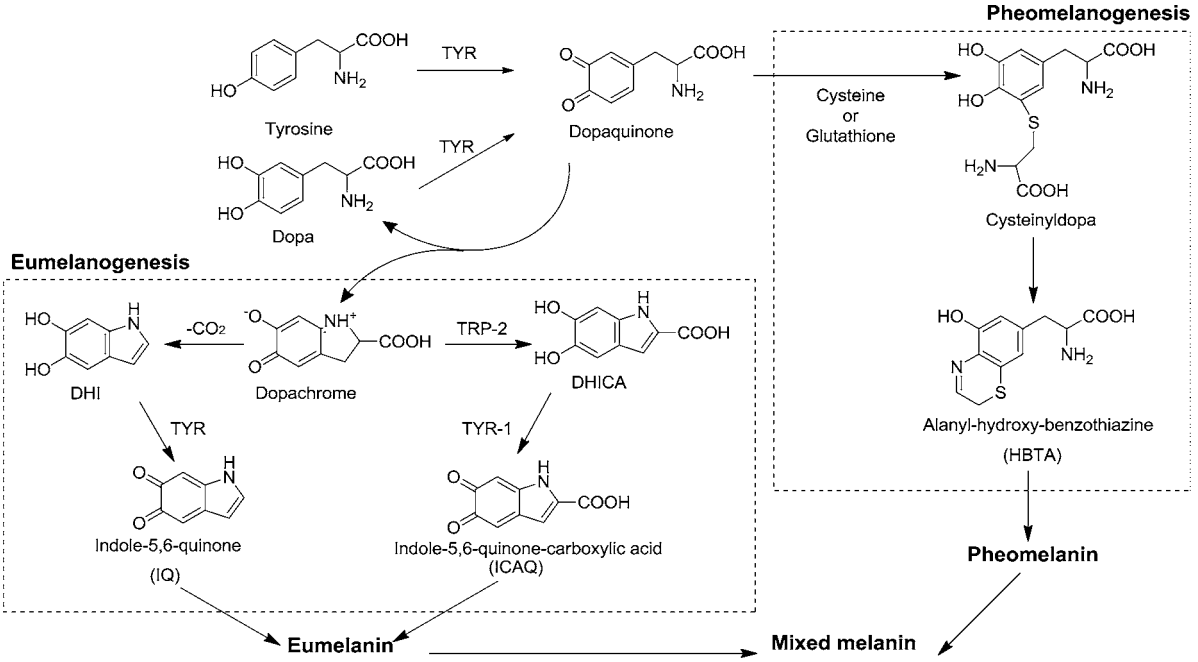

Figure 1. Biosynthetic pathway of melanin involving mushroom tyrosinase. Melanin biosynthesis includes eumelanogenesis and pheomelanogenesis that generate eumelanin and pheomelanin, respectively.

tion of tyrosine to DOPA and the oxidation of DOPA to dopaquinone during melanin formation from tyrosine.[9] In plants, tyrosinase is responsible for browning, which occurs after the long-term storage of fruits and vegetables.[10] In animals, tyrosinase is responsible for skin and hair pigmentation and skin anomalies, namely, hypo- (vitiligo) or hyper- (freckles or flecks) pigmentation.[11,12] Moreover, tyrosinase may play a role in neurodegenerative diseases (e.g., Parkinson's disease) and cancer.[13,14] Therefore, tyrosinase is a crucial topic in the fields of medicine, agriculture, and cosmetics, and considerable attention has been paid to developing and screening for tyrosinase inhibitors.[15]

Some tyrosinase inhibitors, such as hydroquinone,[16,17] arbutin,[18] kojic acid,[19,20] azelaic acid,[21,22] and electron-rich phenols,[23] have been used in cosmetics. However, only a few such inhibitors are sufficiently potent for practical use and are in compliance with safety regulations. Therefore, continual efforts have been exerted to obtain tyrosinase inhibitors synthetically (in laboratories)[24−26] and naturally (through plant extractions).[27−29] Recently, we used phage-displayed tetrapeptide inhibitors[30] and a T1 compound from *Gastrodia elata*,[31] and other researchers have employed peptide-derived compounds for tyrosinase inhibition.[4,32,33] Certain short-sequence oligopeptides, **P3** and **P4**, inhibit mushroom tyrosinase with no cytotoxicity to human melanocyte.[32] The tyrosinase inhibitory potency of kojic acid−tripeptide is superior to that of kojic acid.[34] In addition, a mimosine tetrapeptide, mimosine−FFY, exhibits a marked tyrosinase inhibitory ability when the half-maximal inhibitory concentration (IC_{50}) is 18.3 μM.[33] Peptides are reported to bind with exact specificity to their in vivo targets, resulting in an exceptionally high potency of action and relatively few off-target side effects.[35] Thus, tyrosinase inhibitors have great potential for use as skin-whitening components in medicine and cosmetics.

In a previous study, we established a reasonable and reliable pharmacophore model for screening potent natural products for mushroom tyrosinase inhibition. We identified a potent natural product, A5,[36] that exhibits an apparent tyrosinase inhibitory ability. Moreover, the structure of A5 resembled that of the dipeptide **WY**. Therefore, in this study, we synthesized 20 × 20 dipeptides to comprehensively investigate their tyrosinase inhibitory ability. We found that cysteine-containing dipeptides exhibit an outstanding inhibitory potency against tyrosinase among all others. The tyrosine moiety of tyrosine-containing dipeptides competes with the substrate binding site of tyrosinase to reduce tyrosinase activity. Dipeptides (**CA**, **YC**, **PD**, and **DY**) exhibiting divergent inhibition against tyrosinase were subjected to a cell viability assay and melanin content assessment to study their effects on cytotoxicity and depigmentation. In addition, to identify dipeptides with the strongest tyrosinase inhibitory potency, the IC_{50} values of cysteine-containing dipeptides, which are superior to those of other dipeptides, were calculated. This study reveals the functional roles of the cysteine residue positional preference and the selectivity of specific amino acids of dipeptides for inhibiting tyrosinase. The results can be applied in developing inhibitors for interrupting melanin biosynthesis.

MATERIALS AND METHODS

Materials. Molecular docking studies were conducted using Genetic Optimization for Ligand Docking (GOLD; GlaxoSmithKline PLC, Astex Technology Ltd., Cambridge Crystallographic Data Centre). All calculations were performed at the National Center for High-Performance Computing in Taiwan. Mushroom tyrosinase, L-tyrosine, and a potassium phosphate buffer (PBS, NaH_2PO_4−Na_2HPO_4, 67 mM, pH 6.8) were purchased from Sigma-Aldrich (St. Louis, MO, USA). All 400 peptides (purity = 0.95%) used in this study were custom-synthesized by Kelowna International Scientific, Inc. (New Taipei City, Taiwan).

Methods. *Examination of the Inhibitory Potency of Dipeptides against Tyrosinase.* A tyrosinase inhibition assay was performed, according to a previously reported method,[36] on the synthesized 20 × 20 dipeptides to investigate their effects on tyrosinase activity.[37] In brief, 25 μL of a 5 mM dipeptide solution, 125 μL of a 5 mM L-tyrosine, and 80 μL of a 67 mM PBS were mixed and added to each well of a 96-well enzyme-linked immunosorbent assay plate, which was incubated at 25 °C for 5 min. Subsequently, 20 μL of a 1250 U/mL mushroom tyrosinase

J. Agric. Food Chem. 2015, 63, 6181−6188

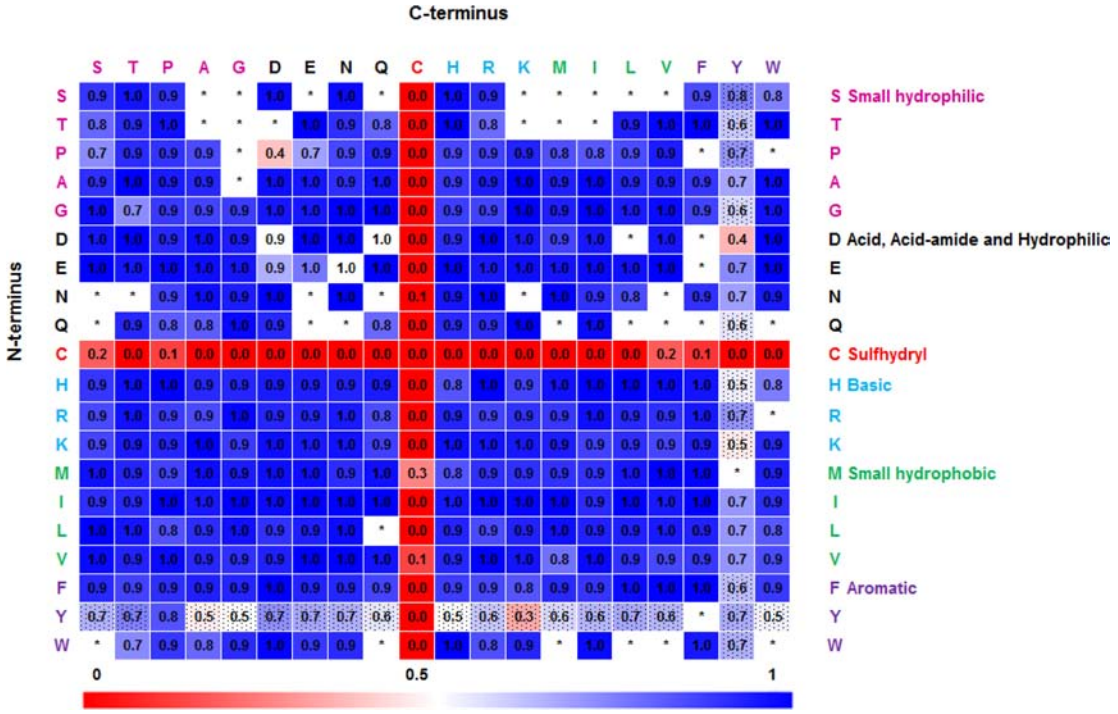

Figure 2. 20 × 20 dipeptide-based tyrosinase inhibition matrix. The comprehensive pre-estimation of the inhibitory ability of 20 × 20 dipeptides against mushroom tyrosinase is summarized in the matrix. The *Y*-axis represents the amino acids that constitute the N terminus of the dipeptides, and the *X*-axis represents the 20 amino acids that constitute the C terminus of the dipeptides. According to the chemical properties of the side chains, 20 amino acids are divided into eight categories: (1) G; (2) nonpolar aliphatic amino acids, A, V, L, I, and P; (3) nonpolar aromatic amino acids, F, W, and Y; (4) polar hydroxyl amino acids, S and T; (5) sulfur amino acids, C and M; (6) amidic amino acids, N and Q; (7) polar negative amino acids, D and E; and (8) polar positive amino acids, R, H, and K. The numbers in each small square with different colors are inhibition indices, which represent the distinct levels of tyrosinase activities. The scale of inhibition indices is from 0 (complete abolished tyrosinase activity; red) to 1 (full tyrosinase activity; blue). An asterisk denotes that the dipeptides are not completely dissolved in ddH_2O. The dipeptides that change the color of the reaction solution and therefore might interfere with the results are marked with a dotted pattern.

solution was added to each well; thus, the final volume in each well was 250 μL. The plate was incubated again at 25 °C for 5 min. In addition, the same concentrations of kojic acid and β-arbutin under the same conditions as those in the wells were used as controls. The amount of dopachrome produced was determined against a blank (solution without tyrosinase) and recorded using a spectrophotometer (Varian Cary 50 Bio UV−visible spectrophotometer) at 475 nm every 10 s for 10 min. The amount of dopachrome produced in the reaction solution was determined using a previously described method.[37] The tyrosinase activity was calculated using the equation

$$\text{tyrosinase activity } \% = \left(\frac{S - B}{C}\right) \times 100$$

where S is the OD_{475} absorbance of the test samples, B is the OD_{475} absorbance of the blank, and C is the OD_{475} absorbance of controls. The IC_{50} of cysteine-containing dipeptides was determined by performing dose-dependent inhibition experiments in triplicate.

Cell Viability and Melanin Quantification Assay. Normal human epidermal melanocytes were purchased from Cascade Biologics (Portland, OR, USA) and cultured in Medium 254 supplemented with human melanocyte growth supplement (Cascade Biologics). During the experiment, confluent cells were trypsinized and suspended in melanocyte growth medium M2 containing 2×10^5 cells/mL. The cells were then placed in 96-well plates (2×10^4 cells/well) for the cell viability assay and in 24-well plates (1×10^5 cells/well) for the melanin content assay. After 24 h, the cells were treated with arbutin (50 μM, 2.5 mM), kojic acid (50 μM, 500 μM), and 1, 10, and 100 μM **CA**, **YC**, **PD**, and **DY**. The cells were then incubated at 37 °C for 72 h. Cell viability was determined using the MTT assay.[38,39] For measuring the melanin content, the melanocyte pellets were dissolved in 1 N hot NaOH (70 °C) for 1 h and centrifuged for 10 min at 10000*g*. The optical density (OD_{405}) of supernatant in each cell of the plate was measured using a microplate reader (Molecular Devices Spectra Max M2).

Molecular Modeling. Models of the dipeptides in complex with tyrosinase were built using molecular docking analysis. GOLD (version 5.2) featuring the Goldscore scoring function was used to predict the positions of dipeptides at the active sites. All cofactors and water molecules were removed before docking. Three-dimensional (3D) structures of the desired dipeptides were generated and optimized through energy minimization by using Discovery Studio version 4.0 (Accelrys Software, Inc., San Diego, CA, USA) and further docked into the active sites of mushroom tyrosinase (PDB ID 2Y9X) by turning on the flexible docking option. Initially, 100 genetic algorithm cycles of computation were performed with ligand torsion angles varying between −180° and 180°. The search efficiency was set at 200% to explore the docking conformational space. All other parameters were applied as the default settings. Finally, from the 100 docking conformations of each dipeptide, the conformation with the highest GOLD fitness score was examined to investigate its binding with the mushroom tyrosinase active site by using Goldscore. The molecular models of the dipeptide−tyrosinase complexes were presented using PyMOL software (http://www.pymol.org).

RESULTS

Comprehensive Investigation of Inhibitory Abilities of 20 × 20 Dipeptides against Tyrosinase. In our previous study, we found a natural product, A5,[36] that exhibits an apparent tyrosinase inhibitory ability. Moreover, the structure of A5 resembles that of dipeptide **WY**. To investigate the inhibitory potency of dipeptides against mushroom tyrosinase, 400 dipeptides were constructed and subjected to the tyrosinase inhibition assay. Their inhibitory abilities were pre-estimated and

DOI: 10.1021/acs.jafc.5b01026
J. Agric. Food Chem. 2015, 63, 6181−6188

summarized in a 20 × 20 dipeptide matrix (Figure 2). The result showed that 5 mM cysteine-containing dipeptides completely ceased the activity of tyrosinase (normalized percentage inhibition index is 0.0−0.3; Figure 2). In addition, 5 mM **PD**, **DY**, and **YK** reduced the activity of tyrosinase by 60−70%. However, dipeptides with a tyrosine residue located at the C or N terminus exerted moderate effects on tyrosinase inhibitory formation efficiency; their normalized inhibition index was approximately 0.5−0.7. The remaining dipeptides showed little or no inhibition against tyrosinase, and some did not even completely dissolve in double-distilled (dd) H_2O (46 peptides labeled with asterisks). Twenty-seven dipeptides (the color of the reaction solution changed; therefore, these might have interfered with the result) are denoted with a dotted pattern (Figure 2).

Cell Viability and Melanin Quantification Assay. According to the 20 × 20 dipeptide matrix for the inhibition of tyrosinase (Figure 2), we randomly selected four dipeptides, two cysteine-containing dipeptides (**CA** and **YC**) and two non-cysteine-containing dipeptides (**PD** and **DY**), to estimate their effects on cell viability and melanogenesis. The cell viability of human normal melanocytes treated with 1.0, 10, and 100 μM dipeptides (**CA**, **YC**, **PD**, and **DY**) is shown in Figure 3; no

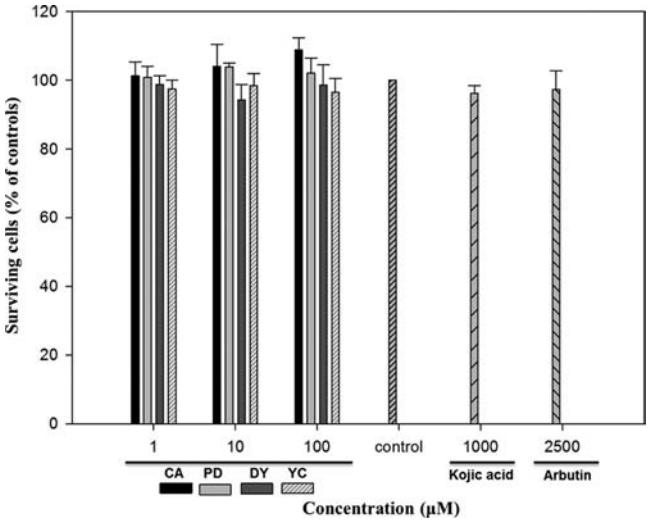

Figure 3. Effects of arbutin, kojic acid, and dipeptides **CA**, **YC**, **PD**, and **DY** on cell viability.

significant cell death was observed under these conditions compared with the controls. The depigmenting effects of these dipeptides were estimated under the same conditions as those of the cell viability assay (Table 1). The results revealed that **CA** and **PD** attenuated 5.6 and 16.5% melanin content, respectively, at 100 μM; notably, **PD** could attenuate 20−30% melanin content at 400 μM. However, **YC** and **DY** showed little or no antimelanogenesis effects.

Table 1. Effects of Dipeptides CA, YC, PD, and DY on Melanogenesis in Normal Human Epidermal Melanocytes

	melanin content (%)			
peptide ID	1 μM	10 μM	100 μM	400 μM
CA	94.5 ± 1.8	93.4 ± 2.9	94.4 ± 1.8	
YC	85.9 ± 3.3	90.2 ± 5.7	109.7 ± 1.8	
PD	88.6 ± 1.1	87.0 ± 2.1	83.5 ± 1.2	71.5 ± 1.5
DY	91.1 ± 3.4	92.8 ± 2.4	102.9 ± 1.3	
kojic acid, 50 μM		97.7 ± 1.8		
kojic acid, 500 μM		91.6 ± 1.0		
β-arbutin, 50 μM		102.1 ± 4.6		
β-arbutin, 2.5 mM		90.6 ± 1.8		

Determination of Inhibitory Potency (IC_{50}) against Tyrosinase. The pre-estimation of the effects of dipeptides on tyrosinase inhibition demonstrated that cysteine-containing dipeptides markedly reduced the activity of tyrosinase. We further determined the IC_{50} to precisely investigate and compare the functional variations. The IC_{50} values of N-terminal cysteine-containing dipeptides are shown in Table 2. According to the table, most of the values ranged from 2.0 to 22.6 μM, showing the effective inhibitory potency, except for **CP** (IC_{50} = 55.8 μM). In addition, **CS**, **CY**, **CF**, **CC**, **CI**, **CM**, and **CQ** considerably inhibited tyrosinase; the IC_{50} was <5 μM. In particular, **CE** exhibited the strongest potency in inhibiting tyrosinase (IC_{50} = 2.0 μM). The inhibition scales of most C-terminal cysteine-containing dipeptides ranged from 4.5 to 140 μM, less potent than the inhibition scales of N-terminal cysteine-containing dipeptides (Table 2). The dipeptides that showed comparable inhibitory potency with those of the C-terminal cysteine-containing dipeptides were **IC**, **NC**, **QC**, **FC**, and **VC** (IC_{50} < 10 μM).

Molecular Modeling. Cysteine-containing dipeptides (**CE**, **CS**, **CY**, **CA**, and **CW**) significantly decreased the activities of tyrosinase (by >6-fold) compared with **EC**, **SC**, **YC**, **AC**, and **WC**. To elucidate the functional deviations of these cysteine-containing dipeptides, we further analyzed the structural interactions of these dipeptides with mushroom tyrosinase by using molecular modeling. Dipeptides **CE**, **CS**, **CY**, **CA**, and **CW** and their reverse forms (**EC**, **SC**, **YC**, **AC**, and **WC**) were docked into the active sites of mushroom tyrosinase (PDB ID 2Y9X), and their detailed molecular interactions were analyzed (Supporting Information Table S1). The result showed that the cysteine residues of all dipeptides most likely contacted closely with the binuclear copper ions at the active sites of tyrosinase, regardless of their location (N or C terminus; Supporting Information Figure S1). In addition, **CE**, with the most profound tyrosinase inhibitory ability, showed extensive strong molecular interactions with tyrosinase (Supporting Information Figure S2 and Table S1). The electrostatic and cation−π interactions supported by residues His244, Asn260, Glu256, and Phe264 were commonly observed within the docked **CE**, **CD**, **CS**, **CY**, **CA**, and **CW**. In addition, hydrogen bonds and hydrophobic interactions were observed among **CE**, **CS**, **CY**, and **CW** active-site residues Arg268, Gly281, Ser282, and Val283 (Supporting Information Table S1). Molecular modeling of **CD** was performed to clarify its functional divergence with **CE**. The result showed that only four of six molecular interactions were observed between tyrosinase and **CD**. The molecular interactions of **EC**, **SC**, **YC**, **AC**, and **WC** with tyrosinase are summarized in Table S1. All N-terminal cysteine-containing dipeptides exhibited electrostatic attractions with Glu256, hydrogen-bond interactions with Asn260, and hydrophobic interactions with Val283. In addition, the molecular models of tyrosine-containing dipeptides, **YK** and **DY**, in complex with mushroom tyrosinase were observed (Figure 4). The tyrosine moiety of **YK** and **DY** went deep into the substrate binding pocket, and π−π interactions were observed between the phenol ring of tyrosine and the imidazole ring of His263. The lysine moiety of **YK** interacted with Phe264 and Arg268 through cation−π interactions and electrostatic interactions, respectively (Figure 4D). The dipeptide **DY** interacted with H85, Ser282, and

Val283 through electrostatic attractions, hydrogen bonding, and hydrophobic interactions, respectively (Figure 4C).

DISCUSSION

According to our previous finding that a natural compound, A5,[36] which possesses potent tyrosinase inhibitory ability, resembles the structure of dipeptide **WY**, dipeptides have great potential for tyrosinase inhibitor development. In this study, we comprehensively estimated 20 × 20 dipeptides for mushroom tyrosinase inhibition, and the results revealed that cysteine-containing dipeptides significantly inhibit tyrosinase. The IC_{50} of cysteine-containing dipeptides was determined for investigating the positional preference of the cysteine residue and the selectivity of functional amino acids against tyrosinase. The results revealed that N-terminal cysteine-containing dipeptides outperformed the C-terminal cysteine-containing dipeptides in inhibiting tyrosinase, and **CE** exhibited the strongest inhibitory potency (IC_{50} = 2.0 μM) (Table 2). In addition, most of the cysteine-containing dipeptides exhibited modest divergence in their inhibitory abilities when the cysteine residue was reversed at the terminus. By contrast, the inhibitory abilities of **CE**, **CS**, **CY**, **CA**, and **CW** decreased >6-fold when the cysteine residues shifted from the N terminus to the C terminus. Furthermore, an extensively attenuated inhibition of tyrosinase was observed; the inhibitory potencies of **CY**−**YC** and **CE**−**EC** were reduced 42.4- and 70.7-fold, respectively. These results indicate that the glutamic acid residue (**E**) is more functional at the C terminus than at the N terminus of dipeptides for inhibition, and the hydroxyl groups of serine and tyrosine residues at the C terminus, not the N terminus, considerably contribute to the inhibitory ability. Moreover, the bulk indole ring of the tryptophan residue located at the C terminus of dipeptides is more bioactive in inhibiting tyrosinase than that located at the N terminus. This study not only demonstrates the importance of the positional preference of the cysteine residue but also reveals the selectivity of the functional amino acids of cysteine-containing dipeptides for inhibiting tyrosinase.

The functional variations resulting from the positional preference of the cysteine residue and the selectivity of specific amino acids among N- and C-terminal cysteine-containing dipeptides were further analyzed using molecular modeling. According to the models, the cysteine residue most likely coordinates with the binuclear copper ions through the sulfur atom of the cysteine residue, regardless of its location (N or C terminus; Figure S1). In addition, one anion−π interaction, one hydrogen bond, and two electrostatic forces were frequently observed in all N-terminal cysteine-containing dipeptides for tyrosinase interactions (Table S1). However, only one hydrogen bond, one hydrophobic bond, and one electrostatic interaction were frequently observed in all C-terminal cysteine-containing dipeptides for tyrosinase interaction. Thus, these variations may mainly cause a functional divergence between N- and C-terminal cysteine-containing dipeptides in the inhibition of tyrosinase. The different inhibitory efficacies of the N-terminal cysteine-containing dipeptides against tyrosinase can be explained by their corresponding interactions with tyrosinase. For example, **CE** and **CY** display a maximum of six molecular interactions with tyrosinase; therefore, they show the strongest inhibitory ability (Figure S1 and Table S1), and **CA**, featuring the fewest molecular interactions with tyrosinase, exhibits the weakest inhibitory potency (Table S1). Similar explanations can be applied to interpret the diverse inhibitory efficiency of C-terminal cysteine-containing dipeptides, except for **EC** and **YC**; their inferior inhibitory ability compared with that of **SC** and **AC** may result from incomplete dissolution in ddH_2O. Moreover, the glutamic acid residue of **CE**, with a longer carboxyl side chain than that of aspartic acid, results in four extra molecular interactions with the active-site residues of tyrosinase (Figure S1A and Table S1), causing a stronger inhibitory ability than that of **CD**. Furthermore, the tryptophan residue of **CW** additionally contacts tyrosinase (one electrostatic interaction with His224, one hydrogen bond with the main chain of Gly281, and an extra hydrophobic interaction with Phe264), rendering it more efficient than **WC** in the inhibition of tyrosinase.

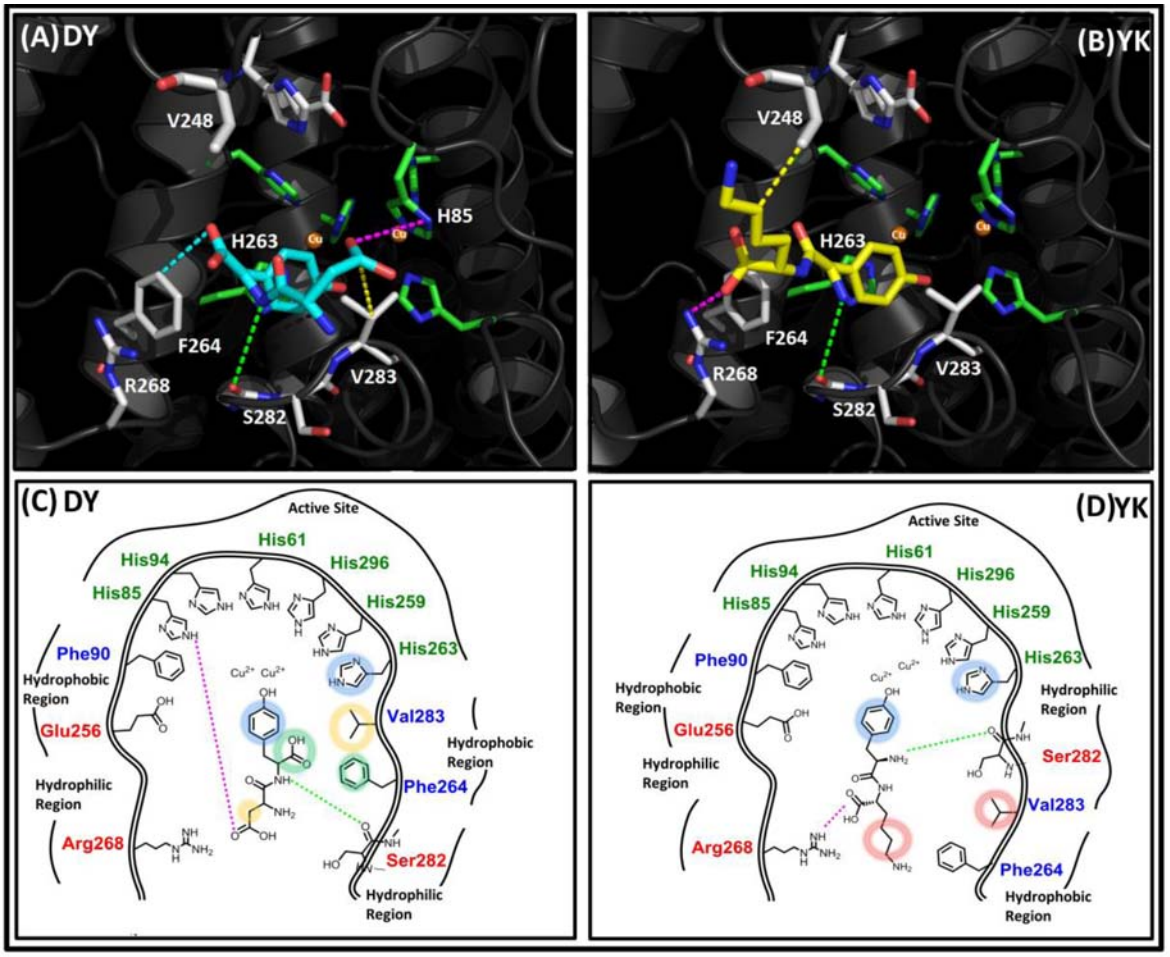

Figure 4. Molecular models of dipeptides **DY** and **YK** in complex with mushroom tyrosinase. (A) Docking model of the dipeptide **DY** (cyan) at the active sites of mushroom tyrosinase. (B) Docking model of the dipeptide **YK** (yellow) in complex with mushroom tyrosinase. The residues interacting with dipeptides **DY** and **YK** are denoted by white and green (six histidine residues), respectively. Green, magenta, and cyan dashed lines represent the H-bonding, electrostatic, and anion−π interactions, respectively, and yellow lines represent the hydrophobic interactions. (C) 2D schematic of the interactions between the dipeptide **DY** and active-site residues of mushroom tyrosinase. (D) 2D schematic of the interactions between the dipeptide **YK** and active-site residues of mushroom tyrosinase. In 2D schemes, green and magenta dashed lines denote H-bonding and electrostatic interactions, respectively; circles in distinct colors represent the relative hydrophobic and/or π−π interactions among the dipeptide and active-site residues of mushroom tyrosinase, respectively.

In this study, the inhibitory abilities of dipeptides were investigated in the presence of tyrosine as the tyrosinase substrate, and dipeptide activity was evaluated for dopachrome formation. Therefore, the inhibition of tyrosinase activity could be accomplished by one of the following: (a) reducing agents, leading to the reduction of dopaquinone; (b) *o*-dopaquinone scavengers, such as thiol-containing compounds; (c) alternative enzyme substrates−phenolic compounds; (d) nonspecific enzyme inactivators, such as acids or bases; or (e) specific tyrosinase inactivator−mechanism-based inhibitors, also called suicide substrates.[7] Cysteine-containing dipeptides are similar to *o*-dopaquinone scavengers, which react with dopaquinone, causing the formation of thiol−dopa conjugates. In vivo, cysteine and GSH are natural thiol compounds that form pheomelanin instead of eumelanin.[40] Similarly, cysteine-containing dipeptides have the potential to form dopaquinone conjugates, thus attenuating dopachrome formation, abolishing eumelanin synthesis, and increasing the pheomelanin amount (Figure 1). The structural components of **CE**, the most potent dipeptide in the inhibition of dopachrome formation, exhibit similarities with those of GSH (Figure 1). Thus, we proposed that cysteine-containing dipeptides can either interact with the active sites of tyrosinase or act as the *o*-dopaquinone scavenger to inhibit dopachrome formation. However, this was disproved by our HPLC and mass spectrometry analysis results (Figure S3, Table S2, and Figure S4). To clarify and identify the possible inhibition mechanism of cysteine-containing dipeptides against tyrosinase, we performed HPLC to purify the products of both N-terminal and C-terminal cysteine-containing dipeptides that reacted with tyrosinase. In addition, mass spectrometry was employed to determine the precise molecular weight of the purified samples. The results showed that none of the peaks corresponding to cysteinyldopa-peptides—the products resulting from the reactions of cysteine-containing dipeptides interacting with dopaquinone—was observed in the HPLC profile, and no molecular weight equilibrant to cysteinyldopa-peptide was identified using mass spectrometry (Figure S4). These results reveal that cysteine-containing dipeptides most likely bind and inhibit tyrosinase directly, instead of interacting with dopaquinone to form cysteinyldopa-peptide.

However, the tyrosine-containing dipeptides possibly belong to the alternative enzyme substrate, where the tyrosine entity can

DOI: 10.1021/acs.jafc.5b01026
J. Agric. Food Chem. 2015, 63, 6181−6188

compete with the tyrosine substrate at the active site of tyrosinase. To elucidate the inhibition mechanism of tyrosine-containing dipeptides against tyrosinase, **CY**, **DY**, **YC**, and **YK** were directly reacted with tyrosinase in the absence of a substrate (tyrosine); the absorbance at 400 and 475 nm of the products was then evaluated. The result showed that the products obtained from the reactions of **CY** and **YC** interacting with tyrosinase exhibited no absorption at 400 and 475 nm (Figure S5A), respectively, indicating that none of the products belongs to a dopachrome-containing and/or dopaquinone-containing peptide. This proved that cysteine-containing dipeptides are inhibitors that use the cysteine moiety mainly to interact with the active site of tyrosinase instead of using the tyrosine. The products from **DY** and **YK** showed weak absorption at 400 nm but not at 475 nm (Figure S5B), indicating that the tyrosine-containing dipeptides are substrate-like inhibitors subject to further catalysis by tyrosinase to form dopaquinone-containing dipeptide. These results clarify that the tyrosine-containing dipeptides act as substrate binding at the active site of tyrosinase, thus exhibiting varying inhibitory efficacies against tyrosinase. When these tyrosine-containing dipeptides exhibit a favorable affinity with tyrosinase, dopachrome formation is attenuated. In addition, approximately 27 tyrosine-containing dipeptides that changed the color of the tyrosinase reaction solutions were observed. Therefore, free tyrosine can react with tyrosinase and form dopachrome. However, tyrosine in a dipeptide can be oxidized by tyrosinase, thus inhibiting dopachrome formation.

Conventional pharmaceutical skin-whitening drugs, such as hydroquinone,[16,17] arbutin,[18] and kojic acid,[19,20] are insufficient because they are reported to be severely carcinogenic and damage the structural architecture of several tissues.[41−43] Moreover, an intriguing recent story was published on a skin-whitening rhododendrol, which has been withdrawn from the cosmetic market because of its toxicity.[44] Recently, several studies have discovered novel proteins and peptides from natural resources, such as the housefly,[45] silk,[46] honey,[47] wheat,[48] and milk,[49] for tyrosinase inhibition. In particular, cyclic peptides,[50] short-sequence oligopeptides,[32] kojic acid tripeptide,[34] mimosine tetrapeptides,[33] and octameric peptides[15] have been thoroughly investigated to determine their tyrosinase inhibitory ability. The current study is the first on the systematical annotation of critical amino acids that constitute potent dipeptides for tyrosinase inhibition in dopachrome formation. The cytotoxicity and depigmenting effects of cysteine-containing **YC** and **CA**, as well as the less potent noncysteine-containing **PD** and **DY**, were examined using cell viability and melanin quantification assays. No significant cytotoxicity was observed in these dipeptide-treated melanocytes, and **CA** and **PD** attenuated 5.6 and 16.5% melanin content, respectively, at 100 μM. In addition, the cells treated with dipeptide **PD** (400 μM) could reduce 20−30% of melanin content. This indicates that the inhibitory effects of **CA** and **PD** on melanin production are not attributable to their cytotoxicity, and **CA** and **PD** can be safely used in skin-whitening products without influencing melanocyte growth.

In conclusion, this study provides insight into the functional role of the cysteine residue positional preference and the selectivity of specific amino acids of cysteine-containing dipeptides for the inhibition of tyrosinase. Therefore, the findings can be applied in developing new inhibitors against tyrosinase.

enabled the analysis of a wide range of compounds from fatty acids to intact high molecular weight lipids such as sterol esters and TGs. UHPLC-HRAM-MS^n has been used to analyze polyphenols, glucosinolates, flavonoids, etc., in this laboratory.[13−17] The fuzzy chromatography mass spectrometric (FCMS) fingerprinting combined PCA was used to visualize the chemical difference between WF and RF. In comparison with full LC separation, FCMS aims to obtain an adequate separation one class of compounds from another as fast as possible on a relatively short (≤50 mm) column. Although optimal separation cannot be achieved on each individual compound, FCMS can avoid ion suppression effects to some extent and speed up high-throughput analysis.

EXPERIMENTAL PROCEDURES

Chemicals. HPLC grade methanol, formic acid, and *n*-butanol were purchased from VWR International, Inc. (Clarksburg, MD, USA). HPLC water was prepared from distilled water using a Milli-Q system (Millipore Laboratories, Bedford, MA, USA).

Materials and Sample Preparation. The bran, germ, and endosperm of the same brand were purchased from local grocery stores. Bran and germ flakes were ground into fine powder and then passed through a 60 mesh sieve. One hundred milligrams of each sample was extracted with 4.0 mL of water-saturated *n*-butanol[5,6,11,18] using a sonicator (Advanced Sonic Processing Systems, Oxford, CT, USA) at 16 kHz with 300 W power for 40 min. The slurry mixture was centrifuged at 13000*g* for 15 min in a Contifuge 28RS centrifuge (Heraeus, South Plainfield, NJ, USA) at 4 °C. The supernatant was filtered through a 17 mm (0.20 μm) PVDF syringe filter (VWR Scientific, Seattle, WA, USA) and stored at −80 °C until analysis. For FCMS analysis, whole wheat flour and all purpose unbleached flour from three different brands were used as WF and RF, respectively. Each of the six samples was extracted in triplicate. The injection volume for all samples was 2 μL.

UHPLC-HRAM-MS^n Conditions. The UHPLC-HRAM-MS^n system consisted of an LTQ Orbitrap XL MS with an Accela 1250 binary pump, a PAL HTC Accela TMO autosampler, an Accela PDA detector (Thermo Fisher Scientific, San Jose, CA, USA), and a G1316A column compartment (Agilent, Santa Clara, CA, USA). APCI and ESI detection were investigated in both the positive and negative ion modes. The ESI conditions were set as follows: sheath gas at 80 (arbitrary units), auxiliary and sweep gas at 10 (arbitrary units), spray voltage at −4.0 kV for negative mode and at 4.5 kV for positive mode; capillary temperature at 300 °C; capillary voltage at −50 V for negative mode and at 50 V for positive mode; and tube lens offset at −120 V for negative mode and at 120 V for positive mode. APCI source was operated at 450 °C, the heated capillary temperature was 275 °C, the corona discharge current was set to 5.0 μA, and sheath gas (N_2) and auxiliary gas (N_2) were at 60 and 5 arbitrary units, respectively. The scan event cycle used a FT full scan mass spectrum at a resolving power of 30000 and three data-dependent MS^2, MS^3, MS^4 events acquired by LTQ triggered by the most intensive ion from each previous scan event. The automated gain control (AGC) target value was set to 200,000 for FT full scan and to 10,000 for IT MS^n scan, respectively. MS^n activation parameters used an isolation width of 1 amu, maximum ion injection time of 200 ms, normalization collision energy at 35%, and activation time of 30 ms.

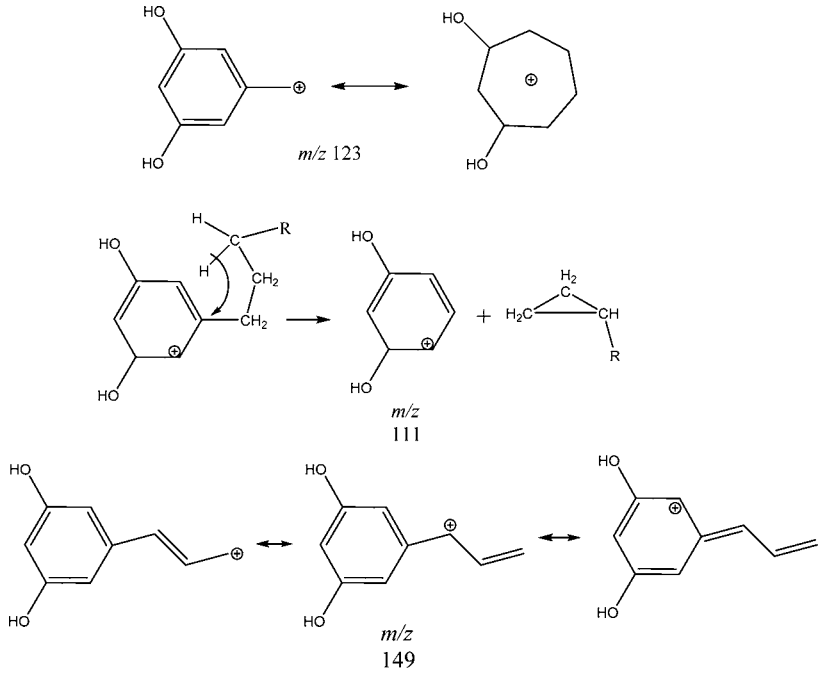

Figure 3. Proposed characteristic ions from CID spectra of ARs in positive mode.

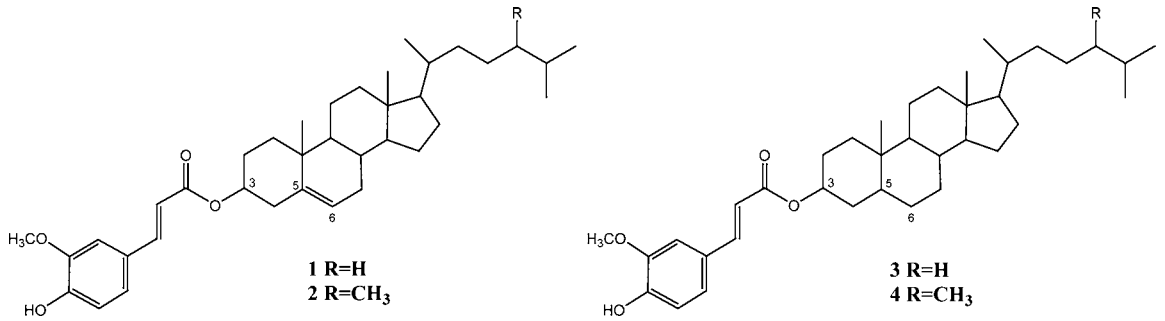

Figure 4. Structures of γ-oryzanol identified in wheat bran: **1**, campesteryl ferulate; **2**, sitosteryl ferulate; **3**, campestanyl ferulate; **4**, sitostanyl ferulate.

The LC separation was carried out on a Poroshell 120EC-C_{18} column (2.1 × 150 mm, 2.7 μm) (Agilent, Santa Clara, CA, USA) with a flow rate of 0.4 mL/min. The mobile phase consisted of a combination of A (0.1% formic acid in water) and B (0.1% formic acid in methanol). A gradient elution program was employed as follows: 85% B at 0−3.0 min, 90% B at 5.0−7.0 min, 95−100% B over 15.0−20.0 min, and held at 100% B until 100.0 min. The column temperature was set at 40 °C.

A Poroshell 120EC-C_{18} column (3.0 × 50 mm, 2.7 μm) was used for FCMS fingerprinting with the same flow rate and temperature. The flowing elution gradient was 85% B at 0−1.0 min, 100% B at 1.1−3.7 min, and 85% B at 3.8−5.0 min.

Data Processing for PCA. Each FCMS fingerprint consisted of a one-dimensional matrix (ion counts versus mass for m/z 100−1300 in nominal resolution), obtained by averaging spectra acquired from 0.1 to 5.0 min. The nominal masses of each FCMS spectrum were exported to Excel (Microsoft, Inc., Bellingham, WA, USA) from Xcalibur for data preprocessing. The preprocessing in Excel involved combining MS fingerprints of all the samples into one matrix, sorting the data by sample names, and aligning the masses (each spectrum had a different number of masses because the m/z below the detection threshold would not be exported into the mass list from the spectrum). A zero was inserted for each missing m/z, using an Excel macro written in-house.

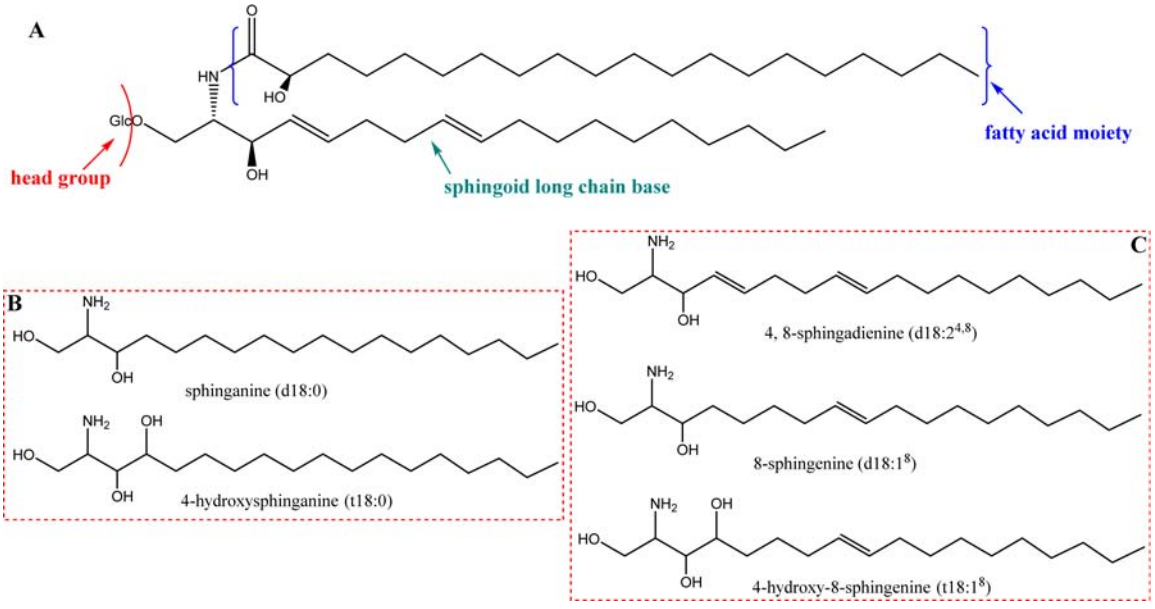

Figure 5. Structures of wheat sphingolipids.

One data matrix for each acquisition mode was obtained: APCI +, APCI−, ESI+, and ESI−. The data matrices were then imported to software SIMCA-P (version 13.0 Umetrics, Umea, Sweden) for PCA.

RESULTS AND DISCUSSION

ESI- and APCI-HRAM-MS^n detection in both positive and negative ionization modes were used to obtain complementary information on the structural features and the conjugated forms of lipids. The total ion chromatograms (TICs) of germ acquired in APCI(±) and ESI(±) are shown in the Supporting Information (Figure S1). From first glance, most of the peaks appearing in the negative spectra were eluted before 40 min; those were identified as free FA, oxylipins, γ-oryzanol, phospholipids, sphingolipids, galactolipids, etc., whereas for positive spectra, DGs were identified from peaks eluting around 20−30 min, ARs were found mainly prior to DGs, and the majority of the peaks eluted after 40 min were identified as TGs. Identification of the lipid compounds was based on chromatographic behavior, accurate mass measurements, consecutive MS^2−MS^4 analyses, ring-plus-double-bond equivalent (RDB), and comparison with data in the literature. A total of 155 lipid compounds were tentatively identified from germ, bran, and endosperm. The MS^n data listed in the tables were from the milling fraction with the most reliable spectra in terms of peak intensity.

Identification of Free Fatty Acids. The FAs of wheat and wheat products have been studied by many investigators in the form of methyl derivatives by gas chromatography (GC).[9] When liquid chromatography is used, the FAs can be analyzed directly without being converted to their methyl esters. The characteristic fragmentation of free FA in APCI negative and positive

modes is demonstrated in Figure S2. The putative identification of wheat free FAs and APCI(±) data are listed in Table 1. The distributions of the three most abundant free FAs across endosperm, bran, and germ are compared in Figure 1 with the germ fraction giving the highest peaks.

Identification of Oxylipins. Oxylipins are a diverse family of secondary metabolites that are produced by oxidative metabolism of polyunsaturated fatty acids (PUFA), such as linolenic acid and linoleic acid.[19−22] In plants, oxylipins serve as signal molecules in developmental processes (e.g., pollen formation) and in defense mechanisms (e.g., pathogenesis, wounding, and herbivores).[23] Milling, baking, and storage are known to trigger autoxidation, leading to the formation of additional oxylipins. A whole-grain wheat feeding study on pigs[24] also found that oxylipins in the plasma of pigs correlated with WF and RF bread consumed, with higher oxylipin concentrations found after consumption of WF. It is not clear whether oxylipins may have health detrimental effects or may just be considered as markers for the shelf life of flour. The oxylipins in wheat are tentatively identified in Table 2 using APCI negative MS, MS^2, and MS^3 spectra and literature research.[19−22,25−28] The characteristic MS^2 and MS^3 spectra in APCI negative mode are shown in Figure S3.

Identification of Alk(en)ylresorcinols. Alkylresorcinols and alkenylresorcinols are amphiphilic derivatives of 1,3-dihydroxybenzene with an odd-numbered alkyl or alkenyl chain at position 5 of the benzene ring (Figure 2). ARs have been extensively evaluated as biomarkers for the intake of whole-grain and bran products of wheat and rye.[29,30] Among commonly consumed foods, ARs have been reported to be found mainly in the bran fraction of cereal grains,[31,32] where homologues with alkyl chains in the range of C15−C25 dominate, although derivatives with unsaturated and oxygenated side chains also exist. The MS/MS spectra of three ARs,

[a]CN, carbon number; DB, double bond.

Identification of γ-Oryzanols. γ-Oryzanol is a mixture of ferulic acid esters of sterols and triterpene alcohols (Figure 4), which is generally found in rice, particularly in the bran fraction.[34−36] It has also been identified in wheat,[37,38] but in low concentrations, 6.3 mg/100 g, as compared with those in brown rice, 60.2−65.6 mg/100 g.[35]

The molecular mass of γ-oryzanol could be resolved by APCI in negative mode on the basis of the formation of the deprotonated anion $[M - H]^-$. The positive mode spectra generated the cation of the intact triterpene alcohol or sterol moieties ($[M + H - 194]^+$ from neutral loss of ferulic acid[36,38] as major peak and protonated ion $[M + H]^+$ in low abundance. CID spectra of deprotonated molecular ions showed abundant ions of $[M - H - CH_3]^{\bullet-}$ resulting from the loss of a methyl group in the ferulic acid moiety. Another anion, $[M - H - 2CH_3]^{\bullet-}$, could be yielded for sterol ferulates with a double bond between

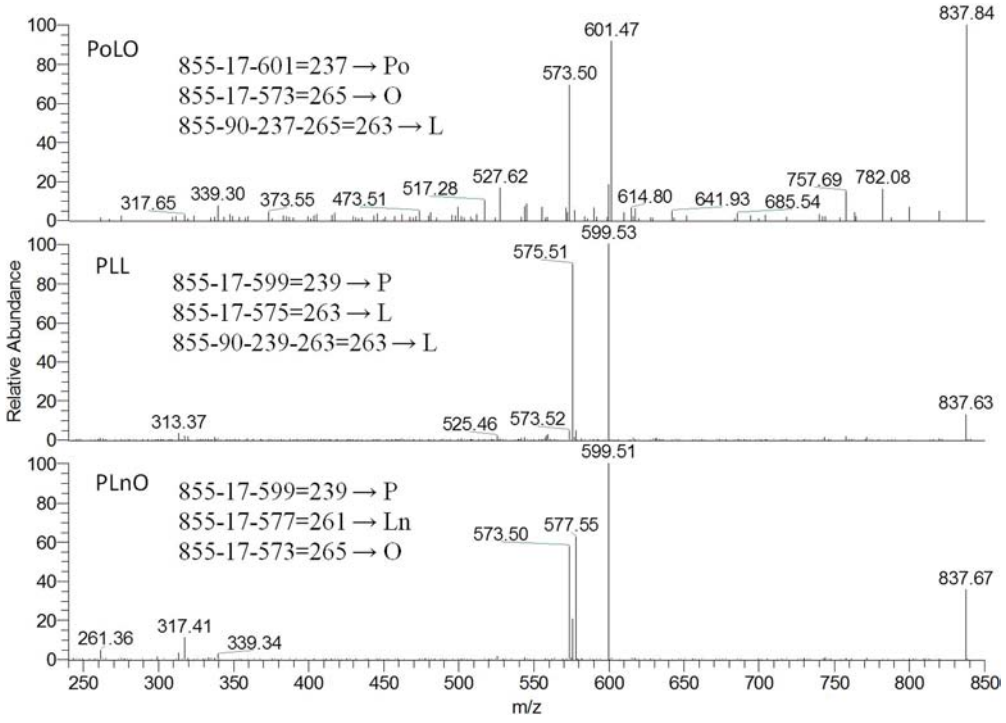

Figure 8. APCI+ MS^2 spectra of $[M + H]^+$ ions from TG isomers at m/z 855.7.

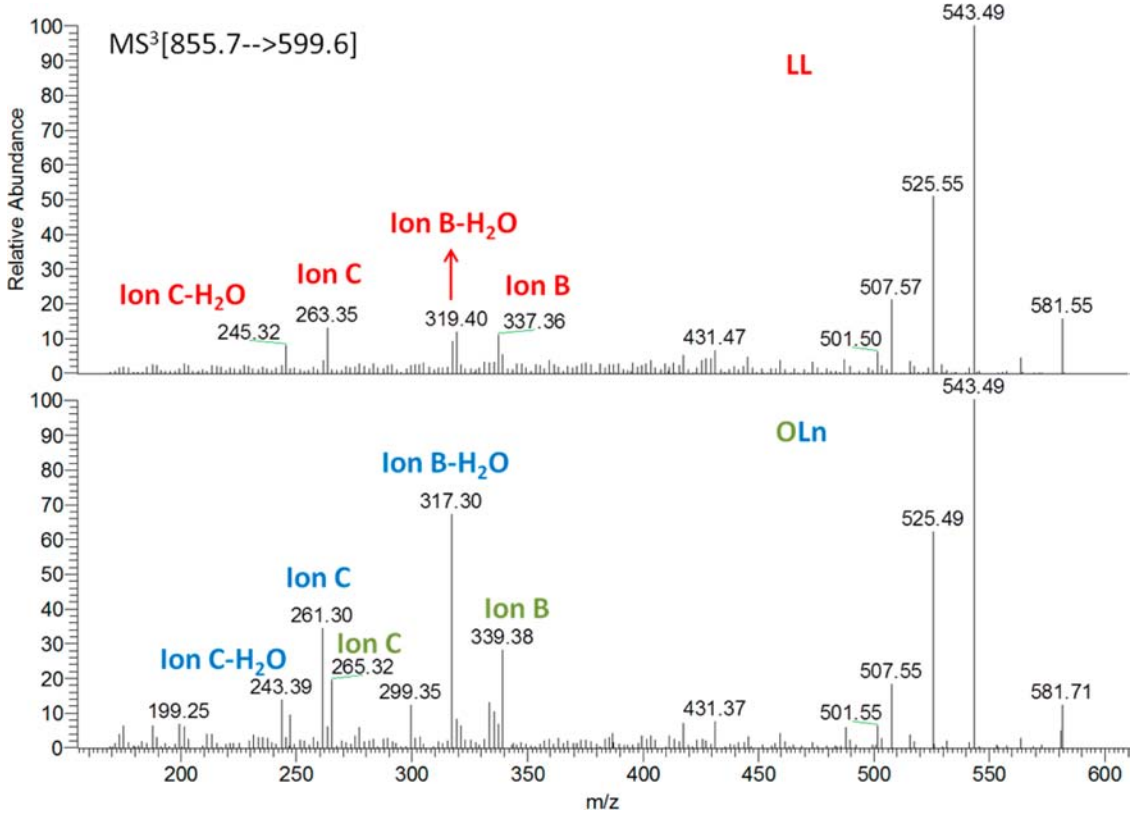

Figure 9. APCI+ MS^3 spectra of A ions from TG isomers [855.7→599.6].

C-5 and C-6. Characteristic ions also include deprotonated ferulic acid at m/z 193 as well as a fragment at m/z 177 derived from deprotonated ferulic acid.[36] The APCI(±) MS^n spectra of campestanyl ferulate re shown in Figure S5. The major γ-oryzanol components were deduced by combining APCI positive and negative data, listed in Table 4.

Identification of Sphingolipids. Sphingolipids constitute a class of distinct compounds that are both endogenous to mammalian cells and available exogenously through dietary consumption. These unique lipids are composed of a sphingoid long-chain base, a fatty acid tethered to the amino group of the sphingosine, and a variable polar headgroup (Figure 5A).

DOI: 10.1021/acs.jafc.5b01599
J. Agric. Food Chem. 2015, 63, 6189−6211

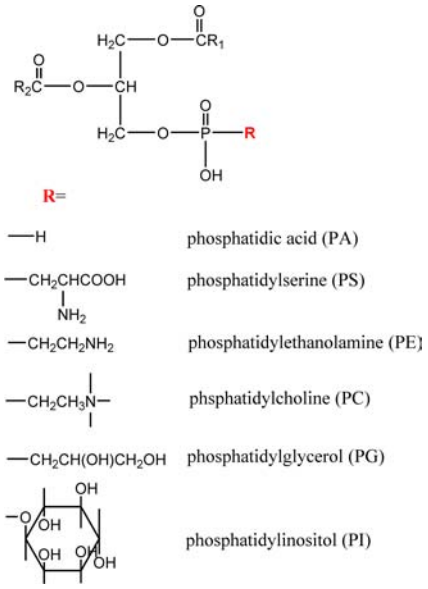

Figure 10. Structures and abbreviations of common wheat phospholipids.

The sphingosine base and the fatty acid constitute ceramide. There is considerable structural variation among the sphingolipids of different organisms with respect to the types of polar head groups and ceramide backbones. The principal molecular species of sphingolipids reported in wheat include the dihydroxy long-chain base sphinganine (d18:0) and the trihydroxy long-chain base 4-hydroxysphinganine (t18:0) for ceramide (Figure 5B) AND 4,8-sphingadienine (d18:2[4,8]), 8-sphingenine (d18:1[8]), and 4-hydroxy-8-sphingenine (t18:1[8]) for glucosylceramide (Figure 5C). The major fatty acids in wheat sphingolipids are 2-hydroxy fatty acids, and the major sugar in wheat monoglycosyl ceramide (cerebroside) is glucose.[39]

In APCI/ESI negative mode, ceramide and cerebroside compounds mainly yielded $[M - H]^-$ and $[M + FA - H]^-$ ions, due to the formation of adducts with formic acid in the mobile phase. The acid adducts were useful diagnostic ions as sphingolipid selective markers. All cerebrosides gave product ions $[M - H - 162]^-$ and $[M - H - 180]^-$ in their MS^2 spectra (Table 6; Figure S6). Anions of 2-hydroxy fatty acids, which can be used to determine the length of the fatty acyl chain moiety, are listed in Table 5.[40,41] Twelve cerebrosides and seven ceramides were tentatively identified (Table 6). Their distributions in three milling fractions were about the same on the basis of the peak areas in their extracted ion chromatography.

Identification of Triglycerides and Diglycerides. According to the literature,[18] TGs in whole wheat contain mainly linoleic acid (59%), palmitic acid (16.7%), and oleic acid (16.5%) with lower concentrations of some other fatty acids, such as linolenic acid (4.3%), arachidic acid (1.9%), palmitoleic acid (0.7%), and stearic acid (0.3%).

The APCI full scan spectra of TGs showed primarily two types of structurally important ions, "molecular ions" ($[M + H]^+$ and $[M + NH_4]^+$) and "diglycerides" $[M - RCOO]^+$ ions, the fragment ions formed by the loss of one fatty acid molecule from the $[M + H]^+$ ion of TGs (Figure 6, A ions). In the ESI full scan spectra, adduct ions $[M + NH_4]^+$ and $[M + Na]^+$ were observed instead of protonated molecules $[M + H]^+$, and no obvious fragment ions were produced. Therefore, the molecular masses of the individual TGs can be readily determined from the peaks of $[M + H]^+$ and $[M + NH_4]^+$ in APCI spectra, or $[M + NH_4]^+$ and $[M + Na]^+$ in ESI spectra, respectively. DGs formed A ions by losing a molecule of water from their $[M + H]^+$ ion. Another abundant fragment ion in the MS/MS spectra of TGs is formed by subsequent losses of a fatty acid molecule and an acyl RCO (B ions). Furthermore, dehydrated ion B, acyl ions (C ions), and dehydrated C ions were observed as well. The structure of the fragment ions observed in both the APCI and ESI MS/MS spectra are shown in Figure 6. The masses of acyls and characteristic fragment ions of TGs/DGs are listed in Table 7.

Molecular weight can also be determined from ions A or C using the following equations:

$$[M + H]^+ = C_1 + C_2 + C_3 + 90$$

$$A_{12} = C_1 + C_2 + 73$$

$$C_1 = [M + H]^+ - A_{23} - 17$$

$$C_2 = [M + H]^+ - A_{13} - 17$$

$$C_3 = [M + H]^+ - A_{12} - 17$$

The above equations are very helpful in elucidating composition of saturated TGs, which showed no or extremely low intensity of $[M + H]^+$ ions in APCI spectra.

Extracted ion chromatograms of A ions could be reconstructed to deconvolute the overlapping peaks, facilitating the identification of TGs/DGs with the same A ion (Figure 7). Every TG molecule contains three distinct attachment sites for fatty acids.

These are numbered *sn*-1, *sn*-2, and *sn*-3, where *sn* stands for stereospecific numbering. Three identical acyls on the glycerol backbone ($R_1R_1R_1$) provide only a single A ion, whereas the $R_1R_1R_2$ or $R_1R_2R_1$ TGs produce two different types of A ions with a statistical abundance ratio of 2:1, and the $R_1R_2R_3$ TGs produce three different types of A ions with the statistical

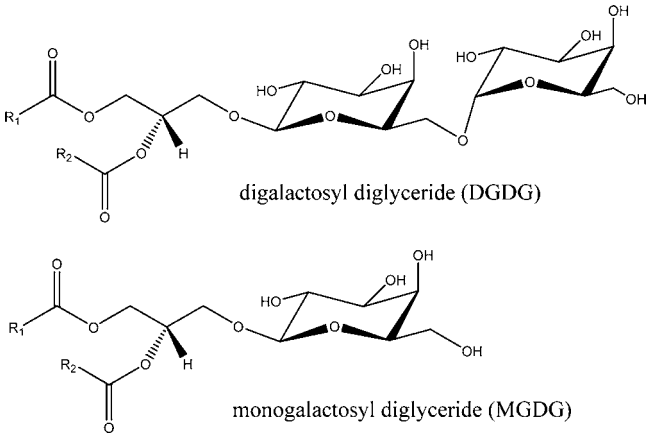

Figure 11. Major galactolipids in wheat.

abundance ratio of 1:1:1. In fact, the loss of RCOOH from the equivalent side position *sn*-1 and *sn*-3 is preferred compared to cleavage from the middle position *sn*-2.[42] The acyls in the *sn*-2 position are determined on the basis of relatively lower abundances of the A_{13} ions with respect to the A_{12} and A_{23} ions. The positions *sn*-1 and *sn*-3 are considered identical: the acyl with a lower mass is consistently attributed to the *sn*-1 position. The standard notation of TGs employs the initial of fatty acid names (Table 7), arranged in the order of their position on the glycerol skeleton (Table 8).

The fatty acids in the *sn*-2 position are much more unsaturated than those in positions *sn*-1 and *sn*-3 for both TGs and DGs. The positional distribution of fatty acids in DG isomers suggested that they originated from 1,2-diacyl-*sn*-glycerol,[10] so the DGs listed in Table 8 were arranged in the order of 1,2-diglycerides for simplicity.

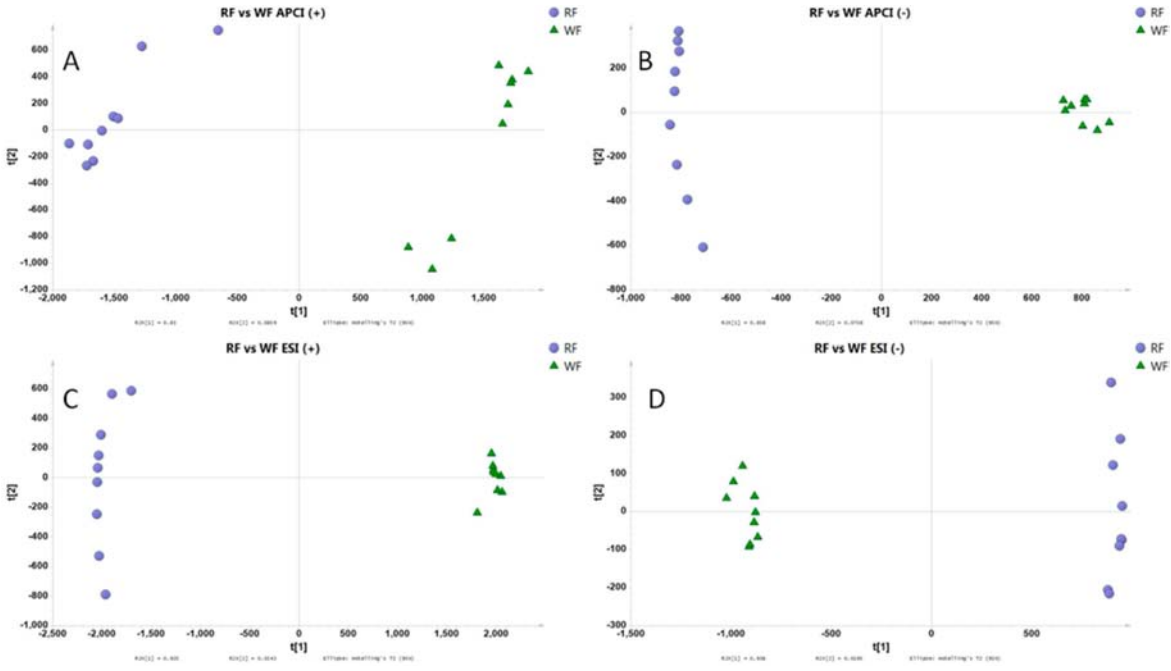

Figure 13. PCA score plot from flour sample RF and WF running on four data sets: (A) APCI+; (B) APCI−; (C) ESI+; (D) ESI−.

Isomers are common in TGs; A ions may or may not share the same value. Figure 8 shows the three MS^2 spectra of $[M + H]^+$ ion at m/z 855.7. The different A ion patterns indicate that there are three different TGs. Even though ions at m/z 599 were observed in the spectra of both PLL and PLnO, the MS^3 spectra of [855.7→599] could differentiate them from each other

DOI: 10.1021/acs.jafc.5b01599
J. Agric. Food Chem. 2015, 63, 6189−6211

unambiguously. As labeled in Figure 9, the compositions of ions at m/z 599 were LL for PLL and OLn for PLnO.

Identification of Glycerophospholipids. Phospholipids are the main constituents of biological membranes and have important structural and functional properties. They are made up of several distinct molecular classes with different polar head groups (Figure 10). Each phospholipid class consists of a mixture of many molecular species containing different combinations of fatty acids in the *sn*-1 and *sn*-2 positions on the glycerol backbone. The phospholipids are a minor proportion of wheat lipids except in the starchy endosperm, where they account for about 50% of the total lipids.[11]

A challenge in identifying phospholipids is that species from different structural classes may have the same masses. For example, exact masses of molecular cations of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) may overlap because their heteroatom compositions are the same ($N_1O_8P_1$). Consequently, characteristic fragmentation behaviors of each class played an important role in the identification process. Positive ion ESI MS/MS provides information on the nature of the headgroup,

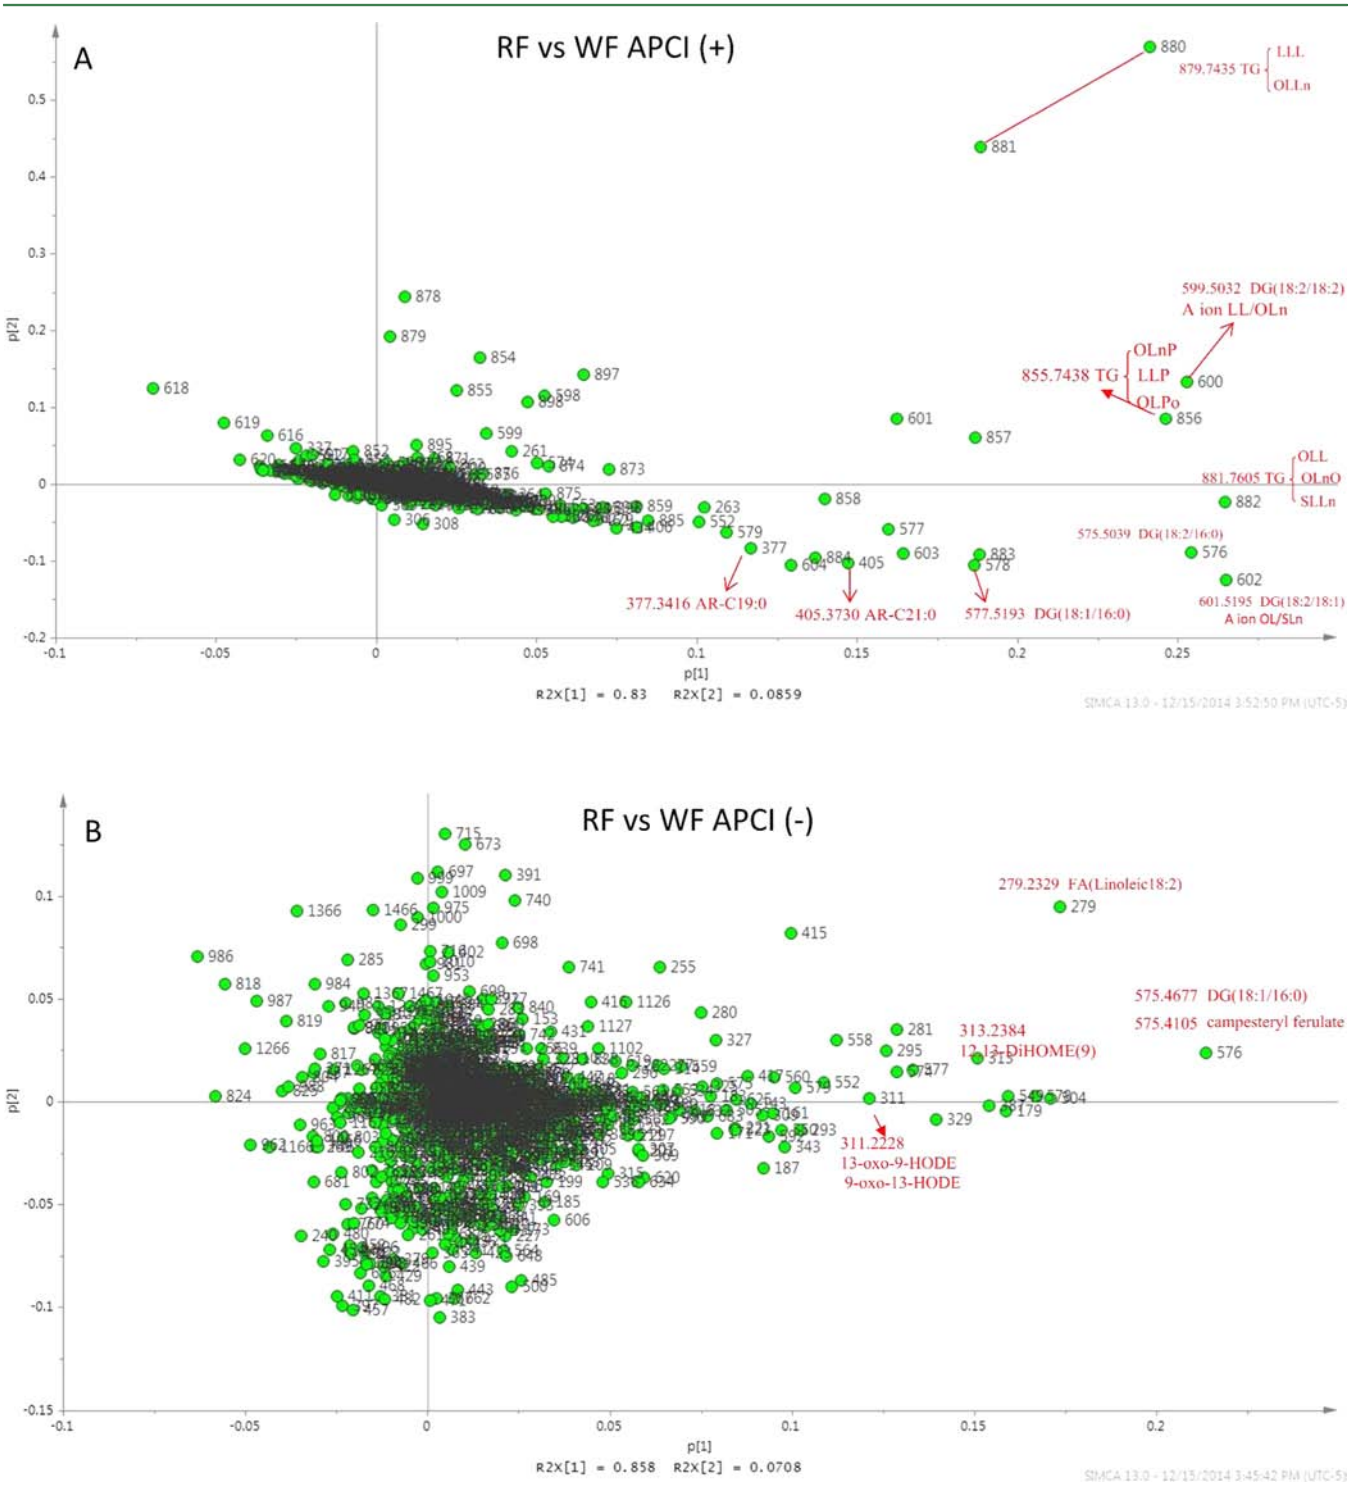

Figure 14. continued

Figure 14. PCA loading plot from flour sample RF and WF running on four data sets: (A) APCI+; (B) APCI−; (C) ESI+; (D) ESI−.

with the formation of an ion corresponding to the headgroup itself, or the loss of the headgroup from the molecular ion $[M + H]^+$ or NH_4^+ or Na^+ adducts. Acyl constituents were identified during negative ion MS/MS from the formation of their $RCOO^-$ or $[M - H - RCOOH]^-$ ions. Negative ESI MS spectra provided information on the regiochemistry of the phospholipids. The regiospecificity of the two acyl linkages could be clearly assigned on the basis of the intensity ratio of *sn*-2/*sn*-1 fragment ions. The ions used to characterize phospholipids in this study are summarized in Table 9. Characteristic MS^n spectra of PC, PE, PG, PI, PA, and PS identified in this work are shown in Figure S7. Tentative identification of the phospholipids with ESI negative data is listed in Table 10. The identification relied on the comparison of MS fragmentation behaviors between our data and the previously reported data.[43−46]

Identification of Galactolipids. Polar lipids, especially galactolipids, make important contributions to dough properties, baking performance, and resistance to bread staleness.[47,48] Plant seeds have a relatively low concentration of galactolipids compared to phospholipids and neutral lipids. The galactolipids

DOI: 10.1021/acs.jafc.5b01599
J. Agric. Food Chem. 2015, 63, 6189−6211

accounted for only about 3% of the total lipids of the seeds examined.[49]

Each of the two major galactolipid classes in wheat, DGDG and MGDG, is composed of various molecular species differing in chain length and the degree of saturation of their fatty acyl groups (Figure 11). The 2-position fatty acids of wheat galactolipids are highly unsaturated, containing 83% linoleic acid and 7% linolenic acid.[7]

Galactolipids were identified by comparing their positive and negative ESI spectra. As shown in Figure 12, the $[M - H]^-$/$[M + FA - H]^-$ and $[M + NH_4]^+$/$[M + Na]^+$ pairs were observed in ESI negative and positive mode, respectively. The MS^2 spectra of ions $[M - H]^-$ and $[M + NH_4]^+$ from DGDG (18:2/18:3) are shown in Figure S8. The principal product ions of $[M - H]^-$ were observed due to the cleavage of the fatty acid, giving $[M - H - R_1COOH]^-$ and $[M - H - R_2COOH]^-$. The less prominent ions were $[M - H - R_1COO - R_2COOH]^-$ at m/z 379 and fatty carboxylate anions R_1COO^- and R_2COO^-. These ions provide information on the composition of the two acyl groups. The $[M + NH_4]^+$ ion loses two galactosyl moieties to yield ions $[M + H - 162 - 162]^+$. One digalactosyl monoglyceride (DGMG), seven DGDG, and three MGDG compounds were identified mainly from endosperm (Table 11).

Lipids Discriminate Whole-Grain and Refined Wheat Flour. WF and RF data acquired by FCMS were used for PCA. Four different ionization modes (APCI+, APCI−, ESI+, and ESI−) were tested. The score plots of all four ionization methods are shown in Figure 13. All four PCA plots displayed excellent separation between RF and WF samples. The first two principal components cumulatively represented 91.6, 92.8, 94.9, and 95.6% of variance, respectively.

The corresponding loadings plots are presented in Figure 14. The loading plots reflect how much each of the variables contributed to the classification. However, different compound classes have different ionization efficiencies in different ionization modes, which lead to their different degrees of importance for discrimination in each mode. TGs/DGs respond to both APCI and ESI source, but form ions $[M + H]^+$/$[M + NH_4]^+$ and $[M + NH_4]^+$/$[M + Na]^+$, respectively, as mentioned above. Galactolipids show weak signals in APCI positive mode but very good signals in ESI positive mode. AR cannot be detected in ESI positive mode, but gives good signal in APCI positive mode.

TGs, DGs, and ARs contributed significantly to the separation in APCI+ mode (Figure 14A). Free FA, oxylipins, γ-oryzanol, or/and DGs contributed most to the separation in APCI− mode (Figure 14B). In ESI+ mode, galactolipids were mainly responsible for the discrimination of RF from WF, and TGs also appeared as characteristic ions of WF, whereas AR had poor ionization efficiency (Figure 14C). Phospholipids and galactolipids were the major contributors in ESI− mode (Figure 14D). The results of this study highlight the potential discriminatory compound categories between WF and RF. Sphingolipids did not show important roles in WF/RF discrimination.

Reagents. DNJ was purchased from Sigma (D9305; Sigma, St. Louis, MO, USA), and DNJ stock solutions were made in deionized distilled water and later diluted in media or phosphate-buffered saline (PBS) prior to use in culture. Rosiglitazone (RGZ), a PPARγ agonist, was purchased from Cayman Chemical (CAS Registry No. 122320-73-4; Ann Arbor, MI, USA). Fetal bovine serum (FBS) was from Hyclone (Logan, UT, USA), BODIPY from Life Technologies (Carlsbad, CA, USA), and 4′,6-diamidino-2-phenylindole (DAPI) from Roche (Basel, Switzerland).

Frozen Section and HE Staining. Baimei is an important Chinese indigenous breed, an obese type with 32% fat in the carcass, whereas Large White pig is widely distributed in most of the world and is a lean type with 15% fat in the carcass. Four fat-type breed Bamei pigs and four lean-type breed Large White pigs at day 180 of age were provided by the experimental farm of Northwest A&F University. All pigs were killed at a slaughterhouse under the guidelines of Northwest A&F University Animal Care Committee. Half an hour post-mortem, 4−6 g samples were taken from LM muscle between the sixth and seventh rib. LM were dissected and rinsed with PBS. Samples were frozen in liquid nitrogen. For frozen section, the samples were fixed with 4% paraformaldehyde and kept at room temperature. Fixed tissues were dehydrated in 30% sucrose (v/v) and sectioned (10 μm) through a sliding microtome (Leica, Solms, Germany). Sections were stained with HE using standard pathologic procedures.[27] The slides were then dehydrated with 95 and 100% ethanol successively followed by xylene (2 × 5 min) and mounted with coverslips. The sections were observed and pictures taken through a microscope (Olympus, New York, NY, USA) at 100× magnification.

Isolation and Culture of Porcine Intramuscular Adipocytes. About 20−30 min post-mortem, 4−6 g of LM per piglet was collected from four piglets (2 of them at 1 day and the others at 2 days of age) and finely minced in 50 mL beakers containing 5 mL of Dulbecco's modified Eagle's medium (DMEM)/Nutrient Mixture F-12 (DMEM/F12; Gibco) with 0.2 mL of kanamycin solution (30 mg/mL) per gram of tissue, respectively. Intramuscular adipocytes were isolated using a type II collagenase (Gibco) method according to previous publications.[28,29] The cells were cultured using a previously published method.[30,31] Briefly, the finely minced tissues were digested at 37 °C for 120 min in a shaking water bath. Digesta were passed through sterile 178 and 74 μm steel mesh filters to isolate digested cells. Cells were rinsed with serum-free DMEM/F12 medium and centrifugation twice at 1500*g* for 10 min. Cells were resuspended in growth medium (GM), plated at 6×10^5 per 60 mm culture dish, and cultured in a 5% CO_2 incubator at 37 °C. Because adipocytes attach much earlier than myoblasts, the culture cells were rinsed three times with PBS to remove myoblasts, insoluble myofibrillar proteins, and other debris at 1 h after plating. Cells were cultured in GM until reaching 70−80% confluence, digested with 0.05% trypsin, collected by centrifugation 1000*g* for 5 min, resuspended in GM, and plated at a density of 2×10^4 cells/cm^2 in 6-well plates. Two days after 100% confluence, the cells were treated with DMEM/F12 supplemented with 10% FBS and the hormone cocktail IBMX−DEX−insulin (MDI; 0.5 mM IBMX, 1 nM DEX, and 5 ng/mL insulin) for 2 days. The medium was changed to differentiation medium (DM), including DMEM/F12 supplemented with 10% FBS and 5 ng/mL insulin, for another 2 days.

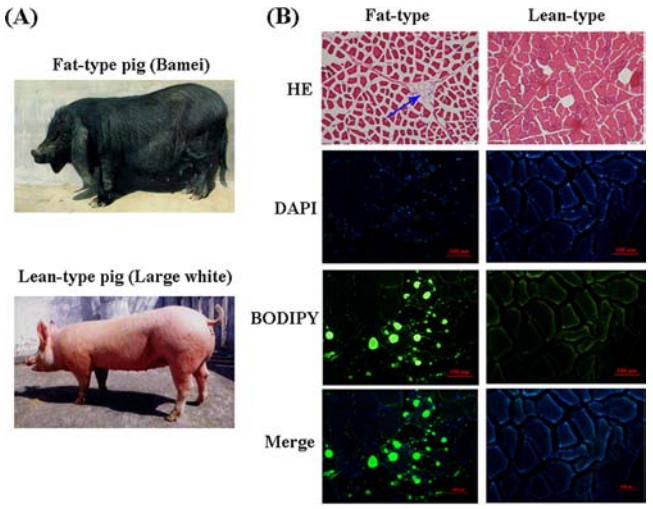

Figure 1. Morphologic observation of LM between obese and lean pigs at 180 days of age: (A) fat-type pig (Bamei) and lean-type pig (Large white); (B) intramuscular adipocyte in LM of fat-type and lean-type pigs. HE, hematoxylin and eosin staining, blue arrow indicates IMF adipocytes; BODIPY staining, lipids indicate green and blue nuclei stained with DAPI. Scale bar = 100 μm.

Table 2. Carcass Weight, Fat Percent and IMF Content of Bamei and Large White Pigs at 180 Days of Age

pig breed	carcass weight, kg	fat, %	IMF content, %
Bamei	37.48 ± 1.09**	31.03 ± 0.41**	4.42 ± 0.45**
Large White	68.74 ± 1.36	17.61 ± 0.27	2.37 ± 0.29

**indicates $P < 0.01$.

Cell Viability Analysis. Porcine intramuscular adipocyte viability was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Cells were seeded in 24-well culture plates at a density of 2×10^4 cells/well, incubated for 48 h, treated with DNJ at various concentrations (2.0, 3.0, 4.0, 5.0, and 6.0 μM) or RSG (0.1, 0.2, 0.3, 0.4, and 0.5 mM) for 48 h to evaluate any dose-dependent effects of DNJ or RSG on cell growth and viability, cultured with 0.5 mg/mL MTT at 37 °C in a humidified atmosphere of 5% CO_2 for another 4 h, and solubilized with isopropanol. The viable cell number was directly proportional to the production of formazan measured spectrophotometrically at 563 nm.

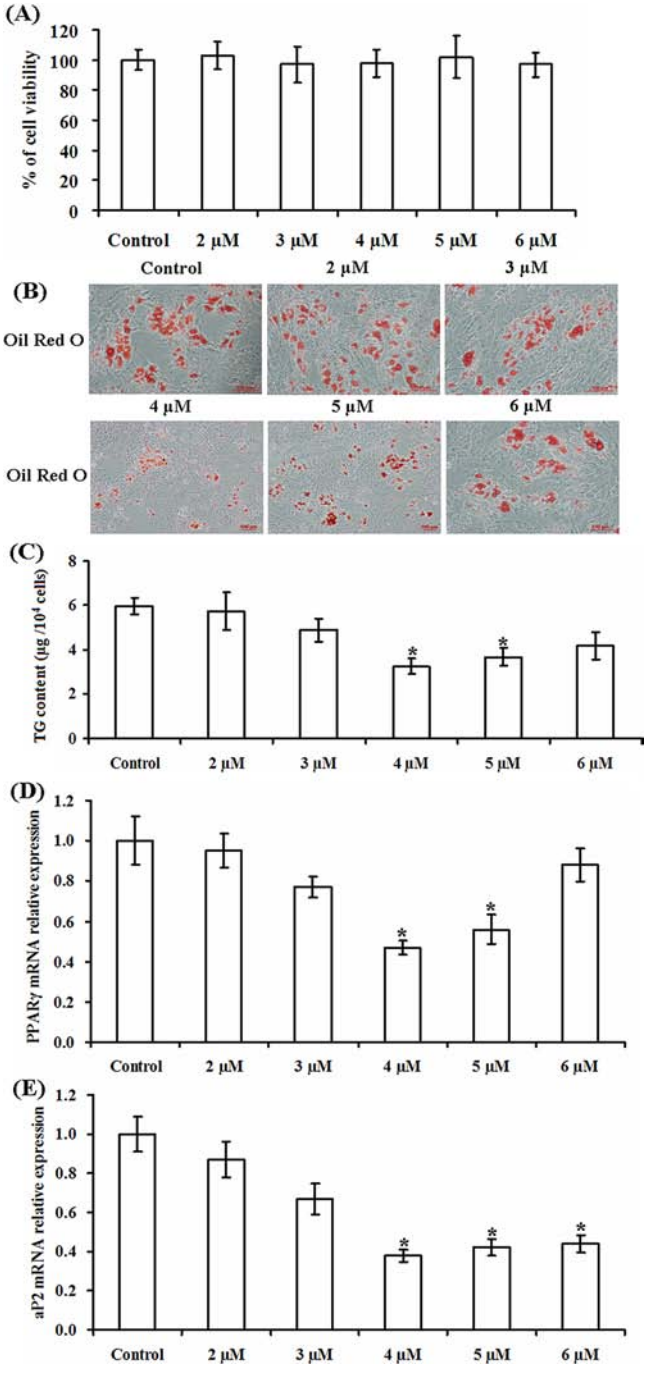

Figure 2. Effects of various concentrations of DNJ on porcine intramuscular preadipocyte differentiation. (A) Effect of DNJ on viability of porcine intramuscular preadipocyte as assessed by the MTT assay. Cells were treated with different concentrations (2.0−6.0 μM) of DNJ for 48 h and then assayed using MTT. (B) Intracellular lipids stained with Oil Red O. Intramuscular preadipocytes were treated with DMSO as control and the indicated concentrations of DNJ at day 8. (C) TG content (μg/10^4 cells) determined at day 8 after treatment. (D, E) mRNA levels of PPARγ and aP2 at day 8 after treatment. Gene mRNA expression was determined by qPCR, normalized to 18S rRNA and expressed relative to expression in the control. Each column represents the mean of four independent experiments ± SEM: (*) $p < 0.05$.

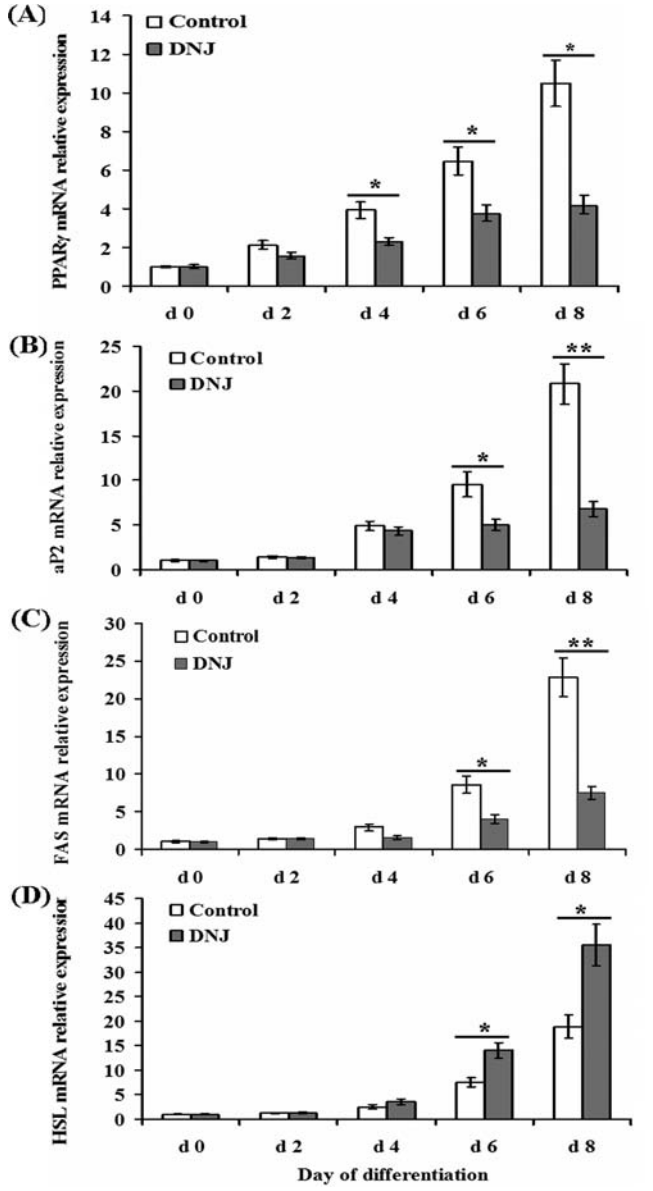

Figure 3. DNJ regulates mRNA expression of key adipogenic and lipolytic genes during lipogenesis of intramuscular preadipocytes: real-time qPCR analysis of (A) PPARγ, (B) AP$_2$, (C) FAS, and (D) HSL mRNA levels, respectively. Porcine intramuscular preadipocytes treated with 4 μM DNJ were induced differentiation and collected at days 0, 2, 4, 6, and 8. Gene mRNA expression was determined by qPCR, normalized to 18S rRNA, and expressed relative to expression in the control at day 0. Data indicate the mean ± SEM: (*) $p < 0.05$ and (**) $p < 0.01$.

Treatment with DNJ and RSG. For the DNJ experiment, porcine intramuscular adipocytes incubated in induced media of differentiation were treated with 0, 2, 3, 4, 5, or 6 μM DNJ for 8 days. For both DNJ and RSG experiment, at day 8 after treatment with 4 μM DNJ, intramuscular adipocytes were incubated with 0.4 mM RSG for 2 days. At the indicated time points, cells were stained by Oil Red O or BODIPY, a triacylglycerol content assay was performed, and total RNA and protein were extracted for analysis of gene expression.

Oil Red O Staining. Oil Red O staining was conducted according to a previously published method.[32]

BODIPY Staining. BODIPY staining was performed according to a previously published method.[32] The sections or cells were observed under fluorescence microscope (Nikon, Tokyo, Japan).

Triacylglycerol (TG) Content Assay. TG content analysis was conducted according to a previously published method.[32]

Real-Time Quantitative PCR. Total RNA was extracted from cells according to the manufacturer's instruction of TRIZOL reagent (Takara, Japan). The RNA concentration was determined, and reverse transcription was performed using the First-Strand cDNA Synthesis Kit

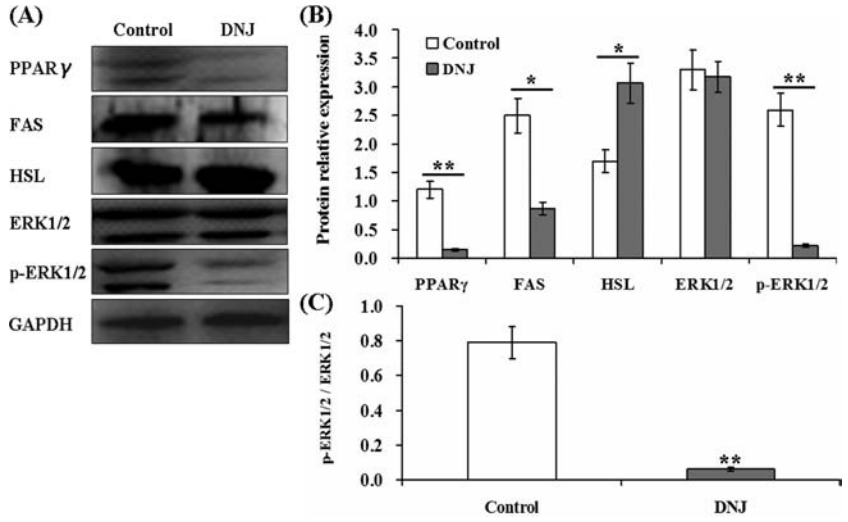

Figure 4. DNJ represses adipogenesis by inhibiting phosphorylation of ERK1/2: (A, B, C) ERK signaling in intramuscular adipocytes under DNJ stimulation condition. On reaching 70−80% confluence, the intramuscular preadipocytes were treated with DMSO as control and 4 μM DNJ for 2 days; the protein levels of adipogenic and lipolytic markers, phosphorylated ERK1/2 (p-ERK1/2), and ERK1/2 proteins were detected by Western blotting at day 8 of differentiation induction. GAPDH was applied as internal reference. Each column represents the mean of four batches ± SEM: (∗) $p < 0.05$ and (∗∗) $p < 0.01$.

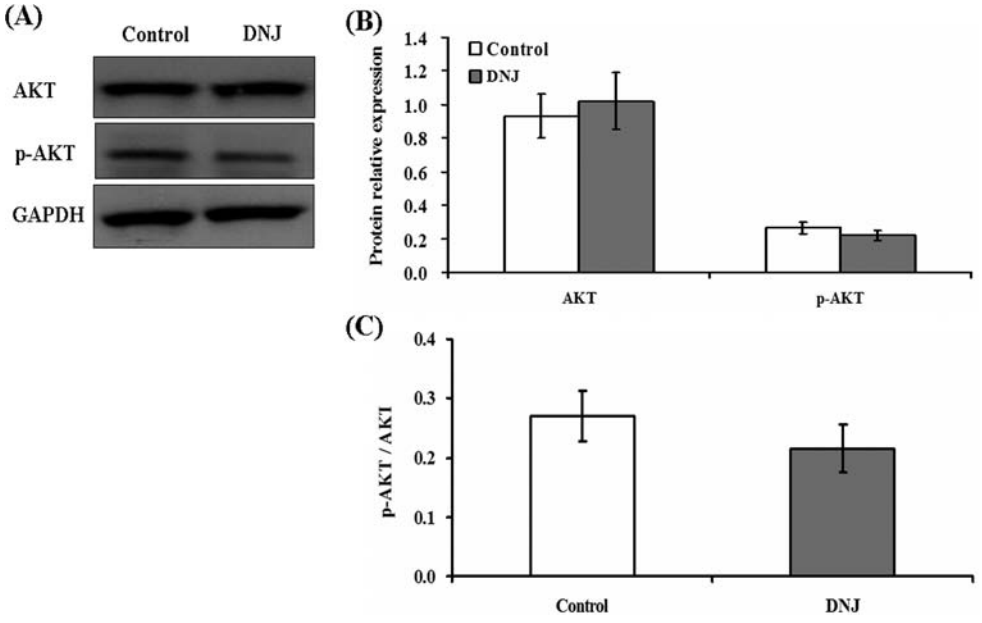

Figure 5. DNJ did not change the levels of AKT and p-AKT: (A, B, C) AKT signaling in intramuscular adipocytes under DNJ stimulation condition. On reaching 70−80% confluence, the intramuscular preadipocytes were treated with DMSO as control and 4 μM DNJ for 2 days; p-AKT and AKT proteins were detected by Western blotting at day 8 of differentiation induction. GAPDH was applied as internal reference. Each column represents the mean of four batches ± SEM.

(Takara, Japan) for qRT-PCR (Bio-Rad iQ5 multicolor Real-Time PCR Detection system) analysis of the functional genes. Real-time PCR was performed by using a Prime Script RT Reagent Kit (Perfect Real Time, Takara, Japan) according to the manufacturer's instructions. Primers are listed in Table 1. In this study, 18S rRNA (18S) was used as the reference gene. The 2-ΔΔCT method is used to analyze the relative changes in the expression of each gene mRNA.

Western Blot Analysis. Cells were lysed in lysis buffer (Beyotime, China), supplemented with 1 mM PMSF. Protein concentration was determined with a BCA protein assay kit (Tiangen, China). The proteins of each sample were separated by 12% SDS-PAGE and electrotransferred to PVDF membrane (Millipore, Bedford, MA, USA) for immunoblot analysis. The following primary antibodies were used: PPARγ (abcam, ab1948, 1:400), FAS (Santa Cruz, sc-20140, 1:300), HSL (cell signaling, 4107, 1:1000), ERK1/2 (cell signaling, 9102, 1:1000), p-ERK1/2 (cell signaling, 9101, 1:1000), AKT (Santa Cruz, sc-8312, 1:500), p-AKT (Santa Cruz, sc-7985-R, 1:500), and anti-GAPDH (Santa Cruz, sc-166574, 1:500), which was used as internal reference. After incubation with the appropriate HRP−conjugate secondary antibody, proteins were detected using a ChemiDoc XRS imaging system and analysis software Quantity One (Bio-Rad).

Statistical Analysis. All experimental data are obtained from four independent experiments. Values are expressed as means ± standard error of the mean (SEM). Statistics are calculated with SPSS statistics v19.0 software. Student's *t* test is used for individual comparisons. Multiple comparisons are assessed by one-way ANOVA followed by Dunnett's tests. Differences between groups are considered statistically significant if $P < 0.05$.

RESULTS

Intramuscular Adipocyte in Fat-Type and Lean-Type Pig Longissimus Dorsi Muscles. Bamei pig is a fat-type breed, and Large White pig is a lean-type breed (Figure 1A). Fat percent

DOI: 10.1021/acs.jafc.5b01680
J. Agric. Food Chem. 2015, 63, 6212−6220

and IMF content of Bamei pigs were significantly greater than that of Large White pigs at 180 days of age (Table 2). Using HE and BODIPY staining, the intramuscular adipocytes and IMF in LM of Bamei pigs were much greater than that of Large White pigs at 180 days of age (Figure 1B).

Effect of Various DNJ Concentrations on Adipogenesis of Porcine Intramuscular Adipocytes. As shown in Figure 2A, DNJ (2, 3, 4, 5, and 6 mM) was not toxic, so these five concentrations were used to test the effect of DNJ on adipogenesis of porcine intramuscular adipocytes. To evaluate the effect of DNJ on lipogensis of porcine intramuscular adipocytes, the cells were treated with different concentrations of DNJ including 0, 2, 3, 4, 5, and 6 μM for 8 days. The results indicated that lipid accumulation was significantly weakened in the treatment with 4 and 5 μM DNJ by Oil Red O staining (Figure 2B) and TG content assay ($p < 0.05$; Figure 2C). Moreover, the mRNA levels of key lipogenic gene PPARγ (4 and 5 μM DNJ; $p < 0.05$; Figure 2D) and aP2 (4, 5, and 6 μM DNJ; $p < 0.05$; Figure 2E) were markedly down-regulated at day 8 after treatment. On the basis of the above results, the following experiments were performed with 4 μM DNJ.

DNJ Inhibited Lipid Accumulation during Intramuscular Adipocyte Differentiation. To further examine the effects of 4 μM DNJ on key lipogenic and lipolytic genes during adipocyte differentiation, the time course of mRNA expressions of aP_2, PPARγ, FAS, and HSL were analyzed by real-time qRT-PCR at days 0, 2, 4, 6, and 8. The results indicated that mRNA levels of PPARγ were decreased at days 4, 6, and 8 compared with controls ($p < 0.05$; Figure 3A), mRNA levels of aP_2 were significantly reduced at days 6 ($p < 0.05$; Figure 3B) and 8 ($p < 0.01$; Figure 3B), and mRNA levels of FAS were down-regulated at days 6 ($p < 0.05$; Figure 3C) and 8 ($p < 0.01$; Figure 3C), whereas the mRNA levels of HSL were up-regulated at days 6 and 8 ($p < 0.05$; Figure 3D).

ERK Signaling Was Repressed in Intramuscular Adipocytes under DNJ Stimulation. To study the effect of DNJ on proteins that play a key role or involve signal transduction during differentiation, the total proteins were extracted from intramuscular adipocytes treated with 4 μM DNJ at day 8 after induction of differentiation for Western blot analysis. The results showed that protein levels of vital adipogenic genes, including PPARγ ($p < 0.01$) and FAS ($p < 0.05$), were significantly reduced (Figure 4), whereas the protein level of HSL ($p < 0.05$), which is a key lipolytic marker, markedly increased in the treatment (Figure 4). Interestingly, compared with the control, levels of ERK1/2 had no striking difference, but levels of phosphorylated ERK1/2 (p-ERK1/2) were markedly inhibited in the DNJ treatment ($p < 0.05$; Figure 4). In addition, levels of AKT and phosphorylated AKT (p-Akt) showed no difference (Figure 5). Therefore, the ERK signaling pathway was implicated in adipogenesis of intramuscular adipocytes under DNJ stimulation condition.

RGZ Improves Adipogenesis of Porcine Intramuscular Adipocytes. As shown in Figure 6A, RGZ (0.1, 0.2, 0.3, 0.4, and 0.5 mM) was not toxic, so these five concentrations were used to test the effect of RGZ on adipogenesis of porcine intramuscular adipocytes. TG contents in intramuscular adipocytes treated with RGZ (0.3, 0.4, and 0.5 mM) were significantly greater than the control ($p < 0.01$; Figure 6B). Moreover, compared with the control, the levels of PPARγ mRNA in cells treated with RGZ (0.3, 0.4, and 0.5 mM) were markedly up-regulated ($p < 0.01$; Figure 6C).

Inhibitory Adipogenesis of DNJ Is Attenuated by RGZ via Up-regulation of PPARγ Expression. To further investigate whether the ERK/PPARγ signaling pathway is involved in regulating adipogenesis of DNJ, the intramuscular adipocytes treated with 4 μM DNJ (for 8 days) were stimulated with 0.4 mM RGZ for 2 days (Figure 7A), then the treated cells were stained with BODIPY and Oil Red O to indicate lipogenesis; protein samples were subjected to a protein array to study the relevant kinases. The results showed that the inhibitory lipogenesis of DNJ was significantly attenuated by RGZ ($p < 0.05$; Figure 7B,C) and recovered the protein levels of PPARγ and FAS ($p < 0.05$; Figure 7D,E). Interestingly, the levels of ERK1/2 and its phosphorylation were not changed (Figure 7E,F) in intramuscular adipocytes treated with 4 μM DNJ plus 0.4 mM RSG. On the basis of the above results, the inhibitory adipogenesis of DNJ was attenuated by RSG via up-regulation of PPARγ. These findings indicate that DNJ inhibits adipogenesis through the ERK/PPARγ signaling pathway.

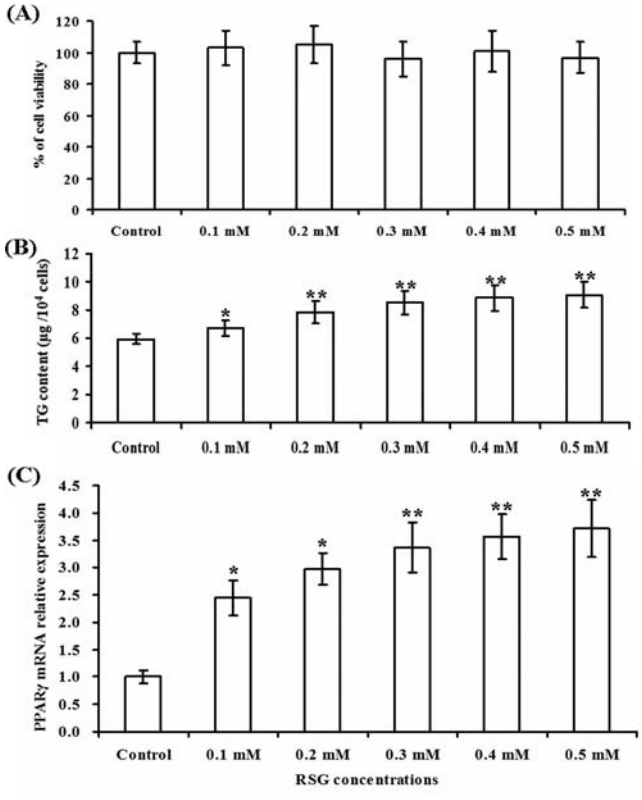

Figure 6. RSG improved adipogenesis in intramuscular adipocytes: (A) effect of rosiglitazone (RSG) on viability of porcine intramuscular preadipocyte as assessed by the MTT assay (cells were treated with different concentrations (0.1−0.5 mM) of RSG for 48 h and then assayed using MTT); (B) TG content (μg/10^4 cells) analyzed at day 8 after treatment; (C) real-time qPCR analysis of PPARγ mRNA levels. 18S rRNA was applied as internal reference. PPARγ mRNA expression was determined by qPCR, normalized to 18S rRNA, and expressed relative to expression in the control. Data indicate the mean ± SEM: (*) $p < 0.05$ and (**) $p < 0.01$.

DISCUSSION

China is the world's largest producer and consumer of pork. However, pork quality becomes bad because of the unfit IMF content. Our previous study showed that IMF content in LM of Bamei pig was much greater than that of Large White pig at 180 days of age.[33] In this study, intramuscular adipocyte and IMF content in fat-type and lean-type porcine LMs were directly

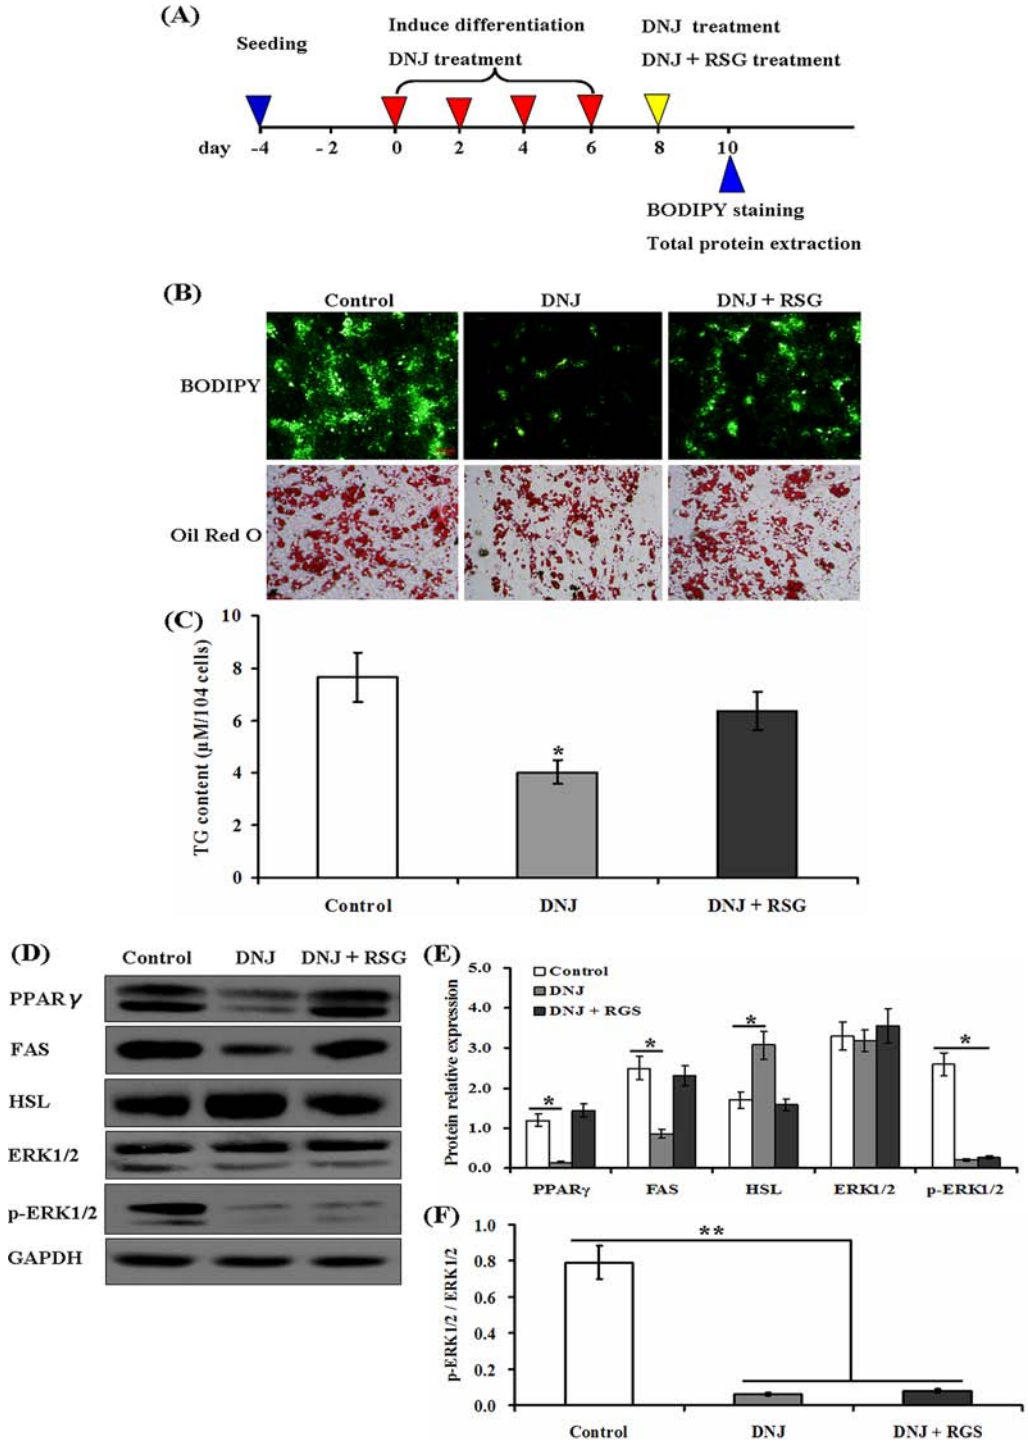

Figure 7. Inhibitory adipogenesis of DNJ was attenuated by RSG via up-regulation of PPARγ expression in intramuscular adipocytes: (A) experimental procedure for DNJ plus RSG treatment of porcine intramuscular adipocytes; (B) BODIPY and Oil Red O staining of intramuscular adipocytes under 4 μM DNJ condition at day 2 after treatment with 0.4 mM RSG; (C) TG content (μg/10^4 cells) analysis; (D, E, F) ERK signaling in intramuscular adipocytes under DNJ plus RSG stimulation condition. Each column represents the mean of four batches ± SEM: (∗) $p < 0.05$ and (∗∗) $p < 0.01$.

shown using HE and BODIPY staining. We think that the suitable IMF content and distribution in Bamei pork are involved in good meat quality.

Improvement of domestic animal meat quality is implicated in the regulatory mechanism of IMF deposition, which is modulated by adipogenensis of intramuscular adipocytes. Our previous studies found that some functional genes and natural extractions, including FoxO1 (Forkhead box O 1),[30,33] Sirt1 (Sirtuim 1),[32] Akt2 (protein kinase B 2),[32] C/EBPβ (CCAAT enhancer-binding protein B),[34] PU.1 (spleen focus forming virus proviral integration oncogene spi1),[35] resveratrol,[36] and camptothecin[31] regulated lipogenesis of porcine subcutaneous adipocytes through differentiation or apopotosis. It was reported that intake of DNJ suppressed lipid accumulation in rat liver and diet-induced obesity through increases in adiponectin in mice.[11,37] At present, the regulatory adipogenesis by DNJ in

DOI: 10.1021/acs.jafc.5b01680
J. Agric. Food Chem. 2015, 63, 6212−6220

porcine intramuscular adipocytes is still unknown. In this study, to explore the effect of DNJ on lipogenesis of intramuscular adipocytes, intramuscular adipocytes were isolated and cultured using the differential speed adherence method.[28] In accordance with Lee's results,[12] we found that DNJ did not affect intramuscular adipocyte viability. Likewise, RGZ, an agonist of PPARγ, was not toxic. DNJ at 4 μM decreased lipid acceleration and TG content, whereas 0.4 mM RGZ showed the opposite effects. Moreover, mRNA levels of key adipogenic genes including PPARγ and aP_2 were down-regulated in intramuscular adipocytes treated with 4 μM DNJ. On the basis of above findings, DNJ and RGZ may regulate IMF deposition by modulated lipogenesis of porcine intramuscular adipocytes.

Interestingly, in middle and later intramuscular adipocyte differentiation, mRNA and protein levels of PPARγ, aP_2, and FAS were markedly decreased, but the mRNA and protein levels of HSL were increased in the DNJ treatment. These results suggested that DNJ inhibited lipogenesis not only by down-regulation of lipogenic genes but also by up-regulation of lipolytic genes.

To investigate whether DNJ influences the activation of ERK1/2 during intramuscular adipocyte differentiation, we detected the levels of total and phosphorylated ERK1/2 in adipocytes treated with 4 μM DNJ at day 8. ERK1 and ERK 2 are members of the mitogen-activated protein kinase (MAPK) family, which play a pivotal role in intracellular signaling pathways of cellular proliferation and differentiation.[38] The blurry functions of ERK1/2 in adipogenesis were reported. Some researchers proved that phosphorylated ERK1/2 inhibited 3T3-L1 adipocyte differentiation by decreasing the activation of PPARγ.[39] In contrast, others reported that ERK1/2 activation has a positive association with adipogenesis in human mesenchymal stem cells and 3T3-L1 adipocytes.[38,40] We think that the opposite effects of ERK1/2 on lipogenesis may be related to different periods during differentiation. Consistent with the latter, our findings indicated that decreasing levels of phosphorylated ERK1/2 (p- ERK1/2) inhibited adipogenesis during the later period of intramuscular adipocyte differentiation at day 8 after treatment with DNJ. Meanwhile, expression levels of PPARγ and aP_2 have an apparently declining trend at days 6 and 8. Interestingly, the levels AKT and p-AKT were not changed under the DNJ treatment, indicating that Akt signaling was not involved in the lipogenesis of DNJ. Therefore, we think that DNJ may inhibit adipogenesis through the ERK/PPARγ signaling pathway intramuscular adipocytes.

To further explore whether ERK/PPARγ signaling is implicated in the regulatory lipogenesis of DNJ, the experiment of treatment with both DNJ and RSG was performed. Although levels of phosphorylated ERK1/2 and PPARγ in the treatment with DNJ were down-regulated, the level of PPARγ was recovered in treatment with DNJ plus RSG. DNJ inhibits lipogenesis of porcine intramuscular adipocyte via directly repressing the level of phosphorylated ERK1/2, then indirectly down-regulating the level of PPARγ through ERK signaling. Therefore, we conclude that DNJ inhibits IMF deposition by the ERK/PPARγ signaling pathway.

DNJ has been reported to be the main component of mulberry leaves, fruits, and silkworms.[41,42] Unlike chemical synthesis drugs, DNJ has no undesirable or significant side effects in vivo or in vitro.[3] Therefore, pork palatability and marbling may be changed by feeding a feedstuff containing a suitable concentration of DNJ, which will be further explored in the future.

A 2.5−3% IMF level is best for pork, but it is much closer to 4−7% in many Chinese indigenous pig breeds, such as the Neijiang pig and Hanjiang Black pig,[43] so DNJ may decrease pork IMF content. In introduced pig breeds, including Large White and Landrace,[43] their IMF contents are often below 2.5%, so it should be increased in these breeds.

In summary, DNJ suppresses lipid accumulation during differentiation of porcine intramuscular adipocytes by the ERK/PPARγ signaling pathway. We need to point out that the effects have been shown here for adipocytes of 1- or 2-day-old piglets and our method of possibly decreasing IMF deposition is only likely to be of practical usefulness for some breeds of pig that are particularly prone to fat deposition. These findings not only help us understand the mechanism whereby DNJ affects adipogenesis but may also provide a novel method to control intramuscular adipogenesis via DNJ for improving pork quality.

the studies have focused on ACN-rich foods[14,16] or beverages,[17] which contain multiple compounds and different concentrations or subclasses of ACNs. Furthermore, the rates of absorption and elimination as well as the relative bioavailability of ACNs present in different foods in vivo are different.[18] Therefore, it is important to examine the direct effects of pure ACNs on liver injury to elucidate their mechanisms of action in vitro and in vivo.[19,20] However, to the best of our knowledge, the direct role of the purified monomer form of ACNs in liver injury remains unclear, and their effects on liver fibrosis in vivo has not been systematically studied.

In the present study, we aimed to explore whether cyanidin-3-*O*-*β*-glucoside (Cy-3-G), the most abundant monomer form of ACNs in plants,[21] could protect against liver damage caused by carbon tetrachloride (CCl_4), as well as suppress the paths of the activation of HSCs.

MATERIALS AND METHODS

Cy-3-G Extraction and Analyses. Black rice (*Oryza sativa* L. *indica*) was obtained from Guangdong province, China. ACNs were extracted from black rice following our previous methods.[10] Then, high purity Cy-3-G was isolated from ACNs by the method of medium-pressure liquid chromatography (MPLC). After analysis by HPLC-PAD, the purity of Cy-3-G was >96.5%. The detailed methods are shown in the Supporting Information.

Reagents and Antibodies. Antibody for *α*-smooth muscle actin (*α*-SMA) was purchased from Sigma-Aldrich (St. Louis, MO, USA) and for glyceraldehyde phosphate dehydrogenase (GAPDH) was obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Anti-desmin and anti-F4/80 antibodies were purchased from Abcam (Cambridge, UK); anti-CD45 antibody and Alex-488 conjugated goat anti-rabbit IgG secondary antibody were purchased from Goodbio Technology (Wuhan, China). All other secondary antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Reagents for immunohistochemistry, such as hydrogen peroxide and diaminobenzidine (DAB), were obtained from Zhongshan Jinqiao Biotechnology (Beijing, China). 4′,6-Diamidino-2-phenylindole (DAPI) was purchased from Beyotime (Nantong, China). Fluorescent probe dihydroethidium (DHE) was from Calbiochem (San Diego, CA, USA). All other chemicals used in this study were of analytical grade from Sigma-Aldrich or Invitrogen unless otherwise noted.

Animals and Diets. This study was carried out in agreement with the recommendations of the Guide for the Care and Use of Laboratory Animals. All animal procedures were approved by the Animal Care and Protection Committee of Sun Yat-Sen University. SPF, male, C57BL/6 mice (8 weeks old) were purchased from the SYSU animal center (Guangzhou, China). The animals were maintained at 25 °C with a 12 h light/dark cycle and ad libitum access to water and chow. Mice were randomly divided into three groups (each with eight mice), including a control group, a CCl_4-treated group, and a Cy-3-G plus CCl_4 group. CCl_4-treated mice were given an intraperitoneal (ip) injection of 10% CCl_4 in olive oil (0.5 *μ*L pure CCl_4/g BW) twice weekly for 8 weeks, whereas the control group received vehicle only. At the same time, Cy-3-G (800 mg/kg diet) was added to standard diet, which was supplied for the Cy-3-G plus CCl_4 group; the other groups of mice lived on standard diet. All of the animals were sacrificed 72 h after the last dose of CCl_4 or vehicle. After narcotizing the mice by pentobarbital sodium, blood was collected by extirpating eyeballs for serum biochemistry analysis. Livers were excised, partly fixed for histological analysis, and the rest was frozen in liquid nitrogen and then stored at −80 °C until analyzed.

Determination of Serum Transaminase Levels and Cytokines. Serums were separated from blood by centrifuging under 4 °C, at 3000 *g* for 15 min, then alanine and aspartate aminotransferases (ALT and AST) were measured by an assay kit from Jiancheng Biotech (Nanjing, China) according to the manual. Serum cytokines (TNF-*α*, TGF-*β*, and IL-17) were analyzed by ELISA technique using commercial kits from eBioscience (San Diego, CA, USA).

Histological Study and Immunohistochemistry. Liver samples were separated and fixed in 10% neutral buffered formalin and then embedded in paraffin, sectioned to a thickness of 5 *μ*m. Then the slides were performed with hematoxylin and eosin (H&E) staining for general observation or with Sirius Red for collagen fiber detection.

Under a light microscope (Leica, Solms, German), inflammatory cell infiltration in hepatic lobules and necrosis were observed. Then, the inflammation activity were evaluated and divided into four parts: portal area inflammation (P), lobular inflammation (L), patch necrosis (PN), and bridging necrosis (including lobular necrosis, BN). Every item was recorded as 1, 2, 3, or 4 on the basis of degrees of pathological changes. The score counting formula was P + L + 2 × (PN + BN).[22] The percentage of fibrosis regions in the liver was measured on five high-power (200×) fields per slide and then calculated by Image-pro Plus 6.0. The observer was blinded to the group distribution when the analyses were made.

Immunostaining was performed on paraffin section. For the test of the activation of hepatic stellate cells, desmin was visualized with Alex-488 conjugated goat anti-rabbit IgG secondary antibody, and DAPI was used for nuclear staining. After the slides had been incubated with anti-F4/80 or anti-CD45 at 4 °C overnight, they were treated with labeled polymer horseradish peroxidase (HRP) secondary antibody for 1.5 h, followed by DAB staining. Positive cells were counted on five high-power (200×) fields per slide.

Measurements of MDA, SOD, and GSH. Liver tissue homogenates were prepared to measure hepatic malondialdehyde (MDA) following the commercial kit's instructions (Jiancheng Biotech, Nanjing, China). Superoxide dismutase (SOD) and glutathione (GSH) were measured by the commercial kits from Beyotime (Shanghai, China).

Measurements of ROS and Apoptosis. The frozen liver samples were cut into 10 *μ*m sections and fixed in paraformaldehyde. After being washed in phosphate buffer saline (PBS) three times, the slides were incubated with DHE (5 mmol/L) in a dark condition for 30 min at 37 °C for redundant reactive oxygen species (ROS) detection. DHE can be oxidized by superoxide and changed to ethidium bromide, which then binds to the DNA of the nucleus, and red fluorescence was detected through the fluorescence microscope (Leica, Solms, Germany) under the 580 nm exciting light.[23] Apoptosis of cells in the liver was detected by terminal-deoxynucleoitidyl transferase mediated nick end labeling (TUNEL) staining (Beyotime) according to the manual; the fluorescence was detected at 510 nm through a fluorescence microscope (Leica). Thereafter, the intensity of the fluorescence was analyzed by Image-pro Plus 6.0.

Protein Extraction and Western Blotting. Proteins were extracted from liver tissue, using RIPA lysis buffer (Beyotime) and 1% PMSF and 1% protease inhibitor cocktail (Sigma-Aldrich). The lysates were centrifuged at 12000 *g* for 15 min, and the supernatants were used for immunoblotting; meanwhile, the total protein concentration of the tissue homogenates was determined by BCA protein assay kit (Thermo, Rockford, IL, USA). Protein extractions were separated by using SDS-PAGE on 10% polyacrylamide gels and transferred to 0.45 *μ*m polyvinylidene fluoride (PVDF) membranes (Millipore, Billerica, MA, USA). After blocking for 2 h with 5% skimmed milk in TBS-T buffer (10 mM Tris, 150 mM NaCl, and 0.1% Tween-20), the membrane was incubated with primary antibodies against *α*-SMA or GAPDH at 4 °C for overnight. The membrane was incubated with HRP-conjugated secondary antibodies and using ECL Reagent Kit (Thermo) to make the film exposed. The band densities were quantified using an image analyzer, Quantity One System (Bio-Rad, Richmond, CA, USA). All protein quantifications were adjusted for the corresponding GAPDH level.

RNA Extraction and Quantitative Real-Time PCR. Total RNA was extracted from liver tissue with Trizol (Invitrogen, Carlsbad, CA, USA), according to the manufacturer's instructions. Then total RNA was reverse-transcribed to complementary DNA (cDNA) using the Reverse Transcription System by the cDNA Synthesis kit (Takara, Dalian, China). Quantitative real-time PCR was performed with SYBR Green Supermix kit (Takara) according to the manufacturer's instructions and played on a Vii7 system (ABI, Carlsbad, CA, USA).

J. Agric. Food Chem. 2015, 63, 6221−6230

Relative gene expression was calculated using the $2^{-\Delta\Delta Ct}$ method. Primers used in the test are shown in the Supporting Information.

Statistical Analysis. SPSS 16.0 (SPSS Inc., Chicago, IL, USA) was used for statistical analysis, and all results are presented as the mean ± SEM. Data were analyzed using Student's *t* test (for two groups), one-way ANOVA, and Dunnett's test (for three groups). Mann−Whitney's rank sum test was used to calculate the statistical significance of the pathological scores of inflammation. $P < 0.05$ was considered statistically significant. Graph bars were obtained using Graph Pad Prism 5.0 software (San Diego, CA, USA).

RESULTS

General Parameters and Histopathological Analysis. During the experiment period, mice with CCl_4 treatment showed a trend of reducing body weight and increasing relative liver weight compared to the control mice without statistical significance as shown in Table 1.

Table 1. Data from General Parameters Evaluated in Different Groups[a]

	control	CCl_4	CCl_4 + Cy-3-G
initial body wt (g)	26.05 ± 0.62	26.11 ± 0.79	26.39 ± 0 0.52
final body wt (g)	28.52 ± 0.73	28.00 ± 0.78	27.43 ± 0.44
food consumption (g/mouse/day)	2.74 ± 0.08	2.83 ± 0.12	2.67 ± 0.13
relative liver wt (%)	3.96 ± 0.13	4.24 ± 0.12	4.10 ± 0.29

[a]Body and relative liver weights were examined in the mice model. Results are expressed as mean ± SEM (n = 8 mice/each). Comparisons between all groups were evaluated using one-way analysis of variance (ANOVA).

To estimate the protective function of Cy-3-G on liver injury, H&E staining and Sirius staining were carried out on liver tissue slides (Figure 1). CCl_4-treated groups developed liver damage with the performance of hepatocellular lesions, inflammation, and liver fibrosis. Whereas Cy-3-G ameliorated the degree of patch necrosis, bridging necrosis and less inflammatory cells (mainly neutrophils) infiltrated into the portal area; fibrillar collagen sediment was rarely found in the portal/periportal area. The inflammatory scores were calculated (Figure 1C; Table 2), and Sirius Red staining for the fibrosis was evaluated (Figure 1D); Cy-3-G ameliorated both scores ($P < 0.05$). Therefore, according to histopathological analysis, Cy-3-G showed a protective effect on liver injury and fibrosis.

Cy-3-G Depressed the Activation of HSCs. HSCs are cores in the progression of liver injury. Their activation, accompanied by cytokine release and production of matrix molecules, proteases, and their inhibitors, finally leads to liver fibrosis. We investigated the suppressing effect of Cy-3-G on the activation of HSCs induced by CCl_4. As shown in Figure 2A, immunoblotting (left panel) and qRT-PCR (right panel) analysis revealed that α-SMA was less expressed in the Cy-3-G group compared to the CCl_4 group. In addition, desmin as another marker of the activated HSCs (Figure 2B,C) was less detected by immunostaining in the Cy-3-G-treated group compared with the CCl_4 group. Moreover, matrix metalloproteinase (MMP), such as MMP-2 and MMP-9, mRNA levels sharply increased in the CCl_4 group, whereas they were significantly decreased by the intervention of Cy-3-G (Figure 2D,E).

Cy-3-G Attenuated Oxidative Stress and Increased Antioxidant. Hepatic levels of ROS increased significantly (Figure 3A), and MDA, the terminal product of lipid peroxidation, elevated sharply after the treatment of CCl_4 (Figure 3B). However, Cy-3-G treatment significantly inhibited the oxidative stress levels of ROS and MDA ($P < 0.05$).

Glutathione (GSH) is an antioxidant, which can prevent damage from reactive oxygen species. After the treatment of CCl_4, the level of GSH significantly decreased (Figure 3C). With the supplementation of Cy-3-G, the level of GSH tends to recover, but without significant difference compared to the CCl_4 group ($P = 0.3102$). Antioxidant enzymes can protect cellular compounds against damage induced by free radicals. In the present study, total SOD was detected by the WST-1 assay. CCl_4 treatment caused a severe decrease of SOD level ($P < 0.05$), whereas addition of Cy-3-G to the diet ameliorated changes of the hepatic SOD activity significantly (Figure 3D).

Cy-3-G Ameliorated Apoptosis of Hepatic Cells. ALT and AST have been recognized as biomarkers of liver injury.[24] The activities of serum ALT and AST were respectively increased 92 and 83% in CCl_4-treated mice compared to the control group (Figure 4A,B). However, the treatment of Cy-3-G showed an inhibition of this elevation; it significantly ameliorated the level of ALT ($P < 0.05$) and decreased the level of AST ($P = 0.159$).

Apoptotic cells in the liver were detected by TUNEL staining (Figure 4C). Dying cells, with DNA damage, can be combined to the fluorescent dye (cyanine 3) by the catalysis of terminal deoxynucleotidyl transferase. Thereafter, cyanine 3 release red fluorescence under excitation of 510 nm light. After treatment with CCl_4, the apoptotic cells in the liver increased significantly. Although the number of apoptotic cells in the Cy-3-G group showed no significant differences compared to the CCl_4 group, it showed a trend of decrease ($P = 0.088$).

Cy-3-G Suppressed Leukocyte Recruitment but Had No Significant Effect on the Activation of Kupffer Cells. Administration of CCl_4 caused hepatocyte injury and followed with more infiltrating inflammatory cells. To investigate periportal inflammation in the liver, we performed immunostaining with anti-CD45 (Figure 5A), which was a biomarker of leukocytes.[25] In the CCl_4 group, positive cells increased nearly 30-fold (Figure 5B), compared to control animals. Adding Cy-3-G to the diet significantly alleviated the number of $CD45^+$ cells compared to the CCl_4 group.

Kupffer cells are resident macrophages in liver, which were activated by damage amplification and recruited from the bloodstream.[26] Upon activation, Kupffer cells release pro-inflammatory cytokines involving TNF-α and fibrogenic factors such as TGF-β1 and PDGF, which will stimulate HSCs to be activated.[27] F4/80 is a specific marker of activated Kupffer cells; after the treatment with CCl_4, F4/80 positive cells increased almost 13-fold compared with the control group (Figure 5C,D). Interestingly, Cy-3-G treatment had no significant effect compared with the CCl_4 group.

Cy-3-G Attenuated the Level of Pro-inflammation Cytokines and Increased the Level of Anti-inflammation Cytokine. Pro-inflammation cytokines are released from both injured hepatocytes and nonparenchymal cells, which play important roles in driving fibrogenesis. In our present study, TNF-α, IL-1α, and IL-17 were detected. After the treatment with CCl_4, TNF-α levels in the serum and tissue (Figure 6A,B) were increased nearly 1-fold compared to the control group, whereas they significantly decreased after treatment with Cy-3-G. However, detected by the qRT-PCR method, IL-1α had no significant changes in the CCl_4 or CCl_4 plus Cy-3-G (Figure 6C) groups. Previous studies have shown that monocyte

Table 2. Pathological Inflammatory Scores in Liver Tissues[a]

group	P + L + 2 × (PN + BN)	S0	S1	S2	S3	S4	*P*
control	0.667 ± 0.083	5	1	0	0	0	
CCl4	2.643 ± 0.280	0	1	4	2	0	0.001*
CCl_4+Cy-3-G	1.750 ± 0.299	1	3	3	0	0	0.017#

[a]The score of inflammation was given by P + L + 2 × (PN + BN) (P, portal area inflammation; L, lobular inflammation; PN, patch necrosis; BN, bridging necrosis). *n* (control): $n(CCl_4)$:$n(CCl_4$+Cy-3-G) = 6:7:7. Mann−Whitney's rank sum test was used to calculate the statistical significance: (*) $P < 0.05$ compared to the control group; (#) $P < 0.05$ compared to the CCl_4 group.

production of TNF-α was a critical downstream response to the IL-17 produced by Th17 cells.[28] The level of IL-17 was detected in both serum and liver tissue by ELISA; IL-17 elevated 1-fold in serum and 0.5-fold in liver tissue after the treatment with CCl_4, which were significantly decreased by Cy-3-G supplementation (Figure 6D,E). IL-10 is a kind of anti-inflammatory cytokine. In our present study, Cy-3-G treatment enhanced the relative mRNA expression of IL-10, which is suggestive of promotion of anti-inflammation cytokine (Figure 6F).

Cy-3-G Treatment Decreased Liver Growth Factors and MCP-1. HSCs are an important source of growth factors in the liver, but also respond to these factors. TGF-β1 and PDGF are two potent growth factors that stimulate activation and proliferation of HSCs.[29] The elevated levels of TGF-β1 and PDGF mRNA expression in the liver induced by CCl_4 were suppressed significantly by treatment with Cy-3-G (Figure 7A,C). Interestingly, Cy-3-G had no significant effect on the level of TGF-β1 in serum (Figure 7B). Monocyte chemotactic protein (MCP-1) is a kind of typical chemokine expressed in various cells in the liver, which in general promotes the migration of fibrogenic cells to the site of liver injury.[30] The relative mRNA expression of MCP-1 dropped nearly 1-fold after Cy-3-G intervention compared to the CCl_4 group (Figure 7D).

DISCUSSION

In our present study, we demonstrated that in CCl_4-treated mice, Cy-3-G extracted from black rice attenuated liver injury and fibrosis. Furthermore, we found that addition of Cy-3-G suppressed the activation of hepatic stellate cells, which may result from the amelioration of liver oxidative stress, hepatocyte apoptosis, and inflammation induced by CCl_4. To our knowledge, this is the first study showing the positive effects of Cy-3-G on CCl_4 injury mouse model and uncovers the possible paths of restraining activation of HSCs.

ACN extractions from plant foods were proved to have a series of benefits on various chronic diseases, but it is difficult to explain the biological mechanism of ACNs, because the food extractions usually contain an enormous variety of bioactive compounds. Through 2009, more than 600 kinds of ACNs had been extracted and identified from plants, such as Cy-3-G, Dp-3-G, and Pg-3-G.[31] Therefore, it is useful and valuable to study one composition of anthocyanin to elucidate the biological effects and the mechanism of actions. Cyanidin exists in about 50% of all ACNs in fruits and vegetables. Moreover, Cy-3-G is the most common anthocyanin with a glycoside.[32] In the

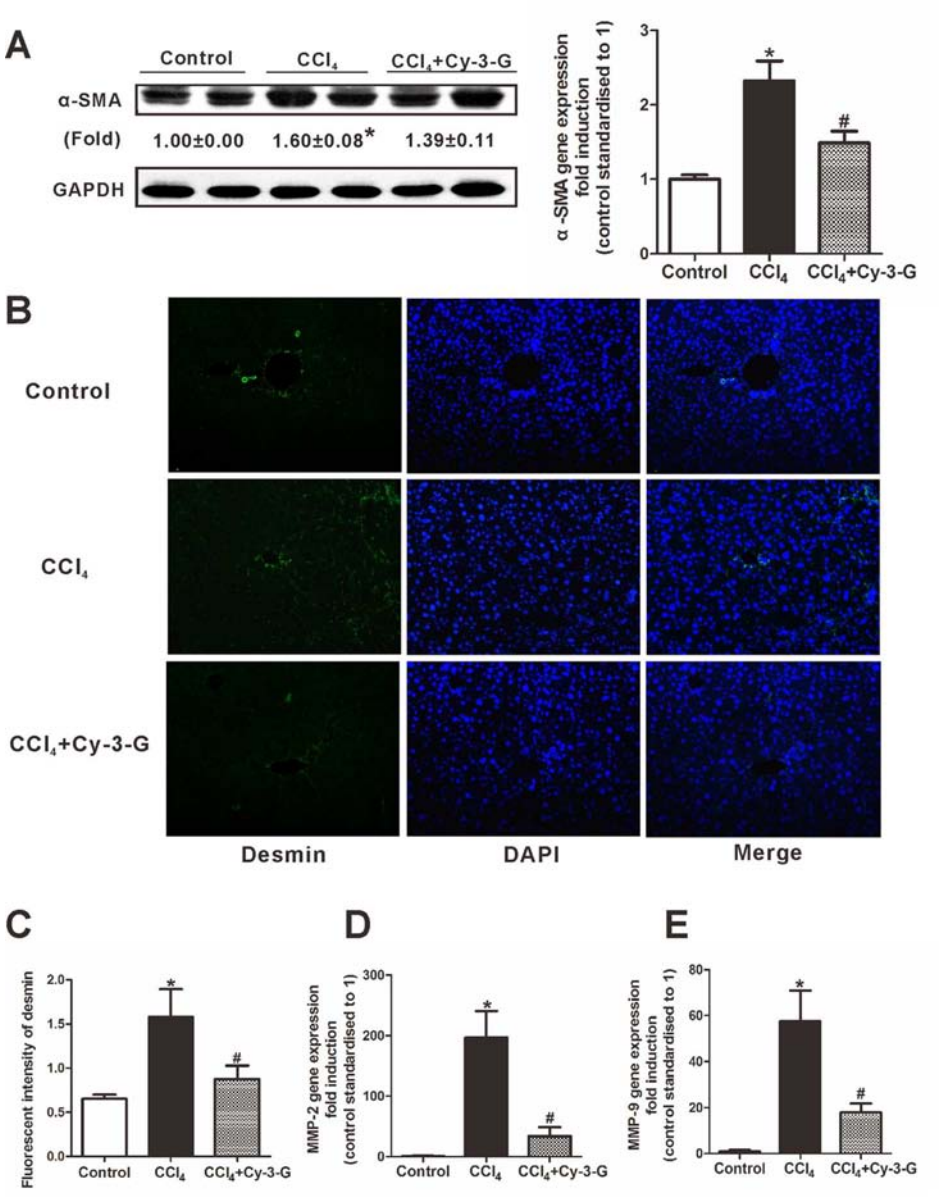

Figure 2. Cy-3-G attenuates the activation of HSCs in liver: (A) α-SMA protein (left panel) and mRNA (right panel) levels were evaluated; (B) desmin was detected by immunofluorescence and then qualified by the fluorescent intensity in every field (C); relative expressions of hepatic MMP-2 and MMP-9 mRNA levels were measured by RT-PCR (D, E). Values are expressed as the mean ± SEM, $n = 5$; (*) $P < 0.05$ compared to the control group; (#) $P < 0.05$ compared to the CCl_4 group.

present study, high-purity Cy-3-G as a monomer of anthocyanin was extracted from black rice and purified by MPLC, which has many merits including lower cost, higher speed, and greater loading of samples compared with the other purification methods.[33] Cy-3-G is nontoxic, and a moderate dose was adopted (800 mg/kg diet) for the present study according to previous researches in vivo.[34−36]

It has been reported that CCl_4 increases free radicals, which further causes lipid peroxidation of cellular and organelle membranes; thus, it is considered as one of the most widely used toxic agents to induce liver injury in animals.[37] We used a very low dose of CCl_4 (0.5 μL/g BW) injection for 8 weeks, which caused a moderate degree of liver injury according to histological analysis (Figure 1). Under this situation, we could investigate the preventive effects of Cy-3-G on liver fibrosis. The present study showed that supplementation of Cy-3-G has great effects on suppressing the liver fibrosis induced by CCl_4.

Hepatic fibrogenesis is a complex pathogenesis responding to various toxic stimuli. HSC activation is considered to play a key role in fibrotic progression. Activated HSCs were marked with higher expression of α-SMA, more desmin, and generation of collagen type I. In the present study, these elevated markers resulting from CCl_4 injection were significantly decreased with the treatment of Cy-3-G. Furthermore, MMP-2 and MMP-9 mRNA levels were significantly suppressed by Cy-3-G. It is universally recognized that MMPs are a family of zinc metallo-endopeptidases, which may contribute to the regression of liver fibrosis through cleavage of the fibrillar extracellular matrix. On the other hand, MMPs are promptly expressed by activated HSCs in response to diverse hepatic injury and are considered to promote disease progression.[38] Thus, MMPs play a dual role

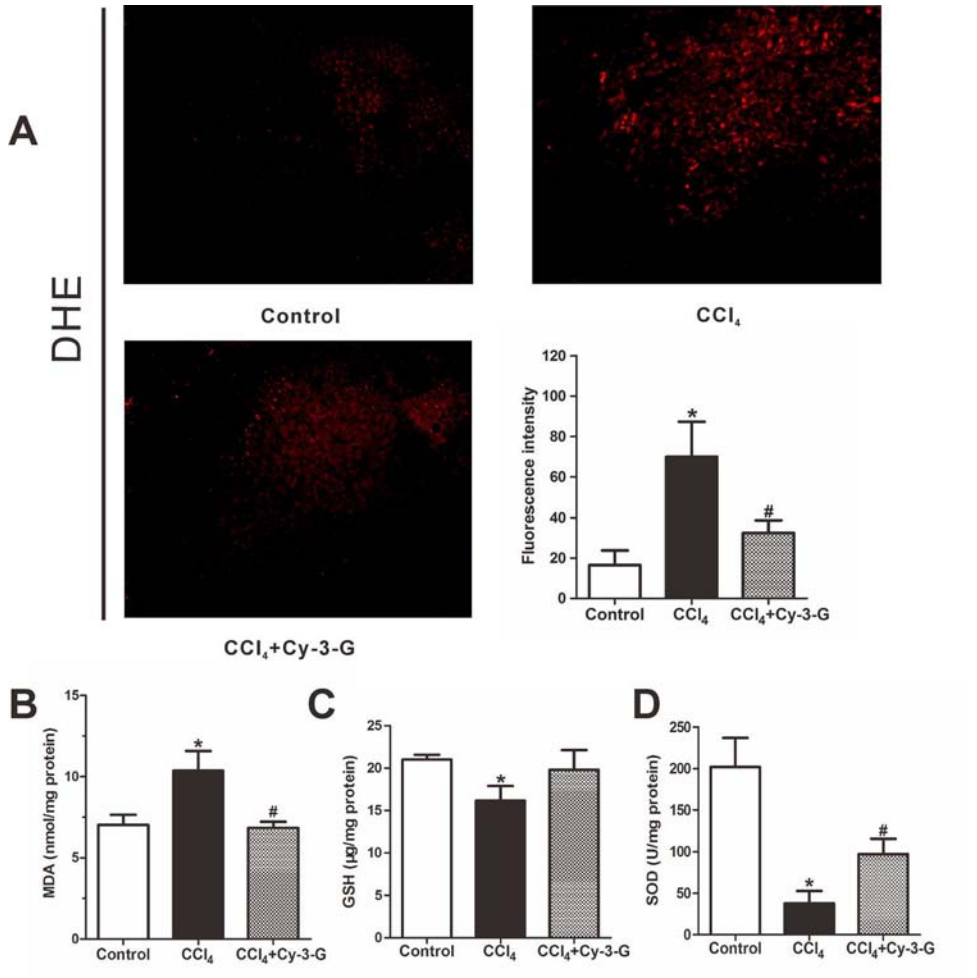

Figure 3. Cy-3-G attenuated oxidative stress and increased antioxidant defense system in CCl_4 administered mice: (A) liver ROS level detected by dihydroethidium (DHE) staining (representative photomicrographs (100×) are shown and mean of red fluorescence density of per field quantified by ImageJ (right panel)); (B) MDA, lipid peroxidation assessed in liver homogenate; (C) hepatic GSH and (D) SOD measured by commercial assay kit (n = 6−7, mean ± SEM; (∗) $P < 0.05$ versus control; (#) $P < 0.05$ versus CCl_4).

in liver fibrosis, depending on the timing of their production. The early temporary high expression of MMPs may destroy the surrounding tissue in order to deposit newly synthesized ECM.[39] In our present study, Sirius Red staining of liver collagens showed the liver fibrosis occurring at an early stage of the animal model, and MMP-2 and MMP-9 expression significantly increased in the CCl_4 group. Because of the early stage of liver fibrosis, MMPs are considered as markers of the activation of HSCs. Cy-3-G could decrease MMP-2 and MMP-9 expression, suggesting that Cy-3-G may suppress the activation of HSCs.

As is well-known, CCl_4 in vivo is metabolized by the cytochrome P450 system to highly reactive free radicals and reactive oxygen species, such as trichloromethyl (CCl_3) and trichloromethyl peroxyl (CCl_3O_2), which initiate lipid peroxidation and generate MDA.[16] Subsequently, elevated ROS attack hepatocytes, which leads to apoptosis.[40] By the treatment with Cy-3-G, ROS level and oxidative products such as MDA were significantly decreased and antioxidative SOD level increased to catalyze the dismutation of superoxide to hydrogen peroxide and oxygen. Nonetheless, GSH as a nonenzymatic defense substance slightly changed in the CCl_4 and Cy-3-G group, which may account for the balance between GSH and glutathione disulfide (GSSG) being restored efficiently at this early phase of liver injury, and the enzyme glutathione reductase was still available to bring GSSG back to GSH.[40] Thus, Cy-3-G showed no significant effect on GSH. ALT and AST were both considered sensitive indicators of hepatocyte integrity. It was revealed that either acute or chronic injury to the liver would eventually result in an increase of aminotransferases.[41] Furthermore, apoptosis is responsible for the physiological removal of unwanted cells, involving damaged cells.[42] We found that the treatment with Cy-3-G significantly diminished the liver apoptosis accompanied by the decreasing AST and ALT levels in circulation. These results indicated that Cy-3-G protective effects on hepatocytes may be related to the reduction of oxidative stress in the liver, similar to a previous report that ACNs or Cy-3-G could protect high glucose or methionine and choline deficiency caused by mouse hepatocyte apoptosis by modulating mitochondrial dysfunction and the PI3K/Akt pathway.[34,43]

The generation of oxidative stress together with the injured hepatocytes could increase tissue inflammation and drive disease progression more intensely.[44] This is reflected in our finding that CCl_4 up-regulated inflammation degree in the liver, whereas Cy-3-G treatment could attenuate liver inflammation significantly. To evaluate liver inflammation, a liver biopsy assessment system was employed to evaluate the inflammation

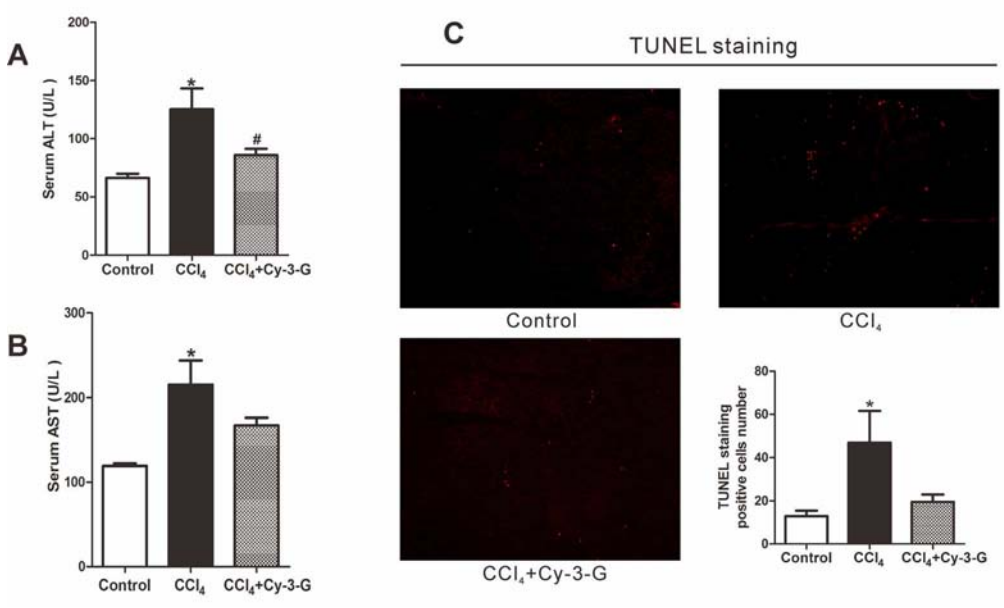

Figure 4. Cy-3-G alleviated apoptosis of hepatic cells. ALT (A) and AST (B) levels in the circulation were evaluated. Cell apoptosis in the liver tissue was detected by TUNEL assay (100×), and positive cells were counted in every field (C). Results are expressed as the mean ± SEM; (∗) $P < 0.05$ significantly different compared to the control group; (#) $P < 0.05$ versus the CCl_4 group.

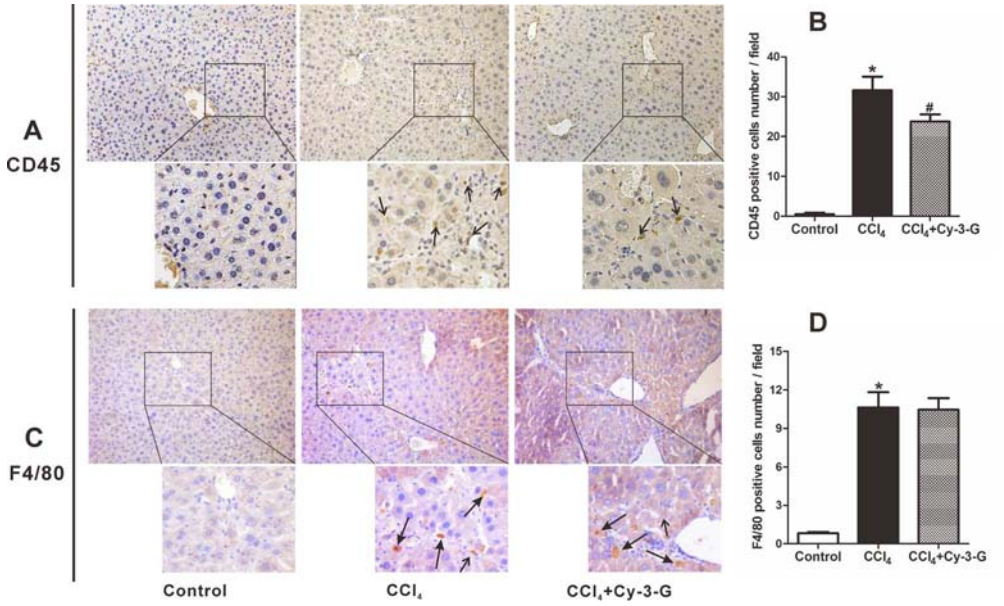

Figure 5. Effects of Cy-3-G on the inflammatory cells recruitment in CCl_4-treated mice. Immunostaining was performed on liver tissue sections. (A) Anti-CD45 was used to detect the infiltration of leukocytes in liver, and (B) F4/80 antibody was used to identify the activated Kupffer cells (magnification 200×). Five typical fields per slide were randomly examined, and then the numbers of positive cells in every field were counted and analyzed (C, D). Values are expressed as the mean ± SEM, $n = 5$; (∗) $P < 0.05$ compared to the control group; (#) $P < 0.05$ compared to the CCl_4 group.

score in our experiments.[22] As our present study showed, Cy-3-G could decrease neutrophils and attained a lower liver inflammation score (Figure 1; Table 2). Furthermore, it reduced liver CD45 positive cells, which were leukocytes, infiltrated to the periportal zone as inflammation cells (Figure 5). We also studied Kupffer cells, resident liver macrophages, which were also activated during liver injury. Activated Kupffer cells are enabled to launch biochemical attack and initiate interactions with HSCs by releasing a variety of biologically active mediators.[26] Interestingly, in our study, the results revealed that Cy-3-G had no significant suppressing effect on the activation of Kupffer cells in CCl_4-treated mice, which seems to be incompatible to previous protective effects on ROS or hepatocyte apoptosis. This phenomenon may be due to the early stage of liver injury and the weak effect of Cy-3-G on Kupffer cells.

With the progression of liver injury, pro-inflammatory cytokines, growth factors, and chemokines are released, which subsequently stimulate the activation of HSCs and migration. Not only are TNF-α, TGF-β, PDGF, and other cytokines produced by Kupffers but also infiltrating neutrophils, macrophages, or HSCs.[45] We identified that Cy-3-G could restrain

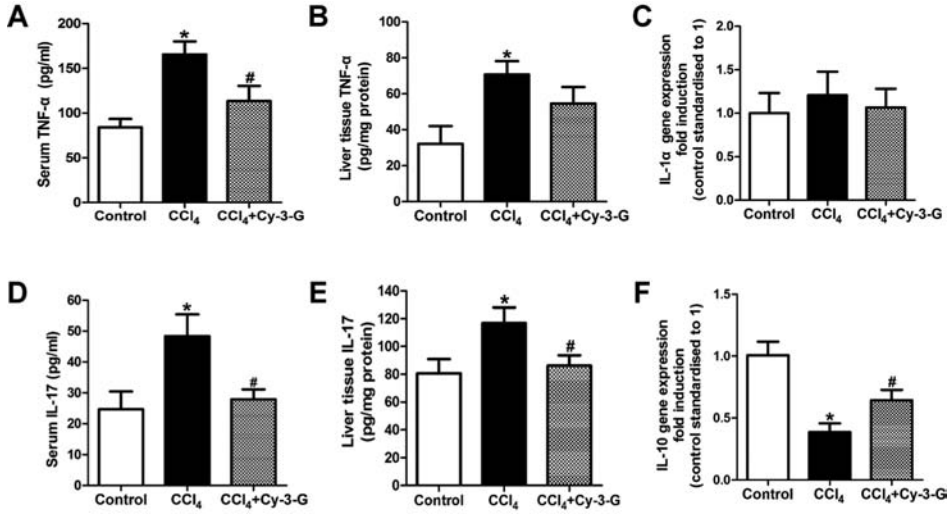

Figure 6. Cy-3-G ameliorated inflammatory cytokines induced by CCl_4 treatment in mice (A) TNF-α and (C) IL-17 in serum and liver tissues measured by ELISA assay. IL-1α (B) and (D) IL-10 mRNA in liver tissue were analyzed by qRT-PCR. Values are expressed as the mean ± SEM, n = 5; (∗) $P < 0.05$ compared to the control group; (#) $P < 0.05$ compared to the CCl_4 group.

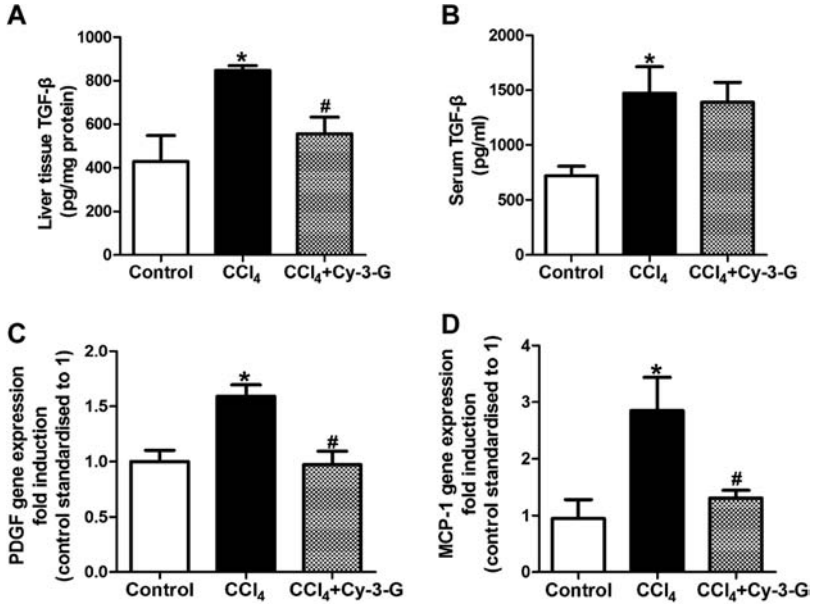

Figure 7. Cy-3-G decreased growth factors and MCP-1 in CCl_4-treated mice. TGF-β in liver tissue (A) and serum (B) were measured by ELISA assay. PDGF (C) and MCP-1(D) mRNA levels in liver tissue were analyzed by qRT-PCR. Values are expressed as mean ± SEM, n = 5; (∗) $P < 0.05$ compared to the control group; (#) $P < 0.05$ compared to the CCl_4 group.

the level of TNF-α, TGF-β, PDGF, and MCP-1 and increase the level of IL-10; the anti-inflammation effects are similar to the previous study about Cy-3-G on obesity, which might result from decreasing NF-κB activity.[46] Furthermore, we detected IL-17, which was significantly down-regulated by Cy-3-G in both liver and circulation. IL-17 is mainly secreted from Th17 cells that can promote tissue inflammation by induction of other pro-inflammatory mediators and recruitment of leukocytes to the site of inflammation.[47] In our present study, a Cy-3-G anti-inflammatory effect was evidenced by restraining inflammation cell recruitment and inflammatory cytokines in liver injury.

The paracrine and autocrine sources of cytokines will finally cause the activation of HSCs. It is assumed that Cy-3-G restrains HSC activation through two possible paths; the first was to suppress the path of generating inflammatory cytokines; the second might be to directly suppress the activation of HSCs (Scheme 1). Cy-3-G can be partly absorbed into circulation[48] and may have an opportunity to react with HSCs. Moreover, Cy-3-G was investigated to prevent HSC proliferation and collagen synthesis in vitro.[20]

In conclusion, Cy-3-G was able to attenuate liver injury and prevent fibrosis in CCl_4-treated mice. Moreover, Cy-3-G could reduce liver oxidative stress, alleviate apoptosis of hepatic cells, suppress liver inflammation, and finally restrain the activation of HSCs. Our study implied that regular intake of Cy-3-G in the daily diet could prevent the progression of hepatic fibrosis and be a potent element to treat liver injury. However, further studies are needed to fully understand the cellular and molecular mechanisms of Cy-3-G on HSCs.

sequencing (NGS), is a powerful and cost-efficient tool for discovering gene expression, novel genes, and differentially expressed genes. Due to its higher accuracy and dynamic range, RNA-seq is replacing other methods for quantifying gene expression, including microarray and serial analysis of gene expression (SAGE). RNA-seq is very sensitive and allows more precise quantification of differential gene expression, as well as the detection of low-abundance transcripts. Furthermore, RNA-seq is useful in nonmodel plants that lack a reference genome because the focus of sequencing is the coding regions. Therefore, the transcriptomes of various nonmodel agricultural crops have been assessed using RNA-seq, including olive,[24] chestnut,[25] and tea.[26] For model agriculture crops such as *Zea mays* and soybean, RNA-seq provides breeders with new tools and methodologies to discover genome-wide expression, to isolate novel transcripts, and to explore alternative RNA splicing events, which allow great steps forward in plant breeding.[27−29]

To investigate the transcriptional profiling in *A. membranaceus* hairy roots in response to MeJA, we used the next-generation Illumina/Solexa HiSeq2000 platform for RNA analysis (RNA-seq). The assembled and annotated transcriptome sequences provide a valuable resource for the molecular characterization of secondary metabolite biosynthesis in *A. membranaceus*. In addition, we identified most genes related to AST, calycosin, and CG biosynthesis in *A. membranaceus*. Transcriptional regulation of AST, calycosin, and CG biosynthetic genes and changes in AST, calycosin, and CG accumulation were investigated in the hairy roots of *A. membranaceus* treated with MeJA. These data may establish new approaches to maximize AST, calycosin, and CG production and biomass productivity in the hairy roots of *A. membranaceus*.

MATERIALS AND METHODS

Establishment of Hairy Root Transformation and MeJA Treatment. Excised cotyledons and leaves of *A. membranaceus* from 20-day-old seedlings were used as the explant materials for cocultivation with wild-type *Agrobacterium rhizogenes* strain R1000. The excised explants were dipped into a liquid *A. rhizogenes* culture in inoculation medium for 10 min, blotted dry on sterile filter paper, and incubated in the dark at 25 °C on agar-solidified half-strength (1/2) MS medium. After 2 days of cocultivation, the explant tissues were thoroughly washed with sterilized distilled water and transferred to a hormone-free 1/2 MS medium containing cefotaxime (500 mg/L). The hairy roots were induced from the wound sites after 20 days of inoculation. Genomic DNA was isolated from several different fast-growing hairy root lines using the method described by Edwards et al.[30] Polymerase chain reaction (PCR) analysis was then performed using primers that detect *rol* A, B, C, and D genes to confirm the integration of *A. rhizogenes* open reading frames into the recipient plant genome (data not shown).

For the next steps, approximately 200 mg of fresh hairy roots was transferred to 30 mL of 1/2 MS liquid medium in 100 mL flasks. Hairy root cultures were maintained at 25 °C on a gyratory shaker (100 rpm) in a growth chamber under standard cool white fluorescent tubes with a flux rate of 35 μmol s^{-1} m^{-2} and a 16-h photoperiod. For MeJA treatments, hairy root samples were treated with MeJA (Sigma) after 3 weeks of culture in 30 mL of 1/2 MS liquid medium. Hairy root samples were harvested 24 h after MeJA treatment. In another study (unpublished data), we found that the production of AST, calycosin, and CG in hairy roots treated with 100 μM MeJA was higher than that in the hairy roots treated with other concentrations of MeJA. Therefore, the hairy roots treated with 100 μM MeJA was chosen for the further transcriptome analysis. Untreated hairy roots were used as the control. The entire experiment was repeated three times, and three independent hairy root replicates were pooled for further analyses. All samples were frozen in liquid nitrogen immediately after harvesting and then stored at −80 °C or freeze-dried for total RNA isolation or HPLC analysis.

RNA Isolation and Illumina Sequencing. The samples were ground into powder using liquid nitrogen, and total RNA was isolated using a Plant Total RNA Mini Kit (Geneaid, Taiwan) according to the manufacturer's instructions. The quality and concentration of total extracted RNA was determined by 1% agarose gel electrophoresis and spectrophotometer analysis in a NanoVue Plus spectrophotometer (GE Healthcare Bio-Science Crop, USA). mRNA was purified from total RNA using Sera-Mag Magnetic Oligo(dT) beads (Illumina, San Diego, CA, USA). cDNA synthesis, library construction, and DNA sequencing were performed using Illumina/Solexa HiSeq2000 platform by SEEDERS Company (Daejeon, Korea). The resulting high-quality reads were then deposited in the Short Read Archive at the National Center for Biotechnology Information (NCBI) with the accession number SRR923811.

De Novo Assembly and Functional Annotation. Reads obtained using an Illumina sequencer were filtered and *de novo* assembled using Velvet and Oases at high *k*-mers of 57, 59.[31] *A. membranaceus* transcripts were searched against the plant genome information in Phytozome (http://www.phytozome.net/) with a wide range of *E*-value cutoff, from 1×10^{-100} to 1×10^{-6}. The numbers of annotated genes stabilize around cutoff values of 1×10^{-6} to 1×10^{-10} (data not shown). Therefore, we chose a default cutoff of 1×10^{-10} for best blast hit number. To assign function to each gene, gene ontology (GO) analysis and clusters of orthologous groups (COG) analyses were performed. To gain an overview of gene pathway networks, genes were mapped according to the Kyoto Encyclopedia of Genes and Genomes (KEGG). Genes encoding transcription factors were identified using the Plant Transcription Factor Database (http://planttfdb.cbi.edu.cn/).

Differentially Expressed Gene Analysis. Differential expression analysis was performed based on the negative-binomial distribution, as described by Anders and Huber.[32] Raw counts data for the control and MeJA-treated hairy roots were compared to determine the $\log_2$-fold change in abundance of each transcript. Differentially expressed genes were those having $\log_2$-fold change of ≤ -1 or ≥ 1 and a false discovery rate of ≤ 0.01.

Identification of Genes Related to AST, Calycosin, and CG Biosynthetic Pathways. Genes involved in the AST, calycosin, and CG biosynthetic pathways were searched for using functional annotation data based on the candidate gene names. In addition, the AST, calycosin, and CG biosynthetic genes of *Arabidopsis* obtained from The *Arabidopsis* Information Resource (TAIR) were used as queries to search for homologous sequences in *A. membranaceus* transcriptome database. Following this, each search sequence was confirmed by using the BLAST program in the National Center for Biotechnology Information GenBank database.

Quantitative Real-Time PCR. On the basis of the sequences of *A. membranaceus* 1-deoxy-D-xylulose 5-phosphate synthase (AmDXS), (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate synthase (AmHDS), acetoacetyl-coenzyme A thiolase (AmAACT), isopentenyl diphosphate isomerase (AmIDI), squalene synthase (AmSS), phenylalanine ammonia lyase (AmPAL1), cinnamic acid 4-hydroxylase (Am4CL), chalcone synthase (AmCHS1), chalcone isomerase (AmCHI), and isoflavone *O*-methyltransferase (AmIOMT), we designed real-time PCR primers using the Primer3 Web site (http://bioinfo.ut.ee/primer3-0.4.0/primer3/; Table S10, Supporting Information). Real-time PCR products were tested for specificity of fragment sizes, melting curves, and sequences by PCR, real-time PCR, and cloning into a T-Blunt vector for sequencing, respectively. The expression levels of these genes were normalized and then analyzed by relative quantification using the *A. membranaceus* adenine phosphoribosyl transferase housekeeping gene (NCBI Genbank accession number KF355974) as a reference. qRT-PCR was performed by previous paper.[33] Three replications for each sample were used in the real-time analyses.

HPLC Analysis. The materials were freeze-dried and ground into a fine powder. AST I, AST II, AST III, AST IV, calycosin, and CG were analyzed by HPLC.[34,35] The concentration of each compound was determined using a standard curve. All samples were analyzed in triplicate.

Statistical Analysis. The data for gene expression and AST, calycosin, and CG content were analyzed using Statistical Analysis System software (SAS version 9.2). Treatment means were compared using Duncan's multiple range test.

RESULTS AND DISCUSSION

Illumina Sequencing and *De Novo* Sequence Assembly. cDNA libraries were constructed from *A. membranaceus* hairy roots treated with 100 μM MeJA for 24 h and from untreated hairy roots and sequenced. In total, 98 257 776 reads of 101 bp from 9 924 035 376 bp were obtained from the Illumina/Solexa HiSeq2000 platform (Table 1). Of these, 77 758 230 paired-end clean reads, with a mean length of 90.81 bp, were obtained from 98 257 776 trimmed reads. The clean reads were assembled into 48 636 transcripts (average length of 1398 bp), which were then clustered into 23 658 loci using Velvet and Oases at high *k*-mers of 57, 59 (Table 2).[31] Because our main goal was to study the nonredundant set of mRNA sequences for *A. membranaceus*, the longest or highest coverage transcript for each locus was chosen to produce 23 658 nonredundant cDNAs (genes), with an average length of 1161 bp, containing 10 311 full-length coding sequences. Distribution of the number of transcripts and genes organized by transcript length and gene length, respectively, are shown in Figure 1.

Table 2. Summary of Sequence Assembly from the *A. membranaceus* Transcriptome

	transcript	locus
number of sequences	48 636	23 658
minimum length (bp)	200	200
maximum length (bp)	14 974	11 135
mean length (bp)	1 398	1 161
annotated sequences	40 904	19 940
full-length coding sequences	21 899	10 311

Functional Annotation. A total of 40 904 transcripts clustering into 19 940 genes were annotated by searching against the plant genome information using Phytozome (http://www.phytozome.net/) with an *E*-value cutoff of 1×10^{-10} (Table S1, Supporting Information). Subsequently, GO and COG analyses were performed to classify the function of predicted *A. membranaceus* genes. GO analysis categorized 19 940 genes as biological process, cellular component, or molecular function (Figure 2). Each gene may have more than one GO term and be assigned to different GO categories. The dominant groups within the biological process, cellular component, and molecular function categories were cellular process (8402 members), cell part (13 182 members), and nucleotide binding (3748 members), respectively. A total of 17 189 genes were aligned to 25 categories of the COG database (Figure 3). The R category "general function prediction only" was the largest group (3505 members), followed by the T category "signal transduction mechanisms" (1996 members) and the S category "function unknown", which has no concrete assignment (1537 members). In addition, 4969 genes were mapped to 116 KEGG pathways (Table S2, Supporting Information). The biosynthesis of plant hormones, phenylpropanoids, terpenoids, and steroids were the three largest groups with 282, 210, and 184 identified genes, respectively. The analyses provided excellent material for the molecular characterization of genes related to secondary metabolite biosynthetic pathways in *A. membranaceus*.

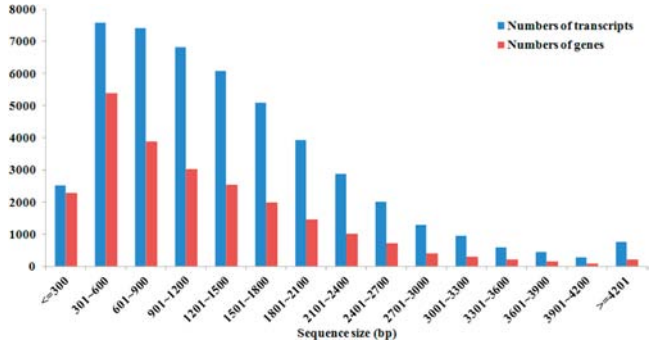

Figure 1. Distribution of transcript and gene numbers based on transcript and gene length, respectively.

Differentially Expressed Gene Analysis in *A. membranaceus* Hairy Roots in Response to MeJA. The differentially expressed gene (DEG) analysis between MeJA-treated and control hairy roots was performed using the DESeq method.[32] Genes were determined to be differentially expressed if they had a $\log_2$-fold change of ≤ -1 or ≥ 1 and a false discovery rate of ≤ 0.01. A total of 3374 genes were found to be differentially expressed in MeJA-treated hairy roots compared with control hairy roots. Of these, 2127 genes were up-regulated and 1247 genes were down-regulated by MeJA. BLASTx searches of 3374 DEGs against the plant genome

information using Phytozome (http://www.phytozome.net/) with an E-value cutoff of 1×10^{-10} revealed that 2920 DEGs, including 1852 up-regulated genes and 1068 down-regulated genes, were annotated (Tables S3 and S4, Supporting Information, respectively). Furthermore, the KEGG analysis revealed that 667 up-regulated genes and 238 down-regulated genes could be mapped to 88 and 76 KEGG pathways, respectively (Tables S5 and S6, Supporting Information, respectively). Of these, MeJA up-regulated a large numbers of genes belonging to the biosynthesis of plant hormone group (71 genes), the biosynthesis of terpenoids and steroids group (44 genes), and the biosynthesis of phenylpropanoids group (34 genes) in *A. membranaceus* hairy roots. The application of MeJA stimulates the transcription of biosynthetic genes and accumulation of secondary metabolites in plants.[36−38] The annotated differentially expressed genes are an important and valuable resource for the identification of novel MeJA-responding genes and for the investigation of specific MeJA-regulated pathways in *A. membranaceus*.

Transcriptional Regulation of Transcription Factors in *A. membranaceus* Hairy Roots in Response to MeJA. Transcription factors are important elements in regulating plant responses to a range of abiotic and biotic stresses by controlling the expression patterns of genes involved in signaling pathways.[39,40] In the *A. membranaceus* transcriptome, 3784 genes encoding transcription factors were annotated (Table S7, Supporting Information). bHLH, NAC, WRKY, MYB-related, and bZIP are the five largest families of transcription factors and have 339, 292, 287, 281, and 227 members, respectively (Figure 4). Of the 3784 identified transcription factors, 395 were up-regulated and 250 were down-regulated by MeJA in *A. membranaceus* hairy roots (Tables S8 and S9, Supporting Information, respectively). A high number of transcription factors regulated by MeJA suggested that transcription factors play various roles in molecular mechanisms in response to MeJA as well as in the defense mechanisms of *A. membranaceus* hairy roots. Moreover, information about transcription factors will be helpful in investigating their roles in secondary metabolite biosynthesis in response to stresses.

MeJA Increases Transcription Levels of Genes Related to the AST Biosynthetic Pathway in *A. membranaceus* Hairy Roots. Triterpene ASTs are built from isopentenyl diphosphate, which is supplied from the cytosol mevalonic acid

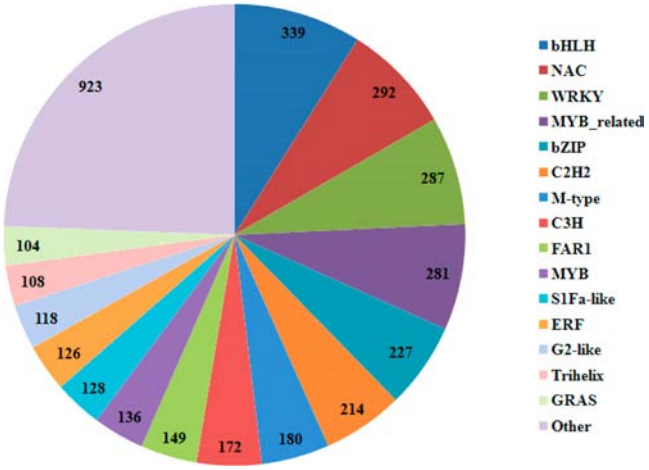

Figure 4. Numbers of genes encoding transcription factors.

(MVA) pathway and the plastid methylerythritol phosphate (MEP) pathway (Figure 5). On the basis of the functional annotation of the *A. membranaceus* transcriptome library, 17 novel genes were identified that encode enzymes related to the AST biosynthetic pathway (Table 3). In the MEP pathway, full-length coding sequences of AmDXS, 2-*C*-methyl-D-erythritol 4-phosphate cytidylyltransferase (AmMCT), 4-(cytidine 5′-phospho)-2-*C*-methyl-D-erithritol kinase (AmCMK), AmHDS, and (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate reductase (AmHDR) and partial-length coding sequences of 1-deoxy-D-xylulose 5-phosphate reductoisomerase (AmDXR) were found. Entire genes that are involved in the MVA pathway were isolated, including AmAACT, 3-hydroxy-3-methylglutaryl coenzyme A synthase (AmHMGS), 3-hydroxy-3-methylglutaryl-coenzyme A reductase (AmHMGR1, AmHMGR2, AmHMGR3), mevalonate kinase (AmMVK), phosphomevalonate kinase (AmPMK1, AmPMK2), mevalonate diphosphate decarboxylase (AmMVD), and AmIDI. In addition, full-length coding sequence of farnesyl diphosphate synthase (AmFDS), an enzyme that functions in the initial step of triterpene formation in the MVA pathway and MEP pathway, was also found in the *A. membranaceus* transcriptome library. These 17 novel AST biosynthetic genes of *A. membranaceus* share high similarity and identity with other orthologous genes (data not shown) and have been submitted to Genbank at the NCBI.

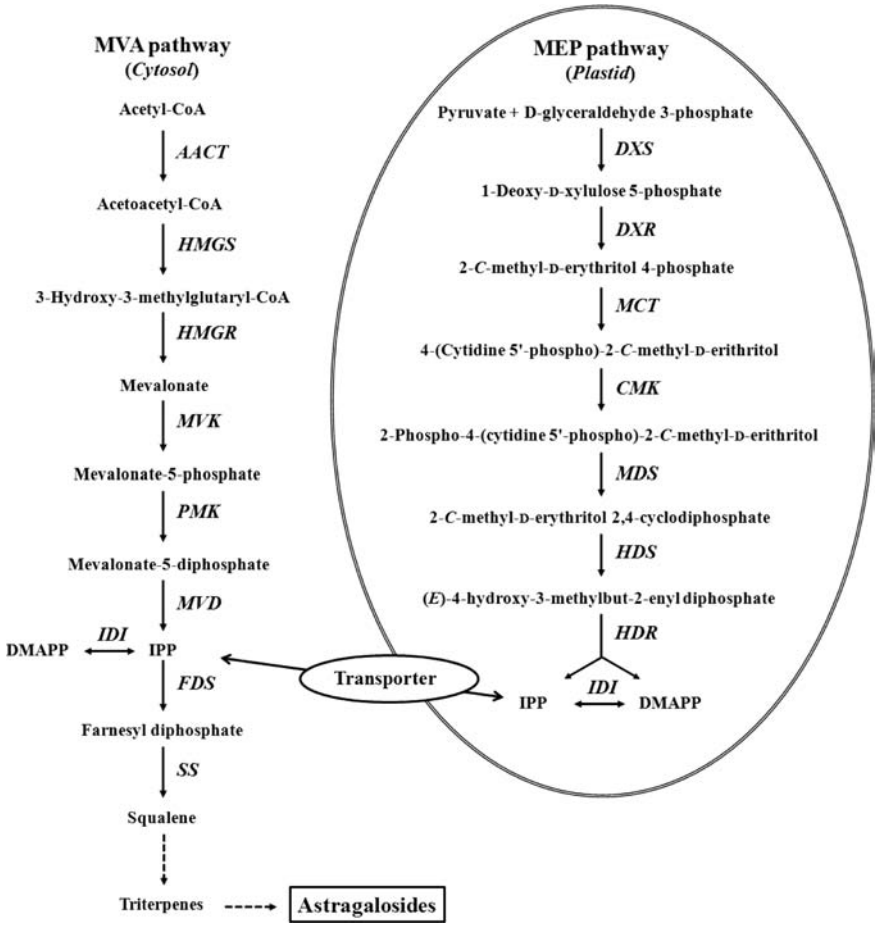

Figure 5. Proposed AST biosynthetic pathway in plants. [a]The genes identified in this study. [b]The full-length coding sequence genes.

RPKM values showed that most genes related to the AST biosynthetic pathway were up-regulated by the application of MeJA in *A. membranaceus* hairy roots. *AmPMK2*, *AmDXS*, and *AmSS* exhibited the highest increases in expression in MeJA-treated hairy roots, with fold changes of 99.7, 27.81, and 14.71, respectively (Table 3). Expression levels of five selected genes were validated by qRT-PCR (Figure 6A). Although the fold-changes of these genes were different than those detected by RNA-seq, their expression profiles were consistent with the RNA-seq. The same hairy root materials as those used for RNA-seq and qRT-PCR were used for HPLC analysis of AST I, AST II, AST III, and AST IV (Figure 6B). The accumulation of AST I, AST II, AST III, and AST IV was significantly increased by 2.98-, 2.85-, 2.30-, and 1.57-fold, respectively, in MeJA-treated hairy roots compared with control hairy roots. These results suggest that the accumulation of ASTs was tightly regulated by the expression levels of genes involved in the MVA and MEP pathways in *A. membranaceus* hairy roots in response to MeJA. Furthermore, large amounts of AST I, AST II, AST III, and AST IV were found in both control (2386.06, 774.85, 401.52, and 124.24 μg/g, respectively) and MeJA-treated (7104.02, 2205.2, 924.98, and 194.77 μg/g, respectively) hairy roots. These amounts were much higher than those of the natural roots of *A. membranaceus*.[10] Hairy roots of *A. membranaceus* may, therefore, be a good material for the production of ASTs.

MeJA Increases Transcription Levels of Genes Related to Calycosin and CG Biosynthetic Pathways in *A. membranaceus* Hairy Roots. AmPAL1, AmC4H1, AmCHS1, chalcone reductase (AmCHR), AmCHI, isoflavone synthase (AmIFS), and isoflavone 3′-hydroxylase (AmI3′H), which are involved in calycosin and CG biosynthetic pathways (Figure 7),[9] were also found in the *A. membranaceus* transcriptome library. In addition, seven new full-length coding

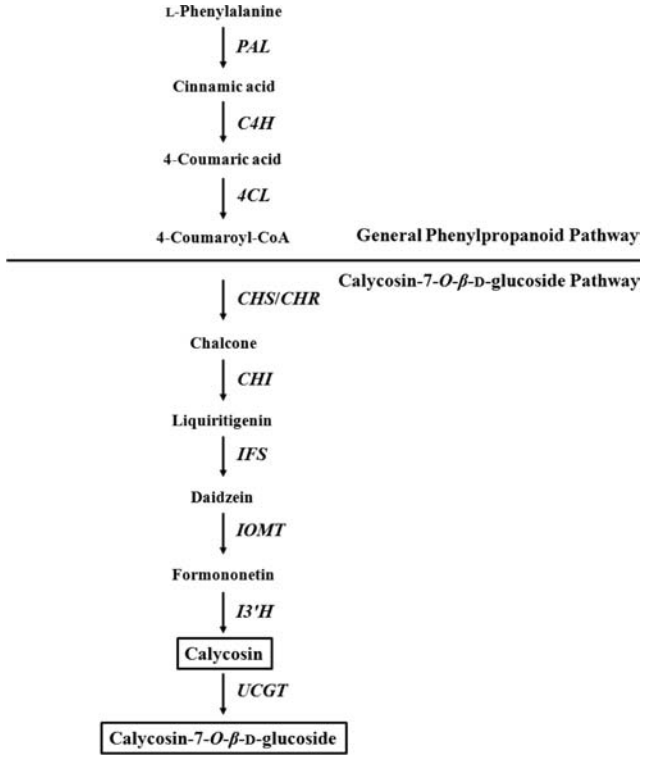

Figure 7. Proposed calycosin and CG biosynthetic pathways in plants. PAL, phenylalanine ammonia lyase; C4H, cinnamate-4-hydroxylase; 4CL, 4-coumaroyl CoA ligase; CHS, chalcone synthase; CHR, chalcone reductase; CHI, chalcone isomerase; IFS, isoflavone synthase; IOMT, isoflavone *O*-methyltransferase; I3′H, isoflavone 3′-hydroxylase; UCGT, UDP-glucose:calycosin-7-*O*-glucosyltransferase.

sequences (AmPAL2, AmPAL3, AmC4H2, Am4CL, AmCHS2, AmIOMT, and UDP-glucose:calycosin 7-*O*-glucosyltransferase (AmUCGT)) were identified (Table 4). BLAST searches of the NCBI Genbank database showed that they exhibited high homology to other orthologous genes (date not shown). The seven new calycosin and CG biosynthetic genes of *A. membranaceus* have been deposited into the NCBI Genbank (accession numbers shown in Table 4).

According to fold change values of RNA-seq, with the exception of *AmIOMT*, all calycosin and CG biosynthetic genes were up-regulated by MeJA in *A. membranaceus* hairy roots (Table 4). Expression levels of *AmUCGT*, *AmCHS1*, and *AmPAL3*, with fold changes of 7.07, 3.79, and 2.89, respectively, increased the most in MeJA-treated hairy roots compared with control hairy roots. qRT-PCR of five selected genes was performed to confirm the gene expression profiles analyzed by RNA-seq (Figure 8A). The higher expression levels of *AmPAL1*, *Am4CL*, *AmCHS1*, and *AmCHI* and the lower expression level of *AmIOMT* detected in MeJA-treated hairy roots by qRT-PCR supported the reliability of RNA-seq analyses. The higher expression levels of calycosin and CG biosynthetic genes were correlated with their higher accumulation in MeJA-treated hairy roots compared with control hairy roots (Figure 8B). Specifically, MeJA-treated hairy roots contained 23.61 μg/g of CG, whereas untreated hairy roots contained 17.75 μg/g. Untreated hairy roots did not accumulate calycosin, but hairy roots treated with MeJA contained 0.54 μg/g of calycosin. These data may not only broaden our understanding of the molecular mechanisms involved in the calycosin and CG biosynthetic pathways in *A. membranaceus* but also aid in their metabolic engineering in plants.

A. membranaceus, one of the most important Chinese traditional herbs, has a wide range of natural products.[6,7] MeJA application increased the expression levels of most genes related to AST, calycosin, and CG biosynthesis and their accumulation. Therefore, MeJA-treated hairy roots of *A. membranaceus* may be an excellent material for the production of ASTs, calycosin, and CG because of their biochemical stability and rapid growth rate.[41,42] On the other hand, although AST, calycosin, and CG were identified a long time ago, the complete biosynthetic pathway and biosynthetic genes of AST, calycosin, and CG are still largely unknown. Recently, based on the hypotheses that genes involved in secondary metabolite biosynthesis are often coordinately regulated at the transcriptional level, coexpression analysis has been widely used to identify new candidate genes in plants. There are numerous examples of successful gene discovery studies using this strategy such as the isolation of two glycosyltransferases involved in anthocyanin modification in *Arabidopsis thaliana*,[43] and the last

four missing steps of the seco-iridoid biosynthesis pathway in *Catharanthus roseus*.[44] The RNA-sequencing transcriptional profiling of *A. membranaceus* hairy roots in response to MeJA in this study will provide useful information to identify novel genes putatively involved in the downstream steps of the AST, calycosin, and CG biosynthetic pathways using coexpression analysis strategy.

Functional food, which contains numerous compounds beneficial to health, recently has attracted much interest. Therefore, much research has focused on developing efficient strategies to optimize the production of beneficial compounds for health in plants without gene modification or breeding. Among them, application of elicitors has been reported to efficiently affect the natural product accumulation in plants.[21−23] Here, we reported that application of MeJA significantly increased the accumulation of AST, calycosin, and CG in the hairy roots of *A. membranaceus*. This finding may provide a new method to develop functional food products having high concentrations of AST, calycosin, and CG in the future.

In conclusion, we identified 23 658 genes by high-throughput sequencing technology. There were 19 940 annotated genes, 4969 genes mapped to 116 KEGG pathways, and 3784 genes encoding transcription factors. RNA-seq analysis revealed that 2127 genes were up-regulated and 1247 genes were down-regulated by 100 μM MeJA in *A. membranaceus* hairy roots. In addition, we isolated 24 novel genes involved in the biosynthesis of ASTs, calycosin, and CG, chemical markers of the quality of *A. membranaceus*. The assembled and annotated transcriptome sequences provide a valuable resource for molecular characterization of ASTs, calycosin, and CG as well as other secondary metabolite biosynthetic pathways in *A. membranaceus*. The up-regulated biosynthesis of ASTs, calycosin, and CG in MeJA-treated hairy roots may lead to new approaches to maximize their production and biomass productivity in the hairy roots of *A. membranaceus*.

[a]AAC and crystallinity data were taken from our previous report.[15] Values in the same column with different superscripts are significantly different ($p < 0.05$).

On the basis of the above investigations, the digestive properties of starch were influenced by both amylose content and amylopectin fine structure. However, the concerted interplay or contributions of amylose and amylopectin fine structures are not completely understood.

Genetic investigations into the mechanisms underlying the formation of SDS and RS content in rice starches are scarce. Some starch mutants such as *amylose extender*, in which the starch branching enzyme IIb (BEIIb) gene is defective, displayed high RS.[10] For a *japonica* high RS mutant "Jiangtangdao 1" with an RS value of 11.67%, BEIIb was found to be the causal gene for the elevated RS content.[11] For another high amylose mutant in *japonica* background (Goami 2), BEIIb was not the causal gene,[12] whereas the genetic controls for some other high RS mutants in *indica* background are still unknown.[13] Low glycemic index (GI) food is able to assist in the management or prevention of type II diabetes, a major chronic disease in developing countries where rice is the staple food. In a study of 235 varieties, the *Waxy* gene was the major gene associated with GI.[14] However, genetic control of the naturally occurring variations in SDS and RS contents in rice starch has not been reported.

To deepen the understanding of the "genetics−structure−functionality" relationships of rice starch, an investigation of diverse rice starch samples with different amylose contents and similar amylopectin fine structures or similar amylose contents (for example, waxy rice) and different amylopectin fine structure combinations is required. Previously, we examined 14 rice cultivars varying in the combination of AAC and gelatinization temperatures for their physicochemical and functional properties.[15] In this study, the same series of rice starch samples were analyzed for starch structure and digestibility. The objectives were (i) to determine the contribution of amylose content and amylopectin fine structure to the in vitro digestion properties of the selected rice starches and (ii) to delve into the genetic contribution of the starch synthesis related genes (SSRGs) to the starch structure and functional properties.

MATERIALS AND METHODS

Materials. Fourteen rice cultivars were selected in the current study and included three waxy (Youzaonuo, Lishuinuo, and Xiangnuo) and eleven normal (Zhefu 504, Ce 482, 93−11, Xiushui 11, Zhonghua 11, Lemont, IR64, Jiayu 293, Zhenshan B, Zaiyeqing 8, and LongB) types as described in a previous report (Table 1).[15] Sample preparation and starch isolation procedures have been previously described.

In Vitro Starch Digestibility. Samples of the starch fraction (550 mg, dry weight basis) were weighed in a screw-capped tube and heated in 10 mL of distilled water for 20 min with frequent mixing. Following this, 15 glass beads (0.5 mm diameter), guar gum (50 mg), and 10 mL of sodium acetate buffer (0.25 M, pH 5.2) were added to each tube. The tubes were then incubated with pancreatic α-amylase (50 units) and amyloglucosidase (35 units) at 37 °C in a shaking water bath. After 20 and 120 min of incubation, the hydrolysates (0.5 mL) were transferred to 20 mL of 80% ethanol to stop the reaction. The amount of released glucose was determined using a glucose oxidase assay kit (Megazyme, Bray, Co. Wicklow, Ireland). The percentages of glucose after 20 (SD_{20}) and 120 (SD_{120}) min incubations were calculated using a glucose standard curve to determine the percent starch digested. The contents of rapidly digestible starch (RDS), slowly digestible starch (SDS), and resistant starch (RS) in rice starch samples were determined according to a previous report.[1]

Gel-Permeation Chromatography (GPC). Rice starch (~3.5 mg) was dissolved in 100 μL of dimethyl sulfoxide (DMSO) with constant stirring overnight. Hot Milli-Q water (800 μL) and 100 μL of 0.1 M NaAc buffer (pH 4.5) were added to the starch−DMSO solution. Isoamylase (1 μL, from *Pseudomonas* sp., 1000 U/mL, EC 3.2.1.68, Megazyme, Bray, Co. Wicklow, Ireland) and 1 μL of pullulanase (from *Klebsiella planticola*, 700 U/mL, EC 3.2.1.41, Megazyme, Bray, Co. Wicklow, Ireland) were added to start the reaction, which was conducted overnight with slow and constant stirring at room temperature. A NaOH solution (100 μL 5 M) was added to the debranched starch sample, and the mixture was centrifuged and then analyzed by gel-permeation chromatography (GPC) on a column (1 × 90 cm) of Sepharose CL 6B (Pharmacia, Uppsala, Sweden) with 0.5 M NaOH as an eluent at a rate of 0.5 mL/min. The column was calibrated by using dextrans with known molecular weights. The carbohydrate content of the collected fractions (0.5 mL) was determined with phenol−sulfuric acid reagent.[16]

Amylopectin Fractionation and Chain-Length Distribution Determination. Amylopectin fractionation followed previous methods based on butanol−alcohol precipitation.[17,18] Purified amylopectin (9 mg) was dissolved in 450 μL of 100% DMSO with constant stirring overnight. The solution was then diluted with 2250 μL of Milli-Q water, and 300 μL of 0.1 M sodium acetate buffer (pH 4.5), 1 μL of isoamylase (from *Pseudomonas* sp., 1000 U/mL, EC 3.2.1.68, Megazyme, Bray, Co. Wicklow, Ireland), and 1 μL of pullulanase (from *Klebsiella planticola*, 700 U/mL, EC 3.2.1.41, Megazyme, Bray,

[a]Values in the same column with different superscripts are significantly different ($p < 0.05$).

Co. Wicklow, Ireland) were added. The debranching reaction was conducted at room temperature with constant stirring overnight and was terminated by heating. The sample was centrifuged and filtered (pore size 0.45 μm) before injection into the HPLC system.

The chain length distributions of debranched samples were analyzed with a method modified from a previous report using a high-performance anion-exchange chromatography (HPAEC) system (Dionex ICS-5000+, Sunnyvale, CA) coupled with a BioLC gradient pump and a pulsed amperometric detector (PAD).[18] The PAD signal was recorded by Chromeleon software (Version 6.8) and corrected to carbohydrate content.[19] Prior to loading of the sample, the column (250 mm × 4 mm, Carbo-Pac PA-100 with a guard column) was eluted at a rate of 1 mL/min with 150 mM NaOH for 20 min and then with a mixture of 150 mM NaOH (eluent A, 93%) and 150 mM NaOH containing 1 M NaOAc (eluent B, 7%) for 20 min. The elution gradient with a rate of 1 mL/min was as follows: from 0 to 1.3 min, 93% eluent A; from 1.3 to 10 min, eluent A changed from 93 to 82% linearly; from 10 to 19 min, from 82 to 78%; from 19 to 111 min, from 78 to 50%; from 111 to 113 min, from 50 to 93% (after which it returned to the starting mixture). The sample was injected during the initial 1.2−1.3 min.

Physicochemical Properties. The parameters of the physicochemical properties used in the current study were described in our previous report.[15]

Association Test. Since all of the 14 accessions were selected from our association panel,[20−22] the genotypes of all the SSRGs (Supplementary Table 1 in the Supporting Information) as well as other markers (i.e., microsatellites) were used in this study, to test the association among SSRGs, starch structure, and functionality (digestive properties). Due to the small amount of samples, the analysis of variance (ANOVA) and the kinship coefficient (K) models were performed with TASSEL Version 2.1 software. The P value determining whether a marker is associated with a trait was set at $P < 0.05$.

Statistical Analysis. All analyses were determined in triplicate. Statistical analysis was conducted using SigmaPlot 9.01 integrated with SigmaStat 3.11 (Systat Software, CA). The results were subjected to one-way analysis of variance (ANOVA) and Tukey's test to determine significant differences.

RESULTS AND DISCUSSION

Molecular Structure Characterization of Rice Starch. The debranched total starch samples were analyzed by gel-permeation chromatography (GPC) with Sepharose CL 6B to determine the molecular size distribution profiles. The typical profiles from selected starch samples are shown in Figure 1. Two major peaks were identified: the fraction from the first peak area (FrI) is amylose, while the fraction of the second

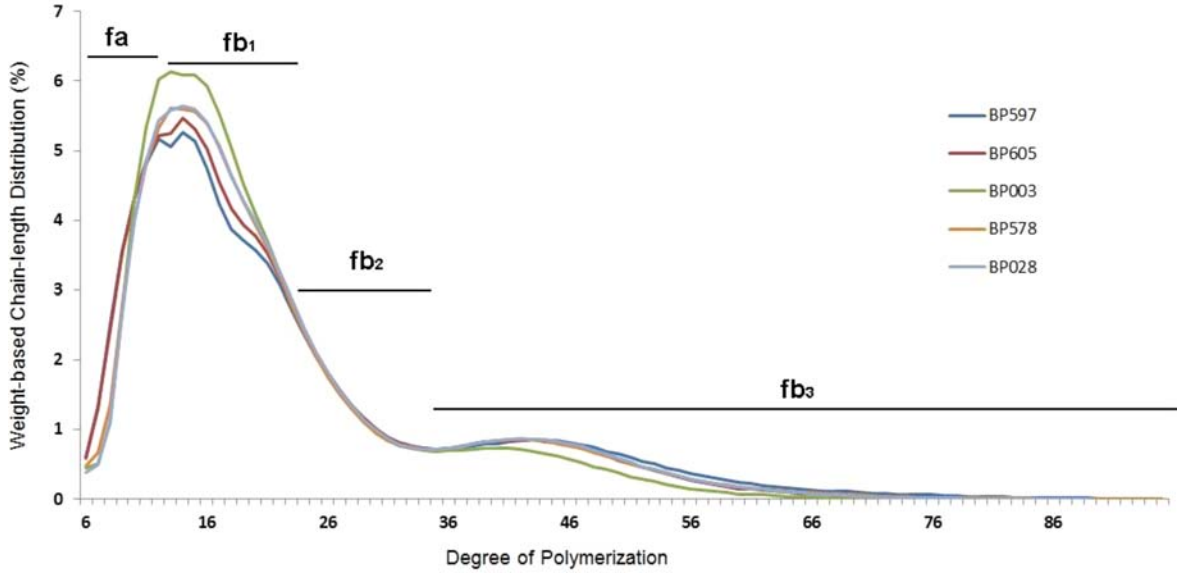

Figure 2. Chain-length profiles obtained by HPAEC of amylopectins from selected rice cultivars.

peak area (FrII) is amylopectin. FrII could be further divided into FrIIb and FrIIa, which are long- and short-unit chains of amylopectin, respectively (Figure 1). As expected, the percentage of FrI from waxy rice starch was low (0.2−1.5%), while nonwaxy rice starch had 16.7−25.6% FrI. The content of FrI followed the general trend of AAC as determined by the iodine reagent method (Table 1). Since the amylose contents obtained from Sepharose CL 2B (before debranching) and 6B (debranched) differ,[23] caution should be taken when comparing the AAC values obtained from the different methods.

Purified amylopectin debranched by enzymes was employed to determine the chain-length profile. The parameters of chain-length distribution and average chain length of amylopectin are summarized in Table 2, and a comparison of amylopectin chain-length distribution profiles from selected rice starch samples is presented in Figure 2. The weight-based chain-length distribution of debranched amylopectin was grouped into four fractions, fa (DP 6−12), fb_1 (DP 13−24), fb_2 (DP 25−36), and fb_3 (DP > 36), according to the division suggested by a previous report.[24] The percentages of fa, fb_1, fb_2, and fb_3 were 18.07%−24.71%, 45.01%−55.67%, 12.72%−14.05%, and 10.80%−20.72%, respectively. The average chain length in rice amylopectin was DP 16.34−17.76, which was in agreement with a previous report on waxy rice;[25] however, these values were lower than those in a recent report describing the average chain lengths of six waxy rice starches, which ranged from DP 21.9 to 24.3.[9] In another study, the average chain length of four waxy rice starches was from DP 20.0 to 20.7.[26] The results showed that amylopectin chain-length profiles from 3 waxy and 11 normal types were similar, which indicated that the amylopectin fine structure was independent of the amylose content. This result challenged a conclusion made in a previous report that amylose content was significantly correlated with amylopectin average chain length and the ratio of long chains to short chains.[27]

Amylopectin chains in high-amylose and intermediate-amylose rice were shown to be longer than those in waxy and low-amylose rice when four rice cultivars were compared;[7] however, when more cultivars were included as in this study, the trend was not clear (Table 2). Generally, waxy and low-amylose (BP005) rice starches had a higher degree of crystallinity than normal types. However, waxy type BP597 had a much lower degree of crystallinity. Notably, fb_1 (DP 13−24) chains in BP597 were lower and fb_3 (DP > 36) were higher than those in the other two waxy types (Table 2), indicating that fb_1 chains contributed to the formation of crystallinity while fb_3 hindered this formation. Normal type BP003 had a higher degree of crystallinity than other normal types, and the highest proportion of fb_1 chains and lowest proportion of fb_3 chains was observed in BP003 (Table 2), which further supported the roles of fb_1 and fb_3 chains in starch crystallinity. It has also been suggested that fb_1 chains form double helices that span the entire length of crystalline regions.[28]

In Vitro Digestibility of Rice Starch. The in vitro methodology for determining nutritional starch fractions was developed by Englyst and co-workers[1] and describes the likely rate and extent of glucose release from foods in the small intestine; it has been verified to match the mean proportion of starch recovered in ileostomy studies.[29,30] These nutritional fractions determine the bioavailability and likely physiological fate of the carbohydrate when it is consumed.[31]

The nutritional fractions of rice starch, including rapidly digestible starch (RDS), slowly digestible starch (SDS), and resistant starch (RS), are presented in Table 3. The RDS content of rice starch ranged from 78.5 to 87.5%. The lowest and highest RDS contents were observed in BP028 and BP011, respectively. Waxy rice starch types had relatively higher RDS content than normal types. SDS content from rice starch samples ranged from 1.2 to 6.0%, with the lowest content observed in BP011 and the highest in BP005. RS content varied from 10.1% (BP005) to 18.0% (BP578) (Table 3). It has been proposed that combining the fractions of SDS and RS was useful for comparison of starch types,[32] and normal rice starch showed relatively higher fractions of SDS and RS than waxy types; this phenomenon was also observed in the current study. Rice starch digestion properties were previously shown to be affected by amylopectin fine structure,[5] starch fine molecular structure, and crystalline structure.[9] RS has been correlated positively with amylose content in rice starch, while SDS decreased as amylose content increased.[7] RDS content of rice

[a]Values in the same column with different superscripts are significantly different ($p < 0.05$).

starches decreased with increasing amylose content,[6] and waxy starches showed greater enzyme digestion than normal types.[33] Higher RDS content in waxy rice starch was attributed to the lower proportion of long chains in amylopectin (DP ≥ 37), the molecular weight in the molecular structure, the onset temperature of gelatinization and crystallinity, and the higher proportion of short A (DP 6−12) chains.[9]

Relating Starch Structure to Functional and Digestion Properties. Starch physicochemical and functional parameters including AAC, starch crystallinity, pasting, and thermal properties were adapted from our previous report.[15] The fraction of short chains (DP 6−12), fa, was negatively correlated with the degree of crystallinity ($r = -0.67$, $p < 0.01$) (Table 4). AAC was previously shown to be negatively correlated with the degree of crystallinity ($r = -0.62$, $p < 0.001$).[15] However, a higher proportion of short chains (DP 10−13) resulted in a higher degree of crystallinity and the degree of starch crystallinity decreased with increasing amylose content in a previous report.[34] Waxy types BP011 and BP601 and normal types BP028 and BP578 exhibited similar amylopectin chain-length profiles regardless of amylose content (Table 2). The waxy types had a higher degree of crystallinity than the normal. Waxy type BP597 had lower proportion of fb_1 chains and a relatively higher proportion of fb_3 chains than the other two waxy types; these differences in amylopectin structure contributed to a lower degree of crystallinity in BP597. On the basis of the above, the starch crystallinity was not affected by amylose content or amylopectin fine structure alone but by the interplay of amylose and amylopectin fine structure.

FrI consisted of debranched amylose and represented the amylose content; thus, it is not surprising that AAC showed a significant positive correlation with FrI ($r = 0.97$, $p < 0.001$) (Table 4). Breakdown viscosity (BD) was positively correlated with the amout of short chains (fa) but negatively correlated with the amount of fb_1 chains. A previous study also indicated that rice starches with higher proportions of fb_1 chains seemingly had lower BD values, whereas those with higher proportions of fa chains had higher BD values.[35] These observations were generally consistent with our current results. No significant correlation between BD and FrI was observed; however, FrI was positively correlated with CPV ($r = 0.78$, $p < 0.001$) and SB ($r = 0.82$, $p < 0.001$) (Table 4). When the starch paste was cooled, aggregation of leached amylose resulted in a strong gel due to the formation of hydrogen bonds from free amylose, which explained the current observed results, and similar observations were reported previously in rice starches with different amylose contents.[6] Gelatinization parameters, including T_o, T_p, and ΔH, had negative correlations with the proportion of short fa (DP 6−12) chains; fa chains were also negatively correlated with RVA pasting temperature ($r = -0.84$, $p < 0.001$) (Table 4). The average chain length of amylopectin (CL_{ap}) was found to be positively correlated with the degree of crystallinity, pasting, and gelatinization temperatures.

Pearson correlation coefficients between rice starch digestion properties and starch structural/functional parameters are presented in Table 5. RDS was negatively correlated with FrI ($r = -0.56$, $p < 0.05$) and AAC ($r = -0.62$, $p < 0.05$), respectively. RDS was positively correlated with amylose content in four lentil starch samples with a narrow range of amylose content from 30.6 to 33.9%.[36] Almost no correlation was found between RDS and amylose content when four rice cultivars with an amylose content of 1.7−55% were investigated.[7] However, RDS was negatively correlated with the AAC when four commercial rice varieties with amylose contents of 4.2−27.2% were studied.[6] The contradictory relationships between AAC and RDS content are because the effects of amylopectin fine structure were not considered.

RDS was positively correlated with the proportion of short chains, FrIIa ($r = 0.56$, $p < 0.05$) (Table 5). The lower proportion of longer branch chains (DP ≥ 37) and higher proportion of short A chains were observed to contribute to higher RDS content.[9] Previously, RDS was shown to be positively correlated with the proportion of DP 6−12 saccharides and negatively correlated with the proportion of DP 13−24 saccharides.[6] However, no significant correlation between amylopectin chain-length distributions and RDS was

identified (Table 5). RVA setback was positively correlated with RDS when rice starch cultivars with similar amylose content were investigated.[5] This correlation was not observed in the current study, indicating that RVA breakdown as a screening tool for selection of rice cultivars with low RDS should be used with caution. In a previous report, SDS decreased as amylose content increased and the correlation between SDS and amylose content was high.[7] The content of combined SDS and RS in three waxy rice starches varied from 12.5% to 20.0%, indicating that amylopectin fine structure influenced the SDS/RS content. Normal starch types showed a significantly higher content of combined SDS and RS content than waxy starch types BP011 and BP601 (Table 3), suggesting that amylose increased the content of combined SDS and RS in rice starches. Hence, the concerted influence of amylose content and amylopectin fine structure contributed to the SDS/RS contents in rice starch.

Relating SSRG Markers to Starch Structure and Functional Properties. Previous studies have shown that *Wx* and *SSIIa* genes are responsible for the genetic control of AAC and gelatinization temperature, respectively.[37−40] In this study, these two genes were also shown to be associated with AAC and gelatinization (thermal) properties (data not shown). We found that *SSIIa* was responsible for the degree of crystallinity, the average chain length of amylopectin (CL_{ap}), and the amount of fa chains in amylopectin (Table 6). This is simply because SSIIa elongates the short A and B_1 chains with a degree of polymerization (DP) <10 to form long B_1 chains of amylopectin,[41] and the amount of fa chains (DP 6−12) and crystallinity were negatively correlated with gelatinization temperature (Table 4). The amount of fb_1 was found to be controlled by *SSIIIa* (Table 6). The *SSIIIa* mutant showed a decrease in DP 6−9 and DP 16−19 chains and an increase in DP 10−15 and DP 20−25 chains.[42] The pattern of the changes in chain length distributions could be explained as the amount of fb_1 chains (DP12−24) controlled by SSIIIa, which

specifically elongates B_2−B_4 long chains of amylopectin.[42] The amount of fb_2 chains was controlled by the ADP-Glucose pyrophosphorylase L1 (*AGPL1*) gene, a gene in the first step of starch biosynthesis. However, in the Kinship (K) model, *Wx* gene was also detected for the amount of fb_2 with a little higher P value ($P = 0.0508$) (Table 6). A previous report showed that superlong chains of amylopectin was controlled by *Wx* gene;[43] it is not known whether GBSS1 encoded by *Wx* works on the chains of DP 24−36 (fb_2) to form superlong chains in amylopectin.

Wx gene was also associated with the amount of fraction from the first peak area (FrI), which is amylose, and the FrIIa, which are short unit chains of amylopectin. This is supported by the correlation results among AAC, FrI, and FrIIa. Both the amount of FrIIa and FrIIb were also related to the *AGPL1* gene on chromosome 5, which was not reported before.

For the RDS, two SSRGs, *Wx* and the starch debranching enzyme gene *isoamylase II* (*ISA2*), were detected. Amylose content was negatively correlated with RDS; thus, it is possible that RDS was detected to be controlled by *Wx*. The *ISA2* gene is responsible for amylopectin biosynthesis,[44] which indicated that the amylopectin structure may play a role in the formation of RDS. However, the function of ISA2 in amylopectin biosynthesis is not well understood and only its expression pattern during grain filling was available.[44] Although *BEIIb* mutants generally had higher RS contents than their counterpart parents, the naturally occurring variation in RS among diverse rice germplasm was controlled by *Wx* gene (Table 6) but not by *BEIIb*. This could be explained by the relationships between AAC and RS (Table 5) and was also supported by a previous study on the genetic control of GI.[14]

CONCLUSION

This is the first study delving into the "genetics−structure−function" relationships of rice starches. The functional properties of rice starches, i.e. digestion properties, were influenced by amylose and amylopectin fine structure to different extents. Rice starch crystallinity was negatively

DOI: 10.1021/acs.jafc.5b02143
J. Agric. Food Chem. 2015, 63, 6241−6248

correlated with the proportion of fa chains in amylopectin. AAC was negatively correlated with RDS content but positively correlated with RS content in rice starch. *SSIIa* gene controls the degree of crystallinity and the amount of fa chains of amylopectin. *SSIIIa* gene controls the amount of fb1 chains. *Wx* gene controls the amount of FrI, FrIIa, RDS, and RS. *ISA2* gene also controls the RDS, which may suggest that RDS was also affected by the amylopectin structure, although no correlation between them was found. However, it should be noted that this is an initial test of these relationships, and further studies involving large sets of rice accessions will provide more in-depth insight. An understanding of the relationships among genetics, starch structure, and functionalities will assist plant breeders and food processors in the design of new rice varieties oriented to functional foods.

J. Agric. Food Chem. 2015, 63, 6241−6248

In food applications GlcN has been used to generate antimicrobial, antioxidant,[14] and taste-enhancing compounds;[15] to enrich beverages[16] or milk;[17] and to modify proteins to enhance their functionality in food systems. For instance, Hrynets et al.[18] took advantage of GlcN reactivity to create novel glycoproteins at moderate temperatures resulting in an enhanced solubility and emulsification capacity.

At the same time, studies have reported a link between GlcN supplementation and diabetes complications,[19,20] presumably due to GlcN-induced β-cell apoptosis and dysfunction.[21] Furthermore, Candiano et al.[22] indicated that GlcN possesses reactivity at physiological temperatures producing fluorescent pyrazine compounds derived from the cyclocondensation between two GlcN molecules, which were later reported to cause DNA strand breakage.[23]

Some of GlcN's effects, for instance, taste-enhancing and antimicrobial properties as well as protein modifications, are likely related to its high reactivity; however, to date no plausible explanations for this phenomenon have been provided. It is also surprising that only a few studies have focused on GlcN degradation at moderate temperatures (i.e., 37 °C)[24,25] and, to the best of our knowledge, no research has evaluated the formation of α-dicarbonyls (α-DCs) from this popular dietary supplement. It was expected that GlcN, a Heyns/Amadori-like compound, would rapidly form reactive intermediates such as α-DCs and several advanced and stable condensation products as compared to GlcNAc. Hence, the main objective of this study was to investigate the chemistry of GlcN degradation in vitro (nonenzymatic degradation) and to compare it to GlcNAc and a reaction mixture containing Glc + NH_3 (Glc-NH_3). To meet this objective, GlcNAc, Glc-NH_3, and GlcN were incubated at 37 °C, and α-DCs were analyzed over time using liquid chromatography and Orbitrap mass spectrometry. Condensation products were also evaluated over time using both spectroscopic and mass spectrometric techniques.

MATERIALS AND METHODS

Chemicals. *N*-Acetyl-D-glucosamine (≥99% purity), D-glucose (≥99.5% purity), D-glucosamine hydrochloride (≥99% purity), potassium phosphate monobasic and dibasic, sodium azide, HPLC grade solvents (acetonitrile, methanol, formic acid), glucosone (2-keto-D-glucose; ≥98.0% purity; M_w 178.14 Da), glyoxal (ethanedial; 40% in H_2O; M_w 58.04 Da), methylglyoxal (2-oxopropanal; 40% in H_2O; M_w 72.06 Da), diacetyl (butane-2,3-dione; ≥95.0% purity; M_w 86.09 Da), and 1,2-diaminobenzene were purchased from Sigma-Aldrich (St. Louis, MO, USA). 3-Deoxyglucosone (3-deoxy-D-*erythro*-hexosulose; ≥95% purity; M_w 162.14 Da) was obtained from Cayman Chemical (Ann Arbor, MI, USA). Ammonium hydroxide was purchased from Fisher Scientific. SPE tC-18 Sep-Pak Vac 6 cc columns were obtained from Waters (Milford, MA, USA). Filtration membranes (0.22 μm) were from Millipore (Billerica, MA, USA). Standard ion calibration solution (Pierce LTQ) for electrospray ionization in positive mode was purchased from Thermo Scientific (Rockford, IL, USA). All buffers and reaction mixtures were prepared with Milli-Q purified distilled water (Millipore, Bedford, MA, USA).

Experimental Design. In this study the nonenzymatic degradation of GlcN, GlcNAc, and Glc-NH_3 was evaluated over time at 0, 0.5, 1, 2, 3, 6, and 12 days in phosphate buffer at 37 °C using UV−vis and fluorescence spectroscopic analyses as well as mass spectrometric techniques. In the first part of the study, UV−vis and fluorescence profiles were assessed over time to understand the major changes occurring during the degradation reaction of the monosaccharides. In this regard, a total of 42 tubes (2 tubes × monosaccharide × incubation time) were randomly placed within the incubator, and the reaction was monitored over time. Three independent trials were conducted, resulting in six replicates per treatment.

Following this exploratory test, a dedicated study on α-DCs identification and production was conducted over time using the same design as reported before. Liquid chromatographic separations and mass spectrometry techniques were used to identify and quantify the major degradation products. Finally, the last part of this study focused on the production of fluorescent and stable condensation products obtained by the reaction between the main α-DCs produced during GlcN degradation and GlcN. In this regard, selected α-DCs (glucosone (G), 3-deoxyglucosone (3-DG), glyoxal (GO), and methylglyoxal (MGO)) were incubated with GlcN at equimolar concentrations for 0, 4, 8, 12, 24, and 48 h at 37 °C, and their UV−vis and fluorescence profiles were recorded. Three tubes per selected α-DC were incubated over time, resulting in six replicates.

Incubation of GlcNAc, Glc-NH_3, and GlcN Aliquots. Solutions (15 mg/mL) of GlcNAc, Glc-NH_3 (equimolar mixture), and GlcN were prepared in 50 mM phosphate buffer. The pH of the final solutions, 7.4, was adjusted (Denver Instrument UltraBasic pH Meter) if necessary. NaN_3 was added to a final concentration of 0.02% to prevent microbial growth. The reaction mixtures were transferred into plastic screw-cap tubes, randomly arranged within an incubator (New Brunswick Scientific, Edison, NJ, USA), and incubated at 37 °C. Samples aliquots were collected at 0.5, 1, 2, 3, 6, and 12 days. The controls were reaction solutions at 0 h. The pH value of the solution over time was checked, but not adjusted during the reaction to enable a natural time course generation of reaction's reactive intermediates. Decrease in pH within 0.3−0.45/0.5 unit was found for GlcN (6−12 reaction days, respectively) and within 0.1 unit for Glc-NH_3 solutions (12 reaction days).

Preparation of α-Dicarbonyls and Glucosamine Reaction Mixtures. Equimolar (2.5 mM) concentrations of GlcN and commercially available standards of G, 3-DG, GO, and MGO were solubilized in 50 mM phosphate buffer (pH 7.4), containing 0.02% NaN_3. Controls included fresh and incubated solutions of GlcN and each α-DC separately. All reaction mixtures were incubated at 37 °C for 4, 8, 12, 24, and 48 h.

Spectrophotometric Measurements. UV−vis absorbance and fluorescence spectra of 15 mg/mL solutions of GlcNAc, Glc-NH_3, and GlcN were recorded using the Spectramax M5 multimode microplate reader (Molecular Devices, Sunnyvale, CA, USA). For both analyses readings were taken with 1 cm quartz cuvettes and samples diluted (1:20, v/v) with 50 mM phosphate buffer (pH 7.4). The absorbance was recorded in the range of 200−500 nm. For fluorescence, the excitation wavelength was set at 347, and an emission was recorded from 364 to 600 nm. A blank (buffer) was subtracted from all spectra automatically. Absorbance (200−600 nm) and fluorescence (λ_{exc} = 347, λ_{em} = 364−600) of α-DC standards separately or in the mixture with GlcN were measured in the same way at the concentration of 2.5 mM. For all GlcN−α-DC mixtures, controls of incubated GlcN and respective incubated α-DCs for each time period were subtracted.

Free α-Dicarbonyl Compounds: Extraction, Identification, and Quantitation. *Solid Phase Extraction (SPE) and Derivatization Procedure.* The extraction procedure was based on a method reported by Papetti et al.[26] with slight modification. Briefly, collected over time aliquots of GlcNAc, Glc-NH_3, and GlcN were spiked with 0.006 g of 1,2-diaminobenzene (*o*-phenylenediamine (OPD)), the pH was adjusted to 3.00 ± 0.02 with 4 M HCl, and the mixture was derivatized at 37 °C for 1 h. The derivatized solution was passed through a preconditioned SPE cartridge (tC-18 Sep-Pak, Waters, Milford, MA, USA). The cartridge was washed with 2 mL of water, and quinoxalines were eluted with 4 mL of a MeOH/H_2O mixture (90:10, v/v) at a flow rate close to 2 mL/min. The first 1 mL was discarded, whereas the next 2 mL was used for analysis. The controls were treated exactly as collected sugar aliquots except no derivatizing agent was added. To ensure complete derivatization, a preliminary test was performed, where derivatization times of 0.5, 1, 2, 4, and 8 h were tested. The maximum peak area was reached after a derivatization for 1 h without further increase during longer derivatization times.

UHPLC-UV Analysis of Quinoxalines Derivatives Formed from α-Dicarbonyl Compounds and o-Phenylenediamine. α-DC analysis was conducted using an ultrahigh-performance liquid chromatography

DOI: 10.1021/acs.jafc.5b02664
J. Agric. Food Chem. 2015, 63, 6249−6261

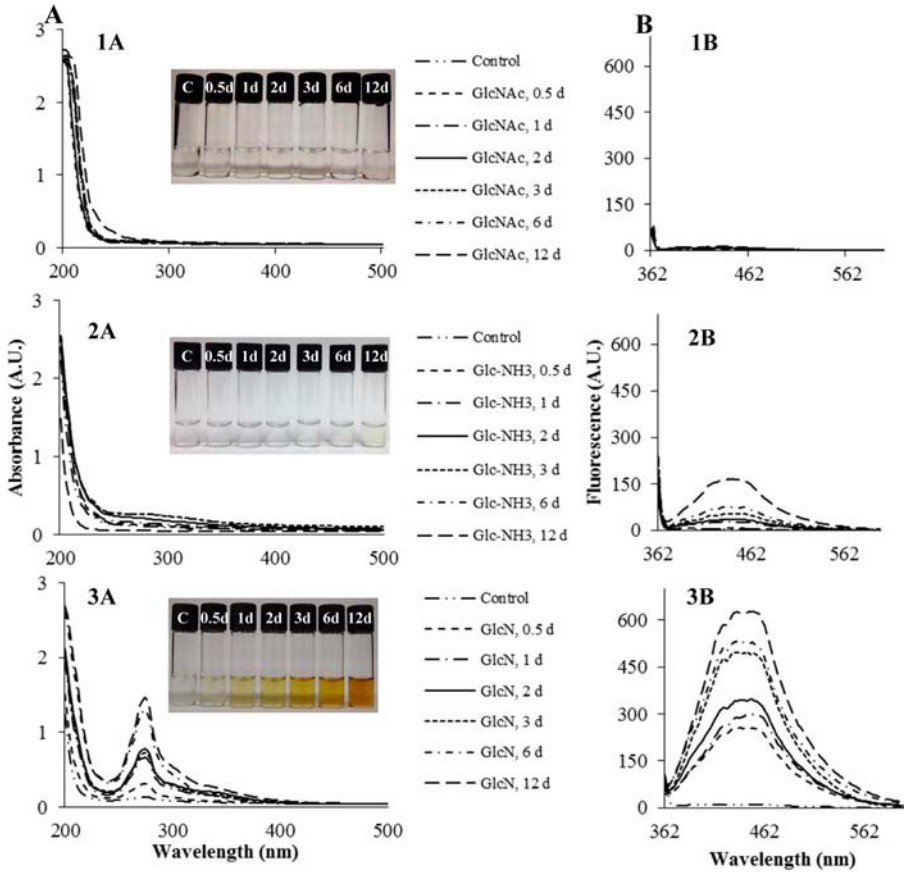

Figure 1. UV−vis absorbance (A) and fluorescence spectra (B) profiles of GlcNAc (1A, 1B), Glc-NH_3 (2A, 2B), and GlcN (3A, 3B) as a function of heating time from 0 to 12 days. The values are expressed in arbitrary units (A.U.). Inset images (left) show photographs of the corresponding incubated sugar solutions. The images were taken for nondiluted experimental solution incubated at 15 mg/mL.

apparatus (Shimadzu, Columbia, MD, USA) consisting of two pumps LC-30AD, an SPD-M20A photodiode array detector (PDA), a DGU-20A5 degasser, an SIL-30AC autosampler (operated at 4 °C), and a CTO-20 AC column oven. The UHPLC system was controlled by a personal computer equipped with LabSolutions software operating in Windows XP. The separation was achieved following the method described by Papetti et al.[26] using an Ascentis Express ES-C18 column (150 × 4.6 mm, 2.7 μm particles; Sigma-Aldrich, St. Louis, MO, USA) with a UHPLC precolumn filter (UltraShield Analytical Scientific Instruments, Richmond, CA, USA) operating at 25.0 ± 0.5 °C and a flow rate of 0.3 mL/min. The binary mobile phase consisted of (A) 0.1% formic acid in water and (B) methanol. The 120 min gradient is described as follows: 0−5 min, 90−85% A; 5−13 min, 85−80% A; 13−40 min, 80% A; 40−65 min, 80−70% A; 65−90 min, 70−50% A; 90−100 min, 50−0% A; 100−105 min, 0% A; and 105−110 min, 0−90% A; the column was then re-equilibrated with the initial mobile phase for 10 min. The injection volume was 5 μL. The PDA detector was set at 314 and 335 nm to record the peaks, and UV spectra were recorded from 215 to 420 nm. Before injection, sample solutions were filtered with a PVDF syringe filter (13 mm, 0.22 μm; Millipore Millex, Billerica, MA, USA).

Identification and Quantitation of Quinoxaline Derivatives. The identification of major α-DCs was based on comparison of their retention times of the reference compounds (quinoxalines derivatives of G, 3-DG, GO, MGO, and DA) and spectral characteristics. For unequivocal identification of the major α-DCs, 10 UHPLC peaks were manually collected and subjected to mass spectrometry analyses. The accurate mass and MS/MS fragmentation patterns were compared to authentic standards and to the reference data. Mass spectrometry analyses were performed in duplicates.

For quantitation external calibration was used. Each quinoxaline derivative was diluted to the final concentrations ranging from 60 to 2000 μM (G), from 30 to 2000 μM (3-DG), from 4.5 to 50 μM (GO), from 1.0 to 10 μM (MGO), and from 1.25 to 7.5 μM (DA). Calibration curves were prepared for each trial, and each concentration was analyzed in triplicate. The peak area was plotted against concentration, and the regression equations were calculated. The correlation coefficients for all calibration curves were $R^2 \geq 0.999$. The average (from three trials) limit of detection (LOD) was calculated as 2.15 ± 0.07 μM (G), 0.27 ± 0.00 μM (3-DG), 0.13 ± 0.00 μM (GO), 0.09 ± 0.00 μM (MGO), and 0.18 ± 0.00 μM (DA). The average limit of quantification (LOQ) was determined as 6.52 ± 0.21 μM (G), 0.81 ± 0.01 μM (3-DG), 0.39 ± 0.01 μM (GO), 0.27 ± 0.01 μM (MGO), and 0.55 ± 0.02 μM (DA) by assuming a signal-to-noise ratio (S/N) of 3:1 for LOD and 10:1 for LOQ. The following ranges of sample concentrations were extrapolated from the calibration curves: 169−861 μM (G), 67−1289 μM (3-DG), 7.9−32 μM (GO), 2.5−6.8 μM (MGO) and 1.9−3.7 μM (DA). These values were then expressed as milligrams per kilogram GlcN.

Direct Infusion Orbitrap Mass Spectrometry Analyses (DIMS). Collected α-DC fractions from UHPLC and GlcN aliquots (diluted in 50:50 (methanol/water, v/v)) were subjected to DIMS. All Orbitrap measurements were carried out by using the Ion Max electron spray ionization (ESI) source (Thermo Fisher Scientific) mounted on an LTQ Orbitrap XL (Thermo Scientific, San Jose, CA, USA). The Orbitrap mass analyzer was calibrated with standard ion calibration solutions (Pierce LTQ, Thermo Scientific). The following parameters were applied: sheath gas flow, 15 arbitrary units; auxiliary gas flow, 5 arbitrary units; and capillary temperature, 275 °C. Samples (3 μL) were injected manually by performing direct infusion using a 100 μL syringe (Hamilton, Reno, NV, USA) and the on-board syringe pump. DIMS analyses were performed at a mass resolution of 60000 at m/z 400, and spectra were acquired over the range of m/z 50−2000. The automatic gain control (AGC) target was set to 1e6 and the

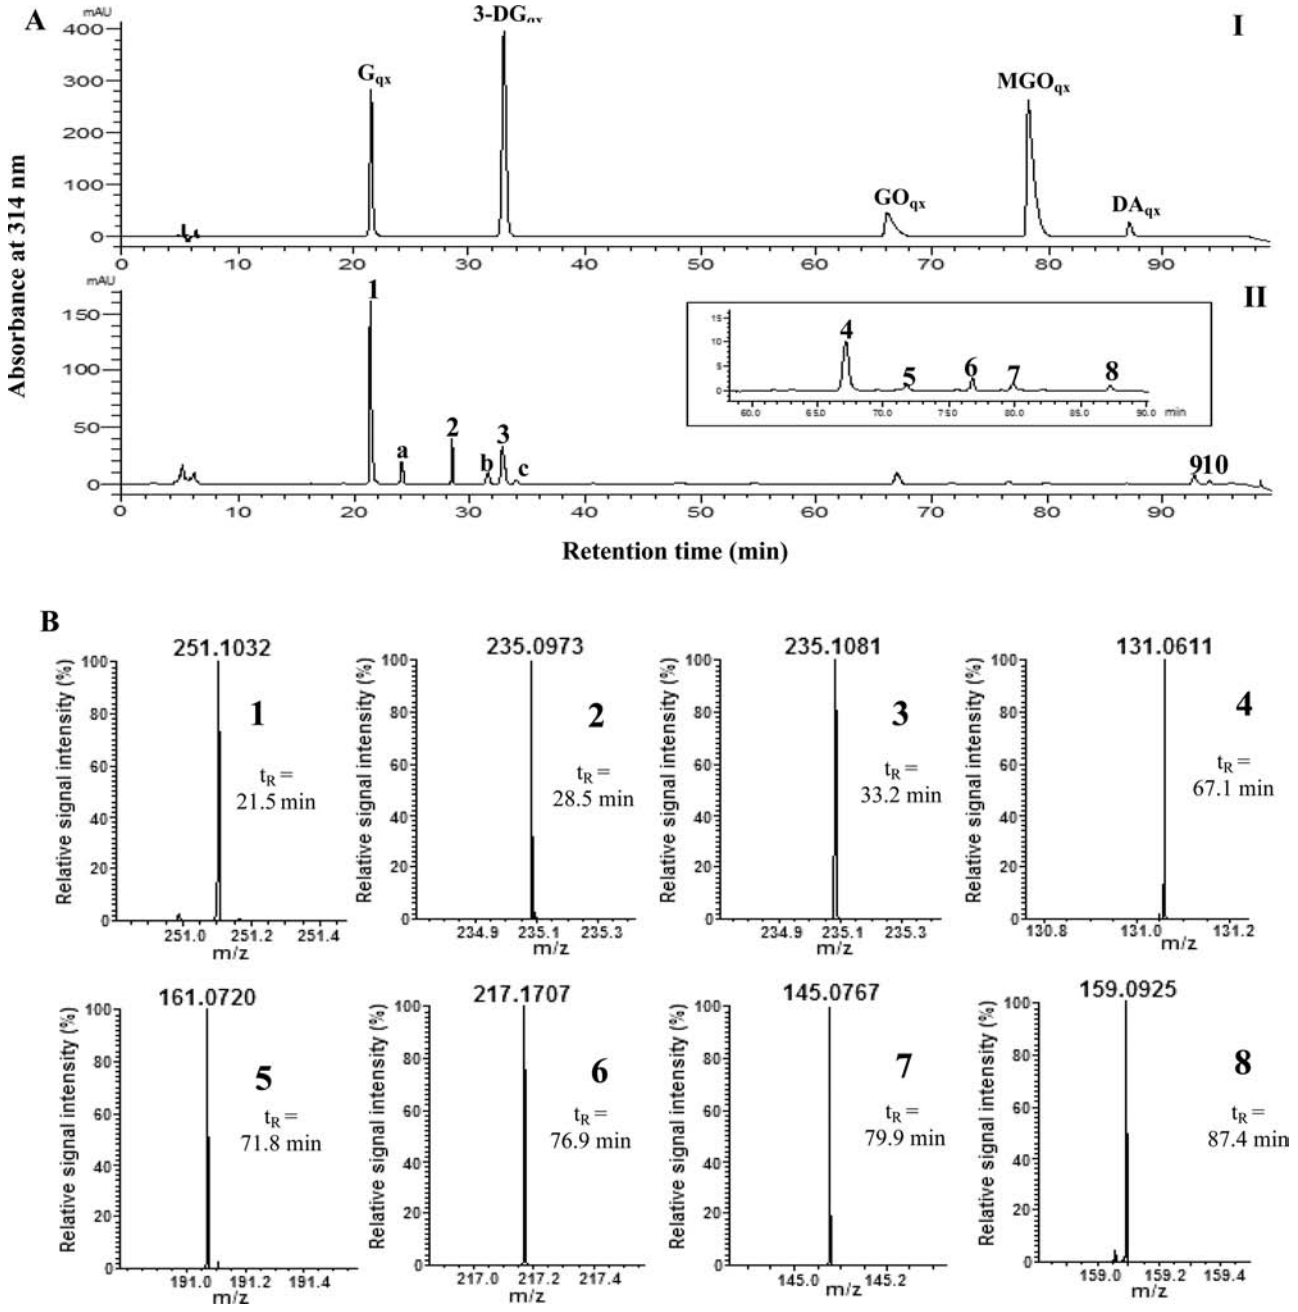

Figure 2. UHPLC and MS analyses of quinoxaline derivatives of α-dicarbonyl compounds produced from GlcN incubation over time. (A) (I) Chromatogram of a reference quinoxaline mixture of glucosone (G), 3-deoxyglucosone (3-DG), glyoxal (GO), methylglyoxal (MGO), and diacetyl (DA). (II) Representative chromatogram of GlcN incubated for 1 day, derivatized with OPD, and acquired by UHPLC with UV detection at 314 nm. Numbers indicate the peaks of the quinoxalines of (1) G, (2) unidentified α-DC, (3) 3-DG, (4) GO, (5) HPA, (6) 3,4-DGE, (7) MGO, (8) DA, (9) 4-GlcN-3-DG, and (10) 4-G-3-DG, and a, b, and c peaks correspond to non-OPD-derived GlcN condensation products. (Inset) Zoomed-in view of the peaks eluted at 60−90 min. (B) Precursor ions and retention times of the peaks corresponding to the same 10 numbers as indicated above for panel AII.

maximum injection time to 250 ms. For MS/MS experiments, ions of interest were isolated with an isolation width of 1−2 Da, and collision-induced dissociation was conducted at various voltages, which were optimized for each sample. An activation time of 30 ms was used with a tube lens voltage of 110 V and a capillary temperature of 275 °C. Data acquisition and processing were performed using Xcalibur software (Thermo Scientific).

Statistical Analysis. Spectroscopic profiles obtained from UV−vis and fluorescence analyses from the three different independent trials were averaged and reported as graphs. α-DC production over time was subjected to an analysis of variance (ANOVA) using the PROC MIXED procedure of SAS (v. 9.3, SAS Institute Inc., Cary, NC, USA). The model tested incubation time as a fixed variable and used the trial replication as a random variable. Tukey's honestly significant difference ($p < 0.05$) multiple-range test was conducted to determine differences between means.

RESULTS AND DISCUSSION

UV−Vis and Fluorescence Profiles of Nonenzymatic Modification of GlcNAc, Glc-NH_3, and GlcN over Time. UV−vis and fluorescent profiles can be a useful and simple tool to understand the major changes occurring during a reaction.

absorbance over time were obtained for GlcNAc, except a slight increase at λ = 220−235 nm at 12 days. A minor absorbance increase was observed in the Glc-NH_3 mixture. On the contrary, steady increases of maxima of 274 and 320−360 nm were obtained for GlcN, suggesting a formation of products that absorb in the UV region. The increase in absorbance at 320 nm was lower than at 274 nm; however, the formation of a light yellow color was apparent after 0.5 day of incubation. The increase in UV absorbance at 274 and 320 nm was also reported by Zhang et al.,[27] who incubated 0.02 M GlcN at 37 °C for 50 h in phosphate buffer (pH 7.4). Candiano et al.[22] and Horowitz[25] indicated that the increase in UV absorption at around 274 nm is due to the formation of pyrazine compounds, which derive from the cyclocondensation between GlcN molecules, which have been confirmed by MS analysis (see Condensation Products from Nonenzymatic Modification of GlcN). At the same time the increase at 320 nm was attributed to the formation of soluble premelanoidins,[28] which was also confirmed by the production of a light yellow-brown color over incubation time (Figure 1(3A, inset)). In addition, this hyperchromicity at 320−340 nm was apparent at longer incubation times. No color production was observed for GlcNAc (Figure 1(1A inset)); the Glc-NH_3 mixture changed from slightly yellow to yellow over 6−12 days (Figure 1(2A inset)), whereas the time course of color development by GlcN was changed from yellowish to brown. The fluorescence profile showed a progressive increase in the emission (λ_{exc} 347 nm/λ_{em} 364−600 nm) intensity over time for GlcN. A broad peak was observed with a maximum intensity ranging from 420 to 450 nm. Glc-NH_3 also showed an increased fluorescence, however, with significantly lower intensity and reaction velocity; at 12 days fluorescence emission was around 3 times lower as compared to GlcN. On the other hand, the GlcNAc fluorescence profile did not change significantly over time. The wavelengths observed were typically used to assess the progress of the Maillard reaction and, more specifically, the development of advanced glycation products (AGEs).[29] Zhang et al.[24] reported the increase in fluorescence intensity (λ_{exc} 340 nm/λ_{em} 420 nm) during GlcN incubation at 37 °C and suggested an increase due to GlcN cyclocondensation and rearrangements. Candiano et al.[22] came to the same conclusion and further proved that the increase in fluorescence emission at 430 nm (λ_{exc} = 362 nm) in a lysine−GlcN reaction mixture was due to GlcN cyclocondensation. The same authors indicated that GlcN cyclocondensation products possessed optical and fluorescent properties of browning compounds, which in turn could explain an increase in color intensity over time (Figure 1(3A inset)). These preliminary results suggest that with prolonged heating time GlcN cyclocondensation and a variety of rearrangements occur and, thus, the formation of higher molecular weight colored compounds.

Identification and Quantitation of the Major α-Dicarbonyls Produced from GlcN Degradation by UHPLC and Mass Spectrometry Analyses. In the previous section, UV and fluorescence analyses were discussed to evaluate the formation of the final stable products of GlcN degradation (i.e., GlcN−GlcN autocondensation products). However, because GlcN is a Heyns-like compound, we hypothesized the production of α-DCs, which in turn have the potential to generate a variety of condensation products. α-DC are highly reactive compounds; thus, they were derivatized (condensation with OPD) to form stable quinoxalines, followed by UHPLC and MS analyses. Separation of quinoxalines achieved with chromatography[26] allowed for the identification of analytes. There were no α-DCs identified in GlcNAc samples up to 12 days of incubation, whereas lower production was observed in Glc-NH_3 samples at 12 days of reaction as compared to GlcN (see Figure S1 in the Supporting Information). Because the production of α-DCs at 37 °C from Glc-NH_3 was lower as compared to GlcN, the main focus

Table 1. Concentrations of Five Different α-Dicarbonyl Compounds Found in GlcN Incubated over Time[a]

	free α-dicarbonyl compounds (mg/kg of GlcN)							
α-dicarbonyl	0 days	0.5 day	1 day	2 days	3 days	6 days	12 days	p value[b]
glucosone	709 ± 68e	2634 ± 87f	3245 ± 90a	2710 ± 134b	2443 ± 85bc	2132 ± 89c	1131 ± 68d	**
3-deoxyglucosone	272 ± 19f	451 ± 32e	571 ± 27de	583 ± 33d	707 ± 63c	1905 ± 42b	4535 ± 82a	**
glyoxal	11.2 ± 1.2e	26.6 ± 2.1bc	34.9 ± 3.4a	28.4 ± 2.1b	24.9 ± 1.6c	17.7 ± 0.9d	12.6 ± 1.1e	**
methylglyoxal	nd[c]	4.5 ± 1.3e	5.5 ± 1.1de	6.4 ± 1.0cd	7.3 ± 0.8c	8.7 ± 0.9b	10.4 ± 2.3a	**
diacetyl	nd	nd	6.1 ± 1.1b	6.9 ± 0.9a	3.7 ± 1.0c	nd	nd	**

[a]All values are expressed as milligrams of α-dicarbonyl compound per kilogram of GlcN. The mean ± standard deviation of three independent experiments ($n = 6$) is shown. Values in the same row with different letters differ significantly ($p < 0.05$). [b]** indicates $p < 0.0001$. [c]nd, not detectable.

was to identify and quantify α-DCs derived from GlcN over time. Figure 2A illustrates the representative UHPLC chromatogram of standard α-DC compounds and α-DCs produced from GlcN incubated for 1 day. For confirmation of the peaks for which commercial standards were available and the identification of unknowns, the major peaks were collected and further subjected to MS analyses. Eight peaks in the UV chromatograms (Figure 2A(II)) were identified by their pseudomolecular peaks ($[M + H]^+$, as detected by MS (Figure 2B). Individual peaks 1−8 were identified as being (1) glucosone, m/z 251.1032; (2) unidentified α-dicarbonyl, m/z 235.0973; (3) 3-deoxyglucosone, m/z 235.1081; (4) glyoxal, m/z 131.0611; (5) 3-hydroxy-2-oxopropanal (hydroxypyruvaldehyde, HPA); m/z 161.0720; (6) 3,4-dideoxyglucosone-3-ene, m/z 217.1707; (7) methylglyoxal, m/z 145.0767; and (8) diacetyl, m/z 159.0925. On the basis of molecular weight and reference data,[26] peaks 9 and 10 were tentatively assigned to the quinoxaline derivatives of 2-amino-2-deoxy-4-glycosyl-5,6-dihydroxy-2-oxohexanal (4-GlcN-3-DG) and 4-glycosyl-5,6-dihydroxy-2-oxohexanal (4-Glc-3-DG), respectively (see precursor ions in Figure S2 in the Supporting Information). The peaks denoted a, b, and c showed m/z in the range of 317−355 (see Figure S3 in the Supporting Information). The nature of these peaks is not clear; however, it is suspected that they derived from a variety of condensation products of GlcN itself or GlcN with α-DCs (i.e., fructosazines). Hence, they are likely non-OPD condensed products, which are highly hydrophilic fructosazines missing the benzene portion of OPD and, despite their high molecular weight, elute at early retention times in the hydrophilic part of the gradient. The product ions and structures of quinoxaline derivatives of the seven identified peaks are shown in Figure 3. For G_{qx} the molecular ion and subsequent losses of three water molecules were observed. Mittelmaier et al.[30] found very similar fragmentation pattern with the loss of three water molecules, except the fragment ion at m/z 173.0 was dominant. Product ion spectra of $3\text{-}DG_{qx}$ and its dehydration product, $3,4\text{-}DGE_{qx}$, showed similar fragment ions, apart from the latter missing fragments at m/z 235.1081 and 171.0918. The MS/MS of the unidentified α-dicarbonyl (peak 2) showed two similar fragment ions (m/z 145.0760/1 and 157.0761) with $3\text{-}DG_{qx}$ and could be an indication of the presence of 1-deoxyglucosone (1-DG), 3-deoxygalactosone, or 4-deoxyglucosone. However, the presence of DA would support the presence of 1-DG, being a precursor of DA[41] (Figure 4A). There was a minimal tendency of fragmentation for GO_{qx} and MGO_{qx}, with three and five fragments, respectively, along with the highest intensity for precursor ions and fragment at m/z 77.0164 (77.1615 in MGO) typical for quinoxaline skeleton fragmentation.[31] For DAqx four major MS/MS fragment ions were found. Under the described MS/MS conditions m/z 161.0709, 143.0602, 133.0759, 131.2694, and 119.0602 were identified as the main fragments of the parent molecule ion (m/z 161.0720) of HPA_{qx}. The fragment ions from eight identified α-DCs were in accordance with previously reported quinoxalines in various foods, such as high-fructose corn syrup;[32] coffee, barley, and soy sauce;[26] and honey.[33] The MS/MS fragmentation and proposed structures of 4-GlcN-3-DG and 4-G-3-DG are reported in the Figure S3 in the Supporting Information. After identification of the α-DC presence, five of them were quantified, and the concentrations expressed in milligrams per kilogram of GlcN are given in Table 1. It was found that G, 3-DG, and GO were already present in control samples, suggesting the partial degradation of GlcN while stored in powder. Even though a freshly ordered GlcN was used in the analyses, rapid development of α-DCs could be a possible explanation for their presence in the nonheated sample. The elevated temperatures (90 °C for hydrolysis, 45 °C for evaporation, etc.) used during GlcN's extraction could induce its degradation and thus dicarbonyl compounds' development. At the beginning of the incubation G was the most abundant α-DC compound followed by 3-DG. However, after 1 day of incubation, the concentration of G decreased significantly ($p < 0.05$) from 3245 to 1131 mg/kg GlcN, along with a significant increase in the amount 3-DG. At 0.5 and 1 day of incubation, G concentration was around 6 times higher than that of 3-DG. After heating for 12 days, the concentration of 3-DG was 4 times higher than that of G. G is a product of oxidative degradation of Amadori or Heyns compounds (see proposed pathway in Figure 4) or autoxidation of sugar (i.e., glucose), whereas 3-DG is formed nonoxidatively through the enolization pathway.[34] These results suggest the prevalence of an oxidative pathway during the first days of incubation, whereas over time the enolization process dominates. In addition, a slight pH drop at 6 and 12 days could aid the 1,2-enolization to produce 3-DG.[35] The concentrations of the other α-DCs, GO, MGO, and DA, were significantly lower in comparison to G and 3-DG. The opposite relationship was observed between GO and MGO formation over time. Whereas the concentration of GO significantly ($p < 0.05$) decreased from 34.9 mg/kg at 1 day to 12.6 mg/kg GlcN after 12 days, the amount of MGO significantly ($p < 0.05$) increased from 4.5 to 10.4 mg/kg GlcN. DA reached the highest concentration at 2 days of incubation (6.9 mg/kg GlcN), dropped almost twice by 3 days, and was not detected with prolonged incubation. Obtained results confirm our hypothesis that GlcN is an unstable amino sugar that degrades more rapidly in phosphate buffer at 37 °C, whereas GlcNAc is stable in the condition used in this study.

Proposed Pathways of α-Dicarbonyl Formation from the Degradation of GlcN. Figure 4 reports the possible pathways

DOI: 10.1021/acs.jafc.5b02664
J. Agric. Food Chem. 2015, 63, 6249−6261

involved in the production of α-DCs identified in the present study. This scheme can be divided into "oxidation" (A1), "enolization" (A2, A5), "enolization/oxidation" (A3), and "interconversion" pathways. Glucosone, for instance, is most likely produced from an oxidative pathway (A1) with a mechanism similar to the one proposed by Hofmann et al.[36] and later verified by Gobert and Glomb.[37] Specifically, the imine or eminol form of GlcN would be directly oxidized to form monoalkylimines, which upon deamination will produce glucosone (Figure 4A1). Subsequently, through a retro-aldol cleavage between C-3 and C-4, G is proposed to form HPA, whereas the C-2/C-3 bond retroaldolization produces glyoxal.[36,38]

3-DG is proposed to be formed through the classical 1,2-enolization typical for the Heyns compound;[39] it has been reported that this compound can go only through the 1,2-enolization, as opposed to the Amadori compound, which can also undergo 2,3-enolization, where 2,3-enediol is deaminated to yield 1-DG.[40] However, Yaylayan and Huyghues-Despointes[39] reported that Heyns products can isomerize to Amadori compounds through an interconversion reaction, similar to Lobry de Bruyn-Alberda van Ekenstein transformation of fructose into glucose. In Figure 5A4 is a proposed reaction scheme in which GlcN interconverts into Amadori compounds via two possible condensation reactions: the first between two GlcN molecules and the second between GlcN and NH_3 formed during deamination of GlcN (see Figure S4 in the Supporting Information). The proposed interconversion pathway would also explain the presence of DA through 1-DG degradation[41] (Figure 4A5). However, other new chemical pathways might be involved in DA production. An increase in 3-DG was accompanied by increasing concentrations of MGO over time (Table 1). Several studies[42,43] suggested 3-DG as the precursor for MGO formation, which is based on the nonoxidative fragmentation of the retroaldolization pathway. In the model experiment of Thornalley et al.[44] 0.09 μM MGO was formed from 50 μM 3-DG, which accounts for 0.18%. In the current study, at 0.5 day, MGO accounted for 1% of 3-DG, whereas with incubation up to 12 days the percentage decreased to 0.23. GO is also proposed to be formed through oxidative (Figure 4A1) and enolization/oxidation pathways (Figure 4A3). Indeed, several pathways are proposed in the case of GO formation. The first, postulated by Hoffman et al.,[36] involves GO production from G as reported in Figure 4A1. The other potential mechanism is via enolization/oxidation pathways, by which GO might be produced from 3-DG (Figure 4A3) via vinylogous retroaldolization forming glycoaldehyde, which subsequently oxidizes to form GO.[45] The mechanism reported in Figure 4A1 is unique, where GO is proposed to originate from direct C-2/C-3 retroaldolization cleavage of GlcN in its aldosamine form, forming erythrose and a two-carbon enaminol compound that will subsequently undergo oxidation and deamination, forming GO. This would be an oxidative pathway similar to the one proposed by Hayashi and Namiki,[46] with the only difference that in this specific case the retro-aldol type cleavage would directly occur on the aldosamine form of GlcN and not on its Schiff base (imine) form. In the Namiki type of rearrangements, GO is produced before and independently of the G precursor. Hofmann and Heuberger[47] reported GO production in a glucose/L-alanine

mixture (pH 7.0, phosphate buffer, 95 °C) at the early stages of the Maillard reaction, prior to deoxyosone formation. A steady decrease in the amount of G was associated with a decrease in GO concentrations (Table 1); therefore, it is plausible to propose both pathways described above as major routes for GO formation in the current study. HPA can also be produced in a similar manner as previously described for GO, with the only difference being that retroaldol degradation is proposed to occur at C-3/C-4 of the Schiff base form of GlcN (Figure 4A1).

Condensation Products from Nonenzymatic Modification of GlcN. As presented in Figure 1, incubation of GlcN results in an increased absorbance and fluorescence, suggesting products are generated over time. To further investigate, aliquots of GlcN incubated for 0.5 (Figure 5A) and 3 days (Figure 5B) were directly injected into a MS to obtain a compound profile. As shown in Figure 5A,B, several molecular ion species were observed. GlcN showed peaks at m/z 180.0860 corresponding to its protonated molecular ion $[M + H]^+$ and at m/z 162.0755 and 144.0649 corresponding to mono- and didehydrated GlcN, respectively. The m/z 218.0418 is likely due to GlcN's potassium adduct $[M + K]^+$, whereas m/z 359.0836 corresponds to $[2M + H]^+$, possibly due to *N*-glycoside formation between two GlcN molecules. m/z 361.1008 can also be due to an *N*-glycoside formation, but from a reduced GlcN molecule (i.e., 2-amino-2-deoxy-D-glucitol) and GlcN. Remarkably, several other species with pseudomolecular weights higher than m/z 300 were present. These species are the result of two types of reactions: cyclocondensation (Figure 6), which results

in pyrazine ring formation, and acyclic condensation (Figure 7), during which no pyrazine rings are formed. One of the products of GlcN cyclocondensation, namely, dihydrofructosazine [2,5-bis(*arabino*-tetrahydroxybutyl)dihydropyrazine)], was identified at m/z 323.1451 (Figure 5A). This compound was originally identified and isolated by Candiano et al.[22] during the incubation of lysine in the presence of GlcN at 37 °C. The products at m/z 321.1286 and 305.1336 believed to be the products of dihydrofructosazine rearrangement produced fructosazine and deoxyfructosazine, respectively.[23] Similar products of GlcN incubation at m/z 321 and 323 were reported previously by Kashige et al.[23] while studying the possible involvement of GlcN-derived dihydrofructosazine in breaking DNA. It is also apparent that many other cyclocondensation products may be produced as a consequence of the reaction between GlcN and α-DCs via the mechanism proposed by Klinger.[48] The proposed reaction mechanisms between the most abundant α-DCs found in this study and GlcN are reported in Figure 6. The term "symmetric cyclocondensation" indicates a reaction scheme that involves two identical GlcN (Figure 6A1) or α-DC molecules (Figure 6A2), and "asymmetric cyclocondensation" refers to a reaction

DOI: 10.1021/acs.jafc.5b02664
J. Agric. Food Chem. 2015, 63, 6249−6261

that occurs between a specific α-dicarbonyl and GlcN (Figure 6A3,A4). Theoretically, the formation of all masses reported in Figure 6 is possible. The mass spectra of underivatized GlcN (Figure 5) at 0.5 and 3 days show the presence of the peaks which correspond to both "symmetric" (Figure 6A1,A2) and "asymmetric" (Figure 6A3,A4) cyclocondensation products, and in some cases the molecular weights of these products coincide (i.e., protonated m/z 305.1348, 321.1298, 323.1454). These data are also corroborated by Figure 8, which represents the UV−vis (Figure 8A) and fluorescence emission (Figure 8B) profiles of an equimolar mixture of G, 3-DG, GO, and MGO with GlcN over a period of incubation from 0 to 48 h. In all cases absorbance and fluorescence emission intensities increased over time owing to the formation of cyclocondensation reaction products. Hence, GlcN possesses a trapping effect to the nascent α-DCs produced from its degradation. Fluorophore formation was also reported[24] to represent the formation of heterocyclic compounds (i.e., pyrazines). Among four α-DCs tested, 3-DG appears to be the most reactive toward GlcN, judging from an extensive accumulation of fluorescence (240 units). 3-Deoxyosones predominantly form pyrazines and imidazoles with ammonia, which in turn are responsible for the sugar coloring.[40] Therefore, the accumulation of 3-DG (Table 1) and its reaction products with GlcN (Figure 8) over time could be partially responsible for GlcN browning with extended incubation periods (Figure 1(3A inset)).

An example of acyclic condensation is the peak at m/z of 343.0889 identified at 3 days of incubation. It is proposed that this molecular ion corresponds to a reduced Schiff base from a condensation between two molecules of GlcN. The possible mechanisms of formation are illustrated in Figure 7, where the reduction of the GlcN−GlcN Schiff base would be promoted from the dehydrogenation of the dihydrofructosazines to fructosazines. Supporting this phenomenon is the observed decrease in intensity of m/z 323.1451 during incubation from 0.5 to 3 days with a concomitant increase intensity of m/z at 321.1286 (Figure 5). Shimamura et al.[49] also reported the reducing capacity of dihydrofructosazine.

In summary, this research demonstrated that GlcN, and not GlcNAc, is the unstable compound, producing 1−6 mg of α-dicarbonyl compounds per gram of GlcN depending on incubation time. The cause of this reactivity lays in the nature of GlcN, which is a Heyns (aldosamine) compound with the potential to generate many reactive α-dicarbonyls, precursors of fluorescent heterocyclic compounds such as pyrazines. By contrast, acetylation of GlcN decreases its reactivity by blocking the nucleophilicity of the free $-NH_2$ group. Considering the ubiquities of GlcNAc in animal tissues, enzymatic acetylation appears to play a crucial role in minimizing the less stable GlcN, which has the potential to form endogenous reactive α-DCs. Also, research interests in GlcN application in food products are dramatically increasing. For instance, Jia et al.[50] proposed the bioconversion of GlcN to deoxyfructosazine and fructosazine to produce flavor compounds for the food industry. Uzzan et al.[17] enriched milk with GlcN with the hope of producing a functional food product; however, the experiment was compromised due to aggregation of milk protein upon pasteurization. This may indicate the cross-linking effects of α-DCs generated from GlcN degradation (unpublished results from our research group also support GlcN-induced myoglobin aggregation at moderate temperatures). In North America, GlcN has the legislative status of "natural health product" (or dietary supplement) and not of a food ingredient; for instance, a specific dose of 1.5 g daily is recommended to treat osteoarthritis. The U.S. Department of Agriculture does not recognize GlcN as "generally recognized as safe" due to lack of clinical studies that its consumption is safe in young children, pregnant women, and diabetics.[16] Hence, more studies are necessary for the use of GlcN as a food ingredient for both technological and safety reasons.

novel industrial enzymes, such as cellulases, hemicellulases, polygalacturonases, and mannanases.[15,16] In this study, we used a fast and effective approach, combining degenerate PCR and thermal asymmetric interlaced PCR (TAIL-PCR), to identify a novel exochitinase gene from pig fecal environment DNA. Our aim was to characterize a novel exochitinase having application potentials in the food and feed industries.

MATERIALS AND METHODS

Sample Collection and DNA Extraction. Pig fecal sample used in this study was collected from Hebei province, China, and stored at −20 °C before use. Pig feces samples (0.5 g) were suspended in 40 mL of prewash buffer (100 mM Tris-HCl, pH 8.0), shaken at room temperature, and centrifuged for 10 min at 14000*g*. The pellet was then dissolved in 9.5 mL of lysis buffer (100 mM Tris-HCl, 100 mM EDTA, 1.5 M NaCl, lysozyme 10 mg/mL) followed by incubation at 37 °C for 2 h.[17] Then 500 μL of 10% sodium dodecyl sulfate and 1 mg of proteinase K were added, and incubation was continued at 70 °C for 30 min. After centrifugation at 14000*g* for 10 min, 9 mL of the supernatant was transferred to a fresh 40 mL tube. Then 9 mL of phenol/chloroform/isoamyl alcohol (25:24:1) mixture was added, mixed gently, and separated by centrifugation at 14000*g* (4 °C) for 10 min. The aqueous phase was transferred to a new 40 mL tube and the preview step repeated. The aqueous phase was transferred to fresh tubes, 0.8 volume of precooled isopropanol was added, and centrifugation was performed at 14000*g* for 10 min. Pellets were washed with ice-cold 75% (v/v) ethanol and dissolved in 1 mL of TE buffer (10 mM Tris-HCl; pH 8.0, 1 mM EDTA). Then the DNA were purified using a Gel Extraction Kit (Biomed Inc., China) according to the manufacturer's protocol and verified by electrophoresis on 1% agarose gels. The presence and size of purified DNA were determined by agarose gel electrophoresis with ethidium bromide staining.

Cloning and Sequence Analysis of the Chitinase Gene (*Echi47*). The conserved regions of glycosyl hydrolase (GH) family 18 chitinases were determined by aligning their amino acid sequences obtained from the NCBI database using CLUSTAL_X (version 1.8). The degenerate primer specific for GH 18 chitinases weas designed using the CODEHOP strategy.[18] Based on the sequence alignment analysis, two highly conserved regions, DG(I/V)D(I/L/F)DWEYP and YDING(F/I/M)W for GH 18 chitinases were identified, and the CODEHOP primer (CHIF, 5′-GGNRTNGAYHTNGAYTGGGAR-TAYCC-3′; CHIR: 5′-CCAATGNCCRTTDATRTCRTA-3′) was designed. The reaction mixture (50 μL) contained 2.5 U of LA *Taq* polymerase (Takara, Japan), 250 μM of each dNTP, 1.5 mM Mg^{2+} in the buffer supplied by the manufacturer (Takara, Japan), 0.5 μM of each primer, and ∼50 ng of template DNA. PCR was performed as follows: 95 °C for 5 min, followed by 8 cycles of 94 °C for 30 s, 48−52 °C (increasing by 0.5 °C after each cycle) for 30 s, and 72 °C for 30 s, then 25 cycles of 95 °C for 30 s, 56 °C for 30 s, and 72 °C for 30 s, and then a final extension at 72 °C for 5 min. PCR products of the appropriate size (280 bp) were recovered from 1.5% agarose gel using the Gel Extraction Kit (Biomed Inc., China), ligated into the vector pGEM-T-Easy (Promega, Madison, WI, USA), and transformed into *E. coli* DH5α following the manufacturer's protocols. Colonies were selected randomly, and then inserts of the correct size were sequenced. The positive transformants were randomly picked and sequenced by Sangon Inc. (Shanghai, China). Sequence similarity analysis and alignment were carried out using BLASTX (http://www.ncbi.nlm.nih.gov/BLAST/). The 5′ and 3′ flanking regions of the chitinase gene fragment were obtained using thermal asymmetric interlaced PCR.[19] The TAIL-PCR runs include primary, secondary, and tertiary amplifications[19] with arbitrary primers (LAD1, 5′-ACGATGGAC-TCCAGAVNVNNNGGAA-3′; LAD2, 5′-ACGATGGACTCCAGA-BNBNNNGGTT-3′; LAD3, 5′-ACGATGGACTCCAGAVVNVNN-NCCAA-3′; LAD4, 5′-ACGATGGACTCCAGABDNBNNNCGGT-3′; AC, 5′-ACGATGGACTCCAGA-3′) and specific primers (FSP1, 5′-TATCCTGCCAGTCCCGAGCAA-3′; FSP2, 5′-TCAATGAAG-CCGAGGATACCA-3′; FSP3, 5′-ATGAAGGATGTTTCCGAG-TTTGC-3′; RSP1, 5′-GCAAACTCGGAAACATCCTTCA-3′; RSP2, 5′-GCTCCTTCTTGCCACCTTTCT-3′; RSP3, 5′-GCTTGTTGC-TCGGGACTGG-3′). The tertiary PCR products of the expected sizes were purified and cloned into pMD18-T vectors (Takara, Japan) for sequencing.

Sequencing and Phylogenetic Analysis. Sequence analysis and multiple alignments were performed by Vector NTI 10.0 (Invitrogen) and BLAST programs (http://blast.ncbi.nlm.nih.gov/Blast.cgi), respectively. N-terminal signal peptide analysis was done using Signal IP version 4.0 (http://www.cbs.dtu.dk/services/SignalP/). Phylogenetic trees were constructed with MEGA version 4.0[20] using the neighbor-joining method. Confidence for tree topology was estimated on the basis of 1000 bootstrap replicates.

Heterogenous Expression and Purification. The gene (*Echi47*) sequence encoding a chitinase was amplified from the environmental genomic DNA. *Nco*I and *Xho*I sites (underlined) were added to the forward and reverse primers (EchiNcoI, 5′-CATGCCATGGGCA-AAGTCATCGTTGGATACTTC-3′; EchiXhoI, 5′-CCGCTCGAG-TGATCTTATTTTGTAGACCTCATT-3′), respectively. The PCR products were gel-purified, digested, and cloned into pET-28a (+) vector, and the recombinant plasmids were transformed into *E. coli* BL21 (DE3) competent cells. The positive transformants were cultured in 20 mL of LB medium containing 50 μg/mL kanamycin at 37 °C to an OD_{600} of 0.5−0.7. The recombinant enzyme was induced by 0.5 mM isopropyl-β-D-1-thiogalactopyranoside (IPTG), and the culture was further grown at 20 °C for 24 h. The recombinant protein was concentrated and purified by Ni-IDA agarose as described before.[21] Briefly, the bound recombinant chitinase (Echi47) was eluted with buffer (50 mM Tris-HCl pH 8.0, 500 mM NaCl, 150 mM imidazole). Fractions with high chitinase activity were pooled and dialyzed against 50 mM citrate buffer (pH 5.0). The purified chitinase was monitored by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE). For detection of chitinase on gel, purified enzyme was added to SDS-PAGE sample buffer and heated at 100 °C for 5 min. The sample was separated with an 10% polyacrylamide gel containing 0.1% glycol chitin, and the gel was immersed in refolding buffer (50 mM Tris-HCl pH 7.5, 1% Triton X-100) at 37 °C overnight. The gel was washed with distilled water and then stained with 0.01% (w/v) CalcoXuor white M2R in 10 mM Tris-HCl (pH 7.5). After 5 min, the brightener solution was removed and the gel was washed with distilled water. The gel was placed on a UV transilluminator to visualize the lytic zone.[22]

The native molecular mass was estimated by Sephacryl S-100 HR column (1 cm × 40 cm) in 20 mM Tris-HCl buffer (pH 7.4) containing 100 mM NaCl at a flow rate of 0.3 mL/min. The molecular mass standards used were phosphorylase *b* (97.2 kDa), bovine serum albumin (66.0 kDa), albumin from egg chicken white (45.0 kDa), α-chymotrypsinogen A (type II from bovine pancreas, 25.7 kDa), and lysozyme (14.4 kDa).

Enzymatic Assay and Protein Determination. The chitinase activity was assayed using the dinitrosalicylic acid (DNS) method,[23] by measuring the reducing sugar. The standard reaction mixture consisting of 0.1 mL of enzyme, 0.1 mL of 1% (w/v) colloidal chitin, and 0.2 mL of 50 mM citrate buffer, pH 5.0, was incubated at 40 °C for 30 min. After incubation, the reaction was terminated by the addition of 0.4 mL of DNS reagent and boiled for 10 min. Then, the samples were rapidly cooled to room temperature and centrifuged at 14000*g* for 3 min. The absorbance of the supernatant was measured at 540 nm. One unit of chitinase activity (U) was defined as the amount of enzyme that releases 1 μmol of *N*-acetylglucosamine per minute under standard assay conditions. The protein concentration was determined according to the method of Lowry et al.[24] using bovine serum albumin (BSA) as the standard. The specific activity was expressed as units (U) per milligram of protein.

Enzyme Characterization. The optimal pH of the recombinant chitinase was determined using 50 mM various buffers within pH 3.0−10.0: citrate (pH 3.0−6.0), acetate (pH 4.0−6.0), phosphate (pH 5.0−7.0), 2-(morpholino)ethanesulfonic acid (MES, pH 6.5−7.5), Tris-HCl (pH 7.0−9.0), and *N*-cyclohexyl-2-aminoethanesulfonic acid (CHES, pH 8.0−10.0). For pH stability determination, residual activity was measured using the standard assay after the enzyme was

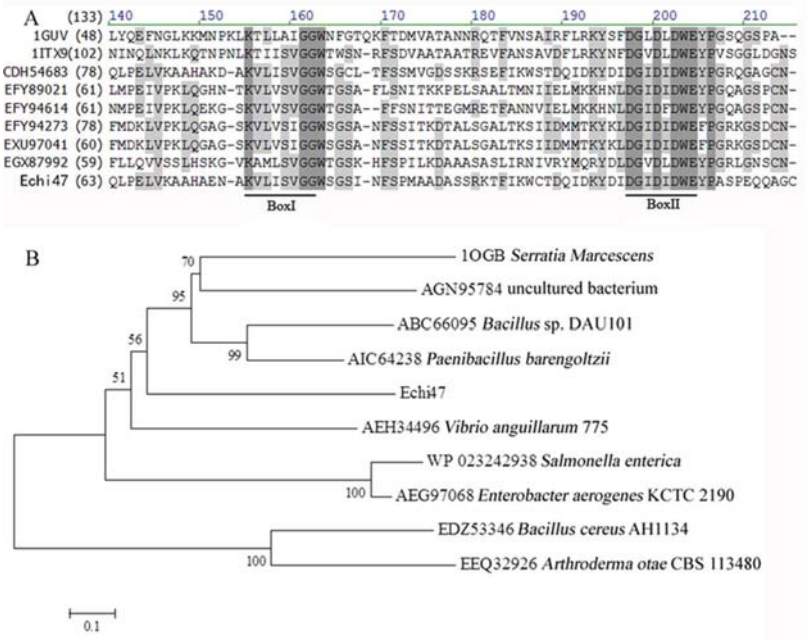

Figure 1. (A) Multiple-sequence alignment of the glycosyl hydrolase (GH) family 18 chitinase sequences. Protein motifs identified within the novel exochitinase Echi47 protein sequence include a chitin-binding motif (BoxI, SxGG) and a catalytic motif (BoxII, DxxDxDxE) with the active site (Glu, 112), indicating that it belongs to GH family 18. Accession numbers in GenBank are 1GUV (*Homo sapiens*), 1ITX (*Bacillus circulans*), CDH54683 (*Lichtheimia corymbifera* JMRC:FSU:9682), EFY89021 (*Metarhizium acridum* CQMa 102), EFY94614 (*Metarhizium robertsii* ARSEF 23), EFY94273 (*Metarhizium robertsii* ARSEF 23), EXU97041 (*Metarhizium robertsii*), and EGX87992 (*Cordyceps militaris* CM01). (B) Phylogenetic tree of the GH family 18 exochitinase based on protein sequence alignment of the catalytic domains. The tree was constructed by the neighbor-joining method using MEGA 4.0. The sequences were selected from GenBank.

incubated at 40 °C for 30 min in the different buffers. Optimal temperature of the purified chitinase was determined by the standard assay at the temperatures ranging from 20 to 70 °C; thermostability was measured after preincubation of enzyme at temperatures from 25 to 70 °C for 30 min.

The enzyme samples were preincubated with various metal ions and chemical reagents (Cu^{2+}, Ca^{2+}, Ni^{2+}, Mg^{2+}, Hg^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Na^{+}, Ba^{2+}, Ag^{+}, Fe^{3+}, Cr^{3+}, Fe^{2+}, K^{+}, EDTA, β-mercaptoethanol, and SDS) in 50 mM citrate buffer, pH 5.0, at 37 °C for 30 min. The residual activities were then measured by the standard assay. The relative activities were determined by comparison with control without metal ions or chemical reagents (100%).

Substrate Specificity and Kinetic Parameters. To evaluate the substrate specificity of the purified chitinase, Echi47 was incubated with 1% (w/v) of different substrates such as colloidal chitin, glycol chitin, glycol chitosan, powder chitin, powder shrimp shell, glucan, carboxymethyl cellulose, Avicel, or 10 mM *p*NP-GlcNAc.

Kinetic data were determined at 40 °C for 5 min using colloidal chitin as the substrate in 50 mM citrate buffer (pH 5.0) with concentrations ranging from 2 to 10 mg/mL. The Michaels−Mention constant (K_m) and maximum velocity (V_{max}) were determined from a Lineweaver−Burk plot.

Hydrolysis Properties of Echi47. The reaction mixture, containing 1% colloidal chitin and 0.5 U of purified chitinase (Echi47), was incubated at 40 °C for 2 h. Hydrolysis products were analyzed by thin-layer chromatography (TLC).[25] High-performance liquid chromatography (HPLC) was carried out in a Shodex sugar KS-802 column (Waters, Milford, MA, USA), which was eluted with acetonitrile/H_2O (100%) at a flow rate of 1 mL/min. The mixture of *N*-acetyl-COSs [(GlcNAc, $(GlcNAc)_2$, and $(GlcNAc)_3$)] was purchased from Megazyme International (Bray, Ireland) and used as the standards. *N*-Acetyl-COSs were eluted and monitored by recording absorption at 210 nm. $(GlcNAc)_2$, $(GlcNAc)_3$, and $(GlcNAc)_4$ were hydrolyzed by Echi47, respectively. The reaction mixture, containing a 0.5 mg solution of the corresponding substrate and 15 mU of purified enzyme in 100 μL of 50 mM citrate buffer (pH 5.0), was incubated at 40 °C for 40 min. Samples were withdrawn at various time points and were then boiled for 5 min to terminate the chitinase.

Protease Treatments. To determine resistance to proteases, the purified Echi47 (4 mU) was incubated with pepsin (pH 2.0; Sigma), trypsin (pH 7.0; Sigma), proteinase K (pH 7.5; Sigma), and flavor protease (pH 7.0; Novozymes) at a ratio of 1:10 (Echi47/protease, w/w) at 37 °C for 1 h. The residual activities were determined using the standard assay. The control was performed under the same conditions without Echi47.

Enzyme Stability and Activity under Simulated Gastric and Intestinal Conditions. The stabilities of Echi47 in simulated gastric fluid (SGF) and simulated intestinal fluid (SIF) were examined using a previously reported method with some modifications.[26] Purified Echi47 (0.2 U) was incubated in SGF or SIF at 37 °C for 20 min. Residual chitinase activity was determined using a standard assay. As a control, purified Echi47 was incubated in SGF and SIF without pepsin/trypsin under the same conditions. The results from three individual experiments were averaged.

The stomach and intestinal digestion phase was simulated according to the model described by Minekus et al.[27] with some modifications. Reaction systems (40 mL of each) containing 2.0 mg/mL NaCl, 200 mM glycine-HCl, 3.2 mg/mL pepsin, and 80 mg colloidal chitin were initially adjusted to pH 2.0 on ice, and then 500 μg of purified Echi47 with the specific activity of 6.84 U/mg was added. The mixture was incubated at 37 °C for 20 min, followed by further incubations for 20 min at pH 3.0, 4.0, 5.0, and 6.0, respectively. The pH changes were done while the reaction mixture was temporarily placed on ice. Finally, 10 mg/mL trypsin was added, the pH was adjusted to 6.8, and the mixture was incubated at 37 °C for 20 min. All procedures were conducted in a rotary incubator with shaking at 100 rpm. Samples (400 μL) were collected at the end of each phase and analyzed according to the DNS method.[23]

RESULTS

Amplification of the Chitinase Gene and Sequence Analysis. The PCR products (~280 bp for GH 18 chitinases) were amplified directly from environmental DNA by touchdown PCR. To obtain the full-length chitinase gene, the 5′ and 3′ fragments flanking the core regions were amplified by TAIL-PCR with three nested insertion-specific primers.[19] The full-length *Echi47* cDNA consisted of 1161 nucleotides (GenBank accession no. KP182406) and encoded an ORF of 386 amino acid residues with a predicted isoelectric point of 5.28. The diagnostic domains SxGG (chitin-binding motif) and DxxDxDxE (catalytic motif), a signature of GH18 chitinases,[28] are conserved in Echi47 (Figure 1A). The consensus sequence locates as DIDWE at positions from 110 to 115 in Echi47, where Glu112 in Echi47 is a putative catalytic residue in the active site.[4] According to the homology search of the deduced amino acid sequences by BLAST, Echi47 showed the identity of 35−77% to other chitinases. The amino acid sequence of Echi47 showed the highest identity of 77% to that of GH family 18 protein (accession no. CDH54683) from *Lichtheimia corymbifera* JMRC:FSU:9682. Echi47 shared 36% identity with the characterized chitinase (accession no. AFD19009) from *Coprinellus congregatus*.[29] Therefore, Echi47 may be a novel GH family 18 chitinase.

Enzyme Expression and Purification. The chitinase gene (*Echi47*) was successfully expressed in *E. coli* as soluble intracellular proteins with His-tags. The recombinant chitinase (Echi47) was purified from the crude cell extract by a single-step purification procedure using a Ni-IDA agarose resin column. It was purified 8.65-fold with a recovery yield of 56.7%. The purified enzyme migrated as a single band on SDS-PAGE with an apparent molecular mass of 47.6 kDa (Figure 2). The

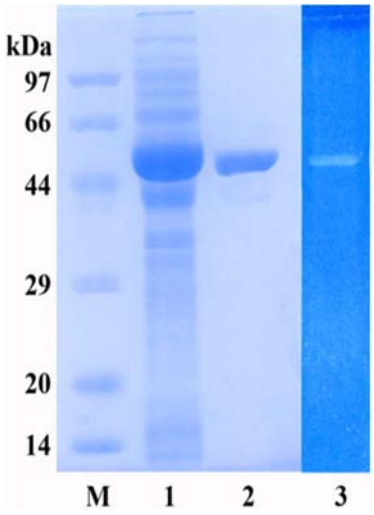

Figure 2. SDS-PAGE and zymogram of purified recombinant exochitinase (Echi47). Lanes: M, protein molecular weight marker; 1, crude extract; 2, purified Echi47; 3, zymogram of the purified chitinase.

lytic zone in the in-gel assay confirmed the chitinase activity of Echi47 (Figure 2). The native molecular mass of the enzyme was estimated to be 47 kDa by gel filtration chromatography on a Sephacryl S-100 HR column, indicating that it is a monomer.

Enzyme Characterization. The purified Echi47 had a maximum activity at pH 5.0 (Figure 3A). The enzyme was stable within pH 4.0−9.0 (Figure 3B). The optimal temperature of Echi47 was 40 °C (Figure 3C). The enzyme retained >50% of the maximum activity when assayed at 30−50 °C (Figure 3C). The enzyme was stable up to 45 °C (Figure 3D). Purified Echi47 was assayed using different substrates. Echi47 showed high activity toward colloidal chitin (6.84 U/mg), followed by glycol chitin (3.38 U/mg), but no activity toward glycol chitosan, powdered chitin, powdered shrimp shell, glucan, carboxymethyl cellulose, Avicel, and *p*NP-GlcNAc. The K_m, V_{max}, K_{cat}, and K_{cat}/K_m values using colloidal chitin as the substrate were 2.2 mg/mL, 12 U/mg, 0.0095 s^{-1}, and 0.0043 mg^{-1} s^{-1} mL, respectively.

The influence of metal ions on chitinase activity of Echi47 was tested by incubating 1 mM of various metal ions with the enzyme samples (Table 1). Among the metal ions and chemicals used, *β*-mercaptoethanol (129.3%), Ni^{2+} (118.4%), Na^{+} (112.8%), and Cr^{3+} (113.1%) increased the enzyme activity, whereas Hg^{2+} (20.5%), Ag^{+} (23.2%), Co^{2+} (64.9%), and EDTA (70.7%) decreased the activity of the enzyme. Ca^{2+}, Cu^{2+}, Mg^{2+}, Fe^{3+}, Zn^{2+}, Mn^{2+}, Ba^{2+}, Fe^{2+}, K^{+}, and SDS had negligible effect on enzyme activity (Table 1). The crustacean shell consists mainly of protein (30−40%), mineral salts (30−50%), and chitin (13−42%).[30] Cu^{2+}, Ca^{2+}, Mn^{2+}, Fe^{2+}, Zn^{2+}, and Ba^{2+} have been found in shrimp shells.[30]

Hydrolysis Properties of Echi47. Hydrolysis properties of Echi47 were analyzed by TLC and HPLC. When colloidal chitin was used as substrate, $(GlcNAc)_2$ was mostly produced in the initial stage. Small amounts of GlcNAc (2.9−8.3%) and $(GlcNAc)_3$ (11.8−2.4%) were detected (Table 2 and Figure 4); finally, at 24 h, the reaction mixture contained $(GlcNAc)_2$ (91.2%) and GlcNAc (8.8%). The amount of $(GlcNAc)_2$ was >10-fold higher than that of GlcNAc. The proportion of $(GlcNAc)_2$ slowly increased with prolonged incubation times (Table 2 and Figure 4A). The proportion of GlcNAc increased along with the reduction of $(GlcNAc)_3$ (Table 2). Moreover, $(GlcNAc)_4$ was hydrolyzed by Echi47 to yield exclusively $(GlcNAc)_2$ (Figure 4C). When $(GlcNAc)_3$ was used as a substrate, the products were $(GlcNAc)_2$ and GlcNAc. Echi47 hardly hydrolyzed $(GlcNAc)_2$.

Protease Resistance and Activity under Simulated Gastric and Intestinal Conditions. Echi47 exhibited excellent resistance to tested proteases, namely, trypsin (94.8%), proteinase K (98.3%), and flavor protease (98.3%), except pepsin (67.8%) (Figure 5). Moreover, Echi47 retained >80% activity at pH 3.0−6.8 at the whole stomach stage with or without the presence of pepsin after incubation in SGF and SIF at 37 °C for 20 min (Figure 6A). Under simulated alimentary tract conditions, Echi47 was very active and efficient in the degradation of substrate, releasing 21.1 mg of *N*-acetyl-COSs from 80 mg of colloidal chitin (Figure 6B).

DISCUSSION

Chitinase plays an important role in the decomposition of chitin and potential utilization of chitin as a renewable resource. Microorganisms are a major source of chitinases. However, only a tiny fraction of natural microorganisms can be cultured by conventional microbiological techniques.[13] A metagenome-based technique has recently been recognized as an attractive approach to mining novel genetic resources in the natural environment.[31] Many novel microbial enzymes have been successfully cloned from various environments, such as xylanase from compost-soil,[32] carboxylesterases from seawater,[33] and chitinase from suppressive soil.[14] Animal fecal microorganisms represent rich resources of novel glycoside hydrolases.[34]

240	8.3 ± 0.26	89.4 ± 3.23	2.4 ± 0.09

Therefore, a novel chitinase gene (*Echi47*) was directly cloned from pig fecal environment DNA, which is the first chitinase isolated from environmental DNA using a genomic walking PCR technique.

Microbial chitinases vary widely in their molecular masses, ranging from as low as 20 kDa to about 200 kDa.[3] Moreover, GH family 18 exochitinases have a size range of 40−60 kDa without carbohydrate-binding modules.[4] Thus, the molecular mass of Echi47 is similar to that of other exochitinases. The specific activity (6.84 U/mg) of the purified Echi47 toward colloidal chitin is higher than that of the chitinase from *Bacillus* sp. DAU101 (0.73 U/mg)[35] and *Vibrio parahemolyticus* (1.5 U/mg),[36] but lower than that of a chitinase from *Paenicibacillus barengoltzii* (19.9 U/mg).[5]

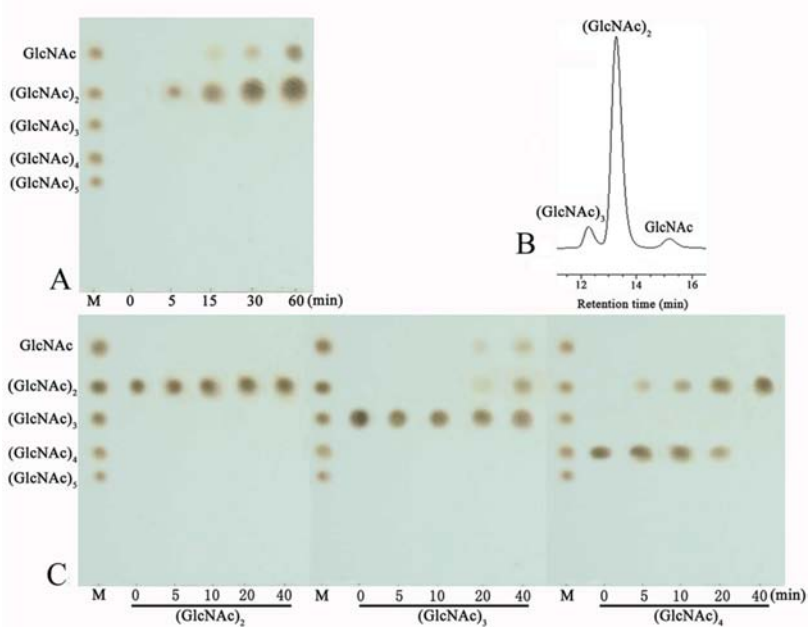

Figure 4. Hydrolysis properties of Echi47: (A) thin layer chromatography (TLC) analysis of colloidal chitin hydrolyzed by purified Echi47; (B) hydrolysis products from colloidal chitin by Echi47 at the stage of reaction (30 min); (C) TLC of various *N*-acetyl-COSs hydrolyzed by Echi47. The reaction mixture (100 μL) containing 0.5 mg of *N*-acetyl-COSs [$(GlcNAc)_2$, $(GlcNAc)_3$ or $(GlcNAc)_4$] in 50 mM citrate buffer (pH 5.0) was incubated with the enzyme (Echi47, 15 mU) at 40 °C. The reaction products were analyzed at the indicated times. Lanes: M, standard *N*-acetyl-COSs from GlcNAc to $(GlcNAc)_5$.

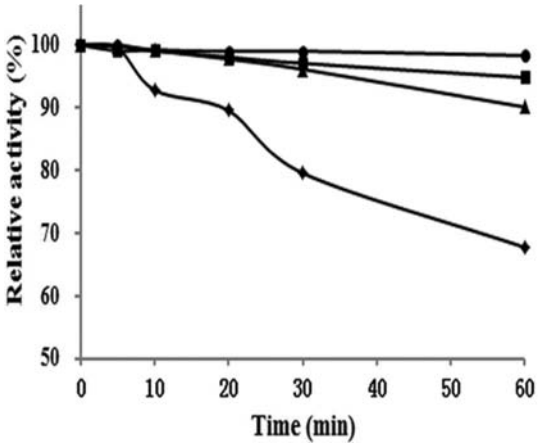

Figure 5. Effect of proteases on activity of purified Echi47. The influence of proteases on the activity of Echi47 was determined at 37 °C using different proteases: pepsin (◆), trypsin (■), proteinase K (▲), and flavor protease (●). Each value represents the mean ± SD (n = 3).

Microbial chitinases are found to be active over a wide range of temperatures (from 30 to 80 °C) and pH (from 3.0 to 10.0), depending on the source of microorganisms.[1,3] The optimal pH 5.0 of Echi47 is lower than that of an exochitinase from *Bacillus* sp. DAU101 (pH 7.5),[35] but higher than that of an exochitinase from *Microbispora* sp. V2 (pH 3.0).[37] Echi47 was most active at 40 °C (Figure 3A), which is intermediate compared with most other exochitinases, which have optimal temperatures in the range of 30−50 °C.[1,5] Interestingly, Echi47 exhibited similar optimal pH and temperature to the intestinal conditions, which make the enzyme valuable in several applications requiring acidic pH and low temperature. Additionally, the pH range for Echi47 activity (≥50% of the maximum activity between pH 4.0 and 9.0) is similar to the physicochemical conditions found for

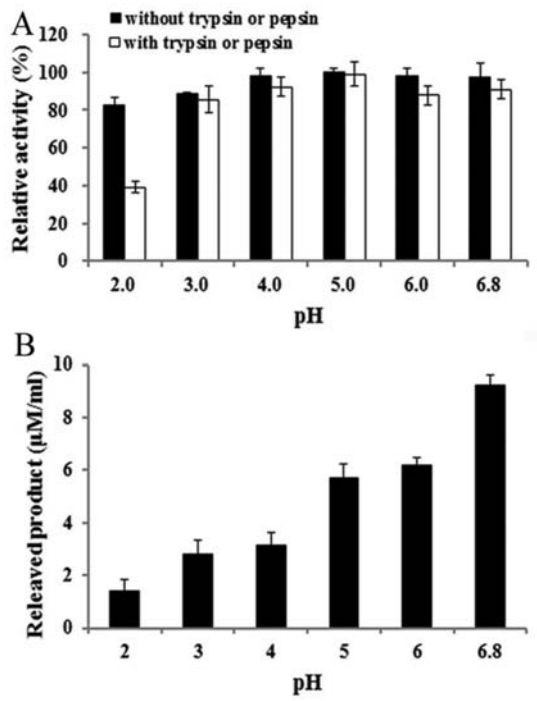

Figure 6. Stability and hydrolytic efficacy of Echi47 in simulated gastric fluid (SGF): (A) stability of the purified Echi47 in SGF (Echi47 stability was determined after incubation in SGF at pH 2.0−6.8 and 37 °C for 20 min; relative activity is expressed as a percentage of the initial activity of Echi47); (B) hydrolysis efficacy of Echi47 in SGF at different pH values. The degradation of colloidal chitin was measured after digestion at pH 2.0−6.8 or in a pH gradient according to gastric passage. Hydrolysis efficacy is calculated as the quantity of released reducing sugar. Each value in both panels represents the mean ± SD (n = 3).

the environments of warm-water fish,[10] which may be meaningful for use as aquaculture feed supplement.

Chitinases[1] are commonly inhibited by Hg^{2+}, Ag^{+}, Cu^{2+}, Zn^{2+}, Fe^{2+}, and Co^{2+}. Hg^{2+}, Ag^{+}, and Co^{2+} inhibited chitinase activity of Echi47. Hg^{2+} and Ag^{+} also inhibited activity of the chitinase from *Streptomyces violaceusniger*.[38] The activity of Echi47 was significantly stimulated by Ni^{2+}, Na^{+}, Cr^{3+}, and β-mercaptoethanol. The activity of Echi47 was stimulated by some of the tested metal ions and was inhibited by the metal ion chelating compound EDTA, suggesting that metals may be important in enzyme stability and/or activity. Additionally, the activity of Echi47 was enhanced by β-mercaptoethanol indicates the presence of sulfhydryl groups on the active site of the enzyme, which was confirmed by the inhibition by Hg^{2+}. Hg^{2+} may react with −SH groups in cysteine residues in the protein chain and disrupt the tertiary structure. Inhibition by Hg^{2+} and β-mercaptoethanol enhancement are similar to the case for the chitinases from *Streptomyces* species.[38]

To ensure efficient degradation of crystalline and inaccessible polymeric chitin substrates, chitinases often have one or more carbohydrate-binding modules (CBMs). CBMs' contribution to the efficiency of substrate conversion is not completely clear. The presence of CBMs increases substrate affinity as well as efficiency of chitin hydrolysis, especially in the hydrolysis of crystalline chitin forms.[38,39] The catalytic efficiency of chitinase-D (a single-domain chitinase from *Serratia proteamaculans*)[40] is increased, for degradation of insoluble chitin substrates, by fusing the heterologous CBMs such as PKD and CBP21. On the contrary, no such typical chitin-binding domain is present in single-domain Echi47, but it has a high affinity for chitin (K_m = 2.2 mg/mL), which is due to the conserved chitin-binding motif. The lack of CBMs in some chitinases suggests that a single catalytic domain is sufficient for catalytic activity of chintinase and further suggests that CBMs may facilitate hydrolysis of insoluble substrates but are not required for chitinase activity. Single-domain chitinases[41] such as Bce Chi36 and Echi47 may have good activity toward partially hydrolyzed or soluble chitin substrates.

Endochitinases randomly cleave β-1,4-glycosidic bonds of chitin, whereas exochitinases cleave the chain to form diacetylchitobiose.[35] $(GlcNAc)_2$ was mostly produced at the early stage of colloidal chitin hydrolyzed by Echi47, indicating that Echi47 is an exotype chitinase. This is similar to that of *Serratia marcescens* ChiB, which is identified as an exochitinase because it generates exclusively $(GlcNAc)_2$ from $(GlcNAc)_4$ and colloidal chitin at initial stage.[42] Exochitinases usually have a deep and tunnel-shaped substrate-binding site, but the endochitinases have a shallow and open substrate-binding site, which is relatively long and accommodates at least five sugar units.[4,43] The exomechanism can occur when the substrate is not released after successful cleavage but slides through the active site for the next cleavage event to occur.[43] In such a mechanism, chitin chains were degraded from one end with release of successive $(GlcNAc)_2$.[43] There is a growing appreciation of the potential of bioactive *N*-acetylchitooligosaccharides (especially *N*-acetylchitobiose). For instance, high antioxidant activities of GlcNAc and $(GlcNAc)_2$ produced by exochitinase from *Bacillus cereus* EW5 have been reported.[44] There are some reports on the bioproduction of $(GlcNAc)_2$.[2] For the production of specific *N*-acetyl-COSs, suitable enzymes and controlled reactions are the primary requisites.[45] $(GlcNAc)_2$ can be obtained as a major hydrolytic product from enzymes by controlling the ratio of *N*-acetyl-β-1,4-D-glucosaminidase to *N*,*N*′-diacetylchitobiohydrolase activities in the crude enzyme of *Aeromonas* sp. GJ-18.[2] $(GlcNAc)_2$ has also been produced from colloidal chitin by the chitinase from *Bacillus licheniformis* strain JS isolated from a mushroom bed.[45] Therefore, Echi47 may be useful for the production of $(GlcNAc)_2$.

The excellent resistance of enzymes to proteases is useful in the feed industries. The activity of the enzymes is inhibited somewhat by proteases and the pH (~7) in the intestine.[46] However, there are very few studies on the protease-resistant chitinases. Echi47 displayed excellent protease resistance as compared to other chitinases. The chitinase from *Aeromonas veronii* B565 has been found to be resistant to pepsin (55.8%), trypsin (81.6%), and proteinase K (59.9%).[10] Additionally, whether or not an enzyme can be used as feed additive depends on its activity and stability under alimentary tract conditions. To date, many other enzymes have high activity under simulated gastric conditions, such as β-galactosidase from *Bispora* sp. MEY-1 and exopolygalacturonase from *Klebsiella* sp. Y1.[26,46] Echi47 was stable and exhibited high hydrolytic ratio at low pH in the presence of pepsin. This is the first report on chitinase activity and stability under alimentary tract conditions. Supplementation of the diet with chitinase complexes containing endochitinases and exochitinases may be effective hydrolysis of chitin. Thus, these properties make Echi47 a potential feed additive.

(MLC1) with a molecular mass of ∼18 kDa and the regulatory light chain (MLC2) with a molecular mass of ∼20 kDa.[20,22] It has been demonstrated that MLC2 is phosphorylated by its kinase, which is regulated the expression of IgE, and is reported to be increased in the smooth muscle of the allergen-sensitized human airway.[23] MLC has been reported to have IgE-binding activity in *L. vannamei*, *C. crangon*, and *P. monodon*, and the immunological effects of recombinant MLC have been analyzed in these organisms. However, it is unclear whether MLC is the major allergen in *P. clarkii*, nor has native MLC been characterized or the isoform identified.

The objectives of this study were to identify and purify MLC from *P. clarkii* and to analyze its physicochemical and immunological characteristics during changes in its secondary structure. We were able to clone the cDNA encoding the MLC proteins and to identify the allergenic MLC isoform. A homology model of the MLC structure was developed and used to predict its epitopes. These data will extend our understanding of MLC and provide valuable references for further research into the molecular nature of hypersensitivity to crayfish.

MATERIALS AND METHODS

Crayfish. Crayfish (*P. clarkii*) were purchased from a local market in Xiamen, China. Crayfish were peeled, and the muscle samples were collected and immediately used in the experiments or frozen at −70 °C for later analysis.

Chemicals. Diethylaminoethyl−Sephacel (DEAE−Sephacel) and Sephacryl S-200 HR were from Amersham Biosciences (Uppsala, Sweden). The protein standards for sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) were from Fermentas (Vilnius, Lithuania), and the prestained protein standards for Western blot analysis were from New England BioLabs (Beverly, Massachusetts, USA). Horseradish peroxidase (HRP)-conjugated goat anti-human IgE antibody was from Kirkegaard and Perry Laboratories (Gaithersburg, Maryland, USA), and the enhanced chemiluminescence (ECL) substrate for Western blot analysis was from Pierce (Rockford, Illinois, USA). 3,3′,5,5′-Tetramethylbenzidine (TMB) was from Tiangen (Beijing, China). Ponceau S concentrate and porcine pancreatic enzymes were purchased from Sigma-Aldrich (St. Louis, Missouri, USA). Porcine pepsin was prepared in our laboratory. All reagents were of analytical grade.

Human Sera. Sera were collected from seven crustacean-allergic patients (nos. 749, 514, 974, 067, 785, 980, and 791), who were referred by the Medical Center of Jimei University in Xiamen, China. Serum samples from nonallergic (NA) individuals (nos. 780 and 981) were used as the negative controls. All patients and NA individuals voluntarily provided their sera (nos. U245749, U394514, T800974, U246067, U390785, U405980, U393791, U397780, and V490981). Written informed consent was obtained from each patient. The IgE level in each serum was measured with an ImmunoCAP assay (Phadia AB, Uppsala, Sweden), and the results are shown in Table 1. An ImmunoCAP score >0.35 kUA/L was considered positive. All sera were stored at −30 °C until analysis.

Purification of the Target Protein. The preliminary treatment was carried out as described previously,[24] with slight modifications. All procedures were performed at 0−4 °C unless otherwise stated. The crayfish muscle tissue was minced and homogenized with 10 vol (v/w) of ice-cold 50 mM NaCl buffer containing 2 mM $NaHCO_3$ and 10 mM EDTA. The homogenate was then centrifuged at 8000*g* for 10 min at 4 °C. The precipitate was resuspended in the same solution and then homogenized and centrifuged again four more times. The last precipitate, which contained the myofibrillar proteins, was washed three times with cold absolute acetone and dried completely. The dried powder was extracted overnight with 10 vol (v/w) of 20 mM Tris-HCl (pH 7.5) containing 1 M NaCl and 1 mM EDTA. The mixture was then centrifuged at 12 000*g* for 20 min at 4 °C. The supernatant was subjected to isoelectric precipitation at pH 4.0 with 1 N HCl. After centrifugation at 12 000*g* for 20 min at 4 °C, the precipitate was dissolved with 20 mM Tris-HCl (pH 7.5) and brought to pH 7.6 with 1 N NaOH and then subjected to ammonium sulfate fractionation with 41−60% saturated ammonium sulfate. Following centrifugation at 12 000*g* for 20 min at 4 °C, the precipitate was dissolved in 20 mM Tris-HCl (pH 7.5) containing 1 mM EDTA and then dialyzed in the same solution overnight. After centrifugation at 12 000*g* for 20 min at 4 °C, the supernatant was applied to a DEAE−Sephacel column (2.5 × 10 cm) and eluted with a linear gradient of 0−0.5 M NaCl at a flow rate of 0.6 mL/min. The fractions containing the target protein were concentrated by the ultrafiltration of a 3 kDa filtering membrane and then applied to a Sephacryl S-200 HR gel column (1.5 × 100 cm) equilibrated with 20 mM Tris-HCl (pH 7.5) containing 0.2 M NaCl. The column was eluted at a flow rate of 0.5 mL/min, and the fractions containing the target protein were collected and detected on a 12% SDS−PAGE gel stained with Coomassie Brilliant Blue R-250 (CBB). The protein concentrations in the eluted solutions were estimated by measuring the absorbance at 280 nm.

Peptide Analysis by Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF-MS). After the 18 kDa target protein had migrated on the 12% SDS−PAGE gel and was stained with CBB, the band was cut from the gel and sent to Shanghai Applied Protein Technology Company Limited (Shanghai, China) to digest with trypsin for analysis with a 4800 Plus MALDI-TOF/TOF analyzer from Applied Biosystems (Foster City, California, USA), based on the method of Yan et al.[25] The MS conditions were as follows: laser source, ND; wavelength, 355 nm; accelerating voltage, 2 kV; and substrate, α-cyano-4-hydroxycinnamic acid. The positive ion mode was used, and the data were obtained automatically. The resulting peptide spectra were compared with those in the National Center for Biotechnology Information (NCBI) database.

Carbohydrate Content and Carbohydrate−Peptide Linkage Characterization. The total carbohydrate content of the 18 kDa target protein was determined with the phenol−sulfuric acid method,[26] with some modifications. In brief, 0.3 mL of 6% phenol in water was added to the sample solution (0.5 mL) in a test tube, and 1.5 mL of concentrated sulfuric acid was added slowly down the side of the tube. The tube was then vortexed, covered, and incubated for 20 min at 100 °C. After all the tubes were cooled to room temperature, the absorbance of each was read at 490 nm. All the experiments were performed in duplicate. The β-elimination was used to determine the carbohydrate−peptide linkages in the target protein, according to a previously described method.[6] The target protein sample (0.3 mg/mL, 90 μL) was mixed with 10 μL of 0.5 M NaOH and incubated at 37 °C for 16 h, after which the absorbance at 220−300 nm was measured. The target protein sample was replaced with the same volume of distilled water, as the blank, and NaOH was replaced with the same volume of distilled water, as the negative control. All experiments were performed in duplicate.

J. Agric. Food Chem. 2015, 63, 6271−6282

Thermal Stability and pH Stability. To determine the thermal stability of the 18 kDa target protein, it was incubated in buffer (10 mM Tris-HCl, pH 7.5) at different temperatures (30, 40, 50, 60, 70, 80, 90, and 100 °C) for 30 min. The protein was incubated at 0 °C as the control. To test its pH stability, the target protein was incubated for 1 h at room temperature in buffer at different pH (1.0, 2.0, 3.0, 4.0, 5.0, 7.0, 9.0, and 11.0). The protein was incubated at pH 7.5 as the control. Then all the samples were analyzed with 15% SDS−PAGE and dot blot.

Stability during Simulated Digestion. The stability of the target protein in vitro in simulated gastric fluid (SGF, pepsin) and simulated intestinal fluid (SIF, pancreatin) was assessed with the method of Chen et al.,[14] with some modifications. The total volume of the reaction solution was 1 mL. For gastric digestion, the ratio of pepsin to the target protein was 1:500 (w/w). An aliquot of 100 μL of the reaction solution was removed after different time intervals (0, 1, 2, 5, 10, 15, 30, or 60 min), and the reaction was immediately terminated by the addition of 30 μL of 200 mM Na_2CO_3. For intestinal digestion, the ratio of pancreatin to the target protein was 1:500 (w/w). The reactions were performed for 0, 1, 15, 30, 60, 120, 180, or 240 min, after which they were immediately terminated by heating at 95 °C for 5 min. A target protein sample, dissolved in SGF/SIF with no corresponding enzyme, was used as the undigested control. The final concentration of each sample was adjusted to 0.25 mg/mL. The samples were analyzed with 15% SDS−PAGE and a competitive inhibition enzyme-linked immunosorbent assay (ELISA).

Western Blot and Dot Blot Analysis. Western blot analysis was performed as described by Chen et al.,[14] with some modifications. Briefly, protein samples separated with SDS−PAGE were electrophoretically transferred to a nitrocellulose membrane, and then the transfer efficiency was determined by Ponceau S staining of the membrane. The membrane was washed with TBST (20 mM Tris-HCl, pH 8.0, containing 0.15 M NaCl and 0.05% Tween-20) and blocked with 5% skim milk in TBST. They were then incubated for 6 h at room temperature with human serum (diluted 1:4) as the primary antibody and washed with TBST. The membrane was then incubated for 1.5 h with HRP-labeled goat anti-human IgE antibody (diluted 1:20000) as the secondary antibody. After being extensively washed with TBST, the proteins were visualized with ECL. In the dot blot analysis, the samples were blotted onto the nitrocellulose membrane, blocked, and incubated with sera from patients (diluted 1:4) and HRP-labeled goat anti-human IgE antibody (diluted 1:20000) as described above. The signal was detected with ECL.

Indirect and Competitive Inhibition ELISA (ciELISA). Each well of a polystyrene 96-well ELISA plate (Nunc Maxisorb, Denmark) was coated with the 18 kDa target protein (0.2 μg) and incubated at 4 °C overnight or at 37 °C for 2 h. The coated plates were washed with TBST and blocked with 200 μL/well 5% skim milk at 37 °C for 2 h. After being washed and blocked, the coated plates were incubated at 37 °C for 2.5 h with 50 μL of patient serum (diluted 1:5 with 1% skim milk in TBST) as the primary antibody and then at 37 °C for 1.5 h with HRP-conjugated goat anti-human IgE (diluted 1:2000) as the secondary antibody. TMB (100 μL) was then added to each well and incubated at 37 °C for 20 min. After the reaction was terminated by the addition of 50 μL of 2 M sulfuric acid, the absorbance was measured at 450 nm with an automated ELISA plate reader (Benchmark 96; Bio-Rad Laboratories, Hercules, California, USA). The specific IgE-binding activity of the purified protein-derived digestion fragments was confirmed with a ciELISA, based on the method of Li et al.[27] In contrast to indirect ELISA, after the plates were blocked with 5% skim milk, 50 μL of human sera (diluted 1:2 with 1% skim milk in TBST) was mixed with the same volume of inhibitor sample (the purified protein-derived digestion fragments), in the concentration range of 0.025−50 μg/mL in another plate. After incubation at 37 °C for 1.5 h, 50 μL of the mixture (serum plus inhibitor) was transferred to the ELISA plate precoated with the purified protein as the allergen and incubated for 1.5 h at 37 °C. As above, after incubation with the secondary antibody and reaction with TMB, the absorbance at 450 nm was measured. The inhibition rate was calculated to evaluate the percentage of inhibition by each inhibitor sample using the following formula:

$$\text{inhibition rate } (\%) = ([X - Y]/[X - Z]) \times 100$$

where X is the absorbance of the patient's serum not incubated with the inhibitor, and Y and Z are the absorbance of an allergic patient's serum and control NA serum reacted with the inhibitor, respectively. All the samples were tested in duplicate and the mean values calculated.

Circular Dichroism (CD) Spectroscopy. Far-UV CD spectra were measured with a Chirascan circular dichroism spectrometer (Applied Photophysics Ltd., Surrey, UK). The measurements of purified protein in buffer (10 mM Tris-HCl, pH 7.5) were made at 25 °C using a rectangular quartz cuvette (Starna, Essex, UK) with a path length of 0.1 cm at a protein concentration of 0.12 mg/mL. The purified protein was treated at different temperatures (0 and 100 °C) for 30 min or at room temperature in different pH buffers (pH 1.0, 7.5, and 11.0) for 1 h. The samples were scanned three times at 1 nm/s at a bandwidth of 1 nm. The response time was 2 s, and the wavelength range was 190−260 nm. The data were averaged, and the spectrum of the sample-free control was subtracted. The secondary structures of the proteins were determined with the CDNN program (version 2.0) based on the variables of the amino acid sequence and the molecular weight of the target protein.[28]

Cloning and Sequencing the MLC Genes. Total RNA was prepared from crayfish (*P. clarkii*) muscle based on the TRIzol method.[29] The first-strand cDNA was synthesized with the TIANScript RT kit (Tiangen, Beijing, China), according to the manufacturer's instructions, and oligo$(dT)_{18}$ primers were designed according to the manufacturer's instructions. Based on the MALDI-TOF-MS results and the alignment of the MLC cDNA sequences of *C. crangon* and *P. monodon*, degenerate oligonucleotide primers were designed as the sense primers for PCR. Using these primers and the synthesized cDNA, a 300 bp fragment of the *MLC* gene was amplified by PCR in the GeneAmp 9700 thermal cycler (Applied Biosystems, Foster City, California, USA). The PCR thermal cycling program was 5 min at 94 °C, followed by 30 cycles of 45 s at 94 °C, 30 s at 57 °C, and 45 s at 72 °C, and a final extension at 72 °C for 7 min. The PCR product was purified by agarose gel electrophoresis and cloned into the pGEM-T Easy vector (Promega), and the DNA sequence was analyzed. 5′-RACE primers and 3′-RACE primers were designed based on the sequence information from the RT−PCR product. RACE and RACE−PCR were performed with the SMART RACE amplification kit (Clontech, Palo Alto, California, USA). The PCR amplification product was purified, cloned, and sequenced. The full-length gene sequences of the *MLC*s (*MLC1*, 1096 bp; *MLC2*, 1362 bp) were obtained by overlapping the RT−PCR fragment, the 3′-RACE fragment, and the 5′-RACE fragment. DNA nucleotide sequencing was performed with the ABI PRISM 3730 DNA analyzer (Applied Biosystems, Foster City, California, USA), and the sequences were compared with the nucleotide sequences in the GenBank database. The sequences were submitted to GenBank under accession numbers JX173714 (gil401606250) for *P. clarkii MLC1* cDNA and JX013934 (gil392499120) for *P. clarkii MLC2* cDNA.

Structural Modeling and Epitope Prediction. The three-dimensional structure of the target protein was simulated at the Web site http://swissmodel.expasy.org/ based on the homology modeling by the amino acid sequence of the target protein to search the suitable template. The continuous linear epitopes were predicted by the DNASTAR Protean software using the method of Kyte−Doolittle for hydrophilicity plot prediction, the method of Karplus−Schulz for flexible regions prediction, the method of Jameson−Wolf for antigenic index prediction, and the method of Emini for surface probability plot prediction. The peptide fragments were selected to satisfy the conditions: (i) highly hydrophilic; (ii) appropriate antigenic index; and (iii) situated in a flexible and surface-exposed region. Discontinuous conformational epitopes were predicted at the DiscoTope 2.0 server (http://www.cbs.dtu.dk/services/DiscoTope/) by the calculation of surface accessibility, a novel epitope propensity, and the propensity of residues in spatial proximity. The three-dimensional structure and epitopes were represented on the molecular surface of the protein with PyMOL.

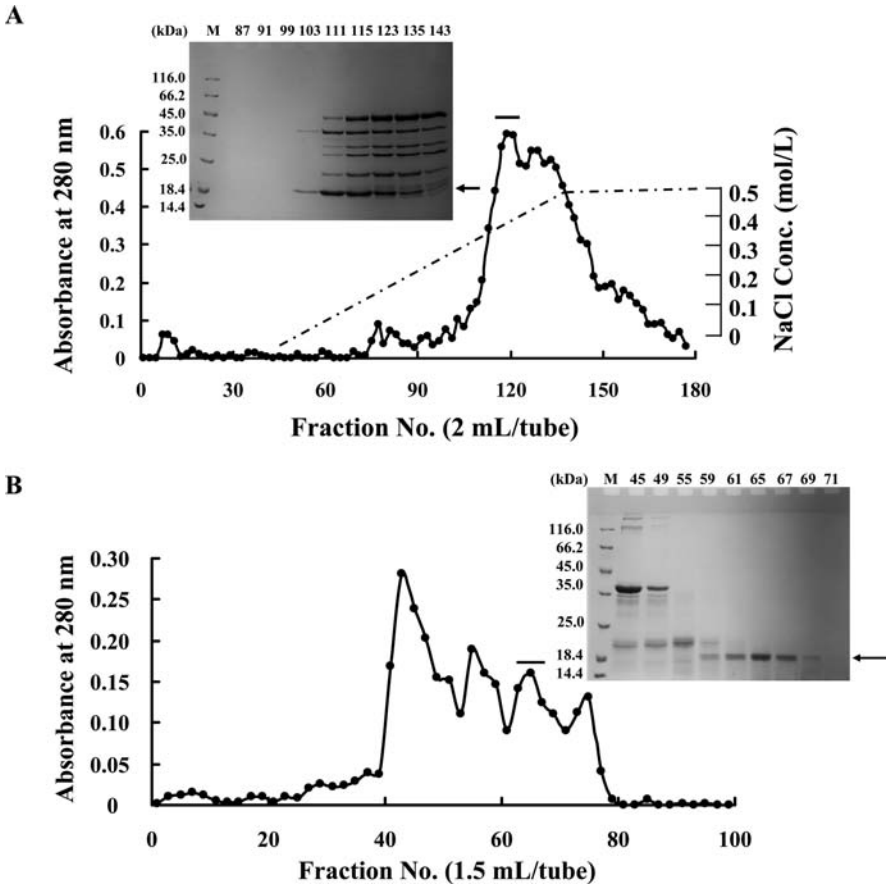

Figure 1. Chromatographic purification of the 18 kDa protein in crayfish. (A) DEAE−Sephacel chromatography. (B) Sephacryl S-200 HR gel chromatography. The numbers above the lanes correspond to the fraction numbers. Target protein fractions under the bar were pooled.

RESULTS

Purification of the 18 kDa Protein. The 18 kDa protein was purified from crayfish muscle with ammonium sulfate precipitation and sequential column chromatography on DEAE−Sephacel and Sephacryl S-200 HR. The fractions from the DEAE−Sephacel column were eluted with a linear gradient of 0−0.5 M NaCl (Figure 1A). The fractions that contained relatively high concentrations of the 18 kDa target protein were then pooled, concentrated, and separated on a Sephacryl S-200 HR gel-filtration column, which removed the contaminating proteins. After Sephacryl S-200 HR chromatography, the highly purified protein migrated on SDS−PAGE as a single band with a molecular weight of about 18 kDa (Figure 1B). Approximately 5.6 mg of the purified protein was obtained from 140 g of crayfish muscle.

Identification by MALDI-TOF-MS. The purified 18 kDa protein band was excised from the SDS−PAGE gel, destained, and digested in-gel with trypsin. The resulting peptides were analyzed with MALDI-TOF-MS. Peptide mass fingerprinting of the purified protein showed multiple peaks ranging from 800 to 4000 Da. The peaks with signal-to-noise ratios >50 were analyzed with MS/MS, as shown in Figure 2A. The effective peaks were compared with the NCBInr database using the Mascot 2.2 search engine. One peptide fragment containing 13 amino acid residues was 100% identical to MLC of *Drosophila yakuba* (gil 195503715) and 92.3% identical to that of *C. crangon* (gil 238477331) and *Marsupenaeus japonicas* (gil290908988) (Figure 2B). These results confirmed the purified 18 kDa protein as MLC.

Glycoprotein Characterization. The results of the phenol−sulfuric acid analysis indicated that the total carbohydrates in MLC accounted for about 4.3 ± 0.05% (w/w) of the whole protein. The β-elimination was used to determine the presence of O-linked glycans in the MLC structure. As shown in Figure 3A, when MLC was treated with alkali, the UV absorbance at 240 nm increased significantly compared with the absorbance before alkali treatment. This result indicates that one or more *O*-glycans may be present in the structure of MLC.

Thermal and pH Stability. Thermal and pH stabilities are accepted characteristics of most allergens. The thermal stability of purified MLC was analyzed with SDS−PAGE and dot blot. As illustrated in Figure 3B, MLC was stable after exposure to different temperatures, even up to 100 °C. MLC IgE-binding activity at different temperatures was determined with dot blot using the patients' sera. The IgE-binding activity of crayfish MLC was detected in this assay and did not increase or decrease obviously in the temperature range of 30−100 °C (Figure 3C).

The pH stability of purified crayfish MLC was also examined with SDS−PAGE and dot blot. As illustrated in Figure 3D, MLC remained stable when exposed to acidic (pH 1.0−5.0) and alkaline (pH 9.0, 11.0) conditions. Dot blot was also used to analyze the IgE-binding activity of MLC. Compared with the control, no obvious change was detected in the IgE-binding activity of MLC after exposure to different pH values (Figure 3E).

Stability during Digestion. It was determined whether MLC was stable under in vitro conditions simulating human gastrointestinal digestion. The stability of purified MLC in

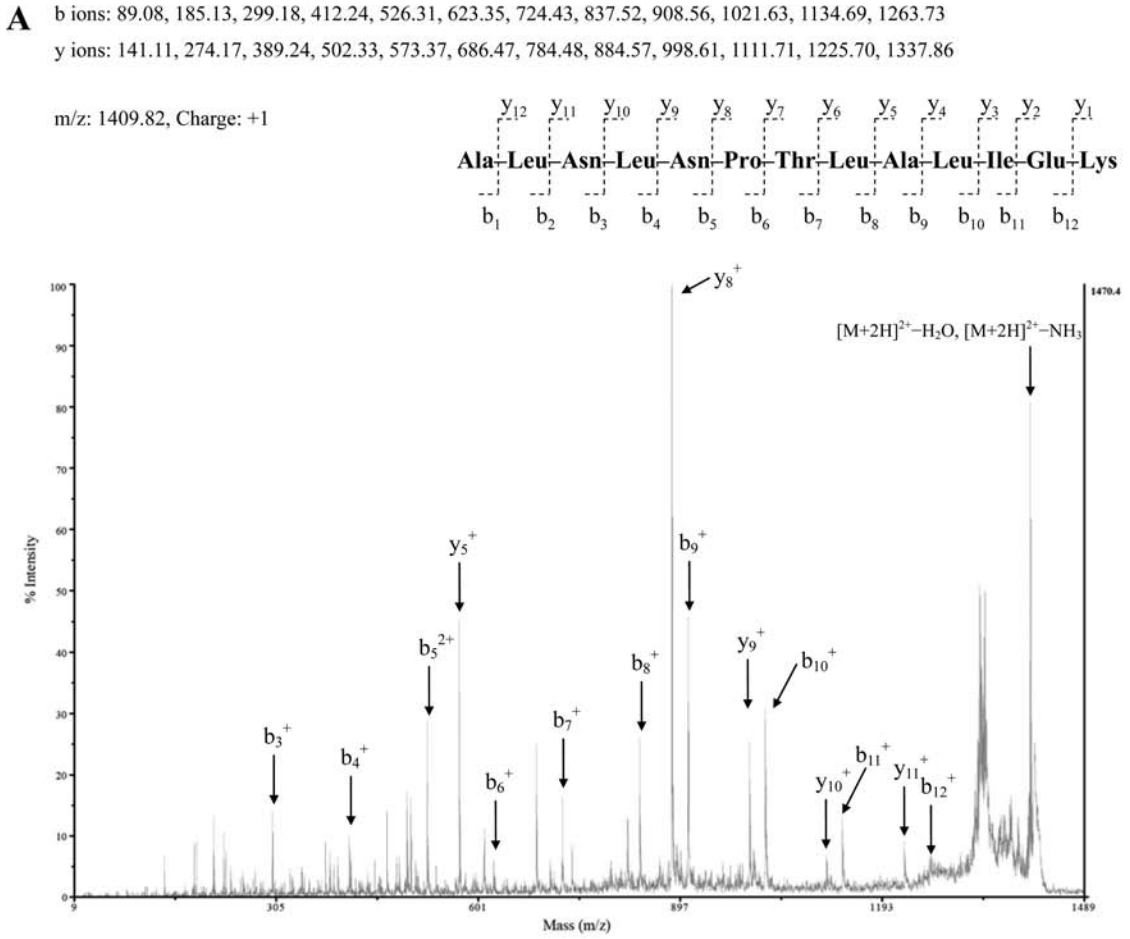

Figure 2. Mass spectrometric analysis of the 18 kDa protein in crayfish. (A) Map of MS/MS. (B) Protein sequence alignments of MLCs from *Procambarus clarkii*, *Drosophila yakuba*, *Crangon crangon*, and *Marsupenaeus japonicus*.

pepsin digestion was analyzed with SDS–PAGE. The original band (18 kDa) was gradually digested over time. Proteolytic fragments smaller than 14.4 kDa appeared after prolonged peptic digestion. The original band was digested into fragments smaller than can be resolved by SDS–PAGE by pepsin within 1 h (Figure 3F). In contrast, a single proteolytic fragment smaller than 14 kDa was observed after the pancreatin digestion of MLC. The ~14.4 kDa fragment appeared after 15 min and remained undigested up to 240 min (Figure 3G). Competitive inhibition ELISA was used to analyze the IgE-binding activity of the MLC-derived digestion fragments. As shown in Figure 3H, the IgE-binding activity of the digested fragments was reduced by pancreatin digestion but not significantly with pepsin digestion. When the concentration of the inhibitor was 2.5 μg/mL, the inhibition rate of the pepsin digestion fragments was 80%, whereas that of the undigested MLC was 85%, and the inhibition rate of the pancreatin digestion fragments was only 57%. The pepsin digestion fragments at a concentration of 0.095 μg/mL were capable of binding 50% of the IgE epitopes bound by undigested MLC at 0.075 μg/mL, whereas the pancreatic digestion fragments had a 50% inhibition rate at concentrations up to 0.224 μg/mL. This indicates that pepsin digestion had little effect on the IgE-binding activity of MLC. However, the IgE-binding activity of MLC that had been digested by pancreatin over a period of 4 h was reduced compared with that of the undigested MLC sample.

Secondary Structure of Purified MLC. Far-UV CD spectra were examined to confirm the predicted structure of purified MLC and to evaluate the effects of different physicochemical conditions on the protein's secondary structure. As shown in Figure 4, the control curves (0 °C and pH 7.5) displayed two minima, around 222 and 208 nm, and one maximum around 190

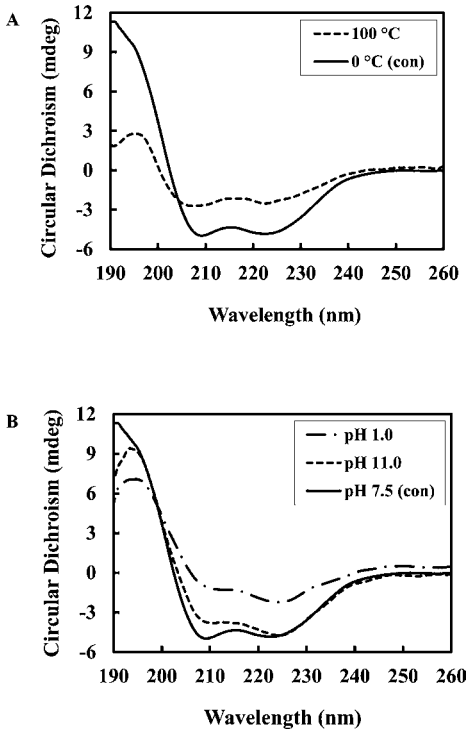

Figure 4. Effects of different experimental conditions on the stability of purified crayfish MLC1. (A) CD spectral analysis of MLC1 subjected to high temperature (100 °C, - - -) or 0 °C (—) as the control. (B) CD spectral analysis of MLC1 subjected to strong acid (pH 1.0, -·-·-); strong alkali (pH 11.0, - - -), or pH 7.5 (—) as the control.

nm, which are typical of α-helical secondary structures, although there was no fully canonical shapes that reflect the presence of other secondary structures, such as the extended strands, the β-turns, and/or the random coils. At 0 °C, the secondary structure was 33.5% α-helices, 16.2% extended strands, and 34.2% random coils. However, high-temperature treatments had a noticeable effect on the secondary structure, significantly increasing the extended strands (23.5%), which are characterized by a maximum at around 195 nm, and partially increasing the β-turns and/or the random coils (Figure 4A). Extended strands (25.6%) and random coils (39.3%) were also markedly increased after strong acid treatment, whereas strong alkali did not significantly increase the extended strands (19.2%) (Figure 4B). Among the different treatments tested, the secondary structure of purified crayfish MLC was most effectively altered by high temperature and strong acid.

Determination of the Predominant Epitope Type of Purified MLC. The IgE-binding activity of the purified crayfish MLC in folded form (with indirect ELISA and dot blot analysis, Figure 5A,B) was compared with MLC in its denatured, linear form (Western blot analysis, Figure 5C), with seven individual serum samples (nos. 749, 514, 974, 067, 785, 980, and 791) from crustacean-allergic patients and two sera from NA individuals that were pooled (nos. 780 and 981). With indirect ELISA (Figure 5A), the IgE from each of the seven sera bound to the native folded MLC, at least 2-fold higher than that of the negative control sera. In the dot blot analysis, all seven sera reacted with the native folded MLC, but no IgE-binding activity was detected in the negative control sera (Figure 5B). However, as shown in Figure 5C, only three sera (nos. 067, 785, and 791) reacted weakly to the denatured, linear MLC in the Western blot analysis. This indicates that the native folded MLC has higher IgE-binding activity than the denatured linear MLC.

Cloning and Sequencing MLC1. To identify the isoform of the purified MLC and to predict of the MLC structures, the *MLC1* gene was cloned. As shown in Figure 6A, the full-length gene sequence of crayfish *MLC1* is 1096 bp, including the ATG start codon at nucleotides (nt) 63−65, the TAA stop codon at nt 523−525, and the poly-A tail. The open reading frame of crayfish *MLC1* is 462 bp, and the predicted protein consisted of 153 amino acid residues, with a predicted molecular weight of 17.59 kDa by DNASTAR EditSeq software, which is equivalent to the ∼18 kDa molecular weight estimated with SDS−PAGE (Figure 1B). The protein has a predicted isoelectric point of 4.58 by DNASTAR EditSeq software. There are two potential N-glycosylation sites in the amino acid sequence of crayfish MLC1 (marked with a box in Figure 6A), which were identified by the conserved motif Asn−X−Ser/Thr/Cys. A protein sequence alignment showed that the MLC proteins from different crustacean species share high homology (Figure 6B). The amino acid sequence of crayfish MLC1 was 92.81% identical to the amino acid sequence of *C. crangon* MLC (gil238477331) and *M. japonicus* MLC (gil290908988), 84.97% to *Palaemon varians* MLC (gil238683675), 64.05% to *Periplaneta americana* MLC (gil 359326577), and 53.80% to *Artemia franciscana* MLC (gil 152013723).

Cloning and Sequencing MLC2. The *MLC2* gene was also cloned to distinguish between the isoforms of MLC. The full-length gene sequence of crayfish *MLC2* is 1362 bp, including the ATG start codon at nt 63−65, the TAA stop codon at nt 589−591, and the poly-A tail (Figure 6C). The open reading frame of crayfish *MLC2* is 528 bp, and the predicted protein consists of 175 amino acid residues, with a predicted molecular weight of 19.07 kDa and a predicted isoelectric point of 4.21 by DNASTAR EditSeq software. There is only one potential N-glycosylation site in the amino acid sequence of crayfish MLC2 (marked with a box in Figure 6C). A protein sequence alignment showed that the sequence homology of MLC1 and MLC2 is only 14.2%, whereas the MLC2 proteins of different crustacean species share relatively high homology (Figure 6D). The amino acid sequence of crayfish MLC2 is 62.92% identical to the amino acid sequence of *P. monodon* MLC2 (gil357640499) and *L. vannamei* MLC (gil 184198734).

Structural Modeling and Epitope Prediction in Crayfish MLC. The three-dimensional structure of crayfish MLC1 was determined based on its amino acid sequence by a homology model (template: 4QBD, 56.95% identity, Figure 7A). Crayfish MLC1 is mainly composed of α-helices (54.25%) and random coils (22.22%), with a few β-turns or extended strands analyzed by SOPMA secondary structure prediction. This is roughly consistent with the results of the CD spectral analysis. The conformational epitopes were identified with the DiscoTope 2.0 server, and the most likely regions included 10 discontinuous amino acid residues (25, 57−60, 96−99, and 136). The 10 predicted discontinuous epitope residues were molecularly mapped onto the three-dimensional structure of crayfish MLC1 and formed four conformational epitopes (labeled with slate in Figure 7B). The linear (continuous) epitopes of crayfish MLC1 were predicted with the DNASTAR Protean software based on its secondary structure. Three continuous regions (amino acid residues 53−58, 76−83, and 95−99) of linear epitopes occurred in the most hydrophilic, flexible, and surface-exposed regions and were shown in blue on the model of crayfish MLC1 (Figure 7C). Crayfish MLC2 is also mainly composed of

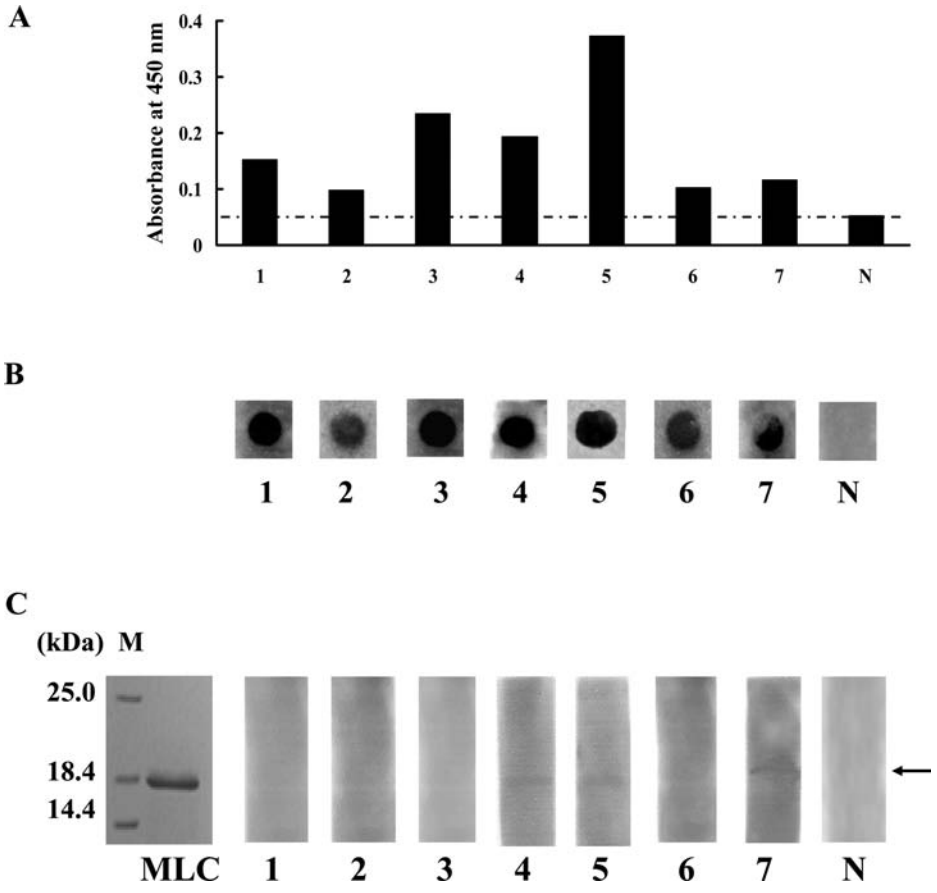

Figure 5. Comparison of IgE reactivity to native and denatured MLC from crayfish. 1−7: sera of seven crustacean-allergic patients (corresponding to serum nos. 749, 514, 974, 067, 785, 980, and 791); N: pooled sera from nonallergic individuals (nos. 780 and 981) as the negative control. (A) ELISA. (B) Dot blot. (C) Western blot. M, protein marker; MLC, SDS−PAGE analysis of the purified MLC.

α-helices (49.14%) and random coils (32.57%), with a few β-turns or extended strands. The most likely regions of conformational epitopes were 47 discontinuous residues (amino acid residues 31−32, 34−36, 38−39, 41−47, 49−71, 73−79, and 81−83), which composed a major conformational epitope. Three continuous regions (amino acid residues 5−11, 92−99, and 169−172) of linear epitopes were predicted (data not shown).

DISCUSSION

The growing international trade in crayfish has increased its popularity and the frequency of its consumption, which has been accompanied by an increase in the incidence of allergic diseases.[1,2] MLC was identified as a novel allergen in the white leg Pacific shrimp (*L. vannamei*),[18] the North Sea Shrimp (*C. crangon*),[10] and the black tiger prawn (*P. monodon*).[19] A previous study of crayfish TM demonstrated that an undefined myofibrillar protein, with a molecular mass about 18 kDa, had IgE-binding activity in the sera from crustacean-allergic patients.[9] It was inferred to be a new allergen in *P. clarkii*, although it is unclear whether this *P. clarkii* protein was MLC and, if so, which isoform it might be. This study was undertaken to determine whether this 18 kDa protein was MLC.

Few studies have purified native MLC for further analysis. In this study, the 18 kDa protein was purified by a combination of isoelectric precipitation, ammonium sulfate precipitation, ion exchange, and size exclusion chromatography and identified as MLC with MALDI-TOF-MS. The MLC content in muscle tissue is very low compared with the content of crayfish AK.[14] Only 11 sera from 137 sera collected from crayfish-allergic patients (which also had IgE-binding activity to other crustaceans) reacted with *P. clarkii* MLC in a serological assay. This indicates that MLC is a minor allergen in *P. clarkii* and may cross-react with the myofibrillar proteins of other crustaceans.

The molecular mass of crayfish MLC is 18 kDa, which is similar to that of *C. crangon* MLC, smaller than that of *L. vannamei* MLC (20 kDa), and larger than that of *P. monodon* MLC (16 kDa). It is interesting that the cloned sequence of the purified MLC was highly homologous to *C. crangon* MLC (Figure 6B), whereas *L. vannamei* MLC (gil184198734) was only 13.11% identical and *P. monodon* MLC (gil357640499) only 13.97% identical to the purified MLC, whereas the *L. vannamei* and *P. monodon* MLCs were 62.92% identical to MLC2 from *P. clarkii* (gil392499121). This indicates that the purified MLCs from *P. clarkii* and MLC from *C. crangon* are MLC1, and that the MLCs from *L. vannamei* and *P. monodon* are MLC2. Because MLC1 is the essential light chain and MLC2 is the regulatory light chain, further studies should be performed to determine whether MLC2 in *P. clarkii* is also allergenic and to compare the allergenic properties of MLC1 and MLC2.

Most food allergens share similar physicochemical characteristics in that they are glycoproteins, relatively stable to heat and acid−alkali, and may remain allergenic after digestion.[14] In this study, the total carbohydrate content of MLC1 was about 4.3 ± 0.05% (w/w) of the whole protein. Two identical potential N-glycosylated sites (Asn−Gly−Thr) were identified by analyzing

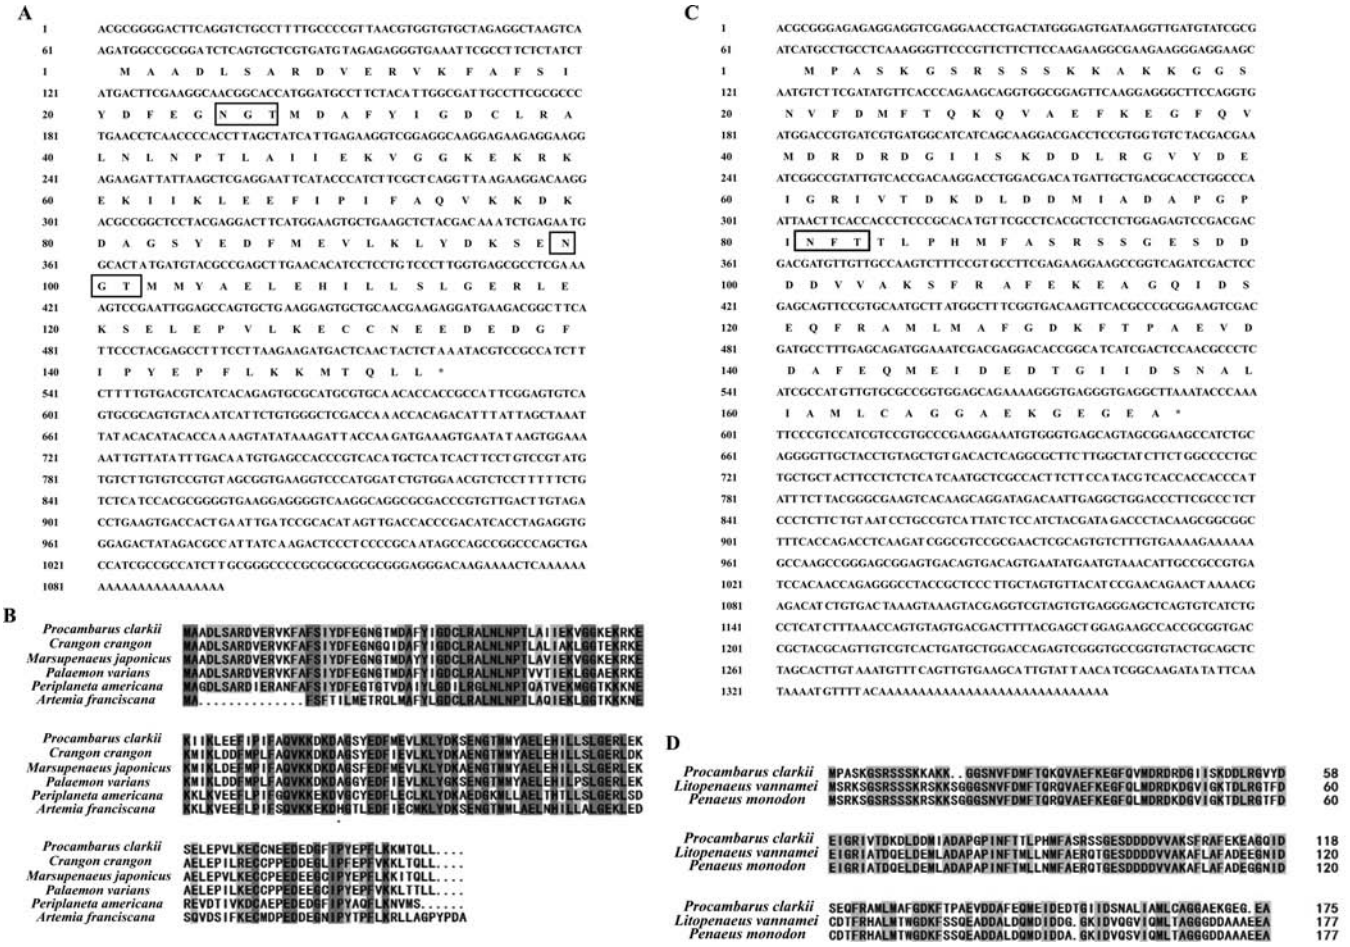

Figure 6. Cloning *MLC* genes and sequence alignment of crayfish MLC proteins. (A) Nucleotide and deduced amino acid sequences of crayfish MLC1 (the N-glycosylation site is marked with a box). (B) Sequence alignment of crayfish MLC1 and the MLC proteins of other crustaceans. (C) Nucleotide and deduced amino acid sequences of crayfish MLC2 (the N-glycosylation site is marked with a box). (D) Sequence alignment of crayfish MLC2 and the MLC proteins of other crustaceans.

the primary structure and mass spectra of the protein. The carbohydrates in crayfish SCP are reported to constitute about 4.9% of the protein, with one N-glycosylation site. MLC and SCP have reportedly similar characteristics, and data in this report support this conclusion.[6,18] An O-linked glycan in the MLC1 structure was detected with β-elimination. The O-glycan, which occurs in clusters along short regions of the peptide chain that contain repeating units of Ser and Thr, is unstable under alkaline conditions at low temperature. After NaOH treatment, Ser and Thr are transformed into α-amino acids. Both of these unsaturated amino acids display characteristic UV absorption at 240 nm.[6] According to the typical characterization of glycoproteins, MLC1 is a glycoprotein. N- and O-linked allergenic glycoproteins, which have common core structures, are associated with the induction of an IgE response in allergic patients.[30] The N-glycosylated sites of MLC1 were partially at the predicted epitope regions (amino acid residues 25 and 99). Therefore, the relationship between the allergenicity and glycosylation of crayfish MLC1 warrants further research.

In this study, MLC1 was stable at 30−100 °C and under strongly acidic and alkaline conditions and retained its IgE-binding activity at different temperatures and pH value. In contrast, a study by Kamath et al.[19] demonstrated that IgE binding to MLC of *P. monodon* was only detected in heated prawn extract and not in raw prawn extract. It was inferred that the thermal stability of MLC1 differs from that of MLC2. The thermal stability and pH stability of crayfish MLC1 were similar to those of TM, another myofibrillar protein and the major allergen of shellfish, which is stable under acidic and alkaline conditions and retains its IgE-binding activity after high-temperature and high-pressure processing.[31] However, the IgE-binding activities of crayfish myosinogens AK and SCP are reduced at high temperatures or under different acidic or alkaline conditions.[6,14] It has been reported that, under different physiological and experimental conditions, some allergens may undergo conformational changes that cause the exposure of different combinations of epitopes recognized by the IgE antibodies of allergic subjects.[18] In this study, the changes in the secondary structure of crayfish MLC1 under severe conditions, including high temperature (100 °C), strong acid (pH 1.0), and strong alkali (pH 11.0), were assessed to observe the changes in its secondary structure. High temperature and strong acid treatments had significant effects on the secondary structure of MLC1, but its IgE-binding activity remained intact despite the changes in its structure. A future study should focus on effective processing methods to mask or disrupt the IgE epitopes. Food allergens generally remain intact during gastrointestinal digestion. Crayfish MLC1 appeared to be more resistant to gastric digestion than to intestinal digestion and retained its immunological activity (detected with ciELISA).

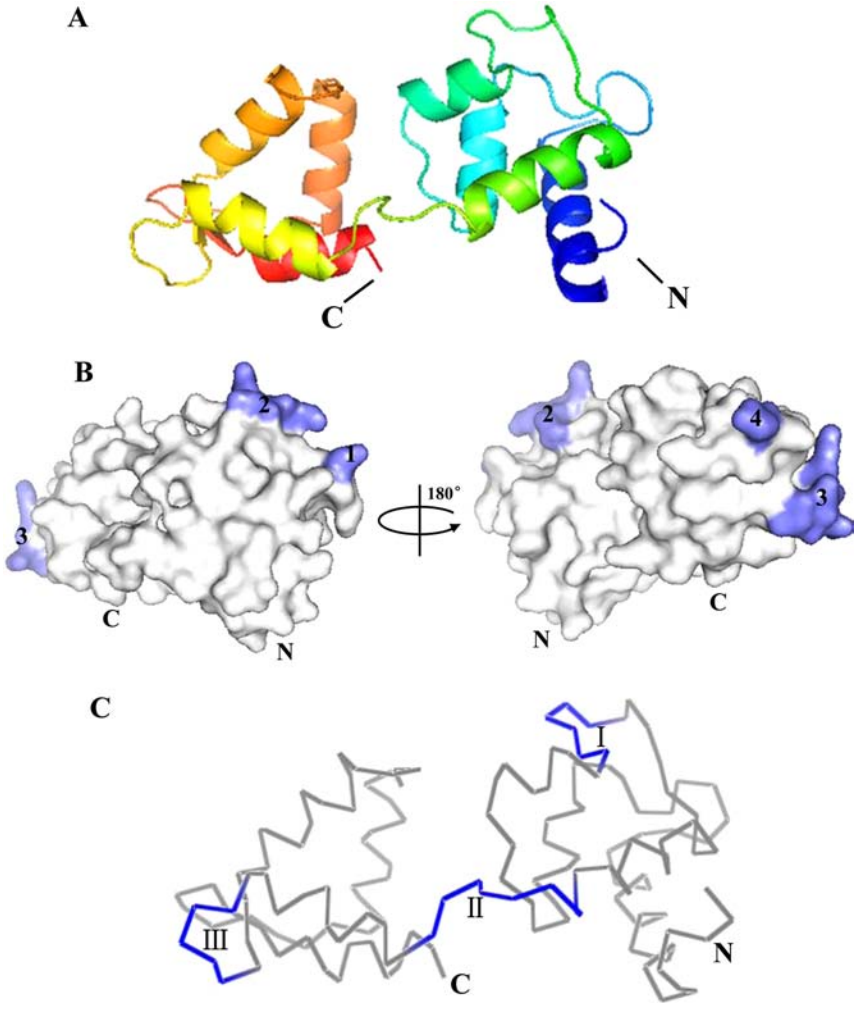

Figure 7. Structural modeling and epitope prediction of crayfish MLC1. (A) Three-dimensional structure of crayfish MLC1. N and C indicate the N- and C-termini, respectively. (B) Molecular mapping of the conformational epitopes of crayfish MLC1 onto its three-dimensional structure. The areas occupied by the conformational epitopes are shown in slate. Epitopes 1−4 are Asn^{25}, Lys^{57}−Glu^{60}, Lys^{96}−Asn^{99}, and Glu^{136}, respectively. (C) Molecular mapping of the linear epitopes of crayfish MLC1 onto its three-dimensional structure. The areas occupied by the linear epitopes are shown in blue. Epitopes I−III, Gly^{53}−Arg^{58}, Lys^{76}−Ser^{83}, and Asp^{95}−Asn^{99}, respectively.

Interestingly, MLC1 was degraded after gastrointestinal digestion, but the degraded fragments had IgE-binding activity almost equivalent to that of the undigested MLC1 sample. In a previous study, crayfish AK and SCP were also degraded to varying degrees by gastrointestinal digestion but remained immunologically active.[6,14] Certain IgE-binding sites on crayfish MLC1 are thought to be left intact by digestive enzymes, and the major IgE-binding sites of allergens in crayfish are stable after digestion. It was reported that Ca^{2+} binding was essential for the formation of the conformation structure of calcium-binding proteins like parvalbumin, and the depletion of Ca^{2+} resulted in the reduction of IgE-binding activity.[32,33] MLC belongs to the EF-hand superfamily, and the influences of Ca^{2+} on the structure of MLC and its allergenicity need further research.

The epitopes can be classified as continuous or discontinuous. Continuous epitopes can be identified in denatured proteins and peptide fragments, whereas discontinuous epitopes depend on the higher-order structures of the native protein.[34] The study of epitopes is critical to understanding the nature of allergens and the improvement of diagnosis, detection, and therapies. To determine the predominant IgE epitope type in crayfish MLC1, indirect ELISA and dot blot analysis were performed on folded MLC1 and Western blot analysis was performed on the unfolded MLC1 with sera from allergic individuals. In both the indirect ELISA and the dot blot analysis, the native MLC1 was immobilized on the plate or a nitrocellulose membrane, respectively. In both of these assays, the folded MLC1 was found to maintain IgE binding under high heat and different pH conditions for all allergic sera tested. In the Western blot, where MLC1 was in denatured or linear form, only the serum IgE from three allergic individuals displayed weakly positive binding. These results imply that the conformational epitopes of MLC1 are predominantly recognized by IgE, rather than the linear epitopes. Considering that the IgE binding by unfolded MLC1 is significantly reduced compared to the folded MLC1, it is possible that the digested fragments retain some structural features that are able to compete with intact MLC1 for IgE binding.

The conformational and linear epitopes of the crayfish MLCs were also predicted in silico. MLC1 was predicted to contain four conformation epitopes and three linear epitopes, and the regions formed by amino acids 57−60 and 96−99 contained both conformational and linear epitopes. MLC2 also showed a major predicted conformational epitope and three linear epitopes. MLC2 clearly was predicted to have more epitopes than MLC1,

DOI: 10.1021/acs.jafc.5b01318
J. Agric. Food Chem. 2015, 63, 6271−6282

but it was not recognized by the IgE in sera from crustacean-allergic patients in a previous study. However, in future studies, it will be important to investigate IgE binding to MLC2 with the same patient sera used in this study for MLC1. Fundamental studies of allergens focus on IgE-binding epitopes, which are used as biomarkers to predict the clinical reactivity of subjects who are sensitized to a specific food, and provide alternative immunotherapeutic strategies.[35] If some parallels can be found between predicted and the experimental IgE-binding patterns, perhaps efforts to reduce the allergenicity of food and diagnostic tools may be improved via epitope prediction tools. Also, recombinant MLC1 and MLC 2 can be used to aid in clinical diagnoses and in further research to provide basic information for the hypersensitization to crayfish and the evaluation of food allergies.

human hydrolyzed plasma was <67 nM for enterolignans and <1 nM for plant lignans. The concentration of lignans in hydrolyzed pig plasma was <2 nM for enterolactone and close to zero for plant lignans and enterodiol.

Test Urine. The concentrations of lignans in unhydrolyzed and hydrolyzed human urine were <3.4 and 100 nM for enterolignans and <0.05 and 17 nM for plant lignans, respectively. Unhydrolyzed urine from pigs contained only traces of lignans. The concentration of lignans in hydrolyzed pig urine was <6.7 nM for enterolactone and <0.2 nM for enterodiol and plant lignans.

Sample Hydrolysis. Plasma samples of 0.5 mL were treated with 1 mL of freshly dissolved β-glucuronidase (≥300000 units/g solid)/sulfatase (≥10000 units/g solid) (2 mg/mL in 50 mM sodium acetate buffer, pH 5) and incubated in a shaker at 37 °C in 19 h according to the method of Smeds et al.[9] Urine samples of 0.25 mL used for the quantitation of plant lignans and 2.5 μL for the quantitation of enterolignans were also treated with 1 mL of β-glucuronidase (2 mg/mL in 50 mM sodium acetate buffer, pH 5) and incubated in a shaker at 37 °C in 19 h. The optimal hydrolysis time for urine samples was determined by incubating samples for longer and shorter periods of time, where 19 h was the time at which lignans reached their maximal concentration. After incubation, 1 mL of 0.2% of formic acid was added, and the samples were centrifuged for 15 min at 4 °C at 60*g* and then ready for solid phase extraction (SPE).

SPE Cleanup of Plasma and Urine. Samples were cleaned up using SPE C18-E columns or SPE C18-E 96-well plates from Phenomenex (Torrance, CA, USA). The SPE method included conditioning, washing, and elution of lignans. The C18-E column or 96-well plate was conditioned with acetonitrile and then with water. Afterward, the samples were loaded and allowed to elute slowly through the C18 material. The column or plate was then washed with 0.5 mL of 5% methanol for plasma or with 20% methanol for urine. Lignans from plasma and urine were eluted with 150 and 300 μL of 100% acetonitrile, respectively. The eluted samples were then diluted to 25% acetonitrile with 450 and 900 μL of water containing glycocholic acid (glycine-1^{13}C) as IS. A final concentration of IS was 20 ng/mL. IS was used for autosampler correction and matrix effects validation. Samples were spun at 10 °C for 5 min prior to LC-MS/MS measurements.

LC-MS/MS Equipment and Method. The LC-MS/MS measurements were performed on a microLC 200 series from Eksigent/AB Sciex (Redwood City, CA, USA) and QTrap 5500 mass spectrometer from AB Sciex (Framingham, MA, USA). The mass spectrometer was equipped with an ESI source. The microLC was equipped with an Ascentis C18 column, 100 mm × 1.0 mm with 3.0 μm partical size from Sigma-Aldrich. The LC conditions were as follows: Eluent A consisted of water with 0.1% formic acid and eluent B was acetonitrile with 0.1% formic acid. The column was equilibrated for 3 min. The gradient started at 75% eluent A and 25% eluent B, was held constant for 1 min, then increased to 85% eluent B during 3.3 min and kept constant for 0.5 min. The total run time was 7.8 min. The autosampler racks were kept at 10 °C, and the column oven was set to 23 °C. Negative mode was used for ionization. The flow injection analysis (FIA) was performed to optimize the turbo V source of the instrument, where curtain gas was set to 20 psig, nebulizer gas (gas1) to 50 psig, heater gas (gas2) to 60 psig, and temperature to 300 °C and ionization spray was operated at −4500 eV. Deprotonated molecules were detected in MRM mode. The compound-dependent parameters were optimized for each lignan by syringe infusion of pure standard and are shown in Table 1. Data analysis was performed in Analyst software 1.6 from AB Sciex.

Calibration Curves. Calibration curves had 7−12 points depending on the analyte. The mixture of pure solvents was prepared in 25% acetonitrile in the range of 0.0244−100 ng/mL. IS was added to the calibration curves at a final concentration of 20 ng/mL. The analyte/internal standard concentration ratio was plotted against the analyte/internal standard peak area ratio as a linear regression curve with $1/x$ weighting.

Accuracy, Precision, and Recovery. The accuracy, precision, and recovery of the lignans were tested at three concentrations, low, medium, and high, using five measurements per concentration. Plasma samples were tested at 0.0977, 1.56, and 50 ng/mL, respectively. Urine samples were tested at 0.39, 1.56, and 50 ng/mL, respectively. For determination of the accuracy and precision at low and medium concentrations, the unhydrolyzed plasma and urine were spiked with standards after SPE extraction, whereas at high concentration hydrolyzed plasma and urine were used. Recoveries of the lignans were determined by spiking plasma and urine with standards prior to enzymatic hydrolysis and SPE using unhydrolyzed plasma and urine for low and medium concentrations and hydrolyzed plasma and urine for high concentration. Blank hydrolyzed or unhydrolyzed plasma and urine were used to subtract the background during the calculations. Quality control (QC) samples were used to validate the interbatch variation. Ten QC samples were used for each run.

Table 1. Compound-Dependent LC-MS/MS Parameters: Declustering Potential (DP), Entrance Potential (EP), Collision Energy (CE), and Cell Exit Potential (CEP)

	Q1 mass (m/z)	Q3 mass (m/z)	DP (V)	EP (V)	CE (eV)	CEP (V)
enterolactone	297.1	189.1	−140	−10	−26	−21
enterodiol	301.1	253.1	−140	−10	−32	−19
matairesinol	357.2	82.9	−145	−10	−26	−7
hydroxymatairesinol	373.1	217.1	−115	−10	−32	−13
secoisolariciresinol	361.2	165.0	−150	−10	−34	−11
lariciresinol	359.1	329.0	−40	−10	−16	−21
isolariciresinol	359.2	344.0	−165	−10	−26	−31
pinoresinol	357.2	151.0	−155	−10	−24	−11
syringaresinol	417.1	181.0	−170	−10	−26	−13
medioresinol	387.2	151.0	−15	−10	−26	−25

Statistics. The accuracy describes the percentage deviation of the mean from the true value. Accuracy was calculated as relative error (ER) of replicated measurements, with acceptance criteria that it should not deviate by >±20% at low concentration or by >±15% at medium and high concentrations. The precision describes the closeness of individual measurements of an analyte applied to the multiple samples. Precision was calculated as relative standard deviation (RSD), where it should not exceed by >20% at low concentration or by >15% at medium and high concentrations. The recovery of the analyte represents the amount of the analyte recovered after the sample preparation procedure. Recovery was calculated as a percentage of the analyte recovered after the SPE procedure. The interbatch precision was validated using QC samples, which can provide the bases of accepting or rejecting the run. The acceptance criterion was that at least 67% of QC samples were within an RSD of 15%. Matrix effects were investigated by calculating the matrix factor (MF) for lignan and IS as the ratio between the peak area in the presence of matrix and in the absence of matrix. If the ratio was close to 100%, no ion suppression had occurred. The IS-normalized MF was calculated by dividing the MF of the analyte with the MF of the IS. The RSD of the IS-normalized MF should not exceed >15%.

Method Validation. The method was validated according to the guidelines of the U.S. Food and Drug Administration (FDA)[12] and European Medicines Agency of Science Medicines Health.[13]

RESULTS

SPE Cleanup. The sample cleanup procedure presented in this paper was developed and optimized for both low and high numbers of plasma and urine samples. Therefore, both single SPE C18 columns and SPE C18 plates can be used. The sample cleanup was kept as simple as possible to minimize transfer losses and labor time involved. A simplified sample cleanup procedure is far more amenable for a high throughput of samples.

Chromatographic Analysis. Chromatographic parameters were optimized to achieve high resolution and efficiency at

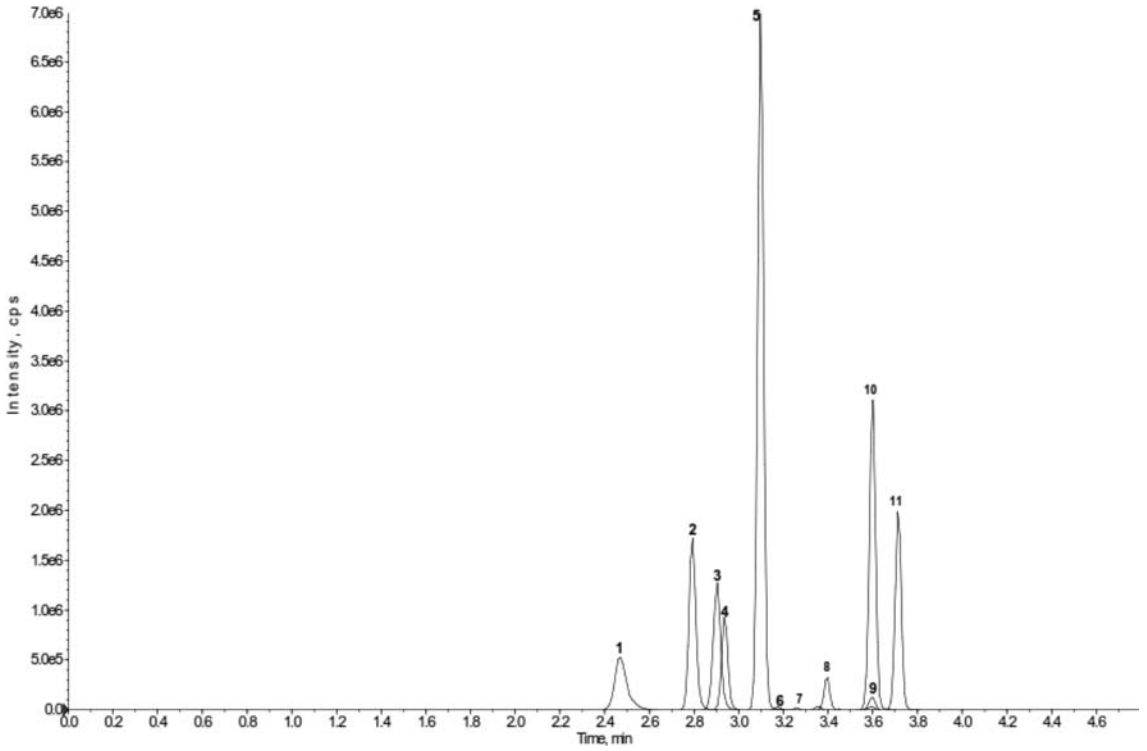

Figure 1. Typical MRM chromatogram of lignan standards at 50 ng/mL. Peaks: 1, isolariciresinol, RT 2.47 min; 2, secoisolariciresinol, RT 2.79 min; 3, hydroxymatairesinol, RT 2.90 min; 4, lariciresinol, RT 2.94 min; 5, enterodiol, RT 3.10 min; 6, syringaresinol, RT 3.17 min; 7, medioresinol, RT 3.26 min; 8, internal standard, RT 3.40 min; 9, pinoresinol, RT 3.60 min; 10, matairesinol, RT 3.60 min; 11, enterolactone, RT 3.71 min.

minimum run time. Good chromatographic separation was achieved at a short run time of 4.8 min, which is desirable when the number of samples is high. Only 2 of 10 lignans had similar retention times (RT) (Figure 1). Isolariciresinol had the lowest affinity to the C18 column, as indicated by the broader peak shape compared to the other lignans. Isolariciresinol was also the first lignan, eluting at 2.47 min, followed by secoisolariciresinol with RT of 2.79 min (Figure 1). Variation in the RT was negligible, with interbatch variation of <6 s. However, column-to-column variation of 10 s was observed. The chromatographic method was optimized using the standards prepared for the standard curve. These series of standards were also used to ensure the reproducibility of the chromatographic method and MS performance and were run each intra- and interbatch. No carry-over effect was observed when running blank samples containing only solvent and zero samples containing the solvent and the internal standard (data not shown). Zero samples also ensured the reproducibility of the IS.

Method Validation. *Quantitative Validation.* Calibration curves of pure standards were used to quantitate unknown concentrations of lignans in plasma and urine. The calibration curves generally consisted of 11 or 12 points; however, in the case of pinoresinol, syringaresinol, and medioresinol, they consisted of 7−10 points. The lower limit of quantitation (LLOQ) was accepted as the lowest standard on the calibration curve if the analyte response was at least 5 times the response of the blank sample. The highest standard defined the upper limit of quantitation (ULOQ). All calibration curves showed good linearity throughout the used range of concentration with LLOQ accuracy varying from 85 to 97% and precision below 20% and ULOQ accuracy from 90 to 105% and precision below 15%. The LLOQ and ULOQ and the corresponding regression coefficients for each lignan are listed in Table 2.

Table 2. Lower Limit of Quantitation (LLOQ) and Upper Limit of Quantitation (ULOQ) and Their Corresponding Regression Coefficients (r)

	LLOQ, nM (ng/mL)	ULOQ, nM (ng/mL)	r
enterolactone	0.16 (0.048)	167.6 (50)	0.9993
enterodiol	0.081 (0.024)	165.4 (50)	0.9997
matairesinol	0.068 (0.024)	139.5 (50)	0.9997
hydroxymatairesinol	0.13 (0.048)	133.6 (50)	0.9992
secoisolariciresinol	0.067 (0.024)	138.0 (50)	0.9997
lariciresinol	0.14 (0.048)	277.5 (100)	0.9996
isolariciresinol	0.068 (0.024)	277.5 (100)	0.9998
pinoresinol	0.27 (0.0975)	279.9 (100)	0.9994
syringaresinol	1.9 (0.78)	239.0 (100)	0.9977
medioresinol	4.0 (1.56)	257.5 (100)	0.998

Matrix Effect Validation. Ion suppression of ESI in MS instruments is a well-known problem. Several methods can be used for the validation of ion suppression due to matrix effects. Because both hydrolyzed and unhydrolyzed plasma and urine contained lignans in different concentrations, which would complicate the standard curve calculations, it was decided to use standards of three concentrations spiked into the pure solvent and SPE extracted plasma and urine. This experiment established that any matrix effect on the analyte response was corrected by a corresponding decrease in the IS response and thus permitted the use of calibration curves in pure solvent. Even though the IS corrected for possible matrix effects, the matrix factor (MF) was calculated for each lignan and IS (data not shown). Furthermore, the average MF was calculated for IS of human and pig plasma and urine and used as a measure indicating the influence of the matrix on the ionization of

DOI: 10.1021/acs.jafc.5b01275
J. Agric. Food Chem. 2015, 63, 6283−6292

lignans. The MFs for human and pig plasma were 99 and 98%, respectively, showing that no ion suppression had occurred. The MF of hydrolyzed versus unhydrolyzed plasma was also compared, but no differences were observed. In the case of enterolignans in urine the MF was close to 100%, whereas it was more variable when plant lignans were measured. Because 10 times more sample volume was used for measuring the plant lignans, variation in MF between the human and pig urine and unhydrolyzed versus hydrolyzed urine was observed. The MFs of the human hydrolyzed and unhydrolyzed urine were 90 and 69%, respectively. The MFs of the pig hydrolyzed and unhydrolyzed urine were 82 and 72%, respectively. The RSD of the IS normalized MF was then calculated for each of the three concentrations of human and pig urine and found to be not greater than 15%.

Accuracy, Precision, and Recovery. The accuracy, precision, and recovery were the main parameters used for the validation of the method. They were tested by the addition of the standards at three concentrations, low, medium, and high (Tables 3 and 4). The low concentration of plasma was chosen as 3 times the LLOQ of the standard curve, and in the case of urine 5 times the LLOQ was chosen, due to higher concentrations of lignans in the test urine. Because the ULOQ was set to 100 ng/mL, the high concentration was selected as the second highest concentration on the standard curve. In the case of precision and accuracy the standards were added to plasma and urine after the SPE procedure to be able to test the matrix effects and overall instrument performance. With regard to recovery of the lignans, the standards were added before the enzymatic hydrolysis and SPE procedure to test the affinity of the lignans to the SPE sorbent. In general, the results in Tables 3 and 4 show good or acceptable accuracy, precision, and recovery for all of the lignans tested in this study.

In the case of plasma (Table 3), the accuracy varied from −2.4% for hydroxymatairesinol to 12.7 and 8.9% for enterolactone and enterodiol, respectively, for human plasma at low concentration. This was opposite for pig plasma, where enterodiol and enterolactone showed the best accuracies of 1.6 and 4.7%, respectively, whereas secoisolariciresinol and hydroxymatairesinol had accuracies of 20 and 16.9%, respectively. At medium and high concentrations the method showed good or acceptable accuracy and precision, which was lower than the acceptance criteria of ±15%. Also, high or acceptable recoveries were observed for all of the lignans for human and pig plasma at all three concentrations.

In the case of urine (Table 4), the precision and accuracy of plant lignans, when corrected by the IS, were acceptable even though some ion suppression due to matrix effect had occurred. The concentration of enterolactone in human urine was too high to be able to calculate accuracy, precision, and recovery at low concentration. In general, the recoveries for enterolactone and enterodiol were high at all three concentrations, whereas in the case of plant lignans recoveries at high concentration were slightly lower compared to low and medium concentrations.

Selectivity and Sensitivity. Panels A and B of Figure 2 show the selectivity of the method in both human test plasma and urine spiked with low concentration of standards for all lignans except pinoresinol, syringaresinol, and medioresinol, where spiked concentrations were medium and high, respectively. A high selectivity of the method was demonstrated for plasma samples, where low background with no interfering peaks was observed (Figure 2A). Only a few additional peaks were visible for isolariciresinol, hydroxymatairesinol, lariciresinol, and

[a]Not quantitated.

syringaresinol. Similar high selectivity was observed for pig plasma (data not shown). In the case of urine higher background and more additional peaks were visible on the chromatograms compared to plasma (Figure 2B). However, no peaks interfered with the signal of the analytes. Moreover, a very low noise level at around 100−700 cps in intensity for plasma and around 200−1500 cps in intensity in the case of urine (Figure 3) increased the sensitivity of the method, allowing quantitation at low concentrations, as described in the quantitative validation section. No difference in noise level or number of additional/interfering peaks was observed for unhydrolyzed versus hydrolyzed plasma (data not shown).

Standard Stability. Repeated analyses of the standard curve over a 3 month period showed that the standards were stable for at least 1 month. Short-term stability of IS in water was also tested by comparison of the IS areas from 4 to 24 h. The result indicated that IS was stable for at least 1 day.

Real Sample Analyses. The applicability of the developed LC-MS/MS method was verified by measuring plant lignans and enterolignans in human and pig plasma and urine from two ongoing studies. Human plasma and urine were obtained from a Nordic lifestyle intervention study involving 24 men with early-stage prostate cancer, where 16 male participants were prescribed a high-lignan diet (HLD, based on whole grain rye) and 8 were used as control and were provided a low-lignan diet (LLD, based on refined wheat) during 6 months. Participants in the HLD group were prescribed 1200 g of whole grain rye per week. The detailed explanation of the intervention is described elsewhere.[14,15] The pig plasma and urine were collected from 10 pigs kept on HLD (based on whole grain rye) and 10 pigs kept on LLD (based on refined wheat) for 3 weeks and 1 week of wash-out LLD in the beginning of the study. Details of this study will be presented elsewhere. The samples from these two studies were run in batches together with 10 QC samples for each batch. Interbatch precision of pig plasma and urine was measured using QC samples of low and high concentrations, whereas in the case of human plasma and urine only one concentration was used (Table 5). The acceptance criterion of RSD of 15% was fulfilled in all cases except one; hydroxymatairesinol, at low concentration, had an RSD of 24.2%. However, this is in agreement with the low recovery and high deviation for this lignan in pig plasma at low concentration previously described under Method Validation. The results of human and pig studies are presented in Table 6. Furthermore, Figures 4 and 5 demonstrate MRM chromatograms of lignans in one of the plasma and urine samples from humans and pigs.

DISCUSSION

SPE Cleanup. One of the advantages of our developed cleanup procedure is the possibility to prepare both urine and plasma samples on the same SPE plate because the procedures are similar. Another simplification of the developed cleanup procedure is that no evaporation or resuspension of the extracted sample is necessary prior to LC-MS/MS, compared to the previously reported SPE methods.[7−9,16,17] After extraction of the analytes from the SPE plate or column, the samples can be diluted and analyzed directly on the LC-MS/MS instrument. Evaporation of the sample is usually time-consuming, and resuspension can contribute to the losses of the analytes.

Chromatographic Analysis. The separation of lignans was achieved with a run time of only 4.8 min, the lowest run time reported so far.[7−9,18] For comparison, Smeds et al.[8,9] reported

DOI: 10.1021/acs.jafc.5b01275
J. Agric. Food Chem. 2015, 63, 6283−6292

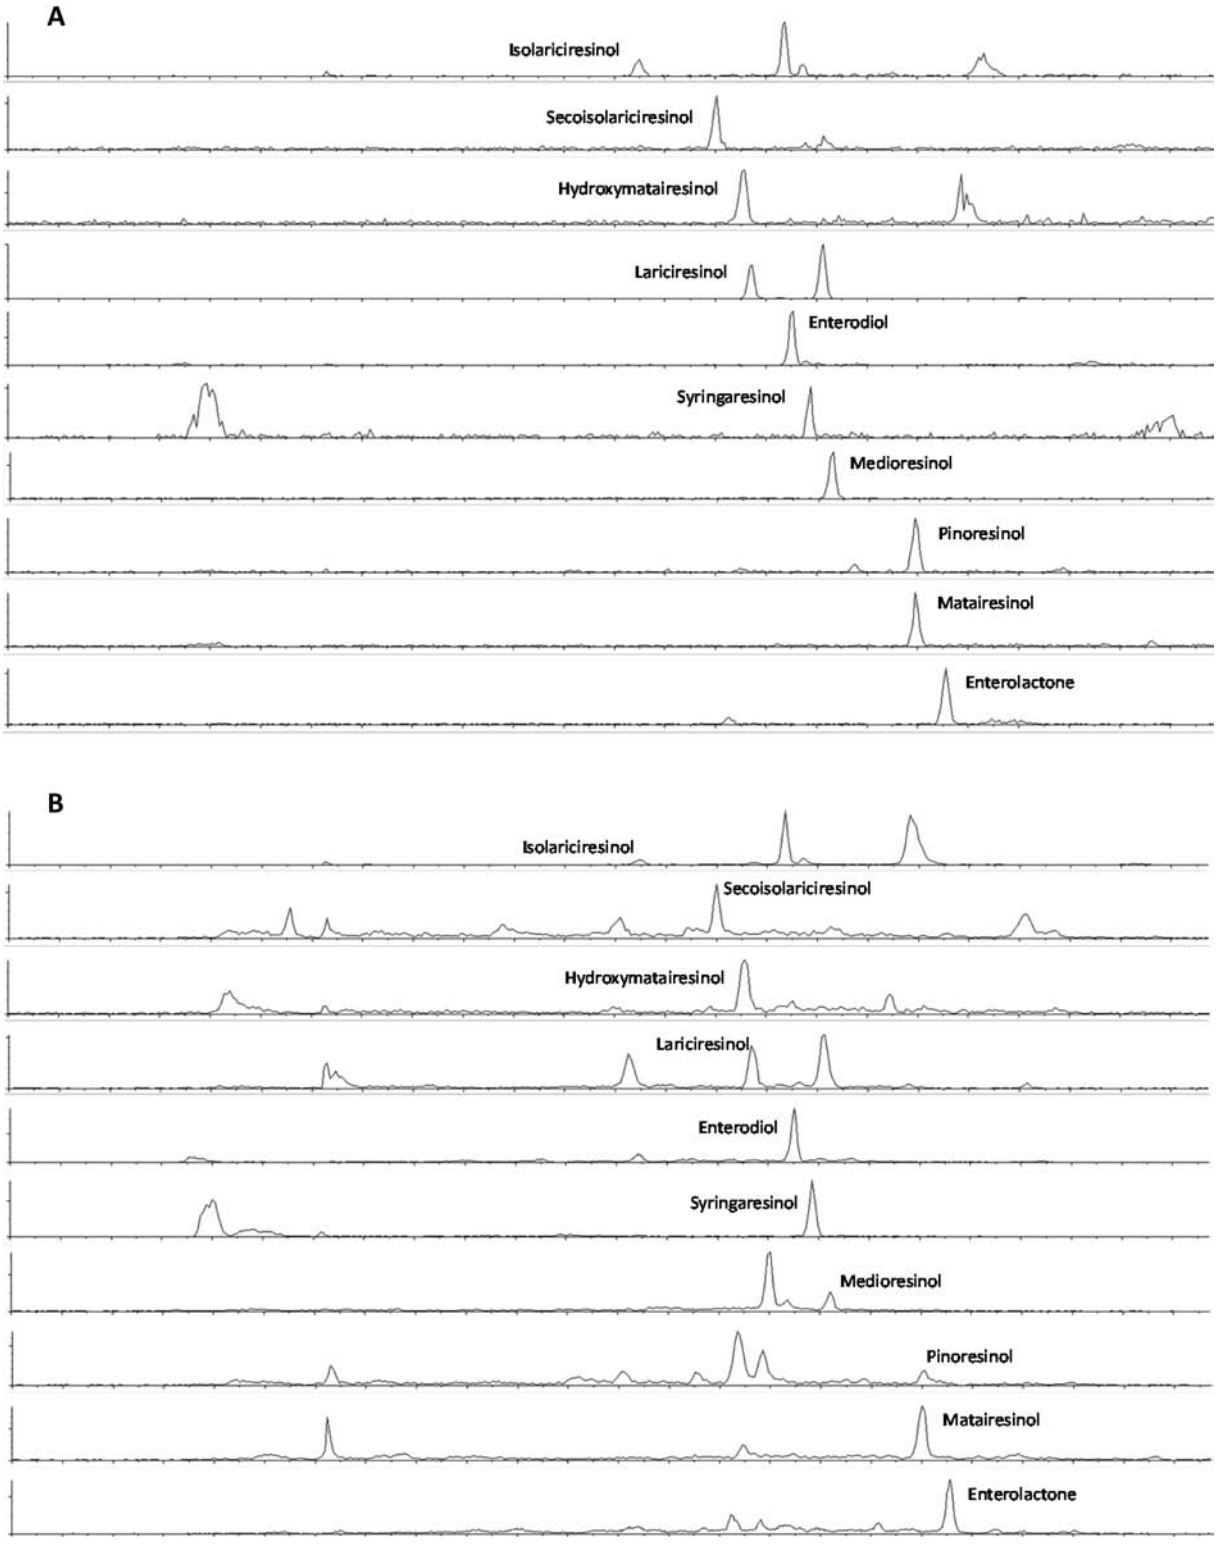

Figure 2. MRM chromatogram of lignans in test plasma spiked with 0.0977 ng/mL of standards for all lignans except pinoresinol, syringaresinol, and medioresinol, where spiked concentrations were 1.56 and 50 ng/mL respectively (A). Extracted ion MRM chromatogram of lignans in test urine spiked with 0.39 ng/mL of standards for all lignans except pinoresinol, syringaresinol, and medioresinol, where spiked concentrations were 1.56 and 50 ng/mL, respectively (B).

run times of 17 and 18 min to separate similar numbers of lignans. However, shorter run times were reported for separation of phytoestrogens in human serum[10] and urine,[11] where only enterolignans were included. The low run time is favorable when large numbers of samples are analyzed, which can effectively minimize the analytical time and therefore decrease the cost of analyses.

Method Validation. *Quantitative Validation.* The sensitivity of the method was demonstrated by low LLOQ and low noise level of the blank test plasma and urine. The sensitivity

was 10−100 times higher depending on the lignan analyzed compared to the previously reported LC-MS/MS method of Smeds et al.[9] This was achieved without the need for concentrating the sample during the SPE procedure; on the contrary, the samples were diluted four times. This improved sensitivity is probably due to the use of the most recent LC-MS/MS system in our laboratory compared to the methods reported nearly 10 years ago. However, newer LC-MS/MS methods recently reported for the determination of phytoestrogens in human serum and urine did not show similar sensitivity either.[10,11] Prasain et al.[10] measured enterolignans in serum at LLOQ of 1 ng/mL, which is >10 times higher than LLOQ of our method. Moreover, to our knowledge no LC-MS/MS method has been published before on the quantitation of pinoresinol, syringaresinol, and medioresinol in plasma and urine. However, the LLOQ for syringaresinol and medioresinol was much higher compared to that of other plant lignans, and therefore syringaresinol was only possible to measure in urine, whereas medioresinol could not be measured in plasma or in urine.

Matrix Effects and Selectivity. Matrix-based and solvent-based calibration curves can be constructed to analyze the matrix effects on the instrument response[7,19] or to analyze the standards at three concentrations both dissolved in solvent and spiked into SPE extracted plasma and urine.[9,20] On the basis of the results of the spiking experiment, no matrix effects were detected for hydrolyzed or unhydrolyzed human and pig plasma, which is in agreement with previous analyses of human plasma reported by Smeds et al.[8,9] The selectivity was not

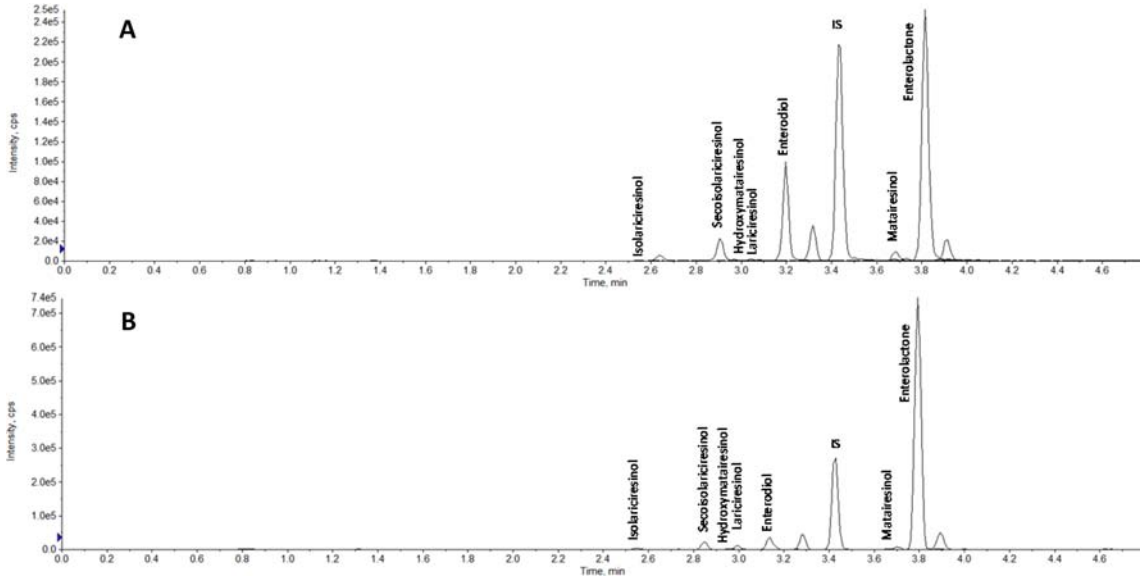

Figure 4. MRM chromatogram of lignans in one human plasma sample (A) and one pig plasma sample (B) from real sample analyses.

affected by hydrolysis of the plasma, where no additional or interfering peaks were observed. Prasain et al.[10] had detected minor to moderate matrix effects when analyzing phytoestrogens in serum. In our study, we measured minor to moderate matrix effects when analyzing plant lignans in urine. Moreover, a difference in matrix effects between hydrolyzed and unhydrolyzed urine was also measured. Our result showed that less ion suppression occurred after hydrolysis of the urine sample. However, no difference in the noise level or selectivity was observed for hydrolyzed/unhydrolyzed urine. To minimize the matrix effects in urine when plant lignans are measured, it is possible to use less sample volume.

Accuracy, Precision, and Recovery. In general, the accuracy and precision of this method for plasma and urine at low, medium, and high concentrations were good or acceptable. As expected, at the low concentration the accuracy and precision had higher deviation compared to the medium and high concentrations. Valentin-Blasini et al.[7] have also reported that the accuracy of their method increased with increasing analyte concentration.

In the case of plasma, at high concentration the accuracy was very good with an ER of only 0.1−4.7% in human plasma and 1.1−5.7% in pig plasma. Similarly, precision was also high at high concentration. At low concentration higher variation was observed among the lignans; also, the differences between human and pig plasma were greater. For example, in the case of enterodiol and enterolactone, the difference between the accuracy of these lignans in human versus pig plasma can probably be explained by the fact that no enterodiol and enterolactone were detected in unhydrolyzed test pig plasma, whereas traces of this compound were detected in human unhydrolyzed test plasma. The opposite situation was observed for hydroxymatairesinol, where low concentration of this compound was detected in both hydrolyzed and unhydrolyzed test pig plasma and no hydroxymatairesinol was detected in human test plasma.

Recoveries of enterolactone and enterodiol were high, not lower than 90% for human plasma and 80% for pig plasma. These data are comparable to previously reported recoveries for enterolignans by others using GC-MS, LC-MS, and LC with coulometric electrode array detector.[7−9,18,19,21] Lower recoveries of 68−91% for enterolignans in human plasma were reported by Nurmi et al.[22] using LC with coulometric electrode array detector and in serum by Prasain et al.[10] Recoveries for plant lignans in plasma were more varied, with the lowest recovery for hydroxymatairesinol, 63.9−94.6% for human plasma and 65.2−79.6% for pig plasma. Similarly low recoveries of 65−69% for hydroxymatairesinol were reported by Smeds et al.[8] Penalvo et al.[18] reported recoveries varying from 77 to 86% for plant lignans in human plasma. Our recoveries for other plant lignans except hydroxymatairesinol in human plasma varied from 76.5 to 107.7%, which is comparable to recoveries reported by Penalvo et al.[18]

In the case of urine, the recoveries for enterolactone and enterodiol were high at all three concentrations and therefore in accordance with recoveries reported elsewhere.[7,16,20] Plant lignans have shown high recoveries at low and medium concentrations, whereas recoveries were slightly lower at high concentration, except pinoresinol. Because our test urine when hydrolyzed contained higher concentrations of lignans compared to unhydrolyzed urine, this could have influenced the result.

Test Plasma and Urine. The increased concentration of lignans after hydrolysis of the plasma and urine was expected because lignans and especially enterolactone and enterodiol have been detected almost exclusively as conjugates of glucuronic acid and sulfate in human serum and urine.[23,24] The results of this study show that pig plasma and urine, similarly to human plasma and urine, contain lignans mainly in conjugated form.

Real Sample Analyses. As consumption of diet containing a high level of lignans is associated with a higher concentration of lignans in the blood and urine compared to a diet containing a low level of lignans, we have tested this newly developed method on real samples from two studies, with humans and with pigs. The analyses of human plasma and urine showed large interindividual variation in the concentration of lignans, which was expected because absorption and bioconversion of lignans depend greatly on the microbiota of the individual. Large interindividual variation in humans was also observed in other studies.[9,25,26] Therefore, the difference between participants consuming HLD and LLD was not so pronounced compared to the pig study, where dietary intake is under more strict control.

J. Agric. Food Chem. 2015, 63, 6283−6292

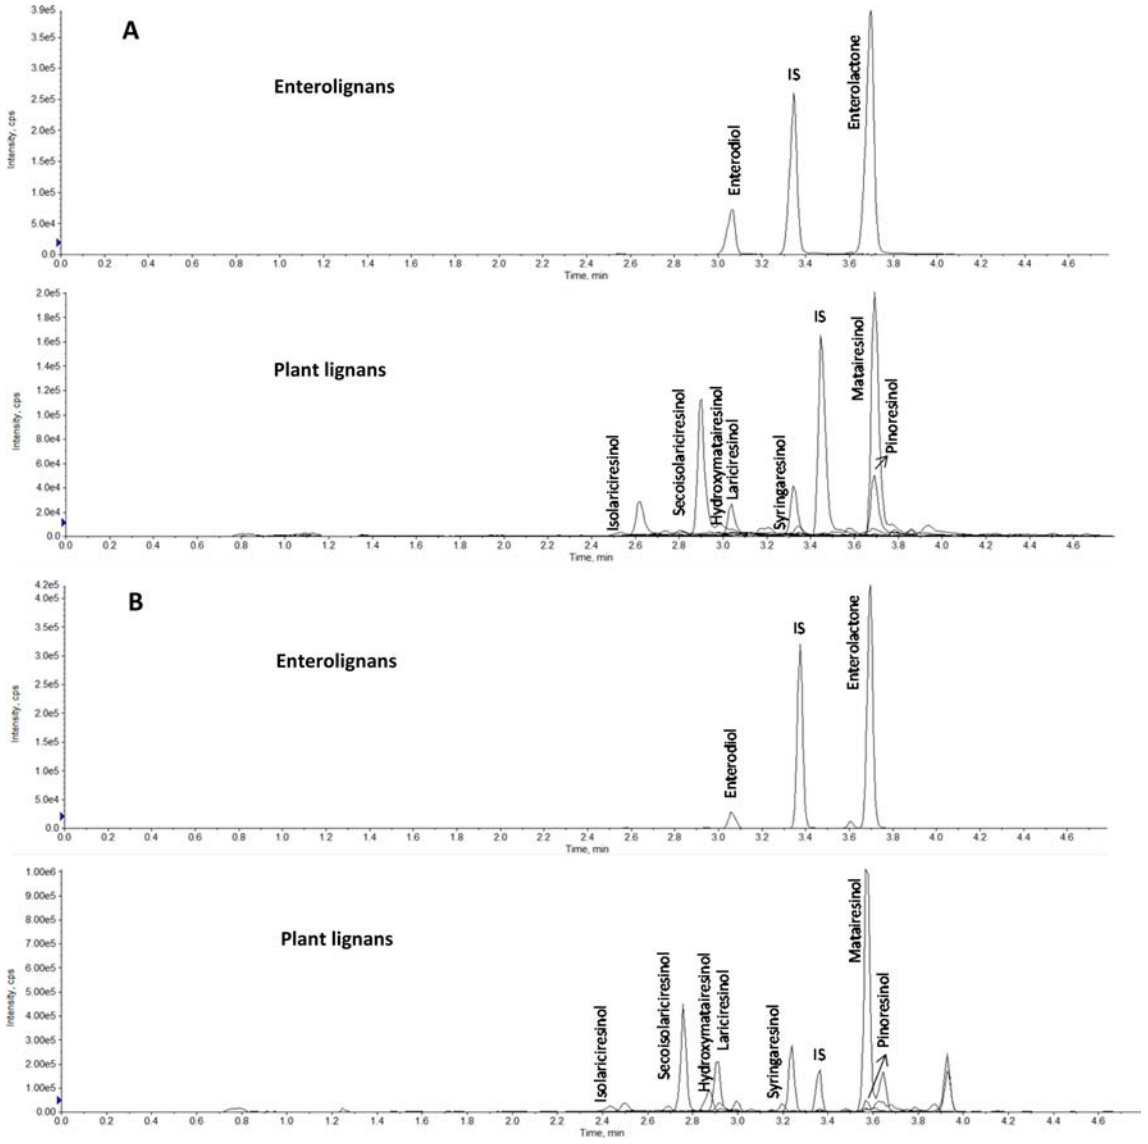

Figure 5. Extracted ion MRM chromatogram of lignans in one human urine sample (A) and one pig urine sample (B) from real sample analyses.

The difference between HLD and LLD in the pig study was large, which was as expected. The two types of diets, used in this pig study, have previously been used in model experiments with pigs, where large differences in lignan concentration between HLD and LLD in the plasma and urine were observed.[27,28] Moreover, interindividual variation among the pigs is much lower compared to humans, because the pigs genetically are more homogeneous and compliant to the experimental diets. It can be noted that the ratio between enterodiol and enterolactone in human plasma and urine was 3−5 times higher compared to pig plasma and urine. This indicates that pigs have a higher capacity to convert enterodiol to enterolactone compared to humans, probably due to a different microbiota. Moreover, the ratio between plant lignans and enterolignans in human plasma and urine after consumption of HLD was also 3−5 times higher compared to pig plasma and urine after consumption of the HLD. In contrast, when the two species consumed a LLD, the ratios between plant lignans and enterolignans in both human and pig plasma and urine were similar. This again can indicate differences in the absorption and bioconversion of lignans between humans and pigs and that the pig's conversion of plant lignans to enterolignans is more efficient. In general, the concentration of enterolignans in plasma and urine from both humans and pigs was higher compared to plant lignans, which is in accordance with our current knowledge that the majority of plant lignans are converted to enterolignans prior to uptake from the gut.[1]

The current paper presents a fast and easy (around 200 samples per day) LC-MS/MS method to quantitate two enterolignans, enterolactone and enterodiol, and eight plant lignans, matairesinol, hydroxymatairesinol, secoisolariciresinol, lariciresinol, isolariciresinol, syringaresinol, medioresinol, and pinoresinol, in biofluids from humans and pigs. The merit of our approach was to simplify the SPE cleanup and to shorten the analytical time used per sample without compromising the analytical performances of our method in terms of accuracy, precision, reproducibility, and sensitivity. Although we were successful in simplifying the SPE cleanup, some matrix effects were observed when plant lignans in urine samples were measured. This problem can be minimized by using a lower sample volume, because the concentration of plant lignans in urine is quite high. Furthermore, the method was successfully applied to quantitate lignans after the

J. Agric. Food Chem. 2015, 63, 6283−6292

consumption of HLD and LLD in plasma and urine. The lignans could be quantitated at pico- to nanomolar concentrations with good accuracy and precision. Moreover, the method is applicable for large numbers of samples and allows simultaneous analyses of plasma and urine from humans and pigs with a wide range of lignan concentrations.

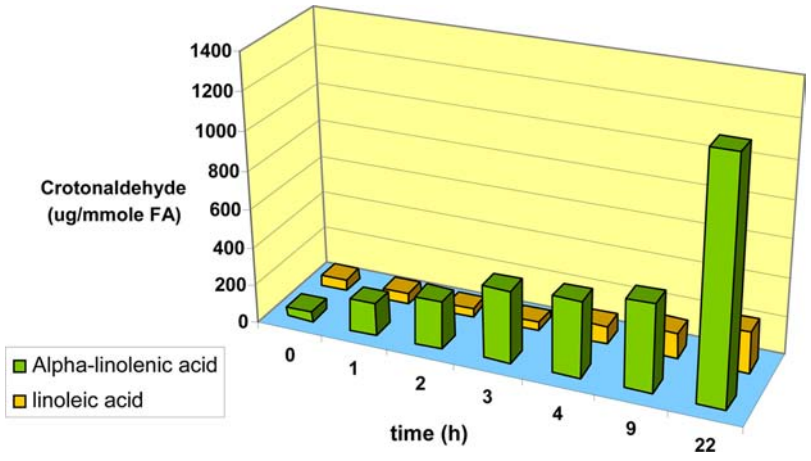

Figure 1. Formation of crotonaldehyde over time.

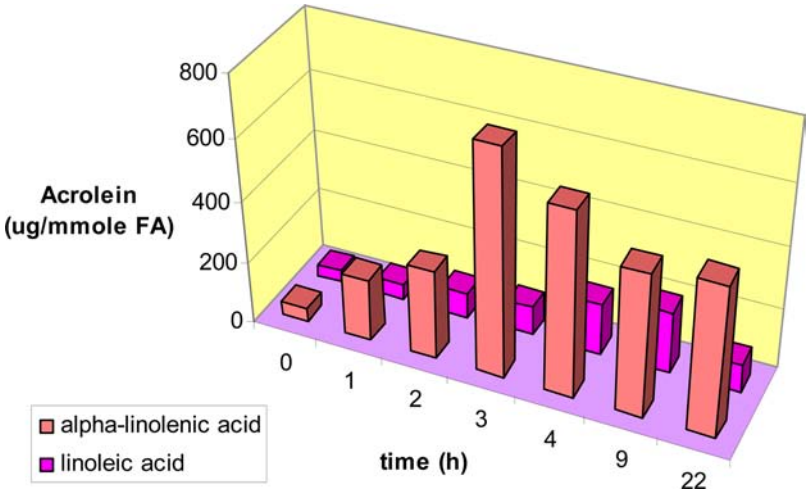

Figure 2. Formation of acrolein over time.

Chromatography was performed using an Agilent 1200 LC system. LC separations were performed using a Zorbax 300SB-C18 column (4.6 × 150 mm; 5 μm; Agilent Technologies) with a flow rate of 1 mL/min. Solvent A was 0.1% formic acid in water, and solvent B was 0.1% formic acid in acetonitrile. A linear gradient was performed as follows: 35% B at 0 min, 85% B at 25 min, 85% B at 30 min, 35% B at 31 min, and 35% B at 35 min.

Semipreparative HPLC. Purification of carbonyl–DNPH was conducted on an Agilent 1260 preparative system. A Zorbax 300SB-C18 column (9.4 × 250 mm; 5 μm; Agilent Technologies) was used with a flow rate of 12 mL/min. Solvent A was 0.1% formic acid in water, and solvent B was 0.1% formic acid in acetonitrile. A linear gradient was performed as follows: 35% B at 0 min, 85% B at 30 min, 85% B at 35 min, 35% B at 40 min, and 35% B at 45 min.

NMR. 1D NMR spectra were acquired on a Varian 300 MHz spectrometer (Palo Alto, CA, USA). Pyridine-d_5 was used as solvent, and VNMR 6.1c and Mestre-C were used for data processing.

Statistical Analysis. Data were expressed as means ± standard deviation (SD) and represent three independent analyses. Statistical significance was examined using Student's t test comparison between the means. A p value of >0.05 was considered statistically significant.

RESULTS AND DISCUSSION

α-Linolenic acid and linoleic acid were used as study material representing omega-3 and omega-6 fatty acids, respectively. They separately underwent autoxidation. Carbonyl compounds generated were derivatized by DNPH. LC-ESI-TOF was used to get the exact mass of each carbonyl derivative, and structure identification was conducted through product ion mode of LC-ESI-MS/MS. Detailed fragmentation paths followed the fragmentation scheme set up by Kölliker and Oehme.[11] For example, a molecular weight of 58.0418 represents acetone derivative and propanal derivative; differentiation of those compounds depended on the fragmentation patterns provided by product ion mode of triple quadrupole. On the basis of the characteristics of DNPH derivatives of carbonyl, ketone showed a much higher m/z 179 ion, and aldehyde showed abundant m/z 163. Therefore, through the ion patterns, compounds particularly with same molecular weight could be identified. All carbonyls were divided into three groups according to their molecular weight. The first group contained small monocarbonyls having a molecular weight of <120. In this group, α-linolenic acid and linoleic acid could generate nearly the same types of carbonyl compounds such as acetaldehyde, acrolein, crotonaldehyde, and pentanal. However, hexanal was detected in linoleic acid oxidation, and heptanal was generated from α-linolenic acid oxidation. Acrolein and crotonaldehyde were reported as highly reactive carbonyls, which can cross-link to DNA and protein and induce certain degenerative diseases.[12,13] Even though acrolein and crotonaldehyde could be detected in both omega-6 and omega-3 fatty acids, the amount generated from them was still a question. Therefore, oxidation of α-

DOI: 10.1021/acs.jafc.5b02376
J. Agric. Food Chem. 2015, 63, 6293–6296

linolenic acid and linoleic acid was conducted separately in a time course manner followed by derivatization by DNPH. MRM was used to quantify acrolein and crotonaldehyde derivatives. Figures 1 and 2 show that α-linolenic acid could generate more crotonaldehyde and acrolein than could linoleic acid. Pan and Chung reported that acrolein and crotonladehyde adducts were primarily derived from omega-3 polyunsaturated fatty acids when deoxyguanosine 5′-monophosphate was separately incubated with different polyunsaturated fatty acids including docosahexaenoic acid, α-linolenic acid, and eicosapentaenoic acid as well as omega-6 fatty acids linoleic acid and arachidonic acid.[14] Their results were perfectly consistent with ours. In accordance with the mechanism of acrolein formation from arachidonic acid,[13] an acrolein formation pathway from α-linolenic acid was proposed in Figure 3. Acrolein can be

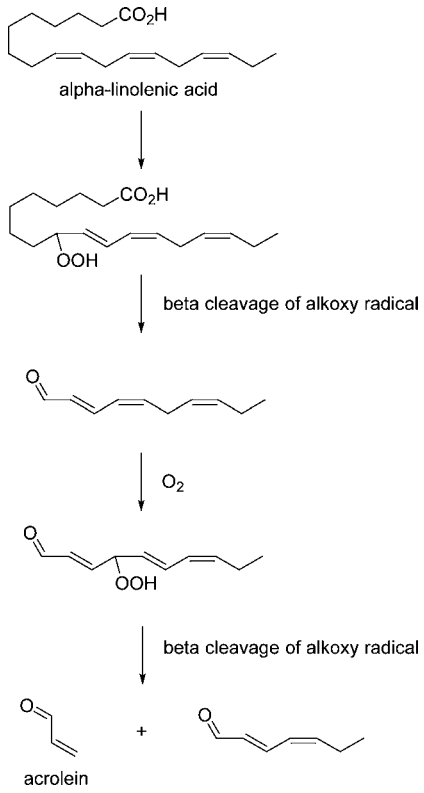

Figure 3. Proposed mechanism pathway of acrolein formation.

released from β-cleavage of lipid hydroperoxide of the corresponding alkoxy radical, which gives an aldehyde and an alkyl fragment (Figure 3). This mechanism pathway explained why hexanal was seen in the oxidation of linoleic acid, whereas heptanal was detected from the oxidation of α-linolenic acid. This mechanism pathway also indicated that both omega-3 fatty acids and omega-6 fatty acids went through the same β-cleavage of lipid hydroperoxide. Study of acrolein−DNA adducts also indicated that formation of adducts was independent from fatty acid type, but its yield related to the number of double bonds in the fatty acids.[14] This result indirectly supported the mechanism pathway of acrolein formation.

The second group contained the medium monoaldehyde having molecular weight >120 but <200. DNPH-derivatized reaction mixture was separated by semipreparative HPLC to get different fractions according to their UV absorbance. 9-Oxononanoic acid fraction accounting for the major peak was collected and identified through ^{1}H NMR. HNE and EDE were identified on the basis of standard comparison. 9-Oxononanoic acid could be found from both linoleic acid and α-linolenic acid and accounted for the biggest peak during separation. HNE and EDE could be identified only from linoleic acid oxidation. The formation pathways of 9-oxononanoic acid, as well as HNE and EDE generated from linoleic acid, are shown in Figure 4. The

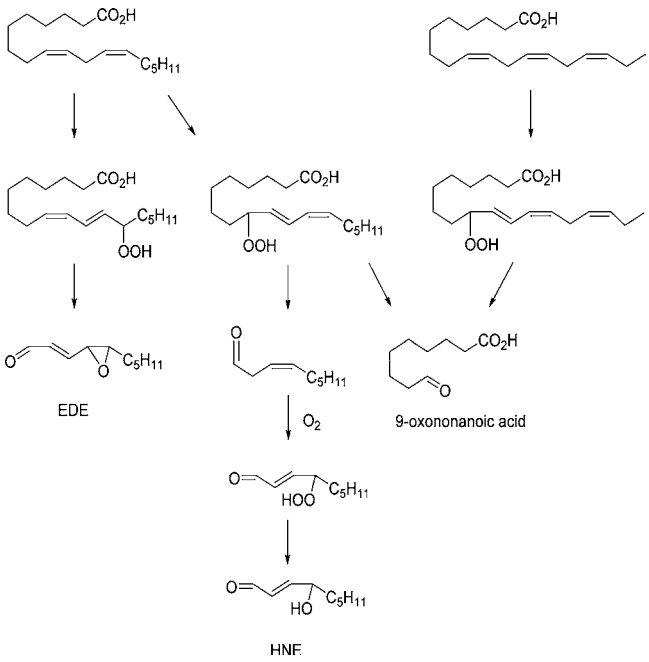

Figure 4. Formation pathways of carbonyl compounds from α-linolenic acid and linoleic acid.

peroxide group attaches to the ninth position of either α-linolenic acid or linoleic acid to form hydroperoxide products. Concurrently, 4-hydroperoxy-2-nonenal was generated only from linoleic acid, which is the precursor for HNE. One more double bond and the position of double bonds cause α-linolenic acid to go through a different oxidation pathway. As compared with dicarbonyl generation in the third group, glyoxal and methylglyoxal could be found in both fatty acids, but malondialdehyde could be detected only from α-linolenic acid under our condition. Three isomers of four-carbon dicarbonyl were shown in the oxidation of α-linolenic acid, whereas only one isomer was found from linoleic acid oxidation. A five-carbon dicarbonyl can be detected from α-linolenic acid, but it was undetectable from linoleic acid. Those results suggested α-linolenic acid might generate more dicarbonyls than would linoleic acid, which explained a limited number of medium-size monoaldehydes generating from α-linolenic acid. Because of the limitation of derivatization agent DNPH, we could not identify those four-carbon and five-carbon dicarbonyls. A new derivatization agent will be studied in the future. The oxidation mechanism of short-chain omega-3 fatty acids (α-linolenic acid) is the same as that of long-chain omega-3 fatty acids (EPA and DHA) because they all are oxidized into hydroperoxides and degraded into acrolein via β-scission. However, more study of long-chain omega-3 fatty acids is still needed to understand the mechanism and potential safety issues.

α-Linolenic acid (an omega-3 fatty acid) can generate more acrolein and crotonaldehyde, which are toxic compounds, in vitro than can linoleic acid, an omega-6 fatty acid. Under certain

DOI: 10.1021/acs.jafc.5b02376
J. Agric. Food Chem. 2015, 63, 6293−6296

circumstances, omega-3 fatty acids are also easily degraded to dicarbonyl compounds, which can bind with proteins.[10] However, omega-3 fatty acids have been considered as health improvement components for a long time. Many products with fortified omega-3 fatty acids are widely accepted by consumers. On the basis of our results, the safety of omega-3 fatty acids should be re-evaluated in vivo. Storage conditions for preventing the oxidation of omega-3 fatty acids should also be addressed.

solvent, which makes its more attractive for routine or aquatic environment analysis.[16] CO_2 has many advantages including its nontoxicity, nonflammability, and easy purification. In addition, a combination of SFC and mass spectrometry could improve the sensitivity using postcolumn polar solvent compensation technology. Furthermore, SFC-MS/MS may be easier to achieve than LC-MS due to the high proportion of volatile CO_2, which enhances the evaporation step during the ionization process.[17] This green technique is becoming more popular. In addition, QuEChERS (quick, easy, cheap, effective, rugged, and safe) sample preparation approaches have been proposed for the analysis of aquatic environmental samples. The procedure for dispersive solid-phase extraction in the QuEChERS method is easy to perform. In comparison to the traditional SPE approach, dispersive-SPE saves time, labor, and solvent by using a much smaller quantity of sorbent.[18] Therefore, we established a method with low cost, faster separation, and better resolution for tebuconazole using SFC-MS/MS.

To the best of our knowledge, this paper provides the first enantioselective analysis of tebuconazole in water and zebrafish samples using SFC-MS/MS. The results from this study will provide a new reference for the development of green chromatographic separation of chiral compound, as well as offer an important foundation for future aquatic safety and accurate risk assessment.

MATERIALS AND METHODS

Chemicals and Reagents. Racemic tebuconazole (98.7% purity) was obtained from the China Standard Material Center (Beijing, China). High-purity CO_2 (≥99.999%) and N_2 (≥99.999%) were acquired from Haike Yuanchang Gas (Beijing, China). HPLC grade acetonitrile and methanol were purchased from Fisher Scientific (Shanghai, China). Ultrapure water was obtained from a Milli-Q system (Bedford, MA, USA). Analytical grade NaCl, $MgSO_4$, and acetonitrile were purchased from Beihua Fine-Chemicals Co. (Beijing, China). The sorbents including primary−secondary amine (PSA) (40 μm), C18 (40 μm), and Florisil (120−400 mesh size) were obtained from Agela Technologies Inc. (Newark, DE, USA). The mobile phase solvents were distilled and filtered through a 0.22 μm pore size filter membrane (Tengda, Tianjin, China) prior to the determination.

The standard stock solutions (100 mg/L) of racemic tebuconazole were prepared in pure acetonitrile. The standard working solutions of *rac*-tebuconazole at 0.01, 0.05, 0.1, 0.5, 1.0, and 5.0 mg/L were prepared in pure acetonitrile from the stock solution by serial dilution. The concentrations of each enantiomer were 0.005, 0.025, 0.05, 0.25, 0.5, and 2.5 mg/L. All of the solutions were protected from light using aluminum foil and stored in a refrigerator at 4 °C prior to analysis. The working standard solutions exhibited no degradation for 3 months.

Supercritical Fluid Chromatography−Tandem Triple-Quadrupole Mass Spectrometry (SFC-MS/MS). An ACQUITY UPC^2 system (Waters, Milford, MA, USA), which was equipped with a binary solvent manager, column manager, convergence manager, sample manager-FL, and Waters 515 compensation pump, was used for the separation of the analytes. The column used for the separation of the stereoisomers of tebuconazole was a 150 mm × 4.6 mm i.d., 3 μm particle size, Chiralpak IA-3 (Daicel, Japan). This column was coated with amylose tris-3,5-dimethylphenylcarbamate. Three additional chiral columns including a Chiralpak IA [amylose tris (3,5-dimethylphenycarbamate), 5 μm], Chiralpak IB-3 [cellulose tris(3,5-dimethylphenylcarbamate), 3 μm], and Chiralpak IC-3 [cellulose tris(3,5-dichlophenylcarbamate), 3 μm] were employed. The separation was carried out using an isocratic elution with solvent A (CO_2) and solvent B (methanol) ratio of 87:13 (v/v) at a flow rate of 2.0 mL/min for 5 min. The ABPR 2200 psi was selected. The flow rate of the 515 compensation pump was 0.15 mL/min, which used 0.1% FA-MeOH (v/v) as a postcolumn additive. The temperature of the column and sample manager were maintained at 30 and 25 °C, respectively. In each run, 1 μL of the sample was injected.

The parameters including the capacity factor (k), separation factor (α), and resolution (Rs) were calculated from the formulas $k = (t - t_0)/t_0$, $\alpha = k_2/k_1$, and $Rs = 2(t_2 - t_1)/(W_1 + W_2)$, where t_0 is the void time at the given conditions (t_0 = 0.85 min, determined using 1,3,5-tri*tert*-butylbenzene), t is the retention time, k is the retention factor, and W is the baseline peak width.

A triple-quadrupole Xevo-TQD mass spectrometer (Waters Inc., Milford, MA, USA) equipped with an electrospray ionization source (ESI) was used to quantify the tebuconazole stereoisomers. The analyses were performed in ESI$^+$ with a 3.5 kV capillary voltage, 150 °C source temperature, and 500 °C desolvation temperature. A 50 L/h cone gas flow and a 900 L/h desolvation gas flow were employed. The nebulizer gas was 99.95% N_2, and the collision gas was 99.99% Ar at a pressure of 2×10^{-3} mbar in the T-Wave cell. MassLynx NT v. 4.1 software (Waters) was used to collect and analyze the obtained data.

Multiple reaction monitoring (MRM) mode was used for MS detection. The monitoring conditions were optimized for tebuconazole. A dwell time of 130 ms per ion pair was used to maintain the high sensitivity of the analysis, and a number of data points across the chromatographic peak were required. The typical conditions were as follows: the cone voltage of tebuconazole was 39 V; m/z 308.1 was selected as the precursor ion for tebuconazole, m/z 70.02 was selected for the product quantitative ion, and m/z 125.03 was selected for the qualitative ion when the collision energy was set to 23 and 37 V (see Table S1 of the Supporting Information). Under the conditions, the retention times of (+)-*S*-tebuconazole and (−)-*R*-tebuconazole were approximately 3.26 and 3.60 min, respectively (Figure 1). These settings were utilized for all subsequent studies.

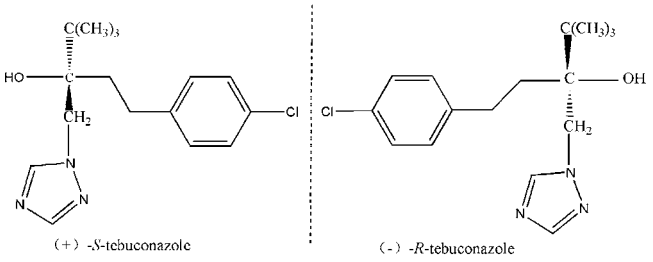

Figure 1. Chemical structures of tebuconazole stereoisomers.

The micropreparation of the stereoisomers was achieved using an Agilent 1100 series HPLC system (Agilent Technology, Waldbronn, Germany) coupled with an online OR-2090 detector (Jasco, Japan). The separation employed *n*-hexane/isopropanol (90:10, v/v) as the mobile phase at 30 °C on a CHIRALPAK AS-H column. It was a 250 mm × 4.6 mm i.d., 5 μm column (Daicel, Japan), which was coated with tris(*S*)-1-phenylethylcarbamate.

Sample Preparation. The water and zebrafish samples (total length of 2.0 ± 1.0 cm, weight of 0.1 ± 0.05 g) were not contaminated by the target analyte. All of the zebrafish were healthy. Each zebrafish was homogenized. Approximately 2.0 g of the blank zebrafish samples (2.0 mL water) was weighed into a 10 mL PTFE centrifuge tube. Suitable concentrations of tebuconazole standard solutions were added to the tube and vortexed for 30 s, followed by equilibration for 2 h at room temperature to allow the pesticide to distribute evenly. Two milliliters of acetonitrile was added, and the tube was vortexed for 3 min. Then, 1 g of NaCl was added to the mixtures. The tube was vortexed again for 1 min followed by centrifugation for 5 min at a relative centrifugal force (RCF) of 2599*g*. Next, 1.0 mL of the upper layer was transferred into a single-use 2 mL centrifuge tube containing 150 mg of Florisil and 150 mg of anhydrous $MgSO_4$ (for the water samples, 1.0 mL of the upper layer was filtered directly using a 0.22-μm nylon syringe filter for SFC-MS/MS injection). The tubes were vortexed for 30 s and centrifuged for 5 min at RCF 2400*g*. Finally, the resulting supernatant (acetonitrile) was filtered using a 0.22-μm nylon syringe filter for SFC-MS/MS injection.

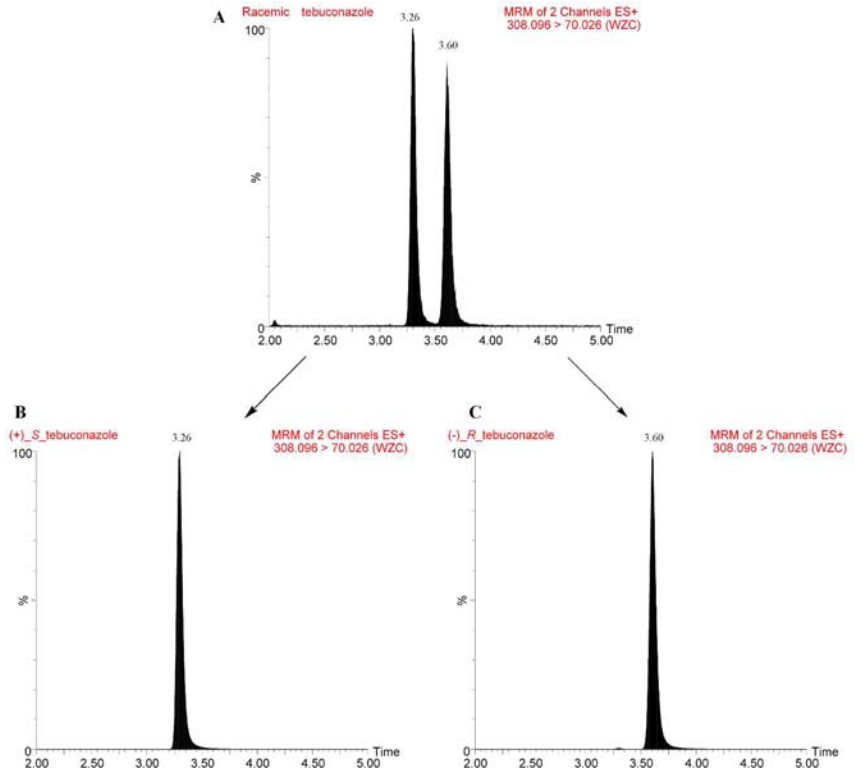

Figure 2. SFC-MS/MS chromatograms for the separation of tebuconazole enantiomers on a Chiralpak IA-3 chiral column: A, chromatogram of racemic tebuconazole; B, SFC-MS/MS chromatogram of (+)-*S*-tebuconazole; C, SFC-MS/MS chromatogram of (−)-*R*-tebuconazole.

For the SPE, the extraction volume was 6 mL, and the cleanup procedure involved transferring 3 mL of the upper layer into rotary evaporation bottles to evaporate to dryness followed by redissolving in a 1 mL mixture (acetone/*n*-hexane = 1:9, v/v). Then 1 mL of solution was passed slowly through a Florisil SPE cartridge at a flow rate of approximately 1 mL/min. The cartridges were preconditioned using 5 mL of acetone/*n*-hexane = 1:9 (v/v) followed by 5 mL of *n*-hexane. Next, a 10 mL mixed solution (acetone/*n*-hexane = 1:9, v/v) was added to elute the target analytes. Then, the organic solvent was evaporated to dryness using a rotary evaporator (30 °C, 0.09 MPa). The resulting residue was redissolved in 1 mL of ACN and filtered using a 0.22-μm nylon syringe filter for chromatographic injection.

For determination of the authentic samples, the water and zebrafish samples were obtained from a bioaccumulation test (Beijing, China); collected 24 h after an exposure period, the spiked solutions were prepared by adding *rac*-tebuconazole dissolved in acetone to deionized water for a final concentration of 1.0 mg/L.

Method Validation. The following parameters were used to evaluate the performance of the developed method: specificity, linearity, limit of detection (LOD), limit of quantitation (LOQ), matrix effect, accuracy, precision, and stability.

Blank samples (water and zebrafish) were analyzed by monitoring the characteristics of selected ion chromatograms. The linearity of the method was determined by analyzing the standard solutions and three matrices in triplicate at five concentrations ranging from 5 to 500 μg/kg for each enantiomer.

The matrix-dependent LOD and LOQ were determined using the blank and calibration standards consisting of water and zebrafish matrices. The LOD for the enantiomers of the chiral pesticide was regarded as the concentration with a signal-to-noise (S/N) ratio of 3, and the LOQ was defined as the concentrations that produced a signal-to-noise ratio of 10. These values were estimated from the chromatogram corresponding to the lowest point used in the matrix-matched calibration. The matrix effect can be computed as follows:

$$\text{matrix effect (ME, \%)} = [(\text{slope of calibration curves in matrix} - \text{slope of calibration curves in solvent})/\text{slope of calibration curves in solvent}] \times 100\%$$

The recovery assays were carried out to investigate the accuracy and precision of the method. Five replicates of the spiked samples at different levels (i.e., 10, 100, and 1000 μg/kg) for water and zebrafish were prepared on three different days. The precision under these conditions for repeatability, which is expressed as the relative standard deviation (RSD), was determined by the intra- and interday assays.

The stability was determined in acetonitrile and in the matrix. The stability of the stock solution was tested monthly by injection of a newly prepared working solution. The stability of the spiked samples (100 mg/kg) with tebuconazole was evaluated monthly, and all of the samples used in the stability test were stored at −20 °C. The results were analyzed using Student's *t* test ($P < 0.05$).

RESULTS AND DISCUSSION

Optimization of Enantioseparation Conditions. *Selection of the Chiral Column.* Four chiral columns (i.e., Chiralpak IA-3, Chiralpak IA, Chiralpak IB-3, and Chiralpak IC-3) were tested for their ability to separate the tebuconazole enantiomers under the same chromatographic conditions. The stationary phase of the four columns was polysaccharide chiral stationary phase. These chiral stationary phases exhibited good feasibility due to their individual chiral carbohydrate monomers and long-range helical secondary structure, which affect the separations. Among the four tested columns, the best chromatographic separation of the two tebuconazole enantiomers was achieved with Chiralpak IA-3 and IA columns (Figure 2). Chiralpak IB-3 and IC-3 columns exhibited insufficient discrimination ability for the tebuconazole stereoisomers. Due to the particle size of the columns and the retention time, Chiralpak IA-3 was chosen. However, Chiralpak IB-3 and IC-3 columns were filled with

DOI: 10.1021/acs.jafc.5b02450
J. Agric. Food Chem. 2015, 63, 6297−6303

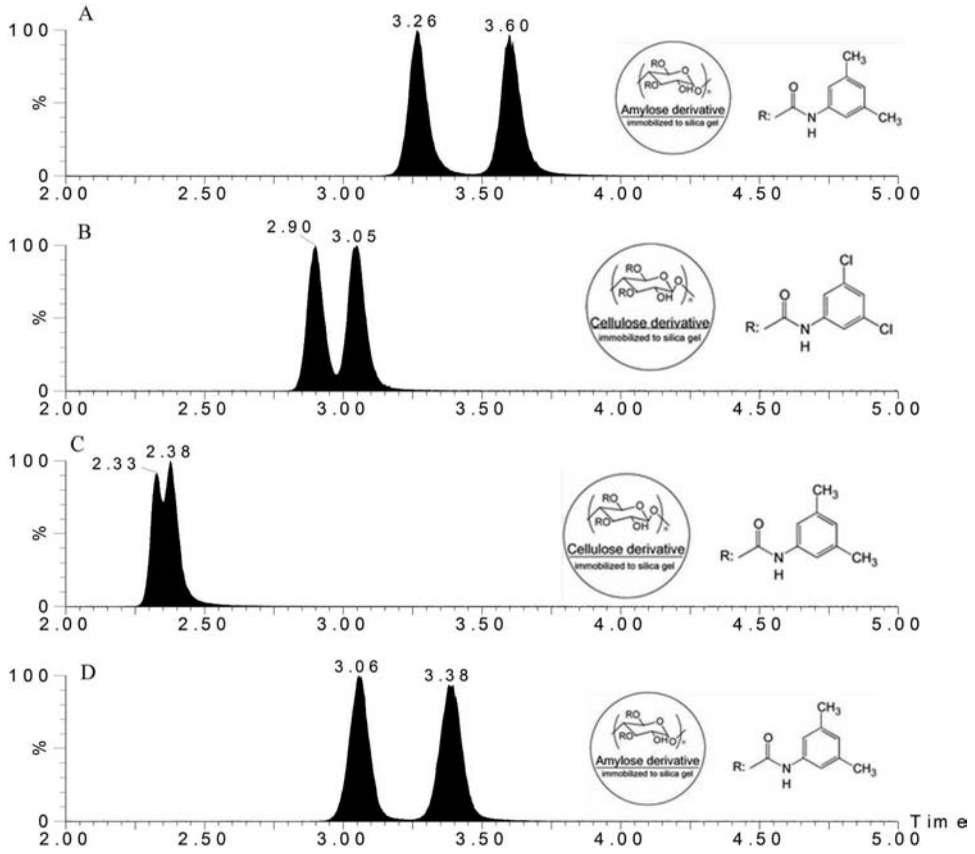

Figure 3. Typical SFC-MS/MS (MRM) chromatograms of tebuconazole on four columns: A, Chiralpak IA-3; B, Chiralpak IC-3; C, Chiralpak IB-3; D, Chiralpak IA.

derivatives of cellulose chiral stationary phase. In addition, Chiralpak IA-3 and IA columns were filled with derivatives of an amylose chiral stationary phase. The polar carbamate groups of CDMPC were thought to be the main chiral recognition regions because those can physically interact with the analytes via hydrogen bonds with the NH groups and dipole−dipole interactions with the C═O groups.[19] The derivatives of amylose exhibited higher recognition abilities for tebuconazole. Flutriafol has a structure similar to that of tebuconazole, which has also been well separated on a Chiralpak IA-3 column using SFC-MS/MS.[20]

In comparison to the 5-μm particles in the Chiralpak IA chiral column, Chiralpak IA-3 has 3-μm particles, and this column exhibited a highly effective chiral separation capacity for tebuconazole. On the basis of the solvent consumption, peak shape, and retention time, the Chiralpak IA-3 column was the optimal choice. The benefits of using columns with smaller particle sizes for chiral analysis have been previously discussed.[21]

Composition of the Mobile Phase. Different compositions of the mobile phase were investigated to achieve good separation of the tebuconazole enantiomers on the Chiralpak IA-3 column. Comparative analysis assays were conducted using methanol, ethanol, 2-propanol, 1-butanol, and acetonitrile. The results indicated that tebuconazole enantiomers were well separated when methanol was used as the modifier. In contrast, lower Rs values were obtained when ethanol and 1-butanol were employed. However, the two enantiomers cannot be separated using acetonitrile or 2-propanol as the modifier.

Different ratios of the modifier (methanol) were also tested (Figure 3A). The retention time of the enantiomers was shorter as the proportion of methanol increased. This result may be due to the strong elution ability of methanol. Finally, CO_2/methanol (83:17, v/v) was chosen as the mobile phase due to the relatively better resolution (2.75) and shorter retention times (3.26, 3.60 min).

Effect of the Auto Back Pressure Regulator (ABPR) Pressure. The ABPR settings can affect the retention time by changing the density of the mobile phase prior to the release of pressure.[20] The retention time decreased as the ABPR pressure increased from 1600 to 4000 psi (Figure 3B). However, the instrument system pressure would be beyond this range at higher ABPR pressures. In addition, higher ABPR pressure is disadvantageous for the lifetime of the chiral columns. Therefore, an ABPR pressure of 2200 psi was the optimal choice.

Effect of Column Temperature. Temperature plays an important role in chiral separation.[22] The column temperature affects the selectivity and retention in SFC-MS/MS. In this study, the column temperature was evaluated from 25 to 40 °C during the chiral separation. The results for the retention time and separation factor indicated that the temperature exhibited only a slight influence on the chiral separation. The two enantiomers were both well separated at all of the tested temperatures. The column temperature was ultimately set to 30 °C. The results were similar to those reported by Li et al.[6]

Flow Rate of the Mobile Phase. Different flow rates of the mobile phase were investigated on the basis of a mobile phase consisting of CO_2/methanol (83:17, v/v). As shown in Figure

DOI: 10.1021/acs.jafc.5b02450
J. Agric. Food Chem. 2015, 63, 6297−6303

3C, the retention time was shorter as the flow rate of the mobile phase increased. Methanol has a strong elution ability. The volume of methanol increased with the high flow rates. Therefore, the elution ability increased due to the high velocity. A rate of 2 mL/min was selected for better resolution (2.75) and a relatively suitable retention time (3.26, 3.60 min).

Flow Rate of the Compensation Pump Solvent. The compensation pump was used to provide the compensation solution, which could improve the ionization efficiency of ESI-MS/MS. A mixture of 0.1% formic acid/methanol is often selected as a compensation solvent. In this study, different flow rates of the compensation pump solvent in a range of 0.15−0.45 mL/min were examined. The results indicated that the flow rate of the compensation pump solvent had no effect on the retention time and resolution. However, this flow rate influenced the peak area (Figure 3D). For comprehensive consideration, the optimal choice was 0.15 mL/min, which provided high peak areas for the tebuconazole enantiomers.

Elution Order of Tebuconazole Enantiomers. The relationships between the absolute configurations and optical rotations (ORs) of the tebuconazole enantiomers were determined in a previous study.[23] Each single isomer and racemic tebuconazole were individually subjected to SFC-MS/MS determination under the same chromatographic conditions mentioned above. In this study, the enantiomer that eluted first was (+)-*S*-tebuconazole, followed by (−)-*R*-tebuconazole. The results were similar to the separation using LC-MS/MS reported by Li et al.[7]

Optimization of Extraction and Cleanup Procedure. The extraction and cleanup procedures are important for residue analysis. The water samples were relatively clean with few impurities. Therefore, the water samples were directly extracted with acetonitrile without purification. For the zebrafish samples, different extraction solvents (acetonitrile and acetonitrile (saturated with *n*-hexane)) were investigated first (Figure 4). The results indicated that acetonitrile extraction performed the best. A comparison between dispersive and solid-phase extraction for the cleanup step was carried out for the zebrafish samples. The dispersive cleanup procedure in the QuEChERS method was simple. Florisil, which is a normal-phase sorbent, can effectively remove lipid interferences. The results indicated that the recovery was high with 150 mg of Florisil. Dispersive solid-phase extraction (D-SPE) exhibited more interaction between the sample and the sorbent, which contributed to better recoveries, improved the cleanup by removing the interferences, and generated less waste due to the smaller volume of organic solvent employed in the sample preparation.[24]

The results indicated that the recoveries were <80% with SPE. Therefore, the QuEChERS method was the optimal choice, and this approach saved time, money, and solvent compared to traditional SPE.

Method Validation. *Specificity, Linearity, and Matrix Effect.* The blank samples (water and zebrafish) were analyzed to evaluate the specificity of the previously mentioned method, and no interference was detected at the retention time of each enantiomer. Linear regression analysis was performed in a concentration range of 5.0−500 μg/kg for each enantiomer. Table S2 in the Supporting Information provides the standard solution and matrix-matched calibration curves (acetonitrile, water, and zebrafish) for each enantiomer, including the slopes and coefficients of determination (R^2). The results indicated that a mean R^2 > 0.9933 was obtained for each enantiomer.

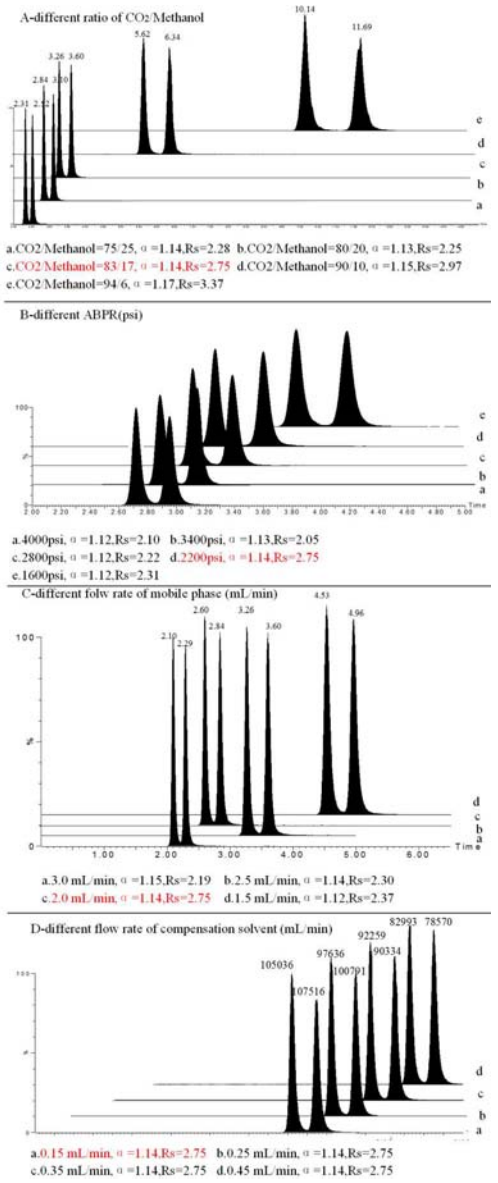

Figure 4. Comparison of effects of different parameters (A, ratio of CO_2/methanol; B, ABPR; C, flow rate of mobile phase; D, flow rate of compensation solvent) on the enantioseparation of tebuconazole enantiomers.

The matrix effects result from coeluting matrix components that affect the ionization of the target analyte, resulting either in ion suppression or in ion enhancement in some cases.[25] Matrix effects can be highly variable and difficult to control or predict. In this study, the matrix effects were investigated by comparing the standards in the solvent with the matrix-matched standards. As shown in Table S2 in the Supporting Information, signal suppression was observed for tebuconazole in the matrices, based on the slope ratios of the matrix/acetonitrile in the range of 0.007−0.010, and the slope values were 99.0 and 99.3%. In general, the suppression or enhancement effect originates from the inadequate removal of endogenous compounds, such as phospholipids, fatty acids, saccharides, phenols, and pigments.[26] Therefore, external matrix-matched standards were selected to obtain more accurate quantification results.

LODs and LOQs. In this study, the LODs for each enantiomer were estimated to be 0.3−0.4 μg/kg and obtained

DOI: 10.1021/acs.jafc.5b02450
J. Agric. Food Chem. 2015, 63, 6297−6303

from all five replicated extractions and analyses of spiked samples at the lowest spiked levels (10 μg/kg). The LOQs in the two sample matrices were 1.0−1.32 μg/kg for the compound based on five replicates at 10 μg/kg.

Accuracy and Precision. The recoveries and RSDs of each enantiomer were measured by spiking the blank samples with three different concentrations (i.e., 10, 100, and 1000 μg/kg) and then analyzing them in quintuplicate (see Table S3 of the Supporting Information). All of the recoveries were determined from analyses of the target compounds in the water and zebrafish samples. The precision of the method was determined using repeatability and reproducibility studies. The intraday precision (expressed as the RSD_r) was measured by comparing the standard deviation of the recovery percentages of the spiked samples run on the same day. The interday precision (expressed as the RSD_R) was determined by analyzing spiked samples from three different days. As shown in Table S3 in the Supporting Information, satisfactory mean recovery values (79.8−108.4%) and precisions were obtained. All of the experimental RSD values were <7.1% at the three fortified concentration levels. In general, the intraday (n = 5) and interday RSDs (n = 15) for the proposed method ranged from 0.7 to 7.1% and from 2.1 to 6.0%, respectively. Figure 4 shows typical chromatograms of the water and zebrafish blanks and spiked samples. On the basis of the results from the recovery studies, satisfactory precisions and accuracies were achieved for the analysis of tebuconazole enantiomers in water and zebrafish samples (Figure 5). In addition, the stabilities of tebuconazole

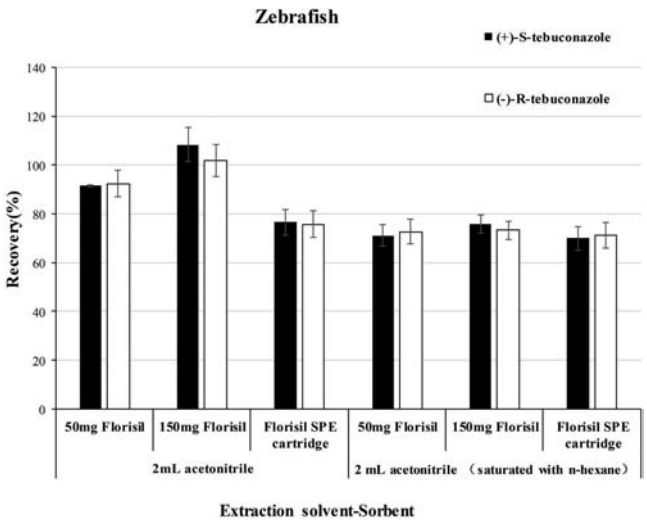

Figure 5. Effect of different kinds of sorbents and extraction solvents for tebuconazole enantiomers in zebrafish at 100 μg/kg level (n = 5).

were evaluated, and no significant difference (P > 0.05) was observed from the solvent and matrix storage treatments, as previously described.

Application to Authentic Samples. The effectiveness of this method for measuring trace levels of *rac*-tebuconazole was evaluated in water and zebrafish samples. (+)-*S*-Tebuconazole and (−)-*R*-tebuconazole in the water and zebrafish samples were detected after 24 h at concentrations of 0.33 ± 0.05 and 0.35 ± 0.04 mg/kg and 3.67 ± 0.46 and 3.06 ± 0.42 mg/kg, respectively.

In the current study, a simple and reliable method using SFC-ESI-MS/MS has been successfully established and validated for the stereoselective determination of tebuconazole in water and zebrafish. On the basis of a modified QuEChERS method, the target compounds were extracted and purified by acetonitrile and Florisil, respectively. This approach is simple and rapid with good mean recoveries and excellent linearities compared to the traditional SPE method. Satisfactory results were obtained for real samples. The current study developed an analytical method to detect tebuconazole enantiomers in water and zebrafish samples using SFC-MS/MS and also to provide technical support for future studies investigating the bioaccumulation, metabolism, and fate of tebuconazole enantiomers in aquatic environments to minimize the risk posed by tebuconazole to humans, animals, and the ecosystem.

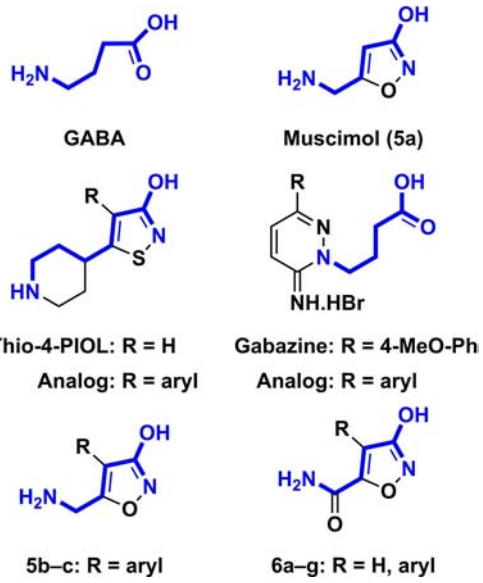

Figure 1. Chemical structures of GABA, muscimol, thio-4-PIOL, gabazine, and the synthesized analogues. Bold blue lines represent the GABA structural scaffold.

(Tokyo, Japan), unless otherwise noted. All air- and moisture-sensitive reactions were performed under an argon atmosphere using oven-dried glassware. Reactions were monitored by thin layer chromatography (TLC silica gel 60 F254 plates, Merck KGaA, Darmstadt, Germany) using UV light or a $KMnO_4$ spray reagent. Column chromatography was performed using silica gel (Wakogel C-200, 75–150 μm, Wako). Melting points were determined using a YANACO MP-500D micro melting point apparatus and are uncorrected. ^{1}H (400 MHz) and ^{13}C (100 MHz) NMR spectra were recorded on a JEOL JNM A-400 spectrometer. Chemical shifts are reported in parts per million (ppm) on the δ scale, and coupling constants (J) are in hertz (Hz). Spin multiplicities are abbreviated as follows: s (singlet), bs (broad singlet), d (doublet), t (triplet), and m (multiplet). Mass spectra (MS) were measured using the positive electrospray ionization mode (ESI) on a Waters XEVO mass spectrometer, and high-resolution mass spectra (HRMS) were obtained using ESI on a Waters SYNAPT G2 spectrometer.

*Synthesis of Methyl 3-Hydroxy-5-isoxazolecarboxylate (**2**).*[17] Dimethyl acetylenedicarboxylate (1.4 g, 10.0 mmol) was added to a solution of 1,8-diazabicyclo[5.4.0]undec-7-ene (1.8 g, 12.0 mmol) and *N*-hydroxyurea (760 mg, 10.0 mmol) in methanol (15 mL) at 0 °C under argon. The solution was stirred at 0 °C for 30 min and then at room temperature for 12 h. After the solvent was evaporated, the residue was dissolved in water (25 mL) and acidified to pH 1 with concentrated HCl. The product was extracted with Et_2O (3 × 30 mL), and the combined organic phases were washed with brine, dried over Na_2SO_4, and evaporated under reduced pressure. The obtained solid was recrystallized from chloroform to give **2** as a light yellow solid (840 mg, 59% yield): ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.97 (1H, s, OH), 6.76 (1H, s, Ar–H), 3.87 (3H, s, $COOCH_3$).

*Synthesis of 3-Benzyloxy-5-methoxycarbonylisoxazole (**3**).*[18] A mixture of **2** (2.1 g, 15 mmol) and K_2CO_3 (3.1 g, 22.5 mmol) in acetone (30 mL) was heated at 70 °C for 1 h. Benzyl bromide (3.8 g, 22.5 mmol) was added dropwise, and the mixture was stirred at 50 °C for 12 h. The mixture was filtered, and the filtrate was concentrated under reduced pressure. Water (30 mL) was added to the filtrate, and the product was extracted with Et_2O (3 × 30 mL). The combined organic phases were washed with brine, dried over Na_2SO_4, and evaporated under reduced pressure. Column chromatography (hexane/EtOAc 15:1) gave **3** as a colorless oil (3.1 g, 87% yield): ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.54–7.28 (5H, m, Ar–H), 6.57 (1H, s, Ar–H), 5.32 (2H, s, OCH_2), 3.95 (3H, s, $COOCH_3$); MS m/z 255.9 $[M + Na]^+$.

*Synthesis of 3-Benzyloxy-5-carbamoylisoxazole (**4**).* A mixture of **3** (466 mg, 2.0 mmol) and aqueous ammonia (5 mL, 28%) was stirred at room temperature for 12 h. The mixture was concentrated to dryness under reduced pressure. Water (15 mL) was added to the residue, and the mixture was extracted with EtOAc (3 × 15 mL). The combined organic phases were washed with brine, dried over Na_2SO_4, and evaporated under reduced pressure to afford **4** as a white solid (395 mg, 91% yield): mp 162–164 °C; ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.48–7.32 (5H, m, Ar–H), 6.59 (1H, s, Ar–H), 6.43 (1H, bs, $CONH_2$), 5.87 (1H, bs, $CONH_2$), 5.31 (2H, s, OCH_2); MS m/z 241.1 $[M + Na]^+$.

*Synthesis of Muscimol Hydrobromide (**5a**).*[19] Borane in THF (1 M, 5 mL, 5.0 mmol) was slowly added to a solution of **4** (480 mg, 2.2 mmol) in dry THF (15 mL) at 0 °C. The solution was stirred at room temperature for 16 h. After acidification (pH 1) with 4 M HCl, the solution was stirred for 1 h and concentrated under reduced pressure. The residue was suspended in water, and the solution was made basic (pH 10) with 4 M NaOH. The product was extracted with EtOAc (3 × 30 mL); the combined organic phases were washed with brine, dried over Na_2SO_4, and evaporated under reduced pressure to afford a light yellow oil. The oil was dissolved in a solution of HBr in AcOH (10 mL, 30%), and the mixture was stirred at room temperature for 24 h. The reaction mixture was concentrated with a subsequent azeotropic treatment of MeOH/toluene (1:1) three times, and the residue was recrystallized (MeOH/Et_2O) to give **5a** as a light brown solid (179 mg, 42% yield): ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.25 (1H, bs, OH), 8.45 (3H, bs, NH_2·HBr), 6.18 (1H, s, Ar–H), 4.14 (2H, s, CH_2); ^{13}C NMR (100 MHz, DMSO-d_6) δ 170.14, 165.22, 96.04, 34.29; HRMS m/z calcd for $C_4H_7N_2O_2$ $[M - Br]^+$ 115.0508, found 115.0502.

*Synthesis of 5-Carbamoyl-3-isoxazolol (**6a**).* Compound **4** (349 mg, 1.6 mmol) was suspended in a solution of HBr in AcOH (10 mL, 30%), and the mixture was stirred at room temperature for 24 h. The reaction mixture was concentrated with a subsequent azeotropic treatment of MeOH/toluene (1:1) three times, and the residue was recrystallized (MeOH/EtOAc) to give **6a** as a white solid (152 mg, 74% yield): mp 236–239 °C (dec); ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.61 (1H, bs, OH), 8.15 (1H, bs, $CONH_2$), 7.81 (1H, bs, $CONH_2$), 6.54 (1H, s, Ar–H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 170.40, 163.58, 157.39, 97.69; HRMS m/z calcd for $C_4H_5N_2O_3$ $[M + H]^+$ 129.0295, found 129.0290.

*Synthesis of 3-Benzyloxy-5-carbamoyl-4-iodoisoxazole (**7**).* A mixture of **4** (1.1 g, 5 mmol), $Pd(OAc)_2$ (112 mg, 0.5 mmol), CsOAc (2.3 g, 12 mmol), $NaHCO_3$ (420 mg, 5 mmol), I_2 (3.8 g, 15 mmol), 4 Å molecular sieves (150 mg), and *N*-methylformamide (30 mL) was stirred at 75 °C for 16 h. After cooling, the reaction mixture was added to $Na_2S_2O_4$ (solid) until the color stopped changing, and then it was filtered through Celite, which was thoroughly washed with EtOAc. The combined organic phases were washed with water twice and then with brine, dried over Na_2SO_4, and evaporated under reduced pressure. Column chromatography (hexane/EtOAc 10:1) gave **7** as a light yellow solid (980 mg, 57% yield): mp 179–182 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.50–7.35 (5H, m, Ar–H), 6.43 (1H, bs, $CONH_2$), 5.94 (1H, bs, $CONH_2$), 5.37 (2H, s, OCH_2); MS m/z 366.9 $[M + Na]^+$.

*General Procedure for the Synthesis of 4-Aryl-3-benzyloxy-5-carbamoylisoxazole (**8b–8g**).* A mixture of **7** (1 mmol), an arylboronic acid (1.5 mmol), $Pd(PPh_3)_2Cl_2$ (0.08 mmol), DMF (5 mL), and aqueous K_2CO_3 (0.5 mL, 3 M, 1.5 mmol) was stirred at 80 °C for 24 h. After cooling, the reaction mixture was filtered through Celite and diluted using Et_2O. The organic phase was washed with water and brine, dried over Na_2SO_4, and evaporated under reduced pressure. Column chromatography (hexane/EtOAc) gave **8b–8g**.

*3-Benzyloxy-4-(3-biphenylyl)-5-carbamoylisoxazole (**8b**):* white solid; yield 82%; mp 145–147 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.93 (1H, s, Ar–H), 7.70–7.26 (13H, m, Ar–H), 6.40 (1H, bs, $CONH_2$), 5.78 (1H, bs, $CONH_2$), 5.42 (2H, s, OCH_2); ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.88, 157.95, 156.60, 141.09, 140.78, 135.39, 129.03, 128.83, 128.74, 128.60, 128.56, 128.09, 127.58, 127.37, 127.20, 126.59, 114.21, 72.27; MS m/z 371.0 $[M + H]^+$, 393.0 $[M + Na]^+$.

DOI: 10.1021/acs.jafc.5b01843
J. Agric. Food Chem. 2015, 63, 6304–6312

*3-Benzyloxy-5-carbamoyl-4-(2-naphthyl)isoxazole (**8c**):* white solid; yield 69%; mp 138−140 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.14 (1H, s, Ar−H), 7.88−7.73 (4H, m, Ar−H), 7.72−7.26 (7H, m, Ar−H), 6.39 (1H, bs, $CONH_2$), 5.84 (1H, bs, $CONH_2$), 5.43 (2H, s, OCH_2); ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.90, 157.95, 156.60, 135.33, 133.21, 132.90, 129.75, 129.58, 128.49, 128.37, 127.90, 127.74, 127.63, 127.26, 126.74, 126.23, 123.56, 114.31, 72.17; MS *m*/*z* 367.0 $[M + Na]^+$.

*3-Benzyloxy-4-(4-biphenylyl)-5-carbamoylisoxazole (**8d**):* white solid; yield 90%; mp 164−167 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.80−7.28 (14H, m, Ar−H), 6.39 (1H, bs, $CONH_2$), 5.75 (1H, bs, $CONH_2$), 5.42 (2H, s, OCH_2); ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.98, 158.03, 156.59, 141.72, 140.66, 135.48, 132.23, 132.13, 130.49, 128.84, 128.67, 128.60, 128.47, 128.08, 127.59, 127.19, 126.95, 125.21, 114.11, 72.34; MS *m*/*z* 371.0 $[M + H]^+$.

*3-Benzyloxy-5-carbamoyl-4-(1-naphthyl)isoxazole (**8e**):* white solid; yield 77%; mp 154−156 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.95−7.25 (12H, m, Ar−H), 6.05 (1H, bs, $CONH_2$), 5.72 (1H, bs, $CONH_2$), 5.34 (2H, s, OCH_2); ^{13}C NMR (100 MHz, $CDCl_3$) δ 170.35, 158.09, 157.37, 135.23, 133.66, 131.57, 129.83, 128.97, 128.52, 128.41, 128.05, 126.56, 126.25, 125.26, 125.19, 123.84, 112.32, 72.02; MS *m*/*z* 367.1 $[M + Na]^+$.

*3-Benzyloxy-5-carbamoyl-4-(6-methoxy-2-naphthyl)isoxazole (**8f**):* light yellow solid; yield 67%; mp 124−126 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.07 (1H, s, Ar−H), 7.78−7.65 (3H, m, Ar−H), 7.46−7.30 (5H, m, Ar−H), 7.18−7.10 (2H, m, Ar−H), 6.40 (1H, bs, $CONH_2$), 6.06 (1H, bs, $CONH_2$), 5.42 (2H, s, OCH_2), 3.91 (3H, s, OCH_3); ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.92, 158.40, 158.21, 156.39, 135.41, 134.54, 129.90, 129.50, 128.55, 128.45, 127.86, 127.79, 126.57, 121.23, 119.11, 114.35, 105.61, 72.12, 55.32; MS *m*/*z* 397.1 $[M + Na]^+$.

*3-Benzyloxy-5-carbamoyl-4-(6-hydroxy-2-naphthyl)isoxazole (**8g**):* light yellow solid; yield 43%; mp 177−179 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 9.73 (1H, s, Ar−OH), 8.11 (1H, bs, $CONH_2$), 7.97 (1H, s, Ar−H), 7.85 (1H, bs, $CONH_2$), 7.75−7.05 (10H, m, Ar−H), 5.41 (2H, s, OCH_2); ^{13}C NMR (100 MHz, DMSO-d_6) δ 169.11, 158.67, 158.25, 155.96, 135.67, 134.12, 129.56, 128.60, 128.37, 128.24, 127.93, 127.31, 127.06, 125.49, 120.77, 118.98, 111.59, 108.54, 71.63; MS *m*/*z* 383.1 $[M + Na]^+$.

*Synthesis of 5-Aminomethyl-4-(3-biphenylyl)-3-isoxazolol Hydrobromide (**5b**).* Compound **5b** was prepared from **8b** (185 mg, 0.5 mmol) according to the procedure described for **5a**. Recrystallization (MeOH/Et_2O) gave **5b** as a white solid (69 mg, 40%): mp 220−222 °C; ^{1}H NMR (400 MHz, CD_3OD) δ 7.75−7.30 (9H, m, Ar−H), 4.36 (2H, s, CH_2); ^{13}C NMR (100 MHz, CD_3OD) δ 163.30, 160.88, 143.29, 141.79, 130.50, 129.95, 129.33, 128.72, 128.66, 128.38, 128.07, 128.02, 111.90, 35.40; HRMS *m*/*z* calcd for $C_{16}H_{15}N_2O_2$ $[M - Br]^+$ 267.1134, found 267.1143.

*Synthesis of 5-Aminomethyl-4-(2-naphthyl)-3-isoxazolol Hydrobromide (**5c**).* Compound **5c** was prepared from **8c** (196 mg, 0.57 mmol) according to the procedure described for **5a**. Recrystallization (MeOH/Et_2O) gave **5c** as a brown solid (85 mg, 47%): mp 226−228 °C; ^{1}H NMR (400 MHz, CD_3OD) δ 8.01−7.86 (4H, m, Ar−H), 7.65−7.50 (3H, m, Ar−H), 4.41 (2H, s, CH_2); ^{13}C NMR (100 MHz, CD_3OD) δ 170.22, 160.92, 134.85, 134.37, 129.63, 129.09, 128.77, 127.69, 127.20, 126.21, 112.05, 35.56; HRMS *m*/*z* calcd for $C_{14}H_{13}N_2O_2$ $[M - Br]^+$ 241.0977, found 241.0989.

*Synthesis of 4-(3-Biphenylyl)-5-carbamoyl-3-isoxazolol (**6b**).* Compound **6b** was prepared from **8b** (333 mg, 0.9 mmol) according to the procedure described for **6a**. Recrystallization (MeOH/EtOAc) gave **6b** as a white solid (210 mg, 83%): mp 193−195 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.03 (1H, bs, OH), 8.09 (1H, bs, $CONH_2$), 7.90 (1H, s, Ar−H), 7.82 (1H, bs, $CONH_2$), 7.71−7.27 (8H, m, Ar−H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 168.62, 158.59, 158.30, 140.04, 139.77, 128.87, 128.42, 128.35, 128.05, 127.43, 126.62, 126.19, 111.31; HRMS *m*/*z* calcd for $C_{16}H_{13}N_2O_3$ $[M + H]^+$ 281.0921, found 281.0914.

*Synthesis of 5-Carbamoyl-4-(2-naphthyl)-3-isoxazolol (**6c**).* Compound **6c** was prepared from **8c** (189 mg, 0.55 mmol) according to the procedure described for **6a**. Recrystallization (MeOH/EtOAc) gave **6c** as a light yellow solid (95 mg, 68%): mp 221−223 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.02 (1H, bs, OH), 8.10 (1H, s, Ar−H), 8.06 (1H, bs, $CONH_2$), 7.95−7.88 (3H, m, Ar−H), 7.79 (1H, bs, $CONH_2$), 7.66 (1H, d, *J* = 8.3 Hz, Ar−H), 7.58−7.47 (2H, m, Ar−H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 168.58, 158.39, 158.28, 132.33, 132.19, 128.35, 127.80, 127.25, 126.92, 126.23, 126.02, 124.96, 111.33; HRMS *m*/*z* calcd for $C_{14}H_{11}N_2O_3$ $[M + H]^+$ 255.0770, found 255.0785.

*Synthesis of 4-(4-Biphenylyl)-5-carbamoyl-3-isoxazolol (**6d**).* Compound **6d** was prepared from **8d** (222 mg, 0.6 mmol) according to the procedure described for **6a**. Recrystallization (MeOH/EtOAc) gave **6d** as a white solid (112 mg, 67%): mp 278−280 °C (dec); ^{1}H NMR (400 MHz, DMSO-d_6) δ 12.03 (1H, bs, OH), 8.09 (1H, bs, $CONH_2$), 7.82 (1H, bs, $CONH_2$), 7.80−7.50 (6H, m, Ar−H), 7.48−7.34 (3H, m, Ar−H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 168.61, 158.56, 158.20, 139.65, 139.58, 129.96, 128.86, 127.48, 126.61, 126.54, 126.04, 110.98; HRMS *m*/*z* calcd for $C_{16}H_{12}N_2O_3Na$ $[M + Na]^+$ 303.0740, found 303.0738.

*Synthesis of 5-Carbamoyl-4-(1-naphthyl)-3-isoxazolol (**6e**).* Compound **6e** was prepared from **8e** (330 mg, 0.96 mmol) according to the procedure described for **6a**. Recrystallization (MeOH/EtOAc) gave **6e** as a white solid (128 mg, 52%): mp 189−191 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.77 (1H, bs, OH), 7.96 (2H, d, *J* = 7.8 Hz, Ar−H), 7.92 (1H, bs, $CONH_2$), 7.68 (1H, bs, $CONH_2$), 7.59−7.41 (5H, m, Ar−H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 169.34, 159.28, 157.69, 133.03, 131.46, 128.66, 128.44, 128.07, 126.08, 125.76, 125.39, 125.15, 110.58; HRMS *m*/*z* calcd for $C_{14}H_{11}N_2O_3$ $[M + H]^+$ 255.0770, found 255.0785.

*Synthesis of 5-Carbamoyl-4-(6-methoxy-2-naphthyl)-3-isoxazolol (**6f**).* Compound **6f** was prepared from **8f** (243 mg, 0.65 mmol) according to the procedure described for **6a**. Recrystallization (MeOH/EtOAc) gave **6f** as a white solid (115 mg, 62%): mp 242−244 °C (dec); ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.99 (1H, bs, OH), 8.03 (2H, bs, $CONH_2$), 7.85−7.70 (4H, m, Ar−H), 7.63 (1H, dd, *J* = 8.8, 2.0 Hz, Ar−H), 7.32 (1H, d, *J* = 2.4 Hz, Ar−H), 7.17 (1H, dd, *J* = 8.8, 2.4 Hz, Ar−H), 3.89 (3H, s, OCH_3); ^{13}C NMR (100 MHz, DMSO-d_6) δ 168.72, 158.58, 158.05, 157.71, 133.70, 129.52, 128.31, 127.89, 127.83, 125.99, 122.60, 118.64, 111.58, 105.90, 55.21; HRMS *m*/*z* calcd for $C_{15}H_{12}N_2O_4Na$ $[M + Na]^+$ 307.0695, found 307.0691.

*Synthesis of 5-Carbamoyl-4-(6-hydroxy-2-naphthyl)-3-isoxazolol (**6g**).* Compound **6g** was prepared from **8g** (90 mg, 0.25 mmol) according to the procedure described for **6a**. Recrystallization (MeOH/EtOAc) gave **6g** as a white solid (52 mg, 77%): mp 210−213 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 11.94 (1H, bs, OH), 9.70 (1H, bs, OH), 8.05−7.50 (6H, m, Ar−H and $CONH_2$), 7.36−7.05 (2H, m, Ar−H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 168.73, 158.61, 157.91, 155.78, 129.56, 128.37, 128.12, 127.56, 127.11, 125.29, 121.64, 118.81, 111.69, 108.51; HRMS *m*/*z* calcd for $C_{14}H_{11}N_2O_4$ $[M + H]^+$ 271.0719, found 271.0714.

Preparation of cRNAs of Housefly RDL and Their Expression in *Xenopus* Oocytes. The cRNAs of four housefly RDL variants (DDBJ accession no. AB177547, complete cds of RDL_{bd}; AB824728, partial cds of exon 3a version; AB824729, partial cds of exon 6c version) were prepared as previously described.[20] In brief, the cDNA templates of four *Rdl* variants (ac, bc, ad, and bd) including the upstream RNA polymerase promoter site were obtained by PCR amplification from pBluescript KS(−)-$MdRdl_{ac}$, -$MdRdl_{bc}$, -$MdRdl_{ad}$, and -$MdRdl_{bd}$ using KOD -Plus- ver. 2 (Toyobo, Tokyo, Japan), a forward primer, 5′-TGTAAAACGACGGCCAGT-3′, and a reverse primer, 5′-CAGGAAACAGCTATGACC-3′. The PCR products were purified using the illustra GFX PCR DNA and Gel Band Purification Kit (GE Healthcare UK, Ltd., Little Chalfont, UK), and the integrity of amplified cDNAs was confirmed by sequence analysis. The capped cRNAs were synthesized using T7 polymerase (mMessage mMachine T7 Ultra Kit; Ambion, Austin, TX, USA). The cRNAs were precipitated with LiCl, dissolved in sterile RNase-free water, and stored at −20 °C until use.

Mature female African clawed frogs (*Xenopus laevis*) were anesthetized with 0.1% (w/v) ethyl *m*-aminobenzoate methanesulfonate in water. The ovarian lobes were dissected out and then treated

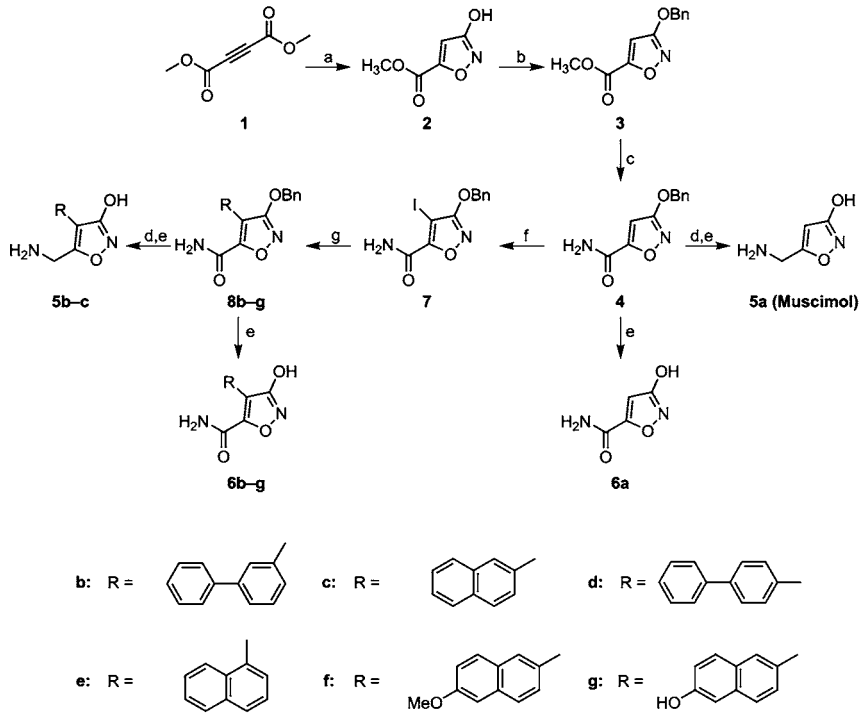
Scheme 1. Synthesis of Muscimol and Target Compounds[a]



[a]Reagents and conditions: (a) *N*-hydroxyurea, 1,5-diazabicyclo[5.4.0]undec-5-ene, MeOH, 0 °C; (b) benzyl bromide, K_2CO_3, acetone, 70 °C; (c) aqueous NH_3, room temperature; (d) BH_3, THF, room temperature; (e) 30% HBr in AcOH, room temperature; (f) I_2, $Pd(OAc)_2$, CsOAc, $NaHCO_3$, DMF, 75 °C; (g) $RB(OH)_2$, $PdCl_2(PPh_3)_2$, K_2CO_3, DMF, 80 °C.

with collagenase (2 mg/mL, Sigma-Aldrich) in a Ca^{2+}-free standard oocyte solution (Ca^{2+}-free SOS) (100 mM NaCl, 2 mM KCl, 1 mM $MgCl_2$, 5 mM HEPES, pH 7.6) at room temperature for 90−120 min. The oocytes were then gently washed with sterile SOS (100 mM NaCl, 2 mM KCl, 1.8 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM HEPES, pH 7.6) containing gentamycin (50 μg/mL, Life Technologies, Thermo Fisher Scientific Inc., Waltham, MA, USA), penicillin (100 U/mL, Life Technologies), streptomycin (100 μg/mL, Life Technologies), and sodium pyruvate (2.5 mM, Sigma-Aldrich). Each oocyte was injected cytoplasmically with 5 ng of cRNA dissolved in RNase-free water (9.2 nL), and then the oocytes were incubated in sterile SOS for 48 h at 16 °C.

Two-Electrode Voltage Clamp (TEVC) Recordings. Electrophysiological experiments were performed as previously described.[14] Briefly, GABA-induced currents were recorded at a holding potential of −80 mV using an Oocyte Clamp OC-725C amplifier (Warner Instruments, Hamden, CT, USA) and Data-Trax2 software (World Precision Instruments Inc., Sarasota, FL, USA). The glass capillary electrodes were fabricated using a micropipette puller (P-97, Sutter Instrument, Novato, CA, USA) and filled with 2 M KCl (resistance ranging from 0.5 to 2.0 MΩ). Oocytes were placed in a recording bath that was continuously perfused with SOS at 18−22 °C.

For agonist assays, GABA dissolved in SOS was applied to oocytes for 3 s, at intervals of 30−60 s, to ensure a full recovery from desensitization. Concentration−response curves were generated by sequential applications of increasing concentrations of GABA. Muscimol hydrobromide was dissolved in SOS and tested using the same procedure as GABA. For antagonist assays, 3-isoxazolols were dissolved in DMSO and then diluted with SOS to the desired concentrations [DMSO, ≤0.1% (v/v)]. The test compound solution was added to the perfusate after two successive control applications of GABA and was then applied consecutively for the remainder of the experiments. Antagonist solutions were perfused alone for 30 s before their coapplication with GABA. GABA, at a concentration corresponding to the EC_{50} for each variant, was then coapplied with an antagonist for 3 s, and the coapplication was repeated at 30−60 s intervals to obtain the highest constant inhibition. All experiments were performed using at least four different oocytes obtained from at least two different frogs.

EC_{50} and IC_{50} values were obtained from concentration−response data by nonlinear regression analysis using OriginPro 8J (OriginLab, Northampton, MA, USA). Statistical significance was assessed using one-way analysis of variance (ANOVA) followed by Duncan's multiple-range test.

Insecticidal Assays. The WHO/SRS strain of houseflies (*M. domestica*) was used to examine the insecticidal activity of **6b**. Compound **6b** dissolved in DMSO (0.1 μL) at various concentrations was injected into the dorsal side of the thorax of adult female houseflies (3−5 days after eclosion). This volume of DMSO solution alone did not affect the viability of houseflies. A total of 12−15 houseflies was used at each concentration. The injected houseflies were maintained with sugar and water at 25 °C. The number of dead or paralyzed flies was counted after 24 h. The experiments were replicated five times. The LD_{50} value was calculated from the mean values of mortality at three dosages using the Probit method.

Molecular Modeling and Ligand Docking Studies. A recently published X-ray crystal structure of the homopentameric human β3 GABAR (PDB ID 4COF)[21] was used as a template to construct a housefly RDL_{ac} GABAR homology model. A sequence alignment of the RDL_{ac} and β subunits was carried out using ClustalW software, and this was used to build all five subunits simultaneously using MOE 2011.10 software (Chemical Computing Group, Montreal, Canada). The obtained pentamer model was optimized geometrically using the AMBER99 force field. GABA and muscimol were created in the zwitterionic forms, and compound **6b** was created in a deprotonated hydroxyl form using MOE Builder. Potential docking sites were searched using SiteFinder of MOE. The created ligands were docked into the potential binding site of the generated model using the ASEDock program (2011.01.27, Chemical Computing Group) with default parameters. The energies of the receptor and ligands were minimized using the MMFF94x force field. The stable conformations of ligands were obtained by a conformational search. The binding

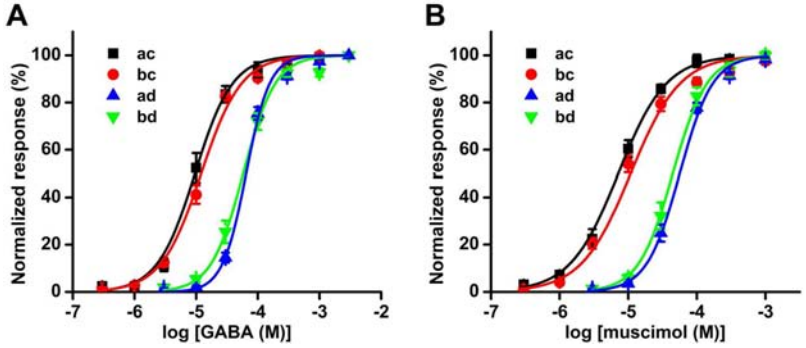

Figure 2. Agonist responses of the four splice variants of housefly RDL GABARs expressed in *Xenopus* oocytes: (A) GABA concentration−response curves of the four variants; (B) muscimol concentration−response curves of the four variants. Responses were normalized relative to the maximum currents induced by 1 mM GABA in the ac and bc variants and by 3 mM GABA in the ad and bd variants. No significant differences were observed in the maximum currents induced by muscimol and GABA in each variant, indicating that muscimol is a full agonist. Data represent means ± SEM (n = 6−9).

mode with the highest score was chosen for the final representation. Structural images were visualized using PyMOL ver. 1.3 (Schrödinger, Tokyo, Japan).

RESULTS AND DISCUSSION

Chemistry. A new, convenient strategy to synthesize 4-aryl-substituted muscimols and 4-aryl-5-carbamoyl-3-isoxazolols starting from dimethyl acetylenedicarboxylate (**1**) was established and is outlined in Scheme 1. 3-Isoxazolol **2** was synthesized from **1** according to a reported method,[17] and the hydroxyl group was protected to give 3-benzyloxyisoxazole **3**.[18] Ammonolysis of ester **3** to amide **4** was followed by reduction with borane and deprotection with hydrobromic acid to afford muscimol hydrobromide (**5a**). Treatment of **4** with 30% hydrobromic acid in acetic acid afforded 5-carbamoyl-3-isoxazolol (**6a**). To introduce aromatic groups into the 4-position of the isoxazole ring, **4** was first iodinated at this position using iodine and $Pd(OAc)_2$ as a catalyst to give **7**.[22] The Suzuki−Miyaura cross-coupling reaction of **7** with the appropriate arylboronic acids in the presence of a palladium catalyst afforded analogues **8b**−**8g** in 43−90% yields, the hydroxyl groups of which were deprotected with hydrobromic acid to give **6b**−**6g**. Compounds **5b**−**5c** were obtained by reduction and subsequent deprotection of **8b** and **8c**, as described for **5a**.

Differential Sensitivity of Housefly GABAR Variants to GABA and Muscimol. Similar to the case of *D. melanogaster*,[5] four splice variants (ac, ad, bc, and bd) of RDL are endogenously generated by alternatively splicing exons 3 (a and b) and 6 (c and d) of *Rdl* in houseflies. The two amino acid residues that differ between the sequences encoded by exons 3a and 3b are located upstream of the agonist-interacting region of the RDL subunit, and the 10 residues that differ between the sequences encoded by exons 6c and 6d are located in a region including loops F and C (Figure S1), which are predicted to be generally involved in the interaction with agonists in Cys-loop receptors.[23] In the present study, the four variants of housefly RDL were expressed in *Xenopus* oocytes, and their responses to the agonists GABA and muscimol were first investigated using a TEVC method.

Application of GABA to the oocytes expressing housefly RDL GABARs induced concentration-dependent inward currents in all four variants when the voltage was clamped at −80 mV. The GABA concentration−response curves show that the order of variants giving higher sensitivity to GABA is $RDL_{ac} \approx RDL_{bc} > RDL_{ad} \approx RDL_{bd}$ (Figure 2A); the EC_{50} values are given in Table 1. The finding that the alternative splicing of exon 3 did not affect the sensitivity to GABA suggests that the two variable residues in exon 3 may not be involved in the interaction with GABA. RDL_{ac} GABARs showed ∼6-fold higher sensitivity to GABA than RDL_{ad} GABARs, and RDL_{bc} GABARs had ∼5-fold higher sensitivity than RDL_{bd} GABARs. This finding indicates that the alternative splicing of exon 6 significantly influences GABA potency in the RDL variants of housefly GABARs. Similarly, muscimol (**5a**) was a more potent full agonist in the ac and bc variants than in the ad and bd variants (Figure 2; Table 1). These different potencies of GABA and muscimol in the four variants are similar to those in *Drosophila* RDL variants.[6−8] The changes of agonist potencies may be due to the residue difference in loop(s) F and/or C in the orthosteric binding site.

Table 1. Potencies of GABA and Muscimol in the Four Splice Variants of Housefly RDL GABARs[a]

	GABA		muscimol	
variant	EC_{50} (μM)	n_H	EC_{50} (μM)	n_H
RDL_{ac}	10.6 ± 1.6a	1.74 ± 0.23	7.1 ± 0.7a	1.25 ± 0.16
RDL_{bc}	12.2 ± 0.7a	1.62 ± 0.24	10.2 ± 1.0a	1.18 ± 0.10
RDL_{ad}	64.1 ± 3.8b	2.29 ± 0.10	54.1 ± 2.2b	1.98 ± 0.26
RDL_{bd}	59.0 ± 5.7b	1.77 ± 0.21	45.8 ± 4.7b	1.76 ± 0.16

[a]Data are means ± SEM (n = 6−9). n_H is the Hill coefficient. Different letters within a column indicate statistically significant difference at $p < 0.01$.

Antagonism of Housefly GABAR Variants by Synthesized Analogues. We examined the activity of synthesized compounds against RDL GABARs from three insect species. The compounds were first tested against common cutworm (*Spodoptera litura* Fabricius) and small brown planthopper (*Laodelphax striatellus* Fallén) RDL_{bd} GABARs expressed in *Drosophila* S2 cells using the fluorescent imaging plate reader (FLIPR) membrane potential (FMP) assays, as previously reported.[14] Unexpectedly, synthesized analogues other than muscimol failed to show significant activity at 100 μM in both insect receptors (data not shown). In contrast to these results, significant results were obtained against housefly RDL GABARs, prompting further investigation described below. These contrasting results suggest that structural or functional

DOI: 10.1021/acs.jafc.5b01843
J. Agric. Food Chem. 2015, 63, 6304−6312

differences in the orthosteric binding sites of RDL GABARs might exist between insect species.

As agonist potencies vary by the variant, synthesized analogues were assessed for their functional characteristics in the four RDL variants of housefly GABARs expressed in *Xenopus* oocytes using a TEVC method. Analogues were first tested at 100 μM in the absence and in the presence of the EC_{50} of GABA to determine if they are agonists or antagonists. Unlike muscimol, all synthesized analogues showed no agonism but exhibited antagonism at 100 μM in the four RDL variants.

In a previous study, we found that the 4-(3-biphenylyl)-thio-4-PIOL and 4-(2-naphthyl)-thio-4-PIOL analogues showed competitive antagonism in housefly RDL_{ac} GABARs and common cutworm RDL_{bd} GABARs, indicating that the 3-biphenyl and 2-naphthyl groups are beneficial for competitive antagonists of insect GABARs.[14] Thus, these groups were introduced into the 4-position of muscimol (**5a**) to afford **5b** and **5c**. Both compounds showed antagonism at 100 μM in all four RDL variants of housefly GABARs, albeit with <40% inhibition of GABA-induced currents (Figure 3A). Although

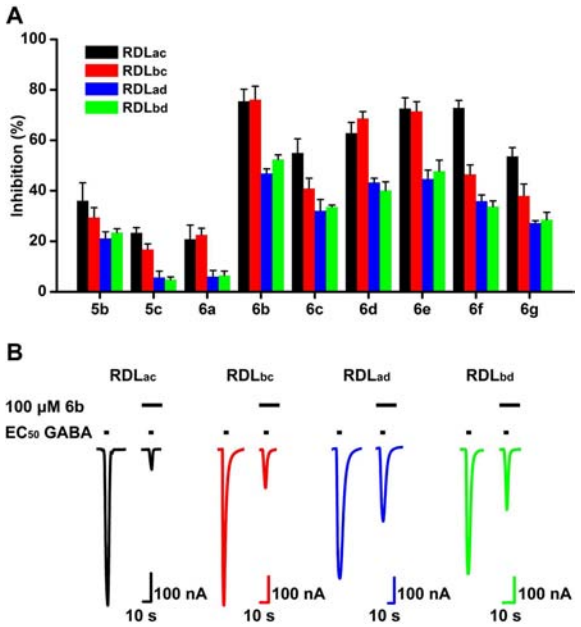

Figure 3. Inhibition of GABA-induced currents by the 3-isoxazolol analogues in the four splice variants of housefly RDL GABARs expressed in *Xenopus* oocytes: (A) inhibition of GABA-induced currents by synthesized analogues at 100 μM in the four variants (data represent means ± SEM (n = 4–6)); (B) examples of GABA-induced currents inhibited by 100 μM **6b** in the four variants. The EC_{50} of GABA for each variant (Table 1) was used to induce control currents in each oocyte.

the potencies of these analogues were low, these results indicate that the 3-isoxazolol scaffold may be useful for developing antagonists of housefly GABARs and that the bicyclic aromatic system at the 4-position of the isoxazole ring may be beneficial for antagonistic activity as it was in thio-4-PIOL analogues.

Replacement of the aminomethyl group of muscimol (**5a**) with a carbamoyl group to give **6a** changed the function of muscimol from an agonist to an antagonist in the four variants, with ~20% inhibition of GABA-induced currents at 100 μM in RDL_{ac} and RDL_{bc} GABARs and ~6% inhibition in RDL_{ad} and RDL_{bd} GABARs. These findings indicate that the protonated amino group is needed for agonist activity and that the carbamoyl group at the 5-position favors antagonism rather than agonism. The introduction of a 3-biphenylyl group at the 4-poisiton of **6a** to give **6b** markedly increased the antagonistic activity against the four variants, leading to 75.5, 76.1, 46.9, and 52.4% inhibition of GABA-induced currents in RDL_{ac}, RDL_{bc}, RDL_{ad}, and RDL_{bd} GABARs, respectively (Figure 3A). Figure 3B shows that GABA-induced currents were inhibited by the 3-biphenylyl analogue (**6b**) at 100 μM in the four RDL variants. Compound **6c**, with a 2-naphthyl substitution at the 4-position of the isoxazole ring, also exhibited higher inhibition than **6a** in all four variants, but relatively lower inhibition compared with **6b**. Additionally, two different aromatic groups, 4-biphenylyl and 1-naphthyl, were introduced into the 4-position to yield **6d** and **6e**, respectively. The inhibition of GABA-induced currents by **6d** and **6e** in the four variants was comparable to the inhibition by **6b**. These findings indicate that analogues with bicyclic aromatic groups at the 4-position of the isoxazole ring are well tolerated at the binding site and that they are effective in inhibiting GABA-induced current in housefly GABARs. To investigate whether the electron-donating groups on the aromatic group at the 4-position increase activity, a methoxyl and a hydroxyl group were introduced to the 6-position of the 2-naphthyl group of **6c** to afford **6f** and **6g**, respectively. Compounds **6f** and **6g** were comparable in activity to **6c** in the four variants, although inhibition by **6f** in the ac variant was higher than that of **6c** (Figure 3A). Overall, the synthesized analogues **5b**, **5c**, and **6b**–**6g** were more potent against RDL_{ac} and RDL_{bc} GABARs than against RDL_{ad} and RDL_{bd} GABARs (Figure 3A), with from ~1.5- to ~4-fold higher inhibition in the former than in the latter. The different sensitivities of the four variants to the synthesized analogues are similar to those of the agonists GABA and muscimol, implying that the synthesized analogues bind to the same site as agonists.

Compounds **6b**–**6g**, which exerted relatively greater inhibitory effects, were further evaluated in RDL_{ac} GABARs with the generation of antagonist concentration–response curves in the presence of 10 μM (EC_{50}) GABA (Figure 4A). The 3-biphenylyl analogue (**6b**), with an IC_{50} value of 30.0 μM, is among the analogues that displayed the greatest antagonism in the ac variant (Table 2). The replacement of the 3-biphenylyl group with a 2-naphthyl and a 4-biphenylyl group to yield **6c** and **6d** resulted in 2.3- and 1.8-fold increases in the IC_{50} value, respectively. The 1-naphthyl analogue (**6e**) had a potency similar to that of **6b** in the ac variant. Thus, the 3-biphenyl group is advantageous compared with the 4-biphenyl group; the 1-naphthyl group is preferable to the 2-naphthyl group. The introduction of a methoxy group into the naphthyl group of **6c** to yield **6f** led to a 1.9-fold increased potency in the ac variant, whereas the potency of **6g**, in which a hydroxyl group was introduced, was similar to that of **6c** in the ac variant.

Compound **6b** was further examined for its potencies in other RDL variants of housefly GABARs. Figure 4B shows concentration–response curves for **6b** in the presence of the EC_{50} of GABA in the four variants. No significant differences were observed in the IC_{50} values of **6b** between the ac and bc variants or between the ad and bd variants, whereas the IC_{50} values of **6b** in the ad and bd variants were ~3-fold greater compared with those in the ac and bc variants (Table 2). These findings were analogous to those in the EC_{50} values of GABA and muscimol in the four variants, indicating that **6b** most likely acts on the same site as agonists. The different amino acid residues in the region encoded by exon 6 in different variants

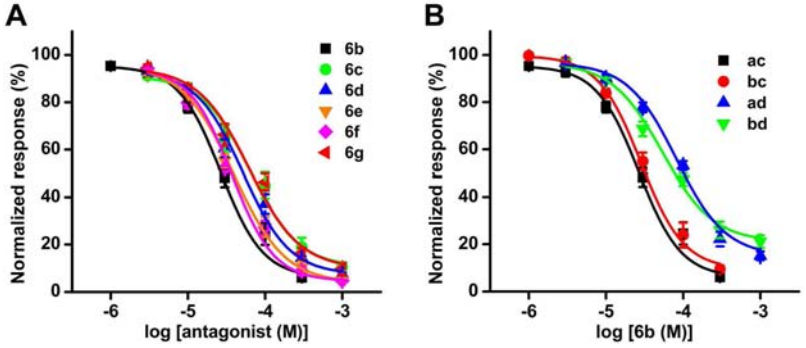

Figure 4. Effects of the 3-isoxazolol analogues on GABA-induced currents in housefly RDL GABARs expressed in *Xenopus* oocytes: (A) concentration−response inhibition curves of 4-aryl-5-carbamoyl-3-isoxazolols (**6b**−**6g**) in the housefly RDL_{ac} variant; (B) concentration−response inhibition curves of **6b** in four GABAR variants. Responses were normalized relative to currents induced by the EC_{50} of GABA for each variant. Data represent means ± SEM (n = 4−6).

Table 2. Inhibition of GABA (EC_{50})-Induced Currents by 4-Aryl-5-carbamoyl-3-isoxazolols (6b−6g) in the Four Variants of Housefly RDL GABARs[a]

	IC_{50} (μM)			
compd	RDL_{ac}	RDL_{bc}	RDL_{ad}	RDL_{bd}
6b	30.0 ± 2.6a	34.3 ± 2.4a	107.2 ± 8.1b	96.0 ± 4.9b
6c	67.7 ± 3.0c	>100	>100	>100
6d	53.3 ± 3.4d	ND	>100	>100
6e	38.5 ± 4.9a	ND	≈ 100	>100
6f	36.0 ± 3.5a	ND	>100	>100
6g	64.9 ± 2.7cd	>100	>100	>100

[a]Data are means ± SEM (n = 4). Different letters within a row and a column indicate statistically significant difference at $p < 0.01$ and $p < 0.05$, respectively. ND, not determined.

may cause the difference in the sensitivity to competitive antagonists and agonists.

Mode of Antagonism. To determine whether synthesized 3-isoxazolols act as competitive antagonists, the GABA concentration−response relationships in the presence and absence of **6b** were examined in the ac variant. The GABA concentration−response curves made a parallel rightward shift with increasing **6b** concentration, indicating a competitive mechanism (Figure 5). The EC_{50} values of GABA in the presence of 30 and 100 μM **6b** were 27.2 and 55.6 μM, respectively. The potency of GABA was decreased 2.6- and 5.2-fold in the presence of 30 and 100 μM **6b**, respectively, whereas

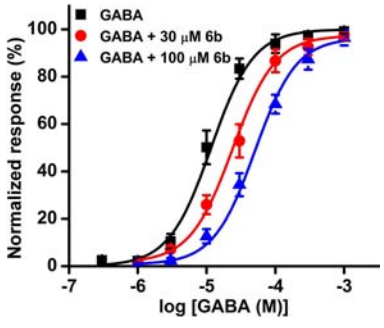

Figure 5. GABA concentration−response curves of housefly RDL_{ac} GABARs in the presence and absence of 30 and 100 μM **6b**. Responses were normalized relative to the maximum current induced by 1 mM GABA in each oocyte. Data represent means ± SEM (n = 4−6).

the efficacy of GABA remained unchanged. These results indicate that **6b** competes with GABA for the orthosteric site to stabilize the closed conformation of chloride channels.

Insecticidal Activity. Competitive antagonists stabilize the closed conformation of GABAR channels and should thus exert insecticidal effects when they act at insect GABARs. There is no information about the insecticidal action of competitive antagonists. We therefore investigated whether **6b**, which showed the highest antagonism, has intrinsic insecticidal activity by injection into adult female houseflies. As a result, **6b** proved to be insecticidal, with an LD_{50} value of 5.6 (4.9−6.3) nmol/fly (95% confidence interval in parentheses). The finding that **6b** shows insecticidal activity by definition is somewhat encouraging, although the activity was not prominent and was observed by injection but not topical application.

Molecular Interaction between Ligands and Housefly RDL GABAR. To understand the molecular mechanisms of the interaction between 3-isoxazolols and insect GABARs, GABA, muscimol, and the 3-biphenylyl analogue (**6b**) were docked into the orthosteric binding site of a housefly RDL_{ac} GABAR homology model constructed on the basis of the X-ray crystal structure of the human homopentameric β3 GABAR. The β3 subunit shares 38.7% amino acid identity with the RDL_{ac} subunit. The most likely binding poses were selected on the basis of the score and are shown in Figure 6. The orthosteric site of Cys-loop receptors, which is located in the extracellular interface of two adjacent subunits (Figure S2), is formed by loops A−C from the principal subunit and loops D−F from the complementary subunit.[24] Similarly, the orthosteric binding pocket of the constructed model is basically formed by Phe144, Val146, Glu202, Ser203, Phe204, Gly205, Ile245, Leu247, and Arg254 from the principal subunit and by Tyr88, Leu90, Tyr107, Arg109, and Met224 from the complementary subunit. The distance between two key residues, Glu202 and Arg109, is approximately 9.0 Å.

The docking simulation showed that the protonated amino groups of GABA and muscimol are located close to Glu202 of loop B and that they form an electrostatic interaction and hydrogen bonds with this residue (Figure 6A,B). Arg109 of loop D electrostatically interacts with the deprotonated carboxyl group of GABA and the deprotonated hydroxyl group (or the isoxazole ring) of muscimol. In addition, Arg109 serves as a hydrogen bond donor for the carboxylate of GABA and the hydroxyl oxygen or the nitrogen atom of muscimol. These important interactions were observed in the docking

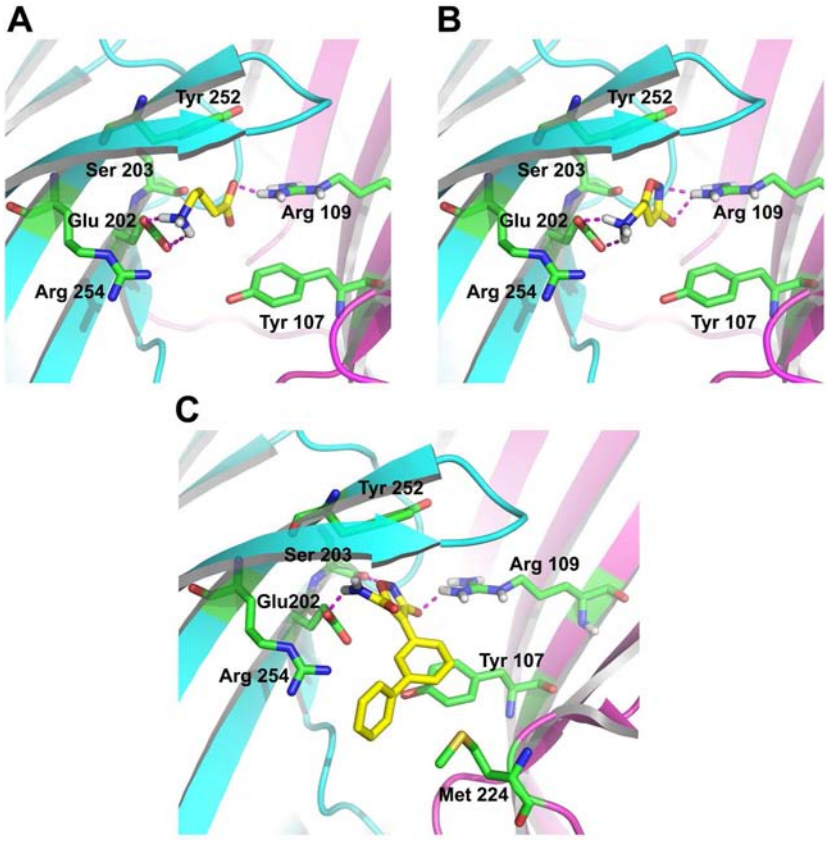

Figure 6. Simulation of the docking of GABA, muscimol, and **6b** into the orthosteric binding site of a housefly RDL_{ac} GABAR homology model: (A) docking of GABA into the orthosteric site; (B) docking of muscimol; (C) docking of **6b**. The crystal structure of the homopentameric human β3 GABAR (PDB 4COF) was used as a template to construct the model.

simulation results using another housefly RDL GABAR homology model in our previous studies and are apparently conserved in *Drosophila* RDL GABARs.[14,15,25−27] Tyr252 of loop C, which surrounds the protonated amino group of GABA and muscimol, may produce a cation−π interaction, as proposed for *Drosophila* RDL GABARs.[25−27] Similar orientations and interactions of GABA and muscimol in the binding site indicate that these two agonists interact with housefly RDL GABARs in an identical mode.

Docking of the 4-(3-biphenylyl) analogue (**6b**) to the homology model of the housefly RDL_{ac} GABAR predicts that the 5-carbamoyl-3-isoxazolol scaffold of **6b** lies between Glu202 (loop B) and Arg109 (loop D) in the same orientation as muscimol. Similar to the cases of GABA and muscimol, the side chain of Arg109 electrostatically interacts with the deprotonated hydroxyl group of **6b** and forms a hydrogen bond with the same group; the side chain of Glu202 functions as a hydrogen acceptor for the carbamoyl group of **6b**. Furthermore, the two amino acid residues, Arg254 of loop C and Tyr107 of loop D, surround the 3-biphenylyl group of **6b**. The present docking studies of **6b** predict that the 3-biphenylyl group points out of the binding site and may form a cation−π interaction with Arg254 and a $\pi-\pi$ interaction with Tyr107. The orientation of the 3-biphenylyl group is in contrast with that of the 4-substitution of thio-4-PIOL analogues in our previous study.[14] This difference may be due to the different templates used in the homology modeling. It has yet to be elucidated which orientation is feasible.

In conclusion, we synthesized a novel class of housefly competitive GABAR antagonists (**6b**−**6g**) by replacing the aminomethyl group of muscimol with a carbamoyl group and simultaneously introducing bicyclic aromatic groups at the 4-position. All of the analogues exhibited antagonism of the four splice variants of housefly GABARs, the most potent compound being 4-(3-biphenylyl)-5-carbamoyl-3-isoxazolol (**6b**). The potencies of **6b** in RDL_{ac} and RDL_{bc} GABARs were ∼3-fold greater than those in RDL_{ad} and RDL_{bd} GABARs, and this potency difference in these variants is similar to the potency difference of agonists. The identification of a novel series of competitive GABAR antagonists serves to widen the current scope for insecticidal chemicals competitively acting at the orthosteric sites beyond those of gabazine and thio-4-PIOL derivatives.

[a]The density, ρ, solubility, c_w, and vapor pressure, P^0, are given at 25 °C. P^0 and c_w values of the citrus flavor molecules are results from, respectively, the MPBWIN and the WSKOW models of EPI Suite at 25 °C.[21]

Henry's constants for more complex flavor molecules and their temperature dependence.

We have developed a methodology to rapidly measure air−water Henry's constants as a function of temperature. It is suitable for a wide range of H values and is based on equilibrium static headspace analysis (ESHA). A solution of volatiles is equilibrated with air in a closed vessel, and then a sample of the air is led through a deactivated fused silica capillary and heated to 130 °C (to avoid condensation issues) into the ionization source (atmospheric pressure chemical ionization) of a quadrupole mass spectrometer (APCI-MS),[15] which is referred to as an MS-Nose. It has a detection threshold of >∼0.01 mg/m^3 of volatiles in the headspace.[15] Note that a proton transfer reaction mass spectrometer (PTR-MS) could also be used.[16] The mass spectrometer is calibrated with a liquid reference. As discussed previously,[17] liquid calibration can be a source of uncertainty, but correct practice gives data comparable to those obtained from the internally calibrated phase ratio variation (PRV) method.[17,18] With the PRV method, the depletion from the liquid to the gas phase is explicitly used for different liquid−gas ratios, to calculate the partition coefficient. However, as elegant as this internal calibration is, the latter is suited for only a limited number of compounds and temperatures, as significant partitioning into the air, that is, H > ∼0.1, is required for accurate results.

To demonstrate consistency with existing methods, we measure Henry's constants for a series of 2-ketones, for which reliable values are known.[3,19,20] We then apply the method to a set of volatiles regularly used to create citrus flavors (herein referred to as citrus flavor molecules).

MATERIALS AND METHODS

Chemicals. The 2-ketones and flavor molecules used in this study are 2-butanone (CAS Registry No. 78-93-3 Acros), 2-pentanone (CAS Registry No. 107-87-9, Sigma-Aldrich), 2-hexanone (CAS Registry No. 591-78-6, Sigma-Aldrich), 2-heptanone (CAS Registry No. 110-43-0, Alfa Aesar), 2-octanone (CAS Registry No. 111-13-7, Fluka), 2-nonanone (CAS Registry No. 821-55-6, SAFC), and cyclopentane (CAS Registry No. 287-92-3, Sigma-Aldrich). Ethyl acetate (CAS Registry No. 141-78-6), *trans*-2-hexenal (CAS Registry No. 6278-26-3), ethyl butanoate (CAS Registry No. 105-54-4), octanal (CAS Registry No. 124-13-0), 1-octanol (CAS Registry No. 111-87-5), citral (CAS Registry No. 5392-40-5), citronellal (CAS Registry No. 2385-77-5), and citronellol (CAS Registry No. 106-22-9) were all obtained internally at Firmenich S.A. All of the molecules and their charachteristics are listed in Table 1. Values for the solubility, c_w, vapor pressure, P^0, and Henry's constant, H, were estimated using, respectively, the MPBWIN (v1.42), WSKOW (v1.41), and HENRYWIN (v3.10) model of the Estimation Program Interface (EPI) Suite.[21]

The molecules were first dissolved in dimethyl sulfoxide (DMSO; CAS Registry No. 67-68-5, Sigma-Aldrich) and then transferred to water. This two-step procedure accelerates dissolution and improves reliability. To determine if the presence of DMSO in any way perturbed the baseline of the molecules being quantified, a DMSO blank was injected into the MS prior to a standard injection. It was observed that DMSO blank did not affect the MS signal. The final concentrations in the aqueous phase, c, are listed in Table 1. They were always <0.1 ppm to ensure that the volatile could be considered being at infinite dilution.

Instrumentation. The MS-NOSE (Micromass ZMD, Manchester, UK; APCI-MS (quadrupole) was operated under the following conditions: corona voltage, 3.8 kV; cone voltage, 14 V; source temperature, 105 °C; heated sample transfer line (deactivated fused silica SGE Analytical) temperature, 130 °C; heated interface gas temperature, 105 °C; and sampling flow rate, 25 mL/min. The signal used for calibration was produced by direct injection of a continuous flow (1 μL/min) of the volatile dissolved in cyclopentane into a controlled air flow (10 L/min). A correction was made for the signal of pure cyclopentane by subtracting the signal produced by the pure cyclopentane from the standard signal.

Headspace Measurements. Figure 1 shows the setup. An aqueous solution (100 mL) of the flavor molecule was transferred to a 250 mL Pyrex bottle containing a Teflon-coated magnetic stirrer. Room temperature measurements were made in a temperature-controlled laboratory (T = 21.0 ± 0.1 °C). For measurements at 35 and 50 °C, the bottles were heated by a heat jacket (Hillesheim, Waghäusel Germany). The bottle was closed with a Teflon cap equipped with a small electric fan (2.5 × 2.5 × 0.5 cm, Conrad.CH Part MFB25B-05) hanging in the headspace. The fan and the magnetic stirrer (300 rpm) ensured good mixing of both phases. Stable signals were obtained after about 15 min of continuous mixing. Therefore, the closed system was allowed to equilibrate for 20 min, and then the volatiles in the headspace were sampled via the heated transfer line (130 °C to avoid condensation issues) of the MS-NOSE for 1 min at a flow rate of 25 mL/min. The signals were corrected by subtracting the signal from the headspace of distilled water, to allow for the effects of humidity and background signal from the laboratory air. For each

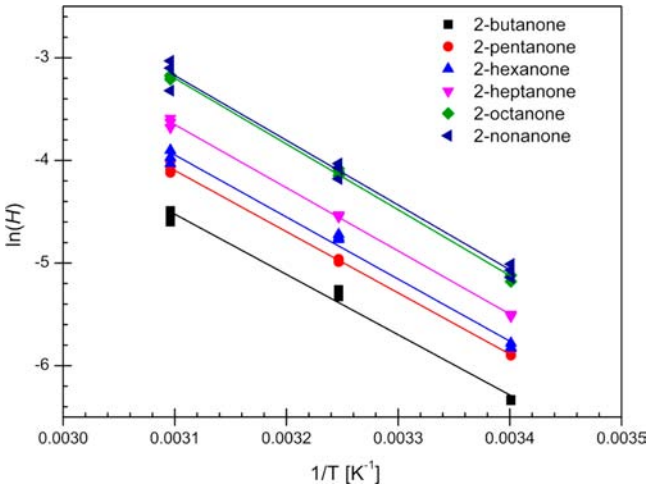

Figure 3. Measured Henry's constants at different temperatures for a series of 2-ketones, including the data from Table 2.

a series of 2-ketones was measured at room temperature using the above method and the values compared to those obtained in the literature.[3] The measured signal of the MS-NOSE, I_s, was translated into the concentration of volatile in the headspace expressed in milligrams per cubic meter, c_{hs}, using the calibration constant, I_{ref}, measured as described above. Notably for volatiles that strongly partition into the headspace, the concentration in the aqueous phase, c, will be significantly lowered by the partitioning. This effect can be taken into account by a straightforward correction to calculate the Henry's constant:

$$H = \frac{c_{hs}}{c - c_{hs}\frac{V_{hs}}{V_{aq}}} \quad (4)$$

c is the added concentration of volatile in the aqueous phase, V_{hs} the volume of the headspace, and V_{aq} the volume of the aqueous phase. For our setup V_{hs}/V_{aq} was 2.2.

Table 2 lists Henry's constants of the 2-ketones, measured as one component at room temperature, including the standard deviation over three repeated measurements. For comparison, interpolated data from Brachet and Chaintreau at 21 °C are included[3] as well as calculated values at 25 °C using EPI Suite.[21] The same data are plotted in Figure 2 as a function of

octanal	−58 ± 6	−161 ± 18
1-octanol	−58 ± 1	−143 ± 5
citral	−57 ± 1	−135 ± 2
citronellal	−47 ± 2	123 ± 6
citronellol	−83 ± 1	−221 ± 1

the molecular weight of the 2-ketones, which shows that in all cases the general trends are similar; however, the calculated values are offset compared to the measured values. In summary, our methodology yields Henry's constants with a standard

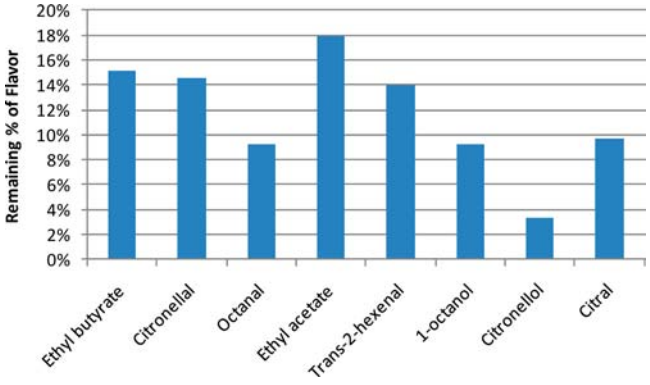

Figure 5. Relative flavor profile at temperature of consumption (50 °C), as compared to preparation at 90 °C. Concentration of headspace at 90 °C is set at 100%.

deviation of ∼10% based on replicates and absolute values that are in good agreement with values reported in the literature.[3] It also shows the need for experimental values as modeled values (EPI Suite) tend to overestimate the Henry's constants for the ketones at higher molecular weights, by up to 100% as shown in Figure 2.

Citrus Flavor Molecules. A set of eight molecules typical of a citrus flavor were selected, including the well-studied molecules ethyl acetate, ethyl butanoate, octanal, and 1-octanol and the less studied *trans*-2-hexenal, citral, citronellal, and citronellol. The molecules are chosen to cover a wide range of solubilities and vapor pressures. The flavor molecules were measured individually. The results are listed in Table 3, including Henry's constants from the literature and estimates calculated using the HENRYWIN model of EPI Suite using the bond and group estimation methods.[21]

In line with our findings for the 2-ketones, we observed a standard deviation in the measured Henry's constants of about 10% within triplicate measurements of the same stock solution of a specific flavor molecule. Our results are in agreement with

DOI: 10.1021/acs.jafc.5b01517
J. Agric. Food Chem. 2015, 63, 6313−6318

reported experimental values for the esters,[3] (Table 2) and octanal and 1-octanol.[19] For these molecules, values from EPI Suite tend to overestimate the experimental values with deviations up to 70%. For the other four molecules, each containing one or more unsaturated bond(s), EPI Suite values overestimate the experimental ones by up to 80% using the group method and by up to an order of magnitude using the bond method. This shows that modeling can give good estimations for Henry's constants (100% deviation for group contribution estimation methods is not uncommon), if an adequate model is used. Nevertheless, for practical purposes there is a strong need to have more reliable values.

Temperature Dependence. To allow the use of measured Henry's constants for the modeling of food processing and consumption, we extended the method to higher temperatures (35 and 50 °C). The experimental setup could easily be heated first in a water bath and then transferred to a heat jacket, without affecting the stirring of the aqueous phase and the headspace. We first tested the method on 2-ketones, for which the results are shown in Figure 3. Because Henry's constants characterize an equilibrium partitioning between two phases, their temperature dependence can be described by van't Hoff's equation:

$$\ln(H) = -\frac{\Delta S_{sol}}{R} + \frac{\Delta H_{sol}}{RT} \quad (5)$$

Here ΔS_{sol} and ΔH_{sol} are respectively the entropy and the enthalpy of solution. The extracted values are listed in Table 4 and compared to literature values deduced from Henry's constants,[3] and measured directly with microcalorimetry.[20,22] For the citrus flavor molecules, ΔH_{sol} values were available for ethyl acetate, octanal, and 1-octanol. The reproducibility of ΔH_{sol} over independent repeated measurements is estimated to be around 10% ΔH_{sol}, whereas ΔS_{sol} shows a larger variability of ≥30% ΔS_{sol}. With this in mind, our results are in excellent agreement with values reported in the literature.

We applied the validated methodology to the citrus flavor molecules. It is clear from the results in Figure 4 that not all molecules have the same temperature dependence, hence the need to determine experimentally the correct values. Table 5 shows the experimental entropies and enthalpies of solution. Within this set of flavor molecules, we found slight differences in ΔH_{sol}, which are directly related to the partitioning of the flavor molecules at higher temperatures. To put these results into context, we take the set of molecules as a hypothetical citrus flavor for fruit tea prepared by a flavorist at room temperature. If one would prepare tea with this flavor, the resulting profile that one would smell while brewing the tea would be very different as the relative presence of the flavor molecules into the humid headspace can vary up to 3 orders of magnitude. This highlights the difficulties in creating flavors for hot and cold beverages and food products, as well as the large differences in the effect of heat treatment on the different volatiles. The bar chart in Figure 5 demonstrates the well-known experience that the taste of fruit tea can be quite disappointing after the attractive smell: the tea cools quickly in the mouth to about 50 °C, reducing the relative amount of volatiles in the headspace by up to an order of magnitude, as well as distorting the flavor profile. This calculation clearly demonstrates that the knowledge of temperature-dependent Henry's constants is crucial for the creation of flavors for hot and cold products. As shown, modeling (using, e.g., EPI Suite) is not accurate enough to give good predictions of the Henry's constants, so the technology described here will be very useful to obtain reproducible and reliable Henry's constants.

[a]Abbreviations: %I, inhibition (%) of the EPR signal of the DPPH free radical; I_{100}, value calculated from the equation describing the relationship between %I and V corresponding to a 100 mL sample; $TEAC_{calcd}$, Trolox equivalent antioxidant capacity calculated by model; $TEAC_{exptl}$, Trolox equivalent antioxidant capacity determined by EPR spectroscopy; a,b,c, various manufacturers.

Such studies are very time-consuming and costly. To reduce the cost and time of measurement, attempts have been made to determine the antioxidant capacity on the basis of empirical or semiempirical mathematical models.[27] This new method allows researchers to reduce the time and costs associated with determining the TEAC value more than five times. In accordance with the above, the goal of this study was to develop and assess an empirical model allowing for an estimation of total antioxidant capacity, along with conversion into Trolox equivalents, among others, depending on the standard curve utilized, and using EPR spectroscopy and DPPH as the free radical standard for a variety of food products.

MATERIALS AND METHODS

Chemicals and Samples. DPPH (Sigma-Aldrich, Poznań, Poland) was used as the source of free radicals. To quantify the antioxidant capacity of the tinctures, Trolox (Acros Organics, Geel, Belgium) was used. All other chemicals and solvents were of analytical grade and used without further purification.

The model was constructed on the basis of the antioxidant capacity, determined by EPR spectroscopy, for a wide range of food products available on the market and in pharmacies with varied antioxidant capacity (substances with both strong and weak antioxidant properties): tea, wine, juice, and herbs.

The study was performed on 20 samples of white wines and 40 red wine samples measured immediately after opening. The following were tested: sweet wines (10 samples), semisweet wines (10 samples), semidry wines (10 samples), and dry wines (30 samples), with differing antioxidant properties. The second group of products represented 24 sample juices. The juices differed in the type of fruit that was used for their production, color, percent fruit content, and turbidity. The following beverages were included in the study: 12 juices (orange, apple, grapefruit, citron, raspberry), 10 drinks (red grape, orange, apple, grapefruit, black currant), and 8 nectars (cherry, plum, apple, black currant). All commercial juices, drinks, and nectars were used immediately after opening. Fresh juice obtained by squeezing also was measured immediately after preparation.

Thirty-six samples of tea produced by various manufacturers were also used: black tea (12 samples), green tea (12 samples), and Earl Gray tea (12 samples). An infusion was prepared from each tea by pouring 200 mL of boiling water over one tea bag.

Moreover, 24 samples of herbs (thyme, lemon balm, sage, heartsease, menthe, chamomile) were used. One hundred milliliters of boiling water was poured over teabags filled with herbs, and the tea was infused for a length of time suggested by the manufacturer.

Tests of the model were performed on samples of herbs, coffees, and juices available on the market and in pharmacies. Thirty-six samples of herbs (lemon balm (S1−S4), heartsease (S5−S8), menthe (S9−S12), horsetail (S13−S16), nettle (S17−S20), chamomile (S21−S24), eyebright (S25−S28), hypericum (S29−S32), fennel (S33−S36)) were used. One hundred milliliters of boiling water was poured over tea bags filled with herbs, and the tea was infused for a length of time suggested by the manufacturer. Thirty-two samples of coffee, ground coffee (S37−S48), instant coffee (S49−S56), instant decaffeinated coffee (S57−S64), and espresso coffee (S65−S72), were also used. The coffee differed in species and manufacturer. An infusion was prepared from each coffee by pouring 150 mL of boiling water over 2 g of coffee. The last group of products used for testing included 12 samples of juices produced by various manufacturers (black currant juices (S73−S76) and orange juices (S77−S80)) (Table 1).

Determination of Antioxidant Capacity. Trolox equivalent antioxidant capacity ($TEAC_{exptl}$) was determined using the method described previously.[4,7,20] The regression equation for the linear relationship between the percent inhibition of EPR signal intensity and the mole number of Trolox was assessed as $\%I = 987.60V + 16.36$, where %I is the inhibition (%) and V is the volume of the sample (mL). This equation was used to calculate the antioxidant capacity of the studied samples in micromoles of TE per 100 mL of the studied sample. The percent inhibition of the EPR spectrum was calculated according to the following equation: $\%\ \text{inhibition} = [(I_0 I)/I_0] \times 100\%$, where I_0 is the area of the EPR spectrum of DPPH (control sample) and I is the area of the EPR spectrum of DPPH with sample.

A typical reaction mixture contained 1 mL of 200 μmol/L DPPH solution in ethanol together with 0.002−0.4 mL of sample, depending on the manifested antioxidant properties. For all samples, the regression equation of the linear relationship between the percent

DOI: 10.1021/acs.jafc.5b01478
J. Agric. Food Chem. 2015, 63, 6319−6324

inhibition (%I) of the EPR signal intensity and the volume of sample (V) was determined. On the basis of this equation the %I corresponding to 100 mL of the studied sample was calculated (I_{100}). Then, from the standard curve obtained for Trolox, the antioxidant capacity given in micromoles of TE per 100 mL of sample was defined. To indicate antioxidant capacity measured using the DPPH by EPR spectroscopy $TEAC_{exptl}$ is used.

EPR spectra were obtained with a Bruker EMX EPR spectrometer (Bruker-Biospin, Karlsruhe, Germany) operating at the X-band frequency at room temperature. The typical instrument parameters were as follows: central field, 3480 G; modulation amplitude, 2.0 G; time constant, 40.96; gain, 1×10^4 G; microwave power, 20.12 mW.

Mathematical Model. The mathematical model was based on three variables: $x = V$, $y = \%I$, and $z = I_{100}$, where V is the volume of antioxidant added to the DPPH free-radical solution (mL), %I is the inhibition (%) of the EPR signal of the DPPH free radical, and I_{100} is the value calculated from the equation describing the relationship between %I and V corresponding to a 100 mL sample. The approximation procedure starts from the variable separation $z(x,y) = f(x)g(y)$. Taking into account the qualitative behavior of the data, that is, a strong decay with respect to x, the volume of antioxidant added to the DPPH, and a boundedness with respect to y, the inhibition, the function $f(x)$ is represented as a Laurent series, which includes terms with negative degrees only

$$f(x) = \sum_{n=0}^{\infty} f_n x^{-n}$$

and $g(y)$ as the Taylor series

$$g(y) = \sum_{m=0}^{\infty} g_m y^m$$

around the origin of coordinates $(x,y) = (0,0)$ that results in the following formal double series:

$$z(x, y) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} g_m f_n x^{-n} y^m \quad (1)$$

As the next step, the polynomial cutoff $\max(n) = N$ is reproduced. The properties of the obtained Laurent polynomial guarantee that the product eq 1 with finitely many negative terms exists.

The last step consists of the choice of the maximal polynomial index for x terms in such a way that $\max(m_n) = N - n$. Thus, the final expression takes the form

$$z(x, y) = \sum_{n=0}^{N} \sum_{m=0}^{N-n} f_n g_m x^{-n} y^m$$

For $N = 3$

$$z(x, y) = a_0 + a_1 y + a_2 y^2 + a_3 y^3 + \frac{a_4 + a_5 y + a_6 y^2}{x} + \frac{a_7 + a_8 y}{x^2} + \frac{a_9}{x^3} \quad (2)$$

where $a_0 = f_0 g_0$, $a_1 = f_0 g_1$, $a_2 = f_0 g_2$, $a_3 = f_0 g_3$, $a_4 = f_1 g_0$, $a_5 = f_1 g_1$, $a_6 = f_1 g_2$, $a_7 = f_2 g_0$, $a_8 = f_2 g_1$, and $a_9 = f_3 g_0$.

Fitting Model to Experimental Data. The model eq 2 was fitted to 1000 data points of EPR spectroscopy measurements.

For each sample, $TEAC_{exptl}$ was determined in three trials, according to the standard method of determining antioxidant capacity, described above, using EPR spectroscopy and DPPH as the free radical. Adjustable parameters a_i were estimated by a nonlinear regression procedure using the Levenberg–Marquardt algorithm in double precision. The set of a_i coefficients and the adjusted coefficient of determination for the nonlinear regression, adj-R^2, are listed in Table 2. One can see that the data satisfy the assumed function with high accuracy.

Table 2. Coefficients of Equation 2 together with the Adjusted Coefficient of Determination for the Nonlinear Regression, Adj-R^2

Testing of the Mathematical Model. The model was tested on 20 sample food products, that is, for 80 EPR spectroscopy measurements.

For each sample, $TEAC_{exptl}$ was determined twice, according to the standard method of determining antioxidant capacity, described above, using EPR spectroscopy and DPPH as the free radical. Next, for two randomly selected volumes of antioxidant sample added to 1 mL of DPPH solution, the EPR measurements were repeated (80 measurements) and %I of the DPPH free radical of EPR signal was determined. On the basis of the value of the V of antioxidant added to the free radical solution, as well as %I of the DPPH free radical EPR signal, the I_{100} value was determined using the model eq 2. On the basis of the I_{100} value the antioxidant capacity $TEAC_{calcd}$ was calculated according to the equation $\%I = 987.60V + 16.36$. Subsequently, the average $TEAC_{exptl}$ values were determined from the two series on the basis of seven measurements in each series, the average calculated $TEAC_{calcd}$ values were determined from the model on the basis of two measurements for each series for each studied sample, and these values were compared to each other.

Statistical Analysis. The presented data are the mean values, whereas errors were calculated as standard deviation (SD). Determination coefficients (R^2), obtained $TEAC_{exptl}$, and expected $TEAC_{calcd}$ were calculated by the Pearson test with a level of significance of $p = 0.05$.

RESULTS AND DISCUSSION

A plot of the proposed model and the observed data points is useful to determine how well the model fits the data. Model eq 2 and the observations are plotted in Figure 1. It is evident from the figure that a definite trend exists in the data and that the model eq 2 proficiently performed the task of capturing that trend. Note that the model was fitted to a larger data set than that shown.

One way of evaluating how well the model fits and predicts the data is to compute not only the deviations between the model and the actual data, analysis of the randomness of the residual plots, and normality of the errors but also deviations between the model and the new data. The proposed mathematical equation allows for a determination of the antioxidant capacity of food products based on a single EPR spectroscopy measurement. The value of the experimental TEAC antioxidant capacity for the products, selected for testing of the model, was situated in the wide range between 21 μmol TE/100 mL of the sample and 2347 μmol TE/100 mL (Table 1). The values of TEAC for the studied food samples are consistent with the TEAC values that have been determined through the use of other research methods described in the literature.[1,28,29]

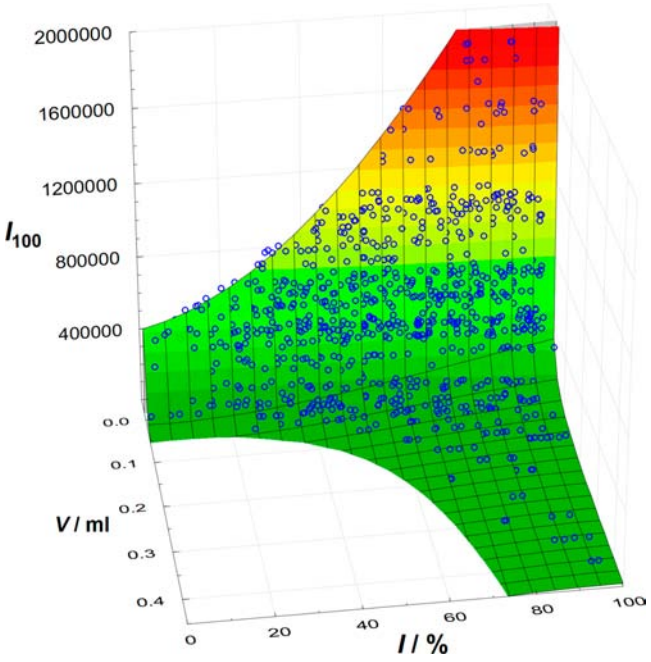

Figure 1. I_{100} as a function of the inhibition of the EPR signal, I, and the volume of antioxidant added to the DPPH solution, V. Points are experimental data on V–I surface calculated using eq 2.

The determination coefficient between TEAC $_{calcd}$ and TEAC $_{exptl}$ was found to be $R^2 = 0.98$ (Figure 2).

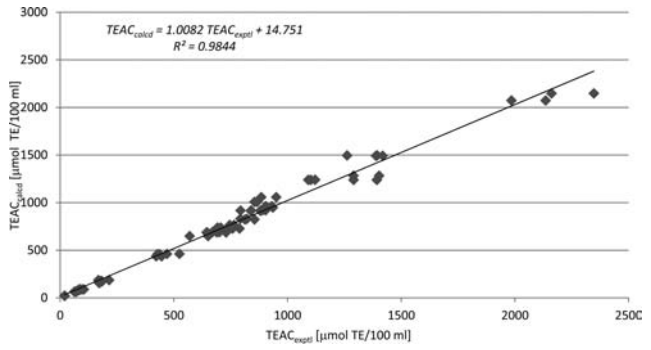

Figure 2. Regression between calculated ($TEAC_{calcd}$) and experimental ($TEAC_{exptl}$) antioxidant capacity.

On the basis of the mathematical model and test conducted, it was concluded that the average relative percentage error of $TEAC_{calcd}$ versus $TEAC_{exptl}$ was 6.6% (95% confidence intervals, CI, 5.5–7.7). It should be noted that for 40 of 80 measurements the value of the error is below 5%, and for 62 of the 80 measurements it was below 10%. The proposed model works for both strong and weak antioxidants. For strong antioxidants (TEAC > 200) the average relative percentage error was found to be 6.5% (95% CI, 5.1–7.8), whereas for weak antioxidants (TEAC < 200) it was 6.8% (95% CI, 4.5–9.0). Such an agreement between $TEAC_{exptl}$ and $TEAC_{calcd}$, as well as an agreement with values found in the literature, indicates the possibility of using this method, which connects mathematical modeling with EPR spectroscopy, for evaluating antioxidant capacities.

For each product the average $TEAC_{exptl}$ and $TEAC_{calcd}$ values from the two series in Figure 3 are presented.

The average relative error for the determined average TEAC calculated values amounted to only 5.25%, which indicates a high utility of the proposed model. To obtain the average antioxidant capacity value via the standard method for determining antioxidant capacity using EPR spectroscopy and DPPH free radicals, it is necessary to perform 22 separate EPR measurements. With the proposed model it is sufficient to perform between two and four EPR experimental and calculated TEAC values to obtain comparable accuracy. Moreover, thanks to the utilization in the model of the I_{100} value, the model offers the possibility of determining the antioxidant capacity in various standards. It is sufficient to develop a standard curve for a standard other than Trolox, to obtain, from one series of measurements, the antioxidant capacities expressed in different standard equivalents.

MATERIALS AND METHODS

Materials. Chlorothalonil, phthalide, quintozene, pentachlorophenol, 2,4-dichlorophenoxyacetic acid (2,4-D), and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) were purchased from Wako Pure Chemical Industries (Osaka, Japan). The pesticides used for residue analysis were of analytical grade. *N*-Hydroxysuccinimide (NHS) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) were purchased from Wako Pure Chemical Industries and Dojindo Laboratories (Kumamoto, Japan), respectively. Bovine serum albumin (BSA, Pro. No. A7888) was purchased from Sigma-Aldrich (St. Louis, MO, USA). Sodium dodecyl sulfate (SDS) and guanidine hydrochloride (GdnHCl) were purchased from Nacalai Tesque (Kyoto, Japan). Horseradish peroxidase-labeled anti-mouse IgG (H+L) antibody from rabbit (Invitrogen) and 96-well microtiter plates (Nunc MaxiSorp) were purchased from Thermo Fisher Scientific (New York, NY, USA). All other chemicals and reagents were of analytical grade and purchased from Wako Pure Chemical Industries or Nacalai Tesque. Anti-chlorothalonil mouse monoclonal antibody (MoAb TPN9A; IgG_1) and the conjugate of *N*-(pentachlorophenoxyacetyl)glycine and BSA (TPN−BSA) were prepared as described previously.[12]

SPR-sensor. SPR-sensors consisted of commercially available instruments of microflow type (Biacore T200; GE Healthcare Europe, Munich, Germany) and a sensor chip, which was coated with carboxymethyldextran (CM5; GE Healthcare Europe). They were functionalized via the following steps based on the instruction manual.

1. Immobilization of TPN−BSA. TPN−BSA was covalently bound to the chip surface by the active ester method. The sensor chip was put to the instrument and was initially rinsed with 10 mmol/L PBS (10 mmol/L phosphate buffer adjusted to pH 7.0, 150 mmol/L NaCl) modified with 0.005% Tween 20 at 5 μL/min for 600 s. A mixture of 80 μL of EDC (400 mmol/L) and 80 μL of NHS (100 mmol/L) in distilled water was made to flow to the channel for 350 s to esterify the carboxyl group of the sensor chip with NHS. The TPN−BSA solution (17 or 44 μg/mL) was dissolved in acetic acid buffer (10 mmol/L; adjusted to pH 5.0) and flowed for 45, 60, 90, or 120 s to bind the activated carboxyl groups to the amino-group residues of TPN−BSA. Ethanolamine (1 mol/L; adjusted to pH 8.5) was made to flow for 350 s to block the residual carboxyl groups. After a rinse with running buffer (50 mmol/L phosphate buffer adjusted to pH 7.0, 75 mmol/L NaCl, 5.0% methanol, and 0.1% BSA), the sensor chip was used for chlorothalonil determination.

2. Premixture of MoAb TPN9A and Chlorothalonil. On the other hand, chlorothalonil was dissolved in methanol and serially diluted to concentrations from 7.8 to 1000 ng/mL in tubes. The diluents were further diluted 10-fold with distilled water, resulting in concentrations from 0.78 to 100 ng/mL in 10% methanol. MoAb TPN9A was also diluted to concentrations from 1.56 to 60 μg/mL with 100 mmol/L PBS (100 mmol/L phosphate buffer adjusted to pH 7.0, 150 mmol/L NaCl) modified with 0.2% BSA, as described previously.[12] The prepared chlorothalonil solution (75 μL) was mixed with the MoAb TPN9A solution (75 μL) in tubes. In this phase, the complex between the MoAb TPN9A and chlorothalonil was formed.

3. Reaction of MoAb TPN9A Not Bound to Chlorothalonil with the Immobilized TPN−BSA. The tubes were put to the instrument. Each mixture was made to flow to the sensor at 20 μL/min for 180 s to react the free MoAb TPN9A, which was not bound to chlorothalonil, with TPN−BSA on the chip. Immediately after the reaction, the flowing solution was replaced with running buffer at 20 μL/min for 180 s.

4. Dissociation of the Bound MoAb TPN9A from the Immobilized TPN−BSA. The sensor chip must be regenerated by removal of the bound antibody from the immobilized TPN−BSA. As the condition, two kinds of solutions were used for the dissociation of the bound MoAb TPN9A after examinations had been carried out to optimize the conditions as described in the results. The dissociation solution A was GdnHCl (3.0 mol/L) in acetic acid (1.0 mol/L; pH 1.9), and the dissociation solution B was 0.2% SDS. The sensor chip was initially washed with solution A at 20 μL/min for 60 s. After 60 s of rinsing with distilled water at 20 μL/min, it was washed again with solution B at 20 μL/min for 120 s. The sensor chip on which the MoAb TPN9A had been dissociated was used again by repeating each of the above steps between (2) premixture of MoAb TPN9A and chlorothalonil and (4) dissociation of the bound MoAb TPN9A from the immobilized TPN-BSA.

5. Data Processing. Raw data were output as a resonance unit (RU), where 1000 RU was defined as 0.1 degree of the refractive index shift by the SPR phenomenon. The actual response curve was drawn; the *x*-axis represented chlorothalonil concentration, and the *y*-axis represented the ΔRUs between the starting point of the reaction and a time point of 180 s.

Indirect Competitive (ic)-ELISA. ic-ELISA was developed as described previously.[12] TPN−BSA (1 μg/mL) was dissolved in 10 mmol/L PBS and added to each well of a 96-well microtiter plate at 100 μL/well. The plate was incubated overnight at 4 °C. Blocking buffer (10 mmol/L PBS modified with 0.4% BSA) was added at 300 μL/well after the wells were washed once with washing buffer (10 mmol/L PBS modified with 0.02% Tween 20). The plate was incubated at 25 °C for 1 h, and the solution was removed from the wells. Chlorothalonil standards were prepared at concentrations from 0.05 to 200 ng/mL in 10% methanol, and the solutions were added at 50 μL/well. The MoAb TPN9A was dissolved in 100 mmol/L PBS with 0.2% BSA and was prepared to a concentration (100 ng/mL) showing an absorbance between 1.0 and 2.0 at 450 nm in this ic-ELISA. MoAb TPN9A was added at 50 μL/well to each well immediately after the standard was added. The plate was incubated at 25 °C for 1 h. After three washings with the washing buffer, horseradish peroxidase-labeled anti-mouse IgG (H+L) antibody, which was diluted 2000-fold in 10 mmol/L PBS with 0.2% BSA, was added at 100 μL/well. The plate was incubated at 25 °C for 1 h. After three washings with the washing buffer, the color development solution (100 μg/mL 3,3′,5,5′-tetramethylbenzidine, 0.006% H_2O_2, 100 mmol/L acetic acid; adjusted to pH 5.5) was added at 100 μL/well. After 10 min at 25 °C, 0.5 mol/L sulfuric acid was added at 100 μL/well to stop the color development reaction. The absorbance was measured at 450 nm by the microplate reader, xMark (Bio-Rad Laboratories, Hercules, CA, USA).

Treatment of Vegetable Samples. Lettuce, cabbage, and long green onion (200 g of each), purchased from a market in Kyoto city, were used for recovery examinations. Cucumber and eggplant (1.0 kg of each), harvested from the experimental farm at the National Institute for Agro-Environmental Sciences, were used for correlation examinations between the SPR-sensor and HPLC. Phosphoric acid solution (phosphoric acid/water = 1:9 v/v) was added at a ratio of 1:2 (w/w) to the vegetable samples and homogenized by a blender. Chlorothalonil was added to the homogenized samples. The final concentrations ranged from 1.0 to 10 mg/kg for the recovery examinations and from 0.2 to 5.5 mg/kg for the correlation examinations.

For the SPR-sensor, pretreatment of the homogenized samples was carried out according to the same procedure as that of direct competitive (dc)-ELISA, as described previously.[12] Methanol (25 mL) was added to the samples (7.5 g) in a 50 mL tube hermetically sealed with a screw cap. The tube was vigorously shaken for 30 min to extract chlorothalonil. The mixture was centrifuged at 3000 rpm at room temperature for 10 min. The supernatant was diluted 8.5-fold with distilled water to become 10% methanol equivalent. The diluted sample was applied to the SPR-sensor without other pretreatments.

For HPLC, acetone was added at 100 mL/sample to the homogenized samples (20 g) and extracted for 3 min, using a homogenizer (Polytron PT2100; Kinematica, Lucerne, Switzerland). The mixture was filtered through a funnel with diatomite by suction. The residue was then re-treated with 50 mL of acetone. Both filtered extracts were mixed and concentrated to 30 mL by evaporation at a temperature lower than 40 °C, in a flask. The sample was transferred to a separating funnel with 100 mL of 10% sodium chloride solution. The above flask was washed with 100 mL of hexane, and the washed solution was also transferred to the funnel. After vigorous shaking for 5 min, a hexane layer was recovered. The liquid−liquid partition was repeated twice. The recovered hexane layer was mixed with

DOI: 10.1021/acs.jafc.5b01980
J. Agric. Food Chem. 2015, 63, 6325−6330

appropriate quantities of anhydrous sodium sulfate. After the filtration, the solution was transferred to a flask and evaporated to dryness at a temperature lower than 40 °C. The dried residue was dissolved with 5 mL of hexane. The dissolved solution was applied to a column in which Florisil (5 g) and anhydrous sodium sulfate (5 g) were filled up with hexane. After the column was washed with hexane (100 mL), chlorothalonil was eluted with a mixture of ethyl acetate and hexane (1:9, v/v; 150 mL). The eluate was dried by evaporation and redissolved with hexane (2.0 mL). A portion of the solution (0.5 mL) was dried by evaporation and redissolved with methanol (1.0 mL). The methanol solution was applied to HPLC.

HPLC Analysis. The HPLC system consisted of an Agilent 1100 series equipped with a quaternary pump, an autosampler, a column oven, and a diode array detector. The wavelength for chlorothalonil detection was 246 nm. The column was a SunFire C18 reversed-phase column (5 μm, 4.6 i.d. × 250 mm; Waters, Milford, MA, USA) with a guard column (5 μm, 4.6 i.d. × 20 mm). The mobile phase was methanol/water (70:30, v/v). The flow rate was 1.0 mL/min, the column oven temperature was 40 °C, and the injection volume was 20 μL.

RESULTS AND DISCUSSION

Development of the SPR-sensor. An SPR-sensor was developed for chlorothalonil determination, using MoAb TPN9A and antigen TPN−BSA. The TPN part of the TPN−BSA has a chlorothalonil-like structure as shown in Figure 1 and reacts with MoAb TPN9A as described

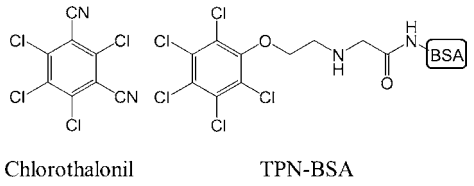

Figure 1. Structures of chlorothalonil and TPN−BSA.

previously.[12] Because the structure is much more chemically stable than that of the binding site in the MoAb TPN9A, TPN−BSA was chosen for immobilization on the sensor chip surface, as it was expected to tolerate the dissociation condition of the TPN−BSA and TPN9A complex.

The TPN−BSA was immobilized at several concentrations and reaction times to determine the optimum conditions: 17 μg/mL and 90 s, 44 μg/mL and 45 s, 44 μg/mL and 60 s, and 44 μg/mL and 120 s. The RU values changed depending on the concentration and the reaction time as shown in Figure 2. Sufficient signal was acquired at a condition of 44 μg/mL and 120 s. These conditions were the minimum concentration of TPN−BSA and time required to obtain a sufficient signal.

The sensor chip should be repeatedly regenerated by dissociation of MoAb TPN9A from the TPN−BSA immobilized on the chip surface. The recommended condition in the instruction manual was SDS (up to 0.5%) or GdnHCl (up to 5.0 mol/L). Only 10% of MoAb TPN9A was dissociated from TPN−BSA by 0.2% SDS, as shown in Figure 3, whereas 84% of MoAb TPN9A was dissociated by 3.0 mol/L GdnHCl, but the dissociation was still incomplete. The k_d value, which was determined after the condition was optimized, was 3×10^{-5} mol/L/s. The result means that the complex is difficult to dissociate at these conditions. Such a phenomenon has already been reported by Svitel et al. for the complex of 2,4-D−BSA and anti-2,4-D antibody.[19] Anti-2,4-D antibody was successfully dissociated from the sensor chip surface by using a non-covalently bound 2,4-D−concanavalin A conjugate instead of a

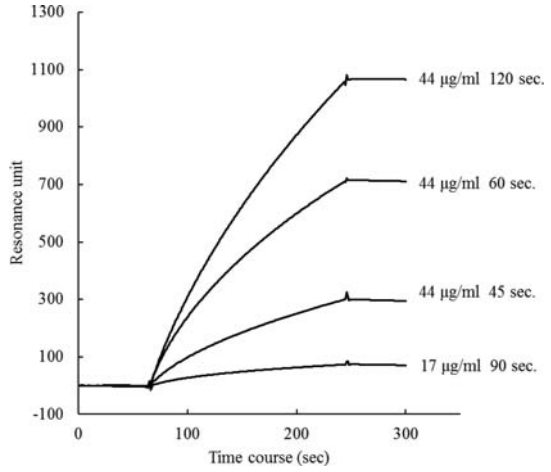

Figure 2. Typical time course of the MoAb TPN9A (7.5 μg/mL) reaction with the immobilized TPN−BSA in the SPR-sensor. The numerals on the right show TPN−BSA concentrations and reaction times for the immobilization.

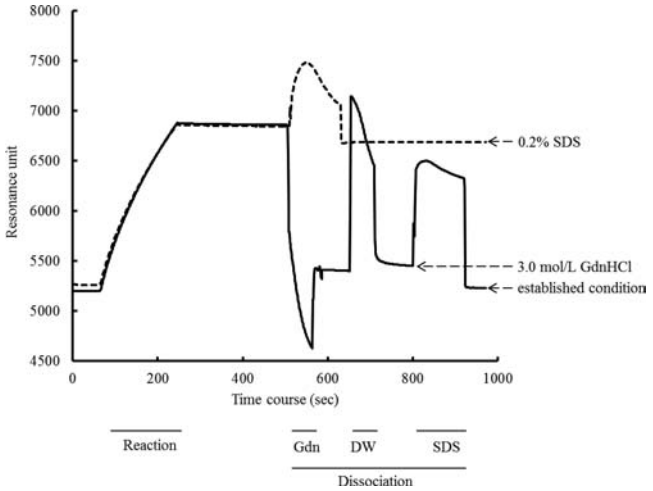

Figure 3. Dissociation of the MoAb TPN9A bound to the immobilized TPN−BSA on the sensor chip. Solid line shows the time course of the signal for the established condition. Dashed line shows the time course of the signal for the dissociation by 0.2% SDS.

2,4-D-BSA conjugate, with which sugar chains were covalently immobilized on the sensor chip surface. This idea was useful for the regeneration of the sensor chip, but re-immobilization of 2,4-D−concanavalin A was necessary for each test. Improvement of the dissociation condition was therefore examined using a combination of GdnHCl and SDS. The dissociation condition was consequently established such that GdnHCl (3.0 mol/L) in acetic acid (1.0 mol/L) was initially made to flow for 60 s, followed by flowing distilled water for 60 s to remove the GdnHCl residue and, finally, 0.2% SDS was made to flow for 120 s. The baseline returned completely to the initial level at this condition, as shown in Figure 3. The established condition made it possible for the sensor chip to be used continuously for 200 cycles, after which the microchannel was physically destroyed by delamination of the thin gold film. This suggests that salting-out by GdnHCl is an effective way to dissociate the complex, and the residual part was dissociated with the surfactant potency of SDS. The MoAb TPN9A and the TPN−BSA complex may have heterogeneous binding forces.

Reactivity in the SPR-sensor. Various concentrations of the MoAb TPN9A solution (1.88−60 μg/mL) were initially applied to the sensor chip, on which TPN−BSA (44 μg/mL) was immobilized, to determine the application dose of MoAb. The minimum required concentration of MoAb TPN9A was 7.5 μg/mL to achieve a ΔRU value of >400 at a time point of 180 s after injection. In turn, this concentration was set as the application dose.

Chlorothalonil solutions were mixed with equal volumes of the MoAb TPN9A solution and then applied to the SPR-sensor. The ΔRU value decreased with an increase in the chlorothalonil concentration (0.78−100 ng/mL), as shown in Figure 4. The K_a value was calculated as 1×10^{10} $(mol/L)^{-1}$

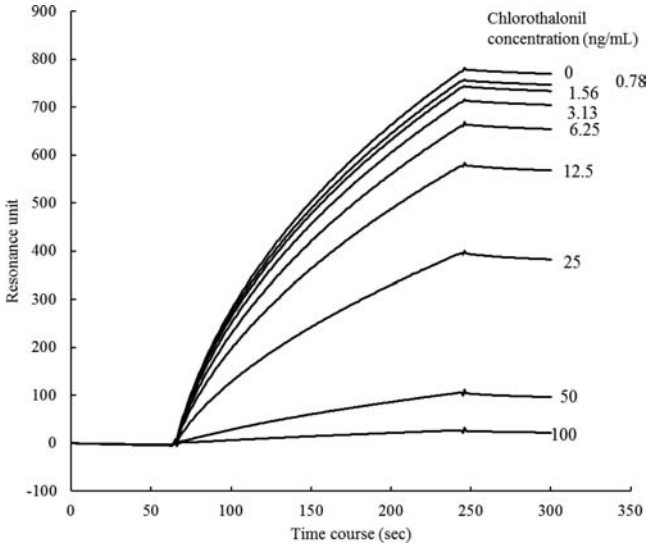

Figure 4. Typical time course of the MoAb TPN9A reaction not bound to chlorothalonil with the immobilized TPN−BSA in the SPR-sensor.

from the results of the SPR-sensor. The inhibition curve 180 s after sample injection for the SPR-sensor was compared with that for ic-ELISA, as shown in Figure 5. The values of 20, 50, and 80% inhibition concentration (IC_{20}, IC_{50}, and IC_{80}) were 8.0, 25, and 44 ng/mL, respectively, for the SPR-sensor. The reactivity at IC_{50} was 10-fold lower than that acquired by ic-ELISA, with which the IC_{20}, IC_{50}, and IC_{80} values were 0.44, 2.5, and 12 ng/mL, respectively. The SPR-sensor required a 44-fold higher concentration of TPN−BSA for immobilization compared with ic-ELISA, which was 44 μg/mL in the SPR-sensor as shown in Figure 2 but 1 μg/mL in the ic-ELISA. The high concentration for the SPR-sensor was derived from the mechanism to monitor the direct signal of the antigen−antibody interaction, differing from signal amplification by horseradish peroxidase in the ic-ELISA. This would be the reason that the sensitivity between them was different as shown in Figure 5, although the same MoAb was used for their constitutions. On the other hand, the SPR-sensor required only 15 min to examine chlorothalonil and showed high reproducibility. The relative standard deviations (RSDs) of SPR were 0.76% (6.25 ng/mL), 2.0% (25 ng/mL), and 8.5% (44 ng/mL) for chlorothalonil, whereas the RSDs of ic-ELISA were 3.8% (0.44 ng/mL), 4.8% (3.1 ng/mL), and 8.6% (13 ng/mL). Thus, the SPR-sensor would be a useful immunoassay method for a simple, quick, and accurate determination, although it had lower sensitivity than ic-ELISA.

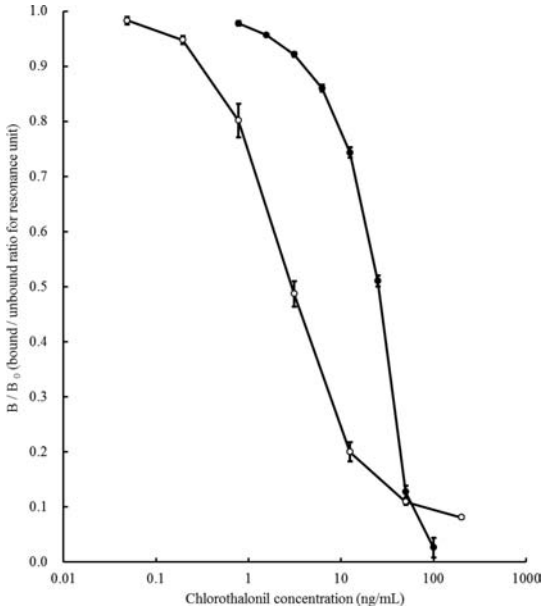

Figure 5. Inhibition curves by chlorothalonil in the ic-ELISA (○) and in the SPR-sensor (●). Each data point is the mean of three replicates from independent examinations. Error bars indicate standard deviations.

Cross-reactivity was examined by the SPR-sensor for structurally related pesticides. The results were slightly less specific compared to those acquired by ic-ELISA, as described in Table 1. Compared with the results of ic-ELISA, phthalide

Table 1. Cross-Reactivity of MoAb TPN9A with Chlorothalonil and the Other Structurally Related Pesticides

Pesticide	CR (%)[a] ELISA	CR (%)[a] SPR	Pesticide	CR (%) ELISA	CR (%) SPR
chlorothalonil			pentachlorophenol		
	100	100		<0.7[b]	1.2
phthalide			2,4-D		
	22	9.1		<0.7	<2.0
quintozene			2,4,5-T		
	17	22.6		<0.7	6.5

[a]CR (%) shows cross-reactivity (%) compared to chlorothalonil. [b]<0.7 shows less than 0.7%.

examined by the SPR-sensor had a slightly lower cross-reactivity, but quintozene, pentachlorophenol, and 2,4,5-T had slightly higher cross-reactivities. The SPR-sensor monitors the early response of the antigen−antibody interactions, whereas ic-ELISA monitors the saturated interactions after 1 h. Because both assays showed only minor differences, it was confirmed that the specificity was a particular characteristic of the MoAb TPN9A.

J. Agric. Food Chem. 2015, 63, 6325−6330

The MRLs of chlorothalonil are set from 0.5 to 50 mg/kg in vegetables in Japan. On the other hand, the SPR-sensor showed a working range from 6.5 to 42 ng/mL. The MRL values were included in concentrations that were 70-fold higher than the working range, for which the dilution rate was usually used for the pretreatment of vegetables in dc-ELISAs.[12] The developed SPR-sensor showed adequate sensitivity to determine chlorothalonil residues in vegetables.

Recovery of Chlorothalonil Spiked into Vegetables. Recovery examination was carried out to confirm applicability of the SPR-sensor in determining chlorothalonil residues in vegetables. Lettuce in the Asteraceae family, cabbage in the Brassicaceae family, and Welsh onion in the Alliaceae family, which are typical leaf vegetables, were chosen as representative species. The vegetable samples before spiking with chlorothalonil had not contained any detectable chlorothalonil in the SPR-sensor (the data not shown). The recovery results within the day are shown in Table 2, and the results across several days

Table 2. Intraday Validation of Chlorothalonil Recovered from Vegetables by SPR-sensor[a]

	lettuce[b]		cabbage[b]		long green onion[b]

10	NT	NT	NT	NT	114	7.4

[a]Each data point is the mean of three replicates for independent examination. [b]The values show recovery (%) and RSD (%). [c]NT, not tested.

Table 3. Interday Validation of Chlorothalonil Recovered from Vegetables by SPR-sensor[a]

	lettuce[b]		cabbage[b]		long green onion[b]	
spike (mg/kg)	recovery	RSD	recovery	RSD	recovery	RSD
1	101	12.6	105	10.4	NT	NT
2	90	7.1	92	9.2	115	6.8
4	NT[c]	NT	107	7.9	NT	NT
5	NT	NT	NT	NT	112	7.5
10	NT	NT	NT	NT	111	8.7

[a]Each data point is the mean of three replicates for independent examination. [b]The values show recovery (%) and RSD (%). [c]NT, not tested.

are shown in Table 3. The SPR-sensor showed good recovery results for both examinations. The recovery ranged from 90 to 118% within the day and from 90 to 115% across several days. The RSD ranged from 2.7 to 13.5% within the day and from 6.8 to 12.6% across several days. These results showed that the developed SPR-sensor has adequate accuracy for the determination of chlorothalonil residues in the vegetables. It was suggested that the SPR-sensor would be applicable to a wide range of vegetables.

Examination of the Correlation between HPLC and SPR-sensor. The results of recovery were confirmed by HPLC analysis, using eggplants and cucumbers, which are typical fruit vegetables. As shown in Figure 6, although the analytical values generally have a bias toward the proposed method (slope = 1.2)

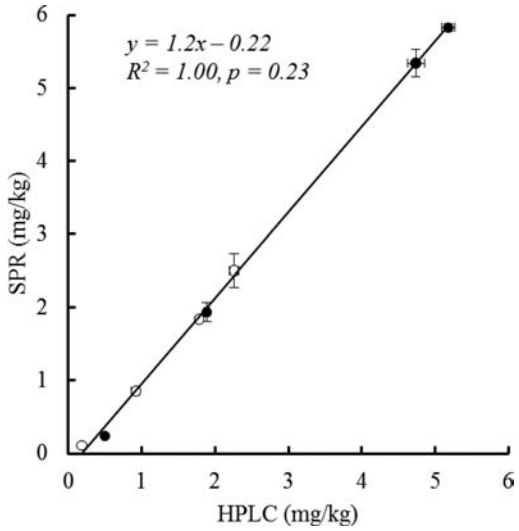

Figure 6. Correlation between the results of the SPR-sensor and the results of HPLC: (○) eggplant; (●) cucumber. Each data point is the mean of three replicates from independent examinations. Error bars indicate standard deviations.

and have y-intercept of −0.22, no significant difference was found in the values obtained from both methods (R^2 = 1.00 and p = 0.23). The results showed that the SPR-sensor developed could determine the chlorothalonil residues in vegetables with adequate quantitative performance in addition to HPLC analysis.

In conclusion, this study showed that the SPR-sensor developed was applicable for the rapid determination of chlorothalonil residues in vegetables around the MRL, although the sensitivity and cross-reactivity were less effective than with the ic-ELISA. The principle of SPR is quite simple, making the real-time determination of pesticides possible. It would be useful for rapid and accurate pesticide residue analysis in garden crops.

identification of which compounds were chelated to the elements.[18]

Some foods with high nutrient content have been used as supplements to meals to improve nutritional values. Nevertheless, antinutritional compounds (phytate, fibers, lignin, and others) can affect the expected result of these supplementations. For example, bread prepared with amaranth flour (which has a high content of iron) was evaluated using bioavailability studies to verify the contribution of this supplementation on its nutritional value. Furthermore, the bioavailable iron fraction was not increased due to the high phytate content in amaranth flour.[19]

The babassu mesocarp has been used as a food supplement, but its composition is not well-known nor is its effect on nutrient bioacessibility. This work aimed to study methods for assessing the interactions of Cu, Fe, and Zn with mesocarp and its effect on the bioaccessibility of these elements in dry whole milk and lignin, with and without babassu mesocarp as supplement, using simulated gastrointestinal digestion.

MATERIALS AND METHODS

Apparatus. An inductively coupled plasma optical emission spectrometer (ICP OES, iCAP 6300 Duo, Thermo Fisher Scientific, Cambridge, UK) equipped with axial and radial viewed plasma, a charge-injection device (CID) detector, an Echelle polychromator, and a radiofrequency source of 27.12 MHz was used for Cu, Fe, Zn, Ca, and Mg determination. The instrumental conditions for the analysis were 1250 W of power, 12 L min^{-1} of plasma gas, 0.5 L min^{-1} of auxiliary gas, and 0.2 L min^{-1} of nebulizer gas. A Babington nebulizer combined with a cyclonic spray chamber was used as sample introduction system. The selected wavelengths were 184.006 nm (Ca), 324.754 nm (Cu), 259.940 nm (Fe), 285.213 nm (Mg), and 202.548 nm (Zn).

A simultaneous atomic absorption spectrometer (SIMAA-6000, PerkinElmer, Norwalk, CT, USA) equipped with a longitudinal Zeeman-effect background corrector, Echelle optical arrangement, solid-state detector, and a standard transversely heated graphite atomizer (THGA) tube with a pyrolytically coated integrated platform was used when the analysis required greater sensitivity, for instance, in the determination of Cu and Fe. The spectrometer was operated using hollow cathode lamps, and the solutions were delivered into the graphite tube by means of an AS-72 autosampler. The instrumental conditions and heating program are shown in Table 1.

Table 1. Instrumental Conditions and Heating Program for the Simultaneous Determination of Cu and Fe by SIMAAS[a]

Instrumental Conditions				
element	wavelength (nm)	current (mA)		slit width (nm)
Cu	324.8	12		0.7
Fe	248.3	25		0.7
Heating Program				
step	temperature (°C)	ramp (s)	hold (s)	Ar flow (mL min^{-1})
drying I	110	1	30	250
drying II	130	15	30	250
pyrolysis	1200	10	20	250
atomization	2000	0	5	0
cleaning	2500	1	3	250

[a]Pyrolysis and atomization temperatures were selected on the basis of the most and least volatile analyte to be simultaneously determined. No chemical modifier was used. The injection temperature of the graphite tube was 30 °C, and the pipet speed of the injection was 100%.

Samples and standard reference materials (SRM) were digested using a high-pressure microwave oven (Speedwave 4, Berghof, Eningen, Germany) equipped with 12 TFM-PTFE vessels (model DAC-17) and infrared sensors for individual temperature and pressure measurements.

Mesocarp and milk drying procedures were carried out in a drying oven, model Q317M-32 (Quimis, São Paulo, SP, Brazil). A shaker table, model Q225 M (Quimis), was used for solution homogenization and stirring during the extraction procedures. For simulated gastrointestinal digestion, a water bath at 36 °C was used at 90 rpm for 120 min (model Q226M2, Quimis). A centrifuge, model Q222TM (Quimis), was used for phase separation. A pH meter, model PH-710 (Unity, Guarulhos, SP, Brazil), was used for pH adjustment of the samples.

Reagents and Samples. All solutions were prepared with high-purity deionized water (18.2 MΩ cm) obtained in a Milli-Q water purification system (Millipore, Belford, MA, USA).

Reference solutions were prepared from Titrisol standard analytical solutions containing 1000 mg L^{-1} iron ($FeCl_3$), copper ($CuCl_2$), zinc ($ZnCl_2$), calcium ($CaCl_2$), and magnesium ($MgCl_2$) (Merck, Darmstadt, Germany) after dilution in HNO_3 0.1% (v v^{-1}) (Merck).

Nitric acid 65% (w v^{-1}) (Merck) and hydrogen peroxide 30% (w v^{-1}) (Merck) were used for sample digestion in a microwave oven, and hydrochloric acid (Merck) and sodium hydroxide (Merck) solutions were used for pH adjustments.

Gastrointestinal fluids were prepared using NaCl (Merck), pepsin (CAS Registry No. 9001-75-6) (Sigma-Aldrich, Saint Louis, MO, USA), HCl (Merck), $NaHCO_3$ (Reagen, Rio de Janeiro, Brazil), K_2HPO_4 (Synth, Diadema, Brazil), NaOH (Merck), pancreatin (CAS Registry No. 8049-47-6) (Sigma-Aldrich), and bile salts (Sigma-Aldrich).

The dialysis procedure was performed using cellulose membranes (Sigma-Aldrich) in 32 mm tubes with 12.4 kDa porosity.

To check the accuracy of the analytical method used for the total determination of the elements, standard reference materials (SRM) of peach leaves (SRM 1547) and bovine liver (SRM 1577c) from the National Institute of Standards and Technology (NIST) were analyzed.

Babassu mesocarp flour samples, purchased in Maranhão state communities, dry milk (Ninho, Nestlé, São Paulo, Brazil), alkaline lignin powder (Sigma-Aldrich), and phytic acid solution 50% (w w^{-1}) (Sigma-Aldrich) were used in simulated gastrointestinal digestion assays.

Procedure. For the total determination of the elements, a mass of 200 mg of mesocarp, milk, or SRMs (SRM 1547 and SRM 1577c) were digested in a microwave oven with 2.0 mL of HNO_3 plus 1.0 mL of H_2O_2 plus 3.0 mL of H_2O, using a heating program in three steps (first step, temperature = 140 °C, ramp = 5 min, hold = 1 min; second step, temperature = 180 °C, ramp = 4 min, hold = 5 min; third step, temperature = 200 °C, ramp = 4 min, hold = 10 min). After digestion, the samples were diluted with deionized water until a final volume of 10 mL and analyzed by ICP OES for Fe, Zn, Ca, and Mg determination. The same solutions were used for Cu determination in a graphite furnace (SIMAA-6000). The calibrations for both techniques were prepared using reference solutions in equivalent acid concentration media of the digestion procedure (HNO_3 2% v v^{-1}). The determination of Ca and Mg was performed in the mesocarp and milk because these elements are considered macronutrients and, consequently, to determine if their presence during the process can influence the bioaccessibility of Cu, Fe, and Zn.

A mass around 2 g of babassu mesocarp was used to extract phytate and other complexing substances with 200 mL of water at pH 7 and 12, adjusted with NaOH. The mixtures were agitated on a shaker table for 30 min (400 rpm), and the mesocarp extract was separated using simple filtration. The residue from the extraction at pH 12 was washed again with NaOH (pH 12) and subsequently washed with three aliquots of water (200 mL) and later dried at 60 °C.

To confirm the extraction of phytate, a standard solution of phytic acid was extracted from mesocarp (obtained at pH 7 and 12) and was scanned in a range between 260 and 800 nm by UV molecular

Cu, Fe, and Zn bioaccessibility in presence of milk + lignin	100 mg of milk 3.2 mg of lignin		soluble and dialyzable fraction	Cu by SIMAAS, Fe and Zn by ICP OES

[a]The gastrointestinal digestion used 3.0 mL of gastric fluid (pH ∼1.5) added to sample. The mixture was shaken (100 rpm) in a thermostatic bath at 36 °C for 2 h, and 0.4 mL of $NaHCO_3$ 3% (w v^{-1}) was added to adjust the pH to 6.8. An aliquot of 3.0 mL of intestinal fluid (pH ∼6.5) was added, and the extract solution was shaken and centrifuged to separate the supernatant.

[a]The total determination of the elements used a mass of 200 mg of mesocarp, milk, or SRMs for digestion in a microwave oven. After digestion, the solution was diluted with deionized water to 10 mL and analyzed. [b]Analysis by SIMAAS. [c]Analysis by ICP OES (n = 3 samples).

absorption spectrophotometry. The pH of each solution was adjusted to 7 before the scan.

Aliquots of Cu, Fe, and Zn reference solutions were added to 2 mL of extracts, the pH was adjusted to 7, and the solution was diluted with water to 3 mL for a final concentration in the 10−300 mg L^{-1} range. Then, the solutions were homogenized on a shaker table for 30 min (400 rpm) and centrifuged at 1700 rpm, and the supernatants were analyzed by ICP OES. A similar procedure was used for the washed mesocarp, adding Cu, Fe, and Zn reference solutions to 50 mg of washed mesocarp and diluting until to 5 mL.

The concentrations of Cu, Fe, and Zn were also determined in the extracts and in a blank prepared for washed mesocarp additions. Thus, the recoveries of additions were calculated as follows: (obtained concentration − blank concentration)/added concentration) × 100%.

The in vitro gastrointestinal digestion procedure was employed to assess the bioaccessibility of the mineral nutrients (Cu, Fe, and Zn) using fluids prepared according to U.S. Pharmacopeia XXIV recommendations.[20] The gastric fluid was prepared by dissolving 0.2 g of NaCl and 0.32 g of pepsin in water. Afterward, 7.0 mL of HCl 10% (v v^{-1}) was added, and this solution was diluted to 100 mL with

DOI: 10.1021/acs.jafc.5b01947
J. Agric. Food Chem. 2015, 63, 6331−6337

deionized water. The intestinal fluid was prepared by dissolving 0.68 g of K_2HPO_4, 1.0 g of pancreatin, 1.25 g of bile salts, and 7.7 mL of NaOH (0.2 mol L^{-1}) and diluted in deionized water to 100 mL.

The general procedure followed to simulate gastrointestinal digestion used 3.0 mL of gastric fluid (pH ~1.5) added to 200 mg of mesocarp. The mixture was shaken continuously (100 rpm) in a thermostatic bath at 36 °C for 2 h. To proceed with the intestinal digestion step, it was necessary to add 0.4 mL of $NaHCO_3$ 3% (w v^{-1}) to adjust the pH to 6.8. Then, 3.0 mL of intestinal fluid (pH ~6.5) was added, and the extract solution was shaken again using the same conditions reported in the gastric step and centrifuged to separate the supernatant. A dialysis procedure was performed to simulate nutrient absorption by human organisms. The supernatants (2 mL) were added into bags formed from cellulose membranes, tied with polyethylene tapes, and immersed into tubes filled with 30 mL of water. After 12 h, the membrane was carefully opened, and the solution was collected from inside and analyzed. The dialyzed fraction was determined by subtracting the retained concentration in membrane from the soluble fraction.[21] The varied conditions established to investigate the Cu, Fe, and Zn bioaccessibility by in vitro gastrointestinal assays are shown in Table 2.

The calibrations for analyses of in vitro gastrointestinal digestions samples by ICP OES and SIMAAS were prepared using reference solutions in HNO_3 0.1% (v v^{-1}). For ICP OES analyzes, the matrix interference effect was evaluated by addition and recovery test. Furthermore, for Fe and Cu determination by SIMAAS, the matrix interference effect was evaluated by comparing calibration curves using reference solutions in sample, blank (gastrointestinal fluid), and HNO_3 0.1% (v v^{-1}).

RESULTS AND DISCUSSION

Total Determination of Elements. The concentrations of Cu, Fe, Zn, Ca, and Mg in mesocarp and milk samples were determined by ICP OES, after microwave oven acid digestion (Table 3). Furthermore, in Table 3 are also shown the method accuracy evaluation by SRMs analysis and addition/recovery test results. The results of SRMs analyses present recoveries ranging from 83 to 99%. Good recoveries (84−116%) were also obtained in addition/recovery tests (Table 3).

The concentrations of Fe and Ca in milk were similar to the information contained in the manufacturer's label (200 μg g^{-1} Fe and 9.4 mg g^{-1} Ca). There was no information about other elements on the milk label to be compared. However, except Cu and Fe, all results were in agreement with those described by the Brazilian Table of Food Composition (TACO) (1.1 μg g^{-1} Cu, 5.0 μg g^{-1} Fe, 27 μg g^{-1} Zn, 8.9 mg g^{-1} Ca, and 0.77 mg g^{-1} Mg).[22] The concentration of Fe was about 40 times greater than the TACO value, owing to the milk sample being enriched with iron pyrophosphate.

By comparison of the obtained concentrations for mesocarp with values previously determined by our group (2.1 μg g^{-1} Cu, 16 μg g^{-1} Fe, 2.4 μg g^{-1} Zn, 432 μg g^{-1} Ca, and 679 μg g^{-1} Mg),[23] differences could be observed for the Cu and Mg concentrations, but for the other elements, the results were similar. When the results were compared with the TACO table values (2.2 μg g^{-1} Cu, 183 μg g^{-1} Fe, 3 μg g^{-1} Zn, 610 μg g^{-1} Ca, and 390 μg g^{-1} Mg), only Zn presented similar values. These differences may be related to the factors that can modify its mineral composition, such as origin, soil, and climate.[23]

Reference daily intakes (RDIs) for essential human nutrition elements have been established by the U.S. Food and Drug Administration (FDA), for instance, Cu (2 mg), Fe (18 mg), Zn (15 mg), Ca (1000 mg), and Mg (400 mg).[24] Considering a portion of 26 g (two spoons) of mesocarp consumed, the contribution percentages to RDIs are 5, 2, 1, 1, and 4% for Cu, Fe, Zn, Ca, and Mg, respectively.

Evaluation of Cu, Fe, and Zn Interaction with the Extract of Babassu Mesocarp. The mesocarp extract obtained at pH 12 had a darker brown color than that obtained at pH 7. This difference must be related to the greater ability of the pH 12 solution to extract organic acids (mainly phytic acid) that are bound to the matrix.

Phytic acid could be the main complexing substance extracted from mesocarp, as this compound is found in high concentrations in vegetables because it has the function of storing phosphorus and energy. Phytic acid also has the ability to bind to metal ions, forming stable complexes.[6−8]

Spectrophotometric analysis of the extracts showed that the spectra of phytic acid and the extracts were similar, and both had a maximum absorbance at 272 nm, demonstrating the presence of this substance in the extract.

The addition of elements in both extracts (pH 7 and 12 solutions) was done with the final pH adjusted to 7, which is similar to the intestinal condition. After the addition of elements to the extracts, a brown precipitate was formed and extract solution discoloration was observed. In aqueous solutions at pH 7, Fe^{III} and Cu^{II} may hydrolyze and precipitate as hydroxides. However, even with the possibility of Fe^{III} and Cu^{II} hydrolysis, the precipitate formed in the extract from mesocarp was provided not only by hydrolysis of these ions but also by complexation with phytate. The discoloration of the extract solutions and the increasing volume of the precipitate indicated that the compound present in the solution had precipitated together with the elements.

The recoveries of elements added (determined in supernatant) to the babassu mesocarp extracts from pH 7 (Figure 1a) and pH 12 (Figure 1b) solutions, after centrifugation, are shown in Figure 1. If only hydrolysis was considered, high Cu and Fe recoveries were not expected, especially for lower addition concentrations. However, the results show that complexes formed between these elements and phytate until a certain concentration, minimizing the effect of hydrolysis, making them more soluble and increasing recovery. The recovery is higher for the extract at pH 12 (Figure 1b) because it contains a higher concentration of phytate. It is well-known that the higher the concentration of cations bound to phytate, the lower the complex solubility. For example, monoferric phytate is highly soluble, whereas tetraferric phytate is insoluble.[25]

This experiment demonstrates that the phytate extract of the babassu mesocarp can strongly interact with Cu^{II} and Fe^{III}, and less so with Zn^{II}, at pH 7.

Evaluation of Cu, Fe, and Zn Interaction with Washed Mesocarp. The recovery of Cu^{II}, Fe^{III}, and Zn^{II} added to the washed mesocarp is shown in Figure 1c. These additions were carried out to evaluate the behavior of these ions in the presence of solid mesocarp, after weakly bound complexing compounds had been removed during the washing. It can be seen that the recoveries of Cu and Fe in the supernatants were <20%. These low recoveries cannot prove their interaction with washed mesocarp because they can be attributed to the hydrolysis and precipitation of Cu^{II} and Fe^{III} at pH 7. On the other hand, at this pH the Zn^{II} does not hydrolyze. However, at lower added element concentrations, lower recoveries for Zn were observed, demonstrating a possible interaction with the complexing compounds that were not extracted from the mesocarp. The increase in recovery may be indicative of saturation of the binding sites in the mesocarp compounds. Therefore, a low concentration of Zn was able to interact with

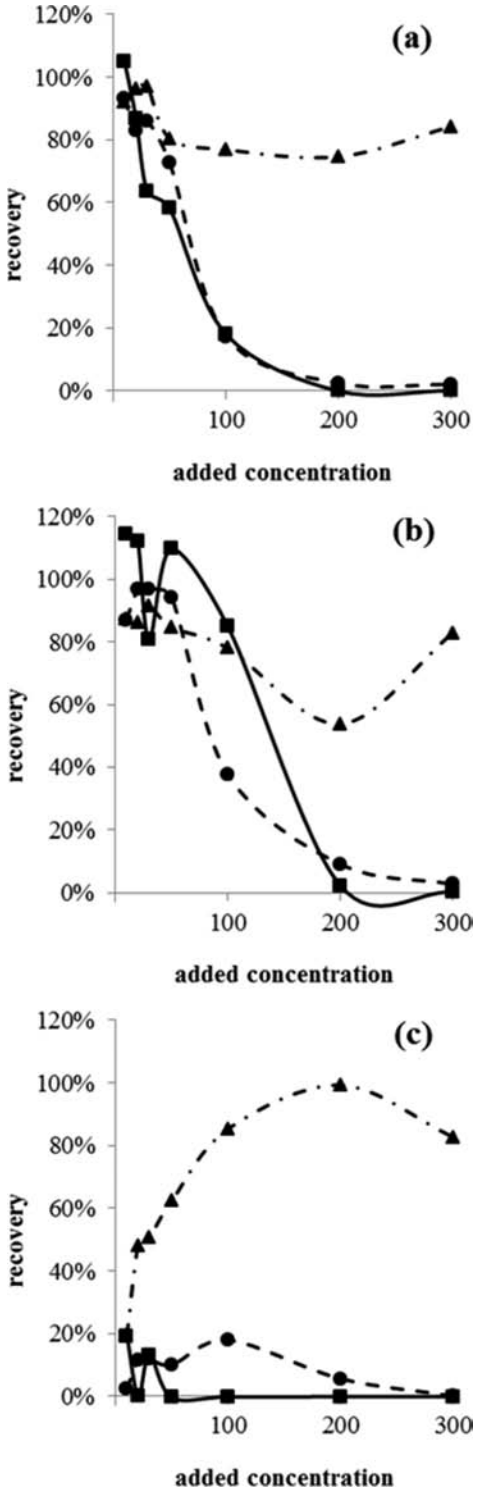

Figure 1. Recovery of Cu (●), Fe (■), and Zn (▲) added to the extract prepared (a) at pH 7 or (b) at pH 12 and (c) in the washed mesocarp.

mesocarp occupying all binding sites. Thus, when a higher concentration was added, the excess of Zn remained in solution.

In Vitro Gastrointestinal Digestion of Babassu Mesocarp. The addition and recovery test shows that ICP OES analyses did not present significant matrix interference effect. The obtained recoveries range from 87 to 107%. Matrix interference was also not observed for SIMAAS analyses. The ratio between the slopes obtained from HNO_3 0.1% (v v^{-1}) solutions and sample and blank media range from 1.0 to 1.2; thus, no significant difference was observed, allowing the calibration with reference solutions in HNO_3 0.1% (v v^{-1}).

The gastrointestinal digestion of babassu mesocarp showed that Fe and Zn present in this material are not extracted, but Cu presented a soluble fraction (96%). This indicates that, besides the presence of Fe and Zn in the babassu mesocarp, as shown in Table 3, these elements are not bioaccessible.

The supernatants of the gastrointestinal digestions with Cu^{II}, Fe^{III}, and Zn^{II} addition exhibited a dark color, possibly caused by the extraction of phytic acid and subsequent complexation with elements such as Fe, as observed in previous results.

Table 4 presents the recoveries of Cu, Fe, and Zn that were added to the babassu mesocarp during gastrointestinal digestion, without and with the addition of Ca^{II} and Mg^{II}. These elements were added in concentrations similar to those present in milk. Without Ca and Mg, 65% of the Cu, 48% of the Fe, and 75% of the Zn remained in the supernatant solution. It is likely that the other fractions of Cu, Fe, and Zn were bound to the compounds present in the mesocarp or precipitate. With the addition of 67 μg of Mg^{II} to the simulated gastrointestinal digestion, the recovery values were not significantly changed (65% for Cu, 49% for Fe, and 73% for Zn). However, with the addition of 880 μg of Ca^{II}, Fe^{III}, and Zn^{II}, recoveries undergo alteration, decreasing to 41% for Fe and 56% for Zn. In this case, the concentration of soluble Cu was also almost the same under all conditions.

Table 4. Addition and Recovery Tests for Fe, Cu, and Zn in Gastrointestinal Digestion of Babassu Mesocarp in the Presence of Ca and Mg[a]

	recovery mass (μg)		
element	without Ca and Mg	with Ca addition	with Mg addition
Fe	134 ± 3	115 ± 2	138 ± 7
Cu	11.7 ± 0.2	11.6 ± 0.3	11.5 ± 0.4
Zn	105 ± 5	78 ± 6	103 ± 3

[a]Addition of 18 μg of Cu, 280 μg of Fe, and 140 μg of Zn.

Upon the addition of Ca^{II}, the color of the solution was clearer than that without Ca^{II}. The dark color of the solution can be related to soluble phytate complexes. Therefore, discoloration caused by the addition of Ca^{II} indicates a decrease in phytate complex solubility. Calcium forms complexes with phytate, and these complexes (Ca−phytate) can bind Zn^{II} and Fe^{III}, forming complexes that are even more insoluble than just Fe−phytate and Zn−phytate complexes.[25]

In Vitro Gastrointestinal Digestion of Milk with Mesocarp and Lignin. In principle, the studies performed to evaluate the bioaccessibility of the elements with babassu mesocarp all utilized standard solutions, which was very important to a better understanding of the system.

To simulate a situation closer to reality, tests were conducted to assess the bioaccessibility of Cu, Fe, and Zn in the gastrointestinal digestion of whole dried milk and milk in the presence of mesocarp and lignin. The Cu, Fe, and Zn bioaccessibility values are shown in Figure 2. In each case, the first column in the graphs (white bar) refers to the total concentration of elements present in the weighed mass of milk and mesocarp. The second column (gray bar) represents the soluble fractions obtained during gastrointestinal digestions, after centrifugation and analysis of supernatant, and the last

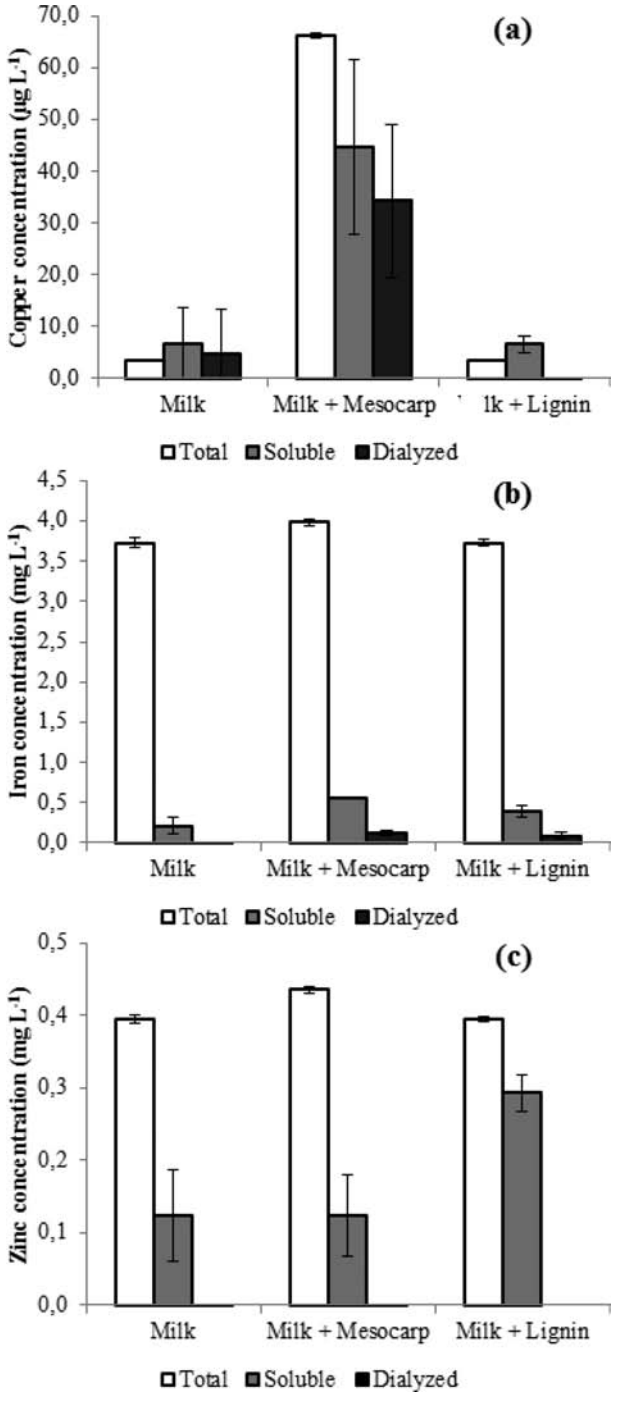

Figure 2. (a) Cu, (b) Fe, and (c) Zn bioaccessibility in milk and in a mixture of milk and mesocarp as well as in a mixture of milk and lignin.

column (black bar) represents the concentration of these elements dialyzed in the cellulose membrane (the fraction that migrated throughout the membrane).

The concentration of Cu in milk is low, but it is fully bioaccessible, as shown in Figure 2a. A comparison of the total and soluble Fe and Zn contents (Figure 2b,c) shows that they are not fully solubilized during the milk gastrointestinal digestion. Furthermore, after dialysis, these elements were completely retained inside the membrane, indicating they were associated with high molecular weight compounds, which probably could decrease their bioaccessibility. The results observed for Fe are very interesting, as the milk used in this research was enriched with ferric pyrophosphate by the manufacturer. This iron compound is widely used for fortify foods. Although it is known that it presents low bioavailabity when compared to other iron species, such as ferrous sulfate, studies demonstrate that it suffers less negative effect of antinutritional compounds.[26,27]

When the milk was mixed with mesocarp, the total concentration of Cu increased meaning fully, owing to the presence of mesocarp that has a concentration 20 times higher than in milk. Consequently, the soluble and dialyzed fractions observed in Figure 2a are from mesocarp. Thus, it was not possible to evaluate the effect on Cu bioaccessibility in milk. The addition of mesocarp to milk increased the concentration of soluble Fe (Figure 2b) and its dialyzed fraction compared to the digestion of milk alone. Fe hydrolyzes and precipitates at intestinal pH; however, nutrients present in food, such as amino acids and peptides, can bind to Fe, turning it soluble and, consequently, bioavailable.[28] Thus, substances present in milk, such as casein or other binding compounds, can form a soluble complex with Fe, thereby enhancing the Fe bioaccessibility in mesocarp. Another suggested explanation is that compounds present in the mesocarp (e.g., phytate) may also form soluble compounds of the elements, depending on their concentrations. The soluble and dialyzed fractions of Zn in the mixture of milk and mesocarp remained unchanged compared to the milk alone (Figure 2c); thus, the mesocarp does not influence Zn bioaccessibility in milk.

Although lignin increases the elements' soluble fractions, the dialyzed fractions were still very low. However, these elements, even when soluble, may not be bioaccessible for absorption by the body, because they are strongly associated with lignin, which is a compound of high molecular weight.

In conclusion, total elemental determination showed that mesocarp babassu contained Fe, Cu, and Zn; however, Fe and Zn are not available after in vitro gastrointestinal digestion. Therefore, the mesocarp cannot be considered as a source of these nutrients. Only Cu was extracted during the simulated digestion, having a soluble fraction of 96%. Furthermore, it was observed that the mesocarp could interact with these elements, and phytate was the main compound responsible for these interactions. It was also noted that Fe^{III} and Cu^{II} ions may hydrolyze and precipitate at intestinal pH, inhibiting their absorption by human organisms. The negative effects on Cu, Fe, and Zn bioaccessibility observed in the studies using reference solutions did not occur when digestion of the milk mixtures was performed. The presence of mesocarp did not reduce the available fractions of elements.

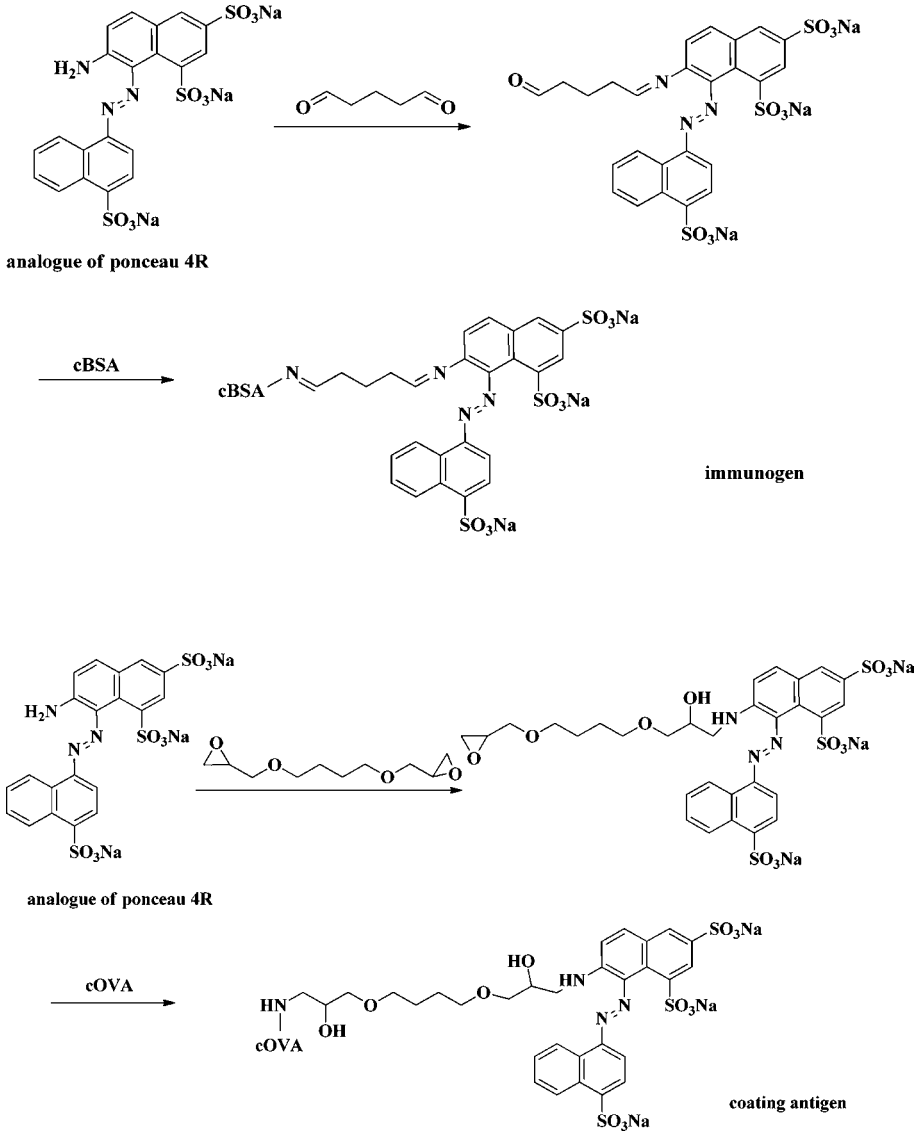

Figure 2. Synthesis of the immunogen and coating antigen for ponceau 4R.

Sciences (Military Medical Institute, Beijing, China). 3,3′,5,5′-Tetramethylbenzidine (TMB) was purchased from Shanghai Sangon Biological Engineering Technology (Sangon Biotech Co., Ltd., Shanghai, China). Dimethylformamide (DMF) and glutaraldehyde of chemical grade were supplied by Guangfu Fine Chemical Research Institute (Guangfu Chemical Co., Tianjin, China). Sodium 4-aminonaphthalene-1-sulfonate and sodium 7-aminonaphthalene-1,3-disulfonate were from TCI (Tokyo Kasei Kogyo Co., Ltd., Tokyo, Japan).

The buffers included (1) phosphate-buffered saline (PBS, pH 7.4), composed of 138 mM NaCl, 1.5 mM KH_2PO_4, 7 mM Na_2HPO_4, and 2.7 mM KCl; (2) washing buffer (PBST), a PBS solution containing 0.05% (v/v) of Tween 20; (3) coating buffer, 0.01 M carbonate buffer (15 mM Na_2CO_3 and 35 mM $NaHCO_3$, pH 9.6); (4) blocking buffer, PBS mixed with 1% of OVA and 0.05% (v/v) of Tween 20; (5) substrate buffer (TMB + H_2O_2), 400 mL of 0.6% TMB−DMSO mixed with 100 mL of 1% H_2O_2 in citrate−acetate buffer (pH 5.5); and (6) borate buffer (pH 8.5), 94.5 mM sodium tetraborate and 151.4 mM NaCl.

The instruments used in this study were listed as follows: (1) The model 680 microplate reader was from Bio-Rad Laboratories Headquarters (Bio-Rad, Hercules, CA, USA) for immunoassay signal

Table 1. Cross-Reactivity (CR) of ELISA for Ponceau 4R and Related Compounds

Compound	Structure	IC_{50} (ng/mL)	CR (%)
Ponceau 4R		36.82	100
Sunset yellow FCF		>50000	<0.07
Tartrazine		>50000	<0.07
Amaranth		>10000	<0.3
Chromotrope FB		>50000	<0.07
Crocein orange G		>50000	<0.07

collection. (2) A Shimadzu UV-1800 (Kyoto, Japan) was used to detect the UV−vis spectra of conjugates. (3) A Bruker Avance 400 NMR spectrometer (Bruker BioSpin, Zurich, Switzerland) was applied to record the ^1H (400 MHz).

Synthesis of Hapten for Ponceau 4R. To prepare immunogen, a hapten of ponceau 4R was synthesized by the following steps (Figure 1). First, 1.0 mmol of 4-aminonaphthalene-1-sulfonate and 1.1 mmol of $NaNO_2$ were sufficiently mixed and added into 4.0 mL of 12.0 M HCl. This mixture was allowed to react at 0−5 °C for 1 h. Second, the mixture was added into the DMF solution (250 μL) containing 1.0 mmol of sodium 7-aminonaphthalene-1,3-disulfonate. Subsequently, 10 M NaOH was used to adjust the pH of the solution to 8−9, and the mixture was kept at 4 °C for 5 h for reaction. Finally, the product was filtered and the precipitate was collected, which served as the hapten of ponceau 4R.

Preparation of Immunogen and Coating Antigen. BSA and OVA were used to prepare the immunogen and coating antigen of ponceau 4R, respectively. To improve the yield of the reaction, the carboxylic acid groups of the carrier protein were converted into primary amine groups with an excess of ethylenediamine as described previously.[33] The activated proteins were named cBSA and cOVA, respectively.

The immunogen and coating antigen of ponceau 4R were initially synthesized in this study, and the details of preparation were described as follows (Figure 2). Accurately weighed cBSA (97.2 mg, 1.43 μmol) and hapten of ponceau 4R (30.2 mg, 0.05 mmol) were dissolved into 6.0 and 3.0 mL of borate buffer, respectively. Then, these two solutions were fully mixed. Next, 98 μL of glutaraldehyde (25%, 0.25 mmol) was added dropwise to the mixture, and it was stirred for reaction at room temperature for 5 h. The product was dialyzed against PBS and distilled water for 3 days, respectively, and the dialysate was refreshed at intervals of 8 h. Finally, the purified resultant, which was the immunogen of ponceau 4R, was lyophilized and stored at −20 °C for further use.

The coating antigen of ponceau 4R was prepared by using BDE as the linker (Figure 2). BDE (13.3 μL; 0.07 mmol) was added into the solution of cOVA (31.5 mg, 0.7 μmol), which was dissolved in 4 mL of borate buffer and then reacted for 24 h. To this solution was dropwise

DOI: 10.1021/acs.jafc.5b02129
J. Agric. Food Chem. 2015, 63, 6338−6345

added hapten of ponceau 4R (14.8 mg, 0.0245 mmol) dissolved into 3 mL of borate buffer, and reaction was continued for another 24 h at room temperature. The coating antigen of ponceau 4R was obtained via the purification steps mentioned above.

Preparation of Polyclonal Antibody. Animal treatments were based on the guidelines of the Chinese Association for Laboratory Animal Sciences. Two male New Zealand white rabbits (2−2.5 kg) were used to produce anti-ponceau 4R polyclonal antibodies by multiple-site subcutaneous injections. The blank blood (1.0 mL) was collected beforehand. In the first immunization, 0.5 mL of normal saline containing 0.5 mg of immunogen and 0.5 mL of cFA was emulsified and subcutaneously injected at the rabbits' back. Then, three booster injections at intervals of 2 weeks followed by the first immunization, and the injected dosage decreased to 0.25 mg of immunogen plus 0.5 mL of iFA and 0.5 mL of normal saline. For the fifth immunization, 0.25 mg of immunogen in 1 mL of normal saline was administered. Seven days after the final injection, the rabbits were exsanguinated by heart puncture under general anesthetic, and the antiserum was collected by coagulation and centrifugation. It was stored at −20 °C until use.

Optimization of the Immunoassay. The concentrations of coating antigen and antibody were optimized first by the checkerboard procedure. The 96-well microplate was coated with the coating antigen at various concentrations (0.001, 0.01, 0.1, 0.5, 1.0, 5.0 μg/mL), and it was incubated at 37 °C for 2 h. After removal of the excess coating antigen by washing with PBST, the blocking buffer was added and the plate was incubated at 37 °C for 2 h subsequently. The antibodies with different dilutions were added (dilution ratio of 1:2500−1:320000, 100 μL per well) after washing with PBST. The plate was incubated at 37 °C for 2 h and washed. Then, goat anti-rabbit IgG-HRP (1:2000, 100 μL) was added into each well and incubated for 0.5 h at 37 °C. Finally, TMB substrate solution was added, which was incubated for 10 min, and the enzymatic reaction was stopped by the addition of 2 M HCl (100 μL per well). Subsequently, the absorbance at 450 nm was recorded. The concentration of antibody and coating antigen with the absorbance value correspondent with their dilution ratio was selected as the optimal condition for further study.

Indirect Competitive ELISA (icELISA). An icELISA procedure was developed under the optimal concentration of coating antigen and antibody, which was studied above. The icELISA was similar to the description above, except that 50 μL of competitor diluent (ponceau 4R) was added before the addition of antibodies. The competitive curve was generated by plotting absorbance at 450 nm versus the logarithm of ponceau 4R concentration. The IC_{50} values were determined to reflect the sensitivity of the assay, which represented the concentration that half of the binding of the antibody to the coating antigen was inhibited.

For the cross-reactivity study, other selected azo dyes were added instead of ponceau 4R at different concentrations from 0.0001 to 10000 ng/mL. Five structural analogues were selected for cross-reactivity study including sunset yellow FCF, tartrazine, amaranth, chromotrope FB, and crocein orange G. The cross-reactivity (CR%) values were calculated to evaluate the specificity of the antibody according to the following equation:

$$CR\% = IC_{50\ \text{ponceau 4R}}/IC_{50\ \text{other pigments}} \times 100\%$$

The accuracy and precision of the method were evaluated by detecting ponceau 4R solutions (1, 100, 10000 ng/mL) five times per day, which was performed for 3 days to calculate the intra- and interassay variations of the method.

Application of the icELISA in Food Samples. To investigate the matrix effects, three food samples including grape juice, a carbonated beverage, and RIO cocktail, in which the use of ponceau 4R as a color additive was permitted, were obtained from local supermarkets. Before detection with the proposed icELISA, the samples were treated simply as follows: carbonated beverage was boiled to remove CO_2 and then centrifuged at 10000*g* for 10 min, grape juice and RIO cocktail were centrifuged at 10000*g* for 10 min and then filtered by a 0.25 μm filter membrane. The matrices were then diluted into a series of concentrations before analysis.

IC_{50} values of ponceau 4R in each prepared sample were compared with that in PBS to obtain the optimum dilution. Recoveries and coefficients of variation (CVs) were determined by the performance of the icELISA in different matrices spiked with ponceau 4R at levels of 50, 100, and 200 ng/mL.

$$\text{recovery}\ (\%) = (\text{concentration measured}/\text{concentration spiked}) \times 100\%$$

Statistical Analysis. All of the experiments in the research were performed at least three times. The data are expressed as the mean ± standard deviation (SD).

RESULTS AND DISCUSSION

Synthesis of Hapten for Ponceau 4R. It is well-known that a small molecule has only immunoreactivity and does not have any immunogenicity. Therefore, ponceau 4R cannot elicit an immune response independently in the bodies of animals. It must be connected to a carrier protein to obtain the capacity of being immunogenic. The important condition of connection with carrier protein is the existence of active groups in the structures of hapten, such as hydroxyl, carboxyl, and amino groups, which could react with protein under relatively mild conditions. As shown in Table 1, there is a hydroxyl group at

position 7, which is adjacent to the azo bond. However, it was reported that azo−hydrazone tautomerism might happen in similar structures.[34] To improve the efficiency of the connecting reaction, a hapten of ponceau 4R was designed and synthesized as shown in Figure 1. A primary amine was introduced into the structure of ponceau 4R, which could react with aldehyde groups or carboxyl groups simply. The synthesized hapten was tested by ^{1}H NMR, and the results were as follows: ^{1}H NMR (400 MHz, DMSO) δ 8.273−8.282 (t, 2H), 8.121 (s, 1H), 8.092 (s, 1H), 8.032 (s, 1H), 8.012 (s, 1H), 7.639 (s, 1H), 7.494 (s, 1H), 7.367 (s, 1H), 7.240 (s, 1H). The NMR data demonstrated that the hapten was synthesized successfully.

Characterization of Immunogen and Coating Antigen. In this study, glutaraldehyde was used to link the hapten and protein (cBSA). The procedure of synthesis is shown in Figure 2. By this method, a linker with a five-carbon length was introduced, which might be beneficial for the specific recognition of the organism. UV−vis spectrophotometry was used to evaluate the effectiveness of the conjugation reaction, and the UV−vis spectra of cBSA, analogue of ponceau 4R, and the immunogen are shown in Figure 3. The characteristic absorption peak of the analogue of ponceau 4R locates at 300 and 420 nm, and that of cBSA appears at 278 nm. However, the maximal absorbance of immunogen is observed at 480 nm, and there is an obviously enhanced peak at 290 nm, which indicates that a red-shift happens. The results of the UV−vis spectra could preliminarily demonstrate that the synthesis of immunogen succeeds.

Characterization of Polyclonal Antibodies. The titer or the highest dilution of the antibody, which represents the lowest concentration needed to get a positive result by ELISA, was measured first. The anti-ponceau 4R polyclonal antibody was doubly diluted, and the titer of the produced antibody was found to be 1:20000. Second, the concentration of the coating antigen and the proper dilution of the antibody for ELISA were optimized. The optimal working concentration of the coating antigen is 2 μg/mL, and the selected dilution of the antibody was 1:4000. On the basis of the optimized conditions, an indirect competitive ELISA was developed by using ponceau 4R as the competitor.

The sensitivity of the assay was evaluated by IC_{50} value from the inhibition curve as shown in Figure 4. The IC_{50} of the proposed icELISA is 36.82 ng/mL, and the limit of detection (LOD, IC_{20}) is 0.80 ng/mL. Additionally, the standard curve of the method was obtained as shown in Figure 5. The standard curve exhibits a wide linear range of 1−10000 ng/mL and good linearity (R^2 = 0.99987, n = 5) with a standard curve equation of $y = 0.98155 - 0.15373x$, where x represents the logarithm of ponceau 4R concentration and y is the ratio of the absorbance value at 450 nm with competitor (B) to that value without competitor (B_0).

The specificity of the anti-ponceau 4R polyclonal antibody was studied by cross-reactivity. Five structural analogues of ponceau 4R were selected as listed in Table 1, and their IC_{50} values were detected by the proposed icELISA. The cross-reactivity of each analogue was calculated as shown in Table 1. It is indicated that the prepared antibody was highly specific with low cross-reactivity to each selected pigment (<0.3). It was remarkable that the structure of one analogue, amaranth, was very similar to that of ponceau 4R. However, the cross-reactivity was considerably low, which demonstrated that the substituent position of sulfonate significantly influences the specificity of the antibody. It also reflected that the synthesis of the immunogen using glutaraldehyde was advisible. The linker with a five-carbon length introduced into the immunogen seemed proper, which might contribute to adequate exposure of the hapten for specific recognition.

To evaluate the accuracy and precision of the assay, three levels of ponceau 4R standard solutions in PBS (1, 100, and 10000 ng/mL) were prepared and detected by the developed icELISA for three consecutive days, which was repeated five times per day. The intra-assay variation and interassay variation were calculated, and the results are listed in Table 2. As shown, the intra-assay variations range from 1.7 to 6.5%, and the interassay variations were <17.7%. The results reflected that the proposed icELISA was accurate and precise for ponceau 4R determination in PBS.

DOI: 10.1021/acs.jafc.5b02129
J. Agric. Food Chem. 2015, 63, 6338−6345

Performance of the Developed icELISA in Foods. The matrix of real samples might interfer with the detection, and it is important to reduce matrix interferences. Three available food samples, which are allowed to add ponceau 4R as pigment, were collected, including grape juice, a carbonated beverage, and RIO cocktail. To minimize the matrix effects, these samples were treated simply and diluted, respectively. The recovery study was performed with the optimized dilution of each sample: grape juice, 1:20; carbonated beverage, 1:10; and RIO cocktail, 1:50. The recoveries of ponceau 4R in these three samples at three different fortified levels are listed in Table 3, and they range from 93.87 to 103.77%. The intra-assay variation is <11.73%, and the interassay variation is <10.58%. The results showed that the developed icELISA for ponceau 4R was stable and reproducible in the food sample detections. It also has the advantage of simplicity in sample preparation, which is a potential tool fitting for field tests of ponceau 4R.

Comparison with HPLC Method. To vertify the accuracy of the proposed icELISA for ponceau 4R, the method of HPLC was employed for comparison. The standard curve shown in Figure 6 exhibited excellent linearity from 40 to 300 μg/mL with the R^2 up to 0.99982. During the detection range of HPLC, 100, 200, and 250 μg/mL were chosen to determine the quantitative examination of ELISA and HPLC (Table 4), which showed that ELISA had results consistent with those of HPLC, and it was more sensitive, with a lower limit of detection, 0.80 ng/mL, and a wider working range, 1−10000 ng/mL, than HPLC as shown in Table 4. (F test showed the variances between ELISA and HPLC were not significantly different and $P > 0.05$.)

In conclusion, an icELISA was developed for the detection of ponceau 4R based on the polyclonal antibody produced in this study. The antibody was specific to ponceau 4R, which had low cross-reactivity with its analogues (<0.3). The good performance of the antibody was derived from the well-synthesized hapten and immunogen by a novel design. All of the data showed that the icELISA for ponceau 4R proposed in this study was sensitive, accurate, specific, stable, and reproducible with a LOD of 0.80 ng/mL. Additionally, this method exhibited the advantages of simplicity, convenience, rapidity, and inexpensiveness. It provides an alternative for the determination of ponceau 4R, which is especially suitable for its monitoring in food samples.

(analytical reagent grade), acetonitrile (HPLC grade), dichloromethane (laboratory reagent grade), hexane (GLC, pesticide residue grade), and methanol (HPLC grade) were obtained from Thermo-Fisher Scientific (Loughborough, UK); benzyl mercaptan (BM) was from Sigma-Aldrich (Poole, UK); phosphate buffered saline (PBS) was from Biomérieux (Marcy l'Etoile, France); Sephadex LH-20 was from GE Healthcare (Little Chalfont, UK); and ultrapure water (MQ H_2O) was from a Milli-Q Plus system (Millipore, Watford, UK).

Preparation of Plant Extracts and Tannin Fractions. Eighteen different plant materials were used: aerial plants of *Onobrychis viciifolia* (OV) were collected on June 7, 2012 (Barham, Kent, UK); *Trifolium repens* flowers were collected from at NIAB (Cambridge, UK; sample TRa) or purchased from Zioła z Kurpi (Jednorożec, Poland; sample TRb); *Lespedeza cuneata* (LC) pellets were from Sims Brothers Seed Co. (Union Springs, AL, USA); *Betulae folium* leaves (*Betula pendula* Roth and/or *Betula pubescens* Ehrh.; BP), *Tilia inflorescentia* flowers (T; a mixture of *Tilia cordata*, *Tilia platyphyllos*, and *Tilia vulgaris* L), *Salicis cortex* bark (SA) from various *Salix* spp. (including *Salix purpurea* L.; *Salix daphnoides* Vill.; *Salix fragilis* L.), and *Ribes nigrum* leaves (sample RNb) were from Flos (Mokrsko, Poland); *Corylus avellana* (CA) pericarp was from Société Inovfruit (Musidan, France); *Juglandis folium* leaves of *Juglans regia* L. (JR) were from Kawon (Gostyń, Poland); inner bark of *Pinus sylvestris* (PS) was from University of Turku (Turku, Finland); *Salix babylonica* catkins (SB) were collected on May 26, 2012 (Emmer Green, UK); *Salix caprea* (SCL and SCT) leaves and twigs were harvested on June 19, 2012 (Goring-on-Thames, UK); *Ribes nigrum* leaves (sample RNa) and *Ribes rubrum* leaves (RR) were collected on August 13, 2012, from Hildred PYO farm (Goring-on-Thames, UK); *Theobroma cacao* beans (TC) were from Peru (imported by "Detox your world" Inc., Norfolk, UK); and *Vitellaria paradoxa* (VP) meal (i.e., residue of VP nuts after fat extraction) was from AarhusKarlshamm Sweden AB, Sweden. Samples OV and TRa were lyophilized; samples PS, CA, SCL, SCT, RNa, and RR were dried at room temperature for <10 days and then stored at room temperature. The different botanical families[23] of each plant are indicated in Table 2.

Extracts were prepared according to the method of Stringano et al.[24] with a few modifications. Plant samples (50 g; <1 mm sieve) were extracted with 70% acetone/H_2O (500 mL, 7:3, v/v) and filtered under vacuum. Chlorophyll and lipids were removed with dichloromethane (125 mL) by liquid−liquid extraction. The remaining solvents were removed from the aqueous phase on a rotary evaporator at 35 °C. The aqueous extracts were centrifuged for 3 min at 4500 rpm (Jouan CR3i multifunction centrifuge) to remove the remaining chlorophyll, insoluble particles, and some precipitates. Extracts were freeze-dried and stored at −20 °C.

Extracts were purified on Sephadex LH-20 chromatographic columns to remove impurities (mainly sugars and small phenolics) with water. Elution with acetone/H_2O (3:7, v/v) yielded fraction 1 CTs (F1); a second elution with acetone/H_2O (1:1, v/v) yielded fraction 2 CTs (F2). In total 36 (18 F1 and 18 F2) fractions were tested using *H. contortus* and *T. colubriformis* infective third-stage larvae (L3).

Tannin Analysis by Thiolytic Degradation and HPLC. The purified CT fractions were subjected to thiolytic degradation as described by Gea et al.[25] with some changes for the analysis of CT contents (% CT) and features (size in terms of mean degree of polymerization, mDP; percentage of prodelphinidins and procyanidins within CTs, % PD and % PC; and percentage of *trans* vs *cis* flavanols, % *trans*, and % *cis*). Freeze-dried samples (4 mg) were weighed into 10 mL glass tubes, and methanol (1.5 mL) was added, followed by acidified methanol (0.5 mL of 3.3% HCl/in MeOH), benzyl mercaptan (50 μL), and a magnetic stirrer. The tube was capped and heated at 40 °C for 1 h in a water bath. Water (2.5 mL) was added to stop the reaction, and the internal standard (0.5 mL of taxifolin: 0.05 mg/mL) was added. Samples were analyzed within 48 h by RP-HPLC.[25]

Gastrointestinal Nematodes. The third-stage larvae (L3) were obtained from feces of donor goats, kept indoors and infected monospecifically, with AH susceptible strains of either *H. contortus* or *T. colubriformis*. The facilities hosting the animals and trial performance met French ethical and welfare rules (agreement C 31 555 27 of August 19, 2010).

Coproculture were maintained for 12 days at 23 °C to obtain the third-stage larvae. Larvae were then recovered from feces using the Baerman technique and stored at 4 °C in a horizontally vented cap flask at a concentration of 1000−1500 L3/mL. Prior to use, the larvae were checked to ensure that at least 90% of them were mobile and ensheathed.

Larval Exsheathment Inhibition Assay (LEIA). The larval exsheathment inhibition assay was performed as described by Bahuaud et al.[26] to compare the inhibitory effects of the various tannin fractions (F1 and F2) on the exsheathment process of *H. contortus* and *T. colubriformis*. For both nematode species a batch of 2-month-old larvae was used to perform the in vitro assays.

Briefly, 1000 ensheathed L3 larvae (*H. contortus* or *T. colubriformis*) were first incubated for 3 h at 20 °C with one of the fractions at serial dilutions from 600, 300, 150, 75, to 37.5 μg/mL in PBS (0.1 M phosphate, 0.05 M NaCl, pH 7.2). In addition to all of the tested fractions, negative controls (L3 in PBS) were run in parallel. After incubation, the larvae were washed and centrifuged, three times in PBS, and then submitted to the artificial exsheathment process by contact with a solution containing sodium hypochlorite (2% w/v) and sodium chloride (16.5% w/v), which had been diluted 1 to 350 in PBS. The exsheathment kinetics were measured under a microscope at ×200 magnification by identifying the proportion of exsheathed larvae. Regular examination was performed at 0, 20, 40, and 60 min after contact with the exsheathment solution. The exsheathment percentage was calculated according to the formula (number of exsheathed larvae) × 100/(number of exsheathed larvae + ensheathed larvae). For each fraction, four replicates were run per concentration and observation time to examine the exsheathment kinetics.

Statistical Analyses of the Results. The effective concentration that causes 50% exsheathment inhibition (EC_{50}) for each tannin fraction was calculated at 60 min (using the software Probit Polo Plus). First, a nonparametric rank correlation of Spearman was calculated using a 2 by 2 correlation to evaluate the relationship between the structural parameters characterizing the tannin fractions and also the relationship between the in vitro AH activity (EC_{50} of each fraction) and quantitative (% CT) and qualitative parameters (mDP, % PD and *trans*) of the respective F1, F2, and combined F1 and F2 (F1+F2) fractions. Significant values ($P < 0.05$) and (close to significance) values ($P < 0.10$) are reported.

Then multivariate analyses, principal component analyses (PCA), were performed separately for each nematode species on the basis of the combined data of F1+F2 to obtain an overall synthesis of the relationships between the effects on larval exsheathment and the main CT features. The five variables composing the column of the two PCA matrices included quantitative (% CT) and qualitative parameters (mDP, % PD and % *trans* values) plus the EC_{50} per species. The 36 rows of the matrix corresponded to the F1 and F2 data of the 18 plant samples. All statistical analyses were performed using Systat 9 software (SPSS Ltd.).

RESULTS

Tannin Analysis and Relationships between Structural Parameters. The parameters that characterized the 18 CT samples are provided in Table 1. The average % CT, mean degree of polymerization (mDP), and % prodelphinidins (PD) values were higher in the F2 compared with the F1 fraction, whereas the mean % *trans* values were lower for F2. The Spearman correlation coefficients were positive and significant between the F1 and F2 fractions for mDP ($r = 0.583$, $P < 0.05$, df = 16), % PD ($r = 0.975$, $P < 0.01$, df = 16), and % *trans* ($r = 0.728$, $P < 0.05$, df = 16), which is due to the fact that these 15 plant species produce different CT types. There was no correlation for the % CT in both fractions ($r = 0.082$, NS, df = 16).

When the Spearman correlation test was applied to the combined F1+F2 data ($n = 36$ samples), there were positive

[a]Calculation of the EC_{50} values relying on the Polo Plus software gave the following values for the effects against *H. contortus* for *T. repens* (b), fraction F1 = 33.2 μg/mL and fraction F2 = 14.5 μg/mL; for *L. cuneate*, fraction F2 = 29.4 μg/mL; and for *V. paradoxa*, fraction F1 = 13.6 μg/mL and fraction F2 = 16.5 μg/mL.

correlation coefficients between % CT and mDP values (r = 0.696; P < 0.01; df = 34). A nonsignificant negative correlation existed between % CT and % *trans* (r = −0.261; NS; df = 34) and between % PD and mDP values (r = 0.270; NS; df = 34). This absence of a link between % PD and mDP is important because column chromatography of CTs from the same plant material tends to lead to fractions, where % PD and mDP are positively correlated (unpublished observations). Therefore, these F1 and F2 fractions enable the investigation of relationships between CT structures and AH activities. Trends were observed for % PD and % *trans* (r = 0.300; P < 0.08; df = 34).

Anthelmintic Activity. The different fractions affected the larval exsheathment process in a dose-dependent way. The EC_{50} values for each of the F1 and F2 fractions per plant sample were used to characterize the AH activity and are shown for *H. contortus* and *T. colubriformis* in Table 2. For both parasites, EC_{50} values were generally lower with F2 than with F1 fractions. In addition, overall, EC_{50} values calculated for *H. contortus* were lower than those of *T. colubriformis*, suggesting that *H. contortus* was more susceptible to these fractions. Thus, the calculation of Spearman's correlation coefficients between EC_{50} values, obtained respectively for F1 and F2, showed significant and positive values for both species separately, that is, *H. contortus* (r = 0.642; P < 0.05; df = 15) and *T. colubriformis* (r = 0.688; P < 0.01; df = 16). However, there were no correlations between the EC_{50} values of the F1 fractions between *H. contortus* and *T. colubriformis* (r = −0.056; NS; df = 15) and also not for the F2 fractions (r = 0.397; NS; df = 16). Finally, there were also no correlations between the EC_{50} values of both parasite species with the F1+F2 combined data (r = 0.164; NS; df = 33).

Figure 1 shows the EC_{50} score values in rank order for *H. contortus* and *T. colubriformis*, respectively. The 25% of the most effective plants against both GIN species (i.e., lowest EC_{50} values) were *Vitellaria paradoxa*, *Trifolium repens*, *Lespedeza cuneata*, *Ribes nigrum*, *Theobroma cacao*, and *Betula* spp. In addition, *Onobrychis viciifolia* was active against *H. contortus*, and *Ribes rubrum* and *Salix babylonica* were active against *T. colubriformis*.

Table 3 presents the Spearman's correlation coefficients between the EC_{50} values and the various CT parameters for both nematode species in terms of the F1, F2, and the combined (F1+F2) data. For *H. contortus*, there were negative trends between EC_{50} and mDP and % PD of the F1 fraction and between EC_{50} and mDP of the F1+F2 data. The correlation between EC_{50} and % PD was negative and significant for the F1+F2 data. Somewhat surprisingly, a significant positive correlation was noted for EC_{50} values and % CT of the F2 fractions.

In contrast, for *T. colubriformis* there were no correlations with mDP or % CT. Instead, negative correlation coefficients between EC_{50} and % PD were close to significance for F1 (r = −0.453; P < 0.10; df = 16) and F2 (r = −0.439; P < 0.10; df = 16) and were significant for the combined (F1+F2) fractions (r = −0.403; P < 0.05; df = 34).

When PCA was applied separately to either *H. contortus* or *T. colubriformis*, the two main components of axis 1 were mDP and % CT. For axis 2, % PD appeared as the key component. The plane defined by the combination of axes 1 and 2 (Figure 2) represented 67% of the overall variability for *H. contortus* and close to 70% for *T. colubriformis*.

The main objective of the PCA was to analyze the overall combined relationships between the different variables and the effects on exsheathment as assessed by the EC_{50} values (Figure 2). Variables that are positively related are located on the same side of the plane. In contrast, variables that are negatively related are located in diagonally opposed quadrants. Analyses of these planes for both GIN species tend to confirm the 2 by 2 Spearman's correlation results. For *Haemonchus*, the EC_{50} values were in opposition to % PD and mDP values and, to a lesser

extent, to the % CT. For *Trichostrongylus*, the EC_{50} values were mainly in opposition to % PD.

DISCUSSION

The study evaluated 36 CT fractions from 18 sources (15 plant species). These plants were chosen because they present a wide range of different CT features in terms of mDP, % PD, and % *trans* values. It was expected that this variation would allow exploring the relationships between CTs and their AH activities. These particular CT parameters have been described previously as being involved in their biological activities.[10,19,20,22,27−29] From these 15 plant species 18 tannin extracts were obtained that yielded two related CT fractions (i.e., F1 and F2 fractions). These 36 samples were used to test the effects of quantitative and qualitative differences between CTs. The range of CT concentrations tested with these fractions was chosen on the basis of previous in vitro data, which had been obtained with plant extracts of known CT concentrations.[16,26,27]

Three in vitro assays are available to explore the interactions between tannins and infective third-stage larvae of gastrointestinal nematodes;[30] these are the larval migration inhibition assay (LMIA), the larval feeding inhibition assay (LFIA), and the LEIA, which has been used in the current study. The LEIA has been widely used to screen the AH activity of either plant extracts,[26,30] tannin fractions,[8,10] or flavan-3-ol monomers.[21,22] The LEIA has proved to be simple and reproducible and, like the LFIA, it also has the advantage that it allows calculation of EC_{50} values, which is rarely the case for the LMIA. Moreover, LEIA has been related to similar in vivo processes.[31] The LEIA was performed with 2-month-old larvae for both nematode species to allow comparison of EC_{50} values obtained with the F1 and F2 fractions of each plant sample and between the two nematodes species.

Overall, CT contents (% CT) were higher in the F2 than in the F1 fractions, and the EC_{50} values for F2 calculated for both nematodes were, in most cases, lower than for F1 fractions. This suggests a role for the % CT in the antiparasitic effect. Similar results were obtained by Williams et al.[20] for the AH

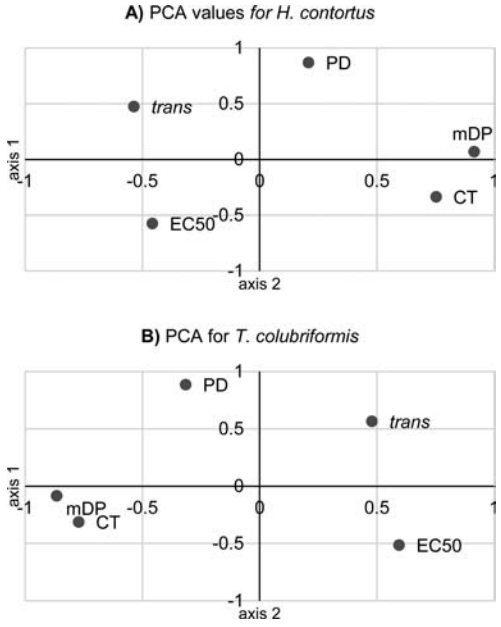

Figure 2. Multivariate principal component analyses (PCA) explained to condensed tannins for each parasite species: (A) *H. contortus*; (B) *T. colubriformis*. For both nematode species, the matrix was composed of 5 variables and 36 lines corresponding to 2 fractions (F1 and F2) of a range of 18 tannin-containing samples. Abbreviations: EC_{50} values based on LEIA (low values reflect high anthelmintic activities), CT (condensed tannins content, units g CT/100 g fraction); mDP (mean degree of polymerization of tannins); PD (% of prodelphinidins) *trans* (% of *trans* flavan-3-ols). The planes represent 67% of the variability for *H. contortus* and 70% for *T. colubriformis*, respectively.

effects against *Ascaris suum* with a subset of these F1 and F2 fractions. Many studies, based on different in vitro tests, have reported a dose-dependent AH effect when using tannin-containing plant extracts. For example, for some legume forages such dose-dependent effects have been described for (i) *O. viciifolia* (sainfoin) with the larval migration inhibition assay (LMIA),[7] LEIA,[31] egg hatch assay (EHA),[28] and larval development inhibition assay (LDIA);[28] and for (ii) *L. pedunculatus* and *L. corniculatus* extracts with the LMIA and LDIA,[27,28] the larval feeding inhibition assay (LFIA), and LEIA.[9] Although, surprisingly, there was a significant positive correlation between CT content and AH activity of the F2 fractions for *H. contortus*, there was no significant correlation when the F1+F2 data were combined. Similarly, Naumann et al.[19] also found no relationship between CT content and the AH activity against *H. contortus* L3 when comparing fractions from three legumes (*Lespedeza stuevei*, *L. cuneata*, and *Arachis glabrata*). Novobilský et al.[10] compared the effects of different CT fractions from *O. viciifolia* on cattle nematodes of either the abomasum (*Ostertagia ostertagi*) or the small intestine (*Cooperia oncophora*). These authors also did not obtain consistent correlations between the CT contents and the in vitro AH activity as measured by LFIA.

This discrepancy in relationship between dose and AH activity obtained with either CT-containing extracts or fractions could perhaps be related to other compounds that are also present in extracts.[7,21] Indeed, Molan et al.[22] also reported deleterious effects of flavan-3-ol monomers against *T. colubriformis* at different life cycle stages, that is, eggs (EHA) and larvae (LDIA, LMIA). The highest AH effect occurred with the epigallocatechin gallate (EGCG) monomer. This observation was confirmed by further studies with green tea fractions that were tested against *Teladorsagia circumcincta* and *T. colubriformis*, where higher EGCG content was linked with a higher AH effect.[8] Similarly, when monomeric subunits of CT were tested in the LEIA on *H. contortus* and *T. colubriformis*,[21] a higher AH activity was observed with (i) the monomeric subunits of PDs (i.e., gallocatechin, epigallocatechin) and (ii) the galloyl derivatives of both PDs and procyanidins.

Besides the possible contribution of CT concentration toward explaining antiparasitic activities, several authors have also suggested that CT structures (or quality) could explain some of the observations.[8−10,19,20,22] For instance, it has been proposed that the biological activity is affected by the hydroxylation at the B-ring in flavan-3-ol monomers and in polymers, where the presence of an additional hydroxyl group (OH) increases the interaction with proteins. This could explain the generally higher activity of PDs compared to PCs. In addition, activity is also increased when galloyl groups are present.[21,32−34]

Results of the 2 by 2 calculations of Spearman's correlation coefficients as well as multivariate analyses (PCA) tended to confirm that the in vitro AH activity in terms of EC_{50} was related to CT structural features for both *H. contortus* and *T. colubriformis*. In addition, our results suggest that different mechanisms appear to be involved for each nematode species. For *H. contortus*, AH activity appeared stronger for CTs with higher PD contents and larger sizes (mDP values), although, as described by Williams et al.,[20] there was no effect of mDP or % PD within F2 fractions on the EC_{50} values. For the F1 fractions, lower EC_{50} values were associated with higher % PD and larger tannins (higher mDP values). Novobilský et al.[10] suggested that mDP was a key factor in the LFIA against L3 of *O. ostertagi* and *C. oncophora* after testing *O. viciifolia* extracts and fractions.

However, Naumann et al.[19] found no clear evidence for CT size and inhibition of *H. contortus* motility. However, only a narrow range of CT sizes was investigated. Conversely to the present data, Manoralaki[35] found that lower mDP values were correlated with higher AH activity when extracts from 40 *O. viciifolia* accessions were tested by LEIA against *H. contortus*. Similarly, Barrau et al.[7] found that a fraction that contained CTs (<2000 Da) plus flavonol glycosides had higher AH effects against *H. contortus* larvae than a fraction that contained only CTs (>2000 Da). At this stage, it is important to note that the complexity of plant extract compositions and difficulties in purifying CTs are likely to account for some of these apparent contradictions. Acetone/water extracts from CT-containing plants consist of CTs plus low molecular weight phenolic compounds (flavones, flavonols, flavonol glycosides, etc.). In addition, CTs usually occur as complex mixtures that contain low to high molecular weight tannins, and the mDP value simply describes the average "tannin size" rather than the distribution profile of all CTs. In fact, we recently discovered that mixtures of CTs and flavonoids had higher AH activities than CTs on their own.[36] Kozan et al.[37] also reported that flavonol glycosides (luteolin-7-β-*O*-glucopyranoside and quercetin-3-*O*-β-glucopyranoside) from *Vicia pannonica* var. *purpuracens* might also participate in the modulation of bioactivity of the highly AH extract and fractions against trichostrongylid larvae. This emphasizes that the proximity of biochemical structure between flavonol glycosides and CT (which are flavan-3-ols' polymers) could suggest a similar or close mechanism of action for both types of compounds. Taken together, the presence of non-CT compounds (such as flavonoid monomers) could, therefore, explain the apparently contradictory observations by Manoralaki[35]

DOI: 10.1021/acs.jafc.5b00831
J. Agric. Food Chem. 2015, 63, 6346−6354

and Barrau et al.[7] The F1 fractions had only half the CT contents of F2 fractions (Table 1). However, the combination of F1+F2 data gave a close to significant correlation of EC_{50} and mDP values (Table 3).

In contrast, for *T. colubriformis*, % PD was consistently (F1, F2, and combined F1+F2) related to AH activity. This agrees with other reports on *T. colubriformis* larvae, which found higher AH in vitro effects of PD-rich compared with PC-rich tannins.[21,22]

Interestingly, there were different susceptibilities between the two parasite species, which suggested that *H. contortus* was more susceptible than *T. colubriformis*. This is indicated by the overall lower EC_{50} values for the abomasal species with both types of CT fractions. Molan et al.[8] also pointed out that the abomasal nematode *T. circumcincta* was more susceptible than *T. colubriformis* to the AH effects of flavan-3-ol monomers and oligomeric CTs in the LMIA. The same conclusion was drawn from in vitro studies that examined extracts from different woody plants (*Rubus fructicosus*, *Quercus robur*, and *Corylus avellana*) against *H. contortus*, *T. circumcincta*, and *T. colubriformis* based on LMIA and LEIA tests.[16] However, other authors found no such differences in the response to quebracho or *O. viciifolia* extracts[11,31] between abomasal or intestinal species. Moreno-Gonzalo et al.[38,39] even found a higher in vitro susceptibility of *T. colubriformis* compared to *H. contortus* and *T. circumcincta* when measuring the AH activity of extracts from different heather species (*Calluna vulgaris*, *Erica cinerea*, and *E. umbellata*). It remains to be seen whether differences in assay conditions could account for some of these contradictory results. Moreover, it will be worth exploring whether there exist species-specific differences in the quality of larval sheath proteins between the abomasal and intestinal species to better understand the mode of actions of polyphenols against the different GIN species.

Although it is difficult to extrapolate from in vitro to in vivo results, our current data provide a screening of CT-containing plants whose AH properties will need to be explored further in controlled in vivo studies to develop their potential for on-farm exploitation. It is also worth noting that the CT fractions from three legumes ranked among the most effective ones (i.e., having the lowest EC_{50} values): *L. cuneata* pellets, *O. viciifolia* plants, and *T. repens* flowers (Figure 1). The past decade has seen an accumulation of in vivo results that confirm the AH effects of *L. cuneata* and *O. viciifolia* against the main GIN species whether offered to small ruminants in the form of freshly grazed pasture[40,41] or as hay,[15,17,42] silages,[42] or pellets.[18]

As far as *T. repens* is concerned, no other data are available because the genus *Trifolium* is usually considered as a tannin-free legume,[43] and consequently the various *Trifolium* species have received little attention for their antiparasitic potential. However, Carlsen and Fomsgaard[44] provided an extensive review of the secondary metabolites in *T. repens* and pointed out the high CT content in flowers. The current study found that CTs from *T. repens* flowers had a strong AH effect and confirmed the dose-dependent inhibition effects of *T. repens* tannins observed for *C. oncophora* in the LFIA.[45]

The CT fractions of *V. paradoxa* were also ranked as highly effective against both nematode species and suggested that some agro-industrial byproducts could be of interest for their antiparasitic properties. It is worth noting that AH effects on *H. contortus* and *T. colubriformis* were recently also described not only for cocoa seed but also for husk extracts using the EHA.[46]

In conclusion, our results showed that structural features of condensed tannins are key factors that affect the anthelmintic effects against gastrointestinal nematodes of ruminants. In addition, there were differences in the susceptibilities of the abomasal as the intestinal nematode species. These differences have been described previously in the literature and could be related to the fact that the nematode sheath proteins differ in these parasite species. This could perhaps affect their interactions with the tannins. It is worth also emphasizing that the current results have been acquired on infective larvae and that other assays that target other parasitic stages might have different outcomes. Further studies will be needed to explore these interactions at the molecular level.

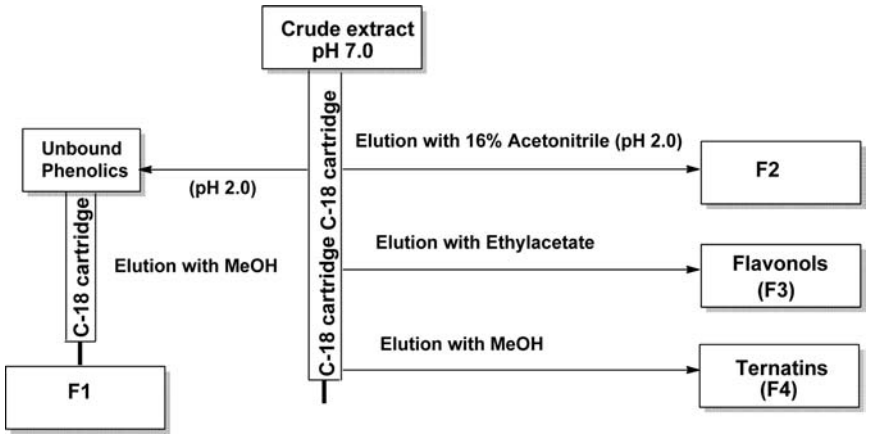

Figure 1. Fractionation scheme used for butterfly pea flower extracts to obtain fractions F1, F2, F3, and F4. Fractions F3 and F4 correspond to enriched fractions of quercetin glycosides and ternatin anthocyanins, respectively.

have been shown to have inhibitory effects on the COX-2 enzyme activity, important for generation of the PGE2 and PGD2, pro-inflammatory mediators.[15,16]

In the present study we hypothesize that the mixture of flavonols and anthocyanins present in the blue flower petals of *C. ternatea* would be responsible for the anti-inflammatory properties claimed by folklore use of butterfly pea extracts. To our knowledge this is the first report of the anti-inflammatory properties of polyphenols from *C. ternatea*. To accomplish our goal we identified the polyphenols by HPLC-DAD-ESI/MS^n, separated them in fractions, and characterized their anti-inflammatory properties, determining the molecular mechanism roles of flavonols and ternatin anthocyanin derivatives in reactive oxygen species (ROS) and nitric oxide (NO) suppression, NF-κB and iNOS modulation, and COX-2 inhibition.

MATERIALS AND METHODS

Materials. Butterfly pea flowers were collected in March 2012 from an uncultivated field near Bogor Agricultural University, Indonesia. The blue color petals of butterfly pea were blanched by steam at 100 °C for 6 min and cooled immediately by soaking in an ice bath, freeze-dried in a FreeZone 6L benchtop Freeze-Dry System model 77520 (Labconco, Kansas City, MO, USA), and shipped to Texas A&M University (College Station, TX, USA). The following chemicals were used in the experiments: 2′,7′-Dichlorofluorescin diacetate (DCFA), Griess reagent, sodium nitrite solution, Dulbecco's modified Eagle's medium (DMEM)/low glucose, phenol red-free DMEM/low glucose, penicillin/streptomyccn mixture, DMSO, and fetal bovine serum (FBS) were purchased from Sigma (St. Louis, MO, USA). Glucose was purchased from Acros Organics (Fair Lawn, NJ, USA), and sodium bicarbonate was purchased from Mallinckrodt Chemicals (Phillipsburg, NJ, USA). The CellTiter 96 AQ_{ueous} Non-Radioactive Cell Proliferation Assay Kit was purchased from Promega (Madison, WI, USA). Antibodies against iNOS, COX-2, and NPM/B23 and against p-NF-κB and actin were purchased from Cell Signaling Technology (Danvers, MA, USA) and Santa Cruz Biotechnology (Dallas, TX, USA), respectively. Macrophage RAW 264.7 (cell line TIB-71) was acquired from the American Type Culture Collection (ATCC) (Manassas, VA, USA). A COX Inhibitor Screening Assay Kit and DuP-697 were purchased from Cayman Chemicals (Ann Arbor, MI, USA).

FA, Folin−Ciocalteu reagent, sodium carbonate (Na_2CO_3), 6-hydroxy-2,5,7,8-tetramethyl-2-carboxylic acid (Trolox), 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH), fluorescein sodium salt, polyvinylpyrrolidine (PVPP), boric acid, β-mercaptoethanol, L-phenylalanine, *trans*-cinnamic acid, diphenyleneiodonium chloride (DPI), Na_2EDTA, ascorbic acid, diethyl dithiocarbamate, NADPH, Tris-HCl, sucrose, riboflavin, methionine, methanol (HPLC grade), and acetonitrile (HPLC grade) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Chlorogenic acid, nitrotetrazolium blue chloride (NBT), and Triton X-100 were purchased from Fisher Scientific (Houston, TX, USA).

Sample Preparation. A 0.1 g portion of lyophilized powder of butterfly pea was dissolved in a mixture of MeOH/acetone/H_2O (5:4:1) and stirred for 24 h at room temperature. The extract was blue in color, and the solution was centrifuged and concentrated at 4000 rpm (2147*g*) and 45 °C until all of the volatile solvents were evaporated in a Centrivap concentrator connected to a cold trap (Labconco, Kansas City, MO). MeOH/H_2O (8:2) was added to the concentrated mixture, and this solvent fraction was used to analyze the profiling of the compounds present in the butterfly pea extract by HPLC/MS.

TLC Analysis and Fractionation of Phenolic Compounds. The crude MeOH/acetone/H_2O extract was spotted in a TLC plate to determine the possible presence of terpenoids using the Liebermann Burchard test,[17] confirming no visible spots for terpenoids due likely to the fact that the solvent used did not remove terpenoids from the blue flower petal freeze-dried samples.

The crude extract was fractionated into phenolic acids (F1), anthocyanins (F2), flavonols (F3), and procyanidins/polymeric anthocyanins (F4) by solid-phase extraction using C18 cartridges as previously described[18] (Figure 1). Briefly, the aqueous extract was adjusted to pH 7.0 with 5 N NaOH. A total of 2 mL of extract was loaded in SEP Pack C18 cartridge (55−105 μm, Waters Corp., Milford, MA, USA) previously conditioned to pH 7.0 with 20 mL of 100% methanol and 50 mL of nanopure water (pH 7.0). The neutral phenolics were absorbed in the cartridge, whereas the phenolic acids were not. The cartridge was washed with 20 mL of water (pH 7.0). The water from the wash was combined with the phenolics that were not adsorbed in the cartridge and adjusted to pH 2.0. This mixture of compounds was loaded into a second cartridge previously conditioned at pH 2.0 with 20 mL of 100% methanol and 20 mL of nanopure water at pH 2.0. Phenolic acids bound to the matrix of the second cartridge (F1) were later eluted with 50 mL of 100% methanol. After the pH was adjusted to 2.0 in the first cartridge, elution of anthocyanins was accomplished by passing 20 mL of 16% acetonitrile at pH 2.0 (F2). The flavonols were eluted using 20 mL of 100% ethyl acetate (F3) and the anthocyanin polymers using 20 mL of 100% methanol (F4). Fractions eluted with low boiling point solvents (F1, F3, and F4) were completely evaporated at 45 °C using a Centrivap (Labconco, Kansas City, MO). Fraction F2 was evaporated using a rotavapor (Büchi, Flawil, Switzerland), at 50 °C and 200 mmHg of pressure. All fractions were kept under nitrogen gas at −20 °C for use in cell culture.

The butterfly pea crude extracts and fractions were analyzed by HPLC-MS. Identification of phenolic compounds was performed at 200−600 nm by a comparison of retention times and the MS/MS

fragments from the original crude extract, which was previously identified.

During the extraction process a yield of ∼72 mg of a MeOH/acetone/H_2O solvent crude extract powder was obtained per each 100 mg of freeze-dried petal powder. Additionally, during the fractionation process yields of ∼2.4, 1.2, 8.1, and 2.2 mg of fraction powders were obtained, respectively, for fractions F1, F2, F3, and F4 per each 20 mg of the MeOH/acetone/H_2O crude extract.

LC-MS Analysis and Conditions. Individual compounds were identified on the basis of retention time, UV spectra, and mass-to-charge ratio using LC-MS/MS. Chromatographic separations were performed on an LCQ Deca XP Max MS^n system (Thermo Finnigan, San Jose, CA, USA) equipped with an autosampler, a Surveyor 2000 quaternary pump, and a Surveyor UV 2000 PDA detector using a Hydro-RP_{18} phase (150 mm × 4.6 mm × 3 mm, Phenomenex, Torrance, CA, USA; particle size = 4 μm and pore size = 100 Å) and a guard column of the same chemistry. The elution gradients were performed with acetonitrile/methanol (1:1), formic acid (0.5:99.5, v/v) (phase A) and formic acid/water (0.5:99.5, v/v) (phase B). The applied elution conditions were as follows: 0−2 min, 2% A; 98% B; 3−5 min, 5% A, 95% B; 5−30 min, 20% A, 80% B; 30−72 min, 35% A, 65% B; 72−83 min, 100% A, 0% B; 83−85 min, isocratic, 100% A; 87−90 min, 2% A, 98% B to bring to the starting condition. The chromatograms were monitored at 365, 330 and 520 nm; complete spectral data were recorded in the range of 200−600 nm. Nitrogen was used as desolvation gas, at 275 °C and a flow rate of 60 L/h, and He gas was used as damping gas. Mass spectra were obtained on a MS Finnigan LCQ Deca XP Max, ion trap mass spectrometer coupled at the exit of the diode array detector and equipped with a *Z*-spray ESI source and run by Xcalibur version 1.3 software (Thermo Finnigan-Surveyor, San Jose, CA, USA). A potential of 30 V and a spray voltage of 1.5 kV were used on the capillary for negative ion mode. A potential of 6.8 V was used on the capillary for positive ion mode. The spray voltage was 4.57 kV, and the source block temperature was held at 285 °C. Results are reported in Table 1.

Analysis of Total Soluble Phenolics (PC) and Determination of Antioxidant Activity [Oxygen Radical Absorbance Capacity (ORAC) Value]. Total soluble phenolics were determined using the method described by Swain and Hillis.[19] Methanolic extracts (13 μL) were diluted with nanopure water (208 μL) in a 96-well microplate well, followed by the addition of 0.25 N Folin−Ciocalteu reagent (15 μL). The mixture was incubated for 3 min, and then 1 N Na_2CO_3 (26 μL) was added. The final mixture was incubated for 2 h at room temperature in the dark. Spectrophotometric readings at 725 nm were collected using a plate reader (Synergy HT, Bio-Tek Instruments, Inc., Winooski, VT, USA). Total phenolics were expressed as milligrams of chlorogenic acid equivalents per milligram of crude extract or fraction. The antioxidant activity was determined with the ORAC assay. The ORAC value was obtained using the procedure of Wu et al.[20] for hydrophilic ORAC with a slight modification as described by Villarreal-Lozoya et al.[21] Results are reported as micromoles Trolox equivalent per gram crude extract or fraction.

Cell Culture and Treatment of Butterfly Pea Extracts and Fractions (F3 and F4). RAW 264.7 macrophages were grown in the DMEM-low glucose (pH 7.2−7.4) including 4 g/L glucose, 3.7 g/L sodium bicarbonate, 10% FBS, and antibiotics (100 units/mL penicillin and 100 μg/mL streptomycin) in a humidified atmosphere with 5% CO_2 at 37 °C. Cells were used at a subculture of 5−9 in this study. It is important to record the approximate number of subcultures because in mammalian cell lines chromosomal aberrations have a tendency to increase with a high number of subculture. In this study we used a low number of subcultures associated with healthy cells.

For treatments of cells with butterfly pea extract and its fractions (F3 and F4), the cells were plated at 2×10^5 or 0.5×10^5 cells/well in 96-well black and clear-bottom plates (Costar, Cambridge, MA, USA) for MTS test and NO/ROS measurements and at 2×10^6 cells/well in 6-well plates (BD Biosciences, Franklin Lakes, NJ, USA) for Western blot analysis and then cultured overnight. The cells were treated with the growth medium containing 1 μg/mL lipopolysaccharide (LPS) for times indicated in this study either with or without a 1 or 5 h of pretreatment of butterfly pea extract and its fractions. The butterfly pea extract and its fractions were dissolved in the growth medium including 0.5% DMSO, which was used as a control in all experiments. Finally, cells and medium at the time points indicated in this study were used for various measurements.

Cell Viability Test. Macrophages were plated at $(0.5-2) \times 10^5$ cells/well in 96-well clear-bottom plates (Costar) and cultured overnight. The cells were treated with butterfly pea extract and its fractions for 24 h and were subjected to the cell viability test, which was evaluated in macrophages using the MTS assay kit (Promega, Madison, WI), according to the manufacturer's instructions. The quantity of formazan product was measured at 490 nm and is directly proportional to the mitochondrial dehydrogenase activity.

Detection of Extracellular Nitric Oxide and Intracellular Reactive Oxygen Species Production. Macrophages were plated at $(0.5-2) \times 10^5$ cells/well in 96-well black and clear bottom plates (Costar) and cultured overnight. The cells were stimulated by LPS for times indicated in this study either with or without a 1 and 5 h of

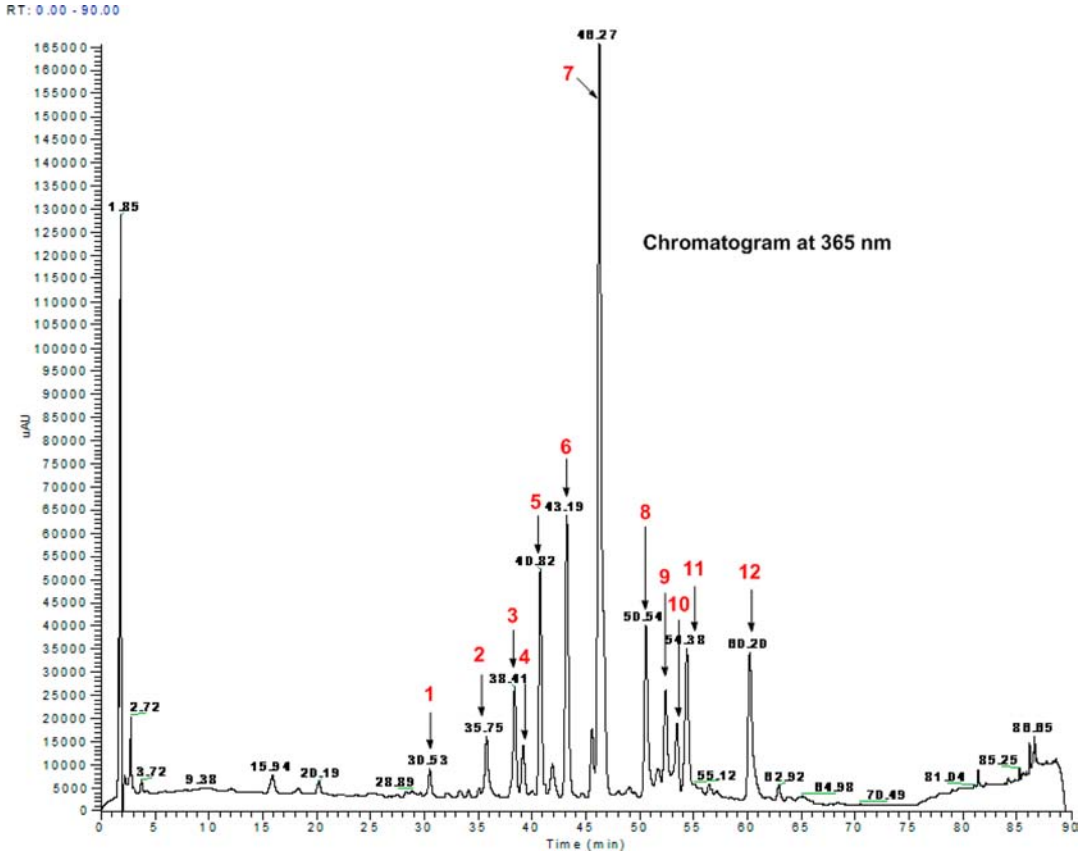

Figure 2. HPLC-MS chromatogram of the total butterfly pea flower extract at 365 nm. Identified quercetin glycoside and ternatin anthocyanin peaks are reported in Table 1. Peaks 1, 2, and 6 are delphinidin derivatives, peaks 3, 4, and 9−12 are ternatin anthocyanins, and peaks 5, 7, and 8 are quercetin glycosides.

pretreatment of butterfly pea extract and its fractions as described above. Finally, cells and medium were used for the ROS and NO detections, respectively.

The NO production was assessed by the accumulation of nitrite (NO_2^-) in the medium using a colorimetric reaction with the Griess reagent. However, because anthocyanins absorb in the 465−560 nm range similarly to the purple azo dye (λ_{max} = 540 nm), a reaction product of nitrite and Griess reagent, and thus interfere with detection of the purple azo dye, the measurement of nitrite (NO_2^-) in the medium including anthocyanins was carried out using an alternative method as described in Wang and Mazza.[22] Briefly, 50 μL of cell culture supernatants was obtained at 19 or 24 h after LPS treatment, and 100 mM sodium nitrite solution was diluted with nanopure water for the preparation of standards from 10 to 100 μM. To obtain absorbance of the anthocyanins interfering with detection of the purple azo dye, medium was mixed with a similar concentration of butterfly pea extract or fractions with ones used for cell treatments. Subsequently, the cell supernatants and standards were mixed with an equal (1:1) volume of Griess reagent, and finally absorbance was measured at 540 nm using a 96-well microplate reader (Synergy HT, Bio-Tek Instruments, Inc.). Eventually, the net absorbance of the product of Griess reaction was obtained by subtracting the absorbance of medium, including blue flower extract or fractions, from the total value.

The intracellular ROS production was measured by DCFA. Briefly, the cell culture medium was removed by aspiration at times indicated in this study after the LPS challenge, and subsequently cells were exposed to 10 μM DCFA in the phenol red/FBS-free DMEM for 30 min and then washed twice with the phenol red/FBS-free DMEM. Finally, fluorescence was read immediately at wavelengths of 485 nm for excitation and 528 nm for emission on a 96-well microplate reader (Synergy HT, Bio-Tek Instruments, Inc., Winooski, VT).

Preparation of Nuclear Extracts and Western Blot Analysis. The LPS stimulation was terminated by the addition of ice-cold PBS, and a modified procedure based on previous methods[23] was used for the preparation of nuclear extracts. Accordingly, 2×10^6 cells per well were washed twice with ice-cold PBS in 6-well plates and were resuspended in 200 μL of hypotonic lysis buffer (10 mM HEPES, pH 7.9; 10 mM KCl, and 1.5 mM $MgCl_2$) supplemented with a protease inhibitor cocktail. After 10 min at 4 °C, cells were lysed by the addition of 25 μL of 2.5% nonidet P-40 (final 0.3%) for 10 min at 4 °C. The tubes were gently vortexed for 15 s, and nuclei were collected by centrifugation at 8000*g* for 15 min in an Eppendorf 5417 R centrifuge (Ependdorf, Hamburg, Germany). The supernatants were stored at −80 °C (cytosolic extracts). The pellets were resuspended in 50 μL of extraction buffer (10 mM HEPES, pH 7.9; 100 mM NaCl, 1.5 mM $MgCl_2$, 0.1 mM EDTA, and 0.1 mM DTT) supplemented with protease inhibitor cocktail and mixed gently for 30 min at 4 °C. Finally, nuclear proteins were extracted by centrifugation at 13000*g* for 15 min, and aliquots of the supernatant were stored at −80 °C (nuclear extracts). The protein levels in the samples were then quantified using the colorimetric method with bicinchoninic acid solution. All steps of cell fractionation were carried out at 4 °C.

Nuclear and cytosolic proteins prepared as described above were loaded on a gel with a prestained, broad-range, molecular weight protein marker (Fermentas). Proteins were fractionated by electrophoresis using 10% polyacrylamide gels. The gels were transferred by wet blotting onto PVDF membranes (Millipore, Bedford, MA, USA). The membranes were blocked with 5% skim milk in Tris-buffered saline with 1% Tween-20 (TBS-T) for 1 h with gentle shaking. Membranes were then incubated overnight with a specific primary antibody against p-NF-κB p65 (1:1000), iNOS (1:1000), COX-2 (1:1000), NPM/B23 (1:1000), and actin (1:5000) at 4 °C. The membranes were washed four times with TBS-T and incubated for 1 h at room temperature with the secondary antibody conjugated with

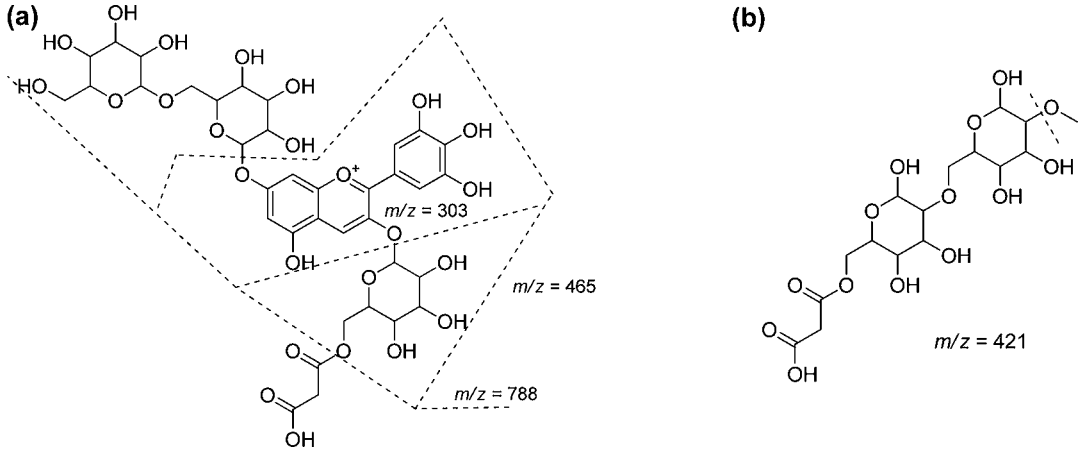

Figure 3. Ternatin anthocyanin from butterfly pea corresponding to peak 1. (a) Tentative description of the fragmentation pattern obtained by MS/MS fragmentation for peak 1 at RT 30.53 having a major MS^2 fragmentation peak at $[M + H]^+$ m/z 303 (delphinidin derivative). m/z 465 corresponds to the m/z 303 and sugar, and m/z 788 corresponds to the m/z 465 and dihexose. (b) Remaining part of the structure from the parent ion m/z 1296. The connectivity of this part is unknown, which could be confirmed by NMR.

horseradish peroxidase (HRP) at 1:5000 dilution. Specific bands were developed using a SuperSignal West Femto enhanced chemiluminescence (ECL) Western blotting detection kit (Pierce, Thermo Fisher Scientific, Inc., Rockford, IL, USA), and the signals were captured by Chemi Doc XRS (Bio-Rad Laboratories, Hercules, CA). Bands were quantified using densitometry with ImageJ software (NIH, Bethesda, MD, USA).

COX-2 Inhibitory Assay. The COX-2 inhibitory assay was carried out using a COX Inhibitor Screening Assay Kit following the manufacturer's instructions (Cayman Chemical, Ann Arbor, MI). Briefly, heme and COX-2 (human recombinant) enzyme were added to test tubes containing COX reaction buffer. The mixture was vortex and exposed either to blue flower extract or fractions or to DMSO (control) for 10 min at 37 °C. This was followed by the addition of arachidonic acid with further incubation for 2 min. Hydrochloric acid (1 M) was added to stop the COX reaction followed by the addition of stannous chloride ($SnCl_2$) solution. This assay measures $PGF_{2\alpha}$ derived from $SnCl_2$ reduction of PGH_2 produced in the COX-2 reaction, through an enzyme immunoassay kit.

Statistical Analysis. The data were analyzed using Student's t test or one-way analysis of variance (ANOVA) followed by the Tukey-HSD test, using the software JMP pro v10.0. Results are expressed as means ± standard errors (SE). Different letters show significant differences ($P < 0.05$).

RESULTS AND DISCUSSION

Characterization and Identification of Phenolic Compounds by LC-MS in Butterfly Pea Extracts and Fractions. Results by LC-MS analysis indicated that peaks 1−4, 6, and 9−12 belong to delphinidin/ternatin derivatives, which are responsible for the blue color in butterfly pea petals (Figure 2). Compound **1** at RT 30.53 with $[M + H]^+$ m/z 1296 yielded MS^2 fragments at m/z 1242, 810, 788, 658, 633, 611, 465, and 303. The fragmentation of m/z 788 can be explained tentatively from the parent ion due to the loss of a malonate group, whereas m/z 465 can be explained due to the loss of 323 Da from the precursor ion m/z 788, which could be due to the loss of a dihexose residue as explained in Figure 3. The remaining part of the structure (fragment m/z 421), obtained from the parent ion m/z 1296, is shown in Figure 3b. However, it was not possible to obtain the connectivity to Figure 3a. The base MS^2 peak at m/z 303 suggests the delphinidin core and hence the complete structure and its connectivity have to be established by NMR spectroscopy.

Compound **2** at RT 35.75 with $[M + H]^+$ m/z 1534 yielded MS^2 fragments at m/z 1329, 1081, 779, 658, 611, 465, and 303. The fragmentation of m/z 465 was similar to that of compound **1** with loss of a dihexose residue as explained in Figure 3, and the m/z 303 was due to a delphinidin core. This compound has not been reported before, and the complete structure could be elucidated by NMR spectroscopy.

Compound **3** at RT 38.41 with $[M + H]^+ m/z$ 1638 yielded MS^2 fragments at m/z 1638, 1615, 1389, 1227, 1081, 964, 860, 663, 611, 437, 303, and 180. This compound was identified as ternatin B3. Compound **4** at RT 39.12 with $[M + H]^+$ m/z 1167 gave MS^2 fragments 1167, 919, 611, 303, 180.8, 163.8, and 149.07; this compound was identified as ternatin D3. Compound **6** at RT 43.19 with $[M + H]^+$ m/z 950 gave MS^2 950, 658, 487, 465, 303, 180.9, and 163.12, and again this compound gave the familiar fragment of m/z 465 and 303, which defines the core structure of delphinidin hexose residue. However, the fragments and the structure were not reported and need to be confirmed by NMR. Compound **9** at RT 52.51 with $[M + H]^+$ m/z 1638 yielded MS^2 fragments at 1638, 1389, 1167, 919, 773, 703, 626, 535, 303, 287, 180.8, and 163.13, and this compound was identified as ternatin B2. Compound **10** at RT 53.51 gave $[M + H]^+$ m/z 1329 and yielded MS^2 fragmentation m/z 1329, 1081, 919, 471, 448, 314, 303, 387, 180.8, 163.07, and 149.09, and this compound was identified as ternatin B4. Compound **11** at RT 54.38 gave $[M + H]^+$ m/z 1491 and yielded MS^2 fragmentation m/z 1492, 1449, 1389, 1257, 1227, 919, 828, 763, 611, 303, 264, 180.8, 163.12, and 149.09, and this compound was identified as ternatin C2. Compound **12** at RT 60.20 gave $[M + H]^+$ m/z 1783 and yielded MS^2 fragments at 1783, 1535, 1255, 1167, 919, 898, 303, and 180, and this compound was identified as ternatin D1. Most of the ternatin derivatives were previously identified from *C. ternatea*, and their MS^2 and fragmentation patterns were in accordance with the literature[1,5]

Compounds **5**, **7**, and **8** gave a UV absorbance within the range of 290−360 nm and suggested that they belong to the flavonoid class (Figure 2). Compound **5** at RT 40.82 gave $[M - H]^-$ at m/z 753 and yielded fragments at 447, 301, 285, and 180.9. The fragment m/z 301 was due to the quercetin core, and the m/z 447 can be explained by the attachment of a rhamnosyl sugar on the quercetin moiety. Hence, this

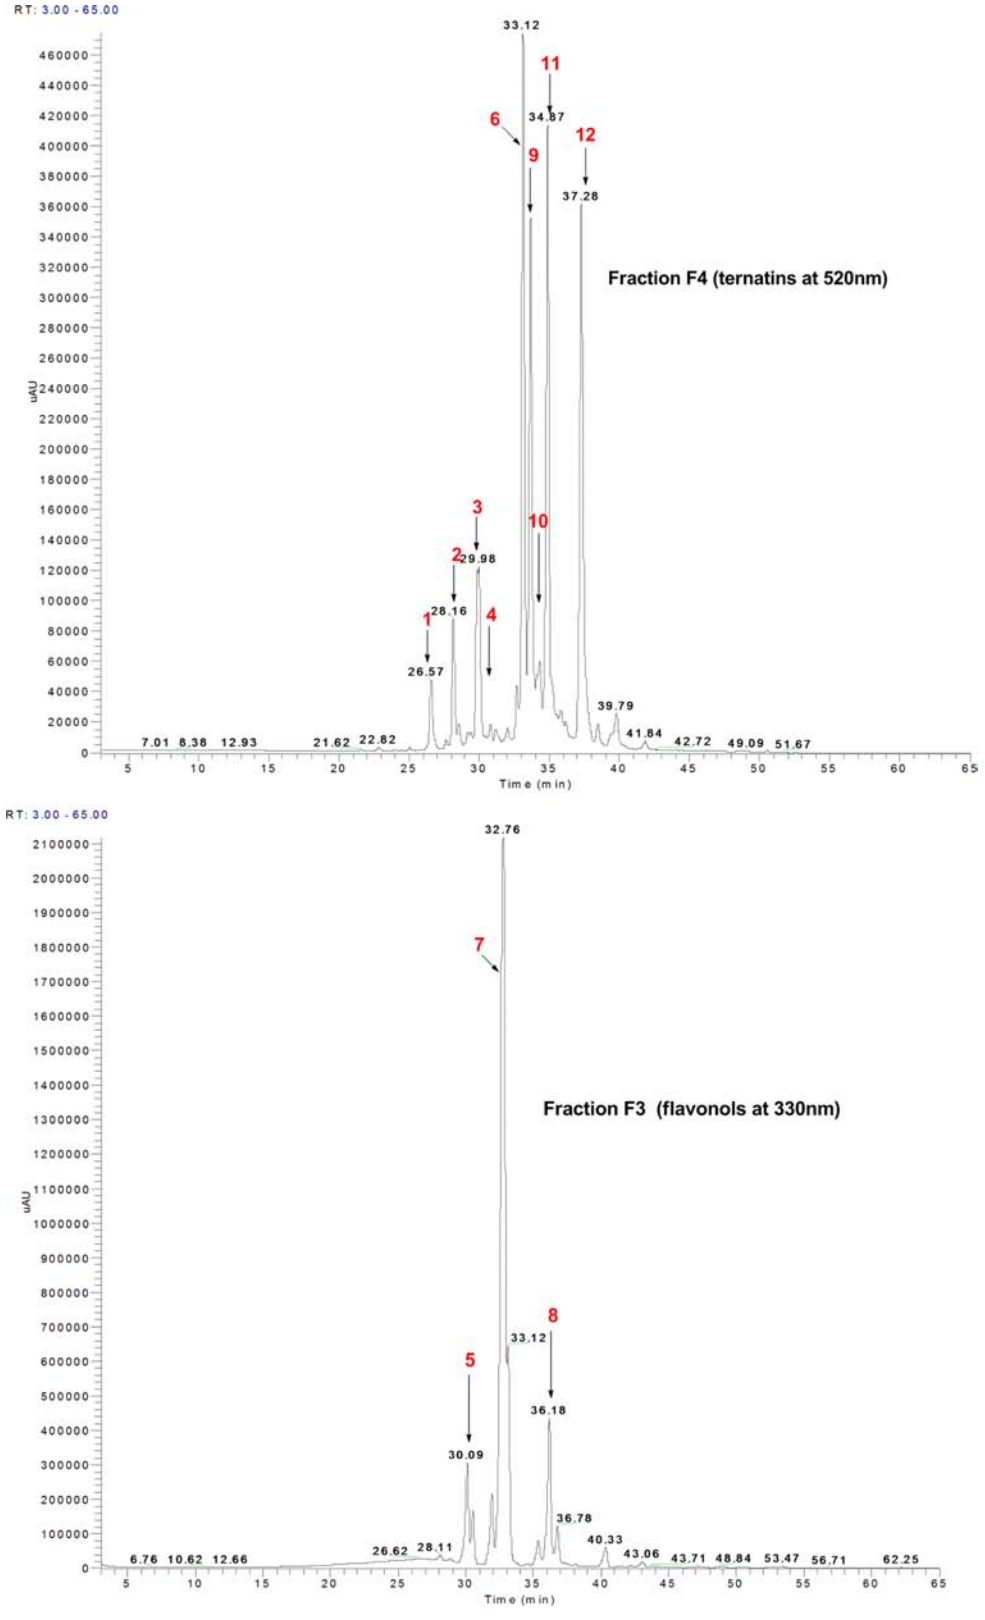

Figure 4. HPLC-MS profiling of the enriched flavonol (F3) and ternatin anthocyanin (F4) fractions from the flower petals of butterfly pea. Chromatograms of fractions F3 and F4 are reported at wavelengths of 330 and 520 nm, respectively. Identified peaks are reported in Table 1. Peaks 1, 2, 3, 4, 6, 9, 10, 11, and 12 from fraction F4 had corresponding areas of 3.5, 5.6, 4.3, 5, 20, 15.9, 4.3, 20.2, and 19.1%, respectively. On the other hand, peaks 5, 7, and 8 from fraction F3 had corresponding peak areas of 14.4, 76.7, and 8.8%, respectively.

compound was identified as manghaslin quercetin 3-[2G]-rhamnosylrutinoside. Compound **7** at RT 46.27 gave $[M - H]^-$ m/z 593 and a major MS^2 fragment 285, and the compound was identified as quercetin 3-*O*-dirhamnoside. Compound **8** at RT 50.54 gave $[M - H]^-$ at m/z 609 and yielded fragments at 301 and 177, and this compound was

Table 2. Yield, Phenolic Content, and Antioxidant ORAC Values for Butterfly Pea Extract and Fractions

extract	yield[a]	phenolic content[b]	antioxidant activity[c]
crude extract	20	0.0952	490.71
fraction F4	2.2	0.1041	260.63
fraction F3	8.1	0.0998	136.97

[a]Yield is expressed in mg of powder. [b]Phenolic content by the Folin–Ciocalteu assay is expressed in mg chlorogenic acid equivalents/mg of crude extract or fraction. [c]Antioxidant activity by the ORAC assay is expressed in μmol Trolox equivalent/g crude extract or fraction.

identified as rutin. Some of these flavonoids were already reported from the petals of butterfly pea.[1]

By solid-phase extraction using C_{18} cartridges, the crude extract was fractionated into phenolic acids (F1), anthocyanins (F2), flavonols (F3), and procyanidins/polymeric anthocyanins (F4) (Figure 1). Results indicated that the polyphenols identified above were present only in fractions F3 and F4, whereas no compounds were present in fractions F1 and F2. Thus, fraction F3, rich in flavonols, contained compounds **5**, **7**, and **8**, whereas fraction F4, rich in ternatin anthocyainins, contained compounds **1**–**4**, **6**, and **9**–**12** (Figure 4).

The fractionation processes showed that fraction F3 was ~3.6 times higher in powder yield compared to fraction F4, suggesting that flavonols constitute the main polyphenols present in butterfly pea extracts. This was also confirmed by actually determining the phenolic content of the fractions (Table 2). For example, fractions F4 and F3 had phenolic concentrations of 0.1041 and 0.099 mg phenolics/mg fraction extract, respectively. Because the powder yield of fractions F4 and F3 were 2.2 and 8.1 mg, respectively, per each 20 mg of crude extract, the amounts of phenolics present in those fraction F4 and F3 powders were 0.22902 and 0.8085 mg phenolics, respectively, confirming that quercetin glycosides are ~3.5 times higher than ternatin anthocyanins in the crude extract.

Furthermore, area chromatogram analysis of compounds indicated that flavonols present in fraction F3 had the following descending order for identified peak areas, 7 ≫ 5 > 8, corresponding to areas of 76.7, 14.4, and 8.8%, respectively (Figure 4). On the other hand, the area chromatogram analysis in fraction F4 indicated that ternatin anthocyanins had the following descending order for identified peak areas, 11 ~ 6 ~ 12 > 9 ≫ 2 ~ 4 ~ 3 ~ 10 > 1, corresponding to areas of 20.2, 20, 19.1, 15.9, 5.6, 5, 4.3, 4.3, and 3.5%, respectively (Figure 4). These results identify which individual compounds were more abundant in each fraction.

The antioxidant ORAC analysis of the dried flower and crude extract gave values of 1096 μmol Trolox equivalent/g dried flower and 490.7 μmol Trolox equivalent/g crude extract, respectively. On the other hand, ORAC analysis of fractions F3 and F4 gave values of 136.9 and 260.6 μmol Trolox equivalent/

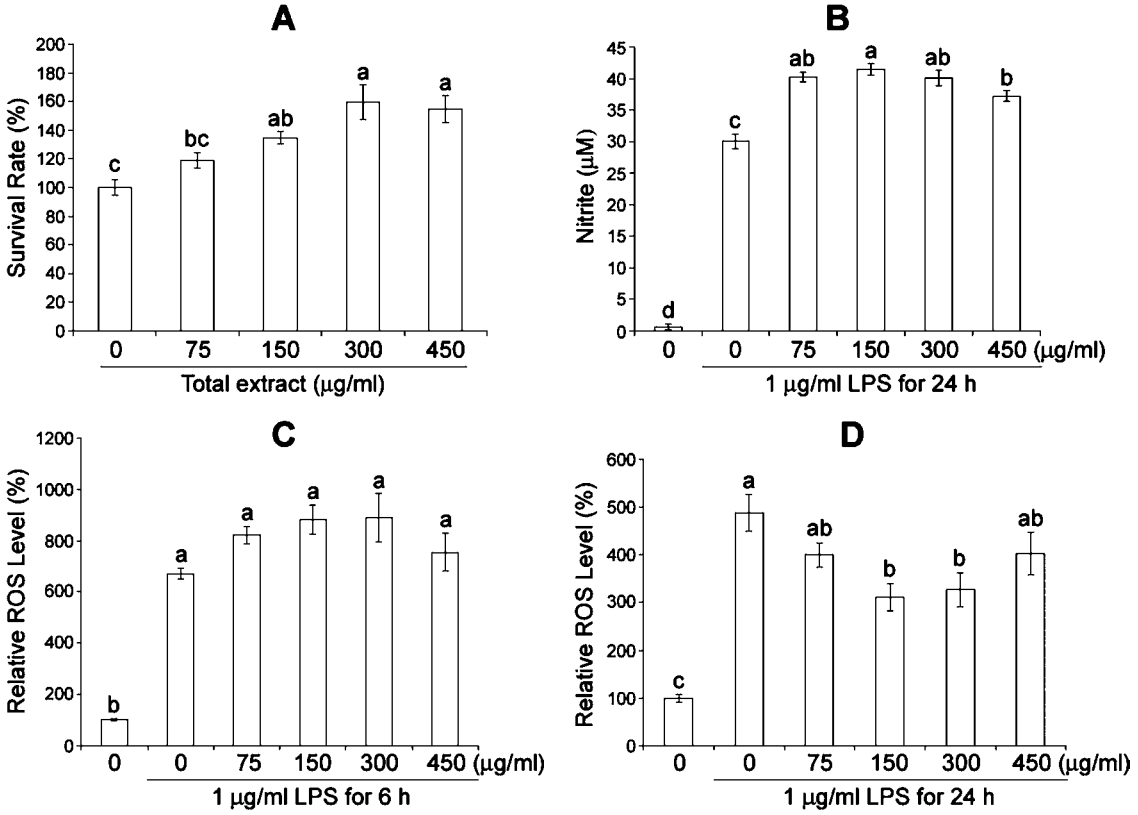

Figure 5. Effect of butterfly pea extract on cell viability and LPS-induced NO and ROS production. (A) Effect of butterfly pea extract on cell viability in macrophage cells. RAW 264.7 cells (2×10^5 cells/well in 96-well culture plates) were treated with 0–450 μg/mL blue flower extract for 24 h, and then the cell viability was measured by MTS assay. (B–D) Effect of blue flower extract on LPS-induced NO and ROS production. RAW 264.7 cells (2×10^5 cells/well in 96-well culture plates) were pretreated with 0–450 μg/mL blue flower extract for 1 h and then stimulated with LPS (1 μg/mL) for 6 or 24 h. Griess reagent was used to detect the generation of extracellular nitrite at 24 h after the LPS challenge (B), and DCFA was used to determine the generation of intracellular ROS at 6 h (C) and 24 h (D) after the LPS challenge. Data, obtained from at least four biological repeats, are shown as mean ± SE values. Different letters indicate significant differences by ANOVA/Tukey-HSD ($p < 0.05$).

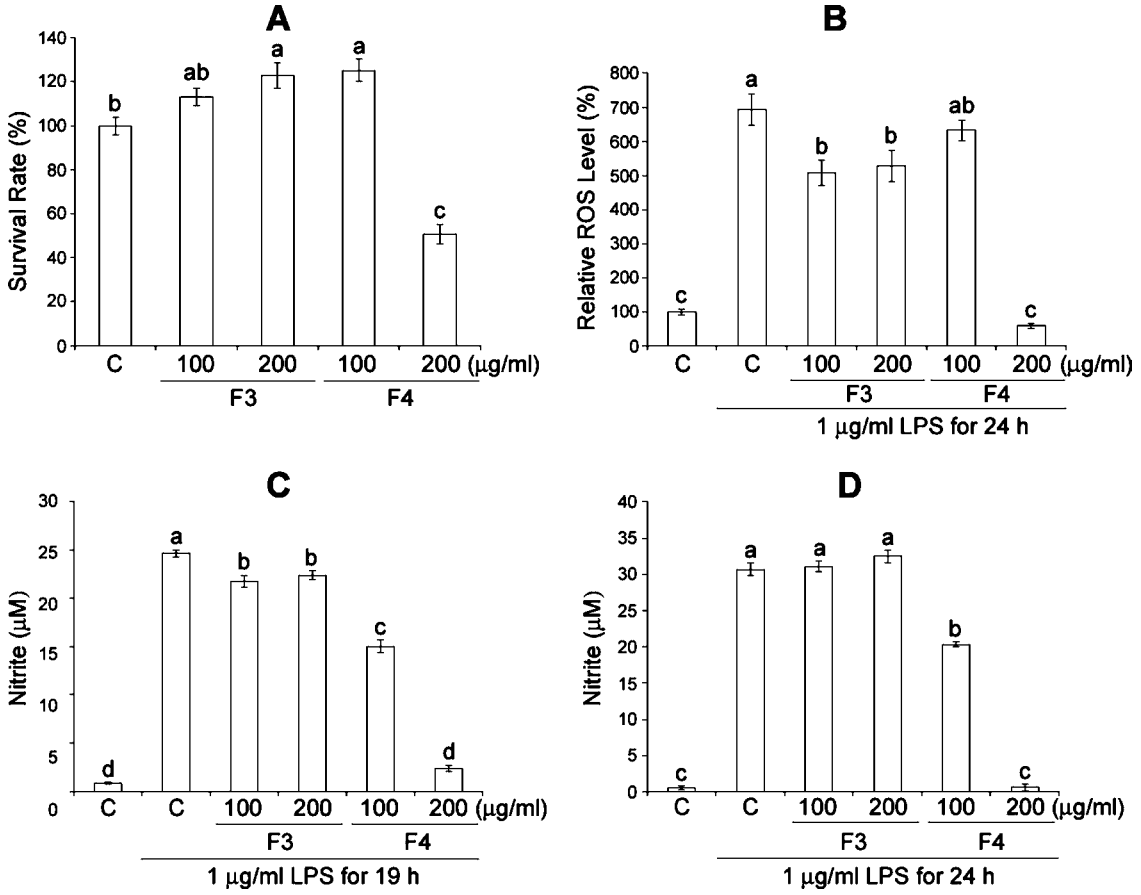

Figure 6. Effect of butterfly pea fractions (F3 and F4) on cell viability and LPS-induced ROS and NO production. (A) Effect of butterfly pea fractions (F3 and F4) on cell viability in macrophage cells. RAW 264.7 cells (0.5×10^5 cells/well in 96-well culture plates) were treated with 100 and 200 μg/mL blue flower fractions (F3 and F4) for 24 h, and then the cell viability was measured by MTS assay. (B–D) Effect of blue flower fractions (F3 and F4) on LPS-induced ROS and NO production. RAW 264.7 cells (0.5×10^5 cells/well in 96-well culture plates) were pretreated with 100 and 200 μg/mL butterfly pea fractions (F3 and F4) for 5 h and then stimulated with LPS (1 μg/mL) for 19 or 24 h. DCFA was used to determine the generation of intracellular ROS at 24 h after the LPS challenge (B), and Griess reagent was used to detect the generation of extracellular nitrite at 19 h (C) and 24 h (D) after the LPS challenge. "C", a control, indicates the pretreatment of 0.5% DMSO in DMEM with or without any LPS stimulation. Data, obtained from at least four biological repeats, are shown as mean ± SE values. Different letters indicate significant differences by ANOVA/Tukey-HSD ($p < 0.05$).

g fraction extract, respectively (Table 2). In general, both fractions showed scavenging properties of peroxyl radicals and potential antioxidant properties. The crude extracts and fractions F3 and F4 were used for the inflammation studies.

Effect of Blue Flower Butterfly Pea Extract and Fractions (F3 and F4) on LPS-Induced Inflammation. Here we assessed the effects of the total extract and its fractions (F3 and F4), prepared from butterfly pea, on inflammation in a LPS-stimulated RAW 264.7 macrophage cell line. Initially the effects of the total extract on inflammation were examined as follows: The MTS assay showed that a dose range of 75–450 μg/mL extract did not affect cell viability (Figure 5A), whereas the NO measurement suggested that the extract had no suppressive effect on LPS-induced NO production (Figure 5B). When LPS-induced ROS production was assessed using DCFA at 6 and 24 h after the LPS challenge, the extract dose range studied did not suppress ROS production at 6 h (Figure 5C); however, at 24 h after the LPS challenge, only doses of 150 and 300 μg/mL extract showed a significantly weak effect on the suppression of ROS production (Figure 5D).

Next, the fractions isolated from the blue flower extract (F3 and F4) were used to identify their possible protective roles against the LPS-induced inflammation process. The MTS assay confirmed that neither doses of 100 and 200 μg/mL of fraction F3 nor a dose 100 μg/mL of fraction F4 affected cell viability; however, a dose of 200 μg/mL of fraction F4 significantly affected it (Figure 6A), resulting in strong suppression effects of ROS and NO production (Figure 6B–D). Fraction F3 (100 and 200 μg/mL) showed a significantly weak effect on ROS suppression at 24 h after the LPS challenge, whereas a dose of 100 μg/mL fraction F4 had no effect (Figure 6B). Accordingly, the antioxidant properties of fractions F3 and F4 (observed with the ORAC assay) seem to be playing a role only in fraction F3, but not in fraction F4, within macrophage cells.

When LPS-induced NO production was assessed at 19 and 24 h after the LPS challenge, fraction F3 (100 and 200 μg/mL) exhibited a significantly slight effect on suppression of NO at 19 h; however, that effect disappeared at 24 h after the LPS challenge. On the other hand, a dose of 100 μg/mL of fraction F4 showed a significantly higher effect on the suppression of NO at 19 h compared to fraction F3, and this effect remained at 24 h after the LPS challenge (Figure 6C,D).

Furthermore, effects of fractions F3 and F4 on LPS-induced iNOS and COX-2 production and NF-κB activation were examined by Western blot analysis. At 19 h after the LPS challenge with 5 h pretreatments of 100 μg/mL of fractions F3

DOI: 10.1021/acs.jafc.5b00928
J. Agric. Food Chem. 2015, 63, 6355–6365

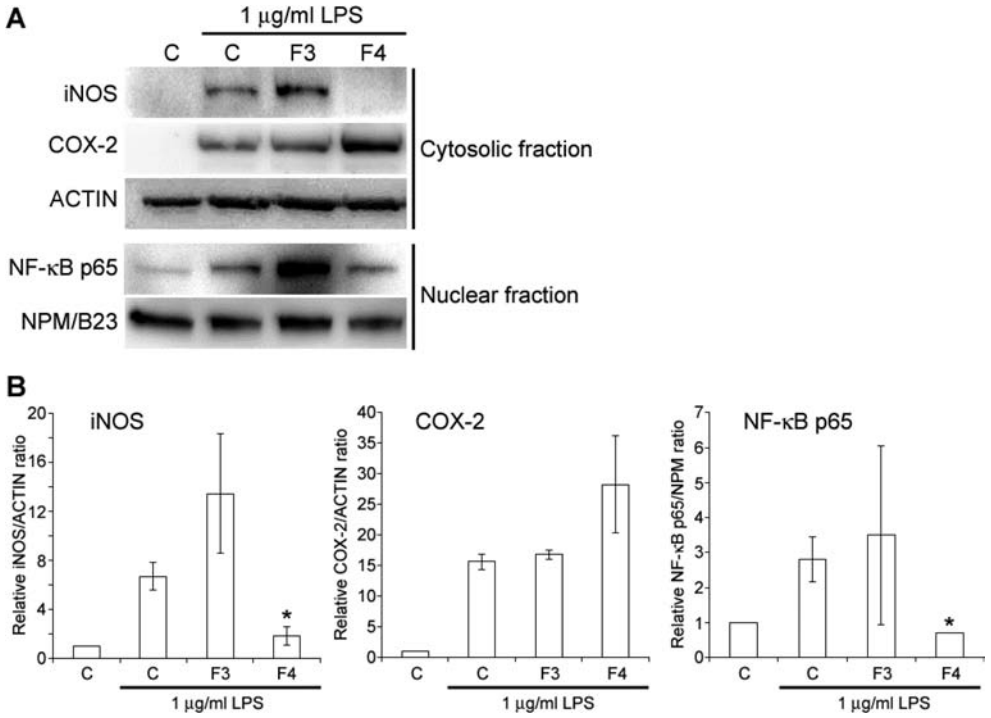

Figure 7. Effects of butterfly pea fractions (F3 and F4) on iNOS, COX-2, and NF-κB in macrophage cells. RAW 264.7 cells (2×10^6 cells/well in 6-well culture plates) were pretreated with 100 μg/mL butterfly pea fractions (F3 and F4) for 5 h and then stimulated with LPS (1 μg/mL) for 19 h. Subsequently, cytosolic and nuclear fractions were isolated as described under Materials and Methods and subjected to SDS-PAGE and Western blot analysis using specific antibodies against iNOS, COX-2, p-NF-κB, actin, and NPM/B23. The protein bands in panel A were detected by chemiluminescence. "C", a control, indicates the pretreatment of 0.5% DMSO in DMEM with or without any LPS stimulation, and actin and NPM/B23 were used to confirm the same amount of total cytosolic and nuclear proteins loaded, respectively. The histograms in panel B represent the relative protein levels measured by ImageJ software using protein bands obtained from panel A. Data, obtained from two biological repeats, are shown as the mean ± SE. Asterisks indicate significant differences by Student's t test ($p < 0.05$).

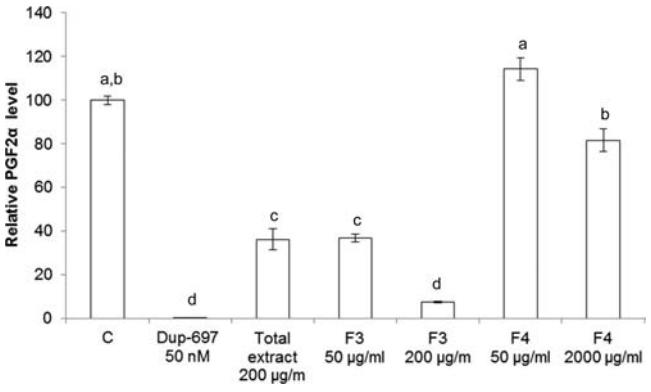

Figure 8. Effect of butterfly pea extract and fractions (F3 and F4) on COX-2 activity. DuP-607 was used as a positive control. The COX-2 inhibitory assay was evaluated using the COX Inhibitor Screening Assay Kit following the manufacturer's instructions (Cayman Chemical, Ann Arbor, MI, USA). Data obtained from three biological repeats are shown as mean ± SE values. Different letters indicate significant differences by ANOVA/Tukey-HSD ($p < 0.05$).

and F4, cell lysates were separated into cytosolic and nuclear fractions and then subjected to Western blot analyses to detect cytosolic iNOS and COX-2 and nuclear NF-κB. As shown in Figure 7, both fractions F3 and F4 had no significant effect on the suppression of LPS-induced COX-2 production. However, fraction F4 significantly suppressed the LPS-induced iNOS production and nuclear NF-κB translocation, whereas fraction F3 did not have that effect (Figure 7).

Inhibition of Cyclooxygenase-2 Activity of Butterfly Pea Extract and Fractions (F3 and F4). The effect of butterfly pea total extract and fractions (F3 and F4) on COX-2 activity is shown in Figure 8. The total blue flower extract and fraction F3 at two concentrations (50 and 200 μg/mL) showed a significant COX-2 inhibitory effect when compared to the control. Moreover, fraction F3 showed a dose-dependent COX-2 inhibitory effect, whereas fraction F4 did not show a significant effect. These results suggest that the flavonol compounds present in fraction F3 are responsible for the COX-2 inhibitory effect of the blue flower *C. ternatea* total extract.

Mechanistic Model of Anti-inflammatory Properties of Butterfly Pea Polyphenols. Macrophages produce various pro-inflammatory mediators when responding to pathogens such as TNFα, IL-1β, IL-6, IFNβ, COX-2, mPGES-1, and iNOS, but excessive production of the pro-inflammatory mediators leads to the development of diseases such as the metabolic syndrome.[24−26] Noticeably, production of the inflammatory mediators is mediated by TLR signaling pathways including the NF-κB, a redox-responsive transcription factor.[24,27,28] For example, binding of LPS, a pathogen-associated molecular pattern, to TLR4 receptor triggers generation of ROS from NADPH oxidase and mitochondria,[29−31] ROS-mediated redox changes activate the nuclear translocation of NF-κB via IκB and Ref-1,[23,28] and then the ROS-dependent NF-κB activation mediates the LPS-induced gene expressions such as *COX-2* and *IFN-β*.[24] Eventually, binding of the LPS-induced IFN-β to an IFN receptor triggers amplification of the iNOS expressions.[32−34] Therefore, this TLR pathway in

J. Agric. Food Chem. 2015, 63, 6355−6365

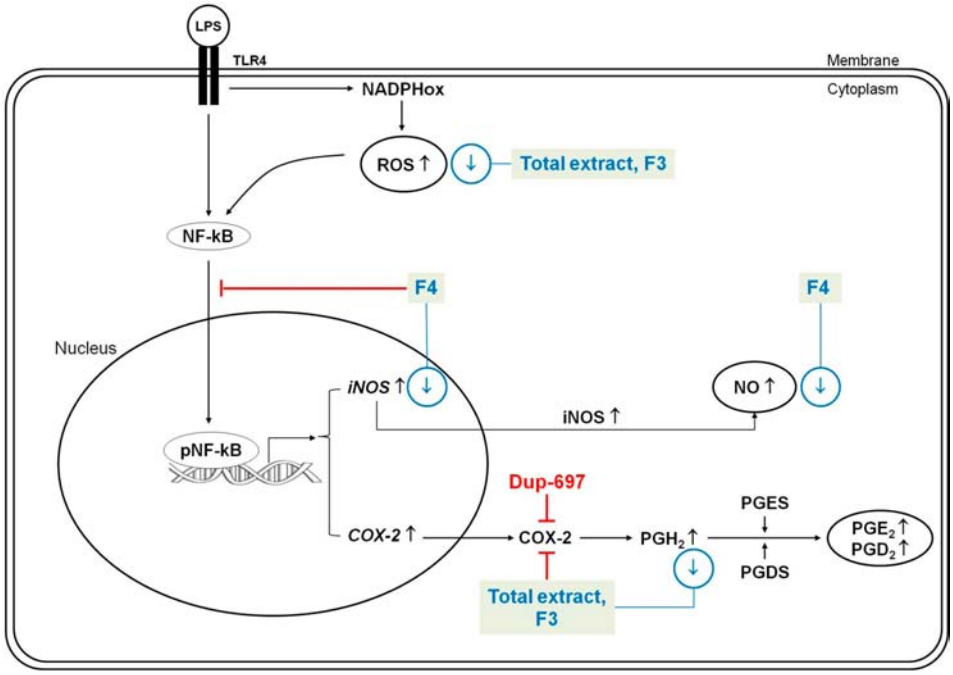

Figure 9. Anti-inflammatory roles of butterfly pea extract and its fractions (F3 and F4) in the TLR4 signaling pathway. Binding of LPS to TLR4 receptor triggers generation of ROS from NADPH oxidase and mitochondria. ROS-mediated redox activates the nuclear translocation of NF-κB via IκB and Ref-1. The NF-κB activation is ROS-dependent and mediates LPS-induced *COX-2* and *IFN-β* expressions. Binding of the LPS-induced IFN-β to an IFN receptor triggers amplification of the *iNOS* expressions. The blue flower extract and fraction F3 showed weak suppressive effects on LPS-induced ROS production. Fraction F3 had strong suppressive effects on PGH_2 production by inhibiting COX-2 enzyme activity. Fraction F4 suppressed *iNOS* expression and NF-κB activation, leading to a suppressive effect of LPS-induced NO production, but affected the COX-2 enzyme activity weakly, compared with fraction F3.

macrophage has guided the screening of many phytochemicals from various crops that have anti-inflammatory properties.

Here we assessed for the first time the effects of the blue flower *C. ternatea* extract and its fractions (F3 and F4) on anti-inflammation properties in a LPS-stimulated RAW 264.7 macrophage cell line. The extract and fraction F3 showed weak suppressive effects on LPS-induced ROS production (Figures 5D and 6B). This F3 fraction had strong suppressive effects on PGH2 production by inhibiting COX-2 enzyme activity (Figure 8) but affected weakly LPS-induced NO production (Figure 6C). On the other hand, fraction F4 suppressed iNOS expression and NF-κB activation (Figure 7), leading to the much stronger suppressive effect of LPS-induced NO production than that of fraction F3 (Figure 6C,D), but did not affect the COX-2 enzyme activity compared with the control and fraction F3 (Figure 8).

In summary, here we report for the first time the anti-inflammatory properties of polyphenols from butterfly pea extracts and identify two fractions, F3 and F4, suppressing the LPS-induced inflammation process through two distinct actions in the TLR pathway (Figure 9). In more detail, fraction F3, which includes quercetin glycosides, plays an important role as an inhibitor of COX-2 activity and as an antioxidant; however, its scavenging properties seem too weak to suppress ROS-mediated NF-κB activation (Figure 9). On the other hand, the ternatin anthocyanins present in fraction F4 suppress the nuclear NF-κB translocation and the protein expression of iNOS as well as NO production by inhibiting signaling factors, through a non-ROS suppression mechanism possibly downstream of ROS in macrophage cells (Figure 9). Accordingly, quercetin glycosides and ternatin anthocyanins from the blue flower petals of *C. ternatea* may be useful in the development of drugs or nutraceuticals protecting against chronic inflammatory diseases by suppressing the excessive production of pro-inflammatory mediators from macrophage cells. Additional, work is needed to confirm these results in in vivo studies as well as to evaluate different butterfly pea accessions that may contain different levels of anthocyanins and other flavonoids as reported in the works of Morris and Wang (2007) and Morris (2009).[35,36]

inhibitory sequences are thus largely unexplored. Although systematic analysis is advisable, the identification and isolation of novel inhibitory peptides in hydrolyzed protein mixtures are challenging tasks: indeed, they are usually based on sequential chromatographic separations of different fractions or components that have to be characterized and tested to identify putative sequences that must then be synthesized and tested for bioactivity. Thus, the development of novel methodologies for the discovery of new active sequences encrypted in food is strongly recommended. Within this framework, the computer-driven screening of peptide sequences may strongly support the discovery of new BPs.

Recently a number of in silico approaches have been successfully applied for the discovery of novel bioactive sequences, also toward ACE enzyme (e.g., ref 10). Basically, two main computer-aided frameworks have been applied so far. The former is based on the in silico simulation of enzymatic cleavage or digestion of protein sequences and the evaluation of the release of bioactive sequences (e.g., refs 10 and 11) by using inhibition assay or by checking the release of already known inhibitory peptides (e.g., ref 12). The second is based on the prediction of inhibitory activity of peptides through the use of computational strategies. Notably, most of them use statistical approach to infer activity solely on the basis of the physicochemical properties of peptides (e.g., ref 13). Nevertheless, when the activity requires a certain degree of a protein−ligand interaction, as in the case of peptide-mediated ACE inhibition, structure-based modeling is more advisable.[14] Therefore, with the aim to discover novel ACE inhibitory peptides from a previously reported peptidomic profile of digested samples of Parma dry-cured ham,[15] we report the benefits achieved by using a hybrid approach involving the integration of in vitro trials and in silico structure-based molecular modeling technique, the reliability of which in predicting the bioactivity of compounds, including peptides, has been previously assessed.[16−21] Parma dry-cured ham has been chosen as the case study because it is one of the most valuable brands in Italy with a significant commercialization in Europe, the United States, and Japan.[22,23] Even if it is among the most consumed traditional Italian cured-meat products,[24] there is a marked lack of data beyond the canonical nutritional values. Thus, the profiling of bioactive compounds, including BPs, is strongly advisable, also considering the efforts to better understand, and rationally improve, the content of health-protective compounds. In particular, dry-cured ham samples have been hydrolyzed by an in vitro simulated gastrointestinal digestion, and then the digested peptide mixtures have been fractionated by preparative LC and the ACE inhibitory activity of each fraction has been evaluated in vitro. In parallel, the priority ranking of peptides in terms of ACE-inhibitory activity has been done on the basis of computational predictions. Finally, in accordance with computational rank and relative occurrence within the most active fractions, some peptides have been synthesized and then assessed for their inhibitory activity by using an in vitro assay.

MATERIALS AND METHODS

In Silico Procedures. *Pharmachopore Models.* The anatomy of the ACE binding sites was investigated by using the Flapsite tool of FLAP software (Fingerprint for Ligand And Protein; http://www.moldiscovery.com),[25] and the GRID molecular interaction fields (MIFs) were used to investigate the corresponding pharmacophoric space.[26] The DRY probe was used to describe the potential hydrophobic interactions, whereas the sp2 carbonyl oxygen (O) and the neutral flat amino (N1) probes were used to describe the hydrogen bond acceptor and donor capacity of the target, respectively. All images were obtained using the software PyMol version 1.7 (http://www.pymol.org).

Molecular Modeling. The models for both C- and N-domains of ACE were derived from the Protein Data Bank (http://www.rcsb.org) structures having PDB codes 4APH and 4BZS, respectively.[27,28] Protein structures and ligands were processed by using the software Sybyl, version 8.1 (www.tripos.com). All atoms were checked for atom- and bond-type assignments. Amino- and carboxyl-terminal groups were set as protonated and deprotonated, respectively. Hydrogen atoms were computationally added to the protein and energy-minimized using the Powell algorithm with a coverage gradient of ≤0.5 kcal/(mol Å) and a maximum of 1500 cycles.

Docking Simulations and Rescoring Procedure. The coupling of GOLD, to perform docking simulations, and HINT software, as rescoring function, has been already proved to be effectively able to evaluate the bioactivity of small molecules,[16,20,21,29] including peptides.[30] The docking simulations of compounds were performed with the GOLD version 5.1 (CCDC; Cambridge, UK; http://www.ccd.cam.ac.uk). All crystallographic waters and ligands were removed, and 25 poses for each compound were generated. No constraints were set up, and the explorable space was defined in a radius of 10 Å from the centroid of the catalytic site. For each GOLD docking search, a maximum number of 100,000 operations were performed on a population of 100 individuals with a selection pressure of 1.1. Operator weights for crossover, mutation, and migration were set to 95, 95, and 10, respectively. The number of islands was set to 5 and the niche to 2. The hydrogen bond distance was set to 2.5 Å and the van der Waals linear cutoff to 4.0. Ligand flexibility options "flip pyramidal N", "flip amide bonds", and "flip ring corners" were allowed. Each best-scored pose according to GOLD scoring function was rescored by HINT. Owing to the huge dimension of the pocket, and to speed the spatial search, molecule positioning has been spatially restrained according to crystallographic pose of the inhibitory drug captopril,[31] whose pattern of interaction and volume occupancy are maintained also by all of the ligands cocrystallized so far.

The software HINT (Hydrophatic INTeraction)[32] was used as the rescoring function on the basis of previous studies attesting to the higher reliability of HINT scoring with respect to other scoring functions, as well as its successful use in the search for ligands for other targets and in the estimation of ligand-binding free energies. In more detail, the score provides the evaluation of thermodynamic benefits of protein−ligand interaction, and therefore low/negative scores indicate no appreciable protein−ligand interactions.[17,19−21,29,30,33−35] GOLD uses a Lamarckian genetic algorithm, and scores may slightly change from run to run. Therefore, to exclude a noncausative score assignment, we conducted simulations in quintuplicate, and the mean values are reported.

In Vitro Experimental Procedures. *Samples.* Parma dry-cured ham samples with 18 and 24 ripening months were provided by the Experimental Station for Food Preserving Industry (Parma, Italy). Samples of biceps femoris muscle were minced by a common mill (Moulinex, Milano, Italy) and stored at freezing temperature (−22 °C) until analysis.

Reagents and Solvents. Doubly distilled water was produced in our laboratory by a Millipore Alpha Q purification system (Waters, Billerica, MA, USA). Pepsin from porcine gastric mucosa, trypsin from porcine pancreas, α-chymotrypsin from bovine pancreas, α-amylase from barley malt (type VIIIa), uric acid, mucin from porcine stomach (type III), glucose, glucuronic acid, glucosamine hydrochloride, bovine serum albumin, pancreatin from porcine pancreas, lipase from porcine pancreas (type II), bovine and ovine bile, sodium dihydrogen phosphate, potassium chloride, sodium hydroxide, sodium phosphate dibasic dodecahydrate, monobasic potassium phosphate, acetonitrile, urea, methanol, trifluoroacetic, triisopropylsilane acid, DL-dithiothreitol, hippuryl-histidyl-leucine (HHL), angiotensin I converting enzyme (ACE; EC 3.4.15.1) from rabbit lung 0.1 U, and glycerol were all purchased from Sigma-Aldrich (St. Louis, MO, USA). Hydrochloric

DOI: 10.1021/acs.jafc.5b02303
J. Agric. Food Chem. 2015, 63, 6366−6375

acid (37% v/v), sodium hydroxide, sodium hydrogen carbonate, calcium chloride, ammonium chloride, potassium thiocyanate, and potassium hydroxide were purchased from Carlo Erba (Milan, Italy). Formic acid was purchased from Acros Organics (Geel, Belgium). Sodium chloride was purchased from AnalaR Normapur (Milan, Italy). Sodium sulfate was purchased from Riedel de Haen (Seelze, Germany). Magnesium chloride hexahydrate and boric acid were purchased from Fluka (Sigma-Aldrich, St. Louis, MO, USA).

Simulated Gastrointestinal Digestion. Simulated gastrointestinal digestion was recently applied to the study of the effect of dry-cured ham maturation time on the composition of the released peptide fraction:[15] the preparation of the relative artificial digestive juices (simulated salivary juice, simulated gastric juice, simulated duodenal juice, and bile) was performed according to the protocol of Versantvoort.[36]

Briefly, the digestion procedure was as follows: minced biceps femoris muscle (2 g) was dispersed in 3 mL of simulated salivary juice (pH 6.8 ± 0.2) and incubated at 37 °C under agitation with a vortex and a horizontal shaker (230 rpm) for 5 min. After this first step, 6 mL of the simulated gastric juice (pH 1.3 ± 0.2) was added, and the mixture was left to react for 2 h under the same conditions. The last step was the addition of bicarbonate (1 mL, 1 M), simulated duodenal juice (6 mL, pH 8.1 ± 0.2), and bile (3 mL, pH 8.2 ± 0.2), and the mixture was left to react at 37 °C for another 2 h under agitation on a horizontal shaker. The enzyme reaction was stopped by heating at 95 °C for 15 min and the mixture was centrifuged at 3200*g* for 20 min to separate the supernatant (chyme) and the pellet (residual matrix). The supernatant was subjected to a final cleanup step by a Sep-Pak C18 cartridge (Waters Co., Milford, MA, USA): after the cartridge was conditioned with CH_3OH (2 mL) and bidistilled water (3 mL), chyme was applied (2 mL), and after the first eluate had been discarded, peptides were eluted with 2 mL of a solution of H_2O/CH_3OH (50:50, v/v). The eluate (2 mL) was evaporated to dryness under nitrogen flow in an Eppendorf tube, and the residue was resuspended with 2 mL of aqueous formic acid (0.1%), centrifuged and, then, fractionated in semipreparative HPLC-UV (conditions reported below).

Semipreparative LC-UV Fractionation of Digested Samples. The digested mixture was fractionated by semipreparative HPLC-UV (λ = 214nm) by collecting one fraction per minute. The digested samples were separated by a RP column (JUPITER 5 μm, C18, 300 Å, 250 × 10 mm, Phenomenex, Bologna, Italy) using a semipreparative HPLC-UV (1525 binary HPLC pump, Waters, Billerica, MA, USA). The following gradient conditions were applied: eluent A, water with 0.1% formic acid and 0.2% acetonitrile; eluent B, acetonitrile with 0.1% formic acid; gradient, 0−12 min, 100% A; 12−77 min, linear from 100 to 50% A; 77−81 min, 50% A; 81−82 min, linear from 50 to 0% A; 82−90 min, 0% A; 90−91 min, linear from 0 to 100% A; 91−110 min, 100% A. Other parameters were as follows: flow rate, 5 mL/min; analysis time, 110 min; column temperature, room temperature; sample temperature, room temperature; injection volume, 2 mL; fractions collected every minute for a total of 51 fractions. The UV detector (2998 photodiode array, Waters) set at λ = 214 nm.

All collected fractions were evaporated to dryness at the rotavapor and dissolved in 2 mL of H_2O + 0.1% HCOOH for analyses.

UPLC-ESI-MS Analyses. UPLC/ESI-MS analyses were performed with a UPLC/ESI-MS system (UPLC Acquity Waters equipped with a single-quadrupole mass spectrometer, Waters Acquity Ultraperformance). Conditions were as follows: column, RP ACQUITY UPLC BEH 300, C18 (1.7 μm, 2.1 × 150 mm, Waters); gradient elution, eluent A, water with 0.1% formic acid and 0.2% acetonitrile, eluent B, acetonitrile with 0.1% formic acid; gradient, 0−7 min, 100% A; 7−50 min, linear from 100 to 50% A; 50−52.6 min, isocratic, 50% A; 52.6−53 min, linear from 50 to 0% A; 53−58.2 min, isocratic 0% A; 58.2−59 min, linear from 0 to 100% A; 59−72 min, isocratic 100% A. LC parameters: flow rate, 0.2 mL/min; analysis time, 72 min; column temperature, 35 °C; sample temperature, 18 °C; injection volume, 10 μL for fraction samples; 2 μL for the calibration curve of LGL peptide. MS parameters: full scan mode; acquisition time, 7−58.2 min; ionization type, ESI+ (positive ions); scan range, m/z 100−2000; capillary voltage, 3.2 kV; cone voltage, 30 V; source block temperature, 150 °C; desolvation temperature, 300 °C; cone gas flow, 100 L/h; desolvation gas flow, 650 L/h. Data were acquired and analyzed by MassLynx 4.0 software (Waters Co., Milford, MA, USA).

HPLC-ESI-MS/MS Analyses. HPLC/ESI-MS/MS analyses were performed using a HPLC (model Alliance 2695, Waters) equipped with a triple-quadrupole mass spectrometer (model Four Micro, Waters) and a RP column JUPITER 5 μm, C18, 300 Å, 250 × 2 mm i.d. (Phenomenex). Gradient elution was as follows: eluent A, water with 0.1% formic acid and 0.2% acetonitrile; eluent B, acetonitrile with 0.1% formic acid; gradient, 0−12 min, 100% A; 12−77 min, linear from 100 to 50% A; 77−81 min, 50% A; 81−82 min, linear from 50 to 0% A; 82−90 min, 0% A; 90−91 min, linear from 0 to 100% A; 91−110 min, 100% A. Samples (fractions) were first analyzed in full scan mode to identify the characteristic ions and the retention time of the unknown compounds and then in daughters scan modality, using a variable collision energy from 10 to 30 eV. HPLC/ESI-MS/MS parameters were as follows: flow rate, 0.2 mL/min; analysis time, 110 min; column temperature, 35 °C; sample temperature, 23 °C; injection volume, 10 μL for full scan mode and 30 μL for daughter scan mode; acquisition time, 90 min; ionization type, ESI+ (positive ions); scan range, m/z 100−2000; capillary voltage, 3.2 kV; cone voltage, 35 V; source block temperature, 100 °C; desolvation temperature, 200 °C; cone gas flow, 100 L/h; desolvation gas flow, 650 L/h. The peptide sequences were assigned on the basis of the obtained mass spectra and using the Bioinfomatics resource portal ExPasy with the tools FindPept (Swiss Institute of Bioinformatics, Switzerland) and with the web application "Proteomics Toolkit" (Institute for Systems Biology, Seattle, WA, USA).

Solid Phase Peptide Synthesis and Purification. Peptides were synthesized using solid phase peptide synthesis according to the Fmoc/*tert*-butyl strategy on Wang-resin (Wang, Calbiochem-Novabiochem, Läufelfingen, Switzerland) using a Syro I Fully Automated Peptide Synthesizer (Biotage, Uppsala, Sweden). Cleavage from the resin was performed using a trifluoroacetic acid (TFA)/triisopropylsilane (TIS)/H_2O/dithiothreitol (DTT) (94:1:2.5:2.5) solution, and peptides were purified by semipreparative RP-HPLC-UV (λ = 214 nm). The purity and molecular mass of peptides were determined by using a liquid chromatograph coupled to a mass spectrometer equipped with an electrospray ionization source (UPLC-ESI-MS).

Evaluation of ACE Inhibition. The percentage of ACE inhibitory activity for pure peptides and digested fractions was determined by using the methods of Cushman et al [37] and Nakamura et al,[38] with some modifications and according to the following equation: $I\% = [(ACE_{max} - B_{max}) - (ACE_{min} - B_{min})]/(ACE_{max} - B_{max}) \times 100$, where ACE_{max} is the maximum activity of ACE (in the absence of the peptides), ACE_{min} is the minimal activity of ACE (in the presence of the peptides), B_{max} is the control blank of ACE and B_{min} is the control blank of sample/digestion blank/pure peptide.

The following solutions were prepared: sodium borate buffer (0.1 M, NaBB) with NaCl (300 mM), pH 8.3; potassium phosphate buffer (0.01 M, KPB) with NaCl (500 mM), pH 7; 5 mM hippuryl-histidyl-leucine (HHL) in NaBB buffer; and ACE 0.1 U/mL in KPB + 5% glycerol (g/mL). The experiment is carried out at 37 °C in a thermostatic bath (WB-OD 24, Falc, Treviglio (BG), Italy) determining the following parameters: maximum activity of ACE (ACE_{max}) = 200 μL of HHL + 80 μL of NaBB + 20 μL of ACE; control blank of ACE (B_{max}) = 200 μL of HHL + 80 μL of NaBB + 20 μL of KPB; minimal activity of ACE (ACE_{min}) = 200 μL of HHL + 80 μL of sample (i.e., fraction or pure peptide) + 20 μL of ACE; control blank of sample (i.e., fraction or pure peptide) (B_{min}) = 200 μL of HHL + 80 μL of sample (i.e., fraction or pure peptide) + 20 μL of KPB. After 60 min of incubation, the reaction was quenched with 250 μL of HCl (1 N). The analysis was performed by HPLC-UV (Alliance 2695 separation, Waters, Billerica, MA, USA) with dual λ absorbance detector model 2487 (Waters), with the following conditions: column, RP JUPITER C18, 5 μm, 300 Å, 250 × 2 mm (Phenomenex); gradient elution, eluent A, water with 0.1% formic acid and 0.2% acetonitrile; eluent B, acetonitrile with 0.1% formic acid; gradient, 0−10 min, 100% A; 10−22.50 min, linear from

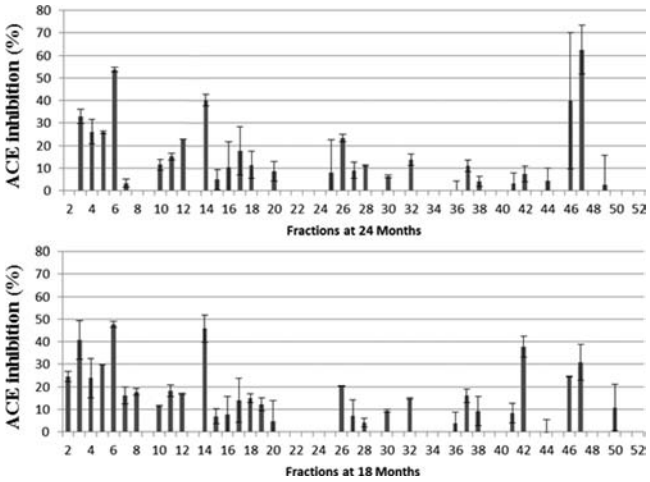

Figure 1. ACE-inhibitory activity of fractions collected after an in vitro gastrointestinal digestion of dry-cured hams at 18−24 months of aging time.

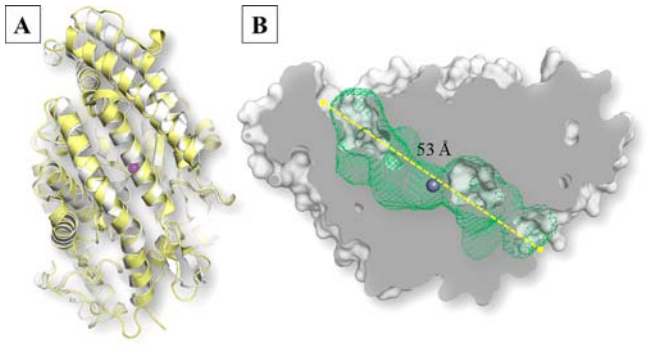

Figure 3. Three-dimensional representation of ACE structures: (A) structures overlapping C-terminal (white) and N-terminal (yellow) domains; (B) cut surface of N-terminal domain. The binding pocket is represented in mesh, and the dark sphere represents Zn ion.

100 to 50% A; 22.50−23.50 min, 50% A; 23.50−30 min, linear from 50 to 100% A; column temperature, 35 °C; sample temperature, room temperature; injection volume, 10 μL for sample fractions and 20 μL for pure peptides; acquisition time, 30 min; flow, 0.2 mL/min; UV detection, λ = 228. Data analysis was performed with Empower software (Waters Co., Milford, MA, USA).

The IC_{50} value is defined as the inhibitor concentration that is able to decrease ACE activity by 50%. To determine IC_{50}, different concentrations of peptides were prepared and their relative ACE inhibitory activity was evaluated. IC_{50} values were determined by plotting the percentage relative inhibition as a function of concentration of test compound.

Peptide Quantification. LGL was quantified by an external calibration curve. The calibration curve was set up by injecting 200 μL of LGL at different concentrations (from 1 to 125 μM) containing 4 μL of internal standard (1 mM Phe-Phe) in UPLC-ESI-MS with the analysis conditions reported above.

RESULTS AND DISCUSSION

ACE Inhibitory Activity of Digested Fractions. We have recently reported the characterization of the peptide mixture obtained by simulated gastrointestinal digestion of Parma dry-cured hams:[15] To characterize the ACE inhibitory activity of the obtained peptides, the digesta were fractionated by semi-preparative HPLC, and the different fractions were tested by in vitro assay, according to common procedures used to identify active sequences.[39] By performing a reverse phase HPLC separation with very tight fraction collection, we obtained 51 fractions: results of in vitro test are reported in Figure 1.

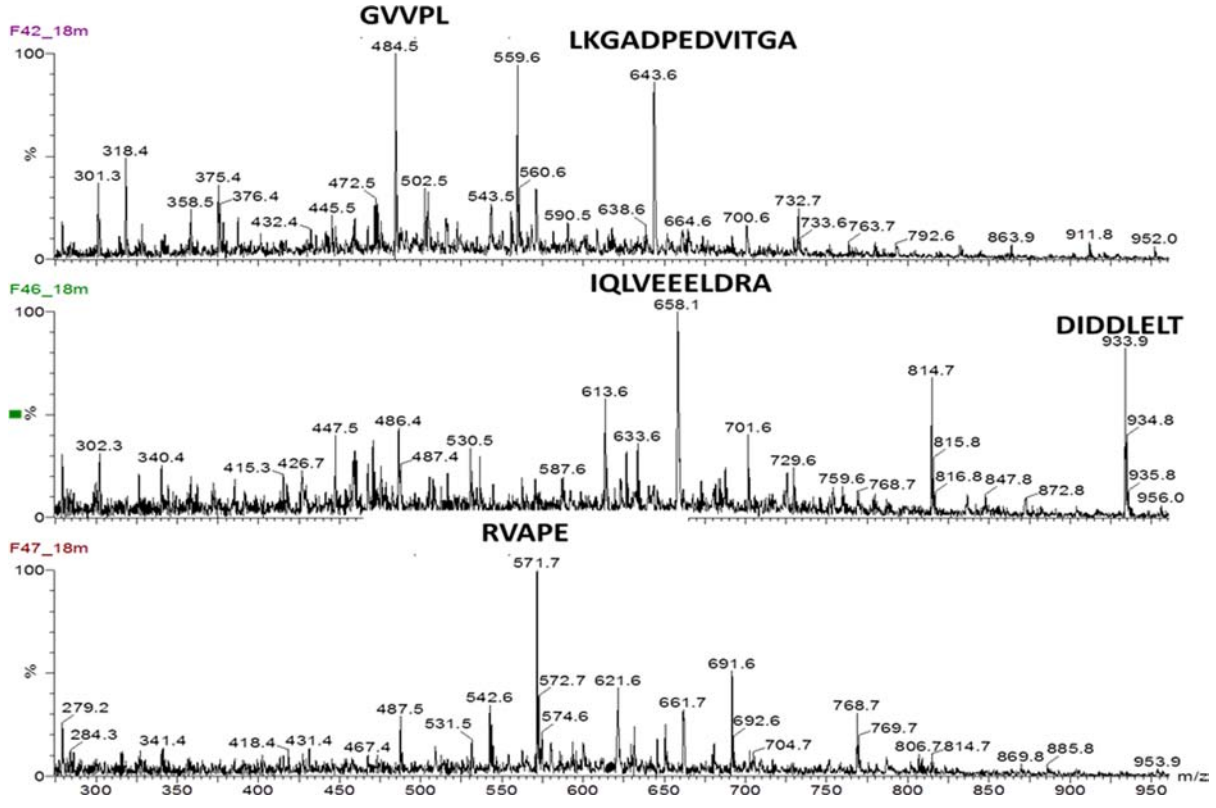

Figure 2. Mass spectra of fractions 42, 46, and 47 of samples at 18 months of aging time.

J. Agric. Food Chem. 2015, 63, 6366−6375

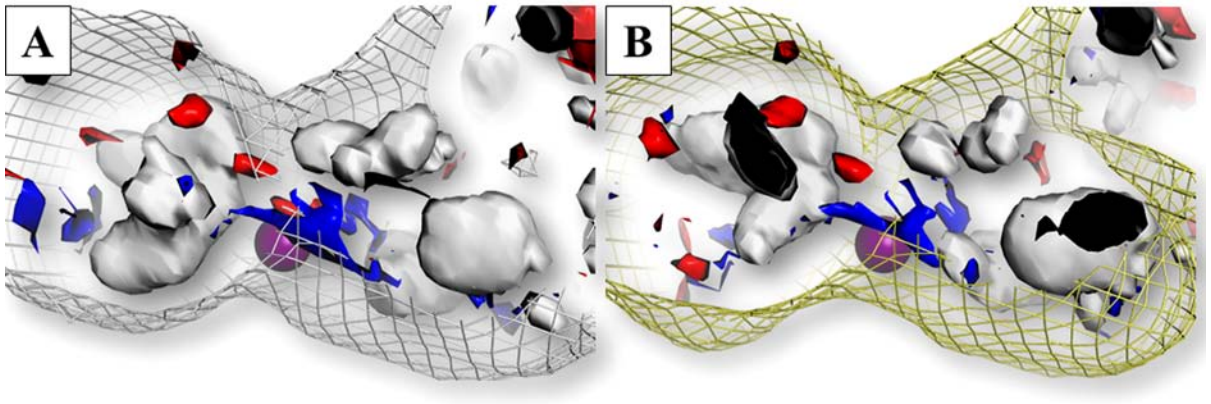

Figure 4. Anatomy of the binding sites: (A) C-terminal domain; (B) N-terminal domain. White, red, and blue contours identify regions sterically and energetically favorable for hydrophobic, H-bond acceptor, and H-bond donor groups, respectively (black regions are due to the back-lighted cut of some contours). The shape of the binding site is represented in mesh.

The inhibitory activity significantly differs among the different fractions, and differences were also observed as a function of aging time. In this respect, indeed, the most active fractions for digested ham sample at 24 months were found to be fractions 6, 14, 46, and 47, whereas for samples at 18 months also fraction 42 showed a relevant activity. To identify the peptides occurring in these fractions, MS and MS/MS analyses have been performed as previously reported.[15] The mass spectrum revealed a prevalence of dipeptides and free amino acids (mainly, tyrosine and phenylalanine) in the early eluted fractions (for both aging time). Conversely, longer peptides were found in fractions 42, 46, and 47: the identified sequences are RVAPE, IQLVEEELDRA, DIDDLELT, DIDSPPITAR, LKGADPEDVITGA, and GVVPL, as reported in Figure 2. Nevertheless, many other fractions have shown significant ACE inhibitory activity. It is worth noting that the activity of a specific fraction is determined by two possible contribution: (i) the activity of the occurring peptides or (ii) the total amount of peptides. Indeed, it is possible that a particular fraction shows high activity for the presence of a particularly active sequence in low amount or to the occurrence of a less active peptide in higher amount. Moreover, synergic effect may not be excluded. This mode of investigation is certainly time-consuming, and it is extremely difficult to quantify the peptides both with the total nitrogen evaluation method (Kjieldahl, owing to the low amount in collected fraction) and by chromatographic analysis (lack of authentic standards). Therefore, we have decided to use an innovative computer-aided framework for the research of novel active peptides by using the unbiased computational screening of sequences in comparison to the canonical piecemeal fractioning just applied.

In contrast with most other in silico approaches used for the analysis of ACE inhibition, we presented a structure-based procedure, based on the evaluation of protein−ligand interaction, which provides as output the qualitative evaluation of inhibitory activity together with the putative architecture of binding of each ACE−peptide complex. It should be kept in mind that insights concerning the spatial organization of enzyme−inhibitor complex are fundamental for the in-depth understanding of molecular mechanisms of action. Furthermore, they can serve for the rational design/optimization of strong inhibitors. As a general statement, it should be mentioned also that virtual screening can be a fast and cost-effective technique for analyzing huge amounts of sequences. Therefore, the systematic use for the analysis of peptidomes found in food digesta and/or hydrolyzed mixtures can be a promising straightforward first step toward the total profiling of the BP composition of food.

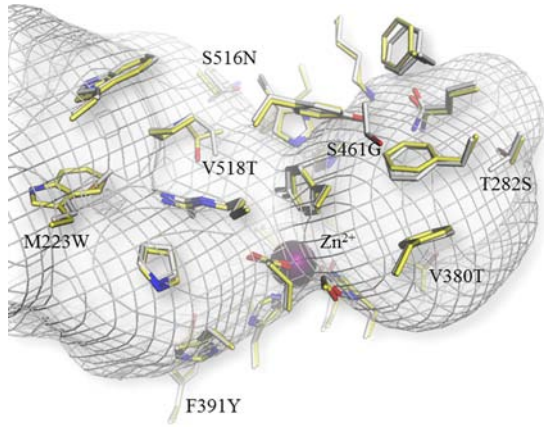

Figure 5. Comparison between catalytic sites of C-terminal and N-terminal domains. The shape of the pocket is represented in mesh, whereas lining amino acids are represented in sticks. The Zn ion is represented by a dark sphere. Residues of C-terminal and N-terminal domains are colored in white and yellow, respectively. Amino acid substitutions are highlighted by labels.

Computational Results. The underlying assumption at the basis of the use of docking-based strategy relies on the concept that the protein−ligand interaction is the sine qua non condition for the inhibitory activity. This means that the protein−ligand interaction is a necessary condition, even if occasionally not sufficient, for the enzymatic inhibition. Consequently, in the case of ACE, peptides able to stably interact with at least one of the two catalytic sites can reduce the conversion of substrates (e.g., angiotensin I in in vivo condition and HHL in in vitro assay), leading to true, substrate-like or pro-drug inhibition mechanisms. For this reason, the evaluation of the binding event at the catalytic site through docking simulations can be a straightforward technique to predict inhibitory potential of peptides. Specifically, to evaluate the enzyme−peptide complex formation, the coupling of docking simulations and rescoring procedures by using the HINT scoring function was chosen, the correlation with the free energy of binding being previously reported. [17]

Anatomy of the Pocket. The two catalytic domains originated from tandem gene duplication[40] and show the same 3D

organization with 51% of sequence identity (according to global alignment by using the Needleman−Wunsch algorithm; http://www.ebi.ac.uk/Tools/psa/emboss_needle). Both domains hold a huge pocket with similar shape, which crosses the entire protein body (Figure 3). Analyses were focused on catalytic sites thus retracing the mode of action of inhibitory drugs (e.g., captopril and lisinopril).[41,42] The regions lining the catalytic site maintain the same organization in both domains, and both pockets share a prevalently hydrophobic environment (Figure 4), albeit they differ for seven amino acid substitutions (Figure 5).

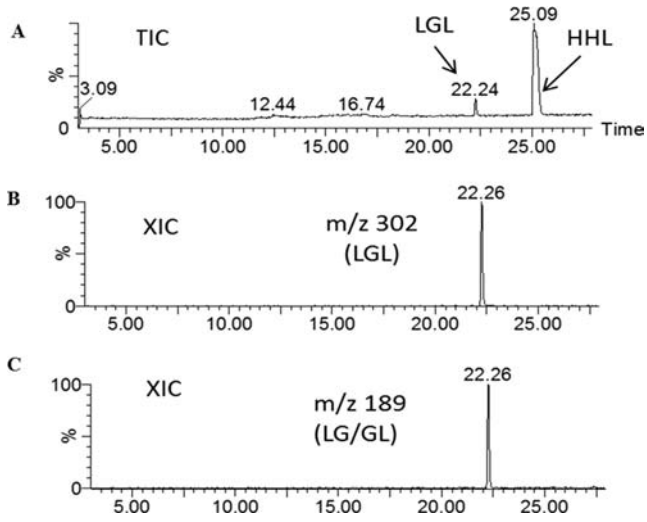

Figure 6. (A) TIC of LGL in the presence of ACE and HHL; (B) XIC of peptide LGL; (C) XIC of peptides LG/GL.

Data Collection. The peptide library was based on the peptidomic profile previously characterized after the in vitro physiological digestion of 18 and 24 months aged dry-cured ham.[15] However, in this study, solely those sequences that were unequivocally identified were considered, thus discarding those for which the Ile-Leu uncertainty subsisted (same M_w). Moreover, because most dipeptides were already known as active like I(L)F, GI(L), AI(L) (BIOPEP database, http://www.uwm.edu.pl/biochemia/index.php/pl/biopep), they were excluded throughout. Overall, a total of 54 sequences were analyzed (Table 1).

Predicted Activity. All of the computational results obtained for the analyzed sequences are reported in Table 1. A total of 25 peptides were predicted as active, and they ranged from three to five amino acids, with the exception of three peptides (i.e., IKAKSALA, SLSTEL, and TSLINTK).

Lead Peptide Identification and in Vitro Assessment of ACE Inhibition. Keeping in mind that the discovery of novel active sequences for future and more detailed analysis is one of the main goals of this work, we decided to synthesize and test for the in vitro ACE inhibition some of the strongest candidates identified by in silico analysis. Because we applied a previously assessed in silico procedure (as aforementioned), which has been followed by experimental confirmations of positive hits, no further validation of the model was needed. Thus, a total of five potentially active peptides were selected by

DOI: 10.1021/acs.jafc.5b02303

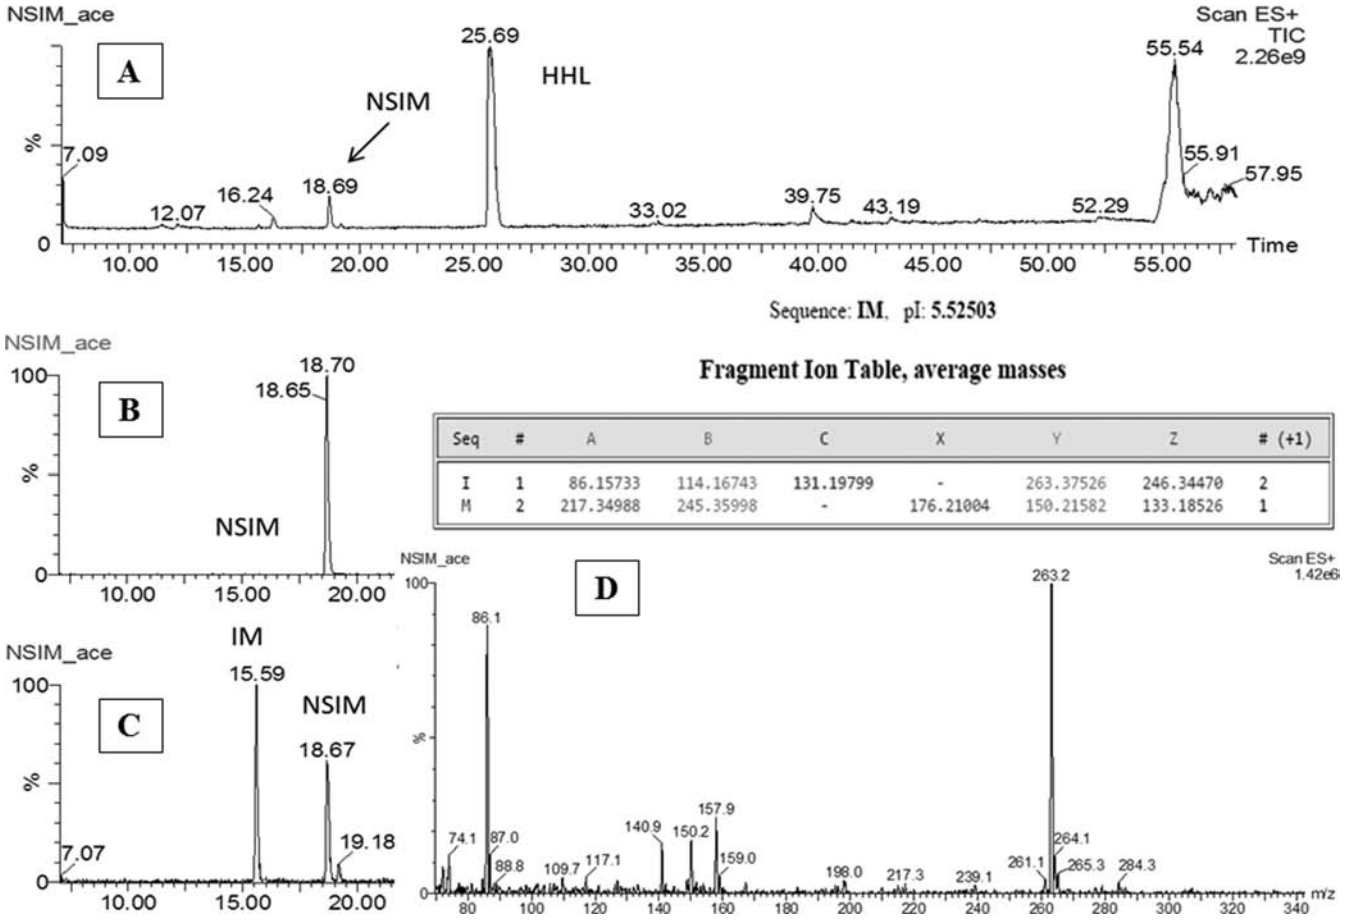

Figure 7. (A) TIC of mixture NSIM in the presence of ACE and HHL; (B) XIC of peptide NSIM; (C) XIC of peptide IM; (D) fragmentation in source of IM and theoretical fragmentation.

taking into account the in silico results and their occurrence in active fractions. The inclusion criteria were based (i) on the finding that short peptides may be easily absorbed through the intestinal epithelium,[5] thus having a greater physiological significance; (ii) on the relative abundance within the most active fraction of digested mixture, approximately evaluated on the basis of the most intense signals in the mass spectrum;[15] and (iii) on the computational results, with the aim to cover a reasonably high range of scores. Therefore, sequences ALM, NSIM, SFVTT, LGL, and GVVPL were synthesized by solid phase peptide synthesis, purified, and then assessed for ACE inhibitory activity. Specifically, LGL showed highest scores for both ACE domains; GVVPL, which was detected in relevant abundance in fraction 42, showed a putative interaction only with the C-domain; and ALM, NSIM, and SFVTT were arbitrarily selected among the remaining peptides with high scores. With respect to this, although a correlation between HINT scores and inhibitory activity cannot be sustained yet, because HINT scores have proved to be correlated with the free energy of binding (as aforementioned), it is reasonable to think that the selection of high-scoring peptides may increase the chances to discover truly active peptides. The inhibitory activity of peptides is expressed as half-maximal inhibitory concentration (IC_{50}), and results of ALM, NSIM, SFVT, LGL, and GVVPL are reported in Table 2. All of the tested peptides showed appreciable inhibitory activity, and the most active sequences were LGL, SFVTT, and GVVPL with IC_{50} values of 145, 395, and 956 μM, respectively. ALM, NSIM, SFVTT, and LGL occurred in fractions 32, 31, 33, and 37, respectively. Interestingly, NSIM and SFVTT were found in fractions with no appreciable activity, whereas ALM and LGL were found in fractions with a relatively low ACE-inhibitor activity (Figure 1). Conversely, GVVPL was present in one of the most active fractions (no. 42; Figure 1). Interestingly, to the best of our knowledge, these inhibitory sequences have never been identified previously.

Because the GL dipeptide is an already known ACE inhibitor[43] (not found in ham digesta), it was assessed whether LGL eventually acted as a pro-drug inhibitor (e.g., peptide converted to true inhibitor after hydrolysis by ACE [44]) upon enzymatic cleavage. Thus, the presence of the GL fragment in the inhibitory assay mixture was checked by UPLC-ESI-MS analysis. As reported in Figure 6, the GL fragment was not detected, and therefore a true inhibition mechanism can be proposed for LGL itself. The same was proposed also for ALM, SFVTT, and GVVPL because hydrolysis fragments were not observed (data not shown). Conversely, with regard to NSIM, a substrate mechanism can be proposed because the IM fragment was released in the assay medium (Figure 7). The pro-drug mechanism was excluded due to the low potency observed.

As far as the utility of this approach, we can easily affirm that, by the evaluation of the activity of single fractions, the GVVPL peptide would have been identified accordingly, due to the high abundance in one of the most active fractions. However, our results showed that the unbiased analysis of the entire peptidomic profile by using the in silico method allowed the

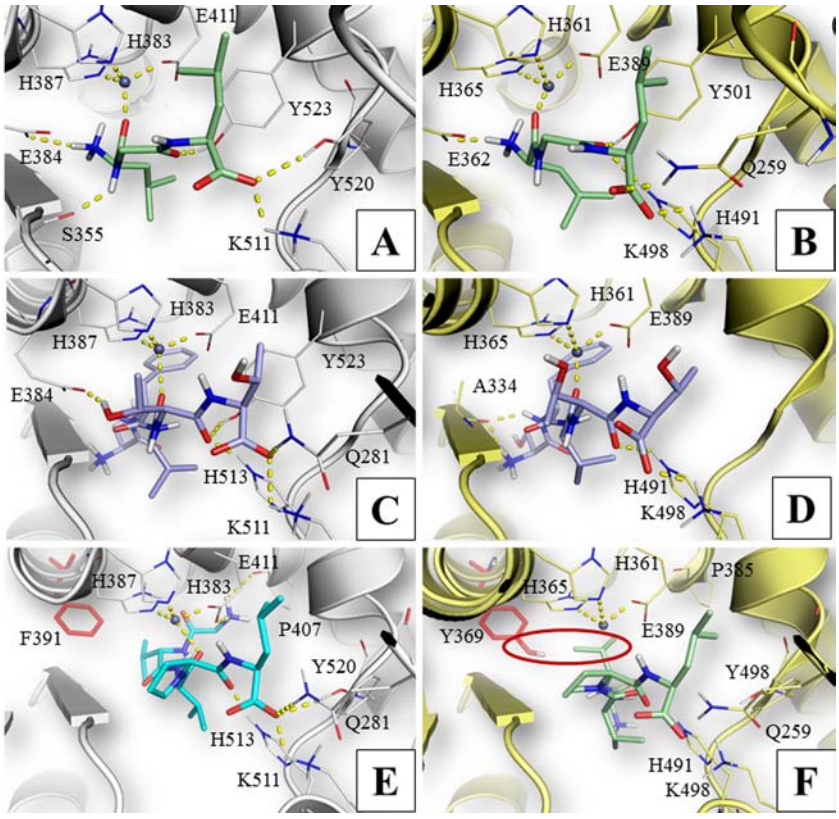

Figure 8. Binding architectures of the most active peptides: (A) LGL within the C-terminal domain; (B) LGL within the N-terminal domain; (C) SFVTT within the C-terminal domain; (D) SFVTT within the N-terminal domain; (E) GVVPL within the C-terminal domain; (F) GVVPL within the N-terminal domain. Amino acids involved in polar contacts and peptides are represented in thin and bold sticks, respectively. The Zn ion is represented in a dark sphere, whereas yellow dotted lines indicate polar contacts. The residues involved in the differential interaction of GVVPL are represented in red sticks, and the hydrophobic−polar mismatch is ringed in red. Because the interaction is predicted as missing, polar contacts between protein and GVVPL are not represented.

identification of other more active sequences (i.e., LGL and SFVTT), which would have been missed otherwise, being encrypted in low-activity fractions. Theoretically, at the present stage, the in silico method herein proposed is unable to distinguish ACE substrates from true inhibitors or pro-drug peptides because the interaction with the catalytic site is a common requirement. Nevertheless, with only the exception of NSIM, all peptides accounted for in vitro analysis proved to be true inhibitors.

Mode of Interaction of Active Peptides. Even if the two domains show some amino acid substitutions at the level of catalytic sites (Figure 5), they did not affect the capability of tested peptides to interact with both domains, with the exception of GVVPL, the binding of which with the N-terminal domain catalytic site was prevented mainly by the F391Y mutation. In particular, the hydroxyl group of Tyr369 within the N-terminal binding site interfered with the side chain of valine in position 2 (from N- to C-terminus), thus preventing the proper positioning of the GVVPL peptide. Therefore, it is proposed that the inhibitory activity of the GVVPL peptide is mediated preferably through the inhibition of the C-domain, whereas the other four peptides can have effects on both catalytic sites. The binding architectures of the three best peptides (LGL, SFVTT, and GVVPL) are reported in Figure 8.

Furthermore, it is worth mentioning that the simulation of the binding architecture can be a solid foothold for further enhancing active sequences. For example, with regard to GVVPL the lack of interaction with the N-terminal domain was predicted owing to charged interferences on valine in position 2. Therefore, it may be hypothesized that the proper substitution with a smaller side chain might increase the activity by gaining interaction with the N-terminal domain. Likewise, with the aim to pursue a domain-specific inhibitor, the loss of the interaction solely with one of the two catalytic sites could be searched. The F391Y mutation can be accounted, accordingly.

Quantification of LGL in Ham Samples. LGL is the most active peptide among those considered herein for in vitro assay. Actually, the gastrointestinal stability of inhibitory peptides and the resistance to cleavage by ACE are not always evaluated even if they are essential requirements for seeking in vivo effects. Keeping in mind that all peptides under analysis originated from gastrointestinal digestion of dry-cured ham samples, and considering that di- and tripeptides may be easily adsorbed by intestinal epithelium,[5] the true inhibitor LGL might be a sequence of great physiological relevance. Moreover, although effective absorption by intestinal epithelium should be considered, solely on the basis of the IC_{50} value, LGL might show a congruent range of activity with respect to the abundance per portion. Indeed, to determine the amount of this peptide in dry-cured ham digested samples, a calibration curve was set up plotting the ratio between the peak areas of LGL and FF (as internal standard) and the LGL concentration. In the digested mixtures of 24 and 18 months aged ham samples, the LGL peptide (M_w 301 g/mol) occurs respectively at concentrations of 62 ± 11 and 112 ± 36 μg/g. With regard to the bioaccessibility in respect to the in vitro gastrointestinal digestion

DOI: 10.1021/acs.jafc.5b02303
J. Agric. Food Chem. 2015, 63, 6366−6375

model, 829 μg of LGL is needed in to reach a concentration able to decrease ACE activity by 50% (which is contained in 13.4 and 7.4 g of 24 and 18 months aged ham, respectively). Furthermore, such a concentration is overcome by 7.5- and 13.5-fold when 24 and 18 months aged ham portions (100 g) are consumed. Therefore, one can hypothesize that physiologically relevant concentrations might be reached after dietary consumption of Parma ham, at least in the intestinal lumen. Accordingly, the high abundance in ham samples, together with the high activity observed in in vitro ACE inhibition, concur to elect LGL as a strong lead compound and also strongly support its inclusion in future and more detailed experimental investigations. Taken as a whole, our findings are an important step forward toward the in-depth and more informed characterization of such a relevant food product beyond its well-known nutritional properties.

[a]Major metabolites are written in bold. Corresponding mass spectra can be found in the SI.

synthase and cyclooxygenase-2 in lipopolysaccharide-induced RAW 264.7 cells via inhibition of the NF-κB pathway.[28,29] Moreover, Mohamad et al. proposed a nociceptive activity of FKB in mice.[30,31]

Despite increasing data regarding bioactivity, to date there is no information about the metabolism of flavokawains. In the present study, we therefore analyzed the in vitro metabolism of flavokawains using human liver microsomes. Different microsomal incubation systems were applied to study phase I metabolism and phase II glucuronidation as well as combined phase I and II metabolism. Metabolites were identified by liquid chromatography–high-resolution electrospray ionization mass spectrometry (LC-HRESIMS) and nuclear magnetic resonance spectroscopy (NMR). A metabolic profile of flavokawains is proposed.

MATERIALS AND METHODS

Chemicals and Reagents. Glucose-6-phosphate sodium salt (G6P), glucose-6-phosphate dehydrogenase (G6PDH), nicotinamide adenine dinucleotide phosphate sodium salt hydrate (NADP), uridine 5′-diphosphoglucuronic acid trisodium salt (UDPGA), and alamethicin (Ala) from *Trichoderma viride* were obtained from Sigma-Aldrich (Taufkirchen, Germany). Acetonitrile (MeCN, LiChroSolv) and methanol (LiChroSolv) were obtained from Merck (Darmstadt, Germany). All other solvents used were of pro analysis quality and derived from Merck or Arcos.

Human Liver Microsomes. Frozen pooled liver microsomes (HMMC-PL, 0.5 mL) were purchased from Life Technologies (Darmstadt, Germany). They derived from 50 adult donors of mixed gender having a total protein concentration of 20 mg/mL and a cytochrome P450 content of 0.286 nmol/mg. Microsomes were stored at −80 °C until use. A detailed certificate of analysis of the used microsomes can be found on the provider's homepage.

Test Compounds. FKA, FKB, FKC, and cardamonin were synthesized during previous work at the Institute of Pharmacy, University of Regensburg, and showed no impurities in the HPLC runs.[7] For preparation of stock solutions, test compounds were first dissolved in DMSO at a concentration of 10 mM and then diluted with EtOH to a concentration of 1 mM.

Microsomal Incubation Systems for Phase I Metabolism and Phase II Glucuronidation. For phase I metabolism, a NADPH regeneration system was used. A typical 1 mL incubation mix consisted of 0.5 mg of liver microsomal protein, 3.3 mM $MgCl_2$, 3.3 mM G6P, 0.4 U/mL G6PDH, 1.3 mM NADP, and 10 μM flavokawain or cardamonin in 0.1 M potassium phosphate buffer.

For phase II glucuronidation, the 1 mL incubation mix was composed of 0.5 mg of microsomal protein, 3.3 mM $MgCl_2$, 2 mM UDPGA, 25 μg/mL Ala, and 10 μM flavokawain or cardamonin in 0.1 M potassium phosphate buffer.

Combined phase I and II metabolism was investigated using a 1 mL incubation system consisting of 0.5 mg of microsomal protein, 3.3 mM $MgCl_2$, 3.3 mM G6P, 0.4 U/mL G6PDH, 1.3 mM NADP, 2 mM UDPGA, 25 μg/mL Ala, and 10 μM flavokawain or cardamonin in 0.1 M potassium phosphate buffer.

The reaction was started by the addition of NADP and/or UDPGA. Incubation was carried out in a shaken water bath at 37 °C for 60 min. Negative control incubations were carried out without microsomes or without cofactors (NADP or UDPGA). Reactions were terminated by the addition of 1 mL of ice-cold EtOH. Samples were vortexed for 5 min and then centrifuged for 5 min at 14000 rpm and 4 °C. Supernatants were subjected to further analysis.

For NMR, sample size was increased to 5 mL and the concentration of chalcones was raised to 100 μM due to the lower sensitivity of NMR compared to MS. An incubation time of 4 h was chosen to maximize transformation rate. Metabolic reactions were stopped by the addition of ice-cold EtOH. To improve storage stability, EtOH was evaporated and samples were refilled with ultrapure water. Then samples were freeze-dried and stored at −20 °C until further analysis.

Liquid Chromatography–High-Resolution Electrospray Ionization Mass Spectrometry (LC-HRESIMS). Samples for LC-HRESIMS analysis were prepared after 0 and 60 min of incubation. Matrix samples without test compound were used as blank controls. Analysis was performed with UHPLC Agilent 1290 infinity, DAD G4212A, and MS Agilent 6540 UHD Q-TOF with negative electrospray ionization using dual ion source. Separation was performed on a Thermo Accucore aQ column (C18, 50 × 2.1 mm, 2.6 μm) using a gradient of 0.1% formic acid (solvent A) and 100% MeCN supplemented with 0.1% formic acid (solvent B). Gradient: 0–10 min, 0 → 98% B; 10–11 min, 98% B; 11–11.1 min, 98 → 0% B; 11.1–13 min, 0% B; flow rate, 0.6 mL/min; injection volume, 5 μL; oven temperature, 40 °C. Data analysis was performed with MassHunter software (B.05.00, Agilent) using automatic mass spectrum integration.

HRESIMS of 5,7-Dimethoxy-flavanone-4′-*O*-glucuronide. HRESIMS of FKC metabolite 5,7-dimethoxy-flavanone-4′-*O*-glucuronide was recorded on a LC-MS/MS system consisting of an Ultimate 3000 series RSLC (Dionex, Sunnyvale, CA, USA) system and an Orbitrap mass spectrometer (Thermo Fisher Scientific, Bremen, Germany). HRESIMS data were analyzed using XCALIBUR (Thermo Fisher Scientific, Waltham, MA, USA) software.

Isolation and Structure Elucidation of Metabolites. Samples were dissolved with a minimum amount of HPLC solvent, and HPLC

DOI: 10.1021/acs.jafc.5b01858
J. Agric. Food Chem. 2015, 63, 6376–6385

fractionation was performed using an Agilent HP1100 series HPLC system (Agilent Technologies, Waldbronn, Germany) equipped with a binary pump G1312A, degasser G1322A, autoinjector 1367A, column oven G1316, and G11315B diode array detector controlled with ChemStationRev.A.08.04 (1008) software. Separation was performed on a LiChrosphere RP-18 column (5 μm, 250 × 4 mm, Merck KGaA, Darmstadt, Germany) with a guard column (5 μm, 4 × 4 mm) using a linear binary gradient of ultrapure water containing 0.1% (v/v) trifluoroacetic acid (solvent A) and MeCN (solvent B) with a flow rate of 0.8 mL/min. The gradient profile was 0−30 min, 20% → 80% B; 30−35 min, 80% B; 35−37 min, 80% → 20% B; and column temperature was set at 30 °C.

NMR spectra were recorded in MeOH-d_4 with a Bruker Avance 500 NMR spectrometer (Bruker-Biospin, Karlsruhe, Germany) operating at 500.13 MHz for ^{1}H and 125.75 MHz for ^{13}C. The spectrometer was equipped with a 5 mm TCI cryoprobe, and capillary tubes (2 mm o.d.; 80 μL filling volume) were used for measuring NMR spectra with standard Bruker pulse sequences. Tetramethylsilane was used as internal chemical shift reference standard. The spectrometer was controlled by TopSpin 3.1 software, which was also used for processing of the NMR spectra. According to the limited amounts, only ^{1}H NMR spectra were recorded of FKA metabolites. In addition to ^{1}H NMR spectra of FKB and FKC metabolites, 2D NMR spectra (^{1}H,^{1}H−COSY; ^{1}H,^{13}C HMBC; ^{1}H,^{13}C HSQC) were recorded.

RESULTS

To gain insight into the metabolism of flavokawains, FKA, FKB, and FKC as well as cardamonin were subjected to different microsomal incubation systems providing phase I reactions or phase II glucuronidation. Furthermore, combined phase I and II metabolism was studied by activation of phase I enzymes and UDP-glucuronosyl transferases in one system. HPLC was used to confirm the stability of the test compounds in phosphate incubation buffer. In the control incubation systems without cofactors or microsomes, no nonspecific metabolism or degradation was observed (data not shown).

Metabolites of FKA. Two phase I metabolites were found for FKA. According to retention times (t_R) and LC-MS data (Table 1), they were identified as helichrysetin (Heli) (t_R = 4.02 min; m/z [M − H]$^-$ 285.0766) and FKC (t_R = 5.07 min; m/z [M − H]$^-$ 299.0920), with FKC being the major phase I metabolite.

Phase II metabolism resulted in glucuronidation of FKA. Despite only one available OH-group at C-2′, two FKA glucuronides (t_R = 3.38, m/z [M − H]$^-$ 489.1402 and t_R = 3.50 min, m/z [M − H]$^-$ 489.1405) were detected, which are suggested to be *E*/*Z*-isomers. Combined phase I and II metabolism led to the formation of a FKA glucuronide (t_R = 3.50 min, m/z [M − H]$^-$ 489.1402) as well as of two FKC glucuronides (t_R = 2.81, m/z [M − H]$^-$ 475.1238, and t_R = 3.87 min, m/z [M − H]$^-$ 475.1239). Additionally, hydroxylation and glucuronidation resulted in the generation of two OH-FKA glucuronides (t_R = 3.71, m/z [M − H]$^-$ 505.1345, and t_R = 3.81 min, m/z [M − H]$^-$ 505.1345) that were identified as minor metabolites. The exact positions of hydroxylation and glucuronidation of major metabolites were established by NMR but could not be determined for minor ones.

The aglycone part of the ^{1}H NMR spectrum of the FKA glucuronides revealed two sets of signals, which by means of the coupling constants and chemical shift differences of H-α and H-β (Table 2) were clearly assignable to the suggested (*E*)- and (*Z*)-isomers of the aglycone with $J_{H\alpha\text{-}H\beta}$ = 15.9 Hz indicating the (*E*)-form being the major one. The (*Z*)-form ($J_{H\alpha\text{-}H\beta}$ = 12.5 Hz) might constitute an artifact that is formed during incubation, sample processing, or isolation procedure because it was detected again after separation of the peak at t_R = 3.50 min by HPLC. Comparison of the ^{1}H NMR spectrum of the FKA glucuronides with the parent compound clearly shows a strong difference in the chemical shifts for H-3′ and H-5′ in ring B and for the two olefinic protons α/β, whereas the chemical shifts of the protons in ring A changed only slightly (Table 2). This constitutes evidence of the glucuronide moiety being attached to 2′-OH. According to the limited availability of the FKA metabolites and the resulting poor signal-to-noise ratio, ^{13}C chemical shifts could not be completely assigned from the HSQC and HMBC spectra, but the obtained data of FKA-2′-*O*-glucuronide ((*E*)-form: δ 95.3 (C-3′), 93.8 (C-5′), 131.8 (C-2/6), 115.6 (C-3/5), 55.7 (4′-OCH$_3$), 56.2 (6′-OCH$_3$), 56.0 (4-OCH$_3$), 164.2 (C-4 and C-4′), and 160.8 (C-6′)) supported the suggested structure. The resonances of the glucuronide moieties could not be completely assigned from the ^{1}H NMR and ^{1}H,^{1}H COSY spectrum of the mixtures of the (*E*)- and (*Z*)-isoform because of strong overlap of signals in the spectral region of carbohydrate signals. A metabolism scheme of FKA is proposed in Figure 2. Although, due to this overlap, the coupling constant of the H-1″ signal was invisible, the β-configuration was inferred from its chemical shift (δ 4.99) for both the (*E*)- and (*Z*)-isomers, whereas a corresponding α-H-1″ signal is expected at lower field.[32]

Table 2. ^{1}H NMR Data (500 MHz, MeOH-d_4) of FKA and (*E*)- and (*Z*)-FKA-2′-*O*-glucuronide

Metabolites of FKB. For FKB, also FKC (t_R = 5.07 min, m/z [M − H]$^-$ 299.0927) was detected as major phase I metabolite (Table 3). In addition, cardamonin (t_R = 5.17 min, m/z [M − H]$^-$ 269.0819) and 2′,4′,6′-trihydroxychalcone (t_R = 4.48 min, m/z [M − H]$^-$ 255.0659) were generated. The 2′-*O*-glucuronide of FKB (t_R = 3.46 min, m/z [M − H]$^-$ 459.1297) was found after phase II metabolism. Combined phase I and II metabolism also led to the formation of 2′-*O*-glucuronide of FKB and additionally to four further glucuronides. Two of them (t_R = 2.81 min, m/z [M − H]$^-$ 475.1239, and t_R = 3.87 min, m/z [M − H]$^-$ 475.1241) were identified as 2′- and 4-*O*-

J. Agric. Food Chem. 2015, 63, 6376−6385

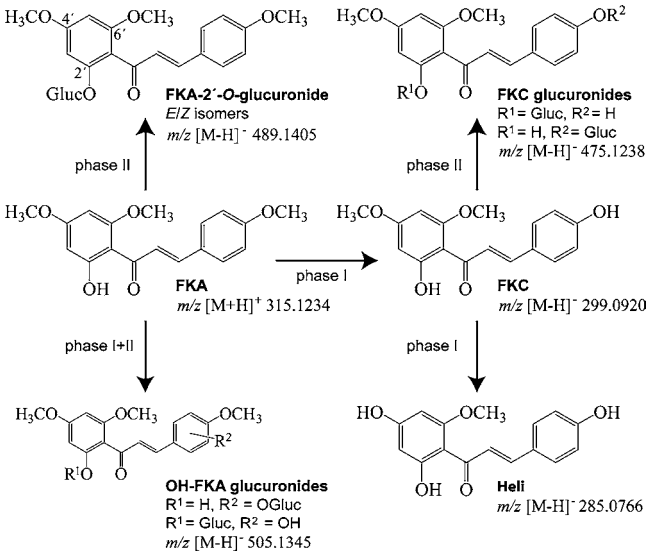

Figure 2. Proposed metabolic pathway of FKA by human liver microsomes. Structures of metabolites that could not be elucidated completely are depicted in smaller size.

glucuronide of FKC. As only two OH-groups are available on FKC, the other two generated glucuronides (t_R = 3.15 min, m/z $[M - H]^-$ 475.1239, and t_R = 3.75 min, m/z $[M - H]^-$ 475.1241) probably are *Z*-isoforms of those metabolites. Furthermore, the phase I metabolite cardamonin was glucuronidated (t_R = 3.95 min, m/z $[M - H]^-$ 445.1123) at either position C-2′ or C-4′.

(*E*)-FKB-2′-*O*-*β*-glucuronide constitutes the major metabolite of FKB, and its structure was unambiguously identified by ^{1}H NMR, COSY, HSQC, and HMBC. Comparison of the ^{1}H NMR spectrum of the major FKB metabolite with that of the parent compound clearly shows the slightly changed chemical shifts for the protons in ring B, whereas a strong change in the chemical shift position occurs for H-3′ and H-5′ and for the two olefinic protons *α*/*β* (Table 4), indicating structural modification near ring A. The large coupling constant $J_{H\alpha\text{-}H\beta}$ = 15.9 Hz indicated that the *E*-configuration at the *α*/*β* double bond has been retained in the metabolite. The signal of the proton (*δ* 5.02) at the anomeric C-1″ displays the coupling constant of $J_{H1''\text{-}H2''}$ = 7.8 Hz, typical of *β*-configuration. This signal also shows a reduced signal-to-noise ratio due to its proximity to the suppressed residual water signal. The ^{1}H NMR signal of H-5″ (*δ* 3.85) is overlapping with the 4′-methoxy signal (*δ* 3.85). The remaining signals of the *β*-glucuronide moiety were assigned by the COSY spectrum even if some signals overlapped. ^{13}C resonances were obtained from HSQC and HMBC spectra (Table 4). ^{13}C NMR chemical shifts of the quaternary C-2′ and the COOH carbon atom were not

Table 4. ^{1}H NMR Data (500 MHz, MeOH-d_4) of FKB and ^{1}H and ^{13}C NMR Data (500 MHz for ^{1}H and 125 MHz for ^{13}C, MeOH-d_4) of (*E*)-FKB-2′-*O*-glucuronide

detected (nd) because of the low signal-to-noise ratio of the HMBC spectrum. Again, signals of (*Z*)-FKB-2′-*O*-*β*-glucuronide (data not shown) were detected as a minor component accompanying the major (*E*)-form. A metabolism scheme of FKB is proposed in Figure 3.

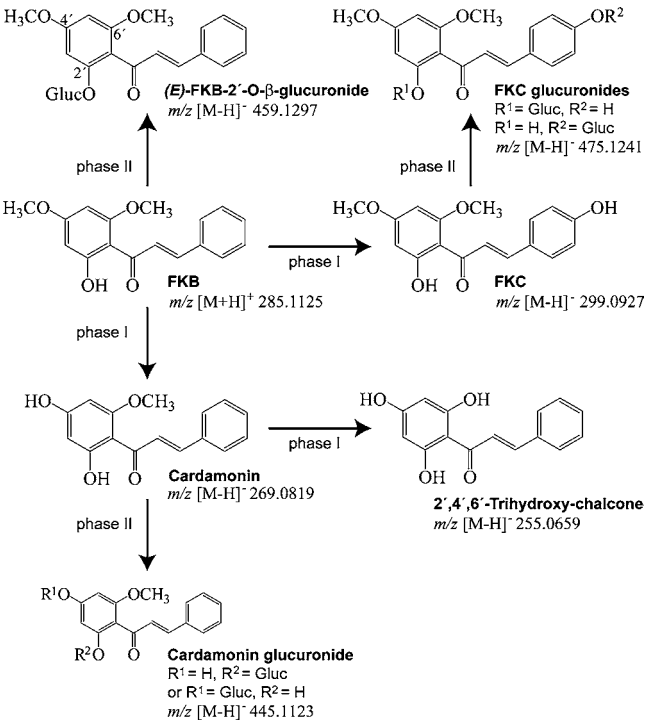

Figure 3. Proposed metabolic pathway of FKB by human liver microsomes. Structures of metabolites that could not be elucidated completely are depicted in smaller size.

Metabolites of FKC. LC-MS data of FKC metabolism samples revealed Heli (t_R = 4.03 min, m/z $[M - H]^-$ 285.0767) as the major phase I metabolite (Table 5). In addition, hydroxylation at undetermined positions generated two OH-FKC (t_R = 4.00 min, m/z $[M - H]^-$ 315.0872 and t_R = 4.52 min, m/z $[M - H]^-$ 315.871). Two major monoglucuronides (t_R = 2.81 min, m/z $[M - H]^-$ 475.1245, and t_R = 3.86 min, m/z $[M - H]^-$ 475.1248) and one minor glucuronide of FKC (t_R = 2.71 min, m/z $[M - H]^-$ 475.1244) were detected after phase II metabolism. Combined phase I and II metabolism resulted in the generation of one Heli-glucuronide (t_R = 3.03 min, m/z $[M - H]^-$ 461.1085) and three different glucuronides of OH-FKC (t_R = 2.83 min, m/z $[M - H]^-$ 491.1183; t_R = 3.18 min, m/z $[M - H]^-$ 491.1188; and t_R = 3.72 min, m/z $[M - H]^-$ 491.1187).

The two major monoglucuronides of FKC (t_R = 2.81 and 3.86 min) were identified by NMR spectroscopy as (*E*)-FKC-4-*O*-*β*-glucuronide and (*E*)-FKC-2′-*O*-*β*-glucuronide, and the minor glucuronide (t_R = 2.71 min) was identified as 5,7-dimethoxy-flavanone-4′-*O*-*β*-glucuronide (Figure 4). Comparing the ^{1}H NMR spectrum of FKC-4-*O*-*β*-glucuronide with that of the parent compound shows the slightly changed chemical shifts for H-3′ and H-5′ in ring A and the olefinic protons *α*/*β*. The chemical shifts of H-2/6 and H-3/5 changed strongly from *δ* 7.51 and 6.82 in the spectrum of FKC to *δ* 7.62 and 7.15 in the spectrum of the glucuronide, indicating a substitution in ring B (Table 6). The large coupling constant of $J_{H\alpha\text{-}H\beta}$ = 15.5 Hz indicated *E*-configuration of the *α*/*β* double bond. The signal of H-1″ (*δ* 5.05) shows a reduced signal-to-noise ratio due to its proximity to the suppressed residual water signal and a spin−spin coupling $J_{H1''\text{-}H2''}$ = 7.7 Hz characteristic of *β*-configuration at the anomeric center. The remaining signals of the *β*-glucuronide moiety were putatively assigned on the basis of ^{1}H NMR data matching with corresponding glucuronide signals of the other metabolites.

Different from FKC-4-*O*-*β*-glucuronide, comparison of the ^{1}H NMR spectrum of FKC-2′-*O*-*β*-glucuronide with that of the parent compound reveals only little chemical shift changes for H-2/6 and H-3/5 in ring B, whereas a strong change in the chemical shifts occurs for H-3′ and H-5′ and for the two olefinic protons *α*/*β* (Table 6). This finding resembles that of

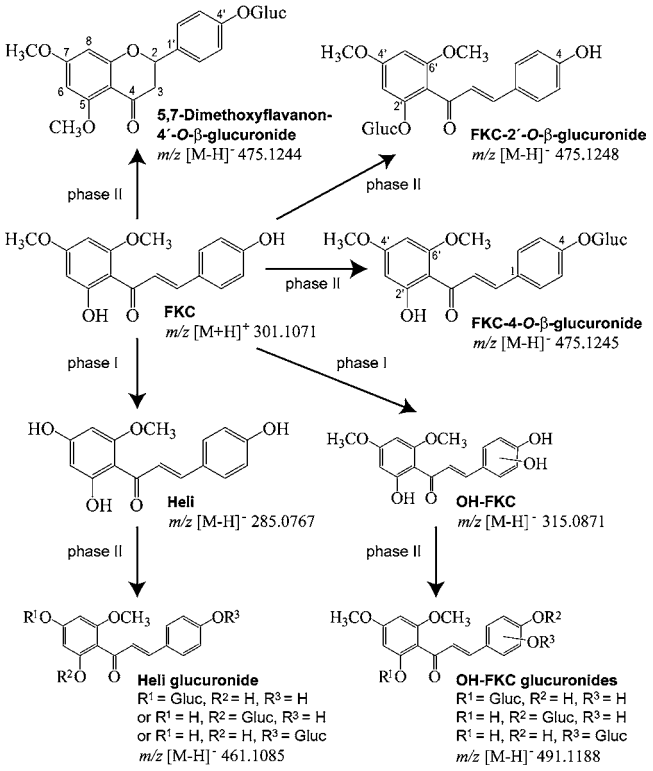

Figure 4. Proposed metabolic pathway of FKC by human liver microsomes. Structures of metabolites that could not be elucidated completely are depicted in smaller size.

major FKA- and FKB-2′-*O*-*β*-glucuronides described above. Thus, the substitution must have occurred in the 2′-position. Well resolved signals of the glucuronide moiety with very good signal-to-noise ratio were detected in the ^{1}H NMR spectrum of FKC-2′-*O*-*β*-glucuronide, allowing the precise determination of the J_{H-H} coupling constants. This included $J_{H1''\text{-}H2''}$ = 7.7 Hz, indicating *β*-configuration at the anomeric center of the sugar unit. In addition, the 2D NMR experiments (^{1}H,^{1}H COSY, HSQC, HMBC) enabled assignment of all ^{1}H and ^{13}C chemical shifts. An HMBC correlation between H-5″ (*δ* 3.97) and the ^{13}C signal at *δ* 171.9, a typical chemical shift for carboxylic carbons, proves the carbohydrate unit to be a glucuronide. The HMBC cross signal between H-1″ (*δ* 7.15) and C-2′ (*δ* 157.8) clearly proved the attachment of the carbohydrate to the 2′-*O*-position. HMBC also enabled assignment of ^{1}H resonances, such as those of the methoxy groups or protons H-3′ and H-5′, that would be otherwise potentially interchangeable.

For 5,7-dimethoxy-flavanone-4′-*O*-*β*-glucuronide, the disappearance of the signals of the olefinic *α*/*β* protons in the ^{1}H NMR spectrum together with the appearance of new resonances of H-2 (*δ* 5.43) and H-3 (*δ* 3.04/*δ* 2.72) enables the assignment of the aglycone skeleton as a flavanone (Figure 4). The molecule was fully identified by means of 1D and 2D NMR spectroscopic data. In addition to the aglycone signals (Table 7), the ^{1}H NMR spectrum displays signals of the glucuronide unit with some overlap of the signals of H-2″, H-3″, and H-4″ and a doublet of the *β*-configured H-1″ (*δ* 4.98; $J_{H1''\text{-}H2''}$ = 7.5 Hz). HMBC correlation between H-1″ and C-4′ (*δ* 158.9) assigned the *β*-glucuronide unit to the hydroxyl group in the para-position of ring B. Interestingly, the signals of H-3*β* (*δ* 2.72) appear as a two double doublets (dd) with integral values corresponding to 0.5 proton each. This could be explained by the assumption that the compound is a racemate, which consists of two diastereomers with opposite configuration at C-2. The signals of H-2 of the 2*R*- and the 2*S*-form as well as the signals of the H-3*α* at *δ* 3.04 are isochronic. Only the dd signals of H-3*β* appear at slightly different chemical shifts (Δ*δ* ∼ 0.01). If this assumption is correct, the 5,7-dimethoxy-flavanone-4′-*O*-*β*-glucuronide is probably generated by a nonenzymatic chemical reaction and therefore an artifact. The HRESIMS spectrum (positive ionization) confirmed the structure. In Figure 4 a metabolic pathway for FKC is proposed.

Metabolites of Cardamonin. For additional information, also the chalcone cardamonin, which was found as a phase I metabolite of FKB, was subjected to phase I and II metabolism as well as combined phase I+II metabolism.

LC-MS data of cardamonin metabolism samples are depicted in Table 8. Three hydroxylated metabolites of cardamonin were found after phase I metabolism; one of them was identified as Heli (t_R = 4.03 min, *m*/*z* [M − H]$^-$ 285.0763). For the other two metabolites (t_R = 4.43 min, *m*/*z* [M − H]$^-$ 285.0763, and t_R = 4.52 min, *m*/*z* [M − H]$^-$ 285.0762), the exact positions for the OH-group could not be determined.

After phase II metabolism, three glucuronides of cardamonin (t_R = 2.67 min, *m*/*z* [M − H]$^-$ 445.1141; t_R = 3.01 min, *m*/*z* [M − H]$^-$ 445.1138; t_R = 3.95 min, *m*/*z* [M − H]$^-$ 445.1140)

[a]Two dd at δ 2.723 and 2.717 with identical coupling constants indicate (2*S*)- and (2*R*)-diastereomers.

were detected. As only two free OH-groups are available, a third corresponding mass suggests the presence or formation of isomers. Additionally to the cardamonin glucuronides, one glucuronide of OH-cardamonin (t_R = 3.58 min, m/z [M − H]$^-$ 461.1081) was found after combined metabolism. Figure 5 suggests a metabolic pathway of cardamonin.

DISCUSSION

In this study, we characterized the in vitro metabolism of FKA, FKB, FKC, and cardamonin using human liver microsomes. In phase I metabolism, demethylation in position C-4 or C-4′ and

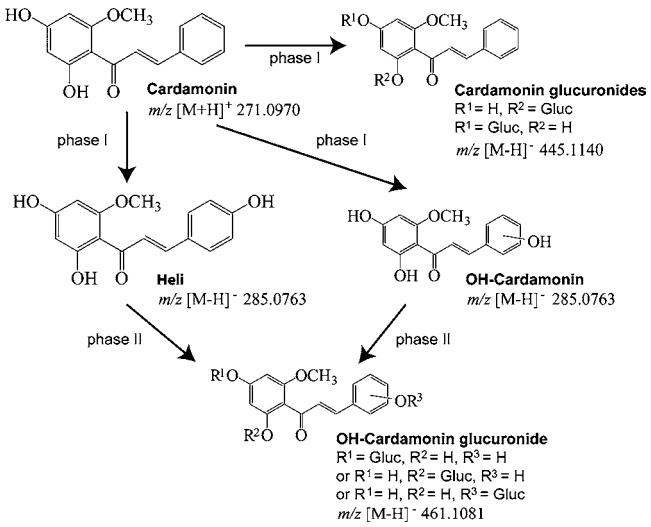

Figure 5. Proposed metabolic pathway of cardamonin by human liver microsomes. Structures of metabolites that could not be elucidated completely are depicted in smaller size.

hydroxylation predominantly in position C-4 occurred. Demethylation at C-4 on the B-ring of FKA as well as hydroxylation at C-4 of FKB leads to the formation of FKC, being the major phase I metabolite. Further demethylation of FKC at C-4′ on the A-ring generated Heli. Demethylation of FKB at C-4′ led to the generation of cardamonin and hydroxylation of cardamonin at C-4 to the formation of Heli. Moreover, other monohydroxylated minor metabolites of FKA and cardamonin were found, but the position of hydroxylation could not be determined by mass spectrometric methods.

He et al. investigated the CYP450-dependent metabolism of cardamonin previously.[33] They identified two monohydroxylated metabolites by MS fragmentation. The exact position of hydroxylation on the B-ring was not determined. However, the authors suggested C-4 being the most likely position. Kohno et al. already described this position as preferential for hydroxylation of chalcones.[34] According to this, in the study of He et al. 4-OH-cardamonin would correspond to Heli, which has also been found in our study. Furthermore, they suggested

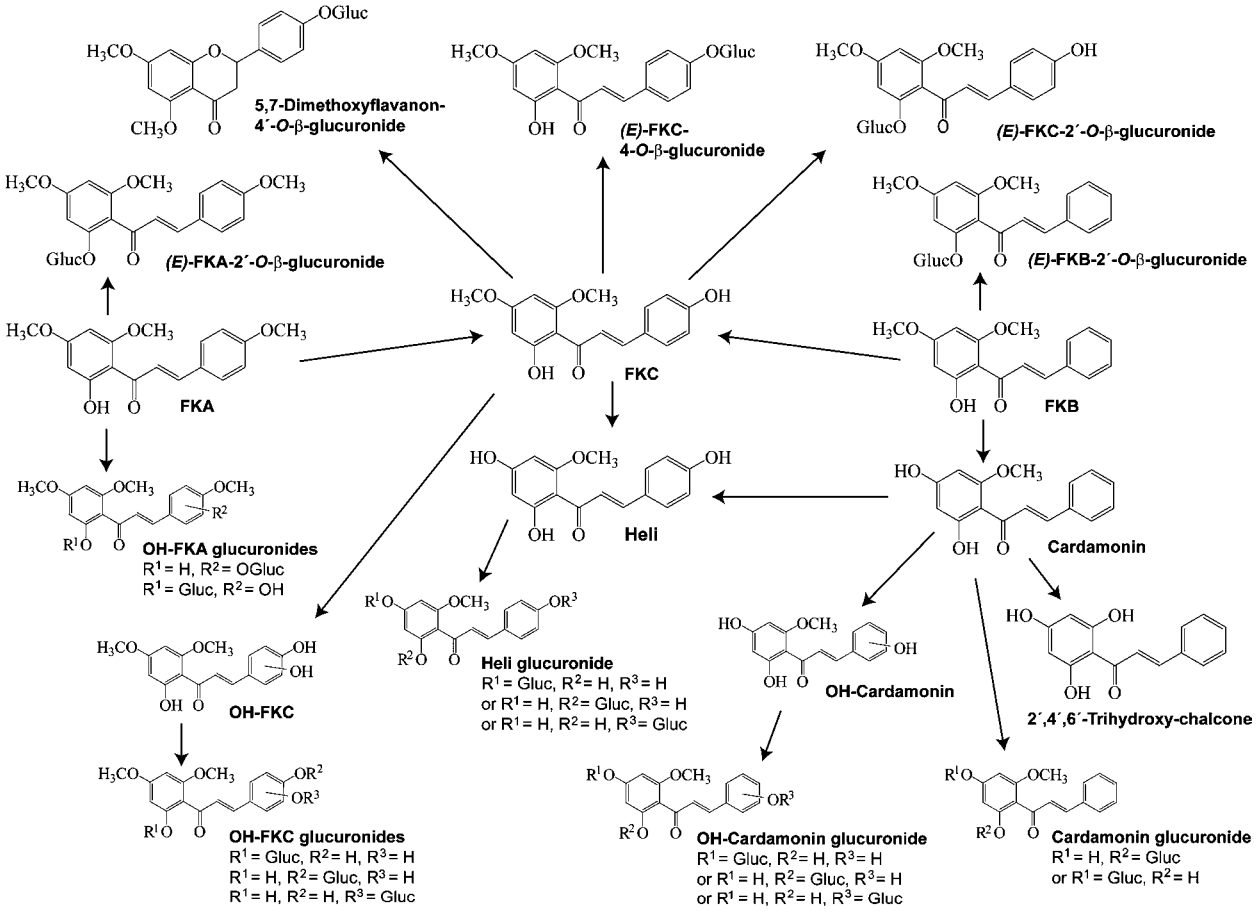

Figure 6. Proposed combined metabolism scheme for FKA, FKB, FKC, and cardamonin. Structures of metabolites that could not be elucidated completely are depicted in smaller size.

hydroxylation in the *β*-position of the unsaturated ketone, which might correspond to another hydroxylated derivative (t_R = 4.43 or 4.52 min) of our study. In contrast to our findings, no third hydroxylated metabolite of cardamonin was described.[33]

The compounds were even more extensively metabolized by microsomal UDP-glucuronosyl transferases in the presence of UDPGA in phase II samples. Corresponding monoglucuronides were detected for all test compounds as the major metabolites of phase II and combined metabolism. The structures of the major flavokawain glucuronides were elucidated by NMR.

After glucuronidation, two metabolite masses corresponding to FKA-glucuronides were detected, despite only one available OH-group at C-2′ of FKA. This can be explained by the occurrence of the major *E*- and the minor *Z*-isomer. For both, ^{1}H NMR signals were detected. The occurrence of three glucuronides of cardamonin, despite only two free OH groups, also suggests the formation of cardamonin *E*/*Z*-isomers.

In addition to the 2′-*O*- and 4-*O*-chalcone-mono-*β*-glucuronides of FKC, also the corresponding 5,7-dimethoxyflavanone-4′-*O*-*β*-glucuronide was identified by LC-NMR. The flavanone-glucuronide is most likely formed by a nonenzymatic chemical reaction and might be an artifact similar to the (*Z*)-isoforms of FKA, FKB, and cardamonin metabolites.

As FKC is a major phase I metabolite of FKA and FKB and Heli is a metabolite of FKC as well as of the FKB metabolite cardamonin, the metabolisms of all three flavokawains (and cardamonin) are closely linked to each other. Therefore, we propose a combined metabolism pathway for the flavokawains in Figure 6.

Although the metabolic conversions occurring in our in vitro system are very likely to also occur in vivo, it is likewise almost certain that they constitute only a part of the entire metabolization that is happening in the body. Therefore, the extent of formation of conjugated metabolites may even be underestimated by the use of microsomes, as phase II reactions in this system are limited to glucuronidation reactions only. As a result, the absolute amount of conjugated metabolites in vivo may be even higher than what we observed in vitro. To include all possible phase II metabolites, liver cell models and in vivo metabolism systems could be used for an additional metabolism analysis. However, the fact that glucuronides dominate over phase I metabolites emphasizes the important role of conjugated chalcone metabolites as presumable in vivo active principle. This was likewise shown for various flavonoids and chalcones, for example, xanthohumol.[35]

Nevertheless, as far as the biological activity or toxicity of chalcones is concerned, to date conjugated metabolites are not routinely included in testing.

Looking ahead, assessment of toxicity and pharmacological characterization of flavokawain glucuronides and other phase II metabolites is mandatory and will be conducted to evaluate their contribution and relevance for the bioactivity of the parent compounds.

(median lethal dose) was also evaluated to test the safety of the new formulation. In addition, we determined the pharmacokinetics and tissue distribution of SME-CA in comparison with CA suspension in rats after a single intravenous (iv) dose.

MATERIALS AND METHODS

Chemicals. CA (99.0% purity) was supplied by Yuancheng Pharmaceutical Co., Ltd. Acetonitrile (HPLC grade) was obtained from Honeywell (Muskegon, MI, USA). All other reagents were of analytical grade. Propiophenone was used as the internal standard (IS). Egg lecithin (Lipoid E80, 80% purity) was supplied by LIPOID Co. (Ludwigshafen, Germany). Soybean oil was purchased from AVIC (Tieling) Pharmaceutical Co., Ltd. (Tieling, China). Glycerol was purchased from Jiahe Biological Technology Co., Ltd. (Shantou, China). Sodium oleate was purchased from Xi'an Libang Pharmaceutical Co., Ltd. (Xi'an, China).

Animals and Cell Lines. Male Sprague−Dawley rats weighing 225−275 g and KM mice weighing 20−25 g were supplied by the Experimental Animal Research Center, Fourth Military Medical University (Xi'an, China). They were kept separately in an individually ventilated cage (IVC) system and fed standard laboratory food and water ad libitum for 5 days before the experiments. All rats were fasted (except for water) overnight and prepared for pharmacokinetic and toxicological study. Experimental procedures involving animals were reviewed and approved by the Institutional Animal Care and Use Committee of the Fourth Military Medical University (Approval 2014-1114-R).

The Eca-109, Hct-116, HepG2, HT-29, A549, Mkn-45, PANC-1, HeLa, SGC-7901, SW 620, and Tca-8113 cell lines were obtained from Xi'an Cell Engineering Center (Xi'an, China). Eca-109, HepG2, Mkn-45, HeLa, SGC-7901, SW 620, and Tca-8113 were cultured at a density of 5×10^4 cells/mL in RPMI 1640 medium; A549 and Panc-1 were cultured in DMEM; Hct-116 and HT-29 were cultured in Myco's medium. All of the cell lines were supplemented with 10% fetal bovine serum, penicillin (100 U/mL), and streptomycin (100 μg/mL) and incubated at 37 °C in a 5% CO_2 humidified atmosphere.

Preparation of SME-CA. SME-CA was prepared by using the following method. Step 1, preparation of the oil phase: 10% (w/v) soybean oil and 0.1% (w/v) vitamin E together with 1.2% (w/v) egg lecithin were heated until the egg lecithin was totally dissolved. Then, 0.5% CA was added into the mixture. Step 2, preparation of the water phase: 85.5% (w/v) water, 2.5% (w/v) glycerinum, and 0.2% sodium oleate were added in order. After that, the mixture was heated to 40 °C until all of the ingredients were dissolved. Step 3, preparation of the pre-emulsion: the oil phase was added into the water phase and homogenized with a high shear dispersing emulsifier (FLUKO FA25, FLUKO Co., Germany) under the condition of 2000 rpm shear force and 55 °C. After 10 min of shearing, a crude emulsion formed and was rapidly cooled to 15−30 °C. Fourth and final step, preparation of emulsion: the colostrum was homogenized with a high-pressure homogenizer (PandaPlus1000; Niro Soavi Co., Italy) at 800 bar under a pressure of 100 bar and then increased to 1280 bar eight times. Consequently, the SME-CA was successfully prepared with 25.6 mg/mL CA loaded into the emulsion.

Pharmacokinetic Study. *Intravenous Administration Study.* In the pharmacokinetic study CA was dissolved in solution with 1:1:8 (polyoxyethylenated castor oil/ethanol/water, by vol). A group of SD rats (n = 5, each group) was intravenously administered 20 mg/kg CA, and blood was collected at 2, 5, 10, 15, 30, 60, 90, 120, and 180 min. These time plots were selected on the basis of previous studies of CA. The blood samples were centrifuged at 3500g, and after 15 min, 200 μL of supernatant was extracted and stored at −80 °C until analysis.

Tissue Distribution Study. SD rats were randomly assigned to two groups (n = 6 per group). These two groups were intravenously administered a single dose of 20 mg/kg CA and SME-CA, respectively. Major tissue samples, such as heart, liver, spleen, lung, kidney, and brain, were collected at 15, 45, and 90 min after administration. Tissue samples were quickly rinsed with saline solution (0.9%) to remove the blood and content. After cleaning, samples were blotted by filter paper and weighed and then homogenized in a 2-fold weight saline solution (0.9%) for all tissue samples by a T10 Basic homogenizer (Staufen, Germany). Then the obtained homogenates were stored at −80 °C until analysis.

Sample Preparation. A liquid−liquid preparation method was utilized to extract target compounds and eliminate the interference of endogenous protein. We found that acetonitrile enhanced the sensitivity and selectivity, especially in minimizing endogenous interference and improving extraction recovery. Consequently, we chose acetonitrile as the optimized solvent for sample preparation. Fifty microliters of propiophenone as internal standard solution (2500 ng/mL) and 500 μL acetonitrile were sequentially added in every 200 μL of homogenate and plasma samples. Then, the solution was thoroughly vortex-mixed for 120 s. After centrifugation at 12000g for 10 min, 1 μL of supernatant was injected into GC-MS for analysis.

GC-MS Analysis. Chromatography was performed on a Trace ISQ Ultra (Thermo Fisher Scientific, Waltham, MA, USA) system combined with a Triplus atuosampler and injector. A DB-5 ms capillary column (30 m × 0.25 mm, 0.25 μm thickness, Agilent Technologies, Santa Clara, CA, USA) was used for separation. The initial oven temperature was set at 50 °C, held for 1 min, then increased to 160 °C at 10 °C/min for 1 min, then increased to 280 at 20 °C/min, and held at the final temperature for 1 min. High-purity helium was used as carrier gas at a constant flow rate of 1.0 mL/min.

The transfer line and ion source of the MS system were both operated at 250 °C. MS analysis was operated in the selected ion monitoring (SIM) mode with the ionization energy being 70 eV. Quantifying ion masses (m/z 131, 105, and 92) were selected for simultaneously investigating IS, CA, methyl cinnamate, and cinnamyl alcohol. The mass spectra of all analytes were analyzed by the NIST library (Shimadzu, Kyoto, Japan) and are shown in the Supporting Information.

Pharmacokinetics and Statistical Analysis. All of the pharmacokinetic data of CA were processed by the DAS 2.0 software supplied by the Anhui Provincial Center for Drug Clinical Evaluation. The different pharmacokinetic features of CA and SME-CA were assessed using the following parameters: area under the curve to termination time (AUC_{0-t}), mean residence time (MRT_{0-t}), half-life ($t_{1/2}$), time at maximum plasma concentration (t_{max}), maximum plasma concentration (C_{max}), plasma clearance (CLz), and volume of distribution (Vz). The data are presented as the mean ± SD, and Student's t test was used to analyze the difference between groups. A P value of <0.05 was considered to be statistically significant.

Antitumor Efficacy. The antitumor efficacy was determined using the MTT assay. All of the cell lines were seeded at a density of 1×10^5 cells/mL in 96-well plates at 37 °C with 5% (v/v) CO_2 for 24 h. After that, 10 μL of different concentrations of CA and SME-CA was added to test the cell viability. After 12 h of incubation, to each well was added 30 μL of MTT and incubated for 4 h. Then the supernatants were discarded, and 150 μL of dimethyl sulfoxide was added to each well to dissolve formazan crystals. The absorbance of formazan crystals was detected and quantified at 570 nm by a microplate reader (Bio-Rad 680, Hercules, CA, USA). The percentage of growth inhibition and the IC_{50} were estimated from a dose response curve. Averages from six replicate wells were used for each sample and control.

Acute Toxicity. The in vivo toxicity of the CA was evaluated using acute toxicity, which is usually expressed as LD_{50} (medium lethal concentration). One hundred KM mice (half males and half females) were randomly divided into 10 groups (n = 10). In the acute toxicity study CA was dissolved in solution with 1:1:8 (polyoxyethylenated castor oil/ethanol/water, by vol). Five groups received a single intravenous injection of CA of 96.0, 84.5, 74.3, 65.4, or 57.6 mg/kg. The other five groups received a single intravenous injection of SME-CA of 152.9, 143.3, 133.7, 124.2, or 114.7 mg/kg. After the treatment, the general behavior and death rate were surveyed for 3 h. For the dead mice, general organs were anatomized for macroscopic observation. Observation was continued for 14 days for behavioral changes and signs of toxicity or death.

J. Agric. Food Chem. 2015, 63, 6386−6392

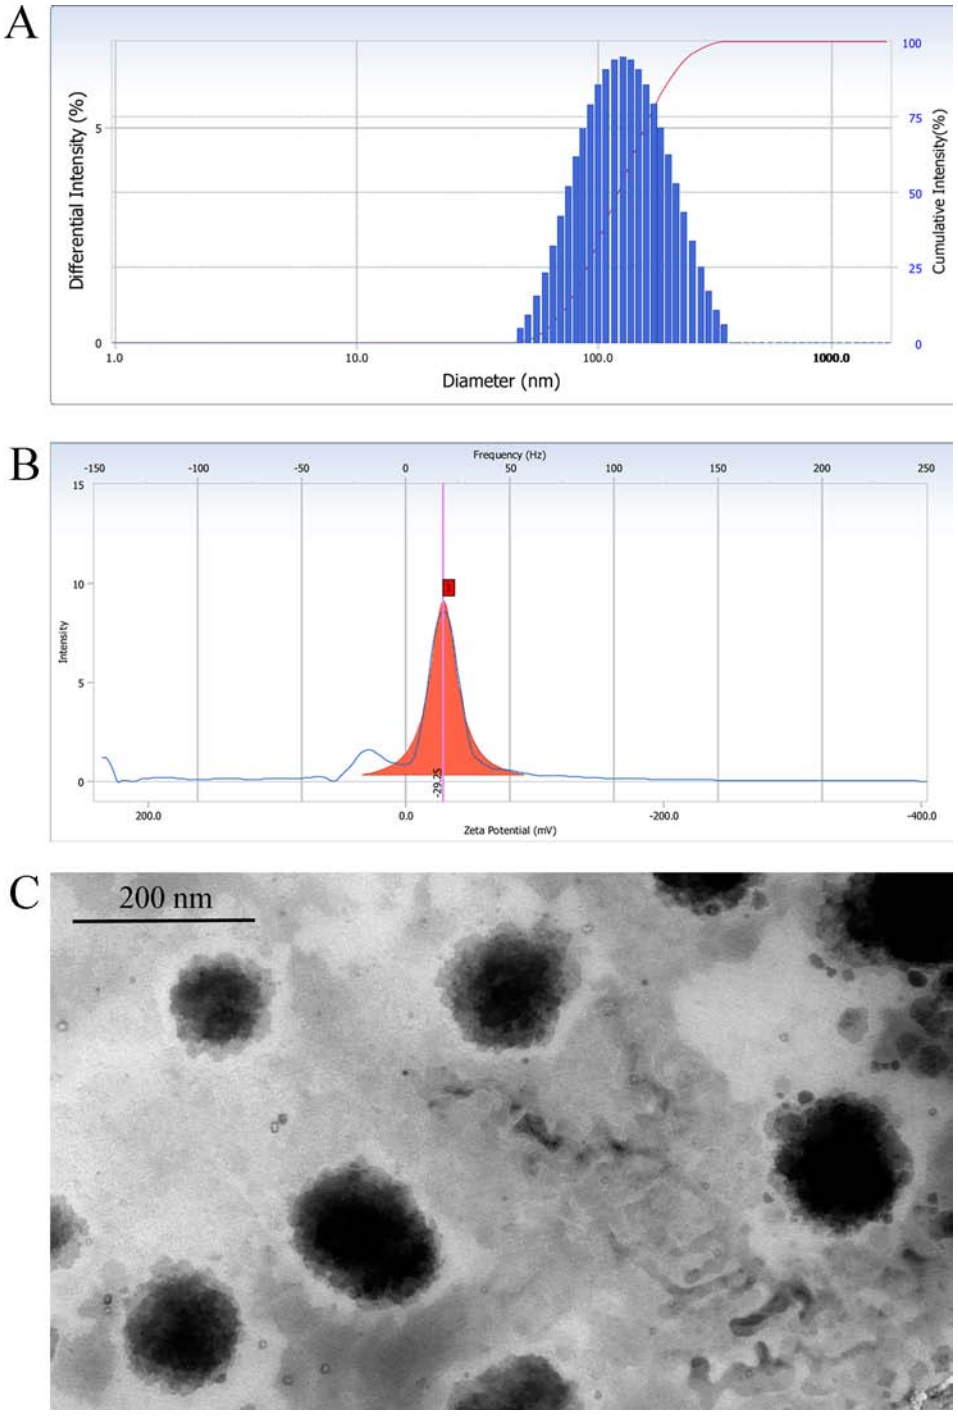

Figure 1. Particle size distribution (A), zeta potential (B), and transmission electron microscopic images of the SME-CA.

RESULTS AND DISCUSSION

Characterization of SME-CA. Previous studies found the size of SME-CA depended on the structure and the concentration of CA; other influential factors including molecular weight, electrical charge, and hydrophobicity of the polymers should also be considered.[24] Among them, the electrostatic properties are very important for emulsion stability as they can reduce or eliminate the influence of flocculation, enhancing the emulsion stability. Panels A and B of Figure 1 show the particle size distribution and zeta potential of the emulsion, measured by dynamic light scattering (DelsaNano Zeta, Beckman Coulter, USA), were 130 ± 5.92 nm and −25.7 ± 6.00 mv, respectively. Encapsulation efficiency was measured by HPLC. In Figure 1C, further morphology confirmation of particle size was performed by using a transmission electron microscope (Tecnai G2, FEI Co., Hillsboro, OR, USA), which demonstrated that the droplet diameter is around 130 ± 5.92 nm.

Long-Term Stability of SME-CA. Because the storage condition may affect the stability of SME-CA, resulting in collapse of membranes and release of encapsulated materials, the stability study was carried out. The particle size, zeta potential, pH value, and encapsulation efficiency of SME-CA were evaluated after 12 months to estimate the stability. The

DOI: 10.1021/acs.jafc.5b01883
J. Agric. Food Chem. 2015, 63, 6386−6392

results showed (Table 1) that SME-CA could maintain its characteristics without significant changes in particle size, zeta potential, pH value, and encapsulation efficiency after 12 months of storage at room temperature.

Table 1. Results of the Long-Term Stability Test for SME-CA (Mean ± SD, n = 3)

characterization of SME-CA	0 days	storage at room temperature for 12 months
appearance	milk white	milk white
particle size distribution (nm)	130 ± 5.92	135 ± 8.74
pH	8.32 ± 0.12	8.11 ± 0.09
zeta potential (mv)	−25.7 ± 6.00	−24.3 ± 7.81
encapsulation efficiency (%)	99.5 ± 0.25	99.4 ± 0.17

Antitumor Efficacy. The MTT assay showed a dose-dependent decrease in cell viability. As shown in Table 2, after 12 h of treatment, a significant decrease in the number of viable cells was observed in the cancer cell lines. The viability of most cell lines showed more reduction when added in SME-CA than in CA, whereas HT-29 and Eca-109 appeared reduction only with a high concentration of both SME-CA and CA. Among all of the results, HeLa and A549 showed relatively higher sensitivity to SME-CA, with the IC_{50} values reaching 0.003 and 0.001 mmol/L, respectively. The IC_{50} of CA was comparatively higher at the concentration of 0.024 mmol/L to HeLa and 0.011 mmol/L to A549. A similar study also demonstrated the antitumor activity can be improved by using a new formulation.[25] CA was also proved be effective in cervical cancer and lung cancer. Further exploration by using SME-CA should also be carried out.[26,27]

Table 2. Effects of CA and SME-CA on the Growth of 11 Kinds of Cancer Cells

	IC_{50} (mmol/L)	
tumor strain	CA	SME-CA
Eca-109	0.985	0.853
Hct-116	0.100	0.110
HepG-2	0.041	0.078
HT-29	1.73	0.867
A549	0.011	0.001
Mkn-45	0.057	0.070
PANC-1	0.321	0.118
HeLa	0.024	0.003
SGC-7901	0.022	0.067
SW 620	0.512	0.278
Tca-8113	0.328	0.272

Acute Toxicity. The results of the acute intoxication study after a single intravenous injection to KM mice were calculated; the LD_{50} values of CA and SME-CA were 74.8 and 125 mg/kg, respectively. Compared with the former formulation, there was a significant optimization in the acute toxicity by using SME-CA. This was mainly because the drug was loaded in a lipid emulsion vehicle, which controlled CA released into blood. Direct and severe irritation was avoided, which makes the body more tolerable to the high dose SME-CA. The main organs of dead mice were anatomized; general performance and macroscopic observation showed no special pathological changes. After 14 days, the behavior of living mice was normal without any changes.

Pharmacokinetic Study. The aim of the pharmacokinetic study was to investigate the different plasma parameters of CA and SME-CA including quantifying the concentration of CA and its metabolites in rats up to 3 h after iv administration. To compare the concentration of CA and its metabolites, the mean plasma concentration−time profiles for CA and SME-CA are shown in Figure 2. Figure 2A shows the AUC_{0-t} of SME-CA was significantly higher than that of CA (589 ± 59.2 vs 375 ± 83.5 ng h/L, $P < 0.01$). The mean peak plasma concentration of CA was 547 ± 142 ng/mL at 2 min after iv injection, whereas, in the case of SME-CA, a significantly higher peak plasma level

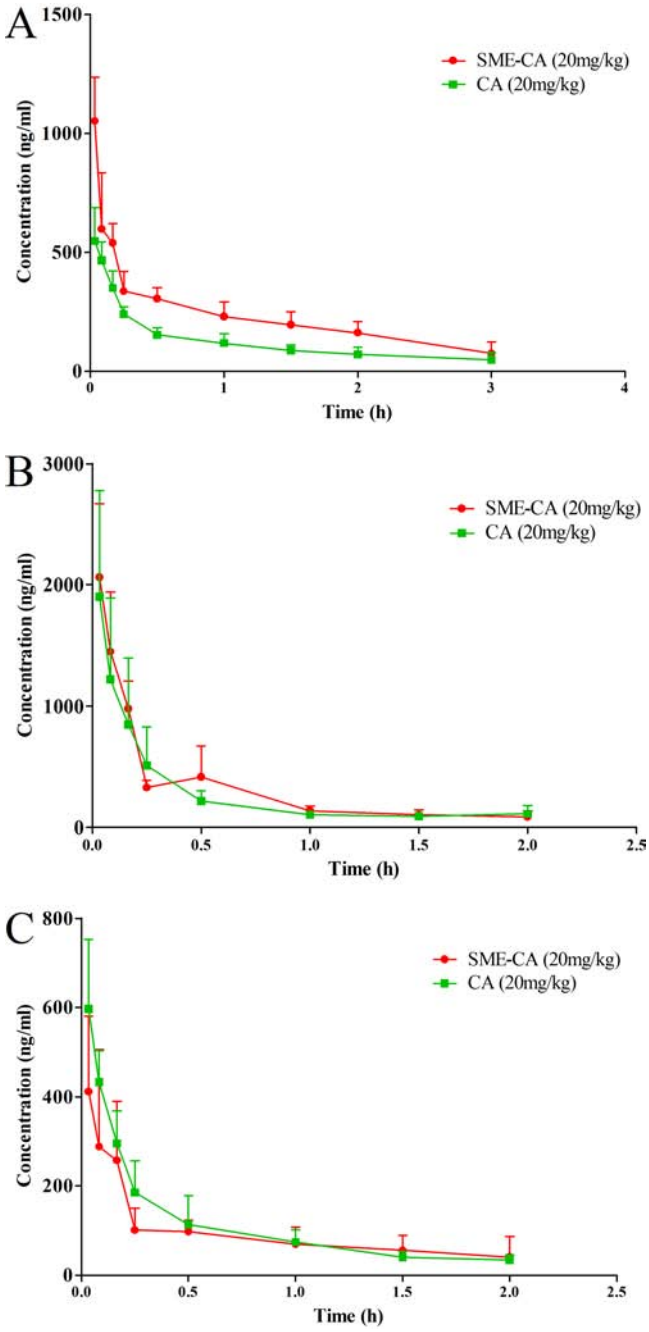

Figure 2. Compared mean plasma concentration−time profile of cinnamaldehyde (A), cinnamyl alcohol (B), and methyl cinamate (C) in rats after a single intravenous administration of SME-CA and CA of 20 mg/kg (mean ± SD, n = 5).

DOI: 10.1021/acs.jafc.5b01883
J. Agric. Food Chem. 2015, 63, 6386−6392

Table 3. Comparison of Main Pharmacokinetic Parameters for SME-CA and CA after 20 mg/kg Intravenous Injection (Mean ± SD, n = 5)

pharmacokinetic parameter[a]		SME-CA	CA	SME-cinnamyl alcohol	cinnamyl alcohol	SME-methyl cinnamate	methyl cinnamate
AUC_{0-t}	ng h/L	589 ± 59.2	375 ± 83.5	632 ± 138	537 ± 181	170 ± 55.6	225 ± 64.0
MRT_{0-t}	h	0.84 ± 0.14	0.96 ± 0.21	0.44 ± 0.12	0.47 ± 0.21	0.61 ± 0.14	0.50 ± 0.13
$t_{1/2}$	h	2.17 ± 0.96	3.26 ± 2.82	0.60 ± 0.26	0.96 ± 0.91	0.96 ± 0.44	0.68 ± 0.26
t_{max}	h	0.04 ± 0.02	0.04 ± 0.02	0.03 ± 0.00	0.03 ± 0.00	0.04 ± 0.02	0.03 ± 0.00
C_{max}	ng/mL	1052 ± 184	547 ± 142	2062 ± 605	1899 ± 878	440 ± 170	596 ± 156
CLz	L/h/kg	20.4 ± 2.19	36.3 ± 22.2	30.5 ± 9.24	32.0 ± 5.80	93.2 ± 44.2	81.9 ± 20.4
Vz	L/kg	62.0 ± 22.9	120 ± 31.0	25.4 ± 11.5	45.1 ± 45.0	115 ± 63.0	77.8 ± 30.1

[a] AUC_{0-t}, area under the curve to termination time; MRT_{0-t}, mean residence time; $t_{1/2}$, half-life; t_{max}, time at maximum plasma concentration; C_{max}, maximum plasma concentration; CLz, plasma clearance; Vz, volume of distribution.

(1052 ± 184 ng/mL, $P < 0.01$) appeared at the same time.[14] This might be related to the lecithin sphere, which creates a steric barrier at the oil/water interface so that the chemical stability of CA was significantly increased and the metabolism of CA was prolonged and changed. There is a similar behavior observed in the research of SME-nitrendipine after iv administration in rats.[28] For the metabolite cinnamyl alcohol, Figure 2B shows a similar concentration−time profile of both formulations. The pharmacokinetic parameters are shown in Table 3. The CLz and $t_{1/2}$ exhibted a slight decrease, but no significant difference was detected after the statistical analysis. Because CA showed a relatively high concentration in SME-CA, the aldehyde part is protected, indicating it can be more effective in the pharmacological area. It is exhibited in Table 3 that the SME-CA had a significant increase in AUC_{0-t} when compared to the previous CA solution. In addition, the Vz after administration of SME-CA was decreased to 62.0 ± 22.8 L/kg. On the other hand, the AUC_{0-t} of cinnamyl alcohol and methyl cinnamate experienced a slight increase and decrease when encapsulated into submicrometer emulsion. Figure 2C shows that the C_{max} of methyl cinnamate was decreased to 440 ± 170 ng/mL in the SME-CA group. It can be concluded that the change of CA in the pharmaceutical characterization has led to a pharmacokinetic change for both CA and its metabolites.

After intravenous injection of SME-CA, the result of tissue distribution is influenced by several variables, such as composition, particle size, and zeta potential. The concentration profiles of CA and its metabolites in various tissues, that is, heart, liver, spleen, lung, kidney, and brain, were quantified and are shown at 15, 45, and 90 min in Figure 3. Comparison of the new formulation with the former drug, improved concentration was found in kidney, liver, spleen, and brain in the SME group.[29] Significant accumulation of CA was detected in the liver and kidney, with the concentration increasing to 334 ± 60.1 and 459 ± 148 ng/g, respectively. This is mainly caused by the dramatic increase in the blood that needed to be metabolized and excreted. Higher concentration was also found for the metabolites of CA in the SME group. A similar phenomenon was exhibited in the previous study with a sharp increase in the liver.[30] To make CA easier to penetrate the endothelium cell barrier, the particle size was reduced to 130 ± 5.92 nm. As a result, 1.27-fold higher free CA (442 ± 180 ng/g) was detected in the brain compared with the former drug. Although the stability and penetrability were enhanced in the new formulation, there is no significant distribution difference found in the lung and heart. The aldehyde part of CA is very easily oxidized to cinnamic acid. However, when it was encapsulated in lecithin and other materials, the chemical stability were significantly enhanced, which resulted in the pharmacokinetic and distribution changes of CA.

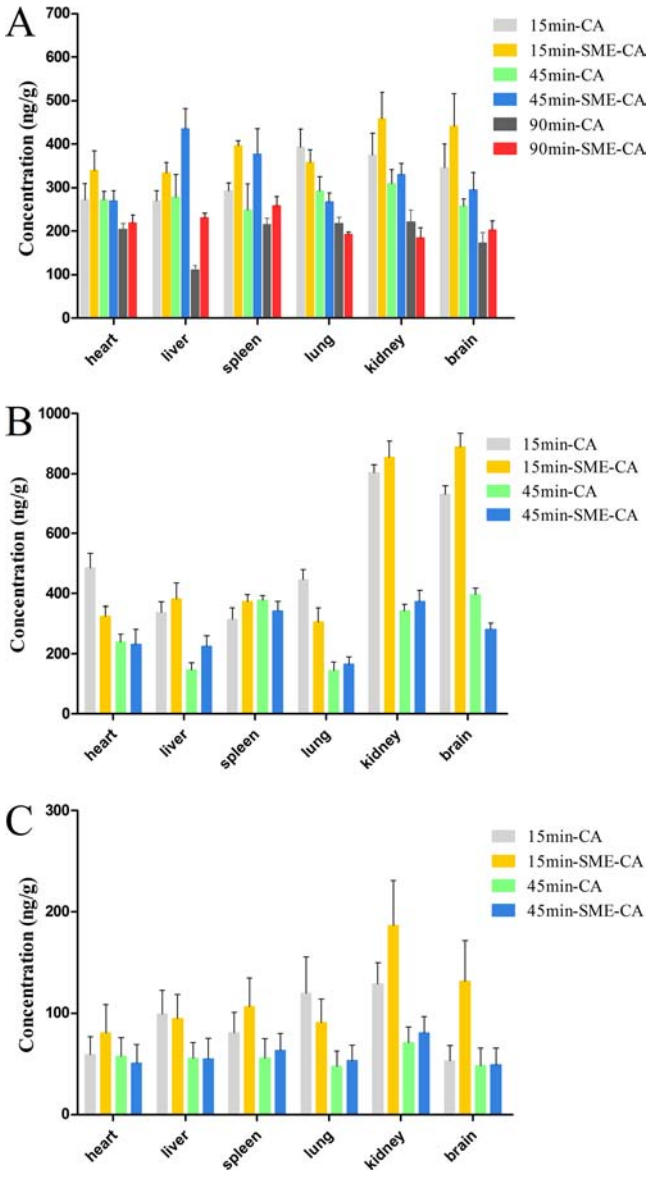

Figure 3. Compared tissue distribution profile of cinnamaldehyde (A), cinnamyl alcohol (B), and methyl cinamate (C) in rats after a single intravenous administration of SME-CA and CA of 20 mg/kg at 15, 45, 90 min (mean ± SD, n = 5).

In the present study, we have tested different excipients and conditions to prepare the submicrometer emulsion and finally exhibited optimal pharmacokinetic properties reported above. Moreover, the new formulation was more easily dissolved in water, which can be administered by various routes such as intragastrically or intraperitoneally. As CA was encapsulated in a submicrometer emulsion, it might affect the pharmacokinetic results when used in oral applications. We believe the development of the new formulation has laid a foundation for the future clinical application of CA.

classified by the Endemic Species Research Institute, Council of Agriculture, Taiwan, as an endemic herb in Taiwan, and it has long been used in folk medicine for the treatment of hepatitis, jaundice, diarrhea, and arthritis.[12] It is reported that extracts or purified compounds from VTT exhibited several biological activities, including antihypertensive,[13,14] antiarthritis,[15,16] neuroprotective,[17] and hepatoprotective[18] activities. The active components were reported to be resveratrol, resveratrol oligomers,[14−16] and other polyphenols.[17,18] Moreover, the ethanolic extract of VTT has exhibited less lipid accumulation through regulation of the AMPK-ACC pathway in hypercholesterolemic rabbits.[19] Therefore, the purpose of this study was to investigate whether VTT could decrease lipid levels to improve glucose tolerances in diet-induced obese rats. In the present study, ethanol extracts (Et) and hot-water extracts (Hw) from the stem (S) and leaf (L) of VTT and their Et partitioned fractions, including ethyl acetate fraction (Et-EA), butanol fraction (E*t*-BuOH), and water fraction (Et-w), were used to investigate yeast α-glucosidase and porcine DPP-IV inhibitory activities. Later, a high-fat (HF) diet was used to induce Wistar rat obesity for 5 weeks. Then VTT-S-Et and VTT-L-Et (20 and 50 mg/kg) were used daily concurrently with the HF diet (HF + S-Et or HF + L-Et) from day 36 to day 68 and were then used to investigate improvements of the impaired glucose tolerances by OGTT. The isolated compounds from S-Et-EA were tested for yeast α-glucosidase and porcine DPP-IV inhibitory activities and related kinetic properties.

MATERIALS AND METHODS

Materials. α-Glucosidase (from *Saccharomyces cerevisiae*, type I, lyophilized powder, ≥10 units/mg protein), DPP-IV (from porcine kidney, lyophilized powder, ≥10 units/mg protein, D-7052), *p*-nitrophenyl α-D-glucopyranoside (pNPG), Gly-Pro-*p*-nitroanilide, dimethyl sulfoxide (DMSO), acarbose, and sitagliptin phosphate were purchased from Sigma Chemical Co. (St. Louis, MO, USA). The HF diet for diet-induced obesity (fat composition provided 60% of total calories, D12942) was purchased from Research Diets, Inc. (New Brunswick, NJ, USA). The standard mouse/rat chow (fat composition provided 12% of total calories, Prolab RMH2500, 5P14 Diet; PMI Nutrition International, St. Louis, MO, USA). The compositions of the standard chow and high-fat diets for providing total calories are listed in Supplementary Table S1 of the Supporting Information. Other chemicals were from Sigma Chemical Co. (St. Louis, MO, USA). For pure compound identifications, optical rotation measurements were measured with a JASCO DIP-180 digital spectropolarimeter, NMR spectra were analyzed in $CDCl_3$ at room temperature using a Varian Mercury plus 400 NMR spectrometer, and the solvent resonance was used as the internal shift reference [tetramethylsilane (TMS) as standard]; electrospray ionization mass was determined on a VG platform electrospray mass spectrometer. Thin-layer chromatography was performed on silica gel 60 F254 plates (Merck, Darmstadt, Germany). Silica gels (230−400 mesh ASTM, Merck) were used for column chromatography. Semipreparative HPLC was performed on a Hitachi L-7000 chromatograph with a Thermo Betasil C-18 column (5 μm, 250 × 10 mm).

Preparation of VTT Extracts and Fractions. VTT leaves and stems were collected in Taichung County, Taiwan, in July 2006. They were cultivated by Dr. Chi-Luan Wen (Taiwan Seed Improvement and Propagation Station, Council of Agriculture, Taichung, Taiwan) and identified by Dr. Tsai-Wen Hsu (Endemic Species Research Institute, Nantou, Taiwan). The specimens were kept in the laboratory of Dr. Chi-I Chang (National Pingtung University of Science and Technology, Pingtung, Taiwan) for reference. All plant materials were oven-dried at 50 °C for 3 days and mechanically ground to a fine powder passing through a 10-mesh sieve. The powder of the leaves and stems (10 kg each) was extracted with ethanol in a solid/solvent ratio of 1:5 at room temperature for 7 days. The combined ethanol extract was filtered through Whatman no. 1 filter paper and evaporated under reduced pressure to obtain the ethanol extracts (Et, 405 and 485 g, respectively), which were suspended in H_2O, and then partitioned sequentially using ethyl acetate (EA) and *n*-butanol (BuOH), to get the ethyl acetate fraction (Et-EA), butanol fraction (E*t*-BuOH), and water fraction (Et-w). For hot-water extraction, 100 g of leaf and stem powder was extracted with 1 L of distilled water in reflux for 3 h. Once cooled to room temperature, the extract was filtered through Whatman no. 1 filter paper and dried under reduced pressure below 45 °C using a rotary evaporator. It was then freeze-dried to obtain hot-water extracts (Hw 5.3 and 3.6 g, respectively) and was stored at −20 °C until further use.

Compounds Isolated from S-Et-EA. The S-Et-EA (39 g) was resolved by silica gel column chromatography (90 × 5 cm) using *n*-hexane−EA gradients as eluent. Twenty-four fractions were collected. Fraction 24 (6.2 g) was in turn passed through an RP-18 reversed phase column (60 × 3 cm) and eluted by using water−methanol gradients (1:1 to 0:1) to obtain seven subfractions (each 200 mL, fractions 24A−24G), among which fraction 24D was further purified by semipreparative HPLC (Thermo Betasil C-18 column; flow rate = 2 mL/min) by water/acetonitrile (9:1 to 1:1) gradients to afford (+)-hopeaphenol (**1**) (7.2 mg, t_R = 39.6 min) and (+)-vitisin A (**2**) (12.3 mg, t_R = 46.8 min), respectively; fraction 24E was finally purified by semipreparative HPLC by water/acetonitrile (9:1 to 5:5) to afford (−)-vitisin B (**3**) (17.2 mg, t_R = 48.7 min). The collections of appropriate sample amounts for studies were carried out by repeated injection under the above HPLC conditions.

α-Glucosidase Inhibitory Assays. The α-glucosidase inhibitory activity was assayed according to a previous study with modifications.[20] Each test sample was dissolved in DMSO. Ten microliters of VTT extracts and fractions (0.1 mg/mL) and different concentrations of purified compounds [(+)-hopeaphenol, 0.78, 1.56, 3.125, 6.25, 12.5, and 25 μM; (+)-vitisin A and (−)-vitisin B, 0.625, 1.25, 2.5, 5, and 10 μM] or acarbose (positive control, 1.67, 3.33, 5.0, 6.67, 8.3, 10, and 11.67 mM) were premixed with 10 μL of α-glucosidase (1 U/mL) at 37 °C for 10 min. Then, 50 μL of 10 mM pNPG (in 200 mM phosphate buffer, pH 6.8) and 50 μL of 200 mM phosphate buffer (pH 6.8) were added and incubated at 37 °C for 30 min. One hundred microliters of 200 mM sodium carbonate was added to stop reactions. DMSO was used instead of tested samples for the blank. For sample background interference determinations, each sample was added into the phosphate buffer only during reactions. The absorbance at 405 nm was measured by using an ELISA reader (TECAN Sunrise microplate reader; Männedorf, Switzerland). The α-glucosidase inhibition (%) was calculated as follows:

$$\frac{[A405_{\text{blank}} - (A405_{\text{sample}} - A405_{\text{background}})]}{A405_{\text{blank}}} \times 100\%$$

The 50% inhibition (IC_{50}) value was calculated as the concentration of samples that inhibited 50% of α-glucosidase activity under tested conditions.

DPP-IV Inhibitory Assays. The DPP-IV inhibitory activity was assayed according to a previous study with modifications.[21,22] The enzyme powder (lyophilized powder, ≥10 units/mg protein) was redissolved in 1 mL of 100 mM Tris buffer (pH 8.0) as a stock solution and a 50-fold dilution (~0.002 unit/mL) as a working solution. Each test sample was dissolved in DMSO. Fifty microliters of VTT extracts and fractions (0.5 mg/mL) and different concentrations of purified compounds [(+)-hopeaphenol, 100, 200, 300, 400, and 500 μM; (+)-vitisin A, 25, 50, 75, 100, 125, 150, and 200 μM; (−)-vitisin B, 2.5, 5, 10, 15, 20, 25, and 30 μM] or sitagliptin phosphate (positive control, 0.01, 0.025, 0.05, 0.1, and 0.2 μM) were premixed with 50 μL of DPP-IV working solution at 37 °C for 10 min. Then, 50 μL of 1 mM Gly-Pro-*p*-nitroanilide and 50 μL of 100 mM Tris buffer (pH 8.0) were added and incubated at 37 °C for 60 min. Fifty microliters of 3% acetic acid was added to stop reactions. DMSO was used instead of tested samples for the blank. To determine sample background

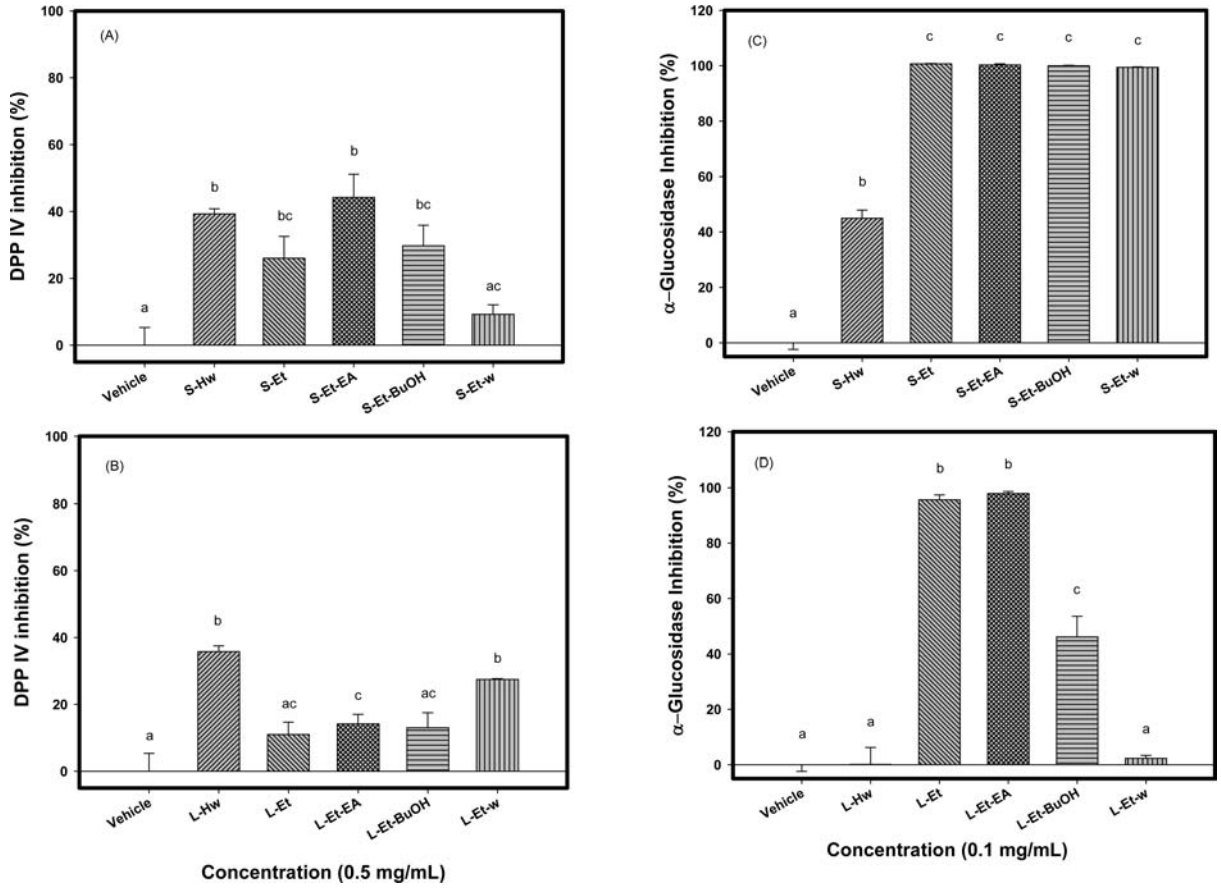

Figure 1. Effect of 0.5 mg/mL extracts and partitioned fractions on dipeptidyl peptidase-IV (DPP-IV) inhibitory activities from stem of *Vitis thunbergii* var. *taiwaniana* (A) and from leaf of *V. thunbergii* var. *taiwaniana* (B); effect of 0.1 mg/mL extracts and partitioned fractions on α-glucosidase inhibitory activities from stem of *V. thunbergii* var. *taiwaniana* (C) and from leaf of *V. thunbergii* var. *taiwaniana* (D). S, stem; L, leaf; Et, ethanol extracts; Hw, hot-water extracts; Et-EA, ethyl acetate partitioned fractions from Et; Et-BuOH, butanol partitioned fractions from Et; Et-w, Et partitioned water fractions. Triplicates were determined and expressed as the mean ± SD. Multiple group comparisons under the same treatment time were performed using one-way analysis of variance followed by the post hoc Tukey's test, and values that have not been marked with the same letter are significantly different ($P < 0.05$).

interference, each sample was added into the Tris buffer only during reactions. The absorbance at 405 nm was measured by using an ELISA reader (TECAN Sunrise microplate reader). The DPP-IV inhibition (%) was calculated as follows:

$$\frac{[A405_{\text{blank}} - (A405_{\text{sample}} - A405_{\text{background}})]}{A405_{\text{blank}}} \times 100\%$$

The 50% inhibition (IC_{50}) value was calculated as the concentration of sample that inhibited 50% of DPP-IV activity under tested conditions.

Kinetic Analyses of α-Glucosidase and DPP-IV. The kinetic properties of α-glucosidase (0.083 unit) without or with different concentrations of (+)-vitisin A (0.3125 and 1.25 μM) and (−)-vitisin B (0.3125 and 0.625 μM) were determined using different concentrations of pNPG as substrate (0.625, 1.25, 2.5, and 5 mM). The kinetic properties of DPP-IV (0.005 unit) without or with different concentrations of (−)-vitisin B (5, 15, and 25 μM) were determined using different concentrations of Gly-Pro-*p*-nitroanilide as substrate (0.1, 0.2, 0.4, 0.6, 0.8, and 1 mM). The K_m, K'_m, V_{max}, and V'_{max} were calculated from Lineweaver−Burk plots. The enzyme−inhibitor dissociation constant (K_i) was the intercept of the *x*-axis calculated (each line slope in the Lineweaver−Burk plot vs the tested inhibitor concentrations), and the inhibitor-enzyme−substrate dissociation constant (K_{is}) was the intercept of the *x*-axis calculated (each line *y*-axis intercept in the Lineweaver−Burk plot vs the tested inhibitor concentrations).

Impaired Glucose Tolerance in Obese Rat Models. Male 10-week-old Wistar rats ($N = 48$) were purchased from the National Laboratory Animal Center (Taipei, Taiwan) and housed in wire-bottomed stainless steel cages in a temperature- and humidity-controlled room (at 22 °C) with a 12-h light/dark cycle and had free access to feed and water. All animal experimental procedures were reviewed and approved by the Institutional Animal Care and Use Committee, Taipei Medical University (LAC-99-0136). After acclimation for 1 week, the rats were randomly divided into three groups ($N = 8$ for each group), including a normal diet (ND) group given standard mouse/rat chow and five HF diet-induced obese groups (one control as HF group, two VTT-S-Et intervened groups, and two VTT-L-Et intervened groups) for 68 days. The Wistar rats were subjected to diet-induced obesity during days 0−35 and then randomly divided into groups for further interventions at days 36−68. The HF was changed every 2 days to avoid oxidation. In the VTT-S-Et and VTT-L-Et intervened groups, S-Et or L-Et (20 and 50 mg/kg, respectively, Et20 and Et50) was orally administered daily by oral gavage together with HF diets (HF + S-Et20, HF + S-Et50; HF + L-Et20, HF + L-Et50) from days 36 to 68. The rat weights were recorded during experiments. The impaired glucose tolerances of HF diet-induced obese rats were measured by OGTT methods following a previous study.[22] Rats of each group at day 68 were fasted for 16 h, and glucose (1g/kg) was administered by oral gavage. Blood (0.1 mL) was obtained from the tail vein at 0 (basal level), 5, 30, 60, 90, and 120 min after the glucose loads. Plasma glucose was determined by using a

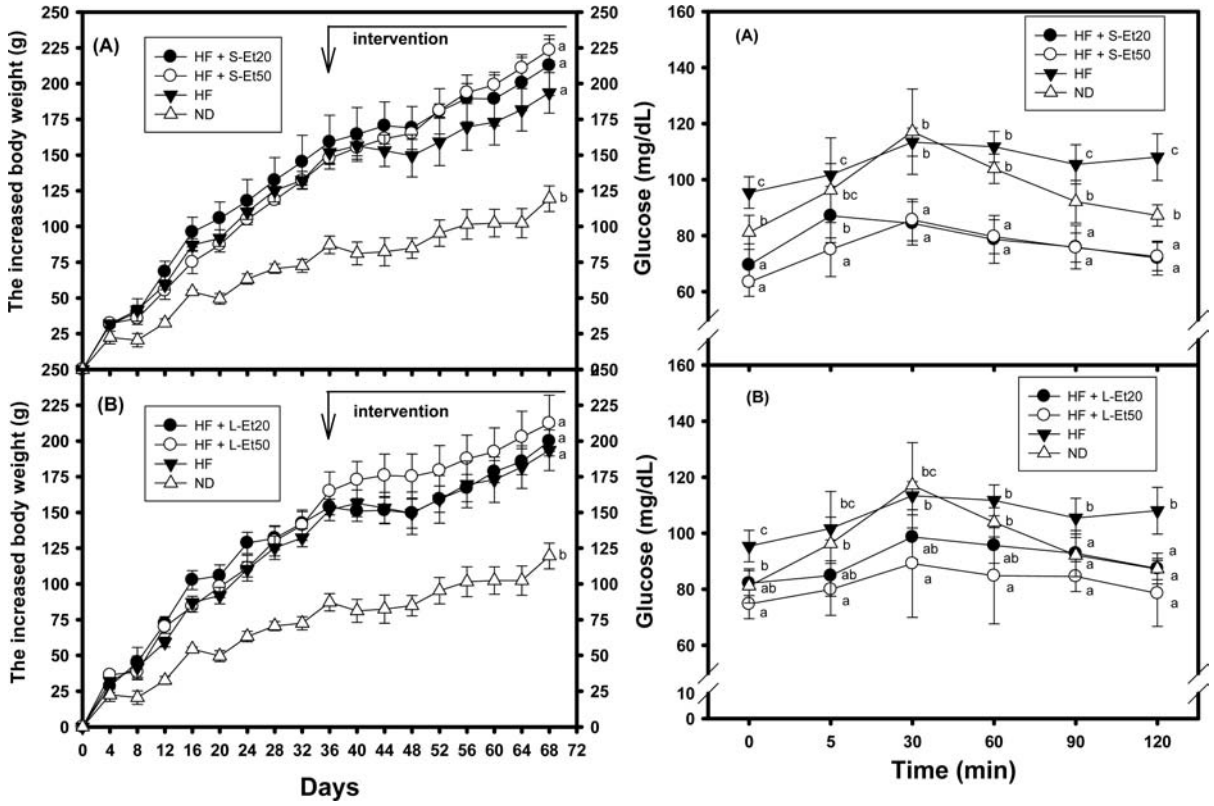

Figure 2. Effects of (A) stem ethanol extracts (S-Et) interventions (20 and 50 mg/kg) and (B) leaf ethanol extracts (L-Et) interventions (20 and 50 mg/kg) of *Vitis thunbergii* var. *taiwaniana* on the changes of increased body weight. Effects of (C) S-Et20 and S-Et50 and (D) L-Et20 and L-Et50 on impaired glucose intolerances of high fat-diet induced obese rats by oral glucose tolerance tests. The HF diet and normal diet (ND) were provided from day 1 to day 68. The arrow indicates the intervened periods from day 36 to day 68. Data are expressed as the mean ± SD. ND, normal diet; HF, high-fat diet; (HF + Et20 or HF + Et50), ethanol extracts (20 mg/kg, Et20; 50 mg/kg, Et50) were intervened daily concurrent with the HF diet. Multiple group comparisons at the end of experiment were performed using one-way analysis of variance (ANOVA) followed by the post hoc Tukey's test. Values that have not been marked with the same letter are significantly different ($P < 0.05$).

RANDOX glucose kit (Randox Laboratories-US, Ltd., Kearneysville, WV, USA).

Statistical Analyses. Data are expressed as the mean ± SD. Multiple group comparisons were performed using one-way analysis of variance (ANOVA) followed by the post hoc Tukey's test. The animal experiments were compared among groups on the day of the experiment end. Values that have not been marked with the same letter are significantly different ($P < 0.05$). Statistical analysis was performed using GraphPad Prism 5.0 software (San Diego, CA, USA).

RESULTS AND DISCUSSION

DPP-IV and α-Glucosidase Inhibitory Activities of VTT Extracts and Fractions. VTT was reported to have different biological activities depending on which plant portions (roots, stems, or leaves) were used in combination with different solvent extracts.[14−19] Therefore, the Et and Hw from S and L and their Et partitioned fractions, S-Et-EA and L-Et-EA, S-E*t*-BuOH and L-E*t*-BuOH, and S-Et-w and L-Et-w, were used to investigate inhibitory activities against DPP-IV (Figure 1A,B) and yeast α-glucosidase (Figure 1C,D). Generally, the VTT extracts and Et partitioned fractions exhibited higher yeast α-glucosidase inhibitory activities than those of the DPP-IV inhibitory ones. At the same concentration of 0.5 mg/mL, the order of VTT extracts for DPP-IV inhibitory activity was S-Hw ≥ L-Hw > S-Et ≫ L-Et; the order of Et partitioned fractions for DPP-IV inhibitory activity was S-Et-EA > S-E*t*-BuOH > L-Et-w ≫ L-Et-EA ≅ L-E*t*-BuOH ≅ S-Et-w, and the maximal DPP-IV inhibition was close to 40% (Figure 1A,B). At the same concentration of 0.1 mg/mL, the order of VTT extracts for α-glucosidase inhibitory activity weas S-Et ≥ L-Et ≫ S-Hw ≫ L-Hw; the order of Et partitioned fractions for α-glucosidase inhibitory activity was S-Et-EA ≅ S-E*t*-BuOH ≅ S-Et-w ≅ L-Et-EA ≫ L-E*t*-BuOH ≫ L-Et-w, and the maximal α-glucosidase inhibition was close to 100% (Figure 1C,D).

Impaired Glucose Tolerance Improvements of S-Et and L-Et in High-Fat (HF) Diet-Induced Obese Rats. HF diets are reported to induce an overweight condition, obesity, dyslipidemia, insulin resistance, and high blood pressure in rodents.[23] The α-glucosidase and DPP-IV inhibitions can reduce postprandial blood glucose levels and prolong GLP-1 and GIP biological activities. Therefore, a HF diet was used to preinduce obese rats, and then Et-S/Et-L was used together with HF to investigate the improved possibility of impaired glucose tolerance in obese rats. Figure 2 shows the increased body weights in Wistar rats fed normal diets (ND) or HF without or with S-Et (Figure 2A) or L-Et (Figure 2B) interventions at doses of 20 mg/kg (Et20) and 50 mg/kg (Et50). The increased body weight (g) at day 68 in HF groups was 212.73 ± 21.05, 223.47 ± 7.66, 199.93 ± 10.46, 212.37 ± 19.67, and 193.53 ± 14.19, respectively, for HF + S-Et20, HF + S-Et50, HF + L-Et20, HF + L-Et50, and HF. The rats in the HF groups without or with S-Et or L-Et interventions showed no significant difference ($P > 0.05$) in weight increases on the day of experiment end. The increased body weight (g) at day 68 in the ND group was only 119.35 ± 9.00. This was significantly

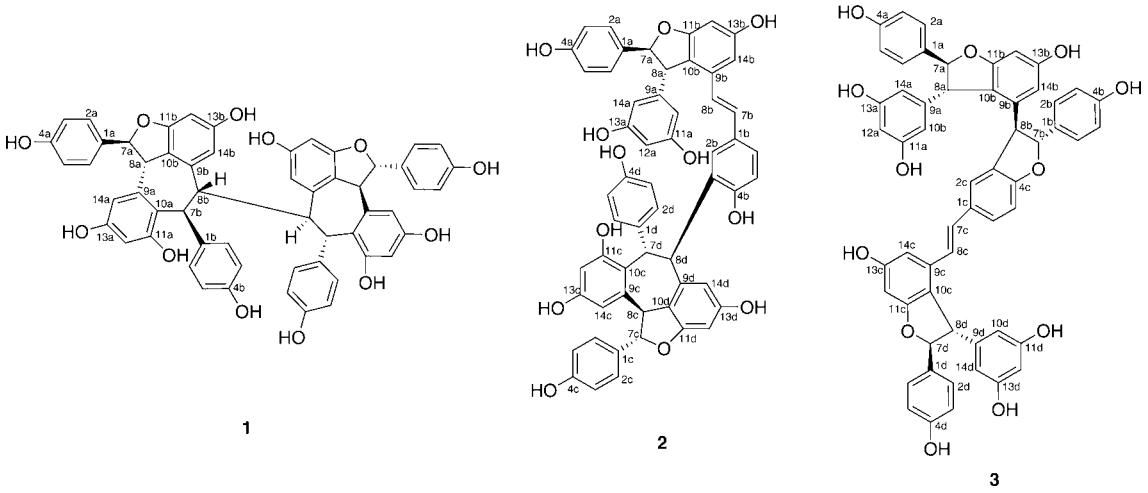

Figure 3. Chemical structures of three compounds, (+)-hopeaphenol (**1**), (+)-vitisin A (**2**), and (−)-vitisin B (**3**), isolated from the ethyl acetate fractions of stem ethanol extracts of *Vitis thunbergii* var. *taiwaniana*.

different ($P < 0.05$) compared to the HF group. The standard chow of normal diet (Table S1) in the present experiment was not a real low-fat diet control, and hence the protocol was not easy to compare to the efficiency of the normal diet group and the HF-induced groups in the increased rat body weights. From the present results, S-Et or L-Et interventions at 20 and 50 mg/kg for around 5 weeks showed no weight reduction in preobese rat models. Meanwhile, rats with similar weights in different HF groups and rats in the ND group were used to evaluate the impaired glucose tolerance by OGTT after fasting for 16 h (Figure 2C,D). Figure 2C shows the basal level (0 min) and plasma glucose concentrations (mg/dL) after glucose loads at 5, 30, 60, 90, and 120 min of HF + S-Et20, HF + S-Et50, HF, and the blank groups. After glucose loads for 120 min, the rats in the HF group still showed high plasma glucose concentrations, a symptom of impaired glucose tolerance. However, the rats in the S-Et intervened groups seemed to improve with respect to impaired glucose tolerance in OGTT profiles. The obese rats in the HF + S-Et20 and HF + S-Et50 groups showed the lowest plasma glucose concentrations at the basal level, and each time the intervals and significant differences ($P < 0.05$) were compared to those of the HF group and the ND group. Figure 2D shows the basal level (0 min) and plasma glucose concentrations (mg/dL) after glucose loads at 5, 30, 60, 90, and 120 min of HF + L-Et20, HF + L-Et50, and HF compared to the ND group. The rats in the L-Et intervened groups seemed to improve with respect to impaired glucose tolerance in OGTT profiles. The plasma glucose concentrations of obese rats in the intervened groups of HF + L-Et20 and HF + L-Et50 showed lower and significant differences ($P < 0.05$) compared to those of the HF group at the basal level and at each time interval. Rats in the L-Et50 intervened groups showed better and significant difference ($P < 0.05$) in OGTT profiles at 0, 5, 30, and 60 min after glucose loads and were comparable at 90 and 120 min time intervals compared to rats in the ND group. From the present OGTT data, S-Et and L-Et interventions showed improved activities against impaired glucose tolerance in obese rats, and S-Et interventions seemed to result in greater improvement than L-Et interventions. Lin et al.[15] reported that VTT-S-Et showed better than VTT-L-Et in angiotensin converting enzyme inhibitory activities, and the oral administration of VTT-S-Et exhibited antihypertensive activities in spontaneously hypertensive rats. The improved OGTT profiles in obese rats of VTT-S-Et or VTT-L-Et interventions together with antihypertensive activities[15] provided evidence that VTT extracts could be processed as health-promoting foods. The HF provides 20 and 60% of total calories, respectively, from carbohydrate and fat in the diets. S-Et and L-Et showed excellent yeast α-glucosidase inhibitory and partial DPP-IV inhibitory activities in vitro (Figure 1), which might correlate with the improvement of impaired glucose tolerance in obese rats (Figure 2C,D). The S-Et intervention showed better than L-Et in OGTT results (Figure 2B). The S-Et-EA fraction in vitro screening test showed good anti-α-glucosidase and DPP-IV inhibitory activities; therefore, the EA partitioned fraction from S-Et was selected to isolate the active compounds for further studies.

Compounds Isolated from S-Et-EA. Stilbenoid compounds are rich in *Vitis* genus plants and are considered as the active constituents in them. All 24 fractions were analyzed by HPLC method and monitored at the characteristic UV absorption wavelength of stilbenoids, 280 nm. Fraction 24 was found to contain the most abundant stilbenoid compounds and was thus selected for further purification. Three resveratrol tetramers, **1**−**3** (Figure 3), were isolated from the S-Et-EA and identified by comparing their physical and spectral data (specific rotation, MS, and NMR) with the available values in the literature. The chemical structures of these compounds were identified as (+)-hopeaphenol (**1**),[24] (+)-vitisin A (**2**),[25] and (−)-vitisin B (**3**),[26] and the spectral properties were as follows.

(+)-Hopeaphenol (**1**): brown-yellow powder; $[\alpha]_D^{25}$ +390.0° (*c* 0.35, MeOH); ESI-MS *m*/*z* 907 $[M + H]^+$; ^{1}H NMR (400 MHz, acetone-d_6) δ 7.12 (2H, d, *J* = 8.4 Hz, H-2a, 6a), 6.89 (2H, d, *J* = 8.4 Hz, H-2b, 6b), 6.77 (2H, d, *J* = 8.8 Hz, H-3a, 5a), 6.54 (2H, d, *J* = 8.8 Hz, H-3b, 5b), 6.28 (2H, d, *J* = 2.4 Hz, H-14a), 5.80 (1H, br s, H-7b), 5.73 (1H, d, *J* = 12.0 Hz, H-7a), 5.71 (1H, d, *J* = 2.0 Hz, H-12b), 5.15 (1H, d, *J* = 2.0 Hz, H-14b), 4.22 (1H, d, *J* = 12.0 Hz, H-8a), 3.93 (1H, d, *J* = 4.8 Hz, H-7b).

(+)-Vitisin A (**2**): brown solid; $[\alpha]_D^{25}$ +210.5° (*c* 0.4, MeOH); ESI-MS *m*/*z* 907$[M + H]^+$; ^{1}H NMR (400 MHz, acetone-d_6) δ 7.19 (2H, d, *J* = 8.5 Hz, H-2a, 6a), 7.14 (2H, d, *J* = 8.5 Hz, H-2c, H-6c), 7.02 (2H, d, *J* = 8.3 Hz, H-2d, H-6d), 6.87 (1H, dd, *J* = 8.4, 2.2 Hz, H-6b), 6.81 (2H, d, *J* = 8.5 Hz, H-

	control	0.3125 μM	1.25 μM	control	0.3125 μM	0.625 μM
inhibition type		mixed noncompetitive			mixed noncompetitive	
K_m or K'_m[a] (mM)	0.719	0.845	0.981	0.719	0.866	1.058
V_{max} or V'_{max}[b]	0.095	0.0871	0.0737	0.095	0.086	0.072
K_i[c] (μM)		1.784			0.633	
K_{is}[d] (μM)		3.842			1.249	

	DPP-IV inhibition (−)-vitisin B			
	control	5 μM	15 μM	25 μM
inhibition type		mixed noncompetitive		
K_m or K'_m[a] (mM)	1.25	1.029	0.941	0.927
V_{max} or V'_{max}[b]	0.0208	0.0153	0.00878	0.00543
K_i[c] (μM)		7.661		
K_{is}[d] (μM)		11.361		

[a]K_m and K'_m are Michaelis constants in the absence and presence of inhibitor, respectively. [b]V_{max} and V'_{max} are maximal velocities in the absence and presence of inhibitor, respectively. [c]Enzyme−inhibitor dissociation constant. [d]Enzyme−substrate dissociation constant.

100% inhibition was found. Therefore, different dilutions and different concentrations for each purified compound were used to perform α-glucosidase inhibition. These three compounds, (+)-hopeaphenol, (+)-vitisin A, and (−)-vitisin B, showed dose-dependent inhibitions against α-glucosidase with IC_{50} values of 18.3, 1.22, and 1.02 μM, respectively, compared to the IC_{50} of acarbose of 6.39 mM. These three resveratrol tetramers with the same molecular mass showed much more significant α-glucosidase inhibitory activities than that of acarbose. (+)-Hopeaphenol, (+)-vitisin A, and (−)-vitisin B showed about 350-, 5340-, and 6265-fold better α-glucosidase inhibitions than acarbose. Therefore, the first two potent α-glucosidase inhibitors of (+)-vitisin A and (−)-vitisin B with similar IC_{50} values were selected for further kinetic analyses. It was found that (+)-vitisin A (Figure 4B) and (−)-vitisin B (Figure 4C) showed mixed-type noncompetitive inhibition against α-glucosidase with respect to pNPG (substrate) and pNPG−α-glucosidase (substrate−enzyme complex). In the absence of (+)-vitisin A, the K_m and V_{max} were 0.719 mM and 0.095 (Δ*A*405/min), respectively; whereas with the 0.3125 and 1.25 μM (+)-vitisin A additions, the K'_m was increased to 0.845 and 0.981 mM, and V'_{max} was decreased to 0.0871 and 0.0737 (Δ*A*405/min). The calculated K_i and K_{is} for (+)-vitisin A, respectively, were 1.784 and 3.842 μM (Table 1). In the absence of (−)-vitisin B, the K_m and V_{max} were 0.719 mM and 0.095 (Δ*A*405/min), respectively; with the 0.3125 μM and 0.625 μM (−)-vitisin B additions, the K'_m was increased to 0.866 and 1.058 mM and V'_{max} was decreased to 0.086 and 0.072 (Δ*A*405/min). The calculated K_i and K_{is} for (−)-vitisin B, respectively, were 0.633 and 1.249 μM (Table 1). Tadera et al.[27] tested 16 flavonoids against yeast α-glucosidase activity (IC_{50}, μM), among which epigallocatechin gallate (2 μM), cyanidin (4 μM), myricetin (5 μM), and quercetin and genistein (7 μM) showed excellent yeast α-glucosidase inhibition with IC_{50} values of <10 μM; however, none of them were active inhibitors against rat intestinal α-glucosidase. In fact, the current results for (+)-vitisin A and (−)-vitisin B exhibited better inhibitory activities than those reported by Tadera et al.[27] The low values of K_i and K_{is} represented less dissociation of the inhibitor−enzyme complex and inhibitor−enzyme−substrate complex, respectively, with high inhibitory potency. Tadera et al.[27] reported the potent flavonoids against yeast α-glucosidase activities in mixed noncompetitive patterns with K_i and K_{is} values of 3 and 7.6 μM for epigallocatechin gallate, 3 μM and 7.6 μM for myricetin, 3.4 μM and 14 μM for quercetin, and 52 μM and 4.2 μM for genistein, which were higher than those with (+)-vitisin A (1.784 and 3.842 μM) and (−)-vitisin B (0.633 and 1.249 μM) in the present study. The yeast α-glucosidase has been widely used to evaluate α-glucosidase inhibitory ability. However, Oki et al.[28] have indicated that the efficacy of α-glucosidase inhibition was greatly affected by different origins. Therefore, α-glucosidase from mammalian will be used for further investigations.

Anti-DPP-IV Activities of (+)-Hopeaphenol, (+)-Vitisin A, and (−)-Vitisin B. Three isolated compounds from S-Et-EA were used to determine the DPP-IV inhibitory activities compared to the positive control of sitagliptin (Figure 5A). Before the determinations of IC_{50} inhibitions, the same 25 μM was used for prescreening tests. For hopeaphenol, about 10% inhibition was found; for vitisin A, about 25% inhibition was found; and for vitisin B, about 80% inhibition was found. Therefore, different dilutions and different concentrations for each purified compound were used to perform DPP-IV inhibitions. These three compounds, (+)-hopeaphenol, (+)-vitisin A, and (−)-vitisin B, showed dose-dependent inhibitions against DPP-IV with IC_{50} values of 401, 90.75, and 15.3 μM, respectively, compared to sitagliptin (IC_{50} = 47.35 nM). (−)-Vitisin B showed about 26- and 6-fold better DPP-IV inhibitions than (+)-hopeaphenol and (+)-vitisin A and less than that of sitagliptin. Therefore, the potent DPP-IV inhibitor (−)-vitisin B was selected for further kinetic analyses. (−)-Vitisin B showed mixed noncompetitive type (close to noncompetitive type) inhibition against DPP-IV with respect to Gly-pNA (substrate) and Gly-pNAp−DPP-IV (substrate−enzyme complex) (Figure 5B). In the absence of (−)-vitisin B, the K_m and V_{max} were 1.25 mM and 0.0208 (Δ*A*405/min), respectively; with 5, 15, and 25 μM (−)-vitisin B additions, the K'_m was decreased to 1.029, 0.941, and 0.927 mM. However, the V'_{max} was also decreased to 0.0153, 0.00878, and 0.00543 (Δ*A*405/min). The calculated K_i and K_{is} for (−)-vitisin B, respectively, were 7.661 and 11.361 μM (Table 1). The DPP-IV inhibitory activities were frequently screened from protein

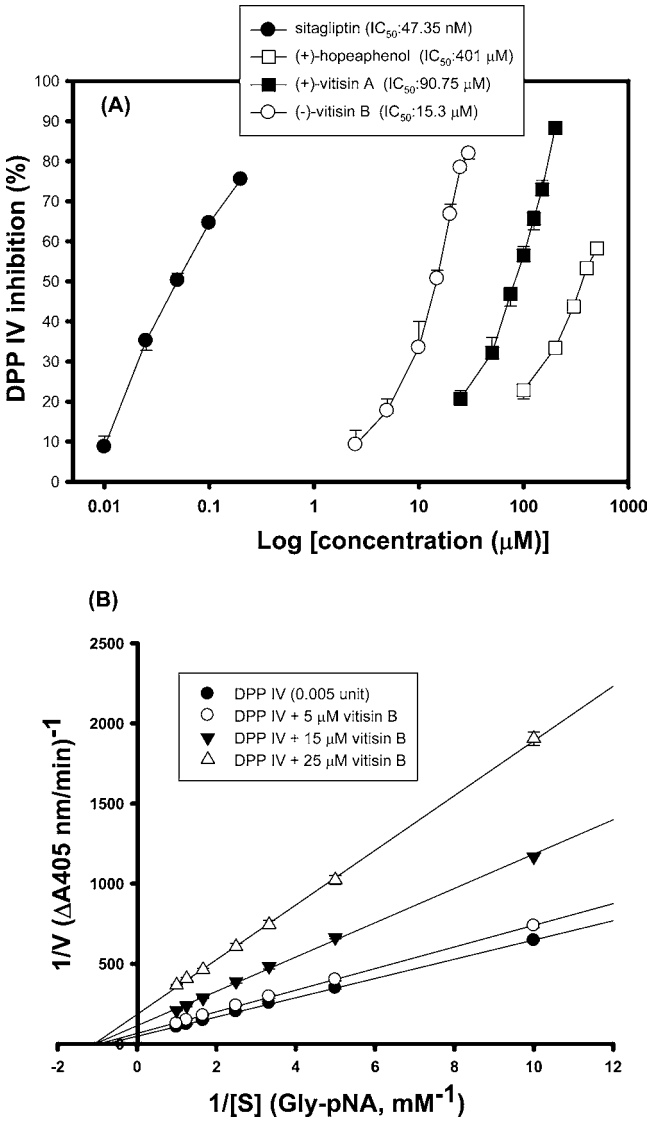

Figure 5. (A) Effect of different concentrations of (+)-hopeaphenol, (+)-vitisin A, and (−)-vitisin B on dipeptidyl peptidase-IV (DPP-IV) inhibitory activities compared to the positive control of sitagliptin. (B) Lineweaver−Burk plots of DPP-IV (0.005 U) without or with (−)-vitisin B at the different concentrations of Gly-Pro-*p*-nitroanilide as substrate (0.1, 0.2, 0.3, 0.4, 0.6, 0.8, and 1 mM). Fifty percent inhibition (IC_{50}) of DPP-IV activity was calculated as the concentration of sample that inhibited 50% of DPP-IV activity under tested conditions. Data are expressed as the mean ± SD (n = 3).

hydrolysates, such as pepsin-treated whey proteins[21] or pepsin-treated yam dioscorin.[22] Fan et al.[29] reported the DPP-IV inhibitory activities from flavonoids by using luciferase assay kits, among which luteolin, apigenin, and flavone for DPP-IV inhibition, respectively, were the noncompetitive type, non-competitive type, and competitive type. For the K_i from the Lineweaver−Burk plot, the results were 4.9, 7.9, and 18.6 μM, respectively. Saleem et al.[30] reported the potent DPP-IV inhibitory activities (expressed as IC_{50}) including quinovic acid (30.7 μM), quinovic acid-3*β*-*O*-*β*-D-glycopyranoside (57.9 μM), and quinovic acid-3*β*-*O*-*β*-D-glucopyranosyl-(28-1)-*β*-D-glucopyranosyl ester (23.5 μM) from *Fagonia cretica* and lupeol (31.6 μM) from *Hedera nepalensis*. It was suggested that the improved impaired glucose tolerance in HF-induced obese rats after S-Et interventions might be in part due to α-glucosidase and DPP-IV inhibitory activities. Interestingly, several results have indicated that VTT ethanol extracts showed an antiobesity effect and preferentially improved glucose and lipid dysregulation in developing obese mice.[31] Moreover, vitisin A could inhibit 3T3L1 adipocyte differentiations through p21-dependent and Rb-dependent cell cycle arrest, which resulted in suppressions of preadipocyte proliferation.[32] Taken together, these results suggested that VTT ethanol extract or vitisin A might reduce serum lipid levels and inhibition against preadipocyte differentiations to suppress the development of obesity. In the present study VTT-Et might act to inhibit α-glucosidase and DPP-IV activities to ameliorate impaired glucose tolerance rather than weight loss in obese rats. Therefore, the conflicting results could be due to different obesity stages.

In conclusion, the current results showed that the isolated compounds, resveratrol tetramers of (−)-vitisin B and (+)-vitisin A, effected excellent inhibitory activities against yeast α-glucosidase and DPP-IV, which might correlate with the VTT-Et interventions in improvements of impaired glucose tolerance in diet-induced obese rats. Therefore, on the basis of the observed biological functions of the current results, the development of VTT extracts as functional foods may be beneficial for blood glucose regulation and diabetic management.

products prone to *Listeria* infections because of its high antilisterial activity and narrow inhibitory spectrum. As information on the structure and underlying mechanisms of durancin GL remains limited at the molecular level, widespread functional screening of its residues must be developed.

In this study, we constructed an in vitro heterologous expression system to produce mature durancin GL in *Escherichia coli*. Alanine substitution was also performed through site-directed in vitro mutagenesis with the constructed expression vector. The effects of mutations on the potency or specificity of the peptide toward *L. monocytogenes* and other selected indicator strains were also determined.

MATERIALS AND METHODS

Bacterial Strains, Plasmids, and Culture Conditions. The strains and plasmids used in this study are listed in Table 1. *Trans1*-T1 phage-resistant chemically competent *E. coli* and *pEASY*-Blunt simple cloning vector (TransGen Biotech, Beijing, China) were used for standard cloning procedures. Chemically competent *E. coli* Rosetta (DE3) was prepared using a competent cell preparation kit (Takara) according to the manufacturer's recommendations. *E. durans* 41D, a bacteriocin-producing strain, and other LAB strains, such as *Lactococcus*, *E. durans*, *Enterococcus faecalis*, and *Enterococcus faecium*, were propagated at 37 °C without agitation in M17 broth (Becton, Dickinson Co. Ltd., Franklin Lakes, New Jersey, USA). *Listeria* spp., *Bacillus subtilis*, *Staphylococcus aureus*, and *Bacillus licheniformis* were propagated in brain heart infusion (BHI) medium (Land Bridge Co., Ltd., Beijing, China) under aerobic conditions at 37 °C. *E. coli* strains were grown in LB medium at 37 °C on a shaking incubator. When required, antibiotics (Ameresco Co., Ltd., USA) were added as selective agents with appropriate concentrations (ampicillin, 50 μg/mL; kanamycin, 50 μg/mL).

Construction of Recombinant Plasmid and DNA Transformation. The constructs used in this study are listed in Table 1. DNA cloning techniques, transformations, and restriction enzyme reactions were performed according to the standard protocols[18] or by following the recommendation of the manufacturers. Plasmids were isolated from *E. coli* by using a high-purity plasmid mini-prep kit (BioTeke, Beijing, China). Restriction enzymes and DNA ligation kit were obtained from Takara Biotech (Dalian, China) and Sangon Biotech Co., Ltd. (Shanghai, China), respectively. Primers were designed according to the plasmid pGL sequence (Accession no. HQ696461.1) and synthesized by Sangon Biotech (Shanghai, China). The *Trans*1-T1 phage-resistant chemically competent *E. coli* and *E. coli* Rosetta (DE3) were transformed using heat-shock method.[19]

DOI: 10.1021/acs.jafc.5b02114
J. Agric. Food Chem. 2015, 63, 6402−6409

The *durAB* genes were amplified using dur1 and dur2 primers and PrimeSTAR HS Premix (TaKaRa) with 1 μL of overnight broth containing fresh *E. durans* 41D as template. Amplification conditions were as follows: preheating at 95 °C for 3 min, 30 cycles of denaturation at 95 °C for 15 s, annealing at 55 °C for 20 s, extension at 72 °C for 40 s, and a final extension at 72 °C for 7 min. PCR-generated fragments were analyzed by agarose gel electrophoresis and purified using a DNA fragment purification recovery kit (Bioteke Corporation, Beijing, China). The DNA fragments were subcloned into a cloning vector by using a *pEASY*-blunt simple cloning kit (TransGen, Beijing, China) to produce the *pEASY*/durAB construct. The ligation mixture was transformed into *Trans*1-T1 phage-resistant chemically competent *E. coli*. The positive clones were screened through PCR using M13-F and M13-R primers and sequenced by Sangon Biotech.

The his-durAB fragment was amplified using GST1 and GST2 primers with *pEASY*/durAB plasmid as template. The amplified fragment was digested with *Bam*H I and *Xho* I before subcloning into the plasmid pGEX-6p-1 to construct the expression vector pGEX/his-durAB (Figure 1). Ligation was then performed with a DNA ligation

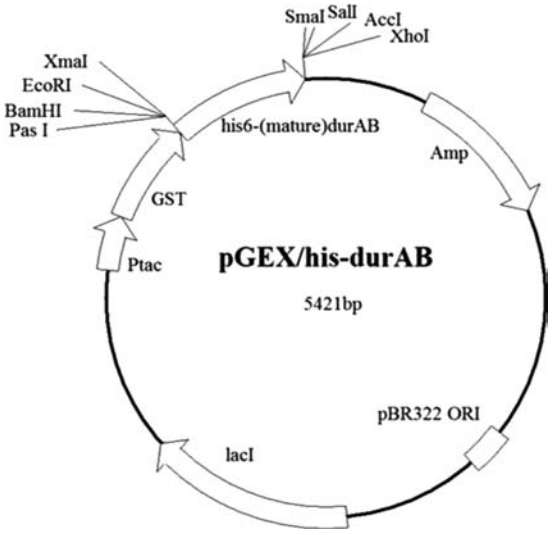

Figure 1. Map of the expression vector pGEX/his-*dur*AB with ORFs indicated by arrows.

kit (TaKaRa). Chimeric DNA was transformed into *Trans*1-T1 phage-resistant chemically competent *E. coli*. PCR analysis with pGEX-3 and pGEX-5 primers and DNA sequencing (Sangon Biotech Co) were used to confirm the correct construction of the plasmid. The correct pGEX/his-durAB plasmid was reisolated and transformed into *E. coli* Rosetta (DE3). By using the cloning strategy proposed in this work, we obtained the translational fusion protein of GST-His-durancin GL.

Site-Directed Mutagenesis and Construction of Variants. Durancin GL mutations were generated using a Mut Express II fast mutagenesis kit (Vazyme Biotech Co., Nanjing, China) with the pGEX/his-durAB plasmid as template. The mutant primers used are presented in Table 2 and Supporting Information Table S1. PCR reactions were established according to the manufacturer's recommendations. The PCR product was digested for 1 h at 37 °C with the restriction enzyme DpnI (Vazyme Biotech) to eliminate the original template and increase mutation efficiency. After homologous recombination and linear plasmid cyclization, the circular mutant plasmid was then transformed into *E. coli*. The proper orientation of the fragments was verified through PCR analysis using pGEX-3 and pGEX-5 primers, and the accuracy of mutagenesis was confirmed through DNA sequencing. After sequence confirmation, the plasmid was introduced into *E. coli* Rosetta (DE3) for protein expression.

Protein Expression and Purification. The fusion protein GST-His-durancin GL was purified by Ni-NTA and GST affinity purification system (GE Healthcare Co., USA) according to the manufacturer's instructions. The transformed plasmids encoding wild-type durancin GL and mutants were grown overnight in 25 mL of LB containing 50 μg/mL ampicillin at 37 °C. About 9 mL of the respective precultures were inoculated into 900 mL of LB, grown at 37 °C until OD_{600} = 0.6, and then induced with 1.0 mM IPTG (final concentration) for 5 h. Cells were collected through centrifugation at 8000*g* at 4 °C for 5 min. The cell pellets were resuspended in 90 mL of Ni−NTA binding buffer (20 mM sodium phosphate, 20 mM imidazole, 500 mM NaCl, pH 7.4) and sonicated in an ice bath (400 W, 400 cycles of 2 s pulses with a 9 s pause). The lysate was centrifuged at 4 °C for 30 min at 12000*g* to remove debris. The supernatant was filtered through a 0.22 μm filter (Sartorius; Goettingen, Germany) before loading onto a 1 mL nickel His-Trap chelating column (GE Healthcare, Beijing, China). After loading, the column was washed with 10 mL of Ni−NTA binding buffer. The bound His-tagged proteins were eluted from the Ni resin with 10 mL of elution buffer (20 mM sodium phosphate, 500 mM NaCl, 500 mM imidazole, pH 7.4). The eluent was dialyzed overnight at 4 °C against 2 L of GST binding buffer (140 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 2 mM KH_2PO_4, pH 7.3) by using 7 kDa MWCO dialysis membranes (Millipore, USA). After centrifugation (12000*g* for 20 min), the supernatant was loaded onto GSTrap 4B column (GE Healthcare). The column was washed with 10 mL of GST binding buffer and 10 mL of enterokinase cleavage buffer (25 mM Tris-HCl, 50 mM NaCl, 2 mM $CaCl_2$, pH 7.6). Enterokinase cleavage mixture (Sangon Biotech) was then loaded onto the column. The column was then incubated at 25 °C for 16 h and eluted with 5 mL of enterokinase cleavage buffer. The eluate was collected and verified through mass spectrometry (MoonBiochem Co., Ltd., Wuhan, China). Final concentration was adjusted to 20 μg/mL for subsequent usage.

Antibacterial Activity Assay of Durancin GL and Its Mutants. The overnight culture of *E. durans* 41D (propagated in MRS broth) was centrifuged at 12000*g* for 10 min to obtain cell-free supernatant, which was used as control. With *L. monocytogenes* and *Listeria innocua* as targets, antibacterial activity assay was performed using agar diffusion method with a peptide concentration of 20 μg/mL.[20] The diameter of each inhibition zone was measured and integrated into calculation for total activity.

For antimicrobial spectrum inspection, minimum inhibitory concentration (MIC) was determined using the method described by Pilet et al.[20] Briefly, 5 μL of 2-fold serially diluted purified peptide (20 μg/mL starting concentration) was spotted in duplicates on BHI agar plates seeded with 0.5% (v/v) of indicator strain cultured for 16 h. The plates were then air-dried and incubated at 37 °C for 10−14 h. The resulting inhibition zones were detected through inspection. MIC was determined as the lowest concentration that inhibited visible growth. The MIC results showed that the required concentration of durancin GL was 2.5 μg/mL, and this concentration was used for all the mutants for antibacterial activity assay.

RESULTS

Expression and Purification of the Fusion Protein of Durancin GL (GST-his-durancin GL) and Its Variants. The sequence of the recombinant plasmid pGEX/his-*dur*AB was consistent with the anticipated results (data not shown). The recombinant GST-His-durancin GL was then expressed in *E. coli* Rosetta (DE3). A clear band of about 31.0 kDa was observed after IPTG induction at 37 °C (Figure 2A), which was consistent with the expected molecular mass of GST-His-durancin GL. After purified through Ni−NTA metal affinity chromatography, GST affinity chromatography and then treated with the recombinant bovine enterokinase. The purity of the isolated peptides was checked through analytical reverse-phase chromatography to be higher than 95% (Figure 2A). As shown in Figure 2B, the expressed cleaved durancin GL was biologically active against the indicator strain *L. monocytogenes* and *L. innocua* as determined through agar diffusion method.

[a]Other primers used for site-directed mutagenesis are listed in the Supporting Information Table S1. [b]Cleavage sites for restriction enzymes are underlined in the primers. Lowercase letters indicate incorporated tag sequences.

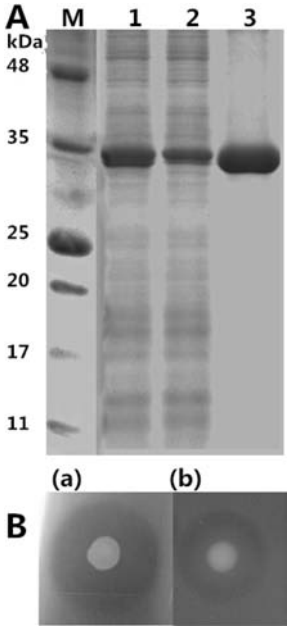

Figure 2. (A) SDS-PAGE analysis of the expression of GST-His-durancin GL and protein purification. Lane M, prestained protein standard; lanes 1 and 2, lysate of *E. coli* Rosetta (DE3) transformed with pGEX/his-*dur*AB; lane 3, GST-His-durancin GL purified with Ni-NTA and GST affinity columns. (B) Bacteriocin activity of the cleaved durancin GL after enterokinase treatment of GST-His-durancin GL; Activity was determined through agar diffusion method with *L. monocytogenes* (a) and *L. innocua* (b) as target microorganisms.

Durancin GL variants were expressed and purified using methods similar to those used for the wild-type. Sequencing of the mutated genes and analysis of the purified peptides through mass spectrometry revealed correct alterations in the primary structure in all samples (results not shown). Our results indicated that durancin GL can be readily subjected to mutagenesis, and large quantities (29.5 mg to 46.3 mg per L) of a desired mutant can be obtained through recombinant expression.

Determination of Antibacterial Activities. Each durancin GL residue was replaced with a hydrophobic small residue (alanine) through site-directed mutagenesis, and activity changes were calculated relative to that of wild-type durancin GL (Table 3). Overall, *L. monocytogenes* was more susceptible than *L. innocua* on the basis of the size of the inhibition zone of the corresponding bacteriocin (e.g., Figure 2B). Two other strains, namely, *E. durans* 9EB8 and *E. faecalis* 6.0603, were further used to detect general trends in mutational effects, and the activities measured using these two strains were in the same trend (data not shown).

As shown in Table 3, no activity was detected in G07A, C10A, and C15A mutants up to 20 μg/mL, indicating that these residues are essential for the antibacterial activity. Ten mutations (N06A, E14A, W16A, D18A, E25A, G27A, I29A, N32A, G33A, and G38A) demonstrated a detrimental effect on the activity (relative activities $\leq$80%), and seven mutations (K12A, K21A, K24A, K28A, I30A, H37A, and R43A) exhibited a relatively high activity (relative activities $\geq$110%). In addition, 21 other mutations were relatively tolerated, resulting in slight reduction or increase in the activity of mutants compared with wild-type durancin GL.

The MIC of all purified mutants was determined using two indicator strains, namely, *L. monocytogenes* and *L. innocua*, through microdilution method. Most mutants displayed antibacterial activity similar to the wild-type, whereas some mutants increased or decreased the activity for about 2-fold (MIC values in the Supporting Information S2). As the activities measured using *L. monocytogenes* and *L. innocua* were in the same trend based on the MIC results, the concentration for the inhibitory spectra determination of the durancin GL and its mutants was determined to be 2.5 μg/mL.

Determination of Inhibitory Spectra against Different Indicator Organisms. The antibacterial activity spectra of durancin GL analogues were assayed through agar diffusion

[a]Antibacterial activity was tested by agar diffusion method with a concentration of 20 μg/mL. Relative to WT (%) was defined as the ratio of the area (mm^2) of the inhibition zone formed by the wild type to that formed by the mutant, multiplied by 100%. –, no inhibition; CFS, cell-free culture supernatant; WT, wild-type; activity of the CFS was determined as control. Data are mean ± SD of three independent experiments.

method against a wide range of Gram-positive microorganisms (Table 4), including foodborne pathogens and probiotics of similar species and related strains. According to the size of the inhibition zones, *E. durans* showed the highest sensitivity to the purified durancin GL and its variants (Table 4). Only some *E. faecium* and *E. faecalis* strains also exhibited sensitivity to the purified durancin GL and its variants at a low level, which indicates that these bacteriocins displayed a relatively narrow spectrum of activity, which was mostly limited to *Enterococcus* (closely related to bacteriocin producer) and *Listeria* cultures.

The inhibitory spectra of durancin GL analogues differed from that of the wild-type. G07A, C10A, C15A, W16A, and N20A mutants showed no antimicrobial activity against any indicator strains at the concentration of 2.5 μg/mL, indicating these residues were important for the bacteriocin activity. D18A, K21A, G27A, and G38A mutants demonstrated a narrow antimicrobial spectrum compared with wild-type durancin GL, implying their importance for target specificity. K12A, Q13A, I30A, and V31A mutants presented a broader target cell spectrum and increased potency than wild-type durancin GL. These mutants also inhibited durancin GL resistant strains, namely, *L. lactis* 1363 and *E. faecium* R36. These results indicated that K12A, I30A, and V31A mutants were "activity enhancing" substitutions for all indicator strains, whereas Q13A mutant enhanced target specific activity against *L. lactis* 1363 and *E. faecium* R35. Therefore, position/orientation may be important to modulate the spectrum of target cells. A similar phenomenon was observed in N6A, V8A, E14A, V17A, S23A, E25A, P39A, and W40A mutants, which demonstrated enhanced specific activity against *E. faecium*. Several other mutants further exhibited activity against five *E. faecalis* strains, whereas some mutants showed a weaker activity against one or two indicators. Generally, most mutants presented no inhibitory activity against four *E. faecium* strains, except in cases with a low level of activity retention.

DISCUSSION

Durancin GL, a class IIa bacteriocin, is highly homologous to bacteriocin 31 and has been recently characterized.[16,17] Durancin GL belongs to the subgroup 4 of subclass IIa bacteriocins, which include bacteriocin 31, bacteriocin RC714, bacteriocin T8, penocin A, and enterocin SE-K4.[21] As durancin GL exhibits a high level of antilisterial activity with a relatively narrow spectrum limited to *Enterococcus* and *Listeria* cultures, it exhibits significant potential to be used as a food-grade preservative for LAB fermentations which are prone to *Listeria* infections. Nevertheless, data (available for durancin GL or even subgroup 4 of IIa bacteriocins) regarding bacteriocin structure and underlying mechanisms are limited at the molecular level; hence, each durancin GL residue must be subjected to systematic functional screening through site-directed mutagenesis. In this study, the recombinant durancin GL was expressed in *E. coli* Rosetta (DE3) fused after GST and His tag. All durancin GL residues were then subjected to systematic mutational analysis.

The fold changes in MIC values were not significant, except for G07A, C10A, and C15A mutants, which exhibited significant detrimental effect on the activity; these findings were consistent with the conservative residues of class IIa bacteriocins.[22] Replacement of Cys10 and Cys15 in durancin GL presented adverse effect on the activity; these highly conserved cysteines are essential for the stability of N-terminal β-sheet domain in all class IIa bacteriocins because of their role in formation of Cys10−Cys15 disulfide bonds.[8] Alanine alteration can disrupt the formation of Cys10−Cys15 disulfide bonds, thus resulting in antibacterial activity loss.

By contrast, mutations, such as Y04A, G05A, N06A, and V08A, at other positions of the conserved motif were well tolerated. The replacement of G7 with alanine triggered a functional loss. This result was in accordance with previous

studie on the corresponding glycine in position 6 of pediocin PA-1 and sakacin P.[23] These findings indicated that G7 in durancin GL plays an important role within the YGNGV motif. As GNGV may assume a β-sheet-like structure, alanine substitution at this position could destroy β-turn and lead to activity loss.[15,24]

In comparison with wild-type durancin GL, activities against *L. monocytogenes* and *L. innocua* were altered to different extents in all variants. The limited effect of most mutants could be attributed to conservative alanine substitution (small and nonpolar) relative to other amino acid replacements (with regard to size, polarity, and charge). However, several mutants, such as Q13A, I30A, and V31A, further displayed changes in their inhibition zones and inhibitory spectra, indicating their importance for durancin GL activity, but their contribution varied in terms of magnitude.

Most substitutions localized in the N-terminal moiety exhibited adverse effect on the activity, but antimicrobial activity was enhanced in K12A mutant. This finding was unforeseen because Lys12 is a highly conserved residue in subgroup 4 of class IIa bacteriocin;[25] moreover, positively charged residues at the N terminus are important for recognition and binding of the target bacterial membrane.[4] Bacteriocin mutants decrease the net positive charge of the N-terminal β-sheet-like domain by introducing a neutral polar residue, resulting in 2−100-fold reduction in activity.[24] In addition, K12 is the only positively charged residue in the N-terminal domain of durancin GL. The negatively charged

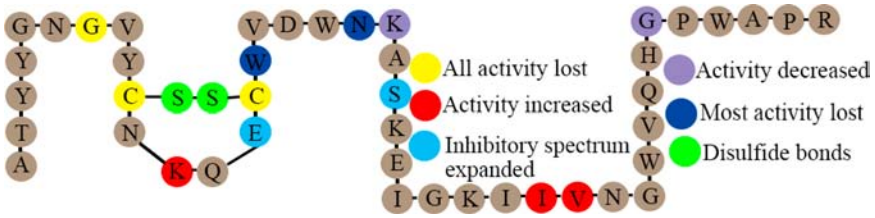

Figure 3. Most important residues unraveled by alanine-scanning method.

replacement E14A further showed a significant decrease in antibacterial activity, but these results were not isolated. Substitutions at K21, K24, K28, H37, R43 (positively charged), D18, and E25 (negatively charged) also exhibited an identical effect on the activity. Notably, D18A considerably decreased the value by approximately 50%, suggesting that this residue is critical for activity. Previous structural analysis of five pediocin-like bacteriocins (leucocin A, carnobacteriocin B2, curvacin A, sakacin P, and sakacin mutation) revealed a flexible hinge at the conserved Asp17/Asn17 in the peptides of subgroup 1; this hinge also possibly existed between the β-sheet N-terminal region and the hairpin-like C-terminal region in the peptides of subgroups 2, 3, and 4.[24] Hence, negative charge and residue position are important. These results may imply that the net charge of durancin GL is essential for its antilisterial activity, and peptides with a net charge of +2 are preferred for its initial interaction with the acidic membrane or receptor proteins of *Listeria*. However, the optimal net charge of bacteriocin to achieve maximum activity remains unknown and requires further mutation studies.

Replacement of the conserved or partially conserved asparagine residue (positions 6 and 32) with alanine reduced bacteriocin activity by more than 30%. By contrast, substitution of N11 or N20 residues, which are less conserved, minimally affected the activity. These results are in agreement with those reported by Gunnar Fimland;[24] in his study, the polar amide group in position 5 and its exact location in space are crucial for pediocin-like bacteriocins to be fully active. Hence, the amide group interacts in a structurally specified and restricted manner with the polar group(s) on target cells, possibly on a peptide receptor or docking site or on the peptide itself. Asn32 may also interact with target cells in a similar manner.

As residue Trp15 (corresponding to Trp16 in durancin GL) is typical in groups 3 and 4 bacteriocins,[21] its replacement abolished the antibacterial activity in the inhibitory spectrum assay; this finding indicated that aromaticity or hydrophilicity is important at this position. Tryptophan residues also play a determinant role in the adsorption and orientation of amphiphilic peptides and proteins in the membranes; these residues can form hydrogen and hydrophobic bonds with the polar and nonpolar groups of polar lipids.[26,27] In particular, Trp16 at the adjoining part of the N- and C-terminal domains could play a major role in the proper domain orientation within the membrane. Trp18 is conserved in groups 1, 2, and 4 bacteriocins, Trp33 is conserved in groups 3 and 4, and Trp39 is partially conserved in groups 1 and 4 (which correspond to Trp19, Trp34, and Trp40 in durancin GL, respectively).[21] However, W16A mutant exhibited negative effects compared with W19, W34, and W40 mutants, which had similar activity to the wild-type but limited effect because hydrophobic and aromatic residues were replaced with small and nonpolar residues. Two tryptophan residues (one in the middle of the peptide and one near the C-terminal end) play a critical role in stabilizing the hairpin-like structure of the C-terminal domain in subgroups 1 and 2 among bacteriocins with one disulfide bridge.[21,25,28] Hence, Trp19, Trp34, and Trp40 are not essential for helix promotion or helix stabilization in the membrane. These results could also be explained by the inability of durancin GL to create a hairpin structure or functional redundancy in tryptophan residues. These hypotheses must be verified in further work through nuclear magnetic resonance or circular dichroism spectral analyses of the mutants.

In conclusion, alanine-scanning results unraveled some of the most important residues in durancin GL as shown in Figure 3. They are G07A, C10A, C15A, W16A and N20A, which caused a loss in antimicrobial activity; K12A, I30A, and V31A, which caused increased inhibitory activity; K21A and G38A, which caused decreased activity; and furthermore, E14A and S23A, which showed expanded inhibitory spectrum. These results shed light on future design of bacteriocins with more activity and specific inhibitory spectrum.

which are set at different temperatures and with decreasing pressures.[22] This technique has been used for the separation of bioactive compounds from herbs, plants, and food industry byproducts as well as for samples for algae and microalgae with different ranges of bioactivities, including antibacterial, antifungal, antiviral, and antioxidant.[23]

With the aforementioned concepts in mind, we performed the bioguided optimization of the leaf extraction on three varieties of sunflower (Stella, Hillian, and Arianna) using CO_2 as a supercritical solvent in an effort to obtain an extract with the highest possible activity.[24−28]

The aims of the study presented here were to isolate and structurally characterize the components of this most active extract. Furthermore, the activities of these compounds were measured to identify those responsible for the activity. It was envisaged that this study would provide a better understanding of the bioactivity of sunflower extracts and indicate the possibility of their future use in applications such as weed control.

MATERIALS AND METHODS

General Experimental Procedures. Infrared (IR) spectra (KBr) were recorded on a Fourier transform infrared (FT-IR) Spectrum 1000 spectrophotometer (PerkinElmer, Waltham, MA, USA). Nuclear magnetic resonance (NMR) spectra were acquired on 400, 500, and 600 MHz spectrometers (Agilent, Palo Alto, CA, USA). Chemical shifts are given in parts per million with respect to residual ^{1}H signals of $CHCl_3$-d_1 (δ 7.25), and ^{13}C signals are referenced to the solvent signal (δ 77.00). Optical rotations were determined at room temperature on a model 241 polarimeter (PerkinElmer) (on the sodium D line). HRMS were obtained on a Synapt G2 UPLC-QTOF ESI mass spectrometer (Waters, Milford, MA, USA). Column chromatography was carried out on silica gel 0.060−0.200, 60A, from Acros Organics (Geel, Belgium). Thin layer chromatography was carried out on TLC silica gel 60 F245 aluminum sheets. Compounds were visualized under $UV_{254/366}$ light and by spraying with H_2SO_4/H_2O/HOAc (4:16:80 v/v/v) followed by heating at 80 °C. HPLC was carried on a HPLC chromatograph (Merck-Hitachi L, Tokyo, Japan), and solvents were eluted by four-channel pumps (Elite LaChrom L-2130) with flow rates of 1 mL/min for analytical columns and 3 mL/min for semipreparative columns and with IR detection (Elite LaChrom RI L-2490). The HPLC columns employed were a semipreparative column (Luna 10 μm, silica (2) 100 Å, 250 mm × 10 mm i.d., 10 μm, with a Security Guard SemiPrep Cartridge silica 10 × 10 mm; Phenomenex, Torrance, CA, USA) and an analytical column (Luna 5 μm, silica (2) 100 Å, 250 mm × 4.60 mm i.d., 5 μm, with an Analytical Security Guard Cartridge System; Phenomenex, Torrance, CA, USA). The extractions and fractionations for the supercritical fluid extraction with CO_2 (SFE) were carried out in equipment supplied by Thar Technology (model SF2000; Pittsburgh, PA, USA).

Chemicals. Chloroform, *n*-hexane, methanol, dichloromethane, ethyl acetate, and acetone (HPLC grade) Hipersolv Chromanorm for HPLC were obtained from VWR International (Radnor, PA, USA). Carbon dioxide (Abelló Linde, S.A., Barcelona, Spain) was used as the supercritical solvent. MagniSolv chloroform-d_1 (deuteration degree minimum 99.8%) for NMR spectroscopy was obtained from Merck (Darmstadt, Germany).

Plant Material. Leaves of *H. annuus* L. var. Arianna were collected manually in June 2009 during the third growth stage of the plant[29] (plants 1.2 m tall with flowers, 1 week before harvest), because it has been found that at this stage the plant shows greater phytotoxicity. These leaves were provided by Rancho de la Merced, Agricultural Research Station (CIFA), Junta de Andalucia, Jerez de la Frontera, Spain. The moisture of the leaves after harvesting was 65%. Samples were dried on blotting paper at room temperature (25 ± 1 °C) until a constant weight was reached.

Extraction Fractionation and Isolation. Dried and ground leaves (75.5 g) were extracted in equipment supplied by Thar Tecnology (model SF2000), and this included an extraction vessel (capacity of 2 L) and a high-pressure pump with a maximum flow rate of 200 g/min of carbon dioxide (P200 model). Two cyclonic separators (500 mL each) connected in series allowed the periodic discharge of extracted material during the SFE process. A pressure regulating valve allowed different conditions to be applied to the separators. The extractions (fractionation process) conducted under the best extraction conditions[28] gave the best results in terms of yield and bioactivities (cytotoxicity and phytotoxicity bioassays). The conditions used in the extractor were 55 °C and 400 bar and in the separators, 90 bar and 40 °C in the first separator S1 and atmospheric conditions in the second separator S2. The flow rate measured for the supercritical carbon dioxide was 20 g/min during 3 h. The extracts were collected in acetone and concentrated under vacuum at the same temperature as the extraction. The dried extract (7.0 g) obtained in the second separator S2 by the fractionation process (SFE), which was free of chlorophylls, was chromatographed on a column (116 cm × 15 cm i.d., 1300 g of silica gel 60 A) using *n*-hexane/ethyl acetate mixtures of increasing polarity from 5 to 100% in ethyl acetate with a 10% increase each time and finishing with 100% methanol (500 mL of each polarity). This procedure afforded seven fractions after comparison by TLC: A (95:5 v/v, 664.8 mg), B (90:10 v/v, 343 mg), C (80:20 v/v, 1.2 g), D (70:30 v/v, 349.6 mg), E (50:50 v/v, 2.5 g), F (20:80 v/v, 644.3 mg), G (100% ethyl acetate, 158 mg), and H (100% MeOH, 63.9 mg).

The data of fractionation and isolation of compounds from fractions B−F are presented in detail in the Supporting Information (Fractionation and Isolation S3).

Spectroscopic Data for the New Compounds. Heliannuol M (**31**): colorless oil; $[\alpha]^{25}_{D} = -11.0°$ (*c* 1.0, $CHCl_3$); IR ν_{max} (KBr) cm^{-1} 3350 (OH), 1620 (aromatic C═C), 1265 (C—O—C); ^{1}H NMR ($CDCl_3$ 400 MHz) data, see Table 1; ^{13}C NMR ($CDCl_3$ 125 MHz) data, see Table 1; HREIMS *m*/*z* (rel intensity) 266.1512 $[M]^+$ (calcd 266.1518); EIMS *m*/*z* 266 $[M]^+$, 248 $[M - H_2O]^+$, 235 $[M - CH_2 - OH]^+$.

Helivypolide K (**36**): colorless oil; $[\alpha]^{25}_{D} = -30.0°$ (*c* 1.0, $CHCl_3$); IR ν_{max} (KBr) cm^{-1} 3466 (OH), 1779 (α,β-unsaturated γ-lactone), 1710 (α,β-unsaturated ester); ^{1}H NMR ($CDCl_3$, 600 MHz) data, see Table 2; ^{13}C NMR ($CDCl_3$, 125 MHz) data, see Table 2; positive-ion HREITOFMS *m*/*z* 375.1441 $[M + H]^+$ (calcd for $[M + H]^+$, 375.1444); EIMS *m*/*z* (rel intensity) 375 $[M + H]^+$, 292 $[M - C_5H_7O + H]^+$, 83 $[C_4H_7O]^+$.

Helivypolide L (**37**): colorless oil; $[\alpha]^{25}_D = -21.7°$ (c 1.0, $CHCl_3$); IR ν_{max} (KBr) cm^{-1} 3468 (OH), 1780 (α,β-unsaturated γ-lactone), 1710 (α,β-unsaturated ester); ^{1}H NMR ($CDCl_3$, 600 MHz) data, see Table 2; ^{13}C NMR ($CDCl_3$, 125 MHz) data, see Table 2; positive-ion HREITOFMS m/z 393.1544 $[M + H]^+$ (calcd for $[M + H]^+$, 393.1549); EIMS m/z (rel intensity) 393 $[M + H]^+$, 310 $[M - C_5H_7O + H]^+$, 83 $[C_4H_7O]^+$.

Helieudesmanolide B (**38**): colorless oil; $[\alpha]^{25}_D = -33.6°$ (c 1.0, $CHCl_3$); IR ν_{max} (KBr) cm^{-1} 3410 (OH), 1776 (α,β-unsaturated γ-lactone), 1700 (α,β-unsaturated ester); ^{1}H NMR ($CDCl_3$, 600 MHz) data, see Table 3; ^{13}C NMR ($CDCl_3$, 125 MHz) data, see Table 3; positive-ion HREITOFMS m/z 363.1806 $[M + H]^+$ (calcd for $[M + H]^+$, 363.1808).

Bioassays. Wheat coleoptile bioassays as well as phytotoxicity bioassays on tomato seeds were performed according to previously described procedures.[30]

Molecular Modeling. Three-dimensional models for the tested chemicals were obtained from PM3 calculations performed by Hyperchem 7.01 software (Hypercube Inc., Gainesville, FL, USA; 2000).

RESULTS AND DISCUSSION

The results indicated that the best extraction yields and activity profiles were obtained from the Arianna variety with an extraction pressure and temperature of 400 bar and 55 °C, respectively, at a flow rate of 20 g/min for 3 h. A cascade fractionation was carried out in an effort to increase the biological activity of the extract obtained under these conditions.[28] This process involved the stepwise precipitation of the extracts obtained in the process. This goal was achieved by modification of the density of CO_2 through changes in the pressure and temperature in the separators. In this way, the compounds that were least soluble in the supercritical solvent precipitated in the first separator, whereas more soluble materials remained in the second separator.

Better bioactivity profiles, yields, and separation of chlorophylls were obtained when the first separator was run at a pressure of 90 bar and a temperature of 40 °C with atmospheric conditions in the second separator. The extract obtained in the second separator (chlorophyll free) showed inhibition levels in the coleoptile bioassay of around 60% at the

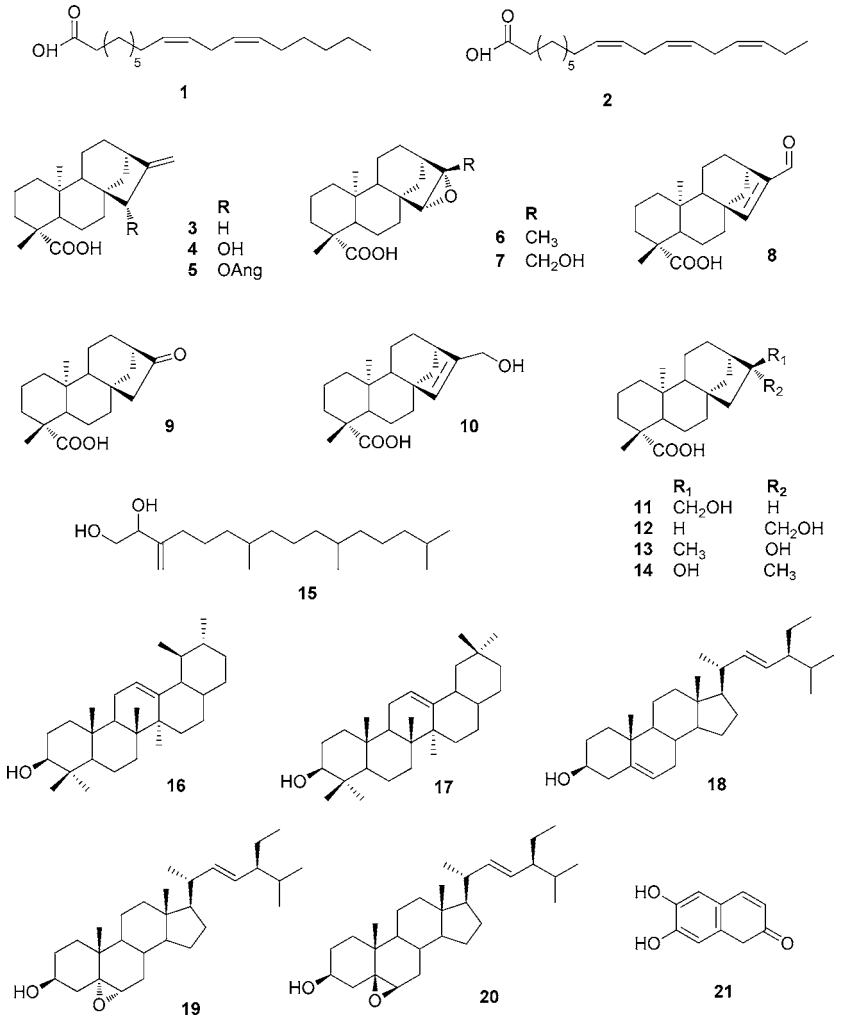

Figure 1. Compounds **1**–**21** isolated from dried leaves of *H. annuus* L. var. Arianna extracted with pure supercritical CO_2.

highest concentration tested (1.0 mg/mL) and 30% at the most dilute concentration (0.075 mg/mL). Phytotoxicity was also analyzed using two different bioassays, namely, a phytotoxicity bioassay carried out on tomato, lettuce, onion, and watercress seeds and a bioassay under hydroponic conditions on tomato.[28] The results were compared with those obtained with the commercial herbicide Logran. The data obtained on tomato showed the highest levels of activity. The extract showed root growth inhibitions of 70% at 0.8 mg/mL and 43% at 0.2 mg/mL (the limiting dilutions tested in this bioassay). Germination of tomato was also affected by this extract with values similar to the standard herbicide, that is, in the range of 78–57% for the three dilutions studied (0.8, 0.4, and 0.2 mg/mL). The bioassay under hydroponic conditions corroborated the activity observed in the Petri dish bioassay. Significant growth inhibition (>60%) of stems and roots of the tomato plants was obtained at 0.8 mg/mL.

Appropriate conditions for the fractionation of the bioactive extract (7 g) by CC and HPLC were identified. The chromatographic separation of fractions B–F led to the isolation of 52 compounds (Figures 1–3), and these were grouped together as 10 different chemical classes depending on their carbon skeleton: 2 fatty acids, 2 monoterpenes, 4 bisnorsesquiterpenes, 2 sesquiterpenes, 14 sesquiterpene lactones, 13 diterpenes, 2 triterpenes, 3 sterols, 8 flavonoids, 1 coumarin, and 1 lignan. The isolated compounds were identified from their spectroscopic data by comparison with the data reported in the literature as presented in the Supporting Information (Identified Compounds S8).

Compounds **6**, **11**, **19**–**21**, **23**, **41**, and **48** were isolated from *H. annuus* for the first time. Heliannuol M (**31**) was previously isolated by our research group from *H. annuus* variety SH-222,[31] and its spectral data are being reported for the first time. Helivypolide K (**36**), helivypolide L (**37**), and helieudesmanolide B (**38**) were characterized as new compounds.

Compound **31** was isolated as a colorless oil. The HRMS contained a peak at m/z 266.1512, which is consistent with a molecular formula of $C_{15}H_{22}O_4$. The ^{1}H NMR and ^{13}C NMR (Table 1) data are very similar to those previously reported for heliannuol D.[11] The only difference observed is the lack of the singlet assigned to one methyl group located on C-11 and the appearance of doublet signals with coupling constants of J = 11.1 Hz at δ 3.93 and 3.52, which are assigned to a hydroxymethylene group located on one of these carbons.

This assignment is fully supported by the ^{1}H NMR and ^{13}C NMR spectra as well as by COSY, HMBC, and HSQC experiments. The relative stereochemistries of C-7 and C-10 can be inferred by comparison with the chemical shifts and coupling constants of protons on the heterocycle of heliannuol D, which are established as 7*R* and 10*R*.[11] Thus, the similarities between the signals of these two compounds indicate that the

J. Agric. Food Chem. 2015, 63, 6410–6421

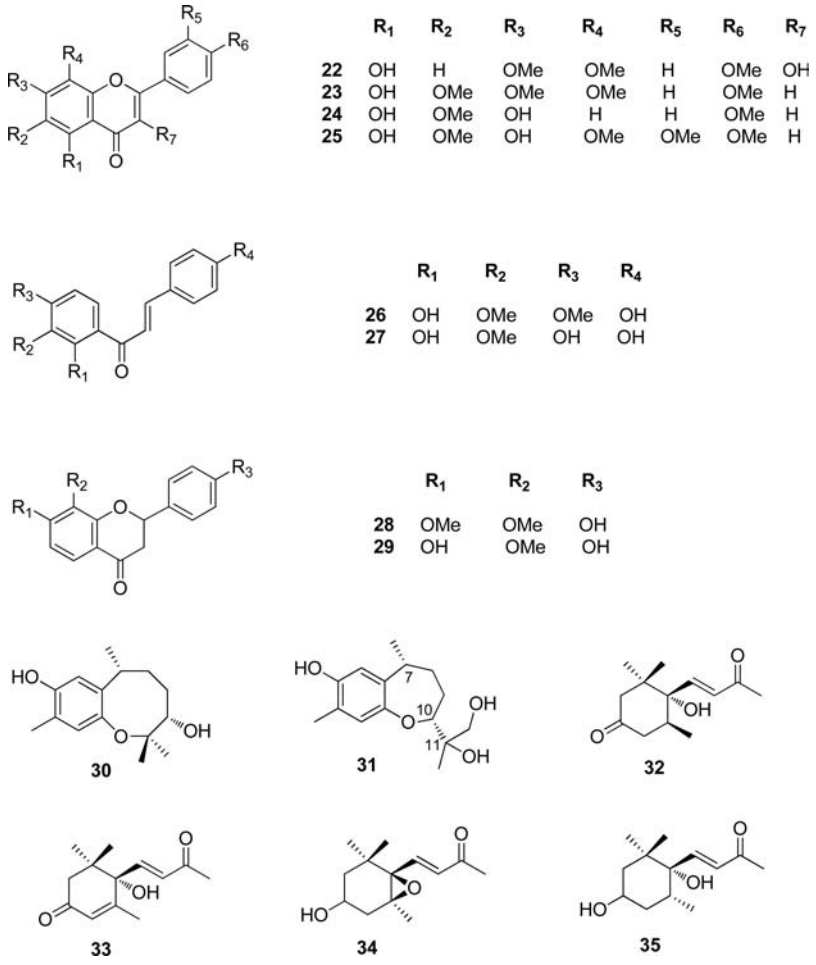

Figure 2. Compounds **22**−**35** isolated from dried leaves of *H. annuus* L. var. Arianna extracted with pure supercritical CO_2.

structure of **31** can be established as 5,11,13-trihydroxy-7*R*,10*R*-heliannane, which is named heliannuol M.[31]

Compound **36** was isolated as a colorless oil. The positive ion mode HREITOFMS contained a peak at *m*/*z* 375.1441 [M + H]$^+$. This result, together with the EIMS fragment ions at *m*/*z* 375 [M + H]$^+$, 292 [M − C_5H_7O + H]$^+$, and 83 [C_4H_7O]$^+$ and the ^{1}H and ^{13}C NMR data (Table 2), is consistent with the molecular formula $C_{20}H_{22}O_7$ (calcd for [M + H]$^+$, 375.1444). The ^{1}H NMR spectrum of this compound was very similar to that of helivypolide F[12] (Table 2), which was previously isolated from *H. annuus*, except for an upfield shift for H-15, which appears instead of the exocyclic-methylene signals. Comparison of the ^{1}H NMR and ^{13}C NMR spectra supports a structure very similar to that of helivypolide F with some modifications at C-4 and C-15.

The absence of a signal assignable to H-4, as well as the presence in the ^{1}H NMR spectrum of two isolated doublets at δ 3.30 and 3.13 (d, $J_{15\alpha,15\beta}$ = 6.5 Hz) for H-15α and H-15β, and the chemical shifts of the signals corresponding to C-4 (δ 60.4) and C-15 (δ 52.4) in the ^{13}C NMR spectrum indicated the presence of an epoxide between C-4 and C-15. This was confirmed by a g-HMBC experiment, in which the coupling of C-4 with H-2, H-5, H-15, and H-15′ was observed (Supporting Information S18). The α-orientation of H-5 was corroborated by an NOE effect observed in the corresponding bidimensional 2D-NOESY spectrum with H-15′ and with H-7 and H-8 (Figure 4). Thus, **36** was established as 8β-angeloyloxy-5β,10β-epoxy-4,15-epoxy-3-oxo-germacrane-1*Z*,11(13)-dien-6α,12-olide and was named helivypolide K.

Compound **37** was isolated as a colorless oil. The positive-ion HREITOFMS showed an *m*/*z* of 393.1544 [M + H]$^+$ which, in conjunction with the ^{1}H NMR data (Table 2), is consistent with the molecular formula $C_{20}H_{24}O_8$ (calcd for [M + H]$^+$, 393.1549). The ^{1}H NMR spectrum was essentially the same as that described above for compound **36** (Figure 5), but with slight differences in some of the chemical shifts. The differences are due to the shielding experienced by H-1 (δ 6.34; $\delta\Delta$ = 0.16) and H-2 (δ 5.99; $\delta\Delta$ = 0.15) and the deshielding of H-15′ (δ 3.71; $\delta\Delta$ = −0.41) and H-15 (δ 3.70; $\delta\Delta$ = −0.57). These findings indicate a modification of the methylene group at C-15 with respect to compound **36**, and once again the signal for H-4 was absent and two doublets were observed for H-15 and H-15′ at δ 3.70 and 3.71, (d, $J_{15,15'}$ = 4.4 Hz) in the ^{1}H NMR spectrum. On the other hand, the changes in the ^{13}C NMR spectrum for C-15 (δ 66.5) and C-4 (δ 69.0) (Table 2) indicated the presence of hydroxyl groups at C-15 and C-4, which correspond to the opened epoxide derivative of **36**. The g-HMBC experiment showed coupling between H-5 (δ 3.73) and C-15 (δ 66.5), and this confirmed the position of a hydroxyl group at C-15. This finding substantiates the significant hydrogen bond obtained in the minimum energy conformation calculations for this compound using PM3 (Figure 6). Thus, **37** was established as 8β-angeloyloxy-5β,10β-epoxy-4,15-dihydroxy-3-oxogermacrane-1*Z*,11(13)-dien-6α,12-olide, which was named helivypolide L.

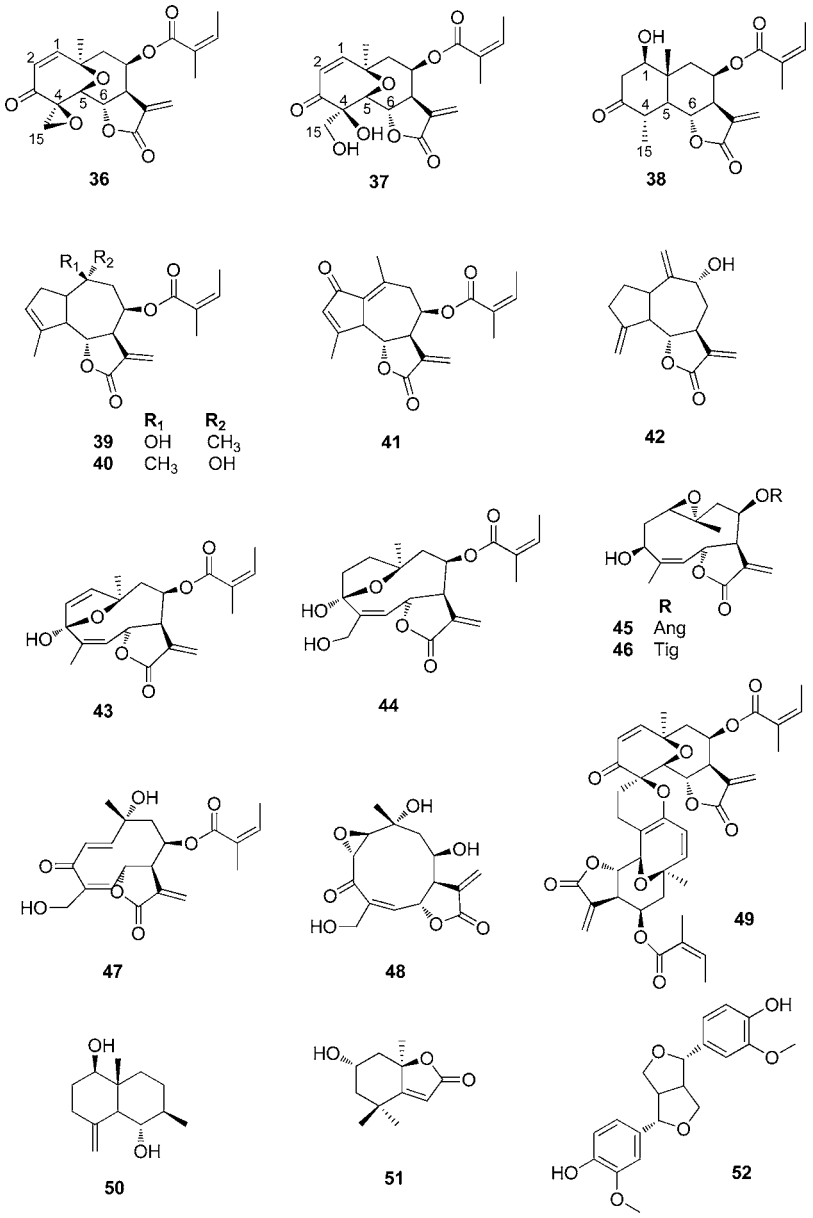

Figure 3. Compounds **36**–**52** isolated from dried leaves of *H. annuus* L. var. Arianna extracted with pure supercritical CO_2.

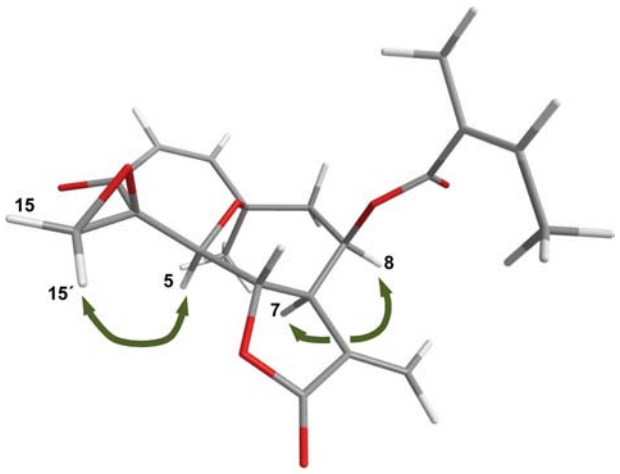

Figure 4. NOE effects observed for the most stable conformer of helivypolide K (**36**).

Compound **38** was isolated as a colorless oil. The positive ion mode HREITOFMS contained an $[M + H]^+$ ion at m/z 363.1806, which is consistent with the molecular formula $C_{20}H_{26}O_6$ (calcd for $[M + H]^+$, 363.1808). The ^{1}H NMR spectrum (Table 3) showed signals characteristic of a sesquiterpene lactone with a eudesmane skeleton very similar to that of helieudesmanolide A,[12] previously isolated from *H. annuus*, except for a doublet due to a methyl group at δ 1.31 ($J_{4,15}$ = 6.75 Hz) on C-4, corresponding to H-15, and the absence of a signal for H-3. In this case the eudesmane skeleton showed a typical methyl signal at δ 1.27 (H-14) and a doublet of doublets at δ 4.46 assigned to H-6 ($J_{5,6}$ = 11.1 Hz, $J_{6,7}$ = 10.8 Hz). The ^{1}H NMR–2D-COSY experiment showed that H-5 (δ 1.60) was coupled with H-4 (δ 2.58, dd, $J_{4,5}$ = 11.3 Hz) and H-15 (δ 1.31, d, $J_{4,15}$ = 6.7 Hz). Signals observed at δ 3.70 (dd, $J_{1,2\alpha}$ = 1.9 Hz, $J_{1,2\beta}$ = 11.6 Hz), δ 2.55 (dd, $J_{2\beta,2\alpha}$ = 12.1 Hz, $J_{1,2\beta}$ = 11.6 Hz), and δ 2.74 (dd, $J_{2\alpha,2\beta}$ = 12.1, $J_{1,2\alpha}$ = 1.9 Hz) were assigned to H-1, H-2β, and H-2α, respectively, and other proton coupling was not observed, which suggests that the C-3

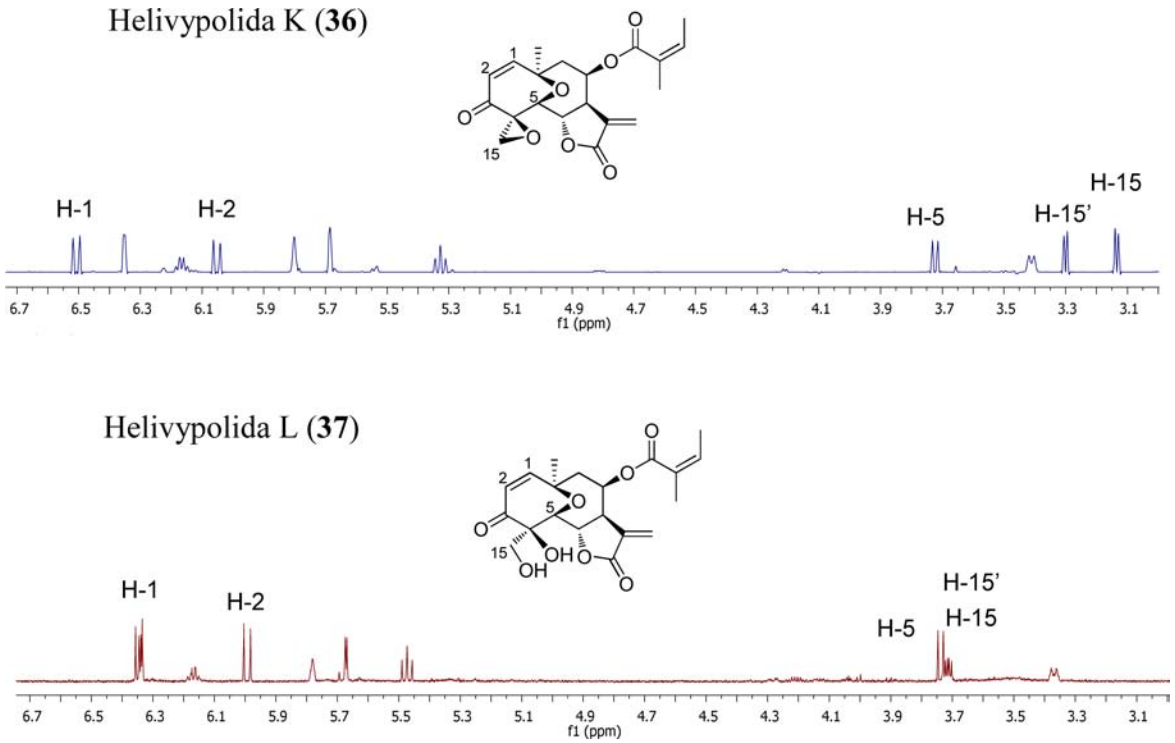

Figure 5. ^{1}H NMR comparison between helivypolide K (**36**) and helivypolide L (**37**).

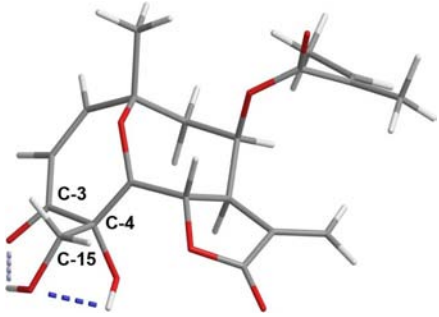

Figure 6. Significant hydrogen bond obtained in minimum energy calculations on the conformation of helivypolide L (**37**) using PM3.

position is occupied. The chemical shifts of C-1 and C-2 in the ^{13}C NMR spectrum at δ 76.3 (CH) and δ 46.2 (CH_2), respectively, indicate that there is a hydroxyl group bonded to C-1. The ^{13}C NMR spectrum (Table 3) contained 20 signals, and the signal at δ 207.5 confirmed the presence of a ketone group, which is located at C-3 due to the absence of a signal assignable to H-3 in the ^{1}H NMR spectrum and the correlations observed in the g-HMBC experiment between protons at δ 2.55 (H-2β), δ 2.74 (H-2α), δ 2.58 (H-4) δ 1.60 (H-5), and δ 1.31 (H-15) with the carbon at δ 207.5 (C-3) (Supporting Information S23).

The orientation of H-5 was established on the basis of the coupling constant with H-6 ($J_{5,6}$ = 11.1 Hz) and assuming a β-orientation for H-6 and an α-orientation for H-7 and H-8. The relative stereochemistry of the molecule was determined on the basis of NOE effects observed in the 2D-NOESY experiment. Thus, NOE effects were observed for proton H-5 with H-1 and H-8 and for H-14 with H-4 and H-6. The latter indicates an orientation α to the methyl at C-4 (H-15) (Figure 7). Thus, **38** was established as 8β-angeloyloxyl-1β-hydroxy-3-oxo-eudesmane-11(13)-en-6α,12-olide, and this compound was named helieudesmanolide B.

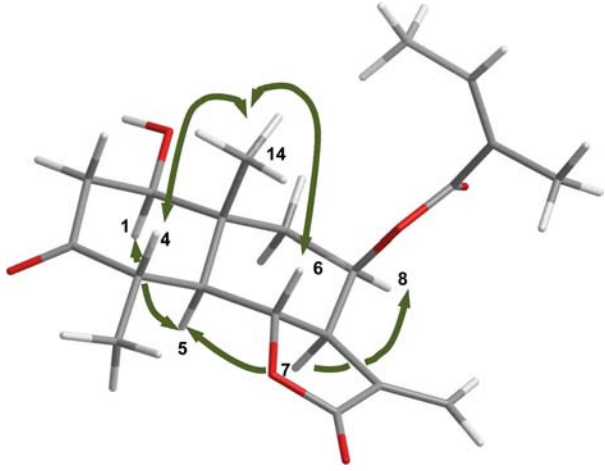

Figure 7. NOE effects observed for the most stable conformer of helieudesmanolide B (**38**) by PM3 calculations.

The bioactivities of 12 diterpenes (**3**−**14**), 1 coumarin (**21**), 8 flavonoids (**22**−**29**), 2 heliannuols (**30** and **31**), 4 bisnorsesquiterpenes (**32**−**35**), and 11 sesquiterpene lactones (**39**−**49**) were assessed in the wheat coleoptile bioassay in a concentration range from 10^{-3} to 10^{-5} M (except for compounds **13**, **27**, **31**, **43**, and **46**, which had a concentration limit of 3×10^{-4} M). The results obtained are summarized in Figures 8 and 9.

The remaining compounds, **15**, **18**, **36**−**38**, and **50**−**52**, were not tested due to the low amounts obtained. Compounds **16**, **17**, **19**, and **20** were not assessed because they were obtained as mixtures. The bioassay employed is rapid (24 h) and sensitive

to a wide range of bioactive substances including plant growth regulators, herbicides, antimicrobials, mycotoxins, and assorted pharmaceuticals.[32]

The activities of some of these compounds have been evaluated previously using the etiolated wheat coleoptile[33] and standard target species (STS)[34] bioassays in the concentration range of 10^{-4}–10^{-9} M.[8,35] To obtain a more complete picture of the compounds isolated in this work, we have reconsidered that, as better candidates for a natural herbicide model, the compounds should be tested in bioassays with a range of activities with the following dilutions: 10^{-3}, 3×10^{-4}, 10^{-4}, 3×10^{-5}, and 10^{-5} M for both bioassays. The commercial herbicide Logran was used as an internal reference.

Diterpene compounds **3**–**14** showed significant inhibitory activity on coleoptile elongation, except diterpenes **13** and **14**. The highest inhibitory activities of these diterpenes were shown by **8**, **9**, and **10**, with values >80% at 10^{-3} M (82, 92, and 96% inhibition, respectively). Some of these values are higher than that of the commercial herbicide Logran at this concentration (Figure 8). These compounds were also active at the second concentration (3×10^{-4} M) (79, 56, and 68% inhibition, respectively), and compound **8** was even active at the third (10^{-4} M with an inhibition of 66%), but these compounds had a little effect at the highest dilutions. Compounds **3** and **5** were less active than those outlined above, but they showed higher persistence with dilution and a better effect was observed at the high concentration for compound **3** (68%) in comparison to compound **5** (53%). On the other hand, compound **6** showed a high inhibition at 10^{-3} M (73%), but this decreased with dilution.

Coumarin **21** also showed high inhibitory activity at the two highest concentrations (10^{-3} and 3×10^{-4} M) (76 and 57% inhibition). Flavonoids **22**–**29** inhibited coleoptile elongation, and in this series, **24** and **26**–**28** had the highest values. These compounds showed high inhibitory activity at the highest concentration (10^{-3} M): **24** (76%), **26** (74%), **27** (73%), and **28** (99%). Even the least active compound had better activity than the commercial herbicide reference at this concentration (Figure 8).

Heliannuol A (**30**) showed high inhibitory activity on coleoptile elongation at 10^{-3} M, with a value of 85% (very close to the value value of Logran, 93%), and at 3×10^{-3} (50%), but the activity decreased significantly with dilution. In contrast, heliannuol M (**31**) had no effect on coleoptile elongation at any concentration (Figure 9). Bisnorsesquiterpene compounds **32**–**35** showed low inhibitory activities at all concentrations assayed (<30%).

Of all sesquiterpene lactones tested (**39**–**49**) compounds **40**, **44**, **45**, **47**, and **49** had the best activity profiles and the highest inhibitory activity on coleoptile elongation (Figure 9). These compounds showed values close to 90% inhibition at the highest concentration (10^{-3} M): **40** (95%), **45** (93%), **44** (89%), and **47** (92%). These values are similar to that of the commercial herbicide at the same concentration. Compound **49** showed the best inhibitory activity profile of all compounds evaluated and also showed the most persistence with dilution (73% at 10^{-3} M and 39% at 10^{-5} M).

Of all the compounds tested on the elongation of etiolated wheat coleoptile, compounds **8**–**10**, **21**, **24**, **26**–**28**, **30**, **40**, **44**, **45**, **47**, and **49** were the most active, and they were selected for the evaluation of phytotoxicity on tomato seed growth (except

J. Agric. Food Chem. 2015, 63, 6410–6421

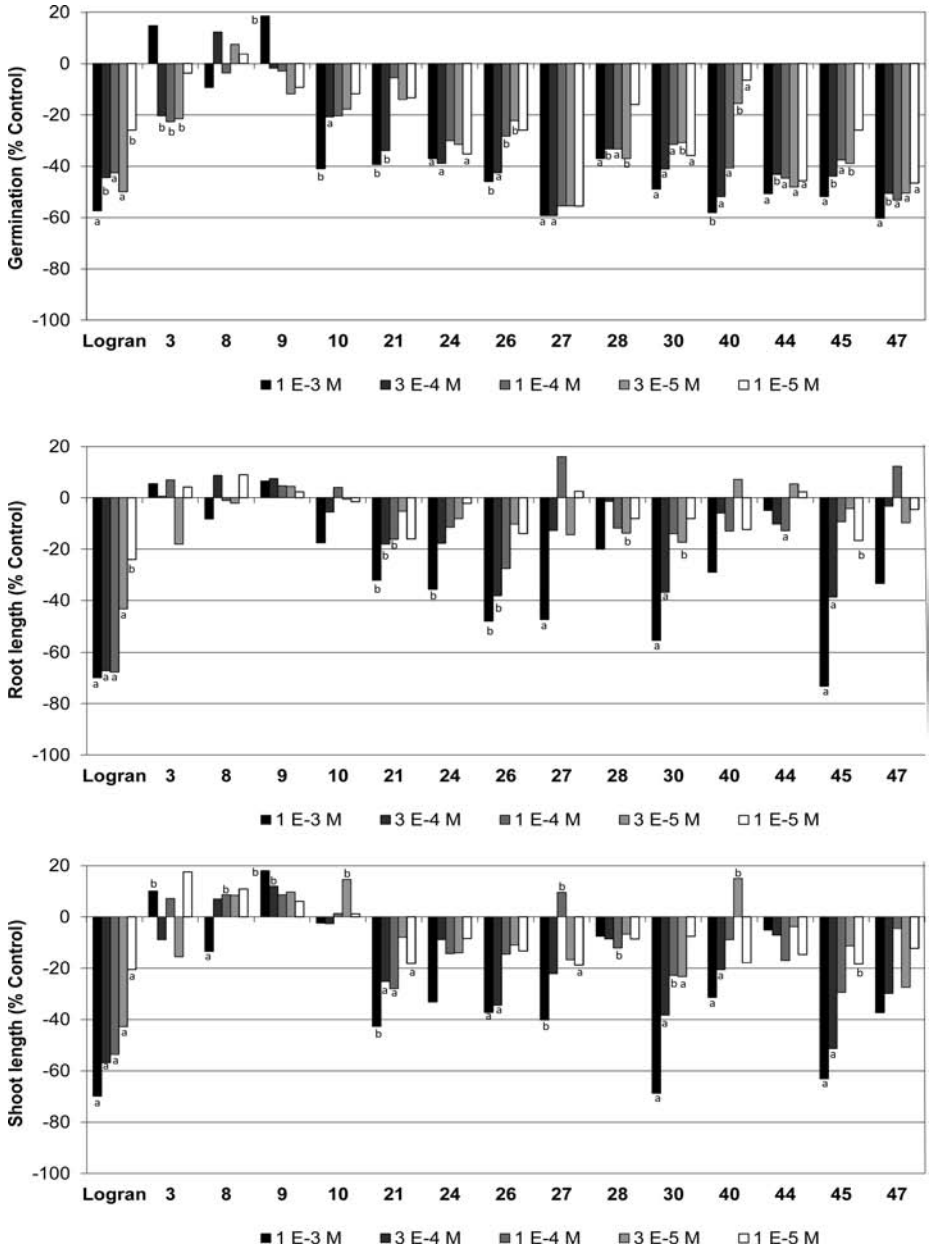

Figure 10. Effects of compounds **3**, **8**−**10**, **21**, **24**, **26**−**28**, **30**, **40**, **44**, **45**, and **47** from the bioactive fraction of the extract of sunflower (*H. annuus* L. var. Arianna) on *L. esculentum* seed growth. Values are expressed as percentage difference from control.

for **49**, due to the low amount available) as this was the most sensitive species in previous bioassays with the initial extract.[28] The commercial herbicide Logran was used as an internal standard.[34] The results of the bioassay are represented in Figure 10, where data are presented as percentage differences from the control. The concentrations tested were identical to those in the coleoptile bioassay.

In this phytotoxicity bioassay the most significantly affected parameter was the germination for all compounds assayed, except for diterpenes **3** and **8**−**10**. Coumarin **21**, flavonoids **24** and **26**−**28**, heliannuol **30**, and sesquiterpene lactones **40**, **44**, **45**, and **47** showed inhibition levels close to that of the herbicide Logran for most dilutions (between 40 and 60%).

Allelopathy is often demonstrated by testing allelochemical effects on germination. The germination process usually begins with water uptake by the seed (imbibition) and ends with the protrusion of the radicle through the testa. The seed germination test has been a widely used bioassay for the determination of allelopathic activity.[36] Another important point is that the observed effects varied with the seed tested. Tomato seeds were found to be more sensitive than other species evaluated. This may be due to differences in seed size, seed coat permeability, differential uptake, and metabolism.[37]

Root and shoot length were the variables that were most affected by heliannuol A (**30**) and the sesquiterpene lactone leptocarpin (**45**) at the first two concentrations (10^{-3} and 3×10^{-4} M), and they showed inhibitory activity similar to that of the commercial herbicide (70%).

Heliannuol A (**30**) was the most active compound on the shoot growth of tomato seeds at the first concentration (10^{-3} M) with 70% inhibition, that is, similar to that of the commercial herbicide. The inhibition of root growth at the same concentration was 56%. Furthermore, this compound had an inhibitory effect on germination at the highest concen-

DOI: 10.1021/acs.jafc.5b02261
J. Agric. Food Chem. 2015, 63, 6410−6421

trations, with values close to those of the standard herbicide (around 50%).

This compound belongs to the sesquiterpene family, which has a basic heliannane skeleton typical of such compounds isolated from sunflower,[11] and it has been reported to have plant growth regulatory activity.[10] The activity shown by this compound at the dilutions tested in both bioassays carried out in this work and the amount isolated from the extract indicate that its role may be related to the allelopathic behavior shown by this species.

The best results on root growth of tomato seeds at the highest concentration were shown by the sesquiterpene lactone leptocarpin (**45**) (10^{-3} M, 73% inhibition). For this compound, shoot inhibition at 10^{-3} M was 63%. The effect on germination of this seed also reached inhibition values similar to that of Logran at the highest concentrations (50%).

Sesquiterpene lactones bearing germacranolide and heliangolide backbones along with diterpenes are the most abundant compounds in the genus *Helianthus*. The activities of these compounds have been related to the presence of the α-methylene-γ-lactone moiety, the presence of an oxygenated group (mainly an angelate ester) at C-8, and/or the different special arrangements that the molecule can adopt.[38] It seems that the accessibility of groups that can be alkylated plays an important role in the activity of these compounds. Moreover, these compounds have shown a wide spectrum of activities: allelopathic, deterrent, cytotoxic, bacteriacidal, fungicidal, etc. Some of these activities can be correlated to the ecological roles of the compounds in the plant, but others are mainly characterized by their toxic properties and their ability to bind to important biomolecules.[39]

Furthermore, there are several studies concerning the regulatory activity of sesquiterpene lactones on germination and plant growth.[40] The observed activity of leptocarpin **45** on the germination and root growth inhibition of *Lycopersicon esculentum* seeds can be related to the flexibility that this molecule has in comparison to the other sesquiterpene lactones tested (**40**, **44**, and **47**) and to the presence of two electrophilic functions, namely, the α-methylene-γ-lactone moiety and the oxirane ring. It can be considered that leptocarpin **45** is another candidate that one would expect to be involved in defense mechanisms of *H. annuus*.

Annuolide G (**40**), niveusin B (**44**), and 15-hydroxy-3-dehydrodeoxytifruticin (**47**) showed low inhibitory effects on root and shoot growth of tomato seeds, but they showed high inhibitory activity on germination, as mentioned above, with values close to that of Logran (at 10^{-3} M: 58, 54, and 60% of inhibition for **40**, **44**, and **47**, respectively). For this parameter, **44** and **47** showed greater persistence as the activity was retained upon dilution, even at 10^{-5} M (50%), when compared to **40**, the activity of which decreased markedly in the last two dilutions. It is noteworthy that these heliangolides (**44** and **47**) have shown antibacterial properties against several organisms, such as *P. vulgaris*, *B. brevis*, *B. subtilis*, and *Streptomyces* sp.,[41] and they are highly active as fungicides, especially against *Eremothecium asbhbyi*,[42] along with leptocarpin **45**, which gave an MIC value as low as 1 ppm for several fungal species.[43]

The compounds that had the smallest effect on the germination and growth of tomato seeds were the diterpenes **3** and **8**−**10**, although these compounds did show good activity in the coleoptile bioassay. These diterpenoids are not usually reported as being phytotoxic agents despite the fact that they constitute a large group of compounds present in the genus *Helianthus*. The ecological role of these compounds has been associated more with antifeedant, insecticidal, and deterrent activity. Moreover, some diterpenoids, such as giberrellins, act as important plant hormones that are involved in growth regulation.[44]

Coumarins are defined as stress or defensive metabolites, and their synthesis is usually induced as a response to both biotic and abiotic stress-inducing agents.[45] The most significant values obtained on tomato seeds by coumarin sculetin (**21**) were found for the inhibition of germination (39%) and shoot length (42%) at a concentration of 10^{-3} M, although this compound did exhibit high levels of inhibition in the coleoptile bioassay at higher concentrations (10^{-3}, 3×10^{-3} M) with values of 77 and 58%, respectively.

Another large group of compounds that are widely distributed in *Helianthus* are the flavonoids, but very few of these have been implicated in allelopathy (some chalcones and dihydrochalcones).[46] These compounds (**24**, **26**−**28**) showed inhibitory effects on tomato seed growth, especially on germination, but they had intermediate effects on shoot and root growth. The structures of chalcones **26** and **27** are very similar as they differ only in the presence of an additional methyl group in **26**; however, their activities on germination are quite different. The reason for this variation could be related to the number and positions of free hydroxyl groups. Chalcone kukulkanin B (**27**) was the most active on germination of the flavonoids tested, and it also showed the best inhibitory activity profile with an average value of 60% from 10^{-3} M to 10^{-5} M (higher values than the commercial herbicide). The chalcone heliannone A (**26**) showed inhibition values of around 47% for the first concentrations (10^{-3} and 3×10^{-4} M). Compounds **26** and **27** both caused inhibition of shoot (around 40%) and root growth (50%) at the first concentration (10^{-3} M). It has been reported that flavonoids and flavones may act as insect attractants or repellents, either playing a defensive role or providing favorable interactions, among other activities.[47]

In conclusion, the results obtained in this study complement the current knowledge of allelopathic behavior shown by sunflower. The new extraction techniques used are environmentally clean and are more effective and selective for the extraction of bioactive natural products. Supercritical fluid extraction is one alternative to supplement or replace the conventional separation systems because the energy yields and separation efficiency are both good. In this study a bioactive extract of medium polarity was selectively obtained using CO_2 as the supercritical solvent. A total of 52 compounds were isolated from this extract, and these belong to 10 different chemical skeletons. Of these, the majority were sesquiterpene lactones (three of them are described for the first time in the literature), diterpenes, and flavonoids.

Because the initial extract showed good activity profiles in the coleoptile bioassay,[28] 38 pure compounds isolated from this fraction were again evaluated in the same bioassay, and >50% of these showed better results than the initial extract, with inhibition values in some cases >90%.

Good results were obtained for the initial extract in a previously reported phytotoxicity bioassay on tomato seeds in terms of percentage inhibition of germination and shoot and root length compared with Logran.[28] Good results were also obtained for the pure compounds, with a remarkable effect observed on germination in particular. The exceptions to this trend were the diterpene compounds. With regard to the development of this seed, sesquiterpene **30** (heliannuol A) and

DOI: 10.1021/acs.jafc.5b02261
J. Agric. Food Chem. 2015, 63, 6410−6421

sesquiterpene lactone **45** (leptocarpin) showed the strongest inhibitory effects, with activities similar to that of the commercial herbicide.

It is clear that allelopathic behavior is a very complex phenomenon and, hence, it cannot be assumed that a single compound, or even a small number of them, can be identified as being responsible for this behavior in all cases. The wide variety and activity of compounds found in the sunflower extract studied, both here and previously, makes, it conceivable that they are implicated in these interactions. Synergistic or additive interactions are usually not comparable to the activity of a single active compound, unless such a compound already participates in the combination. The specific structural factors that operate and determine the activity of a particular combination of compounds remains unclear. The same holds true for the combined effect; the character of such an effect cannot be predicted on the basis of an individual compound acting alone. In some cases, a noninhibitory concentration of a specific compound inhibits growth when this compound acts additively or synergistically with other allelochemicals that are present, and such joint action is the most common situation.

As a consequence, any studies that focus on the understanding of allelopathic interactions in *Helianthus* spp. should involve as many structures as be possible; otherwise, the study will be incomplete. On the other hand, the SFE technique has proven to be a useful tool to obtain bioactive extracts that contain a number of bioactive compounds from an agricultural byproduct. These extracts and compounds could be used in the future for weed control in an environmentally safe way within the context of sustainable agriculture.

of the product. Each modified triglyceride molecule would now have two polar groups and two nonpolar groups, namely, the ester headgroup and the middle polar amino segment of each acyl chain compared to the virgin oil with a traditionally nonpolar tail. We envisioned this change would introduce better packing of the chains, leading to improved density with associated properties for the derivatives. The change in geometry and polarity of the chains would also enhance metal-binding capability in lubricating and chelating applications. It was also anticipated that such changes would find the product to be useful both as a neutralization agent and as a component in metal-working fluids application. Another potential application would be as an agent of sequestration of metal ions in waste effluents. Most amines currently in use for neutralizations or as pH adjusters are monoamines with short- to medium-sized alkyl chains and are generally milder than inorganic bases such as NaOH or KOH, which are at the top of the scale of neutralizing agents. However, the draw for amines as neutralizers is their less caustic nature on equipment, which leads to prolonged useful lifetimes for equipment. The polyamine triglyceride reported here is novel and initiates new characteristics and uses for the modified oil.

MATERIALS AND METHODS

Materials. Polyhydroxy triglycerides of milkweed oil were obtained from our in-house supply from previous work.[10] Initial Dess-Martin Periodinane (DMP), anhydrous $MgSO_4$, sulfuric acid, and anhydrous diethyl ether were obtained from Sigma-Aldrich (St. Louis, MO, USA). Dichloromethane, ethyl acetate, $NaHCO_3$, potassium bromate, 2-iodobenzoic acid, sodium borohydride, and acetic anhydride were obtained from ACROS ORGANICS (Vineland, NJ, USA) whereas $Na_2S_2O_3.5H_2O$ was from J.T. Baker Chemical Co. (Phillipsburg, NJ, USA).

Methods. *Instrumentation. (a) Fourier Transform Infrared (FT-IR) Spectrometry.* FT-IR spectra were measured on an Arid Zone FT-IR spectrometer (ABB MB-Series, Houston, TX, USA) equipped with a DTGS detector. Liquid derivatives were pressed between two NaCl disks (25 mm × 5 mm) to give thin transparent oil films for analysis by FT-IR spectrometry. Absorbance spectra were acquired at 4 cm^{-1} resolution and signal-averaged over 32 scans. Interferograms were Fourier transformed using cosine apodization for optimum linear response. Spectra were baseline corrected, scaled for mass differences, and normalized to the methylene peak at 2927 cm^{-1}.

(b) NMR Spectroscopy. ^1H and ^{13}C NMR spectra were acquired on a Bruker AV-500 MHz spectrometer with a dual 5 mm proton/carbon probe (Bruker, Billerica, MA, USA). The internal standard used was tetramethylsilane.

Refractive Index (RI). RI was measured as a function of temperature (30−80 °C) on a model Mark II Plus Abbe refractometer (Reichert Inc., Depew, NY, USA). The instrument provides data to four-digit precision. RI at 100 °C was obtained by extrapolation of data collected at ≤80 °C.

Density, Viscosity, and Viscosity Index (VI). Density and dynamic viscosity were measured as a function of temperature on a Stabinger SVM3000/G2 viscometer (Anton Paar GmbH, Graz, Austria). The instrument also provides the kinematic viscosity as a function of temperature by automatically manipulating the corresponding measured density and dynamic viscosity data. VI was calculated from kinematic viscosity data at 40 and 100 °C following the procedure outlined in ASTM D 2270-93.[17]

Pour Point (PP) and Cloud Point (CP). PP and CP were determined on a model PSA-70S automatic analyzer from Phase Technology (Richmond, BC, Canada) according to ASTM standard test method D 5949[18] and D 5773,[19] respectively.

Pressurized Differential Scanning Calorimetry (PDSC). PDSC tests were conducted on a Q20P pressure differential scanning calorimeter (TA Instruments − Waters LLC, New Castle, DE, USA) fitted with a computer and software to allow for automatic data acquisition and analysis. All tests were conducted with the cell pressurized with pure oxygen to 500 ± 25 psig in dynamic mode, with a positive oxygen flow rate of 100 ± 10 mL/min. Details of the experimental procedure have been given previously.[20] The resulting heat flow versus temperature data were analyzed using the instrument computer and software to determine onset temperature (OT) and peak temperature (PT). Duplicate runs were conducted on each sample, and average OT and PT values are reported.

Four-Ball Tribometer and Test Specimen. The four-ball tests were conducted on a model KTR-30L four-ball tribometer (Koehler Instruments, Bohemia, NY, USA). The instrument comprises a mechanical unit, an electronic unit, and a computer with TriboDATA software (Koehler Instruments) that allows for setting and controlling test parameters as well as for automatic data acquisition. A detailed description and specification of the instrument can be found elsewhere.[21] Test balls used in four-ball experiments were obtained from Falex Corp. (Aurora, IL, USA) and had the following specifications: material, chrome−steel alloy made from AISI E52100 standard steel; hardness, 64−66 R_c; diameter, 12.7 mm; finish, grade 25 extra polish. Test balls were degreased by two consecutive sonications in isopropyl alcohol and hexane solvents in an ultrasonic bath prior to use. The pot and spindle used for securing the balls were also thoroughly washed with isopropyl alcohol and hexane, wiped with Kimwipe (Kimberly-Clark Worldwide, Inc., Roswell, GA, USA), and allowed to air-dry prior to testing with a new lubricant.

Four-Ball Anti-Wear (AW) Test. The four-ball AW tests were conducted according to the procedure outlined in ASTM D 4172-94[22] under the following test conditions: load, 392 N; speed, 1200 rpm; lubricant temperature, 75 °C; test duration, 60 min. During the test, frictional torque and test conditions (load, speed, temperature) were automatically recorded as a function of time by the instrument computer at a rate up to 300 samples/min. The torque and load data were used to calculate the coefficient of friction (COF) for each test using the procedure outlined in ASTM D 5183.[23] At the end of the AW test, the wear scar diameters (WSD) of each of the three balls in the ball pot were measured parallel and across the wear direction using a wear scar measurement system supplied by Koehler Instrument Co., Inc. The system comprises hardware (for taking a digital image of the wear scar of the three balls without disassembling the ball pot) and software (Scar View, Koehler Instrument Co., Inc.). The WSD along and across the wear direction of the three balls were used to calculate the average WSD for the test. Each test lubricant was used in at least two AW measurements, and average COF and WSD values were reported.

Four-Ball Extreme Pressure (EP) Test. EP tests were conducted according to ASTM D 2783[24] under the following conditions: speed, 1760 ± 40 rpm; temperature, ambient; load, variable; test duration, 10 s. EP tests comprise a series of 10 s tests at increasing loads until welding of the four balls is observed. The load increments are selected on the basis of the expected weld point (WP) for the test lubricant, with finer increments being used close to the WP. The load at which welding is observed is the WP and is a characteristic EP property of the lubricant tested.

Synthesis of Milkweed Polyketone from Polyhydroxy Milkweed Oil. In a typical reaction, polyhydroxy milkweed oil (61.0 g, 57.72 mmol) previously derived from milkweed oil[10−13] was placed into a 500 mL dry round-bottom flask (RBF) containing a magnetic stir bar. Dry dichloromethane (150 mL) was then added and stirred to dissolve the oil. The stirred solution was cooled to −5 °C in an ice bath augmented with NaCl. Dess−Martin periodinane reagent (59.5 g, 140 mmol) was added quickly while stirring was continued. The reaction temperature was gradually allowed to warm to 0 °C over 3 h and then to room temperature overnight. A yellow solid formed, which later redissolved in the dichloromethane. The resulting mixture was then concentrated to dryness under reduced pressure, and the solid was triturated with anhydrous EtOEt (100 mL × 3) and filtered. The filtrate was washed with saturated $NaHCO_3$. The organic layer was rewashed with a mixture of $NaHCO_3$−$Na_2S_2O_3·5H_2O$. After separation of phases, the organic layer was rewashed with brine and

DOI: 10.1021/acs.jafc.5b00598
J. Agric. Food Chem. 2015, 63, 6422−6429

dried over $MgSO_4$ overnight.[14] The filtrate was then concentrated under reduced pressure to give 60.7 g (99.0%) yield of the polyketone triglyceride. The FT-IR spectrum of the product obtained was ν_{NCl} cm^{-1} 2927 vs (−CH_2− asym stretch), 2858 s (−CH_2− sym stretch), 1744 vs (second derivative C═O) ester; 1720 s-m (ketone C═O), 1463 m (CH_2 def), 1370 m (CH_3 def), 1235 m (C—OC−) stretch, 1166 s (−HC—O) stretch, 1097 m (−HCO−) stretch, 1020 m (−CH_2O−) stretch, 723 w (−CH_2−) wag. ^{13}C NMR: δ 213.6, 213.27, 209.7, 208.5, 206.6, 205.58, 205.52, 202.93, 202.8 (polyketone C═O).

Milkweed Schiff Base Formation from the Polyketone. Milkweed polyketone triglyceride (161.3 g, 156.5 mmol) was placed in a dry 1 L RBF) containing a magnetic stirrer. Dry dichloromethane (300 mL) was added and the mixture stirred and cooled to −1 °C in an ice bath; 2-propylamine (92.45 g, 1.564 mol) was then added dropwise to maintain the reaction temperature at 0 °C. After the amine had been added, the temperature was slowly allowed to warm to room temperature overnight. The solvent was removed under reduced pressure at 50 °C, and the crude product was diluted with EtOAc, dried over $MgSO_4$, filtered, and concentrated under reduced pressure followed by pump vacuum drying to give a yield of 158.8 g (70.6%) of the Schiff base. FT-IR cm^{-1}: 3366 w, 2959 sh, 2926 vs, 2874 sh, 2854s, 1741s, 1716 (C═O), 1686, 1588 (C═N of Schiff base), 1468 (−CH_2− def), 1381 (−CH_3 def), 1245, 1169,1018, 726. ^{13}C NMR δ 173.19, 172.77, 172.46, 171.15, (C═O ester), 160.69 (C═O formyl ester), 68.88 (−CH− glyceride backbone), 63.75 methine C of isopropyl), 62.06, 60.36(−CH_2O−glyceride backbone), 44.44, 43.72, 41.19, 40.30, 38.58 (−CH−isopropyl), 34.07− 21.71 (−CH_2−), 20.98−13.89 (−CH_3).

Conversion of the Schiff base (Imine) Triglyceride to the Polyamine Triglyceride. In a 1 L RBF containing a magnetic stir bar, the intermediate imine triglyceride (155.7 g, 0.1084 mmol) dissolved in 50:50 EtOH (300 mL)/1,4-dioxane (300 mL) was placed. Acetic acid (3 mL) was added to the solution and the mixture vigorously stirred and cooled to 0 °C in an ice bath. Powdered $NaBH_4$ (40.0 g) was added portion-wise to maintain the reaction temperature around 0 °C. At the end of the borohydride addition, the reaction was allowed to stir overnight, warming to room temperature. The mixture was then diluted to 1000 mL with 3% AcOH solution followed by extraction with dichloromethane. The extract was then washed with distilled water, dried over $MgSO_4$, and concentrated under reduced pressure at 48 °C followed by further drying at the pump to yield the polyamine product (160.2 g). Density at 24 °C was 1.072 g cm^{-3}; pH 8.09 (EtOH). FT-IR ($NaCl_{film}$) ν cm^{-1}: 3382 (−N—H stretch), 2962 (−CH_3 asym), 2929 (−CH_2− asym) vs, 2873 (−CH_3 sym), 2856 (−CH_2− sym) s, 1741 vs (C═O ester backbone), 1664 m, 1549 m-w (N—C), 1470 s (−CH_2− def), 1376 s (−CH_3 def), 1256, 1240 s (−C—O—C═O), 1167 s, 1109 s, 875, 722 (−CH_2−) wag. ^{13}C NMR DEPT ($CDCl_3$) δ 176.67 (C═O ester), 160.96 (−HC═O), 82.45, 81.54, 80.90, 80.11, 73.81, 71. 85, 68.88, 67.02, 65.80 (−CHN−), 62.05, 60.14 (−CH_2O−), 57.25, 43.55, 41.19, 40.28, 35.94−22.63 (−CH_2−), 21.08−14.19 (−CH_3).

RESULTS AND DISCUSSION

Synthesis and Identification of Milkweed Polyamine. The FT-IR spectrum of the unmodified milkweed oil is shown in Figure 1. This spectrum displays the olefinic −C═C—H absorption mode at around 3009 cm^{-1} as well as the breathing or puckering mode of the C═C bond at around 1658 cm^{-1}. In contrast, the starting material, polyhydroxy oil Figure 2, exhibits the characteristic broad (O−H) stretching band centered around 3448 cm^{-1}. This spectral region is transparent in the virgin oil. Substitution of the hydroxyl groups of polyhydroxy milkweed oil with nitrogen proceeded through an intermediate polyketone triglyceride of milkweed oil. An initial attempt at oxidation of the polyhydroxy oil (Figure 2) to the polyketone using the Jones reagent (chromic acid/H_2SO_4) resulted in an isolated product, which was characteristically not the desired material judging from the ^{13}C NMR spectrum obtained (not

shown here). Use of the Dess−Martin periodinane oxidation technique for the polyhydroxy oil, on the other hand, gave an excellent, almost quantitative, yield of the polyketone triglyceride. Figure 3 shows the synthetic procedure used. Spectroscopic characterization of the polyketone is shown in Figures 4−6. Figures 4 and 5 are the FT-IR spectra of the polyketone. The second derivative of this FT-IR spectrum (Figure 5) shows the carbonyl region of the spectrum with three bands indicating the keto carbonyl absorbance at 1724 cm^{-1}, whereas the ester carbonyl absorption of the triglyceride is at 1746 cm^{-1} and there is a smaller higher frequency band at 1763 cm^{-1}. The ^{13}C NMR spectrum of this product (Figure 6) clearly shows the polyketo resonances (10 lines) from 202.8 to 213.6 ppm corresponding to about 10 keto groups expected in this intermediate from the 10 secondary hydroxyl groups of the polyhydroxy starting material. The arrangement of these carbonyl groups as shown in Figure 7 is such that on its own the polyketone would form a number of coordination spheres with metal ions. The operating principle is that when two keto groups are separated by a methylene species as in this structure (C10−C12 of the linoleyl chains), the two methylene protons at C-11 become more acidic by virtue of being sandwiched between C10 and C12 carbonyls. Enolization tends to be strong and is observed as shown in Figure 7 under appropriate conditions in the ^{13}C spectrum. Evidence are absorbances around 91 and 191 ppm for the enolic carbons in addition to the intact keto forms (spectrum not included here). Because of this enolization tendency, this polyketone bears a strong resemblance to the molecular structure of 2,4-pentanedione (acetyl acetone), which is a known chelating agent. This

skeletal arrangement gives the polyketone intermediate the properties of a powerful chelating agent, and it may be pertinent to note that this is the first reported polyketo vegetable oil.

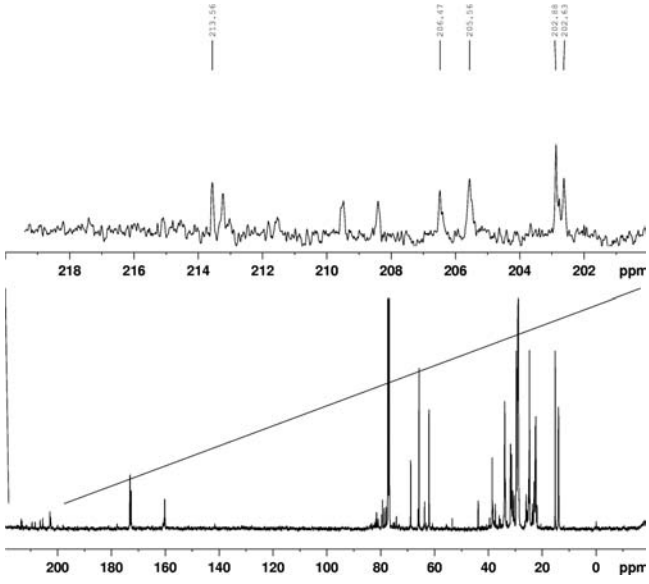

Figure 6. ^{13}C NMR spectrum of milkweed oil polyketone showing keto carbonyl resonances 202.63−213.56 ppm.

Conversion of the polyketone in dry dichloromethane at −1 °C with 2-propylamine as shown in Figure 8 gave the Schiff base (polyimines) in good yield. The polyimine adduct obtained was first characterized by FT-IR spectroscopy (Figure 9), followed by the ^{13}C NMR spectrum. The obtained ^{13}C NMR spectrum showed that the most downfield resonances observed were only those of the ester carbonyl absorbances at 173.19, 172.77, 172.46, and 171.15 ppm (C═O ester), which correspond to the polar headgroup ester functionalities of the triglyceride. The indication is that all of the keto carbonyl groups have undergone reaction with 2-propylamine. Reduction of this polyimine was achieved with sodium borohydride utilizing the method of Haire.[15,16] The polyamine isolated is a reddish viscous liquid. Its FT-IR spectrum (Figure 10) shows a prominent characteristic broad N−H stretching mode of secondary amines at 3384 cm^{-1} and C−N stretching bands at

1668 and 1551 cm^{-1}. The band broadening arose from hydrogen bonding. Figure 11 is the second derivative of Figure 10 and allows us to conclude that the only carbonyl absorption bands present are those of the glyceride backbone ester functional groups at 1755 cm^{-1}, the N−H stretch being around 3500 cm^{-1}.

Physical and Viscosity Properties of Milkweed Polyamine Oil. The effect of temperature on the density and RI of milkweed polyamine is summarized in Table 2. The polyamine is denser than water. Table 3 compares the kinematic viscosities of milkweed oil and its polyamine derivatives as a function of temperature. Also compared in Table 3 are the VIs of the two oils. As shown in this table, polyamination has considerably increased the viscosity of milkweed oil at all temperatures. At 40 °C, the viscosity displayed an almost 20-fold increase and an almost 6-fold increase at 100 °C. This means polyamination

will increase the viscosity range for the application of milkweed oil in lubrication. As expected, Table 3 also shows that although polyamination results in considerable reduction of the VI of the parent milkweed oil to almost half its value, its VI is double that of the polyhydroxy starting oil. Even though the VI of milkweed polyamine is considerably below those of unmodified vegetable oils, it is still comparable to petroleum-based oils widely used in lubrication.[25] Thus, milkweed polyamine can still be competitive with petroleum-based oils in lubrication applications.

Oxidation Stability and Cold Flow Properties of Milkweed Polyamine Oil. Table 4 summarizes the cold flow and oxidation stability data for milkweed polyamine oil.

Table 4. Cold Flow (Pour Point, Cloud Point) and Oxidation Stability (by PDSC) Properties of Milkweed Oil and Milkweed Polyamine[a]

pour point, °C		−4.3 ± 0.6
cloud point, °C		not discernible
oxidation stability		
PDSC − OT, °C	136.78 ± 0.35	173.49 ± 0.79
PDSC − PT, °C	154.32 ± 0.47	194.18 ± 0.07

[a]All data from this work unless noted.

Cold flow properties are evaluated using pour point (PP) and cloud point (CP) data. As shown in Table 4, only PP data could be generated for milkweed polyamine oil because the oil was dark red and clouding could not be easily detected during the test. In general, oils with double-digit below zero PP values are preferred for lubrication applications. However, a PP of below freezing, such as that for milkweed polyamine oil, is not considered bad because it can be easily improved with the use of low concentrations of PP depressants.

Table 4 also shows the results of oxidation stability tests by the PDSC method. In this method, the temperatures at which oxidation of the oil under oxygen atmosphere begins (OT) and peaks (PT) are reported. The higher the values of OT and PT, the higher the oxidation stability of the oil. Table 4 compares the OT and PT of milkweed polyamine oil with those of milkweed oil. As seen in Table 4, polyamination has resuted in considerable improvement in the oxidation stability of milkweed oil. Both OT and PT have increased by almost 40 °C after polyamination. There could be many reasons for this improvement in oxidation stability due to polyamination. A major contributor to such an improvement is the elimination of unsaturation in the oil structure, which eliminates reactive allylic and bis-allylic protons, which are considered major contributors to oil oxidation.

Tribological Properties. Table 5 shows the results of AW and EP tests on milkweed polyamine oil. Also shown in Table 5 are similar AW data for three milkweed polyester derivatives from our previous work.[26] The data in Table 5 indicate that milkweed polyamine oil displays the lowest average COF and the second lowest WSD among the four derivatives. No EP measurements were done on the milkweed polyesters in the study cited. Milkweed polyamine oil showed an EP WP of 140 kgf, which indicates that the oil lacks any significant EP properties. This is consonant with the fact that none of the elements comprising milkweed polyamine oil (C, H, O, N) are expected to display EP characteristics.[26]

Effect of Chemical Structure. Table 6 compares available properties of milkweed oil and several of its derivatives, namely, polyepoxy, polyamine, acetate, butyrate, and valerate polyesters and the polyhydroxy. Table 6 compares the kinematic viscosity, VI, cold flow (PP, CP), and oxidation stability (OS) determined using PDSC (OT and PT) of MWO and the listed derivatives. In Table 6, the oil derivatives are arranged in order of increasing kinematic viscosity from left to right. As can be seen in Table 6, the kinematic viscosity of MWO increases dramatically due to derivatization. Kinematic viscosity increases in the order MWO < polyepoxy < polyvalerate < polyamine < polybutyrate < polyacetate < polyhydroxy. This trend can be explained in terms of intermolecular hydrogen bonding, which will be greatest for the polyhydroxy derivative. The order for the polyesters and polyepoxide could be due to intermolecular polar interactions, which is expected to increase in the order polyepoxy < polyvalerate < polybutyrate < polyacetate. It appears there was no significant hydrogen bonding in the polyamine, and any polar interactions were slightly better than the polyepoxide. On the basis of structural considerations, the polyamine should have shown significantly higher intermolecular interaction and, therefore, significantly higher viscosity than the polyesters. However, the fact that the viscosity of the polyamine was below those of the polyesters implies a different mechanism is at play. A possible explanation for the observed data may lie in the contrast between the linearity of the polyester substituents as against the branched alkyl group on

the nitrogen in the polyamine. It is well-known that increased branching tends to increase the bulkiness of a substrate rather than linearizing it, and this occurring in the middle aspect of the acyl chains of the triglyceride would make the molecule more spherical.[27−29] Such induced sphericity naturally would cause attenuation of the apparent sweep-width of the molecule and hence lower its viscosity as observed for the polyamine triglyceride.

Comparison of the VI of MWO and its derivatives in Table 6 shows an interesting correlation between the oil polarity and VI. MWO, which is the least polar of these substances, has the highest VI, whereas the polyhydroxy derivative, which is the most polar, has the lowest VI. The VI of the rest of the derivatives follows a similar trend and increases in the order polyacetate < polyamine < polybutyrate < polyvalerate < polyepoxy. This observation is similar to what is widely known about the effect of the polar hydroxyl groups on the VI of vegetable oils such as castor oil, which has a VI of ∼89, much lower than that for the nonpolar vegetable oils such as milkweed, soybean, etc., the VI of which is >200.[26] Examination of Table 6 also shows that the VI was a better predictor of polarity than kinematic viscosity, because it predicts the polarity of polyamine to be closer to polyacetate than to polyvalerate. Table 6 also shows the derivatization of MWO to polyamine and polyacetate was not an effective method for improving the PP of MWO, whereas conversion to polybutyrate or polyvalerate was more effective.

[a]Restriction endonuclease recognition sites are underlined.

in the conversion of biomass into sugars, as high temperatures usually promote better enzyme penetration and cell wall disorganization of the raw materials.[9] *Thermoanaerobacterium aotearoense* SCUT27 is a thermophilic anaerobic bacterium isolated from a hot spring in China.[18] Previous studies have demonstrated that it can produce a multiple-enzyme mixture for xylan degradation, making it possible to utilize xylan as the sole carbon source.[19,20] We describe in this study the cloning and sequence analysis of the *xynA* gene from *T. aotearoense* SCUT27. We explore the possibility of the secretion of truncated *xynA*ΔSLH in *B. subtilis* using different signal peptides to increase the expression level of the multidomain xylanase. The recombinant *xynA*ΔSLH was purified and biochemically characterized.

MATERIALS AND METHODS

Chemicals, Reagents, and Materials. Oat spelt xylan and beechwood xylan were from Sigma-Aldrich Co. (St. Louis, MO, USA). Sodium carboxymethylcellulose (CMC-Na) was purchased from Aladdin (Shanghai, China). *T. aotearoense* SCUT27 was isolated by our group previously.[18] Cells were cultured in modified MTC medium. *Escherichia coli* DH5α (Invitrogen, San Diego, CA, USA), BL21(DE3) (Novagen, Madison, WI, USA), and *Bacillus subtilis* 1012wt (MoBiTec, Goettingen, Germany) were used for cloning and heterologous expression of xylanase. *E. coli* and *B. subtilis* were both cultured at 37 °C in Luria−Bertani (LB) medium. When necessary, 50 μg/mL of kanamycin, 100 μg/mL of ampicillin, or 5 μg/mL chloromycetin was added to the medium.

Molecular Techniques. DNA was manipulated using standard procedures. DNA polymerase of PrimeSTAR was purchased from TaKaRa (Dalian, China). FastDigest restriction enzymes were obtained from Fermentas (Thermo Scientific Ltd., Waltham, MA, USA). SanPrep Column Plasmid Mini-preps Kit and SanPrep Column PCR Product Purification Kit (Sangon, Shanghai, China) were used for the purification of plasmids and PCR products.

Xylanase gene (*xynA*) was amplified with the genomic DNA of *T. aotearoense* SCUT27 as the template and with primers of xynA-F1 and xynA-R1 (Table 1). Primers xynA-F1 and xynA-R1 were designed on the basis of the endoxylanase *xynA* gene sequence from *Thermoanaerobacterium* sp. (GenBank U27183.1). A truncated derivative of xylanase gene (x*ynA*ΔSLH) was obtained by PCR amplification with the primer pairs of xynA-F1 and xynA-R2, and the xylanase gene without its signal peptide (NS-*xynA*ΔSLH) was also generated similarly with the primer pairs of xynA-F3 and xynA-R2. The *xynA*, *xynA*ΔSLH, and NS-x*ynA*ΔSLH genes were digested and inserted between the *Nco*I and *Xho*I sites of pET28a vector (Novagen), yielding the plasmids of pET28a-*xynA*, pET28a-*xynA*ΔSLH, and pET28a-NS-*xynA*ΔSLH, respectively.

Preparation of Plasmid for Secretion Expression in *B. subtilis*. The construction of expression plasmids in *B. subtilis* is shown in Figure 1.

DNA fragments (AddHis) encoding the C-terminal 6×His tag were generated by overlapping extension PCR through combining two DNA fragments (His1 and His2) at a 1:1 ratio and inserted into pHT01 (MoBiTec) to obtain pHTHis (between the *Bam*HI and *Aat*II sites).

To generate secretion vectors, DNA fragments containing the signal sequences of ss*PhoD*, ss*BglS*, and ss*Bpr* from *B. subtilis* 168 were amplified by PCR using appropriate primers and genomic DNA isolated from *B. subtilis* 168 (Figure 1 and Table 1).[21] The amplified DNA fragments were digested with isocaudamer enzymes of *Bam*HI and *Bcl*I and inserted into pHTHis cleaved by the *Bam*HI restriction enzyme, generating pHTHisD, pHTHisS, and pHTHisR, respectively. By inputting the gene sequence of ss*SamyQ* (95 bp) into the free software DNAworks (http://helixweb.nih.gov/dnaworks/), six oligo sequences (from SamyQ1 to SamyQ6) were returned and synthesized accordingly (Table 1).[22] These oligos were assembled to *SamyQ* by standard overlapping procedure.[23] Then two flanking primers (SamyQ1 and SamyQ6) were used to amplify the full-length of ss*SamyQ* by standard PCR. Likewise, the ss*SamyQ* were inserted into pHTHis to obtain pHTHisQ.

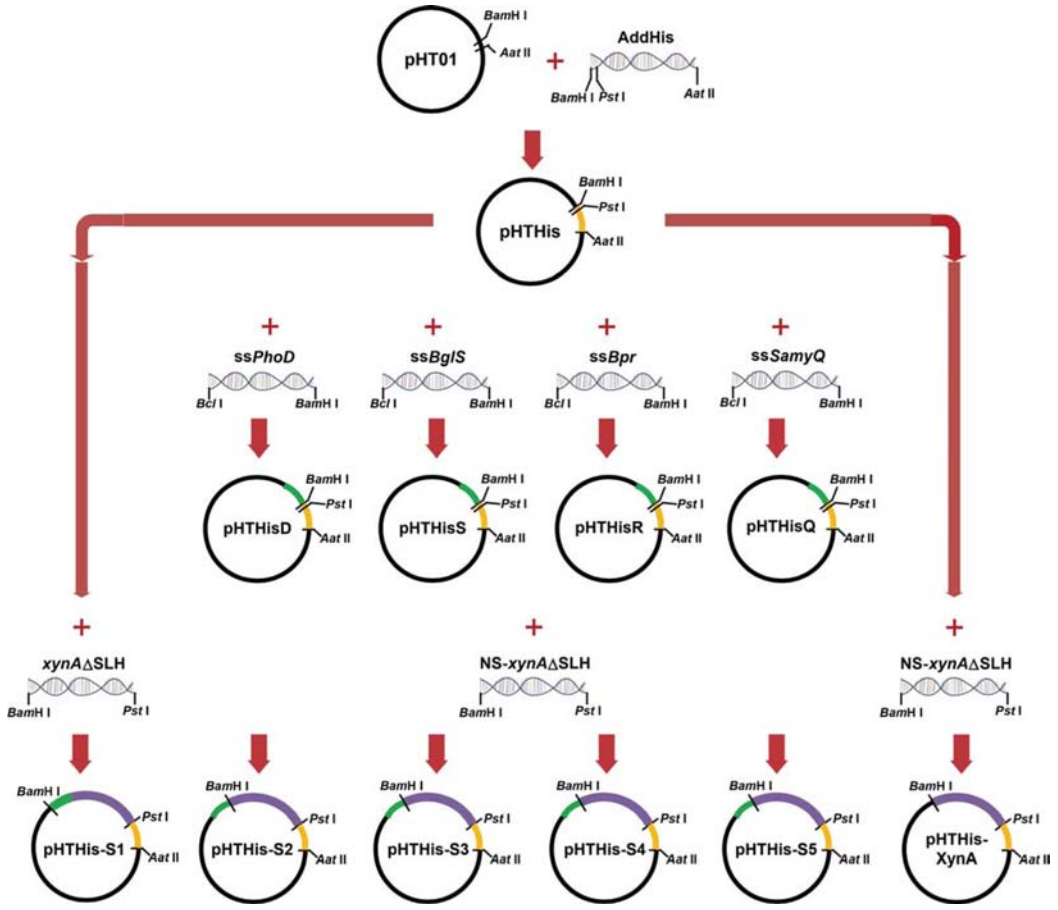

Figure 1. Heterologous expression vector construction for *B. subtilis* 1012wt. pHTHis-XynA is an intracellular expression plasmid derived from pHTHis with the deduced *xyn*AΔSLH. pHTHis-S1 is a secretion expression plasmid containing the deduced *xyn*AΔSLH and its native signal sequence. pHTHis-S2, pHTHis-S3, pHTHis-S4, and pHTHis-S5 are all secretion expression vectors with the deduced *xyn*AΔSLH.

In this study, six types of destination vectors carrying *xynA*ΔSLH expressed in *B. subtilis* were constructed. The *xynA*ΔSLH gene containing its native signal sequence was generated by PCR with primers sXynA-F1 and XynA-R3, then inserted between the *Bam*HI and *Pst*I sites of pHTHis, yielding pHTHis-S1. Similarly, another four secretion types of destination vectors containing different signal peptides were prepared as follows: the NS-*xynA*ΔSLH without its natural signal sequence was amplified by PCR with primers sXynA-F2 and XynA-R3 and inserted between the pHTHisD, pHTHisS, pHTHisR, and pHTHisQ (doubly digested with *Bam*HI and *Pst*I), generating pHTHis-S2, pHTHis-S3, pHTHis-S4, and pHTHis-S5. The vector pHTHis-XynA without signal sequence was constructed by inserting the NS-*xynA*ΔSLH between the *Bam*HI and *Pst*I sites of the plasmid pHTHis. Recombinant expression vectors were transformed into natural competent *B. subtilis* 1012wt as previously described.[24]

Heterologous Expression and Purification of Recombinant Xylanase. *E. coli* BL21(DE3) and *B. subtilis* 1012wt cells with various expression vectors were grown in Erlenmeyer flasks at 37 °C to the early exponential phase, followed by the addition of 1 mM IPTG to induce the expression of enzyme, and then incubated at 30 °C for 8 h for both *E. coli* and *B. subtilis*.

The cells were harvested by centrifugation at 13000*g* for 10 min and then resuspended in 20 mM Tris-HCl buffer (pH 7.5) containing 20 mM imidazole, 0.5 M NaCl, and 2 mg/mL lysozyme, followed by incubation at 45 °C for 1 h and sonication to release the intracellular proteins. The resulting clear supernatant was collected and loaded onto a HiTrap Chelating HP affinity column (GE Healthcare, Uppsala, Sweden) equilibrated with buffer (20 mM Tris-Cl, 20 mM imidazole, 0.5 M NaCl, pH 7.5). After binding, the column was washed with a linear gradient of 20−500 mM imidazole in 20 mM Tris-HCl buffer (pH 7.5) at a flow rate of 1 mL/min. Aliquots containing xylanase activity were pooled and loaded onto a HiPrep 26/10 desalting column (GE Healthcare). Fractions of the elute were stored in 100 mM Bis-Tris-HCl buffer (pH 6.5) containing 20% (v/v) glycerol at −20 °C.

Enzyme Characterization. Protein concentration was determined by a BCA Protein Assay Kit (Sangon, Shanghai, China) using bovine serum albumin (BSA; Sangon) as the standard. Protein homogeneity and molecular mass were estimated by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) in a 10 or 12% separating gel. Isolated proteins were visualized by staining with Coomassie Brilliant Blue R-250 (Sangon).

Xylanase activity was assayed by measuring the amount of reducing sugars released from beechwood xylan. The reaction mixtures contained 90 μL of 1% (w/v) beechwood xylan in 190 μL of 0.1 M Bis-Tris-HCl buffer (pH 6.5) and 20 μL of appropriately diluted enzyme. The catalytic reaction was carried out at 80 °C for 5 min and stopped on ice with the addition of 200 μL of 3,5-dinitrosalicylic acid (DNS) solution. The production of reducing sugars was measured at 540 nm as the literature reported.[25] One unit of xylanase activity was defined as the amount of enzyme required to release 1 μmol of reducing sugar equivalent per minute under assay conditions. All activity measurements were performed at least three times.

The pH profile of purified XynAΔSLH was determined by measuring the enzyme activity at 80 °C over the pH range from 3.5 to 9.0 using potassium acetate buffer (pH 3.5−6.0), Bis-Tris-HCl buffer (pH 6.0−7.0), and Tris-HCl buffer (pH 7.0−9.0). The enzyme activity obtained at the optimum pH was used to calculate the relative percentage of enzyme activity at other pH values. To estimate the pH stability, aliquots of purified enzymes were pre-incubated at 70 °C for 30 min at various pH values. Residual xylanase activities were

[a]Experiments were performed in triplicate and expressed as the mean value. The relative standard deviations were all <5%.

determined under standard assay conditions and expressed as a percent of the initial activity of the enzyme.

To determine the optimum temperature, the enzyme activities were assayed in 0.1 M Bis-Tris-HCl buffer (pH 6.5) at various temperatures ranging from 45 to 90 °C. To evaluate the thermostability, XynAΔSLH was incubated at various temperatures (70, 75, and 80 °C). Aliquots were sampled at appropriate intervals to assay the residual enzyme activity under standard conditions. Furthermore, the remaining xylanase activities were also determined after incubation at a temperature of 75, 76, 77, 78, 79, or 80 °C for 30 min.

To investigate the effects of different metal ions and chemical reagents on the purified XynAΔSLH activity, 1 or 5 mM (final concentration) KCl, NaCl, $CaCl_2$, $MgCl_2$, $MnCl_2$, or $CuCl_2$ and 0.5 or 1 mM EDTA were individually added to the reaction mixture. Residual xylanase activities were determined under standard assay conditions.

The kinetic parameters of purified XynAΔSLH were obtained by measuring the rate of hydrolysis of beechwood xylan at various concentrations ranging from 1 to 8 mg/mL under optimum conditions. The enzymatic kinetic parameters K_m, V_{max}, and K_{cat} were determined graphically from Lineweaver−Burk plots.

Analysis of Xylan Hydrolysis Products. A 2.5 mg/mL solution of xylobiose (X2), xylotriose (X3), xylotetraose (X4), or xylopentaose (X5) or 1% of beechwood xylan was incubated with 60 μg/mL of purified XynAΔSLH in 50 mM potassium phosphate buffer (pH 6.5) at 55 °C. Hydrolysis products of xylooligosaccharides and beechwood xylan were sampled after 30 min and 6 h, respectively. The samples were then analyzed on silica gel plates (CF_{254}, 100 × 100 mm, Merck) with a mixture of chloroform/acetic acid/water (3:6:1) as the solvent system. The sugars on the plate were incubated at 105 °C for 15 min and visualized by spraying with an ethanol concentrated sulfuric acid mixture (95:5, v/v) followed by heating at 105 °C for another 5 min. A xylooligosaccharide mixture containing equal concentrations of xylose, xylobiose, xylotriose, xylotetraose, and xylopentaose (Megazyme, Bray, Ireland) was used as the standard.

Sugar Cane Bagasse Hydrolysis. Sugar cane bagasse obtained from the Guangzhou Sugar Cane Industry Research Institute (Guangzhou, China) was air-dried, milled, and screened through a 0.3 mm sieve.[20] Then 0.2 g of the sugar cane bagasse was hydrolyzed in 20 mL of 0.1 M Bis-Tris-HCl buffer (pH 6.5) containing (a) 10 U of XynAΔSLH (based on the activity toward beechwood xylan), (b) 10 U of XynAΔSLH with 0.2 FPU (filter paper unit) of Cellic Ctec2 (Novozyme, Denmark), or (c) 0.2 FPU Ctec2 only. The hydrolysis was carried out for 18 h at 55 °C. One milliliter of reaction mixture was taken at different time interval for the reducing sugar analysis by the DNS method using xylose as standard.

Nucleotide Sequence Accession Number. The nucleotide sequence of *xynA* has been deposited in the GenBank database under accession no. KP743979.

RESULTS AND DISCUSSION

Cloning and Sequence Analysis of XynA. A xylanase gene (*xynA*), encoding 1432 amino acids with a calculated p*I* of 4.47, was amplified from the strain of *T. aotearoense* SCUT27. A BLAST search showed that XynA shares highest amino acid sequence identities of 93 and 81% with GH10 xylanases from *Thermoanaerobacterium saccharolyticum* (Swiss-Prot P36917.1) and *Ruminiclostridium thermocellum* (Swiss-Prot P38535.1), respectively.

Analysis of the deduced amino acid sequence revealed that there was a putative 32 amino acid signal peptide identified by SignalP 4.0 (http://www.cbs.dtu.dk/services/SignalP/) (Figure 2). It contained a typical "Ala-X-Ala" motif at the −3 and −1 positions relative to the cleavage site (designated +1), which is expected to be in secreted proteins recognized by type I signal peptidase from Gram-positive bacteria.[26] The BLAST algorithm scan of the GenBank database indicated that the mature XynA is a modular protein containing several different domains: a carbohydrate-binding domain (CBM), a catalytic domain (CD), and a surface layer homology (SLH) domain. The CD (D324−G643) is flanked by duplicated noncatalytic domains and shows high homology to catalytic domains of GH10. The highest homology (48%) was found with XynC from *Bacillus* sp. (Swiss-Prot O69230.1).[27] The N-terminal noncatalytic region of XynA contains a duplicated sequence (T5−L144, G162−S306) identified as a carbohydrate-binding module (CBM, CBM22 family), homologous to noncatalytic thermostabilizing domains from other xylanases.[27−29] Bergquist et al. reported that the absence of the CBM22 family module in 1,4-β-xylanase from *Caldibacillus cellulovorans* resulted in a decrease in thermostability of the catalytic domain.[29] However, the previously designated thermostabilizing domains have subsequently been shown to promote binding to xylan.[2] Another two tandem family 9 carbohydrate-binding modules (CBM9)

DOI: 10.1021/acs.jafc.5b01259
J. Agric. Food Chem. 2015, 63, 6430−6439

are located at S658−K822 and I826−T1010 downstream of the CD, playing a role in the microbial degradation of cellulose and hemicellulose. Three SLH domains at the carboxy-terminal end of the cloned *xynA* have been identified. The SLH domains seemingly play a role in anchoring the enzyme to the cell surface in plant polysaccharide degradation.[30,31] Some studies have shown that SLH domains neither contribute to enzyme activity nor are required for substrate binding.[32] The CBM9 and SLH domains were found connected via a linker region of 209 amino acids, which likely provides a certain degree of flexibility, helping attack on the substrate.[31]

Recombinant Expression of XynA. To validate the contribution of the SLH domain and the linker region to the enzymatic activity, *xynA* gene with or without SLH and linker sequences was separately cloned into the pET28a vector and expressed in *E. coli* BL21(DE3). After 8 h of induction by 1 mM IPTG, the crude xylanase activities were measured as 1.35 ± 0.00 and 1.40 ± 0.01 U/mL/OD_{600} for XynA and XynAΔSLH, respectively (Table 2). Results indicated that the SLH domain and linker sequences did not contribute to enzyme activity, as previous research pointed out that the SLH at the C-terminal end of XynA from *T. saccharolyticum* NTOU1 mediated enzyme anchorage on the bacterial surface layer and had no effect on catalytic efficiency.[12] When the N-terminal signal peptide was deleted, the xylanase activity (NS-XynAΔSLH) was further increased by 38% compared with XynAΔSLH. These further demonstrated the fact that the xylanase activity expressed in *E. coli* was negatively influenced by the existence of signal sequence. In the subsequent study, the sequence of *xynA* without signal sequence and SLH domain coding sequence was used for expression and characterization. It was interesting to note that two new protein bands on SDS-PAGE were detected for pET28a-*xynA* compared to the control sample (Figure 3). The molecular weights for the two bands

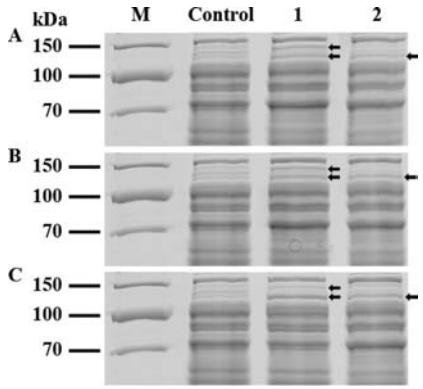

Figure 3. SDS-PAGE (12%) of XynA and XynAΔSLH expressed in *E. coli* BL21(DE3) for 4 h (A), 8 h (B), and 12 h (C). Lanes: control, *E. coli* BL21(DE3)/pET28a; 1, *E. coli* BL21(DE3)/pET28a-xynA; 2, *E. coli* BL21(DE3)/pET28a-xynAΔSLH; M, protein marker, broad range (PageRuler unstained protein ladder, Fermentas, Thermo).

were estimated to be 153 and 113 kDa, which agreed with the calculated molecular masses of XynA and XynAΔSLH from the amino sequence. Considering the fact that total xylanase activities for XynA and XynAΔSLH were nearly the same, we deduced that self-degradation or proteolytic degradation to XynAΔSLH would be occurred in the full-length XynA from *T. aotearoense* SCUT27 when it was expressed in *E. coli*.

Many heterologous protein expression systems have been developed to produce target proteins. Among them, *E. coli* is a valuable organism for the high-level production of recombinant proteins because of its many advantages. However, the application of *E. coli* in heterologous large protein expression is significantly limited, which may be caused by the lack of necessary control of the protein folding rates in the crowded *E. coli* cytoplasm.[33−35] Considered as a GRAS (generally recognized as safe) organism, *B. subtilis* has been developed as one of the best model bacteria for heterologous protein secretion. However, it is often impossible to predict whether a recombinant protein will be exported or to identify the suitable signal peptides for the target protein secretion.[36] To increase the expression level of XynAΔSLH, we constructed several versions of XynAΔSLH expression vectors in *B. subtilis* based on the pHT01 plasmid, including the Sec-dependent signal peptides of *ssBglS*, *ssBpr*, and *ssSamyQ* and the Tat signal peptide, *ssphoD* (Figure 1). The intracellular expression vector without any signal sequence in *B. subtilis* was also constructed.

To evaluate the expression level of XynAΔSLH, the extracellular and intracellular fractions of the recombinant *B. subtilis* were detected on SDS-PAGE (Figure 4) and the xylanase activities were determined (Table 2). Most of the total xylanase activities of XynAΔSLH were higher when expressed in *B. subtilis* than in *E. coli*, which was in part due to the enhanced cell density. Encouragingly, the total xylanase enzymatic activity increased dramatically from the basal level of 5.89 U/mL generated by *E. coli*/pET28a-NS-*xynA*ΔSLH to 11.93 U/mL by *B. subtilis*/pHTHis-XynA. The expression host change from *E. coli* to *B. subtilis* also resulted in a 4.1-fold increase of the specific xylanase activity, indicating that the increase of xylanase activity was due to the ability of a single cell. The results implied that *B. subtilis* 1012wt strain is a potential candidate to achieve a high-level expression of multidomain xylanase for industrial application. Many efforts have been made for high-level expression of xylanase through codon or medium optimization.[37−39] However, the molecular weights of these reported recombinant xylanases were <100 kDa. To our best knowledge, only a few studies focused on the expression level enhancement of multidomain xylanase.[14] Zhao et al. reported the recombinant *E. coli* harboring a multidomain xylanase gene showed a xylanase activity of 5.48 U/mL in shaker flasks.[17]

It should be mentioned that the secretion expression of the studied XynAΔSLH showed relatively much lower xylanase activity compared to the intracellular expression in *B. subtilis*. However, the attempts of secretion expression using *ssbglS*, *ssBpr*, or *ssSamyQ* as signal peptide indicated that the XynAΔSLH could be translocated in an unfolded state via the Sec-dependent pathway.[36] The reason for the inefficient exportation of the recombinant protein was complicated and ambiguous.[40] Tat-type signal peptide secretion system is an attractive alternative for the secretion of heterologous protein in *B. subtilis* because it dedicates the translocation of folded proteins across the bacterial cytoplasmic membrane. Unfortunately, the extracellular enzyme activities exported through this type of signal peptide originated from its native sequence (pHTHis-S1) and ss*phoD* (pHTHis-S2) were not satisfying. The reason might be attributed to the substrate specificity of the Tat-type translocases.[41,42] All these results implied that the secretion of XynAΔSLH from *T. aotearoense* SCUT27 in *B. subtilis* was preferably routed via a Sec-dependent pathway.

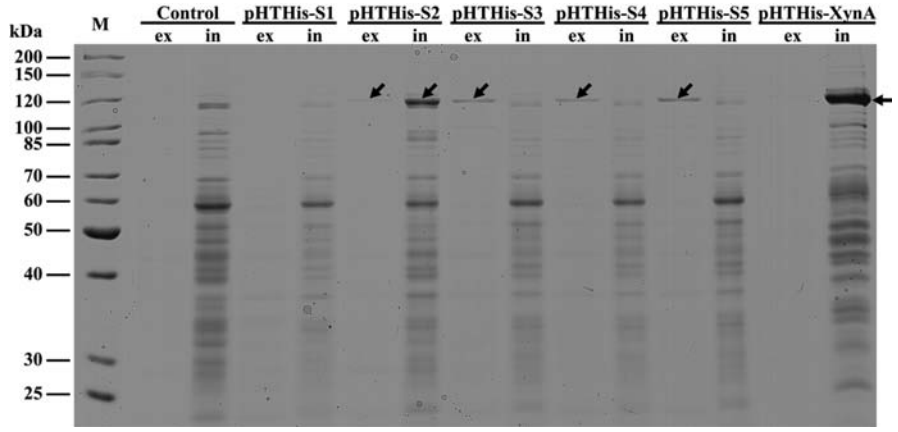

Figure 4. Expression of XynA in *B. subtilis* detected by Coomassie Brilliant Blue-stained 10% acrylamide SDS-PAGE using *B. subtilis* 1012wt as control (denoted "control"). Calculated molecular mass for mature xylanase XynAΔSLH was 113 kDa. Corresponding band positions are indicated by arrows. "ex" indicates extracellular fractions, and "in" denotes intracellular fraction of the cells. Lane M: protein marker, broad range (PageRuler unstained protein ladder, Fermentas, Thermo), the five largest bands of which were 200, 150, 120, 100, and 85 kDa, respectively.

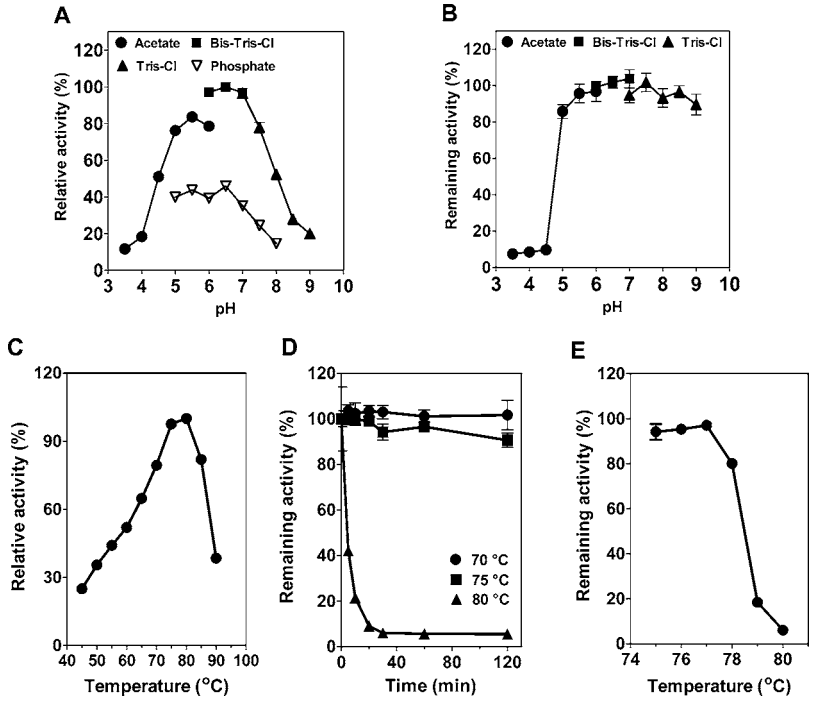

Figure 5. Effects of pH and temperature on the activity and stability of the recombinant XynAΔSLH expressed in *B. subtilis* 1012wt: (A) optimal pH; (B) pH stability (reaction buffers are potassium acetate buffer (pH 3.5−6.0, ●), Bis-Tris-HCl buffer (pH 6.0−7.0, ■), Tris-HCl buffer (pH 7.0−9.0, ▲), and potassium phosphate buffer (pH 5.0−8.0, ▽)); (C) optimal temperature; (D) thermostability of XynAΔSLH at 70 °C (●), 75 °C (■), and 80 °C (▲); (E) remaining activity of XynAΔSLH incubated at different temperatures ranging from 75 to 80 °C for 30 min. Values are the means and standard deviation of the average of three independent experiments.

Determination of Enzyme Activities and Properties. The XynAΔSLH expressed in *B. subtilis* (pHTHis-XynA) was purified by Ni-affinity chromatography and desalting. These procedures resulted in an 18.7-fold purification with a recovery yield of 79.2%, and a specific activity of 379.8 U/mg.

The influences of various buffers and pH on enzyme activities were studied using 100 mM potassium acetate buffer (pH 3.5−6.0), Bis-Tris-HCl buffer (pH 6.0−7.0), Tris-HCl buffer (pH 7.0−9.0) and potassium phosphate buffer (pH 5.0−8.0). Interestingly, XynAΔSLH exhibited relatively high activities in a rather broad pH range (pH 5.0−7.5) with an optimum activity in the Bis-Tris-HCl buffer at pH 6.5 (Figure 5A). At pH 5.0−8.0, the XynAΔSLH in phosphate buffers lost >50% of relative activity compared with the activity in the corresponding other buffers. At pH 6.0, XynAΔSLH was active in acetate and Bis-Tris-HCl buffers, but it was more significantly active in Bis-Tris-HCl buffer. The purified XynAΔSLH was stable between pH 5.0 and 9.0, retaining >80% of the initial enzyme activity after 30 min of incubation at 70 °C. However, it was rapidly irreversibly inactivated with pH <5.0 (Figure 5B).

The XynAΔSLH exhibited its optimal activity at 80 °C. At 85 °C, it showed about 80% of the optimum activity (Figure 5C). However, <40% of maximum activity was detected when the reaction temperature was increased to 90 °C. In contrast, it

DOI: 10.1021/acs.jafc.5b01259
J. Agric. Food Chem. 2015, 63, 6430−6439

displayed relatively low activities at lower temperatures, but sretained 25% of its highest activity at 45 °C.

The recombinant xylanase retained almost 100% of its initial activity when incubated at 70 °C, pH 7.0, for 2 h (Figure 5D) (data for temperatures below 70 °C are not shown). It remained about 90% of its activity after standing for 2 h at 75 °C, which indicated that the half-life of the recombinant xylanase was approximately 14.0 h at this temperature. Furthermore, it was interesting to find that the thermostability of the xylanase was sensitive in the range from 75 to 80 °C. The results showed that the XynAΔSLH lost its activity dramatically after incubation for 30 min at >79 °C. However, the recombinant xylanase retained about 80% of initial activity after being incubated at 78 °C for 30 min (Figure 5E).

With respect to kinetic parameters, the K_m, V_{max}, and K_{cat} of recombinant XynAΔSLH using beechwood xylan as the substrate were 4.10 mg/mL, 813.0 U/mg, and 1539.1 s^{-1}, respectively (Table 3). The K_{cat}/K_m ratio, reflecting the catalytic efficiency of enzyme, was 375.6 mL/mg·s, indicating that XynAΔSLH has great hydrolytic capacity for beechwood xylan. The specific activity of XynAΔSLH (379.8 U/mg) was much higher than that of other multidomain xylanases from *T. saccharolyticum* B6A-RI,[43] *T. saccharolyticum* JW/SL-YS485,[15] and *T. thermarum*.[16]

When various metal ions or EDTA was added into the reaction buffer separately, the activity of XynAΔSLH was not affected (100 ± 5%) by KCl (1 and 5 mM), NaCl (1 mM), or $MgCl_2$ (1 mM), but slightly affected (100 ± 25%) by $MnCl_2$ (1 mM), $CaCl_2$ (1 mM), NaCl (5 mM), and $MgCl_2$ (5 mM). However, its activity was strongly inhibited by $CaCl_2$ (5 mM) and $CuCl_2$ (1 mM). Besides that, EDTA (1 mM) addition in the reaction buffer reduced the activity of XynAΔSLH by 78% (Table 4). These findings suggested that some metal cations may serve to hold the enzyme in a catalytically active conformation. As a common trend, some metal ions are known to affect the xylanase activity. The enzymatic properties reported in this study are similar to those of other multidomain xylanases.[14,16] It should be mentioned that the activity of Xyn10A from *Thermotoga thermarum*, another multidomain xylanase, could be increased by >400% when the Ca^{2+} existed in the reaction mixture.[16]

Substrate Specificity and Products of Xylan Degradation. Experiments were carried out to study the specificity of XynAΔSLH to various substrates. The XynAΔSLH had the highest specific activity of 379.8 ± 3.2 U/mg toward beechwood xylan (defined as 100%), followed by oat spelt xylan (213.8 ± 1.6 U/mg, 56.3%). No obvious catalytic activity was detected when CMC-Na was used as substrate by XynAΔSLH (16.4 ± 0.4 U/mg). These results are contrary to other previously reported results; for example, the endoxylanases isolated from *T. thermarum*[16] and alkaline wastewater sludge[17] showed maximum activity on birchwood xylan, and xylanase from *G. thermoleovoranse* had maximum activity on oat spelt xylan.[13]

Using xylooligosaccharides or beechwood xylan as substrate, the purified XynAΔSLH showed relatively uniform hydrolysis capability (Figure 6). Xylotetraose and xylopentaose could be easily hydrolyzed to xylobiose with a trace of xylose by XynAΔSLH in 30 min of catalysis. However, much of xylotriose was not thoroughly degraded to xylobiose after being incubated at 55 °C for 30 min. Moreover, hydrolysis of xylobiose was not observed during the experiment. To ensure the maximum extent of degradation, the beechwood xylan was

EDTA	37.00 ± 1.46 (0.5 mM)	22.29 ± 0.94 (1 mM)

[a]Enzyme activity was determined under standard conditions in the presence of each compound at concentrations of 1 and 5 mM if it is not annotated. Relative activity was calculated by taking the activity in the absence of metals as 100%. Experiments were performed in triplicate, and data were expressed as the mean ± SD.

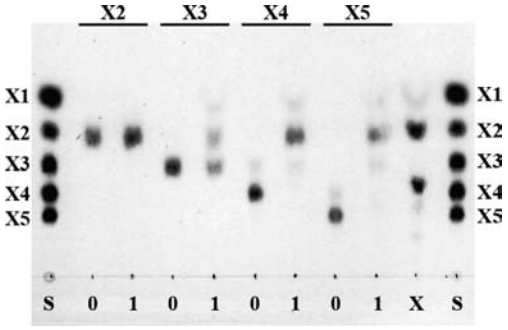

Figure 6. Thin-layer chromatography analysis of xylooligosaccharide or beechwood xylan hydrolysis products by the purified XynAΔSLH. 2.5 mg/mL of X2, X3, X4, or X5 was hydrolyzed by 60 μg/mL of XynAΔSLH in 50 mM potassium phosphate buffer (pH 6.5) at 55 °C for 0 (lane 0) and 30 min (lane 1). Lane X: 1% beechwood xylan hydrolysis was also carried out in 50 mM potassium phosphate buffer (pH 6.5) with 60 μg/mL of XynAΔSLH at 55 °C for 6 h. Lane S: standard mixture containing X1, X2, X3, X4, and X5.

incubated with XynAΔSLH for 6 h at 55 °C. Two major deposits were clearly shown on TLC. According to the mobility relative to the xylooligosaccharide standards, one of them was xylobiose, and the migration velocity of another deposit was a little faster than that of xylotetraose, indicating that it might be methylglucuronoxylotriose ($MeGlcAXyl_3$) according to previous research.[44] It was reported that $MeGlcAXyl_3$ might be the shortest aldouronic acid liberated from methylglucuronoxylan by the GH10 family of xylanases.[44,45] Depolymerization of beechwood xylan by XynAΔSLH also released a little xylose, which was found in the hydrolysis products of xylotriose, xylotetraose, or xylopentaose as well. All of the results suggested that although the middle subsites would be more specific, XynAΔSLH could attack the xylosidic linkage at the terminus while there was not a glucuronic acid as a substituted residue to block the cleavage.

Sugar Cane Bagasse Hydrolysis. Efficient hydrolysis of lignocellulosic biomass into fermentable sugars is the key step in the biofuel production. A combination of a commercial cellulase (Cellic Ctec2) from Novozyme with the purified XynAΔSLH was applied to the sugar cane bagasse hydrolysis. Results showed that XynAΔSLH supplementation in the reaction mixture led to an increase of up to 63.4% of reducing sugar production (Figure 7). After 78 h treatment with Cellic

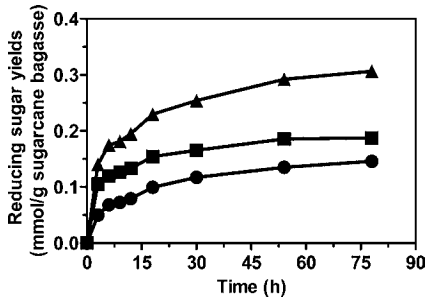

Figure 7. Hydrolysis of sugar cane bagasse by XynAΔSLH and Cellic Ctec2: ●, reaction with XynAΔSLH only; ■, reaction with Cellic Ctec2 only; ▲, reaction with XynAΔSLH and Cellic Ctec2. 0.2 g of sugar cane bagasse was hydrolyzed in 20 mL of 0.1 M Bis-Tris-HCl buffer (pH 6.5) containing 10 U of XynAΔSLH with or without Cellic Ctec2 (0.2 FPU). Experiments were carried out in triplicate, and all standard deviations were <5.0%.

Ctec2 and XynAΔSLH, about 0.3 mmol of reducing sugars per gram of sugar cane bagasse was released. Compared to the hydrolysis without XynAΔSLH, 0.19 mmol of reducing sugars was obtained per gram of sugar cane bagasse. When the purified XynAΔSLH was used as the sole hydrolyzing enzyme, it was also able to release reducing sugars with a final concentration of 0.15 mmol per gram sugar cane bagasse. The sugar cane bagasse contains about 40% of glucan and 20% of xylan.[20] Assuming that xylobiose was the only product by XynAΔSLH, 43.7 mg of xylobiose, accounting for 22.5% of the sugar cane bagasse, was produced. This indicated that almost all of the xylan in the sugar cane bagasse was converted into xylooligosaccharides. Adding XynAΔSLH with other glycosidic hydrolases in the degradation process of lignocellulosic biomass could efficiently enhance the conversion of polysaccharides.

A multidomain xylanase affiliated with the GH10 family from *T. aotearoense* SCUT27 was cloned, sequenced, and analyzed in this study. Successful improvement to the expression of the truncated XynAΔSLH was achieved in *B. subtilis*. Moreover, the wide pH stability, high temperature tolerance and thermostability, high specific activity value, and outstanding performance in the beechwood xylan or sugar cane bagasse hydrolysis make this endoxylanase a suitable candidate for biofuel and bioprocessing industries using cellulosic biomass as substrate.

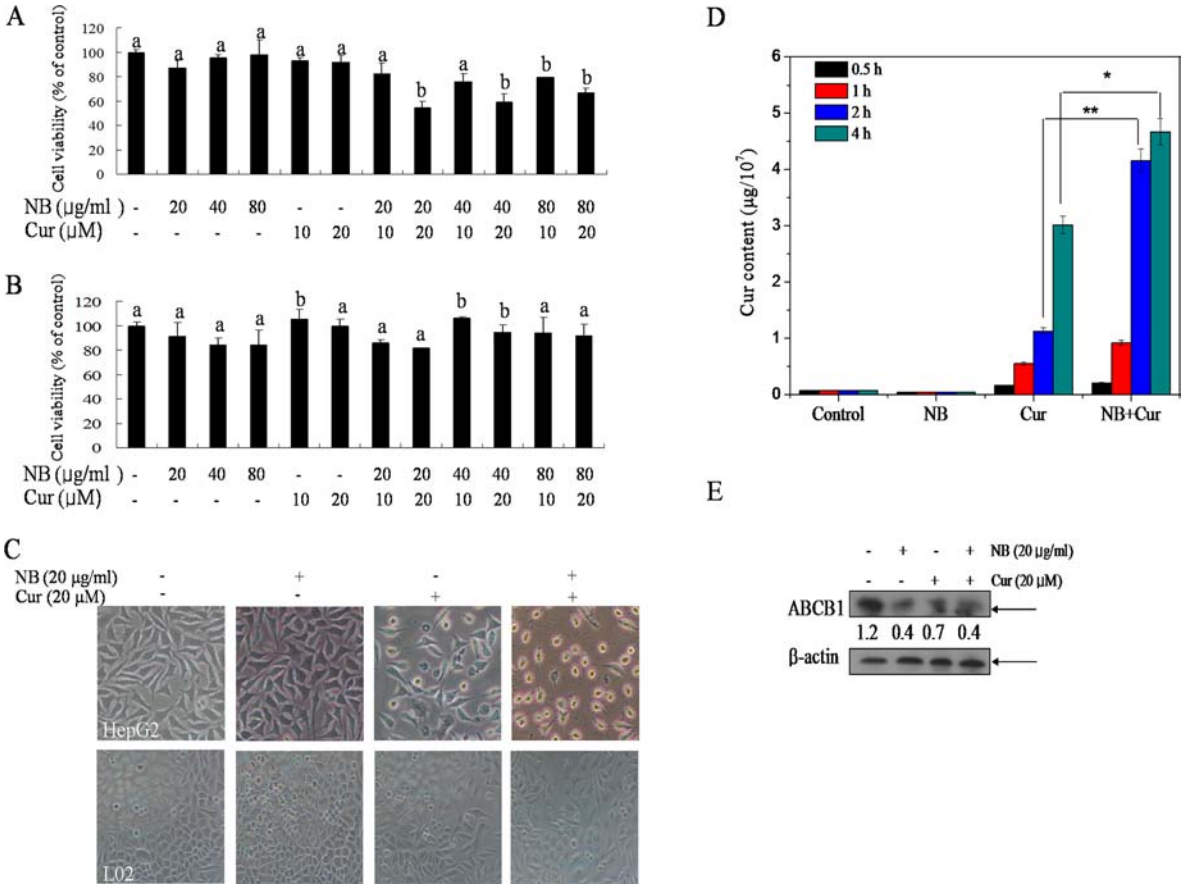

Figure 1. NB enhances the anticancer effects of Cur on HepG2 cells. (A) HepG2 cells were treated with different concentrations of NB (20, 40, 80 μg/mL) and Cur (10, 20 μM) alone and their combinations for 24 h. Bars with different characters are statistically different at the $P < 0.05$ level relative to control. (B) The human fetal liver cells L02 were exposed to different concentrations of NB (20, 40, 80 μg/mL) and Cur (10, 20 μM) alone and their combination for 72 h. Bars with different characters are statistically different at the $P < 0.05$ level relative to control. (C) MTT staining image of cells after treatments as examined by light microscopy (magnification 10×). HepG2 and LO2 cells growth inhibition induced by pretreatment of 20 μg/mL NB for 12 h then incubated with 20 μM Cur for 24 and 72 h, respectively. (D) NB enhances the cellular uptake of Cur. Quantitative analysis of Cur content in HepG2 cells exposed to NB and Cur alone and their combination for 0.5, 1.0, 2.0, 4.0 h, respectively. Bars between NB + Cur groups and Cur groups are significantly different at the $P < 0.05$ (*) or $P < 0.01$ (**) level. (E) Effects of NB on the expression levels of ABCB1 were detected by Western blotting assay. HepG2 cells were pretreated with or without 20 μg/mL NB for 12 h then incubated with or without 20 μM Cur for 24 h.

In the present study, two-dimensional polyacrylamide gel electrophoresis (2-DE) is used to investigate differentially expressed proteins in HepG2 cells under different treatment conditions and 2-DE integrated with matrix assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) has been used to further identify anticancer mechanism of NB and Cur in combination by a comparative proteomics approach.

MATERIALS AND METHODS

Materials. Curcumin (Cur), 3-(4,5-dimethylthiazol-2-yl)-2.5-diphenyltetrazolium bromide (MTT), propidium iodide (PI), and bicinchoninic acid (BCA) kit were bought from Sigma-Aldrich (Sigma-Aldrich, St. Louis, MO, USA). NB was obtained from the Natural Institute for the Control of Pharmaceuticals and Biological Products, Beijing, China. All reagents used in 2-DE were purchased from Bio-Rad Laboratories (Hercules, CA, USA). Antibodies against p53, p21, cdc2, and cyclin B1 were purchased from Cell Signaling Technology (Beverly, MA, USA).

Cell Culture. The human hepatocellular carcinoma cell line HepG2 was purchased from American Type Culture Collection (ATCC, Manassas, VA, USA). The human fetal liver cell line LO2 was obtained from Nanjing KeyGEN Biotech. CO., Ltd. (Nanjing, China). Both the cell lines were cultured in DMEM medium with 10% fetal bovine serum, 100 units/mL penicillin, and 50 units/mL streptomycin at 37 °C in a humidified (5% CO_2, 95% air) atmosphere.

Cell Viability Assay. The HepG2 cells with a density of 2×10^4 cells/well and LO2 cells with a density of 5×10^4 cells/well were seeded in 96-well culture plates for 24 h. The cells were pretreated with or without NB at different concentrations for 12 h and coincubated with or without Cur at different concentrations for different periods of time. Cell viability was determined by the MTT assay as previously described.[27]

Flow Cytometric Analysis. The HepG2 cells were harvested after treatment of NB (20 μg/mL)/Cur (20 μM) for 24 h, washed with PBS, and fixed with 70% cold ethanol at −20 °C overnight. The fixed cells were then stained with PI for 30 min in darkness. The cell cycle distribution was monitored by flow cytometric analysis as previously described by Chen et al.[28]

2-D SDS-PAGE Analysis. The HepG2 cells were treated with NB (20 μg/mL), Cur (20 μM), and NB (20 μg/mL)/Cur (20 μM) for 24 h, respectively. Then, the cells were washed with phosphate buffered saline (PBS) and were lysed with 1000 μL of alkylsis buffer including 20 mM Tris, 7 M urea, 2 M thiourea, 2% 3-[(3-cholamidopropyl)]-dimethylammonio-1-propanesulfonate (CHAPs), and 1 mM phenylmethanesulfonyl fluoride (PMSF). The cell lysates were treated with ultrasound to break nucleic acid and centrifuged at 12000 rpm/min for

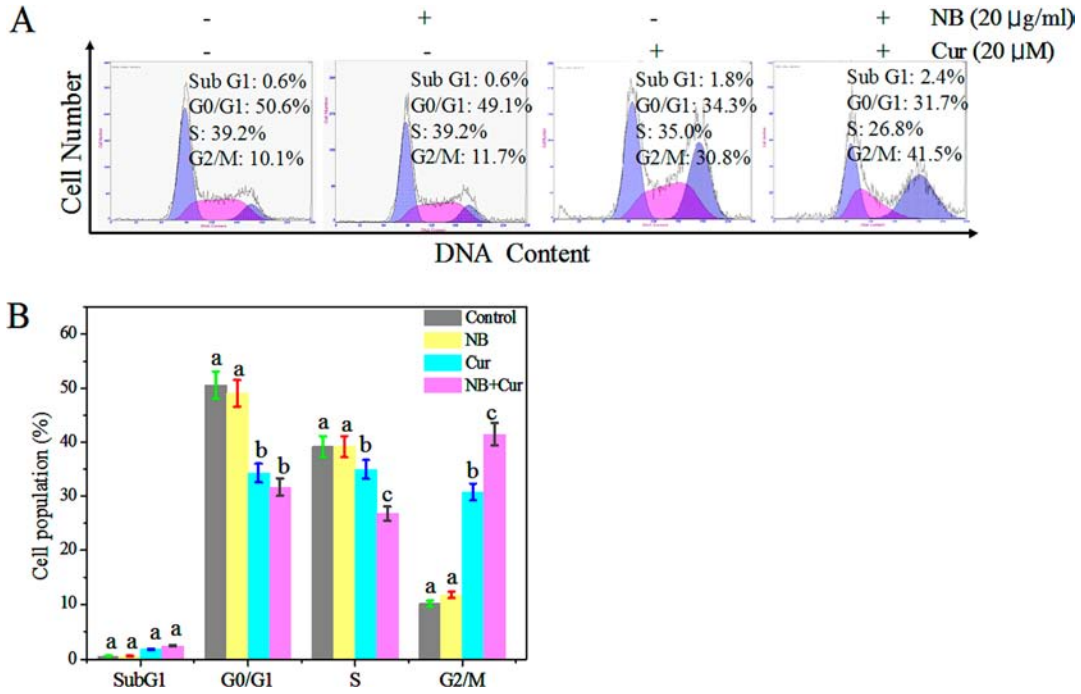

Figure 2. NB enhances Cur induces apoptosis in HepG2 cells. (A) NB/Cur induces G2/M-phase arrest in HepG2 cells. Cells after treatment were harvested and fixed with 70% ethanol before being stained with propidium iodide. (B) Quantitative analysis of NB/Cur induced cell cycle arrest in HepG2 cells by measuring the SubG1, G0/G1, S, and G2/M cell population. All data here are expressed as means ± SD of triplicates. Bars with different characters are statistically different at the $P < 0.05$ level. All images shown here are representative of three independent experiments with similar results.

20 min at 4 °C, and the supernatant was transferred into new EP tubes. Proteins from the supernatant were precipitated by acetone and then kept at −20 °C overnight. The protein concentration was measured using the Bradford assay with bovine serum albumin (BSA) as the standard sample for normalization. The protein samples were diluted to 450 μL rehydration buffer solution containing 7 M urea, 2 M thiourea, 4% CHAPs, 1% dithiothreitol (DTT), 1% immobilized pH gradient (IPG) buffer, and a trace of 1× bromophenol blue. Then, the samples were applied to immobilized dry IPG strips (linear pH gradient from pH 4−7, 24 cm) and rehydrated for 12 h. The samples were then focused for 30 min at 300 V, 30 min at 700 V, 90 min at 1500 V, 3 h gradient at 9000 V, and 4 h at 9000 V, for a total of 52 kV·h, using the Ettan IPGphor 3 isoelectric focusing (IEF) system (GE Health care, Little Chalfont, Buckinghamshire, UK). Focused IPG strips were equilibrated in 8 mL sodium dodecyl sulfonate (SDS) equilibration buffer I (6 M urea, 30% (v/v) glycerol, 2% (w/v) SDS, 50 mM Tris-HCl, pH 8.8, 0.002% bromophenol blue, and 100 mM DTT) for 15 min and then equilibrated for an additional 15 min in SDS equilibration buffer II (6 M urea, 30%(v/v) glycerol, 2% (w/v) SDS, 50 mM tris-HCl, pH 8.8, 0.002% bromophenol blue, and 250 mM iodoacetamide). After equilibration, 12.5% SDS-PAGE was performed on an Ettan DALTsix system (GE Health care, Little Chalfont, Buckinghamshire, UK). The 2-DE gel was then visualized using silver staining.

Protein Identification by MALDI-TOF-MS Analysis. The stained 2-DE gels were scanned with UMAX Powerlook1100 scanner (UMAX) and analyzed using ImageMaster 2D platinum 5.0 (GE Healthcare, Little Chalfont, Buckinghamshire, UK) according to the manufacturer's protocol. The spots of interest were manually excised from the silver-stained gel and subjected to in-gel trypsin digestion. After digestion, the peptides in gel pieces were then extracted using extraction buffer containing 2.5% trifluoroacetic acid (TFA) and 90% acetonitrile (ACN). The extracts were dried completely using a DZF-6020 vacuum drying system (Yiheng instrument Co., Ltd., Shanghai, China). The peptides were redissolved using 0.1% TFA in 30% ACN. Then, 0.5 μL of matrix (5 mg/mL α-cyano-4-hydroxycinnamic acid [CHCA] in 50% ACN and 0.1% TFA) was added into 0.8 μL of peptide solution before spotting on the target plate. Protein identification was carried out on an Ultraflex III MALDI-TOF mass spectrometric analysis (Bruker Dalton, Billerica, MA, USA). The peptides were detected in 355 nm UV wavelength and were accelerated with a 20000 V voltage. The peptides were scanned in the mass range of 700−3200 Da. Peptide masses were matched with the theoretical peptides of all proteins in the NCBI database using the BioTools (Bruker Dalton, Billerica, MA, USA) software. The following parameters were used for the database searching: peptides mass range of 800−4000 Da, first grade mass tolerance of 50 ppm, second grade mass tolerance of 0.5 Da, a maximum of one missed cleavage, monoisotopic masses, methionine oxsidation as a variable modification, cysteine iodoacetamide as a global modification.

Western Blot Analysis. Total cellular proteins were harvested by incubating the cells in the lysis buffer obtained from Cell Signaling Technology. The protein concentrations were determined by BCA kit (Sigma-Aldrich, St. Louis, MO, USA) according to the manufacturer's protocols. Equal amounts of protein (30 μg) loaded per lane were run on 10% SDS-PAGE, and transferred to nitrocellulose membrane at 110 V for 1 h. Following blocking with 5% nonfat milk in TBST buffer (20 mM Tris-HCl [pH 7.4], 137 mM NaCl, and 0.1% Tween-20) for 2 h, the membranes were then incubated with primary antibodies at 1:1000 dilution in 5% nonfat milk overnight at 4 °C and then incubated with secondary antibodies conjugated with horseradish peroxidase at 1:2000 dilution for 1 h at room temperature. Protein bands were visualized on X-ray film using an enhanced chemiluminescence system (Kodak, Rochester, NY, USA).

Measurement of ROS Generation. The intracellular production of reactive oxygen species (ROS) was measured by dihydroethidium (DHE) fluorescence assay according to the previously description.[20]

Statistical Analysis. Experiments were carried out at least in triplicate and repeated three times. All data were expressed as mean ± SD. Statistical analysis was performed using SPSS statistical package (SPSS 13.0 for Windows; SPSS, Inc. Chicago, IL, USA). The difference between two groups was analyzed by two-tailed Student's *t* test. The difference between three or more groups was analyzed by one-way analysis of variance multiple comparisons. Differences with *P*

< 0.05 (*) or P < 0.01 (**) were considered statistically significant. Bars with different characters are statistically different at the P < 0.05 level.

RESULTS AND DISCUSSION

NB Enhances Cur-Induced the Growth Inhibition on HepG2 Cells through Enhancement of the Cellular Uptake of Cur. To determine the cytotoxicity effects of NB and Cur in combination on HepG2 cells, the cells were treated with different concentrations of NB (20, 40, 80 μg/mL) alone and Cur (10, 20 μM) alone and in their combinations for 24 h, while LO2 cells were exposed to NB alone and Cur alone and in their combination for 72 h. As shown in Figure 1A,B, NB not only induced negligible growth inhibition on HepG2 cells, but also slightly promoted cell growth. Meanwhile, Cur alone only demonstrated a slight inhibition of cancer cell growth. However, pretreatment of the cells with NB significantly enhanced the cells growth inhibitory effects of Cur on HepG2 cells. Interestingly, the combination of 20 μg/mL NB and 20 μM Cur exhibited the highest cytotoxicity against HepG2 melanoma cells with the cell viability at 54.3% (cells exposure to NB/Cur for 24 h), but showed the lower cytotoxicity toward LO2 cells with the cell viability at 81.5% (cells exposure to NB/Cur for 72 h). Therefore, we selected 20 μg/mL NB and 20 μM Cur for single or combination treatments in all subsequent experiments.

The above results were also confirmed by microscopic examination. As displayed in Figure 1C, the images showed that HepG2 cells treated with NB and Cur in combination had more cell shrinkage, cell rounding, and formation of apoptotic bodies than those treated with Cur alone and NB alone. In contrast, LO2 cells treated with NB alone and Cur alone and their combination remained intact with regularity in shape.

In order to determine whether NB enhanced the anticancer activity of Cur via the increase of Cur content, fluorescent spectrometry was employed to measure the cellular uptake of Cur. As shown in Figure 1D, compared with Cur treatment alone, HepG2 cells exposed to NB and Cur in combination significantly increased the Cur concentration in a time dependent manner. For instance, after 0.5, 1.0, 2.0, and 4.0 h incubation with NB and Cur in combination, the intracellular concentrations of Cur reached 0.2, 0.9, 4.2, and 4.7 $\mu g/10^7$ cells, which was about 1.2, 1.6, 3.5, and 1.5 times higher than Cur treatment alone (0.2, 0.6, 1.1, and 3.0 $\mu g/10^7$ cells), respectively. These results demonstrated that NB enhanced the cellular uptake of Cur in HepG2 cells.

To further investigate the mechanism of NB enhancement of cellular Cur uptake, we analyzed the expression of ABCB1 (a main multidrug resistance protein) protein by Western blotting assay. The results exhibited that pretreatment of HepG2 cells with NB markedly decreased the expression of ABCB1 compared with Cur treatment alone, which contributed to the enhancement of Cur content induced by NB (Figure 1E).

The results clearly demonstrated that NB enhanced the cellular uptake of Cur to inhibit the cell viability of HepG2 cells.

NB Enhances Cur-Induced the Growth Inhibition on HepG2 Cells through Induction of G2/M Cell Cycle

DOI: 10.1021/acs.jafc.5b01773
J. Agric. Food Chem. 2015, 63, 6440−6449

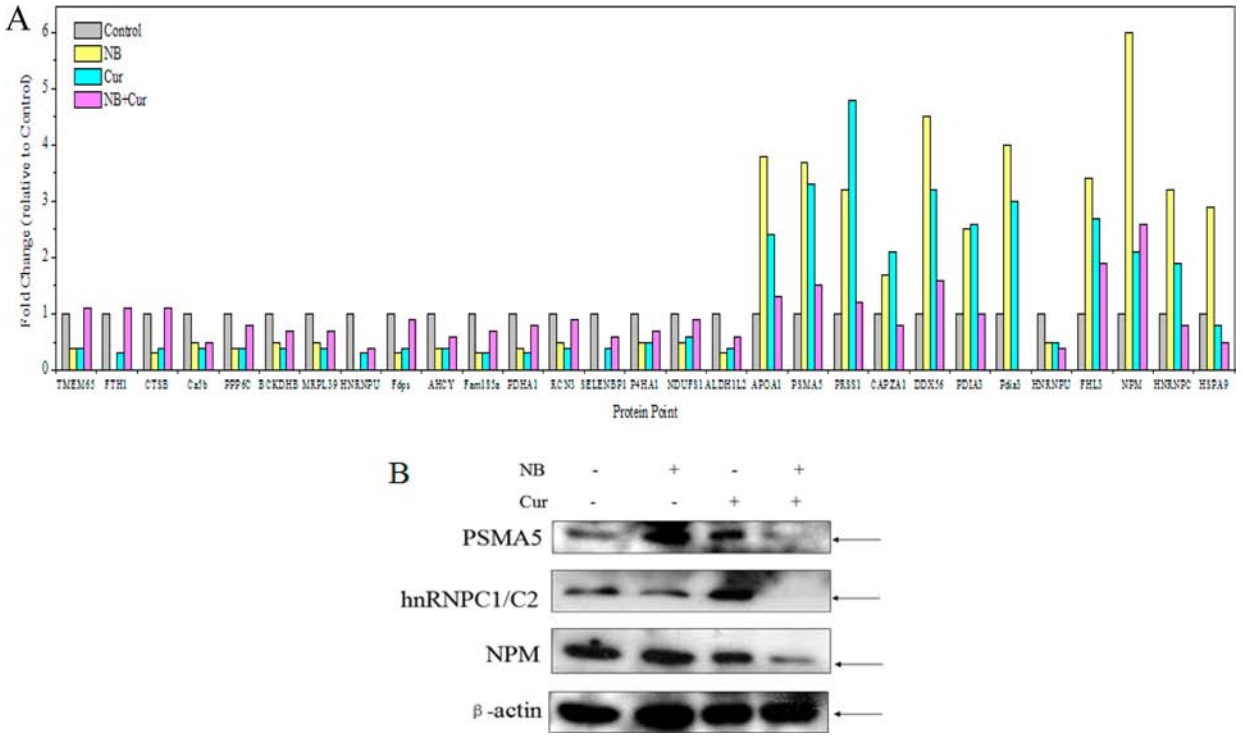

Figure 5. Results of proteomic analysis for alterations of proteins in NB-, Cur-, and NB/Cur-treated HepG2 cells (A) and the effects of NB/Cur on the expression levels of PSMA5, hnRNPC1/C2, and NPM (B). HepG2 cells were pretreated with 20 μg/mL NB for 12 h then incubated with 20 μM Cur for 24 h. The expression levels of PSMA5, hnRNPC1/C2, and NPM were detected by Western blotting assay.

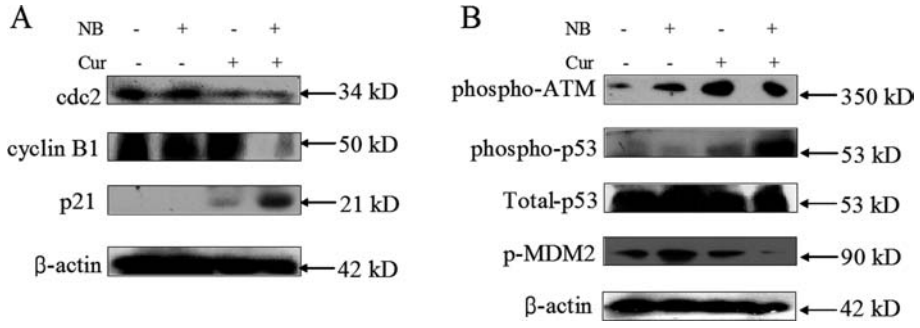

Figure 6. Effects of NB/Cur on the expression levels of cdc2, cyclin B1, and p21. HepG2 cells were pretreated with 20 μg/mL NB for 12 h then incubated with 20 μM Cur for 24 h. (A) The expression levels of cdc2, cyclin B1, and p21 were detected by Western blotting assay. (B) The phosphorylation status and expression levels of ATM, p53, MDM2 were examined by Western blotting analysis.

Arrest. Because of the significant proliferation inhibitory effect of NB and Cur in combination on HepG2 cells, we carried out the effects of NB/Cur on cell cycle distribution by flow cytometry. As shown in Figure 2A,B, the results showed that concomitant with the growth inhibitory effect, NB/Cur treatment induced a strong G2/M-phase arrest. For instance, cell populations in the G0/G1, S, and G2/M phases were 50.6, 39.2, and 10.1% in control HepG2 cells, respectively. No significant increase in the G2/M phase population was observed in cells exposed to NB (20 μg/mL) alone. Treatment of Cur alone increased the G2/M population from 10.1% (control) to 30.8%. However, compared with the treatment of Cur alone, after 24 h of incubation with the combination of NB (20 μg/mL) and Cur (20 μM), the G2/M population was noticeably enhanced by 10.7%. This increase in the G2/M phase cell population was accompanied by a concomitant decrease in the G0/G1 and S phase cell populations. Meanwhile, the sub-G1 population was slightly increased from 0.6% (control) to 2.4% in cells exposed to NB/Cur. The results demonstrated that NB/Cur inhibited the growth of HepG2 cells through induction of G2/M arrest.

Proteomic Analyses of the NB/Cur Effect on HepG2 Cells. To further confirm the induction of G2/M arrest and understand the toxicity of NB/Cur in HepG2 cells from a molecular perspective, the proteomic profile changes induced by NB/Cur were investigated by comparative 2DE proteomic analysis. A total of 32 protein spots were found to be differentially expressed proteins between Cur-treated groups and NB/Cur-treated groups. The position of each spot is shown in Figure 3. On this basis, all these 32 protein spots were further identified by MALDI-TOF-MS, and four protein spots were found to be repeated. Information about each spot is shown in Table 1. The identified proteins have been classified in terms of their biological process and subcellular localization. The proteins were divides into seven classes including proteins related to cell cycle and apoptosis (28.1%), DNA repair (9.4%),

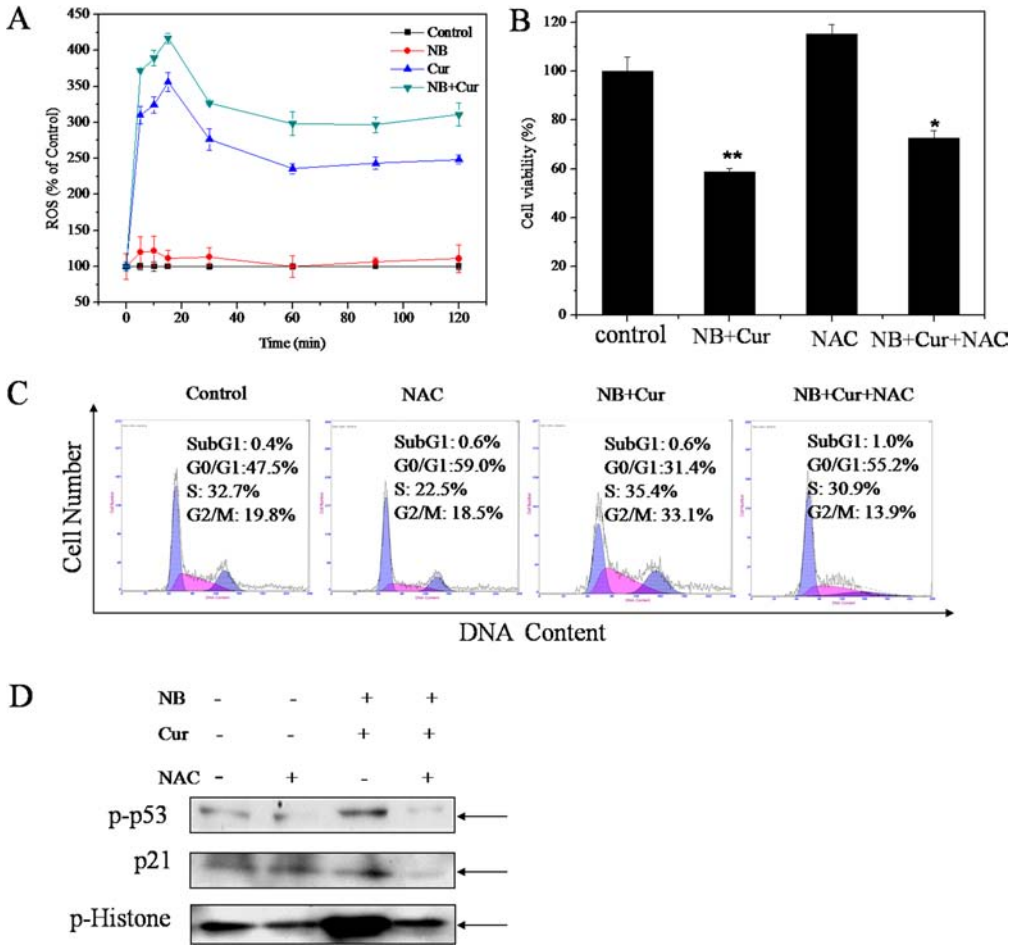

Figure 7. Role of intracellular ROS generation in G2/M cell cycle arrest induced by NB/Cur. (A) Cells were exposed to NB and Cur at indicated concentration for different times, and the levels of the intracellular ROS were analyzed by measuring the fluorescence intensity of an oxidation-sensitive fluorescein DHE. Cells were treated with 20 μg/mL NB with or without 20 μM Cur for different periods of time. (B) Effects of NAC on cell viability of NB/Cur-treated HepG2 cells. Cells were pretreated with 2 mM NAC or for 4 h prior to addition of NB and Cur. Cell viability was determined by MTT assay. All results were obtained from three independent experiments. Bars with a significant difference between treatment and control groups is indicated at the $P < 0.05$ (*) and $P < 0.01$ (**) levels. (C) Effects of NAC on G2/M cell population. Cells were pretreated with 2 mM NAC or for 4 h prior to addition of NB and Cur. Cell cycle was determined by flow cytometric analysis. All results were obtained from three independent experiments. (D) Effects of NAC on the expression levels of p21, p53, and p-histone. Cells were pretreated with 2 mM NAC or for 4 h prior to addition of 20 μg/mL NB and 20 μM Cur. The expression levels of p21, p53, and p-histone were detected by Western blotting assay.

RNA splicing and RNA process (15.6%), metabolism process (18.8%), transport (6.2%), lipid metabolism (3.1%), and others (18.8%) (Figure 4A). Subcellular localization of the detected proteins is illustrated. The majority of identified proteins fall in the nucleus (28.1%), mitochondrion (21.9%), endoplasmic reticulum (15.6%), cytoplasm (15.6%), membrane (6.3%), lysosome (3.1%), and others (9.4%) (Figure 4B). Among all identified proteins, 12 proteins were down-regulated and 17 proteins were up-regulated (Figure 5A). The down-regulated proteins are apolipoprotein A-I (APOA1), proteasome subunit alpha type-5 (PSMA5), DNA-directed RNA polymerases I, II, and III subunit RPABC3 (PRSS1), F-actin-capping protein subunit alpha-1 (CAPZA1), probable ATP-dependent RNA helicase DDX56 (DDX56), protein disulfide-isomerase A3 (PDIA3), protein disulfide-isomerase A3 (Pdia3), neterogeneous nuclear ribonucleoprotein U (HNRNPU), four and a half LIM domains protein 3 (FHL3), nucleophosmin (NPM1), heterogeneous nuclear ribonucleoproteins C1/C2 (HNRNPC), and stress-70 protein (HSPA9), while up-regulated proteins are transmembrane protein 65 (TMEM65), ferritin heavy chain (FTH1), cathepsin B (CTSB), carbonic anhydrase 5B (Ca5b), serine threonine protein phosphatase 6 catalytic subunit (PPP6C), 2-oxoisovalerate dehydrogenase subunit beta (BCKDHB), 39S ribosomal protein L39 (MRPL39), heterogeneous nuclear ribonucleoprotein U (HNRNPU), farnesyl pyrophosphate synthase (Fdps), adenosylhomocysteinase (AHCY), protein FAM185A (Fam185a), pyruvate dehydrogenase E1 component subunit alpha (PDHA1), reticulocalbin-3 (RCN3), selenium-binding protein 1 (SELENBP1), prolyl 4-hydroxylase subunit alpha-1 (P4HA1), NADH-ubiquinone oxidoreductase 75 kDa subunit (NDUFS1), and probable 10-formyltetrahydrofolate dehydrogenase ALDH1L2 (ALDH1L2). These proteins are involved in cell cycle and apoptosis, DNA repair, RNA splicing and RNA process, metabolism process, transport, and lipid metabolism in the anticancer activity of NB and Cur in combination.

Of these proteins, proteasome subunit alpha type-5 (PSMA5), heterogeneous nuclear ribonucleoproteins C1/C2 (hnRNPC1/C2), and nucleophosmin (NPM) were not reported in previous proteomic studies on NB/Cur exposure, which are of particular interest. These three proteins involved

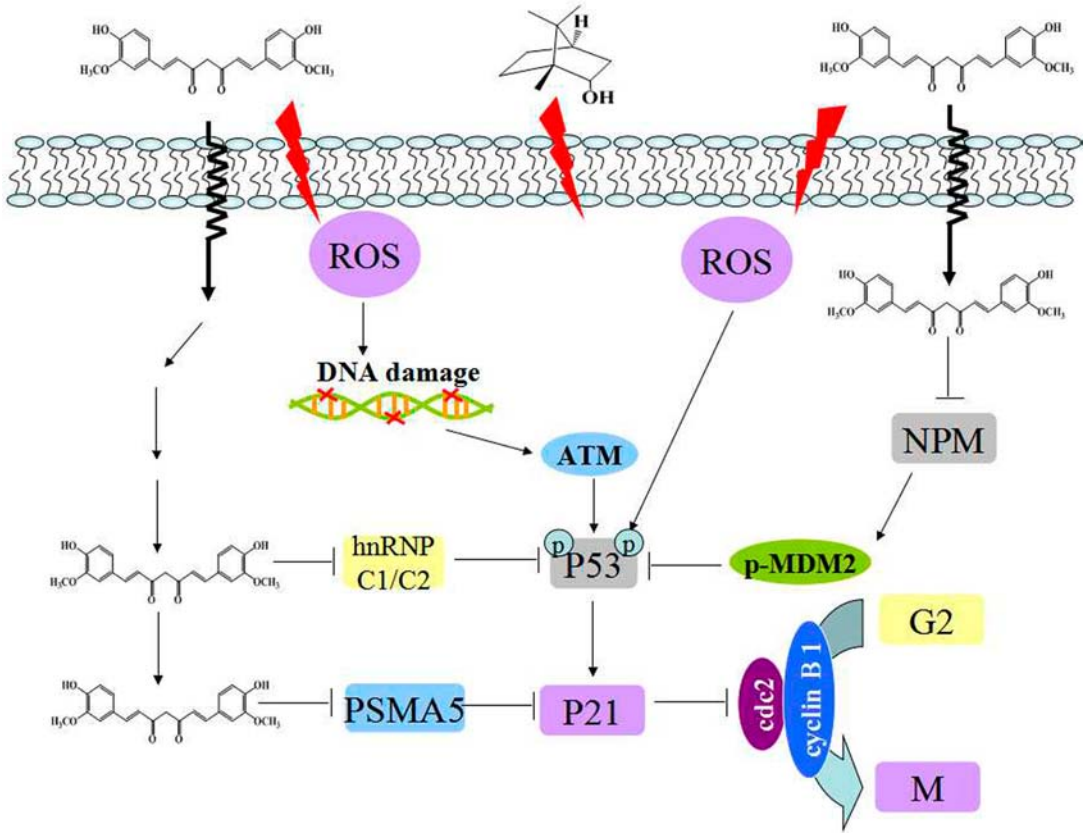

Figure 8. Proposed signaling pathway triggered by NB/Cur in HepG2 cells.

in RNA splicing, DNA repair and cell cycle and apoptosis in the anticancer activity of NB/Cur are discussed below.

Proteasome subunit alpha type-5 (PSMA5) is a subunit of 20S proteasome, which is a high molecular weight proteolytic enzyme and widely presents in the cytoplasm and the nucleus of eukaryotic cells.[29] Previous studies showed that protein degradation by the proteasome is the most regulatory mechanism in the cell, and inhibition of the proteasome activity can induce apoptosis and/or cell cycle arrest in cancer cells.[30−32] Our results indicated that compared with NB or Cur alone treatment, proteasome subunit alpha type-5 (PSMA5) could be down-regulated by NB/Cur. Moreover, further studies using Western blotting also exhibited that exposure of HepG2 cells to NB/Cur markedly down-regulated the expression level of PSMA5 (Figure 5B), which is consistent with the above results.

Heterogeneous nuclear ribonucleoprotein C1/C2 (hnRNP C1/C2), belonging to the hnRNP family, is a nuclear pre-mRNA binding protein that regulates pre-mRNA processing.[33] Studies demonstrated that hnRNP C1/C2 is involved in various biological processes, such as mRNA splicing,[34,35] cell cycle and apoptosis.[36,37] Nucleophosmin (NPM) is a vital player in the DNA-damage response and cell-cycle regulation, and it is an important regulator of p53 by modulating Mdm2.[39] Our results showed that compared to NB or Cur alone treatment, NB/Cur treatment resulted in a decrease in the expression levels of hnRNP C1/C2 and NPM (Figure 5A). These results were further confirmed by a Western blot assay. Indeed, as shown in Figure 5B, the expression levels of hnRNP C1/C2 and NPM were down-regulated when cells were exposed to NB/Cur (Figure 5B).

NB Enhances Cur-Induced G2/M Arrest in HepG2 Cells through Down- Regulation of the Expression of Cdc2 and Cyclin B1. Studies showed that hnRNP C1/C2 can regulate p53 expression and participate in DNA damage repair by the NHEJ pathway.[38,39] Moreover, NPM also can modulate Mdm2 to regulate p53 expression.[39] The enhancement of p53 could increase the expression of p21 protein in response to DNA damage, which in turn inhibits cyclin-dependent kinases activity.[40] p53, a nuclear transcription factor, regulates the G2/M transition by modulation of the cyclin dependent kinase cdc2, which is essential for the entry of cells into mitosis.[41] Therefore, to further confirm the results of proteomics, the effects of NB/Cur on the expression of cell-cycle regulatory protein and their upstream related protein were investigated using Western blot analysis. As shown in Figure 6A, compared with NB or Cur alone, NB and Cur in combination significantly decreased the expression levels of cyclin B1 and cdc2 and increased the expression levels of p21, which contributed to the inhibition of cdc2 activity. To confirm this hypothesis, the expression of phosphorylated p53, phosphorylated ATM, and phosphorylated MDM2 was detected by Western blot analysis. The results exhibited that exposure of HepG2 cells to NB/Cur markedly up-regulated the expression levels of phosphorylated p53 and phosphorylated ATM and down-regulated the expression levels of phosphorylated MDM2 (Figure 6B). These results clearly suggest that NB/Cur inhibited cell-cycle progression via down-regulation of the expression levels of cdc2 and cyclin B1.

NB Enhances Cur-Induced G2/M Arrest in HepG2 Cells through Activation of ROS Overproduction. It has been reported that ROS is involved in various cancer cells apoptosis, and our previous studies also showed that NB/Cur could

DOI: 10.1021/acs.jafc.5b01773
J. Agric. Food Chem. 2015, 63, 6440−6449

increase ROS to induce apoptosis in A375 cells.[20,42] Therefore, we investigated the effects of NB/Cur on ROS generation in HepG2 cells by measuring the DHE fluorescence intensity. As shown in Figure 7A, NB treatment alone exhibited no obvious change on ROS generation. Cur treatment alone resulted in significant ROS generation. NB/Cur treatment caused more ROS generation than Cur alone, indicating that NB/Cur increased ROS generation in HepG2 cells. To further confirm this hypothesis, NAC, a ROS inhibitor, was used to raise the intracellular glutathione levels to improve cell survival. The results showed that compared with the control group, NAC treatment alone had no significant change to the cell viability. HepG2 cell viability rate was 58.7 ± 1.5% when exposed only to NB/Cur, and the rate went up to 72.6 ± 3.1% when pretreated with NAC (Figure 7B). Consistent results are shown in Figure 7C, the G2/M rate was 33.1% when exposed only to NB/Cur, and the rates dropped to 13.9% when pretreated with NAC. Moreover, exposure of HepG2 cells to NAC down-regulated the expression level of p53, p21, and p-histone (Figure 7D), which is agreement with the above results. These results demonstrated that ROS might be upstream of the G2/M arrest signaling pathway.

On the basis of the above results, a signaling network for the synergistic action of NB/Cur was proposed. As depicted in Figure 8, NB/Cur treatment led to the accumulation of ROS, facilitating DNA damage and p53 activation. Moreover, down-regulation of hnRNPC1/C2 and NPM also contributed to the enhancement of p53. Activated p53 and down-regulation of PSMA5 resulted in an increase in p21, which bound and inactivated the cdc2-cyclin B1 complexes, and then led to cell cycle arrest in the G2/M phase.

In summary, the effect of NB/Cur on HepG2 was investigated by proteomic analysis. Our results found that NB/Cur down-regulated hnRNPC1/C2, NPM, and PSMA5 protein, which were associated with the p53 pathway. Moreover, NB/Cur also induced ROS generation, which caused oxidative stress and induced oxidative DNA damage. Both of the two explanations contributed to G2/M arrest induced by NB/Cur in HepG2 cells.

well as poor solubility at a concentration of 10% (w/v) or higher.[16] In this work, the above α-D-glucan has been chosen as a model system to elucidate the advantage of endodextranase for modifying the structural and physicochemical properties. From the data, the mechanism of the chain hydrolysis reaction and solution properties have been revealed, which could lead to insights into the fundamental basis of the structure−function relationship and the development of potential industrial applications as a low-viscosity and soluble filler ingredient for designing novel carbohydrate-based foods.

MATERIALS AND METHODS

Materials. Endodextranase (catalog no. D0443, 500 U/mL) from *Chaetomium erraticum*, polyethylene glycol (average M_w 2000), and deuterium oxide (isotopic purity = 99.99 atom % D) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Arabic gum was kindly provided by Kerry Group (Shanghai, China). All other chemicals were of reagent grade and were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China).

L. citreum SK24.002, with high alternansucrase-producing ability, was obtained from Chinese traditional pickled vegetables. de Man−Rogosa−Sharpe (MRS) medium, composed of 40 g of sucrose, 10 g of yeast extract, 10 mL of Tween 80, 20 g of K_2HPO_4, 0.02 g of $CaCl_2$, 0.2 g of $MgSO_4·7H_2O$, 0.01 g of NaCl, 0.01 g of $MnSO_4·H_2O$, and 0.01 g of $FeSO_4·7H_2O$ per liter (pH 6.9), was used for alternansucrase production.[5]

Methods. *(1→3)(1→6)-α-D-Glucan Biosynthesis.* *L. citreum* SK24.002 was propagated in liquid MRS medium with shaking (160 rpm) at 30 °C for 48 h. Cells and other insoluble components were removed from the medium by centrifugation. Two-phase partition (water−polyethylene glycol) was used to extract the soluble alternansucrase from the supernatants, taking advantage of the dextranosyl−enzyme complex form in which the enzyme would be present in enriched precipitate. The harvested alternansucrase was washed and dissolved in sodium acetate buffer (50 mM, pH 4.5) for further measurements, and the activity was determined by measuring the initial rate of fructose production using the 3,5-dinitrosalicylic acid method.[17]

The alternansucrase solution was supplemented with 20% (w/w) sucrose in a final volume of 2 L. The biosynthesis of water-soluble α-D-glucan was carried out at 40 °C with 1 U/mL of enzyme for 48 h. The polysaccharide was then recovered from the precipitate by adding 1 volume of ethanol at 4 °C followed by centrifugation at 10000*g* for 10 min. The precipitate was resuspended in the deioinized water, and the above procedure was repeated three times and finally with 50% (v/v) ethanol precipitation to discard mono- and oligosaccharides, if any. The final product in supernatant was freeze-dried for further use.

Enzymatic Modification of (1→3)(1→6)-α-D-Glucan. One gram of glucan was dissolved in 20 mL of sodium acetate buffer solution (pH 4.5, 50 mM). The temperature was adjusted to 55 °C, and the endodextranase (0.2 mL) was added. The process with six different flasks was carried out for 10 or 30 min and 1, 2, 4, or 8 h, respectively. Subsequently, the reaction was stopped by heating the solution in the boiling water for 30 min, cooled to room temperature, and precipitated in 3 volumes of 90% ethanol (v/v). The material was centrifuged at 5000*g* for 10 min, resuspended in ethanol, filtered twice, and dried. It was then ground to fine powder (approximately 100 mesh) and stored in a desiccator for further analysis. These samples are designated DG1, DG2, DG3, DG4, DG5, and DG6, respectively, for brevity, in the rest of the paper.

UV Absorption Analysis. The method described by Kobayashi, Utsugi, and Matsuda[18] was adapted to measure the polysaccharide solution absorption using a UV−visible spectrophotometer (UV-2102PC, Unico Instrument Co., Ltd., Shanghai, China). The glucan exhibited a strong absorption at 220 nm, and thus the optical density (OD_{220}) was measured at 220 nm for estimating the extent of structural modification.

Solution Appearance Analysis. The glucan sample was dissolved in water with a concentration of 6% (w/v) at room temperature. The solution was stirred for 30 min until the polysaccharide was completely dissolved and then was transferred to a glass tube. The appearance of glucan solution was recorded using a digital camera (Canon, Shanghai, China).

Scanning Electron Microscopy (SEM). The surface morphology was examined by a Quanta-200 scanning electron microscopy (FEI Co., Eindhoven, The Netherlands). The dried sample was coated with a thin gold film (10 nm) and mounted on an aluminum stub using double-sided tape. The instrument was operated at an accelerating voltage of 5.0 kV.

Molecular Weight Distribution (MWD) Analysis. The sample (0.5 mg/mL) was passed through a cellulose acetate filter (0.45 μm, Whatman, Maidstone, UK) and injected into a high-performance size exclusion chromatography (HPSEC) system coupled with a DAWN HELEOS-II multiangle laser light scattering detector (MALLS) and an Optilab T-rEX refractive-index detector (RI, Wyatt Technology, Santa Barbara, CA, USA). The MALLS was equipped with a He−Ne laser of 658.0 nm. A Shodex OH-pak SB-806 HQ column (8 × 300 mm, Showa Denko K.K., Tokyo, Japan) with an OH-pak SB-G guard column was used at 25 °C. The mobile phase was 0.1 M $NaNO_3$ along with 0.02% of sodium azide, and a flow rate of 0.5 mL/min was used. The data were processed with Wyatt Astra software (version 5.3.4.14, Wyatt Technology).

Spectroscopic Characterization. The FT-IR spectrum was recorded using a Nicolet Nexus 470 FT-IR spectrometer (Thermo Electron Co., Waltham, MA, USA) at room temperature. The polysaccharide powder was blended with KBr at a ratio of 1:100 and pressed into tablets. Scanning was carried out in the region of 400−4000 cm^{-1} at 4 cm^{-1} resolution using 32 scans.

The ^1H NMR spectrum was recorded at 80 °C with an AVANCE III 400 MHz digital NMR spectrometer (Bruker Co., Billerica, MA, USA). The glucan sample (approximately 60 mg) was exchanged with deuterium by lyophilizing it three times with deuterium oxide and then dissolving it in 0.45 mL of 99.99% deuterium oxide. Chemical shifts (δ) were expressed in parts per million and referenced internally with acetone (δ_H 2.225).

Solution Properties. The viscosity was measured at 25 °C using the Brookfield digital viscometer (type DV-II+ Pro, Brookfield Engineering Laboratories, Inc., Middleboro, MA, USA), with an RV3 spindle. Shear thinning was analyzed using the stress-controlled rheometer (AR-G2, TA Instruments, New Castle, DE, USA). The instrument was equipped with a stainless steel cone of 40 mm diameter and 2° angle along with the solvent trap to minimize water evaporation during the analysis. The temperature was maintained at 25 °C using a circulating bath and controlled Peltier system. The apparent viscosity of the polysaccharide was estimated by using a range of shear rates of 0.01−100 1/s.

Statistical Analysis. Data were analyzed using the one-way analysis of variance (ANOVA) procedure using Origin 8.5 (OriginLab Inc., USA). A level of 0.05 was set to determine statistical significance. The results were expressed as the mean value ± standard deviation.

RESULTS AND DISCUSSION

Optical Density. According to Kobayashi, the UV absorbance profile of glucan solution exhibits a strong intensity at 220 nm, which reveals a quantitative determination method for the amount of high M_w glucan without any pretreatments or reagents.[18] The OD_{220} values of the glucan solution as a function of time of enzyme treatment are shown in Table 1. The bioengineered glucan solution exhibits a value of 2.52. Upon endodextranase hydrolysis, the OD_{220} decreased substantially to 1.51 during the first 60 min and then incrementally reached a final limiting OD_{220} of 1.03 after ≥480 min. Moreover, the observations of glucan solution appearance also confirmed the structural change, in which the control sample solution has a more opalescent, bluish-white

DG6	1.03 ± 0.09	7.5 ± 0.08	56.3 ± 1.17

[a]Mean ± standard deviations of triplicate analyses.

color than the modified one, especially for DG 6 (see Figure S1 in the Supporting Information). The larger the molecular size, the deeper was the opalescent color of the glucan solution, revealing that the enzyme treatment affected the depth of solution color. A similar trend was also observed for alternan from *Leuconostoc mesenteroides* strain NRRLB-21297.[19] Those authors also reported that a rapid reduction of UV absorption at 225 nm after adding ≥5 U/mL enzyme solution. Overall, these results clearly highlight the significant role of enzyme treatment in reducing the M_w of polysaccharides. For this bioengineered (1→3)(1→6)-α-D-glucan, some α-1,6 linkages were speculated to be randomly hydrolyzed per endodextranase attack, resulting in a reduction of higher M_w fragment.

Surface Morphology. The scanning electron microscope is a potent tool to elucidate the surface morphology of polymer for predicting its physical properties as suggested by Wang and co-workers.[20] Figure 1 portrays the surface morphologies of the

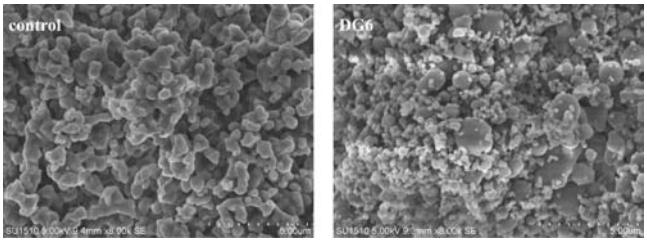

Figure 1. Surface morphology of the enzyme-treated (1→3)(1→6)-α-D-glucans.

(1→3)(1→6)-α-D-glucan after enzyme treatment. The native glucan appears like a cementitious material with a web-like network. The strong attractions between the surface functional groups appear to result in the aggregation of the glucan chains. This type of network arrangement also prevails in the purified exopolysaccharide made from *Leuconostoc dextranicum* NRRL B-1146[21] and *Lactobacillus plantarum* KF5.[20] After enzyme hydrolysis for 480 min, the modified glucan (DG6) had a looser structure with considerable small fragments. These results suggest that the bioengineered glucan after endodextranse modification might produce some particles with smaller size, in accord with the results of molecular weight analysis.

Molecular Weight Distribution. The MWD of the (1→3)(1→6)-α-D-glucan was measured by using HPSEC-MALLS-RI, and the related parameters are given in Table 1.Figure 2A highlights the HPSEC chromatogram of the native glucan appearing as a single symmetrical peak (2.41×10^7 g/mol), indicating that the bioengineered glucan was a homogeneous polysaccharide as suggested by our previous study.[5] Upon

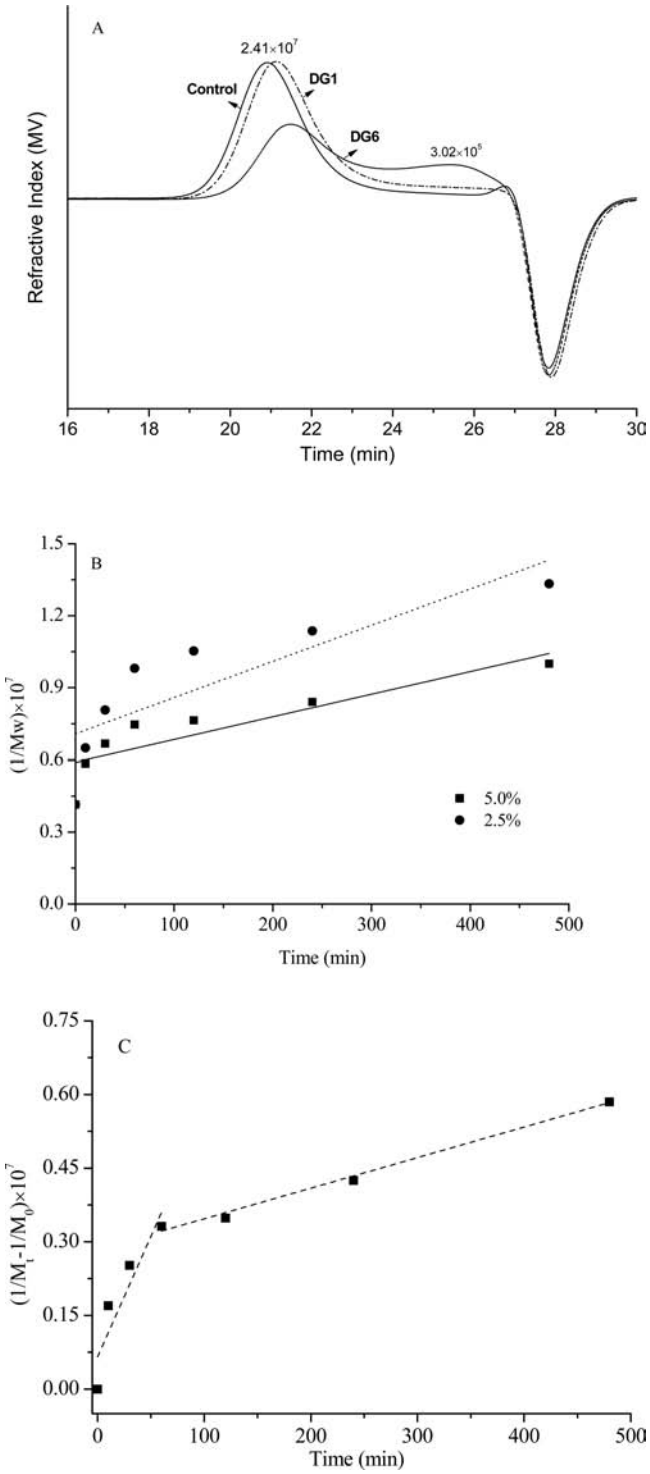

Figure 2. Molecular weight distribution profiles of the native and enzyme-treated glucans for 5% solution (A), comparison of M_w^{-1} as a function of hydrolysis time for 5 and 2.5% solution (B), and ($M_t^{-1} - M_0^{-1}$) as a function of hydrolysis time for 5% solution (C).

enzymatic hydrolysis of native glucan, the distribution gradually shifted to the smaller MWD region with a significant broadening. In addition, a low M_w peak (3.02×10^5 g/mol) appeared after the modification, for example, in DG6, indicating the heterodisperse characteristic of the treated sample. Leathers, Nunnally, and Côté also found a similar behavior in alternan, wherein the high peak of 10^6 −10^7 Da in the

DOI: 10.1021/acs.jafc.5b00472

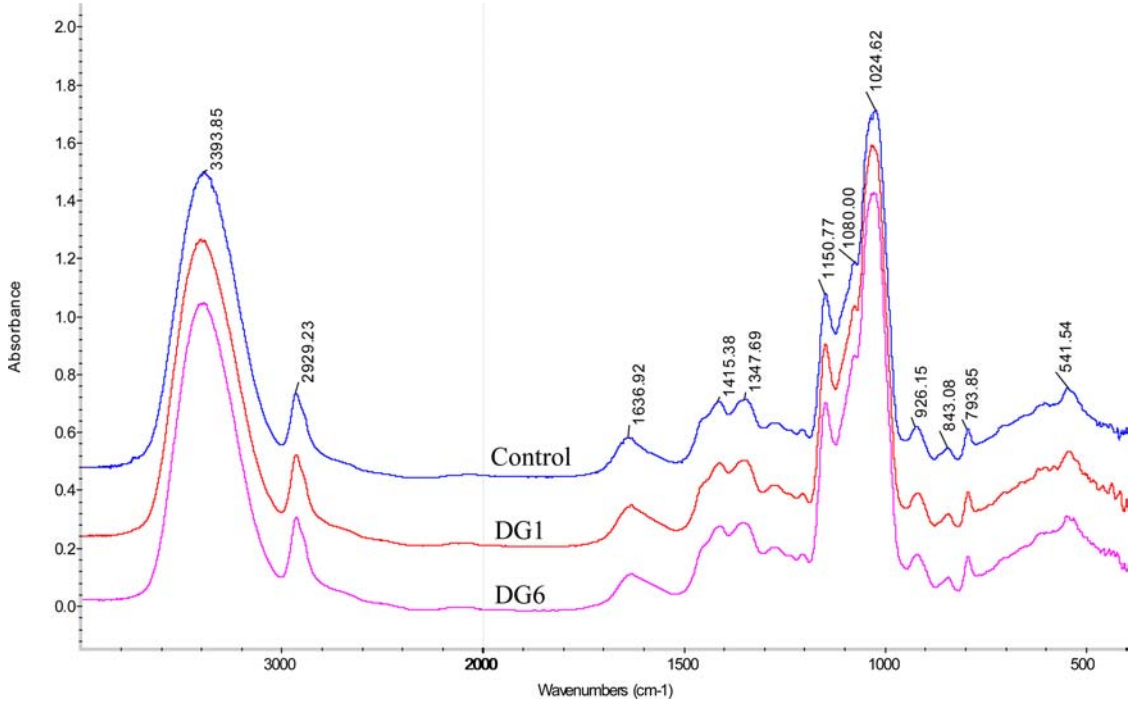

Figure 3. FT-IR spectra of the enzyme-treated (1→3)(1→6)-α-D-glucans.

bioengineered polysaccharide moves to peaks of (5−10) × 10^5 Da and (1−5) × 10^4 Da after modification.[22] Simultaneously, the peak at (1−5) × 10^4 Da) did not change over time, and only its relative proportion increased as the process took a long time, up to 24 h. Moreover, Tayal, Kelly, and Khan[23] observed significant reduction in molecular weight during the course of the enzymatic degradation of a water-soluble guar, with the peak maximum shifting by approximately 2 orders of magnitude, reflecting the scission of backbone linkage by enzyme, which was comparable with our results.

As shown in Table 1, the weight-average M_w decreased sharply from 24.1 × 10^6 (control) to 10.2 × 10^6 g/mol (DG3), and thereafter slowed and finally settled at 7.5 × 10^6 g/mol at 480 min (DG6). This trend is in congruence with the OD_{220} decrease. In particular, a considerable reduction in M_w (approximately 60% M_w reduction) took place at the initial short time, indicating enzymatic hydrolysis of the (1→3)(1→6)-α-D-glucan was a complex reaction for which mechanism analysis could be a combination of two or more reactions with diverse orders as described by Tayal et al.[23] To understand the degradation kinetics of enzymatic hydrolysis, the inverse M_w ($1/M_w$) as a function of process time has been analyzed and highlighted in Figure 2B. A nonlinear relationship between $1/M_w$ and time was observed for enzymatic hydrolysis of either 5.0 or 2.5% (w/v) α-D-glucan solution. The slope of $1/M_w$ versus time decreased as glucan concentration increased from 2.5 to 5.0%, which indicated that the apparent rate constant was dependent on the initial concentration, and the hydrolysis reaction appeared to be of the nth order.

According to Basedow, Ebert, and Ederer, the degradation reaction using enzyme belongs to an nth-order process: $dB/dt = -kB^n$, wherein B is the total number of hydrolyzable linkages, k is the rate constant, and n is the order of reaction.[24] Our data were rationalized as a combination of zeroth- and first-order processes, where the zeroth-order reaction preceded initially for time t', followed by a first-order reaction up to time t.

The two kinetic equations

$$\frac{1}{M'_{t'}} - \frac{1}{M_0} = \frac{k}{mN_0}t' \quad (1)$$

and

$$\frac{1}{M_t} - \frac{1}{M'_{i'}} = \frac{k_1}{m}(t - t') \quad (2)$$

were used to calculate the experimental kinetics of enzymatic hydrolysis, where M_0, M_t', and M_t were the M_w values at time 0, t', and t, respectively; k and k_1 were the rate constants for zeroth- and first-order reactions, respectively; m was the M_w of the monomer (glucose); and N_0 was the total number of molecules. The data in Figure 2C were modeled as a combination of two reactions using the above eqs 1 and 2. The analysis indicates the correlation coefficient (R^2) and rate constant (k) were 0.858 and 4.91 × 10^{-3} g/(mol·min) and 0.989 and 6.22 × 10^{-4} g/(mol·min) for zeroth- and first-order reactions of 5.0% glucan solution, respectively. In some previous papers, a linear relationship between $1/M_w$ and time was used to model the enzymatic degradation of natural polymer.[25−27] However, our data indicated zeroth- and first-order kinetics were better representations.

FT-IR Analysis. The FT-IR spectra of the native glucan and its derivatives are compared in Figure 3. The control and enzyme-treated samples essentially displayed similar spectra, indicating the intact chemical glucan structure and non-destructive nature of the enzyme treatment. In both samples, characteristic bands of ν(O−H) 3400 cm^{-1}, ν(C−H) 2930 cm^{-1}, δ(HOH) 1640 cm^{-1}, δ(O−H) 1420 cm^{-1}, and δ(C−H) 1370 cm^{-1} and a complex bands ν(C−O) and ν(C−C) 1200−1000 cm^{-1} and γ(C−H) 1000−700 cm^{-1} are observed. The broad peak at 3393 cm^{-1} indicates the presence of hydroxyl groups of glucan and water. The bands at 2929 and 1636 cm^{-1} are due to the C−H stretching and water-bending, respectively. The spectra also indicate C−H deformation at 1415 and 1347

DOI: 10.1021/acs.jafc.5b00472
J. Agric. Food Chem. 2015, 63, 6450−6456

cm^{-1}. In the fingerprint region (1200−1000 cm^{-1}), there are three characteristic peaks at 1150, 1080, and 1024 cm^{-1}. The wavenumbers 1150 and 1080 cm^{-1} are attributed to the C−O stretching of the anhydroglucose. The sharp peak at 1024 cm^{-1} could most likely be due to C−O stretching in the C−O−C linkage across the α-1,6-glucosidic bonds. The vibration bands at around 926, 843, and 793 cm^{-1} are attributed to the mixed C−C−H deformations coupled with C−C−O, O−C−O, and C−O−C bending. The peak at 793 cm^{-1} is from the skeletal mode vibrations of the α-1,3-glucosidic linkage.[28] All of these results clearly suggest that both the control and enzyme-treated glucans exhibit similar chemical structures composed of both α-1,3 and α-1,6 linkages. The similarities in the γ(C−H) range further suggest that there are no differences in the D-glucopyranose conformation that prefer $^4C_1$ chair conformation.[6]

NMR Analysis. The linkage changes in the (1→3)(1→6)-α-D-glucan after enzyme treatment are compared in Figure 4, and

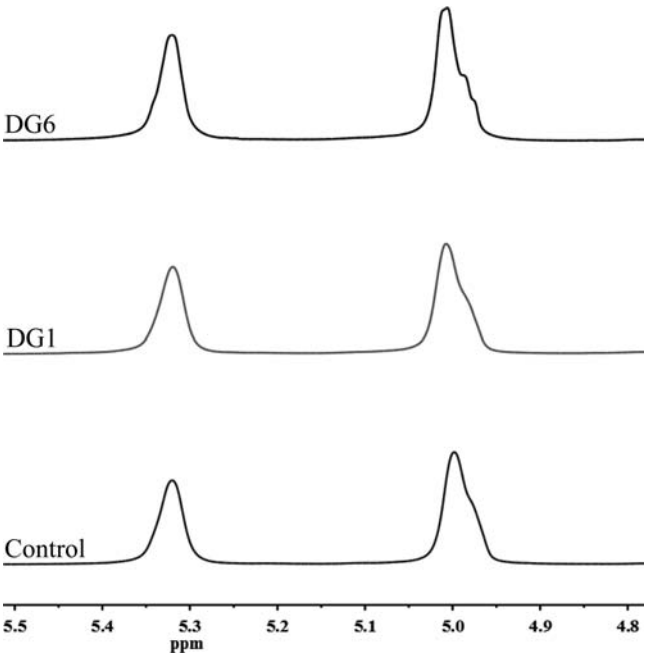

Figure 4. ^{1}H NMR spectra of the enzyme-treated (1→3)(1→6)-α-D-glucans.

the related data are presented in Table 1. In the anomeric proton region (4.5−5.4 ppm), the peaks at 4.98 and 5.32 ppm indicate the H-1 at α-1,6 and α-1,3 linkages, respectively.[29] The percentage of α-1,6 linkages in the control sample was approximately 60%, which agrees with previous observations.[5] As expected, after enzyme treatment this number decreased to 56.3% of DG6, suggesting that the chain fragments with α-1,6 linkages are partially broken.

The main domain of endodextranase is a right-handed parallel β helix connecting to a sandwich domain at the N terminus.[14] In the enzyme−glucan complex, the glycosidic oxygen of the glucose unit from the subsite +1 forms a hydrogen bond to the catalytic active site (Asp395) through a single displacement mechanism. Generally, glucans from *L. citreum* SK24.002 are considered to be resistant to the enzyme action.[5] However, the bioengineered glucan used in this study displayed some short stretches of consecutive α-1,6 linkages in the limited regions, which could be the primary factor for the observed structural changes. Overall, it can be concluded that the enzymatic treatment of (1→3)(1→6)-α-D-glucan is influenced by the unique biopolymer structure, and some specific α-1,6 linkages of the glucan chains were broken with enzyme treatment.

Rheological Analysis. Figure 5A shows the concentration dependence of solution viscosities for the control and its

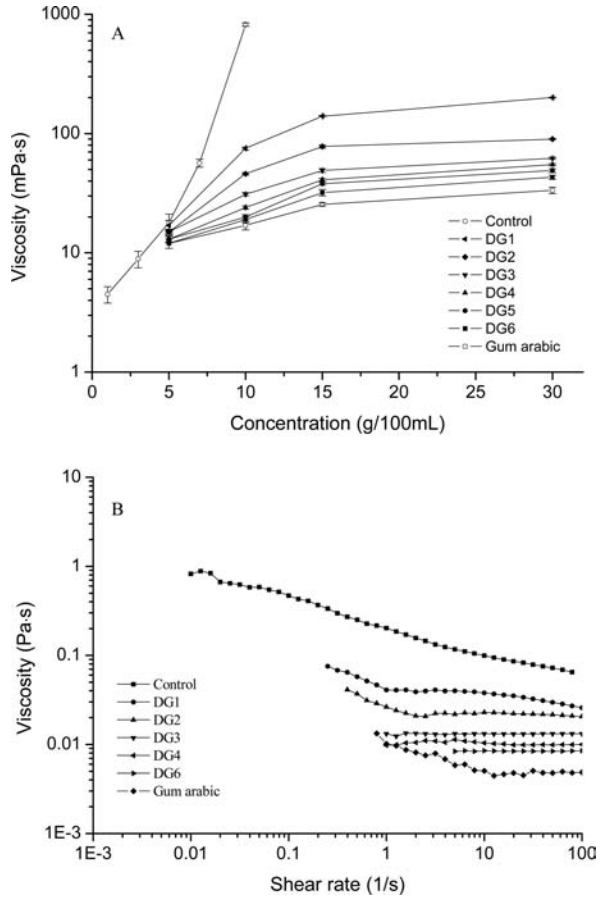

Figure 5. Comparison of the solution properties of the enzyme-treated glucans: (A) viscosity; (B) apparent viscosity.

enzymatic derivatives. The viscosity of bioengineered glucan at 5 g/100 mL concentration is around 18 mPa·s, suggesting a thin liquid for such a high M_w polymer. However, at the higher polymer concentrations, in the range of 5−10 g/100 mL, the viscosity increased exponentially and finally formed a gel-like dispersion. On the other hand, the viscosity of enzyme-treated glucans has decreased considerably, mainly due to the chain degradation, similar to solution behavior of the commercial gum arabic (9%, w/v), which could be dissolved in water to give solutions of ≥30 g/100 mL.

The profiles of viscosity versus shear rate are shown in Figure 5B. The bioengineered glucan displays a non-Newtonian pseudoplastic behavior (shear thinning) in the shear rate range of 0.01−100 1/s, indicating a branched nature of glucan as suggested by Majumder and Goyal.[21] The viscosity decreased with increasing shear rate, but with minimal changes at high shear rates. A similar behavior is noted for glucans synthesized by *Agrobacterium* sp. ZX09.[30] As shown in Figure 5B, the gum arabic (9%, w/v) showed a flat curve at high shear rates (10−100 1/s), indicating it more or less behaves like a Newtonian liquid. Interestingly, Newtonian plateaus are also

DOI: 10.1021/acs.jafc.5b00472
J. Agric. Food Chem. 2015, 63, 6450−6456

observed from the enzyme-treated glucan solutions. In general, polymer chains in solution could exhibit considerable stiffness, thus making themselves more susceptible to orient under suitable shear conditions.[30] The shear thinning property observed in our measurements appears to be the outcome of the orientation effect under shear. In other words, the long chains of (1→3)(1→6)-α-D-glucan after enzymatic hydrolysis became aligned in the direction of flow with increasing shear rate, resulting in less interaction between adjacent chains for modified glucan.

In summary, an environmentally friendly and reproducible enzymatic modification has been used to reduce the M_w and improve the solution properties of the high M_w (1→3)(1→6)-α-D-glucan from *L. citreum* SK24.002. The enzymatic degradation followed both zeroth- and first-order kinetics. Some specific α-1,6 linkages of glucan chains were cleaved with enzyme treatment. The viscosity of the modified glucan solution was markedly reduced, and Newtonian plateaus were also observed at high shear rates (10−100 1/s). The enzymatically modified glucans showed solution viscosity and shear thinning behavior comparable to those of commercial gum arabic, indicating that the modified (1→3)(1→6)-α-D-glucan as a substitute for gum arabic could find potential applications as low-viscosity biomaterials and soluble fillers in the design and development of novel carbohydrate-based foods. Optimizing the processing parameters for biosynthesis modification and glucan retrogradation during storage as well as assessing the bioavailability and bioefficency of the modified glucans will be the focus of future studies.

Syntheses. *D-Galacturonic Acid Methyl Ester.* (Trimethylsilyl)-diazomethane (TMSDM) was used for the esterification of D-galacturonic acid instead of explosive and toxic diazomethane[6] or methanolic hydrochloric acid[7,8] used in most other publications. Methylation of carboxylic acids with TMSDM is more specific and can take place under relatively mild conditions.[9] One hundred milligrams of D-galacturonic acid (0.5 mmol) was dried over phosphorus pentoxide and dissolved in 5 mL of absolute methanol. A solution of 0.2 M TMSDM diluted with diethyl ether was added dropwise until the yellow color of the reagent persisted. The reaction proceeded instantaneously and nearly quantitatively without any influence of other reactive groups. The reaction was easily monitored by the disappearance of the yellow color of TMSDM. The reaction mixture was stirred for 30 min at room temperature and concentrated under reduced pressure to give the corresponding methyl ester. The yellow syrup was purified by recrystallization from 1,4-dioxane and yielded after freeze-drying 83.1 mg (0.39 mmol) of a white powder, which was instantaneously used for model reactions. Purity was confirmed by GC-MS after derivatization with trifluoroacetic acid anhydride (TFAA). For this purpose aliquots of the freeze-dried substance were resolved in 325 μL of dichloromethane. One hundred and fifty microliters of TFAA and 25 μL of pyridine were added, and the sample was shaken for 30 s and afterward derivatized for 3 h at room temperature. After that, 500 μL of dichloromethane was added and the diluted derivatized sample subjected to GC-MS. For the GC-MS analysis of the D-galacturonic acid methyl ester the same setup was used as for pyrrole-2-carboxaldehyde (see below).

FPA. D-Galacturonic acid (10.345 g; 50 mmol) and L-alanine (4.595 g; 52 mmol) were dissolved in 100 mL of distilled water and stirred for 2 h under reflux. The resulting brown/black reaction mixture was extracted with 40 mL of ethyl acetate/diethyl ether (1:1) three times. The combined extracts were concentrated in a nitrogen stream and purified by silica gel flash chromatography (Merck silica gel 60, 0.040−0.063 mm, 230−400 mesh) with ethyl acetate/diethyl ether (1:1) as solvent. Removing the solvent at 30 °C in vacuo yielded 16.6 mg (0.1 mmol) of yellow crystals. Tentative identification and purity control were carried out by GC-MS (setup as described below) after derivatization with TMSDM. For this purpose 10 μL of *N*-methylpyrrole-2-carboxylic acid as internal standard (9 mM in methanol) was added to an aliquot of 10 μL of FPA in methanol (5.5 mM). After that, 150 μL of a TMSDM solution (20 mM) in methanol/diethyl ether was slowly added for derivatization. After 30 min at 25 °C in a reaction tube, the sample was subjected to GC-MS (see Figure 3). A purity of 98% was achieved.

Model Reaction. *D-Galacturonic Acid versus D-Glucuronic Acid and Reducing Sugars.* To investigate the degradation behavior and the formation of key intermediates and degradation products, D-galacturonic acid monohydrate (0.5 M) and L-alanine, L-aspartic acid, or GABA (0.05 M) were dissolved in water. The above-mentioned concentrations were chosen to adapt the model systems as close as possible to foods rich in uronic acids such as juices or jams in which the uronic acid compounds occur in a surplus. The pH value was adjusted to 3.0, 5.0, or 8.0 by adding thinned hydrochloric acid and sodium hydroxide solution. In this case, the application of buffer substances was avoided by choice, because buffers are known to cause unintended side reactions.[10] Aliquots of the model solution were filled into glass ampules and incubated in a heating block at 100 °C for 2 h. The reaction was stopped at various points in time and worked up as follows. Browning was measured as the absorption at 420 nm with a spectrophotometer (UV-1650 PC, Shimadzu, Duisburg, Germany) and the CIELab color with a reflectance attachment with Spectralon integrating sphere (Specord 40, Analytik Jena, Jena, Germany). pH values were measured after the sample had been cooled to room temperature with a pH-electrode (SenTix Mic, WTW, Weilheim, Germany; pH-meter CG 820, Schott, Mainz, Germany). For the analysis of the organic acids, aci-reductones, and pyridines, samples were diluted (1:10) with 1% metaphosphoric acid and 10 mM dithiothreitol and measured by HPLC-DAD. For the quantification of furans, furanones, and pyrroles, samples were diluted (1:100; v/v) with 10 mM phosphate buffer (pH 6.0) and subjected to HPLC-DAD. For α-dicarbonyl compounds, *o*-phenylenediamine hydrochloride (OPD; 20 mM) was added (1:1; v/v). Because advance tests had shown no further chemical change after 3 h of reaction time, the samples were reincubated for at least 3 h at room temperature to obtain UV-active quinoxalines and subsequently analyzed by HPLC-DAD. For identification and quantification of FPA the carboxyl group was methylated with (trimethylsilyl)diazomethane and subjected to GC-MS. Model solutions (0.5 M) of D-glucuronic acid, D-galactose, and D-arabinose with 0.05 M L-alanine were treated and analyzed as the model reactions of D-galacturonic acid.

D-Galacturonic Acid versus D-Galacturonic Acid Methyl Ester. The concentrations of the model reactions were 0.05 M of the carbonyl compound and 0.005 M of the amino acid L-alanine. The procedure and the measurements were the same as in the higher concentrated model systems of D-galacturonic acid.

All experiments were conducted in three independent replications, and the arithmetical mean of all quantified values was calculated. For quantification five-point calibration curves were determined from parent solutions of mixes of different pure reference compound groups.

Qualification and Quantification. *Organic Acids and Aci-reductones.* The diluted samples were analyzed by HPLC-DAD (degasser, Gastorr GT-103; pump, Shimadzu LC-9A; autosampler, Dionex GINA50; column oven, VDS optilab; guard column, YMC ODS-AQ 4.0 × 20 mm, 3 μm; column, YMC-Pack ODS-AQ 150 × 4.6 mm, 3 μm; detector, Gynkotek UVD340S; software, Chromeleon v6.00 build 435) using a phosphate buffer (20 mM, pH 2.8) as an isocratic eluent with a flow rate of 0.6 mL/min, an oven temperature of 25 °C, and an injection volume of 40 μL. The effluent was monitored at wavelengths of 214 nm for organic acids (formic acid (3.9 min), acetic acid (6.3 min), succinic acid (11.4 min), 2-ketoglutaric acid (6.9 min), malic acid (4.2 min)) and 254 nm for reductic acid (7.5 min) detection. Identification of the compounds was tentatively accomplished by comparing their retention times with those of authentic known commercially available references or pure authentic compounds isolated and elucidated from reaction mixtures in our working group.[3] For quantification pure reference compounds were used.

Furans and Furanones. The diluted samples were analyzed by HPLC-DAD (setup as described above; guard column, Macherey-Nagel CC 8/4 Nucleosil 120/3 C18; column, Macherey-Nagel EC 125/3 Nucleosil 120-3 C18) using a solvent gradient starting with a mixture (99:1; v/v) of phosphate buffer (5 mM, pH 6.0) and methanol and increasing the methanol content after 10 min to 20% within 5 min and after another 5 min to 99% within 5 min with a flow rate of 0.5 mL/min, an oven temperature of 40 °C, and an injection volume of 40 μL. By monitoring the effluent at a wavelength of 280 nm for furan-2-carboxaldehyde (6.7 min) and norfuraneol (3.6 min) and at a wavelength of 254 nm for 2-furanoic acid (8.5 min) the compounds were detected. Quantification was performed by external calibration with standard solutions containing known amounts of either commercially available references or pure authentic compounds isolated and elucidated from reaction mixtures in our working group.[3]

α-Dicarbonyl Compounds as Quinoxalines. The derivatized samples were analyzed by HPLC-DAD (setup as described above; guard column, Macherey-Nagel CC 8/4 Nucleosil 120/3 C18; column, Macherey-Nagel EC 250/4.6 Nucleosil 120-5 C18) using a solvent gradient starting with a mixture (95:5; v/v) of water and acetonitrile and increasing the acetonitrile content after 5 min to 10% within 3 min. After another 5 min, the content was increased to 20% within 7 min and after 5 min increased to 50% within 10 min with a flow rate of 1.0 mL/min, an oven temperature of 35 °C, and an injection volume of 40 μL. Quantification was performed by comparing the peak areas with those of a standard solution at 317 nm containing known amounts of each pure reference or pure authentic quinoxaline isolated and elucidated from reaction mixtures in our working group.[11] Identification of unknown quinoxalines was accomplished by LC-MS measurements in the total ion mode of the pre- and postderivatized and diluted samples. The gradient used for the separation was the same (Thermo Fischer Scientific pump Accela, CTC PAL autosampler) as for the HPLC-DAD measurements.

J. Agric. Food Chem. 2015, 63, 6457−6465

Ionization (TSQ Vantage System with Ion Max Source, H-ESI II Probe) in the ESI positive mode followed, using a spray voltage of 3 kV, a vaporizer temperature of 450 °C, a sheath gas pressure of 60 psi, and a capillary temperature of 270 °C. Spectra were obtained by setting the scan at m/z 50−1000. Software Thermo Excalibur 2.1.0.1139 was used for the identification of the substances.

Pyrroles and Hydroxypyridines. The diluted samples were analyzed by HPLC-DAD (see above) in the case of 3-hydroxypyridines using the same method as for organic acids, but monitoring the effluent at a wavelength of 280 nm and in the case of pyrrole-2-carboxaldehyde derivatives with the same method mentioned for furans but monitoring at a wavelength of 293 nm. Quantification was performed by external calibration with pure authentic compounds isolated and elucidated from reaction mixtures in our working group.

For the identification and quantification of FPA a GC-MS method was established. Therefore, the carboxyl group had to be methylated with (trimethylsilyl)diazomethane. For that, 100 μL of a model solution was spiked with 10 μL of *N*-methylpyrrole-2-carboxylic acid in methanol (2 mM) as internal standard in a 1 mL reaction tube. The sample mixture was dried under nitrogen stream and resolved in 100 μL of distilled water. After that, the sample was extracted five times with 100 μL of diethyl ether/ethyl acetate (1:1). The combined extracts were dried under nitrogen stream and resolved in 100 μL of methanol. For derivatization 300 μL of TMSDM (20 mM) was added, and after 30 min at 25 °C, the sample was subjected to GC-MS analysis (Shimadzu GC-2010, AOC-20i autosampler, GCMS-QP2010plus mass spectrometer, Duisburg, Germany) using a fused silica capillary column (Supelco SLB-5 ms, 30 m × 0.25 mm, 0.25 μm). The derivatized samples were applied by a split injection technique at an injection temperature of 250 °C and an oven temperature of 80 °C. The temperature was increased at a rate of 6 °C/min to 104 °C, held for 1 min, increased again at a rate of 10 °C/min to 164 °C, and then increased at a rate of 12 °C/min to 280 °C. Helium 5.0 was used as a carrier gas with a flow rate of 2 mL/min. Software Lab Solutions version 2.71 was used for the identification of the substances.

RESULTS AND DISCUSSION

Formation of Colored Compounds. Thermal treatment of unbuffered solutions of D-galacturonic acid and L-alanine at pH 5.0 and a temperature of 100 °C for 2 h led to a 6 times higher browning compared to L-arabinose, a 7 times higher browning compared to D-galactose, and an almost 3 times higher browning compared to D-galacturonic acid alone (see Figure 1). Its epimer D-glucuronic acid offers a decreased browning trend. More precisely, after a reaction time of 120 min at 100 °C, a D-galacturonic acid model solution exceeded twice the value of the absorption at 420 nm of an equimolar D-glucuronic acid reaction model (results not shown).

Figure 2 shows the influence of several amino acids on browning intensities of the D-galacturonic acid solutions

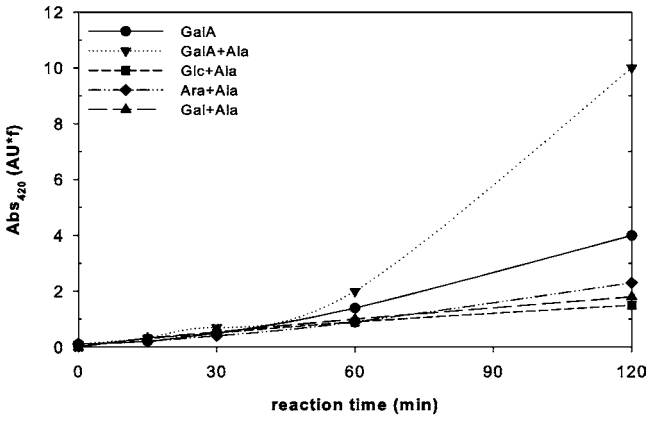

Figure 1. Nonenzymatic browning of D-galacturonic acid (GalA) solutions with and without L-alanine (Ala) compared to solutions of L-arabinose (Ara), D-glucose (Glc), and D-galactose (Gal) with L-alanine thermally treated at 100 °C and a starting pH value of 5.0, measured as absorption at 420 nm.

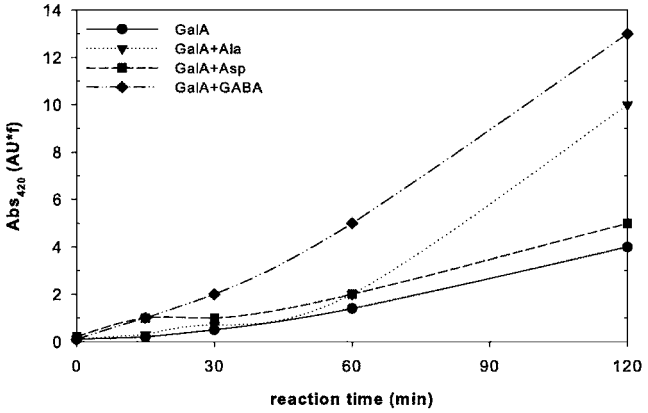

Figure 2. Nonenzymatic browning of D-galacturonic acid (GalA) solutions with L-alanine (Ala), L-aspartic acid (Asp), or γ-aminobutyric acid (GABA) after thermal treatment at 100 °C and a starting pH value of 5.0, measured as absorption at 420 nm.

(starting pH 5.0), which were heated at 100 °C for different time intervals. As expected, GABA promotes browning the most followed by Ala and Asp. Both might degrade more rapidly in the presence of dicarbonyl compounds (Strecker degradation), resulting in a loss of browning-fostering molecules. In comparison to a starting pH of 5.0, an initial pH value of 3.0 caused less absorption at 420 nm, whereas starting at pH 8.0 induced a higher absorption. Despite different browning intensities all starting pH values led to the same order of priority concerning the amino acid influence on color development (results not shown).

Not only the addition of amino acids but also the structure of the carbonyl compound can affect color formation, especially the presence of the carboxyl group on C-6 and the stereochemistry of a $^1C_4$-conformation in the pyranoic form. Eliminative decarboxylation gives a plausible explanation for the carboxyl group's strong influence. Eliminative decarboxylation preferably occurred in the presence of D-galacturonic acid with the substituents at C-4 and C-5 in *trans* position and at elevated temperatures under slightly acidic to neutral conditions.

Table 1 shows the browning values and the corresponding CIELab values for the thermally treated model solutions (2 h) and the calculated yellowness (YI), chroma (C), and saturation (S). Compared to the slightly yellow model solutions of the previously heated reducing sugars (Ara, Glc) the color of uronic acids Maillard reactions was reddish and CIELab measurements revealed that not only the lightness was considerably lower, but the $+a$ (red) as well as the $+b$ (yellow) values were higher in the thermally treated D-galacturonic acid solutions compared to reducing sugars. In the presence of amino acids (e.g., L-alanine) the lightness of the model solutions was lower than without an amino acid, the $+a$ value increased from +19 to +36, whereas the $+b$ value decreased from +54 to +44. Also, the structure of the amino acid influences color and browning intensity. The browning value was highest with GABA (13.1) and lowest with L-aspartic acid (4.5); the average value of L-alanine was (9.9).

Table 1. CIELab Values of Maillard Reaction Models of D-Galacturonic Acid (GalA) Alone or with L-Alanine (Ala), L-Aspartic Acid (Asp), or γ-Aminobutyric Acid (GABA) Compared to Model Solutions of L-Arabinose (Ara) and D-Glucose (Glc) with L-Alanine at a Reaction Temperature of 100 °C after 2 h and a pH Value of 5.0 at the Beginning of the Reaction[a]

	L	*a* (red)	*b* (yellow)	YI	*C*	*S* (%)	Abs_{420}
Ara + Ala	90	−1	22	35	22	24	2.3
Glc + Ala	98	−2	11	16	11	11	1.5
GalA	67	19	54	114	57	65	4.0
GalA + Ala	56	36	44	113	57	71	9.9
GalA + Asp	56	28	43	111	57	71	4.5
GalA + GABA	21	30	−13	90	33	84	13.1

[a]Yellowness (YI), chroma (*C*), and saturation (*S*) were calculated according to the method of Hunter and Harold.[22] Browning intensity (Abs_{420}) was measured as the absorption at 420 nm.

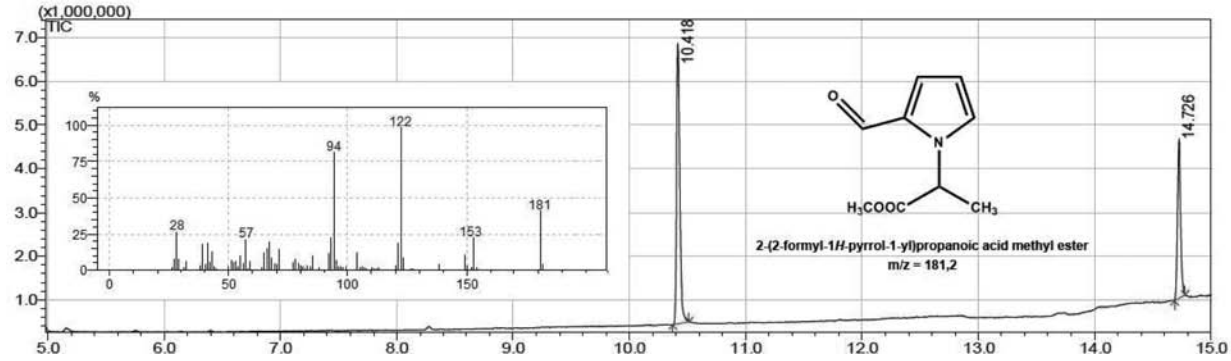

Figure 3. Total ion chromatogram of the FPA as a degradation product of D-galacturonic acid (GalA) and L-alanine by GC-MS after postderivatization with TMSDM and total ion chromatogram of the methylated FPA derivative (t_R 14.73 min) with its embedded fragmentation pattern and the internal standard *N*-methylpyrrole-2-carboxylic acid (t_R 10.42 min).

Furthermore, differences in yellowness, saturation, and chroma could be detected. These three parameters are much higher in thermally treated D-galacturonic acid solutions than in model solutions of reducing sugars as well. These findings emphasize the differences in browning behavior and in the formation of polymeric dyes between uronic acids and common reducing sugars. The browning of D-glucuronic acid was slower than that of D-galacturonic acid, but the characteristic red color of the model was equal (data not shown). Color formation by D-galacturonic acid methyl ester was also slower than that of the unesterified D-galacturonic acid and the browning index detectable after 2 h of heating at 100 °C without amino acid catalysis was only around half of the value of unesterified D-galacturonic acid (data not shown).

As described for the D-galacturonic acid model solutions without amino acid, the pH value of D-galacturonic acid solutions with L-alanine increased steadily from starting pH 5.0 until it reached 5.8 after 120 min (data not shown). Only in model solutions starting at pH 3.0 did the value not change with reaction progress. The pH increase may be caused by heterocyclic or carbocyclic compounds formed during thermally induced decomposition of D-galacturonic acid. These heterocyclic compounds are supposed to be less acidic than short-chained dicarbonyl cleavage products as formic or acetic acid. In addition, a loss of the carboxyl group of the uronic acid itself due to eliminative decarboxylation leads to a deacidification of the model system. In contrast to the almost colorless to slightly yellow color of the common reducing sugar solutions, the color of uronic acid model solutions treated under the same conditions was red-brown. This typical red-brown color of D-galacturonic acid solutions is caused by specific degradation products, such as reductic acid and the pyrroles discussed later, which are involved in the formation of polymeric dyes.[14] Higher pH values as well as the addition of amino compounds accelerated the degradation reaction of D-galacturonic acid and led to a higher absorption at 420 nm and an increase in the +*a* value.

Reactive Intermediates of D-Galacturonic Acid. Our earlier experiments confirmed that 2-ketoglutaraldehyde is a key intermediate in the formation of reductic acid, DHCP, and furan-2-carboxaldehyde.[3] This would support the eliminative decarboxylation mechanism being the main degradation pathway of D-galacturonic acid under slightly acidic to neutral conditions. A concerted mechanism involving a simultaneous dehydration at C-4 and decarboxylation at C-5 of GalA resulting in the formation of 4,5-unsaturated 4-deoxy-L-arabinose, as labile precursor for 2-ketoglutaraldehyde formation, can be assumed. After dehydration, the postulated 4,5-unsaturated 4-deoxypentose can yield the enol form of 2-ketoglutaraldehyde, which leads directly to the formation of reductic acid or, after isomerization, to DHCP and furan-2-carboxaldehyde. However, because Amadori compounds of D-uronic acids are unstable, the 4-deoxypentose can also react with the amino group to form imine intermediates, which then may cyclize to *N*-heterocyclic compounds such as pyrroles and pyridines. 3-Hydroxypyridinium compounds have already been found as degradation products of D-glucuronic acid and peptides by Horvat et al., who postulated a formation pathway that includes the intermediate formation of an Amadori compound.[12]

So far, pyrroles have not been identified as degradation products of thermally treated uronic acids. Figure 3 shows the total ion chromatogram of the GC-MS analysis of an unknown degradation product, which has been isolated from the model

DOI: 10.1021/acs.jafc.5b01121
J. Agric. Food Chem. 2015, 63, 6457−6465

solution of GalA and L-alanine by diethyl ether/ethyl acetate extraction. After methylation with TMSDM, this compound could be identified by GC-MS as FPA and thus also verified pyrroles in general as typical reaction products of D-galacturonic acid and amino acids for the first time. In addition, the formation of pyrrole-2-carboxaldehyde derivatives could also be confirmed in the reaction of D-galacturonic acid with other amino compounds such as L-glycine and GABA, but not with L-aspartic acid (data not shown). These pyrrole-2-carboxaldehydes are also formed during thermal treatment of D-galacturonic acid methyl ester (see Table 3).

The concentration of pyrrole-2-carboxaldehydes formed depends not only on the ratio of carbonyl to amino compound but also on the structure of the carbonyl used (see Figure 4), as well as on the reaction temperature, initial pH value, and reaction time of the model solution. The highest amounts were formed with ratios of uronic acid to amino acid between 2:1 and 1:1, pH values <5.0, and temperatures >100 °C (data not shown).

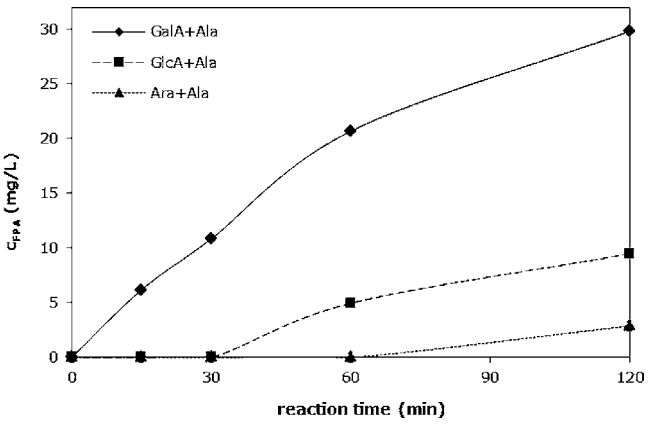

Figure 4. Comparison of FPA formation in model reactions between L-alanine (Ala) and D-galacturonic acid (GalA), D-glucuronic acid (GlcA), and L-arabinose (Ara) at 100 °C and a starting pH value of 8.0.

Table 2 gives an overview of the concentration of the most important products formed during thermal treatment of D-galacturonic acid compared to D-glucuronic acid solutions with and without the presence of L-alanine at 100 °C after 2 h. Relatively high concentrations of FPA **4** and HPA **5** in the reaction of both uronic acids with L-alanine cannot be explained via the formation of the Amadori compound **2c** shown in Figure 5 alone. Amadori compounds are not easily formed under these conditions, because the intermediate *N*-glucosides **2a**−**2c** are not stable and preferably cleaved back to the free uronic and amino acid **1**. A direct dehydration of the *N*-glycoside should lead to the formation of 3-deoxyhexosulosuronic acid **6**, which then preferably degrades to furan-2-carboxaldehyde and reductic acid.[3,5] Compared to the relatively high concentrations of FPA and HPA no furan-2-carboxaldehyde was found in the solutions and only traces of 3-deoxyhexosulosuronic acid could be detected by LC-MS after postderivatization of the solution with OPD (determined as quinoxaline). Thus, a formation pathway of pyrrole-2-carboxaldehyde derivatives and 3-hydroxypyridines distinct from the formation of furan-2-carboxaldehyde and 3-deoxyhexosulosuronic acid is postulated (see Figure 6). Due to eliminative decarboxylation of D-galacturonic acid, the 4,5-unsaturated 4-deoxy-L-arabinose is formed. In the presence of amino acids a nucleophilic addition reaction at C-5 followed by dehydration and cyclization reactions leads to the six-membered *N*-heterocyclic compound HPA. As a competitive reaction the nucleophilic addition at C-1 yields a Schiff base. A concerted cyclization dehydration reaction via a carbenium ion **10**, the (3*Z*)-configuration of which is mandatory for cyclization,[13] results in the five-membered *N*-heterocyclic compound FPA.

Besides pyrroles such as FPA that are formed via a breakdown of the carbohydrate backbone and the incorporation of amino compounds, another reaction pathway was postulated by De Kimpe et al. This pathway suggests pyrroles being built from smaller fragmentation products. Methylglyoxal was identified as an important precursor leading via condensation reactions to highly substituted pyrroles.[14]

3-Hydroxypyridine derivatives are known to be stable compounds and therefore not relevant as color precursors,[15] which was experimentally confirmed (data not shown). However, Tressl et al. identified certain pyrroles as important precursors of polymerization and color and postulated an acid-catalyzed formation of so-called type II polymers. Furan-2-carboxaldehyde could also take part in this polymerization, but decelerated the polymerization speed.[16] Type II polymers possess a red color, but after longer exposure to air, they turn black because of oxidation reactions. The higher the reaction temperature and the higher the amount of amino acids present in the model solutions of uronic acids, the higher was the

Table 2. Concentrations (Micromolar) of the Main Degradation Products Reductic Acid (RA), DHCP, Furan-2-carboxaldehyde (FF), Norfuraneol (Norf), FPA, HPA, and Glyoxal and the Sum of Short-Chain α-Dicarbonyl Compounds (DC) in Model Solutions of D-Glucuronic Acid (GlcA) with and without the Participation of L-Alanine (Ala) Compared to Model Reactions of D-Galacturonic Acid (GalA) after Thermal Treatment for 2 h at 100 °C and with Different Initial pH Values

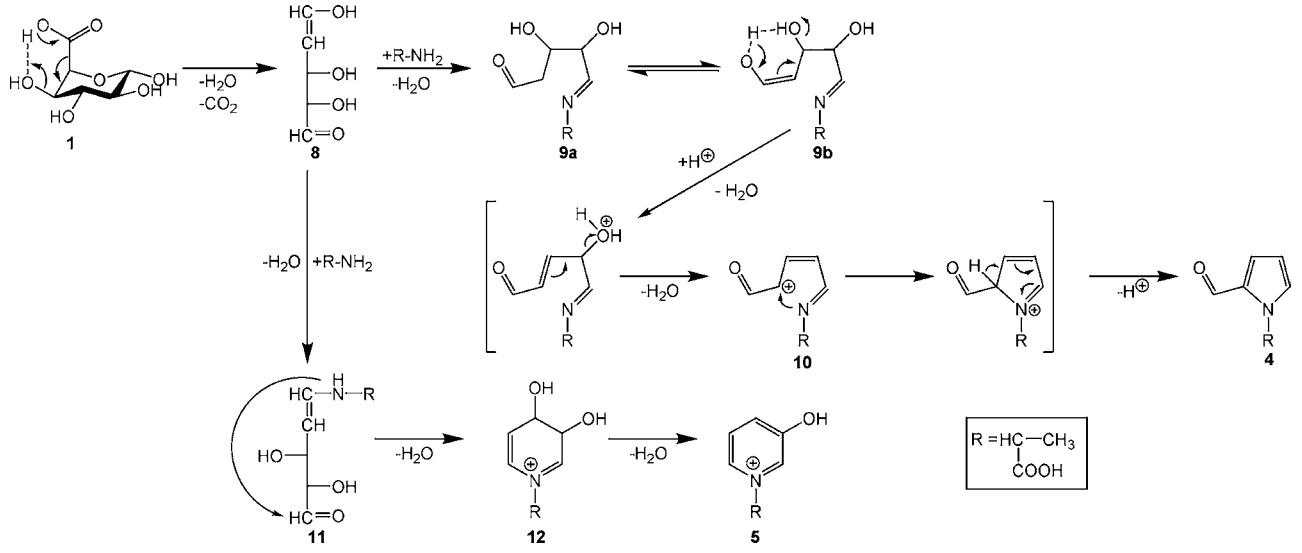

Figure 6. Alternative formation pathway of *N*-heterocyclic compounds due to imine formation on C-5 or C-1 of the 4,5-unsaturated 4-deoxy-L-arabinose **8** with L-alanine and further cyclization and dehydration to FPA **4** or HPA **5**.

concentration of pyrrole-2-carboxaldehyde derivatives and the darker was the color of the model solution (data not shown).

The polymerization speed along with the polymer's solubility depended on the structure of the amino acid. In equimolar solutions of D-galacturonic acid with L-alanine or GABA at a reaction temperature of 160 °C, the associated pyrrole-2-carboxaldehyde derivative (FPA, FPG) was the main degradation product. Figure 7 illustrates the pyrrole-2-carboxaldehyde derivative formation in relation to the browning of the respective model solutions measured at 420 nm. In the above-mentioned reaction with L-alanine the FPA formation was very fast and the maximum concentration was reached after 5 min. Afterward, it slightly decreased because D-galacturonic acid was probably degraded in large part, but because of the accumulated FPA, polymerization could still take place; only the polymerization speed slowed. In the case of L-alanine the polymers were still soluble in the aqueous solution after 2 h of continuous heating. With GABA, the polymerization was even faster than with L-alanine; insoluble black particles were formed

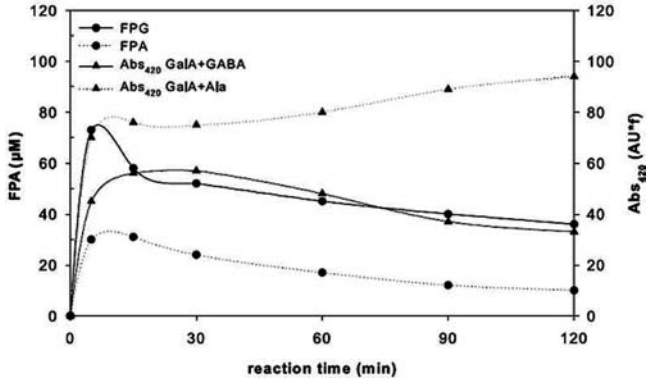

Figure 7. Nonenzymatic browning progress as the absorption at 420 nm and FPA and FPG concentrations of D-galacturonic acid (GalA) solutions with L-alanine (Ala) or γ-aminobutyric acid (GABA) at a reaction temperature of 160 °C, respectively.

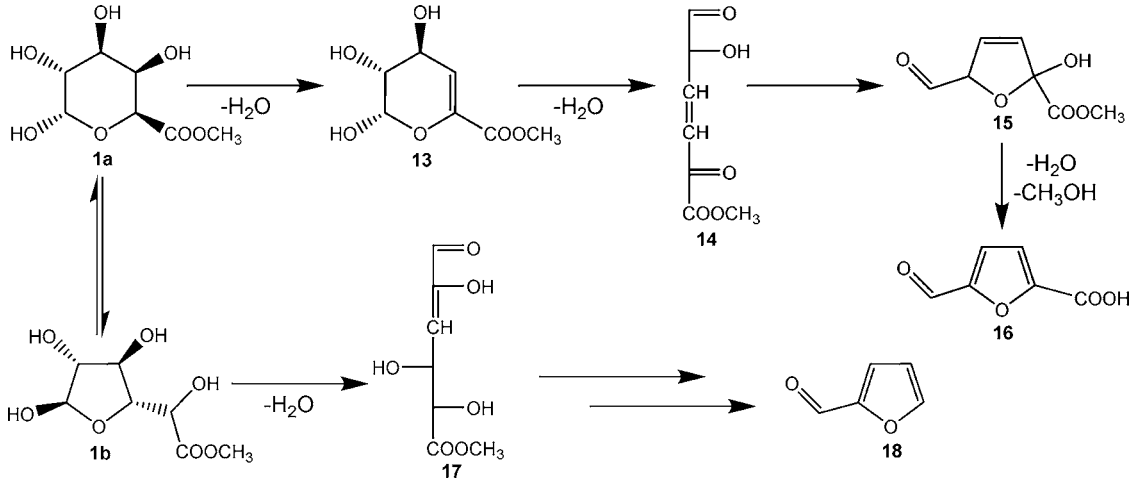

Figure 8. β-Elimination of the pyranoic and the furanoic forms of D-galacturonic acid methyl ester **1a**, **1b** and further degradation to 5-formyl-2-furanoic acid **16** and β-elimination of the furanoic form of the methyl ester **1b** leading to furan-2-carboxaldehyde **18**.

after about 20 min. After reaching an absorption plateau at 420 nm at about 5 min of reaction time, the absorption of the solution with GABA started to decrease again because of the formation of insoluble black particles.

Experiments with several uronic acid derivatives gave indication that the reason for the differences in browning behavior lies within the preferred ring structure of these compounds in aqueous solution. D-Galacturonic acid prefers the lowest energy $^1C_4$ chair conformation with the substituents at C-4 and C-5 in *trans* position.[17] This can be the reason for a relieved eliminative decarboxylation under neutral to slightly acidic conditions resulting in the formation of 2-ketoglutaraldehyde and its isomers and their secondary degradation products discussed recently.[3] D-Glucuronic acid mainly exists in the more labile furanoic hemiacetal form, which is stabilized by a γ-lactone ring under acidic conditions.[18] Due to this lactone ring the proton of the C-4 is acidified and can easily be withdrawn by a base in a β-elimination step at C-3. Dax et al. postulated a degradation pathway that leads to the formation of glyoxal and 3-formyl-2-oxopropanoic acid in acidic solutions of D-glucuronic acid and the formation of 2-ketoglutaraldehyde under more alkaline conditions.[19] This postulated pathway could be confirmed by our investigations, which proved glyoxal as the main α-dicarbonyl compound also formed by the degradation of D-galacturonic acid under slightly acidic conditions. 2-Ketoglutaraldehyde emerged as a key intermediate in browning and the formation of other typical degradation products such as reductic acid and DHCP. In addition, the furanoic compound norfuraneol could be verified as a main degradation product (see Table 2). In reactions with D-galacturonic acid it can especially be found under alkaline conditions, and in participation of L-alanine the amount formed is doubled.

In contrast, D-glucuronic acid model reactions yield only small portions of norfuraneol. Adding L-alanine increases the norfuraneol amount to the level found in alkaline D-galacturonic browning reactions. As mentioned above, this can be explained by D-glucuronic acid mainly existing as γ-lactone in aqueous solutions, which hinders a direct degradation. However, in the presence of amino compounds the degradation reaction toward norfuraneol is catalyzed to a high degree. Compared to model reactions with D-galacturonic acid, the total concentration of the short-chain α-dicarbonyl compounds glyoxal, 2-oxopropanal, diacetyl, and 3-deoxpentosulose, respectively, were 3−4 times higher in D-glucuronic acid models. On the other hand, cyclic nitrogen-containing products such as FPA and HPA are formed on a larger scale in D-galacturonic acid browning reactions. The most obvious reason for these differences in reaction behavior is their special cyclic conformation, as mentioned above. However, more structural elucidation is necessary to clarify this issue. A comparison of degradation products detected after thermal treatment of D-glucuronic and D-galacturonic acid model reactions with and without L-alanine, respectively, after 2 h of reaction at 100 °C and starting pH values of 5.0 and 8.0 can be found in Table 2.

Reactive Intermediates of D-Galacturonic Methyl Ester. The monomeric methyl ester of D-galacturonic acid prefers the furanoic form **1b** (shown in Figure 8) as well, and therefore β-elimination at C-3 is preferred.[20] Subsequent dehydration and elimination of the labile formic acid methyl ester group is supposed to lead to the formation of furan-2-carboxaldehyde (FF) **18** as the main degradation product. This pathway would give an explanation for the comparatively high amounts of FF detected for GalA methyl ester models compared to free D-galacturonic acid model reactions as mentioned above. When the reaction was started at pH 3.0, the pH value remained stable because neither alkaline hydrolysis leading to higher pH values nor acid ester cleavage can take place at these conditions (see Table 3).

Starting GalA methyl ester model reactions at pH 5.0, deesterification and β-elimination proceeded simultaneously and caused a decrease in the pH value from 5.0 to about 4.0. Except for DHCP, all other described degradation products of D-galacturonic acid were formed, but mostly in a lesser extent, with the exception of FF (Table 3). Concerning reductic acid, the thermal D-galacturonic methyl ester degradation yields only a small amount of it compared to its unesterified derivative. Methylation seems to prevent a β-ketoacid-like decarboxylation leading to reductic acid via 2-ketoglutaraldehyde. Starting thermal degradation at pH 3.0, the methyl ester was partially hydrolyzed to the free acid, which could be further converted into its typical and highly browning active degradation products such as reductic acid. In contrast, less acidic starting conditions (pH 5.0) caused a decrease in reductic acid. Under these conditions β-elimination of the relatively stable methyl ester

J. Agric. Food Chem. 2015, 63, 6457−6465

Table 3. Concentrations (Micromolar) of the Main Degradation Products Reductic Acid (RA), Furan-2-carboxaldehyde (FF), Norfuraneol (Norf), FPA, and HPA in Model Solutions of D-Galacturonic Acid Methyl Ester (GalA-Me) with and without L-Alanine (Ala) Compared with Model Reactions of D-Galacturonic Acid (GalA) with and without Ala after Thermal Treatment for 2 h at 100 °C and with Different Initial pH Values

	pH	RA	FF	Norf	FPA	HPA
GalA	3	7	9	nd		
	5	39	2	15		
GalA + Ala	3	38	2	29	50	203
	5	29	38	368	14	84
GalA-Me	3	12	17	nd		
	5	6	30	nd		
GalA-Me + Ala	3	2	43	nd	35	157
	5	2	58	nd	41	84

seemed to be preferred, leading via a 2,3-unsaturated intermediate to FF as already described.

In the presence of Ala a decrease of the browning active RA could be seen at all pH values, probably caused by amino−carbonyl reactions leading to colored polymers. However, the formation of other less reactive compounds such as FF, FPA, or HPA was strongly promoted. Concerning the pH influence, FPA formation seemed analogous to FF, whereas HPA was formed only after acidic ester hydrolysis to a greater extent.

Pectins are important biopolymers that naturally occur in the more ligneous parts of fruits and vegetables. Their backbone mainly consists of D-galacturonic acid methyl ester and D-galacturonic acid units, which are both present in $^4C_1$ chair conformation. When pectins are exposed to alkaline conditions, the methyl ester **1a** is particularly degraded by β-elimination at C-4. Therefrom unsaturated oligogalacturonides occur, which decompose to shortened saturated oligogalacturonides and further degrade via furan-typical dehydration rearomatization reactions to 5-formyl-2-furanoic acid **16**.[21] 2-Furanoic acid, which was also experimentally verified, is supposed to be formed in the same reaction pathway.

Neither furanoic acid could be detected during the degradation of monomeric D-galacturonic acid methyl ester alone, thus confirming the different degradation pathways preferred by the furanoic or pyranoic ring structure according to the constitution of the uronic acid derivative (see Figure 8).

In summary, it can be stated that D-galacturonic acid has emerged as a very potent browning active carbonyl compound within the Maillard reaction compared to other related carbonyl compounds such as D-glucuronic acid or L-arabinose. Model reactions of D-galacturonic acid and L-alanine provoke a >6 times higher browning intensity compared to similar reactions of Ara, Gal, and GalA, respectively. CIELab measurements revealed thereby a uronic acid specific red cast formed during the Maillard reaction.

Besides reductic acid, DHCP, furan-2-carboxaldehyde, and norfuraneol, pyrrole-2-carboxaldehyde and 3-hydroxypyridine-1-ium amino acid derivatives were identified as specific Maillard reaction products of uronic acids. The so-formed relatively high concentrations cannot likely be explained by the Amadori rearrangement pathway alone becaue uronic acid *N*-glucosides are not stable and easily decompose to their starting products. Thus, an alternative reaction pathway has been suggested. Due to eliminative decarboxylation of D-galacturonic acid and an associated carbonyl−amine condensation, Schiff bases of the 4,5-unsaturated 4-deoxy-L-arabinose are formed, which after cyclization and dehydrations lead to the corresponding *N*-heterocyclic compounds.

By comparison of results obtained for D-galacturonic acid model systems with those of the corresponding methyl ester, the ester compound shows less browning activity and degradation under equal reaction conditions. 5-Formyl-2-furanoic acid and 2-furanoic acid could not be identified as specific reaction products of monomeric esters even though thermal pectin decomposition is known to yield these acids. Further short-chain acidic cleavage products such as formic or acetic acid could not be verified as degradation products for both D-galacturonic acid and its methyl ester.

In conclusion, uronic acids are assumed to be responsible for color alteration processes in thermally treated pectin-containing foods. Especially some kinds of juices such as apple juice are susceptible to color change because amino−carbonyl reactions between the endogenous uronic and free amino acids can easily take place during industrial applied pasteurization and storage processes. In this case not only does the undesired color diminish quality but also a loss of free amino acids connected with a decline in nutritional quality is to be expected. For industrial use our findings may implicate changes in cultivation procedures resulting in a reduced free uronic acid content of respective fruits and vegetables and the consideration of negative effects caused by uronic acids during special engineering technologies. However, besides color effects uronic acids affect food quality in many other ways such as texture, taste, and scent, and thus more studies concerning their roles in foods and food technology and their influence on the end product are strongly recommended before a final evaluation.

according to the presence of specific pigments. These marine organisms are rich sources of bioactive compounds from both primary and secondary metabolism, among which fatty acids are highlighted.[14,15] Although marine algae present low lipid content (1−5% of dry matter), PUFA account for almost half of the lipid fraction.[15] Several studies have shown that despite PUFA profiles being highly variable between and within algal groups, linoleic (C18:2 ω6), linolenic (C18:3 ω3), arachidonic (C20:4 ω6), eicosapentaenoic (C20:5 ω3), and docosahexaenoic (C22:6 ω3) acids are predominant in macroalgae.[16−20]

The marine ecosystem is characterized by broad fluctuations of environmental conditions that can be strong stress inducers in macroalgae populations, including extreme temperatures, rapid salinity and nutrient changes, desiccation, and intense sunlight, among others.[21]

Taken together, these observations suggest that macroalgae can be valuable sources of phytoprostanes potentially used as biomarkers of oxidative stress and/or present important biological effects.[9,22] Due to the fact that macroalgae are an integral part of Asian cuisine and recently became a popular addition to some Western diets, our goal was to assess the occurrence of free phytoprostanes, readily bioavailable and absorbed by the human body, in 24 species of macroalgae belonging to Chlorophyta, Phaeophyta, and Rhodophyta. The reason for this characterization was based on the fact that humans do not possess significant esterase activity in the

gastrointestinal tract, rendering impossible the absorption of the esterified form of phytoprostanes.[23]

A fast, selective, and robust ultrahigh-performance liquid chromatography coupled to triple-quadrupole mass spectrometry (UHPLC-QqQ-MS/MS) method, previously validated by Collado-González et al.,[24] was employed. Moreover, all macroalgae species selected for this work were characterized for their composition in α-linolenic acid (**1**) by gas chromatography−mass spectrometry (GC-MS) after alkaline hydrolysis and derivatization.

MATERIALS AND METHODS

Standards and Reagents. Ten phytoprostane standards (9-F_{1t}-phytoprostane (**2**), 9-*epi*-9-F_{1t}-phytoprostane (**3**), *ent*-16-F_{1t}-phytoprostane (**4**), *ent*-16-*epi*-16-F_{1t}-phytoprostane (**5**), 9-D_{1t}-phytoprostane (**6**), 9-*epi*-9-D_{1t}-phytoprostane (**7**), 16-B_1-phytoprostane (**8**), *ent*-16-B_1-phytoprostane (**9**), 9-L_1-phytoprostane (**10**), and *ent*-9-L_1-phytoprostane (**11**)) (Figure 1) were synthesized according to our previous procedures.[25−27] The d_4-15-F_{2t}-isoprostane (8-isoPGF$_{2\alpha}$-d_4) (containing four deuterium atoms at positions 3, 3′, 4, and 4′) was purchased from Cayman Chemicals (Ann Arbor, MI, USA). Authentic standards of fatty acids methyl esters (FAME) for GC-MS analysis were obtained from Supelco (Bellefonte, PA, USA).

Two types of solid-phase extraction (SPE) cartridges were used in this study: Chromabond C18 columns (1000 mg/6 mL) were

DOI: 10.1021/acs.jafc.5b01904
J. Agric. Food Chem. 2015, 63, 6466−6474

obtained from Macherey-Nagel (Düren, Germany) and Strata X-AW (500 mg/3 mL) columns from Phenomenex (Torrance, CA, USA). Butylated hydroxyanisole (BHA), bis(2-hydroxyethyl)-amino-tris-(hydroxymethyl)-methane (BIS-TRIS), chloroform, isooctane, and boron trifluoride (BF_3) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Methanol was acquired from VWR (Fontenay-sous-Bois, France), acetonitrile was obtained from Merck (Darmstadt, Germany), and *n*-hexane was purchased from Panreac (Barcelona, Spain). All LC-MS grade solvents were obtained from J. T. Baker (Phillipsburg, NJ, USA). Water was treated in a Milli-Q water purification system from (Millipore, Bedford, MA, USA).

Macroalgae Samples. Macroalgae samples consisted of 3 Chlorophyta, 5 Rhodophyta, and 16 Phaeophyta species collected between 2010 and 2013 (Table 1). With the exceptions of *G. vermiculophylla*, *S. latissima*, and *Ulva* sp., which were cultivated in integrated multitrophic aquaculture (IMTA) systems and provided by CIIMAR/CIMAR − Centre for Marine and Environmental Research, all samples were randomly collected during low-tide periods from different places of the western coast of Portugal, each sample corresponding to a mixture of three to four individuals in the same stage of development. To prevent sample alterations, after collection they were immediately placed on ice and transported to the laboratory in insulated, sealed ice boxes to protect them from heat, air, and light exposure. Macroalgae were then carefully and quickly washed with NaCl aqueous solution (3.5%) to remove epiphytes and encrusting material, at room temperature, without exposure to direct light, and kept at −20 °C, prior to lyophilization. The dried material was powdered (<910 μm) and kept in the dark, in a desiccator, until it was subjected to extraction. No alteration (color, smell, humidity) of the samples was noted during storage.

α-Linolenic Acid and Extract Derivatization for GC-MS Analysis. The extraction of α-linolenic acid was performed as previously described, with slight modifications.[28] Briefly, 0.25 g of the dried macroalgae was extracted with 25 mL of chloroform/methanol (2:1), under magnetic stirring at 500 rpm, for 10 min, at 40 °C. The extraction procedure was repeated five times and the resulting extracts were pooled and concentrated to dryness under reduced pressure (40 °C). The residue was then hydrolyzed with 1 mL of KOH methanolic solution (11 g/L), at 90 °C, for 10 min. The free fatty acids originally present and those resulting from the alkaline hydrolysis were derivatized to their methyl esters with 1 mL of BF_3 methanolic solution (10%), at 90 °C, for 10 min. FAME were purified with 2 × 10 mL of isooctane, and anhydrous sodium sulfate was added to ensure the total absence of water. The resulting extract was evaporated to dryness under a stream of nitrogen and dissolved in 200 μL of isooctane. Each macroalga species was assayed in triplicate.

GC-MS Analysis of α-Linolenic Acid. GC-MS analysis was performed following a previously established method.[28] Derivatized extracts (1 μL) were analyzed using a Varian CP-3800 gas chromatograph (Walnut Creek, CA, USA) equipped with a Varian Saturn 4000 mass selective detector and a Saturn GC-MS workstation software version 6.8. The column used was a 30 × 0.25 mm, i.d., 0.25 μm, VF-5 ms (Varian). The injector port was heated to 250 °C. Injections were performed in split mode, with a ratio of 1:40. The carrier gas was helium C-60 (Gasin, Portugal), at a constant flow of 1 mL/min. The oven temperature was set at 40 °C for 1 min, then increased at 5 °C/min to 250 °C and at 3 °C/min to 300 °C, and held for 15 min. All mass spectra were acquired in EI mode. Ionization was maintained off during the first 4 min, to avoid solvent overloading. The ion trap detector was set as follows: transfer line, manifold, and trap temperatures were, respectively, 280, 50, and 180 °C. The mass ranged from m/z 50 to 600, with a scan rate of 6 scan/s. The emission current was 50 μA, and the electron multiplier was set in relative mode to autotune procedure. The maximum ionization time was 25000 μs, with an ionization storage level of m/z 35. The analysis was performed in full scan mode. Identification of α-linolenic acid was achieved by comparison of its retention index and mass spectra with those from pure standard injected under the same conditions and from NIST 05 MS Library Database. The amount of methyl ester of α-linolenic acid present in the samples was achieved from the calibration curve of the respective standard prepared in isooctane.

Phytoprostane Extraction. Each pulverized macroalga sample (1 g) was crushed in a mortar and pestle with 5 mL of methanol (0.1% BHA). The sample extracts were centrifuged at 2000*g* during 10 min, and the supernatants underwent SPE using a Chromabond C18 column. Briefly, 10 mL of *n*-hexane was added to 1 mL of the filtered sample and then rediluted in 2 mL of methanol and 2 mL of BIS-TRIS buffer.[24]

The emulsion of each macroalga sample was applied to a previously conditioned and equilibrated Strata-X-AW cartridge. After the column had been loaded with the emulsion, 2 mL of *n*-hexane, followed by 2 mL of Milli-Q water, 2 mL of methanol/Milli-Q water (1:3), and 2 mL of acetonitrile were applied for removing undesired compounds. Target compounds were eluted with 1 mL of methanol and dried under nitrogen stream. The dried residue of each macroalga sample was reconstituted with 200 μL of a mixture of A/B solvents (90:10, v/v), solvent A being Milli-Q water/0.01% acetic acid and solvent B being methanol/0.01% acetic acid. Reconstituted extracts were sonicated, filtered through a 0.45 μm filter (Millipore), and further injected and analyzed in an UHPLC-QqQ-MS/MS apparatus.

UHPLC-QqQ-MS/MS Analysis of Free Phytoprostanes. Separation of the phytoprostanes present in macroalga samples was performed using an UHPLC coupled to 6460 QqQ-MS/MS (Agilent Technologies, Waldbronn, Germany), as previously described.[24] The column used was a 50 × 2.1 mm i.d., 1.7 μm, BEH C18 (Waters, Milford, MA, USA). The column temperature was 6 °C. The mobile phases employed were solvent A (Milli-Q water/acetic acid (99.99:0.01, v/v)) and solvent B (methanol/acetic acid (99.99:0.01, v/v)). The elution was performed at a flow rate of 0.2 mL/min using the following gradient profile: 60% B at 0 min, 62% B at 2 min, 62.5% B at 4 min, reaching 65% B at 8 min, and returning to the initial conditions at 8.01 min. The MS analysis was applied in the multiple reaction monitoring (MRM) negative ESI mode. ESI conditions and ion optics were as previously described.[24] Data acquisition and processing were performed using MassHunter software version B.04.00 (Agilent Technologies). The quantitation of phytoprostanes detected in macroalgae was performed using authentic standards of compounds **2**, **3**, **8**, and **10**. The synthetic isoprostane d_4-15-F_{2t}-isoprostane (8-isoPGF$_{2\alpha}$-d_4) was used as internal standard.

Statistical Analysis. All of the analytical determinations were performed in triplicate, and the mean values were reported. All values obtained were compared using analysis of variance (one-way ANOVA, post hoc Tukey) and unpaired *t* test. Pearson correlations were calculated according to GraphPad Prism 6 Software, Inc. (San Diego, CA, USA). One-way ANOVA, unpaired *t* test, and principal component analysis (PCA) were performed using IBM SPSS Statistic for Windows version 22.0 (Armonk, NY, USA). Differences at $p < 0.05$ were considered statistically significant.

RESULTS AND DISCUSSION

The field of phytoprostanes was opened in 2000 and currently is still in its infancy. As far as we know, our work is the first report of different naturally occurring classes of free phytoprostanes in 24 macroalga species belonging to Chlorophyta, Phaeophyta, and Rhodophyta collected along the western coast of Portugal and from IMTA systems. Likewise, this is the first time a correlation between α-linolenic acid levels and its autoxidation products was ever tried in algae material.

Occurrence of α-Linolenic Acid in Macroalgae. Although the fatty acid profiles of some of the target species in this work have already been characterized, intraspecific variability is common in macroalgae from different geographical locations and/or with exposure to diverse abiotic factors, resulting in different PUFA profiles.[18] In this work we were able to identify and quantitate α-linolenic acid (**1**) in the 24 selected macroalga species (Table 2). The content of this compound

[a]9-F_{1t}-phytoprostane (**2**), 9-epi-9-F_{1t}-phytoprostane (**3**), 16-B_1-phytoprostane (**8**), and L_1-phytoprostane (**10**). Results are expressed as mean (standard deviation) of three determinations. nd, not detected. Different letters in the same column indicate significant differences ($p < 0.05$) between the reported values for each macroalga species.

ranged between ca. 0.7 and 5.6 g/kg of dry algae, *C. tamariscifolia* and *U. lactuca* presenting, respectively, the lowest and the highest amounts. Indeed, previous studies have reported that members of the order Ulvales presented compound **1** as the characteristic PUFA.[17,18] The presence of compound **1** in all of the analyzed species enables and emphasizes the importance of assessing the occurrence of its autoxidation products, the phytoprostanes.

Occurrence of Free Phytoprostanes in Macroalgae. The analysis of phytoprostanes in natural matrices is extremely challenging, requiring highly sensitive and specific tools for their profiling and characterization.[29] Moreover, the great diversity granted by the presence of racemic mixtures of phytoprostanes increases the complexity of these analyses. In this work, a fast, accurate, and robust UHPLC-QqQ-MS/MS method previously developed by Collado-González et al.[24] for the quantitative and qualitative determination of free phytoprostanes in foodstuffs was employed.

Among the 10 available phytoprostane standards, only 3 were detected in the analyzed macroalga samples (Table 2). Neither 16-series of F_{1t}-phytoprostanes nor 9-series of D_{1t}-phytoprostanes was detected in the studied species. Phytoprostane identity was confirmed according to their molecular masses, the precursor ions (m/z 327.2 and 307.2), the characteristic MS/MS fragmentation product ions, and the corresponding retention times. The mass spectrometric information on the phytoprostanes detected in one macroalga sample (*C. tomentosum*) is summarized in Figure 2. Compounds **2** and **3** (Figure 2A) showed the same transition from the precursor ion at m/z $[M - H]^-$ 327.2 to the product ion at m/z 171.2 (Figure 2B,C). Thus, their identification was only possible by the comparison of their retention times: compound **2** eluted at 1.75 min, whereas compound **3** eluted at 1.93 min (Figure 2A,B). Contrary to prostaglandins, phytoprostanes are non-enzymatically formed as regio- and stereoisomeric mixtures.[3] The analytical conditions employed in this study did not allow enantiomer separation. Therefore, compounds **8** and **10** (Figure 2A) were identified and quantitated according to their specific transitions from the precursor ion m/z $[M - H]^-$ 307.2 to the product ions m/z $[M - H]^-$ 235.2 and m/z $[M - H]^-$ 185.2, respectively (Figure 2D,E).

The qualitative profile of phytoprostanes found in the analyzed macroalgae samples showed great variability among the three phyla (Chlorophyta, Phaeophyta, and Rhodophyta) and even between species belonging to the same genus; that is, compounds **2** and **3** were detected in *F. spiralis*, but in *F. serratus* and *F. guiryi* none of the studied phytoprostanes was identified.

In the three studied green macroalgae (*C. tomentosum*, *U. lactuca*, and *Ulva* sp.), as well as in two of the red (*S. coronopifolius* and *G. vermiculophylla*) and eight of the brown species (*C. spongiosus*, *F. spiralis*, *L. ochroleuca*, *P. pavonica*, *S. latissima*, *S. polyschides*, *S. vulgare*, and *S. scoparium*), compounds **2** and **3** were identified. Also, compound **8** was detected in four of the brown species (*P. pavonica*, *S. latissima*, *S. vulgare*, and *S. scoparium*). The brown macroalgae *B. bifurcata* contained only compound **8**. None of the screened phytoprostanes were detected in 10 macroalga species (*A. armata*, *C. tamariscifolia*, *C. usneoides*, *F. guiryi*, *F. serratus*, *Gigartina* sp., *H. filicina*, *P. canaliculata*, *P. cartilagineum*, and *S.*

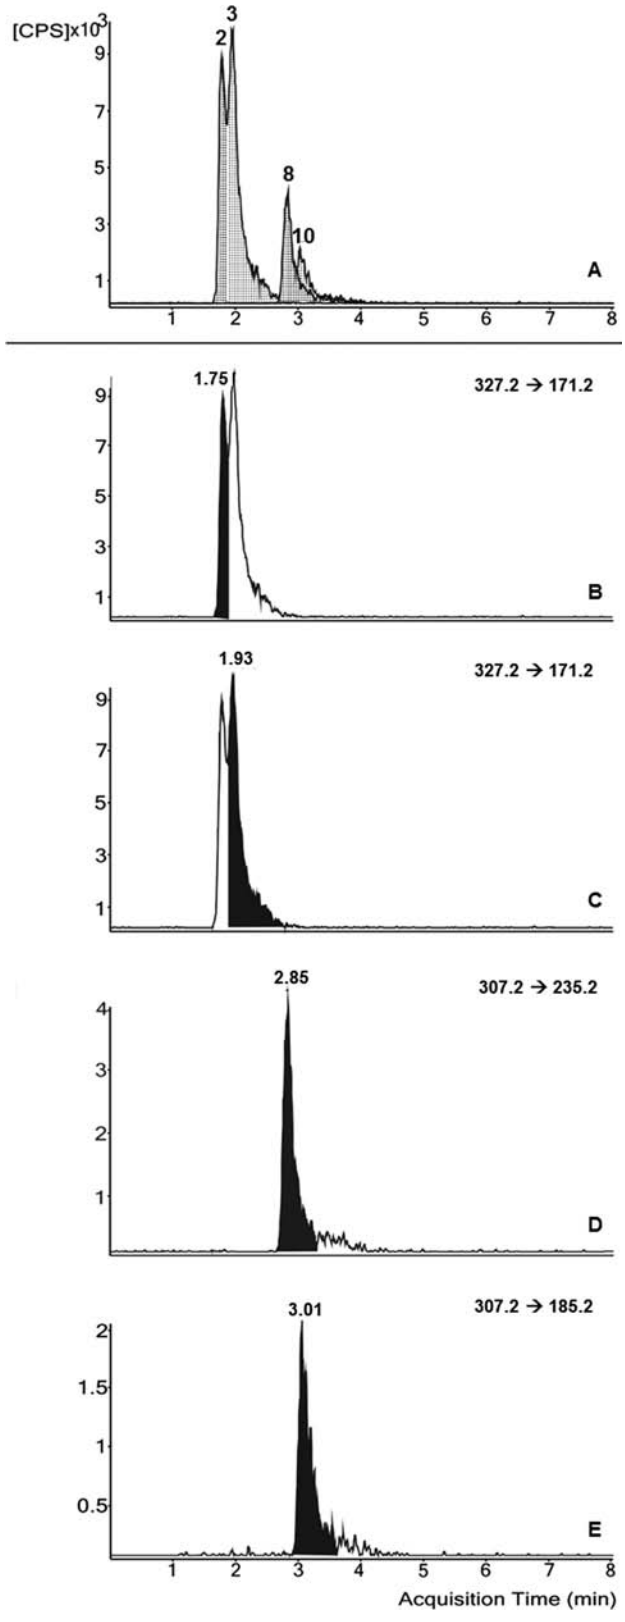

Figure 2. (A) Representative UHPLC-QqQ-MS/MS chromatogram of detected phytoprostanes (*C. tomentosum*) and MRM transitions for quantitation of (B) 9-F_{1t}-phytoprostane (**2**), (C) 9-epi-9-F_{1t}-phytoprostane (**3**), (D) 16-B_1-phytoprostane (**8**), and (E) 9-L_1-phytoprostane (**10**).

muticum). The species *C. spongiosus* and *C. tomentosum* exhibited higher diversity in phytoprostanes.

The determination of phytoprostane levels in macroalgae is of extreme importance, stimulating the exploitation and characterization of new natural dietary sources of these compounds.

The amount of phytoprostanes found in the analyzed samples is shown in Table 2. F_{1t}-phytoprostanes were the dominant class determined in this study, whereas L_1-phytoprostanes were detected in only two macroalga species and at very low levels. Concerning each phytoprostane class, both compounds **2** and **3** were found in higher concentration in the brown macroalgae *S. latissima* (ca. 701 and 668 ng/100 g of dry algae, respectively); *F. spiralis* exhibited the lowest amount of these phytoprostanes (ca. 19 and 17 ng/100 g of dry algae, respectively). The sample with the lowest content of compound **8** was *S. vulgare* (ca. 4 ng/100 g of dry algae), whereas *C. tomentosum* was found to have the highest amount (ca. 14 ng/100 g of dry algae). *C. spongiosus* and *C. tomentosum* were the only samples that presented compound **10** (ca. 5 and 6 ng/100 g of dry algae, respectively).

As observed with the qualitative profile, the quantitation of total phytoprostanes in the studied macroalgae species revealed significant variability. The total phytoprostane content ranged between ca. 6 and 1381 ng/100 g of dry algae. The macroalga species showing the highest amount of phytoprostanes (*S. latissima*) was from IMTA systems. However, no conclusions can be drawn regarding the advantages of IMTA for obtaining higher yields of phytoprostanes, as no marine counterpart of this species was analyzed.

To the best of our knowledge, no information has been published before on the content of naturally occurring free phytoprostanes in macroalgae. Therefore, the results obtained can be compared only with those of previous work performed on plant material and other foodstuffs. Karg et al.[9] found that either D_1- or F_{1t}-phytoprostanes were the dominant classes in vegetable oils, whereas B_1- and L_1-phytoprostanes, including their enantiomers, were minor components.[9] More recently, Collado-González et al.[24] reported that F_{1t}-phytoprostanes were the main class in the green table olive 'Manzanilla de Sevilla'.[24] Likewise, in macroalgae, F_{1t}-phytoprostanes were the main phytoprostanes detected. This class of compounds was also found to occur in the leaves, flowers, and roots of taxonomically distinct plant species, ranging from 43 to 1380 ng/g of dry weight.[30] Although we are aware structural differentiation in macroalgae is likely to be accompanied by variation in chemical composition, the present work used full alga individuals in the same stage of development, rendering it impossible to conclude about the presence and distribution of phytoprostanes in different morphological parts of the selected species.

Although it was theoretically expected to find both 9- and 16-series of F_1-phytoprostanes in equal amounts, we were not able to ensure this hypothetical relation in the studied macroalgae. In fact, previous studies reported only that 9- and 16-series (previously referred to as types II and I, respectively) of A_1-, B_1-, and E_1-phytoprostanes were of equal abundance in different plant tissues.[9] Moreover, Imbusch et al.[31] stated that due to the isomeric complexity of F_1-phytoprostanes, identification and quantitation of this class of compounds are technically difficult. Therefore, studies reporting the presence of F_1-phytoprostanes focused essentially on the differentiation between free and esterified isomers.[9,30−32] The analytical methodology employed in this work was able to differentiate 9-F_1-phytoprostane and 16-F_1-phytoprostane in previous

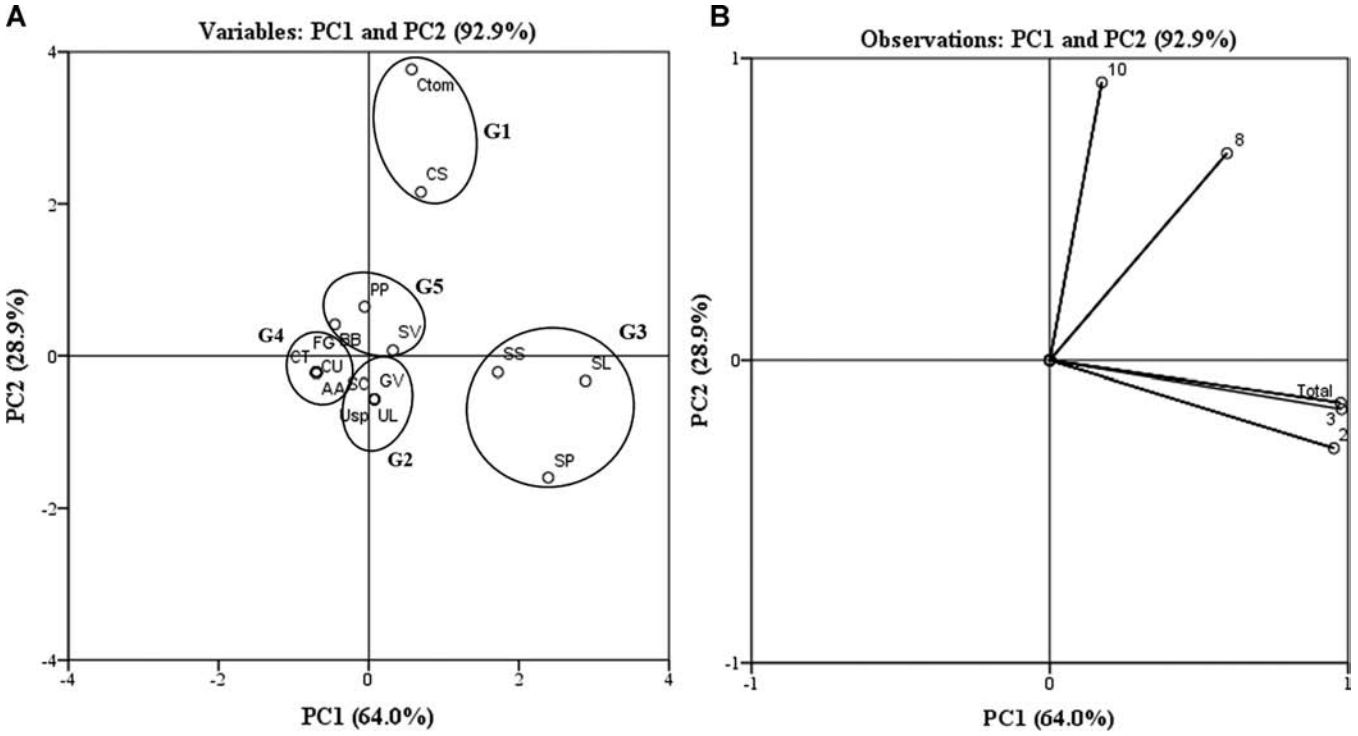

Figure 3. Projection of macroalgae (A) (variables: *A. armata* (AA), *B. bifurcata* (BB), *C. spongiosus* (CS), *C. tomentosum* (Ctom), *C. tamariscifolia* (CT), *C. usneoides* (CU), *F. guiryi* (FG), *F. serratus* (Fser), *F. spiralis* (Fspi), *Gigartina* sp. (Gsp), *G. vermiculophylla* (GV), *H. filicina* (HL), *L. ochroleuca* (LO), *P. pavonica* (PP), *P. canaliculata* (PC), *P. cartilagineum* (Pcart), *S. latissima* (SL), *S. polyschides* (SP), *S. muticum* (SM), *S. vulgare* (SV), *S. coronopfolius* (SC), *S. scoparium* (SS), *U. lactuca* (UL), and *Ulva* sp. (Usp)) and loadings (B) by phytoprostane composition (variables: **2**, **3**, **8**, and **10**) into the plane composed by principal components PC1 and PC2 containing 92.9% of the total variance.

studies using several natural matrices, such as olives and oils.[24] It was reported that the occurrence of these regioisomers was not of equal proportions: in refined sunflower oil the 9-F_1-phytoprostane was found in 44.48 ng/mL, whereas the 16-F_1-phytoprostane was found in 24.40 ng/mL of; in 0.8° and 0.4° extra virgin oil 9-F_1-phytoprostane were not detected, whereas 16-F_1-phytoprostane was found in 2.13 and 3.70 ng/mL, respectively.[24] The reason for these differences is still unclear, and more studies are needed to clarify the underlying response mechanisms of individual free phytoprostanes in natural products.

Statistical Analysis. Principal component analysis (PCA) was performed to determine possible distribution patterns of the identified and quantitated phytoprostanes (**2**, **3**, **8**, and **10**) in all of the analyzed macroalga samples. PCA of the normalized phytoprostane data set explained 92.9% of total variations, PC1 accounting for 64.0% of the variance and PC2 for 28.9%. Five groups were distinguished (Figure 3A). One group (**G1**) includes *C. spongiosus* and *C. tomentosum*, the only two macroalgae species in which compound **10** was identified. **G2** contains *G. vermiculophylla*, *S. coronopifolius*, *U. lactuca*, and *Ulva* sp., which presented similar amounts of both compounds **2** and **3**, whereas **G3** comprises the three macroalgae species that clearly stood out for their high levels in these exact phytoprostanes (*S. latissima*, *S. scoparium*, and *S. polyschides*). The low amounts of compounds **2** and **3** in *F. spiralis* and *L. ochroleuca* led to the inclusion of these two species in another group (**G4**), together with *A. armata*, *C. tamariscifolia*, *C. usneoides*, *F. guiryi*, *F. serratus*, *Gigartina* sp., *H. filicina*, *P. canaliculata*, *P. cartilagineum*, and *S. muticum*, in which none of the available phytoprostanes was identified. Finally, *B. bifurcata*, *P. pavonica*, and *S. vulgare* were grouped together (**G5**) due to their similar amounts of compound **8** (Figure 3). The total amount of phytoprostanes is visibly influenced by the levels of both compounds **2** and **3**, confirming that F_{1t}-phytoprostane is the dominant phytoprostane class in the analyzed samples (Figure 3B).

Pearson correlations were calculated to establish a potential relationship between the presence of α-linolenic acid (**1**) in alga material and phytoprostane composition. Our results showed a lack of correlation between the amount of compound **1** and total phytoprostane content ($r = -0.318$). However, the possibility of enzymatic oxidation of compound **1** cannot be ignored. Although this compound is prone to undergo autoxidation reactions, it can also be released from membrane lipids and metabolized by the enzymatic action of lipoxygenases (LOX).[33] In fact, several studies have already reported the presence of diverse structurally unique oxylipins from enzymatic routes in macroalgae.[34−39] Also recently, Barden et al.[40] conducted a clinical trial with healthy volunteers whose diet was supplemented with linseed oil. They detected high levels of phytoprostanes, but they were not able to assess whether phytoprostanes increased due to enhanced concentration of compound **1** or by direct intake from linseed oil.[40]

Altogether, these observations suggest that the large variations observed in phytoprostane composition can be partially explained by intrinsic factors (e.g., physiological variations within algae organs) and/or extrinsic factors (e.g., geographical origin or area of cultivation, seasonal, and environmental variations, time of harvest, water temperature, salinity levels, and processing methods).

At present, the interest in phytoprostanes comprises two general areas: as biomarkers of oxidative stress in plant-derived foodstuffs and as bioactive mediators with potential benefits in

DOI: 10.1021/acs.jafc.5b01904
J. Agric. Food Chem. 2015, 63, 6466−6474

human health. As an example, Collado-González et al.[41] have recently reported that some phytoprostanes could be considered as early candidate biomarkers of water stress in olive tree.[41] Concerning their biological potential, studies have been shown that certain phytoprostane classes were active in various experimental models.[9,22,42,43] However, further studies are required using different natural dietary sources of phytoprostanes to evaluate the real effect of these oxidized lipids on human health.

In this regard, our study represents a first approach in the assessment of different naturally occurring classes of free phytoprostanes in macroalgae. The rational exploitation of photosynthetic marine organisms as valuable sources of prominent oxidized lipids is encouraged for future application as substitutes of chemically synthesized oxylipins and as pharmaceuticals and/or nutraceuticals, providing a complementary treatment for chronic diseases, including neurodegenerative and inflammation-related pathologies.

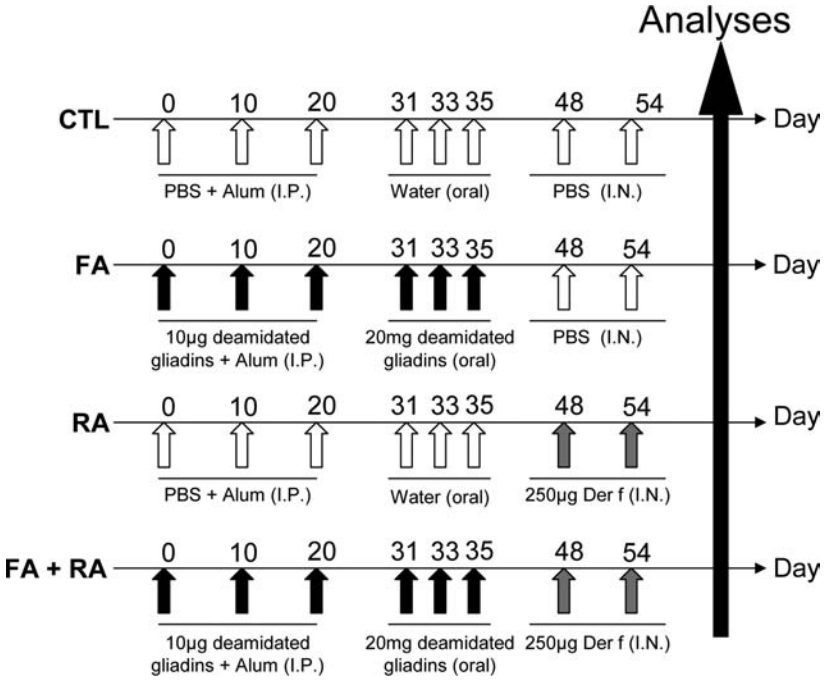

Figure 1. Study design. Mice were distributed into four groups: control (CTL), food allergy (FA), respiratory allergy (RA), and food and respiratory allergy (FA+RA).

MATERIALS AND METHODS

Animals. Balb/c mice (Charles River, France) were fed with an irradiated semisynthetic diet devoid of plant proteins (Safe, Augy, France). The Ethics Committee in Animal Experimentation of Pays de la Loire approved the protocol. (CEEA.2011.52; accreditation no. 4478), and all efforts were made to minimize suffering. All mice were maintained under specific pathogen-free conditions at the institutional animal facility. All animal procedures were conducted on mice between 8 and 12 weeks of age, in accordance with appropriate animal care. At the designated times, the animals were sacrificed according to institutional guidelines, and blood and tissues were collected for analyses.

Allergy Models. Freeze-dried deamidated gliadins were solubilized in 70% ethanol at 5 mg/mL and then diluted to 0.1 mg/mL in sterile PBS. Mice were intraperitoneally sensitized with 10 μg of deamidated gliadins absorbed on aluminum hydroxide (Sigma-Aldrich, Saint Quentin Fallavier, France) on days 0, 10, and 20. Challenge was performed by intragastric administration of 20 mg of deamidated gliadins on days 31, 33, and 35. For this mouse model of atopic march, a delay of 2 weeks was set between the last oral challenge and the first intranasal sensitization. Respiratory allergy was induced by intranasal exposure to 40 μL, containing 250 μg of HDM extract (*Dermatophagoides farinae*, Stallergenes, Antony, France) and approximately 1200 UE/ml of endotoxin, as measured by LAL test (Thermo, Waltham, MA, USA) on mice anesthetized with a 200 μL of mixture of ketamine (80 mg/kg)/xylazine (10 mg/kg) intraperitoneally injected on days 48 and 54. Mice were sacrificed 1 day after the last HDM extract challenge on day 55. As described (Figure 1), mice were then exposed to different protocols: food allergen alone (wheat, FA), respiratory allergen alone (HDM extract, RA), and successive exposure to allergens (wheat and HDM extract, FA+RA). Unexposed mice were used as controls (CTL).

Immunoglobulin Assays. Blood was removed on day 55 by cardiac puncture and centrifuged to collect serum. Sera were stored at −20 °C before immunoglobulin assays. Mouse IgE specific to deamidated gliadins was assayed by indirect F-ELISA as described by Gourbeyre et al.[21] Plates were coated with 5 μg/mL deamidated gliadins in carbonate buffer (30 mM Na_2CO_3 and 70 mM $NaHCO_3$, pH 9.6). Serum samples were diluted 1:50 in PBS with 0.1% Tween-20 and 0.5% gelatin. A detection rat antibody directed against mouse IgE (diluted 1/250 in PBS with 0.1% Tween-20 and 0.5% gelatin) and conjugated to alkaline phosphatase (Southern Biotechnology Associates Birmingham, AL, USA) was used. Fluorescence intensity was measured (at 440 nm after excitation at 360 nm) after incubation with an alkaline phosphatase substrate (4-methylumbeliferin, Sigma-Aldrich). Specific anti-Der f 1 IgE was assessed by indirect ELISA. Briefly, 96-well plates (Nunc) were coated with 100 μL of a solution of 50 μM sodium bicarbonate and 0.25 μg of purified Der f 1 (Indoor Biotechnologies, Cardiff, UK) in each well and left overnight at 4 °C. Then, wells were incubated with bovine serum albumin 1% in PBS for 12 h at 4 °C. Sera were diluted in Can Get Signal immunoreaction enhancer solution 1 (CGS1, Cosmo Bio, Tokyo, Japan), and 100 μL of this solution was incubated overnight at 4 °C. Specific immunoglobulins were detected after incubation at room temperature with an anti-mouse IgE (AbD serotec, Oxford, UK) antibody coupled to horseradish peroxidase and diluted in CGS 2 (Cosmo Bio). Substrate, 2,2′-azinobis[3-ethylbenzothiazoline-6-sulfonic acid] diammonium salt (ABTS, Roche, Basel, Switzerland), was added, and optical density was measured by spectrophotometry (PerkinElmer, Waltham, MA, USA).

Histamine Assay. Blood samples were collected on day 55, and histamine was measured by ELISA (Labor Diagnostika Nord, Nordhom, Germany), according to the manufacturer's recommendations.

Cell Proliferation. Organs were crushed using a tissue grinder (Wheaton, Rochdale, UK) after removal to obtain single-cell suspensions, and after red blood cell lysis, cells were suspended in supplemented RPMI. Cells from Peyer patches were transferred to HBSS/Hepes 1.5%. Fragments were incubated 1 h at 37 °C in HBSS/Hepes 1.5%/FBS 2%/Dispase/DNase (Sigma-Aldrich) solution. Cells were plated at 10^6 cells/well for 96 h at 37 °C in the presence of concanavalin A (1 μg/mL) (Sigma-Aldrich), and proliferation was measured by MTT assay.[21]

Flow Cytometry. Anti-mouse antibodies used were the following: CD3-APC, CD19 PE-Cy7, Ly6G-PerCP-Cy5.5, CD8 APC-H7, and CCR3-PE (BD Biosciences). Dead cells were excluded using DAPI. Stained cells resuspended in PBS-FCS 1% were acquired on a BD LSR II (BD Biosciences) and analyzed on BD FACSDiva software (BD Biosciences). The following cells were stained in the presence of Fc blocker (BD Biosciences): eosinophils (gated on SSC^{high}, $Ly6G^{int}$, and

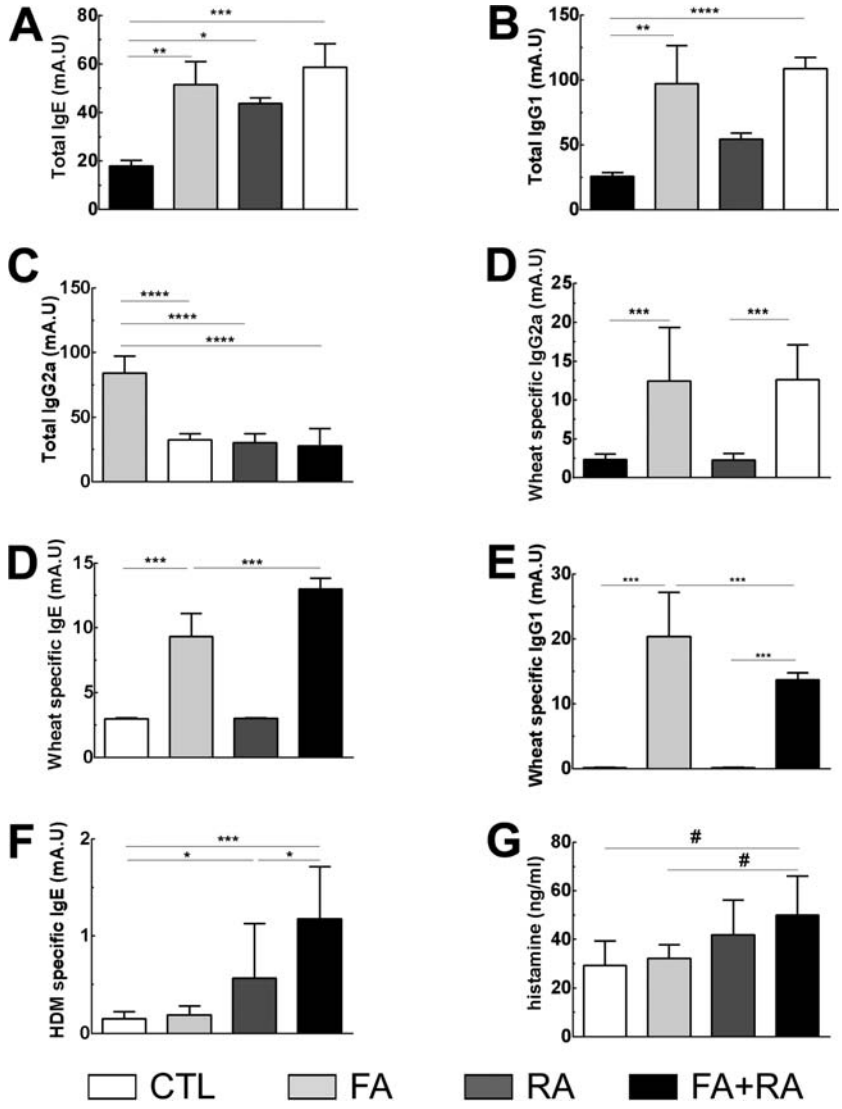

Figure 2. Ig and histamine levels are increased in food and respiratory allergy. Total and wheat-specific IgE (A, D), IgG1 (B, E), IgG2a (C, D), HDM-specific IgE (F), and histamine (G) were measured at day 54 in serum of mice after the last sensitization to HDM (n = 8 animals per group). Bonferroni multiple-comparison test: (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.005$. Dunn's comparison test: (#) $p < 0.05$, (##) $p < 0.01$, and (###) $p < 0.005$.

CCR3$^+$), neutrophils (gated on SSC^{high} and Ly6G^{high}), and lymphocytes (gated on CD3$^+$).

Cytokine Measurements. In lymphoid organs and Peyer patches, cell culture supernatants IL-4 and IFN-γ were assayed using ELISA kits cytoset (Invitrogen, Paisley, UK), and IL-10, IL-17A, and TGF-β were assayed using ELISA Ready-Set-Go! Kits (eBioscience, Paris, France) according to the manufacturer's recommendations. Broncho-alveolar lavages (BAL) were performed by intratracheally administering 1 mL of PBS and gentle aspiration to collect the epithelial lining fluid. IL-4, IL-10, IFN-γ, and IL-17 were quantified by Luminex technology (BioPlex 200 system, Bio-Rad, Hercules, CA, USA) according to the manufacturer's instructions (Bio-Rad).

Histopathological Analysis. The jejunum and proximal colon were collected, formalin fixed, and paraffin embedded. Sections (5 μm thick) were stained with hematoxylin and eosin and inspected for the presence of mucosal inflammation. Histological analysis images were taken with an Axio Imager M1 microscope and an Axiocam HRc (Zeiss). Sections were analyzed using ImageScope for image acquisition (Aperio Technologies, Inc.), and a cell type count for goblet cells and leukocytes was performed on 10 villus/mouse. Grading of intestinal inflammation was determined in a blinded fashion, as previously described.[22] Briefly, sections of mouse jejunum were individually scored on the basis of three parameters. Inflammation was scored as follows: 0, rare inflammatory cells in the lamina propria; 1, increased numbers of cells in the lamina propria; 2, confluence of inflammatory cells extending into the submucosa; and 3, transmural extension of the inflammatory infiltrate. Crypt damage was scored as follows: 0, intact crypts; 1, loss of the basal one-third; 2, loss of the basal two-thirds; 3, entire crypt loss; 4, change of epithelial surface with erosion; and 5, confluent erosion. Ulceration was scored as follows: 0, absence of ulcer; 1, one or two foci of ulcerations; and 2, confluent or extensive ulceration. The total histological score represents the sum of all features evaluated and thus ranges from 0 to 10.

Evaluation of Gastrointestinal Functions. To assess permeability, the jejunum and proximal colon were removed and washed in cold Krebs solution, and segments were mounted in Ussing chambers (Physiological Instruments, San Diego, CA, USA). Paracellular and transcellular permeability were assayed by simultaneously measuring the flux of fluorescein−5.6 sulfonic acid (400 Da; 1 mg/mL, Invitrogen) and horseradish peroxidase (HRP) (44 kDa; 375 μg/mL; Sigma, Saint Quentin Fallavier, France), respectively, over 3 h.

Airway Hyper-reactivity (AHR) Measurement. Enhanced pause (Penh) was measured by whole body plethysmography (Emka

J. Agric. Food Chem. 2015, 63, 6475−6483

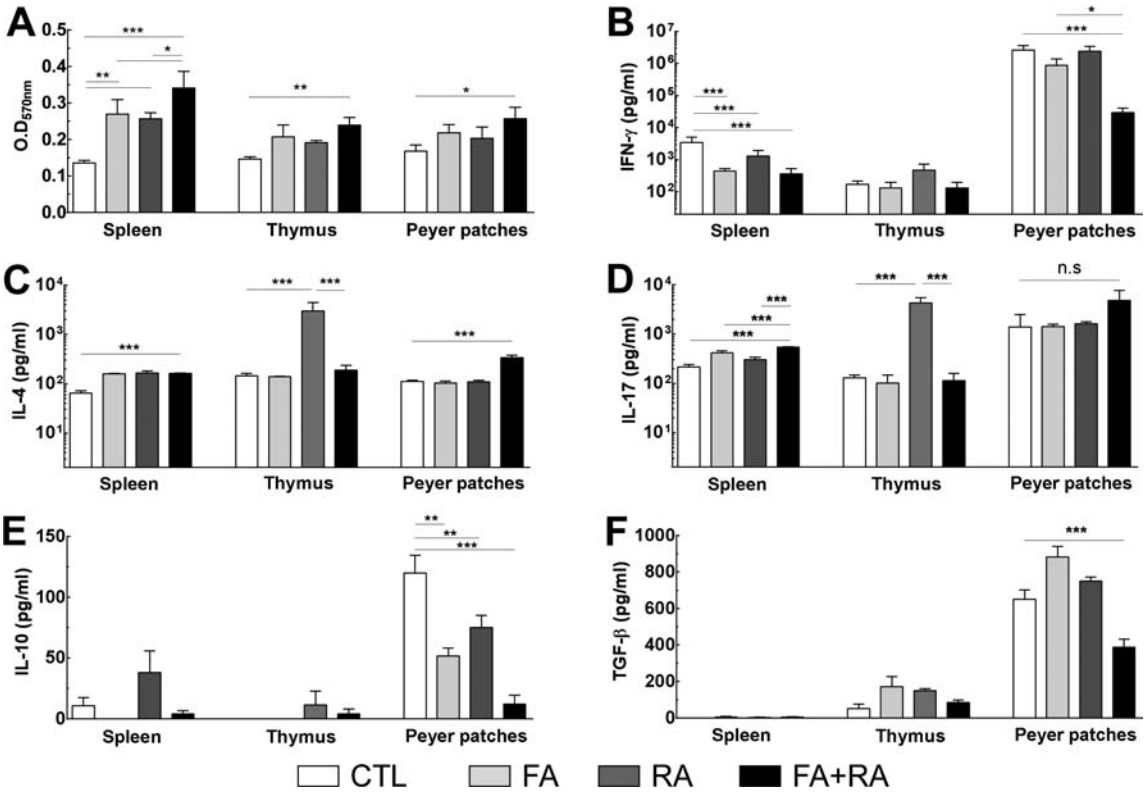

Figure 3. Allergens synergize to increase cell proliferation and cytokine secretion in lymphoid organs. Proliferation from spleen, thymus, and Peyer patch cells in response to ConA was measured (A) in control (white bar), food allergic (light gray bar), respiratory allergic (dark gray bar), and combined allergic (black bar) mice. IFN-γ (B), IL-4 (C), IL-17 (D), IL-10 (E), and TGF-β (F) from those cells were also measured by ELISA. The data represent the mean ± SEM (n = 8 animals per group). Bonferroni multiple comparison test: (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.005$. Dunn's comparison test: (#) $p < 0.05$, (##) $p < 0.01$, and (###) $p < 0.005$.

Technologies, Paris, France) in response to nebulization of methacholine (Sigma-Aldrich) from 0 to 40 mg/mL, as described.[23] Because we previously ascertained in our mouse model using female Balb/c mice that Penh was similar to resistance or other measures determined by FLEXIVENT, intubation (not shown) and whole body plethysmography were determined to be sufficient to explore respiratory function.

Statistics. Values were expressed as the mean ± standard error (SEM). Statistical analysis was performed using GraphPad Prism (GraphPad Software, San Diego, CA, USA). Means were compared among groups using analysis of variance (ANOVA). In the case of positive ANOVA, means were compared by Mann−Whitney test. The results were corrected by a Bonferroni multiple-comparisons correction test. Statistically significant was marked as follow: (*) $p < 0.05$, (**)$p < 0.01$, and (***) $p < 0.001$. For data not following a normal distribution, a nonparametric Kruskal−Wallis test corrected using Dunn's test. Statistically significant was marked as follows: (#) $p < 0.05$, (##)$p < 0.01$, and (###) $p < 0.001$.

RESULTS

Peripheral Effects of Wheat and HDM Sensitization. After the induction of a wheat-induced food allergy and/or the HDM-induced asthma-like reaction protocol (Figure 1), total and specific Ig and histamine levels were assessed in control (CTL), food allergy (FA), respiratory allergy (RA), and combined allergy (FA+RA) mice. Total IgE was increased in allergic mice groups compared to CTL but remained unchanged when compared to the FA, RA, and FA+RA groups (Figure 2A). The level of total IgG1 was also increased in all groups of allergic mice compared to CTL but with no statistically significant difference between the single and double allergies (Figure 2B). Conversely, total IgG2a was decreased in the serum of all groups of allergic mice compared to CTL (Figure 2C). Wheat-specific IgG2a, IgE, and IgG1 were increased in the serum of FA mice (Figure 2D−F) compared to CTL mice. Conversely, they were at the threshold of detection in CTL and RA animals. In mice sensitized to both allergens, wheat-specific IgE and IgG1 levels were significantly increased compared to CTL or RA as well as the FA mice. Symmetrically, HDM-specific IgE was increased in the serum of RA mice (Figure 2F). In animals sensitized to both allergens, HDM-specific IgE levels were twice as high in mice sensitized to HDM only. FA+RA and RA sera but not FA displayed higher levels of histamine than CTL (Figure 2G). Specific IgE was therefore increased for each allergen by the sensitization to its counterpart, whereas histamine release increased only in mice sensitized to HDM, whether or not they were presensitized to wheat.

Cell Proliferation and Cytokine Secretion in Lymphoid Organs. Splenocyte proliferation in response to concanavalin A was evaluated by MTT in the spleen, thymus, and Peyer patches (Figure 3A). In FA+RA mice, immune cells from the spleen, thymus, or Peyer patches displayed increased proliferation by 2.52-, 1.63-, and 1.54-fold, respectively, compared to CTL mice. In FA and RA groups, increases of splenocyte proliferation of 2- and 1.9-fold, respectively, were also found. The proliferation was significantly higher in FA+RA mice compared to both single-sensitization groups only in the spleen.

To further detail the mechanisms linking both types of allergy, cytokine secretion by immune cells was measured in supernatants of spleen, thymus, and Peyer patches cells. After

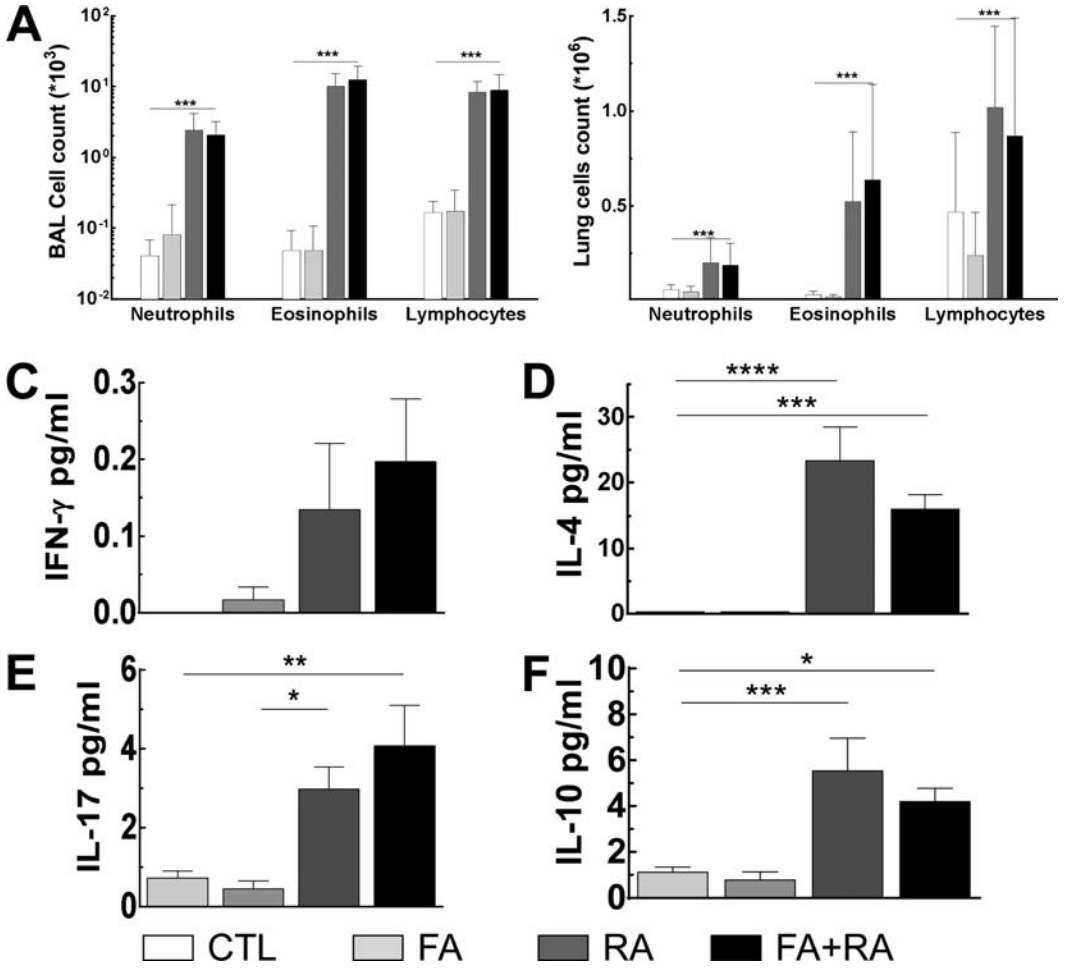

Figure 4. Successive allergies increase neither cell population nor cytokine secretion in the respiratory tract. Different cell populations from each group of mice were analyzed by flow cytometry in the broncho-alveolar lavage (BAL) (A, left panel) and lungs (A, right panel). Cell populations were polymorphonuclear neutrophil cells (neutrophils), polymorphonuclear eosinophil cells (eosinophils), and T lymphocytes (lymphocytes). IFN-γ (C), IL-4 (D), IL-17 (E), and IL-10 (F) were measured in parallel in BAL fluids after the last HDM intranasal challenge (day 54). The data represent the mean ± SEM (n = 8 animals per group). Bonferroni multiple-comparison test: (*) $p < 0.05$, (**$p < 0.01$, and (***) $p < 0.005$.

nonspecific activation by concanavalin A, IFN-γ secretion was reduced in spleen and Peyer patches cell supernatants from FA+RA mice compared to CTL mice. In single-allergy groups, this difference was observed in the spleen only. IFN-γ reduction was not observed in the thymus (Figure 3B). Then, Th2 polarization was evaluated by IL-4 production, which was found to be elevated in FA+RA compared to CTL in the spleen and Peyer patches (Figure 3C). In these compartments, no additive effects were observed, as IL-4 levels remained unchanged between RA or FA and FA+RA in the spleen, even though IL-4 levels were increased compared to controls. In Peyer patches, an effect was observed, as IL-4 levels were higher in FA+RA mice compared to other groups. In the thymus of RA mice, a clear increase in IL-4 secretion was observed (Figure 3C). To obtain a broader view of T-helper polarization, IL-17 production was also measured and shown to be significantly enhanced in the spleen but not in Peyer patches or in the thymus of FA+RA mice compared to CTL, FA, or RA mice (Figure 3D). In the thymus, only cells exposed to respiratory allergens produced elevated levels of IL-17 compared to controls. As a read-out of Treg cell activation, IL-10 and TGF-β levels were measured in the spleen, Peyer patches, and thymus cell supernatants. Low levels of TGF-β and IL-10 were detected in splenocyte and thymocyte supernatants from all groups, whereas in Peyer patches, as high levels of both cytokines were detected in CTL, a drastic reduction was observed in FA+RA mice, suggesting a defect in intestinal T-cell regulation (Figure 3E,F). Furthermore, IL-10 but not TGF-β cell secretion was also attenuated in the Peyer patches of FA or RA mice compared to controls but to a lesser extent than FA+RA.

Our data therefore revealed that in this mouse model of atopic march, the Th1/Th2-related cytokines leaned toward a Th2 response after unspecific activation. Then, inflammation was boosted by the development of Th17 and down-modulation of Treg differentiation and/or activation in lymphoid organs. However, we observed no major change in the thymus except in RA mice.

Cell Population and Cytokine Secretion in the Respiratory Tract. Because our results demonstrated an effect of a food allergy on lymphoid cell proliferation and cytokine secretion, we assayed cell populations and cytokine secretion in the respiratory tract of the mice, including broncho-alveolar lavage (BAL) fluid and lungs (Figure 4). Additionally, we measured cell numbers of different subsets in the BAL and the lungs from each group by flow cytometry. Total cell numbers, polymorphonuclear neutrophils, polymorphonuclear eosinophils, and T lymphocytes (either $CD8^+$ or

DOI: 10.1021/acs.jafc.5b02338
J. Agric. Food Chem. 2015, 63, 6475−6483

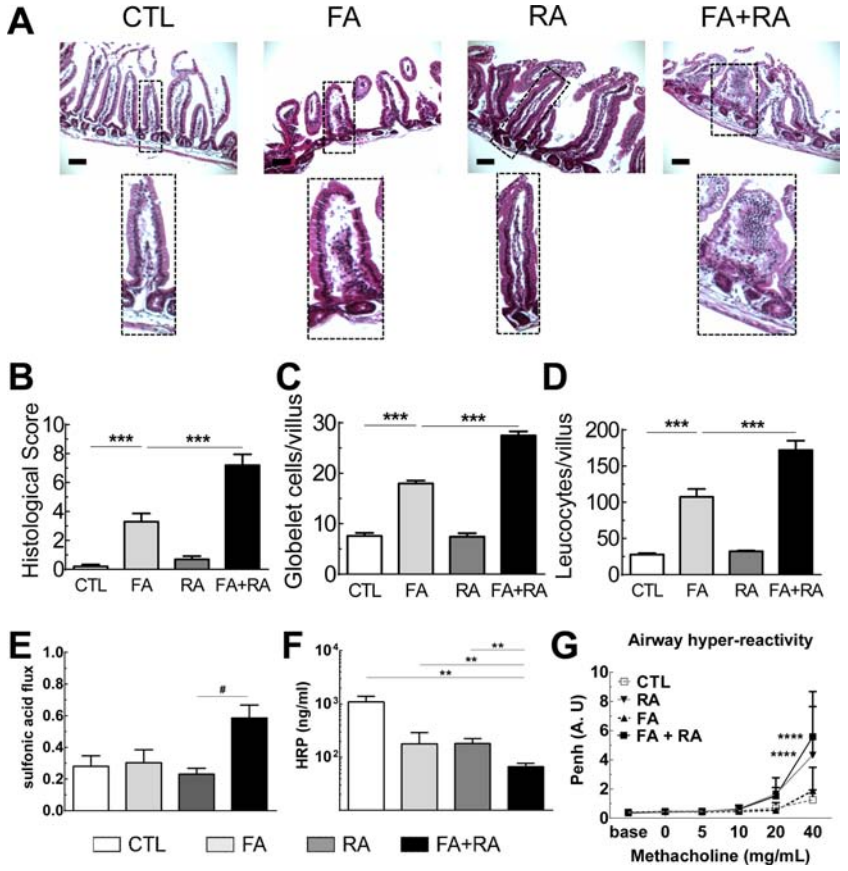

Figure 5. Successive exposure to allergens alters intestinal morphology and exacerbates symptoms without affecting respiratory parameters. At the end of the allergy-inducing protocol, gut segments were collected and processed for histopathology in jejunum (A), scored for inflammation (B), and counted for goblet cells (C) and leukocytes (D). As a critical feature of the gastrointestinal epithelium and function ex vivo paracellular permeability in proximal colon (E) and ex vivo transcellular permeability in jejunum (F) were evaluated in Ussing's chamber using intestine fragments. Respiratory function was determined by airway resistance measurements after methacholine nebulization (G). $n = 8$ animals per group. Bonferroni multiple-comparison test: (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.005$. Dunn's comparison test: (#) $p < 0.05$, (##) $p < 0.01$, and (###) $p < 0.005$. Scale bar = 250 μm.

$CD4^+$) were increased in mice with respiratory or mixed allergy compared to FA or CTL in both the BAL and lungs (Figure 4A, left and right panels, respectively). However, the inflammatory cell counts were equivalent in mice with the mixed or the single-respiratory allergy. Cytokine secretion was also assayed in BAL fluids. As expected, lower levels of cytokines were observed in the BAL compared to cell culture after nonspecific activation. The levels of all cytokines were increased in both groups of HDM-induced asthma-like reaction mice compared to the two other groups (Figure 3C−F). However, no further increase was observed in FA+RA mice. Similar results were observed in the lungs (data not shown). Taken together, our results establish that double allergy impacts the systemic and intestinal but not lung immune response.

Effects of Wheat and HDM Sensitization on Intestinal and Respiratory Functions. Having shown the influence of a double exposure to allergens on immune cell homeostasis and cytokine production, we aimed to explore the morphologic and phenotypic impact linking observations on cell and cytokine levels to the development of allergic symptoms. Therefore, we first determined whether combined allergy was associated with intestinal histological alterations by evaluating the development of inflammation in the jejunum of mice. FA+RA mice developed intestinal inflammation characterized by epithelial ulceration, edema, and leukocyte infiltration in the lamina propria (Figure 5A). These lesions were, to a lesser extent, also present in FA mice. In contrast, in control or RA mice, no mucosal inflammation or edema was observed in the jejunum or proximal colon (Figure 5A and data not shown). Using histological inflammation semiquantitative scoring, we showed an absence of intestinal alterations in CTL and RA mice. In contrast, the inflammatory score was significantly larger in RA mice compared to CTL and even larger in FA+RA compared to FA mice (7.2 versus 3.3, respectively, $P < 0.05$). (Figure 5B). This inflammation is linked to an increase of goblet cells and leukocytes within the villus of the intestine in FA mice compared to CTL mice (Figure 5C,D). Moreover, in line with the histological score, the number of cells was increased in FA +RA mice compared to single-FA mice (Figure 5C,D).

Then, we measured jejunal and proximal colon paracellular and transcellular permeability ex vivo. Paracellular permeability was increased in the proximal colon of FA+RA mice compared to the other groups (Figure 5E). In contrast, HRP flux in the jejunum was significantly reduced in FA+RA compared to the other groups (70.3 versus 1078 and 179 ng/mL for FA+RA, CTL, and FA, respectively) (Figure 5F). No change in HRP flux was observed in the proximal colon (data not shown).

The effect of each allergy protocol on lung function was also evaluated by measuring mouse airway reactivity in response to methacholine. As expected, a gain in methacholine sensitivity

DOI: 10.1021/acs.jafc.5b02338
J. Agric. Food Chem. 2015, 63, 6475−6483

was noted in the RA and FA+RA groups compared to the CTL and FA groups (Figure 5G). However, airway hyperresponsiveness was not higher in RA allergic mice in cases of pre-existing food sensitization.

DISCUSSION

In this study, we aimed to establish that food sensitization primes the immune system to enhance the effects of a subsequent respiratory allergy. Contrasting results were obtained, with a clear effect observed on the systemic and gut hallmarks of allergy but without modification of respiratory inflammation and function.

Dual exposure to food and respiratory allergens exerted effects that can be considered at various levels: (1) the systemic compartment composed of blood, thymus, and spleen; (2) the intestinal mucosa; and (3) the lung mucosa. Exposure to FA and RA led to a higher production of specific IgE directed against each allergen that may cause blood basophils to degranulate and release higher levels of histamine, as observed. The marked secretion of IgE specific to each allergen might be enhanced by a dysregulation of the T-cell population balance, as suggested by the higher levels of IL-4 observed in spleen, whereas IFN-γ levels were moderated in FA+RA mice compared with mice allergic to a single substance. IL-17 was also elevated, suggesting that Th17 could act in synergy with Th2 cells to exacerbate the immune response. Interestingly, a role for Th17 cells in food allergy and asthma has been suggested.[4,5] In contrast, thymocyte cytokine production was much more related to respiratory allergy. In fact, cytokine secretion in the thymus was increased in respiratory allergic mice but not in food allergic mice. Because thymocyte analysis was carried out shortly after the intranasal challenge and at a distance from the gut sensitization, it cannot be excluded that the thymocytes lost their food allergy-related reactivity at the time of analysis. However, in combined allergic mice, the effect of respiratory allergy on thymocytes was no longer observed. Although a negative feedback of food allergy on thymocyte reactivity can be evoked as a potential explanation, it is more likely that the thymocytes may have become unreactive after the first food allergen stimulation.[24,25]

At the level of intestinal Peyer patches, a clear Th2 inflammatory profile was demonstrated in FA+RA mice, with higher IL-4 and lower IFN-γ, IL-10, and TGF-β production. IL-10 secretion by Peyer patch cells was already dampened in mice exposed to a single allergen. It is noteworthy that intranasal exposure to RA induced a decrease in the secretion of IL-10 in the small intestine. Thus, the intestinal mucosal immune system of allergic mice may be more vulnerable to novel allergenic sensitizations by locally dampening tolerance-related cytokines (IL-10 and TGF-β) and increasing Th2 commitment (IL-4). Numerous studies have addressed the role of gut-associated lymphoid tissues (GALT) for oral tolerance induction.[26−29] Notably, Peyer patch dendritic cells (DCs) were shown to produce much more IL-10 than spleen DCs.[26] In addition, gut DCs efficiently promote the differentiation of naïve Th0 cells into inducible Treg cells.[30] Furthermore, GALT were demonstrated to be a preferential site for the induction of the forkhead box P3$^+$ Treg.[26] In healthy animals, CD4$^+$ T cells activated by Peyer patch DCs produce much more IL-4 and IL-10 than CD4$^+$ T cells activated by spleen DCs and promote the differentiation of Th2 cells.[27] Thus, GALT appear to be highly involved in allergy induction through their capacity to induce Th2 cells.

The observed perturbations in T-cell homeostasis induced by FA and RA affected intestinal functions such as a reduced HRP flux observed in FA+RA mice. This reduced flux could reflect either a drop in lysosomal transcellular transport or an increase in the lysosomal activity of epithelial cells. Indeed, an increase in the lysosomal degradation of HRP was observed in cecum treated with toxin A from *Clostridium difficile*.[31] Under our experimental conditions, we could not determine the total amount of HRP that was transported across the epithelium, which could have been accomplished using [^{3}H]HRP. Reduced HRP flux could also be a consequence of villus atrophy (as less surface exchange), as was reported in FA and RA+FA. This discrepancy could be due to the measurement of intact protein but not total HRP in the latter. Proximal colon, but not small intestine, paracellular permeability was increased in FA+RA mice.

Hence, these mice displayed signs of gut permeability perturbation as well as altered intestine morphology linked with allergy pathophysiology.[13] Moreover, the stronger gut alteration in FA+RA mice may be due to a boost in local leucocytes after airway challenge. The mechanisms of intestinal modification under the action of RA are questionable. The ingestion of RA extract during intranasal challenge cannot be excluded. However, the huge pulmonary inflammation observed in lungs after intranasal challenge shows that most if not all of the extract is inhaled. Moreover, the absence of an effect in non-wheat-sensitized mice renders a direct local effect of HDM in the gut most unlikely. An effect of RA-induced systemic effect in wheat-sensitized mice is likely and is in accordance with the Ig and histamine results as well as the spleen data. A local priming by wheat sensitization of intestinal cells is also likely, as demonstrated by results in Peyer patches, and could account for the effects of HDM in wheat-sensitized mice. Interestingly, HDM exposure was necessary to obtain an effect on intestinal functional parameters that were not perturbed by the food allergy alone. However, the latter had a clear effect on intestinal architecture that was largely enhanced by subsequent HDM respiratory exposure.

By contrast, dual exposure did not exert any additive effects on the lung compartment, as all inflammatory parameters (cells and cytokines) were similarly increased in mice sensitized to HDM, regardless of the previous sensitization to gliadins. Moreover, in the lung, contrary to the results in the intestine, dual exposure increased IL-10 production in BAL. In addition, in the lungs, both Th2 and Th17 activation was observed in RA and FA+RA mice. In BAL fluids of asthmatic patients, this pattern of cytokine responses is frequently observed[32] and may be related to a particular property of the lung mucosa. Thus, it can be suggested that the allergy mechanism is much more related to the Th2 pathway in the intestine than in the lung. In accordance with cell and cytokine results, respiratory function was not modified by dual exposure to wheat and HDM allergens compared to HDM only. The absence of a supplementary effect of food allergy on lung inflammation of HDM-sensitized mice could be related to the insensitivity of the lung compartment to the previous wheat sensitization. Another hypothesis is that the second exposure influences only the compartment in which the first sensitization operated. To validate this hypothesis in a further study, it would be interesting to reverse the two sensitization phases with an RA +FA model. However, these views contradict the typical sequence observed in humans, in whom food allergy predisposes to subsequent asthma and in whom respiratory

allergy is not known to aggravate symptoms related to food allergy. It is therefore more likely that the huge inflammation due to the sole HDM sensitization cannot be further extended. Indeed, a synergy between the two processes is still very well documented in the periphery through the increase of specific IgE and histamine release when both allergies are present.

These results are complementary to those we obtained in a model of successive allergies using ovalbumin (OVA) as food allergen and HDM extract. In fact, Bihouée et al.[33] previously demonstrated that food allergy to OVA increases AHR, hypereosinophilia, and global hypercellularity in response to subsequent HDM challenges, although no further increase in OVA-specific IgE was observed. However, physiological intestinal parameters and intestinal architecture were not assessed in dual allergic mice, leaving a gap in the intestinal impact of prior food allergy after respiratory allergy. Moreover, the absence of AHR and lung immunology modification in our experiment could result from the respiratory allergic protocol, which consists of two intranasal doses of HDM. However, the results from Bihouée et al.[33] were obtained after four sensitizations and two intranasal challenges.

The possibility that cross-reaction between the food allergen and the airborne allergen generates IgE that recognizes both antigens has never previously been described. Although cross-reactivity between aero-allergens such as pollen or plant allergens and food allergens such as shrimp and apple has been described[34,35] cross-reactivity with wheat proteins, especially gliadin cross-reactivity with HDM, has not yet been described. Gliadin is known to cross-react with other foods such as milk or rice.

Our study demonstrates that sensitization to a first allergen imprints the immune response and enhances the effects of a novel subsequent sensitization. It therefore shows that multiple allergies observed in atopic subjects in the process of the atopic march are not independent events that occur within a common genetic background, but they synergize to mutually increase the effects of each allergen involved. Further studies are needed to decipher the mechanisms involved in this reciprocal intestine and lung allergic cross talk.

evaluate the effects of such supplementation on Se metabolism differ depending on studies. Schram et al.[17] determined total Se and Se speciation in muscle, Küçükbay et al.[15] measured total Se in both muscle and serum, as well as GPx activity in serum, and Rider et al.[16] quantified total Se in whole body of fish and also determined hepatic GPx and TRx activities. The two latter studies concluded on a beneficial effect of Se supplementation and on the superiority of the organic form of Se supplementation over supplementation with selenite.

In the present study, Se form supplementation was compared in two different types of feeds, based on either fish meal and fish oil (base M0) or plant ingredients and vegetable oils (V0). To be relevant to European regulation limiting Se supplementation at +200 μg kg^{-1} organic Se, supplementation levels were kept rather low (+300 μg kg^{-1}) compared to what is usually found in such studies (maximum supplementation levels were, respectively, +6650 and +6670 μg kg^{-1} in the studies of Schram et al.[17] and Rider et al.[16]). Also, taking into consideration that Se requirement/utilization might differ depending on the age of trout,[18] the study was undertaken with first-feeding swim-up fry of rainbow trout, whereas previously mentioned studies were undertaken with juvenile fish (20 g body mass). Given the uneven distribution of Se in the tissues/organs of fish,[19] it was chosen to measure total Se in the whole body. The objective of the study was hence to evaluate, on the basis of speciation analysis results, whether a plant-based diet may induce a different utilization and fate of Se in rainbow trout compared to the traditional FM-based diet. In addition, the potential benefit of a Se supplementation was investigated, together with the suitability of the chemical form used for supplementation.

MATERIALS AND METHODS

Chemicals and Reagents. All of the reagents used in this study were of analytical grade and purchased from Sigma-Aldrich (Saint-Quentin Fallavier, France). Water (18 MΩ cm) was obtained from a Milli-Q system (Millipore, Bedford, MA, USA). Selenium species standards were prepared from sodium selenite (>99%), sodium selenate (>98%), seleno-DL-methionine (>99%), and seleno-DL-cystine, all purchased from Sigma-Aldrich. Carbamidomethylated selenocysteine (SeCys-CAM) standard was prepared according to the method of Dernovics et al.;[20] briefly, selenocystine in TRIS-HCl buffer was reduced using dithiothreitol and carbamidomethylation was carried out by the addition of iodoacetamide; the excess of resulting iodoacetamide was further destroyed using dithiothreitol.

Instrumentation. Total Se measurements were carried out on an ICP QMS equipped with a collision/reaction cell (Agilent 7500ce, Agilent Technologies, Wilmington, DE, USA). H_2 was used as reaction gas; flow was kept close to 4 mL min^{-1} and optimized daily to achieve proper background signal.[21] Chromatographic separations were performed using an 1100 series HPLC pump (Agilent Technologies) with anion-exchange (PRP-X100, 10 μm, 4.1 × 250 mm; Hamilton Co., Reno, NV, USA) and reversed phase (C8 Altima column, 5 μm 150 × 4.6 mm; Alltech, Deerfield, IL, USA) HPLC columns. HPLC-ICP QMS analyses were achieved by connecting directly the exit of the HPLC column to the Meinhard nebulizer (Glass Expansion, Romainmotier, Switzerland) of the ICP QMS. The lyophilizer was a model LP3 (Jouan, Saint-Herblain, France).

Feeding Trial and Sample Collection. A 12-week feeding trial was carried out using either FM- or plant-based diets supplemented with two different forms of Se (six diets in total, two basal diets, M0 and P0, and four supplemented diets, MSeIV, MSeMet, PSeIV, and PSeMet), as summarized in Table 1. Basically, diets consisted of two groups, one based on marine ingredients (74%) and the other based on plant ingredients (88%). Each group of diets contained one control diet and two diets supplemented with either an inorganic (sodium selenite) or an organic form of Se (Se-enriched yeast Selsaf (Lesaffre, Marcq en Baroeul, France), containing 2200 ± 200 μg kg^{-1} Se with the following composition: SeMet, 63%; SeIV, <1%; SeVI, <0.02%). For both supplementations, diet formulation was made to achieve a supplementation of 300 μg kg^{-1} Se. The ingredient composition of the basal diets is described in Table 2. Diet preparation consisted first of grinding finely together mineral premix with the corresponding Se supplement and wheat. The fine powder obtained was then thoroughly mixed with other powder ingredients, and the mixture was extruded into pellets. Finally, oil was added in a final stage and diets were dried and ground again to reach a size suitable to feed the fry.

Table 1. Main Characteristics of the Diets Used in the Feeding Trial

diet	basal ingredient	supplementation form (amount)
M0	fish meal and fish oil	
MSeIV		Na_2SeO_3 (300 μg(Se) kg^{-1})
MSeMet		Selsaf (300 μg(Se) kg^{-1})
P0	plants	
PSeIV		Na_2SeO_3 (300 μg(Se) kg^{-1})
PSeMet		Selsaf (300 μg(Se) kg^{-1})

Table 2. Detailed Composition (Percent) of Basal Diets

ingredient	M0	P0
fish meal	62	
fish oil	12	5
whole wheat	25	22
corn		18
soy bean		23
other (rapeseed, lupin, pea)		14
vegetable oils (rapeseed, linseed, palm)		11
premix[a]	1	7

[a]Premix consisted of a mixture of vitamins, minerals, and crystalline amino acid blend.

Rainbow trout (*Oncorhynchus mykiss*) swim-up fry (initial average weight was approximately 91 mg) were stocked into 18 50-L tanks supplied with flow-through spring water at 17 °C at a density of 200 fish per tank. Diets were randomly assigned among the tanks, and each was offered to triplicate groups of fish. At the end of the feeding trial, fish were ethically euthanized and frozen in liquid nitrogen for further analysis. Growth (final average weight was approximately 8.1 g) and survival (86%) of rainbow trout fry were not significantly affected by dietary Se sources and levels. Experimental procedure for the feeding trial complied with the European Directive 010/63/EU for the protection of animals used for scientific purposes, as well as French Decree 2001-464 for animal experimentation.

Sample Preparation. Diets were extracted as, given to fish, they consisted of a relatively fine powder. For the analysis of Se species in fish, three whole fry from each tank were thoroughly ground with Milli-Q water using an Ultraturrax t25 (IKA, Staufen, Germany) until a homogeneous light slurry was obtained. Samples were then kept at −20 °C until further analysis.

Total Selenium Determination. For the determination of total Se in samples, a preliminary acid digestion step was conducted using a DigiPrep MS (SCP Science, Quebec, Canada). Nitric acid and hydrogen peroxide were added to the sample (respectively, 2.5 and 1 mL for 200 mg of diet or 1 and 0.5 mL for 100 mg of fish), and the temperature was kept at 85 °C for 6 h. After dilution with water to reach a HNO_3 concentration of 5%, samples were filtered through 0.45 μm cellulose acetate syringe filters (VWR International, Radnor, PA, USA), and total Se was measured using the ICP QMS. Isotopes 77 and 78 were monitored, and quantification for diet samples was achieved

by external calibration using m/z 78. In the case of fish, internal calibration was used with gallium as internal standard.

Inorganic Selenium Species Determination in Diets. A 100-mg portion of feed was extracted with 5 mL of a 0.1 M sodium hydroxide solution, and the mixture was mechanically shaken with an elliptic table during 20 h at room temperature. After centrifugation (2600*g*, 10 min), supernatant was collected and diluted 2 times with HPLC mobile phase. Inorganic selenium species were then separated and detected by HPLC-ICP QMS. A 100-μL aliquot was injected on the anion-exchange chromatography column and eluted with 5 mM ammonium citrate solution (pH 5.3) containing 3% of methanol. Quantification of selenium species was achieved according to the method of standard additions.

Selenoamino Acid Determination. SeMet and SeCys determination was done on the basis of the work of Bierla et al.[22] For SeMet, 100 mg of sample (feeds or fish) was weighed in a polypropylene tube, and 5 mL of a solution of 0.1 M TRIS-HCl, pH 7.5, containing 10 mg of protease type XIV *Streptomyces griseous* was added. This mixture was incubated for 20 h at 37 °C and centrifuged (2600*g*, 10 min). The supernatant was collected and incubated twice with 10 mg of protease. Finally, the supernatant was diluted 2-fold, and 100 μL was injected on the previously mentioned anion-exchange column coupled to ICP QMS. SeCys concentration was determined only in fish samples, and a preliminary derivatization step was carried out using the following procedure. Two milliliters of a 7 M urea solution (in 0.1 M TRIS-HCl, pH 7.5) was added to 100 mg of fish, and the mixture was sonicated for 10 min using an ultrasound probe (VC 505 fitted with a tapered microtip, Sonics & Materials, Newtown, CT, USA) to denature proteins. Then, 30 μL of a dithiothreitol solution at 0.2 M (in 0.1 M TRIS-HCl, pH 7.5) was added, and the mixture was shaken during 1 h. Forty microliters of a 0.5 M iodoacetamide solution (in 0.1 M TRIS-HCl, pH 7.5) was added and the mixture shaken for an additional hour in the dark. Dithiothreitol (375 μL, 0.2 M) was finally added to destroy iodoacetamide excess. Fourteen milliliters of 0.1 M TRIS-HCl was added to decrease urea concentration, and proteolytic digestion was performed with protease as previously described. Sample was then frozen and freeze-dried, the residue was redissolved in 1.2 mL of Milli-Q water, and a 100 μL aliquot was injected on a Superdex Peptide column (300 × 10 mm, Pharmacia, Uppsala, Sweden) eluted with a 10 mM TRIS-HCl, pH 7.5, solution. The low molecular weight fraction was collected (25−35 min) and freeze-dried, and the obtained residue was redissolved and injected on a C8 and eluted with a 0.1% heptafluorobutyric acid solution containing 5% of methanol. For both SeMet and SeCys, m/z 77, 78, 79, and 80 were monitored, and quantification was achieved by using the method of standard additions.

Statistics. Statistical analyses were carried out using the software Statbox (Grimmer Logiciels, Paris, France). Total selenium, SeMet, and SeCys concentrations were analyzed using one-way ANOVA and Student−Newman−Keuls post hoc test ($p < 0.05$) to test the effect of the supplementation form.

RESULTS AND DISCUSSION

Optimization of Sample Preparation Conditions. Several extracting solutions were evaluated for their extraction efficiencies and compatibility with Se species preservation. For inorganic Se species in the diets, tested extractants were water, 50 mM TRIS-HCl buffer, pH 7.5,[17,23] and 0.1 M sodium hydroxide solution.[24] Water and TRIS buffer gave extraction yields of total Se below 20% with a rather large relative standard deviation (36−49%). Sodium hydroxide extraction yields were above 45% with more consistent results (RSD ranged from 6 to 27%). Moreover, the stability of Se species in NaOH extracting solution has been previously demonstrated;[25] it was therefore chosen for analysis of inorganic species in diets.

Determination of SeMet in diets was optimized with regard to the enzymatic digestion. With a single addition of 10 mg of protease XIV, it was found that SeMet concentration obtained in the extract was stable after 20 h of extraction, and extending digestion time to 48 h did not improve results. Defatting the sample with *n*-heptane prior to enzymatic digestion did not increase SeMet concentration in the extract. The use of an ultrasound probe[26] instead of an elliptic table was unsuccessful in improving protein digestion and did not increase extraction yields. Larger amounts of protease XIV (up to 20 mg) as a single addition were also ineffective; however, a second addition of 10 mg of protease in the supernatant resulting from a first digestion clearly improved SeMet concentration in the final extract. Finally, two further additions of 10 mg of protease were used, resulting in an increase of SeMet concentration in the final extract of around 50% compared to single-step digestion.

Se mass balances, determined by measuring total Se in both extract and residue after both extractions, are shown in Table 3. The lower mass balance values obtained in the case of NaOH extraction could be due to the difficulty of collecting residue after extraction because it took in this case the consistency of a very dense slurry.

For SeCys determination in fry, higher (2 and 4 times more) and lower (0.5 and 10 times less) concentrations of derivatization reagents were tested. Although the chromatographic peak height of selenocysteine was not affected with 2 and 4 times the conditions described above, several new minor Se-containing peaks were observed with higher reagent concentrations. It appeared that these new peaks were most likely derivatization products of SeMet and made the chromatogram more complex and not well resolved. Lower concentrations of derivatizing reagents did not increase SeCys peak height, which indicates that no overderivatization occurred in the conditions described above.

Total Selenium in Fish Feeds. The comparison of the two basal diets, M0 and P0, shows that total Se concentration was much higher in the FM-based diet (Table 3). This is not surprising considering the fact that Se concentrations in animal tissues are generally higher than in plants;[27] thus, these concentrations reflect the Se content of the raw materials used for the production of these feeds. This also highlights the fact that plant-based diets may require a Se supplementation to compete with marine diets regarding total selenium content. In addition, these results confirmed that very similar Se levels were reached for both Se supplementations in each diet group. The Se concentrations found in the marine ingredient-based diets were in the same range as data from the literature.[17,28,29] For all feeds used in this experiment, the Se levels were high enough to avoid deficiency situation (<150 μg kg^{-1} of Se dry feed) and were below toxicity threshold (>3000 μg kg^{-1} of Se dry feed).[30]

Selenium Speciation in Fish Feeds. The concentration of SeIV in diet MSeIV was around twice those found in diets M0 and MSeMet (Table 4). Similarly, the concentration of SeIV in diet PSeIV was around 2 times higher compared to diets P0 or PSeMet. In both marine- and plant-based diets, the increase in SeIV concentration resulting from sodium selenite supplementation was close to 60 μg kg^{-1} (respectively, +57 and +60 μg kg^{-1} for diets MSeIV and PSeIV). An example of a chromatogram obtained in HPLC-ICP QMS for a sodium hydroxide extract of diet is given in Figure 1a; it can be observed that without protease, the amount of free SeMet is very low.

For SeMet concentrations, no differences were observed for diets M0 and MSeIV, whereas the SeMet level of diet MSeMet was increased by 102 μg kg^{-1}. For plant-based diets, a very similar increase (98 μg kg^{-1}) was found in diet PSeMet compared to diets P0 and PSeIV. Figure 1b shows an example chromatogram obtained for a protease extract, where it can be noted that inorganic selenium species are not well extracted in the pH condition of proteolytic digestion. All in all, the results of speciation analysis confirmed the supplementation desired in the experimental design, although no quantitative recovery of initial supplementation could be achieved. This could be explained by a potential nonreversible adsorption of Se on dietary ingredients during the feed preparation process (extrusion), which involves both heating and pressure. Nevertheless, supplementation levels for SeIV and SeMet were approximately the same for both plant and marine diets. SeVI was detected only in plant-based diets, which is in agreement with the fact that the main Se source for plants are selenium species found in soils, which are most often inorganic species such as selenite and selenate,[31] and the previously observed low metabolization of SeVI in plants.[32] The three plant-based diets also present the same SeVI level, which indicates that no species conversion of Se used for

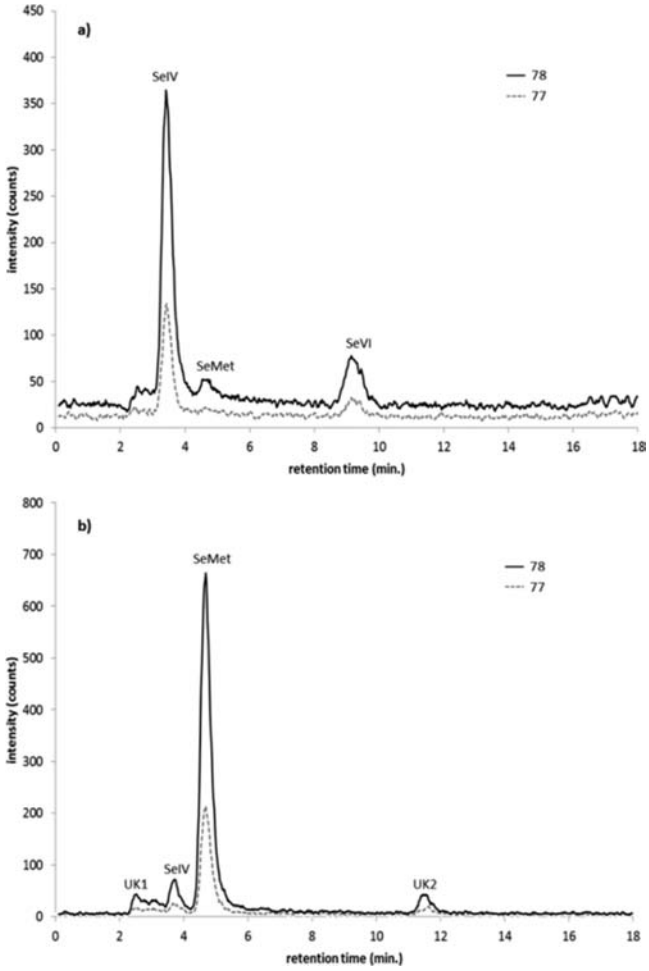

Figure 1. Example anion-exchange chromatograms (HPLC-ICP QMS) for diet (PSeMet) extracts: (a) sodium hydroxide extract; (b) protease extract. UK1 and UK2, unknown Se-containing peaks.

supplementation occurred during diet preparation. Although SeMet concentration found in the basal marine diet was around 3 times higher than in the basal plant diet, it should be noted that the SeMet/total Se ratios, 24 and 20%, respectively, for M0 and P0, were relatively close for these two kinds of feeds. These percentages appear to be rather low compared to values that can be found in the literature for the individual constituents of these diets; it is likely that the feed preparation process mentioned above (extrusion) may have induced transformations in the constituents of diets and thus made the proteolytic digestion not as efficient as the one observed for these constituents when analyzed separately. This is furthermore supported by several observations of the low digestibility of Se from fish meal.[33,34] The percentage of Se identification in diets

DOI: 10.1021/acs.jafc.5b00768
J. Agric. Food Chem. 2015, 63, 6484−6492

ranged from 28 to 33%, these results are similar to those previously reported by Schram et al.[17] This low identification percentage was obtained despite relatively good extraction yields obtained for sodium hydroxide and protease extraction (Table 5). Identification in sodium hydroxide extracts was very low, especially in FM-based diets, which is very likely due to Se being mainly present in proteins in these extracts and therefore not available for detection in this form. In the case of protease extracts, identification was close to 30% except for diet PSeIV, for which identification was 15%; this is relevant with SeIV being the major species found in this diet and the fact that inorganic species were not measured in these extracts because measured concentrations were found to be not repeatable under these pH conditions. A low column recovery was finally found to be responsible for the quite low percentage of identification in protease extracts.

Table 5. Extraction Yields and Percentage of Identification in Extracts for Diet Speciation Analysis[a]

diet	NaOH extraction yield (%)	identification in NaOH extract (%)	protease extraction yield (%)	identification in protease extract (%)
M0	56 ± 2	7 ± 1	82 ± 3	29 ± 2
MSeIV	58 ± 2	11 ± 1	76 ± 2	23 ± 1
MSeMet	51 ± 1	6 ± 1	77 ± 1	30 ± 1
P0	71 ± 7	18 ± 4	73 ± 5	27 ± 2
PSeIV	74 ± 2	19 ± 2	81 ± 3	13 ± 1
PSeMet	63 ± 2	12 ± 1	74 ± 2	30 ± 1

[a]Values are the mean ± standard error of the mean, $n = 3$.

Total Se in Whole Body of Fry. Total Se was determined in initial fry at the beginning of the feeding trial and was found to be 227 ± 2 μg kg^{-1}. Total Se levels in fry at the end of the trial are shown in Table 6; whole body Se was significantly ($p < 0.05$) increased for all groups fed the Se-supplemented diets. Increases of, respectively, +39 and +64 μg kg^{-1} were found for diets MSeIV and MSeMet compared to the basal diet M0. For the plant diets, increases of, respectively, +61 and +86 μg kg^{-1} were found for diets PSeIV and PSeMet compared to the basal diet P0. These results indicate that supplementation with Se yeast has a higher capacity to raise the whole body Se level in comparison to sodium selenite. This is in agreement with previously reported data by Rider et al. in a similar feeding trial using juvenile trouts and higher supplementation levels.[16] In addition, the increases observed were higher in the case of plant-based diets, and it was shown that dose response was almost linear until 2000 μg kg^{-1} regardless of supplementation form,[16] which suggests that Se supplementation is more effective with plant-based diets compared to diets based on fish meal. It can be assumed that this comes from the different speciation of selenium that can be found in diets depending on the basal ingredients; however, due to the low percentage of identification of selenium obtained in diets in this work, this cannot be firmly stated at this point. As previously observed,[17] a good correlation ($R^2 = 0.97$) was found between total Se in diets and total Se in the whole body of fry (Figure 2). The observation that whole body total Se was lower than initial state for fish fed diets P0 and PSeIV does not necessarily imply that these diets were Se deficient but emphasizes the necessity to supplement plant-based diets.

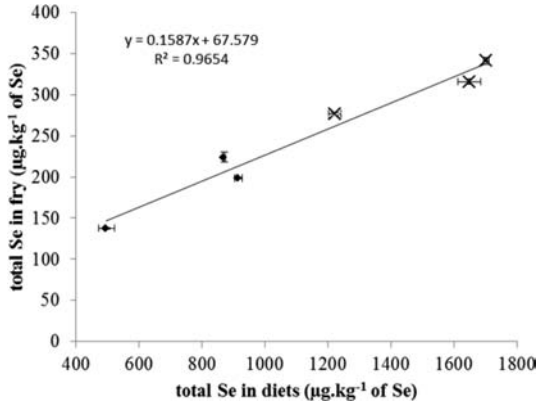

Figure 2. Linear regression between total Se in diets and total Se in whole body of fry: (◆) plant-based diets; (×) fish meal-based diets. Horizontal and vertical error bars are standard error of the mean.

Whole Body Selenomethionine and Selenocysteine Concentration in Fry. A typical chromatogram obtained in HPLC-ICP QMS for a proteolytic digest of fry is given in Figure 3. SeMet concentrations were statistically not changed with selenite supplementation of the basal diet for both marine and plant diets (Table 6), which is in agreement with the suggested metabolic pathway of Se in animals in which SeMet cannot be synthesized from selenite.[35] On the other hand, the two diets supplemented with Se yeast led to increased SeMet concentrations in fry, although this increase was significant only in the case of diet PSeMet ($p < 0.05$). There was a good correlation between SeMet concentrations in diets and SeMet levels in whole body of fry (Figure 4); this concurs with the conclusion of Whanger et al. on the biological significance of SeMet,[36] this selenoamino acid being mostly intact after ingestion, especially in the case of diets containing relatively

low methionine levels such as those based on plant ingredients.[37] With regard to SeCys, the three marine diets lead to the same SeCys concentration at the end of trial, suggesting that Se requirements for selenoprotein expression were already fulfilled with the basal diet M0. Conversely, plant diet P0 led to SeCys concentration in fry significantly ($p < 0.05$) lower than in the case of fry fed the FM-based diets. Both selenite and Se yeast supplementations of the basal diet P0 restored SeCys concentrations to levels similar to those obtained with the marine diets. Furthermore, there was no significant difference between SeCys levels reached for PSeIV and PSeMet diets. An example chromatogram obtained in reversed phase chromatography for a proteolytic extract of fry after SeCys derivatization is shown in Figure 5.

The ratios of SeMet and SeCys concentrations over total Se one were also calculated in fry to roughly estimate the selenium utilization of diets from the speciation point of view. Fry fed diet P0 showed ratios of SeMet/total Se significantly ($p < 0.05$) higher than those fed diet PSeIV, indicating that the major fate of the added selenite in PSeIV was not SeMet production. This is consistent with the inability of selenite to be metabolized in SeMet. Conversely, no significant difference was found for SeMet/total Se ratio between fry fed diets P0 and PSeMet, suggesting that the addition of Se yeast to P0 did not change the proportion of Se in the diet available for incorporation as SeMet in fry proteins. For fry fed FM-based diets, SeMet/total Se ratio was not significantly different for any diets, which could be due to the fact that the proportion of added Se through supplementation in these diets was much lower compared to plant diets (around +40% in FM-based diets versus +80% in plant-based diets), minimizing the effect of the supplementation. The SeCys/total Se ratio was found to be significantly ($p < 0.05$) higher in fry fed diet P0 compared with the ratio for fry fed diet M0, which indicates that Se from diet P0 is mainly transformed into selenoproteins and that the storage of Se in other forms is limited for this diet compared to other dietary treatments. Also, although no difference was found for this ratio between fry fed diets P0 and PSeIV, fry fed diet P0 were found to have a significantly ($p < 0.05$) higher SeCys/total Se ratio than fry fed the PSeMet diet; this seems to indicate that the major fate for added Se yeast was not SeCys synthesis. Nevertheless, no significant difference was found for SeCys/total Se ratio between fry fed diets PSeIV and PSeMet or between fry fed diets MSeIV and MSeMet, whereas all supplemented diets, either FM- or plant-based, increased total Se levels in fry. This confirms the similar abilities of supplemented Se yeast and selenite to be metabolized into SeCys.

Overall, these results indicate that the superiority of Se yeast in increasing Se levels of fry seems to lie in its ability to increase more efficiently SeMet levels. However, according to SeCys determination performed in this study, supplementation with selenite appears to be able to compete with Se yeast when it comes to raising selenoprotein expression. To our knowledge, such an observation has not been made in fish until now, but these results are in agreement with observations made in humans in a study performed by Thomson et al.,[38] where selenate and Se yeast supplementations of 32 New Zealand women were compared. This work demonstrated that higher total Se values in blood were obtained with Se yeast supplementation, but very close glutathione peroxidase activities were achieved with both types of supplementations. This is also in agreement with the fact that SeCys is considered to be the major selenium species formed after selenite

DOI: 10.1021/acs.jafc.5b00768
J. Agric. Food Chem. 2015, 63, 6484−6492

supplementation.[36] The percentage of identification of Se species was higher in fry fed plant-based diets, possibly due to a more complex selenium mixture present in the diets based on fish meal as a consequence of the more developed Se metabolism in fish in comparison to plants. Also, Se identification percentages in whole body were lower in fry fed Se-supplemented diets compared to fry fed basal diets. This may indicate that the part of Se brought through supplementation was transformed to selenium species other than SeMet or SeCys. Another explanation could be that degradation products of these two selenoamino acid were not determined in this study, and a buildup of these species such as presumably selenosugars[35,39] would have led to a drop in identification of Se in whole body of fry.

To our knowledge, such aspects of Se supplementation of fish were until now rather overlooked, principally due to the fact that conclusions of studies were mainly based on total Se observations. Moreover, Se utilization is often assessed through measurements of GPx or TRx activities.[40] Fish have one of the largest selenoproteomes known, with 30−37 selenoproteins versus 25 in humans, and several selenoproteins are specific to fish.[41] Besides, SeCys residues are more numerous in fish selenoproteins in comparison with those known in mammals; for instance, selenoprotein P (selP), which is principally believed to act as SeCys transporter,[42] contains 16−17 SeCys residues in fish, whereas it ranges from 7 to 15 in mammals.[41] Thus, SeCys determination may allow for full coverage of the selenoproteome assessment providing complementary information together with the measurement of activities of selenoenzymes. On the other hand, selenoproteins cannot be differentiated through SeCys determination, which can be troublesome when Se utilization is evaluated, taking into consideration that some selenoproteins are more essential than others and that selenium intake can affect selenoprotein expression pattern.[43] Also, information obtained through SeMet determination should not be disregarded because the transformation of SeMet into SeCys was found to be rather limited in rats; Waschulewski et al.[37] showed that after ingestion of SeMet incorporated in a low methionine containing diet during 21 days, GPx activity dropped close to 50% compared to the initial state. Switching to a Se-deficient diet, GPx activity was increased for a short time and then kept dropping while total Se in tissue also decreased; this short time increase was significantly affected by methionine content of the diet. Therefore, the availability of tissue SeMet for GPx synthesis seems to be related to protein turnover and was found to be quite low. SeMet determination could consequently allow determination of the part of incorporated selenium that is not directly available to the considered organism. Hence, due to the particular metabolism of selenium, attention should be paid to the utilization of this essential element by organisms when the forms of supplementation are compared. In this respect, selenium speciation analysis can provide useful information that cannot be retrieved from total Se analysis.

To conclude, the results obtained in this work showed the usefulness of performing selenium speciation in nutrition studies and the gain in terms of information on metabolic utilization of Se that can be collected. It was shown that the form of Se supplementation can lead to differences in incorporation of Se in both qualitative and quantitative terms. In agreement with previously published data, Se yeast and therefore organic Se showed an undisputably superior ability to increase Se levels in rainbow trout fry compared to inorganic Se. Speciation analyses showed that this is a consequence of the inability of selenite to be incorporated into general proteins under SeMet form and is a clear advantage of Se yeast when the aim is to produce Se-enriched food. On the other hand, the essentiality of Se as a micronutrient is related to its incorporation into selenoproteins, and results obtained here showed that inorganic Se has the ability to fortify this selenoprotein synthesis as organic Se does when supplied in similar amounts. Thus, the determination of SeMet and SeCys provides further knowledge in addition to monitoring selenoenzymes. Although the results in this study did not clearly indicate whether the nonsupplemented plant-based diet led to a Se deficiency situation in fish or not, selenoprotein levels were much lower in this diet compared to the one obtained with the traditional nonsupplemented fish meal-based one, and the increase in SeCys level induced by supplementation appears as a clear benefit for the plant-based diet.

The olive wood samples used in our past studies were collected from trees belonging to cultivar Picual. This olive cultivar is the most abundant in Spain (860,000 ha) and is extensively cultivated in the province of Jaén and partially in Córdoba and Granada provinces, southern Spain.[35] There are approximately 260 olive cultivars in Spain, of which 24 are the dominant cultivar (i.e., "main cultivar") in at least one region. In this paper, we report on the phenolic composition of olive wood samples from 10 Spanish olive cultivars, growing under the same environmental and agronomical conditions. Herein, we report on differences and similarities among olive cultivars. The chosen cultivars, in order of cultivated areas in Spain, were 'Cornicabra' (cv. Cor), 'Hojiblanca' (cv. Ho), 'Lechín de Sevilla' (cv. LS), 'Manzanilla de Sevilla' (cv. MS), 'Empeltre' (cv. Em), 'Arbequina' (cv. Ar), 'Farga' (cv. Far), 'Gordal sevillana' (cv. Gs), and 'Verdial de Badajoz' (cv. VB), along with 'Picual' (cv. Pi) for comparative purposes. Fruits from cv. MS and cv. Gs are used for the preparation of table olives, whereas fruits of the rest of the cultivars are utilized for olive oil production, with the exception of cv. Ho fruits, which are used for both purposes. These 10 olive cultivars are "main cultivars" and are representative of olives cultivated throughout Spain. No study encompassing the phenolics of these 10 cultivars has been reported.

MATERIALS AND METHODS

Chemicals. The solvents used for olive wood extraction (dichloromethane and ethyl acetate) were glass-distilled prior to use. Methanol used for radical-scavenging activity assays and HPLC analyses was of HPLC grade. Two reference compounds were obtained from commercial sources: oleoside 11-methyl ester (**3**) (PhytoLab GmbH & Co., Vestenbergsgreuth, Germany) and eriodictyol (**9**) (Extrasynthèse, Genay, France). Other identified compounds in this work were previously isolated in the authors' laboratory.[14,27,28] 2,2-Diphenyl-1-picrylhydrazyl radical (DPPH$^{\bullet}$) (95%, Sigma-Aldrich Chemie, Steinheim, Germany) was used for radical-scavenging assays.

Plant Material. The olive tree (*O. europaea* L.) wood samples used in this work were collected on March 28, 2014 (during an ordinary day of pruning work), in the "garden of olive cultivars" of the Centro IFAPA "Venta del Llano", Mengíbar (Jaén province), Spain. This experimental farm, located at 280 m above sea level (37° 56′ 26″ N; 3° 47′ 6″ O), consists of a collection of one-trunk olive trees (30 years old), growing at 7 × 7 m distance, under standard growing practices and without artificial irrigation. The farm comprises one or two individual trees per each olive cultivar (around 180 different olive cultivars from Spain and the rest of the world). Thus, a single tree per olive cultivar was chosen to take pruning material. The olive cultivars selected were 'Arbequina', 'Cornicabra', 'Empeltre', 'Farga', 'Gordal sevillana', 'Hojiblanca', 'Lechín de Sevilla', 'Manzanilla de Sevilla', 'Picual', and 'Verdial de Badajoz' (Table 1). Because only one or two old olive branches were cut per tree during the pruning work, it was necessary to take a single piece of wood (approximately 3−4 cm diameter and 50 cm length) from each olive cultivar as not all cultivars had two branches pruned from the south side. In all cases, one old branch was utilized having been pruned from the south-facing side of the tree to minimize microhabitat variation. Thus, all single wood pieces collected for this work were taken from the south side of the trees in order to make the selected pruning material as homogeneous as possible for comparative purposes. Every wood sample was stored for 3 months in a dry and dark place at room temperature with passive ventilation, prior to extraction. Just before the start of the extraction process, the wood piece was shaved in a local sawmill (wood shavings: length, 3−5 cm; thickness, 0.1−0.3 mm).

Extraction. Wood shavings (40 g) were extracted successively with dichloromethane (DCM) and ethyl acetate (EtOAc) (350 mL of each) for 2 h at reflux under nitrogen atmosphere, following a protocol previously optimized by the authors.[29] The solvents were evaporated under reduced pressure to give the corresponding DCM and EtOAc extracts (i.e., dry extracts). DCM dry extracts were discarded, whereas all EtOAc dry extracts were stored under argon in sealed vials at −20 °C until analysis. All of the extractions were carried out in duplicate. Extraction yields are reported in Table 2.

Table 1. Selection of Spanish Olive Cultivars (*Olea europaea* L.) Included in This Work

olive cv. name	abbrev[a]	surface[b] (×1.000 ha)	crop land (provinces)[b]	fruit destination[b]
Picual	Pi	860	Jaén, Córdoba, Sevilla	olive oil
Cornicabra	Cor	269	Ciudad Real, Toledo	olive oil
Hojiblanca	Ho	217	Córdoba, Málaga, Sevilla	olive oil, table olives
Lechín de Sevilla	LS	105	Sevilla, Cádiz	olive oil
Manzanilla de Sevilla	MS	85	Sevilla, Badajoz	table olives
Empeltre	Em	72	Zaragoza, Teruel, Baleares	olive oil
Arbequina	Ar	71	Lérida, Tarragona	olive oil
Farga	Far	45	Castellón, Tarragona	olive oil
Gordal sevillana	Gs	30	Sevilla	table olives
Verdial de Badajoz	VB	29	Badajoz, Cáceres	olive oil

[a]These abbreviations for olive cultivar names are used throughout the text. [b]Information included in this column has been taken from ref 35.

Table 2. Extraction Yields and Radical-Scavenging Percentages of Olive Wood Samples from 10 Spanish Olive Cultivars (*Olea europaea* L.)

olive cultivar[a]	DCM[b]	EtOAc[c]	RSP[d]
Pi	0.7	1.6	91.4 a

Em	0.5	0.3	21.0 e
Ho	0.5	0.3	21.0 e
VB	0.4	0.5	18.6 e

[a]Abbreviated olive cultivar names. See Table 1 for meaning. [b]Yields for dichloromethane extracts. Values are means of two replicates. [c]Yields for ethyl acetate extracts. Values are means of two replicates. [d]RSP (radical-scavenging percentage) values for the ethyl acetate extracts are expressed as DPPH$^{\bullet}$ scavenging (%). Values are means of three replicates, and the RSD is <1%. RSP data values followed by common letters are not significantly different (F = 230.0; P < 0.05).

HPLC-DAD Analysis. High-performance liquid chromatography (HPLC) analyses were performed by an analytical RP-HPLC (Spherisorb ODS-2 column, 250 mm × 3 mm i.d., 5 μm, Waters Chromatography Division, Milford, MA, USA) on a Waters 600E instrument (Waters Chromatography Division) equipped with a diode array detector, with a scan range of 190−800 nm (Waters CapLC 2996 photodiode array detector, Waters Chromatography Division) and operating at 30 °C. Samples for injection were prepared by dissolving each EtOAc dry extract in MeOH at a concentration of 10 mg/mL (injection volume, 5 μL). HPLC separations were achieved following a method previously used by the authors to analyze olive wood extracts:[14] H_2O/CH_3COOH, 99.8:0.2, v/v (solvent A) and CH_3OH/

jaspolyanoside isomer (**17**)[f]	50.0	228, 277	909.2	523.1

[a]An authentic sample of this compound was isolated by the authors from cv. Pi.[27] [b]This compound was identified by comparison with a commercial standard. [c]An authentic sample of this compound was isolated by the authors from cv. Pi.[14] [d]The $[M - H]^-$ ion for this compound was not observed. [e]An authentic sample of this compound was isolated by the authors from cv. Pi.[28] [f]This compound was tentatively identified on the basis of its UV−vis and MS spectra and MS fragmentation pattern.

CH_3COOH, 99.8:0.2, v/v (solvent B) at a flow rate of 0.7 mL/min: linear gradient from 20 to 70% B for 55 min and another 10 min to return to the initial conditions. Quantification of identified compounds in each EtOAc extract was carried out by the external-standard method, using HPLC peak areas at 230 nm (**5**−**7**, **10**−**17**), 239 nm (**3**, **8**), 280 nm (**1**, **2**), 288 nm (**9**), or 346 nm (**4**). The concentration of each compound was measured by comparing it with calibrations made with the pure compound analyzed under the same conditions. Two of them are commercial reference standards (**3** and **9**), and the remainder of the compounds were isolated and characterized previously by us.[14,27,28] Calibration curves were obtained for each standard in the following concentration ranges: hydroxytyrosol (**1**) in the range of 1.0−50.0 μg/mL; oleoside 11-methyl ester (**3**) in the range of 1.0−100.0 μg/mL; aldehydic form of oleuropein aglycone (**4**) in the range of 48.7−325.0 μg/mL; (−)-olivil 4-*O*-*β*-D-glucopyranoside (**5**) in the range of 47.5−316.6 μg/mL; (−)-olivil (**6**) in the range of 51.9−692.5 μg/mL; eriodictyol (**9**) in the range of 29.2−729.0 μg/mL; (+)-1-hydroxypinoresinol 1-*O*-*β*-D-glucopyranoside (**10**) in the range of 100.0−1000.0 μg/mL; oleuropein (**11**) in the range of 120.0−1000.0 μg/mL. Concentration values for compounds **1** and **2** were calculated by external calibration against hydroxytyrosol (**1**). Concentration values for compounds **3** and **8** were calculated by external calibration against oleoside 11-methyl ester (**3**). Concentration values for compounds **4**−**6**, **9**, and **10** were calculated by external calibration against the corresponding pure compounds. Concentration values for compounds **7** and **11**−**17** were calculated by external calibration against oleuropein (**11**). The results were expressed as milligrams of compound per gram of dry weight EtOAc extract.

Because the number of wood samples studied for each olive cultivar was limited (see discussion above), the concentration data were analyzed on the basis of two extraction replicates per cultivar for ANOVA and SNK multiple-range tests of significance.

HPLC-DAD/ESI-MS Analysis. Analyses were performed using an Agilent 1100 HPLC system (Agilent Technologies, Palo Alto, CA, USA) equipped with a diode array detector and an Esquire 6000 ion mass spectrometer (MS, Bruker Daltonics, Bremen, Germany) fitted with an electrospray ionization (ESI) interface, operating in negative mode. Chromatographic separation was achieved using an analytical reverse-phase column (Spherisorb ODS-2, 150 mm × 3 mm i.d., 5 μm, Waters Chromatography Division) using the same solvents and conditions as described above. Ionization and mass spectrometric conditions were optimized by infusing a solution of pure compounds. The nebulizer pressure was 40 psi; dry gas flow, 9 L/min; dry gas temperature, 350 °C; and capillary voltage, 4 kV. Analyses were performed using scans from m/z 50 to 1200.

DPPH Radical-Scavenging Activity Assay. The radical-scavenging activity of EtOAc dry extracts was determined spectrophotometrically with the stable DPPH radical.[36] Methanolic solutions (2.4 mL) of DPPH• (~7×10^{-5} M) with an absorbance at 515 nm of 0.80 ± 0.03 AU were mixed with methanolic solutions (1.2 mL) of EtOAc dry extracts at a concentration of 50 μg/mL. The resulting mixtures were shaken and kept in the dark for 15 min at room temperature. The decrease of absorbance was measured at 515 nm. Results are expressed as radical-scavenging percentage (RSP) and were calculated by using the formula[36]

$$\mathrm{RSP} = \left[\frac{A_B - A_A}{A_B}\right] \times 100$$

where A_B is the absorbance of the blank (t = 0 min) and A_A is the absorbance of tested sample solution (t = 15 min). The experiments were carried out in triplicate.

Statistical and Multivariate Analyses. Data were collected from two independent extractions from each olive cultivar. Thus, each compound (as mg/g DM) was compared among the cultivars (two replicates per cultivar) by one-way ANOVA SNK (Student−Newman−Keuls multiple-range test).[37] Gower or Manhattan metric similarities[38,39] were computed among all cultivars using character weighting of the square root ($F - 1$) (where F is the F ratio of variance among cultivars/variance within cultivars for each compound, taken from ANOVA). Using the square root of ($F - 1$) for character weighting factors places more importance on characters that vary more among the cultivars, thus improving their separation (see discussion in ref 39). Principal coordinate ordination (PCO) factored the association matrix using the formulations of Gower[40] and Veldman.[41]

RESULTS AND DISCUSSION

The olive cultivars included in this work were selected from the group of 24 main Spanish olive cultivars.[35] Table 1 presents information on the 10 olive cultivars, their cultivated areas in Spain, the Spanish provinces where they are mainly cultivated, and the use of their fruits. Each of the 10 olive varieties studied

DOI: 10.1021/acs.jafc.5b02979
J. Agric. Food Chem. 2015, 63, 6493−6500

are the dominant cultivar at least in one district. Thus, they represent all of the olive-growing areas of Spain, from the southern half to northeastern Spain. All of the olive wood samples were collected on the same day and location, so any differences in the phenolic compositions of the samples should be due to genetics rather than different environmental and/or agronomical conditions. The olive wood samples used in the work came from the pruning materials collected at an experimental farm, Jaén province, southern Spain.

Extraction of Olive Wood Samples and Radical-Scavenging Activity. Olive wood shavings were sequentially extracted with dichloromethane and ethyl acetate under reflux conditions. Dichloromethane extractions (0.4−0.7% yield) removed nonpolar components, which are known to have negligible antioxidant activities.[29] Hence, the dichloromethane extracts were discarded. Because it is known that ethyl acetate is an excellent solvent for the extraction of antioxidants,[29] the resulting ethyl acetate extracts (0.3−1.6% yield) were submitted to the DPPH assay. The DPPH assay is based on the ability of the antioxidants to scavenge the model free radical, DPPH$^{\bullet}$, and has been widely used due to its simplicity and worldwide acceptance for comparative purposes.[36] Table 2 presents the extraction yields from wood samples and the antioxidant activities of the ethyl acetate extracts expressed in terms of radical-scavenging percentage (RSP). The ethyl acetate yields for all olive cultivars were <1%, with the exception of cv. Pi (1.6%). ANOVA of antioxidant activities revealed a highly significant difference (F = 230.0, $P = 0.2 \times 10^{-5}$) between the RSP value of cv. Pi and the other cultivars (Table 2). The RSP value for cv. Pi was 91.4%, whereas the RSP of the other olive cultivars ranged from 18.6 to 32.7% (Table 2).

Identification and Quantitative Analysis of Phenolic Compounds. The 10 ethyl acetate extracts were submitted to HPLC-DAD and HPLC-DAD/ESI-MS analyses. The identifications of components were carried out by comparison of retention times and mass and UV spectra with those of authentic samples. Table 3 shows the phenolic compounds studied in order of elution from a C_{18} HPLC column, along with their chromatographic and spectral characteristics. Figure 1 shows the HPLC chromatograms (recorded at 230 nm) of cultivars Ar, Gs, and Pi, which typify the different component profiles of the selection of olive cultivars. Compounds **1**, **2**, **4**−**8**, **10**−**13**, **15**, and **16** have been previously isolated and fully characterized by our laboratory from ethyl acetate extracts of cv. Pi.[14,27,28] Compounds **3** and **9** were identified as oleoside 11-methyl ester and eriodictyol, respectively, by comparison with the corresponding commercial standards (Figure 2). On the other hand, compounds **14** and **17** have mass and UV spectra very similar to those of jaspolyoside (**13**) and jaspolyanoside (**15**), respectively, indicating they are isomers. The 17 compounds belong to five groups of phenolic compounds: (I) simple phenols (**1**, **2**); (II) lignans (**5**, **6**, **10**); (III) flavonoids (**9**); (IV) iridoids (**8**); and (V) secoiridoids (**3**, **4**, **7**, **11**−**17**). All of these compounds have previously been isolated or detected in different parts of the olive tree, although some of them (**5**−**9**, **13**, **15**, and **16**) have been described in *O. europaea* on rare occasions.[14,27,28,42,43] In contrast, it is the first time that compounds **3** and **9** have been described in olive tree wood. Several studies on the biological activities and potential applications of some of these compounds, especially focused on hydroxytyrosol or oleuropein, have been conducted.[44−46]

After identification of the HPLC peaks, the concentration of each compound in all ethyl acetate extracts was calculated by the external standard method, correlating the peak area for each component in a given HPLC chromatogram with the calibration curves obtained using our own standards (**1**, **2**, **4**−**8**, **10**−**13**, **15**, **16**) and those commercial ones (**3**, **9**) (Table 4). Significant differences, both quantitative and qualitative, were found among olive cultivars (Table 4). Compounds **1**, **2**, **4**−**7**, **9**, **10**, and **12** were present in all olive cultivars, whereas compounds **3**, **8**, and **13** were present in only five, three, and four cultivars, respectively (Table 4). In contrast, compounds **11** and **14**−**17** were absent in three cultivars (Table 4). Compound **10** was the major phenolic compound in all cultivars, except in cv. Far and cv. Pi, where it was the second most abundant component. Compound **9** was the second highest concentration component in four cultivars (Cor, Gs, MS, and VB) and the third highest in cv. Ho (Table 4). Compound **6** was also quite abundant, being the third highest concentration component in three cultivars (Em, Gs, and LS), the highest in cv. Far, and the second highest in cv. Ar and cv. Ho (Table 4). Other prominent constituents are compounds **4**, **7**, **12**, and **11**, the latter being the major component in cv. Pi. In

[a]See Table 1 for complete olive cultivar names. Concentration values are expressed as milligrams of compound per gram of dry weight EtOAc extract. Data values in the same row followed by common letters are not significantly different ($P < 0.05$). [b]See Table 3 for complete compound names. [c]*F* ratio = variance among cultivars/variance within cultivars, from ANOVA. [d]*P* = probability of significant difference among the cultivars. Sixteen compounds differ among cultivars at very highly significantly difference ($P < 0.001$) levels; compound **2** is highly significantly different among cultivars ($P < 0.01$).

DOI: 10.1021/acs.jafc.5b02979
J. Agric. Food Chem. 2015, 63, 6493−6500

contrast, compound **2**, with a concentration that ranged from 0.21 to 1.46 mg/g, was a very minor component (Table 4) as were compounds **8** (0−1.88 mg/g) and **1** (0.17−2.96 mg/g). With respect to the phenolics found in our past analyses on olive wood samples from cv. Pi[14,27,28] and those identified in the Picual wood sample analyzed in this work, some minor differences are found; the flavonoid **9** has been detected now for the first time, and the group of lignans (**5**, **6**, **10**) has increased its presence, representing now ca. 30% (in weight) of the reported components. However, oleuropein (**11**) still is the major component, and the group of secoiridoids (**4**, **7**, **11**−**17**) remains the most representative (ca. 70% in weight).

Multivariate Analysis. To investigate the pattern of the chemical relationships among the cultivars, PCO was performed. A similarity matrix was produced using the average values for each of the 17 compounds. Factoring the similarity matrix resulted in five eigenroots that appeared to asymptote after the fifth root. These eigenroots accounted for 43.91, 16.51, 13.68, 8.06, and 4.87% (87.03% total) of the variance among the 10 cultivars. Ordination of the cultivars onto the first three principal coordinates (Figure 3) reveals three major

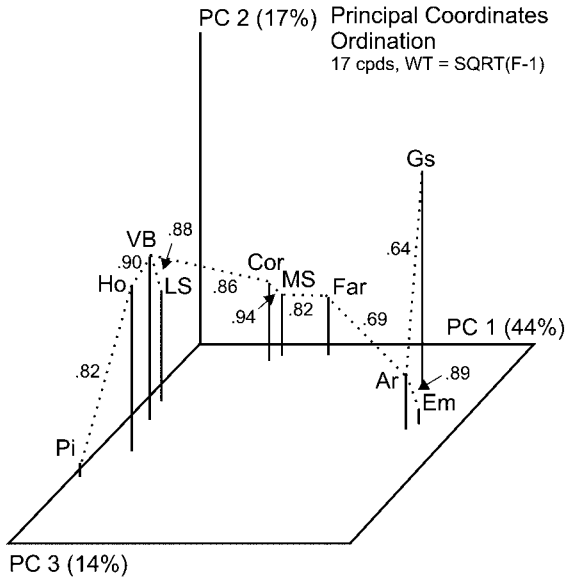

Figure 3. Principal coordinates ordination (PCO) of 10 olive cultivars based on 17 compounds with matches weighted by square root of (F − 1), where F is the F ratio from ANOVA (the dotted line is the minimum spanning network; the numbers next to the dotted line are the similarity between cultivars).

groups (cv. Ar-Em, Cor-MS, and Ho-VB-LS). Cultivar Gs has the most distinct chemical profile (being only 0.64 similar to cv. Ar), followed by cv. Pi (0.82 to cv. Ho) and cv. Far (0.82 to cv. MS) (Figure 3).

An alternative view of the chemical relationships among the cultivars is the minimum spanning network (Figure 4). Three sets of cultivars are very similar in their phenolics chemistry (cv. Cor-MS, Ho-VB, and Ar-Em) (Figure 4; Table 4). Cultivar Gs has the most distinct chemical profile (Figure 4; Table 4) with cv. Pi and Far being somewhat similar to cv. Ho and MS, respectively (Figure 4). It should be noted that the PCO and minimum spanning network reflect similarity in the cultivar's phenolics. This may or may not indicate their genetic relationships. Additional research utilizing DNA sequencing

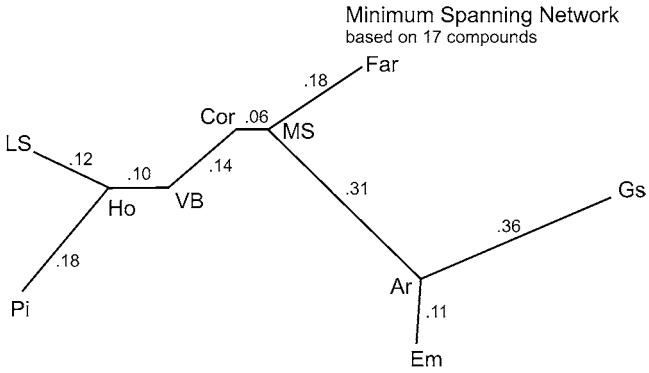

Figure 4. Minimum spanning network for 10 olive cultivars based on 17 compounds (the numbers next to the lines are distances (1 − similarity) between cultivars).

would be needed to more fully explore the overall genetic relationships among these cultivars.

In conclusion, 17 compounds were identified and quantified after analysis of the ethyl acetate extracts of 10 Spanish olive cultivars by HPLC-DAD and HPLC-DAD/ESI-MS. The lignan (+)-1-hydroxypinoresinol 1-*O*-*β*-D-glucopyranoside (**10**) (21.02−90.21 mg/g) and the flavonoid eriodictyol (**9**) (3.00−71.03 mg/g), together with compounds **6** (12.02−51.81 mg/g), **4** (14.91−26.81 mg/g), or **7** (11.92−29.61 mg/g), were prominent components in most cultivars. Multivariate analysis revealed significant quantitative and qualitative differences among the cultivars. The principal coordinates ordination and minimum spanning network established the chemical relationships among cultivars. Three sets of cultivars were found to be similar in their phenolic composition: (a) 'Cornicabra' and 'Manzanilla de Sevilla', (b) 'Hojiblanca' and 'Verdial de Badajoz', and (c) 'Arbequina' and 'Empeltre'. In contrast, cultivars 'Gordal sevillana', 'Picual', and 'Farga' had the most distinct chemical profiles. Despite having only two replicate extractions per cultivar, highly significant differences were found in ANOVA and SNK multiple-range comparisons of the chemical components among cultivars for this important biomass. Considering the abundance of this renewable agricultural byproduct and the influence of the cultivar genotype on the chemical composition, new opportunities for the industry are developing to recover diverse value-added products and explore potential applications from olive tree waste byproduct wood.

crops worldwide.[14] To date, a number of studies have used two-dimensional electrophoresis (2-DE) to investigate gluten protein responses to high temperature, fertilizers, and drought[15−18] and reported changes in as few as 3[15] to as many as 107 2-DE spots;[17] moreover, most research focuses on metabolic wheat grain proteins,[19] whereas fewer studies focus on storage proteins. High temperature (and also water deficit) shortens the duration of grain filling and reduces the time taken to reach apoptosis and harvest maturity.[20] Consistent with these events, transcripts for α-, γ-, and ω-gliadins, HMW-GS, and LMW-GS accumulate and disappear earlier.[21] Yang et al.[17] applied both heat and water stress to a *T. aestivum* cultivar and found the highest gliadin contents at 19 DAA under heat treatment and at maturity under water stress conditions. Moreover, the authors found that high-temperature treatment resulted in higher glutenin and gliadin contents at maturity; this contrasts with the findings of other authors, who found that high temperature can induce synthesis of gliadins in wheat at the expense of glutenins.[22] In contrast to the gliadin fractions, multiple high-temperature or water-deficit events applied at both terminal spikelet and anthesis resulted in significantly higher glutenin contents at maturity than did the single-stress treatments.[17] Moreover, the same authors reported that some storage proteins, including α- and γ-gliadins, LMW-GS, and globulins, decreased and that one globulin and one specific LMW-GS increased in response to water deficit. It is fundamentally important to understand how environmental treatments affect the timing of grain developmental processes in order to pursue wheat quality, because protein synthesis of storage proteins occurs during this stage. However, most research has focused on the effects of high temperature, whereas fewer have focused on the effect of water stress on the accumulation on gluten proteins during grain filling, particularly in durum wheat.

The aim of the present study was to evaluate the effect of terminal drought stress on the gluten protein composition of durum wheat during grain filling by a proteomic approach. For this purpose two Italian cultivars characterized by different technological qualities were used.

MATERIALS AND METHODS

Plant Material and Growth Conditions. Two Italian durum wheat (*T. turgidum* spp. *durum*) cultivars, Ciccio and Svevo, were cultivated in a growth chamber under controlled conditions of temperature, humidity, and light during 2010. The two cultivars were chosen for their different technological performances, Ciccio showing a higher gluten index (84) than Svevo (39) in the seed batch used for sowing.[23] Both cultivars have almost the same growing, flowering, and maturation times. The plants were grown in pots (37 × 15 cm), using a completely randomized design with two replications and three factors (phonological stage, cultivar, and water regimen). Seeds were sown on February 8 with a seeding density of 150 seeds m^{-2} (8 seeds per pot); after emergence, seed density was standardized at 5 seeds per pot. Each pot contained a mixture of sandy clay loam soil, sand, and peat in a 6:3:1 ratio, with a field capacity of 26.9% and a wilting point of 16.4%. Temperature and photoperiod (hours of daylight) were modified during the plant life cycle from 8/6 °C and 10 h at sowing to 28/22 °C and 16 h at physiological maturity. Phosphorus was applied at sowing as diammonium phosphate at a rate of 9 g m^{-2}. Nitrogen was applied as ammonium nitrate at a rate of 3.5 g m^{-2} at sowing, at a rate of 6.5 g m^{-2} at tillering, and at preanthesis at a rate of 2 g m^{-2}. Before anthesis (73 days after sowing), all plants were well watered (WW) by replenishing soil to field capacity whenever the threshold of 50% of available soil water was reached; water stress (WS) was imposed since anthesis by replenishing soil up to 70% of available water, whereas for the control plants soil was replenished up to 100% of available water. Heads were collected at selected time points during grain development under the two water regimens. Under WW, heads were monitored at 2−5 day intervals from anthesis by visual inspection of cut endosperm. Because water stress shortened the grain developmental process, heads were monitored at 1−3 day intervals from anthesis under WS; on this basis the heads were collected at 10 and 14 DAA, at 18 and 21 DAA, and at 28 and 31 DAA in WS and WW, respectively, corresponding to medium milk (stage 75), soft dough (waxy) (stage 85), and physiological maturity (stage 92) of the Zadoks growth scale.[24] The following parameters were determined at physiological maturity: kernel number per spike, 1000 kernel weight (g) (TKW), and protein content (% dw) by using a micro-Kjeldahl.

Storage Protein Extraction. Five ears were harvested at each specific stage from the primary tillers of milk, waxy, and physiological sets of pots. Kernels harvested from the middle part of the ears were used for storage protein extraction. Milk and waxy samples were immediately frozen in liquid nitrogen. All of the samples were freeze-dried. Fifty milligrams of ground grain samples was suspended in 200 μL of KCl buffer solution (100 mM KCl, 50 mM Tris-HCl, pH 7.8, 5 mM EDTA). The suspension was incubated on ice for 5 min, with intermittent shaking, and centrifuged at 14500*g* for 15 min at 4 °C to separate the soluble (supernatant) from the insoluble fraction (pellet), which was mostly gliadins and glutenins. Storage proteins were then extracted from the pellet using 800 μL of SDS buffer (2% SDS, 10% glycerol, 50 mM DTT, 40 mM Tris-HCl, pH 6.8). Proteins were precipitated by adding 4 volumes of cold acetone (−20 °C) to remove the SDS, which interferes with protein determination and prevents separation of proteins by isoelectric focusing (IEF). After overnight incubation at −20 °C and double centrifugation at 16000 rpm for 10 min at room temperature, the acetone was removed. The pellet was suspended in urea buffer solution (8 M urea, 2% Triton X-100, 0.03% DTT, 0.04% BPB, 0.5% IPG buffer) and stored at −20 °C. Protein concentration was measured using the biuret method, with BSA as a standard.[25] Under WW and WS conditions the following results (expressed in mg mL^{-1}) were obtained in milk stage, waxy stage, and physiological maturity, respectively: Ciccio, 0.069 and 0.08, 0.098 and 0.114, and 0.116 and 0.134; Svevo, 0.076 and 0.093, 0.109 and 0.132, and 0.129 and 0.155.

2-DE Analysis. Storage proteins were separated by 2-DE, as reported in Pompa et al.[26] Briefly, IEF was performed by using the Ettan IPGphor 3 isoelectric focusing system (GE Healthcare Bio-Sciences AB, Uppsala, Sweden). Samples containing 200 μg of storage proteins were loaded onto each IEF gel. Immobiline DryStrips (pH 3−10, 13 cm length; GE Healthcare Bio-Sciences AB) were used. SDS-PAGE was carried out using an SE 600 apparatus (Hoefer, Inc., Holliston, MA, USA). Strips were equilibrated and then loaded onto 1 mm × 18 cm × 16 cm vertical polyacrylamide SDS-PAGE gels (T, 12%; C, 1.28%). Separation of both proteins and molecular weight markers (GE Healthcare Bio-Sciences AB) was performed at 30 mA per gel at 10 °C. Staining was performed by GBB 250 Coomassie Brilliant Blue and destaining in deionized water.

Two biological replications were taken into consideration, but these were pooled due to the scarcity of material, especially at the milk and waxy stages. Four replicates were performed on pooled samples for each of the two cultivars (Ciccio and Svevo), each of the two irrigation treatments (WS and WW), and each of the three developmental stages (milk, waxy, and physiological), for a total of 48 gels. 2-DE gels were digitized at 600 dpi by a scanner. ImageMaster 2D Platinum 6.0 software (GE Healthcare Bio-Sciences AB) was used for gel analysis, including spot detection, spot match, and spot and region volume quantification, and the expression levels of protein spots on 2-DE gels were determined by protein abundance (% vol). The 2-DE gels were subdivided into four regions on the basis of protein molecular weight, as reported also in Pompa et al.:[26] the high molecular weight (H) region (>60 kDa, mostly including the HMW-GS); the intermediate (I) region (60−48 kDa, including ω-gliadins and D subunits of LMW-GS); the low molecular weight (L48−35) region (48−35 kDa, including most of the typical LMW-GS, namely, LMW-s and LMW-m types); and the low molecular weight (L<35) region (<35 kDa, including α- and γ-gliadins and c-type LMW-GS).[27]

DOI: 10.1021/acs.jafc.5b01635
J. Agric. Food Chem. 2015, 63, 6501−6512

The gel region data from the four replicates were analyzed using the ANOVA procedure of the M-stat C statistical package (Crop Soil Sciences Department, Michigan State University). Significant differences between the mean values were calculated using Tukey's test. Moreover, the differences between spots were evaluated by the using *t* test.

In-Gel Digestion of Protein Spots and Mass Spectrometry Analyses. *Chemicals.* Unless otherwise indicated, all chemicals used in the preparation of buffers and solutions were of analytical reagent grade. 1,4-Dithiothreitol (DTT) was purchased from Sigma-Aldrich (St. Louis, MO, USA). Formic acid (≥98%), sodium hydroxide, calcium chloride (≥99%), and urea were purchased from Merck (Darmstadt, Germany). Water, methanol, and acetonitrile (LC-MS CHROMASOLV, ≥99.9%) were from Fluka. Chymotrypsin (bovine) was purchased from Princeton Separation (Adelphia, NJ, USA).

In-Gel Chymotrypsin Digestion. The protein spots excised from 2-DE gels were digested by an optimized in-gel chymotrypsin procedure.[26] Gel pieces (3 mm), thoroughly washed with 10 μL of deionized water and dried, were destained with 50 mM ammonium bicarbonate and acetonitrile (ACN) (50:50, v/v) (four times for 5 min). After liquid removal, the gel pieces were dehydrated for 0.5 h using 30 μL of ACN. The dehydrated gel pieces were incubated with 10 mM DTT at 56 °C for 45 min and then with 55 mM iodoacetamide (IoAA) at room temperature in the dark for 30 min; finally, they were washed with a solution of 50 mM ammonium bicarbonate/ACN (50:50, v/v) with gentle agitation for 10 min and briefly dehydrated with ACN. The washing step was repeated twice before the gel pieces were dried. Proteins in the gel pieces were digested with 5 μL of chymotrypsin (5 ng/μL) in 25 mM ammonium bicarbonate at 37 °C for 16 h. Five microliters of 1 M urea at pH 8, as the denaturing agent, and calcium chloride (1 mM) were added to the solution to promote enzyme action. After digestion, the peptides were extracted for 15 min with 5 μL of 50 mM ammonium bicarbonate and 5 μL of ACN/formic acid (FA; 1% in water) solution (50:50, v/v). The solution containing the extracted peptides was collected after 15 min.

Liquid Chromatography and Mass Spectrometry. Digested proteins were separated by a nanoLC apparatus, Ultimate 3000 (Dionex LC-Packings, Amsterdam, The Netherlands) consisting of an autosampler, a low-pressure gradient micropump series, equipped with flow managers, a column thermostat, and a UV detector set at 214 nm. The nanoLC-ESI-IT-MS/MS system was controlled by Chromeleon CHM-1 (Dionex) and Hystar 2.3 (Bruker Daltonics) software. A PepMapTM C18 nano trap column (300 μm i.d. × 5 mm, 5-μm particle size, LC Packings) was used for concentrating and desalting the injected sample. Chromatographic separations were carried out by a PepMap C18 analytical column (15 cm length × 75 μm i.d., 3-μm particle size, 100-Å pore diameter; LC Packings). The mobile phase consisted of ACN/0.1% formic acid (FA) in water (2:98 v/v) (eluent A) and ACN/0.1% FA in water (80:20 v/v) (eluent B). Sample elution through the analytical column was obtained at a flow rate of 0.300 μL/min. The optimized elution gradient was the following: 7 min isocratic step at 98% A and 2% B; 28 min linear gradient to 50% A and 50% B; 1 min linear gradient to 10% A and 90% B; 4 min isocratic step at 10% A and 90% B; 1 min to the initial mobile phase composition (98% A and 2% B), at which the system was re-equilibrated for 19 min; total run time was 60 min. Mass spectrometry analyses were performed by using a high-capacity ion trap, coupled to a nano-ESI source, operating in the positive ion mode. The following parameters were set: spray voltage, 4.5 kV; sheath gas (nitrogen) flow rate, 10 L/min; capillary voltage, 1.5 V; heated capillary temperature, 160 °C. A full scan MS acquisition in the m/z 100−1500 range was performed with the acquisition of base peak chromatogram (BPC) and total ion current (TIC) profiles. MS/MS analysis by collision-induced dissociation (CID) was performed using unattended data-dependent acquisition mode, and the auto-MS/MS event was carried out with a number of precursor ions of 3. The minimal signal required for precursor ion selection was set to an absolute threshold of 10000.

Data Analysis and Database Search. Extraction of mass spectra peak lists from chromatograms, mass annotation, and deconvolution were performed by using Data Analysis 4.0. The acquired MS and MS/MS data sets were submitted to database searches by using Biotools 3.2 and MASCOT search engine (Matrix Science, London, UK). To do further research taking into consideration the wide dynamic range of relative peptide abundance, in addition to the MS/MS spectra obtained along the entire chromatographic run, the TIC chromatogram was divided into a series of time segments corresponding to the main peaks. Each segment was composed of a sequence of MS/MS acquisitions, for a better identification by database search.

The data analysis files were used to search entries under the *other green plant* category of NCBI-nr and SwissProt databases. As variable modifications, the oxidation of methionine, the phosphorylation of serine, threonine, and tyrosine, and the deamination of glutamine and asparagine were set. A maximum number of three missed cleavages was allowed, and a peptide tolerance of 0.3 Da was set for both precursor peptide ion and MS/MS tolerance in the window of error for matching the peptide mass values.

As far as the enzyme selection is concerned, consecutive database searches were performed by setting chymotrypsin as protease.

RESULTS

Gluten Protein Composition during Grain Development. Different durations of grain development were observed for the two irrigation treatments (WW and WS). In particular, both cultivars reached the milk, waxy, and physiological stages earlier under WS than under WW (10 vs 14 DAA, 18 vs 21 DAA, and 28 vs 31 DAA, respectively).

At physiological maturity, the two cultivars presented a significantly lower TKW and higher protein content under water stress. In particular, Ciccio showed TKW values of 37 g in WW and 23 g in WS, whereas Svevo showed TKW values of 36 g in WW and 22 g in WS ($P \leq 0.05$). The protein concentration values were 14.5% in WW and 16.8% in WS for Ciccio and 16.1% in WW and 19.5% in WS for Svevo ($P \leq 0.05$).

The 2-DE gels were highly reproducible (SD range of the total spot volumes of the four technical replicates for each thesis = 4−13%) and presented well-defined spots without streaking (Figures 1 and 2). Under WW, the average numbers of spots at the milk, waxy, and physiological stages were 66, 107, and 99 for Ciccio and 65, 112, and 100 for Svevo; under WS, the average numbers were 57, 82, and 96 for Ciccio and 63, 87, and 107 for Svevo. The number of spots increased progressively in both cultivars from the milk stage to physiological maturity under WS conditions; under WW conditions, the highest number of spots was at the waxy stage, with a slight reduction at maturity (Figures 1 and 2).

During grain filling, some spots apparently changed their isoeletrical point. This was more evident in the waxy stage for HMW-GS that showed more acidic position with respect to the milky and physiological stages; we do not have any reliable explanation for this, since deamidation, which is a common artifact for gluten proteins because of the numerous glutamine residues,[28] should be excluded because this shift was not observed on the same proteins also at physiological stage.

Figure 3 reports the percentages of H, I, L48−35, and L<35 regions for the two cultivars and the two water regimens during grain development.

The H region percentage in Ciccio increased progressively to the maximum value at the physiological maturity, when similar values were observed between the two water regimens. In Svevo, the H region percentage was the same at both milk and waxy stages with a sharp increase at maturity, which was more marked under WS (Figure 3a).

The I region presented the highest percentages at physiological maturity and the lowest percentages at the waxy stage

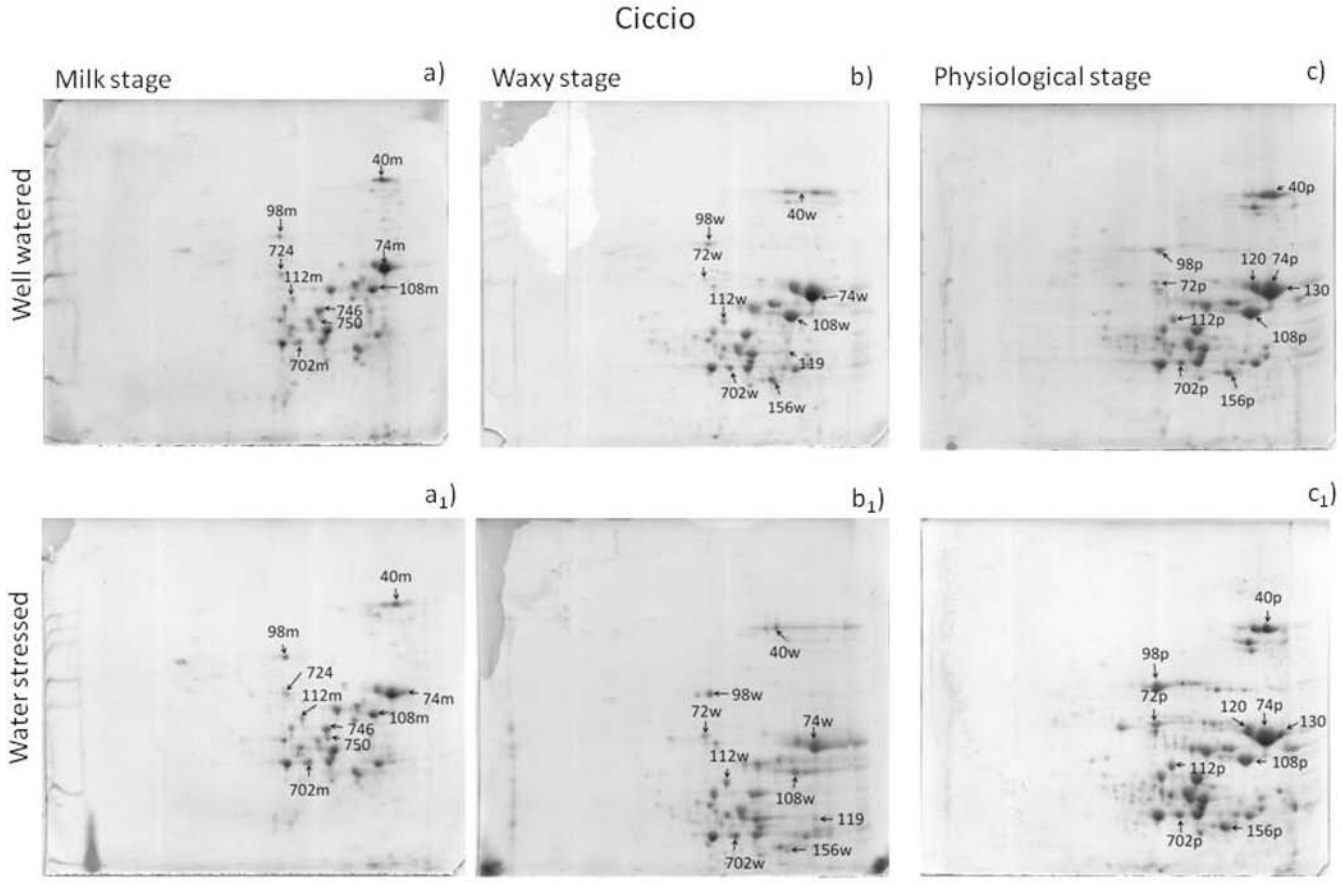

Figure 1. Gluten protein 2DE gels (IEF × SDS-PAGE) of the cultivar Ciccio cultivated under well-watered and water-stress conditions (a, a_1, b, b_1, c, and c_1 are milk, waxy, and physiological stages in WW and WS, respectively).

for both cultivars, generally showing higher values under WS (Figure 3b).

The L48−35 region in both cultivars showed a slight progressive increase during grain development, with lower values under WS (Figure 3c).

Finally, the L<35 region decreased slightly during grain development in both cultivars, with a general increase under WS (Figure 3d).

At physiological maturity, significant differences ($P \leq 0.05$) were found between the two cultivars in the different gel regions. In particular, H was significantly overexpressed in Svevo, especially under WS (11.8 vs 10.7% under WW and 13.5 vs 10.6% under WS); moreover, the L48−35 region was always significantly overexpressed in Ciccio (46.7 vs 43% under WW and 40 vs 35% under WS), and the L<35 region was always significantly overexpressed in Svevo (42.4 vs 36% under WW and 45.3 vs 39% under WS).

Differences in Protein Expression between Well-Watered and Water-Stressed Conditions (WW vs WS). Table 1 reports differentially expressed spots between the two water regimens for the two cultivars in the three grain developmental stages and their *P* levels, whereas Table 2 lists spot identification using nano-HPLC-ESI-IT/MS/MS.

H Region. At the milk stage, Ciccio presented spot 40m significantly down-expressed in WS (Table1). This spot matched spot 40w in the waxy stage, identified as the HMW-GS1Bx7 (Table 2), and spot 40p in the physiological maturity, both down-expressed under WS (Figure 1).

As for Svevo, spot 43m of the milk stage was slightly down-expressed under WS (Table 1). This spot matched spot 43w in the waxy stage, which did not differ between the two water regimens, and spot 43p at physiological maturity, which was overexpressed under WS (Table 1 and Figure 2); at physiological maturity, this spot was identified as the HMW-GS 1Bx (Table 2). Spot 66m, down-expressed under WS and identified as the HMW-GS 1By8 (Tables 1 and 2), matched spot 66p at physiological maturity with the same identification, but with an overexpression under WS (Figure 2 and Table 1). Finally, spot 38w at the waxy stage matched spot 38p at physiological maturity (Figure 2), identified as the HMW-GS 1Bx (allele *1Bx* Tdu-e) (Table 2). In both cases, the spots showed down-expression under WS (Table 1).

I Region. In both Ciccio and Svevo, 98m and 96m spots at the milk stage matched 98w and 96w spots at the waxy stage and 98p and 96p spots at physiological maturity (Figures 1 and 2), which were constantly overexpressed under WS (Table 1); at physiological maturity, these spots have been identified as an ω-5-gliadin (Table 2).

L48−35 Region. In this region, Ciccio significantly overexpressed spot 724 under WS in the milk stage and significantly down-expressed spots 120 and 130 under WS at physiological maturity (Table1); unfortunately, identification using nano-HPLC-ESI-IT/MS/MS was impossible for these spots. Spot 74m presented similar values under the two water regimens and matched spot 74w at waxy stage and spot 74p at physiological maturity, both significantly down-expressed under WS condition (Figure 1 and Table 1); at physiological maturity this spot was identified as a LMW-GS s-type (Table 2). Spot 108m did not present any differences between the two water

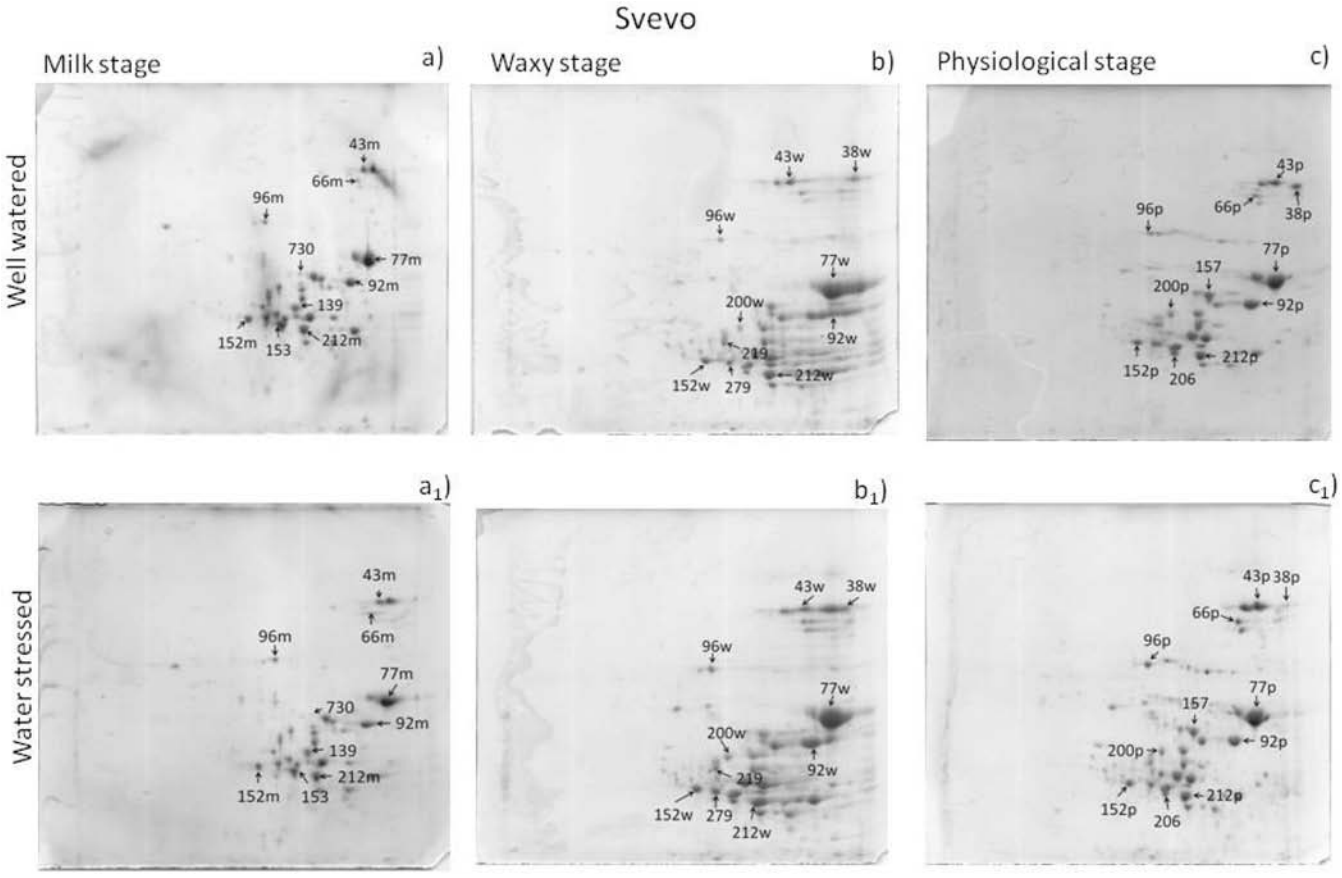

Figure 2. Gluten protein 2DE gels (IEF × SDS-PAGE) of the cultivar Svevo cultivated under well-watered (WW) and water-stress conditions (WS) (a, a_1, b, b_1, c, and c_1 are milk, waxy, and physiological stages in WW and WS, respectively).

regimens and matched spot 108w at the waxy stage and spot 108p at physiological maturity, both down-expressed under WS (Figure 1 and Table 1); spot 108p was identified as a LMW-GS m-type (Table 2). In the waxy stage, spot 72w, identified as a triticin (Table 2), matched spot 72p at physiological maturity (Figure 1), and in both cases an overexpression under WS was observed (Table 1).

As for Svevo, spot 730 at the milk stage and spot 157 at physiological maturity were down-expressed under WS (Table 1), but identification of these spots was unsuccessful. Spot 77m, generically identified as a LMW-GS type 2 (Table 2), matched spot 77w of the waxy stage and spot 77p at physiological maturity (Figure 2); this protein was down-expressed under WS in the milk and waxy stages, but no difference was observed between the two water regimens at physiological maturity (Table 1). Spot 92m, identified as a LMW-GS (Table 2), matched spot 92w at the waxy stage and spot 92p at physiological maturity (Figure 2); these spots were constantly down-expressed under WS (Table 1).

L<35 Region. As for Ciccio, at the milk stage spots 746 and 750 were down-expressed under WS (Table1); spot 746 was identified as an α-gliadin (Table 2). On the contrary, spot 119 at the waxy stage was overexpressed under WS (Table 1); for spots 750 and 119, no identification was possible. Spot 702m was significantly overexpressed under WS (Table 1) and was identified as an α-gliadin (Table 2). This spot matched spot 702w at the waxy stage, significantly overexpressed under WS, and spot 702p at physiological maturity, which did not present any significant differences between the two water regimens (Table 1 and Figure 1). Spot 112m matched spot 112w, identified as an α-gliadin precursor, and spot 112p at physiological maturity (Figure 1 and Table 2); for these spots, significant differences were found between the two water regimens only at the waxy stage, with an overexpression under WS (Table 1). Finally, at the waxy stage, spot 156 was slightly down-expressed under WS (Table 1) and matched spot 156p at physiological maturity, which was significantly down-expressed under WS (Figure 1 and Table 1) and identified as a γ-gliadin (Table 2).

As for Svevo, spots 139 and 153 at the milk stage were identified as α-gliadins (Table 2); both spots were overexpressed under WS (Table 1). Spot 152m has been identified as an α-gliadin (Table 2) and matched spot 152w at the waxy stage and spot 152p at physiological maturity (Figure 2), which were significantly overexpressed under WS at the milk and waxy stages (Table 1). Spot 212m matched spot 212w at the waxy stage and spot 212p at physiological maturity (Figure 2), identified as an α-gliadin constantly overexpressed under WS (Tables 1 and 2). At the waxy stage, spots 219 and 279 were overexpressed under WS (Table 1); no identification was possible for spot 219, whereas spot 279 was identified as an α-gliadin (Table 2). Spot 200w, identified as an α-gliadin precursor (Table 2) matched spot 200p at physiological maturity (Figure 2); in both cases the spots were overexpressed under WS (Table 1). Finally, at physiological maturity, spot 206, the only spot down-expressed under WS (Table 1), was identified as an α-gliadin (Table 2).

DISCUSSION

The shorter grain filling period observed in water stress conditions compared with well-watered conditions agrees with

DOI: 10.1021/acs.jafc.5b01635
J. Agric. Food Chem. 2015, 63, 6501−6512

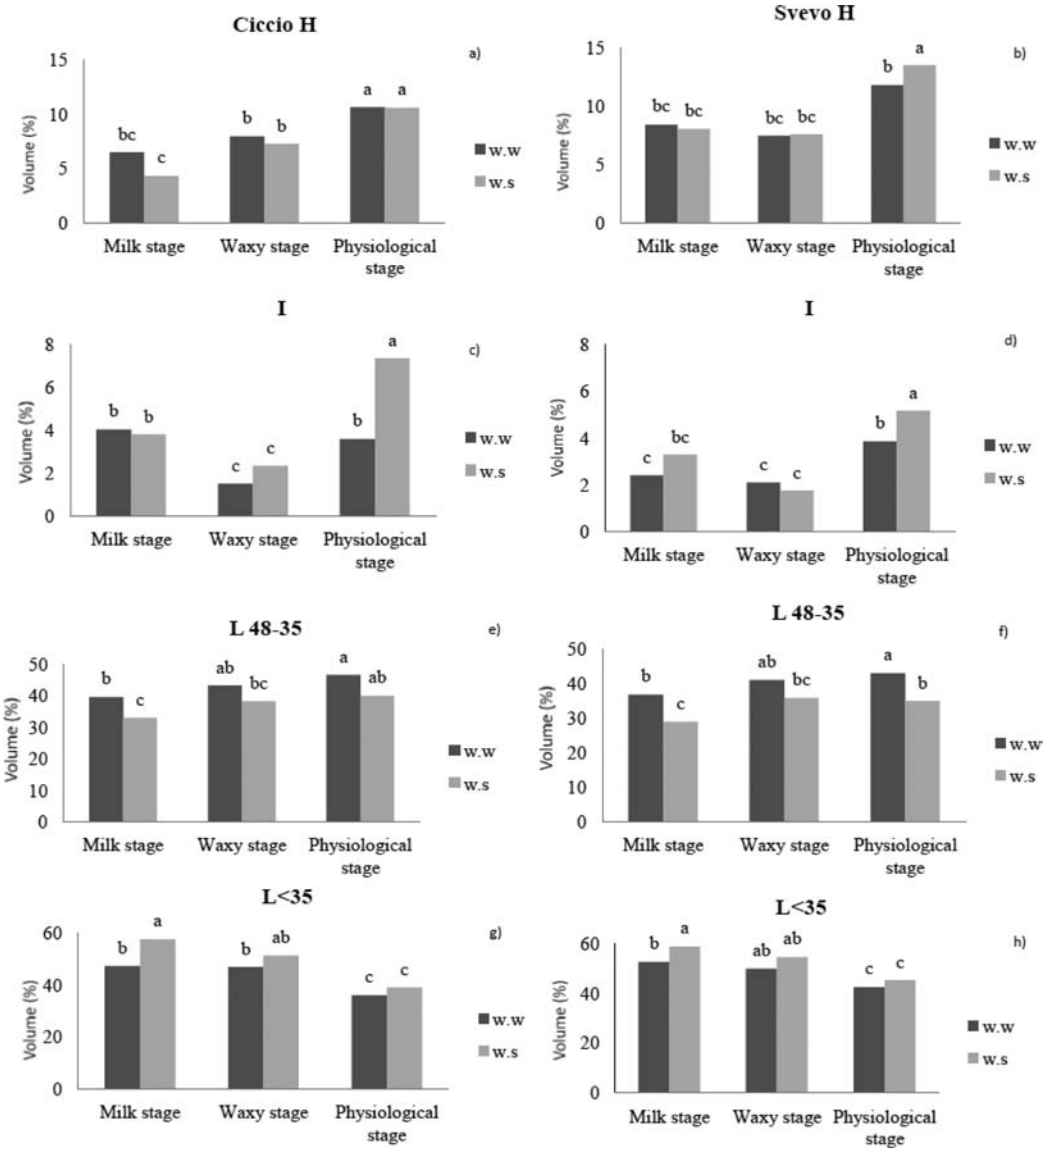

Figure 3. Percentage gel regions volume of the cultivars Ciccio and Svevo cultivated under well-watered (WW) and water-stress (WS) conditions during milk, waxy, and physiological stages (a, b, c, and d are high molecular weight (H), intermediate weight (I), low molecular weight 48−35 kDa, and low molecular weight <35 kDa regions, respectively). Different letters indicate significant differences at $P \leq 0.05$ according to Tukey's test.

several studies carried out in controlled environments, showing that high temperatures and drought accelerate grain development.[29] In addition, the reduced yield and increased protein content observed under WS confirmed what was already observed under the Mediterranean environment.[30,31] Storage protein composition showed significant changes during grain development, differing in relation to cultivar and water regimen in all of the gel regions considered (Figure 3).

H Region. The progressive increase in percentage of the high-molecular-weight region (H) during grain development observed for both cultivars and under both water regimens agrees with Shewry et al.,[10] who found that the HMW-GS belonging to the H gel region accumulated slowly during the early and midgrowth stages and continued to accumulate until maturity. Both Ciccio[32] and Svevo[33] cultivars have a HMW-GS composition consisting of the 1Bx7 and 1By8 subunits that have been associated with good dough properties.[26,33,34] During grain filling, both cultivars showed a differential expression of these proteins in relation to the water regimen. In particular, Ciccio showed a down-expression of HMW-GS1Bx7 under WS at the milk (spot 40m), waxy (spot 40w), and physiological stages (spot 40p), with fold variations of 0.56, 0.83, and 0.87, respectively. In Svevo, both HMW-GS 1Bx7 and HMW-GS 1By8 were down-expressed at the milk stage (spots 43m and 66m), but over-expression was observed at physiological maturity (spots 43p and 66p) under water stress. Thus, in Svevo water stress seems to slow protein synthesis during the milk stage but to promote it at maturity; on the contrary, the effect of water stress on Ciccio was evident only for the 1Bx7 subunit, with a down-expression during the whole period of grain filling, which became more evident at the milk stage. Furthermore, Svevo showed a specific spot, not present in Ciccio, identified as a HMW-GS glutenin subunit encoded at locus *Glu-1B* allele *1Bx* (Tdu-e)[14] detected both in the waxy (spot 38w) and physiological stages (spot 38p). This protein was always down-expressed under WS condition, showing an opposite behavior with respect to the 1Bx7 subunit. However, because Svevo has only the pair of HMW-GS 1Bx7−1By8, it is likely that this protein spot is a procedure artifact.

[a]Fold variation: ratio stressed/well-watered.

I Region. The I region, mainly characterized by ω-gliadins encoded by genes at *Gli-1* loci (*Gli-A1* and *Gli-B1* in tetraploid wheat) and by D subunits of LMW-GS that are modified ω-gliadins,[35] showed a marked increase under water stress at maturity. In this region, a protein spot was expressed in both cultivars during the whole grain filling period; a train of spots was also observed, being more evident at physiological maturity under WS (Figures 1c,c_1 and 2c,c_1). In both cultivars, the protein spots have been identified at physiological maturity (98p and 96p) as ω-5-gliadin, known as Tri a-19, one of the main allergens in wheat-dependent exercise-induced anaphylaxis.[36] This protein was always overexpressed in Ciccio under WS, with a progressively increasing fold variation during grain filling (1.14, 1.46, and 1.75 at the milk, waxy, and physiological stages, respectively). Likewise, it was always overexpressed under WS in Svevo, particularly at the milk stage and at physiological maturity, with a similar fold variation (1.44 and 1.41, respectively). Hurkman et al.[11] also reported an increase in ω-gliadins under different environmental stresses. However, in the same region, a previous study[26] identified a train of spots having the same molecular weight but different p*I* values (shifted toward basic pH) as the globulin 3 protein encoded by the *Glo3A* gene. Train spots can occur due to deamidation of asparagine and glutamine residues,[37] the latter being abundant in gluten proteins. This globulin train spot showed an up-regulation under high temperature, in agreement with Altenbach et al.[38] and Laino et al.,[39] who reported increased globulin during grain development under high temperatures in both *T. aestivum* and *T. durum*. Moreover, Yang et al.[17] found an increase in one globulin in response to water stress.

L48−35 Region. The slight increasing trend in L48−35 percentage region volume observed for both cultivars during grain development agrees with Hurkman et al.,[11] who reported that although the majority of LMW-GS attained their maximum level at 28 DAA, a small group of these gradually increased throughout development and attained their maximum level at 37 DAA.

Relative to the effect of water stress on the L48−35 region, the higher percent values observed in the control with respect to water stress for both cultivars and at all developmental stages, suggest an inhibition of some LMW subunit expression under water stress. This result agrees with Hurkman et al.[11] and also with our previous studies,[26] which showed that high-temperature stress induced a down-expression of LMW proteins.

The L48−35 region included most of the LMW-GS encoded at the *Glu-A3* and *Glu-B3* loci, which correspond to the typical LMW-GS. The *Glu-B3* locus is of particular interest in durum wheat, because the proteins encoded at this locus are involved in the viscoelastic characteristics of durum wheat flour.[40,41] Both s-type and m-type LMW-GS are encoded at this locus, with s-type generally having a greater molecular weight than m-type.[42] LMW-GS encoded at the *Glu-B3* locus have been identified in both Ciccio and Svevo (spot 74p for Ciccio and spot 77m, for Svevo). Spot 74p has been identified as s-type LMW-GS classified as 42 k-like LMW-GS protein;[41] spot 77m has also been identified as LMW-2,[43] reported to be a major component of the glutenin fraction in some good-quality common and durum wheat cultivars.[43,44] The spot volume of this protein increased in both cultivars from the milk to the physiological maturity, with values ranging from 8.9 to 14.1 for Ciccio and from 7.1 to 14.3 for Svevo. Moreover, the behavior of this protein in the two cultivars differed in relation to water stress. In Ciccio, this protein did not vary with the water regimen in the milk stage (spot 74m); however, in the waxy and physiological stages it showed a down-expression under drought conditions (spots 74w and 74p, respectively). This protein was also down-expressed under WS in Svevo, but this behavior was more evident at the milk stage (spot 77m; fold variation = 0.56) than at the waxy (spot 77w; fold variation = 0.81) and physiological stages (spot 77p; fold variation = 0.9). This protein seems to be sensitive to environmental stress, because it resulted in down-regulation under high temperatures.[26] Another LMW-GS identified in both cultivars was an m-type LMW-GS[42] encoded by locus *Glu-B3*. This protein was significantly down-expressed in WS at physiological maturity in both Ciccio (spots 108m, 108w, and 108p) and Svevo (spots 92m, 92w, and 92p). In particular, spot volume tends to increase more from the milk to the physiological maturity stages under WW than under WS (Table 1), allowing us to suppose that water stress inhibits the synthesis of this protein. The volume increase observed during grain filling in WW agrees with Hurkman et al.,[11] who reported that m-type protein gradually increased throughout development and attained maximum levels at physiological maturity. The LMW-GS spot volume was higher for Ciccio than for Svevo (8.67 vs 7.36) at physiological maturity.

Spot 72 detected in genotype Ciccio and identified as a triticin overexpressed under WS (spots 72w and 72p) also belongs to this gel region. This minor storage protein is thought to be involved in the determination of flour quality because of the thiol−disulfide interchange during grain maturation when subjected to dehydration.[45] The literature reports that there are greater accumulations of triticins in superior quality wheat varieties than in lower quality genotypes.[46]

L<35 Region. The L<35 region percentage decreased progressively during grain development in both cultivars and under both water regimens. This was consistent with an increase in the glutenin percentage during grain filling. This result agrees with Kawaura et al.,[47] who analyzed in *T. aestivum* the expression patterns of gene families for α-gliadins based on the frequencies of expressed sequence tags (ESTs). The authors reported that α-gliadin genes from the A genome showed the highest expression level at 20 DAA and then decreased until 30 DAA. Abonyi et al.[48] also found a decrease in gliadin quantity in the final period of ripening, explained as possible

[a]Peptide sequences identified in spots with the highest sequence coverage; underlined amino acids show a deamination.

J. Agric. Food Chem. 2015, 63, 6501−6512
DOI: 10.1021/acs.jafc.5b01635

changes in their solubility caused by aggregation with polar lipids.

With regard to the effects of the water regimen, a higher protein expression was generally observed under water stress, in agreement with the literature, which reports a higher gliadin and gliadin/glutenin ratio under environmental stress during grain filling.[11] In fact, in this region several α-gliadins have been identified, which behave differently in relation to the water regimen. The α-gliadin identified in Ciccio (spots 702m, 702w, and 702p) was significantly overexpressed under WS at the milk and waxy stages, whereas no significant difference was found between the two water regimens at physiological maturity, which showed an effect of water stress on the synthesis of this protein only in the early−mid stage. Finally, the α-gliadin identified in Svevo (spots 212m, 212w, and 212p) was always overexpressed under WS, with a fold variation that decreased from the milk to the physiological maturity stages (fold variation = 1.39, 1.26, and 1.11).

Moreover, several gliadins associated with the immunological potential of wheat changed their expression in relation to the water regimen, especially in Svevo. An α-gliadin involved in wheat allergy[49] was identified in Svevo (spots 152m, 152w, and 152p) as overexpressed under WS at all three stages, especially at the waxy stage (fold variation = 1.43), allowing us to suppose higher synthesis of this protein under water stress, especially in the mid-development stage. Another α-gliadin (partial), known to contain the celiac disease-related T-cell stimulatory epitopes glia-α9 and glia-α20,[50] was identified in Svevo at the milk stage (spot 153), showing a slight overexpression under WS. This protein seems to match spot 206 at physiological maturity, because the molecular weight and isolectric point of the two proteins were very similar in our gel (Figure 2a,c). However, a different identification resulted for spot 206 identified as an α-gliadin, which does not contain epitopes recognized by these T cells.[51] This gliadin was also slightly down-expressed under WS.

The α-gliadin precursor identified in both Ciccio (spots 112m, 112w, and 112p) and Svevo (spots 200w and 200p) was recognized as an allergen involved in baker's asthma.[52] Under WS this protein was significantly overexpressed only in the waxy stage for Ciccio and at physiological maturity for Svevo. Thus, this gliadin was overexpressed under drought conditions in the mid and late developmental stages of the two cultivars under study.

Finally, under WS, the γ-gliadin identified in Ciccio (spots 156w and 156p) was significantly down-expressed only at physiological maturity. In the literature it has been reported that this particular γ-gliadin, with an odd number of cysteine residues, is able to form an intermolecular disulfide bond, thus incorporating this protein into the glutenin polymer fraction. For this reason, it is called γ-type glutenin and likely acts as a terminator of growing polymer chains by causing the molecular weight distribution of the glutenin polymer system to shift downward.[53] Moreover, this protein seems to be sensitive to environmental changes because its down-regulation under high-temperature conditions has been reported.[26]

In summary, the two durum wheat cultivars showed significant differences in the gluten proteome during grain development in relation to the water regimen. The HMW-GS region percentage increased progressively in both cultivars, showing a sharp increase under water stress at maturity in Svevo. In particular, water stress caused a down-expression of HMW-GS 1Bx7 in Ciccio during the whole grain-filling period, whereas in Svevo it seemed to promote the synthesis of the HMW-GS 7 + 8 pair at maturity. Down-expression of the L48−35 region was always observed under water stress, although the reactions of the two cultivars were different. In particular, both m-type and s-type LMW were always down-expressed under water stress; for the s-type LMW belonging to class 2, related to good durum wheat quality, Svevo showed a down-expression in the early−mid period (milk and waxy stages) and Ciccio in the mid−late period (waxy and physiological stages). Instead, for the m-type LMW, both cultivars showed a down-expression under water stress at the waxy and physiological stages. Finally, with regard to the L<35 region, a general increase was observed under water stress; furthermore, several α-gliadins associated with the immunological potential of wheat increased their expression under water stress, especially for Svevo in the early−mid stage. When the two cultivars were compared at physiological maturity, the H region was overexpressed in Svevo; this might be related to its higher protein content, which in the literature was associated with a higher HMW-GS/LMW-GS ratio.[13] Furthermore, Svevo showed an overexpression in the L<35 region and Ciccio in the L48−35 region, which may be responsible for Ciccio's superior gluten quality.

On the basis of these results, it is possible to draw the general conclusion that water stress affects gluten protein accumulation in the two cultivars at all developmental stages by causing an increase in gliadins and gliadin-like proteins (such as C- and D-subunits of LMW-GS) and a reduction in typical LMW-GS. Both an increase in gliadins with respect to glutenins and a higher amount of chain terminators, like C- and D-subunits of LMW-GS are known to negatively affect rheological properties.[54,55] Moreover, typical LMW-GS, especially those coded at the *Glu-B3* locus, are the most important factors determining dough quality and are down-regulated after water stress.

Taken all together, these results suggest that although there was not enough material available to perform predictive technological tests on the collected seeds, it is likely that the observed modifications of protein composition in water-stressed materials have negative effects on gluten quality.

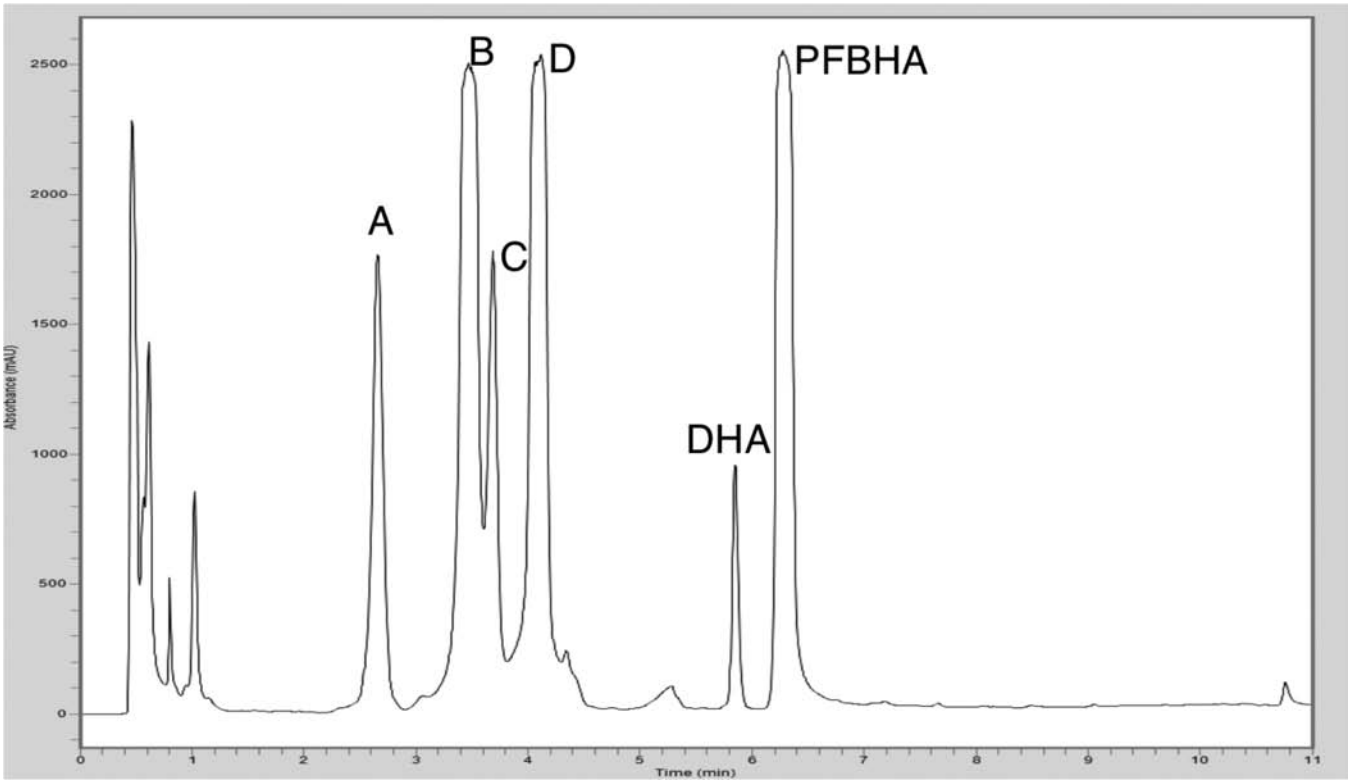

Figure 1. RP-HPLC chromatogram at λ = 200 nm of a *Leptospermum polygalifolium* sample obtained from the Sunshine Coast. The chromatogram shows a sharp peak for DHA derivative at 5.8 min. In contrast, sugar derivatives (A−D) showed high sensitivity and were unable to be accurately quantitated.

Herbarium Depository. Flower and shoot morphology were used to identify wild specimens to species level. Specimens were deposited in the Queensland Herbarium, Toowong, and identified by a chief botanist.

Chemicals. HPLC grade Milli-Q water was used in all analyses. HPLC Chromasolv gradient grade acetonitrile (ACN) was purchased from Merck (Kilsyth, Australia). *o*-(2,3,4,5,6-Pentafluorobenzyl) hydroxylamine hydrochloride (PFBHA) was purchased from Bio-Scientific (Gymea, Australia). Reagent grade citric acid, 1,3-dihydroxyacetone (DHA) (dimer, 97%), D-fructose 99+%, and β-D(+)-glucose 99+% were purchased from Sigma-Aldrich (Ryde, Australia).

HPLC Conditions. Analysis was conducted from an adapted Windsor et al.[20] method, via reverse-phase high-performance liquid chromatography (RP-HPLC) on a PerkinElmer series 200 HPLC with a Phenomenex Synergi Fusion column (75 mm × 4.6 mm, 4 μm particle size) and a Flexar photodiode array. Detection was set for 200 and 243 nm. Mobile phase A (MPA) was water 90%/ACN 10% (v/v), and mobile phase B (MPB) was ACN 100%. The pump program had a flow rate of 1.5 mL/min, with an injection volume of 20 μL. A gradient elution was employed: MPA/MPB = 95:5 (isocratic 0.5 min), 60:40 (gradient 4.0 min), 50:50 (gradient 2.0 min), 10:90 (gradient 2.0 min), 10:90 (isocratic 1.0 min), 95:5 (gradient 0.5 min), and 95:5 (isocratic over 1.0 min).

Preparation of Standards. Standard aqueous solutions of sugars or DHA were prepared with D-fructose (0.500 g) and D-glucose (0.500 g) dissolved in 50.0 mL of water and 0.050 g of DHA in 50.0 mL of water. DHA standards (0, 1, 2, 5, 10, 20, and 40 μL) were added to seven sugar standard solutions (200 μL), which gave DHA/total sugar mass ratios of 0, 250, 500, 1000, 2000, 5000, and 10000 ppm, respectively.

A PFBHA buffer solution was made with 0.20 g of PFBHA dissolved in 10. mL of 0.10 M citric acid buffer (pH 4). The DHA and sugar standards were derivatized quantitatively with 600 μL of PFBHA buffer solution at 65 °C for 2 h, prior to analysis via RP-HPLC as above. A calibration curve was constructed, whereby the known mass ratios (DHA/sugar ppm) were plotted against the peak area ratios of the DHA derivative (λ = 200 nm) to total sugar derivatives (λ = 243 nm).

Sample Preparation. Prior to analysis, thawed nectar samples were derivatized with 400 μL of PFBHA buffer solution and heated at 65 °C for 2 h. RP-HPLC analysis was performed as above, and peak area ratios of DHA (λ = 200 nm) to total sugars (λ = 243 nm) were obtained. The DHA/sugar ppm of individual samples was determined against the calibration curve by linear regression.

Statistical Analysis. The DHA/sugar ratio (ppm) for an individual tree (n) was the calculated mean of the replicated vials per tree. Differences in DHA/sugar concentration between species were analyzed with a Mann−Whitney U test with IBM SPSS (v.22).

RESULTS

Under the derivatization conditions, DHA formed a single compound, eluting at 5.8 min in Figure 1. The fructose and glucose formed four partially resolved derivatives by HPLC, 2.4−4.4 min in Figure 1. The multiple peaks were likely due to cis/trans isomers of the derivative oximes. Hence, total peak area measurements of sugars were used. Initial analysis of PFBHA derivatized sugars and DHA within nectar was performed at 259 nm. At this wavelength neither DHA nor sugars could be accurately quantitated as DHA had low sensitivity and sugars had high sensitivity. Peak sensitivity of DHA was increased 10-fold at 200 nm; however, the sugar peaks were saturated and unable to be accurately quantitated as shown by peaks A−D in Figure 1. In contrast, optimal sensitivity of the sugars was obtained at 243 nm, yet DHA showed poor sensitivity. Optimal sensitivity for both components was achieved when the peak area values were obtained at 200 nm for DHA and at 243 nm for sugars. The

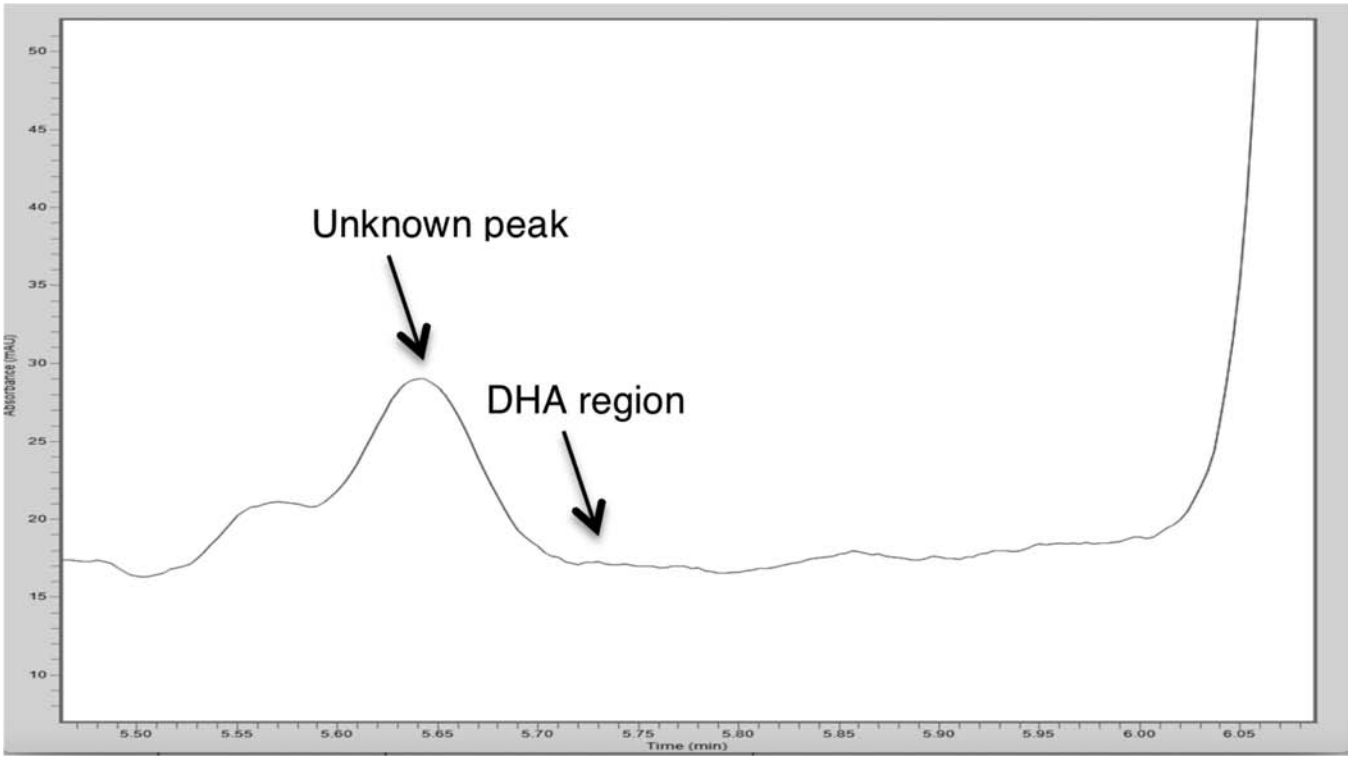

Figure 2. RP-HPLC chromatogram at λ = 200 nm of a *Leptospermum laevigatum* sample obtained from Northern Rivers. The chromatogram shows a broad peak of unknown 5.64 min, which eluted earlier than expected for DHA in relation to the sugars and derivative. No peak was observed in the DHA region.

Table 1. *Leptospermum* Nectar Samples Collected in Replicate from Individual Trees (n) between September and November 2014

	L. laevigatum		*L. polygalifolium*			*L. trinervium*		*L. whitei*	
	NR region	NWT region	NR region	SC region	NR region	SC region	PS region	NR region	SC region
trees (n)	37	1	22	4	22	2	1	10	3

seven standards showed a linear relationship between peak area ratio of DHA/sugar, at 200 and 243 nm, respectively against the known mass ratios of DHA/sugar (R^2 = 0.9982). Therefore, the mass ratio of DHA/sugar in individual samples was determined against the calibration curve by linear regression, as displayed by eq 1:

$$\text{DHA/sugar (ppm)} = \text{DHA/sugar (peak area ratio)} \times 11021 \quad (1)$$

DHA was present in all *L. polygalifolium* and *L. whitei* samples (Figure 1). In contrast, NR *L. laevigatum* samples showed a broad unknown peak with low absorbance at approximately 5.64 min, which eluted earlier than expected for DHA (Figure 2). To confirm whether the unknown peak was DHA, four *L. laevigatum* samples were spiked with 1 μL of DHA standard and analyzed again by RP-HPLC. A sharp DHA peak at 5.72 min was observed in the spiked runs, which verified that the unknown peak was not DHA (data not shown). To determine the identity of the source of the unknown peak, 400 μL of PFBHA buffer solution was analyzed via RP-HPLC alone. The unknown was observed on the chromatogram at 5.62 min, which suggested the unknown was a component within the derivatizing reagent (data not shown). DHA was not detected in any of the *L. laevigatum* samples collected from NR or NWT, nor was DHA detected in any of the *L. trinervium* samples collected from NR, SC, or PS (Table 1).

The DHA/sugar ratio in *L. polygalifolium* and *L. whitei* nectar samples varied between species (Table 2; Figure 3). The highest nectar activity levels were observed in the *L. whitei* samples, where the DHA/sugar ratio ranged from 10169 to 24199 ppm. In comparison, the nectar activity of *L. polygalifolium* ranged from 9321 to 20174 ppm. The data were not normally distributed; therefore, statistical analysis was performed with a nonparametric test. Differences in nectar activity between species were analyzed with a Mann−Whitney U test, which showed that there was a statistically significant difference between the DHA/sugar ratio of *L. polygalifolium* and that of *L. whitei* (U = 270; n_1 = 26, n_2 = 13; $P < 0.05$).

Table 2. Comparison of DHA/Sugar Concentration (ppm) between *Leptospermum polygalifolium* and *Leptospermum whitei* Nectar Collected at Sunshine Coast and Northern Rivers Sites

species	n	min	max	median	IQR
L. polygalifolium	26	9321	20174	12182	4741
L. whitei	13	10169	24199	15625	6909

DISCUSSION

The novel nectar extraction technique developed in this study has not to our knowledge been previously reported. Windsor et al.[20] reported successful analysis of PFBHA derivatized DHA and MGO in Australian *Leptospermum* honeys via RP-HPLC; hence, a modified version of this procedure was used to quantitatively derivatize the sugars and DHA in nectar. The PFBHA derivatization of DHA and sugars improved the chromatographic separation and detection of compounds. The method developed in this study was both rapid and convenient. The nectar solution extracted in situ was derivatized with PFBHA buffer solution upon analysis, and after 2 h at 65 °C, samples were analyzed directly with RP-HPLC and photodiode array detection. In addition, total sugars and DHA were analyzed within the one sample, via detection at two wavelengths. In contrast, the method described by Williams et al.,[15] which analyzed DHA/sugar in New Zealand *L. scoparium* by GC-FID and in Australian *Leptospermum* samples by GC-MS, had increased complexity and involved two separate procedures to detect DHA and sugars. Furthermore, Williams et al.[15] found that approximately 4% of DHA was transferred to the sample bag during flower collection. The method described in this study eliminates such loss, as nectar is deposited directly to the HPLC vial at the time of collection.

The results of this study indicated that perhaps not all species within the *Leptospermum* genus produce DHA within their nectar and, consequently, will not produce non-peroxide active honeys. The results showed that DHA was not detected in any of the *L. laevigatum* nectar samples, as illustrated by the sharp DHA peak when samples were spiked with 1 μL of DHA (data not shown). It was calculated that 1 μL of DHA standard was equivalent to approximately 300 ppm of DHA/sugar in nectar; therefore, it was conservatively estimated that all of the *L. laevigatum* nectar samples had a DHA activity level <100 ppm. No prior studies within the available literature have analyzed *L. laevigatum* nectar, apart from one sample analyzed by Williams et al.,[15] who were also unable to detect DHA. As DHA was also undetectable in the replicated NWT *L. laevigatum* samples, it appeared unlikely that lack of nectar activity was a result of environmental factors, as the NR and NWT samples were separated by approximately 1500 km. Moreover, this suggested that lack of bioactivity in *L. laevigatum* nectar is species wide. Similarly, DHA was not detected in any of the *L. trinervium* samples collected from the SC, NR, and PS regions. As a result, it was concluded that *L. trinervium* samples also had an activity level <100 ppm. No prior studies were found to have previously analyzed monofloral *L. trinervium* honey.

As *L. laevigatum*, *L. polygalifolium*, *L. trinervium*, and *L. whitei* flower at similar times of the year, beekeepers in NNSW target all four species to produce active honey. The results indicated that honey produced from *L. laevigatum* and *L. trinervium* nectar has a high probability of being inactive. Therefore, the findings suggested that beekeepers should avoid both species if they intend to produce active honey. Windsor et al.[20] detected DHA and MGO in *L. leavigatum* and blended *L. trinervium*/*Guioa semiglauca* honey, at low activity levels of <750 and <150 ppm, respectively. However, the presence of DHA may have been attributed to bees collecting nectar from other active *Leptospemum* species in flower at the same time, such as *L. polygalifolium* or *L. whitei*.

DHA was present in all *L. polygalifolium* and *L. whitei* nectar samples, yet nectar activity significantly varied between species. The *L. whitei* samples had the highest nectar activity (Table 2). No previous studies within the available literature have analyzed the DHA/MGO concentration or antibacterial activity of monofloral *L. whitei* honey. The environmental conditions at the sample sites were not quantitatively measured within this study. However, the *L. polygalifolium* and *L. whitei* trees sampled at SC and NR were believed to be wild populations in sandy, low-nutrient soils. It is possible that environmental factors, such as nutrient availability, may have contributed to the variation in nectar activity observed between species. Williams et al.[15] measured soil type, yet no correlation was found between soil type and nectar activity.

Williams et al.[15] classified nectar activity into three categories: low (<1000 ppm), moderate (1000−2000 ppm), and high (>2000 ppm). The study reported that the majority of nectar samples collected from *L. scoparium* trees over a two-year period had a moderate to low activity level. The highest observation was <9000 ppm from a garden cultivar from the Waikato region. In contrast, the lowest observations for *L. polygalifolium* and *L. whitei* in this study were >9000 ppm (Table 2). The high DHA/sugar ratios found in this study suggested that perhaps honey derived purely from *L. polygalifolium* or *L. whitei* may have higher bioactivity than mānuka honey. Research into the antibacterial activity of *L. polygalifolium* and *L. whitei* honey is recommended. In addition, it is possible that the results of this study may not be comparable to the values reported by Williams et al.,[15] due to method-related differences. Overall, the findings of the study have implications for beekeepers and the honey industry. Active honey is of high commercial value; therefore, the findings of this study indicated that Australian beekeepers should target *L. polygalifolium* and *L. whitei* if they intend to produce active honeys.

especially in quantifying calculations.[7,8] For instance, DVE1994 uses fermentable organic matter for these calculations, whereas DVE2010 uses a more complex approach considering a more detailed fractionation of feeds and differences in efficiency of microbial protein synthesis for different types of bacteria and different type of substrates for the rumen microbiota. The objective of the present study was to compare the DVE1994, DVE2010, and NRC-2001 systems in the prediction of truly absorbed microbial protein synthesis, rumen bypass protein, and endogenous protein loss, as well as total metabolizable protein from starchy and protein-rich raw feed materials.

MATERIALS AND METHODS

Chemicals. All chemicals used in this study were of commercial and analytical reagent grade. Sodium hydroxide (purity = 99%), sulfuric acid (purity = 98%), ethyl ether (purity = 99%), sodium borate ($Na_2B_4O_7{\cdot}10H_2O$; purity = 99.5%), sodium phosphate ($NaH_2PO_4{\cdot}H_2O$; purity = 95.5%), copper sulfate (purity = 99%), potassium sulfate (purity = 99%), acetone (purity ≥ 99.5%), thermostable α-amylase (180000 u/ML), ethylenediaminetetraacetic acid (purity = 99.4%), sodium borate (purity = 99%), disodium hydrogen phosphate anhydrous (purity = 99%), and triethylene glycol (purity = 99%) were purchased from Fardan Shimi (Mashhad, Iran).

Starchy and Protein Feedstuffs. Commonly used grains and protein-rich raw feed materials for dairy cattle, including barley, corn, triticale, wheat, soybean meal (SBM), sunflower meal (SFM), cottonseed meal (CSM), and canola meal (CM), were investigated. Samples from these feeds were provided by local distributers (Marvdasht, Fars province, Iran). Half of each sample was ground for laboratory analysis, and the half was stored as backup at −20 °C.

In Situ Incubations. The degradation characteristics of the feedstuffs were estimated with the in situ technique of Ørskov and McDonald,[9] as adapted by CVB (Netherlands Centraal Veevoeder Bureau),[10] but with 96 h instead of 336 h as the prolonged incubation time point. This study was conducted in two experimental runs and, in each run, the treatments were randomly assigned among the three Holstein dairy cows (weight = 605 ± 15.6 kg and 27 ± 2.5 kg/day milk production) fitted with a large rumen cannula with an internal diameter of 10 cm used for measuring rumen degradation characteristics. Cows were housed individually in the Dairy Research building at the Ferdowsi University of Mashhad, during in situ rumen incubation time. Cows were fed according to NRC 2001 recommendations for their milk production level. Ration was based upon corn silage, alfalfa hay, and mixed concentrate consisting of barley grain, corn grain, soybean meal, canola meal, cottonseed meal, micromineral premix, vitamin premixes A and D, limestone, and salt. Animals were fed in the form of TMR daily at 6:00 a.m., 2:00 p.m., and 10:00 p.m. right after milking. The incubation time points were 0, 2, 4, 8, 12, 24, 48, 72, and 96 h. The "gradual addition/all out" method was followed.[8] The 0-h samples were treated in the laboratory according to the procedure of Azarfar et al.[11] to determine the soluble and insoluble washable fractions. After incubation, bags were removed from the rumen and washed in a bucket with cold tap water to remove excess ruminal contents. Subsequently, bags were dried at 70 °C for 48 h. Dried samples were stored in a refrigerated cool room (4 °C) until analysis. The in situ data were fitted to the modified first-order kinetic equation[9,12,13]

$$R(t) = U + D \times e^{-K_d \times t}$$

where $R(t)$ = residue at t h of incubation (%), U = undegradable fraction (%), D = potentially degradable fraction (%), t = time of incubation (h), and K_d = degradation rate of potentially degradable fraction (%/h). In situ parameters were calculated with the NLIN (nonlinear) procedure of SAS.[14]

Chemical Analysis. Laboratory samples of the feedstuffs and rumen residues were prepared by grinding to pass a 1-mm screen. The dry matter (DM; AOAC official method 930.15), ash (AOAC official method 942.05), crude fat (EE; AOAC official method 954.02), and crude protein (CP; AOAC official method 984.13) contents were analyzed according to the procedures of AOAC.[15] The acid detergent fiber (ADF) and neutral detergent fiber (NDF) values were analyzed according to the procedures of Van Soest et al.[16] Neutral detergent fiber was determined without sodium sulfite.[16] The chemical composition and characteristics of these samples are provided in Table 1.

NRC-2001 Model. Calculating metabolizable protein is a summative approach based upon (1) digestible rumen undegradable protein (ARUP), (2) digestible microbial crude protein (AMCP), and (3) rumen endogenous CP (ECP) calculated as

$$MP = ARUP + AMCP + ECP$$

The amount of ruminally (un)degraded feed protein was calculated from crude protein content and ruminally (un)degraded feed protein proportion derived from in situ incubations as

$$RDP = S + D \times K_d/(K_p + K_d)$$

where S = soluble fraction (%), D = potentially degradable fraction (%), K_d = degradation rate of D fraction; and K_p = passage rate; a K_p of 6%/h was adopted.[3] The amount of ruminally synthesized microbial

DOI: 10.1021/jf505961e
J. Agric. Food Chem. 2015, 63, 6518−6524

protein (MCP) was calculated conditionally as 130 g/kg TDN. When RDP exceeded 1.18 × TDN-predicted MCP and was calculated as 0.85 of RDP, the RDP was <1.18 × TDN-predicted MCP. The amount of truly absorbed MCP was estimated assuming that true protein content and digestibility of rumen microbial protein both are 80%; therefore, the amount of truly absorbed MCP was estimated as

$$\mathrm{AMCP_{NRC}} = 0.80 \times 0.80 \times \mathrm{MCP}$$

For feed ingredients, truly absorbed rumen undegraded feed protein in the small intestine (ARUP) was calculated as the amount of RUP multiplied by the intestinal digestibility of RUP (dRUP), and rumen endogenous CP was calculated as

$$\mathrm{ECP} = 6.25 \times 1.9 \times \mathrm{DM}/1000$$

where DM is in g kg^{-1}. Assuming that 50% of rumen endogenous CP passes to the duodenum and 80% of rumen endogenous CP is true protein, the truly absorbed endogenous protein in the small intestine (AECP) was estimated as

$$\mathrm{AECP} = 0.50 \times 0.80 \times \mathrm{ECP}$$

Detailed information about the model is provided by NRC.[2]

DVE1994 System. Truly digested and absorbed protein in the small intestine (DVE1994) is contributed by (1) feed protein escaping rumen degradation (RUP), (2) microbial protein synthesized in the rumen (MCP), and (3) a correction for endogenous protein losses in the digestive tract (EPL). Therefore, the DVE value was estimated as

$$\mathrm{DVE} = \mathrm{ARUP} + \mathrm{AMCP} - \mathrm{EPL}$$

Rumen-undegraded protein from feedstuff (RUP) was calculated as

$$\mathrm{RUP} = 1.11 \times \mathrm{CP} \times \mathrm{RUP_{fraction}}$$

where

$$\mathrm{RUP_{fraction}} = U + D \times K_p/(K_p + K_d)$$

where U = undegraded fraction (%), D = potentially degradable fraction (%), K_d = degradation rate of D fraction, K_p = passage rate, which was assumed to be 6%/h. For feed ingredients, the content of truly absorbed bypass feed protein in the small intestine (ARUP) was calculated as

$$\mathrm{ARUP} = \mathrm{dRUP} \times \mathrm{RUP}$$

Microbial protein synthesized in the rumen (MCP) is considered to be 150 g/kg of organic matter fermented in rumen (FOM). The content of FOM was estimated from digestible organic matter minus the sum of ether extract, $\mathrm{RUP_{DVE}}$, undegradable feed starch in the rumen and fermentation products (not relevant for concentrated feedstuffs). Assuming that 25% of microbial protein N is in the form of nucleic acids, 75% of MCP was added to the undegraded feed protein (RUP) with assumed digestibility of 85%; therefore, the amount of rumen synthesized microbial protein truly absorbed in the small intestine (AMCP) was estimated as

$$\mathrm{AMCP} = 0.85 \times 0.75 \times \mathrm{MCP}$$

A correction is needed for protein losses due to incomplete digestion and from endogenous secretions.

The amount of undigested DM (UDM) that is excreted in the feces was used to calculate losses regarding digestive tract secretions, epithelial cells, and other endogenous protein sources which occur during the digestion process (EPL), calculated as

$$\mathrm{EPL} = 0.075 \times \mathrm{UDM}$$

where UDM was calculated as undigested organic matter (UOM) plus undigested ash (UASH).

More detailed information about the DVE1994 system is provided by Tamminga et al.[3]

DVE2010 System. As with the DVE1994 system, the DVE2010 system calculates the amount of digested true protein in the small intestine from various sources, and dairy cow requirements for protein are represented in DVE units. Several facets of the DVE1994 system such as feed components ruminal degradation, feedstuff fractionation, degradation rates of non-wash-out fraction, and efficiency of microbial protein synthesis were reappraised in the DVE2010 system. Detailed descriptions on concepts and formulas are presented by Van Duinkerken et al.,[6] and a brief explanation on calculation rules follows.

$$\mathrm{DVE} = \mathrm{ARUP} + \mathrm{AMCP} - \mathrm{EPL}$$

The quantity of feed protein not degraded in the rumen (RUP) and the intestinal digestibility of this rumen undegraded feed protein (dRUP) were used to estimate ARUP. ARUP is calculated as

$$\mathrm{ARUP} = \mathrm{CP} \times \%\mathrm{RUP}/100 \times \%\mathrm{dRUP}/100$$

The relative amount of RUP (%RUP) was calculated as

$$\%\mathrm{RUP} = K_{p,S}/(K_{d,S} + K_{p,S}) \times S + K_{p,W\text{-}S}/(K_{p,W\text{-}S} + k_{d,D}) \times (W\text{-}S) + K_{p,D}/(K_{p,D} + K_{d,D}))D + U$$

where S = crude protein soluble fraction (%); (W-S) = crude protein in washable but not soluble fraction, W = washable crude protein fraction (%); D = potentially degradable CP fraction (%) (D = 100 − W − U); U = undegradable crude protein fraction (%); $K_{p,S}$ = passage rate of the S fraction, assuming 11%/h; $K_{p,W\text{-}S}$ = passage rate of the W-S fraction, assuming 8%/h; $K_{p,D}$ = rate of passage from the rumen of the D fraction, assuming 6%/h for concentrates; $K_{d,S}$ = rate of degradation of CP in the S fraction in the rumen, assuming 200%/h; $K_{d,D}$ = rate of degradation of CP in the D and W-S fractions in the rumen (%/h).

Calculation of AMCP in the DVE2010 system is rather sophisticated and complex. It is assumed that within each chemical component, degradation and passage rates of different fractions determine how that component is degraded in the rumen as

$$\mathrm{FCOMP} = \mathrm{COMP} \times (S \times k_{d,S}/(k_{d,S} + k_{p,S}) + (W\text{-}S) \times k_{d,(7W\text{-}S)}/(k_{d,(W\text{-}S)} + k_{(p,W\text{-}S)}) + D \times k_{d,D}/(k_{d,D} + k_{p,D}))$$

where FCOMP is a component fermented in the rumen (g/g DM), COMP is the content of the relevant component (g/g DM), S represents the soluble fraction (g/g), $k_{d,S}$ is the fractional degradation rate of fraction S (/h), $k_{p,S}$ is the fractional rate of passage of fraction S (/h), W is the fraction that leaves nylon bags by washing (g/g), (W-S) is the insoluble portion in washout fraction (g/g), $k_{d,(W\text{-}S)}$ is the fractional degradation rate of fraction (W-S) (/h), $k_{p,(W\text{-}S)}$ is the fractional rate of passage of fraction (W-S) (/h), D is the non-wash-out potentially degradable fraction (g/g), $k_{d,D}$ is the fractional rate of degradation of fraction D (/h), and $k_{p,D}$ is the fractional rate of passage of fraction D (/h).

For each fraction in the FCOMP formula, DVE2010 considers a specific microbial protein yield. So the fermentable organic matter and MCP were calculated as the sum of FCOMP and its related microbial protein yield, respectively. It is assumed that 85% of microbial protein is truly digested, and therefore the amount of truly absorbed rumen synthesized microbial protein in the small intestine (AMCP) was estimated as

$$\mathrm{AMCP} = 0.85 \times 0.75 \times \mathrm{MCP}$$

A correction is needed for protein losses due to incomplete digestion and from endogenous secretions. For calculating endogenous protein losses during the digestion process (EPL), undigested ash (UASH) was added to undigested organic matter (UOM), which represents the amount of undigested DM (UDM) excreted in the feces, and EPL was calculated as

$$\mathrm{EPL} = 0.075 \times \mathrm{UDM}$$

Degraded Protein Balance. Degraded protein balance (RDPB) indicates the balance between microbial protein synthesis potentially possible from rumen degraded feed protein and available energy from total digestible nutrient, calculated as

$$\mathrm{RDPB} = \mathrm{RDP} - 1.18\mathrm{MCP}$$

DOI: 10.1021/jf505961e
J. Agric. Food Chem. 2015, 63, 6518−6524

Rumen degraded protein balance (OEB) in the DVE system (in Dutch, Onbestendig Eiwit Balans) represents the difference (at rumen level) between the maximum possible microbial protein synthesis, based on the available amount of degradable protein, on the one hand, and the maximum possible microbial protein synthesis, based on the available amount of energy, on the other.

$$\text{RDPB} = \text{MCPn} - \text{MCPe}$$

where MCPn = the maximum possible microbial protein synthesis based on available nitrogen and MCPe = the maximum possible microbial protein synthesis based on available energy.

Statistical Analysis. Statistical analyses were performed using the MIXED procedure of SAS 9.3 (SAS Institute, Inc., Cary, NC, USA) using the following model: $Y_{ij} = \mu + \alpha_i + e_{ij}$, in which Y_{ij} was an observation of the dependent variable ij, μ was the population mean for the variable, α_i was the effect of the treatments, and e_{ij} was the random error associated with observation of ij. The significance level for all statistical analyses was declared at $P < 0.05$ and trends at $P < 0.10$. Treatment means were compared using the Tukey test.

RESULTS AND DISCUSSION

The predictions of the potential protein supply (g kg^{-1} DM) to dairy cows from starchy and protein concentrates, using the DVE1994 system, NRC-2001 dairy model, and DVE2010 system are presented in Tables 2 and 3. DVE1994 predictions for ARUP for starchy and concentrates were higher than those of the NRC-2001 model (Table 4), which is in agreement with several previous studies.[17−20] In the DVE1994 system, a

correction factor of 1.11 (as in the French Protein System) was used for ARUP,[4] which represents the regression coefficient of in vivo on in situ degradation data, and in NRC model there is no correction for the difference between in vivo and in situ results.

Instead of this correction factor, in the DVE2010 system the wash-out fraction is divided into two fractions of soluble (*S*) and insoluble (*W-S*). It is assumed that a part of the soluble fraction (5%/h)[6] and the *W-S* fraction (not constant) escape degradation in the rumen and add up to the calculated amount of RUP.[6] The DVE2010 system and NRC-2001 model predicted more intestinally digestible microbial protein (AMCP) for both starchy and protein concentrates. Our results are in agreement with Yu,[21] who reported higher MP and lower protein degraded balance (PDB) estimation from NRC-2001 in comparison to DVE1994 lupin seeds, Damiran et al.[17] and Yu et al.,[8] who reported higher MP and lower protein degraded balance (PDB), predicted by NRC-2001 comparison to DVE 1994 for barley grain and Peng et al.,[18] who reported the same for camelina seeds. Gamage and Yu[22] compared the DVE2010 system with NRC-2001 in modeling metabolic characteristics of proteins in dairy cattle from wheat and wheat distillers dried grain and concluded that the DVE2010 system predicted higher truly absorbed rumen synthesized microbial protein, higher truly absorbed rumen undegraded feed protein, higher endogenous protein, higher total truly absorbed protein in the small intestine, and lower degraded protein balance in comparison with the NRC-2001 model. In the DVE1994 system, it is assumed that 100% of RDP is available for microbial protein synthesis in the presence of enough fermentable energy, whereas in the NRC-2001 model, it is assumed that only 85% of ruminally degraded feed protein could be potentially converted to microbial protein. This indicates assumed conversion rates from rumen degraded protein to microbial protein are different between NRC and DVE. Although the DVE2010 system also assumes that all of the RDP in the presence of sufficient energy could potentially form microbial protein, as mentioned earlier parts of the *S* and *W-S* fractions are considered to leave the rumen. Another source for differences is that NRC-2001 and DVE1994 use constant coefficients for prediction of microbial protein synthesis based on fermentable organic matter or TDN (150 g/kg fermentable organic matter vs 120 g microbial protein synthesis/kg TDN), whereas DVE2010 is a sophisticated model that uses a more dynamic approach for the prediction of microbial protein synthesis based on ATP.[6] This approach is based on the nature of the feed (concentrate vs forage), its components (crude protein, neutral detergent fiber, and etc.), fractions of each component (soluble, wash-out, etc.) and different microbial protein synthesis efficiency for different rumen bacteria (liquid associated bacteria vs particle associated bacteria).[6] Estimations based on the NRC-2001 model for ECP are lower than DVE system predictions of EPL for starchy and protein concentrates. There is a big difference in how endogenous protein loss is taken into account by the NRC-2001 model and DVE systems.

Estimations for endogenous protein loss by the NRC-2001 model for protein concentrates are less than DVE estimations, which is in agreement with several previous studies.[17,19,20,23] Endogenous protein loss is considered as a source of protein that partially can be used by animals in the NRC-2001 model, whereas the DVE system considers the endogenous protein loss as a total waste, which is replaced by a part of available protein in the small intestine, and considers the total balance of available protein.

The proportion of endogenous protein loss is very small compared to other contributors, and overall DVE (MP) estimations, especially in protein concentrates and DVE (MP), do not differ among the models for this type of feedstuff. Predictions for degradable protein balance (RDPB) from the NRC-2001 model are close to RDPB using DVE2010 for starchy concentrates and close to RDPB using DVE1994 for protein concentrates. The RDPB (OEB) value shows the (im)balance between microbial protein synthesis from available rumen degradable CP and potential energy from anaerobic fermentation in the rumen. When the OEB value is positive, it indicates the N-loss from the rumen. When negative, microbial protein synthesis is predicted to be impaired because of a shortage of N in the rumen. The optimum OEB value in a ration is therefore zero or slightly above.[3] The margin for safety is to allow for asynchrony—a factor important in feeding supplements to grazing animal or feeding an ingredient separately from the main basal feed.[8] The present study showed that all starchy feedstuffs had a negative (R)RDPB value predicted by all of the models, which indicates an imbalance between feed N degradation and utilization and indicates a potential shortage of N in the rumen. On the other hand, all of the protein concentrates, except CSM, had positive (R) rumen degraded protein balance (RDPB), which shows excess amounts of N in the rumen compared to ruminally available energy. In the case of CSM, the DVE system predicts a positive RDPB, whereas NRC-2001 estimates a negative RDPB. This is because energy estimations in NRC-2001 are based on TDN instead of fermentable organic matter and CSM contains relatively high amounts of digestible NDF and low amounts of RDP. Because the NRC-2001 model does not fully address many of the potential limitations in diets or management conditions, more complex models are needed to identify why some herds appear to underperform.[5] The DVE2010 system is a mechanistical model that incorporates data and concepts from fundamental research over past decades into a previous model (DVE1994) to overcome shortages in protein evaluation systems. It should be mentioned that, as quoted,[5] besides the advantages of mechanistic models, increased complexity may increase the risk of misuse. As complexity increases there is a potential for users to lose sight of the most important issues, and "hired" relationships may not be properly represented. Furthermore, more complex models require more time and money to specify the required variables.

In conclusion, predictions of the potential protein supply to dairy cows from starchy and protein concentrates are widely different among the tested models. The extent of differences in model predictions is not equal among different types of concentrates. Incorporation of new concepts into the DVE2010 model has a potential to improve predictions, although comparable direct measurements are needed to evaluate the actual ability of different models in predicting the potential protein supply to dairy cows from different feedstuffs.

MATERIALS AND METHODS

Chemicals. The fruiting body of *D. indusiata* was obtained from Zhijin, Guizhou Province, China. Ascorbic acid, sodium selenite (Na_2SeO_3), 5,5′,6,6′-tetraethylimida-carbocyanine iodide (JC-1), 2′,7′-dichlorofluorescein diacetate (DCFH-DA), 4′,6-diamidino-2-phenylindole (DAPI), diethyl pyrocarbonate (DEPC), thiazolyl blue tetrazolium bromide (MTT), bicinchoninic acid, and BCA kit were purchased from Sigma Co. (St. Louis, MO, USA). Human hepatocarcinoma HepG2 cell line, human pulmonary carcinoma A549 cell line, human cervical carcinoma HeLa cell line, human breast carcinoma MCF-7 cell line, and human prostate carcinoma PC3 cell line were obtained from American Type Culture Collection (ATCC, Rockville, MD, USA). Another two cell lines, human normal liver HL-7702 (L02) and human gastric carcinoma SGC-7901 cell line, were purchased from the Medical College of Sun Yat-Sen University (Guangzhou, Guangdong, China). Phosphate-buffered saline (PBS, pH 7.4), streptomycin and penicillin, heat-inactivated fetal bovine serum (FBS), and Dulbecco's modified Eagle's medium (DMEM) were purchased from Gibco Life Technologies (Grand Island, NY, USA). Substrates of caspase-3/7 (Ac-DEVD-AMC), caspase-8 (Ac-IETD-AFC), and caspase-9 (Ac-LEHD-AFC) were purchased from Calbiochem (La Jolla, CA, USA). The 6-well plate and 96-well plate were obtained from Corning Inc. (Corning, NY, USA). Sephadex G-200 and diethylaminoethyl (DEAE)-52 cellulose were purchased from GE Healthcare Life Science (Piscataway, NJ, USA). Ultrapure water was obtained from a Milli-Q water purification system (Millipore, Bedford, MA, USA). All other chemical reagents used in the present study were of analytical grade.

Preparation of DP1. The polysaccharide (DP1) was prepared according to our previous study.[21] Briefly, the natural polysaccharide (DP1) was extracted from the fruiting body of *D. indusiata* using water extraction at 100 °C for 2 h. Then the obtained crude extractions were deproteinated using the Sevage method and precipitated by 75% ethanol. The obtained sample was then sequentially purified by DEAE-52 anion-exchange chromatography and Sephadex G-200 column chromatography.

Preparation of DP1−Zn. Zinc chloride ($ZnCl_2$) was dissolved in distilled water (2 mg/mL). The pH value of the solution was adjusted to 2.0−3.0 by adding 400 μL of 0.3 M HCl solution until the solute was fully dissolved. Then the $ZnCl_2$ solution was mixed with DP1 solution (5 mg/mL) at the ratio of 1:1 (w/w) using a vortex mixer, and the pH value of the mixture was adjusted to 8.0 by NaOH (0.5 mol/L). The prepared mixture was incubated for 48 h at 50 °C in a reciprocating shaker bath. After incubation, the pH of the mixture was adjusted to 3.0, and the crude DP1−Zn chelating product was obtained. It was then subjected to purification by 3000 Da dialysis bag (Spectrum Medical Industries, Inc., Los Angeles, CA, USA) and then freeze-dried using vacuum freeze-dryer (R2L-100 KPS, Kyowa Vacuum Engineering, Tokyo, Japan) for 36 h to the DP1−Zn complex.

Characterization of DP1−Zn. The obtained DP1−Zn was characterized by SEM, model 1530VP, LEO, Oberkochen, Germany). SEM samples were prepared by drawing DP1−Zn solution and dropping on the slides. Then, samples were sputter-coated with gold and observed by SEM. EDX was taken on an EX-250 system (Horiba Ltd., Kyoto, Japan) to examine the elemental composition of DP1−Zn. The infrared spectra of DP1−Zn were analyzed on a FT-IR spectrophotometer (Bruker, Ettlingen, Germany) in the range of 400−4000 cm^{-1}. The synthesized DP1−Zn was further characterized by UV−vis spectrophotomtry (Cary 219 UV−vis double-beam spectrophotometer) for comparison ranging from 200 to 800 nm.

Cell Lines and Cell Culture. The human cell lines used in the present study were maintained in DMEM supplemented with penicillin (100 units/mL), fetal bovine serum (10%), and streptomycin (50 units/mL) at 37 °C in a humidified incubator with 5% CO_2 atmosphere.

Analysis of Cell Viability Using MTT Assay. The antiproliferative activity of DP1−Zn on the selected human cell lines (HepG2, MCF-7, SCG-7901, A549, HeLa, PC3, and L02) was analyzed using the MTT assay.[22] Cells were seeded in 96-well plates at a density of 3×10^3 cells/well. After incubation for 24 h, each well was treated with different concentrations of DP1−Zn (62.5, 125, and 250 μg/mL) and then incubated for 48 h. Cells without treatment of DP1−Zn was used as the control group. The medium was then replaced by MTT (0.5 μg/mL, 200 μL, in PBS) and cultured for 4 h, the supernatant fluid was removed, and the formazan was dissolved in DMSO (100 μL). The plates were placed on a multiplate reader using a test wavelength at 570 nm by Versasax microplatereader (Molecular Devices, Sunnyvale, CA, USA). The cytotoxicity of DP1−Zn was demonstrated by percentage of cell viability (absorbance) of treated cell (A) to the control cell (B), as the following formula:

$$\text{cell viability}\ (\%) = A/B \times 100\%$$

Analysis of Nuclear Morphology Using the Hoechst 33258 Assay. MCF-7 cells were seeded in a 6-well culture plate at 37 °C. The supernatant was removed after 24 h, and the cells were treated with DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h. Then the cells were harvested by centrifugation, washed twice with PBS, and fixed with methanol (4%) at 4 °C for 10 min. After that, the cells were centrifuged, washed, resuspended, and smeared on a glass slide. Staining was performed with Hoechst 33258 for 10 min at room temperature in the dark. Slides were then washed with deionized water and observed under a fluorescence microscope (Nikon Eclipse 80i) with the excitation and emission wavelengths at 345 and 460 nm, respectively.

Analysis of DNA Fragmentation. After the treatment with DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h, MCF-7 cells were accumulated, washed with PBS, and then lysed in lysis buffer (10 mM Tris-HCl, pH 7.5, 10 mM EDTA, 0.5% Triton X-100, 500 μL) . The cell lysates were then dissolved in RNaseA (200 mg/mL) for 1 h at 37 °C and treated with proteinase K (200 mg/mL) for 1 h at 55 °C. DNA was extracted by ethanol from samples and isolated in isopropyl alcohol, and then sodium acetate (0.3M, in 2 volumes of ethonal) was add to precipitate the DNA at −20 °C. Finally, the ethidium bromide (1 mg/mL) stained DNA fragmentations were analyzed via examination of electrophoretic mobility on 2% agarose gel, and the results were visualized by UV transilluminator (Tanon 1600; Tanon, Shanghai, China).

Analysis of Apoptosis and Cell Cycle Arrest Using Flow Cytometry. The apoptosis of MCF-7 was analyzed by flow cytometry using an annexin V-FITC/PI apoptosis detection kit. Cells treated with or without DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h were harvested by trypsinization and washed with PBS three times. Then the cells were resuspended by binding buffer and divided into two groups. Annexin V conjugated with FITC was added to one group of cell suspension, and the suspensions were incubated for 15 min in the dark. The other group of the cell suspension was used as the blank control. Then propidium iodide (PI) was added into each sample, and the stained cells were analyzed by flow cytometry under 488 nm excitation wavelength. The signal from FITC was read at 516 nm, whereas the signal from PI was read at 560 nm. The data were collected and analyzed by the Cell Quest Research Software (Becton Dickinson).

The cell cycle distribution of MCF-7 was monitored in flow cytometry by PI staining method. MCF-7 cells treated with DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h were harvested by trypsinization and washed with PBS three times. The treated cells were stained with PI contained with RNase in the dark after fixation by 70% alcohol solution (−20 °C, overnight). Labeled cells were washed twice with PBS and analyzed by flow cytometry. For each sample, 10000 events were recorded. Cell cycle distribution was determined by the amount of PI intercalated to DNA and analyzed by Cell Quest Research Software.

Analysis of Mitochondrial Membrane Potential (ΔΨm). The ΔΨm of MCF-7 cells was determined by JC-1. JC-1 is a lipophilic and cationic fluorescence probe, which exists as a monomer (green) at low membrane potential or forms red fluorescent aggregates at higher potential. MCF-7 cells were seeded in 6-well plates (1×10^5 cells/well), followed by a 48 h treatment with DP1−Zn at different

concentrations (62.5, 125, and 250 μg/mL). Then the cells were trypsinized, suspended, and dyed in PBS buffer containing JC-1 dye (20 μg/mL) at 37 °C for 15 min in the dark. After removal of JC-1 dye, the cells were washed with PBS and resuspended in PBS (0.5 mL). The percentages of pure red and green fluorescence intensity were tested by flow cytometry analysis. The excitation was set at 488 nm, with the emission at 525 nm for green fluorescence detection and the other emission at 590 nm for red fluorescence. The fluorescence intensity of JC-1 stained was determined using a fluorometer (Thermo Electron Corp., Vantaa, Finland). Finally, the stained cells were also observed using a fluorescence microscope with argon-ion 488 nm laser excitation (Nikon Eclipse 80i, Nikon, Tokyo, Japan).

Assay of Reactive Oxygen Species (ROS) Generation. The effect of the DP1−Zn on ROS generation was determined by using DCFH-DA method reported by Wang and Joseph[23] with some modifications. In the method, the stable nonfluorescent DCFH-DA is hydrolyzed by esterases in cells to nonfluorescent DCFH, and the product is rapidly oxidized by peroxy radicals to highly fluorescent 2′,7′-dichlorofluorescein (DCF), which provides a quantitative assay of ROS formation with fluorometric analysis and microscopic fluorescence. In the current study, MCF-7 cells, which were treated with different concentrations of DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h in advance, were seeded in 6-well plates (1×10^5 cells/well), and then they were washed with PBS and incubated with DCFH-DA (10 μM) in a 37 °C non-CO_2 incubator for 30 min. After being incubated with DCFH-DA, the cells were washed with PBS, lysed, and centrifuged (3000*g*, 10 min) in turn, and then a 200 μL supernatant was harvested and transferred to a 96-well plate. For fluorometric analysis, fluorescence of the MCF-7 cells was determined by using a fluorometer with the excitation and emission wavelengths at 485 and

520 nm, respectively; for the visual image of ROS generation, the fluorescence was visualized by using a fluorescence microscope (Nikon Eclipse 80i) with the excitation and emission wavelengths at 485 and 520 nm.

Caspase Activity Assay. Caspase activity was use to confirm the existing of caspase-dependent apotosis in cell induced by DP1−Zn, and it was monitored by fluorometric method. MCF-7 cells were treated with different concentrations of DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h and harvested as mentioned above. Harvested cell pellets were suspended in cell lysis buffer and incubated on ice for 1 h. After centrifugation (11000*g*, 30 min), supernatants were isolated, collected, and measured for protein concentration immediately by a BCA kit. For caspase activity assay, the cell lysates were placed in 96-well plates and mixed with the specific caspase substrates (Ac-DEVD-AMC for caspase-3/7, Ac-IETD-AMC for caspase-8, and Ac-LEHD-AMC for caspase-9). Plates were then incubated at 37 °C for 1 h, and the caspase activity was determined by fluorescence intensity with the excitation and emission wavelengths at 380 and 440 nm, respectively.

Statistical Analysis. The preparation of DP1−Zn was repeated three times, and the structure and bioactivity assays were done in triplicate for each sample. Results were expressed as the mean with standard deviation. Statistical analysis was performed using SPSS 19.0 software (IBM Corp., Armonk, NY, USA). The difference between the control and the experimental groups was analyzed by two-tailed Student's *t* test. Differences with $P < 0.05$ were considered statistically

significant. The differences among three or more groups were analyzed by one-way ANOVA multiple comparisons.

RESULTS AND DISCUSSION

Preparation and Characterization of DP1−Zn Complexes. In this study, DP1−Zn complexes were successfully synthesized by the reaction of polysaccharide DP1 and zinc chloride. As can be seen from the SEM images, the polysaccharide DP1 showed flocculent and filamentous structure (Figure 1A), whereas after a Zn atom was coupled to the polysaccharide, the formed DP1−Zn complexes exhibited a totally different blocky structure (Figure 1B). The elemental compositions of DP1 and DP1−Zn were investigated using EDX. As compared with DP1 (Figure 1C), a certain level of Zn atoms (6.28%) was observed in the DP1−Zn sample, together with the other two elements, C (61.09%) and O

DOI: 10.1021/acs.jafc.5b00614
J. Agric. Food Chem. 2015, 63, 6525−6534

(32.63%) (Figure 1D). This indicated that Zn has been successfully conjugated to DP1 with a conjugation rate of 6.28%.

The chemical binding of DP1 and Zn atom was further characterized by FT-IR (Figure 1E). It was found that the chelation of Zn with DP1 mainly through the additional absorptions at 1537 and 2007 cm^{-1} corresponded to a nitro group and an aromatic ring. Additionally, the peaks correspond to the stretching vibrations of hydroxyl groups shifted from 3374 to 3497 cm^{-1}, and the absorptions at 2928−2965 cm^{-1} correspond to the vibrations of CH bonds. All of these changes could be due to the formation of Zn−O bonds and physical absorption in the complexes.

Antiproliferative Activity of DP1−Zn. The antiproliferative activity of the DP1−Zn complex on the selected human cells was evaluated by MTT assay. As shown in Figure 2A, DP1 itself had no cytotoxicity on normal cells (human normal hepatocyte L02). Also, most of the cancer cells tested in this study, for example, SCG-7901, A549, HeLa, and PC3, were not sensitive to DP1. As a comparison, MCF-7 cells were more susceptible to DP1 treatment in a dose-dependent manner. As for DP1−Zn (Figure 2B), it was found that a low concentration (62.5 μg/mL) of DP1−Zn had no significant effect on all kinds of cells, but further increase of its concentration to 250 μg/mL could noticeably inhibit MCF-7 cell growth in a dose-dependent manner. Among all of the under-tested cancer cells, the lowest cell viability (18.13%) was observed for MCF-7 cell treated by 250 μg/mL DP1−Zn. For human normal cell line L02, the treatment of DP1−Zn (250 μg/mL) did cause a certain level of cell apoptosis, but it was much safer as compared to the cytotoxicity on cancer cells. Hence, the result suggested that the cytotoxicity of DP1−Zn was cancer-specific. On the basis of the above results, MCF-7 cells were chosen as the targeted cell line to further evaluate the antitumor activity of DP1−Zn.

Induction of Apoptosis by DP1−Zn. Apoptosis is genetically regulated cell demise in living tissues that can be induced by many specific stimuli. Pro-apoptosis is thought to be the key mechanism for antiproliferative action of drugs against cancer cells.[24−26] The process of apoptosis is generally characterized by some distinct morphological characteristics including cytoplasmic and nuclear condensation, DNA breakage, membrane dysfunction, cell cycle arrest, and loss of microvilli. In the present study, the inner changes of the cell nucleus induced by DP1−Zn were analyzed using a DNA-specific fluorochrome (Hoechst 33258). The fluorescence intensity was proportional to the degree of nuclear chromatin condensation. As indicated in Figure 2C, MCF-7 cells treated with DP1−Zn exhibited an increase of fluorescent brightness in a dose-dependent manner. At the concentration of 250 μg/mL, some highlight dyeing areas were found (see the white arrows in Figure 2C), which was an indication of the late-stage apoptosis of cancer cells. These results suggested that apoptosis was involved in the antiproliferative action of DP1−Zn.

DNA fragmentation is one of the hallmarks of apoptosis. The chromosomal DNA was cleaved by specific DNases when the cells suffered apoptotic stimuli. The pro-apoptosis action of DP1−Zn was further confirmed by DNA fragmentation. The total DNA of MCF-7 cells treated with or without DP1−Zn (62.5, 125, and 250 μg/mL) was extracted and analyzed by 2% agarose gel electrophoresis. As shown in Figure 2D, "DNA ladders" were found in the lanes of the samples treated with DP1−Zn. The tail intensity and tail migration of the DNA ladders were significantly aggravated with the increment of DP1−Zn concentration, which indicated that DP1−Zn triggered DNA damage in a dose-dependent manner.

The apoptosis rates and apoptosis period of MCF-7 cells induced by DP1−Zn were investigated using flow cytometric analysis. The results of annexin V-FITC/PI staining assay are shown in Figure 3A; DP1−Zn showed a noticeable effect on the proportion of early apoptotic cells. MCF-7 cells treated with DP1−Zn (62.5 μg/mL) had a significant increase in the proportion of early-stage apoptosis cells (12.71%) compared with the control group (2.27%). A more obvious enhancement was obtained for cells treated by 125 μg/mL DP1−Zn (26.75%) and 250 μg/mL DP1−Zn (58.72%), respectively. Additionally, the ratio of late apoptosis in MCF-7 cells did not show distinct changes. These results proved that the inhibitory effect of DP1−Zn on MCF-7 cell proliferation was mainly in early-stage apoptosis, manifesting the potential application of DP1−Zn as effective anticancer supplements or drugs.

Effects of DP1−Zn on Cell Cycle Arrest. Cell cycle is a repeated round of cell duplication and growth; it is thought that cell proliferation is mainly regulated by cell cycle arrest and apoptosis.[27,28] The effects of DP1−Zn on cell cycle arrest were investigated by PI-flow cytometric analysis. The cell cycle distribution histograms of MCF-7 cells are shown in Figure 3B and Table 1. The results demonstrated an increase in the proportion of S phase arrest of MCF-7 cells with the increment of DP1−Zn concentration. It was 37.28% in the control group and increased to 43.93% after 250 μg/mL DP1−Zn treatment. Besides, no significant change in G0/G1 phase was observed in the treated cells, whereas the percentage of G2/M phase arrested cells was decreased accompanied by the increase of S phase arrested cells. Thus, the antiproliferative effect of DP1−Zn was regulated mainly by S phase cell cycle arrest.

Table 1. Effect of DP1−Zn on MCF-7 Cells in Cell Cycle Pattern

		DP1−Zn		
dip of MCF-7 cells (%)	control	62.5 μg/mL	125 μg/mL	250 μg/mL
G0/G1	45.9	45.1	45.5	48.8
S	37.3	42.0	42.1	43.9
G2/M	16.8	12.9	12.4	7.27

DP1−Zn Induced Cell Apoptosis via Mitochondrial Dysfunction. Mitochondrial dysfunction has been shown to play a central role in the induction of apoptosis. Loss of mitochondrial membrane potential (ΔΨm) is an early event in the apoptotic process.[29] In this study, the changes of mitochondrial membrane potential in MCF-7 cells were analyzed by flow cytometry analysis via JC-1 staining. The mitochondrial stain JC-1 can spontaneously aggregate as J-aggregates, which will emit red fluorescence at high membrane potential in healthy cells, whereas in the apoptotic cells, JC-1 would remain green fluorescent monomers due to mitochondrial membrane depolarization.[30] The changes of ΔΨm in MCF-7 cells induced by DP1−Zn are shown in Figure 3C. The mitochondrial membrane potential of MCF-7 cells was remarkably reduced with the increment of DP1−Zn concentration. Compared with the control group, the proportion of the green fluorescence of cells treated with 62.5 μg/mL DP1−Zn increased from 2.66 to 16.95%, and it further increased to 34.96% (125 μg/mL) and 94.33% (250 μg/mL), respectively. The reduction of ΔΨm was further confirmed by a fluorescence

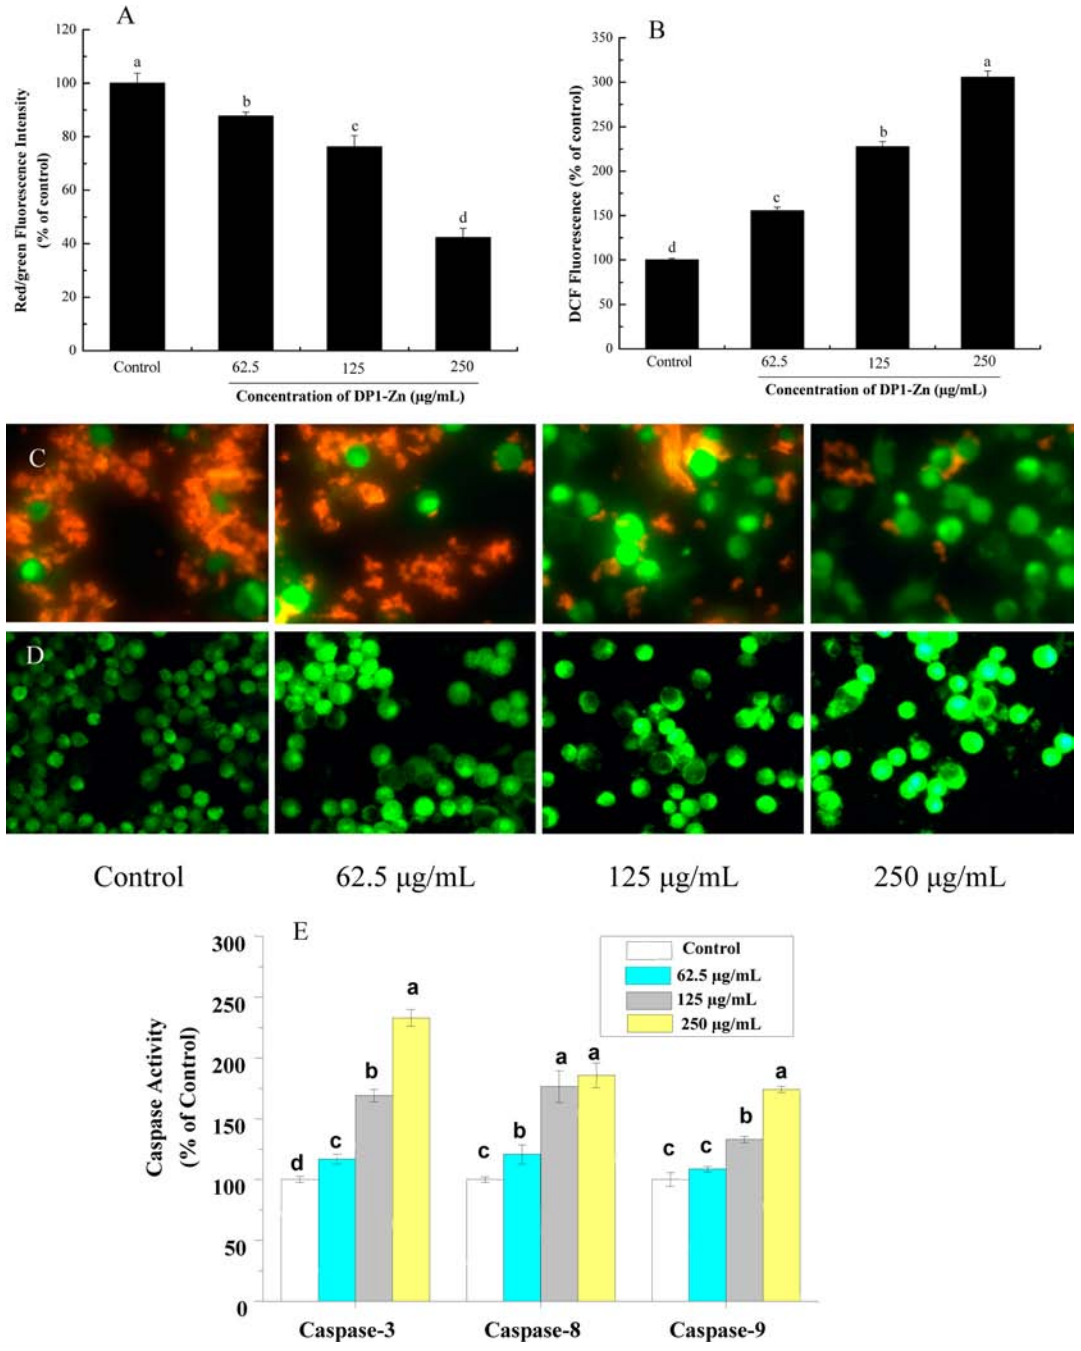

Figure 4. (A) Red/green fluorescence intensity of JC-1 stained MCF-7 cells induced by DP1−Zn. MCF-7 cells were treated with different concentrations of DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h and stained by JC-1. (B) Intracellular ROS level of MCF-7 cells after treatment with DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h. (C) JC-1 staining images after treatment with DP1−Zn (62.5, 125, and 250 μg/mL) for 48 h. (D) ROS generation images under a fluorescence microscope after treatment with DP1−Zn (62.5, 125, and 250 μg/mL) for 2 h. (E) Activation of caspase-3, -8, and -9 in MCF-7 cells incubated with DP-Zn for 24 h.

microscope, as shown in Figure 4C; an increment of green fluorescence and decrement of red fluorescence in MCF-7 cells were clearly observed after treatment with DP1−Zn. The red/green fluorescence intensity ratios decreased by 87.10, 76.18, and 42.22% after treatment with 62.5, 125, and 250 μg/mL DP1−Zn, respectively (Figure 4A). These results indicated that treatment of DP1−Zn induced the reduction of mitochondrial membrane potential, which facilitated the apoptosis of MCF-7 cells.

DP1−Zn Induce Cell Apoptosis Due to ROS Overproduction. Intracellular ROS, such as superoxide anion, singlet oxygen, hydroxyl radical, and hydrogen peroxide, are generated as byproducts in the process of aerobic metabolism. Overproduction of ROS may result in oxidative damage of DNA and mitochondrial dysfunction and eventually lead to cell apoptosis.[21,31] The intracellular ROS level of MCF-7 cells was measured using DCFH-DA (a fluorescein-labeled dye). DCFH can be oxidized into a highly fluorescent compound, DCF, with the presence of ROS. The fluorescence intensity of oxidized DCF was proportional to the level of ROS. As shown in Figure 4D, the fluorescence intensity increased in a dose-dependent manner after treatment with DP1−Zn (62.5, 125, and 250 μg/

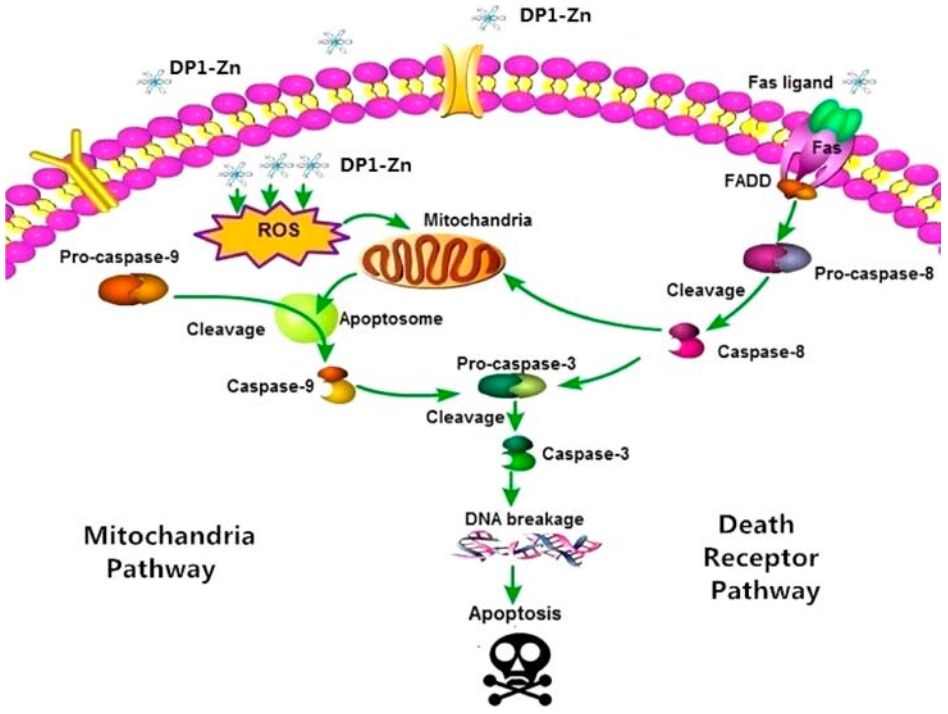

Figure 5. Possible pro-apoptotic mechanisms of DP1−Zn in MCF-7 cells.

mL). Compared with the control group, the DCF fluorescence intensity was increased by 155.04, 226.98, and 305.10% after exposure to 62.5, 125, and 250 μg/mL DP1−Zn, respectively (Figure 4B). Thus, ROS overproduction induced by DP1−Zn might directly lead to DNA breakage, mitochondrial dysfunction, and apoptosis in MCF-7 cells.

Caspase Activation Was Involved in the DP1−Zn-Induced Apoptosis. Caspases are a group of cysteine proteases that are specifically activated in the process of cell apoptosis. They are suggested to be the central executioners of apoptosis. Caspases involved in apoptosis can be divided into initiator caspases (caspases-2, -8, -9, and -10) and effector caspases (caspases-3, -6, and -7). To determine whether caspase activation was involved in the DP1−Zn-induced apoptosis, the activities of initiator caspases (caspases-8 and -9) and the effector caspase-3 were examined by fluorometric assays. As shown in Figure 4E, the activities of caspases-3, -8, and -9 in MCF-7 cells were significantly increased after treatment with DP1−Zn (62.5, 125, and 250 μg/mL, respectively). These enzymes were triggered in response to proapoptotic signals and culminate in cleavage of a set of proteins, resulting in disassembly of the cell.[32] The upstream caspases-8 and -9 are activated via recruitment of signaling complexes that are known as the initiator caspases; they provide a link between cell signaling and apoptotic execution.[33] The activation of downstream caspase-3 depends on the activition of initiator caspases-8 and -9 by transprocessing. These caspases act as the executioner of apoptosis due to the processes of their substrates leading to morphological changes associated with apoptosis, such as DNA degradation, chromatin condensation, and membrane blebbing.[34,35] As a result, the activation of caspases-3, -8, and -9 plays a crucial role in the apoptosis of MCF-7 induced by DP1−Zn.

Zinc is an essential trace element with various physiological functions. Recent evidence has shown that the main chemical forms of zinc in the human body are organic zinc complexes. The organic zinc exhibits higher bioavailability and fewer toxic side effects as compared with inorganic zinc. In this study, a novel organic zinc complex DP1−Zn was successfully prepared by using the chelation of *D. indusiata* polysaccharide (DP1) with zinc chloride, to achieve enhanced bioavailability and reduced toxicity.

The obtained DP1−Zn complexes showed notable antiproliferative effect on the selected human cancer cells through the induction of apoptosis. The DP1−Zn-induced apoptosis was associated with nuclei condensation, DNA fragmentation, S phase cell cycle arrest, and mitochondrial dysfunction. Further study found that the activation of caspases-3, -8, and -9 and ROS overproduction were also involved in the process of DP1−Zn-induced apoptosis. Therefore, the antiproliferative activity of DP1−Zn was via both caspase-dependent and mitochondria-mediated apoptotic pathways, as illustrated in Figure 5. We can infer that the possible molecular mechanism of DP1−Zn-mediated apoptosis may be mainly through two signaling pathways: One is through the extrinsic apoptotic pathway, because DP1−Zn treatment promotes the activation of caspase-8, which consequently activates the downstream caspase-3. Another way is via the intrinsic apoptotic pathway, as DP1−Zn treatment induced the dysfunction of mitochondrion, leading to the activation of caspases-9 and -3. Ultimately, these pathways resulted in the induction of apoptosis.

Overall, the design of DP1−Zn complexes gave a new idea and a new theoretical basis for the synergistic effects of DP1 and Zn as anticancer factors. This antiproliferative activity on cancer cells could be considered as a first screening, and further in vivo animal tests could be taken into consideration for the actual effectiveness of DP1−Zn on cancer prophylaxis and therapy.

involved in the development of coronary heart disease, by 10% at 25 μM.[11] R3S, R3G, and R4G could be shown to reduce colon cancer cell growth at 10−50 μM.[10] Also, as recently shown by Walker et al.,[12] R3S, at a concentration as low as 1 μM, lowered IL-6 expression by 57.8% in an in vitro model of stimulated human macrophages after 6 h of co-incubation with *Escherichia coli* lipopolysaccharides (1 μg/mL). Lipolysaccharide (LPS) from the outer membrane of bacteria is widely used for in vitro studies on inflammation because it activates the NF-κB signaling cascade in the host tissue.[13] Down-stream of NF-κB activation, the CC motif chemokines monocyte chemotactic protein-1 (MCP-1 = CCL2) and macrophage inflammatory protein 1 beta (MIP-1b = CCL4) and the CXC motif chemokine interleukin 8 (IL-8 = CXCL8) and chemokine receptors CXCR2 (transcript variants 1 and 2, CXCR2var1/2), CCR1, and CCR2 are important factors in triggering immune cell trafficking and infiltration from the bloodstream into tissues via chemotaxis, but also enhance local cell activation and proliferation of inflamed tissue and immune competent cells, leading to disease progression.[14,15] Another factor involved in inflammatory processes is the deacetylase Sirtuin-1 (SIRT1), a member of the silent mating type information regulation 2 enzyme family. SIRT1 inhibits NF-κB transcription and is down-regulated in response to LPS.[16] Thus, an up-regulation of SIRT1 results in decreased levels of pro-inflammatory cytokines.[16]

The ability of phenolic dietary compounds to inhibit immune cell migration has been shown in vivo, in a model of allergic airway inflammation in mice, where intraperitoneal epigallocatechin-3-gallate (10 mg/kg body weight for 4 days) potently reduced infiltration of immune cells and was able to inhibit migration of Th1 cells in vitro by 30−50% at a concentration of 1 μM via direct interaction with CXC motif chemokines.[17] RES has also been demonstrated to inhibit monocyte recruitment into endothelium via inhibition of adhesion over a concentration range 0.3−10 μM in vitro.[18] Furthermore, RES inhibited mRNA expression of CCR2 in THP-1 monocytes by 12% after 6 h of treatment and blunted monocyte recruitment on vascular endothelia at a concentration of 10 μM.[19] As for RES metabolites, in an enzymatic study, SIRT1 was activated to the same extent by RES, R3S, and RES-4′-*O*-sulfate over a concentration range from 10 to 500 μM, resulting in attenuated cytokine levels in vitro.[20] In a mouse model of colitis, in which a dose of 100 mg RES/kg body weight was administered for 7 days, the induction of SIRT1 has been linked with attenuated cytokine levels in vivo.[21] Considering the low bioavailability of free RES in vivo, those effects could very likely be caused by present metabolites. Therefore, this in vitro study investigates the effect of RES and its main physiological metabolites on immune chemotactic genes and proteins, as well as SIRT1, in differentiated human U-937 macrophages (U-937 Mϕ). Macrophages were activated with LPS from *Porphyromonas gingivalis* (pgLPS), an oral pathogen responsible for disease progression in periodontitis.[22] Macrophages are exposed to dietary substances either directly during ingestion or via the bloodstream. As the parent compound RES is barely bioavailable after dietary intake, we aimed to identify the potential of RES metabolites, each of which may have the same or higher benefit than the parent compound. Considering plasma metabolite concentrations after intake of dietary-scale doses, in this study, we deliberately used compounds at only 1 μM. The glucocorticoid dexamethasone (DEX), which is known to suppress inflammation via the NF-κB pathway, was used as anti-inflammatory control at 100 nM.[23] Here, we show for the first time the attenuating impact of main physiological RES metabolites on genes involved in macrophage activation and recruitment (chemokines IL-8, MIP-1b, MCP-1, and chemokine receptors CXCR2var2, CCR1, and CCR2) on mRNA and protein levels, as well as their effects on SIRT1 gene expression. Our findings may contribute to the development of more potent nutraceuticals and adjuvants in local and systemic inflammatory diseases containing RES and/or conjugates thereof.

MATERIALS AND METHODS

Chemicals. Methanol (MeOH) of HPLC and LC-MS grade was purchased from Carl Roth (Karlsruhe, Germany). FBS was obtained from Invitrogen (Karlsruhe, Germany) and pgLPS from InvivoGen (San Diego, CA, USA); peqGOLD total RNA isolation kit, peqGOLD Ultra Low Range DNA-Ladder II, and qPCR plates were purchased from Peqlab (Erlangen, Germany); a high-capacity cDNA reverse transcription kit and fast SYBR green Mastermix for PCR experiments were from LifeTechnologies (Carlsbad, CA, USA). ELISA kits for IL-8, MIP-1b, and MCP-1 were obtained from Merck (Vienna, Austria), RayBiotech (Norcross, GA, USA), and LifeTechnologies, respectively. For flow cytometry, fluorescein-labeled CXCR2 and labeled isotype control antibodies (both R&D Systems, Minneapolis, MN, USA) and rabbit anti-human CCR-1 pAb (PromoCell, Heidelberg, Germany) and isotype control rabbit mAb IgG (New England Biolabs, Ipswich, MA, USA) were used. CCR1 and isotype control were labeled with AlexaFluor488 (Abcam, Cambridge, UK). All other chemicals were from Sigma-Aldrich (Vienna, Austria).

Synthesis and Purification of RES Metabolites. The method for synthesis of RES glucuronides was adapted from an already published method,[24] with the following modifications: 1 equiv of RES-phenolate was conjugated with 2 equiv of acetobromo-α-D-glucuronic acid methyl ester, and after 1 h of stirring at 40 °C, the reaction flask was put on ice and adjusted to pH 8−9 with 16.7 mM sodium carbonate solution. The mixture of RES conjugates was evaporated to dryness and kept at −80 °C prior to purification. Metabolites were purified on a Dionex Ultimate 3000 semipreparative LC system (Thermo Fisher Scientific, Vienna, Austria) with the UV detector set to 300 nm. After dissolution of the synthesis product in MeOH/water (1:1, v/v), the first purification step was done on an RP18 column (Synergi Fusion, 250 × 10 mm, 4 μm, Phenomenex, Aschaffenburg, Germany) at a flow rate of 1.5 mL/min, by gradient elution with 10 mM ammonium formate buffer at pH 8.2 and MeOH. LC gradient (*t* (min), % MeOH) was (0, 20), (20, 70), (25, 100), (30, 20), and the column was equilibrated for 10 min after each run. The major peak (retention time of 20.5 min) was collected and subjected to a second purification on an RP18 column (XTerra Prep MS C18, 100 × 50 mm, 5 μm, Waters, Eschborn, Germany). The flow rate was set at 11 mL/min, gradient elution was done with the eluents already mentioned, and the following gradient (*t* (min), % MeOH) was used: (0, 25), (23, 60), (26, 25). Again, the column was equilibrated for 10 min after each run. Five peaks were collected and subjected to LC-MS (LCMS-2020, Shimadzu, Columbia, MD, USA, with LabSolutions software) analysis with an MS detector with ESI source and quadrupole analyzer recording positive and negative total ion current (TIC(±)) and negative single ion monitoring (SIM(−)), with the following MS interface settings: heatblock temperature, 300 °C; desolvation line temperature, 200 °C; nebulizing gas flow, 1.5 L/min; drying gas flow, 15 L/min; gas flows were obtained from a nitrogen generator, scanning speed, 682 u/s. After evaluation of TIC(−) and SIM(−) for *m*/*z* 227 (RES), *m*/*z* 403 (RES glucuronides), and *m*/*z* 589 (RES diglucuronides), structure identification for two fractions of RES monoglucuronides was done by 1D and 2D NMR on a Bruker Avance III 500 MHz instrument (^{1}H, ^{1}H^{1}H, ^{1}H^{13}C, ^{13}C) at the NMR center of the Faculty of Chemistry, Vienna, Austria. NMR spectra were analyzed with SpinWorks 3.1.8.1 software, and chemical shifts and coupling constants were compared to published data sets.[25]

[a] C_T is the cycle when amplification of a target is first detected. C_T values represent the mean ± SD for 6 h incubations with pgLPS (n = 3−4).

Compounds were dissolved in DMSO at 10 mM and stored in aliquots at −80 °C.

Cell Culture. U-937 cell line was obtained from the American Type Culture Collection and cultured in Roswell Park Memorial Institute 1640 (RPMI) medium supplemented with 10% FBS, 100 U/mL penicillin, 0.1 mg/mL streptomycin, and 2 mM glutamine in a humidified incubator with 5% CO_2 at 37 °C and were split every 2−3 days. Differentiation was achieved by incubation with PMA (10 ng/mL) over 48 h, as already published by our group.[12] Incubations were done with complete medium, and DMSO concentration was 0.1% in all experiments.

Cellular Uptake. Uptake of RES and R4G into U-937 Mϕ was tested at 1 μM and, subsequently, 10 μM. Time points chosen were 10 and 30 min and 1, 1.5, 2, 2.5, and 3 h. For R3S, uptake was only measured after 3 h of treatment. Cells were seeded in 24-well plates at a density of 0.2 × 10^6 cells/well and, after differentiation, incubated with compounds at 37 °C. Cell culture plates were then immediately put on ice, and supernatants were removed. For protein precipitation, MeOH (−20 °C) was added to the supernatant (3:1) and centrifuged for 10 min at 4 °C and 16000g. Immediately after removal of the supernatant, cells were washed once with ice-cold PBS and taken up in 300 μL of distilled water, and two freeze−thaw cycles were done by immersing the plates in liquid N_2 and thawing them at ambient temperature. Lysed cells were then centrifuged under the conditions already mentioned. Both supernatants of precipitated incubation medium and lysed cells were filtered through a 0.45 μM PVDF filter and quantified by LC-MS. Limit of detection (LOD, S/N ratio 3.3:1) and limit of quantification (LOQ, S/N ratio 10:1) were calculated by LabSolutions software to be 3.15 and 10.5 nM for RES, 21.3 and 64.5 nM for R3S, and 15.1 and 50.2 nM for R4G, as determined by calibration curve from 0.039 to 10 μM at 300 nm UV detector wavelength. Recoveries for supernatant were 79, 76, and 73% for RES, R3S, and R4G, respectively. Recoveries for cell lysate were 84, 90, and 66% for RES, R3S, and R4G, respectively.

RT-qPCR. For gene expression analysis, cells were seeded in the same manner as for uptake experiments. Compounds were co-incubated in triplicate for 3 and 6 h with 1 μg/mL pgLPS and either DEX (100 nM) or compounds at 1 μM. mRNA of three wells was pooled and isolated and, subsequently, 2 μg, as measured by spectrophotometry at 260/280 nm (TecanInfinite200, Groedig, Austria), was reverse transcribed, following the instructions provided by the manufacturer. RT-qPCR experiments were carried out in triplicate on a StepOnePlus device (AppliedBiosystems, Carlsbad, CA, USA). Primers were designed using PrimerBlast, and data were normalized to PPIA (primer sequences already published).[12] Primers were used at 100 nM, and qPCR cycles were adapted to the number of cycles when amplification of a target is first detected (C_T values) to reach fluorescent plateau phases, with 40 cycles for IL-8 and MCP-1, 45 cycles for MIP-1b, CCR1, and SIRT1, and 55 cycles for CCR2, CXCR2var1, and CXCR2var2 (Table 1). For data analysis, LinRegPCR2012.3 was used, and baseline-corrected starting concentrations (N_0 values) were used for normalization over PPIA. Four independent experiments with three technical replicates were conducted. To confirm PCR product lengths and purities, gene copies were run on a 3.5% agarose gel, with a DNA ladder ranging from 25 to 700 bp. All PCR products showed single bands, and product lengths corresponded to DNA ladder within 10 ± 3 bp.

ELISA. Incubations for the measurement of chemokines in cell culture supernatant were done as described for qPCR experiments. The supernatants of three wells were pooled and centrifuged for 10 min at 4 °C and 16000g, and aliquots were stored at −80 °C. Samples were diluted with complete medium, if necessary. ELISA measurements for IL-8 (Merck, Vienna, Austria), MIP-1b (RayBiotech, Norcross, GA, USA), and MCP-1 (LifeTechnologies, Carlsbad, CA, USA) were completed following the manufacturers' protocols. Four independent experiments were conducted.

Flow Cytometry (FC). For FC measurements, cells were seeded in 6-well plates 48 h prior to experiments at 1 × 10^6 cells/well. After 6 h of incubation, the medium was removed, cells were scraped and taken up in ice-cold FC buffer, consisting of PBS (170 mM NaCl, 3.4 mM KCl, 10.0 mM Na_2HPO_4, 1.8 mM KH_2PO_4, pH 7.4), 10% FBS, and 0.5% sodium azide. All staining and washing steps were done in Eppendorf tubes, centrifugation conditions were 5 min at 4 °C and 400g. The use of sodium azide and working at 4 °C are common strategies to impede further metabolism and prevent membrane proteins from being internalized.[26] Aliquots of 0.2 × 10^6 cells were incubated with antibodies in 200 μL of FC buffer, 30 min for CXCR2 antibody (1:100) and 15 min for CCR1 pAb (1:400), followed by 15

DOI: 10.1021/acs.jafc.5b01830
J. Agric. Food Chem. 2015, 63, 6535−6545

min AlexaFluor488 (1:2000). Subsequently, samples were washed twice with 1 mL of FC buffer and resuspended in Hank's balanced salt solution (Sigma-Aldrich). Samples were transferred to a 96-well plate in duplicate and measured with a Guava easyCyte 8HT flow cytometer (Millipore, Darmstadt, Germany). Geometric mean fluorescence intensity (MFI) was used for effect calculation (treated over pgLPS (%)). Four independent experiments with two technical replicates were conducted.

Statistical Analysis. Data represent means ± SD and were analyzed using SigmaPlot 11.0 (SystatSoftware, USA). Prior to comparative testing, all sets were normality tested (Shapiro–Wilk). If normality was passed, values were *t* tested (*, $p < 0.05$) against pgLPS-control; if equal variance testing failed, a Wilcoxon–Mann–Whitney rank sum test was performed. For comparison of compounds to DEX, ANOVA was used with a post hoc Holm–Sidak test; if prior normality testing failed, a Kruskal–Wallis one-way analysis of variance on ranks followed by Dunn's test for multiple comparisons was performed.

RESULTS AND DISCUSSION

Purification and Structure Elucidation of RES-Metabolites. Compounds in Figure 1 were drawn with ChemBioDraw Ultra 12.0 (Cambridgesoft, Cambridge, MA, USA). R3S and a mixture of RES-3,5-*O*- and -3,4′-*O*-disulfate (59:41, RdS) were synthesized and purified as reported previously.[27] The synthesis of RES-glucuronides resulted in a collection of five peaks after the second purification step, with retention times (Rt, min) of 10.9 ± 0.38 (1), 17.4 ± 0.77 (2), 20.9 ± 1.28 (3), 27.3 ± 1.62 (4), and 30.9 ± 0.27 (5) (averages of 12 measurements; for a representative HPLC chromatogram, see Supplemental Figure A). As TIC(−) and SIM(−) chromatograms for *m*/*z* 403 of peaks 2 and 3 showed only slight impurities (see Supplemental Figure B for MS chromatograms), NMR spectra of those two fractions were taken.

NMR Data. NMR shifts and coupling constants corresponded to data already published for R3G and R4G.[25] Peak 2 (Rt = 17.4 ± 0.77 min) was therefore identified as R4G with a purity of 87.8%, and peak 3 (Rt = 20.9 ± 1.28 min) corresponded to NMR and MS data for R3G, with a purity of 95.0%. Impurities consisted mainly of the other isomer and traces of solvent.

Cellular Uptake. A previously published study on the uptake kinetics of 3–100 μM labeled RES by human hepatic cells showed that RES is taken up in a concentration-dependent manner through a combination of passive diffusion and carrier-mediated transport.[28] In this study, we measured the uptake of RES and R4G into U-937 Mϕ time-dependently over 3 h (Table 2) and of R3S after 3 h of incubation at 37 °C to determine the amount of compound available for biological effects. At the concentration of 1 μM none of the substances could be detected in the cells. To exclude limitations due to LOD (3.15, 21.3, and 15.1 nM for RES, R3S, and R4G, respectively), uptake was repeated at a concentration of 10 μM. At the 10-fold concentration, an uptake at all measured time points could be observed for RES with a maximum of 0.12 ± 0.001 μM (1.37 ± 0.31% of the applied concentration), after 3 h. Following an incubation with 10 μM R3S, this compound could not be detected in the cells; however, after 3 h, its concentration in the supernatant showed a decrease of −1.22 ± 0.82 μM compared to the concentration in the incubation medium ($p = 0.017$), indicating an uptake. Table 2 shows an uptake of R4G at 10 μM into cells only at time points of 10 min (0.023 ± 0.001 μM) and 30 min (0.028 ± 0.003 μM), and the supernatant at 1 and 10 μM showed no differences from the incubation medium at any measured time point, indicating no further uptake into cells. Riha et al.[29] identified RES and R3S as substrates for organic anion transporting polypeptides in Chinese hamster ovary cells, whereas R4G was not taken up at concentrations between 12.5 and 400 μM, partially confirming our results obtained in U-937 cells. The uptake patterns of RES, R3S, and R4G in macrophages could be due to efflux transporters, such as breast cancer resistance protein 1 (BCRP1) and multidrug resistance protein 3 (MRP3), both of which can be found on macrophages.[30] As shown in a study by van de Wetering et al.,[31] RES, R3S, and R3G are substrates for those two ABC transporters. In said study, it was shown that the transport kinetics of RES and R3S for the efflux transporters BCRP1 and MRP3 were similar; therefore, studies for R3S were limited to 3 h of uptake. The glucuronated metabolite, on the other hand, had a much higher affinity to MRP3, leading to a higher efflux rate, as compared to RES and R3S, further confirming our results for RES and R4G.[31] Another point to be considered is the high plasma protein binding of RES (nearly 100%) and metabolites (approximately 50%), reducing the amount of free compound susceptible to transport.[9] In this uptake study in U-937 Mϕ, no further metabolism of substances such as degradation, dehydrogenation, or dimer formation could be observed.

Despite the very limited uptake, our data show effects on gene and protein expression (see following chapters). It is possible that the amounts of the here tested substances in the cells suffice for our observed effects via the already reported interaction with the NF-κB pathway.[1] Another possibility for the observed effects is the interaction of RES with the estrogen receptor α. RES has been shown to be an agonist for the

estrogen receptor α,[32] albeit at concentrations of 3−10 μM, which are higher than the concentration used in this study. The activation of this receptor has been associated with the suppression of the inflammatory response in a model of arthritis in rats.[33]

Activation of U-937 Mϕ with pgLPS. As a control study for the activation of U-937 Mϕ, the effects on gene and protein expression of cells treated with or without 1 μg/mL pgLPS were compared at various time points. As shown in Figure 2, pgLPS significantly up-regulated mRNA levels of IL-8, MIP-1b, and MCP-1 at 3 and 6 h (Figure 2B), the largest effect was measured for MIP-1b at 3 h, with a (59.4 ± 6.98)-fold increase. The corresponding proteins (with the exception of MCP-1 at 3 h) also showed elevated levels, with the highest protein expression for MIP-1b after treatment for 6 h ((53.6 ± 12.1)-fold, Figure 2C). Gene expression of chemokine receptors and SIRT1 (Figure 2A) was down-regulated by pgLPS with maximum decreases for CXCR2var2 (6 h) and CCR1 (3 h) of −74.9 ± 8.20 and −64.6 ± 5.05%, respectively, and −22.4 ± 4.16% for SIRT1 (3 h). A similar decrease in mRNA expression for CXC and CC receptors was published for activated human leucocytes ex vivo and for rats in vivo, as well as down-regulation of SIRT1 deacetylase after incubation with *Escherichia coli* LPS in vitro in RAW264.7 macrophages.[34−36] In U-937 Mϕ, in contrast to decreased receptor mRNA expression (Figure 2A), flow cytometric measurements of CXCR2 and CCR1 after 6 h of treatment with pgLPS showed an increase in surface protein compared to control of 7.70 ± 0.13% for CXCR2 (p = 0.03) and 0.7 ± 0.01% for CCR1 (p = 0.02). Keller et al.[37] reported time-dependent changes in cytokine gene and protein expression in cultured LPS-activated mouse macrophages. In their study, the gene and protein expression of transcription factors of inflammatory pathways underwent repeated oscillating changes over 48 h. Those changes were attributed to an "intrinsic clockwork" in macrophages. Thus, we hypothesize that this oscillation might have contributed to our differential findings for mRNA and protein levels. Also, as shown by Daigneault et al.,[38] the PMA-induced differentiation process of monocytes into macrophages might have caused our here observed elevated levels of membrane receptor proteins.

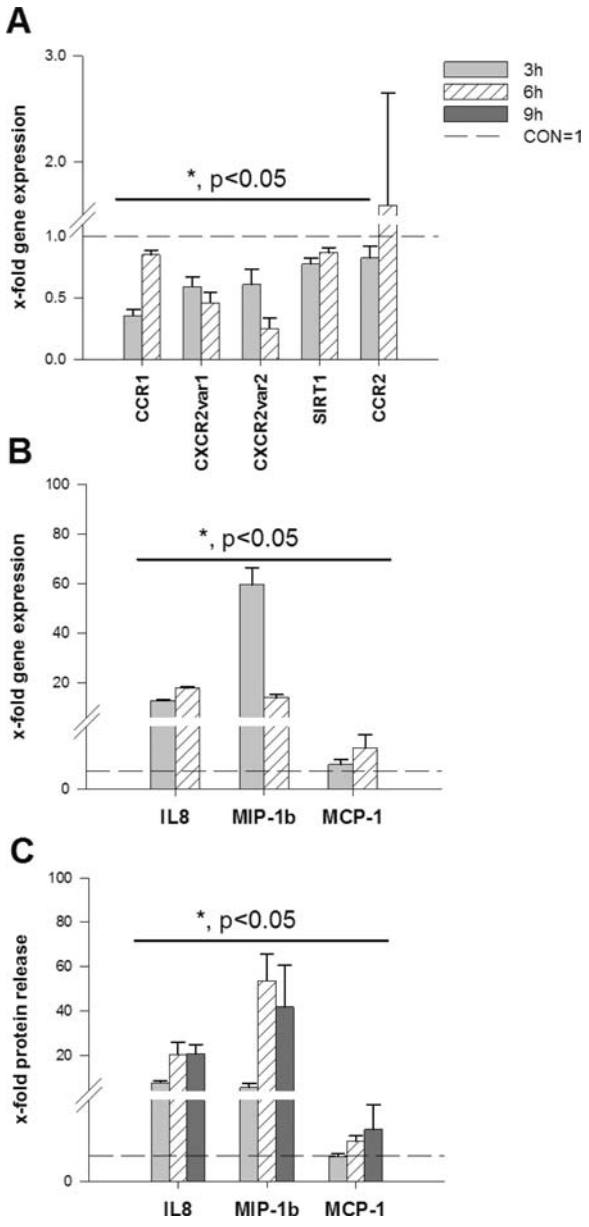

Figure 2. Control data for (A, B) mRNA and (C) protein expression of CCR1, CXCR2var1/2, SIRT1, CCR2, IL8, MIP-1b, and MCP-1 in U-937 Mϕ after treatment with 1 μg/mL pgLPS for indicated time points (see legend). x-Fold changes in pgLPS treated cells were compared to DMSO-control (dashed line = 1-fold). Data represent means ± SD (n = 3−4, tr = 2−3). (*) $p < 0.05$ compared to untreated control.

Gene Expression and Protein Release of Chemokines. Glucocorticoids inhibit inflammation by direct interaction with the NF-κB-pathway.[23] Accordingly, in our experiments, the anti-inflammatory control DEX inhibited mRNA expression and protein expression of all chemokines at 100 nM (Figure 3). As recently reviewed by Joven et al.,[39] especially CC motif chemokines present a promising target for polyphenols in the prevention and treatment of a multitude of inflammatory diseases. In our study, qPCR analysis of MIP-1b and MCP-1 confirmed these results only partially, by showing that mean mRNA levels of MCP-1 (CCL2, Figure 3E), but not MIP-1b (CCL4, Figure 3C), after 3 h of incubation are comparably decreased after treatment with pgLPS and RES, R3S, and RdS by −24.3 ± 11.1, −24.7 ± 5.51, and −28.7 ± 19.2%, respectively. For RES, a similar effect has been shown in adipocytes at a concentration of 10 μM.[40] Yang et al.[41] obtained similar results for human pulmonary artery endothelial cells and reported an attenuating effect on cytokine-induced eotaxin (CCL11) for RES, but not for R3G and R4G at 25 μM. Although IL-8 and MCP-1 are regulated by the same transcription factor in U-937 cells, NF-κB,[42] the here tested compounds had no apparent effect on IL-8 gene expression at the chosen time points (Figure 3A). Interestingly, though, in our experiments, RES, RdS, and R3G did show an inhibiting effect on IL-8 protein release after 9 h (−12.7 ± 7.65, −22.9 ± 3.57, and −16.5 ± 6.04%, Figure 3B). RES, R3S, RdS, and R3G also inhibited protein release for MIP-1b, with the highest inhibiting value of −20.1 ± 7.00% for RdS followed by R3S with −15.4 ± 8.68% (both 9 h of treatment, Figure 3D). An inhibition of MCP-1 protein was measured for RdS after 3 and 9 h treatments (−25.7 ± 8.29 and −23.0 ± 10.1%), RES (9 h, −21.8 ± 16.2%), and R3S (3 h, −20.8 ± 13.9%), as shown in Figure 3F. In contrast to sulfated metabolites and R3G, R4G showed a differential effect on MIP-1b, with an mRNA increase of 24.5 ± 14.8% after 6 h. In our test system, sulfated

metabolites were more anti-inflammatory active than glucuronated metabolites, which is in accordance with previously published work by our group, studying concentrations of 1−10 μM RES, R3S, RdS, R3G, and R4G, where RES and sulfated, but not glucuronated, conjugates inhibited IL-6 and TNF-α protein release.[12] Similarly, in an in vitro study on colon cancer cell progression by Aires et al.,[43] R3S showed inhibiting effects at 30 μM in contrast to R3G and R4G. Considering the results of our uptake experiments, RES and R3S did indeed have effects on gene and protein expression, whereas R4G showed an uptake only at early time points at 10 μM and no changes indicating any further uptake in the concentration of the supernatant at 1 or 10 μM. The pro-inflammatory effect of R4G on MIP-1b could be an indication of the inflammatory properties of glucuronated phenolic metabolites, as reported by Liao and Lin for quercetin-3-glucuronide in isolated mouse

macrophages.[44] In our study, treatment with sulfated metabolites showed no significant difference (ANOVA) to treatment with the parent compound, as also found for COX-1 and iNOS inhibition at a compound concentration of 34 μM.[45] Considering the aggravated inflammatory profile in patients with rheumatoid arthritis, after application of a monoclonal MCP-1 antibody,[46] our results also support the hypothesis that sulfated RES metabolites could prove beneficial in inflammatory diseases, especially targeting MCP-1 and MIP-1b. Additionally, our results show that the impact of compounds should preferably be assessed on both gene and protein levels. Our data provide an interesting insight into the functional impact of minute amounts of RES and the metabolites formed upon ingestion on inflammatory processes. The long-lasting and pronounced effects of sulfated metabolites in macrophages, especially on MCP-1, may be worth further investigation in animal or human studies.

Gene and Surface Protein Expression of Chemokine Receptors. Treatment with pgLPS led to down-regulation of chemokine receptor mRNA (Figure 2A); co-incubation with pgLPS and compounds/DEX for 3 and 6 h did not influence mRNA levels of CXCR2var1 (Table 3). Interestingly, only R4G showed an up-regulation of CCR2 by 224% with a percent range of 48.5% after 6 h (Table 3), suggesting an anti-

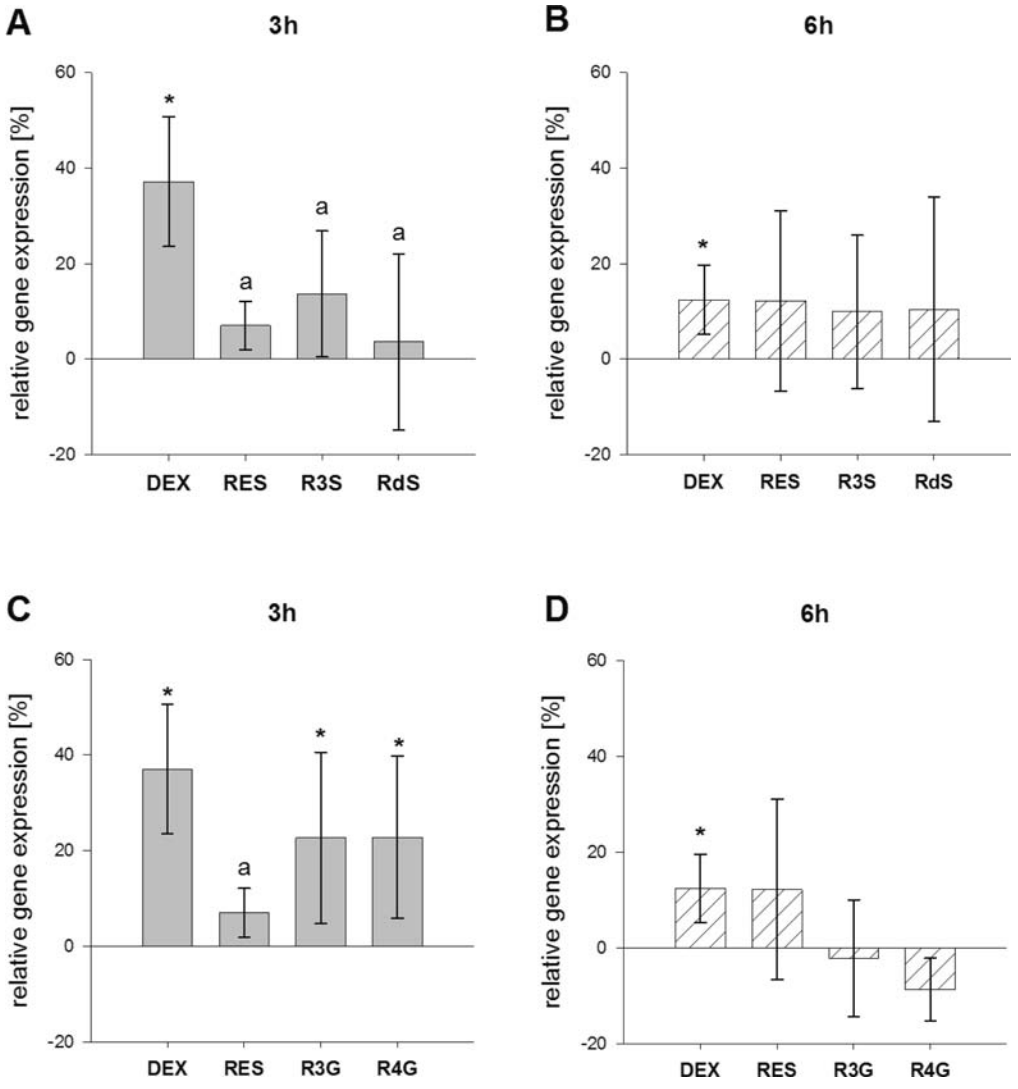

Figure 5. Impact of compounds at 1 μM or 100 nM (DEX) in co-incubation with pgLPS (1 μg/mL) on SIRT1 mRNA expression for (A, B) DEX, RES, R3S, and RdS after 3 and 6 h and for (C, D) DEX, RES, R3G, and R4G after 3 and 6 h. pgLPS-control was set at 0% change; values are differences from pgLPS-control in percent. Data represent means ± SD (n = 3−4, tr = 2−3). The asterisk (∗) indicates statistically significant differences compared to pgLPS-treated control ($p < 0.05$). Letter "a" indicates results for one-way ANOVA versus anti-inflammatory control DEX.

inflammatory activity of this compound. It should be noted that our PCR results show high standard deviations, likely due to low abundances of mRNA in U-937 Mϕ for both genes, which resulted in very high CT values. Hence, we cannot exclude that the here tested compounds could elicit effects on CXCR2var1 mRNA expression in other immune cells. The same applies for CCR2 mRNA expression, as, for example, RES at 10 μM has been shown to inhibit CCR2 expression in THP-1 monocytes.[19]

mRNA levels of chemokine receptors CCR1 and CXCR2var2 were differentially affected by RES metabolites (Figure 4). After 6 h, RES and R3S decreased CCR1 gene expression to the same extent as DEX, whereas R4G (46.3 ± 26.2%) showed the opposite effect (Figure 4A), as also reported for MIP-1b and CCR2 mRNA in this study (Figure 3C; Table 3). CCR1 receptor surface expression after 6 h of co-incubation with pgLPS was not affected by treatments, except for DEX, which down-regulated surface protein levels (Figure 4B). mRNA of CXCR2var2 was up-regulated to the same extent by all treatments, after 3 h of incubation, as tested by ANOVA (Figure 4C), showing that R4G affected the CXC motif receptor differently from the CC motif receptors. After 6 h, no effect for RES and its metabolites on CXCR2var2 mRNA expression could be observed (Figure 4C). An up-regulation of chemokine receptors previously down-regulated by an inflammatory stimulus (Figure 2A) was also demonstrated in cytokine-induced rat synovial fibroblasts treated with green tea extract containing polyphenols (2.5−40 μg/mL catechins).[34] However, it should be noted, that, in our study, the mRNA levels for two different transcript variants of CXCR2 (var1 and var2) were measured separately, with the CXCR2 antibody not being specific for a certain transcript variant, which could account for the differential effects on mRNA and surface protein levels.

In the here presented study, despite the up-regulation of mRNA compared to LPS, CXCR2 surface protein was down-regulated by RdS, R3G, and R4G by −5.33 ± 4.18, −10.6 ± 8.49, and −15.2 ± 5.99%, respectively (Figure 4D). This effect could be due to internalization of CXCR2 receptor proteins upon exposure to inflammatory stimuli.[15,47] Another possibility for the differential effects on CXC-motif gene and protein expression would be the post-transcriptional influence of

DOI: 10.1021/acs.jafc.5b01830
J. Agric. Food Chem. 2015, 63, 6535−6545

microRNAs on CXC-motif receptors, as shown for microRNA146a and the CXC motif receptor 4 (CXCR4).[48] Considering our results on mRNA expression of chemokine receptors CCR1, CCR2, and CXCR2var2, we find it difficult to definitely attribute effects on receptors to be pro- or anti-inflammatory (Figure 4A). Further studies are needed to elucidate the complex mechanisms underlying chemokine receptor regulation.

Sirtuin-1 Gene Expression. High levels of SIRT1 have been demonstrated to exert protective effects in numerous inflammatory diseases.[16,36] SIRT1 is an active inhibitor of NF-κB, leading to reduced levels of chemokines and cytokines.[21] As our data in Figure 5 show, after 3 h of treatment (Figure 5A,C), at 1 μM, up-regulated SIRT1 gene expression for R3G and R4G was comparable to DEX (ANOVA versus DEX, p = 0.392), but not for RES or the sulfated metabolites (ANOVA versus DEX, p = 0.017). R3G and R4G even overcompensated the down-regulation of SIRT1 by pgLPS (Figure 2A) by 22.7 ± 17.9 and 22.8 ± 16.9%, respectively. A similar up-regulation could be shown in HEPG2 cells, after treatment with 10 μM RES and glucuronated conjugates.[49] Further confirming our in vitro results, in an in vivo study in mice, after ingestion of high doses of RES (440 μM/kg bw per day for 2 weeks), an increase of SIRT1 expression of about 25% has been shown in lymphocytes from inflamed colon lamina propria.[21] RES glucuronides are mainly formed and absorbed in the small intestine,[25,50] but as glucuronides are transported via the bloodstream and are substrates for BCRP1 and MRP1,[31] they could affect SIRT1 expression in colon mucosa and other tissues. In our study, in contrast to glucuronated metabolites, at 1 μM, RES and the sulfated conjugates did not show effects on SIRT1 expression after 3 and 6 h of co-incubation with pgLPS (Figure 5A,B) and for glucuronated metabolites, no up-regulation could be measured after 6 h (Figure 5D).

The mRNA of SIRT1 and CXCR2var2, both being important factors in the development and progression of inflammatory diseases, was regulated comparably to the anti-inflammatory control DEX. The effects of sulfated and glucuronated metabolites, as well as DEX, on CC and CXC motif receptors on mRNA and protein levels are ambiguous and require further studies, as mentioned above. With regard to CC and CXC motif chemokines (IL-8, MCP-1, MIP-1b), the sulfated RES metabolites R3S and RdS were more potent than the tested RES glucuronates in inhibiting LPS-induced gene expression and protein expression in immune-competent macrophages. In summary, resveratrol metabolites formed in vivo, at concentrations reached after dietary-scale doses, were demonstrated to influence genes and proteins involved in inflammatory immune processes in immune-competent macrophages.

proteins provide an alternative method. Some recombinant prolamin allergens have already been produced and characterized.[20,21,27−31] Well-defined protein fragments can also be produced by heterologous expression, and such recombinant fragments have been valuable for studying the antigenicity of LMW glutenin subunits and their two domains[30] as well as fragments of high-molecular-weight (HMW) glutenins.[27]

The present work aims to further characterize the structural features linked to allergenicity of proteins belonging to the prolamin superfamily by focusing on two members: α- and γ-gliadins. Different forms (natural/recombinant; native/reduced-alkylated) and fragments (Nt- and Ct-) of α- and γ-gliadins were produced to study the contribution of their structural domains and disulfide bonds to IgE binding. Their secondary structure was determined using synchrotron radiation circular dichroism (SRCD); sera from patients with food allergies to wheat (FAW) or baker's asthma (BA) were used to analyze IgE binding.

MATERIALS AND METHODS

PCR Cloning of Whole Gliadins cDNA and of Their Moieties. rAG has been previously cloned.[29] The same procedure was used for cloning recombinant γ-gliadin. Briefly, total RNA was extracted from immature (14 days before anthesis) wheat grains (Neepawa cultivar). α-Gliadin (rAG) and γ-gliadin (rGG) cDNA were cloned by RT-PCR. First-strand cDNA was synthesized with using Superscript II system (Invitrogen, Carlsbad, CA, USA) containing an oligo-dT and adapter primers. PCR was done using primers described in ref 29 chosen according to dETS sequences found in databases or already cloned γ-gliadin (ID Q94G94) cDNA.[32] Their Nt- and Ct-moieties (rNt-AG, rAG-Ct, rNt-GG, and rGG-Ct) were cloned by PCR using full-length α- and γ-gliadin cDNA clones as templates. The DNA polymerase used was AccuPrime Pfx (Life Technologies). Fragments were cloned with restriction enzymes into a pET28b (Novagen) plasmid in frame with a sequence encoding the hexahistidine Tag (His-Tag). The sequences of the specific primers used in the cloning procedure are described in Supporting Information Table S.1 and in ref 29.

Production and Purification of Natural or Recombinant Gliadins and Fragments. Natural α- and γ-gliadins (nAG and nGG) were prepared from wheat flour (cultivar Recital) by several steps of chromatography.[15] The γ-gliadin corresponded to the γ46 fraction described in ref 33. When indicated, natural proteins were used after reduction/alkylation. After solubilization in 0.5 M Tris-HCl, pH 8.5, containing 8 M urea and 0.01 M EDTA, they were reduced with 0.1 M dithiothreitol (DTT) for 2 h at 37 °C and then alkylated with iodoacetamide in 0.5 M NaOH for 30 min in the dark. *Escherichia coli* strain Rosetta (Novagen) was used for recombinant protein production. Bacteria were transformed with a plasmid encoding rAG or rGG or their domains. Protein production and purification were performed as described in ref 30 with standard culture and IPTG induction, lysis with lysozyme in the presence of RNase A and DNase I (Qiagen), and precipitation steps. Proteins were reduced with DTT and alkylated with iodoacetamide during purification to increase extraction yields except when native full-length proteins were produced.

The purity of materials was checked by SDS-PAGE on a 15% w/w gel; 5 μg of proteins was loaded on the gel, and the proteins were stained with Coomassie Brilliant Blue R250. The presence of Nt-histidines in recombinant proteins was confirmed by Western blot using an anti-HisTag antibody.

Natural α-Gliadin Identification by Mass Spectrometry. nAG (3 mg/mL) was hydrolyzed at 37 °C for 6 h using porcine trypsin (Sigma T8253) and chymotrypsin (Sigma C 4879) in 25 mM NH_4HCO_3 at an enzyme/substrate ratio of 1:100 w/w. The resulting hydrolysate was reduced by mixing with 10 mM DTT and 10% acetonitrile at 45 °C for 1 h in the dark with gentle stirring. After the sample had cooled to room temperature, 0.5 M iodoacetamide was added, and the sample was incubated for 30 min in the dark. Following reduction/alkylation, the peptides were diluted 10 times in water; subsequently, 50 μL of the solution was eluted on C18 resin pipet tips (ZipTip, Millipore Corp, Billerica, MA, USA), cleaned, and finally extracted from the Zip Tip with 30 μL of 1:1 acetonitrile/water containing 0.05% formic acid. The acetonitrile was then evaporated on a Speed Vac, and the sample was stored for mass spectrometry analysis.

Nanoscale capillary liquid chromatography−tandem mass spectrometry (LC-MS/MS) analyses were performed using an Ultimate U3000 RSLC system (Dionex) coupled with an LTQ-Orbitrap VELOS mass spectrometer (Thermo Fisher). Chromatographic separation and mass data acquisition were performed as described in ref 34. Protein identification was performed using the Mascot database search engine and the UniProt databank, which was restricted to *Triticum aestivum* sequences (release 2015_01). Mass tolerance for peptide precursors was set at 5 ppm, with the fragment mass tolerance set at 0.5 Da. Enzyme specificity was set to trypsin and chymotrypsin with a maximum of one missed cleavage. Proteins were identified with at least three peptides according to the above specifications.

Synchrotron Radiation Circular Dichroism (SRCD). Measurements were taken using the DISCO beamline at Soleil synchrotron (Gif-sur-Yvette, France). The samples were prepared in 50 mM sodium phosphate buffer, pH 8, containing 2% SDS and 10 mM sodium sulfate (typical range = 0.5−1.5 g/L). Data acquisition and processing were recorded as previously described.[35] Ratios of secondary structures were determined using the ContinLL program[36] in Dichroweb[37] and SP175 or Set5 as reference sets on the mean spectra from five measurements. Normalized root-mean-square deviation (NRMSD) indicated the most accurate fit for each spectrum; values <0.25 were considered significant.

Sera from Allergic Patients. Sera from 25 patients with FAW and from 5 patients with baker's asthma (BA) were selected on the basis of the presence of gliadin (nAG or nGG) specific IgE as determined by ELISA (Supporting Information Table S.2). All patients with BA were adults and presented rhinitis and asthma. Except for one adult, all patients with FAW were children. Their symptoms included atopic eczema dermatitis syndrome, anaphylaxis, asthma, urticaria, or gastrointestinal disorders. Sensitization to wheat proteins was assessed in patients using skin prick tests (SPT) to wheat flour (Moulins Soufflet), gluten (ALK-Abello), and natural gliadins and/or using specific IgE assays to wheat flour or gluten (Phadia ImmunoCAP). A wheat allergy was confirmed by a positive challenge or evident effect of wheat avoidance. The double-blind placebo-controlled food challenge and the inhalation challenge with wheat flour are described in refs38 and 4, respectively. Blood collection, SPT, and challenges were performed with the informed consent of the patients or their parents and after receiving approval from the biomedical research by the Ethics Committee of Ile de France III and AFSSAPS (Authorization 2008-A01565-50).

IgE Binding to Gliadins and Their Domains. Specific IgE concentrations toward the different forms of AG and GG (natural/recombinant; native/reduced-alkylated) and their Nt- or Ct-domains were determined by F-ELISA as described in ref 39 using alkaline phosphatase-conjugated goat anti-human IgE and 4-MUP as a substrate (Sigma A3525 and A3168, respectively, Saint-Quentin Fallavier, France). Proteins solubilized in PBS were coated at 5 mg/L in carbonate buffer on white 384-well plates (NUNC 460372, Fischer Scientific).

IgE Binding to Solid-Phase Synthetic Peptides (Pepscan). Sera containing high levels of specific IgE toward the gliadins and their domains (n = 6 for AG and n = 5 for GG) and three control sera from nonatopic subjects were used in the Pepscan analysis as described in ref 39. Decapeptides, overlapping on eight amino acid residues, spanned the full-length sequences of α- and γ-gliadins (UniProt ID P04725 and P08453, respectively), which were already used in previous Pescan analysis.[4,22]

Activation of RBL Cells by α-Gliadins and Their Domains. Rat basophil leukemia (RBL SX38) cell degranulation was expressed as the percentage of β-hexosaminidase release with a positive threshold set at

DOI: 10.1021/acs.jafc.5b01922
J. Agric. Food Chem. 2015, 63, 6546−6554

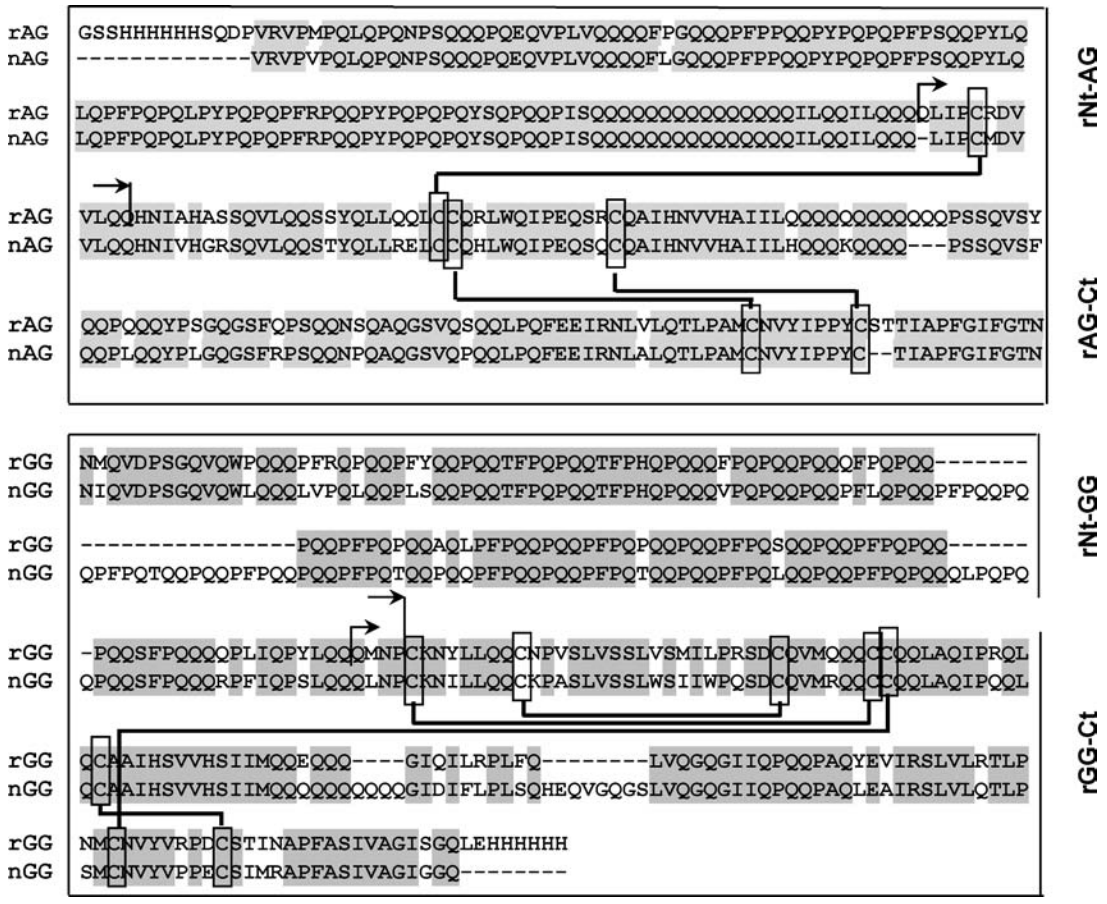

Figure 1. Comparison of the sequences of the recombinant proteins, α-gliadin (rAG) and γ-gliadin (rGG), and of the natural proteins, Uniprot ID Q3S4 V7 for α-gliadin and P08453 for γ-gliadin. The connections correspond to disulfide bonds between surrounded cysteine residues. The end of rNt-domains and the beginning of rCt-domains, (rNt-AG, rAG-Ct) and (rNt-GG, GG-Ct), are indicated by arrows. Identical amino acid residues are highlighted in gray.

11% as described in ref 39. Gliadin samples were tested at 2, 20, 200, and 2000 ng/mL with a pool of two sera (899 + 907) diluted 1:10.

Statistical Analysis. Statistical analyses were performed using GraphPad Prism version 5.04 for Windows (GraphPad Software, San Diego, CA, USA). For the ELISA results, paired tests were performed, and each pairing was confirmed to be significantly effective. Both specific IgE distributions and their paired differences failed the d'Agostino−Pearson omnibus normality test. Wilcoxon signed rank tests or Friedman tests with Dunn's multiple comparisons were then performed to compare the medians ; p values <0.05 were considered significant.

RESULTS

Characterization of Natural and Recombinant Gliadins and Their Domains. The full-length sequences of the recombinant and natural gliadins are shown in Figure 1. The recombinant α-gliadin (rAG) sequence (ID 1834759) shares 96% identity with the protein that was recorded under UniProt ID P02863.2. MS analysis of the natural α-gliadin (nAG) indicated that it contained in majority the α-gliadin ID Q3S4 V7, in addition to several minor isoforms of this protein. Sequence alignment revealed 95% similarity between rAG and nAG. In SDS-PAGE under reducing conditions, rAG migrated to approximately 45 kDa, whereas the nAG migrated to approximately 40 kDa (Figure 2). The sequence of recombinant protein rGG was deduced from its cloned cDNA sequence. It is identical to UniProt ID Q94G94.[32] The natural protein nGG corresponded to a γ46-gliadin type

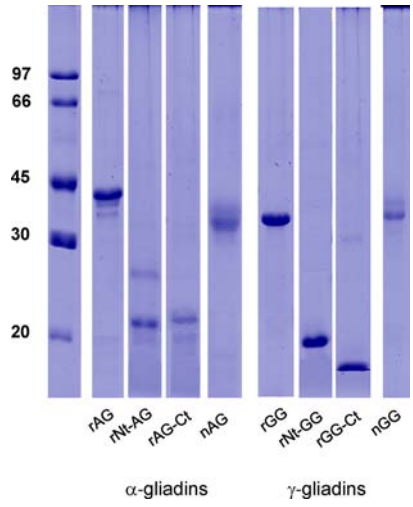

Figure 2. SDS-PAGE analysis of the proteins under reducing conditions colored with Coomassie Brilliant Blue R250. rAG and rGG, recombinant α-gliadin and γ-gliadin; rNt-AG, rNt-GG, rAG-Ct, and rGG-Ct, recombinant Nt- and Ct-domains of α-gliadin and γ-gliadin; nAG and nGG, natural α-gliadin and γ-gliadin.

according to its electrophoretic mobility in acid-PAGE and was previously described as P08453.[33] The rGG and nGG sequences displayed 80% similarity. Their mobility in SDS-PAGE was approximately 40 kDa. The Nt- and Ct-recombinant

J. Agric. Food Chem. 2015, 63, 6546−6554

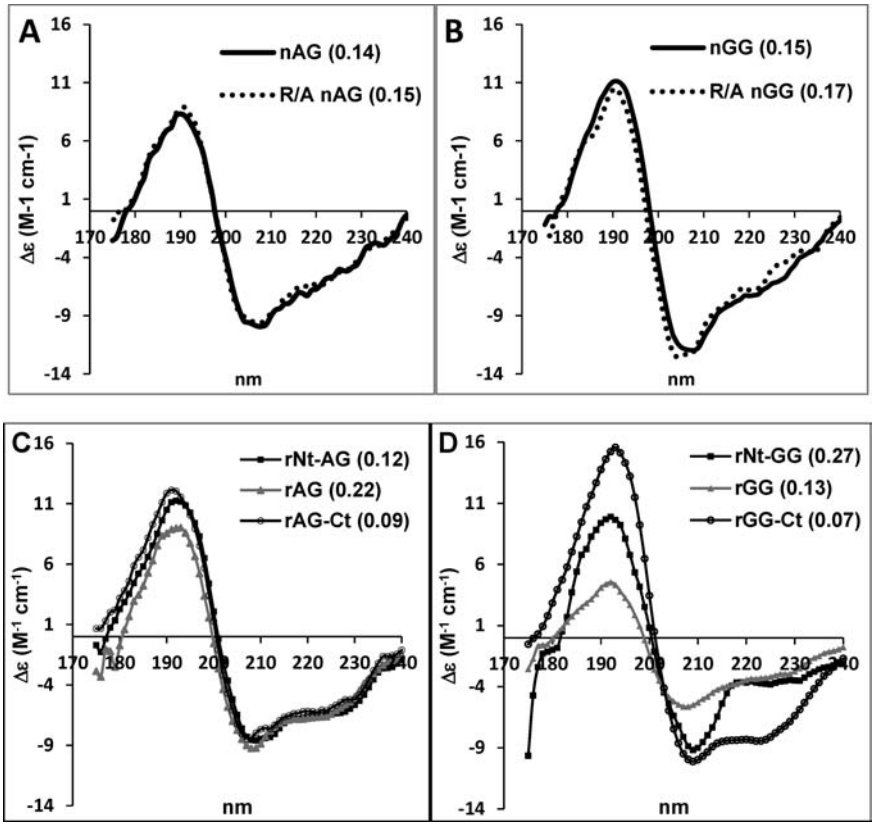

Figure 3. SRCD on natural and recombinant gliadins: spectra of native and reduced alkylated (R/A) natural α-gliadin (nAG) (A) and natural γ-gliadin (nGG) (B); spectra of recombinant full-length, N-terminal (Nt) and C-terminal (Ct) domains, (C) rAG and (D) rGG. NRMSDs are indicated in parentheses.

domains each constitute approximately half of a gliadin protein and migrated approximately 15−22 kDa. Despite their similar sizes, the mobility of the rNt-GG fragment (133 residues) differed that of the rGG-Ct fragment (136 residues). The molecular weights of the prolamins are often overestimated by SDS-PAGE, which has been attributed to the high content of proline in their Nt-repetitive domains.[10]

Secondary Structures of Natural and Recombinant Gliadins and Their Domains. The secondary structure contents of gliadins and of their domains were calculated after the deconvolution of the CD spectra. Low NRMSD values were obtained except for the rNt-GG domain (0.27).

The CD spectra of α-gliadins presented minimal values in the 206−208 and 220−224 nm regions, which reflects the α-helical structures. nAG contained approximately 35% α-helix, 18% turns, and a low level of β-strand. Reduction/alkylation of the protein did not affect the dichroic signal (Figure 3A). rAG and its domains displayed similar dichroic signals (Figure 3C) corresponding to a higher level of α-helix (52−58%) and a lower level of turn structures (11%) compared with nAG.

The secondary structure contents of nGG were approximately 25% α-helix and 16% β-strand and turns, and the reduction/alkylation of nGG did not change the CD spectrum (Figure 3B). The recombinant rGG contained slightly more α-helix (37%) and fewer strands (11%) than did nGG. Unlike rAG, full-length rGG and its Nt- and Ct-domains displayed different spectra (Figure 3D). The rGG-Ct domain is notably folded in α-helices (67%). The CD spectrum of the repetitive rNt-GG domain showed an unusual negative peak at 210 nm, which is characteristic of turn structures. This spectrum could be only poorly deconvoluted with the currently available sets (NRMSD >0.25); hence, its secondary structure was not evaluated.

IgE Binding to Natural and Recombinant Gliadins and the Involvement of Disulfide Bonds. Sera from 28 patients with FAW or BA were used to compare IgE reactivity toward different forms of α-gliadins in an ELISA. As shown in Figure 4 (top), compared with nAG, the IgE binding to rAG was significantly reduced. The mean of the specific IgE concentration was reduced by 60%, but 25 of the 28 sera retained binding to rAG. Reduction/alkylation highly decreased the IgE binding to nAG: the mean reduction was approximately 70%, and 67% of the sera exhibited a reduction of >70%. Reduction/alkylation had a lower but significant impact on IgE binding to rAG, with a 30% reduction.

Sera from 20 patients with FAW were used to compare IgE reactivity toward γ-gliadins. The sera from the five patients with BA had no or very weak IgE reactivity toward nGG. As shown in Figure 4 (bottom), compared with nGG, IgE binding to rGG was reduced. The reduction in the mean specific IgE concentration was approximately 30%, and 18 of the 20 sera retained IgE binding after nGG had been replaced with rGG. The decrease in the mean specific IgE concentration induced by the reduction/alkylation of nGG was approximately 60%, and 37% of the sera exhibited a reduction >70%. In the case of rGG, a significant decrease of approximately 60% was also observed.

Involvement of Nt- and Ct-Domains in IgE Binding to Gliadins. The involvement of the two structural domains of gliadins in IgE binding was analyzed with recombinant

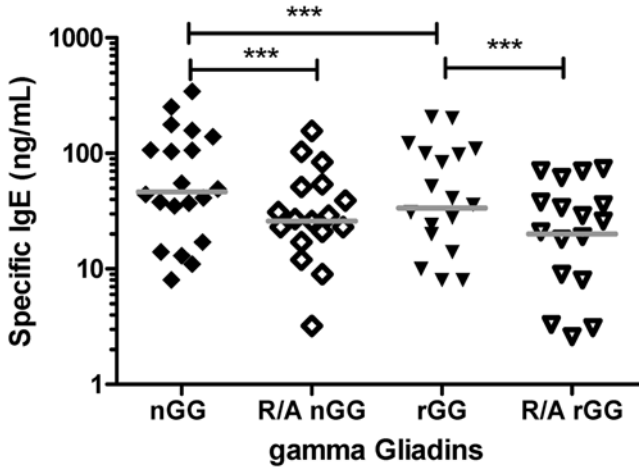
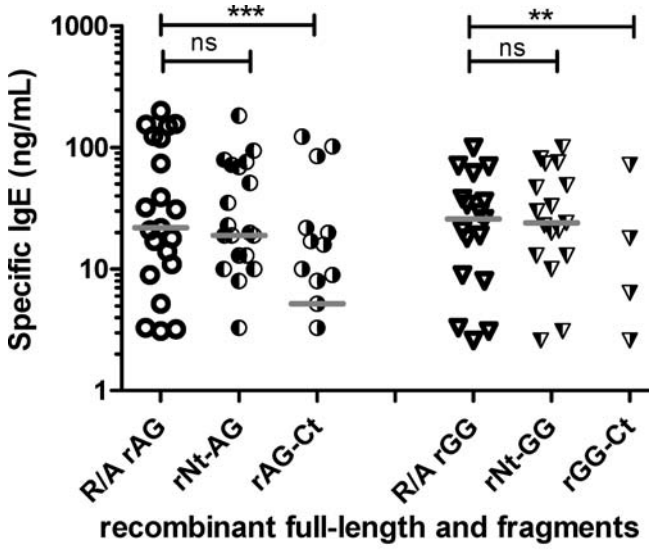
Mean	147	50	62	43
Median	69	19	20	16



Mean	88	37	60	26
Median	47	26	34	20

Figure 4. Effect of heterologous expression and reduction/alkylation of natural and recombinant α-gliadins (top) and γ-gliadins (bottom) on IgE binding measured by ELISA. Means and medians per sample are indicated under the graph. Medians, plotted as gray bars, are significantly different (**, $0.001 < p < 0.01$; ***, $0.0001 < p < 0.001$; ****, $p < 0.0001$; Wilcoxon signed rank test, $n = 28$ for AG and $n = 20$ for GG). Fifteen data points (5 for R/A nAG, 3 for rAG, 7 for R/A rAG) and seven data points (2 for R/A nGG, 2 for rGG, 3 for R/A rGG) were below the detection limit and not included on the graphs.

repetitive domains (rNt) and nonrepetitive domains (rCt). rCt domains were extracted after the reduction/alkylation of cysteines. Because it was shown above that reduction/alkylation affected IgE binding to gliadins, comparisons were then performed with reduced/alkylated full-length recombinant gliadins, and only sera with positive IgE binding to R/A recombinant gliadins were considered (Figure 5). The IgE binding data were analyzed by a Friedman test, which indicated significant difference among full-length gliadins and their fragments ($p < 0.0001$; $F = 19.4$, $n = 21$ for AG and $F = 26.8$, $n = 17$ for GG). For both gliadins, a subsequent Dunn's comparison test comparing the domains with the full-length protein revealed that the differences for the Ct-domain (difference in rank sum = 28.0 for AG, 20.0 for GG) were significant but that the differences were not significant ($p > 0.05$) for the Nt-domain.



Mean	57	39	20	32	36	6
Median	22	19	5	26	24	0

Figure 5. Comparison of IgE binding to the full-length gliadins and to their N-terminal (Nt) or C-terminal (Ct) domains measured by ELISA. Means and medians per sample are indicated under the graph. Statistical differences between medians of specified groups using Friedman and Dunn's multiple comparison post test are indicated. Medians, plotted as gray bars, are significantly different (**, $0.001 < p < 0.01$; ***, $p < 0.001$; $n = 21$ for AG and 17 for GG) or not (ns, $p > 0.05$). Twenty-four data points (2 for rNt-AG, 9 for rAG-Ct, 13 for rGG-Ct) were below the detection limit and not included in the graph.

For the α-gliadins, the mean specific IgE concentration was twice as high for the rNt-AG as it was for rAG-Ct (39 and 20 ng/mL, respectively); IgE from 43% of sera did not bind the Ct-domain, whereas most sera reacted the Nt-domain. The sum of the mean specific IgE concentrations for the two domains was equivalent to the mean concentration for the full-length recombinant gliadin after reduction/alkylation (57 ng/mL). For the γ-gliadins, the rGG-Ct domain was rarely bound by specific IgE (only 25% of the sera). Conversely, all sera displayed IgE binding to the rNt-GG. The mean concentrations of specific IgE for rNt-GG and R/A rGG binding were equivalent (36 and 32 ng/mL).

The involvement of the two structural gliadin domains in IgE binding was also analyzed by searching for continuous epitopes within these sequences. As shown in Supporting Information Table S3, IgE from all six tested sera bound sequences belonging to the Nt-domain of α-gliadin, whereas two sera (no. 451 and 590) did not bind any sequence located in the Ct-domain. Generally, more spots were detected in the Nt-domain than in the Ct-domain. Stretches of peptides were detected by several sera: the sequences ^{1}VRVPVPQLQP^{10}, ^{25}VQQQQFPG^{32}, ^{53}QPYLQLQPFPQQPFPPQLP^{72}, and ^{77}QSFPPQQPYPQQ^{88} in the Nt-domain and the sequence ^{219}QQQPSSQVSFQQ^{230} in the Ct-domain.

DOI: 10.1021/acs.jafc.5b01922
J. Agric. Food Chem. 2015, 63, 6546−6554

The five sera tested on the γ-gliadin sequence displayed IgE binding to several peptides located in the Nt-domain, whereas only one serum (no. 899) displayed IgE binding to a sequence in the Ct-domain. The numerous epitopes in the Nt-domain corresponding to the consensus sequences PQQPFPQQPQ, LSQQPQQTFP, or QPQQ(S/T)FPQ were found with all sera, reflecting a higher homogeneity of repetition in γ-gliadin than in α-gliadin. There is no relationship between the number of peptides detected by Pepscan analysis and the IgE binding measured by ELISA toward the respective domains.

Triggering Potential of Natural, Recombinant, and Nt- and Ct-Fragments of α-Gliadin. The triggering potential of α-gliadin samples was assessed in an RBL assay using a pool of two sera that displayed high levels of specific IgE toward nAG (approximately 400 ng/mL), rAG (approximately 250 ng/mL), R/A nAG (approximately 200 ng/mL), R/A rAG (approximately 150 ng/mL), and the gliadin domains (70 ng/mL for rNt-AG and 100 ng/mL for rAG-Ct). Both nAG and rAG were able to induce cell degranulation in the presence of the pool of sera (Figure 6). However, maximum degranulation (approximately 35%) was obtained at a lower protein concentration for nAG (20 ng/mL) than for rAG (200 ng/mL). Reduced/alkylated nAG or rAG induced low degranulation at similar concentration (200 ng/mL), and none of the recombinant domains were able to induce degranulation above the positive threshold.

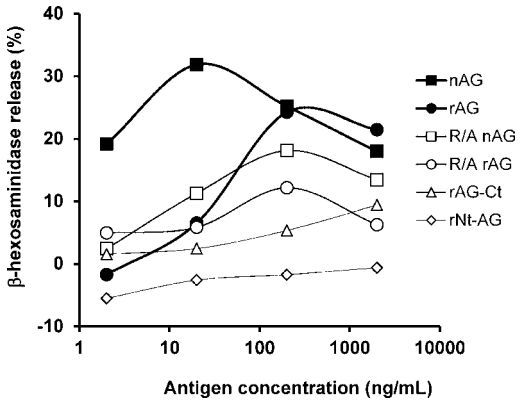


Figure 6. Triggering potential of natural and recombinant α-gliadins and domains tested in an RBL assay with a pool of two sera. Duplicate measurements were performed, and means are represented on the graph.

DISCUSSION

Wheat gliadins are frequently involved in FAW and occasionally involved in BA. This work aimed to elucidate the molecular structures responsible for IgE binding to α- and γ-gliadins by using a collection of sera from patients with FAW and BA and different preparations of gliadin proteins: natural and recombinant full-length proteins (native or reduced), recombinant fragments corresponding to the structural Nt- and Ct-domains, and synthetic peptides.

Like all wheat storage proteins, α- and γ-gliadins are polymorphic and have closely related sequences. The recombinant gliadins rAG and rGG displayed good sequence homology to the isoforms present in the natural AG and GG purified fractions. These recombinant proteins displayed higher contents in α-helical secondary structure (52% for rAG and 36% for rGG) compared with the natural fractions (36% for nAG and 25% for nGG). The results from SRCD are in accordance with the published data indicating that nAG contains primarily α-helical structure,[8,9,29] whereas nGG contains large amounts of α-helical and turn structures.[10,40]

The recombinant α-gliadin rAG showed reduced IgE binding compared with natural α-gliadin nAG, but 90% of the sera were still reactive. We also observed that rAG retained the capacity to induce basophil activation. A smaller reduction in IgE binding was observed for rGG compared to nGG. It is unlikely that these differences arise from the presence of post-translational modifications such as glycosylation, as no evidence of significant levels of glycosylation was found on the natural gliadins.[41] Different folding and a possibly incorrect formation of disulfide bonds by the heterologous expression in *E. coli* may be partly responsible for the different IgE reactivity. The small differences in sequences between the recombinant and natural isoforms (Figure 1) may also partly explain the difference in IgE reactivity. However, recombinant gliadins maintained the IgE reactivity for most sera, as recently reported for recombinant LMW glutenins.[28,30]

The disruption of disulfide bonds in AG and GG led to reduced IgE binding to these allergens for many sera. This disruption also reduced the degranulation potency of AG. Disulfide bonds are located in the Ct-domain of both proteins. Protein reduction likely disrupted some of the conformational epitopes. Only one sera (no. 901) bound to a cysteine-containing peptide of AG by Pepscan analysis. However, reduction may have an indirect but drastic effect on the global folding of the protein. When the proteins were reduced/alkylated, no significant effect was observed on the secondary structures of natural AG and GG. Reduction/alkylation likely modified the tertiary structures of these proteins but, unfortunately, all attempts to crystallize them failed. These results indicate that gliadins with their disulfide bonds are more IgE-reactive for many sera than are gliadins without disulfide bonds. The importance of disulfide bonds for IgE binding has already been shown for other allergens of the prolamin superfamily. For example, wheat LTP and peanut allergen Ara h 6 were poorly recognized by patient IgE after reduction of their disulfide bonds.[4,5] However, in the case of LTP and Ara h 6, secondary structures were also greatly affected by disulfide bond disruption, whereas in the present study, the CD spectra of α and γ-gliadins were not affected by this modification.

IgE binding to peptides and recombinant domains of AG indicated the presence of epitopic regions in both domains of this protein. Nevertheless, stronger binding to the Nt-domain compared with the Ct-domain was observed both by the Pepscan technique and using the recombinant domains. The secondary structure contents of the Nt- and Ct-domains were equivalent, with the high level of α-helix most likely due to the clusters of 13−15 glutamines present in both domains. Recombinant rNt-AG polypeptide and synthetic peptides may represent, to a certain extent, the natural Nt-domain folding, allowing IgE to cross-react with these different entities. Conversely, IgE cross-reactions between the natural Ct-domain and the corresponding (reduced) recombinant domain and synthetic peptides should be less likely. In the case of GG, this phenomenon was more pronounced because very low binding to the Ct-domain was observed by both Pepscan and ELISA using the recombinant domain, whereas numerous continuous epitopes were detected in the Nt-domain. The CD spectra clearly indicated that the two domains have different secondary

DOI: 10.1021/acs.jafc.5b01922
J. Agric. Food Chem. 2015, 63, 6546−6554

structures: the rNt-GG primarily contains turn structures, whereas the rGG-Ct contains a very high content of α-helix.

Despite sequence homologies and similarities in their organization, differences were observed in patients' reactivity toward α- and γ-gliadins: allergenicity of GG was less affected by the reduction of disulfide bridges and more pronounced toward its Nt-domain than in the case of AG. This could be linked to differences in the number and homogeneity of repeated motifs between gliadins.

The continuous epitopes identified in this study by Pepscan in AG confirmed some of the epitopes identified in previous works: PLVVQQQQFPGQQQQ, YLQLQPFPQP, and PAMCNVYIPP.[4,22] The present work supports the hypothesis that AG appears to contain both types of epitopes, with continuous epitopes primarily located in the repetitive sequence domain and discontinuous epitopes most likely in the Ct-domain.[4] Nt-repetitive domains were previously shown to be highly resistant to pepsin hydrolysis;[42] they could more efficiently stimulate the production of specific IgEs compared with the nonrepetitive domains. However, both domains and correctly formed disulfide bonds in the Ct-domain appeared to be required for AG to induce basophil degranulation. This result differs from the reported presence of continuous repetitive IgE epitopes in deamidated ω2-gliadins or fragments from the repetitive domain of HMW glutenin that could induce basophil degranulation.[27,43]

Using recombinant domains of gliadins is a complementary approach to synthetic peptides and expands the possibilities of epitope research by accounting, to a certain extent, for protein folding. The proteins in their native form should be preferentially used for IgE reactivity detection. As for other allergens of the prolamin superfamily, disulfide bond formation appears to be of importance for IgE binding to α- and γ-gliadins. Disulfide bonds in the Ct-domain most likely play a role in generating conformational epitopes within this domain or formed by a combination of residues from both domains. Indeed, studies with Nt- and Ct-fragments of LMW glutenin subunits demonstrated interactions between both parts and their significance in IgE binding.[30]

reaction of gallic acid or ellagic acid with different reagents, were widely used.[15] Although these methods are simple and fast, they generally do not provide accurate quantitative data. Different high-performance liquid chromatography (HPLC) methods have been reported in the literature for the determination of phenolic compounds in pomegranate samples and related products.[14,16−18] However, most of them refer to compounds extracted in aqueous and hydroalcoholic extracts (extractable polyphenols), but ellagitannins can also remain unextracted in the extraction residue, as they can be partly soluble or insoluble in the extraction solvent or remain covalently bound to cell walls and other macromolecules of the fruit.[19,20]

In some fruits, ETs were previously quantified as total ellagic acid on the basis of the fact that when these compounds are exposed to acids or bases release hexahydroxydiphenic (HHDP) acid, which undergoes spontaneous lactonization to ellagic acid. Many authors have reported the total ellagic acid content after acid hydrolysis, mainly in berries and nuts.[21−24] Most of the existing procedures rely solely on the quantification of released ellagic acid, and only some of them[25] consider other compounds formed during hydrolysis, which may provide helpful information on the chemical structure of the naturally occurring ETs. Despite the numerous methods for acid hydrolysis described in the literature, an optimized and validated method for the determination of total ellagic acid and other reaction products in pomegranates after hydrolysis is still lacking.

The objectives of this study were (1) to optimize a method for a more complete characterization of pomegranate ETs by quantitating the ellagic acid and other reaction products released after acid hydrolysis, (2) to carry out an interlaboratory trial to examine the reproducibility of the method, and (3) to demonstrate the applicability of this method in pomegranate extracts and different parts of pomegranate fruits and juices.

MATERIALS AND METHODS

Chemicals and Samples. Standards of ellagic acid, punicalagin (≥98% HPLC purity), and gallic acid were obtained from Sigma-Aldrich (St. Louis, MO, USA). Vescalagin was kindly supplied by Prof. Stéphane Quideau, Université de Bordeaux, France. Methanol (MeOH) and acetonitrile were purchased from J. T. Baker (Deventer, The Netherlands), and dimethyl sulfoxide (DMSO) was from Labscan (Dublin, Ireland). Formic acid 98% and HCl 37% were obtained from Panreac (Barcelona, Spain). Ultrapure water from a Milli-Q system (Millipore Corp., Bedford, MA, USA) was used throughout this experiment. All chemicals and reagents were of analytical grade.

Eleven pomegranate extracts were supplied by Laboratorios Admira (Alcantarilla, Murcia, Spain). Pomegranate juice was provided by a juice processor (AMC, Murcia, Spain). Pomegranates of the cultivar 'Mollar' (Elche, Spain) were purchased in a supermarket. The fruits were manually separated into husk (pericarp), peels (membranes/mesocarp), and arils (containing the seeds) and then were freeze-dried and ground with a mixer grinder. The powders and extracts were kept in a desiccator prior to analyses.

Stock solutions of punicalagin (1 mM), vescalagin (0.5 mM), and gallic acid (10 mM) were prepared in MeOH, and ellagic acid (3 mM) was dissolved in DMSO. Calibration curves were prepared by appropriate dilutions of the stock solutions in methanol at 10 different concentration levels from 1 to 500 μM for punicalagin and vescalagin and from 1 to 1000 μM for ellagic acid and gallic acid.

Polyphenol Extraction from Pomegranate Samples. The homogenized powder of pomegranate samples (extracts and freeze-dried pomegranate fruit parts) were weighed (75 mg) and dissolved with 5 mL of a mixture of MeOH/DMSO/H_2O (40:40:20, v/v/v) containing 0.1% HCl. Samples were vortexed for 10 min and centrifuged at 3500*g* (Eppendorf 5804R) for 10 min. The supernatant was filtered through a 0.45 μm polyvinylidene difluoride (PVDF) filter (Millipore) and measured with HPLC-ESI-UV-MS/MS.

Acid Hydrolysis Optimization of Pomegranate Samples. Optimal acid hydrolysis of ETs was completed using the following protocol: Accurately weighed freeze-dried samples (50 mg) were placed in 10 mL Pyrex screw-cap tubes, and 3.34 mL of water and 1.66 mL of 37% HCl (final concentration of 4 M) were added. Samples were vortexed for 1 min and incubated in an oven at 90 °C for 24 h. After incubation, the samples were allowed to cool to room temperature and the pH was adjusted to 2.5 with 10 and 5 M NaOH. The tubes were centrifuged for 10 min at 3500*g* (Eppendorf 5804R). The supernatant was recovered, and the volume was adjusted to 10 mL with ultrapure water. The supernatant was filtered through a 0.45 μm PVDF filter before injection onto the HPLC column. The resulting pellets, containing the majority of water-insoluble compounds, were dissolved into 10 mL of DMSO/MeOH (50:50, v/v) by vortexing for 2 min, and, after centrifugation as above, the supernatants were filtered through a 0.45 μm PVDF filter. When the concentration in the pellet was high, as in the case of pomegranate extracts, the samples were diluted 1:10 with DMSO/MeOH (50:50 v/v) before injection onto the HPLC column. Hydrolysis experiments were carried out in triplicate.

For juice samples, 3.34 mL of juice was mixed with 1.66 mL of 37% HCl (final concentration of 4 M HCl), vortexed for 1 min, and incubated in an oven at 90 °C for 24 h. The hydrolysis and analysis was performed as described above for solid samples.

HPLC-ESI-UV/MS/MS (IT) Analysis. The analyses of hydrolyzed and nonhydrolyzed samples were carried out on an Agilent 1100 HPLC system equipped with a photodiode array detector and an ion-trap mass spectrometer detector (Agilent Technologies, Waldbronn, Germany). Chromatographic separation was performed on a reverse phase Pursuit XRs C18 column (250 mm × 4 mm, 5 μm particle size) (Agilent Technologies, Waldbronn, Germany). The mobile phases were water with 1% formic acid (A) and acetonitrile (B) following a gradient profile of 0−20 min, 5−30% B; 20−30 min, 30−55% B; 30−38 min, 55−90% B; 38−40 min, 90% B; and then returned to the initial conditions. A volume of 10 μL of sample was injected onto the column operating at room temperature at a flow rate of 1 mL/min. Scan wavelength was performed in DAD at 200−600 nm with scan rate of 2.5 Hz (2 s response) and scan step of 2 nm. UV chromatograms were recorded at 280 and 360 nm with a bandwidth of 8 nm. The ion trap (IT) mass spectrometer was equipped with an electrospray interface (ESI). Nitrogen was used as drying gas with a flow of 11 L/min at a temperature of 350 °C and nebulizing gas at pressure of 65 psi. The capillary voltage was set at 4 kV. Mass scan (MS) and daughter (MS/MS) spectra were recorded in negative mode in the range of m/z 100−1500 with target mass of 500. Maximum accumulation time of ion trap and the number of MS repetitions to obtain the MS average spectra were set at 200 ms and 3, respectively. Compound stability was set at 75%.

Peak identification was performed by comparison with authentic reference standards, and, when they were not available, by using the diode array spectral characteristics, molecular mass, and fragmentation pattern of the compounds. Ellagic acid (360 nm), punicalagin (360 nm), vescalagin (280 nm), and gallic acid (280 nm) were used as external standards to quantify compounds in nonhydrolyzed samples. In the hydrolyzed samples a calibration curve of ellagic acid at 360 nm was used to quantify all of the hydrolysis products except gallic acid, which was quantified with its own standard at 280 nm.

Hydrolysis Method Validation. The limits of detection (LODs) were determined on the basis of a signal-to-noise ratio (S/N) of 3, and a S/N of 10 was used for the limit of quantification (LOQ).

Due to the lack of available standards for most of the hydrolysis products, except for ellagic acid, and the absence of pomegranate matrices free of these compounds, recoveries for each compound after the hydrolysis protocol were calculated as follows: recovery % = (quantity of compound obtained after the optimized protocol/total quantity of compound after adding two more extractions of the pellet with DMSO) × 100. After the optimized protocol (hydrolysis in water

DOI: 10.1021/acs.jafc.5b02062
J. Agric. Food Chem. 2015, 63, 6555−6566

and extraction of the pellet with DMSO/MeOH (50:50, v/v)) the resulting pellet was extracted two more times with pure DMSO to ensure the complete extraction of all hydrolysis products. DMSO has been reported to be adequate for the solubilization of ellagic acid, highly insoluble in water and other solvents.[26] The quantity recovered by applying the optimized protocol was expressed as a percentage of the total amount calculated in the sample.

The effectiveness of the optimized protocol and the effect of acid hydrolysis on pure ellagic acid were checked by hydrolysis of known amounts of punicalagin (225 μM) and ellagic acid (200 μM), respectively. The optimized protocol (hydrolysis in water and extraction of the pellet with DMSO/MeOH (50:50, v/v)) was applied to both standards.

Precision was evaluated by determining repeatability (intraday), intermediate precision (interday and different instruments/analysts), and reproducibility (interlaboratory). Repeatability was evaluated by analyzing data from three measurements of the same hydrolyzed sample three times in the same day. For the intermediate precision the same sample was analyzed on three different days and the method was also applied by 10 different analysts in the same laboratory using the same instrumentation (HPLC DAD equipment as above) and by the same analyst on different equipment (Agilent 1100, Agilent 1200 Infinity Series, Agilent 1220 Infinity series and Hitachi Elite LaChrom HPLC). In addition, a large interlaboratory reproducibility study was conducted analyzing the same pomegranate extract by six European laboratories using different instruments and chromatographic columns (see below).

RESULTS AND DISCUSSION

Identification of Ellagitannins in Pomegranate Extracts. To choose the most appropriate extract to be used in the optimization of the hydrolysis protocol (i.e., the one with the highest/most diverse hydrolyzable tannin content), different pomegranate extracts were analyzed by HPLC-DAD-ESI-MS/MS. The HPLC-UV chromatograms at 280 and 360 nm of the pomegranate peel extract selected for the hydrolysis optimization trial are shown in Figure 1. Twenty-three hydrolyzable tannins and ellagic acid conjugates were tentatively identified by their retention time, molecular mass, fragments obtained by MS/MS experiments, and UV spectra (Table 1). These compounds had been previously described[2,17,18] and include free ellagic acid, ellagic acid glycosides, gallagyl esters, and more complex ETs comprising combinations of hexahydroxydiphenic acid, gallic acid, and glucose. Due to the large number of ETs and isomers, complex chromatograms with many unresolved peaks were obtained, especially at 280 nm (Figure 1B). The complexity of the chromatograms, together with the absence of commercial standards, hampers the correct identification and quantification of pomegranate ellagitannins. Therefore, acid hydrolysis of the samples and quantification of the reaction products could be a good alternative method for ET characterization and quantification.

Acid Hydrolysis Optimization. Several methodologies for the acid hydrolysis of ETs, especially from berries and nuts, have previously been reported.[22−24] In most of these methods, a primary extraction of the polyphenols with hydro-organic mixtures, usually acetone/water or MeOH/water, was applied. After evaporation, the extracts were usually dissolved in MeOH (methanolysis) or in MeOH/water prior to hydrolysis.[22] This extraction process, however, does not allow the quantification of nonextractable ellagitannins, leading to an underestimation of these polyphenols. Studies by Vrhovsek et al.[25] and Da Silva Pinto et al.[21] concluded that acetone/water was the best solvent for the initial extraction and that 2 N trifluoroacetic acid (TFA)

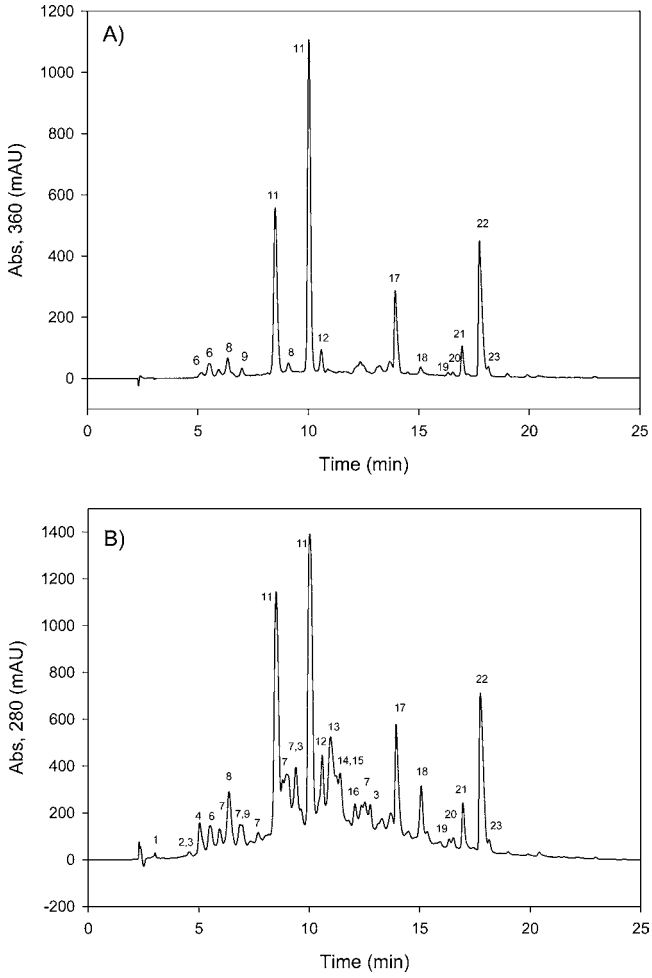

Figure 1. HPLC-UV chromatograms at 360 nm (A) and 280 nm (B) of the nonhydrolyzed pomegranate peel extract. This sample was chosen for the hydrolysis optimization. Numbers refer to compounds described in Table 1.

for 1 h at 120 °C in water and 4 M HCl for 6 h at 90 °C in MeOH were the best hydrolysis conditions for the determination of total ellagic acid in strawberries and raspberries, respectively. As a first step in the optimization process these two hydrolytic conditions were tested in the selected pomegranate extract in both MeOH and water. The freeze-dried samples were hydrolyzed after an initial extraction with acetone/water (0.6 g of pomegranate sample with 25 mL of acetone/water) and also a direct hydrolysis was tested. Figure 2 shows the reaction compounds produced during the hydrolysis of pomegranate samples and the ETs from which they have been formed (described in detail in the next section). The content of the main compounds detected after the different hydrolysis conditions, original ETs (punicalagin and two isomers of punicalin), and reaction products (gallic acid, gallagic acid dilactone, ellagic acid, sanguisorbic acid dilactone, and valoneic acid dilactone) is shown in Table 2. Although similar results were obtained for most of the compounds with and without previous extraction, direct hydrolysis was chosen as the preferred approach as it required less time and solvents and allowed quantification of both the extractable and nonextractable compounds. In general, larger amounts of reaction products were obtained after 6 h of hydrolysis with 4 M HCl at 90 °C. The reaction was better carried out in water as the

hydrolysis in MeOH generated methylated derivatives (methyl gallate, methyl valoneic acid dilactone, and methyl punicalin, among others), preventing the correct quantification due to the lack of authentic standards.[22,24] Although there was a drawback of using water, namely, the very low solubility of ellagic acid in aqueous media,[27] which caused some of the hydrolysis products to remain precipitated in the pellet, re-extraction of the pellet with DMSO/MeOH (50:50, v/v) proved to be very efficient at dissolving highly insoluble compounds such as ellagic acid, gallagic acid dilactone, and valoneic acid dilactone, and these

hydrolysis of pomegranate ETs, different hydrolysis times (0, 1, 2, 4, 6, 8, 10, 12, and 24 h) were tested. Figure 3 shows the evolution of punicalagin and the main reaction products after the hydrolysis of the pomegranate extract (three replicates).

The kinetics showed the fast hydrolysis of punicalagin that disappeared after 2 h of incubation and the much slower hydrolysis of the punicalin produced, taking 24 h to reach a complete hydrolysis. Two punicalin isomers were detected; punicalin 2 was already present in the original extract, whereas punicalin 1 was detected only after acid hydrolysis. The punicalins were hydrolyzed at different rates, punicalin 2 being hydrolyzed more rapidly than punicalin 1. Both punicalins increased gradually during acid hydrolysis as a product of the release of ellagic acid from punicalagin, and then decreased when gallagic acid dilactone was released (Figure 3). This shows that the release of ellagic acid from punicalagin by acid hydrolysis is much more favored than the hydrolysis of the gallagyl ester to release gallagic acid dilactone, as it needs up to 24 h to be completed. Ellagic acid reached a maximum after 4 h because of the fast hydrolysis of punicalagin, and this value was maintained up to 24 h. Longer periods of treatment with HCl did not release more ellagic acid. Gallagic acid dilactone,

originating from punicalagin and punicalin, increased over time, reaching the maximum concentration after 24 h, as well as gallic acid and valoneic acid dilactone. Sanguisorbic acid dilactone reached steady-state concentration between 6 and 10 h.

Finally, hydrolysis for 24 h with 4 M HCl at 90 °C in water and subsequent extraction of the pellet with DMSO/MeOH (50:50, v/v) was selected as the most suitable pretreatment to yield maximum recovery for the main hydrolysis products of pomegranate ETs (see graph of total hydrolysis products in Figure 3).

Reaction Products Obtained after the Hydrolysis. Several reaction products were detected after acid hydrolysis of pomegranate extracts. Figure 4A shows the HPLC-UV chromatograms of the supernatant (360 and 280 nm) and pellet (360 nm) of a pomegranate extract after acid hydrolysis. All of these compounds were identified by their retention time, molecular mass, fragmentation pattern, and the spectral properties shown in Table 3. The UV spectrum for each compound (Figure 4B) is also useful for the identification of the hydrolysis products when only HPLC with UV diode array detectors is available for analysis. All compounds (except gallic

acid) exhibit two major absorption maxima. The first one was around 256 nm and the second one in the region of 350−400 nm with slight differences in the UV maxima depending on the compound. As indicated before, the main reaction products identified and quantified were ellagic acid, gallagic acid dilactone, gallic acid, and two compounds with m/z 469 consistent with ellagic acid derivatives in which an additional gallic acid is linked to the ellagic acid molecule through an ether bond (Figure 5). Traces of punicalin (<1%) were also observed and indicated that the hydrolysis of this compound was incomplete. In general, the main hydrolysis products were ellagic acid and gallagic acid dilactone. In particular, the detection of gallagic acid dilactone could be considered as an unequivocal signal of the presence of pomegranate, as it was produced by hydrolysis of the unique and characteristic ETs (gallagyl esters) of pomegranate, punicalagin and punicalin. After acid hydrolysis, one molecule of punicalagin releases one molecule of ellagic acid and one of gallagic acid dilactone. This last compound could also be released from punicalin (Figure 2). The detection of gallic acid was indicative of the presence of gallotannins and other gallic acid-containing products. The two compounds with m/z^- 469 showed different fragmentation patterns and UV spectra (Table 3; Figures 4 and 5). In both cases, the presence of an M − 44 fragment (m/z 425) was observed, this being consistent with the loss of CO_2 as could be expected for phenolic with a free carboxylic group. According to the literature these isomers could be consistent with valoneic acid dilactone and sanguisorbic acid dilactone. The only structural difference between these two isomers is that the hydroxyl that links the hexahydroxydiphenoyl group (HHDP) to the galloyl group belongs either to the HHDP group or to the galloyl group (Figure 2). According to the literature[25] the hydrolysis of strawberry ellagitannins produces sanguisorbic acid dilactone in addition to ellagic acid. Thus, to identify both isomers the optimized hydrolysis protocol was applied to a strawberry sample. One peak with m/z 469 was detected at 13.46 min, the same retention time of the compound **4** that was tentatively identified as sanguisorbic acid dilactone. The detection of both isomers after hydrolysis of the pomegranate extract indicates the occurrence of other complex ETs with linkages in their structure involving an additional galloyl group linked to the HHDP ester.

Apart from the major compounds, other minor analytes with UV−vis absorbance spectra similar to the spectrum of ellagic acid were detected after the hydrolysis. Two of them with m/z^- 631 and 463 exhibited fragmentation profiles characteristic of *C*-glycosidic compounds with typical losses of 60, 90, 120, and 150 mu, often accompanied by an additional loss of water (−m/z 18 mu). Several isomers for each compound were detected in the MS-MS analysis (Figure 5). Different isomers of ellagic acid *C*-glucoside (**8**) were identified. These could be produced after the hydrolysis of *C*-glycosidic ellagitannins. The occurrence of different isomers indicates that the original HHDP-*C*-glucoside can be cycled in different conformations after the hydrolysis. The presence of these reaction products suggests that *C*-glycosidic ETs such as casuariin, punicacortein, and vescalagin/castalagin could be present in the extract. The identification of compounds **9** and **10** was not possible with the instrumentation used in this experiment, although information about fragmentation patterns and UV spectra is provided in Table 3. Ellagic acid *C*-glucosides represented <3% of the total hydrolysis products, indicating that, in general, *C*-glycosidic ellagitannins were minor constituents of pomegranate samples.

Method Validation. For the quantitation of ETs in nonhydrolyzed samples, the LOD and LOQ, considering the whole protocol, were estimated at 0.06 and 0.20 mg/g for vescalagin, 0.07 and 0.24 mg/g for punicalagin, and 0.01 and 0.03 mg/g for both ellagic acid and gallic acid. For the quantitation of hydrolyzed samples the LOD and LOQ, considering the whole protocol, were 0.03 and 0.10 mg/g for both ellagic acid and gallic acid.

The effectiveness of the optimized hydrolysis protocol was checked by hydrolysis of a known amount of punicalagin standard (225 μM). Complete hydrolysis of punicalagin was observed after 24 h with the presence of two main peaks: ellagic acid and gallagic acid dilactone (Figure 6). Other minor compounds were observed (representing <5%), probably due to the presence of trace amounts of other ETs in the punicalagin standard (standard purity ≥ 98% HPLC isolated from pomegranate). Hydrolysis of punicalagin would theoret-

ically yield 1 mol of ellagic acid and 1 mol of gallagic acid dilactone per mole of punicalagin. UV response factors were similar for both compounds, indicating that the ellagic acid calibration curve can be used as a good proxy for the accurate quantitation of gallagic acid dilactone as no standard was available of the latter compound.

Recoveries of hydrolysis products in pomegranate extracts after hydrolysis were between 97 and 99%, and no decomposition of ellagic acid was observed up to 24 h.

Method precision was evaluated by determining repeatability, intermediate precision, and reproducibility. The optimized method has a high precision with a relative standard deviation (RSD) of peak areas below 5.6% for intraday precision and below 7.5% for interday precision. The intermediate precision assessed by means of using different instruments or having various analysts prepare the samples was estimated at 9.5 and 14%, respectively. Finally, reproducibility of the method was assessed by means of an interlaboratory study conducted by six European laboratories. Reproducibility of the method for most of the main compounds was <15% (Table 4). Only valoneic acid dilactone showed higher values (33%), probably due to its low intensity as this compound is usually present in low concentrations (around 2% of the total hydrolysis products).

Comparison with the Conventional Quantitation (without Hydrolysis). The quantitative results obtained with the new hydrolysis method were compared with those produced with a conventional method (Table 5). The conventional method for pomegranate ETs quantitation involves the individual assessment of each compound after a hydro-organic extraction of the samples. Due to the lack of available standards, each compound was quantified with the most appropriate calibration curve (indicated in Table 5). Direct quantification of extractable ellagitannins using HPLC-DAD and external standards (punicalagin, vescalagin, ellagic acid, gallic acid) yielded 549.1 mg/g dw extract (Table 5A). When the corresponding equivalents of ellagic acid, gallagic acid dilactone and gallic acid, were calculated, the total amount of the equivalents that should be released after hydrolysis of the

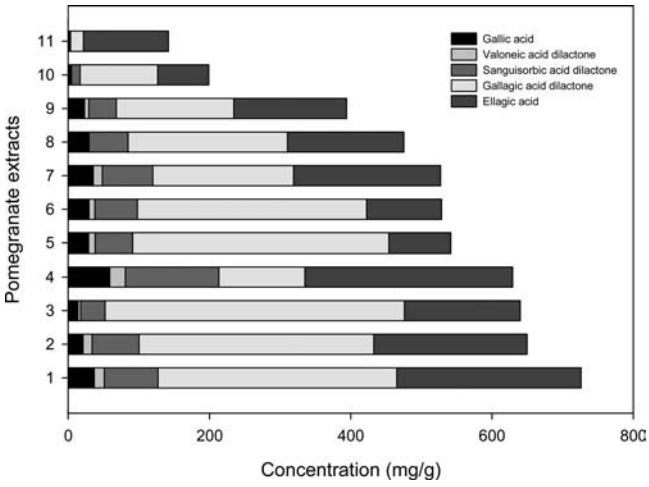

Figure 7. Content of the main hydrolysis products in different pomegranate extracts, expressed as mg of compound/g dw.

extractable ellagitannins reached 349.3 mg/g, and this value should be compared with that obtained after direct hydrolysis without hydroalcoholic extraction that amounted to 635.8 mg/g dw (Table 5B). The results show that around 300 mg/g of the hydrolysis products corresponded to nonextractable ellagitannins (either nonextracted or not quantifiable with the direct HPLC-DAD analysis). Other minor compounds (those with valoneic acid bilactone, sanguisorbic acid bilactone, and *C*-glycosyl ellagitannins) were not quantified in the conventional analysis without hydrolysis (Table 5A), as their quantification in the chromatograms of the nonhydrolyzed extracts was not possible. After hydrolysis, a small amount of these compounds was detected (90.5 mg/g of the valoneic and sanguisorbic acid dilactones and 18 mg/g of ellagic acid *C*-glucoside), therefore increasing even more the content of ETs in the analyzed extract (750.6 mg/g dw) (Table 5B).

As indicated before, the presence of a high background and unresolved peaks in the chromatograms (especially at 280 nm, see Figure 2), together with the absence of available standards for most of the compounds, could lead to an underestimation when using the conventional method. The hydrolysis method has shown to be a good alternative for quantitation purposes.

Application of the Method to Different Pomegranate Samples. The optimized method was successfully applied to different pomegranate extracts, finding large differences in the ellagitannin content (Figure 7). Pomegranate peel extracts have recently attracted interest because of their potential use as natural food preservatives and nutraceuticals.[28,29] Industrial scale extraction of phenolic compounds from pomegranate peel is carried out by using solvents such as water and ethanol or their mixtures. The content of hydrolysis products ranged from 150 mg/g to 750 mg/g extract, showing that different plant materials and different extraction and purification processes had been applied for extract preparation. In addition, highly significant chemical differences ($p < 0.01$) in the ellagitannin composition were observed.

The high variability observed among the different pomegranate extracts was especially important in the amount and ratio of ellagic acid and gallagic acid dilactone, indicating large differences in the presence of the gallagyl esters punicalagin and punicalin. One pomegranate extract containing mainly punicalagin should have a gallagic acid dilactone/ellagic acid ratio around 2. Ratios above 2 indicate that the extract is richer in punicalin, and ratios below 2 indicate that the extracts are richer in ellagitannins based on ellagic acid or extracts with larger amounts of free ellagic acid. Thus, extracts 2, 3, and 10 (Figure 7) show gallagic acid dilactone/ellagic acid ratios that indicate that punicalagin was the main ellagitannin, whereas extracts 5 and 6 contain mainly punicalin and extracts 4 and 11 contain mainly ellagic acid-based ellagitannins. Furthermore, the presence or absence of other hydrolysis products is indicative of other ET content. This variability is in agreement with the literature, where the use of different solvents for peel phenolic extraction is reported to yield different phenolic content ratios and associated different antioxidant activity.[28] Previous studies for the analysis of extractable ETs in pomegranate extracts using HPLC had reported ET contents of 330 mg/g dw[30] and 220 mg/g dw,[31] values that are smaller than those found in the present study, particularly after hydrolysis that takes into account the nonextractable ETs.

The applicability of the method was also tested on different parts of a pomegranate fruit: husk (pericarp), peels and membranes (mesocarp), arils, and commercial juices. Quantitative results are shown in Table 6. The highest concentration of ellagic acid and other hydrolysis products occurred in the husk, followed by the peels, and only traces were present in the arils. This is in agreement with previous studies in which individual quantitations of ETs with conventional extraction methods were assayed.[2,5]

Further research will be conducted to apply this methodology to other ellagitannin-rich food products including berries and nuts and to extrapolate the present findings to a simplified method that can be easily used for the routine analysis of pomegranate ETs in all laboratories and industry.

Table 6. Quantification of Hydrolysis Products in Different Parts of Pomegranate Fruit (mg/g dw) and in Pomegranate Juice (mg/L)[a]

	extract	husk (pericarp)	peels mesocarp	arils	juice

in in vivo tests. In addition to IgE antibodies, a significant percentage of subjects, both kiwifruit allergic and tolerant, were also reported to produce kiwellin-specific IgG4.[7] The subjects positive to kiwellin in IgE-immunoblotting were also positive to KiTH, purified from the natural source, thus suggesting that at least the linear sequence epitopes recognized by IgE antibodies could be located on the kiwellin C-terminal domain.[2] The immunological properties, especially those correlated with the conformational epitopes, were reported to be modulated by the physicochemical features of the environment/experimental conditions, such as solvent pH and polarity.[5]

The effects of kiwellin on human health have so far received more attention than the physiological role of this protein in the natural source. The few papers describing putative homologues from other species provide only vague information on the possible implications of kiwellin in complex plant processes without any attribution of a specific function. For instance, in grape berries, a kiwellin homologue was classified as a "ripening-related protein" because of a marked increase in the mRNA levels associated with the fruit ripening.[8] A DIGE-based quantitative proteomic analysis of the grape berry suggested kiwellin's involvement in fruit development and stress response.[9] In addition, a pathogenesis-related function was hypothesized following experiments in potato leaves showing a strong up-regulation of kiwellin mRNA transcription after infection with *Phytophthora infestans*, an oomycete that causes late blight in *Solanum* spp.[10] It is worth noting that a clear orthologue of kiwellin is not present in *Arabidopsis thaliana*,[11] the model plant for which the entire genome is described. This observation suggests that kiwellin might have a specialized function associated with physiological processes particular to some plant species/families, rather than a basic function found ubiquitously throughout the plant kingdom.

In summary, the biochemical function of kiwellin, as well as its physiological role in kiwifruit, is still unknown. However, the available literature indicates that kiwellin, and its disjoined domains kissper and KiTH, may have some effects on human health, including intriguing pharmacological activities. Very recently, the partial (about 83%) crystal structure of kiwellin from the golden kiwifruit species, registered as allergen Act c 5, was reported.[12] Here we describe an investigation of the structure of kiwellin from green kiwifruit, allergen Act d 5, determined using X-ray crystallography and refined to 2.1 Å. Additionally, attempts to correlate the structural features with possible biological and immunological activities were performed.

MATERIALS AND METHODS

Protein Purification. Kiwellin was purified from the pulp of green kiwifruit (*A. deliciosa* cv. Hayward) following the already described procedure.[13] As a final purification step, the protein was subjected to size exclusion chromatography on a Superdex 75 HR10/30 column (Amersham Biosciences, Uppsala, Sweden), equilibrated and eluted with 10 mM Tris-HCl, pH 7.5, containing 0.25 M NaCl. The protein fractions were pooled and used for crystallization experiments. The protein concentration was estimated on the basis of the molar extinction coefficient at 280 nm (23335 M^{-1} cm^{-1}). The purity of the protein preparation was checked by SDS-PAGE, RP-HPLC, and N-terminal amino acid sequencing, as previously reported.[13]

Crystallization, Data Collection, and Processing. Crystallization experiments were performed at room temperature using the hanging-drop vapor diffusion method and NeXtal plates (Qiagen, Chatsworth, CA, USA). A solution of purified Act d 5 was mixed with glucose such that the final protein and glucose concentrations were 3.5 mg/mL and 50 mM, respectively. The Act d 5−glucose solution was mixed with mother liquor [0.1 M HEPES, pH 7.5, 25% (w/v) polyethylene glycol (PEG) 3350] in a 1:1 ratio and was hung over a reservoir of 26% PEG 400. The crystals were cryo-protected with PEG 400 and cooled in liquid N_2. Data were collected from a single crystal at 100 K at SER-CAT 22ID beamline at the Advanced Photon Source (APS), Argonne National Laboratory (ANL). The crystal belonged to the $P2_1$ spacegroup with two subunits per asymmetric part of the unit cell. The data were processed with the HKL-2000 software package.[14] The data collection statistics are reported in Table 1.

Structure Determination and Refinement. The Act d 5 structure was solved by molecular replacement using a truncated version (residues 176−263) of *Achromobacter lyticus* protease I (PDB ID 1ARB) as a starting model. The starting model was identified after a BLAST[15] search with a sequence of Act d 5 against sequences of proteins with their structures determined experimentally, as reported in the Protein Data Bank.[16] Molecular replacement was performed with HKL-3000[17] integrated with MOLREP[18] and selected programs from the CCP4 package.[19] Models were rebuilt using COOT,[20] Buccaneer,[21] and ARP/wARP[22] and refined with REFMAC.[23] MOLPROBITY[24] and ADIT[25] were used for structure validation. The refinement statistics are summarized in Table 1.

Analysis of Protein Molecular Weight by Size Exclusion Chromatography. The entire molecule, kiwellin, and the C-terminal domain, KiTH, were loaded on a gel filtration column Superdex 75 HR10/30 (Amersham Biosciences), eluted with 10 mM Tris-HCl, pH

DOI: 10.1021/acs.jafc.5b02159
J. Agric. Food Chem. 2015, 63, 6567−6576

7.5, 0.25 M NaCl. Fractions of 0.5 mL were collected, and the absorbance at 280 and 230 nm was recorded.

Circular Dichroism (CD) Experiments. CD spectra were recorded on a JASCO J-810 spectropolarimeter (Easton, MD, USA) as already reported.[5] A quartz cell of 0.1 cm path length was used to record the spectra over the wavelength range of 260−190 nm with a bandwidth of 1.0 nm. The purified protein was first extensively dialyzed against 0.2 M NaCl to eliminate Tris-HCl contained in the solution and then against 2 mM NaCl. After that, the protein solution was concentrated to 1 mg/mL by ultrafiltration. For CD experiments, the protein solution was diluted 10-fold in the appropriate buffer and left for 2 h at 25 °C before acquisition of the spectra. Measurements were performed in 5 mM sodium phosphate, pH 7.4, and 5 mM sodium acetate, pH 4.5, at SDS concentrations from 0 to 100 mM, at 25 °C. The protein concentration was 0.10 mg/mL. Each spectrum was baseline corrected for the contribution of the solvent.

Endoglucanase Activity Assay. Endo-1,4-β-D-glucanase activity was assayed using dyed soluble azo-carboxymethylcellulose (AZO-CMC) as the substrate, according to the manufacturer's protocol (Megazyme, Intl., Bray, Ireland). Five, 20 and 50 μg of kiwellin were incubated overnight, at 37 °C, in the presence of 2% AZO-CMC, at pH 4.0, 5.0, 6.0, and 7.4, in 100 mM sodium acetate or sodium phosphate buffer, in a final volume of 1 mL. The reaction was stopped by adding 96% ethanol. Then, the mixture was centrifuged, and the supernatant absorbance was measured at 590 nm.

3,5-Dinitrosalicylic Acid (DNS) Assay for Reducing Sugars. Kiwellin's capacity to hydrolyze different polysaccharides made of glucose or mannose was analyzed by using the DNS colorimetric method, allowing for a quantitative estimation of released reducing sugars.[26] The substrates used were cellobiose, cellotetraose, mannan, laminarin, curdlan, and lichenan. Each one was analyzed in the following buffers: sodium phosphate, pH 4.0 and 7.4; sodium acetate, pH 5.0; MES, pH 6.0. Amounts of kiwellin corresponding to 12.5, 25, and 50 μg were added to the incubation mixture containing 100 μg of a substrate in 0.1 M buffer, in a final volume of 125 μL. Incubations were carried out at 37 °C for 1 and 3 h and overnight. Then, after 10 min at room temperature, 0.1 mL of DNS reagent was added to the samples, and the mixtures were incubated for 5 min in a boiling water bath. After cooling in an ice bath, the absorbance at 546 nm was measured. Standard curves with glucose as reducing sugar were used as a reference. All assays were carried out in duplicate.

Analysis of Released Glucose by HPLC. To assess the possible hydrolytic activity of kiwellin on cellobiose, the release of glucose was analyzed by chromatographic separation. Twenty-five micrograms of kiwellin was incubated at 37 °C in 50 mM sodium acetate, pH 5.0, in the presence of 100 μg of cellobiose, in a final volume of 0.3 mL. Fifty-microliter aliquots were removed at incubation times of 0, 3, 24, and 72 h and analyzed by an HPLC (Dionex, Sunnyvale, CA, USA), equipped with an anionic exchange column (Carbopac PA-100). Monosaccharides were separated by isocratic elution with 16 mM NaOH at a flow rate of 0.25 mL/min. Glucose was used as an internal standard.

Glycan Array Analysis. Biotinylated Act d 5 was diluted to 0.5 mg/mL in 100 mM Na_2HPO_4, 20 mM NaCl, pH 7.6, and sent to the Consortium for Functional Genomics (CFG) at Emory University to determine if protein−glycan interactions occur. The CFG facility ran the mammalian glycan array assay (version 5.1), testing 610 glycans in replicates of 6 with bacterial lectin as the positive control. The protein was directly labeled with a fluorescent tag for detection. This CFG mammalian glycan array contains glycans of potential interest for the biological effects of kiwellin in human being. It does not include plant cell wall glycans such as cellulose, xyloglucan, and pectins, but recent results indicate kiwellin has negligible affinity for these plant components.[12]

Cell Wall Creep Analysis. Cucumber seedlings were grown in the dark, and hypocotyls were harvested, frozen, abraded, and prepared for wall extension assays as described previously.[27] Seeds of wheat (*Triticum aestivum* L. cv. Pennmore) were germinated on Kimpak Seed Germination Paper K-22 (Seedburo Equipment Co., Chicago, IL, USA) soaked with distilled water, in flats, 50 × 25 × 6 cm, with lids of the same dimensions. Seedlings were grown in the dark for 4 days at 28 °C. Coleoptiles from etiolated grass seedlings were cut, gently abraded by rubbing them between two fingers coated with a slurry of well washed carborundum (320 grit, Fisher Scientific Inc., Fair Lawn, NJ, USA), separated from primary leaves, and then stored at −80 °C before use.

Etiolated wheat coleoptiles and cucumber hypocotyls were inactivated by a 15 s dip in boiling water and clamped in a constant-force extensometer[28] with 5 mm between clamps, a 20-g force, in 200 μL of 20 mM sodium acetate buffer, pH 5.5. To increase the wall sensitivity to wall-loosening agents, the buffer was exchanged at 15 min for 50 mM NaOH for ∼35 min (for coleoptile walls) or 50 mM CDTA (for cucumber walls) and then rinsed in 20 mM sodium acetate buffer. Finally, the buffer was replaced with fresh buffer containing 500 μg/mL kiwellin. All experiments were performed in replicates of four.

Protein Sequencing. Protein direct sequencing was carried out by automated Edman degradation on a Procise 492 automatic sequencer, connected with an online phenyl thiohydantoin (PTH) amino acid analyzer (Applied Biosystems, Foster City, CA, USA). Amino acids were separated by RP-HPLC and identified, as their PTH derivatives, on the basis of coelution with appropriate standards (20 PTH-amino acid standard solution, PerkinElmer Life Sciences).

Immunological Data Collection, Storing, Processing, and Statistics. Act d 5 IgE reactivity, as well as IgE reactivity toward other food and inhaled allergens, was collected by routinely testing 30836 allergics using a molecule-based microarray (ImunoCAP ISAC 103, Phadia Multiplexing Diagnostics, PMD, Vienna, Austria) bearing 103 allergenic proteins. All diagnostic data were stored during testing by online connectivity to the InterAll e-record (Allergy Data Laboratories, Italy). The study was approved by the Institutional Review board (35/IDI-CE/2006).

To understand the immunological behavior of Act d 5, a new statistical procedure was applied to this IgE data set. Act d 5 IgE reactivity was compared to the other 102 allergens using an aggregative hierarchical clustering algorithm with Ward's linkage method. The distance between two allergens was built as a dissimilarity for the categorical value (0 = patient IgE negative to the allergen, 1 = patient IgE positive to the allergen). The chosen dissimilarity was

$$d = \frac{n01 + n10}{n11 + n01 + n10}$$

where $n11$ is the number of patients positive to both allergens, $n10$ the number of patients positive to the first allergen, and $n01$ the number of patients positive to the second allergen, respectively. To remove the effect of the frequency of IgE positive patients, the allergens were divided into four frequency classes, broadly dispersed in a range from 33 for Bla g 5.0101 to 8774 patients for Phl p 1.0101 (Table S1). The results of the analysis are shown in cluster dendrogram graphics. The approximately unbiased (AU) p values for the cluster dendrograms were calculated via multiscale bootstrap resampling (pvclust package in R). To understand whether the findings obtained with the newly applied data analysis were reliable, the same analytical method was applied to a second green kiwifruit molecule, namely Act d 1, actinidin, which is known to have cysteine protease activity.[29] The IgE binding frequency of this allergen was evaluated in comparison with that of other three cysteine proteases, Der p 1, Der f 1, and Ana c 2, immobilized on the same ISAC system, usually grouped together with Act d 1 on the basis of their similar biochemical features.[30] The statistical analysis and graphical visualization of the data were performed using the R software (www.r-project.org). The statistically significant level was set at a p value <0.05.

Other Computational Calculations. The SSM algorithm[31] in COOT was used to superpose protein models. All figures containing protein structures were prepared with PyMOL[32] or Chimera.[33] PDBePISA was used to calculate the possibility of quaternary structure.[34] The Dali server was used to identify structurally similar proteins.[35] The ConSurf server was used to map sequence conservation on the Act d 5 structure.[36] An omit map was calculated with SFCHECK[37] from the CCP4 package.

RESULTS

Structural Analysis of Kiwellin. The Act d 5 molecule is composed of 189 residues (residues 2−41 and 47−189 are visible in the electron density map of subunit A, whereas residues 47−189 are visible in the electron density map of subunit B) that form two domains: the N-terminal kissper domain (residues 1−39) and the C-terminal KiTH domain (residues 40−189). Although Act d 5 crystallized with two subunits per asymmetric unit, PDBePISA indicates that this protein is more than likely monomeric, which is in line with the results from size exclusion chromatography (see below).

The kissper domain is composed of 39 residues, 6 of which are cysteines that form three disulfide bonds between residues 4 and 36, 8 and 20, and 14 and 25. This domain was run through the Dali server, and no significant matches were found. This finding could possibly indicate that kissper forms a new, previously unobserved, structural motif. The electron density for this domain is significantly worse than that of the KiTH domain, and the average *B* factors are 95 Å^2 (Figures S1 and S2). The kissper domain from chain A (Figures S1 and S2), that we were able to trace forms crystal contacts with two other symmetry-related molecules. Therefore, the conformation of the Act d 5 that we observed corresponds to a protein state that was "trapped" by crystal lattice. Most likely, the kissper domain of chain B did not form any stable crystal contacts and was relatively free to move in the crystal. Therefore, there is no well-defined electron density that corresponds to this fragment of the structure.

The KiTH domain, however, is composed 150 residues arranged as a six-stranded β-barrel with two extended loops (residues 81−105 and 144−159) that form a "pincher-like" structure (Figure 1). An additional loop is found at the N-terminal portion of this domain and is stabilized to the core of the KiTH module by two disulfide bridges. KiTH contains eight cysteines in total, all of which participate in disulfide bonds: residues 48 and 66, 56 and 148, 95 and 120, and 142 and 158 (Figure 2). It also has more complete density than the kissper domain, and the average *B* factors of subunits A and B are 34 and 33 Å^2, respectively.

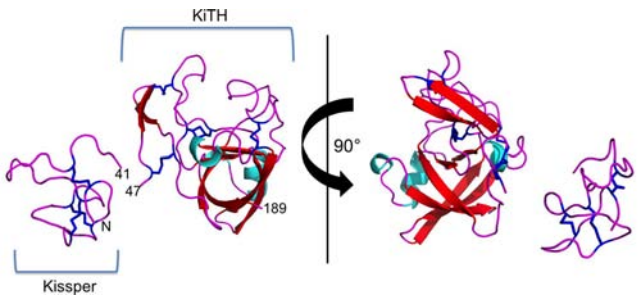

Figure 1. Overall structure of kiwellin. Secondary structural elements are colored separately where α-helices are colored cyan, β-sheets are colored red, loops are colored magenta, and disulfide bonds are colored blue. The N-terminal kissper domain and the C-terminal KiTH domain are labeled.

After performing a search of the KiTH domain using the Dali server, Dali identified kiwellin (PDB code 4PMK) as the most closely related structure. A superposition of 4PMK on our structure results in a root-mean-square deviation (RMSD) of 0.3 Å over 142 aligned Cα atoms. Hamiaux and colleagues recently determined this structure,[12] and although the RMSD is 0.3 Å between the two structures, there are some structural differences. One evident difference between the two structures is seen at the N terminus. Kiwellin from golden kiwifruit has a short fragment of the kissper domain modeled, which contains residues 24−39. Our structure, however, contains a more complete N-terminal domain spanning from residues 2 to 39. With this more complete model, we were able to properly establish which C-terminal (KiTH) domain corresponds to the proper kissper (N-terminal) domain, which was improperly done in the case of the kiwellin from golden kiwifruit.[12] The correct domain organization of the Act d 5 molecule was determined on the basis of the analysis of the crystal packing and the distance from residue 42 to 47 (where there is a gap in electron density); all other subunits, other than the one chosen for our model, were located at a distance that was too far away and therefore could not be correct. With an incomplete model it is not obvious how to correctly match domains. Once this was established, the second protein chain in the asymmetric unit was properly assigned.

Dali also identified the N-terminal (double-ψ β-barrel) domain of several expansin proteins, including one from *Clavibacter michiganensis* (for example, PDB code 4JJO, RMSD value 1.6 Å over 92 aligned Cα atoms, sequence identity of 25%); several expansin−yoaj proteins from *Bacillus subtilis* (for example, PDB code 4FFT, RMSD value 1.6 Å over 91 aligned Cα atoms, sequence identity of 13%); maize allergen Zea m 1 (PDB code 2HCZ, RMSD value 2.0 Å over 101 aligned Cα atoms, sequence identity of 15%); and pollen allergen Phl p 1 (PDB code 1N10, RMSD value 1.4 Å over 89 aligned Cα atoms, sequence identity of 18%) as having the most similar structures to Act d 5. Act d 5 and the previously mentioned similar structures align through the core, β-barrel, domain of the protein, confirming the observations of Hamiaux et al.[12] The differences between the other similar structures and Act d 5 are seen outside the core structure. Mainly, the kissper domain of Act d 5 does not align with any of the similar structures. Furthermore, the N-terminal loop of the KiTH domain (residues 47−72) and the two loops that form the "pincher-like" structure (residues 81−105 and 114−159) do not align with any of the similar structures. These three structural elements, the kissper domain, and the positions of loops 47−72, 81−105 and 114−159, are unique to Act d 5.

Figure 2 also shows surface and ribbon representations of the Act d 5 molecule, indicating conservation among 150 Act d 5-related protein sequences selected by ConSurf. It also includes the sequence of kiwellin, where the most and least conserved residues are indicated, broken down into domains, and disulfide linkages are indicated. Even though the Dali server did not find any structurally significant matches for the kissper domain, the protein sequence is conserved, especially when compared to proteins with uncharacterized function. Electrostatic potentials were calculated using Chimera[33] and are mapped out on the surface of kiwellin, shown in Figure 3. It is interesting to note that a large portion of the KiTH domain is negatively charged, thus suggesting that Act d 5 can bind positively charged ligands and cations.

Identification of Residues 41 and 43 of Kiwellin as Hydroxyproline (Hyp). The primary structure of kiwellin had been elucidated by direct sequencing of the N-terminal region of the native protein and of the peptides obtained by proteolytic digestion of the denatured and alkylated protein.[13] Residues at positions 41 and 43 were interpreted to be histidine (UniProtKB, accession no. P84527). Later it was observed that,

DOI: 10.1021/acs.jafc.5b02159
J. Agric. Food Chem. 2015, 63, 6567−6576

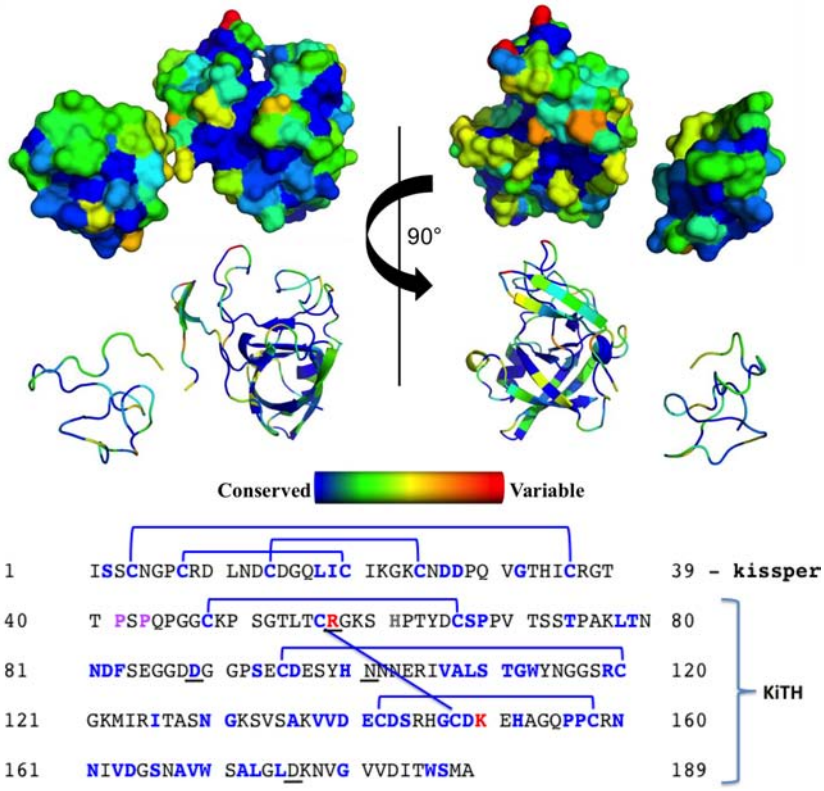

Figure 2. (Top) Surface and ribbon representation of Act d 5 showing conserved residues derived from an alignment of 150 Act d 5-related protein sequences selected by ConSurf. The most conserved residues are shown in blue, whereas the most variable residues are shown in red. (Bottom) Sequence of Act d 5, where the kissper and KiTH domains are separated. The most conserved residues are shown in blue and the most variable residues are shown in red. Residues 41 and 43, shown in purple, are hydroxyprolines. A mutation in residue 61 is seen in the natural variants of the protein where a tyrosine is substituted for a histidine. Due to kiwellin being purified from a natural source, residue 61, shown in gray, is a histidine. The four residues that are different between Act d 5 and Act c 5 are underlined.

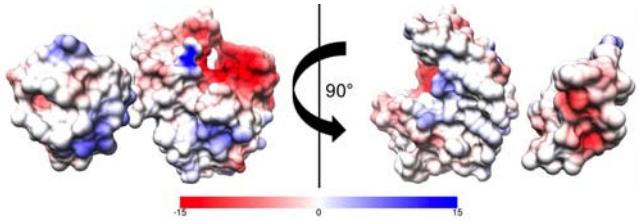

Figure 3. Surface representation of Act d 5 with electrostatic potentials, where blue indicates positive charge and red indicates negative charge in units of kcal/(mol·*e*).

during the sequencing procedure, both residues 41 and 43 were reproducibly eluted by RP-HPLC as two peaks, one almost coeluting with histidine and the other was eluted near alanine, in a peak ratio of about 3:5. This observation, together with literature reports, strongly suggested that residues 41 and 43 are Hyp, as an isomeric mixture,[38] rather than histidine. Nevertheless, no standards used as a reference were available to confirm it. Then, the publication of the DNA-derived protein sequence of kiwellin confirmed that the gene-coded amino acid present in positions 41 and 43 is proline.[11] It was initially confused with histidine because of the post-translational modification, consisting of the hydroxylation of proline residues and affecting their chromatographic behavior during the protein sequencing procedure.

Analysis of Protein Molecular Weight in Solution. On the basis of the elution volume by gel filtration chromatography on a precalibrated Superdex 75, the molecular weight estimated for the entire molecule kiwellin and that for KiTH correspond to 22 and 16 kDa, respectively (Figure 4). These values are in agreement with the size calculated on the basis of the amino acid sequence and indicate that both molecules are monomeric in the conditions of the size exclusion chromatography.

Effect of pH and Hydrophobic Environments on the Structure of Kiwellin, Kissper, and KiTH. SDS was used to

J. Agric. Food Chem. 2015, 63, 6567−6576

mimic hydrophobic environments in buffer solutions. Overlapping CD spectra were obtained with kiwellin in neutral and acidic buffer solution (Figure 5). The presence of SDS causes

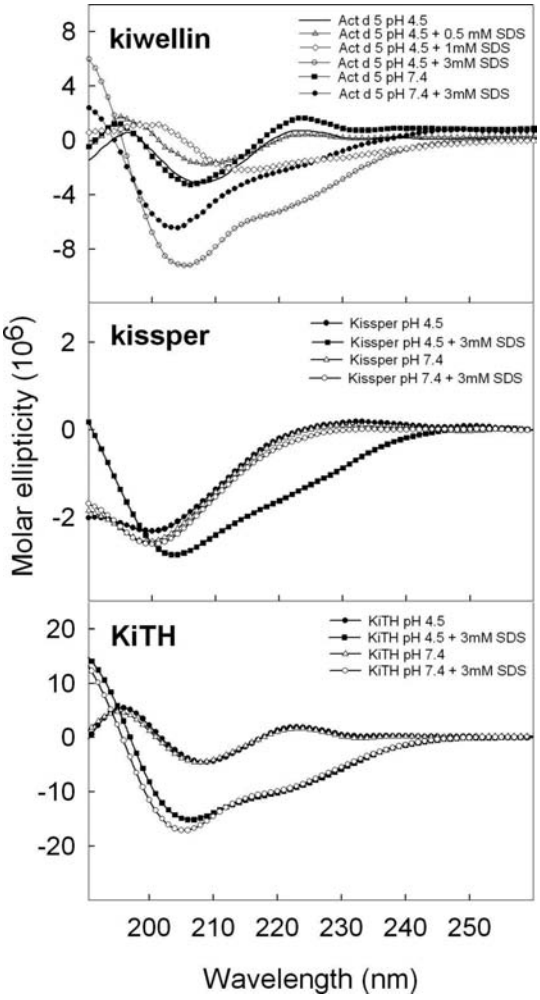

Figure 5. CD spectra of kiwellin, kissper, and KiTH, at pH 7.4 and 4.5, and in the presence of SDS.

significant variation of the structural features. SDS concentrations lower than 3 mM cause a decrease in the structure content. In contrast, at concentrations higher than 3 mM, corresponding to the critical micellar concentration (CMC), SDS induces an increase in secondary structure content, as shown by the large increase in negative ellipticity of the spectra. Spectra at 10 and 100 mM SDS overlap with the spectra at 3 mM and therefore have not been shown in Figure 5. Overall, the shapes of spectra suggest mixed secondary structure content in all of the assayed conditions. In the 3−100 mM SDS range, the presence in the curves of minima at about 208 and 222 nm suggests an increase in the helical content in these experimental conditions.

Kissper displays the typical spectrum of unstructured proteins in both buffers, at neutral and acidic pH. At neutral pH, the addition of 3 mM SDS does not change the spectrum shape. Conversely, the presence of both SDS and acidic pH is the only condition under which kissper shows the spectrum of a structured protein. Unlike kissper, KiTH does not show pH dependence, both in the presence and in the absence of SDS. However, its structure is affected by the presence of SDS that causes an increase in the secondary structure content. The shape of the KiTH spectra suggests a higher content of helical structure in the hydrophobic environment mimicked by SDS.

Attempts To Identify the Biological Function of Act d 5. Assays of glycosidase activity by kiwellin were negative. Results obtained using cellobiose, cellotetraose, mannan, laminarin, curdlan, lichenan, and carboxymethylcellulose as substrates suggest that kiwellin does not have hydrolytic activity on linear and branched glucose chains bearing β-1,3, β-1,4, and β-1,6 glycosidic bonds, as well on oligosaccharides made of mannose units. Indeed, the DNS assay showed a weak positive response when cellobiose was used as a substrate. However, the analysis of the reaction products by a Dionex HPLC revealed the absence of monosaccharidic glucose, thus suggesting the weak positive response observed by DNS assay was attributable to an artifact. Attempts to assess glycan binding to kiwellin likewise gave negative results. The glycan array, completed by the CFG, did not indicate any binding between Act d 5 and any of the 610 different carbohydrates tested.

The cell wall creep assay was performed in 4−8 replicate experiments with two different types of cell wall (cucumber hypocotyl, representing dicot walls, and wheat coleoptile, representing grass walls) and at a high kiwellin concentration of 500 μg/mL. This assay is a very sensitive assay (detection of less than 10 ng/mL of alpha-expansin is possible), but no sign of activity was detected upon kiwellin application (Figure S3). Thus, there was no sign of classical expansin activity in kiwellin.

Attempts To Identify Act d 5 IgE Binding Activity Shared with 102 Other Allergens. Table S1 reports the list of the 103 allergens spotted on the ISAC microarray used in this study and the frequency with which they were recognized by specific IgE of a population composed of 30836 random allergic subjects. On the basis of the frequency of detected IgE positivities, allergens have been divided in four groups. Table S1 shows that Act d 5 is included in the group of "low-frequency allergens", due to the low percentage of subjects having IgE recognizing this molecule. In contrast, the two allergens belonging to the expansin biochemical family, Phl p 1 and Cyn d 1, are included in the group of "high-frequency allergens". The large difference between the relative frequency of positive subjects, ranging from 0.49% for Act d 5 to 28.45% for Phl p 1 and 24.3% for Cyn d 1, emphasizes the different immunological behavior of the kiwifruit allergen when compared to the two expansins. In particular, Act d 5 appears much less allergenic than Phl p 1 and Cyn d 1.

The immunological behavior of Act d 5 was further investigated using a statistical procedure. The analysis of Act d 5 toward the four data sets of Table S1 produced the results shown in Figure S4. The dendrograms of Figure S4 show that no Act d 5 IgE reactivity clustering reaching statistical significance could be obtained with any of the other 102 analyzed allergens, including the two expansins Phl p 1 and Cyn d 1. Conversely, statistically significant clustering was obtained for more closely related allergens, such as the expansins Phl p 1 and Cyn d 1, the LTP Pru p 3 and Art v 3, the cysteine proteases Der p 1 and Der f 1, and so on. The real immunological correlation between the clustered allergens is supported by literature data reporting IgE corecognition.[39] All together, the clustering results and the reported IgE corecognition data highlight that allergenic proteins having similar folds and amino acid sequences generally display similar immunological features, reasonably correlated to a common set of antigenic epitopes. Act d 5 does not show immunological

DOI: 10.1021/acs.jafc.5b02159
J. Agric. Food Chem. 2015, 63, 6567−6576

correlation with expansins or with any of the other analyzed allergens. This observation suggests that, despite the observed folding similarities with expansins, Act d 5 does not bear on its surface the structural determinants of IgE epitopes found in Phl p 1 and Cyn d 1, and more in general that the molecular surface of the kiwifruit allergen is significantly different from that of the two expansins.

As a control, the same statistical procedure was applied to the analysis of another kiwifruit allergen, Act d 1. Act d 1 is a cysteine protease that is reported to be structurally similar to other allergens, including the three spotted on the ISAC 103 microarray, namely, Ana c 2, Der p 1, and Der f 1.[30] In line with the absence of any data attesting immunological cross-reaction with the three homologous cysteine proteases,[30] no Act d 1 IgE reactivity clustering was observed (Figure S5).

DISCUSSION

Here we report the crystal structure of green kiwifruit kiwellin, Act d 5, obtained by X-ray diffraction analysis. This study supplements the very recently reported results for the homologous protein from golden kiwifruit, Act c 5.[12] In fact, the published structure included 158 amino acids, which is approximately 83% of the overall molecule, including residues 24−39 and 48−189 and the four disulfide bridges inside the C-terminal domain, KiTH. The analysis of the electron density maps of green kiwifruit kiwellin, described in this paper, has allowed for the elucidation of additional portions of the structure. Overall, about 97% of the three-dimensional structure of the green kiwifruit allergen has been resolved, and it includes residues 2−42 and 47−189; only five residues, Ile,[1] Hyp,[43] Gln[44], Pro[45], and Gly[46], remain unresolved, which correspond to a flexible linker between the two protein domains. In addition, we report here the description of the post-translational modification occurring on residues 41 and 43 that undergo hydroxylation, producing Hyp. The correction of the sequence data provides useful information that better describes the site recognized by actinidin in the in vivo proteolytic processing of kiwellin. It was previously reported that actinidin cleaves between residues 39−40 and 41−42 of the kiwellin sequence.[2] It is also known that the kiwifruit protease hydrolyzes different types of collagen,[40] which are Hyp-containing proteins. These observations suggest that the two Hyp residues, which are located in the flexible linker region connecting kissper to KiTH, are involved in the formation of kiwellin's proteolytic sites recognized by actinidin. This site is formed by the sequence Thr/Ser-Hyp, where the kiwifruit protease cleaves at the N-terminal side of this motif having Hyp at the P2′ position.

The sequence of green kiwifruit kiwellin was reported to contain heterogeneity in position 61, where Y is sometimes substituted by H. Similar to golden kiwellin, the isoform used in this study had H in position 61. Green and golden kiwifruit kiwellin (accession no. P84527 and L7TT83) share about 98% sequence identity. In fact, only the following residues of the green kiwifruit molecule are substituted in the golden species: R57 with Q, D89 with G, N101 with S, and D176 with N. In line with the very high sequence identity, some major structural features described for the golden kiwifruit kiwellin have been observed in the homologous molecule from the green species. The best defined example is the C-terminal domain, KiTH, characterized by a six-stranded β-barrel with two extended loops forming a "pincher-like" structure and an additional loop found at the N-terminal portion that is connected to the core of this domain by two disulfide bridges.

The structure of the entire N-terminal domain, kissper, has also been determined, and the connectivity of the six cysteine residues, previously suggested on the basis of NMR studies,[3] has been confirmed by the crystal structure analysis. In the structure, kissper appears devoid of clearly defined secondary structural elements such as α-helix or β-sheet. Previous NMR studies indicated that in aqueous solution, at pH 3.5, kissper was characterized by the presence of multiple conformations. Nevertheless, in the experimental conditions of NMR, short regions of regular structure, described as a short antiparallel β-sheet encompassing residues 19−21/24−26 and a short helix spanning residues 32−35, were detected. Therefore, the kissper domain, in solution at low pH, showed some structural features different from those of the crystallized molecule. In line with the crystal structure results, in the conditions of CD experiments, kissper appears completely unstructured in buffer solutions, at both neutral and acidic pH values. Only the combination of acidic pH and SDS, used to mimic the hydrophobic environment of cell membranes, was effective in inducing the peptide folding. This behavior is in line with the reported functional properties. In fact, functional studies showed that kissper displays pore-forming and ion-channeling activities in lipid bilayers, and the efficiency increases at low pH.[3] These data suggest that the N-terminal domain of kiwellin performs its physiological function by interacting with cell membranes in the acidic environment of kiwifruit. It is then conceivable that kissper adopts the native structure, likely corresponding to the most structured conformation, in the cell membranes of the natural source or in experimental conditions mimicking those of kiwifruit membranes. Unfortunately, these conditions could not be used for protein crystallization. Therefore, we speculate that kissper, which is devoid of secondary structural elements in the conditions used for crystallization, may adopt a different conformation in the physiological environment. Unlike kissper, the kiwellin C-terminal domain has well-defined secondary structural elements both in the crystal and in solution. In addition, CD data suggest that the KiTH conformation is not dependent on pH, whereas it is influenced by the hydrophobic environment that causes an increase in secondary structure content. The amount of secondary structure in the entire kiwellin molecule seems to be correlated to the individual contribution of the two independent domains. A higher content of secondary structure when incubated at acidic pH in low-polarity media, namely fluorinated alcohols, had already been reported.[5] Specifically, higher amounts of α-helical structure were detected and the strongest increase in secondary structure was obtained in the environments where low pH was combined with high hydrophobicity. In line with those results, in this paper we show that the amount of kiwellin's secondary structure increases in SDS.

Additionally, it was reported that the immunological properties of kiwellin are also affected by the physicochemical features of the experimental conditions.[5] In fact, protein solubilized in acidic solvent caused positive skin tests in patients that tested negative at neutral pH, and vice versa. This observation therefore indicates that the assay conditions influence the protein conformation and/or surface charge, thus affecting the results of the diagnostic systems by modulating the pattern of exposed IgE-binding epitopes. Intriguingly, some patients allergic to kiwifruit and positive in

DOI: 10.1021/acs.jafc.5b02159
J. Agric. Food Chem. 2015, 63, 6567−6576

skin prick test were negative when tested for IgE binding by serological tests. The above-described structural properties, which are strongly dependent on the features of the environment, support the concept that the discrepant immunological results, obtained using different allergy test systems, can be correlated to different combinations of IgE epitopes exposed on the protein surface as a function of the specific experimental conditions, affecting the kiwellin conformation or surface charge. Due to the changing structure, the definition of immunological properties of kiwellin and patient sensitivity to this molecule becomes a tricky matter. It is worth noting that the behavior of other allergens is also unknown. In fact, the state of the solid phases is not known for either kiwellin or for any other tested protein. Furthermore, the overall conditions of the testing system might generate alterations of the state of any molecule, altering some conformational epitopes and leading to the loss of some IgE reactivity. Therefore, the observations deriving from the study of kiwellin highlight a concept that probably is of general meaning and could cover any protein.

Similarity searches revealed several expansins, including the maize allergen Zea m 1 and the pollen allergen Phl p 1, as the proteins having structures most similar to kiwellin, specifically to the KiTH domain. However, attempts to detect expansin activity (plant cell wall loosening) proved negative for kiwellin. Likewise, kiwellin lacked lytic activity and binding activity toward wall-related polysaccharides (our results and those of Hamiaux et al.[12]). These results are consistent with what we know about expansins:[41] the N-terminal domain of expansin (which is structurally related to KiTH) is not sufficient to cause cell creep; it has negligible affinity for wall polysaccharides, and it lacks wall lytic activity. It is notable that kiwellin has an Asp−Thr pair (D164, T79) that superposes closely with two highly conserved residues in expansins and other structurally related proteins,[42] but it lacks a Tyr residue corresponding to the highly conserved Tyr that makes up the part of the presumptive active site of expansin. Another major difference is that expansin forms an open structure surrounding the conserved Asp−Thr pair, whereas kiwellin has two loops (S84−P92 and S144−C158) that form a tunnel-like/pincher-like structure with D164−T79 at the base of the tunnel. The tunnel is likely able to accommodate a single glycan chain.

An attempt to assess the binding of kiwellin to the 610 different mammalian carbohydrates immobilized on the test system of the Consortium for Functional Genomics indicated negligible binding under the test conditions. In view of the tunnel-like structure of the kiwellin, Figure 6, it is possible that immobilization of the carbohydrates would interfere with their ability to fit into the tunnel. In addition to these structural and functions comparisons, IgE-based immunological data also seem to confirm the absence of similarities of kiwellin with expansins and other carbohydrate-binding allergens. In fact, the analysis performed using a newly adopted statistical procedure shows no Act d 5 IgE reactivity clustering with any of the other 102 tested allergens, thus suggesting the absence of epitope sharing.

In summary, attempts to find a correlation between structural and functional properties of kiwellin indicate important similarities and differences with expansins, but have not revealed a specific function or saccharide ligand that binds tightly. Expansin's N-terminal domain, as well as kiwellin, resembles a protein named barwin.[43] Although barwin's biological function is uncertain, it binds weakly (K_d = 5 mM) to chitin oligosaccharide, and it may be involved in defense mechanisms. Such a role for kiwellin, that is, as an antifungal agent, might be consistent with its high expression in ripening fruit and should be considered in future studies.

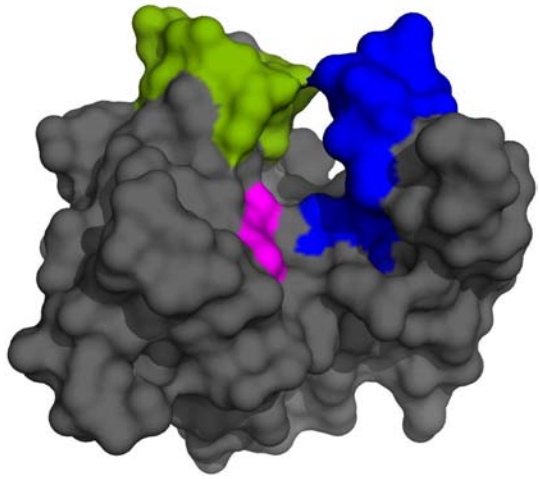

Figure 6. Space-filling model of KiTH domain showing the surface formed by conserved D164−T79 (magenta) at the bottom of a tunnel formed by loops S84−P92 (green) and S144−C158 (blue).

A notable feature of our results is the strong dependence of kiwellin properties on the environmental/experimental conditions. It is not known if the conformation found in the crystal is the same conformation that is exhibited in some tissues of the human body, where it works as an allergen. It is also unclear how the physiological fold of kiwellin is different from that observed in the crystal. However, we do know from the CD experiments in low-polarity media that kiwellin is capable of significant structural changes as a function of the environmental conditions. The results reported in this paper can be considered a collection of valuable data to better design targeted future studies with the aim to understand the structure of the molecule working in the physiological environment and also the structure of the molecule that causes allergic reactions. In fact, it is not obvious that the same fold is correlated with the function in the natural source and also with the allergenic properties.

[a]+, aurovertins were detected in the culture medium; −, no aurovertins were detected in the culture medium. [b]RNK, root-knot nematode.

the F_1-ATPase found on the inner membrane of mitochondria, inhibiting the ATPase and thereby uncoupling oxidative phosphorylation in in vitro bioassays.[17] Furthermore, aurovertin B strongly inhibits the proliferation of breast cancer cell lines and arrests cell cycles at the G0/G1 phase.[18]

However, despite these findings, information on the natural functions of aurovertins in fungi remains scarce. This study has four major goals: (1) to establish the role of fungal aurovertin metabolites in nematodes such as the root-knot nematode *Meloidogyne incognita* and the model species *Caenorhabditis elegans*; (2) to recognize the relationship between different ecological niches such as nematode eggs and worm bodies and the production of the class of fungal aurovertin metabolites; (3) to evaluate whether the aurovertins work on the β subunit of F_1-ATPase in nematodes; and (4) to study the nematode response reaction to this class of fungal metabolites.

Several studies provide evidence that the functions of the secondary metabolites produced by pathogenic fungi in the host may vary according to their concentrations.[19−21] Considering the possibility that the production of aurovertins by *P. chlamydosporia* could lead to the generation of metabolite concentration gradients in the environment and thus potentially exposing nematodes to subinhibitory concentrations of fungal nematicidal aurovertins, we characterized the main effects of aurovertin at subinhibitory concentrations (SICs) on the nematode and tested several different end points including lethality, lifespan, brood size, overall development, and pharyngeal pumping rate. Increasing evidence suggests that frequent exposure to nonlethal (that is, subinhibitory) concentrations of antibiotics plays an important role in the evolution of antibiotic resistance.[19] The well-established model organism *C. elegans*[22] was used as an alternative system for the investigation of the mode of action of the aurovertins in nematodes and aurovertin-induced host responses.

MATERIALS AND METHODS

Fungal Strains and Fermentation. Isolation of *P. chlamydosporia* strains from nematode worms was performed according to the modified method.[23] Tobacco roots infected by *M. incognita* were collected from different fields in Yunnan Province, People's Republic of China. The infected juveniles of *M. incognita* were collected from the roots using the Baermann funnel technique. Three hundred grams of galled roots with lengths of 3−5 cm was collected and placed on a Baermann funnel apparatus. A length of rubber tubing and a collecting tube were attached to the funnel and filled with water. In the funnel, the nematodes moved out of the root tissue and sank to the bottom of the funnel due to gravity. After 24 h, a pinch clamp was applied on the rubber tubing, allowing the collecting tubing containing infected nematodes to be removed. The nematode suspension was concentrated to 1 mL by centrifuge at 8000 rpm, and then 0.2 mL of the resulting suspension containing about 200 juveniles was poured onto each of five Petri dishes containing 2% (w/v) of agar in water. After incubation for 10−20 days at 28 °C, mycelial tips that emerged from naturally infected juveniles were transferred to fresh Petri dishes containing potato dextrose agar (PDA medium consisting of 20% peeled potato, 2% glucose, and 2% agar) and recultured at least three times to obtain genetically identical fungal cultures. Collection of *P. chlamydosporia* strains from nematode eggs was performed according to a procedure described previously.[15]

To identify these fungal isolates, the general fungal primers ITS4 (5′ TCCTCCGCTTATTGATATGC) and ITS5 (5′ GGAAGTAAAAGTCGTAACAAGG) were used for amplifying internal transcribed spacer (ITS) 1, 2, and 5.8s rDNA regions of all the strains. The PCR products were purified followed by sequence analysis. The obtained ITS data were compared to those in the NCBI using a BLAST search. The nucleotide sequences were aligned manually using ClustalX. Phylogenetic analyses were completed using MEGA (ver. 6.06) to construct the neighbor-joining tree (Figure S1). The stability of clades was evaluated using bootstrap tests with 1000 replications. On the basis of the phylogenetic analyses of internal transcribed spacer (ITS) sequences, as well as the macroscopic and microscopic characteristics,[24] 17 fungal strains, including 4 from nematode eggs, 3 from soils, and 10 from nematode worms, were identified as *P. chlamydosporia* and are listed in Table 1. All of the isolates were deposited in the strain collection of the Laboratory for Conservation and Utilization of Bio-Resources & Key Laboratory for Microbial Resources of the Ministry of Education, Yunnan University, Kunming, People's Republic of China.

After the conidia had developed on PDA slants in test tubes at 25 °C, the strains were kept at −30 °C as stock cultures. The *P. chlamydosporia* strains were cultured on a PDA medium for a week and then inoculated into 500 mL flasks each containing 250 mL of medium potato dextrose broth (PDB) consisting of 20% peeled potato and 2%

DOI: 10.1021/acs.jafc.5b02595
J. Agric. Food Chem. 2015, 63, 6577−6587

glucose. The inoculated flasks were incubated at 28 °C for 12 days with shaking at 180 rpm.

Standards and Reagents. Dimethyl sulfoxide (DMSO), juglone (Ju), and oligomycin A (OA) were purchased from Sigma-Aldrich China Inc. Water was obtained from a Milli-Q system (Millipore, Bedford, MA, USA). Acetonitrile (Merck KGaA, Darmstadt, Germany) and formic acid (Roe Scientific Inc., USA) were of HPLC grade. Methanol (Guangdong Xilong Chemical Co., Ltd., Guandong, People's Republic of China) was analytical-reagent grade.

Isolation of Aurovertin Standards. The aurovertins were isolated from *P. chlamydosporia* according to the modified method described in the literature.[15] A 12-day-old fermentation broth of strain *P. chlamydosporia* YMF 1.00613 was filtered to separate the mycelia from the culture. The culture filtrate was concentrated in vacuo and partitioned with acetyl acetate, and the organic part was evaporated to dryness to give an oily residue. The residue was dissolved in $CHCl_3$/MeOH and subjected to a Sephadex LH-20 column, developing with $CHCl_3$/MeOH (1:1, v/v) to give five fractions. Fractions were monitored by TLC, and spots were visualized by spraying with 10% H_2SO_4 in EtOH. Fraction 2 was chromatographed with a silica gel column, eluting with $CHCl_3$/MeOH (7:1, v/v, 1 L) to afford six subfractions. Subfraction 2 was repeatedly subjected to a silica gel column eluting with $CHCl_3$/MeOH (50:1) to yield aurovertin D. Subfraction 4 was rechromatographed over a silica gel column eluting with $CHCl_3$/MeOH (30:1, v/v) to give aurovertin F. Subfraction 3 was repeatedly chromatographed over a silica gel column washing with $CHCl_3$/MeOH (40:1) to obtain aurovertins E and I. All of the purified aurovertins were elucidated and confirmed with ^{1}H NMR data.[17]

TLC Analysis. To determine the presence of aurovertins in the fermentation broths of *P. chlamydosporia* strains, 17 *P. chlamydosporia* strains were cultivated in PD broth medium for 12 days and then filtered to separate the mycelia from the culture. The culture filtrates were dried in vacuo and then were extracted with 10 mL of acetone three times. The extracts were combined and concentrated to 1 mL. About 5 μL of each extract was spotted onto a 10 × 5 cm silica gel 60 F254 layer, and the developing solvent $CHCl_3$/MeOH (13:1, v/v) was used. After treatment with 10% H_2SO_4 in ethanol followed by heating at 120 °C, purple color spots were visualized.

HPLC Analysis. To confirm the presence of aurovertins and determine the contents of aurovertins in the fermentation broths of *P. chlamydosporia* strains, 17 *P. chlamydosporia* strains were cultivated in PDB medium, and then 1 mL of the broths was filtered to separate the mycelia from the culture. The culture filtrate (300 μL) was filtered through a 0.22 μm hydrophilic PVDF membrane (Millipore) for HPLC analysis. HPLC analysis was carried out using an HP 1200 (Agilent, Waldbronn, Germany) unit, employing the following instrumental conditions: column, CAPCELL PAK C18, 5 μm; 4.6 × 250 mm (Shiseido); flow rate, 1 mL/min; mobile phase A, 0.1% formic acid in water; mobile phase B, 0.1% formic acid in acetonitrile. The column temperature was maintained at 40 °C, and the injection volume for the culture filtrates was 25 μL. The HPLC conditions were manually optimized on the basis of separation patterns of the aurovertins and were as follows: gradient program of B (gradient, 0 min, 25% B; 2 min, 25% B; 29 min, 40% B; 31 min, 95% B; 34 min, 95% B; 35 min, 25% B; 45 min, 25% B). Detection was performed at 365 nm. The parameters of the regression equations and the limits of detection (LOD) and quantification (LOQ) were obtained with standard aurovertins D, E, F, and I. All of the aurovertins showed good linearity over the concentration range studied and five points of each calibration curve ($R^2 \geq 0.9992$). LOD and LOQ were determined to evaluate the sensitivity of the method.

Worm Strains and Maintenance Conditions. Root-knot nematode *M. incognita* (race 3) was reared on tomato for about 2 months in a glasshouse at 25 ± 2 °C. Batches of mature egg masses (averaging 4000 eggs/batch) were obtained from infected tomato roots. Batches were collected on 2 cm diameter sieves (74 μm mesh) and placed on a 6 cm diameter sterile Petri dish, and then 15 mL of distilled water was added to promote hatching. Batches were then incubated at 28 °C in the dark. Emerging juveniles J2 (24 h) were removed and collected for the acute toxicity experiments.

Live specimens of the model nematode *C. elegans* Bristol N2 (wild type) were obtained from the Institute of Genetics and Developmental Biology, Chinese Academy of Sciences. Strains CF1308 *daf-16(mu86) I*, CB1370 *daf-2(e1370) III*, VC2255 *atp-2(ok3002) III/hT2 [bli-4(e937) let-?(q782) qIs48] (I;III)*, and TJ356 *zls356[daf-16p::daf-16a/b::gfp; rol-6] IV* were obtained from the *Caenorhabditis* Genetics Center at the University of Minnesota (Minneapolis, MN, USA). All strains were routinely propagated at 20 °C with 42% relative humidity in the dark on nematode growth medium (NGM) plates using *Escherichia coli* strain OP50 as a food source. Synchronization of worm culture was achieved by treating gravid hermaphrodites with hypochlorite bleaching. The hatched L1 arrested worms were age-synchronous and were transferred onto NGM plates with *E. coli* OP50 containing either one of a range of different concentrations of aurovertin D (25, 50, and 100 μg/mL) or DMSO until they reached the desired stages.[25] An Olympus CX31 microscope was used to observe nematodes.

Acute Toxicity Assay. An acute toxicity test was performed according to a procedure described previously.[15] About 300 age-synchronous *C. elegans* wild type N2 L1 were dispensed into 3.5 cm plates containing 1 mL of fungal culture broth. PDB medium was used as a negative control. About 300 age-synchronous root-knot nematode *M. incognita* juveniles J2, model species *C. elegans* wild type N2 L1, *C. elegans* mutant *daf-16(mu86)* L1, *C. elegans* mutant *daf-2(e1370)* L1, and *C. elegans* mutant *atp-2(ok3002)/hT2[bli-4(e937) let-?(q782) qIs48]* L1 were dispensed into 3.5 cm plates containing 1 mL of M9 buffer with variable amounts of aurovertin D (dissolved in DMSO) per plate (0, 12.5, 25, 50, and 100 μg/mL). Control groups were prepared with the same volume of DMSO (0.5% DMSO, v/v). Worms were exposed for 24 h at 20 °C, and the number of dead or live worms was determined by the absence/presence of touch-provoked movement when probed with a platinum wire. The median lethal concentration (LC_{50}) value was calculated using the probit method. All treatments were conducted in triplicate.

Development Assay. Synchronized L1 nematodes [wild type N2, *daf-16(mu86)*, and *daf-2(e1370)*] treated with or without aurovertin D were cultured for 60 h. Then the numbers of nematodes in each stage including L1, L2, L3, L4, and adult were counted at 40× magnification. The development of 50 worms was assessed for each treatment. All treatments were conducted in triplicate.

Pharyngeal Pumping, Lifespan, and Brood Size Assay. Synchronized L4 worms of wild type N2, *daf-16(mu86)*, and *daf-2(e1370)* treated with or without aurovertin D were manually assessed for the pharyngeal pumping rates. The pharyngeal pumping experiments were carried out in triplicate. For lifespan assay, these worms were counted and scored as live or dead, and live worms were transferred to fresh plates every day until no new progeny was generated in a 24-h period and no live worms remained.[26] The brood sizes of nematodes were counted 2 days after the removal of the parents, and the progeny of at least 30 parental nematodes was counted. The lifespan and brood size experiments were carried out in quadruplicate.

Reactive Oxygen Species (ROS) Assay. Cellular ROS levels were quantified by the dihydroethidium (DHE) assay using fluorescence microscopy.[27] Synchronized L2 larvae of wild type N2 were incubated for 24 h at 20 °C in M9 buffer containing DMSO, aurovertin D (100 μg/mL), or juglone (3483 μg/mL, 20 mM). Worms were then allowed to recuperate on NGM plates with *E. coli* OP50 for about 20 h before their viability was determined by touch-provoked movement. After recovery, worms were washed with M9 buffer and then incubated in M9 buffer containing 3 μM DHE for 30 min in the dark. DHE is a fluorogenic probe that is highly selective for superoxide anion radical detection. DHE is cell-permeable and reacts with intracellular ROS to form ethidium, which, in turn, intercalates with DNA, thereby exhibiting a red fluorescence. Recording of the DHE fluorescence intensity was used as an index of the individual intracellular levels of ROS in individual worms. Fluorescence from worms exposed to DMSO as negative control and juglone as positive control was also measured. Three independent experiments were performed per treatment, and in each experiment ROS measurement

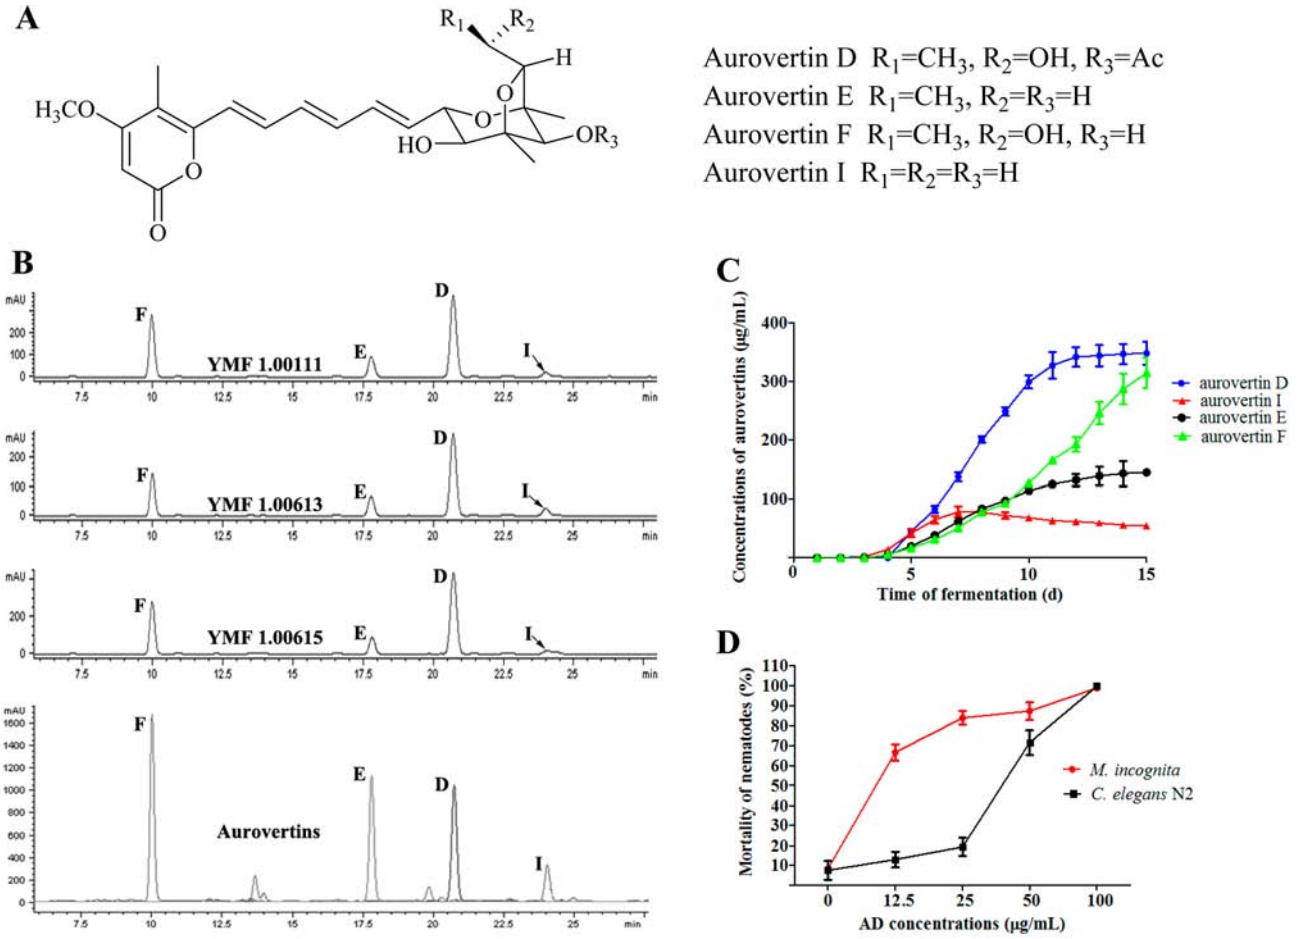

Figure 1. (A) Structures of aurovertins D, E, F, and I. (B) HPLC-DAD profiles of aurovertins in fermentation broths of *Pochonia chlamydosporia* strains YMF 1.00111, YMF 1.00613, and YMF 1.00615, and standard aurovertins. (C) Contents of aurovertins in the fermentation broth of aurovertin-producing *P. chlamydosporia* strain YMF 1.00613 in 15 days. (D) Effects of aurovertin D (AD) on the mortality of *Meloidogyne incognita* J2 and *Caenorhabditis elegans* N2 L1 nematodes in the acute toxicity assay.

was made in at least 36 worms. A Zeiss Axioskop 2 plus microscope was used for the imaging of the red fluorescence of worms. These images were analyzed using Axiovision V4.5 (Zeiss) line tool to determine the mean relative fluorescence intensity of the nematodes. All treatments were conducted in triplicate.

RNA Interference (RNAi). RNAi was administered by feeding worms strains of *E. coli* engineered to transcribe double-stranded RNA homologous to a target gene.[28] Bacteria (HT115) with empty plasmid pPD129.36 were used as a negative control for nonspecific RNAi effects, whereas bacteria expressing *fasn-1* dsRNA were utilized as positive control. Approximately 300 synchronized wild type N2 L1 worms were plated onto 6 cm NGM plates supplemented with 1 mM IPTG and 100 μg/mL ampicillin. The plates were seeded with different RNAi bacteria targeting each subunit of F_1F_O-ATPase, including *asb-1*, *asb-2*, *atp-5*, R04F11.2, R53.4, *asg-1*, *asg-2*, *atp-3*, H28O16.1, T26E3.7, *atp-2*, F58F12.1, *hpo-18*, R05D3.6, and ZC262.5, or with bacteria containing control vectors. Worms matured into adults in 3 days at 20 °C. Following a synchronization of the knockdown adult worms, the growth of L1 worms on NGM plates containing 100 μg/mL aurovertin D or DMSO for 60 h was monitored. Three independent RNAi experiments were performed for each gene tested. All treatments were done in triplicate.

DAF-16::GFP Nuclear Localization. Synchronized L1 worms of the transgenic strain TJ356, which expresses a DAF-16::GFP fusion protein, were fed on NGM plates with or without 50 or 100 μg/mL aurovertin D for 60 h. DAF-16::GFP localization was monitored using a Zeiss M2BIO stereo dissecting microscope fitted with an Axiocam MRC DAGE-MTI CCD-100 camera. Images were acquired at 100× and 400× magnifications in compound mode.

Statistical Analyses. All experiments were performed in either triplicate or quadruplicate. Replicated trials had similar outcomes. Data were analyzed using the software SPSS (SPSS Inc., Chicago, IL, USA), and the results were presented as the mean ± SD. The LC_{50} was calculated using the probit analysis. Statistical significance was determined by Student's *t* test for comparison between the means of two groups or by a one-way analysis of variance (ANOVA) followed by Tukey's honest significant difference tests for equal variances and Dunnett's T3 tests for unequal variances at the $\alpha = 0.05$ level of significance among multiple groups. Differences were considered as significant when $P < 0.05$. Lifespan survival curve data were compared by the log-rank test of the Kaplan−Meier survival function. The relative average/maximal lifespan of worms was calculated according to the following formula:

$$\text{rel av (max) lifespan} = \frac{\text{av (max) lifespan of worms treated with aurovertins}}{\text{av (max) lifespan of worms treated without aurovertins}}$$

RESULTS

Non-nematicidal Activity of Most *P. chlamydosporia* Strains. Seventeen *P. chlamydosporia* strains collected from three different ecological niches, including nematode worms and eggs, and soil, were evaluated for the nematicidal activity of

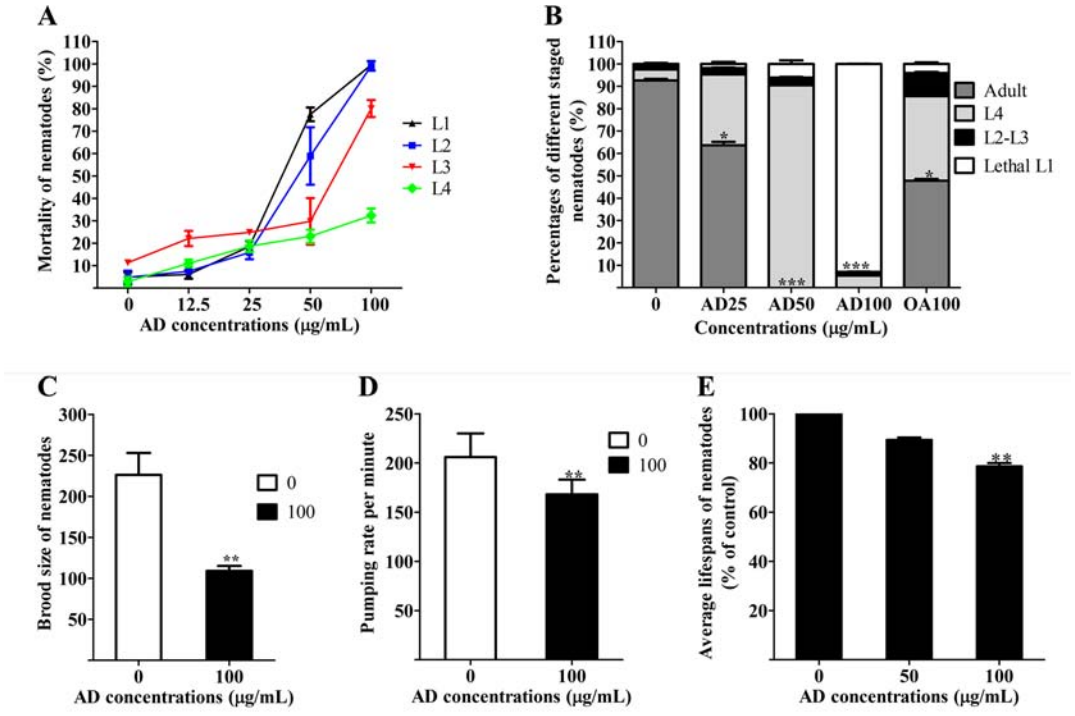

Figure 2. Toxicity effects of aurovertin D on the viability of *Caenorhabditis elegans* wild type N2: (A) effects of aurovertin D (AD) (0, 12.5, 50, and 100 μg/mL) on the mortality of different-staged larvae; (B) effects of aurovertin D (AD) (0, 25, 50, and 100 μg/mL) and oligomycin A (OA) (100 μg/mL) on the developments of L1 nematodes; (C) effects of 100 μg/mL aurovertin D (AD) on brood size of nematodes; (D) effects of 100 μg/mL aurovertin D (AD) on pumping rates of nematodes; (E) effects of aurovertin D (AD) (50 and 100 μg/mL) on the average lifespan of nematodes. (∗) $P < 0.05$; (∗∗) $P < 0.01$; (∗∗∗) $P < 0.001$.

their culture broths toward larval nematodes (Table 1). Among them, three strains, YMF 1.00111, YMF 1.00613, and YMF 1.00615, yielded distinctive luminous yellow in their fermentation broths. Nematicidal bioassays displayed that only these three strains showed 100% inhibitory rates toward the free-living nematode *C. elegans* L1 larvae nematodes, whereas those strains without yellow pigments exhibited no more than 19% inhibitory rates (Table 1).

Aurovertins in the Nematicidal *P. chlamydosporia* Strains. All 17 *P. chlamydosporia* strains were examined for aurovertin production (Table 1; Figure 1A). Analysis with TLC and HPLC revealed that the aurovertins were abundant in the luminous yellow culture broths of the three bioactive strains YMF 1.00111, YMF 1.00613, and YMF 1.00615 (Table 1; Figure 1B). HPLC analysis of the three aurovertin-producing *P. chlamydosporia* strains indicated that these strains grown for ≥4 days yielded a total aurovertin production with contents ranging from 500 to 900 μg/mL (Figure 1C), exceeding the inhibitory concentration of aurovertins during nematicidal bioassays (Figure 1D).

Aurovertin D as the Major Component in the Yellow Pigment Metabolite Profiles of Nematicidal *P. chlamydosporia*. Four major pigment metabolites, aurovertins D (348 μg/mL), E (144.5 μg/mL), F (314.2 μg/mL), and I (54.6 μg/mL), were isolated from the 15-day yellow culture broths of the *P. chlamydosporia* strains and identified with ^{1}H NMR data and confirmed using comparisons with the retention times of the aurovertin standards. HPLC analysis of the aurovertin compositions of all three *P. chlamydosporia* strains YMF 1.00111, YMF 1.00613, and YMF 1.00615 grown between 1 and 15 days revealed that aurovertin D was the major pigment metabolite in the aurovertin-producing *P. chlamydosporia* strains grown for ≥5 days (Figure 1C).

Stronger Toxicity of Aurovertin D toward Root-Knot Nematodes than Free-Living Nematodes. The effects of aurovertin D on the plant-parasitic nematode *M. incognita* J2 and the model species *C. elegans* were evaluated. A dose−response relationship was established. Within 24 h, aurovertin D caused significant death of *M. incognita* J2 with an LC_{50} value of 16.45 μg/mL and inhibited *C. elegans* with an LC_{50} value of 33.50 μg/mL, indicating a stronger inhibitory activity toward root-knot nematodes than free-living nematodes ($P < 0.01$, Figure 1D).

Profound Effects of Aurovertin D on the Viability of Model Species *C. elegans* at a Subinhibitory Concentration. Dose−response curves were generated for different-staged larvae in the acute toxicity assay. The percentage of dead worms was defined as the mortality rate. Aurovertin D was most toxic to the earliest larval stage L1 (Figure 2A). The percentages of different-staged worms indicated that the development of wild type N2 L1 worms treated with various concentrations of aurovertin D was altered in a dose-dependent manner (Figure 2B). When exposed to aurovertin D at concentrations of 50 or 100 μg/mL, none of the worms reached adult stage, and only 5.4% of the worms treated with 100 μg/mL aurovertin D grew into L4 larval stage, whereas 92.6% of the worms in the negative control group grew into adult stage in 60 h (Figure 2B). This indicated that 100 μg/mL aurovertin D significantly inhibited the development of worms ($P < 0.05$). Additionally, aurovertin D displayed stronger inhibitory activity than the positive control oligomycin A (an F_O-ATPase inhibitor, OA) toward larval development because 47.8% of worms exposed to 100 μg/mL oligomycin A grew into

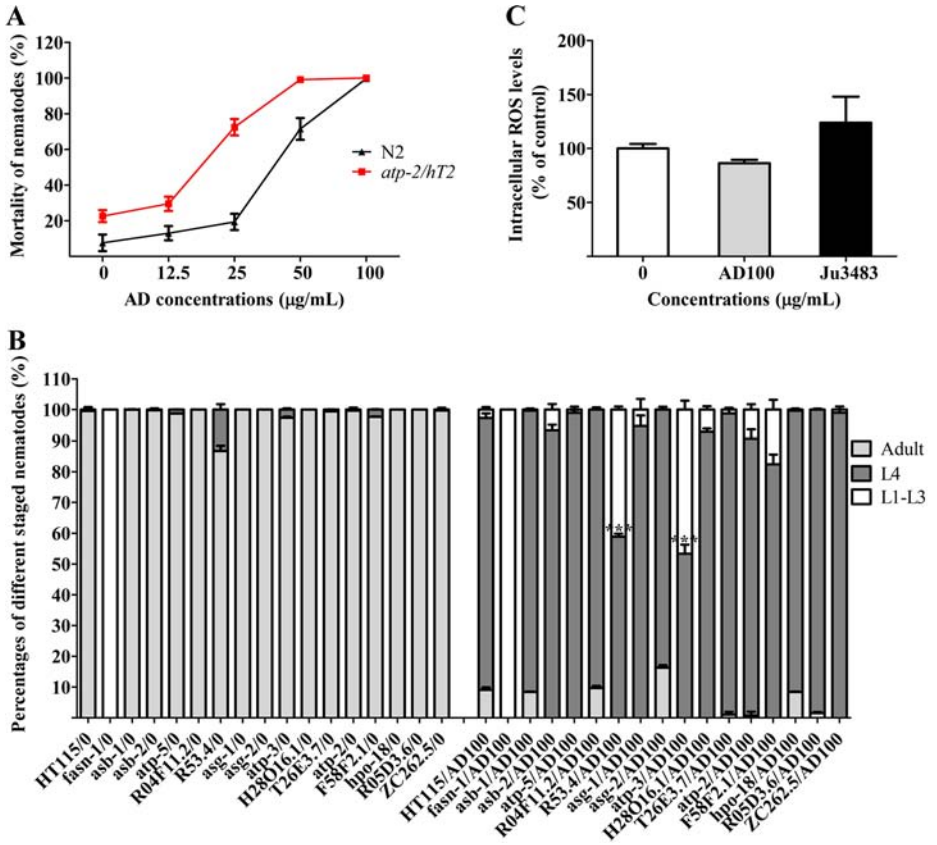

Figure 3. (A) Effects of aurovertin D on the mortality of *Caenorhabditis elegans* wild type N2 and mutant VC2255 (*atp-2/hT2*) L1 nematodes. (B) Effects of 100 μg/mL aurovertin D (AD100) on the development of L1 nematodes fed different RNAi bacteria targeting each subunit of F_1F_O-ATPase, including *asb-1*, *asb-2*, *atp-5*, R04F11.2, R53.4, *asg-1*, *asg-2*, *atp-3*, H28O16.1, T26E3.7, *atp-2*, F58F12.1, *hpo-18*, R05D3.6, and ZC262.5. HT115 was used as negative control, and *fasn-1(RNAi)* was used as positive control for RNAi experiments. The percentages of L4 nematodes fed RNAi bacteria targeting each subunit of F_1F_O-ATPase were compared with that fed control vector (HT115) using a one-way ANOVA with Tukey's honest significant difference test for equal variances and Dunnett's T3 tests for unequal variances post-test following 100 μg/mL aurovertin D treatment. (***) $P < 0.001$. (C) Intracellular ROS levels of wild type N2 nematodes treated with 100 μg/mL aurovertin D (AD100) or 3483 μg/mL (20 mM) juglone (Ju3483) at L2 stage for 24 h.

adult stage. In measuring brood size, L4 worms treated with aurovertin D had a significantly decreased brood size of 51.8% less than those of worms without aurovertin D treatment ($P < 0.01$, Figure 2C). Pharyngeal pumping rates of worms treated with 100 μg/mL aurovertin D were significantly decreased with 17.6% less than those in the negative control ($P < 0.01$, Figure 2D). The relative average lifespan of wild type N2 worms exposed to aurovertin D at a concentration of 100 μg/mL was significantly shortened by 21.5% less than that of the negative control ($P < 0.01$, Figure 2E).

Toxicity of Aurovertin D to β Subunit-Deficient Nematode Mutant. Aurovertin B was regarded as a potent inhibitor of ATP synthesis and ATP hydrolysis catalyzed by mitochondria1 enzyme systems, because it could bind to and inhibit mitochondrial ATPase, thereby uncoupling oxidative phosphorylation.[17] To check if the β subunit of F_1-ATPase was involved in the mode of action of aurovertin D in vivo, we tested the mortality of loss-of-function mutant *atp-2(ok3002)* by exposing the worms to aurovertin D. *C. elegans atp-2* encodes the active site of the β subunit in the F_1F_O-ATPase in *C. elegans*. Unexpectedly, all L1 worms of β subunit-deficient mutant *atp-2/hT2* died when exposed to 100 μg/mL of aurovertin D (Figure 3A). Moreover, the mortality of *atp-2/hT2* was even higher than that of wild type N2, and LC_{50} values of aurovertin D for wild type N2 and *atp-2/hT2* were 33.50 and 17.53 μg/mL ($P < 0.05$), respectively. The results suggested that β subunit-deficient nematode mutant did not display significant resistance to aurovertin D.

Toxicity of Aurovertin D to Nematode Mutants by RNAi Silencing of Each Subunit of F_1F_O-ATPase. RNAi studies were performed to determine whether aurovertin D exerted its effects in *C. elegans* by interfering with the functions of each subunit of F_1F_O-ATPase. Animals in the positive control group with *fasn-1* RNAi were arrested in either the L2 or L3 larval stage and could not reach the L4 stage, indicating the efficiency of this RNAi experiment.[29] Animals treated with strain HT115 with the empty vector were used as negative control. The right-hand panel in Figure 3B displays the developmental stages of each RNAi nematode exposed to 100 μg/mL aurovertin D treatment, and the left-hand panel demonstrates that of each RNAi nematode without aurovertin D. The results indicated that RNAi silencing of the β subunit did not significantly increase the percentage of L4 worms compared to the negative control ($P > 0.05$, Figure 3B). Overall, none of the RNAi worms displayed significant improvement in larval development, and the R53.4 and *hpo-18* nematodes even displayed significant delays (sensitivity, $P < 0.001$) in larval development compared with those in negative control. The results suggested that RNAi silencing of each subunit of F_1F_O-ATPase of nematode did not result in

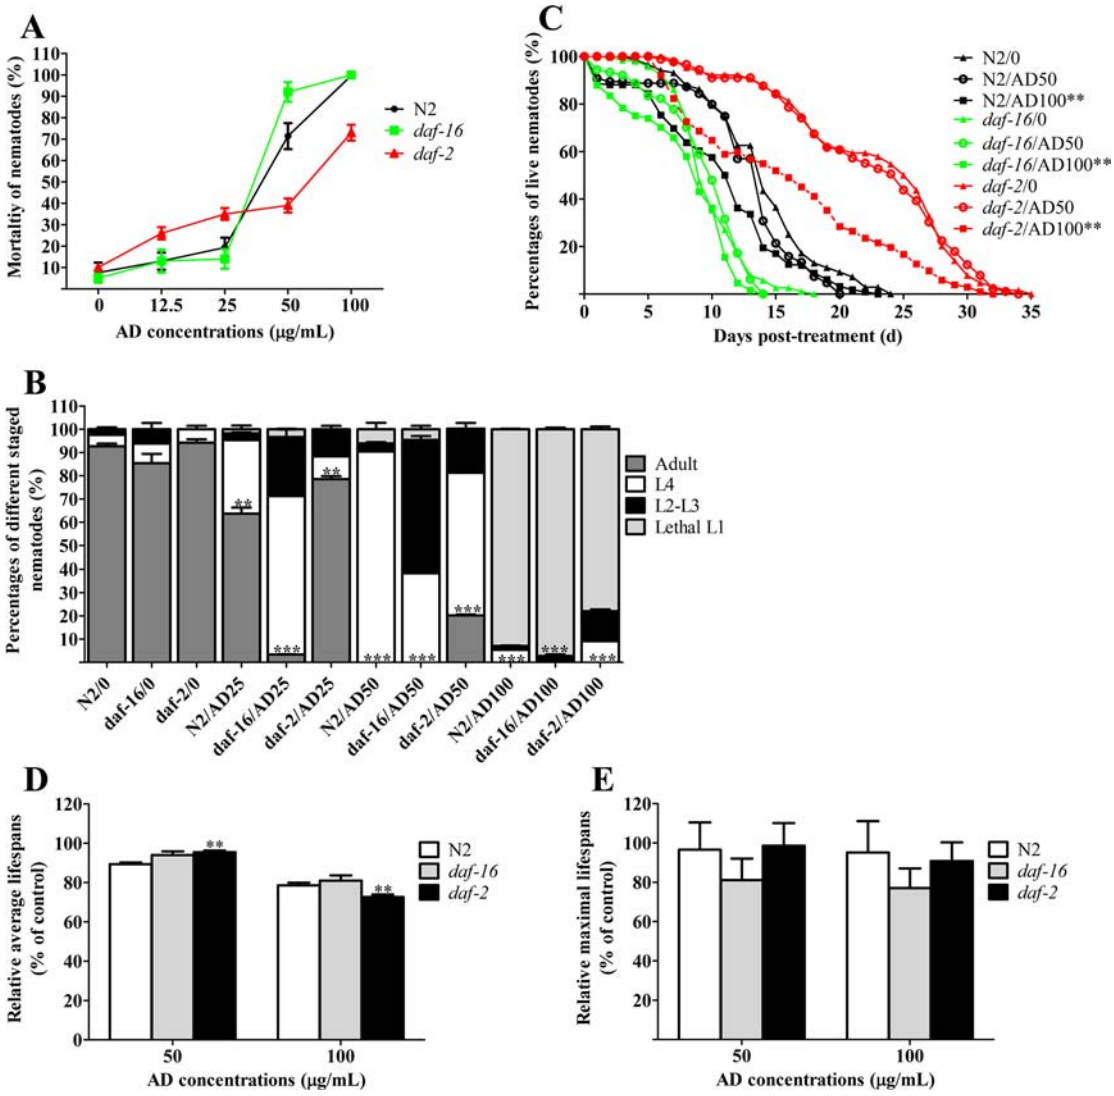

Figure 4. Effects of aurovertin D on the mortality, larval development, and lifespan of *Caenorhabditis elegans* wild type N2, *daf-2(e1370)*, and *daf-16(mu86)*: (A) Effects of aurovertin D (AD) (0, 12.5, 25, 50, and 100 μg/mL) on the mortality of L1 nematodes of wild type N2, *daf-2(e1370)*, and *daf-16(mu86)* L1 nematodes; (B) effects of aurovertin D (AD) (0, 25, 50, and 100 μg/mL) on the development of wild type N2, *daf-2(e1370)*, and *daf-16(mu86)* L1 nematodes [(**) $P < 0.01$; (***) $P < 0.001$]; (C) effects of aurovertin D (AD) (0, 50, and 100 μg/mL) on the lifespans of wild type N2, *daf-2(e1370)*, and *daf-16(mu86)* [(**) $P < 0.01$]; (D) effects of aurovertin D (AD) (0, 50, and 100 μg/mL) on the relative average lifespans (% of control) of wild type N2, *daf-2(e1370)*, and *daf-16(mu86)* nematodes [(**) $P < 0.01$]; (E) effects of aurovertin D (AD) (0, 50, and 100 μg/mL) on the relative maximal lifespans (% of control) of wild type N2, *daf-2(e1370)*, and *daf-16(mu86)*. A one-way ANOVA followed by Tukey's honest significant tests for equal variances and Dunnett's T3 Tests for unequal variances were used to compare the relative average/maximal lifespans between mutants and wild type N2.

significant resistance of nematode mutants against aurovertin D.

ROS Levels in Nematodes Treated with Aurovertin D. The levels of ROS with important roles in cell signaling and homeostasis in nematodes can increase dramatically under environmental stresses including xenobiotics.[30] We tested whether aurovertin D could increase the ROS level in worms. However, aurovertin D did not alter ROS level in nemtaodes compared to negative control treatments (Figure 3C).

Increased Sensitivity of *daf-16* Nematode Mutant to Aurovertin D. DAF-16 is a *C. elegans* FOXO transcription factor and a key mediator involved in multiple stress responses.[31] Experiments were carried out to test whether DAF-16 in nematodes is required for the aurovertin D-induced response. The acute toxicity assay showed that the mortality of *daf-16(mu86)* mutant treated with aurovertin D at a subinhibitory concentration of 50 μg/mL was significantly increased with 26.7% compared to that of wild type N2 ($P < 0.05$) under the same treatment (Figure 4A). The larval growth rates of wild type N2 and the *daf-16(mu86)* mutant synchronized L1 worms exposed to various concentrations of aurovertin D are shown in Figure 4B. When exposed to aurovertin D at a concentration of 25 μg/mL, only 67.9% of *daf-16(mu86)* mutants developed into the L4 larval stage and no *daf-16(mu86)* mutants reached adult stage, whereas 63.6% of wild type N2 reached adult stage (Figure 4B), indicating that the development of *daf-16(mu86)* mutants was significantly inhibited compared to wild type N2 worms. For *daf-16(mu86)* mutant worms grown on medium with aurovertin D at concentrations of 0, 50, and 100 μg/mL, longevity including both average and maximum lifespans correlated with exposure doses (Figure 4C). Both the average lifespans and the

DOI: 10.1021/acs.jafc.5b02595
J. Agric. Food Chem. 2015, 63, 6577−6587

maximum lifespans of *daf-16(mu86)* mutant treated with aurovertin D at a concentration of 100 μg/mL were significantly reduced, with 19.4% ($P < 0.05$) and 23.5% ($P < 0.01$), respectively, less than those of the worms without aurovertin D treatment. However, the relative average lifespan and relative maximal lifespans of the treated *daf-16(mu86)* and wild type N2 worms were not significantly different (Figure 4D,E).

Decreased Sensitivity of *daf-2* Nematode Mutant to Aurovertin D. DAF-2 is the only insulin/IGF-1-like receptor in *C. elegans*, and insulin/IGF-1-like signaling is evolutionarily conserved across the animal kingdom, from single-celled organisms to mammals.[32] To clarify the involvement of DAF-2 in aurovertin D-induced toxicity, we tested the response of *daf-2(e1370)* mutants to aurovertin D exposure. The mortality percentages of *daf-2(e1370)* mutant L1 worms exposed to aurovertin D at concentrations of 50 and 100 μg/mL were significantly decreased at 44.4 and 26.3%, respectively, lower than those of wild type N2 ($P < 0.05$, Student's *t* test) (Figure 4A). Because DAF-2 activity is required for larval developmental timing, maturation of *daf-2(e1370)* mutants to adulthood was delayed compared to wild type N2. In the bioassay, the larval growth development of N2 worms was evaluated at 60 h, whereas *daf-2(e1370)* mutant worms were assessed at 84 h after the synchronized L1 stage worms were exposed to aurovertin D at concentrations of 0, 25, 50, and 100 μg/mL. The result showed that the percentage of *daf-2(e1370)* mutants which reached adulthood was significantly increased at 23.4% higher than that of wild type N2 nematodes following 25 μg/mL aurovertin D treatment ($P < 0.01$, Figure 4B). After exposure to 100 μg/mL aurovertin D, the average lifespan of *daf-2(e1370)* mutant was 56.7% longer than that of the wild type N2, whereas the average lifespan of *daf-2(e1370)* mutant was 69% longer than that of the wild type N2 when exposed to DMSO. The average lifespan of *daf-2(e1370)* mutant treated with 100 μg/mL of aurovertin D was significantly decreased at 27.2% less than the worms without aurovertin D treatment ($P < 0.01$, Figure 4C). Meanwhile, the maximal lifespan of *daf-2(e1370)* mutant was not significantly different when exposed to aurovertin D at concentrations of 50 and 100 μg/mL (Figure 4C). Exposed to aurovertin D treatment, the relative average lifespan of *daf-2(e1370)* mutant was significantly extended at 19.2% higher than that of wild type N2 ($P < 0.01$, Figure 4D). No significant difference was observed for the relative maximal lifespan between *daf-2(e1370)* mutants and wild type N2 upon aurovertin D exposure (Figure 4E).

DAF-16 Nuclear Localization in Nematodes Induced by Aurovertin D. DAF-16 is activated by translocation from the cytoplasm to the nucleus.[31] To determine the contribution of DAF-16/FOXO to the aurovertin D-induced host response, the influence of aurovertin D on the subcellular distribution of DAF-16 was examined using the transgenic strain TJ356. Worms of this strain carry a DAF-16::GFP fusion construct as a reporter gene, allowing the observation of the subcellular localization of DAF-16. The location of the transcription factor of DAF-16 in the cytosol, the nucleus, or an intermediate localization was observed after TJ356 L1 worms were treated with or without 50 and 100 μg/mL of aurovertin D for 60 h. Worms in the control group predominantly revealed a cytosolic localization (83 ± 5%) of DAF-16 (Figure 5A). Only a small fraction of the control worms showed a nuclear (12 ± 4%) or intermediate (5 ± 1%) localization phenotype (Figure 5A). A greater proportion of DAF-16::GFP was translocated to the nuclei in the intestine and other cells in the aurovertin D-treated worms in comparison to the control population. The fraction of worms showing cytosolic localization decreased to 22 ± 3%, and the percentage of worms with nuclear localization increased to 77 ± 6% (Figure 5B,C). Thus, a translocation of DAF-16 from the cytosol to the nucleus was observed in nematodes in response to aurovertin D (Figure 5).

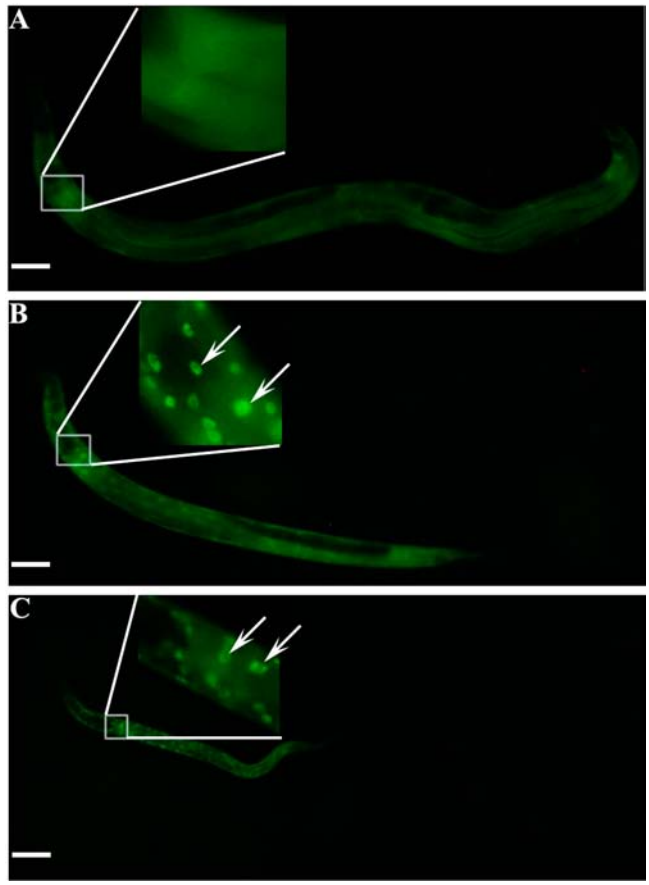

Figure 5. Effects of aurovertin D on nuclear localization of DAF-16::GFP in TJ356: (A) expression of DAF-16::GFP in TJ356 grown on the NGM Petri dishes containing 0.5% DMSO as negative control; (B) expression of DAF-16::GFP in TJ356 grown on the NGM Petri dishes containing 50 μg/mL aurovertin D; (C) expression of DAF-16::GFP in TJ356 grown on the NGM Petri dishes containing 100 μg/mL aurovertin D. The development of TJ356 nematodes was inhibited and nuclear localization of DAF-16 was induced by aurovertin D. Three independent experiments with at least 20 nematodes per group were performed. White arrows indicate nuclear enrichment of DAF-16::GFP. Scale bar = 50 μm.

DISCUSSION

P. chlamydosporia has a great capacity to infect and destroy the eggs and kill females of plant-parasitic nematodes. Increasing numbers of worldwide reports of *P. chlamydosporia* native isolates have been published.[33] Our recent study demonstrated that a *P. chlamydosporia* strain collected from root-knot nematode could produce a class of yellow pigment metabolites that showed nematicidal activity toward the free-living nematode *Panagrellus redivivus*.[15] This study hinted at the potential natural functions of fungal secondary metabolites in the pathosystem of nematode-parasitic fungi. Here we investigated 17 *P. chlamydosporia* isolates obtained from root-knot nematode worms, root-knot nematode eggs, or soils to

DOI: 10.1021/acs.jafc.5b02595
J. Agric. Food Chem. 2015, 63, 6577−6587

evaluate the effects of the ecological niches on the fungal nematicidal activity and the production of nematicidal metabolites in *P. redivevus* strains. Among the 17 *P. chlamydosporia* strains, only three culture broths of the fungal strains showed strong inhibitory activities toward larval nematodes (Table 1), suggesting that only a small portion of the fungal strains might be nematicidal. One of the possible reasons might be the fact that the fungus *P. chlamydosporia* can survive as a saprophyte in the soil in the absence of both plant and nematode hosts, and many strains may thus survive in the soil despite not possessing toxic metabolites toward nematode worms.[33]

Interestingly, all three *P. chlamydosporia* strains with strong nematicidal activities yielded distinctive luminous yellow fermentation broths (Figure 1) and were obtained from the nematode female worms instead of nematode eggs (Table 1). Chemical investigation of the three *P. chlamydosporia* strains demonstrated that the yellow pigment metabolites consisted of polyketide metabolite aurovertins (Figure 1A,B). Among them, four aurovertins, D, E, F, and I, were identified from all three *P. chlamydosporia* strains with distinctive luminous yellow fermentation broths. Further HPLC-DAD analysis of the aurovertin metabolite profiles of the *P. chlamydosporia* strains indicated that aurovertin D became the main component among the yellow pigment metabolites of the aurovertin-producing *P. chlamydosporia* strains grown for ≥5 days. Together with our previous study that among these aurovertins, aurovertin D showed the strongest nematodetoxic activity, more than double that of the second strongest metabolite, aurovertin F, which lacked only one acetyl group compared with the aurovertin D structure,[15] aurovertin D was chosen to be the representative of aurovertin-type metabolites to evaluate the effect of the aurovertins on nematodes and to study the nematode response reaction to this class of fungal metabolites.

Bioassay results revealed that aurovertin D showed stronger toxicity toward root-knot nematode *M. incognita* than toward free-living nematode *C. elegans*. The LC_{50} value of aurovertin D for root-knot nematode *M. incognita* is 16.45 μg/mL, only half of the LC_{50} value for *C. elegans*. These results indicated that the class of aurovertins could be involved in the pathosystem of the nematode-parasitic fungus, and the major aurovertin played a key role in the nematode-killing process of the aurovertin-producing *P. chlamydosporia* strains. The *P. chlamydosporia* strains that colonized the nematode worms tended to produce the nematicidal yellow pigment aurovertins compared to the strains obtained from nematode eggs. This might be attributable to the fact that aurovertins did not affect the nematode egg hatch.[15] From the above results, it could be deduced that some of nematode-parasitic *P. chlamydosporia* strains isolated from nematode body ecological niches instead of nematode eggs tended to produce a highly conserved class of nematicidal yellow metabolites to attack and kill the larval nematode.

Our results demonstrated that exposure to aurovertin D at subinhibitory concentrations led to decreases in brood size, lifespan, and pharyngeal pumping rates and to a retardation in larval development of nematode *C. elegans*. In addition, aurovertin D was more toxic to the younger than to the older individuals. This could be attributed to the immaturity of detoxifying systems in L1 stage larvae of *C. elegans*,[34] which might function better in the L4 larvae, as was observed for the antimicrotubule agent hemiasterlin.[35]

ATPase is a molecular target for various diseases and the regulation of energy metabolism.[36] The enzyme comprises a soluble globular F_1 (subunit composition $\alpha_3\beta_3\gamma_1\delta_1\varepsilon_1$) catalytic sector and a membrane-bound F_O proton-translocating sector.[37] *C. elegans atp-2* encodes the β subunit of the soluble catalytic F_1 portion of ATP synthase and is required for nematode larval development, as well as for normal mobility, pharyngeal pumping, defecation, and growth rate.[36,37] Aurovertins were found to inhibit both membrane-bound and soluble mitochondrial F_1F_O-ATPase of the protozoan *Trypanosoma cruzi*.[38] An aurovertin-resistant mutant of *Saccharomyces cerevisiae* contained an altered nuclear gene that specifies the structure of the β subunit of F_1 portion of ATP synthase.[39] To evaluate whether aurovertin D exerts its toxicity by targeting the β subunit of F_1-ATPase in nematodes, the resistance of nematode mutants deficient in the β subunit to aurovertins was assessed. However, no significant difference between these mutants and wild type N2 nematodes was observed after aurovertin D treatments. Because the catalytic β subunit of F_1-ATPase is required for mitochondrial ATP synthesis, the knockout of the entire β subunit is lethal to nematodes, so the mutants used in this part of study contained *ok3002* allele that had a deletion of only about 500 bp in the third exon of the β subunit encoding gene *atp-2*.[27] Previous study revealed that the change of one base G in the gene *unc D* in *E. coli* resulted in the change of the amino acid β-398Arg of the β subunit of F_1-ATPase and conferred resistance to aurovertins in bacteria.[40,41] It is possible that the mutation in *atp-2/ht2* in *C. elegans* might not occur at the gene fragment which encodes the amino acid target equivalent to that of β-398Arg of the β subunit of F_1-ATPase in *E. coli*. In addition, nematode mutant *atp-2(ok3002)* can develop only through two larval stages and arrest at the L3 stage due to the deficiency in the β subunit,[42] which might lead to greater sensitivity of the impaired mutants to aurovertin D than that of the wild type N2 as shown in Figure 3A.

Further RNAi experiments were performed to evaluate the responses of the mutants deficient in each subunit of F_1F_O-ATPase of *C. elegans* to aurovertin D. The silencing of the β subunit of F_1-ATPase by RNAi did not significantly increase the resistance of worms to aurovertin D compared to the wild type N2. In fact, none of the RNAi worms showed a significant difference in larval development except for those nematodes grown on bacteria expressing double-stranded RNAs (dsRNA) R53.4 and *hpo-18*, respectively, which showed much greater sensitivity to aurovertin D than did the negative control. R53.4 encodes a mitochondrial ATP synthase subunit f homologue and is assumed to be required for the expression of antimicrobial peptides in response to infection,[43] whereas *hpo-18* encodes the *C. elegans* homologue of the oligomycin sensitivity-conferring protein (OSCP) subunit of mitochondrial ATP synthase (complex V), which is crucial for transmitting the energy of AGH+ to the catalytic sector.[44] A previous study revealed that aurovertin inhibited ATPase considerably in the absence of F_O and found that some protective action occurred in the presence of F_O.[45] Furthermore, the gene encoding OSCP is involved in controlling respiration and regulates growth rate and body size, aging, and rates of behaviors such as pharyngeal pumping, defecation, and locomotion. Our results that the RNAi mutants in R53.4 or *hpo-18* caused the nematodes to be more sensitive to aurovertin D were consistent with previous reports.

Previous studies reported that the ATPase inhibitor oligomycin could promote mitochondrial hyperpolarization,

DOI: 10.1021/acs.jafc.5b02595
J. Agric. Food Chem. 2015, 63, 6577−6587

which leads to variation of ROS.[46] ROS not only plays important roles in apoptosis (programmed cell death) but also displays positive effects such as the induction of host defense.[46] The toxicity of aurovertins in nematodes might be partially attributable to varied production of ROS in nematodes, so we checked the ROS levels in nematodes exposed to aurovertin D. However, no significant alteration of ROS levels in nematodes upon aurovertin D exposure was observed, indicating that the *C. elegans* response system might possess alternative mechanisms for dealing with this toxin.

The *C. elegans* FOXO transcription factor DAF-16 represents the end point of several key signaling cascades controlling the stress response, the process of aging, and other important biological functions in *C. elegans* in parallel to FOXO transcription factors in mammals.[31] As DAF-16 is thought to be the main target of the DAF-2 pathway and DAF-2 is negatively correlated with DAF-16 activity and longevity, the mutants *daf-16(mu86)* and *daf-2(e1370)* were used to investigate the signaling pathways involved in the aurovertin D-elicited stress response of nematodes. The higher sensitivity of mutant *daf-16(mu86)* deficient in *daf-16* to aurovertin D indicated that DAF-16 was involved in protecting the nematodes from the effects of aurovertin D. We noted that mutant *daf-16(mu86)* was also significantly more sensitive than the wild type N2 to avermectin and oligomycin B, suggesting that *daf-16* may be involved in a general resistance mechanism in nematodes exposed to outside toxins. At the same time, our results demonstrated decreased sensitivity of *daf-2(e1370)* mutants to aurovertin, just opposite that of *daf-16(mu86)*. The reduced sensitivity of *daf-2(e1370)* to aurovertin D might be attributed to the activation of DAF-16 due to the reduced DAF-2 signal.

Because DAF-16 in *C. elegans* is partially activated by nuclear translocation, the transgenic worm strain TJ356 with DAF-16::GFP fusion reporter protein was utilized to further evaluate the involvement of DAF-16 proteins in aurovertin resistance. Our result revealed DAF-16 nuclear localization in aurovertin-treated worms, confirming the activation of the transcription factor DAF-16/FOXO in nematodes by aurovertin D. A previous study indicated that the absence of food for >1 h resulted in nuclear translocation of DAF-16.[36] It is likely that the aurovertin D-induced DAF-16 nuclear localization was triggered by starvation due to the reduced pharyngeal pumping rate caused by aurovertin D.

In summary, some strains of the nematode-parasitic fungus *P. chlamydosporia* isolated from the worm bodies developed a highly conserved class of yellow chemical compounds capable of inducing the death of the host. The yellow pigment metabolites consisted of polyketide pigment aurovertins. The aurovertin-producing *P. chlamydosporia* strains, when cultured in broth for ≥5 days, yielded a total aurovertin production exceeding the inhibitory concentration of aurovertins. The major aurovertin produced in the broth is more toxic to root-knot nematode than to the model species *C. elegans*. Aurovertins play important roles in reducing the population of nematodes and delaying their growth. Investigation of the mode of action of the major aurovertin in the nematode model *C. elegans* revealed that the β subunit of F_1-ATPase might not be the specific target in nematodes as previously reported. On the other hand, nematodes triggered the DAF-16/FOXO transcription factor to cope with the attack from fungal nematicidal aurovertin metabolites.

tion for optimal linear response. Spectra were baseline corrected, adjusted for mass differences, and normalized to the methylene peak at 2927 cm^{-1}. FTIR spectra of the oils (crude, refined, and products) are shown in Figures 1−3, 5, and 6.

(b) Thin Layer Chromatography (TLC). TLC of the reaction mixtures was carried out using precoated silica gel plates (0.2 mm, 5 × 20 cm; EM Science, Darmstadt, Germany). The solvent system used was (hexane/ethyl acetate/acetic acid 10:5:2). The developed chromatogram was visualized by methanol−sulfuric acid spray and heated to 100−110 °C.

(c) Viscosity Measurements. Kinematic viscosity was determined using a Cannon-Fenske viscometer for transparent liquids (Cannon Instrument Co., State College, PA, USA) in accordance with AOCS Official Method Tq 1a-64. The tube number was 400. The cleaned dry tube was loaded with the sample oil at room temperature and placed in its holder in the constant-temperature bath. The sample was allowed to equilibrate for 10 min at 40 °C or for 15 min at 100 °C before the sample was suctioned into the lower bulb until the meniscus just overshot the mark above the lower bulb. The suction was removed and the meniscus adjusted to the mark. The sample was allowed to flow at the same time the stop clock was started. The time (in seconds) it took for the meniscus to reach the mark below the bulb multiplied by the tube constant gave the viscosity of the sample. The measurement was replicated and averaged to obtain the viscosity.

(d) Nuclear Magnetic Resonance Spectroscopy. ^{13}C NMR spectra were acquired on a Bruker AV-500 MHz spectrometer with a dual 5 mm proton/carbon probe (Bruker, Ballerica, MA, USA). The internal standard was tetramethylsilane.

(e) Density. Sample density measurements were carried out using a pycnometer or Kimble specific gravity bottle (10 mL) equipped with a thermometer and a side arm cap (Kimble Glass Inc., Vineland, NJ, USA). The pycnometer was cleaned with hexane and acetone and dried with an air jet. The reassembled unit was weighed empty and then carefully loaded with the sample, cleaned of excess sample, and reweighed. The process was replicated so that sample masses could be averaged.

(f) Oil Extraction and Degumming. Osage orange oil was extracted from 3 kg of ground seed using a Retsch mill. The seeds were preconditioned in powdered dry ice for several minutes before milling to facilitate particle size reduction. The obtained seed meal was extracted in approximately 1 kg batches in a Soxhlet extractor using hexane. The hexane extract was decolorized with activated carbon before solvent removal to yield the crude oil. The oil content of the seed was calculated to be 30−35% by weight of the dry seed. Portions of the crude oil were chilled (5 °C) and centrifuged (10000*g*) at the same temperature for 30 min to remove phospholipids and waxy content. The free fatty acid component was removed from the degummed oil (Figure 1) by dissolving it in hexane, and the solution

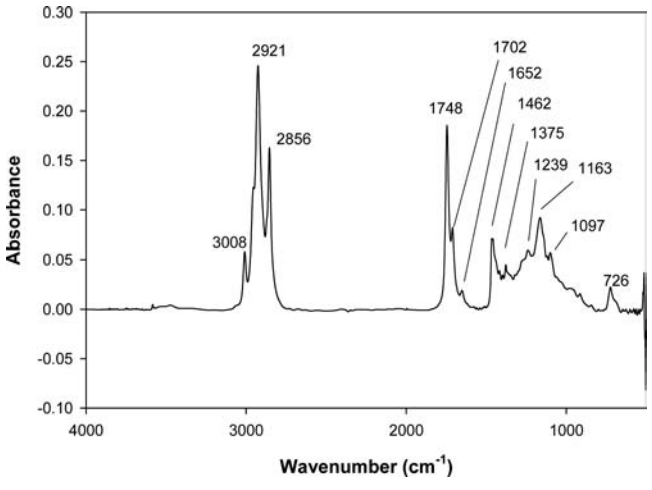

Figure 1. FTIR spectrum of degummed crude Osage orange oil.

was shaken with cold aqueous (0.1 M) ammonium hydroxide solution in a separatory funnel. The separated organic phase was then washed with deionized water until the washings were neutral to litmus. The organic layer was dried over $MgSO_4$, filtered, and concentrated under reduced pressure at 67 °C to give the Osage orange triglyceride (Figure 2); density = 0.979 g mL^{-1} at 23 °C. The free fatty acids were

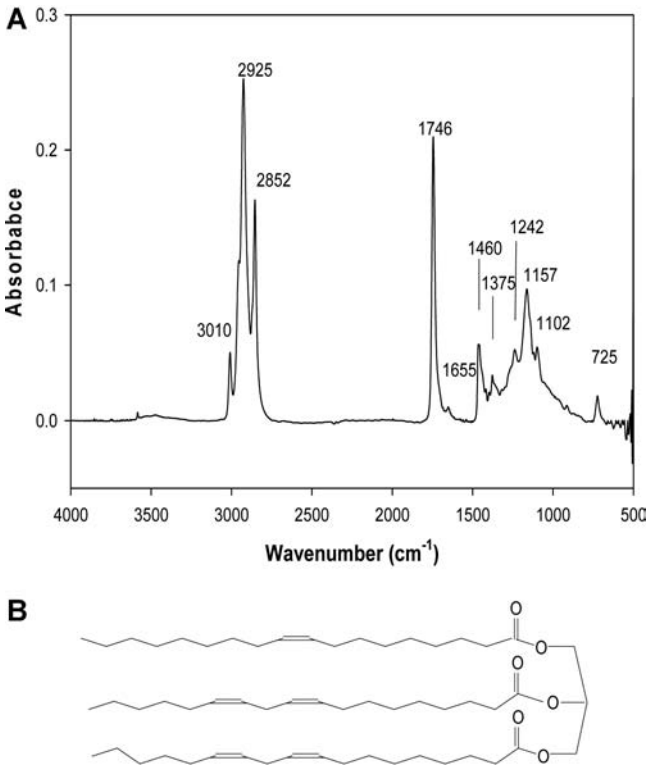

Figure 2. (A) FTIR spectrum of cleaned Osage orange triglyceride and (B) structural representation of the triglyceride molecule.

recovered by acidulation of the combined aqueous layer and washings with dilute HCl followed by extraction with hexane. The hexane extract was dried over $MgSO_4$ and concentrated to give the free fatty acids, which were set aside from the intact triglyceride.

Synthesis of Osage Orange Oxirane. In a 1 L jacketed three-necked reaction flask equipped with an overhead stirrer at a starting temperature of 40 °C was placed Osage orange oil (280.90 g, 320.8 mmol) to which formic acid (88%, 30.50 g, 25.0 mL, 663 mmol, i.e., 0.4 equiv/−C═C−) was added in one portion. On stirring to homogeneity, H_2O_2 (50%, 200 mL, 7.05 mol) was added dropwise, and at the end of peroxide addition the reaction temperature was raised to 70 °C. Progress of the reaction was monitored in 30 min intervals by FTIR spectral analysis of withdrawn samples of the reaction mixture for disappearance of the 3008 and 1648 cm^{-1} bands of the olefin with the concomitant formation of a doublet observable at 822−845 cm^{-1} for the oxirane. After 2 h, the reaction was judged complete; the heat source was then withdrawn and the product mixture allowed to cool to near room temperature, when it was transferred into a separatory funnel with ethyl acetate as diluent and allowed to separate into two layers. The aqueous layer was removed and discarded. The organic phase was washed with a mixture of saturated NaCl and Na_2CO_3 solution followed by drying over $MgSO_4$ overnight. Filtering and concentration of the filtrate gave a quantitative yield, 316.0 g, of the oxirane of Osage orange oil, $d^{22.3}$ 1.067 g mL^{-1}. FTIR spectral features of its film on NaCl disk are given in cm^{-1}: 2928 vs (−CH_2− sym stretch), 2859 s (−CH_2− asym stretch), 1743 vs (−C═O stretch), 1461 s (−CH_2− deform), 1377 m-s (−CH_3 deform), 1236 m-s (−O—C═O), 1160 s (−CH—O− stretch), 1045 (−CH_2O− stretch), 845−824 doublet m (−C—O—C− oxirane asym stretch), 725 (−CH_2− wag). ^{13}C NMR ($CDCl_3$): δ 173.17,

The kinematic viscosity was 131.6 cSt (40 °C) and 19.2 cSt (100 °C); that is, a viscosity index (VI) = 166.

Synthesis of Osage Orange Poly(α-hydroxydibutylamine) Triglyceride. In a dry 250 mL round-bottom reaction flask equipped with an overhead stirrer as above was placed epoxy Osage orange oil (59.5 g, 62.26 mmol), and anhydrous ZnCl$_2$ (1.0 g) was added followed with *N*,*N*-dibutylamine (43.41g, 56.6 mL, 336 mmol, i.e., 5.4 equiv) introduced dropwise into the stirred reaction mixture. A reflux condenser was attached, and the reaction mixture was stirred and heated to gentle reflux. The reaction was monitored by sampling the mixture at 1 h intervals to observe diminution of the 820−845 cm^{-1} band of the oxirane in the FTIR spectrum as ring-opening progressed. The reaction was stopped when no trace of the 820−845 cm^{-1} band was visible, ca. 2.5 h. TLC (hexane/EtAc/AcOH 10:5:2) was a second mode of tracking reaction progress, confirming the absence of starting epoxide. The reaction product was cooled to room temperature, diluted with ethyl acetate, and washed with saturated NaCl solution. The organic phase was dried over MgSO$_4$ and filtered, and the solvent was removed by rotary evaporation under reduced pressure, giving 93.3 g, (i.e., 93.3%) yield of the poly(α-hydroxydibutylamine); $d^{22.6}$ = 0.9985 g mL^{-1}. FTIR film on NaCl disk: ν cm^{-1} 3431 (br OH stretch, second deriv 3586), 2952 s (−CH$_3$ asym stretch, second deriv 2956), 2929 vs (−CH$_2$− sym stretch, second deriv 2931), 2853 s (−CH$_2$− asym stretch, second deriv 2876), 2857 (−CH$_3$ asym stretch), 1739 vs (−C═O stretch, second deriv 1741), 1667 w (−N—C, 1575 vw), 1463 s (−CH$_2$− deform, second deriv 1468), 1378 m-s (−CH$_3$

DOI: 10.1021/acs.jafc.5b01625
J. Agric. Food Chem. 2015, 63, 6588−6595

deform), 1244 m (−O—C═O), 1164 m-s (−CHO− stretch), 1101 m-s (−CHO− stretch), 1035 sh (−CH_2O− stretch), 726 (−CH_2− wag). The kinematic viscosity was 410.54 cSt (40 °C) and 38.57 cSt (100 °C); VI = 141.

RESULTS AND DISCUSSION

Efficient solvent extraction of the fat content of the seed depends on the extent to which particle size of the ground seed could be reduced, especially in a seed of higher fat content. To maximize the particle surface area of the grind, experience suggested that chilling of the dry seed before milling would give the best results. Therefore, at near dry ice temperature the seed was easily ground to a reasonably fine powder without clumping, as would otherwise be experienced. This condition of the meal greatly facilitated hexane extraction of each kilogram batch of the seed meal. This was evidenced by the result that at the end of each 24 h extraction interval, the residual pool of solvent below the extraction thimble was colorless. Concentration of the resulting extract by rotary evaporation gave a crude dark Osage orange oil. Decolorization of the crude was by redissolution in hexane and treatment with activated carbon. The decolorized crude triglyceride obtained after solvent removal was then winterized followed by centrifugation at low temperature (5 °C) to separate the phospholipid and waxy components. Although purification of the degummed crude oil could have been achieved by fractional distillation, we chose the wet chemistry approach for economic reasons. Cold storage of the seed seemed to have slowed the metabolic release of free fatty acids in the oil as seen in Figure 1. The free fatty acid level in the extracted oil was reasonably low judging from the lower intensity of the 1702 cm^{-1} carbonyl absorption band of the free fatty acids compared to that of the intact ester functionality of the triglyceride at 1748 cm^{-1}. Consequently, we opted for the wet chemistry approach, which successfully separated the intact triglycerides (Figure 2A) from the admixture in Figure1. Interpretation of the FTIR spectral features of the cleaned triglyceride (Figure 2A) in relation to the structural representation of the oil (Figure 2B) is as follows. The absorption band at 3010 cm^{-1} is the olefinic (**H—C═**) stretch, whereas the 2956 and 2925 cm^{-1} bands are respectively the terminal methyl (H_3C−) and the methylene (−CH_2−) groups asymmetric stretching modes of the alkyl chains. The symmetric stretching bands of the terminal methyl and that of the methylene groups are seen around 2855 cm^{-1}. The 2855 cm^{-1} band is a composite of the more preponderant methylene groups at 2855 cm^{-1}, whereas the smaller population of methyl symmetric absorption band is at 2865 cm^{-1}. The other prominent diagnostic absorption band of the oil is the very strong carbonyl (**−C═O**) of the ester groups at 1746 cm^{-1}. It should be noted here that the 1740 cm^{-1} region of the spectrum is devoid of any free fatty acid absorption, hence the absence of the 1702−1713 cm^{-1} band as exists in the admixture (Figure 1). The methylene and the terminal methyl deformation bands of the chain are seen at 1460 and 1375 cm^{-1}, respectively. The small band at 1655 cm^{-1} indicates the puckering or breathing mode of the vinylic (**−C═C−**) bonds of the triglyceride. The FTIR absorbance at 1242 cm^{-1} represents the (**−O—C═O**) stretching mode of the ester head groups of the triglyceride, whereas the 1157 and 1102 cm^{-1} bands are those of the glyceryl (HCO). A feature that seems to be missing is the 1050 cm^{-1} band of the (CH_2O) of the glyceryl absorbance, which is here overlapped by the 1102 cm^{-1} band. Finally, the IR band at 725 cm^{-1} is the wagging mode of the long methylene skeleton. The ^1H and ^{13}C NMR spectra of the cleaned triglyceride are shown in Figure 3, panels A and B, respectively. From the chemical shift values, the most downfield protons are the vinylic multiplet at 5.4 ppm (9−10H), immediately followed by a multiplet at 5.3 ppm (1H), which is the glyceryl methine proton by virtue of coupling from the two neighboring methylene groups. A doublet of doublets at 4.3 ppm (J = 4.3 Hz, 2H) and multiplet centered at 4.1 (2H)

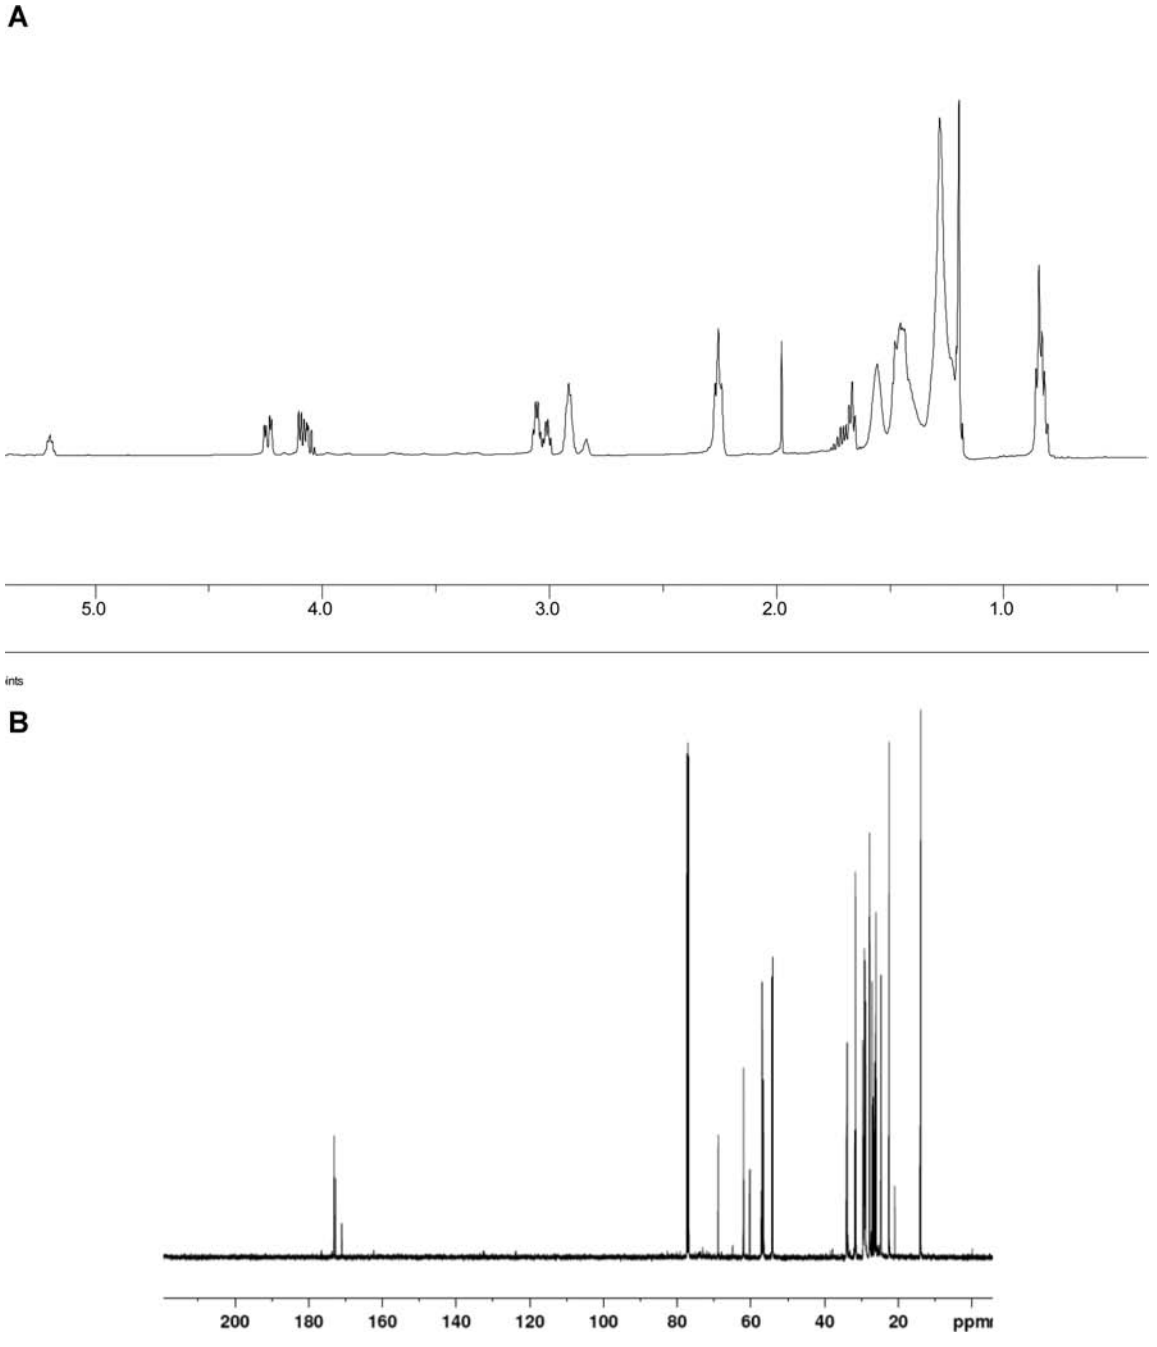

Figure 5. (A) ^{1}H and (B) ^{13}C NMR spectra of the oxirane of Osage orange oil showing resonances of the epoxy methine protons around 3.3 ppm and of the methine carbons from 57.15 to 54.13 ppm.

Table 2. Densities and Kinematic Viscosities of Derivatives

compound	density (g cm^{-3})	kinematic viscosity (cSt)	viscosity index
unmodified triglyceride	0.979 (23 °C)		>200
oxirane	1.067 (22.3 °C)	131.6 (40 °C) 19.6 (100 °C)	166
poly(α-hydroxydibutylamine)	0.998 (22.6 °C)	410.54 (40 °C) 38.57 (100 °C)	141

are the glyceryl CH_2s. The clean triplet centered at 2.75 ppm (J = 6.6 Hz, 6.5 Hz, 4H) represents the methylene groups contiguous to the ester carbonyl, whereas the multiplet at 2.30 ppm represents the 6H of C11 sandwiched between C10, C12, and C14 vinylic carbons of linoleic acid moieties. The multiplet at 2.03 ppm (11H) is the C3 and C4 protons, and the broad multiplet at 1.6 ppm (6H) accounts for C8 protons. The huge multiplet at 1.29 ppm is assigned to the remaining methylene protons, whereas the terminal methyl protons are the overlapping triplets (multiplet) at 0.87 ppm. A profile of the fatty acid methyl esters of Osage orange oil (Table 1) shows the fatty acid composition of this oil.[16]

Epoxidation of the cleaned triglyceride was smooth and high yielding.[17−20] Figure 4A depicts the epoxidation reaction scheme transforming the olefinic units of this oil to the polyoxirane derivative, and Figure 4B is the FTIR spectrum of

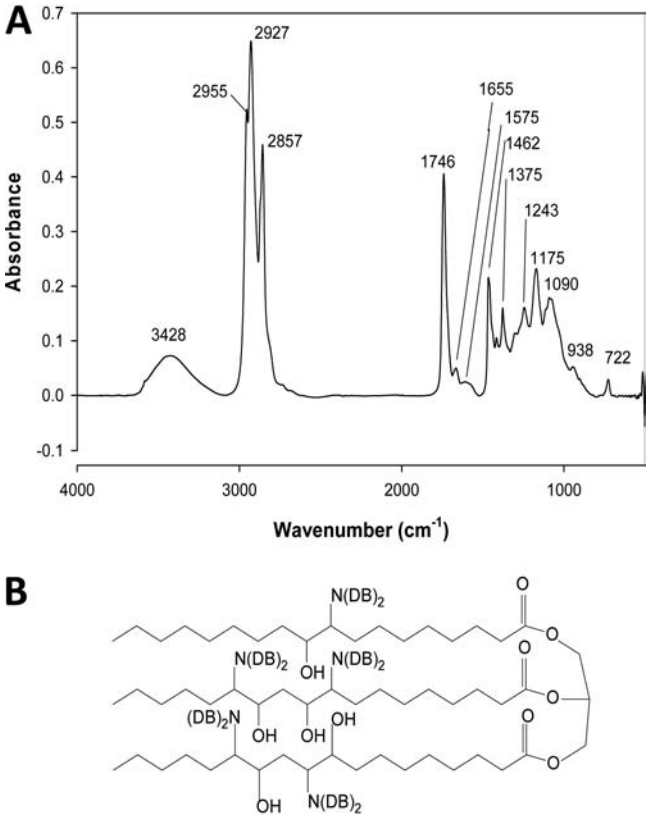

Figure 6. (A) FTIR spectrum of poly(α-hydroxy-*N*,*N*-dibutylamine) triglyceride of Osage orange oil and (B) proposed structure of this derivative.

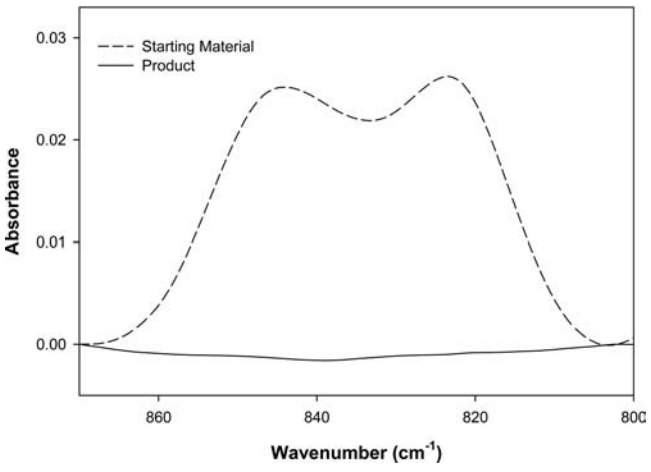

Figure 7. FTIR spectral difference between the epoxy band region before and after reaction with *N*,*N*-dibutylamine.

the polyoxirane of Osage orange oil. The glaring diagnostic spectral feature of the oxirane is the characteristic doublet at 824−845 cm^{-1} for the (−**C**—**O**—**C**−) asymmetric stretching mode of the three-membered ring. A not so obvious absorption band of the oxirane, however, is the methine (**H**—**C**—O—**C**—**H**) band of the three-membered ring that is buried under the strong $-CH_3$ asymmetric stretching mode close to 3000 cm^{-1}. This band is only obvious in the second derivative of the epoxy spectrum at 2994 cm^{-1}. The ^{13}C NMR of the oxirane is shown in Figure 5. The essential diagnostic features observed here are the 10 resonance lines starting from 57.2 to 54.1 ppm

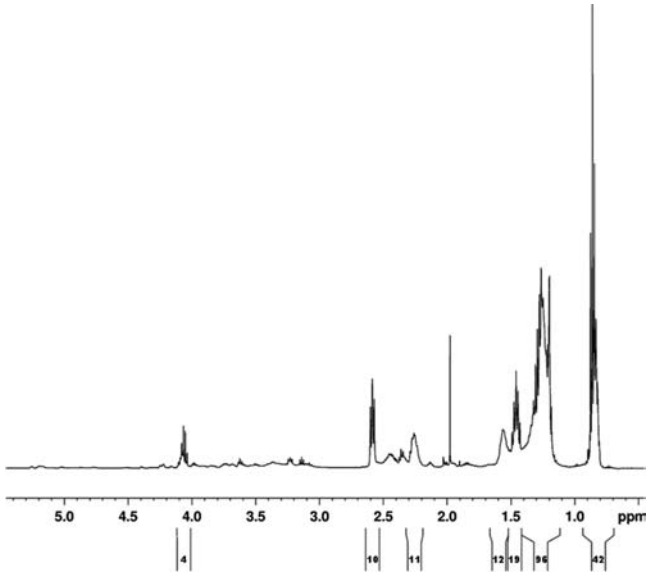

Figure 8. ^1H NMR spectrum of poly(α-hydroxydibutylamine).

resulting from the methine carbons (−**C**—O—**C**−) of the ring. This spectral region is featureless in the parent triglyceride (Figure 3B) and in subsequent derivatives from the oxirane. What is also noticeable from this epoxy spectrum is the complete disappearance or absence of signals of the olefinic moieties (140−120 ppm) in the ^{13}C. In other words, epoxidation of the olefin was complete. The first upfield methylene resonances from the oxirane methine carbons are the three methylene carbons that are proximal to the ester carbonyl at 34.1−33.9 ppm. These are followed by the C-11 carbons sandwiched between the oxirane C-10 and C-12 species at 31.8−31.6 ppm, whereas the six (−**C**H_2−) contiguous to epoxy carbons are observed at 29.6−29.4 ppm. The remaining methylene carbon resonances gradually tend upfield as distance from heteroatoms increases. Thus, some 21 (−CH_2−) invariantly resonate between 29.02 and 24.70 ppm as their location tends toward the alkyl termini. The terminal methyl groups are upfield around 14 ppm. The other spectral features of the ^{13}C NMR are the low-field ester carbonyl resonances at 173.2, 173.1, and 172.7 ppm, whereas the glyceryl methine carbon (−CH−O−) is at 68.9 ppm and its methyleneoxy carbons (−**C**H_2O−) are observed at 62.0 and 60.3 ppm, respectively.

Aminolysis of the oxirane was more sluggish compared to the oxirane formation even as catalyzed by anhydrous $ZnCl_2$ under gentle reflux irrespective of the lower scale of reactants used. The reaction was sometimes run overnight to give the poly-α-hydroxydibutylamine triglyceride derivative in excellent yield.[17,20] This was consistent with earlier observation in amidation ring-opening of other vegetable oxiranes (Milkglyde, Saliglyde, and Soyglyde).[18,19,21] TLC monitoring of the ring-opening of the oxirane showed several discrete spots (R_f = 0.56, 0.52, and 0.48) for the starting epoxide lane in relation to the solvent front when migration was stopped about halfway up the plate height. The polyhydroxydibutylamine tended to smear a bit on the stationary phase even though migrating more slowly with an R_f = 0.26 compared to the oxirane starting material. When development of the loaded plate was allowed to run close to the top of the 5 × 20 cm plate, the developed chromatogram shows up to eight discrete spots in the oxirane lane (R_f = 0.77, 0.74, 0.67, 0.55, 0.48, 0.35, 0.29, and 0.19) as

J. Agric. Food Chem. 2015, 63, 6588−6595

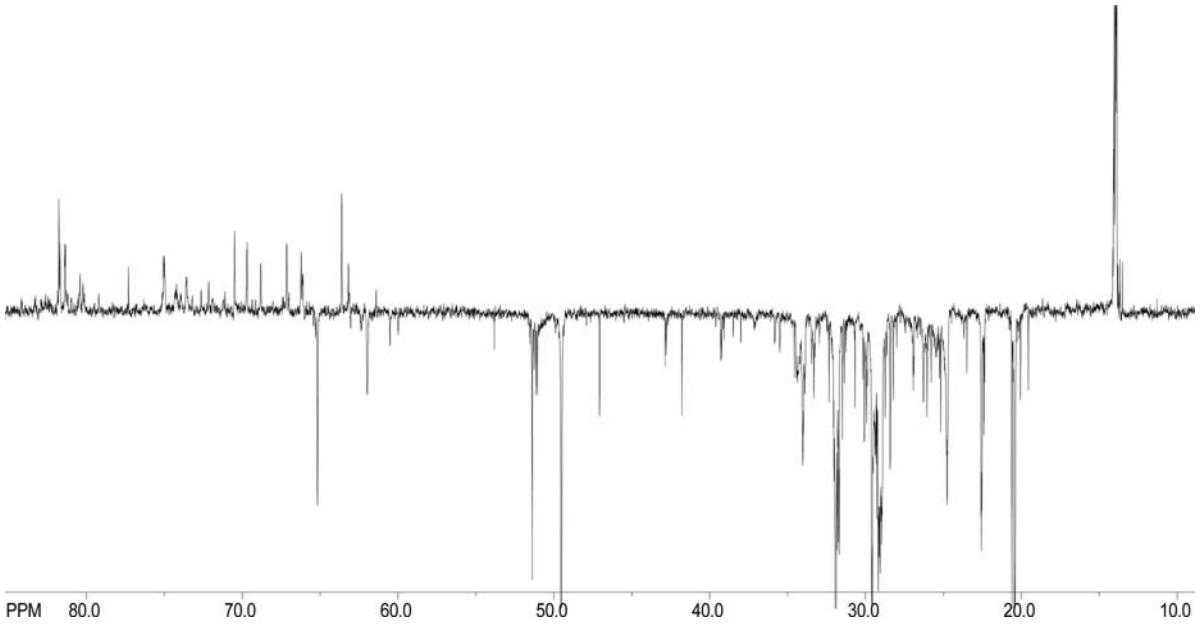

Figure 9. ^{13}C NMR DEPT spectrum poly(α-hydroxydibutylamine).

contrasted to R_f = 0.13 for the product. For an understanding of the TLC data, the cleaned natural oil is a mixture of various C-18 triglycerides and so the epoxidized oil should of necessity contain those permutations. Hence, the species are shown by the TLC spots on the developed plate. The aminolysis seemed to have tamped down the conformational differences into one through streamlining of the structures from the semi sp^2 hybrid in the three-membered rings to full sp^3 configurations that would allow better packing of the chains except for the disrupting influence of the *N*,*N*-dibutylamine substituents. Aminohydration of the chains introduces both higher polarity to the midsection of each acyl chain of the triglyceride and greater sphericity or bulkiness induced by branching of the triglyceride chains. One of the resulting effects of branching in the triglyceride caused by insertion of *N*,*N*-dibutylamine is lowering of the density of the derivatized triglyceride as observed in Table 2. This table also shows enhanced viscosity of the derivative relative to the oxirane. The corresponding FTIR spectrum of the product confirmed complete replacement of the characteristic 820−845 cm^{-1} band of the epoxide with the α-hydroxyl dibutylamine groups.

Figure 7 is an overlay of the FTIR spectra of the starting oxirane over that of the poly-α-hydroxydibutyl amine product in the 800−870 cm^{-1} region, that is, before and after reaction of the starting polyoxirane. This convincingly shows the extent of the ring-opening aminolysis reaction. The broad IR band centered around 3428 cm^{-1} in Figure 6A is the stretching mode of the α-hydroxyl (O−H) groups of the hydroxydibutylamine triglyceride (Figure 6B). The tertiary polyamine generated in the epoxy ring-opening aminolysis reaction is spectroscopically transparent in this region under the product isolation conditions. Inspection of Figure 6A shows attenuation of the ester carbonyl absorption as compared to the strong carbonyl absorption band in the oxirane triglyceride. The explanation lies in the major contribution resulting from the mass effect of adding over 600 mass units of alkyl side chains to the alkyl component of the triglyceride molecule without a corresponding increase in carbonyl moiety contribution. A second but minor contributing factor also is the very weak IR band at 1655 cm^{-1}, which is assignable to a −C−N absorption from the small amount of competing amidation process on the ester head groups. This band is assignable to an "amide I" C−N stretching mode especially as it is accompanied by an unresolved but much smaller band around 1575 cm^{-1} for the "amide II" absorption mode. This phenomenon has been observed in an earlier study of aminolysis ring-opening of new crop epoxy oils.[21] Figure 8 is the ^{1}H NMR spectrum of the poly(α-hydroxydibutylamine). The theoretical total proton count in the product is 194, and the proton integration values when normalized to the spectral resonances of Figure 8 are consistent with characteristics of the desired compound. Figure 9 is the ^{13}C distortionless enhancement proton transfer (DEPT) spectrum of the product. The methylene carbons bound to nitrogen atoms in the product resonate downfield starting at 42.0, 47.1, 49.5, 51.4, and 65.0 ppm, whereas the methine oxygen-bonded carbons are farther downfield from those bonded to nitrogen atoms and are observed between 81.1 and 66.0 ppm. This derivatized vegetable oil is in the exploratory stage for a non-food use in lubricant and related applications, where oxidative stability of the oil is of value. We intend to further modify the hydroxyl units of this tree oil derivative to both lower its polarity and enhance its oxidative stability so as to potentiate its lubricity character.

ward and efficient approach to make large amounts of rubrosterone available for biological testing is urgently required.

It has been well documented that in the sterol-degrading microorganisms, the ring nucleus and side chain are metabolized by different enzyme systems simultaneously and independently.[25] According to previous papers, the microorganism *Mycobacterium* sp. (NRRL B-3805) was a mutant for the selective cleavage of the sterol side chain to generate C_{19} and other useful steroid intermediates.[26] The microorganism *Fusarium lini* (ATCC 9593) was also capable of oxidatively catabolizing the 20*R*,22*R*-dihydroxy side chain in ponasterone A to yield rubrosterone; incubation of β-ecdysone yielded rubrosterone, as well.[27] Nevertheless, this type conversion using *F. lini* was relatively less efficient (15% of ponasterone A and <5% of β-ecdysone).[27]

Previous studies have revealed that some botanical medicines from the genus *Asparagus* (Liliaceae), such as *Asparagus cochinchinensis*, *Asparagus officinalis*, and *Asparagus filicinus* Buch.-Ham, have been widely used in China for a long time.[28] Particularly, the dried roots of *A. filicinus* under the name "Xiao-Bai-Bu" are used as a folk medicine for the treatment of tracheitis, cough, pneumonia, hemoptysis, acariasis, phthisis, and lung cancer.[28] According to the previous studies, 37 compounds, including 8 ecdysteroids, have been extracted from *A. filicinus* so far.[29] In particular, 20-hydroxyecdysone, an analogue of ponasterone A, has been shown to be a predominant constituent in the roots of *A. filicinus*. Therefore, Xiao-Bai-Bu could be an extremely suitable material for the accumulation of rubrosterone.

In the present study, *A. filicinus* was inoculated with 10 plant pathogenic fungi by solid fermentation. Interestingly, the anticipated compound, rubrosterone, was produced in large quantities by *Fusarium oxysporum*, a fungus from the same genus as *F. lini*. To confirm that rubrosterone was transformed from 20-hydroxyecdysone, pure 20-hydroxyecdysone was used in the biotransformation experiment with *F. oxysporum*. The results confirmed the microbial transformation between the two chemical compounds. This study addresses the accumulation of rubrosterone by the solid-state fermentation of *A. filicinus* with *F. oxysporum*.

MATERIALS AND METHODS

Chemicals and Instruments. Acetonitrile and methanol of HPLC grade were supplied by Fisher Scientific (Fair Lawn, NJ, USA). The silica gel used of 200−300 and 300−400 mesh and Sephadex LH-20 for column chromatography (CC) were obtained from the Qingdao Marine Chemical Corp. (Qingdao, China) and GE Amersham Biosciences (Piscataway, NJ, USA), respectively. RP-C18 silica gel of 40−60 μm was provided by Merck KGaA (Darmstadt, Germany). Pyridine-d_5 (99.5 atom % D) was purchased from Qingdao Tenglong Weibo Technology Co., Ltd. (Qingdao, China). The water (resistivity ≥ 18.25 MΩ/cm) was purified with a purity water system. All other chemicals used were of analytical grade.

The ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker DRX-400 (the chemical shift was referred to the solvent peak) at 298 K with tetramethylsilane (TMS) as an internal standard. The HR-ESI-MS spectrum data of the two isolated compounds were recorded by a G3250AA LC/MSD TOF spectrometer (Agilent Technologies, Santa Clara, CA, USA). The HPLC system, equipped with a Delta 600 quaternary pump and 2487 dual wavelength absorbance detector (Waters Corp., Milford, MA, USA) was used for the identification and quantitation of the compounds. The HPLC column used was a 250 mm × 4.6 mm i.d., 5 μm, Zorbax SB-C18 (Agilent). The HPLC-MS were recorded on an Agilent 1100 HPLC system and G3250AA (Agilent) mass spectrometer.

Plant Material. *A. filicinus* was collected in Kunming City, Yunnan Province, of China in November 2013 and authenticated by Prof. Shugang Lu of the School of Life Sciences at Yunnan University. A voucher specimen (No. YNU-XBB01) is deposited in the Key Laboratory of Medicinal Chemistry for Natural Resources at Yunnan University.

Microorganisms and Fermentation. The plant pathogen fungus *F. oxysporum* was obtained from the Stains Collection of Yunnan Institute of Microbiology, Yunnan Institute of Microbiology, Yunnan Province, China. *F. oxysporum* was then activated in PDA (1 L of water, 200 g of potato, 20 g of dextrose, and 15 g of agar) slant culture medium in a constant-temperature incubator at 28 °C for 5 days. The mature plant pathogen fungus was added to the fermentation culture medium containing 5.00 g of *A. filicinus* powder that had been dampened with 8 mL of water, sterilized at 121 °C for 30 min, and then incubated at 28 °C for 30 days. The blank fermented *A. filicinus* was treated the same as the microorganism-fermented *A. filicinus* in the absence of plant pathogen fungus. The nonfermented *A. filicinus* was the original material of the herb.

Extraction and Isolation. The nonfermented *A. filicinus* (5.00 g), blank fermented *A. filicinus* (5.00 g), and microorganism-fermented *A. filicinus* (5.00 g) were immersed with 80% methanol/H_2O (v/v) at a ratio of 1:10 (w/v) for 24 h at room temperature and then exhaustively extracted ultrasonically three times for 30 min each. The extracts were decanted, filtered through Whatman no. 1 filter paper, and concentrated under a rotary evaporator. The nonfermented, blank fermented, and *F. oxysporum*-fermented *A. filicinus* extracts were obtained as E1 (3.41 g), E2 (3.07 g), and E3 (0.56 g), respectively. E3 was then chromatographed on a silica gel column (column, 200 mm × 20 mm) eluted with chloroform/methanol (30:1, 600 mL) to yield fraction A. Fraction A (42.6 mg) was further subjected to silica gel CC (column, 200 mm × 10 mm) with petroleum ether/acetone (3:1, 200 mL) to yield compound **1** (25.1 mg). E1 was passed through a macroporous resin and then isolated by a combination of RP-C18 silica gel (column, 450 mm × 40 mm) and silica gel CC (column, 200 mm × 20 mm) with a gradient elution mixture of chloroform/methanol (10:1, 500 mL) for the acquisition of compound **2** (24.7 mg).

Structure Elucidation of Rubrosterone and 20-Hydroxyecdysone. Rubrosterone, **1**: white crystal (methanol/H_2O); mp 245.0−247.0 °C; HR-ESI-MS *m*/*z* 357.1683 $[M + Na]^+$ (calcd for $C_{19}H_{26}O_5Na$ $[M + Na]^+$, 357.1672); ^{1}H NMR (400 MHz, pyridine-d_5) δ_H 0.85 (3H, s, H-18), 1.04 (3H, s, H-19), 1.58 (1H, dd, *J* = 12.0, 4.8 Hz, H-11), 1.94 (1H, t, *J* = 12.4 Hz, H-1), 2.28 (2H, m, H-15), 3.05 (1H, dd, *J* = 13.2, 3.6 Hz, H-5), 3.54 (1H, m, H-9), 4.15 (1H, dt, *J* = 11.2, 3.2 Hz, H-2), 4.26 (1H, br s, H-3), 6.29 (1H, s, H-7); ^{13}C NMR (100 MHz, pyridine-d_5) δ_C 37.6 (C-1), 67.8 (C-2), 67.8 (C-3), 32.2 (C-4), 51.3 (C-5), 203.1 (C-6), 121.8 (C-7), 162.7 (C-8), 34.8 (C-9), 38.6 (C-10), 19.9 (C-11), 28.7 (C-12), 53.0 (C-13), 79.3 (C-14), 33.4 (C-15), 24.5 (C-16), 217.1 (C-17), 17.0 (C-18), 24.3 (C-19). The NMR data were compared with the literature,[14,15] and compound **1** was determined to be rubrosterone (Figure 1).

20-Hydroxyecdysone, **2**: white amorphous powder; HR-ESI-MS *m*/*z* 481.3137 $[M + H]^+$ (calcd for $C_{27}H_{45}O_7$ $[M + H]^+$, 481.3165), 503.2962 $[M + Na]^+$ (calcd for $C_{27}H_{44}O_7Na$ $[M + Na]^+$, 503.2985), 983.6036 $[2M+Na]^+$ (calcd for $C_{54}H_{88}O_{14}Na$ $[2M + Na]^+$, 983.6072); ^{1}H NMR (400 MHz, pyridine-d_5) δ_H 0.97 (3H, s, H-19), 1.11 (3H, s, H-18), 1.30 (6H, br s, H-26, 27), 1.55 (3H, s, H-21), 2.18 (1H, m, H-24), 2.87 (2H, br s, H-5, 17), 3.47 (1H, br s, H-9), 3.75 (1H, d, *J* = 6.4 Hz, H-22), 4.12 (2H, m, H-2, 3), 6.14 (1H, s, H-7); ^{13}C NMR (100 MHz, pyridine-d_5) δ_C 37.2 (C-1), 67.5 (C-2), 67.6 (C-3), 31.8 (C-4), 50.7 (C-5), 203.3 (C-6), 121.1 (C-7), 165.8 (C-8), 33.8 (C-9), 38.1 (C-10), 20.9 (C-11), 31.4 (C-12), 47.5 (C-13), 83.7 (C-14), 31.1 (C-15), 20.5 (C-16), 49.5 (C-17), 17.3 (C-18), 23.9 (C-19), 76.4 (C-20), 21.1 (C-21), 77.0 (C-22), 26.8 (C-23), 41.9 (C-24), 69.3 (C-25), 29.5 (C-26), 29.4 (C-27). The evidence reported above, combined with the data reported in the literature,[30] led to the assignment of the structure of 20-hydroxyecdysone, **2**, as shown in Figure 1.

HPLC and HPLC-MS Analysis. The identification and quantitation of crude extracts of nonfermented *A. filicinus*, blank fermented *A.*

DOI: 10.1021/acs.jafc.5b02570
J. Agric. Food Chem. 2015, 63, 6596−6602

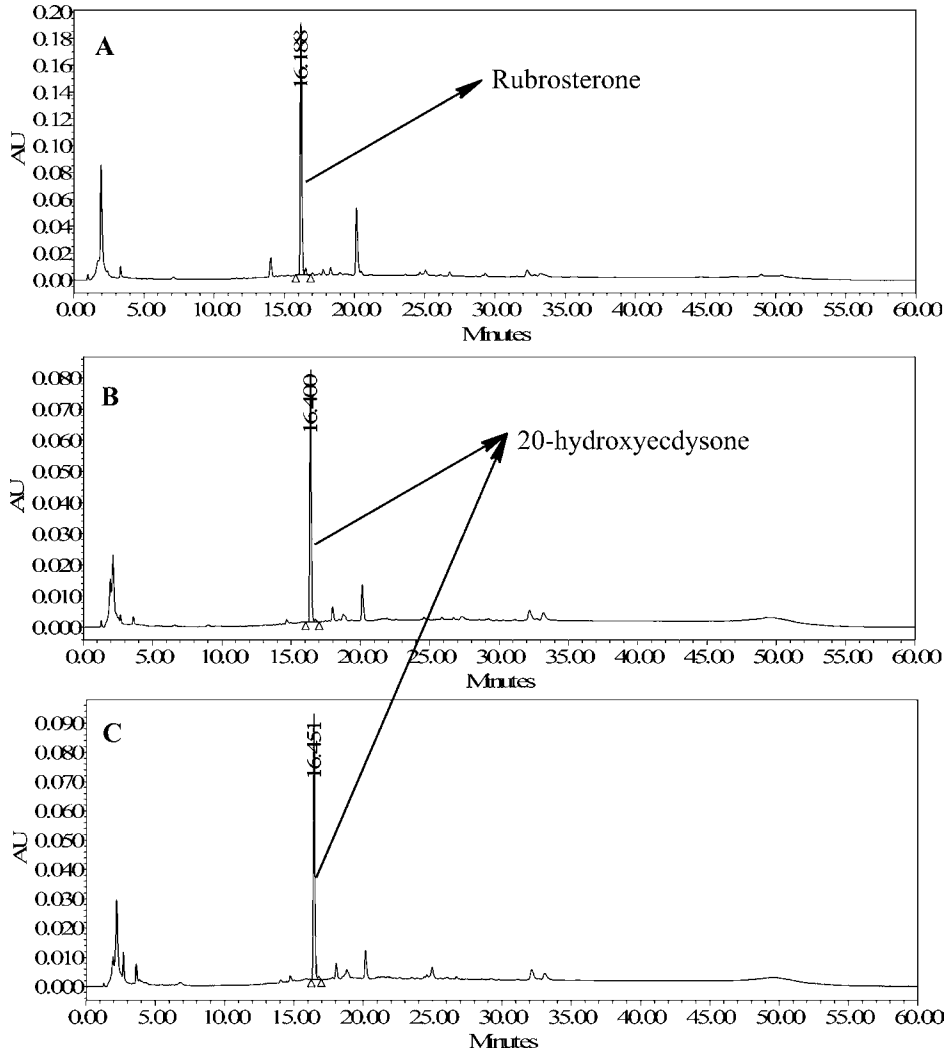

Figure 2. HPLC chromatograms of (A) *F. oxysporum*-fermented *A. filicinus*, (B) nonfermented *A. filicinus*, amd (C) blank fermented *A. filicinus*.

filicinus, and *F. oxysporum*-fermented *A. filicinus* were carried out by an HPLC system. Samples or standards were dissolved with methanol/H_2O and filtered through a 0.45 μm filter before injection into the HPLC system. Mobile phase A was water, mobile phase B was methanol, and mobile phase C was acetonitrile. HPLC fingerprints were obtained by following a linear gradient program: 0−5 min, 5−10% (v/v) solvent B, 5−10% solvent C; 5−10 min, 10−30% solvent B, 10−20% solvent C; 10−20 min, 30−48% solvent B, 20−32% solvent C; 20−40 min, 48% solvent B, 32% solvent C; 40−43 min, 48−40% solvent B, 32−60% solvent C; 43−50 min, 40−5% solvent B, 60−5% solvent C. The peaks were confirmed by the UV absorptions at 245 nm and the retention times, while the flow rate was 1.0 mL/min. The column temperature was maintained at 25 °C, and the injection volume was 10 μL for *F. oxysporum*-fermented *A. filicinus* and 20 μL for nonfermented *A. filicinus* and blank fermented *A. filicinus*, respectively. The standard addition method was used for the identification of ecdysteroids, and an external standard method was applied for quantitation. The limits of detection (LOD) and quantitation (LOQ) of the ecdysteroids were as follows [ecdysteroid compound, LOD (LOQ)]: 20-hydroxyecdysone, 0.00712 μg (0.0200 μg); rubrosterone, 0.01558 μg (0.0400 μg). The accuracy of the method was determined by recovery experiments. The recoveries of two ecdysteroid compounds for quantitation analysis ranged from 95 to 105%. The determination conditions of the HPLC-MS analysis were similar to those of the HPLC assay except for the flow rate, which was 0.6 mL/min.

Fermentation of 20-Hydroxyecdysone with *F. oxysporum*. The archetypal ecdysteroid 20-hydroxyecdysone, which was the most representative compound in *A. filicinus*, was involved in the biotransformation experiment with *F. oxysporum*. The activation process of *F. oxysporum* was the same as that mentioned above. Specifically, chopped potatoes (30 g), potato dextrose broth (PDB) medium (1 L of water, 200 g of potato, and 20 g of dextrose), and Czapek's medium (1 L of water, 3 g of $NaNO_3$, 1 g of K_2HPO_4, 0.5 g of $MgSO_4{\cdot}7H_2O$, 0.5 g of KCl, 0.01 g of $FeSO_4$, 30 g of sucrose) were, respectively, autoclaved at 121 °C for 30 min as fermentation culture media. Afterward, 20 mg 20-hydroxyecdysone isolated from the *A. filicinus* was inoculated with the plant pathogen fungus and cultivated for 20 days (potato medium) and 7 days (PDB medium, Czapek's medium) at 28 °C. The chopped potatoes, PDB medium, and Czapek's medium were autoclaved and inoculated under the same conditions as the blank control groups.

Statistical Analysis. All measurements were performed in triplicate and reported as the mean ± standard deviation (SD).

RESULTS AND DISCUSSION

Transformation from 20-Hydroxyecdysone to Rubrosterone with *F. oxysporum*. In previous studies, our team had emphasized that plant pathogenic fungi fermentation was effective in improving the total phenolic content and antioxidant activities of *Bletilla formosana*[31] and *Bletilla striata*,[32] which might be considered as a novel strategy for processing

DOI: 10.1021/acs.jafc.5b02570
J. Agric. Food Chem. 2015, 63, 6596−6602

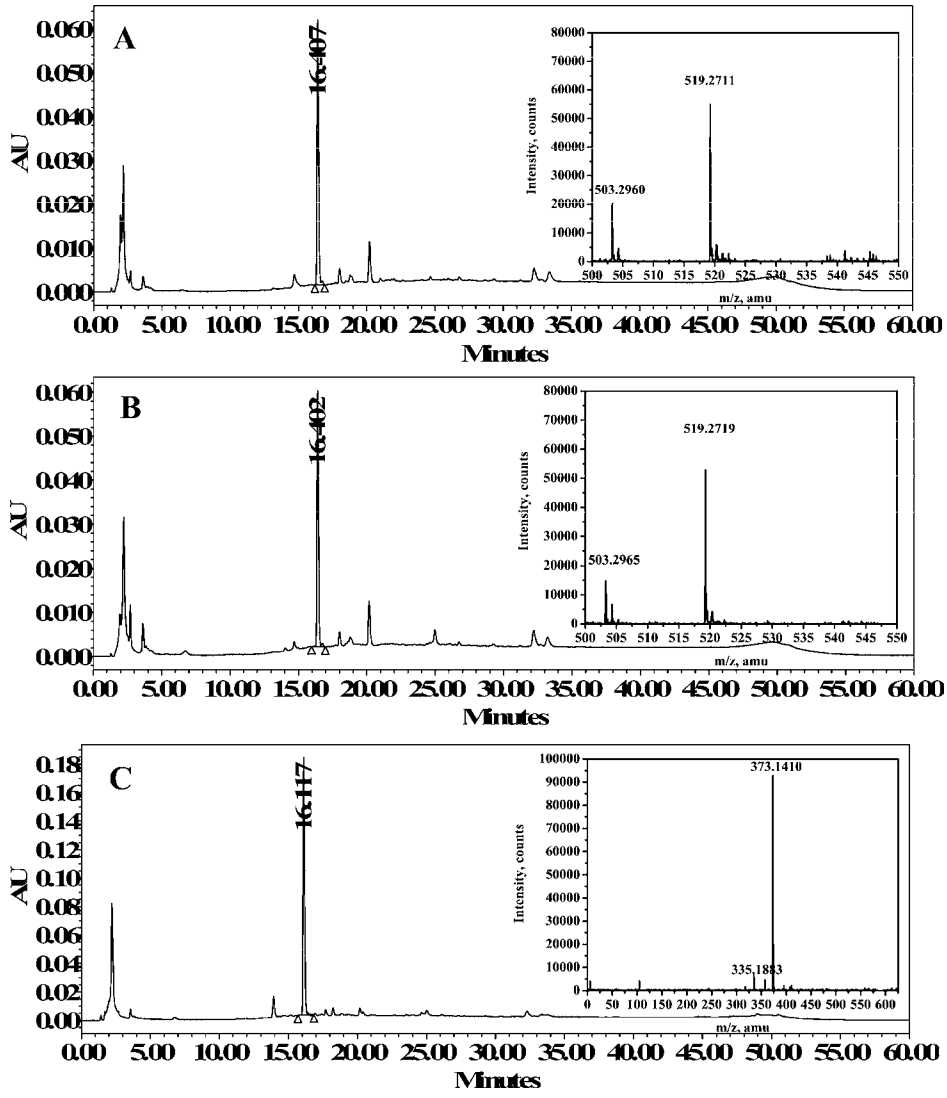

Figure 3. Chromatograms at 245 nm obtained from the HPLC-MS of the extracts of (A) nonfermented *A. filicinus*, (B) blank fermented *A. filicinus*, and (C) *F. oxysporum*-fermented *A. filicinus*.

traditional Chinese medicines. In the present study, *A. filicinus* was fermented with *F. oxysporum* to accumulate rubrosterone. The major plant extract components were determined using HPLC. The results (Figure 2) revealed that the main peak of 20-hydroxyecdysone, with retention time at 16.40 and 16.45 min in E1 (Figure 2B) and E2 (Figure 2C), disappeared in E3. The peak of rubrosterone, which was not present in E1 and E2, was obvious in E3 with a retention time at 16.19 min (Figure 2A). These two compounds were further isolated by silica gel CC from E1 and E3 and identified as 20-hydroxyecdysone and rubrosterone on the basis of extensive spectroscopic methods. Combining all of the above studies, it could be speculated that there might be a transformation between 20-hydroxyecdysone and rubrosterone.

To determine whether other ecdysteroids that share the same skeleton with 20-hydroxyecdysone participate in the accumulation of rubrosterone, HPLC-MS analysis of the extracts of E1, E2, and E3 was conducted. The HPLC-MS analysis results (Figure 3) showed that there were no obvious signals of other possible rubrosterone precursors (Figures 3A, B), such as ecdysone and stachysterone C, which have been reported to be isolated from *A. filicinus*. However, from the previous paper about the constituent study of *A. filicinus*,[33] it could be inferred that 20-hydroxyecdysone was the main precursor in the conversion. It is possible that other compounds were present in quantities too low to detect.

In consideration of the substantial decrease of the weight of the crude extract of E3 (0.56 g) compared with E1 (3.41 g) and E2 (3.07 g), the ^{1}H NMR spectra of all of the crude extracts were recorded to evaluate the specific constituent variations. As observed in Figure 4, the proton signals of saccharides ranging from 3.0 to 3.7 ppm in E1 (Figure 4C) and E2 (Figure 4B) were significantly diminished in E3 (Figure 4A), which implies that a large amount of saccharides was consumed during fermentation of *A. filicinus* with *F. oxysporum*; this is the best explanation for why the weights of the crude extracts of E3 were greatly decreased and why the extraction process was much easier after fermentation. Therefore, fermentation of *A. filicinus* with plant pathogen fungus is also a convenient and simple method to make the process of production and extraction much easier in industry.

Microbiological Transformation of Pure 20-Hydroxyecdysone. To further demonstrate the conclusion that rubrosterone was transformed from 20-hydroxyecdysone, pure

DOI: 10.1021/acs.jafc.5b02570
J. Agric. Food Chem. 2015, 63, 6596−6602

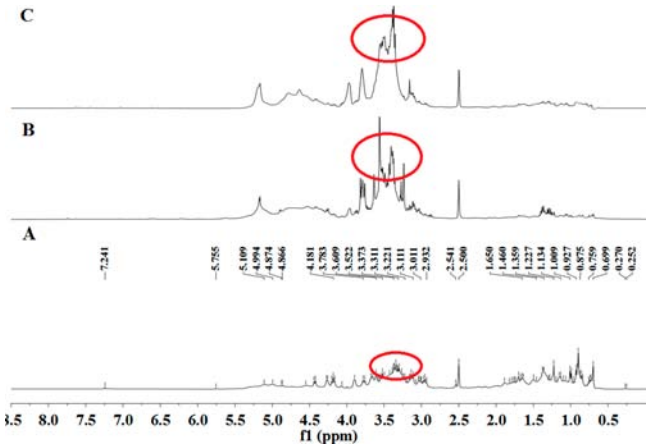

Figure 4. ^{1}H NMR spectra of all crude extracts: (A) *F. oxysporum*-fermented *A. filicinus*; (B) blank fermented *A. filicinus*; (C) nonfermented *A. filicinus*. The red circles ranging from 3.0 to 3.7 ppm indicate the proton signals of saccharides.

20-hydroxyecdysone was used in the biotransformation. Potatoes, PDB medium, and Czapek's medium, containing no rubrosterone and 20-hydroxyecdysone, were used as fermentation culture media, respectively. Similar to what we show in Figure 5, the peak of rubrosterone with retention time at 16.12 min was distinctly detected by HPLC after solid fermentation of 20-hydroxyecdysone with potato medium (Figure 5A). The peak of the initial 20-hydroxyecdysone completely disappeared. This experiment confirmed the microbial transformation between these two chemical compounds.

However, the biotransformations with the PDB and Czapek's media were not successful. The peaks with retention time at 16.39 min (Figure 5C) and 16.45 min (Figure 5E) indicated the obvious presence of 20-hydroxyecdysone. Therefore, liquid culture media are inefficient for the microbial transformation between 20-hydroxyecdysone and rubrosterone, which was consistent with the results obtained previously.[27] The key reason for this problem might be the lower solubility of 20-hydroxyecdysone in the liquid medium. Previous studies have also demonstrated that the steroidal invertase is an intracellular enzyme, and only intracellular substrates (exogenous or endogenous) that have a contact with the enzyme system can participate in the bioconversion reactions. However, steroidal compounds are fat-soluble compounds, which results in a low concentration of substrates in the liquid culture media and low sterol-transforming activity.[34−38] Additionally, the shorter growth cycle of liquid suspension culture might be another reason for the reduced transformation rate. Therefore, as the most commonly occurring and the most abundant resource in both arthropods and plants,[39−43] **2** is a suitable starting material to produce rubrosterone efficiently in solid culture medium.

Content of Rubrosterone in Fermented *A. filicinus*. HPLC was further used to assess the content of rubrosterone in fermented *A. filicinus*. The content of rubrosterone was 3.497 ± 0.007 μg/mg *A. filicinus* sample in *F. oxysporum*-fermented *A. filicinus* (Table 1), which was almost equal to 20-hydroxyecdysone in the original material (4.352 ± 0.008 μg/mg *A. filicinus* sample) and blank fermented *A. filicinus* (4.453 ± 0.011 μg/mg *A. filicinus* sample) ($n_{\text{20-hydroxyecdysone}}/n_{\text{rubrosterone}}$ = 1.1:1.0). Therefore, we could conclude that the transformation from 20-hydroxyecdysone in *A. filicinus* to rubrosterone could be put into practice at a conversion ratio close to 100%. The high conversion rate, which had never been achieved, demonstrated that it was indeed an efficient, simple, prospective, and straightforward approach to produce rubrosterone. These results also indicate that an effective, specific steroidal invertase in the fungus, which could transform 20-hydroxyecdysone into rubrosterone during the process of microbial fermentation, must exist. Furthermore, it also

Table 1. Contents of Rubrosterone, 1, and 20-Hydroxyecdysone, 2[a]

sample	20-hydroxyecdysone	rubrosterone
E1	4.352 ± 0.008	
E2	4.453 ± 0.011	
E3		3.497 ± 0.007

[a]Each value is presented as the mean ± SD (n = 3). Values of contents were expressed as μg compound/mg *A. filicinus*.

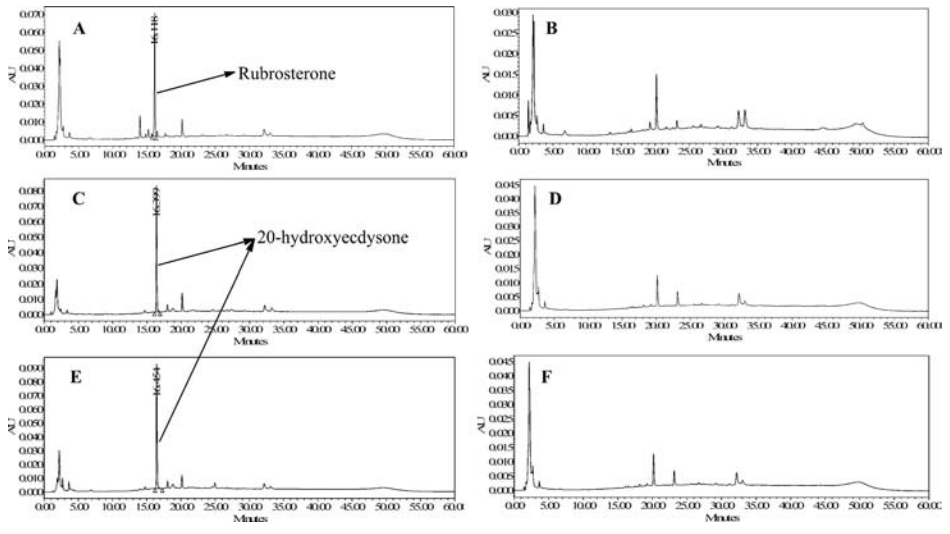

Figure 5. HPLC chromatograms of the microbiological transformation of 20-hydroxyecdysone with three different media: (A) chopped potatoes; (C) PDB medium; (E) Czapek's medium. Blank control trials: (B) potato culture medium; (D) PDB medium; (F) Czapek's medium.

provided us a creative means by which to generate some inaccessible and rare substances.

In summary, there are a few reports of the production of rubrosterone by the use of microbial transformation. However, there are no papers to date regarding the use of the solid-state bioprocess of *A. filicinus* by *F. oxysporum* to obtain rubrosterone. Furthermore, the unique method described herein could generate rubrosterone at the highest conversion ratio reported to date, which was not achieved in other reported methods. Fermentation of *A. filicinus* with *F. oxysporum* also led to a substantial decrease of saccharides, which further results in an easier extraction process. Consequently, the solid-state bioprocessing strategy could be an effective, innovative, and expedient approach to accumulate rubrosterone.

J. Agric. Food Chem. 2015, 63, 6596−6602

In general, the results available in the literature on the formation of solid−gas type clathrates based on CDs are limited. Therefore, the present work aims at studying the possibilities for synthesizing this type of clathrate, using α-, β-, and γ-CDs and different gases (CO_2, N_2, N_2O, Ar). To realize this goal, a number of experimental conditions (temperature, gas pressure, CD concentration, and time) were varied over a relatively large range and a physicochemical characterization of the clathrates' morphology, crystal size distribution, growth rate, and amount and stability of the entrapped gas was performed.

EXPERIMENTAL PROCEDURES

The "CD-gas" type clathrates in this study have been prepared by crystallization from water solution of CDs under the pressure of the gas to be entrapped into the CD molecules. To realize the clathrate syntheses under controlled conditions, two types of reactors were designed and constructed: one from stainless steel for higher pressures (up to 100 atm) and a transparent one from Plexiglas (up to 15−20 atm)). The molar concentrations of α-CD water solutions were 5, 7, 10, and 14%, and the gas pressure was kept constant in the range of 5−40 atm (5, 10, 15, and 40 atm). After the gas was added to the reactor with the solution, the reactor was sealed and remained at room temperature or 5 °C from an hour to a few days (depending on the type of the cyclodextrin and the gas used) to form clathrates. The water solutions of β- and γ-CD were 10 and 20% for both cyclodextrins, as the gas pressure and temperature were varied in the same ranges as for the α-CD; the crystallization process took place again for about a few hours to a few days. The formed clathrates were filtered and washed with ice water to remove the unreacted CD. The purity of the CDs was ≥98%, and the gases were 99.999% pure.

To determine how much gas is trapped in the cavity of the cyclodextrin, thermogravimetry (TG-MS) was applied. The quantity of the trapped gas has also been measured by using a simple foam rise method,[55] where a known amount of clathrate (0.5 g) was added into a hot mixture of 15 wt % skimmed milk powder and 0.5 wt % xanthan gum. The proteins in skimmed milk powder are needed to stabilize the interface of newly formed gas babbles, due to clathrates' dissociation, whereas xanthan gam was added to provide yield stress to the mixture, which will prevent bubbles from fast creaming. The amount of captured gas was measured from the difference of the volume of the mix, before and after addition of the clathrates. It is important to realize that this method measures only the volume of the gas captured and not the total volume of the released gas.

To choose the optimal synthesis conditions, different experimental parameters have been varied (pressure, temperature, time, concentration, nucleation initiators, and additives) as well as clathrates' crystal growth kinetics has been studied. The crystal morphology and size of the clathrates formed under different conditions were characterized by optical and scanning electron microscopy (SEM, JEOL JSM-5510). The structure and microstructure were studied by X-ray diffraction (XRD, TUR-62) of both clathrates and cyclodextrins. The ultrasound treatment of some of the CD water solutions was performed with a 20 kHz probe (with a vibrating titanium tip) for 10 min.

RESULTS AND DISCUSSION

The main synthetic parameters varied in the present investigation were the concentration of the CDs (from undersaturated to saturated at room temperature), temperature (5 and 20 °C), and gas pressure (5−40 atm.). Under the conditions applied in this study clathrate formation (crystallization) was observed with all used gases (N_2, N_2O, CO_2, Ar) only for α-CD; β- and γ-CDs formed clathrates only with N_2 (Table 1). N_2O and N_2 were preferred for our study for technological reasons. Studies report the use of high-pressure N_2O in food technology in pasteurization over CO_2, thus avoiding the pH problems resulting from the formation of carbonic acid.[55,56] Also, CO_2 has a bitter taste and it is not preferred for sweets. With this in mind we focused our study on the comprehensive investigation of CDs with N_2 and N_2O clathrates. By comparing the yield of the α-CD-N_2O and α-CD-N_2 clathrates it was found that it is noticeably higher for α-CD-N_2O, which determined the more emphasized interest to its study. Due to the very low yield of the α-CD-Ar clathrate, it will not be considered further in the study.

Table 1. Clathrates Formation from CDs with Gases

gas	α-cyclodextrin	β-cyclodextrin	γ-cyclodextrin
N_2	yes	yes	yes
N_2O	yes	no	no
CO_2	yes	no	no
Ar	yes (low yield)	no	no

Table 2. Clathrate Synthesis Conditions and Corresponding Average Crystal Size and Clathrate Yield

	pressure (atm)	temperature (°C)	yield (%)	size (μm)
α-CD	5 N_2O	5	20	200−300
α-CD	5 N_2O	20	21	250−300
α-CD	15 N_2O	5	20	130−150
α-CD	15 N_2O	20	20	150−200
α-CD	40 N_2O	5	30	50−60
α-CD	40 N_2O	20	35	100−150

The clathrates' crystal growth kinetics were studied, first, to elucidate some important crystallization parameters (e.g., growth rates, mean crystal size) at different synthetic conditions and, second, to investigate the influence of the crystal morphology and size on the amount and stability of the entrapped gas.

Clathrates Based on α-CD. As already mentioned, under the applied conditions α-CD forms clathrates with all gases used in the study. Table 2 presents the experimental parameters used for these syntheses.

SEM micrographs (Figure 1) show the morphology and crystal size of the clathrates formed by crystallization of α-CD and different gases. Depending on the conditions of crystallization, the clathrates' average crystal size changes from 50 to 300 μm (Table 2) and the crystals' shape from cubic to needle- and plate-like form. For the needle-like crystals their length was measured and used for the crystal size distribution curves.

It was found that α-CD-N_2O clathrates can be formed even at 5 atm of N_2O gas pressure and room temperature (20−25 °C). However, optimization of the pressure and temperature was necessary to achieve the best properties of the clathrate: yield, crystal size and kinetics of crystallization, amount of entrapped gas. For comparison, Figure 2 shows SEM micrographs (including size distribution−crystal length) of some of the clathrates crystallized at fairly different conditions and as a result having noticeable difference in their size. Generally, at higher pressures (40 atm) and lower temperatures (5 °C) the clathrate crystals reveal the smallest size (average size of 50−60 μm) (Figure 3).

At the optimum conditions, with respect to smaller clathrate crystal size (40 atm of N_2O and 5 °C), kinetic analysis of the clathrate growth has been carried out as well. It has to be mentioned that under these conditions the clathrate crystallization starts almost immediately. Ten minutes is sufficient to reach about 20% clathrate yield, whereas for 1 h we obtained around 30% yield. The crystal size distribution curves at different crystallization times are shown in Figure 4. Plotting the average crystal size as a function of time, a linear growth rate of about 100 μm/h can be determined (Figure 4).

DOI: 10.1021/acs.jafc.5b01357
J. Agric. Food Chem. 2015, 63, 6603−6613

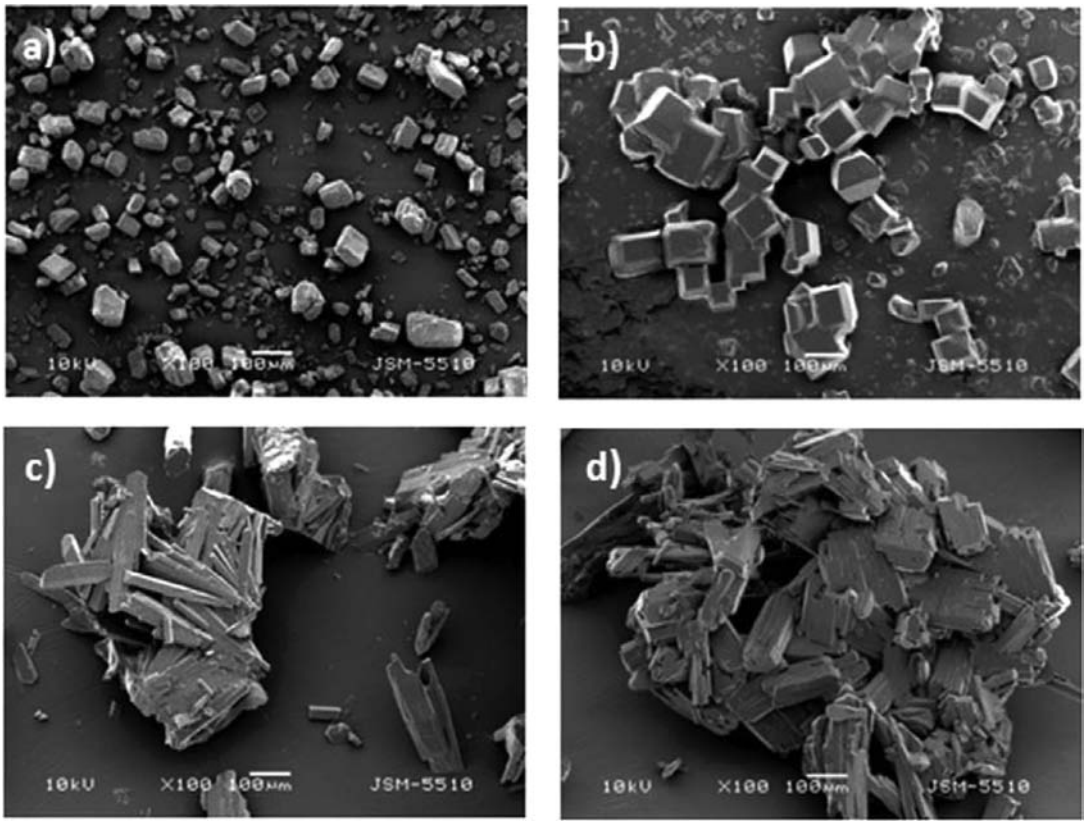

Figure 1. SEM images of α-cyclodextrin-based clathrates: (a) α-CD; (b) clathrate of α-CD and N_2 at 15 atm, 5 °C; (c) clathrate of α-CD and CO_2 at 10 atm, 5 °C; (d) clathrate of α-CD and N_2O at 40 atm, 5 °C.

As mentioned above, α-CD forms crystalline clathrates with CO_2 and N_2 as well, as the synthetic conditions (15−40 atm and 5−20 °C) are almost the same compared to those for the α-CD-N_2O clathrates. Highest yield of about 30−35% is obtained at lower temperatures and higher pressures. The crystal growth kinetics analysis of α-CD-CO_2 clathrates is presented in Figure 5. Linear crystal growth has been observed with growth rates of about 60 μm/h for α-CD-CO_2, which is about 2 times lower than that for α-CD-N_2O. The growth rate for the clathrate α-CD-N_2 is comparable to that for α-CD-CO_2.

From a practical point of view, one of the clathrates' crucial characteristics to be determined is the amount of gas entrapped in the CD molecules. For this purpose both thermogravimetry (PerkinElmer TGS-2, PerkinElmer Diamond SII TG/DTA) and "foam rise method" have been applied. Figure 6 reveals typical thermogravimetric (TG) curves of α-CD and of its clathrate with N_2O (α-CD-N_2O). Two main weight decrease steps for the pure α-CD can be distinguished; the first one starting at about 45−50 °C is associated with the release of weakly bonded water, and the second in the range of 65−90 °C has to be connected with the desorption of water having stronger interaction with the CD molecules.[2] The total amount of water embedded in the α-CD is about 10 wt %, as this quantity is repeated for all measured samples of pure α-CD. Unlike at T = 45−50 °C, the weight of the clathrate is already reduced by about 1−2 wt %, obviously connected with the release of the entrapped gas (N_2O). This result is also confirmed by TG-MS. The amount of N_2O released before 50 °C depends on the conditions of the clathrate formation. Besides, if one considers the final difference in the weight decrease during heating between the α-CD and its clathrate at about 140 °C, it can be seen that it is larger than the weight difference at about 50 °C. Hence, assuming that the differences between the weight reduction of the CD and its clathrate during heating are due to the release of the entrapped gas (N_2O), it could be supposed that there exist weaker and stronger bonded N_2O molecules. Additionally, it is interesting to report that after a stay of 120 days at 25−30 °C, the low-temperature TG step (usually 1−1.5 wt %), observed only for the clathrate, preserves its magnitude even when the total weight decreases during heating of the CD and its clathrate are equal. To prove that the low-temperature weight loss is due to the entrapped gas, the foam rise method has also been applied. The amount of gas determined by this method gives a value of about 7−10 mL gas/g clathrate, which corresponds to the amount determined by TG. Moreover, we cannot claim that the amount of water molecules embedded in the CD is the same in the clathrates compared to the pure α-CD. It is possible that a larger part of the water molecules included in the CD molecules is replaced by the N_2O molecules. In this way the differences in the weight decrease steps measured by TG for the CDs and clathrates cannot directly be used for the determination of the entrapped gas amount, and therefore additional methods (e.g., TG-MS) are necessary for obtaining the accurate gas quantity.

Differential scanning calorimetry (DSC; PerkinElmer DSC-2C) analysis of the CDs and of the corresponding clathrates based on them confirmed the effects observed by TG, both as temperature range of their appearance as well as relative magnitude. Figure 7 shows example calorimetric curves of pure α-CD and of the α-CD-N_2O clathrate. It is clearly seen that the first endothermic DSC peak of the clathrate is shifted to lower temperatures compared to the pure α-CD. It has a maximum

J. Agric. Food Chem. 2015, 63, 6603−6613

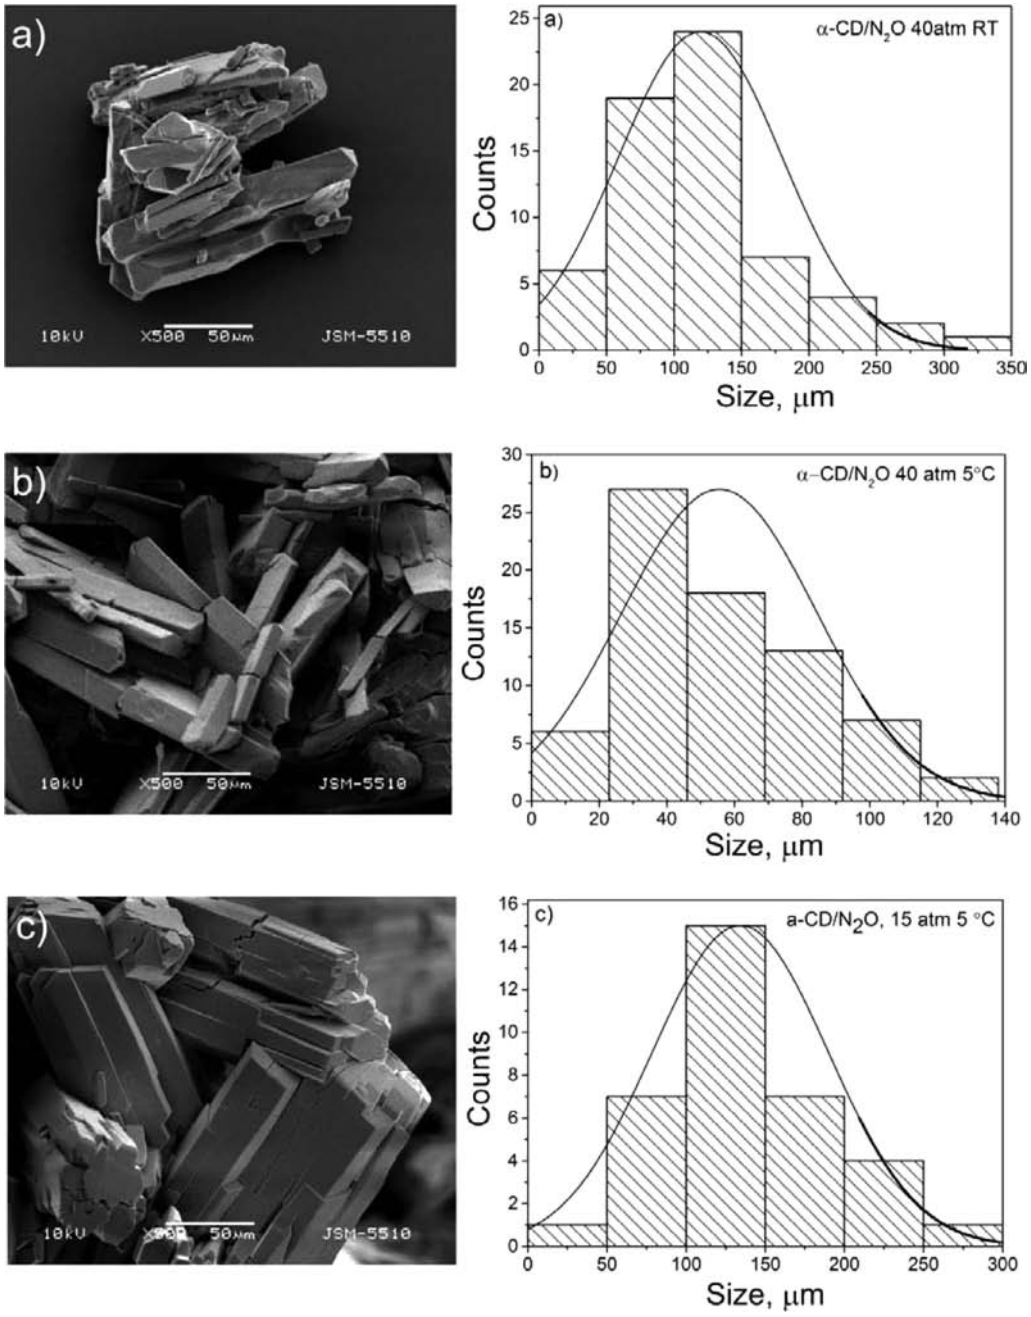

Figure 2. SEM micrographs and crystal size distribution of the clathrates formed from α-CD and N_2O at different conditions: (a) 40 atm gas pressure at room temperature; (b) 40 atm gas pressure at 5 °C; (c) 15 atm gas pressure at 5 °C.

exactly at the temperature of the inflex point of the TG curve. Moreover, the peak is complex with a low-temperature shoulder, indicating overlapping of two endothermic effects. It can be assumed that the low-temperature fraction of the complex peak is due to the evolution of N_2O. To determine, however, the enthalpy (heat) of the N_2O release, deconvolution of the first DSC peak is necessary, which in this case is connected with a large uncertainty. A very rough estimation gives a value of about 20 kJ/mol for the enthalpy of N_2O release.

Another important characteristic of the clathrates is the stability of entrapped gas (N_2O) at room and slightly higher temperatures (25−30 °C). After 30 days at 30 °C, only some of the gas is released (Figure 6b). A continuous stay at 30 °C (120 days) leads to reduction of the amount of entrapped gas, but still about 1−1.5 wt % is desorbing in the temperature

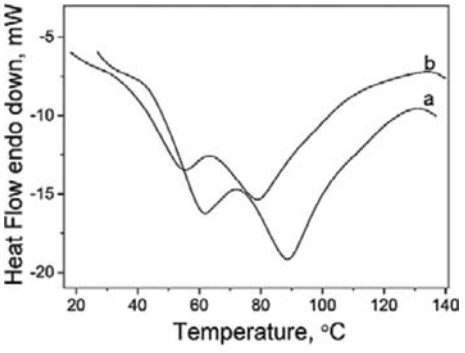

Figure 7. DSC of α-CD (curve a) and its clathrate with N_2O (after 120 days at room temperature) (curve b).

range of 40−60 °C. A similar amount of about 7−8 mL N_2O/g clathrate has been determined by the foam rise method as well.

Similar to the case of α-CD-N_2O clathrates, for α-CD-N_2 and α-CD-CO_2 the direct determination of the gas content by TG analysis was also connected with some uncertainty (Figure 8). For proving the result obtained by TG for the amount of entrapped gas, the foam rise method was applied, and values of about 5−7 mL CO_2/g clathrate and 4−5 mL N_2/g clathrate

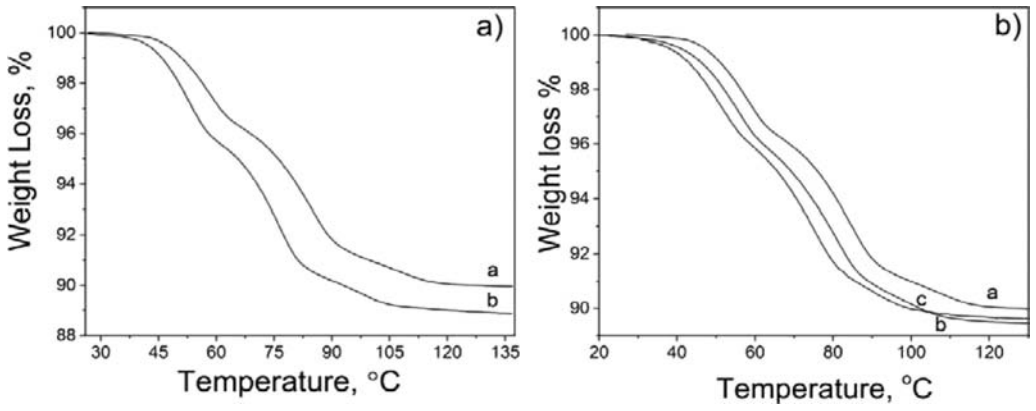

Figure 6. (a) TG analyses of α-cyclodextrin (curve a) and its clathrate formed with N_2O at 40 atm (curve b); (b) TG of α-CD-N_2O clathrates after a stay at 30 °C for different times: (curve a) pure α-CD; (curve b) clathrate after 30 days; (curve c) clathrate after 120 days.

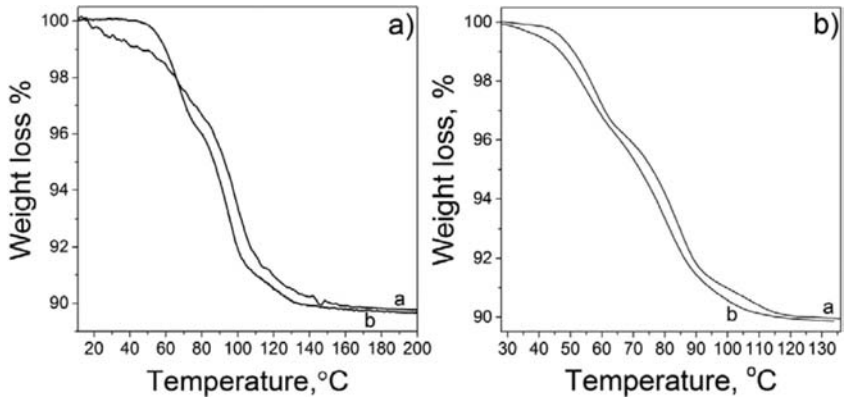

Figure 8. (a) TG curves of α-CD (curve b) and its clathrate with CO_2 (curve a); (b) α-CD (curve a) and its clathrate with N_2 (curve b).

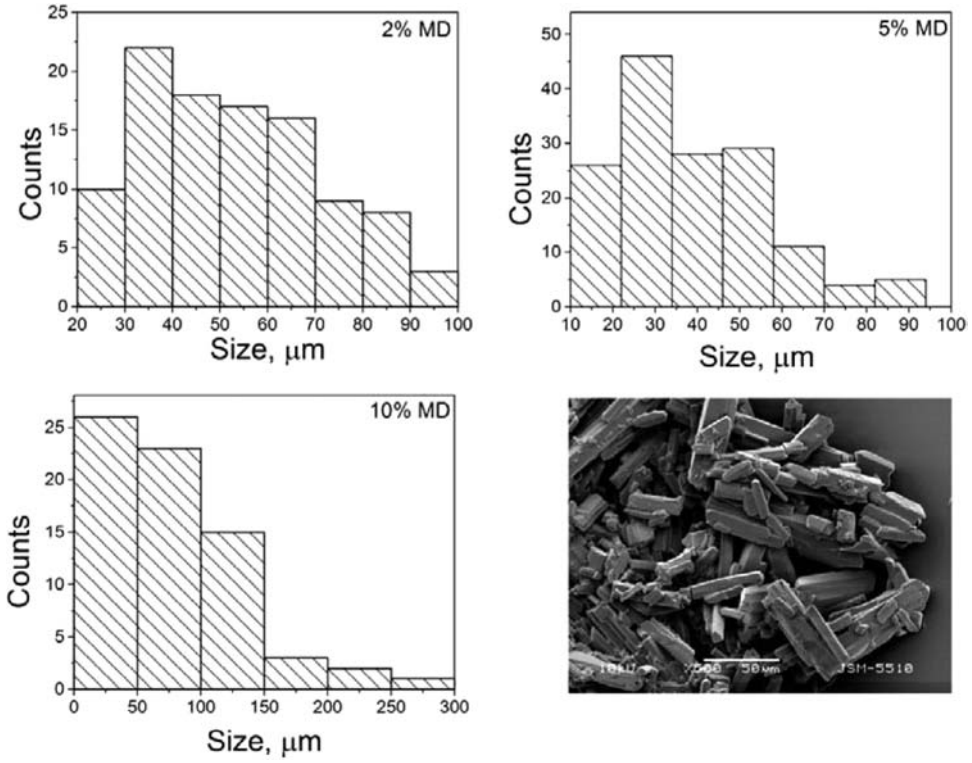

Figure 9. SEM and crystal size distribution of the clathrate formed by α-CD-N_2O with maltodextrin (MD) as nucleation initiator (at different concentrations: 2, 5, 10%).

were determined, which actually correspond quite well with the low-temperature weight decrease steps for the two clathrates, before any mass reduction for the α-CD to be observed (Figure 8). Nevertheless, complete correspondence of the weight decrease detected by TG and the amount of gas obtained by the foam rise method should not be expected, because the amount of water in the CD cavity can be different for the initial CD and for the clathrate formed on its base.

Undoubtedly, one of the important goals of our study was to increase the amount of gas incorporated into the α-CD molecules. For this reason different approaches have been applied: additions of maltodextrin (MD) as nucleation and crystal growth modifier, ultrasound treatment, and precrystallization of the CD. Different amounts of MD (2, 5, and 10 wt %) were added to the CD solution as a nucleation initiator and crystal habit modifier. The clathrate crystal size and morphology

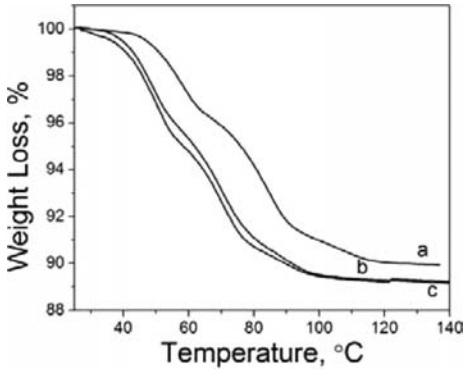

Figure 10. TG curves of α-CD (curve a) and of the clathrates α-CD-N_2O with 2% MD as initiator of the crystal growth, without (curve b) and with (curve c) ultrasound treatment.

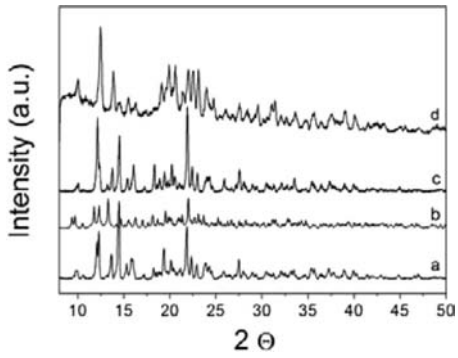

Figure 11. XRD of α-CD (diffractogram a), its theoretical/calculated diffractogram (diffractogram b), and of the clathrates formed with N_2O (diffractogram c) and CO_2 (diffractogram d).

are presented in Figure 9, and the thermogravimetric curve is shown in Figure 10. The ultrasound treatment was applied to the water solution of CD (10 min at 20 kHz) as well as to the CD+MD with the aim to accelerate α-CD solubility. The influence of the ultrasound treatment on the later clathrate crystal formation could also be expected. In general, it is revealed that the amount of the entrapped gas does not differ very much for the samples treated in a different way. This amount varies in the range of 1−1.5 wt %, and it is stable with the time of stay at room temperature. The smallest clathrate crystal size of about 40 μm was obtained with the addition of 5 wt % MD. However, a distinct influence of the clathrate crystal size on the amount and stability of the gas included in the α-CD molecules was not found.

For the amount of entrapped N_2O in α-CD, it can be calculated that if one molecule of N_2O is bonded to one molecule of α-CD, the maximum quantity of N_2O could be about 20−22 mL gas/g clathrate. This result was, however, not obtained experimentally. High-level quantum-mechanical calculations (Dudev and Spassov, unpublished work) reveal that in the *gas-phase* α-CD forms favorably 1:1 complexes with N_2O. Binding of a second N_2O to the host molecule (either inside the hydrophobic cavity or at the larger or smaller hydroxylate rim), however, does not seem energetically favorable as the binding free energies are positive. Note that the present experiments in *condensed* phase support smaller than 1:1 ratios of N_2O to α-CD (see above). The source of discrepancy between the gas-phase quantum mechanical results and experimental observations in condensed phase is intriguing and is the subject of current investigation.

To prove the crystalline state of the clathrates and to get additional information about the average crystal size and possible influence of the included gas on the crystal lattice parameters, X-ray diffraction analyses (XRD) were performed as well. Figure 11 reveals the X-ray diffractograms of α-CD used for the clathrate formation and of the corresponding clathrates with different gases. In the same figure the simulated diffractogram using α-CD structural data (lattice parameters) available in the literature is also plotted. It is seen that the position of the diffraction peaks of the clathrates and the initial α-CD used for their formation are the same, but some of them have different intensities—an indication for a preferred crystal growth in certain crystallographic directions. In addition, the peaks of the clathrates are slightly broader—an indication for smaller crystal size. Moreover, the diffractogram for the α-CD-CO_2 clathrate reveals the presence of an amorphous phase together with the crystalline one.

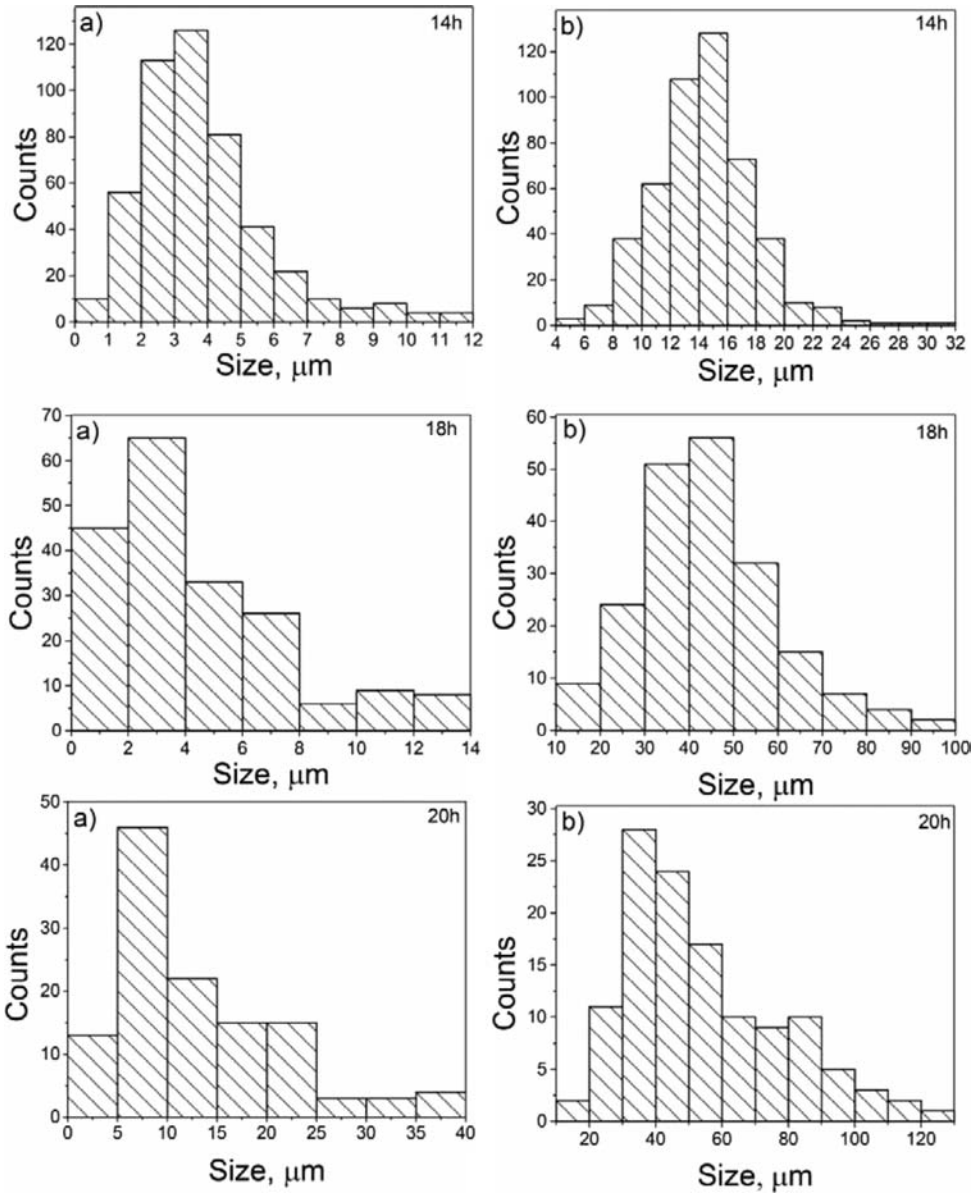

Figure 13. Crystal size distribution histograms of the clathrate of γ-CD-N_2 (taking into account the crystals' width (a) and length (b)).

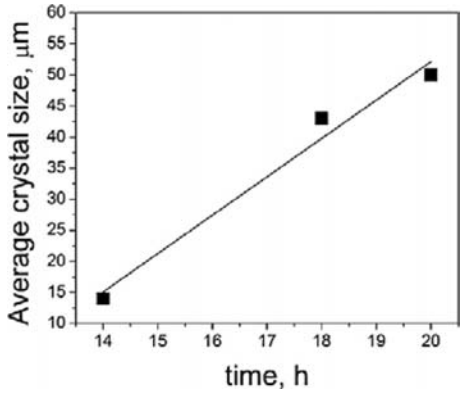

Figure 14. Kinetics of the crystal growth of the clathrate formed by γ-CD and N_2 (length).

Clathrates of β- and γ-CD with N_2. For β- and γ-CDs it was proven that in the gas pressure range of 5−40 atm and temperature range of 5−20 °C they form crystalline clathrates only with N_2 as guest molecule. The synthetic conditions were optimized with respect to the clathrates' yield (∼40−50%), the amount of N_2 trapped in the CD molecules (5−10 mL gas/g clathrate), crystallization kinetics, and crystal size distribution. The following optimal synthetic parameters were determined: nitrogen gas pressure, >10 atm; temperature, ∼5 °C; crystallization time, 10−15 h; saturated water solution at eoom temperature of γ-CD (20 wt %) and β-CD (1 wt %).

Figure12 shows the typical morphology of the β-CD-N_2 and γ-CD-N_2 clathrate crystals. Most of the crystals are elongated with polyhedral shape. From the constructed crystal size distribution diagrams the average crystal size has been determined, and information about the crystal growth kinetics was obtained. To study the nucleation and crystal growth kinetics, the clathrate crystal size distribution was analyzed at different crystallization times, keeping all other synthetic parameters constant (Figure 13). For γ-CD-N_2 two types of size distribution histograms have been obtained: the first one accounts for the distribution of the crystal size considering the width of the crystals, and the second

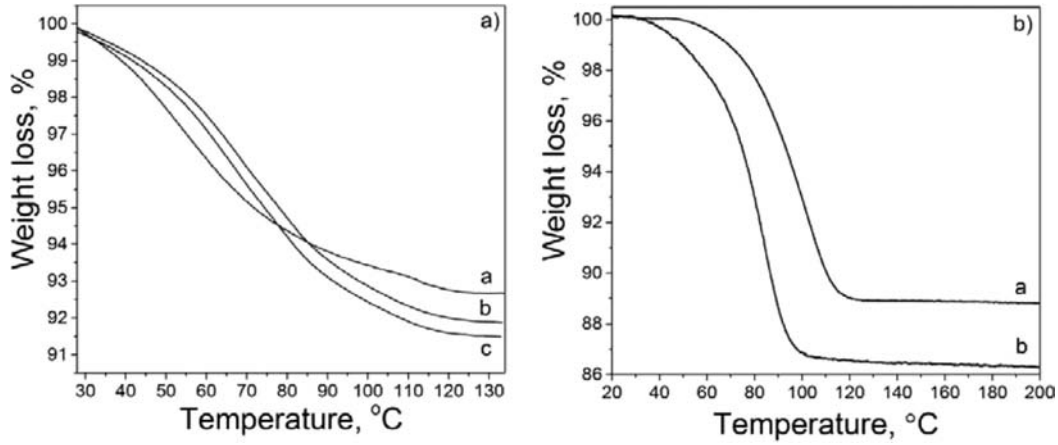

Figure 15. (a) TG curves of γ-CD (curve a) and its clathrate formed with N_2 (curve b); (b) TG curves of β-CD (curve a) and its clathrate with N_2 (curve b).

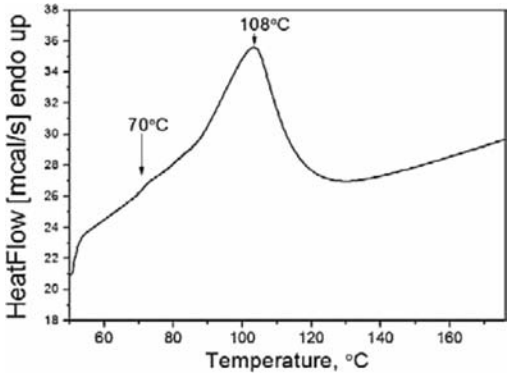

Figure 16. DSC curve of clathrate β-CD-N_2.

takes into account the length of the crystals. An interesting observation for this clathrate crystallization is the long incubation time, about 10 h, before any noticeable clathrate crystals can be detected microscopically. Both the unimodal crystal size distribution and the long incubation time indicate a homogeneous nucleation mechanism. A rough estimation of the nucleation rate gives a value in the range of $(6-8) \times 10^6$ m^{-2} h^{-1}. Figure14 shows the dependence of the mean clathrate crystal size as a function of time. An almost linear rate of crystal growth of about 5−6 μm/h can be detected, which is substantially lower than that of the α-CD-N_2O, α-CD-N_2, and α-CD-CO_2 crystal formations. Analogous crystal size distribution analysis of β-CD-N_2 clathrates gives a mean crystal size of about 60−70 μm and a linear growth rate of 4−5 μm/min.

In summary, with regard to the clathrates' crystallization kinetics it was found that α-CD-N_2O and α-CD-CO_2 crystals grow much faster than those of β- and γ-CD-N_2, most probably due to the larger driving force of the crystallization process for the α-CD-based clathrates.

By TG and foam raise method the amount of the gas trapped in the β- and γ-CDs was determined, and values in the range of 5−15 mL of gas in 1 g of clathrate were found (maximum values of about 15 mL N_2/g clathrate for β-CD-N_2 and about 7−8 mL N_2/g for γ-CD-N_2). Figure 15 presents the TG curves for γ-CD and β-CD and their clathrates with N_2. The DSC analysis of the clathrates confirms the release of N_2 at temperatures of about 60−80 °C, expressed by a broad peak overlapped with the main one (T_{max} = 108 °C) due to water release (Figure 16).

Figure 17 reveals the X-ray diffractograms of β-CD and γ-CD and their clathrates with N_2. The position of the diffraction peaks of the clathrates and the initial CDs used for their formation are the same with some small differences in the peak intensities. The diffraction peaks of the clathrates are slightly broader, due to their smaller crystal size. The presence of some amorphous phase can also be seen from the diffractograms of the clathrates.

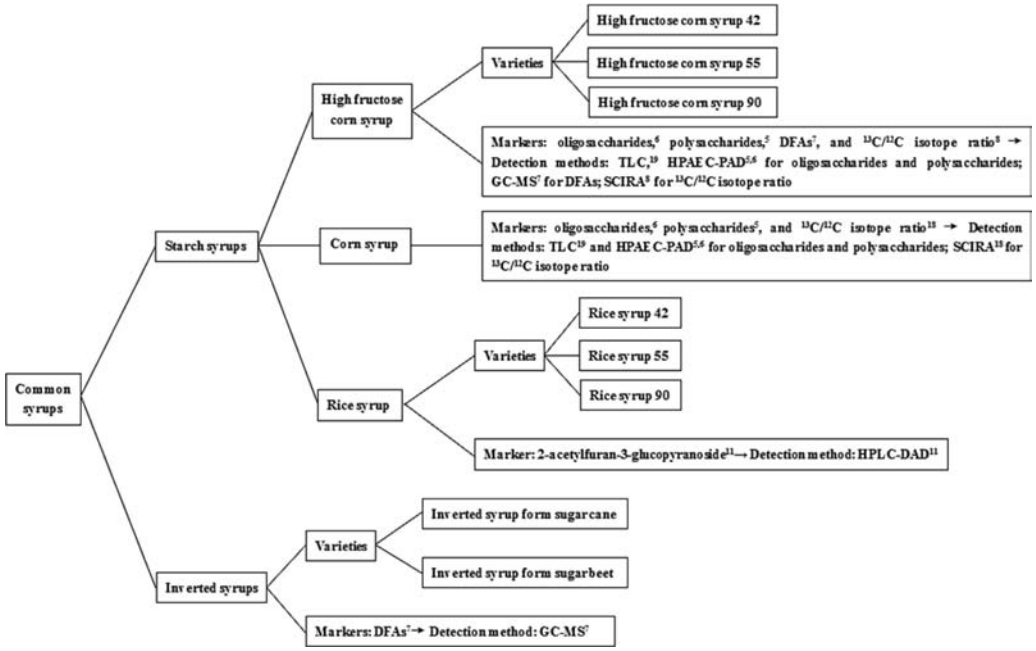

Figure 1. Sugar syrup markers and detection methods.

Quadrupole time-of-flight mass spectrometry (Q-TOF-MS) is a novel detection method that provides accurate mass measurements of full-product ions, thereby ensuring sensitive and accurate analyte identification. Apart from the application in target compound analyses, the identification of nontarget compounds is another advantage of Q-TOF-MS. Q-TOF-MS has been successfully used in the detection of pesticides[27,28] in foods, animal medications[29,30] in feeds, bioactive compounds in healthy foods[31,32] and pharmaceutical drugs,[33,34] and organic contaminants and their nontarget byproducts in water.[35,36] However, there is little information on the application of Q-TOF-MS in honey, especially in honey authenticity.

In this study, a Q-TOF-MS method coupled with UHPLC was developed to detect the presence of sugar syrups in honey samples using polysaccharides, DFAs, and AFGP as markers. This method is simple, rapid, and effective and allows the simultaneous detection of several syrups. Additionally, we evaluated the effects of honeybee feeding on several syrups for 3 days in the winter; the resulting honeys were detected by our developed method to evaluate whether syrups remain in them.

MATERIALS AND METHODS

Samples. In this study, 106 honey samples were used: 20 acacia honey samples (A1−A20), 20 rape honey samples (R1−R20), 20 linden honey samples (L1−L20), 20 jujube honey samples (J1−J20), and 20 multifloral honey samples (MF1−MF20) were obtained from 24 cooperative beekeepers located in Hebei and Henan, Sichuan, Heilongjiang and Jilin, Shaanxi, and Shandong and Xinjiang, respectively. Six manuka honey samples (M1−M6) were obtained from a supermarket in New Zealand. The honey samples were selected on the basis of strict quality criteria to ensure their authenticity.

Forty-five sugar syrup samples were purchased from different markets, including five corn syrups (CS1−CS5), five rice syrups 42 (RS-42-1−RS-42-5), five rice syrups 55 (RS-55-1−RS-55-5), five rice syrups 90 (RS-90-1−RS-90-5), five inverted syrups from sugar beet (IB1−IB5), five inverted syrups from sugar cane (IC1−IC5), five high-fructose corn syrups 42 (HFCS-42-1−HFCS-42-5), five high-fructose corn syrups 55 (HFCS-55-1−HFCS-55-5), and five high-fructose corn syrups 90 (HFCS-90-1−HFCS-90-5). CS, RS-42, RS-55, RS-90, IB, IC, HFCS-42, HFCS-55, and HFCS-90 were added in different concentrations (10, 20, or 30%, w/w) to pure honey samples for analysis.

Two hundred market honey samples (sam1−sam200) were randomly purchased from different Chinese markets in Beijing, Hebei, Henan, Shaanxi, Jilin, and Shandong and analyzed for adulteration of sugar syrups.

Reagents and Standards. An analytical standard of difructose anhydride III (DFA III) was purchased from Sigma Chemical Co. (St. Louis, MO, USA). AFGP (≥95% purity) was obtained by preparative high-performance liquid chromatography (PHPLC) and lyophilization from our previous study.[11] Crude polysaccharide extracts (DP 3−19, ≥90% purity) were purchased from Beijing Langlin Co. Acetonitrile of HPLC grade was purchased from Fisher Chemicals (Fair Lawn, NJ, USA). Deionized water was prepared using a Millipore Milli-Q Plus system (Millipore, Bedford, MA, USA).

Bee-Feeding Experiments. A bee-feeding experiment was conducted in a Ping Hu apiary to evaluate the effects of commercial sugar syrups such as RS (RS-42, RS-55, and RS-90), HFCS (HFCS-42, HFCS-55, and HFCS-90), CS, IB, and IC on the resulting honey. In this experiment, 2 kg of each syrup was fed to each honeybee colony for 3 days during the winter nectar dearth. The resulting honey was analyzed.

Sample Preparation. Sample (1 g) was dissolved in 10 mL of acetonitrile/deionized water (50:50, v/v) and mixed in a vortex for 2 min. The mixture was passed through two 0.22 μm PVDF membranes.

UHPLC/Q-TOF-MS. UHPLC was performed in an Agilent 1260 series UHPLC (Agilent, Palo Alto, CA, USA) equipped with an autoinjector and a quaternary UHPLC pump. An Acquity UPLC BEH Amide column (2.1 mm × 100 mm, 1.7 μm) was used. The mobile phase gradient consisted of 30% water (solvent A) and 70% acetonitrile (solvent B) for the first 5 min. Solvent B was reduced to 45% acetonitrile over 5 min and held at this concentration for 5 min. Subsequently, solvent B was adjusted to 70% over 0.1 min and held at this concentration for 2.9 min to clean the column. The total run time was 18 min, with the flow rate of 0.3 mL/min, and the injection volume was 5 μL. The column temperature was maintained at 50 °C.

MS was performed in an Agilent 6530 ESI-Q-TOF. The optimum MS conditions consisted of a capillary voltage of 3.0 kV in negative ionization mode, a skimmer voltage of 65 V, and a segmented fragmentor at 135 V for the first 5 min and at 200 V for the remaining run. The gas temperature, drying gas flow rate, and nebulizer pressure

were 325 °C, 7 L/min, and 30 psi, respectively. Nitrogen was used as the collision, drying, and nebulizer gas. MS spectra were acquired at m/z 100−3200 using an extended dynamic range and a scan rate of 1.5 spectra/s by varying collision energy with mass. A reference mass solution containing reference ions (301.998139, 1033.988109, 1633.948689, and 1933.930624) was used to maintain mass accuracy during the run. Data were acquired with MassHunter Acquisition B.06.00 (Build 4033.1, 1 Patch) and processed with MassHunter Qualitative Analysis B.06.00 (Build 4.0.479.9, Service Pack 2) and Microsoft Excel 2007. A database was generated using PCDL Manager B.04.00 (Build 92.0).

RESULTS AND DISCUSSION

Sugar Syrup Markers. In general, two main detection methods for honey adulteration were approached: one based on the composition of honey and the other based on the presence of a specific adulterant component, that is, a marker.[37] The latter approach is commonly used as honey composition varies considerably by type and geographic location. The most common sugar syrup markers and their detection methods are summarized in Figure 1. Oligosaccharides and polysaccharides have been used as markers for corn-based syrups in TLC,[19] and HPACE-PAD.[5,6] AFGP is a marker of honey adulterated with RS.[11] DFAs, which are pseudodisaccharides formed during caramelization, consist of two fructose molecules,[38,39] and there are 14 DFA isomers.[38,40] As shown in Figure 1, DFAs have been utilized as markers of HFCS and IS.[7] In this study, polysaccharides, AFGP, and DFAs were used as markers of adulterated honey.

Optimization of UHPLC/Q-TOF-MS Conditions. As shown in Figure 2, the molecular sizes and polarities of these markers were significantly different from each other. Therefore, it was crucial to select an analytical column that could effectively separate the makers. Several commercial columns including a ZORBAX SB-C_{18} column (2.1 mm × 100 mm, 3.5 μm, Phenomenex), a HILIC Analytical Column (2.1 mm × 100 mm, 3.5 μm, Agilent), and an Acquity UPLC BEH Amide column (2.1 mm × 100 mm, 1.7 μm, Waters) were evaluated. The results revealed that, among the three markers, DFAs and polysaccharides could not be reserved on the C_{18} column due to their high polarity. AFGP and polysaccharides were not thoroughly separated by the HILIC column. Additionally, separation of markers by the HILIC column was very low. The Acquity UPLC BEH Amide column (2.1 mm × 100 mm, 1.7 μm) was therefore selected due to its high resolution and adequate signal-to-noise performance. Even though the BEH Amide column has been extensively used in the separation for saccharides,[41,42] there is less information about its application in DFAs and AFGP separation. In this study, the suitability of the BEH Amide column for DFA and AFGP separation was evaluated. The results revealed that an adequate marker separation was achieved with the Acquity UPLC BEH Amide column (Figure 3a). Peaks 1−19 correspond to AFGP, difructose anhydride III (DFA III), oligosaccharides (DP 3−11), and polysaccharides (DP 12−19).

Two mobile phases (water + acetonitrile and water + ammonia + acetonitrile) were evaluated. No significant differences in signal intensities or peak shapes between the two mobile phases were observed. To protect the column, water with acetonitrile and without ammonia was chosen as the mobile phase; 2 mM NH_4COOH was added to the mobile phase to form adducts of $[M + COOH]^-$. Other LC conditions were also evaluated. The most suitable UHPLC conditions consisted of a column temperature of 50 °C and a flow rate of 0.3 mL/min, with an injection volume of 5 μL.

In Q-TOF-MS, the fragmentor is the most influential parameter. A suitable fragmentor contributes to an efficient transmission of parent ions with few fragments. The signal intensities of parent ions with low mass values increase with increasing fragmentor voltage. Once the threshold is surpassed, the signal intensities decrease because the parent ions are fragmented. Parent ions of high mass values require higher voltage. To improve the sensitivity and validity of the method, a segmented fragmentor was utilized: 135 V for the first 5 min and for low mass values (DFAs and AFGP) and 200 V for the remaining run and for high mass values (polysaccharides with DP 12−19). Furthermore, a negative mode was selected for Q-TOF-MS due to the saccharide characteristics. The optimization of other key parameters (capillary voltage, skimmer voltage, gas temperature, drying gas flow rate, and nebulizer pressure) of Q-TOF-MS was performed by injecting a mixture of standard solutions (1 μg/mL) into the MS. To increase accuracy, real time reference mass corrections were performed during each run by applying reference ions having mass values similar to those of the markers.

Database Generation. Databases are useful for searching markers.[43] In this study, a small-scale database was generated for the automatic screening of sugar syrup markers on the basis of their retention time, accurate mass, characteristic ions (i.e., m/z, $[M - H]^-$, $[2M - H]^-$, or $[M - 2H]^{2-}$), and possible adducts (e.g., with $HCOO^-$).

An Excel spreadsheet (Table 1), compatible with the automatic screening software, was generated containing information on the sugar syrup markers, for example, molecular formula, retention time, accurate mass, and m/z values of characteristic ions. As shown in Table 1, AFGP, DFA III, and polysaccharides with DP 12−19 were selected as markers. AFGP, which has lower polarity than the other markers, was present as singly charged ions $[M - H]^-$ and $[2M - H]^-$ with m/z values of 287.0772 and 575.1618, respectively. AFGP was prone to form $HCOO^-$ adducts; therefore, $[M + COOH]^-$ (m/z 333.0822) was used as another characteristic ion. DFA III was used as all DFAs have similar m/z values and exist as long as DFA III is present, which has been certified by GC-MS.[7] The ability of TOF to identify nontarget compounds also guarantees

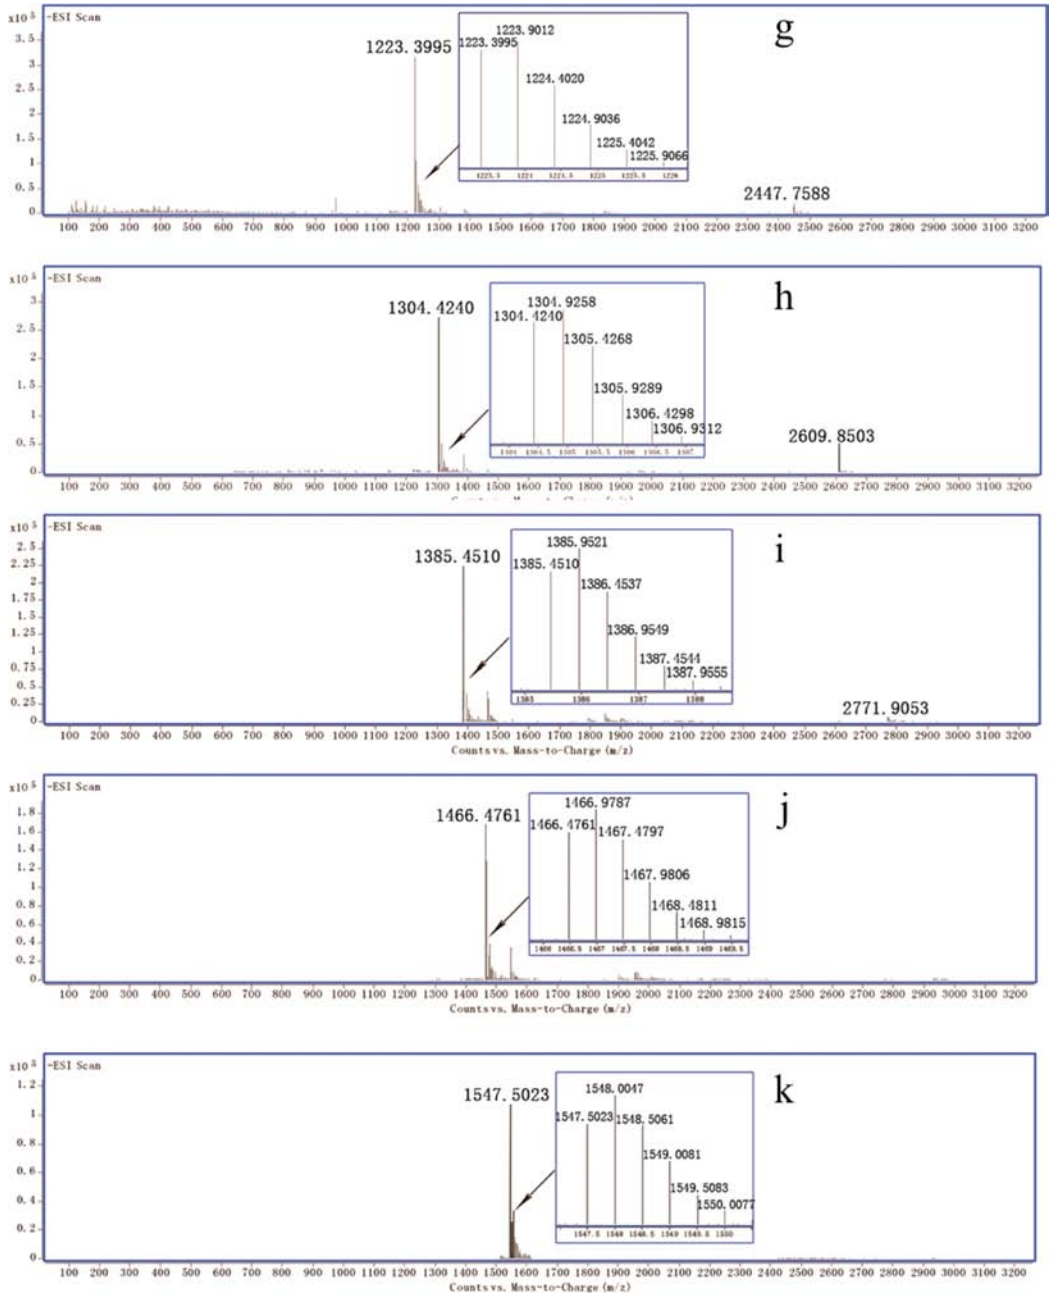

Figure 3. Chromatograms of standards (a), and mass spectra of 2-acetylfuran-3-glucopyranoside (AFGP) (b), difructose anhydride III (DFA III) (c), and polysaccharides (DP 12−19) (d−k). Peaks 1−19 in panel a are 2-acetylfuran-3-glucopyranoside (AFGP), difructose anhydride III (DFA III), oligosaccharides (DP 3−11), and polysaccharides (DP 12−19). The peaks highlighted are two isotope peaks.

the feasibility of DFA III in representing all DFAs. Similar to AFGP, DFA III was deprotonated, resulting in singly charged ions $[M - H]^-$ and $[2M - H]^-$ with m/z values of 323.0984 and 647.204, respectively; $[M + COOH]^-$ with an m/z value of 369.1033 was another characteristic ion of DFA III. Polysaccharides with DP 12−19 were chosen as markers because oligosaccharides with DPs between 3 and 6 have been detected in pure honey.[6,44] In our experiments, the detection of oligosaccharides (DP 7−11) in some honey samples was affected. On the other hand, Megherbiet al.[5] have successfully used polysaccharides (DP > 11) as markers of honey adulteration. The chromatographic profile of polysaccharides (DP 12−19) is shown in Figure 3a. Polysaccharides exist in the form of multicharged ions. In our experiments, polysaccharides (DP 12−19) were deprotonated, forming doubly charged ions $[M - 2H]^{2-}$ and $[M - H]^-$ detected in polysaccharides with DPs between 12 and 17. Isotope peaks were observed when polysaccharides (DP 12−19) were extracted. In the extraction of polysaccharides with DP 12, mass values of 980.3180 and 980.8199 were obtained (Figure 3d). The deviation of 0.5 confirmed the doubly charged form of the polysaccharides ($[M - 2H]^{2-}$). Polysaccharides with DP 13−19 had the same behavior as polysaccharides with DP 12. Polysaccharides with DP 20−25 can be detected using this method with less sensitivity. Therefore, they cannot be used as markers.

Analyses of Sugar Syrups and Honey Samples. The chromatographic profiles and mass spectra of standards, which include AFGP, DFA III, and polysaccharides (DP 12−19), are

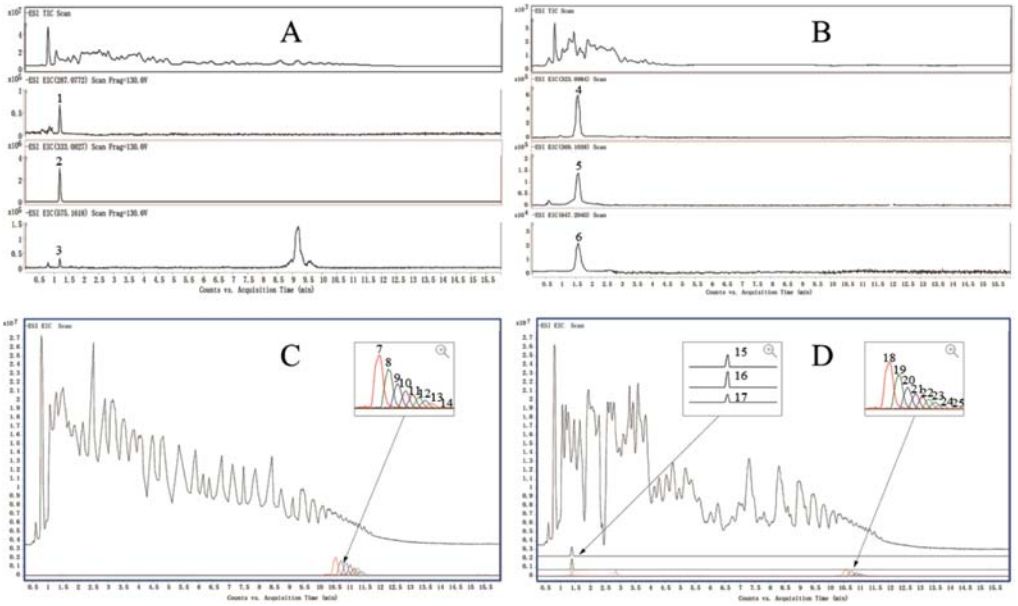

Figure 4. Chromatograms of rice syrup (A), inverted syrup from sugar beet (B), corn syrup (C), and high-fructose corn syrup (D). Peaks 1, 2, and 3 correspond to $[M - H]^-$, $[M + COOH]^-$, and $[2M - H]^-$ of 2-acetylfuran-3-glucopyranoside (AFGP), respectively; peaks 4–6 and 15–17 correspond to $[M - H]^-$, $[M + COOH]^-$, and $[2M - H]^-$ of DFAs; peaks 7–14 and 18–25 correspond to $[M - 2H]^{2-}$ of polysaccharides (DP 12–19).

shown in Figure 3. Peaks 1 and 2 corresponded to AFGP and DFA III, respectively (Figure 3a). Peaks 3–11 were oligosaccharides with DP 3–11, and peaks 12–19 were polysaccharides with DP 12–19. The mass spectrogram of AFGP is shown in Figure 3b; 287.0769, 333.0833, and 575.1637 were the m/z values of $[M - H]^-$, $[M + COOH]^-$, and $[2M - H]^-$, respectively. Figure 3c shows the mass spectrogram of DFA III; 323.0987, 369.1035, and 647.2060 were the m/z values of $[M - H]^-$, $[M + COOH]^-$, and $[2M - H]^-$, respectively. Panels d–k of Figure 3 show the mass spectrograms of polysaccharides with DP 12–19; 980.3180 corresponded to $[M - 2H]^{2-}$ and 1961.6391 corresponded to $[M - H]^-$. Polysaccharides with DP 13–19 have the same characteristic ions as polysaccharides with DP 12, with the exception of $[M - H]^-$, which cannot be detected in the mass spectrograms of polysaccharides with DP 18 or 19.

Sugar syrups including RS, IB, IC, CS, and HFCS were analyzed by UHPLC/Q-TOF-MS. One representative sample was selected from each type of syrup for the chromatographic profile (Figure 4). Figure 4A shows the chromatogram of RS. Peaks 1–3 were identified as characteristic ions of AFGP, the marker of RS. These three peaks correspond to $[M - H]^-$, $[M + COOH]^-$, and $[2M - H]^-$ based on mass spectra. Figure 4B shows the chromatogram of IB. Peaks 4–6 correspond to DFAs, markers of IS. On the basis of mass spectra, the three peaks (retention time: 1.522 min) correspond to $[M - H]^-$, $[M + COOH]^-$, and $[2M - H]^-$. The chromatogram of IC was similar to that of IB. Figure 4C shows the chromatogram of CS. Peaks 7–14 were identified as $[M - 2H]^{2-}$ of polysaccharides with DP 12–19 on the basis of the retention time and mass spectra of the standards. The chromatogram of HFCS is shown in Figure 4D. Peaks 15–17 correspond to $[M - H]^-$, $[M + COOH]^-$, and $[2M - H]^-$ of DFAs based on the DFA III standard. Peaks 18–25 were $[M - 2H]^{2-}$ of polysaccharides with DP 12–19. Therefore, AFGP appeared in RS and polysaccharides with DP 12–19 were detected in RS-42 and RS-55; DFAs were present in IS (from sugar cane and beet) and HFCS (HFCS-42, HFCS-55, and HFCS-90). Polysaccharides with DP 12–19 were present in CS and HFCS except in HFCS-90 because of its high degree of hydrolysis.

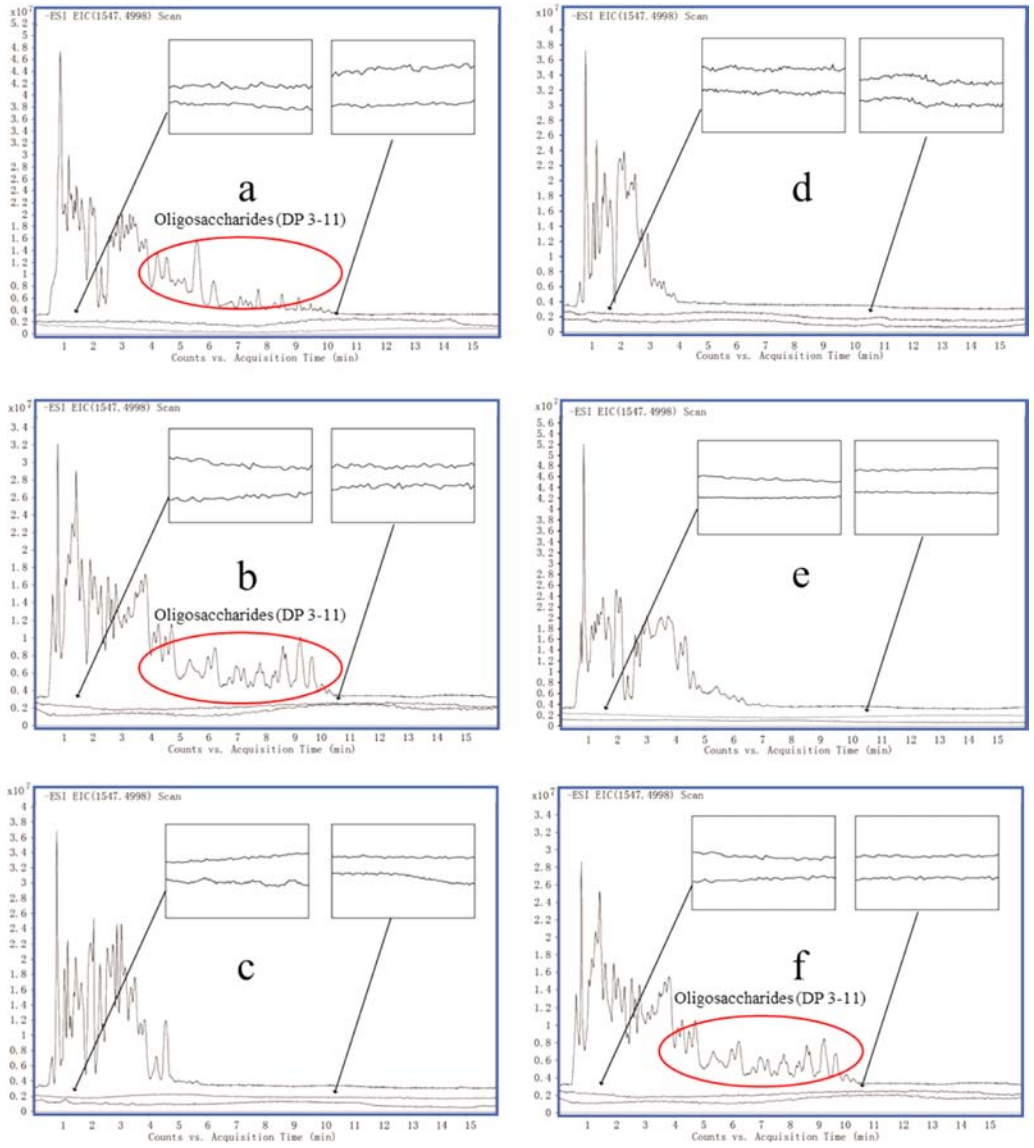

Figure 5. Chromatograms of linden honey (a), manuka honey (b), rape honey (c), jujube honey (d), acacia honey (e), and multifloral honey (f). The highlighted regions correspond to oligosaccharides (DP 3−11).

In addition, 120 pure honey samples were analyzed. The chromatographic profiles of six representative pure honey samples are shown in Figure 5. AFGP, DFAs, and polysaccharides (DP 12−19) were absent in these samples. However, oligosaccharides (DP 3−6) were detected in some honey samples, including linden honey (Figure 5a), manuka honey (Figure 5b), and multifloral honey (Figure 5f), in agreement with previous study findings.[6,44]

Analysis of Spiked Honey Samples. To assess the validity of the method, six pure honey samples including one jujube honey (J 1), one acacia honey (A 1), one rape honey (R 1), one linden honey (L 1), one manuka honey (M 1), and one multifloral honey (MF 1) were selected as representative samples. Mixed syrups composed of equal amounts of CS, RS (RS-42, RS-55, and RS-90), HFCS (HFCS-42, HFCS-55, and HFCS-90), and IS (from sugar cane and beet) were prepared. The amount of marker in each of the individual syrups was low. These six honey samples were spiked with different percentages (10, 20, or 30%, w/w) of the mixed syrups and analyzed by our developed method. The chromatographic profile of rape honey with 10% adulterants is shown in Figure 6. There were characteristic peaks in the chromatographic profile of spiked rape honey: peaks 1−4 correspond to $[M - H]^-$ and $[M + COOH]^-$ of AFGP and DFAs. The amount of dipolymer $[2M - H]^-$ was too low to be detected. Peaks 5−12 were identified as polysaccharides with DP 12−19 ($[M - 2H]^{2-}$). The signal-to-noise ratio of the peak with the lowest response (maltononadecaose, DP 19) was 27:1, which confirmed the feasibility, simplicity, and validity of our developed method. It is noteworthy that the presence of <10% adulterants in honey is nonsignificant.

Analyses of Market Honey Samples. In this study, 200 random honey samples from markets were analyzed. The results were compared with the database to assess whether the honey samples had been adulterated. AFGP was detected in 16 of 200 market honey samples; therefore, 16 samples had been adulterated with RS. DFA III was detected in 28 of 200 market honey samples; therefore, 28 samples had been adulterated with HFCS or IS. Polysaccharides (DP 12−19) were detected in 18 of 200 market honey samples; therefore, 18 samples had

[a]+, detected; −, not detected.

been adulterated with HFCS, CS, or RS. More than one marker was present in the adulterated samples, suggesting that the honeys had been adulterated with more than one sugar syrup. All adulterated honeys were marked as positive samples. The proportion of adulterated honeys ranged from 50 to 100% based on the peak areas corresponding to 10% adulterated honey.

Comparisons with Traditional Analytical Methods. To validate the developed method, 10 positive samples were evaluated by traditional analytical methods (Table 2). AFGPs in positive samples 9 and 18 were successfully detected by HPLC-DAD, suggesting that these two honey samples were adulterated with RS. Positive samples 37, 49, 103, and 129 were successfully detected by SCIRA and GC-MS, suggesting that the syrups used as adulterants were produced from C_4 plants and contained DFAs. Additionally, oligosaccharides and polysaccharides were detected by TLC and HPAEC-PAD in these four samples, suggesting the adulteration with HFCS. Adulterants produced from C_4 plants and DFAs in positive samples 147 and 189 were detected by SCIRA and GC-MS, respectively, suggesting they were adulterated with IS from sugar cane. Positive sample 192 was detected only by GC-MS, which suggested that the sample contained DFAs and had been adulterated with IS from sugar beet. Positive sample 196 was successfully detected by SCIRA, suggesting that the syrups were produced from C_4 plants. Oligosaccharides and polysaccharides were also detected in positive sample 196 by TLC and HPAEC-PAD, indicating adulteration with CS. All positive samples were successfully detected by UHPLC/Q-TOF-MS, revealing that our developed method can simultaneously detect multiclass sugar syrups. Therefore, UHPLC/Q-TOF-MS is a feasible, effective, simple, and rapid detection method of multiclass syrups.

Bee-Feeding Experiment. A bee-feeding experiment in a Ping Hu apiary was performed to evaluate the effects of supplementary sugar syrups on honey quality. Sugar syrups can be used to feed honeybees during the winter, when honeybees produce hardly any honey. Even though HFCS is commonly used by beekeepers, scientists have suggested that all syrups should be tried with bee colonies.[12] Cordella et al.[15] reported that the consequences of overfeeding honeybees with syrups were similar to directly adding sugar syrups to honey. HFCS can affect the quality of the resulting honey.[15] Furthermore, some honeybees die following the consumption of HFCS because of its high levels of hydroxymethylfurfural.[45] Therefore, the resulting honey produced by honeybees for the first time after being fed syrup are not allowed to enter the market because it is considered as another form of honey adulteration.

DOI: 10.1021/acs.jafc.5b01410
J. Agric. Food Chem. 2015, 63, 6614−6623

However, some of these adulterated honeys inevitably enter the market. Therefore, the detection of indirect honey adulteration is important; however, few detection methods have been successfully applied in this field. Guler et al.[13] reported that official analytical methods (e.g., AOAC 978.17, 1995; AOAC 991.41, 1995; AOAC 998.12, 2005) and SCIRA could not effectively detect indirect adulteration of honey. In this study, the results of a simple bee-feeding experiment revealed that our developed UHPLC/Q-TOF-MS method can effectively detect residual syrups in honeys produced by honeybees after being fed syrups for 3 days. The amounts of syrup markers in the resulting honeys were >60% based on peak area variations.

In conclusion, a simple, rapid, and effective method was developed to assess honey adulteration with multiclass sugar syrups. A syrup marker database was generated. Our developed method is simple, rapid, and less time-consuming compared to other published methods. Additionally, UHPLC/Q-TOF-MS allows the simultaneous detection of several sugar syrups. The validity and applicability of the proposed method have been confirmed by comparisons with traditional methods. UHPLC/Q-TOF-MS has broad applications in honey acquisition and honey quality control.
