vineyard in Griffith (Riverina, New South Wales, Australia) (34′17′′00 S; 146′02′′00 E). This vine-growing region is classified as very warm according to the Huglin index[17,18] (HI > 3000). Both cultivars were own-rooted, drip irrigated, and trellised to double cordon with an open sprawling canopy and mechanically pruned. The nitrogen management throughout the season was similar for both cultivars and consisted of fertigating 20 kg of nitrogen per hectare per season via small additions from budburst to veraison. The average crop yields of both plots were approximately 15−20 tons per hectare. Both cultivars were harvested sequentially, at two different dates using the evolution of berry sugar accumulation as indicator in conjunction with °Brix.[19] The first harvest for both cultivars occurred at approximately 21 °Brix and was designated as fresh fruit (FF). The second harvest, designated as mature fruit (MF), occurred at 23 °Brix for both cultivars. At each harvest date, 60 kg of grapes per replicate was randomly harvested across the vineyards with an addition of 40 mg/kg of potassium metabisulfite prior to transport to the Charles Sturt University (CSU)/National Wine and Grape Industry Centre (NWGIC) experimental winery. On arrival, a 100 berry subsample from each replicate was collected and immediately frozen at −20 °C for further analyses.

Winemaking. All replicates were kept separate during the winemaking process. Grapes were destemmed, crushed, and transferred into 100 L stainless steel vats for fermentation. The acidity of each must replicate was adjusted to approximately pH 3.6 using tartaric acid. Fermentation was performed by EC1118 yeast (*Saccharomyces cerevisiae*) and carried out at 25−26 °C with the use of cool rooms. All ferments had identical nutritional supplements, consisting of an addition of 0.3 g/L GoFerm 24 h after yeast inoculation and 0.1 g/L diammonium phosphate (DAP) and 0.25 g/L Fermaid A after a 6 °Brix decrease. This corresponded to total additions of 57 and 15 mg N/L of ammonium and free amino nitrogen, respectively. Malolactic fermentation was carried out using a co-inoculation procedure, with Enoferm alpha LAB (*Oenococcus oeni*) added 2 days post yeast inoculation. Ferments were pressed to 1 bar pressure using a small basket press when the residual sugar decreased to <0.5 g/L. The wine temperature was then maintained at 22 °C until the malic acid concentration decreased to <0.05g/L. The wine was then racked off the gross lees into variable-capacity tanks to prevent ullage and 80 ppm of SO_2 added to achieve levels of 25−30 ppm of free SO_2. Tanks were then moved to a −4 °C cool room for 3 weeks to achieve cold stabilization and racked a further two times during this period for clarification. Heat stability was tested and SO_2 concentrations were adjusted to approximately 30 ppm of free SO_2 to achieve 0.5−0.8 molecular SO_2.Wines were bottled using a four-head filler with CO_2 utilized to prevent oxidation. Bottles were also filled with CO_2 prior to filling and then capped with a Stelvin screwcap.

General Analyses of Grape Maturity, Yeast Available Nitrogen, and Wine Composition. Grape juice samples collected after crushing were analyzed for basic maturity and fermentation parameters. Total soluble solids (TSS), expressed as °Brix, were analyzed with a portable density meter (Anton Paar DMA 35N, Graz, Austria). Titratable acidity (TA) and pH were determined by sodium hydroxide titration to the end point pH 8.2 with an automatic titrator (Metrohm Fully Automated 59 Place Titrando System, Metrohm AG, Herisau, Switzerland). Ammonium, α-amino acids, and acetic acid were determined using commercially available enzymatic tests purposely designed and deployed on an Arena discrete analyzer (ThermoFisher). Yeast assimilable nitrogen (YAN) was calculated from ammonium and free amino nitrogen (FAN) measurements according to a previously published method.[20] Ethanol was measured with an Anton Paar Alcolyser DMA 4500 density meter. Sugar to ethanol conversion rate was calculated as the ratio of potential wine alcohol according to TSS measurements and ethanol level measured in wines.

Ester and Higher Alcohol Analysis in Wines. All of the esters, except ethyl leucate, ethyl acetate, and ethyl phenylacetate, were quantified using a mix of isotopically labeled esters as previously described[21] by employing CDN isotopes (Pointe-Claire, Canada). The final solution used to spike the samples was composed of 20 mg/L [$^2H_5$]-ethyl butyrate, 20 mg/L [$^2H_5$]-ethyl hexanoate, [$^2H_{15}$]-ethyl octanoate, 4 mg/L [$^2H_{23}$]-ethyl decanoate, and 5 mg/L [$^2H_5$]-ethyl cinnamate. Twenty microliters of internal standard mix solution was added to an exact 10 mL volume of wine. A 5 mL sample aliquot was placed into a 20 mL SPME vial previously filled with 3 g of NaCl and diluted with 5 mL of deionized water. The samples were immediately capped and analyzed by HS-SPME-GC-MS as described previously by Antalick et al.[21] with a PDMS-CAR-DVB fiber (Supelco, Bellefonte, PA, USA). Fibers were desorbed into an Agilent 7890 gas chromatograph fitted with a DB-WAXetr capillary column (60 m, 0.25 mm, 0.25 μm film thickness, J&W Scientific, Folsom, CA, USA) using a Gerstel MPX autosampler with a Peltier tray cooler at 4 °C. The GC was coupled to a 5975C mass spectrometer (Agilent Technologies) operating in electron ionization mode using selected ion monitoring (SIM) and scan modes simultaneously. All of the esters, except ethyl leucate, ethyl acetate, and ethyl phenylacetate, were quantified using SIM mode as described elsewhere.[21] *trans*-2-Hexenyl and *cis*-3-hexenyl acetates were quantified with ions 100 and 82, respectively. Ethyl leucate and ethyl phenylacetate were semiquantitatively analyzed in SIM with ions 87 and 91, respectively. Ethyl acetate and the higher alcohols (propanol, isoamyl alcohol, isobutanol, and phenylethanol) were semiquantitatively measured in scan mode using total ion chromatogram (TIC). Relative concentrations were calculated using [$^2H_5$]-ethyl butyrate for ethyl acetate, propanol, isobutanol, and isoamyl alcohol, [$^2H_5$]-ethyl hexanoate for *trans*-2-hexenyl acetate, *cis*-3-hexenyl acetate, and ethyl leucate, and [$^2H_5$]-ethyl cinnamate for ethyl phenylacetate and phenylethanol.

C6-Compounds Analysis in Grapes. Hexanol, hexanal, *E*-2-hexenol, *E*-2-hexenal, *Z*-3-hexenol, and *Z*-3-hexenal were analyzed in grapes using a method adapted from Loscos et al.[22] Grapes were deseeded in the presence of liquid nitrogen and homogenized with a ball mill TissueLyser (Quiagen, Retsch, Shenzhen, China) for 30 s at 20 Hz. Approximately 500 mg of grape berry powder was weighed into the SPME vial in the presence of liquid nitrogen. Two milliliters of acidic buffer containing 5g/L of tartaric acid and 2 g/L of ascorbic acid with pH adjusted to 3.0 was added to the frozen grape berry powder. Samples were spiked with 15 μL of internal standard containing octan-2-ol and [$^2H_{12}$]-hexanal at concentrations of 68 and 46.5 mg/L, respectively, and 0.5 g of sodium chloride was added to the vial. Vials were randomly positioned on a tray cooler set at 4 °C prior to analysis to limit the influence of sample order on the results due to lipoxygenase activity. Samples were analyzed by HS-SPME-GC-MS with a PDMS-CAR-DVB fiber (Supelco). Fibers were desorbed at 250 °C in splitless mode for 1 min into an Agilent 7890 gas chromatograph fitted with a DB-WAXetr capillary column (60 m, 0.25 mm, 0.25 μm film thickness, J&W Scientific) using a Gerstel MPX autosampler with a Peltier tray cooler at 4 °C. The oven temperature was programmed at 40 °C for 5 min, then raised to 220 °C at 3 °C/min, and then held at that temperature for 30 min. The GC was coupled to a 5975C mass spectrometer (Agilent Technologies) operating in electron ionization mode using SIM and scan modes simultaneously. Quantifying ions

[a]Cabff, Cabernet Sauvignon fresh fruit; Cabmf, Cabernet Sauvignon mature fruit; Shff, Shiraz fresh fruit; Shmf, Shiraz mature fruit. [b]One-way ANOVA was used to compare data. Means followed by different letters in a row are significant at $p \leq 0.05$ (Fischer's LSD). All quoted uncertainty is the standard deviation of three replicates per treatment. [c]TSS, total soluble solids; TA, titratable acidity; FAN, free amino nitrogen; YAN, yeast assimilable nitrogen; sugar:ethanol, sugar to ethanol conversion rate; FAN:Am, ratio of free amino nitrogen (mg/L as N) to ammonium concentration (mg/L as N).

chosen for the internal standards were 45 for octan-2-ol and 92 for [$^2H_{12}$]-hexanal. C6-compounds were measured in SIM mode in a semiquantitative way using peak to area ratios and octan-2-ol and [$^2H_{12}$]-hexanal as internal standards for alcohols and for aldehydes, respectively. Compound identity was confirmed by checking the mass spectra in scan mode performed simultaneously to SIM mode and comparing the retention times with those available in the literature. Quantifying ions chosen were 56 for hexanal and hexanol, 83 for *E*-2-hexenal and *Z*-3-hexenal, 57 for *E*-2-hexenol, and 67 for *Z*-3-hexenol.

Lipid Analysis in Grapes. Oleic, linoleic, and linolenic acids were analyzed by semiquantification according to a method adapted from Roufet et al.[23] A 1 g sample of frozen grape powder prepared as previously described was weighed into a 20 mL glass vial and immediately extracted to limit lipid oxidation. Semiquantitative analysis was performed by adding 1 mL of 1 g/L decanoic acid solution as internal standard to samples immediately prior to extraction. The amount of decanoic acid added was approximately 10000 times higher than the initial concentration of this compound present in grape berry samples. Therefore, the initial concentration of decanoic acid present in grapes did not interfere with lipid quantification. Lipid extraction was performed three times for 5 min by stirring in 10 mL, followed by two 5 mL mixtures of chloroform/methanol (2:1). The chloroform phases were collected and pooled. Lipids were thereafter methylated to be analyzed by GC-MS, stirring the chloroform phase with 5 mL of a 3% methanolic solution of HCl for 1 h. The organic phase was washed twice with deionized water and collected for drying over ammonium sulfate. Organic extracts were concentrated to 2 mL by evaporation under low pressure before being injected in GC-MS. A 1 μL sample volume of extract was injected at 250 °C in split mode (ratio 10:1) into the same chromatograph and column as previously described. The oven temperature was programmed at 40 °C, then immediately raised to 220 °C at 8 °C/min, and then held at that temperature for 57.5 min. The mass spectrometer was operating in electron ionization mode using SIM and scan modes simultaneously. Methyl esters of lipids were analyzed in SIM mode in a semiquantitative manner using peak to area ratios and decanoic acid as an internal standard. Quantifying ions chosen were 74 for methyl decanoate, 55 for methyl oleate, 67 for methyl linoleate, and 79 for methyl linolenate. The identity of compounds was confirmed by checking the mass spectra in scan mode performed simultaneously to SIM mode and comparing the retention times with the retention indices available in the literature. Qualification ions were used in SIM mode to avoid any integration mistake (87 for methyl decanoate, 264 for methyl oleate, 294 for methyl linolenate, and 292 for methyl linolenate).

Amino Acid Analysis in Grapes. The extraction protocol for amino acids from frozen grape berry powder was adopted from a previously published method.[24] Grape berry powder sample weight was reduced from 2.5 (±0.1) to 0.1 (±0.0005) g. To maintain the ratio of grape powder/extraction medium 1:1 (w/v),[25] 100 μL of a water/methanol mixture (20:80) was added to the samples. The samples were then vigorously vortexed (MS 3 basic, IKA, Selangor, Malaysia) for 1 min and sonicated at room temperature for 15 min to complete the extraction. Samples were then centrifuged for 10 min at 12000g, and the supernatant was collected and placed in a new Eppendorf tube for the derivatization process as described elsewhere.[25] Briefly, grape extracts were diluted 1:20 (v/v) with 0.25 M borate buffer (pH 8.5). The amino groups were derivatized with 9-fluoroenyl-ethyl chloroformate, and an internal standard of 13.1 mg/L L-hydroxyproline was used. Amino acids were analyzed by high-performance liquid chromatography (HPLC) using a Waters 600 controller (Milford, MA, USA) connected to an autosampler (Waters 717 plus). Separation of amino acids was achieved with a reverse phase column (Thermo 5 μm ODS hypersil, Waltham, MA, USA) and quantification with a fluorescence detector (Waters 2475). The column temperature was increased to 45 °C to separate γ-aminobutyric acid and proline. Quantification was performed as previously reported.[24]

Statistical Analysis. One-way and two-way analyses of variance (ANOVA) for the variables cultivar and harvest date were performed on the chemical data using Statistica, version 12 (StatSoft, Tulsa, OK, USA), and the means were separated using Stats-Fisher's LSD test (different letters account for significant differences at $p \leq 0.05$).

RESULTS AND DISCUSSION

Description of Grape Juice Parameters. In the present study both cultivars were harvested at very similar TSS contents (Table 1); therefore, it is unlikely that differences observed in wine ester profile between cultivars for a given maturity stage originated from yeast sugar metabolism. The FF harvest was performed at approximately 21 °Brix, whereas grapes were harvested at around 23 °Brix for the MF harvest (Table 1).

[a]Cabff, Cabernet Sauvignon fresh fruit; Cabmf, Cabernet Sauvignon mature fruit; Shff, Shiraz fresh fruit; Shmf, Shiraz mature fruit. [b]Two-way ANOVA was used to compare data. Means expressed in μg/L followed by different letters in a row are significant at $p \leq 0.05$ (Fischer's LSD). All quoted uncertainty is the standard deviation of three replicates of one treatment. [c]Significance of two-way ANOVA for cultivar, harvest date, and interaction cultivar × harvest date. Bold numbers indicate significant differences. [d]Compound measured by semiquantification; relative peak areas (compound:internal standard areas ratio) were used to calculate means and standard deviation.

However, the relationship between potential variations in esters during ripening and yeast sugar metabolism is difficult to establish. Yeast ester metabolism depends not only on yeast sugar metabolism,[11] and the relationship between grape berry sugar accumulation and aromatic maturity is complicated, often indirect, and compound specific.[26]

Higher pH and lower TA values were measured for MF stage compared to FF and for Shiraz compared to Cabernet Sauvignon juice (Table 1), but these differences were reduced before fermentation by the addition of tartaric acid. Consequently, TA concentrations were similar in all of the wines, whereas wine pH values were similar between cultivars, remaining higher in the MF stage in comparison to FF (Table 1).

The general nitrogen composition significantly differed between cultivars and, to a lesser extent, maturity stages. Cabernet Sauvignon grapes exhibited higher values of YAN than Shiraz mainly due to higher concentrations of ammonium regardless of nutrient addition (Table 1). In contrast, Shiraz grape juices showed higher concentrations of free amino nitrogen (FAN). Therefore, FAN:ammonium ratios were 3–3.5-fold higher in Shiraz than Cabernet Sauvignon grape juices (Table 1). These values decreased from 1.8- to 2.1-fold higher in Shiraz than Cabernet Sauvignon when the nutrient additions were taken into consideration. The comparison of relative grape juice nitrogen composition between Shiraz and Cabernet Sauvignon has not been previously reported in the literature. In addition, ammonium concentrations significantly decreased during ripening for both varieties, whereas FAN increased over maturation only in Cabernet Sauvignon (Table 1). The decrease of ammonium and the lack of consistency for increasing FAN over grape ripening have both been extensively reported in the literature.[16]

Varietal and Maturity Effect on Esters Concentrations. Quantified esters were grouped according to their origin into three groups: ethyl esters of fatty acids (EEFAs), ethyl esters of branched acids (EEBAs), and higher alcohol acetates (HAAs) (Table 2). A two-way ANOVA was used to assess the effect of cultivar, maturity (harvest date), and cultivar × maturity interactions on esters and amino acid variations. Interestingly, 80% of esters measured in this study were influenced by a varietal effect, whereas only 30% were influenced by grape maturity (Table 2). Similar results were found for most of the amino acids (Table 3).

Ethyl Esters of Fatty Acids. Overall, similar ranges of EEFA concentrations were measured in Cabernet Sauvignon and Shiraz wines (Table 2). However, some variations in EEFAs were observed between wines, and interestingly they were more related to variety than maturity (Table 2). Indeed, five of six EEFAs were influenced by cultivar, whereas only ethyl

[a]Cabff, Cabernet Sauvignon fresh fruit; Cabmf, Cabernet Sauvignon mature fruit; Shff, Shiraz fresh fruit; Shmf, Shiraz mature fruit. [b]Two-way ANOVA was used to compare data. Means expressed in μg/g of berry weight followed by different letters in a row are significant at $p \leq 0.05$ (Fischer's LSD). All quoted uncertainty is the standard deviation of three replicates of one treatment. [c]Significance of two-way ANOVA for cultivar, harvest date, and interaction cultivar × harvest date. Bold numbers indicate significant differences. [d]Compound measured by semiquantification, relative peak area (compound:internal standard areas ratio) were used to calculate means and standard deviation.

hexanoate varied according to maturity (Table 2). Similar results have been recently reported in Australian Riesling;[26] however, the differences in EEFA concentrations between Cabernet Sauvignon and Shiraz wines were significant only for the MF stage (Table 2). EEFA concentrations decreased in Cabernet Sauvignon wines during maturation, particularly for ethyl hexanoate and octanoate. These two esters were subject to interactions between cultivar and harvest stage effect (Table 2). On the other hand, EEFA concentrations in Shiraz wines were steady over maturation (Table 2). Increases of EEFAs concentrations during grape ripening have been recently reported in Australian Cabernet Sauvignon.[27] The contrast observed between the different studies suggests that the link between grape composition and yeast EEFA metabolism is complex. EEFAs are generally synthesized by yeast during alcoholic fermentation, and their levels in wines seem to largely depend on winemaking conditions such as fermentation temperature, aeration, skin contact, and yeast strain.[11,28] In the present study these type of parameters (temperature, yeast strain, time of skin contact, punching down frequency) were standardized by the winemaking protocol. In parallel, the nitrogen composition of grape juice seems to influence EEFA synthesis to a lesser extent,[29] and the relative variations observed for this group of esters were the smallest of all the wine volatiles analyzed in this study (Table 2).

Ethyl Esters of Branched Acids. EEBA variations were largely driven by interactions between grape maturity and the choice of the cultivar (Table 2). In the present study Cabernet Sauvignon and Shiraz displayed opposite trends during grape maturation (Table 2). Although grape maturation favored higher concentrations of EEBAs in Cabernet Sauvignon, it significantly reduced EEBA concentrations in Shiraz wines (Table 2). At FF stage the concentrations of ethyl isobutyrate, isovalerate, and leucate were higher in Shiraz wines, whereas the concentrations of these esters and ethyl 2-methylbutyrate were higher in Cabernet Sauvignon wines at MF stage (Table 2). These variations were particularly evident for ethyl isobutyrate, with concentrations of 30 and 54.7 μg/L in Shiraz and Cabernet Sauvignon, respectively, at FF stage, representing a 1.8 factor difference.

EEBAs are primarily synthesized during wine aging by esterification between branched acids and ethanol.[28,30] However, a small proportion is also biosynthesized by yeast during alcoholic fermentation through branched amino acid metabolism.[31] Consequently, branched amino acid juice composition significantly affects EEBA concentrations and their corresponding acids found in wines. In the present study the concentrations of branched amino acids measured in grapes were predominantly influenced by maturity without specific varietal effect (Table 3). The similar concentrations of branched amino acids measured in Cabernet Sauvignon and Shiraz grapes increased with grape maturity. The variations measured during ripening in Cabernet Sauvignon grapes may be linked to the increase of EEBA concentrations observed in the corresponding wines. Prior observations support the trend of increased EEBAs during grape maturation in Cabernet Sauvignon.[27] On the other hand, the decreases of EEBA concentrations with grape maturity observed in Shiraz wines (Table 2) did not reflect the variations of branched amino acids contents in the corresponding grape berries (Table 3). In that case, EEBA variations could be potentially linked to yeast redox metabolism as suggested by previous studies.[28,31] This hypothesis is supported by the similar variations observed in Shiraz wines for acetic acid and the highest variations measured

DOI: 10.1021/acs.jafc.5b00966
J. Agric. Food Chem. 2015, 63, 4664−4672

for ethyl isobutyrate (Tables 1 and 3). Acetic acid production during alcoholic fermentation is known to depend on yeast redox metabolism,[32] and it has been recently suggested that isobutyric acid could also be a specific marker of yeast redox metabolism.[28,33] However, such speculations will need to be studied in the future using appropriate investigations.

Interestingly, ethyl phenylacetate, ethyl cinnamate, and 2-phenylethanol concentrations were significantly higher in Cabernet Sauvignon wines irrespective of the grape maturity stage (Table 2). Weldegergis et al.[34] reported that Cabernet Sauvignon wines exhibited significantly higher concentrations in 2-phenylethanol than Shiraz wines. Other authors suggested that benzene derivatives could be considered as markers of ripe Cabernet Sauvignon grapes.[35] Ethyl phenylacetate, cinnamate, and 2-phenylethanol are derived from phenyalanine metabolism, originating from yeast, grapes, and yeast and grapes, respectively.[28,35] In the present study, no trend between these compounds in wines and the phenylalanine concentrations of the corresponding grapes are evident (Table 3). The variations measured in wines for ethyl phenylacetate, cinnamate, and 2-phenylethanol might therefore reflect differences of phenylalanine metabolism between Cabernet Sauvignon and Shiraz varieties.

Higher Alcohol Acetates. The most important varietal effect in regard to the relative variations of ester concentrations was observed for HAAs. Conversely, maturity levels exhibited a lower effect on this group of esters (Table 2). Shiraz wines, irrespective of maturity stage, displayed significantly higher concentrations of all HAAs except propyl acetate in comparison to Cabernet Sauvignon wines (Table 2). Two groups of HAAs were influenced by measured parameters: acetates of higher alcohols from yeast nitrogen and sugar metabolism and C6-acetates from grape lipid degradation. Isobutyl, isoamyl, and 2-phenylethyl acetates, classified in the first group, were at concentrations from 1.5- to 3-fold higher in Shiraz compared to Cabernet Sauvignon wines (Table 2). These esters were also influenced by harvest date; however, the effect was ester specific. In Shiraz wines 2-phenylethyl acetate concentration increased with maturity, whereas concentrations of isoamyl and isobutyl acetates decreased slightly. On the other hand, the concentrations of these acetates increased with grape maturity in Cabernet Sauvignon wines. These results are supported by previous observations made in Cabernet Sauvignon wines,[27] whereas there is no previous reported information with regard to Shiraz. Furthermore, important varietal differences were also noted for C6-acetates as hexyl, *cis*-3-hexenyl, and *trans*-2-hexenyl acetates. Concentrations of hexyl and *cis*-3-hexenyl acetates were 9- and 22-fold higher, respectively, in Shiraz than in Cabernet Sauvignon wines. Such quantitative differences in acetate esters, particularly for isoamyl and hexyl acetates, may alter the aromatic profile of red wines.[9]

Investigations on the Origin of Varietal Differences in Higher Alcohol Acetate Composition. Higher alcohol acetates were the group of esters most influenced by variety. Only propyl acetate exhibited variations between harvest dates and cultivars that were well correlated to the variation of the corresponding higher alcohol (Table 2). Other acetates derived from amino acid metabolism, such as isobutyl, isoamyl, and 2-phenylethyl acetate, were quantified at significantly higher concentrations in Shiraz than in Cabernet Sauvignon wines (Table 2). Unlike propyl acetate, no specific relationship could be established between the levels of higher alcohols (isobutanol, isoamyl alcohol, 2-phenylethanol) and the corresponding acetates measured in wines (Table 2). Higher alcohol acetates are mainly synthesized during alcoholic fermentation by yeast from acetyl-CoA and higher alcohols through alcohol acetyltransferase activities.[11] Even though higher alcohol availability strongly influences HAA production, the limiting factor for their synthesis is the expression of alcohol acetyltransferase activities.[11] Oxygen, lipids, and nitrogen are the main nutrients found in must, which are known to particularly regulate alcohol acetyltransferase.[11] It could be reasonably expected that oxygen levels in the grape musts prior to fermentation were similar for all wines due to the standardization of the winemaking protocol. Moreover, unsaturated fatty acids, known to repress alcohol acetyltransferase expression, were higher in Shiraz grapes, whereas Shiraz wines exhibited higher concentrations of HAAs (Figure 1; Table 2). This contrast indicates that it is unlikely that cultivar differences observed for HAAs between Shiraz and Cabernet Sauvignon wines originated from alcohol acetyltransferase repression due to lipid concentrations. The influence of grape lipids on HAA production in Shiraz wines by boosting cellular growth and general yeast metabolism[36,37] cannot, however, be fully excluded.

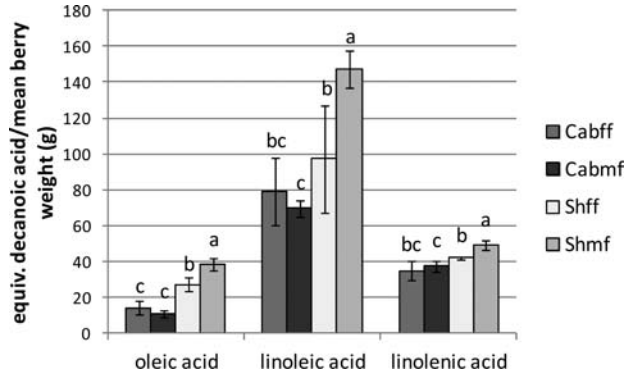

Figure 1. Mean ± SD of unsaturated fatty acids in grape berries expressed as decanoic acid equivalent per gram of berry weight. One-way ANOVA was used to compare data. Different letters above bars indicate significance at $p \leq 0.05$ (Fischer's LSD). All quoted uncertainty is the standard deviation of three replicates per treatment. Cabff, Cabernet Sauvignon fresh fruit; Cabmf, Cabernet Sauvignon mature fruit; Shff, Shiraz fresh fruit; Shmf, Shiraz mature fruit.

Yeast assimilable nitrogen (YAN) is the most common analytical parameter used to assess grape juice nitrogen status. In general, higher YAN concentration favors higher HAA production.[38,39] Must YAN levels could be considered as low to moderate[16] for both cultivars, with slightly higher values in Cabernet Sauvignon compared to Shiraz (Table 1). Consequently, no direct link between YAN and HAA production could be established in the present study. However, YAN composition differed greatly between both varieties with a higher ratio FAN:ammonium measured in Shiraz musts regardless of nutrient addition. This is due to higher FAN and lower ammonium concentrations in Shiraz compared to Cabernet Sauvignon (Table 1).

On the other hand, some of the amino acids assimilable by yeast that contribute to FAN have been classified as "preferred" in regard to their importance for yeast metabolism.[40] Interestingly, Shiraz grapes consistently possessed higher concentrations of "preferred" amino acids than Cabernet Sauvignon (Table 3). High amino nitrogen media may

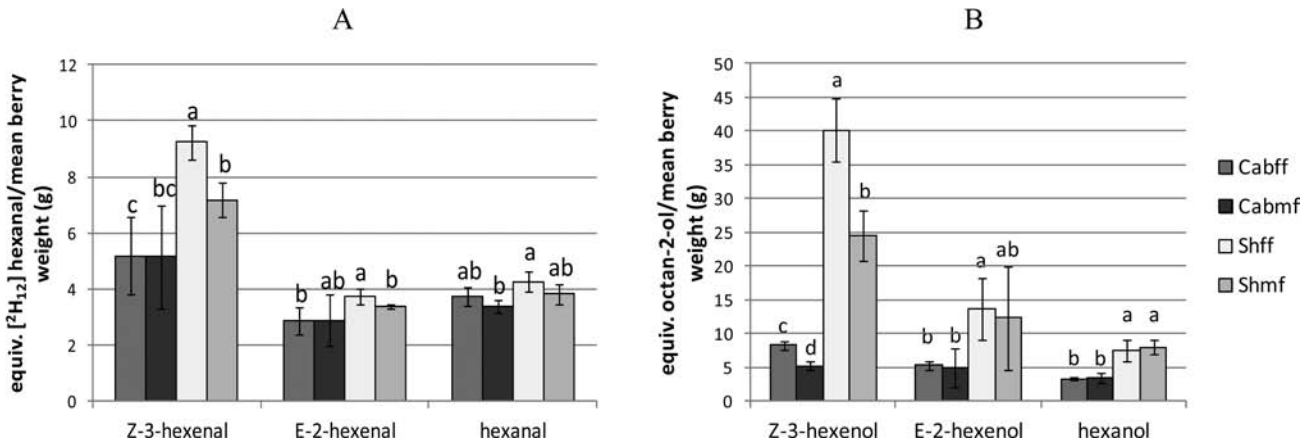

Figure 2. Mean ± SD of C6-aldehydes (A) and C6-alcohols (B) in grape berries expressed as equivalent [$^2H_{12}$]-hexanal and octan-2-ol per gram of berry weight. One-way ANOVA was used to compare data. Different letters above bars indicate significance at $p \leq 0.05$ (Fischer's LSD). All quoted uncertainty is the standard deviation of three replicates per treatment. Cabff, Cabernet Sauvignon fresh fruit; Cabmf, Cabernet Sauvignon mature fruit; Shff, Shiraz fresh fruit; Shmf, Shiraz mature fruit.

stimulate alcohol acetyltransferase expression and, consequently, HAA synthesis by yeast.[41] Furthermore, alcohol acetyltransferase expression has been reported to be particularly important during the early stage of the fermentation.[42] Amino acid uptake by yeast is also known to be maximal during the early phase of alcoholic fermentation as ethanol inhibits their transfer from the external medium into yeast cell.[43] In parallel, ammonium is the first source of nitrogen assimilated by yeast.[16] Therefore, a low ratio of FAN:ammonium in must may down-regulate yeast metabolic activity due to the lower assimilation of amino acids during the early stages of alcoholic fermentation.[43] A relationship between grape nitrogen composition and the varietal differences for HAAs in wines is suggested. Higher levels of FAN and FAN:ammonium ratio found in Shiraz grapes may influence the yeast metabolism that favors alcohol acetyltransferase expression and consequently HAA synthesis. Some cultivars rich in amino nitrogen such as Pinotage are known to exhibit specific esters profile with high concentrations of HAAs.[14] Sugar to ethanol conversion rates were also higher in Shiraz (Table 1). Glycolytic enzymes involved in the conversion of sugar to ethanol are known to be especially influenced by FAN:ammonium balance.[43] This helps explain the differences in HAAs between varieties found in this study and suggests an important relationship between grape nitrogen composition and yeast metabolism regardless of the nitrogen supplementation in the winery. Further studies linking grape nitrogen composition and HAA production by yeast at microbiological and transcriptomic levels are therefore warranted. The influence of other grape metabolites on yeast ester metabolism also requires further investigation.

The varietal differences between Shiraz and Cabernet Sauvignon were the most important for C6-acetates. These esters are derived from the acetylation of C6-alcohols originating from lipid oxidation in grape berries throughout ripening and during crushing.[35,44] Surprisingly, in the present study Shiraz grapes exhibited much higher concentrations of C6-alcohols and C6-aldehydes, particularly *Z*-3-hexenol and *Z*-3-hexenal, than Cabernet Sauvignon (Figure2). Therefore, in this case the stimulation of acetate synthesis in Shiraz wines due to nitrogen composition was accentuated by a higher synthesis of C6-compounds in Shiraz grapes. Interestingly, the levels of linoleic and linolenic acid, from which C6-aldehydes and alcohols are derived, were similar at FF stage between Shiraz and Cabernet Sauvignon grapes (Figure 1), whereas C6-compound contents were significantly higher in Shiraz compared to Cabernet Sauvignon grapes (Figure 2). This result suggests that in the vineyards studied, some enzymes involved in the lipoxygenase pathway may have been more active in Shiraz in comparison to Cabernet Sauvignon, at least for the early stage of grape maturation. For the MF stage, unsaturated fatty acids were measured at higher levels in Shiraz compared to Cabernet Sauvignon grapes (Figure 1), causing the origin of varietal differences of C6-compounds in grapes to be less clear. Further studies that investigate potential differences in the lipoxygenase pathway between Shiraz and Cabernet Sauvignon would be of interest.

This study has demonstrated that red wine ester profiles could be strongly influenced by grape composition and, in particular, grape nitrogen and lipid metabolism. New perspectives for a more detailed investigation to determine the impact of nitrogen and lipid interactions on yeast ester metabolism have been proposed. The present study is the first to investigate varietal differences in ester profiles of Shiraz and Cabernet Sauvignon wines made with grapes harvested from commercial vineyards at different maturity stages. This work was performed in a very warm climatic region of Australia on irrigated vines. Consequently, the variations in ester profiles between Shiraz and Cabernet Sauvignon wines observed in this study may reflect varietal differences in grape composition arising from different responses to abiotic factors and potential stress or constraints (temperature, heat waves, water constraint pre- and post-veraison, and light quality and quantity at the canopy and fruit zone levels) as it has been recently reported in Sauvignon blanc wines.[45] Further investigations will be needed to determine if the varietal differences observed in this study were specific to the site chosen or if they can be extrapolated to a wider scale.

Supporting Information

ABSTRACT: In this work, the interactions of a well-studied hydrophobin with different types of nonpolar model substances and their impact on primary gushing is evaluated. The nature, length, and degree of saturation of nonpolar molecules are key parameters defining the gushing ability or inhibition. When mixed with hydrophobins, the nonpolar molecule-hydrophobin assembly acts as a less gushing or no gushing system. This effect can be explained in the framework of a competition effect between non-polar systems and CO_2 to interact with the hydrophobic patch of the hydrophobin. Interactions of these molecules with hydrophobins are promoted as a result of the similar size of the nonpolar molecules with the hydrophobic patch of the protein, at the expense of the formation of nanobubbles with CO_2. In order to prove the presence of interactions and to unravel the mechanisms behind them, a complete set of experimental techniques was used. Surface sensitive techniques clearly show the presence of the interactions, whose nature is not covalent nor hydrogen bonding according to infrared spectroscopy results. Interactions were also reflected by particle size analysis in which mixtures of particles displayed larger size than their pure component counterparts. Upon mixing with nonpolar molecules, the gushing ability of the protein is significantly disrupted.

1. INTRODUCTION

Hydrophobins are globular surface active proteins produced by filamentous fungi, with a molecular weight of between 7 and 15 kDa and a diameter of 2−3 nm.[1,2] They are not toxic to humans when ingested upon consumption of mushrooms nor cytotoxic or immunogenic.[3] The ability of class II hydrophobins to form self-assemblies results in the possibility to function as nucleation sites for gaseous molecules like CO_2. This occurs in carbonated beverages and causes primary gushing, an important problem in the brewing industry, which is economically disastrous.[4−6] Much research was devoted to explain the basic mechanism of gushing.[7−9] A coherent mechanism was described by Deckers et al.[10,11] They explained that hydrophobins stabilize CO_2 gas bubbles by their hydrophobic patches and form nanobubbles. The formed nanobubbles agglomerate at the gas−liquid interface as nanoparticles surrounded by hydrophobins. On opening the bottle, the pressure drops and the particles grow and explode. This explosion provides the

required energy for the simultaneous formation of more nucleation sites, bubble growth and instantaneous gushing.

Several methods to prevent and to solve gushing have been proposed. For example, the addition of proteolytic enzymes or adsorbents like charcoal or activated alumina during the beer filtration step and the addition of a mixture of different calcium-enriched silicates.[5,12−14] The addition of hop components like free linalool (50 μg/L) and humulones (5 mg/L) to the beer was one of the gushing decreasing methods.[15] The amount of total linalool (free and cell wall bound which will be used by yeast) in beer is 500 μg/L and humulones is 5−20 mg/L, which are high amounts but not free to decrease gushing.[16−18] Membrane filtration of beer (0.1 μm pore size) and the addition of unsaturated fatty acids have also been claimed to decrease gushing.[15,19] Among the curative methods of gushing, one study on hop oils demonstrated that the hydrophobic characteristic of hop oils leads to their accumulation on hydrophobic−hydrophilic interfaces. This would result in nonstable nuclei by making gaps between the molecules of gushing promoting surfactants, therefore reducing the gushing tendency.[15]

Hydrophobins are not the only molecules with gushing ability. In a study by Christian et al.[19] on the gushing provoking tendency of hydrocarbons, they found a relation between structure (either carbon chain length or degree of saturation/unsaturation) and gushing potential of fatty acids. By increasing the carbon length of fatty acids from C_{10} to C_{16}, overfoaming increased, due to the fact that a specific hydrophobic interaction is needed to initiate gushing. Unsaturated fatty acids were not gushing inducers and even suppressed gushing by saturated molecules.

In order to characterize class II hydrophobins, the interaction of these molecules with solid surfaces was studied. Several works reported on the immobilization of hydrophobins on hydrophobic surfaces such as polytetrafluoroethylene (PTFE), poly(lactide-*co*-glycolide) (PLGA), graphite, and silicon surfaces.[20−25] The interaction of hydrophobins with hydrophilic surfaces (glass) was investigated by Qin et al.[26,27] Simulation studies showed that hydrophobins interact with silicon and graphite surfaces through their hydrophobic patch.[24,25] The hydrophobic patch of class II hydrophobin HFBI includes 13 amino acids. Using molecular dynamics simulations mentioned six aliphatic residues of HFBI interacting with the graphite surface including three leucines (Leu12, Leu26, and Leu68), one isoleucine (Ile27), one alanine (Ala66), and one valine (Val62).[24]

Despite the experimental research efforts carried out with a view to prevent gushing, the mechanisms behind gushing inhibitors are not completely understood. This work aims to shed light on this topic by studying the interactions between hydrophobins and nonpolar model substances with differing nature, length, and degree of saturation and how these interactions may influence the inhibition of gushing. To this end, we have used robust characterization techniques. To the best of our knowledge, no systematic studies on the interaction of hydrophobins with nonpolar substances have been published yet.

2. MATERIALS AND METHODS

2.1. Extraction and Purification of Hydrophobins. Hydrophobin HFBI from *Trichoderma reesei* MUCL 44908 was extracted from the mycelium and purified using the method reported by Deckers et al.[6] The molecular mass of purified protein was estimated by means of matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (with an Ultraflex II instrument in linear mode and α-cyano-4-hydroxy cinnamic acid matrix (Brüker Daltonics GmbH)). Fractions containing 7.5 kDa molecular weight peptides were proved to be HFBI by N-terminal amino acid sequence by automated Edman degradation on a capillary protein sequencer (Procise 491cLC, Applied Biosystems). HFBI solutions were dried by lyophilizing and dissolved in distilled water or pure ethanol. The concentration of HFBI was measured with NanoDrop ND-1000 spectrophotometer (Nanodrop Technologies, Wilmington, DE, USA).

2.2. Gushing Measurement. The gushing potential was evaluated for nonpolar model substances such as alkanes, alkenes, and fatty acids and for class II hydrophobin HFBI. In this study, saturated hydrocarbons C_nH_{2n+2} with n ranging from 6 to 28, unsaturated hydrocarbons 1-C_nH_{2n} with n ranging from 7 to 20, and fatty acids were evaluated regarding their effect on gushing. Gushing amounts of sparkling water caused by all these substances were determined according to the modified Carlsberg test (MCT).[28] To ensure comparable results on the gushing potential of hydrocarbons, an identical number of the molecules (5×10^{-5} M) was used. Solid alkanes were dissolved in 1 mL of hot ethanol (purity: 99.9%, temperature: 60 °C) prior to gushing analysis. All gushing experiments were carried out at least five times. Statistical analysis of the data was carried out by IBM SPSS Statistics 22. The normality distribution test and difference of variances were analyzed and used to discuss the gushing results.

2.3. Optical Microscopy. Microscopy analysis was carried out for hydrophobin HFBI, for two model non-polar systems, oleic acid and *n*-hexadecane, and for mixtures of the protein with each of the two nonpolar molecules. Freeze-dried HFBI obtained by RP-HPLC was dissolved to a concentration of 0.15 mg/mL in 1 mL of ethanol. Afterward, the protein sample (20 μL) was spread on a clean microscopic glass slide and dried overnight at room temperature in a closed environment to avoid contamination with small dust particles. Oleic acid (20 μL) and *n*-hexadecane (20 μL) samples were prepared following the same procedure and spread over the microscope slides. The mixtures of HFBI (0.15 mg/mL) with *n*-hexadecane (3.5 μL) and with oleic acid (5 μL) were prepared in a glass tube containing ethanol and mixed for 1 h prior to exposure and drying on a glass slide. Measurements were carried out on an optical microscope (Leica DM LP Leica Microsystems Wetzlar GmbH) using transmitted, reflected, and polarized light (90°).

2.4. Attenuated Total Reflection Fourier Transform Infrared Spectroscopy (ATR/FTIR spectrometry). Attenuated total reflection Fourier transform infrared spectroscopy (ATR/FTIR) is a label-free, nondestructive spectroscopic technique with large analytical potential to study protein crystallization studies, surface properties on protein behavior, and protein structure and function.[29] The principle behind ATR/FTIR consists of directing infrared light (an infrared beam) at an interface between the sample and a ATR crystal, an IR transparent material with a high refractive index. The angle of incidence of the beam is greater than the critical angle, and so total internal reflection takes place. At the surface, a standing wave of light radiation is formed, called the evanescent way, attenuating the exiting IR beam leaving the crystal. The penetration depth of the evanescent wave depends on its IR wavelength and angle of incidence and the refractive indices of ATR crystal and the sample. In this work, we used ATR-FTIR to explore the type of intermolecular interactions present when HFBI interacts with nonpolar model systems.

ATR/FTIR spectroscopy was performed for HFBI, oleic acid, and for the mixture of both compounds. Freeze-dried purified HFBI from RP-HPLC was dissolved to a concentration of 4 mg/mL in ethanol, while the mixture of HFBI with oleic acid (1 mL ethanol containing 0.15 mg/mL HFBI and 5 μL oleic acid) was prepared and stirred for 5 min prior to each measurement. For the current measurements, a Tensor 27 FT-IR spectrometer (Bruker Optik GmbH, 2006) equipped with a mid-infrared source (MIR) (2.5−25 μm) and a mercury−telluride detector (MCT) were used. This system was operated with OPUS (Bruker Optik GmbH) software (version 6.5). The ATR accessory was a three reflection ZnSe/Diamond μATR (6 mm in

diameter) with refractive indices of 2.4 and a path length of 13.08 μm. One-hundred coadded scans were taken at a resolution of 4 cm^{-1} (data points were collected every 2 cm^{-1} due to the software interpolation). For each measurement, 50 μL of the sample under study was placed over the crystal. The ATR accessory was carefully cleaned between measurements using distilled water and dried with a soft nonabrasive tissue. Each sample was measured at least five times at room temperature (22 ± 1 °C).

2.5. Quartz Crystal Microbalance with Dissipative Monitoring Measurements (QCM-D). Quartz crystal microbalance with dissipation monitoring (QCM-D) is an acoustic surface-sensitive technique that provides information on the mass and the viscoelastic properties of adsorbed layers by measuring the changes of resonance frequency Δf and dissipation ΔD.[30−32] QCM-D was used for monitoring in real-time the frequency and dissipation changes, Δf and ΔD, upon binding of n-hexadecane onto a HFBI monolayer. Gold-coated quartz sensors were first ultrasonicated for 15 min in Milli-Q water, cleaned with 98% iso-propanol solution at 70 °C for 15 min, UV-ozone treated with a Digital PSD series UV-ozone system from Novascan for 5 min, and then rinsed with Milli-Q water and dried with N_2 prior to placement in the QCM-D measurement modules. All measurements were performed in a Q-sense E4 instrument (Biolin Scientific, Sweden) with a flow rate of 50 μL/min at 20 °C. After a baseline in water was established, protein solutions with a concentration of 0.15 mg/mL in water were added. After a protein monolayer was formed, n-hexadecane (pure) was introduced at the same flow rate. All the changes were monitored at different overtones (from third to seventh).

2.6. Fiber Optic Surface Plasmon Resonance (FO-SPR). FO-SPR was used, together with QCM-D, to monitor the interactions and binding between HFBI and n-hexadecane. The FO-SPR sensor platform consists of a tungsten halogen light source (HL-2000, Ocean optics, USA), an UV−vis spectrophotometer (USB4000, Ocean Optics, USA), an interchangeable FO-SPR probe inserted in a SMA (SubMiniature version A) connector (Avantes, USA) and mounted in a bifurcated optical fiber (FO) (Ocean optics, USA), a modified T1 thermocycler (Biometra, Germany) to accurately control the rack temperature containing the samples in the PCR tubes (200 μL, Eppendorf, Belgium), and an automated computer-controlled robotic arm programmed using the ColiDrive software (Colinbus, Belgium). The white light is guided from the tungsten halogen lamp through the bifurcated FO toward the sensor's SPR sensitive gold area and afterward is reflected back to the UV−vis spectrophotometer. Depending on the refractive index of the medium in which the fiber is submerged, the spectral resonance SPR-dip occurs at a certain wavelength. Any binding event at the gold surface will trigger a shift in the signal response. The SPR wavelength shifts are plotted as a function of time and allow the monitoring of molecular interaction

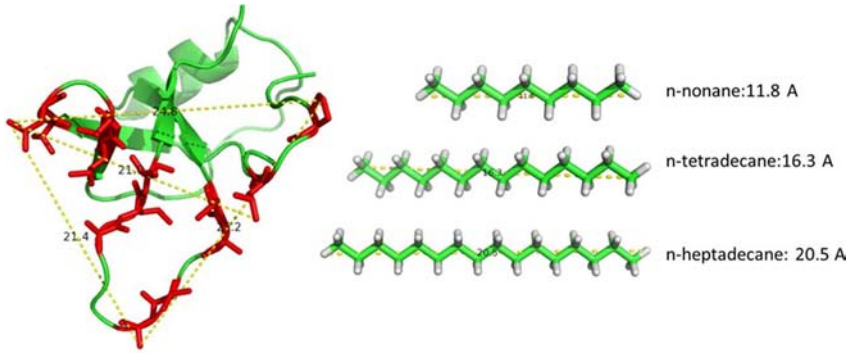

Figure 1. Comparing the length of hydrophobic patch of hydrophobin HFBI (21.4 Å × 25.2 Å × 21.0 Å × 24.8 Å) with *n*-nonane (11.8 Å; decreases gushing by HFBI) and *n*-tetradecane (16.3 Å) and *n*-heptadecane (20.5 Å; suppress gushing by HFBI completely).

phenomena in real time. A detailed description of the FO-SPR setup is given in refs 33 and 34. The interchangeable FO-SPR sensors were manufactured by cutting a 400 μm diameter TEQS multimode fiber (Thorlabs, Germany) to a length of 3.6 cm. A SPR-sensitive zone of 0.6 cm was constructed at one side of the fiber tip by removing the jacket and the polymer cladding in acetone. The fibers were then cleaned in a 30:70 (v/v) solution of hydrogen peroxide and concentrated sulfuric acid (99.8%), subsequently rinsed in distilled water and methanol, and finally dried with nitrogen gas. Next, the fibers were coated with a 50 nm gold layer using a magnetron sputtering device (Quorum Q150T ES, UK) as described in ref 35. The existing interactions between HFBI and *n*-hexadecane are relatively difficult to investigate, due to the typically small molecular structure of the alkane (0.3 kDa) compared to the protein (7.5 kDa). In this context, two approaches were tested in order to assess the weak responses between the two molecules. In the first protocol, the freshly prepared sensors were first dipped in a solution of HFBI (0.15 mg/mL in ethanol) for 10 min and then immersed in pure and diluted (3.5 μL/mL in ethanol) *n*-hexadecane for 20 min, respectively. In the second protocol, the FO-SPR probes were incubated overnight in pure *n*-hexadecane at room temperature and used the next day to detect HFBI (10 min). The experiments were repeated five times for each protocol.

2.7. Particle Size Analysis. Particle size distribution was studied for mixtures of HFBI (4 mg/mL) with a gushing inhibitor, *n*-hexadecane (3.5 μL/mL) in ethanol, and with a noninhibitor, *n*-docosane (5 mg/mL) in hot ethanol (60 °C). In the case of *n*-docosane, hot ethanol was used to dissolve this material completely, and the temperature remained 60 °C during the measurement. The reason for selecting these molecules was to see how a gushing inducer and a nongushing inducer molecule can affect overfoaming of the hydrophobin. Measurements were carried out by a Microtrac Nanotrac Ultra instrument (Particle Metrix GmbH, Meerbusch, Germany) which measures diameters between 0.8 to 6500 nm. Statistical analysis of the data was carried out by IBM SPSS Statistics 22. The normality distribution test and difference of variances were analyzed and used to discuss the results. Descriptive analysis was carried out using an independent samples *t* test for normally distributed data and one way ANOVA for not normally distributed data.

3. RESULTS AND DISCUSSION

3.1. Gushing Reference Measurements. The statistical analysis was carried out by normalizing the obtained data for all systems using the Shapiro−Wilk method. All data displayed normal distributions, thus the independent samples *t* test method was carried out for calculating the variance differences. The gushing potential of the saturated and unsaturated linear hydrocarbons and fatty acids as well as their effect on the gushing amount of sparkling water by hydrophobin HFBI is shown in Table 1. As can be observed, unsaturated hydrocarbons do not induce gushing irrespective of their chain length, while saturated hydrocarbons with $n > 18$ are gushing inducers with increasing gushing potential upon increasing alkyl chain length. As for saturated fatty acids, those with $n > 16$ induce gushing, whereas neither unsaturated oleic acid nor linolenic acid induced gushing. When mixed with HFBI, all analyzed alkanes and alkenes significantly decreased gushing. In turn, mixtures with fatty acids exhibited diverse behavior. Decanoic acid was the only one not to change the gushing by HFBI ($t = 1.209$, $d_f = 8$, $P > 0.05$), while octanoic acid slightly decreased gushing as compared with HFBI. Palmitic and behenic acids significantly increased gushing by HFBI, while oleic and linolenic acids completely inhibited gushing (see Table 1).

The above-exposed results indicate that the carbon chain length and the degree of saturation affect significantly the gushing and gushing inhibition potential of pure substances and of mixtures with hydrophobins, respectively. For pure nonpolar molecules, a critical carbon chain length is required to promote a hydrophobic interaction with CO_2 molecules in order to form the nanostructures needed for gushing: the longer the carbon chain, the stronger the interaction and thus the gushing amount is larger. Shorter carbon chains cannot provide a stable nucleus for CO_2 bubbles and gushing does not occur. In turn, the introduction of double bounds as in the case of oleic and linoleic acids inhibits and weakens the interactions with CO_2 preventing gushing. *Cis* forms of unsaturated bonds are nonlinear, in contrast to *trans* forms and cannot form suitable assemblies. Therefore, *cis*-forms of unsaturated bonds in either fatty acids or alkenes are not gushing inducers. Apart from the configuration of the chains, alkenes with the double bonds between the first and second carbon were tested to investigate whether being unsaturated, regardless of *cis* or *trans* forms, has an influence on the gushing ability. Indeed, comparing *n*-$C_{20}H_{42}$ with 1-$C_{20}H_{40}$ shows that unsaturation is the cause of loss of the gushing potential irrespective of the *cis*/*trans* form.

As regards mixtures with hydrophobin HFBI, both linear saturated and unsaturated hydrocarbons containing 10 to 17 carbons (saturated) and 10 to 16 carbons (unsaturated) were strong gushing suppressors. Among the fatty acids, only oleic and linolenic acids inhibit gushing. These results can be rationalized as follows. The hydrophobic patch of hydrophobins is responsible for the formation of nanobubbles during gushing: the size of this patch turns out to be very similar to the dimensions of the nonpolar molecules that act as gushing inhibitors, as shown in Figure 1. It seems that the similar lengths of hydrocarbon chains are able to interact perfectly with

DOI: 10.1021/acs.jafc.5b01170
J. Agric. Food Chem. 2015, 63, 4673−4682

the hydrophobic patch of hydrophobins and inhibit their further interaction with CO_2. Therefore, gushing is thoroughly inhibited.

3.2. Optical Microscopy of HFBI and Oleic Acid Mixtures. The microscopy images with reflected light of hydrophobin, oleic acid, and their mixture are shown in Figure 2. Though not shown, the results of mixtures of HFBI with *n*-hexadecane are analogous to those with oleic acid. Neither oleic acid nor the mixture of this fatty acid with HFBI induced gushing. The microscopy analysis shows the large changes of HFBI in the presence of gushing suppressive molecules. The crystal structures formed by HFBI molecules disappear when oleic acid is present. These changes may be attributed to the chemical interaction of hydrophobins with the nonpolar molecules that cover the hydrophobic patch of these proteins. Additional experimental techniques used in order to understand the mechanisms behind the observed structural changes will be described in the following.

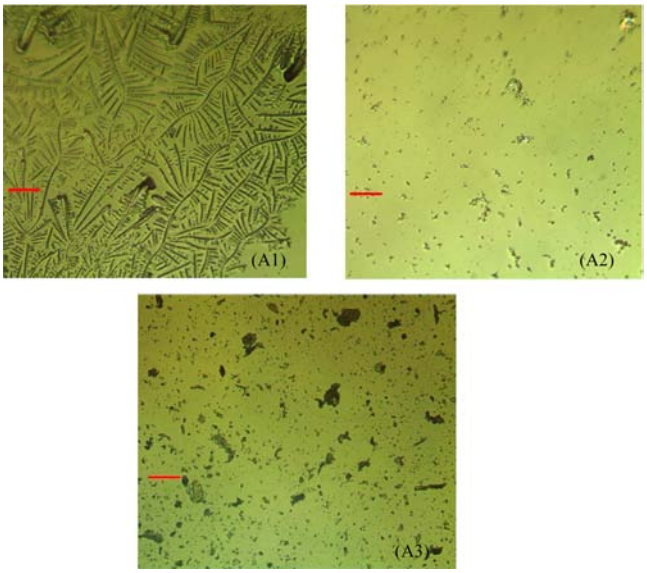

Figure 2. Microscopic image of (A1) crystals formed by HFBI (0.15 mg/mL) in ethanol, (A2) oleic acid (5 μL/mL) in ethanol, and (A3) a mixture of HFBI with oleic acid. All samples were dried on a glass slide at room temperature in an isolated environment. All images are taken by reflected light, and the red scale bars indicate 20 μm. The same preparations for all samples were carried out.

3.3. ATR/FTIR Spectrometry of HFBI and Oleic Acid Mixtures. Figure 3a shows the absorbance spectra for HFBI, oleic acid, and their mixture measured with the μATR (ZnSe/Diamond) crystal. The spectral group frequencies provided in this text were obtained from a practical source written by Coates.[36] In the spectral region between 1900 and 2300 cm^{-1}, there are no absorbance peaks, except of diamond (2300−1900 cm^{-1}), and therefore, this region is shown as a break in the wavenumber axis. In the case of any new covalent bonding, a new spectrum will appear in the MIR absorbance spectra, and it can be identified by referring to the IR range of electromagnetic spectra which have already been published, see for instance ref 36. The spectrum of the mixture of HFBI with oleic acid significantly resembles the spectrum of the individual compounds, indicating that no new covalent bonds are formed by mixing fatty acid with HFBI. Oleic acid exhibits extremely strong hydrogen bonding through its carboxylic group; we focused on detecting hydrogen bonds built. Considering the structure of HFBI, hydrogen bonding is possible between the carboxylic group of oleic acid and the N−H groups in the hydrophobic patch of HFBI, some of which are shown in Figure 3b. An important characteristic of hydrogen bonds is the shifting of peaks to lower frequencies,[37] since they can form a stable dimeric structure. Apart from that, hydrogen bonding produces significant band broadening. However, in these experiments none of these changes are detected.

3.4. Adsorption of HFBI and Alkanes to Gold Crystals Using QCM-D. The frequency and dissipation shifts, Δf and ΔD, upon adsorption and formation of a HFBI monolayer and subsequent binding of *n*-hexadecane are shown in Figure 4. Δf is related to the adsorbed mass of the film, and ΔD accounts for the dissipated energy reflecting the viscoelastic properties of the layer. The rinsing of hydrophobins results in a small increased frequency which is removed to avoid complexity in the graph. Upon adsorption of the protein, Δf decreases rapidly and ΔD slightly increases, indicating the fast physical adsorption and slower formation of a protein layer onto the QCM-D sensors. The small gap in the graph is due to washing off the weakly bound hydrophobins from the gold surface using distilled water. The obtained responses in $\Delta f \sim -25$ Hz and $\Delta D \sim 3 \times 10^{-6}$ reveal the formation of a thin and rigid hydrophobin layer, in agreement with previous experimental works.[38] After a baseline was reached indicating the formation of a stable protein layer, pure *n*-hexadecane was added. The interaction of *n*-hexadecane with the protein layer is reflected by a slight decrease in $\Delta f \sim -4$ Hz and somewhat larger increase in $\Delta D \sim 5 \times 10^{-6}$. These responses can be translated into non-polar molecule mass adsorption onto the protein layer by virtue of the direct relation between frequency shift Δf and mass change Δm introduced by Sauerbrey.[30] This reflects that *n*-hexadecane is immobilized on the gold surface covered with HFBI.

3.5. Adsorption of HFBI and Alkanes to Gold Coated FO-SPR Sensors. The obtained results with the wavelength values at which the SPR-dip occurs plotted as a function of time are represented in Figure 5, where binding events are reflected in a shift of the wavelength. In a first approach, the FO-SPR probes were immersed in HFBI for 10 min and afterward dipped in pure and diluted (3.5 μL/mL in ethanol) *n*-hexadecane, respectively (see Figure 5A). The attachment of HFBI onto the gold-coated fiber surface resulted in an average shift of 1 ± 0.5 nm. Since hydrophobins have both hydrophilic and hydrophobic patches, they are physically adsorbed onto the gold coated fiber surface (positively charged) through their negatively charged area located in the hydrophilic patch (see green part in Figure 1) as reported by Zampieri et al.[39] Afterward, the FO-SPR probes were immersed in pure and diluted *n*-hexadecane, respectively, for 20 min. Alkanes most likely bind to the hydrophobic patch of HFBI, since this hydrophobin interacts with hydrophobic surfaces via its hydrophobic patch. In both cases, the interaction of HFBI with *n*-hexadecane was not detectable. The results showed that when *n*-hexadecane was diluted in ethanol, attached hydrophobins started to be rinsed from the fiber surface (Figure 5A, red curve). Therefore, a second approach was evaluated. An alkane self-assembling monolayer (SAM) was created by incubating the FO-SPR probes overnight in a pure *n*-hexadecane solution. Next, the SAM functionalized FOs and the normal FOs were immersed in HFBI for 10 min (see Figure 5B). As can be observed in the sensogram in Figure 5B, the binding of HFBI onto the alkane-SAM functionalized FO was

twice the size (2.5 ± 0.5 nm) compared to the first approach. These results are in agreement with the ones obtained from QCM-D, showing that there is an effective interaction between alkanes and hydrophobins.

3.6. Particle Size Distribution. Particle size distributions were measured in order to obtain stronger evidence of the interaction of hydrophobin HFBI with gushing suppressive molecules. This method was used not only to compare the particle sizes of individual compounds but also to analyze the changes of particle sizes during the time.

The particle size distribution of HFBI, nonpolar molecules (*n*-hexadecane and *n*-docosane), and their mixtures were all evaluated in ethanol, and the results are presented in Figure 6. As a first step, the particle sizes of pure *n*-hexadecane and *n*-docosane were measured, and afterward, these nonpolar molecules were mixed separately with HFBI, and the particle size distributions were compared with the individual molecules. The results are shown in Figure 6a and b, respectively. In the ethanol solution of HFBI, particles of HFBI with a similar size to that of the monomeric form of HFBI (1−2 nm) are observed (graphs blue, Figure 6a and b), while after mixing

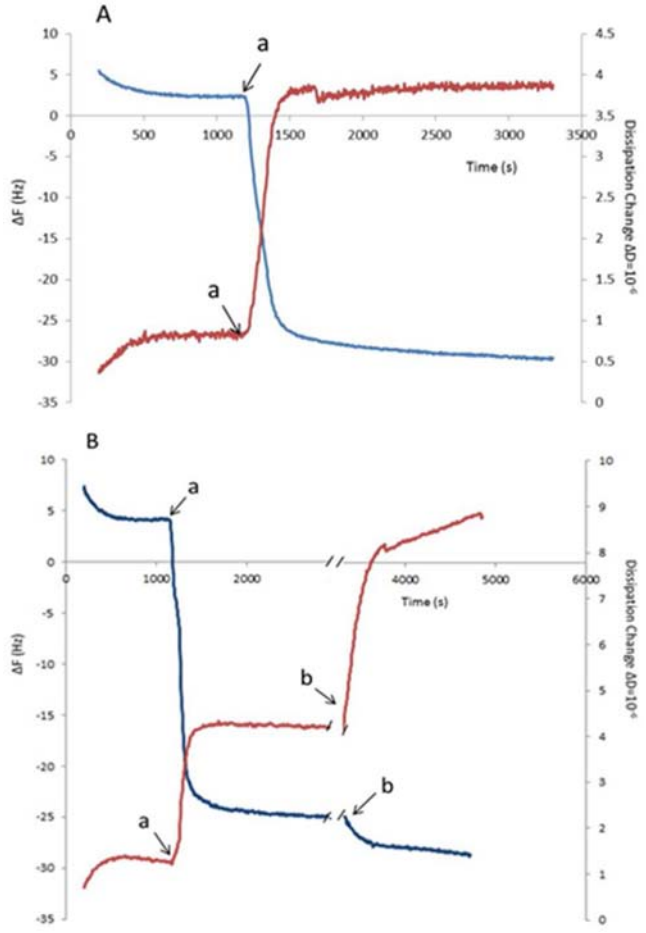

Figure 4. QCM-D data of (A) adsorption of HFBI to the bare gold crystal and (B) adsorption of *n*-hexadecane to gold crystal covered with HFBI. The break in graph B is due to rinsing of weakly bounded HFBI to the gold surface with distilled water. Frequency changes are shown in blue, and dissipation changes are in red. In both graphs, part a corresponds to HFBI injection, and part b in graph B resembles *n*-hexadecane (pure) injection. The experiment was repeated five times.

with nonpolar molecules they are such small sizes that they are no longer detected (graphs yellow, Figure 6a and b). This indicates that by mixing HFBI proteins with nonpolar molecules, these molecules attach to HFBI monomers and form larger particles. Therefore, the 1−2 nm monomers are not observed in the mixture. These large particles had a diameter of 1 μm for the mixture of HFBI with *n*-hexadecane (graph yellow, Figure 6a) and 0.9 μm with *n*-docosane (graph yellow, Figure 6b). The large values of standard deviation STDV in both graphs (Figure 6a and b) can be explained by the quick formation of big particles during the time of the experiment.

The results were validated by analyzing the changes of particle sizes after mixing HFBI with nonpolar molecules during the time and are shown in Figure 6c,d,e. The particle size distribution of HFBI was compared during the time to figure out if the molecules of this protein tend to self-assemble. The results are illustrated in Figure 6c, and multimerization of HFBI molecules is clearly observed after 4, 6, and 8 min of measurement. Afterward, the evaluation of particle sizes in the mixture of HFBI and nonpolar molecules was carried out during the time. As illustrated in Figure 6d, the formation of bigger particles in the mixture of HFBI with *n*-hexadecane was clearly observed among 1, 8, and 9 min after mixing. After mixing HFBI with *n*-docosane, the formation of larger particles was evident among 3, 4, and 5 min after mixing (Figure 6e).

Statistical analysis was carried out for the normal distribution test of data. The variance analyses for particle sizes with normal distribution was carried out with the independent samples *t* test method, and for the data with non-normal distribution, one-way ANOVA was used. The descriptive data analysis is shown in the Supporting Information. In order to reduce the number of data in the table, only the particles with significant differences are shown.

Four different statistical analyses carried out with a view to show whether the particle size distributions of HFBI with nonpolar molecules is significantly different from the individual molecules. The results from this analysis are shown as A, B, C, and D in the Supporting Information. The A and B statistical analyses evaluate whether the particles of HFBI and *n*-hexadecane are significantly different from the particles in their mixture, respectively. The C and D statistical analysis are analogous to A and B but with *n*-docosane. These data clearly show that there are significant differences between the particle sizes when HFBI was mixed with *n*-hexadecane and *n*-docosane. This aggregation is probably due to the presence of a hydrophobic patch at the surface of HFBI which attracts nonpolar molecules.

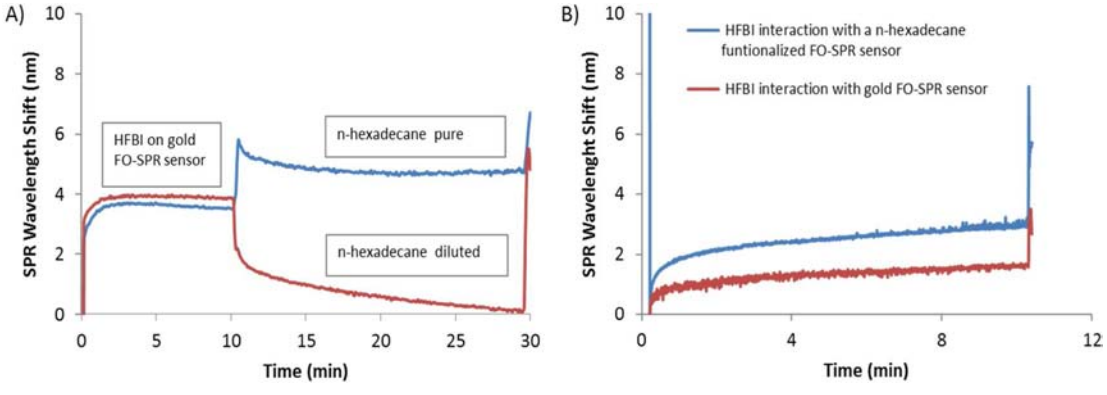

Figure 5. Interaction of HFBI with *n*-hexadecane. (A) FO-SPR sensorgram representing the immobilization of HFBI (0.15 mg/mL in ethanol, 10 min) on the FO-SPR sensor surface and the subsequent immersion of the fires in pure (blue) and diluted (red, 3.5 μL/mL in ethanol) *n*-hexadecane, respectively, for 20 min. (B) FO-SPR sensorgram representing the physical absorption of HFBI (0.15 mg/mL in ethanol, 10 min) on a FO-SPR probe (red) and on a FO-SPR probe functionalized overnight in pure *n*-hexadecane (blue). Number of repeats for these experiments was 5.

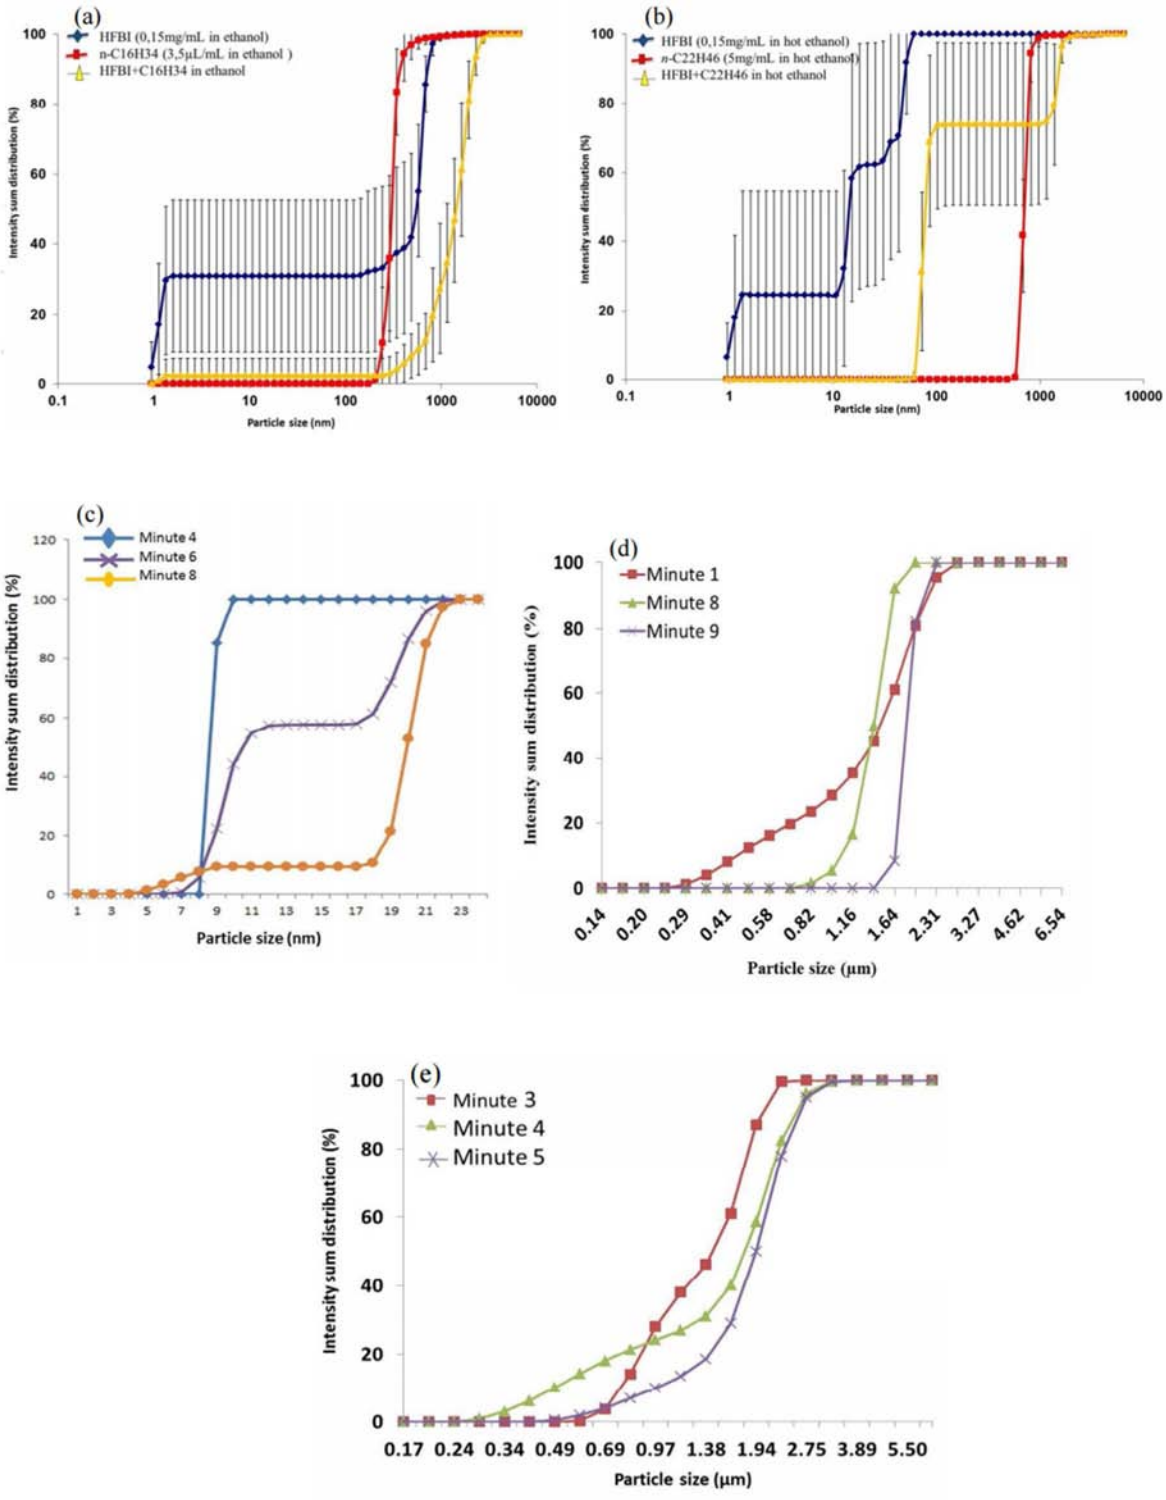

Figure 6. Particle size distribution of (a) hydrophobin HFBI (blue graph), *n*-hexadecane (red graph), and the mixture of HFBI and *n*-hexadecane (yellow graph). (b) Hydrophobin HFBI (blue graph), *n*-docosane (red graph), and the mixture of HFBI and *n*-docosane (yellow graph). Comparison of the particle size distribution over time for (c) hydrophobin HFBI, (d) the mixture of HFBI and *n*-hexadecane in ethanol, and (e) the mixture of HFBI and *n*-docosane in hot ethanol. All results are obtained from 10 runs, five repeats. The standard deviation bars are indicated in all graphs.

In summary, gushing ability reference measurements have provided valuable information on the gushing ability or inhibition of hydrophobin HFBI, nonpolar model systems, and mixtures of them. These measurements show that for pure non-polar molecules, the gushing ability depends strongly of the carbon chain length and the degree of saturation. The longer the carbon chain, the larger the gushing amount. Unsaturation in turn inhibits and weakens the interactions with CO_2 irrespective of the *cis/trans* form. These results are in agreement with the ones reported by Christian et al.[40] As for

DOI: 10.1021/acs.jafc.5b01170
J. Agric. Food Chem. 2015, 63, 4673−4682

mixtures of HFBI with non-polar molecules, the combination acts as the assembly acts as a less gushing or no gushing system. This effect takes place within a specific range of carbon chain length range (C = 10 to 17) and can be explained in the framework of a competition effect between non-polar systems and CO_2 to interact with the hydrophobic patch of the hydrophobin. Interactions of these molecules with hydrophobins are promoted as a result of the similar size of the nonpolar molecules with the hydrophobic patch of the protein, at the expense of the formation of nanobubbles with CO_2. Shorter carbon chain lengths than the above-mentioned range do not form a strong hydrophobic interaction with these patches, and therefore gushing is only decreased. Longer hydrocarbon lengths interact with CO_2 molecules and induce gushing themselves. Thus, their effect on the gushing by HFBI is not detectable.

Complementary measurements of mixtures with HFBI and model non-polar systems by a complete set of characterization techniques support the above statements. Optical microscopy shows dramatic structural changes of HFBI in the presence of oleic acid, while ATR/FTIR results do not indicate the presence of either covalent or hydrogen bonds between HFBI and this system. In turn, both QCM-D and SPR show that there is an effective interaction between *n*-hexadecane and hydrophobins, judging from the increase in the frequency (mass) and wavelength shift responses, respectively. To our knowledge, this is the first study where both QCM-D and SPR are used to monitor hydrophobins and nonpolar molecules interactions. Particle size analysis reveals that particles of HFBI and nonpolar molecules aggregate and form larger particles. On the basis of the obtained results, we believe that the hydrophobic patch in HFBI, which is responsible for the interaction of HFBI with CO_2 molecules, is capped by the interaction of HFBI molecules with nonpolar molecules. Thus, the stable nanobubbles which typically arise by HFBI and CO_2 interactions are not formed, and gushing does not occur. The information provided in this work will be useful both from a fundamental and an applied point of view, helping the understading of the molecular characteristics involved in gushing prevention and application of this knowledge in food beverage companies in general and breweries in particular to provide alternative preventive and curative solutions for overfoaming.

ABSTRACT: This work evaluates the impact of heat processing of parvalbumin, a major fish allergen, on the consequences for quantitative analysis of this protein embedded in different matrices during heating (either isolated, in an aqueous extract, or in whole fillets) to assess potential health risks. It is shown that oligomerization of parvalbumin does occur, but only upon heat treatment above 80 °C. This coincides with the ability of the isolated protein to refold up to this temperature in a fully reversible way, as demonstrated by circular dichroism analysis. In autoclaved samples a disintegration of the protein structure is observed. The situation becomes different when parvalbumin is embedded in a matrix with other constituents, as in fish extracts or whole fillets. The electrophoretic analysis of parvalbumin (SDS-PAGE and immunoblotting) is largely determined by complexation with other proteins resulting in insoluble materials caused by the partial unfolding of the parvalbumin at elevated temperatures. This effect is more strongly observed for cod fish extract, compared to whole cod fillets, as in the latter situation the integrity of the tissue hampers this interprotein complexation. Moreover, it is shown by ELISA analysis of heat-treated samples that using blotting procedures where disintegration of complexes may be promoted, restoring some of the IgG-binding propensity, may provide false outcomes. It was concluded that antibody binding to parvalbumin is dominated by the potential to form heat-induced complexes with other proteins. The possibly less-soluble or extractable character of these complexes may provide confusing information regarding potential health risks of fish and fish protein-containing food composites when such heat-treated samples are analyzed by immunochemical assays.

KEYWORDS: *parvalbumin, Western blot, heat processing, allergen, protein structure*

INTRODUCTION

Fish plays an important role in human nutrition as a source for proteins, polyunsaturated fatty acids, vitamins A and D, and iron and calcium.[1] However, fish is also one of the most frequent causes of food allergy.[2] The rising consumption of fish contributes to the prevalence of fish allergy. Fish-allergic individuals are counselled to follow a strict fish-avoidance diet to prevent reactions. The increasing availability of fish-derived ingredients, including as a powdered constituent in complex food products, raises concerns for fish-allergic consumers. Prevalence rates of fish allergy range from 0.2 to 2.3% of the population, reaching up to 8% among fish-processing workers.[1−3] Individuals allergic to ingestion or inhalation of or even skin contact with fish proteins subjected to cooking or other processing may exhibit IgE-mediated type I responses including symptoms such as urticaria, dermatitis, angioedema, diarrhea, asthma, or anaphylactic reactions.[3]

Parvalbumin (PV) is considered to be a pan-allergen for fish-allergic patients. Parvalbumins from many different fish species commonly consumed in western Europe share similar biochemical and immunochemical characteristics[4,5] and are reported to cross-react with each other and with parvalbumins in frog meat[6] or in tropical fish species consumed in Asian−Pacific countries.[7] Recently it was shown that parvalbumin cross-reactivity is related to the molecular origin of this major allergen.[8]

Parvalbumins are proteins conserved in lower vertebrates and are abundant in white muscle. Parvalbumins are found in fast-twitch skeletal muscles of higher vertebrates, as well as in a variety of nonmuscle tissues, including testes, endocrine glands, skin, and specific neurons,[9] and are involved in muscle contraction, calcium buffering, and signal transduction between cellular compartments.[10−13] For cod it is estimated that 0.15−0.63% of fish muscle tissue (wet weight) consists of parvalbumin.[14] They are typically 10−12 kDa, acidic (pI = 4.0−5.2), and structurally characterized by the presence of three typical helix−loop−helix domains, of which two are capable of binding divalent cations, such as Ca^{+}. The third domain forms a cap that covers the hydrophobic surface of the pair of functional domains.[15,16] On the basis of the amino acid sequences, two distinct phylogenetic lineages of parvalbumins, named α and β, have been identified.[17] The β lineage is reported to be especially allergenic,[3] and its IgE binding has been shown to be strongly calcium-dependent.[18]

Heat treatment is an important food preparation and preservation procedure. It is required to ensure microbial safety or to obtain desirable organoleptic attributes, improving the appearance, texture, flavor, and taste of products.[16]

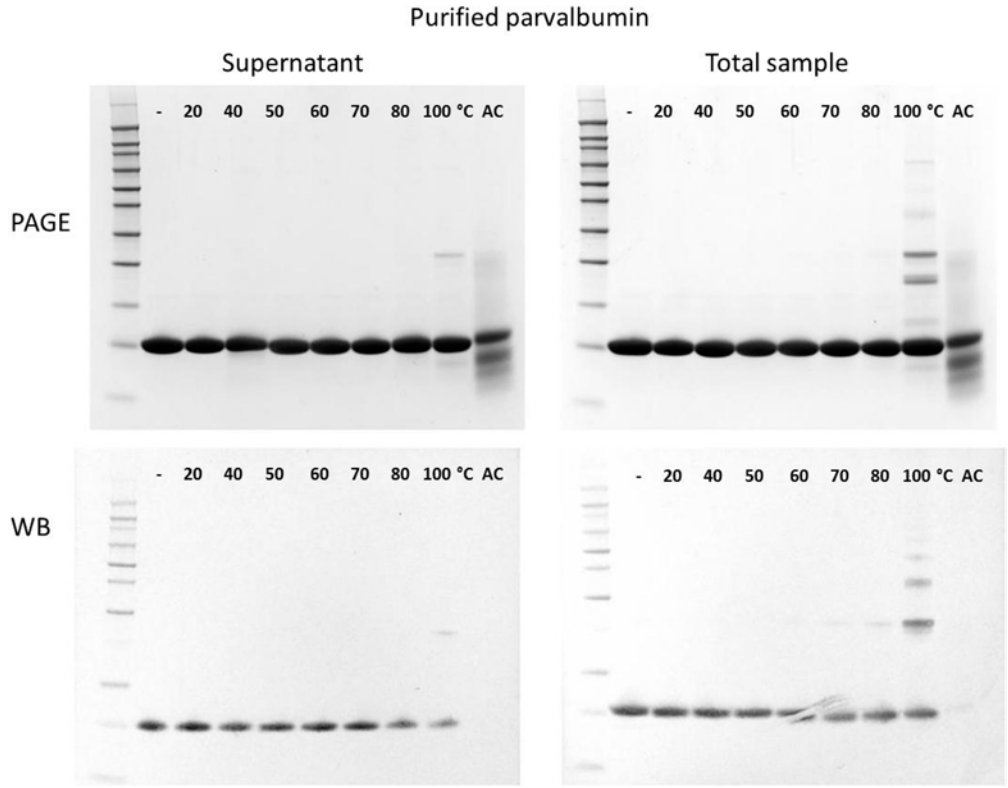

Figure 1. Heating of purified cod parvalbumin: (top panels) SDS-PAGE analysis with protein stain; (bottom panels) immunoblotting with anti-parvalbumin antiserum; (left panels) supernatant; (right panels) total sample. In all lanes 10 μg of total protein was applied. The incubation temperatures (2 h) are indicated.

Parvalbumins are renowned for their strong resistance against heat treatment, associated with the high reversibility in their denaturation in the presence of calcium[19] and other denaturing conditions.[20] The heat stability of parvalbumin provides a major source of risk for fish-allergic consumers.[21] It was recently reported that heat treatment of cod parvalbumin at high temperatures alters the structure of the protein, losing partially its secondary structure and initiating aggregation[22] and thereby affecting antibody reactivity.[8] The thermal stability of parvalbumins is different among isotypes, as has been studied in carp[23] and red stingray,[24] where some isoforms formed aggregates during heat processing.

Allergenicity is described by two key parameters: the potency to sensitize an (atopic) individual and the IgE binding essential to elicit an allergic reaction once an individual is sensitized. Therefore, fish processing may affect structural epitopes responsible for IgE binding to parvalbumin.[25] Boiling and cooking of fish can also lead to the formation of molecular aggregates and thereby enhancement of IgE reactivity as shown for tuna, salmon, cod, flounder, and whiff,[26,27] despite the observation that the allergenicity to certain proteins in tuna and salmon was reduced by heat processing.[28,29] Also, other IgE-binding proteins have been identified in Baltic[30,19] and Atlantic cod.[31,32] Some of these proteins were also recognized by monoclonal parvalbumin antibodies,[19,30−32] associated with dimers or oligomers.[31] It has been suggested that IgE binding to multimers is stronger than to monomeric parvalbumin.[33] The occurrence of monomeric and oligomeric parvalbumin has also been demonstrated in different fish extracts.[8] A direct link between their presence and their IgE-binding potential has not been reported.

The aim of this work is to evaluate the impact of heat processing of PV on structural motifs in relation to the matrix in which PV is embedded (isolated, in an aqueous extract, or in whole fillets). In particular, the heat-induced effects on the PV aggregation state were evaluated by electrophoresis and immunoblotting. Circular dichroism analysis was applied to assess the reversibility of structural motifs in the proteins.

MATERIALS AND METHODS

Materials. Atlantic cod (*Gadus morhua*) was purchased as frozen fillets produced by Albert Heijn (Zaandam, The Netherlands). The fillets were stored at −20 °C until further use. Three types of parvalbumin batches were prepared: sliced pieces of cod fillet, cod fillet protein extract, and purified parvalbumin.

Cod fillet samples were prepared as ∼5 g pieces. Cod fillet protein extracts were from defrosted 20 g portions of cod muscle as described elsewhere.[34] The thawed fillet was homogenized in 60 mL of deionized water and 6.4 mL of 1 M Tris-HCl (pH 9) using an Ultra Turrax blender (IKA, Staufen, Germany). Thereafter the pH was maintained around pH 8 using 1 M NaOH. The slurry was stirred for 2 h on ice and then centrifuged for 30 min at 1800*g* at 4 °C. The supernatant was collected and stored in the freezer. Purified parvalbumin was obtained as described earlier by Koppelman and co-workers.[35]

Heating of Protein Samples. Aliquots of purified parvalbumin, cod fillet protein extracts, and pieces of cod fillet were heated at 20, 40, 50, 60, 70, 80, or 100 °C for 2 h in a water bath. This incubation time was selected to be sufficiently long to avoid uncertainties in warming of the samples and to represent processing-relevant times. For cod fillet pieces, the heating time was extended by 5 min, as a control experiment showed that this time was needed to obtain the set temperature at the interior of the pieces. Alternatively, samples were heated in an autoclave for 2 h at 120 °C. After the heating step, the samples were cooled to room temperature. After centrifugation (3612*g* in a table-top centrifuge at 4 °C for 30 min) of the extracts and

DOI: 10.1021/jf505990h
J. Agric. Food Chem. 2015, 63, 4683−4689

purified parvalbumin, a sample was collected from the supernatant (20 μL). The remaining mass (30 μL) was kept separately and referred to as total sample. The volume ratio for the supernatant was kept at two-fifths of the sample volume to be sure that the supernatant did not contain any pelleted material. As a consequence, the total sample contains the pelleted material and part of the supernatant. Both samples, supernatant and total sample, were immediately mixed with Laemmli buffer (1:1 v/v).

Protein Concentration Determination. Protein concentrations were determined using the Bradford assay kit (Sigma-Aldrich, USA). Bovine serum albumin standards (Sigma-Aldrich, USA) were used, and the absorbance was determined at 595 nm using a UV−vis spectrophotometer (PerkinElmer, USA) in a quartz cell with a path length of 1 cm. It is assumed that in the assay also pelleted protein becomes accessible for Coomassie binding.

SDS-PAGE Analysis. Protein profiles for pure PV, raw extracts, and cod fillet extracts were obtained using sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE). Fish proteins already diluted in Laemmli sample buffer containing 2-mercaptoethanol were heated for 10 min at 70 °C, loaded on a 12% Bis-Tris gel, and subjected to SDS-PAGE using the XCell Surelock Min-Cell (Invitrogen, USA) at 200 V. Novex Sharp Prestained Protein standards (Novex, USA) were used to estimate the molecular weights of individual proteins. Proteins were visualized by SimplyBlue SafeStain (Invitrogen, USA).

Immunoblotting. PV and fish protein extracts were separated using SDS-PAGE as described above and then transferred to an activated PVDF membrane (Invitrogen, USA) using the XCell II Blot Module (Invitrogen, USA) for 1 h at 30 V. After blocking with 5% (w/v) skim milk in TBST for 1 h at 4 °C, membranes were incubated overnight with the primary polyclonal rabbit anti-parvalbumin antibody,[14] diluted 1:2500 in the blocking buffer. Membranes were subsequently washed in TBST (diluted Tris-buffered saline) and incubated with the secondary goat anti-rabbit IgG antibody (Thermo Fisher Scientific) for 1 h. The protein−antigen interaction was visualized using DAB substrate (Roche, Germany). The staining reaction was stopped after 10 min with TBST.

ELISA for Parvalbumin. A sandwich enzyme-linked immunosorbent assay (ELISA) based on affinity-purified polyclonal antibodies (IgG) raised against purified cod parvalbumin was used with all samples.[14] Purified cod parvalbumin was used as standard. First, a wide dilution range using 5-fold serial dilutions was tested to determine the dilution that resulted in a half-maximal signal. Subsequently, a narrow dilution range (serial dilution of 2-fold) around this dilution was tested. Then, five dilutions in this area were tested in triplicate. Calibration curves were fitted using a four-parameter logistic function and had a correlation coefficient (R^2) of at least 0.998. Results are expressed in micrograms of parvalbumin per milliliter in undiluted sample.

Circular Dichroism (CD). The different samples, heated for 2 h at indicated temperatures at a concentration of 2 mg/mL, were diluted to 0.2 mg/mL with deionized water (pH 6.8) and transferred to a quartz cuvette with a 1 mm optical path. Far-UV CD spectra were recorded on a Jasco J-715 spectropolarimeter in the spectral range from 190 to 260 nm with a resolution of 0.2 nm, a bandwidth of 2 nm, a scan speed of 100 nm/min, and an instrumental response time of 0.125 s. The instrument was equipped with a computer-controlled Peltier element to set the temperature or apply temperature ramps between 20 and 95 (±0.1) °C. Sixteen spectra were accumulated and averaged. The spectrum of a protein-free sample was subtracted. Alternatively, the ellipticity at 222 nm was monitored during applied heating and cooling ramps of 1 °C/min.

RESULTS AND DISCUSSION

Electrophoretic Analysis of Heat Processed Purified Parvalbumin. Figure 1 shows that purified parvalbumin in aqueous buffer without heat treatment runs on an SDS-PAGE gel (upper panels) as a single band at approximately 12 kDa, as reported previously.[36] Heating the sample and subsequent centrifugation and analysis using gel electrophoresis under reducing conditions shows that parvalbumin can be found in both the supernatant and total sample. With heat treatments of up to 80 °C even for prolonged incubation for 2 h, no traces of multimeric protein were observed on the SDS-PAGE gel. Incubation at 100 °C leads to a small (estimated as <1%) contribution of dimeric protein in the supernatant. The total sample under this condition contains a more significant contribution (~5%) of aggregated proteins, as judged from

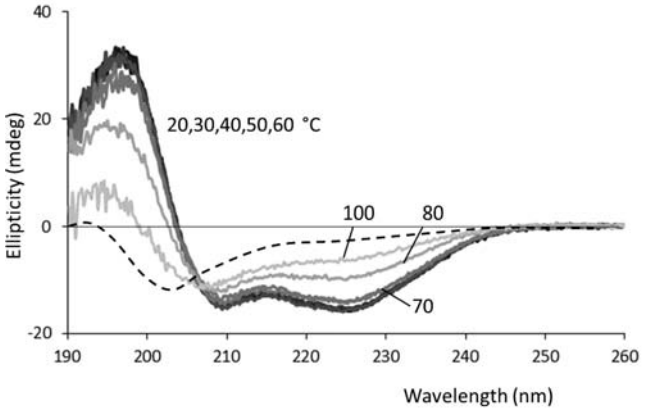

Figure 2. Far-UV CD spectra of 0.2 mg/mL purified parvalbumin samples recorded at 20 °C, pretreated for 2 h at a concentration of 2 mg/mL at indicated temperatures. The dashed line represents the redrawn spectrum of the autoclaved sample (2 h at 120 °C) where the intensity was multiplied by a factor of 5.

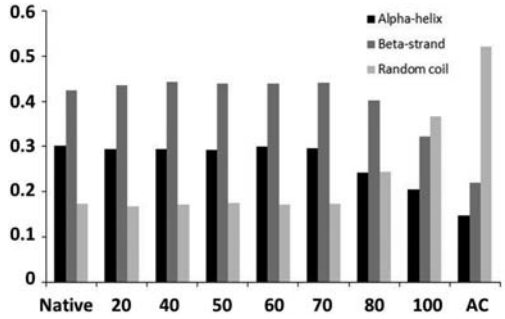

Figure 3. Secondary structure analysis of the spectra shown in Figure 2 using a nonlinear regression fitting procedure with reference spectra as described under Materials and Methods. The α-helix contributions are represented by the black bars, β-strands by the dark gray bars, and nonstructured contributions by the light gray bars.

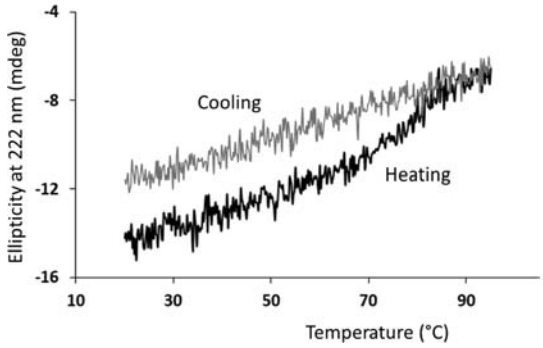

Figure 4. Temperature scans of 0.2 mg/mL purified parvalbumin with a heating and cooling rate of 1 °C/min. The ellipticity is monitored at 222 nm.

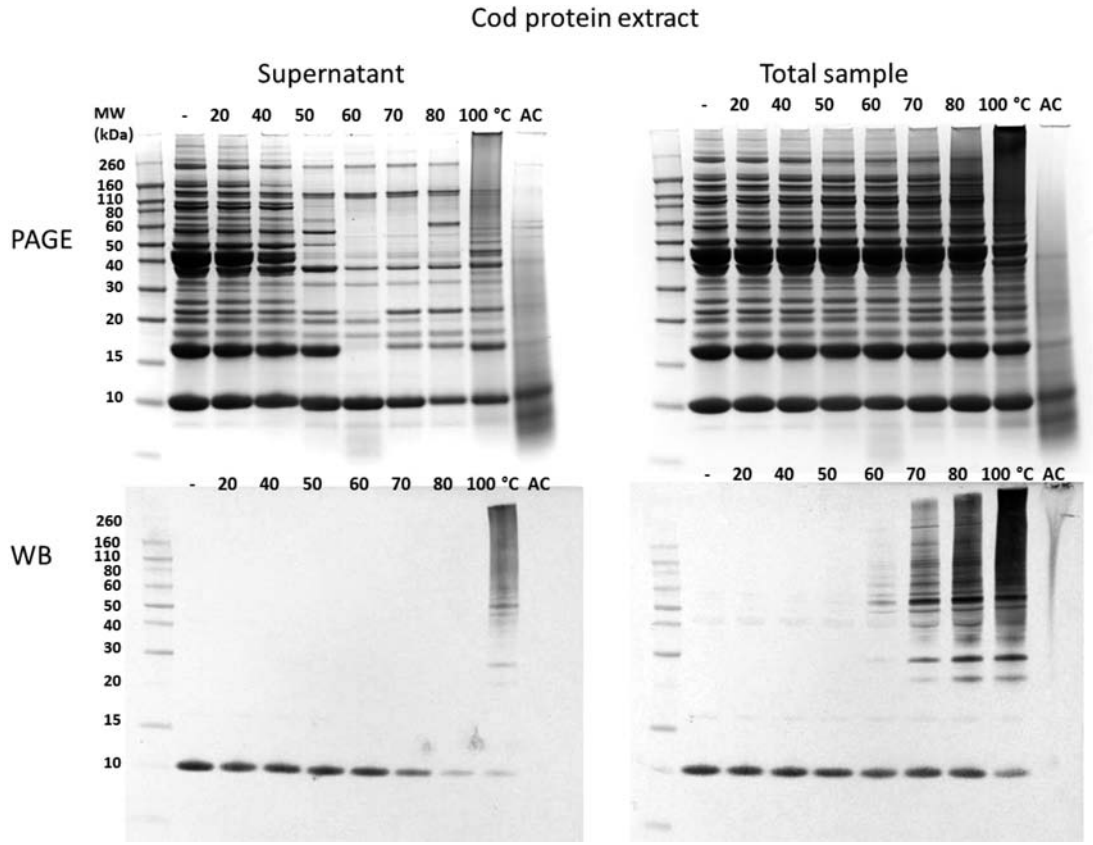

Figure 5. Heating of cod protein extract: (top panels) SDS-PAGE analysis with protein stain; (bottom panels) immunoblotting with anti-parvalbumin antiserum; (left panels) supernatant; (right panels) total sample. In all lanes 10 μg of total protein was applied. The incubation temperatures (2 h) are indicated.

visual inspection of the gel. Monomeric proteins are the predominant fraction, but dimers, trimers, and other aggregates up to hexamers can be distinguished under both nonreducing and reducing conditions with a predominance of the apparent dimeric and trimeric forms. Cod parvalbumin oligomers have been previously reported.[31] Analysis of the autoclaved sample showed that degradation of the protein had occurred into smaller (<12 kDa) peptide fragments in both the supernatant and the total sample. It is likely that the observed degradation products arise from the supernatant contribution to the total sample rather than its insoluble components.

The polyclonal rabbit anti-parvalbumin serum recognizes parvalbumin including all of the oligomeric structures observed in the 100 °C-treated samples as shown by the immunoblot analysis (lower panels in Figure 1). Interestingly, the intensity of staining on the blot decreases progressively with heat treatment (compare with upper panels), especially at temperatures above 80 °C. This effect appears to be stronger for the supernatant compared to the total sample. Moreover, the autoclaved sample does not show any significant IgG binding, except for a very faint band in the total sample.

Heat-Induced Conformational Changes of Parvalbumin. Parvalbumin is rather temperature-resistant, especially due to its refolding propensity.[19] To evaluate this in more detail, the secondary structure of the protein was studied as a function of temperature using CD. Figure 2 shows the CD spectra of samples that were heat-treated at different temperatures for 2 h and subsequently cooled to 20 °C. Typically, the spectra show three extremes, at 198, 208, and 222 nm, indicative for highly structured proteins, as described before.[33] The shape of the spectra deviated from that of the native material only when the sample was heated above 80 °C. Despite the similar protein concentration, the autoclaved sample (dashed line in Figure 2, which is a redrawn spectrum where the intensity was amplified 5 times to allow comparison with the other spectra) showed a low intensity, likely to be caused by disintegration of the protein in smaller fragments as illustrated in Figure 1. This degradation will lower the number of chiral peptide bonds detected with CD. When analysis of these spectra was conducted using a shape-analysis curve-fitting procedure, it was observed that the native protein bears a high secondary structure content with approximately 30% α-helix and 42% β-strands (Figure 3). The proportion of these two secondary structure contributions remains constant up to 70 °C and decreases gradually at higher incubation temperatures to about half their proportions for the autoclaved sample, illustrating the occurrence of some irreversible conformational change. When the temperature profile is shown at an ellipticity of 222 nm during heating from 20 to 95 °C (Figure 4), the secondary structure was in fact gradually reduced already at low temperatures, with a small cooperative unfolding starting between 70 and 80 °C, in line with previous results.[37] Moreover, no cooperative refolding step was observed upon subsequent cooling, and the secondary structure gradually increased again, as evidenced by the increase in absolute ellipticity (Figure 4). The difference at 20 °C prior to heating and after cooling reflects the irreversible unfolding as illustrated in Figure 2. By taking spectra at intervals of 10 °C during heating and cooling and subsequent analysis for the secondary structure content, this gradual unfolding−refolding was evident

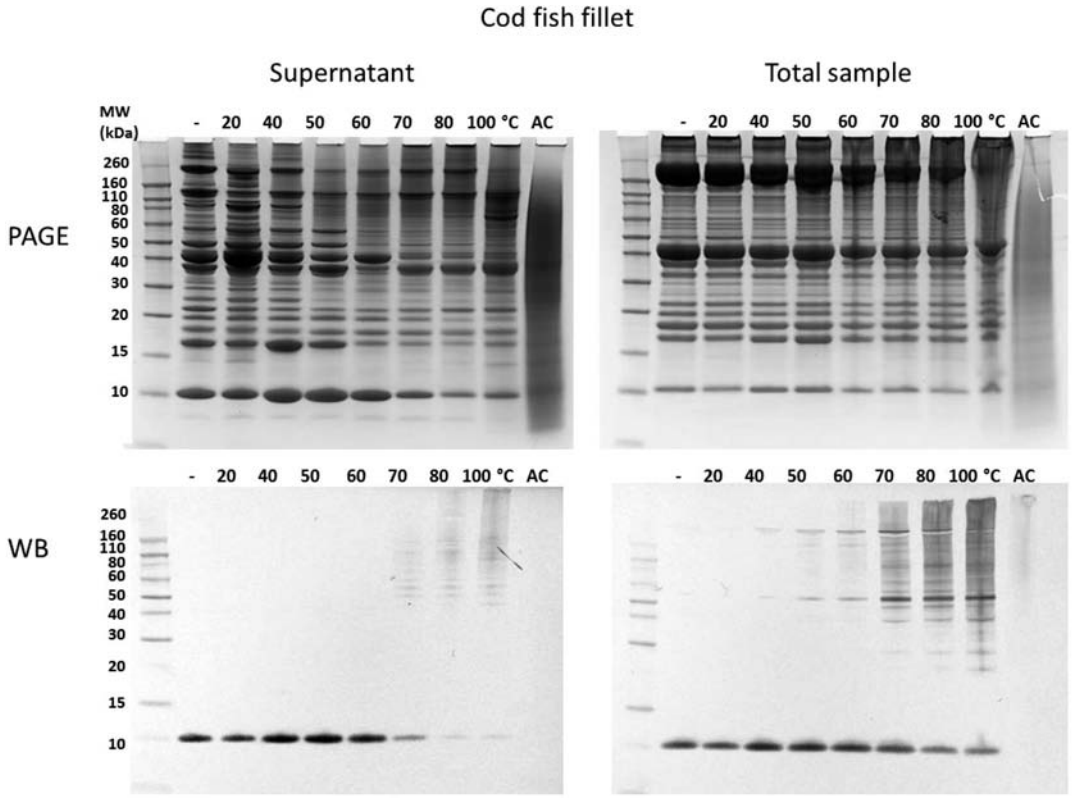

Figure 6. Heating of whole cod fillet: (top panels) SDS-PAGE analysis with protein stain; (bottom panels) immunoblotting with anti-parvalbumin antiserum; (left panels) supernatant; (right panels) total sample. In all lanes 10 μg of total protein was applied. The incubation temperatures (2 h) are indicated.

Table 1. Content of Parvalbumin Extracted from Whole Cod Fillet Incubated for 2 h at Different Temperatures As Detected by IgE Binding in an ELISA Assay

	parvalbumin content in extract (μg/mL)
not heated	388.2
heated at 50 °C	275.4
heated at 80 °C	45.3
heated at 100 °C	29.0
autoclaved (120 °C)	0.5

(results not shown). The spectrum of parvalbumin at 95 °C (not shown) shows a much more profound degree of unfolding (up to about 65% random coil) that partly refolds during cooling. At this point, it cannot be concluded whether this partial refolding reflects an ensemble-averaged behavior of unfolded and fully refolded contributions or whether all denatured proteins refold to a non-native state containing a less defined secondary structure.

At this point it is unclear whether the observed irreversible conformational changes above 80 °C can be held entirely responsible for the diminished staining intensity on the immunoblot. Although the correlation between the structural integrity and the immunoblot band intensity is striking, a more extensive and detailed analysis would be required to determine if these two observations were linked or coincidental. The absence of IgG binding with the autoclaved sample is remarkable and can be partially linked to the degradation of the protein into smaller fragments (Figure 1) with more limited IgG-binding potential. Alternatively, as Figure 1 still shows a significant population of protein in the autoclaved sample that runs with an apparent molecular mass as the native protein, and in view of the presence of a far-UV CD spectrum, it can also be concluded that irreversible unfolding of the protein beyond a certain level of the native protein results in a strongly diminished IgG binding.

Electrophoretic Behavior of Heated Parvalbumin Embedded in Matrices. Figures 5 and 6 show the electrophoretic analysis of parvalbumin heated either in an extract or embedded in a whole fillet and incubated for 2 h at temperatures ranging from 20 to 100 °C. Samples not subjected to heat reatment (lanes next to the marker ane) and those treated in the autoclave (AC) (2 h at 120 °C) (right lanes) are also included. With the cod fish protein extract (Figure 5), a large number of distinctive bands are observed from the nonheated sample with dominant bands, next to that of parvalbumin, at around 16, 36, and 40 kDa. The vast majority of these proteins, with the exception of parvalbumin, lose their solubility when incubated at temperatures above 50 °C. Parvalbumin is very heat resistant and remains soluble at high temperatures, as similarly observed for the pure protein (see Figure 2). Also, proteins can be observed at higher molecular weights in the total sample at elevated temperatures, but there are no indications for extensive aggregation phenomena, because no material can be observed at the top of the (stacking) gel shown in Figure 5. As observed for purified parvalbumin, the autoclave treatment resulted in degradation of the proteins and no apparent aggregation of the material. Immunoblot analysis of these samples shows that the IgG is specific for parvalbumin and does not show any significant cross-sensitivity for other extracted fish proteins. In the supernatant, a pattern similar to that of the pure parvalbumin

DOI: 10.1021/jf505990h
J. Agric. Food Chem. 2015, 63, 4683−4689

is observed where at higher temperatures the relative staining intensity to protein bands on the blot is reduced. Analysis of the total sample suggests that the heat treatment resulted in a complexation of parvalbumin with other fish muscle proteins. For example, bands at approximate molecular weights of 20, 40, and 60 kDa were observed (Figure 5) at heat treatments of 60 °C and above. Identification of these other proteins, however, is currently unresolved.

When parvalbumin is heated in the matrix of whole cod fish fillet (Figure 6), the extensive complexation of parvalbumin with other fish muscle proteins is not as evident as observed for the fish extract (compare with Figure 5). Such complexation could be hampered by the spatial organization of proteins within the tissue, providing a stable network that becomes disrupted in the extraction process. Less extensive complexation was observed after heating of the whole cod fish fillet where only two main contributions were observed at 40 and 200 kDa in addition to monomeric parvalbumin.

ELISA Analysis. Table 1 presents the analysis of the parvalbumin content using the IgG ELISA in the whole cod fish fillet when heated for prolonged times (2 h) at various temperatures. At 50 °C, IgG binding was reduced by 29%, whereas IgG binding was reduced by 93% when heated at 100 °C. The reduced reactivity in ELISA at moderate incubation temperatures (50 and 80 °C) is not in line with the staining intensities observed in the immunoblotting of these samples (Figure 6). Most likely this is related to the blotting procedure where the proteins are exposed to SDS, an unfolding agent, and mercaptoethanol, a reducing agent. The protein-dissociative conditions in the immunoblot analysis might promote the recognition by IgG. Clearly, autoclave treatment caused the complete loss of IgG binding in the ELISA, as similarly observed for the immunoblot analysis. Recent work showed that heating purified parvalbumin (i.e., in the absence of a matrix) for 20 min at 100 °C had no significant influence on IgG binding as assessed by ELISA, whereas the same heat treatment of whole cod fillet reduced the reactivity to only 14% (results not shown[34]). This suggests that the matrix plays an important role in the stability of immunogenicity of parvalbumin. Our observation that autoclave treatment of cod fish fillet strongly reduced the IgG reactivity of parvalbumin is in line with the observation that canned salmon was less reactive then nonheated salmon in an oral food challenge in fish-allergic patients,[38] although at this stage we cannot be sure that the same mechanism plays a role.

Concluding Remarks. This work shows that the matrix affects the aggregation behavior of parvalbumin upon heating. Less aggregation was observed with parvalbumin embedded in whole cod fillets, where the tissue orientation of the protein likely hampers protein complexation and aggregation. Dimerization or oligomerization of parvalbumin does occur, but only to a limited extent and does not interfere substantially with a quantitative analysis of the allergenic potential of a heat-treated material. Sampling conditions, like storage time and incubation buffers, may affect the aggregation process of parvalbumin and, thereby, the degree of oligomerization.

Heat treatment as such, and especially the structural refolding propensity of the protein, is thus only partially responsible for the loss of IgG reactivity. Antibody binding to parvalbumin is dominated by the potential of the protein to form heat-induced insoluble complexes with itself and other proteins, and immunoblot analysis of such heat-treated samples may provide confusing information regarding the potential health risks of heat-processed fish and fish-containing composite foods. Especially when parvalbumin enters the food chain as fish extract as in fish meal, a thorough immunochemical analysis is essential.

Supporting Information

ABSTRACT: ^{1}H NMR spectroscopy offers advantages in metabolite quantitation and platform robustness when applied in food metabolomics studies. This paper provides a ^{1}H NMR-based assessment of seed metabolomic diversity in conventional and glyphosate-resistant genetically modified (GM) soybean from a genetic lineage representing ∼35 years of breeding and differing yield potential. ^{1}H NMR profiling of harvested seed allowed quantitation of 27 metabolites, including free amino acids, sugars, and organic acids, as well as choline, *O*-acetylcholine, dimethylamine, trigonelline, and *p*-cresol. Data were analyzed by canonical discriminant analysis (CDA) and principal variance component analysis (PVCA). Results demonstrated that ^{1}H NMR spectroscopy was effective in highlighting variation in metabolite levels in the genetically diverse sample set presented. The results also confirmed that metabolite variability is influenced by selective breeding and environment, but not genetic modification. Therefore, metabolite variability is an integral part of crop improvement that has occurred for decades and is associated with a history of safe use.

KEYWORDS: *soybean (Glycine max), NMR, metabolomics, canonical discriminant analysis, principal variance component analysis*

INTRODUCTION

Soybean (*Glycine max* L.) is a global food and feed commodity, utilized primarily as a source of protein and oil. It also contains bioactive metabolites such as isoflavones, which are associated with health benefits.[1,2] Globally, breeding programs are committed to developing new varieties with improved agronomic characteristics[3,4] and nutritional profiles.[5] The steady rise in yield potential observed in newer varieties over the past few decades[6−8] has been driven by the need to maintain sustainable production of this important crop to meet the demands of a growing population. Studies have shown that selective breeding as well as differences in crop genetics and environment can affect soybean composition.[8−11] In general, levels of protein and oil, the major value components of soybean, are inversely correlated to each other and vary depending on yield potential, genotype, and environment.[5,12,13] Levels of other soybean components such as isoflavones as well as antinutrients such as certain oligosaccharides are similarly variable. A better understanding of the relationships between agronomic performance and levels of key crop nutrients and metabolites will be of value as improvements to soybean yield potential continue apace.

Metabolomics may be an effective tool in evaluating agronomic and nutritional performance.[2,14−19] In recent mass spectrometry (MS)-based metabolomics studies, it has been demonstrated that soybean cultivars can be differentiated on the basis of metabolite profiles.[1] Nuclear magnetic resonance (NMR) spectroscopy has several benefits as a metabolite profiling technique including ease of sample preparation, high sample throughput, identification of a broad range of chemical compounds in a single experiment, and generation of quantitative data. ^{1}H NMR techniques have been broadly applied in the metabolomics community for biomedical, food, and plant research,[2,15,17−21] including applications to soybean. The objectives of the study described here were to characterize metabolomic variability in soybean seed through application of ^{1}H NMR and applied multivariate statistics and to interpret results in the context of selective breeding and the history of safe consumption of soybean. ^{1}H NMR profiles of nine soybean varieties sharing a genetic lineage representing ∼35 years of breeding (commercial launch years 1972−2008) and increasing yield potential were therefore generated. The selected varieties included four older conventional lines (commercial launch years 1972−1996), two newer conventional lines (1997−2008), and three glyphosate-tolerant genetically modified (GM) lines (1999−2008) that were grown concurrently at two replicated field sites in the United States during the 2011 growing season.

The ^{1}H NMR analysis utilized standard one-dimensional profiling techniques, and a total of 27 metabolites were quantified. Analysis of the metabolite data set included canonical discriminant analysis (CDA), a multivariate approach that finds linear combinations of the quantitative variables that can provide maximal separation between classes or groups. Principal variance component analysis (PVCA) was pursued to assess interrelationships between the seed metabolites as well as the impacts of location and pedigree (variety) on variation in metabolite levels.

MATERIALS AND METHODS

Biological Material. Nine soybean varieties representing a genetic lineage from Williams (1972) to A3555 (2008) were grown concurrently at two sites in Illinois [Jerseyville (ILJE) and Jacksonville (ILJA)] during the 2011 season. Varieties included six conventional and three glyphosate-tolerant (GM) lines. Variety launch year and grouping based on genetic similarity (see the Supporting Information) are listed in Table 1. Starting seeds were planted in a randomized complete block design with six replicates. Soybean plants were treated with maintenance pesticides as necessary throughout the growing season at both sites. The three glyphosate-tolerant varieties were not treated with glyphosate. Seed was harvested at maturity and homogenized by grinding with dry ice to a fine powder, lyophilized, and stored in a freezer set to maintain −20 °C prior to analysis. Two samples (one replicate of AG3705 at ILJA and one replicate of CX375 at ILJE) were lost at harvest.

Table 1. Launch Year and Average Yield of Each Variety

variety	launch year	yield at ILJA[a]	yield at ILJE[a]
Williams	1972	66.5	65.3
A3127	1979	68.2	61.0
CX366	1986	71.9	66.6
CX375	1996	71.8	66.3
A3469	1997	80.3	73.5
AG3701	1999	72.8	71.1
AG3705	2006	80.6	77.2
A3555	2008	85.9	74.2
AG3803	2008	78.8	76.4

[a]Bushels/acre. ILJA represents the Jacksonville, IL, site, and ILJE represents the Jerseyville, IL, site.

Comprehensive compositional and MS-based metabolomics assessments of these study samples have been presented in Harrigan et al.[11] and Kusano et al.,[22] respectively. Genetic characterization of all varieties using the Illumina Infinium platform was also presented in Kusano et al.;[22] a summary of thaose data has been incorporated into Supporting Information Figure 1.

Sample Extraction and NMR Analysis. Ground, lyophilized grain samples (50 mg) were suspended in 1.8 mL of 80% MeOH and sonicated for 15 min at room temperature. Following sonication the sample was centrifuged and supernatant collected. The pellet was re-extracted twice as above. Pooled supernatants were dried and resuspended in 1 mL of NMR buffer (100 mM sodium phosphate, pD 7.4, with 0.5 mM 4,4-dimethyl-4-silapentane-1-sulfonic acid (DSS) chemical shift standard). Samples were filtered prior to loading into NMR tubes (700 μL) due to the presence of insoluble material.

All NMR data were collected on a Bruker AVANCE III spectrometer (600.13 MHz) at 298 K with a Bruker 5 mm TCI CryoProbe. One-dimensional ^{1}H NMR spectra were acquired using a standard Bruker noesypr1d pulse sequence. Each spectrum consisted of 128 scans of 65563 data points with a spectral width of 7.2 kHz, an acquisition time of 4.55 s, and a recycle delay of 1 s per scan. Data collection parameters were based on those used by Chenomx to generate the standard spectra in the library to ensure best possible results for the quantitative fitting of the spectra. Exponential line broadening of 0.3 Hz was applied before Fourier transformation. Spectra were phase corrected manually and referenced to DSS (methyl singlet chemical shift of 0.00 ppm). Processed spectra were uploaded into the Chenomx NMR Suite for metabolite identification and quantitation using the 600 MHz library (version 7.7). The Chenomx software algorithms reconstruct each sample spectrum from a linear sum of the individual standard spectra in the library, and quantitation is based on the concentration of the DSS methyl singlet reference. Spectra were also binned (0.02 and 0.01 ppm bin size) from 0.0 to 10.0 ppm with selected regions excluded to remove variations from residual solvents: δ 3.33−3.36 (residual MeOH), δ −0.04 to 0.04, δ 0.58−0.67, δ 1.75−1.80, δ 2.88−2.93 (DSS), δ 4.68−4.88 (H_2O). Additional regions where spectral alignment was poor were also removed prior to binning the data (δ 6.51−6.8, δ 7.07−7.095, δ 7.2−7.31, δ 7.52−7.60, δ 7.78−7.9, δ 8.09−8.30). Binned data were normalized to the spectrum area excluding the regions that were removed to account for solvent peaks and alignment shifts. These binned data (files S1 and S2) are available as Supporting Information. Chemical shifts of metabolites identified and quantified from ^{1}H NMR spectra of soybean extracts are available in Table 2.

Table 2. Chemical Shifts of Metabolites Identified and Quantified from ^{1}H NMR Spectra of Soybean Extracts

metabolite	^{1}H chemical shift (multiplicity)[a]
2-oxoglutarate	2.43 (t), 2.99 (t)
4-aminobutyrate	1.89 (m), 2.28 (t), 3.0 (t)
acetate	1.90 (s)
alanine	1.47 (d), 3.78 (q)
arginine	1.64 (m), 1.72 (m), 1.89 (m), 1.92 (m), 3.23 (t), 3.76 (t)
asparagine	2.85 (dd), 2.94 (dd), 3.99 (q)
aspartate	2.67 (dd), 2.80 (dd), 3.89 (dd)
choline	3.19 (s), 3.51 (m), 4.06 (m)
citrate	2.53 (d), 2.67 (d)
dimethylamine	2.72 (s)
formate	8.44 (s)
fumarate	6.51 (s)
galactose	3.48 (dd), 3.64 (dd), 3.69 (m), 3.71 (m), 3.73 (m), 3.74 (m), 3.77 (m), 3.80 (dd), 3.84 (dd), 3.92 (d), 3.98 (d), 4.07 (t), 4.57 (d), 5.25 (d)
glucose	3.22 (dd), 3.40(m), 3.46 (m), 3.48 (t), 3.53 (dd), 3.70 (t), 3.72 (dd), 3.76 (dd), 3.82 (m), 3.84 (m), 3.89 (dd), 4.63 (d), 5.22 (d)
glutamate	2.04 (m), 2.12 (m), 2.32 (m), 2.36 (m), 3.75 (dd)
isoleucine	0.93 (t), 1.00 (d), 1.25 (m), 1.46 (m), 1.97 (m), 3.66 (d)
lactate	1.32 (d), 4.11 (q)
leucine	0.95 (m), 1.67 (m), 1.70 (m), 1.73 (m), 3.73 (m)
malate	2.35 (q), 2.66 (dd), 4.29 (d)
O-acetylcholine	2.14 (s), 3.22 (s), 3.72 (m), 4.54 (m)
p-cresol	2.22 (s), 6.84 (m), 7.14 (m)
succinate	2.39 (s)
sucrose	3.46 (t), 3.55 (dd), 3.68 (s), 3.75 (t), 3.79 (m), 3.82 (m), 3.83 (m), 3.88 (m), 4.04 (t), 4.21 (t), 5.40 (d)
threonine	1.32 (d), 3.58 (d), 4.25 (m)
trigonelline	4.42 (s), 8.07 (t), 8.82 (dd), 9.11 (s)
tryptophan	7.18 (m), 7.27 (m), 7.31 (s), 7.53 (d), 7.72 (d)
valine	0.98 (d), 1.03 (d), 2.26 (m), 3.6 (d)

[a]^{1}H chemical shifts used for metabolite identification and quantification were determined at pD 7.4 in 100 mM sodium phosphate buffer and expressed as relative values to that of DSS at 0 ppm. Letters in parentheses denote the peak multiplicities: s, singlet; d, doublet; t, triplet; dd, doublet of doublets; q, quartet; and m, multiplet.

Univariate Statistical Analysis. Means, standard errors, and ranges were calculated in SAS 9.4 (SAS Institute Inc.) (Table 3). Values were combined across both sites. Pearson correlation coefficients were also determined between the 27 metabolites and yield.

Canonical Discriminant Analysis. CDA is a dimension-reduction technique related to principal component analysis and canonical correlation. CDA finds linear combinations of the quantitative variables that provide maximal separation between classes or groups. Given a classification variable and several quantitative variables, the CANDISC procedure in SAS derives *canonical variables*, linear combinations of the quantitative variables that summarize between-class variation in much the same way that principal components summarize total variation.

Principal Variance Component Analysis. The procedure and rationale for applying PVCA to crop compositional data are similar to

[a]Micrograms per 50 mg DW. [b]Grams per 100 seed. [c]Bushel/acre. Least-squares means were based on a total of 12 biological replicates, six from the Jacksonville (ILJA) site and six from the Jerseyville (ILJE) site (n = 12), with an exception for AG3705 (n = 11), where one replicate was lost at harvest at ILJA, and for CX375 (n = 11), where one replicate was lost during harvest at ILJE.

those described in detail in Harrigan et al.[11] Essentially, the first step of the PVCA procedure is to normalize the responses, if necessary. In this study the responses were all approximately normally distributed. The second step is to check for linear dependencies in the data. This can be done by computing the correlation matrix of variables and then computing the rank of that matrix. If the rank is less than the number of variables, then some variables must be dropped from the analysis. The third step is to apply PCA to the correlation matrix. Li et al.[23] continued development of the original PVCA procedure with the principal components, but we added an intermediate step, factor analysis, to assist with results interpretation. Factor analysis with varimax rotation is a method of deriving new linear combinations of variables with information derived from PCA that assist in deciding the appropriate number of factors needed to capture sufficient variability. The final step is to apply variance components analysis to each of the derived factor variables (F^1, F^2, ..., F^j). An ANOVA model is applied, and all of the sources of variation of interest to the researcher are modeled with random effects. In our application of PVCA,[1,11] the principal components and factor scores are strongly correlated with individual compositional analytes if the absolute value of the linear correlation between the derived variable and the analyte exceeds 0.707, with the interpretation that at least 50% of the variation in the analyte can be explained by its linear relationship with the new variable. Absolute correlations between 0.5 and 0.707 can be described as moderately correlated, with the amount of variation in the analyte that can be explained by the factor ranging between 25 and 50%. PVCA was conducted in SAS 9.4 (SAS Institute Inc.).

RESULTS AND DISCUSSION

Selective plant breeding has contributed to an increase in soybean yield over time, as reflected in the varieties assessed in this study (Table 1). The genotypic diversity found in these soybean varieties (see the Supporting Information) allowed an opportunity to evaluate metabolite variability associated with decades of selective breeding and yield differences. ^{1}H NMR spectroscopy was assessed as a profiling technique due to the robustness of the platform and its quantitation capabilities, although it typically detects many fewer metabolites than mass spectrometry-based methods. In this study ^{1}H NMR profiling allowed quantitation of 27 metabolites, which included free amino acids (alanine, arginine, asparagine, aspartate, glutamate, isoleucine, leucine, threonine, tryptophan, valine, 4-amino-butyrate), sugars (galactose, glucose, and sucrose), organic acids (2-oxoglutarate, acetate, citrate, formate, fumarate, lactate, malate, and succinate), choline, *O*-acetylcholine, dimethyl-amine, trigonelline, and *p*-cresol (Table 2). Least-squares means combined across both sites are presented in Table 3. Corresponding ranges and standard errors are included in the Supporting Information. Portions of each spectrum remained unassigned due to the available metabolites in the Chenomx library and spectral overlap. Metabolite coverage could be improved for these soybean samples through the addition of soybean-specific metabolites to the Chenomx library.

Statistical analysis of the data set focused on two key methods. The first method is CDA to determine if linear combinations of the quantitative variables exist that can be used to discriminate between the nine varieties. The second method is PVCA to estimate the percentage of the total variability in the data set attributed to each major source of variability.

Canonical Discriminant Analysis. CDA is a dimension-reduction technique related to principal component analysis and canonical correlation. CDA finds linear combinations of the quantitative variables that provide maximal separation between classes or groups. When applied here, the first three canonical factors (Can 1, Can 2, and Can 3) accounted for 87% of the variation in the data (Supporting Information Table 1). These factors proved effective in providing discrete clustering of the nine different varieties, as shown in Figure 1 and Supporting Information Figure 2. The older varieties were discriminated from the newer varieties, with the exception of AG3705.

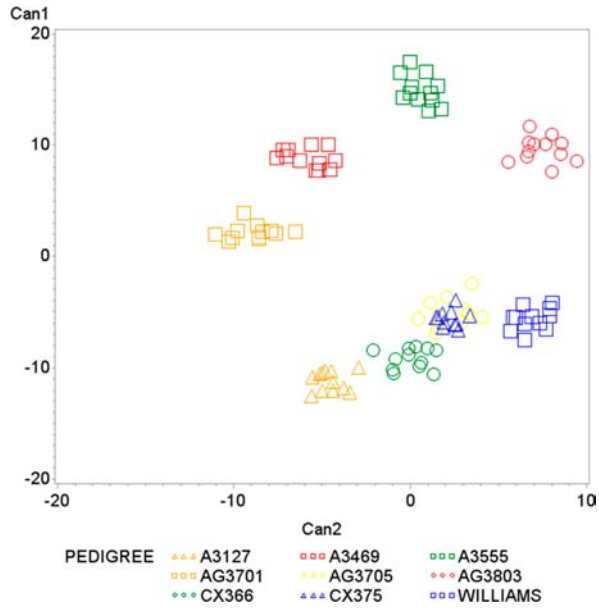

Figure 1. Canonical discriminant analysis of metabolite data for all nine varieties. On canonical 1 axis, the four older varieties (A3127, CX375, CX366, and Williams) can be distinguished from four of newer varieties (A3469, A3555, AG3701, and AG3803). AG3705 clustered with the older varieties and was shown (see text) to have some metabolic features similar to these.

Notably, Can 1 proved highly effective in discriminating between the older varieties and, with the exception of AG3705, the newer varieties. Can 1 was strongly correlated with malate (r = 0.93), fumarate (r = 0.92), glucose (r = 0.86), and glutamate (r = −0.88) (Supporting Information Table 2). The least-squares mean values (combined site) for these metabolites could, at least in part, also differentiate the varieties. For example, mean malate values for the older varieties and AG3705 ranged from 111.11 to 123.83 μg/50 mg DW in contrast to 155.28−179.45 μg/50 mg DW for the newer varieties (excluding AG3705). Corresponding values (older varieties plus AG3705 versus newer varieties excluding AG3705) for the other metabolites were as follows: fumarate, 2.36−2.56 versus 2.63−4.34 μg/50 mg DW; glucose, 21.27−23.09 versus 23.82−28.72 μg/50 mg DW; and glutamate, 58.69−65.70 versus 47.99−59.03 μg/50 mg DW. Other metabolites such as galactose (r = 0.72), trigonelline (r = −0.75), and formate (r = −0.75) also correlated well with Can 1. Varieties contained within either of the two main clusters discriminated by Can 1 showed separation along the Can 2 axis (Figure 1). Can 2 was most highly correlated with *p*-cresol (r = −0.82).

Principal Variance Component Analysis. PVCA included the variables yield and seed size in addition to the metabolite data. It was applied here to investigate the interrelationships among metabolite components as well as the impact of location and pedigree on variability in the levels of these metabolites. A total of eight factors described >80% of the variance in the study (Supporting Information Table 3). Factors F^1−F^5 are discussed in more detail below. The correlation matrix of components listed by factor, as determined by the varimax rotation, can be found in Supporting Information Table 4. Next, analysis of variance with only random effects was used to estimate the variance within each factor from the following sources: location, pedigree (i.e., variety), block (location) (i.e., biological replicate within location), and residual error (Figure 2). Percent of total variability shows that residual accounted for 42.3%; pedigree, 37.8%; unexplained, 17.3%; location, 1.7%; and block (location), 0.9% (Figure 3).

Factor F^1: Free Amino Acids (Alanine, Arginine, 4-Aminobutyrate, Asparagine, Isoleucine, Leucine, and Valine) and an Organic Acid (Fumarate). The first factor, F^1, explained 24.4% of the total variation in the metabolomics study (Figure 2 and Table 4). It was strongly correlated with three free amino acids (arginine, isoleucine, and valine) and moderately correlated with four free amino acids (alanine, 4-aminobutyrate, asparagine, and leucine) as well as the organic acid fumarate. Analysis of variance showed that the largest source of variance in F^1 was pedigree followed by residual error. Figure 4 contains box plots to display the variation of values in F^1 according to pedigree.

These results from PVCA were consistent with those from CDA. For example, in the CDA analysis all amino acids listed above, with the exception of leucine, had correlations with Can 3 of r > 0.6, whereas fumarate, as noted earlier, correlated very strongly with Can 1 (r = 0.92). In other words, metabolites shown by PVCA to be highly variable according to pedigree were also observed to contribute to separation in the CDA plots showing that results from both multivariate approaches were broadly consistent with each other. Variety A3555, which had the highest score for factor F^1 in the PVCA (see Figure 4), also had (or shared) the highest combined-site mean values for alanine, arginine, 4-aminobutyrate, asparagine, isoleucine, leucine, valine, and fumarate. This newer conventional line may therefore be a major contributor to the metabolite variation observed in these data.

Factor F^2: Sugars (Galactose and Glucose), Organic Acids (Lactate and Fumarate), and Free Amino Acids (Alanine and Threonine). The second factor, F^2, explained 16.6% of the total variation in the metabolomics study (Supporting Information Table 5). It was strongly correlated with two sugars (galactose and glucose), two organic acids (lactate and succinate), and the free amino acid threonine. It was moderately correlated with the free amino acid alanine. The largest source of variance in F^2 was residual error. Supporting Information Figure 3 contains box plots that display the variation of values in F^2 according to pedigree. F^2 also had the most notable contribution to variance from location.

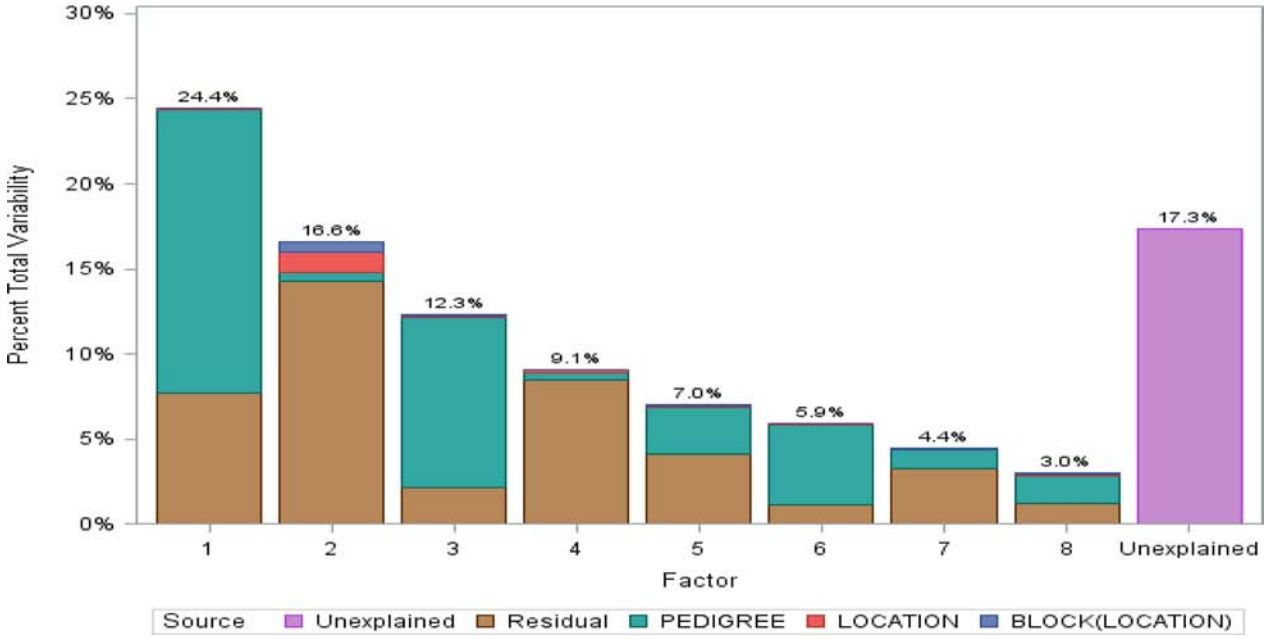

Figure 2. Proportions of variance explained by variance components for each factor.

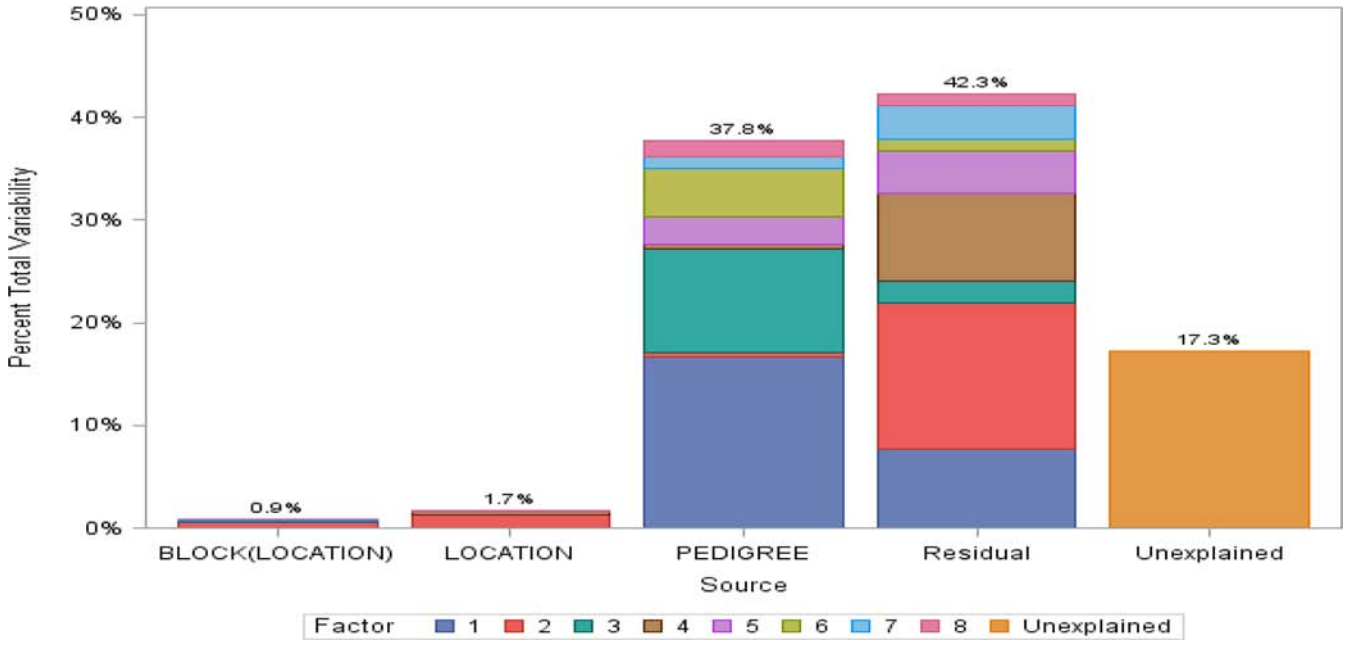

Figure 3. Proportions of variance explained by each factor.

Table 4. Summary of Factor 1 Sources of Variation (24.4%)

source of variance	fraction of variance due to source	PVC contribution
pedigree	68.33	16.67
residual error	31.50	7.69
location	0.18	0.04
block (location)	0.00	0.00

Factor F^3: Yield, Sucrose, Organic Acids (Malate and Fumarate), Glutamate, and *O*-Acetylcholine. The third factor, F^3, explained 12.35% of the total variation in the study (Table 5). It was strongly correlated with malate and glutamate and moderately correlated with yield, sucrose, fumarate, and *O*-acetylcholine. The largest source of variance in F^3 was pedigree. Figure 5 contains box plots to display the variation of values in F^3 according to pedigree. Figure 6 shows the contribution of pedigree to variation in each metabolite associated with F^3.

Figure 5 reveals that the five newer higher yielding soybean varieties have F^3 scores above the zero reference line, whereas the four older lower-yielding lines have negative scores. This is broadly consistent with results from the CDA where Can 1 also discriminated (with the exception of AG3705) the older and newer varieties. Malate, glutamate, and fumarate all correlated highly with Can 1 in that analysis. Sucrose and *O*-acetylcholine had lower correlations with Can 1 (r = 0.51 and −0.55, respectively) with the exception of A3555, 4.27−4.61 mg/50 mg DW (A3555 value = 3.95) versus 3.39−4.16 mg/50 mg DW for the older varieties. Sucrose has been reported to

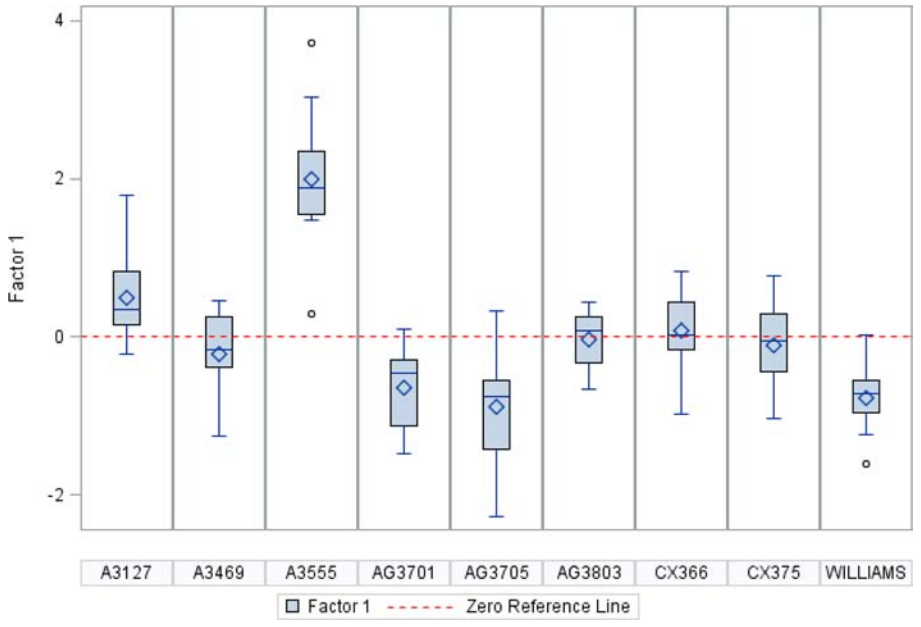

Figure 4. Factor F^1 by pedigree. This factor was highly associated with pedigree (variety). Plotting factor 1 for each pedigree allows a visual representation of how varieties vary in levels of metabolites associated with this factor.

Table 5. Summary of Factor 3 Sources of Variation (12.35%)

source of variance	fraction of variance due to source	PVC contribution
pedigree	81.19	10.03
residual error	17.28	2.13
block (location)	1.07	0.13
location	0.46	0.06

correlate positively with yield,[24] and NMR profiling results are also consistent with those observed in a targeted analysis of the same sample set reported here.[11] Correlation coefficients for individual metabolites and yield (including individual scatter plots) are presented in the Supporting Information; as described there, fumarate, malate, glutamate, and *O*-acetylcholine had some of the highest correlations relative to that of the other metabolites.

Factor F^4: Acetate, Formate, and Dimethylamine. The fourth factor, F^4, explained 9.1% of the total variation in the study (Supporting Information Table 6). It was strongly correlated with acetate, formate, and dimethylamine. The largest source of variance in F^4 was residual error. Supplementary Figure 4 contains box plots to display the variation of values in F^4 according to pedigree. Although variance in F^4 due to pedigree was relatively low, a wide range

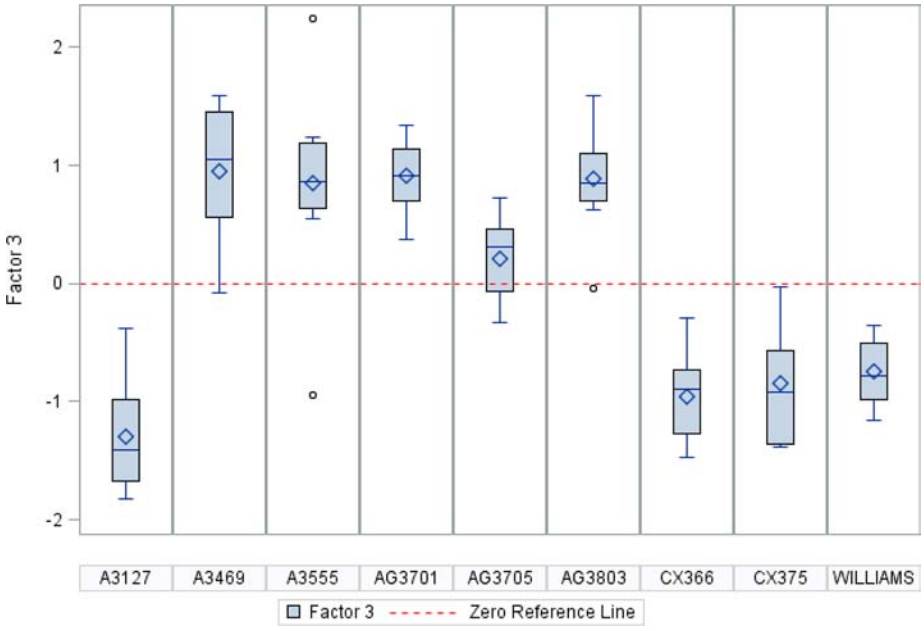

Figure 5. Factor F^3 by pedigree. This factor was highly associated with pedigree (variety). Plotting factor 3 for each pedigree shows that the four older varieties (A3127, CX375, CX366, and Williams) can be distinguished from the newer varieties (A3469, A3555, AG3701, AG3705, and AG3803).

DOI: 10.1021/acs.jafc.5b01069
J. Agric. Food Chem. 2015, 63, 4690−4697

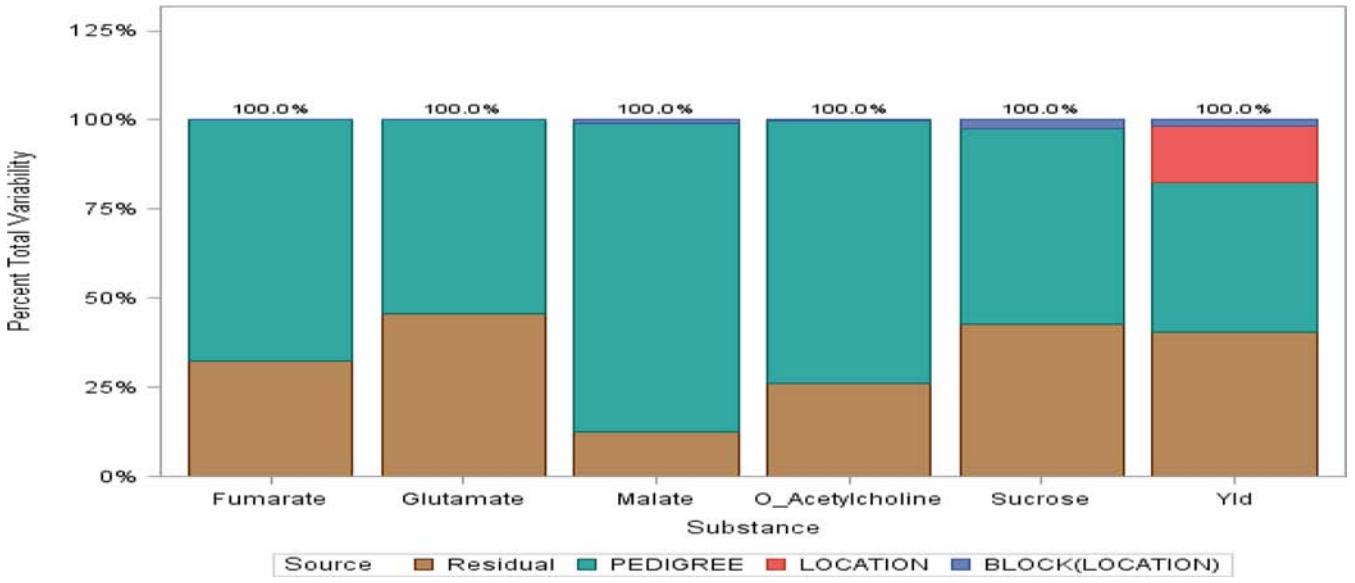

Figure 6. Pedigree effect accounts for notable proportion of variation for those components that strongly correlated with factor F^3. For yield, a location effect also contributed to variation.

of values for these metabolites was observed. This variation did not show a trend with launch era; in fact, the combined-site mean values, as well as the F^4 score, for the oldest variety (Williams, 1972) and one of the newest (A3555, 2008) are most similar.

Factor F^5: Aspartate, Asparagine, Oxoglutarate, and *p*-Cresol. The fifth factor, F^5, explained 7.0% of the total variation in the study (Supporting Information Table 7). It was strongly correlated with aspartate and moderately correlated with asparagine, oxoglutarate, and *p*-cresol. The largest sources of variance in F^5 were residual error and pedigree. Supporting Information Figure 5 contains box plots to display the variation of values in F^5 according to pedigree.

Of these metabolites, the CDA analysis indicated *p*-cresol had the highest correlation with any of the canonical scores (Can 2, $r = -0.82$). Aspartate and oxoglutarate also had negative correlations with Can 2 ($r = -0.62$ and -0.60, respectively). It was noted earlier that Can 2 was effective in within-group separation of the two major clusters discriminated by CDA. For example, the Can 2 scores groups for the newer varieties can be ordered as AG3701 < A3469 < A3555 < AG3803. The difference between AG3701 and AG3803 is reflected both in the F^5 scores and in the individual metabolite combined-site mean values. For example, the mean value for *p*-cresol in AG3701 is 25.26 μg/50 mg DW and in AG3803 is 16.12 μg/50 mg DW. Corresponding values for aspartate are 56.673 and 42.79 μg/50 mg DW, respectively. The wide range appears to be driven predominantly by AG3701, which has the highest *p*-cresol and aspartate values in the entire data set. Otherwise, the within-group variation for these metabolites is very similar for the older and newer varieties.

A better understanding of the relationships between agronomic performance and levels of key crop nutrients and metabolites in soybean seed will be of value as improvements to yield potential continue apace. This study provided a quantitative comparison of seed metabolite profiles from a soybean lineage representing decades of breeding and differing yield potential. The application of ^{1}H NMR spectroscopy and multivariate statistics generated data that could differentiate soybean cultivars based on metabolite profiles. Notably CDA could distinguish older lower yielding from newer higher yielding varieties, which implies the potential for associating metabolite changes with improved soybean yield and quality. PVCA indicated the major source of metabolite variability in the study was associated with variety (pedigree), but location was a notable source of variation for some components. Several metabolites were grouped in the same factor as yield, which suggests those metabolites are correlated with yield potential. This was consistent with the CDA analysis that showed some metabolites were associated with the newer higher yielding varieties as well as correlation analyses of the individual 27 metabolites and yield (Supporting Information). Overall, these analyses suggest that certain metabolite pathways may be linked to yield potential. Other metabolites were less associated with yield potential but were still highly variable when assessed across the entire data set. This would indicate that some pathways are incidental to yield gain but can be expected to vary depending on genetic background and growing location.

The study confirms that crop genetics and breeding for crop improvements can have a notable influence on metabolite variability; some metabolites may be associated with gains in yield potential, and others more incidental to germplasm improvement and/or differences in growing location. In addition, the transgenic and conventional lines were not uniquely distinguishable from each other, which is consistent with numerous publications (e.g., ref 22) and supports the position that genetic modification is not a meaningful contributor to metabolite variability. In summary, metabolite variability is associated with a history of safe use and possibly essential for crop improvement.

ABSTRACT: Micro- and nanotechnology are tools being used strongly in the area of food technology. The electrospray technique is booming because of its importance in developing micro- and nanoparticles containing an active ingredient as bioactive compounds, enhancing molecules of flavors, odors, and packaging coatings, and developing polymers that are obtained from food (proteins, carbohydrates), as chitosan, alginate, gelatin, agar, starch, or gluten. The electrospray technique compared to conventional techniques such as nanoprecipitation, emulsion−diffusion, double-emulsification, and layer by layer provides greater advantages to develop micro- and nanoparticles because it is simple, low cost, uses a low amount of solvents, and products are obtained in one step. This technique could also be applied in the agrifood sector for the preparation of controlled and/or prolonged release systems of fertilizer or agrochemicals, for which more research must be conducted.

KEYWORDS: *nanotechnology, electrospray, microparticles, nanoparticles, foods*

1. INTRODUCTION

Nowadays, food technologists are looking at alternatives to help improve food production for human consumption.[1,2] Among those technologies applied are micro- and nanotechnology[3] used in food microbiology for coatings or bacterial-free packaging,[4] micro- and nanoparticles for encapsulating products derived from food, e.g., bioactive compounds,[5] encapsulation of biological molecules (proteins and carbohydrates),[6,7] production of emulsions,[8] and the current boom for controlled and prolonged release fertilizers for agricultural use.[9]

The electrospray technique or electrohydrodynamic atomization is one of the tools that is included as a novel method for application in the field of micro- and nanotechnology of foods.[10] This technique is based on the production of spheres from a polymer solution, by applying a high electric field and thereby obtaining an encapsulation of different foodstuffs.[11]

Applying this technique in foods facilitates the production of products with endless applications, besides being more friendly for the environment and humans; however, few studies have been realized in the area of food. The aim of this paper is to present the advances and applications of the electrospray technique in the food technology area, showing their advantages and disadvantages.

2. ELECTROSPRAY TECHNIQUE

Electrospray is a variant of the method of electrospinning, which began to be used in medicine with the aim to encapsulate drugs.[12,13] Vonnegut and Neubauer (1952) were pioneers applying voltage to produce micrometer-sized spherical particles for application as sprays.[14] Today this technology is extending to other areas where it is booming in food technology, because it is simple and uses low-cost equipment.[15]

According to the way of collecting the droplets, there are two variants of the electrospray technique: electrospray in plates[16] and electrospray in solution.[17]

(1) Electrospray in plates consists of collecting charged droplets in a grounded plate, and collection can be of two forms. The first one, charged droplet, is deposited individually or can be deposited as an agglomerate of droplets on the plate (Figure 1).[18]

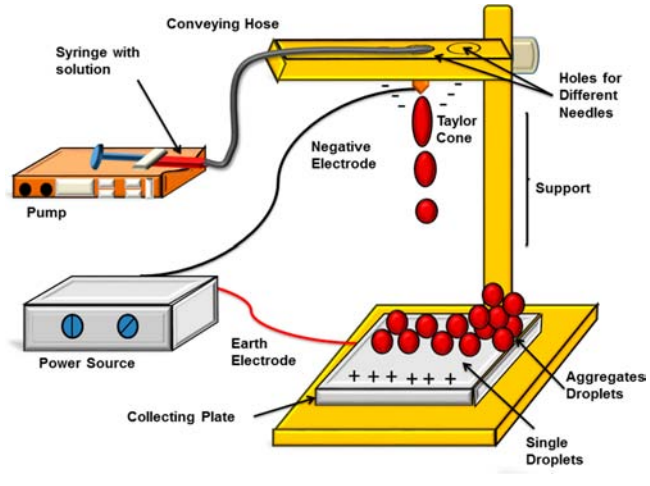

Figure 1. Method of electrospray in plates.

(2) Electrospray in solution is based on collection of charged droplets in a cross-linking solution into a precipitate glass to facilitate the formation of micro- and nanospheres. The most studied and used in this method as a cross-linking agent is calcium chloride ($CaCl_2$) (Figure 2).[17]

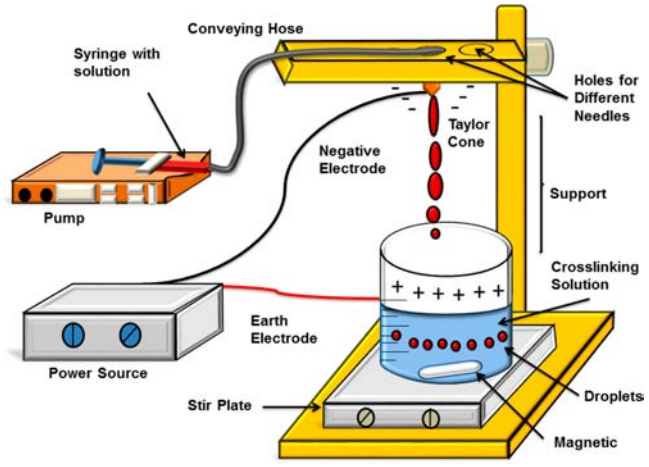

Figure 2. Method of electrospray in solution.

The principle of the electrospray is based on the ability of an electric field to deform the interface of the droplet and get droplets in the range of a micrometer or nanometer depending on the parameters to control.[19] This principle was grounded in the theory of charged droplets which establishes that if an electric field is applied to a droplet, the electric charge generates an electrostatic force into the droplet, known as the coulomb force, which competes with the force of cohesion in the droplet.[20] When the coulomb force applied is capable of overcoming the cohesive force of the droplet, that manifests in the release of the surface tension and formation of nanodroplets (Figure 3). A limit, named the Rayleigh limit L_R, exists to

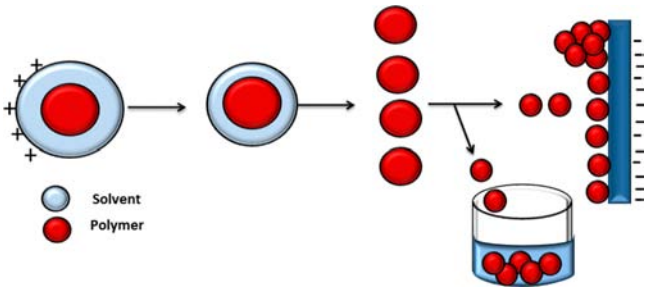

Figure 3. Mechanism of droplets formation during the electrospraying.

determine the rupture of the droplet. This limit is when the surface tension of the drop is overcome by the electrostatic force. Equation 1 represents the Rayleigh limit.[6]

$$L_R = q(64\pi^2\varepsilon\gamma R^3)$$

$$q = 8\pi\sqrt{\varepsilon_0\gamma R^3} \quad (1)$$

where q is charge on the droplet surface, ε is permittivity of the surrounding medium, γ is surface tension of the fluid, and R is radius of the droplet.

Although the electrospray technique is simple, it has to take into account the control variables to obtain desirable polymer particles in particle size and size distribution. These variables involve system parameters such as flow rate of the solution, applied electric potential, collector distance, viscosity of solution, conductivity, surface tension, molecular weight, and concentration of polymer (Table 1).[21]

2.1. System Parameters. Flow rate (Q): knowing this parameter of the method allows prediction of the behavior that the material will have in determining particle size. Chan et al.'s (2010) elaboration of microspheres of poly methylsilsesquioxane (PMSQ) was used as a model material for the microsphere shell encapsulating a core of liquid perfluorohexane (PFH) with a particle size from 310 to 1000 nm.[22] Second, Ghayempour et al. (2013) fabricated micronanoparticles of sodium alginate cross-linked with calcium chloride for the encapsulation of essential oils of particle size from 80 nm to 900 μm.[23] These two works determined how the flow rate affects the particle size obtaining the following results:

(1) At a high flow rate, it can lead to the formation of large size particles. This phenomenon occurs because the rate of the jet and the polymer concentration that drips from the needle are higher; therefore, the solvent does not volatilize completely.

(2) A low flow rate and increasing the electrical conductivity can lead to smaller particles, to 80 nm, since the rate of the jet is smaller, resulting in greater volatilization of the solvent.

Electric potential (Ø): this parameter represents the driving force of importance in the electrospray process, because it affects the size and form of the droplets. A potential of sufficient electric charge can overcome the surface tension of polymer solution to produce micro- and nanoparticles.[24]

Moghadam et al. (2010) applied the electrospray method to investigate the effect of the voltage (0−9 kV).[25] In this study, Moghadam prepared nanospheres of sodium alginate cross-linked with calcium chloride and observed that the range from 4.5 to 6.5 kV was changing the effect drip to jet mode, favoring the production of droplets, and came to the conclusion that higher voltage (9 kV) produces micrometric particles (400 μm). Hartman et al. (2000), Fanzheng et al. (2009), and Nguyen et al. (2014) agreed in their results confirming that higher voltage (15 kV) produces greater stability of the jet cone (Taylor cone) and the diameter of particles of 3.4 μm for Fanzheng and 10 μm for Hartman, but this voltage should not exceed 15 kV because creates an instability of the jet cone.[21,26,27]

Collector distance (L): to control particles formed and uniformity, it must take into account the effective evaporation of the solvent, and this will depend on the collector distance and the evaporation rate of solvent.[28] A fast evaporation rate can cause the inclusion of porous holes even up to reaching the final particle fragmentation and is undesirable for the formation of high quality droplets. On the other hand, if evaporation is slow, the form that these particles adopt is more spherical, since there is more time for the solvent to evaporate and a solvent-free polymer to form.[29]

Other studies show that if the distance of the collector is very small, it will not be possible to evaporate the solvent, and therefore the particle will be more unstable, and the size particle will be great. However, if the distance of the collector is considerable (15−20 cm), it may be easier for volatilization of the solvent and fission of the polymeric particle. However, there are no studies that relate a high jet rate and a long collector distance (15−20 cm) with particle size, as the case of research of Ghayempour et al. (2013) and Nedovic et al. (2001) reported that with a high jet rate and shorter distance (4−8

Table 1. Effect of System Parameters of Electrospray Technique on Size Particle

system parameters	characteristic: increases parameter	characteristic: decreases parameter	reference
electric potential	Range optimum 10−20 kV, 15 kV ideal. At greater voltage there is instability of Taylor cone	There is no formation of Taylor cone	Wang et al.,[24] Moghadam et al.,[25] Hartman et al.[26]
flow rate	There are larger particles, by higher concentration solution and less volatilization of solvent	Ideal to form micro- and nanoparticles	Fanzheng et al.[21]
collector distance	Allows more volatilization of the solvent and generates smaller particles	It increases the electrical conductivity and generates smaller particles, but at low electrical conductivity generates larger particles	Jun et al.,[28] Nedović et al.[30]
viscosity	At higher concentration of the polymer, the viscosity is increased and larger particles are obtained	Increasing the voltage and the flow rate, the viscosity decreases and smaller particles are obtained	Moghadam et al.[25] Moghadam et al.[31]
electrical conductivity	Favors obtaining small particles, but at higher electrical conductivity and higher flow rate, there are larger particles	Does not allow path of the electric charge; therefore, larger particles are obtained	Khan et al.[32]
surface tension	Larger particles are obtained	There is fission of droplets, and particles of smaller size are obtained	Khan et al.[32]

Table 2. Compared of Conventional Methods for Obtaining Micro- and Nanoparticles against the Electrospray Technique

method	advantages	disadvantages
conventional: nanoprecipitation, emulsion-diffusion, double-emulsification, polymer-coated, layer by layer	• Applies to versatile materials • Load wide range of organic or biological molecules • Particles can be used in controlled release system	• Requires several step • High molecular weight polymers are not used • Several solvents are used • Uses one or several surfactants • Have to modify the method for obtained nanometric particles • Generates more residue
Electrospray	• Uses one step • High molecular weight polymers can be used • Nanoparticles are obtained • Low cost • Uses fewer solvents • Does not use surfactant • Generates little residue	• Small amount of particles is obtained • In some cases uses a cross-linking agent

cm) smaller particles are obtained.[23,30] Nedovic et al. prepared nanocapsules of sodium alginate con yeast (*Saccharomyces uvarum*) and obtained particle sizes from 250 μm.[30]

In the meantime, viscosity is an important parameter to obtain particles with a desired diameter and is closely related to the concentration (C) of polymer and the flow rate (Q). Holding constant the concentration, viscosity tend to be the same for obtaining similar sized particles, but if these parameters increase the voltage in a growing range, the diameter of the particles will tend to decrease.[31] Moghadam et al. (2010) studied the relationship of concentration and viscosity in the electrospray technique, and they proved that if the concentration is increased in the range of 10−30 g L^{-1} of sodium alginate an increase flow rate, the viscosity will tend to decrease, being more evident at the concentration of 30 g L^{-1}; conversely, at a concentration of 10 g L^{-1}, there is little variation in viscosity.[25]

The electrical conductivity is another parameter that like the viscosity is influenced by flow velocity and electric potential. It is defined as the ability that a material has to let the electric charge pass, in this case, a polymeric material. In an investigation carried by Khan et al. (2012), a relationship between conductivity and flow rate was predicted, obtaining as result that the increase of conductivity resulted in a decrease of the surface tension and particle size of sunflower oil down 20 μm; however, if the flow rate and electrical conductivity increase, the particle size increases.[32]

The reduction of particle size in range of micro- or nanometric is a parameter that is influenced by the other parameters of the system. Reducing the particle size provides greater surface area; therefore, it allows greater bioavailability of micro- and nanocapsules for biomedical and food application.[33] The importance of particle size was first explained in the medicine area and could be applied in food technology, and is described in eq 2 of Noyes-Whitney (1897):[34]

$$\frac{dm}{dt} = \frac{DA}{h}(C_s - C_b) \quad (2)$$

where (dm/dt) = dissolution rate, A = surface area of the drug exposed to the dissolution medium, D = the diffusion coefficient of the drug, h = the thickness of the boundary layer of the dissolving drug, C_s = saturation concentration (solubility), and C_b = drug concentration in the medium at time t.

If the above-described parameters in function particle size help to obtain favorable particles, it is evident that it must take

DOI: 10.1021/acs.jafc.5b01403
J. Agric. Food Chem. 2015, 63, 4699−4707

into account other aspects involving the nature of the polymer such as molecular weight, interactions, and chemical composition. If it not known how the raw material behaves, the results will not be desirable.

3. ADVANTAGES AND DISADVANTAGES OF ELECTROSPRAY TECHNIQUE

There are currently several techniques both in basic science and in industry for the development of micro- and nanoparticles with different applications. Techniques that stand out for preparation of nanoparticles based mainly on polymers include: nanoprecipitation, emulsion−diffusion,[35] double-emulsification, emulsion−coacervation, polymer-coating, and layer by layer (Table 2).

3.1. Nanoprecipitation Method. The nanoprecipitation method is based on the synthesis of nanocapsules from a phase named solvent (organic) and a phase named nonsolvent (aqueous).[36] In the organic phase, there is a solution or several solutions which include the polymer (synthetic or natural), active substance, oil, and surfactant (oil−water), and the aqueous phase is a nonsolvent or mixture of nonsolvents.[37] The procedure is to include the organic phase in the aqueous phase forming a colloidal suspension, by manipulating conditions such as flow and agitation of the aqueous phase velocity, and obtaining particle smaller size (<100 nm).[38]

3.2. Emulsion−Diffusion Method. Unlike the nanoprecipitation method, the emulsion−diffusion method has three phases: organic, aqueous, and diffusion, allowing the encapsulation of hydrophilic and lipophilic active substances.[39] The method is based on achieving emulsification with organic and aqueous phases by stirring of polymer, surfactant, and a saturated solution; after the solution is subjected to diffusion, the solvent leaves and the active compound enters and nanocapsules smaller than 200 nm form.[40]

3.3. Double-Emulsification Method. Double-emulsification is obtained from a system composed of several emulsifications and is classified as emulsification oil−water−oil (O−W−O) and emulsification water−oil−water (W−O−W). The method is performed in two steps using two surfactants: first a hydrophobic surfactant used to stabilize the interface internal layer W−O, and another that stabilizes the interface of the outer layer of W−O−W.[41] The correct choice of surfactant is essential to shape the film and barrier at the interface of the internal layer, as well as a steric stabilizer in the interface of the outer layer.[42] For the preparation of the nanocapsules by this method, the first emulsion is obtained by ultrasound and surfactant W−O; the second emulsion is also obtained by ultrasound, and dispersion nanocapsules are stabilized by stabilizing agent; finally the solvents are removed by vacuum evaporation. The particle size obtained is in the range 150−200 nm.[43]

3.4. Emulsion−Coacervation Method. The emulsion−coacervation method has been used to develop nanocapsules natural and synthetic polymers. The procedure involves an O−W emulsion with an organic phase (oil, active substance, and solvent for the active substance, if is necessary) and an aqueous phase (water, polymer, stabilizing agent) by mechanical stirring; then the process is given coacervation with electrolytes.[44] This method uses the emulsion as a template phase and phase coacervation to cause precipitation of the polymer and a film to form on the template for the nanocapsules. Finally a cross-linking agent is added to strengthen the nanocapsules.[45]

3.5. Polymer-Coating Method. The method of polymer coating consists of depositing a thin layer of polymer on the surface of the formed nanocapsules. This method is very versatile since it does not provide a unique methodology; it can be applied depending on the conditions in which the particles are obtained. One way is to provide the layer of polymer during the preparation of the nanocapsules, and the other way is to apply the coat of polymer at the end of the formation of the nanocapsule from other conventional methods as nanoprecipitation or double-emulsification.[46]

3.6. Layer by Layer Method. The layer by layer method is based on assembling a series of polymer layers to form nanospheres, where each of these layers is from different materials and therefore a different chemical nature.[47] This method requires a colloidal template on which a layer of polymer is adsorbed by incubation in the solution of polymer, subsequent washes or the decrease in solubility of the polymer, and adding dropwise an immiscible solvent.[48] This procedure is then repeated with a second polymer and multiple layers of polymer are deposited sequentially, one after another.[49]

All these techniques have great advantages as they are applicable to versatile materials, such as the possibility to load and stabilize a wide range of organic or biological molecules, and particles can be released in a controlled manner (by diffusion through the polymer matrix, swelling followed by broadcast, or in response to the local environment).[50−52] The disadvantages of these methods are that they need more than one step for synthesis, using various solvents and surfactants; they are therefore expensive and their residues can harm the environment, they need to be modified to obtain nanometer-sized particle, and it is difficult to obtain particles with polymers of high molecular weight. Table 2 shows that the technique of electrospray, apart from sharing benefits with other methods, nowadays is considered one of the best options to obtain particles, showing few downsides in its application.

4. FIELD APPLICATION IN FOOD

The electrospray technique began to be used in medicine for the purposes of encapsulating drugs that deliver greater bioavailability from its prolonged and/or controlled release. A study by Lee et al. (2010) describes the synthesis of particles of drug coated with poly(lactic-*co*-glycolic acid) by the electrospray method. They showed that the studied system can reach almost 100% efficiency of encapsulation of drugs with proper adjustment of the method, through the variation of the concentration of PLGA and the electrical conductivity of solutions sprayed, obtaining particle sizes from 165 nm to 1.2 μm.[53]

Recently the use of the electrospray expanded beyond food technology, being a novel technique that is booming. In this area, the electrospray technique can be used for three purposes: primarily as an application in the area of inedible food being used to develop intelligent packaging that can resist the entry of a pathogen and cause putrefaction of food;[54] the second one is to apply the use of nanostructures as food ingredients, i.e., to produce particles encapsulating compounds or foodstuffs;[55] and the third application is to use polymeric materials from food to encapsulate any compound or active substance.[56]

4.1. Application Packaging and Containers for Food. The application of nanotechnology to obtain nanospheres has a great impact on many aspects of food and agricultural systems, from the development of new materials of food packaging to the systems of nanorelease, including the analytical control of

DOI: 10.1021/acs.jafc.5b01403
J. Agric. Food Chem. 2015, 63, 4699−4707

the food chain.[57] There are investigations where they review the incorporation of nanoparticles to containers containing preservatives, which are released when food starts to deteriorate, thus prolonging the shelf life and increasing their bioavailability.[58]

Devices are also used in plastic packaging named biosensors that offer the potential for the detection of pathogens and their toxins in real time and provide food security. Polydiacetylene (PDA) is an ideal selection to use as a sensor due to its unique optical properties. PDA molecules can form thin films or vesicles that change from blue to deep red in response to different stimuli, such as temperature, pH, and the presence of biological molecules.[59]

4.2. Encapsulation of Compounds for Use in Food. The nanospheres in the food industry are important for the incorporation of substances or compounds that can be used to encapsulate phytonutrients, prebiotics,[60] bioactive compounds,[61] antioxidants, or some flavor enhancers.[62]

There are studies demonstrating the application of the electrospray technique to encapsulate bioactive compounds. Jung et al. (2013) showed that it can be used to generate stable antimicrobial nanoparticles continuously from natural plant products ethanol extracts.[63] Eltayeb et al. (2013) encapsulated active compounds in a lipid polymeric membrane by the electrospray method, and the parameters used were an electric potential of 13−15 kV and a flow rate in the range of 10−15 μL min^{-1}; obtained particles were between 10 and 100 nm in diameter and encapsulation efficiency and performance were 69.5% and 69%, respectively.[5]

Bocanegra et al. (2005) developed an emulsion W−O of cocoa with aqueous solutions by the electrospray method, which proved to be an effective method for encapsulating ingredients based on aqueous foods such as flavors, flavorings, enzymes, salts, minerals, and vitamins in the micrometer range with a relatively high monodispersity and controllable geometry.[64]

Food oils are other substances that can encapsulated for use in the food, pharmaceutical, and cosmetic industries. Curcume oil has antibacterial, antifungal, antioxidant, and repellent properties of insects but is unstable and volatile. For this reason is encapsulated from a membrane of chitosan and alginate, forming nanometer-size polymer particles.[65]

4.3. Capsules of Polymeric Materials from Food. Micro- and nanoparticles of polymeric materials from food are particles with diameters of 100 nm or less and which have the characteristic of being biodegradable and can be made by the electrospray technique. These polymers are already used heavily in the pharmaceuticals industry, where they serve as the basis for systems of administration of drugs and other compounds. It has been shown that particles can also serve as carriers of antimicrobial components; for example, the nanoparticles of materials from food containing nisin exhibit much more activity against *Escherichia coli* O157: H7 than particles without nisin.[66] The most commonly used polymers are starch, cellulose, chitosan, alginate, gelatin, and gluten and wheat gliadins.

Chitosan is a polymer obtained from chitin widely used to develop micro- and nanocapsules.[67,68] The chitin can be found in marine animals as in the shell of shrimp and some terrestrial origin insects. Some studies have shown that chitosan is widely used and that it serves as a basis to produce particles and encapsulating compounds.[69] Xu et al. (2013) used the coaxial electrospray method to prepare and characterize nanoparticles of folate−chitosan−gemcitabine, obtaining nanoparticles from 200 to 300 nm with activity against pancreatic cancer, and concluding that it is simple to develop nanocomposites of chitosan by this method.[70]

Starch is a natural, renewable, and biodegradable polymer obtained from a variety of vegetables, formed from simpler compounds (amylose and amylopectin).[71] Starch has been widely used to develop micro- and nanoparticles for drug delivery and other natural compounds. Atyabi et al. (2006) studied the effect of cross-linked starch microspheres with epichlorohydrin, controlling the parameters such as morphology, size and release of the drug, type and duration of the cross-linking. Atyaba reported that a concentration 4% epichlorohydrin, 14 h of cross-linking, and 3% of the drug produced spherical particles in the range 425−500 μm.[72] Tan et al. (2009) reported the production of nanoscale, monodisperse, and controlled size of nanospheres of starch acetate.[73] Santander-Ortega et al. (2010) developed nanoparticles from 2 derived from starch (propyl-starch: ps-1 and ps-1.45) for encapsulating flufenamic acid, testosterone, and caffeine as transdermal release systems and obtained particles of 180.3 nm for ps-1 and 185.5 nm for ps-1.45.[74]

Alginate is a polysaccharide that is obtained from the cell walls of marine algae. This polysaccharide is used to develop micro- and nanoparticles for encapsulating substances. It can be used individually or with other materials to form composites.[75] Bhowmik et al. (2006) prepared nanocapsules of alginate loaded with testosterone for application as a prolonged release system and obtained particles of 34.5 nm.[76] Rastogi et al. (2007) prepared sodium alginate microparticles as a carrier hydrophilic for encapsulating isoniazid.[77] Results indicated that the size of the microspheres increased with increasing concentration of the polymer, the cross-linking agent, and the cross-linking time; an encapsulation efficiency of 40−91% was obtained.[77] Shadab et al. (2011) prepared alginate microparticles encapsulating acyclovir to prolong the gastric residence time. Results showed a particle size of 70.6 μm, and an encapsulation efficiency in the range of 51−80%.[78] Tabbei et al. (2012) in their research studied the effect of viscosity, non-Newtonian effects, and thixotropic of alginate solution prepared by the electrospray method.[79]

Gelatin and agar−agar are polymeric substances (polysaccharides) with a complex structure and are colorless and contain amino acids. Gelatin is obtained from collagen found in connective tissue of animals,[80,81] whereas agar−agar is obtained from plants.[82] Doi et al. (2012) developed biodegradable nanospheres of gelatin with a reduction of size distribution for the transport of DNA plasmids into cells.[83] Cursio et al. (2013) prepared biodegradable gelatin nanospheres to evaluate the effect of pH on the release of drugs.[84] Kanmani et al. (2014) reported the development of antimicrobial biopolymer films from extracts of grapefruit for packaging, as an alternative to the synthesis of films for packaging.[85]

Other material from food used to create nanocapsules is wheat gluten. In many countries mainly from the European Union, this material is considered as a byproduct for many processes where wheat is not used as food, for instance, to develop biofuels as well as having viscoelastic capacity.[86] Gluten is a polymer network formed mainly by two proteins (the gliadins and glutenins) attached to the starch granules within the endosperm of the wheat grain. Liao et al. (2012) developed nanocapsules of wheat gluten deaminated with succinic acid for the encapsulation of fish oil with particles of 527 nm.[87]

DOI: 10.1021/acs.jafc.5b01403
J. Agric. Food Chem. 2015, 63, 4699−4707

More recently gliadins, a wheat gluten protein, has been used to develop nanospheres as drug delivery systems.[88,89] Ezpeleta et al. (1996) developed nanoparticles of gliadin for the controlled release of retinoic acid.[90] Gulfam et al. (2012) used an electrospray system in plates to develop nanocomposites of gliadins and gliadin-gelatin for encapsulation and release of anticancer drugs (cyclophosphamide).[91] Results of this study showed that breast cancer cells in culture with 7% gliadin nanoparticles loaded with cyclophosphamide during 24 h suffered apoptosis, and it was concluded that the nanoparticles on gliadin can be a powerful tool for the encapsulation and controlled release of drugs against cancer.[91]

4.4. Other Applications in Food. In the chocolate industry, one of the oldest industries in the world, the electrospray technique has been used to improve the quality of products based on this food. Gorty et al. (2011) applied this technique in chocolate as a new method through which a thin coat and uniformity of chocolate can be obtained.[92] Electrospray helps in the reduction of losses and therefore reduces costs. The objective of this study was to determine the effect of various ingredients of chocolate on the viscosity, yield, and electrical resistance, in turn, determine the effect of these parameters on the quality of the chocolate, which was studied by measuring the size of the droplet and the percentage of covered area.[92]

Edible films and coatings are another application that can be used for food preservation, such as the waxes on fruits to avoid moisture loss and create a bright surface for aesthetic purposes.[93] A film is different from a coating; the film may form a material independently to control the exchange of oxygen, carbon dioxide, and ethylene involved in the process of respiration, and in addition, to prevent the loss of moisture; a coating on the food provides sterility to the surface of the food and helps avoid the loss of important components. Polysaccharides, proteins, and lipids are examples of materials to develop coatings and edible films.[93]

Du et al. (2008) evaluated the storage and antimicrobial activity of edible films of apples containing carvacrol to avoid contamination by *E. coli* O157: H7.[94] Ravishankar et al. (2009) developed edible films of apple containing an extracted antimicrobial plant that inactivated foodborne pathogens in meat and poultry products.[95] Morsy et al. (2014) incorporated essential oils and pullulan nanoparticles in films in order to control food-borne pathogens in meat and poultry products.[96] Kurt et al. (2014) characterized a new edible biodegradable film made of glucomannan and evaluated the rheological properties of the solution.[97] Khazaei et al. (2014) prepared and characterized an edible film from seed gum basil (*Ocimum basilicum L.*) and glycerol as plasticizer and obtained favorable results.[98] Table 3 shows different materials that can be used in the electrospray technique, with potential applications in the food area.

5. FUTURE PERSPECTIVES

The electrospray technique can be applied to produce a wide range of materials at the micro- and nanoscale, which have already been produced by conventional techniques such as nanoprecipitation, emulsion−diffusion, double-emulsification, polymer-coating, and layer by layer. In addition, the use of this new technique produces important advantages; for example, as it is simple, low-cost, does not use various solvents (aqueous and organic), does not use surfactants, and is produced in a single step.

Table 3. Food Applications Where Electrospray Technique May Be Used

material	aplication food	reference
pullulan−corn starch	food packaging	Yan et al.[99]
pullulan−sodium alginate	food packaging	Xiao et al.[100]
cellulose−alginate films	food packaging	Sirviö et al.[101]
chitosan	capsule preparation	Massotti et al.[102]
alginate	capsule preparation	Paques et al.[103]
calcium alginate	capsule preparation	Liu et al.[104]
hyme essential oil and apple skin polyphenols	edible films	Espitia et al.[105]
gelatin-chitosan composite	edible films	Jridi et al.[106]
fish gelatin−chitosan blend edible films	edible films	Fakhreddin et al.[107]
mucilage films containing thyme essential oil	encapsulation of essential oil	Jouki et al.[108]
electrosprayed zein prolamine and omega-3 fatty acid	stabilization of compounds	Torres-Giner et al.[109]

Furthermore, the electrospray technique can be applied to the agrifood sector to develop micro- and nanoparticles of controlled release and prolonged fertilizer.[110] There are studies that show the importance of research in this sector since the demand to make the best fertilizer is a very broad challenge. Currently conventional fertilizer application cause losses to the atmosphere by evaporation, leaching, and denitrification, causing great economic losses and environmental pollution.

6. CONCLUSIONS

The electrospray technique is considered one of the best options for developing micro- and nanospheres above conventional techniques of nanoprecipitation, double-emulsification, and layer by layer, among others. This technique has been applied in the pharmaceutical industry, but today is being applied in the food industry and is seeing great advantages in the encapsulation of bioactive compounds, aromatic enhancers, and manufacturing smart packaging, edible films, and coatings in food. This technique could also be applied in the agrifood sector for the preparation of controlled and/or prolonged release systems of fertilizer or agrochemicals, for which more research must be done.

Supporting Information

ABSTRACT: The lignin deposition in the stem of two sugarcane genotypes was assessed on exposure to water stress. The lignin content and the morphoanatomical characterization of the stem indicated that IACSP94-2094 plants are more lignified than those of IACSP95-5000 genotype, under normal water supply conditions, which was especially associated with higher lignin contents in the rind of mature internodes. Water deficit had negative impact on the biomass production, mostly with IACSP94-2094 plants, possibly due to stress severity or higher susceptibility of that genotype during the stem-lengthening phase. Water deficit led to significant alterations in the expression levels of lignin biosynthesis genes and led to an approximate 60% increase of lignin content in the rind of young internodes in both genotypes. It is concluded that the young rind region was more directly affected by water stress and, depending on the genotype, a higher lignin accumulation may occur in the stem, thus implying lower quality biomass for bioethanol production.

KEYWORDS: *Saccharum, lignocellulosic biomass, gene expression, genetic variability, water stress*

INTRODUCTION

Sugarcane (*Saccharum* spp.) is a C4 grass accounting for an abundant and promising source of plant biomass for the production of biofuels. Residual sugarcane biomass (mainly bagasse and tops + young leaves) accounts for two-thirds of the total energy of the plant, the potential of which is partially used with the incineration of the bagasse, so as to generate electricity at alcohol and sugar mills.[1] It is estimated that a mill currently and daily producing 1000000 L of ethanol from sugarcane juice, rich in sucrose, is potentially capable of initially generating an additional 150000 L of ethanol from the bagasse, provided that the cellulose there contained was available by means of acid hydrolysis, for fermentation with microorganisms.[1] Ethanol derived from bagasse is called second-generation ethanol or cellulosic ethanol, the use of which is restricted by the recalcitrance of the cell wall.

Sugarcane bagasse consists of approximately 50% cellulose, 25% hemicellulose, and 25% lignin.[2] The recalcitrance of sugarcane bagasse and other biomasses is partially attributed to lignin, which serves as a natural mechanical barrier preventing the access of hydrolytic enzymes to cellulose fibrils. Additionally, lignin can absorb the enzymes used during hydrolysis of lignocellulosic material, thus impairing process efficiency. Furthermore, some polymer degradation products may inhibit subsequent fermentation phases.[3]

Lignin is a phenolic polymer complex derived mainly from three hydroxycinnamoyl alcohols varying in methoxylation rate: monolignol *p*-coumaryl, coniferyl, and sinapyl. After incorporation in the lignin polymer, via combinatorial coupling reactions, monolignols originate the subunits *p*-hydroxyphenyl (H), guaiacyl (G), and syringyl (S), respectively.[4,5] Polymerization takes place by means of addition of new monolignol radicals to the growing polymer, usually via a connection in position β, such as β-O-4, β-5, and β-β. The interunit linkage β-O-4 (β-aryl ether) is the most frequent and also the most easily cleaved by chemical processes, whereas condensed linkages (β-5, β-β, 5-5, 5-O-4, and β-1) are more resistant to chemical degradation.[4,6]

Lignin content and composition vary among different taxons, cellular types, and cellular wall layers and are modified by environmental factors throughout plant development.[7] In gymnosperms (softwood), lignin is formed basically by G units and traces of H units, whereas in dicotyledonous angiosperms (hardwood) it consists mainly of G and S units, with few traces of H units. In grasses (monocotyledonous), G

and S units are incorporated at similar levels, while H units are relatively higher, in comparison to dicotyledonous species.[4]

Research into grasses has revealed that the incorporation of H, G, and S units in the lignin polymer is regulated spatiotemporally, varying in primary and secondary cellular walls and also in different tissues.[8,9] Lignin topology and composition in different sugarcane internodes vary among the main cellular types present in the stem: fibers incorporate a significant amount of sinapyl alcohol, forming lignin at a S > G > H proportion; in xylem vessels, G and H units prevail in the protoxylem, whereas metaxylem features a fiberlike composition; parenchyma cells have a great deal of phenolic acids, thus preventing accurate determination of the proportion of each lignin unit.[8] Similarly to other grasses, sugarcane features a significant amount of hydroxycinnamic acids associated with the cellular wall, at higher levels in the parenchyma tissue than in the vascular bundles. Sinapyl, ferulic, and *p*-coumaric acids are preferably deposited in the early stages of lignification, presenting different relative proportions as tissues mature.[8]

Sugarcane internode anatomy shows that it consists basically of parenchyma cells and vascular bundles, featuring two different morphological regions, the rind and the pith. The rind is the region containing mostly vascular bundles, in turn constituted by vessels surrounded by a great number of fibers. The pith is formed by parenchyma cells (which store sucrose), where the vascular bundles are distributed, at a lower number than in the rind.[10]

A recent systematic study reported on physiological, morphological, biochemical, and molecular data for the investigation of lignin deposition throughout sugarcane stem development.[11] The outcome was a detailed profile of lignin and phenolic compounds related to the formation of the cellular wall in two contrasting genotypes for lignin content, highlighting differences regarding polymer content and composition, S/G ratio, and gene expression of lignin biosynthesis in the rind and in the pith of sugarcane internodes.

Alteration in lignin biosynthesis is induced by a range of environmental stresses, such as drought, low temperature, UV-B radiation, mineral deficiency, and pathogen infection.[12] Several studies in corn reported an increased gene expression in lignin biosynthesis and varied content and composition in plants exposed to water deficit.[13,14] Other studies have revealed that the gene expression and presence of enzymes related to lignin and its deposition on the cellular walls can be differentially regulated during water stress. cDNA-AFLP (amplified fragment length polymorphism) and Northern blot analyses have evidenced that the expression of the genes playing a role in cellular growth and extensibility of the cell wall in rice roots was potentiated in the early stages of water stress, whereas gene expression related to lignin biosynthesis was considerably higher during the intermediate and final stages of water deficit.[15] A proteomic study of *Citrullus lanatus* roots submitted to water deficit has proven that proteins related to lignin synthesis, such as CCoAOMT and various class III peroxidases (involved in lignification), were induced mainly in the final stages of the stress.[16]

Supported by a previous systematic study of lignin deposition in sugarcane,[11] the present work has looked into the effects of water deficit on lignin metabolism in the stem of two sugarcane genotypes.

MATERIALS AND METHODS

Plant Material and Growth Conditions. The experiment was carried out at the experimental area of the Department of Plant Biology of the State University of Campinas, at Campinas, SP, Brazil (22°81′77′′ latitude S; 47°03′83′′ longitude W). Two commercial *Saccharum* spp. genotypes were used: IACSP94-2094, deemed drought-resistant,[17,18] and IACSP95-5000, which has not been characterized for drought tolerance so far. Plants were obtained from single nodes of mature culms collected from plants in the field. These "one eye setts" were left to germinate (January 2011) on trays containing vermiculite, and after approximately 1 month 15 plants of each genotype were transferred to 25 L plastic (35 cm height × 25 cm top diameter × 28 cm bottom diameter) vases containing 20 L of commercial organic soil mixture and kept in a greenhouse under no temperature, light, or air humidity control. Secondary sprouts were removed, and only the main stem remained in each vase. The plants were irrigated on a daily basis until the beginning of the water-restriction treatment, on May 2011.

Water-Stress Treatment and Plant Collection. At the age of 5 months, the plants were submitted to three water regimes: namely, severe drought (SD), moderate drought (MD), and control (daily irrigation). SD and MD correspond to maintenance of the water content in the substratum at 40% and 80% of the total water storage capacity of the soil (C_w). Five plants of each genotype were used in each treatment. The C_w value was estimated using the fresh mass of the soil after water saturation (C_{fm}) and the dry mass (C_{dm}) after soil drying in a greenhouse for 24 h at 105 °C and applied in the equation $C_w = (C_{fm} - C_{dm})/C_{fm} \times 100$. At the beginning of the treatments, the vases were water-saturated, drained of water, and weighed. From that moment on, irrigation was suspended and the vases were weighed every second day, assuring maintenance of C_w at 40% or 80% by water addition, considering 1 mL = 1 g. The plants were kept under such conditions for 60 days. Figure S1 in the Supporting Information shows water replacement volumes throughout the stress period, as well as temperature and relative air humidity variation. The average maximum and minimum air temperatures in the greenhouse were 28.4 ± 3.8 and 11.8 ± 2.6 °C, respectively; the relative humidity was not controlled.

By the end of a 60 day period (July 6th, 2011) the following parameters were obtained for each replicate in each treatment: number of green leaves (N_l), number of stem internodes (N_i), stem lengths (L_s), fresh stem mass (FM_s), dry leaf mass (DM_l), and dry root mass (DM_r). For N_l determination only leaves featuring over 50% of leaf blade colored green were considered. Measurements of the leaves and root dry mass were determined after drying the material at 72 °C for 72 h. Stems were numbered from apex to base, so that internode 1 (I1) corresponded to the internode in which the leaf +1 was inserted. The internode stem diameter was measured by means of a digital caliper rule. Then two distinct internode maturation stages were selected for analysis: young or immature region, made of a pool of internodes I1−I3, and mature region, a pool of internodes I8 and I9. Each sample of these stages was separated in rind and pith, as previously identified.[19] The stem material was frozen in liquid nitrogen and divided into two parts, one for biochemical analyses and the other for molecular analyses. The samples for biochemical analyses were lyophilized at −60 °C for 72 h and stored at −80 °C, whereas the samples for molecular analyses were kept at −80 °C.

Biochemical Analyses. Approximately 50 mg of lyophilized (pith) and pulverized material was extracted twice with 1 mL of 80% ethanol in a water bath at 40 °C for 30 min with occasional vortexing. The supernatants were recovered by centrifugation at 8000*g* for 15 min, and the extracts were combined and dried in a SpeedVac (Savant, São Paulo, Brazil). The residue was solubilized in 1 mL of Milli-Q water. For soluble sugar determination 50 μL of each sample was homogenized in 950 μL of 80% acetonitrile in water and an aliquot of 4 μL was injected in an Acquity UPLC-MS (Micromass-Waters, Manchester, U.K.) mass spectrometer coupled to a TDQ triple quadrupole. The chromatographic separation was carried out in an Acquity UPLC C18-BEH column (2.1 mm × 50 mm, 1.7 μm) at a 0.2 mL min^{-1} flow rate. A gradient of 20−35% of 0.1% NH_4OH solution

[a]Sugarcane assembled sequence.

in water (solvent B) and acetonitrile containing 0.1% NH_4OH (solvent A) was used to elute the compounds from the column. The electrospray ionization in the mass spectrometer was set to the negative mode under the following conditions: capillary 3.0 kV and cone 30 V, temperature at ionization source 150 °C, and desolvation temperature 350 °C. The sugar content was estimated from calibration curves obtained with pure standards of glucose, fructose, and sucrose. Free proline content was determined spectrophotometrically.[20]

Morphoanatomical Analyses. Transversal sections of the middle of the third (I3) and ninth (I9) stem internodes in plants of both genotypes, not submitted to water stress, were obtained manually and treated with phloroglucinol[21] for lignin analysis with an optical microscope (Olympus BX51).

Lignin Analyses. The analyses of soluble lignin oligomers in the stem were carried out with 100 mg of lyophilized material according to ref 22. Lignin content was estimated by derivatization with thioglycolic acid from 15 mg of lyophilized material,[23] using lignin alkali, 2-hydroxypropyl ether (Sigma-Aldrich), to build a calibration curve.

Gene Expression Analyses. Gene expression was assayed only in samples from severe drought (SD) treatment. Approximately 200−300 mg of tissue (pith and rind) pulverized in liquid nitrogen was used for the extraction of total RNA.[24] After DNase treatment (Ambion), total RNA was quantified in a spectrophotometer at 260 nm and the quality checked in 1% agarose gel with ethidium bromide and UV visualization. The first cDNA strand was synthesized from 1 μg of total RNA using a Superscript III Reverse Transcriptase kit (Invitrogen, Carlsbad, CA, USA), in accordance with the manufacturer's instructions. The relative number of transcripts was estimated for 12 genes related to lignin biosynthesis. The analyzed genes and their primers are given in Table 1.[11] Quantitative RT-PCR (qPCR) analyses were carried out with a QuantiFast SYBR Green PCR kit (Qiagen, São Paulo, Brazil) on 96-well plates using 50×-diluted cDNA. The reactions were analyzed with an iCycler iQ5Multicolor Real-Time PCR Detection system (Bio-Rad USA) and the correction of the C_t (cycle threshold) values among the plates in the same assay (the same gene) was based on an intercalibrating sample and automatically performed by an iQ5 software tool. Calculation of the relative gene

[a]Different uppercase letters indicate significant differences among water regimes within the same genotype; different lowercase letters indicate differences between the two genotypes under the same water regime. Means were compared by the Tukey test, $P \leq 0.05$. Each value represents the mean ± standard error of five replications.

expression was based on the $\Delta\Delta C_t$ method,[25] and *GAPDH* (glyceraldehyde 3-phosphate dehydrogenase) was the reference gene to normalize expression values in the different samples.[11,26]

Statistics. The experiment was carried out in an entirely randomized design, in a 2 × 3 factorial (two genotypes and three water regimes), with five biological replications. For lignin quantification, data were analyzed as a 2 × 3 factorial (two internode maturation stages and three water regimes) for each sugarcane genotype. Each experimental unit consisted of one plant per vase. Data were submitted to variance analysis (Statistics software, version 10), and significant differences in treatment means were compared by means of the Tukey test and the *F* test ($P \leq 0.05$). Results were presented as means + standard error. For the biochemical and molecular analyses, each replication represents the average of three technical determinations of each sample.

RESULTS

Biometry. Except for dry root mass (DM_r), we have observed that control IACSP94-2094 genotype plants featured better growth rates than those of the IACSP95-5000 genotype (Table 2). We have verified, for instance, that, regarding the number of internodes (N_i), stem length (L_s), and fresh stem mass (FM_s), the performance of IACSP94-2094 plants was 22%, 58%, and 51% better than that of IACSP95-5000 plants, respectively.

Water restriction negatively and progressively (regarding stress intensity) affected plant growth parameters in both sugarcane genotypes (Table 2). Moderate drought (MD) had few effects on plant growth, so that only N_l (in IACSP94-2094) and FM_s parameters (in IACSP95-5000) were reduced. Under severe drought (SD) conditions, IACSP94-2094 plants had significant reduction of all analyzed parameters, in comparison with irrigated plants. N_l, DM_l, and DM_r also decreased in IACSP95-5000 plants under SD, nevertheless without significant alteration in stem-related parameters (N_i and L_s).

The internode stem diameter of stressed plants had a growth profile resembling that of control plants (Figure 1), although the average stem diameter was greater in IACSP95-5000 genotype plants (21.25 mm) than in IACSP94-2094 (19.98 mm). In these plants, intermediate internodes (I4−I8) presented an average diameter above those of the other stem regions, in both sugarcane genotypes. Regardless of the water regime, the plants tended to present lower basal internode (mature) diameters, with values approaching those obtained for apical internode (immature) diameters (Figure 1).

Water deficit caused a reducion of the internode diameter along the stem. IACSP94-2094 plants appear to have been more strongly affected, especially during severe drought. The

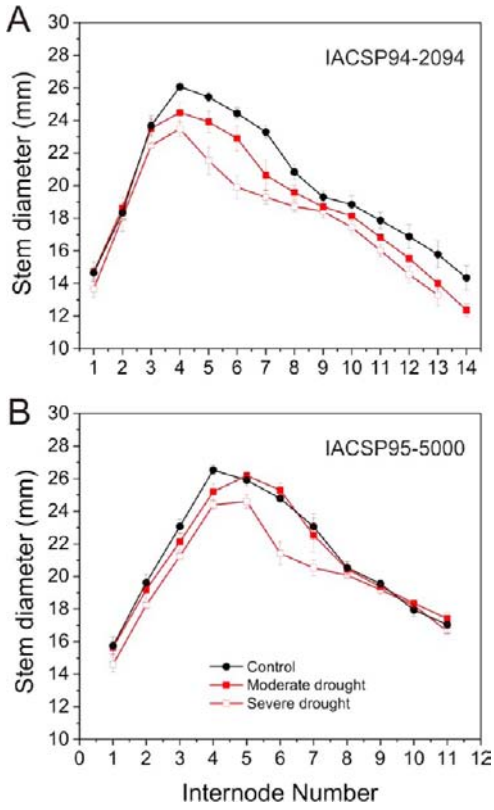

Figure 1. Diameters of stem internodes of plants of sugarcane genotypes IACSP94-2094 and IACSP95-5000 grown under different water regimes. Data are means ± standard error of five replicates.

intermediate internode region presented the most significant reductions: i.e. 14.3% in IACSP94-2094 and 9.3% in IACSP95-5000 (Figure 1). Morphological alterations, such as shortening and/or thinning of the internodes, were observed in both sugarcane genotypes, possibly as a result of cultivation conditions in the vegetation house.

Soluble Sugars and Proline. Sucrose content in the well-watered control plants was higher in immature internodes of IACSP94-2094 genotype, as opposed to IACSP95-5000 genotype, while in mature internodes similar values were observed in the two genotypes (Figure 2A). The amount of sucrose in control plants of both genotypes was approximately 5−6 times higher in mature internodes than in immature internodes. Plants under water restriction (MD and/or SD) posed significantly increased sucrose content in immature

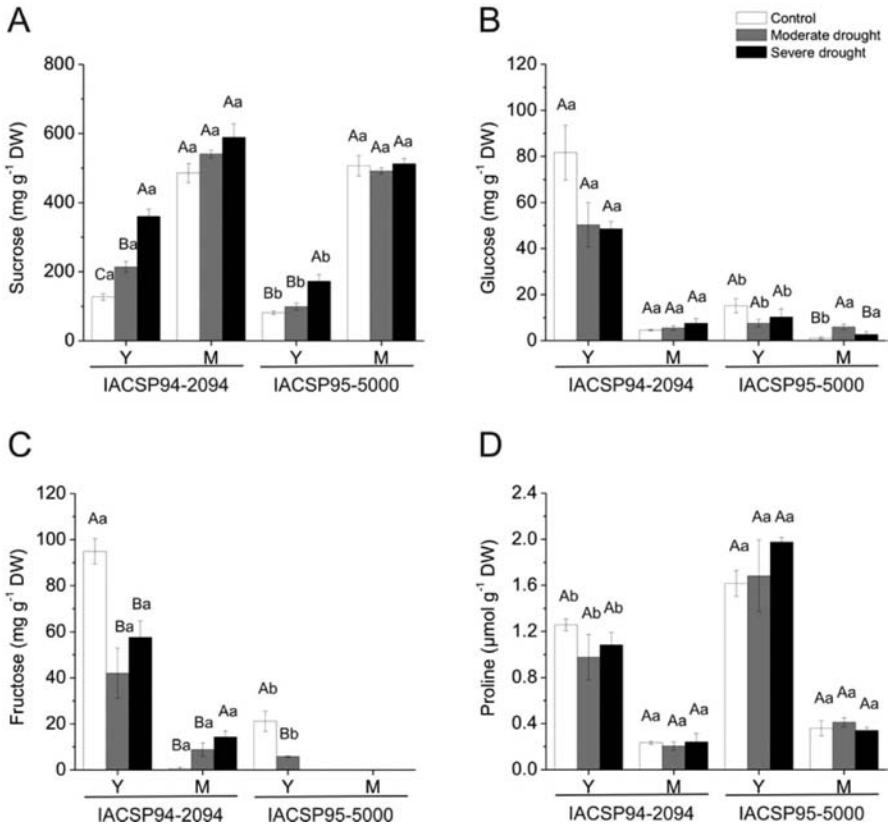

Figure 2. Contents of sucrose (A), glucose (B), fructose (C), and proline (D) in immature internodes (Y) and in mature internodes (M) of plants of sugarcane genotypes IACSP94-2094 and IACSP95-5000 grown under different water regimes. Different uppercase letters indicate significant differences among water regimes within the same genotype, whereas different lowercase letters indicate differences between the genotypes under the same water regime. Data are means ± standard error of four replicates.

internodes. No significant difference was observed in mature internodes of the two sugarcane genotypes under the same water regime (Figure 2A).

Control plants presented higher contents of reducing sugars in immature internodes, in relation to mature internodes (Figures 2B,C). In those plants, we observed that the relative amounts of glucose and fructose were higher in IACSP94-2094 than in IACSP95-5000 in immature and mature internodes. Under water deficit, glucose and fructose contents tended to be reduced in immature internodes, in comparison with that in control plants; however, this reduction was only significant for fructose, in both sugarcane genotypes (Figure 2C). In mature internodes, such sugars posed values similar to those observed in control plants in both genotypes (except for IACSP94-2094 plants under severe drought, which featured higher glucose content in relation to control plants). It was not possible to detect fructose contents in mature internodes of IACSP95-5000 plants (Figure 2C).

Regardless of the water regime, IACSP95-5000 genotype plants always had higher proline content in immature internodes than IACSP94-2094 genotype plants. Free proline contents were higher in immature internodes in comparison with those of mature internodes in both genotypes. Proline content in the stem was not significantly affected by water deficit in either evaluated sugarcane genotype (Figure 2D).

Morphoanatomical Analyses. The analyses of the internal morphology revealed that the sugarcane stem of both varieties studied here consists basically of parenchyma cells, concentrated on the pith region, and of vascular bundles, more abundant in the rind region. Reaction with phloroglucinol evidenced a differentiated lignin deposition pattern in the sugarcane genotypes analyzed in this study. IACSP94-2094 genotype stems present a premature and more intense lignification process, in comparison to IACSP95-5000 genotype plants, as indicated by the thickening of cellular walls and the lignification level of the epidermis and of the vascular bundle elements of the xylem in immature internodes (Figures 3A,C,E,G and 4A,C,E,G).

We have observed that, in immature internodes of IACSP94-2094 plants, the tracheal elements of protoxylem and metaxylem are already lignified (Figures 3E,G), while fibers and subepidermal layers happen to be in an early lignification phase (Figure 3A). In mature internodes, lignin is present in practically all tissues, except for chlorophyllin parenchyma cells (Figure 3B) and phloem cells in the vascular bundles (Figure 3F,H). Tissues tend to become too rigid, because parenchyma cells feature thicker and more lignified walls all over the organ; in addition, xylem fibers also present rather thick and lignified cellular walls (Figure 3F,H).

Stems of IACSP95-5000 plants presented a discrete lignification degree in immature internodes, in which only protoxylem tracheal elements of the vascular bundles were lignified (Figure 4A,E,G). In mature internodes, parenchyma cells were lignified (Figure 4F,H); nevertheless, they posed a less intense reaction in the presence of phloroglucinol, in comparison to IACSP94-2094 plants. Similarly, fibers also became less stained in vascular bundles located both in the rind (Figure 4B,F) and in the pith (Figure 4H).

Abbreviations: pc = parenchymal cell; ep = epidermis; f = fibers; mx = metaxylem; cp = chlorophyllin parenchyma; ph = phloem; vb = vascular bundle; px = protoxylem. Bars: (A, B and E, F) 50 μm; (C, D and G, H) 20 μm.

Soluble Lignin Oligomers. The analyses of soluble lignin enabled outlining the profiles of monomer and oligomer precursors of sugarcane polymer, on the basis of the frequency of such structures, as indicated in Table 3. We have identified G and S monolignols and their aldehydes (coniferyl and sinapyl aldehyde) and four dimers and four trimers of lignin. Type 8-O-4 linkages (less recalcitrant) were relatively frequent among the identified structures; however, linkages 8-5 and 8-8 (more recalcitrant) were also found.

G monomers (coniferyl alcohol, m/z 179) were found more frequently than S monomers (sinapyl alcohol, m/z 209), while H units (*p*-coumaryl alcohol, m/z 149) were not detected (Figure 5), thus confirming previous results.[11] In both genotypes, lignin dimers tended to prevail in the rind and in the pith of immature internodes (YR and YP) in comparison to their content in mature internodes; trimers, in turn, tended to prevail in mature internodes.

In IACSP94-2094 plants, G monomers were more frequently detected in mature internodes than in immature internodes (Figure 5A). Under stressing conditions, G levels tended to decrease in mature internodes (rind). Dimers predominated in immature internodes (YR), and their frequency did not appear to be affected by water deficit. Among dimers, G(8-5)H (m/z 327) was the rarest, while S(8-O-4)G (m/z 435) was the most abundant. Among trimers, G(8-O-4)S(8-8)S (m/z 613) was the least frequent, detected only in mature internodes. In contrast, S(8-O-4)G(8-O-4)S (m/z 631) appeared to be the most frequent trimer, being absent only in the pith immature internodes. Structures G(8-O-4)G(8-5)G (m/z 553) and G(8-O-4)S(8-5)G (m/z 583) were found in immature internodes only under water restriction (MD and SD).

J. Agric. Food Chem. 2015, 63, 4708−4720

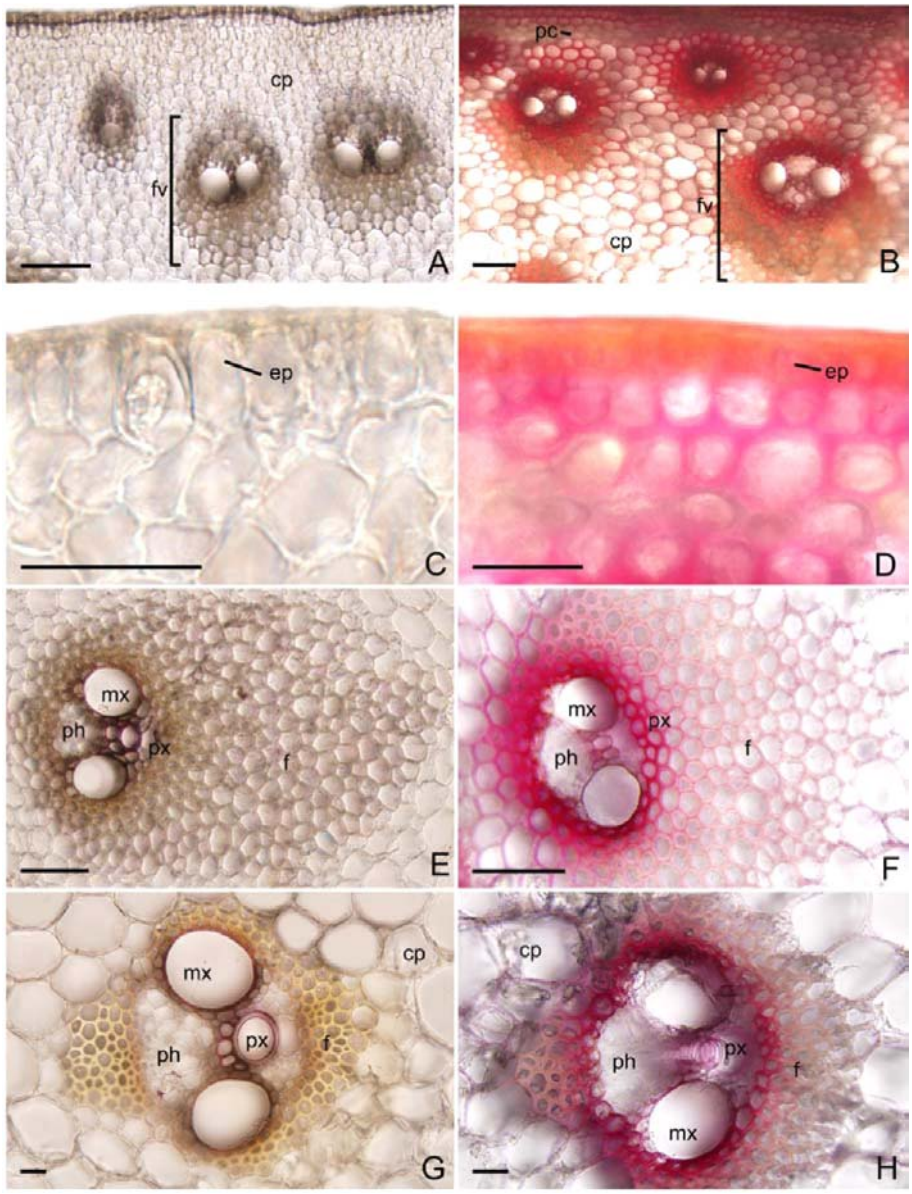

Figure 4. Transversal sections of different regions of sugarcane stems of genotype IACSP95-5000 submitted to acid phloroglucinol for lignin detection; (left column) immature internode; (right column) mature internode; (A, B) rind region; (C, D) detail of epidermis and adjacent cellular layers; (E, F) detail of rind vascular bundle; (G, H) detail of pith vascular bundle. Abbreviations: pc = parenchymal cell; ep = epidermis; f = fibers; mx = metaxylem; cp = chlorophyllin parenchyma; ph = phloem; vb = vascular bundle; px = protoxylem. Bars: (A, B and E, F) 50 μm; (C, D and G, H) 20 μm.

In the IACSP95-5000 genotype, G levels in immature and mature internodes appeared to be negatively affected by water deficit (Figure 5B). Dimers also tended to prevail in immature internodes; their abundance posed no apparent correlation with water stress. In mature internodes, G(8-O-4)S(8-5)G (m/z 583) and S(8-O-4)G(8-O-4)S (m/z 631) were the most abundant trimers. In this tissue region, the presence of G(8-O-4)G(8-5)G (m/z 553) was apparently influenced by the water regime, tending to be more frequent in MR and MP, under drought conditions (MD and SD). On the other hand, S(8-O-4)G(8-O-4)S (m/z 631) tended to be less frequent under water stress.

Lignin Content. Lignin content was positively associated with the maturation status of stem internodes, so that the amount of lignin was higher in mature internodes than in immature internodes (Figure 6). IACSP94-2094 genotype control plants featured lignin content 4.6 times higher in mature internodes in comparison to that in immature internodes (rind region); on the other hand, IACSP95-5000 genotype control plants posed a 3.2× ratio. In mature internodes, the pith was also approximately 2.7× as lignified as in immature internodes, in both sugarcane genotypes (Figure 6). Lignin contents measured in the stems of irrigated plants were similar in the two sugarcane genotypes analyzed, except for MR, which proved to be more lignified in IACSP94-2094, in comparison to that in IACSP95-5000 plants.

Water deficit has induced discrete lignin accumulation in immature internodes (YR and YP) in both sugarcane genotypes (Figure 6). In mature internodes, IACSP95-5000 plants featured significantly increased MR lignin content, on submission to severe water restriction (SD) (Figure 6B).

Gene Expression. The analyses of the expression pattern of the genes coding for enzymes of the lignin biosynthesis pathway in sugarcane showed that the number of transcripts varied in accordance with the developmental phase of stem internodes, tissue type (rind or pith) and water regime (Figure 7). In the control plants, i.e. under irrigation, most analyzed genes were more strongly expressed in mature internodes (MR and/or MP), except for *Sh4CL2* and *ShCCoAOMT3* genes, which featured a higher number of transcripts in immature internodes for some tissues (Figure 7C,H). *ShCAD8* had similar expression patterns in immature and mature internodes (YR, YP, MR, and MP) in control plants (Figure 7L). When comparing transcript levels in the rind and in the pith, we observed that the expression of the analyzed genes was higher in the rind, independently of the maturation phase of stem internodes.

Water deficit has induced alterations in the expression of various genes in lignin biosynthesis (Figure 7). The expression patterns of all analyzed genes were similar in IACSP94-2094 and IACSP95-5000 plants, although stress response intensities differed. In a general way, severe water restriction (SD) has led to increased transcripts of various genes in immature internodes, mainly in YR. Under water stress, except for *ShCCoAOMT3* (Figure 7H) and *ShCAD8* (Figure 7L), all other genes were significantly more expressed in immature internodes (YR), in comparison to the control conditions, in at least one of the analyzed genotypes. Similarly, genes *ShPAL1*, *Sh4CL2*, *ShCOMT1*, *ShCCoAOMT3*, and *ShCCR1* also featured a higher number of transcripts, due to drought in YP (Figure 7A,C,F,H,J). In contrast, mature internodes presented an overall reduction in the expression of the analyzed genes, in comparison to watered control plants. Transcripts of *ShPAL1*, *ShC4H1*, *ShC3H1*, *ShCOMT1*, *ShCCoAOMT1*, *ShCCoAOMT3*, *ShF5H*, *ShCCR1*, and *ShCAD2* genes were significantly decreased in MP under stress, in one or both sugarcane genotypes (Figure 7A,B,E−K). Such reduction in the expression levels was also observed for *ShPAL1*, *ShC3H1*, *ShCOMT1*, *ShCCoAOMT1*, *ShCCoAOMT3*, *ShF5H*, and *ShCAD2* genes in MR, in comparison to irrigated control plants (Figures 7A,E−I,K). Apparently, *ShHCT-like* and *ShCAD8* were slightly affected or not affected at all by the drought, maintaining practically unaltered expression levels (Figure 7D,L). Figure S1 in the Supporting Information shows the summarized main changes in gene expression levels in plants submitted to severe water deficit (SD) and their effects on lignin content in stem internodes.

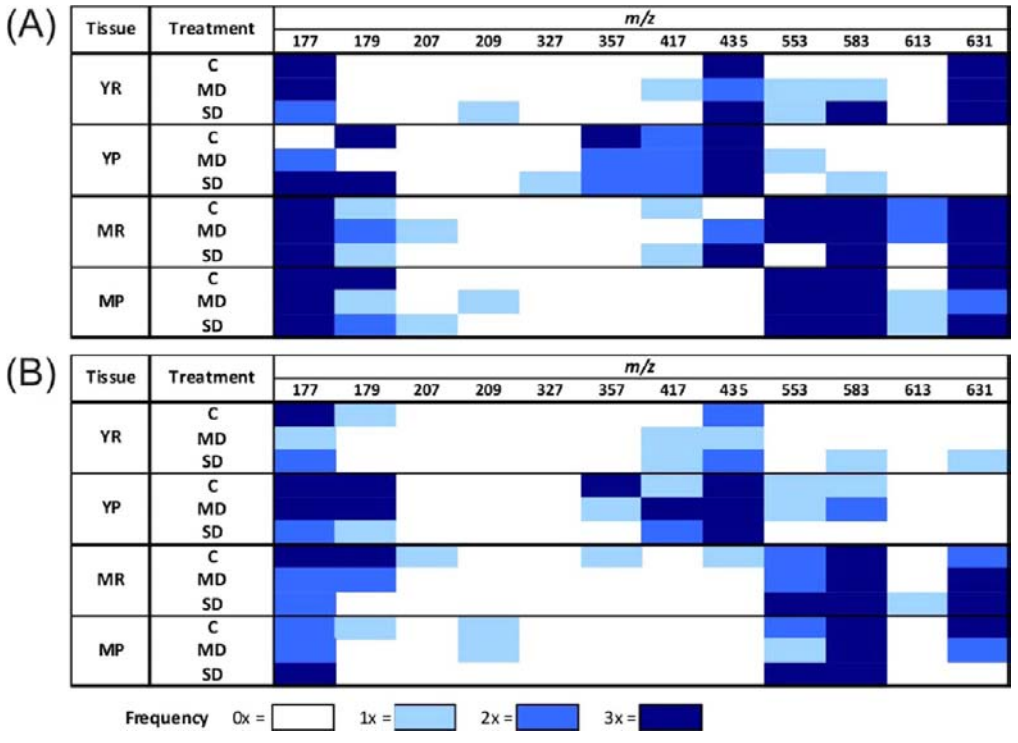

Figure 5. Soluble lignin detection pattern obtained by UPLC-MS analyses in plants of sugarcane genotypes IACSP94-2094 and IACSP95-5000 grown under different water regimes. The frequency of each structure is represented in the diagram by different hues, thus, 0× (white) indicates that the structure was not detected in any biological replicate, and 1×−3× indicate that the structure was detected in one, two, or three biological replicates. Abbreviations: YR = young rind; YP = young pith; MR = mature rind; MP = mature pith.

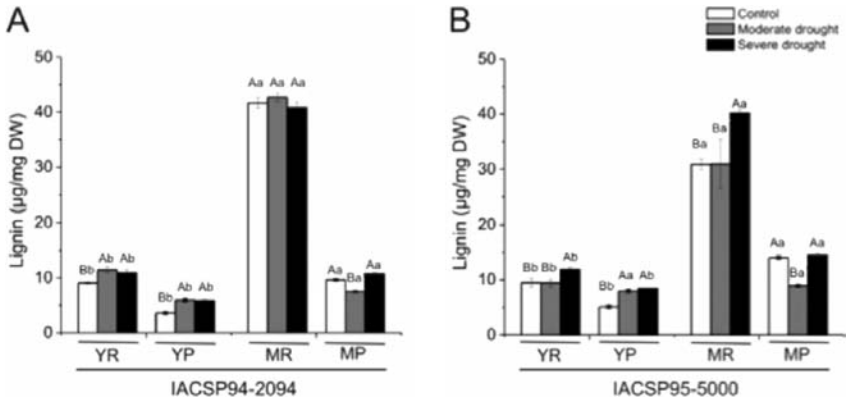

Figure 6. Lignin content in the rind and pith from the stem of plants of sugarcane genotypes IACSP94-2094 (A) and IACSP95-5000 (B) grown under different water regimes. Different uppercase letters indicate significant differences among the water regimes in the same internode, whereas different lowercase letters indicate differences among the internodes (immature or mature) under the same water regime. Data are means ± standard error of four or five replications. Abbreviations: YR = young rind; YP = young pith; MR = mature rind; MP = mature pith.

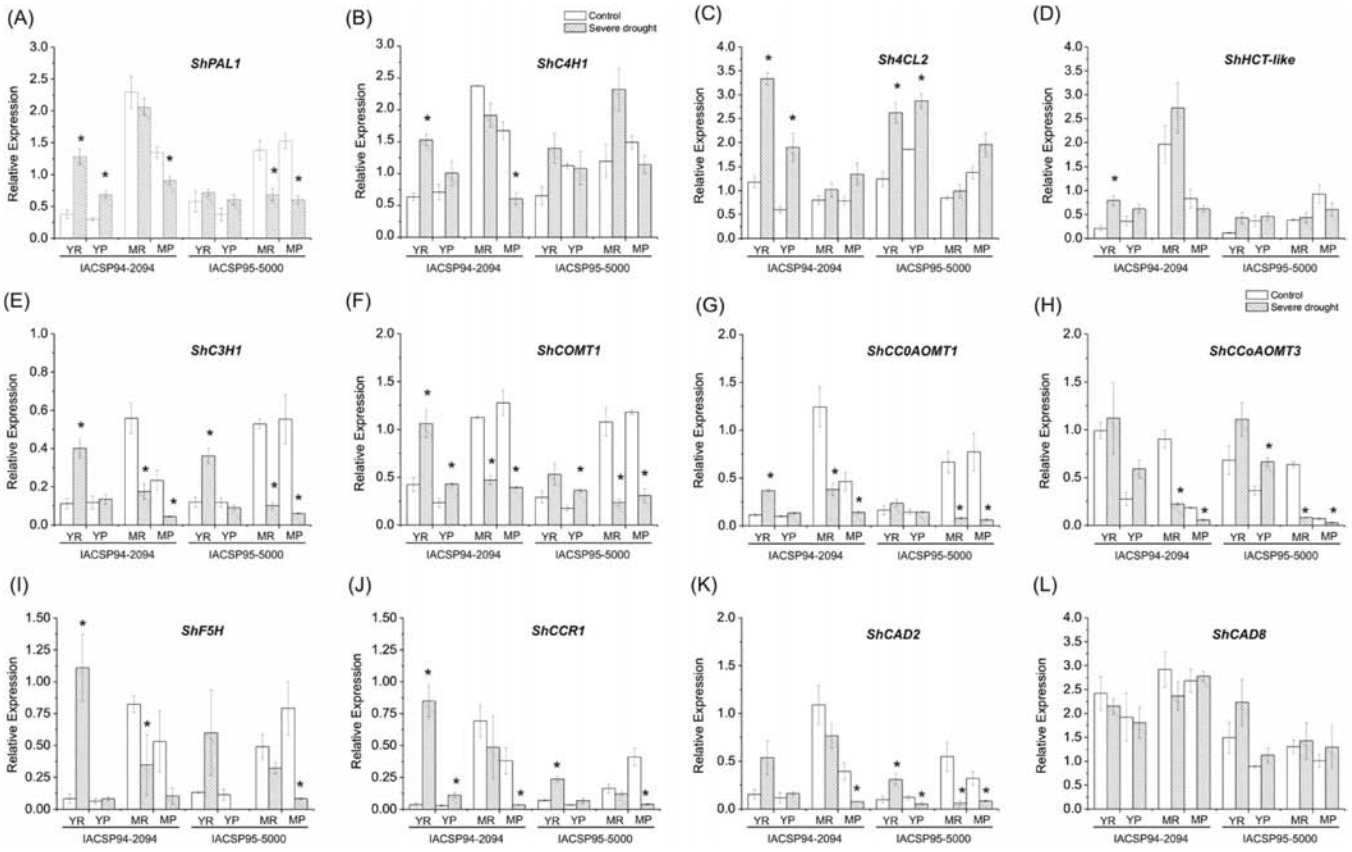

Figure 7. Relative expressions of lignin biosynthesis related genes in the pith and rind from the stem of plants of IACSP94-2094 and IACSP95-5000 sugarcane genotypes grown under different water regimes (A–L). Expression values were normalized by means of *GAPDH* as a reference gene; relative expression was calculated by the $\Delta\Delta C_t$ method. Severely stressed plants (SD) marked with an asterisk differ from the respective control plants (C) within the same genotype group. Data are means ± standard error of three replicates. Abbreviations: YR = young rind; YP = young pith; MR = mature rind; MP = mature pith.

DISCUSSION

Sugarcane bagasse is a material that is coproduced by sucro-alcohol industries, readily available for utilization in the production of cellulosic ethanol. The conversion of the vegetative biomass into ethanol is mainly limited by biomass recalcitrance to chemical, enzymatic, or microbial attack.[27,28] Studies involving gene manipulation in the lignin biosynthesis pathway have indicated that both polymer content and composition influence vegetative biomass recalcitrance.[27,29,30]

The present study has evaluated two commercial sugarcane genotypes, regarding the "modulating" effect of water deficit on lignin content and structure in the stem. Some papers have reported the effect of water stress on lignin biosynthesis in different plant species, indicating complex genetic regulation, the influence of the severity/time of exposure to stress, phenological phase, and organ/tissue of the plant, among other

DOI: 10.1021/jf5061858
J. Agric. Food Chem. 2015, 63, 4708–4720

factors.[14,15,31] As far as we are concerned, there is no available information on the mechanisms regulating lignin biosynthesis and deposition on the cellular wall or on how environmental stress, such as droughts, may affect the lignification process.

The sugarcane genotypes used in our study, IACSP94-2094 and IACSP95-5000, were affected by water stress in different manners. Although IACSP94-2094 genotype is deemed to be drought-resistant,[17,18] plants submitted to severe and prolonged water restriction presented significant reduction in all assessed biometric parameters (N_l, N_i, L_s, FM_s, DM_l, and DM_r), while IACSP95-5000 was less affected, posing decreased N_l, DM_l, and DM_r values (Table 2). The number of green leaves (N_l) and root biomass (DM_r) had the highest reductions, in both sugarcane genotypes: i.e., 39% and 31% in IACSP94-2094 plants and 51% and 35% in IACSP95-5000 plants, respectively. The impact of drought on sugarcane growth accounted for losses of up to 35%.[32]

Additionally, the low performance of IACSP94-2094 plants under water restriction might be related to severity and/or time of exposure to water stress, since only N_l was significantly reduced under moderate stress (MD). The reduction in the number of leaves and leaf senescence in sugarcane plants during water deficit might indicate a strategy to diminish transpiration surface, thus also mitigating energetic expenditure and ensuring basal tissue metabolism.[33−35]

The impact of water deficit on sugarcane productivity is related to specific plant growth stages. Some studies indicate that sugarcane becomes more vulnerable to water deficit during early growth, characterized by accelerated growth and tillering.[18,36] At the same time, other authors claim that higher susceptibility to drought occurs during the stem-lengthening phase, with significant reductions of both mass and sucrose accumulation.[33,37] Our results confirm that water restriction imposed during the stem-lengthening phase has caused stress, expressed in lower growth rates and consequent lower biomass production.

Sugarcane accumulates sucrose in its stem, raising contents as internodes mature.[38] Sucrose and reducing sugars account for the highest fraction of total soluble sugars present in the stem. The proportions of such sugars are altered throughout the different internode maturation stages, being negatively correlated to one another.[39] The results obtained for IACSP94-2094 and IACSP95-5000 plants confirm that in the early stages of development, when growth rates are at their apex, reducing sugar contents (fructose and glucose) were proportionally higher than sucrose contents in immature internodes. The opposite was observed during maturity, when sucrose accumulation was potentiated and reducing sugar contents became significantly low (Figure 2A−C).

Water stress is well known for negatively affecting photosynthesis in plants, as a result of stomatal and nonstomatal limitations.[40] Our data have clearly shown that low water availability has caused sugar balance alterations in the stem, which causes a major drain of photoassimilates in sugarcane. In immature internodes, the accumulation of sucrose contents and the reduction of fructose contents were simultaneously induced by lack of water in both genotypes (Figures 2A−C), which is probably related to reduced growth rates of these internodes during water deficit. On the other hand, the results obtained with Q117 sugarcane genotype revealed that water deficit did not cause significant alteration in the amount of sucrose and reducing sugars in young internodes.[41]

In mature internodes, the contents of sucrose and reducing sugars were not affected by water stress. Considering that photosynthesis is usually affected by drought and consequently the sucrose biosynthesis and export to the culms, the maintenance of the sugar pool in those internodes might be related to cleavage dynamics and sucrose cellular resynthesis, a process regulated by the activity of sucrose phosphate synthase, sucrose synthase, and invertase enzymes.[42] Additionally, our results are partially in agreement with those obtained by others,[41] demonstrating that, despite the absence of alteration in sucrose contents, glucose and fructose contents happened to increase in mature internodes of sugarcane plants during water deficit. The intensity and/or time of exposure to water stress, in addition to the genotypes employed, might explain the different physiological responses.

We aimed here to characterize water stress, rather than tolerance, as information in that respect is available solely for the IACSP94-2094 genotype.[17,18] Free proline contents in the stem were similar in irrigated control plants for both analyzed genotypes; under severe water deficit conditions, no significant alteration in the amount of that amino acid was detected in the stem (Figure 2D). Such results indicate that proline plays no osmoprotective role in the stem, in the event of prolonged water deficit, when the plant might recruit more effective mechanisms. Likewise, the adoption of proline as a biochemical indicator for water stress must be seen with caution;[43] when it comes to sugarcane, contents of such amino acid may vary according to severity and/or time of exposure to stress,[44] as well as the developmental phase of the plant.[45]

Our anatomy analyses are consistent with those previously described,[10] evidencing typical internode organization in two morphologically distinct regions: the rind, characterized by a great number of vascular bundles, and the pith, where predominates reserve parenchyma cells. An estimate of the number of vascular bundles in sugarcane internodes has shown that approximately 50% are located within 3 mm from the rind,[46] thus constituting a region naturally enriched with such types of cellular organization, a rather interesting object for the study of lignin biosynthesis.

A comparison of different lignin deposition patterns in stem internodes in two sugarcane genotypes showed that lignification in IACSP94-2094 plants occurs earlier than that in IACSP95-5000 plants (Figures 3 and 4). The analysis of immature internodes supports such findings: while only protoxylem was lignified in the vascular bundles of IACSP95-5000, both protoxylem and metaxylem were lignified in IACSP94-2094, in addition to the initial lignification of fibers and subepidermal layers. Likewise, parenchyma cells of mature internodes are also lignified, and xylem fibers feature rather thickened and lignified walls. Walsh et al.[46] have revealed that parenchyma cell walls are lignified as internodes mature; in the fourth internode the lignification level is around 5%, while in the tenth internode it may reach 60%.

The lignin contents found in the genotypes studied here confirmed that polymer accumulation varied according to internode maturation (immature or mature) and also according to the tissue region in the stem (rind or pith). Mature internodes were more lignified than immature internodes, and inside each internode, the rind featured higher lignin content than the pith, which was associated with the higher concentration of vascular bundles in the rind region of the internode and with progressive epidermal and hypodermal lignification. We have also observed that mature rind was up to

DOI: 10.1021/jf5061858
J. Agric. Food Chem. 2015, 63, 4708−4720

4.6 times as lignified as young rind in IACSP94-2094, whereas this increase was 3.2 times in IACSP95-5000; in the pith region, lignin content was 2.7 times higher in mature pith than in young pith, in both sugarcane genotypes (Figure 6). Higher rind lignification, as identified in sugarcane stems, is consistent with higher peroxidase activity rates detected in this region, which might be involved in lignin polymerization.[19]

Lignin biosynthesis is under a complex genetic control, resulting in different adaptive responses, which may vary during plant growth and development.[12,47] As for water stress, a number of studies have revealed that gene expression of the biosynthesis pathway and/or lignin content may be altered according to stress time and/or intensity,[15,16] organ and its specific regions,[13,14] and certain cellular types.[48]

The water stress imposed in our study induced significant accumulation of lignin in the rind and pith of immature internodes of both genotypes, in comparison to the respective irrigated control plants. Additionally, IACSP95-5000 plants submitted to severe drought have accumulated 30% more lignin in mature rind, in comparison to irrigated plants. The lignin accumulation in IACSP95-5000, particularly in the rind, might indicate a strategy to enhance xylem vessel resistance, so as to cope with higher tension during water deficit, by reducing water loss. Voelker et al.[49] have shown that the reduced lignification level of transgenic *Populus* spp. plants silenced to *4CL* gene increased xylem vulnerability to embolism.

Different methodologies,[50] among other major factors, such as tissue type, plant age,[48] and genotypic variation[51] may explain the differences found in the literature regarding lignin content in sugarcane. In the present study, lignin content was determined with thioglycolic acid and ranged from 0.4% in young pith to 4.2% in mature rind. Using the same method, de Souza et al.[48] found 4.9% in the leaves and 2.5% in the stem of young sugarcane plants. The high specificity associated with the method, added to the fact that a significant fraction of lignin in grasses has an acid-soluble property (thus remaining in solution during the precipitation phase in acid), might lead to underestimated total lignin values.[50] Regardless of method-related inquiries, our results demonstrate differential lignin accumulation in immature and mature internodes and also between the pith and the rind.

The analysis of soluble lignin in IACSP94-2094 and IACSP95-5000 has shown that, regardless of maturation level (young or mature) and stem region (rind or pith), the frequency of G monomer (coniferyl) was constantly higher than that of S (sinapyl). As observed by Bottcher et al.,[11] H units (*p*-hydroxyphenyl) were not found in sugarcane, probably due to low concentration (typically <5%), even in grasses.[52] Lignin oligomers identified in the present study were positively correlated to the maturation level of sugarcane internodes, so that dimers were more frequent in immature internodes, whereas trimers were more abundant in mature internodes (Figure 5). Similarly, Bottcher et al.[11] have observed that lignin oligomers were preferably accumulated in mature internodes in both sugarcane genotypes, owing to higher lignin deposition, associated with tissue maturation.

Our results also indicated that the oligomer profile varied between rind and pith. For instance, S(8-O-4)G was more abundant in young internodes and, relatively, was the only dimer found in the rind, while the pith featured other structures, such as G(8-5)G and S(8-8)S, in proportions similar to that of S(8-O-4)G. The frequency of some oligomers was also affected by water deficit, featuring structures such as S(8-8)S, G(8-O-4)G(8-5)G, and G(8-O-4)S(8-5)G in young rind solely under stressing conditions, while other oligomers such as G(8-O-4)G(8-5)G and G(8-O-4)S(8-8)S tended to be less abundant in mature rind, in comparison to those in the irrigated control.

Lignin structural complexity appears to be directly associated with the relative frequency of different interunit linkages, which in turn depend upon the abundance of each monomer during the polymerization process. Therefore, lignins constituted mainly by G units, as in conifers, contain a higher number of resistant linkages, such as 8-5, 8-8, 5-5 and 5-O-4, than lignin rich in S units and thus are more resistant to chemical degradation.[4] Unfortunately, we have not determined the ratio S/G, but given the consistencies between our results and those by Bottcher et al.,[11] the observed pattern is very likely to occur in the genotypes studied here.

Lignin deposition is associated with vegetative organ maturity and final differentiating stages of cellular types,[4] which naturally tends to raise the levels of gene expression of lignin biosynthesis in those regions. In irrigated control plants, we have observed that transcript accumulation in mature sugarcane internodes was higher than that in immature internodes (Figure 7). A comparative analysis between the expression profiles of the two sugarcane genotypes has evidenced that, in IACSP94-2094 plants, the abundance of transcripts in mature rinds was higher than that in IACSP95-5000 plants (except for *Sh4CL2* and *ShC3H1*). The high levels of expression observed in IACSP94-2094 support the results of the anatomical analysis of lignin, thus suggesting that this sugarcane genotype features a higher stem lignification level.

When plants of both sugarcane genotypes were submitted to severe water deficit (SD), there were significant alterations in the expression levels of most analyzed genes, with generalized increased transcripts in young internodes (except for *ShCAD8*) and reduced expression in mature internodes, as opposed to the findings in control plants, which tended to feature higher levels of gene expression of lignin biosynthesis in mature internodes (Figure 7). Such data were consistent with the higher lignin content (>60%, when compared to control plants) observed in the pith of young internodes for both sugarcane genotypes under water deficit (Figure 6).

On the other hand, reduced expression of most lignin biosynthesis genes (except for *ShC4H1*) in mature internodes of the stem under drought conditions fails to explain the approximately 30% increase of lignin content in mature rind of IACSP95-5000 plants, in comparison to that in irrigated sugarcane plants. The high-complexity genomes of modern sugarcane cultivars (allopolyploid hybrids), associated with possible functional redundancies among the various members of the same gene family,[11] might justify the apparent lack of correlation between low gene expression and high lignin content observed in this context.

Under severe water restriction, *ShF5H* and *ShCCR1* have proven to be the most differentially expressed genes in IACSP94-2094, approximately 13 and 24 times more expressed in young rind under severe water deficit in comparison with control plants, respectively (Figure 7I,J). *ShF5H* codes for a key enzyme in the production of lignin S units, and the accumulation of its transcripts in the rind region (rich in vascular bundles) might be related to intensified lignin deposition in young internodes induced by stress.

In conclusion, we have demonstrated here that lignin deposition in stem internodes is affected by severe water stress

J. Agric. Food Chem. 2015, 63, 4708−4720

in two sugarcane genotypes. The results on the lignin content and anatomical characterization indicate that, under normal growth conditions, IACSP94-2094 plants are more lignified than IACSP95-5000 plants. The gene expression profile related to lignin biosynthesis confirmed that the accumulation of transcripts of the analyzed genes rises as internodes mature and that, generally speaking, the expression level is constantly higher in the rind than in the pith. The approximately 60% increase in lignin content induced by water deficit in the pith of young internodes, in both genotypes, is positively related to the accumulation of *Sh4CL2* and *ShCOMT1* transcripts, thus suggesting that those genes might play a crucial role in the control of lignin deposition in sugarcane. Our data reinforce the complexity of the mechanisms involved in the spatiotemporal control of lignin deposition.

Regarding the differences in lignin content between rind and pith, there is a correlation between the topochemical distribution of lignin and hydroxycinnamic acids and the efficiency of the enzymatic hydrolysis of sugars released from sugarcane bagasse biomass.[53] Pith samples were promptly hydrolyzed by cellulase, reaching a 63% cellulose conversion after a 72 h hydrolysis, whereas rind samples reached only a 20% conversion. On the other hand, the rind treatment with an acetic/chlorite acid solution, so as to remove lignin and hydroxycinnamic acids, enabled significant increase in cellulose conversion: i.e., approximately 60% after a 4 h hydrolysis. Altogether, such data confirm that sugarcane internode rinds are more recalcitrant than piths and that their high endurance to cellular wall saccharification is probably associated with higher rind lignification, owing to the abundance of vessels in the xylem and fibers. Therefore, our data show that water stress changes lignin deposition in these tissues and therefore might affect recalcitrance and hydrolysis efficiency. Complementary studies are required to further investigate the effect of these changes on the final quality of sugarcane lignocellulosic biomass.

Isolation and Characterization of a Novel Imidacloprid-Degrading *Mycobacterium* sp. Strain MK6 from an Egyptian Soil

Mahrous M. Kandil,*[,†] Carmen Trigo,[‡] William C. Koskinen,[‡] and Michael J. Sadowsky[‡,§]

[†]Department of Soil and Water, Faculty of Agriculture, Alexandria University, Alexandria 21545, Egypt

[‡]Department of Soil, Water, and Climate, and [§]BioTechnology Institute, University of Minnesota, St. Paul, Minnesota 55108, United States

ABSTRACT: Thus far, only a small number and types of bacteria with limited ability in degrading imidacloprid have been reported. Also, genes regulating imidacloprid (IMDA) degradation have yet to be discovered. To study this in more detail, an enrichment technique was used to isolate consortia and pure cultures of IMDA-degrading bacteria. Through this approach, we successfully isolated a novel bacterium capable of completely degrading IMDA as a sole nitrogen source. The bacterium was subsequently identified as *Mycobacterium* sp. strain MK6 by sequence analysis of its 16S rRNA gene (Genbank accession number KR052814). BLASTn searches indicated that 16S rRNA gene from *Mycobacterium* sp. strain MK6 was 99% identical to several *Mycobacterium* spp. *Mycobacterium* sp. strain MK6 transformed 99.7% added IMDA (150 μg mL^{-1}) in <2 weeks ($t_{1/2}$ = 1.6 days) to 6-chloronicotinic acid (6-CNA) as its major metabolite. Although the isolated strain and mixed bacterial consortia were able to degrade IMDA, they failed to grow further on 6-CNA, indicating a lack of IMDA mineralization to carbon dioxide. Small amounts of the desnitro-olefin and desnitro-degradates of IMDA were observed during the incubation but did not accumulate in culture medium.

KEYWORDS: *imidacloprid, 6-chloronicotinic acid, desnitro-olefin, Mycobacterium sp. strains, biodegradation, HFERP*

INTRODUCTION

Insecticides are globally used in agriculture to combat the loss of crops as a result of attack by microbial and insect pests. Insect damage to plants is a severe problem and results in the annual use of 940 million pounds of active ingredients worldwide.[1] It has been reported, however, that more than 99% of applied pesticides do not reach their target pests and may affect non-target species or contaminate the environment.[2] Following their deposition, many factors control the fate of pesticides in the environment, including retention, transport, and transformation processes.[3−5]

The interaction of pesticides with different environmental abiotic and biotic factors results in the transformation of parent compounds. Microorganisms use many pesticides as a source of carbon, nitrogen, and energy, often transforming them into carbon dioxide, water, and diverse sets of metabolites.[6−8] These compounds may be less or sometimes more toxic to target and non-target pests and organisms.[6] For instance, to determine the effect of insecticides on soil microorganisms, various assays, such as nitrification, denitrification, or N_2 fixation, have been commonly used.[9−11] Cycoń et al.[12] used two culture-independent [phospholipid fatty acid analysis (PLFA) and polymerase chain reaction−denaturing gradient gel electrophoresis (PCR-DGGE)], and culture-dependent [community-level physiological profiling (CLPP)] approaches to show that imidacloprid [1-(6-chloro-3-pyridylmethyl)-*N*-nitroimidazolidin-2-ylideneamine (IMDA)] induced significant changes in the composition of microbial communities and their metabolic activity, which, in turn, can influence the maintenance of soil quality.

IMDA is one of the most widely used neonicotinoid insecticides in agriculture.[13−17] While IMDA is mainly applied via foliar application for insect control, it is also used as a seed dressing or stem treatment.[14] IMDA is characterized by variable persistence in soil, with a half-life up to 229 days in the field.[18] In contrast, Wu et al.[19] found under laboratory conditions that the degradation of IMDA was rapid, with half-lives of 4−5 days. The persistence of IMDA in water increased with increasing application rates and pH values.[20] In aquatic environments, it was found that IMDA was more persistent in sediment than in water, with half-lives of 160 and 30 days, respectively.[21−24]

The persistence of IMDA in soil depends upon different physicochemical and biological parameters, such as organic matter, pH, temperature, crops, time, and microbial activity. Oi[25] and Cox et al.[26] established that sorption increased with contact time in soil, thereby decreasing potential availability to degrading organisms in soil. Decreased availability, would, in turn, increase persistence in soil. Dissolved organic carbon reduces IMDA sorption by competing with the pesticide molecules for sorption sites on the soil surface, increasing availability for degradation by microorganism and for leaching of IMDA and potentially increasing groundwater contamination.[27]

The metabolism of IMDA has been studied mainly in plants and mammals, and the proposed pathways for IMDA transformation have mostly been based on studies performed using eukaryotes.[28] However, a few studies have focused on the transformation of IMDA by pure or mixed cultures of soil microorganisms.[29−32] It is crucial to isolate and identify

microorganisms capable of degrading different pesticides for their potential use in bioremediation strategies either directly or via use of their enzymes.

The objectives of this study were to (1) isolate mixed cultures of bacteria-degrading IMDA from an Egyptian soil, (2) purify and characterize unique isolates with the ability to transform IMDA, and (3) identify IMDA metabolites produced during the degradation process. Results of this study are crucial for our understanding of IMDA transformation in the environment and for the development of possible bioremediation strategies.

MATERIALS AND METHODS

Chemicals and Pesticide. Analytical standards of IMDA (99.5% purity) and 6-chloronicotinic acid (6-CNA; 99.5% purity) were purchased from Sigma-Aldrich (St, Louis, MO) and desnitro-imidacloprid 1-(2-chloro-pyridin-5-yl-methyl)-2-imino-imidazolidine (DSN-IMDA; >97% purity), and desnitro-olefin imidacloprid 1-(6-chloro-pyridin-3yl-methyl)-*N*-nitro-1*H*-imidazol-2-imine (DSN-olefin−IMDA; >97% purity) were provided by Bayer Corporation (Stilwell, KS). IMDA and metabolite stock solutions (50 mg mL^{-1}) were prepared in high-performance liquid chromatography (HPLC)-grade acetonitrile (ACN) to ensure full solubility and were stored in the dark at 4 °C until used.

Soil Sample Collection. Soil samples were collected from the Abis Agricultural Research Farm, Alexandria University, Alexandria, Egypt. Five surface (top 15 cm) soil samples of about 1 kg each were collected randomly from an area following a traditional agricultural rotation farming system of wheat and clover. The area was selected on the basis of the farm's record showing no history of IMDA application for the 5 years prior to sampling. Samples were collected using a bleach-sterilized hand shovel, placed in sterile polyethylene bottles, transferred to the lab on ice, and stored at 4 °C until used. The soil samples were mixed to form a composite sample that was used within 24 h for IMDA enrichment cultures. Following standard methods of soil analysis,[33] the composite soil sample was classified as a sandy clay loam texture of 27.9% clay, 10.1% silt, and 62.0% sand with pH 7.6, electrical conductivity (EC), 1.52 mS cm^{-1}; organic matter, 0.75%; and cation-exchange capacity (CEC), 33 $cmol^{(+)}$ kg^{-1} of soil.

Culture Medium and Growth Conditions. An enrichment culture technique was used to isolate IMDA-degrading bacteria from the soil described above. Isolation and degradation experiments were conducted using R-salts minimal medium (RSM) as previously described.[34] The liquid RSM consists of solutions (1) 67.0 mL of 1 M KH_2PO_4 (pH 6.9), (2) 5 mL of R-salt mixture (16.0 g of $MgSO_4 \cdot 7H_2O$, 0.4 g of $FeSO_4 \cdot 7H_2O$, and 0.8 mL of HCl per 200 mL of H_2O), (3) 200 μL of 1 M $CaCl_2 \cdot 2H_2O$, and (4) 1.0 mL of trace element solution (10.0 mg of $ZnSO_4 \cdot 7H_2O$, 3.0 mg of $MnCl_2 \cdot 4H_2O$, 30 mg of H_3BO_4, 20.0 mg of $CoCl_2 \cdot 6H_2O$, 1.0 mg of $CuCl_2 \cdot 2H_2O$, 2.0 mg of $NiCl_2 \cdot 6H_2O$, and 3.0 mg of $Na_2MoO_4 \cdot 2H_2O$ per liter). Glucose stock solution (20%) was prepared and filter-sterilized by polytetrafluoroethylene (PTFE) membrane filters (0.22 μm) and stored at 4 °C. Stock solution (10%) of ammonium nitrate (NH_4NO_3) was prepared. These solutions were autoclaved separately at 121 °C for 20 min and mixed after cooling to 60 °C in a water bath, as needed. Solutions of glucose, NH_4NO_3, and IMDA were added by PTFE syringe filters, as described below.

Isolation of IMDA-Degrading Bacteria by Enrichment Techniques. All experiments were prepared under aseptic conditions. IMDA, $C_9H_{10}ClN_5O_2$, contains carbon and nitrogen on its pyridine and imidazolidine rings and side chain, which might be used as a source of carbon, nitrogen, or both for soil microorganisms. Therefore, various enrichment cultures with or without carbon and nitrogen sources were prepared to isolate bacteria using IMDA as a sole N or C source or both, including all possible control treatments. Nitrogen-free RSM was supplemented with 150 μg mL^{-1} IMDA as a sole nitrogen source and 2 g L^{-1} glucose (10 mL of 20% stock solution) as a carbon source. Carbon-free RSM was supplemented with 150 μg mL^{-1} IMDA as a carbon source and 1 g L^{-1} NH_4NO_3 (10 mL of 10% stock solution) as a nitrogen source.

Enrichment cultures of treatments described above were conducted in 250 mL Erlenmeyer flasks containing 100 mL of respective RSM inoculated with 5 g of fresh weight soil and incubated in the dark at 27 °C on a G24 (New Brunswick, NJ) environmental incubator shaker at 150 rpm for a 3 week period for the first run. This period was implemented to increase the chance of creating a favorable condition for IMDA-degrading bacteria while building a growth-limiting culture for other soil microorganisms after they consume soil organic matter and nutrients, thus ensuring the adaptability of IMDA-degrading bacteria to IMDA and its degradation byproducts. Successive enrichment subcultures were renewed every 2 weeks by transferring 1 mL from the old culture into a fresh enrichment flask containing 100 mL of the corresponding treatment medium. This step was repeated 5 more times to eliminate any impurities of organic matter originating from the soil sample and to attempt to isolate a mixed culture of IMDA-degrading microorganisms.

Isolation and Purification of IMDA-Degrading Bacterial Isolates. A microbial consortium isolated on IMDA was examined for growth and IMDA degradation. After confirmation of the ability of the consortium to degrade IMDA, individual bacterial isolates were obtained by serial dilution and pour plating of the consortium onto RSM solid medium supplemented with 1.5% Noble agar and IMDA (150 μg mL^{-1}) as the sole nitrogen source. Plates were incubated at 28 °C for 15 days. On the basis of morphological features, discrete unique bacterial colonies were picked and further purified by successive streaking on the same medium. This process was repeated several times to ensure isolation of pure cultures and the ability of isolates to grow on IMDA as a sole N source. Pure cultures were preserved in 20% sterile glycerol and stored at −70 °C until used.

IMDA Degradation Assay and Its Kinetics. The consortium and later individual pure culture isolates were tested for their ability to degrade 150 μg mL^{-1} IMDA in RSM liquid medium. Growth was determined by measuring an optical density at 600 nm (OD_{600}), and degradation was determined from analysis of IMDA in solution. Initially, the IMDA concentration in the supernatant of cultures was monitored spectrophotometrically at 270 nm,[28,35] followed by HPLC analysis under the conditions described below. For this assay, 250 mL flasks containing 100 mL of RSM liquid media were inoculated with individual isolates or a consortium and maintained for 15 days under the incubation conditions described above. Aliquots (5 mL) were taken every 2 days under aseptic conditions for measuring bacterial growth by OD_{600} and IMDA concentration in the culture medium. The kinetic parameters for IMDA degradation were calculated using the exponential formula $C_t = C_o e^{kt}$, where C_t is the concentration of IMDA at a time t, C_o is its initial concentration, k is its decay constant, and t is its half-life time ($t_{1/2}$).

HPLC Analysis for IMDA and Its Degradation Products. Culture samples were centrifuged at 10000*g* for 10 min to separate cell pellets from the supernatant. IMDA was measured in the supernatant by HPLC using a Waters HPLC (Milford, MA) with a reverse-phase C-18 (RP18) symmetry shield column (Waters−Millipore) (3.9 mm × 150 cm) and an ultraviolet (UV) detector. A 1.0 mL aliquot of growth medium was taken under aseptic conditions, centrifuged to remove bacterial cells, and filtered through a 0.22 μm sterile Millipore membrane. A 0.5 mL aliquot of filtered supernatant was diluted to 2.5 mL using ultrapure water prior to injection. The HPLC operational conditions used were as previously described:[31] 30 min gradient of HPLC-grade ACN and acidified (pH 3) ultrapure water [0 min, 20:80 (%) ACN/H_2O; 7 min, 22:78 (%) ACN/H_2O; 14 min, 30:70 (%) ACN/H_2O; 21 min, 40:60 (%) ACN/H_2O; and 30 min, 20:80 (%) ACN/H_2O], injection volume of 20 μL, flow rate of 0.6 mL min^{-1}, and UV detection at 270 nm for IMDA and 220 and 247 nm for metabolites. The HPLC column temperature was maintained at 24 °C. Analytical-grade IMDA, DSN-IMDA, DSN-olefin−IMDA, IMDA−urea, and 6-CNA were used to prepare a series of standard solutions. Standards of IMDA and 6-CNA (0−100 μg mL^{-1}) were run at each time of analysis. Standards of metabolites were run only after corresponding peaks were observed in solution. Linear calibration

DOI: 10.1021/acs.jafc.5b00754
J. Agric. Food Chem. 2015, 63, 4721−4727

curves for IMDA and 6-CNA were observed in the range of 1−100 μg mL^{-1} with 0.99 correlations. Retention times were 7.50, 2.50, 2.19, 6.4, and 5.51 min for IMDA, DSN-olefin−IMDA, DSN-IMDA, IMDA−urea, and 6-CNA, respectively. Peak area was plotted against its calibrated linear fitted standards (0−100 μg mL^{-1}) to quantitatively measure the IMDA concentration in culture flasks.

Clustering and Selection of Unique IMDA-Degrading Isolates by Horizontal Fluorophore-Enhanced Rep-PCR (HFERP). A total of 20, morphologically distinct, pure culture isolates were subjected to the HFERP DNA fingerprinting technique.[36] Rep-PCR was performed using a MJ research PTC 100 (MJ Research, Waltham, MA) thermocycler according to a published and well described protocol.[36] Electrophoresis was performed at 4 °C for 17 h at 70 V as previously described, with constant buffer recirculation for separating DNA fragments.[37] All HFERP experiments contained a positive control (*Escherichia coli*) and a negative control (no DNA). DNA fingerprints were captured using a Typhoon 8600 variable mode imager (Molecular Dynamics/Amersham Biosciences, Sunnyvale, CA), and images were subjected to analysis using BioNumerics, version 2.5, software (Applied Maths, Sint-Martens-Latem, Belgium) as previously described.[36]

Amplification of 16S rRNA Gene for the Identification of Unique Isolates. The taxonomic identity of unique bacterial isolates degrading IMDA was determined by sequencing near-full-length copies of 16S rRNA gene. Universal primers 27f (5′-AGAGTTT-GATCMTGGCTCAG-3′) and 1492r (5′-GGTTACCTTGTTAC-GACTT-3′) (Integrated DNA Technologies, Coralville, IA) were used for 16S rRNA gene amplification as described.[38] The amplified 16S rRNA fragment was extracted and purified following the protocol of the QIAquick PCR purification kit (Qiagen, Valencia, CA). PCR reaction conditions were performed as described.[39] The concentration of the purified DNA was determined by a NanoDrop 2000 spectrophotometer (Thermo Scientific, Wilmington, DE), and DNA was sequenced at the Genome Sequencing Center, University of Minnesota (St. Paul, MN). Sequences were assembled using BioEdit software.[40] Assembled contigs were compared to known 16S rRNA gene sequences in the GenBank database by BLASTn search. MEGA4 software was used for multiple alignment and phylogenetic tree generation to examine interrelationships among strains.[41] The sequence of 16S rRNA gene was used for assigning taxonomic status to the isolated strains. The 16S rRNA gene sequence of isolated IMDA-degrading MK6 strain was deposited in the National Center of Biological Information (NCBI) GenBank database under accession number KR052814.

RESULTS AND DISCUSSION

Enrichment of IMDA-Degrading Bacteria. An enrichment culture was used to isolate consortia and eventually pure cultures of bacteria that were capable of transforming IMDA (150 μg mL^{-1}) when used as a sole N source for growth. The enrichment technique has an advantage over direct isolation methods in its high probability of success in isolation because of acclimatization and providing favorable conditions for some species while suppressing the growth of others.[42−44] After 5 cycles of enrichment renewal, we obtained a mixed culture of microorganisms capable of growing on IMDA.

The addition of glucose as the sole source of carbon produced considerable microbial growth through the 5 rounds of subculturing, indicating that IMDA was most likely being used as a nitrogen source. As shown in Figure 1A, growth (OD_{600}) of the mixed culture supplemented with both IMDA and glucose was much greater than other treatments, including those supplemented with both IMDA and nitrogen. Other treatments provided limited and often insignificant growth. As a consequence, the biodegradation of IMDA as a nitrogen source was further investigated throughout this study. HPLC analyses were used to follow the IMDA concentration in mixed culture

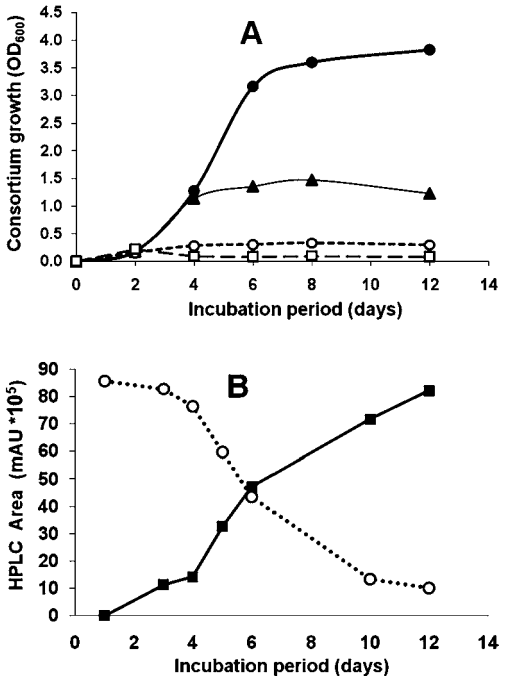

Figure 1. (A) Growth of the isolated bacterial consortium on (○) IMDA (150 μg mL^{-1}) alone, (▲) IMDA + nitrogen, and (●) IMDA + glucose compared to (□) control with none. (B) Biodegradation of (○) IMDA into (■) initially unknown metabolite by the isolated stable consortium in a minimal medium supplemented with glucose (2%).

growth in RSM, where IMDA served as the sole N source. Results in Figure 1B show that, as the quantity of IMDA decreased in the glucose-supplemented culture significantly with time, a single degradate accumulated in the growth medium.

Isolation and Purification of IMDA-Degrading Bacteria from Mixed Culture. A dilution series of the consortium was performed to isolate individual bacterial isolates capable of IMDA degradation. About 20 morphologically distinct colony isolates were selected and subjected to HFERP DNA fingerprint analysis to select for unique clones. Results in Figure 2 show the HFERP DNA fingerprints of these isolates. All 20 isolates could be divided into seven distinct groups that individually degraded IMDA. Strains in each DNA fingerprint group were individually tested for their ability to degrade IMDA. Results in Figure 3 show the growth of the IMDA-degrading consortium and individual isolates grown in minimal medium containing IMDA as a sole nitrogen source. One of these isolates (isolate MK6) showed rapid growth and had IMDA degradation rates similar to that seen with the consortium, while the other isolates showed slower growth on IMDA.

Identification of the Unique Isolates Degrading IMDA. Isolate MK6 was confirmed for IMDA transformation ability and was further identified by analysis of 16S rRNA gene sequence. Sequence similarities were determined by BLASTn analysis and indicated that the near-full-length 16S rRNA gene sequence of isolate MK6 was 99.9% identical to that of *Mycobacterium cosmeticum*, strain LTA-388. To our knowledge, this is the first report of an IMDA-degrading *Mycobacterium* sp. strain. In addition, BLASTn searches showed that the sequence of 16S rRNA gene of this strain was 98−99% identical to those of *Mycobacterium neoaurum* VKM Ac-1815D (CP006936.2),

Mycobacterium rhodesiae NBB3 (CP003169.1), *Mycobacterium gilvum* Spyr1 (CP002385.1), *Mycobacterium smegmatis* str. MC2 155 (CP000480.1), *Mycobacterium smegmatis* strain INHR2 (CP009496.1), and *Mycobacterium gilvum* PYR-GCK (CP000656.1), whose genomes were completely sequenced. A phylogenetic tree (Figure 4) of the IMDA degrading strain was constructed using MEGA4 software (http://www.megasoftware.net/mega4/mega41.html).[41]

Kinetics of IMDA Biodegradation. Results in Figure 5A show that the reduction of the concentration of IMDA in supernatant was concomitant with a continuously rising growth (growth rate, μ = 0.375 day^{-1}) of isolate MK6. On the basis of HPLC analysis, more than 99% of the initial concentration of IMDA (150 μg mL^{-1}) was degraded within 2 weeks by this strain at 27 °C, making it among the most efficient IMDA-degrading bacterium reported to date. For instance, a *Klebsiella* sp. strain was only reported to degrade 78% of 50 μg mL^{-1} IMDA.[45] Figure 5B shows the percentage of IMDA degradation and the concurrent production of its major metabolite. While the IMDA concentration was reduced to traces (<2 μg mL^{-1})

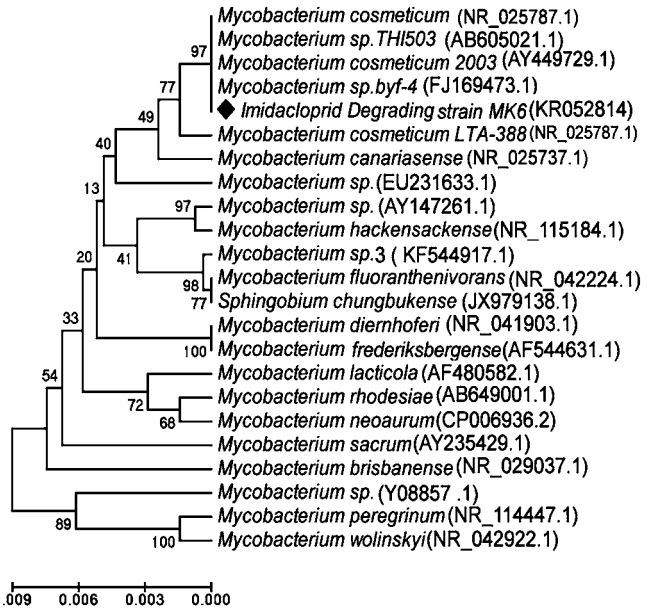

Figure 4. Phylogenetic tree for the confirmed (♦) IMDA-degrading strain MK6. The bootstrap values (%) are indicated at the nodes and are based on unweighted pair group method with arithmetic mean (UPGMA) analysis. The scale bar indicates the genetic distance among strains. Accession numbers of closely related strains are indicated in parentheses.

in minimal medium, one major unknown biodegradation byproduct was increasingly produced (Figure 5B). Using the exponential formula $C_t = C_o e^{kt}$, as described above, the kinetics parameters (k and $t_{1/2}$) of IMDA degradation and the formation of 6-CNA as its major metabolite were calculated and are shown in Table 1. Degradation of IMDA followed a

Table 1. Kinetic Parameters of IMDA Degradation by *Mycobacterium* sp. Strain MK6

parameters[a]	control	IMDA + glucose	IMDA only
k (day^{-1})	0.001	0.442	0.017
$t_{1/2}$ (day)	693.2	1.6	41.0
R^2	0.258	0.844	0.97
IMDA degradation (%)	0	99.8	20
6-CNA production (%)	0	100	31

[a] k, decay constant; $t_{1/2}$, half-life time in days.

first-order decay reaction at the above-described growth conditions in a minimal medium. Data showed that the addition of glucose accelerated the degradation of IMDA and reducing its $t_{1/2}$ to 1.6 days compared to 41 days with IMDA alone.

Identification of Main Byproducts of IMDA Biodegradation. Supernatant samples of IMDA-grown *Mycobacterium* sp. strain MK6 were analyzed by HPLC. Various compounds have been previously reported as degradates of IMDA transformation by microorganisms,[26,29,46,47] plants,[25,48] termites,[49] and mice[50,51] or by photodegradation.[52,53] Results in Figure 6 show the disappearance of IMDA [retention time

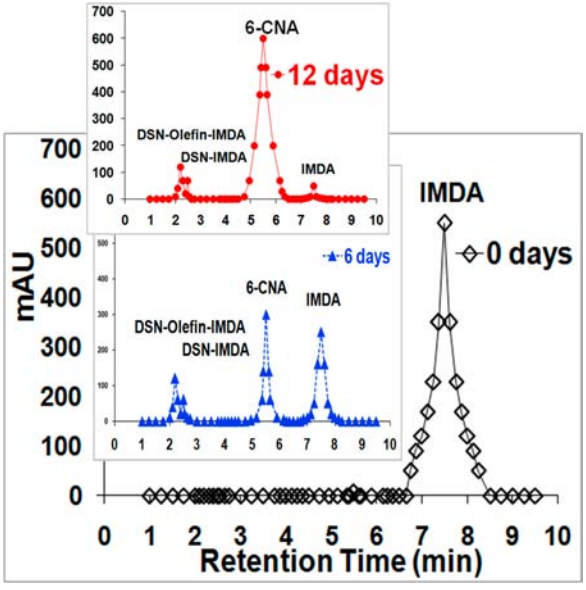

Figure 6. Retention time and HPLC area changes of IMDA and its metabolites at different incubation times, (black ◇) 0 days, (blue ▲) 6 days, and (red ●) 12 days, with *Mycobacterium* sp. strain MK6.

(RT) of 7.50] and appearance of three degradates DSN-olefin–IMDA (RT of 2.19 min), DSN-IMDA (RT of 2.50 min), and 6-CNA (RT of 5.51 min). Another previously observed degradate IMDA–urea, with an RT of 6.14 min,[54,55] was not observed in this study. While the concentration of 6-CNA increased with time, DSN-olefin–IMDA and DSN-IMDA remained relatively constant, suggesting that these two degradates may be intermediate metabolites in the transformation of IMDA to 6-CNA. Also consistent with the findings of this study, olefin–IMDA was previously reported as one of the major IMDA biodegradation byproducts by *Stenotrophomonas maltophilia* CGMCC 1.1788 but substrate mineralization was not reported.[30] Although the degradation of IMDA into other byproducts has been previously reported in some studies, the percent degradation was much lower than that of this study. For instance, IMDA was reported to be co-metabolically transformed by *Leifsonia* sp. strain PC-21 into 6-CNA, but there was no evidence of mineralization of IMDA into CO_2.[31] Shetti and Kaliwal[47] were able to isolate from soil *Brevundimonas* sp. MJ 15, which degraded up to 38% IMDA with no sign of mineralization to CO_2. The mineralization of IMDA was investigated in a water–sediment system, and its disappearance was associated with minimum mineralization into CO_2.[56]

It is significant to point out that results of the present study indicated that IMDA was completely degraded to 6-CNA, but was not further degraded by *Mycobacterium* sp. strain MK6 or mineralized to CO_2 in the time frame of the incubation. It is proposed that the isolated strain metabolizes IMDA through oxidative cleavage of the methylene bridge to form 6-CNA or reduction of the nitro group through a fast process of oxidation of desnitro-olefin as previously concluded.[28,45] Using Using different growth substrates, such as sucrose and succinate, it was suggested that *Stenotrophomonas maltophilia* CGMCC 1.1788 used different degradation pathways via 5-hydroxy-IMDA.[30]

In summary, we isolated a mixed culture capable of biodegrading IMDA using an enrichment culture technique. A single, pure culture of isolate MK6 that fully degraded IMDA was subsequently isolated and purified from the mixed culture. This bacterium was identified as *Mycobacterium* sp. strain MK6 through sequence analysis of its 16S rRNA gene. Although IMDA was transformed completely to 6-CNA by the identified strain, there was no evidence of mineralization to CO_2 in the time frame of the incubation. A proposed biodegradation pathway of IMDA considers DSN-olefin–IMDA and DNS-IMDA as degradation intermediates. Because relatively few species of bacteria degrading IMDA have been identified, we propose to completely sequence *M. cosmeticum* strain MK6, so that genes and enzymes responsible for IMDA degradation can be identified and studied in detail.

Conjugation of the Mycotoxins Alternariol and Alternariol Monomethyl Ether in Tobacco Suspension Cells

Andreas A. Hildebrand, Beate N. Kohn, Erika Pfeiffer, Daniel Wefers, Manfred Metzler, and Mirko Bunzel*

Institute of Applied Biosciences, Department of Food Chemistry and Phytochemistry, Karlsruhe Institute of Technology (KIT), Adenauerring 20a, 76131 Karlsruhe, Germany

Supporting Information

ABSTRACT: The mycotoxins alternariol (AOH) and alternariol-9-*O*-methyl ether (AME) carry three and two phenolic hydroxyl groups, respectively, which makes them candidates for the formation of conjugated metabolites in plants. Such conjugates may escape routine methods of analysis and have therefore been termed masked or, more recently, modified mycotoxins. We report now that AOH and AME are extensively conjugated in suspension cultures of tobacco BY-2 cells. Five conjugates of AOH were identified by MS and NMR spectroscopy as β-D-glucopyranosides (attached in AOH 3- or 9-position) as well as their 6′-malonyl derivatives, and as a gentiobiose conjugate. For AME, conjugation resulted in the D-glucopyranoside (mostly attached in the AME 3-position) and its 6′- and 4′-malonyl derivatives. Pronounced differences were noted for the quantitative pattern of AOH and AME conjugates as well as for their phytotoxicity. Our *in vitro* study demonstrates for the first time that masked mycotoxins of AOH and AME can be formed in plant cells.

KEYWORDS: *masked mycotoxins, modified mycotoxins, Alternaria toxins, malonyl glucosides, plant cell culture*

INTRODUCTION

The cosmopolitan genus *Alternaria* contains many species that are important plant pathogens, infesting all the aerial parts of plants and causing, e.g., early blight diseases of vegetables, brown spot of tangerines, or postharvest black rot of fruit.[1] In addition to economic losses due to preharvest and postharvest decay, *Alternaria* species produce several groups of toxins, which contaminate food and feed and may pose a health problem.[2] For example, *Alternaria* toxins have been associated with an increased incidence of esophageal cancer in certain areas of China.[3] In 2011, the European Food Safety Authority (EFSA) published a Scientific Opinion on the risks for animal and public health related to the presence of *Alternaria* toxins in feed and food.[4] The analysis of 11 730 occurrence data showed that the most frequently detected *Alternaria* toxins were the dibenzo-α-pyrones alternariol (AOH) and alternariol-9-*O*-monomethyl ether (AME) (Figure 1A,B), which were common contaminants of cereals, sunflower seeds, oilseed rape, olives, various fruits, and other food items.[4] AOH and AME exhibit genotoxicity *in vitro* by inducing gene mutations, DNA strand breaks, and inhibition of topoisomerase I and IIα.[5−8]

Both AOH and AME have free hydroxyl groups available for metabolic conjugation (Figure 1A,B). In the mammalian organism, formation of glucuronides is a major pathway of detoxification and excretion. *In vitro* studies have shown that AOH and AME are readily converted to glucuronides upon incubation with hepatic and intestinal microsomes from humans, rats, and pigs in the presence of UDPGA.[9] Whereas AOH gave rise to comparable amounts of the 3-*O*-glucuronide and 9-*O*-glucuronide, AME was predominantly converted to the 3-*O*-glucuronide. In the same study, the activities of 10 recombinant human UDP-glucuronosyltransferases for AOH and AME were determined; nine were found to be active for AOH and eight for AME.

Over the past years, researchers and regulators have become aware that conjugation of mycotoxins (and other compounds such as pesticides) may also occur in plants. Such conjugation reactions are believed to be part of the detoxification system of the plant.[10] Xenobiotic and endogenous compounds carrying hydroxyl groups are frequently converted to glucosides and further processed by addition of a malonyl, hexose, or pentose moiety to facilitate compartmentation and storage.[10] Conjugated compounds escape routine methods of analysis if the method aims exclusively at the detection of the parental compounds. However, upon ingestion of the conjugate by humans or animals, the parental form may be released in the digestive tract and absorbed, thereby increasing the total exposure to the compound. For the first time, this has been unambiguously demonstrated for a glucoside of the mycotoxin zearalenone, and the term "masked mycotoxin" has been coined.[11] Today, several masked forms of zearalenone and other mycotoxins, in particular of trichothecenes like deoxynivalenol and nivalenol are known.[12,13] More recently, the term "modified mycotoxins" has been proposed for a comprehensive definition including, e.g., derivatives formed by thermal reactions or by plant metabolism (so-called "masked" mycotoxins).[14]

Because it is yet unknown whether AOH and AME are converted to conjugated metabolites in plants, the aim of this

study was to analyze AOH and AME conjugation in a tobacco BY-2 suspension cell culture as a model system.

MATERIALS AND METHODS

Chemicals and Reagents. AOH and AME were isolated from a culture of *Alternaria alternata* strain TA7 grown on rice flour containing media for 24 days at 25 °C as described earlier for the isolation of other *Alternaria* toxins.[15] The crude extract was analyzed by LC-MS, and the fractions containing AOH and AME were isolated by preparative HPLC. Identity was confirmed by NMR (see below), and the purity was >98% according to HPLC analysis with UV detection at 254 nm.

Chemicals for the tobacco cell culture and other chemicals and reagents were obtained from Sigma-Aldrich/Fluka (Taufenkirchen, Germany) and Duchefa (Haarlem, The Netherlands) and were of the highest quality available (96−100% depending on the chemical, with the exception of Evan's Blue (>75% purity)). HPLC-MS grade acetonitrile and methanol were purchased from VWR International (Bruchsal, Germany). NMR solvents were from Deutero GmbH (Kastellaun, Germany) and VWR International.

Tobacco Suspension Cell Culture. Tobacco BY-2 cells (*Nicotiana tabacum* L. cv. Bright Yellow 2) were kindly provided by Dr. Jan Maisch (Institute of Botany, KIT). The cells were cultured in the dark at 25 °C on an orbital shaker at 150 rpm in 100 mL Erlenmeyer flasks containing 30 mL of Murashige and Skoog medium supplemented with 30 g/L sucrose, 200 mg/L KH_2PO_4, 100 mg/L inositol, 1 mg/L thiamine, and 0.2 mg/L 2,4-dichlorophenoxyacetic acid. The medium was adjusted to pH 5.8. The cells were subcultured weekly, transferring 1.5 mL (about 0.5 g cell wet weight) of the suspension into 30 mL of fresh medium. The exponential growth phase of the cells started after 3 days and was finished on day seven (about 10 g of cell wet weight or 0.4−0.5 g of cell dry weight in the stationary phase).

Incubation of Tobacco Cells with AOH and AME. Stock solutions (10 mM) of AOH or AME in DMSO were stable at ambient

J. Agric. Food Chem. 2015, 63, 4728−4736

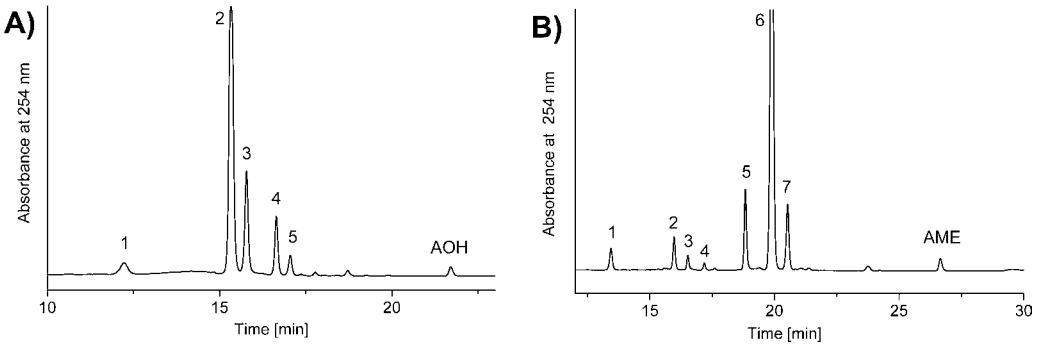

Figure 2. HPLC profiles of metabolites of alternariol (AOH) (A) and alternariol-9-*O*-monomethyl ether (AME) (B) in extracts of cultured tobacco BY-2 cells after 48 h incubation (UV detection at 254 nm). The abbreviations used for the metabolites (AOH-X, AME-X) indicate which metabolite is represented by which peak in the chromatogram (with X describing the peak number).

temperature in the dark for up to two months. The concentration of the mycotoxin in the incubation medium was 50 or 100 μM. The DMSO concentration did not exceed 1%. Control incubations were carried out with DMSO but without mycotoxin. After 24, 48, or 96 h of incubation, cells and medium were separated by filtration and freeze-dried. The dried medium was dissolved in MeOH for chromatographic analysis. The dried cells (10−12 g wet cells yield about 0.6 g dry cells) were ground using mortar and pestle. To extract AOH, AME, and their metabolites, an optimized extraction procedure was used: 0.1 g of the ground material was extracted twice for 2 h at 25 °C with horizontal shaking. For the first extraction, 4.5 mL of MeOH/CH_2Cl_2 (2:1, v/v) was used, whereas 4.5 mL of MeOH/H_2O/acetic acid (79/20/1, v/v/v) was used for the second extraction. The combined extracts were evaporated to dryness using a vacuum evaporator, and the residues were dissolved in 0.4 mL of MeOH and analyzed by using HPLC-photo diode array (PDA)-MS.

Assay To Determine Cell Death. Cells that accumulated Evans blue were considered as dead cells.[16] An aliquot of the cell suspension (200 μL) was incubated with 1.5 mL of 0.05% (w/v) Evans blue at room temperature for 15 min, subsequently washed twice with 1 mL of PBS, and resuspended in 500 μL of PBS. An aliquot of the suspension (20 μL) was transferred on microscope slides, and a total of 500 cells was scored under the light microscope, discriminating between living (uncolored) and dead (blue stained) cells.

HPLC-PDA-MS Analysis. An LXQ Linear Ion Trap MS^n system (Thermo Fisher Scientific, Waltham, MA, USA) equipped with a Finnigan Surveyor HPLC-PDA system was used. Separation was carried out on a reversed phase column (Phenomenex Luna C8(2), 250 × 4.6 mm i.d.). Solvent A was H_2O with 0.1% formic acid, solvent B was acetonitrile with 0.1% formic acid, and the flow rate was 0.5 mL/min. The linear gradient started with 20% B, held for 5 min, ramped to 50% B in 10 min, ramped to 70% B in 9 min, ramped to 100% B in 5 min, held for 2 min, decreased to 20% B in 1 min, and equilibrated for 2 min before the next injection. The metabolites were detected at 254 nm and characterized with MS operating in ESI positive mode. Full scan mass spectra were recorded from m/z 100−1000, MS^2 of the $[M + H]^+$ ions was conducted at CID 35 (35% of 5 V). Nitrogen was used as the sheath gas, auxiliary gas, and sweep gas with flow rates of 30.0, 15.0, and 0.02 L/min, respectively. Spray voltage was 4.47 kV, spray current 3.15 mA, capillary voltage 45.10 V, capillary temperature 350 °C, and the tube lens voltage was 125.58 V. Semiquantitative analyses were carried out by determining peak areas at 254 nm, using AOH or AME as external standard compounds.

Isolation of the Metabolites of AOH and AME. About 12 g of dry cells were collected from several incubations of each mycotoxin and extracted by scaling up the procedure described above, yielding about 40 mL of crude extracts dissolved in MeOH. These extracts were fractionated in portions of 1.5 mL using a preparative HPLC-UVD system (LC-8A pumps, SPD-20A UV detector, Shimadzu, Kyoto, Japan) and a reversed phase column (Phenomenex, Luna C18(2), 5 μm, 250 × 25.0 mm i.d.). Solvent A was water with 0.1% formic acid, solvent B was MeOH with 0.1% formic acid, and the flow rate was 8 mL/min. A linear gradient was started with 20% B held for 5 min, then ramped to 65% B in 20 min, ramped to 90% B in 1 min, and held for 4 min. Fractions of the separated metabolites were collected manually according to the chromatograms. After vacuum-concentration to about half of their volumes, the fractions were freeze-dried for HPLC-PDA-MS and NMR analysis. HPLC-PDA-MS was conducted as described above and showed that the purity of the AOH and AME metabolites used for NMR analysis was >97% (based on UV chromatograms at 254 nm).

Carbohydrate Analysis. Carbohydrate analysis was performed by high performance anion exchange chromatography (HPAEC) with pulsed amperometric detection (PAD) after acidic hydrolysis with 2 M trifluoroacetic acid for 30 min at 121 °C. After evaporation of the acid, the sample was redissolved in water and analyzed on an ICS-5000 HPAEC system (Thermo Scientific Dionex, Sunnyvale, CA, USA) using a CarboPac PA-20 column. The exact chromatographic conditions are described in Wefers et al. (2014).[17] To determine D-/L-configuration of the glucose unit in 9-*O*-β-glucopyranosyl-AOH, the glycosidic linkage was cleaved as described above. The residue after evaporation was derivatized with 150 μL of (*R*)-2-octanol and 5 μL of TFA at 130 °C overnight. After removal of the derivatization reagents, the sample was silylated by using 80 μL of *N*,*O*-bis(trimethylsilyl) trifluoroacetamide and 20 μL of pyridine. Sample analysis was performed by GC-MS (GC-2010 Plus and GCMS-QP2010 Ultra, Shimadzu, Kyoto, Japan) equipped with an Rxi-5Sil MS column (30 m × 0.25 mm i.d., 0.25 μm film thickness, Restek, Bad Homburg, Germany). Detailed chromatographic conditions are given in Wefers et al. (2014).[17]

NMR Spectroscopy. NMR spectra were recorded on a Bruker Ascend^M 500 spectrometer (Rheinstetten, Germany) equipped with a Prodigy cryoprobe. Freeze-dried samples were dissolved in 500 μL of DMSO-d_6. The structures of the isolated oligosaccharides were identified by using ^{1}H, H,H-correlated spectroscopy (COSY), heteronuclear single quantum coherence (HSQC), and heteronuclear multiple bond correlation (HMBC) experiments. Standard Bruker pulse sequences were used; spectra were acquired at 298 K. Chemical shifts (δ) were referenced to the central solvent signals (δH 2.50 ppm and δC 39.5 ppm).[18]

RESULTS AND DISCUSSION

Metabolite Patterns of AOH and AME Obtained from Tobacco BY-2 Cells. AOH and AME were incubated in tobacco BY-2 cell suspensions for 2 days during the exponential growth phase. The incubation medium after cell separation did not contain detectable amounts of free AOH and AME, suggesting complete mycotoxin uptake into the cells. Analysis of the cell extracts after disruption of the intact cells revealed the presence of small amounts of parental AOH and AME. The major part of the mycotoxins was, however, metabolized as demonstrated by five and seven peaks with spectroscopic

characteristics suggesting AOH and AME conjugates, respectively (Figure 2). None of these peaks was present in control incubations without mycotoxins. Variation of the mycotoxin concentration, incubation time, and cell mass did not change the number of potential conjugates, although slight changes in the size of the peaks were observed. All potential conjugates eluted earlier than AOH or AME from the reversed-phase column and had characteristic UV spectra similar to that of the parental mycotoxins, i.e., with absorption bands at about 254, 288, 299, and 340 nm. The m/z values of the quasi-molecular ions of the potential conjugates were higher than those of the parental compounds, but their MS^2 spectra showed the m/z values of the corresponding mycotoxins as major fragments.

To obtain sufficient quantities of the metabolites for structure elucidation, the combined cell extracts of several incubations were fractionated using preparative HPLC. All five metabolites of AOH and four dominant AME metabolites represented by peaks 2, 5, 6, and 7 (Figure 2) were isolated in quantities and purities that allowed for unambiguous structural characterization by NMR spectroscopy. The minor AME metabolites 1, 3, and 4 were isolated in small amounts only. Tentative structures could, however, be proposed based on their UV and mass spectrometric data as discussed later.

Structure Elucidation of the Major AOH and AME Conjugates. *AOH Metabolites.* The molecular mass of the AOH metabolite representing the dominant peak 2 (Figure 2A) was determined as 420 (quasi-molecular ion with m/z 421 $[M + H]^+$) consistent with a metabolite built of AOH and a hexose sugar. The mass difference between the quasi-molecular ion and the fragment m/z 259 $[AOH + H]^+$ also suggests AOH being attached to a hexose. HPAEC-PAD analysis after acidic hydrolysis revealed the hexose to be glucose. The aromatic region of the ^1H NMR spectrum of AOH metabolite 2 showed four AOH doublets with 2 Hz *meta* coupling constants. The carbons shifts of AOH were assigned by using the HSQC and HMBC spectra. Comparison of the ^1H and ^{13}C chemical shifts (Table 1) with those of parental AOH showed larger differences for C9, H8, and H10 suggesting a modification at the phenolic hydroxyl group attached to C9. Because DMSO was used as a solvent, intermolecular proton exchanges were slowed down resulting in several discrete OH signals in most samples. By using the HMBC experiment the phenolic OH protons can be assigned to specific carbons. Here, HMBC correlation peaks showed coupling of the phenolic proton in position 7, demonstrating that this phenolic group was not conjugated. The anomeric proton signal of the glucose moiety showed a coupling constant of 7.3 Hz implicating the β-anomer of the glucose unit. The appearance of one anomeric proton only and comparison of the ^1H and ^{13}C NMR data with those of glucose suggested the glucose to be bound via its lactol group to AOH. An HMBC correlation peak (Figure 3A) between the anomeric proton and C9 of AOH confirmed the glycosidic linkage in the suggested position and proved this compound to be 9-*O*-β-D-glucopyranosyl-AOH (Figure 1C).

Structure elucidation of the compound representing peak 3 (Figure 2A) showed many similarities to 9-*O*-β-D-glucopyranosyl-AOH. However, NMR data clearly demonstrate the linkage between the β-anomer of the glucose unit and the phenolic hydroxyl group in position C3 of AOH via a glycosidic linkage, identifying this compound as 3-*O*-β-D-glucopyranosyl-AOH (Figure 1D).

The remaining three potential AOH conjugates had molecular masses different from AOH glucosides. The mass

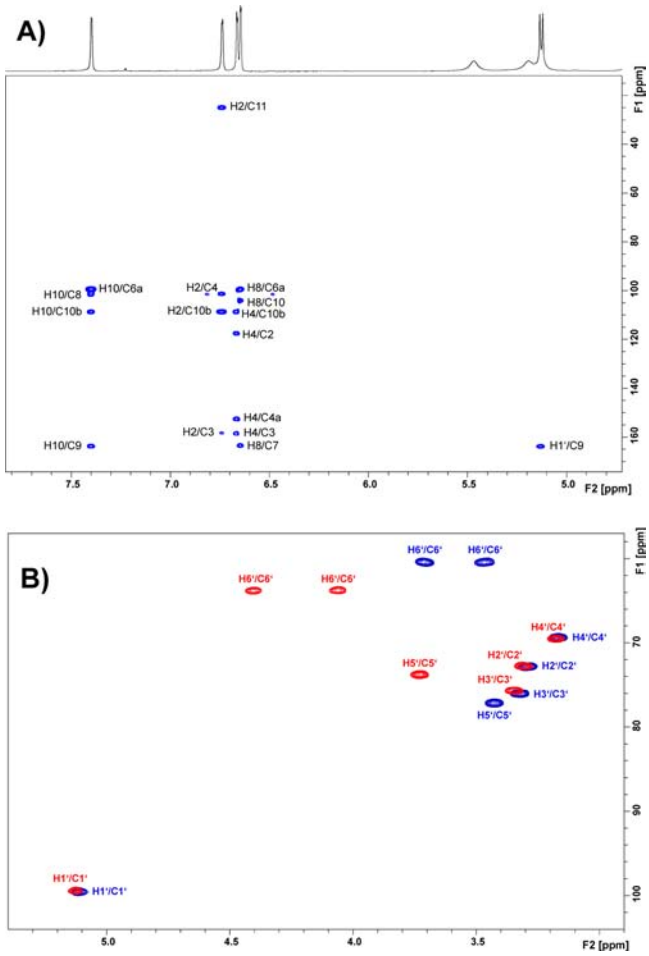

Figure 3. (A) HMBC spectrum (aglycone and anomeric region) of 9-*O*-β-D-glucopyranosyl-alternariol. (B) Overlay of the carbohydrate regions of the HSQC spectra of 9-*O*-β-D-glucopyranosyl-alternariol (blue correlation peaks) and 9-*O*-(6-*O*-malonyl-β-D-glucopyranosyl)-alternariol (red correlation peaks).

spectrum of peak 1 showed quasi-molecular ions with m/z 583 ($[M + H]^+$) and m/z 605 ($[M + Na]^+$), indicating a molecular mass of 582. Two mass losses of 162 Da resulting in m/z 421 and m/z 259 suggested that AOH is attached to a hexose disaccharide. NMR data confirmed this assumption and demonstrated an (1 → 6)-linkage between the two glucopyranose units (diagnostic HMBC signals, downfield shift of about 8 ppm for C6 of one glucose unit). Again, the coupling constants of the anomeric protons (7.2 Hz, 7.8 Hz) demonstrated both glucose anomers to be in their β-position. NMR data of the aglycone suggested its conjugation via the phenolic OH group at C9, which was unambiguously verified by interpretation of the HMBC spectrum. Thus, the compound representing peak 1 was identified as 9-*O*-{β-D-glucopyranosyl-(1 → 6)-β-D-glucopyranosyl}AOH (Figure 1E).

The quasi-molecular ions of the compounds representing peaks 4 and 5 (m/z 507, $[M + H]^+$; m/z 529, $[M + Na]^+$) suggest a molecular mass of 506 that cannot be explained by the formation of simple AOH glycosides. The MS^2 spectra showed a 248 Da mass loss resulting in a fragment with m/z 259 $[AOH + H]^+$. A mass loss of 248 Da indicates the elimination of an anhydro malonylglucoside as was also observed for isoflavone malonylglucosides.[19] Interpretation of the NMR spectra confirmed the substitution of the glucose unit

with a malonyl group. Linkage of the malonyl group to the glucose 6 position was obvious from the ^{1}H and ^{13}C data if compared to data of the non-malonyl conjugated AOH glucoside (Figure 3B, Table 1) and was confirmed by HMBC correlation peaks showing coupling of the malonyl carbonyl carbon and glucose 6 protons. Again, the glucose unit was proven to be in its *β*-configuration. NMR also revealed that the compounds representing peaks 4 and 5 differ in the AOH position to which the 6-*O*-malonyl-*β*-D-glucopyranosyl unit is attached. HMBC correlation peaks show the attachment to AOH position 9 (compound representing peak 4) and 3 (compound representing peak 5) identifying these AOH metabolites as 9-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AOH and 3-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AOH, respectively (Figure 1F,G).

AME Metabolites. Different from AOH, AME carries two phenolic hydroxyl groups only. Because of the methoxyl group in position 9, glycosidation in this position as shown for AOH is not an option. The quasi-molecular ion of peak 2 (Figure 2B) (*m*/*z* 457, $[M + Na]^+$) and the fragment *m*/*z* 273 ($[AME + H]^+$, mass loss of 162 Da) suggested AME to be conjugated with a hexose. NMR data (Table 2) indicated glucose conjugation of AME in position 7, which was confirmed by an HMBC correlation peak between the anomeric proton (*β*-configuration) and carbon 7 of AME identifying this compound as 7-*O*-*β*-D-glucopyranosyl-AME (Figure 1H).

The compound representing peak 5 has a molecular weight of 434 (quasi-molecular ion *m*/*z* 435, $[M + H]^+$), and its NMR-data are closely comparable to those of 3-*O*-*β*-D-glucopyranosyl-AOH with the exception of those data showing the difference between AOH and AME. Complete interpretation of the data including the HMBC correlation peak between the anomeric glucose proton and the AME C3 identified this compound as 3-*O*-*β*-D-glucopyranosyl-AME (Figure 1I).

The mass spectrum of the compound representing peak 6 suggested a malonyl conjugated AME glucoside (quasi-molecular ions of *m*/*z* 521 $[M + H]^+$ and *m*/*z* 543 $[M + Na]^+$, MS^2: *m*/*z* 273 $[AME + H]^+$). Independent interpretation of the NMR data but also comparison to the data of 3-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AOH suggested this compound to be 3-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AME. The linkage positions between AME, glucose, and the malonyl group were unambiguously confirmed by HMBC signals, identifying this compound as 3-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AME (Figure 1J).

Another malonyl glucoside of AME was obtained from peak 7. Again, both the quasi-molecular of *m*/*z* 521 ($[M + H]^+$) and the loss of 248 Da (representing an anhydro malonylglycoside) were indicative for such a structure. NMR data of the AME moiety of this compound were closely comparable to those of 3-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AME; however, large differences were found for the NMR data of the glucose moiety. A downfield shift of the glucose C4 signal and upfield shifts of both the C3 and C5 signals indicate the attachment of the malonyl group to the glucose 4 position, which was also confirmed by interpretation of the HMBC spectrum. Using the described information, this compound was identified as 3-*O*-(4-*O*-malonyl-*β*-D-glucopyranosyl)AME (Figure 1K).

Thus, all metabolites of AOH and AME contain *β*-glucopyranose linked through a glycosidic bond to various

DOI: 10.1021/acs.jafc.5b00806
J. Agric. Food Chem. 2015, 63, 4728−4736

hydroxyl groups of the mycotoxins. To prove that glucose was in its D-configuration, 9-*O*-*β*-D-glucopyranosyl-AOH was hydrolyzed under acidic conditions. The liberated glucose was derivatized with (*R*)-2-octanol, silylated, and analyzed by GC-MS confirming that glucose was present in its D-form. From these results it was assumed that all glucose units in the identified AOH and AME conjugates were in their D-configuration. Whereas both available phenolic hydroxyl groups (in 3- and 7-position) of AME were found conjugated with glucose, a conjugate in which the phenolic hydroxyl group in position 7 of AOH was substituted with glucose was not found as a major AOH conjugate. Lack of conjugation may be due to the hydroxyl group being engaged in hydrogen bonding with the neighboring carbonyl group at C6 (Figure 1). In contrast, 7-*O*-glucosylation occurred in the conjugation of AME to a small extent; 3-*O*-glucosylation was, however, predominant (see below). A similar difference in the conjugation of AOH and AME was observed in an *in vitro* study on the glucuronidation with human hepatic microsomes and recombinant human UDP-glucuronosyl transferases (UGTs). AOH was glucuronidated at the C3 and C9, but not C7 hydroxyl groups, and the rate and ratio of C3 and C9 conjugation were dependent on the individual UGT isoform.[9] For AME, glucuronidation was clearly preferred at C3 by most UGT isoforms, but a few isoforms, e.g., UGT1A7, catalyzed the conjugation at C7. Similar differences in the conjugation can be assumed for plant cells, which are known to differ in their pattern of UDP-glucosyltranferases.[12] For example, Kovalsky Paris et al. (2014) recently identified an UDP-glucosyltransferase from barley, which did not catalyze the common glucosylation of zearalenone at the 14-hydroxyl group only, which is equivalent to the 9-hydroxyl of AOH, but also at the 16-hydroxyl group, which is neighboring a carbonyl group similar to the 7-hydroxyl groups of AOH and AME.[20]

The monoglucosides are, in part, further conjugated at the glucopyranoside moiety with another *β*-D-glucopyranose (forming a gentiobiose conjugate). A gentiobiose conjugate was unambiguously identified for AOH only. However, the MS spectra and HPLC retention times of AME peaks 1 and 3 (Figure 2B) also suggest the existence of an AME-7-diglucoside and an AME-3-diglucoside, respectively. Because NMR spectra were not obtained from the minor quantities of these metabolites, the position of conjugation was deduced from the observation that metabolites with identical conjugate moiety are eluted earlier if conjugated at C7 as compared to those conjugated at C3. In addition, two malonyl glucosides of AOH and two malonyl glucosides of AME were unambiguously identified. On the basis of its mass spectrum and elution behavior a fifth malonyl glucoside was tentatively identified as 7-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AME. Earlier studies describe a malonyl migration for malonyl glucosides of various phytochemicals such as isoflavones. Acyl migration, especially 4 → 6 migrations, are frequently described in the literature.[21] Exemplarily, 4 → 6 migration was observed for malonylgenistin.[19] Therefore, solutions of the isolated AME malonyl glucosides in MeOH and DMSO were tested for their stability. Both compounds 3-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AME and 3-*O*-(4-*O*-malonyl-*β*-D-glucopyranosyl)AME were stable within the test period of up to 2 weeks.

Quantitative Aspects of AOH and AME Conjugation in Tobacco BY-2 Cells. Although it was not the aim of this study to exactly quantitate the metabolites and investigate the kinetics of their formation, a striking difference in the quantitative pattern of the metabolites of AOH and AME was noted. After 48 h incubation of AME (50 μM in medium), about 75% of the applied amount was recovered in the form of extractable conjugates. Conjugation with glucose took place at the phenolic hydroxyl groups located at positions C3 (about 90%) and C7 (10%) (Figure 2B). About 10% of the recovered metabolites remained as the monoglucoside 3-*O*-*β*-D-glucopyranosyl-AME, whereas 80% were further metabolized by malonylation, preferentially (70%) at the glucose 6 position but also at the 4 position (10%). The only notable change in the pattern of AME metabolites due to varying incubation times concerned the proportion of 3-*O*-*β*-D-glucopyranosyl-AME, which decreased from 25% after 24 h incubation to 5% after 96 h, with a concomitant increase of 3-*O*-(6-*O*-malonyl-*β*-D-glucopyranosyl)AME (data not shown).

After 48 h incubation of AOH (50 μM in medium), the total recovery of the applied amount as extractable conjugates was only about 50%, and the major proportion (80%) of the recovered material consisted of the monoglucosides 9-*O*-*β*-D-glucopyranosyl-AOH (60%) and 3-*O*-*β*-D-glucopyranosyl-AOH (20%). Notably, the corresponding malonylated 9-*O*- and 3-*O*-glucosides of AOH together accounted for only 13% of the extractable conjugates. This pattern did not differ much at incubation times of 24 and 96 h. The major difference was an increase of 9-*O*-{*β*-D-glucopyranosyl(1 → 6)-*β*-D-glucopyranosyl}AOH from 7% at 24 h to 25% at 96 h, accompanied by a decrease of 9-*O*-*β*-D-glucopyranosyl-AOH (data not shown). In addition, the total recovery of extractable AOH metabolites decreased to about 35%.

Implications. Our study demonstrated that the *Alternaria* toxins AOH and AME are efficiently conjugated in cultured tobacco BY-2 cells, a widely used *in vitro* model for plant cell metabolism. The first metabolic step for both mycotoxins is conjugation with glucose. Metabolic conjugation during phase II metabolism is comparable in mammals and plants and considered an important first detoxification step for endogenous and exogenous compounds.[22] Major differences, however, between mammals and plants exist in the fate of such conjugated metabolites. Whereas animals and humans are able to rapidly excrete phase II metabolites via urine and bile, plants are basically unable to excrete phase II metabolites. Thus, storage of the metabolites either as soluble conjugates in vacuoles or as insoluble conjugates bound to cell wall components becomes essential. Both options require further modification of the primary conjugates. Whereas malonylation of the glucoside is considered a signal for transport into vacuoles, further glycosylation is supposed to enable incorporation into the cell wall.[22] Both processes are, however, not well understood on a molecular and cellular level. From our first semiquantitative data it appears that malonyl conjugation of the primarily formed glucosides is the preferred pathway for AME, whereas AOH is glycosylated, but less readily malonylated. Thus, it can be assumed that AME detoxification through conjugation and storage in the vacuole is a more efficient process for AME as compared to AOH. The efficient formation of malonyl glucosides and their potential storage in the vacuole may also explain the comparatively high recoveries for AME in our experiments, whereas much less AOH was recovered. Thus, it can be assumed that AOH is preferentially stored in the cell wall, a hypothesis that, however, needs to be investigated in future studies.

Another difference observed between AOH and AME incubations was related to cell growth. Growth of cells

DOI: 10.1021/acs.jafc.5b00806
J. Agric. Food Chem. 2015, 63, 4728−4736

incubated with AME was comparable to control cells without mycotoxin; a reduction of cell mass was, however, noted if the cells were incubated with AOH. Therefore, cell cultures were treated during the lag phase of growth with the mycotoxins (50 μM in medium) for 24, 48, and 72 h, and the wet weight of cells was determined. An aliquot of the cells was stained with Evans blue to indicate dead cells and scored by light microscopy. Whereas the cell mass of AME-treated cells increased up to 6 fold with a slight decrease of dead cells, no significant increase in the cell mass was observed in AOH-treated cells, but the percentage of dead cells increased up to 40% over time. Thus, the impact of *Alternaria* toxins and their conjugates on phytotoxicity is another factor that needs to be investigated in future studies.

While we unambiguously proved the formation of conjugates of *Alternaria* toxins in cell suspensions, the formation of these conjugates also needs to be demonstrated in field plants as a first step to evaluate a potential impact of AOH and AME conjugates on food and feed safety. A very first approach to measure conjugated *Alternaria* toxins was performed by Walravens and co-workers who developed an UPLC-MS/MS method to analyze glucosylated AOH and AME using synthesized standard compounds.[23] Syntheses of 9-*O*-β-D-glucopyranosyl-AOH, 3-*O*-β-D-glucopyranosyl-AOH, and 3-*O*-β-D-glucopyranosyl-AME were described by Mikula et al.,[24] but only 3-*O*-β-D-glucopyranosyl-AOH and 3-*O*-β-D-glucopyranosyl-AME were used for the method development mentioned above. Analyses of 24 cereal-based food products did not detect any 3-*O*-β-D-glucopyranosyl-AOH (the less abundant glucose-conjugated AOH metabolite in our study) or 3-*O*-β-D-glucopyranosyl-AME in these samples, which, however, did not contain AME, too, and only trace amounts of AOH. Therefore, more studies that include the full array of metabolites identified in our study using food products from different plant families are required to estimate the impact of AOH and AME conjugates on food and feed safety.

Supporting Information

ABSTRACT: Many groundwaters used for irrigation contain elevated concentrations of F, but much remains unknown regarding how this F behaves within soils and plants. The present study investigated the adsorption and desorption of F from several soils in short- to medium-term irrigation systems and related foliar F concentrations in three forage plant species to the maximum tolerable level (MTL) in the diets of grazing animals (being 1.8 μmol/g for young cattle, for example). Although adsorption isotherms could be successfully used to predict the behavior (adsorption and desorption) of F within the soil, this was not related to the subsequent accumulation of F in plant foliage. In addition, the extent to which F accumulated in the foliage depended on the plant species. Regardless, F generally did not accumulate in plant foliage to levels exceeding the MTL when used at rates equivalent to irrigation for 25 years. In addition to uptake by roots, F may accumulate in foliar tissues directly due to retention from overhead irrigation. The data presented here regarding the behavior of F in soils and plants will assist in the rigorous regulation of F-containing irrigation water to ensure maximum plant growth while simultaneously minimizing potential harm.

KEYWORDS: *adsorption and desorption, fluoride toxicity, fluoride uptake, lucerne, leucaena, Rhodes grass*

INTRODUCTION

Fluoride (F) is present naturally in the environment and is a common constituent of groundwater. However, agricultural activities, particularly the use of phosphatic fertilizers,[1] and industrial activities can also result in its accumulation to levels which are of concern in both soils and waters. At a concentration of ca. 0.053 mM (1 mg/L), F can mitigate against dental decay and is often added to potable water supplies. However, consumption of excess F can cause dental fluorosis or, in extreme cases, skeletal fluorosis. The concentration of F in groundwater is typically <0.053 mM, but concentrations of 0.25−1.0 mM are not uncommon.[2] The maximum concentration of F permitted in groundwater used for irrigation varies substantially depending upon the country and the conditions under which the water is to be irrigated (for example, soil type), ranging from 0.053 mM (1 mg/L) to 0.79 mM (15 mg/L).[3] In irrigated areas, the use of groundwater containing elevated levels of F is of concern not only due to direct ingestion of water by livestock but also due to its consumption in plant matter following its plant uptake from irrigated soils. The maximum tolerable level (MTL) of F in plant material has been developed as a guideline for the upper limit of F that different classes of animals may consume without a high risk of developing fluorosis, with the MTL for F ranging from 1.8 μmol/g (35 mg/kg) for young beef calves and heifers to >5.3 μmol/g (100 mg/kg) for swine and poultry.[4]

Given the worldwide problem regarding the irrigation of waters containing elevated F, the focus of this study was the Great Artesian Basin (Australia) which is the largest artesian basin in the world, containing an estimated 65000 million ML of groundwater.[5] The groundwater and coal seam water in this basin can be used for agriculture, and concentrations of F are typically <0.26 mM (5 mg/L).[6,7] Of particular interest to this study, the coal seam water, which is released during production of coal seam gas (also termed coal bed methane) can be used beneficially to increase agricultural production, although production of coal seam water only lasts for 10−15 years, after which no further irrigation is possible. Although the general irrigation of groundwater for agricultural production would typically exceed these timeframes, these traditional agricultural systems are not the focus of the present study.

In order to understand the risk of F uptake into forages, three factors are of interest: (i) adsorption and desorption of F by soils, (ii) uptake of F from soils by plant roots, and (iii) retention of F on the foliage of plants grown using overhead irrigation. Although numerous studies have investigated the F adsorption capacities of soils,[8−15] few have investigated desorption of F from soil surfaces back into the soil solution (as required for subsequent plant uptake).[9−12] The accumulation of F in foliar tissues resulting from irrigation with water containing F has also received comparatively little investigation.[16−22] Singh et al.[23] found that irrigation with 6.3 mM F will not harm okra (*Abelmorchus esculentus*) plants and that irrigation with 0.53 mM F resulted in fruit containing F at a concentration of 0.11 μmol/g. Another study investigating

uptake and concentration of F in rice (*Oryza sativa* L.) irrigated with water containing up to 0.21 mM F found the concentration of F in the leaves to be >2.6 μmol/g.[24] Unfortunately, these studies do not differentiate between F taken up by plant roots and that accumulated by foliar tissues through direct contact with irrigation water. Indeed, we are aware of only one study examining the retention of F by foliar tissues as a result of direct contact between F in irrigation water and foliar surfaces.[25] These authors found that the accumulation of F on the foliar surfaces of bush beans (*Phaseolus vulgaris* L.) increased with increased F concentration of irrigation water and increases in irrigation frequency.

The aim of the present study was to investigate the risk of F accumulation above the lowest recommended MTL (young beef calves and heifers, 1.8 μmol F/g) in three forage plant species grown on a range of soils irrigated with groundwater containing concentrations of F above the current conservative regulated limit of 0.053 mM, as used in Australia, the USA, and Canada.[3] In doing so, three key factors were examined: (i) adsorption/desorption of F in soils (and hence concentrations of plant-available F in the soil solution), (ii) plant root uptake of F from the soil solution and translocation to foliar tissues, and (iii) the accumulation of F in foliar tissues from direct contact between F in irrigation water and foliar surfaces. Of particular interest were irrigated systems of short- to medium-term duration (i.e., < 20 years where water resources are limited), such as irrigation of coal seam water, irrigation to establish forestry/grazing systems, or irrigation to supplement the water supply in variable rainfall environments.

MATERIALS AND METHODS

Selection and Preparation of soils. Three experiments were conducted to investigate the movement of F within soils and plants. Experiment 1 was conducted in the laboratory and investigated the adsorption and desorption of F by soils. Experiment 2 was conducted in the greenhouse and investigated the uptake of F from F-loaded soils, and experiment 3 investigated the retention of F due to overhead irrigation. Six soils were used for these experiments: an alfisol, a red vertisol, a brown vertisol, a red ultisol, a yellow ultisol, and a spodosol. These soils were collected from various regions within the Great Artesian Basin and were representative of typical soils used for agricultural production (Table S1, Supporting Information), with the mineralogy being examined using quantitative X-ray diffraction (Table S2, Supporting Information).[26] A washed white quartz sand from North Stradbroke Island (Australia) was included as a control (the sand treatment is referred to as a "soil" for brevity). These soils had not previously been irrigated with groundwater and were selected as they were expected to vary in their F adsorption capacities. All soils were collected, air-dried, mixed, and ground to pass a 1 mm sieve.

Experiment 1: Soil F Adsorption and Desorption. First, a laboratory experiment was conducted to investigate the adsorption of F by soils. The NaF was added to the soil at seven rates, with seven soils (five soils had three separate layers and two soils had only a single layer; Tables S1 and S2, Supporting Information), and three replicates per treatment, yielding a total of 357 experimental units. Triplicate blanks (controls) containing no soil were also included and measured in the same manner as that for the soil samples. Soil subsamples (2 g) were weighed into 15 mL tubes, and 8 mL of deionized water and 2 mL of F solution was added. The solutions added contained F at concentrations of 0, 0.26, 1.1, 2.6, 6.6, 13, and 26 mM, yielding final nominal F concentrations of 0, 0.053, 0.22, 0.52, 1.3, 2.6, and 5.2 mM (0, 1, 4, 10, 25, 50, and 100 mg/L) with corresponding pH values ranging from 6.5 to 7.3. The lower F concentrations used were similar to those of irrigation waters, but much higher values were also used because preliminary experiments showed that these concentrations were required in order to reach maximum sorption. For each soil, a control (i.e., without soil) was included to allow for the measurement of the F added. Samples were shaken for 24 h on an end-over-end mixer[13] and centrifuged for 5 min. Then, 2 mL of the supernatant was mixed with 2 mL of total ionic strength adjusting buffer (TISAB, containing 1 M acetic acid, 1 M NaCl, and 4 g/L CDTA),[27] and the activity of the F^- was measured using an F^- ion selective electrode (TPS IONODE IJ-F, Australia). The pH of the supernatant was measured following shaking, with the pH increasing an average of 0.64 unit following addition of F (Figure S1, Supporting Information).

Second, following its adsorption to the soil matrix, desorption of F was investigated. Subsamples of untreated soils (2 g) were weighed into 15 mL tubes, and 10 mL of artificial groundwater was added containing F at a concentration of either 0.26 or 6.6 mM. Thus, the desorption study consisted of two F concentrations with seven soils (some with three layers), each with three replicates, and with triplicate blanks (controls, with no soil). Soils were allowed to equilibrate with F solution in an end-over-end mixer for 7 days and the samples centrifuged. The supernatant was removed, and the F^- activity was measured following the same procedure outlined above. The supernatant was replaced with 10 mL of deionized water, the sample was resuspended, and the tube was shaken for 1 h before the supernatant was again removed for the measurement of F^-, determining the F desorbed. This desorption process (i.e., addition of water, resuspension, and subsequent removal of supernatant) was repeated a total of seven times.

For statistical analysis of adsorption and desorption, the free F^- (mM) and bound F (mmol/kg) of the adsorption experiment were fitted by nonlinear regression to the Langmuir adsorption isotherm (SigmaPlot 12.3, Systat Software Inc., Chicago, IL, USA) given as

$$Q = Q_{max}\frac{K[A]}{1 + K[A]} \quad (1)$$

where Q is the adsorption capacity, Q_{max} is the maximum adsorption capacity, K is the binding strength, and A is the concentration of F at equilibrium (or free F). Relationships between K and Q_{max} were investigated using Pearson's correlation coefficient (Minitab 16, Minitab Inc., State College, PA, USA).

Experiment 2: Uptake of F by Roots. This experiment aimed to investigate the root uptake of F from four F-loaded soils using leucaena (*Leucaena leucocephala* (Lam.) de Wit ssp. *glabrata* cv. Tarramba), lucerne (*Medicago sativa* L. cv. L91), and Rhodes grass (*Chloris gayana* cv. Top Cut). The three plant species were grown on four of the soils used in experiment 1 (red Ultisol (0−15 cm), yellow Ultisol (0−15 cm), red Vertisol (0−15 cm), and sand) which were loaded with four levels of F: control (0), 2.6, 7.9, and 26 mmol of F/kg of soil (0, 50, 150, and 500 mg of F/kg). The maximum concentration used (26 mmol of F/kg soil) was equivalent to the application of 200 ML/ha water containing 0.26 mM F (5 mg/L F) to the top 20 cm of the soil (assuming an annual irrigation rate of 8 ML/ha, this a loading for ca. 25 years). Thus, there were 12 treatments per soil type (three species and four F concentrations) with four replicates. In addition, there were also three pots of each treatment with no plants. This gave a total of 51 pots per soil and 204 pots across the entire study, which were arranged in a completely randomized design.

In order to incorporate the F, each soil (excluding sand) was weighed and divided into four samples. For three of these samples, F (as NaF) was dissolved into 5 L of deionized water and sprayed evenly across the surface of the soil. The soil was mixed thoroughly while the 5 L of F solution was being applied. Due to its low adsorption capacity, F was added to sand by adding the F to the amount of water required for each pot to reach field capacity (1 L). The soil was placed in pots (200 mm, holding ca. 6 kg of soil per pot), and the pot was wrapped in reflective insulation foil and positioned on a capillary watering bench to reduce leaching through the pot and maintain constant water content within the soil. White polypropylene beads were placed on the top of the soil to reduce evaporation, and a basal application of "Flowfeed EX7" (21 N:3.3 P:17.4 K + trace elements) fertilizer (1 g/L) was added every 2−3 weeks.

DOI: 10.1021/acs.jafc.5b01001
J. Agric. Food Chem. 2015, 63, 4737−4745

Approximately 20 seeds were sown in each pot, and germination was good for all treatments other than the F-containing sand treatments, where no seeds were observed to germinate in the 7.9 and 26 mmol F/kg treatments (and only low germination took place in the 2.6 mmol of F/kg treatment). For these sand treatments, seeds of all species were germinated in the laboratory before transplanting; however, there was again 100% mortality. Following their establishment, seedlings were thinned to three plants per pot and grown for 8 weeks during summer. During this growth period, average minimum temperatures were 22 °C with average maximum temperatures of 33 °C, with typical photosynthetically active radiation levels during the middle of the day of 1500 μmol of photons m^{-2} s^{-1}. The above-ground plant material was harvested, weighed, and dried in an oven at 60 °C for 4 days.

Soil solution was extracted from the soil using centrifugation.[28] The solution was analyzed for pH and F (1:1 with TISAB). To determine the concentration of F within the plant tissues, samples were prepared for NaOH fusion.[29] Prior to the measurement of F, the solution was mixed 10:4 with concentrated TISAB buffer to ensure pH 5.4 and to prevent the F from forming complexes that would interfere with the measurement of F. Our calculations indicate a 10-fold excess of CDTA over Al ions in the assays, with CDTA effectively complexing all soluble Al in soil solution. Activities of the free F^- ion in the solutions were determined by a F ion selective electrode.

The data were analyzed using a two-way analysis of variance (ANOVA) to investigate the relationships between F additions to soils, soil types, and plant species. The F concentration of soil solutions of the four soils was also investigated by conducting a two-way ANOVA, although sand treatments were removed for the soil F concentrations, as the variance did not conform to the normal distribution. Statistical analysis was conducted using Genstat (VSN International, Hemel Hempstead, U.K.) and Minitab 16.

Experiment 3: Foliar Retention of F. This experiment aimed to investigate foliar retention of F from direct contact between foliar surfaces and groundwater containing F. In systems irrigated with coal seam water (as with other systems), foliage will also occasionally be rinsed with low-F water (for example, rainfall). This would potentially remove much of the F previously accumulated on the foliage. To separate the effect of root uptake from foliar adsorption, we grew plants in an oxisol (Table S2, Supporting Information), since this soil had a very high F adsorption capacity and limited plant uptake of F from the soil. Furthermore, the soil surface of the pots was covered with plastic sheets to minimize the infiltration of irrigation water into the soil.

This experiment consisted of the three plant species utilized in experiment 2 and four F concentrations in artificial groundwater (0, 0.053, 0.16, or 0.26 mM, added using NaF and verified by measurement using an ion-selective electrode), each with three replicates arranged in a randomized block design totaling 36 pots (each pot containing three plants). The highest concentration of F utilized for experiment 3 (0.26 mM) represents the highest concentration of F generally found in the groundwater of the Great Artesian Basin (95% of groundwater wells having ≤0.26 mM F).[6] After an initial growing period of ca. 8 weeks, plants were overhead-irrigated twice weekly using irrigation chambers connected to a pump and a 100 L drum containing one of the four F treatments. The 100 L of water was irrigated per treatment, taking around 30 min. Plants were irrigated with the F-containing solutions a total of eight times. To investigate whether any F retained on the leaf surface could be subsequently leached by application of good-quality water following these eight F irrigations, the plants were irrigated with deionized water for 10 min to simulate a rainfall event, allowed to dry overnight, and harvested. Plants were allowed to grow for a further 2 weeks to see if any F remaining in the plant foliage was volatilized and lost over time.

Plant foliage was randomly harvested after 0, 4, and 8 irrigations with F treatments. Plant tissue samples were also collected following irrigation with deionized water and after the subsequent 2 week growth period. Foliar concentrations of F were measured after NaOH fusion (see experiment 2) using an F ion selective electrode, as discussed previously. Approximately 300 g of soil from five randomly selected pots of each treatment (20 pots in total) was collected and the soil solution extracted by centrifugation, as outlined in experiment 2.

Statistical analyses were conducted in Genstat and Minitab 16, with the relationship between number of irrigations and plant F concentrations investigated using a two-way ANOVA. Similarly, the relationship between plant species and F in irrigation water was investigated using a two-way ANOVA.

RESULTS

Experiment 1: Soil F Adsorption and Desorption. The seven soils varied substantially in their capacity to adsorb F—a Langmuir adsorption isotherm could not be fitted to the sand due to its low adsorption capacity (Figure 1 and Table 1). The

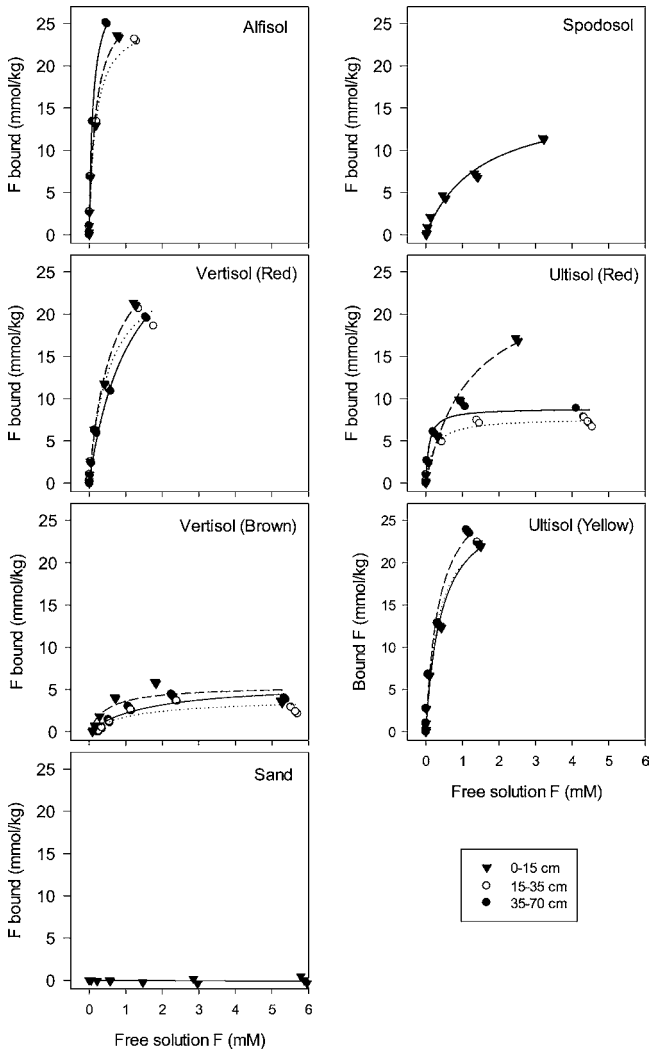

Figure 1. Adsorption isotherms of F for seven different soils (experiment 1) fitted using the Langmuir equation.

lowest binding strength was observed for the brown vertisol (K = 0.6−2.0 mmol/L) and spodosol (K = 0.7 L/mmol), suggesting that these soils weakly bind F. The highest sorption capacity (Q_{max}) was determined for the yellow ultisol (Q_{max} = 26.7−30.3 mmol/kg), alfisol (Q_{max} = 25.8−30.6 mmol/kg), and red vertisol (Q_{max} = 26.7−34.2 mmol/kg) (Figure 1 and Table 1). Interestingly, the red ultisol was the only soil to differ substantially in F sorption on comparison of different layers through the soil profile, with the surface layer (0−15 cm) having a Q_{max} value of 24.7 mmol/kg, decreasing to 8.8 mmol/

	35–70	34 ± 1.8	0.8 ± 0.1	0.994
alfisol	0–15	29 ± 1.0	5.5 ± 0.6	0.991
	15–35	26 ± 0.7	5.7 ± 0.5	0.990
	35–70	31 ± 1.0	9.0 ± 0.8	0.990
spodosol	0–25	16 ± 1.2	0.7 ± 0.1	0.979

[a]The values were determined by nonlinear regression, and the regression parameter R^2 is shown in the last column. The sand is excluded due to inability to fit data to the Langmuir equation with low adsorption capacity.

kg at 35–70 cm depth, whereas the binding strength increased with depth, from K = 0.8 L/mmol in the 0–15 cm layer to 11.4 L/mmol in the 35–70 cm layer.

Next, the desorption of F was investigated. As expected, the extent of F desorption increased with increasing washing steps, with ca. 20–80% of the F desorbed after seven washes (Table 2 and Figure S2 in the Supporting Information). A notable exception was the brown vertisol, which desorbed more F than was initially added in the 15–35 cm (188%) and 35–70 cm (159%) layers (Table 2), thereby indicating that this soil already contained appreciable F. In general, more F was desorbed from soil treated with a higher F concentration (6.6 mM vs 0.26 mM) (Table 2). Importantly, the desorption of F was significantly correlated (negatively) to the K value estimated by the Langmuir equation for both low (0.26 mM) and high (6.6 mM) F treatments (r = −0.54 and −0.68, respectively; P < 0.05), thereby indicating that the binding strength (K) would appear to be a useful measure for predicting the F retention capacity of the soils examined. For example, in the red ultisol, as K increased from 0.8 (0–15 cm depth) to 11.4 (35–70 cm depth), the extent of F desorption decreased from 63 to 38% (Tables 1, and 2 and Figure S2 in the Supporting Information).

Experiment 2: Uptake of F by Roots. The addition of F influenced plant growth to varying extents depending upon the soil type. For the sand, growth was reduced substantially, with almost complete mortality in most of the F-containing treatments. In the yellow ultisol, dry matter of lucerne and Rhodes grass decreased significantly as the F-application rate was increased from 0 to 26 mmol/kg but the dry matter of leucaena was unaffected. In the red ultisol and red vertisol, the addition of F to the rooting environment had no significant effect on the dry matter of the plants (P > 0.05).

For this experiment, increases in soil solution F concentrations followed trends expected from the Q_{max} and K values obtained in the laboratory-based study (i.e., experiment 1). For example, when F was added at a rate of 26 mmol/kg, soil solution concentrations of F were highest in the sand (96 mM), followed by the red ultisol with 4.5 mM, the yellow ultisol with 1.0 mM, and the red vertisol with 0.58 mM (see Figures 1 and 2 and Table 1). For the red ultisol, the addition of F increased the pH of soil solution by ca. 3 pH units, with the increase in the other soils being ca. 1 pH unit (Figure S3, Supporting Information). Interestingly, the pH in the solutions of soils growing Rhodes grass was higher than those for lucerne and leucaena in red ultisol, yellow ultisol and red vertisol in every F treatment (excluding red ultisol 26 mmol F/kg; Figure S2, Supporting Information)—this requires further investigation.

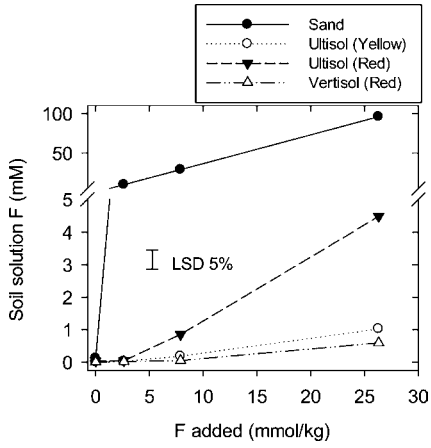

Figure 2. Soil solution F concentration (averaged across all three plant species) for four soils treated with increasing concentrations of F (0, 2.6, 7.9, or 26 mmol F/kg, experiment 2). The vertical bar represents the least significant difference (LSD, 5%) to allow comparison either between soils at a single rate of F or between F rates for the same soil.

J. Agric. Food Chem. 2015, 63, 4737–4745

Given the increase in soil solution F concentrations (see above), it was also not surprising that the addition of F to soils increased the foliar concentrations of F (Figure 3). A significant

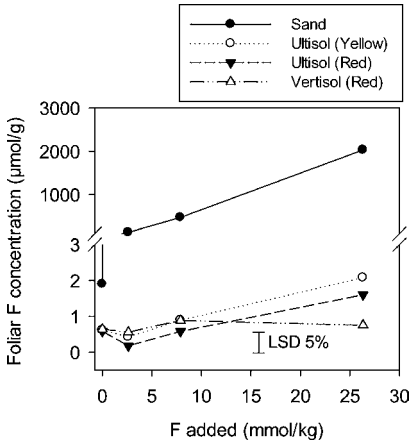

Figure 3. Concentration of F in plant foliar material (averaged across all three species) grown on four soils treated with increasing concentrations of F (0, 2.6, 7.9, or 26 mmol F/kg, experiment 2). The vertical bar represents the least significant difference (LSD, 5%) to allow comparison either between soils at constant F or between F concentrations for the same soil.

interaction ($P < 0.001$) was found between the soil type and the rate of F addition, indicating that while the addition of F to the soil significantly influenced the concentration of F in plant material, the pattern of this response varied for each soil (Figure 3). Indeed, the increase in foliar F was greatest in sand (increasing from an average of 1.9 to 2000 μmol F/g) and least for the red vertisol (increasing from an average of 0.63 to 0.74 μmol F/g) (Figure 3). The uptake of F was influenced not only by soil type but also by plant species. For the yellow ultisol, red ultisol, and sand (but not the red vertisol), analyses of individual plant species identified a significant interaction between the rate of F addition and plant species ($P < 0.001$) (Figure 4). For example, in the sand, yellow ultisol and red ultisol treated with 26 mmol of F/kg, lucerne accumulated significantly more F in the foliage than did Rhodes grass or leucaena.

To determine the factors regulating the uptake of F from the soil solution, the foliar concentrations were first related to total concentrations of F in the soil solution. When the foliar concentrations of F were examined across the different soils, data for the sand had to be excluded from linear regressions, as these high F concentrations had statistically high leverage. Across the remaining three soils, the foliar F concentration was not related to the total concentration of F in the soil solution for either Rhodes grass ($R^2 = 0.079$) or leucaena ($R^2 < 0.001$), although a weak relationship was found for lucerne ($R^2 = 0.539$) (Figure 5). These differences between species are perhaps not surprising, given that lucerne was the only species in which tissue F concentrations increased substantially (excluding the sand treatments) (Figure 4). Unsurprisingly, when the foliar F concentrations were examined for each soil individually, the relationship was also generally poor (other than for the sand) (Figure S4, Supporting Information). Given the lack of relationship with the total soluble F concentrations, thermodynamic modeling was also conducted using PhreeqcI v3.1.2 (Minteq database) to determine if the F concentration in the foliage was related to the speciation of F in the soil solution.

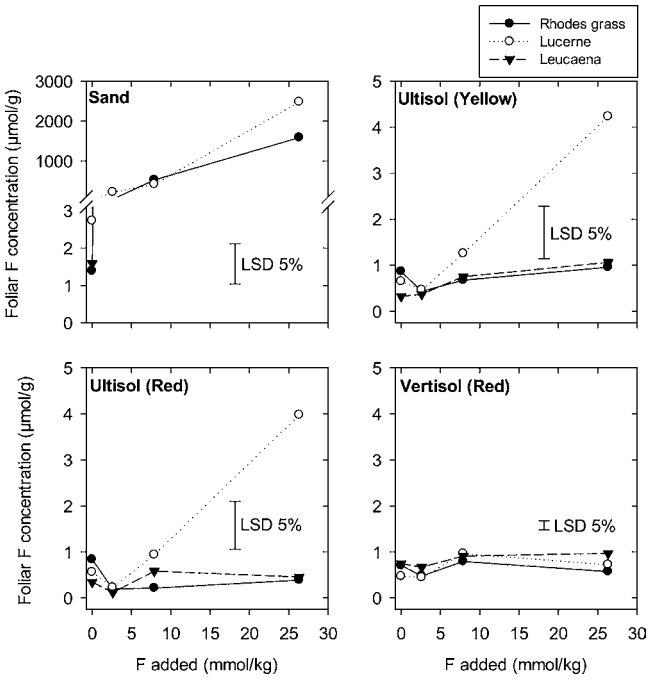

Figure 4. Foliar F concentrations of Rhodes grass, lucerne, and leucaena grown on four soils (a sand, a yellow ultisol, a red ultisol, and a red vertisol) treated with 0, 2.6, 7.9, or 26 mmol F/kg (experiment 2). Due to greatly reduced growth, leucaena plants in the 2.6, 7.9, and 26 mmol F/kg treatments could not be analyzed in the sand due to insufficient dry plant material. The vertical bar represents the least significant difference (LSD, 5%) to allow comparison either between plant species at constant F or between F concentrations for the same species.

As expected, the speciation of F varied substantially between soils, with F present predominantly as the free F^- ion in both the Red Ultisol and the Sand but as Al−F complexes in the yellow ultisol (data not presented). Although various relationships were observed using this thermodynamic modeling, no consistent relationship was found across all four soils and three plant species (data not presented).

Experiment 3: Foliar Retention of F. Overhead irrigation of F-containing groundwater was found to influence the foliar F concentration (Figure 6a). The accumulation of F in the foliage resulting from soil uptake was negligible, given that the concentration of F within the soil solution of the oxisol averaged across all four treatments was <0.003 mM (cf. experiment 2; see Figure 2 for example).

A significant interaction was found between increasing irrigations of F-containing water and plant species ($P < 0.001$), indicating that not only does the cumulative application of F in irrigation water increase foliar F concentrations but also the pattern of response differs between plant species (Figure 6a). Lucerne was found to retain the highest concentration of F in the foliar material; after four irrigations (second harvest) with 0.26 mM irrigation water, the concentration of F in lucerne foliar tissues increased from 0.37 to 1.7 μmol F/g, and following eight irrigations (third harvest) the plant material increased further to 2.3 μmol F/g: a ca. 6-fold increase ($P < 0.05$, Figure 6a). Conversely, increases in tissue concentrations were more modest for the other two plant species, increasing from 0.53 to 0.79 μmol of F/g for Rhodes grass and 0.37 to 1.1 μmol of F/g for leucaena after eight irrigations at ca. 0.26 mM (Figure 6a). The concentration of F within the irrigation water

J. Agric. Food Chem. 2015, 63, 4737−4745

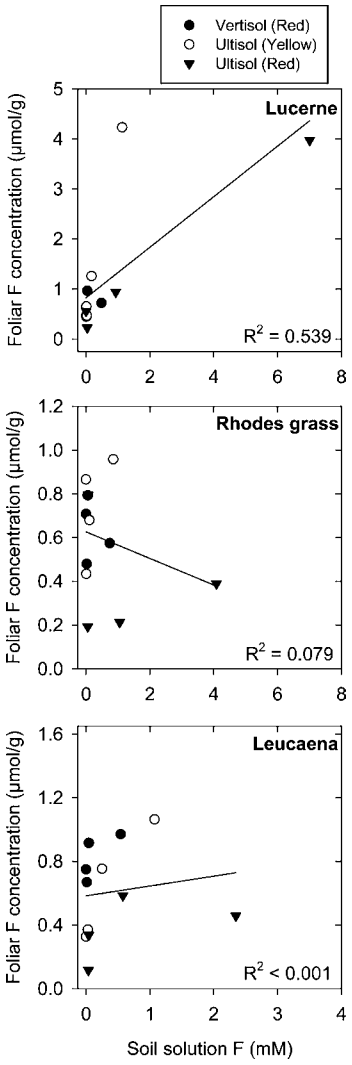

Figure 5. Relationship between the concentration of F in the foliar tissues of three plant species (lucerne, Rhodes grass, and leucaena) with the total concentration of F in the soil solution (experiment 2). Data are presented for three soils, but the data for the sand were excluded because these values had statistically high leverage. Note that the scales are not constant.

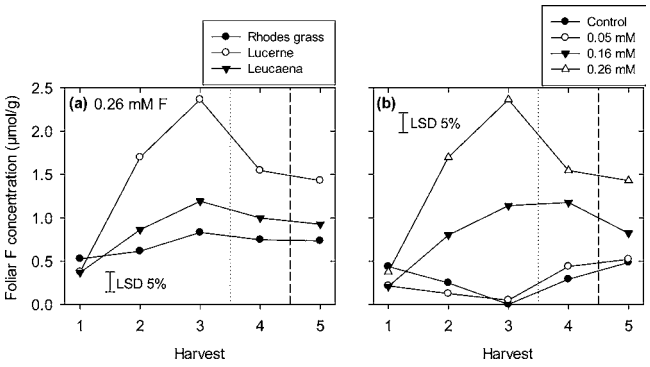

Figure 6. Concentrations of F in plant foliage following four irrigations (harvest 2) or eight irrigations (harvest 3) with artificial groundwater containing F (experiment 3). Plants were then irrigated with deionized water (harvest 4) and grown for a further 2 weeks without overhead irrigation (harvest 5). (a) Concentrations of F in foliage of Rhodes grass, lucerne, and leucaena irrigated with water containing F at a concentration of 0.26 mM. (b) Concentrations of F in the foliage of lucerne irrigated with water containing F at a concentration of 0, 0.053, 0.16, or 0.26 mM. The vertical bar represents the least significant difference (LSD, 5%) to allow comparison between harvests for a single treatment or between treatments for a single harvest.

also had a significant effect on foliar F concentrations, with a significant increase in tissue F concentrations when the F concentration of the water was raised from 0 to ca. 0.16 and 0.26 mM (Figure 6b).

After eight irrigations with F-containing groundwater, deionized water was applied to simulate rainfall and to investigate the potential leaching of F from the foliage. Relative to tissue concentrations after eight irrigations with water containing ca. 0.26 mM, tissue concentrations decreased significantly (from 2.4 to 1.5 μmol of F/g) for lucerne but there were no significant differences for the two other plant species (Figure 6a). For groundwaters containing lower concentrations of F, the effect of rainfall on tissue F concentrations was not clear (Figure 6b). Allowing the plants to grow undisturbed (i.e., no overhead irrigation) for a further 2 weeks after the simulated rainfall generally had no significant effect on tissue concentrations (Figure 6, $P > 0.05$).

DISCUSSION

Both the direct addition of F to soils and the foliar retention of F-containing irrigation water resulted in increases in the foliar F concentration. However, under the current experimental conditions, these increases in foliar F concentrations through either pathway were modest and concentrations generally remained lower than the MTL of 1.8 μmol/g (35 mg/kg) for cattle (excluding plants grown on sand). For example, even when F was added at a rate of 26 mmol/kg (this soil concentration would be reached after irrigation with water containing 0.26 mM at a rate of 5 ML/(ha year) for 25 years), most plant tissue concentrations were <1 μmol/g (with the highest values being for lucerne, 4.2 μmol/g; Figure 4) and hence were generally was less than the MTL of mature beef cattle (2.6 μmol/g), sheep (3.2 μmol/g), chickens (10 μmol/g), and swine (7.9 μmol/g).[4] Furthermore, with addition of F at a rate of 7.9 mmol/kg (i.e., reached after 8 years of irrigation at 5 ML/(ha year) with 0.26 mM) plant foliar tissues did not increase above 1.3 μmol F/g in any treatment, this being less than the MTL for young beef calves and heifers, 1.8 μmol F/g.[4] Therefore, for short- to medium-term irrigation projects (for example, irrigation to establish forestry or grazing systems), the addition of realistic rates of F-containing groundwater is unlikely to increase the soil F concentrations in soils (excluding highly sandy soils) to levels above which plant uptake of F from the soil may affect grazing animals.

These conclusions need to be considered carefully before extrapolating to other situations. For example, the present study examined the irrigation of F-containing water in short- to medium-term systems, but long-term irrigation with water containing high concentrations of F would result in the addition of F at levels higher than those considered here. Also, it is apparent that both the soil type and the plant species influences the retention and uptake of F, with the present study only examining seven soils and three plant species. Finally, irrigation of water with F concentrations lower or higher than this value would also alter the volume of water that could be safely irrigated.

Variation in the Concentration of F in the Soil Solution Depending upon the Soil Type. The extent to which F was available in the soil solution varied substantially depending upon the soil (Figure 1). In the laboratory (experiment 1), the relationship between F adsorbed and F remaining free in the soil solution could be estimated using the Langmuir equation, with Q_{max} providing an estimate of maximum adsorption capacity and K providing an estimate of the binding strength (Figure 1 and Table 1). Similarly, in the greenhouse (experiment 2), the concentrations of soluble F in the soil solutions were related to the Langmuir parameters determined in experiment 1, with total soil solution F present in the 26 mmol of F/kg treatment in the order (decreasing) sand > red ultisol > yellow ultisol = red vertisol (Figure 2). Thus, adsorption isotherms are likely to be useful for (i) identification of soils which are likely to be unsuitable for irrigation with F-containing waters (such as the sand in the current study) and (ii) estimation of the volume of irrigation water which could be applied before the concentration of F in the soil solution exceeds a given threshold (for example, the concentration of F permitted in drainage water). However, within the range of relevance to the MTLs, the relationship between the concentration of F in the foliage and the concentration of F in the soil solution was comparatively poor (see next section). It is known that adsorption (and therefore the amount of F remaining in solution) is determined by a number of factors, among them pH, ionic strength, presence of poorly crystalline Fe and Al hydrous oxides, and clay mineralogy,[13,14,17,30−32] and these factors have differed between the soils used in this study (Tables S1 and S2, Supporting Information). However, there were no clear relationships between these soil factors and the F uptake in this study, likely due to the limited number of soils used.

It was also decided to investigate the desorption of F, given that it is this desorption (i.e., movement back into the soil solution) which will result in a buffering of the F concentration in the soil solution. The desorption of F from all soils was significantly correlated (negatively) to the estimated K, indicating that desorption capacity of soils can be estimated from the Langmuir adsorption parameters. The desorption of F was in the range of ca. 20−40% for soils with high K values, increasing to 60−80% for soils with low K values (Tables 1 and 2). As expected, the proportion of F that desorbed increased as the rate of F addition increased (Table 2), most likely due to the fact that high affinity binding sites for F become saturated, resulting in F being less strongly bound as the rate of F addition increases. It was also noted that the desorption of F decreased when adsorption equilibrium time increased (data not presented) due to the occurrence of slower reactions such as CaF_2 (fluorite) precipitation and diffusion into pores.[9,11] This indicates that desorption rates observed in the present study would likely be reduced further following an increase in equilibration time, as would occur in the field.

Uptake of F from the Soil Solution and Its Accumulation in the Foliage. The accumulation of F in the foliage varied substantially depending upon both the plant species and the soil type (Figures 3 and 4). Under the present experimental conditions, lucerne was the only plant species which accumulated F in the foliage to concentrations >1.3 μmol F/g (excluding sand), although the reason as to why lucerne accumulates more F than other species is not known. Interestingly, Hansen et al.[33] also found lucerne concentrated high F in foliar material, with 5.3 μmol of F/g observed when soils were loaded with ca. 84 mmol of F/kg. Similarly, tissue concentrations of up to 3.4 μmol of F/g were found in lucerne grown in acid soil amended with flue gas desulfurization gypsum.[34] More study is required in this regard, but it is possible that Rhodes grass and leucaena are F excluders, and hence the concentration of F within their tissues was not closely related to F availability within the soil. It is also possible that water use efficiency is lower for lucerne than for other species, resulting in greater F uptake; alternatively, translocation of F complexes in the xylem differs between plant species and it has been suggested that Ca limits translocation from roots to shoots either by membrane effects or by precipitation on the root surface.[30,34,35]

The accumulation of F in the foliage varied substantially depending upon the soil type (Figure 3). This was expected, given the differences observed in the adsorption capacities of these soils (Figure 1) and the resultant variations in soil solution F concentrations (Figure 2). However, despite being the immediately "plant available" fraction, soluble F in the soil solution was not generally related to the concentration of F in the foliage (Figure 5). Similarly, there was no consistent relationship between F uptake and F speciation in the soil solution, with F uptake closely related to F^- activity in some soils but to the activity of Al−F complexes in other soils (data not presented).

Foliar Retention of F from Overhead Irrigation. The overhead irrigation of water containing F at a concentration of 0 or 0.053 mM had no observable impact on the foliar concentrations of F (Figure 6). However, for water containing F at a concentration of either 0.16 or 0.26 mM, overhead irrigation resulted in significant increases in the foliar F concentration (Figure 6). This finding is in agreement with the study of Wallender and Keller,[25] who found that foliar concentrations of F in bush beans increased with increasing concentrations of F in the irrigation water. In the present study, lucerne was the only species to concentrate F in foliar material above the MTL (1.8 μmol/g) following eight consecutive irrigations with water containing 0.26 mM (Figure 6)—further investigation is needed in this regard. For example, it is known that cuticular thickness, cuticular composition, and stomatal density influence the uptake/absorption of foliar applied elements.[36]

The finding that overhead irrigation with good-quality water reduced foliar F concentrations (at least somewhat) is similar to the observation of Maclean et al.,[37] who, in a study of lucerne and tall fescue grass (*Festuca arundinacea*) exposed to atmospheric F, also found that rainfall (or washing with detergent) reduced the foliar concentration of F. Several mechanisms may result in a decrease in tissue F concentrations, including growth dilution, leaf death, translocation, or volatilization, with the last mechanism considered a major contributor of F removal from plants.[38] Therefore, to investigate this possibility, plants were grown without overhead irrigation for another 2 weeks following the irrigation with deionized water. During this time, foliar F further reduced slightly for plants in the 0.16 and 0.26 mM treatments (although this decrease was significant only in lucerne irrigated with 0.16 mM F) (Figure 6). It is known that HF is volatile, and hence if F is on the leaf surface or within foliar material, it is possible that volatilization will occur. However, in the present study, allowing the plants to grow undisturbed (i.e., without overhead irrigation) generally had no significant effect on tissue concentrations of F (Figure 6), possibly because plants were

DOI: 10.1021/acs.jafc.5b01001
J. Agric. Food Chem. 2015, 63, 4737−4745

only grown for 2 weeks before harvest, thereby potentially limiting volatilization.

The present study has examined the accumulation of F within soils and plants on irrigatation with F-containing groundwater. Generally, under the current experimental conditions, F did not accumulate in plant foliage to levels likely to be deleterious to grazing fauna, even when used at rates equivalent to irrigation for 25 years (assuming irrigation at a rate of 5 ML/(ha year) with water containing F at a concentration of 0.26 mM). First, when the F was added to the soil, the extent to which the soluble F concentration increased varied significantly between soils. Given that the extent to which F accumulated in the foliage did not appear to be related to the total concentration of F in the soil solution, it would be difficult to accurately predict the amount of F which could be added to the soil before the MTL would be exceeded. In addition, the extent to which F accumulated in the plant foliage varied depending upon the species (being greatest in lucerne). Second, when water was overhead-irrigated, foliar F concentrations increased in all three species due to foliar contact with F-containing water. However, lucerne was again the only species which accumulated foliar F above MTL for young beef cattle. The data presented here regarding the behavior of F in soils and plants will assist in the rigorous regulation of the maximum volume of F-containing water per soil type and crop species to ensure maximum productivity while simultaneously minimizing potential environmental harm.

One-Step Fabrication of a Multifunctional Magnetic Nickel Ferrite/Multi-walled Carbon Nanotubes Nanohybrid-Modified Electrode for the Determination of Benomyl in Food

Qiong Wang, Jichun Yang, Yuanyuan Dong, and Lei Zhang*

College of Chemistry, Liaoning University, 66 Chongshan Middle Road, Shenyang, Liaoning 110036, People's Republic of China

ABSTRACT: Benomyl, as one kind of agricultural pesticide, has adverse impact on human health and the environment. It is urgent to develop effective and rapid methods for quantitative determination of benomyl. A simple and sensitive electroanalytical method for determination of benomyl using a magnetic nickel ferrite ($NiFe_2O_4$)/multi-walled carbon nanotubes (MWCNTs) nanohybrid-modified glassy carbon electrode (GCE) was presented. The electrocatalytic properties and electroanalysis of benomyl on the modified electrode were investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). In the phosphate-buffered saline (PBS) of pH 6.0, this constructed biosensor exhibited two linear relationships with the benomyl concentration range from 1.00×10^{-7} to 5.00×10^{-7} mol/L and from 5.00×10^{-7} to 1.00×10^{-5} mol/L, respectively. The detection limit was 2.51×10^{-8} mol/L (S/N = 3). Moreover, the proposed method was successfully applied to determine benomyl in real samples with satisfactory results. The $NiFe_2O_4$/MWCNTs/GCE showed good reproducibility and stability, excellent catalytic activity, and anti-interference.

KEYWORDS: *benomyl, $NiFe_2O_4$ nanoparticles, multi-walled carbon nanotubes, cyclic voltammetry*

1. INTRODUCTION

The fungicide benomyl, i.e., methyl 1-(butylcarbamoyl)-2-benzimidazole carbamate, is a synthetic benzimidazole. It is known to exert selective toxicity against fungal cells because of its higher affinity for fungal tubulin than mammalian tubulin.[1] Benomyl is widely used for sterilizing seeds of vegetables as an agricultural chemical against a range of fungal diseases.[2,3] Because of the occurrences of benomyl and carbendazim in the environment and the potential exposure to them through diet, there continues to be ongoing concern over the risks to human health of these fungicides.[4−7] Numerous studies have been conducted to determine the fate of benomyl and its associated residues in soils, plants, and mammals.[8] Further, in mammals, benomyl is known for its ability to induce structural changes in the chromosomes and hepatocyte microtubule cytoskeleton,[9] inhibit protein synthesis[10] and lipid peroxidation, and cause glutathione depletion.[11] Recently, benomyl and carbendazim were reported as endocrine disruptors that increased both expression and activity of aromatase in the human ovarian granulose-like tumor cell line KGN.[12] There has been concern that this compound might influence human health and cause diseases. Further, benomyl is quite unstable, and it decomposes in aqueous solutions into more stable compounds, such as carbendazim and *N*,*N*′-dibutyl urea.[13,14] The determination of benomyl residue in vegetables, fruits, and environmental water samples is a difficult task. To protect consumers from the risk related to benomyl in food and environmental water, the development of a simple, rapid, and reliable method for the determination of benomyl is of great importance.

Thus far, various techniques for the detection of benomyl have been reported in the literature, such as high-performance liquid chromatography (HPLC),[15] frequency domain fluorescence,[16] fluorescence polarization,[17,18] and in-layer chromatography[19] methods. These methods have high accuracy, well reproducibility, and reliable ability of qualitative analysis. However, these methods also suffer from some disadvantages, such as expensive experimental instruments, sophisticated laboratory procedures, trained personnel, and complex sample pretreatment. In comparison to other techniques, electrochemical methods have aroused great interests among researchers because of their relatively high sensitivity, fast response, and ability to be miniaturized.[20] The literature reported that the OV-17 silicon-modified carbon paste electrodes and bare glassy carbon electrode (GCE) were used in the determination of benomyl by differential pulse voltammetry,[21,22] and the detection limit was 6.9×10^{-5} and 1.5×10^{-4} g/L, respectively. Recently, the electroanalysis method is reported for the determination of benomyl by square-wave adsorptive stripping voltammetry,[23] and the detection limit was 2.4×10^{-5} g/L. According to our knowledge, magnetic nickel ferrite/multi-walled carbon nanotubes nanohybrid-modified glassy carbon electrode ($NiFe_2O_4$/MWCNTs/GCE) for determination of benomyl had not been reported. The main objective of this paper is to develop a new method with high sensitivity, simplicity, and efficiency for the detection of benomyl.

In this paper, $NiFe_2O_4$/MWCNTs nanohybrids were synthesized through a one-step hydrothermal method and employed as a modified electrode material for the analysis of benomyl. This method is based on the different properties of the mediators plus nanoparticles, such as strong adsorptive ability, huge specific area, and subtle electronic properties.[24−26] In addition, Ni and Fe have excellent electrocatalytic activity in

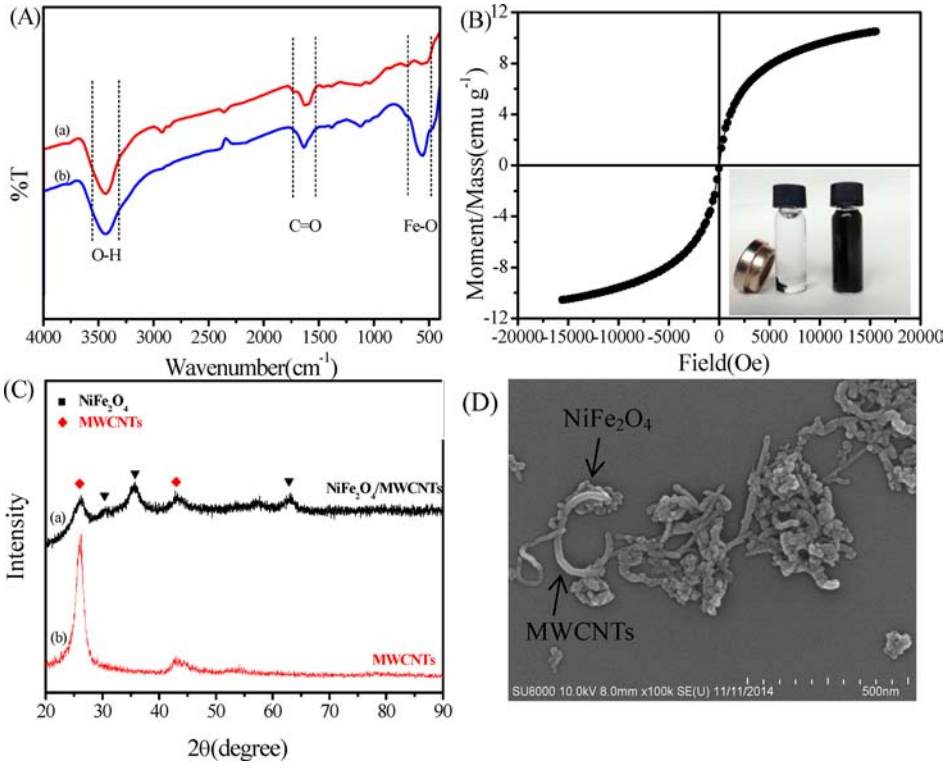

Figure 1. Characterization of MWCNTs and $NiFe_2O_4$/MWCNTs: (A) FTIR spectra of (a) MWCNTs and (b) $NiFe_2O_4$/MWCNTs, (B) VSM image of $NiFe_2O_4$/MWCNTs, (C) XRD patterns of (a) $NiFe_2O_4$/MWCNTs and (b) MWCNTs, and (D) SEM image of $NiFe_2O_4$/MWCNTs.

the catalyst of reactions of organic materials based on their electronic arrangement.[27,28] The results showed that the proposed method is simple, rapid, sensitive, and selective for the quantitative determination of benomyl at the $NiFe_2O_4$/MWCNTs/GCE.

2. EXPERIMENTAL SECTION

2.1. Chemicals and Reagents. MWCNTs (length, 0.5−2.0 μm; specific surface area, >500 m^2/g; outer diameter, <8 nm; and 95% purity) were purchased from Chengdu Organic Chemicals Co., Ltd., Chinese Academy of Sciences, Beijing, China. Benomyl (95% purity) was purchased from HEOWNS Biochemical Technology Co., Ltd. (Tianjin, China). The 5% Nafion ethanol solution (D520) was from HESEN Co., Ltd. (Shanghai, China). All other chemicals were of analytical reagent grade and produced by Shenyang Chemical Company, China.

2.2. Apparatus. A CHI660D electrochemical workstation (Shanghai ChenHua Instruments Co., China) coupled with a conventional three-electrode cell, including a platinum wire auxiliary electrode, a saturated calomel reference electrode (SCE), and a working electrode, was used for electrochemical measurements. X-ray diffraction patterns were recorded on a X-ray diffractometer (XRD, Siemens D5000, Germany) at 40 kV and 150 mA with Cu Kα radiation. The diffraction data were recorded for 2θ angles between 20° and 90°. Fourier transform infrared spectroscopy (FTIR, Avatar 330, Nicolet, Thermo Electron Scientific, Madison, WI) was used to characterize MWCNTs and $NiFe_2O_4$/MWCNTs within a 500−4000 cm^{-1} spectral domain with a resolution of 4 cm^{-1} using a KBr pellet technique at room temperature. A vibrating sample magnetometer (VSM, Lake Shore 7407, Lake Shore Cryotronics, Inc., Westerville, OH) was used to measure the magnetic prosperities of $NiFe_2O_4$/MWCNTs in the field of ±15 kOe at room temperature. The morphologies and microstructures of the material were characterized using scanning electron microscopy (Hitachi SU8000, Japan) under the voltage of 10.0 kV. A S-3C model pH meter (Shanghai Precision Scientific Instrument Co., China) was used for measuring the pH of solutions. Deionized water used throughout experiments was purified using a Sartorius Arium 611 system (Sartorius, Göttingen, Germany).

2.3. Synthesis of $NiFe_2O_4$/MWCNTs. The $NiFe_2O_4$/MWCNTs composite was fabricated by a one-step hydrothermal method. Briefly, 2.0193 g of $Fe(NO_3)_3 \cdot 9H_2O$ (0.005 mol) and 0.7017 g of $NiSO_4 \cdot 7H_2O$ (0.0025 mol) were dissolved in 50 mL of ethanol, and subsequently, 0.5 g of MWCNTs was added. Prior to that, MWCNTs were acidified with HNO_3. The obtained mixture was stirred vigorously for 1.0 h to obtain a homogeneous black solution. Then, it was transferred into a 100 mL Teflon-lined stainless-steel autoclave, heated to 180 °C, and reacted for 12 h. After that, the magnetic composite was separated by a magnet, washed repeatedly with deionized water until neutrality, and then dried at 60 °C for 12 h.

2.4. Preparation of a $NiFe_2O_4$/MWCNTs-Modified Electrode. Before modification, the bare GCE was carefully polished with three grades of alumina slurrys (0.05, 0.30, and 1.00 mm) on polishing cloth, respectively, rinsed thoroughly with deionized water between each polishing step, then washed successively with deionized water, anhydrous alcohol, and deionized water in an ultrasonic bath, and dried in air. A 4 mg/mL $NiFe_2O_4$/MWCNTs dispersion was prepared by dissolving 8.0 mg of $NiFe_2O_4$/MWCNTs in 2 mL of 1% Nafion solution prepared in ethanol. The mixture was then sonicated for 30 min to obtain a stable and well-distributed $NiFe_2O_4$/MWCNTs/Nafion suspension. A 6.0 μL drop of 4.0 mg/mL $NiFe_2O_4$/MWCNTs/Nafion suspension solution was coated on the surface of the GCE, and then the solvent was evaporated under the infrared lamp to obtain the $NiFe_2O_4$/MWCNTs/GCE.

2.5. Procedure for Benomyl Analysis. The electrochemical behavior of benomyl was studied by cyclic voltammetry (CV), and the determination of benomyl was performed by differential pulse voltammetry (DPV). All of the experiments were carried out in a conventional electrochemical cell holding 5.00 mL of 0.2 mol/L phosphate-buffered saline (PBS) at pH 6.0 and a certain amount of benomyl at room temperature. Before benomyl analysis, the 5 mL PBS solution was purged with highly purified nitrogen for 10 min.

2.6. Real Samples. Three samples of apple, mushroom, and spinach were bought in a local supermarket. Suitable amounts of three

DOI: 10.1021/acs.jafc.5b00973
J. Agric. Food Chem. 2015, 63, 4746−4753

kinds of samples were added to a 50.00 mL beaker; then a suitable amount of ethanol was added to dissolve them for 30 min with ultrasonic assistance; and sample solutions were filtrated. All of the above sample solutions were stored in a refrigerator at 4 °C and determined by DPV according to the standard addition method.

3. RESULTS AND DISCUSSION

3.1. Characterization of the $NiFe_2O_4$/MWCNTs Electrode. Curve a in Figure 1A is the FTIR spectra of MWCNTs. Two characteristic peaks of MWCNTs were observed at 1650 and 3430 cm^{-1} corresponding to C═O and O−H band stretching vibrations.[29] Curve b in Figure 1A displays the FTIR spectra of the $NiFe_2O_4$/MWCNTs nanohybrid sample. The new characteristic peak at around 556 cm^{-1} is associated with the Fe−O−Ni stretching vibration.[30] This evidence confirmed that $NiFe_2O_4$ was successfully loaded to MWCNTs. Figure 1B presents the magnetic properties of $NiFe_2O_4$/MWCNTs analyzed by room-temperature VSM with an applied field of $-15.0 \leq H \leq 15.0$ kOe. The value of saturation magnetization (Ms) is about 10.48 emu g^{-1} (inset is the photo of magnetic separation).

The XRD patterns of $NiFe_2O_4$/MWCNTs and pure MWCNTs are shown in Figure 1C. The peaks at 25.9° and 43.2° were attributed to the characteristic peaks of MWCNTs (which can be seen in both curves a and b in Figure 1C).[31] Besides, from curve b in Figure 1C, it could be seen that the diffraction peaks of $NiFe_2O_4$ could be assigned to spinel-type $NiFe_2O_4$ [Joint Committee on Powder Diffraction Standards (JCPDS) 54-0964]. The peaks at the 2θ values of 30.2, 35.5, and 62.4 could be indexed to (220), (311), and (440) crystal planes of spinel $NiFe_2O_4$, respectively. The results indicated that $NiFe_2O_4$ was successfully loaded to MWCNTs.

The morphology of $NiFe_2O_4$/MWCNTs was investigated by scanning electron microscopy (SEM). From Figure 1D, it is observed that $NiFe_2O_4$ nanoparticles were deposited on the surface of MWCNTs.

3.2. Electrochemical Characterization of Benomyl. The CV behavior of benomyl on the bare GCE, $NiFe_2O_4$/GCE, MWCNTs/GCE, and $NiFe_2O_4$/MWCNTs/GCE are illustrated in Figure 2 (curves a, b, c, and d, respectively). As seen, no visible signal was found on the bare GCE (curve a), only a small and broad redox peaks of benomyl occur on the $NiFe_2O_4$/GCE (curve b) and the MWCNTs/GCE (curve c). Meanwhile, a pair of well-defined and quasi-reversible redox peaks was observed at $NiFe_2O_4$/MWCNTs/GCE (curve d), which indicates that the electrochemical reaction of benomyl is a reversible process, and the $NiFe_2O_4$/MWCNTs composite has a strong enhancement ability for the electric signal of benomyl.[32,33] This is most likely to be attributed to the large surface area of $NiFe_2O_4$/MWCNTs, which may provide many favorable sites for electron transfer to molecules, and the $NiFe_2O_4$/MWCNTs nanohybrid has a good synergic effect,[34−36] which may be ascribed to the specific and preferable properties of the magnetic nanoparticles and MWCNTs.

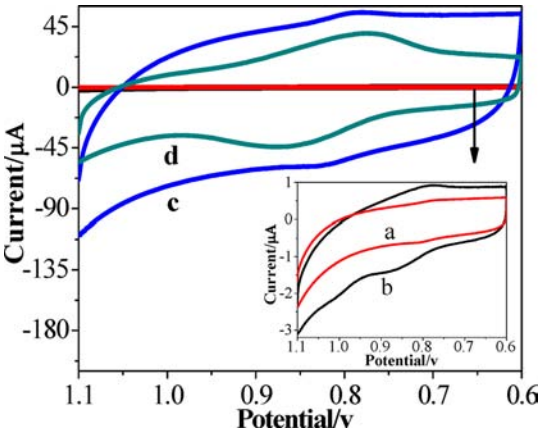

Figure 2. CVs of benomyl in 0.2 mol/L PBS at pH 6.0 solution ($C_{benomyl} = 3.5 \times 10^{-6}$ mol/L). (Inset) (a) benomyl on the bare GCE, (b) benomyl on the $NiFe_2O_4$/GCE, (c) benomyl on the MWCNTs/GCE, and (d) benomyl on the $NiFe_2O_4$/MWCNTs/GCE. Scan rate, 0.1 V/s; quiet time, 600 s.

3.3. Effect of the Modifier Amount on the Oxidation Peak Current. From the experiment, it was found that the redox peak current increased significantly with the amount of modifier (4.0 mg/mL $NiFe_2O_4$/MWCNTs/Nafion suspension solution) increasing from 4.0 to 6.0 μL, and when the amount of the suspension exceeded 6.0 μL, the current decreased. It was ascribed that the active sites for the accumulation of benomyl increased with the increment of modifier amount. The peak current decreased when the volume exceeded 6.0 μL, because the conductivity of the electrode reduced, and the film unstable as $NiFe_2O_4$/MWCNTs could leave off the electrode surface when the film was too thick. Thus, the modifier amount of 6.0 μL was chosen in the experiment.

3.4. Effect of the Accumulation Time. It is important to fix the accumulation time when adsorption studies were undertaken. Bearing this in mind, the effect of the accumulation time has been studied by the DPV method. The accumulation time can improve the amount of benomyl adsorbed on the electrode surface, then improve determination sensitivity, and decrease the detection limit. The DPV peak currents increase rapidly with the increase of the accumulation time from 0 to 600 s. However, for a longer accumulation time, there is no significant increase in the current response. This phenomenon could be attributed to the saturated adsorption of benomyl at the electrode surface. Thus, the accumulation time of 600 s was chosen in the experiment.

3.5. Effect of the pH. The effect of solution pH on the redox peak of benomyl on $NiFe_2O_4$/MWCNTs/GCE investigated at the pH range from 4.0 to 8.0 by CV is shown in Figure 3. As seen, with increasing the pH, the peak currents of benomyl increased and the potentials shifted negatively because of the participation of protons in the electrode reaction. The potentials of benomyl followed the linear regression equations with pH: E_{pa} (V) = −0.060pH + 1.14 (r = 0.9992). The value of the slope was 0.060 pH^{-1}, which is approximately close to the theoretical value of 0.0585 pH^{-1}; therefore, it can be deduced that the proton number is equal to that of the number of transferred electrons. The peak currents of benomyl increase from pH 4.0 and reach a maximum value at pH 6.0; therefore, a pH of 6.0 was chosen for the subsequent analytical experiments.

3.6. Electrochemical Properties of Benomyl. Useful information involving the electrochemical mechanism can generally be acquired from the relationship between the peak current and scan rate.[37,38] Therefore, CVs of benomyl on $NiFe_2O_4$/MWCNTs/GCE with different scan rates ranging from 0.050 to 0.20 V/s in PBS at pH 6.0 were recorded, and results are shown in Figure 4. It can be found that the peak current increased linearly with the scan rate in the range of 0.050−0.20 V s^{-1} (as shown in Figure 4A). The linear regression equations were expressed as follows: I_{pc} (μA) = 100.15v (V/s) − 4.83 (r = 0.996) and I_{pa} (μA) = −132.13v (V/

DOI: 10.1021/acs.jafc.5b00973
J. Agric. Food Chem. 2015, 63, 4746−4753

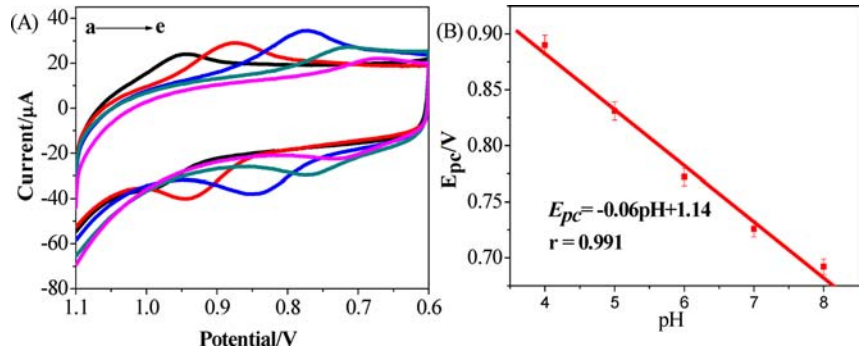

Figure 3. (A) Influence of pH on CVs of benomyl at the $NiFe_2O_4$/MWCNTs/GCE, with the pH range from a to e being 4.0−8.0, at the scan rate of 0.1 V/s, and (B) effects of pH on the potential response.

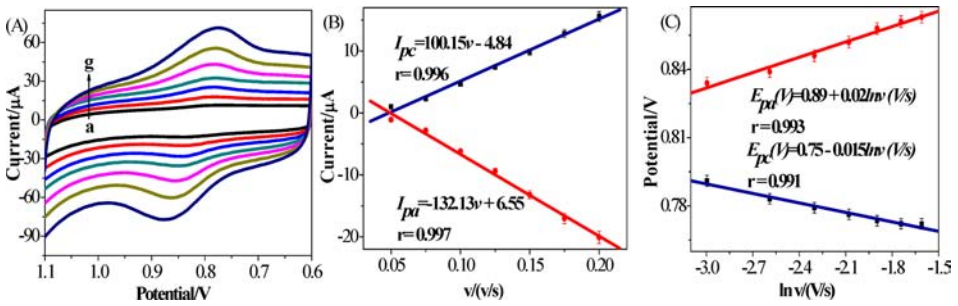

Figure 4. CVs of benomyl at different scan rates, with benomyl at 3.5×10^{-6} mol/L. (A) Scan rates from a to g are 0.050, 0.075, 0.10, 0.125, 0.15, 0.175, and 0.20 V/s, respectively. (B) Dependence of the peak current on the scan rate. (C) Dependence of the plots of E_p versus ln v.

s) + 6.55 (r = 0.997) (as shown in Figure 4B), respectively. It indicates that the redox of benomyl on $NiFe_2O_4$/MWCNTs/GCE is an adsorption-controlled process.[39,40] The ratio of the redox peak current (I_{pa}/I_{pc}) was approximately found to be 1, suggesting that the redox reaction of benomyl on $NiFe_2O_4$/MWCNTs/GCE was a quasi-reversible electrochemical behavior. In this work, the scan rate was chosen as 0.10 V s^{-1}. For an adsorption-controlled and quasi-reversible electrode process, the relationship between peak potentials and the scan rate follows Laviron's equation[41,42]

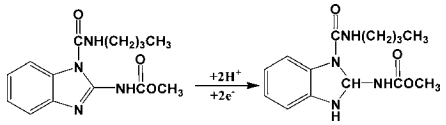
$$E_{pc} = E^0 - \frac{RT}{anF} \ln v \quad (1)$$

$$E_{pa} = E^0 + \frac{RT}{(1-a)nF} \ln v \quad (2)$$

$$\log K_s = a \log(1-a) + (1-a)\log a - \log \frac{RT}{nFv} - \frac{(1-a)anF\Delta E_p}{2.3RT} \quad (3)$$

where E_{pa} and E_{pc} are the anodic and cathodic peak potentials (V), E^0 is the formal potential (V), n is the number of electron transferred, α is the electron transfer coefficient, K_s is the standard rate constant of the surface reaction (s^{-1}), v is the scan rate (V/s), ΔE_p is the peak−peak potential separation, R is the universal gas constant (8.314 J mol^{-1} K^{-1}), T is the temperature (298 K), and F is the Faraday constant (96 500 C/mol). Figure 4C shows the plots of E_p versus ln v; the equations of the straight line were as follows: E_{pc} (V) = 0.75 − 0.015 ln v (V/s) (r = 0.991), and E_{pa} (V) = 0.87 + 0.020 ln v (V/s) (r = 0.993). The values of α and n can be determined from the slope, respectively. The electron transfer number n is close to 2, and the value of α is 0.528. Moreover, the values of K_s were calculated to be 0.951 s^{-1}. The pH effect on E_{pa} demonstrated that the number of electrons and protons involved in the benomyl oxidation process is equal (see section 3.3). Therefore, the redox of benomyl on $NiFe_2O_4$/MWCNTs/GCE is proven participation of a two protons ($2H^+$) and two electron ($2e^-$) process. The mechanism of the electrode process could be described as follows (Scheme 1).

Scheme 1. Proposed Mechanism of Electroreduction of Benomyl on the $NiFe_2O_4$/MWCNTs/GCE



3.7. Estimation of Electrode Real Surface Areas and Γ_s.

The electrochemically effective surface areas of bare GCE and $NiFe_2O_4$/MWCNTs/GCE were determined by the chronocoulometric method according to the formula given by Anson[43]

$$Q(t) = \frac{2nFAcD^{1/2}t^{1/2}}{\pi^{1/2}} + Q_{dl} + Q_{ads} \quad (4)$$

where A is surface area of the working electrode, c is the concentration of the substrate, D is the diffusion coefficient, Q_{dl} is the double-layer charge, and Q_{ads} is the Faradaic charge. Other symbols have their usual meanings. A 0.1 mM $K_3[Fe(CN)_6]$ solution containing 1 mM KCl has a D[44] of $K_3[Fe(CN)_6]$ of 7.60×10^{-6} cm^2 s^{-1}. According to the experimental results (as shown in panels A and B of Figure 5), on the basis of the slope of the linear relationship between Q

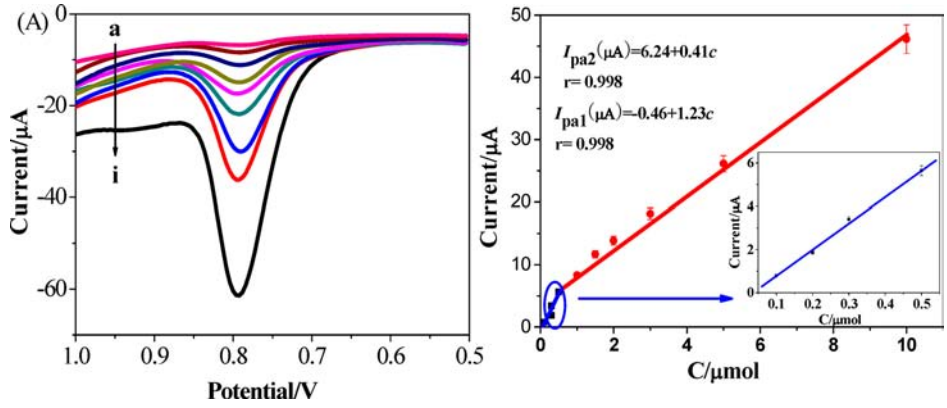

Figure 6. (A) DPVs of benomyl at different concentrations. The concentrations of benomyl from a to l are 1×10^{-7}, 2×10^{-7}, 3×10^{-7}, 5×10^{-7}, 1×10^{-6}, 1.5×10^{-6}, 3×10^{-6}, 5×10^{-6}, 1×10^{-5} mol/L, respectively. (B) Related calibration curve.

Table 1. Comparison of the Developed Method to Some Other Methods for the Determination of Benomyl

method	linear range (g/L)	detection limit (g/L)	recovery (%)	reference
liquid chromatographic	from 1.0×10^{-5} to 2.5×10^{-2}	3.3×10^{-6}		45
GC/MS	from 2.0×10^{-6} to 1.0×10^{-5}	2.0×10^{-8}	74−107	46
fluorescence polarization	from 3.0×10^{-7} to 3.0×10^{-4}	1.1×10^{-7}	104−113	47
bare GCE	from 8.1×10^{-5} to 1.5×10^{-3}	2.4×10^{-5}	99	21
OV-17 silicon-modified carbon paste electrodes	from 1.0×10^{-5} to 4.0×10^{-4}	6.9×10^{-5}	31−83	23
$NiFe_2O_4$/MWCNTs-modified GCE	from 2.9×10^{-5} to 2.9×10^{-3}	7.2×10^{-6}	93−103	present work

and $t^{1/2}$, A was calculated to be 0.013 and 0.072 cm^2 for bare GCE and $NiFe_2O_4$/MWCNTs/GCE, respectively. These results indicated that the specific area of the modified electrodes is nearly 6 times that of the bare electrode, which would enhance the current response and decrease the detection limit.

The diffusion coefficient D and Faradaic charge Q_{ads} of benomyl at $NiFe_2O_4$/MWCNTs/GCE can also be determined by chronocoulometry based on eq 4. As shown in panels C and D of Figure 5, after background subtraction, the plot of Q against $t^{1/2}$ showed a linear relationship. With $n = 2$, $A = 0.072$ cm^2, and $c = 3.5 \times 10^{-6}$ mol/L, D was calculated to be 1.13×10^{-7} cm^2 s^{-1}. According to the equation $Q_{ads} = nFA\Gamma_s$, the adsorption capacity, Γ_s, can be obtained as 1.75×10^{-10} mol cm^{-2}.

3.8. Electrochemical Determination of Benomyl Using DPV. As a highly sensitive and low detection limit electrochemical method, DPV was used for the determination of benomyl. Figure 6 presents DPV curves of benomyl at different concentrations on the $NiFe_2O_4$/MWCNTs/GCE under the

DOI: 10.1021/acs.jafc.5b00973
J. Agric. Food Chem. 2015, 63, 4746−4753

optimum conditions. It can be seen that an increase in the benomyl concentration is accompanied by an increase in anodic current, but there are two linear sections in the regression line that fit the following equations: for concentrations in the range from 1.00×10^{-7} to 5.00×10^{-7} mol/L, I_{pa} (μA) = −0.46 + 1.23c (μmol/L) (r = 0.998), and for concentrations in the range from 5.00×10^{-7} to 1.00×10^{-5} mol/L, I_{pa} (μA) = 6.24 + 0.41c (μmol/L) (r = 0.995). The detection limit was 2.51×10^{-8} mol/L based on 3 times that of the background noise. It could be seen that the proposed method showed a rational linear range and an acceptable detection limit.

The comparison of the developed method to some other methods for the determination of benomyl is listed in Table 1, which showed excellent sensitivity and a wide linear range of the proposed method.

3.9. Reproducibility, Stability, and Interference Study. The $NiFe_2O_4$/MWCNTs/GCE showed good reproducibility, and the relative standard deviation (RSD) was 3.3%, which was evaluated by six repetitive measurements of 3.5×10^{-6} mol/L benomyl in PBS at pH 6.0 (accumulation time, 600 s; scan rate, 0.10 V s^{-1}; and accumulation potential, open circuit potential), which indicates that the electrochemical response of benomyl at the $NiFe_2O_4$/MWCNTs/GCE was highly reproducible. The DPV responses remained 91% of the initial current after the $NiFe_2O_4$/MWCNTs/GCE electrode was stored in a refrigerator at 4 °C for 7 days, suggesting good stability.

Under the optimized conditions, the redox peaks current of 3.5×10^{-6} mol/L benomyl was individually measured in the presence of different interferents and their influence on the analytical signal was investigated. As shown in Figure 7, it was found that 100-fold concentrations of carbendazim, thiabendazole, and tricyclazole, 300-fold concentrations of vitamin C, glucose, and CO_3^{2-}, and 1000-fold concentrations of Ca^{2+}, Mg^{2+}, K^+, Na^+, Zn^{2+}, Cl^-, and NO_3^- have no influence on the signal of benomyl. The results indicated that the peak current of benomyl was not significantly affected by the presence of common existing substances, suggesting a great anti-interference ability of the $NiFe_2O_4$/MWCNTs/GCE.

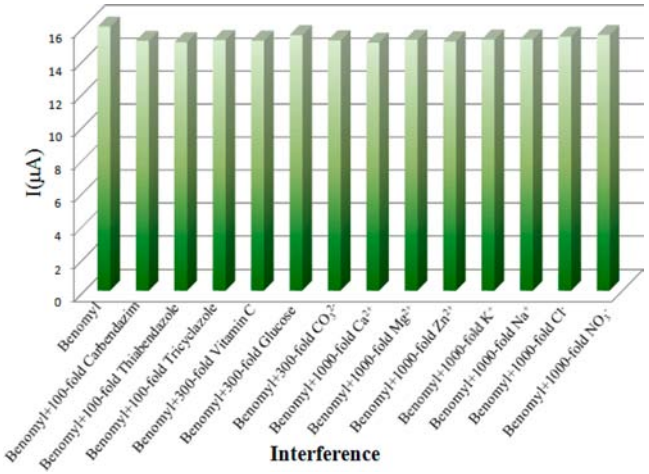

Figure 7. Signal of benomyl in the presence of interfering compounds.

3.10. Analysis of the Real Sample. To evaluate the practical application of $NiFe_2O_4$/MWCNTs/GCE for real sample analysis, apple, mushroom, and spinach were analyzed and detected by DPV under the optimal conditions using the standard addition method. The results are given in Table 2, and the recoveries were determined in the range from 93 to 103%. As indicated by the results, the developed sensor was proven to be a promising and reliable tool for the determination of benomyl in food and possesses potential applications in the analysis of the relevant real samples.

Table 2. Determination of Benomyl in Real Samples

4. CONCLUSION

In this work, a sensitive and reliable electrochemical method was proposed to determine benomyl. The electrochemical sensor based on $NiFe_2O_4$/MWCNTs/GCE displays an electrocatalytic performance to the oxidation of benomyl with a low detection limit. The electrochemical sensor shows good sensitivity, selectivity, and reproducibility. The $NiFe_2O_4$/MWCNTs/GCE is proven to be an accurate and reliable method because of the determination of benomyl in real samples with satisfactory results.

Supporting Information

ABSTRACT: Imidacloprid has become a research hotspot, due to its high toxicity to bees and other nontarget organisms. Photodegradation is a common method for removing imidacloprid in an aquatic environment. Traditional methods of pesticide photodegradation have generally been confined by many factors, such as response to only high-energy ultraviolet light. Herein, the visible-light-driven photocatalyst graphitic carbon nitride (g-C_3N_4) was applied to the photodegradation of imidacloprid. Visible-light illumination (λ >400 nm) resulted in nearly 90% substrate transformation in 5 h. With the illumination of an energy-saving lamp, imidacloprid has also been mostly removed. 1-((6-chloropyridin-3-yl)methylhydroxy)imidazolidin-2-ylidene nitramide) and 4,5-dihydro-*N*-nitro-1-(3-pyridinylmethyl)-1*H*-imidazol-2-amine were the main photoproducts identified by LC-MS analysis. The photocatalytic mechanism has also been discussed. This work could provide new perspective that g-C_3N_4, as a good visible-light photocatalyst could be applied to the cleanup of environmental pesticide pollution.

KEYWORDS: *imidacloprid, graphitic carbon nitride, metal-free, photodegradation, visible light, mechanism*

INTRODUCTION

Under typical field application conditions, only a small portion of the applied pesticide reaches its biological target[1] and the remaining contaminates the land, the air, and particularly the water.[2] It is generally known that less than 1% of the world's fresh water resources are readily available for human use. Worse, it was found in 2012 that 748 million people still rely on unimproved drinking water sources.[3] Thus, there is a pressing need for methods to remove pesticides and their derivatives from wastewater. Imidacloprid has become the most widely used neonicotinoid insecticide for over 140 agricultural crops.[4] In 2011, about 11.4 thousand tons of products containing imidacloprid was applied in China alone.[5] Aside from its benefits to agricultural production and pest control,[6] it has become a threat to agroecosystems and human health.[7] There is evidence that imidacloprid can be toxic to nontarget soil organisms and aquatic arthropods.[8−10] Imidacloprid also could reduce bumblebee colony growth and queen production, which result in further worsening global malnutrition.[4,11] The European Council decided in April 2013 to impose a temporary ban of imidacloprid.[12] In addition, the mobility of imidacloprid in the environment and its high solubility and persistent stability in water have placed a damper on its natural degradation.[13,14]

Various treatment processes have been studied to address the pollution of wastewater by pesticides. Different advanced oxidation processes (AOPs) have been proven to be some of the most commonly used techniques.[15,16] Photocatalytic oxidation (TiO_2/UV) and photo-Fenton or Fenton-like systems (H_2O_2/UV/Fe^{3+}) are the most widely used AOPs for pesticide degradation.[17] However, there are also many drawbacks to these traditional strategies, such as the formation of iron sludge, acidic pH requirements,[18] and high operating costs.[19] Most of these processes use metal catalysts, which may lead to secondary pollution.[20] In addition, it is worth noting that only UV light (4% of the solar spectrum) can be used in those processes.[21] From the standpoint of solar energy availability, visible light (more than 43% of the solar spectrum) active photocatalysts have great prospects in this field.[17]

Graphitic carbon nitride (g-C_3N_4) has been a novel "metal-free", visible-light-induced semiconductor.[22,23] Constructed from tri-*s*-triazine units and connected by planar amino groups, graphitic carbon nitride has been regarded as the most stable allotrope of carbon nitrides under ambient conditions, both on heating and in solutions of pH 1−14.[23] The ideal g-C_3N_4 consists solely of an assembly of C−N bonds without electron localization in the π state.[24] With a band gap of about 2.70 eV, g-C_3N_4 was found to show an intrinsic absorption in the visible region. Recently it has attracted intense attention for hydrogen and oxygen evolution via water splitting,[25] photosynthesis,[26] biosensing,[27] detection of metal ions,[28] and photocatalytic contaminant degradation.[29] Consisting of carbon and nitrogen, g-C_3N_4 is thus environmentally friendly and sustainable[30] and can be easily obtained by direct heat treatment of several precursors, such as melamine, urea, dicyandiamide, etc.[31−33]

Herein, g-C_3N_4 was used as a visible-light catalyst for the degradation of imidacloprid. Synthesized from low-cost and abundant urea, g-C_3N_4 showed an exceptionally high imidacloprid degradation ratio of nearly 90% under visible light over 5 h. Furthermore, optimized supported g-C_3N_4 showed an exceptionally high imidacloprid degradation ratio

of 83.4% under real indoor illumination using an energy-saving lamp, which could promote the practical environmental application of the g-C_3N_4 photocatalyst. As another commonly used precursor, g-C_3N_4 synthesized by melamine was also prepared under identical conditions. It was found that different precursors have a significant impact on the photocatalysis efficiency of g-C_3N_4. Further discussion was also made on the basis of this result. More importantly, the possible mechanism of imidacloprid degradation was deduced on the basis of the interaction between chemical scavengers and different active species.

MATERIALS AND METHODS

Materials. All reagents for synthesis and analysis were commercially available and were used without further treatments. Deionized water was used throughout the experiments.

Preparation of g-C_3N_4 Photocatalyst. g-C_3N_4 materials were prepared by polymerization of urea and melamine molecules under high temperature. Typically, 10 g of precursor powder was placed in a crucible with a cover and then calcined at 550 °C for 4 h in a muffle furnace, at a heating rate of 10 °C min^{-1}. After it was naturally cooled to room temperature, the resulting product was washed with 0.1 M HNO_3 and deionized water several times. Then the pure products were dried at 105 °C for 10 h. The resultant yellow product was collected and milled into powder for further use. The as-prepared g-C_3N_4 samples were labeled as U-g-C_3N_4 (from urea) and M-g-C_3N_4 (from melamine), respectively.

Characterization. Powder X-ray diffraction (XRD) patterns of the as-synthesized samples were recorded with a Bruker D/MAX 2500 X-ray diffractometer. The microstructure was observed using a scanning electron microscope (SEM; FEI, Sirion 200, 10 kV) and transmission electron microscopy (TEM; FEI Tecnai G2F20, 200 kV). Fourier transform infrared (FT-IR) spectra of products were obtained in the range of 400−4000 cm^{-1} (FTIR, PerkinElmer 2000). X-ray photoelectron spectroscopy (XPS) measurements were done using an Escalab 250Xi XPS system. The specific surface areas of the samples were measured by nitrogen sorption at 77 K on a Micromeritics ASAP 2020 analyzer and calculated by the Brunauer−Emmett−Teller (BET) method. For photodegradation, a 300 W xenon lamp (CEL-HFX300W, Beijing) with cutoff filter (λ >400 nm) was used. An Agilent 1100 series high-performance liquid chromatograph (HPLC) with a UV detector was used to determine the concentrations of imidacloprid. An Agilent 1100 LC/MSD ion trap was employed to identify byproducts.

Imidacloprid Photocatalytic Degradation. The photocatalytic degradation of imidacloprid was performed under visible-light (λ >400 nm) irradiation. In a typical experiment, the 0.05 g of the catalyst was suspended in an aqueous solution of imidacloprid (100 mL, 20 mg L^{-1}). The indoor light photocatalytic study was performed using an 8 W energy-saving lamp (commercially available) as the light source. A 0.1 g portion of the catalyst was added to 100 mL of imidacloprid solution (5 mg L^{-1}) with constant stirring. All tests were carried out in a 150 mL reactor fitted with a circulating water system to maintain a constant temperature. Prior to irradiation, the suspensions were magnetically stirred in the dark for 30 min to create an absorption−desorption equilibrium between the catalyst and imidacloprid. To investigate the possible mechanisms involved in the photocatalytic degradation process, a series of experiments were carried out by adding individual scavengers to the photocatalytic reaction system.

RESULTS AND DISCUSSION

Characterization of g-C_3N_4 Samples. The X-ray diffraction (XRD) patterns of U-g-C_3N_4 and M-g-C_3N_4 are presented in Figure 1. The patterns all exhibit peaks at 13.0° (d = 0.676 nm) and 27.7° (d = 0.322 nm), corresponding to the approximate dimension of the tri-*s*-triazine unit and the interlayer stacking peak of aromatic systems, respectively. It is worth noting that

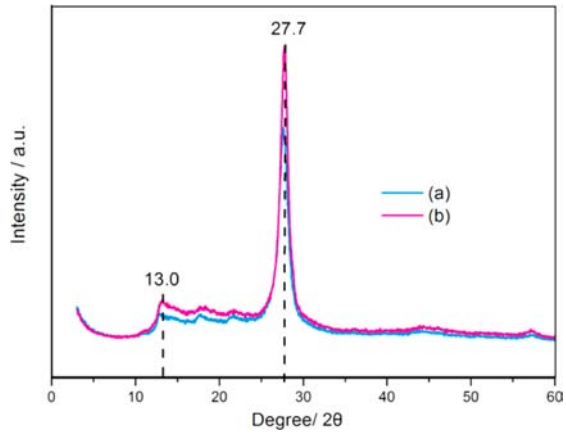

Figure 1. XRD patterns of (a) U-g-C_3N_4 and (b) M-g-C_3N_4.

the intensity of the 27.7° peak varies between urea and melamine samples. A more intense peak suggests a decreased polymerization in M-g-C_3N_4 in comparison to U-g-C_3N_4.[34]

Figure S1 in the Supporting Information displays the FT-IR spectra of U-g-C_3N_4 and M-g-C_3N_4 samples. From the spectra, it can be seen that all photocatalysts have absorption bands at 810 cm^{-1}, corresponding to the breathing mode of the triazine units. The peaks observed at 1200−1650 cm^{-1} are representative of the stretching and bending modes of nitrogen-containing heterocycles. The broad band in the range 3000−3700 cm^{-1} is assigned to stretching modes of −NH− groups and surface-adsorbed water molecules.[21,34,35]

The morphology and microstructure of samples were investigated by SEM, as shown in Figure 2. Figure 2a shows that U-g-C_3N_4 consists of smooth paper-thin sheets, while M-g-C_3N_4 (Figure 2b) is composed of large particles with a layer. The morphological difference between U-g-C_3N_4 and M-g-C_3N_4 is distinctive.

The morphological difference between U-g-C_3N_4 and M-g-C_3N_4 was also consistent with TEM images (Figure 3). As can be seen from the images, U-g-C_3N_4 exhibits two-dimensional smooth and thin layers with typical porouslike morphology. M-g-C_3N_4 exhibits a dense and thick sheetlike morphology with irregular shape. This fact indicates that different heteroatom-containing precursors can result in different morphologies and microstructures of the resultant g-C_3N_4.

The specific bonding and structure of the samples were investigated by X-ray photoelectron spectroscopy (XPS). Figure 4 depicts the high-resolution XPS spectra for the N 1s peak. The N 1s peak has been resolved to three main peaks at 398.7, 399.7, and 400.9 eV correspond to sp^2 C−N−C, sp^3 H−N−$[C]_3$ and C−NH_x, respectively.[36] The 404.4 eV peak was weak and was attributed to the π excitations.[37] C 1s and O 1s XPS spectra of the two samples (U-g-C_3N_4 and M-g-C_3N_4) are shown in Figure S3 of the Supporting Information. A residual O 1s peak could be ascribed to the tiny amount of O_2 adsorbed on the surface of the synthetic product during the calcination process. The C 1s spectra show adventitious carbon species, the tertiary carbon, and a trace amount of C−O bonding at 284.9, 288.2, and 289.2 eV, respectively.[35]

The ratio of sp^2 C−N−C bonds to the sum of sp^3 H−N−$[C]_3$ and C−NH_x bonds is 2.84 in U-g-C_3N_4 and only 1.83 in M-g-C_3N_4 (Tables S1 and S2 in the Supporting Information), which means the former has a lower proton concentration. It might be the key factors affecting the degradation efficiency.

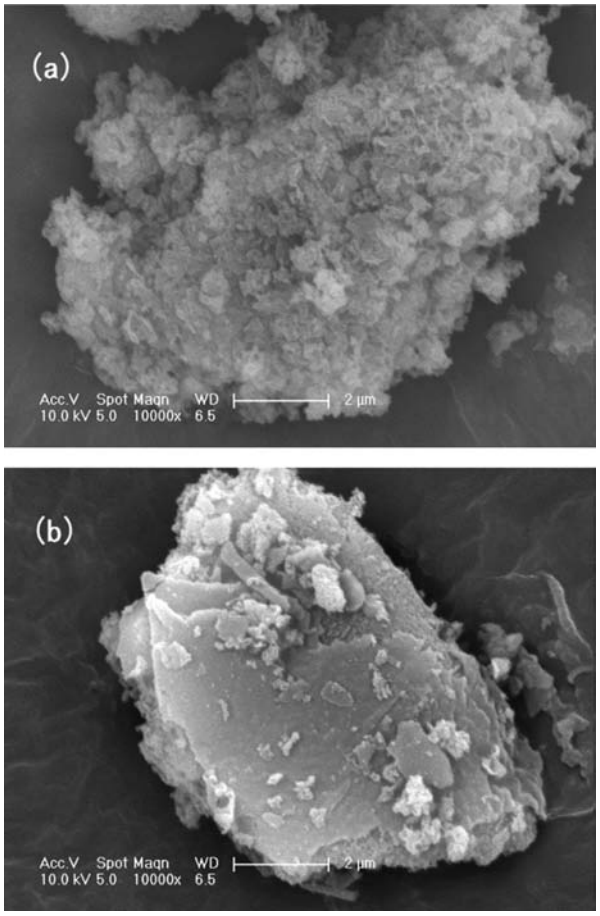

Figure 2. SEM images of (a) U-g-C_3N_4 and (b) M-g-C_3N_4.

Figure 5 shows the nitrogen adsorption−desorption isotherms for U-g-C_3N_4 and M-g-C_3N_4. Type IV hysteresis loops can be observed, indicating the presence of mesopores. The specific surface area of g-C_3N_4 greatly increased after acid treatment.[38] The BET surface areas and pore volumes of U-g-C_3N_4 (393.8 m^2g^{-1} and 0.62 cm^3 g^{-1}) are slightly higher than those of M-g-C_3N_4 (303.9 m^2g^{-1} and 0.44 cm^3 g^{-1}), indicating that the surface area is not the main reason for the photocatalytic activity, in accordance with the results reported in previous papers.[34]

Photocatalytic Degradation. The photocatalytic degradation of imidacloprid in the presence of photocatalyst in the dark could be negligible under the consistent experimental conditions (Figure 6). The photocatalytic activities of U-g-C_3N_4 and M-g-C_3N_4 under visible-light irradiation are shown in Figure 7. After 5 h of visible-light irradiation, the photocatalytic degradation rate of U-g-C_3N_4 for imidacloprid is nearly 90%. The photocatalytic efficiency of M-g-C_3N_4 is only 42.9%.

The photodegradation process has been fitted to pseudo-first-order models, in which the value of rate constant k is equal to the corresponding slope of the fitting line. As indicated in Figure 8, the values for the apparent reaction rate constant k are 0.3941 and 0.1179 h^{-1}, respectively, for U-g-C_3N_4 and M-g-C_3N_4. Even under irradiation with visible light (λ >400 nm), the U-g-C_3N_4 degradation of imidacloprid is more than twice as fast as that of M-g-C_3N_4. On the basis of the results, it is clear that U-g-C_3N_4 shows excellent performance in the photocatalytic degradation of imidacloprid in aqueous solution.

Figure 9 compares the indoor-light-induced photocatalytic degradation of imidacloprid over U-g-C_3N_4 and M-g-C_3N_4. The activity of the M-g-C_3N_4 sample was quite poor, with almost no degradation effect of imidacloprid even after 24 h of indoor-light irradiation. However, the photocatalytic degradation rate of U-g-C_3N_4 for imidacloprid actually reached 83.4%. This result could imply that only relatively low energy is needed for U-g-C_3N_4 to start its photoactivity. This characteristic of U-g-C_3N_4 could provide new perspectives for promoting its large-scale applications in real, natural environments for the degradation of pollutants.

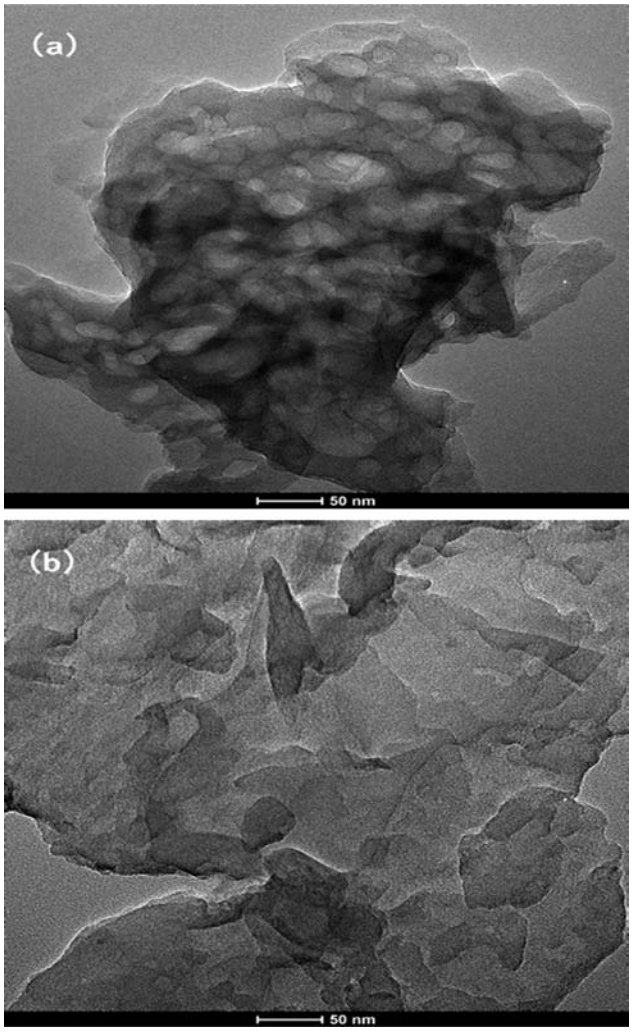

Figure 3. TEM images of (a) U-g-C_3N_4 and (b) M-g-C_3N_4.

Proposed Mechanism of g-C_3N_4 for Degradation of Imidacloprid. $^{\bullet}OH$, h^+, and $^{\bullet}O_2^-$ have been reported as major reactive species for photocatalytic oxidation. When the as-prepared samples are irradiated under visible light, g-C_3N_4 samples can easily absorb visible light and be excited to produce photogenerated electron−hole pairs. After capture by oxygen adsorbed on the surface of g-C_3N_4, the photogenerated electrons can generate $^{\bullet}O_2^-$.

Ethylenediaminetetraacetic acid disodium salt (EDTA-2Na), ammonium oxalate (AO), and potassium iodide (KI) were used as the hole scavengers.[39−41] *tert*-butyl alcohol (TBA) and isopropyl alcohol (IPA) were used as hydroxyl free radical ($^{\bullet}OH$) scavengers.[42,43] Benzoquinone (BQ) was used to remove superoxide radical ($^{\bullet}O_2^-$).[44]

As shown in Figure 10, the photocatalytic efficiencies of imidacloprid are 85.4% and 42.9% without scavengers for

DOI: 10.1021/acs.jafc.5b01105
J. Agric. Food Chem. 2015, 63, 4754−4760

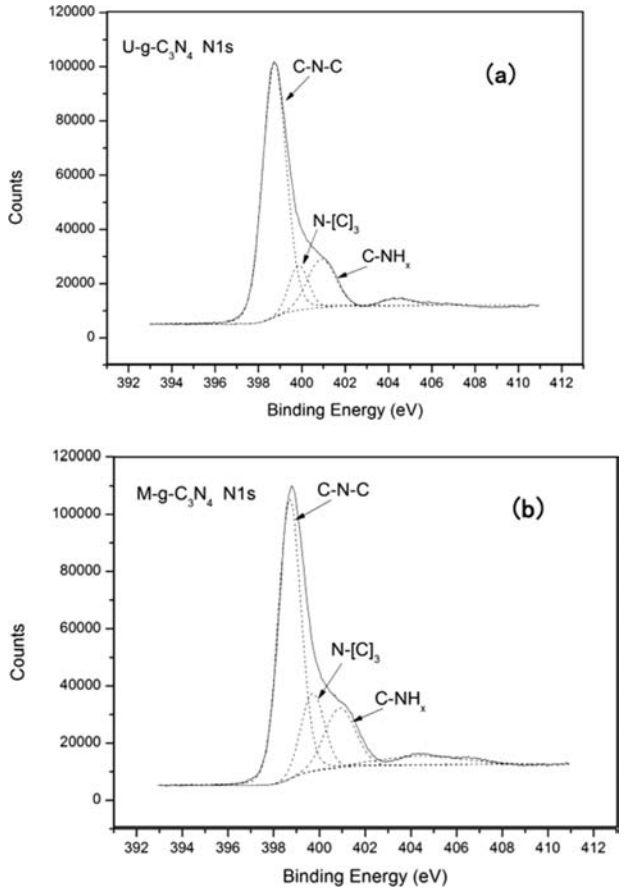

Figure 4. XPS spectra from samples of (a) U-g-C_3N_4 and (b) M-g-C_3N_4.

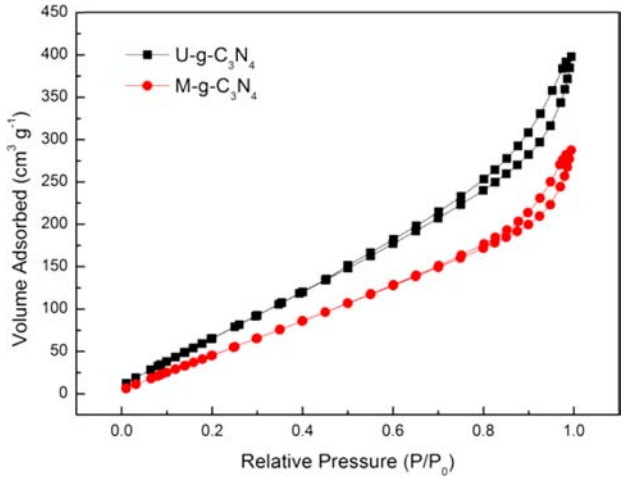

Figure 5. N_2 adsorption−desorption isotherms of U-g-C_3N_4 and M-g-C_3N_4.

U-g-C_3N_4 and M-g-C_3N_4, respectively. The photocatalytic activity of g-C_3N_4 was largely inhibited by the addition of hole capture. However, $^{\bullet}OH$ scavengers have almost no effect on the degradation process. Therefore, the hole is the main oxidative species for g-C_3N_4 samples, rather than $^{\bullet}OH$. Another point is that when benzoquinone (BQ) was used to remove superoxide radical ($^{\bullet}O_2^-$), the photocatalytic activity of g-C_3N_4 was slightly increased. This is because the consumption of superoxide radical ($^{\bullet}O_2^-$) was accompanied by the loss of electrons (e^-), which enhanced the separation efficiency of photoexcited electron−hole pairs.

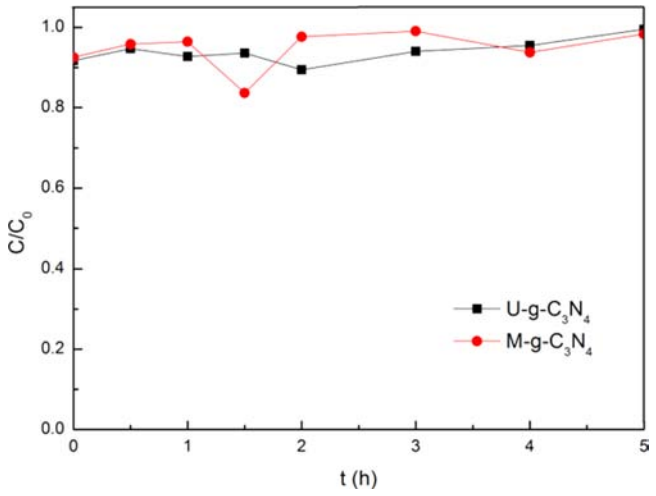

Figure 6. Photocatalytic activities of U-g-C_3N_4 and M-g-C_3N_4 in the degradation of imidacloprid in the absence of light.

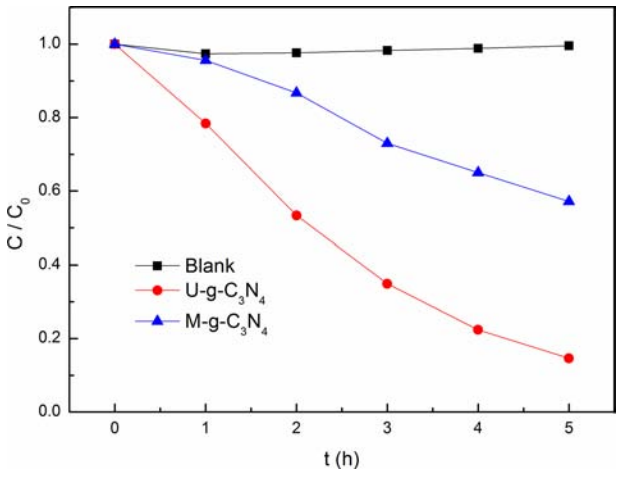

Figure 7. Photocatalytic activities of U-g-C_3N_4 and M-g-C_3N_4 in the degradation of imidacloprid under visible-light irradiation (λ >400 nm).

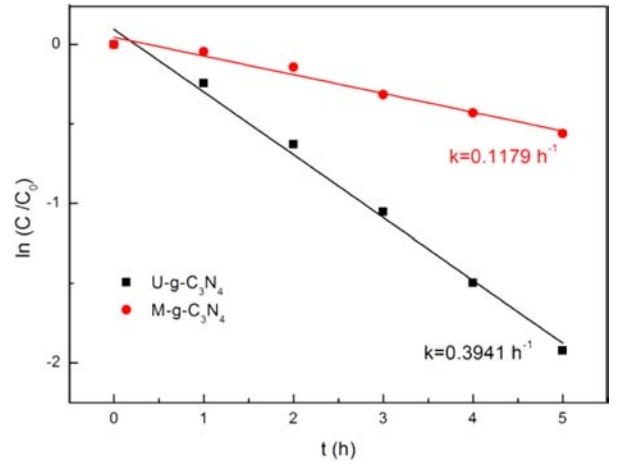

Figure 8. Kinetic analysis for the determination of apparent rate constants of the reaction between imidacloprid and photocatalysts.

On the basis of the above analysis, the photocatalytic degradation mechanism of g-C_3N_4 for imidacloprid is different from that of traditional techniques. Aqueous imidacloprid

degradation may be clarified by a mechanistic explanation using eqs 1−5.

$$g\text{-}C_3N_4 \rightarrow e^- + h^+ \quad (1)$$

Possible Degradation Pathway and Main Degradation Products. In this work, LC/MS analysis of the irradiated

$$h^+ + H_2O \rightarrow {}^{\bullet}OH + H^+ \quad (2)$$

$$e^- + O_2 \rightarrow O_2^{\bullet -} \quad (3)$$

$$h^+(g\text{-}C_3N_4) + \text{imidacloprid} \rightarrow \text{degradation product (compound } \mathbf{1}) \quad (4)$$

$${}^{\bullet}OH + \text{imidacloprid} \rightarrow \text{degradation product (compound } \mathbf{2}) \quad (5)$$

imidacloprid aqueous solution revealed two main products. The formation of 4,5-dihydro-*N*-nitro-1-(3-pyridinylmethyl)-1*H*-imidazol-2-amine (compound **1**) could be due to the mechanisms of holes (h^+). Addition of $^{\bullet}OH$ to the imidazolidine ring allows the formation of 1-((6-chloropyridin-3-yl)methylhydroxy)-imidazolidin-2-ylidene nitramide (compound **2**)[45] (Figure 11).

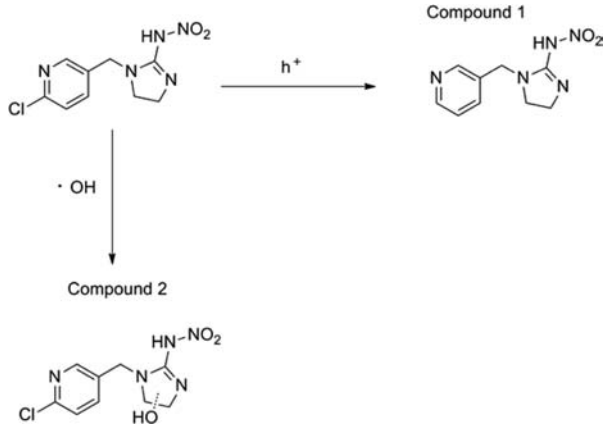

Figure 11. Proposed degradation pathway for imidacloprid using g-C_3N_4 as a visible-light photocatalyst.

To the best of our knowledge, compound **1** has not been reported previously, as a type of imidacloprid degradation product.

The stability of photocatalysts is important for their practical application. The renewable catalytic activity of U-g-C_3N_4 photocatalysts was further investigated. As shown in Figure 12, after three cycles, the high photodegradation rate of imidacloprid

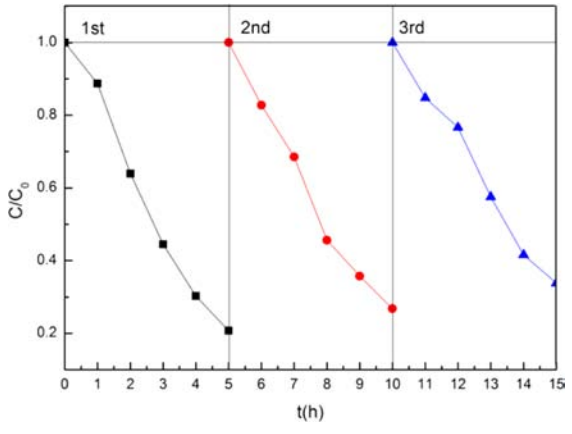

Figure 12. Cycling runs for the photocatalytic degradation of imidacloprid in the presence of U-g-C_3N_4 under visible light.

could be maintained. There was no significant loss of activity with the extension of reaction time, even on irradiation for 15 h. Thus, the present work could promote a new strategy dealing with the pollution of wastewater by pesticides. For the synergy between the reduced proton concentration and the increased polymerization, U-g-C_3N_4 possessed significant photodegradation activity for imidacloprid under both visible- and indoor-light irradiation. The main reactive species responsible for g-C_3N_4 photodegradation was a photogenerated hole. As it is economically feasible and sustainable, U-g-C_3N_4 has promising prospects for environmental applications.

Characterization of the Key Aroma Compounds in a Commercial Amontillado Sherry Wine by Means of the Sensomics Approach

Pauline Marcq and Peter Schieberle*

Deutsche Forschungsanstalt für Lebensmittelchemie, Lise-Meitner-Straße 34, D-85354 Freising, Germany

ABSTRACT: An aroma extract dilution analysis (AEDA) carried out on the volatile fraction isolated by extraction/solvent-assisted flavor evaporation (SAFE) distillation from a commercial Amontillado sherry wine revealed 37 odor-active compounds with flavor dilution (FD) factors in the range of 16−4096. Among them, 2-phenylethanol (flowery, honey-like) and ethyl methylpropanoate (fruity) showed the highest FD factors, followed by ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate (fruity) reported for the first time in sherry wine. A total of 36 aroma-active compounds located by AEDA were then quantitated by a stable isotope dilution assay, and their odor activity values (OAVs; ratio of concentration to odor threshold) were calculated. The highest OAV was displayed by 1,1-diethoxyethane (2475; fruity), followed by 2- and 3-methylbutanals (574; malty) and methylpropanal (369; malty). Aroma reconstitution experiments and a comparative aroma profile analysis revealed that the entire orthonasal aroma profile of the Amontillado sherry wine could be closely mimicked.

KEYWORDS: *GC−O, AEDA, static headspace−olfactometry, OAV, ethyl (2S,3S)-2-hydroxy-3-methylpentanoate, aroma recombinate*

INTRODUCTION

Sherry is a fortified wine produced in the Jerez region in southern Spain. Three different white grape varieties are used in its production, Palomino Fino, Pedro Ximénez, and Moscatel, with the first being the most abundant in dry sherry production, while the others are commonly used to produce sweet sherry wines. Although made from the same grape variety, namely, Palomino Fino, different types of dry sherry wines are manufactured by three different maturation processes: Fino, Amontillado, and Oloroso. Fino is processed by a dynamic biological aging with a layer of yeast, also called *flor*, developing on the surface of the wine, thus protecting it from oxidation. Fino is fortified to 15.5% (v/v) ethanol and results in a pale, yellow product with a sharp and delicate bouquet.[1] Oloroso, which is dark, brown, and full-bodied,[1] is aged under oxidative conditions and fortified to at least 17% ethanol (v/v), hindering the formation of a *flor*, thus allowing direct contact between the wine and ambient air. Amontillado is aged by means of two consecutive steps: a biological step and an oxidative step. Its color is in between that of Fino and Oloroso, and it has been reported to possess a complex flavor.[2] Amontillado is the oldest and most valued of the three wine styles made from the Palomino Fino grape.[3]

A particularity of sherry wine is a dynamic aging system called "*criaderas* and *solera*". The wine is stored in American oak casks (500−600 L) stacked in several levels, with the lowest level containing the older wine and the highest level containing the youngest wine. This technique involves many transfers of wine of different ages and vintages, enabling the production of a consistent and homogeneous sherry aroma. A detailed description of the system can be found in various textbooks cited in reviews.[3,4]

Data on the volatile composition of sherry wine were published as early as 1976,[5] and over 130 volatile components were identified. Subsequently, numerous studies mainly involving gas chromatographic analysis were undertaken, attempting to correlate the entire volatile fraction of sherry wine with its aroma profile.[6−8] Thus, today more than 300 volatiles are known in sherry.[9]

It is well-accepted in state-of-the-art aroma analysis that only a small subset of volatiles cause the aroma perception in the brain initiated by an interaction of odorants with the human olfactory receptors.[10−12] Therefore, it can be assumed that only a few of the numerous volatiles identified in sherry wine are probably odor-active. To characterize the key aroma compounds in foods, the sensomics analysis was suggested by Schieberle and Hofmann[11] as a molecular sensory analysis approach to differentiate the key aroma compounds from the bulk of odorless volatiles. By combination of sensory-supported analysis, such as gas chromatography−olfactometry (GC−O), with modern instrumental techniques, it is possible to determine the combinatorial food aroma code, also called the "aroma blueprint", and various aromas have already successfully been decoded by means of the sensomics analysis.[12]

By application of GC−O, Zea et al.[13] have monitored the aroma profile of Fino during aging; however, no quantitative analysis was performed in this study. In a recent work by Moyano et al.,[14] Amontillado sherry wine was analyzed by GC−O to identify the odorants generated during the sequential biological and oxidative aging steps. A total of 25 compounds were monitored and based on so-called odor spectrum values, and ethyl octanoate, ethyl butanoate, eugenol, ethyl methylpropanoate, and sotolon were proposed as the most potent odorants in Amontillado sherry wine. Several further studies on sherry wines applied the odor activity value concept (OAV; ratio of concentration to odor threshold), however, without performing a preliminary screening of aroma compounds by

GC−O.[2,15−17] Moreno et al.[18] monitored volatile compounds with OAV > 5 in Fino sherry wine during aging on the basis of GC/flame ionization detector (FID) quantitation. In addition to acetaldehyde, these authors suggested sotolon, 1,1-diethoxyethane, and *cis*-whiskylactone as markers of aging.

Although several studies have been performed aimed at identifying important odorants by either applying GC−O or the OAV concept, up to now, no comprehensive studies employing the full sensomics approach[12] have been performed on a sherry wine. Therefore, this research consisted of (i) the identification of the key aroma compounds in an Amontillado sherry wine by means of aroma extract dilution analysis, (ii) the quantitation of these compounds by a stable isotope dilution assay (SIDA), (iii) the determination of the importance of each odorant on the basis of OAVs, and (iv) a validation of the results through aroma reconstitution experiments and sensory evaluation.

MATERIALS AND METHODS

Sherry Wine. The investigated commercial sherry wine was an Amontillado produced in Spain in the Sanlúcar de Barrameda region (Jerez region). The wine was called Don Benigno and has been produced and bottled by Pedro Rodriguez e Hijos. On the basis of the label, it contained 17.5% (v/v) ethanol and carried the Jerez-Xérès-Sherry denomination of origin. The wine was purchased at a local spirit shop. This selection was not performed for advertising purposes nor does it imply a research contract with the manufacturer.

Chemicals. Reference compounds of the odorants were obtained from the sources given in parentheses: acetaldehyde, acetic acid, 4-allyl-2-methoxyphenol (eugenol), 2,3-butanedione, butanoic acid, ethyl butanoate, ethyl 2-hydroxyhexanoate, ethyl propanoate, ethyl octanoate, 4-ethyl-2-methoxyphenol, ethyl methylpropanoate, 4-ethylphenol, hexanoic acid, 4-hydroxy-2,5-dimethylfuran-3(2*H*)-one, 4-hydroxy-3-methoxyacetophenone (acetovanillone), 4-hydroxy-3-methoxybenzaldehyde (vanillin), 2-methyl-1-butanal, 3-methyl-1-butanal, 2-methylbutanoic acid, 3-methylbutanoic acid, 2-methyl-1-butanol, 3-methyl-1-butanol, methylpropanal, methylpropanol, methylpropanoic acid, 3-(methylthio)-propanal, 2-phenylacetic acid, 2-phenylethanol, octanoic acid, and whiskylactone (Sigma-Aldrich, St. Louis, MO); 1,1-diethoxyethane, ethyl hexanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, and 3-hydroxy-4,5-dimethylfuran-2(5*H*)-one (sotolon) (Fisher Scientific, Pittsburgh, PA); ethyl 2-hydroxy-4-methylpentanoate (TCI America, Portland, OR); and (*E*)-*β*-damascenone (Vigon, East Stroudsburg, PA).

The isotopically labeled standards were obtained commercially from the sources given in parentheses: [$^2H_3$]-acetaldehyde, [$^2H_5$]-butanoic acid, [$^2H_4$]-1,1-diethoxyethane, [$^2H_3$]-ethyl butanoate, [$^2H_{11}$]-ethyl hexanoate, [$^2H_{15}$]-ethyl octanoate, [$^2H_{10}$]-4-ethylphenol, [$^2H_4$]-pentanoic acid, [$^2H_2$]-3-methylbutanoic acid, [$^2H_2$]-3-methyl-1-butanal, [$^2H_4$]-3-methyl-1-butanol, [$^2H_3$]-methylpropanoic acid, [$^2H_5$]-2-phenylethanol, and [$^2H_{15}$]-octanoic acid (CDN Isotopes, Inc., Pointe Claire, Canada); [$^{13}C_2$]-acetic acid and [$^{13}C_2$]-2-phenylacetic acid (Isotech Stable Isotopes, Sigma-Aldrich, St. Louis, MO); [$^2H_3$]-2,3-pentanedione, [$^2H_2$]-ethyl methylpropanoate, [$^2H_2$]-methylpropanal, and [$^2H_4$]-(*E*)-*β*-damascenone (Adesis, Inc., New Castle, DE); and [$^2H_3$]-4-allyl-2-methoxyphenol, [$^2H_5$]-ethyl propanoate, [$^2H_5$]-ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate, [$^2H_2$]-ethyl 2-methylbutanoate, [$^{13}C_2$]-3-hydroxy-4,5-dimethylfuran-2(5*H*)-one, [$^{13}C_2$]-4-hydroxy-2,5-dimethylfuran-3(2*H*)-one, [$^2H_3$]-4-hydroxy-3-methoxybenzaldehyde, and [$^2H_3$]-3-(methylthio)-propanal (AromaLab AG, Freising, Germany). [$^2H_2$]-*cis*-Whiskylactone was synthesized as previously reported.[19]

Anhydrous sodium carbonate, anhydrous sodium sulfate, and hydrochloric acid (37%) were obtained from Fisher Scientific (Pittsburgh, PA). Sodium chloride, sodium hydroxide, sodium nitrite, L-isoleucine, and concentrated sodium chloride (26%) were obtained from Sigma-Aldrich (St. Louis, MO). Diethyl ether (Acros, Fisher Scientific, Pittsburgh, PA) and *n*-pentane (Merck, Darmstadt, Germany) were freshly distilled prior to use. Dichloromethane was obtained from Fisher Scientific (Pittsburgh, PA). Silica 60 was purified according to a procedure described by Esterbauer.[20] For chromatographic separation, water was purifed with a Milli-Q Advantage A10 system (Millipore, Molsheim, France). For sensory reconstitution experiments, Deer Park bottled water was used (Nestlé Water North America, Inc., Stamford, CT). D-Glucose and L-(+)-tartaric acid were supplied by Sigma-Aldrich (St. Louis, MO), and glycerol was supplied by Fisher Scientific (Pittsburgh, PA).

Synthesis of Ethyl (2*S*,3*S*)-2-Hydroxy-3-methylpentanoate. This was carried out in two steps and was based on previously published procedures,[21,22] with some modification.

(2S,3S)-2-Hydroxy-3-methylpentanoic Acid. L-Isoleucine (22.9 mmol) was dissolved in aqueous hydrochloric acid (1 mol/L, 22.9 mL), and concentrated acetic acid (45.8 mL) was added with stirring. Then, an aqueous solution of sodium nitrite (23 mmol in 27.6 mL) was added dropwise at 0 °C to the mixture within 30 min with stirring. The solution was stirred for another 20 min at 0 °C and then stirred overnight at room temperature under an argon atmosphere. The solution was concentrated, and the residue was dissolved in water (50 mL) and adjusted to a pH of ∼2 with concentrated hydrochloric acid. After extraction with diethyl ether (3 × 100 mL), the combined organic extracts were washed with saturated sodium chloride solution and dried over anhydrous sodium sulfate. After filtration, the solvent was distilled off using a Vigreux column at 40 °C to yield the target compound.

Ethyl (2S,3S)-2-hydroxy-3-methylpentanoate. The acid was mixed with ethanol (20 mL) and concentrated hydrochloric acid (50 μL) and was refluxed for 150 min. After the mixture was cooled, diethyl ether (50 mL) was added and the organic phase was consecutively washed with sodium carbonate (0.75 mol/L, 20 mL) and bidistilled water (15 mL). The organic layer was dried over anhydrous sodium sulfate and then concentrated using a Vigreux column (60 × 1 cm). The target compound was purified using a water-cooled glass column (30 × 1 cm) containing 20 g of purified silica gel,[20] conditioned in *n*-pentane. For this purpose, the solution (0.2 mL) was placed on the top of the column and separation was performed using the following *n*-pentane/diethyl ether gradient: *n*-pentane (I; 100 mL), *n*-pentane/diethyl ether (II; 95:5, 100 mL), *n*-pentane/diethyl ether (III; 80:20, 100 mL), and finally, diethyl ether (IV; 100 mL). The target compound was detected by GC−O in fraction III and was further purified using flash chromatography (40 g of Lichroprep DIOL phase; particle size of 40−63 μm) under pressure with a flow rate of 2 mL/min and the *n*-pentane/diethyl ether gradient.

MS (EI), *m*/*z* (%): 87 (100), 76 (66), 104 (53), 45 (37), 69 (24), 57 (17), 41 (10), 88 (7), 75 (6), 58 (5), 103 (5), 105 (5), 71 (4), 55 (3), 77 (3), 85 (3), 86 (3), 43 (2), 47 (2), 70 (2), 99 (2), 117 (2), 131 (2), 145 (2), 46 (1), 53 (1), 59 (1), 67 (1), 68 (1), 89 (1), 97 (1), 98 (2), 106 (1), 113 (1), 114 (1).

MS (CI), *m*/*z* (%): 161 (100).

The concentration of ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate was determined by GC/FID using 1-octanol as the internal standard. Its odor threshold was determined in a 17% (v/v) hydroalcoholic solution according to the procedure described previously,[23] with 12 panelists participating in this session (4 males and 8 females, ranging in age from 29 to 51 years old).

Isolation of the Volatiles. The sherry (100 mL) was mixed with sodium chloride (10 g) and was extracted with diethyl ether (total volume of 250 mL). The organic layers as well as the emulsion formed were combined, dried over anhydrous sodium sulfate, and concentrated to 100 mL using an automated solvent evaporator system operating at 25 °C, 0.7 bar, and using nitrogen gas vortex shearing (TurboVap II, Biotage, Uppsala, Sweden). The volatiles were then separated from the non-volatile compounds by high-vacuum distillation using the solvent-assisted flavor evaporation (SAFE) apparatus,[24] and the distillate was separated into an acidic fraction (AF) and a neutral-basic fraction (NBF) by treatment with an aqueous sodium carbonate solution.[25] AF and NBF were washed with saturated sodium chloride solution, dried over anhydrous sodium sulfate, and concentrated to ∼4 mL using the automated solvent evaporator system described above. The distillate was further concentrated to ∼1 mL under a subtle stream of nitrogen at 37 °C.

GC−O. GC−O was performed using an Agilent gas chromatograph type 6890 (Agilent Technologies, Inc., Santa Clara, CA) and the following fused silica capillaries: J&W Scientific DB-FFAP and DB-5 (30 m × 0.32 mm inner diameter, 0.25 μm film thickness) (Folsom, CA). The sample (1 μL) was applied by cool on-column injection at 40 °C using helium as the carrier gas with a flow rate of 2.5 mL/min. The temperature programs were as follow: 40 °C for 2 min, 8 °C/min up to 80 °C, 5 °C/min up to 120 °C, 8 °C/min up to 230 °C, and 230 °C for 15 min (DB-FFAP) and 40 °C for 2 min, 8 °C/min up to 80 °C, 5 °C/min up to 120 °C, 8 °C/min up to 250 °C, and 250 °C for 15 min (DB-5). GC−O was performed with simultaneous flame ionization and olfactometric detection by evenly splitting the effluent using a Y-type glass splitter and two deactivated fused silica glass capillaries of the same length. Both FID and sniffing port temperature were at 220 °C. Linear retention indices (RIs) of the aroma compounds were calculated from the retention times of a series of *n*-alkanes (C_5−C_{26}) as described previously.[26]

Aroma Extraction Dilution Analysis (AEDA). AEDA was performed on the DB-FFAP column. The original NBF and AF were first sniffed by four panelists to ensure a consistency of detection and aroma language selection. Each fraction was then stepwise-diluted with diethyl ether (1:1, v/v) and subjected to GC−O. The flavor dilution (FD) factor of an odorant represented the last dilution in which it could be perceived. Each panelist was trained on a weekly basis by means of solutions of reference odorants in water using a common aroma language.[23]

Static Headspace−Olfactometry (SHO) and Aroma Dilution Analysis (ADA). GC of static headspace samples was carried out by means of a Thermo Trace Ultra gas chromatograph in connection with a cryotrap system type 915 (Braunschweig, Germany), cooled with liquid nitrogen. An aliquot of the sherry wine (10 mL) was equilibrated in a septum-sealed vessel (120 mL) for 15 min at 30 °C. From different samples of the same volume, decreasing headspace volumes (10−0.1 mL) were withdrawn with a gastight syringe, injected by cold on-column injection, and subsequently trapped at −150 °C. The trap was then rapidly heated to 250 °C, and the sample was flushed onto a J&W Scientific DB-5 fused silica column (30 m × 0.25 mm inner diameter, 0.5 μm film thickness) (Folsom, CA). After injection, the temperature of the oven was held at 0 °C for 2 min, then raised at 6 °C/min to 100 °C, followed by 40 °C/min to 240 °C, and held at 240 °C for 2 min. At the end of the column, the effluent was split evenly between an FID and a sniffing port held at 250 and 220 °C, respectively. The flow rate of the carrier gas helium was 0.8 mL/min. The FD factors were calculated by dividing the largest volume analyzed to the lowest volume in which the odorant could be detected.

Gas Chromatography/Mass Spectrometry (GC/MS). Dependent upon the concentration of the aroma compound and the presence of co-eluting compounds, several GC/MS systems were used for identification. The majority of the compounds was identified by means of a gas chromatograph type 6890 coupled to a MS type 5975 (Agilent Technologies, Inc., Santa Clara, CA) operated in the electron impact mode (MS−EI) at 70 eV. Separation was performed at a constant flow (average velocity of 37 cm/s), and the scan was between 35 and 350 amu with 4.45 scans/s. Trace analytes were identified using a two-dimensional GC/MS instrument consisting of an Agilent GC1 and GC2 system type 7890A and 6890N, respectively (Santa Clara, CA).

DOI: 10.1021/acs.jafc.5b01418
J. Agric. Food Chem. 2015, 63, 4761−4770

The column combination consisted of a BP-20 (SGE, Inc., Austin, TX) in the first dimension and a J&W Scientific DB-5 (Folsom, CA) in the second dimension (30 m × 0.32 mm inner diameter, 0.25 μm film thicknesses each). For the identification of low boiling substances, the system used for the SHO described above was coupled to a Varian Saturn 2100 ion trap mass spectrometer (Darmstadt, Germany), and mass spectra were generated by MS−EI at 70 eV. Separation was performed at a constant pressure with an average velocity of 45.103 cm/s. The MS was operated with a scan mode between 45 and 400 amu and a scan speed of 3.99 scans/s.

Quantitation by a SIDA in Combination with GC/MS. Aliquots of the labeled standard in dichloromethane were added to different amounts of sherry wine (1−100 mL) depending upon the concentration of the target compound estimated in preliminary experiments. The samples were stirred for 30 min and then extracted with diethyl ether. Volatiles were isolated according to the method described above, and quantitation of the aroma compounds in the extracts was performed using both the two-dimensional GC/MS system as described above as well as a one-dimensional GC/MS system with an Agilent 6890 gas chromatograph and an Agilent 5973 mass spectrometer (Santa Clara, CA). Separation was performed using a J&W Scientific DB-FFAP column (30 m × 0.32 mm inner diameter, 0.25 μm film thickness) (Folsom, CA) using the following temperature program: 40 °C for 2 min, 5 °C/min up to 240 °C, and 240 °C for 5 min. The temperature of the injector (splitless mode) was at 180 °C, and the flow rate of the carrier gas helium was 1.5 mL/min. Details of the ions selected for the SIDA and the correction factors are given in Table 1. Separation was performed at a constant flow (average velocity of 44 cm/s), and the mass spectrometer was operated in the selected ion monitoring (SIM) mode with a dwell time of 100 ms.

Static Headspace Analysis. The analysis was performed using the GC/MS system described above equipped with an unpolar Restek RT-Q-Bond capillary column (30 m × 0.32 mm inner diameter, 10 μm film thickness) (Bellefonte, PA). The sample (5 mL) was mixed with NaCl (1 g) in a septum-sealed vessel (20 mL), and the labeled standards dissolved in ethanol (17%, v/v) were added to the wine sample (5 mL). To quantitate acetaldehyde, the wine (0.1 mL) was diluted with water to reach a final volume of 5 mL and [$^2H_3$]-acetaldehyde was added. The headspace was generated for 20 min at 40 °C with automatic agitation at 500 rpm, and 1 mL was injected in the splitless mode using a gastight syringe at 50 °C and an injector temperature of 80 °C. The temperature program was as follows: 40 °C for 0 min, 12 °C/min up to 220 °C, 20 °C/min up to 260 °C, and 260 °C for 5 min. The flow rate of the carrier gas helium was 2 mL/min. A calibration factor was determined for each compound by analyzing mixtures of defined amounts of labeled and unlabeled compounds in ratios of 1:3, 1:1, and 3:1, respectively (Table 1). All quantitative analyses were performed in MS−EI at 70 eV, except for *cis*-whiskylactone, which was quantitated in chemical ionization (CI) mode as described previously.[19]

Determination of Ethanol. Ethanol was enzymatically quantitated using a test kit (R-Biopharm, Darmstadt, Germany).

Determination of Isomeric Distribution. 2- and 3-methylbutanoic acids were quantitated according to the procedure described by Frank et al.[25] Ethyl 2-methylbutanoate and ethyl 3-methylbutanote were quantitated in two steps because of the availability of only one labeled standard (Table 1) and mass fragment interferences between the two esters and the labeled standard. First, ethyl 3-methylbutanoate was quantitated (Table 1). Then, the ion intensities of the mass fragments m/z 102 and 88 for ethyl 2-methylbutanoate and ethyl 3-methylbutanoate, respectively, were monitored by MS−EI, and finally, the concentration of ethyl 2-methylbutanoate was calculated using a calibration curve prepared by analyzing defined mixtures of both isomers.

Aroma Profile Analysis. Panelists who participated in the study were all trained for at least 3 months on a weekly basis to recognize and describe the odor qualities of a wide range of odorants and products. In a first step, the wine was evaluated orthonasally by a small panel to generate a list of aroma attributes that were later on ranked on the basis of their frequency of citation as well as their intensity. The following nine aroma attributes were selected for the descriptive analysis: fruity, cooked apple, dark/dry fruit, honey, caramel, alcohol-like, sour/pungent, smoky, and malty. Aqueous solutions of each of the following compounds (OAV = 100) were provided to the panelists as references during each session: ethyl 3-methylbutanoate (fruity), (*E*)-β-damascenone (cooked apple), 2-phenylethanol (flowery, honey-like), 4-hydroxy-2,5-dimethylfuran-3(2*H*)-one (caramel), ethanol (alcohol-like), acetic acid (sour/pungent), 2-methoxyphenol (smoky), and 3-methylbutanol (malty). For the dark/dry fruit descriptor, dry figs and raisins were provided. The wine (20 mL) was poured into a glass vessel (45 mL) and analyzed by ranking the intensity of each attribute on a seven-point scale (steps of 0.5) from 0 (not perceivable) to 3 (strongly perceivable). The aroma profile

[a]RI = retention index. [b]Chemical structure identified on the basis of odor quality and intensity at the sniffing port, with retention indices and mass spectra compared to reference compounds on capillaries FFAP and DB-5. [c]Odor quality perceived at the sniffing port. [d]Fraction in which the aroma compound was detected. [e]FD factor = flavor dilution factor. [f]No unequivocal mass spectrum was obtained. Identification is based on the remaining criteria in footnote *b*.

analysis of Amontillado wine was performed by 21 panelists, and the single evaluations of the panelists were averaged.

Aroma Reconstitution Experiment. An aroma mixture was prepared consisting of all quantitated aroma compounds in the same concentration as determined in the wine. For the isomers quantitated as sum (2- and 3-methylbutanols and 2- and 3-methylbutanals), a mixture of 60:40 of the isomers was used, because their corresponding esters (ethyl 2- and 3-methylbutanoates) and acids (2- and 3-methylbutanoic acids) were found in a similar ratio. For *cis*-whiskylactone, the commercial reference was used, which consisted of a mixture of ∼1:1 *cis*- and *trans*-whiskylactone. The pH was adjusted to 3.6 with hydrochloric acid (0.1 mol/L). The model solution was equilibrated at 4 °C overnight and presented to the panelists at room temperature for evaluation against a control. A volume of 10 mL from the control and from the sample was placed in amber glass containers (30 mL). The control was a freshly opened bottle of Amontillado wine (<1 week, stored at 4 °C under nitrogen gas after opening). The intensities of each attribute determined during the descriptive analysis of the wine (Figure 1) were used as a reference. Panelists were first asked to rate each attribute compared to the reference, and then the panelists were asked to evaluate the similarity between the two samples using a seven-point scale with the following end anchors: "very different" (0) and "very similar" (3), respectively.

Sensory Evaluation of Aroma and Taste Interactions. The model solution described above was prepared in either an aqueous solution of ethanol (17%, v/v) adjusted to pH 3.6 by hydrochloric acid (0.1 mol/L) (recombinate A) or an aqueous solution of ethanol (17%, v/v; pH 3.6) containing L-tartaric acid, D-glucose, and glycerol, each at a concentration falling within the range of concentrations commonly found in dry sherry wines[1,27] (recombinate B). Recombinate B was adjusted to pH 3.6 with sodium hydroxide (5 mol/L). Descriptive aroma profiles were performed as described above with a maximum of two sessions per day. In a last session, Amontillado wines from different bottles were compared. The sherry wine sample was labeled as the "control", whereas the recombinates as well as the sherry wine from a different bottle were labeled as "sample", followed by a sample code. Between 9 and 10 panelists participated in these sessions, and the results obtained were averaged.

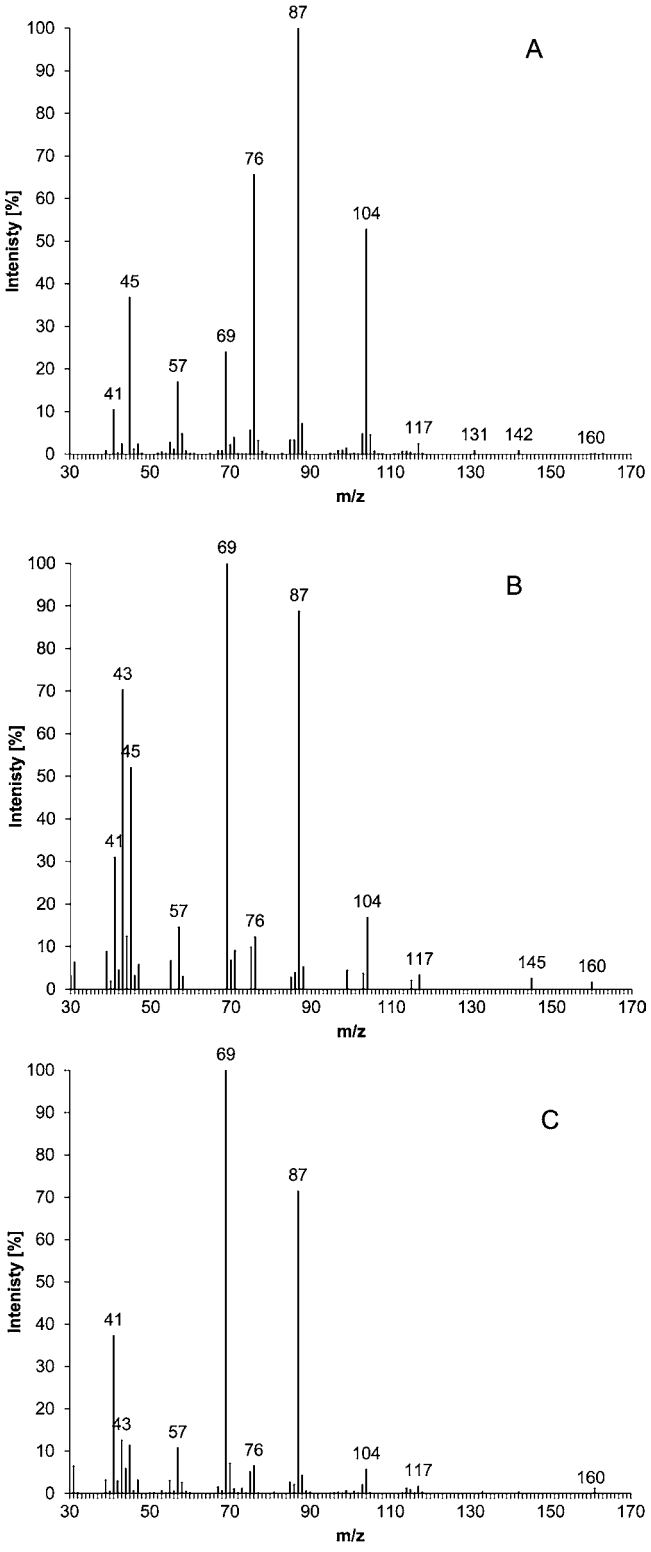

Figure 3. Mass spectrum (MS−EI) of ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate isolated from (A) Amontillado sherry wine. Comparison to (B) mass spectrum of ethyl 2-hydroxyhexanoate and (C) mass spectrum of ethyl 2-hydroxy-4-methylpentanoate.

RESULTS AND DISCUSSION

The aroma profile analysis of the Amontillado sherry wine was carried out by evaluating the intensity of nine aroma attributes on a scale from 0 (not perceivable) to 3 (strongly perceivable) (Figure 1). The sample was characterized by a moderate to strong ethanol-like aroma, followed by moderate fruity, honey/floral, and cooked apple attributes. The odor characteristic dark/dry fruit was also perceived but only as weak to moderate.

Table 3. Most Odor-Active Volatile Constituents in the Headspace above the Amontillado Sherry Wine

odorant[a]	odor quality[b]	RI on DB5[c]	FD factor[d]
acetaldehyde	green/fresh	<500	20
ethanol	solvent/green	500	4
methylpropanal	malty	561	10
2,3-butanedione	buttery	601	10
2- and 3-methylbutanals	malty	660	10
ethyl propanoate	fruity/green	719	2
1,1-diethoxyethane	green/fruity	740	100
2- and 3-methylbutanols	malty	753	20
ethyl methylpropanoate	fruity/liquor	765	100
ethyl butanoate	fruity	803	40
ethyl 2-methylbutanoate	fruity	847	100
ethyl 3-methylbutanoate	fruity	853	100

[a]Chemical structure identified on the basis of odor quality and intensity at the sniffing port, with retention index and mass spectrum compared to reference compounds on a DB-5 capillary column. [b]Odor quality perceived at the sniffing port. [c]RI = retention index. [d]FD factor = flavor dilution factor.

The volatiles were then isolated by solvent extraction followed by SAFE distillation,[24] and a drop of the volatile fraction was applied on a filter paper strip and evaluated by six panelists, who confirmed the presence of the typical aroma of the sherry wine. The method of volatile isolation was thus proven to be adequate for aroma isolation.

Identification of Odor-Active Compounds. GC−O was separately applied on the NBF and AF obtained from 100 mL of wine. A total of 24 compounds with FD factors ranging from 16 to 4096 were detected as the most odor-active compounds in the NBF (Figure 2A), and 13 odorants were additionally found in the AF with FD factors between 16 and 2048 (Figure 2B). The highest FD factors were found for a fruity compound (**4**; FD of 4096) eluting with a retention index below 1000, a flowery, honey-like smelling odorant (**24**), followed by a vanilla-smelling compound (**36**; FD of 2048). In addition, two fruity-smelling compounds (**8** and **16**), a malty-smelling compound (**10**), a sweaty-smelling compound (**20**), a cooked-apple-like-smelling compound (**21**), and a seasoning-like-smelling compound (**31**) appeared with high FD factors.

To identify the compounds responsible for the odors perceived at the sniffing port, first, the retention indices of the odor-active areas were determined on two different stationary GC phases. Thus, by comparison to retention indices of ∼1000 food odorants compiled in an in-house database, a chemical structure could be suggested for most of the odorants. Subsequently, the respective reference compounds were subjected to GC−O and GC/MS, and the identification was confirmed on the basis of odor quality and intensity matching at the sniffing port as well as mass spectra (MS−EI) matching between the reference and analyte. In some cases, the use of two-dimensional GC/MS was necessary to identify trace compounds co-eluting with volatiles present in a high concentration. For example, compound **21** did not yield a signal at the flame ionization detector (data not shown) but was perceived with a FD factor of 1024, indicating a low odor threshold.

On the basis of this approach, the most odor-active compounds in the Amontillado sherry wine were characterized

4-ethyl-2-methoxyphenol	19.3	5.0	GC/MS
cis-whiskylactone	18.1	6.9	2D GC/MS (CI)
4-hydroxy-2,5-dimethylfuran-3(2*H*)-one	3.8	10.1	2D GC/MS
4-allyl-2-methoxyphenol	2.3	0.8	2D GC/MS
(*E*)-*β*-damascenone	1.4	2.2	2D GC/MS

[a]Calculated as a mean value of three different workups. [b]Quantitative method used. MS−EI was used for GC/MS methods, except for *cis*-whiskylactone, which was quantitated in MS−CI.

as ethyl methylpropanoate (**4**) and 2-phenylethanol (**24**) (Table 2). With somewhat lower FD factors, 4-hydroxy-3-methoxybenzaldehyde (**36**), ethyl 3-methylbutanoate (**8**), 2- and 3-methylbutanols (**10**), 2- and 3-methylbutanoic acids (**20**), (*E*)-*β*-damascenone (**21**), and 3-hydroxy-4,5-dimethylfuran-2(5*H*)-one (**31**) were suggested as potential contributors to the overall aroma. For compound **16**, no reference spectrum was available. The mass spectrum obtained (Figure 3A) somewhat matched with the mass spectra of ethyl 2-hydroxyhexanoate (Figure 3B) and ethyl 2-hydroxy-4-methylpentanoate (Figure 3C), respectively. However, the first mentioned compound was excluded, because it elicited a green/rubber-like aroma, but the latter had the same fruity character as compound **16**. However, ethyl 2-hydroxy-4-methylpentanoate was not eluted at the same retention index (RI) as the target analyte (RI_{FFAP} of 1520; Table 2), thus also excluding this structure. A fruity-smelling compound with a similar mass spectrum as found for compound **16** was previously reported in sherry wine;[28] however, its structure remained unknown, despite several attempts of the authors; e.g., different isomers of ethyl 2-hydroxy-4-methylpentanoate were compared to the target analyte, but only ethyl (2*R*,3*R*)-2-hydroxy-3-methylpentanaote was found to have a similar RI and mass spectrum. Thus, we concluded that an enantiomer of ethyl (2*R*,3*R*)-2-hydroxy-3-methylpentanaote might correspond to the fruity-smelling compound **16**. Ethyl 2-hydroxy-3-methylpentanoate has been identified for the first time in Cognac and other grape brandies; however, its stereochemistry was not specified in this study.[29] More recently, Poisson identified ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate in whisky.[21] Because the ester was not commercially available, the compound was synthesized and analyzed by GC−O and GC/MS using two different capillary columns. A complete match of RI, MS, and odor properties with the target analyte finally confirmed the identity of compound **16** as ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate (Table 2). Poisson suggested[21] that the ester may be generated by transamination of L-isoleucine through the action of yeast during fermentation. In the case of Amontillado wine, which undergoes biological aging, it is very likely that this compound is also generated at this production stage.

A total of 35 aroma compounds could be identified in the Amontillado sherry wine (Table 2). It was interesting to find

[a]Odor thresholds were taken from the literature. Odor thresholds from ref 23 were determined in water, while all of the others were determined in hydroalcoholic solutions. [b]OAVs = odor activity values calculated by dividing the concentrations (Table 4) by the respective odor threshold. [c]The odor threshold of the (3) isomer was selected. [d]The odor threshold was determined in the laboratory in a 17% (v/v) water/ethanol mixture. [e]The odor threshold of the (*S*) isomer was used.

that the two vanilla-smelling compounds, vanillin (**36**) and acetovanillone (**37**), as well as wine lactone (**32**) have not been mentioned in any of the previous studies on sherry aroma. While the first two odorants are known to be extracted from the barrel during aging, wine lactone has also been found as an important contributor to white wine aroma because of its very low odor threshold (0.01 μg/L).[30] With the exception of these compounds, all odorants were previously identified in various sherry wines corroborating the assumption that the differences in aroma profiles of the same type of food are due to quantitative rather than qualitative differences in the key odorants.[12]

In addition, a SHO analysis was applied on Amontillado wine to address possible losses in higher volatile compounds during sample preparation. A total of 12 odor-active areas were detected in 10 mL of headspace, while only 4, all with a fruity character, could be detected in the lowest volume (0.1 mL), confirming their importance in the aroma of the Amontillado sherry wine (Table 3), namely, 1,1-diethoxyethane, ethyl methylpropanoate, ethyl 2-methylbutanoate, and ethyl 3-methylbutanoate. Ethanol, methylpropanal, and acetaldehyde were detected as additional odorants to those already detected by the AEDA.

Table 6. Average Similarity Scores of the Aroma Recombinates and Amontillado Wine from Bottle 2 to the Amontillado from Bottle 1 (Control)

sample	*n*[a]	similarity[b]
recombinate A[c]	9	2.5
recombinate B[d]	9	2.7
bottle 2[e]	10	2.8

[a]Number (*n*) of participants. [b]Similarity to sherry wine rated on a seven-point scale from 0 (very different) to 3 (very similar). [c]Model mixture with odorants in their natural concentration (Table 4) in an aqueous solution of ethanol (17%, v/v; pH 3.6). [d]Model mixture (Table 4) with L-tartaric acid (5 g/L), D-glucose (0.05 g/L), and glycerol (5 g/L) dissolved in an aqueous solution of ethanol (17%, v/v; pH 3.6). [e]Amontillado wine from a different bottle.

Quantitation of Aroma Compounds. None of the compounds identified with high FD factors elicited an aroma reminding of sherry wine. Thus, it can be assumed that the overall aroma is generated by a set of key odorants present in a defined concentration. A total of 36 compounds were quantitated in the sherry wine by means of a SIDA. The caramel-like smelling compound 4-hydroxy-2,5-dimethylfuran-3(2*H*)-one was included in the quantitative assay because it occurs in wine,[25,30] and the aroma attribute caramel was selected by the sensory panel to describe the aroma profile of Amontillado wine (Figure 1). The highest concentration was determined for ethanol, followed by acetic acid, 1,1-diethoxyethane, and 2- and 3-methylbutanols (Table 4). With the exception of 1,1-diethoxyethane, these compounds are known metabolites of yeast, with 2- and 3-methylbutanols known to be formed by an enzymatic degradation of the amino acids isoleucine and leucine, respectively. 1,1-Diethoxyethane is formed as an acetal from ethanol and acetaldehyde. Because Amontillado sherry wine is aged under a layer of yeast, acetaldehyde might be formed during this stage by oxidation of ethanol via the action of alcohol dehydrogenase from the yeast. A concentration of 56.9 mg/L was measured (Table 4), but in Fino wines, concentrations up to 1000 mg/L have previously been found.[31] Moyano et al.[14] measured the highest concentration of 409 mg/L acetaldehyde during the aging of an Amontillado wine after 8 years of aging, but its concentration decreased to 196 mg/L after 24 years. The Amontillado wine investigated in their study was from the Montilla-Moriles region and was produced from a Pedro Ximénez grape, which could explain the observed differences. A total of 22 compounds were present in concentrations higher than 200 μg/L (Table 4), and 3 showed concentrations below 5 μg/L, namely, 4-hydroxy-2,5-dimethylfuran-3(2*H*)-one, 4-allyl-2-methoxyphenol (eugenol), and (*E*)-β-damascenone.

Then, OAVs were calculated for all 36 compounds to identify the most potent odorants. With the exception of the threshold for ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate, all odor threshold values were taken from the literature (Table 5). The results

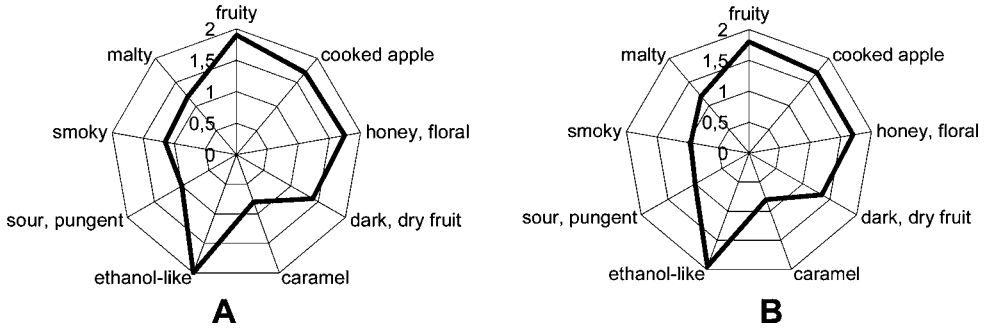

Figure 4. Comparison of (A) aroma profiles of Amontillado wine and (B) aroma recombinate B.

suggested that 28 odorants should contribute to the characteristic aroma of the sherry wine, because their concentrations clearly exceeded their odor thresholds. With an OAV of 2475, 1,1-diethoxyethane is potentially the most important odorant, and high OAVs were also calculated for 2- and 3-methylbutanals, methylpropanal, and ethanol (Table 5). The odor threshold of the newly identified compound ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate was determined in an aqueous matrix with 17% (v/v) ethanol. Its value (0.47 μg/L) is within the range of the odor threshold values determined, in water (0.18 μg/L)[21] and in 40% ethanol (8.0 μg/L). Therefore, with a concentration of 60 μg/L in the wine (Table 4), ethyl (2*S*,3*S*)-2-hydroxy-3-methylpentanoate is a clear contributor to the Amontillado sherry wine aroma. Also, ethyl octanoate, ethyl butanoate, ethyl methylpropanoate, and 3-hydroxy-4,5-dimethylfuran-2(5*H*)-one were found with an OAV above 1 in the sherry wine (Table 5). These four aroma compounds were also previously identified as key odorants in an Amontillado sherry wine from the Montilla-Moriles region.[14] On the other hand, 2-methylbutanoic acid, 4-ethyl-2-methoxyphenol, 4-allyl-2-methoxyphenol, *cis*-whisky-lactone, hexanoic acid, phenylacetic acid, 4-hydroxy-3-methoxyacetophenone (acetovanillone), and 4-hydroxy-2,5-dimethylfuran-3(2*H*)-one showed OAVs below 1, suggesting that these have no or only little contribution to the overall aroma.

Aroma Reconstitution Experiments. To validate the quantitative results, an aroma recombinate containing all key odorants in the "natural" concentrations measured in Amontillado wine (Table 4) was prepared in an ethanolic solution (17%, v/v; pH 3.6). The aroma profile analysis of recombinate A was performed in comparison to the Amontillado wine by rating the intensity of nine odor attributes as well as the overall similarity. On the basis of the intensity ratings of each aroma attribute, recombinate A had a very similar profile compared to the wine (data not shown). However, taking the overall similarity rating (2.5; Table 6) into consideration, it was clear that differences do exist, which could not be explained on the basis of the analytical data. With regard to the comments of the panelists, an overall lower aroma intensity was perceived in recombinate A compared to the wine. It is well-known from the literature that the presence of non-volatile constituents in wine may affect the release of aroma compounds and, therefore, the aroma perceived from the headspace. Therefore, a mixture of non-volatile constituents was added to the recombinate (recombinate B). The mixture consisted of L-tartaric acid, glycerol, and D-glucose at concentrations typically found in dry sherry wines (Table 6). Now, the aroma profile of this recombinate was very close to the wine (Figure 4) and was perceived as more similar to the wine than recombinate A (2.7 versus 2.5 respectively; Table 6). The presence of the non-volatile tastants may have affected the release of the aroma compounds by influencing their air−liquid partitioning. Several studies have demonstrated that different compounds present in wine matrices can change the odorant volatility and concentration in the headspace.[32,33] Frank et al.[25] on the other hand, suggested a strong influence of the non-volatile tastants on the intensity of certain aroma qualities in an aroma recombinate in ethanol.

In a final experiment, the aroma profile of Amontillado wine was compared to the same wine but from a different bottle. This test was performed to investigate the magnitude of the difference, which can be perceived by panelists between two very similar samples. The similarity value was the highest (2.8) compared to recombinate A and recombinate B (Table 6) but not the highest possible degree of similarity as 3.0. This result could be explained by a slight variation in the concentrations of the key aroma compounds between the two bottles or by the well-known tendency of the panelists to avoid end anchors of scale.[34] Without further investigation of the reason for this observation and consideration that a similarity of 2.8 is the maximum value obtained for identical or nearly identical wines, it can be concluded the composition of odorants in that recombinate B closely mimicked the aroma profile of Amontillado sherry wine.

Supporting Information

ABSTRACT: In this study, a simple and convenient method for the determination of *trans*-resveratrol (TRA) in peanut oils based on pollen grain solid-phase extraction (SPE) was developed. Pollen grains were used as normal-phase SPE sorbent to separate TRA from peanut oils for the first time. As a naturally occurring material, pollen grains exhibited an excellent adsorption capacity for polyphenolic compounds due to their particular functional structures such as hydroxyl groups, saturated and unsaturated aliphatic chains with aromatics. Their stable compositions as well as adequate particle size (30−40 μm) also make them suitable for SPE. Several parameters influencing extraction performance were investigated. Coupled with high-performance liquid chromatography-ultraviolet detection (HPLC-UV), a green purification method for fast determination of TRA in peanut oils using pollen grain cartridges as sorbents was established. The linearity range of the proposed method was 10−2500 ng·g^{-1} with a satisfactory correlation coefficient (r^2) of 0.9999. The limit of detection (LOD) for TRA in peanut oils was 2.7 ng·g^{-1}, and the recoveries in spiked oil samples were from 70.2% to 98.4% with the relative standard deviations (RSDs) less than 4.9% (intraday) and 5.2% (interday). This method was successfully applied to the analysis of TRA in several peanut oils with different brands from local market as well as other kinds of vegetable oils.

KEYWORDS: *pollen grains, trans-resveratrol, peanut oils, normal-phase solid-phase extraction, HPLC-UV*

INTRODUCTION

Resveratrol (3,5,4′-trihydroxystilbene) is a phytoalexin, which is produced by a wide variety of plants including grapes, blueberries, knotweed, pistachio nuts, and peanuts.[1] Due to its benefits to human health, such as antioxidative effect,[2] analgesic effect,[3] cardiovascular protective effect,[4] cancer prevention,[5] and antiaging property,[6] resveratrol has been widely studied over the past few decades. Resveratrol exists in two isomeric forms, *trans*- and *cis*-isomers, and *trans*-resveratrol (TRA) appears predominantly and has been proved to be more biologically active.[7]

Peanut oil as one of the main vegetable oils in human diet contains a well-balanced fatty acid profile and antioxidants, which provide protection against harmful substances especially free radicals.[8] Some scientific data showed that the antioxidative effect of peanut oil is due to the presence of phenolic compounds like TRA.[9] However, much attention was focused on the content of TRA in peanut skins,[10] peanut hulls,[11] peanut roots,[12] and peanut leaves[13] in recent years, and analysis of TRA in peanut oils was less reported.[14]

The content of TRA in peanut oil is much lower than that in peanut kernels or peanut skins, and the high-fat matrix cause the main difficulties for the analysis of trace amounts of TRA in oil matrices. Therefore, an effective sample pretreatment method for TRA separation and enrichment before instrument analysis is needed. Very recently, Zhao et al. employed a mixed-mode SPE cartridge purchased from Waters Oasis WCX for direct separation of TRA from soybean and peanut oils.[15] The method was effective, and high recoveries were achieved. However, in their experiment, the cartridge was used only one time, and the price of this commercial cartridge was expensive for routine analysis. Ma et al. utilized homemade hydrophilic multiwalled carbon nanotubes (HMWCNTs) as sorbents for magnetic solid-phase extraction of TRA in vegetable oils.[16] The sample pretreatment procedure was simple and rapid, whereas the preparation of HMWCNTs involved large amount of concentrated acid (H_2SO_4/HNO_3), which was harmful to the manipulator and violates several rules of green analytical chemistry such as the application of less toxic reagents, generating as less waste as possible, increasing safety for operators, among others.[17,18] Therefore, the development of new selective sorbents obtained from renewable source for TRA separation was still desirable.

Pollen grains are naturally occurring material from plants and are the carriers of plant's genetic substance needed for pollination.[19] Exine, the outer pollen wall, consists of an extremely stable and complex biopolymer known as sporopollenin, which is highly resistant to chemical attack and high temperature.[20] Because of the diverse chemical composition of exine, pollen grains have been used in drug deliveries,[21,22] in novel materials as templates,[23,24] as carbon microspheres,[25] in protein chromatography,[26] and during removal of organic pollutants.[27] The particle size of pollen grains is 30−40 μm, and the Fourier transform infrared (FT-IR) spectrum revealed the existence of numerous hydroxyl groups on the surface of pine

pollen grains. Therefore, pollen grains are a promising normal-phase SPE (NP-SPE) sorbent. Recently, we reported a green method for determination of 16 plant growth regulators in fruits and vegetables by using pollen grains as SPE sorbent.[28] Herein, we expand this natural sorbent to the extraction of TRA from peanut and other vegetable oils. When nonpolar solvent was used for sampling and washing, TRA in peanut oils was retained on the pollen grains as a result of the hydrogen-bonding interaction, whereas the matrix of peanut oils such as neutral and nonpolar lipids were removed. Parameters that affect the extraction efficiency were investigated and discussed in detail. By coupling with HPLC-UV analysis, a rapid, simple, and convenient method for the determination of TRA in peanut oils was established.

EXPERIMENTAL PROCEDURES

Chemicals and Materials. Pine pollen (*Pinus massoniana Lamb.*) was obtained from Anhui Guzhitang Edible Fungus Co., Ltd. (Anhui, China). Before use, pollen grains were placed in a thimble holder inside a Soxhlet extractor and then refluxed in methanol for 24 h to remove pigments and fats. The resultant pollen grains were dried under reduced pressure at 60 °C for 12 h.

Methanol, ethanol, acetonitrile, acetone, *n*-hexane, and 2-propanol were purchased from Sinopharm Chemical Reagent (Shanghai, China). 2-Propanol (HPLC grade) and acetonitrile (HPLC grade) were obtained from Tedia Company Inc. (Fairfield, OH, U.S.A.). Purified water was obtained using a Millipore Milli-Q apparatus (Bedford, MA, U.S.A.).

trans-Resveratrol (TRA, 99%) was purchased from Aladdin (Shanghai, China). TRA stock solution was prepared in 2-propanol (HPLC grade) at a concentration of 50 $\mu g \cdot mL^{-1}$ and stored at −20 °C in darkness. With the stock solution, the sample solution was spiked to the desired concentration for the following experiments.

Sample Preparation. Oil samples were prepared by spiking TRA at a known concentration (25 $ng \cdot g^{-1}$) to study the SPE performance under different conditions.

Various kinds of peanut oils were purchased from local markets in Wuhan (China) and stored at room temperature. One refined soybean oil sample which was detected to be free of TRA was used as blank matrix for calibration and validation purposes. Oil sample (2.0 g) was directly spiked with TRA. After mixing uniformly, the sample was diluted to 10 mL with *n*-hexane.

Extraction Procedure. SPE was performed on a Supelco 12-port model SPE Vacuum Manifold (Bellefonte, PA, U.S.A.).

Oil (2.00 ± 0.01 g) was accurately weighed into a 10 mL volumetric flask. It was diluted to the required volume with *n*-hexane and shaken for 1 min. Then, 2 mL of the sample solution was loaded onto a 300 mg pollen grain SPE cartridge (sorbent materials were packed into a 3 mL polypropylene syringe and retained by two polyethylene frits), which was sequentially preconditioned with 3 mL of acetone and 2 mL of *n*-hexane for activation (in Figure 1). After the cartridge was washed with 3 mL of *n*-hexane/2-propanol (80/20, v/v), 1.5 mL of ethanol was used for elution, and the eluate was collected into a centrifuge tube. The collected fraction was evaporated to dryness under a mild nitrogen stream at 35 °C. The residue was dissolved in 200 μL of 2-propanol, and 10 μL of the solution was injected into the HPLC system for analysis.

Analytical Conditions. The HPLC apparatus (Shimadzu, Kyoto, Japan) used in this study consisted of binary LC-20AT pumps, a DGU-20A3 degasser, a SPD-20A ultraviolet detector, a SIL-20A autosampler, and a CTO-20AC column oven. The chromatographic data were acquired by Shimadzu LC Solution (Kyoto, Japan).

The HPLC separation was accomplished on a Hisep C18-T column (150 mm × 4.6 mm i.d., 5 μm), which was obtained from Weltech Co., Ltd. (Wuhan, China). The column temperature was set at 40 °C and the injection volume was 10 μL. A mixture of acetonitrile/0.2% acetic acid in water (30/70, v/v) was used as mobile phase at a flow rate of 1 $mL \cdot min^{-1}$ in isocratic mode. The detection wavelength was set at 306 nm, and the analysis was completed within 15 min.

RESULTS AND DISCUSSION

Optimization of SPE Conditions. Several parameters that might affect the extraction efficiency of SPE were investigated, including sorbent amount, washing volume, and the type and volume of desorption solvent. The oily solution spiked with TRA at the concentration of 5 $ng \cdot mL^{-1}$ was used to study the SPE performance under different conditions, and a total of three replicates were performed in all optimization experiment to obtain a mean value. The extraction efficiency was calculated as the ratio of the peak area obtained in redissolved solution (2-propanol) to the standard solution (2-propanol) spiked with TRA at the concentration of 50 $ng \cdot mL^{-1}$.

Effect of Sorbent Amount. The amount of sorbent is an important factor influencing the extraction efficiency in SPE. Therefore, the cartridges packed with different pollen amounts from 100 to 500 mg were evaluated. The extraction efficiency increased as the amount of sorbents increased from 100 to 300 mg, and then reached a plateau as the sorbent amount further

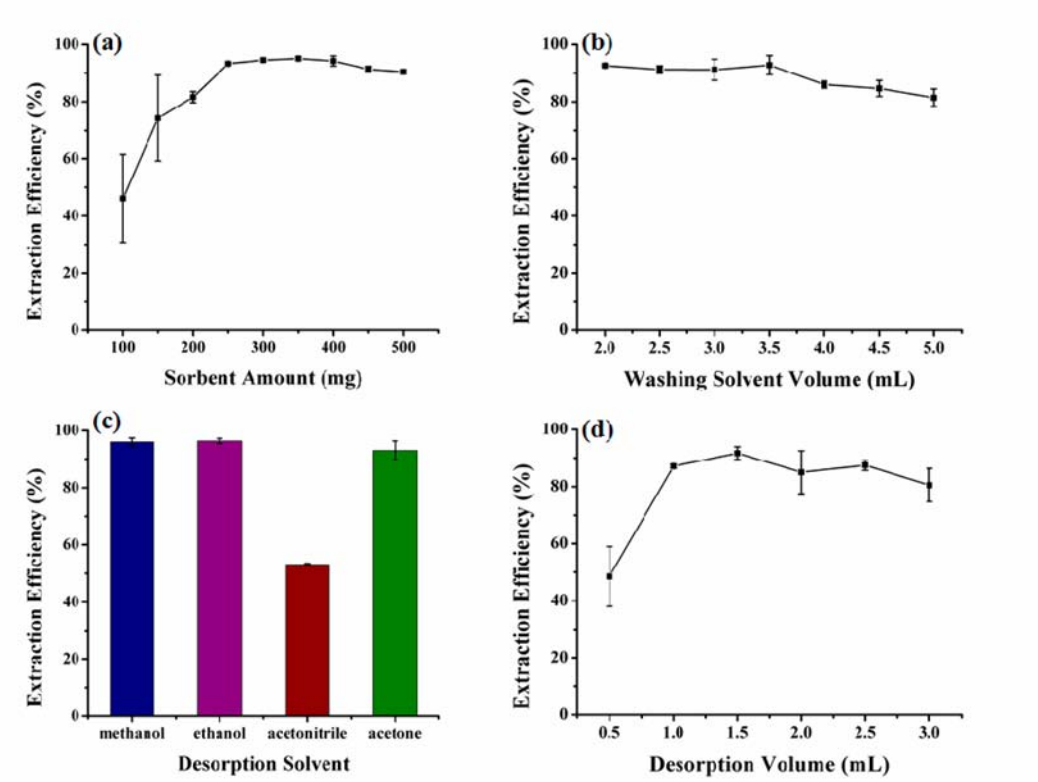

Figure 2. Influence of several parameters on the extraction efficiency: (a) sorbent amount, (b) washing solvent volume, (c) desorption solvent, and (d) desorption volume.

increased (Figure 2a). Consequently, the cartridge of 300 mg was employed in the subsequent experiment.

Effect of Washing Volume. The removal of lipid which was adsorbed on pollen grain SPE cartridge is essential not only to minimize its maintenance in the chromatographic system but also to obtain low detection limits. In this work, *n*-hexane/2-propanol (80/20, v/v) was used as washing solution, and its volume on TRA extraction efficiency was investigated. The result showed that the extraction efficiency of TRA decreased when the volume was higher than 3.5 mL (Figure 2b). Therefore, 3 mL of washing solvent was adopted to avoid significant loss of TRA in the washing step.

Effect of Desorption Solvent. Four different kinds of polar solvents (methanol, ethanol, acetonitrile, and acetone) were investigated as desorption solvent. The adsorption of TRA onto pollen grains behaved as typical normal phase chromatography, and the extraction efficiency increased when more polar solvents were used. The hydroxyl-rich solvents (methanol and ethanol) showed higher extraction efficiency (Figure 2c), indicating that TRA was retained based on the hydrogen bonding interactions. Ethanol was selected as eluent for further experiments due to its low-toxin content.

Effect of Desorption Volume. Desorption volumes ranging from 0.5 to 3.0 mL were investigated. The results showed that extraction efficiency for TRA reached a plateau with 1.0 mL of ethanol (Figure 2d), viz., 1.0 mL of desorption solvent was enough to elute TRA. To ensure complete desorption of TRA, 1.5 mL of ethanol was employed in the following experiment.

Reusability of Pollen SPE Cartridge. The reusability of pollen grain cartridge was evaluated by repeating the extraction procedure with the same SPE cartridge. The results showed that pine pollen grains were highly stable and reusable under the analysis conditions, with RSD of TRA recovery less than 5.0% in 10 cycles of repeated experiments (Table S1), which further demonstrated the known robust nature of the sporopollenin materials. The ability to regenerate and reuse pollen grains using common organic solvents to extract TRA from peanut oils is of value because it will reduce the overall cost and confirm its environmentally friendly merit.

Comparison with Other NP-SPE Sorbents. In order to compare the extraction efficiency of TRA by this novel NP-SPE sorbent with some traditional NP-SPE sorbents, 300 mg of silica gel (~50 μm) or aluminum oxide (neutral, ~100 μm) was loaded in the cartridges separately. Then, three different NP-SPE sorbents were compared following the same extraction protocol as in Figure 1. Each sorbent was performed in triplicate and the recoveries as well as RSD values were recorded in Table 1. When comparing sorbents purification properties, the sampling and washing effluent were collected together in a 10 mL centrifuge tube and then evaporated under a mild nitrogen stream at 35 °C to get rid of the organic solvent. By weighing the residues, we can conclude that 90% of oil matrix components were eluted out by these sorbents, which

Table 1. Comparison of Purification and Extraction Efficiencies among Different NP-SPE Sorbents[a]

sorbent	pollen grains	aluminum oxide	silica gel	silica gel	silica gel	silica gel
amount (mg)	300	300	300	400	500	600
oil removal (g)	0.34	0.32	0.36	/	/	/
recovery%	103.2	0	4.2	5.3	5.8	7.4
RSD%	7.2	/	6.9	4.9	2.5	4.7

[a]The total oil sampling amount was 0.40 g.

DOI: 10.1021/jf505938w
J. Agric. Food Chem. 2015, 63, 4771−4776

demonstrated that pollen grains have the similar cleanup efficiency for the samples in high-fat matrix like silica gel or aluminum oxide. When comparing retention properties of TRA on sorbents, eluate from these three sorbents was evaporated to dryness under a nitrogen stream and redissolved for HPLC analysis. The result showed that aluminum oxide has no retention for TRA, whereas the retention on silica gel was weak. The extraction efficiency did not increase significantly as the amount of silica gel sorbents increased from 300 to 600 mg, which may be ascribed to the fact that silica gel sorbents lack aromatic groups possessed by pollen grains.[28] This result further proved that the selective extraction of TRA from peanut oils by pollen grains is based on the hydrogen-bond and $\pi-\pi$ interaction.

Matrix Effect of Pollen SPE. The matrix effect of the proposed method was evaluated by comparing the assay result obtained with or without oil matrix. As shown in Figure 3b–d,

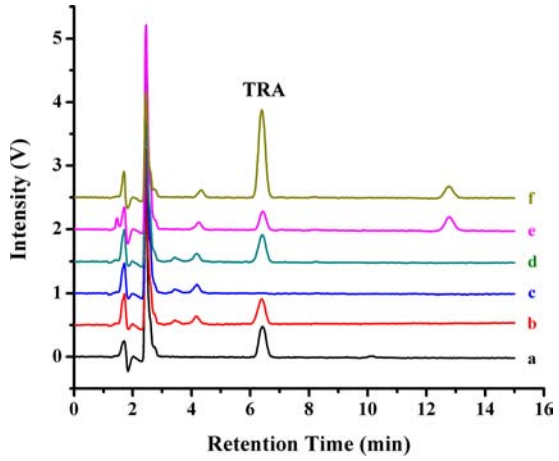

Figure 3. HPLC chromatogram of the following: (a) the standard solution (2-propanol) spiked with TRA at the concentration of 50 ng·mL^{-1}; (b) a *n*-hexane sample spiked with TRA at the concentration of 5 ng·mL^{-1}; (c) a blank soybean oil sample; (d) a blank soybean oil solution spiked with TRA at the concentration of 5 ng·mL^{-1}; (e) peanut oil sample 6; (f) peanut oil solution 6 spiked with TRA at the concentration of 10 ng·mL^{-1}.

the chromatograms of the spiked *n*-hexane sample (5 ng·mL^{-1}) and the oily solution spiked with TRA at the concentration of 5 ng·mL^{-1} were practically the same, which demonstrated that the assay result is not influenced by the presence of oil matrix. Besides, we compared three recoveries of TRA, with one in the standard solution (2-propanol, 50 ng·mL^{-1}) and the other two in blank soybean oil sample spiked before (5 ng·mL^{-1}) and after (50 ng·mL^{-1}) pollen SPE extraction. Those three recoveries were nearly the same (RSD < 4.9%, Table S2), which indicated that the oil matrix can be effectively removed by pollen SPE extraction.

Method Validation. Experiments with regard to linearity, limit of detection (LOD), limit of quantification (LOQ), and reproducibility were performed to validate the proposed method under optimized conditions. The linearity was studied using a blank soybean oil sample spiked with TRA at 10 different concentrations ranging from 10 to 2500 ng·g^{-1} (10, 15, 20, 25, 50, 100, 250, 500, 1000, and 2500 ng·g^{-1}). In the construction of the calibration curve, triplicate measurements of each concentration level of the calibration samples were performed, and the calibration curve was obtained by plotting mean peak area versus concentrations (Figure S1). The linear range, regression data, LOD, and LOQ from the validation are listed in Table 2 (raw data in Table S3). A good linearity was obtained with r^2 up to 0.9999 for the target TRA. A blank soybean oil sample spiked with TRA at 10 ng·g^{-1} gave a peak response with signal-to-noise of ~11.2 (triplicate experiments with the SD of 1.0). The LOD for TRA, calculated at a signal-to-noise of 3, was ~2.7 ng·g^{-1} and the LOQ, calculated at a signal-to-noise of 10, was ~8.9 ng·g^{-1}.

The reproducibility of the method was investigated by determining the intra- and interday precisions. The intra- and interday relative standard deviations (RSDs) were calculated with blank soybean oil spiked with TRA at three different concentrations (25, 100, and 250 ng·g^{-1}). Six parallel extractions of a sample solution over 1 day provided the intraday RSDs, and interday RSDs were determined by extracting sample solutions that had been independently prepared for three continuous days. The RSD and recovery values were recorded in Table 3 (raw data in Table S4). The results showed that the finally adopted experimental protocol for the analysis of TRA is characterized by significantly high recovery values (min 93.7%) as well as low RSD values (max 5.2%). This pollen SPE method shows high accuracy (as recovery%) and well precision (as RSD%) of detection.

Analysis of Real Samples. Ten peanut oil samples with different brands and another five kinds of vegetable oils were analyzed to demonstrate the applicability of the method. All samples obtained were analyzed in three replicates, and the detailed results are outlined in Table 4. The recoveries were obtained by comparing the amount of TRA calculated from the calibration curve with the corresponding spiking amount. As shown in Table 4, the recoveries of the target TRA from various real samples were in the range from 70.2 to 98.4% with RSDs less than 8.7%, indicating the good applicability of the present method in different kinds of vegetable oils. In addition, six peanut oil samples were found to contain a certain amount of TRA with the concentration ranging from 10.9 to 16.9 ng·g^{-1}. Therefore, TRA could be potential biomarker constituents for

quality assessment of peanut oils adulterated with other vegetable oils. Figure 3e showed the HPLC chromatogram of TRA detected in peanut oil sample 6. The results confirmed the feasibility of the proposed method for determination of TRA in real samples.

A comparative study of our developed pollen grains NP-SPE method for TRA analysis in peanut oils to previously reported methods was performed, and the results are presented in Table 5. Comparing to those two sorbents, these natural pollen sorbents obtained from a renewable source avoid cumbersome material synthesis steps, which fully meet the needs of green analytical chemistry. Besides, this pollen SPE cartridge can be reused for at least 10 times, which will reduce the overall cost for routine analysis. The results demonstrate that using pollen grains as constituent of SPE sorbents directly is simple, effective, eco-friendly, and inexpensive. Although the LOD in this developed methodology is not as good as other methods using LC-MS/MS for determination, the HPLC-UV detection possesses several merits like reduced cost, lower power consumption, and easier maintainability. For the next work, we will try to improve the detection sensitivity, and the related study will be conducted in our following experiment.

In conclusion, using pollen grains as a novel normal-phase solid-phase extraction sorbent, coupled with HPLC-UV detection, was demonstrated to be an environmentally friendly and effective method for the determination of TRA in peanut oils. Oil samples after pretreatment can be directly injected for HPLC analysis. The results show that these natural materials have the potential to be applied for the separation and purification of other polar analytes due to its good adsorption properties and low cost.

Supporting Information

ABSTRACT: An easy extraction method that permits the use of a liquid chromatography–isotopic ratio mass spectrometry (LC–IRMS) system to evaluate $\delta^{13}C$ of vanillin in chocolate products and industrial flavorings is presented. The method applies the determination of stable isotopes of carbon to discriminate between natural vanillin from vanilla beans and vanillin from other sources (mixtures from beans, synthesis, or biotechnology). A series of 13 chocolate bars and chocolate snack foods available on the Italian market and 8 vanilla flavorings derived from industrial quality control processes were analyzed. Only 30% of products considered in this work that declared "vanilla" on the label showed data that permitted the declaration "vanilla" according to European Union (EU) Regulation 1334/2008. All samples not citing "vanilla" or "natural flavoring" on the label gave the correct declaration. The extraction method is presented with data useful for statistical evaluation.

KEYWORDS: *LC–IRMS, $\delta^{13}C$, vanillin, chocolate, snack foods*

INTRODUCTION

Numerous studies have been devoted to the authentication of natural flavoring extracts derived from the tropical orchid of the genus *Vanilla*, of which *Vanilla planifolia* and *Vanilla tahitensis* are the most widely used.[1] The increased demand for natural vanilla extracts[2] has encouraged research for new sources of vanillin (4-hydroxy-3-methoxybenzaldehyde), the major flavoring component of vanilla.[1,3] Commercial vanillin available on the market can be derived from chemically synthesized processes, starting from eugenol, guaiacol, or lignin. Another commercial vanillin is the so-called biovanillin, produced through a biotechnological pathway and classified as a "natural flavor" because of the utilization of natural precursors or raw materials.[4] The biovanillin production by microbial fermentation or enzymatic reaction starts from naturally derived precursors, such as ferulic acid, isoeugenol, or curcumin.[1,3,5,6] Agro-wastes are potential sources for biovanillin production, including cereal bran, sugar beet pulp, rice bran oil, and palm oil biomass.[5]

To discriminate between vanillin from authentic vanilla extracts and vanillin derived from extracts adulterated with vanillin from different sources, investigations by chromatographic methods have been proposed and, recently, the Direction Générale de la Concurrence, de la Consommation et de la Répression des Fraudes (DGCCRF) revised the ranges for the vanilla aromatic ratios.[7]

Site-specific natural isotope fractionation combined with nuclear magnetic resonance (SNIF–NMR) measurements has produced data that define the site-specific abundance of deuterium or carbon-13.[8,9] Several reports have shown that ^{2}H NMR spectroscopy allows for the determination of the synthetic or natural origin of vanillin as well as providing information about the starting materials.[6,8−12]

The determination of stable isotope ratio mass spectrometry of carbon is presently a useful method for discrimination between natural vanillin from vanilla beans and synthetic vanillin or that produced from biotechnological methods. Indeed, vanillin from vanilla beans is naturally enriched in ^{13}C and can be distinguished from vanillin produced from other sources. Various authors have therefore suggested the application of the isotope ratio measurements of $^{13}C/^{12}C$, expressed as $\delta^{13}C$,[6,9,13−15] to demonstrate the origin to the various vanillins.

The European Union (EU) Regulation 1334/2008[16] permits the citation of the flavoring source (in our case "vanilla") only if the flavoring component has been obtained exclusively or by at least 95% (w/w) from the referenced source material. The citation in the label "natural flavoring", following the same EU Regulation,[16] may only be used if the flavoring component is derived from a different source material.

$\delta^{13}C$ can be determined by elemental analysis–isotopic ratio mass spectrometry (EA–IRMS) or gas chromatography–isotopic ratio mass spectrometry (GC–IRMS).

Reference values for $\delta^{13}C$ ratios concerning vanillin from various origins can be found in several publications.[9,14,15,17] According to the range reported in the literature, values of $\delta^{13}C$ greater than −21.5[18] or −21.8[17] for vanillin are used as a criterion of authenticity (vanillin from vanilla beans).

Application of a precautionary judgment and consideration of the possible implications of the curing stage,[18] the lower limit of −22.6 may be adopted.

Data referring to vanillin of different origins, i.e., from isoeugenol, lignin, guaiacol, and ferulic acid, result in ratio values lower than −26.8.[6,9,14]

Herein, we report the data produced by analysis of $\delta^{13}C$ for vanillin in 13 chocolate bars and chocolate snack foods available on the Italian market. Applying the suggested extraction method and the LC−IRMS analytical technique made it possible to confirm the lawful use of the term "vanilla" in these labels. Moreover, we report the results from 8 vanilla flavorings from the European flavoring market used for quality control in three food industries. We also included extracts from two sources of authentic vanilla beans. The label declarations of the considered samples are reported.

MATERIALS AND METHODS

Samples. Samples of snack foods and chocolate were directly purchased on the Italian market and represent well-known consumer products. The industrial vanilla flavorings were obtained from industrial suppliers. Two samples of genuine vanilla beans (source Madagascar) were obtained from a direct trader, and the corresponding extracts were produced by a percolation method (50:50 ethanol/water solution) under vacuum for 3 days.

Chemicals. Hexane, ethanol, water, sodium persulfate, and orthophosphoric acid (Sigma-Aldrich, Italy) were analytical-reagent-grade and used without any purification.

Helium (5.6 grade) as the carrier gas and carbon dioxide (4.5 grade) as the reference gas were produced by Messer (Turin, Italy); carbon dioxide was calibrated and controlled using calibrated materials. Solutions and dilutions were prepared with ultrapure Milli-Q water (Milan, Italy). Synthetic vanillin (99%) was a Sigma-Aldrich product.

Sample Preparation. The chocolate bar or chocolate snack food matrix (Table 1) was finely crushed after freezing (T = −20 °C). A portion (50−100 g) of matrix was extracted for 6 h with a Soxhlet device using hexane as the solvent (150−300 mL).

About 10 mL of industrial flavoring samples (samples 14−21 in Table 2) and two vanilla bean extracts produced in our laboratory (samples 22 and 23 in Table 2) were extracted 3 times for 5 min with hexane (30 mL each time) in a 100 mL graduated cylinder. The samples were also subjected to ultrasonic extraction (USE) each time for 15 min (T = 25 °C) at a fixed frequency of 35 kHz. The three hexane fractions are collected and combined.

The hexane extracts were concentrated by rotary evaporation under vacuum to a final volume of 90−100 mL and treated in a separatory funnel 3 times with 5 mL of water/ethanol (30:70), shaking for 5 min. The three water/ethanol phases were collected and pooled. The aqueous−alcoholic phase was concentrated by rotary evaporation to a final volume of 0.1−0.2 mL. For a better control of the concentration and to recover the residue, the round-bottom flask can be fitted in the bottom with a graduated conical tube. Dependent upon the vanillin concentration, the aqueous residue may be appropriately diluted with water and filtered (0.45 μm) before the IRMS analysis.

Instrumentation. *LC−IRMS.* A Delta V Advantage (Thermo Fisher, Bremen, Germany) isotope ratio mass spectrometer was used coupled to a high-performance liquid chromatography (HPLC) system and the LC IsoLink interface (Thermo Fisher, Bremen, Germany).

A P 1000 Thermo Fisher HPLC (Bremen, Germany) was used in conjunction with a Surveyor MS pump, a HTC PAL autosampler (CTC, Zwingen, Switzerland), and a column oven (Mistral, Spark Holland B.V., Emmen, Netherlands). The oxidation reagent consisted of sodium persulfate in water (1.5 M, 30 μL min^{-1}), and the acid reagent was phosphoric acid (1.5 M, 50 μL min^{-1}) pumped by two pump heads. The mixture of these reagents, added by a T piece to the mobile phase, flowed through a capillary oxidation reactor at 100 °C, as described by Krummen et al.[19] for the LC IsoLink. After the oxidation reactor, the mobile phase was cooled and the individual CO_2 peaks were transferred to a counter flow of helium; thereby, the liquid phase was completely degassed. The fluxing helium introduced CO_2 to the mass spectrometer.

For chromatographic separation, a Phenomenex HPX-87C Bio-Rad (Italy) column (300 × 7.8 mm) was used, with ultrapure water as the mobile phase; the flow rate was 0.3 mL min^{-1}, and the injection volume was 15 μL. The column temperature was 50 °C. Water was used to prepare samples and standard solutions for LC−IRMS analysis; all samples were filtered through a polypropylene membrane filter with 0.45 μm porosity and 25 mm diameter. The Isodat 3.0 software (Thermo Scientific Bremen, Germany) was the controlling system. The analysis was repeated twice for each sample, and the average values of these two measurements are listed in Tables 1 and 2.

Table 1. LC−IRMS Data (Averages of Two Measurements) for $\delta^{13}C$ (‰) of Vanillin in a Series of Chocolate Bars and Chocolate Snack Food Samples Available on the Italian Market

	sample	label	$\delta^{13}C$ (‰)	judgment[a]
1	chocolate snack	natural vanilla extract	−23.7	not correct
2	chocolate snack	vanillin	−30.3	correct
3	chocolate snack	vanilla natural flavoring	−22.5	correct
4	chocolate snack	flavoring	−27.5	correct

DOI: 10.1021/acs.jafc.5b02136
J. Agric. Food Chem. 2015, 63, 4777−4781

The $\delta^{13}C$ values (‰) were calibrated to Vienna Pee Dee Belemnite (VPDB) by three pulses of CO_2 reference gas, calibrated against the international standard, and performed at the beginning of the elution run.

EA–IRMS. $\delta^{13}C$ values of synthetic vanillin were measured with an Flash 2000 elemental analyzer coupled to a Delta V Advantage via a ConFlo IV interface. The EA worked under 100 mL min^{-1} helium flux and temperatures of 950 °C in the oxidation tube and 850 °C in the reduction tube. The outlet was equipped with a column that physically retained CO_2 at 70 °C; carbon dioxide was released by increasing the temperature to 210 °C. The overall experiment duration was 600 s.

RESULTS AND DISCUSSION

Method Validation. To evaluate the chemical oxidation of eluted compounds and CO_2 extraction from the IRMS system, the linearity was verified from 0.50 to 20.00 mg L^{-1} synthetic vanillin (99%), analyzing each solution in triplicate. The corresponding area averages by IRMS were reported versus the vanillin concentration in Figure 1, and the correlation indicated the complete oxidation of the eluted molecule to CO_2; also, we demonstrated the complete recovery of the gas.

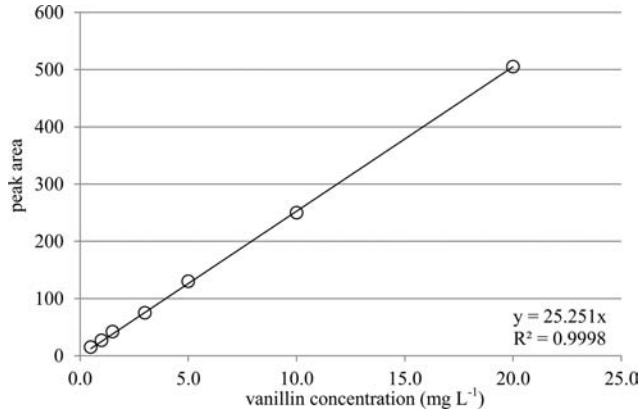

Figure 1. Values of CO_2 peak area LC–IRMS produced by vanillin synthetic solutions at concentrations ranging from 0.5 to 20.0 mg L^{-1}.

The agreement between $\delta^{13}C$ values produced by a sample of synthetic vanillin, determined from the solid by EA–IRMS, and expressed as a mean of five measurements (target value) and the $\delta^{13}C$ values determined by the LC–IRMS method on the same vanillin specimen at different concentration values were also evaluated. The data were distributed in the range ±0.4‰ for concentration values from 0.05 to 20 mg L^{-1} (Figure 2). Therefore, undetectable isotopic fractionation was observable. Reproducibility was checked adopting the Nordic Committee on Food Analysis (NMKL) method[20] and with consideration of the relative repeatability standard deviation (RSDr = 0.011) derived from all data in duplicate obtained for all samples listed in Tables 1 and 2 (see Table S1 of the Supporting Information).

The samples considered in the present study, following the suggested extraction method, had all been previously analyzed by HPLC–diode array detection (DAD) to evaluate the possible influence of other compounds; we were able to demonstrate that the vanillin peak and, consequently, $\delta^{13}C$ values of vanillin in the analyzed samples were not influenced by the nature of the sample matrix.

Furthermore, in all samples analyzed, the *p*-hydroxybenzaldehyde (pHB) peak was at least 25–30 times lower than the vanillin peak because of the partition coefficient of pHB under

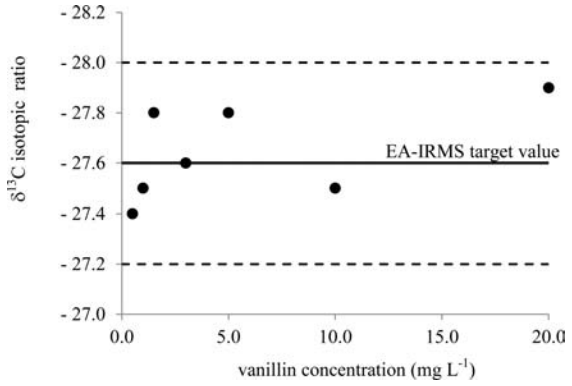

Figure 2. $\delta^{13}C$ values of a sample of synthetic vanillin at concentrations from 0.05 to 20.0 mg L^{-1} produced by LC–IRMS compared to the EA–IRMS mean target value measured on the solid vanillin.

the extraction conditions. Therefore, any influence on the $\delta^{13}C$ value by natural pHB ($\delta^{13}C$ from −15.2 to −17.0) would be irrelevant on the decision concerning the vanillin origin, even if traces of pHB were eluted with vanillin peak. The same observation is even more valid for all other compounds present in the considered matrices. Moreover, under the chromatographic conditions adopted for LC–IRMS, the retention time of pHB was sufficiently differentiated from that of vanillin. In fact, in the LC–IRMS chromatogram, pHB can be coeluted only with caffeine, when this last compound is present. Moreover, the caffeine peak is well-resolved in LC–IRMS from the vanillin peak. Thus, the extraction method adopted in this work allowed us to selectively avoid the influence of other volatile compounds present in the considered matrices. Figure 3 shows two examples of LC–IRMS traces of the vanillin peak that illustrate the good resolution of vanillin from caffeine when the latter substance is present.

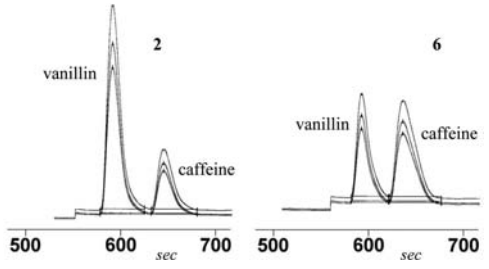

Figure 3. Examples of resolution between vanillin and caffeine peaks in LC–IRMS traces for two samples, where their ratios were different, adopting the suggested operative conditions (samples 2 and 6 in Table 1).

Sample Measurements. The results of the stable isotope ratio analysis of the samples (Tables 1 and 2) identified some discrepancies with the product declaration on the label of the food or flavoring agent.

Of the chocolate bars and chocolate snack foods in Table 1, the samples 1, 3, 7, 8, 9, 10, 11, and 12 were declared as "vanilla" on the label. Only samples 3 and 11 gave results that agreed with this declaration.[16]

Of the other samples 2, 4, 5, 6, and 13, only 2, 4, and 6 reported a lawful declaration[16] because no reference was made to the terms "vanilla" or "natural flavoring". The samples 5 and 13 reported the declaration "natural flavoring", but the data

DOI: 10.1021/acs.jafc.5b02136
J. Agric. Food Chem. 2015, 63, 4777–4781

(−32.5 and −26.9, respectively) did not permit the confirmation that a natural source of vanillin was used. These values may be justified if the flavoring agent was derived from a mixture of biovanillin from ferulic acid and vanillin from vanilla beans. Such a designation would be valid if biovanillin is considered as "natural".

Data reported in Table 2 showed that two samples (16 and 19) of five industrial flavoring agents declared as "vanilla" (14, 16, 18, 19, and 21) were really derived from vanilla beans. Samples 14, 18, and 21 produced data lower than −22.6,[20] which is the lower limit compatible with vanillin from vanilla beans; therefore, for these three samples, the label declaration was not lawful.

The other three samples, 15, 17, and 20, declared "natural flavoring" and showed very low values. Only sample 15 was clearly compatible with biovanillin from ferulic acid,[9] while the other two data values permitted the declaration "natural flavoring" only if derived from a mixture of biovanillin from ferulic acid and vanillin from vanilla beans.

The same analytical method was applied for the two samples produced by laboratory extraction from two samples of genuine vanilla beans (23 and 24) and the values produced results that were strictly included in the range cited by the literature for vanillin from vanilla beans.

From the results of Tables 1 and 2, we deduced that of the 13 samples citing the term "vanilla" on the label, only four of them (3, 11, 16, and 19) were in compliance with the EU Regulation 1334/2008.[16] Three samples not citing the terms "vanilla" or "natural" (2, 4, and 6) showed the correct label.

Accepting that the biovanillin from ferulic acid, which produces a $\delta^{13}C$ value of absolute −36.0, may actually be considered as a "natural flavoring", we were unable to assign a definite judgment for the four samples 5, 13, 17, and 20, which cited the term "natural flavoring", on their labels. Indeed, a wide range of data (from −22.7 to −36.1) corresponded to the various putative mixtures of vanillin from vanilla beans, synthetic vanillin, and biovanillin.

In conclusion, for the food matrices examined in the present work, the suggested method was able to distinguish between flavorings derived from authentic vanilla beans and those flavorings from other sources. Data reported in Tables 1 and 2 permitted us to conclude that only ca. 30% of the samples citing the term "vanilla" were in accordance with the EU Regulation 1334/2008[16] and all of the samples not citing the terms "vanilla" or "natural" agreed with the same regulation.

Only for sample 15, which showed a $\delta^{13}C$ value of −36.0 characteristic of biovanillin from ferulic acid, was it possible to confirm the classification as "natural flavoring".

Supporting Information

ABSTRACT: After slaughter, muscle cells undergo biochemical and physicochemical changes that may affect their autofluorescence characteristics. The autofluorescent response of different rat extensor digitorum longus (EDL) and soleus muscle fiber types was investigated by deep ultraviolet (UV) synchrotron microspectroscopy immediately after animal sacrifice and after 24 h of storage in a moist chamber at 20 °C. The glycogen content decreased from 23 to 18 μmol/g of fresh muscle in 24 h postmortem. Following a 275 nm excitation wavelength, the spectral muscle fiber autofluorescence response showed discrimination depending upon postmortem time (t_0 versus $t_{24\,h}$) on both muscles at 346 and 302 nm and, to a lesser extent, at 408 and 325 nm. Taken individually, all fiber types were discriminated but with variable accuracy, with type IIA showing better separation of $t_0/t_{24\,h}$ than other fiber types. These results suggest the usefulness of the autofluorescent response of muscle cells for rapid meat-aging characterization.

KEYWORDS: *rat muscle fibers, postmortem, meat, UV spectroscopy, histology, fiber types*

INTRODUCTION

Meat comes from skeletal muscle, which generally contains different proportions of the four pure myofiber types: type I, type IIA, type IIX, and type IIB. These contain the myosin heavy-chain isoforms (MyHC) I, IIa, IIx, and IIb, respectively.[1,2] Hybrid fibers intermediate between two pure types and containing two different myosin isoforms (I−IIA, IIA−IIX, and IIX−IIB) are also found. The muscle fibers are characterized by their metabolism (oxidative or glycolytic) and their contraction speed (slow or fast). Type I fibers are slow-twitch fibers, and all type II fibers are fast-twitch fibers. Type I and IIA fibers have an oxidative metabolism, and type IIX and IIB fibers have a glycolytic metabolism.[1,2]

After slaughter of farm animals, muscle undergoes significant metabolic, physical, structural, and biochemical changes that determine the quality of meat and meat products.[3,4] After bleeding, the muscle is deprived of oxygen and nutrients. Muscle cells will try to survive by degrading their glycogen stock through anaerobic glycolysis. Lactate accumulation in cells is accompanied by a drop in pH. When the energy reserves are depleted, muscle pH stabilizes at values generally between 5.7 and 6.2, termed the ultimate pH. The kinetics of change in pH is species-dependent, and the time to reach the ultimate pH can range from 2 h in poultry to 24 h in cattle. After this first phase of postmortem changes, additional biochemical changes and significant ultrastructural alterations are observed, related to the improvement of meat quality, especially meat tenderness.[5,6] The speed of these postmortem changes (also called meat maturation) is dependent upon the species and mostly the metabolic and contractile types of the muscles considered. Degradation of the myofibrillar structure is faster in white fibers than in red fibers.[5,7]

Postmortem changes can be assessed by mechanical measurements and biochemical and/or ultrastructural analyses, but these methods are usually destructive and time-consuming. Some authors have exploited the variation in the physical properties of muscles to characterize differences in composition by fluorescence spectroscopy.[8−10] This highly sensitive method detects fluorophores naturally present in muscle whose properties are very sensitive to changes in their environment. Collagen, tryptophan, tyrosine, or NADH are among the most abundant autofluorescent molecules in muscle.[8] Several years ago, the autofluorescence of the tryptophan signal following meat sample excitation at 290 nm allowed for a correct discrimination of non-aged from aged meat samples.[11] However, the analysis was performed on a macroscopic scale and did not address the metabolic and contractile properties of muscles. The analysis at the cell or even the ultrastructural scale is more difficult because of the low availability fluorescence microscopes that allow for an excitation in the deep ultraviolet (UV), which is relevant for studying biomacromolecules that have a strong absorption in this energy range. Indeed, although spectrometers can often go down to 250 nm, microscopes are usually very limited in this range with either 350 nm cutoff or access to only a limited number of excitation wavelengths.

However, the combination of a microscope with a UV fluorescence spectrometer coupled to synchrotron radiation allows for an excitation range of 200−600 nm that has been used to characterize animal tissues at the ultrastructural level.[12−15]

Thanks to the availability of these tools, it becomes theoretically possible to detect small changes of the tissue and cells and, therefore, characterize the degree of postmortem change in muscle cells. Our goal was to investigate the autofluorescence changes of individual muscle fibers from rat skeletal muscles stored under anoxia during 24 h regarding their metabolism and ultrastructure changes.

MATERIALS AND METHODS

Animals and Samples. The rat model was chosen because it allows for a better control of rearing and slaughter conditions; it is easy to extract entire muscles and obtain early samples in the laboratory by controlling the best kinetic sampling and temperature conditions.

A total of 24 male Wistar rats aged 5 months and weighing about 500 g were bought from Janvier (Saint-Berthevin, France) and housed at 22 °C under 12 h dark/12 h light cycles with water and food *ad libitum* at an INRA animal facility (Installation Expérimentale de Nutrition, Unité de Nutrition Humaine, INRA Theix, Agreement C 63345.14). Rats were anaesthetized by isoflurane gas and decapitated with a guillotine according to the recommendation of our Regional Ethics Committee (C2E2A 2) and French national legislation (JO 87-848). As no act of pain was performed, because the sampling took place after the death of animals, the experimental project was outside the scope of the European Union Directive 2010/63 and, therefore, did not require ethics review. However, the experimental project was followed by the animal welfare structure integrated in the INRA animal facility installation according to French law (Article JO R. 214-103).

Immediately after death, the lower limbs were severed and dissected under sterile conditions. Extensor digitorum longus (EDL), tibialis anterior, gastrocnemius, and soleus muscles from the right and left hindlegs were extracted from tendon to tendon, avoiding any lesions.

Muscle Postmortem Kinetics. Muscles from three rats were immediately cryofixed post-dissection (10 min after decapitation). For the other 21 rats, muscles were suspended at 20 °C in a sterile moist chamber to prevent drying of the muscle and contamination from microorganisms. Lead ballast was attached at the caudal tendon of each muscle (1.5 g for soleus and EDL and 4.5 g for tibialis and gastrocnemius) to preserve the anatomical muscle length (Figure 1).

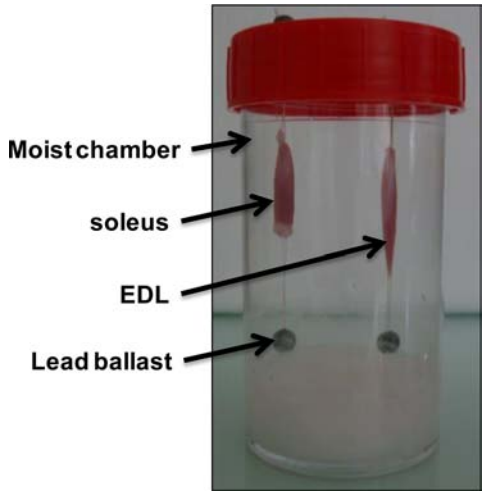

Figure 1. Positioning of the muscles in a moist chamber. Muscles equipped with lead ballast were suspended in a bottle, the bottom of which was lined with a moistened paper towel. The flask was placed in an oven at a temperature maintained at 20 °C.

After 30 min, 1 h, 2 h, 4 h, 8 h, 12 h, and 24 h postmortem, muscles of three rats were removed from their moist chambers and prepared for biochemical and imaging analysis.

pH Measurements. Because EDL and soleus muscles are too small, pH measurements were made on tibialis anterior and gastrocnemius muscles localized around EDL and soleus muscles. pH measurements were made according to the study by Fernandez et al.,[16] adapting to the small quantity of muscle available. Briefly, muscles were weighed and ground in 5 mM idoacetate buffer (2.5 mL/g of muscle), and pH was measured in the muscle suspension at room temperature.

Glycogen Determination. The glycogen content was determined on each right EDL and soleus rat muscle at each time postmortem by enzymatic procedures according to Bergmeyer,[17] with slight modifications. About 0.15 g of muscle tissue was homogenized with 1.8 mL of 0.55 M perchloric acid. On two 0.5 mL aliquots, glycogen was hydrolyzed in glucose with amyloglycosidase. Glucose was converted into 6-phosphogluconolactone after hexokinase and G-6-P dehydrogenase action accompanied by NADH H^+ production. NADH, proportional to glucose content, was determined by spectrophotometry at 340 nm and compared to standards to calculate the glucose concentration. Results are expressed in micromoles per gram of fresh tissue.

Histology. *Cryofixation and Histological Sections.* Parts of left EDL and soleus muscles at 0 (t_0) and 24 h ($t_{24\,h}$) postmortem were positioned on a cork plate with embedding medium (Tissue-Tek) and cryofixed by immersion at −160 °C in isopentane cooled with liquid nitrogen (−196 °C). Serial cross-sections of entire muscles (10 μm thick) were cut using a cryostat (Microm, HM 560) and collected on glass slides for histological stains and quartz coverslips for deep UV (DUV) microspectroscopy fluorescence analyses. Sections were stored at −20 °C under vacuum until use. Periodic acid Schiff (PAS) staining was performed for glycogen characterization.[18]

Muscle Fiber Type Determination. Fiber types were identified by highlighting the different MyHC using specific mouse monoclonal antibodies BA-D5, SC-71, and BFF3 (AGRO-BIO France). The different primary MyHC antibodies were visualized by an Alexa Fluor 488 labeled goat anti-mouse IgG secondary antibody (A 11001, Invitrogen). In addition, the extracellular matrix (ECM) protein laminin, surrounding the muscle fiber, was stained using an anti-laminin primary polyclonal antibody (L9393 Sigma) and a cyanine-3-labeled secondary antibody (111-165-008, Jackson). The myofiber response to the different MyHC antibodies identified fiber types I, IIA, IIB, and hybrid IIX−IIB. IIX fiber types corresponded to the remaining unmarked cells. Controls were performed with no primary antibody to validate the results.

Image Acquisitions. Observations and image acquisitions were performed using a light microscope (Olympus BX 61) coupled to a high-resolution digital camera (Olympus DP 71) and the Cell F software. PAS-stained sections were examined, and images were acquired in bright-field mode. Immunohistochemistry images were acquired in fluorescence mode (Alexa Fluor 488, 495/519 nm; cyanine 3, 550/570 nm).

Transmission Electron Microscopy. Analysis was conducted on EDL and soleus muscles at 0 and 24 h postmortem from six rats (three rats per postmortem time). Pieces of EDL and soleus muscles of about 4 × 1 mm were fixed overnight at 4 °C by immersion in 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer at pH 7.2, taking into account muscle fiber direction. Small cubes of about 1 mm^3 were post-fixed in 1% osmium tetroxide in 0.1 M sodium cacodylate buffer for 1 h at room temperature. These cubes were dehydrated through a graded ethanol series and embedded in epoxy resin (TAAB, Eurobio France). Ultrathin longitudinal sections (90 nm) (parallel to the fiber direction) were stained with uranyl acetate and lead citrate and examined with a transmission electron microscope (Hitachi HM 7650) using a 80 kV acceleration voltage at the CICS cellular imaging lab on the Clermont-Ferrand University campus (France). Micrographs were acquired with a Hamamatsu AMT digital camera system coupled with the microscope.

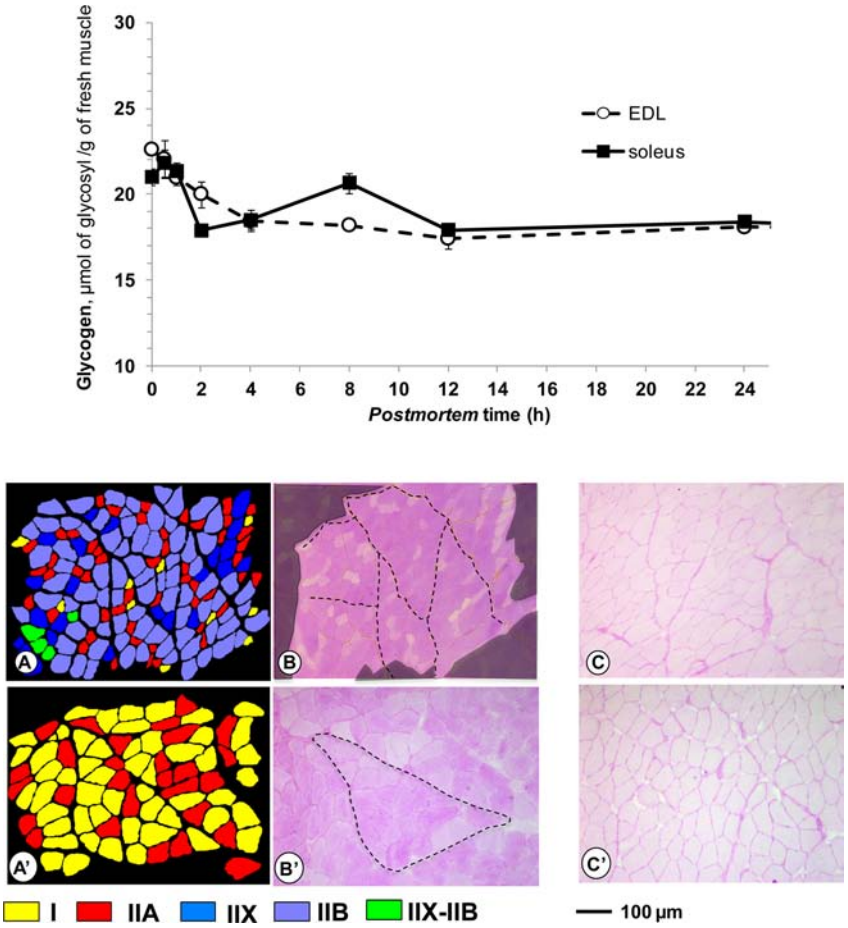

Figure 2. Postmortem evolution of glycogen content in EDL and soleus muscles. The glycogen is degraded in the first hours after slaughter and then stabilizes. Histology revealed the lower glycogen content in oxidative metabolism fibers, particularly in Type IIA fibers. A and A′: Fiber type identification of EDL and soleus muscles, respectively. B and B′: Glycogen staining of EDL and soleus muscle, respectively, 10 min after animal sacrifice. C and C′: Glycogen staining of EDL and soleus muscle, respectively, 24 h after animal sacrifice.

DUV Fluorescence Microspectrocopy. *Spotting of Cell Types on Unstained Muscle Serial Cross-Section.* From two rat soleus and EDL muscles (0 and 24 h postmortem), an unstained serial section was deposited on quartz coverslips, and using fiber-type identification by immunohistofluorescence on other serial sections, 20 soleus muscle fibers (10 type I and 10 type IIA) and 21 EDL muscle fibers (3 type I, 2 type IIA, 5 type IIX, 8 type IIX–IIB, and 3 type IIB) were spotted for fluorescence spectra acquisition by DUV microspectroscopy.

Spectrum Acquisition. Synchrotron DUV microspectroscopy was performed on the DISCO beamline of the SOLEIL synchrotron radiation facility (Saint-Aubin, France).[19,20] DUV monochromatized light was used at 275 nm excitation wavelength to excite tissue sections. The emission spectra were acquired from 290 to 540 nm. For each excited pixel, a fluorescence spectrum was recorded. On each spotted cell, 20 acquisitions were made in the intracellular space.

Spectrum Processing and Statistical Analysis. Autofluorescence spectra were spike- and noise-filtered using an in-house program written in MATLAB, version 7.3 (The MathWorks, Natick, MA). The Unscrambler software (version 9.8, Camo Software AS, Norway) was used to perform a baseline adjustment to zero, apply unit vector normalization that normalizes sample-wise the spectral data to unit vectors, and analyze the processed spectra by principal component analysis (PCA). After analysis, the family label of each spectrum was revealed and the two first of the 10 components tested were plotted. The mean spectrum of each group was also plotted for better referencing of the spectral discriminants. Score plots were used to show similarity maps for comparison of spectra, regardless of sample categories. Loading plots derived from the first principal components (PC1) and second principal components (PC2) were used to reveal and identify characteristic fluorescence peaks.

Numerical variables of fluorescence intensity for wavelengths of interest identified on the PCA loadings were expressed as the mean ± standard error of the mean (SEM). Variance analysis and mean comparisons were performed using one-way variance analysis and the Student–Newman–Keuls test under the XLSTAT software 2010 (Microsoft Office, Redmond, WA).

RESULTS AND DISCUSSION

Postmortem Metabolism Time Course. The level of EDL and soleus muscle glycogen was about 23 μmol/g of fresh muscle at 10 min postmortem and decreased slightly with time for both muscles (Figure 2). The decrease in contrast of PAS staining with time postmortem reflects a decrease in intracellular glycogen, in agreement with our biochemical data and the literature.[3,4] However, soon after animal sacrifice, PAS staining intensity depended upon the fiber type. Glycolytic fibers (IIX and IIB) of the EDL were systematically richer in glycogen than oxidative fibers (I and IIA), fully consistent with the literature on the subject.[3,4] The soleus, which contains only oxidative fibers (I and IIA), also showed a heterogeneous distribution. In this muscle, the IIA fibers contained less glycogen than type I fibers. This result is surprising at first sight because generally IIA fast-twitch fibers have more glycogen reserves than type I slow-twitch fibers to cope with high energy consumption during vigorous exercise. This finding is explained

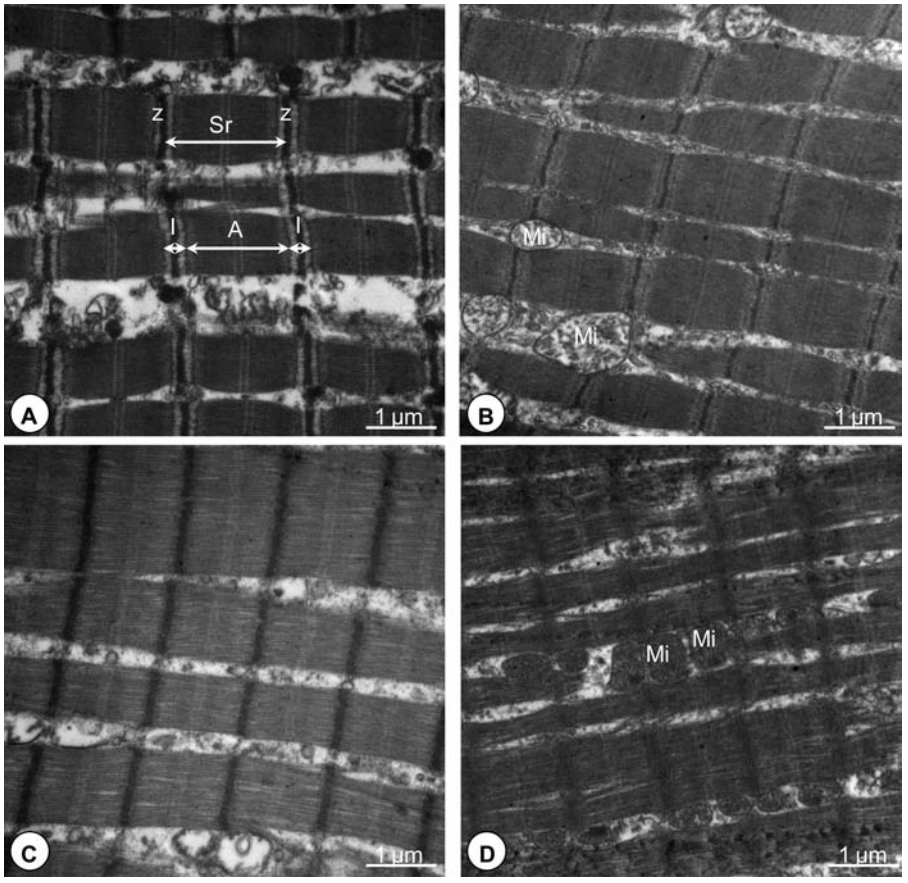

Figure 3. Postmortem ultrastructure changes of EDL and soleus muscles. A, B: EDL muscle at 0 and 24 h postmortem, respectively. C, D: Soleus muscle at 0 and 24 h postmortem, respectively. At slaughter soleus muscle has contracted sarcomeres, which may be the result of cold shortening. The ultrastructure has changed little at 24 h postmortem whatever the considered muscle. Z: Z line, Sr: sarcomere, A: A band, I: I band, Mi: mitochondria.

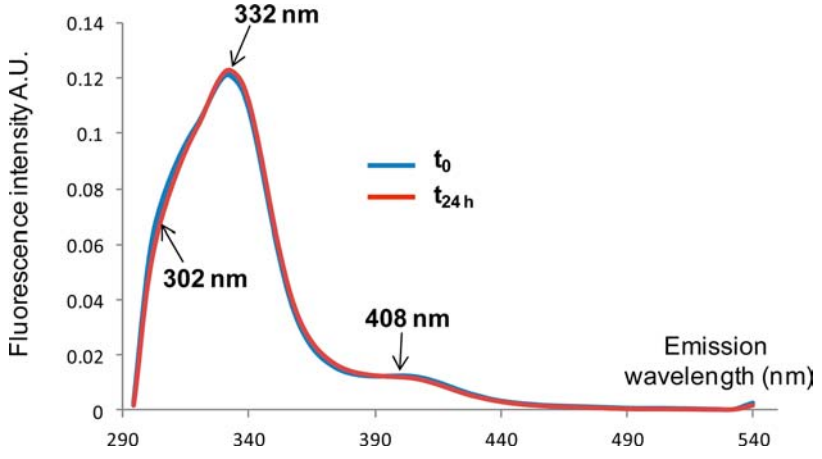

Figure 4. Mean emission fluorescence spectra of 0 (t_0) and 24 h ($t_{24\,h}$) postmortem soleus muscle fibers (excitation wavelength of 275 nm). The UV-excited spectra show peaks at 332 nm and 408 nm with shoulders at 302 nm. Fluorescence emission at 302 and 332 are assigned to tyrosine and tryptophan, respectively. Compounds emitting at 408 nm could be NADH. The postmortem time causes a slight shift of the spectrum.

by a specific feature of rodent muscles (rats and mice), whose type IIA fibers are richer in mitochondria and, thus, more oxidative than their type I fibers.[21,22] It is therefore logical for it to be less richly supplied with glycogen. The initial level of glycogen (around 23 μmol/g of fresh muscle) was lower than reported by others, who found 30−40 μmol/g of fresh muscle in the rat muscle.[23,24] This difference is probably due to the delay of 10 min necessary for muscle dissection when part of the glycogen was depleted; 60% of muscle glycogen is degraded within 5 min after the death of the animal.[23] This hypothesis is in accordance with the initial pH (6.9 in tibialis and gastrocnemius muscles), slightly lower than usual *in vivo* pH (7.2), as a consequence of glycogen degradation associated with a release of protons in the tissue.

The rat muscle glycogen content appeared to be considerably lower than seen in farm animal species, where values of

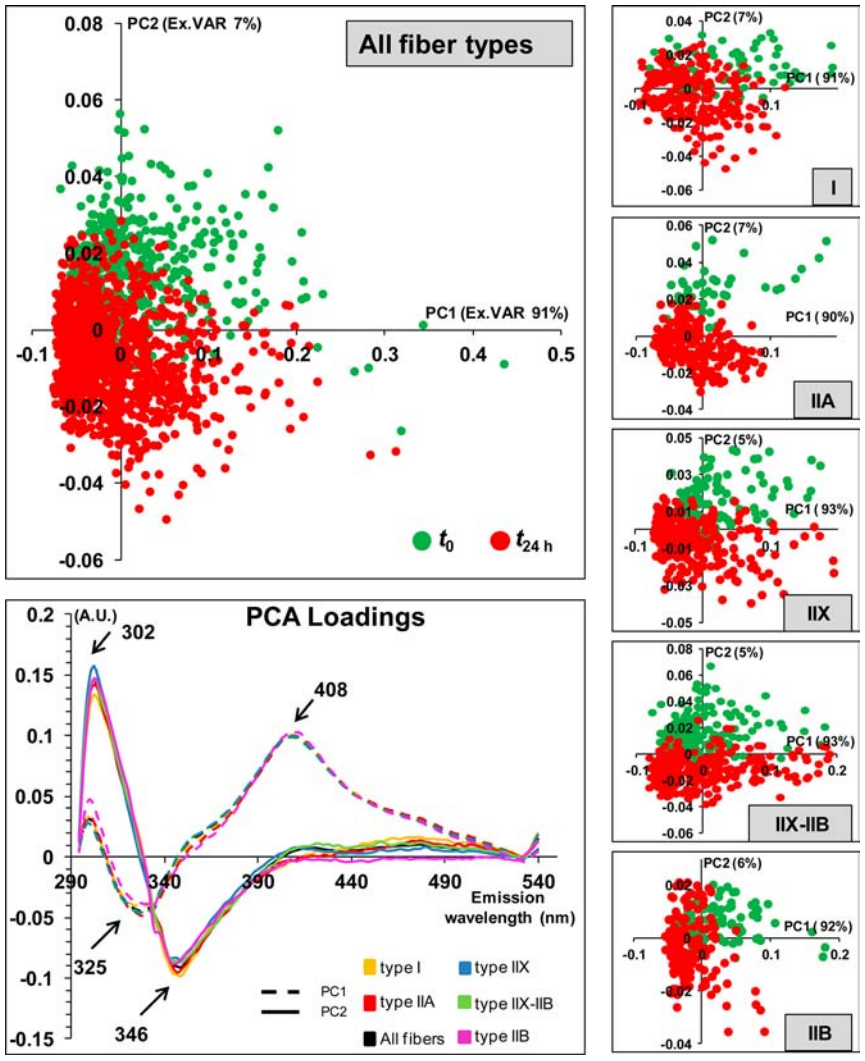

Figure 5. PCA score plots and loadings of fluorescence response of fresh (t_0) and 24 h postmortem ($t_{24\,h}$) EDL muscle. Ex.VAR: explained variance. Postmortem time was most discriminated on the PC2 (346 nm and 302 nm bands) for IIA, IIX, and IIX-IIB fibers and on the PC1 (408 nm and 346 nm bands) for I and IIB fiber types.

glycogen are about 60−70 μmol/g in rabbits,[25] 85−100 μmol/g in pigs,[26,27] 45−50 μmol/g in turkeys,[28] 80−100 μmol/g in cattle,[29,30] and about 70 μmol/g in sheep.[31] Glycogen reserves remained relatively high in rat muscle (Figure 2), unlike in farm animals, whose meat glycogen reserves fall to less than 10 μmol/g after rigor mortis, with a pH stabilization around 5.6−6.0 depending upon the type of muscle.[3,4]

The initial pH of the gastrocnemius and tibialis muscle decreased and has reached its minimum (6.06 ± 0.12 and 6.15 ± 0.03, respectively) after 2.5 h postmortem, which is consistent with the postmortem time of the stopped glycogen consumption in soleus and EDL muscles (Figure 2).

Postmortem Ultrastructural Changes. Representative images of ultrastructural analysis are shown in Figure 3. Shortly after animal sacrifice, the myofibrils were well-preserved with well-defined sarcomeres and aligned Z lines. However, the soleus showed contracted myofibrils that prevented the I bands from being distinguished. This contraction may be related to mechanical stimulation during sampling but also to cold shortening, despite our precautions to avoid this problem (fixative immersion at room temperature). The fact that only the soleus muscle showed this state leads us to believe that it was due to cold shortening because only red muscles are sensitive to cold shortening.[3]

After 24 h postmortem, the myofibrils showed no significant change in their structure. Soleus myofibrils were still contracted; however, Z lines remained aligned, and mitochondria were well-preserved, despite the storage temperature of 20 °C, which promotes the action of endogenous proteases.

Appreciable changes were observed at 48 h postmortem on the muscle sample prepared exactly in the same conditions (see Supplementary Figure S1 of the Supporting Information).

Fluorescence Response of Muscle Fibers According to Time Postmortem. Figure 4 shows the profile of fluorescence spectra acquired in soleus muscle fibers at death (t_0) and 24 h postmortem ($t_{24\,h}$) (spectra acquired on the EDL muscle show the same general pattern). The spectra show a peak at 332 nm characteristic of tryptophan and a shoulder at 302 nm assigned to tyrosine.[12,20,32] The compound that emits fluorescence at 408 nm could not be identified with certainty. Collagen and elastin fluoresce in this wavelength range,[14] but these proteins are located in the ECM, which excludes the involvement of these compounds in the observed fluorescence, because our spectral acquisitions were strictly intracellular. The fluorescence

DOI: 10.1021/acs.jafc.5b00668
J. Agric. Food Chem. 2015, 63, 4782−4789

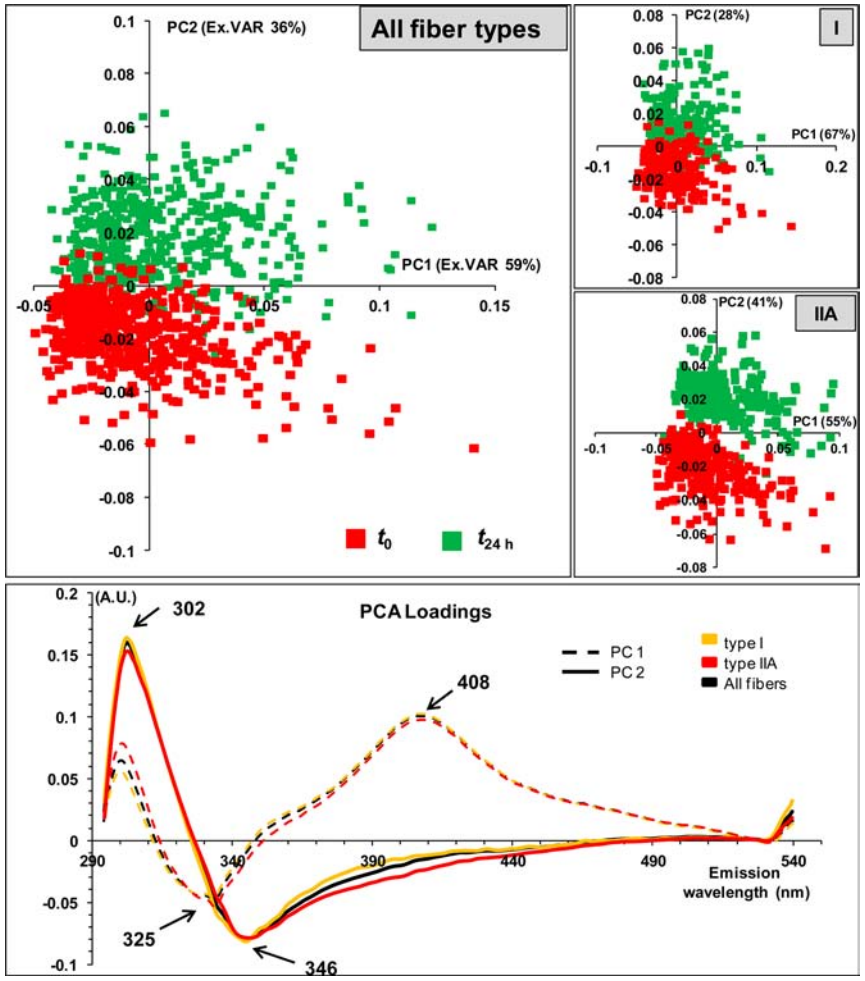

Figure 6. PCA score plots and loadings of fluorescence response of fresh (t_0) and 24 h postmortem ($t_{24\,h}$) soleus muscle. Ex.VAR: explained variance. Postmortem time was best discriminated on the PC2 (346 nm and 302 nm bands) whatever the fiber type of the soleus muscle (I and IIA).

peak at 408 nm could be attributed to NADH, because in living cells, this compound is suspected to fluoresce in this wavelength range.[20]

The superposition of the spectra acquired at t_0 and $t_{24\,h}$ shows some shifts that are however difficult to see with the naked eye. However, these differences are highlighted by the PCA and variance analysis that are presented in Figures 5−7. PCA and loadings indicate a separation of the two postmortem times (t_0 and $t_{24\,h}$) essentially in the PC2 on the fluorescence intensities at 302 and 346 nm and to a lesser extent on the PC1 at 325 and 408 nm, whichever the muscle considered (Figures 5 and 6). In general, 302 and 408 nm fluorescence intensities were higher and 346 and 325 nm fluorescence intensities were lower for t_0 than for $t_{24\,h}$ samples. Separation on the EDL PCA was less clear-cut than in the soleus, mainly because the EDL is composed of four types of fiber plus IIX−IIB hybrid fibers, while the soleus is composed of only I and IIA fibers.

Some cell types allow for a better separation of postmortem times, such as type IIA fibers, which show excellent discrimination of postmortem times on both the EDL and soleus muscles. IIX−IIB hybrid fibers and IIX fibers (absent in the soleus muscle) also show a good separation with regard to postmortem time. Postmortem time of soleus muscle type I fiber discrimination was somewhat less marked than for type IIA but still very sharp. In contrast, postmortem time discrimination of EDL type I and type IIB fibers was not as sharp on PC2. For these fiber types, the postmortem time was discriminating on both PC2 at 302 and 346 nm and PC1 at 408 and 325 nm.

Discriminatory wavelengths of PC1 and PC2 were exactly the same for the two muscles (EDL and soleus) and all types of fibers: 325 and 408 nm for PC1 and 302 and 346 for PC2. Hence, it seems that only few fluorophores are concerned in postmortem time discrimination.

Significant differences in emission fluorescence intensities regarding the postmortem time were amplified by the 346/302 and 408/325 ratios, which were systematically lower and higher, respectively, for t_0 than $t_{24\,h}$ muscle fibers (Figure 7). Soleus t_0 fibers I and IIA have a lower 408/325 ratio than EDL t_0 I and IIA fibers (Figure 7). The fluorescence intensity at 408 nm is significantly higher ($p < 0.01$) in the EDL (0.0195 ± 0.0009 and 0.0170 ± 0.0015 for I and IIA fibers, respectively) than in the soleus (0.0114 ± 0.0002 and 0.0113 ± 0.0002 for I and IIA fibers, respectively), while that at 325 nm has very low variations (around 0.110). Therefore, the difference in response is related to the fluorescence emission at 408 nm suspected to correspond to NADH. Moreover, soleus fluorescence at 408 nm is less affected by postmortem time than that of EDL. These results indicate that, within the same type of fiber, the response of some fluorophores may depend upon the muscle origin. Therefore, it seems that the composition or the

J. Agric. Food Chem. 2015, 63, 4782−4789

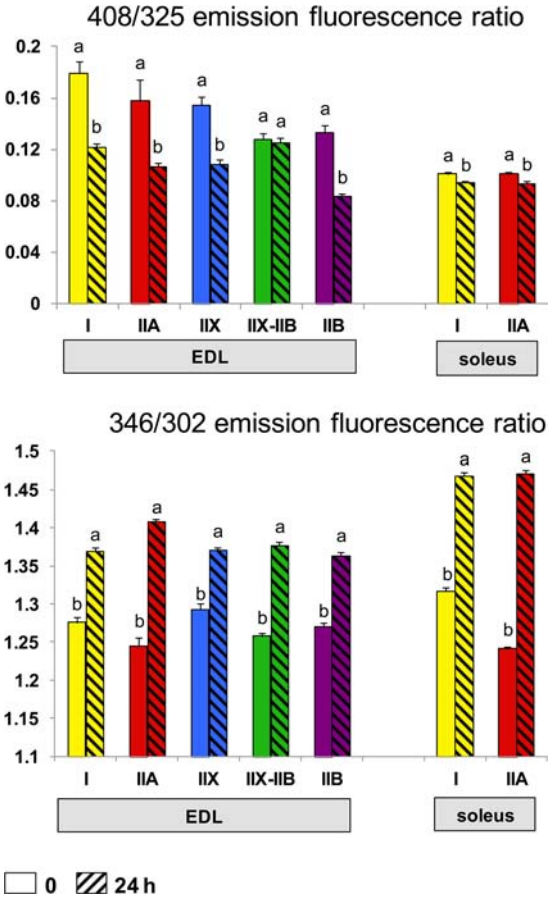

Figure 7. Ratio of fluorescence intensity wavelength evidenced by loadings of PCA regarding the postmortem time. Fluorescence intensity ratio of wavelengths corresponding to discrimination peaks evidenced by PCA allow an amplification of differences. Twenty-four hours postmortem time muscle fibers ($t_{24\,h}$) show higher 346/302 and lower 408/325 values than fresh muscles fibers (t_0). For a given fiber type, different letters indicate a significant difference between 0 and 24 h postmortem samples for $p < 0.01$ (less than 1% that the observed difference is due to coincidence and more than 99% chance that it is related to postmortem time).

intracellular environment of a given fiber type is dependent upon its muscle source.

If the discrimination on 302 and 408 nm is coming from range in fluorescence intensity of tyrosine and NADH, the discrimination on 325 and 346 nm probably originates from slight shifts in the emission fluorescence of tryptophan around 332 nm related to changes in its physicochemical environment.[33,34] Indeed, after animal slaughter, muscle undergoes structural, biochemical, and physicochemical changes.[3,4] The pH drop is accompanied by glycogen decrease, lactate accumulation in cells, and muscle contraction. The plasma membranes are quickly perforated,[35] and ionic gradients gradually collapse, culminating in ion concentration equilibrium in the cells. Nucleus and organelles (mitochondria, lysosome sarcoplasmic reticulum, etc.) degrade, and muscle proteins are degraded into peptides under the action of endogenous proteolytic enzymes.[5,6] All of these phenomena substantially change the intracellular physicochemical environment and, therefore, the fluorescent properties of molecules[33,34] that may explain the t_0 and $t_{24\,h}$ differences in fluorescence intensity of aromatic amino acids.

The level of discrimination seems dependent upon both muscle (EDL or soleus) and fiber type. In comparison to type I fibers, the better postmortem time separation on IIA fibers suggests more marked environmental changes in these cells.

Postmortem time discrimination being less clear-cut on the EDL than on the soleus muscle is probably related to the fact that the EDL contains four pure types of fibers and IIX−IIB hybrids. In the EDL, the postmortem time of types I, IIB, and IIX fibers was discriminated on both PC1 and PC2, with the $t_{24\,h}$ showing a lower fluorescence intensity at 408 nm and a higher fluorescence at 325 nm than the t_0.

In comparison to t_0, the decrease in fluorescence intensity at 408 nm for $t_{24\,h}$ strengthens our hypothesis that this band corresponds to NADH. We know that NADH (fluorescent) is completely oxidized to NAD (non-fluorescent) after a short period of anoxia and all the more so after 24 h postmortem,[36,37] which would explain the difference in 408 nm intensity as demonstrated on the PC1 loading. The fact that the discrimination at 408 nm was not as clear-cut on some types of fiber may be due to the rate of oxidation of NADH depending upon the fiber type.

Our results demonstrate the benefit of exploiting the variation in DUV autofluorescence feature to characterize some postmortem changes in muscle cells. Despite low spectral differences, multivariate analyzes have identified the wavelengths capable of discriminating muscle samples collected at slaughter from those taken 24 h postmortem. A kinetic study will show whether the evolution of postmortem muscle can be characterized by its autofluorescent answer.

ABSTRACT: The objective of this study was to perform a preliminary investigation of the nontargeted search and quantitative capabilities of a single-stage Exactive High-Resolution Mass Spectrometer (HRMS). To do this, the instrument and its associated software performed a non-targeted search for deleterious substances in a dog food sample suspected of causing gastrointestinal problems in dogs. A single-stage Orbitrap/high-performance liquid chromatography method and differential expression analysis software (Sieve) was used to detect and identify, and subsequently quantify, nontargeted compounds occurring only in the suspect dog food sample. When combined with an online database (ChemSpider), a preliminary identification of one of the nontargeted compounds was determined to be potato glycoalkaloids. The diagnostic product ion ratios and quantitative data accuracy generated by the single-stage Orbitrap MS were shown to be similar to results obtained using a triple quadrupole LC-MS/MS. Additionally, the ability of the single-stage Orbitrap instrument to provide precursor and product ion accurate masses and isotope patterns was also investigated.

KEYWORDS: *glycoalkaloids, HRMS, nontargeted search, Orbitrap, Sieve, dog food*

INTRODUCTION

With the introduction of relatively inexpensive high-resolution mass spectrometer (HRMS) instruments, such as time-of-flight (TOF) and Orbitrap mass spectrometers, new capabilities in sample analysis have emerged.[1−3] In addition to the traditional data supplied by triple quadrupole and ion trap instruments (nominal mass/charge measurements and precursor to product ion transition ratios), these HRMS instruments can also provide accurate mass data for precursor and product ions and their corresponding isotopolog ions.[2] Additional data from HRMS measurements not only allow for screening of known compounds, but, more importantly, they allow for the structural elucidation of unknown low molecular weight compounds using the inferred elemental composition of precursor/product ions and the isotope patterns[4] derived from the accurate mass measurements. The full scan data acquisition of HRMS enables the instrument to record virtually all ions[4,5] that reach the detector. This allows for postacquisition identification not only for targeted compounds but also for any other nontargeted compounds with mass/charge values within the scan range of the method.[2,3,6] With proper resolution settings (e.g., ≥ 50 000), the resulting data is also highly selective because narrow ion extraction windows (e.g., ± 5 ppm) can be constructed around the theoretical mass/charge of the compound(s) of interest.[2]

This preliminary investigation was done to determine the nontargeted search capabilities of the single-stage Exactive HRMS and the identification capabilities of its associated Sieve software. Also, the ability of the Exactive to quantify and positively identify (according to FDA and EU guidelines) compounds was also studied. HRMS analysis is a powerful tool for the identification of unknown nontargeted contaminants in a food safety laboratory. A good example of a nontargeted search is the analysis of a food or drug sample for potential contaminants suspected of causing illness or death in humans and/or animals.[7] In these cases, there may be little or no information available to the analyst, only the information provided by the sample packaging and the people involved in the case (i.e., consumer, patient, doctor, etc.). In the past, this type of nontargeted sample analysis was done by using a wide range of analytical instrumentation and extraction techniques to compare the suspect sample against a very similar sample (e.g., the same product from the same manufacturer but from a different lot that was not causing adverse effects). The results from these analyses were then manually compared, and differences between the two were investigated. This approach has led to the successful identification of many contaminants in food and drugs, such as the recent economic adulteration of Chinese protein products with melamine in 2007−2008[7] and the adulteration of Tylenol capsules with cyanide in 1982.[8] However, because it can be time-consuming and is not always successful, a better approach to nontargeted analysis is needed.

One new approach can involve HRMS instruments and their associated software. Analysis using HRMS has been applied to environmental testing,[9] forensics,[10] and food safety.[11] These instruments provide the selectivity and sensitivity required for efficient wide-range screening of samples by combining high,

full-spectral sensitivity with sufficient mass resolution for accurate mass measurements of any ionizable component in a sample. Elemental composition for nontargeted compounds can be deduced from these results. Then a user defined database can be searched (targeted search), or as in this study, a large online database such as ChemSpider[12] can be searched (nontargeted search) for potential matches. These database searches (both targeted and nontargeted) can be done automatically using the equipment manufacturers software.[4]

There are numerous papers describing the use of HRMS methods and data processing using differential analysis software,[13,14] but most are associated with the fields of proteomics or metabolomics.[4,13−16] These analyses are often targeted in nature because the class of compounds is usually known and the analytical methods are more specific. There are few papers addressing low-molecular-weight compounds in adulterated samples where the contaminant is a total unknown. This "small molecule, totally unknown" sample type can be especially difficult as the extraction procedure, instrument method and data processing parameters must all be set to capture a wide range of possible compounds. This results in a massive amount of data that must then be subjected to some type of reduction process to make the number of possible adulterants identified manageable.

This paper describes a high-resolution accurate mass/mass spectrometry (HRMS) analytical method for potential contaminants in dog food and subsequent data analysis using differential analysis software to identify compounds that were only found in the suspect sample. In general, differential analysis software compares the magnitudes of matching chromatographic peaks (i.e., same mass/charge and retention time using user defined limits) found in a suspect sample versus a control sample. These magnitude differences can then be used to filter the data. As an example, the data can be filtered to show only ions that were at least 10 times more abundant in the suspect dog food. Using this approach, only one instrument was needed in this study to identify the unknown compound that could be causing the illness in dogs, as opposed to the multiple analytical techniques used in the past. In addition, the tedious job of comparing the data generated was evaluated automatically in a matter of hours by the software.

MATERIALS AND METHODS

Study Design. A truly nontargeted analysis implies no foreknowledge of what compounds are to be detected, and therefore, generalized extraction and chromatographic parameters need to be used. With this in mind, a simple liquid/solid extraction using common solvents that span a wide range of polarities, followed by filtration, was chosen as the initial extraction procedure. Each extraction solvent (ACN, ACN/H_2O 70:30 (v/v) and MTBE) was used to extract the suspect and control dog food samples in triplicate. The set of three injections of the extracted suspect dog food sample was then compared to the set of three injections of the extracted control dog food sample using Sieve differential analysis software to determine what ions were present in the suspect dog food compared to the control dog food. The software then assigned values to the magnitude of the differences between the suspect sample and the control sample using parameters such as the peak area ratio (treatment peak area/control peak area) or the statistical probability ("p" value) that they come from the same population; the "difference magnitudes" were then used to filter the results. This procedure was applied for each of the three data sets of the extraction solvents.

To further investigate the capabilities of the Orbitrap/Sieve software combination, four additional experiments were performed: (1) the effect of differing resolution settings on the ability of Sieve to correctly identify compounds, (2) the effect of molecular weight cutoff filter (MWCO) during sample extract cleanup, (3) specificity of the Sieve software (i.e., were there any glycoalkaloids identified in a Blank vs Blank Sieve test), (4) lowest concentration at which the nontargeted compounds could be positively identified by the Sieve software. Once glycoalkaloids were identified as the suspect compounds, in addition to the suspect sample, five additional potato-containing and four nonpotato-containing dog foods were purchased to determine the prevalence and range of concentrations of glycoalkaloids. Fortified dog food samples, at various concentrations (0.01 ppm to 20 ppm), were also prepared and analyzed.

Three instrumental methods were used in this study, two for the Orbitrap and one for the triple quadrupole. The initial Orbitrap method was used for nontargeted searching and consisted of a liquid/liquid extraction using three separate solvents mixtures that encompassed a wide range of polarities with a slow HPLC linear mobile phase gradient from low to high organic content. Upon review of the initial data, a second Orbitrap analytical method was developed which better separated the compounds of interest. The second Orbitrap method (extraction, HPLC, and Orbitrap parameters) was then used to generate all quantification and confirmation data presented here. Lastly, some samples were divided into two aliquots to allow for additional analysis using a triple quadrupole LC-MS/MS to compare quantitative and qualitative data obtained by both instrument types; therefore, a third instrument method was required for the additional LC-MS/MS analysis.

Reagents and Supplies. Water (H_2O), acetonitrile (ACN), and methanol (MeOH) were of LC/MS grade, whereas *tert*-butyl methyl ether (MTBE) was of HPLC grade; all were purchased from Fisher Scientific (Pittsburgh, PA, U.S.A.). Nylon syringe filters, 13 mm, 0.2 μm, GD/X disposable, were also purchased from Fisher Scientific. Molecular weight cutoff filters, 3K, were purchased from EMD Millipore (Billerica, MA, U.S.A.). Analytical standards were obtained as follows; solanine (≥95%) and solanidine (≥97%) were purchased from Sigma (St. Louis, MO, U.S.A.), Chaconine (≥95%) was purchased from Chromadex (Irvine, CA, U.S.A.), and solamargine (98%) was purchased from Stanford Materials Corporation (Irvine, CA, U.S.A.)

Standard Solutions. Solanine, solanidine, solamargine, and chaconine standard stock solutions were prepared individually at a concentration of approximately 0.1 mg/mL by dissolving approximately 1 mg of each in 10 mL of 70:30 MeOH/H_2O (v/v). Intermediate stock standards were prepared by various combinations and dilutions of these stock standard solutions in 70:30 H_2O/ACN (v/v). The diluent used for the final dilution before injection of all samples was 95:5 H_2O:ACN (v/v). All solutions were corrected for purity and no internal standard was used in this study.

Calibrant and Fortified Sample Preparation. Powdered dog food, similar to the suspect dog food and previously shown to be free of glycoalkaloids, was spiked in duplicate with varying amounts of intermediate stock standard solutions to prepare fortified extracted standard samples at 0.5, 1.0, 1.25, 2.5, 5.0, 10.0, and 20.0 ppm and fortified extracted samples ranging from 2 to 300 ppb. The fortified samples were allowed to sit uncapped for 20 min. The calibrants were then extracted as described below in the section Final Extraction Procedure.

Sample Preparation. The suspect dog food was obtained personally from the dog owner and consisted of approximately 5 lb of dry brown pellets. The negative control dog food sample, purchased at a commercial pet food chain, was nearly identical to the suspect sample with similar texture, color, and ingredients listed in the same order. The only major difference between the suspect and control samples was that the control dog food contained sweet potatoes, and the suspect dog food contained regular potatoes. After the initial analysis of suspect versus negative control dog food was completed, standards and additional dry dog food samples, with and without potatoes, were purchased to determine the ability of the method to consistently isolate, identify, and quantify compounds present only in the suspect sample. Approximately 5 lb of each dry dog food sample

DOI: 10.1021/acs.jafc.5b00959
J. Agric. Food Chem. 2015, 63, 4790−4798

was ground (approximately 5 min) to a fine homogeneous powder using a food processor (Robot Coupe, Ridgeland, MS, U.S.A.).

Initial Extraction Procedure. In the initial dog food extraction procedure, three extraction solvents of differing polarities (100% ACN, 70:30 v/v ACN/H_2O and 100% MTBE) were used. Five grams of the suspect and control dog food powder and 10 mL of each solvent were added to individual 15 mL polypropylene centrifuge tubes. The samples were vortex mixed at high speed for 15 min, then centrifuged at 4270*g* for 5 min. The supernatant from each sample was transferred to a clean 15 mL centrifuge tube. Each pellet was then washed with an additional 5 mL of the appropriate extraction solvent, centrifuged, and the supernatant was added to the initial extraction solvent. The combined extract was dried under 15 psi nitrogen (Turbo Vap, Hopkinton, MA, U.S.A.) at 40 °C to less than 1 mL and reconstituted to 1 mL with 95:5 (v/v) H_2O/ACN. The resulting liquid was filtered through a 0.2 μm, 13 mm nylon filter (Millipore, Billerica, MA, U.S.A.).

Final Extraction Procedure. In the final extraction procedure, 1 g of dog food powder was extracted, as described in the section Initial Extraction Procedure (above), using only the 70:30 (v/v) ACN/H_2O extraction solvent mixture. The resulting 10 mL of liquid was then dried, reconstituted, and filtered, as described above. The reconstituted solution was then additionally filtered through a 3K amu molecular weight cutoff filter using a microcentrifuge (HERMLE Labortechnik, Wehingen, GmbH) set at 21 000*g* for 15 min.

Initial LC-MS/MS Orbitrap Procedure. The LC system consisted of a Thermo (San Jose, CA, U.S.A.) Accela 1250 HPLC pump/degasser and a Thermo Pal HTC-Accela1-TMO autosampler. The HPLC conditions for the initial nontargeted phase of the analysis consisted of an Agilent (Santa Clara, CA, U.S.A.) Eclipse XDB 4.6 × 150 mm, 5 μm HPLC column with a Phenomenex (Torrance, CA, U.S.A.) Security Guard C18 4 × 2.0 mm guard column. Mobile phase "A" was 0.1% formic acid, and "B" was ACN. The gradient started at 95% "A" and 5% "B", was held for 3 min, then ramped linearly to 5% "A" and 95% "B" over 23 min, held there for 2 min, then brought back to initial conditions over 2 min, and held for 3 min. The flow rate was 0.5 mL/min. Five microliters of extract was injected onto the HPLC column, and the column was kept at room temperature.

A Thermo single-stage Exactive Orbitrap equipped with Xcalibur version 2.1, and Sieve version 2.0 software was used for the initial nontargeted phase of the study; the "Lock Masses" feature was not used. A generic tune file was created by tuning on the Total Ion Chromatogram (TIC) of the Orbitrap positive ion calibration solution. Three scan events were created, all with a mass range of 95 to 900 atomic mass units (u), a resolution setting of 50 000 at full width at half-maximum (fwhm), an automatic gain control (AGC) setting of 1 000 000, and a maximum injection time of 50 ms (ms). The first scan event used no fragmentation (i.e., neither in-source collision induced dissociation (CID) nor higher energy collision dissociation (HCD) was used), the second scan used HCD collision cell energy of 25.0 electron volts (eV), and the third scan used HCD collision cell energy of 40.0 electron volts (eV). The following source settings were used: spray voltage was 4500 (+), capillary temperature was 380 °C, sheath gas was 60 (arbitrary units), Aux gas was not used, and the heated electrospray ionization (HESI) temperature was 350 °C. A 5 ppm mass accuracy window was used to extract all compound masses used for calculations.

Final LC-MS/MS Orbitrap Procedure. The same HPLC as described above was used. Conditions for the analysis phase of the study consisted of an Agilent ODS Prodigy 2.0 × 150, 5 μm HPLC column with a Phenomenex Security Guard C18 4 × 2.0 mm guard column. Mobile phase "A" was 0.1% formic acid, and "B" was ACN. With a flow rate of 0.75 mL/min, the initial pump conditions were isocratic at 81% "A" and 19% "B" for 10 min, then the mobile phase was ramped linearly to 10% "A" and 90% "B" over 2 min, held there for 3 min, then brought back to initial conditions over 2 min, and held for 3 min.

For the final Orbitrap analysis, a tune file was created by tuning on solanidine (m/z 398.3417), which was the least responsive of the glycoalkaloids. Two scan events were created, both used a mass range of 95 to 900 amu with a resolution setting of 25 000 at fwhm, an AGC setting of 1 000 000 and a maximum injection time of 20 ms. The first (full) scan used no fragmentation, whereas the second (fragmentation) scan used an HCD setting of 90 eV. The source settings were the following: spray voltage, 4500 (+); capillary temperature, 380 °C; sheath gas, 60 (arbitrary units); Aux gas, not used; and the HESI temperature was 350 °C. A 5 ppm mass extraction window was used to extract all masses/compounds for calculations.

LC-MS/MS Sciex 5500 Procedure. The HPLC system was an Agilent 1200 series and consisted of a G1379B degasser, a G1312B binary pump, a G1316B column heater (kept at room temperature), and a Leap HTC Pal autosampler. The same LC parameters, injection volume, and HPLC column used in the "Final LC-MS/MS Procedure" of the Orbitrap study above were also used in this study.

An Applied Biosystems (Foster City, CA, U.S.A.) ABSciex 5500 QTrap mass spectrometer with Analyst software version 1.5.1 was used with electrospray ionization (ESI) in the positive ion mode. A tune file was created by tuning on the least responsive glycoalkaloid (solanidine). The precursor and product ions monitored were the same as those extracted from the Orbitrap data. The instrument settings were as follows; resolution for Q1 and Q3 was set at unit resolution; curtain gas (CUR), 25.0; collision gas (CAD), medium; ion spray voltage (IS), 5500.0; temperature (TEM), 600.0; ion source gas 1 (GS1), 60.0; ion source gas 2 (GS2), 50.0; declustering potential (DP), 100.0; entrance potential (EP), 10.0; and collision cell exit potential (CXP), 20.0; fragmentation parameters can be found in Table 1.

Table 1. Masses Monitored

analyte	Orbitrap m/z	Sciex 5500 m/z	Sciex 5500 collision energy (v)
solanine	868.5053[a]	868.5	N/A
frag. 1	98.0965[a]	98.1[a]	160
frag. 2	706.4513	706.5	95
frag. 3	722.446	722.4	95

[a]Product ion used for quantitation, Orbitrap precursor ion also used for quantitation.

Data Analysis with Differential Expression Software. Thermo Sieve (2.0) Automated Label-Free Differential Expression software was used with the "Small molecule", "Chromatographic Alignment and Framing", and "Two Sample Differential analysis" options. Analytical results from three replicate analyses of the suspect dog food (the "Treatment" sample in the Sieve software) were compared against triplicate analyses of a dog food with very similar ingredients to the suspect sample (the "Control" sample in the Sieve software). Sieve first aligns the Control and Treatment chromatograms along the retention time or "*X*" axis (Figure 1a,b). Then, using recursive base-peak framing and user-defined constraints (e.g., allowable variability in mass and retention time), Sieve constructs frames using retention time as the *X* axis and m/z as the *Y* axis (Figure 2). Each frame in the "Treatment" chromatogram(s) is compared to the corresponding frame in the "Control" chromatogram(s). All peaks (masses) detected in the consumer complaint and control sample were then sent to ChemSpider for tentative identification. The compounds identified by ChemSpider can then be filtered using various parameters offered by the Sieve software to limit or expand the amount of data generated such as the ratio of "Treatment" sample peak area/"Control" sample peak area.[17−19]

RESULTS AND DISCUSSION

Analytical Methodology. The objective of this study was to determine the ability of a single-stage Exactive HRMS

instrument to positively identify what compound, if any, in a dog food sample could be causing gastrointestinal problems in dogs and the ability to quantify that compound. The analytical methodology evolved during the course of the study as the focus changed from unknown compound discovery to a more targeted procedure for glycoalkaloids. Initially, this was a true nontargeted analysis utilizing a single-stage Orbitrap and its associated Sieve differential analysis software for sample analysis. The sample extraction consisted of several different solvents covering a wide range of polarities with simple

DOI: 10.1021/acs.jafc.5b00959
J. Agric. Food Chem. 2015, 63, 4790−4798

filtration as the only cleanup in order to facilitate the extraction of a wide range of compounds. With no indication of how much background interference the dog food extracts would have, the Orbitrap resolution was set to 50 000. This resolution reduced the probability of mass errors caused by isobaric interferences, leading to more accurate identification of compounds with the Sieve software. Upon review of the initial data and tentative identification of potato glycoalkaloids as the potential contaminating agent, the instrument resolution was reduced to 25 000 because there was no indication of isobaric interferences. This reduction in resolution increased scan speed with no increase in mass error and no reduction in the ability of the Sieve software to correctly identify all glycoalkaloids. Filtration of the reconstituted sample through a 3K amu molecular weight cutoff filter was added to the extraction procedure resulting in a slight reduction in absolute recovery (glycoalkaloid peak areas were reduced by approximately 5%) but lessened the amount of unwanted material from entering the analytical system. The Sieve software detected glycoalkaloids in all three sample extracts (i.e., ACN, ACN/H2O; 70:30 (v/v) and MTBE) with ACN/H2O giving the greatest response; therefore ACN/H2O was used as the extraction solvent throughout the rest of the study. The HPLC method was adjusted to separate the coeluting glycoalkaloid isomers solanine and solamargine (Figure 3a,b) to ensure accurate calculation of concentrations and product ion ratios.

Differential Analysis. The suspect and negative control dog food samples were injected in triplicate and then analyzed by the Sieve software. The large number of possible compounds initially found by the Sieve software was reduced using the "Ratio" filter (ratio of suspect sample response to control sample response, set at >10:1) and the "PValue" filter (the probability, or "*p*" value, that the set of suspect chromatograms came from the same population as those from the Control chromatograms, set at ≤0.01) available in the software. Although instrument software programs are designed to evaluate large amounts of information generated by HRMS instruments, it can be difficult to set parameters to detect low levels of contaminants without generating a large positive identification list that must then be carefully evaluated. To reduce the extremely large number of compounds generated by this comparison, some assumptions were made: (1) the compound causing the sickness in dogs would be present in the suspect sample at a much higher concentration than in the control sample (at least 10×); (2) it would be present and detected in all three replicates of the suspect sample at approximately the same concentration in each replicate; and (3) that the compound would have a common name in addition to its International Union of Pure and Applied Chemistry (IUPAC) name. The first two assumptions did reduce the number of possible compounds from approximately 6000 to 2000, but this was still too large a number to manually search; therefore, assumption number three was included. It must be remembered that the use of the "common name" restriction may remove from consideration the compound actually causing the sickness in dogs (this assumption can easily be removed to revert to the approximately 2000 compound list). These three assumptions reduced the number or possible contaminants/adulterants to approximately 200 in the suspect dog food examined. These candidates were then either removed from the list due to their known benign nature or a literature search was done to determine the nature of the unknown substance; if benign, they were removed from the list.

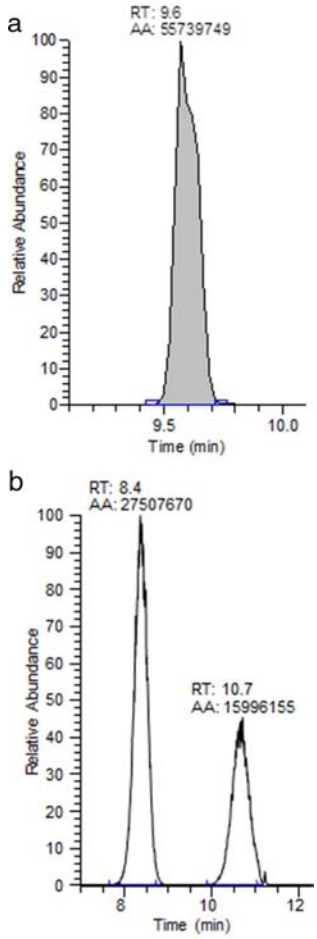

Figure 3. (a) LC-MS chromatogram of solanine and solamargine coeluting. (b) LC-MS chromatogram of solanine and solamargine separated.

Of the remaining substances, those that could cause symptoms similar to those exhibited by the sick dogs (i.e., drowsiness, vomiting, and ataxia) were studied further. One class of compounds detected by the Sieve software that matched all these criteria and was an ingredient in the dog food was potato glycoalkaloids.

All potato glycoalkaloids except solanidine were tentatively identified as occurring in only the suspect sample regardless of the extraction solvent used. An example of Sieve software results for solanine can be seen in Figure 4. Solanine and solamargine are structural isomers (Figure 5 and 6); therefore, the two compounds were indistinguishable to the Sieve/ChemSpider search and both were listed as possibilities.

Identification of Glycoalkaloids. The single-stage Orbitrap does not have the ability to isolate precursor ions (no isolation quadrupole) but was equipped with an HCD cell which was used for the fragmentation of all precursor ions entering the cell over a certain time interval. Extracted ion chromatograms of pertinent precursor and product ions were created using a 5 ppm mass accuracy extraction window; these data were then used for subsequent calculations. A literature search revealed that the masses (Table 1) of parent and product ions generated by the Orbitrap for the tentatively identified glycoalkaloids matched those in the literature[20−22] and that the actual and theoretical isotope patterns also matched (Figure 7a,b). Also, the symptoms exhibited by the sick dogs matched

the symptoms of potato glycoalkaloid poisoning.[23] At this point in the study, we determined that there was enough evidence to purchase standards for comparison against the suspect compound. Spectra (Figure 8a,b), accurate mass and retention time of the standard and sample were compared, the identity of solanine, chaconine, solamargine, and solanidine was then confirmed according to the U.S. Food and Drug Administration's Guidance to Industry 118 "Mass Spectrometry for Confirmation of the Identity of Animal Drug Residues"[24] and the European Union Commission Decision 2002/657/EC of 12 August 2002.[25]

Glycoalkaloids are naturally produced by all potatoes, but the amount produced is determined by many factors such as the potato strain, response to environmental stresses such as insect infestation, temperature extremes, physical bruising, and others.[26−28] Solanine and chaconine make up approximately 95% of the total glycoalkaloids produced, whereas solanidine and solamargine make up only about 5%;[20] therefore, quantitative results for these two lesser compounds are not

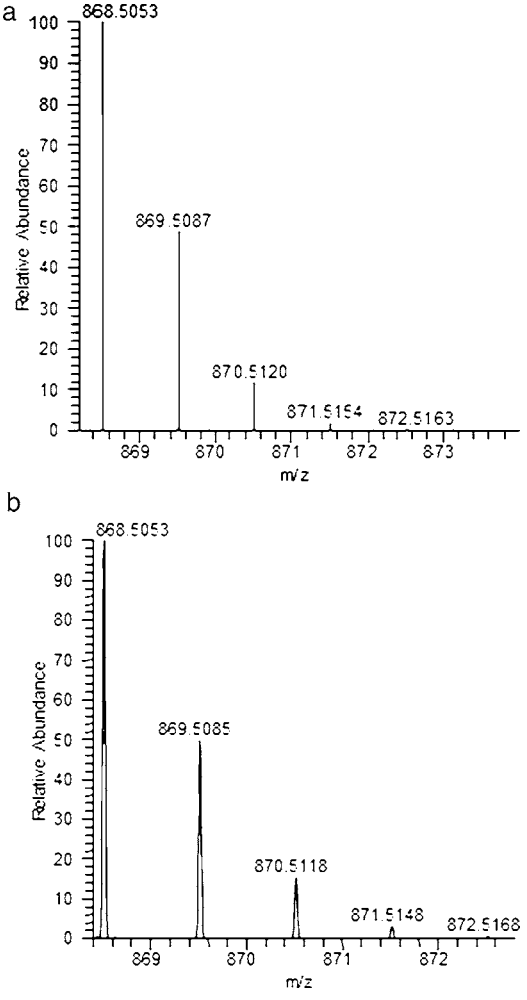

Figure 7. (a) Theoretical isotope pattern of solanine. (b) Measured isotope pattern of solanine.

reported here. The United States Department of Agriculture has set informal guidelines recommending the total glycoalkaloids concentration of potatoes for human consumption be no more than 200 ppm,[29] although no suggested limit could be found for animal feeds. This recommended limit in humans is thought to be too high by many researchers[26−30] and does not take into account various possible aggravating factors such as the synergistic effects of the solanine/chaconine ratio[26,29,31] and differences in species tolerance.[27] Also, the recommended 200

ppm limit refers to an acute dose of glycoalkaloids but does not address the effects of chronic toxicity of glycoalkaloids.[26,30] This chronic toxicity aspect of glycoalkaloids should be kept in mind when considering the following: (1) dog owners are often loyal to one brand of dog food; (2) this single brand of dog food may be the sole source of nutrition; and (3) the dog food may be bought in "bulk" quantities. The concentration of glycoalkaloids in the suspect dog food was 100 times lower than that suggested as safe by the USDA, but it cannot be ruled out as the offending substance because of its chronic toxicity in conjunction with the feeding habits of some dog owners.

Determination of Potato Glycoalkaloids in Dog Food Samples. Once it was determined that potato glycoalkaloids were the compounds of interest, further analysis (quantification and confirmation of identity) for these contaminants in dog food was performed using both the Orbitrap and a triple quadrupole LC-MS. For both mass spectrometers, a linear curve (i.e., $y = mx + b$) was constructed to calculate concentrations using fortified extracted matrix standards. Total glycoalkaloid concentrations (total of solanine and chaconine) ranged from approximately 5 ppm to 180 ppm in the six potato-containing dog foods tested (Table 2), and no glycoalkaloids were detected in the nonpotato-containing dog foods. Linearity (R^2) of all calibration curves, including those from the Sciex 5500 triple quadrupole, was greater than 0.992. Average recovery (using either precursor or product ion data) of solanine and chaconine in dog food samples fortified at 1.0, 1.25, 2.5, 5.0, and 10 ppm ranged from 101.6 to 98.8 (%RSD $\leq$ 20.6%, $n = 18$) for both compounds when calculated against a fortified extracted matrix curve. There was no statistical difference in recovery at the 95% confidence interval ($p \geq 0.71$) between the results generated using precursor or product ion data.

The quantitative and qualitative identification abilities of the single-stage Orbitrap was explored by comparing the data for glycoalkaloids in various potato samples generated by the Orbitrap to data generated by the Sciex 5500 triple quadruple LC-MS/MS. Extracted potato-containing dog food samples were prepared, and the final reconstituted sample was split in half; one sample was analyzed on the Orbitrap and the other on the Sciex 5500 system. There was no statistical difference in concentration results produced by the two instruments at the 95% confidence interval except for the solanine concentration in dog food sample no. 6 and both compounds in sample no. 4 (Table 2). The quantitative data generated by the Orbitrap's precursor ion peak area was compared to that generated by the most abundant product ion peak area of solanine and chaconine. There was no statistical difference at the 95% confidence interval except for one analytical run where the Orbitrap concentration calculation using the precursor ion differed from the calculation using the product ion by only 5.5%.

For both instruments used in this study, positive identification of solanine and chaconine was established by comparing product ion ratios of standards (average of solvent standards and fortified extracted dog food), commercial dog food samples, and fortified control dog food samples. Using the three precursor and three product ion transitions listed in Table 1, solanine and chaconine were confirmed in 99% of the 50 potato-containing dog food samples examined using FDA guidelines[24] and in 92% of samples using EU guidelines.[25] These samples included multiple potato-containing dog food samples analyzed unaltered ($n = 34$) and altered investigative dog food samples ($n = 16$) that had been fortified with various

glycoalkaloid standards or diluted with dog food extract previously shown to be free of glycoalkaloids. The concentrations of these altered/unaltered samples ranged from 0.01 to 180 ppm.

Finally, the "non-targeted search" capabilities of the Orbitrap/Sieve software combination to detect low levels of contaminants were further explored by analyzing extracts from fortified and positive samples with different concentrations of glycoalkaloids. To vary concentrations, two dilution schemes were tested: (1) dilution of potato-containing dog food sample extract with nonpotato-containing extract and (2) fortification of nonpotato-containing dog food sample with various amounts of glycoalkaloids prior to extraction. Both of these sample types were then compared to nonpotato-containing dog food samples. The resulting concentrations of diluted (no. 1 above) and fortified (no. 2 above) samples ranged from 2.7 to 500 ppb. The Sieve software was able to identify solanine and chaconine in all samples down to the 27 ppb level using either dilution scheme (Figure 9).

The single-stage Exactive performed well in this study, and the only possible drawback is the large amount of data generated by HRMS (both TOF and Orbitrap) instruments.[4,9,10] With targeted searches, the challenge lies in the time-consuming process of examining the data for false positive and false negative results.[32,33] Nontargeted searches, such as the one presented here using the Sieve differential analysis software, initially found 10 000 compounds, and this was the limit placed on the software by the user; however, more compounds could have been found by increasing the maximum limit. Both of these "data" problems must be addressed by instrument/software manufacturers before these instruments can reach their full potential.

The results presented here indicate the ability of the single-stage Orbitrap HRMS, and its associated differential analysis software, to compare two analytical sample extracts and determine what chemical compounds are unique to each sample at the ppb level. We have also shown that the Orbitrap is capable of correctly quantifying those compounds using the accurate mass extraction of either the precursor or major product ion.

ABSTRACT: Chymosin is the major enzyme of natural rennet, traditionally used in cheese making for its high milk-clotting activity. For technical reasons, an accurate characterization of rennet should include its total clotting activity and also its enzymatic composition. Monoclonal antibodies specific to chymosin were obtained from mice immunized with purified bovine chymosin, and an inhibition enzyme-linked immunosorbent assay (ELISA) was developed for the quantification of chymosin in solution. No cross-reactivity was observed with other milk-clotting enzymes commonly used in cheese making. The limit of detection and limit of quantification were 125 and 400 ng/mL, respectively. The values of precision within and among runs were 7.23 and 7.39%, respectively, and satisfying recovery, from 92 to 119%, was found for spiked samples. The inhibition ELISA was successfully applied to commercial rennets, and the results were consistent with those obtained using the standard chromatographic method (IDF 110: A, 1987).

KEYWORDS: *chymosin, inhibition ELISA, monoclonal antibody, rennet*

INTRODUCTION

Chymosin (EC 3.4.23.4) is a neonatal gastric aspartic proteinase and is of commercial importance in cheese making. Chymosin is secreted in the abomasal mucosa of newborn ruminants during the first days of life. Its natural function is the hydrolysis of κ-casein once the milk is in the calf's stomach, leading to the formation of a coagulum that can be easily digested.

Once extracted from gastric tissues, chymosin and pepsin (EC 3.4.23.1) constitute the main clotting enzymes of calf, kid, and lamb rennets. In cheese technology, rennet is traditionally added to the vat during the first stage of cheese making to coagulate the milk. Chymosin hydrolyses the Phe^{105}–Met^{106} bond of κ-casein which stabilizes the casein micelles and thereby induces an aggregation reaction leading to a gel and a phase separation of the milk into cheese curd and whey. A fraction of the added chymosin is retained in the curd,[1] which, in most types of cheese, catalyzes the slower hydrolysis of other peptide bonds in casein.[2,3] In the dairy industry, milk-clotting enzymes are characterized by their milk-clotting activity (MCA) and their general proteolytic activity. The ratio between those two properties gives an overview of the essential quality of a milk-clotting enzyme. Only the enzymes with a high MCA/general proteolytic activity ratio are considered suitable for cheese manufacturing; high levels of nonspecific proteolysis lead to a weak gel structure, high losses of protein and fat in the whey, and reduced cheese yield.[4] Depending on technological factors for cheese making, residual active enzymes remain in the curd and can affect cheese maturation and its final quality of flavor/texture.[1,4] In comparison to other milk-clotting enzymes, chymosin is superior in combining a high MCA with a low general proteolytic activity. Chymosin represents >90% of the MCA of a good-quality calf rennet, the remaining activity being due to pepsin.[5]

Rennets available on the market have different values for cheese making because of their enzymatic composition. The relative proportion of the enzymes varies, depending on the age of the animal and its diet. In rennets extracted from young milk-fed calves, chymosin represents 88–94% of the clotting enzymes and pepsin represents 6–12%, whereas pepsin predominates in extracts from older fodder-eating bovines.[6] Rennets are generally prepared from multiple calf stomachs and are heterogeneous in their chymosin content and chymosin/pepsin ratio. Moreover, chymosin and pepsin have different reaction rates in their specific hydrolysis of κ-casein and show quite different effects in their proteolytic action during cheese ripening.[7] Therefore, for economic and quality reasons, the most important parameters of rennet to be analyzed are the MCA and the composition, i.e., the nature and the concentration of the enzymes. To define a rennet accurately, information should be given on its total MCA with its chymosin/pepsin ratio or its composition in active chymosin and pepsin. Today, the total MCA of a bovine rennet is determined according to an international standard method[8] and is expressed in international milk-clotting units (IMCU). For commercialization in France, current regulations require the MCA to be expressed in milligrams of active enzyme, chymosin, and pepsin per liter[9] to give information on the enzyme composition whereas IMCU expresses a global activity.

The enzyme composition has been determined with different methods based on spectrophotometric measurements of the proteolytic activities,[10] chromatographic separation with MCA determination,[11] selective inactivation,[12] and rocket immunoelectrophoresis.[13] More recently, rennets have been characterized by high-performance liquid chromatography (HPLC)[14] and by mass spectrometry.[15] The conventional method for the enzymatic characterization of rennets is a chromatographic one.[9,16,17] First, a desalted sample of rennet is separated by chromatography into two fractions, chymosin and pepsin. Then, the MCA of each of the separated enzymes is measured and converted to weight contents of chymosin and pepsin calculated in percentages[16,17] or in mg of active enzyme/L.[9] Despite being sensitive, the chromatographic method is time-consuming with laborious pretreatment procedures.

Antibodies have widely been used as analytical tools in various methods developed for the detection and quantification of proteins, enzymes, vitamins, allergenic ingredients, and contaminants such as toxins, pesticides, and drugs in food.[18] Immunoassays are easy to perform, rapid, with a large number of samples analyzed at the same time, and give very high sensitivity and specificity, in particular when based on monoclonal antibodies (mAbs). The high specificity of these methods decreases the need for thorough cleanup; therefore, sample-preparation procedures in immunoassays are generally rather simple. Furthermore, mAbs have the advantage of a continuous supply of constant quality.

The aim of the present study was to produce and characterize mAbs specific to bovine chymosin. An mAb-based inhibition enzyme-linked immunosorbent assay (ELISA) specific to the quantification of chymosin in solution was developed. The described assay was applied to the analysis of rennet samples and compared to the IDF standard method (chromatography and MCA measurement)[16] to assess its applicability to the direct quantification of chymosin. Moreover, inhibition ELISA may allow measurements of low chymosin concentrations in complex matrices such as milk, whey, and cheese curd in order to determine chymosin inactivation according to cheese-making steps and its remaining activity in the cheese curd, provided that an efficient method of enzyme extraction is developed.

MATERIALS AND METHODS

Chemicals and Samples. Analytical-grade chemicals were purchased from VWR International (Fontenay-sous-Bois, France). Purified chymosin (rennin from calf stomach) and porcine pepsin were purchased from Sigma-Aldrich (Saint Louis, MO, USA). Calf, kid, and lamb rennets, recombinant chymosin, bovine pepsin, and microbial coagulants were obtained from different suppliers (Chr. Hansen, Denmark; Danisco, Denmark; Laboratoires ABIA, France; Laboratoire Central des Présures S.A.S., France; and Österreichische Laberzeugung Hundsbichler GmbH, Austria).

Production, Purification, and Isotyping of mAbs. Immunization with chymosin was carried out by the foot pad route according to Jeanson et al.[19] Lyophilized chymosin (1.2 mg/mL in 10 mM phosphate-buffered saline pH 7.2 (PBS)) was 1.5-fold diluted in physiological water in order to obtain a 800 μg protein/mL solution. This solution was then emulsified 1:1 (v/v) in Freund adjuvant (Difco Laboratories, Detroit, MI, USA), complete for the first immunization, incomplete for the booster injection 14 days later. Fifty microliters of the emulsion (i.e., 20 μg of proteins) were injected into two female BALB/c mice (Iffa-Credo, St-Germain sur l'Arbresle, France) per foot pad. Three days after the booster injection, popliteal lymph nodes from immunized mice were removed and pooled. Lymphocytes were fused in a 5:1 ratio with Sp2/O-Ag14 myeloma cells using filter fusion according to Buttin et al.[20] Poly(ethylene glycol) (PEG 1000, Merck Millipore, Darmstadt, Germany) was allowed to permeate monolayers of mixed cells adsorbed on membrane filters. The fused cells were propagated in an azaserine/hypoxanthine (AH) selection medium containing 10% horse serum (Life Technologies SAS, Saint-Aubin, France) and plated in 48-well microculture plates incubated at 37 °C with a 6% CO_2 atmosphere. Culture supernatants of resulting hybridomas were collected during the log growth phase of cells and screened for the presence of antibodies that recognized chymosin by indirect ELISA. To avoid cross-reactivity, secreting hybridomas were also screened for bovine and porcine pepsins by indirect ELISA. Selected positive hybridomas were subsequently subcloned by the limiting dilution method and then cryopreserved in liquid nitrogen.

The ascites from the selected clones were obtained according to Jones et al.[21] and purified by a saturated ammonium sulfate (SAS) precipitation followed by affinity chromatography. Briefly, 75 g of ammonium sulfate were dissolved in 100 mL of distilled water at 80 °C and cooled. Four volumes of SAS were added drop to drop with gentle stirring to 6 volumes of ascite. Stirring was continued at 4 °C for at least 60 min; then the mixture was centrifuged at 3220*g* for 6 min at 4 °C. The supernatant was removed, and the precipitated fraction was suspended in 5 volumes of 100 mM phosphate buffer, 150 mM NaCl, pH 7.4. Then, 5 volumes of SAS were added as previously described, followed by a centrifugation at 3220*g* for 6 min at 4 °C. The supernatant was removed, and finally the precipitated fraction of immunoglobulins was suspended in 4 volumes of 100 mM phosphate buffer, 150 mM NaCl, pH 7.4. The resultant solution was dialyzed overnight at 4 °C in a dialysis bag (molecular weight cutoff 10 kDa) against 1000 volumes of 10 mM PBS, 150 mM NaCl.

To purify mAbs, affinity chromatography was used with a HiTrap NHS-activated HP column (GE Healthcare Bio-Sciences, Uppsala, Sweden) as described by Muller-Renaud et al.[22] Briefly, 50 mg of chymosin in 5 mL of coupling buffer (200 mM $NaHCO_3$, 500 mM NaCl, pH 8) were covalently immobilized on the column. Any excess active groups were deactivated by washing with 500 mM ethanolamine, 500 mM NaCl, pH 8.3, and the nonspecifically bound ligands were washed out with 100 mM acetate, 500 mM NaCl pH 4. One milliliter of ascitic fluid prepurified by SAS precipitation, diluted in 7 mL of running buffer (50 mM PBS, pH 7.3), was then injected. The column was washed with running buffer. Antichymosin mAbs were eluted with 10 mM glycine-HCl buffer, pH 2.1, and the eluted fraction was neutralized by the addition of 1:15 (v/v) 1 M Tris-HCl, pH 9. The purified mAbs were then divided into aliquots and stored at −20 °C. The isotypes of the produced mAbs were determined by a mouse monoclonal antibody isotyping kit (RD-Biotech, Besançon, France) according to the manufacturer's instructions.

All animals were maintained in accordance with the French Ministry of Agriculture ethical guidelines for the care and use of laboratory animals (B 21 231 010 EA).

Characterization of mAbs. *By Indirect ELISA.* Culture supernatants were screened by indirect ELISA to assess their specificity for chymosin and their possible cross-reactivity against other milk-clotting enzymes: rennets from different animal sources (calf, kid, and lamb), recombinant chymosin, bovine and porcine pepsins, and microbial coagulants. Microtiter plates (NUNC F96 Maxisorp, 4000 Roskilde, Denmark) coated with 100 μL/well of milk-clotting enzymes (1 μg/mL in 100 mM sodium bicarbonate buffer, pH 9.6 (CB)) were incubated for 90 min at 37 °C. The remaining binding sites were blocked by incubation with 10 g/L gelatin (Merck Millipore, Darmstadt, Germany) in PBS 0.05% Tween 20 (PBS-T) (250 μL/well) for 1 h at 37 °C. Culture supernatants (100 μL/well) previously diluted 1:2 in PBS-T were then added. After 1 h of incubation at 37 °C, 100 μL/well of donkey antimouse immunoglobulin alkaline phosphatase conjugate (Jackson Immunoresearch, Interchim, Montluçon, France) diluted 1:3000 in PBS-T were added. Bound immunoglobulins were detected after 1 h of incubation at 37 °C. Between each incubation step, the plate was rinsed four times for 15 s with PBS-T (250 μL/well) using a HydroFlex microplate washer (TECAN, Männedorf, Switzerland). Finally, 100 μL/well of *p*-nitrophenyl phosphate (Interchim, Montluçon, France) containing 1 g/L of a solution of 1 M diethanolamine-HCl, 1 mM $MgCl_2$, and 0.1

DOI: 10.1021/acs.jafc.5b00990
J. Agric. Food Chem. 2015, 63, 4799−4804

mM zinc acetate were added to the wells. After 30 min, the absorbance at 405 nm ($A_{405\,nm}$) was read against a blank (substrate only) using a NanoQuant Infinite F200 Pro microplate spectrophotometer (TECAN, Männedorf, Switzerland).

By Western Blotting. Chymosin and milk-clotting enzymes were subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) using a 12% acrylamide Novex Tris-glycine gel (Life Technologies SAS, Saint-Aubin, France) according to the manufacturer's instructions. All samples were reduced before analysis using 100 mM DL-dithiothreitol and loaded onto each lane (10 μg/lane). Electrophoresis was performed at 125 V, variable intensity, for 2 h at 10 °C in 25 mM Tris, 192 mM glycine, 0.1% SDS buffer, pH 8.4. Precision Plus Protein Kaleidoscope standards (Life Technologies SAS, Saint Aubin, France) were used as the molecular-weight standard. Immediately after separation, proteins were transferred onto a 0.2-μm-pore-size nitrocellulose membrane (Protran BA83 NC, Whatman GE Healthcare Life Sciences − Europe GmbH, Velizy-Villacoublay, France) for immunoblotting using a TE22 Mighty Small Transfer Tank (Hoefer, Inc., Holliston, MA, USA) at 100 V, variable intensity, for 70 min at 10 °C in 25 mM Tris, 200 mM glycine, 0.01% SDS buffer in 200 mL/L ethanol. The immunodetection was performed as described by Dupont et al.[23]

By Biacore. Real-time binding assays between purified chymosin and purified mAbs were performed using a Biacore 3000 optical biosensor (GE Healthcare Life Sciences − Europe GmbH, Velizy-Villacoublay, France) equipped with a carboxymethyl-dextran-coated (CM5) research-grade sensor chip. The experiments were performed at 21 °C in HBS-EP running buffer (GE Healthcare Life Sciences). Standard amine coupling[24] was used to covalently immobilize rabbit antimouse antibodies (RAM) (GE Healthcare Life Sciences) at a final density of 10 000 response units (RUs). First, mAbs (20 μL) were injected over the RAM surface, and then 20 μL of purified chymosin, 1 mg/mL in HBS-EP buffer, was injected over the flow cell and were able to bind to mAbs in a continuous, pulse-free, controlled flow at a flow rate of 20 μL/min. Data were collected during the 60 s association and 100 s dissociation phases. Regeneration of the chip was achieved with 5 μL of 10 mM glycine-HCl buffer, pH 1.7. A flow cell saturated with 1 M ethanolamine was used as a reference for background subtraction and to check for nonspecific binding. Data analysis was performed using BIAevaluation v3.2 software (GE Healthcare Life Sciences). The binding ability of an mAb toward chymosin was defined as the percentage of chymosin bound compared to the theoretical maximum binding capacity of the mAb (R_{max}).[25]

Reactivity against Active Chymosin. The specificity of mAbs against active chymosin was evaluated by indirect ELISA against heat-treated rennet samples. Two different rennets, A and B, pH adjusted to 6.54, were split into four aliquots (500 μL). One aliquot was used as reference, and the other three aliquots were submitted to a heat treatment by incubation in a block heater (Lab-line, Thermo Fisher Scientific Inc., Ashville, NC, USA): 60 °C/2 min 30 s; 80 °C/2 min, and 100 °C/2 min. For each aliquot, indirect ELISA was performed as described previously, and the MCA was estimated as described in ref 9.

Quantitative Inhibition ELISA. ELISA plates NUNC F96 Maxisorp were coated with 1 μg/mL chymosin in CB (100 μL/well) and incubated for 1 h at 37 °C. Blocking of the remaining binding sites was performed as previously described. Serial dilutions of a rennet of known chymosin concentration (determined according to an IDF standard[16]) in PBS-T were used as standards (concentrations ranging from 0 to 20 000 ng/mL). The chymosin standards or the samples diluted in PBS-T (150 μL) were incubated in test tubes with 150 μL of purified antichymosin mAb (1:10 000 in PBS-T) for 1 h at 37 °C. The mixture (100 μL/well) was then added to the ELISA plate and further incubated for 1 h at 37 °C. The plate washing steps, the revelation of the reaction, and the measurement of the absorbance were performed as already described. The standard curve was obtained by plotting the $A_{405\,nm}$ obtained from each standard against its chymosin concentration (ng/mL). The unknown concentration of chymosin in samples was calculated from the standard curve and adjusted for the dilution factor. Each sample concentration resulted from the mean of three diluted samples analyzed in duplicate.

Validation of the Assay. Immunoassay validation was performed using the limit of detection (LOD), the limit of quantification (LOQ), the precision, and the accuracy. LOD and LOQ were expressed as the chymosin concentration corresponding to the average measured content of 20 blank samples plus 3 or 10 times the standard deviation (SD) of the average value, respectively.[26] The precision was expressed as the relative standard deviation (RSD), measured as the % ratio between the standard deviation of independent results and their mean value. It was estimated with independent results obtained by the same operator in 1 day on 10 successive analyses of the same rennet sample (intra-assay RSD) and on 12 analyses of the same rennet sample in a small time interval (interassay RSD). The interassay RSD was calculated for a low-chymosin rennet (179 mg/L) and a high-chymosin rennet (676 mg/L). All measurements were made in duplicate at three different dilutions. The accuracy was measured as the recovery of exogenous amounts of chymosin, 22, 45, 90, 225, and 450 mg/L, added to a rennet sample (179 mg/L). The accuracy was expressed as the % recovery between the ELISA value and the theoretical value ((detected concentration/concentration of added chymosin) × 100).

Statistical Analyses. Chymosin concentrations in commercial rennet samples determined by IDF standard chromatography[16] and inhibition ELISA were evaluated and compared using Deming regression analysis and the paired samples *t* test (Analyze-it 3.90.2, Analyze-it Software Ltd., U.K.). For Deming regression, the intercept value reflects the constant bias and the slope reflects the proportional bias. Agreement was considered to be good if the 95% confidence interval (CI) of the intercept and slope included 0 and 1, respectively.

RESULTS AND DISCUSSION

mAbs Production and Characterization. One fusion experiment yielded 847 hybridomas. Screening by chymosin-coated indirect ELISA allowed a selection of 42 clones which secreted chymosin-specific mAbs. These clones were used for further investigations based on mAbs specificity. The mAbs tested were of IgG isotypes: 60% IgG1, 20% IgG2a, and 20% IgG2b.

Cross-Reactivity Measurements. Cross-reactivity of mAbs was evaluated by indirect ELISA and immunoblotting against purified chymosin and other milk-clotting enzymes commonly used in cheese making: rennets extracted from different animal sources (calf, kid, and lamb), recombinant chymosin, bovine pepsin, porcine pepsin, and microbial coagulants. Specific mAbs recognized chymosin present in rennets from all of the different animal sources (calf, kid, and lamb) and in recombinant chymosins whereas no cross-reactivity was detected with bovine and porcine pepsins and microbial coagulants with both methods. As observed by immunoblotting (Figure 1), specific mAbs recognized a protein band of 35 kDa, which coincided well with the expected size of chymosin. mAbs also recognized minor bands between 35 and 25 kDa which were identified as degraded chymosin in rennets and recombinant chymosins.[27] These results indicated that mAbs were specific to chymosin whatever its source and thus were suitable for use in the immunoassay.

Binding Interactions between mAbs and Chymosin. To investigate the binding ability of selected mAbs to chymosin, mAbs were screened with a Biacore 3000 optical biosensor. An overview of the assay is shown in Figure 2. Late binding, at the end of the association phase, gives information about the affinity of chymosin for the bound mAb. Late stability, at the end of the dissociation phase, corresponds to the stability of the interaction between chymosin and the bound mAb. The best mAb for further ELISA development should present a high affinity for chymosin with a slow dissociation rate. The binding

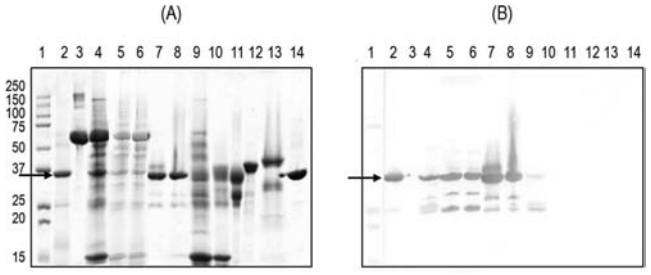

Figure 1. mAbs specificity was characterized by immunoblotting. (A) SDS-PAGE of different milk-clotting preparations. The amount of sample loaded onto each lane of the 12% gel was 10 μg. (B) Western immunoblot of the fractions obtained in (A) incubated with antichymosin mAb (1:1500). Band 1, protein molecular weight marker (kDa); band 2, purified chymosin (highlighted by an arrow); band 3, bovine serum albumin; band 4, calf rennet; band 5, lamb rennet; band 6, kid rennet; bands 7 and 8, recombinant chymosin; band 9, bovine pepsin/chymosin extract; bands 10 and 11, bovine pepsin; band 12, porcine pepsin; bands 13 and 14, microbial coagulants.

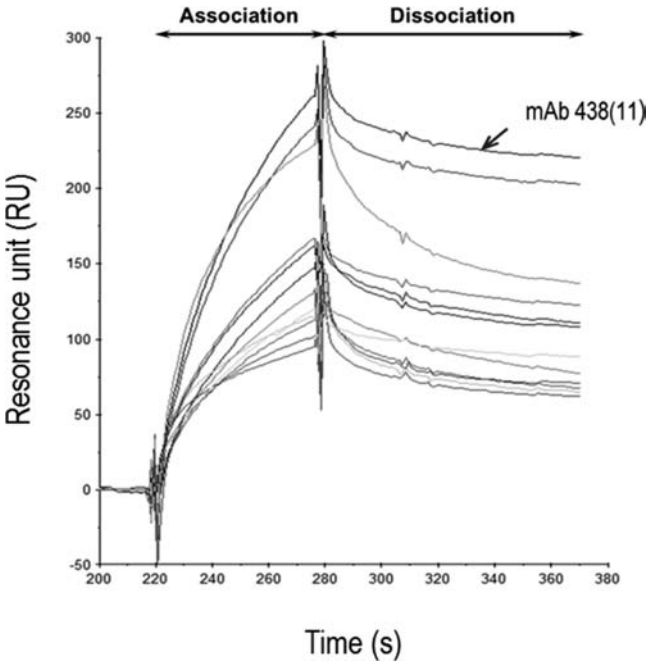

Figure 2. Association and dissociation curves for purified chymosin (1 mg/mL) binding to different mAbs. mAbs were bound to rabbit antimouse antibodies immobilized on a Biacore CM5 sensor chip. Data were collected during the 60 s association and the 100 s dissociation phases. In the association phase, chymosin interacts with the bound mAbs. In the dissociation phase, the complex resulting from the interaction starts to dissociate.

ability of mAbs was calculated from the binding of purified chymosin in percent of maximum theoretical binding, R_{max}. Assuming that the interaction between chymosin and mAb is monovalent, the binding abilities of the tested mAbs varied between 23.03 and 139.80% R_{max}. All tested mAbs were shown to bind to chymosin, but some mAbs had low binding abilities. Values >100% R_{max} may be attributed to the mass transport effect between the chymosin in the flow and the mAbs immobilized on the surface of the sensor chip which can potentially perturb the 1:1 interaction. Only mAbs with a binding ability of >85% R_{max} were kept for further analyses.

Thermal Inactivation of Chymosin. The MCA was affected by the temperature. Holding the rennet at 60 °C for 2 min 30 s decreased its MCA. The clotting time was higher for heat-treated rennet samples: 2.25 and 1.97-times higher for rennet A and B, respectively. A 2 min heating at 80 and 100 °C totally inactivated chymosin: no coagulation was observed after 6 h 30 min for both rennets. The optimum temperature for the coagulation of milk by calf rennet at pH 6.6 is around 45 °C.[5] Indirect ELISA performed on heat-treated rennets showed that the different mAbs tested were specific to chymosin in its active form (Figure 3). The absorbance decreased for high temperatures, 80 and 100 °C. At these temperatures, the inactivated chymosin was not detected by the different mAbs in rennet A but was partially detected in rennet B.

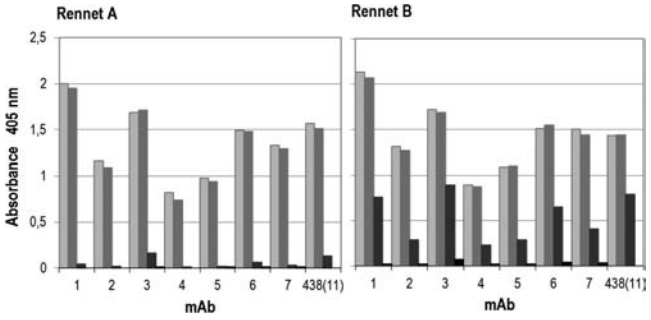

Figure 3. Reactivity of antichymosin mAbs evaluated by indirect ELISA against two different rennets submitted to heat treatment. (Light-gray) not heated; (medium-gray) 60 °C/2 min 30 s; (dark-gray) 80 °C/2 min; (black) 100 °C/2 min. The pH of rennet samples was adjusted to 6.54.

Finally, one positive clone named mAb 438(11) was selected for the development of the inhibition ELISA. This selected mAb was of the IgG1 isotype. It showed a high specificity for chymosin according to indirect ELISA and immunoblotting and a high binding ability toward chymosin according to Biacore results: 98.84% R_{max}.

Characteristics of the Assay. The assay was validated by investigating the LOD, the LOQ, the precision, and the accuracy. The standard curve for the quantification of chymosin was obtained from serial dilutions of a rennet of known chymosin concentration (Figure 4). A good linear correlation between $A_{405\,nm}$ and the chymosin concentration was represented by $A_{405\,nm}$ = 1.093−0.0005[chymosin], R^2 = 0.882, in the range of 200−2000 ng/mL. The LOD and LOQ were 125 and 400 ng chymosin/mL, respectively. The precision was measured by the relative standard deviation (RSD) of samples within and among runs. The RSDs within runs and among runs were 7.23 and 7.39%, respectively, for both low- and high-chymosin rennets, which indicated that there were minimum variations between wells and limited day-to-day variability. The assay had good precision values. Moreover, the level of precision of the immunoassay remained competitive compared to the standard chromatography: 7 vs 5%.[17] ELISA recovery values of chymosin from the spiked rennet samples ranged from 92 to 119% (Figure 5) with a mean recovery value of 102% for a chymosin range from 22 to 450 mg/L. Inhibition ELISA gave acceptable recovery efficiency. These results demonstrated the potential application of immunoassay for the quantification of chymosin in solution.

Application to Commercial Rennets. To assess the applicability of inhibition ELISA for quantification of chymosin

DOI: 10.1021/acs.jafc.5b00990
J. Agric. Food Chem. 2015, 63, 4799−4804

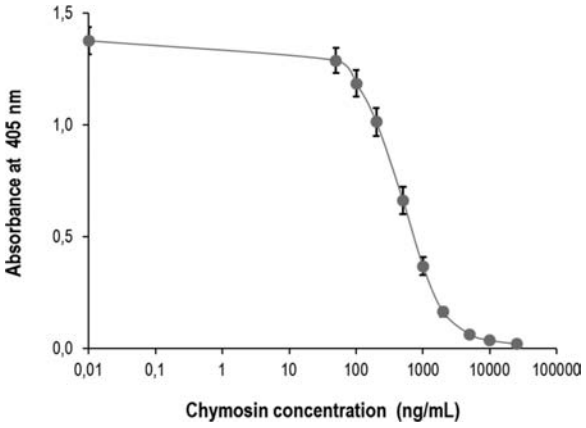

Figure 4. Representative chymosin standard curve obtained with the optimized ELISA. Data are summarized from seven independent curves generated over a 1 month period. The error bar represents the standard deviation of the mean.

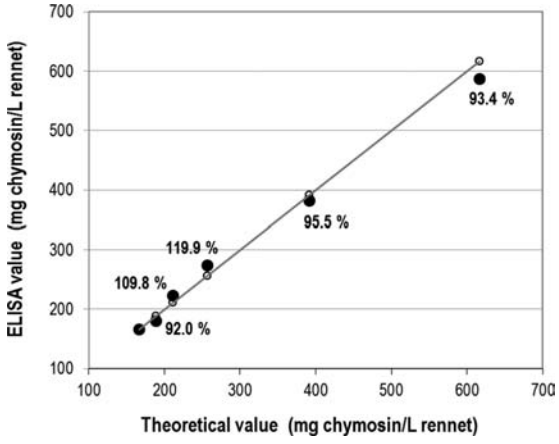

Figure 5. Recovery of chymosin (%) from artificially spiked rennet samples determined by ELISA. Five different amounts of chymosin (22, 45, 90, 225, and 450 mg/L) were added to a rennet sample.

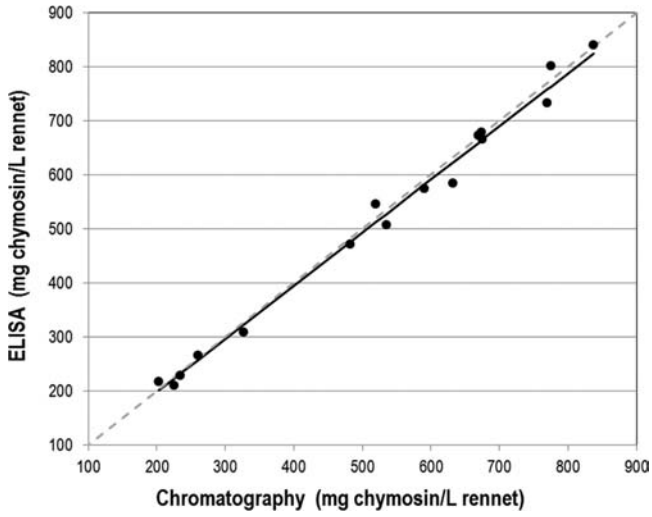

Figure 6. Deming regression fit between chymosin concentrations (mg/L) measured by inhibition ELISA and chromatography in different rennet samples. Sixteen commercial rennets over the range of 200 to 840 mg chymosin/L representative of the diversity available on the market were analyzed. The black line represents the fitted regression line ($[\text{chymosin}]_{\text{ELISA}} = 1.004 + 0.984\text{-}[\text{chymosin}]_{\text{chromatography}}$), and the dotted gray line represents the identity line (methods equal).

Table 1. Correlation between the Developed Immunoassay and the Standard Chromatographic Method by Deming Regression

parameter	estimate	jackknife 95% CI[a]	jackknife SE[a]	p value[b]
slope	0.984	0.922 to 1.045	0.029	0.575
intercept	1.004	−29.25 to 31.26	14.107	0.944

[a]Confidence intervals (CI) and standard errors of the parameter estimates (SE) were calculated with the jackknife (leave one out resampling) method. [b]Significantly equal to 1 (slope) and 0 (intercept): $p > 0.05$.

in solution, 16 commercial rennets, with low and high chymosin contents representative of the diversity available on the market, were analyzed. The concentration of chymosin in the samples was determined with both inhibition ELISA and standard chromatography.[16] Concentrations obtained by ELISA were statistically similar to concentrations obtained with the standard chromatographic method (Figure 6) using the Deming regression analysis, which considers both methods to be subject to measurement error whereas simple regression allows only the immunoassay concentration to be measured with error.[28] The Deming regression equation between ELISA and chromatography results was $[\text{chymosin}]_{\text{ELISA}} = 1.004 + 0.984[\text{chymosin}]_{\text{chromatography}}$ ($R^2 = 0.995$). The 95% CI for the slope and the intercept contained the values 1 ($p = 0.575$) and 0 ($p = 0.944$), respectively (Table 1). In addition to the Deming regression analysis, a comparative evaluation test was carried out to measure how different the immunoassay and the chromatographic method are. A paired-samples t test was performed with the following results: $t(15) = 1.34$, $p = 0.200$. These results indicated that there was no significant difference at the 5% significance level between the two methods. These statistical results indicated that the developed inhibition ELISA could be useful in quantifying chymosin in solution without any pretreatments and that it provided a noticeable advantage over methods requiring laborious pretreatment procedures.

In conclusion, a hybridoma cell line secreting mAbs specific to chymosin was obtained, and chymosin-specific mAbs were used to develop an inhibition ELISA for the quantification of chymosin in solution. The immunoassay has been characterized, optimized, and validated using rennet samples. The comparison of the developed inhibition ELISA with the reference chromatographic method showed the potential of the immunoassay. It provides a versatile alternative tool with high sample throughput and with no pretreatment of the sample for a direct quantification of chymosin, unlike the reference method which is a two-step method with time-consuming pretreatment procedures. Besides, work is underway to quantify (1) bovine pepsin in solution by ELISA in order to completely characterize rennets regarding their enzymatic composition and (2) residual chymosin in cheese by ELISA in order to characterize its remaining activity in the cheese.

Supporting Information

ABSTRACT: Colostrum oligosaccharides are known to exhibit prebiotic and immunomodulatory properties. Oligosaccharide composition is species-specific, and equine colostrum has been reported to contain unique oligosaccharides. Therefore, equine oligosaccharides (EMOS) from colostrum from different horse breeds were analyzed by CE-LIF, CE-MS^n, HILIC-MS^n, and exoglycosidase degradation. Sixteen EMOS were characterized and quantified, of which half were neutral and half were acidic. EMOS showed about 63% structural overlap with human milk oligosaccharides, known for their bioactivity. Seven EMOS were not reported before in equine oligosaccharides literature: neutral Gal(β1−4)HexNAc, Gal(β1−4)Hex-Hex, β4′-galactosyllactose, and lactose-*N*-hexaose, as well as acidic 6′-Sialyl-Hex-Ac-HexNAc, sialyllacto-*N*-tetraose-a, and disialylacto-*N*-tetraose (isomer not further specified). In all colostrum samples, the average oligosaccharide concentration ranged from 2.12 to 4.63 g/L; with β 6′and 3′- galactosyllactose, 3′-sialyllactose, and disialyllactose as the most abundant of all oligosaccharides (27−59, 16−37, 1−8, and 1−6%, respectively). Differences in presence and in abundance of specific EMOS were evident not only between the four breeds but also within the breed.

KEYWORDS: *milk, CE-MS, HILIC-MS, exoglycosidases, mass analysis, chromatography*

INTRODUCTION

Mammalian milk and colostrum contain many structures, which are essential for the nutrition and health of the suckling neonate. Throughout the past decades, specific oligosaccharides, which have been identified in milk and colostrum, have been shown to beneficially affect health.[1] For example, human milk oligosaccharides (HMOS) carrying the so-called bifidogenic factor (Gal(β1−3)GlcNAc) have been illustrated to enhance the growth of bifidobacteria in the intestine of neonates.[2] When bifidobacteria selectively ferment HMOS, they produce short-chain fatty acids (SCFA), leading to a pH decrease in the intestine. The lowered pH in the intestine creates a less favorable environment for the growth of the pathogens and stimulates the production of mucin, which in turn, enhances the host's resistance to infections.[3] The production of SCFA also leads to a stimulation of the immune system through a direct interaction with the immune cells of the intestine.[3,4] Moreover, increasing evidence has come forward to demonstrate direct immunomodulatory properties of oligosaccharides derived from milk and colostrum. Some properties could derive from interaction with specific receptors on intestinal epithelial cells and immune cells, such as carbohydrate receptors and Toll-like receptors.[4−6] In addition, milk oligosaccharides serve as soluble ligands for pathogens, preventing viral and bacterial attachment to the intestinal mucosa.[5]

The core structure of mammalian milk oligosaccharides (MMOs) is, in most cases, a lactose unit (Gal(β1−4)Glc) at the reducing end. However, in cow's, horse's, and goat's milk, *N*-acetyllactosamine (Gal(β1−4)GlcNAc) is also found at the reducing end instead of the lactose unit.[7,8] Starting from these disaccharides, glycosyltransferases can elongate the core structure with neutral and charged sugars. The neutral sugars that can be attached to the core structure are D-galactose (Gal), L-fucose (Fuc), *N*-acetylglucosamine (GlcNAc), and with the exception of HMOS, also *N*-acetylgalactosamine (GalNAc).[7]

The charged sugars that can decorate the core structure are sialic acids, both *N*-acetyl- and *N*-glycolyl-neuraminic acids, and glucose or *N*-acetylglucosamine substituted with one phosphoric group (e.g., in milk oligosaccharides of horses and cattle).[7−9] Depending on the linkage present in their chains, the MMOs are divided into two groups: Type I group contains Gal(β1−3)GlcNAc, and Type II group contains Gal(β1−4)GlcNAc.[10]

The reported mature-milk oligosaccharide concentration is 12−13 g/L for human milk and approximately 0.05 g/L for cow's milk.[8,11] The oligosaccharide concentration in colostrum is higher than the concentration in mature milk: 24 g/L in human colostrum and more than 1 g/L in cattle's colostrum.[7,12] So far, 43 equine milk oligosaccharides (EMOS) have been reported, of which 31 are neutral and 12 are acidic.[7,8,13] Compared to the HMOS, the EMOS have a higher degree of sialylation (20−30% and 60%, respectively)[11] and a lower degree of fucosylation (70% and 5%, respectively).[11] The previously documented EMOS showed a 17% overlap with oligosaccharides present in human milk. Although not reported so far, the presence and relative abundance of individual EMOS

may vary between individual animal breeds, comparable to the variations in HMOS in different human populations.[14−16]

This study focuses on the analysis of EMOS in colostrum samples of four different horse breeds: Dutch Warmblood horse, Shetland pony, Crossbred Arabian/New Forest pony, and Friesian horse. After isolation from the colostrum samples, the EMOS were identified and quantified, highlighting the interbreed (EMOS for the different horse breeds) and the intrabreed (EMOS for the same breed) variations.

MATERIALS AND METHODS

Materials. Colostrum samples of horses belonging to four different breeds were obtained from private Dutch owners with consent. Five colostrum samples were available for the Crossbred Arabian/New Forest pony (Nederlands Rijpaarden and Pony Stamboek), four colostrum samples were available for the Dutch Warmblood horse (Royal Warmblood Studbook of The Netherlands), two colostrum samples were available for the Friesian horse, and one colostrum sample was available for the Shetland pony. Each colostrum was collected within 12 h postpartum and frozen (−20 °C) until use.

The standards 3′-, and 6′-sialyllactose, 3′-, and 6′-sialyl-*N*-acetyllactosamine, lacto-*N*-tetraose, sialyllacto-*N*-tetraose-a, and lacto-*N*-hexaose were purchased from Dextra Laboratories (Reading, U.K.). The standards β 3′-, 4′- , and 6′-galactosyllactose, lacto-*N*-tetraose, and lacto-*N*-neotetraose were bought from Carbosynth (Compton, U.K.). The labeling of the oligosaccharides was accomplished using the Carbohydrate Labeling and Analysis Kit (Beckman Coulter, Fullerton, CA, U.S.A.). All other chemicals used were of analytical grade. Millipore water (Millipore, Darmstadt, Germany) was referred to as water in the text.

Extraction of Equine Colostral Sugars. The Dutch Warmblood colostrum samples were available in larger quantities than those of other breeds. Therefore, a mixture of the Dutch Warmblood colostrum samples was used to optimize the extraction method and to obtain enough material to be loaded in the preparative Size Exclusion Chromatography. Specifically, 1.25 mL of each colostrum sample was pooled together and mixed with a vortex for 2 min. After method optimization, EMOS were extracted from 1 mL of the 12 individual colostrum samples. The optimized sugar extraction from the colostrum samples was performed by modification of the method of Nakamura et al.[13] Briefly, colostrum (5 mL) was treated with 4 volumes of chloroform. After 2 h of head over tail mixing, the sample was centrifuged (5000*g*, 30 min, 5 °C), and the supernatant was treated with 2 volumes of methanol. After the same mixing and centrifugation procedure, the methanol−water solution was concentrated by vacuum evaporation. The remaining water solution was freeze-dried.

Purification and Fractionation of EMOS. Size Exclusion Chromatography (SEC) was used to remove lactose from the extracted carbohydrates of the pooled Dutch Warmblood colostrum, in order to obtain pools containing EMOS with difference degrees of polymerization (DP). In total, four pools were obtained, and they were analyzed for the characterization of the EMOS. The fractionation was carried out at 35 °C on three Superdex 30 Hiload 26/60 preparative grade columns (GE Healthcare, Pittsburgh, PA, U.S.A.) connected in series on a AKTA Purifier (GE Healthcare). After manual injection, the EMOS (200 mg) were eluted with water containing 0.5% (v/v) EtOH and collected in 9 mL fractions. The fractions were pooled as follows: pool 1: 290−492 mL, pool 2: 493−688 mL, pool 3: 689−730 mL, and pool 4: 731−758 mL. Using water solution as eluent, charged oligosaccharides were excluded from the column material and were eluted first. Neutral oligosaccharides were instead fractionated based on their size. Lactose and monomers were the last to be eluted and were excluded from further analysis. The neutral oligosaccharides were pooled according to the retention times shown by a mixture of neutral galacto-oligosaccharides (DP from 1 to 6) (Vivinal GOS syrup) (FrieslandCampina Domo, Borculo, The Netherlands), which was considered a reference for its retention time. After freeze-drying, the resulting powders were rehydrated with 1 mL of water prior to analysis.

Solid Phase Extraction (SPE) was used to reduce the lactose content from the 12 individual colostrum samples. The extracted carbohydrates (1 mg) were solubilized in 1 mL of water and loaded onto activated graphitized carbon cartridge (150 mg bed weight, 4 mL tube size; Grace, Deerfield, IL, U.S.A.). Elution with water (1.5 mL) was used to remove salts, and 2% (v/v) acetonitrile (ACN) (1.5 mL) was used in order to elute monomers and lactose. The EMOS, still bound to the graphitized carbon cartridge, were recovered with 1.5 mL of 40/60% (v/v) ACN/water solution containing 0.05% (v/v) trifluoroacetic acid. The obtained EMOS were dried overnight under a stream of nitrogen and subsequently solubilized in 0.5 mL of water.

Capillary Electrophoresis with Laser-Induced Fluorescent and Mass Spectrometry Detection. The EMOS fractionated either by SEC or SPE were labeled with a fluorescent label (9-aminopyrene-1,4,6-trisulfonate, APTS) for their analysis by capillary electrophoresis (CE) with laser-induced fluorescence (LIF) detection as reported previously with minor modifications.[17] Briefly, 100 μL of sample containing 5 nmol of xylose, as internal standard, was dried and labeled with APTS. Each oligosaccharide standard (10 nmol), containing 5 nmol of xylose, was labeled with the APTS and run together with the EMOS samples. The labeled samples were diluted 40 times before the analysis. The experiment was performed using a ProteomeLab PA 800 system (Beckman Coulter), equipped with a LIF detector (Beckman Coulter). During the run, the sample was loaded hydrodynamically (7 s at 0.5 psi) into a polyvinyl alcohol (NCHO) coated capillary (50 μm × 50.2 cm (Beckman Coulter). Resultant peaks were integrated manually using Chromeleon software 6.8 (Dionex, Sunnyvale, CA, U.S.A.). In the CE technique, the oligosaccharides are linked in a molar ratio of 1:1 with the fluorescent, negatively charged label (APTS). The resulting migration times of the linked oligosaccharides depend on their size and on their net charge.

The SEC-fractionated, labeled EMOS were also analyzed for their masses by the PA 800 plus system (Beckman Coulter) coupled to a Velos Pro mass spectrometer (LTQ Velos Pro ion trap MS, Thermo Scientific, Waltham, MA, U.S.A.), after 20 times dilution. The CE-MS^n experiment conditions were performed as reported by Albrecht et al.[18]

HILIC-ESI-MS^n. The EMOS pools, derived from SEC, were also analyzed through hydrophilic interaction liquid chromatography (HILIC) with mass spectrometry detection (MS^n) as described by Remoroza et al. with some minor modifications.[19]

Briefly, an Accela UHPLC system (Thermo Scientific) coupled to a mass spectometer (LTQ Velos Pro ion trap MS, Thermo Scientific) was used. The chromatographic separation was performed on an Acquity HILIC BEH Amide column (1.7 μm, 2.1 mm × 150 mm) combined with a Van Guard precolumn (1.7 μm, 2.1 mm × 5 mm; Waters Corporation, Milford, MA, U.S.A.). The acquisition time was 72 min, and the eluents had a flow rate of 600 μL/min. The injection volume was 5 μL. The composition of the three mobile phases were (A) water with 1% (v/v) ACN, (B) 100% (v/v) ACN and (C) 200 mM ammonium formate (pH 3.0). The elution program was performed as follows: 2 min isocratic 80% B; 58 min linear gradient from 80% to 30% B; followed by 12 min of column washing with a linear gradient from 30% to 20% B and column re-equilibration form 20 to 80% B. The eluent C was kept at 5% during the elution.

Exoglycosidase Degradation. To determine the linkage type of the sialic acid decorating the EMOS, two types of sialidases were used: Sialidase S and Sialidase T (ProZyme, Hayward, CA, U.S.A.). Sialidase S is specific for the α2−3 linked neuraminic acid, while Sialidase T splits α 2−3 and α 2−6 linked neuraminic acid. For the structural analysis of the neutral EMOS Glyco(β1−3)galactosidase, Glyco(β1−4)galactosidase, Glyco(β1−4,6)galactosidase, and Glykoβ-*N*-acetylhexosaminidase (ProZyme) were used. All reactions were performed as suggested by the manufacturer. After the enzyme degradation at 37 °C overnight, the solutions were centrifuged (5000*g*, 5 min, 25 °C), and the supernatants were analyzed by HILIC-MS^n.

Quantification of the EMOS. In CE-LIF, the quantification of the oligosaccharides was enabled by the use of an internal standard and by a 1:1 stoichiometry between the oligosaccharide and the APTS

DOI: 10.1021/acs.jafc.5b01127

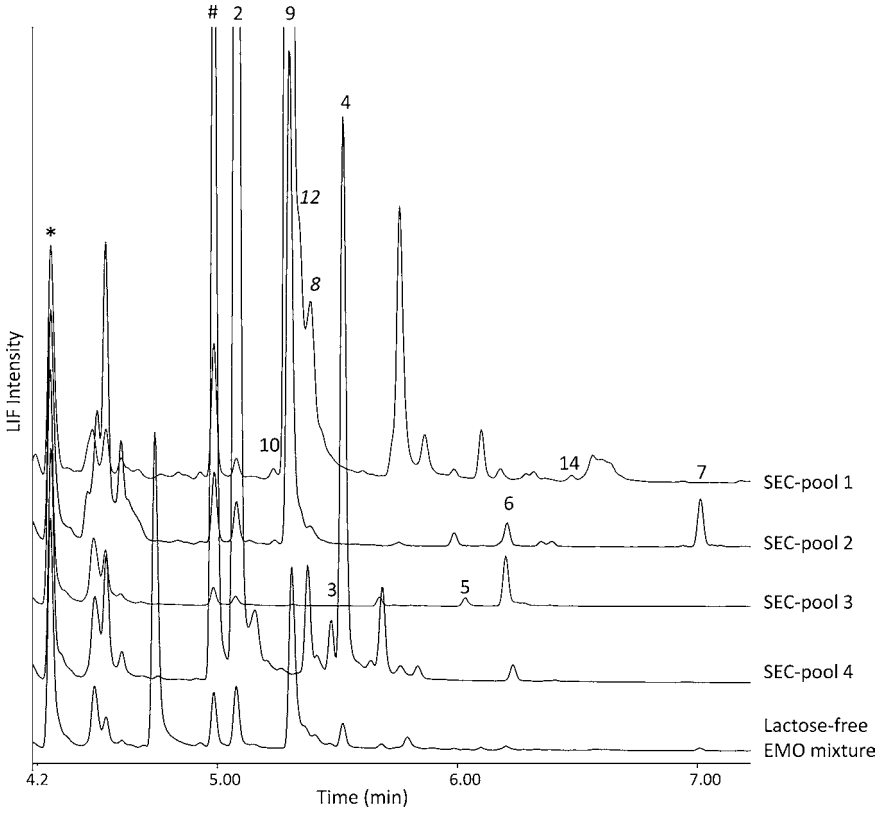

Figure 1. CE-LIF electropherograms of lactose-free EMO mixture and the EMO SEC pools 1−4. *: Internal standard xylose, #: Lactose, 1−14: identified peaks as named in Table 1

molecule. A linear correlation between concentration and CE-LIF peak area has been shown.[17] CE-LIF peak areas were converted to the corresponding EMOS nanomoles and their concentrations in the colostrum samples (g/L). The samples were run in duplicate, and the quantification was validated with the help of labeled neutral and acidic oligosaccharides standards. The quantification of 3′-sialyl-*N*-acetyllactosamine (3′-SLN) and Gal(β1−4)Hex-Hex, annotated by HILIC-MS^n and not assigned in the CE-LIF electropherograms, was performed with HILIC-MS^n. A calibration curve was made based on the peak areas in mass spectrometry of the 3′-SLN and β 4′-galactosyllactose (β 4′-GL) standards, respectively. The curves fitting the 3′-SLN and β 4′-GL standards had a linear correlation with R^2 of 0.997 and 0.998, respectively.

RESULTS AND DISCUSSION

Structural Characterization of the Equine Milk Oligosaccharides. In order to elucidate the structure of the EMOS, a colostrum mixture was prepared using Dutch Warmblood colostrum. After sugar extraction, part of the oligosaccharides was fractionated using Size Exclusion Chromatography (SEC). A lactose-free EMO mixture was obtained pooling part of the SEC fractions. Lactose-free EMO mixture and four SEC pools obtained were labeled with the fluorescent dye APTS and subsequently analyzed by CE-LIF and CE-MS^n.

In Figure 1, CE electropherograms of labeled lactose-free EMO mixture and SEC pools are shown. The migration times of labeled EMOS were compared with available standards and with HMOS elution patterns, which have been described in literature.[20] In total, 24 peaks were counted of which 11 peaks were annotated (numbers 2−14, Figure 1). Together with remaining lactose after SEC (symbol #, Figure 1), the annotation of five oligosaccharides was confirmed by CE-MS^n analysis. Acidic oligosaccharides were the first eluted from the SEC columns, and they were mainly pooled in pool 1. Pool 2 contained sialyllactose together with neutral pentamer and hexamer oligosaccharides. Pool 3 and pool 4 contained neutral tetramer and trimer, respectively.

In the CE-MS^2, the APTS-labeled oligosaccharides showed a specific fragmentation behavior due to the fluorescent molecule attached at their reducing end and a multiple charge state in their fragments spectrum. One example of CE-MS^n identification is given for lacto-*N*-novo-pentaose I, previously identified in equine milk, and shown in Figure 2.[8,21] APTS-lacto-*N*-novo-pentaose I loses one terminal galactose yielding a APTS-tetramer fragment, with m/z 573 and m/z 382, having charge states −2 and −3, respectively. The APTS-tetramer fragment loses a terminal galactose producing the fragment GlcNAc-Gal-Glc-APTS with m/z 492 and 328, having charge states −2 and −3, respectively. The GlcNAc-Gal-Glc-APTS subsequently forms APTS-lactose, with m/z 391, having charge state −2, via the loss of the terminal *N*-acetyl-glucosamine. From the fragmentation of the APTS-lactose, a molecule of APTS-glucose was formed, with m/z 310, having charge state −2.

In order to enhance the characterization of the EMOS, the mass analysis was also performed with HILIC-MS^n with non-labeled oligosaccharides obtained after SEC fractionations. With this technique, five more EMOS were annotated. All found molecules had a charge state of −1. One example for HILIC-MS^n identification of 3′-sialyl-*N*-acetyllactosamine (3′-SLN) is shown in Figure 3. Two peaks are highlighted for the sialyl-*N*-acetyllactosamine (Figure 3a). The highest peak refers to 3′-SLN, while the lowest peak refers to 6′-SLN. Each of the molecules were found as a double peak. It is hypothesized that

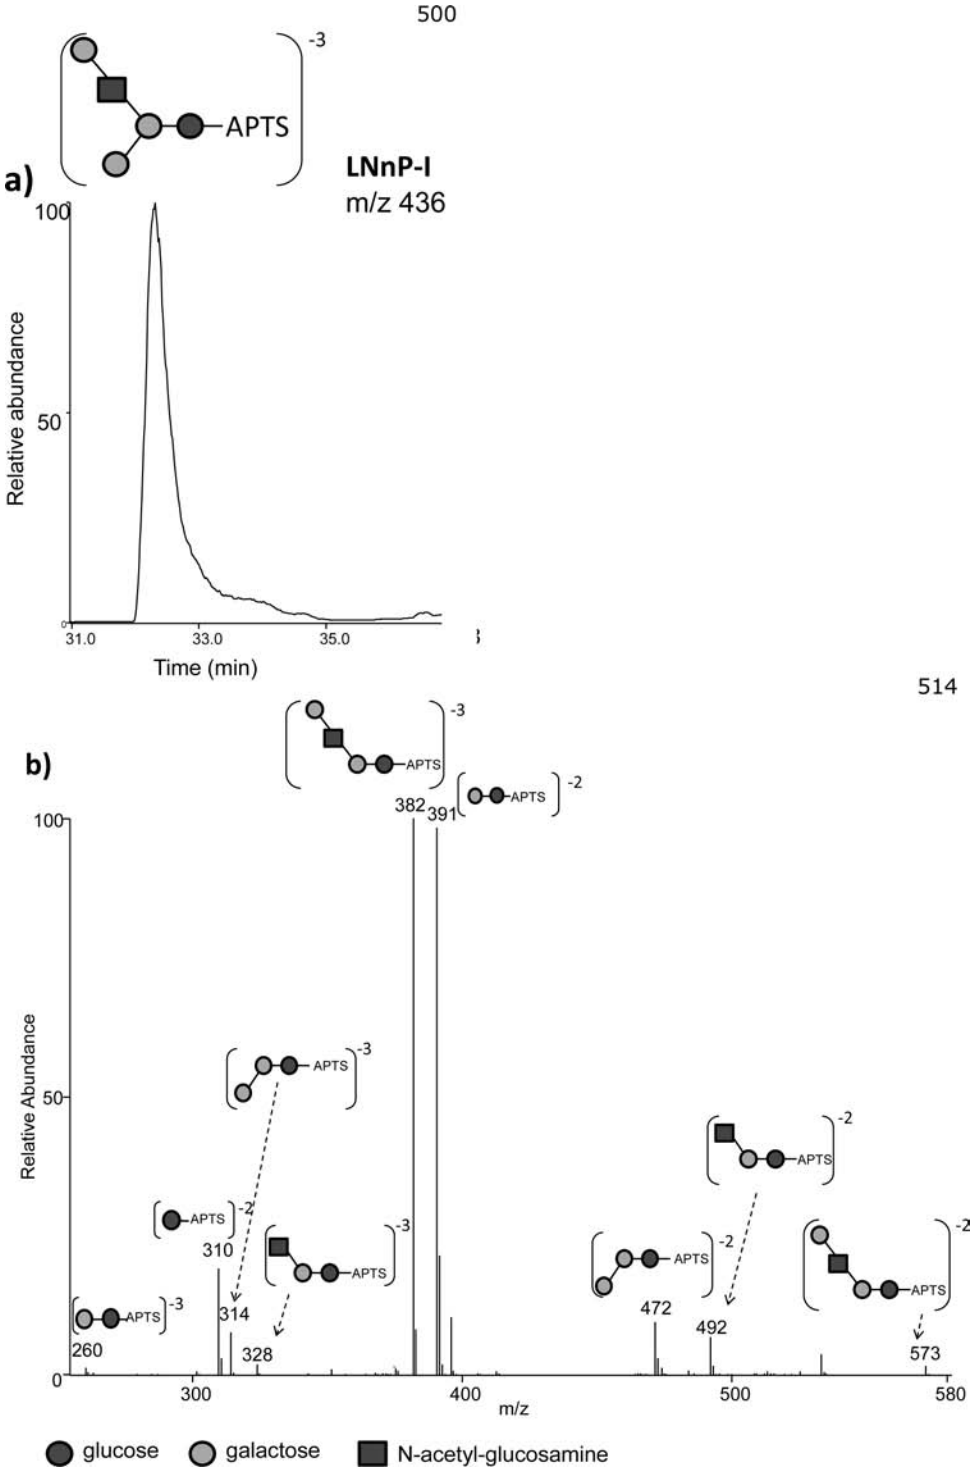

Figure 2. Selected base peak for the lacto-*N*-novo-pentaose-I (LNnP-I) in CE-MSn as present in lactose-free EMO mixture (a). Corresponding MS2 fragmentation patterns and structural composition of LNnP-I (b). m/z 436 precursor ion in CE-MS^n. [−2], [−3]: charge state of the molecules formed after fragmentation.

the double peaks correspond to the α/β conformation of the reducing end.[22] The MS^2 fragmentation of the 3′-SLN was compared with existing literature and with MS^2 fragmentation of available standard.[23] The 3′-SLN loses water (Figure 3b), forming thereby the fragment with m/z 655. A characteristic intraring fragmentation of the molecule leads to the formation of the fragment with m/z 572. The fragment with the highest intensity refers to the *N*-acetylneuraminic acid, with m/z 290.

With respect to four milk oligosaccharides, enzymatic degradation was necessary to determine their linkages. The neutral dimer Gal(β1−4) HexNAc and the trimer Gal(β1−4)Hex-Hex could be characterized only by using Glyco-galactosidases specific for β1−3, 1−4, and 1−4, 6 linkages, in addition to using the Glykoβ-*N*-acetylhexosaminidase. The acidic 6′-sialyl-Hex[Ac]-HexNAc and 3′-sialyllacto-*N*-tetraose a (LSTa), could be characterized only by using Sialidase S

(specific for the *α*2−3 linked *N*-acetylneuraminic acid), Sialidase T (specific for *α*2−3 and 6 linked *N*-acetylneuraminic acid), and Glyko*β*-*N*-acetylhexosaminidase. After their enzyme degradation, the samples were analyzed by HILIC-MS^n. As an example, Figure 4 illustrates the enzymatic degradation of Gal(*β*1−4)HexNAc and LSTa prior to analysis by HILIC-MS^n. The Gal(*β*1−4)HexNAc was found as double peak (Figure 4a), as consequence of *α*/*β* conformation of the reducing end. Using the enzymes tested, Gal(*β*1−4)HexNAc was digested by Glyco(*β*1−4)galactosidase (Figure 4b), while neither Glyco-(*β*1−3)galactosidase nor Glyko-*N*-acetylhexosaminidase showed any activity, indicating the presence of a *β*1−4 linked, terminal galactose. The LST molecule, as found in the mare colostrum samples, was digested by Sialidase S (Figure 4f), proving the presence of a terminal *N*-acetylneuraminic acid *α* 2−3 linked. Moreover, the identification of LSTa was confirmed by its migration time in CE, similar to commercially available LSTa standard (Table S1, Supporting Information).

Through the combination of CE and HILIC mass analysis and enzyme degradation of the SEC pools, it was possible to identify 16 EMOS. All identified EMOS are listed in Table 1, and an overview of methods used in order to characterize them (CE migration time, mass over charge values, and retention times in CE-MS^n, and HILIC-MS^n, and enzymes) are described in Supporting Information (Table S1). Comparing the outcomes of this study with previous data, seven EMOS were not reported previously and were presented in Table 1 in **bold**: the neutral oligosaccharides Gal(*β*1−4)HexNAc, Gal(*β*1−4)Hex-Hex, *β*4′-galactosyllactose, and lactose-*N*-hexaose, as well as the acidic oligosaccharides 6′-sialyl-Hex-Ac-HexNAc, LSTa, and disialylacto-*N*-tetraose (isomer not further specified).[7,8] Full identification was possible for six of the novel EMOS, while partial identification was possible for three of the novel EMOS. For 6′-sialyl-Hex-Ac-HexNAc, the presence of an additional acetyl group (Ac) was confirmed by mass fragmentation. An additional acetyl group linked to acidic milk oligosaccharides has previously been reported in equine colostrum.[8] The additional acetyl group was reported to be linked to the sialic acid group, while in our study it was found to be linked to the hexose moiety.

Comparison of the Equine Milk Oligosaccharides per Breed. After annotation of the EMOS, peaks in the CE-LIF electropherogram of the lactose-free EMO mixture were assigned. The peaks assigned were used as a reference for the identification of EMOS in the CE profiles of the 12 colostrum samples of the four horse breeds. In Figure 5, the EMO profiles of the four breeds are shown, including the peak assignments. The CE-LIF electropherograms of the labeled EMOS showed high reproducibility and high peak resolution.

Interbreed EMOS Comparison. The comparison of the EMO profiles for the four breeds (A, B, C, and D in Figure 5) reveals that the presence and relative abundance of the different oligosaccharides varied depending on the breed. Quantification was carried out after manual integration of CE-LIF peaks area. For two compounds, Gal(*β*1−4)Hex-Hex and 3′-sialyl-*N*-acetyllactosamine, the assignment in the CE-LIF EMO profiles was not possible. For these two molecules, the quantification was obtained with HILIC-MS^n.

The total concentrations of EMOS varied between the different colostrum samples: 4.63 g/L for the Shetland pony, 1.81−6.71 g/L for the Crossbred Arabian/New Forest ponies, 1.42−2.75 for the Dutch Warmblood horses, and 1.76−2.48 g/

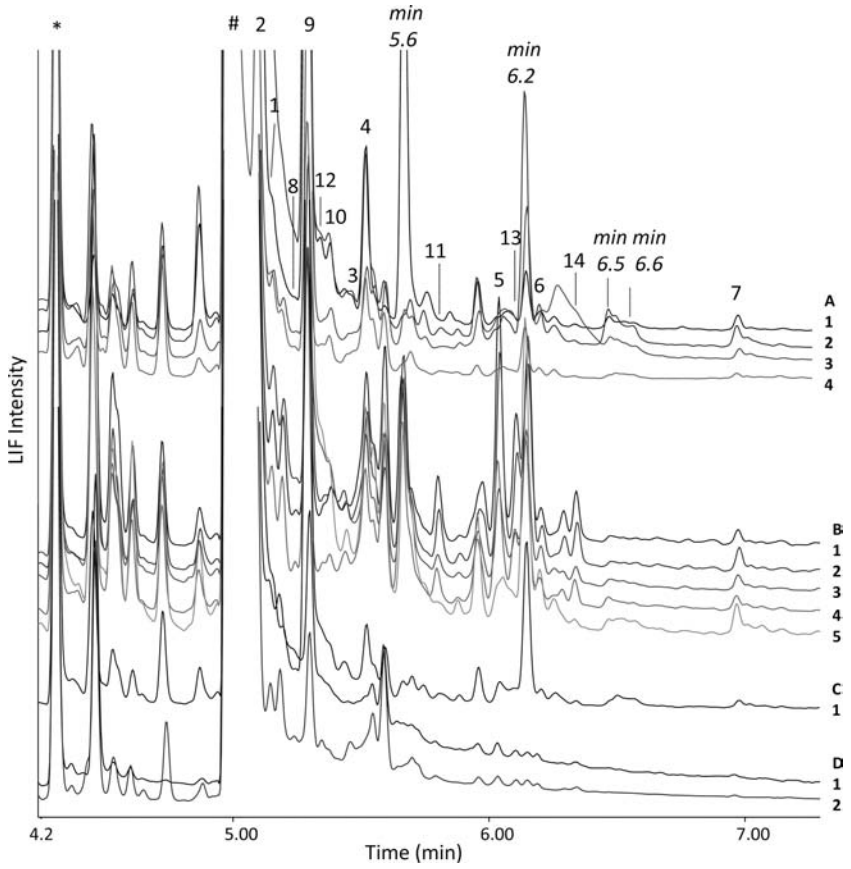

Figure 5. CE-LIF electropherograms of APTS-derivatized oligosaccharides for the four breeds. A: Dutch Warmblood horse; B: Crossbred Arabian/New Forest pony; C: Shetland Pony; D: Friesian horse. *: Internal standard xylose, #: Lactose, 1−14: identified peaks as named in Table 1

L for the Friesian horses (Table 1). Oligosaccharide concentrations found in this study are higher than concentration found in cow colostrum (about 1 g/L).[8] For other animals, the oligosaccharide concentration has only been reported for mature milks with levels (0.02 to 0.25 g/L), as expected, lower than the values obtained in this study for equine colostrum.[24] Although a large variation in the total concentration of EMOS was observed, it was noticed that the ponies' colostrum samples contained the highest concentration of EMOS, followed by the Dutch Warmblood horses' and the Friesian horses' colostrum samples.

Twelve out of the 16 EMOS were present in all colostrum samples. Gal(β1−4)Hex-Hex and 3′-sialyl-*N*-acetyllactosamine were absent in the Friesian horses' colostrum samples, β4′-galactosyllactose was absent in the Crossbred ponies' colostrum samples, and 6′-sialyl-*N*-acetyllactosamine was absent in the Dutch Warmblood horses' colostrum samples (Table 1).

In all breeds, the most abundant oligosaccharides were β3′-galactosyllactose, β6′-galactosyllactose, 3′-sialyllactose, and disialyllactose (numbers 2, 4, 9, and 12 in Table 1). The highest concentrations of β6′-galactosyllactose, β3′-sialyllactose, and disialyllactose were found in the colostrum sample of the Shetland pony (concentrations of 1.91 g/L, 1.73 g/L, and 0.23 g/L, respectively). These values for EMOS present in Shetland pony colostrum are only an indication, because only one colostrum sample was available for the analysis. The highest concentration of the β3′-galactosyllactose was found in the colostrum samples of the Crossedbred ponies, with an average concentration of 0.14 g/L.

In profiles A1 and B1−5 (Figure 5) high concentrations of non-characterized EMOS, migrating at 5.6 and 6.2 min, were observed. From the CE migration time, it could be suggested that these are neutral trimers and pentamers, respectively. The unidentified peaks with a retention time of 6.5 and 6.6 min (Figure 5), suggesting acidic or neutral hexamers, were present in all colostrum samples.

The oligosaccharide with the lowest observed concentration in all colostrum samples was 3′-sialyl-*N*-acetyllactosamine with an average concentration of 0.02 g/L.

Intrabreed EMOS Comparison. Evaluating the EMOS profiles within the same breed, differences were also noticed. Specifically, for the Dutch Warmblood profiles, β6′-galactosyllactose and 3′-sialylactose (numbers 2 and 9 in Table 1) were the most abundant oligosaccharides, and their concentrations varied by a factor 3.2 and 4, respectively. β6′-Galactosyllactose was present with a concentration of 0.65−2.08 g/L, while 3′-sialylactose with was present with a concentration of 0.29−1.16 g/L.

Looking at the overall electropherograms, the Crossbred ponies' colostrum samples contained the same EMOS structures, although they highly varied in concentration. β4′-Galactosyllactose, however, was not detected in three colostrum samples (B3−5, Table 1). In the Crossbred ponies' colostrum samples, similarly to the Dutch Warmblood horses' colostrum samples, the most abundant oligosaccharides were the β6′-galactosyllactose and the 3′-sialylactose. The β6′-galactosyllactose was present in a concentration of 0.55−3.15 g/L, while the 3′-sialylactose with was present in a concentration of 0.38−1.75 g/L, exhibiting a 5.7 and a 4.6 factor, respectively. Intrabreed

analysis showed relatively high variation in EMOS concentration (Table 1). Most probably the variation in EMOS concentration could be dependent on the intrinsic variation in composition and in quality of colostrum among individuals, as shown before for cow milk and colostrum.[25,26]

Presence of Equine Milk Oligosaccharides Structures in Comparison with the Profile in Milk of Other Mammals. Ten out of the 16 EMOS found in this study were also found in milk samples from other domestic animals (Table 2). So far, β6′- and 3′- galactosyllactose, 3′-sialylactose, and 3′-sialyl-*N*-acetyllactosamine have been found in bovine, caprine, and ovine milk, while 6′-sialyllactose and disialyllactose have been found both in bovine and caprine milk.[7,27] Lacto-*N*-hexaose was characteristic for caprine milk, while β4′-galactosyllactose, lacto-*N*-novo-pentaose I, and 6′-sialyl-*N*-acetyllactosamine were present in bovine milk.[7,9,27] Ten out of 16 milk oligosaccharide structures present in equine colostrum were previously reported to be present in human milk: the neutral trimers, tetramer, and hexamer, and the acidic 3′-, 6′-sialyllactose, tetramer, pentamer, and hexamer.[10,20]

The presence of milk oligosaccharides carrying the bifidogenic factor (Gal(β1−3)GlcNAc) (numbers 6, 7, and 13 in Table 1) and the presence of eight EMOS decorated with sialic acids suggest bioactivity of the EMOS, such as being bifidogenic and soluble ligands for intestinal pathogens.[2,28−31] In this study, EMOS decorated with *N*-glycolylneuraminic acid (Neu5Gc) were not detected, while they were reported to count for less than 1% in previous study.[8] The presence of Neu5Gc linked to milk oligosaccharides is not rare in oligosaccharides derived from domestic animals. For example, such oligosaccharides account for about 6% of the oligosaccharides in cows' colostrum.[8] On the contrary, milk oligosaccharides decorated with Neu5Gc are absent in human colostrum, which is considered as beneficial because blood antibodies against Neu5Gc are present in several diseases such as acute and chronic hepatitis, hyperacute transplant rejection, and cancer.[10,31−33]

In summary, oligosaccharide profile of colostrum from horses showed significant differences between breeds as well as per individual. EMOS identified showed quite some overlap with oligosaccharides present in milk from human and other mammals, although also horse specific structures were identified. The presence of EMOS carrying the bifidogenic factor and/or the *N*-acetylneuraminic acid, together with low concentrations of EMOS with *N*-glycolylneuraminic acid, could make equine colostrum a good source for further research into in vitro bioactive effects of milk oligosaccharides.

Supporting Information

ABSTRACT: The influence of green coffee genotype on the bioactive compounds and the in vitro antioxidant capacity against the principal reactive oxygen ($ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, and HOCl) and nitrogen ($NO^{\bullet}$ and $ONOO^{-}$) species of biological relevance was investigated. This is the first report on the capacity of green coffee to scavenge H_2O_2, HOCl, and $NO^{\bullet}$. Variations in the contents of total chlorogenic acids (22.9−37.9 g/100 g), cinnamoyl−amino acid conjugates (0.03−1.12 g/100 g), trigonelline (3.1−6.7 g/100 g), and caffeine (3.9−11.8 g/100 g) were found. Hydrophilic extracts of *Coffea canephora* and *Coffea kapakata* were the most potent scavengers of $ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^{-}$ due to their chlorogenic acid contents, which were, on average, 30% higher than those found in *Coffea arabica* and *Coffea racemosa*. The results showed that genotype is a determinant characteristic in the bioactive compound contents and consequently in the antioxidant capacity of green coffee.

KEYWORDS: *Rubiaceae, cultivars, varieties, germplasm bank, reducing capacity, phenolic compounds, methylxanthines*

INTRODUCTION

Coffee plants belong to the Rubiaceae family and to the genus *Coffea*, which has 103 species. *Coffea arabica* (arabica coffee) and *Coffea canephora* (robusta coffee) are the only species used for commercial production, representing about 60 and 40%, respectively, of the world coffee market.[1,2] The other coffee species, although having no commercial relevance, are important for genetic improvement of coffee plants, because they constitute gene reserves for resistance against pests, diseases, and adverse environmental conditions. Coffee species show considerable variation in their morphological, agronomical, and biochemical characteristics.[3] The biochemical differences are responsible for the variations in chemical composition of the coffee fruits and even between genotypes of the same coffee species.[3,4]

Green coffee beans are rich in bioactive compounds, with a highlight on caffeine, trigonelline, chlorogenic acids,[5] tocopherols (α, β, γ), and diterpenes (mainly kawheol and cafestol).[6] A number of health properties were reported for these specific compounds in the literature. Caffeine presents various biological activities such as stimulation of the central nervous system, diuretic effect, peripheral vasoconstriction, smooth muscle relaxation, and myocardial stimulation.[7] Trigonelline exerts antidiabetic action by decreasing serum glucose and increasing the insulin sensitivity index.[8] Chlorogenic acids have been related to a series of health benefits such as reduction in type 2 diabetes[9] and antihypertensive activity,[10] as well as antibacterial, anti-inflammatory[11,12] and antioxidant[13] activities. Vitamin E, represented by the tocotrienols and the tocopherols, is a potent antioxidant, anti-inflammatory, and anticarcinogenic agent.[14] Diterpenes present anticarcinogenic properties and stimulate the intracellular antioxidant defense mechanisms.[15]

The inverse relationship between the ingestion of foods rich in antioxidants and the decreased risk for the development of some chronic-degenerative diseases has already been well established.[16] Oxidative and nitrosative stress, resulting from a disequilibrium between the antioxidant defense of the cells and the generation of oxygen (ROS) and nitrogen (RNS) reactive species, causes damage to some important cell components, including lipids, proteins, and DNA. Due to these effects, oxidative and nitrosative stress can cause human diseases such as heart and degenerative diseases, diabetes, cancer, and nearly all liver pathologies and also take part in the aging process.[17,18] Antioxidants consumed in the diet are important to maintain the equilibrium of ROS and RNS, especially when the endogenous antioxidant defense system is not capable of efficiently deactivating the reactive species generated during oxidative and nitrosative stress.[18]

Several epidemiological studies indicated that the consumption of green coffee extracts had an antihypertensive effect in rats and humans,[19] improved vasoreactivity in humans,[20] had an inhibitory effect on the accumulation of fat and on the increase in body weight in rats and humans,[21,22] and modulated glucose metabolism in humans.[9] Health effects associated with coffee consumption largely depend on the bioacessibility and bioavailability of its bioactive compounds. After coffee ingestion, chlorogenic acids appear in the circulatory system as methylated, sulfated, and glucuronated metabolites in plasma concentrations that rarely exceeds nanomolar. Substantial quantities of both the parent compounds and their metabolites pass to the colon, where they are degraded by the action of the local microbiota, giving rise principally to small phenolic acid and aromatic catabolites that are absorbed into the circulatory system.[23] With regard to caffeine bioavailability, rapid absorption, metabolization, and

excretion of caffeine and its derived methylxanthines and methyluric acids have been observed after consumption of a green/roasted coffee product.[24] It is extremely important to take into account that the plasma antioxidant activity measured after the intake of coffee could be related to both the parent compounds and their metabolites.[23]

The bioactive compound profile of green coffee beans is mainly influenced by genetic aspects, such as species and variety, and by physiological aspects, such as maturity degree.[25] For example, green coffee beans from *C. canephora*, *C. liberica*, *C. congensis*, *C. eugenioides*, *C. stenophylla*, *C. racemosa*, and *C. kapakata* present considerable variation in their chlorogenic acid (3.29−6.22 g/100 dry weight) and caffeine (0.96−2.12 g/100g dry weight) contents.[3]

Considering the importance of the genotype on the bioactive compound contents of coffee endosperm and consequently on the antioxidant capacity of the coffee extract, in this work we first evaluated the influence of coffee genotype on the bioactive compound qualitative and quantitative profiles. Second, we evaluated the in vitro scavenging capacity of coffee genotypes against the main biological relevant ROS and RNS, namely, peroxyl radical ($ROO^{\bullet}$), hydrogen peroxide (H_2O_2), hydroxyl radical ($HO^{\bullet}$), hypochlorous acid (HOCl), nitric oxide radical ($NO^{\bullet}$), and peroxynitrite anion ($ONOO^{-}$). This is the first time that the capacity of green coffee to scavenge H_2O_2, HOCl, and $NO^{\bullet}$ is reported. In addition, we estimated the contribution of each bioactive compound (5-caffeoylquinic acid, caffeic acid, trigonelline, caffeine, and theophylline) to the antioxidant capacity of the hydrophilic extracts from the 12 evaluated coffee genotypes.

MATERIALS AND METHODS

Reagents. Caffeine, 5-caffeoylquinic acid (5-CQA), caffeic acid, *p*-coumaric acid, ferulic acid, trigonelline, theobromine, theophylline, trolox, ascorbic acid, quercetin, cysteine, and rutin standards were acquired from Sigma-Aldrich (St. Louis, MO, USA), presenting a minimum of 95% of purity as determined by HPLC-DAD. HPLC grade methanol, glacial acetic acid, and formic acid were acquired from J. T. Baker (Phillipsburg, NJ, USA), and analytical grade formic acid was from Merck (Darmstadt, Germany). Folin−Ciocalteu reagent, fluorescein, α,α'-azodiisobutyramidine dihydrochloride (AAPH), lucigenin, 30% hydrogen peroxide solution (w/v), luminol, dihydrorhodamine 123 (DHR), *N*,*N*-dimethylformamide (DMF), sodium hypochlorite solution with 10−15% available chlorine, 4,5-diaminofluorescein (DAF-2), and 3-(aminopropyl)-1-hydroxy-3-isopropyl-2-oxo-1-triazene (NOC-5) were acquired from Sigma-Aldrich. Sodium carbonate, sodium phosphate monobasic monohydrate, sodium phosphate dibasic, sodium hydroxide, sodium nitrite, sodium chloride, potassium chloride, and sodium carbonate were acquired from Synth (São Paulo, Brazil). Sodium phosphate tribasic dodecahydrate and 2-amino-2-(hydroxymethyl)-1,3-propanodiol (TRIS) were acquired from Sigma-Aldrich, ferrous chloride tetrahydrate was from J. T. Baker, and citric acid and ethylenediaminetetraacetic acid (EDTA) were from Quemis (Joinville, Brazil). Ultrapure water was obtained from a Millipore purification and filtration system (Billerica, MA, USA).

Coffee Samples. Twelve green coffee samples belonging to four different species were evaluated: one *C. kapakata*; one *C. racemosa*; three cultivars of *C. arabica*, Catuaí Vermelho IAC 144 (Caturra Amarelo IAC 476-11 × Mundo Novo IAC 374-19), IAC Ouro Verde (Catuaí Amarelo IAC H2077-2-12-70 × Mundo Novo IAC 515-20), and Tupi IAC 1669-33 (Vila Sarchi × Híbrido de Timor CIFC 832/2); and seven varieties of *C. canephora* (Robusta IAC 3597, Robusta IAC 1655, Robusta IAC 1650, Kouilou IAC 70-14A, Kouilou IAC 70-14B, Laurentii, and Bukobensis). The term "genotype" will be used to denominate the different species, cultivars, and varieties of coffee throughout this paper. Eight of the 12 evaluated coffee genotypes are commercially cultivated (3 *C. arabica* and 5 *C. canephora* of the varieties Robusta and Kouilou).

All of the plants are maintained in the Coffee Germplasm Bank and are cultivated in the experimental center of the Campinas Agronomy Institute (IAC) in Campinas, SP, Brazil, located at a latitude of 22°54′ S, a longitude of 47°05′ W, and an altitude of 640 m. Coffee fruits were harvested in the cherry maturation stage during the 2010/2011 harvest.

Sample Preparation. After harvesting, hulling, and manual removal of the mucilage, the coffee endosperms with their parchment were immediately frozen in liquid nitrogen. The parchment and silver skin were manually removed; the endosperms were frozen in liquid nitrogen and freeze-dried for 129 h at −65 °C below 40 μm Hg (Liobras, São Paulo, Brazil). The freeze-dried endosperms were ground, sieved through a 0.5 mm sieve (ABNT 35, Tyler 32), vacuum packed (Jumbo Plus, Selovac, São Paulo, Brazil) in polyethylene bags, and stored in the dark at −80 °C until extraction.

Preparation of Hydrophilic Extracts. The hydrophilic extract was obtained according to the method of Prior et al.[26] with some modifications. The freeze-dried ground coffee (2.0 g) was weighed in a 50 mL Teflon tube, defatted three times with 20 mL of hexane, and centrifuged (Beckman Coulter Allegra 64R, Palo Alto, CA, USA) at 9000*g* for 15 min at 20 °C, and the supernatants were discarded. The solid residue was extracted three times with 20 mL of an acetone/water/acetic acid solution (70:29.5:0.5, v/v/v). The extraction consisted of vortexing for 30 s followed by sonication for 4 min and finally centrifugation at 9000*g* for 15 min at 20 °C, collecting the supernatant. The three supernatants were combined in a round-bottom flask, and the organic solvent was removed in a rotary evaporator (T < 30 °C). The concentrated extract (aqueous phase) was frozen at −80 °C and freeze-dried for 120 h at −92 °C below 60 μmHg. After freeze-drying, the hydrophilic extract was transferred to an amber flask and stored at −80 °C.

The yield of the hydrophilic extract was calculated according to eq 1:

$$\text{yield (\%, w/w)} = \left(\frac{\text{mass of hydrophilic extract (g)}}{\text{mass of freeze-dried coffee (g)}}\right) \times 100 \quad (1)$$

Determination of the Hydrophilic Extract Composition by HPLC-DAD and HPLC-DAD-MS^n. The hydrophilic extract was suspended in a water/methanol (80:20, v/v) solution in the proportion of 5 mg of hydrophilic extract/1250 μL of solution, vortexed for 30 s, and centrifuged at 25000*g* for 10 min at 10 °C. The supernatant was filtered through a 0.45 μm membrane (Millipore, São Paulo, Brazil) and injected into a HPLC-DAD or HPLC-DAD-MS^n.

The quantitative analyses of the hydrophilic extract composition were carried out in a high-performance liquid chromatograph (HPLC, Shimadzu HPLC, Kyoto, Japan) equipped with a binary pump system (LC-10AD), helium gas degasser (DGU-2A), automatic injection system (SIL-10A), and diode array detector (DAD) (SPD-M10A). Trigonelline, theobromine, theophylline, caffeine, and the chlorogenic acids were separated on an ODS-C_{18} Shim-pack column (5 μm, 250 × 4.6 mm, Shimadzu) coupled to an ODS-C_{18} precolumn (5 μm, 4 × 3 mm, Phenomenex, Torrance, CA, USA), using a mixture of 80% (v/v) 10 mM citric acid (pH 2.5) and 20% (v/v) methanol (solvent A) and methanol (solvent B).[27] The gradient was programmed as follows: 100:0 (solvent A/solvent B) for 19 min, from 100:0 to 80:20 in 10 min, then to 60:40 in 15 min, maintaining this condition for 10 min, changing to 100:0 in 1 min, and finaly maintaining this proportion for 9 min. The flow rate was 1.0 mL/min and the column temperature 30 °C.

Trigonelline was quantified at 262 nm; theobromine, theophylline, and caffeine were quantified at 272 nm and the chlorogenic acids and caffeic acid at 325 nm. Quantitation was performed using analytical curves with six concentrations prepared in triplicate, and all of the analytical curves were linear (R^2 = 0.99, p < 0.05). The limits of detection (LOD) and quantification (LOQ) were calculated on the basis of the parameters of the analytical curves (Table S1 of the Supporting Information). The chlorogenic acids and their derivatives were quantified using the area of the 5-CQA standard combined with

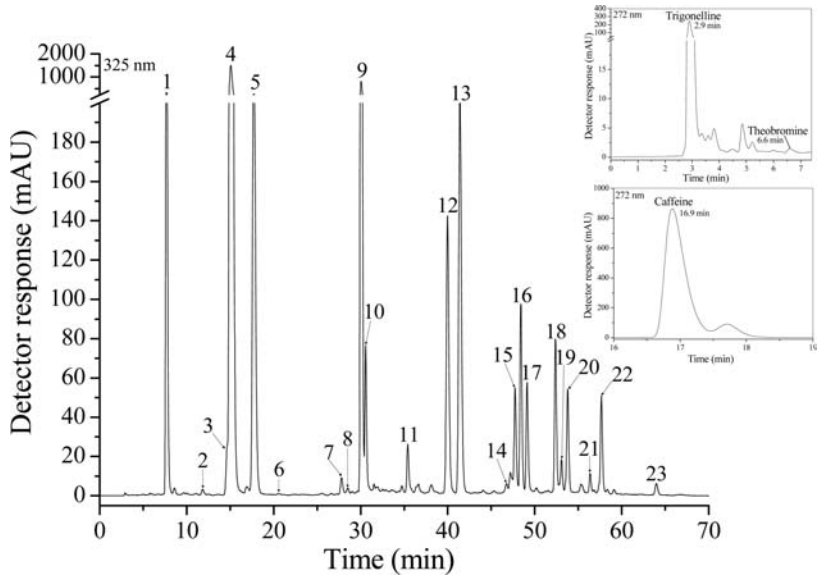

Figure 1. Chromatograms, obtained by HPLC-DAD, of the hydrophilic extract of *C. canephora* var. Kouilou IAC 70-14B recorded at 325 and 272 nm. Compound identification is shown in Table 1.

the molar extinction coefficients as described by Farah et al.[27] Due to the lack of a molar extinction coefficient for *p*-coumaroylquinic acid, this compound was quantified using the area of the 5-CQA standard. The cinnamoyl−amino acid conjugates were quantified using the molar extinction coefficient for 5-CQA as correction factor,[28] and caffeoylferuloylquinic, *p*-coumaroylcaffeoylquinic, dimethoxycaffeoylquinic, and dimethoxyferuloylquinic acids were quantified using the mean of the molar extinction coefficient of the three dicaffeoylquinic acid isomers.[29]

The compounds present in the hydrophilic extract were identified using an HPLC (Shimadzu) equipped with a quaternary pump (LC-20AD), an online degasser (DGU-20A5), a Rheodyne valve with a 20 μL sample loop, a DAD detector (Shimadzu, SPD-M20A) connected to a mass spectrometer (MS) with an electrospray ionization source (ESI), and an ion trap analyzer (Bruker Daltonics, model Esquire 4000, Bremen, Germany). The chromatographic conditions were the same as described for quantification analyses, except that citric acid in solvent A was substituted by 0.3% formic acid (pH 2.5) because citric acid generates fragments at m/z 191, which interfere in compound identification. The mass spectra were acquired in the range from m/z 70 to 600, and the parameters used were as follows: ESI in the negative mode, capillary voltage of 2500 V, drying gas (N_2) temperature of 310 °C and flow of 8 L/min, nebulizer = 30 psi, and the fragmentation energy of the MS^2 and MS^3 = 1.6 V.

Trigonelline, theobromine, theophylline, caffeine, 5-CQA, and caffeic acid were identified on the basis of the combined results of the following parameters: elution order on reversed phase column, cochromatography with standards and characteristics of UV−visible and mass spectra as compared with those obtained with the standards analyzed under the same conditions. The other chlorogenic acids and their derivatives, for which no commercial standards were available, were tentatively identified on the basis of their elution order on the reversed phase column and characteristics of UV−visible and mass spectra (m/z of the deprotonated molecule, fragmentation pattern of the MS^2 and MS^3 spectra) as compared to those found in the literature.[28,30−32]

Assays to Determine the Reducing Capacity and ROS/RNS Scavenging Capacity. The hydrophilic extract was suspended in the specific buffer solution for each method in the proportion of 5 mg of hydrophilic extract/1250 μL of buffer, vortexed for 30 s, and centrifuged at 25000*g* for 10 min at 10 °C, and the supernatant was used in the reducing capacity and ROS/RNS scavenging capacity analyses.

The assays were carried out in a microplate reader (Synergy Mx, Bio-Tek, Winooski, VT, USA) equipped with a thermostat and two reagent dispensers. The following control assays were carried out for all microplates: (i) without the addition of the radical generator or reactive species, such that no interaction between the probe and the extract was observed, and (ii) inclusion of an analytical quality control (positive control), that is, a compound with antioxidant capacity known to scavenge the specific reactive species. Each assay corresponded to three experiments carried out in triplicate. The variation in the responses of the positive controls was below 15% during the assays. With the exception of the reducing capacity and the $ROO^•$ scavenging assay, the results were expressed in IC_{50} values, calculated by nonlinear regression analysis using the software GraphPad Prism 5.03.

Reducing Capacity. The reducing capacity of the hydrophilic extract was determined using the Folin−Ciocalteu colorimetric method,[33] which was adapted for analysis using a microplate reader.[32] The reaction mixture contained the following reagents (final volume = 300 μL): hydrophilic extract dissolved in ultrapure water (33 and 73 μg/mL), Folin−Ciocalteu reagent (8.3%, v/v), and sodium carbonate solution (2.3%, w/v). The absorbance was monitored at 765 nm for 120 min at 25 °C, and quantification was done by way of an analytical curve for gallic acid in the range between 2 and 12.5 μg/mL, with the results expressed in milligrams of gallic acid equivalents per gram of extract (mg GAE/g).

Peroxyl Radical Scavenging Assay. The $ROO^•$ was generated by the thermal decomposition of AAPH at 37 °C. The $ROO^•$ scavenging capacity was measured by monitoring the effect of the hydrophilic extract on the fluorescence decay due to fluorescein oxidation induced by $ROO^•$.[34,35] The reaction mixture contained fluorescein (61 nM), hydrophilic extract (five concentrations, 0.5−5.2 μg/mL), and AAPH (19 mM) dissolved in 75 mM phosphate buffer (pH 7.4). The mixture was pre-incubated in the microplate reader during 10 min before AAPH addition. The fluorescence signal (excitation at 485 ± 20 nm and emission at 528 ± 20 nm) was monitored every minute until it reached 0.5% of the initial fluorescence signal. Quantification was carried out using an analytical curve for trolox in the range from 1 to 12 μmol, and the results were expressed in micromoles of trolox equivalents per gram of extract (μmol TE/g).

Hydrogen Peroxide Scavenging Assay. The H_2O_2 scavenging capacity was measured by monitoring the effect of the hydrophilic extract on reducing the luminescence resulting from lucigenin oxidation induced by H_2O_2.[34] The reaction mixture contained lucigenin (0.8 mM) and hydrophilic extract (five concentrations, 350−2400 μg/mL) dissolved in 50 mM Tris-HCl buffer (pH 7.4) and

1% H_2O_2 (v/v). The chemiluminescence signal was measured after 5 min of incubation at 37 °C.

Hydroxyl Radical Scavenging Assay. The HO$^\bullet$ was generated by the Fenton reaction ($FeCl_2$−EDTA−H_2O_2). The HO$^\bullet$ scavenging capacity was measured by monitoring the effect of the hydrophilic extract on reducing the luminescence resulting from luminol oxidation induced by HO$^\bullet$.[34] The reaction mixture contained hydrophilic extract (five concentrations, 0.4−8.0 μg/mL) dissolved in ultrapure water, luminol (20 μM) in 0.5 M carbonate buffer (pH 10), $FeCl_2$−EDTA (25 μM, 100 μM) solution in ultrapure water, and H_2O_2 (3.5 mM). The chemiluminescence signal was measured after 5 min of incubation at 37 °C.

Hypochlorous Acid Scavenging Assay. The HOCl scavenging capacity was measured by monitoring the effect of the hydrophilic extract on reducing the fluorescence resulting from the oxidation of DHR to rhodamine 123 induced by HOCl.[34] The HOCl was prepared by adjusting the pH of a 1% NaOCl (w/v) solution to 6.2 with 10% H_2SO_4 (v/v). The HOCl concentration was determined spectrophotometrically at 235 nm using the molar absorption coefficient of 100 M^{-1} cm^{-1}, and the other dilutions were made in 100 mM phosphate buffer (pH 7.4). The reaction mixture contained hydrophilic extract (five concentrations, 0.7−71 μg/mL), DHR (5 μM), and HOCl (5 μM) dissolved in 100 mM phosphate buffer (pH 7.4). The fluorescence signal (excitation at 485 ± 20 nm and emission at 528 ± 20 nm) was measured immediately after the addition of HOCl at 37 °C.

Nitric Oxide Scavenging Assay. NO$^\bullet$ was generated by thermal decomposition of NOC-5. The NO$^\bullet$ scavenging capacity was

[a]The results correspond to the average of triplicate ± standard deviation, expressed as mg/100 g of hydrophilic extract. Means with different letters in the same column are significantly different ($p < 0.05$). [b]CQA total, caffeoylquinic acid (sum of 3-CQA, 4-CQA, and 5-CQA). [c]FQA total, feruloylquinic acid (sum of 3-FQA, 4-FQA, and 5-FQA). [d]*p*-CoQA total, *p*-coumaroylquinic acid (sum of 3-*p*CoQA, 4-*p*CoQA, and 5-*p*CoQA). [e]di-CQA total, dicaffeoylquinic acid (sum of 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA). [f]CFQA total, caffeoylferuloylquinic acid (sum of 3C,4FQA, 3C,5FQA, 4F,5CQA, and 4C,5FQA). [g]CGA, total chlorogenic acid (sum of CQA, FQA, *p*-CoQA, di-CQA, CFQA, *p*-coumaroylcaffeoylquinic acid, and dimethoxycinnamoylquinic acid). [h]TCTrp, cinnamoyl−amino acid conjugates (sum of caffeoyltyrosine, caffeoyltryptophan, and *p*-coumaroyltryptophan). [i]nd, not detected (limit of detection, caffeic acid = 0.09 μg/mL).

measured by monitoring the effect of the hydrophilic extract in the reduction of the fluorescence resulting from the oxidation of 4,5-diaminofluoresceine (DAF-2) to triazolofluoresceine induced by $NO^{\bullet}$.[34] The reaction mixture contained DAF-2 (5 μM), hydrophilic extract (five concentrations, 0.7−85 μg/mL), and NOC-5 (60 μM) dissolved in 50 mM phosphate buffer (pH 7.4). The fluorescence signal (excitation at 485 ± 20 nm and emission at 528 ± 20 nm) was measured after 30 min of incubation at 37 °C.

Peroxynitrite Anion Scavenging Assay. The $ONOO^-$ scavenging capacity was measured by monitoring the effect of the hydrophilic extract on the reduction of the fluorescence resulting from the oxidation of DHR to rodamine 123 induced by $ONOO^-$.[34] The $ONOO^-$ was synthesized as previously described by Gomes et al.[36] The reaction mixture contained DHR (5 μM) in phosphate buffer (90 mM NaCl, 50 mM Na_3PO_4, 5 mM KCl, pH 7.4), the hydrophilic extract (five concentrations, 0.3−35 μg/mL) dissolved in phosphate buffer, and $ONOO^-$ (600 nM). The fluorescence signal (excitation at 485 ± 20 nm and emission at 528 ± 20 nm) was measured after 5 min of incubation at 37 °C. To simulate the physiological CO_2 concentration, an assay was carried out in parallel in the presence of 25 mM $NaHCO_3$.

Contribution of Each Bioactive Compound to the Antioxidant Capacity. The contribution of each bioactive compound (5-CQA, caffeic acid, trigonelline, caffeine, and theophylline) to the antioxidant capacity of the hydrophilic extract was calculated considering the antioxidant capacity of the extract, the antioxidant capacity of the analytical standard of each bioactive compound previously evaluated by Rodrigues et al.,[34] and the concentration of each bioactive compound present in the extract. In the assays of reducing capacity and $ROO^{\bullet}$ scavenging capacity, the percent contribution (a) was calculated using eq 2. In the assays of H_2O_2, $HO^{\bullet}$, HOCl, $NO^{\bullet}$, and $ONOO^-$ scavenging capacity, for which the antioxidant capacity was expressed as the IC_{50}, the following steps were used to calculate the percent contribution (b): (1) calculation of the concentration of the bioactive compound in the fraction of the hydrophilic extract responsible for inhibiting 50% of the probe oxidation (eq 3) and calculation of the decimal logarithm of this concentration; (2) calculation of the percent inhibition of the bioactive compound present in the extract using the equation of the dose−response curve obtained for each analytical standard (eq 4).

$$\%\ \text{contribution}\ (a) = \frac{[\text{concentration}] \times \text{reducing capacity of the standard}}{\text{reducing capacity of the extract}} \quad (2)$$

$$\text{concentration}\ (\mu\text{g/mL}) = \frac{[\text{concentration}] \times IC_{50}\ \text{of extract}}{100} \quad (3)$$

$$\%\ \text{contribution}\ (b) = 100/1 + 10^{(\log IC_{50} - X) \times \text{Hill slope}} \quad (4)$$

where [concentration] = concentration of the bioactive compound in the extract (g/100 g), log IC_{50}= logarithm of the IC_{50} of the analytical standard, and X = logarithm of the concentration of the bioactive compound present in the extract.

Statistical Analysis. The results obtained for the contents of bioactive compounds, reducing capacity, and ROS/RNS scavenging capacities of the hydrophilic extracts were submitted to an analysis of variance (ANOVA), and the means were compared by Tukey's test using Origin 8 software. The similarity of the hydrophilic extracts with respect to reducing capacity and scavenging capacity against ROS/RNS was determined using the method of hierarchical clustering by nonpondered average and the Euclidean distance as similarity index. The principal component analysis was applied to characterize the hydrophilic extracts according to their reducing capacity, scavenging capacity against ROS/RNS, and the content of bioactive compounds using Statistica 6.0 software. The reducing capacity and ROS/RNS scavenging capacity were used as the active variables. The chlorogenic acid (sum of caffeoylquinic, feruloylquinic, *p*-coumaroylquinic, dicaffeoylquinic, caffeoylferuloylquinic, *p*-coumaroylcaffeoylquinic, dimethoxycaffeoylquinic, and dimethoxyferuloylquinic acids), cinnamoyl−amino

acid conjugates (sum of caffeoyltyrosine, caffeoyltryptophan, and *p*-coumaroyltryptophan), caffeic acid, trigonelline, theobromine, theophylline, and caffeine contents were used as the supplementary variables in the derivation of the principal components, being projected in the same space.

RESULTS

Bioactive Compounds in the Hydrophilic Extracts. Figure 1 shows a typical chromatogram of the separation of trigonelline, theobromine, caffeine, and chlorogenic acids and derivatives in the hydrophilic coffee extract. A total of 23 hydroxycinnamic derivatives were identified and quantified in the hydrophilic extracts (Table 1), 19 being chlorogenic acids, 3 cinnamoyl–amino acid conjugates, and 1 free cinnamic acid. A detailed description of the identification of each hydroxycinnamic derivative by HPLC-DAD-MS^n in green coffee beans was previously presented in the literature, and the references for these papers can be found in Table 1. The UV–visible spectra of the compounds identified in hydrophilic coffee extracts are presented in Figure S1 of the Supporting Information. The nomenclature of all chlorogenic acid isomers cited in the present work was based on the recommended IUPAC numbering system.[37]

In general, the qualitative profiles of the bioactive compounds were similar in all of the coffee genotypes (Tables 2 and 3), and the differences occurred in relation to the concentrations of these compounds in the extracts. On average, the hydrophilic extracts of *C. canephora* (34.5 g/100 g) and *C. kapakata* (33.4 g/100 g) showed 30% more chlorogenic acids

DOI: 10.1021/acs.jafc.5b00530
J. Agric. Food Chem. 2015, 63, 4815–4826

than those of *C. arabica* (24 g/100 g) and *C. racemosa* (24.7 g/100 g) (Table 2).

In addition to the differences in total chlorogenic acid contents, differences were found in the contributions of the subgroups of the compounds making up the chlorogenic acids. For example, the subgroups CQA, FQA, *p*-CoQA, di-CQA, and CFQA represented, on average, 79, 6.7, 1.3, 12, and 0.4% of the total chlorogenic acid contents of the *C. arabica* extracts, whereas they represented, on average, 64, 17, 0.4, 14, and 3.6% of the *C. canephora* extracts. Among the chlorogenic acid subgroups, the elevated contents of FQA and CFQA in the *C. canephora* extracts stood out, being, on average, 4 and 12 times higher than the respective values found in the *C. arabica* extracts. On the other hand, the *C. arabica* extracts contained, on average, twice the amount of *p*-CoQA found in the *C. canephora* extracts. In general, the hydrophilic extracts presented 5-CQA, 5-FQA, 5-*p*CoQA, 3,5-diCQA, and 3C,5FQA as the majority isomers of each subgroup (Tables S2 and S3 of the Supporting Information).

The cinnamoyl−amino acid conjugates were not found in the hydrophilic extracts of *C. kapakata* or *C. racemosa*, and the contents found in *C. canephora* (832 mg/100 g) were, on average, 16 times higher than those found in *C. arabica* (51 mg/100 g) (Table 2). Caffeine was the major alkaloid found in the hydrophilic extracts of all the coffee genotypes studied (Table 3). *C. racemosa* beans presented a distinct behavior, because in addition to caffeine, which was the major alkaloid, the theobromine contents were, on average, 10 times higher than those found in C. *arabica* (Tupi cultivar) and *C. canephora* (Kouilou varieties). The hydrophilic extracts of *C. canephora* presented twice the amounts of caffeine found in the other coffee species. On the other hand, *C. kapakata* and *C. racemosa* stood out for their elevated contents of trigonelline.

Reducing Capacity and ROS/RNS Scavenging Capacity of the Hydrophilic Extracts. The 12 hydrophilic coffee extracts presented reducing capacity and were able to scavenge all of the evaluated ROS ($ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, and HOCl) (Table 4) and RNS ($NO^{\bullet}$ and $ONOO^-$) (Table 5), always in a dose-dependent manner and with IC_{50} values to the order of micrograms per milliliter. On average, the reducing capacity and $ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^-$ scavenging capacities of the hydrophilic extracts were, respectively, 3, 8, 6, 12, 17, and 8 times lower than that of the positive control used in each assay. On the other hand, the capacity of the hydrophilic extracts to scavenge HOCl was, on average, 6 times higher than that of the cysteine standard used as positive control.

The capacity of the hydrophilic extracts to scavenge $ONOO^-$ was also evaluated in the presence of $NaHCO_3$ with the objective of simulating the physiological CO_2 concentrations. Under this condition, the CO_2 could modulate the reactivity of $ONOO^-$ due to the rapid reaction between these two compounds, generating nitrogen dioxide radical ($NO_2^{\bullet}$) and the carbonate radical anion ($CO_3^{\bullet -}$), which are the main radicals responsible for the oxidation and nitration reactions observed in vivo.[38] In general, the hydrophilic extracts maintained their IC_{50} values in the assays carried out in the presence of $NaHCO_3$ (Table 5), indicating that they are also effective in scavenging $NO_2^{\bullet}$ and $CO_3^{\bullet -}$.

The antioxidant capacity of the hydrophilic coffee extracts was influenced both by the coffee genotype and by the evaluated reactive species. When the cluster analysis was applied using the reducing capacity and ROS/RNS scavenging capacity of the hydrophilic extracts as the variables, two large groups were formed (Figure 2). The first group was formed by the three *C. arabica* extracts and the *C. racemosa* extract. The second group was formed by the seven *C. canephora* extracts and the *C. kapakata* extract.

$^A IC_{50}$ = *in vitro* inhibitory concentration necessary to decrease by 50% the oxidative effect of the reactive species in the tested media (mean of triplicate ± standard deviation). Means with the different superscript letters at the same column are significantly different ($p < 0.05$).

The same two groups formed in the cluster analysis were also formed in the principal components analysis. The first group, formed by the three *C. arabica* extracts and the *C. racemosa* extract, was located to the right of the first principal component (PC1), and the second, formed by the seven *C. canephora* extracts and the *C. kapakata* extract, was to the left of PC1 (Figure 3c). The hydrophilic extracts from the second group presented higher reducing capacity and higher scavenging capacity against $ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^-$ than the hydrophilic extracts from the first group (Figure 3a,c). The higher capacity to scavenge these five reactive species was positively correlated with chlorogenic acid, cinnamoyl−amino acid conjugate, and caffeine contents (Figure 3b).

Estimate of the Contribution of Each Bioactive Compound to the Antioxidant Capacity. 5-CQA was mainly responsible for the reducing capacity and ROS/RNS scavenging capacity of the hydrophilic extracts, with the exception of HOCl (Table 6), among the five analytical standards of bioactive compounds present in the evaluated

hydrophilic extracts. Caffeic acid, trigonelline, caffeine, and theophylline did not contribute to the ROS/RNS scavenging capacity of the extracts, with the exception of the contribution of trigonelline to scavenge H_2O_2 (2.4−14.6%) and of caffeic acid to scavenge HOCl (1.5−2.0%).

DISCUSSION

Studies carried out with green coffee beans of the two main species cultivated in the world, *C. arabica* and *C. canephora*, showed that the *C. canephora* beans contained higher amounts of chlorogenic acids, cinnamoyl−amino acid conjugates, and caffeine.[29,39,40] The results of the present study confirmed this information and also showed that the quantitative profile of each chlorogenic acid subgroup was also an important factor in discriminating between *C. arabica*, *C. canephora*, *C. kapakata*, and *C. racemosa* beans. The chlorogenic acid subgroups that aided in the discrimination between the coffee species evaluated in this study were caffeoylferuloylquinic and feruloylquinic acids (both with higher contents in *C. canephora* beans) and *p*-coumaroylquinic acid (with a higher content in *C. arabica* beans). In addition, cinnamoyl−amino acid conjugates and caffeine (both with higher contents in *C. canephora* beans) and trigonelline (with a higher content in *C. kapakata* and *C. racemosa* beans) also contributed to differentiating among the species (Tables 2 and 3).

The quantitative profile of the bioactive compounds was also used to explain the high antioxidant capacity of the hydrophilic extracts from different coffee genotypes against $ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, HOCl, $NO^{\bullet}$, and $ONOO^-$ and possibly against $NO_2^{\bullet}$ and $CO_3^{\bullet-}$ (indirectly evaluated reactive species). The hydrophilic extracts of coffee could be considered potent antioxidants due to (i) the low IC_{50} values required to scavenge the reactive species, to the order of micrograms per milliliter, and (ii) the similar or higher antioxidant capacity when compared to coffee brews and fruit and plant extracts (with recognized antioxidant capacity against ROS and RNS IC_{50} values cited by Rodrigues et al.[34]).

The hydrophilic extracts from the seven *C. canephora* varieties and from *C. kapakata* stood out for their elevated reducing capacities and capacities to scavenge $ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^-$ (Figure 3). These green coffee hydrophilic extracts presented higher capacities to scavenge $ROO^{\bullet}$ (3.20−4.74 μmol TE/mg), $HO^{\bullet}$ (IC_{50} = 1.25−1.77 μg/mL), $NO^{\bullet}$ (IC_{50} = 6.11−9.96 μg/mL), and $ONOO^-$ (IC_{50} = 1.08−1.68 μg/mL) than mana-cubiu pulp extracts ($ROO^{\bullet}$, 0.32 μmol TE/mg; $HO^{\bullet}$, 36 μg/mL; $ONOO^-$, 20 μg/mL)[41] and artichoke leaf extracts ($NO^{\bullet}$, 5.5−11.0 μg/mL; $ONOO^-$, 3.4−5.1 μg/mL),[42] 5-CQA being the main phenolic compound identified in both of these extracts. The greater scavenging capacity of the green coffee hydrophilic extracts was probably related to their higher 5-CQA concentration (15−23%, w/w) when compared to mana-cubiu (0.4%, w/w) and artichoke (4.0−6.4%, w/w) extracts. In addition, the study of the estimated contribution of each bioactive compound to the antioxidant capacity showed that 5-CQA was the main component responsible for the scavenging capacity of the hydrophilic extracts against ROS and RNS (Table 6). In fact, 5-CQA was the major phenolic compound found in coffee, corresponding respectively to 52 and 68% of the total chlorogenic acids present in the hydrophilic extracts of *C. canephora* and *C. kapakata* (Table S2 of the Supporting Information).

This group of results indicates 5-CQA as the main contributor to the reducing capacity and $ROO^{\bullet}$, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^-$ scavenging capacities of coffee hydrophilic extracts. Some studies have reported the mechanism by which phenolic compounds such as 5-CQA scavenge some of these reactive species. Phenolic compounds can scavenge $ROO^{\bullet}$ and $HO^{\bullet}$ by transfer of hydrogen atoms or electrons and by addition to double bonds.[43,44] The three mechanisms can occur, but the $ROO^{\bullet}$ scavenging by phenolic compounds occurs mainly due to the transference of a hydrogen atom.[35]

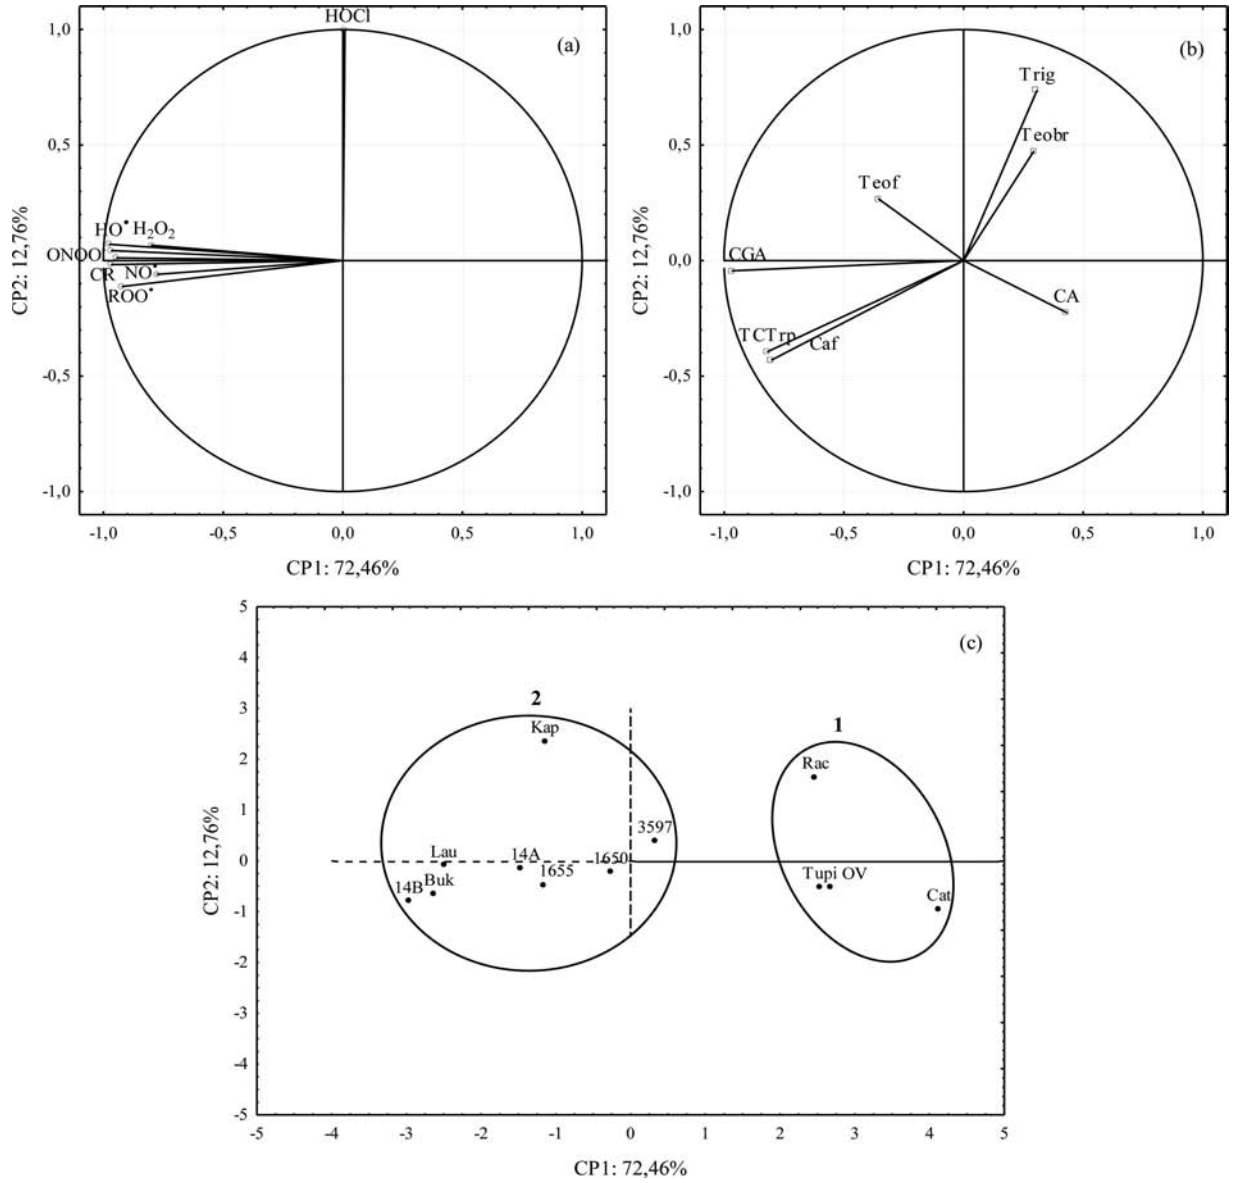

Figure 3. Principal component analysis of the reducing capacity and ROS/RNS scavenging capacity of hydrophilic extracts: (a) active variable projection; (b) supplementary variable projection; (c) scatter plot for the hydrophilic extracts. CR, reducing capacity; $ROO^{\bullet}$, peroxyl radical; H_2O_2, hydrogen peroxide; $HO^{\bullet}$, hydroxyl radical; HOCl, hypochlorous acid; $NO^{\bullet}$, nitric oxide; $ONOO^{-}$, peroxynitrite anion; CGA, chlorogenic acids; TCTrp, cinnamoyl−amino acid conjugates (caffeoyltyrosine, caffeoyltryptophan, and *p*-coumaroyltryptophan); CA, caffeic acid; Trig, trigonelline; Caf, caffeine; Teobr, theobromine; Teof, theophylline; Rac, *C. racemosa*; Tupi, *C. arabica* cv. Tupi IAC 1669-33; OV, *C. arabica* cv. IAC Ouro Verde; Cat, *C. arabica* cv. Catuaí Vermelho IAC 144; Kap, *C. kapakata*; 14B, *C. canephora* var. Kouilou IAC 70-14B; 14A, *C. canephora* var. Kouilou IAC 70-14A; Lau, *C. canephora* var. Laurentii; Buk, *C. canephora* var. Bukobensis; 1655, *C. canephora* var. Robusta IAC 1655; 1650, *C. canephora* var. Robusta IAC 1650; 3597, *C. canephora* cv. Robusta IAC 3597.

The literature has also reported the $ONOO^{-}$ scavenging capacity of phenolic compounds, which can occur by two mechanisms depending on the structural characteristcs of the phenolic compound. Monophenols, such as feruloylquinic and *p*-coumaroylquinic acids, act preferably by nitration, and the catechols, such as the caffeic, caffeoylquinic, and dicaffeoylquinic acids and the cinnamoyl−amino acid conjugates, act by electron donation.[45] On the other hand, the elevated reducing capacity of the hydrophilic extracts is related to the electron transfer mechanism carried out by the phenolic compounds. The study of reducing capacity is important because some ROS and RNS can be scavenged after they receive one or more electrons.

The compounds 5-CQA, 3-CQA, and 4-CQA are formed by the esterification of a caffeic acid molecule with quinic acid and present a catechol in their structure. The catechol group of the phenolic compounds has an important role in scavenging ROS and RNS, because it can act in the transference of hydrogen atoms and electrons. Other compounds containing catechol groups in their structures are also present in the green coffee hydrophilic extracts, such as dicaffeoylquinic acids, caffeoylferuloylquinic acid, caffeoyltyrosine, and caffeoyltryptophan. Within this group, the dicaffeoylquinic acids stand out because they present two catechol groups in their structure, conferring a high antioxidant capacity with respect to the radical DPPH and the superoxide anion radical.[46] This structural characteristic of the dicaffeoylquinic acids allied to an elevated concentration in the hydrophilic *C. canephora* and *C. kapakata* extracts (Table 2) probably contributed to the high reducing capacity and $ROO^{\bullet}$,

Table 6. Estimate (Percent) of the Contribution of the Standards of Each Bioactive Compound on the Reducing Capacity and ROS and RNS Scavenging Capacity of the Hydrophilic Coffee Extracts

scavenging capacity assay	5-CQA	caffeic acid	trigonelline	caffeine	theophylline
reducing capacity	53−74	0.03−0.07	NC	0.1−0.4	NC
$ROO^{\bullet}$	47−74	0.03−0.08	NC	0.01−0.02	NC
H_2O_2 [a]	15−26	NC	2.4−14.6	NC	NC
$HO^{\bullet}$ [a]	18−41	NC	NC	NC	NC
HOCl[a]	0.7−2.9	1.5−2.0	NC	NC	NC
$NO^{\bullet}$ [a]	9−25	0.08−0.39	NC	NC	NC
$ONOO^-_a$ [a]	36−48	0.06−0.22	NC	NC	NC
$ONOO^-_p$ [a]	33−49	0.004−0.02	NC	NC	NC

[a]The estimate is based on concentration necessary to decrease by 50% the oxidative effect of the reactive species in the tested media (IC_{50}). NC, no contribution; $ROO^{\bullet}$, peroxyl radical; H_2O_2, hydrogen peroxide; $HO^{\bullet}$, hydroxyl radical; HOCl, hypochlorous acid; $NO^{\bullet}$, nitric oxide; $ONOO^-_a$, peroxynitrite anion in the absence of $NaHCO_3$; $ONOO^-_p$, peroxynitrite anion in the presence of 25 mM $NaHCO_3$; 5-CQA, 5-caffeoylquinic acid.

H_2O_2, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^-$ scavenging capacities of these extracts.

The hydrophilic extracts were potent HOCl scavengers, presenting a scavenging capacity on average 6 times higher than that of cysteine, the positive control used in the method. Despite contributing <3% of the IC_{50} value, among the evaluted bioactive compounds 5-CQA and caffeic acid were the only ones that contributed to this ROS scavenging (Table 6). It has already been reported that phenolic compounds are capable of scavenging HOCl by donating two electrons from the phenolic ring, forming an *o*-quinone.[47] HOCl, an oxidant with two electrons, is particularly active with thiols and methionine residues and can also convert amine groups to chloramines.[48] Thus, the presence of other compounds capable of donating two electrons in the extract, such as proteins and amino acids, could explain the HOCl scavenging by the hydrophilic extracts.

The present work was focused on the screening of the in vitro scavenging capacity of hydrophilic coffee extracts against the main ROS and RNS produced in biological systems. Considering that each reactive species has specific chemical properties and distinct mechanisms of action, this screening becomes relevant in establishing the complete in vitro antioxidant capacity profile of hydrophilic green coffee extracts. On the other hand, this kind of assay presents some limitations; thus, the extrapolation of the in vitro antioxidant capacity to possible in vivo effects should always be made with extreme care. For instance, in general, the concentrations of bioactive compounds used in antioxidant capacity assays are higher than the physiological concentrations of these compounds in cells. Moreover, other bioactive compounds derived from the ingested compounds could be also bioavailable and possess antioxidant capacity.

The results of this study show that the genotype is a determinant factor in the bioactive compound contents and consequently in the antioxidant capacity of the green coffee. The hydrophilic extracts of *C. canephora* and *C. kapakata* were the most potent scavengers of $ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^-$ due to the fact that they contained, on average, 30% more chlorogenic acids than *C. arabica* and *C. racemosa*. Among the studied coffees, the species *C. canephora* and *C. kapakata* stood out as sources of hydrophilic antioxidant compounds for the food, pharmaceutical, and cosmetics industries. In addition, the study carried out to estimate the contribution of each bioactive compound in the antioxidant capacity of the hydrophilic coffee extracts showed that the chlorogenic acids and derivatives were responsible for the potent antioxidant capacity against the studied reactive species ($ROO^{\bullet}$, H_2O_2, $HO^{\bullet}$, $NO^{\bullet}$, and $ONOO^-$) and that HOCl was probably scavenged by the presence of other compounds in the extract, such as proteins and amino acids.

Lipid-Encapsulated Echium Oil (*Echium plantagineum*) Increases the Content of Stearidonic Acid in Plasma Lipid Fractions and Milk Fat of Dairy Cows

Melissa L. Bainbridge,[†] Adam L. Lock,[§] and Jana Kraft*[,†]

[†]Department of Animal Science, University of Vermont, 570 Main Street, Burlington, Vermont 05405, United States

Supporting Information

ABSTRACT: The objective of this study was to evaluate the impact of feeding lipid-encapsulated echium oil (EEO) on animal performance and milk fatty acid profile. Twelve Holstein dairy cows were used in a 3 × 3 Latin Square design with 14 day periods. Treatments were a control diet (no supplemental fat), 1.5% dry matter (DM) as EEO and 3.0% DM as EEO. Treatments had no negative effect on animal performance (dry matter intake, milk yield, and fat yield). The milk fat content of total n-3 fatty acids and stearidonic acid (SDA) increased with EEO supplementation ($P < 0.001$). The proportion of SDA increased in all plasma lipid fractions with EEO supplementation ($P < 0.001$). Transfer of SDA from EEO into milk fat was 3.4 and 3.2% for the 1.5 and 3% EEO treatments, respectively. In conclusion, EEO increases the content of n-3 fatty acids in milk fat; however, the apparent transfer efficiency was low.

KEYWORDS: *blood metabolites, γ-linolenic acid, bioactive fatty acids, plasma lipid fractions, transfer efficiency*

INTRODUCTION

The increased understanding of the relationship between nutrition and health has led to a growing interest in promoting functional foods enriched with bioactive compounds. One class of bioactive compounds is n-3 fatty acids (n-3 FA), which are known for their protective effects against inflammation,[1] neurological disorders,[2] and cardiovascular diseases,[3,4] as well as their importance to growth and development.[5] Current dietary sources do not meet the requirements for n-3 FA in the human diet,[6] driving the pursuit to develop functional foods enriched with n-3 FA.

The fatty acid profile of milk is predominantly influenced by the diet of dairy cows,[7] and research has demonstrated that FA derived from supplemental oils can be incorporated into milk fat.[8,9] There are several challenges, however, when supplementing dairy cows with oils rich in polyunsaturated FA (PUFA). One is the extensive biohydrogenation of dietary unsaturated FA by rumen bacteria, which often exceeds 85%.[10] This produces *trans*-fatty acid isomers that decrease lipogenesis in the mammary gland, leading to milk fat depression, and reduce the amount of unsaturated FA available to the mammary gland for milk fat synthesis.[10] Various protection methods have been developed to try to minimize ruminal biohydrogenation of feed-derived unsaturated FA, such as chemical treatment, calcium salt, protein aldehyde matrix, and encapsulation with saturated lipid. Hence, protecting n-3 FA from bacterial degradation in the rumen is essential to increase the amount of n-3 FA in milk while maintaining animal performance.[11]

Docosahexaenoic acid (DHA; 22:6 4*c*,7*c*,10*c*,13*c*,16*c*,19*c*) and eicosapentaenoic acid (EPA; 20:5 5*c*,8*c*,11*c*,14*c*,17*c*) are long-chain, highly unsaturated n-3 FA that are preferentially incorporated into plasma cholesterol esters and phospholipids.[12] Both plasma lipid fractions are unavailable to the mammary gland for production of milk fat,[13] resulting in a low transfer efficiency of EPA and DHA into milk.[14] Recent research demonstrates the two shorter carbon chain n-3 FA, *α*-linolenic acid (ALA; 18:3 9*c*,12*c*,15*c*) and stearidonic acid (SDA; 18:4 6*c*,9*c*,12*c*,15*c*), show similar health benefits to EPA and DHA.[15,16] SDA bypasses the initial rate-limiting step of *δ*-6-desaturase in the biosynthesis of EPA and DHA and, thus, is converted 4−5-fold more efficiently to EPA than ALA.[17] Moreover, recent research suggests that uptake of FA by the mammary gland is based on the fatty acid composition of plasma triacylglyceride (TAG), as an intravenous infusion of a TAG emulsion of ALA exhibited a higher transfer efficiency (28%) to milk fat when compared to DHA (11%).[18]

Echium oil (EO) from the seed of *Echium plantagineum*, a member of the Boraginaceae family, is a plant-based source of SDA (13% of total FA), ALA (31% of total FA), and *γ*-linolenic acid (GLA; 18:3 6*c*,9*c*,12*c*; 9% of total FA). GLA has been shown to possess anticarcinogenic and anti-inflammatory properties,[19,20] and several studies have shown the health benefits of echium oil, as well as its promise as an alternative to fish oils.[21,22] Kitessa and Young[23] demonstrated an increase in the n-3 FA content of milk with inclusion of a formaldehyde-treated EO on a pasture-based diet using five dairy cows. Lipid protection may provide more resilience against rumen biohydrogenation and thus may result in higher incorporation into milk fat.[11] There can also be considerable variation in response to supplementation depending upon basal diet and inclusion level;[24] thus, an evaluation of EO fed at incremental

levels on conserved forages is needed to determine the optimal inclusion rate for commercial feasibility. It is necessary to determine which plasma lipid fractions EO-derived FA are preferentially incorporated into and hence to what extent they can be incorporated into milk fat. We hypothesized that the inclusion of lipid-encapsulated echium oil (EEO) in the diet of dairy cows fed a total mixed ration (TMR) would increase the ALA, SDA, EPA, DHA, and GLA contents of milk fat. Our objectives were to (1) evaluate the effects of feeding an EEO supplement on milk production parameters, (2) determine the transfer efficiency of EO-derived FA to milk fat by supplementing incremental levels of EEO, and (3) assess the incorporation of EO-derived FA into plasma lipid fractions.

MATERIALS AND METHODS

Experimental Design. All experimental procedures were approved by the Michigan State Institutional Animal Care and Use Committee. Twelve multiparous Holstein dairy cows in late lactation (229 ± 62 DIM) were used in a 3 × 3 Latin Square design with 14 day experimental periods. Cows averaged body weights of 749 ± 69 kg and body condition scores of 3.56 ± 0.39 (1−5 in 0.25 increments[25]) at the start of the study. Diets were formulated to meet NRC (2001) nutrient requirements (Table 1) and fed as TMRs. Treatments were diets containing no supplemental fat (control; CON), diets supplemented with EEO at 1.5% of DM (low EEO; LEO), and EEO at 3% of DM (high EEO; HEO). EEO replaced soy hulls in the diet. EO was purchased from Technology Crops International (Winston-Salem, NC, USA) and lipid-encapsulated with hydrogenated vegetable oil by Jefo (Saint-Hyacinthe, Canada) using the spray cooling method with a prilling automizer. Lipid encapsulation technology is based on the inherent property of saturated lipids being resistant to enzymes in the rumen, yet susceptible to enzymatic digestion in the small intestine.[11] EO contained 35% ALA, 15% 18:1 9*c*, 15% SDA, 10% 18:2 9*c*,12*c*, 10% GLA, and 3% 18:0. The lipid-encapsulated supplement contained 25% EO, and the fatty acid profile of the supplement is presented in Table 2. A 10 day period before the start of the trial served as a preliminary period. Milk samples were collected during the last 3 days of this period, and cows were subsequently blocked by fat-corrected milk (FCM) yield and assigned to treatments. Cows were housed in individual tie stalls, blocked from feed at 8:00 a.m., fed once daily at 10:00 a.m., and milked twice daily at 4:00 a.m. and 3:00 p.m. Corn silage and alfalfa silage DM were determined twice weekly, and TMR was adjusted accordingly. Diets were fed ad libitum (12−17% orts) throughout the experiment. Fresh drinking water was available continuously.

Data and Sample Collection. Milk weights and samples were taken at each milking during the last 4 days of each period; an aliquot was preserved with 2-bromo-2-nitropropane-1,3-diol and analyzed for fat, protein, lactose, and milk urea nitrogen (MUN) by mid-infrared spectroscopy by the Michigan Herd Improvement Association (Universal Lab Services, Lansing, MI, USA). Another aliquot was stored at −20 °C without preservative for fatty acid analysis. Feed offered and refusals were weighed and recorded daily. Feed ingredients and TMR were sampled during the last 4 days of each period and stored at −20 °C until further analysis. Blood was collected from coccygeal vessels into evacuated tubes containing K_2EDTA (Becton Dickenson, Franklin Lakes, NJ, USA) at 9:00 a.m. on the last day of each period. Blood samples were placed immediately on ice, and plasma was obtained within 2 h of blood collection by centrifugation at 900*g* for 15 min at 4 °C and stored at −20 °C.

Feed and Orts Samples. Samples for each period were composited and dried in a forced-air oven at 65 °C for 48 h. Dried samples were weighed to determine dry matter and ground with a Wiley mill using a 1 mm screen (Arthur H. Thomas, Philadelphia, PA, USA). Individual feed ingredients and orts were analyzed for neutral detergent fiber (NDF) with heat-stable α-amylase and sodium sulfite,[26] crude protein (CP),[27] and starch composition[28] (Cumberland Valley Analytical Services Inc., Hagerstown, MD, USA). Reported NDF values are inclusive of ash. The fatty acid composition of feed samples was determined according to a modified method of Sukhija and Palmquist.[29] Glyceryl tridecanoate (Nu-Check Prep, Elysian, MN, USA) was used as an internal standard (1 mg/mL in acetone). Two milliliters of toluene and 2 mL of 5% methanolic sulfuric acid (Sigma-

[a]CON, control (0% of DM as lipid-encapsulated echium oil). [b]LEO, 1.5% of DM as lipid-encapsulated echium oil. [c]HEO, 3% of DM as lipid-encapsulated echium oil. [d]$\sum$ other, 12:0, 14:0, 15:0, *cis*-9 16:1, 17:0, *cis*-11 18:1, 20:0, 20:1 n-9, 21:0, 20:2 n-6, 22:0,22:1 n-9, 20:4 n-6, 23:0, 24:0. [e]Total SFA, sum of saturated fatty acids (4:0 to 26:0). [f]Total MUFA, sum of monounsaturated fatty acids (14:1 to 24:1). [g]Total PUFA: sum of polyunsaturated fatty acids (18:2 to 22:5).

Aldrich, St. Louis, MO, USA) were added to 500 mg of ground sample and shaken overnight at 50 °C. Samples were cooled to room temperature, and 5 mL of 5% sodium chloride solution and 2 mL of *n*-hexane were added. The extraction procedure was repeated twice with 1 mL of *n*-hexane each. The samples were washed with 4 mL of saturated potassium bicarbonate solution; the *n*-hexane phase was removed, dried over 1 g of anhydrous sodium sulfate, and purified using silica gel and activated charcoal. A 1% fatty acid methyl ester (FAME) solution was prepared in *n*-hexane, and samples were stored −20 °C until gas chromatography (GC) analysis.

Milk FA Analysis. Milk samples from the last 4 days of each period were composited by fat yield, and an aliquot was centrifuged at 17800*g* for 30 min at 8 °C to collect the cream. Milk lipids were extracted using the method of Hara and Radin,[30] and FAME were prepared by base-catalyzed transmethylation. Briefly, a total of 25 mg of lipid extract was solubilized in 2.5 mL of *n*-hexane, and 0.5 mL of 0.5 M sodium methoxide was added to the lipid solution and subsequently vortexed for 5 min. Following, enough sodium bisulfate monohydrate was added to the vial to cover the lower layer. The supernatant containing the FAME was transferred into a 2 mL vial and directly used for GC analysis.

Plasma Lipid Fraction FA Analysis. Plasma lipids were extracted according to the method of Folch et al.,[31] using chloroform/methanol in a 2:1 ratio (v/v). The chloroform layer, containing the lipids, was dried down under nitrogen gas, and the lipids were resuspended in 1 mL of *n*-hexane/methyl *tert*-butyl ether/acetic acid (100:3:0.3; v/v) and stored at −20 °C. Lipid classes were separated by solid-phase extraction (SPE) using aminopropyl cartridges (Fisher Scientific, Waltham, MA, USA). The columns (100 mg matrix) were preconditioned with 1.2 mL of acetone/water (7:1; v/v) and 4 mL of *n*-hexane prior to use. The lipid solution was loaded onto the column, and 14 mL of *n*-hexane was added to elute cholesterol esters (CE) at a flow rate of 0.3 mL/min. TAG were extracted with 8 mL of *n*-hexane/chloroform/ethyl acetate (100:5:5; v/v). The column was then washed with 6 mL of chloroform/isopropanol (2:1; v/v), and this solution was discarded. Free FA (FFA) were eluted in 8 mL of chloroform/methanol/acetic acid (100:2:2; v/v), and phospholipids (PL) were eluted by adding 10 mL of methanol/chloroform/water (10:5:4; v/v) to the column. All fractions except for the PL were dried down under nitrogen gas, redissolved in chloroform, and then stored at −20 °C until transesterification. PL were washed with 5% sodium chloride before being dried down under nitrogen gas and redissolved in chloroform and stored at −20 °C for further analysis. The TAG fraction was methylated with sodium methoxide as described above. PL, CE, and FFA fractions were methylated with 1 mL of sodium hydroxide at 100 °C for 10 min. One milliliter of 10% (w/w) boron trifluoride−methanol solution (Sigma-Aldrich) was added and incubated at 100 °C for 10 min. Once these fractions had cooled to room temperature, 2 mL of saturated potassium bicarbonate and 2 mL of *n*-hexane were added. The extraction step was repeated twice with 2 mL of *n*-hexane each and then transferred over anhydrous sodium sulfate. The samples were dried under nitrogen gas and resuspended in *n*-hexane to achieve a 0.1% FAME solution and stored at −20 °C for GC analysis.

Gas Chromatography. The total fatty acid composition covering ca. 110 FA in the range from C4:0 to C24:0, including branched-chain FA, isomers of octadecenoic acid (18:1) and conjugated linoleic acids (CLA), were determined by GC analysis of the FAME on a GC-2010 gas chromatograph (Shimadzu, Kyoto, Japan) equipped with a split injector (1:100 split ratio) and a flame ionization detector (FID) using an SP-2560 fused-silica capillary column (100 m × 0.25 m × 0.2 μm). Hydrogen was used as the carrier gas at a flow rate of 1 mL/min and for the FID at 40 mL/min. The other gases were purified air at 400 mL/min and nitrogen makeup gas at 30 mL/min. Injector and detector temperatures were kept at 250 °C. The oven program was as follows: initial temperature of 45 °C, held for 4 min, programmed at 13 °C/min to 175 °C, held for 27 min, then programmed at 4 °C/min to 215 °C, and held for 35 min[32] The injection volume was 1 μL of the FAME mixture containing about 1−2 μg/μL. Integration and quantitation were accomplished with GCsolution software (version 2.30.00) and based on the FID response. FAME were identified by comparison of retention times with known FAME standards (Nu-Check Prep 463, 674, CLA mixture; Supelco PUFA-3 mixture and linoleic and linolenic acid mixture). The short-chain FAME were corrected for mass discrepancy using the correction factors published by Wolff et al.[33]

Plasma Metabolite Quantification. Commercially available kits were used to analyze the plasma concentrations of FFA (Serum/Plasma Fatty Acid Detection Kit, ZenBio; Research Triangle Park, NC, USA), β-hydroxybutyrate (BHBA) (β-Hydroxybutyrate assay kit, Sigma-Aldrich), and glucose (Glucose (GO) Assay Kit, Sigma-Aldrich) according to the manufacturers' instructions. Samples were analyzed in duplicate, and all coefficients of variance were <5%.

Calculations. Apparent transfer efficiency was determined as

DOI: 10.1021/acs.jafc.5b00857
J. Agric. Food Chem. 2015, 63, 4827−4835

$$100 \times \left[\frac{\mathrm{MFA(t)} - \mathrm{MFA(c)}}{\mathrm{EOFA(t)}}\right] \quad (1)$$

where MFA is the FA yield (g/day) in milk, EOFA is the amount (g/day) of FA supplied by the EEO supplement, t is treatment (i.e., LEO and HEO), and c is control (CON).

Statistical Analyses. Data were analyzed using the fit model program of JMP Pro (version 11; SAS Institute, Cary, NC, USA). The following model was used for all data:

$$Y_{ijk} = \mu + S_i + C(S)_{ij} + P_k + T_l + e_{ijkl}$$

Y_{ijk} = dependent variable, μ = overall mean, S_i = fixed effect of square (i = 1−4), $C(S)_{ij}$ = random effect of cow nested within square (j = 1−12), P_k = fixed effect of period (k = 1−3), T_l = fixed effect of treatment (l = 1−3), and e_{ijk} = residual error. Treatment by period interactions were evaluated and removed because $P > 0.15$. A post hoc Tukey's honestly significantly difference (HSD) test was used to determine differences between dietary treatments. Differences between plasma lipid fractions were determined by an unpaired t test. Reported values are least-squares (LS) means and standard error (SE). Significance was declared at $P \leq 0.05$ and trends at $0.05 \leq P \leq 0.10$.

RESULTS

Animal Performance. FA intakes are shown in Table 3. CON, LEO, and HEO treatments provided 50.4, 84.5, and 116.4 g/day of ALA, respectively (Table 3; $P < 0.001$). The intakes of SDA were 0.0, 10.6, and 21.7 g/day for CON, LEO, and HEO treatments, respectively ($P < 0.001$). Treatments had no effect on DMI, which averaged 26.6 kg/day (Table 4). Milk yield (30.7 kg/day), energy-corrected milk (34.0 kg/day), and feed efficiency (1.3) were unaffected by EEO supplementation (Table 4). There was a trend toward increased 3.5% fat-corrected milk in the HEO treatment ($P = 0.09$; Table 4). The percentage of milk fat (4.1 vs 4.3%; $P = 0.03$) and fat yield (1.25 vs 1.32 kg/day; $P = 0.04$) was higher in the HEO treatment compared to CON. Milk protein percentage decreased between CON and HEO treatments (3.56 and 3.47%, respectively; $P = 0.002$; Table 4); however, protein yield did not differ among treatments and averaged 1.1 kg/day. Milk urea nitrogen was lower in the HEO treatment when compared to CON (10.1 and 10.9 mg/dL, respectively; $P = 0.01$). Percentage of milk lactose and lactose yield were unaffected by treatment. There was no difference between treatments for plasma glucose (74.0 mg/dL), FFA (0.12 mmol/L), or BHBA (0.67 mmol/L) (Table 5).

Table 4. Daily Dry Matter Intake (DMI), Milk Yield, Milk Components, and Feed Efficiency of Dairy Cows[a] in Response to Dietary CON,[b] LEO,[c] and HEO[d] Treatments

	treatment				
	CON	LEO	HEO	SE	P value

[a]LS means are based on 12 dairy cows per treatment. LS means without a common letter differ significantly ($P < 0.05$). [b]CON, control (0% of DM as lipid-encapsulated echium oil). [c]LEO, 1.5% of DM as lipid-encapsulated echium oil. [d]HEO, 3% of DM as lipid-encapsulated echium oil. [e]3.5% FCM = [0.43 × milk yield (kg/day)] + [16.22 × fat yield (kg/day)]. [f]ECM = [12.82 × fat yield (kg/day)] + [7.13 × protein yield (kg/day)] + [0.32 × milk yield (kg/day)]. [g]Feed efficiency = kg of 3.5% FCM/kg DMI.

Table 5. Plasma Metabolites[a] of Dairy Cows in Response to Dietary CON,[b] LEO,[c], and HEO[d] Treatments

	treatment				
	CON	LEO	HEO	SE	P value
FFA (mmol/L)	0.11	0.12	0.12	0.01	ns
glucose (mg/dL)	75.8	74.5	71.7	1.20	0.07
BHBA (mmol/L)	0.71	0.69	0.61	0.06	ns

[a]LS means are based on 12 dairy cows per treatment. LS means without a common letter differ significantly ($P < 0.05$). [b]CON, control (0% of DM as lipid-encapsulated echium oil). [c]LEO, 1.5% of DM as lipid-encapsulated echium oil. [d]HEO, 3% of DM as lipid-encapsulated echium oil.

Milk FA Composition. Supplementation with EEO altered the milk FA profile (Table 6 and Supplemental Table 1). LEO and HEO treatments decreased the content of de novo synthesized FA (<16 carbon atoms) by 5 and 12%, respectively, relative to CON ($P < 0.001$). The EEO treatments increased the preformed fatty acid (>16 carbon atoms) content in milk fat by 9% (LEO) and 16% (HEO) when compared to CON ($P < 0.001$). Total saturated fatty acid (SFA) content of milk fat was reduced in LEO and HEO relative to CON (Table 6; $P < 0.001$). The content of MUFA in milk fat increased from CON to LEO treatment (by 6%) and from CON to HEO treatment (by 12%; $P < 0.001$). The largest change in MUFA was seen in the *trans*-18:1 isomers; increasing 18% (LEO) and 37% (HEO), respectively, relative to CON ($P < 0.001$; Table 6). Total PUFA content increased in milk fat with increasing EEO supplementation ($P < 0.001$). Total n-3 FA showed the largest percentage change of all PUFA when compared to CON, increasing by 34% for the LEO treatment and by 66% for the HEO treatment ($P < 0.001$), compared to CON. The content of n-6 FA decreased in LEO (by 5%) and HEO (by 7%), compared to CON ($P < 0.001$). Similarly, the n-6/n-3 ratio decreased from 5.9 in CON to 4.1 and 3.3 for LEO and HEO treatments, respectively ($P < 0.001$). Both LEO and HEO treatments increased the content of FA derived from EO in milk fat. Compared with CON, the ALA content in milk fat increased 25 and 53% for LEO and HEO ($P < 0.001$), respectively. GLA increased, relative to CON, in LEO (by 80%) and HEO (by 145%) treatments ($P < 0.001$). The SDA content of milk fat increased 3.4-fold in the LEO treatment and 5.4-fold in the HEO treatment when compared to CON ($P < 0.001$). Milk fat from EEO-treated cows had a higher content of EPA than CON, increasing 43 and 61% for LEO and HEO, respectively ($P < 0.001$). DHA was not detected in milk fat. Total CLA increased 14% in the LEO treatment and 36% in the HEO treatment compared to CON ($P < 0.001$). Branched-chain FA decreased, relative to CON, by 6 and by 12% for LEO and HEO, respectively ($P < 0.001$).

The apparent transfer efficiencies of ALA from the EEO supplement to milk fat were 3.4 and 3.9% for LEO and HEO treatments, respectively (Table 7). SDA showed similar transfer efficiencies of 3.2% for LEO and 3.4% for HEO. The apparent transfer efficiencies of GLA were 3.0 and 2.8% for LEO and HEO, respectively.

Plasma Lipid Fraction FA Composition. The fatty acid composition of plasma lipid fractions, TAG, FFA, CE, and PL, are presented in Figure 1 and Supplemental Tables 2−5. Overall, 18:0 and 16:0 made up the predominant proportion of TAG and FFA fractions (Supplemental Tables 2 and 3), whereas 18:2 n-6 was the most abundant fatty acid in the CE and PL fractions (Supplemental Tables 4 and 5). The ALA ($P = 0.02$) content increased in plasma TAG in response to LEO (18%) and HEO (33%) treatments. SDA was not detected in CON plasma TAG and increased ($P < 0.001$) in response to LEO and HEO treatments. The GLA content of plasma TAG increased from CON to HEO (48%; $P < 0.01$) but not between CON and LEO (Figure 1). There was no increase of EPA in plasma TAG. Changes in the composition of most plasma FFA were negligible; however, there was a 41% increase in GLA ($P < 0.05$) between CON and HEO treatments, a 13-fold increase in SDA from CON to LEO, and a 39-fold increase from CON to HEO ($P < 0.001$). Plasma CE had the highest proportions of

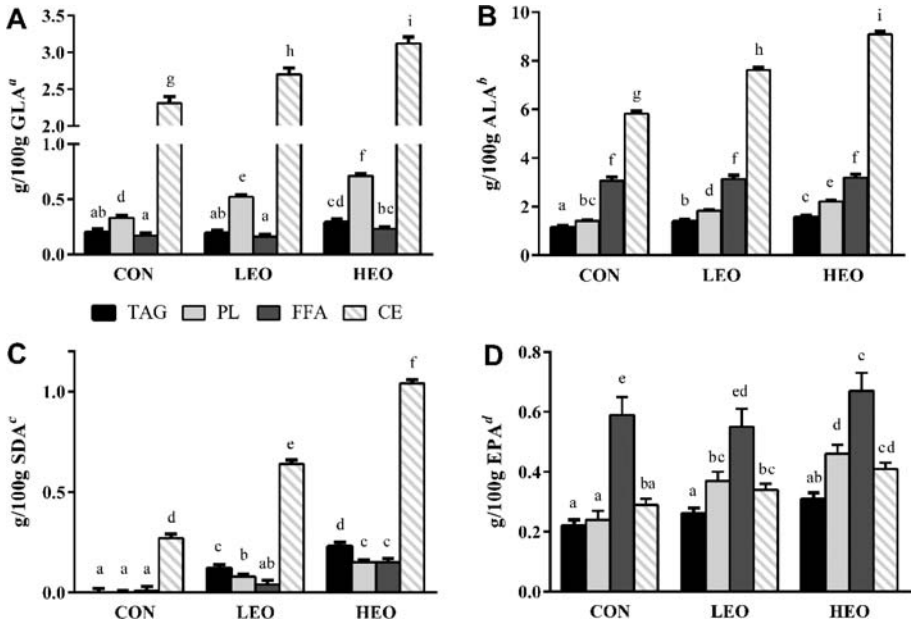

Figure 1. Content (g/100 g within plasma lipid fraction) of γ-linoleic acid (GLA) (A), α-linolenic acid (B), (ALA) stearidonic acid (C) (SDA), and eicosapentaenoic acid (D) (EPA) in plasma lipid fractions of dairy cows supplemented 0% DM as lipid-encapsulated echium oil (EO) (CON), 1.5% DM as EO (LEO), and 3% DM as EO (HEO). TAG, triacylglycerols; CE, cholesterol esters; PL, phospholipids; FFA, free fatty acids. Data are presented as least-squares means (n = 12) and standard error. LS means within fatty acids without a common letter differ significantly (P < 0.05).

ALA, GLA, and SDA of all plasma lipid fractions. ALA was 30% higher in plasma CE of LEO than CON and 55% higher in plasma CE of HEO than CON (P < 0.001). GLA increased 15 and 34% from CON to LEO and HEO treatments, respectively (P < 0.001). There was a 2.4-fold increase in SDA of plasma CE from CON to LEO and a 3.9-fold increase from CON to HEO (P < 0.001). EPA increased 20 and 44% in plasma CE from CON for LEO and HEO treatments, respectively (P < 0.01). Plasma PL showed a similar pattern of incorporation with significant increases in ALA, GLA, SDA, and EPA with increasing EEO inclusion in the diet (P < 0.001). There was a 56% (LEO) and 111% (HEO) increase in the content of GLA in plasma PL from CON (P < 0.001). ALA increased 30% in plasma PL from CON to LEO and 56% from CON to HEO (P < 0.001). EPA content of plasma PL increased 55 and 92% from CON to LEO and HEO, respectively (P < 0.001).

DISCUSSION

Animal Performance. Increasing the inclusion of EEO in the diet increased the intake of EO-derived FA (ALA, SDA, GLA) in the LEO and HEO treatment groups. Intakes of 18:0 and 16:0 also increased due to the lipid encapsulation of the EEO supplement. A primary consideration when supplementing dietary FA to dairy cows is their effect on production and performance. Inclusion of EEO in the diet of dairy cows at 1.5 and 3% of DM increased milk fat concentration and yield. These results are consistent with some experiments supplementing oil containing SFA or n-3 FA;[34,35] however, others have shown no change or a decrease in milk fat with n-3 FA supplementation.[9,15] This observation can be explained by the increase in fat content of the treatment diets. There was a slight decrease in milk protein percentage, but no change in the protein yield.

Milk FA Profile. Milk fat from cows supplemented with EEO contained less de novo synthesized FA and more preformed FA, which is similar to results observed with linseed oil or fish oil in the diet.[8,9] Unsaturated FA are known to inhibit de novo synthesis of milk fat, resulting in a greater uptake of preformed FA by the mammary gland.[36] A decrease in total SFA was observed despite the increase in SFA intake supplied by the lipid-encapsulated product. This can also be attributed to a reduction in de novo synthesized FA as they are composed primarily of SFA. The MUFA content of milk fat increased, mainly due to an increase in *trans* 18:1 isomers and a greater content of *cis*-9 18:1. The 18:0 δ-9-desaturase index [*cis*-9 18:1/(18:0 + *cis*-9 18:1)] decreased due to treatments; thus, the higher proportion of *cis*-9 18:1 in milk fat is explained by the increased supply of its precursor, 18:0, from the diet.

As expected, supplementation with EEO enhanced the content of PUFA in milk fat, particularly GLA, ALA, SDA, and their downstream metabolites: *cis*-8,*cis*-11,*cis*-14,*cis*-17 20:4, EPA, and *cis*-7,*cis*-10,*cis*-13,*cis*-16,*cis*-19 22:5 (docosapentaenoic acid; DPA). Similar results were seen by Kitessa and Young[23] when supplementing formaldehyde-treated EO for 10 days on a pasture-based diet. They noted, however, a decrease in milk production that was not observed in the present study. DHA was not detected in milk fat, despite the increase in DPA, which is consistent with Kitessa and Young.[23] Bernal-Santos et al.[37] also saw no change in the content of DHA in milk with abomasal infusion of SDA-rich soybean oil, containing 27.1% SDA. δ-6-Desaturase acts in both the pathways of converting ALA to SDA and EPA to DHA, and thus increasing ALA in the diet could saturate δ-6-desaturase in the conversion of ALA to SDA and cause a lower activity of this enzyme in the conversion of EPA to DHA.[38] Angulo et al. demonstrated the ability to increase DHA in milk fat by supplementing DHA-rich marine algae at 0.4% of DM for 10 weeks.[39]

Apparent Transfer Efficiency and Plasma Lipid Fraction Incorporation of EO-Derived FA. Apparent transfer efficiencies of dietary FA to milk fat vary with individual FA, diet, length of supplementation, protection method, and stage of lactation.[40,41] The apparent transfer

DOI: 10.1021/acs.jafc.5b00857
J. Agric. Food Chem. 2015, 63, 4827−4835

efficiencies of ALA from the EEO supplement into milk fat were 3.4 and 3.9% for LEO and HEO treatments, respectively. This is similar to reports using formaldehyde-treated flax oil[42] and extruded or micronized flaxseed.[43] The apparent transfer efficiencies of SDA to milk fat were 3.4% for the LEO treatment and 3.2% for the HEO treatment. The metabolism of SDA to EPA, however, is not accounted for in this model; thus, when the increase in EPA from CON to treatments was included in the apparent transfer efficiency equation of SDA, values were 4.7 and 4.1% for LEO and HEO, respectively. Bernal-Santos et al.[37] infused SDA-enriched soybean oil into the abomasum of dairy cows and reported an apparent transfer efficiency for SDA of 39.3%, whereas ruminal infusion of SDA-enriched oil resulted in a 1.7% apparent transfer efficiency to milk fat. Therefore, there is potential for a greater transfer efficiency if the FA successfully bypass the rumen, as with abomasal infusion. The apparent transfer efficiency of GLA was similar to those of ALA and SDA, being 3.0 and 2.8% for LEO and HEO, respectively, indicating consistent transfer efficiencies among n-6 and n-3 PUFA.

The overall low transfer of FA from EEO to milk may be due to (1) partial ruminal biohydrogenation of the n-3 FA in the supplement, (2) low release and/or decreased absorption of EO-derived FA in the intestine, or (3) incorporation of FA into plasma lipid fractions unavailable to the mammary gland. Our data support a combination of these factors. *trans* 18:1 isomers, a marker of incomplete biohydrogenation, were significantly increased from LEO to HEO, but no difference was observed between CON and LEO, suggesting biohydrogenation of the unsaturated FA in the HEO treatment despite the lipid encapsulation. The release of encapsulated oil and absorption of EO-derived FA in the small intestine could not be assessed in this study; however, others have noted that lipid-protected oils may have lower digestibility.[14]

Mammary lipoprotein lipase utilizes TAG from circulating chylomicrons and LDL; thus, TAG are the main source of preformed FA for milk fat synthesis.[44] Supplementing n-3 FA in the diet of dairy cows can saturate the normal esterification capacity of the small intestine and cause an increased uptake of n-3 FA into plasma TAG.[44] In our study ALA, SDA, and GLA contents increased in plasma TAG, demonstrating potential for these FA to be incorporated into milk fat. This increase, however, was small, compared to the increase in the CE and FFA fractions, suggesting not enough of these FA were available to substantially increase enterocyte esterification of n-3 FA into TAG. Plasma CE had the highest contents of SDA, GLA, and total n-3 FA, demonstrating preferential incorporation of SDA and GLA into plasma CE, which are unavailable to the mammary gland for milk fat synthesis.[12,13] Plasma FFA are also available to the mammary gland for milk fat synthesis.[45] The only n-3 FA to show a significant increase in incorporation into plasma FFA was SDA; however, the concentration of FFA available to the mammary gland of mid-late lactation dairy cows in positive energy balance is negligible.[46] To our knowledge, there are no studies delineating the incorporation of SDA into plasma lipid fractions and only a few studies evaluating the incorporation of other n-3 FA. Stamey et al.[14] supplemented mid-lactation Holstein dairy cows with a lipid-encapsulated algal oil and algal biomass for 7 days and showed that DHA was preferentially incorporated into plasma PL, with very little DHA found in plasma TAG. Sterk et al.[35] supplied 1.6% DM as ALA to early-lactation dairy cows via a formaldehyde-treated linseed oil and demonstrated a 2-fold higher content of ALA in plasma TAG than the HEO treatment in the current study that supplied 0.4% DM as ALA. The increased incorporation of ALA into plasma TAG coincided with a 13% apparent transfer efficiency of ALA to milk fat;[35] differences could be due to supplementation level, oil protection method, or the use of early-lactation dairy cows, as previous research has demonstrated an increased availability of preformed FA to the mammary gland in early lactation.[47]

Human Health Considerations. The increase of n-3 FA in the diet of dairy cows led to a decrease in the n-6/n-3 ratio in milk fat of the LEO and HEO treatments when compared to CON. The n-6/n-3 balance is critical as dietary n-6 and n-3 FA compete for the same enzymes in the production of eicosanoids, and in general n-6 FA produce inflammatory signaling molecules, whereas eicosanoids derived from n-3 FA have anti-inflammatory properties.[48] A lower n-6/n-3 FA ratio in the diet of humans is associated with improved health and reduced risk of disease.[49] The milligrams of n-3 FA per gram of milk fat were estimated by mass correcting FA values to triglyceride equivalents using a correction factor of 0.87; one serving of EO-FA enriched whole milk [1 cup (244 g) of 3.25% milk fat] would provide 56 mg of n-3 FA. The amount of n-3 FA provided in EO-FA enriched milk is comparable to levels of n-3 FA supplied by commercially available whole-milk products with added marine oils (50 mg of EPA/DHA per serving; Organic Valley Omega-3 Milk, Organic Valley, La Farge, WI, USA; 32 mg DHA per serving; Horizon Organic DHA Omega-3 Milk, Horizon Organic, Broomfield, CO, USA). Supplementing dairy cows with EEO increased the milk fat content of GLA but did not increase the content of its downstream pro-inflammatory metabolite arachidonic acid. Human studies have demonstrated that consuming GLA leads to increased serum arachidonic acid; however, because EO also contains SDA, this conversion is inhibited, allowing for the accumulation of the anti-inflammatory GLA.[50] Moreover, research shows that consuming GLA along with EPA and DHA reduces risk of heart attack and lowers blood TAG levels more effectively than EPA and DHA alone.[51] Milk fat from cows supplemented with EEO had an increased proportion of *trans*18:1 FA in milk. *trans* 18:1 FA have been generally associated with increased risk of cardiovascular disease in humans by increasing low-density lipoprotein (LDL) and decreasing high-density lipoprotein (HDL).[52] However, the majority of these trials were conducted with *trans* FA from partially hydrogenated vegetable oils (PHVO). Ruminant-derived *trans* FA do not show the same negative health effects as *trans* FA from PHVO due to the difference in the composition of *trans* 18:1 isomers.[53] The predominant *trans* 18:1 in milk fat is vaccenic acid (VA), and epidemiological studies suggest that consumption of VA may impart health benefits.[54] Thus, the increase in the content of *trans* FA in the EO-enriched milk does not influence the healthfulness of the product.

Conclusion. Developing functional food products enriched with n-3 FA is a challenging endeavor in ruminants. The n-3 FA must be both protected from ruminal biohydrogenation and released in the small intestine and then subsequently incorporated into plasma TAG to be available to the mammary gland for milk fat synthesis. Supplementing an EEO at 1.5 and 3% of DM increased the content of n-3 FA in milk fat; whereas percentage increases of n-3 FA were high, the actual content of these FA in milk is still relatively low. ALA, and SDA showed the highest incorporation into plasma TAG and milk, whereas EPA also increased in milk but not in plasma TAG. The

DOI: 10.1021/acs.jafc.5b00857
J. Agric. Food Chem. 2015, 63, 4827−4835

greatest increase in content of n-3 FA occurred in the plasma PL and CE, explaining the low apparent transfer efficiency of ALA and SDA to milk fat. High transfer efficiencies are feasible only if rumen protection and postrumen absorption are optimized; thus, further research is needed to assess the protection of the EEO supplement in the rumen and digestibilily in the small intestine and whether longer term supplementation or increasing the SDA content of the oil would increase the apparent transfer efficiency to milk fat.

Quantitative Analysis of Phenylpropanoid Glycerol Glucosides in Different Organs of Easter Lily (*Lilium longiflorum* Thunb.)

John P. Munafo, Jr. and Thomas J. Gianfagna*

Plant Biology Department, Rutgers—The State University of New Jersey, 59 Dudley Road, New Brunswick, New Jersey 08901, United States

ABSTRACT: The Easter lily (*Lilium longiflorum* Thunb.) is esteemed worldwide as an attractive ornamental plant, and the flower buds and bulbs are used for both culinary and medicinal purposes in many parts of the world. *L. longiflorum* contains significant amounts of phenylpropanoid glycerol glucosides, a group of compounds that may contribute to plant pathogen defense, ultraviolet/high-intensity visible light (UV/high light) protection, and the purported medicinal uses of lilies. To define the natural distribution of these compounds within the plant, a liquid chromatography−mass spectrometry (LC-MS) method performed in selected ion monitoring (SIM) mode was employed for the quantitative analysis of five phenylpropanoid glycerol glucosides, namely, (2*S*)-1-*O*-caffeoyl-2-*O*-*β*-D-glucopyranosylglycerol, **1**; (2*R*)-1-*O*-*β*-D-glucopyranosyl-2-*O*-*p*-coumaroylglycerol, **2**; (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-glucopyranosylglycerol, **3**; (2*S*)-1-*O*-caffeoyl-2-*O*-*β*-D-glucopyranosyl-3-*O*-acetylglycerol, **4**; and (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-glucopyranosyl-3-*O*-acetylglycerol, **5**, in the different organs of *L. longiflorum*. The *p*-coumaroyl-based **3** and its acetylated derivative **5** were determined to be the most abundant of the phenylpropanoid glycerol glucosides found in Easter lily bulbs, at 776.3 ± 8.4 and 650.7 ± 32.6 *μ*g/g dry weight, respectively. The acetylated *p*-coumaroyl- and caffeoyl-based derivatives, **5** and **4**, accumulated to the highest concentration in the closed flower buds, at 4925.2 ± 512.8 and 3216.8 ± 406.4 *μ*g/g dry weight, respectively. Compound **4**, followed by **5** and **1**, proved to be the most abundant in the mature flowers, occurring at 6006.2 ± 625.8, 2160.3 ± 556.5, and 1535.8 ± 174.1 *μ*g/g dry weight, respectively. Total concentrations of the phenylpropanoid glycerol glucosides were 10−100-fold higher in the above-ground plant organs as compared to the bulbs and fleshy roots. Two of the five compounds, **1** and **2**, were identified in *L. longiflorum* for the first time. The quantitative analysis of phenylpropanoid glycerol glucosides in the different plant organs of *L. longiflorum* will establish the direction of investigations aimed at defining how these compounds function in the physiology and chemical ecology of the plant and also as a starting point for determining their possible effects on human health, which has not been investigated.

KEYWORDS: *Lilium longiflorum Thunb., Liliaceae, Easter lily, phenylpropanoid glycerol glucosides, regalosides*

INTRODUCTION

The Easter lily (*Lilium longiflorum* Thunb., family Liliaceae) is primarily grown as an ornamental plant because of its large, fragrant, white flowers. Although not well-known as a food in the United States, lily flower buds and bulbs are used as both food and medicine in many Asian countries, especially China and Japan. In Chinese cuisine the bulbs of various lily species, including *L. longiflorum*, are a common ingredient in soups, stir-fries, and stew-like dishes such as "hot pot". Lily bulbs and flower buds are an important part of the Asian diet and are consumed on a regular basis. Despite this fact, very little is known about their chemical composition and impact on human health. In addition to their culinary value, lily bulbs have a long history of documented medicinal use as sedatives, anti-inflammatory agents, and antitussives.[1−3] In fact, preparations of lily bulbs from *Lilium* species, referred to in China as "Bai-he," are employed in Traditional Chinese Medicine (TCM) as effective treatments for inflammation and some lung ailments.[1,2] However, although the medicinal use of *L. longiflorum* is well documented, the bioactive phytochemicals responsible for the putative medicinal properties as well as their mechanisms of action remain elusive.

Plants from the *Lilium* genus are an abundant source of a number of natural products. Many classes of compounds have been reported from the genus, including phenolics,[4] alkaloids,[5] flavonoids,[6] carotenoids,[7] sterols,[7] steroidal saponins,[2,8−17] and steroidal glycoalkaloids.[15,17−19] In addition, the *Lilium* genus contains an abundant supply of cinnamic acid derivatives, in particular, phenylpropanoid glycerol glucosides, a group of natural products, with many structural analogues, first isolated and characterized from *Lilium regale* E. H. Wilson and thus trivially named regalosides.[20] Cinnamic acid derivatives, most notably *p*-coumaric, caffeic, and ferulic acids, are widely distributed in plants and naturally occur as both esters and glycosides. Regalosides are acylated glycerol glucosides. As such, they characteristically contain *p*-coumaric, caffeic, or ferulic acids, but less often cinnamic acid. Typically, they are esterified at the C1 or C2 carbon of a glucosylated glycerol backbone, with *S* configuration at the 2-position, (2*S*)-regalosides, being the most common, and *R* configuration, (2*R*)-regalosides, less usual. Moreover, a few acetylated and methylated regalosides have been described.[6,9,20−22] Regalosides have been identified in members of the Liliaceae family including *L. regale*,[20] *Lilium henryi* Baker,[21] *Lilium pardalinum* Kellogg,[3] *Lilium auratum* Lindl.,[3,23] *Lilium lancifolium* Thunb.,[22]

L. longiflorum,[6,22] *Lilium brownii* F. E. Br. ex Miellez,[2,15] *Lilium speciosum* Thunb.,[14] and *Lilium mackliniae* Sealy.[9]

Earlier studies have identified phenylpropanoid glycerol glucosides in the bulbs of *L. longiflorum*, specifically, (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-glucopyranosylglycerol, **3**; (2*S*)-1-*O*-caffeoyl-2-*O*-*β*-D-glucopyranosyl-3-*O*-acetylglycerol, **4**; and (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-glucopyranosyl-3-*O*-acetylglycerol, **5**.[22] Additionally, a 4-acetyl derivative of (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-glucopyranosylglycerol has been reported from *L. longiflorum* flowers that exhibited mild cyclooxygenase and lipid peroxidation inhibition activities.[6] Although these compounds may be involved in plant pathogen defense, ultraviolet/high-intensity visible light (UV/high light) protection, and the putative medicinal activities of lilies,[1−3,17] reports on the biological activities of phenylpropanoid glycerol glucosides are scarce. Phenylpropanoid glycerol glucosides are reported to be bitter in taste,[20] which may suggest a possible role in antiherbivory; however, the bitter taste thresholds of the compounds have not been quantitated nor have the antiherbivory activities of the compounds been investigated.

The dual aim of our present investigation has been to develop a liquid chromatography−mass spectrometry (LC-MS) method for the quantitative analysis of five phenylpropanoid glycerol glucosides in plant tissues and to identify and quantitate the concentration of the compounds in the different plant organs of Easter lily. The results were anticipated to lay the groundwork for defining how these compounds function in the physiology and chemical ecology of the plant and also as a starting point for determining their possible effects on human health when consumed as a food, which has not been investigated.

MATERIALS AND METHODS

Plant Material. Cultivar 7-4 *L. longiflorum* bulbs were cultivated, harvested, lyophilized, and milled according to the methods described in Munafo et al.[19] Three fully mature plants, containing all stages of the vegetative and reproductive organs, were harvested and dissected into fleshy bulb scales, fleshy roots, leaves, lower stems, upper stems, flower buds, and mature flowers. The fleshy bulb scales were 0.8−2.0 cm in width and 0.9−4.0 cm in length. The fleshy roots were approximately 2−4 mm in diameter and the leaves about 6−14 cm in length. Lower stems (the part growing below the soil surface) ranged in size from 6 to 10 cm and were white to yellow in color. Upper stems (the part growing above the soil surface) ranged in size from 19 to 31 cm and were green. The flower buds were approximately 3−6 cm in length, fully closed, and green in appearance. The mature flowers ranged between 6 and 14 cm in length, were fully open, and were white in appearance. Each of the organ types from an individual plant were pooled together. Three individual plants were used in the analysis (n = 3). After harvest, all samples were immediately frozen under liquid nitrogen, lyophilized, and stored at −80 °C prior to analysis.

Chemicals. All solvents, acetonitrile, 1-butanol, dimethyl sufoxide (DMSO), ethyl acetate, ethanol, formic acid, methanol, tetrohydrofuran (THF), and pentanes were of chromatographic grade and were obtained from Thermo Fisher Scientific Inc., Fair Lawn, NJ, USA. Methanol-d_4 (0.03% v/v TMS) was obtained from Sigma-Aldrich, St. Louis, MO, USA. Deionized (DI) water (18 MΩ cm) was generated using a Milli-Q-water purification system (Millipore, Bedford, MA, USA).

Purification of Phenylpropanoid Glycerol Glucosides 1−5 as Analytical Standards. *Sequential Solvent Extraction of Lyophilized L. longiflorum Bulbs.* Lyophilized lily bulbs (100 g) were milled to a fine powder after freezing in liquid nitrogen. To remove lipids, the bulb powder was extracted with pentanes (3 × 100 mL) at room temperature for 15 min each time on a shaker. The extract was centrifuged (5000 rpm) for 10 min and the solvent was decanted. The residue was then allowed to dry overnight in a fume hood. The dried defatted residue was extracted with ethanol and DI water (7:3, v/v; 2 × 150 mL) for 45 min at room temperature on a shaker. The extract was centrifuged (5000 rpm) for 10 min and the supernatant was saved and vacuum filtered. The supernatant was rotary evaporated (30 °C; 1.0×10^{-3} bar) and lyophilized, yielding a crude bulb extract (fraction I, 12.4 g). Next, the lyophilized crude bulb extract was dissolved in DI water (100 mL) and extracted with ethyl acetate (5 × 100 mL), and the aqueous phase, containing the highly polar compounds such as carbohydrates and steroidal glycosides, was discarded. The organic phase was rotary evaporated to dryness (30 °C; 1.0×10^{-3} bar) (fraction II), redissolved in DI water (100 mL), and sonicated for 10 min. The extract was centrifuged (5000 rpm) for 10 min, vacuum filtered, and the supernatant was collected. The aqueous phase was then extracted with 1-butanol (5 × 100 mL). The organic phase was rotary evaporated (30 °C; 1.0×10^{-3} bar) and lyophilized, yielding 1-butanol extract (fraction III, 1.9 g).

Semipreparative Reverse-Phase High-Performance Liquid Chromatography (RP-HPLC). The 1-butanol extract (fraction III) was fractionated by semipreparative RP-HPLC on a 250 mm × 21.2 mm i.d., 10 μm, Luna C18 column (Phenomenex, Torrance, CA) to afford **1**−**5** (Figure 1) using an LC-6AD liquid chromatograph (Shimadzu

Scientific Instruments Inc., Columbia, MD, USA) equipped with a UV/vis detector and a 2 mL injection loop. The mobile phases were mixtures of (A) 0.1% formic acid in DI water and (B) 0.1% formic acid in acetonitrile. The flow rate was set to 20 mL/min, column temperature was 23 ± 2 °C, and UV detection was recorded at λ 210 nm. The 1-butanol extract (fraction III, 200 mg) was dissolved in a mixture of mobile phase A and mobile phase B (90:10, v/v; 2 mL) and filtered through a 0.45 μm PTFE syringe filter prior to injection (injection volume = 1 mL). The butanol extract was fractionated using a linear gradient of 5−24.4% B for 35 min and then ramped to 90% B in 5 min, with a hold at 90% B for additional 5 min. The solvent mixture was reset to 5% B for 10 min before subsequent injections. Fractions containing the compounds of interest were collected (Figure 2), and the solvent was rotary evaporated (30 °C; 1.0×10^{-3} bar) and lyophilized, yielding **1** (15.2 mg), **2** (12.1 mg), **3** (39.6 mg), **4** (10.2 mg), and **5** (40.3 mg) as pale yellow amorphous powders with >98% purity as determined by LC-MS and NMR.

*Compound **1**, (2S)-1-O-Caffeoyl-2-O-β-D-glucopyranosylglycerol (regaloside K).* 1D and 2D NMR data were consistent with ^{1}H NMR and ^{13}C NMR reported in the literature.[9]

*Compound **2**, (2R)-1-O-β-D-Glucopyranosyl-2-O-p-coumaroylglycerol (regaloside H).* 1D and 2D NMR data were consistent with ^{1}H NMR and ^{13}C NMR reported in the literature.[23]

*Compound **3**, (2S)-1-O-p-Coumaroyl-2-O-β-D-glucopyranosylglycerol (regaloside D).* 1D and 2D NMR data were consistent with ^{1}H NMR and ^{13}C NMR reported in the literature.[3]

*Compound **4**, (2S)-1-O-Caffeoyl-2-O-β-D-glucopyranosyl-3-O-acetylglycerol (regaloside E).* 1D and 2D NMR data were consistent with ^{1}H NMR and ^{13}C NMR reported in the literature.[3]

J. Agric. Food Chem. 2015, 63, 4836−4842

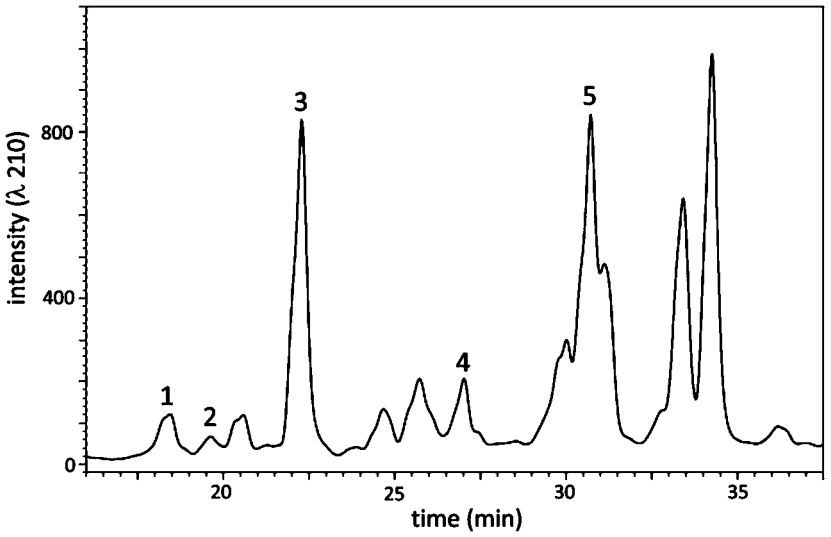

Figure 2. Semipreparative RP-HPLC chromatogram (λ 210 nm) of **1**−**5** purified from *L. longiflorum* 1-butanol extract (fraction III).

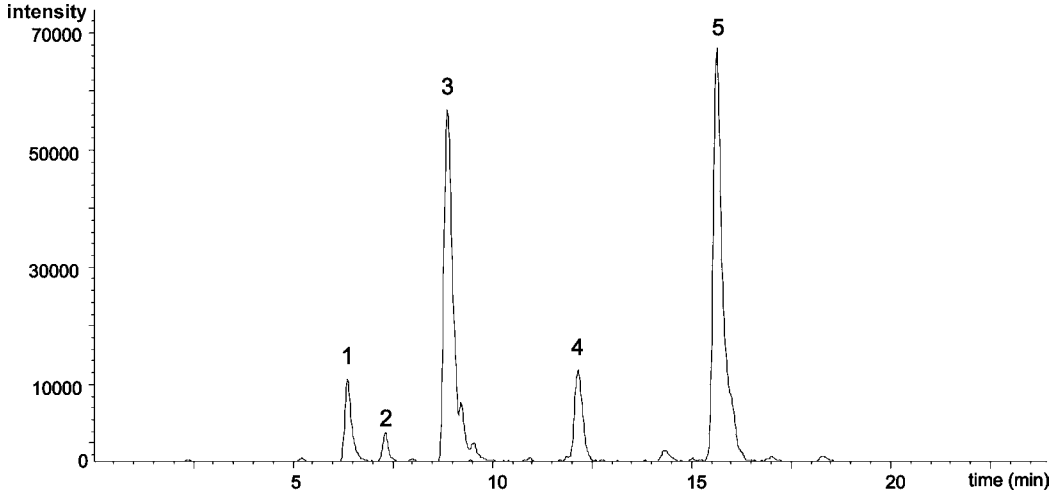

Figure 3. LC-MS chromatogram for the quantitative analysis of compounds **1**−**5** in a *L. longiflorum* bulb scale operating in selective ion monitoring (SIM) mode.

Compound **5**, *(2S)-1-O-p-Coumaroyl-2-O-β-D-glucopyranosyl-3-O-acetylglycerol (regaloside B).* 1D and 2D NMR data were consistent with ^{1}H NMR and ^{13}C NMR reported in the literature.[20]

Nuclear Magnetic Resonance Spectroscopy (NMR). 1D ^{1}H NMR spectra was acquired with a 400 MHz spectrometer (Bruker, Rheinstetten, Germany). 2D heteronuclear multiple-bond coherence (HMBC), heteronuclear single-quantum coherence (HSQC), and H−H correlation spectroscopy (H−H COSY) spectra were acquired on a 500 MHz spectrometer (Bruker). Samples for NMR analysis were dissolved in methanol-d_4, and chemical shifts were calculated as δ values with reference to tetramethylsilane (TMS).

Optimization of Sample Extraction Parameters for Quantitative Analysis. *Solvent Composition and Extraction Efficiency Determination.* Six neat organic solvents (methanol, ethanol, DMSO, acetone, acetonitrile, and THF) as well as different ratios of methanol and DI water (1:0, 9:1. 8:2, 7:3, 6:4, 5:5, 4:6, 3:7, 2:8, 1:9, and 0:1, v/v) were used for experiments aimed at optimization of the extraction solvent system for phenylpropanoid glycerol glucosides **1**−**5** from lyophilized *L. longiflorum* tissue. Performing successive extraction of the same plant tissue from one to three times determined extraction efficiency. Lyophilized lily bulb tissue was extracted with methanol and DI water (8:2, v/v) solvent mixture. Results from each successive extraction were collected separately and filtered through a 0.45 μm PTFE syringe filter prior to LC-MS analysis.

Quantitative Analysis of Phenylpropanoid Glycerol Glucosides 1−5 in *L. longiflorum*. *Sample Preparation.* Following removal from the freezer, lyophilized lily organ samples were thawed to ambient temperature. The samples (40 mg each) were milled to pass through a 200 mesh sieve, weighed separately, transferred into a 15 mL centrifuge tube, and covered with methanol and DI water (8:2, v/v; 7 mL each). The samples were extracted with shaking (10 min), sonicated (10 min), and filled to final volume (10 mL) with methanol and DI water (8:2, v/v). The samples were vortexed (1 min), and centrifuged (5000 rpm for 10 min), and the supernatant was collected. The pellet was re-extracted with methanol and DI water (8:2, v/v; 10 mL), shaken (10 min), sonicated (10 min), centrifuged (5000 rpm for 10 min), and the supernatants were combined (total volume ∼ 20 mL). Prior to LC-MS analysis, all samples were filtered through a 0.45 μm PTFE syringe filter.

Analytical Standard Preparation. Phenylpropanoid glycerol glucosides **1**−**5**, isolated and purified as described above, were used as analytical standards. Each compound was weighed into volumetric flasks (10 mL), dissolved with methanol and DI water (8:2, v/v; 7 mL each), and sonicated for 5 min before taken to full volume. Working solutions were prepared for calibration equations by diluting the stock solutions. External standard equations were calculated from six data points covering a concentration range of 1−300 μg/mL. To establish calibration equations, mean peak areas (n = 3) from the standard

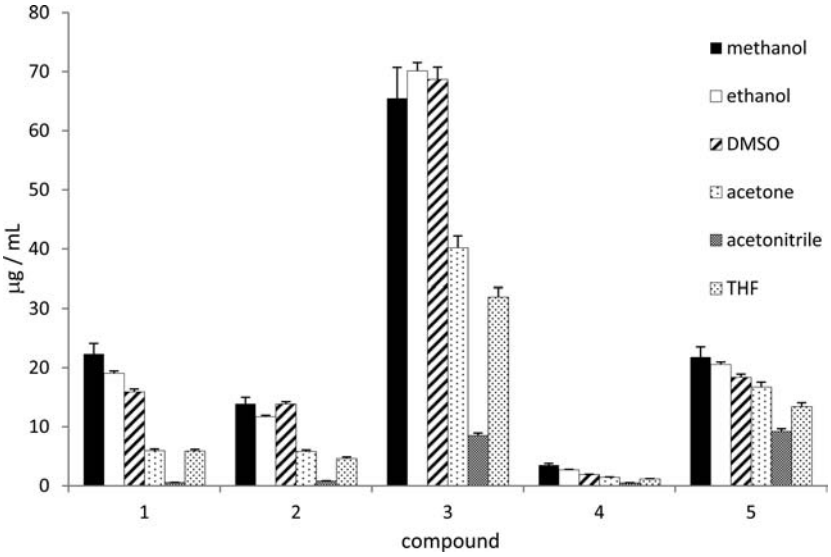

Figure 4. Evaluation of six organic solvents on the extraction of compounds **1**−**5** from *L. longiflorum* bulbs. Concentrations are means of triplicates ± SD.

solutions were plotted versus concentration. Standard solutions were stored at 4 °C and equilibrated to ambient temperature before use.

Liquid Chromatography–Mass Spectrometry (LC-MS). LC-MS analysis of *L. longiflorum* extracts was performed using an Agilent 1100 series HPLC system (Agilent Technologies Inc., Santa Clara, CA, USA) equipped with an autoinjector, quaternary pump, column heater, diode array detector and interfaced to a 1100 series single-quadruple mass selective detector (MSD) equipped with an API-ESI ionization source. Chromatographic separations were made on a 250 mm × 4.6 mm i.d., 5 μm Prodigy C18 column (Phenomenex) operated at a flow rate of 1.0 mL/min, column temperature set to 23 ± 2 °C, and an injection volume of 10 μL. The binary mobile phase consisted of (A) 0.1% formic acid in DI water and (B) 0.1% formic acid in acetonitrile. Phenylpropanoid glycerol glucosides were separated using a linear gradient of 15−34.6% B for 28 min and then ramped to 95% B in 5 min with a hold at 95% B for 5 min. The system was reset to 15% B for 10 min before each sample injection. ChemStation software was used for data acquisition and analysis. Negative ionization mode was used to quantify the phenylpropanoid glycerol glucosides using SIM. The following ions were selected for each compound: **1**, *m*/*z* 415; **2**, *m*/*z* 399; **3**, *m*/*z* 399; **4**, *m*/*z* 457; and **5**, *m*/*z* 441 (Figure 3). Ionization conditions were as follows: capillary voltage, 3.5 kV; nebulizer pressure, 35 psi; drying gas flow, 10.0 mL/min; and drying gas temperature, 350 °C. MSD signal parameters included mode, SIM; polarity, negative; fragmentor voltage, 70 V; gain, 1.0; dwell time, 144 ms; and percent relative dwell time, 25.

Recovery. The standard addition method was used to calculate recovery rates.[24] Lyophilized lily organs were milled to pass through a 200 mesh sieve, separately weighed (40 mg), and transferred into 15 mL centrifuge tubes containing one of three different concentrations (50, 100, and 200 μg/g) of pure compounds dissolved in methanol and DI water (8:2, v/v). To the sample tubes was added a solution of methanol and DI water (8:2, v/v; 7 mL), and the extract was shaken (10 min), sonicated (10 min), and then filled to final volume (10 mL) with the same solvent. The samples were vortexed (1 min) centrifuged (5000 rpm for 10 min), and the supernatant was recovered. For a second time, the centrifuge tube containing the pellet was filled to final volume (10 mL), extracted with shaking (10 min), sonicated (10 min), and centrifuged (5000 rpm for 10 min), and the supernatants from the two extractions were pooled (total volume ∼ 20 mL). All samples were syringe filtered (0.45 μm PTFE) and the phenylpropanoid glycerol glucosides quantified as described above. The percentage recovery for each of the phenylpropanoid glycerol glucosides **1**−**5** in vegetative and reproductive organs was determined by subtracting the amount found in the lily organ sample that was not spiked with additional standards (control) from the amount of standard found in the spiked sample, with three replicate samples for each analysis.

Statistical Analysis. To compare differences in phenylpropanoid glycerol glucosides content in the lily plant organs, LC-MS data were first transformed to the logarithmic function, and an analysis of variance (ANOVA) was conducted. Means were separated with Tukey's test (α = 0.05) using JMP 10 software (SAS Institute Inc., Cary, NC, USA). Two-way hierarchal cluster analysis (HCA) and the resulting color map, visually depicting the differences in concentration of compounds **1**−**5** throughout the lily plant organs, were generated using JMP 10 software (SAS Institute Inc.).

RESULTS AND DISCUSSION

Isolation and Identification of Compounds 1 and 2 from *L. longiflorum* Bulbs. The crude 1-butanol extract was fractionated by repeated semipreparative RP-HPLC to yield compounds **1**−**5**. On the basis of 1D ^{1}H and 2D (HMBC, HSQC, and H−H COSY) NMR, compounds **3**, **4**, and **5** were confirmed to be (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-gucopyranosylglycerol, (2*S*)-1-*O*-caffeoyl-2-*O*-*β*-D-glucopyranosyl-3-*O*-acetylglycerol, and (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-glucopyranosyl-3-*O*-acetylglycerol, respectively. All three of these compounds have been previously reported from *L. longiflorum* bulbs.[22] On the basis of 1D ^{1}H and 2D (HMBC, HSQC, and H−H COSY) NMR, compounds **1** and **2** were confirmed to be (2*S*)-1-*O*-caffeoyl-2-*O*-*β*-D-glucopyranosylglycerol, **1**, and (2*R*)-1-*O*-*β*-D-glucopyranosyl-2-*O*-*p*-coumaroylglycerol, **2**, respectively. Compound **1** was previously reported from fresh bulb scales of *L. mackliniae*[9] and **2** from *L. auratum*.[23] This is the first report of **1** and **2** as natural products identified in *L. longiflorum*.

Optimization of Quantitative Extraction Parameters. *Solvent Composition Determination.* The determination of an effective extraction solvent system for the quantitative analysis of **1**−**5** was achieved by first analyzing the resulting extracts prepared from six neat organic solvents, namely, methanol, ethanol, DMSO, acetone, acetonitrile, and THF (Figure 4). Various combinations of methanol and DI water were then evaluated with the goal of determining a solvent system that effectively extracted **1**−**5**. On the basis of these data, the combination of methanol and DI water (8:2, v/v) was chosen

DOI: 10.1021/acs.jafc.5b00893
J. Agric. Food Chem. 2015, 63, 4836−4842

as the optimum solvent system of the solvent combinations evaluated (Figure 5).

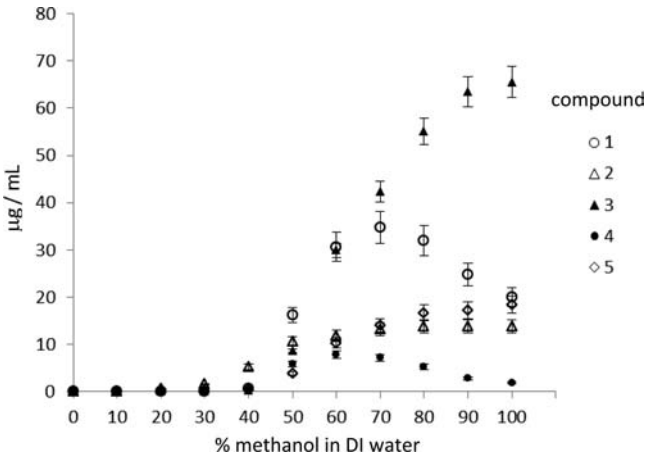

Figure 5. Evaluation of various ratios of methanol and DI water on the extraction of compounds **1**−**5** from *L. longiflorum* bulbs. Concentrations are means of triplicates ± SD.

Extraction Efficiency. Sequential solvent extraction of the lyophilized lily bulb powder using methanol and DI water (8:2, v/v) was employed to estimate the optimal number of extraction cycles for quantitative analysis. The results indicated that between 77.6 and 89.6% of compounds **1**−**5** were recovered in the first extraction. An additional 9.3−17.7% was found with the second extraction and approximately 0−5.1% after the third cycle. On the basis of these observations, the combined supernatants generated from two successive extraction cycles were chosen for further quantitative analysis, resulting in an estimation of 94.4−98.9% extraction efficiency for compounds **1**−**5**.

Method Validation. To quantitate the distribution of five phenylpropanoid glycerol glucosides in *L. longiflorum* organs, **1**−**5** were purified from lily bulbs as analytical reference standards. For quantitative analysis, extracts were prepared from lyophilized plant parts and analyzed using LC-MS in SIM mode. To determine linear relationships between peak area and concentration for the quantitative method, six-point calibration plots were constructed, which demonstrated good linearity over the concentration range of 1.0−300 μg/mL for compounds **1**−**5**. The correlation coefficients ranged from R^2 = 0.9998 to 0.9999. Accuracy of the method was assessed by calculating recovery rates for **1**−**5** in each of the plant organs using the standard addition method.[24] Recovery rates were calculated for each of the plant organs (bulb scales, 94.7−100.8%; roots, 94.8−101.4%; leaves, 96.7−102.9%; lower stems, 93.7−99.8%; upper stems, 94.9−103.3%; flower buds, 96.3−102.0%; and mature flowers, 95.2−101.9%). For compounds **1**−**5** the recovery rates in all of the plant organs assayed were between 93.7 and 103.3%. The precision of the method was evaluated by analyzing the same sample multiple times (bulb; n = 6) and subsequently calculating the relative standard deviation (RSD) of **1**−**5** in the sample. The RSD values for **1**−**5** were 4.14, 3.53, 2.81, 2.73, and 3.57%, respectively. These data demonstrate satisfactory linearity, recovery rates, and RSD, which suggests that the LC-MS method operating in SIM mode is a suitable method for the quantitation of phenylpropanoid glycerol glucosides **1**−**5** in *L. longiflorum* plant organs.

Quantitation of Phenylpropanoid Glycerol Glucosides 1−5 in the Different Organs of *L. longiflorum*. Concentrations of **1**−**5** were quantitatively determined in all plant organs of *L. longiflorum* (Table 1; Figure 6). The *p*-coumaroyl-based compound **3** and its acetylated derivative **5** were determined to be the most abundant of the phenylpropanoid glycerol glucosides found in Easter lily bulbs, at 776.3 ± 8.4 and 650.7 ± 32.6 μg/g dry weight (dw), respectively. As previously mentioned, lily bulbs are regularly consumed as a food, and preparations from lily bulbs, referred to in China as "Bai-he", are employed as effective treatment for various inflammations and some lung ailments; however, the bioactive phytochemicals responsible for the putative medicinal properties remain unknown.[1,2] Compounds **3** and **5** occurred at the highest concentration in the root tissues at 584.4 ± 34.3 and 345.8 ± 32.6 μg/g dw, respectively. Similar to the bulbs and roots, **3** and **5** occurred at the highest concentration in the upper stem and lower stem. Compound **3** occurred at higher concentrations in the lower stem versus the upper stem, and the concentrations of compound **5** were similar in both the lower and upper stems.

The above-ground plant organs of Easter lily (upper stems, leaves, buds, and flowers) showed a different trend of phenylpropanoid glycerol glucoside concentrations from that of the below-ground plant organs (bulbs, roots, and lower stem). The above-ground organs displayed more caffeoyl-based compounds and a greater abundance of acetylation than the below-ground organs. The caffeoyl-based compounds **1** and **4** were the highest in the leaves, at 2007.4 ± 207.5 and 1786.0 ± 200.9 μg/g dw, followed by the *p*-coumaroyl-based compounds **3**, **2**, and **5**, at 1074.8 ± 53.1, 1003.5 ± 36.4, and 935.1 ± 103.9 μg/g dw, respectively. The acetylated *p*-coumaroyl- and caffeoyl-based derivatives, **5** and **4**, had the highest concentrations in the closed flower buds, at 4925.2 ± 512.8 and 3216.8

Table 1. Concentrations of Compounds 1−5 in the Different Organs of *L. longiflorum*

	compound concentration[a] (μg/g dw)				
organ	1	2	3	4	5
bulb	68.4c ± 11.4[b]	80.3bc ± 8.43	776.3a ± 8.4	116.7b ± 29.1	650.7a ± 32.6
root	95.7c ± 12.6	62.8d ± 1.70	584.4a ± 34.3	85.5c ± 12.5	345.8b ± 17.1
leaf	2007.4a ± 207.5	1003.5b ± 36.4	1074.8b ± 53.1	1786.0a ± 200.9	935.1b ± 103.9
lower stem	381.3c ± 49.0	152.8e ± 13.0	1281.7a ± 26.5	275.8d ± 14.1	860.0b ± 47.2
upper stem	274.1c ± 15.6	242.7c ± 25.4	1011.3a ± 35.2	619.0b ± 34.6	1125.0a ± 105.7
bud	762.9d ± 34.0	636.7d ± 40.5	1771.2c ± 104.3	3216.8b ± 406.4	4925.2a ± 512.8
flower	1535.8b ± 174.1	385.9d ± 10.6	736.2c ± 16.4	6006.2a ± 625.8	2160.3b ± 556.5

[a]Concentrations are means of triplicates ± SD, expressed on a dry weight basis (dw). [b]Values with the same letter in each row are not significantly different (p < 0.05).

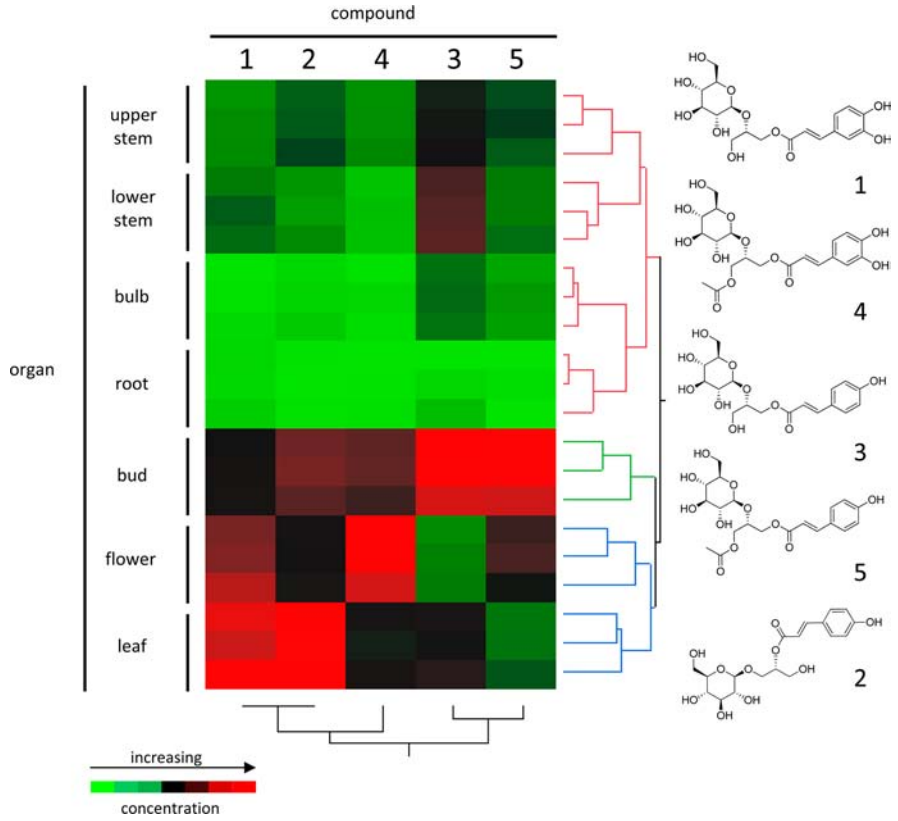

Figure 6. Two-way hierarchal cluster analysis (HCA). Color map visually depicting the differential concentrations of compounds **1**−**5** in the different plant organs of *L. longiflorum*. Colored branches on the dendrogram denote clusters. Upper stem, lower stem, root, and bulb, red cluster; flower and leaf, blue cluster; bud, green cluster.

± 406.4 μg/g dw, respectively. In parts of Asia, lily flower buds, similarly to lily bulbs, are commonly consumed as snacks and in soups, stir-fries, and stew-like dishes. Easter lily flower buds are rich in acetylated phenylpropanoid glycerol glucosides **5** and **4** and differ dramatically from the phytochemical profile of the bulbs. Most abundant in the mature flowers was compound **4**, followed by **5** and **1**, occurring at 6006.2 ± 625.8, 2160.3 ± 556.5, and 1535.8 ± 174.1 μg/g dw, respectively. Interestingly, mature Easter lily flowers are also a plentiful source of acetylated phenylpropanoid glycerol glucosides.

The *p*-coumaroyl-based compound **3** and its acetylated derivative compound **5** had similar distribution profiles in *L. longiflorum* plant parts; however, compound **5** occurred in higher concentrations than compound **3** in the flower buds and mature flowers. Compounds **3** and **5** were the highest occurring phenylpropanoid glycerol glucosides measured in the bulb scales, but their highest concentrations were determined to be in the flower buds as compared to the other plant organs. Notably, compounds **3** and **5** were both higher in the flower buds as compared to mature flowers.

Compound **2** was determined to be a structural isomer of compound **3**, differing only in the linkage arrangement of the glucose and *p*-coumaroyl moiety to the glycerol backbone. In compound **2**, the acyl group is linked to the C2 carbon and the glucose to the C1 carbon, (2*R*)-1-*O*-*β*-D-glucopyranosyl-2-*O*-*p*-coumaroylglycerol, whereas in compound **3**, the acyl group is linked to the C1 carbon and the glucose to the C2 carbon of the glycerin backbone, (2*S*)-1-*O*-*p*-coumaroyl-2-*O*-*β*-D-glucopyranosylglycerol. An acetylated derivative of compound **2** was not identified in the present investigation. Its natural distribution differed from that of the other compounds investigated in the study. The highest concentration of compound **2** was determined to be in the leaves as compared to the other plant organs (Table 1).

The caffeyol-based compound **1** and its acetylated derivative compound **4** had similar profiles in the various organs of *L. longiflorum*; however, as with compounds **3** and **5**, the acetylated derivative, compound **4**, occurred in higher concentrations than compound **1** in the flower buds and mature flowers (Table 1). Compound **4** was the most abundant phenylpropanoid glycerol glucoside measured in the mature flowers.

Upon comparison of the total phenylpropanoid glycerol glucoside concentrations in the plant organs, it is clear that the highest concentrations of these compounds are found in the above-ground portions of the plant (Figure 6). Leaves, flower buds, and flowers have 10−100 times the concentrations of phenylpropanoid glycerol glucosides compared to bulbs and roots, suggesting possible functions for these compounds unique to the above-ground environment. In general, free phenylpropanoid acids do not accumulate in plants, but are usually found as glycosides or esterified to glycerol or organic, fatty, and amino acids. In *Arabidopsis*, malic acid esters and glucosides of the phenylpropanoid sinapic acid accumulate in the leaves, where they provide protection from UV-B light stress and function as sunscreens.[24] It is possible that phenylpropanoid glycerol glucosides may play a similar role in Easter lily, a plant native to the unshaded rocky shores of the subtropical Ryukyu Islands of Japan. The high concentrations of phenylpropanoid glycerol glucosides in the leaves and flower buds may also serve as a constitutive reserve of fungitoxic phenolic acids as in cucumber leaves, where attack by a

DOI: 10.1021/acs.jafc.5b00893
J. Agric. Food Chem. 2015, 63, 4836−4842

powdery mildew fungus triggers the hydrolysis of glucosides of *p*-coumaric acid methyl ester and other phenylpropanoid acid conjugates, significantly reducing disease symptoms.[26]

The unequal distribution pattern of the phenylpropanoid glycerol glucosides between above- and below-ground organs is similar to the distribution of two types of steroidal glycosides of lily bulbs. The proportion of the steroidal glycoalkaloids to furostanol saponins in light-exposed organs was greater; moreover, this ratio decreased from the above-ground organs to those growing farther below the soil surface, suggesting that these compounds may be involved in different physiological processes particular to their growing environment.[27]

In conclusion, this is the first report of the natural distribution of phenylpropanoid glycerol glucosides within the different organs of a plant and the first report that these compounds are present in plant organs other than the bulbs and flowers. The *p*-coumaroyl-based compound **3** and its acetylated derivative **5** were determined to be the most plentiful of the phenylpropanoid glycerol glucosides found in Easter lily bulbs, whereas the acetylated *p*-coumaroyl- and caffeoyl-based derivatives **5** and **4** were found in the highest concentrations in the flower buds. Quantitative analysis of phenylpropanoid glycerol glucosides in the component parts of *L. longiflorum* is a prelude to understanding their function in plant physiology, development, and pathogen defense. The results of this study will also form the basis for research on the benefits of lily bulb consumption to human health and for the development of functional foods, cosmetics, and pharmaceuticals containing lily bulb compounds.

Carnosic Acid as a Major Bioactive Component in Rosemary Extract Ameliorates High-Fat-Diet-Induced Obesity and Metabolic Syndrome in Mice

Yantao Zhao, Rashin Sedighi, Pei Wang, Huadong Chen, Yingdong Zhu, and Shengmin Sang*

Center for Excellence in Post-Harvest Technologies, North Carolina Agricultural and Technical State University, North Carolina Research Campus, 500 Laureate Way, Kannapolis, North Carolina 28081, United States

ABSTRACT: In this study, we investigated the preventive effects of carnosic acid (CA) as a major bioactive component in rosemary extract (RE) on high-fat-diet-induced obesity and metabolic syndrome in mice. The mice were given a low-fat diet, a high-fat diet or a high-fat diet supplemented with either 0.14% or 0.28% (w/w) CA-enriched RE (containing 80% CA, RE#1L and RE#1H), or 0.5% (w/w) RE (containing 45% CA, RE#2), for a period of 16 weeks. There was the same CA content in the RE#1H and RE#2 diets and half of this amount in the RE#1L diet. The dietary RE supplementation significantly reduced body weight gain, percent of fat, plasma ALT, AST, glucose, insulin levels, liver weight, liver triglyceride, and free fatty acid levels in comparison with the mice fed with a HF diet without RE treatment. RE administration also decreased the levels of plasma and liver malondialdehyde, advanced glycation end products (AGEs), and the liver expression of receptor for AGE (RAGE) in comparison with those for mice of the HF group. Histological analyses of liver samples showed decreased lipid accumulation in hepatocytes in mice administrated with RE in comparison with that of HF-diet-fed mice. Meanwhile, RE administration enhanced fecal lipid excretion to inhibit lipid absorption and increased the liver GSH/GSSG ratio to perform antioxidant activity compared with HF group. Our results demonstrate that rosemary is a promising dietary agent to reduce the risk of obesity and metabolic syndrome.

KEYWORDS: *rosemary, carnosic acid, obesity, metabolic syndrome, high-fat diet, oxidative stress*

INTRODUCTION

Obesity is now a global epidemic and is a high risk factor for chronic diseases such as type 2 diabetes, cardiovascular disease, hypertension, nonalcoholic fatty liver disease (NAFLD), osteoarthritis, cancer, and stroke.[1] More than one-third (34.9%, more than 78 million) of adults in the United States were obese in 2011−2012.[2] In addition, 90% of type 2 diabetic patients are overweight or obese.[3,4] A poor dietary habit is one of the most common causes of obesity and type 2 diabetes.[5,6] Dietary intervention with functional food has been proven to be an effective approach to reduce the risk of obesity and related type 2 diabetes.[7,8] Much research is currently being devoted to the bioactive food components to improve metabolic syndrome.

Rosemary (*Rosmarinus officinalis* L.) is well-known for its antioxidant properties and has been widely employed and commercialized as a preserving agent in the food industry, cosmetic additives, and nutritional supplements.[9−12] The rosemary extract (RE) has been approved by the European Union (EU) for use in food preservation and has been categorized by the FDA as "generally recognized as safe". Rosemary itself contains a variety of polyphenolic compounds, including carnosic acid (CA), carnosol, rosemanol, rosmarinic acid (RA), and many others.[13−15] CA has been used as a principal component for the standardization of commercial rosemary extract in food or supplements.[11]

Only a few studies have investigated the beneficial effects of RE on obesity and metabolic disorders in various rodent models of high-fat (HF)-diet-induced[16,17] and genetic obesity.[18,19] Ibarra et al.[17] demonstrated that RE (containing 20% CA) supplement at 500 mg of RE/kg of body weight for 16 weeks inhibited weight gain and improved glucose and lipid homeostasis in HF-diet-fed male C57BL/6J mice. In another study, the male C57BL/6J mice were fed HF diet for 11 weeks and then given RE (containing 2.5% CA, 4% RA, and 5.6% carnosol) for 50 days. This 200 mg/kg of RE administration significantly reduced weight and fat mass gain and protected obesity-induced liver steatosis.[16] In those two HF-diet-induced obesity studies, even though the body weight was limited by oral RE administration, two different kinds of rosemary extract were used and it is hard to determine which component is the major active compound in rosemary. The objective of the present study was to determine whether CA is a major active component in RE and the dose−response effect of CA against HF-induced obesity and related metabolic syndrome in mice.

MATERIALS AND METHODS

Chemicals and Reagents. Commercial RE with 45% CA was purchased from Changsha Yaying Biotechnology Inc. (Changsha, People's Republic of China). The CA content of rosemary extracts was determined by high-performance liquid chromatography (HPLC), and the main compounds of RE were determined by liquid chromatography/mass spectrometry (LC/MS). Antibodies against RAGE were purchased from Santa Cruz Biotechnology (Dallas, TX, USA). Antibodies against β-actin and horseradish peroxidase (HRP) conjugated donkey antirabbit IgG were purchased from Cell Signaling

(Danvers, MA, USA). CA standard and other chemicals were purchased from Sigma (St. Louis, MO, USA). HPLC-grade solvents and other reagents were obtained from VWR Scientific (South Plainfield, NJ, USA). LC/MS-grade methanol and water were obtained from Thermo Fisher Scientific (Waltham, MA, USA).

Preparation of RE with 80% CA. RE with 80% CA was prepared from the commercial RE (45% CA) in our laboratory according to the method described in the US patent 5,256,700[20] with modification. In brief, 50 g of RE (45% CA) was subjected to column chromatography over silica gel (230−400 mesh, Sorbent Technologies Inc., Atlanta, GA) and eluted with a gradient of hexane/acetone (50/2, 50/3, 50/4, 50/5, and 0/100) to give five fractions (Fr A−E). Fraction B (23.3 g) was applied to reverse-phase C_{18} silica gel medium-pressure column chromatography (35 mm × 400 mm, 60 Å, Sigma) eluted with 75% methanol/25% water containing 0.05% formic acid to give four subfractions (Fr. B_1−B_4). Fraction B_2 (6.85 g) was identified as the CA-enriched fraction (80% CA) by HPLC. These steps were repeated five times in order to accumulate enough samples for the mouse study.

Determination of the Major Components in RE by LC/MS. LC/MS was carried out with a Thermo-Finnigan Spectra System, consisting of an Accela high-speed MS pump, an Accela refrigerated autosampler, and an LTQ Velos ion trap mass detector (Thermo Electron, San Jose, CA, USA) incorporated with an electrospray ionization (ESI) interface. A Gemini C18 column (150 × 4.6 mm, 5 μm; Phenomenex, Torrance, CA) was used for separation at a flow rate of 200 μL/min. The column was eluted with 100% solvent A (5% aqueous methanol with 0.2% acetic acid) for 3 min, followed by linear increases in B (95% aqueous methanol with 0.1% acetic acid) to 60% from 3 to 8 min, then to 75% from 8 to 30 min to 82% from 30 to 48 min, and then with 100% from 48 to 55 min. The column was then re-equilibrated with 100% A for 5 min. The injection volume was 10 μL for each sample. Nitrogen gas was used as the sheath gas and auxiliary gas. The collision-induced dissociation (CID) was conducted with an isolation width of 2 Da and normalized collision energy of 35 for MS^2 and MS^3. The mass range was measured from m/z 50 to 1000. Data acquisition was performed with Xcalibur version 2.0 (Thermo Electron, San Jose, CA, USA).

Animals, Diets, and Experimental Design. Male C57BL/6J mice (5 weeks old) were obtained from Jackson Laboratory (Bar Harbor, ME, USA) and were acclimated for 1 week before being randomly assigned to different experimental groups. All of the mice were maintained on a 12 h light/dark cycle on a standard chow diet until experimental analysis. Control low-fat diet (10% kcal energy from fat, D12450J, LF), high-fat diet (60% kcal energy from fat, D12492, HF), and HF mixed with 0.14% or 0.28% of CA-enriched RE (80% CA, RE#1L and RE#1H) and 0.5% of commercial RE (45% CA, RE#2) were produced from Research Diets (New Brunswick, NJ). All diets were pelleted, and the composition of diets is shown in Table 1. The experimental animal protocol was approved by the Institutional Animal Care and Use Committee of the North Carolina Research Campus (No. 12-012). After adaptation for 1 week, mice were randomly divided into five groups (n = 15 in each group, 5 mice per cage): (1) control low fat (LF); (2) control high fat (HF); (3) HF + 0.14% (w/w) CA-enriched RE (RE#1L); (4) HF + 0.28% (w/w) CA-enriched RE (RE#1H); (5) HF + 0.5% (w/w) commercial RE (RE#2). The RE#1H and RE#2 diets contain the same concentration of CA, and the RE#1L diet has half the amount of CA in comparison with those in RE#1H and RE#2 diets. Water and food were available to the animals ad libitum. Body weight and food intake were recorded weekly. At the end of the experiment, the animals were sacrificed by euthanization with isofluorane after fasting for 8 h, and plasma, liver, kidney, and adipose tissue (epididymal, retroperitoneal, and mesenteric) were collected, weighed, frozen under liquid nitrogen, and stored at −80 °C until further analyses.

Body Composition-MRI Analysis. Whole body composition (fat and lean tissues) was determined using nuclear magnetic resonance technology with an EchoMRI Analyzer system (Model MRI-100, Houston, TX, USA) at week 15 (day 102). The EchoMRI-100 instrument provides measurements of whole body composition parameters: total fat, lean mass, and total body water in live mice without the need for anesthesia or sedation in about 2 min.

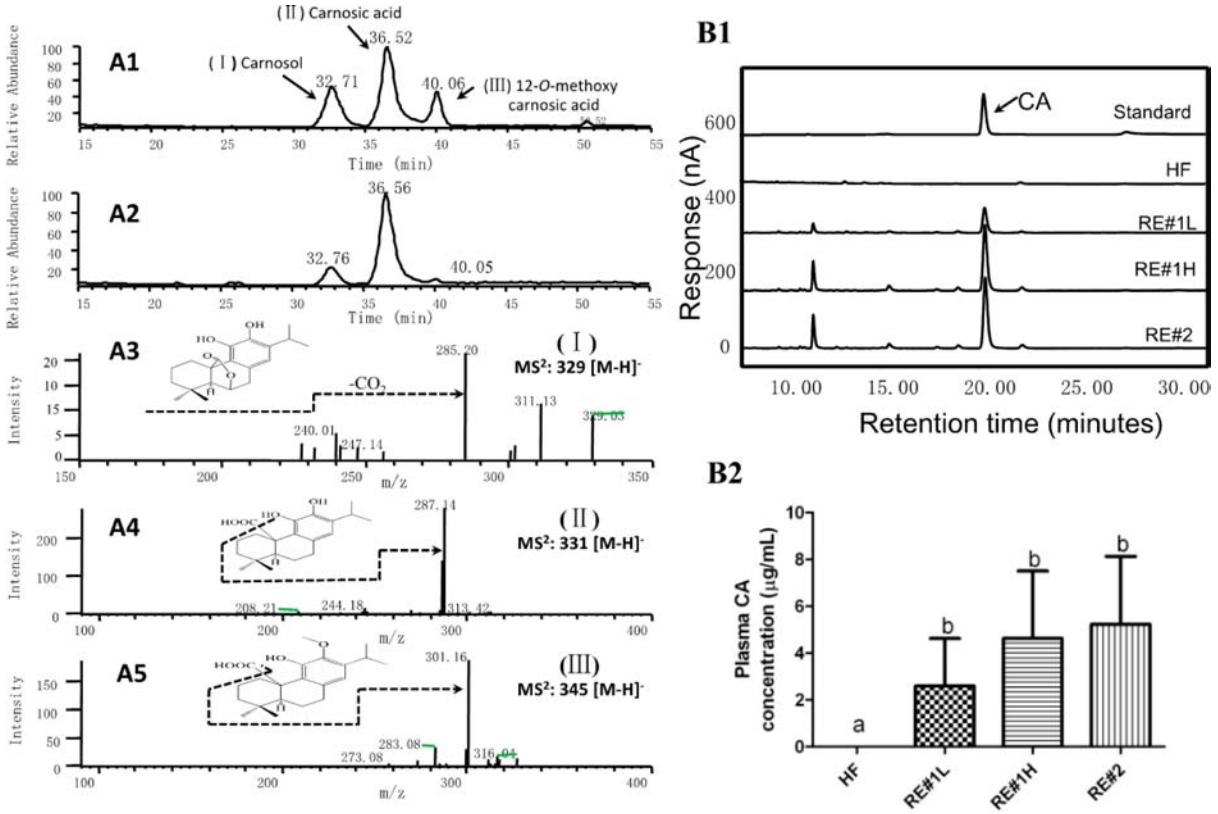

Figure 1. Chemical profiles of rosemary extracts (REs) used in this study and plasma carnosic acid (CA) concentrations in mice treated with REs. LC chromatograms of commercial RE (A1) and CA-enriched RE (A2) with negative ESI-MS as detector and MS/MS (negative) spectra of peaks I–III (A3–A5). Representative HPLC-ECD chromatograms of CA standard and the corresponding CA peak in plasma samples from mice in HF, RE#1L, RE#1H, and RE#2 groups (B1) and plasma CA concentrations of different groups (B2). Results are means ± standard deviations (n = 15), represented by vertical bars. Significant differences (p < 0.05, ANOVA) are identified by the different letters among HF, RE#1L, RE#1H, and RE#2 groups.

Plasma CA Concentrations Determined by HPLC Coupled with an Electrochemical Detector (ECD). Enzymatic deconjugation of the plasma samples was performed as described before, but with slight modification.[21] In brief, plasma samples (100 μL) were treated with β-glucuronidase (250 U) and sulfatase (3 U) for 45 min at 37 °C. This mixture was extracted with 2.5 mL of *n*-hexane by shaking for 5 min and centrifuged at 16.1 (×1000*g*) for 10 min at 4 °C, and then the supernatant was transferred to another tube and evaporated to dryness under a gentle stream of nitrogen at room temperature. The pellet was reconstituted in 150 μL of methanol containing 0.2% acetic acid and filtered through a 0.22 μm filter prior to injecting to the HPLC-ECD system.

CA was quantified using an HPLC-ECD system (ESA, Chelmsford, MA, USA) consisting of an ESA Model 584 HPLC pump, an ESA Model 542 autosampler, an ESA organizer, and an ESA CoulArray detector coupled with two ESA Model 6210 four-sensor cells. A Gemini C_{18} column (150 × 4.6 mm, 5 μm; Phenomenex, Torrance, CA, USA) was used for chromatographic analysis at a flow rate of 1.0 mL/min. The mobile phases consisted of solvent A (30 mM sodium phosphate buffer containing 1.75% acetonitrile and 0.125% tetrahydrofuran, pH 3.35) and solvent B (15 mM sodium phosphate buffer containing 58.5% acetonitrile and 12.5% tetrahydrofuran, pH 3.45). The gradient elution had the following profile: 30% B from 0 to 3 min; 30–65% B from 3 to 10 min; 65–100% B from 10 to 40 min; 100% B from 40 to 45 min; and 30% B from 45 to 50 min. The cells were then cleaned at a potential of 1000 mV for 2 min. The injection volume of the samples was 10 μL. The eluent was monitored by the Coulochem electrode array system (CEAS) with potential settings at −50, 0, 100, 200, 300, 400, 500, and 600 mV. Data for Figure 2B1 was from the channel set at 200 mV of the CEAS. For CA, the limit of detection (LOD) and the limit of quantification (LOQ) were 0.1 and 0.5 μg/mL, respectively. The linearity ranged from LOQ to 10 μg/mL (the upper limit was not tested) with a correlation coefficient of 0.999.

Biochemical Analyses of Blood Samples. Blood samples were collected by cardiac puncture, and plasma was obtained by centrifuging the blood at 8000*g* for 15 min at 4 °C. Plasma alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities were colorimetrically measured using Infinity ALT and AST Reagent provided by Thermo Scientific (Waltham, MA). Plasma TNF-α was measured using a Mouse TNF-α ELISA kit (Millipore, Temecula, CA). To measure blood glucose, mice were fasted for 8 h before measurement. Blood was collected from the tail vein, and glucose concentrations were measured using a OneTouch Ultra2 Blood Glucose Meter (LifeScan, Milpitase, CA, USA) at weeks 0, 10, and 16. Insulin levels were determined using an Ultrasensitive Insulin ELISA kit (ALPCO, Salem, NH, USA). Homeostasis model assessment of insulin resistance (HOMA-IR) was calculated using the following formula: [fasting glucose (mg/dL) × insulin (mU/L)]/405.[22]

Hepatic Lipid Analyses. Quantitative assay of lipids was conducted by measuring triglyceride and free fatty acids (FFA) concentrations in the liver. Hepatic lipids are extracted by homogenizing liver tissue in chloroform using 1% Triton X-100. The organic extracts were air-dried, vacuumed, and dissolved in Trition X-100. Triglyceride and FFA concentrations in extracts were determined using commercial kits (BioVision, Milpitase, CA).

Fecal Lipid Excretion. The feces harvested during a 24 h period were collected at week 16, frozen at −80 °C, and pulverized. Total lipids were extracted from 100 mg of dried feces using the following method.[23] The feces were cleaned and dried for 24 h by a freeze-dryer, incubated with 2 mL of chloroform/methanol (2/1) for 30 min at 60 °C with constant agitation, and then centrifuged. Water (1 mL) was added to the supernatant, and following vortexing, phase separation was induced by low-speed centrifugation (500*g* for 10 min). The lower chloroform

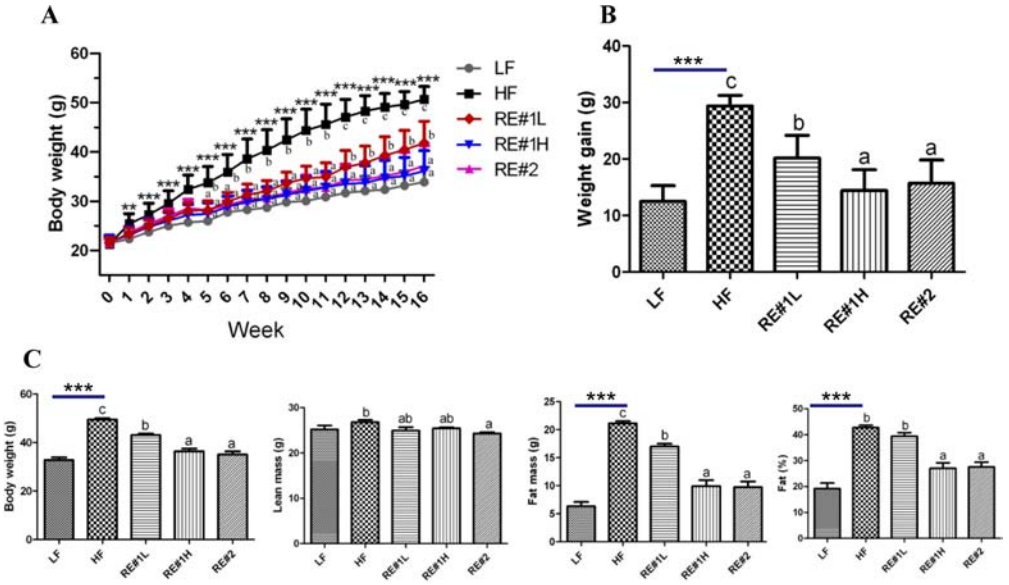

Figure 2. Effects of long-term carnosic acid (CA) enriched rosemary extract (RE) (RE#1L, RE#1H, and RE#2) administration on body weight (BW) (A), weight gain (B), and body composition (C) in high-fat-diet-fed C57BL/6J mice. Results are means ± standard deviations (n = 15 for A and B; n = 5 for C) represented by vertical bars. The asterisk (*) denotes a significant difference of the HF group in comparison with the LF group: (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$. Significant differences ($p < 0.05$, ANOVA) are identified by the different letters among HF, RE#1L, RE#1H, and RE#2 groups.

phase was then removed and transferred to a new tube, and the sample was evaporated to dryness by a nitrogen evaporator and weighed.

Hepatic GSH/GSSG and Oxidative Stress Levels. The ratio of GSH/GSSG in the liver was determined by a commercial Glutathione Assay Kit (Trevigen, Gaithersburg, MD, USA). The lipid peroxidation product malondialdehyde (MDA) in the plasma and liver was measured by the thiobarbituric acid reactive substances (TBARS) method using a commercial kit (Cayman Chemical, Ann Arbor, MI, USA).

Liver Histology. Liver tissues were fixed with 10% formalin and processed for paraffin embedding. Tissue sections were cut to 5 μm and stained with hematoxylin and eosin (H&E) for assessing histopathological changes.

Plasma and Liver AGEs. The plasma AGE level was measured on the basis of the methods of Henle,[24] Munch,[25] and Raposeiras-Roubin.[26] In brief, plasma was diluted 1/20 with PBS (pH 7.4), and the fluorescence intensity was recorded at 360 nm excitation and 460 nm emission wavelengths by a multimode microplate reader (Synergy 2, Biotek). Fluorescence intensity was expressed in arbitrary units (AU), and the fluorescence was normalized with the LF group.

The liver AGE level was determined according to the methods of Nakayama[27] and Yamabe.[28] In brief, minced liver tissue was delipidated with chloroform and methanol (2/1, v/v) with overnight shaking. After it was washed with methanol and distilled water, the tissue was homogenized in 0.1 N NaOH, followed by centrifugation at 8000g for 15 min at 4 °C. The amounts of AGEs in these alkali-soluble samples were determined by measuring fluorescence at 360 nm excitation and 460 nm emission wavelengths. The fluorescence reading of 1 mg/mL of BSA was defined as 1 unit. The fluorescence values of samples were measured at a protein concentration of 1 mg/mL and expressed in arbitrary units (AU) normalized by the reading from 1 mg/mL of BSA.

Western Blot Assay of Proteins. Whole protein lysates of liver tissue were extracted using RIPA buffer (25 mM Tris-HCl (pH 7.6), 150 mM NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS, Thermo Fisher Scientific) supplemented with 1% protease inhibitor cocktail and 1% phenylmethylsulfonyl fluoride. Protein concentrations were measured using a BCA Protein Assay Kit (Thermo Scientific, Rockford, IL, USA). Aliquots containing 50 μg of protein were loaded onto a 10−12% sodium dodecyl sulfatepolyacrylamide gel, transblotted onto a polyvinylidene difluoride (PVDF) membrane (Bio-Rad), blocked with Tris-buffered saline with 1% Casein with 0.1% Tween-20, and then incubated with each of the primary antibodies of RAGE and β-actin. The membrane was then incubated with horseradish peroxidase conjugated donkey antirabbit or goat antimouse IgG (Cell signaling, Danvers, MA, USA). The bound complexes were detected with SuperSignal Chemiluminescent Subtract (Thermo Scientific, Rockford, IL, USA). The immunoblot bands were quantified by densitometry analysis, and the ratio to β-actin was calculated and presented, setting the values of low-fat diet fed mice as 1.

Statistical Analysis. All results are presented as means ± standard deviation. A Student's t test was performed using GraphPad Prism version 5.04. An asterisk (*) means a significant difference of HF group in comparison with the LF group: (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$. The intergroup variation was measured by one-way ANOVA with Tukey's test. Significant differences are identified by the different letters among HF, RE#1L, RE#1H, and RE#2 groups, and a p value of <0.05 was considered statistically significant.

The inhibition of gains and biochemical parameters by RE-treated groups is expressed as a percentage calculated as inhibition percentage (%) = ((HF − RE)/(HF − LF)) × 100.

RESULTS

Preparation of CA-Enriched RE. In order to determine whether CA is the active component in RE against obesity and related metabolic syndrome, we further enriched CA from commercial RE using different column chromatography techniques. The three major peaks in the commercial RE were identified as carnosol, CA, and 12-*O*-methoxy carnosic acid by analyzing their tandem mass (Figure 1A). The CA concentrations of commercial RE and CA enriched RE were quantified by HPLC-ECD and determined to be 45% and 80%, respectively.

Plasma CA Concentrations in RE-Treated Mice. The plasma CA concentrations were quantified by HPLC-ECD. The CA levels of mice in the RE#1L group were much lower than those in RE#1H and RE#2 groups; even though the difference is not significant (Figure 1B), the results are consistent with the levels of CA in the RE#1L, RE#1H, and RE#2 diets.

Effects of Long-Term RE Supplementation on Body Weights and Organ Weights. Three different RE treatments, RE#1L, RE#1H, and RE#2, were used in this study. RE#1H and RE#2 had the same amount of CA (0.224% in the diet), which was twice that in RE#1L (0.112% in the diet). Body weights

[a]Values are means ± SD. The asterisks (*) denote significant difference of the HF group in comparison with the LF group: (*) $p < 0.05$; (**) $p < 0.01$; (***) $p < 0.001$. Significant differences ($p < 0.05$, ANOVA) are identified by the different letters among HF, RE#1L, RE#1H, and RE#2 groups.

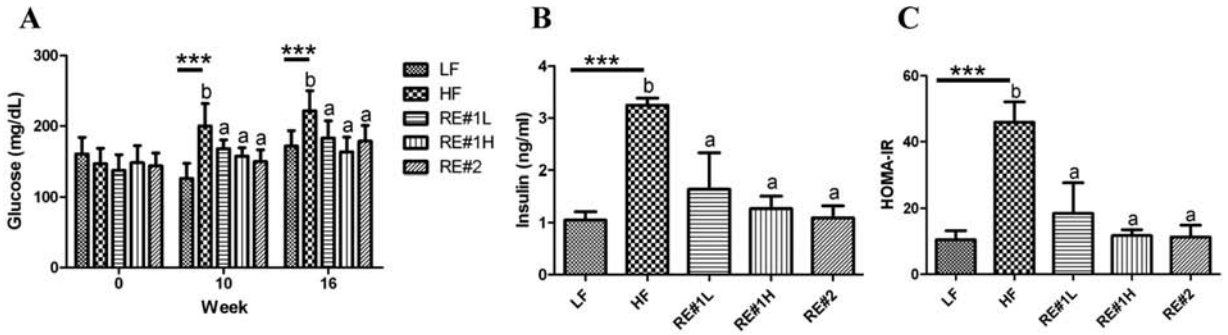

Figure 3. Effects of long-term rosemary extract (RE) dietary treatments on glucose (A), insulin (B), and HOMA-IR (C) in high-fat-diet-fed C57BL/6J mice. HOMA-IR was calculated on the basis of the formula [fasting glucose (mg/dL) × insulin (mU/L)]/405 to express the degree of insulin resistance. Values are presented as mean ± standard deviations ($n = 15$ for A and $n = 5$ for B and C) represented by vertical bars. The asterisk (*) denotes a significant difference of the HF group in comparison with the LF group: (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$. Significant differences ($p < 0.05$, ANOVA) are identified by the different letters among the HF, RE#1L, RE#1H, and RE#2 groups.

between the HF and LF groups began to differ significantly after the first week of treatment ($p < 0.01$). RE supplementation significantly decreased body weight gain induced by the HF diet after the fifth week of treatment ($p < 0.05$). Meanwhile, body weights of RE#1H- and RE#2-treated mice were significantly lower than those in the RE#1L group after 12 weeks of treatment ($p < 0.05$). After 16 weeks of treatment of LF, HF, and HF plus RE diets, HF-treated mice showed a significantly higher body weight and body weight gain in comparison with those of LF-treated control (BW, 50.67 ± 2.58 g vs 33.89 ± 3.05 g, $p < 0.001$, Figure 2A; BW gain, 29.39 ± 1.88 g vs 12.49 ± 2.78 g, $p < 0.001$, Figure 2B). HF plus RE diet treated mice showed a significantly lower final body weight (41.80 ± 4.40, 36.13 ± 4.14, and 37.10 ± 4.18 g, respectively, $P < 0.05$) and body weight gain (20.17 ± 4.00, 14.41 ± 3.70, and 15.67 ± 4.16 g, respectively, $p < 0.05$) with 54.5%, 88.7%, and 81.2% inhibition of weight gain by RE#1L, RE#1H, and RE#2 treatments, respectively, in comparison with those of HF mice. Meanwhile, the RE#1H and RE#2 mice had lower body weight than RE#1L mice ($p < 0.05$) at the end of the 16 week experimental period.

HF mice had significantly increased liver weight ($p < 0.001$) and liver/body weight ratio ($p < 0.001$) in comparison with those of LF mice, which were normalized by RE supplementation (Table 2). Similar effects of RE supplementation were observed on kidney weight ($p < 0.01$) and kidney/body weight ratio ($p < 0.001$, Table 2). Consistent with the body weight results, the weights of epididymal ($p < 0.05$), mesenteric ($p < 0.001$), and retroperitoneal fat ($p < 0.001$) significantly increased in the HF group in comparison with the LF group. RE supplementation significantly decreased the weights of mesenteric ($p < 0.05$) and retroperitoneal fat ($p < 0.05$); however, the weight of epididymal fat was increased by the RE supplementation. The total body fat weights of mice in RE#1H and RE#2 groups were decreased significantly ($p < 0.05$) but not for the RE#1L group (Table 2). These results were further confirmed by the MRI data (Figure 2C). HF mice had a significantly increased percent body fat (42.72 ± 2.08%) in comparison with LF mice (19.17 ± 4.88%, $p < 0.001$). RE-treated mice had significantly lower percent body fat (39.41 ± 3.00%, 27.00 ± 4.78%, and 27.57 ± 4.06% for RE#1L, RE#1H, and RE#2, respectively, $p < 0.05$) in comparison with HF mice; meanwhile, the percent body fat values for RE#1H and RE#2 mice were much lower than those of RE#1L mice ($p < 0.05$). Altogether, CA-enriched RE supplementation could dose-dependently limit body weight and total fat mass gains. RE#1H and RE#2 had almost identical effects and were much more potent than RE#1L.

RE Supplementation Improved Blood Glucose and Insulin Levels and HOMA-IR Index in HF Diet Fed Mice. We determined the fasting blood glucose levels at weeks 0, 10, and 16 (Figure 3A). HF mice had significantly higher blood glucose levels in comparison with those of LF mice after 10 and 16 weeks of treatment ($P < 0.001$). CA-enriched RE supplementation significantly decreased the fasting blood glucose levels elevated by the HF diet ($P < 0.05$).

At the end of the experiment, a higher insulin level (3.24 ± 0.14 ng/mL) was observed in the HF group in comparison with

J. Agric. Food Chem. 2015, 63, 4843−4852

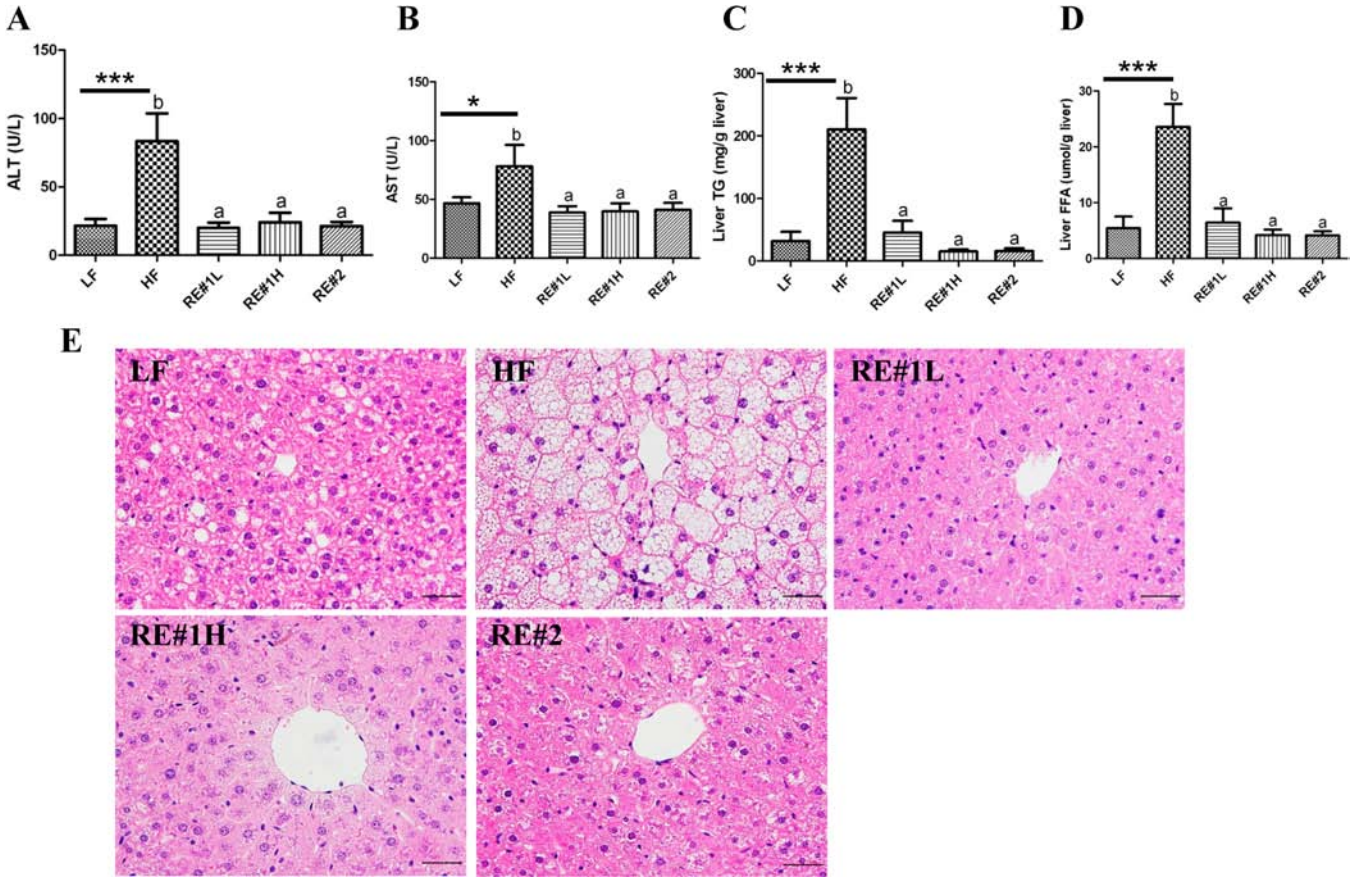

Figure 4. Effects of long-term rosemary extract (RE) dietary treatments on biomarkers of liver injury, liver lipid levels, and liver histology in high-fat-diet-fed C57BL/6J mice. Plasma ALT (A), AST (B), liver triglyceride (TG) (C) and liver free fatty acid (FFA) (D) were determined using commercial kits. Histological examination (E) was determined using H&E staining for liver samples of LF, HF, RE#1L, RE#1H, and RE#2 feeding mice. Scale bar: 50 μm. Values are presented as mean ± standard deviations (n = 6 for A–D and n = 8 for E) represented by vertical bars. The asterisk (*) denotes a significant difference of the HF group in comparison with the LF group: (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$. Significant differences ($p < 0.05$, ANOVA) are identified by the different letters among HF, RE#1L, RE#1H, and RE#2 groups.

that of the LF group (1.05 ± 0.16 ng/mL) (Figure 3B). The insulin levels were almost normalized to the levels in the LF group by RE supplementation in RE#1L, RE#1H, and RE#2 groups (1.64 ± 0.69, 1.27 ± 0.24, and 1.09 ± 0.23 ng/mL, respectively). The mice of RE#1L, RE#1H, and RE#2 groups experienced 72.9%, 90.0%, and 98.1% less increase in plasma insulin levels ($p < 0.05$). HOMA-IR index was calculated on the basis of the final blood glucose and insulin concentrations. HF mice had a significantly higher HOMA-IR index than LF mice ($p < 0.001$; Figure 3C), whereas RE supplementation dramatically decreased the HOMA-IR index at 71.9%, 96.4%, and 97.7% of RE#1L, RE#1H, and RE#2, respectively, in comparison with HF mice ($p < 0.05$; Figure 3C).

RE Supplementation Attenuated HF-Induced Liver Injury and Lipid Accumulation. HF mice had a significantly larger liver size in comparison to LF mice ($P < 0.001$; Table 2). These mice also had elevated plasma ALT ($p < 0.001$; Figure 4A) and AST ($p < 0.05$; Figure 4B) concentrations and liver triglycerides ($p < 0.001$; Figure 4C) and free fatty acids (FFA, $p < 0.001$; Figure 4D) levels. RE supplementation significantly reduced liver weight (53%, 57%, and 54% inhibition of RE#1L, RE#1H, and RE#2, respectively), plasma ALT (102.7%, 96.1%, and 100.5% inhibition, respectively) and AST (96.8%, 121.8%, and 117.6% inhibition, respectively) concentrations, and liver triglyceride (92.4%, 109.4%, and 108.9% inhibition, respectively) and FFA (94.3%, 106.7%, and 107.1% inhibition, respectively) levels.

Histological analysis of liver sections from the five groups of mice demonstrated enlargement of hepatocytes and steatosis represented by the vacuolation in hepatocytes of the HF mice in comparison with those in the LF mice, and fat deposits were obviously reduced by RE#1L, RE#1H, and RE#2 treatments in comparison with those in the HF group (Figure 4E). There was no obvious difference among RE#1L, RE#1H, and RE#2 groups with regard to liver histology.

RE Supplementation Increased Fecal Lipid Excretion. The fecal lipid excretion of the mice in the HF group was significantly higher than that of the mice in the LF group after 16 weeks of treatment ($p < 0.05$; Figure 5). Dietary RE supplementation significantly inhibited lipid absorption and increased the fecal lipid excretion in comparison with the HF group (52.4%, 91.5%, and 96.2% increase of RE#1L, RE#1H, and RE#2, respectively). The fecal lipid excretions of mice in RE#1H and RE#2 groups were significantly higher than that in the RE#1L group.

RE Supplementation Attenuated HF-Induced Oxidative Stress and Inflammation. As an indicator of oxidative stress, the lipid peroxidation product MDA was significantly increased by HF diet feeding in plasma (30.92 ± 7.15 μM, $p < 0.05$) and liver (1.39 ± 0.41 nmol/mg protein, $p < 0.05$) in comparison with that in the LF group (19.99 ± 4.16 μM and 0.86

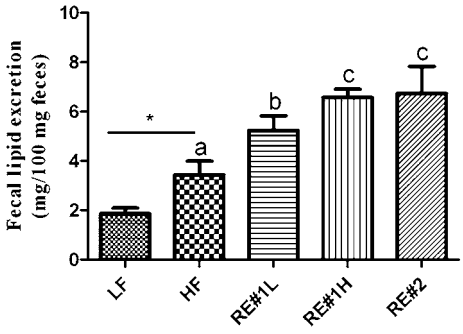

Figure 5. Effects of long-term rosemary extract (RE) dietary treatments on fecal lipid excretion in high-fat-diet-fed C57BL/6J mice at week 16. Values are presented as mean ± standard deviations ($n = 3$) represented by vertical bars. The asterisk (*) denotes a significant difference of the HF group in comparison with the LF group: (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$. Significant differences ($p < 0.05$, ANOVA) are identified by the different letters among HF, RE#1L, RE#1H, and RE#2 groups.

± 0.098 nmol/mg protein, respectively), and these increases were significantly inhibited by RE supplementation (52.4%, 89.7%, and 93.0% inhibition in plasma, 100.5%, 119.9%, and 119.9% inhibition in liver of RE#1L, RE#1H, and RE#2, respectively; Figure 6A,B). The plasma MDA levels were normalized to that of the LF mice in the RE#1H and RE#2 groups (21.12 ± 2.39 and 20.75 ± 5.31 μM, respectively) but not in the RE#1L group (25.19 ± 2.12 μM). The GSH/GSSG ratio in liver of mice in the HF group was significantly lower than that of the LF group ($p < 0.01$), and this decrease was normalized by RE supplementation (Figure 6C). However, there was no difference among the three RE-treated groups. Proinflammatory cytokine TNF-α level was measured using ELISA. RE supplementation significantly decreased the proinflammatory TNF-α levels elevated by HF-diet treatment (86.4%, 87.2%, and 91.3% inhibition of RE#1L, RE#1H, and RE#2, respectively; Figure 6D).

RE Supplementation Attenuated HF-Induced AGEs Accumulation and RAGE Activation. A HF diet induced significant AGE accumulation in plasma ($p < 0.001$) and liver (p

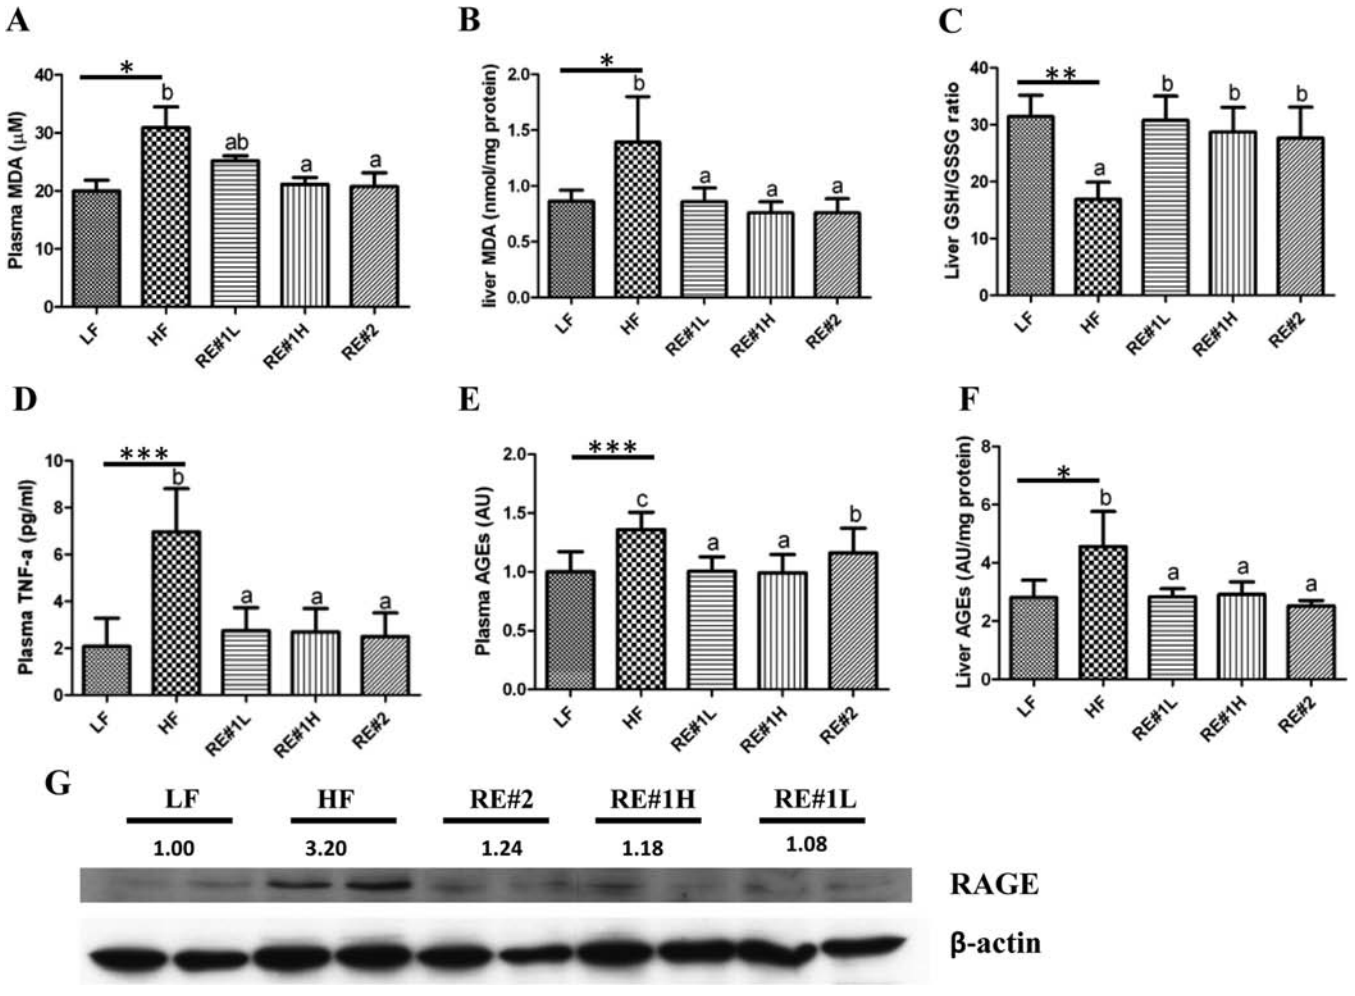

Figure 6. Effects of long-term rosemary extract (RE) dietary treatments on biomarkers of oxidative stress, inflammation, and protein glycation. The levels of plasma and liver malondialdehyde (MDA) (plasma, A; liver, B), liver GSH/GSSG (C), and plasma TNF-α (D) were measured using a commercial kit. The AGE levels (plasma, E; liver, F) were determined by a fluorescence method. The expression of liver RAGE (G) was determined by Western blot; the immunoblot bands were quantified by densitometry analysis, and the ratio to β-actin was calculated by setting the value of LF as 1. Values are presented as mean ± standard deviations ($n = 6$ for A–C and E, $n = 12$ for D, $n = 15$ for E, and $n = 2$ for G). The asterisk (*) denotes a significant difference of the HF group in comparison with the LF group: (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$. Significant differences ($p < 0.05$, ANOVA) are identified by the different letters among HF, RE#1L, RE#1H, and RE#2 groups.

< 0.05) in comparison with the LF group, and this accumulation was significantly inhibited by dietary RE supplementation (52.1%, 99.8%, and 102.3% inhibition in plasma and 116.4%, 94.0%, and 98.3% inhibition in liver of RE#1L, RE#1H, and RE#2, respectively; Figure 6E,F). There was a significant difference in plasma AGE levels of RE#1H and RE#1L groups in comparison with those of the RE#2 group, but there was no difference between the RE#1H and RE#1L groups. Meanwhile, HF diet feeding for 16 weeks induced a significant increase of liver RAGE expression by 3.20-fold in comparison with the LF group (Figure 6G). This increase induced by HF was significantly reduced by dietary RE supplementation.

DISCUSSION

In this study, we gave male C57BL/6J mice a HF diet containing 60% kcal of fat for 16 weeks to induce obesity and type 2 diabetes. The body weight gain of the mice fed this HF diet was dramatically increased in comparison with that of LF diet fed mice. The liver weight, fat mass, and other metabolic parameters of the obese mice, such as plasma ALT, AST, glucose, insulin levels, and liver TG and FFA levels, were significantly elevated by HF treatment. RE supplementation significantly decreased body weight gain of HF-treated mice. We provide the first evidence that CA is a major active component of rosemary which effectively and dose-dependently attenuates body weight gain and counteracts metabolic disorders, especially obesity-associated liver damage, induced by a HF diet in mice.

The dose of commercial RE (RE#2 with 45% CA) at 0.5% (w/w) was selected on the basis of a literature study which reported that 0.5% of RE with 20% CA could limit weight gain in mice on a high-fat diet.[17] The dose of 0.28% CA-enriched RE (RE#1H with 80% CA) was calculated on the basis of the amount of CA in 0.5% commercial RE in order to have the same amount of CA in RE#1H and RE#2 to determine whether CA is a major bioactive component of RE against obesity induced by HF. In order to elucidate the dose-dependent effect of CA-enriched RE, we also included the half-dose of RE#1H, 0.14% CA-enriched RE (RE#1L with 80% CA). Considering the difference between mice and humans in terms of calorie consumption, the 0.5% dose in diet (w/w) (500 mg/kg of BW per day calculated on the basis of each mouse with 30 g of BW eats 3 g of diet) in mice approximately equals 40 mg/kg BW per day in humans (on the basis of 60 kg BW).[29] However, this estimated human dose needs to be validated experimentally, since humans and mice are different at least in terms of absorption and metabolism of compounds in RE.

Body weight was significantly decreased by RE supplementation in comparison to the HF group, and an almost complete prevention of body weight gain was observed in the groups receiving diets containing higher CA content (RE#1H and RE#2), without affecting food intake (data not shown). Our finding is in agreement with the two previous rosemary extract supplementation studies in HF-diet-fed mice, in which it was shown that RE supplementation apparently reduced weight gain in comparison to the control.[16,17] In the Harach et al. study, administration of 200 mg/kg of BW per day RE supplementation for 50 days reduced body weight gain in diet-induced obese mice. However, the RE used in that study contained 2.5% CA, 4% RA, and 5.6% carnosol, which is very different from the RE used in the present study. Ibarra et al. reported that the RE (containing 20% CA) supplementation in the HF diet (45% kcal from fat) for 16 weeks inhibited the weight gain in HF-diet-fed mice, but only one dose of RE (500 mg/kg) was used and the inhibitory effect by RE with 20% CA was not as dramatic as that observed in the present study.

We found that the 16 week RE treatment also significantly decreased total fat, percent body fat, and visceral fat weight. The weights of the mesenteric and retroperitoneal fat depots were significantly decreased by RE supplementation, with the larger decrease occurring in the mesenteric depot. Interestingly, the weight of epididymal fat was not significantly decreased but increased by the RE treatment. This is the opposite of the findings from Harach's and Ibarra's studies. Further studies are warranted to pinpoint the mechanism behind this observation. It has been reported that decreases in body fat may be partially due to the inhibitory effects of RE on lipid absorption and lipase activity.[16,17] Indeed, we found that long-term RE treatment increased fecal lipid excretion in RE supplementation groups in comparison with HF-diet-fed mice, supporting the hypothesis that RE decreased lipid absorption.

Metabolic syndrome is a group of pathological conditions related to obesity, dislipidemia, insulin resistance, and prediabetes. We found that long-term dietary RE administration significantly decreased blood glucose, insulin, and insulin resistance in HF-diet-fed mice. A significant decrease in glucose by RE treatment was also observed in Ibarra's study.[17] However, RE administration did not alter glucose and insulin levels in Harach's study, in which the RE had a very low level of CA (2.5%),[16] indicating that CA is the potential active component altering glucose and insulin levels.

Meanwhile, RE treatment histologically and biochemically prevented hepatic steatosis induced by the HF diet. The liver weights of RE-treated mice were significantly lower than these of HF-diet-fed mice. However, there was no alteration of liver weight observed after the treatment of RE with 20% CA or 2.5% CA,[16,17] further indicating that CA is the major active component in RE. The liver TG and FFA levels were also significantly decreased by RE treatment, which agrees with the findings from a chronic CA administration mouse study.[30] Park et al.[30] reported that dietary CA suppressed HF-diet-induced hepatic steatosis through downregulation of the expression of hepatic lipogenic genes (SREBP-1c, L-FABP, SCD-1, and FAS) to decrease de novo lipogenesis and increase fatty acid β-oxidation-related genes (PPAR-α, CPT-1, and ACO), as well as fatty acid elongation. Wang et al.[31,32] also reported that CA prevented obesity and hepatic steatosis in *ob/ob* mice and inhibited lipid accumulation in hepatocytes through the EGFR/MAPK signaling pathway to inhibit expression of protein and activity of PPARγ. Tu et al.[33] reported that RE increased glucose consumption in HepG2 cells and potentially increased liver glycolysis and fatty acid oxidation through activating AMPK and PPAR pathways. Thus, the likely mechanisms of the preventive effect on fatty liver of RE are inhibition of lipid absorption, decrease of de novo lipogenesis, increase of fatty acid β-oxidation, and regulation of lipid metabolism in liver of mice.

In the present study, we determined MDA levels as an indicator of oxidative stress in plasma and liver and proinflammatory cytokine TNF-α in plasma. A significant increase of MDA levels in plasma and liver was observed in HF-diet-fed mice in comparison with those in LF-diet-fed mice, which confirms previous reports.[34,35] The elevated MDA levels were normalized by all of the RE treatments (RE#1L, RE#1H, and RE#2) in liver and by RE treatments with higher levels of CA (RE#1H and RE#2) in plasma. The RE supplementation significantly decreased the elevated TNF-α in plasma induced by HFD feeding. We also demonstrated that RE treatments

DOI: 10.1021/acs.jafc.5b01246
J. Agric. Food Chem. 2015, 63, 4843−4852

significantly increased the GSH/GSSG ratio in comparison with that of the HF group. It is well-known that the Nrf2 signaling pathway plays a key role in regulating GSH levels.[36,37] However, we did not observe the translocation of Nrf2 from cytoplasm to nucleus in liver using immunohistochemical (IHC) and immunofluorescent (IF) staining (data not shown). It is possible that CA can activate the Nrf2 pathway at early stages of the treatment, which needs to be proved experimentally.

Protein damage due to reaction with carbohydrates, the nonenzymatic formation of advanced glycation end products (AGEs), is thought to be the major pathogenesis cause of diabetic complications. Therefore, we measured AGE levels in plasma and liver tissue in the present investigation. The HFD significantly induced AGE accumulation in plasma and liver in comparison with that of LF-diet-fed mice. This concurs with a previous report that HF induced AGE accumulation in mice.[38] These elevated AGE levels in plasma and liver were decreased by the RE administrations. HF-diet feeding also induced overexpression of RAGE in the liver, which was significantly decreased by RE treatment. Even though there have been some reports that rosemary exhibited antiglycative effects in vitro,[39−41] we demonstrated for the first time that RE administration lowered the AGE levels in plasma and liver in HF-diet-induced obese and diabetic mice.

In conclusion, our present study demonstrated that CA is a major active component of rosemary extract and could dose-dependently ameliorate obesity and metabolic syndrome induced by HF diet in mice. It will be worthwhile to further study the underlying molecular mechanisms of CA against obesity and identify the effective dose range of CA. Whether CA or RE can prevent/treat obesity in humans is another topic of future study.

Structural and Gel Textural Properties of Soy Protein Isolate When Subjected to Extreme Acid pH-Shifting and Mild Heating Processes

ABSTRACT: Changes in the structural and gel textural properties were investigated in soy protein isolate (SPI) that was subjected to extreme acid pH-shifting and mild heating processes. The SPI was incubated up to 5 h in pH 1.5 solutions at room temperature or in a heated water bath (50 or 60 °C) to lead to protein structural unfolding, followed by refolding at pH 7.0 for 1 h. The combination of pH-shifting and heating treatments resulted in drastic increases in the SPI gel penetration force ($p < 0.05$). These treatments also significantly enforced the conversion of sulphydryl groups into disulfides, increased the particle size and hydrophobicity values, reduced the protein solubility ($p < 0.05$), and strengthened the disulfide-mediated aggregation of SPI. The intrinsic fluorescence spectroscopy results indicated structural unravelling when protein was subjected to acidic pH-shifting in combination with heating processes. The slight loss of secondary structure was observed by circular dichroism. These results suggested that pH-shifting combined with heating treatments provide great potential for the production of functionality-improved SPI, with the improved gelling property highly related to changes in the protein structure and hydrophobic aggregation.

KEYWORDS: *pH shifting, heating, soy protein isolate, protein structure, gel textural property*

INTRODUCTION

Soy protein as a health-promoting and inexpensive functional composition is widely used in meat products, nutraceutical products, and beverages.[1] In general, untreated soy proteins display only limited functionality, such as emulsifying, gelation, and other processing properties.[2] Therefore, additional studies are needed to modify the soy protein isolate (SPI) structures to exhibit broadened functionality, such as solubility, emulsification, and gelation.

The ability of SPI to form gel is usually regarded as a very important functional property of SPI, and thus, it is worth probing into the inner link between the structure and gel characteristics of soy protein.[3] The thermal-induced protein gel is a complicated process that includes protein aggregation and unfolding before forming a complex network structure.[4] The molecular weight and size of the protein aggregates have a relationship to the gel network and gel properties.[5] As the major components in the SPI, 7S and 11S play a decisive role in the gelling property. One study found that 7S and 11S mainly affect the gel viscoelasticity and hardness and that the B subunit of 11S and β subunit of 7S undergo macromolecule aggregation by electrostatic interactions, which were considered to have an important effect on the gel properties.[6] Damodaran and Kinsella[7] reported that the existence of 7S definitely inhibits the dissociation of the 11S subunits. Hence, both protein aggregation and each subunit play an important role in gelation. In recent years, numerous researchers have made some effects to change the protein structures to produce certain conformations that are in favor of producing a desirable functionality.[8] When exposed to extreme pH conditions, many globular proteins undergo significant conformational changes, typically referred to as the molten globule (MG) state.[8] The discovery of an extreme pH-shifting-induced intermediate state in SPI has resulted in an interest in investigating acid or alkaline treatments to improve the functionality of these protein.[9−13] Jiang et al.[13] proved that acidic or alkaline pH treatments could cause MG structure formation in SPI, resulting in enhanced emulsifying ability. Some studies have revealed that extreme pH treatments might dissect protein into subunits, thus leading to improved SPI functional properties,[13] particularly the enhanced gelation of mixed myofibrillar and soy protein sols.[14]

Heating is the easiest method to enhance the functional properties of protein, producing numerous desirable structural changes in the SPI, in favor of protein gel formation.[14] It is conceivable that SPI becomes more sensitive to temperature changes after exposure to extreme pH values. The heating temperature in the present study was 50 or 60 °C. The SPI is substantially but not completely denatured (unfolded) by the extreme pH treatment. However, the MG state (a metastable state) induced by pH shifting renders soy proteins more susceptible to further structural changes and hydrophobic aggregation. Hence, the low temperatures of 50 and 60 °C, which would not normally affect the structure of 7S or 11S globulins in control SPI, now become effective. When the pH shifting is combined with mild heating, a number of desirable structural and functional changes can occur. A clear knowledge of the gel textural profiles of soy proteins treated by acidic pH shifting alone or pH shifting combined with heating is crucial for the food industry. The aim of this research was to evaluate the effect of extreme acid pH-shifting combined with 50 or 60 °C heating treatments on the gelation and structural properties

of SPI and to identify the relative structural contributions that produced the functionality improvements.

MATERIALS AND METHODS

Materials. Defatted soy flakes were obtained from Harbin High-Tech Group (Harbin, Heilongjiang, China). Ethylenediaminetetraacetic acid (EDTA), 2-nitro-5-thiobenzoate (NTB), and 1-anilino-8-naphthalene-sulfonate (ANS) were obtained from Sigma Chemical Co. (St. Louis, MO). All of the reagents and chemicals were of analytical grade.

Preparation of SPI. SPI was prepared according to the method of Jiang et al.[13] and Chen et al.[15] The samples were freeze-dried and stored in a 4 °C cooler. The protein content of the prepared SPI was 94.76% (w/w), as determined by the Kjeldahl method.

pH-Shifting and Heating Process-Treated SPI. The pH-treated SPI was prepared according to Jiang and Xiong.[13] Suspensions of SPI (30 mg/mL protein) was centrifuged at 12000*g* for 15 min at 4 °C. The supernatant was adjusted to pH 1.5 with 2 M HCl. After holding at pH 1.5 for 0, 1, 3, or 5 h under different temperature conditions, room temperature (20 ± 2 °C), 50, or 60 °C, to unfold the protein, the solutions were neutralized with 2 M NaOH to pH 7 and kept at this pH for 1 h to make partial refolding. Meanwhile, to remove any salts brought from the pH adjustments, proteins from the treatments were precipitated at pH 4.5, washed 3 times, and then resolubilized at neutral pH.[14] The control sample did not treat with pH shifting and heating. The SPI samples treated in a 50 or 60 °C water bath were used for comparison.

Testing of Gel Strength. The SPI (120 mg/mL) samples were suspended in deionized water, and gels were formed in 25 × 40 mm (length × diameter) glass vials in a 90 °C water bath for 30 min. Then, the gels were stored overnight at 2−4 °C. Before analysis, the gels were equilibrated at room temperature (22−24 °C) for 30 min. Gel strength of the SPI gels was analyzed with a model TA-XT2 texture analyzer (Stable Micro Systems, Ltd., Godalming, U.K.) attached to a 5 kg load cell. The gels were axially penetrated to a depth of 12 mm at a speed of 50 mm/min with a P/0.5 flat-surface cylindrical probe (12 mm in diameter). The penetration force, defined as the force required to rupture the gel, was expressed as gel strength.

Protein Solubility. Protein samples (treated and control SPI) were completely dispersed (20 mg/mL) in sodium phosphate buffer (10 mM, pH 7.0). Then, the protein solutions were centrifuged at 10000*g* for 15 min. Protein concentrations of the supernatants and whole suspensions were determined by the Biuret method. Protein solubility was calculated according to the method of Jiang et al.[13]

Particle Size Distribution. Each SPI suspension (0.2 mg/mL, in 10 mM sodium phosphate buffer at pH 7.0) was transferred to a square cuvette for dynamic laser light scattering analysis (Zetasizer Nano-ZS, Malvern Instruments, Worcestershire, U.K.). The particle size was expressed as the average of at least six readings of the volume surface mean diameter (D_{32}) and volume mean diameter (D_{43}).

Total Sulfhydryl (SH) and Exposed SH Contents. SH content was measured according to the method of Beveridge et al.[16] SPI samples (15 mg) were suspended in 5.0 mL reaction buffer (0.09 M glycine, 0.086 M Tris, and 4 mM EDTA at pH 8.0) with (total SH) or without (exposed SH) 8 M urea. After the addition of 50 μL of Ellman's reagent, the resultant suspensions were incubated for 1 h at room temperature (23 ± 1 °C) with occasional vibrating and then centrifuged for 15 min at l0000*g*. The absorbance of the supernatant was read at 412 nm with the reagent buffer as the blank. The protein content of samples was measured by the micro-Kjeldahl method. The total SH and exposed SH contents in micromoles per gram of protein were calculated using the extinction coefficient of NTB, which is 13 600 M^{-1} cm^{-1}.

Surface Hydrophobicity. The surface hydrophobicity of the samples was measured using ANS as a fluorescence probe.[17] Briefly, 4 mL aliquots of the SPI samples (0.005−0.5 mg/mL) were dissolved in 0.01 M phosphate buffer at pH 7.0 and mixed with 50 μL of 8 × 10^3 M ANS. After the reaction had proceeded for 10 min at room temperature, the fluorescence intensity (FI) was determined with an emission at 484 nm and excitation at 365 nm (both with a slit width of 5 nm) on a fluorescence spectrophotometer (Hitachi F-4500, Hitachi, Ltd., Tokyo, Japan). The initial FI slope versus protein concentration plot was used to determine the protein surface hydrophobicity.

Intrinsic Fluorescence Emission Spectra. The intrinsic emission fluorescence spectra of the protein solutions were obtained using a fluorometer (F-4500 model, Hitachi, Tokyo, Japan). The protein solutions (0.2 mg/mL) were prepared in 10 mM phosphate buffer (pH 7.0). The protein solutions were excited at 295 nm, and the emission spectra were recorded from 300 to 400 nm with a constant slit of 2.5 nm for both excitation and emission.

Circular Dichroism (CD). Far-ultraviolet (UV) CD spectra of the protein samples were determined at 25 °C using a CD spectropolarimeter (Mos-450, Biologic, Claix, France) to measure the influence of the different treatments on the secondary structure according to the methods of Jiang et al.,[13] with some modification. Each SPI sample (0.5 mg/mL) was dissolved in 10 mM phosphate buffer at pH 7.0 and scanned 5 times between 190 and 250 nm to obtain an averaged value. Phosphate buffer was used as the blank solution. The bandwidth, step resolution, and scan rate were 1.0 nm, 0.2 nm, and 100 nm/min, respectively. The residue ellipticity (θ) values were calculated as $[\theta]$ (deg cm^2 dmol) = $(100XM)/LC$, where X is the signal (millidegrees) obtained by the CD spectrometer, M is the average molecular weight (MW) of amino acid residues (assumed to be 115), C is the protein concentration (mg/mL) of the sample, and L is the cell path length (1 cm).

Electrophoresis. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) was conducted as described by Liu and Xiong.[18] The stacking gel and resolving gel contained 5 and 12% acrylamide, respectively. Electrophoresis samples were prepared both without and with β-mercaptoethanol. For the SDS−PAGE samples without β-mercaptoethanol, 1 mM *N*-ethylmaleimide (NEM) was added to prevent the formation of disulfide artifacts.

Statistical Analyses. The experiment was replicated 3 times, and for each of the replications, at least triplicate samples were analyzed. The data were analyzed using the general linear model procedure. An analysis of variance (AOV) was performed to determine the significance of the main effects. Tukey's procedures were used to identify the significant differences ($p < 0.05$) between the means.

RESULTS AND DISCUSSION

Penetration Testing. Penetration testing is useful way to determine gel properties. For samples treated with pH-shifting alone or 50 °C mild heating alone, there were no significant changes ($p > 0.05$) in the penetration force with the increased incubation time (Figure 1). The penetration force of the sample

with 60 °C heating alone for 5 h was 2.26 N, and it was significantly higher than that of control samples (2.13 N) ($p <$ 0.05). However, the combination of pH-shifting with 50 and 60 °C heating treatments led to drastic increases in the penetration force of SPI gels ($p < 0.05$), with the value increased by 44.1

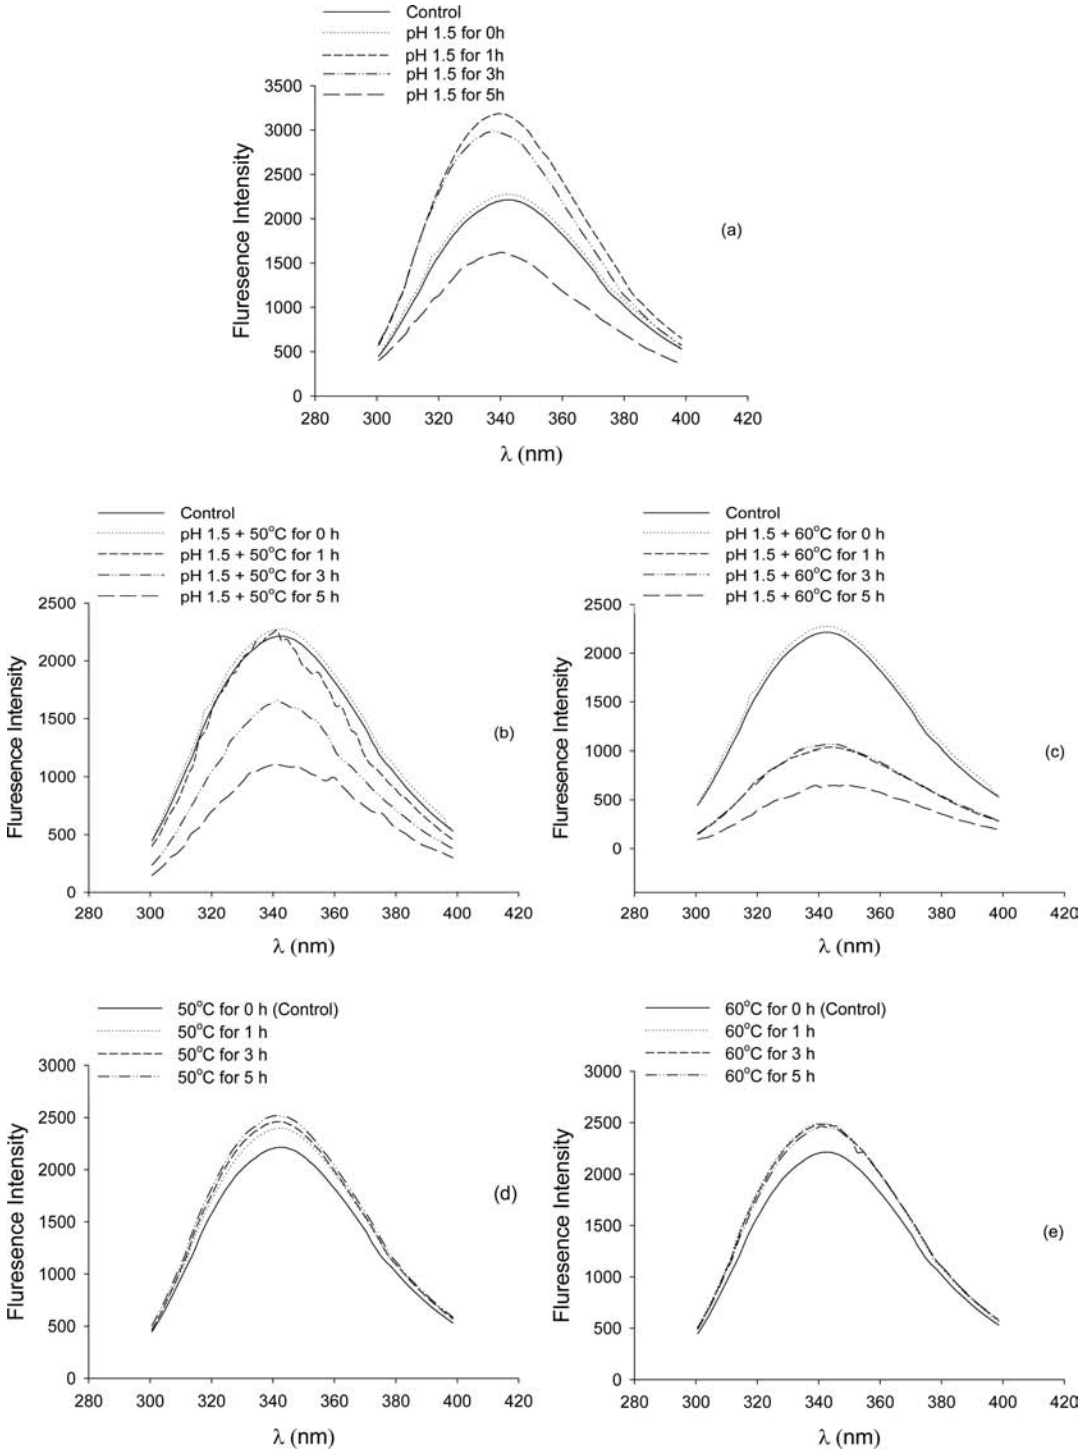

Figure 6. Intrinsic emission fluorescence spectra of SPI after acidic pH-shifting combined with heating treatments at various holding times.

and 69.0% after holding for 5 h, respectively, compared to control SPI.

A protein gel can be stabilized by both non-covalent and covalent forces. The gelation or coagulation of SPI was shown to include covalent cross-links and hydrophobic interactions.[19] Results from SDS−PAGE (Figure 8) and SH content measurements (Figure 4) confirmed the formation of disulfide bonds during heating. Some researchers have suggested that this disulfide bond formation helps to reinforce the gel structure.[20] Furthermore, O'Kane et al.[21] also showed that network formation by the legumin proteins was caused by hydrogen and hydrophobic bonds, and Mleko and Foegeding[22] revealed the increase in shear moduli of whey protein gels and increase in temperature during heating mainly to the presence of hydrophobic forces.

Protein Solubility. Solubility can affect protein surface-active properties. As depicted in Figure 2, the solubility of control SPI was 94.4%, with heating the SPI at 50 and 60 °C alone causing no significant change in solubility ($p > 0.05$). When the sample was treated with pH 1.5 shifting, the solubility decreased sharply with increasing incubation times ($p < 0.05$), which dropped to 77.9% after 5 h. Yuan et al.[23]

DOI: 10.1021/acs.jafc.5b01331
J. Agric. Food Chem. 2015, 63, 4853−4861

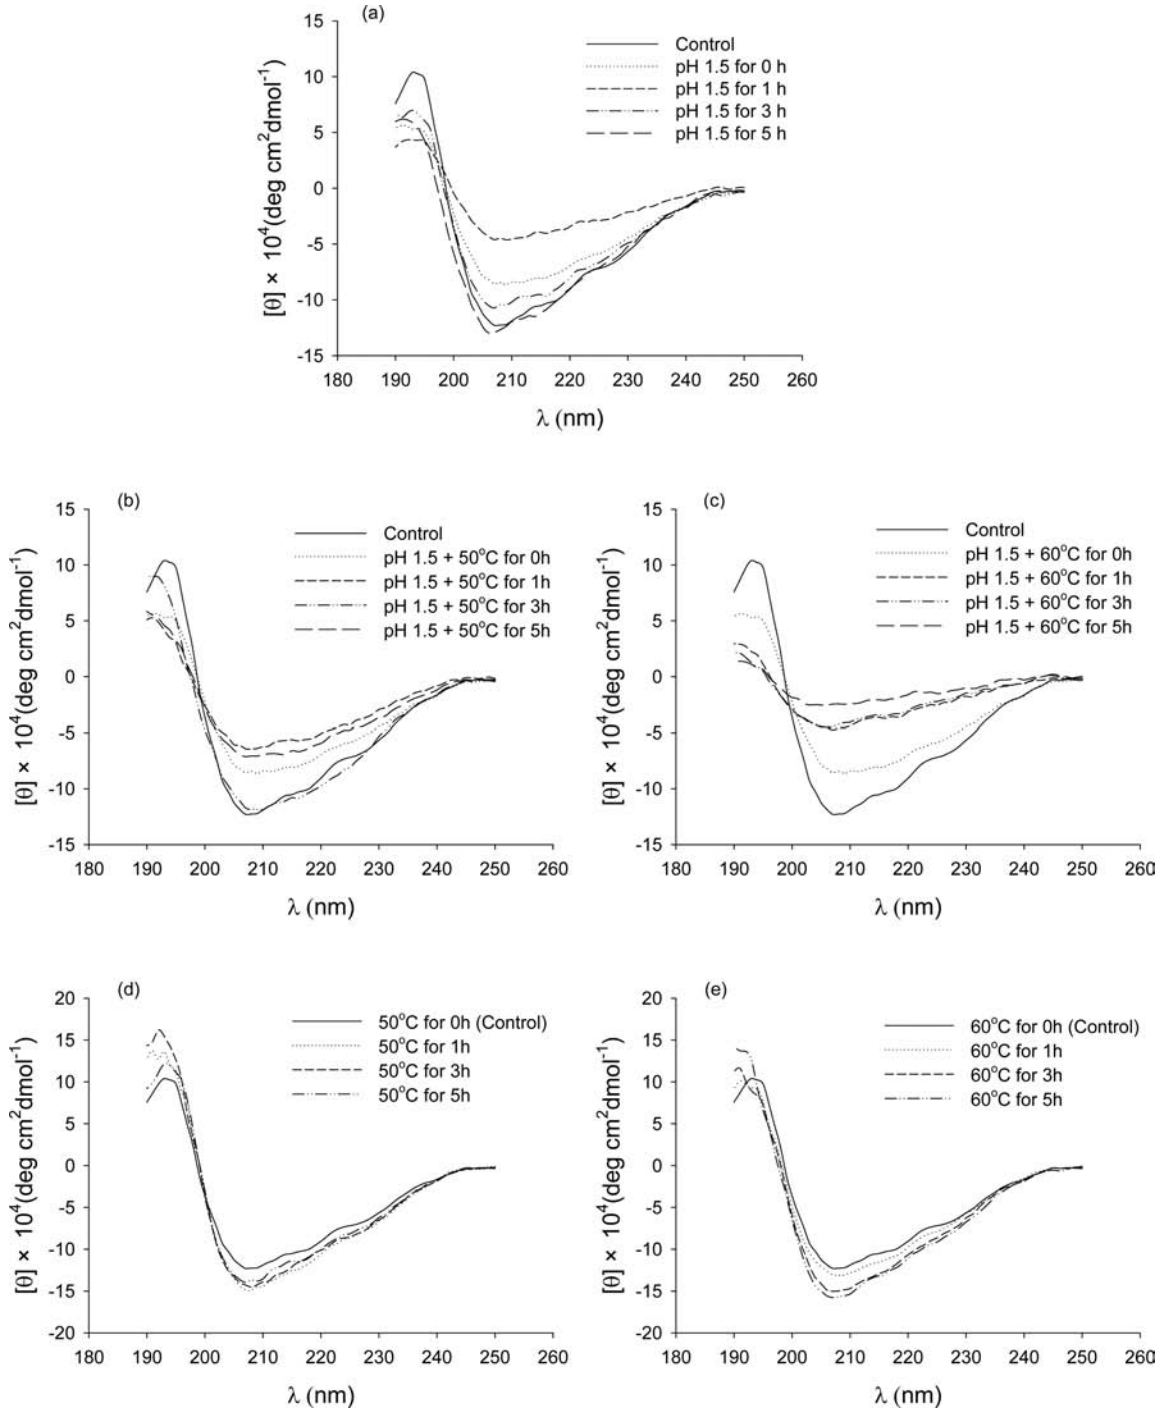

Figure 7. CD spectra of SPI after acidic pH-shifting combined with heating treatments at various holding times.

reported that, because of the effect of acid (pH 2.0) treatment, SPI would unfold, aggregate, and expose more hydrophobic residues. Meanwhile, similar trends were observed for samples treated with pH 1.5 + 50 or 60 °C, which rendered more solubility reduction than that for the pH 1.5 shifting treatment alone for 1, 3, and 5 h, respectively ($p < 0.05$). This phenomenon indicated that SPI was more susceptible to denaturation under extremely low pH-shifting combined with heating conditions. Jiang et al.[13] suggested that the decrease in protein solubility was mainly contributed to the formation of disulfide cross-linking and hydrophobic aggregation under the extremely low pH-shifting treatments. Liu et al.[24] also noted that the solubility had a obvious correlation with surface hydrophobicity of whey protein, which was affected by the aggregation state of the protein. The results were also supported by SH contents, surface hydrophobicity, and SDS–PAGE analysis, as discussed below.

Particle Size Determination. The volume surface mean diameter (D_{32}) and volume mean diameter (D_{43}) of control or modified SPI dispersions were measured by a dynamic laser light scattering instrument (Figure 3). The D_{32} and D_{43} of control SPI were 102.3 and 188.2 μm, respectively, and heating the SPI at 50 and 60 °C alone caused no significant change in particle size ($p > 0.05$). As expected, pH-shifting treatment

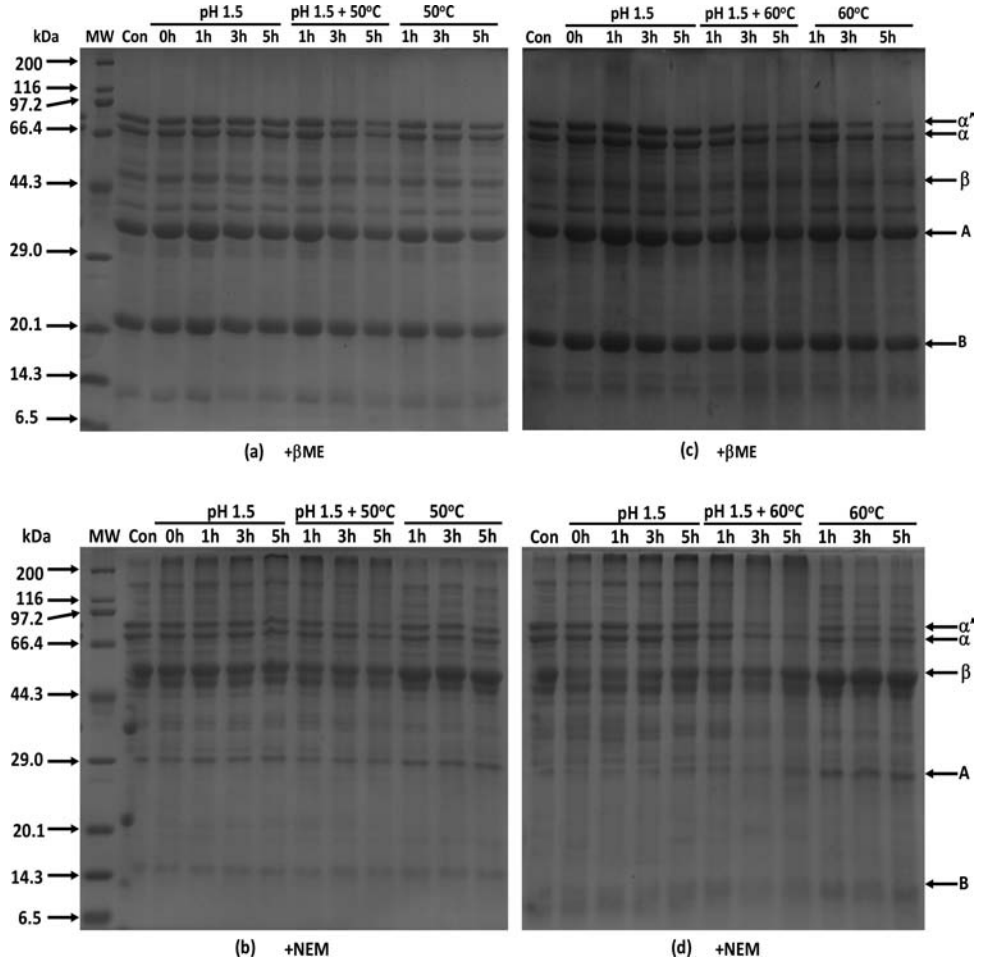

Figure 8. SDS−PAGE pattern of SPI after acidic pH-shifting combined with heating treatments at various holding times. Con: SPI solutions at pH 7.0 without pH-shifting and heating treatment. The SDS−PAGE samples were prepared (a and c) with or (b and d) without β-mercaptoethanol. MW: molecular weight marker (Da). SPI constituents: α' (86 kDa), α (66 kDa), and β (51 kDa) for conglycinin; A, the acidic subunit (34−43 kDa), B, the basic subunit (17−26 kDa) for glycinin.

significantly increased the particle size of SPI ($p < 0.05$), and D_{32} and D_{43} increased 1.26- and 1.42-fold after 5 h of incubation, respectively. Moreover, SPI samples treated with pH 1.5 + 50 or 60 °C exhibited a larger particle size than that with the pH 1.5 shifting treatment alone ($p < 0.05$). Yuan et al.[23] pointed out that the mean hydrodynamic diameter of SPI obviously increased after acid (pH 2.0) treatment for 1 h. Gulseren et al.[25] found that non-covalent interactions were the immediate driving force for the protein aggregation. In addition, according to Kohyama et al.,[26] hydrophobic interactions between protein molecules induced by the aggregation of the protein were the predominant factors for a fine gel network structure. Hu et al.[27] also suggested that exposition of hydrophobic residues might facilitate the formation of protein−protein aggregates, leading to a better gel network and water-holding capacity. Consequently, it can be concluded that complicated hydrophobic aggregation of SPI occurs under pH-shifting combined with mild heating treatments.

SH Contents. The pH-shifting and heating treatments caused some changes in the SH contents that seemed to have some relation to protein unfolding. The total SH and exposed SH in the SPI samples decreased with increasing incubation times ($p < 0.05$; Figure 4). The total SH in control SPI samples was 4.495 μmol/g of protein, and the value significantly decreased ($p < 0.05$) by 22.6, 9.2, 10.18, 45.5, and 80.23% at 5 h for the samples treated with pH 1.5 shifting, 50 °C heating, 60 °C heating, pH 1.5 + 50 °C, and pH 1.5 + 60 °C, respectively. The acidic pH-shifting treatments alone had little effect ($p > 0.05$) on the total SH after treating for 5 h, which was in accordance with the results of Jiang et al.[13] The heating treatment at 50 °C alone also had minimal effect on decreasing the total SH ($p > 0.05$), and the effect of 60 °C treatment was larger than the effect observed for 50 °C treatment ($p < 0.05$). However, the acidic pH-shifting or heating treatments alone had significant effects in decreasing the exposed SH ($p < 0.05$) of SPI for 5 h of incubation, which were different from the effects on the total SH. The combination of pH-shifting and heating treatments could significantly enforce the conversion of SH groups into disulfides ($p < 0.05$). The amount of detectable total SH and exposed SH in the pH 1.5 + 60 °C samples after incubation exhibited more decreases than observed in the pH 1.5 + 50 °C samples.

The decreased number of SH contents can be used to explain the improved gel texture of SPI gel in Figure 1. It was noteworthy that incubations over 1 h resulted in a loss of SH contents, which were mainly due to protein structure opening in control proteins being particularly sensitive to the heating as well as the formation of S−S bonds leading to a decreased number of total and exposed SH. The disulfide covalent

DOI: 10.1021/acs.jafc.5b01331
J. Agric. Food Chem. 2015, 63, 4853−4861

polymers have been illustrated by the SDS−PAGE results (Figure 8). Some researchers reported that acidation leads to the removal of disulfide bonds; however, with consistent heating treatments, the repeated formation of intra- and intermolecular disulfide bonds and the occurrence of oxidation may give rise to the loss of total SH and reaction SH contents.[28] The reason that total SH contents have no significant changes in pH 1.5 shifting treated samples may be due to the lower pH-treated samples only displaying limited denaturation (as proven by the hydrophobicity and CD analysis; Figures 5 and 7) and disulfide bonds being relatively stable at acidic conditions.[29] The decrease in the SH content incubation of pH-shifting + heating samples was maybe due to the formation of disulfide bonds by SH oxidation and SH/SS interchange reactions, which is favored by heating.[30] This result revealed that the SH contents or disulfide linkages in SPI were important residue factors for the protein conformational stability.

Surface Hydrophobicity. Surface hydrophobicity allows for the detection of changes in the distribution of hydrophobic groups at the surface, which are caused by changes in the molecular structure of protein upon denaturation. The other factors that may cause an increase in surface hydrophobicity include the expansion of peptide chains or the dissociation of protein subunits.[31] Studies had reported that treatment conditions, including temperature, time, and protein concentration, influenced protein surface hydrophobicity.[32] In our study, acidic pH-shifting treatment alone showed a slight effect on the surface hydrophobicity of soy protein, and surface hydrophobicity rose significantly ($p < 0.05$) only after 5 h of treatment (Figure 5). Conversely, the acidic pH-shifting combined with heating (50 °C for more than 3 h or 60 °C for more than 1 h) markedly increased the hydrophobicity values of SPI ($p < 0.05$), where the pH 1.5 + 60 °C treatment samples had the highest hydrophobicity.

As Jiang et al.[8] reported, at the extreme acidic pH conditions, most of the proteins in SPI might be deacetylated and the removal of charged COO− groups would mainly account for the increased surface hydrophobicity, which resulting in enhanced attractive interactions between individual protein molecules. Temperature increases cause proteins to unfold, exposing the SH and hydrophobic groups. For example, glycinin has secondary structure alterations and a surface hydrophobicity that increases upon heating.[33,34] Heating the SPI, which consists of both glycinin and β-conglycinin, induces the development of specific interactions among the subunits[35] and leads to the formation of soluble complexes between the β subunit of β-conglycinin and the basic subunit of glycinin.[36] However, in Figure 3, heating the SPI at 50 and 60 °C alone caused no significant change in the hydrophobicity value ($p > 0.05$). Hence, acidic pH-shifting treatment might cause proteins to unravel their spatial structure and render a MG state[13,37] when combined with mild heating and would further disrupt the structure, with more hydrophobic groups exposed on the surface, as the temperature and time increase.

Emission Fluorescence Spectroscopy Analysis. Intrinsic fluorescence spectroscopy reflect the movement of protein side chains.[38] As depicted in panels a, b, and c of Figure 6, the λ_{max} of the samples treated with pH 1.5 shifting, pH 1.5 + 50 °C, and pH 1.5 + 60 °C, respectively, had marked shifts in the maximum emission wavelength compared to the control SPI, while the fluorescence spectra of both 50 and 60 °C heating samples had no obvious blue shift (panels d and e of Figure 6). The blue shift was mainly attributed to an alter in the three-dimensional positions and the shift of the Trp microenvironment toward a more hydrophobic microenvironment.[39] Jiang et al.[13] reported that some buried side chains could be exposed to the polar surface after acid pH-shifting treatments. Wu et al.[40] noted that blue shifts of the maximum emission wavelength revealed that the previously exposed Trp residues of SPI were buried in the interior of the modified SPI molecules. As expected, the intrinsic fluorescence results are consistent with those from the ANS analyses (Figure 5), which expressed the gradual exposure of hydrophobic clusters initially buried in the extreme pH-shifting combined with heating processes.

CD Spectra. To understand the impact of acidic pH and heating processes on the secondary structure of SPI, the soy protein samples were subjected to CD determination. According to Kelly and Price,[41] the ellipticities at 222 and 208 nm allow for the evaluation of the α-helix content in a protein. Moreover, the blue shift of the peak wavelength and the attenuation of the 210 nm negative peaks suggest losses in the α-helical structure content. As shown in Figure 7a, the CD spectra for the pH-shifting samples were not markedly altered during the first 1 h of incubation; however, after 3−5 h of treatment, the negative peak changed and blue shifted. Jiang et al.[8,13] noted that the CD spectra of the pH-shifted SPI samples incubated for shorter times exhibited only slight changes. However, after acidic pH-shifting combined with heating treatments, considerable changes occurred in the SPI (panels b and c of Figure 7). The negative peak attenuated with the holding time and the peak minimum shifted from 209 to 207 nm in the pH-shifting + 50 °C sample incubated for 5 h, which indicates partial disruption of the α helix. A similar result was obtained for samples under pH-shifting + 60 °C treatment, where the peak minimum reduced to 206 nm. To prove that this change was not exclusively caused by heating, the controls for 50 and 60 °C heating alone were measured and are shown in panels d and e of Figure 7. Clearly, no obvious changes in the CD spectra were observed, and the secondary α-helix conformation did not appear to be disrupted by mild heating treatments alone. These results indicate that a change in secondary structure is commonly observed among samples subjected to a combination of pH 1.5 shifting and mild heating processes. In addition, there was a negatively linear correlation between surface hydrophobicity and the α-helix structure content of SPI, which was supported by the results of Hou and Chang.[42]

SDS−PAGE. SDS−PAGE of the protein samples treated with β-mercaptoethanol or *n*-ethylmaleimide (NEM) was used to study the role of S−S linkages in forming protein aggregates in protein samples incubated under acidic pH and heating conditions (Figure 8). The SDS−PAGE patterns of the control SPI had the characteristic bands corresponding to the subunits of β-conglycinin (α', α, and β) and glycinin (A and B). As shown in panels b and d of Figure 8, under non-reducing conditions (+NEM), large polymers were observed in both the pH-shifting and pH-shifting and heating samples that accumulated at the top of the gel. These high-molecular-weight (MW) bands were disulfide covalent polymers and aggregates from soy globulins. The gradual disappearance of the α', α, and β subunits in the pH 1.5 + heating samples during incubation suggested that β-conglycinin was the precursor of those high-MW polymers. Moreover, the glycinin subunits (A and B) showed unremarkable changes during incubation.

DOI: 10.1021/acs.jafc.5b01331
J. Agric. Food Chem. 2015, 63, 4853−4861

For the reducing SDS−PAGE (panels a and c of Figure 8), the large MW aggregates and polymers were completely dissociated into the corresponding α', α, and β subunits of β-conglycinin. All protein samples expressed a similar electrophoretic pattern. These results demonstrate that disulfide cross-linking of β-conglycinin was responsible for the production of protein aggregates and polymers during the pH-shifting and heating processes, which also explains the increased protein gelation observed in Figure 1. Both inter- and intramolecular SH/SS interchanges are dynamic and are expected in the observed protein polymer formation.[14] Such reactions more likely would result in less SH groups and more S−S linkages, which might lead to some favorable changes in the protein functional properties.

In conclusion, our results demonstrated that the pH treatments under extremely acidic (pH 1.5) conditions combined with proper heating (50 and 60 °C) produced structurally modified SPI samples that displayed enhanced gelling ability. The pH-shifting and heating denaturation induced an increase in the particle size, surface hydrophobicity, and SH content and a decrease in the solubility, resulting in protein cross-linking. The CD and fluorescence spectroscopy analyses revealed secondary and tertiary structural changes in pH-shifting and heating samples. Overall, the improvement in the protein gelling property induced by pH-shifting combined with heating treatments was party related to the change in secondary and tertiary structures and mainly attributed to the connection and interaction between protein subunits through hydrophobic association, hydrogen bonds, and disulfide bonds. The pH-shifting combined with mild heating treatments give great potential for the production of functionality-improved SPI.

Supporting Information

ABSTRACT: The aim of this study was to use a detailed rheological characterization to gain new insights into the gelation behavior of natural waxes. To make a comprehensive case, six natural waxes (differing in the relative proportion of chemical components: hydrocarbons, fatty alcohols, fatty acids, and wax esters) were selected as organogelators to gel high-oleic sunflower oil. Flow and dynamic rheological properties of organogels prepared at critical gelling concentrations (C_g) of waxes were studied and compared using drag (stress ramp and steady flow) and oscillatory shear (stress and frequency sweeps) tests. Although, none of the organogels satisfied the rheological definition of a "strong gel" (G''/G' $(\omega) \leq 0.1$), on comparing the samples, the strongest gel (highest critical stress and dynamic, apparent, and static yield stresses) was obtained not with wax containing the highest proportion of wax esters alone (sunflower wax, SFW) but with wax containing wax esters along with a higher proportion of fatty alcohols (carnauba wax, CRW) although at a comparatively higher C_g (4%wt for latter compared to 0.5%wt for former). As expected, gel formation by waxes containing a high proportion of lower melting fatty acids (berry, BW, and fruit wax, FW) required a comparatively higher C_g (6 and 7%wt, respectively), and in addition, these gels showed the lowest values for plateau elastic modulus (G'_{LVR}) and a prominent crossover point at higher frequency. The gelation temperatures ($T_{G'=G''}$) for all the studied gels were lower than room temperature, except for SFW and CRW. The yielding-type behavior of gels was evident, with most gels showing strong shear sensitivity and a weak thixotropic recovery. The rheological behavior was combined with the results of thermal analysis and microstructure studies (optical, polarized, and cryo-scanning electron microscopy) to explain the gelation properties of these waxes.

KEYWORDS: *organogels, natural waxes, rheological characterization, cryo-SEM, microstructure, wax-based gels*

INTRODUCTION

Organogels are a class of soft matter systems that are considered to be at an interface of complex fluids and phase-separated states of matter. They comprise an organic liquid that is physically immobilized by a network of dispersed, self-assembled aggregates of gelator molecules.[1,2] The normal phase separation into aggregated gelator molecules and liquid solvent phase is avoided in organogels due to the organization of aggregated gelator molecules into an interconnected solid-like, three-dimensional (3D) network, resulting in the formation of strong or weak gels depending on the gelator−gelator interactions as well as the solvent properties.[1,3,4] The possibility of transforming different types of organic liquids into solid-like viscoelastic gels (at relatively lower mass fractions of gelator molecules) makes organogelation an attractive subject of investigation in varied research domains for many different applications. For example, systems where triacylglycerol solvents (vegetable oils) are gelled using natural components, have found potential applications in biorelated fields such as drug delivery,[5−7] cosmetics,[8−10] and foods.[11−13] Among various gelators explored for gelling vegetable oils, natural waxes are considered to be the most promising ones because of their excellent oil binding properties,[14] economical value (capable of gelling oils at a significantly lower mass fractions, $w_c \ll 0.1$),[15,16] and availability of a number of waxes approved for use in humans.[17,18] Moreover, the gels formed using waxes have interesting properties such as themoreversibility[19,20] and emulsion stabilization,[21−23] which further justifies their popularity as organogelators for vegetable oils.

In spite of such widespread interest in these systems, a clear fundamental understanding of the physical properties of wax-based organogels is still missing. Unlike other low molecular weight gelators, waxes have a multicomponent chemical nature, comprising of components such as hydrocarbons (HCs), wax esters (WEs), fatty acids (FAs), and fatty alcohols (FALs), and such chemical diversity makes characterization of wax-based organogels very complicated. Some fundamental studies have been published in recent years where the gelation behavior of waxes was explored based on the chemical properties of waxes (composition, impurities),[15] thermodynamics and kinetic aspects of wax crystallization (fractal aggregation, thermal properties, crystal morphology, and cooling rates),[14,24,25] and some rheological[26−28] and large deformation studies (texture analysis) of the formed gels.[20] As seen with fats (high-melting triacylglycerols, TAGs), waxes also crystallize in low-melting TAGs (liquid oil) when the temperature is decreased well below their melting temperatures. Fundamentally, this type of

crystallization includes characteristics of both melt crystallization (crystallization due to supercooling) and crystallization of solute from the solvent (crystallization due to the decreased solubility of waxes in oils at lower temperatures). Similar to fat crystallization, the formed crystallites of waxes undergo further thermodynamically induced structural reorganization including clustering and aggregation. These crystalline aggregates can act as building blocks to trap the liquid oil into a gel-like structure, resulting in organogel formation. The structure is stabilized via weak interactions (among the neighboring building blocks) such as H-bonding and polar−polar interactions among constituents with polar moieties as well as weak intermolecular interactions such as induced dipole−induced dipole interactions (London dispersion force) among nonpolar components.

In our opinion, there is a need for a comprehensive comparative rheological profiling of wax-based organogels in order to further probe the link between the macroscopic flow/deformation response of gels and the microscopic interactions between the constituent building blocks (crystalline aggregates). In the present study, we report a detailed rheological characterization using a range of steady and dynamic shear measurements to understand the gelation behavior of natural waxes. To make a comprehensive case, six natural waxes (differing in the relative proportion of chemical components: HCs, WEs, FAs, and FALs) were selected to prepare organogels using high-oleic sunflower oil as the triacylglycerol solvent. The critical gelling concentrations (C_g) for different waxes were identified, and the flow and dynamic rheological properties of organogels prepared at C_g of waxes were studied and compared using drag (stress ramp), steady flow (flow and 3ITT (3 interval thixotropy test)), oscillatory shear (stress and frequency sweeps), and mixed flow−oscillatory shear tests. The results obtained from these measurements were combined with the results from thermal behavior and microstructure studies to characterize the physical properties of organogels. The C_g is the minimum concentration of wax at which the gelation of solvent occurs, and since we are considering wax-based organogels as fractal gels, the C_g in this case corresponds to the minimum volume fraction of crystalline particles at which a space-filling network of rarefied fractal flocs is formed.[29] Below this concentration, the dispersed particles contribute only in increasing the viscosity of the sol, whereas at concentrations higher than C_g a decrease in the size of fractal flocs is observed with a resultant increase in fractal dimensions due to the densification of flocs.[30] Thus, the viscoelasticity of fractal gels is best studied at C_g in order to better understand the nature of molecular interactions involved in gel formation at low volume fractions of particles.

MATERIALS AND METHODS

Materials. Refined high-oleic sunflower oil, HOS (TAGs > 99% wt), was received from Vandemoortele Lipids N.V. (Izegem, Belgium). Sunflower wax, *Helianthus Annuus Seed Cera* (SFW, acid value: 2−8 mg KOH/g, saponification value: 75−95 mg KOH/g), carnauba wax, *Copernicia Cerifera Cera* (CRW, acid value: 2−7 mg KOH/g, saponification value: 78−95 mgKOH/g), candelilla wax, *Euphorbia Cerifera Cera* (CLW, acid value: 12−22 mg KOH/g, saponification value: 43−65 mgKOH/g), bees wax, *Cera Alba* (BZW, acid value: 17−22 mg KOH/g, saponification value: 70−80 mgKOH/g), berry wax, *Rhus Verniciflua Peel Cera* (BW, acid value: 48−54 mg KOH/g, saponification value: 180−220 mgKOH/g), and fruit wax, *Myrica Cerifera* (FW, acid value: 5−25 mg KOH/g, saponification value: 210−240 mgKOH/g) were received as gift samples from Kalh GmbH & Co. KG (Trittau, Germany). Chemical composition of waxes was determined in-house using HPLC-ELSD to understand the distribution of main components. The main components of six waxes are listed in Table S1. More details on the experimental setup and result analysis will be published elsewhere.

Preparation of Organogels. Waxes were dispersed in HOS at varying concentrations by heating above their melting points until complete melting of waxes was achieved. The clear oily dispersions were subsequently cooled to 5 °C at a rate of approximately 2 °C/min under mild stirring (200 rpm) using a magnetic stirrer (model EM3300T, Labotech Inc., Germany). The critical gelling concentration (C_g) for all six waxes was identified using rheological characterization (oscillatory frequency sweeps). Samples prepared at different concentrations of waxes were subject to frequency sweeps at a constant stress of 0.02 Pa. The resultant values of elastic and viscous modulus (G' and G'', respectively) were compared at low frequency, and the corresponding concentrations at which $G' > G''$ were identified as C_g for individual waxes. The samples were stored at 5 °C until used further for characterization. The photograph of gels prepared at the respective C_g of waxes is shown in Figure S1.

Thermal Characterization. The thermal behavior of neat waxes and wax-based organogels was determined in triplicate using a Q1000 DSC (TA Instruments, New Castle, DE, USA) equipped with a refrigerated cooling system. Nitrogen was used as purge gas. The cell constant and temperature were set with indium (TA Instruments). An additional temperature calibration was done using azobenzene (Sigma-Aldrich, Bornem, Belgium) and undecane (Acros Organics, Geel, Belgium). The wax samples were heated at 90 °C in sealed aluminum pans (TA Instruments) before being cooled to 0 °C, kept isothermally at 0 °C for 20 min, and reheated to 90 °C. Heating and cooling were done at a constant rate of 2 °C/min. Characteristic parameters of the thermal curves, including onset and peak maximum temperatures for crystallization and melting (T_c onset, T_m onset, T_c peak, and T_m peak), were obtained using the software TA Universal Analysis provided by the instrument supplier.

Microstructure Studies. The microstructure of wax crystals was observed under normal and polarized light (PLM) using a Leica DM2500 microscope (Wetzlar, Germany) equipped with a Leica MC170 HD color camera. For cryo-scanning electron microscopy (cryo-SEM), deoiling of organogel samples was carried out using butanol to remove the surface liquid oil in order to visualize the wax crystals. Precisely, the deoiling was carried out in two different ways: (1) A known quantity of organogel was weighed in a glass vial followed by addition of butanol (at a gel:butanol ratio of 1:50 w/w approximately), which led to the collapse of the gel structure and resultant sedimentation of the crystalline fraction. After overnight storage, the supernatant liquid was decanted to collect the sediment, which was then placed on the sample holder. (2) The organogel sample was directly placed on a specialized stub (sample holder with grooves) followed by a dropwise addition of butanol to remove the liquid oil. The stub was left for overnight drying in inverted position to drain out all the solvent. The stub was then plunge-frozen in liquid nitrogen and transferred into the cryo-preparation chamber (PP3010T Cryo-SEM Preparation System, Quorum Technologies, UK), where it was freeze-fractured and subsequently sputter-coated with Pt and examined in a JEOL JSM 7100F SEM (JEOL Ltd., Tokyo, Japan).

Rheological Measurements. An advanced rheometer AR 2000ex (TA Instruments, USA) equipped with a Peltier system for temperature control was used for all rheological measurements. A parallel plate cross-hatched geometry of diameter 40 mm was used (geometry gap = 1000 μm) for the following tests: (a) amplitude sweeps: oscillatory stress = 0.001−1000 Pa, frequency = 1 Hz, and temperature = 5 °C; (b) frequency sweeps: oscillatory stress = 0.02 Pa, angular frequency = 0.6−240 rads^{-1}, and temperature = 5 °C; (c) temperature ramps: oscillatory stress = 0.02 Pa, frequency = 1 Hz, and temperature = 90−5 °C; (d) stress ramp: shear stress (0.08−300 Pa) and temperature = 5 °C; (e) flow-frequency test: samples were subjected to a range of shear rate = 0.01−20 s^{-1} followed by frequency sweeps (ν = 0.01−10 Hz); and (f) 3-ITT: samples were subjected to alternating intervals of low and high shear rates (0.1 s^{-1} for 10 min, 1

DOI: 10.1021/acs.jafc.5b01548

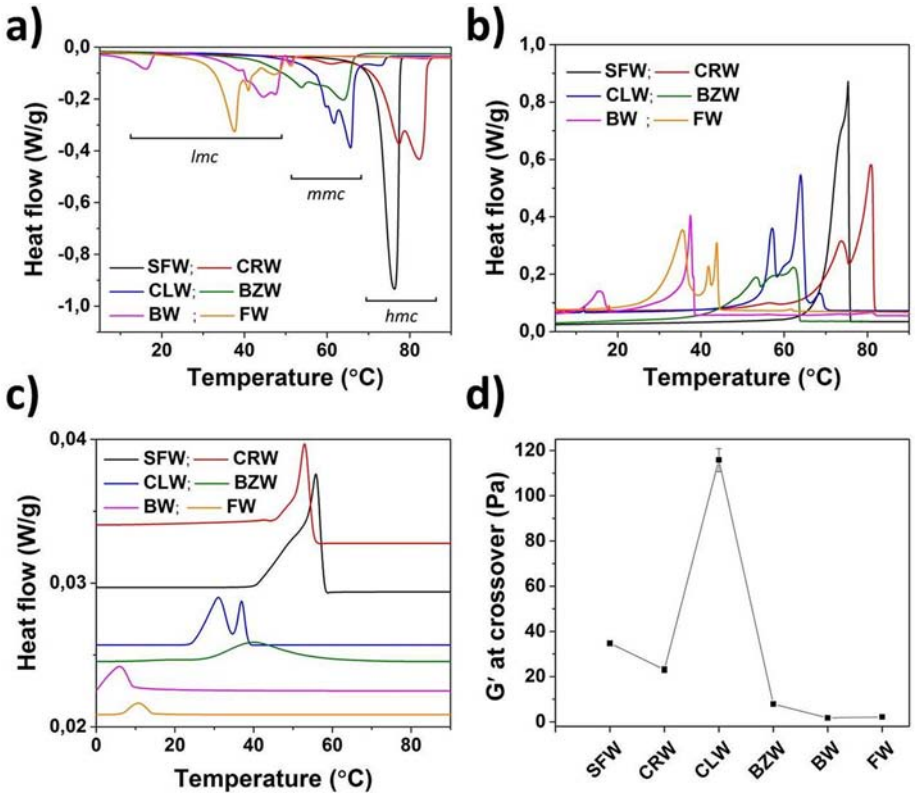

Figure 1. Comparative heating (a) and cooling (b) curves of neat waxes; (c) cooling curves of organogels prepared at the C_g of respective waxes; and (d) elastic modulus (G') at crossover point for organogels prepared at the C_g of respective waxes (also refer to Figure S3).

s^{-1} for next 5 min, followed by 0.1 s^{-1} for 10 min) at a temperature of 5 °C. The apparent yield stress was measured by fitting the stress versus shear rate data to a three-parameter model (Hershel Bulkley model) as discussed later.

Statistical Analysis. Data from texture and sensorial evaluation of cakes were compared using statistical analysis. An unpaired, two-tailed Student's *t* test was used on the data (SPSS Statistics) to establish the statistical significance in the differences observed.

RESULTS AND DISCUSSION

Waxes are a complex mixtures of a number of nonpolar and polar components with major components being HCs, WEs, FAs, and FALs with varying carbon chain lengths (representative molecular structures of main components are shown in Figure S2). When a liquid dispersion of a melted wax in an apolar solvent is cooled to temperatures well below the melting temperatures of wax (supercooling), the components separate out into crystalline phase that aggregate and further interconnect to form a 3D network that physically traps the liquid solvent into a gel structure.[31,32] Depending on the major component(s) as well as the carbon chain lengths of these components, the waxes display strikingly different gelation properties. The goal of this study was to have a detailed rheological profiling of wax-based physical gels in order to better understand their physical properties. To accomplish the goal, we selected six chemically diverse (differing in the proportions of major components) natural waxes: SFW, CRW, CLW, BZW, BW, and FW as listed in Table S1. DSC melting and cooling curves of neat waxes are shown in Figure 1a and b. On the basis of the melting peaks, the samples were categorized into waxes containing high-, mid-, and low-melting components (*hmc*, *mmc*, and *lmc*, respectively). SFW was predominantly rich (>95%wt) in WEs and showed single melting and crystallization peaks and, hence, was considered as a monocomponent wax, while the other five waxes contained at least two chemical components in high proportions as follows: CRW (WEs, ∼62% wt; FALs, ∼30%wt), CLW (HCs, ∼73%wt; WEs, ∼16%wt; FAs, ∼9%wt), BZW (WEs, ∼58%wt; HCs, ∼27%wt; FAs, ∼9% wt); BW (FAs, ∼96%wt; FALs, ∼4%wt), and FW (FAs, ∼36% wt; FALs, ∼63%wt). Please note that some FAs in BW and FW are esterified to a glycerol backbone. The multicomponent nature of these waxes is further confirmed from multiple melting and crystallization peaks seen in Figure 1a and b.

To identify the critical gelling concentration (Table 1), a series of oily dispersions were made by varying the concentration of waxes, heating them at 90 °C, and subsequently cooling the dispersion to 5 °C at a constant rate of 2 °C/min. The gelation was noted first by simple tube flipping observation to identify the concentration ranges where the gels did not flow under the influence of gravity, followed by

oscillatory rheological measurements (amplitude sweeps) to distinguish between a gel ($G' > G''$) and a viscous sol ($G'' > G'$) at low applied shear (τ_o). Oscillatory measurements offer a convenient way of measuring the flow and deformation properties of viscoelastic samples and also facilitate the classification of samples into strong gels, weak gels, and viscous sols based on frequency sweeps.[33]

For viscoelastic materials, the frequency-dependent functions G' and G'' give a measure of solid-like and liquid-like characteristics, respectively. Typically, for gels the elastic component (G') dominates over the viscous component (G'') at small applied shear and attains a plateau (G'_{LVR}) in the linear response region (LVR, or linear viscoelastic region).[34] The end of the LVR is marked by the first point where the G' varies by 10% of the G'_{LVR} value, and the corresponding stress at this point is referred to as the critical stress (τ^*). As the applied shear increases further, a permanent deformation (yielding) of the materials may occur ($G' = G''$), and the corresponding stress value at this point is referred to as oscillatory or dynamic yield stress (τ_{dy}).[35] The τ^* represents the onset of nonlinearity (and hence structure breakdown), while τ_{dy} represents the transition from solid- to liquid-like behavior, and the zone spanning these two events is referred to as the yield zone.[36,37]

There is a significant discussion in the literature relating that the monocomponent gel formation in apolar solvents by low molecular weight gelators is usually achieved by a competitive interplay of fibrous structure formation and crystallization. The gelator−gelator interactions (mediated via hydrogen bonding, electron transfer, etc.) need to be anisotropic (unidirectional) to promote assembly into 1D fibers, and the relative absence of such interactions in the other two dimensions prevents lateral growth and subsequent crystallization.[38,39] The self-assembly gets more complicated when dealing with multicomponent systems; when more than one self-assembling components are present, they can either coassemble (heterogeneous assembly) or undergo "self-sorting" (coexisting, monomolecular assemblies) depending on the intermolecular interactions arising from similarities and dissimilarities in the chemical structures.[40] As the concentration of the gelator(s) exceeds a certain concentration (C_g), the equivalent spherical volumes of self-assembled linear aggregates (of anisotropically stacked gelator molecules) start overlapping and an interconnected 3D network is formed, leading to the formation of physical gels.[1,2] Such a behavior can be compared to the overlapping of hydrodynamic volumes of polymeric chains in semidilute solutions at a defined overlap concentration (C^*) that is specific for a polymer−solvent combination.[41]

As seen from Table 1, SFW, CLW, and BZW could form a gel at a significantly lower concentration ($C_g \leq 1$%wt), whereas BW and FW required concentrations as high as 6 and 7%wt, respectively to gel the liquid oil. The higher C_g values for BW and FW were expected since these waxes are devoid of components with a larger "carbon backbone"; they are mainly composed of low-melting short-chain FAs ($C_{14:0}$, $C_{16:0}$, $C_{18:0}$) and FALs (C_{20-22}). The relatively higher solubility of these components is also confirmed from the crystallization peaks of BW and FW organogels (Figure 1c), where the peaks are shifted to much lower temperatures compared to the peaks of neat waxes. To further understand the relationship between crystallization and gelation, a single frequency test was done on samples where the material functions (G' and G'') were measured as a function of temperature (at constant $\tau = 0.02$ Pa and $\nu = \omega/2\pi = 1$ Hz). The temperature ($T_{G'=G''}$) and G' at the crossover point (or sol−gel transformation point) for organogel samples at C_g of individual waxes are shown in Figure 1d. Interestingly, for waxes containing high- and mid-melting components, a prominent delay in gelation was evident with $T_{G'=G''}$ being much lower than T_c peak (Table 1), while for BW and FW the gelation and crystallization occurred simultaneously. On comparing the G' values for the gels at their respective crossover points, one can assume that the gelation of BW and FW gels ($G' < 2.5$ Pa) is not preceded by extensive microstructure development, in contrast to the gels formed by waxes containing high- and mid-melting components. In BW and FW, most FAs are not free but esterified to a glycerol backbone, and these nonlinear molecules display lateral packing leading to the formation of large crystals.

Due to the formation of relatively larger spherical crystal/crystalline aggregates (Figure 2a−f) by BW and FW (along with a comparatively higher crystalline weight fraction), the possibility of creating loose entanglements is higher. These entanglements can act as transient junction points, which can contribute to the elasticity but sustain only a very low magnitude of stress, as confirmed from amplitude and frequency sweeps discussed later in the text. The platelet-like crystals are clearly distinguishable in spherical crystalline aggregates of BW (Figure 2c), while flat crystals are seen radiating outward from the center to form spherical units in the case of FW (Figure 2f). Among the other four waxes, the most striking results were observed for the CLW gel, where the G' at the crossover point was exceptionally high (~115 Pa), while the gelation occurred only after completion of the crystallization event, indicating that gel formation is a result of a significant reorganization of the crystalline phase at lower temperatures. As seen from Figure 2h and i, CLW crystallizes into very fine linear particles that are further organized into an open aggregate-like structure (Figure 2g). The sparse (noncompacted) packing is also evident from a low birefringence seen in the polarized light microscopy image (Figure 2h). The formation of such crystalline particles by CLW is attributed to a high proportion of linear hydrocarbons (*n*-alkanes).[42] The formation of gels with higher elasticity at lower crystalline mass

fraction is in agreement with previously reported studies on CLW-oil organogels.[16,20]

The plots from oscillatory amplitude and frequency sweeps done on organogels are shown in Figure 3. As seen from the

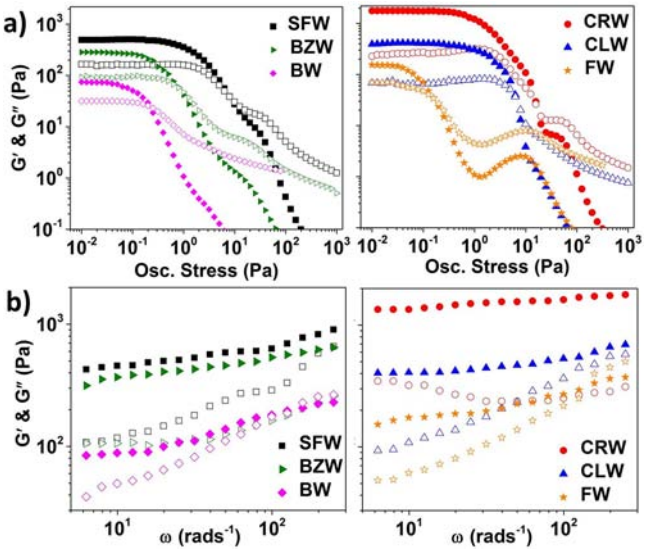

Figure 3. (a and b) Amplitude (at ν = 1 Hz) and frequency (at τ = 0.02 Pa) sweeps for gels made at the C_g of respective waxes. G' and G'' are shown as filled and open symbols, respectively.

graphs, none of the studied samples satisfied the rheological definition of a "strong gel" (G''/G' (ω) $\leq$ 0.1). However, the CRW gel did show the least frequency dependence (more or less linear curve in Figure 3b), higher G'_{LVR} value, and higher oscillatory yield stress in comparison to other gels. As discussed earlier, the elasticity of BW and FW organogels is attributed to loose entanglements of large crystals, and because of this structure, the gels can sustain only a lower magnitude of stress, which is confirmed from low values of dynamic moduli in the linear response region. Moreover, these gels also showed very low values of τ^* (<0.05 Pa) and a narrow yield zone with τ_{dy} <0.25 Pa.

The yield zone or, more specifically, the slope of the curve in the yield zone gives information about the breakage of intermolecular forces holding up the structure. A narrow yield zone points at the fact that the structure breakdown occurs at once (all bonds break at the same force). The weak structure of BW and FW gels is further evident from a prominent crossover (tan $\delta = G''/G' > 1$) at higher ω, which is a confirmation of structure breakdown at high rates of deformation. When comparing the gels made with waxes containing *hmc*, it can be seen that SFW gel was much softer than CRW and yielded at much lower force (τ_{dy} = 9.9 Pa compared to 19.8 Pa for the CRW gel). However, it should be noted that SFW gel was formed at a C_g of only 0.5%wt, whereas a high C_g of 4%wt was required for CRW.

The differences in C_g can be explained from the morphology of crystals formed in these two gels (Figure 4a–f). SFW crystals had an anisotropic, rod-like morphology (with lengths spanning the micrometer range), which is considered to be the most desirable shape of elementary assemblies (building blocks) to immobilize a large volume of solvent for efficient gelation.[35] The rod-like morphology of SFW is attributed to its high content (>95%wt) of wax esters, which are known to be the

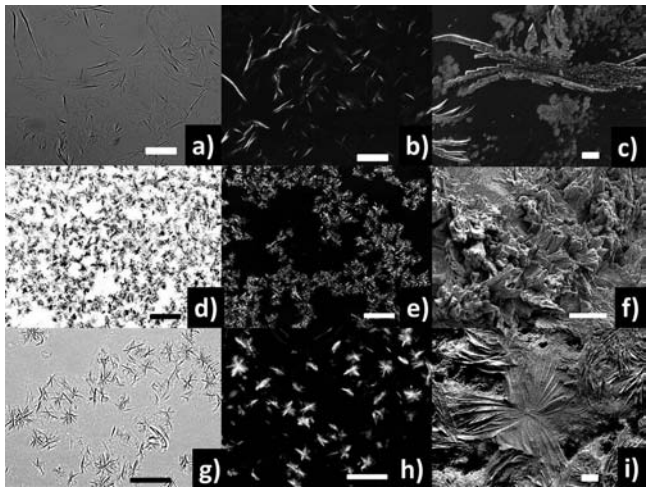

Figure 4. Optical microscopy (under normal and polarized light) and cryo-SEM images of gels of (a–c) SFW; (d–f) CRW; and (g–i) BZW. Scale bars = 50 μm (a, b, d, and e); 20 μm (g and h); 10 μm (c and f); and 1 μm (i).

main components responsible for excellent gelation behavior of most natural waxes.[14,15,25] Interestingly, in recently published work by Blake and Marangoni,[43] they have concluded based on cryo-SEM imaging that the morphology of SFW (along with other waxes such as CLW and rice bran wax) was "platelet-like", contrary to the observed morphology in the current work. In the case of CRW, the three-dimensional crystals of less than 10 μm in size are seen stacked closely together into larger aggregates (50–100 μm), and thus, a relatively higher crystalline mass fraction is required for gelation because the network formation is expected to be a result of the overlapping of spherical volumes of these aggregates. For waxes with *mmc*, both CLW and BZW gels showed similar frequency dependence, but the gel formed by BZW was comparatively more brittle and showed breakdown and yielding at lower stress values. The crystal morphology in the BZW gel was quite different from other waxes, showing a distinct "sea urchin"-like morphology (Figure 4i). Formation of such interestingly organized structures has been explained through crystal design and engineering and is attributed to a two-stage crystallization process initiated by a three-dimensional spherulite formation at the nucleation center followed by the organization of needle-like crystals in the outer layer, resulting in a radially oriented growth.[44,45] Such structures are also easily identifiable when viewed under an optical microscope (Figure 4g and h).

The yielding-type behavior with a strong shear thinning nature of all the gels is evident from the curves of apparent viscosity (η_{app}) versus shear rate ($\dot{\gamma}$) as shown in Figure 5b. Flow parameters such as apparent yield stress ($_{app}\tau_y$) and flow index (n) were calculated by fitting the data to a three-parameter model (Hershel Bulkley, eq 1).

$$\tau = {}_{app}\tau_y + K\dot{\gamma}^n \quad (1)$$

where K = consistency coefficient and $\dot{\gamma}$ = shear rate.

The Hershel Bulkley model is one of the most commonly used models for characterizing materials that display non-Newtonian behavior after yielding, and the value of n can be used as a measure to define the degree of shear thinning (n < 1) or shear thickening (n > 1) of the material. All the gel samples showed a prominent shear thinning flow behavior (n < 1), but the degree of shear thinning was highest for CRW gels, which

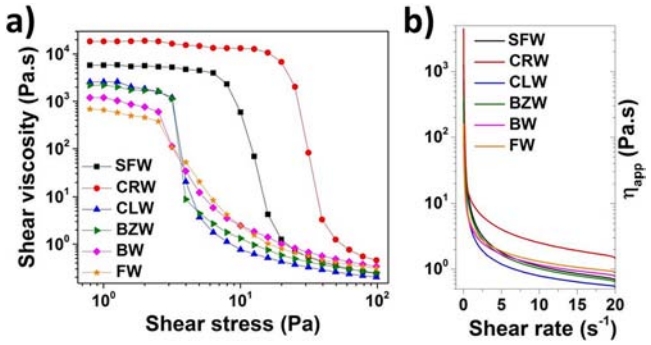

Figure 5. (a) Data from stress ramp shown as shear viscosity versus shear stress and (b) apparent viscosity (η_{app}) versus shear rate.

incidentally also had the highest ${}_{app}\tau_y$ (Table S2). In addition, the CRW gel also showed the highest static yield stress (τ_{sy}) determined from the plots of the stress ramp (Figure 5a). The τ_{sy} measured using methods such as stress ramp and stress growth is defined as the minimum stress required for initiating flow, whereas the ${}_{app}\tau_y$ determined by model fitting is defined as the minimum stress required for maintaining flow and is often lower in values than the former.[37,46,47] The τ_{sy} and ${}_{app}\tau_y$ for all the gels were close to each other except for the CRW gel, where the τ_{sy} was almost 3 times larger than ${}_{app}\tau_y$. Such a big difference in stresses required for initiating and maintaining flow is taken as an indication of the existence of more than one structure that makes up the body of a material.[37,47] One of these structures is built up only during rest and can undergo breakdown under relatively lower shear, while a more robust structure that can withstand moderate shear rates contributes to the ${}_{app}\tau_y$.[46,47] Since τ_{sy} is a consequence of combined structures, it is expected to be higher than ${}_{app}\tau_y$. The high zero-shear viscosity of CRW gel (Figure 5b) confirms that the network structure is built up by overlapping spherical volumes of large aggregates, and a strong shear thinning behavior is a consequence of the disruption of aggregate clusters into smaller ones, which is driven by the mechanical energy. It is also important to note that although the yield stress values of these gels are rather low, they are still appreciably high to prevent gravitational settling of the particle network that structures the gels,[32] which was also confirmed from the absence of any phase separation in our samples stored for more than a month at 5 °C. Moreover, the stored samples were also periodically tested using oscillatory rheological measurements to evaluate any structure changes over 4 weeks of storage, and the results (Figure S4) confirm the stability of these gels.

Thixotropy has been defined in different ways by different authors over the years. While some authors refer to thixotropy simply as a time-dependent decrease in viscosity at a constant shear rate, other authors also include the reversible and gradual recovery of the consistency (which was lost on shearing) when the stress or shear rate is removed.[48−50] The term "gradual" when understood in terms of "finite time" required for structure recovery, makes the definition of thixotropy complete by enabling the inclusion of shear-thinning materials that show a rapid recovery (near zero time of recovery), which were previously known by the term "structural viscosity".[50] The word "reversible" could mean both a complete recovery (viscosity attains the original values or almost close to the original values on removal of shear) or a less desirable, partial recovery (flow-induced irreversible structural changes leading to an irreversible loss in viscosity on removal of shear). Thus, the thixotropic behavior is best studied by tracking the material response resulting from stepwise changes in shear rate, as the coupled effect of time and shear rate can be clearly separated in such experiments.[51,52] A specific rheological test that is utilized to measure thixotropy is known as 3-ITT; it consists of three consecutive steps in control rate mode with alternating low and high shear rates.[36] The fraction of η_{app} recovered in the third step or interval gives a measure of thixotropic recovery of the material.[22,53] The plots from 3-ITT done on organogels are shown in Figure S5. The thixotropic recovery for the gels were as follows: SFW (43.52%), CRW gel (15.84%), CLW (58.64%), BZW (67.34%), BW (80.77%), FW (56.52%). The CRW gel showed the least thixotropic recovery among the studied gels in spite of having a comparatively highest viscosity at rest as well as the highest τ_{sy} and ${}_{app}\tau_y$. Such behavior is usually associated with brittle gels that display a high gel strength and a narrow LVR as well as yield zone. However, from the results discussed in Figure 3, the CRW gel did not show a "brittle-type" failure, as confirmed from a broader yield zone, which indicates that the bonding in the network of crystalline particles is more heterogeneous, leading to a nonuniformity in bonding strength and consequent "ductile-type" failure.[54] This nonuniformity in the bonding strength is also evident from almost a 3-fold difference between τ_{sy} (~20.06 Pa) and ${}_{app}\tau_y$ (6.99 Pa), which basically tells us that 3 times higher force is required to initiate the flow compared to maintaining flow. The network structure in CRW can thus be assumed to be a random agglomeration of aggregated crystalline particles, and the local bonding strength among the aggregates may be stronger in certain regions compared to other regions due to localized crowding of aggregates. As the gel is sheared, with time, the structure breaks down into smaller clusters of aggregates that can contribute to the viscosity enhancement of the solvent, but the restructuring of these clusters into a coherent network is avoided because the Brownian motion is overcome by shear forces. In contrast, BW and BZW gels showed a reasonable thixotropic recovery (80.77% and 67.34%, respectively). From the microstructure studies, these two gels show spherical-type building units that are connected together into a network by a weak yet more uniform type of bonding (homogeneous bonding strength), and thus, all bonds can be broken down at the same applied force (supported well by narrow yield zone seen for these samples), resulting in a flow-induced structure breakdown that is non-time-dependent (linear curves in first and third interval of 3ITT, Figure S5). To further understand the structure of the sheared sample, mixed flow-oscillatory measurements were carried out on samples by first subjecting them to increasing shear rates from 0.01 to 20 s^{-1} followed by frequency sweeps (0.01−10 Hz or 0.06−62.8 $rads^{-1}$). The graphs of shear moduli plotted as a function of angular frequency are shown in Figure 6. As seen from the figure, the quick recovery from flow-induced structure breakdown was seen only in BW and BZW samples ($G' > G''$ at ω_0 = 0.06 rad s^{-1}), while the rest of the gels showed liquid-like behavior at low frequency. CRW gels, on the other hand, showed complete liquification, with a viscous component dominating over the entire frequency range. On comparing these curves with results from frequency sweeps done on unsheared samples, it can be seen that, out of the six waxes studied in this work, CRW showed a maximum loss of structure (G' values showing more than 100-fold reduction after the flow step), while BW showed the least structure loss

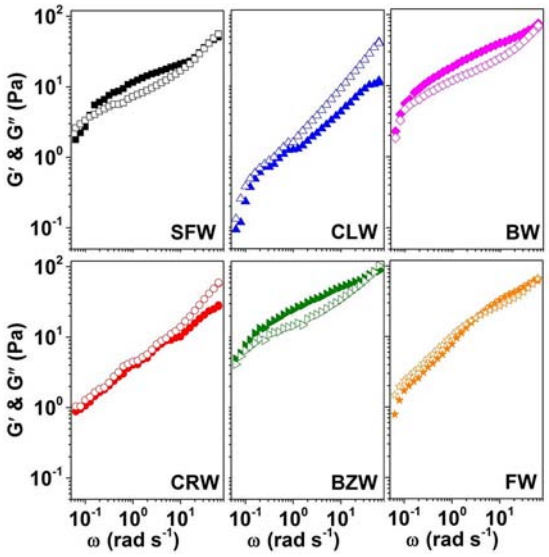

Figure 6. Data from frequency sweeps (from the flow-frequency tests) done on samples that were subjected to the flow test.

(G' values showing close to 2-fold reduction after the flow step), which is in agreement with 3ITT results.

To conclude, the rheological behavior of wax-based physical gels can be assumed to have characteristics of a flocculated suspension (at low volume fractions of colloidal particles) as well as a semidilute polymer solution. At a certain concentration, C_g (analogous to C^* in the case of a semidilute polymer solution), a 3D network or agglomeration of aggregated crystalline particles is created to form a viscoelastic gel, which might show "ductile-type" or "brittle-type" deformation under applied shear depending on the uniformity of bonding strength connecting the aggregated particles (as seen in a flocculated suspension). The C_g and the rheological behavior are strongly influenced by the morphology of the primary crystalline particles as well as the subsequent aggregation of these primary particles, which, in turn, depends on the chemical components present in waxes. The waxes studied in this work are of natural origins, and thus, they can be used for potential applications in biorelated fields such as food, pharmaceutical, and cosmetics industries.[55] For instance, the gelling of edible oils at such low concentrations of waxes can be exploited in the formulation of food products with low saturated fat content. The information obtained through this work will help us in setting criteria for selecting waxes. For instance, it is not the melting range but the relative proportion of individual chemical constituents that determines the rheological properties of obtained gels. However, since these gels are rather "weak" in nature with high shear sensitivity and low thixotropic recovery, incorporation of high-melting fats will be necessary to obtain structured oil systems (i.e., hybrid systems) with desired properties for actual food applications.[56]

Supporting Information

ABSTRACT: Plants produce an excess of volatile organic compounds, which are important in determining the quality and nutraceutical properties of fruit and root crops, including the taste and aroma of carrots (*Daucus carota* L.). A combined chemical, biochemical, and molecular study was conducted to evaluate the differential accumulation of volatile terpenes in a diverse collection of fresh carrots (*D. carota* L.). Here, we report on a transcriptome-based identification and functional characterization of two carrot terpene synthases, the sesquiterpene synthase, *Dc*TPS1, and the monoterpene synthase, *Dc*TPS2. Recombinant *Dc*TPS1 protein produces mainly (*E*)-β-caryophyllene, the predominant sesquiterpene in carrot roots, and α-humulene, while recombinant *Dc*TPS2 functions as a monoterpene synthase with geraniol as the main product. Both genes are differentially transcribed in different cultivars and during carrot root development. Our results suggest a role for *DcTPS* genes in carrot aroma biosynthesis.

KEYWORDS: *Daucus carota, terpenes, (E)-β-caryophyllene, geraniol, terpene synthase*

INTRODUCTION

Carrots (*Daucus carota* L.) are popular vegetables because of their health benefits and characteristic flavor.[1,2] Carrot quality is determined by several traits that affect taste, aroma, and nutritional value.[3] In particular, terpene secondary metabolites, which are synthesized during carrot root development, have a direct effect on root quality and flavor.

Terpenes constitute the largest class of plant secondary metabolites, represent major components of floral scents and essential oils of herbs,[4] and are important in determining the quality and nutraceutical properties of horticultural food products, including the taste and aroma of wine and melon.[5,6] Plants produce terpenoids that function in primary metabolism, such as phytohormones (absisic acid, gibberellins, and brassinosteroids), and are part of photosynthetic pigments (phytol and carotenoids).[7] Terpenes can serve as phytoalexins in defense against plant pathogens[8] or direct defense against herbivores.[9] In addition, volatile terpenoids can function as indirect defensive compounds by attracting predators or parasitoids of the attracting insect.[10]

All plant terpenes are made from the 5-carbon precursor, isopentenyl diphosphate (IPP), and its isomer, dimethylallyl diphosphate (DMAPP), both of which are derived from two alternative pathways, the mevalonate (MVA) pathway in the cytosol or the methylerythritol phosphate (MEP) pathway in plastids. Condensation of the C_5 precursors leads to the formation of C_{10}, C_{15}, and C_{20} *trans*- or *cis*-prenyl diphosphate intermediates, such as geranyl diphosphate (GPP), neryl diphosphate (NPP), *trans,trans*-farnesyl diphosphate or *cis,cis*-farnesyl diphosphate [(*E,E*)-FPP or (*Z,Z*)-FPP], and all-*trans*-geranylgeranyl diphosphate (GGPP) that are converted into monoterpenes (C_{10}), sesquiterpenes (C_{15}), and diterpenes (C_{20}), respectively, by the activity of terpene synthase (TPS) enzymes.[11] GGPP also functions as a precursor in the carotenoid biosynthetic pathway by condensation of two GGPP units to C_{40}-phytoene.[12] TPSs are the primary enzymes in the formation of low-molecular-weight terpene metabolites. To date, TPSs have been identified and characterized in many species,[13,14] including *Arabidopsis thaliana*,[15] *Cucumis melo* L.,[6] *Gossypium hirsutum* L.,[16] *Solanum lycopersicum*,[17] *Vitis vinifera* L.,[18] *Coriandrum sativum*,[19] and *Thapsia garganica*. TPSs are encoded by large gene families and have the ability to produce multiple terpene products from a single substrate. The formation of mixtures of structurally diverse compounds contributes to the specific aroma and flavor characteristics of

[a]Volatile terpenes were measured by auto-HS−SPME−GC−MS. T = traces. The results shown are an average of three biological replicates. [b]IC = identification criteria. The identification criteria were based on mass spectra matching with the standard NIST-98.L and Wiley 7N.I libraries (MS), comparison of the retention index (RI), and comparison to the authentic standard (STD).

plant tissues.[17] Transcriptional regulation plays an important role in controlling volatile organic compound biosynthesis, but it is not the only mechanism involved. While little is known about post-transcriptional regulation of volatile organic compound formation, recent comprehensive reviews provide a thorough discussion of the regulation of the MVA and MEP pathways.[7,20] Recently, it has been reported that the progressive biosynthesis of (*E*)-β-caryophyllene in *Arabidopsis* inflorescence after flowering is regulated by miR156-targeted SQUAMOSA promoter binding protein-like (SPL), which directly activates TPS21 expression.[21]

Carrots produce a large number of different mono- and sesquiterpene volatiles in leaf and root tissues.[22] In carrot roots, terpenes are more abundant in mature tissues and primarily synthesized in an interconnected network of oil ducts located in the phloem.[23] Labeling experiments with stable isotope precursors also indicated *de novo* biosynthesis of terpenes in the xylem.[24]

Despite the characterization of a large number of plant TPSs, surprisingly, no carrot TPSs have been described to date. Here, we report on the isolation and functional characterization of two carrot terpene synthase genes, *Daucus carota* terpene synthase 1 (*DcTPS1*) and *D. carota* terpene synthase 2 (*DcTPS2*), whose encoded enzymes catalyze the formation of the sesquiterpene, (*E*)-β-caryophyllene, and the monoterpene alcohol, geraniol, respectively. We show that *DcTPS1* is expressed in all five cultivars investigated in this study and is most likely associated with the production of high amounts of (*E*)-β-caryophyllene in these cultivars. *DcTPS1* gene transcript levels peak at week 12 post-germination in correlation with highest concentrations of terpene compounds at this developmental stage.

MATERIALS AND METHODS

Chemicals. Unlabeled FPP and GPP (1 mg/mL), terpene standards, other chemicals, and reagents were purchased from Sigma-Aldrich, unless noted otherwise.

Plant Material. Commercial colored carrot cultivars, orange "Nairobi", orange "Rothild", purple "Purple Haze", yellow "Yellowstone", and white "Crème de Lite" (Kiepenkerl Profi-Line, www.kiepenkerl.com), were grown in the "Newe Ya'ar" Research Center in northern Israel, under standard field irrigation and fertigation conditions. Freshly harvested 9−12-week-old carrot roots were crushed in liquid nitrogen and stored at −80 °C for terpene and transcript analysis.

Statistical Analysis. Amounts of terpenes are presented as means ± standard error (SE). Chemical terpene data were analyzed by multivariate data analysis [principle component analysis (PCA)] using the JMP software (SAS Institute, Inc.).

Extraction of Volatile Compounds from Fresh Carrot Roots. Three replicates of fresh 10-week-old root carrots (1 g) of each cultivar were ground into a uniform powder under liquid nitrogen with a mortar and pestle. The fine powder was placed in a 20 mL DuPont autosampler vial (DuPont Performance Elastomers, http://www.dupontelastomers.com) with a white solid-top polypropylene cap (Alltech, http://www.alltech.com). Samples were overlaid with 5 mL of NaCl (25%) solution and 1 g of NaCl (for inhibition of enzyme activity). Each sample was supplemented with 1 mg/kg [1 part per million (ppm)] of 2-heptenone as an internal standard. Samples were incubated at room temperature (25 °C) for 1 h, and thereafter, volatile compounds were collected with a solid-phase microextraction (SPME) device PDMS-100 with a polydimethylsiloxane fiber (Supelco, http://www.sigmaaldrich.com) by inserting the fiber into the tube and leaving it in place for 20 min at room temperature. After this incubation step, the SPME fiber was injected directly into gas chromatography−mass spectrometry (GC−MS).

Auto-Head Space (HS)−SPME−GC−MS Analysis of Carrot Root Volatile Compounds. Volatile compounds were analyzed on a GC−MS apparatus (Agilent Technologies, Santa Clara, CA) equipped with an Rtx-5SIL MS (30 m × 0.25 mm × 0.25 μm) fused-silica capillary column. He (1 mL min^{-1}) was used as a carrier gas. The

DOI: 10.1021/acs.jafc.5b00546
J. Agric. Food Chem. 2015, 63, 4870−4878

injector temperature was 250 °C, set for splitless injection. The oven was set to 50 °C for 1 min, and then the temperature was increased to 220 °C at a rate of 5 °C min^{-1}. For SPME analysis, thermal desorption was allowed for 40 min. The detector temperature was 280 °C. The mass range was recorded from m/z 41 to 450, with an electron energy of 70 eV. Identification of the main components was performed by comparison of mass spectra and retention times to those of authentic standards and supplemented with a Wiley GC−MS library. Quantification of absolute amounts was performed for (*E*)-*β*-caryophyllene, *α*-humulene, and the monoterpenes listed in Table 1 by comparing their retention time and mass spectra to those of authentic standards.

For the construction of the calibration curves, a mixture of straight-chain alkanes (C_7−C_{23}) was run under the above-mentioned conditions to determine retention indices. The amount of each compound in the sample was calculated as (peak area × internal standard response factor) divided by (response factor × internal standard peak area).[25] For compounds for which no standards were available, only normalized peak areas are shown. Total terpene levels were based on normalized peak areas of all compounds.

Isolation and Characterization of Carrot Terpene Synthases. Putative carrot *TPS* encoding genes were identified using Blastx to compare known *TPS* genes in *Arabidopsis* (*At2g24210* and *At5g23960*) to the *de novo* assembled RNA-Seq carrot transcriptome contigs from Iorizzo et al.[26] The expression levels of these candidate genes in the purple (B7262) cultivar and an orange cultivar (B6274) were estimated by mapping the Illumina GAII reads for each sample from Iorizzo et al.,[26] (SRA accessions SRR187758−SRR187763) using the "Map to Reference" feature of the Geneious (BioMatters, Ltd.) alignment software.

Two specific primers corresponding to the 5′ and 3′ ends of the *DcTPS1* coding sequence (P1: 5′-ATG TCT CTC AAT GTT CTG GC-3′) and (P2: 5′-TGA TGG AAC CCG ATC AAT GA-3′) were designed. *DcTPS2* was obtained using the forward primer P3 (5′-ATG GCC CTC CCA GCT CTG TTT T-3′) and the reverse primer P4 (5′-CTG GCT AAG AGT AAA GGG TTC GAC C-3′).

RNA from carrot roots of all colored cultivar was isolated using the Spectrum Plant Total RNA Kit (Sigma-Aldrich). To produce a cDNA clone, 5 *μ*g of total RNA from the Nairobi (orange) cultivar was reverse-transcribed using the SuperScript one-step reverse transcriptase polymerase chain reaction (RT-PCR). The DNA molecule was then amplified using Platinum *Taq* DNA polymerase (Invitrogen), yielding a 1683 bp specific fragment for *DcTPS1* and a 1782 pb fragment for *DcTPS2*, respectively. The cDNAs were ligated into the pEXP5-CT/TOPO TA expression vector (Invitrogen Corporation, Carlsbad, CA), producing pEXP-*DcTPS1*, and pEXP-*DcTPS2*, respectively, in which the *DcTPS1* and *DcTPS2* coding sequences were fused with a His-tag-coding extension at the C terminus and transformed into *Escherichia coli* TOP10 cells. The constructs were verified by DNA sequencing.

Preparation of Bacterial Lysates. A 3 mL preculture of *E. coli* BL21 (DE3) was grown overnight at 37 °C in lysogeny broth (LB) medium containing 100 g/mL ampicillin. The culture was used to inoculate 500 mL of fresh medium to which 500 *μ*M isopropyl-1-thio-*β*-D-galactopyranoside (IPTG) was added after 3 h to induce protein expression. Cells were further grown for 12 h at 30 °C. After centrifugation for 10 min at 11000*g*, the bacteria were resuspended in 50 mM Bis-Tris at pH 6.9, containing 10% (v/v) glycerol, 10 mM dithiothreitol (DTT), and 5 mM $Na_2S_2O_5$. Cells were lysed by a combination of a 30 min lysozyme treatment (1 mg/500 mL of culture) and subsequent ultrasonication (five pulses of 20 s at 20 W, at 4 °C). After the cells lysed, the suspensions were centrifuged (20000*g* for 30 min at 4 °C). The supernatant containing the soluble recombinant *Dc*TPS1 and *Dc*TPS2 proteins, respectively, were purified by metal (nickel) affinity chromatography (Qiagen, Valencia, CA) with a stepwise gradient of increasing imidazole concentrations using standard procedures. The *Dc*TPS1- and *Dc*TPS2-containing fractions were pooled and desalted with 50 mM Bis-Tris at pH 7.0 containing 10% (v/v) glycerol and 10 mM DTT, using Vivaspin 20 [GE Healthcare, molecular weight cutoff (MWCO) of 10 kDa]. Proteins were checked for purity by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE). Protein concentrations were determined by the method of Bradford[27] using reagent obtained from Bio-Rad. Bovine serum albumin was used for calibration.

Assay for Terpene Synthase Activity. Enzyme activity assays were performed in screw-capped 2 mL GC glass vials, using 1 to 500 ng of purified recombinant proteins, 10 *μ*M substrate (GPP or FPP), 10 mM $MgCl_2$, 10 *μ*M $MnCl_2$, and 50 mM Bis-Tris at pH 7.0 assay buffer in a total volume of 100 *μ*L. The reactions were incubated for 30 min at 30 °C. After incubation, the samples were analyzed by auto-HS−SPME−GC−MS for the identification of volatile terpenes generated during the 30 °C incubation. As controls, *E. coli* cells transformed with control plasmids devoid of the *DcTPS1* and *DcTPS2* genes, and heat-inactivated DcTPS1 and DcTPS2 proteins or assays without GPP/FPP as a substrate were used.

***DcTPS* Transcript Analysis.** For quantitative RT-PCR (qRT-PCR) analysis of *DcTPS1* and *DcTPS2*, total RNA (5 *μ*g) from the orange carrot cultivar Nairobi was extracted (Spectrum Plant Total RNA Kit, Sigma-Aldrich) and reverse-transcribed using an oligo-dT primer and the SuperScript II first-strand system (Invitrogen).

qRT-PCR was performed on an Applied Biosystems StepOnePlus real-time PCR system (Life Technologies) using ABsolute Blue qPCR SYBR Green ROX Mix (Tamar Laboratory Supplies, Ltd., Israel), 5 ng of reverse-translated total RNA, and 100 ng of each primers. Primers for *DcTPS1* were *DcTPS1*-qRT-F (5′- CCTCTACTGTGTTCCG-CAAATA-3′) and *DcTPS1*-qRT-R (5′-CTGAAGTGCTTCCTC-CAGTATC-3′), and primers for *DcTPS2* were *DcTPS2*-qRT-F (5′-AAAGATGACACAGCGGGTAAA-3′), and *DcTPS2*-qRT-R (5′-GCCTCTGAAACCGAAGAAAGA-3′). A relative quantification of gene expression was performed using the housekeeping gene tubulin from carrot as a reference gene. The primers used for tubulin were Tubulin_F_qPCR (5′-TCTTGGAGGTGGCACAGGAT-3′) and Tubulin_R_qPCR (5′-ACCTTAGGAGACGGGAACACAGA-3′).

The difference in relative expression levels of *DcTPS1* and *DcTPS2* were calculated from the $2^{-\Delta\Delta C_t}$ value after normalization of *DcTPS1* and *DcTPS2* data to tubulin. All analyses were performed using at least three biological replicates.

RESULTS AND DISCUSSION

Terpene Profiles in Colored Carrot Cultivars. We previously demonstrated that variation in norisoprenoid accumulation in different colored carrot cultivars is genotype-dependent.[2] Also, variation in the total content of carrot terpenes has been reported.[28−31] However, to the best of our knowledge, the role of TPSs in the formation of mono- and sesquiterpene volatiles and their flavor properties in carrots has not been reported. Our primary goal is to decipher the role of individual TPSs in terpene flavor variation in different carrot cultivars. To this end, we first examined the volatile compound composition of freshly harvested (10 week old) tissue of five colored cultivars (orange "Nairobi", orange "Rothild", purple "Purple Haze", yellow "Yellowstone", and white "Crème de Lite") using SPME−GC−MS. More than 41 volatile compounds were detected, among which 23 were identified or predicted to be monoterpenes and 17 were found or predicted to be sesquiterpenes (Table 1 and Supplemental Table 1 of the Supporting Information). The orange carrot cultivar, Rothild, accumulated the highest levels of total volatile compounds, and the yellow carrot cultivar, Yellowstone, accumulated the lowest level of total terpenes (see Supplemental Table 1 of the Supporting Information). Our analyses unveiled the presence of different terpenes in carrot roots according to the variety analyzed (Table 1 and Supplemental Table 1 of the Supporting Information). The main sesquiterpene compounds found in all cultivars were (*E*)-*β*-caryophyllene, (*E*)-*γ*-bisabolene, and *α*-humulene, and the main monoterpenes were terpinolene, *γ*-

J. Agric. Food Chem. 2015, 63, 4870−4878

terpinene, myrcene, *p*-cymene, and *α*-pinene (Table 1 and Supplemental Table 1 of the Supporting Information).

To determine whether the terpene volatile compositions in carrot cultivars of diverse color are influenced by the genotypes, PCA was applied. The results are visualized by mean values and as bi-plot (PC1 versus PC2) (Figure 1), showing the first two

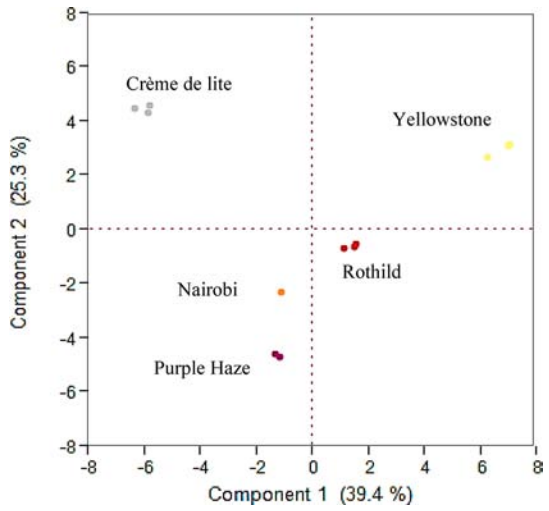

Figure 1. PCA analysis of 41 volatile compounds in five different colored carrot cultivars: orange "Nairobi", orange "Rothild", purple "Purple Haze", yellow "Yellowstone", and white "Crème de Lite". All analyses were performed using three biological replicates.

PCs to explain 64% of the variation. A large proportion of the variation in the terpene volatiles is found in PC1 (39.4%), whereas PC2 (25.3%) mainly explains a chemical variation in the terpene content. Our analysis showed that mono- and sesquiterpene profiles varied widely among different genetic stocks (Figure 1). These findings of genotypic differences are supported by other previous analyses of diverse carrot varieties.[28−31]

Analysis of Terpene Levels during Carrot Root Development. To better understand the pattern of terpene accumulation during carrot root development, we determined the total terpene content of the orange carrot cultivar Nairobi between 9 and 12 weeks after sowing (Figure 2). This time period of root maturation overlaps with the time of harvest 10−14 weeks post-seeding.[32]

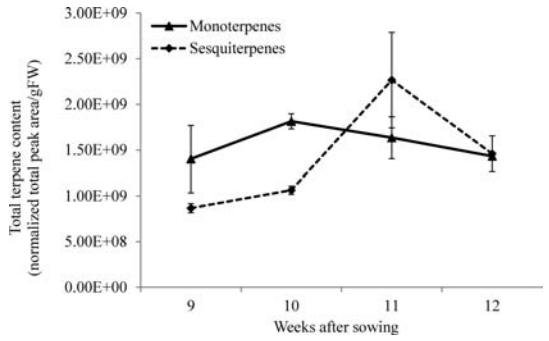

Figure 2. Terpene volatile accumulation during carrot root development in the orange cultivar Nairobi. The authenticity of mono- and sesquiterpenes was confirmed by comparing their retention time and mass spectra to those of authentic standards. Values are the mean ± standard error (n = 4).

Auto-HS−SPME−GC−MS analysis of total terpene volatile accumulation demonstrated that mono- and sesquiterpene concentrations consistently increased between the 9th and 11th week of carrot root development prior to a slight decrease in week 12 (Figure 2). The accumulation of sesquiterpenes was more rapid than that of monoterpenes between weeks 10 and 11. The reduced concentration observed after week 11 may be attributable to a period where root growth outpaced terpene accumulation. The composition of compounds during carrot root development further depends upon the different soils, climates, and genetic variability of the carrot cultivars.[32,33]

The chemical profile of terpenes found in carrot roots was first assessed to facilitate the design of PCR primers for the isolation of *TPS* genes catalyzing the biosynthesis of particular classes of terpenes. Interestingly, (*E*)-*β*-caryophyllene account as the main sesquiterpene compounds found in all cultivars (Table 1). A possible rationale would be to identify the TPSs that are responsible for producing the predominant terpene products in carrot roots. Therefore, two candidate *DcTPS1* and *DcTPS2* genes were chosen on the basis of sequence homology to other known plant TPSs for further characterization (see below).

Isolation and Functional Characterization of Carrot TPSs. Despite the characterization of a large number of plant TPSs, surprisingly no TPS enzymes or their encoding genes have been isolated and characterized from *D. carota*. Moreover, the role of TPSs in the formation of mono- and sesquiterpene volatiles and their flavor properties in carrots have not been reported. To identify the genes responsible for mono- and sesquiterpene volatile formation in carrot roots, we performed a homology search of RNA-Seq carrot transcriptome sequences, which had previously been obtained by Iorizzo et al.[26] Blastx searches of the assembled contigs in the "additional file 2" (1471-2164-12-389-S2.FASTA) from Iorizzo et al.,[26] against *TPS* genes in Genbank identified more than a dozen candidate *TPS* genes. At least six were full-length carrot *TPS* cDNAs, of which three are predicted to be monoterpene synthases and three may be sesquiterpene synthases (Table 2). The wide variation observed in the number of mapped reads for these genes in the purple (B7262) and orange (B6275) cultivars suggests substantial differences in gene expression between the two cultivars (Table 2).

J. Agric. Food Chem. 2015, 63, 4870−4878

We then generated cDNAs for the *DcTPS* contig 4929 (called *DcTPS1* from here on) and *DcTPS* contig 43814 (called *DcTPS2* from here on) from RNA isolated from the orange cultivar Nairobi in our cultivar collection. Amino acid sequences encoded by *DcTPS1* and *DcTPS2* were 90% identical to those identified from the B7262 and B6274 cultivars. Recombinant *Dc*TPS1 protein expressed in *E. coli* converted (*E*,*E*)-FPP to (*E*)-β-caryophyllene, the predominant sesquiterpene in all cultivars (Table 1), as the primary product, along with α-humulene (Figure 3A). Incubation of *Dc*TPS1 with GPP led to the production of several monoterpenes, including β-myrcene, limonene, and geraniol (Figure 3C). *E. coli* cells transformed with control plasmids devoid of the *DcTPS1* gene, and heat-inactivated DcTPS1 protein or assays without GPP/FPP as a substrate were used as a control (panels B and D of Figure 3).

Our results confirm previous findings in other plants indicating that sesquiterpene synthases, e.g., β-caryophyllene synthase from *Artemisia annua*, produced monoterpenes[34] and 9-*epi*-caryophyllene from *Lavandula* × *interminda*,[35] and *trans*-α-bergamotene synthase from *Lavandula angustifolia*,[36] produced monoterpenes when assayed with GPP as a substrate. The mono- and sesquiterpenes formed by *Dc*TPS1 were found as constituents of the carrot volatile blend in all carrot cultivars (Table 1). However, it can be assumed that *Dc*TPS1 most likely functions as a sesquiterpene synthase *in vivo* because of the lack of a plastidial targeting sequence (Figures 3A and 7). TPS enzymes producing (*E*)-β-caryophyllene and α-humulene have been reported primarily from aboveground tissues of a variety of plants, where these sesquiterpenes are assumed to function in mutualistic interactions and in plant defense.[37,38] Functions of root-specific (*E*)-β-caryophyllene synthases have been less well-described, with the exception of a maize (*E*)-β-caryophyllene synthase that is involved in indirect defense against root herbivores.[39]

Analysis of reaction products formed after incubation of the *Dc*TPS2 protein with GPP showed the presence of two monoterpene compounds, geraniol and β-myrcene (Figure 4A). As control experiments, heat-inactivated DcTPS2 protein and *E. coli* cells transformed with control plasmids devoid of the *DcTPS2* gene or assays without GPP as a substrate were used (Figure 4B). Geraniol and β-myrcene are not actually the major monoterpenes accumulated. Besides terpinolene, some monoterpene hydrocarbons, e.g. *E*-β-ocimene, β-myrcene, and sabinene, are the major compounds in all carrot cultivars investigated in this study (Table 1 and Supplemental Table 1 of the Supporting Information).

Volatile mono- and sesquiterpenes have been reported to be synthetized and accumulated in roots and rhizomes of various plant species.[40,41] It has been reported that root-emitted volatile compounds can be involved in the plant defense by directly repelling herbivores or pathogens or recruiting enemies of their aggressors to limit or eliminate further damage.[42,43] Besides their ecological benefits to plants, terpene-specialized compounds are widely used by humans as flavors, fragrances, or pharmaceuticals.[6] However, terpene oils produced in carrot root tissues are assumed to contribute significantly to the aroma and flavor of carrots,[1,28,29] and they could also play interesting defensive roles in belowground biotic stress. The terpene products found for *Dc*TPS1 and *Dc*TPS2 represent only a fraction of the terpene constituents detected in carrot roots. Additional *TPS* gene transcript analysis, enzyme characterization, and subsequent targeted gene silencing will provide a better understanding of the individual or overlapping functions of root carrot *TPS* genes in terpene biosynthesis.

Cultivar-Specific and Developmental Expression Patterns of *DcTPS1* and *DcTPS2* Genes. To examine whether terpene volatile compound accumulation during carrot root development and differences in terpene composition between carrot cultivars could be related to the expression of terpene biosynthetic genes, transcript levels of *DcTPS1* and *DcTPS2* were analyzed by qRT-PCR (Figure 5) in the same samples as used for auto-HS−SPME−GC−MS analysis.

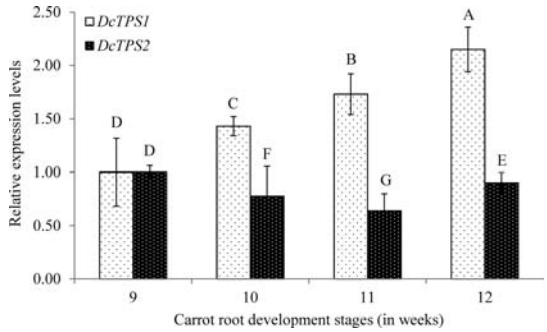

Figure 5. Expression patterns of *DcTPS1* and *DcTPS2* during carrot root development from 9 to 12 weeks after sowing in the orange carrot cultivar Nairobi. Quantification of *DcTPS1* and *DcTPS2* transcript levels by real-time RT-PCR analysis normalized to equal levels of tubulin transcripts. All analyses were performed using three biological replicates. Bars labeled with different letters indicate significant differences as determined by JMP statistic software [$F < 0.0001$; Tukey−Kramer honestly significant difference (HSD) test].

Transcripts of *DcTPS1* and *DcTPS2* were observed in all four stages in the Nairobi cultivar, demonstrating that these two genes were expressed at all developmental stages. Furthermore, transcript abundance increased during root maturation for the *DcTPS1* gene, with maximum transcript levels occurring in 12-week-old roots (Figure 5), which is consistent with the accumulation of high terpene levels in this time period (Figure 2). The expression level of *DcTPS1* and *DcTPS2* varied statistically between carrot tissues at all developmental stages (Figure 5).

We also examined possible differences in the expression of *DcTPS1* and *DcTPS2* in the five different carrot cultivars (Figure 6). Transcript abundance was highest for both genes in the Rothild cultivar, consistent with high levels of total terpenes in this cultivar (see Supplemental Table 1 of the Supporting Information). The lowest level of both gene transcripts was observed in the cultivar Yellowstone (Figure 6), correlating with lowest terpene concentrations in this cultivar (see Supplemental Table 1 of the Supporting Information). Also, the expression level varied statistically between *DcTPS1* and *DcTPS2* in the five different carrot cultivars investigated in this study (Figure 6). However, *DcTPS1* and *DcTPS2* expression levels did not directly correlate with the amounts of (*E*)-β-caryophyllene and geraniol in the different cultivars, which indicates the presence of other TPSs producing the same compounds or possible post-transcriptional/translational regulatory mechanisms. Post-transcriptional regulation of TPS enzymes[44] as well as light-dependent substrate availability[45] are also discussed as regulatory steps in terpene formation.

***Dc*TPS1 and *Dc*TPS2 Are Members of the TPS-a and TPS-b Families.** The predicted *Dc*TPS1 protein sequence

DOI: 10.1021/acs.jafc.5b00546
J. Agric. Food Chem. 2015, 63, 4870−4878

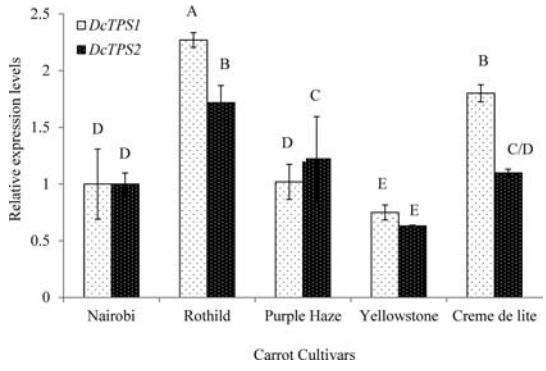

Figure 6. Quantitative RT-PCR analysis of *DcTPS1* and *DcTPS2* expression in roots of five different colored carrot varieties. Bars labeled with different letters indicate the significant differences as determined by JMP statistic software ($F < 0.0001$; Tukey–Kramer HSD test).

consists of 560 amino acids, with a calculated molecular mass of 64.7 kDa (see Supplemental Figure 1 of the Supporting Information). No chloroplast-targeting sequence was identified for *Dc*TPS1, which is indicative for the function of this enzyme as a cytosolic sesquiterpene synthase. The *Dc*TPS2 protein consists of 593 amino acids with a calculated molecular mass of 68.4 kDa. In contrast to *Dc*TPS1, *Dc*TPS2 appears to carry a 53 amino acid N-terminal plastidial transit peptide (see Supplemental Figure 1 of the Supporting Information), as predicted by the ChloroP 1.1 software (http://www.cbs.dtu.dk/services/ChloroP/), suggesting a function of *Dc*TPS-2 as a monoterpene synthase *in vivo*.

Both *Dc*TPS1 and *Dc*TPS2 sequences contain the conserved features of plant TPSs, including the asparate-rich motif DDxxD and the RxR motif, both of which are involved in catalysis (see Supplemental Figure 1 of the Supporting Information).[13,1446] A RR(x)8W motif is present in the N-terminal region of *Dc*TPS1 and downstream of the N-terminal transit peptide of *Dc*TPS2 (see Supplemental Figure 1 of the Supporting Information). The motif is assumed to participate in the ionization of the substrate[47] and is characteristic of most TPS members of the subfamilies TPS-a and TPS-b.[4849]

To analyze the phylogenetic relationship of the carrot TPS proteins (*Dc*TPS1, *Dc*TPS58617, *Dc*TPS52846, *Dc*TPS2, *Dc*TPS1324, and *Dc*TPS21245) with known TPSs of other plants, a phylogenetic tree was constructed using the neighbor-joining method (Figure 7). On the basis of protein sequence and function, plant TPSs were recently organized into seven subfamilies. These include three angiosperm-specific clades (TPS-a, TPS-b, and TPS-g), a gymnosperm-specific subfamily (TPS-d), a subfamily most conserved among land plants (TPS-c), two subfamilies most conserved among vascular plants (TPS-e and TPS-f), and a subfamily specific to *Selaginella moellendorffii* (TPS-h).[13]

*Dc*TPS1, *Dc*TPS58617, and *Dc*TPS52846, along with some TPSs from Apiaceae, the same plant family as *D. carota*, e.g., the sesquiterpene cyclase from *Centella asiatica* (55% identity of amino acids), STS1 and STS2 from *Thapsia garganica* (51 and 55% identity of amino acids, respectively),[50] β-caryophyllene synthases from *Solanum lycopersicom*[37] and *Vitis vinifera*, and pinene synthase from *Malus* × *domestica*,[51] belong to the TPS-a group of the terpene synthase superfamily (Figure 7). Furthermore, the *Dc*TPS1 protein displays a high degree of sequence similarity to the α-copaene synthase (62% identity)

Figure 7. Phylogenetic tree of deduced amino acid sequences of plant sesquiterpene synthases. The sequences were aligned using phylogeny analysis (http://www.phylogeny.fr). The evolutionary history was inferred using the neighbor-joining methods and drawn by TreeView. The TPS family was subdivided into six subfamilies, designated TPS-a–TPS-f, each distinguished by sharing a minimum of 40% identity among members.[49] Cu is *Citrus unshiu*; Vv is *Vitis vinifera*; Md is *Malus* × *domestica*; Rc is *Ricinus communis*; Ch is *Citrus hystrix*; Sh is *Solanum habrochaites*; Sl is *Solanum lycopersicum*; Fv is *Fragaria vesca*; Ga is *Gossypium arboretum*; Lh is *Lycopersicon hirsutum*; Mt is *Medicago truncatula*; At is *Artemisia annua*; Cb is *Clarkia breweri*; Cc is *Clarkia concinna*; Pg is *Picea glauca*; Pt is *Populus trichocarpa*; Ta is *Triticum aestivum*; Ag is *Abies grandis*; Ob is *Ocimum basilicum*; Am is *Antirrhinum majus*; La is *Lavandula angustifolia*; Os is *Oryza sativa*; Aa is *Artemisia annua*; Mg is *Magnolia grandiflora*; Eg is *Eucalyptus grandis*; Cs is *Coriandrum sativum*; Ca is *Centella asiatica*; and Tg is *Thapsia garganica*. The black bold underline indicates the carrot TPSs, *Dc*TPS1, *Dc*TPS2, *Dc*TPS58617, *Dc*TPS52846, *Dc*TPS1324, and *Dc*TPS21245 proteins, identified in this study.

from *Eleutherococcuc trifoliatus*, a sesquiterpene synthase (60% identity) from *Panax ginseng*, and (*E*)-β-caryophyllene synthase (54% identity) from *Vitis vinifera*.

*Dc*TPS2, *Dc*TPS1324, and *Dc*TPS21245 cluster in the TPS-b clade, together with *S*-linalool synthase (39% identity of amino acids) and γ-terpinene synthase (41% identity of amino acids) from *Coriandrum sativum* (Apiaceae family),[19] α-terpinol synthase and myrcene synthase from *Vitis vinifera*,[48] and D-limonene synthase from *Citrus* (Figure 7).[52] *Dc*TPS2 showed the highest amino acid similarity to terpene synthase (63% identity) from *Jatropha curcas*, (*R*)-limonene synthase (59%

DOI: 10.1021/acs.jafc.5b00546
J. Agric. Food Chem. 2015, 63, 4870–4878

identity) from *Ricinus communis*, and α-terpineol synthase (54% identity) and β-bisabolene synthase (52% identity) from *Eucalyptus grandis*.

In conclusion, several terpene volatile compounds and the total volatile terpene content varied widely among different colored carrot genotypes. Two TPSs (*Dc*TPS1 and *Dc*TPS2) of a larger carrot TPS family were found to produce (*E*)-β-caryophyllene, the predominant sesquiterpene constituent of carrot roots, and the monoterpene component, geraniol, respectively. The identification of carrot *TPS* cDNAs will facilitate the cloning of additional genes of the *TPS* family in *D. carota* and will allow for future molecular, physiological, and biochemical studies of the regulation of flavor and aroma formation during carrot root development. The *TPS* genes described here and potential other *TPS* genes from *D. carota* may be developed into molecular markers to aid in breeding and improvement of cultivars with superior carrot flavor and aroma.

Supporting Information

ABSTRACT: The effects of oxidative stress induced by H_2O_2 were tested in liquid cultures in the fumonisin-producing fungus *Fusarium verticillioides*. The quantitative analysis of fumonisins B_1, B_2, B_3, and B_4 was achieved by means of liquid chromatography coupled to high-resolution mass spectrometry. Two effects in *F. verticillioides*, consisting of different abilities to produce fumonisins in response to oxidative stress, were identified. Following H_2O_2 addition, two *F. verticillioides* strains produced significantly more fumonisin (>300%) while three other strains produced significantly less (<20%) in comparison to control cultures. Transcriptional studies with seven biosynthetic genes showed a significant increase in transcript levels in the strain that made more fumonisin and either no or minimal changes in the strain that made less fumonisin. Our data indicate the important role of oxidative stress toward the modulation of the fumonisin biosynthesis and suggest the necessity to verify the presence of such divergent behavior in *F. verticillioides* populations under natural conditions.

KEYWORDS: *Fusarium verticillioides, fumonisins, oxidative stress, fum genes, H_2O_2, LC-high-resolution MS analysis*

INTRODUCTION

Fusarium verticillioides is one of the most common pathogenic fungi affecting maize,[1] characterized by low virulence. *F. verticillioides* is often endophytically seed borne[2] but can also penetrate through damaged tissues, causing severe ear rot and accumulation of fumonisins in kernels.[3] Fumonisins, the most common mycotoxins in maize, are primarily produced by *F. verticillioides* and *F. proliferatum*.[4] They occur at biologically significant levels both on maize grains and on a variety of derived human and animal food products worldwide.[5]

Fumonisin B_1 (FB_1) is the most abundant and toxicologically active type B fumonisin produced by *F. verticillioides*, followed by the other congeners FB_2, FB_3, and FB_4 (Figure 1).[6]

One of the most investigated research areas in relation to mycotoxin production is the influence of stress factors. Abiotic stress, such as unfavorable temperature, water activity (a_w), and pH, can influence mycotoxin biosynthetic pathways.[7] Previous experiments have shown that intracellular oxidative stress can affect aflatoxin[8] and trichothecene production,[9] and a positive correlation between these mycotoxins and the accumulation of reactive oxygen species has been observed.[10,11] In particular, in *Fusarium graminearum* during in vitro growth, both mycotoxin accumulation and expression of *tri*-cluster genes were modulated by oxidative stress induced by H_2O_2. It has been proposed that the differential modulation of toxin biosynthesis is linked to the fungal ability to protect itself from oxidative damage.[12]

In response to biotic and abiotic stresses,[13−15] plants have developed a broad range of strategies to protect themselves. Plant responses include rapid production of reactive oxygen species (ROS),[16] such as superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), hydroxyl radical (HO^-), and lipoperoxides (LOOH). A correlation is known to exist between environmental stress and mycotoxin biosynthesis.[7,17] The ability of antioxidant phenolic compounds and scavenging oxidative chemical species to decrease in vitro mycotoxin biosynthesis[18,19] suggest the involvement of ROS compounds. Moreover, it was previously hypothesized that plant compounds, including ROS, involved in plant−pathogen interactions during the infection process by *Fusarium* spp. could modulate mycotoxin production in host tissues.[12]

In our study, we investigated the in vitro effect of oxidative stress induced by hydrogen peroxide on fumonisin production in *F. verticillioides*. We have also analyzed, under the same conditions, the expression of several fumonisin cluster genes involved in the fumonisin biosynthetic pathway, including *fum1* (polyketide synthase), *fum6* (cytochrome P450 monooxygenase), *fum10* (acyl-CoA synthetase), *fum14* (peptide synthase), and *fum19* (ABC-transporter), the regulatory gene *fcc1*, a C-type cyclin, and *fum21*, a transcription factor.

MATERIALS AND METHODS

Strain Isolation and Experimental Conditions. Five *F. verticillioides* strains (named *Fv*1, *Fv*3, *Fv*4, *Fv*7, and *Fv*8) isolated from maize kernels grown in Veneto (Italy) were chosen for this study, and monoconidial cultures were obtained as reported previously.[20] To confirm the identification at the species level, the *Fusarium*

monoconidial strains were submitted to molecular analysis by PCR using VER1 and VER2 primers.[21]

Five randomly chosen monoconidial strains were grown on PDA at 25 °C under dark conditions for 8 days before spore collection. For each strain, 100 μL of a conidial suspension at the density of 10^8 conidia/mL was inoculated in 100 mL of GYAM medium (8 mM L-asparagine, 1.7 mM NaCl, 4.4 mM K_2HPO_4, 2 mM $MgSO_4$, 8.8 mM $CaCl_2$, 0.05% yeast extract, 0.24 M glucose, and 5.0 mM malic acid) and incubated at 25 °C on a rotary shaker at 150 rpm in the dark. Cultures were grown for 2 days before H_2O_2 treatments. These treatments consisted of H_2O_2 addition every 24 h to obtain a final concentration of 0.5, 2, or 0.5 mM supplemented with 100 units of catalase (Sigma–Aldrich, St. Louis, MO). Control cultures were supplemented with sterile water.

The incubation period was 21 days for biomass and fumonisin quantitation and 5 days for gene expression analysis.

For gene expression analysis, *Fv*8 and *Fv*1 were selected as fumonisin-promoted and -inhibited representative strains, respectively.

Effect of H_2O_2 on Fungal Growth and Fumonisin Production. Fungal strains were grown for 21 days as previously described; biomass and supernatant were collected by centrifugation at 3000*g* for 5 min. The supernatant was filtered through Whatman paper No. 4 and stored at −20 °C before LC-MS analysis. Fungal mycelia were dried and weighed to normalize fumonisin production and to analyze the effect of H_2O_2 treatment on fungal growth. Each experiment was performed in triplicate.

Reagents and Chemicals. Analytical standard solutions of FB_1 and FB_2 and of FB_3, both at 50 μg/mL in acetonitrile/water (50/50, v/v), were from Sigma-Aldrich. All standard dilutions were made with the same solution. The isotope-labeled fumonisin B_1 $^{13}C_{34}$ (25.1 μg/mL in acetonitrile/water 50/50, v/v) (Sigma-Aldrich) was diluted to 0.5 μg/mL and used as an internal standard (IS) for quality control purposes. A composite working standard solution of FB_1, FB_2, and FB_3 at 83.3 ng/mL was obtained from appropriate dilution of stock solutions. Formic acid (reagent grade, min 99%) and LC-MS grade acetonitrile and methanol were purchased from Sigma-Aldrich. Water was purified (18 MΩ cm) using a Milli-Q Water System (Millipore, Darmstadt, Germany).

Fumonisin Extraction and HPLC-MS Analysis. One milliliter of each cultured strain was centrifuged for 10 min at 10000 rpm and 25 °C. A 100 μL aliquot of supernatant was diluted 1/10 with a solution of LC mobile phases (50/50 v/v) and spiked with IS at a concentration of 4 ng/mL, and finally 5 μL was injected into the LC-MS detection system. An Ultimate 3000 UHPLC (Thermo Fisher Scientific, Waltham, MA), consisting of a vacuum degasser, autosampler, quaternary pump, and column oven, was coupled to a Q-Exactive mass analyzer with an HESI source (Thermo Fisher Scientific) in positive ionization mode.

Optimization of peak separation was achieved with a 150 mm × 2 mm i.d., 2.6 μm Kinetex C18 column (Phenomenex, Bologna, Italy) thermostated at 30 °C. The mobile phase components A and B were water and acetonitrile, respectively, both acidified with 0.1% of formic acid. The eluent flow rate was 0.3 mL/min. The mobile phase gradient profile is as follows: 0–5 min, 0% B; 5–16 min, 0–100% B; 16–19 min, 100% B; 19–20 min, 100–0% B; 20–27 min, 0% B. MS parameters were as follows: spray voltage 4 kV; sheath gas 40 psi; auxiliary gas 20 arbitrary units; ion transfer tube temperature 320 °C; vaporizer temperature 310 °C; S-lens RF level 60 V.

The mass calibration was performed weekly using the manufacturer's solution. For all chromatographic runs, m/z 391.2843 relative to the $[M + H]^+$ ion from diisooctyl phthalate, always present as an impurity, was set as the lock mass for accurate mass analysis. A simultaneous MS (resolution 70000 at m/z 200) and MS/MS (resolution 17500 at m/z 200) acquisition was performed with the data-dependent feature, using the $[M + H]^+$ pseudomolecular ions of the selected analytes in the preferred inclusion list with an isolation width of 4 amu. Centroid MS spectra were recorded over the range m/z 150–1000, setting the normalized collision energies at 50. The highest fragment ion obtained was used for confirmatory purposes, while the pseudomolecular ion $[M + H]^+$ was used for quantitative analysis. The automatic gain control was set at 3×10^6 ions with a maximum injection time of 200 ms for MS and at 1×10^5 ions with a maximum injection time of 50 ms for MS/MS. Mass spectra acquisition and data analysis were processed with Excalibur 2.2 Software (Thermo Fisher Scientific).

All analyses performed showed a mass accuracy better than 0.1 ppm, allowing the correct identification of the target (FB_1, FB_2, and FB_3) and nontarget (FB_4) fumonisins. The quantitation of fumonisins was performed using the corresponding external calibration curve with least-squares regression, obtained by plotting the area of each analyte normalized with the internal standard area (A/A_{IS}), related to the extracted ion chromatogram (extraction accuracy 10 ppm) of the molecular ion $[M + H]^+$. A five-point calibration curve, ranging from 0.2 to 50 ng/mL, was injected in duplicate for each set of analysis, showing that R^2 was always higher than 0.9995.

Quantitation of fumonisin B_4 was made by assuming the same molar response of the B_2 variant, since a commercial standard was not available. Limits of detection, assessed from the lowest point of the calibration curve and corresponding to an S/N value of 3, were estimated to be 0.5 ng/mL in the matrix.

Values with different letters in the rows are significantly different ($p < 0.05$) on the basis of ANOVA and Tukey's HSD tests. Statistical analyses were performed separately per strain.

Gene Expression Analysis. A set of genes involved in both the fumonisin regulatory (*fcc1* and *fum21*) and biosynthetic pathways (*fum1*, *fum6*, *fum10*, *fum14*, and *fum19*) was analyzed by quantitative real-time PCR (qPCR). *Fv*8 and *Fv*1 were grown on GYAM as previously described, and RNAs were extracted on 5 day old mycelium according to Brown et al.[22] A 30 mg portion of fresh mycelium was ground in a mortar with liquid nitrogen, and the total RNA was extracted using an Illustra RNAspin Mini Kit (GE Healthcare, Chalfont St. Giles, U.K.) according to the manufacturer's instructions. RNA concentrations were determined by both spectrophotometer and densitometric analysis of RNA bands following agarose gel electrophoresis. Total RNA (10 μg) was treated with 10 units of RQ1 RNase-free DNase (Promega, Madison, WI) and 2 units of RNasin Ribonuclease Inhibitor (Promega) for 30 min and then purified by phenol−chloroform extraction and precipitated in isopropyl alcohol. For cDNA synthesis, DNase-treated RNA (2 μg) was reverse-transcribed using the Reverse Transcription System according to the manufacturer's instructions (Promega). Real-time PCR was performed by a 7500 real-time PCR detection system (Applied Biosystems) according to the manufacturer's guidelines. A total of 1 μL of a cDNA dilution (corresponding to 25 ng of total RNA) was amplified in a 25 μL reaction containing Power SYBR Green PCR Master Mix (Applied Biosystem) and 200 μM in each primer.

Primer pairs used for gene expression were designed from published sequences available in the NCBI database using software Primer3 v0.4.0 software.[23] Primers for each gene were designed to anneal at 56−60 °C and amplify a fragment of approximately 150 bp. Gene expression analyses were performed with a real-time PCR 7500 Applied Biosystem using Power SYBR Green PCR Master Mix (Applied Biosystems). One-tenth of a cDNA reaction mixture was used to optimize PCR amplification and primer efficiency. Each amplification reaction was conducted according to the manufacturer's instructions with a primer concentration of 200 nM.

The amplification conditions consisted of 40 cycles as follows: 95 °C for 15 s, annealing at 56 °C for 30 s, and extension at 72 °C for 35 s, followed by a final extension step of 4 min at 72 °C. All reactions were performed in triplicate. The absence of dimer formation was checked in nontemplate samples by product dissociation analysis and electrophoretic separation in agarose gel. Relative expression of the RT-PCR products was determined using the method described by Pfaffl[24] by Q-Gene 4.3.10 software.[25] β-Tubulin (β-tub) was used as a reference gene to normalize quantitative expression data.

Statistical Analysis. Values of fungal growth, fumonisin content, and gene expression were log-transformed before statistical analysis, the Kolmogorov−Smirnov test was performed to verify that the data had a normal distribution, and the Levene test was used to check the homogeneity of variance.

Statistical analysis of the effect of H_2O_2 supplementation on *F. verticillioides* growth and fumonisin content was performed by ANOVA followed by Tukey's HSD test, in which treatment (T) and strain (S) were independent variables. Gene expressions were statistically analyzed by ANOVA followed by Tukey's HSD test. All analyses were conducted using the software SPSS 14.0. These results were computed from experiments performed in triplicate. Data on fumonisin levels and dry biomass obtained from separate experiments were expressed as percent values relative to the treatment controls.

RESULTS AND DISCUSSION

Fumonisin Accumulation under Oxidative Stress by H_2O_2 from Different *F. verticillioides* Strains. As a first approach to clarify the influence of ROS in fumonisin modulation, our study has examined the in vitro impact of oxidative stress induced by hydrogen peroxide treatment on five strains of *F. verticillioides*. Further, catalase, which degrades H_2O_2, was applied to the fungus to verify the link between fumonisin biosynthesis and oxidative stress. Fumonisin production was measured in culture medium supplemented with two concentrations of H_2O_2 (0.5 and 2 mM) and also in the presence of catalase. The results indicate that different oxidative stress conditions can modulate production of fumonisins in relation to the fungal strain; in particular *Fv*3 and *Fv*8, on treatment with the two concentrations of H_2O_2, were stimulated to produce fumonisins, while in the other three strains analyzed (*Fv*1, *Fv*4, and *Fv*7), fumonisin production was strongly inhibited.

For promoted strains, treatment with 0.5 mM H_2O_2 increased fumonisin yields (549% and 230% for strains *Fv*3 and *Fv*8, respectively), while the effect was slightly lower with the higher H_2O_2 concentration (457% and 140%, respectively), as reported in Table 1.

Results obtained for two out of five *F. verticillioides* strains studied for fumonisin synthesis were similar to those reported for *Aspergillus flavus* synthesis of aflatoxin[8] and *F. graminearum* synthesis of trichothecenes:[10] that oxidative stress positively influences toxin production. However, here, for the first time, we report that the response to oxidative stress is strain dependent. Moreover, we also confirm what was previously reported for *Aspergillus flavus* and *F. verticillioides*: that mild stress caused by environmental factors increases mycotoxin production but severe stress conditions can reduce it.[7,26]

In addition to promoted strain, we found that the synthesis of fumonisin was inhibited in three other strains by the same oxidative conditions. Inhibited cultures suppressed fumonisin biosynthesis almost completely at lower H_2O_2 concentration (84% and 92% reduction for *Fv*1 and *Fv*7, respectively), whereas the 2 mM treatment caused a slight increase of fumonisin production of 47% and 16% for *Fv*1 and *Fv*7, respectively, but no significant changes were observed for *Fv*4 strain (Table 1). Statistical analysis showed a significant influence of fungal strain (F 4.533, $p < 0.016$) and treatment (F 4.864, $p < 0.035$) on fumonisin production as well as the interaction between the two factors (F 4.124, $p < 0.008$). Finally, our analysis showed that FB_1 was the major fumonisin

analogue produced by *F. verticillioides* strains. The isoform composition for each strain (Table 2) indicates that all strains

in this study belong to *F. verticillioides* chemotype $FB_1 > FB_3 > FB_2 > FB_4$ according to the Szécsi classification.[27] Type B fumonisin ratios were not significantly different upon treatments (data not shown).

In catalase-treated cultures, all *F. verticillioides* strains reduced mycotoxin biosynthesis, thus reducing fumonisin levels from 80 to 91% in comparison to the control culture, independent of their response to H_2O_2 supplementation. Our results for *Fv* strains promoted or inhibited by hydrogen peroxide demonstrate that the addition of an antioxidant-activity enzyme causes a low production of fumonisins. On the other hand, the addition of chemical antioxidant compounds has also been reported to counteract the fumonisin accumulation.[28,29]

Studies on *F. graminearum* provide evidence that catalases affect the exogenous H_2O_2 treatment, which work as an inducer of deoxynivalenol or as an inhibitor of nivalenol and fusarenon-X biosynthesis, supporting the notion that this enzyme, acting as a scavenger for the oxidant compounds, can modulate the mycotoxin biosynthesis.[30] Furthermore, in the same fungus the chemotypes could be related to virulence[31] and to the different abilities to detoxify hydrogen peroxide.[30] On the basis of our study, it appears evident that different sensitivities to oxidative stress in *F. verticillioides* determine the variable responses to fumonisin production; however, these experiments were not performed to discriminate the sensitivity of different *Fv* isolates to H_2O_2, and we cannot advance a hypothesis regarding whether inhibited strains are more susceptible or resistant to this stress with respect to promoted strains.

Since fumonisin production seems to be required for *F. verticillioides* virulence,[32] the investigation of fumonisin modulation by oxidative stress on the fitness and virulence may represent a future challenge. Different sensitivities to oxidative stress affecting fumonisin production open the question as to the benefit of having an adaptive system toward oxidative stress. The *F. verticillioides* population presenting different sensitivities to the oxidative stress under field conditions remains to be investigated.

Oxidative balance status during plant−fungus interactions can play a role in the establishment of plant defense responses.[33] Since virulent fungal pathogens appear able to suppress the plant oxidative response,[34] the modulation of oxidative stress, as observed for some strains in our study, could be part of the fungal capability to establish the endophytic phase, the typical habit of this species in maize.

Relation of Fumonisin Production to Fungal Biomass. Treatment with an oxidative agent at the adopted doses affected the *Fv* strains differently. The effect of lower levels of H_2O_2 on fungal growth was similar among *Fv* strains, although the capability to produce mycotoxins varied greatly; in contrast, when the concentration of H_2O_2 was increased to 2 mM, two strains (*Fv*1 and *Fv*4) showed a biomass decrease of approximately 10% (Table 3). Furthermore, when 100 U of catalase was added to the cultures, the fungal biomass of each strain was found to be comparable to that of the control culture.

No correlation between fungal biomass and fumonisin accumulation was observed: *F. verticillioides* strains with similar growth (*Fv*1 with *Fv*8; *Fv*3 with *Fv*4 and *Fv*7) accumulate very different amounts of fumonisins; however, while the strains *Fv*1 and *Fv*4 were both inhibited in biomass and fumonisin production by the higher concentration of H_2O_2, this behavior was not observed for the *Fv*7 strain. This result suggests a lack of correlation between fungal growth changes and the levels of fumonisin production under mild oxidative stress conditions. Differently, at the highest oxidative stress levels the reduced growth in two strains out of the five analyzed suggests the possibility of differences in sensitivity to H_2O_2 treatment.

During growth, the final pH values of each fungal culture did not show variation between treatments (data not shown).

Correlation of Gene Expression Analisys upon H_2O_2 with the in Vitro Fumonisin Production. The variability in fumonisin accumulation in different *Fv* strains may be due to a different epigenetic regulation of *fum* cluster[35] or to different positions and numbers of cis-acting promoter elements.[36] In our work, we provide evidence that oxidative stress induced by H_2O_2 can affect the kinetics of *fum* gene expression. Moreover, sublethal doses of azole fungicides, known to trigger oxidative stress, has been demonstrated to upregulate *fum1* gene in *F. verticillioides*.[37]

This study also indicates that changes in fumonisin accumulation in different *Fv* strains seem to be linked to an up- or downregulation of some genes involved in the fumonisin biosynthesis pathway in response to oxidative stress. In contrast to *F. graminearum*, where exogenous H_2O_2 treatment increases

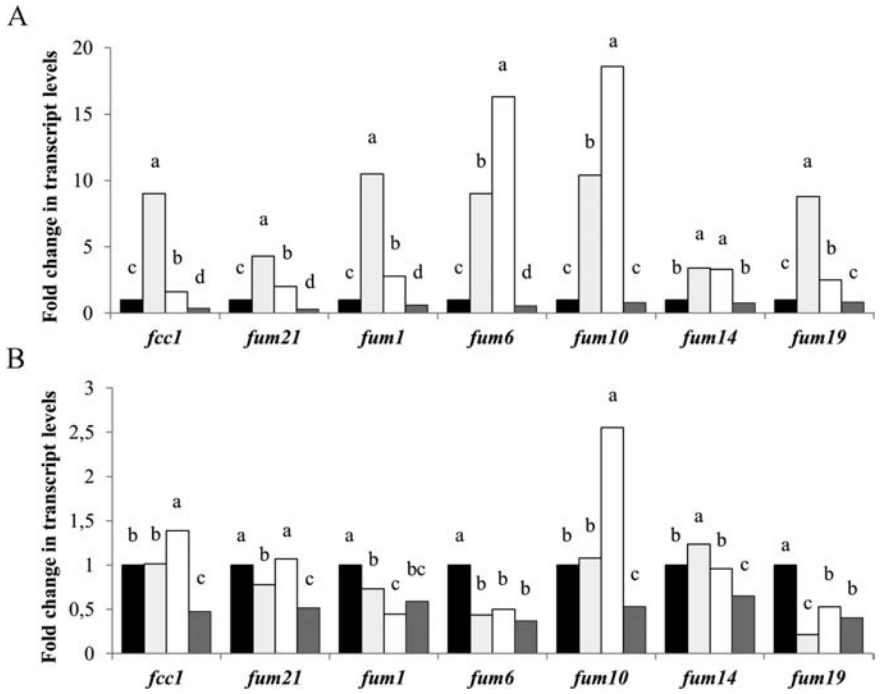

Figure 2. Fold changes in fumonisin gene levels for (A) promoted *Fv*8 and (B) inhibited *Fv*1 strains after hydrogen peroxide treatment. Treatments considered were as follows: control (black bar); 0.5 mM H_2O_2 (light gray bar); 2 mM H_2O_2 (white bar); 0.5 mM H_2O_2 plus catalase (dark gray bar). The fold change was normalized to control gene expression. Tubulin expression was used as the reference gene. Mean values for gene expression were analyzed by an ANOVA test with $\alpha = 0.05$. Bars represent the average of three independent experiments, and different letters indicate data sets significantly different according to ANOVA followed by Tukey's test ($P < 0.05$).

mycotoxin production,[30] inducing the expression of trichothecene biosynthetic genes,[12,38] in *F. verticillioides* two different responses were observed, after exogenous H_2O_2 treatment.

Two *F. verticillioides* representative strains, *Fv*8 as the promoted strain and *Fv*1 as the inhibited strain, were grown under stress conditions induced by H_2O_2 treatment. In addition, the expression levels of genes involved in the fumonisin biosynthetic pathway were analyzed in the absence or presence of catalase treatment.

In the promoted strain *Fv*8, the transcription of genes involved in fumonisin biosynthesis was generally enhanced by both H_2O_2 concentrations with some differences (Figure 2A). Supplementation with 0.5 mM H_2O_2 appeared to increase expression of all seven genes between 3.4- and 10.5-fold, relative to their expression in the control culture. In contrast, supplementation with 4-fold more H_2O_2 (2 mM) appeared to minimally increase five genes (1.6- to 3.3-fold) while significantly increasing the expression of two genes between 16.3- and 18.6-fold. The inclusion of catalase to a culture supplemented with 0.5 mM H_2O_2 led to a slight decrease or minimal change in transcript levels for all seven genes, relative to the control culture.

In contrast, under the same conditions, the inhibited *Fv*1 strain showed a generalized decrease of fumonisin-related transcripts to levels similar to or lower than those observed in the control cultures (Figure 2B). Supplementation with 0.5 mM H_2O_2 led to insignificant differences in transcription of two genes relative to the control culture; four genes were inhibited (0.2- to 0.7-fold), while a slight increase was reported for one gene (1.25-fold). In contrast, supplementation with 2 mM H_2O_2 appeared to minimally increase two genes (1.4- to 2.5-fold) while the others reported no significant changes or a slight decrease (0.5-fold) relative to the control culture. The inclusion of catalase to a culture supplemented with 0.5 mM H_2O_2 led to a general decrease (0.3- to 0.6-fold) in transcript levels for all seven genes, relative to the control culture. This result shows that this fungal species could be composed of a heterogeneous population of toxigenic fungi that differentially respond to oxidative stress for the gene expression.

The regulatory *fcc1* gene encodes a putative receptor to sense environment or extracellular stress and interacts with other regulatory genes involved in conidiation and FB biosynthesis.[39,40] Until now, *fcc1p* has been found to be activated by pH signaling or nitrogen starvation;[40,41] however, we provide evidence that this gene is also differentially affected by oxidative stress in a strain-dependent manner. Comparable behavior was also evident under oxidative stress conditions for *fum21*, which encodes a $Zn^{II}_2Cys_6$ binuclear DNA-binding transcription factor for most of the genes involved in the fumonisin biosynthetic pathway.[22] Under lower stress conditions, *fum21* and *fum1* were upregulated in the promoted strains; the same behavior but with downregulation was observed in the inhibited strain, as expected for the role of FUM21, an upstream transcription factor of the *fum* cluster. The *fum1* gene encodes a polyketide synthase (PKS) required for fumonisin production. Changes in *fum1* expression during the stress conditions correlate with other PKS proteins that, although not linked to mycotoxin biosynthesis, are involved in detoxification, pigmentation, and virulence and are found to be responsive to H_2O_2.[42,43] As *fum19*, as well as *fum1*, is considered to be a good marker for fumonisin production,[44] its expression was surveyed. Expression of *fum19*, an ABC transporter involved in extracellular export of fumonisins and responsive to stress challenges,[45] appears to be more or less sensitive at lower or higher levels of H_2O_2, respectively, in promoted or inhibited strains; however, its regulation could depend on either the

J. Agric. Food Chem. 2015, 63, 4879−4885

oxidative stress or the amount of mycotoxin produced, and our results do not permit us to clarify this model. *Fum14* encodes a nonribosomal peptide synthetase (NRPS) necessary to confer toxicity to fumonisin, and its lack leads to the accumulation of hydrolyzed forms of FB_3 and FB_4.[46] The present results suggested an enhancement of *fum14* transcription in the presence of H_2O_2 supplementation, even if it was not strong relative to the other studied genes; this behavior is in accordance with previous findings in which the synthesis of fumonisins was reduced at high expression levels of *fum14*.[17] *Fum6* encodes a bifunctional cytochrome P450 monooxygenase-NADP reductase,[47] and *fum10* encodes an acyl-CoA synthase required for tricarballylic ester formation;[48] both were overexpressed with H_2O_2 concentrations of 2 mM. *Fum10* is upregulated, in both promoted and inhibited strains, whereas *fum6* follows the same behavior as *fum10* only in the promoted strain, indicating that the regulation of *fum6* is strain dependent. Further studies will be necessary to elucidate the role of these stress conditions on enzymatic activities of the *fum* gene products.

Since catalase has been proven to drastically reduce the *tri* gene expression levels in *F. graminearum*,[30] we investigated the effect of the enzyme on fumonisin gene expression in *F. verticillioides*. Here, we report that catalase downregulates the expression of *fum* genes in both the inhibited and promoted *Fv* strains in comparison to the control cultures, and this result correlates with the low amount of fumonisins produced in all of the five isolates studied.

ABSTRACT: Bracken fern (*Pteridium aquilinum*) is a worldwide plant containing toxic substances, which represent an important chemical hazard for animals, including humans. Ptaquiloside, **1**, a norsesquiterpenoid glucoside, is the major carcinogen of bracken detected in the food chain, particularly in the milk from farm animals. To date, ptaquiloside has been shown in the milk of cows feeding on a diet containing bracken fern. This is the first study that shows the systematic detection of ptaquiloside, **1**, and reports its direct quantitation in pooled raw milk of healthy sheep and goats grazing on bracken. Ptaquiloside, **1**, was detected by a sensitive method based on the chemical conversion of ptaquiloside, **1**, into bromopterosine, **4**, following gas chromatography−mass spectrometry (GC−MS) analysis. The presence of ptaquiloside, **1**, possibly carcinogenic to humans, in the milk of healthy animals is an unknown potential health risk, thus representing a harmful and potential global concern of food safety.

KEYWORDS: *bracken fern, ptaquiloside, pterosine, milk, sheep, goats*

INTRODUCTION

Bracken fern (*Pteridium aquilinum*) is a ubiquitous fern, one of the five most common plants on the planet.[1] This plant contains a number of toxic components, the consumption of which produces acute and chronic toxic syndromes in different animal species. Acute bracken poisoning is characterized by a thiamine deficiency in horses and pigs and a depression of bone marrow activity leading to severe leucopenia, thrombocytopenia, and acute hemorrhagic crisis in cattle. Chronic bracken poisoning is responsible for a progressive retinal degeneration, resulting in blindness in sheep, and is associated with tumors of the upper alimentary tract in cattle;[2] furthermore, it causes a syndrome known as chronic enzootic hematuria in cattle and in water buffaloes characterized morphologically by urothelial tumors of the urinary bladder and clinically by the presence of blood in the urine.[3,4]

Ptaquiloside, **1**, a norsesquiterpene glucoside of the illudane type, is known to be the major carcinogen of bracken, readily undergoing glucose elimination to form an unstable conjugated dieneone intermediate, named ptaquilodienone, **2**, and pterosine B, **3** (Figure 1).[5] The reactive cyclopropane moiety of ptaquilodienone, **2**, is capable of breaking DNA strands and/or alkylating selected DNA bases. Thus, the biological properties of ptaquiloside, **1**, are characterized by mutagenic, clastogenic, and carcinogenic effects.[6,7]

It has been suggested that bracken fern increases the oncogenic risk also in humans.[8,9] Indeed, ptaquiloside, **1**, is responsible for severe human chromosomal abnormalities[10,11] and is suspected of causing cancer in humans.[7,12−16]

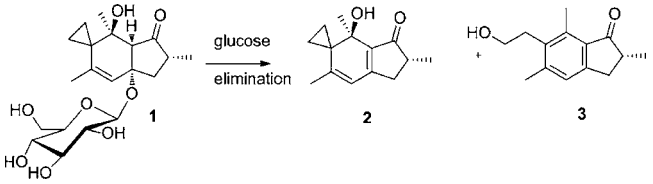

Figure 1. Structure of ptaquiloside, **1**, and of its degradation products ptaquilodienone, **2**, and pterosine B, **3**.

Epidemiological surveys revealed that bracken consumption is positively correlated with esophageal cancer in many geographical areas of the world[17] and with stomach cancer in population of farmers living in some rural regions of Wales and Costa Rica.[17−21]

Several routes may led to human exposure to ptaquiloside, **1**, namely, eating the plant,[22] breathing air containing bracken spores,[23] and consumption of milk and meat of affected animals.[24−26] Drinking water appears to be an additional important route of transmission.[27] Indeed, ptaquiloside, **1**, has been detected in both groundwater below bracken vegetation and surface water.[28]

Ptaquiloside, **1**, is responsible for H-Ras activation via an initial alkylation of adenine of the codon 61, resulting in a

transition (A to G) or transversion (A to T/C).[6] Any amino acid substitution at this position, except glutamic acid, blocks the guanosine triphosphate (GTP) hydrolysis of the Ras−GTP complex. The deregulation of hydrolysis is believed to result in the aberrant Ras signaling pathway, which causes an abnormal cell growth, proliferation, and survival.[29] Although oncogenic pathways remain to be elucidated, recent molecular studies provided new insights. Indeed, ptaquiloside, **1**, has been shown to induce a deregulation of the expression of a panel of genes related to cell cycle arrest in gastric epithelial cells. Furthermore, ptaquiloside, **1**, has been found to be responsible for glycophenotypic alterations of gastric mucosa and play a synergistic effect with *Helycobacter pylori* infection, leading to the gastric carcinogenesis process.[30,31]

Thus far, ptaquiloside, **1**, has been detected in milk of cows experimentally fed on a diet containing bracken fern.[32−34] It has been shown that the administration of milk from bracken-fed cows to mice was responsible for a high incidence of pulmonary and mammary tumors.[33] No systematic data are available about the naturally occurring presence of ptaquiloside, **1**, in milk of farm animals other than cows. The aim of the present paper is to report the detection and direct quantitation of ptaquiloside, **1**, in the pooled raw milk of healthy sheep and goats grazing on bracken fern-infested pastures, using a gas chromatography−mass spectrometry (GC−MS)-based method.

MATERIALS AND METHODS

Materials, Chemicals, and Reagents. Acetonitrile, ethyl ether, and ethyl acetate were purchased from Sigma-Aldrich (Milan, Italy). All solvents were of analytical grade and used as supplied. Ultrapure water was obtained from a Milli-Q plus system (Millipore, Bedford, MA). Sulfuric acid (Suprapur grade) was purchased from Merck (Darmstadt, Germany). Cartridges (1.2 cm inner diameter) filled with graphitized carbon black (500 mg of Carbograph 4) were prepared and provided by LARA (Rome, Italy). Carbograph 4 has a surface area of 200 m^2/g, and it is commercially also referred to as Carboprep (Resteck, Bellefonte, PA). Polyethylene frits (20 μm) were included. d_4-Bromopterosine, used as an internal standard in the calibration procedure, was synthesized according to a recent protocol.[35] Solutions of deuterated standard were prepared in methanol or ethyl acetate and stored at −20 °C.

Instrumentation. An Agilent Technologies 6850 Series II gas chromatograph, coupled with a 5973 mass selective detector (MSD) (Agilent Technologies, Santa Clara, CA), was used. The carrier gas was helium at 1.7 mL/min of 99.999% purity. The HP-5MS capillary column used was a 30 m × 0.25 mm inner diameter, 0.25 μm film thickness (Agilent, 5% phenyl methyl siloxane). The GC oven temperature was initially held at 100 °C for 1 min, then ramped at 20 °C/min to 280 °C, and held at this temperature for 2 min. Temperatures of injector and transfer line were 280 °C. Analyses were performed in splitless mode, and 0.5 μL was injected. The software MSDchem (Agilent Technologies) has been used to obtain graphics and quantitative data.

Calibration Procedure for Milk Samples. For the quantitative analysis of milk, a five-point calibration curve was obtained by spiking milk, free from ptaquiloside, **1**, with known amounts of internal standard to cover a concentration range of 3−20 ng/mL ptaquiloside, **1**. The amount of ptaquiloside, **1**, was determined in each experiment as previously described,[36] namely, by comparing the sum of the areas of three ions monitored m/z 187, 201, and 280 for the bromopterosine and m/z 189, 205, and 284 for the deuterated reference (d_4-bromopterosine). Each experimental value corresponds to the average of three independent measurements.

The limit of detection (LOD) and limit of quantitation (LOQ), calculated following the directives of the International Union of Pure and Applied Chemistry (IUPAC) and American Chemical Society's Committee on Environmental Analytical Chemistry, were 0.3 and 0.4 ng/mL, respectively. For comparison, the method recently published by Aranha and co-workers[34] declared a LOQ of 5.8 ng/mL.

Sample Preparation. Sample preparation was carried out following a protocol reported elsewhere.[37] The carbograph cartridge was washed with 6 mL of a mixture of acetonitrile/water (7:3, v/v); it was subsequently activated with diluted HCl (pH 2, 20 mL) and, finally, washed with 6 mL of water. A total of 10 mL of milk was passed through the cartridge; the eluate was discarded; and the cartridge was washed with 6 mL of water. The cartridge was then eluted with 7 mL of a mixture of acetonitrile/water (7:3, v/v), and 20 ng of d_4-bromopterosine and 2 g of NaBr were added to this eluate. After evaporation of the upper phase (acetonitrile) in nitrogen stream, the solution was made alkaline (pH 12) and heated at 45 °C for 1 h. The solution was cooled, acidified at pH 2, and extracted 3 times with ethyl ether. The resulting ether solution was evaporated to dryness, and finally, the extract was diluted to 20 μL in a micro (conical) test tube with ethyl acetate.

Collection of Milk Samples. For this study, flocks composed of both goats and sheep that had grazed on pasturelands covered by an abundance of bracken fern in several topographically distinct territories in southern Italy were selected. Milk samples were collected in different periods of the year from healthy sheep and goats sharing the same pastures located within 300−500 m above sea level (asl) (Martirano), within 500−800 m asl (Decollatura), and within 800−1000 m asl (Serrastretta and Carlopoli) altitudinal ranges. In Martirano, the flocks were composed of 117 crossbred sheep and 115 goats that have grazed on lands where bracken fern germinates in March−mid-April. Furthermore, in these lands, borage (*Borago officinalis* L.), Rowan tree (*Sorbus domestica* L.), myrtle (*Myrtus communis* L.), Scotch broom (*Spartium junceum* L.), poppy (*Papaver rhoeas* L.), chicory (*Cichorium intybus* L.), fennel (*Foeniculum vulgare* Mill.), blackberry bush (*Rubus ulmifolius* Schott), clover (*Trifolium pratense* L.), white clover (*Trifolium repens* L.), and sulla clover (*Hedysarum coronarium* L.) were also present. Flocks from Decollatura were composed of 124 Sarda sheep and 46 Maltese and Syria-derived goats that have grazed of lands covered with bracken fern, the fronds of which start to emerge from underground rhizomes in May. Amaranth (*Amaranthus retroflexus* L.), heather (*Erica arborea* L.), clematis (*Clematis vitalba* L.), butcher's broom (*Ruscus aculeatus* L.), ivy (*Hedera helix* L.), and hawthorn (*Crataegus monogyna* Jacq.) are the prevailing herbaceous plants of those lands. Flocks from Serrastretta were composed of 60 crossbred sheep and 67 Nicastrese goats; Carlopoli flocks were composed of 109 Sarda sheep and 100 crossbred, Saanen and Alpine, goats. Pigweed (*Portulaca oleracea* L.), asparagus (*Asparagus acutifolius* L.), aniseed (*Pimpinella anisum* L.), watercress (*Nasturtium officinale* R.), Italian ryegrass (*Lolium multiflorum* L.), tall fescue (*Festuca pratensis* Huds.), oregano (*Origanum heracleoticum* L.), bush (*Rubus canescens* DC.), strawberry (*Fragaria vesca* L.), wild rose (*Rosa canina* L.), horsetail (*Equisetum telmateia* Ehrh.), milk thistle [*Silybum marianum* (L.) Gaertn.], nettle (*Urtica dioica* L.), and wild lettuce [*Reichardia picroides* (L.) Roth.] were herbs prevalently found in the lands of Serrastretta and Carlopoli.

Furthermore, we collected pooled raw ovine and caprine milk samples from flocks composed of 90 crossbred sheep and 86 Nicastrese goats grazing on bracken fern-free lands located near the sea (Sant'Eufemia Gulf of Calabria, southern Italy). In these samples, no ptaquiloside, **1**, has been detected in either ovine or caprine milk.

In each flock, bulk ovine milk was harvested and separately kept from pooled caprine milk. The daily average of milk production for each flock was 60−80 L for ovine milk and 80−100 L for caprine milk. Following milking of all animals, the samples were obtained from tanks containing the pooled raw milk before undergoing any physical and/or other treatments. According to European Union (EU) legislation, "raw milk" is defined as milk produced by the secretion of the mammary gland of farmed animals that has not been heated to more than 40 °C or undergone any treatment that has an equivalent effect [Regulation (EC) No. 853/2004]. All milk samples were investigated within 1 week since harvesting.

Determination of Ptaquiloside, 1, Content. Determination of ptaquiloside, **1**, content in milk samples was obtained with the

DOI: 10.1021/acs.jafc.5b01937
J. Agric. Food Chem. 2015, 63, 4886−4892

previous method,[37] with small modifications. All of the analyses were made as triplicates. This method takes advantage of the click conversion of ptaquiloside, **1**, into bromopterosine, **4**, in the presence of bromide ions (Figure 2) and the stability and easy detectability of bromopterosine, **4**, by conventional GC−MS techniques.

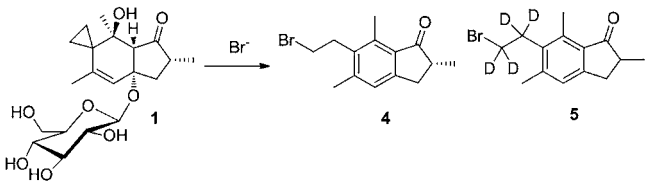

Figure 2. Structure of bromopterosine, **4**, obtained upon treatment of ptaquiloside, **1**, with bromide ions. On the right, the structure (**5**) represents the tetradeuterated standard obtained by total synthesis.

Fresh milk has been filtered over cartridges filled with graphitized carbon black, a matrix with high affinity toward free sugars and glycosylated compounds (such as ptaquiloside, **1**). Freezing and subsequent unfreezing of the milk resulted in a dense sample, likely because of protein precipitation, whose filtration over cartridges gave nonreproducible results, and therefore, this procedure was avoided.

Cartridges were then eluted with a mixture of acetonitrile/water (7:3, v/v), and the reference compound d_4-bromopterosine (**4**) (in place of d_2-bromopterosine used in the previous method) and NaBr were added to the eluate. After evaporation of the acetonitrile phase and workup, the resulting ethyl acetate solution was injected in the GC−MS instrument, using helium as the carrier gas and a HP-5MS capillary column.

RESULTS AND DISCUSSION

The amount of ptaquiloside, **1**, present was determined as a result of the comparison of the sum of the areas of three ions for bromopterosine (m/z 187, 201, and 280) and the corresponding ions of the deuterated reference compound (m/z 189, 205, and 284) (Figure 3). The obtained data, reported in Table 1, show a significant presence of ptaquiloside, **1**, in the milk of both goats and sheep and an absence in the milk from animals as controls. Ptaquiloside, **1**, was detected earlier in milk of goats that have grazed on lowlands (Martirano), which may suggest that the higher the altitude of land where the animals are at pasture, the later bracken fern toxin in the milk can be detected. Furthermore, higher doses have been detected in goat's milk rather than sheep's milk from the same mixed flocks and in the same seasonal period. Very likely, this is because goats more than sheep tend to browse young leaves and nibble the palatable shoots, such as bracken crosiers. It has been shown that ptaquiloside, **1**, occurs in the highest concentrations in the young developing part parts of bracken, such as the crosiers, and the unfolding parts during the spring and early summer.[7] Furthermore, it has been suggested that a few herbaceous plants other than bracken fern contain high levels of ptaquiloside, **1**.[38,39] The variety of herbs of all lands that we examined allowed us to suggest that ptaquiloside, **1**, came from bracken fern only. *Pteridium aquilinum* ssp. *aquilinum* (L.) Kuhn is the only species of bracken fern contaminating all of the lands where the animals, the milk of which we examined, have grazed. Therefore, also edaphic and/or environmental causes might influence the ptaquiloside, **1**, content detected in milk in different seasonal periods.

This is the first study that shows the systematic detection and reports the direct quantitation of ptaquiloside, **1**, in the pooled raw milk of healthy sheep and goats sharing pasturelands covered by bracken fern. The ptaquiloside, **1**, amount was detected by a sensitive method based on the chemical conversion of ptaquiloside, **1**, into bromopterosine, **4**, and following GC−MS analysis,[36,37] easily reproducible in non-specialized laboratories. Because this method has been reported to be able to quantitate up to 80% of ptaquiloside, **1**, present in the sample,[37] it is reasonable to presume that the real ptaquiloside, **1**, values in the pooled raw milk are even higher than we found. We have no data about the amount of bracken fern ingested daily; therefore, experimental procedures are needed to know ptaquiloside, **1**, metabolism in small animals too. It has been experimentally shown that the average value of total ptaquiloside, **1**, excreted in milk of cows is 8.6 ± 1.2% of the amount ingested; furthermore, ptaquiloside, **1**, was detected in milk, for the first time, 38 h after feeding cows with bracken fronds.[33] Direct quantitation of ptaquiloside, **1**, was evaluated in plasma and several tissues (liver, kidney, and skeletal muscle) after feeding two daily cows with a diet containing about 19% of *P. esculentum* for 25 days.[26] New sensitive methods allowing ptaquiloside, **1**, and its decay product, pterosine B, **3**, to be quantified directly and simultaneously in both soil, groundwater, and surface water[27,28] and biological fluids, such as plasma, urine, and milk, have been proposed.[34] All of these methods, including ours, showing low detection limits, have important implications for studies of ptaquiloside, **1**, toxicokinetics in animals and for screening animal tissues suitable for human consumption.

It has been recommended that the priority to reduce the risk to consumers from bracken should be the identification of the amount of ptaquiloside, **1**, that occurs in meat, offal, milk, and dairy products from animals naturally exposed to bracken without any signs of toxicity.[40] Thus far, reports about the presence of ptaquiloside, **1**, in milk and tissues have been from cows in experimental procedures.[26,32,33] No information was available on the amount of ptaquiloside, **1**, or other components of bracken that can occur in milk from animals naturally grazing on bracken fern-infested lands.[40] It is believed that the toxicity of bracken toward domestic animals may affect people too, particularly in the case of ptaquiloside-induced carcinogenesis.[12] Indeed, it has been suggested that ptaquiloside, **1**, can be potentially carcinogenic to humans at all levels of ingestion.[40]

Currently, the International Agency for Research on Cancer (IARC) assigned ptaquiloside, **1**, to Group 2B (possibly carcinogenic to humans) on the basis of epidemiological and experimental evidence. However, the sixth IARC Monographs Advisory Group on priorities for future evaluations made a urgency list of agents and exposures to be considered in the future IARC Monographs Programme. The IARC Group considers ptaquiloside, **1**, and bracken fern high priorities among "naturally occurring substances". Furthermore, the IARC Group recommends that new animal carcinogenicity data should be collected soon and encourages the need to have more defined molecular, epidemiological, and ecological aspects of the impact of bracken fern.[41] In this context, it is worthwhile remembering that urinary bladder tumors caused by ptaquiloside, **1**, intoxication have recently been described, for the first time, in captive fallow deer.[42] Furthermore, a novel syndrome characterized by intestinal adenocarcinomas in adult farmed Sika deer that have grazed on bracken-infested pastures has just been described. Therefore, it has been suggested that ptaquiloside, **1**, plays a crucial role in deer intestinal tumorigenesis too.[43]

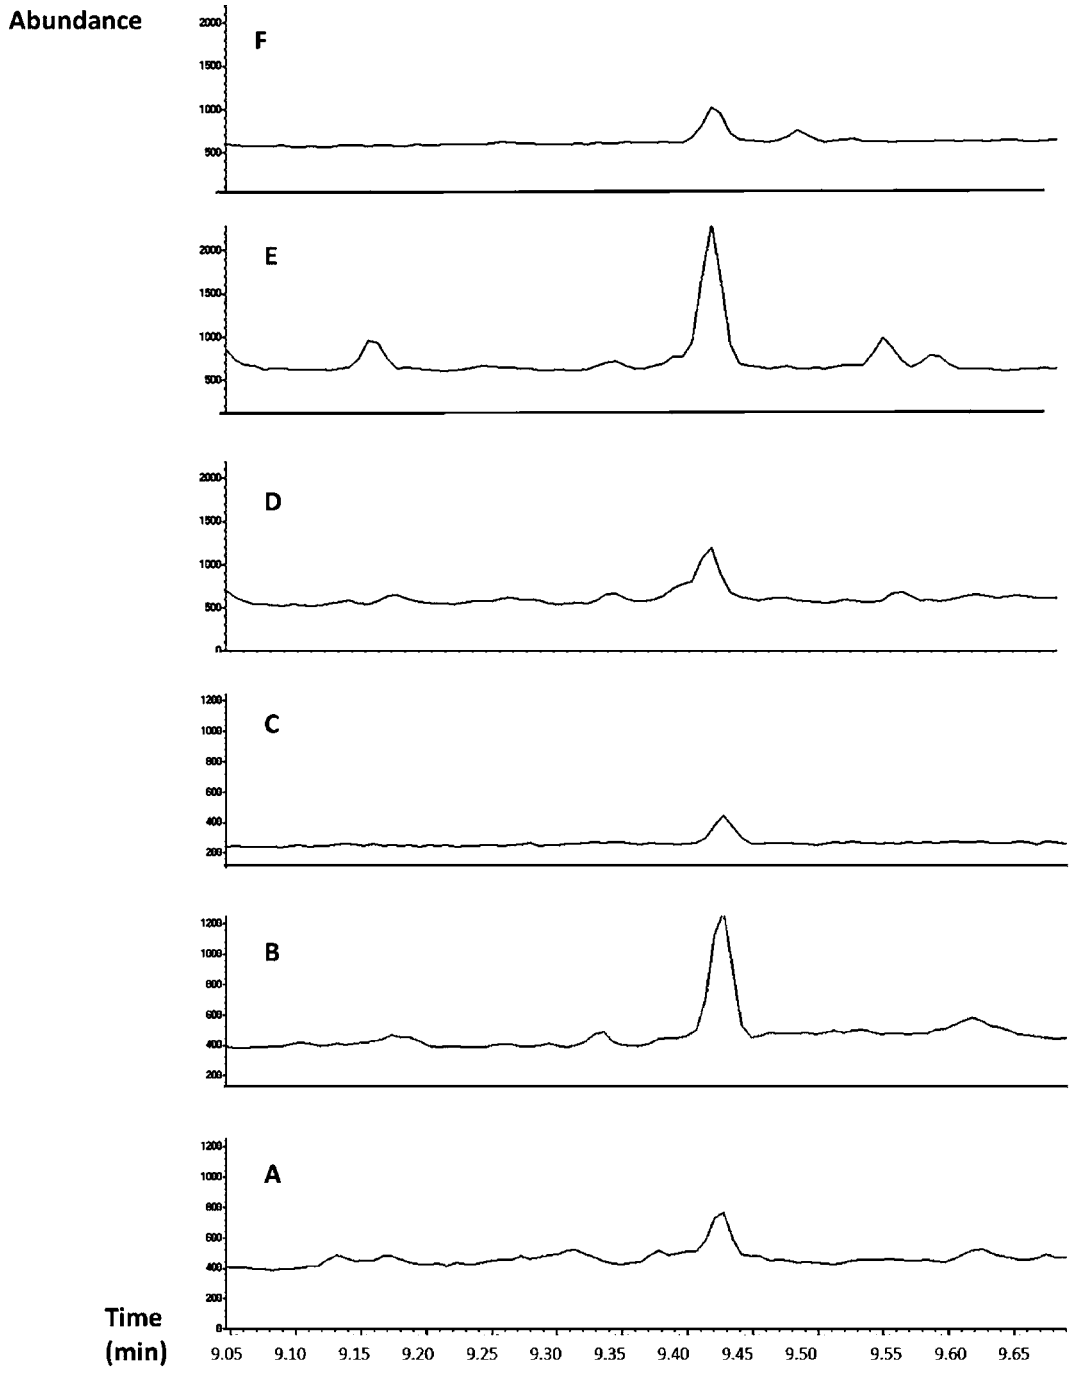

Figure 3. Representative GC traces of the monitored ions. The graphic corresponds to the sample goat/Decollatura/June 2014 in Table 1. Panels A, B, and C refer to the monitoring of ions at m/z 187, 201, and 280. Panels D, E, and F refer to the corresponding deuterated ions at m/z 189, 205, and 284. The retention time of the analyte is 9.42 min.

Finally, it is well-known that thousands of chemicals to which humans are exposed have inadequate data useful to predict their potential for toxicological effects.[44] Risk assessment of ptaquiloside, **1**, presents particular difficulties because the effects of some substances are normally regarded as being without a threshold.[45] Therefore, how long ptaquiloside, **1**, takes to reach toxicological thresholds necessary for its identification and characterization as hazardous, two important steps in the concept of "safe levels of exposure", remains to be elucidated.[46]

Recent epidemiological studies emphasize the potential role of sheep's milk and goats' milk as a risk factor for esophageal squamous cell carcinoma in the high risk area of northern Iran.[47,48] It has been shown that low doses of diterpene ester toxins can be detected in the milk of small ruminants fed by a family of Euphorbiaceae flower plants; therefore, it has been suggested that the high incidence of esophageal cancer observed in certain areas in the Caspian littoral of Iran may be associated with a greater consumption of sheep's milk and goats' milk contaminated by these toxins.[49]

The stability of ptaquiloside, **1**, and its hydrolysis have already been carefully analyzed according to different pH conditions in aqueous solutions.[5] Further interesting aspects to be investigated in the near future are (i) the effect of thermal

Supporting Information

ABSTRACT: Twenty lactating dairy cattle were intravenously infused with either lipopolysaccharide (LPS) (n = 10) or sterile saline (n = 10). Five cattle in each group received three doses of flunixin meglumine administered by either intravenous infusion or intramuscular injection at 24 h intervals. Milk, urine, and tissues were collected. Thirty-six hours after the last flunixin administration, milk from six cows contained 5-hydroxyflunixin (5OHF) levels greater than the milk tolerance of 2 ng/mL; by 48 h, milk from two cows, a saline and a LPS-treated animal, had violative milk concentrations of 5OHF. A single animal treated with LPS and intramuscular flunixin contained violative flunixin residues in liver. The ratio of urinary flunixin/5OHF was correlated (P < 0.01; R^2 = 0.946) with liver flunixin residues in LPS-treated animals, but not (P = 0.96; R^2 = 0.003) in cows treated with saline in lieu of LPS. Violative residues of flunixin in dairy cattle may be related to LPS inhibition of flunixin metabolism.

INTRODUCTION

Flunixin meglumine is a nonsteroidal anti-inflammatory analgesic with antipyretic activities. Approval for flunixin use in cattle to treat pyrexia associated with bovine respiratory disease and to treat pyrexia and inflammation in endotoxemia has been granted[1] by the U.S. Food and Drug Administration (FDA) Center for Veterinary Medicine (CVM). The label was extended in 2004[2] to include lactating dairy cattle for the control of pyrexia associated with mastitis. Under label specifications, flunixin meglumine may be administered to cattle as an intravenous infusion (iv) of 1.1−2.2 mg/kg body weight. Infusion should occur either once per day as a single dose or twice per day as two doses separated by approximately 12 h for a maximum of three consecutive days. In practice it is often difficult to administer flunixin meglumine or other drugs by iv infusion to cattle, especially on a repeated basis. As a consequence, flunixin meglumine is commonly administered via intramuscular (im) or subcutaneous (sc) injection. In 2007, the CVM reminded veterinarians that im flunixin meglumine has the potential to cause violative residues in meat or milk products of cattle and that convenience is not an acceptable basis for extra-label flunixin use.[3] Due to the persistent problem of violative flunixin residues, especially in dairy cattle,[4,5] the bases for these violations remains to be of interest to producers, regulatory agencies, and consumers.

Although the United States has an excellent regulatory system for minimizing drug residues in meat and milk products, instances of violative residues do occur. For example, in 2011 the USDA FSIS confirmed 974 instances of violative chemical residues in inspector-generated samples screened using the kidney inhibition swab (KIS).[4] Of these violations, 15% (142) were violations with flunixin. All of the flunixin violations were in cattle, with no violations in hogs. The major contributor to total flunixin violations was in dairy cows, comprising 63% of the total violations, with veal calves (23%) and beef cows and steers (14%) accounting for the remaining violations.[4] Data from 2012[5] indicated a similar trend with 928 instances of violative chemical residues in inspector-generated samples screened using the KIS assay and confirmed with selective assays. Of these violations, 11% (101) were due to excessive flunixin residue. Similar to 2011, all of the flunixin residue violations occurred in cattle. Dairy cows comprised 58% of the

2011 flunixin violations; veal calves (19%) and beef cows and steers (14%) were the bulk of the remaining violations. The magnitude of flunixin residues has been reported sufficient to cause the contamination of bulk milk. For example, Kissell et al.[6] measured a violation rate of 0.2% for residues of 5-hydroxyflunixin (5OHF, the marker residue for flunixin in milk) in bulk milk from tanker trucks. Deyrup et al.[7] have suggested that the probability of a violative flunixin residue increases in cull dairy cows that appear as "suspect", with suspect including animals that appear to be lame, that appear to have mastitis, metritis, or that have lesions associated with injection. Kinetic studies in beef cattle[8] have shown that rates of plasma flunixin depletion did not differ ($P > 0.05$) after subcutaneous or intravenous administration, but a study with larger numbers of dairy cattle indicated that the dosing route did influence terminal half-lives of flunixin.[9]

Another contributing factor to flunixin violations could be drug use with an insufficient preslaughter withdrawal period. Alternatively, violations could occur after flunixin is dosed to sick animals even after observation of the required 4 day withdrawal period. The latter instance could occur if illness affects the kinetics of flunixin elimination, as suggested by the data of Kissell et al.[10] in mastitic cows treated with flunixin. For example, because flunixin tends to accumulate in inflamed tissues,[11,12] its release from those tissues in animals with systemic infection could be altered significantly. In addition, flunixin efficacy is maintained even when plasma or serum concentrations are very low.[13] Collectively, such observations suggest that nonplasma tissue pools of flunixin exist, but the locations of these "deep compartments" are unknown. Pharmacokinetic parameters of serum flunixin, however, did not differ after experimental induction of mastitis by mammary inoculation with *Escherichia coli*.[14] In cows having naturally occurring mastitis, however, flunixin clearance (mL/h/kg) decreased and area under the curve (μg·h/mL) increased, relative to healthy cows.[10]

We hypothesized that route of administration or systemic inflammation could significantly alter flunixin kinetics and tissue residues in lactating dairy cows. If true, flunixin violations could occur in healthy or sick animals dosed intramuscularly with the maximum label dose (2.2 mg/kg bw) for the maximum dosing period of three consecutive days, but slaughtered with the label withdrawal period of 4 days. The systemic inflammatory responses observed during mastitis in cows can be mimicked by systemic lipopolysaccharide (LPS) administration.[15] Therefore, the objective of this study was to determine the tissue residues of flunixin after intravenous (label) and intramuscular (off-label) administration of flunixin meglumine to healthy and LPS-challenged dairy cows in regulated (milk, muscle, liver, kidney, adipose) and nonregulated (offal) tissues and urine.

MATERIALS AND METHODS

Study Overview. The study was designed and conducted as a 2 × 2 factorial experiment (Table 1) with main factors being route of drug administration (iv or im) and lipopolysaccharide challenge (LPS or saline). The study was conducted as five replicate trials for a total "*n*" of five cows per treatment, with each treatment being replicated once in each trial. Lactating Holstein cows were randomly assigned to receive either an iv infusion of 0.2 μg/kg BW of LPS (endotoxin) or saline. Two hours after LPS or saline infusion, each cow received 2.2 mg/kg BW of flunixin meglumine either by iv infusion or by im injection. Flunixin administration was repeated 24 and 48 h after the first flunixin dose; cows were slaughtered 96 h after the final flunixin administration. During the dosing and withdrawal periods, blood, milk, urine, and saliva were serially collected at predetermined intervals. Saliva data, however, are not reported in this treatise. A detailed animal use protocol was reviewed and approved by the North Dakota State University Institutional Animal Care and Use Committee (IACUC) prior to the initiation of the live phase of the study.

[a]Each treatment was replicated five times using a single cow per treatment per trial. [b]Lipopolysaccharide (0.2 μg/kg BW).

Animals and Animal Husbandry. Lactating dairy cattle were purchased from either the North Dakota State University dairy herd (8 animals) or from a commercial dairy (12 animals) located in Jamestown, ND, USA. Upon delivery to the NDSU Animal Nutrition and Physiology Center (ANPC), each cow was weighed and placed in a tie stall with full access to water and a corn silage-based ration. Cows were milked twice daily at approximate 12 h intervals using a single-cow portable milking machine (InterPuls, Albinea, Italy). Animals were adapted to the ANPC barn facility for a minimum of 7 days prior to the start of the study. Animal weights, used as the basis for dosing LPS and flunixin, were collected 2−3 days prior to the actual dose date. Cow weights did not differ ($P = 0.83$) between the iv-saline, iv-LPS, im-saline, and im-LPS treatment groups (645 ± 75, 607 ± 92, 606 ± 62, and 636 ± 93 kg, respectively; mean ± SD).

LPS or Saline Administration. LPS purified from *E. coli* 0111:B4 (Sigma Chemical Co., St. Louis, MO, USA) was dissolved (10 μg/mL) in sterile saline. Immediately prior to administration of LPS or saline, cows were placed into a squeeze chute, and an 18 gauge, 6.25 cm, catheter (Milcath, Elanger, KY, USA) was placed into the jugular vein. Animals selected for LPS treatment were administered 0.2 μg/kg BW LPS (0.02 mL/kg BW) via iv infusion over a 1−2 min period; cows randomly selected for saline treatment were infused with 0.02 mL/kg saline in the same manner as LPS-dosed cows. Catheters were removed immediately after LPS or saline infusion.

Flunixin Administration. Intramuscular flunixin meglumine (Banamine; Merck Animal Health; Millsboro, DE, USA) was delivered via 3.8 cm, 18 gauge, needles into neck muscles in locations caudal to the head and 7.6−10.2 cm abaxial to the spine (Supporting Information Figure S1). Sites for flunixin administration, and subsequent "injection site" recovery at slaughter, were marked by shaving a series of three sequential, vertically oriented patches (~16 cm^2 for each patch) for each injection day. Patches were also shaved on the necks of iv-treated animals to facilitate collection of equivalent muscles at slaughter. Between-day injections alternated between right and left aspects with separation between day 1 and 3 injections of approximately 10 cm (Figure S1). The maximum volume for a single injection site was 10 mL; because all animals required total daily doses of >10 mL, separate injections were delivered to the required volume in a vertical alignment with respect to the initial, within-day injection. The time of each flunixin treatment was recorded.

Milk Collection. Cows were milked twice daily before and after the initiation of the study protocol with milk yield being measured gravimetrically. Milk was thoroughly mixed, and multiple aliquots (~10 mL) of milk from each time point were frozen (≤ −20 °C) until analysis.

Urine Collection. Urine samples were collected prior to dosing and at 2, 4, 8, 12, and 24 h on the initial dosing day and on dosing day 2; subsequent to dosing on day 3, urine was collected at 2, 4, 8, 12, 24,

DOI: 10.1021/acs.jafc.5b01509
J. Agric. Food Chem. 2015, 63, 4893−4901

36, 48, 60, 72, and 96 h. Urine was collected by inducing micturition or during nonstimulated urination; samples were frozen (≤ −20 °C) until analysis.

Blood Collection. Blood samples were collected by jugular venipuncture (21 ga needles) on treatment day 1 at 0, 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, 8, 12, 18, and 24 h. Subsequent to dosing on day 2, blood was drawn at 0.5, 1, 2, 4, 8, 12, and 24 h. After dosing on treatment day 3, blood was drawn at 0.5, 1, 2, 4, 8, 12, 24, 36, 48, 60, 72, 84, and 96 h. Blood samples were collected into BD Vacutainer tubes containing 158 units of sodium heparin, gently inverted eight times, and centrifuged at 1160*g* for 10 min. Plasma aliquots were distributed into replicate, labeled, 2 mL polypropylene vials and were placed in a freezer (≤ −20 °C) until analysis.

Tissue Collection. Cows were slaughtered by captive bolt stunning followed by rapid exsanguination[16] 96 h after the last flunixin administration. Cattle were exsanguinated and eviscerated using standard industry practices. Day 1, 2, and 3 injection sites were removed so that approximately 500 g of tissue was gathered per site. Liver, kidney, skeletal muscle (longissimus dorsi), and adipose tissue were collected, diced, and placed into labeled containers. Livers were sampled, after removal of the gall bladder, by removing a cross section of 6 ± 2 cm width across all lobes. Kidneys were collected in their entirety, and the fibrous capsule was removed, diced, pooled, and frozen. All tissue samples were frozen at ≤ −20 °C until analysis.

Specialty tissues including lung, tongue, heart, brain, tail base (oxtail), reticulum, abomasum, ileum, and mammary tissue were collected. Aliquots of the gastrointestinal tissues were removed, and contents were removed by rinsing with water, placed in labeled containers, and frozen until analyses.

Sample Stability. On the basis of stability data published by Boner et al.[17] flunixin in nonhepatic tissues is stable for a minimum of 2 months and in hepatic tissues is stable for a minimum of 1 year when stored at ≤ −20 °C. In addition, flunixin residues have been demonstrated to be stable after three freeze−thaw cycles.[17] Jedziniak et al.[18] established that 5OHF is stable when stored at −20 ± 2 °C for 9 months. Thus, additional stability studies were not conducted. Nevertheless, all tissue analyses were conducted within 1 year of tissue collection.

Analyses. Milk flunixin and 5OHF concentrations were determined at the North Carolina State University Center for Chemical Toxicology Research and Pharmacokinetics as described by Kissell et al.[10] The milk assay limit of quantitation was 0.1 ng/mL for each analyte.

Plasma flunixin and 5OHF concentrations were quantified at the University of California Davis School of Veterinary Medicine, Veterinary Drug Residue Laboratory, as described by Buur et al.[19] and modified with respect to the UPLC system by Shelver et al.[8] In addition, the flunixin standard curve was expanded to include points at 0.5, 1, 2, 20, 200, 500, 1000, and 2000 ng/mL in the current study. Limits of detection and quantification were 0.1 and 0.5 ng/mL for flunixin and 0.3 and 0.9 ng/mL for 5OHF, respectively.

Flunixin residues in liver and skeletal muscle were determined at both the USDA FSIS Midwestern Laboratory in St. Louis, MO, USA, and at the Biosciences Research Laboratory in Fargo, ND, USA. The FSIS Midwestern Laboratory used slight modifications of method CLG-FLX4.03.[20] Briefly, the method employed a Waters Acquity UPLC triple-quadrupole instrument with a 1.7 μm, BEH C18, 2.1 × 50 mm column and gradient mobile phase consisting of 0.4% formic acid (solvent A) and 4 parts of CH_3CN in 5 parts of MeOH with 0.18% formic acid (solvent B) at a flow rate of 0.650 mL/min. The solvent gradient (8 min total) was as follows: 0 min, 55:45 A/B; 0.42 min, 65:35 A/B; 5.53 min, 65:35 A/B; 5.64 min, 5:95 A/B; 6.36 min, 5:95 A/B; 6.42 min, 55:45 A/B; 8.00 min, 55:45 A/B. The FSIS method quantifies tissue residues to only half of the tolerance of 125 ng/g in liver and 25 ng/g in skeletal muscle.

Flunixin free acid in edible tissues, injection sites, and specialty tissues was determined at the USDA ARS Fargo laboratory using the method of Boner et al.[17] on which method CLG-FLX4[20] is based. However, matrix-matched standard curves were prepared at 0.25, 1.25, 6.25, 12.5, and 18.75 ng flunixin free acid/mL of extract corresponding to tissue concentrations of 1, 5, 25, 50, and 75 ng/g, which allows quantitative analyses well below half the tolerance of skeletal muscle. With each sample set, blank tissues were fortified at 5 and 50 ng/g and extracted contemporaneously with incurred samples. Flunixin was measured using ultrahigh-performance liquid chromatography (Acquity, Waters, Milford, MA, USA) coupled to a tandem quadrupole mass spectrometer (Acquity; Waters) using the conditions described in FSIS method CLG-FLX4.03.[20] Liver 5OHF concentrations were measured exactly as described for flunixin except that a water-based external standard curve equivalent to 1, 5, 25, 50, and 75 ng/g of tissue was used for quantitation based on the m/z 313 → 295 ion transition with qualifier m/z transitions of 313 → 280 and 313 → 109.

Details of urinary flunixin and 5OHF analyses will be described elsewhere (Shelver et al., in preparation). Briefly, 1 part of urine and 4 parts of 6 N formic acid were mixed and heated at 120 °C for 2 h. Urine samples were then diluted to 1:100 in 50% acetonitrile in water containing 250 ng/mL of flunixin-d_3 and 5-hydroxyflunixin-d_3 as internal standards. If analyte concentration for a given urine sample was outside the range of the calibration curve, fresh urine aliquots were rediluted at either 1:10 in 50% aqueous acetonitrile or 1:250 using 1:100 control urine as diluent, depending on approximations from the original analysis, and reanalyzed. A matrix-matched calibration curve with appropriate dilution strength was run concurrently with all incurred samples. Within each set, blank urine was fortified at 1, 20, and 500 ng/mL each of flunixin and 5OHF and analyzed concurrently with unknowns. Quantitative analyses were performed on an Acquity UPLC (Waters Corp., Milford, MA, USA) coupled to a tandem quadrupole mass spectrometer with a heated electrospray ionization source operated in the positive ion mode (Acquity; Waters). The column was an Acquity UPLC HSS T3 (1.8 μm, 2.1 × 100 mm) maintained at 35 °C. The mobile phase was 0.1% acetic acid/acetonitrile (32:68) at a flow rate of 0.4 mL/min. Ions were monitored in the multiple reaction monitoring mode with flunixin 297 → 279, flunixin-d_3 300 → 282, 5OHF 313 → 295, and 5OHF-d_3 316 → 298 serving as quantified transitions. Flunixin 297 → 264 and 297 → 259, flunixin-d_3 300 → 264 and 300 → 112, 5OHF 313 → 280 and 313 → 109, and 5OHF-d_3 316 → 280 and 316 → 112 transitions each served as qualifiers.

Pharmacokinetic Parameter Estimates. Noncompartmental pharmacokinetic analyses of flunixin plasma concentration versus time profiles were performed on an individual cow basis using Phoenix NCA module (version 1.3; Certara, Cary, NC, USA). Estimates of C_{max} and t_{max} after im injection, flunixin clearance at steady state (CL_{ss}/F), volume of distribution at steady state (V_{ss}/F), area under the plasma concentration−time curve from time zero to the time of the last observation (AUC_{last}), mean residence time (MRT), and half-life ($t_{1/2}$) were calculated using standard procedures.

Statistical Analyses. Within collection time, the effects of LPS treatment and route of flunixin administration on milk yield were evaluated using a two-way analysis of variance (ANOVA). Across time points, there was no effect of route of flunixin administration ($P > 0.05$) on milk yield, but significant ($P < 0.05$) effects of LPS administration on milk yield were measured. Therefore, milk yield data are presented in terms of main effects only.

The main effect of LPS on the milk flunixin/5OHF ratio was tested at each collection time point by a simple one-way ANOVA. For the 12, 24, 36, 48, and 72 h collection points, ratios were non-normally distributed (Shapiro−Wilk, $P < 0.05$) so the Kruskal−Wallis analysis of variance on ranks was employed. For the 84, 96, and 108 h collection points, ratios were normally distributed ($P > 0.05$) and ordinary one-way ANOVAs were conducted.

Within tissue, flunixin concentrations were analyzed using a two-way ANOVA with main effects of endotoxin status (+LPS or saline) and route of flunixin administration (iv or im). Data were transformed if normality or equal variance assumptions were not met. The method of transformation for a particular set of means is included in tables summarizing means. For instances in which the ANOVA returned a significant main effect, the Holm−Sidak test was employed to infer differences in treatment means.

RESULTS AND DISCUSSION

Milk Yield. There was no ($P > 0.05$) effect of route of flunixin administration on milk yield (Figure 1; Supporting Information Table S1); however, administration of LPS to lactating dairy cows reduced ($P < 0.05$) milk yield relative to the milk yield of saline-treated cows (Figure 1). The magnitudes and duration of milk yield reductions following iv LPS administration were comparable to those observed after iv infusion of *E. coli* LPS to lactating Holstein cows by Waldron et al.[21] LPS-associated reduction in milk yields or milk fat yields are well characterized after dietary induction of ruminal LPS and the resulting inflammatory response in dairy cattle.[22,23] Such results in cows used for the present study strongly suggest that LPS infusion was successful in mediating a systemic, but temporary, inflammatory response.

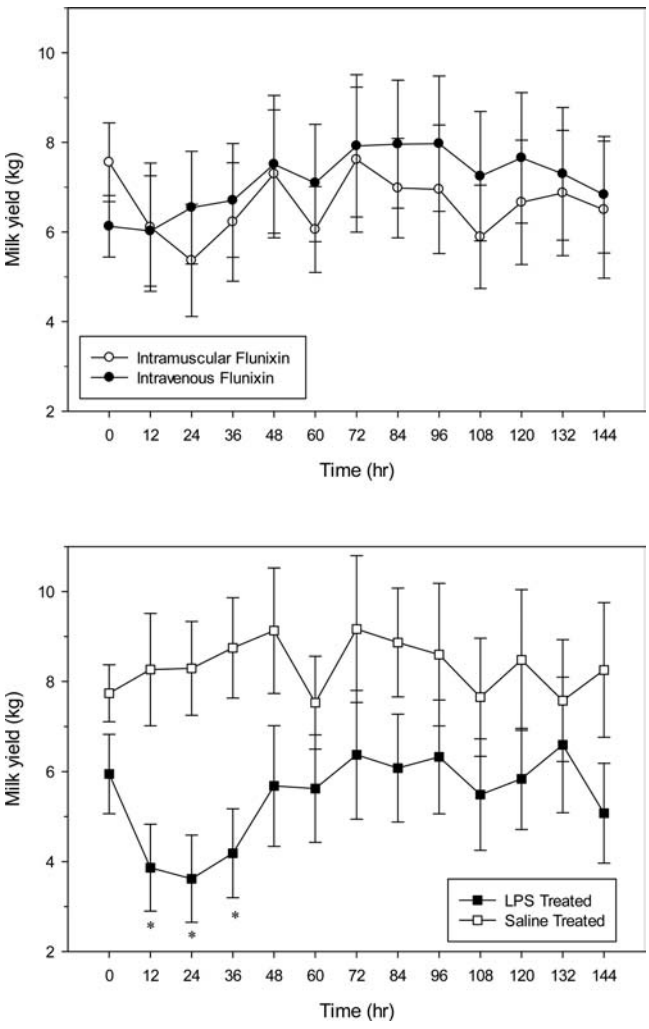

Figure 1. Effects of route of flunixin administration (top panel) or lipopolysaccharide (LPS) treatment (bottom panel) on mean milk yield (±SE) during the study period (10 cows per treatment group for each main effect). Route of drug administration had no effects ($P > 0.05$) on milk yield, but LPS treatment caused reductions (*) in milk yields at 12 ($P = 0.012$), 24 ($P = 0.004$), and 36 h ($P = 0.007$). By 48 h, the effect of LPS on milk yield was marginal ($P = 0.091$) and, thereafter, negligible ($P > 0.1$).

Kinetic Parameter Estimates. Estimated pharmacokinetic parameters for parent flunixin are shown in Table 2. Across treatments, terminal plasma half-life, AUC_{last}, Vd_{ss}/F, and MRT were larger than parameter estimates of previous studies in lactating dairy cattle.[9,10,14,24−26] This study differed from earlier studies in several respects: (a) cows were sequentially dosed with flunixin over a 3 day period; (b) the plasma flunixin assay was very sensitive, with an LOQ of 0.5 ng/mL, and blood samples were collected for 96 h after the final flunixin dose. In many instances, quantifiable flunixin residues were present 84−96 h after dosing with the resulting pharmacokinetic parameters being influenced by the prolonged concentration−time curve relative to other studies. Within these data, however, LPS administration increased ($P < 0.05$) AUC_{last}, clearance, and the volume of distribution in cows dosed with iv flunixin. For cows dosed im with flunixin, LPS administration increased ($P < 0.05$) clearance (CL_{ss}/F) and mean residence time.

Milk Residues. Concentrations of 5OHF and flunixin in milk after withdrawal periods of 36, 48, and 96 h are shown in Table 3; there were no effects of either route ($P > 0.50$) or LPS status ($P > 0.45$) on 5OHF concentrations at either 36 or 48 h. Consistent with the results of Feely et al.,[27] 5OHF was typically measurable in milk for longer periods of time than was parent flunixin (Supporting Information Tables S2 and S3), corroborating the metabolite as an appropriate marker for milk. At the minimum milk discard time of 36 h, 6 of the 20 cattle (30%) had 5OHF concentrations that met or exceeded the 2.0 ng/mL tolerance for 5OHF in milk. Similarly, 5OHF exceeded 2 ng/mL 36 h after the last flunixin dose in 25% of the eight cattle studied by Feely et al.[27] and in 8 of 20 cattle studied by Kissell et al.[10] With a 48 h withdrawal time, 2 of the 20 animals (10%) in the present study had 5OHF levels greater than allowable under U.S. statutory limits: a single cow from the iv-flunixin (−)LPS group (label conditions; cow 1) and a single cow from the im-flunixin (+)LPS group (off-label conditions; cow 18). Again, this result does not seem remarkable given the fact that of the eight cows dosed by Feely et al.,[27] a single cow secreted 17 ng/g of total radioactive residue (TRR) after a 48 h withdrawal period; assuming that 5OHF represented 20% of the total TRR in this milk, 5OHF would have exceeded tolerance levels at 3.4 ng/mL. In recent studies, Kissell et al.[9] measured violative 5OHF levels in milk of two cows 36 h after the last im or subcutaneous flunixin administration, but residues were not present at a 48 h withdrawal time. In contrast, 5OHF residues were measurable in milk from 3 of 10 mastitic cows after a 48 h withholding time.[10]

Milk yield was considered a significant ($P < 0.1$) covariate with the rate of 5OHF elimination in cows by Kissell et al.[9] Cows producing <20 kg of milk/day eliminated 5OHF at slower rates than cows producing >30 kg of milk per day. In the current study, average daily milk production across *all* cows was 13.8 ± 7.5 kg/day (mean ± SD), indicative of the fact that each cow used for the study represented an animal selected for culling because of age, poor reproductive performance, or low milk production. None of the animals were selected for elimination from the herd because of mastitis. For these low-producing cows, there was no relationship ($R^2 = 0.1509$, $P = 0.09$) between milk yield and milk 5OHF concentration at 36 h of withdrawal.

Kissell et al.[10] noted that for mastitic animals, the relative quantity and duration of parent flunixin secreted into milk was surprisingly great, with three cows eliminating 13 ± 11 ng/mL after a 60 h withdrawal period. In the current study, parent flunixin was detectable in 12 of 20 milk samples collected 60 h after the last flunixin administration, but average concentrations

[a]The tolerance for 5OHF in milk is 2.0 ng/mL; a minimum 36 h milk discard time is required. Milk values of 5OHF shown in bold exceed the tolerance at the indicated times. Concentrations of 5OHF and flunixin in milk collected from 0 to 96 h are shown in Tables S2 and S3 of the Supporting Information.

were only 0.9 ng/mL. For cows 1 and 18 (which had violative milk residues at 48 h), parent flunixin remained at relatively high levels (>1 ng/mL) until slaughter at 96 h. On the basis of the data of Kissell et al.[10] one might predict that cow 1 was mastitic or sick, and the milk record of cow 1 does suggest that this cow was not well. On the first day of dosing, cow 1 produced a total of 16 kg of milk; thereafter, the daily milk production decreased progressively from 8.3, 4.0, 3.2, 1.1, 0.2, to 0.1 kg on days 2−7, respectively (Supporting Information Table S1). Although the cows were not mastitic when purchased, we cannot rule out the development of mastitis during the study period. Cow 18 was in the im flunixin (+)LPS treatment group and was a low-producing cow, secreting an average of 2.0 kg of milk per day.

Figure 2 shows the ratio of flunixin to 5OHF secreted into milk across the study period for the control and LPS-treated cows. Cows pretreated with 0.2 μg/kg LPS consistently secreted greater ($P < 0.05$) ratios of flunixin/5OHF in milk than control cows, suggesting that either the transport or metabolism of flunixin in LPS-treated animals was altered relative to control animals. These data are consistent with the findings of Kissell et al.,[10] who demonstrated that mastitic cows secreted flunixin and 5OHF in ratios ranging from 6 to 45 from 2 to 48 h after flunixin dosing, whereas control cows had milk secretions containing ratios ranging from 0.4 to 0.8 for 24 h after dosing (neither flunixin nor 5OHF was detected in milk of

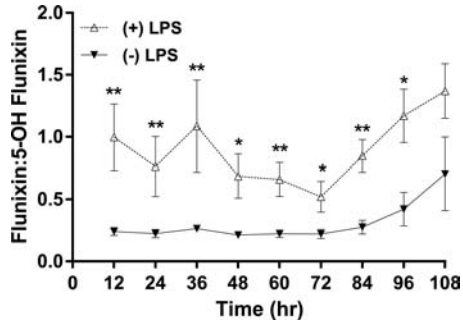

Figure 2. Ratio of flunixin to 5OHF secreted into milk by cows treated with LPS [(+)LPS] or with saline [(−)LPS]. Data are expressed as the mean ratios ± SEM of the concentration of flunixin to 5OHF in milk ($n = 10$ per treatment) by collection time. Asterisks indicate probabilities of significant differences between treatment means (*, $P < 0.05$; **, $P < 0.01$).

control animals after 24 h). Similarly, healthy cows used by Jedziniak et al.[28] secreted flunixin and 5OHF into milk at ratios estimated to be on the order of 0.1. Metabolite ratios in the current study were not as pronounced as those measured by Kissell et al.[10] but were highly consistent with the notion that inflammation may alter flunixin metabolism and disposition.

Tissue Residues. Mean concentrations of flunixin in edible and specialty tissues are shown in Table 4. There was no effect

brain (ng/g)	<LOQ[d]	<LOQ	<LOQ	<LOQ				

[a]Data were transformed [(log *X*)] prior to statistical analyses to meet normal variance and normality assumptions. [b]Data were transformed [(log *X*)] prior to statistical analysis to meet ($P > 0.05$) normal variance and approach ($P = 0.032$) normality assumptions. Two animals each in the (IM −LPS) and (IM + LPS) groups had residues less than the LOQ. These animals were included at 0.5 ng/g (half the LOQ) for purposes of calculating mean adipose tissue values. [c]Data were transformed [$(\log X)^{-2}$] prior to statistical analyses to meet normal variance and normality assumptions. [d]All animals in the −LPS treatments had residues less than the LOQ (1.0 ng/g); a single animal each in the (IV + LPS) and (IM + LPS) groups had residues above the LOQ (1 ng/g).

($P > 0.05$) of route of flunixin administration or pretreatment of cows with LPS on tissue flunixin concentrations, with the exception of flunixin residues at the injection site. That is, im administration of flunixin caused greater ($P < 0.001$) injection site residues than in equivalent muscles of iv-treated cows. Within the im group, cows dosed with LPS had greater ($P < 0.05$) injection site residues than cows treated with saline in lieu of LPS. However, it should be noted that with only five cows per treatment, the statistical power for observing treatment differences in this study was limited. In a larger study ($n = 12$), Kissel et al.[9] observed that the plasma half-life of flunixin was greater in sc-treated cows relative to iv-treated cows; the implication of such data is that given sufficient numbers of animals, tissue residues could also be greater in animals treated extravascularly such as im or sc with flunixin.

As a portion of this study, liver and muscle tissues were sent to the USDA FSIS Midwestern Laboratory for flunixin analysis using the validated FSIS regulatory flunixin method.[20] Hepatic flunixin concentrations less than half the tolerance (62.5 ng/g) were interpolated from the standard curve at the FSIS laboratory without the benefit of regressions based on low-concentration standards. Aliquots of the same livers were also extracted and analyzed at the Fargo laboratory, but with an extended standard curve so that residues below half the tolerance values could be accurately quantified. Measured liver flunixin concentrations returned by the FSIS and ARS laboratories did not differ ($P = 0.686$; $n = 20$), demonstrating the linearity of the FSIS method, even in the absence of low-level analytical standards. Analytical results obtained from the analysis of skeletal muscles were not compared because of the low concentrations of flunixin in skeletal muscle.

Whereas average concentrations of flunixin across treatment (Table 4) did not indicate treatment-related causes for residue violations, a singular instance of a tissue flunixin violation occurred (Supporting Information Table S4). The liver of cow 18, (im-flunixin + LPS treatment) contained 177.5 ng/g of flunixin residue, which exceeded the liver tolerance of 125 ng/g by approximately 50 ng/g. Flunixin residues in other tissues of cow 18 were also consistently numerically greater than flunixin residues of the same tissues in other cows (Table S4). For this reason, cow 18 was treated as an "outlier", and statistical analyses were rerun to determine whether route of flunixin administration or the presence of LPS influenced tissue flunixin residues. After removal of cow 18 from the statistical analyses, no treatment effects ($P > 0.05$), other than the effect of im administration on injection site residues, were apparent.

Although statistical analyses between tissues were not performed, the rank order of flunixin among tissues (excluding injection site) was liver > kidney ≈ lung > mammary, ileum, abomasum, heart, reticulum, tongue > skeletal muscle, adipose tissue > brain. Residue analysis of specialty tissues indicated that flunixin residues would not represent a food safety risk for consumers of those tissues. This assertion is based on the fact that flunixin concentrations in specialty tissues were <20 ng/g, the consumption of specialty tissues relative to skeletal muscle, and the established tolerance of 25 ng/g for skeletal muscle.[2]

Urine Residues. Figure 3 shows urinary excretion of flunixin and its major metabolite, 5OHF, across the dosing and withdrawal periods. Error bars are not shown in Figure 3 for the sake of clarity; in addition, it should be recalled that prior to analysis conjugates of flunixin were hydrolyzed by acid digestion. Flunixin and 5OHF were detectable in the urine of most cows throughout the 96 h depuration period. Such detection is not surprising because flunixin was present in most tissues at the 96 h withdrawal period and because renal excretion tends to concentrate residues in urine relative to tissues. Jones et al.[29] also were able to detect flunixin in urine of beef heifers as long as 96 h after a single iv flunixin administration. Of note is the fact that urinary flunixin concentrations accurately reflect the rapid absorption and elimination described by previous kinetic studies.[9,10] In addition, the graphical data (Figure 3) do not strongly suggest

DOI: 10.1021/acs.jafc.5b01509
J. Agric. Food Chem. 2015, 63, 4893−4901

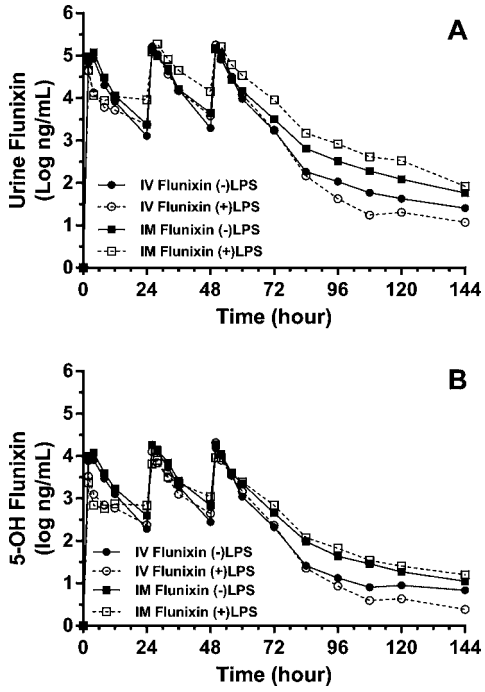

Figure 3. Urinary excretion of flunixin (A) and 5OHF (B) as a function of time. Data are expressed as the log analyte concentrations in ng/mL.

treatment differences with respect to flunixin or 5OHF excretion during the 3 day dosing period. Only at about 72 h (24 h after the last flunixin dose) does it appear that concentrations of both flunixin and 5OHF are at least numerically greater in im-dosed cows. Such results are likely due to the slower release of residual flunixin from the injection sites, relative to its distribution into the body after iv infusion. The second observation gleaned from the urinary data was the fact that flunixin was present in urine at concentrations about 10 times higher than the metabolite, 5OHF, again with the im-treated animals having numerically higher concentrations of 5OHF than iv-treated animals.

Figure 4 show the ratios of flunixin to 5OHF excreted in urine during the dosing and depuration periods. Cow 18, a member of the im (+)LPS treatment group, was not included in the means shown for the im (+)LPS treatment group, but cow 18 is included as a stand-alone element of Figure 4. Across all time points, mean (±SEM) flunixin/5OHF ratios for the iv saline, iv (+)LPS, im saline, and im (+LPS) treatment groups were 8.9 ± 0.4, 9.8 ± 0.4, 7.4 ± 0.4, and 13.4 ± 0.5, respectively. Within the cows treated with iv flunixin, there was no difference (P = 0.06) between the LPS and saline groups, but for the im-treated cows, the LPS-exposed animals had a greater (P < 0.001) mean flunixin/5OHF urinary ratio than the saline-treated cows. Within the group of cows that did not receive LPS (saline controls), im-treated cows had a higher (P = 0.009) mean ratio than iv-treated cows, whereas for cows infused with LPS the im group also had a greater (P < 0.001) mean ratio than the saline-treated group. Thus, these data suggest that LPS pretreatment may have altered either the hydroxylation or the excretion of flunixin. Circumstantial evidence presented in Figure 5, supports, but by no means proves, such a supposition. When the average urinary flunixin/5OHF ratio of saline-treated cows was regressed against the respective liver flunixin concentrations (Figure 5A), no relationship (P = 0.96; R^2 = 0.0003) could be discerned. In

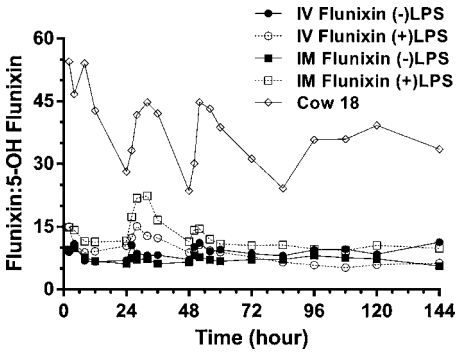

Figure 4. Urinary flunixin/5OHF ratio by treatment with cow 18 excluded from the mean of the im (+)LPS treatment group and plotted independently.

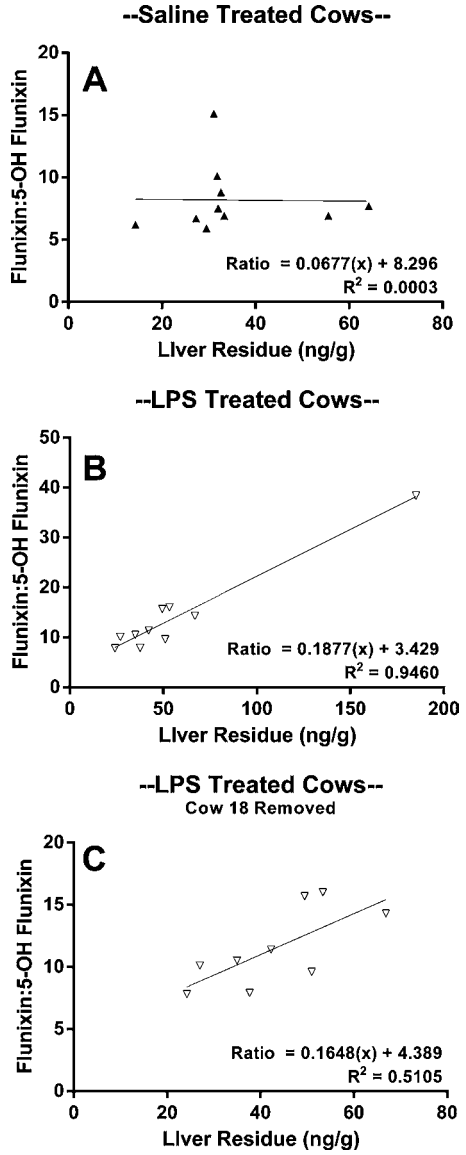

Figure 5. Relationship between lipopolysaccharide (LPS) treatment and the level of liver flunixin residues in dairy cows: (A) control cows; (B) LPS-treated cows; (C) LPS-treated cows without cow 18.

DOI: 10.1021/acs.jafc.5b01509
J. Agric. Food Chem. 2015, 63, 4893−4901

contrast, when the average urinary flunixin/5OHF ratios of LPS-treated cows were regressed with the respective liver flunixin concentrations (Figure 5B), a significant linear ($P < 0.0001$; $R^2 = 0.9460$) relationship was apparent. Recognizing that cow 18, which had a very high urinary flunixin/5OHF ratio and liver flunixin concentration, could greatly bias the least-squares regression, the regression was repeated with data from cow 18 removed (Figure 5C). Even with the influence of cow 18 removed, a linear relationship ($P = 0.03$) between the flunixin/5OHF ratio and liver flunixin residues remained, albeit with a much lower correlation coefficient ($R^2 = 0.5105$).

Such data suggest that LPS treatment could affect the metabolism or excretion of flunixin in cows. To be sure, the role of LPS in the down-regulation of several cytochrome P_{450} (CYP) isoforms has been well established in rodents and human cell models,[30−32] with the systemic administration of LPS generally down-regulating several constitutive[33] and inducible hepatic CYPs[34] at the transcription and protein levels.[32] It is unknown what CYPs metabolize flunixin in dairy cows or other livestock species. Indeed, the idea that flunixin is metabolized by CYPs in livestock is a presumption because no studies have been published investigating the enzymes responsible for flunixin clearance in livestock. Nevertheless, inhibition of hepatic CYP expression or activity by LPS would be consistent with the correlation between the flunixin/5OHF ratio in urine and hepatic flunixin levels in LPS-treated cows observed in this study. Likewise, such a supposition would also explain the greater propensity for mastitic cows to secrete violative 5OHF residues in milk than healthy cows,[10] presumably because of slower clearance. Finally, the inhibition of CYP-mediated hydroxylation of flunixin in LPS-treated cows would be consistent with the fact that 5OHF was measurable in livers of 5 of 10 control cows in this study but in only 1 of 10 LPS-treated cows (see the Supporting Information).

Collectively, data from this study strongly suggest that cattle undergoing inflammatory processes, especially those mediated by infection with LPS-producing organisms, could be contributing to the inventory of animals that test positive for flunixin at the slaughterhouse. The data reported herein suggest that even with observation of the appropriate regulatory withdrawal period, such animals could still test positive for violative flunixin residues. Further study with larger numbers of observations will be necessary to either support or refute such a supposition.

Supporting Information

ABSTRACT: Potato (*Solanum tuberosum* L.) is a good source of dietary antioxidants. Chlorogenic acid (CGA) and caffeic acid (CA) are the most abundant phenolic acid antioxidants in potato and are formed by the phenylpropanoid pathway. A number of CGA biosynthetic routes that involve hydroxycinnamoyl-CoA quinate hydroxycinnamoyl transferase (HQT) and/or hydroxycinnamoyl-CoA shikimate/quinate hydroxycinnamoyl transferase (HCT) have been proposed, but little is known about their path in potato. CA production requires a caffeoyl shikimate esterase (CSE), and CA serves as a substrate of lignin precursor ferulic acid via the action of caffeic/5-hydroxyferulic acid *O*-methyltransferase (COMT I). CGA is precursor of caffeoyl-CoA and, via caffeoyl-CoA O-methyltransferase (CCoAOMT), of feruloyl-CoA. Feruloyl-CoA is required for lignin and suberin biosynthesis, crucial for tuber development. Here, metabolite and transcript levels of the mentioned and related enzymes, such as cinnamate 4-hydroxylase (C4H), were determined in the flesh and skin of fresh and stored tubers. Metabolite and transcript levels were higher in skin than in flesh, irrespective of storage. CGA and CA production appear to occur via *p*-coumaroyl-CoA, using HQT and CSE, respectively. HCT is likely involved in CGA remobilization toward suberin. The strong correlation between CGA and CA, the correspondence with *C4H*, *HQT*, *CCoAOMT2*, and *CSE*, and the negative correlation of *HCT* and *COMT I* in potato tubers suggest a major flux toward suberin.

KEYWORDS: *antioxidant, caffeic acid, flavonoid metabolism, phenolic acids metabolism, Solanum tuberosum, storage*

INTRODUCTION

Potato (*Solanum tuberosum* L.) is an important food crop worldwide. It is considered a cheap source of high-quality proteins, minerals, and antioxidants, including vitamin C, carotenoids, and phenolic compounds such as chlorogenic acid (CGA) and flavonoids.[1] Phenolic acids have been extensively studied because they are involved in defense mechanisms induced upon biotic and abiotic stresses in plants.[2] Recently, they have been associated with health-promoting effects, mainly related to their antioxidant activity.[3,4] In particular, CGA has been reported to protect against degenerative diseases, cancer, heart disease,[5] hypertension,[6] and viral and bacterial diseases. Since differences in CGA levels of 1−2 orders of magnitude among varieties have been reported,[4] the biosynthesis of CGA in potato appears to be an important subject of study.

CGA and other phenolic acids, as caffeic acid (CA), are derived from the complex phenylpropanoid biosynthesis, part of the secondary metabolism. In the first steps of the "core phenylpropanoid pathway", primary metabolite phenylalanine is converted to *p*-coumaroyl-CoA by the consecutive action of phenylalanine-ammonia-lyase (PAL), cinnamate 4-hydroxylase (C4H), and 4-coumarate-CoA ligase (4CL). *p*-Coumaroyl-CoA is the general precursor of the flavonoid metabolism, a precursor of lignin biosynthesis, and the starting point for two routes of CGA production (Figure 1).[7,8] Route I consists of esterification of quinic acid with *p*-coumaroyl-CoA, followed by hydroxylation of *p*-coumaroylquinic acid to form CGA (Figure 1). Route II requires four consecutive steps: esterification of shikimic acid with *p*-coumaroyl-CoA, hydroxylation of *p*-coumaroyl shikimate to form caffeoyl shikimic acid, and then de-esterification to produce caffeoyl-CoA, which in turn is re-esterified with quinic acid to form CGA (Figure 1). It has long been assumed that caffeoyl-CoA can also be synthesized from *p*-coumaric acid (CouA) via CA,[9] which is the second most abundant phenolic in potato tuber. Furthermore, a heteromeric C3H/C4H complex that converts CouA to CA has been identified in *Populus trichocarpa* (route III, Figure 1).[10] A fourth route, producing CGA via caffeoyl-glucose, has been proposed in sweet potato tuber (not shown in Figure 1).[11] Key enzymes appear to be hydroxycinnamoyl-CoA quinate hydroxycinnamoyl transferase (HQT) and hydroxycinnamoyl-CoA shikimate/quinate hydroxycinnamoyl transferase (HCT), two very closely related, homologous enzymes. Note that two reactions supposedly require HCT, one reaction may utilize HQT or HCT, and in one reversible reaction HQT and HCT catalyze opposite reactions (Figure 1). Using gene silencing and overexpression, HQT was shown to be the principal enzyme for CGA accumulation in tomato leaves.[8] Tobacco HCT is involved in CGA remobilization toward caffeoyl-CoA, as silenced *HCT* tobacco plants were shown to accumulate large amounts of CGA in the stem.[12]

Recently, caffeoyl shikimate esterase (CSE) was shown to be involved in the biosynthesis of CA and, via 4CL, caffeoyl-CoA in *Arabidopsis thaliana*, bypassing the second HCT reaction.[13] Activity of caffeic/5-hydroxyferulic acid *O*-methyltransferase (COMT I) and caffeoyl-CoA *O*-methyltransferase

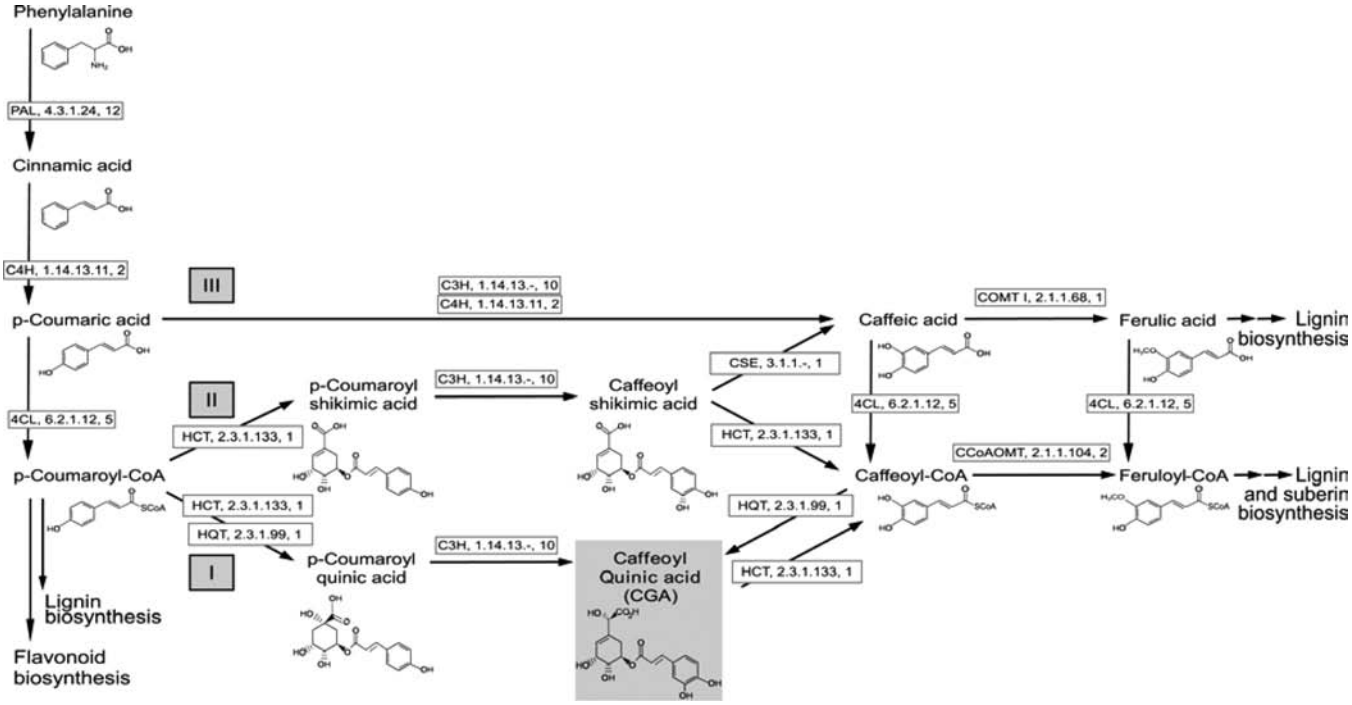

Figure 1. Chlorogenic acid biosynthetic pathways in plants. I, II, and III indicate possible biochemical routes toward CGA. The abbreviated enzyme names are boxed and followed by the corresponding EC number and the number of possible isoenzymes identified in the potato genome. Abbreviations: PAL, phenylalanine-ammonia-lyase; C4H, cinnamate 4-hydroxylase; 4CL, 4-coumarate-CoA ligase; HCT, hydroxycinnamoyl-CoA shikimate/quinate hydroxycinnamoyltransferase; C3H, *p*-coumarate 3′-hydroxilase; HQT, hydroxycinnamoyl-CoA quinate hydroxycinnamoyl transferase; CSE, caffeoyl shikimate esterase; COMT I, caffeic/5-hydroxyferulic acid *O*-methyltransferase; CCoAOMT, caffeoyl-CoA *O*-methyltransferase.

(CCoAOMT), respectively, results in ferulic acid (FA), a lignin precursor, and feruloyl-CoA, a precursor of both lignin and suberin (Figure 1).

It has been generally accepted that phenylpropanoid biosynthesis is mostly regulated by transcriptional control.[14] Several studies performed in CGA-accumulating plant families (i.e., Asteraceae, Rubiaceae, and Solanaceae) show that transcript levels reflect metabolites levels.[15−21] Relatively little is known about the regulation of the phenolic acids biosynthesis in potato tuber. André et al.[22] studied the expression of various genes involved in the phenylpropanoid pathway in tubers under normal and drought stress conditions. Constitutive and drought-induced expression profiles of *PAL*, *HCT*, and *C3H* genes were coordinated and correlated with phenolic acids levels, suggesting that also in potato tuber these enzymes are regulated at the transcriptional level; curiously, this was less clear for *C4H* and *HQT*. In a similar study, Payyavula et al.[23] found that phenylpropanoid gene expression appeared coordinately regulated and was well correlated with metabolite pools. In accordance with André et al.,[22] the correlation observed between *HQT* and CGA was less clear than that between the other phenylpropanoid genes and CGA. Enzymes that act downstream of CGA synthesis, such as CCoAOMT, were shown to be involved in suberization of potato tuber skin.[24] However, it is not clear how downstream events catalyzed by COMT I and CCoAOMT affect CGA levels. To the best of our knowledge, there are no studies regarding the role of CSE in CGA synthesis nor secondary metabolism in potato.

The phenolic acids contents of potato tuber are determined by both intrinsic and extrinsic factors. Genotype, developmental stage, and tissue are the major intrinsic factors.[25−36] It should be noted that most studies on the regulation of CGA synthesis have been carried out in whole tubers, although it has been shown that metabolite levels between flesh and skin differ significantly.[25,30,33,34] The major extrinsic factors, cultivation conditions (e.g., location, year of cultivation, and fertilization)[29,37,38] and cold storage, have not yet been studied extensively. The literature suggests that during cold storage, a period in which potatoes may undergo high metabolic changes,[39] their phenolics content either remains constant or increases.[40−42] A similar observation has been reported for antioxidant activity.[43−45] However, there are no studies on the effect of cold storage on transcription levels of genes involved in CGA biosynthesis in potato tubers. The aim of this work was to determine the transcriptional regulation of the synthesis of CGA and related phenolics, such as CA, through a comparative analysis of flesh and skin tissues of fresh and stored tubers of five carefully selected processing potato varieties.

MATERIALS AND METHODS

Plant Material. Twelve white- or yellow-fleshed processing varieties of *Solanum tuberosum* ssp. *tuberosum* were grown in fields located in Balcarce, Buenos Aires, Argentina, during the 2009/2010 campaign of McCain Argentina S.A. All varieties were planted on the same date in random plots and harvested at the end of their respective cycles. For each variety, skin and flesh from 10 tubers that were either freshly harvested ("fresh") or stored for 3 months in darkness at 8 °C and a relative humidity of 80−90% with forced air ventilation ("stored") were pooled to generate a representative sample. The material was immediately frozen in liquid nitrogen and stored at −80 °C until analysis.

Total Phenolics. Total phenolics were determined using the Folin−Ciocalteu reagent following the procedure described by Campos et al.[46] with minor modifications. Briefly, a 300 mg sample

was homogenized in a mortar with liquid nitrogen, suspended in 3 mL of 95% ethanol, and subsequently incubated at 4 °C for 24 h. A 0.5 mL aliquot of extract was diluted with 7.5 mL of water, mixed with 0.5 mL of water-diluted Folin−Ciocalteu reagent (1:7), and allowed to react for 3 min. Next, 1 mL of 0.5 M Na_2CO_3 was added and allowed to react for 10 min. The absorbance at 725 nm was measured in a visible light spectrophotometer (Hitachi U-1900). Chlorogenic acid (Sigma-Aldrich) was used as standard for the calibration curve, and total phenolics contents were expressed as micrograms of CGA equivalents per gram fresh weight (FW). Blank samples consisted of 95% ethanol.

Antioxidant Activity. Antioxidant activity was measured using the 2,2-diphenyl-1-picrylhydrazyl (DPPH) assay described by Reddivari et al.[28] with minor modifications. A 100 mg sample, homogenized in a mortar with liquid nitrogen, was suspended in 1 mL of methanol and incubated at 4 °C for 24 h. The extract was obtained by centrifugation at 10000*g* for 10 min at 4 °C. A DPPH solution was freshly prepared by dissolving 4 mg of DPPH in 100 mL of methanol to obtain an absorbance of ∼1.1 at 515 nm. Next, 150 μL of the extract was mixed with 2850 μL of DPPH solution and incubated for 24 h at room temperature in the dark. The absorbance at 515 nm was measured using a visible light spectrophotometer (Hitachi U-1900). Blank samples consisted of methanol. Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) was used as standard for the calibration curve. The results were expressed as micrograms of Trolox equivalents per gram FW.

Phenolic Acids Analysis. One gram of tissue homogenized in a mortar with liquid nitrogen was incubated with extraction buffer (25 mL of 90% methanol with 0.1% HCl) for 60 min at 4 °C in darkness with constant agitation. After centrifugation at 4000*g* for 20 min at 4 °C, the extract was first concentrated using a rotary evaporator, and the remaining solvent was then completely evaporated in a vacuum centrifuge (Savant AES 1010 Automatic Environmental Speed Vac). The residue was dissolved in 1 mL of extraction buffer and filtered through a 0.45 μm PVDF syringe filter. Quantification of phenolic compounds was carried out using an Agilent 1100 system equipped with a quaternary pump, an autosampler, and a diode array detector (DAD). A flow rate of 1 mL min^{-1} was used, and 20 μL samples were injected onto a C-18 Phenomenex Luna column (250 × 4.6 mm i.d.; 5 μm particle size). The mobile phases were (A) acetonitrile and (B) buffer, pH 2.3 (HPLC-grade water acidified with H_3PO_4). The solvent gradient was as follows: 0 to 20 min, linear gradient of A 20% to 100% then back to 20% to 25 min and held until 30 min. Identification of phenolic compounds was carried out by comparing retention times and spectra of authentic standards. The external standard method of calibration and peak areas were used for quantitation. Phenolic acids were expressed in μg g^{-1} FW.

Primer Design. A BLAST analysis[47] was performed at the Web site of the Potato Genome Sequencing Consortium (http://potato.plantbiology.msu.edu/blast.shtml) in order to identify the phenolic acids' biosynthetic genes, *PAL*, *C4H*, *4CL*, *HCT*, *C3H*, *HQT*, *CSE*, *COMT*, and *CCoAOMT*, from the *Solanum phureja* genome. Housekeeping genes *ACTIN* and *L2*, previously used to normalize transcript levels of genes involved in the phenylpropanoid pathway in potato tubers,[22,23,35,36,48−50] were identified by BLAST at NCBI. Primers were designed with Fast-PCR software[51] and the Primer3 online primer design tool.[52] Amplicon sizes were selected around 150 bp, and temperatures of annealing were set around 60 °C. The *HCT*, *HQT*, *CSE*, *COMT I*, and *CCoAOMT* primers are intron spanning. Primers (sequences given in Table 1) were tested by BLAST at NCBI, and against *Solanum* DNA and cDNA. When possible, primer sequences were designed to anneal in regions conserved among *S. tuberosum*, *S. lycopersicum*, *S. melongena*, *S. pinnatisectum*, and *S. cardiophyllum*.

RNA Extraction and cDNA Synthesis. RNA was extracted from tuber samples using the cetyltrimethylammonium bromide (CTAB) method.[53] Samples were ground to fine powders in mortars precooled with liquid nitrogen. Next, 100 mg portions of the powders were transferred to RNase-free tubes filled with 1 mL of prewarmed extraction buffer, including 20 μL of β-mercaptoethanol, and vortex-mixed. The samples were incubated at 65 °C for 20 min and vortex-mixed every 5 min. An equal volume of chloroform/isoamyl alcohol (24:1) was added prior to the final vortex-mix. After centrifugation for 10 min at 15000*g* at 4 °C, the aqueous phase was extracted twice with an equal volume of chloroform/isoamyl alcohol. The supernatant was then mixed with 1/3 volume of 8 M lithium chloride. RNA was precipitated overnight at −20 °C and harvested by centrifugation for 10 min at 15000*g* at 4 °C. The pellet was dissolved in 400 μL of distilled, RNase-free water (dH_2O), reprecipitated with 1/10 volume of 3 M sodium acetate (pH 5.2) and 3 volumes of 100% ethanol at −20 °C for 30 min, and harvested by centrifugation for 10 min at 15000*g* at 4 °C. The RNA pellet was washed with 75% ethanol and finally dissolved in 30 μL of dH_2O. RNA was quantified by measuring the OD260 and OD280 values using a spectrophotometer (Hitachi U-1900), and quality was assessed by agarose gel electrophoresis. cDNA was synthesized using 2 μg of total RNA, previously treated with RNase-free DNase I (Invitrogen), anchored oligo(dT) 15 VN primers, and MMuLV reverse transcriptase according to the manufacturer's description (Invitrogen).

J. Agric. Food Chem. 2015, 63, 4902−4913

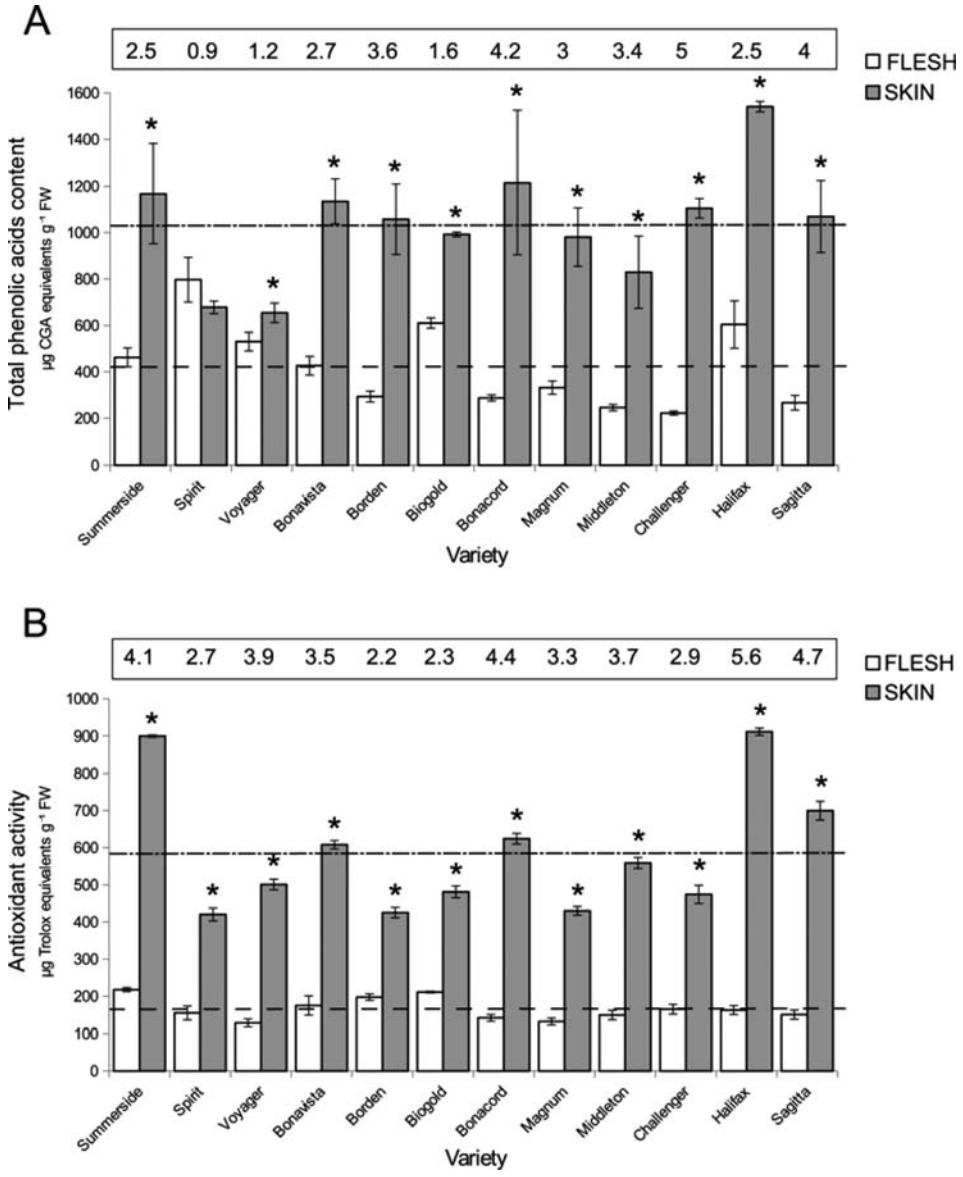

Figure 2. Phenolic acids contents and total hydrophilic antioxidant activity in flesh and skin of tubers from 12 processing potato varieties. (A) Total phenolic acids contents determined by the Folin−Ciocalteu reaction, and (B) total antioxidant activity determined by the DPPH assay in flesh (white bars) and skin (gray bars). Values are presented as the mean ± SD of three independent extractions. Dashed and dash-dotted lines indicate the mean values considering the 12 varieties in flesh and skin, respectively. Numbers in the upper boxes represent the skin-to-flesh ratios. Asterisks denote significant differences between flesh and skin by Student's *t* test ($p < 0.05$).

qRT-PCR Experiments. Relative transcript levels were determined by qRT-PCR in a 10 μL reaction volume with 20 ng of RNA equivalent cDNA, 300 nM gene-specific primers, and 5 μL of SYBR Green Mix (Roche, Mannheim, Germany). Amplification was done using a StepOne real-time PCR system (Applied Biosystem) according to the manufacturer's description, with a 10 min preincubation step at 95 °C, followed by 40 cycles of 15 s denaturation at 95 °C and 1 min annealing/extension at 60 °C. Relative expression was calculated by the ΔCT method[54] by normalizing the CT levels of target genes to the geometric mean of CT levels of both housekeeping genes, *ACTIN* and *L2*. Specificity of amplification was assessed by dissociation curve analysis and agarose gel electrophoresis. qRT-PCR data represent the normalized means ± SD of two independent experiments with two technical replicates each.

C4H2 Sequencing. Genomic DNA (gDNA) was extracted from leaves of *in vitro* grown potato plants using the PureLink genomic plant DNA purification kit (Invitrogen) according to the manufacturer's instructions. The *C4H2* locus was amplified with specific primers C4H2seqfw (5′ GTGCAGCAGTATAGAGGG 3′) and C4H2seqrv (5′ CCTTGCAAATCTTCAAGTAC 3′) from purified gDNA by standard PCR conditions. PCR products were purified from agarose gel using the DNA PuriPrep-GP kit (Inbio, Tandil, Argentina). Purified fragments were sequenced using an internal primer C4H2seqint1rv (5′ AAAGCTCTGAGCCAATCTACTCC 3′) by the sequencing service of Unidad de Genómica, Instituto de Biotecnología, INTA Castelar, Argentina.

Statistical Analysis. Pearson product moment correlation coefficients (*r* values) were calculated with Microsoft Excel using the means of metabolite concentrations or relative gene expression values and visualized with HeatMapper Plus.[55] Differences in the contents of metabolites and transcripts between flesh and skin were evaluated with *t* test.[56] For all statistical analyses, normality and homoscedasticity of the data set were tested using the Kolmogorov−Smirnov and Cochran tests, respectively.[56] When necessary, data were transformed to fit parametric assumptions.

RESULTS

Selection of Potato Varieties with Different Phenolic Acids Profiles. In order to study the aspects that determine the levels of CGA, it is necessary to have a group of potato varieties with different levels of CGA and related metabolites. Therefore, and since CGA is the major phenolic acid in potato tuber,[57] varieties with different contents of total phenolic acids were selected, taking into account differences in skin and flesh tissue content. Phenolic acids contents in flesh and skin of fresh tubers of 12 processing potato varieties were determined by means of the Folin−Ciocalteu reaction (Figure 2A). Total phenolic acids in flesh ranged from 220 (Challenger) to 800 (Spirit) μg CGA equivalents g^{-1} FW (mean concentration 423.2 μg), whereas in skin the content varied between 650

DOI: 10.1021/jf505777p
J. Agric. Food Chem. 2015, 63, 4902−4913

(Voyager) and 1550 (Halifax) μg CGA equivalents g^{-1} FW (mean concentration 1035.6 μg). Total phenolics were 1.2 (Voyager) to 5 (Challenger) times more abundant in skin than in flesh (Figure 2A). Curiously, Spirit showed slightly higher phenolic acids levels in flesh than in skin.

Five potato varieties were selected for subsequent in-depth analysis on the basis of differences in their skin-to-flesh ratios. Briefly, Voyager shows a low, Summerside and Halifax an intermediate, and Challenger and Sagitta a high skin-to-flesh ratio.

Phenolic acids form a major source of hydrophilic antioxidants. In order to demonstrate the contribution of phenolic acids to antioxidant levels, the hydrophilic antioxidant activity was quantified in both tissues by the DPPH assay (Figure 2B). Antioxidant activity was 2.2 (Borden) to 5.6 (Halifax) times higher in skin than in flesh. Antioxidant activity in flesh ranged from 130 (Voyager) to 220 (Summerside) μg Trolox equivalents g^{-1} FW (mean concentration 165.4 μg), while in skin it varied between 420 (Spirit) and 910 (Halifax) μg Trolox equivalents g^{-1} FW (mean concentration 586.2 μg; Figure 2B). There is a weak positive correlation between total phenolic content and antioxidant activity in skin but not in flesh (data not shown). These results indicate that there are differences in either the phenolic acids or the non-phenolic acids antioxidant composition.

Chlorogenic and Caffeic Acids Levels Are Higher in Skin than in Flesh and Largely Independent of Storage. Because producing fresh potatoes throughout the year is unfeasible, storage is essential[58] but might affect phenolic acids content. Therefore, the levels of CGA, CA, CouA, FA, and cinnamic acid (CinA) were quantified via HPLC-DAD in flesh and skin of both fresh and 3 months stored tubers of the five selected potato varieties (Table 2).

Table 2 shows that CGA is the major phenolic acid in the skin and flesh of both fresh and stored potato tubers (89.6−97.2%). CA, CouA, and FA are minor components (0.1−9.7%), whereas CinA could not be detected by HPLC-DAD. In correspondence to what was found for total phenolics in the initial Folin−Ciocalteu screening, the abundance of most compounds was higher in skin than in flesh. For instance, CGA levels were 10.9 (Voyager) to 20.1 (Sagitta) times more abundant in skin than in flesh. Skin-to-flesh ratios of CA were even higher, reaching up to 71-fold in fresh tubers of the Sagitta variety. In general, CouA and FA exhibited minor differences among tissues, as reflected by their skin-to-flesh ratios. During storage, the levels of CGA and CA either diminished or did not alter significantly. The levels of CouA and FA fluctuated without a clear pattern (Table 2).

CGA Synthesis Is Regulated at the Transcriptional Level in Potato Tuber and Is the Result of a Dynamic Balance between the Influx via C4H and HQT and the Outward Flux through CSE and HCT, Irrespective of the Effect of Storage. With the aim to explore the molecular mechanisms that determine the levels of CGA and CA, a qRT-PCR transcript level analysis of key enzymes *C4H*, *HQT*, *HCT*, *CSE*, *COMT I*, and *CCoAOMT* was performed on the skin and flesh of both fresh and stored tubers of the five selected potato varieties. *CCoAOMT* appears to be encoded by two nearly identical (86%) genes, which were both evaluated. *C4H* shows two 98% identical genes, of which *C4H2* initially appeared to be a pseudogene. The genome sequence of *Solanum phureja*[59] shows that *C4H2* has a single nucleotide deletion, resulting in a reading frame shift. SNP analysis of publicly available EST data could not unequivocally show that *C4H2* is a pseudogene in all *S. tuberosum* varieties (data not shown). Part of the *C4H2* locus from the *S. phureja* variety that was sequenced by the Potato Genome Sequencing Consortium as well as two varieties used in our analysis was amplified and sequenced with locus-specific primers. Surprisingly, none of the obtained sequences demonstrates the single nucleotide deletion identified in the genome sequence (see Supporting Information, Figure S1). Hence, gene-specific primers for both *C4H* genes were designed and used in qRT-PCR analysis. *ACTIN* and cytoplasmic ribosomal protein *L2* transcript levels were used for normalization (Figure 3). In general, the results show that transcript levels were higher in skin than in flesh, in both fresh and stored tubers (Figure 3). Levels in stored and fresh tubers were of the same order of magnitude. Transcript levels of *C4H1*, *C4H2*, *HQT*, and *CCoAOMT2* were of the same order of magnitude, although *CCoAOMT2* levels showed larger fluctuations. *HCT* and *CCoAOMT1* levels were about 1−2 orders of magnitude lower (skin and flesh, respectively), whereas the lowest transcript levels were found for *CSE* and *COMT I* (Figure 3). Transcript levels of the genes involved in CGA synthesis were tissue- and condition-specific. Expression patterns of *C4H1*, *C4H2*, and *HQT* were similar in flesh of fresh tubers (Figure 3) and in accordance with the levels of CGA (Table 2) in all studied varieties except for Voyager. Voyager showed the highest expression levels of *C4H2* and *HQT*, but intermediate levels of *C4H1* and CGA (Figure 3 and Table 2). The transcript level of *HQT* reflects CGA levels in skin of fresh potato tubers in four of the five varieties (Figure 3 and Table 2). Nevertheless, Voyager has intermediate transcript levels of *HQT* but lower CGA levels.

A Pearson correlation analysis was performed in order to quantify associations between metabolite and transcript levels. Figure 4 shows the correlation between fresh flesh transcript and metabolite levels as well as fresh skin metabolite levels of four of the five initially selected varieties. The Voyager data were not included since this cultivar exhibits a different behavior which might hinder detecting otherwise obvious trends. The complete set of analysis of all four conditions of the four selected varieties can be found in the Supporting Information, Figure S2.

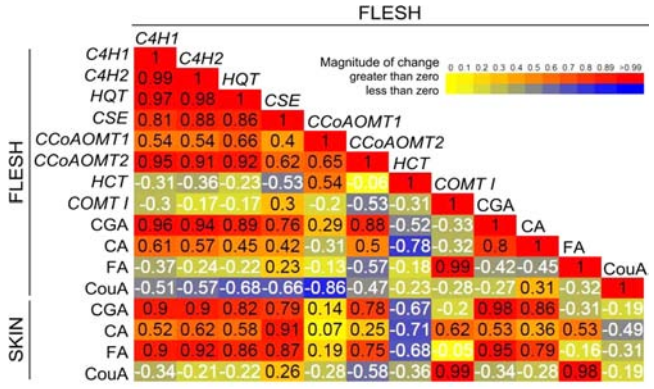

Figure 4. Correlation analysis of transcript and metabolite levels of fresh tubers from four selected processing potato varieties. Pearson correlation coefficients were calculated using the means of metabolite concentrations from fresh flesh and/or fresh skin and/or relative gene expression values from fresh flesh and used to generate a heatmap. Abbreviations are listed in Figure 1 and Table 2.

DOI: 10.1021/jf505777p
J. Agric. Food Chem. 2015, 63, 4902−4913

In fresh flesh, transcript levels of *C4H1*, *C4H2*, *HQT*, *CSE*, and *CCoAOMT2* show mutual positive correlations and exhibit positive correlations with the major metabolites CGA and, to a lesser extent, CA. In contrast, *HCT* and *COMT I* show an almost consistent negative correlation with all other transcripts and most metabolites. An important exception to the latter is the mutual positive correlation between *COMT I* and *CSE* transcripts and FA, the metabolite downstream of the consecutive action of the corresponding enzymes. *CCoAOMT1* shows lower *r* values than *CCoAOMT2* and exhibits a positive correlation with *HCT* (Figure 4).

The metabolite levels in skin are higher than in flesh, in correspondence with transcript levels. Nevertheless, Figure 4 also shows the correlation between fresh flesh transcript and metabolite levels with fresh skin metabolite levels in order to analyze putative metabolite transport. A high correlation between CGA levels in skin and flesh (r = 0.98; Figure 4) suggests metabolite contribution from flesh toward skin. Accordingly, flesh *C4H1*, *CH42*, and *HQT* transcript levels correlate well with skin CGA levels (r = 0.90, 0.90, and 0.82, respectively). Furthermore, skin FA levels show a better correlation with flesh than with skin *C4H* transcript levels (Figures 4 and S2; also see Discussion section).

DISCUSSION

The present study was directed at the elucidation of the biosynthesis of the dietary antioxidant CGA in the staple crop potato. Metabolite and transcript levels in flesh and skin from fresh and stored tubers from five carefully selected potato varieties were determined. The initial selection of five from 12 varieties was made on the basis of total phenolic acids contents determined by Folin−Ciocalteu assay. Total phenolic acids in flesh were in accordance with reports for white- or yellow-fleshed cultivars by Al-Saikhan et al.[60] and Reddivari et al.[29] Antioxidant activity in flesh was similar to or slightly lower than that in previous reports.[28,61] As with total phenolic acids content, antioxidant activity was higher in skin than in flesh and correlated well with it in skin but not in flesh. Differences in the composition of phenolics and other antioxidants present in methanol extracts may cause the lack of correlation in flesh. It has been shown that CA has higher antioxidant activity than CGA[28] and vitamin C is an abundant, methanol-soluble antioxidant in potato.[62]

The Folin−Ciocalteu assay showed higher values for total phenolic contents than the sum of all the individual phenolic compounds quantified by HPLC-DAD. These results fit with those obtained by other groups[33,63] and can be explained by the fact that compounds like thiol derivatives, vitamins, and amino acids may interact with the Folin−Ciocalteu assay.[64] A strong correlation was found between the results obtained by the two different methods (r = 0.93 for flesh, r = 0.83 for skin), as previously reported by André et al.,[27] even though fold differences between samples appear less clear in the Folin−Ciocalteu assay. This supports the idea that the Folin−Ciocalteu assay remains a rapid and economic alternative for comparative purposes.

CGA and CA Levels Are Significantly Higher in Skin Tissue. CGA is the predominant phenolic acid in both skin and flesh. CA contributes significantly, around 1−10%, whereas other phenolic acids contribute little to the total phenolic content. This is in agreement with other reports that show CGA is the most abundant phenolic acid in potatoes, followed by CA,[27,32,33,42,65] with CouA and FA being the least abundant.[33,66] We could not identify CinA in skin nor in flesh. CinA was earlier identified only in tuber skin.[25]

Both CGA and CA levels are 10−70 times higher in skin than in flesh. Similar results were obtained by Im et al.[30] in skin and flesh of five commercial potato varieties. Other previous data indicated that phenolic compounds are found mostly between the cortex and potato skin[67] or in the potato skin and adjoining tissues, with decreasing concentrations toward the center of potato tubers.[68] This is likely related to suberin deposition in skin tissue during tuber growth.[69]

During storage, the levels of CGA and CA diminished or remained unaffected. Conversely, Madiwale et al.[61] reported that 90 days of storage at 4 °C led to a 1.3- to 4-fold increase of CGA and CA content. These differences might be attributed either to cultivar-dependent storage responses or to storage conditions.

Transcript and Metabolite Levels Are Highly Correlated. Transcript levels of phenolic acids biosynthetic genes were also, in general, higher in skin than in flesh (see Figure 3). The good correspondence between transcript and metabolite levels suggests that the control of gene expression is essential in the control of CGA biosynthesis and that the enzymes are coordinately regulated, at least in part, at the transcriptional level. This confirms earlier work[14−21] and is fundamental in the use of Pearson correlation analysis for metabolic modeling. Interestingly, *HCT* shows a consistent negative correlation, whereas *COMT I* shows a prevalent negative correlation with most metabolites, FA forming the obvious exception (Figure 4).

Of particular interest is C4H, encoded by two genes. The close proximity of the two genes in the *S. phureja* genome combined with the high sequence identity suggests that these genes are under concerted evolution.[70] Although the genome sequence of *S. phureja* shows *C4H2* has a fatal deletion, resequencing of the locus amplified by locus-specific primers indicates that *C4H2* is a functional gene (see Figure S1). André et al.[22] used indiscriminative primers, which might explain the lack of positive correlation between *C4H* transcript and CGA levels they demonstrated. The consistent positive correlation of the *C4H* transcripts corresponds with a major role for the sink in the metabolism of both CA and CGA. *HQT* transcripts correspond very well with CGA, which indicates that HQT is the principal enzyme for CGA accumulation. This is in correspondence with results found in tomato leaves, where overexpression of *HQT* increased CGA content, whereas *HQT* silencing caused a reduction but had no detectable effects on lignin accumulation.[8] An in-depth study of *HCT*-silenced *Nicotiana benthamiana* plants revealed that lignin biosynthesis depends on HCT activity *in vivo*.[12] In correspondence, we found that CGA shows a negative correlation with *HCT* transcript levels in all studied conditions (Figure S2).

Toward a Model for CGA and CA Metabolism. CGA is the major phenolic acid in potato tuber, and its biosynthesis is very well explained by the transcript levels of its structural genes, as shown in Figure 4. We did not analyze transcript levels of structural genes of the flavonoid pathway, but previously CGA was shown to correlate better with flavonoid biosynthetic enzymes than with *HQT* transcript levels.[22,23] Thus, phenolic acid and flavonoid metabolism are linked, under direct transcriptional control, and must be subject to metabolic regulation. Using the Pearson correlation analysis shown in Figure 4, we developed an initial model of CGA and CA biosynthesis that appears to be driven by both the source CouA

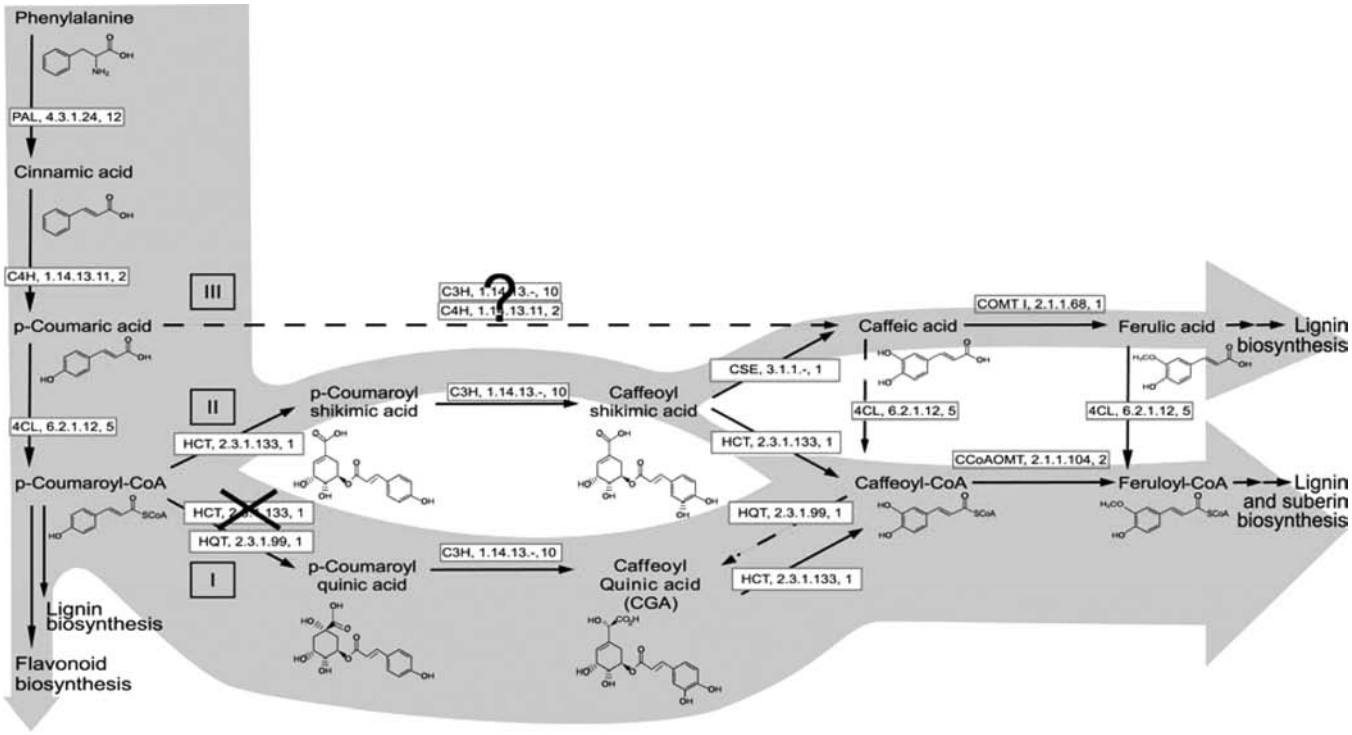

Figure 5. Proposed flux model of biochemical pathways leading to CGA and CA production in potato tuber. Dashed lines, question mark, and cross indicate unlikely routes, uncertain enzyme complexes, and unfeasible reaction, respectively. Enzyme names are listed in Figure 1.

and the sink suberin (Figure 5). The model explains the correlation between CA and CGA ($r = 0.8$, see Figure 4) by the high correlation of both metabolites with *C4H* transcript levels and, hence, the sink via CouA. Then, the positive correlation between *CSE* and CA indicates route II is actively involved in CA biosynthesis. Note that HCT and CSE will compete for substrate, which contributes to the negative correlation of *HCT* with CA, which can further be explained by additional or alternative CA formation via route III. Although, theoretically, CGA biosynthesis could occur via CA and caffeoyl-CoA, the negative correlation of *HCT* points toward a role for HCT in CGA remobilization toward lignin and suberin. Thus, route I would be the major route, and HQT is the major enzyme in CGA biosynthesis. Note also that *HCT* transcript levels are consistently low in flesh and show up to ~18-fold induction in skin, where suberin is deposited in the primary cell wall. This suggests that CGA is transported to the skin. The positive correlation of *CCoAOMT*, required for feruloyl-CoA and downstream suberin, and the negative correlation of *COMT I*, required for FA and downstream lignin, also suggest a central role for suberin deposition in potato tuber. It should be mentioned that, given the complexity of the phenylpropanoid, lignin, and suberin biosynthetic pathways, this merely a trend, and other fluxes can and likely will occur.

The model was based on the fresh flesh data set but also explains the fresh skin data set quite well, albeit that the correlation values are not so high. This could be caused by metabolite transport, suggested by the correlations between flesh transcript and skin metabolite levels (Figure 4). Such metabolite transport would have a minor effect on the voluminous flesh tissue but a major effect on skin metabolite levels. On that proposition, the skin data are not reliable resources for model construction. Then, the stored tuber data sets shows less clear patterns. Nevertheless, the stored flesh data correspond with the model. *C4H2*, *HCT*, *CSE*, and *COMT I* correlate well to each other. On the other hand, *C4H1*, *HQT*, and CGA correspond well, whereas *CCoAOMT* appears to have an inconsistent correlation. Within the proposed model, this would mean that, upon storage, there is more emphasis on lignin production, or less emphasis on suberin production. This is not reflected in the levels of CA, CGA, and FA but might be reflected in the levels of caffeoyl-CoA and feruloyl-CoA. It should be mentioned that the model corresponds with poor rather than negative correlations of *HCT*. However, in all likelihood, no model can account for the consistent negative correlation of *HCT*. Then, the model was made on the basis of an incomplete data set since we ignored the Voyager data set in the Pearson correlation analysis, this in order to more easily detect the major trends. However, the Voyager data set does actually also correspond quite well with the model. An increased flux toward lignin and suberin, reflected by the highest levels of *CSE* and *HCT* observed in fresh tubers of Voyager variety, would explain why even though it showed high expression levels of *C4H* and *HQT*, it has intermediate levels of CGA. In other words, CGA levels are the result of a dynamic balance between the influx via C4H and HQT and the outward flux through CSE and HCT.

The model in Figure 5 should be seen as an initial model that requires both substantiation and elaboration. The model is clearly based on the oversimplification that transcript levels reflect metabolite levels and that no post-translational regulation is involved. Hence, for instance, differences in enzyme kinetics between various cultivars cannot be captured by such a simple model but would require a more delicate systems biology approach. The same should be mentioned regarding the proposed metabolite transport and the Voyager data set, which complicate Pearson correlation analysis but can readily be included in more delicate and elaborate analyses such

DOI: 10.1021/jf505777p

as flux balance analysis, thereby contributing to an improved, possibly even semiquantitative model.

ABSTRACT: Imidacloprid (IMD) is a neonicotinoid insecticide soil-drenched on sandy soils of southwest Florida for the control of *Diaphorina citri* Kuwayama or Asian citrus psyllid (ACP). The ACP vectors causal pathogens of a devastating citrus disease called citrus greening. Understanding the behavior of IMD in these soils and plants is critical to its performance against target pests. Samples from Immokalee fine sand (IFS) were used for sorption kinetics and equilibria experiments. IMD kinetics data were described by the one-site mass transfer (OSMT) model and reached equilibrium between 6 and 12 h. Batch equilibrium and degradation studies revealed that IMD was weakly sorbed (K_{OC} = 163−230) and persistent, with a half-life of 1.0−2.6 years. Consequently, IMD has the potential to leach below the citrus root zone after the soil-drench applications.

KEYWORDS: *one-site mass transfer, soil partition coefficient, zero-order transformation, pesticide transport, Asian citrus psyllid, integrated pest management*

INTRODUCTION

Imidacloprid [1-(6-chloro-3-pyridylmethyl)-*N*-nitroimidazolin-2-ylideneamine (IMD)] is a systemic insecticide of the neonicotinoid class. Neonicotinoids are synthetic derivatives of nicotine, an alkaloid found in the leaves of many plants in addition to tobacco.[1] IMD translocates through plant tissue after application, acting by contact and ingestion to control plant-sucking pests, such as psyllids and aphids, and some chewing insects, including termites and soil insects, and even fleas on pets.[2,3] IMD targets post-synaptic nicotinic acetylcholine receptors in the insect nervous system.[4] The binding affinity of IMD at the nicotinic receptors in mammals is much less than that of insect nicotinic receptors.[5] IMD has been extensively applied to many crops, such as sugar beet, tomato, eggplant, cabbage, and mustard.[1,6−8] In Florida, IMD is used to control the Asian citrus psyllid (ACP), *Diaphorina citri* Kuwayama, the vector of the pathogens believed to cause the devastating huanglongbing or citrus greening disease.[9] Insecticides, including IMD, are soil-drenched around the trunk of the citrus tree, so that they are absorbed by the roots and translocate to growing tender shoots, where the insects feed and reproduce.[9,10]

IMD data on the soil sorption coefficient normalized to the soil organic carbon content (K_{OC}) range from 156 to 960, with a half-life of several weeks to years.[11−14] The half-life increases with an increase in the initial applied concentration of IMD as observed with non-agricultural application rates (>50 $\mu g\ g^{-1}$) to control termites.[15] On the other hand, much shorter IMD half-lives have been reported for agricultural application rates (e.g., 0.56 kg ha^{-1} around the root biomass of perennial commodities, such as citrus) or concentrations higher than 10 $\mu g\ g^{-1}$.[10,16,17]

Moderate to high leaching potential has been observed for IMD and most other neonicotinoids.[18] From 1999 to 2005, the U.S. Geological Survey (USGS) detected IMD in 13% of groundwater monitoring wells located in citrus orchards of the Central Florida Ridge.[19] This area is dominated by sandy, deep, and excessively drained Entisols.[20] In southwest Florida, the dominant soils are Spodosols, which are sandy, low-lying, flat, and poorly drained, with shallow water tables.[20,21] One example of these soils is Immokalee fine sand (IFS) that is excessively permeable, with a low organic carbon content in its A and E diagnostic horizons.[20] It also has a poorly drained spodic layer (Bh), high in organic matter, with accumulation of Fe and Al.[20]

Currently, it is unclear how IMD reacts with these soils, and there are no data describing IMD transport and persistency in southwest Florida soils treated to control ACP. To address these questions, the study goals were to characterize IMD sorption and degradation in Florida sandy soils, specifically IFS diagnostic horizons A, E, and Bh. The data will provide a technical basis for IMD transport studies in the field regarding IMD application rates to citrus, leaching potential, and ACP control. The hypotheses tested were that (a) IMD has a small soil sorption coefficient (K_D) and slow degradation rate (k) in IFS, (b) the spodic layer has a higher IMD sorption coefficient and faster degradation rate than the overlaying A and E horizons, because of its higher organic matter and clay contents, and (c) there is high leaching potential beyond the citrus root zone (0−45 cm) after IMD soil-drench applications (and

subsequent irrigation and rainfall events), during ACP-integrated pest management programs.

MATERIALS AND METHODS

Soil Sampling. The soil used in this study was IFS classified as sandy, siliceous, hyperthermic, Arenic Alaquods.[21] Soil samples were taken at the Southwest Florida Research and Education Center (SWFREC), University of Florida (UF), Immokalee, FL (latitude, 26° 27.75′ N; longitude, 81° 26.83′ W). The soil organic carbon (SOC) content was determined using the Walkley−Black method,[22] and the soil pH was determined with electrometric methods using a soil/solution ratio of 10:25 in water.[23] Soil cation-exchange capacity (CEC) and texture data were obtained from the Florida Soil Characterization Database of the Institute of Food and Agricultural Sciences (IFAS), UF.[24] The selected physical and chemical properties of IFS are presented in Table 1.

In a SWFREC experimental plot, planting beds for young citrus trees were built to conduct studies on IMD leaching and ACP control. During planting bed construction, soils from the A horizon (surface) and E horizon (albic, subsurface) were somewhat mixed. Soil samples from the planting beds were collected from five depths using a bucket auger with dimensions of 5.0 cm (inner diameter) × 15.0 cm. The soil samples from the planting beds were used for the sorption kinetics study (Table 2) to generate transport parameters to model IMD movement in the field during ACP control.

Table 2. OSMT Model Parameters (α and K_D) Optimized for IMD Sorption Kinetics Using an Initial Concentration (C_o) of 2.5 μg mL^{-1} Equilibrated in IFS Diagnostic Horizons A, E, and Bh[a]

[a]Soil samples are from citrus planting beds. Standard deviations are in parentheses. [b]K_D values are from 24 h batch sorption equilibrium isotherms.

The batch equilibria and degradation studies were conducted on IFS samples taken from a site with secondary forest regrowth. The soil samples were collected from a pit, from five depths divided in 15 cm increments from the soil surface. The five depths were representative of the A, E, and Bh soil diagnostic horizons of IFS (Table 1).

Soil Sorption Kinetics Experiments. A kinetic batch study was conducted to estimate equilibration times for the IMD concentration in solution using samples from disturbed (bedded) flatwood soils, from IFS diagnostic horizons A, E, and Bh. Triplicate 5 g samples of air-dried soil (m) were weighed in 50 mL centrifuge tubes (Nalgene, Thermo Scientific). The equilibration volume (v) was 10 mL of 0.01 M $CaCl_2$ spiked with three IMD concentrations of 2.5, 12.5, and 25 μg mL^{-1}, representing three initial soil solution concentrations (C_o; eq 1). The highest initial concentration used in the kinetics and batch studies was based on the label-recommended application rate for young non-bearing citrus trees in Florida, where IMD is soil-drenched around the tree trunk. Blank samples (no added IMD) were also prepared in 0.01 M $CaCl_2$. The centrifuge tubes (and soil samples) were equilibrated in the dark using an Eberbach horizontal shaker, for 2, 6, 14, and 24 h. After shaking, the tubes were centrifuged at 6000 rpm for 20 min, and then the supernatant was filtered with Whatman 42 filter paper. The filtrate was refiltered with a Fisherbrand 0.45 μm nylon sterile syringe filter before analysis by high-performance liquid chromatography with ultraviolet detection (HPLC−UV).

Batch Sorption Kinetics Model. The sorption kinetics phenomena in soils may be caused by the hydrophobicity or hydrophilicity of the organic chemical, the natural heterogeneity of sorption sites, and the diffusion pathways in the porous media.[25] In this study, the kinetic parameters were optimized using the one-site mass transfer model (OSMT; eqs 1−3). This model assumes that all sites in the soil have rate-limited sorption or type 2 sites.[26,27] The model is a special case of the two-site non-equilibrium (TSNE) model[28,29]

$$\frac{C_t}{C_o} = \frac{1}{R} + \left(1 - \frac{1}{R}\right)\exp[-\alpha R t] \quad (1)$$

$$R = 1 + (m/v)K_D \quad (2)$$

$$\beta = 1/R \quad (3)$$

where C_t is the solute concentration in solution (μg mL^{-1}) at any time, C_o is the initial IMD solution concentration (μg mL^{-1}), m is the mass of soil (g), v is the volume of soil solution (mL), R is the expression for retardation, β represents the fraction of retardation as a result of kinetic sites, α is the kinetic rate coefficient for desorption from type 2 sites (h^{-1}), t is the time (h), and K_D is the sorption coefficient at equilibrium (mL g^{-1}). The parameters α and K_D in the OSMT were optimized using nonlinear regression procedures.[30]

Soil Sorption Equilibria. The batch slurry equilibrium study was conducted using triplicated soil samples for each soil depth (0−15, 15−30, 30−45, 45−60, and 60−75 cm) and each equilibrium concentration. Triplicate 10 g samples of air-dried soil were weighed in 50 mL polycarbonate centrifuge tubes (Nalgene, Thermo Scientific). The soil samples were equilibrated with 10 mL of 0.01 M $CaCl_2$ solution spiked with IMD initial concentrations of 2, 4, 6, and 8 μg mL^{-1} (C_o; eq 4). Blank samples were also equilibrated in 0.01 M $CaCl_2$. All samples were equilibrated for 24 h in an Eberbach horizontal shaker. After equilibration, the tubes were centrifuged for 20 min at 6000 rpm and then filtered with Whatman 42 filter paper. Before analysis by HPLC−UV, the aqueous filtrate was refiltered with a Fisherbrand 0.45 μm nylon sterile syringe filter. The measured solution concentration was considered as equilibrium concentrations (C_e, μg mL^{-1}; eq 4). The IMD-sorbed equilibrium concentration (S_e, μg g^{-1}) is given by eq 4 based on mass balance

$$S_e = \frac{V}{m}(C_o - C_e) \quad (4)$$

$$S_e = K_D C_e \quad (5)$$

$$K_{OC} = K_D/OC \quad (6)$$

DOI: 10.1021/acs.jafc.5b00532
J. Agric. Food Chem. 2015, 63, 4915−4921

where v is the volume of solution added (mL) and m is the mass of oven-dry soil (g). The sorption coefficient K_D (mL g^{-1}) was calculated using simple linear regressions (eq 5) and then normalized to account for the influence of OC (soil organic carbon, g g^{-1}) on the sorption phenomena for hydrophobic organic compounds, such as IMD (eq 6).

Soil Degradation Study. IFS soil samples were maintained at the initial moisture content found in the field for the degradation study, to keep microbial communities as intact as possible. The samples from five depths (0−15, 15−30, 30−45, 45−60, and 60−75 cm) were thoroughly mixed, and the moisture content was measured. Triplicate 10 g samples of soil were weighed into polycarbonate centrifuge tubes (Nalgene, Thermo Scientific) and kept at room temperature (21 °C). The samples were spiked with an IMD solution in deionized water and homogenized with vortex for 2 min. The intended initial spiking concentration S_o was 10 μg of IMD/g of oven-dry soil. The tubes were stored in the dark, loosely capped, and maintained at a constant field capacity (FC) of 10% moisture content on a gravimetric basis. The FC water content (or mass) for each tube was checked every other week during the entire study period (514 days), by replacing any lost moisture with deionized water using a dropper. The final soil mass and moisture contents were checked before sample extraction.

The IMD degradation experiments consisted of soil samples from 0 to 15, from 15 to 30, and from 30 to 45 cm depths that were extracted at 9, 52, 120, 241, and 514 days after spiking. The soil samples from 45 to 60 and from 60 to 75 cm were extracted roughly every 12 weeks at 85, 168, 246, 329, and 434 days. Also, alongside the degradation experiment samples, autoclaved soil samples were spiked with the same solution, kept in a freezer, and then extracted to estimate IMD extraction efficiency as a function of time.

The spiked samples were extracted using a soil/solution ratio of 1:2, adding 20 mL of acetonitrile/water (80:20) to the centrifuge tubes. The samples were shaken for 2 h, centrifuged for 20 min at 6000 rpm, and then filtered with Whatman 42 filter paper. Before the analysis by HPLC−UV, the filtrates were diluted with HPLC-grade water (1:1) and refiltered with Fisherbrand 0.45 μm nylon sterile syringe filters. The fraction of organic solvent in the extracting solutions of acetonitrile/water was based on the solvophobic theory, which states that the sorption coefficient for hydrophobic organic compounds (HOCs) decreases exponentially as the fraction of organic co-solvent increases in the extracting mixture.[31,32]

Extraction Efficiency (ε), Degradation Rate (k), and Half-Life ($t_{1/2}$). The extraction efficiency was assumed constant during the degradation experiment for all soil depths. The initial IMD concentration in the soil sample was defined as S_o^* (μg g^{-1}), and the concentration at a given time was defined as S_t^* (μg g^{-1}). The asterisk (∗) denoted the measured extracted concentration not corrected for extraction efficiency ε (eq 7). The ε was the absolute extraction efficiency estimated for each soil depth at each extraction date, using autoclaved control samples to eliminate microbial degradation. After autoclaving, these samples were spiked with the same solution (to obtain an approximate initial concentration of 10 μg g^{-1}), and were frozen alongside unspiked samples. We assumed that the baseline to calculate ε was the concentration from the autoclaved frozen samples extracted about 9 days after spiking, because no IMD metabolites were observed from the autoclaved samples during analysis by HPLC−UV. This was conducted during the first 8 months of the degradation experiment (241 days), to ensure analytical consistency[15] and to avoid estimation errors for IMD degradation rates. Our study showed that IMD degradation followed a zero-order process for soil samples from all depths (eqs 7 and 8).

$$\frac{S_t^*}{\varepsilon} = \frac{S_o^*}{\varepsilon} - kt \tag{7}$$

$$S_t^* = S_o^* - k^*t \tag{8}$$

Here, we propose that the overall ε was constant during the experiment, affecting the estimate of k in the zero-order process (eqs 8 and 9). Assuming that ε was constant, the correct IMD degradation rate value (k) would be given by eq 9. Consequently, S_o ($S_o = S_o^*/\varepsilon$) and k (eq 9) were used in this study to estimate IMD half-life (eq 10) for each soil depth.

$$k = k^*/\varepsilon \tag{9}$$

$$t_{1/2} = S_o/2k \tag{10}$$

Analytical Procedures and Statistics. Analytical-grade standards for IMD were obtained from ChemService, Inc., West Chester, PA. A 100 ppm standard stock solution was prepared in 0.01 M $CaCl_2$, and mixed thoroughly. The sorption equilibrium batch spikes (2, 4, 6, and 8 μg mL^{-1}) were serially diluted in 0.01 M $CaCl_2$ using HPLC-grade water. The HPLC calibration curve for the batch samples had IMD concentrations of 0, 2.5, 5.0, and 10.0 μg mL^{-1}.

On each sampling date during the degradation experiment, freshly made calibration standards were prepared from a stock solution of 100 μg of IMD mL^{-1} in pure acetonitrile. The HPLC−UV calibration curve standards were serially diluted to solutions of 1.25, 2.5, 5.0, 10.0, and 20.0 μg of IMD mL^{-1} in a matrix of acetonitrile/water (40:60). The IMD soil extracts (degradation study) and equilibration solutions (sorption kinetics and sorption equilibria studies) were analyzed using an Agilent Infiniti 1260 HPLC−UV with a mobile phase of HPLC-grade acetonitrile/water (40:60), a Supelcosil LC-18 column (150 × 4.6 mm; Sigma-Aldrich Co.), an injection volume of 20 μL, a flow rate of 1 mL min^{-1}, and an absorption wavelength of 270 nm. The analysis by HPLC−UV for the sorption and degradation studies had limit of detection and quantitation (LOD and LOQ) values of 0.40 and 1.25 μg mL^{-1}, respectively (eqs 11 and 12)

$$\mathrm{LOD} = \mathrm{sd}t \tag{11}$$

$$\mathrm{LOQ} = 3\mathrm{LOD} \tag{12}$$

where sd is the standard deviation of the recovered spikes and t is the one-tailed statistic for 99% confidence using six replications. All degradation extracts were diluted with HPLC-grade water to obtain a mixture of acetonitrile/water of 40:60. All solutions were filtered before analysis by HPLC−UV using Fisherbrand 0.45 μm non-sterile syringe filters. The retention time for IMD under the above conditions was 2.70 min.

The K_D values and IMD degradation rate (k) values were obtained by a simple linear regression conducted in JMP Pro 9.[33] The linear regression fitted parameters were checked using analysis of variance (ANOVA) and t tests. Multiple comparison Tukey honestly significant difference (HSD) tests on the sorption coefficients (K_D) and degradation rates (k) were conducted using an analysis of covariance (ANCOVA) procedure to assess the effect of the covariate (soil depth) on the linear regression slopes between soil depths.[34]

RESULTS AND DISCUSSION

IMD Sorption Kinetics. IMD sorption kinetics data were fitted properly by the OSMT model.[28,35] The fitted parameters are summarized in Table 2 for each of the five soil depths. To avoid crowding the figures, the data presented correspond only to the 2.5 μg mL^{-1} initial concentration (C_o). Data in Figure 1 show that the OSMT model provided a good fit for IMD kinetic data, with a sharp decrease in the solution concentration and then reaching equilibrium between 6 and 12 h when the concentration in solution remained relatively constant. This trend was observed in every combination of C_o and soil depth. IMD has been reported to have a rapid equilibration time of 6 h or less in soils with low organic matter content, but the sorption kinetics data were described with various models.[36] However, the OSMT model has been reported to describe sorption kinetics of hydrophobic organic chemicals in soils and organoclays.[28,35]

The OSMT parameter α value was highest in the upper part of the E horizon (15−45 cm), which has the lowest organic matter content. The parameter α had lower values in the other sampling depths (A, E2, and Bh). Also, β values (eq 3) were

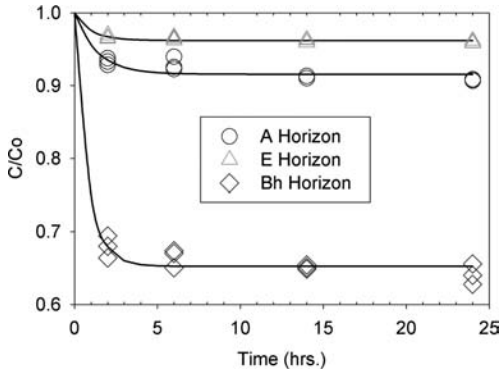

Figure 1. IMD sorption kinetics with an initial spiking concentration (C_o) of 2.5 μg mL^{-1} in IFS samples from A, E, and Bh soil horizons. Symbols indicate observed relative concentrations as a function of time. Solid lines represent the OSMT kinetic model.

close to 1 for all depths. This is in agreement with the OSMT model assumption that most sorption sites were kinetic. In essence, IMD showed that sorption equilibrium was reached much sooner than 24 h, which is the standard protocol for sorption equilibrium studies, confirming the validity of our batch equilibrium experiments and the obtained distribution coefficients (K_D).

IMD Sorption Equilibria. The sorption isotherms for IMD are shown in Figure 2. In Table 3, K_D values are compared

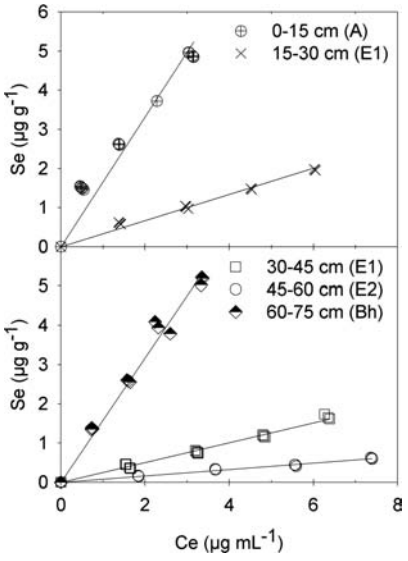

Figure 2. IMD sorption isotherms in samples from five soil depths (0−15, 15−30, 30−45, 45−60, and 60−75 cm) comprising IFS horizons A, E, and Bh (Table 3). Symbols represent equilibrium concentrations in solution (C_e) and soil sorbed (S_e).

between different depths and horizons. The K_D values for the 0−15 cm (A horizon) and 60−75 cm (Bh horizon) samples were very similar (1.66 ± 0.042 and 1.59 ± 0.032 mL g^{-1}, respectively). This was confirmed by Tukey's HSD test showing no significant differences between the two (q = 1.7; p > 0.50). The soil samples from the E horizon (15−30, 30−45, and 45−60 cm) were statistically different from each other (q = 36.8; p < 0.001). The sorption coefficients were lowest in the E horizon samples (0.08−0.31), as was expected because this soil horizon has the lowest organic matter content in IFS.

Table 3. IMD Sorption Coefficients (K_D and K_{OC}) for Different Depths (cm) and Diagnostic Horizons in IFS[a]

horizon	depth (cm)	K_D ± SE[b] (mL g^{-1})[c]	K_{OC}	log K_{OC}
A	0−15	1.66 ± 0.04 a	208	2.3
E1	15−30	0.31 ± 0.01 b	163	2.2
E1	30−45	0.23 ± 0.01 c	230	2.4
E2	45−60	0.08 ± 0.001 d	13	1.1
Bh	60−75	1.59 ± 0.03 a	63	1.8

[a]Soil samples are from IFS with secondary forest regrowth. [b]SE = standard error. [c]Different letters indicate significant difference between K_D values.

In essence, sorption equilibrium data confirmed that IMD was a weakly sorbed chemical in IFS (Table 3). However, the K_{OC} values for 45−60 cm (E2) and 60−75 cm (Bh) were much lower than the layers above (A and E1) and were not consistent with the K_{OC} concept. Initially, we hypothesized that the spodic layer would show higher IMD sorption. In contrast, the surface horizon samples (0−15 cm) showed higher K_{OC} value than the Bh horizon. It is possible that the nature and functional groups of the organo-mineral complexes in the Bh horizon could have reduced IMD sorption on this layer.

Previous studies have suggested that IMD sorption in soils is predominantly explained by the soil organic carbon content,[11] which is a characteristic for hydrophobic organic chemicals partitioning in soils.[37] IMD studies on soil sorption have found similar values for IMD K_{OC} in soils with low organic matter content. Liu et al.[38] found values averaging 220 in soils with low organic matter content (0.25−0.71%).

IMD Degradation. The extraction efficiency (ε) data obtained from the autoclaved−frozen soil samples did not show a significant relationship with time based on the linear regression (p > 0.31; Table 4). The data confirmed the assumption that our degradation experiments had an extraction efficiency (ε) constant as a function of time, as was previously reported for IMD.[15] However, the co-solvents used in our study (80:20 acetonitrile/water) yielded ε values very close to 100% during the first 8 months of the degradation experiment, especially in the A and E horizons (Table 4). Therefore, if ε is 100%, then $k = k^*$ and $S_o = S_o^*$ (eqs 7−10).

Data in Figures 3 and 4 show the linear relationship between extracted concentrations and time (p < 0.0001) based on a zero-order degradation rate. The t tests on the regression slopes showed that k values were significantly different from zero (p < 0.0001). The degradation rates were also significantly different from each other, with p < 0.0001 (Table 5 and Figures 3 and 4). IMD degraded at different rates in the A horizon samples (0−15 cm) compared to the other depths. The E1 horizon samples (15−30 and 30−45 cm) showed very similar degradation rates as well as the highest $t_{1/2}$ values. The E2 layer (45−60 cm) and the Bh layer (60−75 cm) showed no significant difference in degradation rates and had the lowest $t_{1/2}$ values.

IMD half-life ($t_{1/2}$) ranged from 0.98 to 2.60 years across all sampling depths. The insecticide was very persistent at the rate used, and degradation was not a function of the concentration (i.e., a zero-order process). Baskaran et.al.[15] data were somewhat similar to ours, showing that IMD had $t_{1/2}$ values of 2.71 years in soils and 2.95−3.37 years in construction bedding materials (sand).

This is the first study evaluating IMD sorption and degradation in sandy soils of Florida. The data revealed that

IMD undergoing sorption kinetics is a weakly sorbed chemical with K_{OC} values of 163−230 in the A and E horizons and is very persistent, with $t_{1/2}$ of 0.98−2.60 years. The main concern in Florida Spodosols after IMD soil-drench applications is the shallow and fluctuating water table. This study showed that IMD sorption (and, therefore, retardation) would be lowest in the E horizon. Consequently, once the chemical moves beyond the first 15 cm of soil (A horizon), the potential for leaching beyond the citrus root zone increases considerably. This was an expected outcome for IFS that has a very low organic matter content, especially in the eluviated horizon (E), which is generally stripped of colloidal coatings (clay and organic matter) that could help to retain important plant nutrients[20] and possibly organic solutes, such as IMD.

Our data on IMD sorption and degradation confirmed a high potential for IMD leaching beyond the citrus root zone and that it is necessary to establish field studies to evaluate different IMD soil-drench application rates, to monitor irrigation and rainfall events after soil drenching, and to estimate how much leaching is occurring under such conditions. Furthermore, IMD fate and transport modeling in sandy soils of Florida will have to consider the plant uptake component, not only to avoid loss by leaching but also to ensure ACP control across seasons. In the event that IMD is actually leaching, one strategy would be to increase the residence time in the citrus root zone with

amendments of pyrolyzed organic matter (biochar) or organic composts.[39] These amendments as agricultural practices need further research and validation.

Behavior of Multiclass Pesticide Residue Concentrations during the Transformation from Rose Petals to Rose Absolute

Oriane Tascone,[†,‡] Yoann Fillâtre,[†] Céline Roy,[†] and Uwe J. Meierhenrich*[,‡]

[†]European Research Institute on Natural Ingredients (ERINI), 06130 Grasse, France

[‡]University Nice Sophia Antipolis, Institut de Chimie de Nice, UMR 7272 CNRS, 06108 Nice, France

ABSTRACT: This study investigates the concentrations of 54 multiclass pesticides during the transformation processes from rose petal to concrete and absolute using roses spiked with pesticides as a model. The concentrations of the pesticides were followed during the process of transforming the spiked rose flowers from an organic field into concrete and then into absolute. The rose flowers, the concrete, and the absolute, as well as their transformation intermediates, were analyzed for pesticide content using gas chromatography/tandem mass spectrometry. We observed that all the pesticides were extracted and concentrated in the absolute, with the exception of three molecules: fenthion, fenamiphos, and phorate. Typical pesticides were found to be concentrated by a factor of 100−300 from the rose flowers to the rose absolute. The observed effect of pesticide enrichment was also studied in roses and their extracts from four classically phytosanitary treated fields. Seventeen pesticides were detected in at least one of the extracts. Like the case for the spiked samples in our model, the pesticides present in the rose flowers from Turkey were concentrated in the absolute. Two pesticides, methidathion and chlorpyrifos, were quantified in the rose flowers at approximately 0.01 and 0.01−0.05 mg kg^{-1}, respectively, depending on the treated field. The concentrations determined for the corresponding rose absolutes were 4.7 mg kg^{-1} for methidathion and 0.65−27.25 mg kg^{-1} for chlorpyrifos.

KEYWORDS: *pesticides, rose flowers, concrete, absolute, natural extracts, dispersive SPE, aroma and perfume chemistry, cosmetic industry*

INTRODUCTION

Extracts of roses, such as essential oils (EOs) or absolutes, are among the leading products in the field of perfumes. Perfumes generated by the most prestigious brands use rose absolute in their formulations. More than approximately 10 tons of concrete and 4 tons of essential oils are produced worldwide each year despite their low extraction yields: 0.03% (w/w) for EO and 0.3% (w/w) for concrete.[1] The most commonly used roses are *Rosa damascena* species from Turkey, Bulgaria, and Morocco. Fewer roses are produced in France. *Rosa centifolia* is the only species cultivated in France.

In general, the EO from roses is obtained by steam distillation and mainly contains monoterpene alcohol (citronellol, linalool, nerol, geraniol).[2] The concrete from roses is obtained by maceration of rose flowers in *n*-hexane. This complex sample contains alcohols, terpenes, terpenoids, and stearoptenes.[3,4] The concrete is then extracted with ethanol to produce the absolute.[1,5] During this process, stearoptenes are usually removed from the concrete, while compounds such as phenylethyl alcohol, citronellol, geraniol, nerol, eugenol, nonadecane, nonadecene, and many others are extracted and concentrated in the absolute.

The crop production of these flowers is habitually based on monoculture and involves the use of pesticides. The raw materials intended for perfume, aroma, and cosmetic products have been increasingly regulated in terms of the residual levels of chemicals allowed because of their impact on public health and on the environment. During the processes of extraction, treatment, and concentration of the natural ingredients, pesticides have the potential to be coextracted with the target olfactory compounds.[6] However, presently, the behavior of the pesticides during the extraction and transformation of the natural ingredients remains unknown and requires a systematic analysis of the pesticides at each step during the process. As highlighted in a recent review, little research has been dedicated to the analysis of pesticides in natural extracts:[7] three studies mentioned multiclass pesticide analyses in essential oils,[8−10] three investigations were performed on concrete,[6,11,12] and there are no studies regarding absolutes.

Due to the extraction recovery and the few studies on absolutes, we describe here the concentration of pesticide during the extraction process from rose flowers to rose absolute. The first stage of our work was to develop new analytical methodologies based on dispersive solid phase extraction (d-SPE) to determine the pesticide content in those extracts.[13,14]

The study of pesticides was performed on spiked roses from an organic field and their extracts and on real samples of roses and their extracts from classically treated Turkish fields. Fifty-four pesticides that are representative of multiclass pesticide residues used in agricultural phytosanitary treatments, mainly in the form of organophosphates, organochlorines, and pyrethroids, were selected for the development of the method. Due to the chemical nature of the targeted molecules, a gas chromatograph/tandem mass spectrometry system (GC-MS/MS) was employed to quantify the pesticide residues.

MATERIALS AND METHODS

Chemicals and Materials. Acetonitrile (Optima LCMS grade) and acetic acid (HOAc Optima) were purchased from Fisher Scientific (Illkirch, France). Toluene (Chromasolv for HPLC 99.9% grade) was obtained from Sigma-Aldrich (Saint-Quentin Fallavier, France).

A modified QuEChERS approach for the sample preparation was developed. For the extraction/partitioning step, pouches (DisQuE) containing 1 g of sodium citrate, 1 g of sodium chloride, 4 g of magnesium sulfate ($MgSO_4$), and 0.5 g of sodium sesquihydrate were purchased from Waters (Wexford, Ireland). For the d-SPE cleanup, tubes containing 900 mg of $MgSO_4$, 150 mg of primary and secondary amines (PSAs), and 150 mg of C18 were obtained from Waters (Wexford, Ireland). A 150 μg graphitized carbon black (GCB) sorbent purchased from Agilent Technologies (Massy, France) was added to the cleanup tubes. The reconstituted matrix contained phenethyl alcohol from Yinghai (Canghzou, People's Republic of China), citronellol from BASF (Ludwigshafen, Germany), linalool from DSM Nutritional (Heerlen, Netherlands), geranyl acetate, citronellyl acetate, and eugenol that were internally prepared, and alkanes (C_7−C_{40}), geraniol, and fatty acid esters from Sigma-Aldrich (Saint-Quentin Fallavier, France).

The pesticide reference standards (mixture and individual standards) were of ≥95% purity and were obtained from CPI International (Santa Rosa, USA) and Dr. Ehrenstorfer GmbH (Augsburg, Germany).

Preparation of the Standard Solution. Individual pesticide standard stock solutions were prepared at 1000 μg mL^{-1} in toluene and stored at −18 °C. From these solutions, a 100 μg mL^{-1} working standard mixture (mix 1) in toluene was prepared. Two other mixtures of pesticides from CPI International at 1000 μg mL^{-1} were mixed and diluted in toluene to 100 μg mL^{-1} (mix 2). Mix 1 and mix 2 were stored at −18 °C and used for the preparation of the matrix-matched calibration levels.

A third mixture (mix 3) was prepared to spike the roses. One milliliter of each individual pesticide standard (1000 μg mL^{-1}) and the two mixtures of pesticide standards from CPI International (1000 μg mL^{-1}) were mixed in 200 mL of ethanol.

Origin and Transformation of the Rose Flowers. Rose flowers from both organic and nonorganic origins were collected to produce concretes and absolutes following the process described in Figure 1. To study the behavior of pesticides during the illustrated transformation process, 22.5 kg of French *centifolia* roses was picked from a French organic field at the Musée International de la Parfumerie (MIP) in Grasse. From the 22.5 kg of rose flowers, 10 kg was spiked (MIP spiked flowers) with 54 pesticides at a concentration of 0.1 mg kg^{-1}. To improve the uniformity and to simplify the spiking, flowers were divided into five barrels with exactly 2 kg each. In each one, the flowers were spiked by pulverization with 40 mL of mix 3. Small quantities of spiked flowers were spiked gradually and mixed until all 2 kg of the flowers was spiked. After 24 h of permeation, the MIP spiked flowers were combined and extracted for the production of the concrete. The remaining 12.5 kg of MIP organic flowers was used as a blank.

To evaluate the results obtained from the MIP organic spiked flowers, *damascena* rose flowers coming from four different nonorganic fields in Turkey were collected. These fields were chosen according to the confidence in the farmers regarding the veracity of their field treatments. To be consistent with our previous article, we named these fields B−E.[13]

All six rose flower samples (MIP organic flowers, MIP spiked flowers, and field B−E flowers) were transformed into concrete by a maceration of the roses in *n*-hexane followed by a filtration step and finally solvent evaporation. The absolute was produced by extracting 20 g of the concrete with ethanol followed by freezing of the mixture, filtration, and solvent evaporation. For each step of the process, the weights of the initial sample and the final extract, as well as the extraction recoveries, were recorded as indicated in Figure 2. For the MIP experiments, samples of fresh and spent roses, extracts, waste, and solvents (before and after the process) were taken at each step of the transformation for analysis of the pesticide residues. For Turkish fields, samples of fresh roses, the concrete, and the absolute were analyzed.

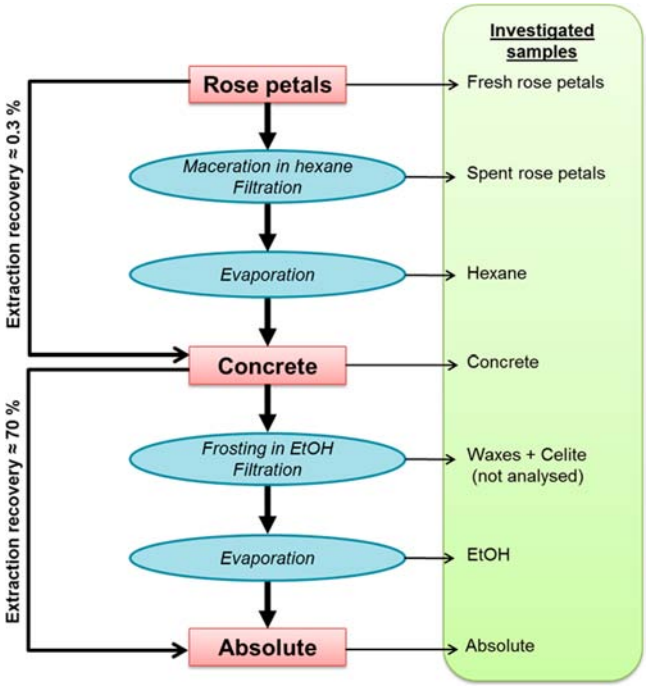

Figure 1. Transformation process from rose flowers to absolute and a list of the investigated samples for each transformation step. The average total mass recoveries of the concrete and absolute extractions are indicated.

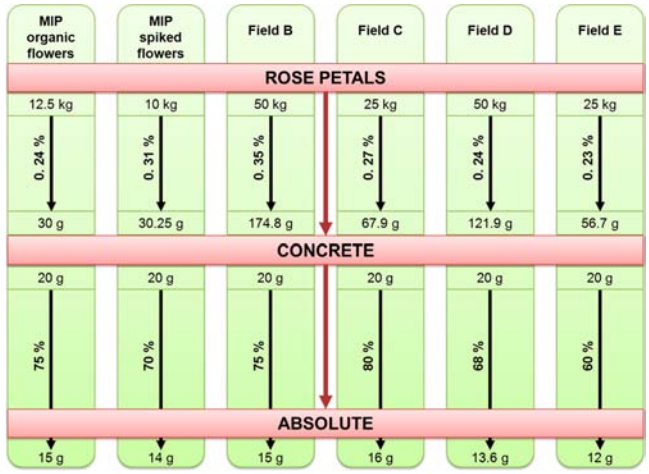

Figure 2. Total mass recoveries for the extraction of each rose. The recoveries for the transformation of rose from petal to concrete varied between 0.23% and 0.35%. In each case, 20 g of concrete was extracted. This step was performed on a laboratory scale, and the recoveries showed relatively large variation between 60% and 80%.

Sample Preparation. The rose flowers were cut and immediately stored in the freezer at −18 °C. Due to the close dry weight of fresh flowers and spent rose flowers (approximately 20%), fresh and spent rose flowers were prepared using the previously published validated protocol.[13] Briefly, 100 g of the rose flowers was ground and homogenized after freezing. A 5.0 g subsample of the rose flowers was transferred into a 50 mL centrifuge tube, and 15 mL of acetonitrile was added. The tube was shaken by hand for 1 min and placed in the refrigerator at 4 °C for 4 h. The contents of a pouch ($MgSO_4$, sodium citrate, NaCl, and sodium sesquihydrate) were added to the tube to remove any residual water and to assist in the extraction of the

DOI: 10.1021/acs.jafc.5b00985
J. Agric. Food Chem. 2015, 63, 4922−4932

pesticides from the matrix. The tube was vigorously shaken with a vortex mixer for approximately 30 s. Subsequently, the mixture was centrifuged for 10 min at 2630 rcf. Then, 8.0 mL of the supernatant was transferred into a d-SPE cleanup tube containing $MgSO_4$ (900 mg), PSA (150 mg), C18 (150 mg), and GCB (150 mg), and 3 mL of toluene was added. The tube was vigorously shaken with a vortex mixer for 1 min. Subsequently, the mixture was centrifuged for 10 min at 2630 rcf. The extract was transferred into a second purification tube that also contained $MgSO_4$, PSA, C18, and GCB and shaken with a vortex mixer. After centrifugation, 4 mL of the resulting solution was evaporated under nitrogen flow at 35 °C until approximately 200 μL remained. Then, the residue was transferred into a GC vial. The tube was washed with a small amount of toluene. The final volume was adjusted to 1 mL.

For the concretes and absolutes, the protocol previously described and validated was applied with slight modifications.[14] The main modifications of the protocol used for the rose flower samples were the weight of the subsample, 2.5 g of the concrete and 2.5 g of the absolute (compared to 5.0 g used for the rose flowers), and the addition of 2.5 g of water. Additionally, a 2-fold dilution of the final extract was performed just before analysis of the absolute.

For analysis of the *n*-hexane and ethanol solvents, 50 mL of the solvent was evaporated under a nitrogen flow to 500 μL and analyzed by GC-MS/MS. The quantification was performed using external calibration.

Each described sample (roses, concrete, absolute, and solvents) was prepared and analyzed in duplicate.

GC-MS/MS Analysis. GC-MS/MS analyses were performed on an Agilent 7000 triple-quadrupole mass spectrometer interfaced with an Agilent 7890A GC system. The GC was equipped with a fused silica 95% dimethylpolysiloxane 5% phenyl capillary ZB5-MSi (30 m × 0.25 mm i.d. × 0.25 μm film thickness) column from Phenomenex (Le Pecq, France). The carrier gas was helium at a constant flow of 1 mL min^{-1}. The GC was equipped with an Agilent 7683 autosampler and a split/splitless injector. The temperature program was as follows: initial temperature of 90 °C, held at 90 °C for 1 min, 30 °C min^{-1} ramped to 180 °C, then 3 °C min^{-1} ramped to 280 °C, and held at 280 °C for 5 min. The temperature of the injection port was 280 °C, and a 1 μL volume was injected in pulsed splitless mode.

The MS transfer line and ion source temperatures were both set to 280 °C. An electron ionization energy of 70 eV was used.

Analyses were performed in the selected reaction monitoring (SRM) mode on the basis of the use of one transition for quantification (quantifier) and one transition to confirm the compound identity (qualifier). For each analyte, the collision energy (CE) was optimized. To optimize the sensitivity of the detection of each pesticide, the SRM method was divided into 20 time segments.

RESULTS AND DISCUSSION

Pesticide Concentrations in MIP Spiked Flowers. The first step of the study was to determine the initial concentration of pesticides in the MIP spiked flowers (c_0) after a theoretical spiking of 0.1 mg kg^{-1}. It is important to precisely determine the amount of pesticides absorbed by the rose flowers, which is likely to be extracted in the concrete and then in the absolute. The analysis of the blank sample of the MIP organic flowers showed that no pesticides were present (limit of quantification: 0.01 mg kg^{-1}) prior to spiking.

For the MIP spiked flowers, the pesticide concentrations (c_0) determined, along with their recovery rates (R_0), calculated from a theoretical spiking of 0.1 mg kg^{-1}, are detailed in columns 3 and 4 of Table 1.

The bar charts in Figure 3 depict the number of active substances as a function of the recovery rate (R_0).

As shown in Figure 3, 52 molecules were quantified, 17 molecules of which showed $R_0 < 50\%$ (undetected < c_0 < 0.05 mg kg^{-1}); 5 molecules showed $50\% \le R_0 < 70\%$ (0.05 mg $kg^{-1} \le c_0 <$ 0.070 mg kg^{-1}), and 29 molecules showed $70\% \le R_0 \le 120\%$ (0.07 mg $kg^{-1} \le c_0 \le$ 0.12 mg kg^{-1}). The 2,4-D isopropyl ester and acetochlor were undetected (ND) (signal to noise ratio <3). One pesticide, endosulfan sulfate, showed $R_0 > 120\%$ ($c_0 >$ 0.12 mg kg^{-1}). It should be noted that, according to our previous article,[13] the determinations of pesticides in flowers are validated with a reporting limit of quantification of 0.05 mg kg^{-1} for all pesticides. However, for most of the pesticides, the analytical sensitivity was sufficient to enable an accurate quantification below 0.05 mg kg^{-1}. Therefore, we considered it important to report the results for the 19 pesticides with $c_0 <$ 0.05 mg kg^{-1}, although they should be considered with caution.

As shown in Table 1, most of the low recovery rates were observed for the pesticides that eluted early. Indeed, 19 pesticides among the first 23 eluted pesticides had recoveries ND < R_0 < 59%. This phenomenon can be attributed to both the volatility of the residues and the experimental conditions for the pesticide application. The spiking solution, which was made from pesticide standards without a fixing agent, as in commercial solutions, was sprayed on the MIP rose flowers stocked in barrels outside where the temperature was approximately 20−25 °C. Then, the barrels were left half-opened to avoid maceration and they remained outside for 24 h before the concrete extraction. Therefore, the probability of volatilization of some of the pesticides is rather high. Another explanation could be the degradation of the residues containing a thioether group (for example, fenthion and fenamiphos), which are known to be prone to oxidation.[15] Under the conditions found in the environment, they usually quickly degrade to sulfoxide and sulfones. Thiophosphate sulfides (for example, malathion and parathion-methyl) can be oxidized to oxons.[15]

Endosulfan sulfate is a particular case, because it is the only pesticide that exhibits a high recovery rate (R_0 = 135%) and a high concentration (c_0 = 0.135 mg kg^{-1}) in the rose flowers. Endosulfan sulfate is known to be the main metabolite resulting from the degradation of endosulfans.[16] The low α-endosulfan concentration (c_0 = 0.043 mg kg^{-1}, R_0 = 43%) corroborates the hypothesis for the degradation of endosulfan. α,Endosulfan is known to be less stable than β-endosulfan (c_0 = 0.109 mg kg^{-1}, R_0 = 109%).

A complete explanation of these results would require further investigations that are beyond the scope of this paper. The aim was to determine the amount of pesticides likely to be extracted during the production of concretes and absolutes. Therefore, the previously determined pesticide concentrations c_0 in MIP spiked rose flowers will serve as a reference for the rest of the study.

Pesticide Concentrations in the Concrete from the MIP Spiked Roses. To examine pesticide concentrations during the extraction of the MIP spiked rose flowers in the concretes, samples of concretes, spent roses, *n*-hexane before extraction, and *n*-hexane after extraction were analyzed.

The analysis of the concrete from the MIP organic flowers (blank matrix) showed that no pesticide was present and/or introduced during the process. Analyses of *n*-hexane showed that no pesticides were present before the extraction, but some traces of pesticides were found in the *n*-hexane after the extraction (Table 1 column 9, c_{hexane}). Twenty-two pesticides were detected below the limit of quantification (LOQ), and six pesticides (phorate, lindane, fenitrothion, chlorpyrifos, parathion, and triazophos) were quantified at 0.01 mg L^{-1}.

The analysis of spent roses showed the presence of all the pesticides except 2,4-D isopropyl ester, acetochlor, and

fenamiphos. The respective concentrations of each pesticide found in the spent roses ($c_{1,spent}$) are reported in Table 1, column 8, and in the bar charts of Figure 4, which depict the

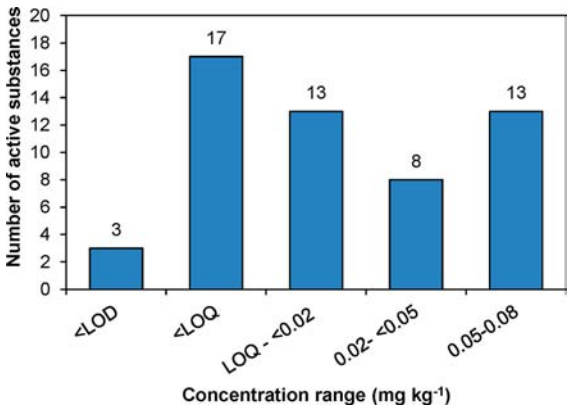

Figure 4. Distribution of the pesticide concentrations in the spent roses ($c_{1,spent}$). Thirty-three pesticides showed concentrations lower or close to the limit of quantification. Seventeen molecules were detected below the LOQ (0.01 mg kg^{-1}).

number of pesticides found within different concentration ranges in the spent roses.

As shown in Figure 4, 33 of the 54 pesticides have $c_{1,spent}$ < 0.02 mg kg^{-1}. Twenty pesticides had $c_{1,spent}$ < LOQ. Most of these 20 pesticides corresponded to the pesticides showing the lowest concentrations in the rose flowers (c_0). More than half of the pesticide content remained in the spent roses for the 13 pesticides quantified between 0.05 and 0.08 mg kg^{-1}.

The analysis of the concrete showed that all of the pesticides were detected in the concrete. The determined concentrations c_2 for each pesticide are shown in Table 1, column 6. On the basis of the experimental results for the fresh roses (c_0) *and* of the recoveries from the concrete extraction (Figure 2), the maximum concentration of the pesticides in the concrete (c_2'), corresponding to 100% pesticide transfer from the MIP spiked roses to the rose concrete, can be calculated. Assuming that a pesticide is fully extracted following an average concrete extraction yield of 0.31% (see Figure 2), the theoretical concentration of a pesticide in the concrete (c_2') is 323-fold the concentration of a pesticide in the rose flowers (Table 1, column 5):

$$c_2' = 323c_0$$

On the basis of this value, the corresponding recovery rates (R_2) were calculated: $R_2 = 100c_2/c_2' = 100c_2/(323\ c_0)$. The observed concentrations of pesticides in the concrete vary from c_2 = 0.85 mg kg^{-1} (2,4-D isopropyl ester) to c_2 = 18.87 mg kg^{-1} (lindane), and the recovery rates span from R_2 = 35% (*p,p′*-DDT) to R_2 = 315% (parathion-methyl).

The results are illustrated in the bar charts of Figure 5, which show the superposition of the pesticide amounts in the spent roses and in the concrete ($c_0 + c_2$) in comparison to the theoretical pesticide amounts in the concrete (c_2'). This representation shows the amount of each pesticide (in mg) coextracted into the concrete, the amount that remained in the spent roses, and the comparison of the total of these two with the theoretical value, assuming a 100% transfer of the pesticides into the concrete.

In Figure 5, two groups of pesticides can be distinguished. Group G1 contains the 46 pesticides whose levels found in the concrete and the spent roses agree with the theoretical quantity. Within this group, 2 subgroups can be distinguished.

G1a: 11 pesticides were quantified in the concrete and had a low concentration in the spent roses ($c_{1,spent}$ < LOQ). Their concentrations varied from c_2 = 5.96 mg kg^{-1} (fenamiphos) to c_2 = 18.87 mg kg^{-1} (lindane), and the recovery rates ranged from R_2 = 62% (isofenphos) to R_2 = 116% (fenitrothion).

G1b: 35 pesticides, including chlorpyrifos, prothiofos, DDT isomers, ethion, cypermethrin isomers, and cyfluthrin isomers, were found to be distributed between the spent roses and the concrete. Between 2% (endosulfan sulfate) and 84% (*p,p′*-DDE) of the pesticide content remained in the spent roses.

The second group, G2, is composed of 8 pesticides (o-phenylphenol, phorate, propetamphos, diazinon, chlorpyrifos-methyl, parathion-methyl, malathion, and methidathion) that have concentrations c_2 above the maximum concentration c_2' and recovery rates R_2 of between 135% (chlorpyrifos-methyl) and 315% (parathion-methyl). With the exception of chlorpyrifos-methyl, none of these pesticides were found in the spent roses. All of these pesticides had the 11 lowest concentrations in the MIP spiked roses (near LOQ or not detected). As mentioned in the previous section, the concentrations of these pesticides in the MIP spiked roses were lower than the reporting limit of 0.05 mg kg^{-1}, and the results are subject to errors. These recovery rates can be explained by considering the low concentrations in the fresh roses and the potentially high concentration factor in the concrete (323-fold concentrated). A difference of 0.01 mg kg^{-1} in the quantification of the pesticides in the fresh roses leads to a difference of 3.23 mg kg^{-1} in the concrete and could therefore have a significant impact on R_2. The effect is presented in Table 2 for 4 of the pesticides. According to these results, an underestimation of 0.01 mg kg^{-1} in the pesticide concentrations in the MIP rose flowers yields recoveries in the concrete closest to 100%. For example, taking into account an underestimation of 0.01 mg kg^{-1} in the rose (c_{0max} = 0.023 mg kg^{-1}) for phorate yields a theoretical concentration of c_{2max}' = 7.42 mg kg^{-1} in the concrete. Thus, the corresponding recovery rate would be $R_{2,min}$ = 117%. Similar phenomena were observed for the 3 other pesticides (chlorpyrifos-methyl, $R_{2,min}$ = 106%; methidathion, $R_{2,min}$ = 113%; propetamphos, $R_{2,min}$ = 113%).

Pesticide Concentrations in the Absolute from the MIP Concrete. To examine the concentrations of pesticide during the transformation from the concrete to the absolute, samples of the absolute, as well as ethanol (before and after extraction), were analyzed for pesticide levels.

DOI: 10.1021/acs.jafc.5b00985
J. Agric. Food Chem. 2015, 63, 4922−4932

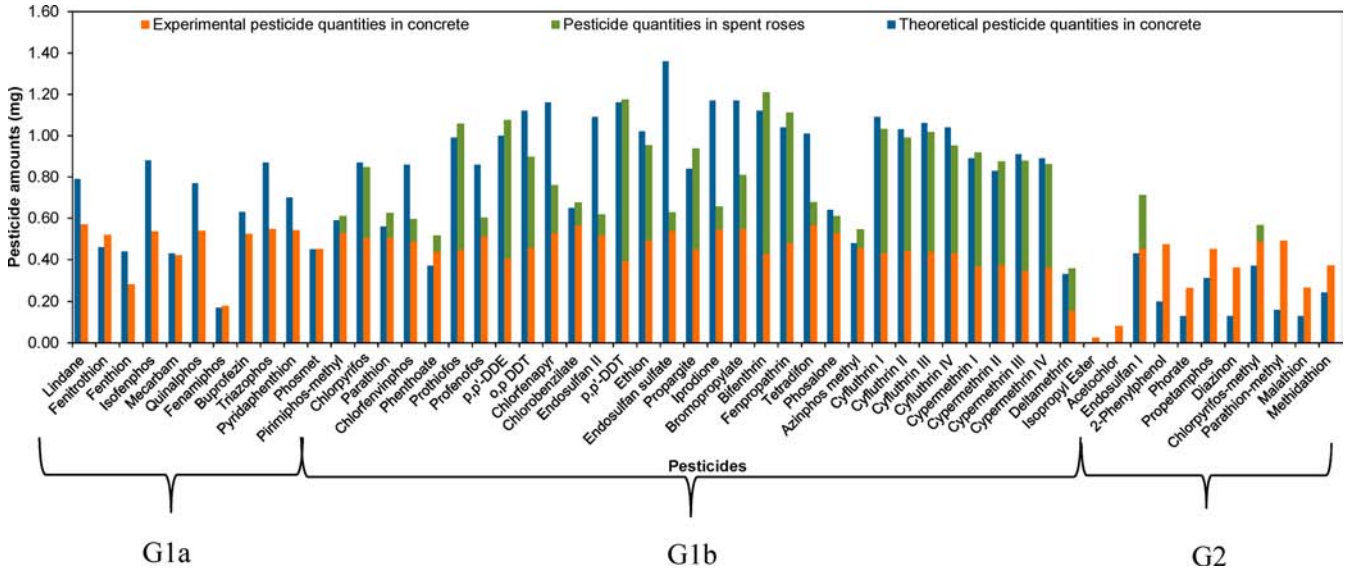

Figure 5. Pesticide content in the spent roses (green) and in the concrete (orange) in comparison to the theoretical pesticide content in the concrete (blue). Pesticide quantities in the fresh roses were distributed in the concrete and in the spent roses for most of the investigated molecules. Two groups can be distinguished: G1 with G1a and G1b, in which the theoretical pesticide amounts are in agreement with the total pesticide amounts in the spent roses and the concrete, and G2, in which the pesticide content in the concrete is above theoretical amounts.

Table 2. Examples of the Effect of the Variation in the Pesticide Concentrations in the MIP Spiked Roses on the Pesticide Concentrations in the Concrete and on the Recovery Rate R_2[a]

	c_0 ($c_{0,min}$–$c_{0,max}$) (mg kg^{-1})	c_2' ($c_{2,min}'$–$c_{2,max}'$) (mg kg^{-1})	c_2 (mg kg^{-1})	R_2 ($R_{2,min}$–$R_{2,max}$) (%)
chlorpyrifos-methyl	0.037 (0.027–0.047)	11.94 (8.71–15.17)	16.11	135 (106–185)
phorate	0.013 (0.003–0.023)	4.19 (0.96–7.42)	8.71	208 (117–907)
propetamphos	0.031 (0.021–0.041)	10.00 (6.77–13.23)	14.91	149 (113–220)
methidathion	0.024 (0.014–0.034)	7.74 (4.51–10.97)	12.29	159 (113–272)

[a]Abbreviations: c_0 ($c_{0,min}$–$c_{0,max}$), pesticide concentrations in the MIP spiked roses (concentration taking into account a variation of 0.01 mg kg^{-1} in c_0); c_2' ($c_{2,min}'$–$c_{2,max}'$), maximum pesticide concentration in the concrete from MIP spiked roses (theoretical concentration in the concrete from the MIP spiked roses taking into account a variation of 3.23 mg kg^{-1} in c_2'); c_2, pesticide concentrations quantified in the concrete; R_2 ($R_{2,min}$–$R_{2,max}$), recovery rates between the maximum theoretical concentrations of pesticides in the concrete and quantified pesticide concentrations in the concrete (recovery rate taking into account the variation in c_2').

The analysis of the blank matrix (the absolute from the concrete that originated from the MIP organic flowers) showed that no pesticide was present or introduced during the transformation process.

Analyses of the ethanol showed that no pesticides were present prior to extraction and some traces of pesticides were found in the ethanol after the extraction, $c_{ethanol}$ (Table 1, column 15). Seven of the pesticides had levels below the LOQ, and 13 of the pesticides were determined to be $c_{ethanol} \geq 0.01$ mg L^{-1}. Two of the pesticides, *o*-phenylphenol and lindane, were determined to be $c_{ethanol} = 0.03$ and 0.04 mg L^{-1}, respectively. The $c_{ethanol}$ values measured are considered relatively small and are therefore negligible for this pesticide study.

The analyses of the absolute from the MIP spiked roses showed the presence of all the pesticides in this extract, as indicated by c_3 (Table 1, column 13). The calculated concentrations, c_3', that correspond to a 100% pesticide transfer from the concrete to the absolute are shown in Table 1 column 12. As shown in Figure 2, the recovery from the absolute extraction was 70%. Thus, the extracted pesticides are potentially concentrated 1.4-fold from the concrete to the absolute:

$$c_3' = 1.4c_2$$

All of the pesticides were extracted in the absolute with recovery rates R_3 between 69 and 88%, with the exception of *o,p'*-DDT ($R_3 = 57\%$), phorate ($R_3 = 2\%$), fenthion ($R_3 = 2\%$), and fenamiphos ($R_3 = 2\%$). The levels of phorate ($c_{ethanol} = 0.1$ mg L^{-1}), fenthion ($c_{ethanol} <$ LOQ), and fenamiphos ($c_{ethanol} <$ LD) in ethanol are not sufficient to explain the very low R_3 values. More probable explanations are that the pesticides were retained in waxes blended with Celite, which were not analyzed, or were degraded during the concrete transformation process.

The model on MIP spiked roses showed that some pesticides were lost during the spiking of pesticides. During the transformation of the rose flowers to the concrete, we observed that the majority of the pesticides are extracted and concentrated into the concrete, although some of the pesticides did partially remain in the spent roses. With the exceptions of phorate, fenthion, and fenamiphos, all of the pesticides present in the concrete were also extracted into the absolute with $R_3 > 57\%$. Therefore, during the entire process, the pesticides present in flowers were found to be at least 100-fold concentrated in the absolute (Table 1, column 16). To verify this trend, the same study was performed on 4 samples from the Turkish fields.

Real Samples Cultivated in Turkey. The behavior of the pesticides was studied in roses and their extracts were obtained from classically treated crops. Four fields were investigated, and in each case, the rose flowers, concretes, and absolutes were analyzed for their pesticide content. For consistency with our

DOI: 10.1021/acs.jafc.5b00985
J. Agric. Food Chem. 2015, 63, 4922–4932

previous article, we named these samples B−E, corresponding to the 4 different fields.[13] The treatment was performed on the selected fields at least 3 weeks before harvest (rose tree with rose bud, before rose blooming). To our knowledge, only chlorpyrifos among the 54 targeted pesticides was applied to fields D and E. The other pesticides applied to these fields, including imidacloprid, thiacloprid, and hexaconazole, are not in our list and are amenable to liquid chromatography. Table 3 summarizes the results of the pesticide content found in the rose flowers, the concrete, and the absolute for each field.

Samples Cultivated from Field B. Among the 54 targeted pesticides, 11 pesticides were detected in at least one of the 3 samples (rose, concrete, or absolute). Most of them were present in amounts below the LOQ. Only cypermethrin isomers ($c_{3,B} \approx 0.25$ mg kg^{-1} in the absolute), methidathion ($c_{2,B} = 0.22$ mg kg^{-1} in the concrete, $c_{3,B} = 0.22$ mg kg^{-1} in the absolute), and chlorpyrifos ($c_{0,B} = 0.01$ mg kg^{-1} in the rose flowers, $c_{2,B} = 1.63$ mg kg^{-1} in the concrete, $c_{3,B} = 1.73$ mg kg^{-1} in the absolute) could be quantified. Thus, the corresponding recovery rates during the concrete extraction ($R_{2,B}$) and during the absolute extraction ($R_{3,B}$) were calculated for methidathion ($R_{3,B} = 75\%$) and for chlorpyrifos ($R_{2,B} = 47\%$; $R_{3,B} = 79\%$).

These recovery rates for the transformation from the concrete to the absolute are consistent with our previous results in our model spiked samples, in which chlorpyrifos and methidathion were extracted at $R_3 = 78\%$ and 76% into the absolute, respectively. A more significant difference was observed for the recovery rate of chlorpyrifos during the concrete extraction for the sample from field B. In our spiked model, chlorpyrifos was extracted at $R_2 = 60\%$ in the concrete, whereas it was extracted at $R_{2,B} = 47\%$ in the concrete from field B.

Samples Cultivated from Field C. Among the 54 targeted pesticides, 14 pesticides were detected in at least one of the 3 samples (rose, concrete, or absolute). Unlike the results for field B, most of them were present in amounts above the limit of quantification. Cypermethrin isomers (in the rose flowers, concrete, and absolute), chlorpyrifos, malathion, methidathion, *p,p′*-DDT, *o,p′*-DDT, and *p,p′*-DDE (all in the concrete and absolute) were quantified. Thus, the recovery rates could only be determined for the cypermethrin isomers ($R_{2,C} = 16\%$; $R_{3,C} = 120\%$) during concrete extraction and absolute extraction. For the other pesticides, only the recovery rates for the absolute extraction ($R_{3,C}$) could be determined.

For chlorpyrifos ($R_{3,C} = 80\%$), malathion ($R_{3,C} = 76\%$), and methidathion ($R_{3,C} = 80\%$), the recovery rates observed for the transformation process from the concrete to the absolute were consistent with our previous results using our MIP spiked samples, in which chlorpyrifos, malathion, and methidathion were extracted at $R_3 = 78\%$, 76%, and 76%, respectively, in the absolute. More significant differences were observed for the recovery rates of *p,p′*,-DDT, *o,p′*-DDT, *p,p′*-DDE, and cypermethrin isomers, with differences between 11% for *p,p′*-DDE and 49% for cypermethrin isomers and *p,p′*-DDT. As in our MIP spiked samples, less than 50% of *o,p′*-DDT was extracted during the absolute extraction.

Samples Cultivated from Field D. With the exception of acetochlor, the same 13 pesticides found for samples from field C were detected in at least 1 of the 3 samples (rose, concrete, or absolute). Most of the pesticides were present in amounts above the limit of quantification. Only chlorpyrifos and methidathion were quantified in all three samples ($c_{0,D}$ = 0.05 and 0.01 mg kg^{-1} in the rose flowers, $c_{2,D} = 18.87$ and 3.42 mg kg^{-1} in the concrete, and $c_{3,D} = 27.78$ and 5.03 mg kg^{-1} in the absolute, respectively). The other pesticides were quantified in the concrete and the absolute, with recovery rates of extraction in the absolute of $32\% < R_{3,D} < 141\%$.

The observed recovery rates for malathion, *p,p′*-DDT, *o,p′*-DDT, and *p,p′*-DDE were within the same order of magnitude as those previously obtained for the samples from field C. More significant differences were observed for the recovery rates of chlorpyrifos ($R_{2,D} = 100\%$) and methidathion ($R_{2,D} = 64\%$) during the extraction from the rose flowers in comparison to those obtained in our MIP spiked samples ($R_2 = 60\%$ and 159%, respectively). These differences were also significant for the recovery rates of chlorpyrifos ($R_{3,D} = 98\%$) and methidathion ($R_{3,D} = 93\%$) during the absolute extraction in comparison to those obtained in our MIP spiked samples ($R_3 = 78\%$ and 76%, respectively). The chlorpyrifos recovery rates were higher than those obtained for the samples from the other studied fields for this pesticide.

Samples Cultivated from Field E. Among the 54 targeted pesticides, 11 pesticides were detected in at least one of the 3 samples (rose, concrete, or absolute). Four pesticides were detected in amounts below the limit of quantification. As in the case of field D, only chlorpyrifos and methidathion were quantified in all three samples ($c_{0,E}$ = 0.05 and 0.01 mg kg^{-1} in the rose flowers, $c_{2,E} = 4.74$ and 1.64 mg kg^{-1} in the concrete, and $c_{3,E} = 9.52$ and 2.60 mg kg^{-1} in the absolute, respectively). The levels of malathion ($c_{2,E} = 0.07$ mg kg^{-1} in the concrete, $c_{3,E} = 0.10$ mg kg^{-1} in the absolute) and cypermethrin isomers ($c_{3,E} = 0.16$ mg kg^{-1} in the absolute) were also quantified. Thus, the corresponding recovery rates for the concrete extraction ($R_{2,E}$) and for the absolute extraction ($R_{3,E}$) were calculated for malathion ($R_{3,B} = 84\%$), methidathion, and chlorpyrifos.

The corresponding recovery rates obtained for methidathion ($R_{2,E} = 31\%$; $R_{3,E} = 95\%$) and chlorpyrifos ($R_{2,E} = 23\%$; $R_{3,E} = 120\%$) were significantly different from those obtained for our MIP spiked samples ($R_2 = 159\%$ and 60%, $R_3 = 76\%$ and 78%, respectively). The recovery rates obtained for the 2 pesticides chlorpyrifos and methidathion were respectively 4-fold and 2-fold lower than those obtained for the samples from field D.

Table 4 summarizes the minimum and maximum concentrations and recovery rates for each detected pesticide in each sample and for all the fields. Among the 54 targeted pesticides, 17 pesticides were identified. The pesticide concentrations varied between 0.01 mg kg^{-1} (chlorpyrifos, methidathion, and cypermethrin) and 0.05 mg kg^{-1} (chlorpyrifos) in the roses, between 0.04 mg kg^{-1} (diazinon, methidathion, and *p,p′*-DDE) and 18.9 mg kg^{-1} (chlorpyrifos) in the concrete, and between 0.03 mg kg^{-1} (*p,p′*-DDE) and 27.25 mg kg^{-1} (chlorpyrifos) in the absolute. Only chlorpyrifos and methidathion were detected in every field and in every sample. The observed recovery rates for the pesticide extraction during the rose extraction show a large range for chlorpyrifos, with values between 23% and 100%. Significant differences between the recovery rates of methidathion in the concrete from real samples (31−64%) and from MIP spiked roses (159%) are also noted.

Among the 17 pesticides identified in the 4 Turkish fields, nine pesticides are not approved in Europe under the regulation EC 1107/2009 (methidathion, DDT isomers, diazinon, parathion-methyl, acetochlor, profenofos, *p,p′*-DDE, and phosalone). Although Turkey is not subject to European regulations, it is important for importation. Two pesticides, chlorpyrifos and methidathion, were detected and quantified in each field throughout the transformation process from the rose flowers to the absolute via the concrete. In these 4 fields, the pesticides

[a]Abbreviations: $c_{0,min}$–$c_{0,max}$, minimum and maximum pesticide concentrations observed in roses from Turkish fields; $c_{2,min}$–$c_{2,max}$, minimum and maximum pesticide concentrations observed in the concrete from the roses cultivated in Turkish fields; $c_{3,min}$–$c_{3,max}$, minimum and maximum pesticide concentrations observed in the absolute from the roses cultivated in Turkish fields; $R_{2,min}$–$R_{2,max}$, minimum and maximum recovery rates between the theoretical concentrations of pesticides in the concrete and the quantified pesticide concentrations in the concrete; $R_{3,min}$–$R_{3,max}$, minimum and maximum recovery rates between the theoretical concentrations of the pesticides in the absolute and the quantified pesticide concentrations in the absolute; $R_{2,model}$, recovery rate observed in model obtained from MIP spiked roses, Table 1, column 7; $R_{3,model}$, recovery rate observed in model obtained from MIP spiked roses, Table 1, column 14.

that were present in the rose flowers were extracted and concentrated in the concrete and in the absolute. Their recovery rates were found to vary during the transformation process from one field to another and, in some cases, were significantly different from the recovery rates observed for our MIP spiked samples. Several parameters should be taken into account to explain these results. As previously detailed, the uncertainty of the quantification of the pesticides in the rose flowers near the LOQ combined with the high concentration factor that occurs during the concrete extraction is one possible explanation. Other explanations include the variation in the recoveries for the concrete extraction (Figure 2: 0.24–0.31%) and the absolute transformation (Figure 2: 60–80%) as well as the variation in rose species (MIP, *Rosa centifolia*; Turkey, *Rosa damascena*) and the differences in the industrial processes. For example, new *n*-hexane was used for each rose extraction of our MIP spiked samples, whereas in Turkey, the solvent was recycled, and cross-contamination could occur. A test of the *n*-hexane before extraction of the roses from field D revealed that chlorpyrifos was present in the solvent. To our knowledge, a different solvent batch was used for the extraction of the roses from field E.

CONCLUSION

This study systematically investigated the behavior of 54 pesticides during the extraction process from rose flowers to rose absolute via rose concrete. We showed that pesticides in the MIP spiked rose flowers were extracted with matrix molecules during the transformation process. With an initial concentration $c_0 \leq 0.1$ mg kg^{-1} in the MIP spiked rose flowers, the pesticides were concentrated to reach approximately 20 mg kg^{-1} in the final absolute. Thus, 34 of the targeted pesticides were concentrated between 100- and 300-fold from the MIP spiked roses to the MIP rose absolute. Three pesticides, fenthion, phorate, and fenamiphos, were concentrated less than 100-fold. Some pesticides, such as pirimiphos-methyl, fenitrothion, mecarbam, chlorobenzilate, phosmet, and azinphos-methyl, were concentrated more than 300-fold in the final absolute.

These results were confirmed by the analysis of rose flowers, concrete, and absolute from 4 treated Turkish fields. Indeed, 17 of the 54 pesticides were detected in at least one of the samples. In the process from the concrete to the absolute, the pesticides were concentrated with recovery rates between 32% (*o,p′*-DDT) and 130% (cypermethrin). In these Turkish fields, the concentration factor from the rose flowers to the absolute varied from 87 (cypermethrin in field C) to 545 (chlorpyrifos in field D). It is important to highlight that, with the exception of chlorpyrifos in fields D and E, none of the detected pesticides were applied to the fields during the year of crop. However, concentrations for these pesticides above 1 mg kg^{-1} were found in the concrete and the absolute. One hypothesis that explains their presence could be the persistence of pesticides over time due to old treatments or cross-contamination resulting from bag storage, solvents, or other crops in the same area as the rose fields.

Although some variation was observed in terms of recovery rates, this study shows for the first time that most of the investigated pesticides present in the raw materials (rose flowers) are extracted into the concrete and the absolute, leading to a significant concentration in these extracts. These results from the rose samples show the importance of controlling pesticide levels in natural extracts. Further investigation should be performed on the nonextracted pesticides, such as fenamiphos, which is approved by regulation, in the absolutes. Moreover, other phenomena, such as pesticide degradations and pesticide transformation, could occur in the plant crop or during the processing of the plant extraction and require further investigation.

Analysis of Polynuclear Aromatic Hydrocarbons in Olive Oil after Solid-Phase Extraction Using a Dual-Layer Sorbent Cartridge Followed by High-Performance Liquid Chromatography with Fluorescence Detection

Katherine K. Stenerson,* Olga Shimelis, Michael R. Halpenny, Ken Espenschied, and Maochun M. Ye

Sigma-Aldrich, 595 North Harrison Road, Bellefonte, Pennsylvania 16823, United States

ABSTRACT: A simple and easy direct solid-phase extraction (SPE) method was developed for the analysis of polynuclear aromatic hydrocarbons (PAHs) in olive oil using a dual-layer cartridge containing activated Florisil and a mixture of octadecyl (C_{18})-bonded and zirconia-coated silicas. Undiluted olive oil was applied directly to the SPE cartridge, and the sample was eluted with acetonitrile solvent. Background in the extract was found to be low enough for either gas chromatography–mass spectrometry (GC–MS) or high-performance liquid chromatography with fluorescence detection (HPLC–FLD) analysis. Average recoveries for 16 different PAHs from spiked olive oil replicates were >75%, with intraday precisions of <20% relative standard deviation (% RSD). Detection limits ranged from 0.2 to 1.0 μg/kg and, specifically for the PAHs listed in EC Regulation 835/2011, benzo(*a*)anthracene, chrysene, benzo(*b*)fluoranthene, and benzo(*a*)pyrene, were from 0.3 to 0.7 μg/kg. The method was then applied to determine the PAH content present in commercial samples of refined versus extra-virgin olive oils.

KEYWORDS: *polynuclear aromatic hydrocarbons, PAHs, olive oil, solid-phase extraction, SPE, HPLC*

INTRODUCTION

Polynuclear aromatic hydrocarbons (PAHs) are a group of lipophilic compounds comprised of two or more fused aromatic rings. They are ubiquitous in the environment, resulting from natural combustion, such as volcanic eruptions and forest fires, and from man-made activities such as cigarette smoke, automobile exhaust, coal production, and other industrial processes.[1−3] Their occurrence in edible oils can be a result of environmental exposure to particulates contaminated with PAHs and of processes used to produce the oil, such as exposure to combustion gases in drying steps.[2−4] In the case of olive oil, PAH contamination can occur directly on the fruit itself through exposure to exhaust from harvesting equipment and from air pollution in the vicinity of the olive grove.[1] Processes used in the production of refined grades of olive oils can influence PAH content, such as processing steps prior to refining, and decolorization with carbon or clay. In the latter case, PAH content can be reduced as a result of decolorization and/or bleaching.[1,5,6]

A major source of human exposure to PAHs is through food, and in 2002, the European Scientific Committee on Food recommended the monitoring of food for these compounds. It was concluded that benzo(*a*)pyrene could be used as a marker of the content of carcinogenic PAHs present.[7] This recommendation was then adopted by the International Olive Oil Council for olive oil and olive pomace oil and by the European Union (EU) for oils and fats intended for human consumption, with both setting a maximum contaminant level of 2 μg/kg for benzo(*a*)pyrene.[8−10] More recently, the European Union has amended its regulation of PAH content in edible oils to include maximum contaminant levels for additional PAHs. Specifically, a maximum level of 10 μg/kg for the sum of benzo(*a*)anthracene, chrysene, benzo(*b*)-fluoranthene, and benzo(*a*)pyrene together, in addition to the 2 μg/kg level for benzo(*a*)pyrene only.[11] These regulations have driven the requirement for routine testing of olive oils for PAHs and created a need for a simple and rapid testing method.

Established methods (ISO and CEN) exist for the analysis of PAHs in edible oils, and encompass a variety of somewhat complicated and laborious extraction and cleanup techniques, including column chromatography, liquid extraction followed by solid-phase extraction (SPE), online SPE, and direct dilution followed by gel permeation chromatography (GPC).[11−15] Alternate sample preparation methods have also been proposed. A review of methodology performed by Moret and Conte in 2000 for PAHs in fats and oils found three of the most common procedures for extraction to be liquid–liquid partition, caffeine complexation, and saponification.[4] With all of these approaches, a second step for purification of the sample extracts was required, most commonly using column chromatography with silica gel, Florisil, alumina, or polymeric resins.[4,16,17] Since 2000, researchers have more frequently used SPE in place of column chromatography for cleanup. These newer approaches include direct dilution of the oil followed by silica gel SPE and/or GPC, and liquid–liquid extraction (LLE) followed by SPE with C_{18}, silica gel, or amino-phase sorbents.[2,5,18−22] While SPE cleanup requires less solvent than column chromatography, all of these methodologies still require a separate extraction step. Also, if GPC cleanup is used, special instrumentation is required. A more recent method-

ology review performed in 2010 by Plaza-Bolaños et al. for analysis of PAH in food and beverages included reference to a quick and easy direct SPE method for the analysis of benzo(*a*)pyrene in olive oil using a dual-layer SPE cartridge.[3] This method, introduced by Bogusz et al. in 2004, describes a combination of the extraction and cleanup steps by direct loading of undiluted olive oil on a dual-layer SPE cartridge containing Florisil and C_{18}. Subsequent elution of PAHs was accomplished with acetonitrile. The resulting extract was then concentrated and analyzed by both high-performance liquid chromatography (HPLC) and gas chromatography−mass spectrometry (GC−MS).[23] This simplified combined extraction and cleanup procedure did not require the use of large solvent volumes or special instrumentation; however, data were not presented for PAHs other than benzo(*a*)pyrene. This direct SPE approach provides an easy and inexpensive method for benzo(*a*)pyrene analysis; however, in light of the amended EU regulation that requires monitoring of additional PAHs, a need exists for a method that can be used to test a wider range of these compounds.

The purpose of this study was to develop a quick and easy direct SPE method based on the work performed by Bogusz et al. for the extraction of 2−6-ring PAHs from olive oil. The goals of the method were adequate sensitivity to allow testing for EU regulations, speed, ease of use, and reduced solvent consumption over other methods. In addition to conventional Florisil and C_{18} sorbents, the addition of zirconia-coated silica was investigated for retention of a fatty matrix. Zirconia-coated silica was originally developed for removing phospholipids from biological samples prior to analysis of drugs and other small molecules. The empty d orbitals of zirconia act as a Lewis acid (i.e., electron acceptor) and interact with phospholipids through the electron pair on the oxygen atom within the phosphate moiety.[24] When that concept was extended to other types of lipids, it was believed that zirconia should be able to interact in a similar manner with the OH groups found in acylglycerols, which are a major component of fats. This has been applied in recently published works in which zirconia-coated silica was used as a cleanup sorbent in quick, easy, cheap, effective, rugged, and safe (QuEChERS) methodology with fat-containing food samples. It was successfully applied as a sorbent in the cleanup of catfish samples for analysis of PAHs, polychlorinated biphenyls, and flame retardants and in the cleanup of avocado and almond extracts in the analysis of pesticides.[25,26] For these reasons, it was theorized that the retention mechanism provided by the zirconia-coated silica, combined with C_{18} and Florisil, would be useful in the retention of the fats present in olive oil. At the same time, the zirconia-coated silica was not expected to be detrimental to the recovery of the PAHs. The final optimized method used a simple SPE cartridge format to provide direct extraction of PAHs from olive oil without the need for special instrumentation or additional cleanup steps.

MATERIALS AND METHODS

Samples. Samples of olive oils were obtained at local supermarkets. Labeling indicated the oils to be either "extra-light olive oil" or "extra-virgin olive oil". All samples were stored at room temperature prior to extraction and analysis.

A single brand of extra-light olive oil was used for all validation studies. Spiked samples were prepared by the addition of a PAH spiking solution in methylene chloride to the oil, followed by thorough mixing. Samples were then allowed to sit for a minimum of 1 day at room temperature prior to extraction.

Standards. A standard mixture containing the United States Environmental Protection Agency (U.S. EPA) PAHs listed on the target compound list (TCL) at 2000 μg/mL in methylene chloride was obtained from Supelco (Bellefonte, PA) and used for preparation of spiking and calibration standards. Spiking solutions for the olive oil samples were prepared by dilution of the standard in methylene chloride. Calibration standards were prepared by dilution of the PAH standard into acetonitrile. Benzo(*b*)chrysene was used as an internal standard (IS) and obtained from Accustandard (New Haven, CT) as a neat material. An IS mother solution was prepared by dissolving 3 mg of benzo(*b*)chrysene into 10 mL of 1:1 benzene/methylene chloride. This solution was then diluted into acetonitrile to prepare a spiking solution for samples and standards.

Materials. Dual-layer SPE cartridges were obtained from Supelco (Bellefonte, PA). The cartridges consisted of 12 mL polypropylene tubes containing 1.25 g of activated Florisil in the top sorbent bed and 1.25 g of a mixture of zirconia-coated silica and C_{18} in a ratio of 1:2.5 in the bottom bed. Acetone and acetonitrile solvents were obtained from Aldrich Chemical Co. (Milwaukee, WI) and of the highest purity available.

Sample Preparation. The SPE cartridges were first conditioned by allowing 10 mL of acetone to flow through under gravity and then dried by applying vacuum at −15 in. Hg for 10 min. Samples (500 μL, approximately 0.4 g) of olive oil were weighed directly onto the dried SPE cartridge and allowed to penetrate the frit. The IS, benzo(*b*)-chrysene in acetonitrile, was then added directly. Direct addition of the IS to the oil on the SPE cartridge was found to be easier and more reproducible than spiking the oil prior to loading. Elution was performed using 15 mL of acetonitrile solvent, setting a collection rate of approximately 1 drop/s. The eluent was concentrated under nitrogen purge at 40 °C to a final volume of 0.2 mL and analyzed directly by GC−MS for background evaluation during method development, or by HPLC−fluorescence detection (FLD) for PAH detection and quantitation.

Instrumentation. The background remaining in the olive oil extracts was evaluated using GC on an Agilent (Little Falls, DE) 6890 gas chromatograph connected to a 5973N mass spectral detector. The GC column used was a SLB-5 ms (Supelco, Bellefonte PA), bonded and highly cross-linked silphenylene polymer, with polarity equivalent to poly(5% diphenyl/95% dimethylsiloxane). Column dimensions were 20 m × 0.18 mm inner diameter, 0.18 μm. The GC oven conditions were 60 °C, hold for 1 min, ramp at 15 °C/min to 250 °C, ramp at 8 °C/min to 330 °C, and hold for 10 min. The MS interface temperature was 330 °C, and source and quadrupole temperatures were 250 and 200 °C, respectively. Helium was used as the carrier gas at 1 mL/min, with constant flow. The injection port temperature was set to 300 °C. The injection volume was 1 μL and was introduced into a 4 mm inner diameter tapered FocusLiner using a pressure-pulsed injection of 50 psi until 0.75 min, at which point the splitter was opened. The total flow to the inlet was set to 75 mL/min. The mass spectrometer was run in full-scan mode, with a scan range of m/z 40−450, and tuned using a standard autotune macro.

The PAH content was analyzed by HPLC on a Dionex Ultimate 3000 UHPLC system connected to a 3000RS programmable fluorescence detector (Thermo Scientific, Sunnyvale, CA). The system was equipped with a quaternary pumping system and an autosampler. Chromeleon Client 6.8 SR11 software was used for instrumental control and data analysis. Chromatographic analysis was performed on a Supelcosil LC-PAH column (Supelco, Bellefonte, PA) with dimensions of 25 cm × 4.6 mm inner diameter, 5 μm particle size. A water/acetonitrile gradient was used at a flow rate of 1.4 mL/min, starting at 40% acetonitrile, holding 5 min, ramp to 100% acetonitrile over 15 min, and holding at 100% acetonitrile for 12 min. The excitation and emission wavelengths were programmed as described in Table 1. The sample injection volume was 20 μL, and the column temperature was held at 30 °C.

Sample Analysis for PAH Content. As shown in the chromatogram of a spiked olive oil sample in Figure 1, no background interference was noted co-eluting with any of the analyte peaks. This allowed PAHs to be identified in all samples by retention time match

to peaks in the mid-level calibration standard (Table 1). Quantitation of sample extracts was performed against a multi-point calibration curve prepared in acetonitrile. Corresponding concentrations for each identified PAH peak were determined using peak area and were calculated relative to the peak area of the IS. Concentrations were then corrected for sample weight to a final concentration of micrograms of PAH per kilogram of sample (μg/kg). Olive oil blanks (unspiked extra-light olive oil) were analyzed during method validation studies and used for blank correction where indicated. SPE method blanks (solvent and IS, no olive oil) were used to monitor PAH background in the laboratory during the extraction process.

Method Validation. Validation was performed following procedures and protocols described by the International Union of Pure and Applied Chemistry (IUPAC) and the Eurachem guide to method validation.[27,28] Method linearity was determined with samples of extra-light olive oil spiked at five levels from 0.5 to 20 μg/kg and analyzed in triplicate. Unspiked olive oil was analyzed and used for blank subtraction. The average amount of each PAH was measured in μg/kg, blank-corrected when necessary, and plotted against the spiked concentration. Correlation values (r^2) were determined for each compound using regression analysis in Excel. Method accuracy (percent recovery) and intraday precision [percent relative standard deviation (% RSD)] were determined using replicates of extra-light olive oil samples spiked at 2 μg/kg, prepared and analyzed in a single day (n = 8).[29] The spiking level was chosen based on the maximum levels for PAHs in edible oils listed in the amendment to EC Regulation 1881/2006.[11] The approaches for calculation of limit of detection (LOD) and limit of quantitation (LOQ) were taken from the Eurachem guide. LOD and LOQ were calculated for each PAH using 3× and 10× the standard deviation of the average amounts measured in the n = 8 set of 2 μg/kg of spiked olive oil samples. Standard deviation values were blank-corrected using the equation: $s'_o = s_o(1/n + 1/n_b)^{1/2}$, where s_o is the standard deviation of the average amount of PAH measured in the set of spiked replicates (without blank correction), n is the number of sample replicates (n = 8), and n_b is the number of blank or unspiked olive oil replicates (n_b = 3).[28] Interday precision (% RSD) was determined from duplicate olive oil spikes (2 μg/kg) prepared and analyzed on three different days (n = 6).

RESULTS AND DISCUSSION

Method Optimization. Optimization of the final SPE method involved evaluation of the elution solvent, maximum sample capacity, and cartridge conditioning. These parameters were optimized to balance acceptable PAH recovery and low background. While HPLC was used to determine PAH recovery, background was evaluated using GC−MS in full-scan mode. This later analytical technique was chosen because of its ability to detect fatty components that may not produce a signal by HPLC−FLD but can still lead to chromatographic anomalies, such as an unstable baseline or band broadening.

For the elution step, 10 mL of acetonitrile was used initially; however, recoveries for 5- and 6-ring PAHs were <50%. The addition of methylene chloride to the elution solvent was then investigated, and it was found that the addition of ≥10% methylene chloride to the acetonitrile elution solvent was necessary to increase recoveries. However, methylene chloride had the unwanted effect of increasing background, as determined by GC−MS. The total ion chromatogram (TIC) in Figure 2 shows the background remaining in an olive oil extract after elution from the SPE cartridge using 15 mL of acetonitrile. The TIC in Figure 3 shows the same sample after elution with 10 mL of a mixture of 90:10 acetonitrile/methylene chloride. The peaks eluting in the 12−13 min region were determined by spectral match to be fatty acid esters, and the large peak eluting after 16 min was determined by spectral match to be squalene. This indicated that methylene chloride in the elution solvent was preventing adsorption of fatty components in the olive oil onto the Florisil bed. The fatty

[a]Parameters were measured using extra-light olive oil samples spiked at 2 μg/kg. [b]s'_o = standard deviation (n = 8). [c]LOD = limit of detection. [d]LOQ = limit of quantitation. [e]% RSD = percent relative standard deviation (%).

acts as a Lewis acid catalyst) results in transesterification of the fatty components to form fatty acid esters. The elution volume using 100% acetonitrile was then increased from 10 to 15 mL. This increased volume produced PAH recoveries comparable to the addition of 10% methylene chloride but did not have the same effect on the background.

Using 15 mL of acetonitrile for elution, the capacity of the SPE cartridge was studied with different sample sizes of olive oil from 0.4 to 1.4 g. Squalene was detected by GC−MS in extracts prepared from sample sizes of >0.7 g. Sample sizes of >0.9 g exhibited breakthrough, which was observed as oil droplets in the final extract. On the basis of these findings, a sample size of 0.4 g was chosen for the final method, to ensure that the capacity of the sorbents for retaining background was not exceeded.

The final step in method optimization was investigation of a conditioning step prior to loading the olive oil sample onto the SPE cartridge. Because of the mixed functionality of the sorbents used in the cartridge, a traditional conditioning scheme was not employed. Instead, conditioning with acetone followed by drying of the cartridge was used. This step produced extracts with lower background, as determined by GC−MS. The TIC in Figure 4 shows the background in an olive oil extract prepared using an acetone conditioning step as part of the SPE procedure. A significant reduction in background was observed over the same procedure without the acetone conditioning step (Figure 2). It is believed that the acetone conditioning removes residual water present on the Florisil, making it more adsorptive to fatty acids. It could also be expelling residual methanol from the zirconia-coated silica/C_{18} sorbent mix, thus preventing the catalytic transesterification reaction discussed earlier. The dry time for the SPE cartridges of 10 min was increased from an initial time of 5 min to ensure that all residual acetone was removed prior to sample loading.

Method Validation Parameters and Detection Levels. Parameters determined for method linearity are summarized in Table 2. The average values measured at each spiking level are reported after blank subtraction. Correlation values were >0.92 for all PAHs and >0.98 for 11 of the 15 target compounds. The highest deviations in measured versus spiked values were observed at the 0.5 μg/kg spiking level, indicating that this is below the LOQ for the method. Especially for the lighter PAHs (naphthalene through pyrene), accurate quantitation could not be obtained at 0.5 μg/kg. These PAHs were detected in the unspiked olive oil and, subsequently, affected low-level quantitation.

Method parameters summarizing accuracy, standard deviation, LOD, LOQ, and intraday (n = 8) and interday (n = 6) precision are presented in Table 3. Accuracy, determined as recovery, was >75% for all PAHs, which meets requirements described in ISO Method 15753 and CEN 16621 and for benzo(*a*)pyrene in EU Regulation EC 333/2007.[13,15,29] Recoveries were better than those obtained by Moret using silica gel SPE and comparable to methods using GPC cleanup.[2,5,18,22] In the case of benzo(*a*)pyrene, recovery was higher than that reported previously by direct SPE using the Florisil/C_{18} dual-layer tube.[24] Looking specifically at the four PAHs designated in EU Regulation 835/2011, benzo(*a*)-anthracene, chrysene, benzo(*b*)fluoranthene, and benzo(*a*)-pyrene, all had recoveries of 100−110%. LOD values were <1 μg/kg for all PAHs, except naphthalene, and LOQ values ranged from 0.5 to 3.4 μg/kg. Higher LOD and LOQ values for naphthalene and phenanthrene could be attributed to the baseline levels of 3.9 and 2.8 μg/kg, respectively, present in the olive oil used for spiking.

Intraday precision was acceptable, with % RSD values of <20% for all PAHs. Interday precision over 3 different days with two different analysts performing the method and spanning a 9 month time period was <25% RSD for most of the PAHs. In the case of naphthalene, acenaphthene, and phenanthrene, high background levels of these PAHs were detected in SPE method blanks on one of the test days (11.6, 1.1, and 3.6 ng/cartridge, respectively) and contributed to variation in the measurement of samples.

Analysis of Commercial Olive Oil Samples. Virgin olive oils cannot be processed in any way that will alter them from their natural composition. Refined olive oils are defined as those obtained from the processing of virgin olive oils, as long as the processes do not alter the glyceridic structure of the oil.[30] Previous studies have shown that the refining process, which

can include neutralization, bleaching, and deodorization of the oil using activated charcoal and/or clays, reduces PAH content.[6,31] Several different samples of commercially purchased olive oils were extracted and analyzed using the described method. Products described as "extra-light olive oil" and "extra-virgin, first cold press" were selected to see if a difference in PAH content could be detected. Information on the product labels of the samples indicated their countries of origin. The extra-light samples consisted of a blend of oils from several different countries. Oils described as "olive oil" are blends of refined and virgin olive oils. Thus, it was expected that the extra-virgin olive oils (EVOOs) would show more PAH content than the refined oils. Samples were analyzed in triplicate, and the average PAH levels measured are reported in Table 4. SPE method blanks were analyzed alongside the olive oil samples and used for blank subtraction of each olive oil analyzed. All PAHs present above the calculated LOD were reported. PAHs indicated as "<LOD" were detected but at levels below the method LOD. "ND" indicates that no PAH was detected. PAH levels were found to be higher in the two EVOO samples than in the "extra-light" oils. This is in agreement with previous data comparing PAH levels in virgin and refined olive oils.[6,32] This difference was attributable mainly to the lighter PAHs of 2−4 rings, which are known to be reduced by the deodorization step used in the processing of refined olive oil.[31] For PAHs of 4−6 rings, chrysene was detected above the LOD in one EVOO sample. None of the PAHs listed in EU Regulation 235/2011 was detected above the 2 and 10 μg/kg total limits described.[11]

The direct SPE method described includes the first use of a zirconia-coated silica in a dual-layer cartridge configuration in the simultaneous extraction and cleanup of olive oil samples for analysis of PAH content. Zirconia was combined with C_{18} and Florisil to retain most of the fatty constituents of olive oil while allowing elution of PAHs with acetonitrile. The matrix background in olive oil extracts was low, as evidenced by GC−MS analysis. The resulting extract in acetonitrile can thus be analyzed directly by either GC−MS or HPLC−FLD without the need for a solvent exchange step. The LOD of the method ranged from 0.2 to 1 μg/kg, and the LOQ of the method ranged from 0.65 to 3.4 μg/kg. At a 2 μg/kg spiking level, recoveries of PAHs were >75%, with precision of <20% RSD for replicate analyses. The method, when applied to olive oils of different origins, was able to detect differences in PAH content between EVOO and refined samples. The number and complexity of process steps in the method is minimal, and solvent usage is reduced compared to previously described methodologies.[2,5,6,12,13,17−22] The method required less time than approaches such as column chromatography, liquid−liquid extraction, and GPC. In addition, the use of expensive glassware, chlorinated solvents, and special instrumentation with associated calibration procedures was not required.

Supporting Information

ABSTRACT: This paper reports the development of a screening fluorescence polarization immunoassay (FPIA) for the simultaneous detection of fumonisins B_1 (FB_1) and B_2 (FB_2) in maize. Three FB_1 tracers including FB_1-fluorescein isothiocyanate isomer I (FB_1-FITC), FB_1-5-([4,6-dichlorotriazine-2-yl]amino)-fluorescein (FB_1-5-DTAF), and FB_1-Texas Red-X succinimidyl ester (FB_1-TRX) were synthesized and studied to select appropriate tracer−antibody pairs using seven previously produced monoclonal antibodies (mAbs). An FPIA employing the pair of FB_1-FITC and mAb 4B9 showing 98.9% cross-reactivity (CR) toward FB_2 was used to simultaneously detect FB_1 and FB_2. Maize flour samples were extracted with methanol/water (2:3, v/v). After optimization, the FPIA revealed a limit of detection (LOD) of 157.4 μg/kg for FB_1 and an LOD of 290.6 μg/kg for FB_2, respectively. Recoveries were measured for spiked samples of FB_1 or FB_2 separately, ranging from 84.7 to 93.6%, with a coefficient of variation (CV) of <9.9%. Total time needed for FPIA including sample pretreatment was <30 min. The FPIA was used to screen naturally contaminated maize samples. Results detected by FPIA showed good agreement with that of HPLC-MS/MS with a fit of R^2 = 0.99 for the simultaneous detection of FB_1 and FB_2. The established method offered a rapid, simple, sensitive, and high-throughput screening tool for the detection of fumonisins in maize.

INTRODUCTION

Fumonisins are a class of mycotoxins produced as secondary metabolites by fungi of the genus *Fusarium*, notably *Fusarium verticillioides* and *Fusarium proliferatum*.[1,2] Since the first description and characterization of fumonisins in 1988, at least 18 different fumonisin analogues classified into A, B, C, and P groups have been identified.[3−6] The B group, mainly fumonisins B_1 (FB_1) and B_2 (FB_2) with a ratio of 10:3, is believed to be the most prevalent and toxic in naturally contaminated cereals throughout the world.[7,8]

Fumonisins have received much attention due to their hepatotoxicity and carcinogenic effects on animals by interfering with sphingolipid metabolism. For example, fumonisins have been implicated as contributors to leukoencephalomalacia in equines and rabbits, pulmonary edema syndrome and hydrothorax in swine, and apoptosis in the liver of rats.[4,9] In humans, there is a correlation between the consumption of FB_1 highly contaminated home-grown maize and an incidence of esophageal and liver cancer in those regions of China.[10] On the basis of these available data, the International Agency for Research on Cancer has assessed the cancer risk of FB_1 and rated it as a group 2B human carcinogen.[11]

To protect public health from unacceptable contamination, guidance or regulations for fumonisins have been enforced in many countries. The U.S. Food and Drug Administration issued recommended maximum levels of 2−4 mg/kg for total FB_1, FB_2, and fumonisin B_3 (FB_3) in human foods.[12] The scientific committee for food of the European Commission has set action levels for the sum of FB_1 and FB_2, which ranged from 200 μg/kg in processed maize-based foods and baby foods to 4000 μg/kg in unprocessed maize.[13,14]

Several analytical methods for fumonisin detection have currently been developed, including high-performance liquid chromatography (HPLC) with fluorescence detection and liquid chromatography coupled to mass spectrometry (LC-MS) or tandem mass spectrometry (LC-MS/MS).[15−17] These instrumental methods, generally suffering from sophisticated instrumentation, tedious sample preparation, and the need for highly trained/skilled technicians, especially are expensive and time-consuming for routine screening of suspected contami-

nants in many samples. Immunoassays, mainly enzyme-linked immunosorbent assay (ELISA), have frequently been reported for the determination of fumonisins because they are highly sensitive, cost-effective, and easy to use.[18−24] However, ELISA is a heterogeneous method in solid phase, which is limited by requiring multiple incubation and washing steps, and generally needs from 15 to 60 min for the analysis of fumonisins. Thus, with the increasing demand for quicker, easier, and high-throughput screening of contaminants, much effort has been focused on exploring alternatives.

Fluorescence polarization immunoassay (FPIA) is a homogeneous assay based on the competition between unlabeled analyte and fluorescein-labeled tracer for specific antibody in solution phase, which uses changes in fluorescence polarization (FP) to detect the presence of target.[25] Compared with ELISA, FPIA takes only as little as a few seconds or minutes before measuring, and no separation or washing steps are required, which makes the method rapid and simple with high-throughput suitable for the analysis of large numbers of samples. Recently, FPIA has been applied to detect mycotoxins, including aflatoxins (AFs), fumonisins, deoxynivalenol (DON), T-2 toxin, ochratoxin A (OTA), and zearalenone (ZEA).[18,19,25−32] Maragos et al.[18] initially developed an FPIA method in tube format for the measurement of FB_1 by utilizing tracer FB_1-6-([4,6-dichlorotriazine-2-yl]amino)-fluorescein (FB_1-6-DTAF) and monoclonal antibody (mAb) P2A5-3-F3 with a limit of detection (LOD) of 500 μg/kg in maize. After this pioneering work, Nasir et al.[19] improved the sensitivity of the assay, which employed the same immunoreagents with an LOD of 100 μg/kg by refining the tracer and each step of the FPIA. However, the FPIAs reported were both performed in glass tubes, which are low throughput as samples need to be inserted into the instrument one after another, and only FB_1 was detected in maize.

In the current work, an FPIA in a microplate reader format was developed for the simultaneous detection of FB_1 and FB_2 in maize samples. For this purpose, we synthesized three tracers and paired them with seven already produced mAbs. After optimization, the developed FPIA was applied to detect FB_1 and FB_2 in spiked maize and in naturally contaminated maize samples.

MATERIALS AND METHODS

Safety Information. Mycotoxins and related samples used in studies should be handled with extreme caution to avoid exposure to all of these contaminants.

Reagents and Materials. FB_1 was purchased from Pribolab Pte. Ltd. (Singapore City, Singapore), and FB_2 was obtained from LKT Laboratories, Inc. (St. Paul, MN, USA). FB_3, fluorescein isothiocyanate isomer I (FITC), and 5-([4,6-dichlorotriazine-2-yl]amino)-fluorescein hydrochloride (5-DTAF) were supplied by Sigma-Aldrich (St. Louis, MO, USA). Texas Red-X succinimidyl ester (TRX) was acquired from Life Technologies (Carlsbad, CA, USA). Aflatoxin B_1 (AFB_1), ZEA, OTA, DON, and T-2 toxin were purchased from Fermentek Biotechnology (Jerusalem, Israel). Water was obtained from a Milli-Q system (Bedford, MA, USA). All other reagents were of analytical grade or better unless specified otherwise and were acquired from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Precoated TLC silica gel 60 F_{254} aluminum sheets were acquired from Merck (Darmstadt, Germany). Black opaque 96-well microtiter plates with a nonbinding surface were purchased from Corning (Oneonta, NY, USA). The 0.45 μm syringe filters were obtained from Tianjin Jinteng Experiment Equipment Co., Ltd. (Tianjin, China).

Seven mAbs to FB_1, named 2B9, 4B9, 7C9, 2D7, 4F5, 5F8, and 2H8, were previously prepared.[23] Two batches of flour samples of naturally contaminated maize were kindly provided by Prof. Sarah De Saeger (Ghent University) and were stored at −20 °C.[33]

Borate buffer (50 mM, pH 8.0) with 0.1% sodium azide was used as a working buffer solution in this study. Stock solutions (5 mg/mL) of FB_1 and FB_2 were prepared by dissolving 1 mg of standard in 200 μL of methanol, respectively, and were stored at −20 °C until use.

Apparatus. FPIA was performed using a Spectramax M5 microplate reader obtained from Molecular Devices (Sunnyvale, CA, USA) to measure FP and fluorescence intensity (FI) signal.

Preparation of Fluorescein-Labeled FB_1 Tracers. As FB_1 has a single primary amine to enable coupling reactions, it was directly conjugated to fluorescein according to the protocol with minor modifications.[34] Briefly, a stock solution of FB_1 (50 μL) was added to FITC (2 mg) dissolved in 50 μL of methanol followed by the addition of triethylamine (10 μL). After overnight reaction at room temperature in the dark, a small portion (20 μL) of crude product was purified by thin layer chromatography (TLC) using a trichloromethane/methanol/acetic acid (40:10:1, v/v/v) mobile phase. The major yellow band at R_f 0.1 was scraped from the plate and eluted with 100 μL of methanol. Other tracers FB_1-5-DTAF and FB_1-TRX were prepared in the same way and were stored in the dark at −20 °C. All of the tracer solutions were further diluted with borate buffer to get the working concentration with FI about 20 times that of borate buffer background.

Sample Preparation. An amount of 1 g of maize flour sample was added into a 50 mL plastic centrifuge tube. Then the samples were extracted with 5 mL of methanol/water (2:3, v/v) at room temperature. After 1 min of vortexing and ultrasonication for 5 min, the mixtures were centrifuged at 10000 rpm at 4 °C for 10 min. The supernatant (2 mL) was filtered through a 0.45 μm syringe filter, and 1 mL of filtrate was mixed with 3 mL of borate buffer. Finally, 70 μL of the diluted extract was analyzed by FPIA without further treatment.

To acquire the accuracy and repeatability of the FPIA method, 1 g of blank maize flour was spiked with known amounts of standard solutions of FB_1 or FB_2 to obtain samples with different concentrations ranging from 300 to 2000 μg/kg before extraction.

Fluorescence Polarization Immunoassay. *Antibody Dilution Curve.* The antibody dilution curve was performed by mixing 70 μL per well of tracer solution at a working concentration with 70 μL per well of 2-fold serially diluted mAb. Borate buffer was added to reach an overall volume of 210 μL per well.

Maize Matrix-Based Calibration Curve. The concentration of fumonisins in naturally contaminated maize samples was determined relative to the maize matrix-based calibration curve of FB_1 or FB_2 prepared in blank matrix extracts.

The assay was conducted by adding 70 μL per well of tracer working solution and 70 μL per well of prepared standards (or samples) to the microplate, followed by the addition of 70 μL per well of optimal diluted mAb corresponding to a 70% tracer binding based on the antibody dilution curve. After the mixture was shaken for 10 s in the microplate reader, FP values were measured at λ_{ex} 485 nm and λ_{em} 530 nm with emission cutoff of 515 nm for FB_1-FITC and FB_1-5-DTAF or at λ_{ex} 585 nm and λ_{em} 620 nm with emission cutoff of 610 nm for FB_1-TRX, respectively.

The sigmoidal curve was obtained by plotting the measured FP values against the concentration of fumonisins and fitting them to a four-parameter logistic equation by OriginPro 8.0 (Northampton, MA, USA). The LOD was experimentally defined as IC_{10}, the concentration of standard inhibiting 10% of tracer binding with antibody, that is, the concentration corresponding to 10% inhibition of the maximal FP signal.[35] The detectable range corresponds to the concentration of standard varying from IC_{20} to IC_{80}.

Cross-Reactivity (CR) Determination. To determine the specificity of this method, CR with other mycotoxins including FB_2, FB_3, AFB_1, ZEA, OTA, DON, and T-2 toxin were calculated by the following equation, where the IC_{50} value was the concentration of standard inhibiting tracer binding by 50%.

$$\mathrm{CR}\ (\%) = (\mathrm{IC}_{50}\ \text{of}\ \mathrm{FB}_1)/(\mathrm{IC}_{50}\ \text{of other mycotoxins}) \times 100\%$$

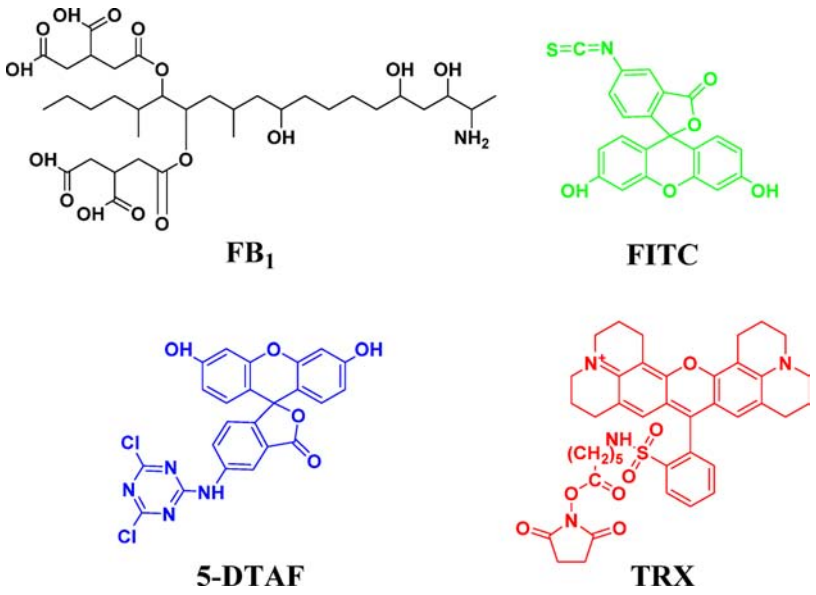

Figure 1. Chemical structures of fluorescein (FITC, 5-DTAF, and TRX) and FB_1 used in this study.

Accuracy and Precision. The accuracy (expressed as recovery), the precision containing repeatability (denoted by coefficient of variation (CV)), and reproducibility were measured for the developed FPIAs. Correlation studies were conducted to determine the reproducibility. Samples of naturally contaminated maize already detected by HPLC-MS/MS were analyzed by the developed FPIA.

RESULTS AND DISCUSSION

Synthesis and Characterization of Tracers. In previous papers, several tracers of FB_1 were prepared and used in FPIA for the determination of fumonisins, including FB_1-DTAF, FB_1-iodoacetamido-fluorescein (FB_1-IAF), and FB_1-carboxy-fluorescein (FB_1-FAM).[18,19] Different tracers have shown different performances in FPIA when using the same mAb P2A5-3-F3. Among these tracers, FB_1-DTAF had the most rigid structure as well as the least "propeller effect" and was found to be the best one.

In this study, three tracers (hapten labeled with three fluorescein including FITC, 5-DTAF, and TRX) were synthesized to achieve the most sensitive FPIA (Figure 1). After purification by TLC, tracers were primarily characterized for binding with seven mAbs by the addition of saturating amount of mAbs (dilution of 1/100) to tracer working solutions. The main bands of TLC at R_f 0.1 for both FB_1-FITC and FB_1-5-DTAF and R_f 0.5 for FB_1-TRX were used as tracers in the following studies because they have an affinity with antibodies as FP signals significantly increased before and after mAbs were added (Figure 2). The couple of FB_1-TRX and mAb 2H8 gave the largest increase in FP signal with δ FP (FP_{bind} minus FP_{free}) of about 392.4 mP (millipolarization units) showing the highest affinity. Meanwhile, FP values of other combinations were also increased and ranged from 49 to 218 mP.

Selection of Tracer–Antibody Pairs. It is reported that the combination of tracer and antibody may have a significant impact on the sensitivity and specificity in the development of an FPIA.[35,36] In this assay, IC_{50} values of FPIA calibration curves for FB_1 in borate buffer, which were obtained by using working concentration of tracers and diluted mAbs that correspond to a 50% tracer binding, was mainly applied to select the optimal tracer–antibody pairs. The highest sensitivity

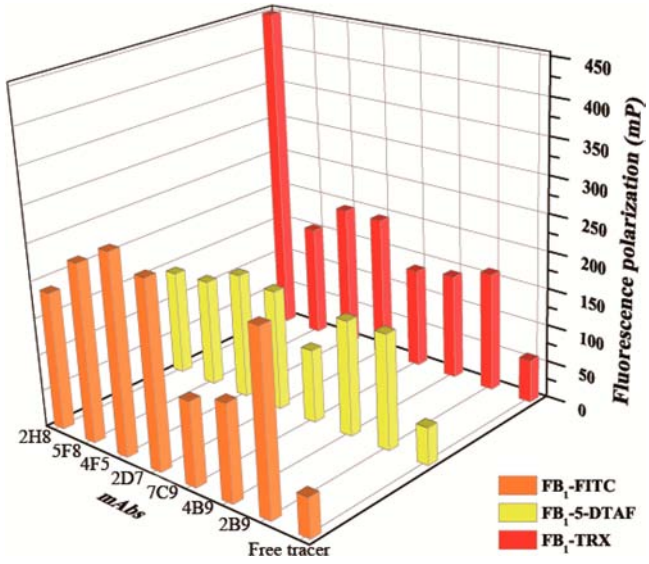

Figure 2. Results of three tracers binding with 100-fold diluted mAbs.

(lowest IC_{50} = 18.8 ng/mL) was achieved when using FB_1-FITC and the 4F5 mAb produced by immunogen FB_1-KLH via conjugating the carboxylic group of FB_1 to the carrier protein (Table 1). Also, this combination gave the widest assay window (δ FP, FP_{max} minus FP_{min}) and lowest background compared with other mAbs and FB_1-FITC pairs. Among the tracers we prepared, FB_1-FITC gave the best performance followed by FB_1-5-DTAF and then FB_1-TRX when seven mAbs were used (Table 1). It should be noted that FB_1-TRX could specifically bind to all of these mAbs and gave an adequate increase in FP signals. However, obvious inhibitions of FB_1 were not found for most of these antibodies. This may be because FB_1-TRX has the most "propeller effect" based on its flexible chemical structure in accordance with previous studies.[19]

Remarkable differences in sensitivity and specificity may be achieved by using the same tracer and different antibodies.[37] The specificity of FB_1-FITC and mAb combinations was obtained by evaluating CR with other occurring mycotoxins (FB_2, FB_3, AFB_1, ZEA, OTA, DON, and T-2 toxin) by FPIA.

Table 1. IC_{50} Parameter (Nanograms per Milliliter) of Competitive FPIA Calibration Curves of FB_1 in Borate Buffer Using Three Tracers and Seven mAbs

	mAbs						
tracer	2B9	4B9	7C9	2D7	4F5	5F8	2H8
FB_1-FITC	23.3	90.1	491.3	23.9	18.8	50.7	158.4
FB_1-5-DTAF	34.4	93.0	552.4	24.2	21.4	246.1	202.0
FB_1-TRX	–[a]	–[a]	–[a]	79.0	60.9	–[a]	223.0

[a]No obvious concentration-dependent FP changes were observed.

Unlike the 4F5 mAb, 4B9 was obtained using immunogen FB_1-GA–BSA through conjugation of the amino group of FB_1 to the carrier protein as reported.[23] The sensitivity of the FB_1-FITC and 4B9 pair was lower than that of the FB_1-FITC and 4F5 combination. However, high CR to FB_2 (98.9% in maize matrix) was acquired when using the FB_1-FITC and 4B9 combination (Table 2). Thus, method 1 employing FB_1-FITC and 4B9 was used for the simultaneous detection of FB_1 and FB_2 in maize. In addition, method 2 employing the pair of FB_1-FITC and 4F5 could be used for specific determination of FB_1 due to its low CR toward FB_2 (2.3% in maize matrix). The results also showed negligible CR of both mAbs 4F5 and 4B9 coupled with FB_1-FITC to AFB_1, ZEA, OTA, DON, and T-2 toxin.

Table 2. Cross-Reactivity of FB_1-FITC and mAb Combinations to FB_1 and Other Mycotoxins by FPIA in Maize Matrix

Mycotoxins	Structures	mAbs			
		4B9		4F5	
		IC_{50} (ng/mL)	CR (%)	IC_{50} (ng/mL)	CR (%)
FB_1		118.5	100.0	18.0	100.0

Investigation of Matrix Effect. In general, fumonisins can be extracted from maize with a mixture of organic solvent and water (methanol/water or acetonitrile/water).[38] In this study, methanol/water (2:3, v/v) was used to extract fumonisins from maize samples according to the previous paper.[24]

As a homogeneous assay, FPIA was more susceptible to interference by matrix effects than other heterogeneous assays. Therefore, the investigation of matrix effect is an important part of FPIA. For the purpose of acquiring information on matrix effects of maize samples, calibration curves were performed in both borate buffer and diluted sample extracts. Results show that the matrix effect could not be reduced simply through a dilution of the extract. The main reason may be that varieties of colored or fluorescent contents are also extracted along with fumonisins when using organic solvent.[39] In FPIA, PBS substantially free of organic solvent was also used for the extraction of FB_1 in maize samples, but the matrix effect still exists with the protocol that 150 μL of extract was added to 150 μL of antibody in PBS and then 200 μL was taken out and mixed with 1.4 mL of tracer.[18] Therefore, a maize matrix-based calibration curve was used to determine the concentration of fumonisins in naturally contaminated maize samples to reduce the background interference of maize extracts.

Development of FPIA in Maize Matrix. Because tracer concentration influences the sensitivity of an assay markedly, the lowest possible concentration should be used to get the most sensitive assay, but this also resulted in low precision of FP signal.[35,36,40] Generally, optimal concentration of tracer was chosen when FI was at least 10 times higher than that of borate buffer background.[41] According to the manual of the microplate reader used in this assay, it was recommended that the precision expressed as standard deviation (SD) of FP be <5 mP. The working concentration of tracer was optimized in borate buffer when the FI of tracer was about 5, 10, 20, and 40 times higher than background following the procedure previously published.[42] The results show that the precision of the FP signal depended on tracer concentration. When FI was about 20 times higher than that of background, tracer at this concentration was selected as working concentration because the SD of FP values of both free and bound tracer was <5 mP.

Antibody dilution curves in the maize matrix were obtained for the FB_1-FITC and 4B9 combination, as well as the pair of FB_1-FITC and 4F5. Theoretically, the optimal concentration of antibody corresponding to a 50% tracer binding would receive the best sensitivity. However, in this research antibody dilution that corresponds to 70% tracer binding was chosen as optimum concentration so as to get a wider analytical range according to previous studies.[43] The best antibody dilution was observed for FB_1-FITC with 4B9 (1/46) and 4F5 (1/2900) in maize matrix.

Under optimal conditions, calibration curves were plotted in blank maize matrix (Figure 3). FP signals were read every 5 min for 90 min. No incubation time was needed as the equilibrium of competition was quickly completed just after samples, tracer, and antibody were mixed (data not shown). Method 1 employing the combination of FB_1-FITC and 4B9 could be used to detect FB_1 and FB_2 in maize samples simultaneously with an LOD of 157.4 μg/kg for FB_1 or 290.6 μg/kg for FB_2 (Table 3). Meanwhile, method 2 showed an LOD of 53.6 μg/

DOI: 10.1021/acs.jafc.5b01845

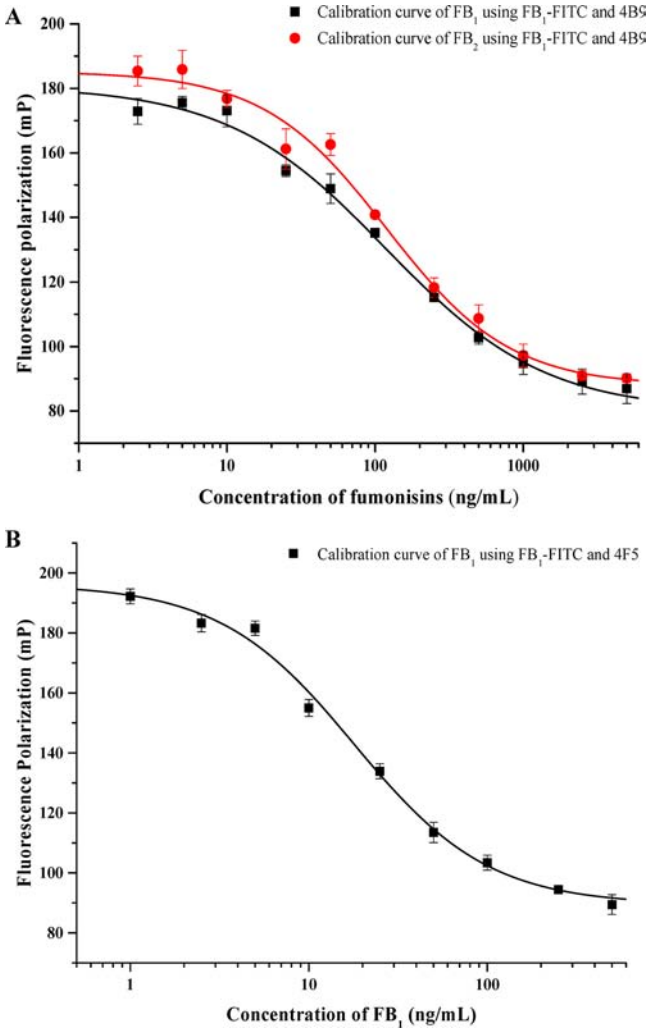

Figure 3. Calibration curves based on optimal conditions in maize matrix of (A) FB_1-FITC and 4B9 pair and (B) FB_1-FITC and 4F5 pair. Each point represents the average of triplicates for a given concentration (n = 3).

Table 3. Analytical Characteristics of Calibration Curves in Maize Matrix

			parameters		
fumonisin	tracer	mAb	LOD (μg/kg)	IC_{50} (μg/kg)	detectable range (μg/kg)
FB_1	FB_1-FITC	4B9	157.4	2370	426.8−13166
FB_2			290.6	2396	632.8−9072
FB_1	FB_1-FITC	4F5	53.6	360.4	108.0−1201

kg for FB_1 specifically in maize samples by using the FB_1-FITC and 4F5 pair. This LOD is about 2-fold lower than that of the published FPIA method (0.1 mg/kg in maize samples) for the determination of FB_1.[19] Also, the detectable ranges in method 1 were 426.8−13166 μg/kg for FB_1 and 632.8−9072 μg/kg for FB_2, whereas in method 2 it was 108.0−1201 μg/kg for FB_1 in maize. Moreover, the whole analysis could be completed within 30 min, including extraction time. Its unrivalled speed and high throughput make it ideally suited for screening for targets in large numbers of samples.

Recovery and Precision Study. The recoveries of method 1 spiked with FB_1 or FB_2 separately at 500, 1000, and 2000 μg/kg were 84.7−93.6%, with CV values <9.9% (Table 4). In spiked maize samples of FB_1 at 300, 500, and 1000 μg/kg, the recoveries of method 2 ranged from 68.5 to 87.0%, with CV values of no more than 3.6%. Acceptable recoveries and CV values were acquired for this assay system.

Table 4. Recoveries and CVs of Fumonisin-Spiked Blank Maize Samples (n = 3)

fumonisin	tracer	mAb	spiked concentration (μg/kg)	recovery (%)	CV (%)
FB_1	FB_1-FITC	4B9	2000	89.2	6.1
			1000	89.9	4.0
			500	93.6	3.9
FB_2			2000	87.3	3.2
			1000	85.4	7.6
			500	84.7	9.9
FB_1	FB_1-FITC	4F5	1000	68.5	3.6
			500	87.0	1.6
			300	80.2	2.7

Two batches of naturally contaminated maize samples, one contaminated with multiple mycotoxins including FB_1 and FB_2, the other with FB_1 and DON, were analyzed by FPIA and HPLC-MS/MS (Table 5). The total concentrations of FB_1 and FB_2 in the first batch of maize were determined relative to the maize matrix-based calibration curve of FB_1 standard using the FB_1-FITC and 4B9 combination. Meanwhile, the concentrations of FB_1 in the second batch of maize were determined by the maize matrix-based calibration curve of FB_1 standard using the combination of FB_1-FITC and 4F5. The results between FPIA and HPLC-MS/MS were compared using a correlation test, which showed good agreement with a fit of R^2

Development of a Sandwich ELISA for Quantification of Gly m 4, a Soybean Allergen

Tao Geng,* Kang Liu, Ronald Frazier, Lifang Shi, Erin Bell, Kevin Glenn, and Jason M. Ward

Monsanto Company, 800 North Lindbergh Boulevard, St. Louis, Missouri 63167, United States

ABSTRACT: Gly m 4 is a key soybean allergen that causes allergic symptoms in the skin, gastrointestinal tract, or respiratory tract of sensitive individuals. To understand naturally variable levels of Gly m 4 among conventional soybean varieties, a sandwich ELISA was developed and validated using a mouse anti-Gly m 4 monoclonal antibody and a goat anti-Gly m 4 polyclonal antibody as capture and detection antibodies, respectively. The ELISA shows high specificity to Gly m 4 without any cross-reactivity to other soybean proteins and has a quantification range of 7.8−250 ng/mL using an *Escherichia coli*-produced recombinant Gly m 4, with 2.1 ng/mL being the limit of detection. Within the quantification range, the coefficients of variation of the intra-assay and interassay precision are less than 5 and 12%, respectively. Moreover, extraction efficiency and dilutional parallelism experiments were completed to demonstrate the assay is accurate. The validated assay was used to quantify Gly m 4 levels in 128 soybean samples from 24 conventional soybean varieties grown at 8 distinct geographical locations. There was a 13-fold difference between the least and greatest amounts of Gly m 4 concentrations among the samples, and the results demonstrate that the most significant sources of variability in Gly m 4 levels in the conventional varieties were related to location and variety.

KEYWORDS: *soybean, allergy, Gly m 4, ELISA, natural variability*

INTRODUCTION

Soybean (*Glycine max*) seed has protein constituting 34.1−56.8% of total content on a dry weight basis,[1] which makes it a good source of nutritional protein for animal and human consumption. Soybean and its byproducts are widely used in the food, feed, and pharmaceutical industries because of their nutritional values and physicochemical properties.[2] Because of the extensive use and need for protecting crop productivity, genetically modified (GM) soybeans have become the overwhelming majority of soybean varieties grown. In 2014, 82% (90.7 million of the 111 million hectares) of the soybeans planted globally were GM soybean.[3] To enable the commercialization of a GM soybean variety, an extensive safety assessment that includes an allergy safety assessment is completed.[4] This assessment includes a comparison of endogenous allergen levels in the GM soybean and conventional control. To evaluate this comparison of endogenous allergen levels, an understanding of the variability in allergen levels would be useful for supporting eventual determinations of exposure levels. Therefore, quantification of endogenous allergens from variable non-GM varieties is needed.

To date, eight soybean endogenous proteins have been shown to cause allergic symptoms in soybean-allergic individuals, including Gly m 3, Gly m 4, Gly m 5 (β-conglycinin), Gly m 6 (glycinin), Gly m 8 (2S albumin), Gly m Bd 28K, Gly m Bd 30K, and Kunitz trypsin inhibitor.[5]

Gly m 4, also called SAM22, is a pathogenesis-related (PR) protein that is specifically expressed in response to plant pathogens or environmental factors that affect plant physiology.[6] It belongs to the family of PR proteins that also includes several other pollen and food allergens[7−10] and thus shows high amino acid sequence identity (>50%) to birch (53% with Bet v 1),[11] hazelnut (58% with Cor a 1.0401),[12] apple (53% with Mal d 1),[13] and cherry (54% with Pru av 1)[14] pollen or food allergens. In addition to high amino acid sequence identity, Gly m 4 showed almost identical three-dimensional structure and cross-reaction to a major birch pollen allergen, Bet v 1,[8,15−17] suggesting a possible causal association between exposure to birch pollen and soy food allergy.

Although several studies have focused on Gly m 4 structure and its clinical implications, little is known about its expression levels in soybeans grown under different environmental conditions. Julka et al.[18] developed and validated a two-dimensional liquid chromatography approach with ultraviolet and mass spectrometry to quantify Gly m 4 from soybean seeds, but the method requires time-consuming processes and expensive equipment. Although Mittag et al.[17] generated a rabbit anti-Gly m 4 antibody and performed a quantitative Western blot, the method is low throughput and hard to validate. The enzyme-linked immunosorbent assay (ELISA), the most common method used by food industries and food control agencies to identify and quantify allergens,[2,19−21] could be the best approach to quantify a large amount of samples because of its sensitivity and high throughput. For these reasons ELISA methods for the detection of several soy allergens have been developed, including Gly m Bd 30K,[22,23] Gly m Bd 28K,[24,25] glycinin/Gly m 5,[26] β-conglycinin,[27,28] and Kunitz trypsin inhibitor.[29] However, to date, there is no validated ELISA method to detect and quantify Gly m 4 levels from soybean seeds.

In this study, a recombinant Gly m 4 (rGly m 4) protein was expressed, purified, and used as a reference standard protein for an ELISA. Mono- and polyclonal antibodies were generated using the rGly m 4 as an antigen and used to develop and validate a sandwich ELISA. The experiments completed during the assay validation demonstrated that the ELISA is sensitive, specific, accurate, and precise for Gly m 4 levels in soybean samples. Following the validation, the newly developed assay was used to quantify Gly m 4 levels from different soybean varieties grown under a variety of environmental conditions. The result showed that this key soybean food allergen has high variability across conventional soybean varieties grown in different locations.

MATERIALS AND METHODS

Soybean Varieties. Conventional soybean varieties (24 varieties) were grown in a U.S. field trial during the 2010 growing season at eight geographically diversified sites (one site each in Arkansas, Illinois, Missouri, Indiana, and Pennsylvania and three sites in Iowa), with each site planted in a randomized complete block design with four replicated blocks. Normal agronomic practices were followed for each site. Seed was harvested at the R8 growth stage[30] (95% of the pods had reached mature pod color) when the moisture content was approximately 12−15% and was stored at ambient temperature after harvest.

Protein Extraction from Soybean Seeds. Soybean seed samples were ground using a mega grinder (Monsanto Co., St. Louis, MO, USA) for approximately 1 min. Protein was extracted from about 100 mg of each ground sample by using a Harbil Mixer (Fluid Management, Inc., Wheeling, IL, USA) with 10 mL (1:100 tissue to buffer ratio) of 0.01 M phosphate-buffered saline with 0.05% (v/v) Tween-20, pH 7.4 (PBST), and 8 chrome beads (0.25 in. in diameter) for 3.5 min at 1500 rpm. Insoluble material was removed from soybean seed extract using a 16 mm × 4 in. serum filter (catalog no. 02-681-51, Fisher Scientific, Pittsburgh, PA, USA).

Expression, Purification, and Characterization of rGly m 4. The Gly m 4 cDNA sequence (GI 134194, NCBI) fused with a His tag at C-terminal was synthesized by Integrated DNA Technologies, Inc. (Coralville, IA, USA) and then ligated into pET24 vector (Novagen, Madison, WI, USA) using *Nde*I/*Xho*I restriction sites. The *Escherichia coli* BL21 (DE3) strain harboring pET24 rGly m 4 was grown in 800 mL of Terrific Broth (Sigma, St. Louis, MO, USA) containing 50 μg/mL kanamycin (Fisher Scientific). The cells were grown overnight at 37 °C with rotary shaking (250 rpm). The cultures were induced by the addition of IPTG (Invitrogen, Grand Island, NY, USA) to 200 μM and then grown for another 48 h at 15 °C. The cells were harvested by centrifugation at 20000*g* for 30 min.

The cell paste was homogenized in 1 L of 50 mM Tris-HCl, 100 mM NaCl, pH 8, using a cell disruptor (Constant Systems Inc., Kennesaw, GA, USA) at 15000 psi. The cell lysate was centrifuged at 20000*g* for 30 min, and the supernatant was incubated with 25 mL of NiNTA resin (Qiagen, Valencia, CA, USA) on an orbital shaker for 1 h at 4 °C. The resin slurry was then poured into a column and washed with an additional 200 mL of lysis buffer. The resin was washed with 100 mL of lysis buffer containing 20 mM imidazole and then eluted with 75 mL of lysis buffer containing 200 mM imidazole. The eluted protein was dialyzed into 50 mM Tris-HCl, 100 mM NaCl, pH 8, and stored at −80 °C.

The purified rGly m 4 protein concentration was determined by ACQUITY UPLC amino acid analysis using an AccQ-tag Ultra derivatization kit (Waters, Milford, MA, USA) and measured by a UPLC-UV detector (Waters). The protein was first acetone precipitated to get rid of the Tris-HCl buffer and then vapor phase acid hydrolyzed in 6 N HCl at 150 °C for 90 min. The hydrolyzed amino acids were precolumn derivatized with the AccQ-tag Ultra kit according to the manufacturer's protocol and then injected into the ACQUITY UPLC. Individual amino acid concentration was determined by an amino acid standard H calibration curve (Life Technology, Rochester, NY, USA). The final protein concentration was determined by total amino acid concentration on the average of five replicates. BSA standard (Sigma) with known concentration was used as control to evaluate the system suitability.

The purified rGly m 4 protein was diluted with Laemmli buffer with β-mercaptoethanol and separated on a precast Tris−glycine 4−20% polyacrylamide gradient gel (Invitrogen). Gel was stained with colloidal Brilliant Blue G (Sigma). Gel image was captured and the protein purity analyzed using a GS-800 scanning densitometer equipped with Quantity One software (Bio-Rad, Hercules, CA, USA).

N-terminal sequence analysis of rGly m 4 protein was performed for 15 cycles. The analysis was conducted using an Applied Biosystems 494 Procise Sequencing System (Applied Biosystems, Foster City, CA, USA).

The purified rGly m 4 protein was also characterized by mass spectrometry. Briefly, the protein was run on a 4−20% SDS-PAGE Tris−glycine gel (Invitrogen), and the band corresponding to rGly m 4 at ∼17 kDa was excised. The protein was extracted, reduced, alkylated, and digested. The digest was applied to an Applied Biosystems Voyager DE-Pro Biospectrometry Workstation with the supplied Data Explorer software for the mass spectrometry (MS) analysis.

Preparation of the Polyclonal Antibody. The production of goat polyclonal antibody (pAb) for Gly m 4 was conducted by Harlan Bioproducts for Science, Inc. (Madison, WI, USA). Briefly, two goats, G1195 and G1196, were immunized with the purified rGly m 4 by four subcutaneous injections. The first injection contained 1 mg of rGly m 4 emulsified in complete Freund's adjuvant (FCA; Sigma). The three subsequent boosts contained 500 μg of rGly m 4 emulsified in incomplete Freund's adjuvant (IFA; Sigma) and were given every 3 weeks. Blood was harvested from each goat 2 weeks after the final booster. The titers and the specificity of sera were determined by using the direct binding ELISA and Western blots as described below, respectively.

The goat sera were then affinity purified by a 5 mL HiTrap protein G column (GE Healthcare, Piscataway, NJ, USA) with an AKTA FPLC (GE Healthcare) according to the manufacturer's instruction. The purified total IgG was further purified by a rGly m 4 conjugated HiTrap NHS-Activated HP column (GE Healthcare) with an AKTA FPLC (GE Healthcare) according to the manufacturer's instruction. Briefly, about 10 mg of rGly m 4 was conjugated by amide linkage to a 5 mL prepacked column of *N*-hydroxysuccinimide (NHS) cross-linked to HP Sepharose beads. The total IgG in PBS (pH 7.4) was flowed through the rGly m 4 column. Unbound IgG was washed out by using PBS, and Gly m 4 specific IgG was eluted out with 100 mM glycine (pH 2.5). To prevent antibody still binding to the column, 3.5 M $MgCl_2$ in PBS was used to wash the column after elution. The specificity of the rGly m 4 column-purified IgG was assessed by Western blots by using soybean seed extract. The purified Gly m 4 specific IgG was dialyzed overnight by using 10K molecular weight cutoff (MWCO) dialysis cassettes (Thermo Scientific, Rockford, IL, USA) in the 4 L of PBS, with three changes of buffer, and then biotinylated by using an EZ-link Sulfo-NHS-LC-biotin kit (Thermo Scientific) according to the manufacturer's instruction. The ratio of antibody and biotin was determined as 1:7 by using a Biotin Quantitation kit (Thermo Scientific). The biotin-conjugated pAb served as the detection antibody in the sandwich ELISA for Gly m 4.

Preparation of the Monoclonal Antibody. The production of mouse monoclonal antibody (mAb) for Gly m 4 was conducted by Rockland Immunochemicals, Inc. (Gilbertsville, PA, USA). Prior to primary immunization, five BALB/c mice were fed a soybean-free diet for 2 weeks. The mice were then subcutaneously immunized with 50 μg of emulsified in CFA (Sigma). Two weeks later, the mice were reimmunized with 25 μg of rGly m 4 emulsified in IFA (Sigma). Three more boosts were given every 3 weeks with 25 μg of rGly m 4 emulsified in IFA. The titer of the test bleed of each boost was determined by using the direct coating ELISA, and the specificity of bleeds was assessed by using Western blots. The mouse with the highest antibody titer and specific to Gly m 4 was selected for cell fusion.

DOI: 10.1021/acs.jafc.5b00792
J. Agric. Food Chem. 2015, 63, 4947−4953

One week following cell fusion, the supernatant culture fluid from all wells was tested by the direct coating ELISA and Western blots. Cell lines with high affinity and specificity for Gly m 4 were selected for subcloning. Two stable subclones were injected intraperitoneally into five mice for each clone to produce ascites. Finally, the monoclonal antibodies were purified from the ascites by a 5 mL HiTrap protein G column (GE Healthcare) with an AKTA FPLC (GE Healthcare). After screening by direct plate binding ELISAs, the mAb with the highest titer was selected and applied as the capture antibody in the sandwich ELISA for Gly m 4.

Direct Binding ELISA To Measure Gly m 4. A direct binding ELISA was carried out to determine the titers of goat sera, mouse sera, and the hybridoma cell lines. rGly m 4 was used as the plate-coating antigen. A 96-well microtiter plate (Thermo Fisher Scientific, Rochester, NY, USA) was coated with a solution (100 μL/well) containing rGly m 4 (10 μg/mL) in 0.05 M carbonate/bicarbonate buffer with 0.15 M NaCl (pH 9.6) and incubated overnight at 4 °C. The plates were washed three times with 300 μL/well washing buffer (PBST, PBS containing 0.05% (v/v) Tween-20, pH 7.4) using a plate washer (ELC405, Biotek, Winooski, VT, USA) to remove unbound antigen. The plates were then blocked by 200 μL/well 1% (w/v) casein in PBS (Thermo Fisher Scientific) for 1 h at 37 °C. All plates were subsequently washed three times. Serially diluted goat sera, mouse sera, and the supernatants of hybridoma cell lines in PBST with 0.1% (w/v) BSA were added (100 μL/well) and incubated at 37 °C for 1 h. After three washings of the plate with PBST, rabbit anti-goat IgG-HRP (Thermo Fisher Scientific), or goat anti-mouse IgG-HRP (Cell Signaling) diluted to 1:2000 using PBST with 0.1% (w/v) BSA was added (100 μL/well) and incubated at 37 °C for 1 h, followed by three washings with PBST; peroxidase substrate TMB solution (KPL, Gaithersburg, MD, USA) was added (100 μL/well) and incubated at room temperature for 10 min. The reaction was terminated by 6 M H_3PO_4 solution (100 μL/well), and the optical density (OD) was measured at 450 nm with reference wavelength at 620 nm by a plate reader (SpectraMax 384 Plus, Molecular Devices, Sunnyvale, CA, USA) with a SoftMax software (version 5.4).

SDS-PAGE and Western Blot. Western blot was performed to assess the specificity of the goat sera, mouse sera, the hybridoma cell lines, monoclonal antibody, and polyclonal antibody for Gly m 4. The rGly m 4 and the soybean seed extract were diluted initially in PBST and further diluted 1:2 (v/v) in Bio-Rad 2X Laemmli Buffer and then heated in a 95 °C metal block for approximately 5 min. The denatured proteins and prestained protein ladder (BenchMark, Invitrogen) or Bio-Rad broad range protein markers were subjected to SDS-PAGE using a midi-gel apparatus (Invitrogen) with precast Novex Tris−glycine 4−20% (w/v) polyacrylamide gels (Invitrogen). The separated proteins were eletrophoretically transferred from the gels to a 0.45 μm polyvinylidene fluoride (PVDF) microporous membrane (Invitrogen) in a vertical midi-format electrophoresis cell (Criterion, Bio-Rad). Blotting was performed at 100 V for 60 min. The membrane was blocked overnight at 4 °C in PBS containing 0.3% (v/v) Tween-20. The membrane was rinsed three times for 10 min each in PBST and probed for 1 h at room temperature with either antisera or purified IgG in PBST with 0.1% (w/v) BSA. After three washings with PBST for 10 min each, the membrane was probed with rabbit anti-goat IgG-HRP (Thermo Fisher Scientific) or goat anti-mouse IgG-HRP (Cell Signaling) for 1 h at room temperature. After three rinses with PBST, SuperSignal West Pico Chemiluminescent Substrate (Thermo Scientific) was added onto the membrane. The luminescence signals were captured by photographic films (Amersham Hyperfilm ECL, GE Healthcare, Buckinghamshire, UK) in a dark room using a Konica SRX-101A automated film processor (Tokyo, Japan). Different exposures were taken, and a single exposure was scanned using a Bio-Rad GS-800 densitometer with the supplied Quantity One software (version 4.6.7).

Indirect Sandwich ELISA. An indirect sandwich ELISA was developed and validated to detect Gly m 4 from soybean seed quantitatively. Ninety-six-well microtiter plates were coated with 100 μL/well of purified mAb (2 μg/mL) in 0.05 M carbonate/bicarbonate buffer with 0.15 M NaCl (pH 9.6) and incubated overnight at 4 °C. The plates were washed three times with 300 μL/well PBST using a plate washer (ELC405, Biotek) to remove unbound mAb. Excess binding sites were blocked with 200 μL/well of Poly-HRP dilution buffer (Thermo Scientific) for 1 h at 37 °C. The plates were subsequently washed three times, and 100 μL of rGly m 4 standards and samples diluted in PBST with 0.1% (w/v) BSA at various concentrations was added into each well and incubated for 1 h at 37 °C. After three washings of the plate with PBST, biotinylated pAb with 1:4000 dilution in PBST with 0.1% (w/v) BSA was added (100 μL/well) and incubated for 1 h at 37 °C. Following three washings of the plates, a Poly-HRP streptavidin conjugate (Thermo Scientific) with 1:10000 dilution in Poly-HRP dilution buffer (Thermo Scientific) was added to each well (100 μL/well) and incubated for 0.5 h at 37 °C. Following three washings with PBST, peroxidase substrate 3,3′,5,5′-tetramethylbenzidine (TMB) solution (KPL, Gaithersburg, MD, USA) was added (100 μL/well) and incubated at room temperature for 10 min. The reaction was terminated by 6 M H_3PO_4 solution (100 μL/well), and the optical density (OD) was measured at 450 nm with reference wavelength at 620 nm. Calibration curve was obtained by plotting the OD values against Gly m 4 concentrations. A buffer blank, a negative control (QC−), and a positive control (QC+, 60 ng of rGly m 4 in PBST with 0.1% (w/v) BSA) were also included on every ELISA plate. All samples were run in triplicate. The sandwich ELISA was subsequently validated for its precision, limits of detection and quantitation (LOD and LOQ), dilutional parallelism, and extraction efficiency.[6,31]

Statistical Analysis of Gly m 4 Levels from Conventional Soybean Varieties. The Gly m 4 level was calculated according to the following equation:

$$\text{ppm} = (\text{ng/mL of extract}) \times (\text{dilution factor}) \times (\text{buffer to tissue ratio mL/g}) \div 1000\ \text{ng/μg}$$

Variance components analysis (VCA) was conducted for Gly m 4 from 24 soybean varieties to estimate the proportion of random effects contributing to the total variance, on the basis of the following analysis of variance (ANOVA) model by combining all eight sites:

$$Y_{ijk} = U + T_i + L_j + B(L)_{jk} + LT_{ij} + e_{ijk}$$

Y_{ijk} is the unique individual observation, U is the overall mean, T_i is the soybean variety effect, L_j is the location effect, $B(L)_{jk}$ is the block within location effect, LT_{ij} is the location by variety interaction effect, and e_{ijk} is the residual error.

In this application, all of the effects in the ANOVA model were set as random effects. The SAS procedure PROC MIXED was employed to run the analysis. The output table of covariance parameter estimates from SAS PROC MIXED procedure gives estimates of the variance component parameters.[32] The variance component parameters of each model component were divided by the total variance to get the variance proportions for each of the components.

RESULTS

Expression, Purification, and Characterization of rGly m 4. The soybean protein was expressed in *E. coli* with a histidine tag to facilitate purification (Figure 1). The cell lysates of pET24 rGly m 4/BL21 (DE3) showed a His-tagged rGly m 4 at 17 kDa with other proteins from *E. coli* (lane 3, Figure 1). After elution with imidazole in a NiNTA resin column, a single rGly m 4 band at the expected molecular weight was observed by SDS-PAGE (lanes 5 and 6, Figure 1). The rGly m 4 was stored in the buffer with 50 mM Tris-HCl, 100 mM NaCl, pH 8. By calculating rGly m 4 protein band intensity over total intensity on lane 6 (Figure 1), its purity was determined as 97%. The purity-corrected concentration was used to prepare ELISA standard curves.

The N-terminal sequence of rGly m 4 showed exact matches of 15 amino acids to the predicted amino acid sequence. MS

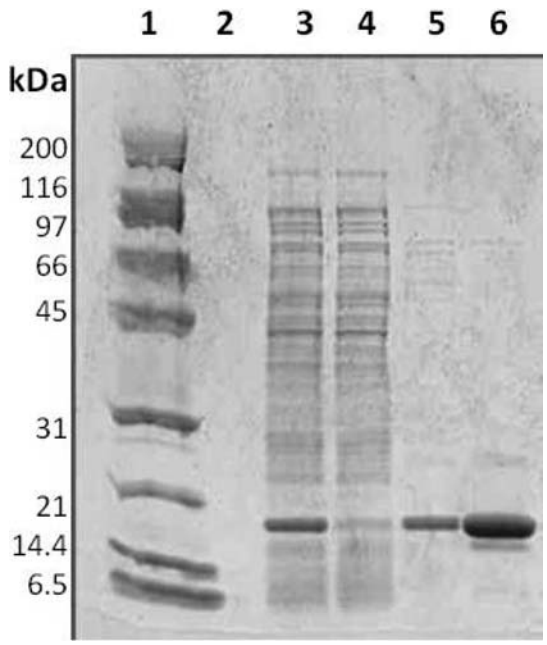

Figure 1. SDS-PAGE analysis of the expression and purification of rGly m 4 protein from *E. coli*. Lanes: 1, molecular weight markers; 2, blank; 3, lysates of pET24 rGly m 4/BL21 (DE3); 4, NiNTA flowthrough; 5, elution with 20 mM imidazole; 6, elution with 200 mM imidazole. The purity of rGly m 4 was determined as 97%.

result showed 41.8% sequence coverage. Overall, the identity of the rGly m 4 was confirmed by N-terminal sequence analysis and mass spectrometry.

Characterization of Antibodies. Monoclonal antibodies were purified from ascites of clone 46F8.B4 that showed the highest titer of 1:102,400. Similarly, polyclonal antibodies, purified from sera of two goats, were screened by using direct plate binding ELISA. The goat with the highest titer (1:6400) was selected for further characterization. Western blots were used to determine the specificity of both antibodies to the rGly m 4 and Gly m 4 in soybean extract (Figure 2). For these Western blots the rGly m 4 protein and soybean seed extract were serially diluted and loaded onto SDS-PAGE gels. Following the transfer of separated proteins onto the membranes, the blots were probed by using either monoclonal antibody (Figure 2a) or goat polyclonal antibody (Figure 2b). The Western blot results show both antibodies react with His-tagged rGly m 4 (approximate 17 kDa band in lanes 2−6) and Gly m 4 in soybean extract (approximate 16 kDa band in lanes 7−10). The monoclonal antibody showed more band intensity compared to the polyclonal antibody as expected on the basis of their respective titers. There were very faint cross-reaction bands (lanes 2−3) at approximately 49 kDa (Figure 2a) or at 60 and 26 kDa (Figure 2b) from rGly m 4, indicating both antibodies could have very slight immunoreactions with proteins from *E. coli*. This could be due to the small amount of impurities present in the rGly m 4 that was used as an immunogen for the antibody productions. Most importantly, both antibodies showed negligible cross-reaction with other soy proteins in the soybean seed extracts (Figure 2, lanes 7−10), indicating they were specific for Gly m 4 and could be used for the development of a Gly m 4 sandwich ELISA for soybean seed samples. From these experiments a monoclonal antibody and a polyclonal antibody were selected as capture and detection antibodies, respectively.

ELISA Method Optimization and Validation. A sandwich ELISA was optimized to use 2 μg/mL of mAb to capture Gly m 4 and a 1:4000 dilution of the pAb to detect Gly m 4. Using these antibody amounts, the assay showed low background values and high sensitivity. The quantification range of the standard curve was established from 7.8 to 125 ng/mL with anchor points of 0 and 500 ng/mL (Figure 3). A 60 ng/mL positive quality control (QC+) was used to evaluate the accuracy of the assay.

The precision of the assay across the entire working range of rGly m 4 protein levels was determined both within a run (intra-assay precision of technical replicates) and across runs (interassay precision of assay plates over a period of time). To do this the seven-point standard curve of rGly m 4 (at concentrations shown in Table 1) and the QC+ sample were assayed in triplicate wells over 36 assay runs carried out on three different days by three different analysts. Assay precision was calculated as the percentage coefficient of variation (%CV) using the interpreted concentrations of the QC+ samples and the standards observed over all assay runs (Table 1). The %CV of intra-assay and interassay precisions of standards and QC+ were much less than 15%, the commonly accepted limit in industry bioanalytical method validation.[33]

To ensure accurate detection of Gly m 4 in the soybean seed, it was also important to determine the lowest concentration of

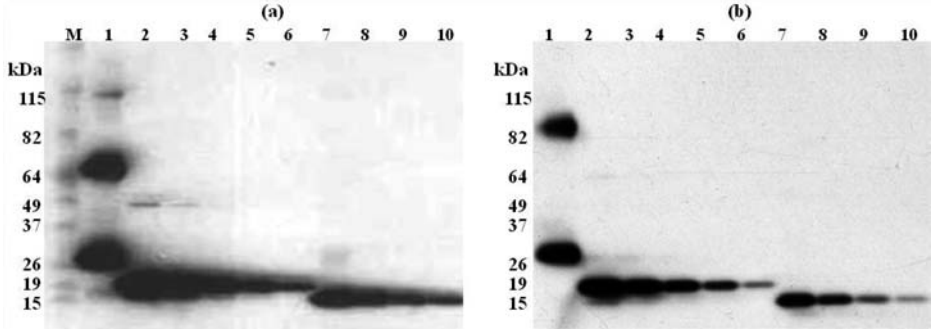

Figure 2. Western blot analyses of monoclonal antibody (a) and polyclonal antibody (b) with rGly m 4 and soybean seed extract. Lanes: M, prestained protein ladder; 1, mouse IgG (a) or goat IgG (b) as positive controls; 2, antibodies reacted with 32 ng of rGly m 4; 3, 16 ng of rGly m 4; 4, 8 ng of rGly m 4; 5, 4 ng of rGly m 4; 6, 2 ng of rGly m 4; 7, soybean extract with 1:200 total dilution; 8, soybean extract with 1:400 total dilution; 9, soybean extract with 1:800 total dilution; 10, soybean extract with 1:1600 total dilution. These Western blots demonstrate that the monoclonal and polyclonal antibodies are specific for both rGly m 4 and Gly m 4 from soybean.

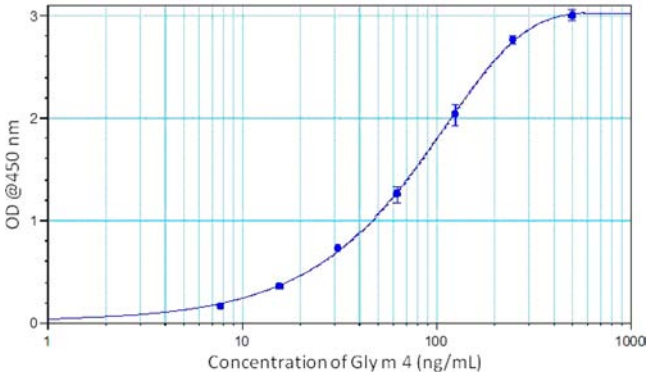

Figure 3. Standard curve of sandwich ELISA for Gly m 4. Each point represents the optical density (OD) of each Gly m 4 concentration with mean ± standard deviation from three determinations. The coefficient of determination (R^2) is 1.00. The quantification range of the standard curve is 7.8−125 ng/mL.

Table 1. Gly m 4 ELISA Dose-Dependent Intrarun and Inter-run Precisions of Seven Standard Points and the QC+ Sample

concentration of standard (ng/mL)	%CV intrarun	%CV inter-run
250.0	3.9	3.9
125.0	1.1	2.4
62.5	1.0	1.8
31.3	1.3	1.9
15.6	1.7	2.8
7.8	4.0	5.0
QC+	4.3	11.5

Gly m 4 that can reliably be detected above the assay's background level. Because no negative matrix could be used to determine this lowest concentration, 21 replicate buffer samples (seven in one assay buffer, total three lots of the assay buffer) were analyzed in triplicate wells on three ELISA runs by three different analysts. The limit of detection (LOD) was defined as the average concentration of Gly m 4 that could be calculated from the background OD observed in the assay buffers plus three standard deviations of the concentration. By these criteria, the LOD for Gly m 4 in the soybean seed samples was determined to be 2.1 ng/mL. The limit of quantification (LOQ) for Gly m 4 was defined as the lowest concentration on the standard curve with a %CV ≤ 15% and was determined to be 7.8 ng/mL.

In addition to assay precision using a standard curve and QC +, it is important to confirm that the Gly m 4 ELISA is accurate across a range of expression levels in soybean seed samples. Dilutional parallelism is a method used to demonstrate the accuracy of an ELISA assay. Dilutional parallelism was demonstrated by testing multiple dilutions of a soybean protein extract to demonstrate that the ELISA method is accurate regardless of the sample dilution being tested. To test dilutional parallelism of Gly m 4, five independently extracted samples were analyzed at four dilution factors (20-, 30-, 40-, and 50-fold) that were within the quantitative range of the standard curve. Each result was then corrected for the appropriate dilution factor and compared to the average concentration of all dilutions for that sample. The recovery of Gly m 4 across the multiple dilutions of five soybean seed samples ranged from 89 to 104% (Figure 4), indicating that this assay can accurately detect Gly m 4 from soybean seed samples across a range of working concentrations.

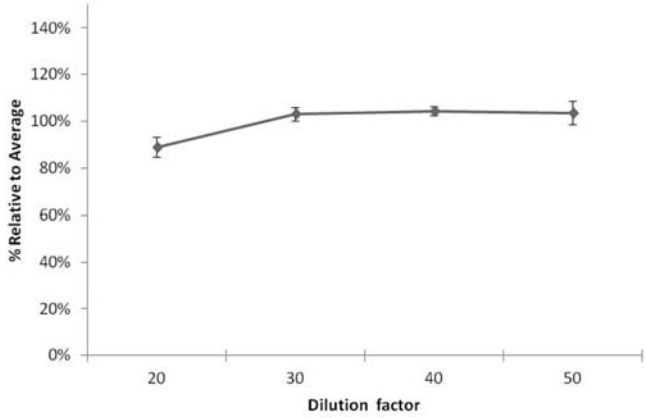

Figure 4. Dilutional parallelism of the sandwich ELISA for Gly m 4. The recovery of Gly m 4 across the multiple dilutions of soybean seed extracts ranged from 94 to 103%, indicating that this assay can accurately detect Gly m 4 from soybean seed samples across a range of working concentrations.

Finally, an extraction efficiency experiment was also performed to estimate the efficiency of the procedure used to extract Gly m 4 from soybean seed. This experiment is completed by performing successive extractions on the same material and analyzing each extract to determine the amount of Gly m 4 protein that remains after the first extraction. The extraction efficiency is expressed as the percent of Gly m 4 protein recovered in the first extraction (supernatant, E1) compared to the total recovered from the consecutive re-extractions of the same sample. For this evaluation, Gly m 4 from three soybean seed samples was extracted, and the average extraction efficiency was calculated to be 76%.

Overall, the validation results demonstrate that this sandwich ELISA is precise and accurate and provides sensitive and reliable reproducible quantification of Gly m 4 levels in soybean seed samples.

Gly m 4 Levels in Soybean Varieties Grown at Eight Locations. The ELISA assay was used to measure Gly m 4 levels in 24 different soybean varieties grown across eight different commercial soybean growing locations in the United States. The results showed that the range of Gly m 4 levels was about 13-fold difference (from 24 to 311 ppm; Figure 5a). Variance component analysis showed location and substance as well as residual (from uncontrolled systematic variability, including biological variability) are the three main contributions to the total variability of Gly m 4 expression in soybeans, indicating that both environmental and germplasm differences do affect endogenous allergen levels (Figure 5b).

DISCUSSION

Gly m 4 has been identified as a key allergen in soybean.[34] Here a Gly m 4-specific sandwich ELISA is described, using antibodies generated by immunization of a histidine-tagged recombinant form of soy Gly m 4 (Figure 1). The ELISA shows high specificity and sensitivity to Gly m 4 in soybean seed extract, without any cross-reactivity to other soybean seed proteins (Figures 2 and 3). The intra- and interassay precisions of this Gly m 4 ELISA were well within the limit of variability accepted by industry bioanalytical method validation criteria

DOI: 10.1021/acs.jafc.5b00792
J. Agric. Food Chem. 2015, 63, 4947−4953

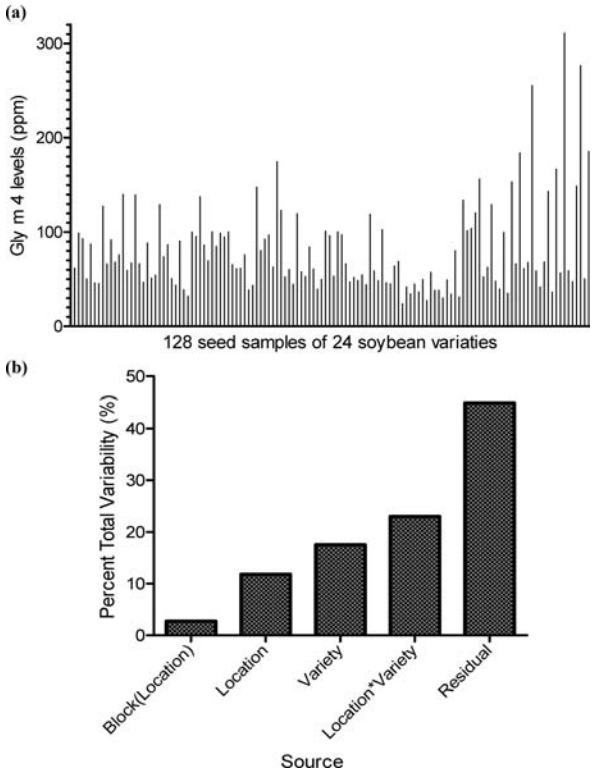

Figure 5. Gly m 4 levels in soybean seed samples: (a) Gly m 4 levels from 24 soybean varieties from 8 locations representing the major U.S. commercial growing areas; (b) sources of variation estimates from variance component analysis (VCA). Location is the environmental effect from eight growing locations; variety is the variety effect soybean from 24 soybean varieties; block is the block effect within each location; location × variety is the location by variety interaction effect, and the residual is the residual error from uncontrolled systematically variation.

(Table 1).[33] Additionally, extraction efficiency and dilutional parallelism experiments demonstrated the high level of accuracy that the ELISA method has in quantifying Gly m 4 (Figure 4) in soybean seed extracts. Taken together, the Gly m 4 ELISA described is shown to have the specificity, sensitivity, accuracy, and precision required for use in the assessment of this soybean allergen in samples from both GM and conventional soybean samples.

The purpose of the endogenous allergen assessment for GM soybean varieties is to compare the endogenous allergen levels in the GM variety to those in non-GM varieties. To evaluate this comparison of endogenous allergen levels, an understanding of the variability in allergen levels safely consumed by nonallergic individuals must be established. For this reason, the developed ELISA method was used to measure Gly m 4 in 24 conventional soybean varieties planted in different locations. The result showed that Gly m 4 levels could vary up to 13-fold (from 24 to 311 ppm) for soybean seed samples from different varieties and grown in different locations. This high level of natural variability of Gly m 4 is similar to those previously reported by Mittag et al. using a quantitative Western blot method, which showed Gly m 4 level ranged from 8 to 224 ppm.[17] Similar observations were obtained for other soybean allergens. By using SDS-PAGE, Martinez-Villaluenga et al. found β-conglycinin and glycinin of 15 soybean genotypes ranged from 0.0 to 35.7% and from 23.1 to 50.8% of total protein, respectively.[35] By using ELISA, Hei et al. observed that β-conglycinin ranged from 3.99 to 14.78% of total weight from 469 soybean seed samples,[36] and Chen et al. found that glycinin ranged from 2.72 to 19.56% of total weight from the same set of soybean seed samples.[37] For Gly m Bd 30k (P34) determined by ELISA in 138 soybean cultivars from a diverse germplasm collection from 10 different countries, the lowest and highest levels were 2.32 and 27.75 mg/g defatted flour, respectively.[38] The effects of environment and genotype on Gly m 4 levels from conventional soybeans are also consistent with previous studies on compositional differences.[39−43] Further investigation of environmental and genotypic effects on allergenicity is needed for other endogenous allergens.

In conclusion, a robust sandwich ELISA for Gly m 4 has been developed and validated for soybean seed extracts. Use of this ELISA has shown that this common soybean food allergen has high variability across conventional soybean varieties grown in different locations.

Supporting Information

ABSTRACT: This article describes the international validation of the quantitative real-time polymerase chain reaction (PCR) detection method for Golden Rice 2. The method consists of a taxon-specific assay amplifying a fragment of rice Phospholipase D α2 gene, and an event-specific assay designed on the 3′ junction between transgenic insert and plant DNA. We validated the two assays independently, with absolute quantification, and in combination, with relative quantification, on DNA samples prepared in haploid genome equivalents. We assessed trueness, precision, efficiency, and linearity of the two assays, and the results demonstrate that both the assays independently assessed and the entire method fulfill European and international requirements for methods for genetically modified organism (GMO) testing, within the dynamic range tested. The homogeneity of the results of the collaborative trial between Europe and Asia is a good indicator of the robustness of the method.

KEYWORDS: *international validation, Golden Rice 2 (GR2), quantitative real-time PCR (qPCR), genetically modified organism (GMO), endogenous taxon-specific gene, event-specific method*

INTRODUCTION

In rice the biosynthetic pathway of β-carotene, a precursor of vitamin A, is normally active in leaves but not in the eaten part of the plant, the grain, mainly constituted by endosperm. Golden Rice 2 (GR2) produces and accumulates β-carotene in the endosperm and was engineered with the aim of fighting vitamin A deficiency, which affects the life of millions of people who do not have access to enough fresh vegetables, dairy product, eggs and meat, but rely on rice as a staple food.[1−5] GR2 belongs to the second generation of Golden Rice plants and accumulates significantly more β-carotene in the endosperm than the first generation of Golden Rice. The International Rice Research Institute in the Philippines (IRRI) is coordinating the introgression (i.e., introduction by conventional breeding) of the GR2 trait into local varieties widely used by farmers and fit for the target growing conditions.[6] Cultivation in the target countries will require authorization by the responsible authorities, which in most cases is guaranteed only if a method for the detection and, in case of labeling requirements, quantification of the GM event is available.

The use of DNA-based methods, and in particular polymerase chain reaction (PCR), is preferred to other analytical approaches for genetically modified organisms (GMOs) screening and quantification because PCR has been proven to be very accurate, both when applied to raw ingredients and to processed food/feed samples.[7−11] PCR and real-time PCR are internationally recognized and recommended for GMO analysis.[12,13] For the development of a method for the detection of GR2, IRRI asked for the collaboration of the Molecular Biology and Genomics (MBG) Unit of the Institute for Health and Consumer Protection of the European Commission Joint Research Centre. The MBG Unit hosts the European Union Reference Laboratory for Genetically Modified Food and Feed (EU-RL GMFF), which has 10 years of experience in validation of quantitative real-time PCR (qPCR) methods and has fully validated about 60 methods for GMO detection.[14−17] The EU-RL GMFF, together with the European Network of GMO Laboratories (ENGL), defined globally accepted performance requirements for analytical methods of GMO testing.[18] These requirements are also in line with the Codex Alimentarius guidelines for methods for detection, identification, and quantification of specific DNA sequences and proteins in food.[19] The developed method is a simplex TaqMan event-specific method for the determination of the relative content of GR2 DNA to total rice DNA and is composed of two qPCR assays: a new rice taxon-specific assay, PLD-GR, which amplifies a 124 bp fragment of rice Phospholipase D α2 (PLD) gene, and an event-specific assay, GR2, which amplifies a 121 bp fragment across the 3′ junction between transgenic insert and plant DNA. Detailed information on the development and single laboratory validation of the method, including assessment of the copy number and stability of the taxon-specific assay, and of the specificity, limit of detection (LOD), limit of quantification (LOQ), dynamic range, and robustness of the PLD-GR and GR2 assays, can be found in the dedicated article.[20]

This paper reports on the subsequent international validation of the method through a collaborative trial. Such a validation trial is a fundamental step to ensure that the method performance measured during single laboratory validation is reproducible when the method is run by different laboratories, operators, instruments, and conditions, and in this study notably in different geographic regions. It verifies the robustness and fitness for purpose of the method, by testing that its performance matches pre-established criteria when it is used in a population of laboratories that is representative of the target users.[21−23] The immediate purpose of the development of the detection method for GR2 is the authorization for cultivation and for food use of the GM rice in the Philippines, where labeling is mandatory for foods containing GM ingredients above a 5% threshold,[24] and at later stages in other Asian countries (e.g., Indonesia and Bangladesh). However, the method could in the future be needed by European control laboratories to check for the presence of GR2 in rice imports from Asia.[25−29] Thus, for the validation of the GR2 detection method, we selected eight laboratories in Europe, of which seven are European national reference laboratories and one operates in Switzerland,[30] and eight laboratories in Asia, belonging to the official GMO control networks including universities, national institutes, and food safety authorities. The 16 laboratories were selected among those potentially going to use the method on the basis of their geographic location, with the aim of obtaining a good distribution of test results across the European and Asian territory.

The analytical procedures for the detection of GMOs, from sampling to determination of GM content, are composed of distinct successive or parallel steps, termed modules. Different modules can be validated separately and combined together afterward, provided that the pre-established performance criteria are respected for the preceding or parallel module.[23,31−33] This approach allows higher flexibility than the validation of the full method because independently validated modules (e.g., DNA extraction and qPCR) can be combined together according to their availability or appropriateness for the target material. In many cases it allows reducing the costs of method validation: when one or more modules that constitute a method are already validated there is no need to include them in the validation study. We considered that the taxon- and the event-specific PCR-assays that constitute a qPCR method can also be regarded as modules and, thus, chose to validate them independently.[31−34] The validation samples were prepared in haploid genome equivalents (hge), calculated by taking into account a rice haploid genome size of 0.5 pg.[35] The rice material used for this study was homozygous, with a ratio between the GM event and the taxon-specific gene of 1;[20] the GM percentages expressed in hge percentages are thus equivalent to mass GM percentages.

The experimental design and results of the validation of the qPCR detection method for GR2 are presented and discussed in the following paragraphs.

MATERIALS AND METHODS

Material and ***DNA extraction*** are described in the Supporting Information.

Quantitative Real-Time PCR. The qPCR reactions for the PLD-GR taxon-specific assay and the GR2 event-specific assay are optimized to be performed in a volume of 25 μL including 5 μL of DNA sample; the primers and probe sequences for each assay are reported in Table S1, Supporting Information. The qPCR reaction mixtures of PLD-GR and GR2 assays contained the following reagents: 1× TaqMan universal master mix (Applied Biosystems, Warrington, United Kingdom), 300 nM primer forward, 300 nM primer reverse (Eurofins Genomics, Ebesberg, Germany), 150 nM probe (Applied Biosystems, Warrington, United Kingdom), 5 μL DNA solution (between 0.02 ng and 200 ng of template DNA per reaction), and nuclease free water (Promega, Madison, USA) to reach the volume of 25 μL. The thermal profile was as follows: 50 °C for 2 min; 95 °C for 10 min; 45 cycles of 95 °C for 15 s, and 60 °C for 60 s; fluorescence data were acquired at the end of the elongation step of each cycle.

Sample Preparation. Two sets of samples were prepared, one for the validation of the taxon-specific assay, labeled PLD, and one for the validation of the GR2 event-specific assay and for a test of the performance of the entire method, labeled GR2. The two sets of samples, consisting of five standard curve samples and 20 blind samples each, were prepared and shipped to all laboratories. PLD and GR2 standard curve samples were prepared from non-GM and GM DNA, respectively, by serial dilution and were labeled S1−S5 PLD/GR2. The hge content and DNA concentration of the standard curve samples are described in Tables S2 and S4, Supporting Information. PLD and GR2 blind samples were prepared independently and consisted of five samples at different DNA concentrations labeled B1−B5 PLD/GR2, which were then subdivided into four samples each and randomly labeled from U1 to U20 PLD/GR2. PLD blind samples were prepared with non-GM DNA, diluted to obtain the desired hge content; GR2 blind samples were prepared with GM DNA, diluted in a background of non-GM DNA to obtain the desired GM hge content in the defined total hge content. The hge content and DNA concentration of the blind samples are described in Tables S3 and S5, Supporting Information. All dilutions were prepared with 0.1× TE and all samples were thoroughly homogenized before any subsequent use. After preparation the samples were tested with a qPCR experiment and divided into 21 aliquots each. The validation kits were prepared from those aliquots and one randomly chosen kit was tested in accordance to the validation protocol prior to the shipment of kits to participating laboratories.

International Collaborative Trial. The collaborative trial was organized by the EU-RL GMFF: 16 laboratories evenly distributed over European and Asian countries were selected to participate to the study (see list of participating laboratories in Table S6, Supporting Information). Each laboratory received a kit for the validation study that included all reagents and samples needed for the validation, with the exception of the no-template control sample, that had to be prepared. Kits were shipped in dry ice to all laboratories with the exception of those located in China and India, for which blue ice had to be used due to the impossibility to ship in dry ice to those countries. All participating laboratories also received a detailed protocol to follow and an excel file for reporting results and were requested to report any deviation from the protocol which may have occurred during the preparation and execution of the qPCR experiments. The laboratories had to run three qPCR plates: one loaded with PLD standard curve samples and PLD blind samples (plate A), for the quantification of PLD blind samples with the PLD-GR assay; one for the quantification of GR2 blind samples with the GR2 assay, loaded with GR2 standard curve samples and GR2 blind samples (plate B); and one for the quantification of the amount of rice taxon-specific PLD target in GR2 blind samples with the PLD-GR assay, loaded with PLD standard curve samples and GR2 blind samples (plate C). Each sample was pipetted in three adjacent wells and the three resulting Cq values were averaged. A no template control was included in the plate, also pipetted in triplicate. The four blind samples with the same hge content were considered as independent replicates, yielding a total of four replicated measurements per laboratory for each blind sample. The layout of the plate setup is available in Figures S1−S3, Supporting Information.

Performance Parameters. In accordance with ISO 5725-1[21] we evaluated two measures of accuracy: trueness and precision. Trueness was expressed as mean percent bias (difference between the mean value of the test results and the accepted reference value divided by the

accepted reference value). Precision was expressed as relative repeatability standard deviation (RSD_r) in percent relative to the accepted reference value, and as relative reproducibility standard deviation (RSD_R) in percent relative to the accepted reference value. We evaluated also two other performance parameters associated with each assay: the amplification efficiency, in percent, and the linearity, expressed as coefficient of determination, R^2. The amplification efficiency was calculated from the slope of the standard calibration curve using the formula: efficiency = $((10^{(-1/\text{slope})}) - 1) \times 100$. Linearity was calculated as coefficient of determination of the standard curve obtained by linear regression analysis. The ENGL minimum performance requirements for analytical methods of GMO testing (MPR) set the criteria that a method must meet to be accepted for validation, and the criteria to be respected to declare the method valid after the international validation. These criteria are in line with Codex Alimentarius guidelines.[18,19] We referred to the criteria set in the MPR and Codex documents to evaluate the performance of the qPCR assays and method. According to them the percent bias should be within ±25% of the accepted reference value over the whole dynamic range assessed; the RSD_r should be below or equal to 25% over the whole dynamic range and the RSD_R should be below 35% over the whole dynamic range, or below 50% at relative concentrations minor than 0.2% or hge lower than 100; the average slope values of the standard curves should be in the range between −3.6 and −3.1, corresponding to amplification efficiencies between 90% and 110%; average R^2 values of the standard curves should be equal to or above 0.98.

Data Analysis. The results of the collaborative trial were analyzed following the steps described in ISO 5725-2.[36] The identified outlying results and/or laboratories were excluded from the analysis, in accordance with ISO 5725-2, and were evidenced throughout the text. For the PLD-GR assay, results from plate A and C were compared by evaluating differences in slope, linearity, and efficiency of the standard curves through Bland−Altman plots for agreement. Limits of agreement were obtained as the average difference between paired values from plates A and C plus/minus twice the standard deviation of all paired differences, following the Bland−Altman approach.[37] Homogeneity of results between European and Asian laboratories was assessed by comparing method performance parameters such as mean measured hge/GM % content, RSD_r, RSD_R, and bias. Mean measured GM content and bias were compared by means of two-tailed Student's 95% confidence intervals, whereas variability was evaluated by estimating the coefficient of variation of the measured GM content alongside the 95% confidence interval using the modified McKay method.[38]

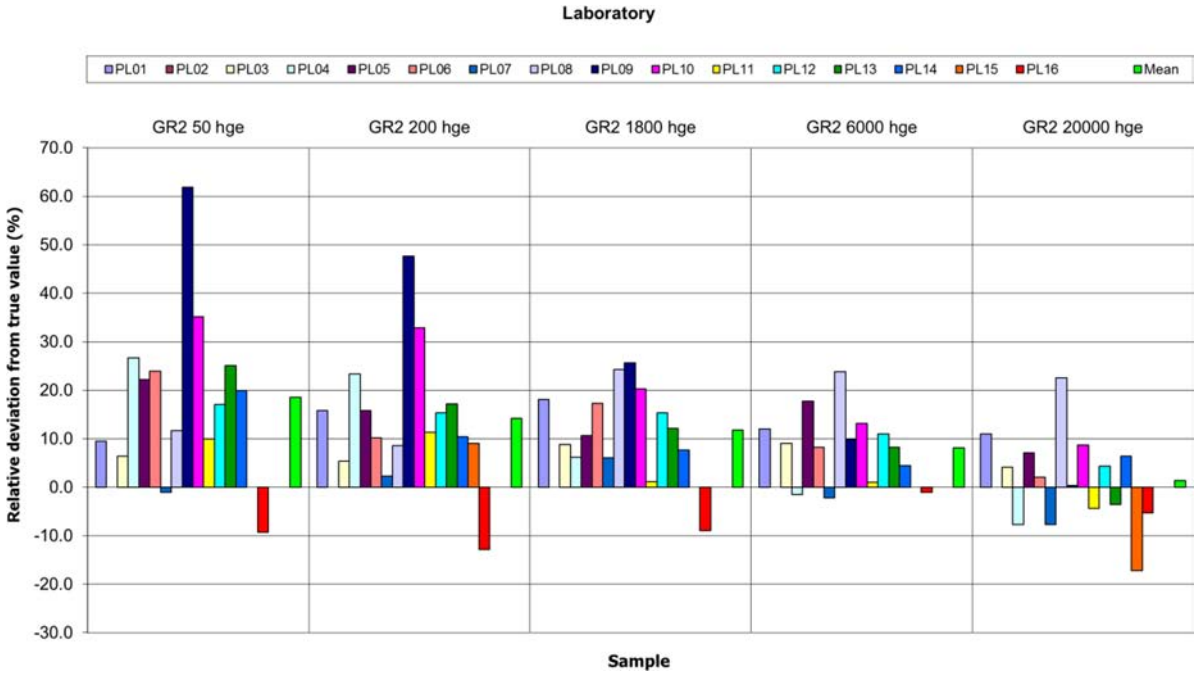

Figure 2. Relative percent deviation from the target hge content for GR2 event-specific assay. Colored bars represent the difference between the hge content measured by each laboratory and the true hge content in percentage of the latter; the green bar on the right represents the mean of the relative deviations for each level of hge content over the analyzed laboratories. PL01−PL16: codes assigned to the 16 testing laboratories. The following values do not show up in the graph: PL2 results for the five levels because they were excluded from the analysis as outliers; PL15 results at 50, 1800, and 6000 hge because they were excluded from the analysis as outliers.

RESULTS

Validation of PLD-GR Taxon-Specific Assay. Results submitted by one laboratory for level 3, and from a second laboratory for level 2, were identified as outliers by the Cochran test at 1% significance level and discarded; results from a third laboratory for level 1 were identified as outliers from the single/double Grubbs test at 1% significance level and discarded from the analysis. The relative deviation from the target hge content (accepted reference value) for each blind sample tested for each laboratory is shown in Figure 1. Mean measured hge content, RSD_r, RSD_R, and bias are reported in Table 1. The measured RSD_r, RSD_R, and the bias measured for three out of five samples meet the criteria, but the two blind samples with lower hge content showed a bias of −30.2% and −29.6%, thus above the limit of −25% set by MPR and Codex guidelines.[18,19] The 95% confidence intervals calculated around the measured hge content include the accepted reference value for level 3, while the accepted reference value for level 2 is higher than the calculated 95% confidence interval and those for levels 1, 4, and 5 are lower. The 95% confidence intervals calculated around the measured bias overlap with the range of values considered acceptable for all tested levels (see Table 1). The full set of quantification results submitted by laboratories is available in Tables S7 and S8, Supporting Information. In addition to the experiment described above (plate A), PLD standard curve samples were tested in a second plate for the relative quantification experiment (plate C) that is described in the paragraph Relative Quantification below. The values obtained by participating laboratories for the slope, amplification efficiency and linearity (R^2) of PLD-GR standard curves are reported in Table S9, Supporting Information. One laboratory could not run plate C, thus standard curve parameters were not reported for plate C for that laboratory. Standard curve parameter values were within the established criteria, ranging from −3.52 to −3.28, with an average of −3.43 for slope, from 92.4 to 101.8, with an average of 95.7% for PCR efficiency and from 0.995 to 0.999, with an average of 0.998 for linearity. Additionally, since plate A and C were performed independently, we compared the slope, PCR efficiency and linearity of the PLD-GR standard curve measured for plate A and C for each laboratory, to identify possible differences between the two plates, yet none was identified. Bland−Altman plots are presented in Figure S4, Supporting Information, and suggest a satisfactory level of concordance between the plates having narrow limits of agreement.

Validation of GR2 Event-Specific Assay. One laboratory was identified as outlier at all hge levels for both Cochran and single/double Grubbs tests at a 1% significance level, thus results from this laboratory were excluded from the analysis. Additionally, results submitted by one laboratory for level 5 were identified as outlier by all outlier tests considered at a 1% significance level and discarded; results from the same laboratory for levels 2 and 3 were identified as outliers by the Cochran test considered at a 1% significance level and discarded. The relative deviation from the target hge content for each blind sample tested for each retained laboratory is shown in Figure 2. In Table 2 the mean hge content, the percentage RSD_r, RSD_R, and bias, all meeting the established criteria, are reported. The accepted reference value for level 1 is included in the 95% confidence interval calculated around the measured hge content, while for levels 2, 3, 4, and 5 the accepted reference value is lower than the calculated 95% confidence interval. The 95% confidence intervals calculated around the measured bias overlap with the range of values considered acceptable for all tested levels (see Table 2). The full set of quantification results submitted by laboratories is available in Tables S10 and S11, Supporting Information. Table

S12, Supporting Information, reports the slope, amplification efficiency, and linearity values obtained by the participating laboratories for the GR2 standard curve with the GR2 event-specific assay (plate B). Slope values ranged from −3.50 to −3.93, with an average of −3.65; the PCR efficiency ranged from 79.8 to 93.1%, with an average of 88.0%. These values of slope and efficiency slightly exceed the MPR and Codex guidelines.[18,19] However, one laboratory presented outstanding deviation in terms of slope and PCR efficiency for the GR2 assay, very likely due to fact that it received the validation samples with some delay. If we exclude the values of slope and PCR efficiency for that laboratory we obtain an average slope of −3.63 and an average efficiency of 89% for the GR2 assay. Measured linearity, which ranged from 0.993 to 1.000 with an average of 0.997, indicates that the GR2 assay has a linear response over the dynamic range tested.

Relative Quantification. GR2 blind samples were designed to have a variable GM content in a fixed total amount of rice DNA, and the relative GM % content of these samples was calculated by dividing the measured GR2 hge content by the measured PLD taxon-specific gene hge content and multiplying by 100 (GM % = GR2/PLD × 100). The measured GR2 hge content of GR2 blind samples was obtained from the plate run for GR2 event-specific assay validation (plate B); the measured PLD taxon-specific gene hge content was obtained from the plate for the quantification of GR2 blind samples with PLD-GR taxon-specific assay (plate C, see Figures S2 and S3, Supporting Information). Out of 16 laboratories, 14 were retained for the analysis. One laboratory could not run plate C and did not present results for the relative quantification of GR2 samples. Additionally, since the relative quantification of the GM % content of GR2 samples relied on the results of both plates B and C, the outliers discarded during the analysis of the results of plate B were discarded also from this analysis. We thus discarded all results from one laboratory and the results submitted by another laboratory for levels 2, 3, and 5. The relative deviation from the target GM % content for each blind sample tested for each laboratory is shown in Figure 3. Table 3 reports the mean GM % content measured, the percentage RSD_r, RSD_R, and bias calculated for the laboratories retained for the analysis. The 95% confidence intervals calculated around

the measured GM % content include the accepted reference value for level 1, while the accepted reference values for levels 2, 3, 4, and 5 are lower than the calculated 95% confidence interval. The 95% confidence intervals calculated around the bias measured overlap with the range of values considered acceptable for all levels tested (see Table 3). The full set of GM % contents calculated on the basis of data submitted by all laboratories is available in Tables S13 and S14, Supporting Information.

Homogeneity of Validation Results. The two geographical areas included in the validation study, Europe and Asia, present differences in terms of climate (e.g., average temperature and relative humidity), length of samples traveling time, and quality certification requirements for GMO testing laboratories. We hypothesized that these differences might have influenced the results presented by laboratories, introducing a factor of nonuniformity that would limit the significance of the results of the validation study. To verify the homogeneity of the results received we compared data presented by the laboratories located in Europe (laboratories from Austria, Belgium, France, Germany, Italy, Slovenia, Spain, and Switzerland; see Table S6, Supporting Information) with the results of the laboratories located in Asia (two laboratories from China, one from India, Japan, Korea, Malaysia, Philippines, and Singapore). The results that were identified as outliers and removed from the analysis of the full set of validation data presented above were removed also from this analysis. Detailed results for the two assays and the complete method are reported in Tables 4−6 and in Figure 4.

PLD-GR. For PLD-GR taxon-specific assay the results presented in Table 4 and Figure 4a are based on eight laboratories for both groups. Consistently with the overall analysis, results submitted by two European laboratories, one for level 3 and another for level 2 and from one Asian laboratory for level 1 were discarded from the analysis. No significant difference was identified between the two groups for the measured hge content, bias and coefficient of variation of the measured PLD hge content, at a 95% confidence level, for any of the levels tested. As observable in Figure 4a, for the taxon-specific assay the coefficient of variation of the measured hge content is generally higher for the Asian group than for the European group, and it tends to decrease with the increase of hge content for both groups. The RSD_r and RSD_R are within MPR and Codex guidelines for both groups, the percent bias is slightly higher than recommended for the two levels with a lower DNA content for both groups, in line with the results of the overall analysis.[18,19]

GR2. For GR2 event-specific assay the results presented in Table 5 and Figure 4b are based on eight laboratories for the European group and on seven laboratories for the Asian group. Consistently with the overall analysis, results submitted by one Asian laboratory for levels 2, 3, and 5 were discarded from the analysis. No significant difference was identified between the two groups for the measured hge content, for bias, and for the coefficient of variation of the measured hge content, at a 95% confidence level, for any of the levels tested. For the GR2 assay the coefficient of variation of the measured hge content is generally higher for the Asian group than for the European

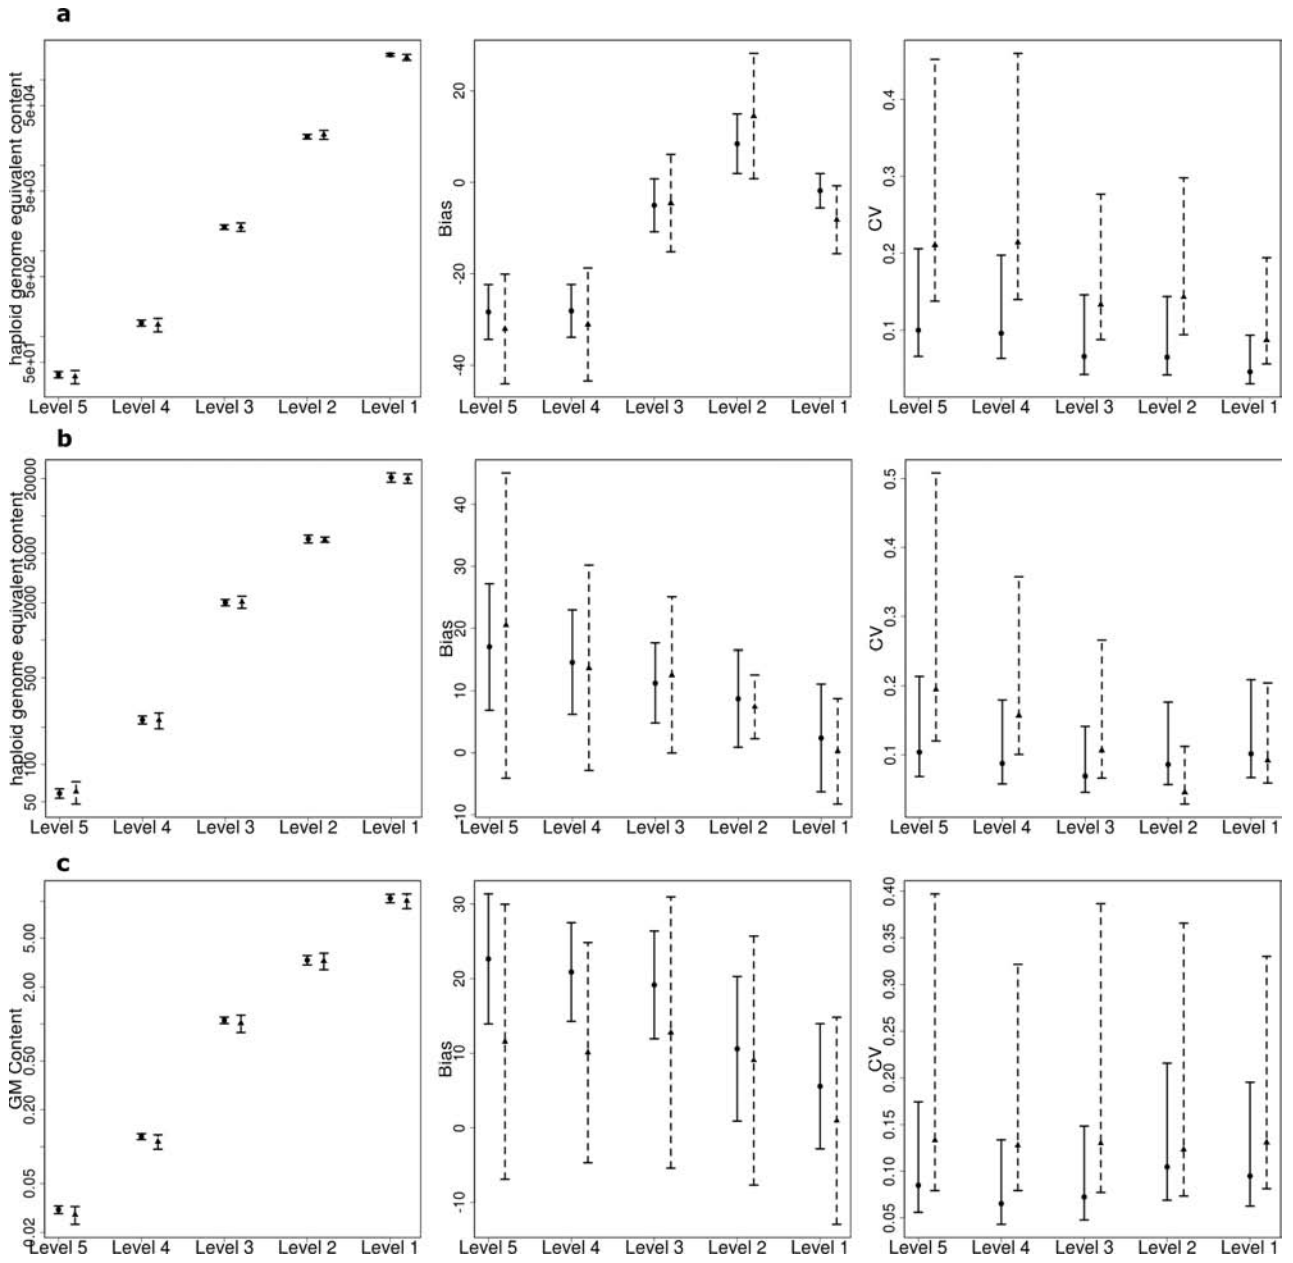

Figure 4. Scatterplots of the measured hge/GM content, bias and coefficient of variation of the measured hge/GM content with 95% confidence intervals for European (dot) and Asian (triangle) laboratories. (a) PLD-GR taxon-specific assay; (b) GR2 event-specific assay; (c) GR2 complete method. The *y* axis of the measured hge/GM content scatterplots is in logarithmic scale.

group only for levels 3, 4, and 5, and it remains constant across the levels for European laboratories, while it decreases with the increase of GR2 hge content for Asian laboratories (Figure 4b). The RSD_r, RSD_R, and percent bias are within the acceptance criteria for both groups.

GM %. For the entire method the results presented in Table 6 and Figure 4c for the European group are based on eight laboratories, those for the Asian group on six laboratories. Results submitted by one Asian laboratory for levels 2, 3, and 5 were discarded from the analysis. No significant difference was identified between the two groups for the measured GM % content, bias, and coefficient of variation of the measured GM % content, at a 95% confidence level, for any of the levels tested. For the entire method the coefficient of variation of the measured GM % content is generally higher for Asian laboratories and rather constant across the GM % levels for both groups (Figure 4c). The RSD_r, RSD_R, and percent bias are in line with the requirements for both Asian and European laboratories.

DISCUSSION

We presented the results of the international validation of the two modules that constitute a qPCR detection method for GR2, the PLD-GR taxon-specific assay and the GR2 event specific assay. These results show that the two assays have a good performance in terms of RSD_r, RSD_R, and bias when assessed with an international collaborative trial, both as independent modules, with absolute quantification, and when combined together, with relative quantification. The dynamic range assessed goes from 50 to 200 000 hge for the PLD-GR taxon-specific assay, from 50 to 20 000 hge for the GR2 event-specific assay and from 0.025% to 10% relative hge/hge GM %

content for the combined method. The RSD_r, RSD_R, and bias measured meet the MPR and Codex guidelines for all tested levels and assays/methods, with the exception of the samples at 50 and 200 hge of the PLD-GR taxon-specific assay. For those levels the percentage bias measured was of −30.2% and −29.6%, respectively. However, the 95% confidence interval calculated for the bias of these two levels includes the limit of −25% suggested for bias.[18,19] Thus, from a purely statistical point of view it cannot be excluded that their measured bias lies inside the accepted range. It is also important to note that 50 and 200 rice hge correspond to 0.025 and 0.1 ng of rice DNA, respectively, and that while it is important that the event-specific method is able to reliably quantify very small amounts of DNA, it is in practice very unlikely that the taxon-specific assay is used to quantify such small amounts of rice DNA. Therefore, the limitation mentioned above for the PLD-GR assay is of negligible relevance for the practical application of the method. In fact, hypothesizing a 5% GM labeling threshold, 200 rice hge per reaction would correspond to 10 GM event hge per reaction, far below the LOQ of the GR2 assay (50 hge). At 2000 rice hge per reaction the number of GM hge would instead correspond to 100, thus reliably quantifiable with the GR2 assay, and generally with any GM event-specific assay. The RSD_r measured with this validation study for PLD-GR taxon-specific and GR2 event-specific assays is in line with the RSD_r measured during the single laboratory validation of two assays, whose data is presented in the article on the development and single laboratory validation of GR2 qPCR detection method.[20] In fact, for the PLD-GR assay the RSD_r for samples at 50 and 200 000 hge was 19.8% and 4.2%, respectively, in the single laboratory validation and 19.6% and 8.1%, respectively, in this collaborative trial (Table 1). The RSD_r for the GR2 assay was 13.5% and 11.7%, respectively, in the single laboratory validation for samples containing 50 and 20 000 hge of the GR2 event and 10.5% and 5.1%, respectively, in this collaborative study (Table 2). The efficiency and linearity of

DOI: 10.1021/acs.jafc.5b00951
J. Agric. Food Chem. 2015, 63, 4954−4965

the PLD-GR taxon-specific assay and the linearity of the GR2 event-specific assay were fully within the established performance criteria, while the efficiency of the GR2 assay was slightly lower than recommended, with an average slope of −3.65 and an average efficiency of 88.0%.[18,19] Given that GR2 blind samples were quantified correctly with the event-specific assay, both with absolute and relative quantification, this slight underperformance in terms of efficiency does not constitute a serious problem. In addition to this, if we exclude from the calculation of the GR2 assay average slope and efficiency the values measured by Lab 9, which presented deviations for those parameters, we obtain an average slope of −3.63 and an average efficiency of 89%, even nearer to the recommended value range.

In this validation study, we adopted the principle of modularity, according to which the different assays that constitute a detection method can be validated separately, provided that the pre-established performance criteria are respected for the preceding or parallel assay,[31−34] and we validated the taxon-specific and the event-specific assays that constitute the GR2 detection method independently. Validating the taxon-specific and event-specific assays independently has different advantages. Establishing the dynamic range of the two assays separately allows the users of the method complete freedom in the choice of GM percentages and DNA concentrations to test and establishes clearer limits on the highest and lower DNA concentrations that can be used in function of the target GM percentage. This is important when countries with different labeling regulations regarding GMO presence in the food or feed chain and different labeling thresholds set for unintended GMO presence are going to use the method.[7,11,24,39−41] The independent validation of the taxon-specific and event-specific assays also allows the users of the method to decide whether to use a delta Ct method or a two-standard curves method, depending on sample availability and quality, screening strategies or the experience of laboratory personnel. For example, a delta Ct method normally requires more DNA than a two-standard curves method for the preparation of standard curve samples, but it may be preferred for other reasons. The taxon-specific assay can be immediately used for other rice GM event-specific detection methods, without the need to revalidate both assays; in this case only the event-specific qPCR method would need to be developed and validated. On the other hand, if a GMO testing laboratory has already implemented the use of one rice taxon-specific assay, it may adopt only the event-specific assay and use it in combination with the pre-existent taxon-specific assay. Among the taxon-specific assays previously developed for rice GM quantification[42−48] only the qPCR assay developed on the sucrose phosphate synthase gene (SPS) was internationally validated independently from an event-specific GM detection method.[45,46] However, to our knowledge this is the first time that both the assays that constitute a GM event-specific qPCR detection method have been developed and validated independently, in absolute hge, and that a relative quantification experiment was performed to confirm the results obtained with the independent assays. The relative quantification experiment was performed by running the taxon-specific and the event-specific assays on two different plates with two independently prepared standard curves; some laboratories run the two plates on different days. Despite these factors are potential sources of variability, the results showed that when the two assays were combined to quantify GR2 DNA in relation to total rice DNA content, their performance in terms of accuracy was comparable, if not better, to the one of the single assays and in line with MPR and Codex guidelines,[18,19] confirming the robustness of the two assays. The samples tested were designed to comply with the European legislation on GMOs,[25−30] so that this qPCR detection method will be available in case of need.

According to ISO 5725-1 and to the IUPAC protocol for the design, conduct and interpretation of method-performance studies,[21,22] if a method is intended for international use, the laboratories participating to the collaborative trial should be from different countries. We chose to include laboratories from the two main areas where the method was developed and is likely to be used: Asia and Europe. These two geographical areas, however, present differences in terms of climate, distance from the organizing laboratory and quality certification requirements for GMO testing laboratories. The assumption behind a collaborative study is that the measured repeatability should be homogeneous between participating laboratories, in order to be able to consider the repeatability standard deviation (RSD_R) obtained with the study applicable to any laboratory.[21] We thus considered important to verify the homogeneity of the results of the collaborative study, by comparing the two subgroups that presented possible sources of variability, Europe and Asia. This analysis did not identify any significant difference between the results of the two groups for what concerns the measured hge/GM percentage content, bias and coefficient of variation, thus confirming the homogeneity of the results received. However, the coefficient of variation of the measured hge/GM percentage content was generally higher for Asian laboratories, a factor that does not compromise the homogeneity of results and that was expected, given that the group covers an area that is wider and more heterogeneous than Europe. To our knowledge, this is the first time that the homogeneity of the results of the international validation of a qPCR detection method was verified.

In conclusion, with the cooperation of the laboratories that participated to this collaborative trial, we have validated the taxon-specific and the event-specific assays that constitute the qPCR detection method for the GR2 event. The two assays were validated independently, a factor that will allow the users of the GR2 detection method to test a wide range of GM concentrations with flexibility on starting sample DNA concentration. This method, developed in collaboration with IRRI, optimized, single laboratory-tested[1] and validated by the EU-RL GMFF can be reliably used for the quantification of GR2 DNA in a sample, over the validated dynamic range.

ABSTRACT: A fluorescence sensing material based on quantum dots with excellent optical properties and molecularly imprinted polymer (QDs@MIP) with specific recognition has been developed. First the surface of CdSe/ZnS QDs was modified with ionic liquids (ILs) by electrostatic interaction. The fluorescence sensing material was constructed from anchoring the MIP layer on IL modified CdSe/ZnS QDs by copolymerization, which had been developed for the detection of carbaryl in rice and Chinese cabbage. The MIP fluorescence was more strongly quenched by carbaryl than the non-imprinted polymer (NIP) fluorescence, which indicated that the QDs@MIP could selectively recognize the corresponding carbaryl. Furthermore, the developed QDs@MIP method was validated by HPLC and ELISA respectively, and the results of these methods were well correlated (R^2 = 0.98). The fluorescence sensing material had obvious advantages, such as being easily prepared and having specific recognition and photostability. The developed method was simple and effective for the detection of carbaryl. And, it could also provide the technical support for the rapid detection in food safety fields.

KEYWORDS: *quantum dots, molecularly imprinted polymer, carbaryl, fluorescence sensing material*

INTRODUCTION

Molecular imprinted polymers (MIPs) are prepared by the template molecule, functional monomer, cross-linker, and initiator with a heat or light trigger. After the template molecules are eluted from the MIPs, they have a cavity match, in such aspects as size and shape in space and chemical action, which can specifically combine with the template molecules. For the structure−activity reservation, specific recognition and extensive applicability, MIPs are being researched and developed in many fields such as solid-phase extraction,[1−4] chromatography,[5,6] and sensor technology.[7,8]

Quantum dots (QDs) are semiconductor nanoparticles composed of groups II−VI or III−V elements with unique optical properties. QDs have unique quantum size and surface effect, showing good spectral characteristics and chemical stability. Consequently, they have been widely applied as fluorescence labels for biomolecules and as optoelectronic devices for sensitive detection of analytes.[9]

On the basis of quantum dots with excellent optical properties and an MIP with specific recognition, fluorescence sensing material (QDs@MIP) have been developed and have drawn considerable attention. Many researchers have constructed fluorescence materials based on QDs for determination of analytes. It is reasonably believed that the molecular imprinting technique will be a powerful tool to improve the selectivity of the optical detection. For example, Wang et al. proposed MIPs coated with QD fluorescence materials for highly selectivity and sensitive determination of ractopamine,[10] vitamin E,[11] and tocopherol.[12] Xie et al.[13] developed a high affinity dipheolic acid (DPA)-MIPs-QD sensor using DPA as a dummy template, for selective determination of trace tetrabromobisphenol A in water and soil samples. Li et al.[14] reported a simple procedure for the synthesis of molecularly imprinted silica nanosphere-embedded mercaptosuccinic acid-coated CdTe quantum dots for selective recognition of λ-cyhalothrin.

To illustrate the usefulness of the MIPs combined with QD materials, carbaryl was chosen as a target. Carbaryl (1-naphthol-*N*-methylcarbamate) was the first successful carbamate insecticide used due to its broad-spectrum efficacy to control insecticide pests. It is widely used in Chinese agricultural systems to combat amounts of pests. Through inhibiting the activity of cholinesterase and the accumulation of acetylcholine in the organization, the normal secretion of biological systems was disrupted.[15−17] Various methods have been explored to detect carbaryl, such as chromatographic techniques,[18] biosensors,[19] enzyme-linked immunosorbent assay,[20,21] et al. MIP-capped QD fluorescence sensing material for analytical applications is still in rapid developed. As far as we know QDs@MIP fluorescence material for the quantitative analysis of carbaryl has not been reported. In this study, we synthesized fluorescence material for detection of carbaryl. The sensing material is based on fluorescence quenching when carbaryl are selectively recognized and combined with QDs@MIP. The participation of QDs exhibits a Stern−Volmer quenching behavior.[22] This method is prospected to realize a fast and efficient detection method for carbaryl without derivation.

MATERIALS AND METHODS

Materials and Reagents. Carbaryl, metolcarb, and isoprocarb were purchased from J&K Chemicals (Shanghai, China) (shown in Figure 1). CdSe/ZnS QDs (catalog Q1565) were purchased from

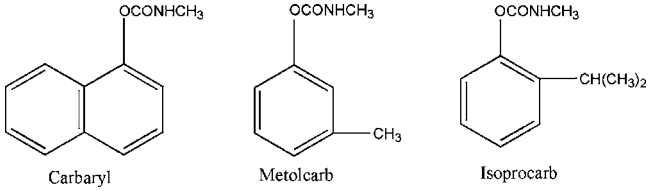

Figure 1. Structures of carbaryl, metolcarb, and isoprocarb.

Jiayuan (Wuhan, China). The 1-vinyl-3-hexyllimidazoliumhexafluorophosphate ILs was purchased from the Chinese Academy of Sciences (Lanzhou, China). Whatman filter paper no. 1 was purchased from GE Healthcare Worldwide. The functional monomer methacrylic acid (MAA), the cross-linker ethylene glycol dimethacrylate (EDGMA, 98%), and the initiator 2, 2-azobis(isobutyronitrile) (AIBN, 99%) were purchased from J&K Chemicals (Shanghai, China). The MAA and EDGMA were distilled under reduced pressure and AIBN was recrystallized in ethanol before use. All of the reagents were analytical grade.

Instruments. Fluorescence (FL) spectrophotometry was performed on an FLR Varian Cary Eclipse (Varian, USA) equipped with a quartz cell (1 cm × 1 cm). Ultraviolet−visible (UV−vis) spectra (200−800 nm) were recorded on a Cary 100-Bio UV spectrometer (Victoria, Australia). Scanning electron microscopy (S-4800, JEOL) was used to observe the surface morphologies of QDs@MIP and fluorescence material based on quantum dots and non-imprinted polymer (QDs@NIP). Fourier-transform infrared (FT-IR) spectra (4000−400 cm^{-1}) were recorded using a Thermo Scientific Nicolet IS 50 (Thermo Fisher Scientific, USA).

Synthesis of Fluorescence Material QDs@MIP. ILs are considered to be a green reaction media because of their nonvolatility, nonflammability, high ionic density, and high ionic conductivity, and they are widely used in areas such as synthesis, separation, and catalytic chemistry. In this study, ILs were used as the medium in the preparation of MIPs. They were anchored on the surface of QDs by electrostatic interaction. Under dark conditions, CdSe/ZnS QDs (50 μmol) were dissolved in chloroform (10 mL), mixed with 1-vinyl-3-hexyllimidazolium hexafluorophosphate IL (3 mmol), and stirred for 3 h at room temperature. Then, synthesis of molecularly imprinted fluorescence material based on IL-modified CdSe/ZnS QDs was carried out as follows: The carbaryl (1 mmol) and MAA (4 mmol) were added. The mixture was stirred overnight before adding cross-linker (EDGMA; 20 mmol) and AIBN (40 mg). After purging with nitrogen 5 min, the mixture was placed in a water bath at 60 °C for 24 h. When the polymerization reaction finished, the template molecules were removed by Soxhlet extraction with methanol and acetic acid (200 mL, v:v = 9:1) until no analyte was detected by UV−vis spectrophotometry. Finally, the polymers were dried in a vacuum oven at 55 °C. And, the QDs@MIP was obtained. The QDs@NIP was prepared without the template molecules.

Fluorescence Analysis. In the adsorption experiments, QDs@MIP and QDs@NIP nanoparticles (20 mg, 200 mesh screens) were dispersed in a 15 mL plug centrifuge tube, containing carbaryl standard solution (10 mL) with the concentration of 0−100 mg L^{-1}. After shaking for a certain time at room temperature, the templates were bound to the QDs@MIP, causing fluorescence quenching of the QDs. To further evaluate the analytical performance of the fluorescence sensing material, the detection limit and linear range were investigated. The detection limit (LOD) was calculated as the concentration of carbaryl that quenched three times the standard deviation of the blank signal divided by the slope of the standard curve. Metolcarb and isoprocarb were used as structural analogues in selectivity experiments. In the experiment, all the FL detections were performed under the same conditions: the excitation wavelength was set at 280 nm with a recording emission range of 450−650 nm, and the slit widths of the excitation and emission were both 2.5 nm. Then the mixture was mixed thoroughly and quickly scanned by the Cary Eclipse spectrophotometer.

RESULTS AND DISCUSSION

Preparation and Characterization of QDs@MIP and QDs@NIP. The general scheme for the synthesis of QDs@MIP and QDs@NIP was illustrated in Figure 2. First, the CdSe/ZnS QDs were modified with the ILs through electrostatic interactions. Then the ILs-modified CdSe/ZnS QDs were reacted with MAA through covalent bonding and the carbaryl was reacted with the MAA by hydrogen-bond interactions. The C═C bonds of ILs, anchored on the surface of QDs, participated in the polymerization process of MIPs. The introduction of ILs could increase the surface functional groups of QDs and improve the fluorescence stability of QDs.

After the template molecules were extracted from the composites by decomposing the hydrogen bonds, the identification of specific cavity sites was made in the composites and the QDs@MIP was obtained. Before removal of the

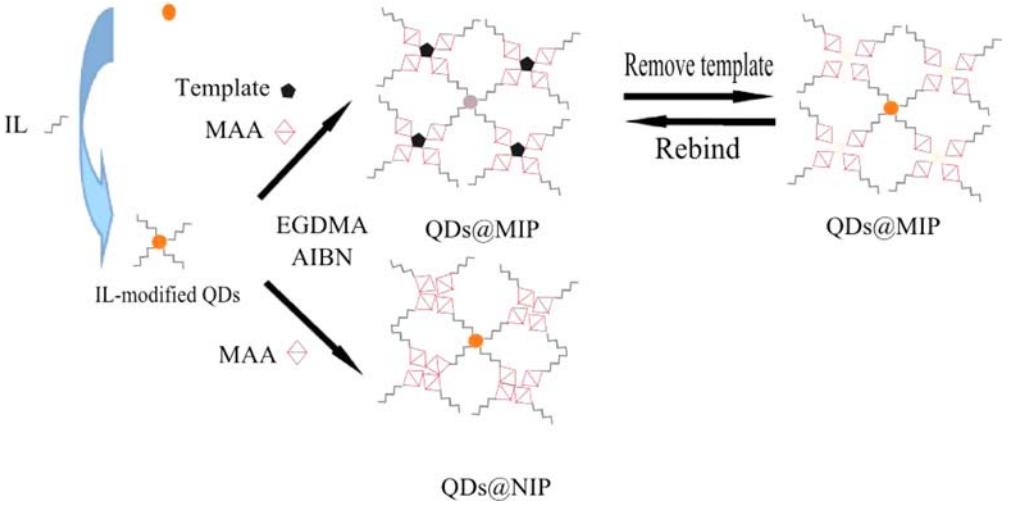

Figure 2. Schematic illustration of the preparation of QDs@MIP.

DOI: 10.1021/acs.jafc.5b01072
J. Agric. Food Chem. 2015, 63, 4966−4972

template molecules, the FL intensity of the QDs@MIP was about 24.4% of that of the QDs@NIP, while after removal of it, the FL intensity of the QDs@MIP increased to 96.6% of that of the QDs@NIP (Figure 3). This result indicated that the template molecule (carbaryl) was removed cleanly from the composites.

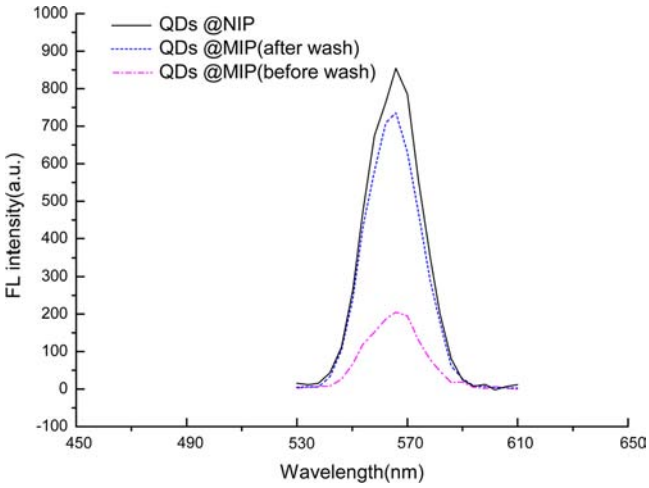

Figure 3. FL spectra of QDs@NIP, QDs@MIP (after wash), and QDs@MIP (before wash).

Characterization of QDs@MIP and QDs@NIP. The surface morphologies of QDs@MIP and QDs@NIP were observed by SEM (Figure 4). The QDs@ MIP (Figure 4a) had better uniformity and spherical structure and a rougher surface than QDs@NIP (Figure 4b), indicating that the template molecules' sites were left in the QDs@MIP.

FT-IR spectroscopy is performed to further characterize the QDs@MIP (Figure 5). The characteristic peaks of IL-QDs were shown in Figure 5b: the bands at 3173 and 3113 cm^{-1}were the stretching vibrations of aromatic C−H, the 2963 and 2940 cm^{-1} were the stretching vibrations of saturated C−H, the strong bands at 1666 cm^{-1} were the stretching vibrations of C═C, the bands at 1554, 1465, and 1178 cm^{-1} were the stretching vibrations of C═N, aromatic C═C, and C−N, respectively. The characteristic peaks of QDs@MIP were shown in Figure 5a: the peaks at 2981 and 2958 cm^{-1} were the stretching vibrations of saturated C−H, the bands at 1456 and 1159 cm^{-1} were respectively the stretching vibrations of aromatic C═C and C−N in ILs. The strong peak at around 1731 cm^{-1} of C═O, indicating that the cross-linker (EDGMA) had been successfully incorporated into the polymers.

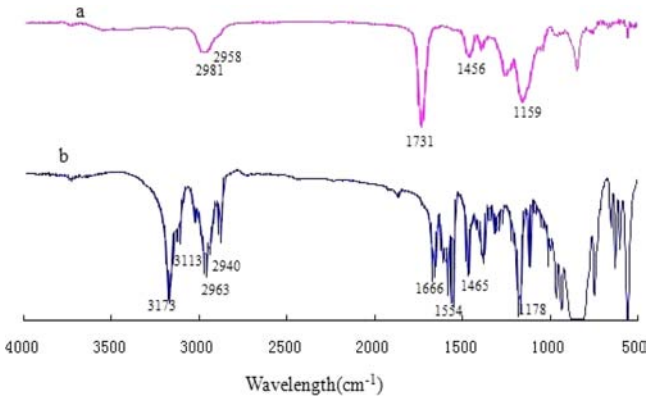

Figure 5. FT-IR spectra of (a) QDs@MIP and (b) IL-QDs.

Furthermore, the characteristic C═C peaks of 1666 cm^{-1} in IL-QDs disappeared markedly from the QDs@MIP, which showed the covalent interactions between the ILs and MAA. All these results indicated that the QDs@MIP was successfully grafted on the surface of the IL-coated CdSe/ZnS QDs.

Adsorption Capacity of the QDs@MIP and the QDs@NIP. In order to investigate the binding performance of the QDs@MIP and QDs@NIP, an equilibrium binding analysis was carried out using 10 mg L^{-1} carbaryl. First, to compare the effects of different solvents on the adsorption, acetonitrile, ethanol, methanol, and chloroform were selected. The difference in FL intensity between the QDs@MIP and the QDs@NIP was obvious when acetonitrile as solvent, showing that acetonitrile was a more suitable solvent for adsorption of carbaryl than the others. Therefore, acetonitrile was chosen as the adsorption solvent in the following experiments.

Effect of Adsorption Time. The influence of adsorption time on the fluorescence intensity investigated at different times was showed in Figure 6. It was found that the mixture showed a rapid decrease in fluorescence intensity after the carbaryl was added. The reaction reached equilibrium within 30 min, and the fluorescence intensity was kept constant with the rise of adsorption time beyond 30 min (Figure 6a). In addition, the UV−vis spectra of carbaryl (Figure 6b) decreased gradually until no carbaryl was detected after 30 min. This result was in accordance with the FL result. This further indicated that the optimal adsorption time was 30 min.

Optosensing of Carbaryl by QDs@MIP. QDs@MIP was used in this study as a sensing material to detect carbaryl. As shown in the absorption spectrum of the carbaryl and QDs@MIP (Figure 7), the UV absorption band of carbaryl is close to the band gap of the QDs@MIP and there is no spectral overlap

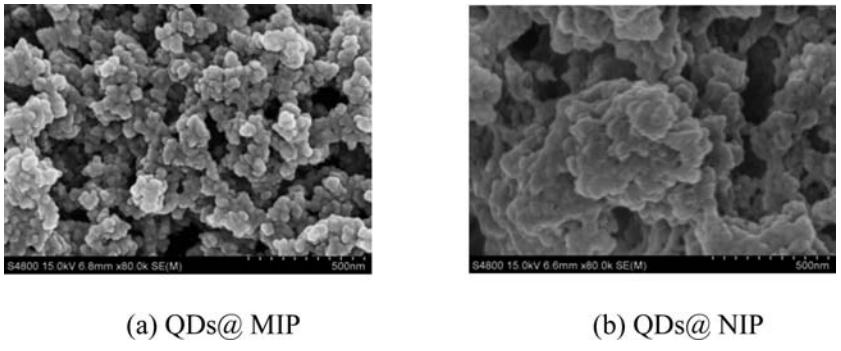

Figure 4. SEM images of (a) QDs@MIP and (b) QDs@NIP.

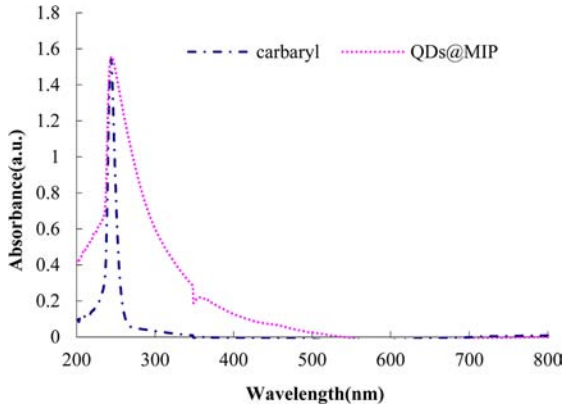

Figure 7. UV−vis spectra of carbaryl and QDs@MIP.

between the absorption spectrum of the carbaryl and the emission spectrum of the QDs@MIP (Em 565 nm). On the basis of former studies,[23,24] the mechanism of the decrease in fluorescence intensity may be charge transfer instead of energy transfer from the QDs to carbaryl. The QD valence band is full of charges; when a beam of light shines on the QDs, the charges tranfer to the conduction band. Charges in the conduction band are usually instable and can go back to the valence band, emitting photons and causing fluorescence. When carbaryl was presented, the charges of the conductive bands of the QDs could transfer to the lowest unoccupied molecular orbital of the UV band of carbaryl. They could not go back to the valence band, and there was no more fluorescence. That was FL quenching between carbaryl and QDs. The FL quenching in this system followed the Stern−Volmer equation.

$$F_0/F = 1 + K_{SV}[Q] \quad (1)$$

F_0 and F were the FL intensity of the QDs in the absence and presence of carbaryl, respectively, K_{SV} was the Stern−Volmer constant, and $[Q]$ was the concentration of carbaryl. This equation was used to quantify the different quenching constants in this research, and the ratio of the K_{SV} values of the MIP and NIP ($K_{SV,MIP}/K_{SV,NIP}$) was defined as the imprinting factor to evaluate the selectivity of the materials.

Selectivity Adsorption of QDs@MIP. Metolcarb and isoprocarb were selected as structural analogues to evaluate the selectivity of QDs@MIP (Figure 8). In Figure 8a and b, the FL changes of QDs@MIP were obvious between carbaryl and its structural analogues but less obvious in QDs@NIP. There are customized recognition sites in QDs@MIP after removing templates molecule that can specifically adsorb carbaryl, while

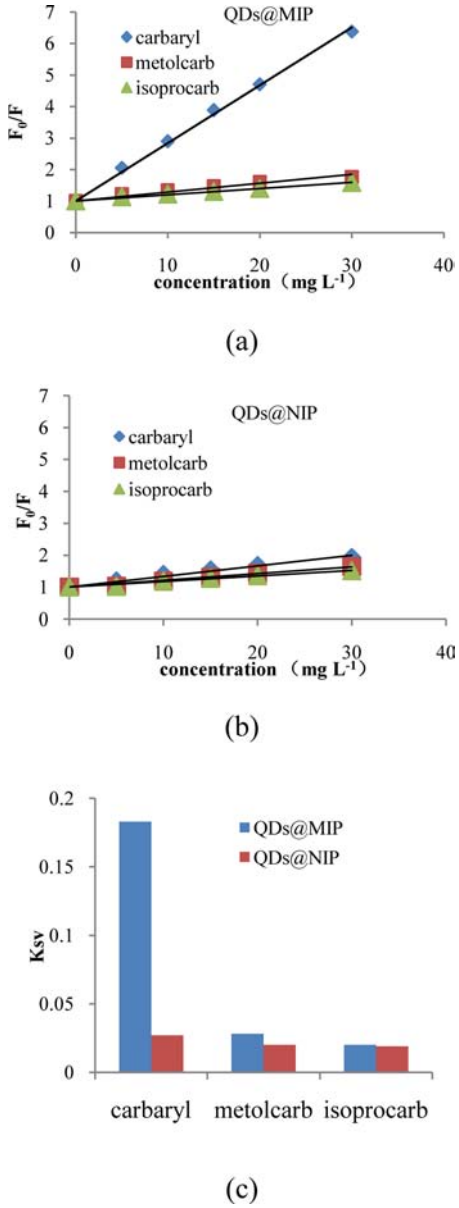

Figure 8. Selectivity of QDs@MIP (a) and QDs@NIP (b) for carbaryl, metolcarb, and isoprocarb and quenching constant of QDs@MIP and QDs@NIP (c) for carbaryl, metolcarb, and isoprocarb.

metolcarb and isoprocarb are not easy to identify. And there are no customized recognition sites formed in the QDs@NIP. This demonstrated the recognition mechanism of QDs@MIP is

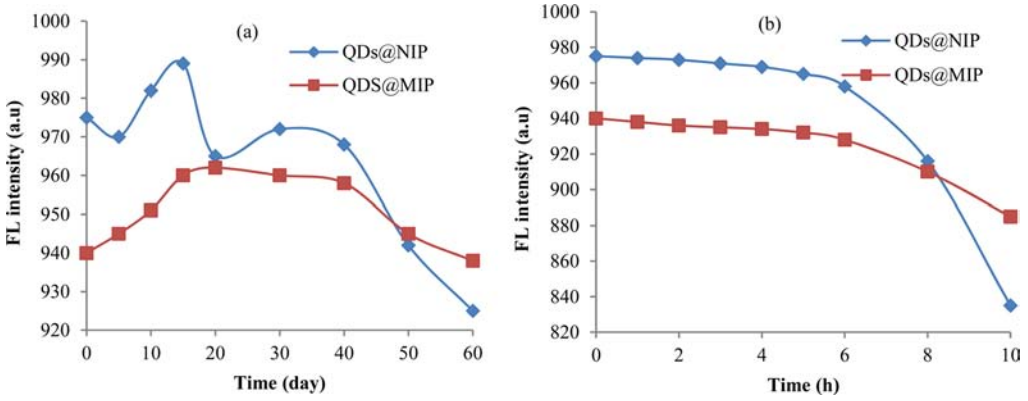

Figure 9. FL stability of QDs@ MIP and QDs@ NIP: (a) room temperature away from light for 60 days, (b) continuous UV irradiation for 10 h.

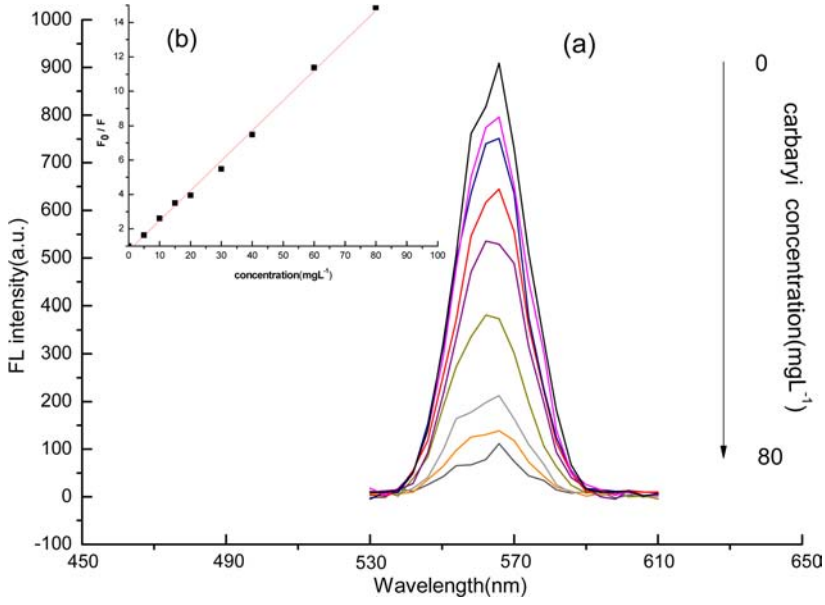

Figure 10. (a) FL spectra of QDs@MIP with increasing concentration of carbaryl. (b) Effect of carbaryl concentration on the FL intensity of QDs@ MIP.

based on the interactions of the structure and function of the templates. As shown in Figure 8c, the QDs@MIP exhibited a larger K_{SV} than the QDs@NIP. And the K_{SV} of carbaryl was much higher than its structural analogues. The ratio of $K_{SV,\ MIP}$ to $K_{SV,NIP}$ was the highest for carbaryl, at 6.78, indicating efficient imprinting.

Stability of QDs@MIP. The stability of QDs@MIP was also studied. The FL stabilities of QDs@MIP and QDs@NIP are shown in Figure 9 under the conditions of room temperature away from light for 60 days and with continuous UV irradiation for 10 h, respectively. It could be seen that for QDs@MIP in Figure 9a, FL decreased less than 5% at room temperature away from light for 60 days. For UV irradiation, the FL change was not obvious within 6 h. After 10 h, the FL of QDs@MIP reduced by 5.8%, and QDs@NIP was down 14.4%. It was known that the shelf life of bare QDs was very short and the solution turned to opaque black easily without surface-modification. However, the sensing material of QDs@MIP had better photostability. It could be explained that the package of an MIP layer outside might protect the photo stability of QDs.
